This book is dedicated to my wife,
Francisca Margarita, who has
staunchly supported my efforts for
more years than I wish to remember.

Preface

This book is designed to document all of the alkaline earth compounds known to date in the scientific literature. It is a reference book intended to bring together, in an organized fashion, information difficult to find, or dispersed in many published journals and books. Many of these references are obscure and not easily discovered except by persistent searching. This is the main value of this content. As such, the previously published subject matter has been the source of information presented here. The author has assembled results and conclusions, published by various researchers in the open literature, regarding a particular compound. He then used his personal knowledge and experience to discuss various viewpoints and judgments reached by various authors concerning the physical and chemical properties for each compound presented within this volume. The reader then has a starting point concerning whether a particular compound is known to exist and what properties it may exhibit. Although there are many other resources for inorganic compounds like the Wiley encyclopedia, Scifinder, Scopus/Scirus, the Gmelin Handbooks, PubMed, Springer/Link, the NIMS Materials database and the Web of Science, they cover a vast multitude of compounds and are, in some cases, difficult to access. In contrast, the present book is limited to alkaline earth compounds. This is the major worth of the book—a place to determine what alkaline earth compounds are known to exist.

However, the reader will soon discover that references to the literature, including tables, drawings and figures, are not given. There is a good reason for this. Early in the writing of the manuscript, the author assembled known data and results published as papers and books in the open literature. He then described succinctly was known about a particular alkaline earth compound and added references. Since his description was based upon the compilation and personal assessment of what several authors had published in the past, just one compound required 6–8 citations. Many compounds required 8–10 references and sometimes even more. Therefore, the decision was made not to include citations because the reference pages would consume a large part of the book. If the reader wishes to ascertain which authors discovered the properties of a particular compound, a good starting point is the Internet.

Concerning figures, the author has drawn all of these, starting with figures published within various articles and books. In many cases, more than one author(s) published essentially the same result, each a refinement of the previous one. The author then formed the figure (such as a crystal structure) according to the latest results known to date. For example, the author redrew many phase diagrams which were not complete and added known data to complete the diagram. Because most of the figures had several contributors, no citations have been included since they, like the information presented for each compound, would consume a considerable space within the manuscript.

Most of the tables are compilations of previously published data derived from books and journals. For example, some tables present unit-cell occupancies for a specific crystal structure. These were derived from the literature but have many authors. No specific citations are presented for these tables as well.

R.C. Ropp - October 2012

CHAPTER

1

The Alkaline Earths as Metals

OUTLINE

1.1. General Properties 1

1.2. Properties of the Alkaline Earth Metals 4

1.2.1. Beryllium 4

1.2.2. Magnesium 8

1.2.3. Calcium 12

1.2.4. Strontium 15

1.2.5. Barium 18

1.2.6. Radium 19

The alkaline earth metals comprise Group 2 of the periodic table and include the elements Be, Mg, Ca, Sr, Ba and Ra. These metals form cations with a formal charge of +2 in solution and are the second most electropositive metals of all of the elements (the alkali metals are the most electropositive). The name of this specific group in the periodic table stems from the fact that their oxides produce basic alkaline solutions and that these elements melt at such high temperatures that they remain solid (earths) in fires. The alkaline earth metals provide a good example of group trends in chemical properties within the periodic table, with well-characterized homologous behavior as one goes down the group. With the exception of Be and Mg, the metals have a distinguishable flame color, orange-red for Ca, magenta-red for Sr, green for Ba and crimson-red for Ra.

1.1. GENERAL PROPERTIES

Like other groups, the members of this family show specific patterns in their electron configuration, especially the outermost shells, that results in trends in chemical behavior (Table 1.1).

Another way to depict the electronic structure of these elements is shown in Table 1.2.

All of the alkaline earth metals have two electrons in their outer valence shell, so the energetically preferred state of achieving a filled electron shell is to lose two electrons to form doubly charged cations, M^{2+}. The alkaline earth metals are silver-colored, soft metals that react readily with halogens to form ionic salts. They also react with water, though not as rapidly as the alkali metals, to form strongly alkaline (basic) hydroxides. For example,

TABLE 1.1

Z	Element	No. of electrons/shell
4	Beryllium	2, 2
12	Magnesium	2, 8, 2
20	Calcium	2, 8, 8, 2
38	Strontium	2, 8, 18, 8, 2
56	Barium	2, 8, 18, 18, 8, 2
88	Radium	2, 8, 18, 32, 18, 8, 2

TABLE 1.2

Element	Symbol	Electronic configuration
Beryllium	Be	$[He]2s^2$
Magnesium	Mg	$[Ne]3s^2$
Calcium	Ca	$[Ar]4s^2$
Strontium	Sr	$[Kr]5s^2$
Barium	Ba	$[Xe]6s^2$
Radium	Ra	$[Rn]7s^2$

Encyclopedia of the Alkaline Earth Compounds

whereas Na and K react with water at room temperature, Mg reacts only with steam and Ca with hot water:

$$\mathrm{Mg(solid) + 2\ H_2O(gas)} \Rightarrow \mathrm{Mg(OH)_2(solid) + H_2(gas)}$$

Be is an exception. It does not react with water or steam, and its halides are covalent.

The alkaline earth metals are named after their oxides, the *alkaline earths*, whose old-fashioned names were Beryllia, Magnesia, Lime, Strontia and Baryta. "Earth" is the old term applied by early chemists to nonmetallic substances that were insoluble in water and resistant to heating, properties shared by these oxides. The realization that these earths were not elements but compounds is attributed to the chemist Antoine Lavoisier. In his "Traité Élementaire de Chemie" (*Elements of Chemistry*) of 1789, he called them "salt-forming" earth elements. Later, he suggested that the alkaline earths might be metal oxides, but admitted that this was mere conjecture. In 1808, acting on Lavoisier's idea, Humphrey Davy became the first to obtain samples of the metals by electrolysis of their molten "earths".

If the alkaline earths are compared to the alkalis, many similarities are apparent. The main difference is the electron configuration, which is ns^2 for alkaline earth metals and ns^1 for alkali metals. But for the alkaline earth metals, the nucleus also contains an additional positive charge. Also, the elements of Group 2 (alkaline earths) have much higher melting points and boiling points compared to those of Group 1 (alkali metals). The alkalis are softer and more lightweight than the alkaline earth metals that are much harder and denser.

The second valence electron is very important when it comes to comparing chemical properties of the alkaline earth and the alkali metals. The second valence electron is in the same "sublevel" as the first valence electron. Therefore, the Z_{eff} is much greater. This means that the elements of Group 2 have a smaller atomic radius and much higher ionization energy than those of Group 1. Even though the Group 2 contains a much higher ionization energy, they still form ionic compounds containing 2+ cations. Beryllium, however, behaves differently. This is due to the fact that in order to remove two electrons from this particular atom, significantly more energy is required. It never forms the Be^{2+} cation and its bonds are polar covalent.

Atomic and ionic radii increase smoothly down the Group. The ionic radii are all much smaller than the corresponding atomic radii. This arises because the atom contains two electrons in an s level relatively far from the nucleus. It is these electrons that are removed to form the ion. Remaining electrons are thus in levels closer to the nucleus, and in addition the increased effective nuclear charge attracts the electrons toward the nucleus and decreases the size of the ion.

These elements are all found in the Earth's crust, but not in the elemental form because they are so reactive. Instead, they are widely distributed in rock structures. The main minerals in which magnesium is found are "Carnellite", "Magnesite" and "Dolomite". Calcium is found in "Chalk", "Limestone", "Gypsum" and "Anhydrite". Magnesium is the eighth most abundant element in the Earth's crust, and calcium is the fifth.

Some of the physical properties of the alkaline earth metals are shown in Table 1.3.

The metals of Group 2 are harder and denser than sodium and potassium, and have higher melting points. These properties are due largely to the presence of two valence electrons on each atom, which leads to stronger metallic bonding than occurs in Group 1.

Three of these elements give characteristic colors when heated in a **flame**:

$$\mathrm{Mg} = \text{brilliant white} \qquad \mathrm{Ca} = \text{brick} - \text{red} \qquad \mathrm{Sr} = \text{crimson}$$

In all their compounds, these metals have an oxidation number of +2 and, with few exceptions, their compounds are ionic in nature. The reason for this can be seen by examination of the electron configuration, which always has two electrons in an outer quantum level. These electrons are relatively easy to remove, but removing the third electron is much more difficult, as it is close to the nucleus and in a filled quantum shell. This results in the formation of M^{2+}. The ionization energies reflect this electron arrangement. The first two ionization energies are relatively low, and the third very much higher.

In general, the chemical properties of Group 2 elements are dominated by the strong reducing power of the metals. The elements become increasingly electropositive as one descends within the Group. In direct contact with oxygen or chlorine gas, little or no reaction occurs. However, once started, the reactions with oxygen and chlorine are vigorous:

$$\mathrm{2Mg(solid) + O_2(g)} \Rightarrow \mathrm{2MgO(solid)} + \text{heat}$$

$$\mathrm{Ca(solid) + Cl_2(gas)} \Rightarrow \mathrm{CaCl_2(solid)} + \text{heat}$$

All the metals except beryllium form oxide layers in air at room temperature that dulls the surface of the metal. Barium is so reactive that it is stored under oil. All of the metals except beryllium reduce water and dilute acids to hydrogen:

$$\mathrm{Mg(solid) + 2H^+(aq)} \Rightarrow \mathrm{Mg(aq) + H_2(gas)}$$

Magnesium reacts only slowly with water unless the water is boiling, but calcium reacts rapidly even at room temperature, and forms a cloudy white suspension of sparingly soluble calcium hydroxide.

TABLE 1.3

Element	Atomic number	Relative atomic mass	Melting point, °C	Density in kgm/m^3
Be	4	9.012	1551	1847.7
Mg	12	24.31	922	1738
Ca	20	40.08	1112	1550
Sr	38	87.62	1042	2540
Ba	56	137.33	1002	3594

	Ionization energies in kJ/mol		
	1st	2nd	3rd
Be	899.4	1757.1	14,848
Mg	737.7	1450.7	7732.6
Ca	589.7	1145	4910
Sr	549.5	1064.2	4210
Ba	502.8	965.1	3600

	Atomic radius/Å	Ionic radius/Å (M^{2+})	Standard electrode potentials/V
Be	1.13	0.34	−1.85
Mg	1.60	0.78	2.36
Ca	1.97	1.06	−2.87
Sr	2.15	1.27	−2.89
Ba	2.17	1.43	−2.90

Calcium, strontium and barium can reduce hydrogen gas when heated, forming the hydride:

$$Ca(solid) + H_2(gas) \Rightarrow CaH_2(solid)$$

The hot metals are also sufficiently strong reducing agents to reduce nitrogen gas and form nitrides:

$$3Mg(solid) + N_2(gas) \Rightarrow Mg_3N_2(solid)$$

Magnesium can reduce, and burn, in carbon dioxide:

$$2Mg(solid) + CO_2(gas) \Rightarrow 2MgO(solid) + C(solid)$$

This means that magnesium fires cannot be extinguished using carbon dioxide fire extinguishers.

The oxides of alkaline earth metals are normally prepared by heating the hydroxide or carbonate to release carbon dioxide gas. They have high lattice enthalpies and melting points. Peroxides, MO_2, are known for all these elements except beryllium. It appears that the Be^{2+} cation is too small to accommodate the peroxide anion.

Calcium, strontium and barium oxides react with water to form hydroxides:

$$CaO(solid) + H_2O(liq) \Rightarrow Ca(OH)_2(solid)$$

Calcium hydroxide is known as "slaked lime". It is sparingly soluble in water and the resulting mildly alkaline solution is known as "limewater" which is used to test for the acidic gas, carbon dioxide.

The Group 2 halides are normally found in the hydrated form. They are all ionic except beryllium chloride. Anhydrous calcium chloride has such a strong affinity for water that it is used as a drying agent.

Of the elements in this Group only magnesium is produced on a large scale. It is extracted from seawater by the addition of calcium hydroxide, which precipitates out the less soluble magnesium hydroxide. This hydroxide is then converted to the chloride with HCl, which is electrolyzed in a "Downs Cell" to extract magnesium metal. The metal is used in flares, tracer bullets and incendiary bombs as it burns with a brilliant white light. It has also been alloyed with aluminum to produce a low-density, strong material used in aircraft. Magnesium oxide has such a high melting point that it is used to line furnaces.

The alkaline earth elements are found in all living organisms. However, beryllium's low aqueous solubility means that it is rarely available to biological systems. That is, it has no known role in living organisms. It is generally highly toxic if encountered by them.

In contrast, magnesium and calcium are ubiquitous and essential to all known living organisms. These elements are involved in more than one role. For example, Mg/Ca ion pumps play a pivotal role in some cellular processes, where magnesium functions as the active center in some enzymes, while calcium salts take a structural role (e.g. bones and teeth) in animals.

Strontium and barium display a lower availability in the biosphere. Strontium plays an important role in marine aquatic life, especially hard corals. They use strontium to build their exoskeleton. These elements also have some uses in medicine, for example "barium meals" in radio graphic imaging, while strontium compounds are employed in some toothpastes. Radium has a low availability and is highly radioactive, making it toxic to life.

1.2. PROPERTIES OF THE ALKALINE EARTH METALS

Each of these metals display specific properties which differ from the others but have some characteristics that are nearly the same.

1.2.1. Beryllium

The name *beryllium* comes from the Greek word for *bérullos*, *beryl*, and from the Prakrit *veruliya*, in allusion "to become pale", in reference to the pale semiprecious gemstone "Beryl". For about 160 years, beryllium was also known as **glucinium** (with the accompanying chemical symbol **Gl**), the name coming from the Greek word for "sweet", due to the sweet taste of its salts. A bivalent element, beryllium is found in nature as a combination with other elements in minerals. Notable gemstones which contain beryllium include "Beryl" (Aquamarine, Emerald) and "Crysoberyl". The free element is a steel-gray, strong, lightweight, brittle, alkaline earth metal with an atomic weight of 9.01218 g/mol. It is primarily used as a hardening agent in alloys, notably beryllium–copper. Structurally, beryllium's very low density (1.85 times that of water), high melting point (1278 °C), high temperature stability, and low coefficient of thermal expansion, make it in many ways an ideal aerospace material, and it has been used in rocket nozzles and is a significant component of future-planned space telescopes. Because of its relatively high transparency to X-rays and other ionizing radiation types, beryllium metal also has a number of uses as filters and windows for radiation and particle physics experiments.

Commercial use of beryllium metal presents technical challenges due to the toxicity (especially by inhalation) of beryllium-containing dusts. Beryllium produces a direct corrosive effect to human tissue, and can cause a chronic life-threatening allergic disease called "Berylliosis" in susceptible persons. The author has had direct contact with such persons who present skeletal aspects of facial appearance and torso as the disease progresses.

TABLE 1.4

Location	ppb by weight	ppb by atoms
Universe	1	0.1
Sun	0.1	0.01
Meteorite (carbonaceous)	30	70
Crustal rocks	4900	4300
Seawater	0.0006	0.00041
Streams	0.1	0.01
Humans	0.4	0.3

Beryllium is a relatively rare element in both the Earth and the Universe because it is not formed in conventional stellar nucleosynthesis. It more accurately was formed during the "Big Bang", and later from the action of cosmic rays on interstellar dust.

The abundance of beryllium is shown in Table 1.4.

The beryllium content of the earth's surface rocks is about 4–6 ppm. Beryllium is a constituent in about 100 out of about 4000 known minerals, the most important of which are "Bertrandite" ($Be_4Si_2O_7(OH)_2$), "Beryl" ($Al_2Be_3Si_6O_{18}$), "Crysoberyl" (Al_2BeO_4), and "Phenakite" (Be_2SiO_4). Precious stone forms of beryl are "Aquamarine", "Bixbite" and "Emerald".

Beryllium has one of the highest melting points of any of the light metals. It has exceptional elastic rigidity (Young's modulus = 316 GPa). The modulus of elasticity of beryllium is approximately 50% greater than that of steel. The combination of this modulus plus beryllium's relatively low density gives it an unusually fast conduction of sound at standard conditions (about 12.9 km/s).

Other significant properties are the high values for specific heat (1925 J/kg K) and thermal conductivity (216 W/m K). This makes beryllium the metal with the best heat dissipation characteristics per unit weight of all of the metals. In combination with the relatively low coefficient of linear thermal expansion (11.4×10^{-6}/K), these characteristics ensure that beryllium demonstrates a unique degree of dimensional stability when heated. At STP (standard temperature and pressure), beryllium resists oxidation when exposed to air (its ability to scratch glass is due to the formation of a thin layer of the hard oxide BeO). It also resists corrosion by concentrated HNO_3.

Beryllium has a large scattering cross section for high-energy neutrons, thus effectively slowing the neutrons to the thermal energy range where the cross section is low (0.008 b). The predominant beryllium isotope, ^9Be, also undergoes a (n, 2n) neutron reaction to form ^8Be, i.e. beryllium is a neutron multiplier, releasing more neutrons than

TABLE 1.5

Known isotopes of beryllium

Nuclide	Z	N	Isotopic mass	Half-life	Decay mode
^{5}Be	4	1	5.04079	No data available	Proton emission
^{6}Be	4	2	6.019726	4.06848×10^{-21} s [0.092 MeV]	Alpha decay
^{7}Be	4	3	7.01692983	53.22 days	Electron capture
^{8}Be	4	4	8.00530510	6.72206×10^{-17} s [6.8 eV]	Alpha decay
^{9}Be	4	5	9.0121822	Stable	Stable
^{10}Be	4	6	10.0135338	1.51×10^{6} years	β-minus decay
^{11}Be	4	7	11.021658	13.81 s	β-minus decay
^{12}Be	4	8	12.026921	21.31 ms	β-minus decay
^{12}Be	4	8	12.026921	2.71×10^{-21} s	Neutron emission
^{14}Be	4	10	14.04289	4.84 ms	β-minus decay
^{15}Be	4	11	15.05346	<200 ns	No data
^{16}Be	4	12	16.06192	<200 ns	No data

it absorbs. Beryllium is highly permeable to X-rays and neutrons are liberated when it is struck by alpha particles.

Of beryllium's isotopes, only ^{9}Be is stable and the others are relatively unstable or rare. It is thus a "mono-nuclide" element. "Cosmogenic" ^{10}Be is produced in the atmosphere by cosmic ray spallation of oxygen and nitrogen. Cosmogenic ^{10}Be accumulates at the soil surface, where its relatively long half-life (1.51 million years) permits a long residence time before decaying to ^{9}Be. Thus, ^{10}Be and its daughter products have been used to examine soil erosion and soil formation from "regolith" (which is soil formed by material originating through rock weathering or plant growth), the development of lateritic soils as well as variations in solar activity, and the age of ice cores. Solar activity is inversely correlated with ^{10}Be production, because the solar wind decreases the flux of galactic cosmic rays which reach the Earth (Table 1.5).

Beryllium-10 is also formed in nuclear explosions by a reaction of fast neutrons with ^{13}C in the carbon dioxide in air, and is one of the historical indicators of past activity at nuclear test sites.

The fact that ^{7}Be and ^{8}Be are unstable has profound cosmological consequences as it means that elements heavier than beryllium could not have been produced by nuclear fusion in the "Big Bang" since there was insufficient time during the nucleosynthesis phase of the Big Bang expansion to produce carbon by fusion of ^{4}He nuclei. The other factor was the relatively low concentrations of ^{8}Be available because of its short half-life. Astronomer Fred Hoyle first showed that the energy levels of ^{8}Be and ^{12}C allow carbon production by a triple-alpha process in helium-fueled stars where more synthesis time is available. ^{7}Be decays by electron capture. Therefore, its decay rate is dependent upon its electron configuration—a rare occurrence in nuclear decay.

The shortest-lived known isotope of beryllium is ^{13}Be which decays through neutron emission. It has a half-life of 2.7×10^{-21} s. ^{6}Be is also very short lived with a half-life of 4.96×10^{-21} s. The exotic isotopes ^{11}Be and ^{14}Be are known to exhibit a "nuclear halo".

Beryllium has the electronic configuration $[He]2s^2$ and exhibits only the +2 oxidation state. The only evidence of a lower valence state of beryllium is in the fact that Be is soluble in $BeCl_2$. The small atomic radius ensures that the Be^{2+} ion is highly polarizing, a fact leading to significant covalent character in beryllium's bonding within various compounds. Beryllium is 4 coordinate in complexes e.g. $[Be(H_2O)_4]^{2+}$ and tetrahaloberyllates, BeX_4^{2-}. This characteristic is used in analytical techniques for determining Be using EDTA as a ligand which preferentially forms octahedral complexes, thus absorbing other cations such as Al^{3+} which might interfere in the solvent extraction of a complex formed between Be^{2+} and acetylacetone.

Beryllium metal lies above aluminum in the electrochemical series and would be expected to be a reactive metal. However it is passivated by an oxide layer and does not react with air or water even at red heat. Once ignited however, beryllium burns brilliantly in air forming a mixture of BeO and Be_3N_2.

Beryllium dissolves readily in nonoxidizing acids, such as HCl and H_2SO_4, but not in nitric acid as this forms the oxide on the surface of the metal. This behavior is similar to that of aluminum metal. Another strange feature is that Be is **amphoteric**. This means that it has the properties of both an acid and a base. The following two reactions show this factor:

$$Be(OH)_2(solid) + H_2SO_4(aq) \Rightarrow BeSO_4(solid) + 2\,H_2O(liq)$$

$$Be(OH)_2(solid) + 2\,NaOH(aq) \Rightarrow Na_2Be(OH)_4(aq) \Leftrightarrow 2\,Na^+(aq) + Be(OH)_4^{2-}(aq)$$

Beryllium, again similarly to aluminum, dissolves in warm alkali to form the berylliate anion, $Be(OH)_4^{2-}$ and hydrogen gas. The solutions of salts, e.g. beryllium sulfate and beryllium nitrate are acidic because of hydrolysis of the $[Be(H_2O)_4]^{2+}$ ion. For example:

$$BeSO_4(solid) + 4\,H_2O(liq) \Rightarrow [Be(H_2O)_4]^{2+}(aq) + SO_4^{2-}(aq)$$

$$[Be(H_2O)_4]^{2+}(aq) + H_2O \Rightarrow [Be(H_2O)_3(OH)]^{+}(aq) + H_3O^{+}(aq)$$

The hydrolytic reactions of beryllium(II) ions have been calorimetrically studied at 25 °C in aqueous solution and dioxane–water mixtures, both containing 3.0 mol/dm^3 Li_2ClO_4 as a constant ionic medium. On the basis of the formation constants determined, the enthalpy and entropy changes for the reaction:

$$x\ Be^{2+} + y\ H_2O \Rightarrow (Be_x(OH)_y)^{2(x-y)+} + y\ H^+,$$

were estimated for the Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes in aqueous solution and 0.1 mol fraction dioxane–water mixture and for Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, and $Be_2(OH)_2^{2+}$ complexes in 0.2 mol fraction dioxane–water mixture. The enthalpy and entropy changes of formation of the $Be_x\ (OH)_y)^{2(x-y)+}$ complex in solutions of various mole fractions of dioxane were obtained and shown to abide by the following reaction:

$$2Be^{2+} + H_2O \Rightarrow Be_2OH^{3+} + H^+$$

Thus, it is clear that the Be^{2+} cation in aqueous solution never appears but is an "aquo-complex". This illustrates the amphoteric nature of beryllium salts.

Beryllium differs from its brothers (or sisters) in Group 2 in that it usually forms covalent bonds. But, unlike other covalent molecules, it is soluble in organic solvents and is a poor conductor when molten.

Because of its high affinity for oxygen at elevated temperatures and its ability to reduce water when its oxide film is removed, the extraction of beryllium from its compounds is very difficult. Although electrolysis of a fused mixture of beryllium and sodium fluorides was used to isolate the element in the nineteenth century, the metal's high melting point makes this process more energy intensive than the corresponding production of alkali metals by the Down's Process. Early in the twentieth century, the production of beryllium by the thermal decomposition of BeI_2 was investigated following the success of a similar process for the production of zirconium, but this proved to be uneconomic for volume production. Beryllium metal is available commercially and is never normally made in the laboratory. Its extraction from ores is complex.

The mineral beryl, $[Be_3Al_2(SiO_3)_6]$ is the most important source of beryllium. It is roasted with sodium hexafluorosilicate, Na_2SiF_6, at 700 °C to form beryllium fluoride. This salt is water soluble and beryllium may be precipitated as the hydroxide $Be(OH)_2$ by adjustment of the pH to 12.

Pure beryllium may be obtained by electrolysis of molten $BeCl_2$ containing some NaCl. Salt is added since molten $BeCl_2$ conducts very poorly. Another method involves the reduction of beryllium fluoride with magnesium at 1300 °C:

$$BeF_2 + Mg \Rightarrow MgF_2 + Be$$

Although emeralds and beryl were known to ancient civilizations, they were first recognized as the same mineral ($Be_3Al_2(SiO_3)_6$) by Abbé Haüy in 1798. Later that year, Louis-Nicholas Vauquelin, a French chemist, discovered that an unknown element was present in emeralds and beryl. Attempts to isolate the new element finally succeeded in 1828 when two chemists, Friedrich Wölhler of Germany and A. Bussy of France, independently produced beryllium by reducing beryllium chloride ($BeCl_2$) with potassium metal in a platinum crucible. Today, beryllium is primarily obtained from the minerals Beryl ($Be_3Al_2(SiO_3)_6$) and Bertrandite ($4BeO\cdot 2SiO_2\cdot H_2O$) through a chemical process or through the electrolysis of a mixture of molten beryllium chloride ($BeCl_2$) and sodium chloride (NaCl).

Beryllium metal did not become readily available until 1957. Currently, the metal is produced by reducing BeF_2 with Mg metal. The price on the US market for vacuum-cast beryllium ingots was $338 per pound ($745/kg) in 2001.

The metal, beryllium, has had many uses and applications in Industry. Among these are the following:

- Because of its low atomic number and very low absorption for X-rays, the oldest and still one of the most important applications of beryllium is in radiation windows for X-ray tubes. Extreme demands are placed on purity and cleanliness of Be to avoid artifacts in the X-ray images. Thin beryllium foils are used as radiation windows for X-ray detectors, and the extremely low absorption minimizes the heating effects caused by high intensity, low energy X-rays typical of synchrotron radiation.
- Vacuum-tight windows and beam tubes for radiation experiments on synchrotrons are manufactured exclusively from beryllium. In scientific setups for various X-ray emission studies, the sample holder is usually made of beryllium because its emitted X-rays have much lower energies (~100 eV) than the X-rays from most studied materials.
- Because of its low atomic number, beryllium is almost transparent to energetic particles. Therefore it is used to build the "beam pipe" around the collision region in "Collider Particle Physics" experiments. Notably all four main detector experiments at the Large Hadron Collider Accelerator in Berne, Switzerland use a beryllium beam pipe.
- Beryllium's low density allows collision products to reach the surrounding detectors without a significant interaction. Its stiffness allows a powerful vacuum to be produced within the pipe to minimize interaction with gases. Its thermal stability allows it to function correctly at temperatures of only a few degrees above the absolute zero, and its diamagnetic nature keeps it from interfering with the complex multipole

magnet systems used to steer and focus the particle beams.

- Due to its stiffness, lightweight, and dimensional stability over a wide temperature range, beryllium metal is used in the defense and aerospace industries for lightweight structural components in high-speed aircraft, missiles, space vehicles and communication satellites. Several liquid-fueled rockets use nozzles of pure beryllium.
- Beryllium is used as an alloying agent in the production of beryllium–copper, which contains up to 2.5% beryllium. Beryllium–copper alloys are used in many applications because of their combination of high electrical and thermal conductivity, high strength and hardness, nonmagnetic properties, along with good corrosion and fatigue resistance. These applications include the making of spot-welding electrodes, springs, non-sparking tools and electrical contacts.
- The excellent elastic rigidity of beryllium has led to its extensive use in precision instrumentation, e.g. in gyroscope inertial guidance systems, and in support structures for optical systems.
- Beryllium mirrors are a field of particular interest in astronomical applications. Large-area mirrors, frequently with a honeycomb support structure, are used. For example, in meteorological satellites where low weight and long-term dimensional stability are critical, the use of beryllium is essential. Smaller beryllium mirrors are used in optical guidance systems and in fire control systems, as in the German "main-battle" tanks of World War II. In these systems, very rapid movement of the mirror is required which again dictates low mass and high rigidity. Usually the beryllium mirror is coated with hard electroless nickel that can be more easily polished to a finer optical finish than beryllium. In some applications, though, the beryllium blank is polished without any coating. This is particularly applicable to a cryogenic operation where any thermal expansion mismatch can cause the coating to buckle.
- The James Webb Space Telescope (JWST), a planned infrared space observatory (which will replace, in part, the Hubble Space Observatory), will have 18 hexagonal beryllium sections for its mirrors. Because JWST will face a temperature of 33 K, the mirror is made of beryllium, because it is capable of handling extreme cold better than glass. Beryllium contracts and deforms less than glass and remains more uniform at such temperatures. For the same reason, the optics of the Spitzer Space Telescope, launched by NASA in 2003, are entirely built of beryllium metal.
- An earlier major application of beryllium was in brakes for military aircraft because of its hardness, high melting point and exceptional heat dissipation. Environmental and toxicity considerations have since led to substitution by other materials.
- Cross-rolled beryllium sheet is an excellent structural support for printed circuit boards in surface-mounted technology. In critical electronic applications, beryllium is both a structural support and a heat sink. The application also requires a coefficient of thermal expansion that is well matched to that of alumina and polyimide glass substrates. The beryllium–beryllium oxide composite "E-Materials" have been specially designed for these electronic applications and have the additional advantage that the thermal expansion coefficient can be tailored to match diverse substrate materials.
- Due to their non-magnetic properties, beryllium-based tools are often used by military naval personnel when working on or around sea-mines, as these devices often have fuses that detonate on direct magnetic contact or when influenced by a magnetic field.
- Beryllium-based tools are used for maintenance and construction near MRI scanners. Magnetic tools would be pulled by the scanner's strong magnetic field. Apart from being difficult to remove once magnetic items are stuck in the scanner, the induced missile effect can have dangerous consequences.
- In the telecommunications industry, tools made of beryllium are used to tune the highly magnetic klystrons used for high-power microwave applications.
- Beryllium is used in nuclear weapon designs as the outer layer of the "pit" (the core of an implosion weapon—the fissile material and any reflector or tamper bonded to it) of the primary stage, surrounding the fissile material. It is a good implosion pusher and a very good neutron reflector, and is used in certain moderated reactors such as "Molten-salt Reactors".
- Beryllium is sometimes used as a neutron source in which the beryllium is mixed with an alpha emitter such as ^{210}Po, ^{226}Ra, ^{239}Pu or ^{241}Am.
- Beryllium has also been proposed as a cladding material for nuclear fuel, due to its combination of mechanical, chemical, and nuclear properties.
- Beryllium's characteristics (low weight and high rigidity) make it useful as a material for high-frequency audio-drivers in audio applications. Until recently, most beryllium tweeters used an alloy of beryllium and other metals. This was due to beryllium's high cost and difficult formability. These challenges, coupled with the high performance of beryllium, caused some manufacturers to falsely claim that they used pure beryllium. Some high-end audio companies now manufacture pure beryllium tweeters or speakers using such tweeters. Because beryllium is many times more expensive than titanium, hard to shape due to its brittleness,

and toxicity if mishandled, these tweeters are limited to high-end and "public address" applications.

- Beryllium is an effective p-type dopant in III–V semiconductors. It is widely used in materials such as GaAs, AlGaAs, InGaAs, and InAlAs grown by "Molecular Beam Epitaxy".
- BeO is useful for many applications that require the combined properties of an electrical insulator, an excellent heat conductor with high strength and hardness, with a very high melting point. Beryllium oxide is frequently used as an insulator base plate in high-power transistors in RF transmitters for telecommunications. Beryllium oxide is also being studied for use in increasing the thermal conductivity of UO_2 nuclear fuel pellets.
- Beryllium compounds were once used in fluorescent lamps as zinc beryllium silicate phosphor, but this use was discontinued because of berylliosis induced in the workers manufacturing the phosphor and fluorescent lamps. Although the use of beryllium compounds in fluorescent lighting was discontinued in 1949, potential for exposure to beryllium still exists in the nuclear and aerospace industries and in the refining of beryllium metal and melting of beryllium-containing alloys, the manufacturing of electronic devices, and the handling of other beryllium-containing material.

Early researchers tasted beryllium and its various compounds for sweetness in order to verify its presence. Modern diagnostic equipment no longer necessitates this highly risky procedure and no attempt should be made to ingest this highly toxic substance. Beryllium and its compounds should be handled with great care and special precautions must be taken when carrying out any activity that could result in the release of beryllium dust (causing lung cancer is a possible result of prolonged exposure to beryllium laden dust). This substance can be handled safely if certain procedures are followed. No attempt should be made to work with beryllium before familiarization with correct handling procedures.

A successful test for beryllium in air and on surfaces was developed and published (2006) as an international voluntary consensus standard (ASTM D7202; www.astm.org). The procedure uses dilute ammonium bifluoride for dissolution and fluorescence detection with beryllium bound to sulfonated hydroxybenzoquinoline, allowing detection up to 100 times lower than the recommended limit for beryllium concentration in the workplace. Fluorescence increases with increasing beryllium concentration. This procedure has been successfully tested on a variety of surfaces and is effective for the dissolution and ultratrace detection of refractory beryllium oxide and siliceous beryllium (Table 1.6).

TABLE 1.6

Physical properties of beryllium metal	
CAS number	7440-41-7
Phase	Solid
Density at rt	1.85 g/cm^3
Liquid density at MP	1.690 g/cm^3
Melting point	1560 K, 1287 °C, 2349 °F
Heat of fusion	7.895 kJ/mol
Heat of vaporization	297 kJ/mol
Specific heat capacity	16.443 J/mol K
Electronegativity	1.57 (Pauling scale)
Ionization energies	1st: 899.5 kJ/mol
	2nd: 1757 kJ/mol
	3rd: 14,848 kJ/mol
Atomic radius	1.12 Å
Covalent radius	0.96 Å
Van der Waals radius	1.53 Å
Crystal structure	Hexagonal
Magnetic ordering	Diamagnetic
Thermal conductivity	200 W/mol K (at 300 K)
Thermal expansion	11.3 μm/mol K (25 °C)
Speed of sound (thin rod)	12,870 ms (at rt)
Young's modulus	287 Gpa
Shear modulus	132 Gpa
Bulk modulus	130 Gpa
Poisson ratio	0.032
Mohs hardness	5.5
Vickers hardness	1670 Mpa
Brinell hardness	600 MPa

1.2.2. Magnesium

Magnesium is a Group 2 element (Group IIA in older labeling schemes). This element has the symbol Mg, atomic number 12, atomic weight of 24.305 g/mol and common oxidation number +2. It is the eighth most abundant element in the earth's crust by mass, although ninth in the Universe as a whole. This preponderance of magnesium in the Universe is related to the fact that it is easily built up in supernova stars from a sequential addition of three helium nuclei to carbon (which in turn is made from three helium nuclei). Magnesium constitutes about 2% of the Earth's crust by mass, which makes it the eighth most abundant element in the crust.

TABLE 1.7

Location	ppb by weight	ppb by atoms
Universe	600,000	30,000
Sun	700,000	30,000
Meteorite (carbonaceous)	120,000,000	100,000,000
Crustal rocks	29,000,000	25,000,000
Seawater	1,326,000	337,000
Stream	4,100	170
Humans	270,000	70,000

Magnesium ion's high solubility in water helps to ensure that it is the third most abundant element dissolved in seawater.

The name originates from the Greek word for a district in Thessaly called "Magnesia". It is related to the terms "magnetite" and "manganese", which also originated from this area, and required differentiation as separate substances. Magnesium is the seventh most abundant element in the Earth's crust by mass and eighth by molarity. It is found in large deposits of Magnesite, Dolomite and other minerals, and in mineral waters, where the magnesium ion is soluble. The abundance of magnesium is shown in Table 1.7.

In 1618 a farmer at Epsom in England attempted to give his cows water from a well. They refused to drink because of the water's bitter taste. However the farmer noticed that the water seemed to heal scratches and rashes. The fame of "Epsom Salts" spread. Eventually the compound was recognized to be hydrated magnesium sulfate, $MgSO_4$.

The first person to propose that magnesium was an element was Joseph Black of Edinburgh in 1755. In 1792, an impure form of metallic magnesium was produced by Anton Rupprecht who heated magnesia (magnesium oxide, MgO) with charcoal. He named the element "Austrium" after his native Austria. In 1808, a small sample of the *pure* metal was isolated by Humphry Davy by the electrolysis of moist MgO. He proposed the name "magnium" based on the mineral Magnesite ($MgCO_3$) that came from Magnesia in Greece. Neither name survived and eventually the metal was called magnesium. The metal itself was first produced in quantity in England by Davy in 1808 using then the new method of electrolysis of a mixture of molten magnesia and mercuric oxide. Antoine Bussy prepared it in a consistent form in 1831.

The known isotopes of magnesium are listed in Table 1.8.

Magnesium has three stable isotopes: ^{24}Mg, ^{25}Mg and ^{26}Mg. All are present in significant amounts (see Table 1.8). About 79% of Mg is ^{24}Mg. The isotope ^{28}Mg is radioactive and in the 1950s to 1970s was made commercially by several nuclear power plants for use in scientific experiments. This isotope has a relatively short half-life (21 h) and so its use was limited by shipping times. ^{26}Mg has found application in isotopic geology, similar to that of aluminum. ^{26}Mg is a radiogenic daughter product of ^{26}Al, which has a half-life of 717,000 years. Large enrichments of stable ^{26}Mg have been observed in the Ca–Al-rich inclusions of some carbonaceous chrondrite meteorites. The anomalous abundance of ^{26}Mg is attributed to the decay of its parent ^{26}Al in the inclusions. Therefore, the meteorite must have formed in the solar nebula before the ^{26}Al had decayed. Hence, these fragments are among the oldest objects in the solar system and have preserved information about its early history.

It is conventional to plot $^{26}Mg/^{24}Mg$ against an Al/Mg ratio. In an isochronic dating plot, the Al/Mg ratio plotted is $^{27}Al/^{24}Mg$. The slope of the isochron has no age significance, but indicates the initial $^{26}Al/^{27}Al$ ratio

TABLE 1.8

in the sample at the time when the systems were separated from a common reservoir.

Magnesium is a rather tough metal. Elemental magnesium is a moderately strong, silvery-white, lightweight metal (two-thirds the density of aluminum). Magnesium tarnishes slightly in air, and finely divided magnesium readily ignites upon heating in air and burns with a dazzling white flame, making it a useful ingredient in flares. Normally, magnesium is coated with a layer of oxide, MgO, that protects magnesium from air and water.

Like its neighbor, Ca, magnesium reacts with water at room temperature, though it reacts much more slowly than calcium. When it is submerged in water, hydrogen bubbles will almost unnoticeably begin to form on the surface of the metal. If powdered, it will react much more rapidly. The reaction occurs much faster at higher temperatures. Magnesium also reacts exothermically with most acids, such as hydrochloric acid (HCl). As with aluminum, zinc and many other metals, the reaction with hydrochloric acid produces the chloride of the metal and releases hydrogen gas.

Magnesium is a highly flammable metal, but, while it is easy to ignite when powdered or shaved into thin strips, it is difficult to ignite in mass or bulk. Once ignited, it is difficult to extinguish, being able to burn in both nitrogen (forming magnesium nitride), and also in CO_2 (forming magnesium oxide and carbon). This property was used in incendiary weapons used in the "fire bombing" of cities in World War II, the only practical civil defense being used to smother a burning flare under dry sand to exclude the atmosphere. On burning in air, magnesium produces a brilliant white light. Thus, magnesium powder (as "flash powder") was used as a source of illumination in the early days of photography. Later, magnesium ribbon was used in electrically ignited flash bulbs.

Magnesium powder is used in the manufacture of fireworks and marine flares where a brilliant white light is required. Flame temperatures of magnesium and magnesium alloys can reach 1371 °C (2500 F), although flame height above the burning metal is usually less than 300 mm (12 in). Magnesium may be used as an ignition source for "thermite", or otherwise difficult to ignite mixture of aluminum and iron oxide powder.

Magnesium compounds are typically white crystals. Most are soluble in water, providing the sour-tasting magnesium ion, Mg^{2+}. Small amounts of dissolved magnesium ion contribute to the tartness and taste of natural waters. Magnesium ion in large amounts is an ionic laxative, and magnesium sulfate (known as "Epsom Salts") is sometimes used for this purpose. So-called "milk of magnesia" is a water suspension of one of the few insoluble magnesium compounds, $Mg(OH)_2$. The undissolved particles give rise to its appearance and name. Milk of magnesia is a mild base commonly used as an antacid.

The metal is now mainly obtained by electrolysis of magnesium salts obtained from brine. Commercially, the chief use for the metal is as an alloying agent to make Al–Mg alloys, sometimes called "magnalium" or "magnelium". Since magnesium is less dense than aluminum, these alloys are valued for their relative lightness and strength.

Magnesium is an important element for plant and animal life. Chlorophylls are porphyrins (a class of pigments including heme and chlorophyll) whose molecules contain a flat ring of four-linked heterocyclic groups, based upon magnesium. The adult human daily requirement of magnesium is about 0.3 g/day. Magnesium is the 11th most abundant element by mass in the human body. Its ions are essential to all living cells, where they play a major role in manipulating important biological polyphosphate compounds like ATP, DNA and RNA. Hundreds of enzymes thus require magnesium ions in order to function. Magnesium, being the metallic ion at the center of chlorophyll, is thus a common additive to fertilizers. Magnesium compounds are used medicinally as common laxatives, antacids (i.e. "Milk of Magnesia"), and in a number of situations where stabilization of abnormal nerve excitation and blood vessel spasm is required (i.e. to treat eclampsia). Magnesium ions are sour to the taste, and in low concentrations help to impart a natural tartness to fresh mineral waters.

Magnesium metal can be made commercially by several processes and would not normally be made in the laboratory because of its ready availability. There are massive amounts of magnesium in seawater. This can be recovered as magnesium chloride, $MgCl_2$ through reaction with calcium oxide, CaO:

$$CaO + H_2O \Rightarrow Ca^{2+} + 2OH^-$$

$$Mg^{2+} + 2OH^- \Rightarrow Mg(OH)_2$$

$$Mg(OH)_2 + 2HCl \Rightarrow MgCl_2 + 2H_2O$$

Electrolysis of hot molten $MgCl_2$ produces magnesium as a liquid. This is poured off and chlorine gas is recovered:

$$\text{cathode: } Mg^{2+}(liq) + 2e^- \Rightarrow Mg(solid)$$

$$\text{anode: } Cl^-(liq) \Rightarrow {}^1/_2\, Cl_2(gas) + e^-$$

The other method used to produce magnesium involves Dolomite, i.e. $MgCa(CO_3)_2$, an important magnesium mineral, and involves a non-electrolytic method. In this process, Dolomite is "calcined" by heating to form the oxide, "calcined dolomite" = $MgO \cdot CaO$, and this product is then reacted with ferrosilicon alloy:

$$2[MgO \cdot CaO] + FeSi \Rightarrow 2Mg + Ca_2SiO_4 + Fe$$

Magnesium, as the metal, may be distilled out from this mixture of solid products (BP = 1091 °C). Although magnesium is found in over 60 minerals, only Dolomite-($MgCa(CO_3)_2$), Magnesite-($MgCO_3$), Brucite-($Mg(OH)_2$), Carnallite-($KMgCl_3 \cdot 6H_2O$), Talc-($Mg_3Si_4O_{10}(OH)_2$) and Olivine-($(Mg,Fe)_2SiO_4$) are of commercial importance.

The Mg^{2+} cation is the second most abundant in seawater (occurring at about 12% of the mass of sodium cations), which makes seawater and sea-salt an attractive commercial source of Mg. To extract the magnesium, $Ca(OH)_2$ is added to seawater to form $Mg(OH)_2$ as a precipitate:

$$MgCl_2(aq) + Ca(OH)_2(solid) \Rightarrow Mg(OH)_2(solid) + CaCl_2(aq)$$

Magnesium hydroxide is insoluble in water so it can be filtered out and then reacted with hydrochloric acid to obtain concentrated magnesium chloride:

$$Mg(OH)_2(solid) + 2\,HCl(aq) \Rightarrow MgCl_2(aq) + 2\,H_2O$$

From molten magnesium chloride, an electrolysis process produces magnesium.

In the United States, magnesium is principally obtained by electrolysis of fused magnesium chloride from brines, wells, and seawater. The United States has traditionally been the major world supplier of this metal, supplying 45% of world production even as recently as 1995. Today, the US market share is at 7%, with a single domestic producer left, "US Magnesium", a company born from the now-defunct "Magcorp". As of 2005, China has taken over as the dominant supplier, pegged at 60% world market share, which increased from 4% in 1995. Unlike the above-described electrolytic process, China is almost completely reliant on a different method of obtaining the metal from its ores, the so-called "Silicothermic Pidgeon" process which involves the reduction of the oxide at high temperatures with silicon.

Magnesium is the third most commonly used structural metal, following steel and aluminum. Magnesium, in its purest form, can be compared with aluminum, and is strong and light so that it is used in several high-volume part manufacturing applications, including automotive and truck components.

Specialty, high-grade car wheels of magnesium alloy are called "mag wheels". In 1957 a Corvette SS, designed for racing, was constructed with magnesium body panels. An earlier Mercedes-Benz race car model had a body made from "Elektron", a magnesium alloy; these cars ran (with successes) at Le Mans and other world-class race events in 1955. Volkswagen Group has used magnesium in its engine components for many years. For a long time, Porsche AG has used a magnesium alloy for its engine blocks due to the weight advantage. There is renewed interest in magnesium engine blocks, as featured in the 2006 BMW 325i and 330i models. The application of a magnesium alloy in the 2006 Corvette engine cradle has advanced the technology of designing robust automotive parts using magnesium. These alloys, recent developments in high-temperature low-creep metals, are becoming competitive to aluminum because of lower costs.

The second application field of magnesium is in electronic devices. Due to low weight, good mechanical and electrical properties, magnesium is widely used for manufacturing of mobile phones, laptop computers, cameras, and other electronic components.

Historically, magnesium was one of the main aerospace construction metals and was used for German military aircraft as early as World War I and extensively for German aircraft in World War II. The Germans coined the name "Elektron" for the magnesium alloy that is still used today. Due to perceived hazards with magnesium parts in the event of fire, the application of magnesium in the commercial aerospace industry was generally restricted to engine-related components. Currently the use of magnesium alloys in aerospace is increasing, mostly driven by the increasing importance of fuel economy and the need to reduce weight. The development and testing of new magnesium alloys continues, notably Elektron-21, which has successfully undergone extensive aerospace testing for suitability in engine, internal and airframe components. The European Community currently runs three R&D magnesium projects in its Aerospace Priority agenda called "Six Framework Program".

Magnesium is flammable, burning at a temperature of approximately 1371 °C (1644 K; 2500 °F). The autoignition temperature of magnesium ribbon is approximately 510 °C (783 K; 950 °F) in air. The high temperature at which magnesium burns makes it a handy tool for starting emergency fires during outdoor recreation. Other related uses include flashlight photography, flares, pyrotechnics and fireworks sparklers.

Magnesium is also used:

- To remove sulfur from iron and steel.
- To refine titanium in the "Kroll" process.
- To photoengrave plates in the printing industry.
- To combine in alloys, where this metal is essential for airplane and missile construction.
- In the form of turnings or ribbons, to prepare "Grignard Reagents", which are useful in organic synthesis.
- As an alloying agent, improving the mechanical, fabrication and welding characteristics of aluminum.
- As an additive agent in conventional propellants and the production of "nodular graphite" in cast iron.
- As a reducing agent for the production of uranium and other metals from their salts.
- As a desiccant, since it easily reacts with water.
- As a sacrificial (galvanic) anode to protect underground tanks, pipelines, buried structures, and water heaters.

TABLE 1.9

Physical constants of magnesium	
CAS number	7439-95-4
Phase	Solid
Density	1.738 g/cm^3
Liquid density at MP	1.584 g/cm^3
Melting point	923 K, 650 °C, 1202 °F
Boiling point	1363 K, 1091 °C, 1994 °F
Heat of fusion	8.48 kJ/mol
Heat of vaporization	128 kJ/mol
Specific heat capacity	24.869 J/mol/K
Electronegativity	1.31 (Pauling scale)
Atomic radius	1.60 Å
Covalent radius	1.41 Å
Van der Waals radius	1.73 Å
Crystal structure	Hexagonal
Magnetic ordering	Paramagnetic
Electrical resistivity	43 nΩ m
Thermal conductivity	156 W/m K (at 300 K)
Speed of sound (thin rod)	4940 ms
Young's modulus	45 Gpa
Shear modulus	17 Gpa
Bulk modulus	46 Gpa
Poisson ratio	0.29
Mohs hardness	2.5
Brinell hardness	260 Mpa

Stable isotopes		
^{24}Mg	78.99%	^{24}Mg is stable with 12 neutrons
^{25}Mg	10%	^{25}Mg is stable with 13 neutrons
^{26}Mg	11.01%	^{26}Mg is stable with 14 neutrons

Magnesium metal and its alloys are explosive hazards. They are highly flammable in their pure form when molten or in powder or in ribbon form. Burning or molten magnesium metal reacts violently with water. When working with powdered magnesium, safety glasses for eye protection are employed, because the bright white light produced by burning magnesium contains UV light that can permanently damage human eye retinas.

Physical constants of Mg metal are listed in Table 1.9.

1.2.3. Calcium

Calcium is the chemical element with the symbol **Ca** and atomic number 20. It has an atomic weight of 40.078 g/mol. Calcium is the fifth most abundant dissolved ion in seawater by both molarity and mass, after Na^+, Cl^-, Mg^{2+} and SO_4^{2-}. Calcium metal is quite reactive. It readily forms a white coating of calcium nitride (Ca_3N_2) in air at room temperature. It reacts with water and the metal burns in air with an orange-red flame, forming largely the nitride, but some oxide.

In the visible portion of the spectrum of many stars, including the Sun, strong absorption lines of singly ionized calcium ions are evident. Prominent among these are the H line at 3968.5 Å and the K line at 3933.7 Å of singly ionized calcium, or Ca II. For the Sun, and stars with low temperatures, the prominence of the H and K lines is an indication of strong magnetic activity in the chromosphere. Measurement of periodic variations of these active regions can also be used to deduce the rotational periods of these stars.

Calcium as the element is a gray silvery metal. The metal is relatively hard. Calcium is an essential constituent of leaves, bones, teeth, and shells in the Earth's environment. Calcium is the fifth most abundant element in the earth's crust and makes up more than 3% of the crust by weight. Calcium does not occur as the metal itself in nature and instead is found in various minerals including Limestone and Fluorite. Stalagmites and stalactites contain calcium carbonate ($CaCO_3$). Calcium occurs most commonly in sedimentary rocks in the minerals "Calcite", "Dolomite" and "Gypsum". It also occurs in igneous and metamorphic rocks chiefly in the silicate minerals: "Plagioclase"-($CaAl_2Si_2O_8$), "Amphiboles"-($Ca_2Mg_5Si_8O_{22}(OH)_2$), "Pyroxenes"-($CaMg(Si,Al)_2O_6$) and "Garnets"-($Ca_3Al_2(SiO_4)_3$. The abundance of calcium is shown in Table 1.10.

Calcium (Latin word *calcis* meaning "lime") was known as early as the first century when the Ancient Romans prepared lime as calcium oxide from limestone and used "slaked lime" as a "whitewash" on various homes and buildings. Literature dating back to 975 AD notes that "Plaster-of-Paris" (calcium sulfate), is useful for setting broken bones. The metal was not isolated until 1808 when Sir Humphrey Davy of England electrolyzed a mixture of lime and mercuric oxide, using then the new "Voltaic Cell" as an energy source. Davy was trying to isolate calcium. When he heard that Swedish chemist Jöns Berzelius and his colleague, Pontin, had prepared calcium amalgam by electrolyzing lime in mercury, he set up a similar system and was successful. He worked with electrolysis throughout his life and also

TABLE 1.10

The abundance of calcium		
Location	**ppb by weight**	**ppb by atoms**
Universe	70,000	2000
Sun	70,000	2000
Meteorite (carbonaceous)	11,000,000	5,200,000

Seawater	4220	650
Stream	1500	38
Humans	14,000,000	2,200,000

discovered/isolated boron, sodium, potassium, magnesium, calcium, strontium and barium. Calcium metal was not available on a large scale until the beginning of the twentieth century.

Calcium, with a density of 1.55 g/cm^3, is the lightest of the alkali earth metals. Magnesium (1.74) and beryllium (1.84) are heavier although they are *lighter* in atomic mass. Both strontium and barium metals get heavier along with the heavier atomic mass. Calcium has a higher resistivity than copper or aluminum. Yet, weight for weight, allowing for its much lower density, it is a better conductor than either. However, its use in terrestrial applications is usually limited because of its high reactivity when exposed to air.

Chemically, calcium is reactive and soft for a metal (though harder than lead, it can be cut with a knife with some difficulty). It is a silvery metallic element that must be extracted by electrolysis from a molten salt like $CaCl_2$. Once produced, it is not stable when exposed to air. It is somewhat difficult to ignite, unlike magnesium, but when lit, the metal burns in air with a brilliant high-intensity reddish light.

Calcium metal reacts with water, evolving hydrogen gas at a rate rapid enough to be noticeable, but not fast enough at room temperature to generate much heat. In powdered form, however, the reaction with water is extremely rapid, as the increased surface area of the powder accelerates the reaction with the water. Part of the slowness of the calcium–water reaction results from the metal being partly protected by an insoluble white $Ca(OH)_2$ layer. In acid solutions where the salt product is water soluble, calcium reacts vigorously. Calcium has 24 known isotopes, as shown in Table 1.11.

Calcium has four stable isotopes (^{40}Ca and ^{42}Ca through ^{44}Ca), plus two more isotopes (^{46}Ca and ^{48}Ca) that have such a long half-lives that for all practical purposes they can be considered stable. It also has a cosmogenic isotope, radioactive ^{41}Ca, with a half-life of 103,000 years. Unlike cosmogenic isotopes that are produced in the atmosphere, ^{41}Ca is produced by neutron activation of ^{40}Ca. Most of its production is in the upper meter or so of the soil column, where the cosmogenic neutron flux is still sufficiently strong. ^{41}Ca has received much attention in stellar studies because it decays to ^{41}K, a critical indicator of solar system anomalies.

A major part (97%) of naturally occurring calcium is in the form of ^{40}Ca. This isotope is one of the daughter products of ^{40}K decay, along with ^{40}Ar. While K/Ar dating has been used extensively in the geological sciences, the prevalence of ^{40}Ca in nature has impeded its use in dating. Techniques using mass spectrometry and a "double-spike" isotope dilution have been used for K/Ca age dating.

TABLE 1.11

Nuclide	Z	N	Isotopic mass	Half-life	Nuclear spin

^{56}Ca	20	36	55.98557	10 ms	0+
^{57}Ca	20	37	56.99236	5 ms	5/2−

The most abundant isotope, ^{40}Ca, has a nucleus of 20 protons and 20 neutrons. This is the heaviest stable isotope of any element known that has equal numbers of protons and neutrons. In supernova explosions, calcium is formed from the reaction of carbon with various numbers of alpha particles (helium nuclei), until this most common calcium isotope (containing 10 helium nuclei) has been formed.

Calcium salts are colorless (unless the anion is colored) and ionic solutions of calcium (Ca^{2+}) are colorless as well. Many calcium salts are not soluble in water. When in solution, the calcium ion to the human taste varies remarkably, being reported as mildly salty, sour, "mineral like" or even "soothing". It is apparent that many animals can taste, or develop a taste, for calcium, and use this sense to detect the mineral in "salt licks" or other sources. In human nutrition, soluble calcium salts may be added to tart juices without much effect to the average palate.

Calcium is essential for living organisms, particularly in cell physiology, where the movement of the calcium ion, Ca^{2+}, into and out of the cytoplasm operates as a signal for many cellular processes. As a major material used in mineralization of bones and shells, calcium is the most abundant metal by mass in many animals. Calcium is the fifth most abundant element by mass in the human body, where it is a common cellular ionic messenger for many bodily functions, and serves also as a structural element. The relatively high atomic number of calcium in the skeleton causes bone to be radioopaque. Of the human body's solid components after drying (as for example, after cremation), about a third of the total mass is approximately 1 kg of calcium that composes the average skeleton (the remainder being mostly phosphates and oxides).

Calcium is an important component of a healthy diet and a necessary mineral for maintaining life. Calcium plays an important role in building stronger, denser bones early in life and keeping bones strong and healthy later in life. Approximately 99% of the body's calcium is stored in the bones and teeth. The rest of the calcium in the body has other important uses, such as "neurotransmitter release", muscle contraction and "exocytosis" (a durable process by which a cell directs the contents of secretory vesicles out of the cell membrane). Especially important are "neurotransmitter release", and muscle contraction. In the electrical conduction system of the heart, calcium replaces sodium as the mineral that depolarizes the cell, thereby proliferating the action potential. In cardiac muscle, sodium influx commences an action potential, but during potassium efflux, the cardiac myocyte experiences calcium influx, prolonging the action potential and creating a plateau phase of dynamic equilibrium.

Long-term calcium deficiency can lead to rickets and poor blood clotting. In case of a menopausal woman, it can lead to "Osteoporosis", in which the bone deteriorates and an increased risk of fractures develops. While a lifelong deficit can affect bone and tooth formation, over-retention can cause "hypercalcemia" (elevated levels of calcium in the blood), impaired kidney function and decreased absorption of other minerals. High calcium intakes or high calcium absorption was previously thought to contribute to the development of kidney stones. However, recent research has indicated that a high calcium intake is associated with a lower risk for kidney stones. Vitamin D is needed to absorb calcium.

Calcium metal is readily available commercially. Commercially it is made by the electrolysis of molten calcium chloride, $CaCl_2$:

$$\text{cathode: } Ca^{2+}(\text{liq}) + 2e^- \Rightarrow Ca(\text{solid})$$

$$\text{anode: } Cl^-(\text{liq}) \Rightarrow {}^1/_2\,Cl_2(\text{gas}) + e^-$$

in the same way that magnesium is produced. The calcium chloride is made by the action of hydrochloric acid upon calcium carbonate. Calcium chloride is also a by-product in the Solvay process used to make sodium carbonate:

$$CaCO_3 + 2\,HCl \Rightarrow CaCl_2 + H_2O + CO_2$$

Alternatively, and on a small scale, calcium can be made through the reduction of CaO with aluminum or of $CaCl_2$ with sodium metal:

$$6CaO + 2Al \Rightarrow 3Ca + Ca_3Al_2O_6$$

$$CaCl_2 + 2Na \Rightarrow Ca + 2NaCl$$

Some important uses of calcium metal are:

- Use as a reducing agent in the extraction of other metals, such as uranium, zirconium and thorium.
- Use as a deoxidizer, desulfurizer, or decarbonizer for various ferrous and nonferrous alloys.
- Use in the making of cements and mortars to be used in construction.
- Calcium is also used to remove oxygen, sulfur and carbon from certain alloys.
- Calcium can be alloyed with aluminum, beryllium, copper, lead and magnesium.
- Calcium is also used in vacuum tubes as a getter, a material that combines with and removes trace gases from vacuum tubes.
- Use in dehydrating oils, decarburization and desulfurization of iron and its alloys.
- Also used in fertilizer, concrete and plaster of paris (Table 1.12).

Enthalpy of fusion:	8.54 kJ/mol
Vapor pressure	254 Pa at 839 °C
Abundance of calcium	Earth's crust: 41.000 ppm
	Seawater: 390 ppm
	Sun = 2.24 × 10^6 (relative to H = 10^{12})
Main isotopes of calcium	^{40}Ca = 96.941% ^{41}Ca = trace
	^{42}Ca = 0.647% ^{43}Ca = 0.135%
	^{44}Ca = 2.086% ^{48}Ca = 0.187%

Due to its high reactivity with common materials like water, there is very little demand for metallic calcium.

1.2.4. Strontium

Strontium has the symbol **Sr**, the atomic number 38 and an atomic weight of 87.623 g/mol. As an alkaline earth metal, strontium is a soft silver-white or yellowish metallic element that is highly reactive chemically. Due to its extreme reactivity with oxygen and water, this element occurs naturally only in compounds with other elements. The metal turns yellow when exposed to air. It occurs naturally in the minerals "Celestine" ($SrSO_4$) and "strontianite" ($SrCO_3$). The isotope, ^{90}Sr, is present in "radioactive fallout" and has a half-life of 28.90 years.

The following table presents the abundance of strontium. Strontium commonly occurs in nature, the 15th most abundant element on earth, averaging 0.034% in all igneous rock. It is found chiefly as the form of the sulfate mineral "Celestite" ($SrSO_4$) and the carbonate "Strontianite" ($SrCO_3$) (Table 1.13).

Of the two, Celestite occurs much more frequently in sedimentary deposits of sufficient size to make the development of mining facilities attractive. Strontianite is more useful of the two common minerals because strontium is used most often in the carbonate form, but few deposits have been discovered that are suitable for development. The metal can be prepared by electrolysis of melted $SrCl_2$ containing a small amount of KCl (to assist conductivity):

$$Sr^{2+} + 2e^- \Rightarrow Sr$$

$$2Cl^- \Rightarrow Cl_2(gas) + 2e^-$$

TABLE 1.13

Abundance of strontium		
Location	**ppb by weight**	**ppb by atoms**
Universe	40	0.6
Sun	50	0.7
Meteorite (carbonaceous)	8900	2000
Crustal rocks	360,000	85,000
Seawater	8100	570
Streams	60	0.7
Humans	4600	330

This is similar to those methods used for the other alkaline earth metals. Alternatively it is made by reducing strontium oxide with Al metal in vacuum at a temperature at which strontium distills off. Three allotropes of the metal exist, with transition points at 235 °C ($\alpha \Rightarrow \beta$) and 540 °C ($\beta \Rightarrow \gamma$). The largest commercially exploited deposits are found in England.

Both strontium and "Strontianite" are named after Strontian, a village in Scotland near which the mineral was first discovered in the ores taken from the lead mines. In 1787, an intriguing mineral came to Edinburgh from a Lead mine in a small village on the shores of Loch Sunart, Argyll, in the western highlands of Scotland. At that time, the substance was thought to be some sort of Barium compound. It was 3 years later that Scott's Irish chemist, Adair Crawford, published a paper claiming that the mineral held a new species including a new chemical element. Other chemists later prepared a number of compounds with the element, noting that it caused the candle's flame to burn red, while barium compounds gave a green color. The new mineral was named "Strontite" in 1793 by Thomas Hope, another professor of medicine at the University of Glasgow.

This element was eventually isolated by Humphrey Davy in 1808 during his studies of the electrolysis of various "alkaline earths" containing molten chloride such as $SrCl_2$ and mercuric oxide. He announced his work in a lecture to the Royal Society on 30 June 1808. In keeping with the naming of the other alkaline earths, he changed the name to *Strontium*.

Strontium is a gray/silvery metal that is softer than Ca. It is even more reactive in water, and reacts on contact to produce $Sr(OH)_2$ and hydrogen gas. It burns in air to produce both SrO and Sr_3N_2. But since it does not react with nitrogen below 380 °C, it only forms the oxide spontaneously at room temperature. It should be kept under kerosene to prevent oxidation. Freshly exposed strontium metal rapidly turns a yellowish color as the oxide forms. Finely powdered strontium metal will ignite spontaneously in air at room temperature. Volatile strontium salts impart a crimson color to flames, and these salts are used in pyrotechnics and in the production of flares.

Strontium has four naturally occurring isotopes ^{84}Sr (0.56%), ^{86}Sr (9.86%), ^{87}Sr (7.0%) and ^{88}Sr (82.58%), but there are 33 known isotopes (Tables 1.14 and 1.15).

This element (**Sr**) has four stable, naturally occurring isotopes: ^{84}Sr (0.56%), ^{86}Sr (9.86%), ^{87}Sr (7.0%) and ^{88}Sr (82.58%). Only ^{87}Sr is radiogenic since it is produced by decay from the radioactive alkali metal ^{87}Rb, which has a half-life of 4.88×10^{10} years. Thus, in any material, there are two sources of ^{87}Sr. That formed during primordial nucleosynthesis along with ^{84}Sr, ^{86}Sr and ^{88}Sr, and that formed by radioactive decay of ^{87}Rb. The ratio $^{87}Sr/^{86}Sr$ is the parameter typically reported in geologic investigations. The ratios reported in minerals and rocks have values ranging from 0.7 to greater than 4.0. Because strontium has an electronic configuration similar to that of calcium, it readily substitutes for Ca in minerals.

Sixteen unstable isotopes are known to exist. Of greatest importance are strontium-89 (^{89}Sr) with a half-life of 50.57 days, and strontium-90 (^{90}Sr) with a half-life of 28.78 years. They decay by emitting an electron and an anti-neutrino (ν_e) in beta-minus decay (β^- decay) to become yttrium, ^{90}Y (half-life = 64 h). ^{89}Sr is an artificial radioisotope that is used in the treatment of bone cancer. In circumstances where cancer patients have widespread and painful bony metastases, the administration of ^{89}Sr results in the delivery of β-particles directly to the area of the bony problem, where calcium turnover is greatest. ^{90}Sr is a by-product of nuclear fission found in "nuclear fallout" and presents a health problem since it substitutes for calcium in bone, preventing its expulsion from the body. Significant absorption usually results in death.

Because it is a long-lived high-energy beta-emitter, ^{90}Sr is used in SNAP (Systems for Nuclear Auxiliary Power) devices. These devices hold promise for use in spacecraft, remote weather stations, navigational buoys, etc., where a lightweight, long-lived, nuclear-electric power source is required.

According to the latest records, China was the top producer of strontium in 2007, with over two-thirds world share, followed by Spain and Mexico. Annual worldwide production is around 137,000 t. Primary mining areas are UK, Tunisia, Russia, Germany, Mexico and USA.

Several uses for radioactive strontium have emerged:

- The species, ^{89}Sr, is the active ingredient in Metastron, a radiopharmaceutical used for bone pain secondary to metastatic bone cancer. The strontium acts like

0.93 W of heat per gram (it is lower for the form of ^{90}Sr used in RTGs, which is SrF_2). But, ^{90}Sr has a lifetime approximately three times shorter and has a lower density than ^{238}Pu, another RTG fuel. The main advantage of ^{90}Sr is that it is cheaper than ^{238}Pu and can be recovered from nuclear waste.

- ^{90}Sr is also used in cancer therapy. Its beta emission and long half-life are ideal for superficial radiotherapy.
- $^{87}Sr/^{86}Sr$ ratios are commonly used to determine the likely source in areas of sediment in natural systems, especially in marine and fluvial environments. Dasch (1969) showed that surface sediments of Atlantic displayed $^{87}Sr/^{86}Sr$ ratios that could be regarded as bulk averages of the $^{87}Sr/^{86}Sr$ ratios of geological terranes from adjacent landmasses. A good example of a fluvial marine system to which Sr isotope provenance studies have been successfully employed is the River Nile–Mediterranean Sea system.
- Due to the differing ages of the rocks that constitute the majority of the Blue and White Nile catchment areas reaching the River Nile delta and East Mediterranean Sea, the changing provenance of sediment can be discerned through Sr isotopic studies. Such changes have been climatically controlled in the Late Quaternary eras.
- More recently, $^{87}Sr/^{86}Sr$ ratios have also been used to determine the source of ancient archaeological materials such as timbers and corn in Chaco Canyon, New Mexico.
- $^{87}Sr/^{86}Sr$ ratios in teeth may also be used to track animal migrations or in criminal forensics.
- A recent in vitro study conducted in the NY College of Dental Sciences using strontium to stimulate "osteoblasts" showed marked improvement of bone-building by osteoblasts.

As a pure metal, Sr is used in strontium 90%–aluminum 10% alloys of an eutectic composition for the modification of aluminum–silicon casting alloys. The AJ62 alloy, a durable creep-resistant magnesium alloy used in car and motorcycle engines by BMW Motor Car company contains 2% by weight of strontium metal.

Other than its usage as radioactive tracers and radioactive sources for human body treatment, the only other usage has been in fireworks where the crimson red color is due to strontium.

1.2.5. Barium

Barium has the symbol **Ba**, atomic number 56, and is the fifth element in Group 2. Its atomic weight is 137.332 g/mol. Barium is a soft silvery metal. It is never found in nature in its pure form due to its reactivity with air. Its oxide is historically known as "Baryta" but because it reacts with water and carbon dioxide, it is not found as a mineral. The most common naturally occurring minerals are the very insoluble barium sulfate, $BaSO_4$ (Barite), and barium carbonate, $BaCO_3$ (Witherite). Barium's name originates from the Greek word "bary", meaning "heavy", describing the high density of some common barium-containing ores. Alchemists in the early Middle Ages knew about some barium minerals. Smooth pebble-like stones of mineral Baryte found in Bolona, Italy were known as "Bologna Stones". After exposed to light, they would glow for years (probably because they contained some barium sulfide (BaS) formed during the calcination of the "stone" with charcoal carbon). It was this quality that attracted them to witches and alchemists.

Though barium minerals are dense, barium metal itself is comparatively light. Its cosmic abundance is estimated as 3.7 atoms (on the same basis, Si = 106 atoms). Barium constitutes about 0.03% of the Earth's crust, chiefly as the minerals "Barite" (also called barytes or heavy spar) and "Witherite". The abundance of barium is 0.0425% in the Earth's crust and 13 μg/l in seawater. A rare gem containing barium is known, called "Benitoite" ($BaTiSi_3O_9$). Large deposits of Barite are found in China, Germany, India, Morocco, and in the US. Because barium quickly oxidizes in air, it is difficult to obtain the free metal and it is never found free in nature. The following table lists the abundance of barium as found in nature (Table 1.16).

Barium is a soft and ductile metal. Its simple compounds are notable for their relatively high specific gravity (as compared to the other alkaline earth elements). Barium, which is slightly harder than lead, has a silvery white luster when freshly cut.

The Swedish chemist Carl Wilhelm Scheele discovered (1774) a new base (baryta, or barium oxide) as a minor constituent in "Pyrolusite", but could not isolate barium as the metal. From this base, he prepared some crystals of barium sulfate, which he sent to Johan

TABLE 1.16

Abundance of Barium

Humans	300	14

Gottlieb Gahn, the discoverer of manganese. A month later Gahn found that the mineral Barite is composed of barium sulfate. Only after the electric battery became available could Sir Humphry Davy finally isolate (1808) the element itself by electrolysis. Oxidized barium was at first called "barote", by Guyton-de Morveau, a name that was changed by Lavoisier to *baryta*. Barium was first isolated by electrolysis of molten barium salts in 1808, by Davy, who, by analogy with calcium named "barium" after baryta, with the "-ium" ending signifying a metallic element.

Because barium quickly oxidizes in air, it is difficult to obtain the free metal and it is never found free in nature. The metal is primarily found in, and extracted from, Barite. Because Barite is so insoluble, it cannot be used directly for the preparation of other barium compounds, or barium metal. Instead, the ore is heated with carbon to reduce it to barium sulfide:

$$BaSO_4 + 2\,C \;\Rightarrow\; BaS + 2\,CO_2$$

The barium sulfide is then hydrolyzed or treated with acids to form other barium compounds, such as the chloride, nitrate or carbonate.

Barium is commercially produced through the electrolysis of molten barium chloride ($BaCl_2$):

$$\text{(Cathode reaction)}\ Ba^{2+}(liq) + 2e^- \;\Rightarrow\; Ba(solid)$$

$$\text{(Anode reaction)}\ 2\,Cl^- \;\Rightarrow\; Cl_2(gas) + 2\,e^-$$

This process is similar to that of the other alkaline earth metals. Barium metal is also produced by the reduction of barium oxide with finely divided aluminum at temperatures between 1100 and 1200 °C:

$$4\,BaO + 2\,Al \;\Rightarrow\; BaO{\cdot}Al_2O_3 + 3\,Ba(gas)$$

The barium vapor is cooled by means of a water jacket and condensed into the solid metal. The solid block may be cast into rods or extruded into wires. This is the most effective method i.e. the reduction of the oxide by heating with aluminum or silicon in a high vacuum, to produce the metal. A mixture of barium monoxide and peroxide can also be used in the reduction. Being a flammable solid, it is packaged under Argon gas in steel containers or plastic bags. Only a few tons of the metal are produced each year.

Barium reacts exothermically with oxygen at room temperature to form both BaO and BaO_2. The reaction is violent if the barium is powdered. It also reacts violently with dilute acids, alcohol and water:

$$Ba + 2\,H_2O \;\Rightarrow\; Ba(OH)_2 + H_2(gas)$$

At elevated temperatures, barium combines with chlorine, nitrogen and hydrogen to produce $BaCl_2$, Ba_3N_2 and BaH_2, respectively. Barium reduces oxides, chlorides and sulfides of less reactive metals. For example:

$$Ba + CdO \;\Rightarrow\; BaO + Cd$$

$$Ba + ZnCl_2 \;\Rightarrow\; BaCl_2 + Zn$$

$$3\,Ba + Al_2S_3 \;\Rightarrow\; 3\,BaS + 2\,Al$$

When heated with nitrogen and carbon, it forms the cyanide:

$$Ba + N_2 + 2\,C \;\Rightarrow\; Ba(CN)_2$$

Barium combines with several metals, including aluminum, zinc, lead and tin, forming intermetallic compounds and alloys.

About 40 isotopes of barium have been isolated as shown in Table 1.17.

Naturally occurring barium is a mixture of seven stable isotopes: barium-138 (71.66%), barium-137 (11.32%), barium-136 (7.81%), barium-135 (6.59%), barium-134 (2.42%), barium-130 (0.101%), and barium-132 (0.097%). About six times this many radioactive isotopes have been prepared with mass numbers ranging from 114 to 153. Of the 40 isotopes known, most are highly radioactive and have half-lives in the several milliseconds to a few days range. The only notable exceptions are ^{133}Ba with a half-life of 10.51 years, ^{128}Ba (2.43 days), ^{141}Ba (11.50 days) and ^{140}Ba (12.75 days).

The element is used in metallurgy, and its compounds in pyrotechnics, petroleum mining, and radiology. Metallic barium has few industrial uses. It has been historically used to scavenge air in vacuum tubes. There, the metal is used as a getter in electron tubes to perfect the vacuum by combining with final traces of gases. It is also used as a deoxidizer in copper refining, and as a constituent in certain alloys. The alloy with nickel readily emits electrons when heated and, for this reason, is used in electron tubes and in spark plug electrodes. The presence of barium (atomic number 56), observed after uranium (atomic number 92) had been bombarded by neutrons, was the clue that led to the recognition of nuclear fission (1939).

The most important use of elemental barium is as a scavenger removing last traces of oxygen and other gases in television and other electronic tubes. Additionally, an isotope of barium, ^{133}Ba, is routinely used as a standard source in the calibration of gamma ray detectors in nuclear physics studies.

Physical properties of Ba metal shown in Table 1.18.

1.2.6. Radium

Radium has the symbol Ra and atomic number 88. Its atomic weight is 226.0254 g/mol. Radium is an alkaline

earth metal that is found in trace amounts in uranium ores. Its most stable isotope, ^{226}Ra, has a half-life of 1602 years and decays into radon gas.

The heaviest of the alkaline earth elements, radium is intensely radioactive and resembles barium in its chemical behavior. This metal is found in tiny quantities in the uranium ore "Pitchblende", and various other uranium minerals. Radium preparations are remarkable for maintaining themselves at a higher temperature than their surroundings, and for their radiations, which are of three kinds: alpha particles, beta particles and gamma rays.

When freshly prepared, pure radium metal is almost pure white, but blackens when exposed to air (probably due to nitride formation). Radium is luminescent when struck by electromagnetic radiation of the proper wavelength (giving a faint blue color). It reacts violently with water to form radium hydroxide and is slightly more volatile than barium. The normal phase of radium is a solid. Since all the isotopes of radium are radioactive and short-lived on the geological time scale, any primeval radium would have disappeared long ago. Therefore, radium occurs naturally only as a disintegration product in the three natural radioactive decay series (Thorium, Uranium, and Actinium series). Radium-226 is a member of the uranium decay series. Its parent is Thorium-230 and its daughter Radon-222. The following lists the known abundance of radium (Table 1.19).

Radium is a decay product of uranium and is therefore found in all uranium-bearing ores. (One ton of Pitchblende yields one seventh of a gram of radium). Radium was originally acquired from pitchblende ore from the Czech Republic. Carnotite ($K_2(UO_2)_2(VO_4)_2 \cdot 3H_2O$) sands in Colorado provide some of the element, but richer ores are found in the Democratic Republic of Congo and the Great Lakes area of Canada. Radium can also be extracted from uranium processing waste. Large radium-containing uranium deposits have been located in Canada (Ontario), the United States (New Mexico, Utah and Virginia), Australia, and in other places.

TABLE 1.19

Humans	0.0000011	0.00000003

Radium (Ra) has no stable isotopes. A standard atomic mass cannot be given (but is usually given as 226.0 g/mol). The longest lived, and most common, isotope of radium is ^{226}Ra that occurs in the disintegration chain of ^{238}U (often referred to as the radium series). Radium (Ra) has 33 different known isotopes, four of which are found in nature, with ^{226}Ra being the most common. ^{223}Ra, ^{224}Ra, ^{226}Ra and ^{228}Ra are all generated naturally in the decay of either Uranium (U) or Thorium (Th). ^{226}Ra is a product of ^{238}U decay, and is the longest-lived isotope of radium with a half-life of 1602 years. The next longest is ^{228}Ra, a product of ^{232}Th breakdown, with a half-life of 5.75 years (Table 1.20).

Radium is over 1 million times more radioactive than the same mass of uranium. Its decay occurs in at least seven stages. The successive main products have been studied and were called "radium emanation" or "exradio" (now identified as radon), radium A (polonium), radium B (lead), radium C (bismuth), etc. Radon is a heavy gas in contrast to the others (which are solids). These solid products are themselves radioactive elements, each with an atomic weight a little lower than its predecessor.

The chemistry of radium is what would be expected of the heaviest of the alkaline earths, but the intense radioactivity is its most characteristic property. One gram of radium-226 undergoes 3.7×10^{10} disintegrations per second, producing energy equivalent to 6.8×10^{-3} calories, sufficient to raise the temperature of a well-insulated sample at the rate of 1 °C every 10 s. The practical energy release is even greater than this due to the production of a large number of short-lived radioactive decay products. The alpha particles emitted by radium may be used to initiate nuclear reactions. Radium loses about 1% of its activity in 25 years, being transformed into elements of lower atomic weight with lead being the final product of disintegration.

The SI unit of radioactivity is the "Becquerel" (Bq), equal to one disintegration per second. The "Curie" is a non-SI unit defined as the amount of radioactivity which has the same disintegration rate as 1 g of Ra-226 (3.7×10^{10} disintegrations per second, or 37 GBq).

Radium (Latin *radius*, ray) was discovered by Pierre Curie, Marie Curie, and an assistant, G. Bémont. This occurred after Marie Curie had observed that the radioactivity of pitchblende was four or five times greater than that of the uranium it contained and was not fully explained on the basis of radioactive polonium, which she had just discovered in pitchblende residues originating from North Bohemia, in the Czech Republic. While studying pitchblende the Curies removed uranium from it and found that the remaining material was still radioactive. They then separated out

In 1910, radium was isolated as a pure metal by Curie and Debierne through the electrolysis of a pure radium chloride solution by using a mercury cathode and distilling it in an atmosphere of hydrogen gas. The separation was followed by the increase in intensity of the new lines in the ultraviolet spectrum and by a steady increase in the apparent atomic weight of the material until a value of 225.18 was obtained, remarkably close to the accepted value of 226.03. By 1902, 0.1 g of pure radium chloride was prepared by refining several tons of pitchblende residues, and by 1910 Marie Curie and André-Louis Debierne had isolated the metal itself.

Radium was first industrially produced in the beginning of the twentieth century by Birac, a subsidiary company of UMHK in its Olen plant in Belgium. This company offered to Marie Curie her first gram of radium. Historically the decay products of radium were known as radium A, B, C, etc. These are now known to be isotopes of other elements as shown in Table 1.21.

On February 4, 1936 radium E became the first radioactive element to be made synthetically. Since all the isotopes of radium are radioactive and short-lived on the geological time scale, any primeval radium would have disappeared long ago. Therefore, radium occurs naturally only as a disintegration product in the three natural radioactive decay series (thorium, uranium, and actinium series). Radium-226 is a member of the uranium decay series. Its parent is thorium-230 and its daughter radon-222.

Radium was formerly used in self-luminous paints for watches, nuclear panels, aircraft switches, clocks, and instrument dials. More than 100 former watch-dial painters who used their lips to shape the paintbrush died from the radiation from the radium that had become stored in their bones. Soon afterward, the adverse effects of radioactivity became widely known. Nevertheless, radium was still used in dials as late as the 1950s. Although the beta-radiation from tritium is

potentially dangerous if ingested, it has replaced radium in these applications.

Radium was also put in some foods for taste and as a preservative, but this also exposed many people to radiation. Radium was once an additive in products like toothpaste, hair creams, and even food items due to its supposed curative powers. Such products soon fell out of vogue and were prohibited by authorities in many countries, after it was discovered they could have serious adverse health effects. In the United States, nasal radium irradiation was also administered to children to prevent middle ear problems or enlarged tonsils from the late 1940s through early 1970s.

In 1909, the famous Rutherford experiment used radium as an alpha source to probe the atomic structure of gold. This experiment led to the Rutherford model of the atom and revolutionized the field of nuclear physics.

Radium (usually in the form of $RaCl_2$) was used in medicine to produce radon gas which in turn was used as a cancer treatment. For example, several radon sources were used in Canada in the 1920s and 1930s. The isotope ^{223}Ra is currently under investigation for its use in cancer treatment of bone metastasis.

Some of the few practical uses of radium are derived from its radioactive properties. More recently discovered radioisotopes, such as ^{60}Co and ^{137}Cs are replacing radium in even these limited uses because several of these isotopes are more powerful emitters, safer to handle, and available in more concentrated form. The current price for radium metal is ~$40 million per lb (Table 1.22).

The major isotopes of Radium as a metal are listed in Table 1.23.

In the next chapters, we will survey the properties of the alkaline earths as they form compounds. We will begin with the Halides of Group 17 since they are the most electronegative elements in the Periodic Table. This will be followed by a description of the compounds formed with succeeding Groups in the Periodic Chart encompassing Groups 16, 15, 14, and 13.

2.1. HYDRIDE COMPOUNDS OF THE ALKALINE EARTHS

Hydrogen forms compounds with less electronegative elements, such as most of the metals and the metalloids such as B, Si, Ge, As, Sb, Te and Po. These compounds are known as hydrides. In inorganic chemistry, hydrides can also serve as bridging ligands that link two metal centers in a coordination complex. This function is particularly common in Group 13 elements such as boranes (boron hydrides) and aluminum complexes. The term "hydride" implies that the H atom has acquired a negative or anionic character, denoted H^-, and is used when hydrogen forms a compound with a more electropositive element. The existence of the hydride anion, first suggested by G.N. Lewis in 1916 for Group 1 and 2 salt-like hydrides, was demonstrated by Möers in 1920 by the electrolysis of molten lithium hydride (LiH). This reaction produced a *stoichiometric quantity* of hydrogen at the anode. For hydrides other than Group 1 and Group 2 metals, the term is quite misleading, considering the low electronegativity of hydrogen. An exception in Group 2 hydrides is BeH_2, which is polymeric. In $[AlH_4]$, the anion carries hydridic centers firmly attached to the Al(III) ion. Although hydrides can be formed with almost all main group elements, the number and combination of possible compounds varies widely. For example, there are over 100 binary borane hydrides known, but only one binary aluminum hydride.

2.1.1. Types of Hydrides

There are four main groups (or types) of hydrides known. These are: ionic hydrides, covalent hydrides, interstitial hydrides and transition-metal complexes.

Saline hydrides (Groups 1 and 2) have significant ionic character.
Covalent hydrides (Groups 13, 14 and 15) include the hydrocarbons and many other compounds.
Interstitial hydrides (Group 11 and part of Groups 4, 10 and 12) may be described as having metallic bonding.
Transition metal hydrido complexes (which are not true hydrides).

The following diagram shows their location in the periodic chart (Fig. 2.1).

2.1.2. Ionic Hydrides (Groups 1 and 2)

Ionic or saline hydrides, consists of a hydrogen atom bound to an extremely electropositive metal, generally one of the **alkali** metals or the **alkaline earths**. In these compounds, the metal has donated an electron to the 1s orbital of protium, producing the following:

$$M^+H^- \text{ or } M^{2+}H_2^-$$

Saline hydrides are insoluble in conventional solvents, reflecting their nonmolecular structures. Most ionic hydrides exist as "binary" materials involving only including hydrogen and another element. Ionic hydrides are used as heterogeneous bases and reducing reagents in organic syntheses. An example is given in Fig. 2.2.

Typical solvents for such reactions are ethers. Water and other protic solvents are not able to serve as

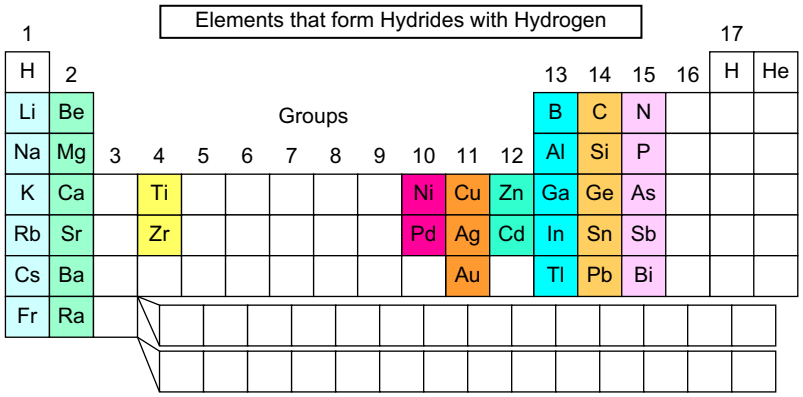

FIGURE 2.1

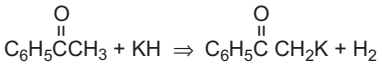

FIGURE 2.2

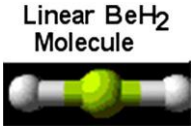

FIGURE 2.3

a solubilizing medium for pure ionic hydrides because the hydride ion is a stronger base than hydroxide and most other hydroxyl anions. Hydrogen gas is liberated in a typical acid–base reaction.

$$NaH + H_2O \Rightarrow H_2\ (gas) + NaOH\ \Delta H = -83.6\ kJ/mol,\ \Delta G = -109.0\ kJ/mol$$

Beryllium Hydride

BeH_2 was first synthesized in 1951 by reacting dimethylberyllium, $Be(CH_3)_2$, with lithium aluminum hydride, $LiAlH_4$. A purer grade of BeH_2 can also be formed from the pyrolysis of di-tert-butylberyllium, $\{Be(C(CH_3)_3)_2\}$ at 210 °C. The purest beryllium hydride is obtained by the reaction of triphenylphosphine, i.e. PPh_3, with beryllium borohydride, $Be(BH_4)_2$ by the reaction:

$$Be(BH_4)_2 + 2PPh_3 \Rightarrow 2Ph_3PBH_3 + BeH_2$$

Note that unlike the other elements in Group IIA where the hydride can be prepared by reaction of the elements, the reaction of the metal with hydrogen to produce beryllium hydride has not proved possible.

BeH_2 is usually formed as an amorphous white solid, but a hexagonal crystalline form with a higher density (~0.78 g/cm^3) has also been reported. This was prepared by heating amorphous BeH_2 under pressure, with 0.5–2.5% LiH as a catalyst. A more recent investigation found that crystalline beryllium hydride has a body-centered orthorhombic unit cell, containing a network of corner-sharing BeH_4 tetrahedra (there are 12BeH_2 molecules in the unit cell) in contrast to the flat, hydrogen-bridged, infinite chains previously thought to exist in crystalline BeH_2. Studies of the amorphous form also find that it consists of a network of corner-shared tetrahedra. The density is 0.755 g/cm3.

Molecular BeH_2 has been confirmed in a recent study as a linear structure with a Be–H bond length of 1.33376 Å. Because of the long-term toxicity of Be toward the human body, no actual uses of beryllium hydride have been promulgated. The structure is shown in Fig. 2.3.

The actual structure has the form shown in Fig. 2.4.

Cell parameters are: $a = 4.161$ Å, $b = c = 6.3084$ Å, $\alpha = \beta = \gamma = 70.748°$, cell volume = 145.59 Å3, cell occupancy is shown in Table 2.1.

Physical properties of BeH_2 are listed in Table 2.2.

Beryllium hydride is not used in Industry and remains an Academic oddity.

Magnesium Hydride

MgH_2 contains 7.66% by weight of hydrogen and has been studied as a potential hydrogen-storage medium. It was discovered in 1912, during the pyrolysis of ethyl magnesium iodide (a Grignard reagent), which produced small amount of MgH_2. In 1951, preparation from the elements was first reported involving direct hydrogenation of Mg metal at high pressure and temperature (200 atmospheres, 500 °C) with magnesium iodide as a catalyst:

$$Mg + H_2 \Rightarrow MgH_2$$

Lower temperature production from Mg and H_2 using nano-crystalline Mg produced in ball mills has been investigated. Other preparations include:

1. The hydrogenation of magnesium anthracene under mild conditions:

$$Mg(anthracene) + H_2 \Rightarrow MgH_2 + C_{14}H_{10}$$

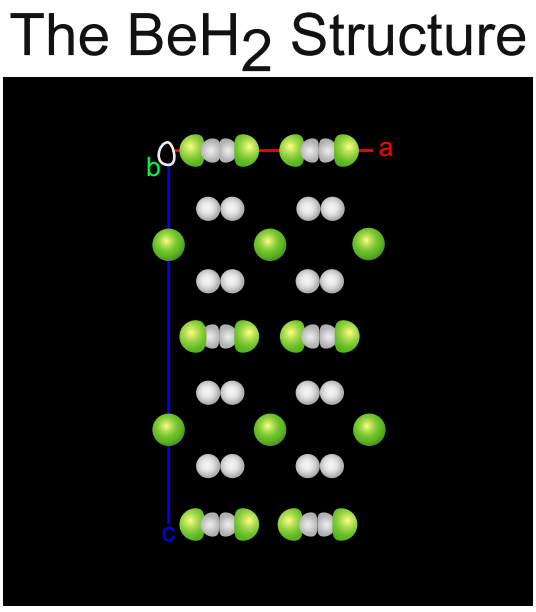

FIGURE 2.4

2. The reaction of diethyl magnesium with $LiAlH_4$
3. An adduct of complexed MgH_2, e.g. $MgH_2 \cdot THF$ by the reaction of phenylsilane (C_6H_8Si) and dibutyl magnesium in ether or hydrocarbon solvents in the presence of THF (C_4H_8O) using TMEDA (Tetramethylethylenediamine = $(CH_3)_2NCH_2CH_2N(CH_3)_2$) as a ligand.

The room temperature form, β-MgH_2, has a rutile structure. There are two high temperature forms, α-MgH_2 with the α-PbO_2 structure and γ-MgH_2. Additionally, a nonstoichiometric $MgH_{(2-\delta)}$ has been characterized. The bonding in the rutile form has been sometimes described as being covalent in nature rather than purely ionic. However, charge density determination by synchrotron X-ray diffraction indicates that the magnesium atom is fully ionized and spherical in shape and the hydride ion is elongated. Molecular forms of magnesium hydride such as MgH, MgH_2, Mg_2H, Mg_2H_2, Mg_2H_3, and Mg_2H_4 molecules were identified in matrix isolated samples at <10 K by their vibrational spectra. They were formed following laser ablation of magnesium in the presence of hydrogen. The Mg_2H_4 molecule has a bridged structure analogous to dimeric aluminum hydride, i.e. Al_2H_6. The structure of magnesium hydride is shown in Fig. 2.5.

This is the TiO_2 type of structure with cell parameters of: $a = 3.025$ Å, $b = c = 4.520$ Å, $\alpha = \beta = \gamma = 90°$. Cell volume = 61.80 Å^3, cell occupancy is shown in Table 2.3 and physical properties are shown in Table 2.4.

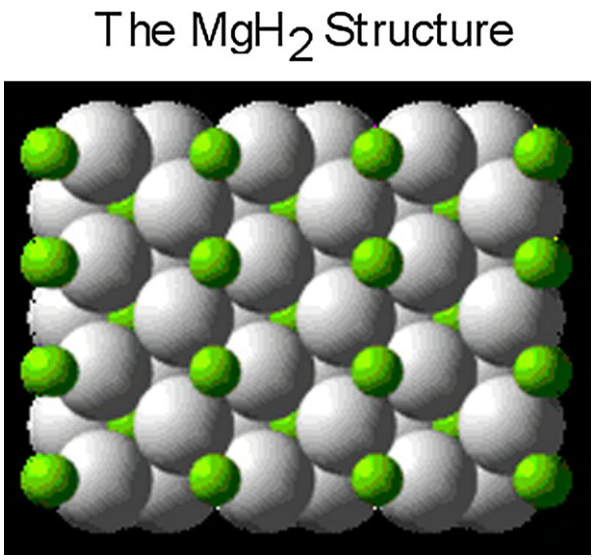

FIGURE 2.5

MgH_2 readily reacts with water to form hydrogen gas:

$$MgH_2 + 2H_2O \Rightarrow 2H_2 + Mg(OH)_2$$

At 300 °C, it decomposes to produce H_2 at 1 bar pressure. The high temperature required is seen as a limitation in the use of MgH_2 as a reversible hydrogen-storage medium. Its potential as reversible-"storage" medium for hydrogen has lead to interest in improving the hydrogenation and dehydrogenation reaction kinetics. An alternative approach under investigation is the production of a pumpable slurry of MgH_2 (which is safe to handle), the release of H_2 by the reaction with water and a reprocessing of the $Mg(OH)_2$ into MgH_2. Physical properties of MgH_2 are shown in Table 2.4.

No significant Industrial usage of magnesium hydride has yet arisen.

Calcium Hydride

Calcium hydride is a gray powder (white if pure, which is rare). It reacts vigorously with water liberating H_2 gas. CaH_2 is thus used as a drying agent, i.e. a desiccant. It is prepared directly from the metal or by reacting $CaCO_3$ with hydrogen at elevated temperatures. The overall reaction is shown as follows:

$$CaCO_3 + \text{heat} + H_2 \Rightarrow CaH_2 + H_2O + CO_2$$

CaH_2 is a saline hydride, meaning that its structure is salt-like. The alkali metals and the alkaline earth metals all form saline hydrides. These species are insoluble in all solvents with which they do not react because they have extended structures. CaH_2 crystallizes in the $PbCl_2$ structural pattern.

The reaction of CaH_2 with water can be represented as follows:

$$CaH_2 + 2H_2O \Rightarrow Ca(OH)_2 + 2H_2$$

The two hydrolysis products, H_2, a gas, and $Ca(OH)_2$, an aqueous mixture of solid plus liquid (i.e. a slurry), are

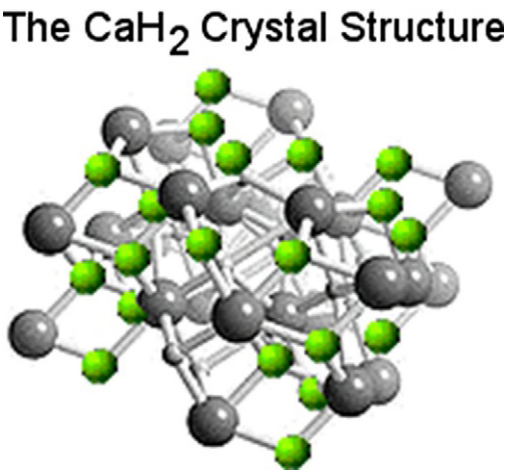

FIGURE 2.6

readily separated from the solvent by distillation, filtration, or decantation.

Calcium hydride is a relatively mild desiccant. It is safer than the more reactive agents such as sodium metal. Calcium hydride is widely used as a desiccant for basic solvents such as amines and pyridine in organic syntheses. It is also used to pre-dry solvents prior to the use of a more reactive desiccant. The compound has, however, been widely used for decades as a safe and convenient means to inflate weather balloons. Likewise, it is regularly used in laboratories to produce small quantities of highly pure hydrogen for experiments. The crystal structure is shown in Fig. 2.6.

Cell parameters are: $a = 3\ 602$ Å, $b = 5.957$ Å, $c = 6.809$ Å, $\alpha = \beta = \gamma = 90°$, Cell volume $= 146.31$ Å^3, cell occupancy is shown in Table 2.5.

Physical properties of CaH_2 are listed in Table 2.6.

Strontium Hydride

This hydride, SrH_2, is formed from the metal in the presence of hydrogen, under similar reaction conditions to that of calcium. Because of its great resemblance to calcium, little practical usage has evolved. It is an electronically neutral reagent chemical. In contact with water, it decomposes to form hydrogen:

$$SrH_2 + H_2O \Rightarrow Sr(OH)_2 + H_2$$

TABLE 2.6

Physical properties
Molecular formula = CaH_2
Molar mass = 42.094 g/mol
Appearance = gray powder (colorless when pure)
Density = 1.70 g/cm^3, solid
Melting point = 816 °C
Solubility in water = reacts violently

Melting point = 675 °C decomposes
Density = 3.72 g/cm^3
Solubility: organic liquids = insoluble; water = decomposes
Melting point = 675 °C (decomposes)
Boiling point = sublimes at 1000 °C (in H_2)

The following lists the physical and chemicals properties of this compound (Table 2.7).

SrH_2 has the same type of structure as CaH_2 except that the cell parameters are: $a = 3.875$ Å, $b = 6.364$ Å, $c = 7.343$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 181.08 Å^3, cell occupancy is shown in Table 2.8.

Barium Hydride

BaH_2 forms in a manner similar to that of strontium hydride with the $PbCl_2$ type of structure. It too has found little usage in Industry. Cell parameters are: $a = 4.168$ Å, $b = 6.792$ Å, $c = 67.858$ Å, $\alpha = \beta = \gamma = 90°$, Cell volume $= 222.45$ Å^3, cell occupancy is shown in Table 2.9.

Known physical properties are listed in Table 2.10.

Radium Hydride

No hydride of radium is known.

2.2. HALOGEN COMPOUNDS OF THE ALKALINE EARTHS

The chemical properties of the halo-acids such as HF and HCl are relevant to the type of compounds that the alkaline earths can form.

2.2.1. Halogen Acids

Hydrofluoric Acid

HF is a solution of hydrogen fluoride in water. While this acid is extremely corrosive and difficult to handle, it is technically a weak acid. Hydrogen fluoride, often in the aqueous form as hydrofluoric acid, is a valued source of fluorine, being the precursor to numerous pharmaceuticals such as fluoxetine (Prozac), diverse polymers such as polytetrafluoroethylene (Teflon), and most other synthetic materials that contain fluorine. Hydrofluoric acid is best known to the public for its ability to dissolve glass by reacting with SiO_2 (silicon dioxide), the major component of most glass, to form silicon tetrafluoride gas and hexafluorosilicic acid. This property has been known since the seventeenth century, even before hydrofluoric acid had been prepared in large quantities by Scheele in 1771. Because of its high reactivity toward glass, hydrofluoric acid must be stored (in small quantities) in polyethylene or Teflon containers. It is also unique in its ability to dissolve many metal and semimetal oxides. Hydrofluoric acid attacks glass by reaction with silicon dioxide to form gaseous or water-soluble silicon fluorides. This dissolution process proceeds as follows:

$$SiO_2\ (\text{solid}) + 4HF\ (\text{aq}) \Rightarrow SiF_4\ (\text{gas}) + 2H_2O\ (\text{liq})$$

$$SiO_2\ (\text{solid}) + 6HF\ (\text{aq}) \Rightarrow H_2SiF_6\ (\text{aq}) + 2H_2O\ (\text{liq})$$

Hydrofluoric acid is very dangerous to handle, because the human skin becomes easily saturated with the acid. Even though skin absorption of small areas of only 25 square inches (160 cm^2) may be relatively painless, yet the exposure may be ultimately fatal. High concentrations of hydrofluoric acid and hydrogen fluoride gas will also quickly destroy the corneas of the eyes.

Hydrogen fluoride ionizes in aqueous solution in a similar fashion to other common acids:

$$HF + H_2O \Rightarrow H_3O^+ + F^-$$

Due to its low degree of ionization in dilute solution, hydrofluoric acid is the only hydrohalic acid that is not considered a strong acid.

When the concentration of HF approaches 100%, the acidity increases dramatically due to the following shift in equilibrium:

$$2HF \Rightarrow H^+ + FHF^-$$

The FHF^- anion is stabilized by very strong hydrogen–fluorine hydrogen bonds. Industrially, hydrofluoric acid is produced by treatment of the mineral Fluorite (CaF_2) with concentrated sulfuric acid. When combined at 250 °C, these two substances react to produce hydrogen fluoride and calcium sulfate according to the following reaction:

$$CaF_2 + H_2SO_4 \Rightarrow 2HF\ (gas) + CaSO_4\ (solid)$$

Although bulk fluorite is a suitable precursor, most HF is produced as a by-product of the production of phosphoric acid, which is derived from the mineral Apatite. Apatite sources typically contain a few percent of fluorite. The acid hydrolysis of fluorite-containing minerals generates an impure gas stream consisting of SO_2 (from the H_2SO_4), water, and HF, as well as particulates. After separation from the solids, the gases are treated with sulfuric and oleum to afford anhydrous HF. Owing to the corrosive nature of HF, its production is accompanied by the dissolution of silicate minerals, and in this way a significant amount of fluorosilicic acid is generated.

Diluted hydrofluoric acid (1–3 %wt) is used in the "Oil Patch" in a mixture with other acids (HCl or organic acids) in order to stimulate the production of water, oil and gas wells specifically where sandstone is involved. HF is also used in oil refining. In a standard oil-refinery process known as Alkylation, isobutane is alkylated with low-molecular weight alkenes (primarily a mixture of propylene and butylene) in the presence of a strong acid catalyst, hydrofluoric acid. The catalyst is able to protonate the alkenes (propylene, butylene) to produce reactive "carbo-cations", which cause alkylation of isobutane. The reaction is carried out at mild temperatures (0 and 30 °C) in a two-phase reaction. It is important to keep a high ratio of isobutane to alkene at the point of reaction to prevent side reactions that lead to a lower octane product, so the plants have a high recycle of isobutane back to feed. The phases separate spontaneously, so the acid phase is vigorously mixed with the hydrocarbon phase to create sufficient contact surface.

Hydrofluoric acid (HF) is used principally in organofluorine chemistry. Many such compounds are prepared using HF as the fluorine source, including "Teflon™", fluoropolymers, fluorocarbons and "Freon™" refrigerants.

Additionally, most high-volume inorganic fluoride compounds are prepared from hydrofluoric acid. Foremost are Na_3AlF_6, (Cryolite), and AlF_3(aluminum trifluoride). A molten mixture of these solids serves as a high-temperature solvent for the production of metallic aluminum. Concerns about fluorides in the environment have led to a search for alternative technologies. Other inorganic fluorides prepared from hydrofluoric acid include NaF and UF_6.

The ability of hydrofluoric acid to dissolve metal oxides is the basis of several applications. It removes oxide impurities from stainless steel in a process called *pickling*. Surface oxides are removed from silicon with hydrofluoric acid in the Semiconductor Industry. For this purpose, dilute hydrofluoric acid is sold as a household rust stain remover. Recently, it has even been used in "Car-Wash" facilities in "wheel cleaner" compounds.

Due to its ability to dissolve oxides, hydrofluoric acid is useful for dissolving rock samples (usually powdered) prior to analysis. Similarly, this acid has been used to extract organic fossils from silicate rocks. Fossiliferous rock may be immersed directly into the acid, or a cellulose nitrate film may be applied (dissolved in amyl acetate), which adheres to the organic component and allows the rock to be dissolved around it.

Hydrochloric Acid

This acid is the result of solution of HCl gas in water. It is a highly corrosive, strong mineral acid and has many major industrial uses. It is found naturally in "gastric acid" of the human body. Historically, it has been called **muriatic acid** or **spirits of salt**. Hydrochloric acid was first produced from vitriol (H_2SO_4 or "oil of vitriol") and salt. The Alchemist, Jabir ibn Hayyan, formally described it in the eighth century. During the Middle Ages, alchemists used it in the quest for the "Philosophers Stone", and later by European scientists including Glauber, Priestley and Davy in their scientific research.

Major production of HCl started during the Industrial Revolution of the 1800s where hydrochloric acid was used in the chemical industry. Today, it is used in a wide variety of industrial applications as a chemical reagent. It has numerous smaller scale applications, including household cleaning, production of gelatin and other food additives, removal of scale from metals and leather processing. About 20 million metric tons of hydrochloric acid is produced annually.

Hydrochloric acid was first discovered around AD 800 by the alchemist Jabir ibn Hayyan, who mixed salt with sulfuric acid (vitriol) to form gaseous HCl. He discovered many important chemicals, and recorded his findings in over 20 books. His chemical knowledge of hydrochloric acid and other basic chemicals remained the foundation of chemistry for hundreds of years. Jabir's invention of the gold-dissolving "aqua-regia", consisting of hydrochloric acid and nitric acid, was of great interest to alchemists searching for the Philosopher's Stone.

In the Middle Ages, hydrochloric acid was known to European alchemists as *spirits of salt* or *acidum salis* (salt acid). Both names are still deployed, notably in non-English languages, such as German: *Salzsäure* and

Dutch: *Zoutzuur*. Gaseous HCl was called *marine acid air*. The old name *muriatic acid* has the same origin (*muriatic* means "pertaining to brine or salt"), and this name is still sometimes used. In the seventeenth century, Glauber, used sodium chloride and sulfuric acid for the preparation of sodium sulfate, releasing hydrogen chloride gas. Priestley prepared pure hydrogen chloride in 1772, and in 1818, Davy proved that the chemical composition included hydrogen and chlorine.

During the Industrial Revolution in Europe, demand for acidic and alkaline substances increased. A new industrial process by LeBlanc enabled cheap large-scale production of sodium carbonate (soda ash). In this process, common salt is converted to soda ash, using sulfuric acid, limestone, and coal, releasing hydrogen chloride gas as a by-product. Until the British Alkali Act of 1863 and similar legislation in other countries, the excess HCl was vented to the air. After the passage of the act, soda ash producers were obliged to absorb the waste gas in water, producing hydrochloric acid on an industrial scale.

In the twentieth century, the Leblanc process was effectively replaced by the Solvay Process without a hydrochloric acid by-product. Since hydrochloric acid was already fully settled as an important chemical in numerous applications, the commercial interest initiated other production methods, some of which are still used today. After the year 2000, hydrochloric acid is mostly made by absorbing by-product hydrogen chloride from industrial production of organic compounds.

The latest method consists of synthesis of hydrogen chloride by burning hydrogen gas and chlorine gas in graphite acid-synthesis equipment. This has proved to be an economical and reliable operation. This is true particularly in those processes where chlorine gas is produced as a by-product or where hydrogen chloride or hydrochloric acid is required for on-site use. Typical uses occur in brine electrolysis, vinyl chloride manufacture, paper and pulp production and various metallurgical processes.

Since 1988, hydrochloric acid has been listed as a Table II precursor under the 1988 UN Convention—Illicit Traffic in Narcotic Drugs because of its use in the production of heroin, cocaine and methamphetamine.

Hydrogen chloride (HCl) is a monoprotic acid. In aqueous hydrochloric acid, the H^+ joins a water molecule to form a hydronium ion, H_3O^+:

$$HCl + H_2O \Rightarrow H_3O^+ + Cl^-$$

The other ion formed is Cl^-. Hydrochloric acid can therefore be used to prepare chloride salts. Hydrochloric acid is a strong acid, since it is essentially completely dissociated in water.

For a strong acid like HCl, the K_a is large. When chloride salts such as NaCl are added to aqueous HCl they have practically no effect on pH, indicating that the Cl^- aqueous ion is an exceedingly weak conjugate base and that HCl is fully dissociated in aqueous solution. For intermediate to strong solutions of hydrochloric acid, the assumption that the H^+ molarity equals the HCl molarity is excellent, agreeing to four significant digits.

Of the seven common strong mineral acids in chemistry, hydrochloric acid is the monoprotic acid least likely to undergo an interfering oxidation–reduction reaction. It is one of the least hazardous of the strong acids to handle. Despite its acidity, it consists of the nonreactive and nontoxic chloride ion. Intermediate-strength hydrochloric acid solutions are quite stable upon storage, maintaining their concentrations over time. These attributes, plus the fact that it is available as a pure reagent, mean that hydrochloric acid makes an excellent acidifying reagent.

Hydrochloric acid is the preferred acid in titration for determining the amount of bases present. Strong acid titrants give better results due to a more distinct endpoint. Azeotropic or "constant-boiling" hydrochloric acid can be used as a primary standard in Quantitative Analysis, although its exact concentration depends on the pressure of the atmosphere when it is prepared (because of Henry's Law).

Hydrochloric acid is frequently used in digest samples for analysis. Concentrated hydrochloric acid dissolves many metals and forms oxidized metal chlorides and hydrogen gas, and it reacts with basic compounds such as calcium carbonate or cupric oxide forming the dissolved chlorides that can be analyzed.

The physical properties of hydrochloric acid, such as boiling point or melting point, density and pH depend on the molarity of HCl in the acid solution. They range from those approaching 0% HCl to values for fuming hydrochloric acid at over 40% HCl. The following table summarizes some of these values (Table 2.11).

Hydrochloric acid, as the binary (two-component) mixture of HCl and H_2O, has a constant-boiling azeotrope at 20.2% HCl and 108.6 °C (227 F).

There are four "constant-crystallization" eutectic points for hydrochloric acid, which form crystals which the solution is cooled:

$HCl \cdot H_2O$ (68% HCl)

$HCl \cdot 2H_2O$ (51% HCl)

$HCl \cdot 3H_2O$ (41% HCl)

$HCl \cdot 6H_2O$ (25% HCl)

and Ice (0% HCl).

TABLE 2.11

Conc as % HCl per kg	kg HCl/m^3	Density kg/L	Molarity in Mols/dm^3	pH	Viscosity (mPa·s)	Vapor pressure (Pa)	BP °C	MP °C
10%	104.80	1.048	2.87	−0.5	1.16	0.527	103	−18
20%	219.60	1.098	6.02	−0.8	1.37	27.3	108	−59
30%	344.70	1.149	9.45	−1.0	1.70	1410	90	−52
32%	370.88	1.159	10.17	−1.0	1.80	3130	84	−43
34%	397.46	1.169	10.90	−1.0	1.90	6733	71	−36
36%	424.44	1.179	11.64	−1.1	1.99	14,100	61	−30
38%	451.82	1.189	12.39	−1.1	2.10	28,000	48	−26

There is also a metastable eutectic point at 24.8% between ice and the $HCl{\cdot}3H_2O$ crystallization point. However, these crystals cannot be separated and used since they are unstable and give rise to HCl gas and water.

Hydrogen chloride can be generated in many ways, and thus several precursors to hydrochloric acid exist. The large-scale production of hydrochloric acid is almost always integrated with the industrial scale production of other compounds.

Hydrochloric acid is produced in solutions up to 38% HCl (concentrated grade). Higher concentrations are possible up to about 40% but the evaporation rate of HCl gas is then so high that storage and handling need extra precautions, such as pressure and low temperature. Bulk industrial grade is therefore 30%–34%, as optimized for effective transport and limited product loss by HCl vapors. Solutions for household purposes in the US, mostly cleaning, are typically 10%–12%, with strong recommendations to dilute before use. In the United Kingdom, where it is sold as "Spirits of Salt" for domestic cleaning, the potency is the same as the US industrial grade.

Major producers worldwide include Dow Chemical at 2 million metric tons annually (2 Mt/year), calculated as HCl gas. FMC and Georgia Gulf Corporation in the U.S., Tosoh Corporation (Japan), Akzo Nobel, and Tessenderlo (Europe) each produce about 0.5 to 1.5 Mt/year each. Total world production, for comparison purposes expressed as HCl, is estimated at 20 Mt/year, with 3 Mt/year from direct synthesis, and the rest as a secondary product from organic and similar syntheses. By far, most hydrochloric acid is consumed captively by the producer. The open world market size is estimated at 5 Mt/year.

One of the most important applications of hydrochloric acid is in the "pickling of steel" to remove rust or iron oxide scale from iron or steel before subsequent processing, such as extrusion, rolling, galvanizing, and other techniques. Technical quality HCl at typically 18% concentration is the most commonly used pickling agent for the pickling of carbon-steel grades:

$$Fe_2O_3 + Fe + 6HCl \Rightarrow 3FeCl_2 + 3H_2O$$

The spent acid has long been reused as iron(II) chloride (also known as ferrous chloride) solutions, but high heavy-metal levels in the pickling liquor have decreased this practice.

The steel-pickling industry has developed hydrochloric acid regeneration processes, such as the "spray roaster" or the fluidized bed HCl regeneration process, which allow the recovery of HCl from spent pickling liquor. The most common regeneration process is the "pyrohydrolysis process", applying the following reaction:

$$4FeCl_2 + 4H_2O + O_2 \Rightarrow 8HCl + 2Fe_2O_3$$

By recuperation of the spent acid, a closed acid loop is established. The iron(III) oxide by-product of the regeneration process is valuable and used in a variety of secondary industries.

Another major use of hydrochloric acid is in the production of organic compounds such as vinyl chloride, used to form the plastic, PVC. This is often captive-use, consuming locally produced hydrochloric acid that never actually reaches the open market. Other organic compounds produced with hydrochloric acid include Biphenol-A for polycarbonate plastic, activated carbon, and ascorbic acid, as well as numerous pharmaceutical products:

$$2CH_2 = CH_2 + 4HCl + O_2 \Rightarrow 2ClCH_2CH_2Cl + 2H_2O$$

(vinyl chloride by oxchlorination)

$$\text{wood} + HCl + \text{heat} \Rightarrow \text{activated carbon}$$

(chemical activation)

Numerous products can be produced with hydrochloric acid in normal acid–base reactions, resulting in various inorganic compounds. These include water treatment chemicals such as ferric chloride and polyaluminum trichloride (PAC).

$$Fe_2O_3 + 6HCl \Rightarrow 2FeCl_3 + 3H_2O$$

(iron(III)chloride from magnetite)

Both iron(III) chloride and PAC are used as flocculation and coagulation agents in sewage treatment, drinking water treatment, and paper production.

Other inorganic compounds produced with hydrochloric acid include road application salts such as $CaCl_2$, $NiCl_2$ for electroplating, and $ZnCl_2$ for the galvanizing industry and battery production:

$$CaCO_3 + 2HCl \Rightarrow CaCl_2 + CO_2 + H_2O$$

(calcium chloride from limestone)

Hydrochloric acid can be used to regulate the basicity (pH) of solutions:

$$OH^- + HCl \Rightarrow H_2O + Cl^-$$

In industries demanding purity (food, pharmaceutical, drinking water), high-quality hydrochloric acid is used to control the pH of process water streams. In less-demanding industry, technical-quality hydrochloric acid suffices for neutralizing waste streams and swimming pool treatment.

High-quality hydrochloric acid is used in the regeneration of ion-exchange resins used for "water-softening". A cation-exchange mechanism is widely used to remove ions such as Na^+ and Ca^{2+} from water, producing "demineralized" water. The acid is used to rinse the cations from the resins:

$$Na^+ \text{ is replaced by } H^+$$

$$Ca^{2+} \text{ is replaced by } 2H^+$$

Ion exchangers and demineralized water are used in all chemical industries for drinking water production, and many food industries.

Hydrochloric acid is also used for a large number of small-scale applications, such as leather processing, household cleaning, and building construction. In the crude-oil industry, oil production may be stimulated by injecting hydrochloric acid into the limestone rock formation of an oil well, dissolving a portion of the rock, and creating a large-pore structure. Oil well acidizing is a common process in the North Sea oil production industry.

Many chemical reactions involving hydrochloric acid are applied in the production of food, food ingredients, and food additives. Typical products include aspartame, fructose, citric acid, lysine, hydrolyzed vegetable protein as a food enhancer, and in gelatin production. Food-grade (extra-pure) hydrochloric acid can be applied when needed for the final product.

Gastric acid is one of the main secretions of the stomach. It consists mainly of hydrochloric acid and acidifies the stomach content to a pH of 1–2. Gastric acid acts as a barrier against microorganisms to prevent infections and is important for the digestion of food. Its low pH denatures proteins and thereby makes them susceptible to degradation by enzymes.

Concentrated hydrochloric acid (fuming hydrochloric acid) forms acidic mists. Both the mist and the solution have a corrosive effect on human tissue, with the potential to damage respiratory organs, eyes, skin, and intestines. Upon mixing hydrochloric acid with common oxidizing chemicals, such as bleach (NaClO) or potassium permanganate ($KMnO_4$), the toxic gas, chlorine is produced:

$$NaClO + 2HCl \Rightarrow H_2O + NaCl + Cl_2$$

$$2KMnO_4 + 16HCl \Rightarrow 2MnCl_2 + 8H_2O + 2KCl + 5Cl_2$$

Rubber or PVC gloves, protective eye goggles, and chemical-resistant clothing and shoes are used to minimize risks when handling hydrochloric acid. The hazards of solutions of hydrochloric acid depend on its concentration. The properties of commercial HCl can be summarized as in Table 2.12.

Hydrobromic Acid

This is a strong acid formed by dissolving the diatomic molecule HBr in water. "Constant-boiling" hydrobromic acid is an aqueous solution that distills at 124.3 °C and contains 47.6% HBr by weight. Hydrobromic acid has a pK_a of −9, making it a stronger acid than hydrochloric acid, but not as strong as HI, hydroiodic acid. Hydrobromic acid is one of the strongest mineral acids known.

TABLE 2.12

CAS number = 7647-01-0
Molar mass = 36.46 g/mol (as HCl)
Appearance: Clear colorless to light-yellow liquid
Density = 1.18 g/cm^3 (variable, value for assay = 36−38% w/w)
Miscible in water
Soluble in diethyl ether, ethanol and methanol
Acidity (pKa) = 8.0
Refractive index, (n_D) = 1.342
Viscosity = 1.9 MPa at 25 °C

Hydrobromic acid is mainly used for the production of inorganic bromides, especially the bromides of zinc, calcium, and sodium. It is a useful reagent for generating organobromine compounds. Certain ethers are cleaved with HBr. It also catalyzes alkylation reactions and the extraction of certain ores. Industrially significant organic compounds prepared from hydrobromic acid include allyl bromide, tetrabromobis(phenol), and bromoacetic acid.

Hydrobromic acid can be prepared in the laboratory via the reaction of Br_2, SO_2 and water. Another laboratory preparation involves the production of anhydrous HBr, which is then dissolved in water.

Hydrobromic acid has commonly been prepared industrially by reacting bromine with either sulfur or phosphorous and water. However, it can also be produced electrolytically. It can also be prepared by treating bromides with nonoxidizing acids like phosphoric or acetic acids. Hydrobromic acid is available commercially in various concentrations and purities.

The properties of hydrobromic acid can be summarized as in Table 2.13.

Hydroiodic Acid

This is a strong acid, made by dissolving HI gas in water. However, hydrogen iodide and hydroiodic acid differ in that the former is a gas under standard conditions whereas the other is an aqueous solution of said gas. They are noninterconvertible. That is, once the acid is formed with water, it cannot be recovered like HCl or HBr. Hydroiodic acid is used in organic and inorganic synthesis as one of the primary sources of iodine and as a reducing agent.

With moist air, HI gas gives a mist (or fumes) of hydroiodic acid. It is exceptionally soluble in water. One liter of water will dissolve 425 L of HI, the final solution containing only four water molecules per molecule of HI. As stated, although chemically related, hydroiodic acid is not pure HI but a mixture containing it. Commercial "concentrated" hydroiodic acid usually contains 90–98% HI by mass.

The solution forms an azeotrope boiling at 127 °C containing 57% HI, 43% water. Hydroiodic acid is one of the strongest of all the common halide acids due to the high stability of its corresponding conjugate base. The iodide ion is much larger than the other common halides. This results in the negative charge being dispersed over a larger space. By contrast, a chloride ion is much smaller, meaning its negative charge is more concentrated, leading to a stronger interaction between the proton and the chloride ion. This weaker H^+–I^- interaction in HI facilitates dissociation of the proton from the anion, and is the reason HI is the strongest acid of the hydrohalides:

$$HI_{(gas)} + H_2O_{(liq)} \Rightarrow H_3O^+_{(aq)} + I^-_{(aq)} \quad K_a \approx 10^{10}$$

$$HBr_{(gas)} + H_2O_{(liq)} \Rightarrow H_3O^+_{(aq)} + Br^-_{(aq)} \quad K_a \approx 10^{9}$$

$$HCl_{(gas)} + H_2O_{(liq)} \Rightarrow H_3O^+_{(aq)} + Cl^-_{(aq)} \quad K_a \approx 10^{8}$$

The industrial preparation of HI involves the reaction of I_2 with hydrazine, which also yields nitrogen gas:

$$2I_2 + N_2H_4 \Rightarrow 4HI + N_2$$

When performed in water, the HI must be distilled to obtain the anhydrous form. HI can also be distilled from a solution of NaI or other alkali iodide in concentrated H_3PO_4 (note that sulfuric acid will not work for acidifying iodides as it will oxidize the iodide to elemental iodine).

Another way HI may be prepared is by bubbling a hydrogen sulfide steam through an aqueous solution of Iodine, forming hydroiodic acid (which is then distilled) and elemental sulfur (this is filtered):

$$H_2S + I_2 \Rightarrow 2HI + S$$

Additionally, HI can be prepared by simply combining H_2 and I_2. This method is usually employed to generate high-purity samples:

$$H_2 + I_2 \Rightarrow 2HI$$

For many years, this reaction was considered to involve a simple bimolecular reaction between molecules of H_2 and I_2. However, when a mixture of the gases is irradiated with the wavelength of light equal to the dissociation energy of I_2, (about 578 nm), the rate increases significantly. This supports a mechanism whereby I_2 first dissociates into two iodine atoms, which each attach themselves to a side of an H_2 molecule and break the H–H bond:

$$H_2 + I_2 + 578\text{ nm radiation} \Rightarrow H_2 + 2I \Rightarrow I\text{–}H\text{–}H\text{–}I \Rightarrow 2HI$$

TABLE 2.13

Molar mass	80.91 g/mol
Appearance	Colorless liquid
Density	Variable
Melting point	Variable
Boiling point	Variable
Solubility in water	Aqueous solution
Acidity (pK_a)	−9

The HI is then dissolved in water to form the acid. In the laboratory, another method involves the hydrolysis of PI_3, the iodine equivalent of PBr_3. In this method, I_2 reacts with phosphorous to create phosphorous triiodide, which then reacts with water to form HI and phosphorous acid:

$$3I_2 + 2P + 6H_2O \Rightarrow 2PI_3 + 6H_2O \Rightarrow 6HI + 2H_3PO_3$$

Hydroiodic acid will undergo oxidation if left open to air according to the following pathway:

$$4HI + O_2 \Rightarrow 2H_2O + 2I_2$$

$$HI + I_2 \Rightarrow HI_3$$

HI_3 is dark-brown in color, which makes aged solutions of HI often appear dark brown. Like HBr and HCl, HI adds to alkene compounds:

$$HI + H_2C{=}CH_2 \Rightarrow H_3CCH_2I$$

HI is also used in organic chemistry to convert primary alcohols into alkyl halides. This reaction is an S_N2 substitution, in which the iodide ion replaces the "activated" hydroxyl group (water). HI is preferred over other hydrogen halides because the iodide ion is a much better nucleophile than bromide or chloride. Thus, the reaction can take place at a reasonable rate without much heating. This reaction also occurs for secondary and tertiary alcohols, but substitution occurs via the S_N1 pathway (Fig. 2.7).

HI (or HBr) can also be used to cleave ethers into alkyl iodides and alcohols, in a reaction similar to the substitution of alcohols. This type of cleavage is significant because it can be used to convert a chemically stable and inert ether into more reactive species. In the following example, diethyl ether is cleaved into ethanol and iodoethane. The reaction is regioselective, as iodide tends to attack the less sterically hindered ether carbon (Fig. 2.8).

HI reduces certain α-substituted ketones and alcohols replacing the α-constituent with a hydrogen atom.

Hydroiodic acid is currently listed as a Federal DEA List 1 Chemical. Owing to its usefulness as a reducing agent, reduction with HI and red phosphorus has become the most popular method to produce methamphetamine in the United States. Clandestine chemists react pseudo-ephedrine (recovered from decongestant pills) with hydroiodic acid and red phosphorus under heat, HI reacts with pseudoephedrine to form iodoephedrine, an intermediate which is reduced primarily to methamphetamine.

The properties of this acid may be summarized as in Table 2.14.

2.2.2. Halide Compounds of Beryllium

The hydrolytic reactions of beryllium(II) ions have been calorimetrically studied at 25 °C in aqueous solution and dioxane–water mixtures, both containing 3.0 mol/dm^3 Li_2ClO_4 as a constant ionic medium. The formation constants, on the basis of the enthalpy and entropy changes, for the reaction:

$$x\mathrm{Be}^{2+} + y\mathrm{H_2O} \Rightarrow \{\mathrm{Be}_x\,(\mathrm{OH}_y)\}^{(2x-y)+} + y\mathrm{H}^+,$$

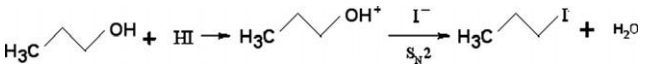

FIGURE 2.7

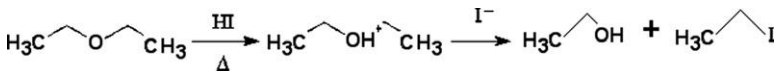

FIGURE 2.8

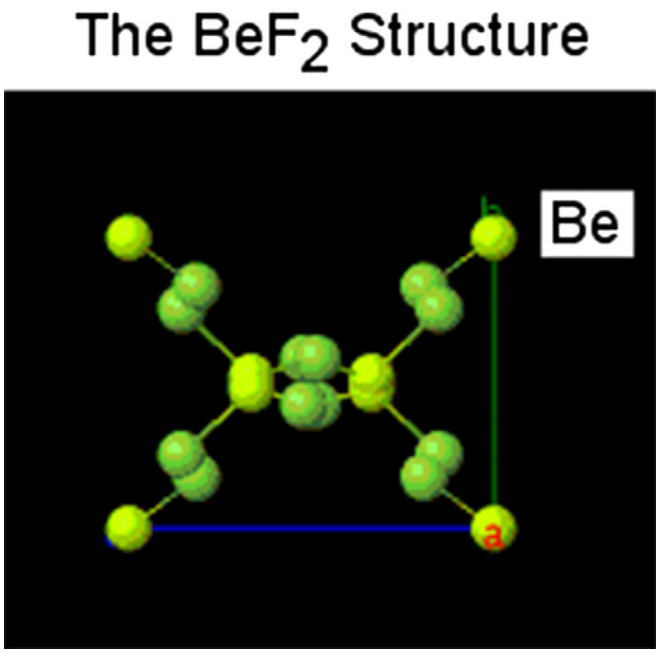

FIGURE 2.8A

were determined for the Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes in aqueous solution, for the 0.1 mol fraction dioxane–water mixture, and for Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, and $Be_2(OH)_2^{2+}$ complexes in 0.2 mol fraction dioxane–water mixture. The enthalpy and entropy changes of formation of the $Be_x(OH)_y^{(2x-y)+}$ complex in solutions of various mole fractions of dioxane were obtained and shown to abide by the following reaction:

$$2Be^{2+} + H_2O \Rightarrow (Be_2OH)^{3+} + H^+$$

Thus, it is clear that the Be^{2+} cation in aqueous solution never appears but is an "aquo-complex". Therefore, if one desires the halide and oxo-halogen compounds of beryllium, they are usually prepared via a solid-state method, not an aqueous one.

Beryllium Fluoride

Beryllium fluoride has the formula, BeF_2, and is a hygroscopic, **amorphous** solid with a melting point of 800 °C. It is soluble in water and is used in beryllium metallurgy in which the metal, Be, is employed as an alloy. It is the binary Be compound with the greatest amount of ionic character (due to the high electronegativity of fluorine), but even so it is not considered ionic but covalent by many chemists. This synthetic material is the principal precursor for the manufacture of beryllium metal, which is obtained by reduction of BeF_2 at 1300 °C:

$$BeF_2 + Mg \Rightarrow Be + MgF_2$$

Solid crystalline BeF_2 has a silica-like structure with beryllium in a four-coordinate position. The structure has the form shown in Fig. 2.8A.
with cell parameters of: $a = b = 4.802$ Å, $c = 5.240$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 104.82 Å^3, cell occupancy is shown in Table 2.15.

Molecular BeF_2, is isoelectronic with CO_2 and SiO_2. As determined in the gas phase above 1160 °C, beryllium fluoride is a linear molecule with a Be–F distance of 1.77 Å. The condensed form adopts a number of different polymeric structures similar to those formed by silica {namely α-quartz, β-quartz, "Crystobalite" (a polymorph of quartz) and "Tridymite" (a high-temperature polymorph of quartz stable between 870 and 1470 °C)}. The difference between the ambient temperature structures of BeF_2 and CO_2 reflects the decreased tendency of alkali metals to form multiple bonds. An analogy exists between BeF_2 and AlF_3. Both adopt extended structures at mild temperatures. The following illustrates the various polymeric structures of BeF_2 which exist as a function of temperature:

$$\alpha Q - BeF_2 \overset{220^\circ C}{\Leftrightarrow} \beta Q - BeF_2 \overset{420-450^\circ C}{\Leftrightarrow} T - BeF_2$$

$$\overset{552^\circ C}{\Leftrightarrow} \text{melt} \overset{690^\circ C}{\Leftrightarrow} \beta C - BeF_2 \overset{730^\circ C}{\Leftrightarrow} \alpha C - BeF_2$$

where "Q" is the quartz structure, "T" is the tridymite structure, and "C" is the Crystobalite structure. Note that the allotropic changes of Crystobalite occur in the melt. The melt does not recrystallize upon cooling but forms an amorphous glass-like silica.

Beryllium fluoride is used in biochemistry, particularly protein crystallography, since it binds in some of the same ways as phosphate does in human tissues. ADP and beryllium fluoride together tend to bind to ATP sites and inhibit protein action, making it possible to crystallize proteins in the bound state.

Beryllium fluoride forms a basic constituent of the preferred fluoride salt mixture used in liquid-fluoride nuclear reactors. Typically, beryllium fluoride is mixed

with LiF to form a base solvent, into which fluorides of uranium and thorium are introduced. Beryllium fluoride is exceptionally chemically stable and LiF/BeF_2 mixtures have low melting points and the best neutronic properties of any of the fluoride salt combinations appropriate for reactor use (Table 2.18).

Beryllium Chloride

Beryllium chloride has the formula $BeCl_2$ with a molecular weight of 79.9176 g/mol. Beryllium chloride, $BeCl_2$, melts at 405 °C and boils at 520 °C. That compares with 714 °C and 1412 °C for magnesium chloride. The solid is a one-dimensional polymer consisting of edge-shared tetrahedra. In contrast, BeF_2 is a three-dimensional polymer, with a structure akin to that of quartz. In the gas phase, $BeCl_2$ exists both as a linear monomer and a bridged dimer with two bridging chlorine atoms where the beryllium atom is 3-coordinate. This linear shape contrasts with the monomeric forms of some of the dihalides of the heavier members of group 2, e.g. CaF_2, SrF_2, BaF_2, $SrCl_2$, $BaCl_2$ and Ba that are all nonlinear.

The linear chain structure of the solid is illustrated as Fig. 2.8B.

In the solid, the $BeCl_2$ molecules polymerize to make long chains. They do this by forming coordinate bonds (dative covalent bonds) between lone pairs on chlorine atoms and adjacent beryllium atoms. The orthorhombic unit, $a_0 = 9.86$, $b_0 = 5.36$, $c_0 = 5.26$ Å contains four beryllium chloride molecules. The structure consists of continuous chains with an essentially tetrahedral configuration about beryllium. The Cl–Be–Cl bond angle within the four-membered rings is 98.2° which is less than the tetrahedral angle, as is found in SiS_2, instead of more, as in dimethylberyllium. The bond angles indicate that all bonds in beryllium chloride contain an electron pair, so that chlorine uses an unshared pair in forming bridge bonds. Hence, chlorides isomorphic with electron-deficient metal alkyls are not to be classified as electron-deficient compounds.

Although early workers (1798) obtained the chloride in solution, the pure salt was not made until about 1827 when one worker of the time prepared it in the sublimed anhydrous state by passing chlorine gas over a heated mixture of carbon and beryllium oxide. Finally (1885), it was prepared as the pure chloride in very pure form for the purpose of determining its vapor density by the action of dry hydrochloric acid gas on the metal, but the pure salt was not produced until 1898 when one worker made it by heating the double fluoride of ammonium and beryllium, which had previously been dried over phosphoric anhydride, in a current of dry carbon dioxide and cooled in an atmosphere of the same gas. He also prepared it by the action of hydrofluoric acid gas on the carbide. No matter what method is used, it was determined that the materials must be absolutely dry if a pure chloride is to be obtained.

The pure chloride is a glassy, transparent mass having a specific gravity of 2.01 at 15 °C. It becomes fluid toward 440 °C, passing through a viscous condition, but above 800 °C it begins to volatilize, yielding white and very deliquescent crystals. It dissolves readily in water, but is only slightly soluble in absolute alcohol. By cooling an alcoholic solution to −23 °C, one can obtain a white crystalline mass which, however, melts easily as the temperature rises. It is also soluble in a mixture of ether and alcohol. The majority of metalloids like copper or titanium do not react with the chloride. It is insoluble in anhydrous hydrofluoric acid and is not altered by it. It is readily attacked by sulfuric acid. The alkali metals and magnesium reduce it. With potassium, the reaction begins below 500 °C. Lithium and magnesium act at about 650 °C. Aluminum fuses it without alteration. The anhydrous chloride is a white crystalline solid having a melting point about 440 °C. The boiling point is about 520 °C.

$BeCl_2$ can be prepared by treating Be metal with hydrogen chloride:

$$Be + 2HCl \Rightarrow BeCl_2 + H_2$$

It is said to hydrolyze upon contact with water to give the aquo complex, $[Be(H_2O)_4]Cl_2$. It is also readily soluble in alcohol, and yields a crystalline compound with it, but is almost insoluble in benzene, chloroform, carbon tetrachloride and sulfur dichloride.

Beryllium chloride reacts vigorously and exothermically with water with the evolution of acidic, steamy hydrogen chloride gas. This is typical of covalent chlorides. Beryllium chloride dissolves in water with great avidity and, unless special precautions are taken, with loss of chlorine as hydrochloric acid. In this case, it reacts to give hydrated beryllium ions, $[Be(H_2O)_4]^{2+}$, HCl and chloride ions. The question concerning whether the solvation is water molecules or hydroxy ions remains unsolved.

Beryllium chloride is stable in dry air, but absorbs moisture in air forming the tetrahydrate, $BeCl_2 \cdot 4H_2O$. It readily dissolves in water undergoing hydrolysis and evolving hydrochloric acid:

$$BeCl_2 + 2H_2O \Rightarrow Be(OH)_2 + 2HCl$$

A cold aqueous solution of beryllium chloride reacts with hydrogen sulfide to form beryllium sulfide that decomposes on heating in air:

$$BeCl_2\ (aq) + H_2S \Rightarrow BeS\ (aq) + 2HCl$$

$$BeS + \text{heat}\ Be + SO_2$$

Beryllium chloride, an electron-deficient compound similar to aluminum chloride, is a Lewis acid. The anhydrous salt is used as a catalyst in organic reactions. Physical constants are presented in Table 2.17 and thermochemical data are presented in Table 2.18.

Beryllium Bromide

Beryllium bromide has the formula $BeBr_2$. It is very hygroscopic and is soluble in water. It has the molecular weight of 168.821 g/mol. The structure has not been documented. Beryllium bromide can be prepared by reacting Be metal with elemental bromine at temperatures of 500 °C–700 °C:

$$Be + Br_2 \Rightarrow BeBr_2$$

Beryllium bromide is also formed when beryllium oxide with HBr in aqueous solution or hydrogen bromide in the gas phase:

$$BeO + 2HBr \Rightarrow BeBr_2 + H_2O$$

This bromide compound was first prepared by Wohler (1828) by the action of bromine vapor on the metal and also upon a mixture of carbon and beryllium oxide. Berthemot (1831) obtained it in solution by dissolving the oxide in hydrobromic acid. Humpridge (1883) also prepared it by acting on a mixture of the oxide and carbon with dry bromine.

The anhydrous bromide is always obtained by sublimation as colorless white crystals. Its vapor density determined by Humpridge (1886) is in accord with the formula $BeBr_2$. Its melting point is about 490 °C where it fuses and begins to sublime. It also sublimes somewhat below this temperature. The fused salt does not conduct electricity so that it cannot be used to make Be metal. It dissolves in water with avidity, losing hydrobromic acid on evaporation. It is soluble in absolute alcohol and forms a crystalline compound therewith. It combines with ammonia and with the organic bases, Physical properties of $BeBr_2$ are shown in Table 2.19.

Beryllium Iodide

Beryllium iodide has the formula BeI_2. It is very hygroscopic and reacts violently with water, forming hydroiodic acid. Beryllium iodide can be prepared by reacting Be metal with elemental iodine at temperatures of 500 °C–700 °C:

$$Be + I_2 \Rightarrow BeI_2$$

Beryllium iodide is also formed when beryllium carbide reacts with hydrogen iodide in the gas phase:

$$Be_2C + 4HI \Rightarrow 2BeI_2 + CH_4$$

The iodine in beryllium iodide is easily replaced with the other halogens. It reacts with F_2 gas giving beryllium fluoride and fluorides of iodine, or with Cl_2 gas giving beryllium chloride, or with Br_2 gas giving beryllium bromide. Beryllium iodide also reacts violently with oxidizing agents such as chlorate and permanganate to give the purple vapor of iodine. The solid and vapor are both flammable in air.

Beryllium Iodide, BeI_2, was first prepared by Wöhler (1828) and Debray (1855) who prepared the iodide by the action of iodine upon the metal. Lebeau (1898), was the first to prepare large quantities (for the time) by the action of gaseous hydroiodic acid, or a mixture of hydrogen and iodine vapor, on the carbide at about 700 °C.

Beryllium iodide, as obtained in the sublimed state, consists of colorless crystals, which are quickly decomposed in moist air. Its specific gravity at 15 °C is close to 4.20 g/cm^3. It begins to sublime below its melting point which is 510 °C. The melted iodide boils between 585 and 595 °C. It is insoluble in benzene, toluene, spirits of turpentine, and but slightly soluble in carbon disulphide. The slightest trace of water attacks it immediately, but if it is first fused, its sensitivity to water is much less. It can be distilled without alteration in dry hydrogen, nitrogen or carbon dioxide. At this point in time, the structure BeI_2 has not been published.

Reaction of BeI_2 with fluorine gas forms fluorides of both beryllium and of iodine. The reaction of fluorine and chlorine with BeI_2 occurs even when cold, giving off heat and light. Cyanogen acts upon it at about a red heat, producing a white material, less volatile than the iodide, which with water gives a clear solution reacting for cyanides. Heated in oxygen, it burns at a red heat and the vapor itself will burn even in air. Heated with sulfur it yields a sulfide of beryllium, which is readily decomposed by water. The vapor of phosphorus also attacks it, probably forming a phosphide of beryllium.

Sodium, potassium and lithium metals reduce BeI_2 at about 350 °C. Magnesium reduces it at about 450 °C. Aluminum, silver, copper and mercury are without action below the temperature of the softening temperature (~585 °C) of glass. Hydrogen sulfide acts upon it, but only at elevated temperatures and yields a white sulfide, BeS. It absorbs large amounts of ammonia gas and forms compounds which melt easily and can be crystallized on cooling.

Ammoniated Beryllium Iodide is classified as an explosive and propellant (However, these compounds have not been fully characterized). It reacts with a large number of organic compounds, particularly amines. It is soluble in alcohol and produces a crystalline compound therewith. It also combines with ether. It differs from the iodide of aluminum in not reacting with cold tetrachloride of carbon. Acetic anhydride and anhydrous chloral give energetic reactions with beryllium iodide. Ammonium compounds and organic bases, especially aniline and, produce crystalline compounds with it Physical properties of BeI_2 are shown in Table 2.20.

2.2.3. Halide Compounds of Magnesium

Magnesium Fluoride

Magnesium fluoride (MgF_2) is a white crystalline salt. It is used in the electrolysis of aluminum ore to produce metallic aluminum and also as a reflective coating on various types of optical components. It is a tetragonal, birefringent crystal with the TiO_2 type of structure shown in Fig. 2.9.

Cell parameters are: $a = 3.052$ Å, $b = c = 4.612$ Å. $\alpha = \beta = \gamma = 90°$, cell volume = 64.82 Å3, cell occupancy is shown in Table 2.21.

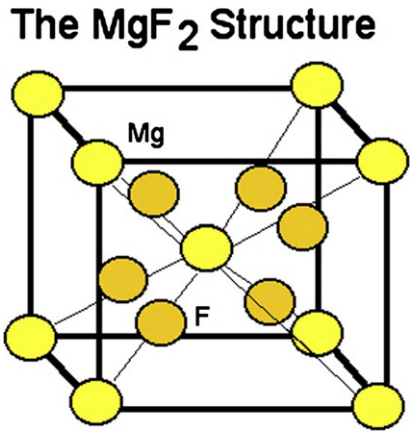

FIGURE 2.9

Magnesium fluoride is transparent over an extremely wide range of wavelengths. Windows, lenses, and prisms made of this material can be used over the entire range of wavelengths from 0.120 μm (vacuum UV) to 8.0 μm (IR). The range of transmission is shown in Fig. 2.10.

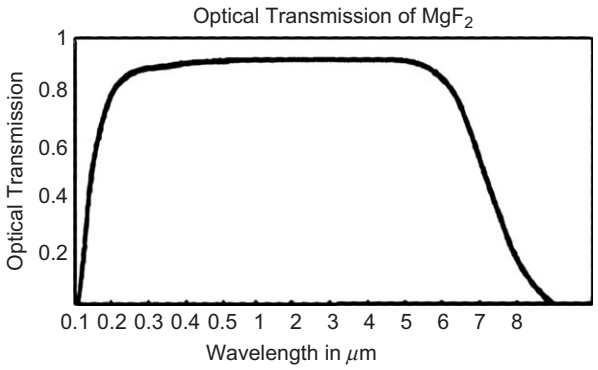

FIGURE 2.10

Good synthetic VUV grade MgF_2, without vacancies or other structural defects, is quite expensive, in the region of $3000/kg (2007). But the real cost of optics in this material is due to relatively low-volume manufacture. Nevertheless, similar to LiF, it is one of the two materials that will transmit in the vacuum ultraviolet range at 121 nm and this is where it finds its application. Lower grade MgF_2 is sometimes used in the IR but it is inferior to calcium fluoride.

MgF_2 is tough and works and polishes well. Since it is slightly birefringent, it should be cut with the optic axis perpendicular to the plane of the window or lens {i.e. so that the Verdet Constant of MgF_2 at 632.8 nm is 0.00810 arc-min/g/cm}.

Thin layers of MgF_2 are frequently applied to the surfaces of optical elements as part of optical coatings such as antireflective coatings. It is the only optical material that combines wide spectral band transmittance with the birefringence phenomenon. Magnesium Fluoride has superior features such as its hardness and resistance to mechanical shock and water. The material is sensitive to thermal shock but does not cleave.

Irradiation does not lead to color centers. This Vacuum UV material is the least susceptible to radiation-induced color centers of any known material. Magnesium Fluoride is a proven material for high-energy lasers, and in particular for lasers operating in UV and VUV range. Generally, all optical elements are manufactured with working surface perpendicular to the *c* axis of the crystal.

The following table lists some of the parameters that are used to form thin layers of MgF_2 on various substrates (Table 2.22).

TABLE 2.21

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	F1	F	4	f	m.2m	0.30478	0.305	0	1.0
2	Mg1	Mg	2	a	m.mm	0	0	0	1.0

TABLE 2.22

Container	Graphite, Ta, Mo or Al_2O_3
Evaporation temperature	~950 °C
Substrate temperature	150–250 °C
Evaporation pressure	10^{-5}–10^{-6} Torr

Vacuum-melted MgF_2 granules can be evaporated by either electron beam or resistance heating. Graphite or tantalum containers are suggested. They are loaded to the top with material. For thermal evaporation, a large heater-shaped like an open boat is used. The power should be increased slowly, and in the case of E-beam sources, the beam should be swept for even heating. Preconditioning for granules of MgF_2 consists of fully melting the charge. The shutter should remain closed until the melt is uniformly red hot. No outgassing is experienced during the preconditioning cycle or during evaporation with MgF_2-coating material.

The pressure should be in the low 10^{-6} Torr range. When completely melted, the material can be evaporated at a smooth rate of 20 Å/s without spitting. The temperature of the substrate should be at least 250 °C for high-film hardness and density on glass or zinc sulfide substrates. In difficult cases, a thin, initial bonding layer of yttrium oxide, Y_2O_3, can promote nucleation and adhesion. Films will grow and adhere to glass substrates heated to as low as 150 °C. Glow discharge cleaning is recommended for low temperature depositions. The melt can be reused until reaction with the holder begins. The factor that limits MgF_2 layer thickness to ~1 μm is internal stress. MgF_2 can be doped with BaF_2 to reduce this stress and permit thicker layers to be grown.

Films of MgF_2 that have been deposited on high-temperature substrates (250–300 °C) using E-beam deposition are mechanically hard but grow with densities only ~80% of bulk density. Voids in the microstructure admit water upon exposure to air, increasing the mean refractive index of the film. Absorption bands are seen in the UV spectra at 3 and 6 μm. Multilayers that include MgF_2 will shift in wavelength upon venting the deposition system to room air. Films that are bombarded by high-energy ions during growth achieve higher densities, since an amorphous structure is created. This produces an environmentally stable film with a higher refractive index. Excessively high-ion energies can, however, deplete the fluorine content and produce absorption in the UV (Table 2.24).

Magnesium Chloride

Magnesium chloride is chemically represented as $MgCl_2$. It is usually obtained from seawater and is generally found in a hydrated form. Magnesium chloride in its pure state is colorless, odorless, highly soluble in water and bitter to taste. Magnesium chloride has the molecular weight of 95.221 g/mol. It occurs as a white

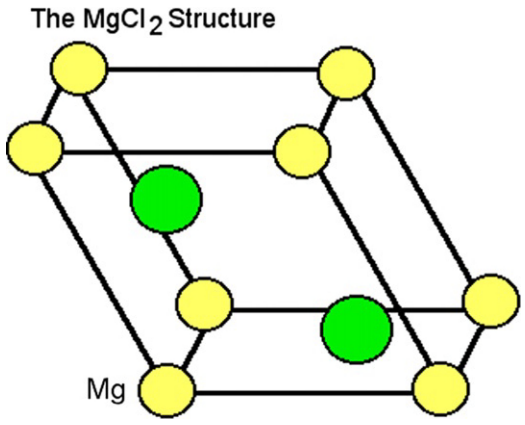

FIGURE 2.11

powder and its CAS number is 7791-18-6. Its density is 2325 kg/m^3, its melting point is 714 °C and its boiling point is 1412 °C. However, it generally is obtained as the hexahydrate, $MgCl_2 \cdot 6H_2O$, which has a molecular weight of 203.3 g/mol and a CAS number of 7791-18-6. Its water solubility is 2350 g/l (20 °C).

Various hydrates occur, denoted as $MgCl_2 \cdot (H_2O)_x$. These salts are typical ionic halides, being highly soluble in water. Hydrated magnesium chloride can be extracted from brine or seawater. Magnesium chloride as the natural mineral "bischolite" is also extracted (solution mining) out of ancient seabeds, for example in the Zechstein seabed in NW Europe or the Permian Period seabed in the central parts of the US. Anhydrous magnesium chloride is the principal precursor to magnesium metal which is produced on a large scale.

It also occurs as the mineral "carnolite". Carnolite is an important source of potash, an invaluable fertilizer. "Sylvite" is the more important source of potash, but Carnallite makes a significant contribution. Carnallite's magnesium output is of much lesser importance worldwide but is still Russia's most significant source.

Metallic magnesium was first produced in 1828 by the French scientist A. B. Bussy. His work involved the reduction of molten magnesium chloride by metallic potassium. In 1833, the English scientist Michael Faraday was the first to produce magnesium by the electrolysis of molten magnesium chloride. $MgCl_2$ crystallizes in the CdI_2 structure, which features an octahedral Mg coordination. The structure has the form shown in Fig. 2.11.

Cell parameters are: $a = b = 3.641$ Å, $c = 5.927$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$. Cell volume = 68.05 Å^3, cell occupancy is shown in Table 2.24.

A variety of hydrates are known with the formula $MgCl_2 \cdot (H_2O)_x$, and each loses water with increasing temperature:

$x = 12$ (−16.4 °C), 8 (−3.4 °C), 6 (116.7 °C), 4 (181 °C), 2 (ca. 300 °C).

In the hexahydrate, the Mg^{2+} remains octahedral, but is coordinated to six water ligands. The thermal dehydration of the hydrates $MgCl_2(H_2O)_x$ ($x = 6$, 12) does not occur straight forwardly since HCl gas begins to form at those temperatures. As suggested by the existence of these hydrates, anhydrous $MgCl_2$ is a Lewis acid, although a relatively weak one.

In the "Dow Process" (which is the electrolytic method of extracting bromine from brine), magnesium chloride is regenerated from magnesium hydroxide by hydrochloric acid:

$$Mg(OH)_2\ (s) + 2HCl \Rightarrow MgCl_2\ (aq) + 2H_2O$$

It can also be prepared from $MgCO_3$ by a similar reaction. Magnesium chloride is ionic and so will undergo ***electrolysis*** when it is molten. Electricity is carried by the movement of the ions within the melt and their discharge at the electrodes. However, solid magnesium chloride is a nonconductor of electricity because the ions are immobile. In most of its derivatives, $MgCl_2$ forms octahedral complexes. Derivatives with tetrahedral Mg^{2+} are less common. Examples include salts of $(Et_4N)_2MgCl_4$ and adducts such as $MgCl_2$(TMEDA = Tetramethylethylenediamine).

When magnesium ions are broken off the solid lattice and go into solution, there is enough attraction between the 2+ ions and the water molecules to get coordinate (dative covalent) bonds formed between the magnesium ions and lone pairs on surrounding water molecules. Hexa-aqua-magnesium ions are formed, $[Mg(H_2O)_6]^{2+}$. Ions of this sort are acidic, the degree of acidity depending on how much the electrons in the water molecules are pulled toward the metal at the center of the complex. The hydrogen atoms are made more positive than they would otherwise be, and more easily removed by a base. In the case of magnesium, the amount of distortion is quite small,

TABLE 2.24

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	Cl	Cl	2	d	3m.	1/3	2/3	0.25	1.0
2	Mg	Mg	1	a	-3m.	0	0	0	1.0

and only a small proportion of the hydrogen is removed by a base—in this case, by water molecules in the solution.

The presence of the hydroxonium ions in the solution causes it to be acidic. The fact that there are not many of them formed (the position of equilibrium lies well to the left), means that the solution is only weakly acidic. This is shown in the following equilibrium:

$$\{Mg(H_2O)_6\}^{2+}\,(aq) \Leftrightarrow \{Mg(H_2O)_5(OH)\}^{+}\,(aq) + H_3O^{+}$$

Magnesium chloride serves as precursor to other magnesium compounds, for example by precipitation:

$$MgCl_2\,(aq) + Ca(OH)_2\,(aq) \Rightarrow Mg(OH)_2\,(solid) + CaCl_2\,(aq)$$

It can be electrolyzed by melting the salt to give Mg metal:

$$MgCl_2\,(liq) \Rightarrow Mg\,(solid) + Cl_2\,(gas)$$

This process is practiced on a large scale commercially to produce Mg metal.

Magnesium chloride is used for a variety of other applications besides the production of Mg metal. It is used in the manufacture of textiles, paper, fireproofing agents, cements and refrigeration brine. It has also been used in dust and erosion control. Mixed with hydrated magnesium oxide, magnesium chloride forms a hard material called "Sorel-cement". The cement is a mixture of MgO (burnt magnesia) with $MgCl_2$ with the approximate chemical formula $Mg_4Cl_2(OH)_6(H_2O)_8$, corresponding to a weight ratio of 2.5–3.5 parts MgO to one part $MgCl_2$. This usage of magnesium chloride is unmatched by any other compound. $MgCl_2$ was one of the earlier antiseptics, first used for that purpose by Dr Pierre Delbert in 1915. One veterinary study in 1989 indicated some effectiveness against tumors when used as a feed additive.

The fact that it can store hydrogen gas is a unique property of this compound. A single molecule of ammonia is rich in hydrogen atoms. Ammonia can be absorbed on the surface of solid magnesium chloride as $Mg(NH_3)_6Cl_2$. On application of mild heat, ammonia is easily released from magnesium chloride and when it is made to pass through a catalyst, hydrogen gas is obtained.

Magnesium chloride in liquid form acts as an anti-icer on roadways. During winter months, it is sprayed on pavements before precipitation. As a result, snow and ice formation is reduced on the surface of the road. Thus, it prevents the vehicles from skidding and ensures road safety. Magnesium chloride is the more preferred deicer than sodium chloride because the former is a less corrosive substance, as compared to the latter, and does not cause much harm to plant life, road concrete or the steel electric poles on the roads. It is also used in crystalline form to deice sidewalks and driveways of home and offices. The crystals are applied, after precipitation, on the accumulated ice.

A commercial form of liquid $MgCl_2$ called "DustGard Liquid" is used to control dust on unpaved roads, construction sites and similar surfaces. Because it is produced from naturally occurring minerals, it improves air quality and visibility with minimal environmental impact. It also decreases vehicle maintenance costs, prevents soil erosion and reduces the need for blading, watering and gravel replacement. Road departments and private industry may apply liquid or powdered magnesium chloride to control dust and erosion on unimproved (dirt or gravel) roads and dusty job sites such as quarries. Its hygroscopicity makes it absorb moisture from the air, controlling the number of small particles which become airborne. Similarly, owners of indoor arenas (e.g. for horse riding) may apply magnesium chloride to sand or other floor materials to control dust. When it is applied in, either liquid or powdered form on dusty places, then the dust get suppressed onto the floor. Thus, it prevents small dust particles from spreading into the air. This is commonly used in places like excavation sites, indoor sport arenas, racecourses etc.

Magnesium ion Mg^{2+} (usually added as the chloride) is an important component in the polymerase chain reaction (PCR), a procedure used to amplify DNA fragments. Magnesium ions (Mg^{2+}) from $MgCl_2$ are an important component of PCR reactions where they interact with the DNA template, dNTPs and the *Taq* DNA Polymerase. It is generally used in experimental biology whenever RNA and DNA and their enzymes are to function in vitro, since Mg^{2+} is a necessary associate ion for nucleotides in biology, such as ATP.

Magnesium chloride is also used in several medical and topical (skin-related) applications. It has been used in pills as supplemental sources of magnesium, where it serves as a soluble compound which is not as laxative as $MgSO_4$, and more bio-available than $Mg(OH)_2$ and MgO, since it does not require stomach acid to produce soluble Mg^{2+} ion. It can also be used as an effective anesthetic for cephalopods, some species of crustaceans, and several species of bivalves, including oysters.

Magnesium chloride is an important coagulant used in the preparation of "tofu" from soy milk. In Japan, it is sold as *"Nigari"*, (derived from the Japanese word for "bitter"). It is a white powder produced from seawater after the sodium chloride has been removed, and the water evaporated. In China, it is called "Lushui", Nigari or Lushui and consists mostly of magnesium chloride, with some $MgSO_4$ and other trace elements. It is also an ingredient in baby formula milk.

TABLE 2.25

A number of state highway departments throughout the United States have decreased the use of rock salt and sand on roadways and have increased the use of solutions of magnesium chloride as a deicer or anti-icer. Magnesium chloride is much less toxic to plant life surrounding highways and airports, and is less corrosive to concrete and steel (and other iron alloys) than salt. The liquid magnesium chloride is sprayed on dry pavement (tarmac) prior to precipitation or on wet pavements prior to freezing temperatures in the winter months to prevent snow and ice from adhering and bonding to the roadway. The application of deicers is utilized in an effort to improve highway safety. Magnesium chloride is also sold in crystal form for household and business use to deice sidewalks and driveways. In these applications, the compound is applied after precipitation has fallen or ice has formed, instead of previously.

Magnesium chloride has shown promise as a storage material for hydrogen gas. Ammonia can be effectively adsorbed onto solid magnesium chloride, forming $Mg(NH_3)_6Cl_2$. When the ammonia is released by mild heat, and is then passed through a catalyst, hydrogen gas is retrieved. The solubility of magnesium chloride in water is shown in Table 2.25.

Physical properties of $MgCl_2$ are listed in Table 2.26.

Magnesium Bromide

Magnesium bromide ($MgBr_2$) has a molecular weight of 184.11 g/mol and a CAS number of 7789-48-2. It is white powder that is very deliquescent. It is often used as a mild sedative and as an anticonvulsant for treatment of nervous disorders. It is an electrolytic component in certain dry-cell batteries. The melting point of the anhydrous form is 711 °C.

Magnesium bromide occurs in seawater, surface and subterranean brines. The Dead Sea is significantly different from that of ocean water, consisting of approximately 53% $MgCl_2$, 37% potassium chloride and 8% sodium chloride (common salt) with the remainder consisting of other alkali ions. The sulfate, SO_4^{2-}, content is very low, but the bromide ion concentration is the highest of all dormant waters on Earth.

A number of hydrates occur. The decahydrate, $MgBr_2 \cdot 10H_3O$ is known but it easily loses waters of hydration to form the more stable hexahydrate. This salt, $MgBr_2 \cdot 6H_2O$, is deliquescent, colorless, and the crystals are bitter tasting. They melt at 172 °C (dissolving in their own "water of hydration"), are soluble in water and are slightly soluble in alcohol. This compound has also been used in medicine and in the synthesis of organic chemicals. Its molecular weight is 292.20 g/mol, density is 3.72 g/cm^3 and its CAS number is 13446-53-2.

Thermodynamic Properties of $MgBr_2 \cdot 6H_2O$ include:

$$\Delta_f H^0 \text{ (gas)} = -74.0 \text{ kcal/mol}$$

$$\Delta_f H^0 \text{ (crystal)} = -125 \text{ kcal/mol}$$

$$\Delta_f H^0 \text{ (aqueous)} = -169.7 \text{ kcal/mol}$$

$$\Delta_f G^0 \text{ (crystal)} = -120.4 \text{ kcal/mol}$$

$$S^0 \text{ (crystal)} = 28.0 \text{ cal/°C/mol}$$

Magnesium bromide is prepared by treating MgO with hydrobromic acid and then crystallization above 0.0 °C in solution. The product is the hexahydrate salt:

$$MgO + 2HBr \Rightarrow MgBr_2 + H_2O \Rightarrow MgBr_2 \cdot 6H_2O$$

The anhydrous form may also be prepared by heating the hexahydrate with dry HBr gas. This compound can also be formed directly from the elements:

$$Mg + Br_2 \Rightarrow MgBr_2$$

This salt has the same type of structure as $MgCl_2$ except that the unit cell parameters are elongated: $a = b = 3.851$ Å, $c = 6.256$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$. Cell volume = 78.85 Å^3, cell occupancy is shown in Table 2.27.

The major use of $MgBr_2$ has been in the commercial production of bromine. The **Dow process** is an electrolytic method of bromine extraction from brine, and was Herbert Dow's second revolutionary process for generating bromine commercially (1889).

Before Dow got into the bromine business, bromine-rich brine was evaporated by heating brine with wood chips. This crystallized sodium chloride that was removed by filtration. An oxidizing agent was added, and bromine formed in the solution was then distilled. This was a very complicated and costly process. Dow's first process involved eliminating the heating. First he oxidized the bromine with a bleaching agent, then dripped it onto burlap, and blew air under the burlap. The air contained bromine gas, which was then reacted with iron (or alkalis) producing $FeBr_2$. In the second method, Dow became the first to use an electrolytic method of extracting bromine from brine in a commercial process. He used a 15-V generator powered by a steam engine. He later established the "Dow Chemical Co." which remains one of the major chemical companies in the U.S.

Current processes involving production of bromine gas involve treating bromide-rich brines with chlorine gas while simultaneously flushing through with air. In this treatment, bromide anions are oxidized to bromine by the chlorine gas:

$$2Br^- + Cl_2 \Rightarrow 2Cl^- + Br_2$$

Magnesium bromide has also been used in organic syntheses. An efficient and environmentally friendly procedure for the one-pot synthesis of tetrahydropyrimidines from aldehydes, α-diketones and urea/thiourea by using magnesium bromide as an inexpensive and easily available catalyst under solvent-free conditions has been described. Compared with the classical Biginelli reaction conditions, this new method has the advantage of good to excellent yields (74%–94%) and short reaction times (45–90 min). The structure of the Biginelli reaction product from α-diketone, salicylaldehyde and urea has been proposed to possess an oxygen bridge by cyclization (intramolecular Michael addition). The solubility of magnesium bromide is shown in Table 2.28.

Physical properties of $MgBr_2$ are listed in Table 2.30.

Magnesium Iodide

Magnesium iodide has the formula MgI_2 and forms various hydrates, expressed as $MgI_2 \cdot (H_2O)_x$. These salts are typical ionic halides, being highly soluble in water. $MgI_2 \cdot 8H_2O$ is a crystalline powder, white and deliquescent, discoloring in air; soluble in water, alcohol, and ether. This salt has been used in medicine. The anhydrous compound has a molecular weight of 278.1139 g/mol,

TABLE 2.29

Solubility in ethanol	6.9 g/100 ml at 20 °C
Crystal structure	Rhombohedral Space group = P-3m1
Standard enthalpy of formation	$\Delta_f H_{298} = -524.3$ kJ/mol
Standard molar entropy	$S_0 = 117.2$ J/mol K

a melting point of 637 °C, a density of 4.43 g/cm^3 and a water solubility of 1480 g/l at 18 °C. MgI_2 has the same type of structure (CdI_2) as the chloride and bromide except that the cell parameters differ. Its crystal structure is shown in Fig. 2.12.

Cell parameters are: $a = b = 4.412$ Å, $c = 6.884$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 102.12 Å^3, cell occupancy is shown in Table 2.30.

Magnesium iodide can be prepared from MgO, $Mg(OH)_2$, and $MgCO_3$ by treatment with HI:

$$MgO + 2HI \Rightarrow MgI_2 + H_2O$$

$$Mg(OH)_2 + 2HI \Rightarrow MgI_2 + 2H_2O$$

$$MgCO_3 + 2HI \Rightarrow MgI_2 + CO_2 + H_2O$$

Magnesium iodide is stable at high heat under a hydrogen atmosphere, but decomposes in air at normal temperatures, turning brown due to the release of elemental iodine. When heated in air, it decomposes completely to magnesium oxide, releasing iodine vapor.

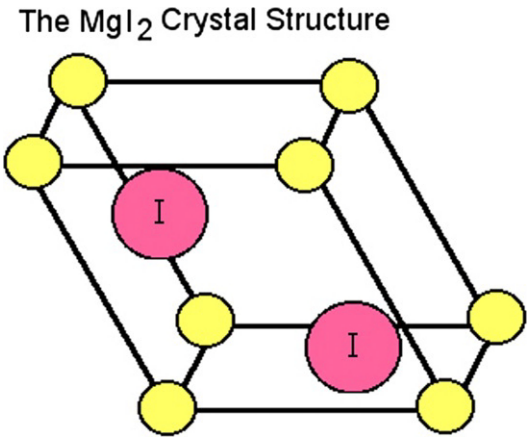

FIGURE 2.12

Magnesium iodide is known to form three hydrates, $MgI_2 \cdot 6H_2O$, $MgI_2 \cdot 8H_2O$ and $MgI_2 \cdot 10H_2O$ of which the decahydrate is claimed to be the most stable.

Magnesium iodide has few commercial uses but can be used to prepare many compounds for organic synthesis. Usage of magnesium iodide in the "Baylis–Hillman" reaction (an organic reaction of an aldehyde and an α,β-unsaturated electron-withdrawing group catalyzed by MgI_2) tends to give vinyl-specific compounds.

Another example of the usage of MgI_2 as a catalyst involves the reaction of 2,3,4,6-tetra-O-benzyl-D-gluconolactone or 2,3,4,6-tetra-O-benzyl-D-mannono-lactone with MgI_2 in EtOH which afforded the respective C-2 epimer.

Anhydrous magnesium iodide (MgI_2) has been shown to be an effective promoter of the homo 3 + 2 dipolar cyclo-addition of nitrones with 1,1-cyclopropane diesters. In almost all cases, the products, tetrahydro-1,2-oxazines, are formed in excellent yields. These reactions are highly dia-stereoselective for a cis relationship between the constituents at the 3- and 6-positions on the tetrahydro-oxazine ring. As an alternative to using a preformed nitrone, the reaction may be performed in a 3-component sense by combining an aldehyde,

2.2.4. Halide Compounds of Calcium

Calcium Fluoride

Calcium fluoride (CaF_2) is an insoluble ionic compound composed of Ca^{2+} and F^- ions. It occurs naturally as the mineral "Fluorite" (also called fluorspar) and as "Blue-John". This salt is the source of most of the world's fluorine. This insoluble solid adopts a cubic structure wherein calcium is coordinated to eight fluoride anions and each F^- ion is surrounded by four Ca^{2+} ions (Fig. 2.13).

The structure is face centered in Ca^{2+} ions. Cell parameters are: $a = b = c = 3.865$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 40.83$ Å^3, cell occupancy is shown in Table 2.34.

Although the pure material is colorless, the mineral is often deeply colored due to the presence of "F-centers"

(which are electrons trapped by a vacancy in the crystal structure). Fluorite, the mineral, is well known and prized for its glassy luster and rich variety of colors. The range of common colors for fluorite starting from the hallmark color purple, then blue, green, yellow, colorless, brown, pink, black and reddish orange is amazing and is only rivaled in color range by quartz. Intermediate pastels between the previously mentioned colors are also possible. It is easy to see why fluorite earns the reputation as *"The Most Colorful Mineral in the World"*.

Naturally occurring CaF_2 is the principal source of hydrogen fluoride, a commodity chemical used to produce a wide range of materials. Fluoride is liberated from the mineral by the action of concentrated sulfuric acid:

$$CaF_2\,(\text{solid}) + H_2SO_4\,(\text{liq}) \Rightarrow CaSO_4\,(\text{solid}) + 2HF\,(\text{gas})$$

The resulting HF is converted into fluorine, fluorocarbons, and diverse fluoride materials. As of the late 1990s, 5 billion kilograms were mined annually.

CaF_2 is used as an optical component because of its chemical stability under adverse conditions. Exposure to 100% relative humidity at room temperature does not fog polished surfaces even after 1 month. In normal working conditions, polished surfaces will not degrade. For temperatures exceeding 600 °C, calcium fluoride surfaces will degrade in the presence of moisture. In dry environments, calcium fluoride can be used up to 1000 °C, and it does not begin to soften at 800 °C. Calcium fluoride is inert to organic chemicals and many acids, including HF. It will slowly dissolve in nitric acid.

Hughes Aircraft observed that the mean modulus of rupture for 900 °C forgings was 74.2 MPa for a 77% reduction. Rupture always occurred with no evidence of yield, indicating that the ultimate strength is still higher. This is shown in Table 2.35.

The thermodynamic properties of CaF_2 are presented in Tables 2.36 and Table 2.37.

Calcium fluoride is commonly used as a window material for both infrared and ultraviolet wavelengths, since it is transparent in these regions (about 0.15 to 9 μm) and exhibits an extremely low-refractive index.

TABLE 2.35

Specific heat of fusion = 0.41 kJ/g	

This material is fairly inert chemically so that these windows are not attacked. Nevertheless, at wavelengths as low as 157 nm, which are useful for semiconductor manufacturers, the refractive index of calcium fluoride exceeds tolerable limits. This problem can be mitigated through an optimized growth process. It is particularly important as an ultraviolet optical material for "integrated circuit lithography". The camera manufacturer, Canon, also uses artificially crystallized calcium fluoride components in some of its L-Series lenses to reduce light dispersion. As an infrared optical material, calcium fluoride is sometimes known by the Eastman Kodak Co. trademarked name "Irtran-3," although this designation is now obsolete.

Its transmission spectrum is shown in Fig. 2.14.

Calcium Fluoride is a water insoluble calcium source for use in oxygen-sensitive applications, such as metal production. In extremely low concentrations (ppm), fluoride compounds are used in health applications. Fluoride compounds also have significant uses in synthetic organic chemistry. They are also commonly used to alloy metal and for optical deposition. Thus, it is useful from the far-UV to the near-IR, both as a coating and as an optical element. CaF_2 is superior in such applications because of its exceptional hardness and inertness. Only MgF_2 exhibits a wider and useful range of transmission wavelengths.

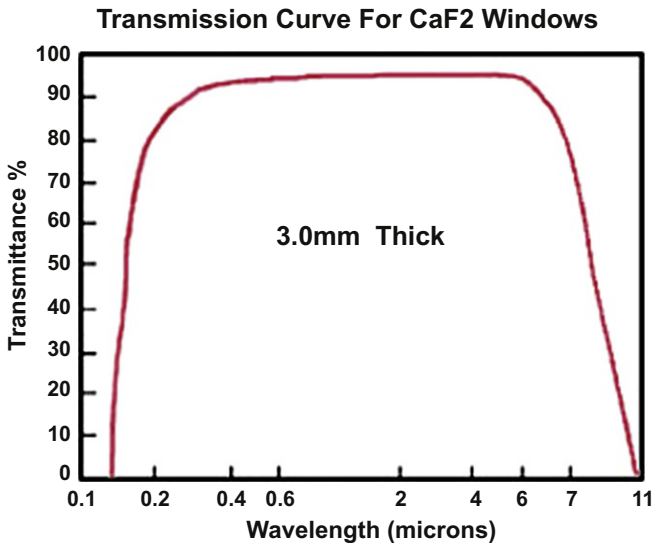

FIGURE 2.14

It is an optical material used in place of crown glass to produce lenses with extraordinary correction of chromatic aberrations. Its high coefficient of thermal expansion and its tendency to absorb moisture limit its range of application.

Uranium-doped calcium fluoride was the second type of solid-state laser invented, in the 1960s. Peter Sorokin and Mirek Stevenson at IBM's laboratories in Yorktown Heights (US) achieved lasing at 2.5 μm shortly after Maiman's ruby laser.

It is also used as a flux for melting and liquid processing of iron, steel and their composites. Its action is based on its similar melting point to iron, on its ability to dissolve oxides and on its ability to wet oxides and metals.

Physical properties are listed in Table 2.38.

Calcium Chloride

Calcium chloride, $CaCl_2$, is a typical ionic halide and is a solid at room temperature. Its molecular weight is 110.98 g/mol and its melting point is 772 °C. Very few natural minerals occur. The occurrence of a dihydrate (mineral "Sinjarite") and hexahydrate ("Antarcticite") is very rare and is connected mainly with dry lakes and brines. "Chlorocalcite", $KCaCl_3$, is a related mineral (also very rare).

It has a unique structure as exemplified by MgF_2 except for cell parameters of: $a = 4.166$ Å, $b = 6.264$ Å, $c = 6.436$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 167.87$ Å^3, cell occupancy is shown in Table 2.39 and the crystal structure is shown in Fig. 2.15.

Calcium chloride, being very soluble, can serve as a source of calcium ions in a solution, unlike many other calcium compounds, which are insoluble:

$$3CaCl_2 + 2K_3PO_4\ (aq) \Rightarrow Ca_3(PO_4)_2\ (solid) + 6KCl\ (aq)$$

Molten $CaCl_2$ can be electrolyzed to produce Ca metal and chlorine gas:

$$CaCl_2\ (liq) \Rightarrow Ca\ (solid) + Cl_2\ (gas)$$

Calcium chloride is one of the most versatile of the basic chemicals. It has been produced commercially for over 100 years. The properties and characteristics of $CaCl_2$ make it useful in a large number of applications. It has several common applications such as brine for refrigeration plants, ice and dust control on roads, and in concrete. The anhydrous salt is also widely used as a desiccant, where it will absorb so much water that it will eventually dissolve in its own crystal lattice water (water of hydration). It can be produced directly from limestone, but large amounts are also produced as a by-product of the "Solvay Process" (which is a process to produce soda ash from brine). Because of its hygroscopic nature, the anhydrous form must be kept in tightly sealed containers.

Because the anhydrous salt is strongly hygroscopic, air or other gases can be channeled through a column of calcium chloride to remove moisture. In particular, calcium chloride is usually used to pack "drying tubes" to exclude atmospheric moisture from a reaction setup while allowing gases to escape. It cannot, however, be used to dry alkaline gases such as ammonia because it will form addition products. It is used to dry kelp, which

is then used to produce soda ash. It can also be added to liquids to remove suspended or dissolved water.

The dissolving process is highly exothermic and rapidly produces temperatures of around 60 °C (140 F). In this capacity, it is known as a drying agent or desiccant. It is converted to a brine as it absorbs the water or water vapor from the substance to be dried:

$$CaCl_2 + 2H_2O \Rightarrow CaCl_2 \cdot 2H_2O$$

Aided by the intense heat evolved during its dissolution, calcium chloride is also used as an ice-melting compound. Unlike the more common NaCl (rock salt or halite), it is relatively harmless to plants and soil. However, recent observations in Washington state suggest it may be particularly harmful on roadside evergreen trees It is also more effective at lower temperatures as a "deicer" than sodium chloride.

Used for its hygroscopic property, it can be applied to keep a liquid layer on the surface of the roadway, which holds dust down. It is used in concrete mixes to help speed up the initial setting, but chloride ion leads to corrosion of steel "rebar", so it is not be used in reinforced concrete. Anhydrous calcium chloride, used for this purpose, can provide a measure of the moisture present in concrete.

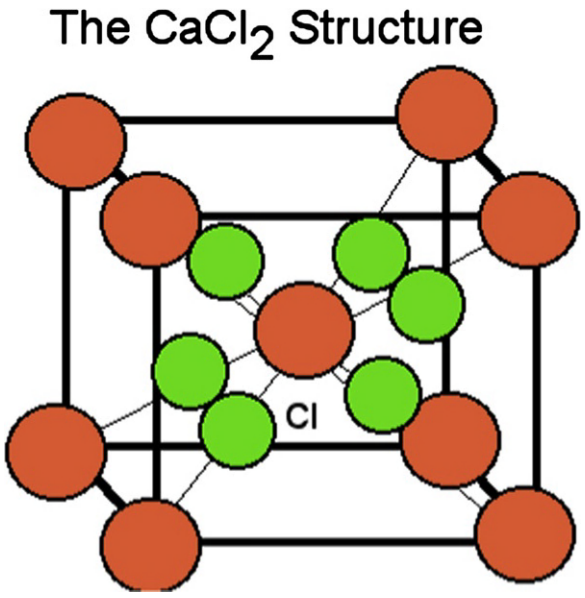

FIGURE 2.15

Aqueous calcium chloride (in solution with water) lowers the freezing point as low as −52 °C (−62 °F), making it ideal for filling agricultural implement tires as a liquid ballast, aiding traction in cold climates.

Calcium chloride is also commonly used as an additive in swimming pool water as it increases the "calcium hardness" value for the water. Low calcium hardness values in pool water cause pool water to be corrosive on equipment, pumps and metal fittings.

Other industrial applications include use as an additive in plastics, as a drainage aid for wastewater treatment, as an additive in fire extinguishers, as an additive in control scaffolding in blast furnaces, and as a thinner in "fabric softeners". North American consumption in 2002 was 1,687,000 tons (3.7 billion pounds). A Dow chemical company manufacturing facility in Michigan produces about 35% of the total U.S. production of calcium chloride.

As an ingredient, it is listed as a permitted food additive in the European Union for use as a sequestrant and "firming agent" with the number E509, and considered as generally recognized as safe (GRAS) by the U.S. Food and Drug Administration (FDA). The average intake of calcium chloride as food additives has been estimated to be 160–345 mg/day for individuals. Ingestion of concentrated or pure calcium chloride products may cause gastrointestinal irritation or ulceration. The anhydrous form has been approved by the FDA as a packaging aid to ensure dryness.

Solutions of pure calcium chloride above 69% cannot be prepared by boiling a solution at 760 mm pressure because a eutectic causes the dihydrate to separate as a solid phase and the solution remains constant boiling. Four hydrates have been identified in the open literature. Their properties are shown in the following Table 2.40.

Its solubility in water is shown in Table 2.41.

Calcium chloride is commonly used as an "electrolyte" and has an extremely salty taste, as found in sports drinks and other beverages such as Nestle bottled water. It can also be used as a preservative to maintain firmness in canned vegetables or in higher concentrations in pickles to give a salty taste while not increasing the food's sodium content. It is even found in snack foods, including Cadbury chocolate bars.

It has been used to make a substitute "caviar" from vegetable or fruit juices or added to processed milk to

restore the natural balance between calcium and protein for the purposes of making cheese such as Brie and Stilton. Calcium chloride's exothermic properties are exploited in many "self-heating" food products where it is activated (mixed) with water to start the heating process, providing a nonexplosive, dry fuel that is easily activated.

In brewing beer, calcium chloride is sometimes used to correct mineral deficiencies in the brewing water. It affects flavor and chemical reactions during the brewing process, and it can also affect yeast function during fermentation.

Calcium chloride can be injected as intravenous therapy for the treatment of "hypocalcemia" (low serum calcium). It can be used for insect bites or stings (such as Black Widow spider bites), sensitivity reactions, particularly when characterized by "urticaria" (hives). It has also been used in the treatment of:

- Magnesium intoxication.
- As an aid in the management of the acute symptoms in lead colic.
- In cardiac resuscitation, particularly after open heart surgery.
- It can help to protect the myocardium from dangerously high levels of serum potassium in "hypercalcemia".
- Calcium chloride can be used to quickly treat "calcium channel blocker" toxicity, from the side effects of drugs such as Diltiazem, helping avoid potential heart attacks.
- The aqueous form of calcium chloride is used in genetic transformation of cells by increasing the cell membrane permeability, inducing competence for DNA uptake (allowing DNA fragments to enter the cell more readily) (Table 2.42).

Physical constants of $CaCl_2$

Calcium Bromide

Calcium bromide has the chemical formula $CaBr_2$. It was first prepared by Pfeiffer, Klossmann and Angern in 1924. It is a deliquescent salt that has the form of colorless hexagonal crystals that are soluble in water

TABLE 2.42

CAS number	1004-82-4 (anhydrate) 22691-02-7 (monohydrate) 10035-04-8 (dihydrate) 25094-02-4 (tetrahydrate) 7774-34-7 (hexahydrate)

and absolute alcohol. Its molecular weight is 199.90 g/mol for the anhydride. When strongly heated in air, calcium bromide will produce CaO (lime) and Br_2. It is generally obtained as the dihydrate, $CaBr_2 \cdot 2H_2O$, in the form of a white crystalline powder. A hexahydrate, $CaBr_2 \cdot 6H_2O$, is also known. Anhydrous calcium bromide is obtained by dehydration (250 °C, vacuum) of the dihydrate $CaBr_2 \cdot 2H_2O$. On contact with hot surfaces or flames, $CaBr_2$ decomposes forming bromine as a toxic and corrosive fume. It also reacts with strong acids to produce corrosive fumes of bromine. It adopts the $CaCl_2$ structure with the cell

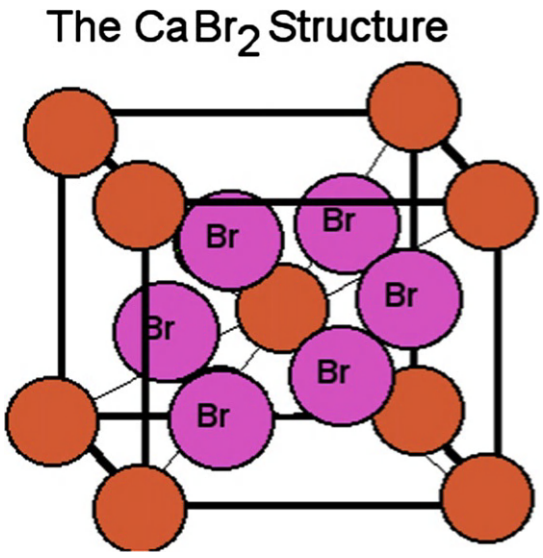

FIGURE 2.16

parameters of: $a = 4.342$ Å, $b = 6.584$ Å, $c = 6.871$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 196.43$ Å^3, cell occupancy is shown in Table 2.43 and Fig. 2.16.

In its solid anhydrous state, it is a white powder. $CaBr_2$ can be found in drilling muds, neuroses medication, freezing mixtures, food preservatives, photography and fire retardants. The anhydride has a melting point of 730 °C and a boiling point of 810 °C where it decomposes. Its density is 3.41 g/cm^3. It is moderately soluble in water at 142 g/100 ml of water.

$CaBr_2 \cdot 2H_2O$ has a melting point of 38 °C where it dissolves in its own waters of hydration. Its density is 2.290 g/cm^3. It can be prepared by reaction in solution with HBr on the carbonate:

$$CaCO_3\ (solid) + HBr\ (liq) \Rightarrow CaBr_2\ (liq) + CO_2\ (gas)$$

An improved method for producing calcium bromide has been developed by reacting hydrogen bromide with calcium hydroxide in the presence of water.

Calcium bromide has a number of useful applications. Used in the oil and gas fields, the compound is a true working example. At almost every stage of the oil and gas extraction process, calcium bromide has found extensive usage. Stability, dependability and ease of use distinguish calcium bromide in the drilling process. There, it is used in "drilling muds" worldwide.

Because of this, bromine has recently become a tracked sector of the financial markets. The cost of

calcium bromide, as one of the bromines, has thus become subject to a variety of market pressures. Worldwide production of calcium bromide exceeds 15 megatons. Speculation in the bromine market now contributes to the cost of dollars spent on calcium bromide, not just the cost of the chemicals themselves. In addition to these speculative increases, the price of calcium bromide has also jumped due to increases in the price of calcium. Thus, the increased cost of exploration for oil and gas reserves has skyrocketed. As the cost of multiple components that make up the drilling operation continue to move upward, each cost must be examined closely for ways in which it can be most effectively exploited. To mitigate the damage due to the increased chemical costs have on an overall drilling budget, it is necessary to choose the correct fluids from the start of the project. Calcium bromide solutions are used in site preparation to increase the overall productivity of an oil or gas well. The compound is also widely found to be one of the most effective completion fluids currently used in the industry. Calcium bromide can be adjusted to meld seamlessly with the specific characteristics of individual drill holes. In addition, it protects the inner surface of the drill lines and can actually aid in the repair of the interior surfaces of the drill hole.

Calcium bromide reduces seepages and damage to the productive zone of the original drill site. Use of calcium bromide-based fluids also makes it easier to go back into the original drill zone and branch out into secondary productivity zones. Accessing the hardpan or rock-layers with low permeabity to get at lesser oil and gas reserves greatly increases the productivity of a well overall. The solubility of $CaBr_2$ in water is shown in Table 2.44.

Physical properties are listed in Table 2.45.

Calcium Iodide

Calcium iodide has the formula, CaI_2. This colorless, deliquescent solid is highly soluble in water. Its properties, including structure, are similar to those for related salts, such as $MgCl_2$ or $CaCl_2$. Its cell parameters are: $a = b = 4.482$ Å, $c = 6.963$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 120.98 Å^3, cell occupancy is shown in Table 2.46.

It is used in photography but the specific usage is not clear. CaI_2 is not stable and reacts in air with carbon dioxide to form the carbonate and iodine. For this reason, calcium iodide has not found many usages in Industry. The tetrahydrate, $CaI_2 \cdot 4H_2O$, is known but is no more stable than the anhydrate. A hexahydrate, $CaI_2 \cdot 6H_2O$, is also known which has a melting point of 42 °C.

In 1808, an impure form of calcium metal was prepared by H. Davy. The pure metal was later made by H. Moissan in 1898 by reducing calcium iodide with sodium:

$$CaI_2 + 2Na \Rightarrow 2NaI + Ca$$

Appearance	White solid
Density	3.956 g/cm^3
Melting point	779 °C (anhydrate)
Boiling point	1115 °C (anhydrate)

Calcium iodide can be formed by treating calcium carbonate with hydroiodic acid:

$$CaCO_3 + 2HI \Rightarrow CaI_2 + H_2O + CO_2$$

The reaction is reversible in the air, liberating iodine, which is responsible for the faint yellow color of impure samples. This salt has a specific gravity of 3.956 g/cm^3, a melting point of 630–740 °C (depending upon purity) and a boiling point of 708–719 °C. It is soluble in water, ethyl alcohol and amyl alcohol.

Bromine replaces the iodine in calcium iodide to form calcium bromide and free iodine. The equation for this reaction is:

$$CaI_2 + Br_2 \Rightarrow CaBr_2 + I_2$$

CaI_2 has been used for measuring low-energy X-ray scintillation as a CaI_2:Eu^{2+} single-crystal detector. It is shown that on account of their layered structure, perfect cleavage, and high-light output, calcium iodide scintillators can be used to fabricate thin-film detectors for long-wavelength X-rays.

The solubility of CaI_2 in water is shown in Table 2.47.

Physical properties are listed in Table 2.48.

2.2.5. Halide Compounds of Strontium

Strontium Fluoride

Strontium fluoride, SrF_2, also called "strontium difluoride" and "strontium (II) fluoride", is a stable, brittle, white crystalline solid with a melting point of 1477 °C and a boiling point of 2460 °C. Its molecular weight is 125.62 g/mol. Its density is 4.24 g/cm^3. Its melting point has also been given as 1463 °C and a boiling point of 2489 °C. It is virtually insoluble since its solubility in water is 0.00012 g/100 ml of water at 18 °C.

The solid adopts the fluorite structure of CaF_2 with the cell parameters of: $a = b = c = 4.1012$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 48.78 Å^3, cell occupancy is shown in Table 2.49.

In the vapor phase, the SrF_2 molecule is nonlinear with an F–Sr–F angle of approximately 120°. This is an exception to the model generally used to predict the shape of individual molecules since it would predict a linear structure {This is called the "Gillespie–Nyholm" theory, named after its two main developers which is based upon the extent of electron-pair electrostatic repulsion}. Ab-initio calculations have been cited that propose the contributions from d-orbitals of the Sr atom in the shell below the valence shell are responsible for the nonlinear conformation.

SrF_2 is almost insoluble in water (its K_{SP} value is approximately 4.33×10^{-9} at 25 °C). It irritates eyes and skin, and is harmful when inhaled or ingested.

Similar to other alkaline earth fluorides like CaF_2 and BaF_2, SrF_2 presents "superionic conductivity" when heated to elevated temperatures. This phenomenon involves the electrical conductivity exhibited by a small group of solids that show high **ionic** conductivity and negligible electronic conductivity in the solid state unless heated beyond a specific temperature. In

general, ionic conductivity is due to the motion of ions, whereas the electronic conductivity results from the flow of electrons within the solid. For superionic conductors, also called fast ion conductors or solid electrolytes, the specific conductivity is usually within the range from about 10^{-3} to 10 S/cm (or mhos) whereas metals have typical values ranging from 10 to 10^5 S/cm. These values are very high for a crystalline ionic solid, but are still an order of magnitude lower than many electronic conductors such as metals or semiconductors.

Strontium fluoride is transparent to light in the wavelengths from the vacuum UV (150 nm) to the near IR (11 μm). Its optical properties are intermediate to CaF_2 and BaF_2. Strontium fluoride is used as an optical material for a small range of special applications, for example, as an optical coating on lenses and also as a thermoluminescent dosimeter crystal. Another use is as a carrier of the ^{90}Sr radioisotope in thermoelectric generators. SrF_2 is also used as a single crystal for lasers. Some optical properties of single-crystal SrF_2 are listed in Table 2.50.

Strontium fluoride can be prepared by the reaction of strontium chloride with fluorine gas, or by action of hydrofluoric acid on strontium carbonate:

$$SrCl_2\ (aq) + F_2\ (gas) \Rightarrow SrF_2\ (solid) + Cl_2\ (gas)$$

$$SrCO_3 + 2HF \Rightarrow SrF_2 + CO_2 + H_2O$$

Note that the first reaction depends upon the insolubility of SrF_2 in water. Strontium fluoride is a water-insoluble source for use in oxygen-sensitive applications, such as metal production since it in nonhygroscopic (Table 2.51).

Strontium Chloride

Strontium chloride has the formula $SrCl_2$ and the molecular weight of 247.43 g/cm^3. It is a typical salt, forming neutral aqueous solutions.

Strontium chloride can be prepared by treating strontium hydroxide or strontium carbonate with hydrochloric acid:

$$Sr(OH)_2 + 2HCl \Rightarrow SrCl_2 + 2H_2O$$

$$SrCO_3 + 2HCl \Rightarrow SrCl_2 + CO_2 + H_2O$$

Crystallization from a cold aqueous solution gives the hexahydrate, $SrCl_2 \cdot 6H_2O$. Dehydration of this salt occurs in stages, commencing above 61 °C and ending at 320 °C, where full dehydration occurs. The dihydrate, $SrCl_2 \cdot 2H_2O$, is a metastable form before the anhydrate begins to form at 200 °C. The hydrates formed in solution have one, two or six waters of crystallization.

$SrCl_2 \cdot 6H_2O$ is a hexagonal system consisting of colorless long-needle crystals. It loses four crystal waters of hydration at 61.4 °C to form plate crystals of $SrCl_2 \cdot 2H_2O$ which become the monohydrate at 100 °C and anhydrate at 200 °C.

The solid anhydrate adopts a deformed rutile structure as well as the CaF_2 type of structure. Cell parameters for the CaF_2 type are: $a = b = c = 4.9321$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 84.84 Å^3, cell occupancy is shown in Table 2.52.

The structure is shown in Fig. 2.17.

In the vapor phase, the $SrCl_2$ molecule is nonlinear with a Cl–Sr–Cl angle of approximately 130°, similar to that of $CaCl_2$. Apparently, the same rules (Gillespie–Nyholm) apply.

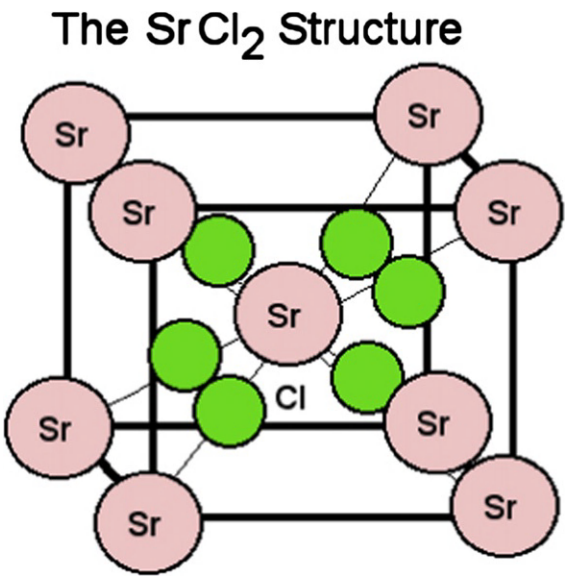

FIGURE 2.17

Strontium chloride is the precursor to other compounds of strontium, such as yellow $SrCrO_4$, which is used as a corrosion inhibitor for aluminum. The precipitation proceeds analogously to the related isostructural sulfate:

$$SrCl_2 + Na_2CrO_4 \Rightarrow SrCrO_4 + 2NaCl$$

Like all compounds of Sr, this salt emits a bright red color in a flame. Its optical and chemical properties are intermediate between those found for its neighbors in Group 2, such as $BaCl_2$ (which is more toxic), and calcium chloride (which is more common). Strontium chloride is the compound usually used as a red coloring agent in fireworks. It imparts a much more intense red color to the flames than other alternatives. It is employed in small quantities in glass making and metallurgy. The radioactive isotope, strontium-89, used for the treatment of bone cancer. It is usually administered in the form of strontium chloride. Seawater aquaria require small amounts of strontium chloride, which is consumed in the production of the exoskeletons of certain planktons.

$SrCl_2$ is useful in reducing tooth sensitivity by forming a barrier over microscopic tubules in the dentin-containing nerve endings that have become exposed by gum recession. Known in the US as "Sensodyne", these products are called "strontium chloride toothpastes," although most now use KNO_3 instead which works as a nerve calming agent rather than a barrier.

Another common hydrate, $SrCl_2 \cdot 2H_2O$, is composed of white, crystalline needles which have a sharp, bitter taste. It can be prepared by fusing $SrCO_3$ with $CaCl_2$ at high temperature and then extracting the melt with water. The solution is then concentrated and then crystallized to form $SrCl_2 \cdot 6H_2O$, which is then dehydrated at 68 °C to form the dihydrate.

Anhydrous strontium chloride is a colorless crystal or a white powder with a molecular weight of 158.53 g/mol and a density of 3.05 g/cm^3. Its melting point is 875 °C and its boiling point is 1250 °C. It is easily soluble in water but slightly soluble in anhydrous alcohol and acetone. It is not soluble in liquid ammonia. Its solubility in water is shown in Table 2.53.

Physical properties are listed in Table 2.54.

Strontium Bromide

Strontium bromide has the formula $SrBr_2$. At room temperature, it is a white, odorless, crystalline powder with the molecular weight of 247.43 g/mol. Strontium bromide burns bright red in a flame test. It is used in flares and also has some pharmaceutical uses. Several hydrates have been characterized including the monohydrate and the hexahydrate, $SrBr_2 \cdot 6H_2O$. This salt is a white, hygroscopic powder soluble in water and alcohol. It loses water at 180 °C, melts at 643 °C and is used in medicine and as an analytical reagent.

The structure of $SrBr_2 \cdot 6H_2O$ is tetragonal with $a_o = 11.633$ Å and $c_o = 7.155$ Å. Density measurements

are consistent with 10 molecular units per cell. The space group is $D_{4n}^{7}-P_n^{4mm}$ or $C_{4h}^{3}-P_n^{4}$. $SrBr_2 \cdot 6H_2O$ is a white, hygroscopic powder soluble in water and alcohol which loses water at 180 °C when heated, and the resulting anhydrate melts at 643 °C and decomposes at 1135 °C to form the oxide plus Br_2 gas.

The anhydrate, $SrBr_2$, is a colorless, transparent, crystal, odorless, having a bitter, saline taste. It is very deliquescent and soluble in water and is readily soluble in alcohol and amyl alcohol. The specific gravity of $SrBr_2$ is 4.210 g/cm^3. It can be prepared by treating $SrCO_3$ with a hydrogen bromide solution. Alternatively, a strontium salt (carbonate, sulfate, chloride, etc.) is treated with bromine or hydrobromic acid in presence of a reducing agent. It has the structure as shown in Fig. 2.18.

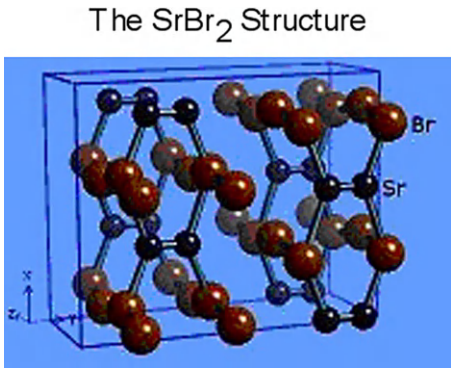

FIGURE 2.18

Cell constants are: $a = 7.133$ Å, $b = c = 11.645$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 962.30 Å^3 cell occupancy is shown in Table 2.55.

Its solubility in water is shown in Table 2.56.

Very little use has been found for this salt in Industry. Physical properties of this salt are given in the following Table 2.57.

Strontium Iodide

Strontium iodide (SrI_2) is an ionic, water-soluble, deliquescent compound that has been used in medicine as a substitute for potassium iodide. Strontium iodide crystals are colorless, transparent, hexagonal in structure, and have a bitter, saline taste. Soluble in 0.6 part of water at 15 °C, they are also soluble in alcohol.

Strontium iodide can be prepared by reacting strontium carbonate with hydroiodic acid:

$$SrCO_3 + 2HI \Rightarrow SrI_2 + H_2O + CO_2$$

Strontium iodide turns yellow when exposed to air due to the formation of iodine at the surface of the crystals. At high temperatures (when in the presence of air), strontium iodide completely decomposes to form strontium oxide and free iodine.

Three types of structures are known (Fig. 2.19).

CELL PARAMETERS

$Sr(OH)_2$ type: $a = 4.921$ Å, $b = 8.394$ Å, $c = 12.328$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 508.52 Å^3, cell occupancy is shown in Table 2.58.

$PbCl_2$ type: $a = 4.632$ Å, $b = 8.889$ Å, $c = 11.232$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 462.18 Å^3, cell occupancy is shown in Table 2.59.

SrI_2 type: $a = 7.896$ Å, $b = 8.251$ Å, $c = 15.268$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 994.71 Å^3, cell occupancy is shown in Table 2.60.

Several hydrates are known including $SrI_2 \cdot 6H_2O$. This salt is a white crystalline substance composed of small plates. It decomposes in moist air due to its deliquescence. Its specific gravity varies from 4.415 g/cm^3 to 4.549 g/cm^3, depending upon how the crystals are formed. It loses water at 78 °C and the anhydrate forms above 200 °C. The melting point of SrI_2 is 507 °C and its boiling point is 645 °C where it decomposes to the oxide and iodine. It is soluble in water as shown in Table 2.61.

Researchers have grown and characterized scintillation crystals of strontium iodide (SrI_2). Scintillation energy resolution and light yield proportionality surpass NaI and are similar to $LaBr_3$. The SrI_2 scintillators doped with europium (Eu) exhibit very high light yields (>100,000 photons/MeV), extremely good energy resolution (<3% at 662 keV) and excellent light yield proportionality. Europium-activated strontium and barium iodide single crystals have been found to be readily formed by the Bridgman method and are used to produce crystals having high scintillation light yields. SrI_2:Eu^{2+} emits in the blue Eu^{2+} band, centered at 435 nm, with a decay time of 1.2 μs and a light yield of ~90,000 photons/MeV. It offers an energy resolution better than 4% full width at half maximum at 662 keV, and exhibits excellent light yield proportionality. An additional broad impurity-mediated recombination band is present at 550 nm (>3 μs decay), and is probably due to the presence of Tb^{3+} unless high-purity feedstock is used. Physical properties are listed in Table 2.62.

2.2.6. Halide Compounds of Barium

Barium Fluoride

Barium fluoride (BaF_2), also known as barium(II) fluoride, is a solid which can also be a transparent crystal. Its molecular weight is 175.34 g/mol. It occurs in nature as the mineral "Frankdicksonite". It occurs as a white powder with a melting point of 1290 °C and a boiling point of 2259 °C. It is slightly soluble in water (0.159 at 0.0 °C and 0.162 g/100 ml of water at 20 °C).

The solid generally assumes the fluorite structure, but when subjected to high pressure, changes to the $PbCl_2$ structure. In the vapor phase, the BaF_2 molecule is nonlinear with an F–Ba–F angle of approximately 108° (Fig. 2.20).

CELL PARAMETERS

$PbCl_2$ type (SG = 0P12): $a = 3.979$ Å, $b = 6.159$ Å, $c = 7.853$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 192.45 Å^3, cell occupancy is shown in Table 2.63.

CaF_2 type: $a = b = c = 4.3842$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 59.58 Å^3 (Table 2.64).

Barium fluoride crystal is transparent from the ultraviolet to the infrared, i.e. from 150–200 nm to 11–11.5 μm, and can be used as a material to make optical components such as lenses. It is used, for example, in windows for infrared spectroscopy. Its transmittance at 200 nm is relatively low (0.60), but at 500 nm it goes up to 0.96–0.97 and stays at that level until 9 μm, then it starts falling off (0.85 for 10 μm and 0.42 for 12 μm). The refractive index is about 1.46 from 700 nm to 5 μm (Table 2.65).

Barium fluoride is also a common, very fast (one of the fastest) scintillator for the detection of X-rays, gamma rays and other high-energy particles (That is, its decay time is very short). One of its applications lies in the detection of 511 keV gamma photons in measurements of "positron emission" tomography. {The other material used in this application is "bismuth germanate", $Bi_4Ge_3O_{12}$ ("Evlitine" structure)}. Its measured crystal properties are included in the following Table 2.66.

BaF_2 as a crystal responds also to alpha and beta particles, but, unlike most scintillators, it glows in ultraviolet light. It can also be used for detection of high-energy (10–150 MeV) neutrons, and for use as

a "pulse shape" discriminator to separate them from simultaneously occurring gamma photons.

It is corroded by water vapor, even up to 500 °C, but in a dry environment, it can be used up to 800 °C. Prolonged exposure to moisture degrades its transmission in the vacuum UV range. It is less resistant to water than calcium fluoride. However, it is the most resistant of all the optical fluorides to high-energy radiation, though its far ultraviolet transmittance is lower than theirs. It is quite hard, but is very sensitive to thermal shock.

Barium fluoride is used as a "pre-opacifying" agent in enamel and glazing frits in the production of ceramic products. Its other use is in the production of welding agents:

- as an additive to some welding fluxes,
- a component of coatings,
- for welding rods,
- in welding powders.

It is also used in metallurgy, as a molten bath for refining aluminum metal (Table 2.67).

Barium Chloride

Barium chloride has the formula, $BaCl_2$ and is an ionic chemical compound. It is one of the most important water-soluble salts of barium-containing compounds. Like other barium salts, it is toxic and imparts a yellow-green coloration to a flame. It is also hygroscopic. Barium chloride was the by-product of the discovery of radium by Madame Curie (1898).

Hardness (Knoop): 82 psi
Young's modulus: 53.07 GPa
Modulus of rupture: 3900 psi
Structure: Cubic—111 cleavage plane

When refining radium, the final separation resulted in barium chloride and radium chloride.

$BaCl_2$ crystallizes in both the cubic "fluorite" and "lead chloride" crystal structures, both of which accommodate the preference of the large Ba^{2+} ion for coordination numbers greater than six. There are four structure types known (Fig. 2.21).

CELL PARAMETERS

Fe_2P type: $a = 4.059$ Å, $b = c = 7.083$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 176.31 Å, cell occupancy is shown in Table 2.68.

TABLE 2.66

Chemical formula	BaF_2
Crystal class	Cubic

$PbCl_2$ type, SG = mP24: $a = 4.604$ Å, $b = 8.613$ Å, $c = 11.901$ Å, $\alpha = 92.6°$, $\beta = \gamma = 90°$, cell volume = 471.48 Å^3, cell occupancy is shown in Table 2.69.

$PbCl_2$ type, SG = 0P12: $a = 4.732$ Å, $b = 7.872$ Å, $c = 9.425$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 651.08 Å^3, cell occupancy is shown in Table 2.70.

In aqueous solution, $BaCl_2$ behaves as a simple salt. In water, it is a 1:2 electrolyte and the solution exhibits a neutral pH. Electrolysis of molten barium chloride produces barium metal. This can be used for obtaining barium salts for commercial uses. Barium chloride reacts with sulfate ion to produce a thick white, insoluble precipitate of barium sulfate:

$$Ba^{2+}(aq) + SO_4^{2-}(aq) \Rightarrow BaSO_4\ (solid)$$

Oxalate effects a similar reaction:

$$BaCl_2\ (aq) + Na_2C_2O_4\ (aq) \Rightarrow BaC_2O_4\ (solid) + 2NaCl\ (aq)$$

Barium chloride can be prepared from barium hydroxide or barium carbonate, the latter being found naturally as the mineral "Witherite". These basic salts react to give hydrated barium chloride. On an industrial scale, it is prepared via a two-step process from the mineral "Baryte":

$$BaSO_4 + 4C \Rightarrow BaS + 4CO\ (gas)$$

This first step requires high temperatures. The second step requires fusion of the reactants:

$$BaS + CaCl_2 \Rightarrow BaCl_2 + CaS$$

The $BaCl_2$ is then be leached out from the mixture with water. From water solutions of barium chloride, the dihydrate can then be crystallized as white crystals, $BaCl_2 \cdot 2H_2O$, which are colorless, translucent rhomboidal tablets or lamellae. The dihydrate is stable in the air at room temperature, but loses one-half of its water above 55 °C (131 °F), and becomes anhydrous at 121 °C (250 F). As a cheap, soluble salt of barium, barium chloride finds wide application in the laboratory. It is commonly used as a test for sulfate ion. In industry, barium chloride is mainly used chiefly in the synthesis of pigments and in the manufacture of rodenticides and pharmaceuticals. It is also used:

- In the purification of brine solution in caustic chlorine plants,

Its solubility in water in grams per 100 ml of water is shown in Table 2.71.

Physical properties are listed in Table 2.72.

Barium Bromide

Barium bromide has the molecular formula of $BaBr_2$. Like barium chloride, it is soluble in water but is toxic if ingested. $BaBr_2$ crystallizes in a $PbCl_2$ motif, as white orthorhombic crystals that are deliquescent. In aqueous solution, $BaBr_2$ behaves as a simple salt. It adopts the same type of $PbCl_2$ type of structures as $BaCl_2$ (Fig. 2.22).

CELL PARAMETERS

$PbCl_2$ type, SG = 0P12: $a = 4.935$ Å, $b = 8.252$ Å, $c = 9.915$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 402.77 Å^3, cell occupancy is shown in Table 2.73.

$PbCl_2$ type, SG = mP24: $a = 4.896$ Å, $b = 9.302$ Å, $c = 12.773$ Å, $\alpha = 92.6°$, $\beta = \gamma = 90°$, cell volume = 581.36 Å^3, cell occupancy is shown in Table 2.74.

Barium bromide reacts with the SO_4^{2-} ion to produce insoluble $BaSO_4$ as a precipitate:

$$BaBr_2\ (aq) + SO_4^{2-} \Rightarrow BaSO_4\ (solid) + 2Br^-\ (aq)$$

Similar reactions occur with oxalic acid, HF and H_3PO_4. Barium bromide can be prepared from barium sulfide or barium carbonate by reaction with hydrobromic acid to give hydrated barium bromide:

$$BaS + HBr \Rightarrow BaBr_2 + H_2S$$

$$BaCO_3 + HBr \Rightarrow BaBr_2 + CO_2 + H_2O$$

Barium bromide can be crystallized from its solution as a dihydrate, $BaBr_2 \cdot 2H_2O$ (molecular weight: 333.19), which forms the anhydrate by heating to 120 °C. It dissolves in its own water-of-hydration at 75 °C before decomposing to the anhydrate. Barium bromide is a precursor to chemicals used in photography as well as to form other bromides.

Historically, barium bromide was used to purify radium in a process of fractional crystallization devised by Marie Curie. Since radium precipitates preferentially in a solution of barium bromide, the ratio of radium to barium in the precipitate was found to be higher than the ratio in the solution.

The solubility of barium bromide in water is shown in Table 2.75.

Physical properties are listed in Table 2.76.

Barium Iodide

Barium iodide occurs in two forms, one anhydrous and the other as a dihydrate. Both are white solids. There are three forms of the anhydrous salt (Fig. 2.23).

CELL PARAMETERS

Fe_2P type: $a = 5.173$ Å, $b = c = 9.142$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 374.42 Å^3, cell occupancy is shown in Table 2.77.

$PbCl_2$ type (SG = mP24): $a = 5.022$ Å, $b = 9.572$ Å, $c = 13.501$ Å, $\alpha = 91°$, $\beta = \gamma = 90°$, cell volume = 648.90 Å^3, cell occupancy is shown in Table 2.78.

$PbCl_2$ type (SG = mP12): $a = 5.298$ Å, $b = 8.904$ Å, $c = 10.685$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 504.05 Å^3, cell occupancy is shown in Table 2.79.

Crystal structure	Orthorhombic, oP12 Space group = Pnma, No. 62
Standard enthalpy of formation	$\Delta_f H\ominus_{298} = -181.1$ kcal/mol

This salt is stable, but air and light sensitive. It is also hygroscopic and moisture sensitive. Barium iodide is incompatible with strong oxidizing agents. Barium iodide is made by the neutralization of barium carbonate with HI in water:

$$BaCO_3 + 2HI\ (aq) \Rightarrow BaI_2\ (aq)$$

It is also made by the reaction of BaH_2 with ammonium iodide in pyridine:

$$BaH_2 + 2NH_4I\ (aq) \Rightarrow BaI_2\ (aq) + 2NH_3\ (gas) + H_2\ (gas)$$

The product crystallizes as the hydrate $BaI_2 2H_2O$. If this heated, dehydration to anhydrous BaI_2 occurs. The dihydrate dehydrates at 539 °C to form BaI_2.

Another view of one of the structures is shown as follows. Europium-doped barium iodide was found to be readily growable by the Bridgman method and to produce high **scintillation** light yields. BaI_2:Eu^{2+} produces >30,000 photons/MeV as the divalent Eu^{2+} emission band at 420 nm (Fig. 2.24).
that has a decay time less than 1.0 μs. High-Z crystal barium iodide is less prone to crack, as compared to lanthanum halides.

In another report, barium iodide crystals, activated by Eu^{2+} were also grown. Radioluminescence spectra and time-resolved decay were measured. BaI_2:Eu exhibits luminescence from both Eu^{3+} at 420 nm (with a 450- ns

decay), and a broad band at 550 nm (about a 3- μs decay) that was assigned to a trapped exciton. The 550 nm luminescence decreases relative to the Eu^{2+} luminescence when the barium iodide is zone refined prior to crystal growth.

Solubility in water is shown in Table 2.80.

Physical properties are listed in Table 2.81.

2.2.7. Halide Compounds of Radium

Radium and radium halide compounds find utilization in many areas in making commercial products and for medical applications. Radium is utilized in creating radon gas and this product is used for medical radiation treatment for diseases such as cancer. There are many compounds such as radium fluoride, radium chloride, radium bromide, radium iodide, radium oxide, and radium nitride. These compounds are regarded as very dangerous for humans and are not allowed in products that people use for normal consumption.

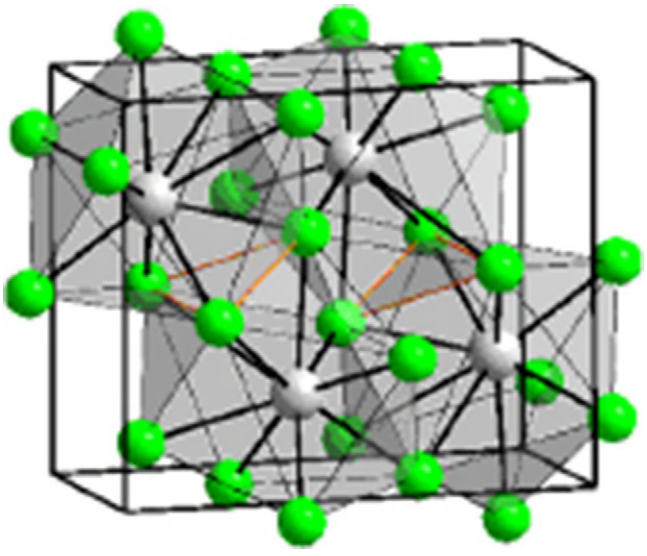

FIGURE 2.24

Radium and radium halide compounds are utilized in the nuclear and atomic areas for the production of weapons and also for creating electrical power. Radium bromide is employed in the extraction and separation of radium from the naturally occurring mineral ore of uranium. Radium chloride is used in the process of chemical extraction of radium from the naturally occurring ores such as pitchblende. The products had been used before 1950 to make dials for watches but now this practice is stopped because the items are deadly.

Radium Fluoride

This compound has the chemical formula of RaF_2 and a molecular weight of 263.8214 g/mol. Its structure is similar to that of CaF_2, the cubic fluoride. It can be prepared by reaction of HF gas on the metal:

$$Ra + 2HF \Rightarrow RaF_2 + H_2$$

Although this compound is listed as a viable salt of radium, no scientific studies of the properties of this material are readily available. Furthermore, RaF_2 is not offered for sale nor are there any descriptions of its physical and chemical properties. However, this compound

TABLE 2.80

has been given a CAS number of 20610-49-5, presumably because of its dangerous inherent radioactivity.

Radium Chloride

Radium chloride, $RaCl_2$, was the first radium compound to be prepared in a pure state and was the basis of Marie Curie's original separation of radium from Barium. The first preparation of radium metal was by the electrolysis of a solution of radium chloride using a mercury cathode. The structure remains unknown.

Radium chloride is soluble and crystallizes from solution as the dihydrate. It may be dehydrated by heating to 100 °C in air for 1 h followed by 5 h at 520 °C under Argon gas. If the presence of other anions is suspected, the dehydration may be effected by fusion under hydrogen chloride gas.

Radium chloride is a white solid having a blue-green luminescence, especially when heated. It is less soluble in water than other alkaline earth chlorides, a fact which is used in the first stages of the separation of radium from barium by fractional crystallization. It is only sparingly soluble in azeotropic HCl (20.2% HCl) and virtually insoluble in concentrated hydrochloric acid.

Gaseous radium chloride exists as $RaCl_2$ molecules, as do the other alkaline earth metal halides. The gas shows strong absorptions in the visible spectrum at 676.3 nm and 649.8 nm (red). The dissociation energy of the radium–chlorine bond is estimated as 2.9 eV, and its length is 2.92 Å.

Radium chloride is still used for the initial stages of the separation of radium from barium during the extraction of radium from the mineral "Pitchblende". The large quantities of material involved (tons of ore for milligrams of radium) favor this less costly (but less efficient) method over those based on radium bromide or radium chromate (used for the later stages of the separation).

$RaCl_2$ is used to produce radon gas that in turn is used as a cancer treatment in medicine. This compound is not offered for sale to the general public. Physical properties are listed in Table 2.82.

Radium Bromide

Radium bromide is the bromide salt of Ra with the formula $RaBr_2$. It is used primarily in separating radium from uranium ore. $RaBr_2$ is a water-soluble, poisonous, radioactive white powder or white orthorhombic crystals that is corrosive to skin or flesh. It melts at 728 °C used in medicine, physical research, and luminous paint. Its structure remains unknown.

Radium bromide has been used for skin complaints such as acne, moles, skin, cancer, eczema, dermatitis, and acne–rosacea. It is also used in research projects but is not offered for sale to the general public. Known physical properties are listed in Table 2.83.

Radium Iodide

This compound has the molecular formula of RaI_2 and a molecular weight of 479.834 g/mol. Its CAS number is 20610-52-0. It can be prepared by reaction of the metal with hydroiodic acid:

$$Ra + 2HI \Rightarrow RaI_2 + H_2$$

Little is available concerning its physical or chemical properties. As with radium fluoride, no scientific studies are easily accessed. Its structure has not been determined. RaI_2 is not offered for sale to the general public.

2.3. OXY-CHLORINE COMPOUNDS OF THE ALKALINE EARTHS

The alkaline earths do not form oxy-fluoride types of compounds. They do form a number of different types of compounds with the other oxy-halide acids. The compositions obtained are based upon the types of acids that can form. The following presents the characteristics of these oxy-acids in relation to the type of alkaline earth compounds that are known.

2.3.1. Oxy-Chlorine Acids

Hypochlorous acid is a weak acid where the chlorine atom is in the +1 oxidation state and has the formula HClO. It forms when Cl_2 dissolves in water. It cannot be isolated in pure form due to rapid equilibration with its precursor. Addition of chlorine to water gives both hydrochloric acid (HCl) and hypochlorous acid:

$$Cl_2 + H_2O \Rightarrow HClO + HCl$$

Physical properties are listed in Table 2.84.

Chlorous acid has the formula $HClO_2$. It is a weak acid. The chlorine atom possesses oxidation state +3 in this acid. The pure substance is unstable and disproportionates to hypochlorous acid (Cl oxidation state +1) and chloric acid (chlorine oxidation state +5).

$$2HClO_2\ (aq) \Rightarrow HClO\ (aq) + HClO_3\ (aq)$$

Chlorite salts such as sodium chlorite are stable conjugate bases derived from this acid. These salts are sometimes used in the production of chlorine dioxide, ClO_2 (Table 2.85).

Chloric acid, $HClO_3$, is an oxoacid of chloride, and the formal precursor of chlorate salts. It is a strong acid ($pK_a = -1$) and a strong oxidizing agent. It is stable in cold aqueous solution up to a concentration of approximately 30%, and solution of up to 40% can be prepared by careful evaporation under reduced pressure. Above these concentrations, and on warming, chloric acid solutions decompose to give a variety of products, for example:

$$8HClO_3 \Rightarrow 4HClO_4 + 2H_2O + 2Cl_2 + 3O_2$$

Note that it disproportionates into perchloric acid in which the chlorine atom has a +7 oxidation state and also the zero oxidation state of chlorine gas (an oxidation–reduction reaction). Thus, under the proper conditions, it can also be used to make perchloric acid (Table 2.86).

$$3HClO_3 \Rightarrow HClO_4 + H_2O + 2ClO_2$$

Perchloric acid, $HClO_4$, is a colorless liquid soluble in water. It is a strong acid comparable in strength to sulfuric and nitric acids. It is useful for preparing perchlorate salts, but it is also dangerously corrosive and readily forms explosive mixtures. Perchloric acid

Dichlorine tetroxide = Cl_2O_4
Dichlorine heptoxide = Cl_2O_7

is produced by the treatment of sodium perchlorate with sulfuric acid and by the electrochemical oxidation of aqueous chlorine (Table 2.87).

2.3.2. Oxy-Chlorine Acid Anhydrides

Each of the above acids has an "anhydride" which is a member of the chlorine–oxygen family. Chlorine and oxygen form a number of differing compounds. These are included in Table 2.88.

Of these, the following are "anhydrides" of the known oxy-chlorine acids (Table 2.89).

Dichlorine monoxide, Cl_2O, is one of the "chlorine-oxide" creators of the oxy-chlorine acids. It is a brownish yellow gas at room temperature that can explode at high concentrations when heated or subjected to sparks. It is best prepared by treating fresh yellow mercuric oxide with Cl_2 gas:

$$2Cl_2 + 2HgO \Rightarrow HgCl_2 \cdot HgO + Cl_2O$$

It can also be prepared by reaction of Cl_2 gas with moist sodium carbonate, Na_2CO_3. Dichlorine monoxide is very water soluble. It is the anhydride of hypochlorous acid. Much of the Cl_2O manufactured industrially is used to make hypochlorites. It is also the unstable decomposition product of calcium hypochlorite (Fig. 2.25).

TABLE 2.87

CAS number	7601-90-3
Molecular formula	$HClO_4$
Molecular weight	100.46 g/mol
Appearance	Colorless liquid
Density	1.67 g/cm^3
Melting point	−112 °C
Boiling point	19 °C (decomposes)
Solubility in water	Miscible

The shape of dichlorine monoxide is bent, due to the two lone pairs of electrons orbiting the nucleus of the oxygen atom that are not used to bond with the chlorine atoms. Its molecular weight is 86.9054 g/mol. Its melting point is –130 °C (−153 K, −185 F) and its boiling point is 2.2 °C (275 K, 36 F). It is a strong oxidizer when added to a water solution. The crystal structure is shown in Fig. 2.26.

Lately, it has been determined that it is best to generate dichlorine oxide for use commercially rather than use one of the salts of the alkalis or the alkaline earths. As a matter of fact, only the calcium salt has seen extensive usage in Industry or domestically as "bleaching powder". This accounts for the paucity of data concerning the various alkaline earth hypochlorites. The advantage of Cl_2O for bleaching paper pulp

Perchloric acid ($HClO_4$)	= Dichlorine heptoxide (Cl_2O_7)

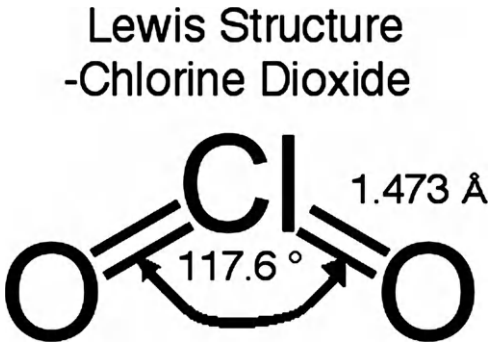

FIGURE 2.25

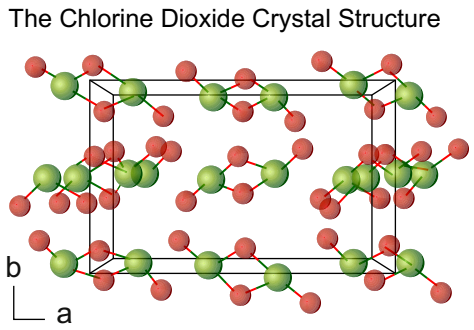

FIGURE 2.26

lies in the fact that it is a gas and can be manipulated much easier than a solid like sodium hypochlorite or its solution. The disadvantage is that Cl_2O reacts with any water vapor present and must be kept anhydrous until it is used. The amount of Cl_2O gas used for oxidation of paper pulp, for example, in the U.S. is in the many tons per year area. Physical properties are listed in Table 2.90.

Dichlorine trioxide, Cl_2O_3, is a chlorine oxide that is the anhydride of chlorous acid. It is a dark brown gas discovered in 1967 which is explosive even below 0 °C. It is formed by the low-temperature photolysis of ClO_2 and is formed along with Cl_2O_6, Cl_2 and O_2. Its structure is believed to be OCl–ClO_2 with possible isomers such as Cl–O–ClO_2. It is very soluble and forms chlorous acid if dissolved in water:

$$Cl_2O_3\ (gas) + H_2O \Rightarrow 2H_2ClO_2\ (aq)$$

It is less stable than chlorous acid, its more stable product, and therefore is not used commercially as an oxidizing agent. Its solubility in water is low, about 3.42 g/100 ml of water but it slowly reacts to form chlorous acid at room temperature. Raising the temperature causes it to decompose to form chlorine gas that remains soluble in aqueous solution (Table 2.91).

Dichlorine Pentoxide

This compound has not been characterized and its physical and chemical properties remain unknown.

Dichlorine Hexoxide, Cl_2O_6, is the mixed oxide of chloric and perchloric acids.

It is produced by reaction between chlorine dioxide and excess ozone:

$$2ClO_2 + 2O_3 \Rightarrow 2ClO_3 + 2O_2 \Rightarrow Cl_2O_6 + 2O_2$$

It is a dark red fuming liquid at room temperature that crystallizes as an ionic compound, chloryl perchlorate, $[ClO_2]^+[ClO_4]^-$. It was originally reported to exist as the monomeric chlorine trioxide ClO_3 in gas phase, but was later shown to remain an oxygen-bridged dimer after evaporation and until thermal decomposition into chlorine perchlorate, Cl_2O_4, and oxygen. Cl_2O_6 is diamagnetic and is a very strong oxidizing agent. Although stable at room temperature, it explodes violently on contact with organic compounds and reacts with Au to produce the chloryl salt $[ClO_2]^+[Au(ClO_4)_4]^-$. Many other reactions involving Cl_2O_6 reflect its ionic structure, $[ClO_2]^+[ClO_4]^-$, including the following:

$$NO_2F + Cl_2O_6 \Rightarrow NO_2ClO_4 + ClO_2F$$

$$NO + Cl_2O_6 \Rightarrow NOClO_4 + ClO_2$$

$$2V_2O_5 + 12Cl_2O_6 \Rightarrow 4VO(ClO_4)_3 + 12ClO_2 + 3O_2$$

$$SnCl_4 + 6Cl_2O_6 \Rightarrow [ClO_2]_2[Sn(ClO_4)_6] + 4ClO_2 + 2Cl_2$$

Nevertheless, it can also react as a source of the ClO_3 radical:

$$2AsF_5 + Cl_2O_6 \Rightarrow 2ClO_3AsF_5$$

Dichlorine Heptoxide is a chemical compound with the formula Cl_2O_7. Dichlorine heptoxide is the anhydride of perchloric acid and is related to perchlorates in general. It is produced by the careful distillation of perchloric acid in the presence of a dehydrating agent such as phosphorus pentoxide:

$$2HClO_4 + P_4O_{10} \Rightarrow Cl_2O_7 + H_2P_4O_{11}$$

It is also produced by the careful distillation of perchloric acid that has been dehydrated with P_2O_5.

The distillation is usually safe at atmospheric pressure if it is truly free of perchloric acid. It is slowly hydrolyzed back into perchloric acid if allowed to sit in air. This can be dangerous since the resulting acid will be anhydrous, and anhydrous perchloric acid can detonate without reason.

It may also be formed by illumination of mixtures of chlorine and ozone. It slowly hydrolyzes back to perchloric acid, if allowed to contact moisture in any way. Dichlorine heptoxide melts at −91.5 °C and boils at 82 °C. It is highly explosive and can be set off with flame, mechanical shock, and on contact with organic substances. Cl_2O_7 is an endothermic molecule, which means that it is intrinsically unstable:

$$2Cl_2O_7 \Rightarrow 2Cl_2 + 7O_2 \ (\Delta H = +135 \text{ kJ/mol})$$

The Cl_2O_7 molecule is bent with a Cl–O–Cl angle of 118.6° giving the molecule C_2 symmetry. The terminal Cl–O distances are 1.709 Å and the Cl–O distances are 1.405 Å. In this compound, chlorine exists in its highest formal oxidation state of +7, although the bonding in this hypervalent molecule is significantly covalent (Fig. 2.27).

Dichlorine heptoxide reacts with primary and secondary amines in carbon tetrachloride solution to yield *N*-perchloryls:

$$2RNH_2 + Cl_2O_7 \Rightarrow 2RNHClO_3 + H_2O$$

$$2R_2NH + Cl_2O_7 \Rightarrow 2R_2NClO_3 + H_2O$$

It also reacts with olefins to give alkyl perchlorates. For example, it reacts with propene in carbon tetrachloride solution to yield isopropyl perchlorate and 1-chloro-2-propyl perchlorate.

Although it is the most stable chlorine oxide, Cl_2O_7 is strong oxidizer as well as an explosive that can be set off with flame or mechanical shock, or by contact with iodine. Nevertheless, it is less strongly oxidizing than the other chlorine oxides, and does not attack sulfur, phosphorus, or paper when cold. It has the same effects on the human body as elemental chlorine.

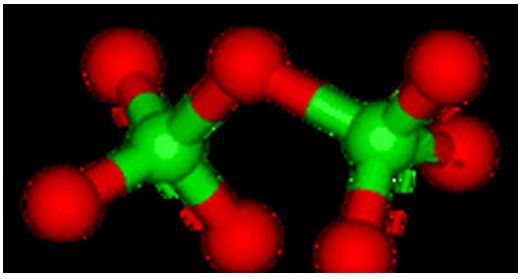

FIGURE 2.27

2.3.3. Alkaline Earth Oxy-Chlorine Compounds

The alkaline earths all form oxy-chlorine compounds with all of these complexes, $Ae(ClO_x)_2$ where x varies from 1 to 4, i.e. the acids discussed above. These compounds are strong oxidizers and corrosive to most materials with which they react. Of the four classes of chlorine-based oxidizers, the hypochlorous salts (ClO^-) have found the most usage commercially in Industry and domestically where they are used to bleach (whiten) wood pulp, paper, textiles and as cleaning, sanitizing and antibacterial aids for wastewater, sewage industrially and in the home. A large number of research papers can be found in the scientific literature concerning their properties and chemical reactions upon materials.

The chlorites (ClO_2^-) have not been employed to any great extent and relevant scientific literature is sparse whereas the chlorates (ClO_3^-) have found a number of commercial and domestic niches of usages. A number of research investigations are readily available concerning their properties. In contrast, the perchlorates (ClO_4^-) have found little applications industrially and have not been explored extensively as to their properties in the research literature.

There are only three oxyanions that form anhydrous salts: chlorites (ClO_2^-), chlorates (ClO_3^-) and perchlorates (ClO_4^-). Their stability increases with the increasing oxidation state of the halogen. There is no clear evidence of the existence of stable, stoichiometric, anhydrous hypochlorites since there is an evidence of the odor of chlorine, indicating continuous decomposition at room temperature.

Alkaline Earth Hypochlorites

BERYLLIUM HYPOCHLORITE

The stability and formulation of beryllium hypochlorite remain in question since the Be^{2+} cation is not formed in solution. The chemical formula would be $Be(ClO)_2$ if it did. Thus, since Be is amphoteric in solution and forms anions, the existence of a beryllium salt in solution like the hypochlorite remains in doubt. It may be that the small size of the Be atom precludes formation of a stable compound with the larger hypochlorite radical. Of course, the possibility of formation of a cation like $Be(OCl)^+$ exists but it has never been characterized. It could be prepared by reacting a hypochlorite salt like sodium hypochlorite with beryllium chloride in the solid state:

$$BeCl_2 + 2NaOCl \Rightarrow 2Be(OCl)_2 + 2NaCl$$

Of course, one would have to separate the two salts but any difference in solubility of the hypochlorite remains unknown. However, there is no data available

for such a reaction nor is there any description of the physical properties of beryllium hypochlorite.

Beryllium hypochlorite is not offered for sale nor is there any scientific data in the literature concerning its properties. The reason for this lies in its amphoteric nature in solution where the following reaction:

$$2Be^{2+} + H_2O \Rightarrow (Be_2OH)^{3+} + H^+$$

has been documented. Thus, it is clear that the Be^{2+} cation in aqueous solution never appears but is an "aquo-complex", and any formulation depicting "waters of hydration" in an oxy-chlorine compound is not completely accurate and valid.

MAGNESIUM HYPOCHLORITE

Magnesium hypochlorite has the chemical formula of $Mg(OCl)_2$ and the molecular weight of 127.286 g/mol. Its assigned CAS number is 10233-03-1. It can be prepared by reaction of hypochlorous acid upon magnesium carbonate in water. However, the product is not stable in water and decomposes to form basic magnesium hypochlorite, $Mg(OCl)_2 \cdot 2Mg(OH)_2$, which is useful in bleaching and sanitizing applications. The structure of this compound remains unknown.

A better process for the production of pure dibasic magnesium hypochlorite is said to comprise the reaction of a solid magnesium salt and a solid hypochlorite where one of the solid reactants is in the hydrate form. The process produces dibasic magnesium hypochlorite with excellent recovery of chlorine values and with reduced requirements for the disposal of solutions containing available chlorine. In this case, the reactants are magnesium chloride hexahydrate with calcium hypochlorite and its hydrates as preferred solid hypochlorite reactants:

$$MgCl_2 \cdot 6H_2O + Ca(ClO)_2 \Rightarrow Mg(ClO)_2 + CaCl_2 \cdot 6H_2O$$

wherein the solid components are reacted together by fusion at an elevated temperature. In general, the product is a mixture of compounds that is similar to the compound known as "bleaching powder"

Basic magnesium hypochlorite, $Mg(OCl)_2 \cdot 2Mg(OH)_2$, is a solid compound having an available chlorine content in the range of from about 50 to 60%. Textiles are bleached by immersing them in an aqueous solution of this salt. Bleaching takes place at any suitable temperature such as those in the range of about 10 – 100 °C, but preferably from about 30 to 80 °C. Textiles are held in contact with the aqueous solution of dibasic magnesium hypochlorite for a period of time sufficient to provide the materials with the desired degree of bleaching.

This salt is available commercially but has not found widespread usage since the calcium hypochlorite salt is cheaper and just as effective in these applications.

CALCIUM HYPOCHLORITE

Calcium hypochlorite has the molecular formula of $Ca(ClO)_2$ and a molecular weight of 142.974 g/mol. Its CAS number is 7778-54-3. Its specific gravity is 1.21 g/cm^3. When dissolved in water, it can provide nascent chlorine and oxygen to sterilize pool water or industrial wastewater. The structure of calcium chlorite, $Ca(ClO_2)_2$, has been refined from X-ray powder diffraction data using the Rietveld method. The compound crystallizes in the orthorhombic space group *Ccca* (*Ccce*), with $Z = 4$. The structure is based on separate layers parallel to the *ac* plane, consisting of calcium cations that are coordinated by chlorite anions; the O atoms form almost ideal square antiprisms. Within the layers, each anion bridges four metal cations. The Ca atoms are located on special positions of 222 symmetry, the Cl atoms lie on twofold axes and the O atoms are in general positions. The compound is isostructural with strontium chlorite, $Sr(ClO_2)_2$, and lead chlorite, $Pb(ClO_2)_2$.

It is manufactured by two main processes, the so-called "calcium process" and the "sodium process". These are essentially the same as described for the $Mg(ClO)_2$ salt method given above except that a sodium hypochlorite salt is used in one case and a calcium chloride salt in the other. The products are nearly the same. It is manufactured by the calcium process:

$$2Ca(OH)_2 + 2Cl_2 \Rightarrow Ca(ClO)_2 + CaCl_2 + 2H_2O$$

Bleaching powder is actually a mixture of calcium hypochlorite ($Ca(ClO)_2$) and the basic chloride $CaCl_2$, H_2O with some slaked lime, $Ca(OH)_2$. The product is generally called "**bleaching powder**". It consists of a mixture of calcium chloride ($CaCl_2$), calcium hypochlorite ($Ca(OCl)_2$), and calcium chloride hypochlorite (CaCl(OCl)).

In another method developed for the manufacture of $Ca(ClO)_2$, chlorine gas is reacted with calcium hydroxide:

$$Ca(OH)_2 + 2Cl_2 \Rightarrow Ca(ClO)_2 + 2HCl$$

In this method, it is claimed that the excess HCl is neutralized by excess $Ca(OH)_2$ to form $CaCl_2$. The product is said to be more "neutral" chemically and more stable than that produced by other methods.

Bleaching powder is white or gray white granular material, with a strong irritative odor. Its main component is calcium hypochlorite that exhibits several hydrates, the dihydrate, the trihydrate and the tetrahydrate.

The anhydrate releases a great deal of heat (heat of solution = 150 kcal/mol) and nascent oxygen and chlorine when solved in water:

$$Ca(ClO)_2 + H_2O \Rightarrow Ca^{2+}(aq) + ClO_2\,(aq)$$
$$\Rightarrow Cl + 2O\cdot + 2H^+$$

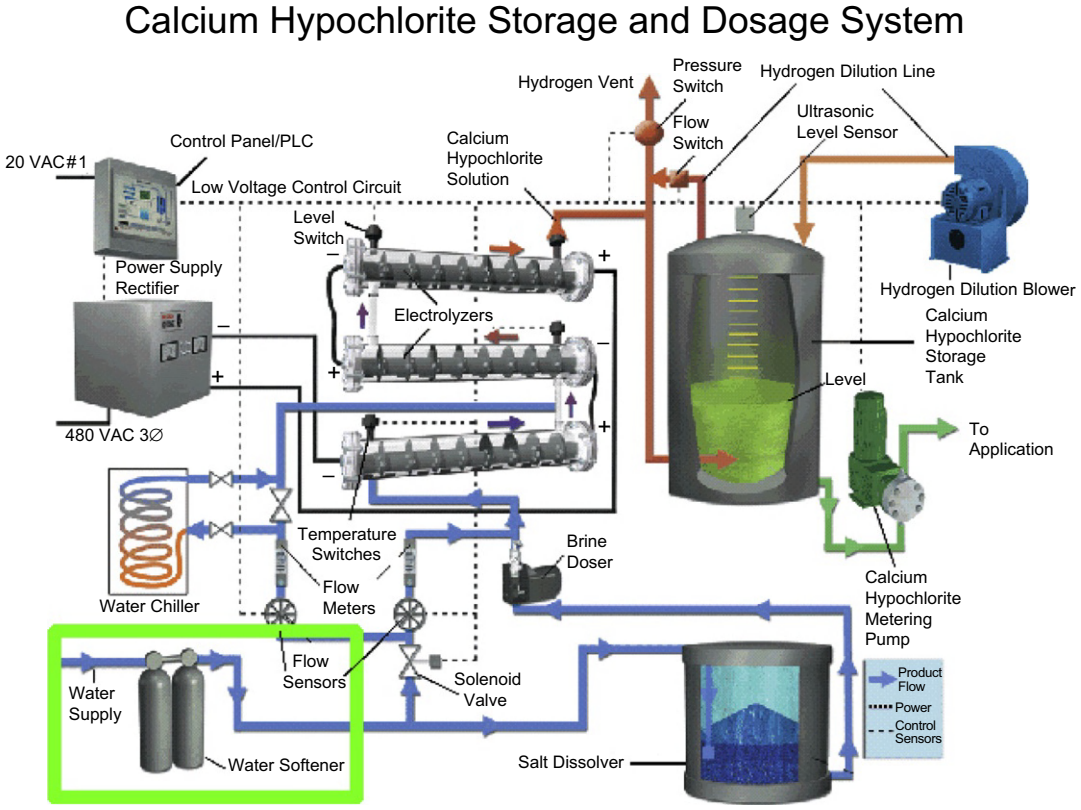

FIGURE 2.28

If the solid salt, calcium hypochlorite, is heated, its decomposition may cause an explosion. Reaction of the solid calcium hypochlorite with an acid may release chlorine, reaction of solid calcium hypochlorite with organics and oils may cause burning, and calcium hypochlorite tends to decompose and explode at high temperature. When stored at normal temperature, calcium hypochlorite is stable, with the effective chloride loss not more than 10% for sodium method. This salt is generally supplied to the public as a 3% solution. Specific methods of storage for large users (such as textile manufacturers) have been developed, as shown in Fig. 2.28.

Calcium hypochlorite is a powerful oxidizing agent, particularly in the presence of water or at higher temperature as it decomposes to release oxygen and chlorine gases. Therefore, it is necessary to contain the solution until it is used. When large quantities become necessary upon short notice, the above equipment becomes economical. As strong oxidant, calcium hypochlorite may react with vigor in combination with carbon compounds, and combination with finely divided carbon particles forms an explosive mixture. Reaction with acetylene leads to creation of explosive chloroacetylenes. Contact with organic matter, oil, hydrocarbons and alcohols such as methanol or ethanol may cause a violent explosion. Reaction with nitromethane causes a delayed violent reaction. Organic sulfur compounds such as sulfides react by self-ignition and explosion. Iron oxide in metal containers catalyze oxygen-evolving decomposition of the oxidant.

It forms highly explosive NCl_3 on contact with urea. This salt produces highly toxic gaseous chlorine gas when heated or on contact with acids. Mixture of damp sulfur with hypochlorite caused a violent reaction, that ejected molten sulfur.

$Ca(ClO)_2$ is used in industrial wastewater treatment, sanitation and cleaning, epidemic prevention and household sanitation facilities, as well as for disinfection and sterilization of swimming pools, drinking water, cleaning vegetables, and sanitizing fishponds.

The development of bleaching powder (calcium hypochlorite) by Scottish chemist Charles Tennant in the early 1800s, based on the discoveries of French chemist Claude Louis Berthollet, revolutionized the bleaching processes in the textile industry of that time by dramatically reducing the time required (from months to days) for the traditional process then in use. This outdated process required repeated exposure to the sun in bleach fields after soaking the textiles with alkali or sour milk.

Bleaching of textile fabrics with solid chlorine-containing compounds such as calcium hypochlorite or sodium chlorite has been practiced for many years. Calcium hypochlorite has had limited use in this manner as it can produce pinholes in fabrics. The use of calcium chlorite in bleaching processes requires the generation of chlorine dioxide which is toxic to humans and corrosive to equipment. Calcium hypochlorite has been used for bleaching of cotton, hemp, fiber, pulp and starch, disinfection of surfaces, and as a sterilant for water treatment. It has also been proposed as a solid fire extinguisher. This composition comprises a mixture of hydrated calcium hypochlorite with at least two hydrated inorganic salts, having an enthalpy, ΔH_0, of at least 150 cal/g, and having a phase transition temperature, as defined by the melting point of 19 °C–200 °C, whereby said mixture provides water release in an endothermic reaction to sufficiently quench dangerous reactions and reduce potential for a conflagration while providing increased chlorine stability as compared to blends containing a single-hydrated inorganic hypochlorite salt.

Calcium hypochlorite is available commercially but is most often generated in situ at the site of usage.

STRONTIUM HYPOCHLORITE

Strontium hypochlorite has the molecular formula $Sr(ClO)_2$ and the molecular weight of 190.514 g/mol. It is offered commercially for sale but the scientific literature concerning its uses or physical and chemical properties is not readily available. Its CAS number is 14674-76-1. The structure of the solid has not been determined.

BARIUM HYPOCHLORITE

Barium hypochlorite has the formula, $BaClO_2$ and the molecular weight of 240.234 g/mol. Its CAS number is 13477-10-6. It is white-colored crystalline solid that is denser than water. Contact may irritate skin, eyes and mucous membranes. It may be toxic by ingestion. It will accelerate the burning of combustible materials. Prolonged exposure to heat or flames may result in an explosion. It reacts with acids, evolving chlorine, an irritating, corrosive and toxic gas. It reacts fiercely with cyanides when heated or by friction. It may form explosive mixtures with combustible material, powdered metals or ammonium compounds. It is not offered commercially for sale nor is the scientific literature concerning its uses or physical and chemical properties readily available.

RADIUM HYPOCHLORITE

Radium hypochlorite remains unknown and the scientific literature remains devoid of any description of such a salt. Presumably, it can be prepared by the same method used for barium hypochlorite but no data are available concerning radium hypochlorite. Presumably, this is due to the difficulty in handling radioactive ^{226}Ra and the lack of interest in Industry for any uses of this salt.

Alkaline Earth Chlorites

BERYLLIUM CHLORITE

Beryllium chlorite has the molecular formula of $Be(ClO_2)_2$ and a molecular weight of 143.9158 g/mol. It is a white solid with a melting point of 1278 °C and a boiling point of 2970 °C. Its density is 1.85 g/cm^3 and it is insoluble in water.

Because chlorous acid is so unstable, it is difficult, if not impossible, to prepare beryllium chlorite by the use of dichlorine trioxide or chlorous acid. Furthermore, because of the amphoteric nature of beryllium, the existence of this compound in solution is questionable. It is said to have been prepared via the solid-state method but its physical and chemical properties have not been studied extensively. It is not offered for sale commercially due, perhaps, to the toxicity of beryllium to humans. Again, this beryllium salt is subject to restrictions concerning its degree of "hydration". The reason for this lies in its amphoteric nature in solution where the following reaction has been observed:

$$2Be^{2+} + H_2O \Rightarrow (Be_2OH)^{3+} + H^+$$

Thus, it is clear that the Be^{2+} cation in aqueous solution never appears alone but is an "aquo-complex", and any formulation depicting "waters of hydration" in an oxy-chlorine compound of beryllium is not completely accurate nor valid.

MAGNESIUM CHLORITE

Magnesium chlorite has the molecular formula of $Mg(ClO_2)_2$ and a molecular weight of 81.757 g/mol. As a solid, it has a melting point of 648 °C and a boiling point of 1090 °C. Its density is 1.738 g/cm^3. It reacts in water to produce dichlorine oxide, the anhydride of hypochlorous acid.

$$Mg(ClO_2)_2 + H_2O \Rightarrow Mg(OH)_2 + Cl_2O$$

Magnesium chlorite can be prepared by reaction of chlorous acid with magnesium carbonate:

$$MgCO_3\ (\text{solid}) + 2HClO_2\ (\text{aq}) \Rightarrow Mg(ClO_2)_2 \cdot 6H_2O$$

It crystallizes as the hexahydrate which has a tetragonal crystal structure with space group of $P4_2/nmc$. The lattice parameters are: $a_0 = 7.471$ Å and $c_0 = 7.780$ Å.

There is a paucity of data regarding this salt and it is offered for sale only in research quantities. Its solid structure has not been documented.

CALCIUM CHLORITE

Calcium chlorite, $Ca(ClO_2)_2$, has the molecular weight of 174.98 g/mol. Its density is 2.71 g/cm^3. Its CAS number is 14674-72-7. Calcium chlorite can be prepared by reaction of chlorous acid with calcium carbonate:

$$CaCO_3\ (solid) + 2HClO_2\ (aq) \Rightarrow Ca(ClO_2)_2 \cdot 6H_2O$$

It is a white granular solid and if formed in solution, crystallizes as the hexahydrate. Calcium hypochlorite, hydrated, is a white granular solid having an odor of chlorine. It is noncombustible and accelerates the burning of combustible materials. It is decomposed by water with evolution of chlorine gas and heat. Prolonged exposure to fire or heat may result in an explosion. It is decomposed by water to form calcium hydroxide and chlorine dioxide, an explosive oxidizing gas:

$$Ca(ClO_2)_2 + H_2O \Rightarrow Ca(OH)_2 + 2ClO_2$$

It has the structure shown in Fig. 2.29.

Calcium chlorite is a strong oxidizing agent. It ignites on contact with potassium thiocyanate and reaction with chlorine yields explosive chlorine dioxide gas. Reaction with ammonia produces ammonium chlorite, which is shock sensitive and explodes. If mixed with finely divided metallic or organic substances, the combination is highly flammable and may be ignited by friction.

A three-dimensional structure is shown in Fig. 2.30.

The structure of calcium chlorite, $Ca(ClO_2)_2$, has been refined from X-ray powder diffraction data. The compound crystallizes in the orthorhombic space group *Ccca* (*Ccce*), with $Z = 4$. The structure is based on separate layers parallel to the *ac* plane, consisting of calcium cations that are coordinated by chlorite anions; the O atoms form almost ideal square antiprisms. Within the layers, each anion bridges four metal cations. The Ca atoms are located on special positions of 222 symmetry, the Cl atoms lie on twofold axes and the O atoms are in general positions. The compound is isostructural with strontium chlorite, $Sr(ClO_2)_2$, and lead chlorite, $Pb(ClO_2)_2$.

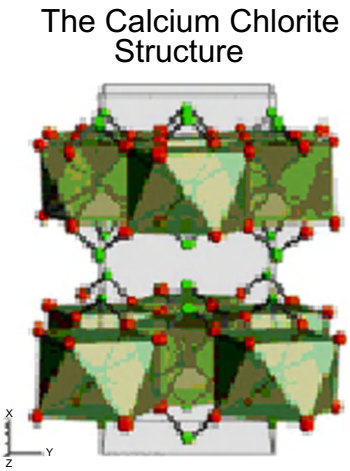

FIGURE 2.29

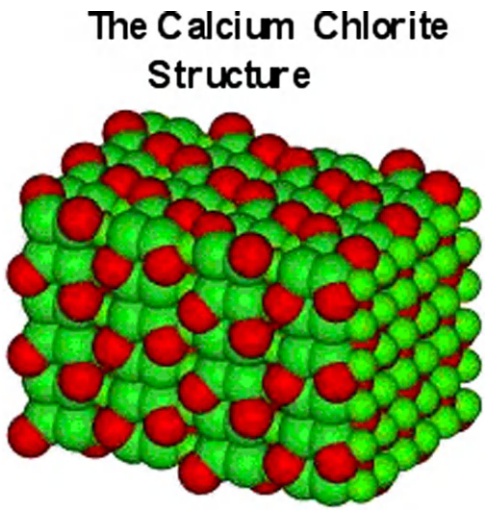

FIGURE 2.30

Currently, no manufacturer is registered for the product CALCIUM CHLORITE [CAS 14674-72-7]. There is a paucity of data concerning the physical properties of this salt and they are not easily accessible.

STRONTIUM CHLORITE

Strontium chlorite, $Sr(ClO_2)_2$, has the molecular weight of 155.072 g/mol. Its density is 2.61 g/cm^3. Its CAS number is 14674-72-7. Its melting point is 757 °C and it has a boiling point of 1484 °C. Strontium chlorite can be prepared by reaction of chlorous acid with strontium carbonate:

$$SrCO_3\ (s) + 2HClO_2\ (aq) \Rightarrow Sr(ClO_2)_2 \cdot 6H_2O$$

It is a white granular solid and, if formed in solution, crystallizes as the hexahydrate. Like its calcium homologue, strontium chlorite is a strong oxidizing agent. It accelerates the burning of combustible materials, ignites on contact with potassium thiocyanate and reaction with chlorine yields explosive chlorine dioxide gas. Reaction with ammonia produces ammonium chlorite, which is shock sensitive. If mixed with finely divided metallic or organic substances, the

combination is highly flammable and may be ignited by friction.

The structure of strontium chlorite, $Sr(ClO_2)_2$, has been refined from X-ray powder diffraction data using the Rietveld method. The compound crystallizes in the orthorhombic space group *Ccca* (*Ccce*), with $Z = 4$. The structure is based on separate layers parallel to the *ac* plane, consisting of strontium cations that are coordinated by chlorite anions; the O atoms form almost ideal square antiprisms. Within the layers, each anion bridges four metal cations. The Sr atoms are located on special positions of 222 symmetry, the Cl atoms lie on twofold axes and the O atoms are in general positions.

Strontium chlorite is not offered for sale commercially, due in part to the cost of strontium as compared to the same calcium salt which is just as effective as an oxidizing agent.

BARIUM CHLORITE

Barium chlorite, $Ba(ClO_2)_2$, is a solid with the molecular weight of 204.779 g/mol. Its density is 3.61 g/cm^3. Its CAS number is 14674-74-9. Its melting point is 727 °C and it has a boiling point of 1640 °C. Barium chlorite can be prepared by reaction of chlorous acid with barium carbonate:

$$BaCO_3\ (s) + 2HClO_2\ (aq) \Rightarrow Ba(ClO_2)_2 \cdot 7H_2O$$

It is a white granular solid and if formed in solution, crystallizes as the heptahydrate. Like its strontium homologue, barium chlorite is a strong oxidizing agent. It accelerates the burning of combustible materials, ignites on contact with potassium thiocyanate and reaction with chlorine yields explosive chlorine dioxide gas. Reaction with ammonia produces ammonium chlorite, which is shock sensitive. If mixed with finely divided metallic or organic substances, the combination is highly flammable and may be ignited by friction.

The structure of barium chlorite hydrate, $Ba(ClO_2)_2 \cdot 3.5H_2O$, has been determined by single-crystal X-ray analysis at 150 K. The structure is monoclinic, space group $C2/c$, with $Z = 8$. It contains layers of Ba^{2+} cations coordinated by ClO_2^- anions and water molecules. There are also solvate water molecules involved only in hydrogen bonding of the layers. Three solvate water oxygen atoms are on sites of twofold symmetry, while all other atoms are in general positions. The full coordination environment of the Ba^{2+} cation consists of 10 O atoms belonging to six chlorites and three water molecules, forming a bicapped square antiprism. Its solubility in water is:

Substance	Formula	0 °C	10 °C	15 °C	30 °C	50 °C	70 °C	90 °C
Barium chlorite	$Ba(ClO_2)_2$	43.9	44.6	45.4	47.9	53.8	66.6	80.8

Barium chlorite is not offered for sale commercially, due in part to the cost of barium as compared to the same calcium salt which is just as effective as an oxidizing agent. Very little data is available regarding its physical properties.

RADIUM CHLORITE

Radium chlorite remains unknown and the scientific literature remains devoid of any description of such a salt. Presumably, it can be prepared by the same method used for barium chlorite but no data is available concerning radium chlorite. This is probably due to lack of interest by those who use radioactive salts as well as the fact that the isotope, ^{226}Ra, is a very strong radioactive species.

Alkaline Earth Chlorates

The structure of alkaline earth chlorates is unique in that the chlorine atom is in the +5 valence state but the chlorate anion is triangular and mononegative in nature, i.e. Fig. 2.31.

In this case, the negative charge and the double bonds are not one Lewis structure but is a combination of all three where the negative charge is in resonance with all three oxygen atoms and the double bonds shift accordingly (Fig. 2.32).

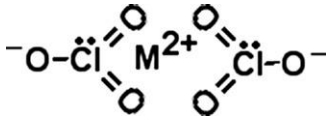

FIGURE 2.31

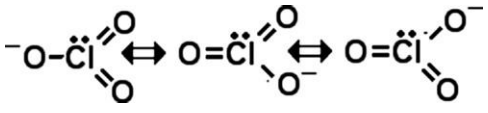

FIGURE 2.32

BERYLLIUM CHLORATE

Beryllium Chlorate, $Be(ClO_3)_2$ has the molecular weight of 92.4632 g/mol and is a solid having a melting point of 1278 °C and a boiling point of 2970 °C. Its density is 1.85 g/cm^3 and it is insoluble in water.

It is a strong oxidizer and reacts with organic compounds if mixed intimately. Because of its insolubility in water, its reactivity is much lower than corresponding soluble homologues like the magnesium or calcium salt. Little data is available concerning its physical properties. In view of the amphoteric nature of beryllium ion, the formula given above may not be completely accurate but may include hydroxy groups when formed from solution:

$$BeCl_2\ (aq) + 2HClO_4 + xH_2O \Rightarrow Be(OH)_x(ClO_4) + (x+2)\ H_3O^+$$

The reason for this lies in its amphoteric nature in solution where the following reaction has been observed:

$$2Be^{2+} + H_2O \Rightarrow (Be_2OH)^{3+} + H^+$$

Thus, it is clear that the Be^{2+} cation never appears in aqueous solution but is an "aquo-complex", and any formulation depicting "waters of hydration" in a beryllium oxy-chlorine compound is not completely accurate and valid.

Beryllium chlorite is not offered for sale nor is there a listed manufacturer of this salt. It has no CAS number. No structural data are available.

MAGNESIUM CHLORATE

Magnesium chlorate has a molecular weight of 299.33 g/mol and a CAS number of 10326-21-3. It is composed of white deliquescent crystals (or as a powder) that is soluble in water. It is denser than water. It poses a dangerous fire risk when in contact with organic materials or heat. This salt is irritating to skin, eyes and mucous membranes. It can be prepared by reaction of chloric acid upon magnesium carbonate:

$$MgCO_3 + 2HClO_3 \Rightarrow Mg(ClO_3)_2 + CO_2 + H_2O$$

Two hydrates are formed in solution and may be crystallized from solution, the dihydrate has a CAS number of 36355-97-2 while that of the hexahydrate, $Mg(ClO_3)_2 \cdot 6H_2O$, has a CAS number of 10326-21-3. The hexahydrate is a colorless rhomboidal needle-like crystal powder with a density of 1.80 g/cm^3, a 35 °C melting point and a boiling point of 120 °C where decomposition takes place. It is a water-soluble white powder, bitter tasting and hygroscopic. It is soluble in acetone and alcohol. At 35 °C, it loses two waters of hydration to form the tetrahydrate. This salt is deliquescent. It is stable, not explosive, but when mixed with sulfur, phosphorus or organic matter, friction, impact or other detonations causes an explosion. Its molecular weight is 407.402 g/mol.

If the hydroxide is reacted with chlorine gas in water, a mixture of compounds results:

$$6Mg(OH)_2\ (solid) + 6Cl_2\ (gas) \Rightarrow 5MgCl_2\ (aq) + Mg(ClO_3)_2\ (aq) + 6H_2O$$

The magnesium chlorate formed can then be extracted with acetone. This salt can also be prepared from magnesium chloride by an electrochemical method:

$$MgCl_2\ (aq) + 6H_2O\ (aq) + e^- \Rightarrow Mg(ClO_3)_2 + 6H_2$$

in which a platinum anode and a rotating stainless steel cathode are used. Yields up to 68% have been achieved.

Magnesium chlorate is a powerful oxidizer. There is an explosive reaction with copper(I) sulfide, an incandescent reaction with antimony(III) sulfide, arsenic(III) sulfide, tin(II) sulfide, and tin(IV) sulfide. This salt is incompatible with Al, As, C, Cu, MnO_2, organic matter, organic acids, phosphorus or sulfur. Mixtures with ammonium salts, with powdered metals, silicon, sulfur, or sulfides are readily ignited and potentially unstable, even at room temperature.

A combination of finely divided aluminum and magnesium chlorate can explode by heat, percussion, or friction. The solubility of $Mg(ClO_3)_2$ is shown in Table 2.92.

Magnesium chlorate is readily available commercially.

CALCIUM CHLORATE

Calcium chlorate $Ca(ClO_3)_2$ is the chemical compound formed from calcium and the chlorate anion. Like $KClO_3$, it is a strong oxidizer and can be used in pyrotechnic formulations. Its molecular weight is 206.98 g/mol. Its

TABLE 2.92

		g/100 ml of water								
Material	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**49 °C**	**50 °C**	**60 °C**	**80 °C**	**100 °C**
Magnesium chlorate	$Mg(ClO_3)_2$	114	123	135	155	178		242		268

solubility in water is 209 g/100 ml at 20 °C. It is slightly soluble in alcohol. Calcium chlorate has a melting point of 325 °C and its density is 2.71 g/cm^3. Its CAS number is 10017-74-3. A dihydrate, $Ca(ClO_3)_2 \cdot 2H_2O$, forms as white monoclinic crystals, which are decomposed by heating above 150 °C. No structural data is available.

Calcium chlorate can be prepared by the Liebig process which is also used to prepare the alkali chlorates. In Liebig's process, chlorine is passed into milk of lime, at or above a temperature of 1000 °C, the apparent reaction being:

$$6Ca(OH)_2 + 6Cl_2 \Rightarrow 5CaCl_2 + Ca(ClO_3)_2 + 6H_2O.$$

But this may comprise two minor reactions:

$$2Ca\ (OH)_2 + 2Cl_2 \Rightarrow CaCl_2 + Ca(OCl)_2 + 2H_2O;$$

$$3Ca(OCl)_2 \Rightarrow 2CaCl_2 + Ca(ClO_3)_2$$

where the hypochlorite undergoes a redox reaction. It is possible, however, that the hypochlorite may decompose thus:

$$Ca(OCl)_2 \Rightarrow CaCl_2 + O_2,$$

causing a waste of chlorine and a double salt in the final product. To prevent this, an excess of chlorine must always be present. Theoretically, only one molecule of calcium chlorate is obtained from 12 atoms of ch1orine. The other product is the dichloride of calcium, $CaCl_2$. This salt can also be prepared from calcium chloride by an electrochemical method:

$$CaCl_2\ (aq) + 6H_2O\ (aq) + e^- \Rightarrow Ca(ClO_3)_2 + 6H_2$$

using a platinum anode and a rotating stainless steel cathode. Yields of the dihydrate up to 78% have been achieved. The hydrogen produced can be "burned" to reform water.

Calcium chlorate undergoes the same type of reactions with other compounds like that described for the magnesium chlorate salt. It is a strong oxidizer. There is an explosive reaction with copper(I) sulfide, an incandescent reaction with antimony(III) sulfide, arsenic(III) sulfide, tin(II) sulfide, and tin(IV) sulfide.

This salt is incompatible with Al, As, C, Cu, MnO_2, organic matter, organic acids, phosphorus or sulfur. Mixtures with ammonium salts, with powdered metals, silicon, sulfur, or sulfides are readily ignited and potentially unstable. A combination of finely divided aluminum and calcium chlorate can explode by heat, percussion, or friction.

Calcium chlorate is used as a herbicide in agriculture, in making fireworks and is available commercially.

The physical properties of calcium chlorate may be summarized as in Table 2.93.

TABLE 2.93

CAS number	10017-84-3
Molecular formula	$Ca(ClO_3)_2$
Molecular weight	206.98 g/mol
Appearance	White solid
Density	2.71 g/cm^3
Melting point	325 °C
Solubility in water	209 g/100 ml (20 °C)

STRONTIUM CHLORATE

Strontium chlorate, $Sr(ClO_3)_2$, has a molecular weight of 254.52 g/mol. It is a white solid with a melting point of 120 °C and a density of 3.152 g/cm^3. It is soluble in water (174 g/100 ml at 20 °C). Its CAS number is 7791-10-8.

$Sr(ClO_3)_2$ is shock sensitive, and is highly flammable if allowed to sit in air. These white, water-soluble crystals decompose at 120 °C. It is used in pyrotechnics and tracer bullets. There are two coexisting crystal hydrates that undergo interconversion, the dihydrate and the hexahydrate. These compounds are not as shock sensitive as the anhydrate.

Strontium chlorate can be produced by the Liebig method which consists of passing chlorine gas through a solid such as $Sr(OH)_2$:

$$6Sr(OH)_2 + 6Cl_2 \Rightarrow 5SrCl_2 + Sr(ClO_3)_2 + 6H_2O.$$

However, separating the two salts remains problematic since both are soluble in water. Strontium chloride solubility is 42.9 g/100 ml of water at 20 °C while that of strontium chlorate is 174.9 g/100 ml of water at 20 °C.

Strontium chlorate is a strong oxidizing agent. It forms a flammable mixture with combustible materials (can be ignited by friction). Such mixtures may be explosive. Contact with concentrated sulfuric acid can cause fires or explosions. When mixed with ammonium salts, spontaneous decomposition and ignition may result. This compound liberates explosive chlorine dioxide gas in the presence of strong acid; heating with a dibasic organic acid in the presence of moisture liberates chlorine dioxide and carbon dioxide. Mixtures with ammonium salts, powdered metals, silicon, sulfur, or sulfides are readily ignited and potentially explosive.

Paramagnetic color centers produced by irradiation of $Sr(ClO_3)_2$ single crystals have been studied by electron spin resonance. The products of *x*- or δ-irradiation at 298 K are ClO_2 and O^{3-} centers. ClO_2 is trapped at six magnetically inequivalent sites in the crystal lattice, forming three pairs. The magnetic parameters for two of the pairs, that is, ClO_2(B) and ClO_2(C), are in close agreement

with ClO_2 centers reported in other systems; while the third pair, that is ClO_2(A), has slightly different hyperfine parameters. The principal g-values of this center (A) are $g_{xx} = 1.9984$, $g_{yy} = 2.0170$ and $g_{zz} = 2.0142$ and those of the A tensor are $A_{xx} = 90.0$ G, $A_{yy} = -8.7$ G and $A_{zz} = -5.0$ G. The chlorine centers that are trapped at six magnetically inequivalent sites produced by radiation damage reveal hexagonal symmetry among themselves. UV or thermal bleaching (at 90 °C) removes all the chlorine centers, giving a single anisotropic line, trapped at two magnetically inequivalent sites with a $g_{av} = 2.0092$. This new center is identified as an O^{3-} center.

Strontium chlorate is extremely volatile and is used mainly for pyrotechnics and selected fireworks. It is available commercially, worldwide.

BARIUM CHLORATE

Barium chlorate has the molecular formula of $Ba(ClO_3)_2$ and a molecular weight of 304.229 g/mol. Its density is 3.18 g/cm^3 and its melting point is 413.9 °C. It is a white crystalline solid, a skin irritant and if consumed can cause nausea, vomiting, and diarrhea. Its CAS number is 13477-00-4. It is used in fireworks to produce a green color. It also forms a monohydrate, $Ba(ClO_3)_2 \cdot H_2O$ whose CAS number is 10294-38-9.

The structure of the monohydrate crystal is monoclinic with lattice parameters of $a = 8.86$ Å, $b = 7.80$ Å and $c = 9.85$ Å with $\beta = 93°\ 30'$. The space group is C2/c. The lattice structure of $Ba(ClO_3)_2$ differs from that of the monohydrate and most probably belongs to the space group F$d2d$ with a crystal structure of orthorhombic face centered. The monohydrate begins to decompose to the anhydrate when heated to 85 °C.

Shock-sensitive compounds are formed with organic compounds, reducing agents, ammonia-containing agents, and metal powders. The substance decomposes violently on heating, producing oxygen, toxic fumes, and causing fire and explosive hazards. This salt is a strong oxidant and reacts with most combustible and reducing materials.

Barium chlorate can be produced through a double replacement reaction of barium chloride and sodium chlorate:

$$BaCl_2 + 2NaClO_3 \Rightarrow Ba(ClO_3)_2 + 2NaCl$$

It can also be produced through a more complicated process involving barium carbonate and ammonium chlorate, both of which are produced in situ. There are four separate reactions used to produce this salt:

$$BaCl_2 + Na_2CO_3 \Rightarrow BaCO_3 + 2NaCl$$

or

$$BaCl_2 + 2NaHCO_3 \Rightarrow BaCO_3 + 2NaCl + H_2O + CO_2 \quad (1)$$

In a separate step, ammonium chlorate is produced by reaction of tartaric acid, $C_4H_6O_6$, to produce ammonium bitartrate. This is then reacted with potassium chlorate which produces potassium bitartrate and ammonium chlorate:

$$C_4H_6O_6 + NH_4OH \Rightarrow NH_4C_4H_5O_6 + H_2O \quad (2)$$

$$NH_4C_4H_5O_6 + KClO_3 \Rightarrow KC_4H_5O_6 + NH_4ClO_3 \quad (3)$$

The produced barium carbonate is then reacted with ammonium chlorate:

$$2NH_4ClO_3 + BaCO_3 + \text{heat} \Rightarrow Ba(ClO_3)_2 + 2NH_3 + H_2O + CO_2 \quad (4)$$

The final product is obtained without having to handle the chlorate solutions or product before the final product is obtained. The potassium bitartrate remains soluble while the barium chlorate crystallizes from solution as the monohydrate. The reason that such a method is used is to mitigate the potential for an explosive mixture causing a serous fire and injury during its manufacture

It can also be produced via the Liebig process similar to that of the strontium homologue which consists of passing chlorine gas through a solid such as $Ba(OH)_2$:

$$6Ba(OH)_2 + 6Cl_2 \Rightarrow 5BaCl_2 + Ba(ClO_3)_2 + 6H_2O$$

However, separating the two salts remains problematic since both are soluble in water. Barium chloride solubility is 33.9 g/100 ml of water at 20 °C while that of barium chlorate is 35.9 g/100 ml of water at 20 °C. However, the solubilities change at 100 °C, being 104.9 g/100 ml of water for barium chlorate and 59.4 g/100 ml of water for barium chloride. Thus, one runs the risk that the chlorate will decompose. It is for this reason that the Liebig method is not used for the commercial production of barium chlorate.

Its solubility in water is shown in Table 2.94.

Polycrystalline $Ba(ClO_3)_2 \cdot (H_2O)_x$, with x between zero and one, and $Ba(ClO_3)_2 \cdot D_2O$ have been

investigated by ^{35}Cl nuclear quadrupole resonance and X-ray diffraction experiments. Frequency, line width, and intensity of the chlorine resonance signal change with increasing loss of water and the quadrupole effects become less distinct as the hydrate decomposes to form anhydrous barium chlorate. X-ray diffraction and Raman measurements show that the lattice structure of $Ba(ClO_3)_2$ differs from that of the monohydrate and it most probably belongs to the space group F*d*2*d*. The dehydration of the monoclinic fully hydrated $Ba(ClO_3)_2 \cdot H_2O$ transforms into the orthorhombic face centered (ofc) fully anhydrous $Ba(ClO_3)_2$. The dehydration process begins at 85 °C and the transition proceeds through intermediate steps, where the two phases coexist with a gradual dominance of the anhydrous phase as the temperature increases. The role of the loss of the water of crystallization in the process is clarified by invoking a two-step mechanism for the accomplishment of the structural changes within the crystal. This comprises random nucleation and growth of clusters of vacancies, left by the exit of H_2O molecules, which, up to a certain critical size, can retain the original crystal structure. This is followed by a sudden onset of the phase transition within each of the overcritically sized clusters. As this process goes on, the concentration of clusters increases and the transition is further enhanced by cluster–cluster interactions. Barium Chlorate is a powerful oxidizer, due in part to the presence of the two lone-pair electrons on the chloride atom (Fig. 2.33).

Barium chlorate is used in the pyrotechnics industry to give a bright light for illumination (especially green light) (Fig. 2.34).

The crystalloluminescence and mechanoluminescence of $Ba(ClO_3)_2 \cdot H_2O$ crystals has been investigated. The crystalloluminescence spectra are almost similar to the photoluminescence spectra. However, they differ completely from the mechanoluminescence spectra. The crystalloluminescence excitations is believed to take place due to the various chemical processes: (i) the recombination of ions, (ii) from amorphous to crystalline transition, (iii) from the phase change during the crystallization, and (iv) from the dielectric breakdown by the electric field produced due to the creation of microfracture during the crystal growth. It is concluded that the crystalloluminescence excitation in $Ba(ClO_3)_2 \cdot H_2O$ crystals is probably chemical in origin.

$Ba(ClO_3)_2 \cdot H_2O$ is a powerful oxidizing agent. It is used to manufacture explosives and matches because of its ability to produce oxygen. This salt is available commercially. Physical properties are listed in Table 2.95.

RADIUM CHLORATE

Radium chlorate, $Ra(ClO_3)_2$, is a white solid with a molecular weight of 303.451 g/mol. Its melting point is 703 °C and its boiling point is 1737 °C. Its density is

FIGURE 2.34

TABLE 2.95

CAS number	13477-00-4
Molecular formula	$Ba(ClO_3)_2$
Molecular weight	304.23 g/mol
Appearance	White solid
Density	3.18 g/cm^3
Melting point	414 °C

5.10 g/cm^3. It is insoluble in water. It can be prepared by methods similar to those used for the other alkaline earth chlorates.

Radium chlorate is a strong oxidizer and the same precautions, already described for chlorate salts, apply. Additionally, radium itself is highly radioactive so that its uses, both Industrial and domestic, are miniscule to none. It is available commercially but only in research quantities.

Alkaline Earth Perchlorates

With the exception of Be, the alkaline earth perchlorates (Mg, Ca, Sr & Ba) have been shown to be extraordinarily soluble in water with the solubility specified in terms of mols per liter of water rather than in g/l. The freezing point of these solutions has been of special interest where the actual solubility is given as kg/l. For example, the strontium salt solution shows a freezing point of −67°C at a concentration of 1.15 kg/l. But at 0°C, the saturated solution of 8.16 mols/l (2.34 kg/l) was reported to be −2°C. A similar situation was determined also for the Mg, Ca and Ba salts, i.e.- $M(ClO_4)_2$, except that the differences were not as extreme.

BERYLLIUM PERCHLORATE

Beryllium perchlorate has the molecular formula of $Be(ClO_4)_2$ and a molecular weight of 207.012 g/mol. Its CAS number is 13597-95-0. It can be prepared by reaction of beryllium oxide in a water solution of an alkali perchloric salt or perchloric acid itself. The reaction is very slow and there is some doubt as to whether the oxide actually dissolves but is converted directly to the perchlorate directly.

The hydrolytic reactions of beryllium(II) ions have been calorimetrically studied at 25 °C in aqueous solution and dioxane–water mixtures, both containing 3.0 mol/dm^3 Li_2ClO_4 as a constant ionic medium. On the basis of the formation constants determined, the enthalpy and entropy changes for the reaction:

$$x\ Be^{2+} + y\ H_2O \Rightarrow \{Be_x\ (OH)_y\}^{(2x-y)+} + y\ H^+,$$

were estimated for the Be_2OH^{3+} and $Be_3(OH)_3^{3+}$ complexes in aqueous solution and 0.1 mol fraction dioxane–water mixture and for Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, and $Be_2(OH)_2^{2+}$ complexes in 0.2 mol fraction dioxane–water mixture. The enthalpy and entropy changes of formation of the $Be_x(OH)_y^{(2x-y)+}$ complex in solutions of various mole fractions of dioxane were obtained and shown to abide by the following reaction:

$$2Be^{2+} + H_2O \Rightarrow (Be_2OH)^{3+} + H^+$$

Thus, it is clear that the Be^{2+} cation never appears in aqueous solution but is an "aquo-complex".

Beryllium forms what is called a "tetrahydrate" which probably is a hydroxy complex. Its solubility in water is 146.6 g/100 ml at 20 °C. These are very hygroscopic crystals that hold their "waters of hydration" very tenaciously. That is, when heated to higher temperatures, they do not lose water molecules to form the anhydrate. The reason for this may be seen by examining the following formula:

$$\{Be_2\ (OH)^{3+}\}_2\{Cl(OH)O_3\}^{6-}$$

Here, the chlorine atom is in the +7 oxidation state, i.e. it is the central atom in a peroxide anion. Thus, when heated, these salts cannot eject a water molecule, leaving the rest of the molecule intact, unlike the other alkaline earth perchlorates which form anhydrates, but breaks down to form chlorine gas and an oxide. These results were discussed in connection with interactions between the hydroxo complexes and the solvent molecules and with those between solvent molecules in the mixed solvents of the solvent beryllium cation. This concept may be better understood by examining the following diagram where the tetrahedral nature of the perchlorate anion is depicted (Fig. 2.35).

The introduction of a hydroxy group in the tetrahedron changes the oxidation state of the chlorine atom. Therefore, it is unlikely that such an anion exists for the beryllium perchlorate salt.

Beryllium perchlorate is not employed in industry, medicine or other domestic usages. It is not available commercially. It has no CAS number.

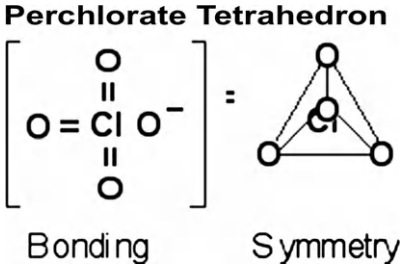

FIGURE 2.35

MAGNESIUM PERCHLORATE

Magnesium perchlorate is a powerful oxidizing agent, with the formula $Mg(ClO_4)_2$. Magnesium perchlorate decomposes at 250 °C. The heat of formation is −568.90 kJ/mol. The following table lists the CAS numbers assigned, the molecular formulas and the molecular weights of these compounds (Table 2.96).

If water is added to magnesium perchlorate, the reaction is highly exothermic and may cause damage to the eyes. Thus, this salt should be added to a sufficient amount of water in order to form a dilute solution. It can be prepared by reacting magnesium carbonate with a solution of perchloric acid:

$$MgCO_3 + HClO_4 \Rightarrow Mg(ClO_4)_2 + CO_2$$

This salt can also be prepared by an electrochemical method in water whereby magnesium perchlorate is formed from magnesium chlorate in which a platinum anode and a rotating stainless steel cathode are employed. The effect of electrolyte concentration, cathode and anode current densities, pH and temperature of the electrolyte and cathode rotation on current efficiency for the preparation of magnesium perchlorate has been studied. A maximum current efficiency of 65–72% was achieved. When formed from an aqueous solution, the hexahydrate is obtained. However, a tetrahydrate and a dihydrate are also known.

The previously unknown crystal structure of magnesium perchlorate anhydrate, determined and refined from laboratory X-ray powder diffraction data, represents a new structure type. The compound was obtained by heating magnesium perchlorate hexahydrate at 523 K for 2 h under vacuum. It crystallizes in the monoclinic space group $P2_1/c$. The asymmetric unit contains one Mg (site symmetry on special position 2*a*), one Cl and four O sites (on general positions 4*e*). The structure consists of a three-dimensional network resulting from the corner sharing of MgO_6 octahedra and ClO_4 tetrahedra. Each MgO_6 octahedron share corners with six ClO_4 tetrahedra (Fig. 2.36).

Each ClO_4 tetrahedron shares corners with three MgO_6 octahedra, with one O-atom corner dangling. The ClO_4 tetrahedra are oriented in such a way that one-dimensional channels parallel to [100] are formed between the dangling O-atoms.

$Mg(ClO_4)_2 \cdot 6H_2O$ is composed of white, deliquescent crystals which are soluble in water and alcohol but explosive when in contact with reducing materials. This compound is used as a drying agent for gases. This salt is highly exothermic when added to water and releases steamy HCl gas. It can be dried to form the anhydrate by heating to 250 °C under vacuum. The hexahydrate losses two molecules of water at 244 °C in air and further decomposes to the dihydrate at 336 °C and the anhydrate at 438 °C.

Electron paramagnetic resonance of Mn^{2+} doped $Mg(ClO_4)_2 \cdot 6H_2O$ crystals has been studied from room temperature (300 K) down to liquid nitrogen temperature at *X*-band. The room temperature results show three inequivalent sites for Mn^{2+} in the crystal. Hyperfine forbidden transitions are observed when the magnetic field is not oriented along one of the principal axes. Two structural phase transitions have been observed at temperatures of 272 ± 1 and 103 ± 1 K, respectively. The transition occurring at 272 ± 1 K has been observed for the first time. The transition occurring at 103 ± 1 K is the one detected earlier through Mössbauer studies.

The anhydrate has been used as a desiccant to dry gas streams or air samples. However, it is no longer used since perchlorates tend to form explosive compounds with a variety of organic materials as well as other substances. Physical properties are listed in Table 2.97.

TABLE 2.96

Compound	CAS number	Formula	g/mol
Magnesium perchlorate	10034-81-8	$Mg(ClO_4)_2$	223.21

CALCIUM PERCHLORATE

Calcium perchlorate has the formula, $Ca(ClO_4)_2$ with a molecular weight of 238.9792 g/mol and a CAS number of 13477-36-6. It can be prepared by reacting calcium carbonate with a solution of perchloric acid:

$$CaCO_3 + HClO_4 \Rightarrow Ca(ClO_4)_2 + CO_2$$

This salt can also be prepared by an electrochemical method in water whereby calcium perchlorate is formed from calcium chlorate in which a platinum anode and a rotating stainless steel cathode is employed. The effect of electrolyte concentration, cathode and anode current densities, pH and temperature of the electrolyte and cathode rotation on current efficiency for the preparation of calcium perchlorate was studied. A maximum current efficiency of 65–72% was achieved. When formed from an aqueous solution, the tetrahydrate is obtained, $Ca(ClO_4)_2 \cdot 4H_2O$. Its CAS number is 15627-86-8.

The anhydrate is a white to yellow crystalline solid with a density of 2.651 g/cm^3. Contact with this salt will irritate the eyes, skin and mucus membranes. If ingested, it is toxic in sufficient quantities. The structure of the molecule is shown as a Lewis structure where the actual shape of the molecule is a tetrahedron (Fig. 2.37).

When formed from an aqueous solution, the tetrahydrate is obtained. Calcium perchlorate tetrahydrate has the formula $Ca(ClO_4)_2 \cdot 4H_2O$ and the CAS number 15627-86-8. Its molecular weight is 311.04 g/mol and

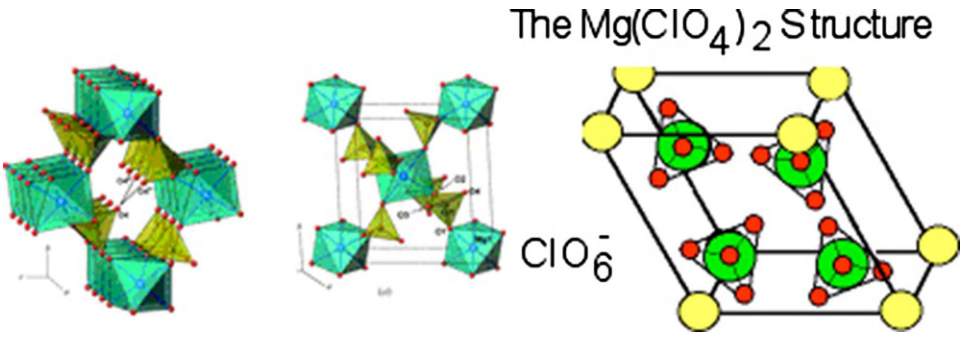

FIGURE 2.36

its density is 2.651 g/cm^3. Its solubility in water is 188 g/100 ml at 20 °C.

Melting processes and the thermal decomposition of $[Ca(H_2O)_4](ClO_4)_2$ was studied by thermogravimetry analysis (TG) and differential scanning calorimetry (DSC). The gaseous products of the decomposition were identified by a quadruple mass spectrometry. The loss process for waters of hydration starts at ca. 340–350 K and continues up to about 600 K. Tetra-aqua-calcium perchlorate dissolves in own waters-of-hydration (melts) at $T_m = 350$ K. The decomposition of the sample proceeds in three main stages. In stage I (351–602 K), dehydration of $[Ca(H_2O)_4](ClO_4)_2$ to anhydrous $Ca(ClO_4)_2$ undergoes two steps, in which two molecules of water are liberated consecutively forming the dihydrate and then the anhydrate. In stage II (602–701 K), anhydrous $Ca(ClO_4)_2$ has one solid-solid phase transition at $T_c = 619$ K and then melts at $T_m = 689$ K. Stage III (above 700 K) is connected with decomposition of melted $Ca(ClO_4)_2$ to oxygen and solid $CaCl_2$.

Very little physical data is available for this salt, although it has been the subject of a number of research studies. It is available commercially.

TABLE 2.97

Solubility in ethanol	24.0 g/100 ml

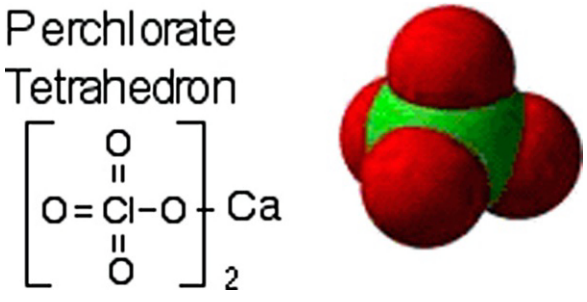

FIGURE 2.37

STRONTIUM PERCHLORATE

Strontium perchlorate has the formula, $Sr(ClO_4)_2$ and a molecular weight of 286.52 g/mol. It is a white solid with a melting point of 100 °C. Its density is 2.073 g/cm^3 and it is lightly soluble in water (3.21 g/100 ml at 20 °C). It can be prepared by reaction of strontium carbonate with a solution of perchloric acid or ammonium perchlorate:

$$SrCO_3 + 2HClO_4 \Rightarrow Sr(ClO_4)_2 + H_2O + CO_2$$

In an aqueous solution, the hexahydrate results. $Sr(ClO_4)_2 \cdot 6H_2O$ has the molecular weight of 394.63 g/mol and a CAS number of 13450-97-0. A trihydrate, $Sr(ClO_4)_2 \cdot 3H_2O$ is also known, having the molecular weight of 340.57 g/mol and a CAS number of 15650-09-6. The features of the solubility polytherm of strontium perchlorate, that distinguish it from those of other Group II metal perchlorates, can be explained in terms of these two coexisting interconverting crystal hydrates. The anhydrate can be formed by careful heating of these hydrates to about 155 °C. But the anhydrate is unstable and is likely to explode due to external shock whereas the hydrates are relatively stable.

Strontium perchlorate can be prepared by an electrolytic method. The electrochemical preparation of strontium perchlorate, $Sr(ClO_4)_2$, from strontium chlorate, employing a platinum anode and a rotating stainless steel cathode, has been studied. The effect of electrolyte concentration, current density, pH and temperature of the electrolyte and cathode rotation on current efficiency for the

preparation of strontium perchlorate was measured. A maximum current efficiency of 42% was achieved corresponding to an energy consumption of 6.1 (kilowatt-hours)./Kg.

The solubility of strontium perchlorate in water is shown in Table 2.98.

Very little physical data is available for this salt, although it has been the subject of a number of research studies. Several hydrates exist, the dihydrate and possible a monohydrate. $3Sr(ClO_4)_2{:}2H_2O$ also exists. Its molecular weight is (anhydrous) 286.52 g/mol.

Currently, no manufacturer is registered for the product **STRONTIUM PERCHLORATE** [13450-97-0]. It is not available commercially.

BARIUM PERCHLORATE

Barium perchlorate has the molecular formula of $Ba(ClO_4)_2$ and the molecular weight of 336.228 g/mol with a density of 3.21 g/cm^3. Its CAS number is 1346595-7. The following lists some of its physical properties:

Melting point: 505 °C	Density: 3.2 g/cm^3 at 25 °C
Flash point: 21 °C	Storage temperature: 2–8 °C
Shock sensitive	Hygroscopic
Appearance: white crystalline powder.	

It may be prepared by reaction of barium carbonate with a solution of perchloric acid or ammonium perchlorate:

$$BaCO_3 + 2HClO_4 \Rightarrow Ba(ClO_4)_2 + H_2O + CO_2$$

In an aqueous solution, several hydrates result as shown in the following Table 2.99.

TABLE 2.98 Solubility of strontium perchlorate

Temperature, °C	Mols $Sr(ClO_4)_2$ per 1000 g of water
0	8.16
5	8.57
10	9.03
15	9.49
20	10.18
25	10.54
30	11.43
35	12.02
40	12.70

The tetrahydrate, $Ba(ClO_4)_2{\cdot}4H_2O$ forms colorless hexagons which are used in pyrotechnics. The trihydrate, $Ba(ClO_4)_2{\cdot}3H_2O$, is hexagonal, space group-$P6_3/m$, $a = 7.277$ Å, $c = 9.656$ Å, $V = 442.9$ Å^3, $Z = 2$. The calculated density is 2.93 g/cm^3. The barium atoms in this structure are coordinated by six water oxygen atoms (O_3) at 2.919 Å and by six perchlorate oxygens (O_2) at 3.026 Å in a slightly distorted icosahedral arrangement. The Cl–O bond length is 1.433 Å and each axial (O_1) perchlorate oxygen is hydrogen bonded to three water molecules.

The thermal decomposition of the anhydrate to barium chloride and oxygen was studied gasometrically at 718 K. The amount decomposed (α) vs t plot for the salt alone displays (i) initial gas evolution, (ii) an induction period, (iii) a short acceleratory stage and (iv) a long-decay stage. The most pronounced features of the (a)-(t) curves are an initial acceleratory period, which is succeeded by an approximately linear period and then, after a sharp break (reduction in rate), by a deceleratory period which conforms to the contracting-volume kinetic law. The latter stage is associated with the decomposition of barium chlorate and has an activation energy of 59 kcal/mol. The first two stages comprise the decomposition:

$$3ClO_4^- \Rightarrow = 2ClO_3^- + C1^- + 3O_2$$

The succeeding reactions all follow this mode of reaction.

The enthalpy of formation of barium perchlorate has been determined to be:

$$\Delta_f H_m^0(BaClO_4, \text{crystal}) = -796.26 \text{ kJ/mol}.$$

Its solubility in water is shown in Table 2.100.

Very little physical data is available for this salt, although it has been the subject of a number of research studies. It is available commercially.

RADIUM PERCHLORATE

No data is available for this salt. It apparently has not been synthesized or studied. Its physical properties remain unknown. It is not available commercially, perhaps due to the radioactivity of radium and the extreme oxidation properties of the perchlorate anion.

2.4. ALKALINE EARTH OXY-BROMINE COMPOUNDS

The alkaline earths form a number of compounds with the oxy-bromine acids, of which there are four.

TABLE 2.99

Name	CAS number	Formula	MW
Barium perchlorate tetrahydrate	15318-52-2	$Ba(ClO_4)_2 \cdot 4H_2O$	408.30 g/mol
Barium perchlorate trihydrate	10294-39-0	$Ba(ClO_4)_2 \cdot 3H_2O$	390.29
Barium perchlorate anhydrous	13465-95-7	$Ba(ClO_4)_2$	336.24

2.4.1. Oxy-Bromine Acids

Hypobromous acid is a weak, unstable acid with the chemical formula HBrO, where the bromine atom is in the +1 oxidation state. It is also called "bromanol" or "hydroxidobromine". It occurs only in solution and has chemical and physical properties that are very similar to those of hypochlorous acid, HClO. In aqueous solution, hypobromous acid only partially dissociates into the hypobromite anion BrO^- and the cation, H^+. The salts of hypobromous acid are called **hypobromites**. Like the acid, these salts are unstable and when evaporated or boiled to dryness, they undergo a disproportionation reaction, yielding the respective bromate and bromide salts.

If bromine is dissolved in water, not only bromide anion (Br^-) is formed, but also the hypobromite anion (OBr^-). This hypobromite anion is responsible for the bleaching abilities of bromine solutions. In warm solutions, the disproportion reaction of the hypobromite is quantitative. The resulting bromate is a strong oxidizing agent and very similar to the chlorate:

$$3BrO^- \Rightarrow BrO_3^- + 2Br^-$$

Very few salts of these alkaline earth compounds have been characterized.

Bromous acid with the formula $HBrO_2$ contains bromine in the +3 oxidation state. The salts of bromous acid are called **bromites**. The acid is not stable and only occurs as an intermediate, for example in the oxidation of hypobromites. If bromine gas is added to an aqueous hydroxide (such as sodium or potassium hydroxide), at 20 °C, the reaction is rapid:

$$Br_2(aq) + 2OH^-(aq) \Rightarrow Br^-(aq) + BrO^-(aq) + H_2O(l)(1)$$

In this reaction, the bromine disproportionates (undergoes both reduction and oxidation) from oxidation state 0 (Br_2) to oxidation state –1 (Br^-) and oxidation state +1 (BrO^-).

Bromous acid can thus be produced by a classical chemical or an electrochemical method in which hypobromite is oxidized to the bromite anion:

$$HBrO + HClO \Rightarrow HBrO_2 + HCl$$

or

$$HBrO + H_2O + e^- \Rightarrow HBrO_2 + H_2$$

Also disproportioning of hypobromous acid will give bromous acid and hydrobromic acid:

$$2HBrO + \text{heat} \Rightarrow HBrO_2 + HBr$$

In addition, a rearrangement reaction of bromic acid and hydrobromic acid will produce bromous acid:

$$2HBrO_3 + HBr \Rightarrow 3HBrO_2$$

Bromic acid or the **bromate** anion, BrO_3^-, is a bromine-based oxoanion where the bromine atom is in the +5 oxidation state. The acid is bromic acid, $HBrO_3$. Examples of bromates include sodium bromate ($NaBrO_3$) and potassium bromate ($KBrO_3$).

Perbromic acid or **perbromate** ion is BrO_4^- and the acid is **perbromic acid**, $HBrO_4$, where the bromine atom is in the +7 oxidation state. A **perbromate** is a compound that contains this group. Perbromic acid is unstable and cannot be formed by displacement of chlorine from perchlorate, as some periodates are prepared.

The acid was discovered when a sample of radioactive selenate, SeO_4^{2-}, was left to decay. It is a strong acid, and strongly oxidizing, and is the least stable of the halogen(-VII) acids. It decomposes rapidly on standing to bromic acid and oxygen, with the evolution of brown bromine vapor. The perbromates are not accessible through electrolysis like the perchlorates, but only by reacting bromate solutions with fluorine or ozone.

2.4.2. Alkaline Earth Hypobromites

Because of the unstable nature of hypobromous acid, only a few of these compounds have been prepared. They are not, in general, offered for sale and only a few scientific studies are available. Their physical properties have not been documented.

Hypobromous acid is a very weak acid and oxidizing agent, unlike the hypochlorites, and has not found extensive usage in Industry or domestically.

Beryllium Hypobromite

This substance, $Be(OBr)_2$, appears to be unknown. This is not surprising in view of the solution behavior of beryllium salts. If bromine vapor or liquid is dissolved in water, hypobromous acid results. If beryllium is present, the cation formed is a aquo-based cation or a hydroxy-based anion and all species remain soluble. The possibility of extracting a compound like $Be(OBr)_2$ and measuring its properties is remote.

Nonetheless, a compound like $Be(OH)^+(OCl)^-$ is possible but has never been reported.

Magnesium Hypobromite

Magnesium hypobromite has the molecular formula of $Mg(BrO)_2$ and the molecular weight of 127.2098 g/mol. When bromine is added to an aqueous hydroxide (such as sodium or potassium hydroxide) at 20 °C the reaction is rapid:

$$Br_2(liq) + 2OH^-(aq) \Rightarrow Br^-(aq) + BrO^-(aq) + H_2O(liq)$$

In this reaction, the bromine disproportionates (undergoes both reduction and oxidation) from oxidation state 0 (Br_2) to oxidation state –1 (Br^-) and oxidation state +1 (BrO^-). However, if the reaction is carried out at 0 °C, the reaction is slow and in the presence of magnesium chloride in solution, the salt $Mg(ClO)_2$ forms. Removing this salt from solution is problematic since a secondary reaction, where hypobromite spontaneously disproportionates to **bromide** (bromine oxidation state –1) and **bromate** (bromine oxidation state +5) takes place rapidly at 20 °C and slowly at <0 °C:

$$3BrO^-(aq) \Rightarrow 2Br^-(aq) + BrO_3^-(aq)$$

Hence, the formation and proportions of the –1, +1 and +5 bromine oxidation state products can be controlled by temperature.

Because of the instability of the hypobromite anion, magnesium hypobromite is always supplied as a solution. Although the pH could be raised by the addition of NaOH or the like, the resulting solution is no more stable than NaClO (which is cheaper and easier to prepare). Thus, although the magnesium salt can be prepared to form a stable solution, the solid form cannot be isolated from solution. This accounts for its limited usage in Industry.

The scientific literature is completely lacking concerning the physical properties of this salt, except for papers published in the late 1880s to 1920s (whose content may not be entirely correct or consistent). Magnesium hypobromite is available commercially in limited quantities.

Calcium Hypobromite

Calcium hypobromite has the molecular formula of $Ca(BrO)_2$ and the molecular weight of 142.9778 g/mol. It can be prepared by the same methods as the magnesium salt, namely—the addition of bromine to a basic solution at a temperature <0 °C:

$$Br_2(liq) + 2OH^-(aq) \Rightarrow Br^-(aq) + BrO^-(aq) + H_2O(liq)$$

If $CaCl_2$ is present, a soluble salt, $Ca(ClO)_2$ results. However, removal of the salt by vacuum evaporation causes a disproportionation reaction in which the bromide and bromate are obtained. Because of this redox reaction, even at 0 °C, calcium hypobromite is always supplied as a solution. The holding container must be carefully sealed since bromine vapor will escape from the solution. Because of this instability, calcium hypobromite has found little usage in Industry. Alkali solutions are more basic than alkaline earth solutions (i.e. NaOH vs $Ca(OH)_2$) and have proven more useful.

A discussion of the physical and chemical properties of this salt is completely lacking in the scientific literature.

Calcium hypobromite is available commercially in limited quantities. However, it is usually prepared in situ as needed at the site of usage.

Strontium Hypobromite

Strontium hypobromite has the molecular formula of $Sr(BrO)_2$ and the molecular weight of 190.5248 g/mol. It may be prepared by the same methods given above for the magnesium or calcium salts.

$$Br_2(liq) + 2OH^-(aq) \Rightarrow Br^-(aq) + BrO^-(aq) + H_2O(liq)$$

If $SrCl_2$ is present, a soluble salt, $Sr(ClO)_2$ results. However, removal of the salt by vacuum evaporation causes a disproportionation reaction in which the bromide and bromate are obtained. Because of this redox reaction, even at 0 °C, strontium hypobromite is always supplied as a solution. The holding container must be carefully sealed since bromine vapor will escape from the solution.

Because of this instability, strontium hypobromite has found little usage in Industry. Alkali solutions are more basic than alkaline earth solutions (i.e. NaOH vs

$Sr(OH)_2$) and have proven more useful. No CAS number is available and this salt is not available commercially.

Barium Hypobromite

Barium hypobromite has the molecular formula of $Ba(BrO)_2$ and the molecular weight of 240.2348 g/mol. It is known only in solution and is prepared by the same methods given for the Mg and Ca salts. $Ba(OH)_2$ is generally used and bromine is added to an aqueous solution thereof:

$$Br_2(liq) + 2Ba(OH)_2\ (aq) \Rightarrow BaBr\ (aq) + Ba(BrO)_2\ (aq) + 2H_2O(liq)$$

However, removal of the salt by vacuum evaporation causes a disproportionation reaction in which the bromide and bromate are always obtained. Because of this redox reaction, even at 0 °C, barium hypobromite is always supplied as a solution or is made in situ as needed.

Barium hypobromite has been used in several research studies to oxidize specific organic molecules to form another type. One example is the conversion of leucine to valeric aldehyde. The reason is that barium compounds like $BaCO_3$ or $Ba(OH)_2$ are much more insoluble than the homologous compounds of the alkaline earths so that they can be removed by filtration from the reaction mixture (Fig. 2.38).

Barium hypobromite is unstable and so is not available commercially.

Radium Hypobromite

Radium hypobromite is expected to possess the molecular formula of $Ra(ClO)_2$ and the molecular weight of 328.9282 g/mol. However, in view of the extreme degree of radioactivity of ^{226}Ra, it is clear that this compound has never been prepared. Whether the compound is stable enough to be prepared in solution remains a conjecture because of cost as well as difficulty in handling. There is no demand or reason to obtain this unstable salt.

It is not available commercially.

2.4.3. Alkaline Earth Bromite Compounds

Beryllium Bromite

Beryllium bromite has the molecular formula of Be(OH)BrO_2 and the molecular weight of 137.9223 g/mol. It can be prepared by a reaction of bromous acid or sodium bromite:

$$Be(OH)_2 + NaBrO_2 \Rightarrow Be(OH)BrO_2 + NaOH$$

The most stable method to produce this salt involved the use of sodium bromate and HBr gas:

$$3Be(OH)_2\ (solid) + 2NaBrO_3\ (aq) + HBr\ (gas) \Rightarrow 3Be(OH)BrO_2\ (aq) + 2NaOH\ (aq) + 4H_2O$$

Nevertheless, there are no reports of the preparation of this salt and any such description of its physical and chemical properties remain a conjecture. It is not offered commercially nor does it have a CAS number.

Magnesium Bromite

Magnesium bromite has the molecular formula of $Mg(BrO_2)_2$ and a molecular weight of 248.1106 g/mol. It can be prepared by a number of means including the disproportionation of hypobromous acid, prepared by dissolving bromine in water:

$$Mg(OH)_2 + 2HBrO \pm heat \Rightarrow Mg(BrO_2)_2$$

However, a by-product of the reaction is likely to be MgBr. The best way to prepare the pure salt, uncontaminated by other forms is to react sodium bromate with HBr gas in solution:

$$3Mg(OH)_2\ (solid) + 2NaBrO_3 + 6HBr\ (gas) \Rightarrow 3Mg(BrO_2)_2\ (aq) + 2NaBr\ (aq)$$

Whether this salt can be isolated from solution remains a mystery since no research papers have appeared describing its physical or chemical properties.

Magnesium bromite is not available commercially nor does it have a CAS number.

Calcium Bromite

Calcium bromite has the molecular formula of $Ca(BrO_2)_2$ and the molecular weight of 263.8836 g/mol. It can be prepared by reacting calcium chloride with sodium bromite:

$$CaCl_2 + NaBrO_2 \Rightarrow Ca(BrO_2)_2 + 2NaCl$$

However, calcium bromite is much less stable than the sodium analogue so that it is used to prepare the sodium salt which is used extensively in Industry to bleach and desize cellulose fabrics like rayon. The main attractive attribute of calcium bromite is that it can be isolated as a solid which is relatively stable and

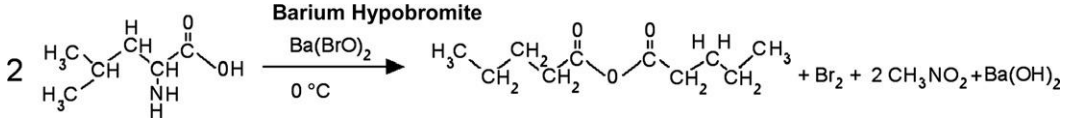

FIGURE 2.38

can be shipped with little fear of decomposition or danger of fire.

One method to produce **solid** calcium bromite has been described as:

> "Calcium hydroxide or "milk of lime" was first added to water in the reaction chamber to form a relatively insoluble hydroxide layer. This bottom layer was cooled to 5 °C, and bromine was added therein while stirring; then milk of lime and bromine were alternately added at controlled feed rates so that the stoichiometric excess of lime relative to the bromine present did not exceed 0.7% by weight of mixture and that, during the addition of bromine, the pH did not fall below 10. After all the milk of lime was introduced into the reaction vessel, the pH of the medium approached 10.05. Bromine was then added very slowly so as to adjust the pH to 9.62. The weight ratio of $Ca(OH)_2$/water in the mixture was 32.5%. The bromite content of the reaction mixture was 64% relative to the total oxidizing power. The mixture was stirred continuously for another 125 min while the temperature was maintained at 5 °C. The bromite yield then reached 71%, and the hypobromite content of the mixture decreased to 9.6%. The solid precipitate is then separated from the mother liquor by filtration and a moist product is obtained having the following composition in percent by weight: $Ca(BrO_2)_2 = 57.5$; $Ca(BrO)_2 = 1.4$; $Ca(BrO_3)_2 = 1.2$; $CaBr_2 = 9.6$ and $Ca(OH)_2 = 1.8$. If a substantially pure salt is desired, the washed product is dissolved in alkaline water, and the bromite is recrystallized by evaporation and cooling. There obtained is a crystalline calcium bromite with 3.0 mols of water $Ca(BrO_2)_2 \cdot 3H_2O$ substantially free from calcium hypobromite and bromide and containing only 0.2% of 30 calcium bromate. The composition of this salt after 165 h in a closed bottle away from light at a temperature of 35 °C was practically unchanged. Calcium bromite, as with all other bromites prepared heretofore, is an excellent oxidizing agent in alkaline media".

In a patent issued in 1963, a method of preparing alkaline earth bromites, particularly calcium bromite, was published. The method consisted of the steps shown in the following diagram (Fig. 2.39) and was applicable to all types of bromite salts.

Nonetheless, this salt has not been characterized extensively and most of the available data was generated in the early work by investigators in the 1890s to 1910s. Calcium bromite does not have a CAS number but is not available commercially. It is usually made "in situ" as needed.

Strontium Bromite

Strontium bromite has the molecular formula of $Sr(BrO_2)_2$ and the molecular weight of 311.4256 g/mol. Only the dihydrate is known but there may be others. This salt has not been the subject of any research and only a few patents mention it. No papers can be found in the open literature.

Alkaline earth bromites such as strontium bromite can be produced by various processes as described below:

$$3Sr(OH)_2\ (\text{solid}) + 2NaBrO_3 + 6HBr\ (\text{gas}) \Rightarrow 3Sr(BrO_2)_2\ (\text{aq}) + 2NaBr\ (\text{aq})$$

Before isolation of the pure solid crystalline strontium bromite, a solid composition of matter is obtained containing a major proportion of the crystalline strontium bromite, together with impurities such as the hypobromite or bromide, or bromate or hydroxide or carbonate

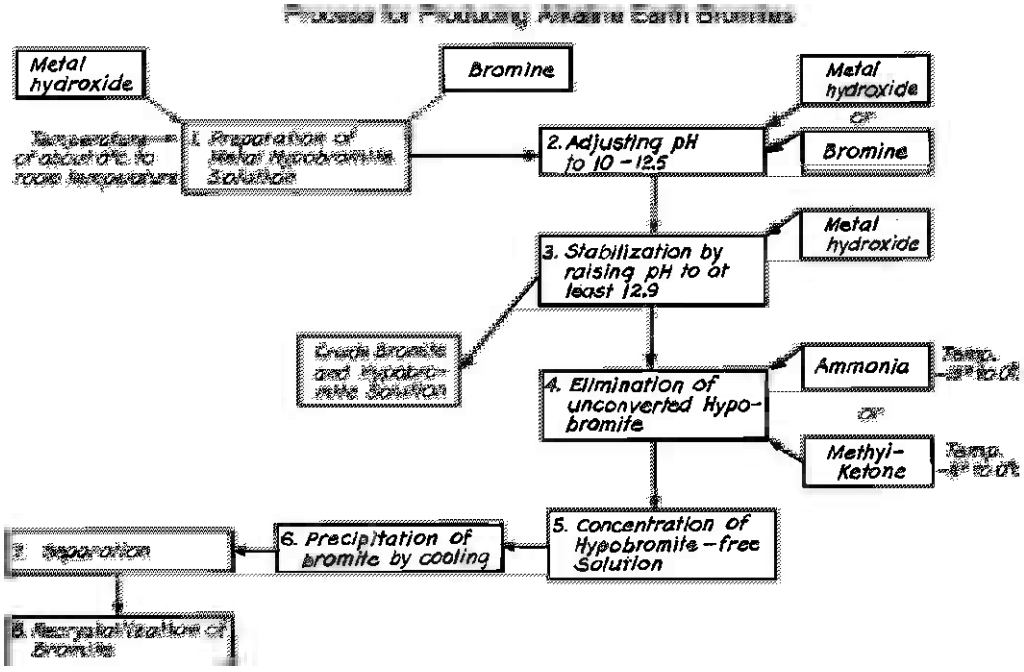

FIGURE 2.39

and mixtures thereof, of the respective alkaline earth metal. The pure solid crystalline strontium bromite is $Sr(BrO_2)_2 \cdot 2H_2O$. This bromite is definitely identifiable under X-ray examination wherein *d*-values are available.

Strontium bromite is a surprisingly stable compound in the solid state, thus being particularly suitable for relatively inexpensive transportation. For example, strontium bromite crystals have been heated to 58 °C under reduced pressure for about 3 h without noticeable decomposition. When heated to 80 °C under reduced pressure for 3 h, about 40% of the initially present bromite is decomposed. The composition of the crystallized solid held under vacuum at 0 °C remains practically unchanged for 6 months and longer.

It has further been found that a saturated solution of strontium bromite containing about 80 g of active bromine per liter, remains unchanged when exposed to daylight at room temperature for at least 3 months. Strontium bromites is an excellent starting materials for the preparation of the alkali metal bromites by cation exchange reaction, for instance, with sodium carbonate. The resultant sodium bromite can then be advantageously employed as a desizing agent in textile operations.

It is also to be noted that strontium bromites are also useful as oxidizing agents, in general, and are particularly advantageous because of their relative stability under atmospheric conditions.

The impure solid can be purified by dissolving it in water at about 0 °C in order to obtain an aqueous solution saturated in strontium bromite, which is then concentrated at ambient temperature (20–25 °C). The precipitate so formed is filtered, washed with an aqueous solution saturated in strontium hydroxide, and dried. There is obtained pale yellow crystals of substantially pure strontium bromite containing 99.2% of $Sr(BrO_2)_2$–$2H_2O$. The solid strontium bromite is a stable compound, its decomposition begins when heated at about 80 °C. By heating at 81 °C during 3 h, about 3% of the initially present strontium bromite is decomposed.

For numerous industrial uses (for instance as oxidizing agent), it is not necessary to dispose of substantially pure strontium bromite. In this case, the impure solid obtained after evaporation of water and containing 37.8% of $Sr(BrO_2)_2$ is merely washed with 0.10 N strontium hydroxide as an aqueous solution at a temperature of about 0 °C, the quantity of washing solution being about 40% by weight of the solid to be treated. After washing and drying, a product is obtained with a higher content of strontium bromite.

In spite of the stability of strontium bromite as a solid, little research has occurred concerning its physical or chemical properties as an oxidizing agent.

This salt has no CAS number nor is it offered for sale commercially.

Barium Bromite

Barium bromite has the molecular formula of $Ba(BrO_2)_2$ and the molecular weight of 361.1356 g/mol. Only the dihydrate is known but there may be others. This salt has not been the subject of any research and only a few patents mention it. No papers can be found in the open literature. Like its strontium analogue, barium bromite can be prepared as a stable compound and so has found favor in Industry for preparing sodium bromite in situ for use as a bleaching process for rayon fibers. Barium bromite has the added advantage, unlike the strontium salt, of being able to remove all traces of Ba^{2+} ions by forming $BaSO_4$ and washing it out of the fabric or plastic rayon fibers. In order to obtain a pure solid, devoid of other forms of soluble oxy-bromine components, it is necessary to form the barium bromite (which contains a significant amount of unstable bromite compounds such as hypobromite or bromide, or bromate or hydroxide or carbonate and mixtures thereof, of the respective alkaline earth metal:

$$BaCl_2 + NaBrO_2 \Rightarrow Ba(BrO_2)_2 + 2NaCl$$

Barium bromite forms as a solid which is removed by filtration and then resuspended in water to recrystallize it. The pure solid crystalline barium bromite is $Ba(BrO_2)_2 \cdot H_2O$, and can be identified by X-ray powder patterns.

Barium and strontium bromites are surprisingly stable compounds in the solid state, with the barium compound being the most stable. Thus, it is very suitable for relatively inexpensive transportation since the oxidation properties are suppressed. For example, barium bromite crystals have been heated to 58 °C under reduced pressure for about 3 h without noticeable decomposition. When heated to 80 °C under reduced pressure for 3 h, about 40% of the initially present bromite is decomposed. The composition of the crystallized solid held under vacuum at 0 °C remains practically unchanged for 6 months and longer.

It has further been found that a saturated solution of barium bromite containing about 130 g of active bromine per liter, remains unchanged when exposed to daylight at room temperature for at least 3 months.

Both barium and strontium bromites are excellent starting materials for the preparation of the alkali metal bromites by cation exchange reaction, for instance, with sodium carbonate. The resultant sodium bromite can then be advantageously employed as a desizing agent in textile operations.

The moist solid mass can be recrystallized directly without washing, by adding water to obtain a solution saturated in barium bromite at 0 °C. The soluble barium bromate is eliminated by filtration. By slow evaporation

of water at about 30 °C under reduced pressure (15–20 Torr), and after separation of the crystals from the solution by decantation or filtration and subsequent washing with an aqueous saturated barium bromite solution, there is obtained a practically pure barium bromite of the following composition:

$$Ba(BrO_2)_2 \cdot H_2O = 98.1\%$$

$$Ba(BrO_3)_2 \cdot H_2O = 1.0\%$$

$$BaBr_2 = \text{Traces}$$

It is also to be noted that barium bromite is also useful as an oxidizing agent, in general, and is particularly advantageous because of its relative stability under atmospheric conditions. In spite of this, barium bromite has found little usage in Industry since the bromates are more stable and easier to prepare.

Radium Bromite

Radium bromite has the molecular formula of $Ra(BrO_2)_2$ and the molecular weight of 449.8311 g/mol. In view of the intense radioactivity of ^{226}Ra, there has been little incentive to prepare this salt. It can be prepared by the same methods used for its barium homologue, namely:

$$RaCl_2 + NaBrO_2 \Rightarrow Ra(BrO_2)_2 + 2NaCl$$

According to one literature source, radium bromite (also known as "Radium-Bromatum") has been used to treat mange-spots on dogs. The reason to use a radioactive chemical is not known except that radium bromite is both radioactive and oxidative. Radium bromite is not available commercially and does not have a CAS number.

2.4.4. Alkaline Earth Bromate Compounds

Beryllium Bromate

Beryllium bromate has the molecular formula of $Be(OH)BrO_3$ and the molecular weight of 153.9217 g/mol. It can be prepared by a reaction of bromic acid or sodium bromate:

$$Be(OH)_2 + NaBrO_3 \Rightarrow Be(OH)BrO_3 + NaOH$$

The most stable method to produce this salt involved the use of sodium bromate and HBr gas:

$$3Be(OH)_2\ (\text{solid}) + 2NaBrO_3\ (aq) + HBr\ (\text{gas}) \Rightarrow 3Be(OH)BrO_3\ (aq) + 2NaOH\ (aq) + 4H_2O$$

Nevertheless, there are no reports of the preparation of this salt in the technical literature and any such description of its physical and chemical properties remains a conjecture. It is not offered commercially nor does it have a CAS number

Magnesium Bromate

Magnesium bromate has the molecular formula of $Mg(BrO_3)_2$ and the molecular weight of 280.1094 g/mol. It has the CAS number of 14519-17-6. It can be prepared by the reaction of bromic acid and magnesium carbonate:

$$MgCO_3 + 2HBrO_3 \Rightarrow Mg(BrO_3)_2 + CO_2 + H_2O$$

However, magnesium bromate is not stable in an acidic environment and tends to decompose if one attempts to remove it from solution. Thus, the best method of preparation involves the use of sodium bromate which is basic enough to prevent such decomposition in solution:

$$Mg(OH)_2 + 2NaBrO_3 \Rightarrow Mg(BrO_3)_2 + 2NaOH$$

The product is a hexahydrate, $Mg(BrO_3)_2 \cdot 6H_2O$ whose molecular weight is 388.201 g/mol. This salt is soluble in water (58.2 g/100 ml) and must be recrystallized by vacuum evaporation at 15–20 °C in order to obtain a crystalline solid (which is the stable form). This salt can also be prepared by adding a solution of magnesium sulfate to a suspension of barium bromate:

$$MgSO_4\ (aq) + Ba(BrO_3)_2\ (s) \Rightarrow Mg(BrO_3)_2\ (aq) + BaSO_4\ (s)$$

The solution is then evaporated to recrystallize the hexahydrate, $Mg(BrO_3)_2 \cdot 6H_2O$.

These occur as large, colorless, octahedral crystals which melt in their own waters of hydration. It loses the water molecule above 60 °C and decomposes when heated to a higher temperature, forming MgO and bromine.

Magnesium bromate hexahydrate is a white crystalline compound that is insoluble in alcohol, but soluble in water. It reacts with methyl alcohol to form a complex. It is a fire hazard but is used as an analytical reagent. Its CAS number is 7789-36-8 and its density is 2.29 g/cm^3. On heating to 50–60 °C, magnesium bromate first decomposes to form the dihydrate. It loses the other two waters of hydration at 105 °C. The anhydrate then decomposes at 200 °C and forms the oxide plus bromine and oxygen:

$$2Mg(BrO_3)_2 + \text{heat} \Rightarrow 2MgO + 2Br_2 + 5O_2$$

This mechanism differs from that of the other alkaline earth bromates which decompose to form the bromide plus oxygen. Its water solubility is shown in Table 2.101.

Magnesium bromate has found little usage in Industry because there are better oxidizing agents available. It is offered for sale commercially but in limited quantities.

Calcium Bromate

Calcium bromate has the molecular formula of $Ca(BrO_3)_2$ and the molecular weight of 295.8824 g/mol.

TABLE 2.101

		g/100 ml of water							
Material	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**50 °C**	**65 °C**	**75 °C**	**81 °C**
Magnesium bromate	$Mg(BrO_3)_2 \cdot 6H_2O$	42.3	45.6	48.7	51.4	57.3	62.5	66.8	70.1

Its CAS number is 5743-36-2 and it is soluble in water (125 g/100 ml at 20 °C). It may be prepared by reacting calcium hydroxide with sodium bromate or by reacting calcium sulfate with barium bromate:

$$Ca(OH)_2 + 2NaBrO_3 \Rightarrow Ca(BrO_3)_2 + 2NaOH$$

$$CaSO_4\ (aq) + Ba(BrO_3)_2\ (solid) \Rightarrow Ca(BrO_3)_2\ (aq) + BaSO_4\ (solid)$$

Of the two methods, the latter seems to be more stable one since the temperature can be as high as 80 °C in solution. The usual product is a monohydrate, $Ca(BrO_3)_2 \cdot H_2O$; F.W.: 313.90 g/mol; CAS number: 10102-75-7.

Calcium bromate monohydrate occurs as colorless, monoclinic crystals or prismatic plates which are soluble in water. This salt loses its water below 180 °C and decomposes above that temperature to form calcium bromide plus oxygen.

The solubility of calcium bromate monohydrate in water from −20 to +100 °C has been determined. Its solubility in water is: 230 g/100 ml at 20 °C and 181.3 g/100 ml at 80 °C. Differential thermal analysis (DTA) indicates a loss of water at 130–150 °C and decomposition to calcium bromide at 270–300 °C. In contact with acids such as HCl or HNO_3, the bromate decomposes forming HBr as a gas.

A proton magnetic resonance spectrum of calcium bromate monohydrate showed that there are two orientations of the water molecule in the crystal. The *p–p* distances are 1.58 ± 0.02 and 1.59 ± 0.02 Å, respectively. Their orientations with respect to the crystallographic axes were measured as functions of orientation at room temperature and of temperature in a single crystal of calcium bromate monohydrate. The *b* crystallographic axis was the axis of rotation of the crystal. The proton-resonance relaxation time was essentially independent of orientation of the crystal in the external magnetic field. The temperature dependence was characteristic of 180° flipping motion of the H_2O molecule whose activation energy was 6.7 ± 0.4 kcal/mol. The H_2O molecules were determined to be hydrogen bonded to the O(5) and O(2) atoms in the crystal.

Calcium bromate is used as a maturing agent and dough conditioner in bromated flours. However, it is relatively expensive at $252 for 5 kg. About 75 ppm is used as a bromating agent which costs about $20/100 lb of flour.

Other than this usage, this salt is not utilized in Industry. It is available commercially.

Strontium Bromate

Strontium bromate has the chemical formula of $Sr(BrO_3)_2$ and the molecular weight of 343.4244 g/mol. Its CAS number is 10102-75-7. It can be prepared by reacting strontium hydroxide with sodium bromate or by reacting strontium sulfate with barium bromate:

$$Sr(OH)_2 + 2NaBrO_3 \Rightarrow Sr(BrO_3)_2 + 2NaOH$$

$$SrSO_4\ (aq) + Ba(BrO_3)_2\ (solid) \Rightarrow Sr(BrO_3)_2\ (aq) + BaSO_4\ (solid)$$

Of the two methods, the latter seems to be more stable since the temperature can be as high as 80 °C in solution. The usual product is a monohydrate, $Sr(BrO_3)_2 \cdot H_2O$; F.W.: −361.4397 g/mol; CAS number: 14519-18-7. Strontium bromate is about 40 times more soluble in water than barium bromate. The increased solubility plus the greater stability of the barium compound allows the formation of the strontium bromate-monohydrate to be recrystallized easily. The monohydrate decomposes at 76 °C to form the anhydrate.

$Sr(BrO_3) \cdot H_2O$ occurs as small, colorless but lustrous, monoclinic crystals which are prismatic in nature. It is somewhat soluble in water and loses its water of hydration if heated to about 110 °C. It decomposes at 240 °C forming strontium bromide and oxygen.

Chemically this salt is soluble in water (30.9 g/100 ml at 20 °C), and is a moderately strong oxidizing agent. It is also toxic if ingested and irritates the skin and respiratory tract if come into contact with or inhaled, respectively.

The crystal structures of the isostructural halates $Sr(BrO_3)_2 \cdot H_2O$, $Ba(BrO_3)_2 \cdot H_2O$, $Ba(IO_3)_2 \cdot H_2O$, $Pb(ClO_3)_2 \cdot H_2O$, and $Pb(BrO_3)_2 \cdot H_2O$ were determined using X-ray single-crystal data (monoclinic space group $C2/cC$, $Z = 4$). The mean bond lengths and bond angles of the halate ions in the $Ba(ClO_3)_2 \cdot 1H_2O$-type compounds, which correspond to those of other halates, are ClO, 149.0, BrO, 165.9, IO, 180.2 pm, ClO_3^-, 106.4, BrO_3^-, 104.0, and IO_3^-, 99.6°. The structure data obtained were discussed in terms of possible orientation disorder of the water molecules, strengths of the hydrogen bonds, influence of the lead ions on the structure, and site group distortion of the halate ions.

Strontium bromate is rarely used in the laboratory or in Industry. It is available commercially but in limited quantities.

Barium Bromate

Barium bromate has the molecular formula of $Ba(BrO_3)_2$ and the molecular weight of 393.1344 g/mol. It may be prepared by reaction of the hydroxide with sodium bromate:

$$Ba(OH)_2 + 2NaBrO_3 \Rightarrow Ba(BrO_3)_2 + 2NaOH$$

Barium bromate is relatively insoluble, and has a value of 0.782 g/100 ml of water at 298 K; its enthalpy of solution is +54 kJ/mol and the solubility product is 2.43×10^{-4}. If recrystallized, it forms a monohydrate, $Ba(BrO_3)_2 \cdot H_2O$, which occurs as white or colorless, prismatic crystals. Its solubility in hot water increases but it is decomposed by strong acids, forming HBr and the corresponding salt:

$$Ba(BrO_3)_2 + 2HCl \Rightarrow 2HBr + BaCl_2 + 3O_2$$

$Ba(BrO_3)_2 \cdot H_2O$ loses its water of hydration at about 190 °C and decomposes to the bromide at 265 °C, forming the bromide plus oxygen:

$$Ba(BrO_3)_2 \cdot H_2O + \text{heat} \Rightarrow BaBr_2 + H_2O + 3O_2$$

A new and general method of inducing a precipitation from homogeneous solution has been applied to the separation of barium and strontium. The precipitation of barium bromate, a water-soluble compound, is brought about by a gradual change in the composition of the solvent media. An organic compound, such as methanol or tetrahydrofuran, is allowed to diffuse into the original water solution, thus slowly converting the solution into a water–organic mixture. Strontium bromate is about 40 times more soluble in water than barium bromate. The increased solubility plus the greater stability of the strontium MEDTA chelate tend to hold the strontium in solution. The chief advantage of this method over the separation of Sr from Ba by precipitation of barium chromate is in the preparation of barium compounds. Usually, barium must be separated from the chromate before proceeding. However, barium bromate can be easily converted to the oxide, eliminating this separation step.

Barium bromate-monohydrate has a molecular weight of 411.1734 g/mol and is monoclinic in structure with a space group of I2/c, $a = 9.0696$ Å, $b = 7.8952$ Å, $c = 9.695$ Å, $\beta = 93.26°$, $V = 688.4$ Å^3, $Z = 4$. Each Ba atom has 11 oxygen neighbors at 2.702 Å – 3.057 Å. The average bond length is 1.652 Å and the O…O bond length is 2.832 Å in a hydrogen bond.

The results of proton magnetic resonance absorption spectrum of barium bromate monohydrate indicate that there is only one orientation of the water molecule in the crystal. The p–p distance is 1.61 ± 0.01 Å and direction angles of the p–p vector are $\alpha_0 = 30°$, $\beta_0 = 95°$, and $\gamma_0 = 122°$.

Barium bromate is used extensively to form other bromates, including the alkali metal bromates which are used extensively in Industry. $HBrO_3$, a colorless liquid, is made by the addition of dilute sulfuric acid to barium bromate. It dissociates extensively in aqueous solution and is a strong acid.

The solubility of barium bromate-monohydrate is shown in Table 2.102.

The scientific literature contains a few studies of barium bromate chiefly due to interest in Industry for its use to prepare other bromate salts.

This salt is available commercially, worldwide.

Radium Bromate

Radium bromate would have the molecular formula $Ra(BrO_3)_2$ and the molecular weight of g/mol. There is no report for the preparation of radium bromate. Perhaps this is due to the fact that the thermodynamic data for the bromates of the other alkaline earths are incomplete. This salt could be prepared by the reaction of sodium bromate and radium chloride:

$$RaCl_2 + 2NaBrO_3 \Rightarrow Ra(BrO_3)_2 + 2NaCl$$

In view of the extreme degree of radioactivity of ^{226}Ra, there is no industrial or commercial demand for this salt and it has no CAS number.

2.4.5. Alkaline Earth Perbromates

Beryllium Perbromate

Beryllium perbromate has the molecular formula of $BeOHBrO_4$ and the molecular weight of grams per mole. This salt can be prepared by the reaction of sodium perbromate and the hydroxide salt in aqueous solution:

$$Be(OH)_2 + NaBrO_4 \Rightarrow BeOHBrO_4 + NaOH$$

TABLE 2.102

		g/100 ml of water									
Material	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**50 °C**	**60 °C**	**80 °C**	**90 °C**	**100 °C**
Barium bromate monohydrate	$Ba(BrO_3)_2H_2O$	0.29	0.44	0.65	0.95	1.31	1.75	2.27	3.65	4.45	5.71

A description of the preparation and properties of this salt is completely lacking in the literature. Whether an attempt to prepare such a salt has been accomplished remains a mystery.

It has no CAS number and it is not offered for sale commercially.

Magnesium Perbromate

Magnesium perbromate has the molecular formula of $Mg(BrO_4)_2$ and the molecular weight of gm/mol. This salt can be prepared by the reaction of sodium perbromate and the chloride salt in aqueous solution:

$$MgCl_2 + 2NaBrO_4 \Rightarrow Mg(BrO_4)_2 + 2NaCl$$

The solution is then evaporated slowly under partial pressure to produce the hexahydrate, $Mg(BrO_4)_2 \cdot 6H_2O$. Little is known concerning this salt. The physical parameters describing this salt have not been documented. Presumably, $Mg(BrO_4)_2 \cdot 6H_2O$ loses its six waters sequentially below about 240 °C where it decomposes at 250 °C to form $MgBr_2$ plus oxygen. It may form the oxide, MgO plus bromine and oxygen but this has not been the subject of a research investigation.

$Mg(BrO_4)_2 \cdot 6H_2O$ is not used in Industry but it is mentioned in a few patents concerning a Ziegler–Natta catalyst and part of a gas-generating mixture for automotive air bags. Whether this compound has ever been used commercially remains unknown. It does not have a CAS number and is not offered for sale commercially.

Calcium Perbromate

Calcium perbromate has the molecular formula of $Ca(BrO_4)_2$ and the molecular weight of gm/mol. It can be prepared by the reaction of sodium perbromate and the chloride salt in aqueous solution:

$$CaCl_2 + 2NaBrO_4 \Rightarrow Ca(BrO_4)_2 + 2NaCl$$

The solution is then evaporated slowly under partial pressure to produce the tetrahydrate, $Ca(BrO_4)_2 \cdot 4H_2O$. This salt is very slightly soluble in water and is not as stable as the barium salt. Therefore, it is recrystallized from solution and stored under dry conditions.

The structure of calcium perbromate is similar to other perbromates. There are columns of Ca^{2+} cations surrounded by four columns of perbromate anions and four columns of water molecules. The eight coordinating O atoms in the CaO_8 complex form a polyhedron of a square antiprism. In this complex, Ca is coordinated by four water molecule oxygens at 2.37 Å and four anion O atoms at 2.57 Å.

The literature of calcium perbromate is sparse. A comprehensive description of physical, as well as chemical, properties of this salt is lacking in the technical literature or reference books.

This salt is not used in Industry and does not have a CAS number.

Strontium Perbromate

Strontium perbromate has the molecular formula of $Sr(BrO_4)_2$ and the molecular weight of gm/mol. It can be prepared by the reaction of sodium perbromate and the chloride salt in aqueous solution:

$$SrCl_2 + 2NaBrO_4 \Rightarrow Sr(BrO_4)_2 + 2NaCl$$

The solution is then evaporated slowly under partial pressure to produce the trihydrate, $Sr(BrO_4)_2 \cdot 3H_2O$. Its structure is very likely like that of its barium homologue and is hexagonal in structure. However, the specific lattice parameters have not been documented in the open literature.

Very little data concerning the physical properties of this salt exist. It too is mentioned in a few patents concerning catalytic converters for automobiles. Strontium perbromate does not have a CAS number and is not offered for sale commercially.

Barium Perbromate

Barium perbromate has the molecular formula of $Ba(BrO_4)_2$ and the molecular weight of gm/mol. It can be prepared by the reaction of sodium perbromate and the chloride salt in aqueous solution:

$$BaCl_2 + 2NaBrO_4 \Rightarrow Ba(BrO_4)_2 + 2NaCl$$

The solution is then evaporated slowly under partial pressure to produce the trihydrate, $Ba(BrO_4)_2 \cdot 3H_2O$. It is very slightly soluble even in boiling water. This salt has a molecular weight of 479.1926 g/mol and is hexagonal in structure. Lattice parameters include: $a = 7.414$ Å, $c = 9.965$ Å, $V = 474.4$ Å^3, $Z = 2$ and density $= 3.35$ g/cm^3 (Fig. 2.40).

The Ba atoms in this structure are coordinated by 12 oxygen atoms in a near-icosahedral arrangement, with an average Ba–O bond length of 2.987 Å. The perbromate ion has regular tetrahedral symmetry and an average Br–O bond length of 1.608 Å. Each perbromate

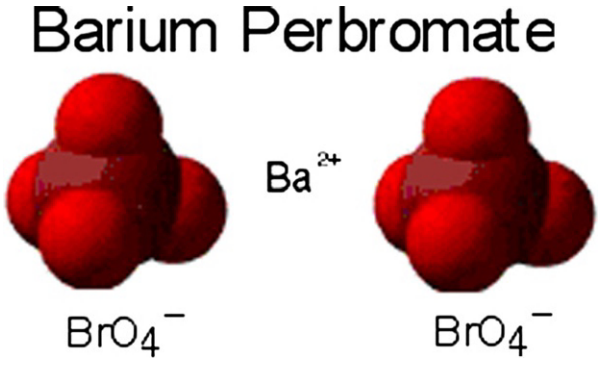

FIGURE 2.40

ion in the structure is hydrogen bonded to three water molecules.

This salt has been the subject of a few research papers but has no CAS number. It is not offered for sale commercially.

Radium Perbromate

Radium perbromate is expected to have the molecular formula of $Ra(BrO_4)_2$ and the molecular weight of gm/mol. This salt can be prepared by the reaction of sodium perbromate and the chloride salt in aqueous solution:

$$RaCl_2 + 2NaBrO_4 \Rightarrow Ra(BrO_4)_2 + 2NaCl$$

The solution is then evaporated slowly under partial pressure to produce the trihydrate, $Ra(BrO_4)_2\ 3H_2O$. It is expected to be very slightly soluble even in boiling water. However, there is no description of its physical or chemical properties in the technical literature. It has no CAS number and is not offered for sale commercially.

2.5. ALKALINE EARTH METALS OXY-IODINE COMPOUNDS

The alkaline earths all form oxy-iodine compounds of assorted compositions. These are based upon the oxy-acids of iodine.

2.5.1. Oxy-Iodine Acids

Iodous acid, HIO_2, with the iodine atom in the +3 oxidation state apparently does not exist. Thus, alkaline earth "Iodites" cannot exist (Neither do "hypo-iodites" or "per-iodites").

Iodic acid, HIO_3, can be obtained as a white solid. It dissolves in water very well, but it also exists in the pure state, as opposed to chloric acid or bromic acid. Iodic acid contains iodine in the oxidation state +5 and it is one of the most stable oxo-acids of the halogens in its pure state. When iodic acid is carefully heated, it dehydrates to iodine pentoxide. On subsequent heating, the iodine pentoxide further decomposes, giving a mixture of iodine, oxygen and lower oxides of iodine.

Iodic acid is a relatively strong acid with a pK_a of 0.75. It is strongly oxidizing in acidic solution, less so in basic solution. When iodic acid acts as oxidizer, then the product of the reaction is either iodine, or iodide ion. Under some special conditions (very low pH and high concentration of chloride ion, e.g. in concentrated hydrochloric acid), iodic acid is reduced to iodine trichloride, a golden yellow compound in solution and no further reduction occurs. In the absence of chloride ions, when there is an excess amount of reducing agent, then all iodate is converted to iodide ion. When there is an excess amount of iodate, then only part of the iodate is converted to iodine.

Iodic acid can be produced by oxidizing I_2 with chlorine in an aqueous solution. Iodic acid can be used to synthesize sodium or potassium iodate salts (which are used in salt as a source of iodine in the human body.

Periodic acid, or **iodic(VII) acid is** an oxoacid of iodine having a chemical formula HIO_4 or H_5IO_6. In dilute solution, periodic acid exists as H^+ and IO_4^-. When more concentrated, **orthoperiodic acid**, H_5IO_6, is formed. Note that this compound is essentially a dihydrate, $HIO_4 \cdot 2H_2O$. This can be obtained as a crystalline solid. O-periodic acid can be dehydrated to **metaperiodic acid**, m-HIO_4. Further heating gives di-iodine pentoxide (I_2O_5) and O_2. The anhydride *di-iodine heptoxide*, i.e. I_2O_7, does not exist in nature but can be formed synthetically.

Thus, two forms of periodates exist. One relating to the acid m-HIO_4, the other relating to o-H_5IO_6. The former results in metaperiodates (meta—meaning less water) and the latter, orthoperiodates (ortho—meaning more water). Metaperiodates have solubilities and chemical properties similar to perchlorates (similar but larger ion size) though they are less oxidizing than perchlorates. The reason that these homologues are cited refers to their behavior when dissolved in water:

$$HIO_4(\text{solid}) \Rightarrow H^+ + IO_4^-$$

$$H_5IO_6(\text{solid}) \Rightarrow H^+ + H_4IO_6^-$$

Thus, two differing anions form in aqueous solution. These act chemically in a similar manner even though the anionic complex differs. A probable structure for the O-periodate anion is shown in Fig. 2.41.

In this anion, the iodine atom remains in the +7 oxidation state but the complex is not a "dihydrate" but is similar to its tellurium analogue in alkali tellurates.

Periodic acid is also used in organic chemistry for structural analysis. Periodic acid will cleave a vicinal

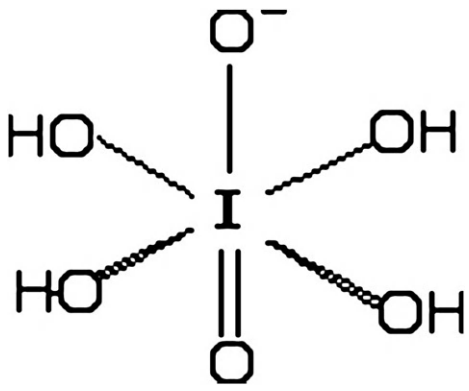

FIGURE 2.41

diol into two aldehyde fragments. This can be useful in determining the structure of carbohydrates.

2.5.2. Alkaline Earth Iodates

Beryllium Iodate

Beryllium iodate is expected to have the molecular formula, $Be(IO_3)_2$ and the molecular weight of 374.1104 g/mol. In view of the hydrolysis of the Be^{2+} cation in other compounds prepared in aqueous solution, the composition is expected to be $Be(OH)IO_3$. However, beryllium forms a complex iodate in solution which has been characterized by X-ray analysis as $Be(IO_3)_2 \cdot 2HIO_3$ It can be prepared by reaction of iodic acid and beryllium hydroxide:

$$Be(OH)_2 + 3HIO_3 \Rightarrow Be(IO_3)_2 \cdot 2HIO_3 + H_2O$$

The product is expected to be relatively insoluble like the other alkaline earth iodates. The compound $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$ has been identified by quantitative analysis, IR spectra and X-ray diffraction analysis. On the basis of the absorption bands in the IR spectra of the compound and its partially deuterated analogue, the basic structural units making up the compound were shown to be $Be(H_2O)_4(IO_3)_2 \cdot 2HIO_3 \cdot 2H_2O$, as well as the existence of two kinds of nonequivalent water molecules (whether this is actually the compound, $Be(OH)_4(IO_3)_2 \cdot 2HIO_3 \cdot 2H_2O$, i.e. the OH-radical or an actual water molecule coordinated to the Be atom in the structure, remains a conjecture). Nonetheless, it is this compound which results if HIO_3 is in excess, i.e. the $Be(OH)_2$ is added to the acid. If HIO_3 is added to the $Be(OH)_2$ slurry, then the "normal" salt results:

$$Be(OH)_2 + 2HIO_3 \Rightarrow Be(IO_3)_2 \cdot 8H_2O + H_2O$$

The thermal decomposition of $Be(IO_3)_2 \cdot 2HIO_3 \cdot 6H_2O$ was studied by means of DTA and DSC methods. The important phase transitions were determined to involve $Be(IO_3)_2 \cdot I_2O_5$ that was isolated and identified as an intermediate.

The thermal decompositions of two beryllium periodate hydrates, $Be(IO_4)_2 \cdot 8H_2O$ and $Be(H_4IO_6)_2 \cdot 2H_2O$, were studied by DTA and TGA in the temperature range from 298 to 1073 K, and by DSC from 298 to 723 K. The intermediates of the thermal decompositions were identified via quantitative analysis, IR spectroscopy and the TG curves. The data obtained to show that the two periodates decompose via an anhydrous beryllium iodate, and the final residue is beryllium oxide. This is the mechanism expected for this type of iodate.

Beryllium iodate has found little usage in Industry but has been available commercially in limited quantities. Perhaps, this is due to the toxicity of beryllium in general.

Magnesium Iodate

Magnesium iodate has the molecular formula, $Mg(IO_3)_2$ and the molecular weight of 374.1104 g/mol. It can be prepared by reaction of iodic acid and magnesium hydroxide:

$$Mg(OH)_2 + 2HIO_3 \Rightarrow Mg(IO_3)_2 + H_2O$$

A tetrahydrate results that is relatively insoluble.

This salt has the CAS number 7790-32-1 and a molecular weight of 446.1715 g/mol. It is soluble in water as shown in Table 2.103.

Magnesium iodate tetrahydrate occurs as well-defined monoclinic crystals of high luster. It is easily soluble in sulfuric acid. When heated, it loses two waters of hydration at 510 °C and the other two at 620 °C. The anhydrate is stable to 680 °C where it decomposes into MgO, iodine and oxygen:

$$Mg(IO_3)_2 + \text{heat (580 °C)} \Rightarrow MgO + I_2 + 3O_2$$

The phase transitions of $Mg(IO_3)_2 \cdot 4H_2O$ crystals occurring in the heating process have been investigated by means of thermal analyses and X-ray diffraction at high room temperature. There are two phases observed on heating or cooling, a high temperature one, β-$Mg(IO_3)_2$ and a low-temperature one, α-$Mg(IO_3)_2$. The crystal structure of β-$Mg(IO_3)_2 \cdot 4H_2O$ has been determined by means of the method of single-crystal diffraction, it has been found that the space group of $Mg(IO_3)_2 \cdot 4H_2O$ is P2 or Pm. There are two formula units per unit cell. Lattice parameters are: $a = 8.307$ Å, $b = 6.627$ Å, $c = 8.541°$, $\beta = 100.5°$. The crystal structure of α-$Mg(IO_3)_2$ has been determined by X-ray powder method. The unit cell of α-$Mg(IO_3)_2$ is hexagonal, with $a = 5.4777$ Å, $c = 5.1282$ Å, $c/a = 0.9362$ at 14 Å. There is one formula unit per unit cell. The space group is $P6_3$. 6-0^{II} are situated at the 6(c) positions, 2-I^{V} are situated at 2(b) positions, and Mg^{+2} ion is disorderly distributed at half of 2(a) positions. The atomic parameters found to be $X_c = 0.096$, $Y_c = 0.344$, $Z_c = 0.162$, $Z_b = 0$, $Z_a = 0.981$. The crystal structure of α-$Mg(IO_3)_2$ is isomorphic with α-$LiIO_3$. α-$Mg(IO_3)_2$ is different from α-$LiIO_3$ only in that the Mg^{++}-ion is disorderly distributed at one-half of 2(a) positions and the other half is vacant.

TABLE 2.104

		g/100 ml of water						
Compound	**Formula**	**0 °C**	**20 °C**	**40 °C**	**50 °C**	**65 °C**	**80 °C**	**100 °C**
Calcium iodate monohydrate	$Ca(IO_3)_2 \cdot H_2O$	0.09	0.24	0.52	0.59	0.65	0.80	0.95

A DTA and DSC study was made of the thermal dehydration and decomposition of $Mg(IO_3)_2 \cdot 4H_2O$ and $Mg(IO_3)_2 \cdot 4D_2O$. The data obtained show that the dehydration takes place in one stage. The ΔH°_{deh} values obtained were used to calculate ΔH°_{f}, and comparisons were made with the literature data. It was confirmed that the thermal decomposition passes through an intermediate $Mg_5(IO_6)_2$, which is unstable and immediately decomposes to MgO (note that this salt is an ortho-iodate). An isotope effect is observed in both DTA and DSC curves. Thermogravimetric data on $Mg(IO_3)_2 \cdot 4H_2O$ showed that the thermal decomposition of magnesium iodate was a two-step reaction which starts at 588 and 615 °C, respectively. It is noted that the enthalpy change of magnesium iodate to intermediate orthoperiodate—$Mg_5(IO_6)_2$—is 65.4 kcal/mol and that of orthoperiodate to magnesium oxide is 99.0 kcal/mol.

The anhydrate, $Mg(IO_3)_2$, is a monoclinic structure. It crystallizes in the monoclinic crystal system, space-group type $P2_1$ (no.4) with a pseudo-hexagonal lattice, as shown by the lattice parameters of $Mg(IO_3)_2$ for example: $a = 11.247$ Å, $b = 5.045$ Å, $c = 11.246$ Å, $\beta = 120.02°$, $V = 552.5$ Å^3, $Z = 4$. This monoclinic symmetry with a to c and $\beta = 120°$ leads to a three-individual pseudo-hexagonal twin by pseudo-merohedry. The structure reveals a three-dimensional network in which each octahedrally coordinated cation is linked to ten others via iodate bridges.

Magnesium iodate is not employed extensively in Industry but is available commercially.

Calcium Iodate

Calcium iodate has the molecular formula, $Ca(IO_3)_2$, and the molecular weight of 389.8834 g/mol where iodine atom is in the +5 oxidation state. This composition occurs as a mineral "**Lautarite** (*Calcium Iodate·Monohydrate*). It can be prepared by the reaction of iodic acid upon the carbonate:

$$CaCO_3 + 2HIO_3 \Rightarrow Ca(IO_3)_2 + CO_2 + H_2O$$

The monohydrate formed has limited solubility in water and can be separated by filtration. Its CAS number is 40563-56-2 (anhydrate) and 7789-80-2 (monohydrate). The slurry can be evaporated to increase the yield. The monohydrate has a density of 4.519 g/cm^3 and a solubility of 0.24 g at 20 °C.

The solubility, as a function of temperature is shown in Table 2.104.

This salt also occurs as the hexahydrate whose crystals are efflorescent, rhombic and occur as microprisms. This salt too is very slightly soluble in hot water but more soluble in HNO_3. It is insoluble in sulfuric acid or alcohol but is decomposed by HCl where it forms $MgCl_2$ plus iodine and oxygen. Whether I_2O_5 is an intermediate in the decomposition has not been determined.

The monohydrate loses its water of hydration at 160 °C and decomposes at 560 °C to form the oxide plus iodine and oxygen. The hexahydrate, $Ca(IO_3)_2 \cdot 6H_2O$, has a solubility product of $K_{SP} = 7.10 \times 10^{-7}$. When heated to 130 °C, the hexahydrate loses five waters of hydration to form the more stable monohydrate. However, if the monohydrate is then exposed to water, then the hexahydrate is again obtained (Fig. 2.42).

Calcium iodate (also called **Lautarite**) is used as an oxidant added to lotions and ointments as an antiseptic and deodorant. It is also used in the food industry in animal feed, and the manufacture of disinfectants.

The forms of iodine most commonly used in animal feed are **calcium iodate**, ethylenediamine dihydriodide (EDDI), and potassium iodide. Calcium iodate is usually the most stable source of iodine. All three major sources of iodine (calcium iodate, EDDI, and potassium iodide) are roughly equivalent in biological availability.

Crude iodine (99.9% iodine) is refined as a coproduct from brines associated with underground gas and oil wells in Japan and the U.S. In Chile, it is refined as a coproduct with potassium nitrate from Caliche deposits which are mined by open pit methods. Iodine salts are manufactured from crude iodine and are very pure. There are three major converters of crude iodine to feed grade salts in the U.S. and Canada.

Calcium iodate is available commercially.

Strontium Iodate

Strontium iodate has the molecular formula, $Sr(IO_3)_2$ and the molecular weight of 437.4254 g/mol. Its CAS

$$Ca(IO_3)_2 \cdot 6H_2O \underset{H_2O}{\overset{110°C}{\rightleftharpoons}} Ca(IO_3)_2 \cdot H_2O$$

FIGURE 2.42

number is 13470-01-4. It can be prepared by the reaction of iodic acid upon the carbonate:

$$SrCO_3 + 2HIO_3 \Rightarrow Sr(IO_3)_2 + CO_2 + H_2O$$

The product is either a monohydrate or a hexahydrate (like the calcium homologue). Its occurs as a triclinic crystal with a density of 5.045 g/cm^3 and a solubility of 0.165 g/100 ml of water at 20 °C. Strontium iodate monohydrate, $Sr(IO_3)_2 \cdot H_2O$ has the solubility product of 3.77×10^{-7} while the value of strontium iodate hexahydrate, $Sr(IO_3)_2 \cdot 6H_2O$, is 4.55×10^{-7}.

The hexahydrate is a crystalline powder that is slightly soluble in water but is soluble in dilute nitric acid where it forms the nitrate plus iodine. The solubility of this salt in water is 0.19 g/100 ml at 20 °C and 0.35 g/100 ml at 100 °C. The magnetic susceptibility of the salt is 108 g/10^{-6} cm^3/mol.

Strontium iodate, $Sr(IO_3)_2$, has been prepared by hydrothermal reactions at 170 °C. The X-ray single-crystal structural analysis showed that it crystallizes in a new structure type with space group $P1$, $a = 7.0130$ Å, $b = 7.0520$ Å, $c = 13.088$ Å, $\alpha = 84.12°$, $\beta = 84.80°$, $\gamma = 63.48°$, $Z = 4$. The crystal structure of $Sr(IO_3)_2$ consists of pyramidal IO_3^- anions and Sr^{2+} cations, which are alternately arranged along the a-axis in a 2:1 ratio to form a layer-like structure. Infrared spectra further confirmed that the compound contains low-symmetric IO_3^- groups. This salt has found little usage in Industry, but is offered for sale commercially.

Barium Iodate

Barium iodate has the molecular formula, $Ba(IO_3)_2$ and the molecular weight of 487.1354 g/mol. It can be prepared by the reaction of iodic acid upon the carbonate:

$$BaCO_3 + 2HIO_3 \Rightarrow Ba(IO_3)_2 + CO_2 + H_2O$$

The product is either a monohydrate or a hexahydrate (like the calcium homologue). The monohydrate occurs as lustrous, monoclinic crystals or a white crystalline powder. It is somewhat soluble in hot water but slightly in cold water. It is insoluble in sulfuric acid or alcohol. It loses its water of hydration at 130 °C.

The solubility of barium iodate in water is shown in Table 2.104.

The solubility product of the monohydrate at 25 °C is 2.7×10^{-9}. This salt is not used in Industry but is offered for sale commercially in limited quantities.

Radium Iodate

Radium iodate has the molecular formula, $Ra(IO_3)_2$ and the molecular weight of 575.8308 g/mol. It can be prepared by the reaction of iodic acid upon the hydroxide of radium:

$$Ra(OH)_2 + HIO_3 \Rightarrow Ra(IO_3)_2 + CO_2 + H_2O$$

It occurs as the monohydrate with a solubility product of 1.16×10^{-9}. Its solubility in water is 0.04 g/100 ml at 20 °C. Very little data is available concerning the physical or chemical properties of this salt. Little use has been found by Industry and it is not offered for sale commercially.

2.5.3. Alkaline Earth Periodates

There are two forms of periodates, the "meta-" (m^-) and the "ortho-" (o^-). Metaperiodates have the formula m-HIO_4 whereas that of the orthoperiodates is o-H_5IO_6. Metaperiodates have solubilities and chemical properties similar to perchlorates (similar but larger ion size) though they are less oxidizing than perchlorates. In general, the O-periodates form the $H_4IO_6^-$ anion in solution while the m-periodates form the IO_4^- anion in solution. However, both types of anion behave similarly chemically even though the two types of differ in chemical constitution. Both contain the iodide atom in the +7 oxidation state but differ stereochemically, i.e. Fig. 2.43.

Little information in the literature is available for these salts.

Beryllium Periodate

Beryllium periodate has the molecular formula of $Be(H_4IO_6)_2$ and a molecular weight of gm/mol. It can be formed by reacting periodic acid with beryllium hydroxide:

$$Be(OH)_2 + HIO_4 \Rightarrow Be(H_4IO_6)_2$$

This is an orthoperiodate with the structure shown in Fig. 2.44.

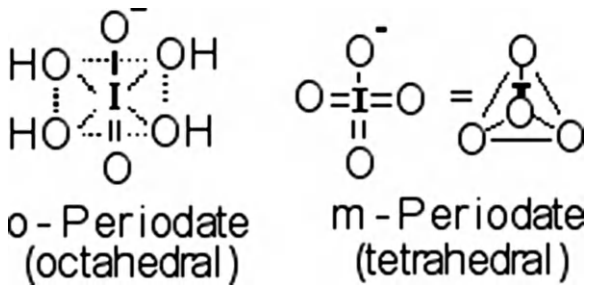

FIGURE 2.43

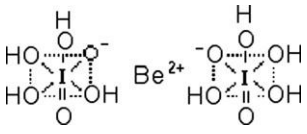

FIGURE 2.44

Note that $Be(H_3IO_6)_2$ and $Be_2(HIO_6)$ are also possible (Fig. 2.45).

At least one of these compositions has been reported in the literature.

Phase relationships and thermal decomposition of beryllium iodates and periodates were studied by X-ray and spectroscopic (IR and Raman) measurements. $Be(IO_3)_2 \cdot 4H_2O$, $Be(IO_3)_2$, and $Be(H_4IO_6)_2 \cdot 4H_2O$ have been characterized. $Be(H_4IO_6)_2 \cdot 4H_2O$ (hitherto claimed in the literature to be a metaperiodate) dehydrates on heating with decomposition to form $Be(IO_3)_2$. Anhydrous beryllium periodate was not obtained in this study.

In another research paper, the thermal decompositions of two beryllium periodate hydrates, $Be(IO_4)_2 \cdot 8H_2O$ and $Be(H_4IO_6)_2 \cdot 2H_2O$, were studied by DTA and TGA in the temperature range from 298 to 1073 K, and by DSC from 298 to 723 K. The intermediates of the thermal decompositions were identified via quantitative analysis, IR spectroscopy and the TG curves. The data obtained were utilized to suggest a scheme for the thermal decompositions of the two periodates. Both compounds decomposed via an anhydrous beryllium iodate, $Be(IO_3)_2$, and the final residue was beryllium oxide, i.e.

$$Be(IO_4)_2 \cdot 8H_2O + \text{heat} \Rightarrow Be(IO_4)_2 + 8H_2O$$
$$\Rightarrow Be(IO_3)_2 + O_2 \Rightarrow BeO + I_2 + 3O_2$$

The enthalpies of the phase transitions were determined from the DSC curves.

In another study, a new beryllium periodate hydrate has been synthesized whose composition was $Be_2HIO_6 \cdot 6.5H_2O$. It was identified by DTA, TG, DSC, IR spectra and X-ray powder diffraction. The compound is thermally stable up to 60 °C, followed by a three-step dehydration and decomposition to form BeO. The IR spectra proved the presence of the following structural groups: HIO_4^{6-}, BeO_4 and H_2O.

$Be(H_4IO_6)_2 \cdot 4H_2O$, beryllium tetrahydrogen-hexaoxoiodate(VII) tetrahydrate, is built up from slightly deformed $Be(OH_2)_4$ tetrahedra (*a,b*) and $IO_2(OH)_4$ octahedra (*A,B*) with *cis* configuration of the oxo ligands. They are arranged along the [001] direction, forming layers with stacking *aBAbABaBAbAB*. The $[H_4IO_6]^-$ and $Be(OH_2)_4^{2+}$ ions are held together by a network of eight independent hydrogen bonds of different strength. Two of the H atoms of $[H_4IO_6]^-$ are disordered over O–H H–O split positions.

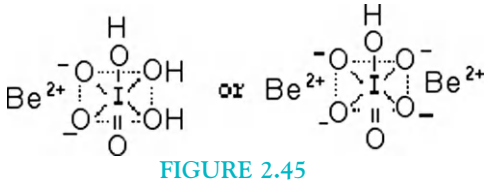

FIGURE 2.45

Beryllium periodate has found little usage in Industry but is available in limited quantities commercially.

Magnesium Periodate

m-Magnesium periodate has the molecular formula, $Mg(IO_4)_2$ and the molecular weight of 406.1092 g/mol. It may be prepared by reaction of magnesium hydroxide and periodic acid:

$$Mg(OH)_2 + 2HIO_4 \Rightarrow Mg(IO_4)_2$$

The product is an octahydrate, $Mg(IO_4)_2 \cdot 8H_2O$. The products differ depending upon the mode of addition. If the acid is added to the $Mg(OH)_2$ slurry, i.e. the Mg^{2+} cation is in excess, then the meta-salt results. In the opposite in which the acid is in excess, the ortho-salt, $Mg(H_4IO_6)_2$, results.

A composition, $Mg_2I_2O_9 \cdot 11H_2O$, has been reported and its thermal decomposition was studied in the temperature interval of 20–600 °C by means of emanation thermal analysis (ETA) and DTA. This composition differs from that which is usually presented. According to a Lewis structure analysis of this composition, the formula should be $Mg_2(H_4I_2O_9)_2 \cdot 9H_2O$ (Fig. 2.46).
where the waters of hydration are omitted. This would be a metaperiodate and orthoperiodate salt. Whether this is correct remains unknown at this point in time. It too decomposes to form MgO and iodine plus oxygen.

Additionally, in another study, it was claimed that the compositions, $Mg(H_4IO_6)_2 \cdot 4H_2O$ and $Mg(IO_4) \cdot 8H_2O$, are wrong and that the dimesoperiodate composition, $Mg(H_4I_2O_{10})_2 \cdot 6H_2O$, is the correct one. The Lewis structure would be (minus the waters of hydration) (Fig. 2.47).

This would mean that a direct bond between the iodine atoms had to exist. Whether this is true remains unsolved. Direct bonds in compounds like these are extremely rare and have not been documented. In addition, the molecular formula is described as $Mg(H_4I_2O_{10})_2 \cdot 6H_2O$ whereas it would have to be $Mg(H_6I_2O_{10})_2 \cdot 6H_2O$ if only one Mg^{2+} cation is present.

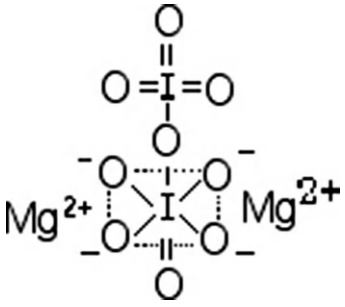

FIGURE 2.46

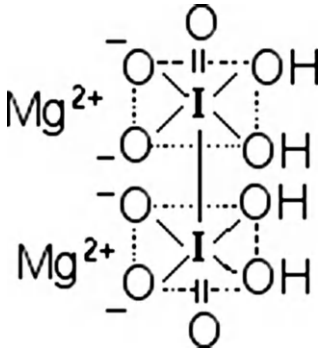

FIGURE 2.47

In this study, crystal structure, DRIFT, Infrared and Raman spectra were employed, and the results of thermal analyses of the hitherto wrongly described dimesoperiodate, $Mg_2(H_4I_2O_{10})_2 \cdot 6H_2O$, were reported. This compound crystallizes in the monoclinic space group $P2_1$ ($Z = 2$) with $a = 10.710$ Å, $b = 5.470$ Å, $c = 11.949$ Å, and $\beta = 112.58°$. The structure, which was refined from X-ray single-crystal data of the magnesium compound ($R_1 = 2.72\%$, 3824 independent reflections), is built up from isolated distorted $M(H_2O)_6^{2+}$ octahedra and dimesoperiodate ions, $H_4I_2O_{10}^{2-}$, connected by a network of hydrogen bonds formed by the $H_4I_2O_{10}^{2-}$ ions and six crystallographically different hydrate H_2O molecules. The strength of the hydrogen bonds ranges from unusually weak bonds corresponding to uncoupled (isotopically dilute samples) OD stretching modes of >2600/cm and very strong ones (OD <2200/cm). The IO stretching modes of the *trans*-configured $H_4I_2O_{10}^{2-}$ ions are assigned to terminal I–O groups (816/cm), I–OH groups (746 and 762/cm) and bridging I–O groups (618 and 647/cm). On heating, $Mg_2(H_4I_2O_{10})_2 \cdot 6H_2O$ undergoes dehydration in the range of 373–485 K (DSC) to two different polymorphs of magnesium metaperiodate, $Mg(H_4I_2O_{10})_2 \cdot 2(IO_4) + 2(H_2O)$. Anhydrous $Mg(IO_4)_2$ is unstable. Above 423 K (high-temperature Raman data), it decomposes to magnesium iodates and finally MgO.

However, another study confutes the above finding:

> "Crystals of hexaaquomagnesium trihydrogenhexaoxoiodate(VII), $[(Mg(OH_2)_6][H_3IO_6]$, are monoclinic, space group Pc1. The unit-cell constants are $a = 5.180$ Å, $b = 9.886$ Å, $c = 10.625$ Å, $\beta = 116.90°$, $Z = 2$. The structure consists of octahedral cations, $[Mg(OH_2)_6]^{2+}$, and octahedral anions, $(H_3IO_6)^{2-}$. The iodine–oxygen bond lengths range from 2.01 to 1.78 Å and the magnesium–water bond lengths range from 2.15 to 2.06 Å. The hexa-aquo-cations and the trihydrogenhexaoxo-iodato (VII) anions are held together by a dense network of hydrogen bonds. There are 14 independent possible hydrogen bonds 0…0, shorter than 2.86 Å, the shortest being 2.65 Å".

The Lewis structure for this octahedrally coordinated compound is shown as follows, where the waters of hydration are shown as well as that of the $(H_3IO_6)^{2-}$ anion (Fig. 2.48).

Thus, the question of the actual composition of magnesium periodate has not been answered satisfactorily.

Magnesium periodate is not used in Industry but is offered for sale in limited quantities commercially.

Calcium Periodate

m-Calcium periodate has the molecular formula, $Ca(IO_4)_2$, and the molecular weight of 421.8822 g/mol. O-calcium periodate has the molecular formula of $Ca(H_4IO_4)_2$ and the molecular weight of 425.9140 g/mol. They can be prepared by the reaction of periodic acid and calcium hydroxide:

$$Ca(OH)_2 + 2HIO_4 \Rightarrow Ca(HIO_4)_2 + H_2O$$

As in the case of the Mg^{2+} cation, the nature of the periodate compound produced depends upon concentration of the components, the temperature of precipitation and the mode of addition of the two solutions, including that of the $(Ca(OH))_2$ slurry. The meta-salt is formed when the acid is in excess and the ortho-salt when the hydroxide is in excess. However, a detailed study of these conditions upon the product produced has not been available.

The precipitate formed is relatively insoluble but no specific data has been presented. The meta-salt forms a monohydrate whereas the ortho-salt forms either a monohydrate or a tetrahydrate. The CAS number of m-$Ca(HIO_4)_2$ is 13478-04-1 while that of the ortho-salt is 77353-51-6. Calcium periodate is offered commercially as a variety of salts (Table 2.105 and Table 2.106).

A variety of molecular weights and molecular formulas are presented in the literature. The correct Lewis structure and formulas for these salts are shown in Fig. 2.49.

Note that at least one of the formulas given for the ortho-salt is incorrect. In addition, these salts are only offered in small quantities and are expensive.

According to the "Code of Federal Regulations", the food additive "calcium periodate" may be safely used in accordance with the following prescribed conditions:

(a) The additive is produced by reacting calcium iodate with calcium hydroxide or calcium oxide to form a substance consisting of not less than 60% by weight of penta calcium orthoperiodate containing 28%–31% by weight of iodine.

(b) It is used or intended for use in salt for livestock as a source of iodine.

This is the only commercial usage identifiable in the literature.

Additionally, a combination salt, calcium meta-orthoperiodate has been studied. Details on its preparation have not been forthcoming. Thermal decomposition of $Ca_2I_2O_9 \cdot 8H_2O$ in the temperature interval of 20–600 °C was studied by means of ETA and DTA. The calcium dimesoperiodate octahydrate upon thermolysis forms a hexavalent iodate, $CaIO_4$ as an intermediate product which with increasing temperature decomposes to its orthoperiodate, $Ca_5(10_6)_2$ via presumably the formation of $Ca_2I_2O_7$-type compounds. Its Lewis structure is shown in Fig. 2.50.

$CaIO_4$ compounds can be made from dimesoperiodates by heating at 220–240° for 2 h. The hexavalent state of iodine in $CaIO_4$ has been verified by chemical analysis, magnetic moment measurement and EPR spectra. These compounds undergo hydrolytic decomposition to metal iodate and hydroxide accompanied by the evolution of oxygen. The energy of activation, the order of reaction and the enthalpy change for the conversion of the iodates to the orthoperiodates have been evaluated by nonisothermal kinetic study.

As stated above, calcium periodate is available commercially and is used in Industry as a food additive for animals and some food products for humans.

Strontium Periodate

m-Strontium periodate has the molecular formula, $Sr(IO_4)_2$, and the molecular weight of 469.4242 g/mol. It has no CAS number. It can be formed by the reaction of periodic acid on strontium hydroxide:

$$Sr(OH)_2 + 2HIO_4 \Rightarrow Sr(IO_4)_2$$

A mono-hydrate of the metaperiodate, $Sr(IO_4)_2 \cdot H_2O$, is generally obtained. By crystallization from a strong acidic aqueous solution strontium-tetrahydrogen-hexaoxoperiodate-trihydrate $Sr(H_4IO_6)_2 \cdot 3H_2O$ has been obtained. In the structure of this compound (space group = P1, lattice parameters: $Z = 2$, $a = 6.361$ Å,

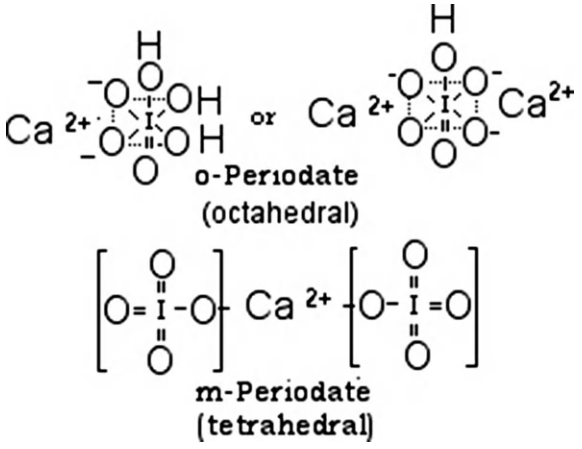

FIGURE 2.49

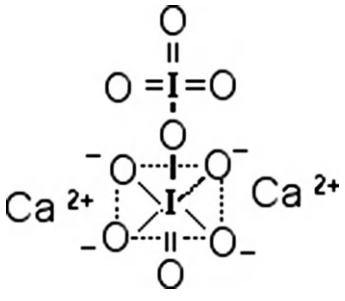

FIGURE 2.50

$b = 9.939$ Å, $c = 10.445$ Å, $\alpha = 114.54°$, $\beta = 95.61°$, and $\gamma = 97.11°$), two crystallographically different $H_4IO_6^-$ anions are linked by two and three common oxygen atoms, respectively, to $SrO_5(H_2O)_4$ polyhedra which are of the form of monocapped distorted square antiprisms. The IR- and Raman-spectra of this compound are analyzed with respect to the internal vibrations of the periodate anion and the O–H vibrations of the hydrogen bonds. The dehydration and decomposition of the compound, studied by thermal analysis, high-temperature Raman experiments and mass spectrometric analysis of the evolved gases, takes place via a metaperiodate $Sr(IO_4)_2$, results at 265 °C in the formation of $Sr(IO_3)_2$ in an exothermic reaction and finally $Sr_5(IO_6)_2$ is formed in a disproportionation reaction.

The dimesoperiodate of strontium, $Sr_2I_2O_9 \cdot 3H_2O$ on thermolysis forms a hexavalent iodate, $SrIO_4$, as an intermediate product which with increasing temperature decomposes to its orthoperiodate, $Sr_5(I0_6)_2$, via presumably the formation of $Sr_2I_2O_7$ type of compound. $SrIO_4$ compounds can be made from dimesoperiodates by heating at 220–240° for 2 h. The hexavalent state of iodine in $SrIO_4$ has been verified by chemical analysis, magnetic moment measurement and EPR spectra. This compound undergoes hydrolytic decomposition to metal iodate and hydroxide accompanied by the evolution of oxygen. Anhydrous strontium iodate prior to its decomposition undergoes a phase transition that is not observed in calcium iodate. The energy of activation, the order of reaction and the enthalpy change for the conversion of the iodate to the orthoperiodate has been evaluated by nonisothermal kinetic study.

Strontium periodate has not found usage in Industry and is not offered for sale commercially.

Barium Periodate

m-Barium periodate has the molecular formula, $Ba(IO_4)_2$, and the molecular weight of 519.1342 g/mol. It can be prepared by the reaction of periodic acid on barium hydroxide:

$$Ba(OH)_2 + 2HIO_4 \Rightarrow Ba(IO_4)_2$$

Its CAS number is 13718-58-6. This salt is relatively insoluble and can be removed from solution by filtration. It is a white powder and is a strong oxidizing agent that will explode if mixed with organics or other oxidizable compounds. By crystallization from strongly acidic aqueous solutions barium-tetrahydrogen-decaoxodiperiodatedihydrate, $BaH_4IO_{10} \cdot 2H_2O$ has been obtained (space group: C2/c, no. 15) with the lattice constants $a = 12.728$ Å, $b = 7.987$ Å, $c = 9.459$ Å, and $\beta = 94.07$). Its CAS number is 26946-37-2. IR and Raman spectra are given and analyzed with respect to the internal vibrations of the $H_4I_2O_{10}^{2-}$ ion and the hydrogen bond system. According to high-temperature Raman spectra and DTA and TGA measurements, the compound decomposes via unknown salts with the anion IO_4^- above 230 °C to the corresponding iodate which above 575 °C starts to disproportionate to the periodate $Ba_5(IO_6)_2$.

This would have the Lewis structure of Fig. 2.51.

Thermal decomposition of $Ba_2I_2O_9 \cdot 9H_2O$ (which is a combination of meta-orthoperiodate) in the temperature interval of 20–600° was studied by means of ETA and DTA. Its Lewis structure is shown in Fig. 2.52.

The dimesoperiodate of $Ba_2I_2O_9 \cdot 3H_2O$ on thermolysis form a hexavalent iodate, $BaIO_4$ as an intermediate product which with increasing temperature decomposes to its di-orthoperiodate, $Ba_5(IO_6)_2$, via presumably the formation of $Ba_2I_2O_7$-type compounds. $BaIO_4$ compounds can be made from di-mesoperiodates by heating at 220–240° for 2 h. The hexavalent state of iodine in $BaIO_4$ has been verified by chemical analysis, magnetic moment measurement and EPR spectra. These compounds undergo hydrolytic decomposition to metal iodate and hydroxide accompanied by the evolution of oxygen. Anhydrous barium iodate prior to its decomposition undergoes a phase transition, this change is less defined in the strontium compound and is not observed in calcium iodate. The energy of activation, the order of reaction and the enthalpy change for the conversion of

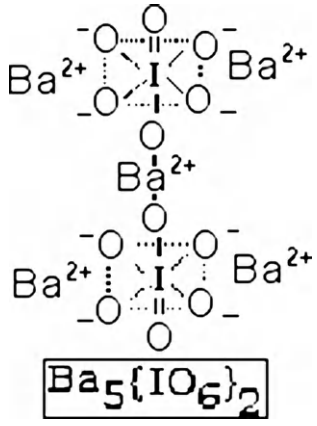

FIGURE 2.51

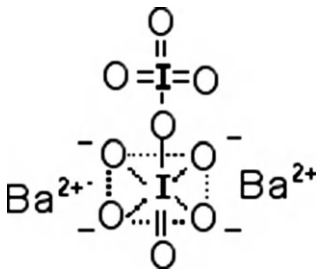

FIGURE 2.52

the iodates to the orthoperiodates have been evaluated by nonisothermal kinetic study.

Barium periodates are offered commercially for sale but only in limited quantities.

Radium Periodate

m-Radium periodate has the molecular formula, $Ra(IO_4)_2$, and the molecular weight of 607.8296 g/mol. It could be formed by the reaction of periodic acid on radium hydroxide:

$$Ra(OH)_2 + 2HIO_4 \Rightarrow Ra(IO_4)_2$$

However, there is no record of such a preparation and radium periodate remains unknown both to Industry and to commercial sales. Perhaps this is due to the radioactivity of ^{226}Ra and the lack of potential usage of such a compound.

2.6. ACTINIUM AND THE ALKALINE EARTHS

Although actinium is a member of the halide series of the periodic table, it is too electropositive and does not form any compounds with alkaline earths. Actinium is a radioactive element with the symbol **Ac** and atomic number of 89. It was discovered in 1899 by Andre Debeime, a French chemist. It was the first nonprimordial radioactive element to be isolated. Po, Ra and radon were observed before actinium, but they were not isolated until 1902. It was actinium that gave the name to the "Actinide" series of elements, a group of 15 similar elements between actinium and lawrencium in the periodic table.

A soft, silvery-white metal, actinium reacts rapidly with oxygen and moisture in air forming a white coating of actinium oxide that prevents further oxidation. As does most lanthanides and actinides, actinium assumes the +3 oxidation state in nearly all its chemical compounds and does not form any known compounds with the alkaline earths. Actinium is found only in traces in uranium ores as the ^{227}Ac isotope. This decays with a half-life of 21.772 years, predominantly emitting β-rays. About 0.2 mg of actinium is contained from 2000 lbs of uranium ore (907,600 g) or 22 ppb (parts per billion). The close similarity of physical and chemical properties of actinium and lanthanum makes separation of actinium from the uranium ore impractical. Instead, the element is prepared, in milligram amounts, by the neutron irradiation of ^{226}Ra in a nuclear reactor. Owing to its scarcity, high price and radioactivity, actinium has no significant industrial use. Its current applications include uses as a neutron source and an agent for radiation therapy, targeting cancer cells in the body. Only a limited number of actinium compounds are known including AcF_3, $AcCl_3$, $AcBr_3$, AcOF, AcOCl, AcOBr, Ac_2S_3, Ac_2O_3 and $AcPO_4$. Except for $AcPO_4$, they are all similar to the corresponding lanthanum compounds and contain actinium in the oxidation state +3.

Group 16 (O, S, Se, Te) Alkaline Earth Compounds

OUTLINE

3.1. Oxides and Hydroxides of the Alkaline Earths 106
3.1.1. Alkaline Earth Oxides 106
Beryllium Oxide 106
Magnesium Oxide 108
Calcium Oxide 109
Strontium Oxide 112
Barium Oxide 113
Radium Oxide 115
3.1.2. Alkaline Earth Hydroxides 116
Beryllium Hydroxide 116
Magnesium Hydroxide 118
Calcium Hydroxide 120
Strontium Hydroxide 122
Barium Hydroxide 123
Radium Hydroxide 124
3.1.3. Alkaline Earth Peroxides 124
Beryllium Peroxide 125
Magnesium Peroxide 125
Calcium Peroxide 126
Strontium Peroxide 128
Barium Peroxide 129
Radium Peroxide 130
3.1.4. Hyperoxides of the Alkaline Earths 130
Beryllium Hyperoxides 130
Magnesium Hyperoxides 130
Calcium Hyperoxides 130
Strontium Hyperoxides 131
Barium Hyperoxides 132
Radium Hyperoxides 132

3.2. Alkaline Earth Oxy-Sulfur Compounds 132
3.2.1. Oxy-Sulfur Acids 132
Hydrogen Sulfide 132
Sulfurous Acid 133
Sulfuric Acid 133
Thiosulfuric Acid 136
Pyrosulfuric Acid or Disulfuric Acid 136
Dithionic Acid 137
3.2.2. Alkaline Earth Sulfides 137
Beryllium Sulfide 137
Magnesium Sulfide 138
Calcium Sulfide 138
Strontium Sulfide 140
Barium Sulfide 141
Radium Sulfide 142
3.2.3. Alkaline Earth Sulfites and Bisulfites 142
Beryllium Sulfite 143
Magnesium Sulfite 143
Calcium Sulfite or Bisulfite 145
Strontium Sulfite 149
Barium Sulfite 149
Radium Sulfite 150
3.2.4. Alkaline Earth Sulfates 150
Beryllium Sulfate 150
Magnesium Sulfate 150
Calcium Sulfate 152
Strontium Sulfate 155
Barium Sulfate 156
Radium Sulfate 158
3.2.5. Alkaline Earth Thiosulfates 158
Beryllium Thiosulfate 158
Magnesium Thiosulfate 158
Calcium Thiosulfate 159
Strontium Thiosulfate 159
Barium Thiosulfate 160
Radium Thiosulfate 160

3.5. Polonium-Based Alkaline Earth Compounds 197

3.1. OXIDES AND HYDROXIDES OF THE ALKALINE EARTHS

The alkaline earth metals all form oxides, hydroxides, peroxides and superoxides. These compounds are used extensively in industry and are readily available commercially. A few, such as beryllium peroxide, are unknown. Most of the oxo-alkaline earth compounds are ubiquitous on the Earth and have been used for centuries, both domestically and industrially.

3.1.1. Alkaline Earth Oxides

Beryllium Oxide

Beryllium oxide (**BeO**) is a white crystalline oxide. It occurs in nature as the mineral "Bromellite". Historically, beryllium oxide was called **glucina** or glucinium oxide. It is an electrical insulator and its thermal conductivity is such that it is higher than any other nonmetal except diamond, and actually exceeds that of some metals. Its high melting point leads to its use as a refractory.

Beryllium oxide can be prepared by calcining beryllium carbonate, dehydrating the hydroxide or igniting the metal with oxygen gas, as shown in the following reactions:

$$BeCO_3 \Rightarrow BeO + CO_2$$

$$Be(OH)_2 \Rightarrow BeO + H_2O$$

$$2Be + O_2 \Rightarrow 2BeO$$

Igniting beryllium in air gives a mixture of BeO and the nitride Be_3N_2. Its CAS number is 1304-56-9 and its molecular weight is 25.0116 g/mol. It is a white solid with a density of 3.02 g/cm^3. Its melting point is 2507 °C, its boiling point is 3905 °C and its band gap (electronic) is 10.6 eV.

The heat of formation, $\Delta H_{f(solid)}$ is −609.4 kJ/mol while the standard molar entropy, $S_{\Theta(solid)}$ is 13.8 J/mol·K. Its heat capacity, C_p, is 25.6 J/mol·K. Beryllium oxide formed at high temperatures (>800 °C) is inert but may be easily dissolved in hot aqueous ammonium bifluoride (NH_4HF_2) or a hot solution of concentrated sulfuric acid (H_2SO_4) and ammonium sulfate ($(NH_4)_2SO_4$).

BeO is polymorphic. The low-temperature form is hexagonal (hP4) and its space group is $P6_3/mc$ (#186). The high temperature form, β-BeO, is tetragonal (c/2) and space group of Im3m. It is highly toxic to the human body. BeO at normal temperatures has the hexagonal wurtzite, from which differs from those of other members of Group 2, whose oxides have the cubic rock salt structure shown in Fig. 3.1.

The resulting structure has a BeO bond distance of 1.659 ± 0.003 Å parallel to the *c* axis and three distances of 1.645 ± 0.003 Å completing the tetrahedral coordination. The difference of 0.014 Å appears statistically significant and indicates that the long bond has slightly more ionic character than the other three. At high temperature, the structure transforms to a tetragonal form. BeO is a unique metallic compound in that it is a nonionic oxide. Lattice parameters are:

α-BeO: $a = 0.2288$ Å; $c = 0.4377$ Å (21 °C)

β-BeO: $a = 0.4751$ Å; $c = 0.2741$ Å (2103 °C)

Beryllium oxide is extracted from the naturally occurring minerals "Beryl"-$Be_3Al_2(SiO_3)_6$ and "Bertrandite"—$Be_4Si_2O_7(OH)_2$, and produced as a powder by the thermal decomposition of $Be(OH)_2$.

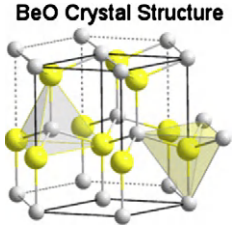

FIGURE 3.1

Sintered beryllium oxide, which is very stable, is used for rocket engines, catalysts, semiconductors, moderators-of-atomic-reactors, and neutron reflectors. When it is evaporated at temperatures around 2500 °C, as studied using graphite furnace atomic absorption spectrometry (GFAAS), beryllium has an atomization mechanism similar to the other alkaline earth elements with one significant difference. For the alkaline earth elements (Mg, Ca, Sr and Ba), the species preceding the appearance of the free element has been the simple oxide, MO. Beryllium, on the other hand, forms a polymeric oxide, $(BeO)_n$ and then release of the free element proceeds as follows:

$$BeO + \text{heat} \Rightarrow (BeO)_n\,(ad) \Rightarrow (BeO)_{n-1}(gas) + \cdots + BeO(gas)$$

$$BeO(ad) \Rightarrow Be(gas) + O(gas)$$

Beryllium oxide is used in many high-performance semiconductor parts for applications such as radio equipment because of its good thermal conductivity while also being a good electrical insulator. It is used as a filler in some thermal interface materials such as "THERMAL GREASE". Some high-powered semiconductor devices have used beryllium oxide ceramic between the silicon chip and the metal mounting base of the package in order to achieve a higher degree of thermal conductivity than for a similar construction made with Al_2O_3. It is also used as a structural ceramic for high-performance microwave devices, vacuum tubes, magnetrons and gas lasers. Currently, there are only two companies in the United States that manufacture beryllium oxide. These are American Beryllium Inc. in Haskell, NJ and Brush Ceramics in Tucson, AZ.

Beryllium oxide has a number of physical properties that are very attractive to industry (Table 3.1).

Beryllium oxide (BeO) is a space age technical ceramic material that offers a combination of desirable properties not found in any other material. Distinguished by excellent high heat and thermal conductivity, it retains dielectric constant, loss factor and dielectric strength in the range of most electrical insulators. Along with good mechanical strength and stiffness to weight ratios, this unique combination of properties provides designers with a material that can reduce the size of heat-generating circuitry while retaining essential high-power capability and improved thermal stability.

For certain applications, the use of a single-crystal of BeO is more appropriate. However, the very high melting point of BeO has been a deterrent. Recently, a method, which circumvents this difficulty, has come to the forefront. A process for growing large single crystals substantially free of surface inclusions within

TABLE 3.1

Impact resistance = 6 inch-lbs.
Maximum use temperature = 1800 °C

several days involves the concept of promoting further growth on seed crystals from a melt composition of suitable oxides which form a lower temperature eutectic. Growth occurs as the crystal seed is rotated and pulled slowly from the melt composition. The temperature decrease of such a melt is such that the temperature can be defined by the liquidus curve of the melt composition phase diagram. Growing single crystal beryllium oxide at a temperature of about 1980 °C from a melt composition having 56 wt% beryllium oxide and 44 wt% calcium oxide is an example of this process. The single crystal can be cut into thin slices for use in integrated circuitry.

Sintered beryllium oxide is a promising thermoluminescent material with a very low sensitivity to thermal neutrons (0.2 gamma rays equivalent per 1010 neutrons/cm^2). It has a fairly high sensitivity to gamma rays, and a good energy response. These properties enable beryllium oxide to be used successfully in mixed fields of thermal neutrons and gamma rays, such as exist in nuclear reactor facilities.

Beryllium and/or beryllium oxide in any form is quite expensive, and this fact limits their use. The current price (2004) for the powder metal was $375 per pound, and for copper master alloy, $160 per pound of Be content.

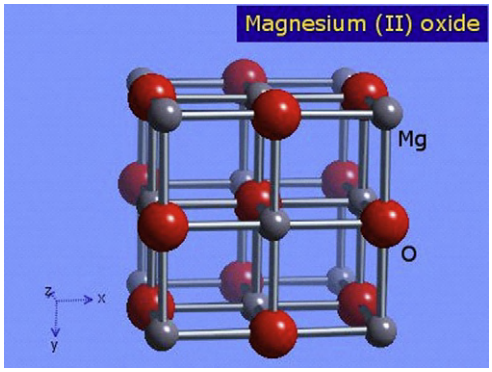

FIGURE 3.2

Magnesium Oxide

Magnesium oxide has the formula of MgO and can be formed by reacting the metal with oxygen gas. Magnesium oxide is easily formed by burning magnesium metal ribbon. Mg oxidizes and emits a bright white light, rich in ultraviolet and hard to extinguish. Extreme care must be taken if MgO is to be prepared by this method. Magnesia is a white solid mineral that occurs naturally as "Periclase" and is used as a source of magnesium metal. Magnesium oxide is hygroscopic in nature and care must be taken to protect it from moisture. It reacts with water and forms the hydroxide:

$$MgO + H_2O \Rightarrow Mg(OH)_2$$

However, this reaction can be reversed by heating it to remove moisture. MgO has the CAS number of 1309-48-2 and its molecular weight is 40.3044 g/mol. Its density is 3.58 g/cm^3. Its melting point is 2852 °C (3125 K, 5166 °F) and its boiling point is 3610 °C (3873 K, 6512 °F). It is slightly soluble in water at 0.0086 g/100 ml at 20 °C. MgO is an excellent insulator both electrically and electronically (with a band gap of 7.8 eV). It has a halite cubic structure (cF8) and a space group of Fm3 m (No. 225). Both Mg^{2+} and $O^{=}$ occupy octahedral positions in the structure in Fig. 3.2.

MgO is a very stable molecule. When it is evaporated, as studied using GFAAS. Mg oxide (MgO) and Ca oxide (CaO) vaporize from the graphite surface as oxides and in the vapor phase dissociates giving atoms.

The thermal conductivity of polycrystalline magnesium oxide has been measured over the temperature range from 400 to 1300 K using a modified guarded hot plate design. Three different thicknesses of specimens having 93% of theoretical density were tested to verify the operation, accuracy, and reproducibility of the apparatus. The measured thermal conductivity ranges from 30 W/m·K down to 8 W/m·K.

MgO is an efficient moisture absorbent used by many libraries for preserving books. It is also one of the raw materials for making cement in dry process plants;

specifically, Portland cement. If too much of MgO is added, the cement may become expansive.

In medicine, magnesium oxide is used for relief of heartburn and sore stomach, as an antacid, magnesium supplement, and as a short-term laxative. It is also used to improve symptoms of indigestion. Side effects of magnesium oxide may include nausea and cramping.

There are several grades of MgO supplied commercially. These are:

DEAD-BURNED MAGNESIUM OXIDE

Temperatures used when calcining to produce refractory grade magnesia will range between 1500 °C and 2000 °C and the magnesium oxide is referred to as "dead-burned" since most, if not all, of the reactivity has been eliminated. Refractory grade MgO is used extensively in steel production to serve as both protective and replaceable linings for equipment used to handle molten steel.

HARD-BURNED MAGNESIUM OXIDE

A second type of magnesium oxide produced from calcining at temperatures ranging from 1000 °C to 1500 °C is termed "hard-burned". Due to its narrow range of reactivity, this grade is typically used in applications where slow degradation or chemical reactivity is required such as with animal feeds and fertilizers.

LIGHT-BURNED MAGNESIUM OXIDE

The third grade of MgO is produced by calcining at temperatures ranging from 700 °C to 1000 °C and is termed "light-burn" or "caustic" magnesia. Due to the material's wide reactivity range, industrial applications are quite varied and include plastics, rubber, paper and pulp processing, steel boiler additives, adhesives, and acid neutralization to name just a few.

Using relatively simple chemistry, it is also possible to add certain ingredients to magnesium oxide to generate a broad range of new magnesium-based compounds. As in the high-purity magnesium oxide process, magnesium hydroxide slurry is a convenient medium for these additions. Examples of typical reactions are included in Table 3.2.

TABLE 3.2

Slurry reactants	Slurry + additive	End-product
$2MgO + 2H_2O \Rightarrow$	$2Mg(OH)_2 + 4HNO_3 \Rightarrow$	$2Mg(NO_3)_2 + 4H_2O$
$2MgO + 2H_2O \Rightarrow$	$2Mg(OH)_2 + 2H_2SO_4 \Rightarrow$	$2MgSO_4 + 4H_2O$
$2MgO + 2H_2O \Rightarrow$	$2Mg(OH)_2 + 2CO_{2(gas)} \Rightarrow$	$2MgCO_3 + 2H_2O$

MgO is used in many industrial areas, as shown in Table 3.3, presented on the next page.

- Magnesium oxide's ancient usage was mostly in masonry construction. It was used primarily as a mortar component and stabilizer for soil bricks. MgO has also been identified in the Great Wall of China and other ancient landmarks. Roman cement is reported to have contained high levels of MgO. In the U.S., Portland cement has replaced MgO for masonry uses.
- Due to its fire resistance and safety ratings, New York and New Jersey were early adopters of MgO board. Florida has adopted MgO for its mold/mildew resistance. It is hurricane and impact tested and approved in Florida.
- MgO board for building construction is available in various sizes and thickness. It is a nonpaper-covered material and generally light gray, white or beige in color. It comes in various grades, such as smooth finishes, rough textures, and utility grades.
- It is used as a reference white color in colorimetry, owing to its good diffusing and reflectivity properties. It may be smoked onto the surface of an opaque material to form an integrating sphere.
- It is used extensively in electrical heating as a component of "CalRod"-styled heating elements. There are several types available and most commonly used ones are 40 and 80 mesh, as per the American Foundry Society. The extensive use is due to its high dielectric strength and average thermal conductivity. MgO is usually crushed and compacted with minimal air gaps or voids. The electrical heating industry also experimented with Al_2O_3, but it is not used anymore.
- Pressed MgO is used as an optical material. It is transparent from 0.3 to 7 μm. The refractive index is 1.72 at 1 μm and the Abbe number is 53.58. It is sometimes known by the Eastman Kodak Co. trademarked name **Irtran-5**, although this designation is long since obsolete. Crystalline pure MgO is available commercially and has small use in infrared optics.

MgO is manufactured in a number of areas around the world, primarily near areas where MgO ore ("periclase" = MgO) deposits are mined. Major deposits are found in China, Europe, and Canada. MgO ore deposits in the US are negligible. Estimates put the use of MgO board products at 8 million SQF in Asia alone. It is gaining popularity in the US, particularly near coastal regions.

MgO is available in large quantities commercially.

Calcium Oxide

Calcium oxide (CaO), commonly known as **quicklime**, is a widely used material. It is a white, caustic, alkaline solid at room temperature. As a commercial

TABLE 3.3

Area of industry	Usage
Abrasives	As a binder in grinding wheels
Animal feed supplement	Source of magnesium ions for chickens, cattle and other animals
Boiler (oil-fired) additives	Raises melting point of ash generated to produce a friable material that is easily removed; reduced corrosion of steel pipes holding steam as well as sulfur emissions into the environment
Boiler feedwater treatment	Reduces iron, silica and solids
Chemicals	Starting point for the production of other magnesium salts such as sulfate and nitrate
Coatings	Pigment extender in paint and varnish
Construction	Basic ingredient of oxychloride cements used for flooring, wallboard, fiber board, and tile
Electrical	Semiconductors; heating elements insulating filler between wire and outer sheath
Fertilizers	Source of essential magnesium for plant nutrition
Foundries	Catalyst and water acceptor in shell molding
Glass manufacture	Ingredient for specialty, scientific and decorative glassware and fiberglass
Insulation	Light, flexible mats for insulating pipes
Lubricating oils	Additive to neutralize acids
Pharmaceuticals	Special grades of magnesium hydroxide, oxide and carbonate are used in antacids, cosmetics, toothpaste, and ointments
Plastics manufacture	Filler, acid acceptor, thickener catalyst and pigment extender
Refractory and ceramics	Basic ingredient in product formulations for the steel industry
Rubber compounding	Filler, acid acceptor, antiscorch ingredient, curing aid, pigment
Steel industry	Annealing process; coating for grain-oriented silicon steel used in electrical transformers
Sugar refining	Reduces scale build-up when used in juice clarification and precipitation
Sulfite wood pulping	Source of base for cooking liquors
Uranium, gallium and boron processing	Precipitation initiator by acid neutralization
Wastewater treatment	Acid stream neutralizer; precipitates heavy metals
Building construction	MgO is a versatile material used in residential and commercial building Construction. It is suitable for a wide range of general building board usages and for applications requiring a fire rating as well as mold and mildew control as well as sound control applications. MgO boards were approved for construction use in the US around 2003.

product, lime often also contains MgO, silicon oxide (sand) and smaller amounts of aluminum oxide and iron oxide. This is due to the fact that "limestone" contains these impurities. It is primarily $CaCO_3$ which when fired at high temperatures forms CaO:

$$CaCO_3 + \text{heat} \Rightarrow CaO + CO_2$$

This is accomplished by heating the material to about 825 °C, a process called "calcination" or *lime burning*, to liberate a molecule of CO_2, leaving "quicklime". This process is reversible, since once the quicklime product has cooled, it immediately begins to absorb carbon dioxide from the air, until, after enough time, it is completely converted back to calcium carbonate. The CAS number of CaO is 1305-78-8 and its molecular weight is 56.0768 g/mol. It is a white to pale yellow powder with a density of 3.35 g/cm^3. Its melting point is 2572 °C and its boiling point is 2853 °C. It is soluble in acids, glycerol and a sugar solution. If dissolved in water ($Ca(OH)_2$) exhibits a pH of 12.5. CaO has the cubic "halite" structure. Calcium oxide transforms from the B1 (sodium chloride type) to the B2 (cesium chloride type) structure at 60 to 70 GPa (0.6 to 0.7 megabar) pressure with a volume decrease of 11%.

The CaO molecule is relatively stable even in the vapor state. When the evaporation of CaO was using GFAAS, Ca oxide (CaO) vaporized from the graphite surface as oxides and in the vapor phase dissociated, thereby giving atoms.

Quicklime is very corrosive and reacts violently with water. A relatively inexpensive substance, quicklime produces heat energy by the formation of the hydrate, calcium hydroxide, as in the following equation:

$$\mathrm{CaO(solid) + H_2O(liq) \Rightarrow Ca(OH)_2\ (aq)} \times (\Delta H_f = -63.7\ \mathrm{kJ/mol\ of\ CaO})$$

The hydrate can be reconverted to quicklime by removing the water in the reversible equation. If the hydrated lime is heated to redness, the quicklime will be regenerated to reverse the reaction. As it hydrates, an exothermic reaction results. One liter of water combines with approximately 3.1 kg of quicklime to give calcium hydroxide plus 3.54 MJ of energy. This process can be used to provide a convenient portable source of heat, as for on-the-spot food warming in a self-heating can.

The production of calcium oxide from limestone is one of the oldest chemical transformations produced by man. Its use predates recorded history. Most ancient languages have a word for calcium oxide. In Latin it is *calx*, from which the name of the element calcium is taken. In Old English, its name is *lïm*, which is the origin of the modern commercial name for calcium oxide, namely lime. The abundance of limestone in the Earth's crust and the ease of its transformation to calcium oxide do not alone explain why the lime is one of the oldest products of chemistry. Lime has many properties that make it quite valuable. It is so useful, that it is today produced industrially on a vast scale; over 20 million metric tons were produced in the U.S. in 2000.

Lime is produced in several grades or types. If the limestone is fired at about 850 °C, a "Standard Quicklime" grade is produced which is used in most applications.

The use of powdered calcium oxide with a surface area of about 4 cm^2/g, obtained by calcining calcium carbonate at 1250 °C, yields dense, defect-free specimens. Firing then at 1700–1750 °C yields nearly fully sintered ceramics of relative density 0.91–0.92 with an open porosity of about 0.5%.

An increase in the firing temperature to 2000 °C in a vacuum furnace in argon, or an increase in the sintering period in a flame furnace, leads to a certain further densification (relative density 0.93–0.94). The sintered, defect-free specimens of CaO of enhanced purity can be stored in air without damage for long periods (for a period of a month).

In contrast, if 325-mesh (43 μm) particles of $Ca(OH)_2$, formed by precipitation from solution, are fed slowly into a hot (750–780 °C) fluidized-bed furnace, nanosized quick lime results which is extremely reactive to air and moisture. Nanoscale calcium oxide particles are typically 20–80 nm with specific surface area (SSA) in the 15−50 m^2/g range and also available in with an average particle size of 100 nm range with a SSA of approximately 5−10 m^2/g. Nano calcium oxide particles are available in ultrahigh and high purity, transparent, and coated and dispersed forms. They are available as a nanofluid as well. Nanofluids are generally defined as suspended nanoparticles in solution either using surfactant or surface charge technology. Nanofluid dispersion and coating selection technical guidance is also available. Nanostructures available include nanorods, nanowhiskers, nanohorns, nanopyramids and other nanocomposites. Surface functionalized nanoparticles allow for the particles to be preferentially adsorbed at the surface interface using chemically bound polymers. Development research is underway in nano electronics and photonics materials, such as MEMS and NEMS, bio-nano materials, such as bio-markers, biodiagnostics and bio-sensors, and related nano materials, for use in polymers, textiles, fuel-cell layers, composites and solar energy materials. The most important usage today is in dental work where implants are positioned.

Quicklime or CaO, as hydrated or "slaked lime" $Ca(OH)_2$ (mineral "portlandite"), is used in mortar and plaster. Lime is also used in glass production and its ability to react with silicates is also used in modern metal production industries (steel in particular) to remove impurities as "slag".

Lime is also used in water and sewage treatment to reduce acidity, as a flocculent in swimming pools to remove phosphates and other impurities; in paper making to dissolve lignin, and in paper bleaching as a coagulant; in agriculture to improve acidic soils; and in gas scrubbers to desulfurize waste gases and to treat many liquid effluents. It has traditionally been used in the burial of bodies in open graves, to hide the smell of decomposition, as well as in forensic science, to reveal fingerprints.

Perhaps the most commercially important property of lime is its ability to form solutions with silicates. When lime is heated with silica sand (SiO_2) and sodium carbonate (Na_2CO_3), a solution is formed that does not crystallize when it is cooled. Instead, it hardens to an amorphous, clear, and nearly colorless solid, namely "soda lime" glass. Because it is a mixture and not a pure compound, glass does not have a distinct melting point; it gradually softens as it is heated. Therefore, it can be molded and blown into many useful shapes. The production of glass from lime is another of the ancient uses of lime and dates back at least 12,000 years.

The most important modern use of lime also relies on its ability to form solutions with silicates. Nearly, 45% of lime produced is used in the steel industry. Steel and iron are smelted from ores, which are rocks that contain iron oxides. Many of these ores also contain a large amount of silicates. When lime is mixed with the ore

and the mixture melted, these silicates combine with the lime, forming a liquid solution called slag. Slag is immiscible with molten iron, so the silicates can be removed from the iron by draining off the slag. Approximately, 80 kg of lime is used in the production of each metric ton (1000 kg) of iron. Lime is also used in the production of other metals. For example, it is used to remove silicates from alumina (Al_2O_3) before the alumina is reduced to aluminum metal.

Lime is also an important material in the manufacture of chemicals. Its major use here is in the production of calcium carbide, CaC_2. Calcium carbide is manufactured by heating lime with coke:

$$2CaO(solid) + 5C(solid) \Rightarrow 2CaC_2(solid) + CO_2(gas)$$

Calcium carbide reacts with water, releasing acetylene:

$$CaC_2(solid) + H_2O(liq) \Rightarrow C_2H_2(gas) + Ca(OH)_2(solid)$$

Acetylene is an important fuel for welding and is also a starting material for a range of organic compounds, including vinyl chloride, neoprene, and acrylonitrile, all of which are raw materials for polymers. Pollution control is a rapidly expanding consumer of lime. Lime is also used in stack gas scrubbers to reduce sulfur dioxide emissions from power plants. Sulfur dioxide reacts with lime to form solid calcium sulfite:

$$SO_2(gas) + CaO(solid) \Rightarrow CaSO_2(solid)$$

Lime is added to sewage to remove phosphates as well:

$$3CaO(solid) + 3H_2O(liq) + 2PO_4^{3-}(aq) \Rightarrow Ca_3(PO_4)_2(solid) + 6OH^-$$

The pretreatment of water supplies involves the use of lime to decrease the acidity, to soften, and to clear drinking water.

A variety of other industrial processes also make extensive use of lime. It is used as an opacifier in plastics. The paper industry uses it in pulping wood; because lime is highly alkaline, it dissolves the lignin that binds the fibers together in wood. Precipitated calcium carbonate (PCC), calcium oxide, and calcium hydroxide have a diverse range of functionality in the paper industry. Calcium carbonates are used in both paper coating and as a paper filler, while calcium oxide and calcium hydroxide are used in pulp/PCC manufacturing applications. In the refining of sugar, lime causes coagulation of plant material, allowing it to be more easily separated from the sugar syrup.

When quicklime is heated to 2400 °C (4300 F), it emits an intense glow. This form of illumination was known as a "limeLight", and was used broadly in theatrical productions prior to the invention of electric lighting.

Annual worldwide production of quicklime is around 283 million metric tons. China is by far the world's largest producer, with a total of around 170 million metric tons per year. The United States is the next largest with around 20 million metric tons per year in 2000.

Calcium oxide is available in large quantities commercially.

Strontium Oxide

Strontium oxide has the formula of SrO and the molecular weight of 103.6225 g/mol. Strontium oxide or **strontia**, SrO, is formed when Sr metal reacts with oxygen:

$$2Sr + O_2 \Rightarrow 2SrO$$

Burning strontium in air results in a mixture of strontium oxide and strontium nitride. It also forms from the decomposition of strontium carbonate $SrCO_3$. It is a strongly basic oxide. SrO has the CAS number of 1314-11-0 and a density of 4.70 g/cm^3. Its melting point is 2531 °C and its boiling point exceeds 3000 °C. It reacts with moisture forming the hydroxide and with carbon dioxide in the air to form the carbonate. However, the latter reaction is much slower than that of MgO. SrO has the halite (cubic-NaCl) structure with both Sr^{2+} and $O^{=}$ atoms in octahedral positions within the structure. The space group is Fm3M (#25). The enthalpy of formation, ΔH_f, is –592.036 kJ/mol (−141.50 kcal/mol) and the entropy S_0, is 55.5271 J/K. (−13.271 cal/mol) (Fig. 3.3).

Specific heat capacity, C_P, is 44.41 J/mol·K and the Gibbs Free energy, ΔG_f^0, is –562.4133 kJ/mol, (−134.42 kcal/mol).

SrO is a relatively stable molecule. When evaporated above 2500 °C, it first forms SrO molecules in the vapor state (as determined by GFAAS). SrO vaporizes from the graphite surface as oxides and in the vapor phase dissociates giving atoms.

There has been some uncertainty surrounding the vaporization of Sr oxide. It was suggested that SrO(s) vaporizes directly to SrO(g). However, mass spectrometric studies by others suggested direct formation of the gaseous elements from the solid oxide. Nagdaev and Bukreev (using a graphite rod atomizer) showed that the most probable mechanism for free Sr and Ba atom formation is

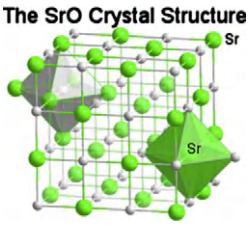

FIGURE 3.3

sublimation of the oxide with dissociation in the gas phase which directly preceded the appearance of free Sr atoms.

SrO decomposes above 3000 °C. A quadrupole mass filter was used to establish the partial pressures of Sr(g) and SrO(g) over strontium oxide heated on a platinum-ribbon filament. The ion currents of $^{88}Sr^{+}$ and $^{88}Sr^{16}O^{+}$ were measured while the filament temperature was continuously increasing at a heating rate of about 14 °C/min; the calculations of the partial pressures were carried out by the integral method for Sr(g) and by the sensitivity-calibration method for SrO(g). The data are represented by:

$$\log P_{Sr(g)}(\text{mm Hg}) = 6.633\text{–}2.536 \times 10^4/T$$

in the temperature range of 1643–1851 K, and by:

$$\log P_{SrO(g)}(\text{mm Hg}) = 6.707\text{–}2.793 \times 10^4/T$$

in the 1747–1850 K range. From the values of the partial pressures, the dissociation energy of strontium oxide was determined to be $D_0^\circ(\text{SrO}) = 96.2$ kcal/mol by the third-law treatment and $D_0^\circ(\text{SrO}) = 102 \pm 5$ kcal/mol by the second-law treatment.

About 8% by weight of TV picture tube glass is strontium oxide, which has been the major use of strontium since 1970. Color televisions and other devices containing color CRT's sold in the United States are required by law to use strontium in the faceplate to block X-ray emission. (PbO can be used in the neck and funnel, but causes discoloration when used in the faceplate.)

SrO is also used in medicine, pyrotechnics, pigments, greases, soaps, and as a chemical intermediate. It is also produced as high-purity strontium oxide rotatable sputtering targets with the highest possible density and smallest possible average grain sizes for use in semiconductor, photovoltaic, and coating applications by chemical vapor deposition and physical vapor deposition and optical applications. Most oxide compounds are not conductive to electricity. However, certain perovskite-structured oxides are electronically conductive finding application in the cathode of solid oxide fuel cells and oxygen-generation systems. "Sputtering" allows for thin film deposition of an ultra high-purity sputtering oxide material onto another solid substrate by the controlled removal and conversion of the target material into a directed gaseous/plasma phase through ionic bombardment.

One of the reasons why rare metals are restrained from wide use in production is their high cost. Strontium and its oxide are an exception: 1 kg of strontium oxide costs no more than 1 dollar. Low price and unique characteristics of strontium, its oxide and salts are in favor of their wide use in metallurgy, mechanical engineering and other branches of industry. Promising branches of industry in which strontium is being used are automobile construction, production of modifiers for aluminum casting, electronics (photomagnetic elements of memory), laser technology (active material for solid lasers), and manufacturing of high-temperature superconducting ceramics.

Samples of strontium oxide on nickel alloy or platinum substrates show a blue-green luminescence when excited at 100 K with photons of energy greater than 3·9 eV (318 nm). The emission spectrum shows peaks at 2·1 (591 nm), 2·8 (443 nm) and 3·1 eV (400 nm), the 3·1 eV peak increasing in intensity as the oxide sample is subjected to thermion activation. In SrO samples, luminescence maxima were observed at photon energies of 4.9 eV (253 nm), 3.7 eV (335 nm), 3.2 eV (388 nm), and 2.4 eV (517 nm). The 4.9-eV band intensity increases with the thermion activity of the sample whereas that of the 3.2-eV band decreases.

In vacuum tubes, a "hot" cathode is an electrode which emits electrons due to "thermion emission" ("Cold" cathodes emit electrons by "field emission" and do not require heating). The heating element is usually a coiled tungsten electrode. SrO has long been used in "Triple-Carbonate" mixtures applied to such electrodes that are used in electronic devices such as TV guns which emit electrons to excite a phosphor screen in color TV tubes or fluorescent lamps. In all of these, the electrode, made from coiled-coil tungsten wire, is heated to incandescence (~800–900 °C). The coil is first coated with a mixture of Ba–Sr–Ca carbonates which decompose to the oxides when the coil is "activated" by applying an electrical current. A maximum of 750 °C (dull red heat) is used for decomposition to prevent loss of barium during the activation stage. The oxide coating thereby formed lowers the "work-function" of the tungsten surface and allows a longer life of the electrode during the ionic emission of electrons during the life of the device. Typically made of a selected mixture of barium, strontium and calcium oxides, the coating is sputtered away through normal use, eventually resulting in failure of the device.

Strontium oxide is readily available for sale commercially in large lots. Its usage in industry is expanding every year.

Barium Oxide

Barium oxide has the molecular formula of BaO. It is a white, hygroscopic formed by the burning of Ba metal in oxygen or the decomposition of the carbonate salt:

$$2\text{Ba} + \text{O}_2 \Rightarrow 2\text{BaO}$$

$$\text{BaCO}_3 \Rightarrow \text{BaO} + \text{CO}_2$$

It transforms into the hydroxide on contact with water.

$$\text{BaO} + \text{H}_2\text{O} \Rightarrow \text{Ba(OH)}_2$$

Its CAS number is 1304-28-5 and its molecular weight is 153.3328 g/mol. Its density is 5.72 g/cm^3 and its melting point is 1924 °C. Its boiling point is close to 2000 °C. Its solubility in water is 3.48 g/100 ml but it rapidly transforms to the hydroxide. It is soluble in ethanol, dilute acids and alkalis but insoluble in acetone and liquid ammonia. BaO has the cubic structure (cF8) and the space group–Fm3m (#225).

Three oxides of barium are known, namely, the monoxide, BaO, the peroxide, BaO_2, and a suboxide, obtained by heating BaO with Mg in a vacuum to 1100 °C. The monoxide is formed when the metal burns in air, but is usually prepared by the ignition of the nitrate, oxygen and oxides of nitrogen being liberated. It can also be obtained by the ignition of an intimate mixture of the carbonate and carbon, and in small quantities by the ignition of the iodate. It is a grayish-colored solid, which combines very energetically with water to form the hydroxide, much heat being evolved during the combination; on heating to redness in a current of oxygen it combines with the oxygen to form the dioxide, which at higher temperatures breaks up again into the monoxide and oxygen.

The following are thermodynamic values determined for BaO (Table 3.4).

BaO is a stable molecule even in the gaseous phase. It has been studied using GFAAS. For Ba, the oxide is thought to exist predominately in the vapor phase as a gas. Free Ba is formed from the gas phase thermal dissociation of the oxide and thermodynamic calculations show that the hydroxide (gaseous and liquid) and the gaseous oxide are the precursors to gaseous Ba atom formation. One investigator added oxygen to the purge gas to produce signal shifts giving evidence in support of the gaseous oxide dissociation hypothesis. The final analysis showed BaO as the precursor to Ba atom formation during the evaporation of this oxide.

Barium oxide is used as a coating for "hot cathodes" in a variety of electronic devices such as TV's and lamps. It replaced lead oxide in the production of certain kinds of glass. While lead oxide raised the refractive index of the glass, it also raised the dispersion, i.e refraction of various colors of light resulting in distortion of images which barium oxide does not alter. Barium oxide also has use as an ethoxylation catalyst in the reaction of ethylene oxide and alcohols which takes place between 150 and 200 °C. Nanoscale Barium Oxide Particles are typically 20–80 nm with SSA in the $10-50$ m^2/g range and also available in with an average particle size of 100 nm range with a SSA of approximately $7-10$ m^2/g. Nano barium oxide particles are also available in ultrahigh purity and high purity, transparent, and coated and dispersed forms. They are also available as a nanofluid through the AE Nanofluid production group. Nanofluids are generally defined as suspended nanoparticles in solution either using surfactant or surface charge technology. Applications for barium oxide nanocrystals include as a flame retardant in coatings, plastics, fiber and textiles and in certain alloy and catalyst applications.

In vacuum tubes, a "hot" cathode is an electrode that emits electrons due to "thermionic emission" ("cold" cathodes emit electrons by "field emission" (application of an electric field) and do not require heating). The heating element is usually a coiled tungsten electrode. SrO has long been used in "triple-carbonate" mixtures applied to such electrodes that are used in electronic devices such as TV guns that emit electrons to excite a phosphor screen in color TV tubes or fluorescent lamps. In all of these, the electrode, made from coiled-coil tungsten wire, is heated to incandescence (~800–900 °C). The coil is first coated with a mixture of Ba–Sr–Ca carbonates which decompose to the oxides when the coil is "activated" by applying an electrical current. A maximum of 750 °C (dull red heat) is used for decomposition to prevent loss of barium during the activation stage. The oxide coating thereby formed lowers the "work-function" of the tungsten surface and allows a longer life of the electrode during thermionic emission of electrons during the life of the device. Typically made of a selected mixture of barium, strontium and calcium oxides, the coating is sputtered away through normal use, eventually resulting in failure of the device.

The thermionic emission from thin evaporated films of barium oxide has been studied extensively. Thin barium oxide films have a good emission following evaporation. The emission improves a little during heat treatment, and is then similar to that from a sprayed cathode coating of barium oxide. There is a maximum emission at a thickness of 10^{-5} cm. The method of

TABLE 3.4

State of matter, Gibbs free energy		Enthalpy of formation			Entropy of formation	
	(kcal/mol)	(kJ/mol)	(cal/K)	(J/K)	(kcal/mol)	(kJ/mol)
(s)	−131.0	−548.104	17.23	72.09032	−124.38	−520.40592
(l)	−117.50	−491.62	23.08	96.56672	−112.63	−471.24392
(g)	−29.60	−123.8464	56.25	235.35	−34.61	−144.80824

Knudsen has been applied to this problem. In this method, the oxide escapes through a small aperture in the wall of a "blackbody'" at a rate so small that the equilibrium vapor pressure is not sensibly disturbed. The final results are in agreement with those of Claassen and Veenemans. The vapor pressure of barium oxide is given by:

Log_{10} p (mm Hg) $= 8.63 - 19.400 \times 10^3/\mathrm{T}$ (1200–1800 K).

In another paper, it was determined that excess barium, which is indispensable to a well-activated oxide cathode, can exist in two forms in BaO crystal: oxygen vacancies and barium ultrafine particles (UFPs). When the density of the oxygen vacancies exceeds the critical value, the formation and the growth of the barium UFPs take place. Some experimental results related to BaO crystal with excess barium are interpreted, and the role of barium UFPs is accentuated. The optical absorption of BaO around photon energy 2.0 eV is attributed to barium UFPs embedded in BaO, and the low work function of the oxide cathode is considered to arise from the presence of oxygen vacancies. The physical origin of the photoemission from the oxide cathode bears a resemblance to that of the photoemission from Ag–O–Cs cathode in visible and infrared region.

The field emission microscope has been used to investigate the state of adsorption of barium oxide molecules deposited on tungsten by evaporation. Precautions are taken so as to keep the tube pressure at ultra high vacuum. Pulse method is adopted to protect the state of adsorption from changing with steady application of intense fields. Surface migration of adsorbed molecules over the entire surface is pronounced only above 700 °C and its activation energy is about 4.6 eV. Work function decreases very rapidly for the first 0.15 layer with the rate which can be explained quantitatively by considering the adsorbed molecules as oriented dipoles. The mean dipole moment of an adsorbed molecule is estimated to be $(13.5 \pm 8.1) \times 10\text{^}<-18>$ esu. Crystallites of barium oxide are formed when covering factor amounts to about unity.

BaO is a critical component of "high-temperature" superconductors, discovered in 1987. The following describes how this material is prepared.

PREPARATION OF THE CERAMIC OXIDE SUPERCONDUCTORS

The most common method of making the yttrium-barium-copper oxide superconductors is to mix dry powders of yttrium oxide, barium carbonate, and cupric oxide in the proper molecular ratios. (Barium carbonate is used instead of barium oxide because commercially available barium oxide is very impure. Also, much of the barium oxide tends to be converted into barium hydroxide and barium carbonate upon exposure to air.)

After the chemicals are thoroughly mixed, they are heated in a furnace at about 950 °C for about 18 h. This forms the basic crystal structure and eliminates the carbon dioxide from the barium carbonate. The chemical reaction that occurs in this step is:

$$0.5Y_2O_3 + 2BaCO_3 + 3CuO \Rightarrow YBa_2Cu_3O_{6.5} + 2CO_2$$

This first firing results in a porous dark gray or black clump. If the powders are not mixed well enough, a green phase will appear as well. This mass is ground into a fine powder and placed again in the furnace. This time an oxygen flow is maintained as the material is heated to about 950 °C for about 18 h. After this firing, the sample will show some signs of superconductivity. But an additional grinding and firing under flowing oxygen is usually necessary to obtain a good quality superconductor. In the process of being heated under oxygen flow, the oxygen content of each crystal unit is increased from 6.5 atoms of oxygen to approximately 7. There was considerable uncertainty during much of 1987 about the "ideal" oxygen content. One early report showed that a good yttrium-based superconductor had an oxygen content of 6.72[5]. It is now generally believed that the compound should have an oxygen content that is as close to 7 as possible. The chemical formula of the superconducting compound is:

$$YBa_2Cu_3O_7$$

The rate of cooling in this final firing must not exceed 100°/h until the temperature of the material is below 500 °C. This slow rate of cooling is an absolute necessity for producing superconductors with a critical temperature above the temperature of liquid nitrogen.

Barium oxide is available in large lots commercially and is being used in industry in new applications each year.

Radium Oxide

Radium oxide has the molecular formula of RaO and a molecular weight of 241.9994 g/mol. Its CAS number is 12143-02-1. It can be prepared by heating radium metal in air to give a mixture of white radium oxide, RaO, and radium nitride, Ra_3N_2. The superoxide RaO_2 is also likely to form in this reaction. Radium, four places below magnesium in the periodic table is more reactive with air than magnesium:

$$2Ra(solid) + O_2(gas) \Rightarrow 2RaO(solid)$$

$$Ra(solid) + O_2(gas) \Rightarrow RaO_2(solid)$$

$$3Ra(solid) + N_2(gas) \Rightarrow Ra_3N_2(solid)$$

Radium reacts very readily with water to form radium hydroxide, $Ba(OH)_2$ and hydrogen gas (H_2).

The reaction is expected to be more violent than that of barium:

$$Ra(solid) + 2H_2O(gas) \Rightarrow Ra(OH)_2(aq) + H_2(gas)$$

Reported are the mechanism of vaporization and optimum experimental conditions for the determination of Ra by electrothermal vaporization inductively coupled plasma mass spectrometry (ETV-ICP-MS). Calculated and published data along with new experimental results suggest that this element is vaporized from the surface of the graphite tubes oxides. These oxides are then transported to the argon plasma where dissociation and ionization take place. Appearance temperatures and maximum pyrolysis temperatures obtained experimentally generally agree with values obtained using GFAAS. For Ra, the optimum pyrolysis and vaporization temperatures were 1400 and 2500 °C, respectively.

Radium oxide is often used as a precursor to the formation of other radium compounds which are used in radiotherapy of humans.

3.1.2. Alkaline Earth Hydroxides

All of the alkaline earths form hydroxides, many of which are used extensively in industry. "Slaked Lime" is just one example where $Ca(OH)_2$ is used in paper making. The alkaline earth hydroxides can be divided into two groups depending on the hydration of the solid. First, the sparingly soluble anhydrous beryllium, magnesium and calcium hydroxides, whose freshly precipitated solids are poorly crystalline and show decreasing solubility with aging, and whose solubility in water decreases with increasing temperature. Second, the soluble strontium and barium hydroxide octahydrates that form crystalline precipitates which do not show changes in solubility on aging, and whose solubility in water increases with increasing temperature.

Beryllium Hydroxide

Beryllium hydroxide has the formula $Be(OH)_2$ and the molecular weight of 43.0268 g/mol. A more likely formula is $Be(OH)^+OH^-$. It can be prepared by reacting the oxide with water:

$$BeO + H_2O \Rightarrow Be(OH)_2$$

It is a white solid with a density of 1.92 g/cm^3. Its heat of formation, ΔH_f, is –20.98 kJ/g and its specific heat capacity, C_p, is 1.443 J/K. If heated, it decomposes at 1273 °C. Its solubility in water is slight and its solubility product $K_{sp(H_2O)}$ is 6.92×10^{-22}. It is soluble in acids and bases. The enthalpy of formation, ΔH_f, is –902.5 kJ/mol; the Gibbs free energy, ΔG_f^0, is –815.0 kJ/mol; Entropy of formation, S_0, is 45.5 J/mol and the heat capacity, C_P, is 62.1 J/mol. Its vapor pressure at 25 °C is 24.5 mm Hg, probably because there is a negligible enthalpy of vaporization of 45.5 J/mol K.

Beryllium hydroxide, $Be(OH)_2$, is an amphoteric hydroxide, dissolving in both acids and alkalis. Industrially it is produced as a by-product in the extraction of beryllium metal from the ores, "beryl" and "bertrandite" When alkali is added to beryllium salt solutions, the α-form (a gel) is formed. If this left to stand or boiled the rhombic β-form precipitates. This has the $Zn(OH)_2$ structure with tetrahedral beryllium centers. The alkali dissolution forms a "beryllate":

$$2NaOH(aq) + Be(OH)_2(solid) \Rightarrow Na_2Be(OH)_4(aq)$$

With acids, beryllium salts are formed involving the $Be(OH)^+$ cation. With sulfuric acid, H_2SO_4:

$$2Be(OH)_2 + H_2SO_4 \Rightarrow [Be(OH)]_2SO_4 + 2H_2O$$

Thus, the probable formula for beryllium hydroxide is Be(OH)OH. However, this has never been reported. Beryllium hydroxide dehydrates completely at 400 °C to form a white powder of acid soluble beryllium oxide:

$$Be(OH)_2 + heat \Rightarrow BeO + H_2O$$

Further heating at higher temperature produces acid insoluble BeO.

Proton magnetic resonance spectra of beryllium hydroxide β-$Be(OH)_2$ and products of its thermal decomposition were studied at room temperature and 123 K. It was shown, based on these spectra and differential thermal analysis (DTA) and X-ray diffractometry data, that, heated to above 500 K, β-$Be(OH)_2$ decomposes into a finely dispersed BeO and H_2O to convert finally to an amorphous beryllium oxyhydroxide. At a temperature above 600 K, a crystalline BeO is formed involving dehydration of the finely dispersed BeO and amorphous oxyhydroxide phase.

Beryllium hydroxide is a strategic component concerning the usage of beryllium metal and its compounds in industry. The following narrative illustrates this fact:

> "One company in Utah mined Bertrandite ore and recovered beryllium hydroxide from this ore and from domestic beryl. Beryllium hydroxide was shipped to a plant in Ohio, where it was converted into beryllium metal, alloys, and oxide. Another company in Pennsylvania purchased beryllium oxide and converted this material into beryllium alloys. Small quantities of beryl were recovered as a by-product of U.S. pegmatite mining operations in various states. Beryllium consumption of 205 tons was valued at more than $70 million, based on the producer price for beryllium-copper master alloy. The use of beryllium (as an alloy, metal, and oxide) in electronic and electrical components, and aerospace and defense applications accounted for more than 80% of consumption".

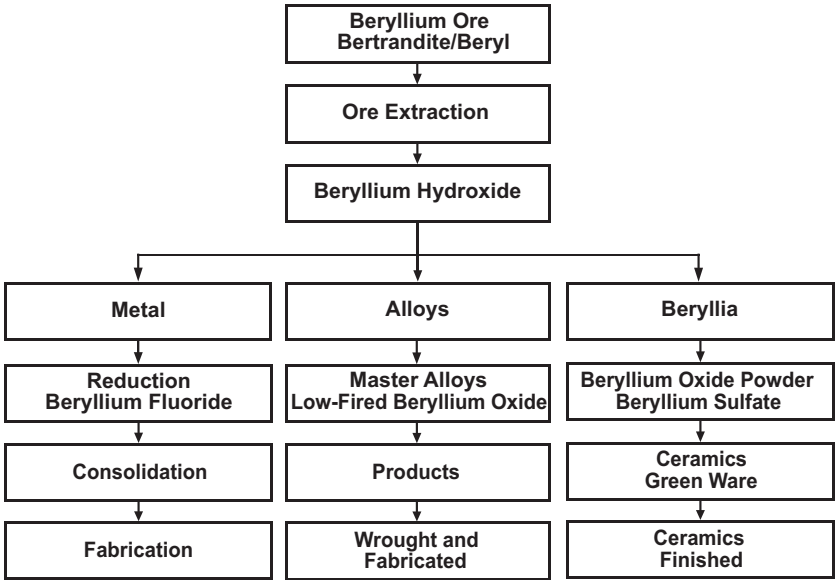

FIGURE 3.4

Beryllium hydroxide is the key compound used to prepare a variety of beryllium products. One method used to extract it from an ore like beryl is:

1. Grind up the ore and add sodium silicofluoride and soda ash. Press the mixture into briquettes. Heat the briquettes to 700 °C in a rotating hearth furnace until they become a coherent mass. Crush, mill and leach the heated briquettes to remove any remaining water.
2. Remove the red mud waste from the resulting material, which will leave a high concentration of sodium beryllium fluoride in solution. Add sodium hydroxide until the pH of the solution is 12 and allow beryllium hydroxide to precipitate out, leaving beryllium fluoride. The major portion will be beryllium hydroxide.
3. Add magnesium to the beryllium fluoride and heat to 1300 °C. The beryllium fluoride will be reduced to pure beryllium by the following equation: $BeF_2 + Mg \Rightarrow MgF_2 + Be$.

These steps are summarized in Fig. 3.4.

Note that $Be(OH)_2$ is the primary product used to prepare the metal and various beryllium salts.

The United States has very little beryl that can be economically hand sorted from pegmatite deposits. The Spor Mountain area, Utah, an epithermal deposit, contains a large reserve base of Bertrandite, which was being mined. Proven Bertrandite reserves in Utah total about 16,000 tons of contained beryllium. World beryllium reserves and reserve base are not sufficiently well delineated to report consistent figures for all countries (Table 3.5).

TABLE 3.5

World production of beryllium ores in tons

	2004	2005
United States	900	900
China	200	200
Mozambique	30	30
Other countries	10	10
World total	1140	1140

Beryllium hydroxide exists in three forms: as a metastable tetragonal crystalline solid (α-$Be(OH)_2$; as a stable orthorhombic crystalline solid (β-$Be(OH)_2$); and in a slightly basic pH, it appears as a slimy, gelatinous substance ($Be(OH)_4^{2-}$). It is soluble in acids and alkalis but insoluble in water. Beryllium oxide (BeO) occurs as a white amorphous powder or gel which is insoluble in both cold and hot water but is soluble in acids, alkalis, and ammonium carbonate. It is BeO that has found most usage in industry in electronic components but it is the hydroxide from which it is prepared. One method to produce an oxide suitable for this purpose is:

> "This method provides a process for producing beryllium oxide with a controlled mean particle size and morphology. Powdered beryllium hydroxide is admixed with a calcination additive, and the mixture is calcined to directly convert the beryllium hydroxide to beryllium oxide. Calcination additives include any calcium and/or magnesium compound which forms the corresponding oxide when subject to calcination. These additives facilitate the calcination reaction and recrystallization of the beryllium oxide product. Preferred calcination additives are magnesium basic carbonate and calcium

carbonate, present in amounts of 0.10% to 0.70% by weight relative to the beryllium oxide. Calcination is preferably accomplished in air at 1000° to 1300 ° C. Nitrogen, argon and hydrogen are also suitable calcination atmospheres. Mean particle size and morphology are controlled by the type and quantity of calcinations additive, final calcination temperature and, to a limited degree, by the initial morphology of beryllium hydroxide. The resultant beryllium oxide is characterized by low fluorine content, preferably not more than about 100 ppm, low surface area, preferably not more than about 1.5 m^2/g, and a mean particle size in the range of 2 μm to 25 μm. Surface area depends on the precise quantity of magnesium additive and the final calcination temperature. It reflects the morphology and particle size distribution of the beryllium oxide, e.g., a low surface area powder is normally well crystallized with a large mean size. High surface area powders are less crystallized and have lower mean particle sizes. Known ceramic comminuting treatments may be applied to change the final size distribution of BeO powder".

Maleic and phthalic acids are found to react with $Be(OH)_2$, generated in situ from $BeSO_4$ and $Ba(OH)_2$, in aqueous solution at pH 3.0 or 4.4, respectively (25 °C), to give solutions containing the complexes:

$$(H_2O)_2Be[(OOCCH)_2] \quad (1)$$

$$(H_2O)_2Be[(OOC)_2C_6H_4] \quad (2)$$

The products can be isolated in high yield and identified by microanalytical data. With two equivalents of the dicarboxylic acids and the pH adjusted to 5.5 and 5.9, respectively, by addition of ammonia, the following bis-chelate complexes are obtained, which can also be isolated:

$$[(NH)_4)^+]_2\{[Be[(OOCCH)_2]_2\}^-_2 \quad (3)$$

$$[(NH)_4)^+]_2\{[Be[(OOC)_2C_6H_4)_2]_2\}^-_2 \quad (4)$$

The compounds show distinct ^9Be, ^1H, and ^{13}C resonances in their NMR spectra in aqueous solutions. Layering of an aqueous solution of compound-4 with acetone at ambient temperature leads to the precipitation of single crystals suitable for an X-ray structure determination. This salt was found to contain the bis-chelated dianion, $\{[Be[(OOC)_2C_6H_4)_2]_2\}^-_2$ with the beryllium atom in the spiro-center of two seven-membered rings and an overall geometry approaching closely C_2 symmetry. These anions are associated with two crystallographically independent but structurally similar counter ions $[MeC_O)CH_2CMe_2NH_3]^+$, which are the product of a condensation reaction of the ammonium cation with the acetone solvent. In the crystal, the ammonium hydrogen atoms of the cations form N–H–O hydrogen bonds with the oxo-functions of the dianion.

The largest usage of beryllium hydroxide is to make the oxide or the metal that is used in many industries. The total tonnage is not large but substantial.

Beryllium hydroxide is available commercially in large quantities.

Magnesium Hydroxide

Magnesium hydroxide has the chemical formula $Mg(OH)_2$ and the molecular weight of 58.3197 g/mol. Its CAS number is 1309-42-8 and its density is 2.345 g/cm^3. It decomposes when heated to 360 °C and forms the oxide, MgO. It is very slightly soluble in water at 0.00122 g/100 ml and has a solubility product of 5.61×10^{-12}. Crystals of $Mg(OH)_2$ have a refractive index of 1.559. Its heat of formation is –925 kJ/mol with an entropy of 63 J/mol·K.

As a suspension in water, it is often called **milk of magnesia** because of its milk-like appearance. The solid mineral form of magnesium hydroxide is known as "brucite". It can be prepared by the metathesis reaction between any soluble magnesium salts and an alkali hydroxide such as sodium or even ammonium:

$$Mg^{2+}(aq) + 2OH^-(aq) \Rightarrow Mg(OH)_2(solid)$$

Magnesium hydroxide is a common component of antacids and laxatives. It interferes with the absorption of folic acid and iron. Magnesium hydroxide has low solubility in water, with a K_{SP} of 1.5×10^{-11}. All of magnesium hydroxide that does dissolve does dissociate into ions. Since the dissociation of this small amount of dissolved magnesium hydroxide is complete, magnesium hydroxide is considered a strong electrolyte. Its low solubility makes it a weak base.

In 1829, Sir James Murray used a fluid magnesia preparation of his own design to treat the Lord Lieutenant of Ireland, the Marquis of Anglesey. This was so successful (advertised in Australia and approved by the Royal College of Surgeons in 1838) that he was appointed resident physician to Anglesey and two subsequent Lords Lieutenants, and knighted. His fluid magnesia product was patented 2 years after his death in 1873.

The term *milk of magnesia* was first used for a white-colored, aqueous, mildly alkaline suspension of magnesium hydroxide formulated at about 8% by weight by Charles Phillips in 1880 and sold under the brand name *Phillips' Milk of Magnesia* for medicinal usage.

Suspensions of magnesium hydroxide in water (milk of magnesia) are used as an antacid to neutralize stomach acid, and a laxative. This may cause diarrhea and loss of potassium with concomitant muscle cramps. Magnesium hydroxide is also used as an antiperspirant armpit deodorant. Milk of magnesia is useful against "canker sores" (aphthous ulcer) when used topically. Milk of magnesia is sold for medical use to alleviate constipation, but also to relieve indigestion and heartburn. Milk of magnesia is also used as a folk remedy, applied and massaged in (a few minutes before washing), to relieve symptoms of "seborrhea" and "dandruff". It is also said to be used for seborrheic dermatitis, which is

a drying and flaking of the skin similar to dandruff but often occurring on the face.

Magnesium hydroxide powder is used industrially as a nonhazardous alkali to neutralize acidic wastewaters. Solid magnesium hydroxide has also smoke suppressing and fire retarding properties. This is due to the endothermic decomposition it undergoes at 332 °C (630 °F):

$$Mg(OH)_2 \Rightarrow MgO + H_2O$$

The heat absorbed by the reaction acts as a retardant by delaying ignition of the associated substance. The water released dilutes any combustible gases and inhibits oxygen from aiding the combustion.

The commercial production of $Mg(OH)_2$ involves brines and dolomite ores. The following reaction is an example:

$$\underset{\text{brine}}{[CaCl_2 + MgCl_2](aq)} + H_2O + \underset{\text{magnesium hydroxide}}{[CaO\cdot MgO]} + 2H_2O$$
$$\Rightarrow 2\underset{\text{calcined dolomite}}{Mg(OH)_2(solid)} + 2CaCl_2(aq) + H_2O$$

The magnesium hydroxide and calcium chloride produced from this reaction exist together but in two distinct physical states: magnesium hydroxide is formed as solid particles while the calcium chloride is dissolved in the liquid or watery phase. The bottom solids are then filtered to remove any remaining water and given a series of water washes to remove chlorides from the material. This results in a damp filter cake which is finally directed to a source of heat, such as a rotary kiln, where it is thermally decomposed (calcined) to produce magnesium oxide:

$$2Mg(OH)_2 - \text{heat} \Rightarrow 2MgO + 2H_2O(\text{steam})$$

Common uses of magnesium hydroxide as a fire retardant include plastics, roofing, and coatings. Magnesium hydroxide, $Mg(OH)_2$, as a flame retardant functions in the same manner as ATH, however, there is one important difference: it undergoes endothermic decomposition with water release at 330 °C (626 F). Magnesium hydroxide is marketed as a slurry for use as a neutralizing agent in the treatment of acidic wastewaters.

The basic structure of magnesium hydroxide consists of stacked sheets of octahedrons of magnesium hydroxide. The octahedrons are composed of magnesium ions with a +2 charge bonded to six octahedrally coordinated hydroxides with a −1 charge. Each hydroxide is bonded to three magnesium atoms. The result is a neutral sheet since $+2/6 = +1/3$ (+2 charge on the magnesium atoms divided among six hydroxide bonds) and $-1/3 = -1/3$ (−1 charge on the hydroxides divided among three magnesium atoms); Thus, the charges cancel.

Another method of commercial manufacture of magnesium hydroxide involves the chloride obtained from seawater. After the chloride is recrystallized several times to obtain a level of purity, it is calcined at about 1000 °C:

$$MgCl_2\cdot 6H_2O \Rightarrow MgCl_2 + 6H_2O$$
$$\Rightarrow Mg(OH)_xCl_{2-x} + xHCl$$
$$\Rightarrow MgO + (2-x)HCl$$

The chloride first dissolves in its own waters of hydration, then forms a basic chloride before decomposing to the oxide. It is the oxide which is reacted in water to form a hydroxide slurry. Although NaOH could be added to the chloride itself, contamination by sodium ion, Na^+, is, in many cases, undesirable. The use of ammonia, NH_4OH, is not feasible since the pH of the solution must exceed 10.5.

Crystallization of magnesium hydroxide by a continuous mixed suspension mixed product removal crystallizer was conducted to make clear the characteristics of reactive crystallization kinetics of magnesium hydroxide, which was produced by the precipitation from magnesium chloride with calcium hydroxide. The following operating factors affecting the crystallization kinetics were investigated:

- the initial concentration of feeds,
- residence time of reactants,
- feed ratio of reactants,
- concentrations of hydroxide and chloride ions.

It was determined that the nucleation rate and the growth rate are correlated by the power law model and that the kinetic order in the power law model is correlated with concentrations of OH^- and Cl^-.

Because $Mg(OH)_2$ belongs to the bivalent metal hydroxides group with a layered CdI_2-type structure (space group P3m1), systematic studies to produce nanoparticles have been presented. In such materials, successive hexagonal Mg^{2+} ion layers and OH^- ion layers are stacked one upon another, favoring the formation of the plate-like crystals but being difficult to induce. However, by careful control of the process parameters, such as the reactants, the temperature, the supersaturation, the solvent, the template and the surfactant etc., it was reported that:

- $Mg(OH)_2$ nanoneedles with a length of 100–4000 nm and a diameter of 10–95 nm were prepared by the orderly addition of ammonia and NaOH solution to $MgCl_2$ solution to maintain the one-dimensional morphology and increase the yield of $Mg(OH)_2$.
- $Mg(OH)_2$ nanorods with a length of 3 μm, a diameter of 30 nm and a coarse surface were obtained by hydrothermal treatment (160 °C, 16 h) of the mixture containing 0.1 mol/l $MgSO_4$ and ammonia at pH = 12.

- $Mg(OH)_2$ nanorods with a length of 200–450 nm and a diameter of 8–20 nm were also synthesized by hydrothermal treatment (180 °C, 20 h) of Mg or MgSO4 in the presence of ethylenediamine, where ethylenediamine acted as a template for the formation of platelet-like $Mg(OH)_2$ via the interaction of bidentate ligand and Mg^{2+}.
- $Mg(OH)_2$ nanoneedles, having a length of 50–100 nm and a diameter of 3–5 nm, coexisted with some nanosheets that were produced by hydrothermal treatment (180 °C, 6 h) of a mixture containing $Mg(CH_3COO)_2$ and NaOH in the presence of citrate, where the preferential adsorption of citrate on the (001) surface of $Mg(OH)_2$ inhibited the growth of $Mg(OH)_2$ along the [001] direction.
- $Mg(OH)_2$ nanotubes with a length of 5–10 μm, an outer diameter of 80–150 nm and a wall thickness of 30–50 nm were obtained via hydrothermal conversion (180 °C, 6 h) of $Mg_{10}(OH)_{18}Cl_2 \cdot 5H_2O$ nanowires in ethylenediamine.

These nanoparticles have found usage as flame retardants in plastics and the like where they exhibit superior properties not found in other flame retardants.

Magnesium hydroxide is available commercially in large quantities.

Calcium Hydroxide

This salt has the molecular formula of $Ca(OH)_2$ and the molecular weight of 74.0931 g/mol. It may be prepared by the reaction of "lime" and water, where the product is called "slaked lime":

$$CaO + H_2O \Rightarrow Ca(OH)_2$$

the solubility of calcium hydroxide is 0.185 g/100 ml at 0 °C and 0.077 g/100 ml at 100 °C. Its $K_{sp} = 4.68 \times 10^{-6}$ at 25 °C. Its CAS number is 1305-62-0 and a density of 2.211 g/cm^3. It is a colorless crystal or white powder, obtained when CaO (called *lime* or *quicklime*) is mixed, or "slaked" with water. It can also be precipitated by mixing $CaCl_2$ and NaOH. The name of the natural, mineral form is "portlandite". It is a relatively rare mineral, known from some volcanic, plutonic, and metamorphic rocks. It has also been known to be formed in burning coal dumps.

The structure of calcium hydroxide is trigonal, space group = P3m1, with $a = 3.589$ Å, $C = 4.911$ Å and $V = 64.8$ Å^3 ($Z = I$). The positions of the Ca, O and H atoms are at: 1(a) (0,0,0,), 2(d) (1/3,2/3, $z_0 = 0.234$) and 2(d) (1/3,2/3, $z_0 = 0.425$), respectively in space group P3m1. Ca(OH)2 is a layered compound with the layers being builtup with distorted, edge-sharing CaO_6 octahedra. Each hydroxyl group is linked to three Ca atoms in its layer and surrounded by three (3) other hydroxyl groups belonging to the adjacent layer. A view of the structure is given in Fig. 3.5.

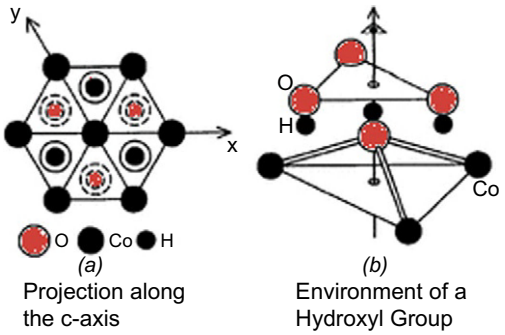

FIGURE 3.5

When heated to 512 °C, calcium hydroxide decomposes into calcium oxide and water. A suspension of fine calcium hydroxide particles in water is called milk of lime. The solution is called "lime water". It is important to differentiate between these two terms (which have been confused in the past. Lime water is a medium strength base that reacts violently with acids and attacks many metals in presence of water. It turns milky if CO_2 is passed through the solution, due to precipitation of $CaCO_3$.

Calcium hydroxide, a weak base, has many diverse uses. Among the most important ones are:

FLOCCULANTS

This salt is a flocculent, used in water and sewage treatment where, in sewage treatment, it is used to control acidity and to help remove soluble phosphates from the sewage stream. It is also used in improvement of acid soils.

PAINTS AND SEALANTS

Whitewash (also known as **calcimine**, **kalsomine**, or **calsomine)** is a very low-cost type of paint made from slaked lime (calcium hydroxide) and chalk (whiting). Various other additives have also been used. Whitewash cures through a reaction with CO_2 in the atmosphere to form calcium carbonate in the form of "calcite", a reaction known as "carbonization". When the paint initially dries it is uncured, and has almost no strength. It takes up to a few days, depending on climate, to harden. It is usually applied to exteriors—however, it is traditionally used internally in food preparation areas—particularly rural dairies—for its mildly antibacterial properties. In Britain and Ireland, whitewash was used historically, both externally and internally—in workers' cottages and still retains something of this association with rural poverty.

Whitewash is especially effective on adobe-like materials because it is absorbed easily and the resultant chemical reaction hardens the substrate. In addition,

whitewash and adobe are both very low-cost building materials. In the early to middle of the twentieth century, when dairy-barns in the mid-West were common, whitewash was a necessary part of routine barn maintenance. A traditional animal barn contains a variety of extremely rough surfaces that are difficult to wash and keep clean. Whitewash aids in sanitation by coating and smoothing over the rough surfaces. Successive applications of whitewash buildup layers of scale which flake off and in the process remove surface debris with it. In addition, it "sweetened" the offal which was carried out to the fields as fertilizer.

Lime wash is pure slaked lime in water. It produces a unique surface glow due the to refraction of calcite crystals. Lime wash and whitewash both cure to become the same material. When lime wash is initially applied it has very low opacity, which can lead novices to overthicken the paint. Drying increases opacity, and subsequent curing increases opacity again.

MORTAR

Mortar is a workable paste composed of calcium hydroxide and other ingredients used to bind construction blocks together and fill the gaps between them. The blocks may be stone, brick, cinder blocks etc. Mortar becomes hard when it sets, resulting in a rigid aggregate structure. Modern mortars are typically made from a mixture of sand, a binder such as lime (and sometimes cement) and water. Mortar can also be used to fix, or *point*, masonry when the original mortar has washed away. Originally, lime mortars were used.

PORTLAND CEMENT MORTAR

This was often known simply as cement mortar and was invented in 1794 by Joseph Aspdin and patented on 18 December 1824, largely as a result of various scientific efforts to develop stronger mortars than existed at the time. It was popularized during the late nineteenth century, and, owing to the First World War, by 1930 it had superseded lime mortar for new construction. The main reasons for this were that Portland cement sets hard and quickly, allowing a faster pace of construction, and requires less skilled workers. However, as a general rule, Portland cement should not be used for the repair of older buildings constructed in lime mortar, which require the flexibility, softness and breathability of lime if they are to function correctly.

LIME PLASTER

Lime plaster is a mixture of calcium hydroxide and sand (or other inert fillers). Carbon dioxide in the atmosphere causes the plaster to set by transforming the calcium hydroxide into calcium carbonate (limestone). To make lime plaster, limestone (calcium carbonate) is heated to produce quicklime (calcium oxide). Water is then added to produce slaked lime (calcium hydroxide), which is sold as a white powder. Additional water is added to form a paste prior to use. The paste may be stored in airtight containers. Once exposed to the atmosphere, the calcium hydroxide turns back into limestone, causing the plaster to set.

Lime plaster was a common building material for wall surfaces in a process known as "lath and plaster", whereby a series of wooden strips on a studwork frame was covered with a semidry plaster that hardened into a surface. The plaster used in most lath and plaster construction was mainly lime plaster, with a cure time of about a month. To stabilize the lime plaster during curing, small amounts of plaster of paris were incorporated into the mix. Because plaster of paris sets quickly, "retardants" were used to slow setting time enough to allow workers to mix large working quantities of lime putty plaster. A modern form of this method uses expanded metal mesh over wood or metal structures, which allows a great freedom of design as it is adaptable to both simple and compound curves. Today, this building method has been partly replaced with "drywall", also composed mostly of gypsum plaster. In both methods, a primary advantage of the material is that it is resistant to a fire within a room and so can assist in reducing or eliminating structural damage or destruction provided the fire is promptly extinguished.

Lime plaster is used for true "frescoes". Pigments, diluted in water, are applied to the still wet plaster. Lime plaster is not to be confused with "plaster of paris" which is a calcium sulfate composition.

Other uses that have occurred in industry include:

- An alkali used as a lye substitute (NaOH) in no-lye hair relaxers.
- A chemical depilatory agent found in Nair™.
- A calcium supplement in mineral fortified baby formulas.
- A chemical reagent used to form a long-lasting fungicide.
- In "reef-aquariums" for adding bio-available calcium in solution for calcium-using animals such as algae, snails, tube worms and corals and also to increase the alkalinity of the water.
- In the tanning industry for neutralization of acid, the liming of hides and skins and the flocculation of resultant wastewater.
- In the oil industry for the manufacture of oil additives (salicatic, sulphatic, fenatic).
- In the chemical industry for manufacture of calcium stearate.
- In the food industry for processing water (for alcoholic and soft drinks).
- Used in the separation of sugar from sugar cane in the sugar industry.

- Used in the processing of Norwegian "Lutefisk". Dried cod fish is soaked in a mixture of slaked lime and soda to produce a soft-fleshed fish fillet that is steamed or baked and served with potato "Lefse".
- In the manufacture of brake = pads, ebonite and pesticides.
- In dentistry, it is used as dressing in paste form used for antimicrobial effect during a dental root canal procedure. Calcium hydroxide is known to have a strong antimicrobial effect and is a bone-regeneration stimulant.
- In the production of metals, lime is injected into the waste gas stream to neutralize acids, such as fluorides and chlorides prior to being released to atmosphere.

Calcium hydroxide is readily available commercially in large lots.

Strontium Hydroxide

Strontium hydroxide has the molecular formula of $Sr(OH)_2$ and the molecular weight of 121.6324 g/mol. It occurs as an anhydrate whose prismatic, colorless crystals are deliquescent. A monohydrate and octahydrate are also known. The respective molecular weights are: 139.6523 g/mol and 265.7634 g/mol. The CAS numbers are: 311-10-0 (Octahydrate); 18480-07-4 (Anhydrate). Densities are: 3.625 g/cm^3 (anhydrate) and 1.91 g/cm^3 for the octahydrate. The melting point of the anhydrate is 375 °C and its boiling point is 710 °C, a point where it decomposes to the oxide. Solubility in water for the anhydrate is 0.41 g/100 ml at 0 °C, 1.77 g/100 ml at 20 °C and 21.83 g/100 ml at 100 °C. The anhydrate is insoluble in acetone but soluble in acids and ammonia chloride.

It can be prepared by the reaction of water upon the oxide but because $Sr(OH)_2$ is very slightly soluble in water, its preparation can be easily carried out by the addition of a strong base such as NaOH or KOH to a solution of any strontium salt, most commonly the nitrate, $Sr(NO_3)_2$. $Sr(OH)_2$ crystals will precipitate out as a fine white powder. From here, the solution is filtered, and the $Sr(OH)_2$ is washed with cold water and dried. However, strontium hydroxide is sufficiently soluble that a major part remains in solution.

Evaporating the solution causes the octahydrate, $Sr(OH)_2 \cdot 8H_2O$ to crystallize. The octahydrate may also be obtained by precipitating the hydroxide from strontium nitrate solution with NaOH and washing the precipitate with cold ethyl alcohol.

Strontium hydroxide octahydrate $Sr(OH) \cdot 8H_2O$ crystallizes in the tetragonal space group $P4/ncc$ with cell constants $a = 9.017$ Å and $c = 11.603$ Å. The crystal structure has been refined and it was possible to localize the positions of all hydrogen atoms for the first time and to describe the hydrogen-bonding scheme in detail. The Sr^{2+} ions are square antiprismatically coordinated by eight water molecules. These $\{Sr(H_2O)_8\}^{2+}$ coordination polyhedra are linked with each other via hydrogen bonds in a way that linear columns parallel to the c axis result. The two hydroxyl anions of the asymmetric unit are linked by weak hydrogen bonds and are not coordinated to strontium atoms. Like the strontium atoms, they form linear chains parallel to the c axis. Both, $\{Sr(H_2O)_8\}^{2+}$ columns and OH^- chains, are interconnected through two types of additional hydrogen bonds. The structure is reminiscent of the calcium homologue (see above), except that the coordination is octagonal, not hexagonal.

Strontium hydroxide is slightly soluble in water but, surprisingly, the octahydrate is much more soluble. It is the latter that is supplied commercially for most applications. A comparison of water solubilities may be seen in Table 3.6.

When the octahydrate is heated, seven waters of hydration are lost to form the monohydrate and finally the oxide:

$$Sr(OH)_2 \cdot 8H_2O + \text{heat} \Rightarrow Sr(OH)_2 \cdot H_2O + \text{heat} \Rightarrow SrO + H_2O$$

The thermal behavior of strontium hydroxide octahydrate was studied by thermal analysis, an X-ray diffraction technique and optical microscopy. Up to 210°, this compound transforms to the hexahydrate and then to the monohydrate. Anhydrous strontium hydroxide crystallizes in the tetragonal system and a polymorphic transformation may occur at 480°. From 530° on, it decomposes in three stages. Amorphous strontium oxide is obtained at 700°.

Strontium hydroxide is used chiefly in the refining of beet sugar and as a stabilizer in plastic. It may be used as

TABLE 3.6

G/100 ml of water									
Compound	**Formula**	**0 °C**	**10**	**20**	**40**	**60**	**80**	**90**	**100**
Octahydrate	$Sr(OH)_2 \cdot 8H_2O$	0.91	1.25	1.77	3.95	8.42	20.2	44.5	91.2
Anhydrate	$Sr(OH)_2$	0.41		1.77					21.8

a source of strontium ions when the Cl^- ion is undesirable. Strontium hydroxide absorbs carbon dioxide from the air to form strontium carbonate.

This salt is available commercially in sizable quantities.

Barium Hydroxide

Barium hydroxide has the molecular formula of $Ba(OH)_2$ and the molecular weight of 121.6324 g/mol. It occurs as an anhydrate whose prismatic, colorless crystals are very deliquescent. Barium hydroxide can be prepared by dissolving barium oxide (BaO) in water:

$$BaO + 9H_2O \Rightarrow Ba(OH)_2 \cdot 8H_2O$$

It crystallizes as the octahydrate, which converts to the monohydrate upon heating in air. Barium oxide has been found to react with water vapor at temperatures from 1443 to 1593 K to form gaseous $Ba(OH)_2$ according to the reaction:

$$BaO(solid) + H_2O(gas) \Rightarrow Ba(OH)_2(gas)$$

The standard free energy of formation is given by the equation, $\Delta G_r^{\circ} = 49{,}400 - 16.6\ T$ (cal/mol) in the present temperature range. From the thermodynamic cycle, the bond energy between barium and two hydroxyl groups has been found to be 196.8 kcal/mol.

A better method of preparation involves addition of NaOH to the nitrate. Since barium hydroxide is fairly soluble, it is necessary to evaporate the solution to crystallize $Ba(OH)_2 \cdot 8H_2O$. Ethanol is added to aid in this crystallization. The crystals are washed in cold ethanol to remove sodium ions and then dried. Barium hydroxide octahydrate forms crystalline precipitates which do not show changes in solubility on aging and whose solubility in water increases with increasing temperature.

When heated, the octahydrate decomposes to the monohydrate at about 78 °C and to the anhydrate at about 375 °C. The thermal dehydration of crystalline barium hydroxide octahydrate has been studied. The octahydrate first dissolves in its own waters of hydration (78 °C) and then loses four waters to form the trihydrate at about 125 °C. The trihydrate is not stable and it is the monohydrate which is obtained at 180 °C. Gradual thermal treatment in air leads to the formation of anhydrous barium hydroxide at 375 °C. Barium oxide is formed at about 410 °C in an inert atmosphere. The hydroxide is converted directly to the peroxide in the temperature range 400–600 °C.

Physical properties of these barium hydroxide compounds are listed in Table 3.7.

Barium hydroxide is used in analytical chemistry to titrate weak acids, particularly organic acids. It forms clear aqueous solutions that are free from carbonate, unlike those of the alkali hydroxides, since barium carbonate is insoluble in water. This allows the use of indicators such as phenolphthalein or thymophthalein (with alkaline color changes) without the risk of titration errors due to the presence of weakly basic CO_3^{2-} ions.

TABLE 3.7

CAS Number	Anhydrate-17194-00-2
	Monohydrate-22326-55-2
	Octahydrate-12230-71-6
Molecular weight	Anhydrate-171.3422 g/mol
	Monohydrate-189.3925 g/mol
	Octahydrate-315.4636 g/mol
Density	Anhydrate-4,495 g/cm^3
	Monohydrate-3.743 g/cm^3
	Octahydrate-2.18 g/cm^3
Melting point	78 °C—octahydrate
	407 °C—Anhydrate
Boiling point	780 °C—Anhydrate
Basicity	$PK_d = -2.02$
Refractive index	$\eta_D = 1.51$ (octahydrate)
Enthapy of formation	$\Delta_f H = -944.7$ kJ/mol
Standard entropy	$S^0_{solid} = 100 \pm 6$ J/mol·K
Heat of fusion	$\Delta H_f = 93.38$ kJ (anhydrate)

Barium hydroxide is used in organic synthesis as a strong base, for example for the hydrolysis of esters and nitriles (Fig. 3.6).

It has been used to hydrolyze one of the two equivalent ester groups in dimethyl endecanedioate. It is also used in the preparation of cyclopentanone, diacetone alcohol and d-Gluonic γ-lactone (Fig. 3.7).

Barium hydroxide is used as an additive in thermoplastics (such as phenolic resins), rayon and PVC stabilizers to improve plastic properties. This material is used as a general-purpose additive for lubricants and greases. Other industrial applications for barium hydroxide include sugar fabrication, manufacturing soaps, fat saponification, fusing of silicates and chemical synthesis of other barium compounds and organic compounds.

Barium hydroxide is an important component in the preparation of "high-temperature superconductors". High-quality bulk $YBa_2Cu_3O_{7-x}$ was synthesized by fusing stoichiometric amounts of yttrium and copper nitrates and barium hydroxide in air, using an ordinary Bunsen burner. The starting materials go through a short-lived liquid phase yielding a solid black product which was subsequently heat treated (900 °C, 18–24 h in air, followed by 500 °C, 5 h in O_2). These materials were greater than 99% phase-pure with CuO as the only other

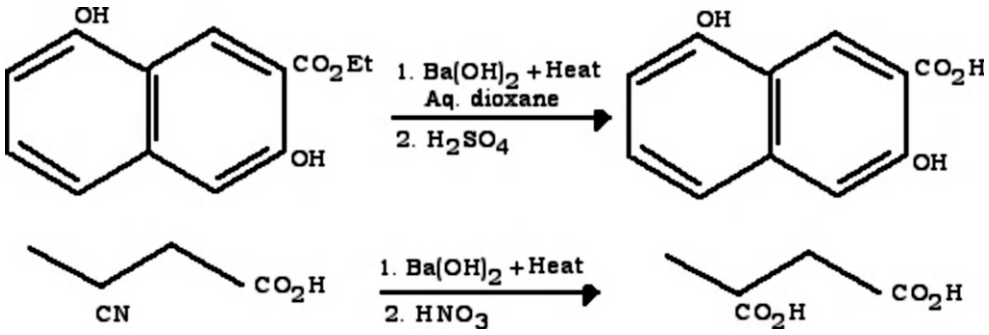

FIGURE 3.6

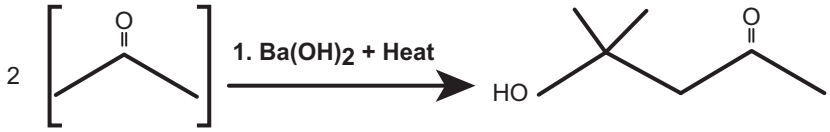

FIGURE 3.7

phase and they exhibited a transition temperature of 92 K, a 15.5% perfect diamagnetic response (field cooled). This synthesis represents an improvement over the much more labor and time intensive conventional methods in that it allows high-quality superconducting materials of varied compositions to be prepared quickly.

The structure of barium hydroxide trihydrate has been determined. It is orthorhombic; space group = Pnma with $a = 7.640$ Å, $b = 11.403$ Å, $c = 5.965$ Å, $V = 519.7$ Å^3, $Z = 4$ and density = 2.88 g/cm^3. The water molecules exhibit strong hydrogen bonds to the hydroxide anion with H–O distances of 1.693 Å (H_2O-I), 1.672 Å (H_2O-II) and 1.667 Å (H_2O-III). The hydroxide anions themselves are not hydrogen bonded. The OH bond lengths are 0.99–1.01 Å (H_2O) and 0.948 Å (OH^-). The HOH angles are 102° (H_2O-I) and 107.6° (H_2O-II).

This salt has been used as a catalyst for the oxidative coupling of methane to form higher molecular weight hydrocarbons. The catalytic performance of the alkaline earths, Be, Mg, Ca, Sr, and Ba, was studied for the oxidative coupling of methane to form $(C_xH_y)_n$ hydrocarbons ($n \geq 2$). To compare the various catalytic compounds, normalized reaction conditions were applied: $T = 740$ °C, $PoCH_4 = 660$ mbar, $PoO_2 = 80$ mbar, $PoN_2 = 260$ mbar at a total pressure of 1 bar. C_{2+} selectivity increased from BeO (22%) via MgO (22 to 53%) and CaO (47 to 55%) to SrO and BaO (70 to 72%) with $Ba(OH)_2$ being the most promising.

Barium hydroxide is offered for sale both as the octahydrate and the monohydrate. It is available in large quantities commercially.

Radium Hydroxide

Radium hydroxide has the formula, $Ra(OH)_2$ and the molecular weight of grams per mole. Radium hydroxide is the most soluble of the alkaline earth hydroxides and more basic than barium hydroxide. It may be prepared by the reaction of BeO added to water. The reaction is violent with evolution of considerable heat:

$$RaO + H_2O \Rightarrow Ra(OH)_2$$

It may also be prepared by reacting the nitrate with NaOH in solution. There is no record of this salt actually having been prepared. However, it is expected that beryllium hydroxide is soluble so that the solution needs to be evaporated at a low temperature (with vacuum) in the presence of ethanol to crystallize the salt, $Be(OH)_2 \cdot 8H_2O$. The crystals are then washed in cold ethanol to remove traces of sodium ions and then dried. The crystals are strongly absorbent of carbon dioxide from the air, forming the carbonate as an end-product.

The CAS number of radium hydroxide is 98966-86-0. When an aqueous solution of radium salt is kept in a closed flask, there is a continuous evolution of radon, hydrogen, and oxygen. The last two are produced by the decomposition of water by the radium, as well as the radon.

There is no demand for this salt and it is not available commercially.

3.1.3. Alkaline Earth Peroxides

The peroxides of the alkali metals and Ca, Sr and Ba are ionic in electronic character. The peroxides of a number of other electropositive metals such as Mg

show an intermediary character, between ionic and covalent.

Beryllium Peroxide

Beryllium peroxide is expected to have a molecular formula of Be(OH)OOH. There is no experimental proof documented in the literature for the existence of any beryllium peroxide compound. All recent pertinent preparative attempts described in such work, using a range of beryllium salts with various peroxides as reagents under mild conditions, were equally unsuccessful. $^{(1)}$H and $^{(9)}$Be NMR investigations of aqueous solutions containing beryllium salts and hydrogen peroxide in a broad pH range also gave no definite evidence for the presence of peroxoberyllates as components of the manifold equilibria in such solutions. Quantum chemical calculations have therefore been carried out to delineate the energetics and structures of various beryllium peroxide model compounds.

Standard Hartree–Fock and density functional methods were employed at various levels of sophistication. The series of prototypes considered consists of $[BeOH]^+$, $Be(OH)_2$, Be(OH)(OOH), $Be(OOH)_2$, $(BeO_2)_2^{2-}$, $BeO_2(OH_2)_2$, and $Be_2(O_2)_2(OH_2)_4$ (all in the gas phase). Surprisingly, the triatomic cation $[BeOH]^+$ has been found to have a linear structure. All the Be–O (peroxide) bonds are found to be rather long, suggesting weaker bonding compared to the Be–O bonds in aquo, hydroxo, or oxo complexes. Hydrogen peroxide or anions derived thereof are therefore not able to compete successfully with water (hydroxide anions) in aqueous solution. In the mononuclear beryllium peroxide molecules, the peroxide groups form chelating units at tetrahedrally 4-coordinate metal atoms. The binuclear compound $Be_2(O_2)_2(OH_2)_4$ has a puckered six-membered ring structure, close to the standard chair conformation. A significant lengthening of the O–O bonds upon coordination to the Be^{2+} centers has been calculated, but it is unlikely that the polarization of the peroxide group by the high-positive charge density at $Be^{2+}$is significant to cause an intrinsic instability of beryllium peroxides. All structures represent distinct local minima on the potential energy surface and are predicted to be (meta)stable species in nonaqueous media. The field of aluminum peroxides is a similar gray area on the map of metal and metalloid peroxides and is reminiscent of the well-established "diagonal-relation" of Be and Al in the periodic table of the elements.

Beryllium peroxide and similar salts have not been described in the literature and they are not available commercially.

Magnesium Peroxide

Magnesium peroxide has the molecular formula of MgO_2 and the molecular weight of 56.3038 g/mol.

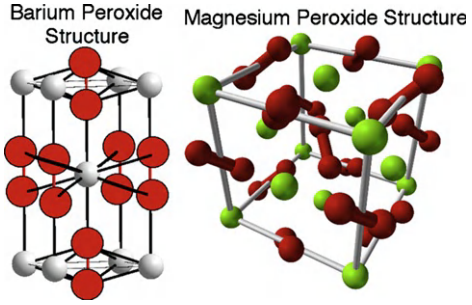

FIGURE 3.8

Magnesium peroxide is a fine powder with a white to off-white color. It is similar to calcium peroxide because magnesium peroxide also releases oxygen by breaking down at a controlled rate when in contact with a hydrous fluid. It is used in bleaching, disinfecting, and deodorizing. In contact with water, it decomposes by the reactions:

$$MgO_2 + 2H_2O \Rightarrow Mg(OH)_2 + H_2O_2$$

$$2H_2O_2 \Rightarrow 2H_2O + O_2$$

Its CAS number is 1335-26-8. A high-purity product is also offered for sale as an "analytical reagent". Its CAS number is 14452-57-4. MgO_2 has a density of 3.04 g/cm^3 and a melting point of 223 °C. Its boiling point is 353 °C, a temperature at which it decomposes. It is not very soluble in water. Its structure is cubic, cP12 (#205). This structure differs from that of the other alkaline earth peroxides, as shown in Fig. 3.8.

The peroxide-"dumbbells" are in-line on the (100), (001) and (010) directions of the lattice while the O–O dumbbells are at (002) points in the BaO_2 lattice.

Magnesium peroxide is used for enhanced aerobic bioremediation. This is a process in which organic contaminants found in soil and/or groundwater are degraded by indigenous or inoculated microorganisms, transforming them to harmless end-products. Magnesium peroxide has a very low solubility in water that allows the product to continue to release its active oxygen content for many months. The duration of oxygen release depends upon many factors including soil type, its pH and buffering capacity, kind of contaminants and their concentration, the presence of other organics or metals in the soil, etc. Because of its stable oxygen release rate and environmentally benign character, magnesium peroxide is widely used in agricultural, environmental, pharmaceutical and cosmetic industries. Magnesium peroxide is primarily used as the main oxygen source for in situ bioremediation. It was the first inorganic peroxide to be used for this purpose. It was originally introduced into wells or drilled holes as a permeable "sock" where it is slowly dissolved in water to remediate the enhanced

bio-remediation of many organic pollutants by indigenous bacteria. Later technology evolved in the injection of an MgO_2 slurry containing about 7–10% of "active", i.e. nascent, oxygen. The addition of oxygen releasing compounds to groundwater can be an effective treatment technology capable of reducing the levels of contaminants in groundwater. Magnesium peroxide is applied to aid in the remediation of petroleum hydrocarbons and other similar contaminants found in groundwater. Magnesium peroxide is very effective for the bioremediation of contaminated soils and improvement of soil quality for plant growth and metabolism.

The thermal stability of magnesium peroxide, using preparations containing up to 75% MgO_2 has been studied using DTA. It has been shown, by an interpretation of the thermograms, that these preparations release bulk of water of the adsorbed mother liquor at 110° and are entirely dehydrated at 260°. In this case, there is a partial decomposition of MgO_2 with evolution of oxygen and the formation of $Mg(OH)_2$. The mixture of MgO_2 and $Mg(OH)_2$ formed decomposes exothermically within the range 360–375°, liberating oxygen and forming MgO. The following reactions are responsible for the exothermicity of the effect on the heating curves of magnesium peroxide preparations:

$$MgO_2 + 2H_2O \Rightarrow Mg(OH)_2 + H_2O_2$$

$$H_2O_2 \Rightarrow H_2O + \tfrac{1}{2}O_2.$$

The heating curve is characterized by the presence of two exothermic effects. The first, beginning at 50 °C passes through a maximum at 105 °C and ends at 125 °C. This corresponds to the decomposition to form hydrogen peroxide. The second effect, beginning at 305 °C, passes through a maximum at 330 °C and ends at 345 °C. This pertains chiefly to the decomposition of H_2O_2 and MgO_2 and has been confirmed by measurement of oxygen evolution.

The major advantage that MgO_2 possesses over other oxidative agents is its steady long-term release of oxygen. It was determined that the MgO_2(s) decomposition, followed a rate law derived from a shrinking-core model for fixed-size particles. The rate of the reaction was controlled by diffusion through the $Mg(OH)_2$(s) product layer rather than by chemical reaction at the core surface. Compared with ionic peroxides, MgO_2(s) was found to be a potential O_2-generating agent for generating oxygen gas during a relatively long period of time. For this reason, MgO_2 has appeared in many "teeth-whitening" products of late.

Magnesium peroxide has also been used to "dehair" cattle hides prior to conversion to "cowhide" leather. Dehairing reaction conditions that rapidly removed 80% or greater of hair from cattle hide pieces were observed for magnesium peroxide (5%, 15% NaOH, 200% float, 45 °C, 8 min, hair-burn process) and potassium peroxymonosulfate (5%, 15% NaOH, 200% float, 45 °C, 7 min, hair-burn process). Leather produced from matched side pieces that were subjected to these oxidative dehairing treatments was determined to take up less chromium yet was tougher than leather produced using conventional hairburn with sodium sulfide.

Additionally, magnesium peroxide has been developed into a form suitable for use as an antibacterial agent for cotton and cotton-blend fabrics. Development of environmentally benign antibacterial agents for application to textiles and other materials is necessary and desirable because many of the older, effective antibacterial agents have been or are in the process of being removed from commercial use. The new antibacterial agent has been characterized by elemental and functional group analysis, infrared spectroscopy and thermal analysis as magnesium dihydroperoxide (MDHP), i.e. $MgO_2 \cdot 2H_2O$. This agent is water insoluble, but dispersible and may be applied as dispersions to fabrics and affixed by conventional pad-cure methods. Aqueous dispersions of this agent are remarkably stable since it retains more than 75% of its peroxide activity after 6 months. Cotton-and cotton/polyester-blend fabrics containing the agent are antibacterial to representative gram-positive and gram-negative bacteria after curing. This activity is retained for 30 launderings on the blend fabrics and up to 50 launderings on cotton fabrics.

This salt is readily available commercially from many manufacturers.

Calcium Peroxide

Calcium peroxide (CaO_2) is a solid peroxide with a white or yellowish color. Its molecular weight is 72.0772 g/mol and its CAS number is 1305-79-9. Its density is 2.91 g/cm^3 and its melting point is 196 °C. For all practical purposes, calcium peroxide is insoluble in water but will dissolve in acid to form H_2O_2. When in contact with water, it will immediately begin to decompose releasing oxygen. It is a tetragonal crystal with a space group of I4/mmm and point group D_{4h}^{17} (Fig. 3.9).

Calcium peroxide is manufactured to varying specifications and purity and has been used in different areas of

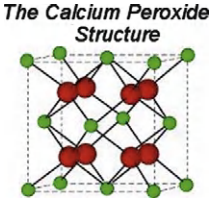

FIGURE 3.9

TABLE 3.8

Salt	Hydrogen peroxide	Magnesium peroxide	Calcium peroxide
Appearance	Liquid	Powder	Powder
Concentration	Dilute	25–35%	60–75%
Active oxygen	0.5–3.0%	7–10%	14–17%
Solubility in water	Soluble	Low solubility	Low solubility
Rate of oxygen release	Instantaneous	3–9 months, based on soil conditions	3–9 months, based on soil conditions

industry and agriculture. In agriculture, it is used as a fertilizer and is also used in the presowing treatments of rice seed. Also, calcium peroxide has found use in the "aqua-culture" industry where it is used to oxygenate and disinfect water, and in the ecological restoration industry as it is used in the treatment of soils. Calcium peroxide is used in a similar manner to MgO_2 for environmental restoration programs. It is used to restore soil and groundwater contaminated with petroleum hydrocarbons by stimulating aerobic microbial degradation of the contaminants in a process known as "Enhanced-Insitu-Bioremediation". Lately, calcium peroxide has begun to replace MgO_2 for this treatment because of its greater availability of nascent oxygen and lower cost. The following table shows a comparison (Table 3.8).

Additionally, calcium peroxide has found use in a coating to supply oxygen to rice seeds during germination. Rice seeds coated with CaO_2, held in place with sodium silicate, were reported to produce more seedlings of better quality and faster growth due to the availability of oxygen over a period of time. Prior practice has involved planting seedlings directly (of which only a fraction survived) whereas more seeds can be planted in submerged soil at a cheaper cost and better seedling plant features than previous methods used for centuries in far East countries.

Calcium peroxide is an ecologically pure substance that has been used in various fields of industry and agriculture.

In environmental protection, it is used:

- For treating wastewater and remediation of groundwater
- For decontaminating soil

In agriculture, it is used:

- As a fertilizer rich with oxygen
- For stimulating seed growth and their germination capability
- For presowing treatment of rice seed, which allows to do planting not by seedlings, but by dry seeds, coated with calcium peroxide. Such a technique sufficiently decreases the work expenditure and increases crop capacity.

In aquaculture, it is used:

- To provide sufficient dissolved oxygen
- To adjust pH value
- To reduce the subaqueous content of ammonium and nitrogen
- To eliminate carbon dioxide and sulfureted hydrogen
- To prevent anaerobic bacteria from proliferation and application to manure heaps to kill disease-carrying bacteria originating from animal defecation.

In poultry raising, it is used:

- To decontamination of fodder
- To increase productivity, safety from disease in hens and improving their eggs.

In cattle breeding, it is used:

- For prophylaxis of casein-stone formation in the abdomen and to prevent diarrhea with newborn calves
- As an antimicrobic agent to prevent disease
- For stimulating protective organism strength
- For normalizing activity of the alimentary canal
- For activating digestion work
- For great increasing live-stock safety.

In the bakery industry, it is used:

- To improve bread crumb and its porosity
- To keep moisture in dough during its baking
- To initiate yeast growth.

The alkaline earths, with the exception of Be and Mg, all form octahydrates in a manner similar to those of the hydroxides. By slow diffusion of NH_3 gas into a very cold solution of the nitrate and hydrogen peroxide, crystals of these compounds have been obtained. Calcium peroxide octahydrate is tetragonal with a space group of D_h^2-P4/mmc. The crystal lattice parameters are: $a = 6.202$ Å and $c = 5.502$ Å. Ca^{2+} atoms reside at (0,0,0) and O′ atoms are at (1/2, 1/2, ±w). H_2O molecules are shown in Fig. 3.10.

(x,y,z) $(\bar{x},\bar{y},z)$ $(x,y,\bar{z})$ $(\bar{x},\bar{y},\bar{z})$ $(x,\bar{y},z)$ $(\bar{x},y,z)$ $(x,\bar{y},\bar{z})$ $(\bar{x},y,\bar{z})$

FIGURE 3.10

where $w = 0.12$, $x = 0.32$, $y = 0.11$ and $z = 0.25$ within the unit cell.

In connection with an investigation on the formation and structure of certain alkaline-earth peroxides and superoxides, the dehydration of the compound $CaO_2 8H_2O$ has been studied. It has been proved that drying this hydrate with phosphorus pentoxide at room temperature will not yield pure CaO_2, but a substance with the following approximate composition:

$$Ca^{2+}\ [(O_2^{2-})_{0.87}\ (O_4^{-})_{0.16}\ (H_2O)_{0.10}]$$

Thus, the formation of a "superoxide" is involved as well as the peroxide.

Calcium peroxide may be used to rapidly de-hair cattle hides with efficiency similar to that of sodium sulfide. Under alkaline conditions (pH $\geq$ 13), a 5–15% (w/w) calcium peroxide mixture, applied in two back-to-back applications, afforded either complete or nearly complete unhairing within 10 min of total reaction time at a reaction temperature of 45 °C. Most of the removed hair was essentially broken down or dissolved in this rapid oxidative hairburn process. Alternatively, intact long strands of hair could be removed and recovered (hairsave) with a single application of the calcium peroxide solution (solids removed) followed by rapid adjustment of the hair solids to an approximately neutral pH. However, hair stubble remained on the hide after subjected to this latter "hairsave" process. The study revealed that shrinkage temperature, physical testing, dye shading, dye levelness and grain appearance were comparable to the sulfide process. In addition, several commercially available nonsulfide sharpening agents, added during "reliming" of hide pieces, were demonstrated to remove residual hair stubble that remained after the rapid oxidative hairburn.

The peroxidation of lime to CaO_2 was studied as a possible step in the commercial production of H_2O_2. Experiments were made with commercial grade CaO, which averaged about 60% CaO initially, and with high-purity (90 to 95%) CaO at oxygen pressures of 1000 and 1525 psia. The equilibrium temperatures of the CaO–CaO_2–O system for these two pressures were determined to be 106 °C and 111 °C, respectively. Only traces of CaO_2 were formed from CaO and oxygen gas. The experimental results indicated that the equilibrium relationships of this system are not favorable for the peroxidation of lime.

Calcium peroxide is available commercially both as a powder and a slurry.

Strontium Peroxide

Strontium peroxide has the molecular formula of SrO_2 and the molecular weight of 119.6194 g/mol. It is an oxidizing agent that is used for bleaching. It has also been used in some pyrotechnic displays to provide a vivid-red color. Its CAS number is 1314-18-7 and its density is 4.56 g/cm^3. When heated to 215 °C, it decomposes. Like the other alkaline earth peroxides, it can be prepared by reaction of the nitrate and sodium peroxide in a cold solution:

$$Sr(NO_3)_2 + Na_2O_2 + xH_2O \Rightarrow SrO_2 \cdot xH_2O + 2NaNO_3$$

The hydrated form is usually the octahydrate. If the anhydrate is desired, the hydrated peroxide is dried and then sintered at 350 °C for 10 min or less:

$$SrO_2 \cdot xH_2O + \text{heat} \Rightarrow SrO + SrO_2 + H_2O$$

About equal amounts of oxide and peroxide form. The ratio is a function of the time and temperature of heating. To separate the two forms, the heated mass is plunged into a large volume of water where the oxide forms the hydroxide. The peroxide is insoluble whereas the hydroxide is soluble, allowing the separation of the two by filtration. The peroxide is then vacuum dried. If desired, the hydroxide solution can be mixed with hydrogen peroxide to form the octahydrate that is then dehydrated as described.

Like its calcium homologue, strontium peroxide octahydrate is insoluble in water but will dissolve in acid to form H_2O_2. When in contact with water, it will immediately begin to decompose releasing oxygen. It is a tetragonal crystal with a space group of D_{4h}^{17} I4/mmm. The crystal lattice parameters are: $a = 6.322$ Å and $c = 5.552$ Å. Sr^{2+} atoms reside at (0,0,0) and O′ atoms are at (1/2, 1/2, ±w). H_2O molecules are shown in Fig. 3.11.

(x,y,z) ($\bar{x}$,$\bar{y}$,z) (x,$\bar{y}$,z) ($\bar{x}$,y,$\bar{z}$) ($\bar{x}$,y,z) ($\bar{x}$,y,z) ($\bar{x}$,y,$\bar{z}$) ($\bar{x}$,y,$\bar{z}$)

FIGURE 3.11

where $w = 0.11$, $x = 0.32$, $y = 0.13$ and $z = 0.27$ within the unit cell. The following diagram presents the structure of SrO_2 as the anhydrate.

Eight single crystals of strontium peroxide as the anhydrate were prepared and the crystal structure was characterized by X-ray diffraction. The crystallographic data were successfully refined as the calcium carbide structure (space group $I4/mmm$, $Z = 2$). The results clearly indicate that the peroxide is a nonstoichiometric compound, MO_{2-x} (M = Sr), with a peroxide deficiency and **that oxide ions are present on interstitial lattice sites** (Fig. 3.12).

The composition rage extends from near stoichiometry to compounds with a total oxygen content of 1.90 in the anhydrous strontium peroxide. It was found that the oxide ions, replacing the peroxide molecular ions, occupy an interstitial position that is in the middle of the replaced peroxide molecular ion. A decrease of peroxide content in the crystal results as well as a decrease in the c axis of the tetragonal unit cell of the

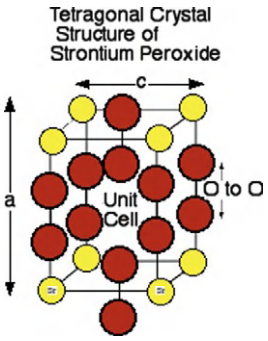

FIGURE 3.12

structure. But, the *a* axis remains almost constant. Furthermore, the peroxide bond length decreases, as confirmed by Raman spectroscopy. Thus, the nonstoichiometry results due to the size of the Sr^{2+} atom in the structure.

Strontium peroxide is available commercially.

Barium Peroxide

Barium peroxide has the chemical formula of BaO_2 and the molecular weight of 169.3324 g/mol. Its CAS number is 1304-29-6. Its density is 5.68 g/cm^3 and its melting point is 450 °C. Its boiling point is 810 °C, a point where it decomposes to BaO and oxygen. It is relatively insoluble in water. This gray-white solid is one of the most common of the inorganic peroxides since it has been traditionally used to prepare them. The original method to prepare oxygen gas was based upon the "Brin process". It was noted by Boussingault (1878), that when Baryta (BaO) is heated to low redness (~700 °C) in a current of air, it takes up oxygen and becomes barium dioxide (BaO_2). Further heating of this dioxide at a higher temperature converts it into free oxygen and Baryta, the latter being ready for use again. It was L. D. Brin who perfected a commercial process to produce oxygen gas. He discovered that, by heating the dioxide in a partial vacuum, the temperature necessary to drive off its oxygen was much reduced. He also found that by supplying the air to the Baryta under a moderate pressure, its absorption of oxygen was greatly assisted. Under these conditions, and by carefully purifying the air before use, it became possible to use the Baryta an indefinite number of times. Thus, the process became practical, as it was theoretically, continuous.

Barium peroxide is best prepared by reacting barium nitrate with sodium peroxide in a cold solution:

$$Ba(NO_3)_2 + Na_2O_2 + xH_2O \Rightarrow BaO_2 \cdot xH_2O + 2NaNO_3$$

The hydrated form is usually the octahydrate. If the anhydrate is desired, the hydrated peroxide is dried and then sintered at 350 °C for 10 min or less:

$$4BaO_2 \cdot xH_2O + \text{heat} \Rightarrow 2BaO + 2BaO_2 + xH_2O + O_2$$

About equal amounts of oxide and peroxide form. The ratio is a function of the time and temperature of heating. To separate the two forms, the heated mass is plunged into a large volume of water where the hydroxide is formed. The peroxide is insoluble whereas the hydroxide is soluble, allowing the separation of the two by filtration. The peroxide is then vacuum dried. If desired, the hydroxide solution can be mixed with hydrogen peroxide to form the octahydrate that is then dehydrated as described.

BaO_2 is an iron gray or white powder. It is slowly decomposed in air, forming the hydroxide and oxygen. It does not dissolve in water, but can slowly hydrolyze, forming hydrogen peroxide in solution. It is a strong oxidizing agent and will explode if direct contact with organic matter occurs. Therefore, barium peroxide is always diluted to form a slurry before usage.

Barium peroxide is a strong oxidizing agent that is used for bleaching. Barium peroxide contains O_2^{2-} subunits wherein the oxygen atoms bond to each other as well as to the barium.

Hydrogen peroxide can also be prepared via the related reaction:

$$BaO_2 + H_2SO_4 \Rightarrow H_2O_2 + BaSO_4$$

Thus, barium peroxide will react in solution with a soluble sulfate salt to produce other peroxides:

$$BaO_2(\text{solid}) + Na_2SO_4(aq) \Rightarrow 2NaO_2(aq) + BaSO_4(\text{solid})$$

$BaO_2 \cdot 8H_2O$ has the tetragonal lattice structure. The crystal lattice parameters are: $a = 6.508$ Å and $c = 5.752$ Å. Ba^{2+} atoms reside at (0,0,0) and O' atoms are at (1/2, 1/2, ±w). H_2O molecules are shown in Fig. 3.13.

$$(x,y,z)\ (\bar{x},\bar{y},z)\ (\bar{x},y,z)\ (\bar{x},y,\bar{z})\ (x,y,\bar{z})\ (\bar{x},y,z)\ (\bar{x},\bar{y},z)\ (\bar{x},y,\bar{z})$$

FIGURE 3.13

where $w = 0.10$, $x = 0.32$, $y = 0.12$ and $z = 0.27$ within the unit cell. The unit cell has the tetragonal crystal structure, as shown for the SrO_2 compound. In this structure, Ba^{2+} is bound to ten oxygen atoms, eight at 2.788 Å and two at 2.648 Å. The bond length in the peroxide anion is 1.482 Å.

The crystal structures of eight single crystals of barium peroxide, prepared by high-pressure, high-temperature synthesis, were determined by X-ray diffraction. The crystallographic data were successfully refined in the calcium carbide structure (space group $I4/mmm$, $Z = 2$). The results clearly indicate that this peroxide is a nonstoichiometric compound, BaO_{2-x}, with a peroxide deficiency and that oxide ions are present on interstitial lattice sites. The composition rage extends from near stoichiometry to compounds

with a total oxygen content of 1.72 in the barium peroxide. The oxide ions, replacing the peroxide molecular ions, occupy an interstitial position that is in the middle of the replaced peroxide molecular ion. A decrease of the peroxide content in the crystal results in a decrease of the *c* axis of the tetragonal unit cell of the structure, while the *a* axis remains almost constant. Furthermore, the peroxide bond length decreases, as confirmed by Raman spectroscopy.

Barium peroxide is used as a hydrogen peroxide source and oxygen oxidant, as well as a bleaching agent. Its main usage has been for making hydrogen peroxide and oxygen, in organic syntheses, fabric printing and dyeing.

Barium peroxide is available commercially, primarily as the oxctahydrate (which is the more stable form of this peroxide).

Radium Peroxide

Radium peroxide is expected to have the molecular formula of RaO_2 and the molecular weight of 258.0242 g/mol. It could be prepared by the reaction of $Ra(OH)_2$ with sodium peroxide in a cold solution:

$$Ra(OH)_2 + Na_2O_2 \Rightarrow RaO_2 + 2NaOH$$

The octahydrate is the expected product but there is no record of this compound ever having been prepared because of the lack of interest by industry and academia. RaO_2 is expected to have a tetragonal structure but it has not been measured. Whether the Ra^{2+} cation is too large to fit into the Ca_2C structure, like the Sr and Ba homologues, remains unknown.

3.1.4. Hyperoxides of the Alkaline Earths

The term "hyperoxide" is meant to include literature data on the molecular oxygen anions O_2^{2-}, O_2^-, and O_3^- that characterize the structures of simple peroxy-compounds: peroxides, superoxides, and ozonides. Most of the alkaline earth compounds are not stable in comparison to those of the alkali metals. In general, the superoxide and ozonide salts of magnesium are stable at room temperature while those of calcium are stable up to about 0 °C and those of strontium and barium up to about –70 °C.

Beryllium Hyperoxides

In view of the fact that beryllium (Be^{2+}) does not form peroxides, there is little likelihood that a superoxide can be produced. Thus, a compound like the superoxide, $Be(O_2)_2$ or $Be(OH)(O_2)_2$, {BeO_4 or $Be(OH)O_4$} is implausible. Even an ozonide like $Be(O_3)_2$ or $Be(OH)(O_3)_2$, {BeO_6 or $Be(OH)O_6$} is questionable. The fact that the peroxide does not form is related to the small size of the Be^{2+} cation, compared to the oxide ($O^=$) anion.

Magnesium Hyperoxides

Magnesium forms both superoxides and ozonides having a general formula: $Mg(O_2)_2$ or MgO_4. They may be prepared by the reaction of the peroxide, suspended in Freon-12 (Cl_2F_2C = dichloro-difluoro-methane) with a solution of ozone in the same medium:

$$2MgO_2 + 2O_3 \Rightarrow Mg(O_2)_2 + Mg(O_3)_2$$

The superoxide is more stable than the ozonide which will decompose to form the superoxide. Magnesium superoxide has a rhombohedral lattice with $\alpha_{hex} = 11.44$ Å, $c/a/ = 1.12$ ($\alpha_{rhombohedron} = 7.88$ Å, $\alpha = 93°$). Above 10 °C, magnesium ozonide decomposes to the superoxide which then decomposes to the peroxide (Fig. 3.14).

Optical and resonance Raman spectra of the reaction products of Mg, Ca, Sr, and Ba with ozone were observed in argon and nitrogen matrices. The visible spectra were characterized by strong, vibronically structured absorptions between 540 and 350 nm, and are assigned to the alkaline earth metal ozonides, $M(O_3)_2$. Vibrational analysis yielded ω_1- and $\omega_1 x_1$ values of about 900 and 6/cm, respectively, with only slight variation from metal to metal. Resonance Raman spectra consisted of a strong fundamental near 1020/cm and two overtones with decreasing intensity. Oxygen-18 substitution confirmed the vibrational assignments, which agree very well with the alkali metal ozonide spectra.

Magnesium superoxides are not stable enough to be available commercially.

Calcium Hyperoxides

Calcium forms at least two hyperoxides, an ozonide, CaO_3 and a di-superoxide, CaO_4 or O_2CaO_2. The usual method for making such compounds involves the use of liquid ammonia or Freon-12, but calcium ozonide does not form under such conditions. The best method involves the use of potassium ozonide in a reaction with calcium peroxide:

$$CaO_2 + 2KO_3 \Rightarrow Ca(O_3)_2 + KO_2$$

Originally, attempts to prepare CaO_4 have centered around the reaction between CaO and aqueous hydrogen peroxide, illustrated as follows:

$$CaO + 3H_2O_2 \Leftrightarrow CaO_4 + 3H_2O$$

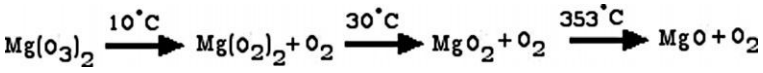

FIGURE 3.14

The removal of the water posed problems and resulted in low yields of CaO_4. In view of this problem of water removal inherent in the use of hydrogen peroxide, other methods were sought searching for an improved method of making superoxides in a water-free system. During these investigations, it was discovered that the superoxides could be prepared by the ozonation of alkaline earth metal oxides, usually in the presence of an alkali metal compound as a catalyst or ozone carrier, with subsequent thermal decomposition of the resulting alkaline earth metal ozonide to the superoxide.

The following is a description of a method used to prepare calcium ozonide:

> "The alkaline earth metal starting material needs to be substantially free of water at the start of the ozonation treatment. For example, lime may be dried by use of an inert gas heated as high as 400–500 ° C. Also, traces of water in CaO may be removed by mixing, with this starting material, alkali metal in the form of an oxide, such as the peroxides Na_2O_2 or K_2O_2 which absorb the moisture to form the hydroxide. Thus, the alkali metal compound is present usually as the hydroxide. The peroxides are most often used, as may be also the hydroxides. Enough of the alkali metal peroxide or hydroxide is employed to give a catalytic effect, at least 0.1 to 10% by weight of the reaction mass, preferably about 0.5 to 6%".
>
> Ozone may be supplied by any convenient means and in a concentration suitable for the desired conversion to oxonide. Usually, the ozone is supplied as a 1 to 5% concentration in oxygen, e.g. about 3%. This gas mixture is readily obtained by passing relatively pure oxygen through an electric arc. Since the instability of ozone increases at higher temperatures and is quite pronounced at above about 100 °C, ambient temperature (20 °C) is often chosen for the reaction to form ozonide. The gas should be substantially anhydrous.
>
> The ozonide is decomposed to alkaline earth metal superoxide by a gentle treatment with oxygen at a slightly elevated temperature. Usually, the temperature should be kept below 100 °C. The oxygen may be diluted with inert gases, but the presence of nitrogen should be avoided to obviate nitride formation. The end of the reaction is often signaled by a color change in the treated solid. For example, calcium superoxide is yellow.

In another method, the following description was made:

> "About 10 g of dry commercially obtained calcium peroxide was mixed with 0.5 g KOH and heated to about 400–500 °C to thoroughly dry it by passing oxygen through it. After cooling, the powder was subjected to a stream of dry 3% ozone for about 2 h at room temperature. At this time, the reaction mixture containing calcium ozonide is subjected to a stream of dry oxygen and the temperature is raised to about 100 °C. After about 1 h, the reaction mixture is cooled and the resulting calcium superoxide is recovered and maintained free from moisture".
>
> About 100 g of calcium nitrate mixed with about 1 g Na_2O_2 is first heated to about 350–400 °C in flowing oxygen for several minutes. The dry calcium nitrate is then allowed to cool and is subjected to a stream of a dry 3% ozone–oxygen mixture at room temperature. After about 2 h, the resulting calcium ozonide is subjected to oxygen at about 60–80 °C and the calcium superoxide is recovered.

Both the superoxide and ozonide products of calcium are decomposed by water so that moisture should be excluded from the reaction site and from the product obtained. Thus, the ozone–oxygen mixture should be free from moisture, and storage containers should be blanketed with a dry gas. Ordinary ambient temperatures, about 20–30 °C, can be used, but because of the tendency of the ozonides to decompose at even moderately elevated temperatures, it is preferred to use low temperatures. Temperatures as low as −80 °C and lower are feasible for use in carrying out the process, but the reaction at such low temperatures is quite slow. The preferred temperature is about 0 °C, where the reaction takes place at a satisfactory rate while little or no decomposition is ordinarily encountered. Temperatures higher than 30 °C. should be avoided.

In the case of $Ca(O_2)_2$, the reaction gives primarily the 3_B2 open bent O_2CaO_2 superoxide product, but the reaction in condensed N_2 favors the 1_A1 cyclic CaO_2 peroxide species. Calcium superoxide, O_2CaO_2, is characterized as a D_{2d} species with +1.12 charge on Ca and −0.28 on each O, in contrast to calcium peroxide, CaO_2, a C_{2v} molecule with +1.05 charge on Ca and −0.525 on each oxygen atom.

Calcium ozonide, CaO_6 or $Ca(O_3)_2$, decomposes appreciably at 25 °C, strontium ozonide a little below 0 °C, and barium ozonide at 0 °C. Calcium and oxygen isotopic data (^{44}Ca and ^{18}O) strongly support the observation of rhombic CaO_4 and isosceles triangular CaO_6 species.

Neither calcium ozonide nor calcium superoxide is available commercially.

Strontium Hyperoxides

The reaction of a solution of ozone in Freon 12 with a suspension of strontium peroxide in the same medium at a negative temperature gives a mixture of the ozonide $Sr(O_3)_2$ and the superoxide $Sr(O_2)_3$. The ozonide is not formed above –70 °C, and the superoxide is not formed above –20 °C. The heating curve for the preparation obtained at –100 °C is characterized by the presence of one endothermic effect which begins at –173 °C and is accompanied by a vigorous evolution of oxygen. This decomposition effect, corresponding to the ozonide transforming into the superoxide, could not be separated. Thus, the decomposition relates to the formation of a mixture of the two compounds:

$$2SrO_2 + 2O_3 \Rightarrow Sr(O_3)_2 + Sr(O_2)_2$$

and is caused by the transfer of an electron from the negatively doubly charged O_2^{2-} ion to ozone.

Strontium peroxide forms a hydrogen peroxide "hydrate", i.e. $SrO_2 \cdot 2H_2O_2$ which decomposes at 50 °C to form a series of compounds, including the superoxide:

$$SrO_2 \cdot 2H_2O_2 \Rightarrow Sr(O_2)_2\ (36\%) + SrO_2\ (56\%) + Sr(OH)_2\ (8\%)$$

ESR spectroscopy showed that the product obtained as the result of the disproportionation of SrO_2 $2H_2O_2$ contains strontium superoxide [$Sr(O_2)_2$] with a paramagnetic O_2^- molecular anion.

Strontium ozonide has been synthesized, starting from cesium ozonide, via cation exchange in liquid ammonia. From these solutions, if kept at −78 °C for 14 days, an ammoniate, $Sr(O_3)_2 \cdot 9NH_3$, crystallizes. The coarse, ruby red crystals decompose above the boiling temperature of ammonia and are extremely sensitive to moisture. According to a single-crystal structure determination (P4/nmm; $a = 7.597$ Å, $Z = 2$); $Sr(O_3)_2 \cdot 9NH_3$ consists of ozonide anions and strontium cations. The complex cations form an virtual cubic close packing, where the octahedral and half of the tetrahedral interstices are occupied by ozonide anions. The anions are orientationally disordered.

There are no listed suppliers for either the ozonide or superoxide of strontium.

Barium Hyperoxides

The reaction of a solution of ozone in Freon 12 with a suspension of barium peroxide in the same medium at a negative temperature gives a mixture of the ozonide $Ba(O_3)_2$ and the hyperoxide $Ba(O_2)^2$. The ozonide is not formed above –70°, and the superoxide is not formed above –40°. The formation of barium ozonide $Ba(O_3)_2$ with a yield of 82% of the basic substance by the reaction of ozone dissolved in Freon-12 with a suspension of barium peroxide in the same medium at –100 to –105° was demonstrated. It was determined that barium ozonide is thermally stable below –70° and that the primary decomposition product of barium ozonide is the superoxide $Ba(O_2)_2$. The thermal stability of these hyperoxide compounds is illustrated in Fig. 3.15.

There is no listed commercial supplier for these compounds and they are not available for sale.

Radium Hyperoxides

No radium hyperoxide compounds are known.

3.2. ALKALINE EARTH OXY-SULFUR COMPOUNDS

The alkaline earths form a series of compounds with sulfur, including sulfides, sulfites and sulfates. These are primarily based upon the acids, H_2S, H_2SO_3 H_2SO_4, and variations thereof. sulfur forms a large number of oxy-sulfur anions including those provided in Table 3.9.

Many of these anions are the result of decomposition of one phase into another. We will describe only those salts that form from the acids or those that have been studied in the scientific literature. Many of these acids, such as dithionic acid, are not stable and are only known in solution. However, it is possible to form stable compounds from the stable acids in solution even though the acids cannot be formed separately.

3.2.1. Oxy-Sulfur Acids

Hydrogen Sulfide

Hydrogen sulfide has the chemical formula of H_2S. It is a colorless, very poisonous, flammable gas with the characteristic foul odor of rotten eggs. It often results from the bacterial breakdown of organic matter in the absence of oxygen, such as in swamps and sewers where anaerobic digestion can take place. It also occurs in volcanic gases, "natural gas", and some well waters. Hydrogen sulfide has numerous names, some of which are archaic.

Hydrogen sulfide is slightly heavier than air with a specific gravity of 1.363 g/l. The CAS number is 7788-06-4 and its molecular weight is 34.0822 g/mol. Its melting point is –80.3 °C and its boiling point is –60.3 °C. A mixture of H_2S and air is explosive. Hydrogen sulfide and oxygen burn with a blue flame to form SO_2 and H_2O. In general, this compound acts as a reducing agent. It is soluble in water at 0.41 g/100 ml (20 °C) and 0.255 g/100 ml (90 °C). H_2S is soluble in carbon disulfide, methanol, acetone and alkanolamines. The heat of formation, ΔH_f, is –20.599 kJ/mol.

Hydrogen sulfide is somewhat soluble in water and acts as a weak acid, giving both the hydrosulfide ion HS^- ($pK_a = 6.9$ in 0.01–0.1 mol/l solutions at 18 °C) and the sulfide anion S^{2-} ($pK_a = 11.96$):

$$H_2S \Leftrightarrow HS^- + H^+ \Leftrightarrow S^= + H^+$$

A solution of hydrogen sulfide in water is initially clear but over time turns cloudy. This is due to the slow reaction of hydrogen sulfide with the oxygen

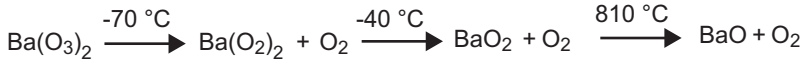

FIGURE 3.15

TABLE 3.9

Name	Formula
Peroxomonosulfate	SO_5^{2-}
Sulfate	SO_4^{2-}
Sulfite	SO_3^{2-}
Peroxodisulfate	$S_2O_8^{2-}$
Pyrosulfate	$S_2O_7^{2-}$
Dithionate	$S_2O_6^{2-}$
Metabisulfite	$S_2O_4^{2-}$
Dithionite	$S_2O_4^{2-}$
Thiosulfate	$S_2O_3^{2-}$
Tetrathionate	$S_4O_6^{2-}$

dissolved in water, yielding elemental sulfur, which precipitates out.

Small amounts of hydrogen sulfide occur in crude oil, but natural gas can contain up to 90%. About 10% of the total global emission of H_2S is due to human activity. By far the largest industrial route to H_2S occurs in petroleum refineries. The "hydrodesulfurization" process liberates sulfur from petroleum by the action of hydrogen. The resulting H_2S is converted to elemental sulfur by partial combustion via the Claus process that is a major source of elemental sulfur (In the Claus process, hydrogen sulfide is catalytically reacted with oxygen from the air to produce sulfur and sulfur dioxide). Other anthropogenic sources of hydrogen sulfide include coke ovens, paper-mills (using the sulfate method), and tanneries, where Na_2S is used for processing cowhide to form leather. H_2S arises from virtually anywhere where elemental sulfur comes in contact with organic material, especially at high temperatures.

Hydrogen sulfide is extremely lethal and 0.0047 ppm (4.7 ppb) in the air is the "recognition threshold", the concentration at which 50% of humans can detect the characteristic odor of hydrogen sulfide: less than 10 ppm has an exposure limit of 8 h per day; 10–20 ppm is the borderline concentration for eye irritation; 50–100 ppm leads to eye damage; at 150–250 ppm the olfactory nerve is paralyzed after a few inhalations, and the sense of smell disappears, often together with awareness of danger; 320–530 ppm leads to pulmonary edema with the possibility of death; 530–1000 ppm causes strong stimulation of the central nervous system and rapid breathing, leading to loss of breathing; 800 ppm is the lethal concentration for 50% of humans for 5-min exposure; and concentrations over 1000 ppm cause immediate collapse with loss of breathing, even after inhalation of a single breath.

Sulfurous Acid

Sulfurous acid has the formula H_2SO_3 and the molecular weight of 82.075 g/mol. Its CAS number is 7782-99-2. There is no clear evidence that sulfurous acid exists in solution, but the molecule has been detected in the gas phase. The conjugate bases of this elusive acid are, however, common anions: bisulfite (or hydrogensulfite) = HSO_3^- and sulfite, $SO_3^=$. Bisulfite salts are typically prepared by treatment of alkaline solutions with excess sulfur dioxide:

$$SO_2 + NaOH \Rightarrow NaHSO_3$$

HSO_3^- is the conjugate base of sulfurous acid, H_2SO_3 and its appearance is a function of solution pH:

$$H_2SO_3 \Leftrightarrow HSO_3^- + H^+$$

Sulfurous acid has not been isolated as a separate compound and does not appear to exist in solution either. An equilibrium that is much more consistent with spectroscopic evidence is given as:

$$SO_2 + H_2O \Leftrightarrow HSO_3^- + H^+$$

HSO_3^- is a weak acidic species with a pK_a of 6.97. Its conjugate base is the sulfite anion, SO_3^{2-}:

$$HSO_3^- \Leftrightarrow SO_3^{2-} + H^+$$

Bisulfites are reducing agents, as are all sulfites and sulfur dioxide, which contains sulfur in the same oxidation state of +5. Raman spectra of solutions of sulfur dioxide in water show only signals due to the SO_2 molecule and the bisulfite ion, HSO_3^-. The intensities of the signals are consistent with the following equilibrium:

$$SO_2 + H_2O \Leftrightarrow HSO_3^- + H^+$$

$$K_a = 1.54 \times 10^{-2};\ pK_a = 1.81.$$

Aqueous solutions of sulfur dioxide, which sometimes are referred to as "sulfurous acid" are used as reducing agents and as disinfectants, as are solutions of bisulfite and sulfite salts. They are also mild bleaches, and are used for materials that may be damaged by chlorine-containing bleaches.

Sulfuric Acid

Sulfuric (or sulfuric) acid, H_2SO_4, is a strong mineral. It is soluble in water at all concentrations. Sulfuric acid has many applications, and is one of the top products of the chemical industry. World production in 2001 was 165 million tons, with an approximate value of $8 billion.

Sulfuric acid is produced from sulfur, oxygen and water via the conventional contact process (DCDA) or the wet sulfuric acid process (WSA). Principle uses include lead acid batteries for cars and other vehicles,

ore processing, fertilizer manufacturing, oil refining, wastewater processing, and chemical synthesis.

Pure (undiluted) sulfuric acid is not encountered naturally on Earth, due to its great attraction for water. Sulfuric acid is a constituent of acid rain, which is formed by oxidation of sulfur dioxide by oxygen in the air in the presence of water—i.e. oxidation of sulfurous acid to sulfuric acid. Sulfur dioxide is the main by-product produced when sulfur-containing fuels such as coal or oil are burned.

Sulfuric acid is formed naturally on the Earth by the oxidation of certain sulfide minerals, such as iron sulfide. The resulting water can be highly acidic and is called acid-mine-drainage or acid-rock-drainage. This acidic water is capable of dissolving metals present in sulfide ores, which results in brightly colored, toxic streams. Sulfuric acid is produced in the upper atmosphere of the planet Venus by a photochemical reaction induced by the Sun's rays on carbon dioxide, sulfur dioxide and water vapor. Ultraviolet photons of wavelengths less than 169 nm can photodissociate carbon dioxide into carbon monoxide and atomic oxygen. The atomic oxygen is highly reactive and reacts with the SO_2 to produce SO_3 that can combine with water vapor, another trace component of Venus's atmosphere, to yield sulfuric acid. In the upper, cooler portions of Venus's atmosphere, sulfuric acid exists as a liquid, and thick sulfuric acid clouds completely obscure the planet's surface when viewed from above. The main cloud layer extends from 45 to 70 km above the planet's surface, with thinner hazes extending as low as 30 and as high as 90 km above the surface. The permanent Venusian clouds produce a concentrated acid rain, just as the clouds in the atmosphere of Earth produce water rain.

The discovery of sulfuric acid is credited to the eighth century Muslim alchemist, Jabir ibn Hayyan. The acid was later studied by the ninth century Persian and alchemist Ibn Zakariya (Rhazes), who obtained the substance by dry distillation of minerals including iron(II) sulfate heptahydrate, $FeSO_4 \cdot 7H_2O$, and copper(II) sulfate pentahydrate, $CuSO_4 \cdot 5H_2O$. When heated, these compounds decompose to Fe_2O_3 and CuO, respectively, giving off water and sulfur trioxide, which combine to produce a dilute solution of sulfuric acid. This method was popularized in Europe through translations of Arabic and Persian treatises, as well as books by European alchemists, such as the thirteenth century German Albertus Magnus.

Sulfuric acid was known to medieval European alchemists as *oil of vitriol*, *spirit of vitriol*, or simply *vitriol*, among other names. The word vitriol derives from the Latin vitreus, "glass", referring to the glassy appearance of the hydrated sulfate salts, which also carried the name vitriol. Salts called by this name included $CuSO_4$ (blue vitriol, or rarely Roman vitriol), $ZnSO_4$ (white vitriol), $FeSO_4$ (green vitriol), $Fe_2(SO_4)_3$ (vitriol of Mars), and $CoSO_4$ (red vitriol). However, red vitriol is also a twentieth century technical name for a grade of sulfuric acid.

In the seventieth century, sulfuric acid was prepared by burning sulfur together with KNO_3, in the presence of steam. As saltpeter decomposes, it oxidizes the sulfur to SO_3, which combines with water to produce sulfuric acid. This method was used in 1736, to begin the first large-scale production of sulfuric acid.

In 1746 in Birmingham, John Roebuck adapted this method to produce sulfuric acid in lead-lined chambers, which were stronger, less expensive, and could be made larger than the previously used glass containers. This "lead-chamber" process allowed the effective industrialization of sulfuric acid production. After several refinements, this method remained standard for sulfuric acid production for almost two centuries. This method used "lead chambers" where sulfur dioxide was introduced along with steam and oxides of nitrogen into three large chambers lined with sheet lead where the gases are sprayed down with water and chamber acid. The sulfur dioxide and nitrogen dioxide dissolved and over a period of a few tens of minutes, the sulfur dioxide oxidized to sulfuric acid. The presence of nitrogen dioxide was necessary for the reaction to proceed. The process is highly exothermic, and a major consideration of the design of the chambers was to provide a way to dissipate the heat formed in the reactions. Early manufacturing plants used very large wooden rectangular chambers (Faulding box chambers) that were cooled by ambient air. Around the turn of the nineteenth century, such plants required about half a cubic meter of volume to process the sulfur dioxide equivalent of a kilogram of burned sulfur. In 1831, British merchant Peregrine Phillips patented the "Contact method", which was a far more economical process for producing sulfur trioxide and concentrated sulfuric acid. Today, nearly all of the world's sulfuric acid is produced using this method. Sulfuric acid is produced today from sulfur, oxygen and water either by the conventional "Contact process" or the "wet sulfuric acid" process.

In the first step of the **Contact process**, sulfur is burned to produce sulfur dioxide:

$$S(\text{solid}) + O_2(\text{gas}) \Rightarrow SO_2(\text{gas})$$

This is then oxidized to sulfur trioxide using oxygen in the presence of a vanadium(V) oxide catalyst.

$$2SO_2 + O_2(\text{gas}) \Rightarrow 2SO_3(\text{gas}) \text{ (in the presence of } V_2O_5)$$

The sulfur trioxide is absorbed into 97–98% H_2SO_4 to form "oleum" ($H_2S_2O_7$), also known as "fuming sulfuric

acid". The oleum is then diluted with water to form concentrated sulfuric acid. The reactions are:

$$H_2SO_4(liq) + SO_3(gas) \Rightarrow H_2S_2O_7(liq)$$

$$H_2S_2O_7(liq) + H_2O(liq) \Rightarrow 2H_2SO_4(liq)$$

Note that directly dissolving SO_3 in water is not practical due to the highly exothermic nature of the reaction between sulfur trioxide and water. The reaction forms a corrosive aerosol that is very difficult to separate, instead of a liquid.

$$SO_3(gas) + H_2O(liq) \Rightarrow H_2SO_4(gas\ and\ liq)$$

In the first step of the **wet sulfuric acid** method, sulfur is burned to produce sulfur dioxide:

$$S(solid) + O_2(gas) \Rightarrow SO_2(gas)$$

or, alternatively, H_2S gas is incinerated to SO_2 gas:

$$2H_2S(gas) + 3O_2(gas) \Rightarrow 2H_2O(gas) + 2SO_2(gas)\ (+518\ kJ/mol)$$

This is then oxidized to sulfur trioxide using oxygen with V_2O_5 as a catalyst.

$$2SO_2(gas) + O_2(gas) \Rightarrow 2SO_3(gas)\ (+99\ kJ/mol)$$

The sulfur trioxide is hydrated into sulfuric acid H_2SO_4:

$$SO_3(gas) + H_2O \Rightarrow H_2SO_4(gas)\ (+101\ kJ/mol)$$

The last step is the condensation of the sulfuric acid to liquid 97–98% H_2SO_4:

$$H_2SO_4(gas) \Rightarrow H_2SO_4(liq)\ (+69\ kJ/mol)$$

The overall process can be summarized as shown in Fig. 3.16.

The technology is able to treat one or more sulfur-containing streams such as:

- H_2S gas from amine-gas treating units.
- Off-gas from sour water strippers (SWS gas).
- Spent acid from alklyation units.
- Claus process tail gas.
- Heavy residue or petcoke-fired utility boiler off-gas.
- Boiler flue gases from various processes.
- Metallurgical process gas.

Prior to 1900, most sulfuric acid was manufactured by the lead chamber process.

The current process (2005) used to manufacture H_2SO_4 is shown in Fig. 3.17.

This process takes advantage of the fact that several steps in the manufacturing are highly exothermic. The heat is absorbed in water and then transferred to the steps that are more endothermic. The process starts with dry air from the drying tower and sulfur which is "burned" in air to form a gas containing about 10% SO_2 at a temperature of 950–1000 °C. The first boiler removes some of that heat so that the gas entering the #1 catalytic section of the catalytic converter is about 420 °C (the optimum temperature for conversion) where about 60–65% of the SO_2 is converted to SO_3. The reaction is very exothermic and the gas remainder is cooled in the #2 boiler before entering the #2 section of the converter. From there, the gas stream is directed to the "hot-heat" exchanger before entering the #3 section. From there, the gas stream is directed through the "cold-heat" exchanger and then through the "first-absorber" where the SO_3 is allowed to react with water to form the acid. The gas stream, at about 80 °C, is directed back through the "hot-heat" exchanger where its temperature is adjusted and then through the final stage #4 section of the converter.

The gas stream, which is now essentially all SO_3 gas (>99.5%), goes to the final absorber and the depleted gas stream is directed to the stack. The liquid stream is directed among various stages of acid pumps and water is added. The acid stream is finally cooled and directed to the "drying-tower" and then to "acid-storage".

This manufacturing design process was mandated by the legislation regarding "acid rain", therein, all stack emissions must contain no more than 0.5% SO_2 in their emissions to the atmosphere. Sulfuric acid is a very important commodity chemical, and indeed, a nation's sulfuric acid production is a good indicator of its industrial strength.

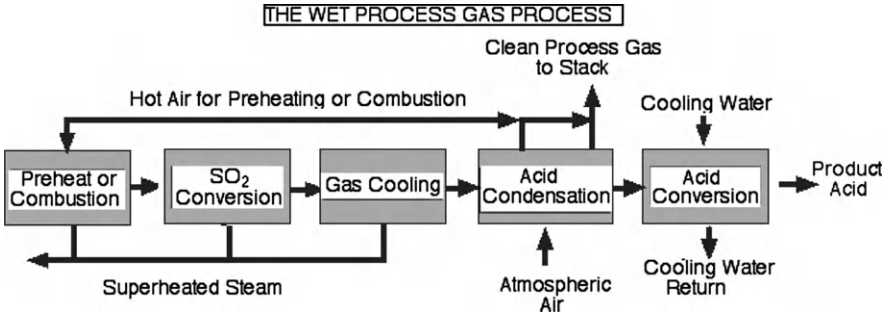

FIGURE 3.16

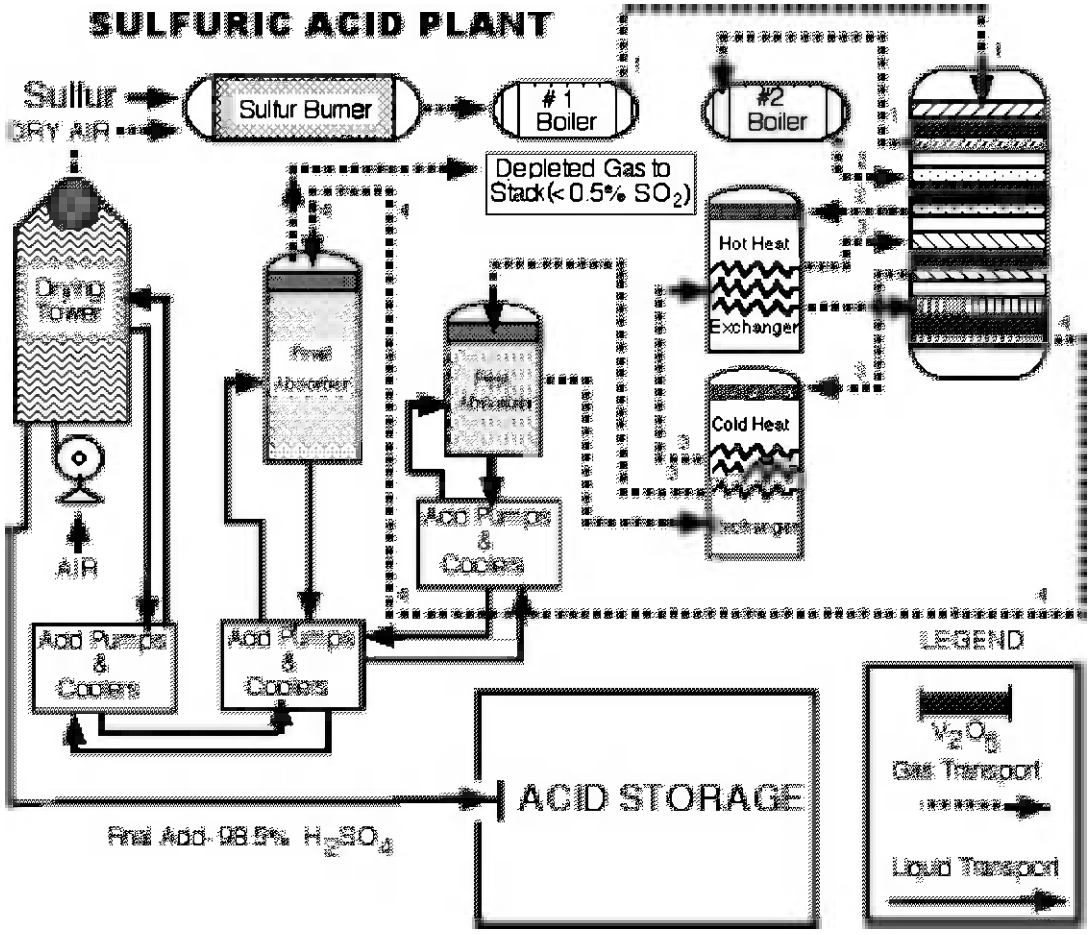

FIGURE 3.17

Thiosulfuric Acid

Thiosulfuric acid is a sulfur oxoacid. The free acid cannot be prepared by acidifying thiosulfate salts as the acid readily decomposes in water. The decomposition products can include S, SO_2 H_2S, H_2SO_4, polysulfanes $= H_2S_n$ and polythionates such as the tetrathionate anion, $S_4O_6^{2-}$, depending on the exact reaction conditions. Anhydrous methods of producing the acid are:

$$H_2S + SO_3 \Rightarrow H_2S_2O_3 \cdot n Et_2O \text{ (in diethyl ether at } -78\ ^\circ C)$$

$$Na_2S_2O_3 + 2HCl \rightarrow 2NaCl + H_2S_2O_3 \cdot 2Et_2O$$
(in diethyl ether at $-78\ ^\circ C$)

$$HSO_3Cl + H_2S \Rightarrow HCl + H_2S_2O_3 \text{ (low temperature)}$$

The anhydrous acid also decomposes below 0 °C:

$$H_2S_2O_3 \Rightarrow H_2S + SO_3$$

There is another isomeric form, a white crystalline adduct of hydrogen sulfide and sulfur trioxide, $H_2S \cdot SO_3$, which can also be prepared at low temperature. Thiosulfuric acid contains the sulfur in the +6 oxidation state and has the Lewis structure shown in Fig. 3.18.

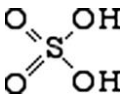

FIGURE 3.18

where the molecule is tetrahedral. The CAS number is 13686-28-7 and its molecular weight is calculated to be 114.145 g/mol. It decomposes below 0 °C in nonaqueous media and goes directly to sulfur and sulfur dioxide in water.

Pyrosulfuric Acid or Disulfuric Acid

Although the salts are called pyrosulfates, the acid is called disulfuric acid. Disulfuric acid has the molecular formula of $H_2S_2O_7$ where the S-atom is in the +5 oxidation state and a Lewis structure shown in Fig. 3.19.

Its CAS number is 7783-05-3 and its molecular weight is 178.1417 g/mol. It melts at 36 °C. It is a major

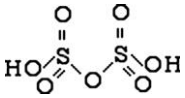

FIGURE 3.19

constituent of fuming sulfuric acid (also known as "oleum") described by the formula $ySO_3 \cdot H_2O$ where y is the total molar sulfur trioxide content. The value of y can be varied, to include different types of "oleum". They can also be described by the formula: $H_2SO_4 \cdot xSO_3$, which are also minor constituents of liquid anhydrous sulfuric acid due to the equilibria:

$$H_2O + SO_3 \Leftrightarrow H_2SO_4 + SO_3 \Leftrightarrow H_2S_2O_7$$

Thus, the disulfuric acid is prepared by reacting excess SO_3 with sulfuric acid:

$$H_2SO_4 + SO_3 \Rightarrow H_2S_2O_7$$

Disulfuric acid is a strong acid and protonates sulfuric acid in the (anhydrous) sulfuric acid solvent system. An alternative IUPAC name is *(sulfo-oxy)sulfonic acid*.

Dithionic Acid

Dithionic acid, $H_2S_2O_6$, is a chemical compound known only in solution. This acid is dibasic and salts called dithionates are known. All dithionates are readily soluble in water. They are mild oxidizing and mild reducing agents. The structure of dithionate ion is like ethane, but two SO_3 groups adopt an almost eclipsed conformation. The S–S length is 2.15 Å; S–O bonds are rather short with bond length of 1.43 Å. The Lewis structure is shown in Fig. 3.20.

The sulfur atoms are in the +6 oxidation state and are directly bonded to each other. In the pyrosulfate molecule, they are separated by an oxygen atom. Only a few dithionates are known, including barium dithionate. All of the other alkaline earth dithionates are less stable and have not been studied extensively. Thus, for the alkaline earths combined with sulfur-containing compounds, one would expect to find sulfides and salts of the oxo-sulfur acids:

Sulfides = MS
Sulfites
Hydrogen sulfites (Bisulfites)
Sulfates
Thiosulfates
Pyrosulfates or disulfates
Dithionates or tetrathionates

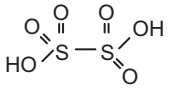

FIGURE 3.20

3.2.2. Alkaline Earth Sulfides

Beryllium Sulfide

Beryllium sulfide has the molecular formula of BeS and the molecular weight of 41.077182 g/mol. It can be prepared by the direct reaction of the elements, calcined in an inert atmosphere, at a 1.0:1.05 molecular ratio:

$$Be + S + \text{heat} \Rightarrow BeS$$

Beryllium does not form a polysulfide. Its CAS number is 13598-22-6. Its density is 2.36 g/cm^3 and its refractive index is 1.741. Its crystals are isometric and the structure is of the cubic-sphalerite type. The space group is $F\bar{4}3m$ (T_4^2) with the unit-cell dimension of $a = 4.862$ Å. There are four BeS units per cell. Crystals are isotropic (Fig. 3.21).

Due to their large energy gap and hardness, beryllium sulfides and selenides are interesting materials for improving the lifetime of optical devices made of other II-VI-semiconductors by forming multicombinatory alloys, notably with ZnS or CdS. Among them, beryllium sulfide (BeS) is an indirect semiconductor with a band gap of 7.4 eV direct and 4.7 eV indirect. BeS, which has only been prepared in powder form, is the only sulfur-containing II-VI-compound without any published experimental information about its electronic structure. This is due to the fact that the commonly employed method of choice (photoelectron spectroscopy) cannot be applied to this insulating powder because of charging effects, the lack of a suitable surface preparation method, and the fact that no sufficiently large single crystals have been available. According to theory, BeS is an indirect semiconductor material with the highest valence band edge at Γ and the lowest conduction band edge at X. The electrical conductivity of BeS has been found to be p-type. This has been attributed to Be vacancies or $S^=$ interstitials.

Thermodynamic properties of BeS are:

$$\Delta H_f = -234.3 \text{ kJ/mol}$$

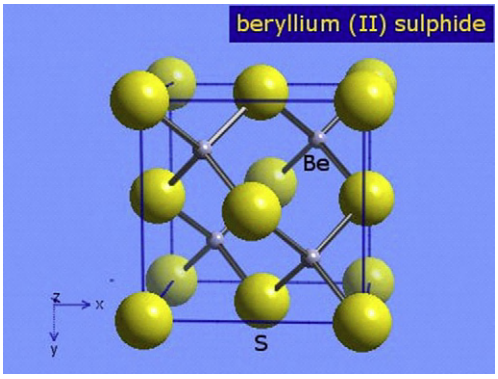

FIGURE 3.21

$$S_0 = 34.0\ \mathrm{J/mol\cdot{}^\circ K}$$

$$C_p = 34\ \mathrm{J/mol\cdot{}^\circ K}$$

Danalite is an iron, beryllium sulfo-silicate mineral with the formula: $(Fe^{2+})_4Be_3(SiO_4)_3S$. It is a rare mineral that occurs in various types of granites, pegmatites, and gneisses. It has been found at a number of places in the U.S., Canada, England, Russia, Australia and Japan.

Beryllium sulfide is available in limited quantities commercially.

Magnesium Sulfide

Magnesium sulfide has the molecular formula of MgS and the molecular weight of 58.3826 g/mol. It can be prepared by the direct reaction of the elements, calcined in an inert atmosphere, at a 1:1.1 molecular ratio:

$$\mathrm{Mg + S + heat \Rightarrow MgS}$$

Its CAS number is 12032-36-9. Its density is 2.68 g/cm^3 and its melting point is 2085 °C. MgS also forms by the reaction of hydrogen sulfide gas with soluble magnesium salts in solution. Aside from being a component of some slags, MgS is a rare **nonterrestial** mineral "niningerite" detected in some meteorites. MgS is also found in the circumstellar envelopes of certain evolved "carbon-stars", i.e. C/O > 1. Magnesium polysulfide, MgS_x, does not exist at ambient temperature and pressure.

MgS is a white crystalline material but is often encountered in an impure form that is a brown noncrystalline powder. It crystallizes in the rock salt structure (cubic-cF8 and space group = $Fm\bar{3}m$ (#225). The lattice parameters are: $a = 5.20182$ Å, $V = 140.76$ Å^3, $Z = 4$. The effective radius and electron density of the Mg atom in the crystal was found to be 1.28 Å, yielding a net charge of +1.50 (Fig. 3.22).

The chemical properties of MgS resemble those of related ionic sulfides such as those of Na, Ba, and Ca. It reacts with oxygen to form the corresponding sulfate, magnesium sulfate. MgS reacts with water to give hydrogen sulfide and magnesium hydroxide.

It is generated industrially in the production of metallic iron. In the BOS steel-making process, sulfur is the first element that needs to be removed. Sulfur is removed from the impure blast furnace iron by the addition of several hundred kilograms of magnesium powder. Magnesium sulfide is formed, which then floats on the molten iron and is then removed.

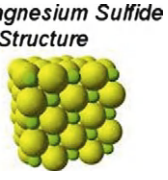

FIGURE 3.22

MgS is a wide band gap direct semiconductor of interest as a blue-green emitter, a property that has been known since the early 1900s. Although MgS has been considered as a phosphor for television and the like, its efficiency as a cathode ray emitter is not as great as those of its calcium and strontium homologues.

Atomic and bulk properties of rare earth doped wide band gap semiconductors, particularly alkaline earth sulfides, have been tailored and a novel storage technique, "power-gated hole burning", has been devised. It has been demonstrated that this combination of materials and method of storage allows for ultradense, fast, persistent, and rewriteable spectral memories. The improvement in performance parameters has been by orders of magnitude, and more importantly, all favorable characteristics of spectral storage have been combined in a single material, magnesium sulfide doped with Europium. It has been demonstrated that with the exception of low-temperature operation, the performance of this materials matches or exceeds the standards of current commercial memories. On the basis of these investigations, it is apparent that almost all barriers to a commercially viable device based on spectral hole burning can be removed.

The lattice energy for MgS has been calculated:

$$\mathrm{Mg^{2+}(gas) + S^{2-}(gas) \Rightarrow MgS(solid)}$$

$$\Delta H^\circ_{\mathrm{MgS}} = -3406\ \mathrm{KJ/mol}$$

Magnesium sulfide is available commercially from a number of suppliers.

Calcium Sulfide

Calcium sulfide has the molecular formula of CaS and the molecular weight of 74.1432 g/mol. It can be prepared by the direct reaction of the elements, calcined in an inert atmosphere, at a 1:1.05 molecular ratio:

$$\mathrm{Ca + S + heat \Rightarrow CaS}$$

This white material crystallizes in a cubic structure-like rock salt and the bonding is highly ionic. This is consistent with its description as an ionic solid.

In the crystal, each S^{2-} ion is surrounded by an octahedron of six Ca^{2+} ions, and complementarily, each Ca^{2+} ion surrounded by six S^{2-} anions. Like many salts containing sulfide ions, CaS typically has an odor of hydrogen sulfide, a foul-smelling gas, which results from a small amount of this gas being formed from hydrolysis of the salt by atmospheric moisture (Fig. 3.23).

Its CAS number is 20548-54-3 and its density is 2.59 g/cm^3. Its melting point is 2528 °C and it is slightly soluble in water but insoluble in alcohol. It

TABLE 3.10

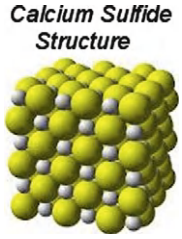

FIGURE 3.23

reacts with acids, producing hydrogen sulfide gas. Calcium sulfide is pale yellow to light gray with a bitter taste. It is hygroscopic, producing an odor of H_2S in moist air. Its refractive index is 2.137 and Mohs hardness is 4.0.

Thermochemical properties
ΔH_f° − 115.30 kcal/mol
ΔG_f° − 114.10 kcal/mol
S° − 13.50 cal/degree·mol
C_P − 11.33 cal/degree·mol

CaS can also be produced by the "carbothermic reduction" of calcium sulfate, which entails the conversion of carbon, usually as charcoal, to CO_2:

$$CaSO_4 + 2C \Rightarrow CaS + 2CO_2$$

This can react further:

$$3CaSO_4 + CaS \Rightarrow 4CaO + 4SO_2$$

Thus, this type of preparation cannot be used to prepare a pure CaS salt. Calcium sulfide decomposes upon contact with water, including moist air, giving a mixture of $Ca(SH)_2$, $Ca(OH)_2$, and Ca(SH)(OH):

$$CaS + H_2O \Rightarrow Ca(SH)(OH)$$

$$Ca(SH)(OH) + H_2O \Rightarrow Ca(OH)_2 + H_2S$$

"Milk of lime", $Ca(OH)_2$, reacts with elemental sulfur to produce a "lime sulfur", which has been used extensively as an insecticide. The active ingredient is probably a calcium polysulfide, not CaS. This salt, CaS_6, has been used in the remediation of Cr(VI) ions in groundwater where the Cr_2S_3 produced is insoluble in water and is easily removed.

A major usage of CaS has been its behavior as a phosphor for CRT and for flat-panel display usage. Although the alkaline earth sulfides have been known to provide excellent hosts as CRT phosphors, their main drawback has been the deleterious hydrolysis behavior experienced when one tries to prepare a CRT screen. That is, they are chemically unstable in water and other solutions generally used in the manufacture of CRTs. Thus, none of these compositions received much attention until the recent past. Of all of these sulfides, only CaS and SrS are stable enough to be used, and only if they are prepared in a suitable manner.

Dry $CaSO_4 \cdot 2H_2O$ is fired in an open silica boat in a tube furnace in an atmosphere of H_2 gas (at about 50 cc per minute gas flow for a 4-inch tube) for 0.5 to 1.0 h at 1000 °C. At the end of this period, the gas flow is changed to that of H_2S (about 100 cc per minute for a 4-inch tube) and the firing continues for another 45 min at 1000 °C. At the end of this period, the boat is pushed into the cool zone and allowed to cool in the H_2S atmosphere. The result is a white, very fluffy CaS powder with no traces of oxide, sulfate, etc. (Note that the use of the H_2S atmosphere is very dangerous and adequate air-scrubbing equipment must be used).

The nominal composition of one phosphor is: $CaS:Ce^{3+}_{0.010}:Cl_{0.050}$. If chloride (or other halide) is not used in the formulation, the resulting composition will be nonluminescent. The emission is green (bands at 520 and 560 nm) and the decay is classified as medium short ($t_{10} = 70$ μs). A good red phosphor can be made using the following composition: $CaS:Ce^{3+}_{0.01}:Eu^{2+}_{0.10}$. The resulting phosphor has its emission peak near to 6500 Å. In this case, the broad emission band is due to the Eu^{2+} activator in the CaS host. Note that the usual blue emission band of Eu^{2+} is shifted to the red region of the spectrum due to the very strong crystal field of the CaS lattice. Although it had a deep red saturation in color and a high screen brightness due its high cathode ray efficiency, it has not been used as a CRT screen to any great extent.

However, $CaS:Eu^{2+}$ and variations thereof is beginning to find usage with blue-emitting light-emitting

diodes (LEDs) to manufacture "white" LED lamps. The highly efficient red-emitting phosphors $(Ca_{1-x}Sr_x)S:Eu^{2+}$ and $(Ca_{1-x}Sr_x)Se:Eu^{2+}$, in combination with commercial green phosphor $SrGa_2S_4:Eu^{2+}$ and a blue LED are proposed for a three-band white LED.

"Oldhamite" is the name for mineralogical form of CaS. It is a rare component of some meteorites and has scientific importance in solar nebula research. Burning of the coal dumps can also produce such compound. Calcium sulfide has several applications. The "luminous" calcium sulfide is used in phosphors, luminous paints and varnishes. Calcium sulfide is also used as an additive to lubricants and as a flotation agent in ore extraction.

When heated in dry air or oxygen, the compound is oxidized to calcium sulfite and then to the sulfate, $CaSO_4$:

$$2CaS + 3O_2 \Rightarrow 2CaSO_3 + O_2 \Rightarrow 2CaSO_4$$

Partial decomposition occurs in hot water with the evolution of H_2S.

Evaporation and crystallization of the solutions give corresponding calcium salts:

$$CaS + 2HCl \Rightarrow CaCl_2 + H_2S$$

Vigorous to violent reactions can occur with oxidizing agents, such as potassium chlorate, potassium nitrate or lead dioxide.

Calcium sulfide is available commercially as the pure sulfide as well as the polysulfide due to its extensive usage in the past as an insecticide both agriculturally and in home gardens.

Strontium Sulfide

Strontium sulfide has the molecular formula of SrS and the molecular weight of 119.6852 g/mol. It can be prepared by the direct reaction of the elements, calcined in an inert atmosphere, at a 1:1.05 molecular ratio:

$$Sr + S + \text{heat} \Rightarrow SrS$$

SrS can also be produced by the "carbothermic reduction" of calcium sulfate, which entails the conversion of carbon, usually as charcoal, to CO_2:

$$SrSO_4 + 2C \Rightarrow SrS + 2CO_2$$

This can react further:

$$3SrSO_4 + SrS \Rightarrow 4SrO + 4SO_2$$

A mixture of oxide–sulfide is the result. Thus, this type of preparation cannot be used to prepare a pure SrS salt. Strontium sulfide has the CAS number of 1314-96-1 and is a gray powder with a density of 3.73 g/cm^3. Its melting point is 2078 °C and it is slightly soluble in water. It decomposes in acids, forming

FIGURE 3.24

hydrogen sulfide gas. It has the cubic halite structure (cF8) and the space group of $Fm\bar{3}m$. Both Sr^{2+} and $S^{=}$ occupy octahedral coordination positions in the lattice and there are four molecules per unit cell (Fig. 3.24).

Strontium sulfide has long been known as a phosphor. It is prepared in the same manner as the calcium sulfide salt. $SrCO_3$ is placed in a silica boat and is fired in a flowing argon atmosphere in a tube furnace (about 200 cc of gas per minute) for about 1.0 h at 1100 °C. At the end of this period, the argon gas is replaced by H_2S gas, using a flow of about 100 cc per minute through a 4-inch tube, and the firing is continued for at least 1.0 more hour. At the end of the firing period, the boat is pushed into a cool zone and allowed to cool. (The same safety precautions discussed above apply).

The result is again a fluffy white powder devoid of oxide, etc. However, it may still contain some Mn^{2+} which imparts a weak yellow fluorescence under either 2537 Å or 3650 Å excitation (This property may be used to detect its presence).

A better way to prepare SrS completely free from Mn^{2+} is as follows. One starts by dissolving $Sr(NO_3)_2 \cdot 4H_2O$ in water. The solution is then heated to near boiling. A few pieces of Mg metal ribbon are added to the solution with stirring. The Mg does not dissolve entirely, but causes heavy metal impurities left in the solution to precipitate preferentially on the metal or to precipitate as hydroxides due to the $Mg(OH)_2$ present in solution. This method is especially successful in removing any Mn^{2+} that may be present which would cause a deviation in the expected spectral properties of the SrS phosphors.

The solution is then filtered and diluted H_2SO_4 is added to precipitate $SrSO_4 \cdot 2H_2O$. The white precipitate is then allowed to settle, is washed with pure water several times, and the supernatant liquid is decanted. Washing continues until the excess sulfate is no longer detected. The precipitate is then filtered, washed in alcohol, and then dried in a vacuum oven at about 100–125 °C overnight.

Dry $SrSO_4 \cdot 2H_2O$ is fired in an open silica boat in a tube furnace in an atmosphere of H_2 gas for 0.5 to 1.0 h at 1000 °C. At the end of this period, the gas flow is changed to that of H_2S and the firing continues for another 45 min at 1000 °C. At the end of this period, the boat is pushed into the cool zone and allowed to

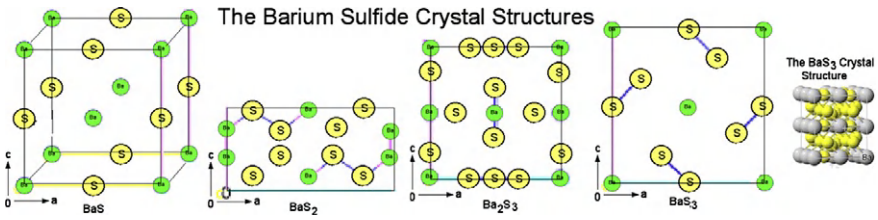

FIGURE 3.25

cool in the H_2S atmosphere. The result is a white, very fluffy SrS powder with no traces of oxide, sulfate, etc. (Note that the use of the H_2S atmosphere is very dangerous and adequate air-scrubbing equipment must be used.)

It is important to store the SrS powder under dry conditions before it is used to prepare the phosphor compositions. SrS itself is somewhat hygroscopic before use and needs to be protected from the atmosphere. A satisfactory formula for SrS is SrS = 1.0 mol; CeO_2 = 0.0050 mol; NH_4Cl = 0.0055 mol; S = 0.0624 mol. The mix is then placed in a covered silica crucible and fired in a tube furnace with a flowing H_2S atmosphere for 2 h at 1200 °C. After firing, when the phosphor cakes are cool, they are inspected under ultraviolet light and crushed. This green-emitting phosphor is then sifted through a 325-mesh screen and then is washed in alcohol. It is then filtered and dried at 125 °C in air for 12 h. The best phosphor is composed of: $Ca_{0.5}Sr_{0.4}S{:}Ce_{0.01}{:}Cl_{0.0075}$.

Strontium sulfide is available commercially but not in a "phosphor-grade".

Barium Sulfide

Barium sulfide has the molecular formula of BaS and the molecular weight of 169.3942 g/mol. It can be prepared by the direct reaction of the elements, calcined in an inert atmosphere, at a 1:1.05 molecular ratio:

$$Ba + S + \text{heat} \Rightarrow BaS$$

Its CAS number is 21109-95-5. If the sulfur is in excess, barium also forms several other sulfides. Among them are:

Barium hydrosulfide, $Ba(SH)_2$ [CAS = 25417-81-6]

Barium disulfide, BaS_2 [CAS = 12230-99-8]

Dibarium trisulfide, Ba_2S_3 [CAS = 53111-28-7]

Barium trisulfide, BaS_3 [CAS = 12231-01-5]

Barium pentasulfide, BaS_5 [CAS = 12448-68-9]

If the precipitation occurs in an aqueous solution, the product will be:

Barium tetra-sulfide monohydrate, $BaS_4 \cdot H_2O$ [CAS = 12248-67-8].

A two-dimensional structural comparison of some of these compounds is shown in the above diagram where a three-dimensional structure is also included (Fig. 3.25).

The change in arrangement of the sulfide atoms within the unit cells is typical of the alkaline earth sulfide systems in general.

BaS is a colorless crystalline solid with a density of 4.25 g/cm^3; its refractive index is 2.155 and it melts at 1200 °C. BaS is soluble in water (decomposes) but is insoluble in alcohol.

Thermochemical properties

ΔH_f^0 −110 kcal/mol
ΔG_f^0 −109 kcal/mol
S^0 −18.7 cal/degree mol
C_P −11.8 cal/degree mol

Barium sulfide is prepared commercially by heating barite (BaO) with coal or petroleum coke in a rotary kiln at 1000 °C to 1250 °C in an oxygen-free atmosphere. The product, black ash, is a gray or black powder containing carbonaceous impurities and unreacted barite. Barium sulfide is separated from impurities by extraction with hot water and filtration. It is obtained as an aqueous solution of 15–30% strength. The commercial product is 80% to 90% BaS. Barium sulfide may also be made by high temperature reduction of barium sulfate with methane.

Barium sulfide dissolves in water, dissociating to about 10%, forming barium hydrosulfide and barium hydroxide:

$$2BaS + 2H_2O \Rightarrow Ba(SH)_2 + Ba(OH)_2$$

The solution is highly alkaline. When the aqueous solution is cooled, crystals of barium hydroxide appear first. The aqueous solution of barium sulfide oxidizes slowly in the air forming elemental sulfur and various anions of sulfur including sulfite, thiosulfate, polysulfides and sulfate. The yellow color of barium sulfide solution is attributed to the presence of dissolved elemental sulfur that results from its slow oxidation in the air. In the presence of an oxidizing agent, barium sulfate is formed.

Violent to explosive oxidation may occur when BaS is heated with strong oxidants such as phosphorus pentoxide or potassium chlorate. Barium sulfide undergoes double decomposition reactions with hydrochloric acid

and nitric acid, giving barium chloride and barium nitrate, respectively, when the solution is evaporated. Reaction with carbon dioxide produces barium carbonate and hydrogen sulfide:

$$BaS + CO_2 + H_2O \Rightarrow BaCO_3 + H_2S$$

Barium sulfide is available commercially in large lots from many manufacturers.

Radium Sulfide

Radium sulfide has the molecular formula of RaS and the molecular weight of grams per mole. It can be prepared by the direct reaction of the elements, calcined in an inert atmosphere, at a 1:1.05 molecular ratio:

$$Ra + S + \text{heat} \Rightarrow RaS$$

It has no CAS number. If the sulfur is in excess, radium undoubtedly forms several other sulfides. However, this aspect has never been studied. There is very little information available for RaS and there is no qualified manufacturer of radium sulfide.

3.2.3. Alkaline Earth Sulfites and Bisulfites

Sulfurous acid is a diprotic acid and the anions involve either the HSO_3^- ("Bisulfite") or the SO_3^{2-} (sulfite) ion. The appearance of these two anions in solution is a function of pH and the manner in which they are prepared. If a basic salt such as sodium sulfite is used, the product will be a sulfite because of the basicity of Na^+ in solution. The ratio of **bisulfite to sulfite** at pH 6.0 is 8:1. At pH 8, the opposite is true. The pure sulfite ion is obtained at pH 10–11. To obtain such a pH, sodium sulfite is usually added to sodium sulfite before the solution is used to prepare an alkaline earth sulfite. Ammonium sulfite may be added to achieve an intermediate pH and bisulfite anions. A diagram illustrating this behavior follows (Fig. 3.26).

All of the alkaline earths form bisulfites and sulfites. The cations added to achieve a certain pH are shown in the upper part of this diagram. The addition of SO_2 gas to sodium hydroxide first generates sodium sulfite. The addition of excess SO_2 gas to sodium sulfite serves to reverse the pH in the solution, thus forming bisulfite:

$$2NaOH + SO_2 \Rightarrow Na_2SO_3 + H_2O$$

$$Na_2SO_3 + SO_2 + H_2O \Rightarrow 2NaHSO_3$$

Thus, sulfur dioxide forms both sulfite and bisulfite anions in water:

$$SO_2(aq) \Leftrightarrow H^+ + HSO_3^-$$

$$pK_a = 1.98\ (K_a = 1.05 \times 10^{-2})$$

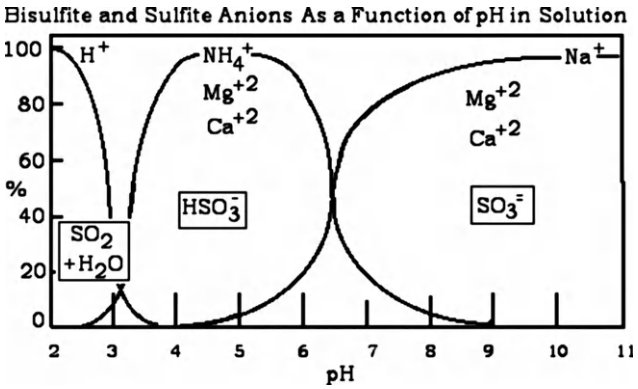

FIGURE 3.26

$$HSO_3^- \Leftrightarrow H^+ + SO_3^{2-} \quad pK_a = 7.30\ (K_a = 5.02 \times 10^{-8})$$

and at very high concentrations:

$$HSO_3^- + SO_2(aq) \Leftrightarrow HS_2O_5^-$$

$$K_a = 1.55 \times 10^{-2};\ pK_a = 1.81$$

Such ratios of bisulfite/sulfite are particularly important in the "wood-pulping" industry to manufacture paper.

The solubilities of the alkaline earth sulfites vary greatly as one progresses down the Group 2 series:

If one wishes to determine the dependence of the distribution of ionic species as a function of pH for a diprotic acid such as H_2SO_3, the simplest approach is to express the concentration of the three forms (H_2SO_3, HSO_3^-, and SO_3^{2-}) in terms of any one of them. The relevant equation is:

$$H_2SO_3 \Leftrightarrow H^+ + HSO_3^+ \Leftrightarrow H^+ + SO_3^{2-}$$

We then find the fraction of each by dividing by their sum. Since bisulfite is intermediate between these anions, we express the concentrations in terms of $HSO_3^- = 1.0$, to produce:

$$H_2SO_3 = [(HSO_3)(H^+)]/K_1 \quad (1)$$

$$SO_3^{2-} = [(HSO_3)(K_2)]/(H^+) \quad (2)$$

(where $K_1 = 1.05 \times 10^{-2}$ and $K_2 = 5.02 \times 10^8$). The term $[H_2SO_3]$ is taken to be equal to the actual H_2SO_3 present plus the dissolved (hydrated) SO_2 that has not

TABLE 3.11

Gram/100 ml of water				
Sulfite	**Mg**	**Ca**	**Sr**	**Ba**
	27.1	0.0044	0.0033	0.0022
Relative to Ba	1240×	2.0×	1.5×	1.0

reacted to form H_2SO_3. Now, if the total sulfite in all different forms is denoted by s, then:

$$s = [H_2SO_3 + HSO_3^- + SO_3^{2-}] \quad (3)$$

Combining these three equations, we obtain:

$$s = [H^+/K_1 + 1.0 + K_2/H^+][HSO_3^-]$$

where we have defined the relative proportion of the busulfite anion as 1.0. Thus, the relative proportions of the three species in solution are therefore:

$$[H_2SO_3]:\ [HSO_3^-]:\ [SO_3^{2-}] = [H^+/K_1]:\ 1/0:\ [K_2/H^+]$$

At any solution pH, the ratio of bisulfite to sulfite ions in solution is:

$$[HSO_3]:\ [SO_3^{2-}] = 1:\ K_2/H^+ = [5.1 \times 10^{-8}]/[10^{pH}]$$

and pH = 10 produces a ratio of 1:500 of bisulfite to sulfite anions in solution. We can then calculate relative bisulfite concentration form from near 0 to near 100% as shown in the above curve. To calculate the SO_3^{2-} concentration, we use the same approach except that we define SO_3^{2-} as 1.0. The result is given in the diagram presented above.

Beryllium Sulfite

Beryllium sulfite would have the formula of $[Be(OH)]_2SO_3$ and the molecular weight of 132.0824 g/mol. It could be prepared by the reaction of a magnesium hydroxide slurry and SO_2 gas:

$$Be(OH)_2 + SO_2(gas) + H_2O \Rightarrow BeSO_3 \cdot 6H_2O$$

No article on "beryllium sulfite" can be found in the scientific literature. There is no scientific data that beryllium sulfite even exists as no studies have documented such a salt. The same may be said for the compound "beryllium bisulfite".

Magnesium Sulfite

Magnesium sulfite has the formula of $MgSO_3$ and the molecular weight of 104.3682 g/mol. It can be prepared by the reaction of a magnesium hydroxide slurry and SO_2 gas:

$$Mg(OH)_2 + SO_2(gas) + H_2O \Rightarrow MgSO_3 \cdot 6H_2O$$

If the solution temperature is kept below 40 °C, the hexahydrate results. Above 40 °C, the trihydrate, $MgSO_3 \cdot 3H_2O$, is the usual product. Magnesium sulfite may also be prepared by adding a solution of sodium sulfite to a solution of magnesium chloride. The mix is kept at 25 °C for 1–2 h and the solid phase which forms is separated and washed with isopropanol and dried at 60 °C. Again, the hexahydrate results.

The anhydrous form is hygroscopic. The CAS number is 7757-88-2 (hexahydrate) and its molecular weight is 212.4599 g/mol. The solubility of the hexahydrate in water is less than that of the anhydrate (Fig. 3.27).

The structure of magnesium sulfite hexahydrate is rhombohedral, space group—R3, and $a = 5.911$ Å, $\alpha = 96.52°$, $V = 202.6$ Å^3, $Z = 1$. The sulfite $O^=$ atoms carry a negative charge and are considerably expanded compared to free oxygen atoms. An extended lone pair of electrons is observed at the apex of the sulfur atom pyramid. The net charge on the sulfite group was estimated at –1.0 e^-. The shape of the hydrate oxygen lone-pair lobes is clearly affected by cation and hydrogen bond interactions. The dimensions of the SO_3^{2-} ion are S to O = 1.528Å and the angle of O to S to O = 104°. The O–H distances in the water molecules are in the range of 0.957–0.980 Å.

$MgSO_3 \cdot 6H_2O$ is thermally decomposed to $MgSO_3 \cdot 3H_2O$ at about 78 °C or to $MgSO_3 \cdot 2H_2O$ at about 120 °C. $MgSO_3 \cdot 3H_2O$ (and other lower hydrates of $MgSO_3$), decomposes to amorphous anhydrous $MgSO_3$ at about 395 °C. A crystalline compound of $MgSO_3 \cdot xH_2O$ with $x = 1/2$ forms from the dihydrate. Thermoanalytical data (DTA, TG, DTG, high- and low-temperature X-ray diffraction patterns), IR and Raman spectroscopic data of these hydrates have been reported. The crystal data are:

$MgSO_3 \cdot 3H_2O\ (P4_12_12)$, $(CoSO_3 \cdot 2H_2O$ type);
$a = 9.444$ and $c = 10.255$ Å, $Z = 8$

$MgSO_3 \cdot 2H_2O\ (P2_1/n)(ZnSeO_3 \cdot 2H_2O$ type):
$a = 6.359$, $b = 8.54.7$, $c = 7.544$ Å, and $\beta = 98.72°$,
$Z = 4$

$MgSO_3 \cdot ½H_2O\ (P2_1/n)$, $(MnSO_3 \cdot ½H_2O$ type):
$a = 4.699$, $b = 12.823$, $c = 5.63.2$Å, ß = 90.26°,
$Z = 4$.

Solubilities of $MgSO_3$-$6H_2O$ in Water

t, °C	gm of $MgSO_3$/liter	t, °C	gm of $MgSO_3$/liter
43.0	11.04	79.0	40.17
51.4	14.19	84.1	53.73

71.5	28.87	94.0	95.19

FIGURE 3.27

Magnesium sulfite has found usage in the "Kawasaki process" as first developed in Japan. It involves absorption of SO_2 gas from gaseous effluents of coal-burning electrical generating power plants ("flue gas") using a slurry composed of magnesium and calcium sulfites plus magnesium hydroxide, which forms soluble magnesium sulfite and insoluble calcium bisulfite. The following diagram presents one design of such as flue-gas plant (Fig. 3.28).

Here, the spent slurry is continuously withdrawn and sent to an air oxidizer where the sulfites and bisulfites are converted to their corresponding sulfates. This results in the production of magnesium sulfate and gypsum. The gypsum is removed by thickening and centrifugation for sale in commercial applications such as "dry-wallboard" manufacturing. The recovered liquid is returned to the scrubbing tower while the remainder is sent to the magnesium hydroxide regeneration tank where it is reacted with lime to convert $MgSO_4$ back into $Mg(OH)_2$ along with precipitation of additional gypsum. The regenerated slurry is then fed back into the scrubber.

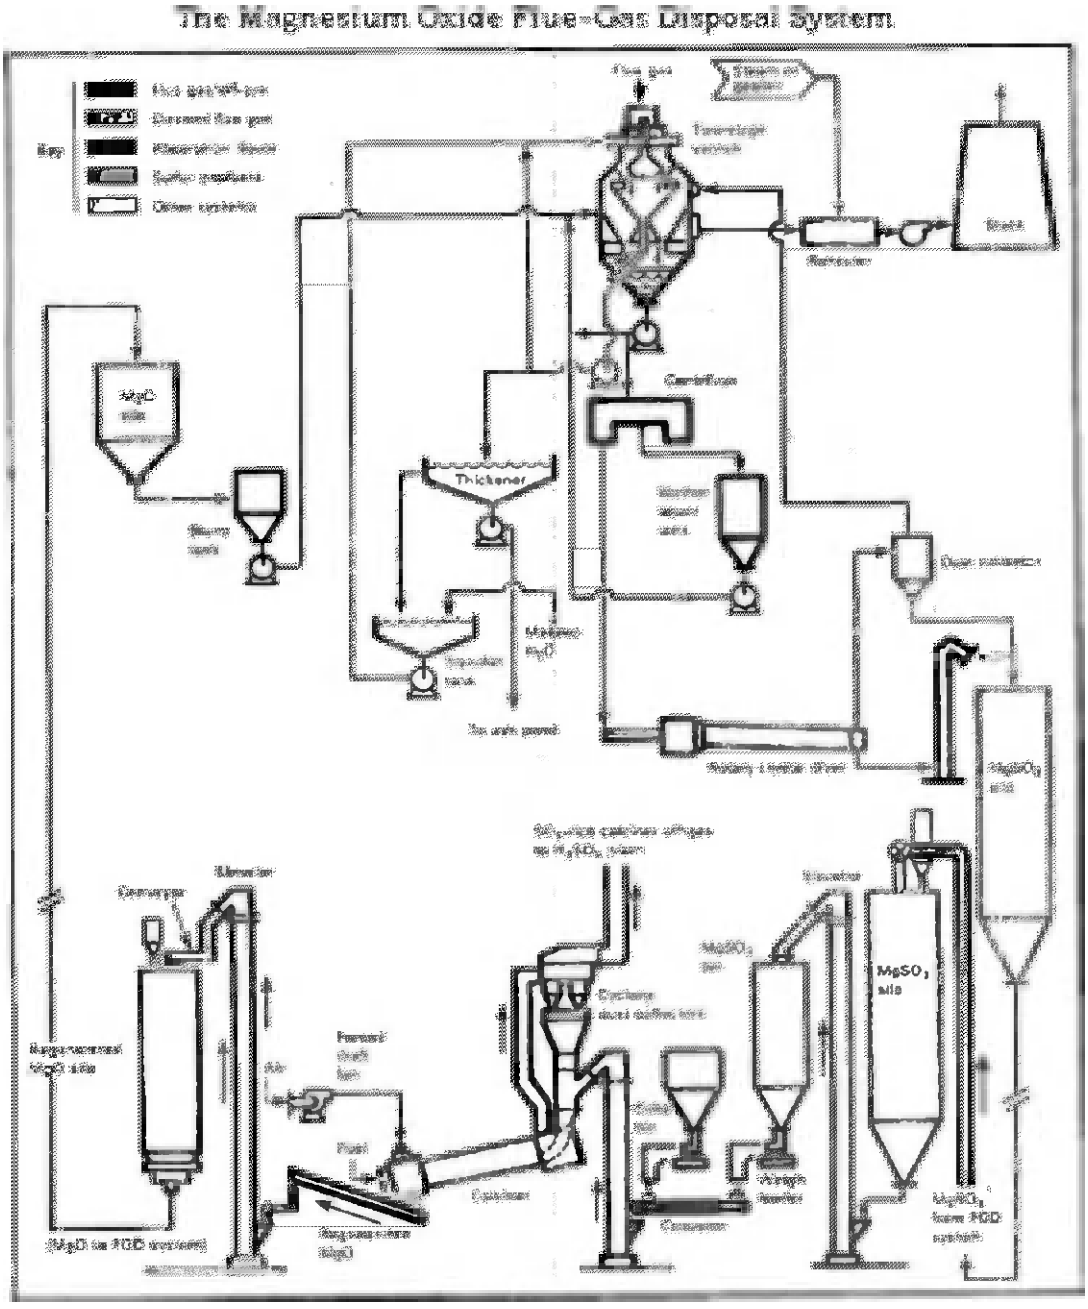

FIGURE 3.28

Although magnesium sulfite has found a number of usages in industry, it is the bisulfite compound that is used extensively in the wood-pulping process. Originally, it was the calcium salts, both bisulfite and sulfite that were used in the wood-pulp industry because of the low cost of lime and limestone. Dolomite can contain up to 40% magnesium and it was determined that calcium was more proficient in the "sulfite process" whereas magnesium bisulfite is used in the "Kraft process" of making wood pulp used to manufacture paper and cardboard products used extensively today. The sulfite process, SO_3^{2-}, involving calcium sulfite, has been used in the past but it is the magnesium bisulfite (Kraft Process) that is used today. "Kraft woodpulp" manufacturing plants have almost supplanted "sulfite woodpulp" plants nowadays because of environmental motives, even though magnesium salts cost more than the corresponding calcium salts. However, the history of pulp making from wood and trees involves the use of limestone and lime, because of availability of magnesium compounds at that time. For this reason, the detailed description of the paper-pulping processes is given in the next sectional discussion of calcium sulfites and bisulfites.

Magnesium sulfite and/or magnesium bisulfite are readily available commercially, although many paper-pulping industries make their own from readily available magnesium chemicals.

Calcium Sulfite or Bisulfite

Calcium sulfite has the molecular formula of $CaSO_3$ and the molecular weight of grams per mole. It can be prepared by the reaction of sodium sulfite with calcium chloride:

$$CaCl_2 + Na_2SO_3 \Rightarrow CaSO_3 + 2NaCl$$

The dihydrate, $CaSO_3 \cdot 2H_2O$ is formed. This salt is white powder that is soluble in dilute sulfurous acid to form the bisulfite. It may be dehydrated at 150 °C to form the anhydrous salt. It is used in the sulfite process for the manufacture of wood pulp. The anhydrate has the CAS number of 10257-55-3 and a melting point of 604 °C. It is slightly soluble in water at 0.0043 g/100 ml. If the hydroxide is used instead of the chloride, a hemihydrate is formed: $(CaSO_3)_2 \cdot H_2O$. The crystal data for calcium sulfite hemihydrate are: orthorhombic, space group-Pmna, $a = 9.808$, $b = 10.676$, $c = 6.496$ Å, and $Z = 8$. The structure consists of two alternating layers. The calcium ions are coordinated by six O atoms: five originate from the sulfite ions, and one from the water molecule.

A major use of calcium sulfite in the past has been the use of "lime" ($Ca(OH)_2$) in "flue-gas" desulphurization (removal of SO_2 gas) at "fossil-fuel" electrical power generating plants. Since calcium sulfite is relatively insoluble in water, it can be removed from the slurry by filtration and converted to gypsum, $CaSO_4 \cdot 2H_2O$. This has been superseded by magnesium bisulfite absorption processes (as described above).

The other usage of calcium sulfite or bisulfite compounds has been in the "wood-pulping" industry. Chemical wood pulping involves the extraction of cellulose from wood by dissolving the lignin that binds the cellulose fibers together. The four processes principally used in chemical pulping have been:

"Soda"
"Sulfite"
"Kraft"
"Neutral sulfite semi-chemical"

arranged in order of initial usage. The first three display the greatest potential for causing air and water pollution. The Kraft process alone accounts for over 80% of the chemical pulp produced in the United States today. The choice of pulping process is determined by the desired product, by the wood species available, and by economic considerations.

There have been two major competing processes, the "Kraft process" and the "sulfite process" to manufacture wood pulp for paper making. The former employs calcium or magnesium sulfite or bisulfite (at basic pH) while the latter uses calcium or magnesium bisulfite (at a more acidic pH).

Originally, domestic or financial transactions were stored on baked-clay tablets (about 5000 years ago). The Chinese developed a form of paper from crushed plants about 4000 years ago. With the coming of papyrus (made from flattened stems of a water plant) in Egypt on which permanent records could be stored (about 3000 years ago), the modern notion of paper was born. Parchment, made from animal skins, was used in the Middle ages in Europe from about 50 to 1600 AD. The use of wood to make pulp for paper did not begin until about 1840 with the development of mechanical pulping in Germany. The use of chemicals to aid this process soon followed. Caustic (NaOH) was the first, followed by the use of sulfur dioxide in water (sulfites and bisulfites)

TABLE 3.12

Kraft process	Sulfite process
Produces highest strength pulp	Produces brighter unbleached pulp
Utilized proven technology for efficient chemical recovery	Pulp is easier to bleach to full brightness
Handles wide variety of wood species	Produces higher yield of bleached pulp
Tolerates bark in the pulping process	Pulp is easier to refine

and then by the use of calcium bisulfite, $Ca(HSO_3)_2$, to pulp wood in 1867.

The first process used was the "soda process" which used NaOH or Na_2CO_3 to process wood chips and to make wood pulp for paper. This process was developed in 1851. The action of caustic soda on wood is very appreciable at ordinary temperatures, and is much more rapid and complete as the temperature is raised. It is, therefore, customary to cook the wood in the form of chips in closed digesters at high temperature and pressure. A major fault of the Soda Process was that acidic constituents in the wood tended to neutralize the caustic so that it could only process a certain amount of wood chips.

The second chemical method for pulp making was the "sulfite" process, invented by Benjamin C. Tilghman, who experimented with the effect of sulfurous acid on wood shortly after the Civil War in 1867. Almost a decade later, the first commercial Sulfite Mill was built in Sweden. It used magnesium as the counter ion. By 1900, sulfite pulping had become the dominant means of producing wood pulp, surpassing mechanical pulping methods. The amount of wood processed with the sulfite process was 11.1 million tons (dry wt) but there are virtually no Plants in the U.S. today using the calcium sulfite or bisulfite chemicals, derived from lime or limestone. The problem is that these calcium salts are more insoluble than the corresponding magnesium or ammonium homologues that dissolve more easily and are more soluble at the pH values required for dissolving lignin in the wood chips to make wood pulp.

In the sulfite process, a mixture of sulfurous acid and the bisulfite ion are used to attack and solubilize in the cooking liquor, and the chemical structure of the lignin is left largely intact. The chemical base for the bisulfite can be ionic calcium, magnesium, sodium, or ammonium. Sulfite pulping can be carried out over a wide range of pH. "Acid sulfite" denotes pulping with an excess of free sulfurous acid (pH 1–2), while "bisulfite" cooks are carried out under less acidic conditions (pH 4–6).

The cooking liquor for the acid-sulfite process is made by burning sulfur to form sulfur dioxide. This is then absorbed in water in the presence of calcium hydroxide or carbonate to form calcium sulfite, which is relatively insoluble, but which dissolves as calcium bisulfite when more sulfur dioxide is added. Care must be taken to avoid the formation of SO_3 since it produces sulfuric acid. Sulfuric acid is undesirable since it promotes hydrolysis of cellulose without contributing to delignification. The solution containing calcium bisulfite and an excess of sulfur dioxide forms the usual cooking liquor, or "acid," for the sulfite process. Sulfite pulping is carried out between pH 1.5 and 5, depending on the counter ion to sulfite (bisulfite) and the ratio of base to sulfurous acid. The pulp is in contact with the pulping chemicals for 4 to 14 h and at temperatures ranging from 130 to 160 °C. The spent cooking liquor from sulfite pulping is called "red or brown liquor" (compared to "black liquor" from the Kraft process). Ammonia-based processes do not allow recovery of the pulping chemicals since ammonia or ammonium salts are oxidized to N_2 or NO_x products when burned. The earliest process used calcium, obtained as inexpensive limestone and there was little incentive to recover the inorganic materials. Sodium-based processes use a recovery system similar to that used in the Kraft process, except that there is no "lime cycle".

In some plants, a high magnesia lime, containing about 40% magnesia, is used; in others a high calcium lime which contains about 92–95% calcium oxide. An acid solution prepared with a sodium base instead of calcium can be used equally well, and even has an advantage in cooking those woods which do not permit "ordinary acid" to penetrate easily. An all-magnesia base acid "Kraft process" is now being used in many mills, as is also an ammonia base acid. These last three—soda, magnesia and ammonia—enable the waste liquors to be treated for recovery of the base constituent, and so aid in avoiding stream pollution, which is becoming a more and more serious problem.

The sulfite pulping process depends on two principal reactions, which probably take place simultaneously to a considerable extent. These are the splitting of the cellulose–lignin complex of the wood by hydrolysis, and the combination of the lignin with the calcium bisulfite to form calcium lignosulfonate, which is soluble in the hot cooking liquor, and can be easily washed out at the end of the cook. The hydrolytic reaction also causes the easily decomposable hemicelluloses to dissolve with the formation of sugars. Fortunately, the chief portion of the cellulose is relatively stable under conditions of cooking, though it is not entirely unattacked.

These reactions are less drastic than those of the alkaline pulping (Kraft) processes, so the wood must be selected more carefully. The woods most commonly used for sulfite pulp are spruce, hemlock, balsam and the true firs; the woods of many deciduous trees can be cooked by this process, but are not largely used because their short fibers impart low strength to papers in which they are employed. Sulfite pulps are lighter in color than Kraft pulps and can be bleached more easily, but the paper sheets are weaker than equivalent Kraft sheets. The sulfite process works well for such softwoods as spruce, fir, and hemlock, and for such hardwoods as poplar and eucalyptus. Resinous softwoods and tannin-containing hardwoods, however, are more difficult to handle. This sensitivity to wood species, along with the weaker strength and the greater difficulty

in chemical recovery, are the major reasons for the decline of sulfite pulping relative to Kraft. The trend toward whole-tree chipping puts sulfite at a further disadvantage because of its intolerance to bark.

The competing chemical pulping process, the bisulfate or "Kraft process" started (in Sweden) in 1890. It was the invention of the "recovery boiler" in the 1930s that allowed Kraft Mills to recycle almost all of their pulping chemicals. It enabled the recovery and reuse of the inorganic pulping chemicals such that a Kraft mill is nearly a closed cycle with respect to inorganic chemicals, apart from those used in the bleaching process. For this reason, in the 1940s, the Kraft process surpassed the sulfite process as the dominant method for producing wood pulp. This, along with the ability of the Kraft process to accept a wider variety of types of wood and produce stronger fibers that made it become the dominant pulping process starting in the 1940s. Sulfite pulps now account for less than 10% of the total chemical pulp production and the number of Sulfite Mills continues to decrease.

A diagram of a typical magnesium-base process is shown in Fig. 3.29.

Pulp washers, using counter-current flow, remove the spent cooking chemicals and degraded lignin and hemicellulose. The extracted brown liquor is concentrated in multiple-effect evaporators. The concentrated brown liquor can be burned in the recovery boiler to generate steam and recover the inorganic chemicals for reuse in the pulping process or it can be neutralized to recover the useful by-products of pulping. The recovery process used in magnesium-based sulfite pulping the "magnetite" process is well developed. The concentrated brown liquor is burned in a recovery boiler, producing MgO and SO_2, both of which are recovered from the flue gases. Magnesium oxide is converted in a wet scrubber to give a slurry of $Mg(OH)_2$. This magnesium hydroxide slurry is then used in another scrubber to produce a magnesium bisulfite solution that is clarified, filtered and used as the pulping liquor.

Digestion is carried out under high pressure and high temperature, in either batch mode or continuous digesters, and in the presence of a sulfurous acid/bisulfite cooking liquid. When cooking is completed, either the digester is discharged at high pressure into a blow pit, or its contents are pumped into a dump tank at lower pressure. The spent sulfite liquor (also called red liquor) then drains through the bottom of the tank and is treated and discarded, incinerated, or sent to a plant for recovery of heat and chemicals. The pulp is then washed and processed through screens and centrifuges to remove knots, bundles of fibers, and other material. It subsequently may be bleached, pressed, and dried in papermaking operations.

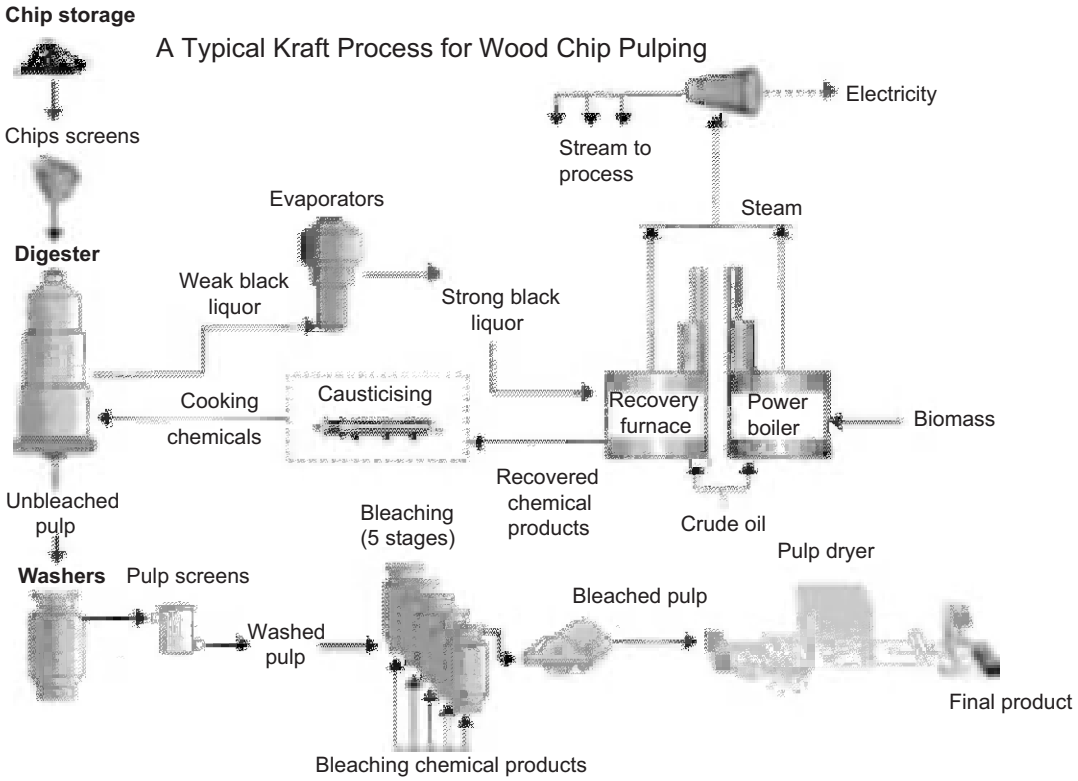

FIGURE 3.29

Because of the variety of cooking liquor bases used, numerous schemes have evolved for heat and/or chemical recovery. In calcium-based systems, found mostly in older mills, chemical recovery is not practical, and the spent liquor is usually discharged or incinerated. In ammonium base operations, heat can be recovered by combusting the spent liquor, but the ammonium base is thereby consumed. In sodium or magnesium base operations, the heat, sulfur, and base all may be feasibly recovered.

In the magnesium bisulphite wood pulping process, recovery of the spent process chemicals is of both economical and environmental importance. One part of the complex recovery system of the acid magnesium sulphite pulping process is the absorption unit, which is attached to the recovery burner. There, the waste gas from the thick liquor burning is cleaned from SO_2 by reaction to magnesium bisulphite. The main part of the SO_2 absorption recovery system of absorption system is a four-stage scrubber, operating according to the venturi principle, working at 65 °C and at pH values from 7 to 8. In a two-step reaction, where the flue gas is exposed to $Mg(OH)_2$, magnesium bisulphite is formed, which is reintroduced in the washing solution pulping process as cooking liquor.

Oxidation of lignosulfonates was used to produce "vanillin" (artificial vanilla), and this process is still used by one supplier (Borregaard, Norway) while all North American production by this route ceased in the 1990s. Acid hydrolysis of cellulose during sulfite pulping produces monosaccharides, predominanently mannose, which can be fermented to produce ethanol.

In order to transform wood chips into a NBSK pulp, wood fibers undergo a multistep process involving the following principal stages: wood chips, screening, cooking, pulp washing and screening, bleaching and drying, and finally, chemical recovery.

The following diagram is a brief description of such a process (which includes the steps necessary for chemical recovery) (Fig. 3.30).

WOOD CHIP SCREENING

This Kraft-mill currently uses a mix of softwood fibers composed of approximately 70% of Black Spruce and 30% of Jack Pine and other softwoods. In the initial processing stage, wood chips are screened to remove oversized chips and sawdust:

WOOD CHIPS COOKING

After the screening stage, the accepted chips are conveyed to a pressurized digester where they are heated and cooked with chemicals. This process softens and eventually dissolves the phenolic material called lignin that binds the fibers together in the wood.

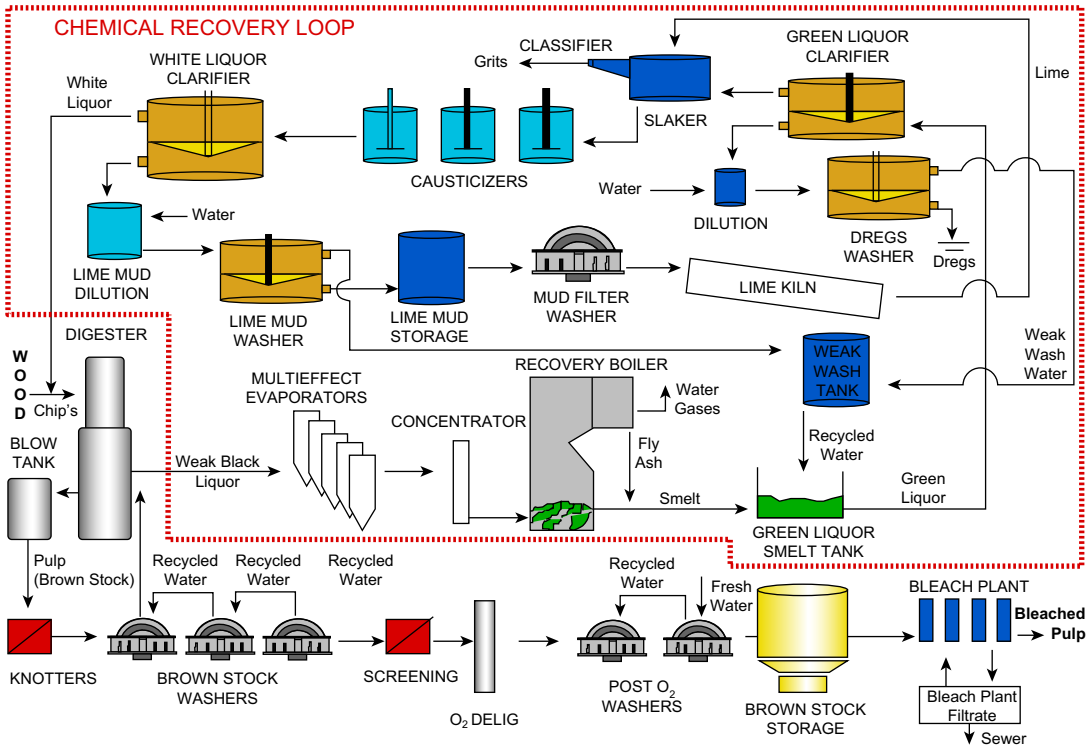

FIGURE 3.30

PULP WASHING AND SCREENING

When the cooking process is completed, the pulp is pressure blown out of the digester. The pulp is then washed and screened to remove most of the residual spent chemicals, called black liquor, and partially cooked wood chips.

BLEACHING AND DRYING

As pulp is initially brown in color when it exits the digester, it must undergo a series of bleaching stages where the brightness of the pulp is gradually increased to 95% ISO brightness. The Saint-Félicien Mill's bleaching process is elemental chlorine free. Finally, the bleached pulp is sent to the pulp machine where it is dried to achieve a dryness level of 93% air dry.

EXPEDITION

The pulp is then ready to be cut in sheets, baled and shipped to customers, by truck, railed car or boat depending on the destination.

RECUPERATION

A significant feature of Kraft pulping technology is the recovery system, whereby chemicals used in the process are captured and extracted for reuse, which reduces raw material costs and improves the mill's environmental performance. During the cooking stage, dissolved organic wood materials and chemicals are extracted from the digester through the weak black liquor. After undergoing an evaporation process, black liquor, now called strong black liquor, is burned in a recovery boiler. The heat produced by the recovery boiler is used to generate high-pressure steam. The chemical compounds of the black liquor are collected from the recovery boiler and reconstituted into cooking chemicals used in the cooking stage through additional processing in the recaustisizing plant. Additional steam is generated by the mill's power boiler through the combustion of biomass consisting of bark and other residues, including the ones generated by the mill's effluent treatment system. Bunker C (a type of crude oil) can also be used as needed. The steam produced by the recovery and power boilers is used to meet the mill's steam requirements, and to generate electricity through two turbo generators.

Calcium sulfite and bisulfite are available commercially in large quantities from a number of manufacturers worldwide.

Strontium Sulfite

Strontium sulfite has the molecular formula of $SrSO_3$ and the molecular weight of 167.6832 g/mol. It may be prepared by the reaction of sodium sulfite and strontium hydroxide:

$$Sr(OH)_2 + Na_2SO_3 \Rightarrow SrSO_3 + 2NaOH$$

This salt is sparingly soluble in water at 0.0033 g/100 ml at 20 °C, 0.00025 g/100 ml at 60 °C and 0.001525 g/100 ml at 100 °C. It solubility product is 4.2×10^{-8} and its CAS number is 13451-02-0. The question of the existence of hydrates remains unanswered. Strontium sulfite occurs as colorless, crystallites which decompose upon heating to 380 °C to the oxide plus SO_2 gas. It is soluble in sulfuric acid and HCl.

There is virtually no literature concerning the physical properties of this salt and the chemical properties have not been delineated except in general terms.

Strontium sulfite is, however, available in limited quantities commercially.

Barium Sulfite

Barium sulfite has the molecular formula of $BaSO_3$ and the molecular weight of 217.3912 g/mol. It can be prepared by reacting sodium sulfite with barium chloride:

$$BaCl_2 + Na_2SO_3 \Rightarrow BaSO_3 + 2NaCl$$

Its CAS number is 7787-39-5. It occurs as white, monoclinic crystals with a density of 4.44 g/cm^3. Its solubility in water is low (0.001125 g/100 ml) and it is insoluble in ethanol. When heated, it decomposes at 480 °C to the oxide and SO_2 gas.

It has been used as a weighting material on oil-drilling rigs to prevent "blow out" during drilling operations. This salt is used for such purposes, presumably because of its ability to absorb SO_2 and H_2S gases trapped in the rocks as drilling proceeds. The demand for barium sulfite is low.

Very little scientific studies of barium sulfite have ensued in the literature. The physical properties of this salt remain unspecified. One paper presents the formation of spherulites of $SrSO_3$ and $BaSO_3$, synthesized in agar–agar gels (0–40 °C). The reactants were sodium sulfite and the chloride of the respective metals. Each spherulite consists of fibrous crystals which are arranged minutely in a radial manner from the center. A linear relation was recognized between (mean diameter)^2 and reaction time in the same manner as the $CaSO_3$ $0.5H_2O$ spherulite reported. The slopes of the lines, namely the growth rates of the spherulites, were greater in the order of calcium sulfite > strontium sulfite > barium sulfite. The ratio of (mean diameter)^2/time was dependent upon the concentration of the agar–agar gel (0.5%–2.0%) and the reaction temperature (0–40 °C); the ratios decreased linearly with an increase of the gel concentration and increased with an increase of temperature.

Barium sulfite is available in limited quantities, commercially.

Radium Sulfite

Radium sulfite would have the molecular formula of $RaSO_3$ and the molecular weight of 306.0866 g/mol. It could be prepared by the reaction of RaO and gaseous SO_2 at an elevated temperature of about 650 °C:

$$RaO(solid) + SO_2(gas) \Rightarrow RaSO_3(solid)$$

However, there is no report of this salt ever having been prepared.

There is no demand for this salt and it is not clear whether it has ever existed. It is not available commercially.

3.2.4. Alkaline Earth Sulfates

Beryllium Sulfate

Beryllium sulfate has the molecular formula of $[Be(OH)]_2SO_4$ and the molecular weight of 105.0852 g/mol. Beryllium sulfate may be prepared by treating an aqueous solution of any beryllium salt with sulfuric acid, followed by evaporation of the solution and crystallization. The hydrated product may be converted to anhydrous salt by heating at 400 °C. The anhydrate may also be prepared by reacting the oxide with SO_2 gas at elevated temperature. Its CAS number is 13510-49-1. If the solution method is used, a tetrahydrate forms, $(BeOH)_2SO_4 \cdot 4H_2O$ whose molecular weight is 177.1462 g/mol with a CAS number of 7787-56-6.

Beryllium sulfate is a colorless crystalline solid with a tetragonal crystal system. It is hygroscopic and its density is 2.50 g/cm^3 (tetrahydrate = 1.71 g/cm^3). The tetrahydrate salt loses water of crystallization on heating to about 110 °C to form a dihydrate. Upon heating to 400 °C, it then forms the anhydrate. Further heating to 550 °C causes decomposition of the anhydrate to BeO and SO_2 and O_2.

Beryllium sulfate is soluble in water, tetrahydrate being more soluble in water (30.5 g/100 ml at 30°) than the anhydrous salt; both are insoluble in alcohol.

Thermochemical properties of this salt include:

Thermochemical properties

$\Delta H_f^\circ = -288.2$ kcal/mol
$\Delta G_f^\circ = -261.5$ kcal/mol
$S^\circ = 18.63$ cal/degree mol
$C_P = 20.49$ cal/degree mol

No major commercial application of beryllium sulfate is known and it has not been offered for sale.

Magnesium Sulfate

Magnesium sulfate has the molecular formula of $MgSO_4$ and the molecular weight of 120.3662 g/mol. It may be prepared by the reaction of sodium sulfate and any soluble magnesium salt:

$$MgCl_2 + N_2SO_4 \Rightarrow MgSO_4 + 2NaCl$$

Hydrated magnesium sulfate occurs in nature as the minerals "kieserite" and "epsomite". The salt is mined in large scale from these and other naturally occurring minerals. The salt is also prepared in the laboratory by the action of sulfuric acid on magnesium oxide, hydroxide, or carbonate followed by evaporation and crystallization:

$$MgO + H_2SO_4 \Rightarrow MgSO_4 + H_2O$$

$$Mg(OH)_2 + H_2SO_4 \Rightarrow MgSO_4 + 2H_2O$$

$$MgCO_3 + H_2SO_4 \Rightarrow 4 + CO_2 + H_2O$$

Crystallization at temperatures between 1.8 and 48 °C yields the heptahydrate, $MgSO_4 \cdot 7H_2O$. Below 1.8 °C, a dodecahydrate, $MgSO_4 \cdot 12H_2O$ crystallizes out. Above 48 °C, a lower hydrate crystal forms. The anhydrous salt is obtained by heating the heptahydrate at about 500 °C or dehydrating above 150 °C in the presence of sulfuric acid. The heptahydrate, $MgSO_4 \cdot 7H_2O$, is commonly called **Epsom salt**. A number of hydrates have been prepared and assigned CAS numbers. These are shown as follows along with their mineral names and CAS numbers:

Hydrate	Mineral name	Formula	CAS No.
Monohydrate	Kieserite	$MgSO_4 \cdot H_2O$	[14168-73-1]
Tetrahydrate	Starkeyite	$MgSO_4 \cdot 4H_2O$	[24378-31-2]
Pentahydrate	Pentahydrite	$MgSO_4 \cdot 5H_2O$	[15553-21-6]
Hexahydrate	Hexahydrite	$MgSO_4 \cdot 6H_2O$	[13778-97-7]
Heptahydrate	Epsomite	$MgSO_4 \cdot 7H_2O$	[10034-99-8]

In their hydrated form, these salts have a pH of 6.0 (5.5 to 6.5) in solution. These magnesium sulfates are white crystalline solids. Their densities are: 2.66 g/cm^3 (anhydrous); 2.445 g/cm^3 (monohydrate); 1.68 g/cm^3 (heptahydrate). Solubilities in water are: *anhydrous* = 26.9 g/100 ml (0 °C); *monohydrate* = 25.5 g/100 ml (20 °C); *heptahydrate* = 71 g/100 ml (20 °C).

Magnesium sulfate is found in nature in many salt deposits and mineral waters, occurring as hydrates or double salts. The heptahydrate or Epsom salt was discovered in 1695, found in the mineral water at Epsom. Kieserite and epsomite are the two most important minerals. Other than these and the above hydrates, magnesium sulfate is also found in several other minerals, including:

Langbeinite, $K_2SO_4 \cdot 2MgSO_4$ [CAS #13826-56-7]

Leonite, $K_2SO_4 \cdot MgSO_4 \cdot 4H_2O$ [15226-80-9]

Vanthoffite, $3Na_2SO_4 \cdot MgSO_4$ [15557-33-2]

Bloedite, $Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$ [15083-77-9]

Kainite, $4KCl \cdot 4MgSO_4 \cdot 11H_2O$ [67145-93-1]

Polyhalite, $K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$ [15278-29-2].

The anhydrous salt, $MgSO_4$, consists of colorless rhombohedral crystals with a density of 2.66 g/cm^3; it decomposes at 1124 °C. It is soluble in water (269 g/100 ml at 0 °C). It is also soluble in ethanol and glycerol but sparingly soluble in ether (1.16 g/ml at 18 °C); it is insoluble in acetone.

The monohydrate $MgSO_4 \cdot H_2O$, as the mineral Kieserite, consists of colorless monoclinic crystals, having a refractive index of 1.523, a density of 2.445 g/cm^3. It becomes anhydrous on heating at 200 °C; it is soluble in water.

Epsom salt, or heptahydrate $MgSO_4 \cdot 7H_2O$, constitutes colorless, monoclinic or rhombohedral crystals with a refractive index of 1.433; a density of 1.68 g/cm^3. It loses six molecules of water of crystallization at 150 °C and converts to the anhydrous form at 200 °C. The heptahydrate is highly soluble in water (71 g/100 ml at 20 °C) but slightly soluble in alcohol and glycerol.

Thermochemical properties

$\Delta H_f^0(MgSO_4)$ −307.1 kcal/mol

$\Delta H_f^0(MgSO_4 \cdot 2H_2O)$ −453.2 kcal/mol

$\Delta H_f^0(MgSO_4 \cdot 4H_2O)$ −596.7 kcal/mol

$\Delta H_f^0(MgSO_4 \cdot 6H_2O) = -737.8$ kcal/mol

$\Delta H_f^0(MgSO_4 \cdot 7H_2O) = -809.9$ kcal/mol

$\Delta G_f^0(MgSO_4) = -279.8$ kcal/mol

$\Delta G_f^0(MgSO_4 \cdot 6H_2O) = -629.1$ kcal/mol

$\Delta G_f^0(MgSO_4 \cdot 7H_2O) = -686.4$ kcal/mol

$S^0(MgSO_4) = 21.9$ cal/degree mol

$S^0(MgSO_4 \cdot 6H_2O) = 83.2$ cal/degree mol

$S^0(MgSO_4 \cdot 7H_2O) = 89.0$ cal/degree mol

$C_P(MgSO_4) = 23.0$ cal/degree mol

$C_P(MgSO_4 \cdot 6H_2O) = 83.2$ cal/degree mol

The anhydrous salt decomposes at elevated temperatures to magnesium oxide, oxygen, sulfur dioxide, and sulfur trioxide. The decomposition commences around 900 °C and is complete at about 1100 °C. The overall reaction is:

$$MgSO_4 + \text{heat} \Rightarrow MgO + O_2 + SO_2 + SO_3$$

On the other hand, heating hydrated sulfate above 150 °C yields magnesium oxysulfate, a hydrolysis reaction. No dehydration or thermal decomposition occurs. The anhydrous salt may be reduced to magnesium oxide when heated with carbon at 750 °C:

$$MgSO_4 + C \Rightarrow MgO + SO_2 + CO$$

Magnesium sulfate undergoes three important types of reactions in aqueous solution. These are:

Double decomposition,
Double salt formation,
Formation of oxysulfate cements.

Many insoluble magnesium salts may be precipitated out by double decomposition reactions:

$$MgSO_4 + 2NaOH \Rightarrow Mg(OH)_2 + 2Na^+ + SO_4^{2-}$$

$$3MgSO_4 + 2Na_3PO_4 \Rightarrow Mg_3(PO_4)_2 + 6Na^+ + 3SO_4^{2-}$$

Magnesium sulfate forms several double salts having varying stoichiometric compositions. When gaseous ammonia is bubbled through magnesium sulfate solution, several hydrated double salts are obtained by crystallization. Magnesium sulfate double salts have the compositions:

$$MgSO_4 \cdot NH_3 \cdot 3H_2O$$

$$MgSO_4 \cdot 2NH_3 \cdot 4H_2O$$

$$MgSO_4 \cdot 2NH_3 \cdot 2H_2O$$

Similarly, in sulfuric acid, crystals of double salts form:

$$MgSO_4 \cdot H_2SO_4 \cdot 3H_2O$$

$$MgSO_4 \cdot H_2SO_4$$

$$MgSO_4 \cdot 3H_2SO_4$$

Addition of magnesium oxide to magnesium sulfate solutions yields crystalline oxy-sulfates at varying stoichiometric compositions, such as:

$$MgSO_4 \cdot 3MgO \cdot 11H_2O$$

$$MgSO_4 \cdot 5MgO \cdot 8H_2O.$$

Treatment of barium peroxide, BaO_2, with a concentrated solution of magnesium sulfate, yields magnesium peroxide MgO_2, a white powdery material used as a bleaching and oxidizing agent, and as an antacid in medicine.

Anhydrous magnesium sulfate is used as a drying agent since it is highly hygroscopic. This property limits its usefulness and the hydrate is generally preferred when weighing out the material for preparing solutions,

for example in medical preparations. Epsom salt has been traditionally used as a component of bath salts.

Magnesium sulfate is used widely in several industries including fertilizer, cement, textile, chemicals, and medicine. In the cement industry, it is used in manufacturing oxysulfate cement. In medicine, it is an analgesic and cathartic. An important application of anhydrous magnesium sulfate in the laboratory involves drying organic solvents required for syntheses and GC analysis. In the textile industry, magnesium sulfate is used in finishing composition for dressing cotton; for weighting and sizing silk; as a mordant for fixing basic dyestuffs on wool; and in fireproofing fabrics. It is also a component of certain types of electrolytic plating baths; of various photographic solutions; of cosmetic lotions. It is a catalyst carrier; a dietary supplement in cattle feed; a coagulant for rubber and plastic; and is used in making citric acid and several magnesium salts, such as magnesium stearate.

Both are, however, not the highest known hydrates of $MgSO_4$ due to the recent terrestrial find of Meridianite, $MgSO_4 \cdot 11H_2O$, which is thought to also occur on Mars.

In agriculture and gardening, magnesium sulfate is used to correct magnesium deficiency in soil, since magnesium is an essential element in the chlorophyll molecule. It is most commonly applied to potted plants, or to magnesium-hungry crops, such as potatoes, tomatoes, peppers, and roses. The advantage of magnesium sulfate over other magnesium compounds (such as dolomitic limestone) is its high solubility. $MgSO_4$ has been used in organic synthesis to remove water from nonaqueous solutions before the organic reaction is started. Since it is insoluble in most organic solvents, its addition forms hydrates that can be easily removed.

Epsom salt is also used to prepare footbaths, intended to soothe sore feet. The reason for the inclusion of the salt is partially cosmetic. However, magnesium sulfate can also be absorbed into the skin, reducing inflammation. It is also sometimes found in bottled mineral water, and accordingly is sometimes listed in the contents thereof. Magnesium sulfate heptahydrate is also used to maintain the magnesium concentration in marine aquaria which contain large amounts of stony corals as it is slowly depleted in their calcification process, precipitation into calcium carbonate. Oral Epsom salt is used as a saline laxative as well as for replacement therapy in "hypomagnesaemia" (lack of Mg^{2+}) in animals and humans. Magnesium sulfate paste has been used as an agent for dehydrating (drawing) boils, carbuncles or abscesses. Magnesium sulfate solution has also been shown to be an effective aid in the fight against blemishes and acne when applied directly to problematic areas. Magnesium sulfate, when used through soaking, can soothe muscle pains and help improve rough patches in the skin. Soaking in a warm bath containing Epsom salt (magnesium sulfate) can be beneficial to soothe and relieve herpes outbreak symptoms, such as itching and lesions relating to genital herpes or shingles.

Magnesium sulfate salts are available commercially in large lots in a variety of compositional hydrates for varied uses in the home and in industry.

Calcium Sulfate

Calcium sulfate has the molecular formula of $CaSO_4$ and the molecular weight of 136.1452 g/mol. It may be prepared by the addition of a soluble calcium salt to a solution of sodium sulfate:

$$CaCl_2 + Na_2SO_4 \Rightarrow CaSO_4 + 2NaCl$$

The product is generally a dihydrate although other hydrates are also known. The CAS numbers of these materials are: 7778-18-9 (anhydrite); 10034-76-1 (hemihydrate); 10101-41-4 (dihydrate). The molecular weight of the hydrates is: 145.15 g/mol (hemihydrate); 172.172 g/mol (dihydrate). These white solids are odorless. Known densities are: 145.15 g/mol (hemihydrate); 172.172 g/mol (dihydrate). The anhydrate melts at 1462 °C. It is a basic salt with a pK_a of 10.4 (anhydrous); 7.3 (dihydrate). The thermochemical constants for the three forms of calcium sulfate are:

Thermochemical properties

ΔH_f° (anhydrite) −342.76 kcal/mol

ΔG_f° (anhydrite) = −315.93 kcal/mol

S° (anhydrite) = 25.50 cal/degree mol

C_p (anhydrite) = 23.82 cal/*degree mol*

ΔH_f° (hemihydrate) = −376.85 kcal/mol

ΔG_f° (hemihydrate) = −343.41 kcal/mol

S° (hemihydrate) = 31.20 cal/degree mol

C_p (hemihydrate) = 28.54 cal/degree mol

ΔH_f° (dihydrate) = −483.42 kcal/mol

ΔG_f° (dihydrate) = −429.60 kcal/mol

S° (dihydrate) = 46.40 cal/degree mol

C_p (dihydrate) = 44.46 cal/degree mol

The structure of the "anhydrite" is shown in Fig. 3.31.

Its crystal symmetry is orthorhombic, 2/m 2/m 2/m, with unit cell parameters of: $a = 6.245(1)$ Å, $b = 6.995(2)$ Å, $c = 6.993(2)$ Å; $Z = 4$. Calcium sulfate is a common laboratory and industrial chemical. It is most often used as "gypsum" which is the dihydrate. In the form of β-anhydrite (the nearly anhydrous form), it is used

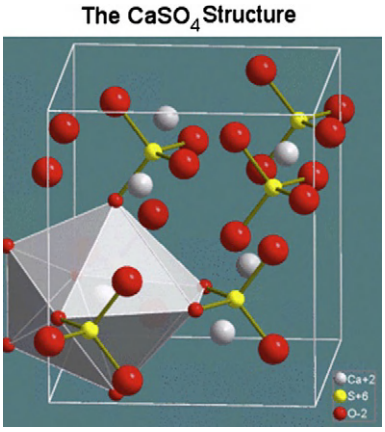

FIGURE 3.31

as a desiccant. It is also used as a coagulant in products like "tofu", which is a "bean curd". When sold as a color-indicating variant under the name "Drierite™", it appears blue or pink due to impregnation with cobalt chloride, which functions as a moisture indicator.

Gypsum is moderately water soluble (~2.0–2.5 g/l at 25 °C) and, in contrast to most other salts, it exhibits a retrograde solubility, becoming less slightly less soluble at higher temperatures (Table 3.13).

As for β-anhydrite, its solubility in saline solutions and in brines is also strongly dependent on the salt concentration. Because gypsum dissolves over time in water, gypsum is rarely found in the form of sand. However, the unique conditions of the "White Sands National Monument" in New Mexico have created a 710-sq. km (270 sq. mile) expanse of white gypsum sand, enough to supply the construction industry with dry wall for 1000 years. Commercial exploitation of the area, strongly opposed by area residents, was permanently prevented in 1933 when the gypsum dunes were declared a protected national monument.

In its natural state, unrefined calcium sulfate is a translucent, crystalline white rock. Many forms are known, including "Alabaster" and "Gypsum". Selenite, Satin spar, Desert rose, and Gypsum flower are four varieties of Gypsum minerals; all four varieties are crystalline. The four "crystalline" varieties of gypsum are sometimes grouped together and called selenite. All have the same chemical formulation, $CaSO_4 \cdot 2H_2O$. All varieties of gypsum are very soft minerals (hardness: 2 on Mohs scale). This is the most important identifying characteristic of gypsum, as any variety of gypsum can be easily scratched with a fingernail.

TABLE 3.13

Gram/100 ml of water									
		0 °C	10	20	30	40	60	80	100
Calcium sulfate	$CaSO_4 \cdot 2H_2O$	0.223	0.244	0.255	0.264	0.265	0.244	0.234	0.205

The origin of the word, "Alabaster", comes from Middle English, through Old French *alabastre*, in turn derived from the Latin, *Alabaster* and that from the Greek. This substance, the "alabaster" of the ancient Egyptians and the Bible, often is termed *Oriental alabaster*, since the early examples came from the far East. This name may derive further from the ancient Egyptian word *a-labaste*, which refers to vessels of the Egyptian goddess "Bast", who was represented as a lioness or it may have been derived from the town of Alabastron in Egypt where the stone was quarried. Additionally, an Arabic etymological origin has also been suggested. However, the origin of the mineral name remains obscure. Thousands of gypsum alabaster artifacts dating to the late fourth millenium BC also have been found in Mesopotamia (Syria) which dates back into the first half of the third millennium BC.

The finest mineral alabaster deposits occur in England in many places. Deposits at all of these localities have been worked extensively. In the fifteenth century, its carving into icons and altarpieces was a valuable local industry, as well as a major English export. Alabaster is also found, although in subordinate quantity, in Spain and Scandinavia. *Black Alabaster* is a rare form of the gypsum-based mineral. This black form is only found in three veins in the world, one each in Oklahoma (USA), Italy, and China.

The hemihydrate, $CaSO_4 \cdot 1/2H_2O$ is better known as "plaster of paris" while the dihydrate ($CaSO_4 \cdot 2H_2O$) occurs naturally as Gypsum. The anhydrous form occurs naturally as β-Anhydrite. Anhydrite is a mineral—anhydrous $CaSO_4$. It is not to be confused with "anhydride" which is the hemihydrate. It has the orthorhombic crystal system, with three directions of perfect cleavage parallel to the three planes of symmetry. It is not isomorphous with the orthorhombic barium or strontium sulfates, as might be expected from the chemical formulas. Distinctly developed crystals are somewhat rare, the mineral usually presenting the form of cleavage masses. The hardness is 3.5 and the specific gravity is 2.9. The color is white, sometimes grayish, bluish or purple. When exposed to water, anhydrite readily transforms to the more commonly occurring $CaSO_4 \cdot 2H_2O$ by the absorption of water. Depending on the method of calcination of calcium sulfate dihydrate, specific hemihydrates are sometimes distinguished: α-hemihydrate and β-hemihydrate. They appear to differ only in crystal size. α-hemihydrate crystals are more prismatic than β-hemihydrate crystals and, when mixed with water, form a much stronger and harder superstructure.

Heating gypsum to between 100 °C and 150 °C (302 F) partially dehydrates the mineral by driving off

approximately 75% of the water contained in its chemical structure. The temperature and time needed depend on ambient partial pressure of H_2O. Temperatures as high as 170 °C are used in industrial calcination, but at these temperatures β-anhydrite begins to form. The reaction for the partial dehydration is:

$$CaSO_4 \cdot 2H_2O + \text{heat} \Rightarrow CaSO_4 \cdot 1/2H_2O + 1.5H_2O \text{ (steam)}$$

The partially dehydrated mineral is called calcium sulfate hemihydrate or calcined gypsum (commonly known as plaster of paris = $CaSO_4 \cdot nH_2O$, where n is in the range 0.5 to 0.8). The dehydration begins at approximately 80 °C (176 °F), although in dry air, some dehydration will take place already at 50 °C. The heat energy delivered to the gypsum at this time (the heat of hydration) tends to go into driving off water (as water vapor) rather than increasing the temperature of the mineral, which rises slowly until the water is gone, then increases more rapidly. The endothermic property of this reaction is exploited in "drywalls" to confer fire resistance to residential and other structures. In a fire, the structure behind a sheet of drywall will remain relatively cool as water is lost from the gypsum. This prevents (or substantially retards) damage to the wood framing (through combustion of wood or loss of strength of steel members at high temperatures) and consequent structural collapse.

In contrast to most minerals, which when rehydrated simply form liquid or semiliquid pastes, or remain powdery, calcined gypsum has an unusual property: when mixed with water at normal (ambient) temperatures, it quickly reverts chemically to the preferred dihydrate form, while physically "setting" to form a rigid and relatively strong gypsum crystal lattice:

$$CaSO_4 \cdot \tfrac{1}{2}H_2O + 1.5H_2O \Rightarrow CaSO_4 \cdot 2H_2O$$

This reaction is exothermic and is responsible for the ease with which gypsum can be cast into various shapes including sheets (for Drywall), sticks (for blackboard chalk), and molds (to immobilize broken bones, or for metal casting). Mixed with polymers, it has been used as a bone repair cement. Small amounts of calcined gypsum are added to earth to create strong structures directly from bricks, an alternative to adobe (which loses its strength when wet). The conditions of dehydration can be changed to adjust the porosity of the hemihydrate, resulting in the so-called alpha and beta hemihydrates (which are more or less chemically identical).

On heating to 180 °C, the nearly water-free form, called γ-anhydrite ($CaSO_4 \cdot nH_2O$ where $n = 0$ to 0.05) is produced. β-Anhydrite reacts slowly with water to return to the dihydrate state, a property exploited in some commercial desiccants. On heating above 250 °C, the completely anhydrous form called β-anhydrite or "natural" anhydrite is formed. Natural anhydrite does not react with water, even over geological timescales, unless very finely ground.

The variable composition of the hemihydrate and β-anhydrite, and their easy interconversion, is due to their possessing nearly identical crystal structures, containing "channels" that can accommodate variable amounts of water, or other small molecules such as methanol.

When exposed to water, anhydrite readily transforms to the more commonly occurring gypsum ($CaSO_4 \cdot 2H_2O$), by the absorption of water. Anhydrite is commonly associated with the minerals, calcite, halite, galena, chalcopyrite and pyrite in vein deposits. The word gypsum is derived from the Greek word for "chalk" or "plaster". Because the gypsum from the quarries of the Montmarte district of Paris has long furnished burnt gypsum used for various purposes, this material has been called "plaster of paris".

Gypsum and β-anhydrite have been used as "plaster" throughout the centuries as a building material. The Sumerians who lived in Mesopotamia (Ancient Iraq) from the mid-sixth millennium to the second millennium BC used plaster to face off dried mud bricks to preserve them and lengthen their lifetime in construction. The story of Sumerian architecture is overwhelmingly one of clay masonry and of increasingly complex forms of stacked bricks. Because these bricks were sun baked, Sumerian buildings eventually deteriorated. They were periodically destroyed, leveled, and rebuilt on the same spot.

Common materials of Greek architecture were wood, used for supports and roof beams; plaster, used for sinks and bathtubs; unbaked brick, used for walls, especially for private homes, limestone and marble used for columns, walls, and upper portions of temples and public buildings; terracotta, used for roof tiles and ornaments; and metals, especially bronze, used for decorative details. Gypsum was used as "Stucco" for a variety of purposes. As a building material, stucco is a durable, attractive, and weather-resistant wall covering. It was traditionally used as both an interior and exterior finish applied in one or two thin layers directly over a solid brick or stone surface. The finish coat usually contained an integral color and was typically textured for appearance. A stucco face from the ancient Greek city of Al Khanoum I, Afghanistan, third-second century BC is known. Stucco has also been used as a sculptural and artistic material. Baroque and Rococo architecture made heavy use of stucco. Examples can be found in churches and palaces from the eighth to sixteenth century, where stucco is mostly used to provide a smooth, decorative transition from walls to ceiling, decorating and giving measure to ceiling surfaces. Since stucco can be used for decoration

as well as for figurative representation, it provides an ideal transitive link from architectural details to wall paintings such as the typically Baroque ceilings. Here, the real architecture of the church is visually extended into a heavenly architecture with a depiction of Christ or the Virgin Mary at the center. Stucco is used to form a semiplastic extension of the real architecture that merges into the painted architecture. Many of the greatest paintings in Europe, like Michelangelo's Sistine Chapel ceiling are executed or painted on a thin layer of wet plaster, called intonaco (in fact the general term for plaster in Italian); the pigments sink into this layer so that the plaster itself becomes the medium holding them, which accounts for the excellent durability of fresco. Additional work may be added *"a-secco"* on top of the dry plaster, though this is generally less durable.

Stucco is still used today as a building material. It is applied as a cover coat to wallboard and stylized. A major usage has occurred with the introduction and development of light wood-framed construction methods, in which stucco was adapted for a new use by adding a reinforcement lattice, or lath, attached to and spanning between the structural supports, thereby increasing the thickness and number of layers of the total system. The lath added support for the wet plaster and tensile strength to the brittle, cured stucco; while the increased thickness and number of layers helped control cracking. The traditional application of stucco and lath occurs in three coats—the scratch coat, the brown coat and the finish coat. The two base coats of plaster are either hand applied or machine sprayed. The finish coat can be troweled smooth, hand textured, floated to a sand finish or sprayed.

Plaster may be cast directly into a damp clay mold. In creating this *piece molds* (molds designed for making multiple copies) or *waste molds* (for single use) would be made of plaster. This "negative" image, if properly designed, may be used to produce clay productions, which when fired in a kiln become terra-cotta building decorations, or these may be used to create cast concrete sculptures. Plaster expands while hardening, then contracts slightly just before hardening completely. This makes plaster excellent for use in molds, and it is often used as an artistic material for casting. Plaster is also commonly spread over an armature (form), usually made of wire, mesh or other materials, a process called *direct plaster*.

Plaster is widely used as a support for broken bones; a bandage impregnated with plaster is moistened and then wrapped around the damaged limb, setting into a close fitting yet easily removed tube. Plaster is also used within radiotherapy when making immobilization casts for patients. Plaster bandages are used when constructing an impression of the patient's head and neck, and liquid plaster is used to fill the impression and produce a plaster bust. Perspex is then vacuum formed over this bust creating an immobilization shell. In dentistry, plaster is used for mounting casts or models of oral tissues. These diagnostic and working models are usually made from dental stone, a stronger, harder and denser derivative of plaster which is manufactured from gypsum under pressure. Plaster is also used to invest or flask wax dentures, the wax being subsequently removed and replaced with the final denture base material which is cured in the plaster mold.

The main sources of calcium sulfate are naturally occurring gypsum and anhydrite that occur at many locations worldwide as "evaporites". These may be extracted by open cast quarrying or by deep mining. World production of natural gypsum is around 127 million tons per year. In addition to natural sources, calcium sulfate is produced as a by-product in a number of chemical processes. In "flue gas" desulfurization, exhaust gases from fossil fuel burning power plants and other processes (e.g. cement manufacture) are scrubbed to reduce their sulfur dioxide content, by injecting finely ground limestone or lime. This produces an impure calcium sulfite, which oxidizes on storage to calcium sulfate. In the production of H_3PO_4 from phosphate rock, calcium phosphate is treated with sulfuric acid and calcium sulfate precipitates. Over 200 million tons per annum of calcium sulfate waste is produced by the phosphate industry worldwide. In the production of HF, calcium fluoride is treated with sulfuric acid, precipitating calcium sulfate. Calcium sulfate can also be recovered and reused from scrap drywall at construction sites.

Strontium Sulfate

Strontium sulfate has the molecular formula of $SrSO_4$ and the molecular weight of 183.6842 g/mol. It can be prepared by the reaction of sodium sulfate and strontium chloride:

$$Na_2SO_4 + SrCl_2 \Rightarrow SrSO_4 + 2NaCl$$

Strontium sulfate occurs in nature as "celestite" and is mined from its natural deposits. Also, the sulfate can be made by reacting strontium oxide, hydroxide, or carbonate with dilute hydrochloric acid:

$$SrO + H_2SO_4 \Rightarrow SrSO_4 + H_2O$$

$$SrCO_3 + H_2SO_4 \Rightarrow SrSO_4 + CO_2 + H_2O$$

No hydrates are known. Its CAS number is 7759-02-6. It is a white, orthorhombic crystal with a refractive index of 1.622 and a density of 3.96 g/cm^3. Its hardness is 3.3 Mohs. It melts at 1608 °C. Its solubility in water is 0.015 g/100 ml at 25 °C and 0.014 g at 35 °C. It is insoluble in ethanol and acetone, but slightly soluble in acids and alkalis. It is soluble in alkali chloride solutions. The

heat of formation, ΔH_f, is –1453 kJ/mol with an entropy value, S_0, of 117.0 J/mol K. Its Mohs Hardness is 3.0–3.5. A water solution has a pH of 7.5. Its specific gravity ranges from 3.8 to 4.0 g/cm^3.

Thermochemical properties

$$\Delta H_f = -347.3 \text{ kcal/mol}$$

$$\Delta G_f = -320.05 \text{ kcal/mol}$$

$$S_0 = 28 \text{ cal/deg mol}$$

It occurs in nature as the mineral "celestine". Celestite is a favorite among mineral collectors. Its sky blue (or *celestial*) color is very pretty, and is unique in the mineral kingdom. Celestite also forms with other colorful minerals, making very nice combinations. Blue celestite with bright yellow sulfur is one of the most famous colorful combinations of minerals. Color is usually blue but can also be colorless, yellow and tints of red, green and brown. The luster is vitreous. Crystals can vary from transparent to translucent. Crystal system is orthorhombic; 2/m 2/m 2/m. The name Celestine comes from a Latin word meaning "heaven." This refers to the sky blue, "celestial" color often seen in this mineral. Since celestine is the most common mineral that contains the metal strontium, it is the predominate ore for that element. Compounds of strontium color a flame red, and they sometimes are used in the manufacture of fireworks.

Celestite has been found in various places in Europe and North America, but the state of Ohio is famous for having many of the best deposits. This mineral has been reported in 11 of Ohio's counties. Northwestern Ohio produces crystals of this mineral in colors ranging from white to a beautiful pale blue. Crystal cave on South Bass Island is a large jug filled with very large crystals of celestine. In the southwestern part of the state, it occasionally found in the area of Serpent Mound State Memorial where an unusual geological disturbance occurred.

Strontium sulfate is a polymeric material, isostructural with barium sulfate. Under certain conditions, it grows as "dendrites" which are layered (Fig. 3.32).

The compound, $SrSO_4$, is orthorhombic, with a space group *Pnma* ($a = 8.359$, $b = 5.351$, $c = 6.869$ Å, $Z = 4$), with 11 variable atomic positional parameters, and gives a fairly complex powder pattern with many overlapping peaks. Accurate high-resolution synchrotron X-ray powder diffraction (XRD) data were obtained at three energies: 14, 225 and 5133 eV below the Sr *K* edge. From combinations of two of the three data sets, partial Patterson densities were derived and used to phase the 71 uniquely resolved reflections, allowing a complete solution of the rest of the structure.

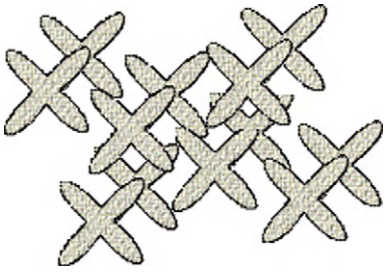

FIGURE 3.32

The crystal habits of $SrSO_4$ crystals grown from 0.015 M solution with and without the addition of polyvinyl sulfonate have been compared. Pure strontium sulfate precipitate consists of single crystals, about some tens of microns long, with distinctly visible growth steps. Crystals grown with polyvinyl sulfonate in stirred solutions show a striking change of habit: they are sponge-like structures, composed of minute crystallites, of size in the nanometer range.

The thermoluminescence of $SrSO_4$ and $BaSO_4$ doped with dysprosium and thulium has been studied. The phosphors were crystallized from H_2SO_4 solution by evaporation. $SrSO_4$:Dy and $SrSO_4$:Tm exhibit the same glow curve, both having a major glow peak at 140 °C. $BaSO_4$:Dy and $BaSO_4$:Tm also exhibit identical glow peaks at 130 °C which are similar to the $SrSO_4$ peaks except for the small shift in temperature. The sensitivities of $SrSO_4$:Dy and $BaSO_4$:Dy relative to $CaSO_4$:Dy are 90 and 27%, respectively, for ^{60}Co irradiation.

Crystallized strontium sulfate is utilized by a small group of protozoa as a main constituent of their skeleton. It is sometimes used to impart iridescence to glass and pottery glazes or used as a fining agent in crystal glass.

There is very little demand for this salt in industry. It is available in limited quantities commercially.

Barium Sulfate

Barium sulfate has the molecular formula of $BaSO_4$ and the molecular weight of 233.3896 g/mol. It can be prepared by the reaction of barium carbonate and sulfuric acid:

$$BaCO_3 + H_2SO_4 \Rightarrow BaSO_4 + CO_2 + H_2O$$

Barium sulfate is a soft crystalline solid. It is a rhombic crystal. The pure salt is white but the color of the mineral "barite" can vary between red, yellow, gray or green, depending on impurities. Its density is 4.50 g/cm^3 and its refractive index is 1.64. It melts around 1580 °C but decomposes above 1600 °C. Its hardness is 4.3 to 4.6 Mohs. It is virtually insoluble in water (285 mg/l at 30 °C) and insoluble in alcohol. Its K_{sp} is 1.1×10^{-10}. It is soluble in concentrated sulfuric acid. The crystal structure of BaSO4 is known to be rhombic, with a space group pnma. The lattice

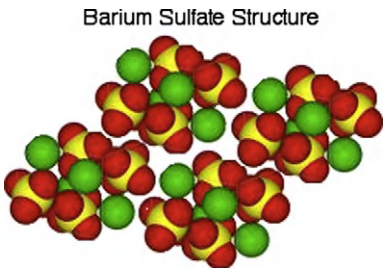

FIGURE 3.33

parameters are: $a = 8.896$ Å, $b = 5.462°$, $c = 7.171$ Å, $V = 348.4$ Å^3. Its three-dimensional structure is shown in Fig. 3.33.

Strontium sulfate has an identical structure. Thernodynamic constants are given by the following table. These values are for 293 K (Table 3.14).

Natural barium sulfate is widely distributed in nature and occurs as the mineral "barite" (also known as barytes or heavy spar). It often associated with other metallic ores, such as fluorspar. Barites containing over 94% $BaSO_4$ can be processed economically. It also contains silica, ferric oxide and fluoride impurities. Silica is the prime impurity that can be removed as sodium fluorosilicate by treatment with hydrofluoric acid followed by caustic soda. Very pure barium sulfate may be obtained by treating an aqueous solution of a soluble barium salt with sodium sulfate:

$$BaCl_2 + Na_2SO_4 \Rightarrow BaSO_4 + 2NaCl$$

Barium sulfate is one of the most insoluble salts of the alkaline earths. It does not undergo double decomposition reactions in aqueous phase like its Mg homologue. It dissolves in concentrated H_2SO_4 to form an acid sulfate that breaks down to $BaSO_4$ upon dilution. Reduction with coke under heating produces barium sulfide:

$$BaSO_4 + 3C \Rightarrow BaS + 2CO + CO_2$$

The accidental discovery of this conversion many centuries ago led to the discovery of the first luminescent material in 1803. The sulfide, unlike the sulfate, is water soluble. Sometime prior to the autumn of 1803, the Englishman John Dalton was able to explain the results of some of his studies by assuming that matter is composed of atoms and that all samples of any given compound consist of the same combination of these atoms. Dalton also noted that in a series of compounds like barium sulfate, the ratios of the masses of the second element that combine with a given weight of the first element can be reduced to small whole numbers (the law of multiple proportions). This was further evidence for the existence of "atoms".

TABLE 3.14

Thermochemical properties
$\Delta H_f = -352.3$ kcal/mol
$\Delta G_f = -325.7$ kcal/mol
$S^0 = 31.6$ cal/degree mol
$C_p = 24.3$ cal/degree mol
$\Delta H_{fusion} = 9.71$ kcal/mol

$BaSO_4$ reacts violently when heated with aluminum or explosively when mixed with potassium. Sulfamic acid, HSO_3NH_2 is a moderately strong acid. Water solutions are unstable and slowly hydrolyze to NH_4HSO_4. It has been used to produce nanosized barium sulfate particles.

Barium sulfate has many commercial applications. It is used either as natural barite, or precipitated $BaSO_4$. The precipitated salt in combination with equimolar amount of co-precipitated zinc sulfide formerly was used as a white protective coating pigment, known as "lithopone". Similarly, in combination with sodium sulfide, it is used to produce fine pigment particles of uniform size, known as "blanc fixe". Natural barite, however, has greater commercial application than the precipitated salt. It is used as an additive in drilling mud in crude oil, well drilled to lubricate and cool the drilling bit, and to plaster the walls of the drill hole to prevent caving. It is used as a filler in automotive paints, plastics and rubber products. It also is used as a filler in polyurethane foam floor mats, white sidewall rubber tires and as a flux and additive to glass to increase the refractive index.

Barium sulfate is frequently used clinically as a contrast agent for X-ray imaging and other diagnostic procedures. It is most often used in imaging of the gastrointestinal tract. It is administered, orally or by enema, as a suspension of fine particles in an aqueous solution. Although barium, and its water-soluble compounds are often highly toxic, the extremely low solubility of barium sulfate protects the patient from absorbing harmful amounts of the metal. Barium sulfate is also readily removed from the body, unlike prior compounds, which it replaced. Its absorbance of X-rays is also higher.

Barium sulfate mixtures are used as white pigment for paints. In oil paint, barium sulfate is almost transparent, and is used as a filler or to modify consistency. One major manufacturer of artists' oil paint sells "permanent white" that contains a mixture of titanium white pigment and barium sulfate. Barium sulfate itself is called *blanc fixe* (French for "permanent white").

A scientific-grade, barium sulfate-based paint is offered for sale that exhibits near-perfect diffuse reflectance at levels up to 98% in the UV-VIS-NIR wavelength

range. It is applied by spray painting to almost any substrate (metals, plastics, glass) for use in integrating spheres, laser cavities, lamp reflectors and display backlights. It is characterized by a near-perfect Lambertian (i.e. diffuse) reflectance of up to 98% in the spectral range from 250 to 2500 nm.

Other chemical applications of barium sulfate are used as a pigment for photographic paper. It is also used to prepare many other barium salts. It is available in many forms commercially.

Radium Sulfate

Radium sulfate has the molecular formula of $RaSO_4$ and the molecular weight of 322.0626 g/mol. It can be prepared by dissolving radium oxide in sodium sulfate solution:

$$RaO + Na_2SO_4 + H_2O \Rightarrow RaSO_4 + NaOH$$

Radium sulfate is insoluble in water with a solubility product of 3.66×10^{-11}. The solubility of **radium sulfate** would appear as at least 100-fold less than barium sulfate. Thus, it is the most insoluble sulfate known. Its CAS Number is 7446-16-4. It appears as white crystals. Since radium is a decay product in the ^{238}U series which then allows radon to accumulate in household basements, it is $RaSO_4$ that has received some attention in the scientific literature.

There is absolutely no demand for this salt and there are no listed suppliers commercially.

3.2.5. Alkaline Earth Thiosulfates

The thiosulfate ion, $S_2O_3^{2-}$, is a structural analog of the SO_4^{2-} ion in which one oxygen atom is replaced by one S atom. However, the two sulfur atoms in $S_2O_3^{2-}$; are not equivalent. One of the S atoms is a sulfide-like sulfur atom that gives the thiosulfate its reducing properties and complexing abilities. Thiosulfates readily oxidize to dithionate, then tetrathionate and finally to sulfates. A representation of the S–SO_3 molecule is given in Fig. 3.34.

Beryllium Thiosulfate

Beryllium thiosulfate would have the molecular formula of $[Be(OH)]_2S_2O_3$ and the molecular weight of 155.1571 g/mol. It can be prepared by the reaction of sodium thiosulfate upon the chloride:

$$BeCl_2 + Na_2S_2O_3 \Rightarrow [Be(OH)]_2S_2O_3 + 2NaCl$$

Since this thiosulfate is expected to be soluble in water, the solution must be evaporated at a low temperature to crystallize the product [salt-out temperature ~15 °F (−9.4 °C)]. However, there is absolutely no description in the scientific literature of the preparation of this compound, either by the use of sodium thiosulfite (basic solution) or the use of thiosulfuric acid (acidic solution).

Beryllium thiosulfate is not commonly mentioned in the literature or reference books. Only a few articles prevail, mostly in patents, which discuss technically specific physical uses along with many other similar compounds.

There is no designated supplier of beryllium thiosulfate and it is not available commercially, even in limited quantities.

Magnesium Thiosulfate

Magnesium thiosulfate has the molecular formula of MgS_2O_3 and the molecular weight of 136.4352 g/mol. It is also known as "hyposulfite". It can be prepared by the reaction of sodium thiosulfate upon the chloride in water:

$$MgCl_2 + Na_2S_2O_3 \Rightarrow MgS_2O_3 + 2NaCl$$

Since magnesium thiosulfate is soluble in water (50 g/100 ml at 20 °C), the solution must be evaporated at a low temperature to crystallize the product (salt-out temperature ~15 °F (−9.4 °C). A hexahydrate, $MgS_2O_3 \cdot 6H_2O$, is the result. Its CAS number is 13446-30-5 while that of the anhydrate is 10124-53-5. Thiosulfuric acid could also be used to prepare this salt at an acidic pH. The expected result is the hexahydrate. However, there is no report of an investigation concerning the product(s) formed as a function of pH of precipitation.

These are colorless crystals that lose water at 170 °C to form the trihydrate. Further heating to 420 °C then forms the anhydrate. Further heating to 600 °C will cause the production of magnesium sulfate, sulfur and oxides of sulfur:

$$2MgS_2O_3 + 2O_2 + \text{heat} \Rightarrow 2MgSO_4 + S + SO_2$$

The anhydrate has a density of 1.236 g/cm^3 and a melting point of 1710 °C while the density of the hexahydrate is 1.818 g/cm^3.

Magnesium thiosulfate hexahydrate has the rhombic structure with: space group = Pnma; $a = 9.324$ Å, $b = 14.461$ Å, $c = 6.862$ Å, $V = 925.2$ Å^3, $Z = 4$. Both neutron and X-ray diffraction were used to determine this structure. Peaks of about 0.25 e/Å^3 were observed at the midpoints of the S–O and S–S bonds. Extended

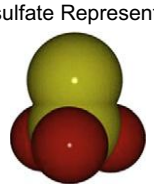

FIGURE 3.34

lone-pair electron regions up to 0.30 e/Å^3 were found at the back of the sulfate oxygen atoms. These were rather diffuse. Three of the water molecules are directly associated with the Mg^{2+} cations. The three independent water molecules show O–H bond peaks of 0.35–0.40 e/Å^3. Their lone-pair peaks amount to 0.30–0.37 e/Å^3 and are considerably extended normal to the H–O–H plane.

Magnesium thiosulfate is considered to have a low toxicity to humans. It has been used to remove ozone from either a water stream, such as a drinking water or wastewater stream being treated with ozone, or scrubbing ozone from a gaseous stream by contacting the gaseous stream with solid magnesium thiosulfate. It has also been used to remove chlorine gas from a water stream by contacting the stream with magnesium thiosulfate solution. In yet another aspect, a method of scrubbing chlorine from a gaseous stream comprises contacting the gas stream with solid magnesium thiosulfate.

Magnesium thiosulfate is not commonly referenced in scientific literature. The few articles that prevail discuss technically specific physical properties of the end product itself. Synthetic methods are described in some Japanese patents and there is mention of MgTS in a short German description in Handbuch der Anorganischen Chemie, vol. 11, 1984. Both refer to adding sulfur to magnesium sulfite to produce magnesium thiosulfate. Neither reference describes the pH nor physical consistency of the "sulfite" intermediate, although the German article does note the "color change" observed as SO_2 is purged into MgO: the slurry becomes yellow.

Magnesium thiosulfate is available in limited quantities commercially.

Calcium Thiosulfate

Calcium thiosulfate has the molecular formula of CaS_2O_3 and the molecular weight of 152.2082 g/mol. It can be prepared by the reaction of sodium thiosulfate upon the chloride:

$$CaCl_2 + Na_2S_2O_3 \Rightarrow CaS_2O_3 + 2NaCl$$

Since calcium thiosulfate is soluble in water (50.2 g/100 ml at 20 °C), the solution must be evaporated at a low temperature to crystallize the product (salt-out temperature ~15 °F (−9.4 °C). A hexahydrate, $CaS_2O_3 \cdot 6H_2O$, is the result. Its CAS number is 10124-43-3 while that of the anhydrate is 10124-41-1. Its density is 1.87 g/cm^3 and it loses four waters of hydration at 45 °C and the other two at about 85 °C. Further heating to 112 °C causes it to decompose, forming S, SO_2 and calcium sulfate:

$$2CaS_2O_3 + \text{heat} \Rightarrow 2CaSO_4 + S + SO_2$$

Thiosulfuric acid could also be used to prepare this salt at an acidic pH. The expected result is the hexahydrate. However, there is no report of an investigation concerning the product(s) formed as a function of pH of precipitation. A high-purity calcium thiosulfate can be prepared by a metathesis reaction of ammonium thiosulfate and calcium hydroxide or calcium oxide. Aqueous solutions of high-purity calcium thiosulfate, in concentrations up to about 30% by weight, are prepared by removing substantially all of the co-product ammonia under conditions that minimize the decomposition of the thiosulfate ion. Heating the reaction mixture to a temperature of about the boiling point at atmospheric pressure is used to prepare aqueous solution of about 10% by weight calcium thiosulfate, and lower reaction temperatures are employed to prepare more concentrated aqueous solutions of calcium thiosulfate up to about 30% by weight, which is the saturation point.

Calcium thiosulfate is supplied as a solution commercially. The clear solution has little odor, and the pH is in the range of 6.5–7.5. It is used in dechlorination, ozone and hydrogen peroxide quenching, concrete and cement formulations, photographic processes, coatings, stabilizers, and reactant for precious and nonprecious metals. It is also used as a "liquid lime" in agriculture.

Calcium thiosulfate is a reducing agent. It is routinely used as a titrant to determine concentrations of oxidants such as hypochlorite in bleach and dissolved oxygen in water. It instantly dechlorinates water, and is used to stop a bleaching action in the paper making industry.

Triclinic $CaS_2O_3 \cdot 6H_2O$ is builtup from $[Ca(H_2O)_6(S_2O_3)]$ chains, parallel to the [100] direction, of alternating S_2O_3 and $Ca(H_2O)_6O_2$ groups sharing common O atoms. It crystallizes centrosymmetrically in the pinacoidal class (point group 1). The structure is characterized by chains, parallel to [100], of alternating S_2O_3 and $Ca(H_2O)_6O_2$ groups sharing common O atoms. The composition of each chain link is $[Ca(H_2O)_6(S_2O_3)]$. The geometry has been analyzed and compared in detail with the structural features of monoclinic strontium(II) thiosulfate pentahydrate. Calcium thiosulfate is offered commercially, mostly as a solution of up to 30% by weight.

It is available commercially in large quantities.

Strontium Thiosulfate

Strontium thiosulfate has the molecular formula of SrS_2O_3 and the molecular weight of 199.7502 g/mol. It can be prepared by the reaction of sodium thiosulfate upon the chloride:

$$SrCl_2 + Na_2S_2O_3 \Rightarrow SrS_2O_3 + 2NaCl$$

It is moderately soluble in water (12.5 g/100 ml at 15 °C) so that the solution must be evaporated at a low

temperature to crystallize the product (salt-out temperature ~15 °F (−9.4 °C). A pentahydrate, $SrS_2O_3 \cdot 5H_2O$, is the result. Its CAS number is 15123-90-7 while that of the anhydrate is 10124-40-1. Its density is 2.17 g/cm^3 and it loses four waters of hydration at 100 °C and decomposes at 225 °C. In air, it forms sulfur plus strontium sulfate but the decomposition in an inert atmosphere remains unknown.

It is insoluble in ethanol and acetone. Its solubility in water varies with temperature (Table 3.15).

Monoclinic $SrS_2O_3 \cdot 5H_2O$ consists of $[Sr(H_2O)_3 O(S_2O_3)]$ layers of alternating S_2O_3 and $Sr(H_2O)_4O_5$ groups, parallel to (100), sharing O atoms and O-O edges. Strontium (II) thiosulfate pentahydrate, $SrS_2O_3 \cdot 5H_2O$, forms layers, parallel to (100), of alternating S_2O_3 and $Sr(H_2O)_4O_5$ groups connected via common O atoms and O-O edges. Each layer contains $[Sr(H_2O)_3 O(S_2O_3)]$ as the unique repeat unit.

Very little information is available for this salt in the scientific literature. It is classified as a "rare" chemical commercially and is available only in small quantities. There are no reference books which discuss this salt in depth. It is mentioned "in passing" as an alkaline earth salt.

It has no CAS number and there is no listed supplier for this salt.

Barium Thiosulfate

Barium thiosulfate has the molecular formula of BaS_2O_3 and the molecular weight of 249.4602 g/mol. It can be prepared by the reaction of sodium thiosulfate in water with the chloride of barium:

$$BaCl_2 + Na_2S_2O_3 \Rightarrow BaS_2O_3 + 2NaCl$$

It is not very soluble in water (0.25 g/100 ml at 15 °C) so that the solution does not need to be evaporated at a low temperature to crystallize the product. A monohydrate is the result. $BaS_2O_3 \cdot H_2O$ has the CAS number of 35112-53-9. It is insoluble in ethanol. It is a white, crystalline, water-insoluble, poisonous solid. It loses the water of hydration at 110 °C and decomposes at 228 °C to form the sulfate, sulfur and SO_2. The CAS number of the anhydrate is 7787-40-8.

$BaS_2O_3 \cdot H_2O$ is used chiefly in the manufacture of explosives, matches, paints, and varnishes. However, the demand for this chemical is not substantial and it is classified as a "rare" chemical.

Barium thiosulfate monohydrate is available in small quantities commercially.

TABLE 3.15

Gram/100 ml of water									
Material	**Formula**	**0 °C**	**10**	**20°**	**30**	**40°**	**60°**	**80°**	**100**
Strontium thiosulfate	$SrS_2O_3 \cdot 5H_2O$	8.78		15.6	21.1	26.8		30.4	

Radium Thiosulfate

Radium sulfate would have the molecular formula of RaS_2O_3 and the molecular weight of 338.1556 g/mol. It could be prepared by the reaction:

$$RaCl_2 + Na_2S_2O_3 \Rightarrow RaS_2O_3 + 2NaCl$$

It is expected to be insoluble in water so that the solution does not need to be evaporated at a low temperature to crystallize the product. The question of hydrate formation remains unknown as there is no record of this salt ever having been prepared. It has no CAS number. It is expected to be insoluble in ethanol. It is expected to be a white, crystalline, water-insoluble, poisonous, radioactive material.

Almost no information is available for this salt in the technical literature and it is not offered commercially.

3.2.6. Alkaline Earth Pyrosulfates or Disulfates

Although the salts are called pyrosulfates, the acid is called disulfuric acid. Disulfuric acid has the molecular formula of $H_2S_2O_7$ where the S-atom is in the +6 oxidation state. The structure of the acid, and of the alkaline earth compounds, consists of two sulfate tetrahedral directly connected by one oxygen. Thus, the acid would have the following Lewis structure while the magnesium (and other alkaline earths) would have the appearance shown in Fig. 3.35.

However, the actual structure is tetrahedral (Fig. 3.36).

Beryllium Pyrosulfate

Beryllium pyrosulfate is not stable in aqueous solution and so must be prepared via a solid-state reaction. It would have the molecular formula of BeS_2O_7 and

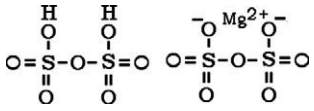

FIGURE 3.35

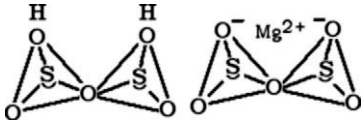

FIGURE 3.36

the molecular weight of 185.1401 g/mol. It could be prepared by the reaction involving "fuming" sulfuric acid (oleum) with beryllium sulfate:

$$[Be(OH)]_2SO_4 + (H_2SO_4)_n \Rightarrow 2BeS_2O_7 + (n+2)\ H_2O$$

The $[Be(OH)]_2SO_4$ salt is added to the oleum and allowed to dissolve in an excess of acid. The acid is heated to 150–175 °C to drive off the water. This is an equivalent of using $H_2S_2O_7$. The solution is allowed to equilibrate and crystals of the anhydrous salt appear. These are separated and allowed to dry. Beryllium disulfate is stable and may be heated to a red heat before it begins to decompose to the sulfate and SO_3.

There is no data or description of this salt in the open literature and its physical and chemical properties have not been studied. It has no CAS number and is not described in the industrial or commercial literature, including patents.

Magnesium Pyrosulfate

Magnesium pyrosulfate has the molecular formula of MgS_2O_7 and the molecular weight of 200.4328 g/mol. Almost no data concerning this salt is available either in patents, scientific or technical literature, or in reference books. Since this salt is not stable in water, it must be prepared by a solid-state reaction. One such reaction involves heating ammonium pyrosulfate with the oxide:

$$MgO + (NH_4)_2S_2O_7 + \text{heat} \Rightarrow MgS_2O_7 + 2H_2O + 2NH_3$$

It is known that the lower molecular weight alkaline earth pyrosulfates are not very stable in moist air or aqueous solution and hydrolyze to sulfate:

$$S_2O_7^{2-} + H_2O \Rightarrow 2SO_4^{2-} + 2H^+$$

$$MgS_2O_7 + H_2O \Rightarrow 2MgSO_4 + 2H^+$$

This may explain why the data on the Mg salt is sparse to nonexistent. The use of pyrosulfuric acid (as an acid solution) to form this compound is not feasible and solid state is required. When the solid persulfate is heated, it loses oxygen to form pyrosulfate:

$$2MgS_2O_8 \Rightarrow 2MgS_2O_7 + O_2$$

The evolved oxygen contains a small amount of ozone, which is identifiable by its smell. The pyrosulfate further decomposes into magnesium sulfate and sulfur trioxide, but the reaction only takes place when sulfuric acid is present:

$$MgS_2O_7 + H_2SO_4 \Rightarrow MgSO_4 + SO_3$$

The sulfuric acid plays the role of a catalyst in that it does not take part in the overall reaction, but without its presence, no SO_3 is formed.

Magnesium pyrosulfate, once formed, is relatively stable in dry air and can be heated to about 750 °C before it decomposes to the sulfate. It has no CAS number and is not offered for sale commercially.

Calcium Pyrosulfate

Calcium pyrosulfate has the molecular formula of CaS_2O_7 and the molecular weight of 216.2078 g/mol. There are few references in the scientific literature concerning this salt. This salt is not expected to be stable in aqueous solution and is expected to decompose to the sulfate. This may explain why the data on the Ca salt is sparse to nonexistent. It can be prepared via a solid-state reaction with ammonium pyrosulfate:

$$CaCl_2 + (NH_4)_2S_2O_7 + \text{heat} \Rightarrow CaS_2O_7 + 2NH_3(\text{gas}) + H_2O(\text{gas})$$

The solubility of this salt has not been reported. The existence of hydrates is unlikely. However, if one heats the persulfate, a pyrosulfate salt can be obtained:

$$2CaS_2O_8 \Rightarrow 2CaS_2O_7 + O_2$$

Further heating then forms the sulfate plus oxygen. These reactions have not been studied critically and no decomposition temperatures can be quoted. Another method of preparation involves the sulfate. If calcium sulfate is mixed with fuming sulfuric acid (to minimize the water present), it dissolves, forming a syrup which upon heating to 150 °C deposits the pyrosulfate crystals which are stable. Further heating removes the excess acid. These crystals are stable to about 720 °C where they decompose to form the sulfate plus sulfur trioxide.

Calcium pyrosulfate has no CAS number and is not offered for sale commercially.

Strontium Pyrosulfate

Strontium pyrosulfate has the molecular formula of SrS_2O_7 and the molecular weight of 263.7478 g/mol. It is expected to be more stable to decomposition in water than the Be, Mg and Ca homologues but no specific data on this aspect has appeared in the literature. There are no references in the scientific literature concerning this salt. Whether this salt is stable in aqueous solution remains unknown. This may explain why the data on strontium pyrosulfate (disulfate) is sparse to nonexistent. It can be prepared via a solid-state reaction with ammonium pyrosulfate:

$$SrCl_2 + (NH_4)_2S_2O_7 + \text{heat} \Rightarrow SrS_2O_7 + 2NH_3(\text{gas}) + H_2O(\text{gas})$$

The solubility of this salt has not been reported. The existence of hydrates is unknown. However, if one heats the persulfate, a pyrosulfate salt can be obtained:

$$2SrS_2O_8 \Rightarrow 2SrS_2O_7 + O_2$$

Further heating then forms the sulfate plus oxygen. These reactions have not been studied critically and no decomposition temperatures can be quoted. Another method of preparation involves the sulfate. If strontium sulfate is mixed with fuming sulfuric acid (to minimize the water present), it dissolves forming a syrup which upon heating to 150 °C deposits the pyrosulfate crystals which are stable. Further heating removes water and the excess acid. These crystals are stable to about 720 °C where they decompose to form the sulfate plus sulfur trioxide.

Strontium pyrosulfate is not offered commercially and has no CAS number.

Barium Pyrosulfate

Barium pyrosulfate has the molecular formula of BaS_2O_7 and the molecular weight of 313.4578 g/mol. There is no data concerning this salt is available either in patents, scientific or technical literature, or in reference books. Indeed, it has been stated that "This salt does not exist—it was first prepared by J.J. Berzelius in 1843 …." "It is decomposed by water … Apart from some doubt as to its precise structure, the compound is of little interest, and has never been more than a chemical curiosity—1933". However, this salt can be prepared by the solid-state reaction of ammonium pyrosulfate with barium chloride:

$$BaCl_2 + (NH_4)_2S_2O_7 + \text{heat} \Rightarrow BaS_2O_7 + 2HCl(\text{gas}) + 2NH_3(\text{gas})$$

However, a better method of preparation involves reaction of the sulfate with fuming sulfuric acid (Oleum):

$$BaSO_4 + H_2SO_4 \Rightarrow BaS_2O_7 + H_2O$$

The syrupy solution is heated to >150–175 °C to drive off the water and allow crystals to appear. Once formed, barium pyrosulfate is stable to about 720 °C where it decomposes to the sulfate plus sulfur trioxide gas. It can also be prepared by heating the persulfate:

$$2BaS_2O_8 + \text{heat} \Rightarrow 2BaS_2O_7 + O_2$$

The persulfate is also called peroxodisulfate. Further heating will form the sulfate, $BaSO_4$ plus sulfur trioxide. It is expected that this salt will be unstable in water. However, the solubility of this salt has not been reported.

Barium pyrosulfate has no CAS number and remains unknown commercially as there is no demand for this salt.

Radium Pyrosulfate

Radium pyrosulfate would have the molecular formula of RaS_2O_7 and the molecular weight of 402.1532 g/mol. However, there is no demand for this salt and it is not mentioned in the scientific literature. It could be prepared by dissolving radium sulfate in oleum and then heating the syrupy liquid to >150 °C to drive off the water:

$$RaSO_4 + H_2SO_4 \Rightarrow RaS_2O_7 + H_2O$$

A description of its physical or chemical properties remains unavailable and it has no CAS number. It is not available commercially.

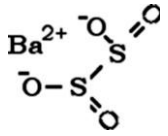

FIGURE 3.37

3.2.7. Alkaline Earth "Thionites and Thionates"

The **dithionite** anion, $S_2O_4^{2-}$, is an anion formally derived from the hypothetical compound "dithionous acid", $H_2S_2O_4$. Dithionous acid has not been detected either as a pure compound or in solution. Its IUPAC name is *sulfinatosulfinate*, the name of its corresponding acid is *sulfinosulfinic acid*. Dithionite anions are prepared by the reaction of sulfurous acid and a bisulfite. They undergo both acid and alkaline hydrolysis to thiosulfate and bisulfite, and sulfite and sulfide, respectively:

$$2S_2O_4^{2-} + 2H^+ \Leftrightarrow S_2O_3^{2-} + 2HSO_3^-$$

$$3S_2O_4^{2-} + 6OH^- \Leftrightarrow 5SO_3^{2-} + S^{2-} + 3H_2O$$

The alkali salts are well known. The sodium salt of dithionous acid, sodium dithionite, finds widespread use in industry as a reducing agent. Of the alkaline earths, only the barium salt has received any attention in technical studies or industrial usage. It has the Lewis structure shown in Fig. 3.37.

The decomposition of dithionite produces reduced species of sulfur that can be very aggressive for the corrosion of steel and stainless steel.

The **dithionate** anion, $S_2O_6^{2-}$, is derived from "dithionic acid", $H_2S_2O_6$. Its IUPAC name is *sulfonatosulfonate*. It has the Lewis structure shown in Fig. 3.38. where the barium salt is shown. The sulfur atoms of

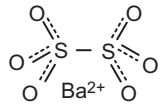

FIGURE 3.38

the dithionate ion are in the +5 oxidation state due to the presence of the S–S bond. Note that the individual bonds are resonant bonds, not double bonds. In general,

only the barium compound has been studied intensively. Generally, dithionates form stable compounds that are not readily oxidized or reduced. Strong oxidants oxidize them to sulfates and strong reducing agents reduce them to sulfites and dithionites:

$$S_2O_6^{2-} + H_2O_2 \Rightarrow 2SO_4^{2-} + H_2O$$

$$3S_2O_6^{2-} + 4H_2 \Rightarrow 2SO_3^{2-} + 2S_2O_4^{2-} + 4H_2O$$

Aqueous solutions of dithionates are quite stable and can be heated to 250 °C without decomposition. The alkali dithionates are well known but the alkaline earths compounds have not been explored.

The **tetrathionate** anion, $S_4O_6^{2-}$, is derived from the compound tetrathionic acid, $H_2S_4O_6$. Two of the sulfur atoms present in the ion are in the +2 oxidation state and two are in oxidation state +5. Alternatively, the compound can be viewed as the adduct resulting from the binding of the sulfide to sulfite. Tetrathionate is one of the polythionates, a family of anions with the formula $[S_n(SO_3)_2]^{2-}$. Its IUPAC name is (sulfonatodisulfanyl) sulfonate; the name of its corresponding acid is (sulfodisulfanyl)sulfonic acid. Tetrathionate is the product of the oxidation of thiosulfate, $S_2O_3^{2-}$, by iodine, I_2:

$$2S_2O_3^{2-} + I_2 \Rightarrow S_4O_6^{2-} + 2I^-$$

The tetrathionates of the alkalis are well known but those of the alkaline earths, with the exception of Ba, remain relatively unknown in the scientific literature. A comparison of these types of compounds is shown in Fig. 3.39.

Beryllium Thionates

Beryllium dithionite is expected to have the molecular formula of BeS_2O_4 and the molecular weight of 153.1412 g/mol. The "thionite" and "thionate" salts of beryllium would include:

Beryllium dithionite = BeS_2O_4
Beryllium dithionate = BeS_2O_6
Beryllium tetrathionate = BeS_4O_6

Beryllium dithionite could be prepared in solution by the reaction of beryllium chloride with sodium dithionite:

$$BeCl_2 + Na_2S_2O_4 \Rightarrow [Be(OH)]_2S_2O_4 + 2NaCl$$

However, there is no record of this reaction ever having been attempted. Alternatively, it may be prepared by the solid-state reaction of SO_2 gas upon the sulfite:

$$Be(HSO_3)_2 + SO_2(gas) + heat \Rightarrow BeS_2O_4 + H_2O$$

This reaction could probably be carried out in solution as well. But, the product would differ due to the hydrated-solution characteristics of the beryllium cation in water. However, the reaction would be dependent upon the pH of the solution and a pH of about 5.0 would produce the hydrosulfite:

$$BeCl_2 + 2(NH_4)_2SO_3 + SO_2 + H_2O \Rightarrow [Be(OH)]_2S_2O_4 + 2NH_4Cl$$

The description of the physical and chemical properties of this salt are completely lacking in the scientific and technological literature. Only barium dithionite is mentioned in a few patents as a reducing agent. Indeed, Parsons in "The Chemistry and Literature of Beryllium"-1909 states "The normal dithionite salt has not been produced". The older reference books like Sidgewick or Remy (1933 or 1950) do not list such a compound as being known.

It has no CAS number and has no commercial value.

Beryllium dithionate, BeS_2O_6, would have the molecular weight of 297.4538 g/mol. It could be prepared by the following method:

$$NH_3(gas) + SO_2(gas) + H_2O \Rightarrow (NH_4)_2SO_3(liq)$$

$$(NH_4)_2SO_3(liq) + MnO_2(solid) \Rightarrow MnS_2O_6(liq)$$

$$MnS_2O_6(liq) + Be(OH)_2(solid) \Rightarrow [Be(OH)]_2S_2O_6(liq) + Mn(OH)_2(solid)$$

In the first reaction, sulfur dioxide gas was passed through a cooled, continuously agitated solution to produce the ammonium compound. The solution was heated to remove excess sulfur dioxide. In the second reaction, the MnO_2 was allowed to dissolve over a period of 2–5 h and was then diluted. The third reaction served to form the insoluble manganese hydroxide that was removed by filtration and the resulting solution was evaporated at a low temperature to form dihydrate crystals. On allowing the solution to evaporate at a moderate temperature, rhombic dihydrate crystals are obtained.

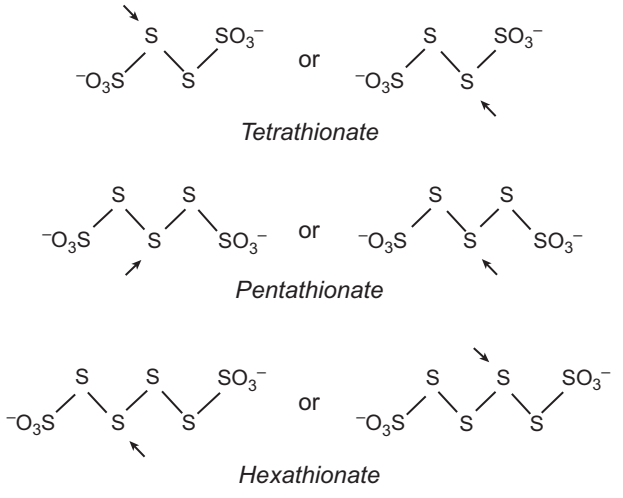

FIGURE 3.39

Beryllium dithionate dihydrate crystallizes as orthorhombic crystals; $a = 1.482$ Å, $b = 6.660$ Å, $c = 9.195$ Å, $\beta = 111.1°$, $Z = 4$, $V = 710.3$ Å^3. There are four molecules per unit cell. The space group is C2/c.

Other than the crystal data, no further description of the physical and chemical properties of beryllium dithionate has been forthcoming. This salt has no interest in industry and is not available commercially. It has no CAS number.

Beryllium Tetrathionate, BeS_4O_6, would have the molecular weight of 233.2726 g/mol. It could be prepared by the reaction of beryllium thiosulfate with iodine:

$$2BeS_2O_3 + I_2 \Rightarrow BeS_4O_6 + BeI_2$$

The tetrathionate is expected to be insoluble in ethanol and addition of alcohol to the reaction mixture serves to cause precipitation. If this is done slowly, crystals of the dihydrate should appear. However, there is no record of this reaction ever being tried or accomplished. In another method, the chloride is reacted with ammonium tetrathionate:

$$BeCl_2 + (NH_4)_2S_2O_6 \Rightarrow BeS_4O_6 + 2NH_4Cl$$

The tetrathionate can be crystallized as a dihydrate from solution by slow evaporation and the addition of alcohol.

Orthorhombic and triclinic **beryllium pentathionate** dihydrate, $BeS_5O_6 \cdot 2H_2O$, crystals have been reported. The presence of unbranched and nonplanar sulfur chains have been demonstrated in this compound. The penta-thionate chain contains three divalent sulfur atoms, together with terminal sulfur atoms to each of which are attached three oxygen atoms, respectively. The sulphonate groups, together with the adjacent divalent sulfur atoms, constitute thiosulfate groups, which have the shape of distorted tetrahedrons. The pentathionate compound is thus built of two thiosulfate groups linked by one divalent sulfur atom. The Lewis structure thus appears as in Fig. 3.40.

The structure actually consists of $S(S_2O_3^{2-})_2$ units in this salt. The structure of the hexa-thionate salt has not been determined.

Beryllium tetrathionate is available in small commercial quantities. Its usage in industry has not been established to date.

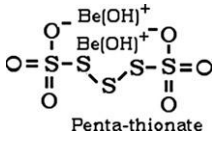

FIGURE 3.40

Magnesium Thionates

Magnesium dithionite has the molecular formula of MgS_2O_4 and the molecular weight of 168.4341 g/mol. The "thionite" and "thionate" salts of magnesium include:

Magnesium dithionite = MgS_2O_4
Magnesium dithionate = MgS_2O_6
Magnesium tetrathionate = MgS_4O_6

Magnesium dithionite, MgS_2O_4, may be prepared by the reaction of magnesium chloride with sodium dithonite:

$$MgCl_2 + Na_2S_2O_4 \Rightarrow MgS_2O_4 + 2NaCl$$

Alternatively, it may be prepared by the solid-state reaction of SO_2 gas upon the sulfite:

$$Mg(HSO_3)_2 + SO_2(gas) + heat \Rightarrow MgS_2O_4 + H_2O$$

This reaction could probably be carried out in solution as well. However, the reaction would be dependent upon the pH of the solution and a pH of about 5.0 would produce the hydrosulfite:

$$MgCl_2 + 2(NH_4)_2SO_3 + SO_2 \Rightarrow MgS_2O_4 + 2NH_4Cl + H_2O$$

This method is mentioned in a patent where all of the other alkaline earths are cited as well. The description of the physical and chemical properties of this salt are completely lacking in the scientific and technological literature. Magnesium dithionite is mentioned in a few patents as a reducing agent to decolorize wood pulp. The older reference books like Sidgewick or Remy (1933 or 1950) do not list such a compound as being known. It has no CAS number and has no commercial value.

Magnesium dithionate, MgS_2O_6, has the molecular weight of 297.4538 g/mol. It has been prepared by the following method:

$$NH_3(gas) + SO_2(gas) + H_2O \Rightarrow (NH_4)_2SO_3(liq)$$

$$(NH_4)_2SO_3(liq) + MnO_2(solid) \Rightarrow MnS_2O_6(liq)$$

$$MnS_2O_6(liq) + MgCO_3(solid) \Rightarrow MgS_2O_6(liq) + MnCO_3(solid)$$

In the first reaction, sulfur dioxide gas was passed through a cooled, continuously agitated solution to produce the ammonium sulfite compound. The water was cooled to 10 °C and then saturated with gaseous ammonia and sulfur dioxide. In the second reaction, the MnO_2 was added over several hours such that the temperature remained between 10 °C and 15 °C. The finely powdered MnO_2 reacted rapidly with a slight exotherm. Upon completion of the MnO_2 addition, the excess SO_2 was removed by heating the solution to 40 °C under a N_2 (g) sparge for 8 h. The third reaction served to form the insoluble manganese

carbonate by adding an aqueous solution of sodium magnesium carbonate to the well-stirred solution of manganese dithionate over 30 min. The precipitated manganese carbonate was removed by vacuum filtration, using a 1-μ glass microfibre pad, and the aqueous magnesium dithionate filtrate was collected. The filtrate was reduced in-vacuo to a solid. The product was isolated as the solid heptahydrate is greater than 95% yield based on MnO_2. On allowing the remaining solution to evaporate at a moderate temperature, rhombic crystals were obtained. The product is a heptahydrate, $MgS_2O_6 \cdot 7H_2O$. It has the CAS number of 13845-15-3 and the molecular weight of 184.4312 g/mol. The decomposition of $MgS_2O_6 \cdot 7H_2O$ has been studied using TG and DTG. Magnesium dithionate heptahydrate dehydrates in three separate steps, first forming the tetrahydrate at about 78 °C and then the dihydrate at 120 °C. The anhydrate is formed by 155 °C which decomposes at >650 °C to form the sulfate plus sulfur dioxide gas.

A description of the physical properties of this salt is not available. It has been cited in several patents as being useful in metal surface cleaning since it is water soluble and is a good reducing agent. Rust is easily dissolved. Nonetheless, the sodium compound is just as efficient and much cheaper. Other than the references cited (6 in all), no citations are given in the technical or scientific literature regarding this salt.

It is available in limited quantity commercially for sale.

Magnesium tetrathionate, MgS_4O_6, has the molecular weight of 248.56 grams per mole.

Magnesium tetrathionate can been prepared by reaction of magnesium thiosulfate with iodine:

$$2MgS_2O_3 + I_2 \Rightarrow MgS_4O_6 + BaI_2$$

The tetrathionate is insoluble in ethanol and addition of alcohol serves to cause precipitation. If this is done slowly, crystals of the octahydrate appear. In another method, the chloride is reacted with ammonium tetrathionate:

$$MgCl_2 + (NH_4)_2S_2O_6 \Rightarrow MgS_4O_6 + 2NH_4Cl$$

The tetrathionate can be crystallized from solution by slow evaporation and the addition of alcohol. The crystals of this salt are prismatic. Upon heating, the octahydrate loses 4 waters at about 105 °C and two other water molecules at about 160 °C. The last two water molecules are lost at about 185 °C.

The penta- and hexa-thionate chains contain three and four divalent sulfur atoms, respectfully, together with terminal sulfur atoms to each of which are attached three oxygen atoms. The sulphonate groups, together with the adjacent divalent sulfur atoms, constitute thiosulfate groups, which have the shape of distorted tetrahedrons. The pentathionate compound is thus built of two thiosulfate groups linked by three divalent sulfur atoms.

Magnesium tetrathionate is available in small commercial quantities. Its usage in industry has not been established to date.

Calcium Thionates

Calcium dithionate has the molecular formula of CaS_2O_4 and the molecular weight of grams per mole. The "thionite" and "thionate" salts of calcium include:

Calcium dithionite = CaS_2O_4
Calcium dithionate = CaS_2O_6
Calcium tetrathionate = CaS_4O_6

Calcium **dithionite**, CaS_2O_4, may be prepared by the reaction of calcium chloride with sodium dithonite:

$$CaCl_2(solid) + (NH_4)_2S_2O_4(solid) + heat \Rightarrow CaS_2O_4(solid) + 2NH_3(gas) + HCl(gas)$$

Alternatively, it may be prepared by the solid-state reaction of SO_2 gas upon the sulfite:

$$Ca(HSO_3)_2(solid) + SO_2(gas) + heat \Rightarrow CaS_2O_4(solid) + H_2O$$

This reaction could probably be carried out in solution as well. However, the reaction would be dependent upon the pH of the solution and a pH of about 4.5 would produce the hydrosulfite:

$$CaCl_2 + 2(NH_4)_2SO_3 + SO_2 \Rightarrow CaS_2O_4 + 2NH_4Cl + H_2O$$

The description of the physical and chemical properties of this salt are completely absent in the scientific and technological literature. Calcium dithionite is mentioned in a few patents as a reducing agent. The older reference books like Sidgewick or Remy (1933 or 1950) do not list such a compound as being known. It has no CAS number and has no commercial value. However, it is offered for sale either as "dithionite" or "hydrosulfite".

There is some confusion in the commercial literature concerning calcium dithionite, CaS_2O_4. Most manufacturers list the dithionite as synonymous with "hydrosulfite", $Ca(H_2SO_3)_2$. Its CAS number is 15512-36-4. However, the two are completely different compounds.

Calcium hydrosulfite is supplied as a colorless or slightly yellow colored liquid with a strong sulfur odor. It is a strong reducing agent. It is corrosive to skin and eyes and may be toxic by ingestion or inhalation. It is spontaneously combustible upon exposure to air or moisture. In contrast, calcium dithionite is stable in air and reacts slowly with moisture, releasing SO_2 gas. But, it dissolves in water, forming calcium hydrosulfite:

$$CaS_2O_4 + 2H_2O \Rightarrow Ca(HSO_3)_2 + 2H^+ \Rightarrow Ca(OH)_2 + 2SO_2$$

Both compounds react with oxidizing agents to generate heat and products that may be flammable, combustible, or otherwise reactive. These reactions may be violent. Sulfites generate gaseous sulfur dioxide in contact with oxidizing acids and nonoxidizing acids.

Calcium dithionate, CaS_2O_6, has the molecular weight of 297.4538 g/mol. It has been prepared by the following method:

$$NH_3(gas) + SO_2(gas) + H_2O \Rightarrow (NH_4)_2SO_3(liq)$$

$$(NH_4)_2SO_3(liq) + MnO_2(solid) \Rightarrow MnS_2O_6(liq)$$

$$MnS_2O_6(liq) + Ba(OH)_2(solid) \Rightarrow BaS_2O_6(liq) + Mn(OH)_2(solid)$$

In the first reaction, sulfur dioxide gas was passed through a cooled, continuously agitated solution to produce the ammonium compound. The solution was heated to remove excess sulfur dioxide. In the second reaction, the MnO_2 was allowed to dissolve over a period of 2–5 h and was then diluted. The third reaction served to form the insoluble manganese hydroxide that was removed by filtration and the resulting solution was evaporated at a low temperature to form dihydrate crystals. On allowing the solution to evaporate at a moderate temperature, rhombic crystals are obtained. The product is a tetrahydrate, $CaS_2O_6 \cdot 4H_2O$.

It can also be prepared from the sodium salt:

$$CaCl_2 + Na_2S_2O_6 \Rightarrow CaS_2O_6 + 2NaCl$$

The addition of alcohol to a cooled solution, while slow evaporation occurs, serves to form the tetrahydrate salt. It has the CAS number of 13813-19-9.

It is expected to be soluble in water but no data has been forthcoming. It occurs as white crystals that lose water of hydration at about 145 °C. Its density is 3.54 g/cm^3. It is slightly soluble in alcohol. Solid dithionate(V) salts when heated decompose to the corresponding sulfates with loss of sulfur dioxide. With these hydrated salts and complexes, it is often possible to distinguish two separate stages. For example with $CaS_2O_6 \cdot 4H_2O$, losses take place (a) between 120 and 200 °C and (b) between 250 and 320 °C, corresponding to loss of water and sulfur dioxide, respectively.

The lattice parameters and crystal structure of calcium dithionate tetrahydrate are: space group = $P6_422$, $a = 12.706$ Å, $c = 39.636$ Å, $V = 627$ Å^3, $Z = 3$. This structure is a superstructure of the strontium salt with doubling of all three axes where the $S_2O_6^{2-}$ anions occupy two sites on either side of a two-fold axis along [110] plus three sites around [001]. The water oxygen atoms occupy three sites around [001]. The Lewis structure is shown in the following diagram where the molecule is bent at the S–S bonds and the Ca^{2+} ion is bonded to the two oxygen ions (Fig. 3.41).

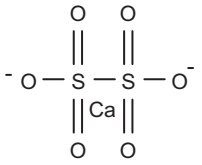

FIGURE 3.41

However, the two SO_3^-—groups are not tetrahedrally bonded in the strict sense of the configuration (which is actually a "strained" type of tetrahedra).

The optical rotatory dispersion (ORD) issue was discovered in 1867 by Pape (which is the main reason why these compounds have received some attention in the Literature). The origin of ORD was attributed to the dithionate grouping in this compound in 1987. Only the calcium and strontium dithionates as the tetrahydrates appear to possess the ORD characteristics. It seems to be absent in the Be, Mg and Ba compounds of a similar nature.

Calcium dithionate tetrahydrate is available commercially in limited quantities.

Calcium tetrathionate, CaS_4O_6, has the molecular weight of grams per mole. It has been prepared by the reaction of the thiosulfate with iodine:

$$2CaS_2O_3 + I_2 \Rightarrow CaS_4O_6 + CaI_2$$

It is advertised for sale with the CAS number 19188-83-1. However, its composition is not specified. There is no current information existing on the properties of this salt and whether it actually exists is not known. According to prior work in the late 1870s, only the trithionate was found. When the reaction with calcium thiosulfate with SO_2 was attempted, the product was identified as the trithionate:

$$4CaS_2O_3 + SO_2 \Rightarrow 2CaS_3O_5 + CaI_2$$

This was reported early in 1877 but has not been confirmed to date. If calcium thiosulfite is reacted with HCl, the thiosulfate (hyposulfite) is not split into calcium sulfite and sulfur but forms the trithionate:

$$5CaS_2O_3 + 6HCl \Rightarrow 2CaS_3O_6 + 3CaCl_2 + 4S + 3H_2O$$

A secondary reaction was said to occur:

$$2CaS_2O_3 + 3SO_2 \Rightarrow 2CaS_3O_6 + S$$

On heating, it was stated that the trithionate decomposes to $CaSO_4$ plus S and SO_2. Nevertheless, the physical properties of the calcium trithionate salt remain unknown. It appears that Ca^{2+} as a cation tends to form only the trithionate compound and not the pentathionate or hexathionates similar to the strontium or barium cations.

In another early source in the literature, it was stated:

> "Trithionate of calcium is generally the most stable polythionate, and often is found among the products of oxidation reduction of thiosulfate. In acid media, trithionate slowly hydrolyzes to sulfuric acid, colloidal sulfur, and sulfur dioxide. In alkaline media, it hydrolyzes to sulfate and thiosulfate. Trithionate is produced by reaction of thiosulfate with oxygen, catalyzed by copper compounds".

Calcium "tetrathionate" is offered for sale under the CAS number of 19188-83-1, and stated to have a molecular weight = 264.3344 g/mol or CaS_2O_6. Calcium tetrathionate is said to be an effective fungicide against powdery mildew.

Strontium Thionates

The "thionite" and "thionate" salts of strontium include:

Strontium dithionite = SrS_2O_4
Strontium dithionate = SrS_2O_6
Strontium tetrathionate = SrS_4O_6

Strontium dithionite, SrS_2O_4, may be prepared by the reaction of strontium chloride with sodium dithonite:

$$SrCl_2 + Na_2S_2O_4 \Rightarrow SrS_2O_4 + 2NaCl$$

Alternatively, it may be prepared by the solid-state reaction of SO_2 gas upon the sulfite:

$$Sr(HSO_3)_2(solid) + SO_2(gas) + heat \Rightarrow SrS_2O_4(solid) + H_2O$$

This reaction could probably be carried out in solution as well. However, the reaction would be dependent upon the pH of the solution and a pH of about 4.5 would produce the compound:

$$SrCl_2 + 2(NH_4)_2SO_3 + SO_2 \Rightarrow SrS_2O_4 + 2NH_4Cl + H_2O$$

The description of the physical and chemical properties of this salt are completely lacking in the scientific and technological literature. Strontium dithionite is mentioned in a few patents as a reducing agent to decolorize certain plastics. The older reference books like Sidgewick or Remy (1933 or 1950) do not list such a compound as being known. It has no CAS number and has no commercial value.

Strontium **dithionate**, SrS_2O_6, has the molecular weight of 297.4538 g/mol. It has been prepared by the following method:

$$NH_3(gas) + SO_2(gas) + H_2O \Rightarrow (NH_4)_2SO_3(liq)$$

$$(NH_4)_2SO_3(liq) + MnO_2(solid) \Rightarrow MnS_2O_6(liq)$$

$$MnS_2O_6(liq) + Sr(OH)_2(solid) \Rightarrow SrS_2O_6(liq) + Mn(OH)_2(solid)$$

In the first reaction, sulfur dioxide gas was passed through a cooled, continuously agitated solution to produce the ammonium compound. The solution was heated to about 40 °C to remove excess sulfur dioxide. In the second reaction, the MnO_2 was allowed to dissolve over a period of 2–5 h and was then diluted. The third reaction served to form the insoluble manganese hydroxide that was removed by filtration and the resulting solution was evaporated at a low temperature to form crystals. On allowing the solution to evaporate at a moderate temperature, prismatic crystals are obtained. The product is a tetrahydrate, $SrS_2O_6 \cdot 4H_2O$ with a molecular weight of 319.8422 g/mol.

Strontium dithionate tetrahydrate crystallizes as a hexagonal structure with $a = 6.3529$ Å and $c = 19.218$ Å, $Z = 3$, and $V = 671.7$ Å^3. The space group assigned, $P6_422$, is indicative of a dextro-rotative crystal. The structure is disordered about the twofold axis along the [110] direction. Disorder arises from the fact that the $S_2O_6^{2-}$ anion occupies two sites on either side of this axis. The dithionate anions are located in symmetry centers and the strontium cations lie in special positions along the twofold axes. Each strontium ion is ten coordinated to four water molecules and six oxygen atoms from six dithionate groups.

It is soluble in water at 22.2 g/100 ml at 16 °C and 64.5 m/100 ml at 100 °C. Its CAS number is 13845-17-5. It occurs as white crystals that decompose at about 145 °C. Its density is 2.373 g/cm^3. It is slightly soluble in alcohol. Dehydration of $SrS_2O_6 \cdot 4\ H_2O$ takes place in two steps. When the hydrate is heated to 90 °C, loss of four molecules of water of hydration occurs. On further heating to 210 °C, it decomposes to $SrSO_4$.

The description of the physical and chemical properties of this salt are sparse in the scientific and technological literature. Strontium dithionite is mentioned in a few patents as a reducing agent. The older reference books like Sidgewick or Remy (1933 or 1950) do not list such a compound as being known.

Strontium dithionate is available commercially in limited quantities.

Strontium tetrathionate, SrS_4O_6, has the molecular weight of 311.87 grams per mole. This salt has been prepared by reaction of strontium thiosulfate with iodine:

$$2SrS_2O_3 + I_2 \Rightarrow SrS_4O_6 + SrI_2$$

The tetrathionate is insoluble in ethanol and addition serves to cause precipitation. If this is done slowly, crystals of the hexahydrate appear. In another method, the chloride is reacted with ammonium tetrathionate:

$$SrCl_2 + (NH_4)_2S_2O_6 \Rightarrow SrS_4O_6 + 2NH_4Cl$$

The tetrathionate can be crystallized from solution by slow evaporation and the addition of alcohol to form the hexahydrate. The crystals of this salt are

prismatic but its lattice parameters have not been published. Presumably, it resembles the structure of the barium homologue and is hexagonal. It is expected that there are four molecules per unit cell and that the sulfur chain of the tetrathionate anion is unbranched and nonplanar. The space group is expected to be C_{2h}^5 – $P2^1/c$.

Orthorhombic and triclinic strontium pentathionate dihydrate, $SrS_5O_6 \cdot 2H_2O$, structures have also been reported. The presence of unbranched and nonplanar sulfur chains has been demonstrated in these compounds. The penta- and hexa-thionate chains contain three and four divalent sulfur atoms, respectfully, together with terminal sulfur atoms to each of which are attached three oxygen atoms. The sulphonate groups, together with the adjacent divalent sulfur atoms, constitute thiosulfate groups, which have the shape of distorted tetrahedrons. The pentathionate compound is thus built of two thiosulfate groups linked by three divalent sulfur atoms. The Lewis structure thus appears as in Fig. 3.42.

The structure of the hexa-thionate salt has not been determined. The structure actually consists of $S(S_2O_3^{2-})_2$ and $S_2(S_2O_3^{2-})_2$ units in these salts.

Strontium tetrathionate is available in small commercial quantities. Its usage in industry has not been established to date.

Barium Thionates

The "thionite" and "thionate" salts of barium include:

Barium dithionite = BaS_2O_4
Barium dithionate = BaS_2O_6
Barium tetrathionate = BaS_4O_6

Barium dithionite, BaS_2O_4, may be prepared by the reaction of barium chloride with sodium dithonite:

$$BaCl_2 + Na_2S_2O_4 \Rightarrow BaS_2O_4 + 2NaCl$$

Alternatively, it may be prepared by the solid-state reaction of SO_2 gas upon the sulfite:

$$Ba(HSO_3)_2(\text{solid}) + SO_2(\text{gas}) + \text{heat} \Rightarrow BaS_2O_4(\text{solid}) + H_2O(\text{gas})$$

This reaction could probably be carried out in solution as well. However, the reaction would be dependent upon the pH of the solution and a pH of about 5.0 would produce the hydrosulfite and then the dithionite:

$$BaCl_2 + 2(NH_4)_2SO_3 + SO_2 \Rightarrow BaS_2O_4 + 2NH_4Cl + H_2O$$

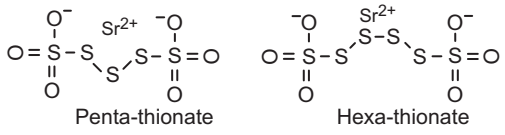

FIGURE 3.42

The description of the physical and chemical properties of this salt are completely lacking in the scientific and technological literature. Barium dithionite is mentioned in a few patents as a reducing agent. The older reference books like Sidgewick or Remy (1933 or 1950) do not list such a compound as being known. It has no CAS number and has no commercial value.

Barium dithionate, BaS_2O_6, has the molecular weight of 297.4538 g/mol. It has been prepared by the following method:

$$NH_3(\text{gas}) + SO_2(\text{gas}) + H_2O \Rightarrow (NH_4)_2SO_3(\text{liq})$$

$$(NH_4)_2SO_3(\text{liq}) + MnO_2(\text{solid}) \Rightarrow MnS_2O_6(\text{liq})$$

$$MnS_2O_6(\text{liq}) + Ba(OH)_2(\text{solid}) \Rightarrow BaS_2O_6(\text{liq}) + Mn(OH)_2(\text{solid})$$

In the first reaction, sulfur dioxide gas was passed through a cooled, continuously agitated solution to produce the ammonium compound. The solution was heated to remove excess sulfur dioxide. In the second reaction, the MnO_2 was allowed to dissolve over a period of 2–5 h and was then diluted. The third reaction served to form the insoluble manganese hydroxide that was removed by filtration and the resulting solution was evaporated at a low temperature to form dihydrate crystals. On allowing the solution to evaporate at a moderate temperature, rhombic crystals are obtained. The product is a dihydrate, $BaS_2O_6 \cdot 2H_2O$. It is soluble in water at 24.4 g/100 ml (18 °C) and 50.2 g/100 ml at 100 °C. Its CAS number is 13845-17-5. It occurs as white crystals that decompose at about 145 °C, its density is 4.54 g/cm^3, its solubility in water is 22.1 g/100 ml and it is slightly soluble in alcohol. When the dihydrate is heated to 90 °C, loss of the two molecules of water of hydration occurs. On further heating, it decomposes to $BaSO_4$:

$$BaS_2O_4 + \text{heat} \Rightarrow BaSO_4 + BaS$$

Barium dithionate dihydrate crystallizes as orthorhombic crystals; $a = 12.482$ Å, $b = 6.660$ Å, $c = 9.195$ Å, $\beta = 111.1°$, $Z = 4$, $V = 710.3$ Å^3. Its density is 3.118 g/cm^3. There are four molecules per unit cell. The space group is C2/c. The dithionate anions are located in symmetry centers and the barium cations lie in special positions along the twofold axes. Each barium ion is ten-coordinated to four water molecules and six oxygen atoms from six dithionate groups. The systematic absences may be summarized as: hkl when $h + k = 2n + 1$; h0l when $l = 2n + 1$ and $h = 2\pi + 1$; 0k0 when $k = 2n + 1$.

The γ-irradiation of crystalline dithionates produces sulfite [SO_3^-] anions. The unpaired electron in the SO_3^- radical can be detected by electron paramagnetic resonance (EPR) means and barium dithionate has been proposed as the basis for a radiation detector. Crystalline barium dithionate dihydrate ($BaS_2O_6 \cdot 2H_2O$) is thought to be a promising material for manufacturing dosimetric

EPR sensors for detection of gamma and beta radiation. For the purposes of EPR dosimetry, barium dithionate powder specimens are used, since it has been shown that a single narrow line of SO_3 radicals results, the intensity of which is proportional to the exposure dose. This has been confirmed in the irradiated powders concerned.

The results of EPR studies dealing with the accumulation of SO_3^- radicals in gamma-irradiated powder specimens have been reported, and the values of some parameters of their EPR spectra were presented; in particular, $g_{powder} = 2.0036$, the EPR line halfwidth $\Delta H_{powder} = 0.55$ mT and the isotropic constant of superfine interaction with the nuclear spin of the sulfur isotope 33S $A_{powder} \approx 11.5$ mT. SO_3^- radicals in natural $BaSO_4$ single crystals were also studied. These crystals have the same orthorhombic symmetry as $BaS_2O_6 \cdot 2H_2O$ crystals do. This work showed that there are several types of paramagnetic centers in this material, and some of them can occupy two magnetically nonequivalent states. But their spectra are described by different EPR parameters. This work aimed at studying, by the method of EPR spectroscopy, the radiation-induced centers in powder specimens of crystalline barium dithionate dihydrate, which emerge under the influence of gamma and UV irradiation, as well as due to the annealing of initial and irradiated specimens, and form the spectrum that is used in EPR dosimetry.

Barium dithionate is available commercially for sale in limited quantities.

Barium tetrathionate, BaS_4O_6, has the molecular weight of grams per mole. Barium tetrathionate has been prepared by reaction of barium thiosulfate with iodine:

$$2BaS_2O_3 + I_2 \Rightarrow BaS_4O_6 + BaI_2$$

The tetrathionate is insoluble in ethanol and addition serves to cause precipitation. If this is done slowly, crystals of the dihydrate appear. This salt was first isolated by Fordos and Gëlis in 1842. In another method, the chloride is reacted with ammonium tetrathionate:

$$BaCl_2 + (NH_4)_2S_2O_6 \Rightarrow BaS_4O_6 + 2NH_4Cl$$

The tetrathionate can be crystallized from solution by slow evaporation and the addition of alcohol. The crystals of this salt are prismatic and monoclinic with cell parameters of $a = 5.17$ Å, $b = 9.46$ Å, $c = 19.07$ Å, $\beta = 96°$. There are four molecules per unit cell. The sulfur chain of the tetrathionate anion is unbranched and nonplanar. Three oxygen atoms are arranged in approximately tetrahedral positions around each of the terminal sulfur atoms, at an average distance of 1.41 Å, the length of the sulfur–sulfur bond is 2.02 Å and that of the terminal S to S bonds is 2.12 Å, the bond angle between the two divalent sulfur atoms is 103° and the dihedral angle is 90°. The space group is $C_{2h}^5 - P2^1/c$.

TABLE 3.16

Crystal structure parameters

Salt	*a*	*b*	*c*	*α*	*β*	*γ*	Space group	*Z*
$BaS(S_2O_3)_2 \cdot 2H_2O$	5.01	10.37	11.54	109°	97°	97°	P1	2
$BaS(S_2O_3)_2 \cdot 2H_2O$	5.01	10.31	21.81		—		Pnma	4
$BaS(S_2O_3)_2 \cdot H_2O$	5.04	10.47	13.61		104°		$P2_1/m$	
$BaS(S_2O_3)_2 \cdot 2H_2O$	9.18	13.27	21.25		—		A2/m	
$BaS(S_2O_3)_2 \cdot 2H_2O$	5.04	10.56	13.81		108°		$2P_1/m$	

Two dimorphs of barium pentathionates exist, orthorhombic and triclinic barium pentathionate dihydrate, $BaS_5O_6 \cdot 2H_2O$ and barium hexathionate, BaS_6O_7 has also been reported. There are five dihydrates, which crystallize in three different space groups, a triclinic, an orthorhombic and a monoclinic one. The following lists the crystal parameters of some of these compounds (Table 3.16).

The presence of unbranched and nonplanar sulfur chains have been demonstrated in these compounds. The penta- and hexa-thionate chains contain three and four divalent sulfur atoms, respectfully, together with terminal sulfur atoms to each of which are attached three oxygen atoms. The sulphonate groups, together with the adjacent divalent sulfur atoms, constitute thiosulfate groups, which have the shape of distorted tetrahedrons. The pentathionate compound is thus built of two thiosulfate groups linked by three divalent sulfur atoms.

The Lewis structures thus appear as thiosulfates in which one of the sulfur atoms is divalent (Fig. 3.43).

The structure of the hexa-thionate salt has not been determined. The structure actually consists of $S(S_2O_3^{2-})_2$ and $S_2(S_2O_3^{2-})_2$ units in these salts.

Barium tetrathionate is available in small commercial quantities. Its usage in industry has not been established to date.

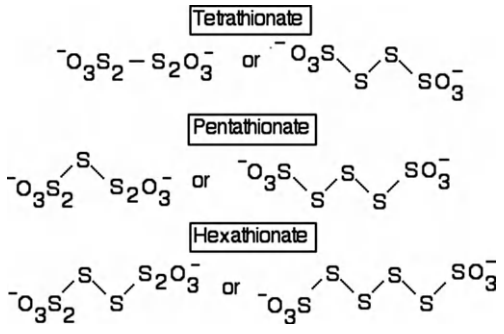

FIGURE 3.43

Radium Thionates

Radium dithionate would have the molecular formula of RaS_2O_4 and the molecular weight of grams per mole. The "thionite" and "thionate" salts of radium would include:

Radium dithionite = RaS_2O_4
Radium dithionate = RaS_2O_6
Radium tetrathionate = RaS_4O_6

Radium dithionite, BaS_2O_4, could be prepared by the reaction of radium chloride with sodium dithonite:

$$RaCl_2 + Na_2S_2O_4 \Rightarrow RaS_2O_4 + 2NaCl$$

Radium tetrathionate could be prepared by reaction of barium thiosulfate with iodine:

$$2RaS_2O_3 + I_2 \Rightarrow RaS_4O_6 + BaI_2$$

However, there is absolutely no industrial or domestic usage for these compounds and it is doubtful that they have been, or ever will be, prepared. They have no commercial value at this time and they have no CAS number.

3.2.8. Alkaline Earth Peroxysulfites and Peroxysulfates

The alkaline earths do not form many peroxy-sulfites or peroxy-sulfates.

Peroxy Acids

The acids involved include:

Oxydisulfuric acid is a chemical compound having the formula $H_2S_2O_5$. In structural terms, it can be written as $HO_3S–SO_2H$. The salts are commonly called "metabisulfites". Essentially, this acid is a "sulfate–sulfite acid". It is related to the "dithionites" except for the addition of an extra oxygen atom to the molecule. The **dithionite** anion, $S_2O_4^{2-}$, is an anion formally derived from the hypothetical compound "dithionous acid", $H_2S_2O_4$.

Although the alkalis such as Na and K form metabisulfites, very few alkaline earths do. Such compounds are commonly used as food preservatives. Metabisulfite compounds have been demonstrated to cause asthma and other allergic reactions in sensitive individuals.

Peroxymonosulfuric acid, also known as persulfuric acid, peroxysulfuric acid, or as **Caro's acid**, has the formula, H_2SO_5, a liquid at room temperature. In this acid, the S(VI) center adopts its characteristic tetrahedral geometry; the connectivity is indicated by the formula HO-O-S(O)$_2$-OH. H_2SO_5 is sometimes confused with $H_2S_2O_8$, known as "peroxydisulfuric acid". The disulfuric acid, which appears to be more widely used as its alkali metal salts, has the structure HO-S(O)$_2$-O-O-S(O)$_2$-OH.

The laboratory scale preparation of Caro's acid involve the combination of chlorosulfuric acid and hydrogen peroxide:

$$H_2O_2 + ClSO_2OH \Rightarrow H_2SO_5 + HCl$$

Large-scale production of Caro's acid is usually done on site, due to its instability. According to the patent by Martin, Caro's acid is produced by reacting >85% sulfuric acid and >50% hydrogen peroxide (also known as "Piranha solution"):

$$H_2O_2 + H_2SO_4 \Rightarrow H_2SO_5 + H_2O$$

H_2SO_5 has been used for a variety of disinfectant and cleaning applications, e.g. swimming pool treatment and denture cleaning. Alkali metal salts of H_2SO_5 show promise for the "pulping" of wood. Caro's acid is a strong oxidizing agent but few alkaline earth compounds have been prepared.

Peroxydisulfuric acid has the formula $H_2S_2O_8$. It is also called Marshall's acid. In structural terms, it can be written as HO_3SOOSO_3H. It is one of a group of sulfur oxoacids. Its salts, commonly known as persulfates, are industrially important but the acid itself is not. Alkali salts are commonly used but most alkaline earth peroxydisulfates remain unknown.

The Lewis structure for these acids is shown in Fig. 3.44.

Alkaline Earth Metabisulfites or Pyrosulfites

Beryllium metabisulfite—this salt is unknown.

Magnesium metabisulfite has the formula MgS_2O_5 and the molecular weight of 168.4342 g/mol. It is mentioned in a few patents as an oxidizing agent for fabric stabilization of dyes and is offered for sale as the tetrahydrate, $MgS_2O_5 \cdot 5H_2O$. These suppliers tend to mislabel the bisulfite, MgS_2O_6, as the metabisulfite.

Calcium metabisulfite has the formula CaS_2O_5 and the molecular weight of 1184.2072 g/mol. It is mentioned in a few patents as a catalyst for synthesis

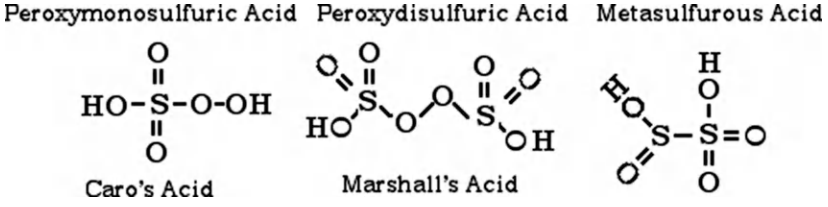

FIGURE 3.44

of certain indoles and for the treatment of coconut meat. It is offered for sale by certain commercial suppliers but it is often confused with calcium hydrosulfite (which is the product of SO_2 gas and calcium hydroxide in water).

The following "pyrosulfites" or "metabisulfites" are unknown:

Beryllium metabisulfite = BeS_2O_5 = Beryllium Pyrosulfite

Strontium Metabisulfite = SrS_2O_5 = Strontium Pyrosulfite

Barium Metabisulfite = BaS_2O_5= Barium Pyrosulfite

Radium Metabisulfite = RaS_2O_5 = Radium Pyrosulfite

Alkaline Earth Peroxymonosulfates

Many of the peroxymonosulfates have never been formed. An example is beryllium peroxymonosulfate.

Magnesium peroxymonosulfate has the molecular formula of $MgSO_5$ and the molecular weight of 136.3682 g/mol. It can be produced by the reaction of magnesium hydroxide, fuming sulfuric acid and hydrogen peroxide:

$$Mg(OH)_2 + H_2O_2 + H_2SO_4 \Rightarrow MgSO_5 + 3H_2O$$

The hexahydrate results upon evaporation and recrystallization of the solution at a low temperature of ~15 °C. This salt is offered for sale as $MgSO_5 \cdot 6H_2O$ and is used as a fumigant and biocide in hospitals. It is a very strong oxidizing agent and care must be taken in handling. This compound provides powerful non-chlorine oxidation for a wide variety of industrial and consumer uses. Its applications may be found in pool and spa shock and disinfection, oral hygiene formulations, polymerization initiator and oxygen-releasing agent in aquiculture.

Strontium peroxymonosulfate would have the molecular formula of $SrSO_5$ and the molecular weight of 152.1412 g/mol. It could be produced by the reaction of calcium hydroxide, fuming sulfuric acid and hydrogen peroxide:

$$Sr(OH)_2 + H_2O_2 + H_2SO_4 \Rightarrow SrSO_5 + 3H_2O$$

Upon evaporation and recrystallization of the solution at a low temperature of ~15 °C, it is expected that a hexahydrate would result. However, the scientific literature is completely devoid of mention of the preparation of such a salt and no physical or chemical properties have been documented. It is not known whether this salt or others like it could be prepared or are stable. Since both Mg and Ba form stable compounds, the mystery of why this salt has not been described remains unknown. No interest has been shown by industry or academia to detail the properties of this salt.

Barium peroxy-monosulfate has the molecular formula of $BaSO_5$ and the molecular weight of 249.3932 g/mol. It can be produced by the reaction of barium hydroxide, fuming sulfuric acid and hydrogen peroxide:

$$Ba(OH)_2 + H_2O_2 + H_2SO_4 \Rightarrow BaSO_5 + 3H_2O$$

The question of the existence of hydrates remains unknown since this salt is soluble, is very toxic and is used as a solution. It is referred to in a few patents that describe methods of producing pyrrolidine derivatives. The Lewis structure would be shown in Fig. 3.45.

This salt is sometimes mistaken for the persulfate which has the Lewis formula shown in Fig. 3.46.

These groups are aligned in a cubic array to form the structure shown in Fig. 3.47.

The following peroxysulfates remain unknown:

Beryllium peroxysulfate = $BeSO_5$
Calcium peroxysulfate = $CaSO_5$
Strontium peroxysulfate = $SrSO_5$
Radium peroxysulfate = $RaSO_5$

Alkaline Earth Peroxydisulfate Salts

Beryllium peroxydisulfate remains unknown.

Magnesium peroxydisulfate has the molecular formula of MgS_2O_8 and the molecular weight of

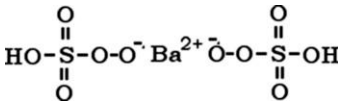

FIGURE 3.45

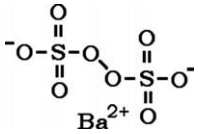

FIGURE 3.46

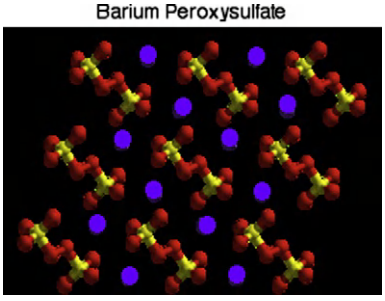

FIGURE 3.47

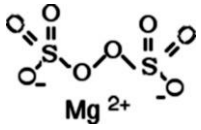

FIGURE 3.48

216.4322 g/mol. It can be prepared by the reaction of barium peroxydisulfate with magnesium sulfate in solution:

$$BaS_2O_8(aq) + MgSO_4(aq) \Rightarrow BaSO_4(solid) + MgS_2O_8(aq)$$

The barium sulfate precipitate is removed by filtration and the solution is evaporated at a low temperature of about 15–20 °C to produce the hexahydrate, $MgS_2O_8 \cdot 6H_2O$. The Lewis structure is shown in Fig. 3.48.

It has no CAS number and is not offered for sale by any commercial manufacturer.

STRONTIUM PEROXODISULFATE

Strontium peroxodisulfate has the molecular formula of SrS_2O_8 and a molecular weight of 279.7472 g/mol. It has been synthesized by the reaction of solid $Sr(OH)_2$, taken in 30% excess, with an aqueous solution of $(NH_4)_2S_2O_8$:

$$Sr(OH)_2 + (NH_4)_2S_2O_8 \Rightarrow SrS_2O_8 + 2NH_4OH$$

This solution is then evaporated at low temperature to form crystals of the tetrahydrate. Strontium peroxydisulfate has been used to etch copper circuits in the manufacture of integrated circuits for computers and the like. However, it is only mentioned in patents and there are no papers in the scientific literature describing its physical properties.

It is not offered for sale nor does it have a CAS number.

BARIUM PEROXODISULFATE

Barium peroxodisulfate has the molecular formula of BaS_2O_8 and a molecular weight of 329.4572 g/mol. It has been synthesized by the reaction of solid $Ba(OH)_2$, taken in 30% excess, with an aqueous solution of $(NH_4)_2S_2O_8$:

$$Ba(OH)_2 + (NH_4)_2S_2O_8 \Rightarrow BaS_2O_8 + 2\,NH_4OH$$

This solution is then evaporated at low temperature to form crystals of the tetrahydrate.

Barium peroxydisulfate has been used to etch copper circuits in the manufacture of integrated circuits for computers and the like. However, it is only mentioned in patents and there are no papers in the scientific literature describing its physical properties.

Barium peroxydisulfate, BaS_2O_8, in sharp contrast with the sulfate, is soluble in water. Among the uses of this compound is the saponification of fats and of soap, the oxidation of some dyestuffs and the promotion of certain polymerization processes, especially in the synthetic rubber industry. It is offered for sale by several suppliers but does not have a CAS number.

The following compounds remain unknown:

Beryllium peroxydisulfate = BeS_2O_8
Calcium peroxydisulfate = CaS_2O_8
Radium peroxydisulfate = RaS_2O_8

They are not offered for sale nor do they have a listed commercial supplier or CAS number.

3.3. ALKALINE EARTH SELENIDES AND OXY-SELENIUM COMPOUNDS

The seleno-oxo compounds of the alkaline earths include the compositional states of Se^{2-}, SeO_3^{2-} and SeO_4^{2-}, i.e. the selenides, selenites and the selenates, respectively. Selenium occurs in several valence states: −2 (hydrogen selenide and selenides), 0 (elemental selenium), +4 (selenium dioxide, selenious acid and selenites) and +6 (selenic acid and selenates).

Selenides are chemical compounds in which the Se atom has the valence state (oxidation state) of –2, similar to that of sulfur in sulfides. The chemistry of the selenides parallels that of the sulfides. Similar to sulfide, the selenide ion, Se^{2-}, is prevalent only in very basic conditions. In neutral conditions, hydrogen selenide anion, HSe^-, is most common. Under acid conditions, hydrogen selenide, H_2Se, is formed. It is a colorless, flammable gas under standard conditions. It is the most toxic selenium compound known with an exposure limit of 0.3 ppm over an 8-h period. This compound has the very irritating smell of decayed "horseradish". Its CAS number is 7783-07-5 and its molecular weight is 80.9832 g/mol. Its density is 3.553 g/cm^3. It has a melting point of –55.7 °C (207.4 K) and a boiling point of 41.2 °C (232 K).

H_2Se adopts a "bent" structure with a H–Se–H bond angle of 91°. Consistent with this structure, three infrared active vibrational bands are observed at 2358, 2345, and 1034/cm (Fig. 3.49).

The properties of H_2S and H_2Se are similar, although the selenide is more acidic with $pK_a = 3.89$, and the second $pK_a = 11.0$ at 25 °C. Reflecting its acidity, H_2Se is soluble in water.

H_2Se is usually prepared by the action of water on Al_2Se_3, which produces aluminum hydroxide. A related reaction involves the acid hydrolysis of FeSe.

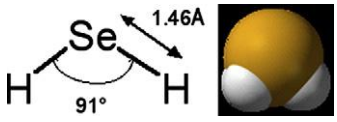

FIGURE 3.49

$$Al_2Se_3 + 6H_2O \Rightarrow 2Al(OH)_3 + 3H_2Se$$

According to the Sonoda method, H_2Se is generated from the reaction of H_2O and CO on Se in the presence of triethyl-amine. H_2Se can also be synthesized by the direct reaction of H_2 with elemental Se at temperatures greater than 300 °C. Elemental selenium can be recovered from H_2Se through a reaction with aqueous sulfur dioxide (SO_2):

$$2H_2Se + SO_2 \Rightarrow 2H_2O + Se + S$$

Selenous acid (also known as **selenious acid**) has the formula H_2SeO_3, written perhaps more descriptively as $(HO)_2SeO$. Selenous acid is the principal oxoacid of selenium when the Se atom is in the +4 oxidation state.

Selenous acid is analogous to sulfurous acid, but it is more readily isolated. Selenous acid is easily formed upon the addition of selenium dioxide gas to water. As a crystalline solid, the compound appears as pyramidal molecules that are interconnected with hydrogen bonds. In solution, it is a diprotic acid:

$$H_2SeO_3 \Rightarrow H^+ + HSeO_3^- \ (pK_a = 2.62)$$
$$\Rightarrow H^+ + SeO_3^{2-} \ (pK_a = 8.32)$$

It is moderately oxidizing in nature, but kinetically slow to react in aqueous solutions. In 1 M H^+, the following reaction occurs:

$$H_2SeO_3 + 4H^+ + 4e^- \Rightarrow Se + 3H_2O \ E\ominus = +0.74 \text{ V}$$

In 1 M OH^-, the following reaction occurs:

$$SeO_3^{2-} + 4e^- + 3\ H_2O \Rightarrow Se + 6OH \ (E\ominus = -0.37 \text{ V})$$

Thus, instead of selenites as a product, one sometimes obtains elemental selenium. Selenious acid has been used in organic synthesis for the synthesis of 1,2-diketones (e.g. glyoxal).

Selenic acid has the formula H_2SeO_4 where Se is in the +6 oxidation state. Oxoacid is more descriptively written as $(HO)_2SeO_2$, which emphasizes that the Se atom is attached to four oxygen atoms. Thus, the selenium center is tetrahedral. Selenic acid has the molecular weight of 144.9734 g/mol and the density of 2.95 g/cm^3. Its CAS number is 7783-08-6. It is a colorless crystal with a melting point of 58 °C and a boiling point of 261 °C (533 K) where it decomposes. Its solubility in water is 130 g/100 ml at 30 °C. The crystals have a refractive index of $\eta_d = 1.5174$.

Selenic acid can be prepared by oxidation of selenium dioxide with hydrogen peroxide:

$$SeO_2 + H_2O_2 \Rightarrow H_2SeO_4$$

To obtain the anhydrous acid as a crystalline solid, the resulting solution is evaporated at temperatures below 140 °C (413 K; 284 F) in a vacuum.

Like H_2SO_4, selenic acid is a strong acid that is hygroscopic and extremely soluble in water. Concentrated solutions are viscous. Crystalline mono- and di-hydrates are known. Unlike sulfuric acid, H_2SeO_4 is a sufficiently strong oxidizer to liberate chlorine from chloride ions, while being reduced to H_2SeO_3 (selenium[IV] acid). Selenic acid reacts with barium salts to precipitate $BaSeO_4$, analogous to the sulfate. Calcium selenate is more soluble than the sulfate.

Treatment of selenic acid with fluorosulfuric acid gives the dioxydifluoride (whose BP = −8.4 °C):

$$H_2SeO_4 + 2HO_3SF \Rightarrow SeO_2F_2 + 2H_2SO_4$$

Hot, concentrated selenic acid is capable of dissolving gold, forming a reddish-yellow solution of gold(III) selenate.

3.3.1. Alkaline Earth Selenides

Beryllium Selenide

Beryllium selenide has the molecular formula of BeSe and the molecular weight of 87.9722 g/mol. Its CAS number is 12232-25-6. The literature concerning BeSe is very sparse and the physical constants such as melting point have not been published. It can be prepared by reacting the elements at about 650 °C in an inert atmosphere:

$$Be + Se \Rightarrow BeSe$$

Beryllium selenide crystallizes in the zincblende unit cell with a lattice parameter of 5.1521 Å. Space group = F43m-T_d^2. It is not very stable in air and tends to hydrolyze with moisture to form H_2Se gas (which is toxic to humans). Because of this instability, BeSe has not been employed by itself as a semiconductor even though its band gap is classified as wide. A three-dimensional structure is shown in Fig. 3.50.

Interest in BeSe originates from the fact that formation of ternary BeZnSe or BeMgZnSe compositions allows the formation of deposited layers that can be matched to silicon substrates.

They can also be used to form a blue-green emitting ZnSe-based laser diode grown on GaSe.

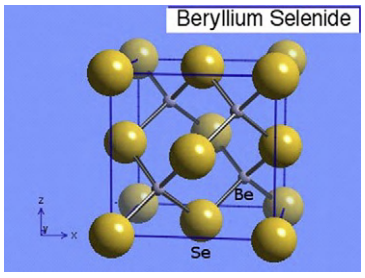

FIGURE 3.50

BeSe is an indirect band gap material with the highest edge at Γ, the top of the valence band, and X, the excitation edge at the bottom of the band gap, making the direct band gap 5.6 eV (221 nm) at 20 °C and the indirect band gap at $E_g \sim 3.5$ eV (354 nm) for the Γ ⇒ X transition.

Beryllium selenide telluride $BeSe_{0.41}Te_{0.59}$ is a zinc-blende semiconductor lattice matched to silicon with indirect band gap $E_G \sim 3.5$ eV. The high-stacking fault energy, thermal stability, and chemical compatibility of BeSeTe allow good crystalline quality epitaxial growth on silicon. The silicon substrates are vicinal (100), offcut 4° toward (011), annealed to form a double-stepped surface and arsenic passivated. Si regrowth on BeSeTe is done by solid-phase epitaxy. Deposition of ~30 Å amorphous Si at low substrate temperatures near room temperature, followed by crystallization anneal to 660 °C, yields a smooth double-stepped silicon surface as shown by the streaky single-domain pattern.

BeSe is available commercially in target form for sputtering in small quantities.

Magnesium Selenide

Magnesium selenide has the molecular formula of MgSe and the molecular weight of 103.2652 g/mol. It is a stable, light gray to brown crystalline powder with a refractive index, $\eta_D = 2.44$. Its density is 4.21 g/cm^3 and it decomposes in water:

$$MgSe + 2H_2O \Rightarrow Mg(OH)_2 + H_2Se$$

Thus, it cannot be prepared by bubbling H_2Se gas through a soluble Mg^{2+} aqueous solution. MgSe can be prepared by a variety of other methods. Among the easiest are the reaction of magnesium oxide and selenium. Alternately, the two elements can be reacted together to form the selenide:

$$MgO(solid) + Se(solid) + heat \Rightarrow MgSe(solid) + SeO_2(gas)$$

$$Mg(solid) + Se(solid) + heat \Rightarrow MgSe(solid)$$

In the first reaction, Se melts at 225 °C while the MgO is stable. Selenium dioxide sublimes at 320 °C. The reaction is carried out in an inert atmosphere at about 550 °C. If a tube furnace is used, crystals of SeO_2 appear at the cool end of the tube. In the second reaction, an inert atmosphere is mandatory and the reaction temperature is also 550 °C (which is below the melting point of Mg metal).

Magnesium selenide has the CAS number of 1313-04-8. It is not stable in air and reacts with moisture to form H_2Se, a foul-smelling and toxic gas:

$$MgSe + H_2O \Rightarrow Mg(OH)_2 + H_2Se$$

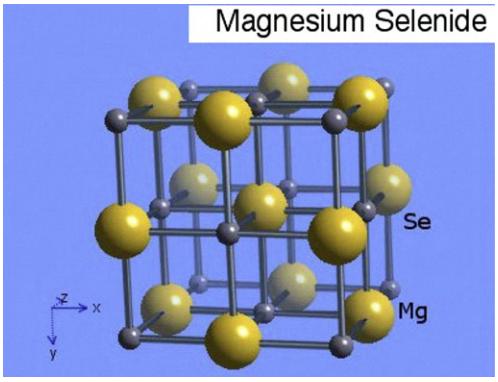

FIGURE 3.51

MgSe has the rock salt structure with $a = 5.462$ Å and a dielectric constant of 3.8 and a band gap of 4.05 eV. It is a wide-band semiconductor but is not very stable by itself. Other data concerning this salt, such as thermodynamics constants, are not available. A three-dimensional structure is shown in Fig. 3.51.

MgSe has the rock salt structure. It has been shown that, for MgSe, a transition under pressure occurs from the rock salt to the iron silicide structure at about 107 GPa. Industrial and academic interest in MgSe stems from the fact that the realization of a high p-type conductivity can be significantly improved by alloying ZnTe with ZnSe. Moreover, the ZnSe–ZnTe alloys, particularly alloy compositions near $ZnSe_{0.7}Te_{0.3}$ have excellent *p*-type and *n*-type doping properties without MgSe but with a band gap lower than that of ZnSe.

The addition of MgSe to the ZnSe–ZnTe alloy makes it possible to realize band gaps equal to and larger than that of ZnSe, while maintaining the superior n-type and p-type doping properties of the solid-state compound.

The vertical Bridgman method[1] was used to obtain crystals of $Zn_{1-x}Mg_xSe$ solid solutions ($0.03 \leq x \leq 0.55$). The composition of the samples was determined by means of electron probe microanalysis (EPMA). The methods of optical microscopy and X-ray analysis were used to investigate the structure of the crystal and to determine their lattice parameters. Investigated were the microhardness and microbrittleness of the grown crystals, as well as their polarizational, optical, photoelectric and dielectric properties depending on Mg concentration. The obtained crystals were found to possess anisotropy of physical properties. The largest anisotropy of their mechanical, polarizational and optical properties is observed in the crystals containing 5–6 atomic percentage of Mg. The samples with such a concentration of Mg are believed to be applicable as a base for making thermostable

[1]See: "Luminescence and the Solid State–2nd Ed." by R C Ropp, p298, Elsevier, (2004) – ISBN 0 444 51661 1.

multifunctional IR optical elements that can operate within a wide IR spectral region.

Further studies have established the temperature dependency of the refractive index of wide-gap $Zn_{1-x}Mg_xSe$ ($x = 0.5$) single crystals. It was established that, in the temperature range 300–530 K, the value of dn/dT for such crystals grown by the vertical Bridgman method is 9.31×10^{-5} at $x = 0.63$ m and 5.29×10^{-5} at $x = 10.6$ m. The obtained values of the coefficients dn/dT for hexagonal Zn_{1-x} Mg_xSe single crystals are close to the corresponding values for cubic ZnSe single crystals and are much lower than those for hexagonal CdS. Examples of practical application of single crystals of the ZnMgSe substitutional solid solution as a thermostable material for polarization optical elements in the IR range have been presented.

The XRD patterns for three bulk $Zn_{1-x}Mg_xSe$ crystals have been reported. The data were obtained with the help of an automated Bragg–Brentano diffractometer using Ni-filtered Cu *K* radiation. One of the samples is of the sphalerite structure type, and it has the magnesium content slightly below the sphalerite–wurtzite phase transition. The two remaining ones are of the wurtzite type with low and high magnesium content. The lattice constant for the sphalerite $Zn_{0.86}Mg_{0.14}Se$ is $a_0 = 5.701$ Å. For the wurtzite alloys, the lattice constants are $a_0 = 4.0540$ Å, $c_0 = 6.6270$ Å (for $Zn_{0.72}Mg_{0.28}Se$), $a_0 = 4.1195$ Å, $c_0 = 6.6941$ Å (for $Zn_{0.37}Mg_{0.63}Se$).

MgSe is available commercially as a sputtering or plasma targets for preparing thin-layer electronic structures for diodes, solid-state lasers and the like. MgSe has been assigned a CAS number of 1313-04-8.

Calcium Selenide

Calcium selenide has the molecular formula of CaSe and the molecular weight of 119.0452 g/mol. Its CAS number is 1305-84-6. It is a white to brown cubic crystal with a melting point of 1408 °C (where it decomposes, in air, to CaO and SeO_2). Its density is 3.81 g/cm^3 and it is unstable in air or moisture. Its refractive index is 2.274. Because of its instability in the presence of water, it cannot be prepared in an aqueous solution. Its structure is shown in Fig. 3.52.

CaSe can be prepared by the reaction of calcium oxide and selenium:

$$CaO(solid) + Se(solid) + heat \Rightarrow CaSe(solid) + SeO_2(gas)$$

Alternately, the two elements can be reacted together to form the selenide:

$$Ca(solid) + Se(solid) + heat \Rightarrow CaSe(solid)$$

In the first reaction, Se melts at 225 °C while the CaO is stable. Selenium dioxide sublimes at 320 °C. The reaction is carried out in an inert atmosphere at about 550 °C. If a tube furnace is used, crystals of SeO_2 appear at the cool end of the tube. In the second reaction, an inert atmosphere is mandatory and the reaction temperature is also 550 °C (which is below the melting point of Ca metal). However, the reaction does not go to completion and only about 50% of theoretical CaSe is formed. To achieve close to 100% reaction, the selanate can be reduced to form CaSe:

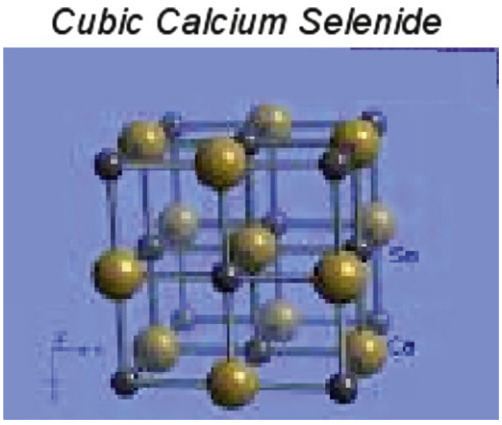

FIGURE 3.52

$$CaSeO_4 + H_2 + heat \Rightarrow CaSe + H_2O$$

The major usage of CaSe has been as a phosphor. Lenard and Pauli first described this phosphor, CaSe:Sm^{3+}, as an infrared stimulable material about 100 years ago. CaSe:Ce^{3+} is a blue-emitting (~4500 Å) phosphor. However, due to its instability, CaSe was never used in the lighting industry. More recently, it has been combined with the strontium compound to form phosphors.

$(Ca_{1-x},Sr_x)Se:Eu^{2+}$, which is an efficient red-emitting phosphor, was prepared by solid-state reaction at high temperatures in CO atmosphere. These phosphors can be excited efficiently by visible light from 430 to 490 nm and emit red light with broadband excitation from blue LED chips. If the Sr/Ca ratio is decreased, the lattice parameters get smaller, and the emission wavelength shows a red shift. A suitable wavelength can be obtained by adjusting the Sr/Ca ratio. Because of the commercial afterglow exhibited by calcium sulfide phosphor, these synthesized phosphors have higher emission efficiency and are a good choice for manufacturing white LED lamps. These phosphors are promising candidates for emitting red light for LEDs. When mixed with a green phosphor on a InGaN-based blue chip, the as-synthesized red phosphors generated white light for LEDs.

Additionally, a phosphorescent (long glow time) phosphor comprising a crystalline matrix including sulfur or a combination of sulfur and selenium, one or more metals including Sr or combination of Sr and Ca, and first and second activators consisting essentially of Eu and Cu, has been prepared. Its general composition

is $Ca_{1-x}Sr_xSe:Eu^{2+}:Cu^{+}$. This phosphor is capable of storing energy upon exposure of the phosphor to visible or ultraviolet exciting light and emitting said stored energy in the form of visible light after cessation of said exposure of said phosphor to said exciting visible light.

In contrast to MgSe, CaSe is a direct band gap semiconductor. However, under pressure, CaSe shows a progressive transition from a direct to an indirect gap semiconductor at a pressure of about 2 GPa, in the rocksalt phase. An insulator–conductor change was also observed at 70 GPa, in the zinc-blende phase. The structure is identical to that of MgSe except for the lattice dimensions.

CaSe is available commercially in both high purity and chemical grades.

Strontium Selenide

Strontium selenide has the molecular formula of SrSe and the molecular weight of 166.5852 g/mol. It is a white cubic crystal whose CAS number is 1315-07-7. Its melting point is 1605 °C and its density is 4.54 g/cm^3. It reacts with water and so cannot be prepared by an aqueous precipitation method. It can be prepared by the reaction of the oxide with Se metal:

$$2SrO + Se + Heat \Rightarrow SrSe + SeO_2$$

It can also be prepared by reducing the selenate with hydrogen gas:

$$SrSeO_4 + 4H_2 + heat \Rightarrow SrSe + 4H_2O$$

Strontium selenide and barium selenide both have a simple cubic structure, with cube edges equal to 3.117 Å and 3.308 Å, respectively. In the case of SrSe, the ions at the corners are Sr^{++} and Se^{--}, and the calculated density is 4.53 (Fig. 3.53).

The major usage of SrSe has been as an infrared stimulable phosphor. Photoluminescent materials useful for detection of infrared light are prepared using a base material, such as SrSe. Up to three dopants, Sm^{3+}, cerium, Ce^{3+} and Eu^{2+} compounds are used for the purpose of providing electron traps. The base material can be a combination of alkaline earth metal selenides such as strontium selenide, calcium selenide, or a mixture of these. Luminescence is a long known phenomenon of nature reaching back very far in history. Recorded observations reach back to the last century. Seeback and Becquerel observed momentary visible afterglow in certain materials. In 1889, Klatt and Lenard also observed some effects with infrared. During this time period, words like "phosphor" and "luminescence" appeared. In 1904, Dahms distinguished between "stimulation" and "quenching"; meaning inducing or stopping afterglow. Much of the later work is associated with Lenard, who received the Nobel Prize in 1905 in physics for cathode ray emission. He studied different phosphors until at least 1918. Later work can be found by Urbach in 1926 through 1934. These early scientists basically observed very small luminescent effects.

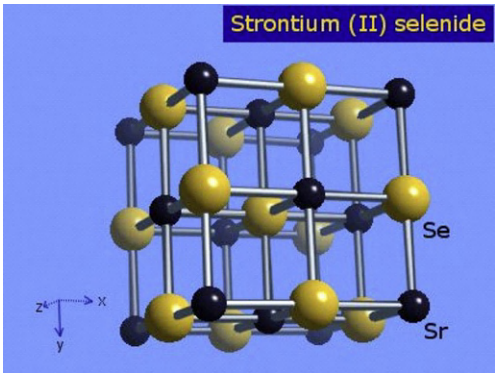

FIGURE 3.53

Phosphors can be categorized in accordance with their behavior as fluorescent, phosphorescent or stimulable. As used in this disclosure, such categories should be understood as based upon the predominant behavior of the phosphor at about room temperature, i.e at about 20 °C.

- A "stimulable" phosphor is one that, at room temperature, stores energy absorbed upon exposure to excitation by electromagnetic radiation and releases the predominant portion of the stored energy upon exposure to stimulating electromagnetic radiation.
- A phosphorescent phosphor at room temperature will store absorbed energy for an appreciable time but will release the predominant portion of the stored energy spontaneously.
- A fluorescent phosphor will release the predominant portion of the absorbed energy as emission radiant energy substantially simultaneously with exposure to the exciting radiant energy.

Typical IR-stimulable phosphors include:

$$SrSe:Sm^{3+}:Eu^{2+}$$

$$SrSe:Bi^{3+}:Eu^{2+}$$

This material will absorb and store energy upon exposure to ultraviolet or blue visible exciting radiation and will emit the stored energy as orange visible light upon stimulation by infrared radiation. One method of preparing such phosphors is:

STRONTIUM SELENIDE–SAMARIUM–EUROPIUM PHOSPHOR

To 3 gram of pure strontium chloride, solutions of samarium(III) and europium(III) chlorides are added

to give 0.5 mg of europium ion and 1.2 mg of samarium ion per gram of strontium chloride. The water is evaporated and the mixture dried at 200 °C. Twenty-five grams of strontium selenide and 2.5 g of the strontium chloride containing the activators are ground together in a porcelain mortar in a dry box. The mixture is heated in a platinum boat for 56 h at 1050 °C in a stream of purified nitrogen and cooled in the same nitrogen stream. Its excitation characteristics are the same as those of the corresponding sulfide phosphor, but the emission color is yellowish green.

The preferred phosphorescent phosphors have absorption and emission spectra similar to those of the IR-stimulable phosphors referred to above. Thus, the absorption spectrum typically extends from about 220 nm to about 540 nm, with peaks at about 300–350 nm and about 400–450 nm. The emission spectrum typically is between about 500 to about 700 nm, most preferably about 510 to 630 nm, with an emission peak at about 550 to about 600 nm, most preferably at about 560–570 nm. Eu and Cu together form an activator system for incorporation into an activated SrSe or (Sr,Ca)Se phosphor to provide phosphorescent behavior. This activator system is especially useful in phosphors wherein the base matrix incorporates sulfur and selenium, and particularly those in which the alkaline earth component of the base matrix is strontium or a combination of strontium and calcium, (Sr,Ca)(Se,S):Eu^{2+}:Cu^{+}.

Strontium selenide is available commercially from several suppliers.

Barium Selenide

Barium selenide has the molecular formula of BaSe and the molecular weight of 216.2956 g/mol. Its CAS number is 1304-39-8. It is a white crystalline powder having a melting point of 1782 °C. Its density is 5.02 g/cm^3. It reacts with water so that an aqueous method of precipitation cannot be used to prepare this compound. Barium selenide is very moisture sensitive, and must be handled under inert conditions. It can be prepared by reaction of the oxide or carbonate with Se, or by the reduction of the selenate with hydrogen gas:

$$2BaCO_3 + 5Se + Heat \Rightarrow 2BaSe + 3SeO_2 + CO_2$$

$$BaSeO_4 + 4H_2 \Rightarrow BaSe + 4H_2O$$

Strontium selenide and barium selenide both have a simple cubic structure, with cube edges equal to 3.117 Å and 3.308 Å, respectively.

In contrast to the other alkaline earth selenides, barium forms at least three other selenide compounds shown in Table 3.17.

TABLE 3.17

Compound	Symbol	Space group	Structure type
BaSe	cF8	Fm3m	NaCl-cubic
Ba_2Se_3	—	—	Unknown
$BaSe_2$	mC12	C2/c	ThC_2—monoclinic
$BaSe_3$	hP3	$P3_121$	Tetragonal

The last three compounds form by peritetic reactions at 930 °C, 840 °C and 760 °C, respectively. BaSe is formed at 712 °C. These reactions occur if an excess of Se is present. Ba metal melts at 727 °C while Se melts at 223 °C. Thus, the reactions take place in a selenium melt and form at the indicated temperatures shown in the following phase diagram (Fig. 3.54).

Barium selenide has been used to construct a photocell that has been used extensively to measure the solar irradiance of the Sun at various points on the globe. It is used because other photocell elements like selenium tend to decline in output and saturate under the intense radiance of the Sun. BaSe remains quasi-linear and can be used to measure intensity from 2000 Å to 7200 Å using a double monochrometer as a spectrum analyzer. As a portable unit, it uses narrowband (20–50 Å halfwidth) interference glass filters in 14 steps as a spectrum analyzer over the range 3100 Å to 16,300 Å, but the recording is manual. The field of view is $<3°$ of the solar irradiance over the face of the Sun.

BaSe is available commercially as a sputtering target or in limited quantities as a powder.

Radium Selenide

Radium selenide has the molecular formula of RaSe and the molecular weight of 304.984985 g/mol. It has the CAS number of 23320-14-1. It reacts with water so that an aqueous method of precipitation cannot be used to prepare this compound. Radium selenide is very moisture sensitive, and must be handled under inert conditions. It can be prepared by reaction of the oxide or carbonate with Se, or by the reduction of the selenate with hydrogen gas:

$$2RaO + 3Se \Rightarrow 2RaSe + SeO_2$$

$$2RaCO_3 + 5Se + Heat \Rightarrow 2RaSe + 3SeO_2 + CO_2$$

$$RaSeO_4 + 4H_2 \Rightarrow RaSe + 4H_2O$$

Radium selenide is expected to have a simple cubic structure but the crystal lattice parameters have never been published.

RaSe has been used in the past (1920s–1930s) in the treatment of certain types of cancer, primarily mammography where it was injected directly into tissue. It is no longer used in the U.S. but is employed in some European countries. RaSe is available commercially in selected dosages and quantities.

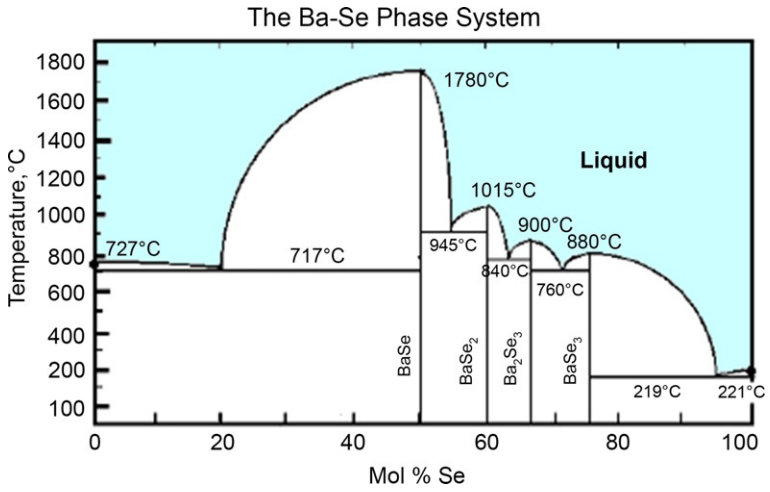

FIGURE 3.54

3.3.2. Alkaline Earth Selenites

A number of selenites are known.

Beryllium Selenite

Beryllium selenite has the molecular formula of $BeSeO_3$ and the molecular weight of 135.969 grams per mole. It can be prepared by adding sodium selenite to a solution of beryllium chloride:

$$BeCl_2(aq) + Na_2SeO_3(aq) \Rightarrow (BeOH)_2SeO_3 \cdot 2H_2O(solid)$$

It can also be prepared by treating a solution of beryllium chloride with selenous acid and adding sodium carbonate to start precipitation. By heating the dihydrate to 100 °C, one obtains the monohydrate, $(BeOH)_2SeO_3 \cdot H_2O$.

The monohydrate and dihydrate of **beryllium selenite** have not found usage in industry and they have no CAS number. These compounds are not commercially available.

Magnesium Selenite

Magnesium selenite has the molecular formula of $MgSeO_3$ and the molecular weight of 151.2658 g/mol. Its melting point is 557 °C. Its CAS number is 15593-61-0. It is relatively insoluble in water at 0.05454 g/100 ml. However, the most common form is the hexahydrate obtained by adding sodium selenite to a solution of magnesium chloride:

$$MgCl_2(aq) + Na_2SeO_3(aq) \Rightarrow MgSeO_3 \cdot 6H_2O(solid)$$

It can also be prepared by treating a solution of magnesium chloride with selenous acid and adding sodium carbonate to start precipitation. The hexahydrate is a colorless crystal with a density of 2.09 g/cm^3 that is insoluble in water. It is soluble in dilute acids. It is orthorhombic in crystal structure and when heated in a sealed tube to 150 °C forms monoclinic prisms of the dihydrate, when heated to 100 °C in air, it loses 5.0 mol of water to form the monohydrate. The monohydrate then loses the last water of hydration around 190 °C to form the anhydrate.

The dihydrate has been the subject of further investigation. Hydrothermally prepared $MgSeO_3 \cdot 2H_2O$ consists of pairs of edge-sharing MgO_6 (4O, $2H_2O$) octahedra [d_{av}(Mg–O) = 2.095 Å]. These are linked by pyramidal SeO_3 units [d_{av}(Se–O) = 1.697 Å] and hydrogen bonds forming a three-dimensional network (Fig. 3.55).

A 7.5 hydrate has also been discovered. The crystal structure of magnesium selenite as the 7.5-hydrate, $Mg(SeO_3) \cdot 7.5H_2O$ (space group = $P6_3/mmc$), is characterized by two crystallographically distinct $[Mg(H_2O)_6]^{2+}$ octahedra, one of which is disordered over two different orientations. The selenite groups and water molecules (with partially disordered H atoms) bridge the octahedra via hydrogen bonds. All the atoms are located on special positions, except for one water molecule (Fig. 3.56).

The selenites, in general, have several versatile and practical applications. The Mg and Ca salts are used as

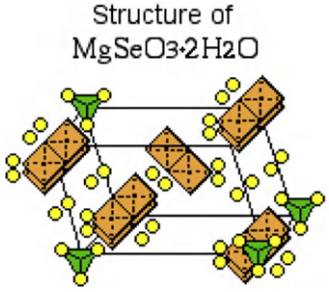

FIGURE 3.55

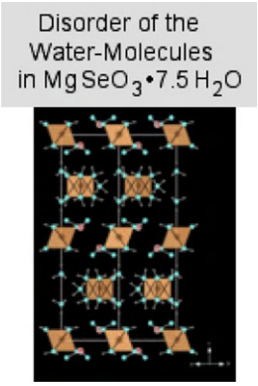

FIGURE 3.56

microfertilizers and repellants in agriculture. They are also used as catalysts in organic synthesis and they are precursors for the preparation of pure selenides of stoichiometric proportion. They are also important intermediate products in the production and purification of selenium metal itself.

$MgSeO_3$ is available commercially from a number of suppliers.

Calcium Selenite

Calcium selenite has the molecular formula of $CaSeO_3$ and the molecular weight of 167.0410 g/mol. It can be prepared by the addition of sodium selenite to a solution of magnesium chloride:

$$CaCl_2(aq) + Na_2SeO_3(aq) \Rightarrow CaSeO_3 \cdot H_2O(solid)$$

It can also be prepared by treating a solution of calcium chloride with selenous acid and adding sodium carbonate to start precipitation. The monohydrate is a colorless crystal with a density of 2.09 g/cm^3 that is insoluble in water. The K_{sp} is $1.2 \times 10^{-7.27}$. It is soluble in dilute acids. A dihydrate has also been observed whose molecular weight is 203.0669 g/mol. The monohydrate has a molecular weight of 185.0569 g/mol and is a monoclinic crystal with $a = 7.622$ Å, $b = 6.745$ Å, $c = 7.922$ Å, $\beta = 108.46°$, $V = 386.4$ Å^3, $Z = 4$ with a density of 3.18 g/cm^3. The polyhedron around the calcium atoms is pentagonal bipyramidal and the selenite group forms a trigonal pyramid with Se and O atoms at the apices. These pyramids form layers parallel to the *bc* plane which are connected by hydrogen bonds involving crystal water. The selenite group acts as a bidentate ligand.

The chemistry of the system CaO–SeO_2–H_2O has been investigated at 23 and 80 °C. The existence of four major phases in this system:

$$CaSeO_3 \cdot H_2O$$

$$Ca(HSeO_3) \cdot 2H_2O$$

$$Ca_2(SeO_3)(Se_2O_5)$$

$$Ca_2(HSeO_3)_2 \quad (5)$$

These have been confirmed, and the equilibria among them determined. At 23 °C, $CaSeO_3 \cdot H_2O$ and $Ca(HSeO_3) \cdot 2H_2O$ are the stable calcium selenites. $CaSeO_3 \cdot H_2O$ exists over the pH range 12.5–3.7, making it the most important phase for natural systems as well as most technological applications. $Ca(HSeO_3) \cdot 2H_2O$ is the more acidic phase; it exists over the pH range 3.7–0.4. Incongruent dissolution of $Ca(HSeO_3) \cdot 2H_2O$ forms $CaSeO_3 \cdot H_2O$. These results indicate $Ca_2(HSeO_3)_2(Se_2O_5)$ is not a stable phase at 23 °C. At 80 °C, $CaSeO_3 \cdot H_2O$, $Ca_2(SeO_3)(Se_2O_5)$, and $Ca_2(HSeO_3)_2(Se_2O_5)$ are the stable calcium selenite phases. $Ca(HSeO_3) \cdot 2H_2O$ has not been observed. Thus, $CaSeO_3 \cdot H_2O$ exists over the broadest pH range, 11.0–3.9. $Ca_2(SeO_3)(Se_2O_5)$ and $Ca_2(HSeO_3)_2(Se_2O_5)$ dissolve incongruently. The formation of $Ca_2(SeO_3)(Se_2O_5)$ and $Ca_2(HSeO_3)_2(Se_2O_5)$ at 80 °C demonstrates the increasing stability of the $Se_2O_5^{2-}$ ion and the decreasing stability of the $HSeO^{3-}$ ion with increasing temperature.

Calcium hydrogen selenite monohydrate and dicalcium diselenite {bis(hydrogenselenite)} were synthesized and their crystal structures determined:

Crystal data for **$Ca(HSeO_3)_2 \cdot H_2O$** were: $a = 6.911$, $b = 7.369$, $c = 6.739$ Å, $\alpha = 90.51°$, $\beta = 90.93°$, $\gamma = 107.46°$, $V = 327.3$ Å^3, space group (No. 2), $d_{calcd} = 3.19$ g/cm^3, $Z = 2$, and $R = 0.036$ for 1503 reflections.

Data for **$Ca_2(HSeO_3)_2(Se_2O_5)$**: $a = 14.719$, $b = 7.059$, $c = 11.793$ Å, $\beta = 117.96°$, $V = 1082.3(4)$ Å^3, space group $C2/c$ (No. 15), $d_{calcd} = 3.52$ Mg/m^3, $Z = 4$, and $R = 0.047$ for 1251 reflections.

Both structures form a three-dimensional network. The coordination polyhedron around calcium is a monocapped trigonal prism in dicalcium diselenite bis(hydrogenselenite) and a bicapped trigonal prism in calcium hydrogenselenite monohydrate. The Ca–O distance varies from 2.368 to 2.615 Å. Thermal behavior was investigated and the infrared spectrum assigned for dicalcium diselenite bis(hydrogenselenite).

In another study, selenious acid solutions containing a suspension of CaO were held under mild shaking for 1 month at 25 °C. The original analytical data for the solutions, wet residues and precipitates were presented graphically as the ternary phase diagram for the CaO–SeO_2–H_2O system. It was obvious from this graphical procedure that two compounds, $Ca(HSeO_3)_2 \cdot H_2O$ and $CaSeO_3 \cdot H_2O$ existed. Also, the chemical analysis of three precipitates obtained at around pH = 12.0 gave a mole ratio of Ca/Se(IV) of 2.0, corresponding to the $Ca_2SeO_3(OH)_2 \cdot 2H_2O$ species with CaO = 40.47 wt%, SeO_2 = 40.04 wt% and H_2O = 19.49 wt%. In this system, there are three invariant points. The first invariantvv point lies at the point where $Ca(HSeO_3)_2 \cdot H_2O$ and

$CaSeO_3 \cdot H_2O$ coexist. The second lies at the point E ($CaO = 0.06$ wt%, $SeO_2 = 0.003$ wt%) where $CaSeO_3 \cdot H_2O$ and $Ca_2SeO_3(OH)_2 \cdot 2H_2O$ coexist. The third lies at the point ($CaO = 0.08$ wt%, $SeO_2 = 0.00004$ wt%) where $Ca_2SeO_3(OH) \cdot 2H_2O$ and $Ca(OH)_2$ coexist. It was noted that $Ca(HSeO_3)_2 \cdot H_2O$ with a Ca/Se(IV) mole ratio of 0.5 is stable at a pH below 3.5, $CaSeO_3 \cdot H_2O$ with Ca/Se(IV) mole ratio of 1.0 in the pH range 3.5–12.3 and $Ca_2SeO_3(OH)_2 \cdot 2H_2O$ with Ca/Se(IV) mole ratio of 2.0 in the pH range 12.3–12.5. In this system, there are three invariant points at pH 3.5, 12.3 and 12.5, and at each point, a two-point solid phase coexists:

$$Ca(HSeO_3)_2 \cdot H_2O \text{ and } CaSeO_3 \cdot H_2O$$

$$CaSeO_3 \cdot H_2O \text{ and } Ca_2SeO_3(OH)_2 \cdot 2H_2O$$

$$Ca_2SeO_3(OH)_2 \cdot 2H_2O \text{ and } Ca(OH)_2$$

Calcium selenite is available as the monohydrate from a number of commercial suppliers.

Strontium Selenite

Strontium selenite has the molecular formula of $SrSeO_3$ and the molecular weight of 214.5782 g/mol. It can be prepared by adding strontium hydroxide or carbonate to selenous acid which has been stabilized by sodium carbonate to form the sodium salt:

$$Sr(OH)_2(\text{solid}) + Na_2SeO_3(\text{aq}) \Rightarrow SrSeO_3 \cdot 7H_2O(\text{solid}) + H_2O$$

The product is a heptahydrate whose CAS number is 14590-38-6. This compound is insoluble in water but soluble in dilute acids. An acid selenite, $Sr(HSeO_3)_2$, has been reported that is soluble in water. However, its existence has not been confirmed. If it exists, it would be obtained by low temperature evaporation of the solution at an acid pH (~pH = 5.5) and would probably require the presence of ammonium hydroxide during the evaporation to form the crystals. The existence of a hydrate remains unknown.

Another method of preparation of strontium selenite has been given:

A solution of 77 g of sublimed selenium(1 V) oxide in 154 ml of distilled water is added to 500 ml of pure strontium nitrate solution prepared as previously described. The solution is heated to boiling and fresh ammonium hydroxide solution is added until no further precipitation of strontium selenite occurs. The precipitate is drained and washed six times with 300-ml portions of hot distilled water. The nitrate content should be less than 5 parts per million as determined by the diphenylamine-sulfuric acid test. The strontium selenite is dried at 200° for several hours. The yield is about 125 g.

During synthesis of the monazite-type strontium selenate, $SrSeO_4$, a new compound $SrSe_2O_5$ was obtained. This compound was formed by the reaction of hydrogen peroxide upon a mixture of strontium oxide plus selenous acid at a 1:2 molar ratio:

$$2SrO + 4H_2SeO_3 + 2H_2O_2 \Rightarrow 2SrSe_2O_5 + 6H_2O + O_2$$

Essentially this "diselenite" is a mixed compound, $SrSeO_3 \cdot SeO_2$, whose molecular weight is 325.54 g/mol. It is triclinic with a space group of P1 and the lattice parameters of $a = 6.916°$, $b = 6.971°$, $c = 10.875$ Å, $\alpha = 85.07°$, $\beta = 81.46°$, $\gamma = 79.56°$, $V = 509.0$ Å^3, $Z = 4$. The mean Sr–O distance for the eight-coordinated Sr(1) atom is somewhat shorter than that for the nine-coordinated Sr(2) atom. The two crystallographically different diselenite groups have Se–O bond lengths to the bridging O-atoms ranging from 1.822 to 1.879 Å, and others from 1.645 to 1685 Å. The Se–O–Se angles are 120.7° and 122.5°.

Strontium selenite has been used to prepare the selenide by heating it in a hydrogen atmosphere:

$$2SrSeO_3 \cdot 7H_2O + 6H_2 + \text{heat} \Rightarrow 2SeSe + 13H_2O$$

Strontium selenite is available commercially from several manufacturers.

Barium Selenite

Barium selenite has the molecular formula of $BaSeO_3$ and the molecular weight of 264.2865 g/mol. Its CAS number is 13718-59-7. It is a white solid that is insoluble in water. It can be prepared by the addition of sodium selenite to a solution of barium chloride:

$$BaCl_2(\text{aq}) + Na_2SeO_3(\text{aq}) \Rightarrow BaSeO_3(\text{solid})$$

It can also be prepared by treating a solution of barium chloride with selenous acid and adding sodium carbonate to start precipitation. There is no record of a hydrate and the anhydrate is stable upon heating to over 950 °C.

The heat of formation of barium selenite is:

$$\Delta_f H_{298} - BaSeO_3 = 2230.6 \text{ kcal/mol } (-964.7 \text{ kJ/mol}).$$

The precipitate of barium selenite is not oxidized by air during drying at 110 °C. In air, however, it oxidizes to the selenate at about 700–750 °C:

$$2BaSeO_3 + O_2 + \text{heat} \Rightarrow 2BaSeO_4$$

Barium selenite is a fine white crystalline powder that is mainly used in the glass industry to color and decolor glass. Barium selenite is primarily chosen for producing special glass and leads to the formation of glass with high index of refraction. Barium selenite has weak oxidizing or reducing powers. Redox reactions can however still occur. The majority of compounds in this class are slightly soluble or insoluble in water. Noncombustible, the substance itself does not burn but may decompose upon heating to produce corrosive and/or toxic fumes of SeO_2.

A study of the ternary phase diagram for the BaO–SeO_3–H_2O system at 25 °C has been made. In this equilibrium experiment, $Ba(OH)_2 \cdot 8H_2O$ was used as the starting material. The results indicated the existence of two solid phases, $BaSe_2O_5$ and $BaSeO_3$. At one invariant point, (BaO = 0.56 wt%, SeO_2 = 0.83 wt%), these two solid phases are in equilibrium. The stability and solubility regions for barium selenites as a function of pH at 25 °C indicated that $BaSe_2O_5$ having Ba/Se(IV) mole ratio = 1/2 is stable at a pH below 4.6 and $BaSeO_3$ having Ba/Se(IV) = 1/1 is stable in the pH range 4.6 to 13.7. Furthermore, the system Ba–Se(IV)–H_2O at pH 4.6 has two invariant points where $BaSe_2O_5$ and $BaSeO_3$ coexist and at pH 13.7 where $BaSeO_3$ and $Ba(OH)_2.H_2O$ coexist.

The volatility of selenium in making selenium ruby glass has been studied. About 75% of the selenium added to the batch was lost by volatilization. Sodium selenite and barium selenite were stable at 950 °C and are probably stable at higher temperatures. Regardless of whether selenium or the compounds studied are used, the resulting glass contains about equal amounts of selenium. Methods of preparing sodium and barium selenites are described. An outline is given of an analytical procedure by which selenium is determined in glass.

Barium selenite is available commercially as $BaSeO_3$ from a number of suppliers.

Radium Selenite

Radium selenite has the molecular formula of $RaSeO_3$ and the molecular weight of 352.9832 g/mol. It can be prepared by the addition of sodium selenite to a solution of radium chloride:

$$RaCl_2(aq) + Na_2SeO_3(aq) \Rightarrow RaSeO_3(solid)$$

It can also be prepared by treating a solution of radium chloride with selenous acid and adding sodium carbonate to start precipitation. There is no record of a hydrate. $RaSeO_3$ has been administered in the past as a irradiative treatment of certain tumors but there is no substantive evidence concerning its efficacy in this regard. $RaSeO_3$ has no CAS number and is not available commercially.

3.3.3. Alkaline Earth Selenates

Only a few selenates are known.

Beryllium Selenate

Beryllium selenate has the molecular formula of $BeSeO_4$ and the molecular weight of 224.0354 g/mol. Its density is 2.03 g/cm^3. If prepared in solution, the formula is likely to be $(BeOH)_2SeO_4 \cdot 4H_2O$. Nevertheless, the literature persists in relating the compound produced as $BeSeO_4$. The addition of beryllium carbonate and sodium carbonate to a selenic acid solution is sufficient to form the tetrahydrate:

$$BeCO_3(solid) + Na_2CO_3(solid) + H_2SeO_4(aq) \Rightarrow (BeOH)_2SeO_4 \cdot 4H_2O(solid) + 2NaOH(aq) + CO_2(gas)$$

It is soluble in water and the solution must be evaporated to obtain the crystalline salt. Beryllium selenate tetrahydrate has the CAS number of 10039-31-3 and a molecular weight of 267.0582 g/mol. Its density is 2.032 g/cm^3 and it is very soluble in water (49.6 g/100 ml at 20 °C). It is isomorphous to the sulfate and it has been determined to have three indices of refraction at 4681 Å (F-line) which depend upon the orientation of the crystal:

$$\eta_{d(a)} = 1.5105,\ \eta_{d(b)} = 1.5084,\ \eta_{d(c)} = 1.4725$$

The crystal and molecular structure of $BeSeO_4 \cdot 4H_2O$, as determined by single crystal X-ray diffraction and infrared spectroscopy have been determined. $BeSeO_4 \cdot 4H_2O$ crystallizes in the orthorhombic space group *Cmca* (at 295 K), $a = 11.920$ Å, $b = 11.449$ Å, $c = 10.764$ Å, $V = 1468.8$ Å^3, $Z = 2$, $R_2 = 0.057$ for 2035 reflections and 68 variables. The crystal structure is composed of isolated $Be(H_2O)_4$ and SeO_4 tetrahedra which are interconnected by strong hydrogen bonds with O–O lengths between 2.619 and 2.661 Å. Contrary to expectation, the cell volume and the mean Be–O and Se–O distances increase with decreasing temperature. The structure is closely related with that of accentric tetragonal $BeSO_4 \cdot 4H_2O$, but differs in pronounced polyhedral rotations and a partial rearrangement of the hydrogen bonding scheme.

The infrared spectrum of $BeSeO_4 \cdot 4H_2O$ in the region of the uncoupled order-disorder (OD) modes (matrix-isolated HDO molecules) reveals that very strong hydrogen bonds are formed in this compound, analogical to other hydrated beryllium salts due to the strong synergetic effect of the Be^{2+} ions. The appearance of two bands only (2327 and 2239/cm) corresponding to OD stretches instead of four expected was attributed to both the similar O…O hydrogen bond distances and the strong Be–OH_2 and O–O–SeO_3 interactions. The water librations that couple intensively with the translatory modes of the Be^{2+} ions (BeO_4 skeleton vibrations) are also discussed.

The thermal dehydration of $BeSeO_4 \cdot 4H_2O$ has been studied by the use of TG, DTA and DSC analysis methods. The tetrahydrate first decomposes to form the dihydrate. The dehydration occurs in four steps and intermediate hydrates $BeSeO_4$ $2H_2O$, $BeSeO_4$ H_2O and $BeSeO_4$ $0.5H_2O$ are formed at 101 °C, 142 °C, and 182 °C, respectively.

$BeSeO_4 \cdot 2H_2O$ and $BeSeO_4$ have been studied via X-ray methods: $BeSeO_4 \cdot 2H_2O$ forms orthorhombic

crystals with lattice constants: $a = 5.843$ Å; $b = 9.790$ Å; $c = 4.692$ Å; $V = 268.4$ Å^3. The crystals of $BeSeO_4$ are tetragonal: $a = 4.648(1)$ Å; $c = 7.084$ (3) Å; $V = 153.1(1)$ Å^3, SG I. The enthalpies of dehydration of the observed dehydration processes have been determined. The higher value of H_{deh} of $BeSeO_4 \cdot 4H_2O$ as compared to those of other metal selenate tetrahydrates is discussed in terms of the strong Be–H_2O interaction. The enthalpies of formation of $BeSeO_4$ $4H_2O$ and $BeSeO_4$ $2H_2O$ have been calculated.

This salt is available commercially as $BeSeO_4 \cdot 4H_2O$.

Magnesium Selenate

Magnesium selenate has the molecular formula of $MgSeO_4$ and the molecular weight of 167.2566 g/mol. It can be prepared by reacting sodium selenate with magnesium chloride in solution:

$$MgCl_2(aq) + Na_2SeO_4(aq) \Rightarrow MgSeO_4 + 2NaCl(aq)$$

It is soluble in water and the solution must be evaporated to obtain crystals of the hexahydrate, $MgSeO_4 \cdot 6H_2O$. Its molecular weight is 275.3641 g/mol. It is a white, monoclinic crystal with a density of 1.928 g/cm^3. Its CAS number is 13446-58-1 and it is soluble in water (55.52 g/100 ml at 60 °C). The anhydrate is stable upon heating to 1338 °C the heat of formation, $\Delta H_f^\circ = -968.5$ kJ/mol.

Its solubility in water as a function of temperature is shown in Table 3.18.

$MgSeO_4 \cdot 6H_2O$ is isostructural with its sulfate analog and the corresponding cobalt(II) salt. The structure is based on alternating layers of $Mg(H_2O)_6$ octahedra and SeO_4 tetrahedra parallel to (001), connected via hydrogen bonds. All atoms are on general positions except Mg1 and Mg2 (site symmetries 2 and $\bar{1}$, respectively). The average Mg–O and Se–O bond lengths are 2.066 and 1.639 Å, respectively. The structure is shown on the next page.

A number of studies concerning the dehydration of magnesium selenate hexahydrate have been conducted:

I. "The thermal dehydration of the compounds, $MgSeO_4 \cdot 6H_2O$, $MgSeO_4 \cdot 4H_2O$ and $MgSeO_4 \cdot 2H_2O$, has been studied by TG, DTA and DSC. The dehydration of the hexahydrate occurs in steps and the intermediate hydrates $MgSeO_4 \cdot 5H_2O$, $MgSeO_4 \cdot 4H_2O$, $MgSeO_4 \cdot 2H_2O$ and $MgSeO_4 \cdot H_2O$ are produced at 78 °C, 110 °C, 205 °C and 235 °C, respectively. The enthalpies of dehydration of the observed stages have been determined. The enthalpies of formation of $MgSeO_4 \cdot 6H_2O$, $MgSeO_4 \cdot 4H_2O$, $MgSeO_4 \cdot 2H_2O$ and $MgSeO_4 \cdot H_2O$ have also been calculated from the DSC data" (Fig. 3.57).

TABLE 3.18

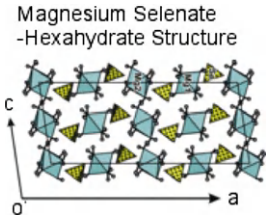

FIGURE 3.57

II. The dehydration of **$MgSeO_4 \cdot 6H_2O$** has been studied using an XRD method at elevated temperatures. Five different crystalline phases have been identified in the temperature interval of 20–450 °C:

$MgSeO_4 \cdot 6H_2O$

$MgSeO_4 \cdot 5H_2O$ (with a small amount of $MgSeO_4 \cdot 4H_2O$)

$MgSeO_4 \cdot 2H_2O$

Magnesium selenate(VI) monohydrate, $MgSeO_4 \cdot H_2O$

Crystalline $MgSeO_4$

Amorphous $MgSeO_4$

$MgSeO_4 \cdot 5H_2O$ crystallizes in the triclinic system with the lattice parameters: $a = 6.403$ Å, $b = 10.576$ Å, $c = 6.196$ Å, $\alpha = 98.63°$, $\beta = 110.36°$, $\gamma = 75.25(3)°$, space group = P1.

$MgSeO_4 \cdot 2H_2O$ forms orthorhombic crystals with lattice parameters: $a = 10.304$ Å, $b = 10.351$ Å, $c = 9.138$ Å.

$MgSeO_4 \cdot H_2O$ has been prepared and studied roentgeno-graphically. It is a monoclinic system with the lattice constants: $a = 6.064$ Å, $b = 13.773$ Å, $c = 8.062$ Å, $\beta = 91.82(7)°$, space group = $P2_1/n$.

The crystalline anhydrous magnesium selenate, **$MgSeO_4$** crystallizes in the orthorhombic system with the lattice parameters: $a = 4.925$ Å, $b = 9.026$ Å, $c = 6.816$ Å.

According to expectation, the magnesium selenate hydrates are determined to be isomorphous with the corresponding magnesium sulfate hydrates.

III. "$MgSeO_4 \cdot 6H_2O$ is isostructural with its sulfate analog and the corresponding cobalt(II) salt (monoclinic, space group = C2/c with eight formula units per unit cell and $a = 10.224$ Å, $b = 7.370$ Å, $c = 24.866$ Å, $\beta = 98.5°$, $V = 211.4$ Å^3, $Z = 4$). The structure is based

on alternating layers of $Mg(H_2O)_6$ octahedra and SeO_4 tetrahedra parallel to (001), connected via hydrogen bonds. All atoms are on general positions except Mg1 and Mg2 (site symmetries 2 and 4, respectively). The average Mg–O and Se–O bond lengths are 2.066 and 1.639 Å, respectively".

IV. "The crystal structure of a new compound $[Mg(H_2O)_4(SeO_4)]_2(H_2O)$ (monoclinic, $P2_1/a$, $a = 7.2549$ Å, $b = 20.059$ Å, $c = 10.3934$ Å, $\beta = 101.989$, $V = 1479.5$ Å^3) has been solved by direct methods and refined to $R_1 = 0.059$ for 2577 observed reflections with $|F\ hkl| \geq 4 \leq |F\ hkl|$. The structure consists of $[Mg(H_2O)_4(SeO_4)]^0$ chains formed by alternating corner-sharing Mg octahedrons and $(SeO_4)^{2-}$ tetrahedrons. O atoms of Mg octahedrons that are shared with selenate tetrahedrons are in a *trans* orientation. The heteropoly-hedral octahedral-tetrahedral chains are parallel to the *c*-axis and undulate within the (010) plane. The adjacent chains are linked by hydrogen bonds involving H_2O molecules not bound with M^{2+} cations."

Magnesium selenate has found little usage in industry but is available commercially by several manufacturers.

Calcium Selenate

Calcium selanate has the molecular formula of $CaSeO_4$ and the molecular weight of 201.0598 g/mol. It can be prepared by reacting sodium selenate with calcium chloride in solution:

$$CaCl_2(aq) + Na_2SeO_4(aq) \Rightarrow CaSeO_4 + 2NaCl(aq)$$

The result is calcium selenate dihydrate $CaSeO_4 \cdot 2H_2O$ whose CAS number is 7790-74-1. It is slightly soluble in water at 9.22 g/100 ml at 20 °C.

Evaporating the solution serves to form white, monoclinic crystals whose molecular weight is 219.07 g/mol, with a density of 2.75 g/cm^3. The solubility varies with temperature (Table 3.19).

The structure of the high-temperature form of $CaSeO_4$, formed by dehydration of the gypsum-type structure dihydrate has been presented. The material is equivalent to that described previously as a $P2_12_12_1$ form, but is however, a monazite with unit cell $a = 6.8566$ Å, $b = 7.04962$ Å, $c = 6.68817$ Å and $\beta = 104.2675°$ in space group $P12_1/n_1$. Also presented was evidence for two intermediate trigonal and pseudo-trigonal phases related to the structurally similar minerals rhabdophane, bassanite, and α-$CaSO_4$. This result permits closer comparisons between intermediate-temperature structures of the selenate with related sulphates, and orthophosphates with a view to extending structural stability via synthesis of solid solutions.

TABLE 3.19

G/100 ml of water

Compound	Formula	0 °C	10	20	30	40	60	80	90	100
Calcium selenate	$CaSeO_4 \cdot 2H_2O$	9.73	9.77	9.22	8.79	7.14				

Various compounds can be formed by adjusting the pH of the solution. Four calcium selenates have been found which are represented by the formulas, $CaSe_2O_7$, $CaSeO_4$, $CaSeO_4 \cdot 2H_2O$ and $Ca_2SeO_3(OH)_2$. The X-ray data for $CaSeO_4 \cdot 2H_2O$ are known. On the other hand, the XRD data for three compounds, $CaSe_2O_7$, $CaSeO_4$ and $Ca_2SeO_4(OH)_2$ are not listed in the ICCD Cards.

The stability and solubility regions for calcium selenates as a function of pH at 25 °C were established. It was noted that $CaSeO_4 \cdot 2H_2O$ having Ca/Se(VI) mole ratio of 1.0 is stable over a wide range of pH, while $Ca_2SeO_3(OH)_2$ having Ca/Se(VI) mole ratio of 2.0 is stable in the very narrow range of pH 11.8 to 12.2. Also, there are two invariant points where $CaSeO_4 \cdot 2H_2O$ and $Ca_2SeO_3(OH)_2$ coexist at pH 12.0 and $Ca_2SeO_3(OH)_2$ and $Ca(OH)_2 \cdot H_2O$ coexist at pH 12.2. It was determined that the calcium concentration in solutions in equilibrium with $CaSeO_4 \cdot 2H_2O$ stayed constant at 0.42 mol/l in the pH range 0.6 to 12.0 and then decreased to 0.14 mol/l. The selenium(VI) concentration slightly decreases with increasing pH from 0.6 to 1.4 and then remains constant at same value of calcium concentration in the same pH range. A further increase in pH leads again to a decreased selenium(VI) concentration until it is reached to 11.1 g/l (0.14 mol/l). The free energy of formation for these compounds was determined to be:

$$\Delta_f G^\circ_{298} - CaSeO_3 \cdot H_2O = -284.2 \text{ kcal/mol} \quad (-1189.1 \text{ kJ/mol})$$

$$\Delta_f G^\circ_{298} - Ca_2SeO_3(OH)_2 \cdot 2H_2O = -556.9 \text{ kcal/mol} \quad (-2330.1 \text{ kJ/mol})$$

$$\Delta_f G^\circ_{298} - CaSeO_4 \cdot 2H_2O = -352.7 \text{ kcal/mol} \quad (-1475.6 \text{ kJ/mol})$$

$$\Delta_f G^\circ_{298} - Ca_2SeO_4(OH)_2 = 453.1 \text{ kcal/mol} \quad (-1895.9 \text{ kJ/mol})$$

SeO_4^{2-} ions can substitute for sulfate in the gypsum structure. In this work, crystals of different $Ca(SO_4,SeO_4) \cdot 2H_2O$ solid solutions were precipitated by mixing a $CaCl_2$ solution with solutions containing different ratios of Na_2SO_4 and Na_2SeO_4. The compositions of the precipitates were analyzed by EDS and the cell parameters were determined by XRD. Moreover, a comparative study on dehydration behavior of selenate-rich and sulfate-rich $Ca(SO_4,SeO_4) \cdot 2H_2O$ solid solutions was carried out by thermogravimetry. The

experimental results show that the $Ca(SO_4,SeO_4)\cdot 2H_2O$ solid solution presents a symmetric miscibility gap for compositions ranging from $X_{CaSO_4 2H_2O} = 0.23$ to $X_{CaSO_4 2H_2O} = 0.77$. By considering a regular solution model, a Guggenheim parameter $a_0 = 2.238$ was calculated. The solid phase activity coefficients obtained with this parameter were used to calculate a Lippmann diagram for the system $Ca(SO_4,SeO_4)\cdot 2H_2O$–$H_2O$.

A major use for calcium selenate has been the formation of CaSe by reduction with hydrogen gas. This salt is readily available commercially by several manufacturers.

Strontium Selenate

Strontium selanate has the molecular formula of $SrSeO_4$ and the molecular weight of 230.5798 g/mol. It can be prepared by reacting sodium selenate with strontium chloride in solution:

$$SrCl_2(aq) + Na_2SeO_4(aq) \Rightarrow SrSeO_4 + 2NaCl(aq)$$

The result is strontium selenate whose CAS number is 7446-21-1. It is slightly soluble in water at 0.656 g/100 ml at 20 °C. Evaporating the solution serves to form white, orthorhombic crystals, with a density of 4.25 g/cm^3. It is less soluble in hot water at 0.1152 g/100 ml at 100 °C and soluble in hot HCl.

$SrSeO_4$ is monoclinic with a space group of $P2_1/n$ and lattice parameters of: $a = 6.853°$, $b = 7.352°$, $c = 7.102°$, $\beta = 0.7107°$, $V = 348.0$ Å^3, $Z = 4$. The major use for this compound has been to form SrSe by reduction:

$$SrSeO_4(solid) + H_2(gas) + heat \Rightarrow SrSe(solid) + H_2O(gas)$$

Strontium selenate is available commercially from several manufacturers.

Barium Selenate

Barium selanate has the molecular formula of $BaSeO_4$ and the molecular weight of 280.2748 g/mol. It can be prepared by reacting sodium selenate with barium chloride in solution:

$$BaCl_2(aq) + Na_2SeO_4(aq) \Rightarrow BaSeO_4 + 2NaCl(aq)$$

Barium selenate is slightly soluble in water at 0.0052 g/100 ml at 20 °C. Its CAS number is 7787-41-9. It is a white rhombic crystal which decomposes when heated beyond about 425 °C. It is slightly soluble in water at 0.0152 g/100 ml at 20 °C. Its solubility product is 3.40×10^{-8}.

The heat of formation of barium selenate is:

$$\Delta H_{298}\ BaSeO_4 = -249.0\ \text{kcal/mol}\ (-1041.8\ \text{kJ/mol}).$$

As a result of the measurements, it has been found that for the reaction:

$$Ba_{solid} + Se_{solid} + 2O_2 = BaSeO_4$$

$$\Delta H_{298} = -279.2\ \text{cal/mol}$$

$$\Delta F_{298} = -249.1\ \text{cal/mol}$$

From the thermodynamic data for H_2SeO_4, $SrSeO_4$, and $BaSeO_4$, the average value of the entropy of the aqueous SeO_4^{2-} ion is $\Delta S = 5.5 \pm 0.3$ entropy units.

A ternary phase diagram for the system BaO–SeO_3–H_2O at 25 °C was constructed. It was obvious from this diagram that two compounds can be identified. These are represented by the formulas $BaSe_2O_7$ and $BaSeO_4$. At the invariant point, the two solid phases are in equilibrium and the liquid has a low concentration of BaO between 0.40 and 0.47 wt% and a high concentration of SeO_3 between 75.53 and 77.30 wt%. The XRD pattern for the compound, $BaSe_2O_7$, could not be identified, whereas the XRD patterns for the other compound were matched with that for $BaSeO_4$. The stability and solubility regions for barium selenates as a function of pH at 25 °C. It was noted that $BaSeO_4$ having Ba/Se(VI) mole ratio = 1/1 is stable over the wide range of pH and at the invariant point of pH 13.7, $BaSeO_4$ and $Ba(OH)_2\cdot H_2O$ coexist. It was also noted that the barium concentration in solution in equilibrium with $BaSeO_4$ increases with an increase in pH and then remains constant at 2×10^{-3} mol/l in the pH range 5.4 to 10.9 and increases again until the solution is saturated with $Ba(OH)_2\cdot H_2O$. The selenium(VI) concentration reversely decreases with an increase in pH and then remains constant at 1×10^{-3} mol/l in the same pH range (5.4–10.9) as well as the barium content. A further increase in pH leads again to a decreased selenium(VI) concentration until it is reached to about 16 mg/l. This lowest concentration of selenium (VI) is much higher than the limit of industrial wastewater regulation for selenium (0.1 mg/l).

Barium selenate has not found much usage in industry but is available from a few manufacturers commercially.

Radium Selenate

Radium selanate has the molecular formula of $RaSeO_4$ and the molecular weight of 368.9826 g/mol. It can be prepared by reacting sodium selenate with radium chloride in solution:

$$RaCl_2(aq) + Na_2SeO_4(aq) \Rightarrow RaSeO_4 + 2NaCl(aq)$$

Radium selenate is expected to be insoluble in water but there is no record of this compound ever having been prepared. It had no CAS number. There is no demand for this compound and it is not available commercially.

3.4. ALKALINE EARTH TELLURIUM COMPOUNDS

The alkaline earths form a series of compounds with tellurium. These are based primarily upon the acids,

tellurous, H_2TeO_3 and telluric, H_2TeO_4. They also form tellurides, H_2Te. As is the case for selenium, tellurium only forms the –2, +4 and +6 oxidation states in this series of compounds. In comparison to S and Se, Te in these compounds shows less anionic and more cationic behavior. That is, Te has a far greater cationic character and tends to form compounds in which it is the cation. Thus, oxy-sulfur and oxy-selenate compounds are stable and easy to prepare, but not oxy-tellurium compounds (particularly when the cation is large like Sr or Ba). Compounds include metatellurates and orthotellurates. Metatellurates are analogous to sulfates, but they are rare. Orthotellurates are much more common and this forms most of the chemistry of tellurates.

3.4.1. Tellurium Acids

A number of acids based upon tellurium exist.

Hydrogen Telluride

Hydrogen telluride has the formula, H_2Te. The simplest hydride of Te, it is rarely encountered because of its tendency to decompose to the constituent elements. Most compounds with Te–H bonds are unstable with respect to loss of H_2. H_2Te is chemically and structurally similar to H_2S, and both are acidic species with H–X–H angles approaching 90°. The tellurides of the alkaline earth metals tend to immediately decompose on exposure to air, with liberation of tellurium.

H_2Te is prepared by the acidification of salts of Te^{2-}, such as Al_2Te_3 and Na_2Te. Na_2Te can be generated by the reaction of Na and Te in anhydrous ammonia. The intermediate in the acidification, the HTe^- is a stable anion.

H_2Te is an endothermic compound, and is unstable in air, rapidly decomposing into water and elemental tellurium:

$$2H_2Te + O_2 \Rightarrow 2H_2O + 2Te$$

It is almost as acidic as phosphoric acid ($pK_a = 8.1 \times 10^{-3}$), having a pK_a value of about 2.3×10^{-3}. It reacts with many metals to form tellurides. However, many of these are unstable relative to their decomposition to the elements. Its CAS number is 7783-09-7 and its molecular weight is 129.6158 g/mol. It is a colorless gas and is toxic if breathed. Its density is 3.310 g/cm^3 and its melting point is –49 °C with a boiling point of –2.2 °C. Its solubility in water is 0.701 g/100 ml of water at 20 °C.

Tellurous Acid

H_2TeO_3 has been synthesized as a solid but it is not well characterized. If tellurium dioxide, TeO_2, is added to water, tellurous acid does not easily form, but it can be made other ways. Its CAS number is 10049-23-7.

Tellurous acid can be formed from the chlorides. Two chlorides are known, the *dichloride*, $TeCl_2$, and the *tetrachloride*, $TeCl_4$. They are both obtained by passing chlorine over tellurium, the product being separated by distillation (the tetrachloride is the less volatile). The dichloride is an amorphous, readily fusible, almost black solid. It is decomposed by water with formation of tellurium and tellurous acid:

$$2TeCl_2 + 3H_2O \Rightarrow Te + H_2TeO_3 + 4HCl$$

However, pure tellurous acid, H_2TeO_3, can be obtained when the tetrachloride is decomposed by water, or on dissolving tellurium in nitric acid and pouring the solution into water. It is a colorless solid and behaves as a dibasic acid. The alkali tellurites are soluble in water. They also gives rise to super acid salts, such as $KHTeO_3 \cdot H_2TeO_3$.

Telluric Acid

Telluric acid, H_6TeO_6, is obtained in the form of its salts when tellurium is fused with potassium nitrate plus carbonate, or by the oxidizing action of chlorine on a tellurite in alkaline solution. The free acid may be obtained by decomposing the barium salt with sulfuric acid and concentrating the solution. Originally, this crystalline mass was thought to have the composition $H_2TeO_4 \cdot 2H_2O$ but it was soon determined to possess the form shown in Fig. 3.58.

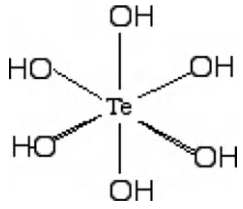

FIGURE 3.58

where tellurium is in an octahedral coordination. Telluric acid, $Te(OH)_6$, has the CAS number of 7803-68-1 and a molecular weight of 229.6425 g/mol. It is a white, monoclinic crystal with a density of 3.07 g/cm^3. Its melting point is 136 °C and its solubility in water is 50.1 g/100 ml.

It is also formed when tellurium dioxide is oxidized by hydrogen peroxide in caustic solution (A. Gutbier, *Zest. Anorg. Chem.*, 1904, 40, p. 260), and perhaps best of all by oxidizing tellurium with a mixture of nitric and chromic acids. It crystallizes as prisms, which lose their water of hydration at 160 °C. The tellurates of the alkaline earth metals are more or less soluble in water, those of the other metals being very sparingly or almost insoluble in water. Some tellurates exist in two forms, a colorless form soluble in water and acids, and a yellow form insoluble in water and acids.

Telluric acid itself is a white solid made up of octahedral $Te(OH)_6$ molecules and this structure persists in aqueous solution as $Te(OH)_4O^{-2}$. There are two crystalline forms of telluric acid, rhombohedral and monoclinic, and both contain octahedral $Te(OH)_6$ molecules. Telluric acid is a weak acid, is dibasic, and forms tellurate salts with strong bases like the alkali metals.

Telluric acid can also be formed by the oxidation of Te or TeO_2 with a powerful oxidizing agent such as hydrogen peroxide, chromium trioxide or sodium peroxide:

$$TeO_2 + 2H_2O_2 + 2H^+ \Rightarrow Te(OH)_6$$

Crystallization of telluric acid solutions below 10 °C gives $Te(OH)_6 \cdot 4H_2O$.

The anhydrous acid is stable in air at 100 °C but, above this temperature, it dehydrates to form polymetatelluric acid, a white hygroscopic powder (approximate composition $(H_2TeO_4)_{10}$), and allotelluric acid, an acid syrup of unknown structure (approximate composition $(H_2TeO_4)_3(H_2O)_4$). Strong heating above 300 °C produces the alpha-crystalline modification of tellurium trioxide, α-TeO_3. Reaction with diazomethane gives the hexamethyl ester, $Te(OMe)_6$.

Telluric acid and its salts mostly contain hexacoordinate Te. This is true even for salts such as magnesium tellurate, $MgTeO_4$, which is isostructural with magnesium molybdate and contains TeO_6 octahedra. It is oxidizing, as shown by the electrode potential for the reaction below, although it is kinetically slow in its oxidations:

$$H_6TeO_6 + 2H^+ + 2e^- \Rightarrow TeO_2 + 4\,H_2O \quad E\ominus = +1.02\ V$$

Metatelluric acid, H_2TeO_4, the tellurium analog of sulfuric acid, H_2SO_4, is unknown. Allotelluric acid, of approximate composition $(H_2TeO_4)_3(H_2O)_4$, is not well characterized and may be a mixture of $Te(OH)_6$ and $(H_2TeO_4)_n$. The meta-tellurates are based upon this acid even though it cannot be isolated.

There is also a related acid, Teflic acid, with the formula $HOTeF_5$. This strong acid is related to orthotelluric acid, $Te(OH)_6$. Teflic acid has octahedral geometry and, ignoring its bent Te–O–H bond, has point group symmetry C_{4v}. It has no CAS number but its molecular weight is 239.6512 g/mol. Teflic acid is a colorless solid that melts at 39.1 °C and has a boiling point of 59.7 °C (Fig. 3.59).

Many elements form teflates but only Barium appears to be large enough in atomic radius to form a stable compound.

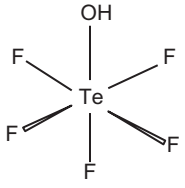

FIGURE 3.59

3.4.2. Alkaline Earth Tellurides

Beryllium Telluride

Beryllium telluride (BeTe) is a chemical compound whose molecular weight is 136.6122 g/mol. Its CAS number is 12232-27-8 and it has a density of 5.12 g/cm^3. Its structure is one of the sphalerite cF8 group with a space group of F43m (#216). It is a crystalline solid with face-centered symmetry, $a = 5.615$ Å at 300 K (Fig. 3.60).

It can be prepared by heating the elements together in an inert atmosphere:

$$Be + Te + \text{heat} \Rightarrow BeTe$$

Te melts at 450 °C and Be melts at 1287 °C. A heating temperature of 750 °C is sufficient to cause complete reaction. BeTe is a crystalline solid with the lattice constant of 0.5615 nm. It is a semiconductor with a large energy gap of around 3 eV. Toxicity is unknown, but both beryllium and tellurium are toxic. Toxic H_2Te gas is evolved on exposure to water.

BeTe, like ZnTe, tends toward p-type conductivity. Using plasma-assisted doping of nitrogen, very high *p*-type concentrations above 10^{20}/cm^3 have been achieved. *N*-type conductivity has not been reported. The composite wave variational version of the APW method has been used in conjunction with the LCAO interpolation scheme to compute the energy bands and the joint density of states of the compounds BeS, BeSe and BeTe at various symmetry points and axes of the brillouin zone. From these computed bands, all three materials are found to be semiconductors having band gaps of 6.10 eV, 4.75 eV and 1.49 eV, respectively. From the joint density of state characteristics, various optical transitions have also been predicted. The results have been favorably compared with those of Stükel. Since BeTe is found to be a small gap semiconductor, its possible technological importance has also been

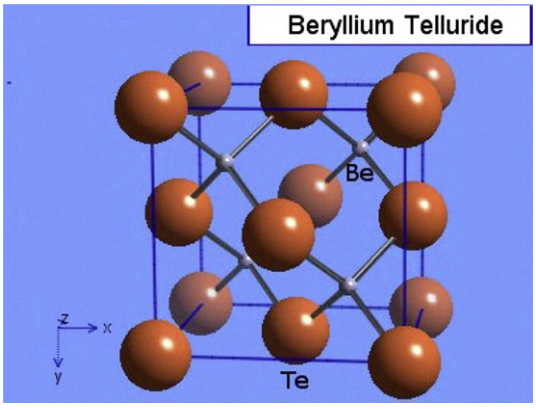

FIGURE 3.60

emphasized. BeTe has been used in efficient pseudomorphic p-contacts for ZnSe laser diodes.

BeTe is available commercially in small quantities as a sputtering target.

Magnesium Telluride

Magnesium telluride has the molecular formula of MgTe and the molecular weight of 151.9146 g/mol. It can be prepared by heating the elements together in an inert atmosphere:

$$\mathrm{Mg} + \mathrm{Te} + \mathrm{heat} \Rightarrow \mathrm{MgTe}$$

Te melts at 450 °C and Mg melts at 650 °C. A heating temperature of 750 °C is sufficient to cause complete reaction. MgTe powder can also be prepared by reaction of stoichiometric quantities of Mg and Te in a pure graphite crucible in vacuum at 480 °C during 48 h. MgTe single crystals were grown by vacuum sublimation in a two-zone furnace at a sublimation temperature of 960 °C. The crystals are transparent hexagonal columns with a length up to 12 mm and extremely hygroscopic. They have a high index of refraction. The lattice parameters are: $a = 4{,}5303$ Å, $c = 7.4056$ Å and the band gap, $E_g = 3.49$ eV. MgTe is a direct gap semiconductor. It tends toward *p*-type conductivity and very high concentrations above 10^{21} have been achieved.

MgTe in its stable (wurtzite) and high-pressure phases (NiAs) has been studied. The latter provided the ground-state properties such as lattice parameter, bulk modulus and its pressure derivatives. The transition pressure at which this compound undergoes the structural phase transition from the NiAs to CsCl phase is calculated as 69.6 Gpa.

The NiAs-type (*B*8) MgTe structure is shown in Fig. 3.61.

The electronic structure, the charge density, and the total energy of MgTe in the wurtzite (B4), nickel arsenide ($B8_1$), and iron silicide (B28) structures have been determined, using first-principles self-consistent local-density calculations in a large plane wave basis employing soft nonlocal pseudopotentials. For MgTe, the experimental ground state is the wurtzite (cubic) structure, while the nickel arsenide structure obtained at 1.1–3.5 GPa persists after unloading to normal pressure. Up to 60 Gpa, no other transition was observed. Theoretically, the ground state is a nickel arsenide structure with a transition to the cesium chloride structure at 69.6 GPa. The wurtzite and nickel arsenide structures are energetically very close. The difference at the minimal energy in these two structures is only 20.3 meV per atom.

In another study, *Ab Iinitio* phonon calculations on NiAs-type (*B*8) MgTe are performed to probe the structural behaviors of MgTe under high pressure. We predicted an unstable transverse acoustic mode and a phase transition of *B*8 ⇒ orthorhombic *Pnma* (*B*31) driven by this soft mode is thus identified. The polymorph of *B*31 in MgTe adopts MnP-type structure containing chains of metal atoms and is stable above 42.7 GPa through the enthalpy calculations. With the discovery of the *B*31 phase, the previously theoretical high-pressure structures of the tetragonal *P*4/*nmm* (*PH*4*I*) and the CsCl (*B*2) are ruled out.

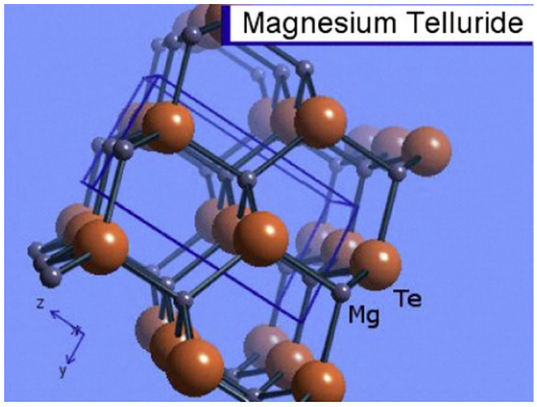

FIGURE 3.61

Theoretical modeling of two-junction tandem solar cells shows that for optimal device performance, the band gap of the top cell should be in the range of 1.6 to 1.8 eV. $Cd_{1-x}Mg_xTe$ (CMT) alloys have a lattice constant close to that of CdTe, and the addition of a small amount of MgTe changes the band gap considerably. Work on developing CMT for solar cell applications has shown considerable promise. CMT films were prepared by vacuum deposition with co-evaporation of CdTe and MgTe on substrates heated to 300–400 °C. Films with a composition in the range of $x = 0$ to 0.66 were fabricated, and optical analysis of the films showed that the band gap of the samples ranged from 1.5 to 2.3 eV and varied linearly with composition. All the $Cd_{1-x}Mg_xTe$ alloy films deposited at substrate temperature of 300 °C exhibit the sphalerite structure characteristic of CdTe, and only a small variation in lattice constant as expected for these alloys. Optical and structural properties of these samples show that CMT alloy films are well behaved in the composition range covered in this study. Devices fabricated using these films show promising device performance and attest to the device quality of polycrystalline CMT thin films.

Magnesium telluride is available commercially.

Calcium Telluride

Calcium telluride has the molecular formula of CaTe and the molecular weight of 167.6782 g/mol. It can be prepared by heating the elements together in an inert atmosphere:

$$\mathrm{Ca} + \mathrm{Te} + \mathrm{heat} \Rightarrow \mathrm{CaTe}$$

Te melts at 450 °C and Ca melts at 842 °C. A heating temperature of 750 °C is sufficient to cause complete reaction. CaTe powder can also be prepared by reaction of stoichiometric quantities of Ca and Te in a pure graphite crucible in vacuum at 480 °C for 48 h. Its molecular weight is 119.04 g/mol. Calcium telluride has the CAS number of 12013-57-9. It is a crystalline solid with a density of 4.872 g/cm^3. It has the rock salt structure with octahedral coordination of the Ca^{2+} cation. Its refractive index is 2.51. If heated to 1605 °C, it decomposes (Fig. 3.62).

The ternary compound, PbCaTe, has been grown using the technique of molecular beam epitaxy. Source ovens containing Ca, Te, PbTe, Tl_2Te (p dopant) and Bi_2Te_3 (n dopant) were used to grow films on (111) oriented BaF_2 substrates or on (100) oriented PbTe substrates. Auger electron spectroscopy studies of $Pb_{1-x}Ca_xTe$ films have shown that the incorporation of calcium is independent of substrate growth temperature in the range 300–400 °C, despite the relatively high vapor pressure of elemental calcium in this temperature range. The diffusion coefficient of Ca in PbTe is 3×10^{-17} cm^2/s at 370 °C. The energy band gap increases as $dE_g/dx = 2.5$ eV for small x, as determined by infrared transmission studies at room temperature. For $x = 0.15$, the energy gap is 0.65 eV. The index of refraction decreases with increasing calcium concentration up to $x \sim 0.15$, but increases anomalously for $x = 0.26$. The electron and hole mobilities at 80 K are comparable and decrease to a few hundred cm^2/V s for $x = 0.15$. From X-ray diffraction studies, the crystal lattice constant is almost independent of x for $x < 0.15$. These results suggest that PbCaTe may be a useful material for long wavelength (>2 μm) diode lasers.

CaTe has found very little usage in industry and the only available information academically deals with its usage to form ternary tellurides. It is available commercially in limited quantities.

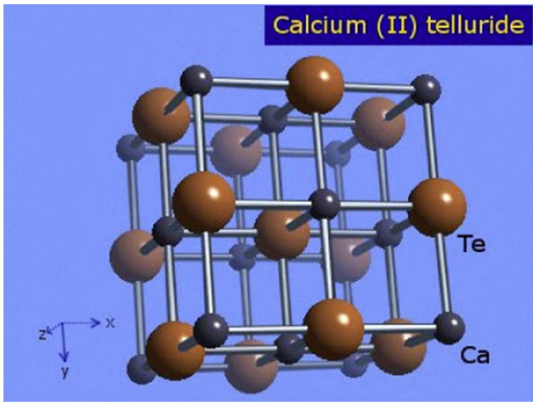

FIGURE 3.62

Strontium Telluride

Strontium telluride has the molecular formula of SrTe and the molecular weight of 215.2238 g/mol. It can be prepared by heating the elements together in an inert atmosphere:

$$Sr + Te + \text{heat} \Rightarrow SrTe$$

Te melts at 450 °C and Sr melts at 778 °C. A heating temperature of 750 °C is sufficient to cause complete reaction. SrTe powder can also be prepared by the reaction of stoichiometric quantities of Sr and Te in a pure graphite crucible in vacuum at 480 °C during 48 h. Its molecular weight is 166.58 g/mol. Strontium telluride has the CAS number of 12040-08-3. It is a white, crystalline solid with a density of 4.83 g/cm^3. It has the rock salt structure with octahedral coordination of the Sr^{2+} cation. Its refractive index is 2.408. If heated to 1605 °C, it decomposes.

$Pb_{1-x}Sr_xTe$ films were prepared by hot-wall epitaxy on BaF_2(111) substrates. X-ray diffraction analysis, optical transmission measurement, Hall measurement and EPMA were performed on the films. It was observed that the increasing rate of the lattice constant of the $Pb_{1-x}Sr_xTe$ films with the SrTe content was considerably larger than that estimated from Vegard's law. $Pb_{1-x}Sr_xTe$/PbTe double-heterostructure (DH) and multiple quantum well (MQW) lasers were also prepared for the first time by hot-wall epitaxy. Pulsed laser operations were obtained up to 227 K (4.1 μm) for the DH laser and up to 220 K (3.5 μm) for the MQW laser. Large output energy shifts due to misfit strain in the active layer were observed.

Strontium telluride is not used in industry for any purpose and the scientific literature concerning it has been very scattered. Most of the known data concerning this compound originated in the 1900s. SrTe is mentioned in a few patents where complete coverage of all possibilities was desired.

SrTe is available commercially in small quantities as a sputtering target.

Barium Telluride

Barium telluride has the molecular formula of BaTe and the molecular weight of 264.9270 g/mol. It can be prepared by heating the elements together in an inert atmosphere:

$$Ba + Te + \text{heat} \Rightarrow BaTe$$

Te melts at 450 °C and Ba melts at 728 °C. A heating temperature of 750 °C is sufficient to cause complete reaction. BaTe powder can also be prepared by reaction of stoichiometric quantities of Ba and Te in a pure graphite crucible in vacuum at 480 °C during 48 h. Its molecular weight is 216.31 g/mol. The heat of formation, ΔH^o at that temperature is 9.29 kJ/mol. Barium telluride can also be prepared by direct reduction of barium tellurate.

Barium telluride has the CAS number of 12009-36-8. It is a white, crystalline solid with a density of 4.94 g/cm^3. It has the rock salt structure with octahedral coordination of the Ba^{2+}cation. Its refractive index is 2.408. The melting point of barium telluride was found to be 2070 ± 10 °C.

A fast-growing interest in solid-state telluride chemistry has taken place during the past several years. Research in this area has been primarily on the development and applications of several synthetic techniques that can be applied to the synthesis of the tellurides over a wide temperature range (100–1200 °C). These techniques include chemical vapor transport, molten-salt, and hydro(solvo)thermal methods. A number of binary, ternary, and quaternary metal tellurides, $BaTe_2$, $TaCu_3Te_4$, $RbTaCu_2Te_4$, $K_2BaSnTe_4$, and $K_2Ag_2SnTe_4$, synthesized by the molten-salt (alkali-metal polytelluride flux) reactions at intermediate temperatures (400–550 °C). The crystal structures of these compounds have been determined by single-crystal X-ray diffraction techniques. Crystal data: $BaTe_2$, space group $I4/mcm$ (No. 140), $a = 7.181$ Å, $c = 8.898$ Å, $Z = 4$, $R1 = 1.55\%$, $wR^2 = 3.46\%$; $RbTaCu_2Te_4$, space group $P2_1cn$ (No. 33), $a = 5.982(2)$, $b = 20.316(3)$, $c = 8.192(2)$ Å, $Z = 4$, $R1 = 7.13\%$, $wR^2 = 4.95\%$; $TaCu_3Te_4$, space group P-43m (No. 215), $a = 5.930(2)$ Å, $Z = 1$, $R1 = 2.40\%$, $wR^2 = 6.48\%$; $K_2BaSnTe_4$, space group I-43m (No. 217), $a = 8.393(1)$ Å, $Z = 2$, $R1 = 2.52\%$, $wR^2 = 3.56\%$; $K_2Ag_2SnTe_4$, space group I-42m (No. 121), $a = 8.732(5)$, $c = 7.425(3)$ Å, $Z = 2$, $R1 = 3.06\%$, $wR^2 = 7.25\%$.

The compound, barium ditelluride, $BaTe_2$, was grown by a flux-growth technique, the first alkaline earth metal dichalcogenide prepared by this method. The crystal structure of $BaTe_2$ was determined by single-crystal X-ray diffraction methods. It belongs to the tetragonal space group I4/mcm (No. 140) with lattice constants $a = 7.181$ Å, $c = 8.898$ Å, $V = 458.8$ Å^3, and $Z = 4$. The final residual index is converged to $R = 1.5\%$, $wR^2 = 3.5\%$. $BaTe_2$ is a Zintl-type compound isostructural to SrS_2. Pairs of tellurium atoms form dimeric units $(Te_2)^{2-}$ with a Te–Te separation of 2.7722 Å. The synthesis of $BaTe_2$ at relatively low temperature has provided an alternative and convenient route for preparing new compounds in this category.

Single crystals of barium telluride were grown in graphite crucibles using a Bridgman–Stockbarger technique. A procedure for seeding the melt with a portion of a previously grown crystal was used. The lattice constant for barium telluride was found to vary, depending on the history of the sample, from a value of 7.000 Å for freshly prepared powder to as low as 6.950 Å for samples melted in an open crucible.

The photoelectric emission from barium telluride has been investigated by measuring the total photoelectric-yield spectra and the distributions in kinetic energy of the emitted electrons, using a magnetic velocity analyzer tube. From the threshold for photoelectric emission from the valence band, the energy of the top of the valence band was estimated to be 4.8 eV below the vacuum level. Using an estimate of 3.4 eV for the band gap, the electron affinity was estimated to be 1.4 eV. The kinetic energy distributions showed two peaks which were interpreted as being associated with direct ionization of defect levels located approximately 2.9 and 3.6 eV below the vacuum level. At photon energies above about 4.1 eV, these fast peaks were observed to become distorted. No evidence was seen for an exciton-induced component in the photoelectric emission.

Long wavelength diode lasers operating in the 3–10 μm wavelength range are of interest as optical sources for future fiber optics communications and sensor systems. PbEuSeTe large optical cavity single quantum well diode lasers have so far attained the highest operating temperatures (174 K cw, 280 K pulsed) in this wavelength range. Two alternative materials systems PbSrTe and PbBaTe have now been grown for the first time by molecular-beam epitaxy. The choice of these ternaries was motivated by the fact that SrTe and BaTe have the same face centered cubic crystal structure as PbTe and roughly comparable lattice constants, but much larger energy band gaps. In the $Pb_{1-x}Ba_xTe$ system, X-ray diffraction studies show clear evidence of phase segregation for $x \geq 0.05$. The carrier mobilities decrease monotonically with barium concentration in the single-phase region, which suggests that disorder-related scattering is dominant. The energy band gap increases approximately as $dE_g/dx = 3.2$ eV for small x, and the index of refraction decreases monotonically with increasing x. A combination of X-ray diffraction, energy band gap and other data clearly demonstrate that the solubility of BaTe in PbTe is limited to about 4%, possibly because of the relatively large difference in lattice constants between PbTe (6.460 Å) and BaTe (7.001 Å). These results imply that PbSrSeTe grown lattices matched to PbTe is a promising material system for long wavelength diode lasers and LEDs but that BaTe is too large in lattice size for this application.

A new binary material, $BaTe_2$, the first alkaline earth metal dichalcogenide prepared using flux-growth technique, has been prepared. It belongs to the tetragonal space group I4/mcm (No. 140) with lattice constants: $a = 7.81$ Å, $c = 8.898$ Å, and $Z = 4$. $BaTe_2$ is a Zintl-type compound isostructural to SrS_2. Pairs of tellurium atoms form dimeric units $(Te_2)^{2-}$ with a Te–Te separation of 2.7722(8) Å. The synthesis of $BaTe_2$ at relatively low temperature has provided an alternative and convenient route for preparing new compounds in this category.

Barium telluride has been sadly overlooked in industry but not as a research subject in the literature. According to early sources, BaTe ought not to exist but a few workers have found methods to prepare it.

However, the physical data such as melting point for this compound have not been available. It is, however, readily available commercially.

Radium Telluride

Radium telluride has the molecular formula of RaTe and the molecular weight of 353.6254 g/mol. It can be prepared by heating the elements together in an inert atmosphere:

$$\mathrm{Ra + Te + heat \Rightarrow RaTe}$$

Te melts at 450 °C and Ra melts at 695 °C. A heating temperature of 750 °C is sufficient to cause complete reaction. RaTe powder can also be prepared by reaction of stoichiometric quantities of Ra and Te in a pure graphite crucible in vacuum at 480 °C during 48 h. Its molecular weight is 305.36 g/mol. Radium telluride has no CAS number. It is expected to be a white, crystalline solid with the rock salt structure. However, it has never been prepared. Moreover, there is no report of such a compound in the scientific literature and there is no demand for this material. It is not available commercially.

3.4.3. Alkaline Earth Tellurites

Beryllium Tellurite

Beryllium tellurite has the molecular formula of $BeTeO_3$ and the molecular weight of 184.61 grams per mole. It can be prepared by means of the solid-state reaction:

$$\mathrm{BeO + TeO_2 + heat \Rightarrow BeTeO_3}$$

An inert atmosphere is required. This salt is a metatellurite but its formation and physical properties have not been reported in the literature. If a solution method is used, the result is likely to be quite different in that a hydroxy-tellurite is formed:

$$\mathrm{BeCl_2 + Na_2TeO_3 \Rightarrow [Be(OH)]_2TeO_3}$$

Additionally, this compound can be prepared by reacting tellurium dichloride in a solution of beryllium chloride:

$$\mathrm{BeCl_2 + 2TeCl_2 + 4H_2O \Rightarrow Te + [Be(OH)]_2TeO_3 + 6HCl}$$

Nonetheless, there is absolutely no description of these compounds in the literature and whether a hydrate appears remains unknown.

Beryllium tellurite has no CAS number and no manufacturer is listed as a commercial source.

Magnesium Tellurite

Magnesium tellurite has the molecular formula of $MgTeO_3$ and the molecular weight of 199.9032 g/mol. It can be formed by the solid-state reaction:

$$\mathrm{MgO + TeO_2 + heat \Rightarrow MgTeO_3}$$

An inert atmosphere is required. This salt is a metatellurite. If a solution method is used, the result is likely to be quite different in that a hydrate is formed:

$$\mathrm{MgCl_2 + Na_2TeO_3 \Rightarrow MgTeO_3}$$

Additionally, this compound can be prepared by reacting tellurium dichloride in a solution of magnesium chloride:

$$\mathrm{MgCl_2 + 2TeCl_2 + 3H_2O \Rightarrow Te + MgTeO_3 + 6HCl}$$

In all cases involving solution chemistry, the product is either a pentahydrate or hexahydrate, $MgTeO_3 \cdot 5H_2O$ or $MgTeO_3 \cdot 6H_2O$. The former results if the solution temperature is ~80 °C while the hexahydrate results at T_{Soln} °C < 25 °C.

The molecular weights of these compounds are 289.9799 g/mol and 307.9952 g/mol, respectively. If the hexahydrate is heated, a loss of water of hydration occurs at about 105 °C. The further loss of water has not been published in the literature but is estimated to be:

$$\mathrm{MgTeO_3 \cdot 5H_2O \xrightarrow{180^\circ C} MgTeO_3 \cdot H_2O \xrightarrow{240^\circ C} MgTeO_3}$$

Magnesium tellurite occurs as a mineral, **zemannite** (*Hydrated magnesium zinc iron tellurite*) = $Mg_{0.5}[Zn^{2+}\ Fe^{3+}\ (TeO_3)_3] \cdot 4.5\ H_2O$ whose molecular weight is 741.25 g/mol.

Polycrystalline samples of $MgTeO_3$ have been prepared by a conventional solid-state reaction technique at 750 °C. The XRD analysis showed the formation of a single-phase $MgTeO_3$ compound with cell parameters $a = 4.421$ Å, $b = 14.916$ Å and $c = 12.289$ Å in an orthorhombic crystal system. Detailed studies of dielectric and electrical properties confirmed that the compound has a sharp ferroelectric phase transition of first order.

The structure of the hexahydrate has also been studied. It is rhombohedral with a space group of R3 and $a = 3.011$ Å, $c = 5.965°$, $\alpha = 97.36°$, $V = 211.3$ Å^2, $Z = 1$. Its density is 2.42. The structure is isomorphous with $MgSO_3 \cdot 6H_2O$.

Magnesium tellurite has no CAS number. Only a few manufacturers are listed as a supplier of this compound.

Calcium Tellurite

Calcium tellurite has the molecular formula of $CaTeO_3$ and the molecular weight of 233.6015 g/mol. It can be formed via the solid-state reaction:

$$\mathrm{CaO + TeO_2 + heat \Rightarrow CaTeO_3}$$

An inert atmosphere is required. This salt is a metatellurite. If the solution method is used, a monohydrate is formed:

$$\mathrm{CaCl_2 + Na_2TeO_3 \Rightarrow CaTeO_3 \cdot H_2O + 2NaCl}$$

Additionally, this compound can be prepared by reacting tellurium dichloride in a solution of calcium chloride:

$$CaCl_2 + 2TeCl_2 + 3H_2O \Rightarrow Te + CaTeO_3 \cdot H_2O + 6HCl$$

In all cases involving solution chemistry, the product is a monohydrate. Its CAS number is 13812-57-2 and its molecular weight is 233.6915 g/mol.

Calcium tellurite occurs in mineral form:

Carlfriesite (*calcium tellurite*) = $CaTe_3O_8$ or $CaTe^{4+}Te^{6+}O_8$

Crystal system: monoclinic

Class (H-M): $2/m$ – prismatic

Space group: B_2/b {B_112/b} {C_2/c} {C_12/c_1}

Cell parameters: $a = 12.576$ Å, $b = 5.662$ Å, $c = 9.994$ Å, $\beta = 115.56°$

Ratio: a:b:c = 2.221:1:1.765

Unit cell volume: $V = 641.98$ Å^3 (calculated from unit cell), Z**:** 4

Mroseite (calcium tellurite carbonate oxide)

$CaCO_3 \cdot TeO_2 = \{CaTe^{4+}(CO_3)O_2\}$

Molecular weight = 259.69 g/mol

$a = 6.93$ Å, $b = 11.16$ Å, $c = 10.54$ Å, $Z = 8$, $V = 815.15$ Å^3, Density = 4.23 g/cm^3

Orthorhombic-dipyramidal, symbol (2/m 2/m 2/m), space group: Pbca

In the solid-state method of synthesis, an excess of TeO_2 produces a combined product of tellurium dioxide and the tellurite that has a different composition and structure from the tellurite:

$$CaO + 2TeO_2 \Rightarrow CaTe_2O_5 = CaTeO_3 \cdot TeO_2$$

In contrast to the tellurite, this compound, a "ditellurite", has received some attention in the literature. When the oxides, $0.30[MgO_xCaO_{30-x}] - 0.70[TeO_2]$, with $0 \leq x \leq 30$ mol %, were heated together at 750 °C for 4 h, the resulting compounds were identified by means of X-Ray diffraction, Raman and infrared spectroscopy. The X-ray diffraction results showed that two phases are observed in the samples, which have the separate compositions: $MgTe_2O_5$ and $CaTe_2O_5$. Raman spectroscopy studies showed that the vibrations of the samples are identical with α-TeO_2 vibrations, with a shift of about 40–50/cm. Strong bands are observed around 435, 616, 689, 785, and 807/cm. As the concentration of the modifier, MgO and CaO increased, the coordination of TeO_4 was transformed from the corner-sharing structure, α-TeO_2, to the edge sharing, β-TeO_2, structure.

The phase diagram of the CaO–TeO_2 system has been experimentally determined in the composition range 50–100 mol% TeO_2 employing DTA, room temperature and high-temperature XRD and quenching techniques. Only two intermediate compounds, $CaTeO_3$ and $CaTe_2O_5$, melting congruently at 1072 °C and 876 °C, respectively, were observed. $CaTeO_3$ exhibited two high temperature polymorphs, β and γ, with corresponding transition temperatures at 882 and 894 °C while $CaTe_2O_5$ showed three phase transformations at 802, 845 and 857 °C. The system has one eutectic reaction between $CaTeO_3$ and $CaTe_2O_5$ at 870 °C and 62.5 mol% TeO_2, that is: α-$CaTeO_3$ + $CaTe_2O_5$ and another one between $CaTe_2O_5$ and TeO_2 at 650 °C and 87 mol% TeO_2, that is: β-$CaTe_2O_5$ + TeO_2.

Single crystals and microcrystalline samples of the calcium tellurite(IV) phases α, β, β′ and γ-$CaTeO_3$ as well as of two solid solutions $Ca_xSr_{1-x}TeO_3$ ($x = 0.55$ and 0.77) have been synthesized and characterized by X-ray diffraction and thermal analysis. A comparative description of the structures and the relations between the polymorphs is given. The main building units of the hitherto unknown structures are isolated $[Te^{IV}O_3]^{2-}$ units and [(Ca,Sr)O_x] (x = 6–8) polyhedra. All structures exhibit channels in which the Te^{IV} electron lone pairs protrude. The low-temperature phase, α-$CaTeO_3$, is stable up to 1168 K. It exhibits nearly cylindrical channels (diameter = 4 Å) and differs structurally from the other phases, whereas the metastable high-temperature phases are closely related to each other. They feature oval channels (shortest and longest diameter = 2 and 8 Å). γ-$CaTeO_3$ can be described as an OD structure of two nonpolar layers with layer groups $p12_1/m1$ and $p12_11$. The γ-$CaTeO_3$ crystal under investigation consists of two polytypes with a maximum degree of order. The two phases $CaxSr_1$-$xTeO_3$ ($x = 0.55$ and 0.77) are isostructural to the MDO_1 polytype of γ-$CaTeO_3$. β-$CaTeO_3$ shows a distinct reversible phase transition at 293 K. The low-temperature modification β′-$CaTeO_3$ as well as its high-temperature modification β-$CaTeO_3$ can be considered as three-fold superstructures along [100] based on the MDO_1 polytype of γ-$CaTeO_3$.

The crystalline phases of **glasses** in TeO_2–CaO system revealed α-TeO_2 phase which transforms into the stable β-TeO_2 phase up to 500 °C. IR and Raman studies show the transition of TeO_4, TeO_{3+1} and TeO_3 units with increasing CaO content. The value of refractive index and density of glasses have been measured.

Single crystals of a new compound $Ca_4Te_5O_{14}$, were obtained during phase formation experiments in the systems Ca–Te–O. The crystal structure {$Ca_4Te_5O_{14}$: *Pbca*, $Z = 8$, $a = 10.9536$ Å, $b = 16.556$ Å, $c = 15.779$ Å}, was determined and refined from single-crystal X-ray diffraction data. This compound exhibits a new structure type consisting of complex frameworks between the main building units; one-dimensional channels with cavities about 4.0 Å in size are observed. Calcium tellurite(IV), $Ca_4Te_5O_{14}$, is made up of [CaO_7] polyhedra and $Te^{IV}O_3$ and $Te^{IV}O_4$ groups.

The compounds $CaTe_2O_5$ and $SrTe_2O_5$ were obtained as mica-like plates by slowly cooling their melts.

Dielectric properties were similar to those of mica. Optical and infrared spectra showed appreciable transmittance from 0.33 to 7 μm on with a cutoff at 10 μm. The compounds have refractive indices greater than 2. X-ray diffraction studies showed that the calcium and strontium compounds are not isomorphous.

Calcium tellurite is available commercially from several manufacturers.

Strontium Tellurite

Strontium tellurite has the molecular weight of 215.6761 g/mol and the molecular formula of $SrTeO_3$. It can be formed via the solid-state reaction:

$$SrO + TeO_2 + \text{heat} \Rightarrow SrTeO_3$$

An inert atmosphere is required. This salt is a metatellurite. If a solution method is used, a monohydrate is formed:

$$SrCl_2 + Na_2TeO_3 \Rightarrow SrTeO_3 \cdot H_2O + 2NaCl$$

Additionally, this compound can be prepared by reacting tellurium dichloride in a solution of strontium chloride:

$$SrCl_2 + 2TeCl_2 + 3H_2O \Rightarrow Te + SrTeO_3 \cdot H_2O + 6HCl$$

In all cases involving solution chemistry, the product is a monohydrate. Its CAS number is 13812-57-2 and its molecular weight is 233.6915 g/mol. Strontium tellurite ($SrTeO_3$) has been shown by Yamada and Iwasaki (1972) to possess ferroelectric properties (ferroelectric = a substance exhibiting permanent electric polarization that varies in strength with the applied electric field).

The crystal structure of strontium tellurite, $SrTeO_3$, has been determined at room temperature using X-ray diffraction data obtained from single crystals grown by the Czochralski method. Selection of a noncentrosymmetric (*C*2) structure model was confirmed by the second harmonic generation (SHG) test. The structure of strontium tellurite is built up of three types of distorted [SrO_x] polyhedra ($x = 6$, 7 and 8) that share their oxygen anions with TeO_3 pyramidal units. These main anionic polyhedra are responsible for establishing two types of tunnels required for the electron lone pairs of the Te^{4+} cation.

In another systematic investigation of strontium tellurite, $SrTeO_3$, with particular emphasis on crystal chemistry and phase transitions, the structure of the γ-phase has been determined at 583 K using a single-crystal analysis. Both structural and nonlinear optical measurements indicate a β ⇒ γ first-order phase transition temperature that is close to 563 K. The structure of the γ-phase is monoclinic (*C*2) and does not differ essentially from the α-phase (*C*2). Comparison of the α and γ structures shows that the main atomic shifts and tilting are connected with Te_4, Te_5 and Te_6 pyramids.

$SrTeO_3$ has also been studied by powder neutron diffraction (PND) experiments and by SHG method at a series of temperatures between 20 and 560 °C. The $SrTeO_3$ low temperature (22 °C) form was found to crystallize in space group C2/c with the unit-cell parameters, $a = 28.133°$, $b = 5.904$ Å, $c = 28.418$ Å, $\gamma = 114.303°$. The Sr atoms are coordinated by six, seven, or eight oxygen atoms. Each Te atom has a similar "pyramidal" geometry, coordinated by three oxygen atoms having similar TeO bond lengths. The Te^{4+} lone-pair (E) plays an active stereochemical role. The SrO polyhedra form an open framework with two types of channels. Inside the channels the tellurium atoms are located. The TeO_3E pyramids do not connect to each other; instead they share their oxygen atoms with Sr polyhedra. The discontinuous change of the $SrTeO_3$ lattice parameters in the region 260–310 °C and abrupt growth of SHG signal in this temperature region correspond to the onset of the ferroelectric phase in a first-order phase transition. However, from the diffraction data acquired at 410 °C, no evidence of lowering of the symmetry was found. The structure model of the $SrTeO_3$ high temperature (410 °C) modification is proposed in the same space group C2/c. The plausible reasons of the discrepancy between the PND and SHG results have been discussed.

The compound, $SrTe_2O_5$, was obtained as mica-like plates by slowly cooling its melt. Dielectric properties were similar to those of mica. Optical and infrared spectra showed appreciable transmittance from 0.33 to 7 μm on with a cutoff at 10 μm. The compound has a refractive index greater than 2.

Single crystals of $Sr_3Te_4O_{11}$ were grown from $SrTeO_3$–TeO_2 melts. $Sr_3Te_4O_{11}$ crystallizes in the triclinic system, space group *P*1 (No. 1). The lattice parameters are $a = 7.531$, $b = 9.240$, $c = 9.546$ Å, $\alpha = 98.07(1)°$, $\beta = 109.55(1)°$, $\gamma = 102.19(1)°$, $Z = 2$. The $Sr_3Te_4O_{11}$ crystal structure has been solved by X-ray single-crystal techniques up to a final R value 0.0455 and wR^2 value 0.1245, using 2490 observed reflections. $Sr_3Te_4O_{11}$ forms a three-dimensional lattice consisting of trigonal TeO_3 pyramids, trigonal TeO_4 bipyramids, and irregular polyhedra (with 7, 8, or 9 apices) of Sr.

Aluminate sodalites containing the telluride and tellurite ions have been synthesized for the first time. The structures of $Sr_8[AlO_2]_{12}(TeO_3)_2$ and its reduced product $Sr[AlO_2]_{12}Te_2$ have been determined using Rietveld refinement of powder neutron-diffraction (PND) data. In $Sr_8[AlO_2]_{12}Te_2$, the anion occupies a position at the sodalite cage center, while in $Sr_8[AlO_2]_{12}(TeO_3)_2$ the larger tellurite ion is displaced to allow reasonable coordination to the strontium ions.

$Sr_{1-x}Pb_xTeO_3$ ($0 < x < 0.2$) and $Sr_{1-x}La_{2x}Te_{1+2x}O_{3+6x}$ ($0 < x < 0.15$) solid solutions are synthesized (the latter, for the first time), and their properties are studied. The

results demonstrate that partial substitutions of Pb and La for Sr extend the temperature stability range of ferroelectric $SrTeO_3$.

Although a number of research papers have been published, its usage in industry is miniscule. It is, however, available commercially by several manufacturers.

Barium Tellurite

Barium tellurite has the molecular formula of $BaTeO_3$ and the molecular weight of 265.4015 g/mol. Its CAS number is 58440-17-8. It can be formed via the solid-state reaction:

$$BaO + TeO_2 + \text{heat} \Rightarrow BaTeO_3$$

An inert atmosphere is required. This salt is a metatellurite. A series of $BaO–TeO_2$ binary ceramic compounds were explored for microwave dielectric applications with ultralow processing temperatures. During the calcination of mixed $BaCO_3$ and TeO_2 raw powders, $BaTe_4O_9$, $BaTe_2O_6$, $BaTeO_3$, and Ba_2TeO_5 phases were obtained through the sequential phase formations from Te-rich to Ba-rich phases at temperatures ranging from 500 to 850 °C. Sintering temperatures were as low as only 550 °C for the Te-rich phases. Barium tellurate ceramics exhibited excellent microwave dielectric properties with intermediate dielectric permittivities and high-quality factors (Q). The dielectric properties at microwave frequencies were:

$$\varepsilon_r = 10^{-21},\ Q \times f = 34{,}000–55{,}000\ \text{GHz, and}$$
$$TCf = -51 \text{ to } -124\ \text{ppm/°C},$$

depending upon compositions. The structure of the compound, Ba_4TeO_{11} has been solved: It is monoclinic, space group = P1 with $a = 9.4245$ Å, $b = 9.9759$ Å, $c = 7.8877$ Å, $\alpha = 110.58°$, $\beta = 103.27°$, $\gamma = 97.80°$, $V = 658.5$ Å^3, $Z = 2$. The structure consists of TeO_3^{2-} and $Te_3O_8^{4-}$ anions which form $Te_8O_{22}^{12-}$ rings around a center of symmetry with Te–O bonds of about 2.7 Å in length. The Ba^{2+} cations couple these rings together. The TeO_3^{2-} has the usual pyramidal shape while the $Te_3O_8^{4-}$ anion has a pseudo two-fold axis.

If a solution method is used, a trihydrate is formed:

$$BaCl_2 + Na_2TeO_3 \Rightarrow BaTeO_3 \cdot 3H_2O + 2NaCl$$

Additionally, this compound can be prepared by reacting tellurium dichloride in a solution of strontium chloride:

$$BaCl_2 + 2TeCl_2 + 3H_2O \Rightarrow Te + BaTeO_3 \cdot 3H_2O + 6HCl$$

In all cases involving solution chemistry, the product is either a trihydrate or a monohydrate. The trihydrate CAS number is 28557-54-2 and its molecular weight is 319.4477 g/mol. The trihydrate is obtained at ~20 °C and the monohydrate at >80 °C solution temperature.

The crystal structure of barium tellurite monohydrate has been solved. The crystals are monoclinic, $P2_1/a$ (C_{2h}^5), with $a = 8.582$ Å, $b = 7.631$ Å, $c = 7.704$ Å, $\beta = 106.2°$, $V = 478.1$ Å^3, $Z = 4$ with a density of 4.62 g/cm^3. The structure contains TeO_3 pyramids with Te–O distances of 1.864 Å. The water molecule is loosely coordinated to a Te atom. The Te–O distance being 3.33 Å. One other oxygen atom has a second Te atom as a neighbor at a distance of 3.03 Å. There are systematic absences at: k0l for h-odd and 0h0 for k-odd.

The standard molar Gibbs energy of formation of barium tellurite, $BaTeO_3$(s), was determined by the transpiration technique using pure oxygen as the carrier gas in the temperature range 1133 to 1260 K. The condensate was exclusively identified as TeO_2(s) by chemical analysis. From a quantitative chemical analysis of the condensed TeO_2(s), the vapor pressure of TeO_2(g) over pure $BaTeO_3$(s) was calculated and is given by: $\ln \{p(TeO_2,g)/\text{kPa} \pm 0.1\} = 18.64 - 30863.2 \cdot (K/T)$. The Gibbs energy of formation of $BaTeO_3$(s) was computed from the values of ln {p(TeO_2, g)/kPa} and the values of $\Delta_f G_m^\circ$ for BaO(s) and TeO_2(g) taken from the literature. This is given by $\{\Delta_f G_m^\circ(BaTeO_3,(s),T)/\text{kJ/mol}\} = -856.5 + 0.2067$ (T/K). The enthalpy increments of $BaTeO_3$(s) were measured using a high-temperature Calvet microcalorimeter in the temperature range 304 to 1000 K. Enthalpy increment values are represented by a polynomial of the form $\{\Delta H°(T) - \Delta H°(298.15\ K)\}/(J_{mot\text{-}1}) = -39{,}190 + 118.96$ (T/K) + [4.235×10^{-3} (T/K)]^2 + 9.975×10^5 (K/T), with an accuracy of ±0.4% over the interval: (304° ≤ T/K ≤ 1000°).

It is possible to achieve a "zero-stress" glass with barium selenite (defined as a glass that no internal strain due to external stress during its formation). Zero stress-optic glasses are achieved traditionally through a high content of lead oxide or other closely related p-block metal oxide. It has been found that the underlying cause for this behavior is the combination of high metallicity and low coordination numbers adopted by compounds such as lead oxide. Barium tellurite glasses also show zero stress-optic and negative stress-optic response, at very low barium content. This response results from the fact that barium oxide bonds have very high metallicity, and at the same time barium modifies tellurite by lowering the Te coordination number. The two effects together are sufficient to produce zero stress-optic response.

The properties of novel ternary tellurite glasses, based on the $TeO_2–BaO–Bi_2O_3$ system, have been reported for their applications in online chemical sensing and process control by characterizing the fundamental frequencies of molecular vibrations in the 2–5 μm spectral region of mid-IR. The chemical sensing for process control also requires above room temperature operation (>100 °C) for prolonged periods of time. Bulk samples of ternary tellurite glasses with

a number of different compositions were prepared using the heavy molecular weight oxides of TeO_2, BaO, and Bi_2O_3. Infrared and Raman spectroscopic analysis were carried out together with DTA to study the relationship between glass structure and thermal and viscosity properties. The temperature dependence of the viscosities of the glasses was also reported.

The Mössbauer spectrum of tellurite glasses, containing 5-mol% Fe_2O_3 as a probe, consisted of a paramagnetic quadrupole doublet with an isomer shift of 0.39 ± 0.01/ms. This indicated that Fe^{3+} ions are present at substitutional sites of Te^{4+} ions constituting distorted TeO_4 trigonal bipyramids, each of which has one oxygen vacancy at an equatorial site. On increasing the K_2O content from O to 35 mol%, the quadrupole splitting (Λ) for potassium tellurite glasses decreases continuously from 0.76 to 0.44 mm/s. On the other hand, Λ for magnesium and barium tellurite glasses increases with increasing MgO and BaO content, respectively. When the alkali or alkaline earth oxide contents are the same as each other, Λ increases in proportion to the ionic potential (Z/r) of the alkali or alkaline earth metal ion. These results suggest that the glass matrices of alkali and alkaline earth tellurite glasses are continuously changed into chains or a three-dimensional network structure, respectively. DTA studies revealed that there exists a linear relationship between the glass transition temperature, T_g, and the quadrupole splitting, Λ, indicating that T_g is primarily determined by the magnitude of the distortion of TeO_4 trigonal bipyramids. This relationship is also applicable to several other oxide glasses.

Thermal resistance against crystallization, electronic polarizabilities and optical basicities of ternary tellurite glasses of R_2O–R′O–TeO_2 (R = Li, Na, K, R′ = Mg, Ba, Zn, $TeO_2 = 70$ to 80 mol%) having a high potential as new optical functional glasses are examined from differential thermal analyses, density and refractive index measurements. Ternary tellurite glasses containing ZnO or both Li_2O and BaO show a high resistance against recrystallization. Large electronic polarisabilities of oxide ions of 2.1–2.4 Å and large optical basicities of 0.9–0.97 are obtained even in the ternary tellurite glasses. Correlation between experimental optical basicities $\Lambda(n_0)$ estimated using refractive index and theoretical optical basicity σth calculated using optical basicity values of each oxide is examined. It is proposed that the modified optical basicity value for TeO_2 oxide, $\Lambda(TeO_2) = 0.93$ gives a good agreement between $\Lambda(n_0)$ and Λ_{th}. The effect of glass structure (i.e.−TeO_4 and TeO_3 network structural units) on the optical basicity of tellurite glasses and the validity of large electronic polarisabilities of oxide ions was also examined.

Barium tellurite has not found much usage in industry but is available commercially. In spite of the extensive study of barium tellurite as a component of tellurite glasses, the physical properties such as melting point, etc. are not available.

Radium Tellurite

Radium tellurite has the molecular formula of $RaTeO_3$ and the molecular weight of 354.0969 g/mol. It has no CAS number. It can be formed via the solid-state reaction:

$$RaO + TeO_2 + \text{heat} \Rightarrow RaTeO_3$$

An inert atmosphere is required. This salt is a meta-tellurite. It can also be formed by a solution method:

$$RaCl_2 + Na_2TeO_3 \Rightarrow RaTeO_3 + 2NaCl$$

Additionally, this compound can be prepared by reacting tellurium dichloride in a solution of strontium chloride:

$$RaCl_2 + 2TeCl_2 + 3H_2O \Rightarrow Te + RaTeO_3 + 6HCl$$

The question of a hydrate remains unknown. There is absolutely no mention of this compound in the scientific literature and its physical properties remain unknown. There is no listed supplier for this compound and it is doubtful that it has ever been prepared.

3.4.4. Alkaline Earth Tellurates

The two forms of telluric acid create *tellurate* salts containing the TeO_4^{2-} and TeO_6^{6-} anions. The former is tetrahedral in structure while the latter is octahedral. Salts of these are named "meta-" and "ortho-" tellurates.

Beryllium Tellurate

Beryllium tellurate has the molecular formula of $BeTeO_4$ and the molecular weight of 200.61 grams per mole. Its solubility is 6.72 g/100 ml at 20 °C. It can be prepared by the solid-state reaction of TeO_3 and BeO:

$$BeO + TeO_3 \Rightarrow BeTeO_4$$

This is the tetragonal composition. It can also be formed in the same manner by solid-state reaction of telluric acid:

$$BeO(\text{solid}) + H_2TeO_4(\text{solid}) \Rightarrow BeTeO_4(\text{solid}) + H_2O(\text{gas})$$

Telluric acid is soluble in water and produces $Te(OH)_4O^{2-}$ anions in solutions. If beryllium chloride is added, the product is a tetrahydrate:

$$BeCl_2(aq) + H_2Te(OH)_4(aq) \Rightarrow \{Be(OH)\}_2Te(OH)_4$$

The Lewis structure is shown in Fig. 3.63.

However, the literature presents the formulation as $BeSeO_4 \cdot 4H_2O$, i.e. the meta-tellurate. Note that a compound such as $\{Be(OH)\}_6TeO_6$ is possible or $\{Be(OH)\}_4 \cdot H_2TeO_6$. It is said to be isomorphous

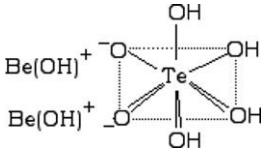

FIGURE 3.63

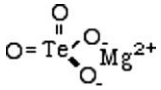

FIGURE 3.64

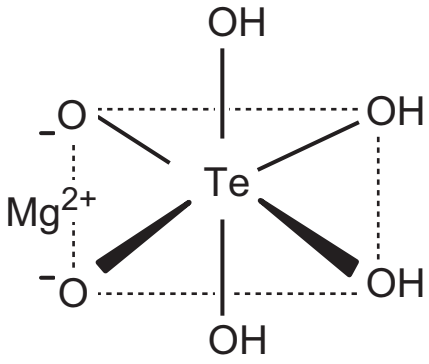

FIGURE 3.65

with the sulfate and loses water at 105 °C forming the dihydrate. If so, then the dehydration reaction involves:

$$\{Be(OH)\}_2Te(OH)_4 + \text{heat} \Rightarrow \{Be(OH)\}_2TeO_4 + 2H_2O$$

where the tellurate complex changes from an octahedral to a tetrahedral configuration. Although the chemistry of beryllium tellurate was studied earlier, it has received no attention in the current literature. According to Topsoe (1872), beryllium tellurate crystallizes in the rhombohedral system with a ratio of lattice parameters $a{:}b{:}c = 1{:}0.9602{:}0.9027$. More recently, this compound has been said to be cubic and have a structure very similar to spinel, $MgAl_2O_4$. A compound having the molecular formula of Be_4TeO_7 is said to be isomorphous to spinel as well. More likely, its composition is $Be(OH)_4H_2TeO_6$.

Beryllium tellurate has no CAS number and is not offered for sale commercially.

Magnesium Tellurate

Magnesium tellurate has the molecular formula of $MgTeO_4$ and the molecular weight of 215.9026 g/mol. Its CAS number is 15852-08-1. Its density is 3.16 g/cm^3 and it is sparingly soluble in water (4.07 g/100 ml of water at 20 °C). It can be prepared by the solid-state reaction of TeO_3 and MgO:

$$MgO + TeO_3 + \text{heat} \Rightarrow MgTeO_4$$

TeO_3 melts at 430 °C and a temperature of 550 °C serves to drive the reaction to completion. This is the tetragonal composition. It can also be formed in the same manner by solid-state reaction of telluric acid:

$$MgO(\text{solid}) + H_2TeO_4(\text{solid}) \Rightarrow MgTeO_4(\text{solid}) + H_2O(\text{gas})$$

This is also tetragonal (magnesium meta-tellurate) and the Lewis structure is shown in Fig. 3.64.

Telluric acid is soluble in water and produces $Te(OH)_4O^{2-}$ anions in solutions (Fig. 3.65).

If magnesium chloride is added, the product is a tetrahydrate:

$$MgCl_2(aq) + H_2Te(OH)_4(aq) \Rightarrow MgTeO_2(OH)_4$$

However, the literature presents the formulation as $MgTeO_4 \cdot 4H_2O$. Note that a compound such as Mg_3TeO_6 is possible or even $Mg_2H_2TeO_6$ (see diagram presented above). Mg_3TeO_6 is rhombohedral, space group R_3, with six molecules in a hexagonal unit cell, where $a = 8.58$ Å. The crystal structure is closely related to Y_6UO_{12} with octahedrally coordinated Mg and Te and mean Mg–O and Te–O bond lengths of 2.18 and 1.75 Å.

The salt, lead magnesium tellurate, Pb_2MgTeO_6, undergoes two structural phase transitions at about 194 and 142 K. The structures of the cubic and of the lower temperature phase have been refined by the Rietveld method at three different temperatures (350, 220 and 6 K). The relative simplicity of the structure has allowed the incommensurately modulated structure for powder samples to be characterized. The modulated displacements of O atoms give rise to a large spread of bond lengths. Pb atoms are disordered and their average positions are away from the threefold axis. The structural resolution is compared to that from the analysis of the symmetry-adapted coordinates of the optic modes becoming totally symmetric in the lower temperature phase.

The literature concerning magnesium tellurate is sparse and limited to structural studies in general.

Magnesium tellurate is available commercially but in limited quantities.

Calcium Tellurate

Calcium tellurate has the molecular formula of $CaTeO_4$ and the molecular weight of 231.68 grams per mole. Its CAS number is 712354-41-1 and its solubility in water is 0.727 g/100 ml at 20 °C. It can be prepared by the solid-state reaction of TeO_3 and CaO:

$$CaO + TeO_3 + \text{heat} \Rightarrow CaTeO_4$$

TeO_3 melts at 430 °C and a temperature of 600 °C serves to drive the reaction to completion. This is the tetragonal meta-tellurate composition. It can also be formed in the same manner by solid-state reaction of telluric acid:

$$CaO(\text{solid}) + H_2TeO_4(\text{solid}) \Rightarrow CaTeO_4(\text{solid}) + H_2O(\text{gas})$$

This is also tetragonal in structure, with the meta-tellurate configuration. Of the two possible configurations, the meta-tellurate is said to be the most stable.

Telluric acid is soluble in water and produces $Te(OH)_4O^{2-}$ anions in solutions: If calcium chloride is added, the product is a tetrahydrate:

$$CaCl_2(aq) + H_2Te(OH)_4(aq) \Rightarrow CaTeO_2(OH)_4$$

However, the literature presents the formulation as $CaTeO_4 \cdot 4H_2O$. If this compound is heated, it loses water at 120 °C to form the dihydrate and 180 °C to form the anhydrate, $CaTeO_4$. The tetrahydrate compound is orthorhombic with a space group of Pbcn and the lattice parameters: $a = 5.231$ Å, $b = 12.676$ Å, $c = 4.977$ Å, $V = 330.0$ Å^3, $Z = 4$ and a calculated density of 4.66 g/cm^3. It contains strings of TeO_6^{2-} octahedra similar to those of Na_2TeO_6. There are systematic absences of 0kl with $k = 2n$ +1, h0l with $l = 2n + 1$ and hk0 with $h + k = 2n + 1$, thus producing the space group Pbcn.

The structure of the dihydrate or the anhydrate has not been published.

Calcium tellurate has been used to isolate telluric acid by heating TeO_2 with and excess of CaO at 975 °C in air at a ration of 1:5 equivalents. The dioxide was completely oxidized and the product was $CaTeO_4$. Ratios less than this affected the overall yield. By adding nitric acid, soluble calcium nitrate and insoluble telluric acid were formed:

$$5CaO(solid) + TeO_2(solid) + heat \Rightarrow CaTeO_4(solid)$$

$$CaTeO_4(solid) + HNO_3(aq) \Rightarrow Ca(NO_3)_2(aq) + H_2TeO_4(solid)$$

If calcium tellurite(IV) is heated, in N_2 atmosphere, with stoichiometric amounts of CaO, the reaction product, proceeding at 380–620 °C, contained orthotellurate and telluride anions formed in disproportionation:

$$3CaTeO_3 + CaO + heat \Rightarrow CaTeO_4 + 2CaTe$$

The scientific literature concerning calcium tellurate is exceedingly limited and no data on its physical properties have been published. It has found little usage in industry but is available commercially in small quantities for use in research.

Strontium Tellurate

Strontium tellurate has the molecular formula of $SrTeO_4$ and the molecular weight of 279.216 grams per mole. Its CAS number is 15852-10-5. It can be prepared by the solid-state reaction of TeO_3 and SrO:

$$SrO + TeO_3 + heat \Rightarrow SrTeO_4$$

TeO_3 melts at 430 °C and a temperature of 600 °C serves to drive the reaction to completion. This is the tetragonal meta-tellurate composition. It can also be formed in the same manner by solid-state reaction of telluric acid:

$$SrO(solid) + H_2TeO_4(solid) \Rightarrow SrTeO_4(solid) + H_2O(gas)$$

This is also tetragonal in structure, with the meta-tellurate configuration. Of the two possible configurations, the meta-tellurate is said to be the most stable (Fig. 3.66).

Telluric acid is soluble in water and produces $Te(OH)_4O^{2-}$ anions in solutions. If strontium chloride is added, the product is a tetrahydrate:

$$SrCl_2(aq) + H_2Te(OH)_4(aq) \Rightarrow SrTeO_2(OH)_4$$

The orthotellurate, $SrTeO_2(OH)_4$, is orthorhombic with $a = 5.574$ Å, $b = 13.114$ Å, $c = 4.911$ Å, $V = 365.6$ Å^3, $Z = 4$ and density (calc) = 5.07 g/cm^3. Strings of Te–O octahedral complexes are apparent in the structure. The orthorhombic Sr_3TeO_6 (with a structure related to cryolite = Na_3AlF_6) forms a solid solution with Ba_3TeO_6 that is quadratic and changes to cubic. The quadratic phase exhibits highly anisotropic thermal expansion above the phase transformation to cubic as it changes between 370 and 670 °C (Fig. 3.67).

The literature concerning strontium tellurate is scattered and little has been published concerning the physical properties of the meta- or ortho-tellurate.

It is available commercially even though it has found little use in industry.

Barium Tellurate

Barium tellurate has the molecular formula of $BaTeO_4$ and the molecular weight of 328.9742 g/mol. Barium

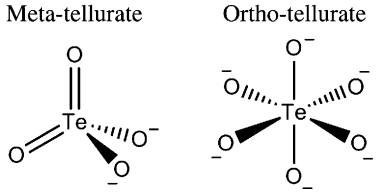

FIGURE 3.66

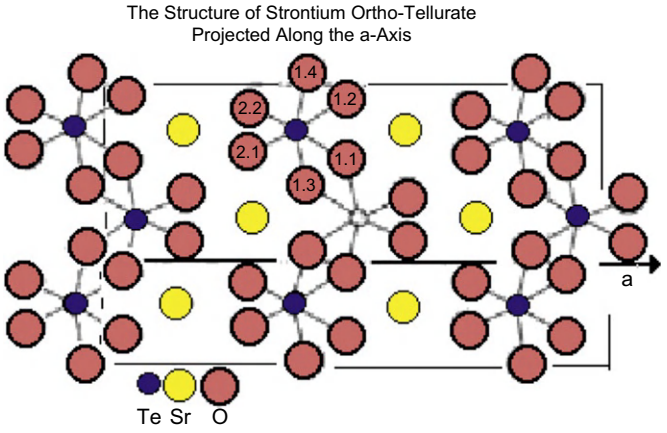

FIGURE 3.67

tellurate has the molecular formula of $BaTeO_4$ and the molecular weight of 328.936 grams per mole. Its CAS number is 13466-24-5 and its solubility in water is 0.727 g/100 ml at 20 °C. It can be prepared by the solid-state reaction of TeO_3 and BaO:

$$BaO + TeO_3 + \text{heat} \Rightarrow BaTeO_4$$

TeO_3 melts at 430 °C and a temperature of 650 °C serves to drive the reaction to completion. This is the tetragonal meta-tellurate composition. It can also be formed in the same manner by solid-state reaction of telluric acid:

$$BaO(\text{solid}) + H_2TeO_4(\text{solid}) \Rightarrow BaTeO_4(\text{solid}) + H_2O(\text{gas})$$

This is also tetragonal in structure, with the meta-tellurate configuration. Of the two possible configurations, the ortho-tellurate is said to be the most stable. A major usage for barium ortho-tellurate has been the production of other ortho-tellurates as well as ortho-telluric acid. Reduction of $BaTeO_4$ with hydrogen has been used to produce BaTe, used as a thermionic emitter in various types of cathodes in electronic instruments. If the ratio of TeO_3 and BaO is varied, it is possible to form a compound by solid-state reaction of:

$$BaO + TeO_3 + \text{Heat} \Rightarrow BaTeO_4$$

Telluric acid is soluble in water and produces $Te(OH)_4O^{2-}$ anions in solutions: If calcium chloride is added, the product is a trihydrate:

$$BaCl_2(aq) + H_2Te(OH)_4(aq) \Rightarrow BaTeO_2(OH)_4$$

However, the literature presents the formulation as $BaTeO_4 \cdot 3H_2O$. If this compound is heated, it loses water at 120 °C to form the dihydrate and 180 °C to form the anhydrate, $BaTeO_4$. This compound is essentially insoluble in water at 0.000523 g/100 ml at 20 °C. The trihydrate is slightly more soluble at 0.0056 g/100 ml but is more soluble in boiling water. It dissolves in most aqueous acids. Its CAS number is 28557-54-2.

The compound, $Ba_2Te(OH)_2O_2$, is known but specific data on its chemical and physical properties have not been clarified.

Barium tellurate is available as the trihydrate commercially.

Radium Tellurate

No data in the technical literature is available concerning this compound.

3.4.5. Alkaline Earth Teflates

Teflic acid can be prepared from barium tellurate and fluorosulfonic acid:

$$5HOSO_2F + BaO_2 \cdot Te(OH)_4 \Rightarrow HOTeF_5 + 4H_2SO_4 + BaSO_4$$

It is also the first hydrolysis product of tellurium hexafluoride:

$$TeF_6 + H_2O \Rightarrow HOTeF_5 + HF$$

The conjugate base of teflic acid is called the teflate anion, F_5TeO^- (not to be confused with "triflate"). Many teflates are known, examples being $B(OTeF_5)_3$ and the acid anhydride $O(TeF_5)_2$. Pyrolysis of the boron compound gives the dimer $(TeF_4O)_2$:

$$2B(OTeF_5)_3 + \text{heat} \Rightarrow 2B(OTeF_5)_2F + (OTeF_4)_2$$

The teflate anion is known to resist oxidation. This property has allowed the preparation of several highly unusual species such as the hexateflates $M(OTeF_5)_6^-$ (M = As, Sb, Bi).

Although some of the transition elements of Groups 3 to 12 do form teflate compounds, the alkaline earths do not. At least, there is no record of their formation or chemical and physical properties available. The following compounds remain unknown at this date:

$$Be(TeF_5O)_2 \cdot Mg(TeF_5O)_2$$

$$Ca(TeF_5O)_2Sr(TeF_5O)_2$$

$$Ba(TeF_5O)_2$$

3.5. POLONIUM-BASED ALKALINE EARTH COMPOUNDS

Polonium, Po, has 39 known isotopes, all of which are radioactive. The chemistry of polonium is similar to that of tellurium and bismuth. Polonium dissolves readily in dilute acids, but is only slightly soluble in alkalis. The hydrogen compound PoH_2 is liquid at room temperature (MP = −36.1 °C, BP = 35.3 °C). Halides of the structure PoX_2, PoX_4 and PoX_6 are known.

The two oxides PoO_2 and PoO_3 are the products of oxidation of polonium.

Fluorides

None listed

Chlorides

Polonium dichloride: $PoCl_2$
Polonium tetrachloride: $PoCl_4$

Bromides

Polonium tetrabromide: $PoBr_4$

Iodides

Polonium diiodide: PoI_2
Polonium tetraiodide: PoI_4

However, these compounds are the only ones that have been characterized in the available scientific literature. Polonium is too metallic in nature and forms no type of "polonites" or "polonates" with the alkaline earths.

CHAPTER

4

Group 15 (N, P, As, Sb and Bi) Alkaline Earth Compounds

OUTLINE

4.1. Alkaline Earth Nitrides and Oxo-Nitrogen Compounds **201**
4.1.1. Nitrogen Acids *201*
Trihydrogen Nitride 201
Nitrous Acid 201
4.1.2. Alkaline Earth Nitrides *201*
Beryllium Nitride 201
Magnesium Nitride 202
Calcium Nitride 205
Strontium Nitride 207
Barium Nitride 209
Radium Nitride 210
4.1.3. Alkaline Earth Nitrites *210*
Beryllium Nitrite 210
Magnesium Nitrite 210
Calcium Nitrite 211
Strontium Nitrite 212
Barium Nitrite 213
Radium Nitrite 215
4.1.4. Alkaline Earth Nitrates *215*
Beryllium Nitrate 215
Magnesium Nitrate 216
Calcium Nitrate 218
Strontium Nitrate 220
Barium Nitrate 221
Radium Nitrate 223

4.2. Alkaline Earth Phosphides and Oxo-Phosphorous Compounds **223**
4.2.1. Phosphorous Oxy-Acids *223*
Phosphorous Oxide Anhydrides 223
Phosphorous Acids 224
4.2.2. Alkaline Earth Phosphides *229*
Beryllium Phosphide 229
Magnesium Phosphide 230
Calcium Phosphide 231
Strontium Phosphide 232
Barium Phosphide 233
Radium Phosphide 234
4.2.3. Alkaline Earth Hypophosphites *234*
Beryllium Hypophosphite 234
Magnesium Hypophosphite 235
Calcium Hypophosphite 236
Strontium Hypophosphite 236
Barium Hypophosphite 237
Radium Hypophosphite 237
4.2.4. Alkaline Earth Phosphites *237*
Beryllium Phosphite 238
Magnesium Phosphite 238
Calcium Phosphite 239
Strontium Phosphite 239
Barium Phosphite 240
Radium Phosphite 241
4.2.5. Alkaline Earth Phosphates *241*

4.1. ALKALINE EARTH NITRIDES AND OXO-NITROGEN COMPOUNDS

Nitrogen has three valence states, N^{3-}, N^{3+} and N^{5+} or "nitrides, nitrites" and "nitrates". The compounds formed with these anions are based upon the acids, H_3N, HNO_2 and HNO_3.

4.1.1. Nitrogen Acids

Trihydrogen Nitride

The hydride of nitrogen is NH_3, an azane known as ammonia. Nitrogen forms a quasi-like hydride, NH_3. It is normally encountered as a gas. However, it does not behave as a typical hydride in that it does not decompose in water to form hydrogen but dissolves in water to form a weak base:

$$NH_3 + H_2O \Rightarrow NH_4^+ + OH^-$$

Ammonia, as used commercially, is often called *anhydrous ammonia.* This term emphasizes the absence of water in the material. It is lighter than air, its density being 0.589 times that of air. It is easily liquefied due to the strong hydrogen bonding between molecules; the liquid boils at −33.3 °C, and solidifies at −77.7 °C (195 K, −108 F) to white crystals. Because NH_3 boils at −33.34 °C, the liquid must be stored under high pressure or at low temperature. Its solubility in water is 47% (0 °C), 31% (25 °C), 28% (50 °C). Its density is 0.86 g/cm^3 (1.013 bar at boiling point), 0.73 g/cm^3 (1.013 bar at 15 °C), 681.9 g/cm^3 at −33.3 °C (liquid), 817 g/cm^3 at −80 °C (transparent solid). It is a flammable gas with a flash point of 11 °C and an auto-ignition temperature of 651 °C. Nitrides of the alkaline earths are generally made by heating the metals in pure nitrogen gas.

Nitrous Acid

Nitrous acid (molecular formula = HNO_2) is a weak and monobasic acid known only in solution and in the form of nitrite salts. Nitrous acid rapidly decomposes into nitrogen oxide, nitric oxide and water when in solution:

$$2HNO_2 \Rightarrow NO_2 + NO + H_2O$$

It can also decompose into nitric acid and nitrous oxide and water.

$$4HNO_2 \Rightarrow 2HNO_3 + N_2O + H_2O$$

Nitric acid (HNO_3), also known as "aqua fortis" and "spirit of nitre", is a highly corrosive and toxic strong acid that can cause severe burns. It is colorless when pure and a slight yellow when "glacial". Older samples tend to acquire a yellow cast due to the accumulation of various oxides of nitrogen. If the solution contains more than 86% nitric acid, it is referred to as "fuming nitric acid". Fuming nitric acid is characterized as "white fuming nitric acid" and "red fuming nitric acid", depending on the amount of nitrogen dioxide present.

4.1.2. Alkaline Earth Nitrides

Beryllium Nitride

Beryllium nitride has the molecular formula of Be_3N_2 and the molecular weight of 55.0652 g/mol. It can be prepared from the elements at high temperature (1100–1500 °C). Be_3N_2 decomposes in vacuum into beryllium and nitrogen:

$$3Be + N_2 + \text{heat} \Rightarrow Be_3N_2 + \text{heat (Vac)} \Rightarrow 3Be + N_2$$

It is a white to yellow powder with a density of 2.71 g/cm^3. Its melting point is 2208 °C and a boiling point of 2240 °C. Its CAS number is 1304-54-7. It is soluble in water and is readily hydrolyzed forming beryllium hydroxide and ammonia:

$$Be_3N_2 + 3H_2O \Rightarrow 3Be(OH)_2 + 2NH_3$$

It has two polymorphic forms: cubic α-Be_3N_2 with a defect anti-bixbyite structure ($a = 8.1452$ Å), and hexagonal β-Be_3N_2. A three-dimensional structure is shown in the following Fig. 4.1.

It reacts with silicon nitride, Si_3N_4 in a stream of ammonia at 1800–1900 °C to form $BeSiN_2$. Calorimetric determinations of the heats of reaction of beryllium

FIGURE 4.1

TABLE 4.1

Enthalpy of formation energy		Entropy of formation			Gibbs free energy
(kcal/mol)	(kJ/mol)	(cal/K)	(J/K)	(kcal/mol)	(kJ/mol)
−140.6	−588.2704	8.16	34.14144	−127.4	−533.0416

and of α- and β-beryllium nitride with chlorine has produced the following heats of formation (Table 4.1):

$$\Delta H^{\circ}_{f_{298}}(\alpha\text{-}BeCl_2) = -117.1 \text{ kcal/mol}$$
$$\Delta H^{\circ}_{f_{298}}(\alpha\text{-}Be_3N_2) = -141.0 \text{ kcal/mol}$$
$$\Delta H^{\circ}_{f_{298}}(\beta\text{-}Be_3N_2) = -136.7 \text{ kcal/mol}$$

Another calorimetric determination of the heat of reaction of beryllium with ammonia gave a heat of formation of α-beryllium nitride, $\Delta H^{\circ}_{f_{298}}(\alpha\text{-}Be_3N_2) = -140.5 \pm 0.3$ kcal/mol. $\alpha\text{-}Be_3N_2$ has the space group of Ia3 while that of $\beta\text{-}Be_3N_2$ is $P6_3/mmm$. The low temperature heat capacity, C_p, of $\alpha\text{-}Be_3N_2$ at 0 °C is 15.39 cal/mol.

Beryllium nitride ($\beta\text{-}Be_3N_2$) vaporizes congruently in the range 1640° to 1960 K by the reaction:

$$Be_3N_2(\text{solid}) \Rightarrow 3Be(\text{gas}) + N_2(\text{gas}).$$

The equilibrium nitrogen partial pressure, in atmospheres, at the composition for congruent sublimation is given by the expression:

$$\log P_{N2} = [-1.952 \times 10^4/T] + 6.509$$

The measured enthalpy of decomposition (370 kcal at 298 K) yields an enthalpy of formation for Be_3N_2(s) of -136 ± 6 kcal/mol. The upper limit to the evaporation coefficient at 1600°–2000 K can be set as 10^{-4}. The apparent enthalpy of activation for the reaction is 409 ± 7 kcal/mol at 1800 K.

Beryllium nitride reacts with mineral acids producing ammonia and the corresponding salts of the acids:

$$Be_3N_2 + 6HCl \Rightarrow 3BeCl_2 + 2NH_3$$

Beryllium nitride is salt-like. The literature presents the formulations as containing Be^{2+} cations whereas they are, in reality, hydroxylated ($Be(OH)^{+}$) cations. The reaction, $Be(H_2O)_n^{2+} \Rightarrow Be(H_2O)_{n-1}^{+} + H^{+}$ is known. In strong alkali solutions, a beryllate forms, with evolution of ammonia:

$$Be_3N_2 + 6NaOH \Rightarrow 3Na_2BeO_2 + 2NH_3$$

Both the acid and alkali reactions are brisk and vigorous. Reaction with water, however, is very slow:

$$Be_3N_2 + 6H_2O \Rightarrow 3Be(OH)_2 + 2NH_3$$

Reactions with oxidizing agents are likely to be violent. It is oxidized when heated at 600 °C in air. Beryllium nitride (Be_3N_2) is used in refractory ceramics as well as in nuclear reactors and used to produce radioactive ^{14}C for tracer applications.

Extreme ultraviolet and soft X-ray optical systems require low absorbing materials for many technological applications. It has been determined that this compound can substitute for Be metal, a widely used material in this context. Thus, the dielectric function of Be and Be_3N_2 were determined in the 4–100 eV energy interval by means of reflection electron energy loss spectroscopy. It was found that the absorption coefficient of Be and Be_3N_2 are similar in the 40–100 eV energy range. Thereafter, the superior chemical stability and mechanical properties of Be_3N_2 makes it a promising substitute for Be as optical material in severe environments. Beryllium nitride thin films can be grown on silicon substrates by laser ablating a beryllium foil in a molecular nitrogen ambient. A low-absorption coefficient in the visible region and an optical band gap of 3.8 eV, determined by reflectance ellipsometry, were obtained for films grown at nitrogen pressures higher than 25 mTorr. The results showed that the reaction of beryllium with nitrogen is very effective using this preparation method in producing high-quality films.

The system, nitrides of beryllium, involving Be metal and N_2 gas, has not been investigated thoroughly. At a temperature between 500 and 900 °C, nitride formation is slow (from 24 to 60 h), but can be catalyzed if hydrogen is added to nitrogen, hydrogen (2–6%) being the catalyst for this reaction. Kinetics of the reaction of beryllium with nitrogen indicate that the reaction rate at temperatures up to 850 °C is slow; even at 950 °C, the reaction proceeds two times slower than the corresponding oxidation of beryllium.

To obtain a pure beryllium nitride powder, the metal was reacted with ammonia at a temperature of 1000 °C for 5 h at 800 °C and 17 h at 900 °C to produce a pure product. After subsequent processing of these products in a vacuum at 2000 °C, an X-ray of graphically pure beryllium nitride was obtained.

At temperatures up to 500 °C, Be_3N_2 is resistant to oxidation with dry oxygen but at 1000 °C is rapidly oxidized.

Beryllium nitride is available commercially from several manufacturers.

Magnesium Nitride

Magnesium nitride has the molecular formula of Mg_3N_2 and the molecular weight of 100.9494 g/mol. It can be prepared by the reaction of Mg metal in a pure stream of nitrogen gas:

$$3Mg + 2N_2 \Rightarrow Mg_3N_2$$

At room temperature and pressure, it is a greenish yellow powder. Its density is 2.712 g/cm^3 and it melts at about 1500 °C. Its CAS number is 12057-71-5. It reacts with water to produce ammonia gas, as do many metal nitrides:

$$Mg_3N_2 + 6H_2O \Rightarrow 3Mg(OH)_2 + 2NH_3$$

In fact, when magnesium is burned in air, some magnesium nitride is formed in addition to the principal product, MgO. The Lewis structure can be visualized as in Fig. 4.2.

Where two Mg^{2+} ions are directly linked together. The lattice parameter and coordinates of Mg_3N_2 were obtained. It is a cubic anti-bixbyite structure with lattice parameter $a = 9.9528$ Å. The metal (Mg) atoms are in general positions 48 e of space group *Ia*3 (*x; y; z*). There are two crystallographically different kinds of N atoms: N_1 is in positions 8b (1/4, 1/4, 1/4), and N_2 in positions 24d (x, 0, 1/4). In this structure, the N-arrays are fairly close to ideal cubic close packing. The 12 shortest N–N distances are in the range from 3.31 to 3.72 Å. Each nitrogen atom is coordinated by six Mg atoms. N_1 has six Mg neighbors with a distance of 2.145 Å, while N_2 is coordinated by six Mg with different N–Mg distances ranging from 2.084 to 2.179 Å. The Mg–Mg distances are 2.72 Å.

Formation of magnesium nitride was first discovered by Sainte-Claire Deville and Caron (1854) during a study of sublimation of magnesium in the air. Magnesium nitride is thus formed in the form of colorless needle-like crystals that are rapidly decomposed by water with formation of magnesium hydroxide and ammonia gas. The first systematic study (1885) of the process of formation of magnesium nitride was accomplished by heating magnesium powder in an atmosphere of ammonia. It was found that the reaction between magnesium and nitrogen begins at 450 °C, and proceeds most intensely at 600–700 °C, at atmospheric pressure of ammonia. Temperature dependence of the reaction rate was determined to be parabolic in nature, and the activation energy of the process was found to be 31.7 kJ/mol. It was also established that magnesium nitride is easily obtained by simply heating magnesium metal in a glass container in the air in the flame of a gas burner.

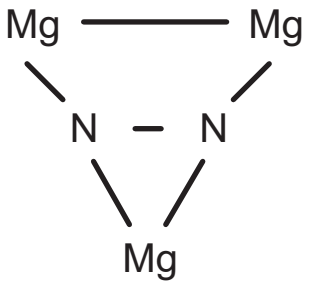

FIGURE 4.2

Most researchers suggested, at that time, a relatively high temperature nitriding of magnesium, in the range from 700 to 900 °C. The interaction of magnesium with nitrogen to form nitride begins at 780–800 °C, and, within 4–5 h at a temperature of 800–850 °C, forms a nitride whose nitrogen content is 27.3–27.6%, that almost exactly corresponds to the calculated content of nitrogen in Mg_3N_2 (which is equal to 27.74%).

The structural changes of Mg_3N_2 under pressure have been investigated up to 40.7 GPa at room temperature by means of angle-dispersive X-ray diffraction (XRD). A reversible, first-order structural phase transition from the ambient cubic phase (*Ia*) to a high-pressure monoclinic phase ($C2/m$) is found to start at 20.6 GPa and was said to be complete at 32.5 GPa. The equation of state determined yielded bulk moduli of 110.7 and 171.5 GPa for the cubic and monoclinic phases, respectively, indicating the higher incompressibility of the high-pressure phase of Mg_3N_2. In addition, a second-phase transition from the monoclinic phase to a hexagonal phase (Pm_1) was predicted around 67 GPa for Mg_3N_2. The electronic band structures of the three phases of Mg_3N_2 were also calculated.

The hydriding and dehydriding reactions occurring in mixtures of lithium and magnesium nitrides (Li_3N and Mg_3N_2) were investigated using fixed composition ratios. A mixture of 80-Li_3N–20 atom% of Mg_3N_2 after heat treatment at 833 K was hydrogenated at 523 K and a pressure of 35 MPa according to the following overall reaction:

$$4Li_3N + Mg_3N_2 + 12H_2 \Rightarrow 12LiH + 3Mg(NH_2)_2$$

This reaction is one of the candidates for reversible hydrogen-storage functions in which 9.1 mass% of hydrogen can be stored in the solid state.

Due to the rapid decomposition of Mg_3N_2 in the presence of water in the atmosphere, the synthesis of single-crystalline Mg_3N_2 nanowires has been a challenge. It has been demonstrated that carbon nanotubes may serve as nanoreactors for a simple thermal reaction process resulting in the fabrication of high-quality, large-yield, single-crystalline Mg_3N_2 nanowires. The Mg_3N_2 nanowires are homogeneously sheathed over their entire lengths with very thin graphitic carbon tubular layers, which effectively prevent their decomposition.

Magnesium nitride was the catalyst in the first practical synthesis of cubic boron nitride. Ab *initio* band structure calculations have been performed for $MgSiN_2$ and Mg_3N_2. Calculations show that both nitrides are semiconductors with direct energy gaps at 3.2 eV. The valence bands are composed mainly of N-2p states hybridized with s and p characteristics of the metals. The bottom of the conduction band consists of the "s" characters of Mg and N for Mg_3N_2, as well as for $MgSiN_2$, while the characters of Si are higher in energy.

The experimental optical-diffuse spectra show an energy gap of about 2.8 eV for Mg_3N_2 and 4.8 eV for $MgSiN_2$, in agreement with the calculated values.

The phase interactions in the Mg_3N_2–BN system at high pressures were refined. Along with the known compound, Mg_3BN_3, Mg_6BN_5 is formed in this system (hexagonal crystal lattice: $a = 5.397$ Å and $c = 10.585$ Å, $Z = 2$). At atmospheric pressure and 900 °C, Mg_6BN_5 breaks down to Mg_3BN_3 and Mg_3N_2. In the range 500–1150 °C, the conductivity of the solid solutions increases with Mg_3N_2 concentration. The ionic transference number is close to unity, and the ionic transport is mainly due to boride ions.

$MgSiN_2$ is noted as an alternative ternary compound for high-temperature applications, showing good physical properties such as a reasonable thermal conductivity, a rather good fracture toughness and hardness, and a good oxidation resistance up to 920 °C. $MgSiN_2$ is also promising as a substrate material with an electrical resistivity at room temperature comparable to (and at high temperature greater than) that of AlN. $MgSiN_2$:Eu has not only luminescence properties similar to AlN, but also a quantum yield for the green band as high as 40%, as compared to 8% for AlN. $MgSiN_2$ crystallizes in an orthorhombic structure, which is derived from the Wurtzite structure. The hexagonal structure is distorted because of the presence of the two metal atoms and the displacement of the nitrogen atoms from the ideal positions in the Wurtzite structure.

Most studies of $MgSiN_2$ have concentrated on its preparation, characterization, mechanical and thermal properties. There has been almost no work performed relating to the electronic properties, except the optical reflectance experiments, which showed $MgSiN_2$ has an energy gap of about 4.8 eV.

Mg_3N_2 is widely used as a catalyst in the preparation of some nitrides, such as silicon nitride ceramics and cubic boron nitride. It was found in 1933 that some alkaline earth metal nitrides M_3N_2 (M = Be, Mg, Ca) have the anti-bixbyite structure. However, it was not until 1997 that the fully refined structure for Mg_3N_2 was demonstrated by use of the neutron time-of-flight diffraction data. In this refined structure, the Mg atoms are at the tetrahedral sites of an approximately cubic close-packed array of N atoms (MgN_4). $MgSiN_2$ is orthorhombic, with lattice parameters: $a = 5.2708$ Å, $b = 10.4692$ Å and $c = 4.9840$ Å. All the atoms are at general positions 4a of the space group *Pna*21. Both Mg^{2+} and Si^{4+} atoms are tetrahedrally coordinated by N^{3+} atoms. The average Mg–N distance is 2.090 Å, which is shorter than that in Mg_3N_2 (2.141 Å). The Si–N distances range from 1.728 to 1.766 Å. The average Si–N distance is 1.752 Å, longer than that in Si_3N_4 (1.732 for α-Si_3N_4, 1.738 Å for β-Si_3N_4). The Mg–Mg distances are about 3.09 to 3.11 Å, which are also longer than those in Mg_3N_2, but shorter than those (about 3.20 Å) in the Mg metal. The shortest N–N distance is about 2.829 Å, larger than that in β-Si_3N_4 (2.77 Å). A three-dimensional structure is shown in the following Fig. 4.3.

Experiments in the system RE–Mg–N (RE = La, Ce, Gd) have been accomplished to explore the possible synthesis of nitrides using Mg as reactive melt and to extend the number of known nitride compounds containing Mg. Since these experiments produce only binary nitrides, mixed Na/Mg melts were used and the quaternary nitrides:

$$BaMg_{3.33}Nb_{0.67}N_4 \quad (1)$$

$$BaMg_{3.33}Ta_{0.67}N_4 \quad (2)$$

$$Eu_4TaMgN_5 \quad (3)$$

were discovered. These were characterized by single-crystal structure analysis. The $BaMg_{3.33}M_{0.67}N_4$ compounds are isotypic to UCr_4C_4 which is a filled $MoNi_4$

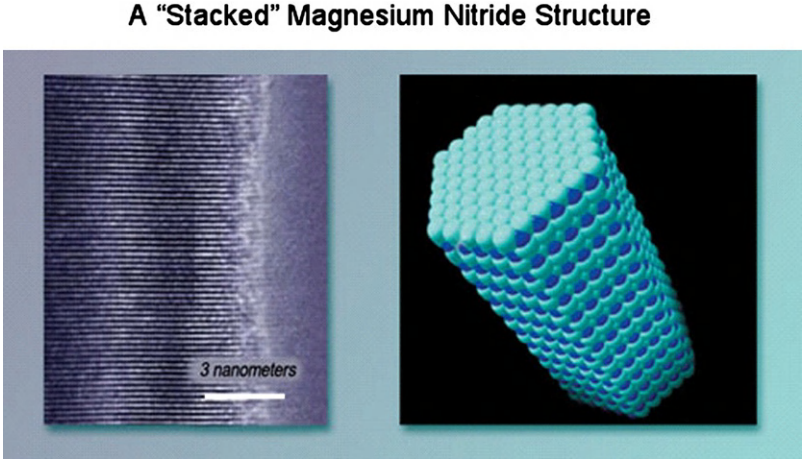

FIGURE 4.3

type and crystallize in the space group I4/*m* (#87) with the lattice parameters $a = 8.5640$ Å and $c = 3.5390$ for (**1**), and $a = 8.5961$ Å and $c = 3.5421$ Å for (**2**). The third type crystallizes in a new structure type in the acentric orthorhombic space group $Pna2_1$ (#33) and with the lattice parameters $a = 12.655$ Å, $b = 10.159$ Å and $c = 6.925$ Å.

The published literature concerning magnesium nitride itself is very sparse and a description of its physical properties is not extensive. There is little demand for this compound in industry. It is, however, available commercially.

Calcium Nitride

Calcium nitride has the formula of Ca_3N_2 and the molecular weight of grams per mole. It can be prepared by the reaction of Ca metal in a pure stream of nitrogen gas:

$$3Ca + 2N_2 \Rightarrow Ca_3N_2$$

A second method is the decomposition of an amide:

$$3Ca(NH_2)_2 + \text{heat} \Rightarrow Ca_3N_2 + 4NH_3$$

This must be accomplished in an inert atmosphere (not nitrogen gas). It is a reddish-brown powder. Its CAS number is 12013-82-0 and its density is 2.76 g/cm^3. It melts at 1195 °C (2183 F). α-Calcium nitride is the commonly encountered form. It has an anti-bixbyite structure similar to Mn_2O_3, except that the positions of the ions are reversed: calcium (Ca^{2+}) ions take the oxide (O^{2-}) positions and nitride ions (N^{3-}) that of the manganese (Mn^{3+}). If Ca metal is burned in air, it forms the oxide, CaO, and the nitride, Ca_3N_2. The latter reacts with atmospheric moisture to produce the hydroxide of calcium and ammonia:

$$Ca_3N_2 + 6H_2O \Rightarrow 3Ca(OH)_2 + 2NH_3$$

It absorbs hydrogen above 350 °C. The Lewis structure diagram is shown in Fig. 4.4.

Calcium is a unique element, as it is the only element in the s-block that forms both ionic and subnitrides with nitrogen. For a long time, it was believed that there were many compounds in the Ca–N system, including α-Ca_3N_2, β-Ca_3N_2 and γ-Ca_3N_2, calcium pernitride, Ca_3N_4 and a compound of composition $Ca_{11}N_8$. α-Ca_3N_2 is the only compound that has been extensively characterized. Further published work has practically ruled out the existence of all other forms of calcium nitride. Those compounds all appear to be a calcium nitride cyanamide, $Ca_4N_2(CN_2)$ or $Ca_{11}N_6(CN_2)_2$. The carbon contamination most likely was derived from steel in crucibles and reactors or even from the calcium metal itself.

α-Ca_3N_2 has been characterized by X-ray powder diffraction and its structure confirmed by a crystal structure refinement using the Rietveld method. A three-dimensional structure is presented as shown on the next page. Ca_3N_2 and the isostructural Mg_3N_2 crystallize in the anti-bixbyite structure of the mineral $(Mn,Fe)_2O_3$ in the body-centered space group of $Ia3(T_7h)$. It has a distorted form of this structure, in which Ca is tetrahedrally coordinated to N, whereas N is octahedrally coordinated to Ca. The general appearance of their infrared and Raman spectra resembles that of the sesquioxides belonging to the same space group. Both compounds decompose into $Mg(OH)_2$ and NH_3, when exposed to the atmosphere. The presence of NH_4^+ vibrational bands in the decomposition products was explained in terms of the existence of Brønsted acid centers on the surface of the solid (Fig. 4.5).

During the initial stages of decomposition, infrared bands characteristic of adsorbed NH_3 were observed, showing that Lewis centers also exist on the surface. The decomposition product $Mg(OH)_2$ has weaker proton-donating centers than that of $Ca(OH)_2$. The kinetics of the decomposition of Mg_3N_2, which is a much slower reaction than that of α-Ca_3N_2, has been studied with Fourier transformation-infrared (FT-IR) microspectrometry. It was shown that the formation of $Mg(OH)_2$ involves a three-dimensional diffusion process

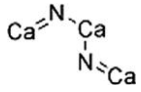

FIGURE 4.4

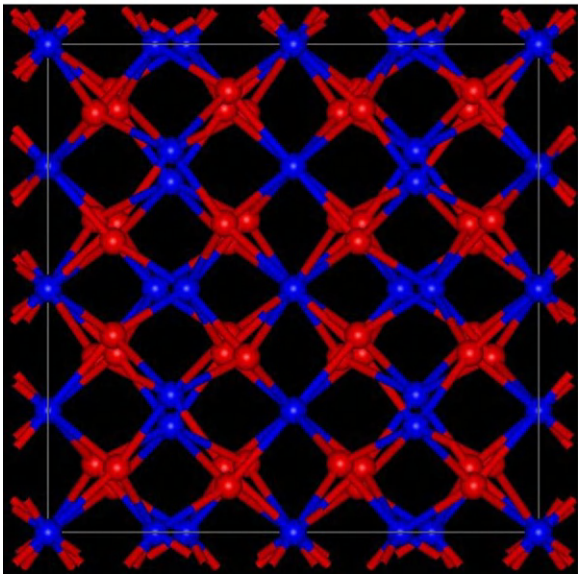

FIGURE 4.5

while the proton donation by the hydroxide to adsorbed NH_3 to form NH_4^+ ions is a quasi-first-order reaction.

It has been found that aluminum nitride single crystals of reproducibly good quality and large size can be grown by a novel technique that involves the use of calcium nitride as a solvent system in the solution growth of these crystals. In general, the method involves the use of calcium nitride (Ca_3N_2) as a solvent for aluminum nitride at elevated temperatures. Aluminum nitride is dissolved by calcium nitride and then recrystallized from solution as a single crystal. The synthesis of single crystals by this method is known as the Solution Growth Method. For example, to synthesize the aluminum nitride material as a crystal, the general procedure is to intimately mix from about 8 to 40 mol % aluminum nitride (AlN) and from about 92 to 60 mol% calcium nitride. The mixture is heated in an appropriate crucible to a temperature above the melting point of the mixture which is generally in the range of about 1525 to 1650 °C. After the temperature of the molten solution is maintained from 1 to 2 h, the solution temperature is slowly cooled to a temperature slightly below its saturated solubility temperature at a programmed rate of from about 0.5 to about 3 °C/h.

Recent advances in the utilization of single crystals for a wide variety of purposes, especially in various electronic surveillance and detection applications, has generated considerable research in the development of improved techniques for growing single crystalline materials. A problem has arisen, however, in that many of the methods relied upon heretofore fail to grow crystals having a reproducibly high quality. Calcium nitride as a high temperature solvent has been used in the recrystallization of refractory aluminum nitride, that is growing single crystals of aluminum nitride from a molten solution containing the refractory material as the solute, and calcium nitride as the solvent. Crystallization is accomplished by the precipitation or crystallization of the solute, the solute being the desired crystal, from the molten solution.

Large, water white aluminum nitride single crystals have never been grown from its melt because of the following reasons. First, aluminum nitride sublimes and decomposes according to the reaction $2AlN(s) \Rightarrow 2Al\,(g) + N_2\,(g)$ at temperatures far below (c.a. 1723 K) the temperature range (3023 K) in which AlN is reported to melt. Secondly, materials that could be used as crucible materials to contain aluminum nitride in its melting temperature range are violently attacked, particularly under high pressures. Thirdly, the state of materials science, as far as crystal growth is concerned, has not developed high-pressure chamber materials capable of sustaining pressures greater than 100 atmospheres for long periods (3 weeks) at elevated temperatures (2000 °C). It is highly improbable, therefore, that in the near future, large, good quality aluminum nitride single crystals will be grown from its own melt at least by present day techniques. The use of molten calcium nitride as a solvent has solved most of these problems.

The sublimation pressure of calcium nitride was measured, based upon the reaction:

$$Ca_3N_2\,(\text{solid}) \Rightarrow Ca\,(\text{gas}) + N_2\,(\text{gas})$$

The second-law and third-law heats of sublimation were found to be 217.3 and 227.9 kcal/mol, respectively. The free-surface vapor pressure of calcium nitride in the temperature range of 1152–1479 K was: $\log P_L \pm 1.108 \times 10^4/T + 3.528$, where P is in atmospheres and T is the absolute temperature.

The high-pressure behavior of Ca_3N_2 was studied up 100 GPa using density functional theory. Evaluation of many hypothetical polymorphs of composition A_3X_2 led to the proposal of four high-pressure polymorphs for both α- and β-Ca_3N_2: (1) an anti-Rh_2O_3(II) structure at 5 GPa, (2) an anti-B-sesquioxide structure at 10 GPa, (3) an anti-A-sesquioxide structure at 27 GPa, and (4) a hitherto unknown hexagonal structure ($P6_3/mmc$), derived from the post-perovskite structure of $CaIrO_3$, at 38 GPa. However, only α-Ca_3N_2 has been confirmed to date.

α-Ca_3N_2 belongs to the series of curious alkaline earth nitride salts that are constrained by their stoichiometry of 3-to-2 divalent alkaline earth cations to trivalent nitride anions, to form odd cubic crystals containing cation vacancies ordered along their <111> axes, in a $2 \times 2 \times 2$ supercell of an anti-fluorite arrangement, that nonetheless exists in a high space group symmetry of Ia-3 [3]. In a high-pressure study using a conventional diamond anvil cell, the nature of these cation vacancies was probed as a function of pressure to a maximum pressure, as measured by the equation of state of Au [5], of 137 Kb. No phase transition was observed in the α-Ca_3N_2 salt to 137 Kb but a compression of the unit cell was observed in diffraction photographs taken of the sample at several pressures, by conventional Debye-Scherrer powder methods.

A similar compound, Ca_2N, has also been discovered. It can be synthesized by heating α-Ca_3N_2 in vacuum. Ca_2N adopts the anti-$CdCl_2$ structure in which two sheets of calcium ions enclose a sheet of N^{3-} ions, with each calcium bonded to three N^{3-} at 2.4500 Å and each nitrogen octahedrally coordinated by six calcium atoms. Within one calcium sheet, each metal has three others at 3.2944 Å and a further six at 3.6271 Å. The distance between two calcium layers with no intervening nitrogen layer is 4.3221 Å, and this intervening region contains no observable electron density. Neutron and X-ray powder diffraction studies have shown that the *c*-axis dimension changes with the synthetic method employed. In the single crystal, *c* is significantly lower, reflecting the higher temperature employed in its formation.

Calcium nitride hydride (Ca_2NH) was obtained as a single-phase material by reacting either calcium metal or calcium hydride (CaH_2) in an argon atmosphere containing 5–7% H_2 and 1–7% N_2. Imide ions substituting for hydride and nitride ions constitute a major chemical defect in this material. Long-range ordering of the nitride and hydride ions occurs, giving rise to a double cubic crystal symmetry. This order breaks down at 600–650 °C. Applying the same reaction conditions to strontium metal results in a mixed phase of strontium nitride hydride and imide. No long-range order in the nitride hydride phase could be observed. Doping Ca_2NH with lithium hydride (LiH) causes the appearance of a second calcium imide phase, whereas doping with sodium hydride (NaH) increases the amount of imide ions as a defect in the nitride hydride structure, thereby decreasing the long-range ordering of nitride and hydride ions.

Closely related to calcium nitride hydride, Ca_2NH, are calcium imide, CaNH, and calcium amide, $Ca(NH_2)_2$. Calcium imide has the rock salt structure, with calcium octahedrally coordinated to nitrogen in a cubic closest packed array of nitrogen ions. Hydrogen is positioned close to the nitrogen ion with a large degree of disorder. Calcium amide has the tetragonal Anatase structure, which is closely related to calcium imide. It can roughly be viewed as two imide unit cells stacked on top of each other, with only half of the calcium ions now occupied. The hydrogen in the amide ions was shown to have a large degree of disorder by assuming in and out of plane movements relative to the nitrogen ion. The compounds have been synthesized via the following reactions:

Ca_2NH has previously been synthesized either by reacting Ca_3N_2 in hydrogen atmosphere or by reacting Ca_3N_2 with CaH_2 in vacuum, both at high temperatures:

$$4Ca_3N_2 \Rightarrow 6Ca_2NH + N_2 \text{ (Reacted in } H_2 \text{ and } T > 850\ ^\circ\text{C)}$$
$$Ca_3N_2 + CaH_2 \Rightarrow 2Ca_2NH \text{ (Vacuum } T > 950\ ^\circ\text{C)}$$

Calcium imide is traditionally obtained by thermally decomposing calcium amide, which in its turn is obtained by thermally decomposing calcium hexaammonia complex (calcium metal dissolved in ammonia):

$$Ca(NH_3)_6 \Rightarrow Ca(NH_2)_2 + 4NH_3 + H_2$$
$$Ca(NH_2)_2 \Rightarrow CaNH + NH_3$$

A great deal of work is currently being undertaken to provide phosphors which absorb the blue emission of (In,Ga)N or (Al,Ga,In)P light-emitting diodes (LEDs). The work has centered around alkaline earth silicide–nitride compositions which have a sufficient crystal field strength to "Stokes Shift" the intrinsic UV absorption of the Eu^{2+} ion to the blue region of the spectrum where the LED emits. A synthetic $Ca_2Si_5N_8$:Eu^{2+} phosphor was prepared through a solid-state reaction and its structural and luminescent properties investigated. Refinement of the crystal structure of $Ca_{1.9}Eu_{0.1}Si_5N_8$ revealed that Eu atoms substituting for Ca atoms occupy two crystallographic positions. Between 10 and 300 K, $Ca_2Si_5N_8$:Eu^{2+} phosphor shows a broad red emission band centered at ~1.97–2.01 eV (617–629 nm). The gravity center of the excitation band is located at 3.0–3.31 eV (374 nm). The centroid shift of the 5*d* levels of Eu^{2+} is determined to be ~1.17 eV (1059 nm), and the red shift of the lowest absorption band to be ~0.54 eV (2296 nm) due to the crystal field splitting. The temperature dependence of photoluminescence (PL) was analyzed by using a configuration coordinate model. The Huang–Rhys parameter $S = 6.0$, the phonon energy $hv = 52$ meV, and the Stokes shift, $S = 0.57$ eV, were obtained. The emission intensity maximum occurring at ~200 K can be explained by a trapping effect. Both PL emission intensity and decay time decrease with temperature increasing beyond 200 K due to the nonradiative process.

However, the main focus of research on LED–phosphor modifiers involves the $(Ba,Sr,Ca)_2Si_5N_8$:Eu^{2+} family which can be "fine-tuned" to emit in specific ranges from green, yellow, orange and red and can be pumped with any blue emitter in the 425–480 nm range very efficiently LED = Light emitting diodes.

Calcium nitride is a minor part of such compositions. Calcium nitride is available from a number of commercial suppliers.

Strontium Nitride

Strontium nitride should have the molecular formula of Sr_3N_2 and the molecular weight of 290.8752 g/mol. However, according to some sources, Strontium does not form the ionic compound Sr_3N_2 and Sr_2N is the only compound that has been properly characterized to date. The reaction of Sr metal in a pure stream of nitrogen gas produces the "subnitride":

$$4Sr + N_2 \Rightarrow 2Sr_2N$$

A second method would be the decomposition of an amide:

$$2Sr(NH_2)_2 + \text{Heat} \Rightarrow 2Sr_2N + 2NH_3 + H_2$$

This must be accomplished in an inert atmosphere (not nitrogen gas). Sr_2N was shown to be iso-structural to Ca_2N. The excess electron is mobile and gives these subnitride materials their electronic conductivity. The electronic conductivity is highly an isotropic and they can therefore be seen as two-dimensional metals, with reasonable conductivity in the direction parallel to the N–A layers.

However, some commercial sources offer "strontium nitride" as Sr_3N_2 (CAS number = 12033-82-8). It is apparently prepared by reaction of Sr metal in a nitrogen atmosphere. Strontium nitride is described as Sr_3N_2,

produced by burning strontium metal in air (resulting in a mixture with strontium oxide) or in nitrogen. Like other alkaline earth metal nitrides, it reacts with water to give strontium hydroxide and ammonia:

$$Sr_3N_2 + 6H_2O \Rightarrow 3Sr(OH)_2 + 2NH_3$$

In air, it strontium metal burns and produces strontium oxide and strontium nitride. But, since it does not react with nitrogen below 380 °C, it will only form the oxide spontaneously at room temperature. To produce the pure nitride, it is necessary to maintain the temperature above 380 °C in air or to heat the metal in pure nitrogen gas. In air, the molten mass, as it cools from 380 °C, tends to convert some of the nitride to oxide. However, a prominent supplier of "Materials Used in the Manufacture of Tomorrow's Phosphor Formulations" (Cerac, Milwaukee, Wisc 53201) offers Ca_3N_2 and Ba_3N_2 for sale but not Sr_3N_2.

The alkaline earth metal nitride compounds: Sr_2N, $(Sr_{0.48}Ba_{0.52})_2N$, Ba_2N, Sr_2NCl and Sr_2NBr have been synthesized and investigated by the means of XRD. These compounds all have crystal structures closely related to the anti-α-$NaFeO_2$ structure type. The reaction products obtained from the nominal starting compositions "Sr_2NH_x" ($0 \leq x \leq 1$) were also analyzed by X-ray powder diffraction. With $x \geq 0.75$, Sr_2NH_{1-x} is the only product observed, but for $x \leq 0.75$, Sr_2N is found in equilibrium with Sr_2NH_{1-x}.

A number of new, layered nitride mixed halides have been synthesized in the quaternary phase systems Sr–N–Cl–Br and Sr–N–Br–I. The variation in structure with composition has been investigated by powder X-ray and powder neutron diffraction techniques and the structure of strontium nitride iodide, Sr_2NI, has been determined for the first time (rhombohedral space group $R-3m$, $a = 4.0103$ Å, $c = 23.1138$ Å, $Z = 3$). A continuous solid solution exists between Sr_2NCl and Sr_2NBr with intermediate compounds adopting the same *anti*-α-$NaFeO_2$ structure (rhombohedral, space group = R-3m) as the ternary end members. A similar smooth and linear relationship between structure and composition is seen from Sr_2NBr to Sr_2NI and hence cubic close packing of metal–nitrogen layers is adopted regardless of halide. While nitride and halide anions occupy distinct crystallographic sites, there is no ordering of the halides in the quaternary materials irrespective of stoichiometry or temperature (between 3 and 673 K).

Sr_2N has been used to produce other subnitrides. Bulk thermal- or filament-initiated reactions of mixed powders of transition metal chlorides and Sr_2N produces transition metal nitrides (TiN, ZrN, HfN, VN, V_2N) in good yield. The products were characterized by X-ray powder diffraction, scanning electron microscopy (SEM)/EDAX, FT-IR, microelemental analysis and imaging XPS. The effect of diluting the reaction by the addition of LiCl was used to lower reaction temperatures and in the case of WCI_4 and Li_3N produced WN. Reaction propagation was investigated by using various mixtures of nitriding reagent (Li_3N, Mg_3N_2, Ca_3N_2), this was correlated with $T_{ad(s)}$ the maximum adiabatic combustion temperature for salt formation only.

A major effort is currently being conducted to produce white-emitting LED (light emitting diode) lights for both outdoor and interior lighting, thereby replacing the "standard" light sources. These LED lights have the advantage of long-life (~30,000 h) and low wattage compared to conventional lamps.

A simple, inexpensive, and high-yield synthetic route to $Sr_2Si_5N_8$:Eu^{2+}-based red nitridosilicate phosphors for white LEDs has been described. Through the chemical reaction of $SrCO_3$, Eu_2O_3, and Si_3N_4 rather than the air-sensitive Sr, Eu, Si(NH), Sr_3N_2, and EuN powders, a complex phosphor consisting of $Sr_2Si_5N_8$:Eu^{2+} (64 wt%) and Sr_2SiO_4:Eu^{2+} (36 wt%) were obtained by firing the powder mixture at 1600 °C under 0.5 MPa N_2. The structural characterization, luminescence spectra, quantum efficiency, and thermal quenching of the synthesized phosphor were investigated and compared with those of $Sr_2Si_5N_8$:Eu^{2+} prepared by the conventional method. It was shown that the emission of the existing Sr_2SiO_4:Eu^{2+} is extremely low (about 0.04% of that of $Sr_2Si_5N_8$:Eu^{2+}) under ultraviolet light irradiation, and it is not responsive under the blue light excitation ($\lambda_{Ex} = 400$–480 nm); therefore, it was concluded that the luminescence of the complex phosphor solely arises from $Sr_2Si_5N_8$:Eu^{2+}. The $Sr_2Si_5N_8$:Eu^{2+}-based phosphor is orange-red in color and emits strongly in the red region of 616–670 nm depending on the Eu^{2+} concentration when excited at $\lambda_{Ex} = 450$ nm. Furthermore, the $Sr_2Si_5N_8$:Eu^{2+}-based phosphor synthesized by this novel method shows equal optical properties, such as high emission intensity, high quantum efficiency, and very low thermal quenching, when compared to those prepared by the conventional approaches. This makes it a promising red luminescent material for white LEDs".

In another research paper, undoped and Eu^{2+}-doped $M_2Si_5N_8$ (M = Ca, Sr, Ba) materials were obtained by a solid-state reaction of MN_x, EuN_x and α-Si_3N_4 powder at 1300–1400 °C under an N_2–H_2 (10%) atmosphere. The maximum solubility of Eu^{2+} is about 7 mol% in the $Ca_2Si_5N_8$ lattice. In contrast, Eu^{2+} can be completely incorporated into the $M_2Si_5N_8$ (M = Sr, Ba) lattice because the $M_2Si_5N_8$ (M = Sr, Ba) compounds are isostructural with $Eu_2Si_5N_8$. Eu-doped $M_2Si_5N_8$ shows a typical broad-band emission of Eu^{2+} in the spectral range from orange to red (570–680 nm) due to the 4f65d ⇒ 4f7 transition. With increasing Eu^{2+} concentration, the emission band shifts to longer wavelength depending on the type of M ion and the Eu content. This was found to be proportional

to the changes of the unit cell volume for M = Sr and Ba. This red shift is related to an increase of the Stokes shift and possibly can also be attributed to some reabsorption by Eu^{2+}. The absorption and excitation bands of $M_2Si_5N_8$:Eu^{2+} materials ranging from 370 to 460 nm perfectly match with the emission of InGaN-based LEDs making them attractive as conversion phosphors for white LED applications. The best material for this purpose was shown to be $Sr_2Si_5N_8$:Eu^{2+} with a conversion (i.e. quantum) efficiency of 75–80% for 465 nm excitation and a very favorable thermal quenching behavior.

A number of nitride-containing compounds have also been studied. These include:

> "Strontium nitride carbodiimide, $Sr_4N_2(CN_2)$, is isostructural with the calcium analog and consists of a framework of edge- and vertex-sharing Sr_6N octahedra forming channels within which almost linear and almost symmetrical carbodiimide anions reside, surrounded by eight strontium ions".
>
> "Single crystals of Sr_2NI have been grown for the first time. Redetermination from single-crystal XRD data confirms the anti-α$NaFeO_2$ structure, previously found from powder diffraction data [Bowman, Smith and Gregory (2006). *J. Solid State Chem.* **179**, 130–139]. Iodide ions occupy octahedral voids between layers of edge-sharing NSr_6 octahedra".
>
> "The synthesis of single crystals of Sr_2NiN_2 has been accomplished in a liquid sodium flux from strontium or strontium nitride, nickel, and sodium azide. The decomposition of sodium azide provides additional nitrogen for the synthesis. The structure of Sr_2NiN_2 is derived from the Na_2HgO_2 structure type. However, Sr_2NiN_2 forms with a twinned superstructure. Single crystal XRD was used to determine the structure of the tetragonal subcell: **I4/mmm**, $a = 3.8874$ Å, $c = 13.992$ Å, $Z = 2$, with the Ni and N positions split into two sites, each half occupied. The superstructure can be modeled as a $2 \times 1 \times 1$ ordering of the subcell in **Pnma**. The physical properties are unusual since Sr_2NiN_2 displays metallic conductivity and Pauli paramagnetism even though it is comprised of isolated NiN_2 units. In addition, Sr_2NiN_2 possesses a Ni^{2+} formal charge, whereas the oxidation states for nickel nitrides are typically Ni^{+} and Ni^{0}".
>
> "The synthesis of calcium, strontium and barium–nitride–fluorides has been accomplished by using a 3 to 1 mol ratio of the metal to metal fluoride for the Sr_2NF and Ba_2NF syntheses, and a 4 to 1 mol ratio for Ca_2NF syntheses. The reaction mixtures were annealed in an inert argon environment at a temperature of 1000 °C for 24 h and then reacted in nitrogen gas for 5 h at 450 °C. Following this treatment, the calcium, strontium, and barium reaction mixtures were sintered in a nitrogen gas flow for 24 h at 1000, 950, 700 °C, respectively. The Ca_2NF that was found was a light yellow color, although colors of the other two phases were not reported. The products were reportedly characterized using Debye-Scherrer powder XRD. The resulting patterns suggested the presence of both the MF_2 and M_2NF phases (where M is a symbol for the appropriate metal) in representative lines".

Strontium nitride is available commercially from several suppliers.

Barium Nitride

Barium nitride purportedly has the molecular formula of Ba_3N_2 and the molecular weight of 439.9944 g/mol. Its CAS number is 12047-79-9. It is offered for sale by several reputable manufacturers but the actual composition and identity may not coincide with the formula presented. Although Mg, Ca (and to some extent Sr) forms a number of compounds based upon the general formula M_3N_2, there is no report in the literature that or Ba forms such compositions. The literature is devoid of any data relating to Ba_3N_2 and the subnitride is mentioned only in the presence of Sr_2N.

Barium nitride has been reported to be metastable and sublimes in the 915 to 1050 °C temperature range. The reported equation for this behavior is: $\log P = 6.38 \times 10^4/T(\mathrm{K})$ and it decomposes when heated beyond this range to form the metal and nitrogen gas, i.e. it is metastable. Thus, the existence of barium nitride is doubtful and no report of its formation or properties exists to date.

The metal combines with nitrogen and hydrogen at elevated temperatures producing barium nitride hydride, Ba_2NH:

$$4Ba + N_2 + H_2 \Rightarrow 2Ba_2NH$$

Barium–nitride–hydride is one of the few documented H^--ionic conductors. It crystallizes in the α-$NaFeO_2$ structure (space group R_m) with distorted Ba-octahedra centered alternately by H^- and N^{3-}. Neutron diffraction shows that the hydrogen ions are distributed independent of temperature over lattice sites: 85% on (3a) and 15% on (6c). At $T > 525$ K a sharp increase of the ionic conductivity can be observed. The diffusion process takes place by uncorrelated jumps of hydrogen ions between regular lattice sites. Using quasielastic neutron scattering techniques and a planar jump diffusion model, we were able to determine the mean residence time on a H^--site to be $\tau = 20 \pm 2$d ps and the diffusion constant D to be 2.1×10^{-5} cm^2/s at $T = 823$ K.

Ba_2N has been used to produce other subnitrides. Bulk thermal or filament-initiated reactions of mixed powders of transition metal chlorides and Ba_3N_2 produces transition metal nitrides (TiN, ZrN, HfN, VN, V_2N) in good yield. The products were characterized by X-ray powder diffraction, SEM/EDAX, FT-IR, microelemental analysis and imaging XPS. The effect of diluting the reaction by the addition of LiCl was used to lower reaction temperatures and in the case of WCI_4 and Li_3N produced WN. Reaction propagation was investigated by using various mixtures of nitriding reagent (Li_3N, Mg_3N_2, Ca_3N_2), this was correlated with $T_{ad(s)}$, the maximum adiabatic combustion temperature for salt formation only

The latest innovation has been the invention of a new class of red-emitting nitride phosphors $M_2Si_5N_8$:Eu^{2+} (M = Ca, Sr, Ba) that has triggered a renewal in the field of luminescent materials. Subsequently, a number of new nitride-based phosphors has been found and

investigated. For $M_2Si_5N_8$:Eu^{2+} (M = Ca, Sr, Ba), it has been reported that unusual long-wavelength Eu^{2+} emission (620–660 nm) with absorption bands in the visible range can be achieved. The long-wavelength emission is attributed to a large covalency and crystal-field splitting effect on the Eu^{2+} 5d band due to the presence of coordinating nitrogen. Later, studies presented the luminescence properties in a series of $Ba_{2-x}Eu_xSi_5N_8$ compounds which revealed two emission maxima peaking at about 600 nm, corresponding to two crystallographic Ba(Eu) sites in the $Ba_2Si_5N_8$ host lattice. The emission maxima shift to longer wavelength with increasing Eu content due to reabsorption processes of Eu^{2+}.

Further work has clarified the solubility of Eu^{2+} in these lattices. It has been established that Eu^{2+} forms the same type of compounds with the Si_5N_8 lattice with corresponding Sr or Ba Si_5N_8 lattices while that of Ca differs. This limits the amount of Eu^{2+} that can be dissolved in the calcium compound as shown in the following Table 4.2.

Barium nitride is offered for sale commercially but the exact nature of its composition remains in doubt.

Radium Nitride

It is doubtful whether such a compound such as Ra_3N_2 could be prepared. Furthermore, there is absolutely no demand or usage in industry for such a compound because of the radioactivity of ^{226}Ra. Whether Ra could form a compound like the nitride hydride, Ra_2NH, remains a mystery.

4.1.3. Alkaline Earth Nitrites

Nitrites are usually prepared by addition of a soluble salt to sodium nitrite. Of this, $NaNO_2$ = sodium nitrite, is usually prepared by electrolytic reduction of the nitrate.

Beryllium Nitrite

According to Sidgwick, Beryllium nitrite cannot be prepared, owing to the weakness of the acid, HNO_2. Parsons states that beryllium nitrite has never been prepared. The efforts of Vogel (1903) proved fruitless as the solution immediately hydrolyzed with loss of the oxides of nitrogen. It might possibly be prepared in nonaqueous solutions. However, there is no record of this having ever been done.

If beryllium nitrite is to be prepared by the usual double decomposition reaction of sodium nitrite and $BeCl_2$:

$$2NaNO_2\,(aq) + BeCl_2 \Rightarrow Be(NO_2)_2\,(aq) + 4NaCl\,(aq)$$

The product is likely to be $Be(OH)NO_2$ if it is obtained under vacuum evaporation at 10 °C. Whether a hydrate forms or not remains unknown. Furthermore, the product probably will not be stable in air and will decompose at room temperature unless protected from the atmosphere.

It has no CAS number and is not listed as available commercially.

Magnesium Nitrite

Magnesium nitrite has the formula of $Mg(NO_2)_2$ and the molecular weight of 116.3164 g/mol. It can be made by the usual double decomposition reaction of sodium nitrite and $CaCl_2$:

$$2NaNO_2\,(aq) + MgCl_2 \Rightarrow Mg(NO_2)_2\,(aq) + 4NaCl\,(aq)$$

It forms a trihydrate having a molecular weight of 170.3626 g/mol. Magnesium nitrite is soluble in water and the solution must be evaporated at very low temperatures to obtain crystals. The solution is stable and is slightly hydrolyzed in the cold but at 60° and above it evolves oxides of nitrogen. Its CAS number is 15070-34-5 and it occurs as white, hydroscopic crystals that must be protected from moisture to prevent decomposition. The trihydrate, when heated, forms the monohydrate at 100 °C and then decomposes to $NO + NO_2$ and MgO at >130 °C. It is soluble in alcohol.

The instability of magnesium nitrite, even when dissolved in water, has not engendered any usage in

TABLE 4.2

Crystal system	$Ca_2Si_5N_8$ Monoclinic Cc	$Sr_2Si_5N_8$ Orthorhombic Pmn21	$Ba_2Si_5N_8$ Orthorhombic Pmn21
Maximum solubility of Eu2+	$x = 0.14$	$x = 2.0$	$x = 2.0$

Stokes shift (cm^{-1})	3800	3700	3500
Conversion efficiency (%)	50–55	75–80	75–80

industry. Although it has a CAS number, no research papers dealing with its physical or chemical properties are currently accessible. Most of the known data comes from early (before 1890) work in the technical literature.

Magnesium nitrite is available in small quantities commercially.

Calcium Nitrite

Calcium nitrite has the formula of $Ca(NO_2)_2$ and the molecular weight of 132.0894 g/mol. It can be made by the usual double decomposition reaction of sodium nitrite and $CaCl_2$. It forms a tetrahydrate that is isomorphous with the strontium and barium salts:

$$2Na_2NO_2\,(aq) + CaCl_2 \Rightarrow Ca(NO_2)_2\,(aq) + 4NaCl\,(aq)$$

Calcium nitrite, $Ca(NO_2)_2$, has the CAS number of 13780-06-8 and occurs as yellow-white crystals. It is very hygroscopic. Its density is 2.23 g/cm^3 and it decomposes at 392 °C to form nitrogen oxides and CaO. It is slightly soluble in alcohol. $Ca(NO_2)_2 \cdot 4H_2O$ loses two waters of hydration at about 80 °C and one at 105 °C to form the monohydrate. It loses the other at about 155 °C. The anhydrate, if further heated, is unstable and oxidizes to the nitrate in air above 220 °C:

$$Ca(NO_2)_2 + O_2 + \text{heat} \Rightarrow Ca(NO_3)_2$$

Calcium nitrite monohydrate, $Ca(NO_2)_2 \cdot H_2O$ and has the CAS number of 10031-34-2. It occurs as colorless crystals. The Lewis structure is shown in Fig. 4.6.

Industrially, calcium nitrite is manufactured by reacting "NOX" gas with "lime":

$$Ca(OH)_2 + NO + NO_2 \Rightarrow Ca(NO_2)_2 + H_2O$$

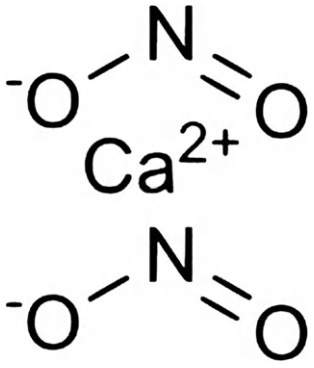

FIGURE 4.6

By carefully controlling calcium nitrite conditions, the selectivity on converted lime, on a molar basis, is over 95% pure. It is soluble in water (98.2 g/100 ml at 20 °C) and the solution must be evaporated at low temperature to obtain the tetrahydrate. If heated with NO_2 gas, it also form the nitrate:

$$Ca(NO_2)_2 + NO_2 \Rightarrow Ca(NO_3)_2 + NO$$

Anhydrous calcium nitrite is unstable and slowly oxidizes in air to form the nitrate. It is also soluble in alcohol at 0.97 g/100 ml at 20 °C. It has the CAS number of 13780-06-8. Its solubility is shown in Table 4.3.

This product is supplied as a clear, light yellow to colorless solution which has a slight sweet odor. It is a mild reducing agent and the CAS number of the commercial solution is 10124-37-5. Two major manufacturers in the world produce this product with plants in Wilmington, NC and Augusta, Ga and the other in China. The calcium nitrite plant in Wilmington, NC was based on technology Grace had licensed from the Japanese chemical firm, Nissan. The Nissan process utilized three (3) reactors. In this scheme, the so-called Rich NOX gas entered the first reactor, and so-called Lean NOX gas from the first reactor went to the second reactor (Fig. 4.7).

Calcium nitrite has several industrial uses:

1. Calcium nitrite has high solubility, so can be used as a solution or powder in concrete as an "anti-freeze" during winter months as needed. Using this antifreeze at negative temperature can promote the hydration of minerals in cement, and the freezing point of operative temperature can be reduced to –25 °C.
2. This salt is a steel rust inhibitor: calcium nitrite can clean steel and protect it from rust, and can protect steel material in concrete used to construct buildings and structures, to extend the useful life of concrete in buildings.
3. In concrete, $Ca(NO_2)_2$ acts as a coagulator: calcium nitrite is free of chlorine and alkali, capable to reduce alkali aggregation of concrete and improve its early strength and compressive resistance. The calcium nitrite protects steel reenforcing bars from chloride-induced corrosion. One advantage to calcium nitrite is that its protection mechanism is well defined. Data are known that show the levels of chloride to which given levels of calcium nitrite will protect. Once

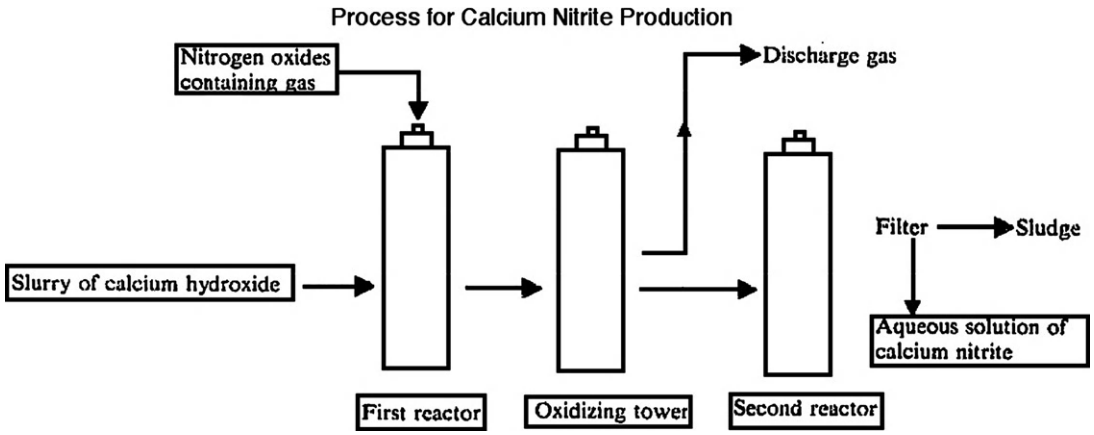

FIGURE 4.7

corrosion initiates, the rates are lower with calcium nitrite present. These results have been used to produce reinforced concrete structures with durability in excess of 50–100 years.

4. Calcium nitrite can be used as corrosion inhibitor when added to lubricating agents.
5. Calcium nitrite can also be used in pharmaceutical, dyes and metallurgy industries, as a mild reducing agent.

Calcium nitrite is readily available commercially in large quantities.

Strontium Nitrite

Strontium nitrite has the formula of $Sr(NO_2)_2$ and the molecular weight of 179.6311 g/mol. It can be made by the usual double decomposition reaction of sodium nitrite and $SrCl_2$. It forms a tetrahydrate which is isomorphous with the calcium and barium salts:

$$Na_2NO_2\,(aq) + SrCl_2 \Rightarrow SrNO_2\,(aq) + 2NaCl\,(aq)$$

Anhydrous strontium nitrite, $Sr(NO_2)_2$, has the CAS number of 13780-06-8 and occurs as yellow-white crystals. It is very hygroscopic. Its density is 2.23 g/cm^3 and it decomposes at >650 °C to form nitrogen oxides and SrO. It is slightly soluble in alcohol (0.04 g/100 ml at 20 °C) but soluble in water at 72.1 g/100 ml at 20 °C.

$Sr(NO_2)_2 \cdot 4H_2O$ loses two waters of hydration at about 80 °C and one at 105 °C to form the monohydrate. It loses the other at about 155 °C. The anhydrate, if further heated, is unstable and oxidizes to the nitrate in air above 240 °C:

$$Sr(NO_2)_2 + O_2 + \text{heat} \Rightarrow Sr(NO_3)_2$$

Strontium nitrite monohydrate, $Sr(NO_2)_2 \cdot H_2O$, has the CAS number of 13470-06-9 and a molecular weight of 197.6464 g/mol. It occurs as yellow-white crystals which are hygroscopic. Its density is 2.84 g/cm^3. In air, the crystals begin to decompose at about 245 °C. It is soluble in water at about 58.5 g/100 ml at 20 °C.

When heated in a nitrogen atmosphere, $Sr(NO_2)_2 \cdot H_2O$, undergoes a single loss of water at around 150 °C followed by a $\text{solid}_1 \Rightarrow \text{solid}_2$ phase transition in the anhydrous solid $Sr(NO_2)_2$ phase at around 265 °C with subsequent melting at about 365 °C. There is a very slight decomposition commencing even before melting which becomes more significant at 500 °C and very rapid above 650 °C. The final product is cubic SrO as identified by powder XRD. EGA (evolved gas analysis) studies of the decomposition in a vacuum were consistent but indicated lower temperatures of dehydration and particularity of decomposition. The quantities of product gases evolved during the complex decomposition region followed the order $NO > NO_2 \approx O_2 > N_2 > N_2O$. $Sr(NO_3)_2$ is a probable intermediate species during the decomposition.

$Sr(NO_2)_2 \cdot H_2O$ is a newly characterized material with pyroelectric coefficient $p_2 = 20\ \mu C/m^2/K$ and second-order nonlinear dielectric susceptibility about 0.06×10^{-12}/V/m at room temperature. Its space group is $P2_1$. The monoclinic unit cell has dimensions $a = 12.5831$ Å, $b = 8.94941$ Å, $c = 4.4860$ Å, and $\beta = 99.111°$ at 295 K. The linear thermal expansion coefficients at room temperature are $\alpha_1 = 37 \times 10^{-6}$/K, $\alpha_2 = 41 \times 10^{-6}$/K, and $\alpha_3 = 25 \times 10^{-6}$/K.

In another study, it was determined that a new phase transition at 538 K occurs in $Sr(NO_2)_2$ with an entropy gain, on passing from phase II to phase I, of 18.9 J/mol/K. On quenching, phase I is metastable to 296 K but reverts on heating to phase II at about 467 K. Phase II is orthorhombic, with lattice constants at 296 K of $a = 7.5320$ Å, $b = 8.1496$ Å, $c = 6.4820$ Å, and four $Sr(NO_2)_2$ molecules per unit cell. Thermal expansion coefficients, as given by $a_T = a_{296}\ [1 + \alpha\Delta T + \beta(\Delta T)^2]$, are: $\alpha(a) = 33$, $\alpha(b) = 39$, and $\alpha(c) = 62 \times 10^{-6}$/K, $\beta(a) = -119$, and $\beta(b) = 61 \times 10^{-9}/K^2$, i.e. the thermal expansion of the a and b axes is nonlinear, that of the

c-axis is linear (Here, a, b & c are lattice directions while α, β & γ are expansion coefficients). The volume expansion, as given by $V_T = V_{296}\ [1 + \beta\Delta T]$, is linear with $\beta(V) = 123 \times 10^{-6}$/K. Phase I is cubic with $a = 7.5752$ Å at 538 K, $\alpha(a) = 29 \times 10^{-6}$/K; crystals of phase I melt at 637 K. The increase in volume at the phase transition is 6.0%. The postulate of threefold positional disorder by the nitrite ions about the cubic body diagonals results in an expected entropy increase of $R \ln 9 = 18.27$ J/mol/K.

If strontium nitrite is added to a mixture of magnesium–strontium nitrate, normally used in pyrotechnic formulations, it prevents aging of the nitrate mixture in the presence of water until usage in fireworks. Studies by isothermal microcalorimetry show that the addition of strontium nitrite to a 50% magnesium–50% strontium nitrate composition eliminated the induction reaction normally observed in closed ampoule studies in air at 50 °C and relative humidity in the range 65–69%.

Strontium nitrite is available commercially from several manufacturers, notably Chinese.

Barium Nitrite

Barium Nitrite has the molecular formula of $Ba(NO_2)_2$ and the molecular weight of 247.3532 g/mol. Barium *nitrite* is made by double decomposition from barium chloride and sodium nitrite:

$$BaCl_2 + 2NaNO_2 \Rightarrow Ba(NO_2)_2 + 2NaCl$$

It is soluble so that the solution must be evaporated at low temperature to obtain crystals. The product is a monohydrate whose molecular weight is 247.4356 g/mol and whose CAS number is 7787-38-4. It loses water at about 100 °C and the anhydrous salt melts with decomposition at 217 °C. It occurs as yellowish-white crystals whose solubility is 75.3 g/100 ml. It is insoluble in ethanol.

Barium nitrite, $Ba(NO_2)_2$ has the CAS number of 13465-94-6 and the molecular weight of 229.338 g/mol. It occurs as colorless hexagonal crystals which decompose upon heating at about 267 °C. Its density is 3.234 g/cm^3 and it is soluble in water at 79.525 g/100 ml at 25 °C (Table 4.4).

$Ba(NO_2)_2 \cdot H_2O$ is hexagonal with a space group of $P6_1$ and $a = 7.070$ Å, $c = 17.886$ Å, $V = 774.3$ Å^3, $Z = 4$. $Ba(NO_2)_2 \cdot H_2O$ undergoes a sluggish reversible phase transition on heating to 350 K, followed by water loss to form the hemihydrate at about 425–435 K. The final half-molecule of water is lost by 455 K. Differential thermal analysis (DTA), thermogravimetry, differential scanning calorimetry (DSC), infrared spectroscopy, XRD, and optical microscopic techniques were used to characterize this salt. The entropy change of 36 J/K/mol measured at the phase transition is consistent with five new orientations becoming available to each water molecule above 350 K (77 °C), accompanied by related reorientations of the two independent NO_2^- ions as new hydrogen bonds are formed. Both the high-temperature monohydrate and the hemihydrate phases are unstable.

Further work has shown that phase transitions at 462 K and 495 K occur in $Ba(NO_2)_2$. The increase in entropy at each transition is about 13 J/mol/K. A gain of two orientations per independent NO^{-2} ion at each transition corresponds to an entropy increase of 11.5 J/mol/K. The crystal melts at 516 K. The high-temperature phase I is metastably retained at 298 K on rapid solidification, reverting to phase III on reheating above 350 K. Phase III is orthorhombic with lattice constants at 298 K of $a = 7.657$, $b = 8.355$, and $c = 6.742$ Å and four $Ba(NO_2)_2$ in the unit cell. The linear thermal expansion coefficients are 30.7, 14.0, and -5.9×10^{-6} Å/K for the a, b, and c axes, respectively. The powder pattern for phase II has not been indexed. Phase I may be fitted by a monoclinic unit cell with $a = 6.692$, $b = 7.052$, and $c = 9.638$ Å and $\beta = 104.61°$ at 507 K with four $Ba(NO_2)_2$ in the unit cell. A dielectric anomaly is observed at 468 K in the frequency range 0.1–1 MHz: dielectric losses obscure the anomaly at lower frequencies.

The phase relation and the dehydration behavior of barium nitrite hydrates have been examined by DTA under various external pressures, and by thermogravimetry and differential thermal analysis (TG–DTA) in air. The equilibrium water vapor pressures of the mono-, hemi-, and 1/3-hydrates have been measured. The temperatures of III ⇒ II and II ⇒ I phase transitions and melting point of the anhydrate are 469, 497 and 542 K, respectively (196, 224, 269 °C). The dehydration in air atmosphere proceeds as in Fig. 4.8.

A phase transition has been observed at 211 K in crystalline barium nitrite hemihydrate, $Ba(NO_2)_2 \cdot 1/2H_2O$, by DTA and dielectric measurements. A dielectric relaxation phenomenon was also found and the activation energies governing the relaxation were determined to

FIGURE 4.8

be 23 kJ/mol and 41 kJ/mol below and above the transition temperature, respectively. Some discussions have been made on the nature of the phase transition.

Neutron diffraction studies of barium nitrite monohydrate [$Ba(NO_2)_2 \cdot H_2O$] have been made at 20, 102, and 298 K on the same crystal. Intensities of 954 (20 K), 2179 (102 K), and 2393 (298 K) reflections were measured at the Brookhaven National Laboratory high-flux beam reactor. The structures were refined on the basis of the hexagonal space group $P6_5$ to yield agreement factors R (F^2) = 0.028 (20 K), 0.034 (102 K), and 0.061 (298 K). The thermal expansion is nonlinear along both the a and c axes, with $\alpha_1 = 3.8 \times 10^{-6}/\text{K}$, $\beta_1 = 2.8 \times 10^{-8}/\text{K}^2$, $\alpha_3 = 21.3 \times 10^{-6}/\text{K}$, $\beta_3 = 10.9 \times 10^{-8}/\text{K}^2$. The cell dimensions are:

$$a = 7.0524\ \text{Å},\ c = 17.6372\ \text{Å at 20 K}$$
$$a = 7.0559\ \text{Å},\ c = 17.6810\ \text{Å at 102 K}$$
$$a = 7.07492\ \text{Å},\ c = 17.89087\ \text{Å at 298 K.}$$

The mean-square amplitude of thermal motion of Ba is proportional to temperature in the range 298–20 K, with small departures from linearity for the O and N amplitudes and larger departures for the H nuclear amplitudes. The Ba^{2+} cation is coordinated by nine oxygen atoms and one nitrogen atom at an average distance of 2.881 Å at 20 K, 2.884 Å at 102 K, and 2.902 Å at 298 K. The increase in length corresponds completely to the lattice expansion. A maximum difference within a nitrite ion of 0.015 Å in N–O bond lengths, observed at 298 K, is reduced to 0.008 Å at 20 K for a mean N–O distance of 1.254 Å. One O–H bond of 0.958 Å, which forms a bifurcated hydrogen bond with two oxygen atoms, is identical in length to that in the free water molecule; the other is slightly elongated by formation of a nearly linear hydrogen bond to a nitrogen atom. The largest nuclear displacement between 298 and 20 K in this pyroelectric crystal is only 0.038 Å along the polar axis.

In another study, Barium nitrite monohydrate, $Ba(NO_2)_2 \cdot H_2O$, was found to be strongly pyroelectric at room temperature and crystallizes in the hexagonal system with space group $P6_5$, or the enantiomorphous (mirror-like) $P6_1$, with six formulas in the unit cell. The lattice constants at 298 K are $a = 7.07490$ Å and $c = 17.89087$ Å ($CuK\alpha_1 = 1.540598$ Å). The integrated intensities of most reflections within a quadrant of reciprocal space having radius $(\sin\theta)/-1.15$ or $1.08/\text{Å}$ were measured on two different crystals, each with different diffractometer, resulting in 3218 F_{meas} for one set and 3671 F_{meas} for the second set of independent structure factors. The crystal structure was solved from Patterson and Fourier series, and refined by the method of least squares. The final agreement factor $R = 0.026$ for the first set, 0.018 for the second set of F_{meas} (Fig. 4.9).

The two sets of F_{meas} and the derived structural parameters are compared using normal probability plot analysis. The two NO^{2-} ions have a mean N–O distance of 1.246 ± 0.002 Å and O–N–O angle of $114.2 \pm 0.2°$. The Ba^{2+} ion is coordinated by nine-oxygen and one-nitrogen atoms at an average distance of 2.899 Å. The water molecule has a weighted mean O–H distance of 1.04 ± 0.03 Å and H–O–H angle of $102.7 \pm 4.3°$: it is hydrogen bonded to two independent NO_2^- ions by an O–H to O bond of 2.878 Å and an O–H to N bond of 2.951 Å.

Using ^{1}H nuclear magnetic resonance (NMR), the diffusive properties of the pyroelectric and piezoelectric compound, $Ba(NO_2)_2 \cdot H_2O$, were investigated. Spin-lattice relaxation times of the quiesecent and the rotating frames (T_1 and T_{1q}) as well as the dipolar relaxation times (T_{iD}) were measured. Single crystals were used for measuring these spin-lattice relaxation times and polycrystalline samples for the temperature dependencies. $Ba(NO_2)_2 \cdot H_2O$ undergoes a reversible phase transition at 350 K (77 °C), followed by a water loss upon further heating. In the room temperature phase, two major processes were found to be responsible for the relaxation. These dominate the relaxation in separate temperature regions. The activation energies, E, associated with the low-and high-temperature regions are 25 kJ/mol and 57 kJ/mol, respectively. The high activation energy process is clearly a 180° flip motion of the water molecules. The other process could not be clearly defined. The pre-exponential factor

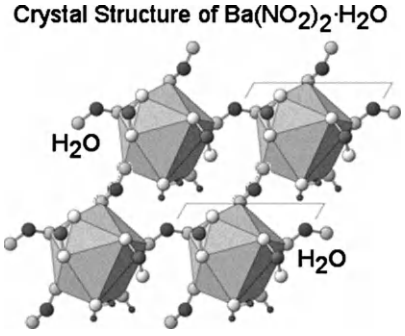

FIGURE 4.9

for the correlation times of the H_2O flip motion is 1.1×10^{-15} s.

The infrared spectra of crystalline barium nitrite monohydrate and of the deuterium substituted or anhydrous counterparts were investigated at various temperatures up to the melting point of the anhydride 516 K (243 °C). Samples were prepared as mineral oil mulls, single-crystal plates, and oriented polycrystalline sheets and were measured in polarized or unpolarized radiation. In addition to observations of the dehydration occurring near 430 K (167 °C) as temperature is increased and transitions among the three forms of anhydride (I, II, and III) known from X-ray and thermal measurements, a new transition near 348 K (75 °C) in the monohydrate was investigated, and a new, room temperature form of anhydride (IV) was discovered.

In another paper, infrared and Raman spectroscopy and normal coordinate analysis were used to investigate the detailed forms of the internal vibrations and the librations of the water molecule in $Ba(NO_2)_2 \cdot H_2O$. The asymmetric bonding situation is shown to result in normal vibrations that tend to give displacements more or less localized to one O–H bond of the water molecule. Thus, the mixing of twisting and wagging produces two normal modes which are more like H(1) and H(2) out-of-plane displacement, respectively. The corresponding mixing of bending and rocking also occurs, but to a smaller extant. Vibrational amplitudes for the hydrogen nuclei of the water molecule are derived in two ways; from earlier diffraction studies and from the normal coordinate analysis. The agreement between the two sets of amplitude is found to be very good in the O–H bond directions and in the out-of-plane direction, but somewhat poorer in the in-plane direction which is perpendicular to the O to H bonds. Some systematic deviations from the equilibrium geometry of the water molecule as obtained by neutron diffraction were discussed in view of the calculated normal vibrations and the vibrational model used in the diffraction experiment.

The IR spectra of undeuterated and partially deuterated $Ba(NO_2)_2 \cdot H_2O$ were recorded between 4000 and 1000/cm. The single HOH bending frequency confirms that the six H_2O molecules in the unit cell are equivalent. The splitting of the fundamentals of isotopically dilute HDO shows that the water molecules are asymmetrically hydrogen bonded, with one strong and one weak hydrogen bond. The asymmetry decreases gradually with increasing molecular motion at higher temperatures. The nonequivalence of the two hydrogen atoms shows that the space group $P6_122$-D_6^2 (or $P6_522$-D_6^3) proposed on the basis of XRD studies is incorrect. The space group is one of lower symmetry, probably $P6_1$-C_6^2 (or $P6_5$-C_6^3). The considerable asymmetry of the water molecules may explain the discrepancy, reported by Tramer and Mathieu, between the directions of the experimental transition moments and those calculated on the assumption that the water molecules are symmetric.

Barium nitrite monohydrate is available commercially from several suppliers. No CAS numbers have been assigned to date.

Radium Nitrite

There are no reports on the experimental preparation of **radium nitrite.** It could be prepared by the aqueous reaction between sodium nitrite and radium chloride:

$$RaCl_2 + 2NaNO_2 \Rightarrow Ra(NO_2)_2 + 2NaCl$$

However, this preparation has likely never been attempted since the industrial demand for this salt is zero. The question of a hydrate and how it is obtained remain unknown. It has no CAS number and is not available commercially or otherwise.

4.1.4. Alkaline Earth Nitrates

Since nitric acid, in contrast to nitrous acid, is stable in aqueous solution, the acid can be used to prepare these salts. Thus, the pH of solution can be controlled from acidic to basic, as required, by the use of acid, ammonia salts or alkali salts.

Beryllium Nitrate

Beryllium nitrate is said to have the molecular formula of $Be(NO_3)_2$ and the molecular weight of grams per mole. It is very soluble in water (Table 4.5).

It could be prepared by the action of nitric acid on beryllium carbonate, oxide or hydroxide:

$$BeCO_3 + 2HNO_3 \Rightarrow Be(NO_3)_2 + CO_2 + H_2O$$
$$Be(OH)_2 + 2HNO_3 \Rightarrow Be(NO_3)_2 + 2H_2O$$

It is described as $Be(NO_3)_2 \cdot 4H_2O$, a compound that forms colorless, deliquescent crystals that are soluble in water, and used to introduce beryllium oxide into

TABLE 4.5

		g/100 ml of water						
Compound	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**60 °C**	**100 °C**
Beryllium nitrate	$Be(NO_3)_2$	97	102	108	113	125	178	Decomposes

materials used in incandescent mantles. However, in view of recent developments concerning the behavior of the Be^{3+} cation in solution, the more likely reactions are:

$$BeCO_3 + 2HNO_3 \Rightarrow Be(OH)NO_3 + CO_2 + 1/2H_2O$$
$$Be(OH)_2 + 2HNO_3 \Rightarrow Be(OH)NO_3 + 3/2H_2O$$

The result is either the tetrahydrate at low HNO_3 concentrations or the trihydrate or the monohydrate at more concentrated nitric acid solutions. The trihydrate is usually the commercial product. These would have the molecular formula of:

$Be(H_2O)_3(OH)NO_3$—tetrahydrate
$Be(H_2O)_2(OH)NO_3$—trihydrate
$Be(H_2O)(OH)NO_3$—monohydrate

It is notable that these hydrates are "quasi-stable" and heating them up to $\geq$100 °C causes decomposition and evolution of nitrogen oxides.

DTA analysis of the tetrahydrate showed that it dissolves in its own waters of hydration at about 60.4 °C. Heating above 101 °C causes decomposition with loss of water and oxides of nitrogen plus formation of the oxide. The decomposition is complete at 250 °C. Thermal decomposition of these salt hydrates occurs by release of nitric acid which then breaks down to form the nitrogen oxides, rather than break down of the nitrate anion itself. The anhydrate has been prepared by the reaction of beryllium chloride with N_2O_4 dissolved in ethylacetate. If heated in a vacuum above 50 °C, the product, $Be(NO_3)_2 \cdot 2N_2O_4$, evolves oxides of nitrogen to produce the anhydrate.

The tetrahydrate has a CAS number of 13597-99-4 and molecular weight is grams per mole. Anhydrous beryllium nitrate is a white to pale yellow crystalline solid. Beryllium nitrate trihydrate (CAS number = 7787-55-5) forms slightly yellow crystals with a vapor pressure 49.8 mm Hg at 25 °C. Its melting point is 60.5 °C and it decomposes completely at 102.3 °C. Its Enthalpy of vaporization = 37.72 kJ/mol and its boiling point is 83 °C at 760 mm Hg where it becomes anhydrous. Beryllium nitrate is a tumorigen, mutagen and reproductive effector in rats and, presumably in humans.

Beryllium metal dissolves readily in nonoxidizing acids such as HCl and H_2SO_4, but not in nitric acid as this forms the oxide (this behavior is similar to that of aluminum metal). Beryllium, again similarly to aluminum, dissolves in warm alkali to form the beryllate anion, $Be(OH)_4^{2-}$, and hydrogen gas.

The solutions of salts such as beryllium nitrate are acidic because of hydrolysis of the $[Be(H_2O)_4]^{2+}$ ion, for example:

$$[Be(H_2O)_4]^{2+} + H_2O \Rightarrow [Be(H_2O)_3(OH)]^{+} + H_3O^{+}$$

Thus, the chemistry of soluble beryllium salts is dominated by the formation of hydroxy-complexes.

The vaporization of 20–50 g of beryllium from nitrate solution was observed in graphite furnace atomizers using pyro-coated and Ta-lined tubes. A charge coupled device (CCD) spectrometer was employed to follow the evolution of absorption spectra (200–475 nm), light scattering and emission. Molecular bands of NO and NO_2 were observed below 1000 °C. Beryllium absorption at 234.9 nm was prominent in spectra above 2200 °C and 1900 °C, respectively. The most intense Be atomic absorption, light scattering and emission were observed when the maximum temperature reached 400 °C.

The study of beryllium nitrate has not been extensive and even the decomposition of the tetrahydrate has not been fully elucidated. Beryllium nitrate is offered commercially as trihydrate crystals or as a solution containing 35% by weight beryllium nitrate of 99.99% purity.

Magnesium Nitrate

Magnesium nitrate has the molecular formula of $Mg(NO_3)_2$ and the molecular weight of 148.3152 g/mol. It is very soluble in water (Table 4.6).

Magnesium nitrate is prepared by the action of nitric acid on magnesium carbonate, oxide or hydroxide:

$$MgCO_3 + 2HNO_3 \Rightarrow Mg(NO_3)_2 + CO_2 + H_2O$$
$$Mg(OH)_2 + 2HNO_3 \Rightarrow Mg(NO_3)_2 + 2H_2O$$

The salt crystallizing at room temperature after evaporation is the hexahydrate, $Mg(NO_3)_2 \cdot 6H_2O$. Two stable hydrates are formed, the hexahydrate [CAS number =13446-18-9] and the dihydrate, $Mg(NO_3)_2 \cdot 2H_2O$ [CAS number = 15750-45-5].

The magnesium nitrate used in commerce has been synthesized in a variety of ways. The reaction between nitric acid and magnesium metal is one way and reaction with MgO is another. Magnesium hydroxide and

TABLE 4.6

		g/100 ml of water							
Compound	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**60 °C**	**80 °C**	**90 °C**
Magnesium nitrate	$Mg(NO_3)_2$	62.1	66	69.5	73.6	78.9	78.9	91.6	106

ammonium nitrate also form the product but ammonia is released as a by-product:

$$2HNO_3 + Mg \Rightarrow Mg(NO_3)_2 + H_2$$
$$2HNO_3 + MgO \Rightarrow Mg(NO_3)_2 + H_2O$$
$$Mg(OH)_2 + 2NH_4NO_3 \Rightarrow Mg(NO_3)_2 + 2NH_3 + 2H_2O$$

Since magnesium nitrate has a high affinity for water, heating the hexahydrate does not result in the dehydration of the salt. Instead, it decomposes into magnesium oxide, oxygen and nitrogen oxides:

$$4Mg(NO_3)_2 \cdot 6H_2O + \text{heat} \Rightarrow 4MgO + 2NO_2 + 2N_2O + O_2 + 6H_2O$$

Heating the hexahydrate above its melting point first forms basic nitrates, such as $Mg(NO_3)_2 \cdot 4Mg(OH)_2$. It is this salt that decomposes at 400 °C, forming magnesium oxide and oxides of nitrogen. The absorption of these nitrogen oxides in water is one possible way to synthesize HNO_3. Although it is inefficient, it does not require the use of another strong acid and the mineral, nitromagnesite, can be used in this context. This mineral is monoclinic with space group = $P2_1/c$ (2/m) and $a = 6.194$, $b = 12.71$, $c = 6.6$, $Z = 2$; $\beta = 93°$, $V = 518.88$ Å^3, density (Calc) = 1.64 g/cm^3.

The anhydrous salt (CAS number = 10377-60-3) consists of white cubic crystals whose density is 2.32 g/cm^3 and is very soluble in water. It is very hygroscopic and in air quickly forms the hexahydrate with the formula $Mg(NO_3)_2 \cdot 6H_2O$. The dihydrate (CAS number = 15750-45-5) is a white crystalline solid having a density of 1.456 g/cm^3. It decomposes at about 100 °C and is soluble in water and ethanol. The hexahydrate, $Mg(NO_3)_2 \cdot 6H_2O$ (CAS number = 13446-18-9 and molecular weight of 256.41 g/mol), is a colorless solid having monoclinic crystal structure and density of 1.464 g/cm^3. The salt is hygroscopic and very soluble in water and moderately soluble in ethanol. Of these salts, the hexahydrate is the most stable in air at room temperature. It melts in its own waters of hydration at 88.9 °C (362 K) and begins to decompose at 330 °C (Table 4.7).

The nonahydrate has not received much attention whereas the hexahydrate, $Mg(NO_3)_2 \cdot 6H_2O$, occurs in mines and caverns as the mineral *"Nitromagnesite"*. This form is not common, although it may be present where in caves where guano contacts magnesium-rich rock. It is used in the ceramics, printing, chemical and agricultural industries. It is a fertilizer and is listed as 11-0-0 (%N-P-K) grade with 9.4% Mg (which is an essential fertilizer as well). Fertilizer blends containing magnesium nitrate plus ammonium nitrate, and calcium nitrate are used in the greenhouse and hydroponics trade. Magnesium nitrate is also used in pyrotechnics; and in the manufacture of concentrated nitric acid where it removes water and concentrates the acid vapors to 90–95% HNO_3. It is also used to aid coating and prilling in production of ammonium nitrate. The salt is also used as an analytical standard for magnesium and a matrix modifier in furnace atomic absorption spectroscopic analysis. It also finds some limited application as a nitrogenous fertilizer.

TABLE 4.7

Thermochemical properties of the hexahydrate
$\Delta H_f^0 = -189.0$ kcal/mol
$\Delta G_f^0 = -147.4$ kcal/mol
$S_0 = 39.2$ cal/degree mol
$C_P = 33.9$ cal/degree mol

A phase diagram of the relation of these hydrated salts is shown in the following Fig. 4.10 and Fig. 4.11.

$Mg(NO_3)_2 \cdot 6H_2O$ shows a two-stage melting process including an additional phase transition. It has been investigated as a phase-change material for storing waste energy from urban waste heat emerging from co-generation systems, typically available at temperatures of 60–100 °C. Several authors have investigated latent heat storage by these materials with phase change temperatures in the above range, and focused on a mixture of magnesium nitrate hexahydrate as a base material and magnesium chloride hexahydrate as an

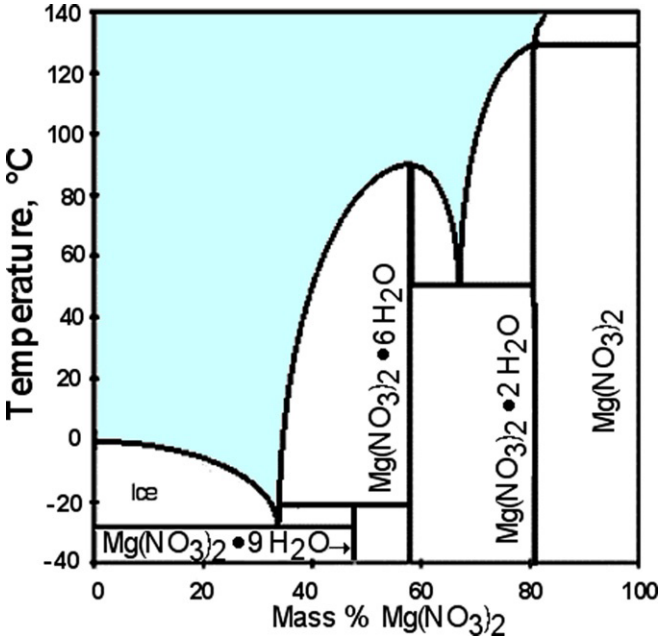

FIGURE 4.10

$LiNO_3 \cdot 3H_20$	29	459 kJ /dm^3 or 298 kJ / kg	Melts Congruently
$Mg(NO_3)_2 \cdot 6H_2O$	89	262 kJ /dm^3 or 160 kJ / kg	Melts Congruently

FIGURE 4.11

additive to modulate the melting point. Addition of 5–10 wt% of the latter resulted in a modulated melting point of around 80 °C and a heat of fusion of about 150 kJ/kg. Increasing the mix ratio had little effect on heat of fusion, but allowed the melting point to be reduced to about 60 °C. Repeated melting and solidification tests showed that the heat of fusion and melting point retained their original values even after 1000 cycles.

The structural results for $Mg(NO_3)_2 \cdot H_2O$ at the low temperature of 173 K using neutron single-crystal diffraction confirmed the monoclinic space group $P2_1/c$ and yielded lattice constants: $a = 6.190(2)$ Å, $b = 12.614(4)$ Å, $c = 6.56(1)$ Å, and $\beta = 93.72(1)°$, which is exactly those of the hexahydrate at room temperature.

The salt, cerium magnesium nitrate, $Mg(NO_3)_2 \cdot Ce(NO_3)_3$, has been of interest in low-temperature physics, largely because of its use as a coolant in adiabatic demagnetization experiments. Magnetic interactions of the Ce^{3+} magnetic moments are smaller in this matrix than in any other known salt and this, together with the extreme anisotropy in the ground state g-factor makes it ideal for use in experiments below 1 K. This salt has also been used to establish an absolute temperature scale in the range of 0.0100–0.0010 K. Systematic deviations were found below 0.003 K in the temperature dependence of nuclear orientation of Ce^{137} in cerous magnesium nitrate, using the temperature scale proposed by Daniels and Robinson. The temperature scale below 0.006 K was redetermined using a new method: nuclear orientation. This has the advantage over the γ-ray heating method of having high sensitivity at the lowest temperature. The most striking result is that a value of 1/T of 520 was found, rather than the previously accepted 324, obtained by demagnetization from initial conditions of 18.8 kG/deg. The useful absolute temperature range is thus extended by at least 60% in 1/T. Auxiliary experiments on oriented Pm^{144} gave similar results and provided independent confirmation both of the inadequacy of the old temperature scale and of the validity of the new one.

There are over 3 million registered exporters of this salt and it is readily available commercially.

Calcium Nitrate

Calcium nitrate has the molecular formula of $Ca(NO_3)_2$ and the molecular weight of 164.0935 g/mol. Its CAS number is 10124-37-5. Calcium nitrate may be prepared by the reaction of nitric acid with calcium carbonate or calcium sulfide:

$$CaCO_3 + 2HNO_3 \Rightarrow Ca(NO_3)_2 + CO + H_2O$$
$$CaS + 2HNO_3 \Rightarrow Ca(NO_3)_2 + H_2S$$

It is very soluble and forms a tetrahydrate, $Ca(NO_3)_2 \cdot 4H_2O$ if the solution is evaporated to dryness. The CAS number of the anhydrate is 10124-37-5 while that of the tetrahydrate is 13477-34-4. As with the beryllium nitrate salts, variation of the nitric acid concentration affects the type of hydrate produced. The trihydrate is known (CAS number 10124-37-5) but not the monohydrate. The anhydrate is a white cubic crystal that is hygroscopic; its density is 2.504 g/cm^3 and it melts at 561 °C. This salt is highly soluble in water and also dissolves in alcohols and acetone. The tetrahydrate melts in its own waters of hydration at 42.7 °C and loses $4H_2O$ molecules at 132 °C. It decomposes to form nitrogen oxides and CaO similar to the behavior of the other alkaline earth nitrates. The anhydrous salt is soluble at 121.2 g/100 ml at 20 °C and 271.2 g/100 ml at 40 °C (Table 4.8).

Synonyms include: Lime nitrate; Lime saltpeter; Norwegian saltpeter, Nitrocalcite. The anhydrate salt absorbs moisture from the air to form the tetrahydrate, which is the stable form of this salt. It is mainly used as a component in fertilizers. Nitrocalcite is the name for a mineral which is a hydrated calcium nitrate that

TABLE 4.8

		g/100 ml of water						
Compound	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**80 °C**	**100 °C**
Calcium nitrate tetrahydrate	$Ca(NO_3) \cdot 4H_2O$	102	115	129	152	191	358	363

forms as an efflorescence in places where manure contacts limestone (or concrete) in a dry environment such as caverns or stables.

Norgessalpeter was the first synthetic nitrogen fertilizer to be manufactured. Production began at Notodden, Norway in 1905. It was produced by treating limestone with nitric acid, followed by neutralization with ammonia:

$$CaCO_3 + 2HNO_3 \Rightarrow Ca(NO_3)_2 + CO_2 + H_2O$$

It is also a by-product of the "ODDA Process" invented in 1925 for the extraction of calcium phosphate:

$$Ca_3(PO_4)_2 + 6HNO_3 + 12H_2O \Rightarrow 2H_3PO_4 + 3Ca(NO_3)_2 + 12H_2O$$

The mixture is cooled to below 0 °C, where the calcium nitrate crystallizes and can be separated from the phosphoric acid:

$$2H_3PO_4 + 3Ca(NO_3)_2 + 12H_2O \Rightarrow 2H_3PO_4 + 3Ca(NO_3)_2 \cdot 4H_2O$$

The resulting calcium nitrate produces nitrogen fertilizer. The filtrate is composed mainly of phosphoric acid with some nitric acid and traces of calcium nitrate, and this is neutralized with NH_3 gas to produce a compound fertilizer:

$$Ca(NO_3)_2 + 4H_3PO_4 + 8NH_3 \Rightarrow CaHPO_4 + 2NH_4NO_3 + 3(NH_4)_2HPO_4$$

If KCl or K_3PO_4 is added, the result will be NPK fertilizer. This early process was an innovation for requiring neither the expensive H_2SO_4 nor producing gypsum waste.

Like related alkaline earth nitrates (as well as $LiNO_3$), calcium nitrate decomposes upon heating to release nitrogen dioxide:

$$2Ca(NO_3)_2 \Rightarrow 2CaO + 4NO_2 + O_2 \quad \Delta H = 369 \text{ kJ/mol}$$

Calcium nitrate is used in explosives, matches and pyrotechnics. Other applications are in the manufacture of incandescent mantle; and as an additive to diesel fuel for corrosion inhibition (Table 4.9).

TABLE 4.9

Thermochemical properties
$\Delta H_f^\circ = -244.24$ kcal/mol
$\Delta G_f^\circ = -177.53$ kcal/mol
$S^\circ = 46.18$ cal/degree mol
$C_p = 35.71$ cal/degree mol

The hydration structure of calcium nitrate tetrahydrate, $Ca(NO_3)_2 \cdot 4H_2O$, which melts at 328 K (55.1 °C) has been investigated by an X-ray scattering method. Analysis of the radial distribution function and model fitting revealed that in the hydrate melt, a Ca^{2+} ion is surrounded by about six oxygen atoms, 4.1 of which come from water molecules at the average distance of 2.41 Å, 2.0 coming from the nitrate ions at the average distance of 2.54 Å. In the first coordination shell of the melt, the formation of a direct Ca^{2+}–NO^{3-} correlation, such as contact ion pairs, was suggested. The hydration structure of the melt analyzed was compared with that of $Ca(NO_3)_2 \cdot 3H_2O$ melt previously reported, and the decrease from nine of the reported melt to six in this melt was observed in the number of the nearest neighbor oxygen atoms around a Ca^{2+} ion. This implies that in the highly concentrated aqueous solution, the structure of the first coordination shell around the cation changes markedly with a small difference in the water molecule content.

Calcium nitrate tetrahydrate exists in two monoclinic crystalline forms (alpha, specific gravity 1.93 and beta, specific gravity 1.82). The melting point of α-$Ca(NO_3)_2 \cdot 4H_2O$ is 44 °C with a boiling point of 83 °C at 760 mm Hg. Enthalpy of vaporization is 37.72 kJ/mol at a vapor pressure of 49.8 mm Hg at 25 °C. β-Calcium nitrate tetrahydrate is a white columnar shape crystal of the monoclinic system whose specific density is 1.82 g/cm^3. Melting point is 39.7 °C. It decomposes at 40 °C or so, and converts into anhydrous calcium nitrate due to thorough dehydration when heated at 151 °C. When heated further to 500 °C, calcium nitrate will first break down in vacuum to calcium nitrite accompanied with emission of oxygen gas, then degrade to calcium oxide and nitrogen oxide. β-Calcium nitrate tetrahydrate dissolves in water, methanol, ethanol, acetone, methyl acetate and liquid ammonia. This calcium nitrate is useful as an oxidizer but its hygroscopic nature, results in extreme deliquescence in air. The unit-cell parameters of these two isomers are shown in Table 4.10.

TABLE 4.10

Crystal system = monoclinic

β	98.6°	106.5°
Z	4	4
Density	1.91 g/cm^3	1.88 g/cm^3
Space group	$P2_1/n$	$P2_1/c$

The structure contains mostly of $Ca_2(NO_3)_4 \cdot (H_2O)_8$ dimers joined by hydrogen bonding, (i.e. $[Ca(NO_3)_2 \cdot (H_2O)_4]$–$[Ca(NO_3)_4 \cdot (H_2O)_4]$.

Calcium nitrate is mainly used as a flocculent in rubber latex and in refrigerant manufacture. And it is also employed in oil exploratory wells and sewage treatment. In agriculture, it is used in hydroponic culture and as a fast-effective fertilizer for acid soil. It can also be used to make fireworks, to produce explosives in national defense industry, and to paint negative poles in the electronic instrument industry. It is also a raw material in making other nitrates. It is this usage that calcium nitrate finds most of its employment in industry, other than its use in agriculture.

Calcium nitrate is a strong oxidizing agent. Mixing it with organic substances such as fuel oil or hydrocarbons or other oxidizable compounds can cause an explosion.

Calcium nitrate has been evaluated as a component for heat storage devices. Enthalpy of melting can be used to store heat in a simple way for time periods of hours and days. The storage capacity first of all depends on the volume-specific enthalpy of melting. At temperatures below 423 K, the largest values are found for salt hydrates. However, for practical performance besides the heat storage capacity, appropriate melting–crystallization temperatures within a few degrees are crucial for intended applications. Also, reversible phase changes over many heating–cooling cycles have to be ensured, which is easier with congruent melting than with incongruent melting hydrates.

Applications of salt hydrates require fine-tuned melting temperatures, which can be achieved by using mixtures. The best mixture found to date consists of $LiNO_3$–$Mg(NO_3)_2$–$Ca(NO_3)_2$.

Calcium nitrate has been found to be an excellent host and solvent for dissolving organic compounds which then react within the waters of hydration, with calcium nitrate acting as a catalyst for the reactions (Fig. 4.12).

The synthesis of 1,2,3,4-dihydropyrimidinone/thione derivatives was achieved in good to excellent yields using calcium(II) nitrate as a catalyst to promote Biginelli three-component condensation reactions from a diversity of aromatic aldehydes, -keto compounds and urea or thiourea. The reaction was carried out under solvent-free conditions. This represents a new usage of such salts and further work to elucidate the exact mechanisms is currently being conducted at various laboratories.

Calcium nitrate is manufactured in tonnage quantities and is offered commercially for sale, by many industrial chemical firms. Major production occurs in Norway for distribution throughout the World.

Strontium Nitrate

Strontium nitrate has the molecular formula of $Sr(NO_3)_2$ and the molecular weight of 211.6327 g/mol. Strontium nitrate is prepared by treating strontium carbonate with nitric acid. The solution is evaporated and crystallized:

$$SrCO_3 + HNO_3 \Rightarrow Sr(NO_3)_2 + CO_2 + H_2O$$

Crystallization yields the tetrahydrate, $Sr(NO_3)_2 \cdot 4H_2O$, which, on heating, melts at 31.3 °C in its own waters of hydration and then decomposes >100 °C to form the anhydrous nitrate. The anhydrate melts at 570 °C (It begins to decompose as low as 545 °C), is soluble in water (70.3 gm/100 ml at 20 °C) and is very slightly soluble in ethanol. These colorless crystals, or white powder, have a density of 2.986 g/cm^3 and its CAS number is 10042-76-9. It is very soluble in water, as shown in Table 4.11 on the following

TABLE 4.11

		g/100 ml of water							
Compound	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**60 °C**	**80 °C**	**90 °C**
Strontium nitrate	$Sr(NO_3)_2$	39.5	52.9	69.5	88.7	89.4	93.4	96.9	98.4

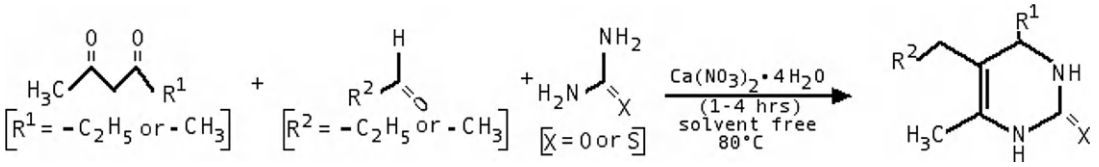

FIGURE 4.12

page. Strontium nitrate apparently forms only the tetrahydrate when a solution is evaporated below 80 °C. Otherwise it decomposes at higher solution temperatures to $Sr(OH)_2$ and nitrogen oxides. The nitric acid concentration makes little difference in the hydrate produced, in contrast to other alkaline earths like Ca and Mg.

The anhydrate is cubic with $a = 7.7813$ Å and space group = Pa3, $Z = 4$.

The tetrahydrate, $Sr(NO_3)_2 \cdot 4H_2O$, has a molecular weight of 283.69 g/cm^3 and a density of 2.21 g/cm^3. It is composed of colorless monoclinic crystals but loses all water of crystallization at 100 °C. The anhydrate is stable to 1100 °C where it converts to strontium oxide, SrO, at 1100 °C. There are three (3) allotropes of the anhydrate known. When $Sr(NO_3)_2$ is heated to 547 °C, a change in structure occurs, i.e. γ-$Sr(NO_3)_2 \Rightarrow \beta$-$Sr(NO_3)_2$ (547 °C). Two other transitions are known: β-$Sr(NO_3)_2 \Rightarrow \alpha$-$Sr(NO_3)_2$ (547 °C) and α-$Sr(NO_3)_2 \Rightarrow$ liq-$Sr(NO_3)_2$ (918 °C). ΔH for liquidification is 44.6 kcal/mol. Decomposition to nitrogen oxides takes place at about 1110 °C. It is very soluble in water, 60.4 g/100 ml at 0 °C, 206 g/100 ml at 100 °C. It is also soluble in liquid ammonia and very slightly soluble in ethanol and acetone (Table 4.11).

The growth behavior of the primary α-phase ($Sr(NO_3)_2$ and the secondary β-phase ($Sr(NO_3)_2 \cdot 4H_2O$) in a $Sr(NO_3)_2$–H_2O peritectic system was observed in situ in a solution flow system. The two phases grew simultaneously below the peritectic temperature in the solution with the composition near the peritectic point. The β-phase grew much faster than the α-phase due to the difference in both supersaturation and kinetic property for two phases. This resulted in the peritectic structure that the β-phase engulfed the α-phase. Using Michelson interferometry, growth rate was measured on the most widely developed faces, the (1 1 1) face of the α-phase and the (1 1 0) face of the β-phase. The β-phase had the larger growth rate and step velocity and the smaller hillock slope than the α-phase at a given supersaturation. The kinetic coefficient β_s and the edge-free energy, α_s, of steps were evaluated as follows: $\beta_s = 5.1 \times 10^{-2}$ cm/s and $\alpha_s = 3.6$ mJ/m^2 for the α-phase; $\beta_s = 5.3 \times 10^{-1}$ cm/s and $\alpha_s = 18$ mJ/m^2 for the β-phase. This indicates that the step kinetics influences the growth of the two phases more significantly than that of the surface energy of step edge.

Industrial uses of strontium nitrate are rather limited and have rather limited commercial value because the corresponding calcium and barium compounds serve the same purpose yet are cheaper. A few, however, have found application in industry and elsewhere. Strontium nitrate, $Sr(NO_3)_2$, and strontium chlorate, $Sr(ClO_3)_2$, are extremely volatile and impart a brilliant crimson color to flames; they are thus used in fireworks and similar displays.

Studies have been made of the band-spectra produced by strontium in an oxy-hydrogen flame, in a "vacuum arc" in water vapor, in a "vacuum arc" in heavy water vapor (D_2O), and in an arc in air at atmospheric pressure. For Sr^{2+}, a band with some structure at 6050 Å and diffuse bands with maxima at 6460, 6590, 6675 and 6820 Å are attributed to SrOH, in agreement with James and Sugden's suggestion, the assignment being supported by small isotopic displacements with SrOD. Bands at 5950 Å, 6050 Å and the far red, obtained best in the arc at 1 atmosphere, have a very complex structure suggesting a polyatomic emitter and variation of strength with concentration when strontium nitrate solution is sprayed into a flame supports assignment to the dimer of the oxide, Sr_2O_2.

Recent clinical studies demonstrate that when strontium nitrate is applied to the facial skin, it significantly reduces skincare-induced burning, stinging and facial redness. These findings are very important to Rosacea sufferers, who report facial burning and flushing to topical skincare products and environmental insults such as wind, sun, heat and cold. This is the first compound that selectively blocks the irritation-producing nerve endings (type C nociceptors) that become activated when itching, burning and stinging occur from any cause. Glycolic acid removes the upper layer of old and dead skin cells, while encouraging the growth of younger, smoother and evenly pigmented looking skin. Strontium nitrate is a substance capable of inhibiting tingling sensations and irritations associated with peels containing glycolic acid. It reduces irritations, inflammations, and redness caused by glycolic acid peels.

Strontium nitrate is available as the tetrahydrate and as a solution from several manufacturers.

Barium Nitrate

Barium nitrate has the molecular formula of $Ba(NO_3)_2$ and the molecular weight of 261.3745 g/mol. It is also known as "nitrobarite". Its CAS number is 10022-31-8. It is soluble in water (Table 4.12).

It can be prepared by a number of methods. The reaction between nitric acid and barium metal is one way and reaction with BaO or $BaCO_3$ is another. Barium hydroxide and ammonium nitrate also form the product but ammonia is released as a by-product:

$$2HNO_3 + Ba \Rightarrow Ba(NO_3)_2 + H_2$$
$$2HNO_3 + BaO \Rightarrow Ba(NO_3)_2 + H_2O$$
$$Ba(OH)_2 + 2NH_4NO_3 \Rightarrow Ba(NO_3)_2 + 2NH_3 + 2H_2O$$

TABLE 4.12

		g/100 ml of water							
Compound	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**60 °C**	**80 °C**	**100 °C**
Barium nitrate	$Ba(NO_3)_2$	4.95	6.67	9.02	11.5	14.1	20.4	27.2	34.4

Barium nitrate can also be prepared by the reaction of barium carbonate or barium carbonate with nitric acid:

$$BaCO_3 + 2HNO_3 \Rightarrow Ba(NO_3)_2 + CO_2 + H_2O$$

In this method, barium carbonate is suspended in nitric acid. The solution is filtered and the product crystallizes out. Alternatively, barium carbonate and nitric acid are added to a saturated solution of barium nitrate. The product is then obtained by crystallization. It may also be prepared by adding sodium nitrate to a saturated solution of barium chloride. Barium nitrate precipitates out from the solution. The precipitate is filtered, washed with alcohol and dried.

Barium nitrate is always anhydrous. It is slightly soluble in water and alcohols (water = 9.1 g/100 ml at 20°; methyl alcohol = 0.057 g/100 ml at 25° and ethyl alcohol = 0.0033 g/100 ml at 20 °C). It is a white, cubic crystal with $a = 8.1184$ Å, space group = Pa3 and a density of 3.24 g/cm^3. Its melting point has been stated as 595.2 °C. However, the exact number is in doubt since 262 °C and 284 °C have been cited. When heated, some decomposition begins as low as 256 °C. The most probable melting point (formation of a liquid) is about 610 °C. The thermolysis of $Ba(NO_3)_2$ has been studied by thermogravimetric analysis (TGA) and DTA. It has been determined that a complex reaction, involving melting, decomposition to produce BaO_2 and BaO, and the transformation of BaO_2 to produce BaO occurs in three stages. This suggested that the thermal decomposition of $Ba(NO_3)_2$ at temperatures higher than 800 °C would be required to obtain BaO directly.

$$Ba(NO_3)_2(\text{solid}) \Rightarrow BaO_2(\text{solid}) + 2NO(\text{gas}) + O_2(\text{gas}) \quad (1)$$

$$Ba(NO_3)_2(\text{solid}) \Rightarrow BaO(\text{solid}) + 2NO(\text{gas}) + 3/2O_2(\text{gas}) \quad (2)$$

Because the BaO_2 decomposes during these temperature intervals, the following overall reaction also occurs:

$$BaO_2\ (\text{solid}) = BaO(\text{solid}) + 1/2O_2(\text{gas}) \quad (3)$$

Barium nitrate is used to produce green color in flares, pyrotechnic devices, in green signal lights; and in tracer bullets. Barium nitrate is used in industry in the production of green signal lights, to remove gases from vacuum tubes, and in the production of barium oxide. The following shows the color of a flare at night (Fig. 4.13). Thermochemical properties are shown in Table 4.13.

TABLE 4.13

Thermochemical properties
$\Delta H_f^o = -237.11$ kcal/mol
$\Delta G_f^\circ = -190.42$ kcal/mol
$S^o = 51.1$ cal/degree mol
$C_P = 36.2$ cal/degree mol

A $Ba(NO_3)_2$ crystal, 60 mm long, was activated by a Q-switched Nd:YAG laser pulses at 1.067 μm with intracavity energies of up to 10 mJ. Intracavity Raman shifting of the barium nitrate crystal led to pulses with energies of 2.5 mJ at 1197 nm. The output pulse duration

FIGURE 4.13

was reduced to 8.5 ns compared to 50 ns at the fundamental wavelength. Beam quality improvement was observed. The Raman radiation was frequency doubled into the yellow spectral region from 580 to 599 nm, which is difficult to reach with other solid-state lasers.

A high-efficiency eye-safe Raman laser was demonstrated by use of the third Stokes radiation in a $Ba(NO_3)_2$ crystal pumped by a 1064 nm Nd:YAG laser. The output wavelength of the Raman laser was 1598.5 nm with a full-width at half-maximum of 1.5 nm. With an incident pump energy of 140 mJ, a maximum of 18-mJ Raman output energy was generated at a repetition rate of 30 Hz, corresponding to an optical-to-optical conversion efficiency of 12.9%. The Raman pulse duration was shortened to 2.9 ns compared with that of the pump pulse of 19.3 ns. The eye-safe solid-state Raman laser is expected to have wide applications in range finding, telemetry, laser radar, and other aspects.

At elevated temperatures above 800 °C, barium nitrate decomposes to barium oxide, nitrogen dioxide, and oxygen, In an atmosphere of nitric oxide, thermal decomposition produces barium nitrite, $Ba(NO_2)_2$. Reactions with soluble metal sulfates or sulfuric acid yield barium sulfate. Many insoluble barium salts, such as the carbonate, oxalate and phosphate of the metal, are precipitated by similar double decomposition reactions. $Ba(NO_3)_2$ is an oxidizer and reacts vigorously with common reducing agents. The solid powder, when mixed with many other metals such as aluminum or zinc in their finely divided form, or combined with alloys such as aluminum–magnesium, ignites and explodes on impact.

This salt is available commercially both as a solid and a solution from many suppliers.

Radium Nitrate

Radium nitrate had the molecular formula of $Ra(NO_3)_2$ and the molecular weight of 350.0343 g/mol. It can be prepared by a number of methods. The reaction between nitric acid and radium metal is one way and reaction with Ra RaO or $RaCO_3$ is another. Radium hydroxide and ammonium nitrate also form the product but ammonia is released as a by-product:

$$2HNO_3 + Ra \Rightarrow Ra(NO_3)_2 + H_2$$
$$2HNO_3 + RaO \Rightarrow Ra(NO_3)_2 + H_2O$$
$$Ra(OH)_2 + 2NH_4NO_3 \Rightarrow Ra(NO_3)_2 + 2NH_3 + 2H_2O$$

Radium nitrate can also be prepared by the reaction of radium carbonate with nitric acid. The product is soluble but can be isolated by evaporation of the solution at low temperature. It occurs as the anhydrate, like barium nitrate, but is slightly more soluble at 12.1 g/100 ml at 20 °C. Its CAS number is 10213-12-4. When heated, $Ra(NO_3)_2$ decomposes at about 280 °C to form RaO. A number of other oxides have been proposed but this decomposition mechanism has not been thoroughly studied. Like the barium analog, the decomposition is probably complex and may involve the peroxides as well. Temperatures above 820 °C are probably required to obtain an oxide. Whether the nitrite is involved during the decomposition is not known.

Little interest has been shown for this compound in industry. The main academic and scientific interest in radium nitrate has been the fact that, since it is soluble (and the ^{226}Ra isotope has a 1600 year half-life), the presence of radium nitrate, even in pico-gram quantities (10^{-12} g/ml) of ingested water is sufficient to cause health problems in the human body because it accumulates in the bones while continuing to emit energetic γ-rays.

Radium nitrate is available commercially in very small quantities.

4.2. ALKALINE EARTH PHOSPHIDES AND OXO-PHOSPHOROUS COMPOUNDS

The alkaline earths form a continuous series of compounds with phosphorous. The valence state of phosphorous can vary from –3, +1, +3, to +5 in the associated acids, H_3P, H_3PO_2, H_3PO_3, HPO_3, $H_5P_3O_{10}$, $H_4P_2O_7$, and H_3PO_4. The oxides are used to prepare the corresponding acids in some cases.

4.2.1. Phosphorous Oxy-Acids

Phosphorous Oxide Anhydrides

The formation of phosphorus oxides is complex. Phosphorus forms two well-defined oxides, namely, diphosphorous trioxide and diphosphorous pentoxide, having the empirical formula P_2O_3 and P_2O_5, respectively. An intermediate oxide, diphosphorous tetroxide, P_2O_4, and possibly the suboxide P_4O (phosphorous tetrioxide) are known.

DIPHOSPHOROUS TRIOXIDE

P_2O_3 has been prepared by the action of the trichloride on phosphorous acid, thus:

$$H_3PO_3 + PC1_3 \Rightarrow P_2O_3 + 3HC1$$

It is also produced when phosphorous trichloride is used to replace the hydroxyl group of anhydrous acetic acid, thus:

$$3CH_3COOH + 2PC1_3 = P_2O_3 + 3HC1 + 3CH_3C(O)C1_3$$

The trioxide sublimes as a mist of solid particles that are difficult to condense completely. The condensate forms a snow-like mass of minute crystals, or large feathery crystals, which is very fusible, deliquescent

and inflammable. The trioxide can be crystallized from dry carbon disulphide in an atmosphere of carbon dioxide at −18 °C. The crystals are filtered off and washed with petroleum ether.

PHOSPHOROUS(III) TETRAOXIDE

P_4O_6 (also called tetraphosphorous hexoxide) is an acid anhydride of phosphorous acid and hence readily reacts with water. P_4O_6 is formed by the combustion of phosphorus in a limited supply of oxygen or air. It contains traces of free phosphorus, which can be removed by dissolving it in carbon disulphide and exposing the solution to the light so that the free phosphorus goes over into the insoluble red form, filtering, and recrystallizing the product as P_4O_6. It melts at 23.8 °C, and boils at 173 °C. It can also be formed by heating the vapor of P_2O_3 above 210 °C. It has the same composition as hypophosphoric acid ($H_4P_2O_6$) but does not form this acid when dissolved in solution. The structure of P_4O_6 is like that of P_4 with an oxygen atom inserted between each of the P–P bonds. The structure of P_4O_{10} is like that of P_4O_6 with the addition of one oxygen bond to each phosphorus atom via a double bond and protruding away from the tetrahedral structure (Fig. 4.14).

PHOSPHOROUS(V) PENTOXIDE

P_2O_5, diphosphorous pentoxide (or P_4O_{10}—called tetraphosphorous decaoxide) may be prepared by direct combustion, in a full supply of air or oxygen, of white phosphorus (ignition temperature about 60 °C), or from phosphorous (III) oxide (50–70 °C), or from red phosphorus (about 260 °C). This solid has long been known to be polymorphic. The form first produced by the combustion of phosphorus has a vapor pressure of 1.0 atmosphere at 359 °C, but if heated to 400° or so, it soon changes into another form with a far smaller vapor pressure. The relations of the various forms are: (I) hexagonal, the volatile form first produced, (II) orthorhombic, [obtained by heating (I)], and (III) tetragonal, obtained by further heating. Once formed, the tetragonal form (III) is the stable modification at all temperatures. Phosphorous pentoxide dissolves in water, first forming metaphosphoric acid HPO_3 and then transforms to the pyro- and ortho-acids. P_4O_{10} is particularly a good dehydrating agent that can even remove water from concentrated nitric acid, HNO_3. It is the most efficient drying agent known (magnesium perchlorate is nearly as good). It is always practically the first (hexagonal) form that is used for drying because it naturally has the largest surface. It has been shown, however, that for equal surfaces all three modifications absorb moisture from the air at about the same rate. But on addition to liquid water, the hexagonal reacts violently, the orthorhombic reacts very slowly even at 100 °C, and the tetragonal at once forms a jelly, which then slowly liquefies. Phosphorous pentoxide is as efficient as drying agent at 90° as it is at 0°. For the most part, these oxides can be used to form "oxy-acids".

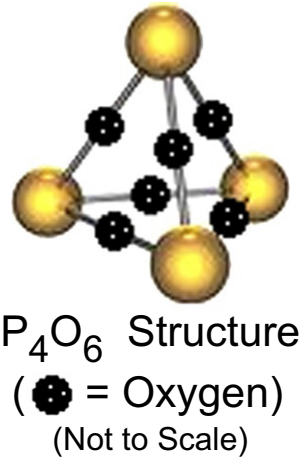

FIGURE 4.14

Phosphorous Acids

Phosphorous acids can have acidic protons bound to oxygen atoms and nonacidic protons which are bonded directly to the phosphorus atom. Although many oxy-acids of phosphorus are formed, only six are important and three of them, hypophosphorous acid, phosphorous acid, and phosphoric acid are the particularly important ones. Two other "peroxy"-acids are included since there properties have been described in the literature.

A summary of these acids is given in the Table 4.14.

HYDROGEN PHOSPHIDE AS AN ACID

Liquid Hydrogen Phosphide: Analysis of this compound shows that it is hydrogen hemiphosphide, $(PH_2)_X$, and the molecular weight corresponds to tetrahydrogen diphosphide, P_2H_4. This liquid, which is the cause of the spontaneous inflammability of phosphine, PH_3, is prepared by passing the gas resulting from the action of water upon calcium phosphide through a freezing mixture. The condensate is a mobile liquid having a density of about 1.01 g/cc that vaporizes between 30 and 40 °C. The boiling point at 735 mm was found to be 57 to 58 °C.

The compound is unstable and decomposes when heated. It is also unstable upon standing and changes, slowly in the dark and quickly in the light, into gaseous and solid hydrides. Since 100 parts by weight produces 38 parts of the solid and 62 parts of the gaseous hydride, this decomposition may be represented by the equation:

$$5P_2H_4 \Rightarrow 6PH_3 + P_4H_2$$

TABLE 4.14

Oxidation state	Formula	Name	Acidic protons	Compounds
+1	H_3PO_2	Hypophosphorous acid	1	Acid and salts
+3	H_3PO_3	(ortho)Phosphorous acid	2	Acid and salts
+5	H_3PO_4	(ortho)Phosphoric acid	3	Acid and salts
+5	$(HPO_3)_n$	Metaphosphoric acids	n	Salts ($n = 3,4$)
+5	$H_4P_2O_7$	Pyrophosphoric acid	4	Acid and salts
+5	$H_4P_2O_6$	Hypophosphoric acid	4	Acid and salts
+5	H_3PO_5	Peroxophosphoric acid	3	Acid and salts
+5	$H_5P_3O_{10}$	Triphosphoric acid	3	Salts

The diphosphide is a yellow powder, which is tasteless, odorless and insoluble in most solvents. It decomposes in the light giving phosphine, and is easily decomposed by heating in an atmosphere of hydrogen. It ignites in air at temperatures between 100 and 200 °C. The empirical formula is $(P_2H)_n$. The molar weight, deduced from the lowering of the freezing point of white phosphorus, corresponds to the formula $P_{12}H_6$. The density is 1.83 g/cm^3 at 19 °C. The heat of formation from white phosphorus and hydrogen is given as +35.4 cal/mol. $P_{12}H_6$ is dissociated when heated in an inert gas into its elements at 175 °C or into phosphorus and phosphine at 215 °C. The ignition temperature in air is 120 to 150 °C. The only liquids that dissolve it without decomposition are phosphorus and PH_3. It dissolves in ammonia at −40 °C with evolution of phosphine. When the diphosphide is gradually heated to 175 °C in vacuo, or when its ammoniate is heated, a reddish powder is formed.

HYPOPHOSPHOROUS ACID

Hypophosphorous acid is a powerful reducing agent with a molecular formula of H_3PO_2. Inorganic chemists refer to the free acid by this name although its IUPAC name is dihydridohydroxidooxidophosphorus, or the acceptable name of phosphinic acid. It is a colorless low-melting compound, which is soluble in water, dioxane, and alcohols. The formula for hypophosphorous acid is generally written H_3PO_2, but a more descriptive presentation is $HOP(O)H_2$ which highlights its monoprotic character. Salts derived from this acid are called **phosphinates** (hypophosphites). Its Lewis structure is shown in Fig. 4.15.

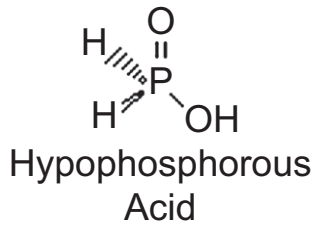

FIGURE 4.15

PHOSPHOROUS ACID

Phosphorous acid, H_3PO_3, is diprotic (readily ionizes two protons), not triprotic as might be suggested by this formula. Phosphorous acid is as an intermediate in the preparation of other phosphorous compounds. Because preparation and uses of "phosphorous acid" actually pertain more to the major tautomer, phosphonic acid, it is more often referred to as "phosphorous acid". Phosphorous acid has the chemical formula H_3PO_3, which is best expressed as $HPO(OH)_2$ to show its diprotic character. $P(OH)_3$ (IUPAC: phosphorous acid) has CAS number 10294-56-1. It has been shown to be a stable tautomer.

Its Lewis structure is shown as in Fig. 4.16.

Diphosphorous acid is made by condensation:

$$2P(OH)_3 \Leftrightarrow (OH)_2POP(OH)_2 + H_2O$$

For phosphorous acid, an **oligophosphorous acid** refers to a few molecules condensed into a molecule with the loss of H_2O as each unit of $P(OH)_3$ is added on. The general formula is $(HO)_2PO[P(OH)O]_{n-2}P(OH)_2$,

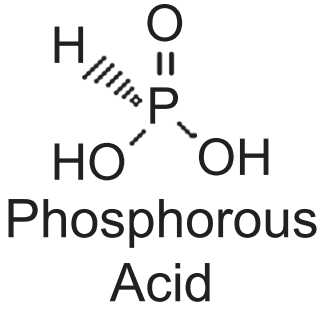

FIGURE 4.16

where $n = 2$, 3, 4, etc. = oligo-. Here, as with phosphonic acid, the repeat unit is $(HPO_2)_{n-2}$. This repeat unit (HPO_2) is called phosphenous acid.

PHOSPHORIC ACID

Chemists refer to orthophosphoric acid as *phosphoric acid*, which is the IUPAC name for this compound. The prefix "ortho" is used to distinguish the acid from other phosphoric acids, which are generally called polyphosphoric acids. Orthophosphoric acid is a nontoxic, rather weak triprotic acid. When pure, it is a solid at STP. Orthophosphoric acid is a very polar molecule which makes it highly soluble in water. The valence state of phosphorous in orthophosphoric acid and other phosphoric acids is +5. Triprotic means that the orthophosphoric acid molecule can dissociate up to three times, producing a hydrogen cation, H^+, each time. This typically combines with H_2O, as shown in the following ionization reactions:

$$H_3PO_4\ (\text{solid}) + H_2O\ (\text{liq}) \Rightarrow H_3O^+\ (\text{aq}) + H_2PO_4^-\ (\text{aq})$$

$$K_{a_1} = 7.25 \times 10^{-3}$$

$$H_2PO_4^-\ (\text{aq}) + H_2O_{(l)} \Rightarrow H_3O^+\ (\text{aq}) + H_2PO_4^{2-}\ (\text{aq})$$

$$K_{a_2} = 6.31 \times 10^{-8}$$

$$HPO_4^{2-}\ (\text{aq}) + H_2O\ (\text{liq}) \Rightarrow H_3O^+\ (\text{aq}) + PO_4^{3-}\ (\text{aq})$$

$$K_{a_3} = 3.98 \times 10^{-13}$$

The anion produced after the first dissociation, $H_2PO_4^-$, is the *dihydrogen phosphate* anion. The salt produced is "monobasic phosphate". The anion after the second dissociation, HPO_4^{2-}, is the *hydrogen phosphate* anion (dibasic phosphate). The anion after the third dissociation, PO_4^{3-}, is the orthophosphate anion (tribasic phosphate). For each of the dissociation reactions shown above, there is a separate "acid-dissociation constant", called K_{a_1}, K_{a_2}, and K_{a_3}. Associated with these three dissociation constants are corresponding values, $pK_{a_1} = 2.12$, $pK_{a_2} = 7.21$, and $pK_{a_3} = 12.67$ values at 25 °C. Even though all three hydrogen (H^+) atoms are equivalent in the molecule, the successive K_a values differ because it is energetically less favorable to lose another H^+ if one (or more) has already been lost so as to cause the molecule/ion to become more negatively charged.

Because of the triprotic dissociation of orthophosphoric acid, its conjugate bases (the phosphates mentioned above) cover a wide pH range, and, because phosphoric acid/phosphate solutions are, in general, nontoxic, mixtures of these types of phosphates are often used as buffering agents or to make buffer solutions, where the desired pH depends on the proportions of the phosphates in the mixtures. Phosphates are found pervasively in biology, especially in the compounds derived from phosphorylated sugars, such as DNA, RNA and adenosine triphosphate (ATP), which are found in all of the cells comprising the human body.

Upon heating orthophosphoric acid, condensation of the phosphoric units, i.e. driving off the water formed from condensation of the molecules produces polyphosphates. When one molecule of water has been removed for each two molecules of phosphoric acid, the result is pyrophosphoric acid, $H_4P_2O_7$. When an average of one molecule of water per phosphoric unit has been driven off, the resulting substance is a glassy solid having an empirical formula of HPO_3 and is called metaphosphoric acid.

Metaphosphoric acid is a singly anhydrous version of orthophosphoric acid and is sometimes used as a water- or moisture-absorbing reagent. Further dehydration is very difficult, and can be accomplished only by means of an extremely strong desiccant (and not by heating alone). This produces "phosphoric anhydride", which has an empirical formula P_2O_5, although the actual molecule has a chemical formula of P_4O_{10}. Phosphoric anhydride is a solid, which is very strongly moisture absorbing and is mainly used as a desiccant.

METAPHOSPHORIC ACID

When an average of one molecule of water per phosphoric unit has been driven off from phosphoric acid, H_3PO_4, the resulting substance is a glassy solid having an empirical formula of **HPO_3** and is called metaphosphoric acid. Metaphosphoric acid is a singularly anhydrous version of orthophosphoric acid and is sometimes used as a water- or moisture-absorbing reagent. Metaphosphoric acid has phosphorus in the formal oxidation state of +5. Although it has several CAS numbers: 10343-62-1, 135306-83-1, 13566-25-1, and 37267-86-0, only the last two are associated with the IUPAC name "phosphenic acid".

Metaphosphoric acid units can be bonded together in rings (cyclic structures), chains (catena), or branched by condensation yielding water as each acid unit is added. These structures consist of linked metaphosphoric acid molecules. For example, trimetaphosphoric acid is the simplest cyclophosphoric acid. Metaphosphoric acid would need to share the doubly bonded oxygen with neighboring phosphorus atoms to form polymers itself. Many oligamers are possible with the alkaline earths but the trimetaphosphates and hexametaphosphates seem to be the most prevalent. These would have the general formula of MHP_3O_9 and $M_2HP_6O_{18}$. Trimetaphosphates are often moderately soluble, e.g. $Ag_3(PO_3)_3 \cdot H_2O$ and $Ba(HPO_3)_3 \cdot 6H_2O$.

Monometaphosphates are known but only with alkali cations. Dimetaphosphates form with transition elements like Zn^{2+} and Mn^{2+} while tetrametaphosphates form compounds with the alkaline earths like Ba^{2+}. Calcium,

strontium and barium salts, when added to solutions of pentametaphosphates, gave gummy or flocculent precipitates of uncertain character. Hexametaphosphates of the alkaline earths are also known. The complex basic phosphates such as $5CaO \cdot 3P_2O_5$, which was made by passing the vapor of phosphorus pentoxide over anhydrous calcium oxide, are supposed to be derived from more hydrated condensed acids such as $H_5P_6O_{20}$. However, this has never been confirmed in the current literature.

PYROPHOSPHORIC ACID

Pyrophosphoric acid, also known under the name **diphosphoric acid**, is colorless, odorless, hygroscopic and is soluble in water, diethyl ether and ethyl alcohol. It is produced from phosphoric acid by dehydration. Pyrophosphoric acid slowly hydrolyzes in the presence of water into phosphoric acid.

$$H_4P_2O_7 + H_2O \Rightarrow 2H_3PO_4$$

Pyrophosphoric acid is a medium strong acid. It has the Lewis structure shown in Fig. 4.17.

Upon heating, phosphoric acid loses water, being converted successively, and to some extent concurrently, into the pyro- and meta-acids:

$$2H_3PO_4 \Rightarrow H_4P_2O_7 + H_2O$$
$$nH_3PO_4 \Rightarrow (HPO_3)_n + [H_2O]_n$$

According to early investigators, the pyro-acid is formed as low as 100 °C, and the conversion is complete between 255 and 260 °C. Phosphorous oxychloride reacts with phosphoric acid in the following manner:

$$5H_3PO_4 + POC1_3 \Rightarrow 3H_4P_2O_7 + 3HC1$$

A mixture of the ortho- and meta-acids may be condensed together to form the pyro-acid by heating on the water bath:

$$nH_3PO_4 + [HPO_3]_n \Rightarrow [H_4P_2O_7]_n$$

The concentrated acid, prepared by dehydration of orthophosphoric acid, is a highly viscous liquid and probably is polymerized.

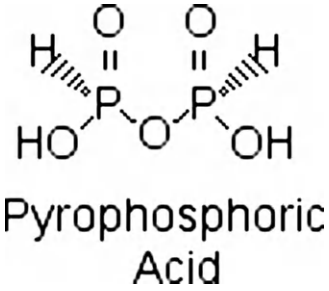

FIGURE 4.17

The heats of transformation by means of liquid water were found to be:

$$H_4P_2O_7 \text{ (solid)} + H_2O \Rightarrow 2H_3PO_4 \text{ (solid)} \quad \Delta H_{Trans} = +6.97 \text{ cal/mol}$$
$$H_4P_2O_7 \text{ (liq)} + H_2O = 2H_3PO_4 \text{ (liq)} \quad \Delta H_{Trans} = +9.09 \text{ cal/mol}$$
$$H_4P_2O_7 \text{ (aq).} = 2H_3PO_4\text{(aq)} \quad \Delta H_{Trans} = +4.25 \text{ cal/mol}$$

All the evidence shows that pyrophosphoric acid is tetrabasic and that each hydrogen is that of a stronger acid, i.e. more dissociated at the same dilution, than orthophosphoric acid.

Salts of these acids are prepared by heating the orthophosphates to form the pyrophosphate.

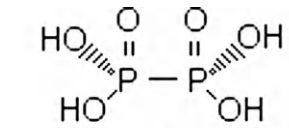
HYPOPHOSPHORIC ACID

This acid has the general formula of $H_4P_2O_6$ and differs from the other oxy-phosphorous acids. It has many peculiarities. It is formed along with phosphorous and phosphoric acids, when phosphorus is oxidized by moist air. If white phosphorus is exposed to air, and sodium acetate is added to the liquid which forms, the somewhat insoluble sodium hypophosphate, $Na_2H_2P_2O_6 \cdot 6H_2O$ separates. The sodium hypophosphate monohydrate, however, is very soluble and deliquescent at ~98.7 g/100 ml.

$H_4P_2O_6$ can also be prepared by (I) treating red phosphorus with concentrated sodium hydroxide and hydrogen peroxide, and (II) also by the action of alkaline hydrogen peroxide on P_2I_4, or by the hydrolysis of phosphorous trichloride or tribromide in presence of iodine. It is to be noticed that methods I and II start with a material containing P–P links. Hypophosphoric acid is not formed by the hydration of P_4O_8, which only yields phosphorous and phosphoric acids. Lead and barium hypophosphates are insoluble, and the free acid can be obtained from them by means of hydrogen sulfide or sulfuric acid. It forms a hydrate $H_4P_2O_6 \cdot 2H_2O$, M.P. = 70°most chemists know that M.P. = melting point. The anhydrous acid can be formed on standing *in vacuo* in the presence of a dehydrating agent like phosphorous pentoxide.

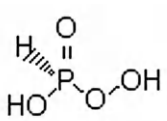
The best method seems to be the addition of hydrogen peroxide to a suspension of red phosphorus in water. The peroxide is added slowly over a period of time because an intense, explosive reaction will occur. When most of the P_4 has dissolved, then NaOH is added to pH 4.5. Cooling causes the crystallization of $Na_2H_2P_2O_6 \cdot 6H_2O$. Ethyl alcohol is added to aid in the formation of the crystals. The final pH is adjusted to 5.2. All alkaline earths hypophosphates are insoluble. If the oxidation reaction is carried out in an alkaline medium, the products include phosphite, phosphate diphosphate and hypophosphate.

Hypophosphoric acid has far less reducing power than phosphorous acid, and it is hydrolyzed in strongly

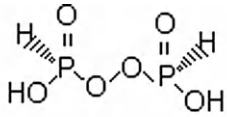


Hypophosphoric Acid

FIGURE 4.18



Peroxyphosphoric Acid



Peroxydiphosphoric Acid

FIGURE 4.19

acid solution at elevated temperature to phosphorous and phosphoric acid:

$$H_4P_2O_6 + H_3O^+ \Rightarrow H_3PO_4 + H_3PO_3$$

The double formula $H_4P_2O_6$ was established by molecular weight determinations by the freezing point of solutions in water of the free acid and of the salt $Na_2H_2P_2O_6 \cdot 6H_2O$. Also the rate of hydrolysis of the acid by hydrogen ion to $H_3PO_4 + H_3PO_3$ is strictly monomolecular for $H_4P_2O_6$. It is thus clear that the acid is $H_4P_2O_6$, and probable Lewis structure for this acid is shown in Fig. 4.18, where a direct bond between the two P-atoms is evident.

PEROXOPHOSPHORIC ACID

Two of these acids have been prepared, a peroxymonophosphoric acid H_3PO_5 and a peroxydiphosphoric acid $H_4P_2O_8$. Note that the latter is related to pyrophosphoric acid. Both are formed with 30% hydrogen peroxide, the first with phosphorous pentoxide:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$

The reaction is very violent, but it can be moderated by using acetonitrile as a solvent. At higher concentrations, the peroxydiphosphoric acid can be produced. This is a stronger oxidizing agent than peroxymonosulphuric acid. With silver salts, it forms oxygen plus silver phosphate Ag_3PO_4. It converts aniline into nitroso- and nitrobenzene, and manganous salts quickly in the cold into permanganates. If pyrophosphoric acid is treated with hydrogen peroxide the diperoxy-acid $H_4P_2O_8$ is formed along with the monoacid. The two behave differently with potassium iodide: the monoacid separates iodine at once, and the other acid only slowly. In water, the two acids go over into one another, the mono- predominating in acid and the di-(peroxy-) in alkaline solution. Their Lewis structures are shown in Fig. 4.19.

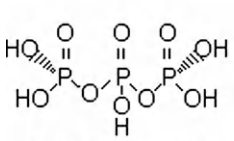
TRIPOLYPHOSPHORIC AND TETRAPOLYPHOSPHORIC ACID

Triphosphoric acid, also tripolyphosphoric acid, with formula $H_5P_3O_{10}$, is a condensed form of phosphoric acid. In the series, polyphosphoric acids, it is the next after pyrophosphoric acid, $H_4P_2O_7$, which is also called diphosphoric acid. It can be made by condensing pyrophosphoric acid with phosphoric acid:

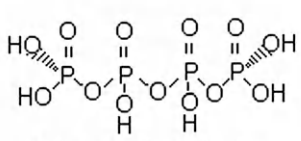
$$H_3PO_4 + H_4P_2O_7 + \text{heat} \Rightarrow H_5P_3O_{10} + H_2O$$

Both tripolyphosphoric and tetrapolyphosphoric acids are known. The tripoly acid is related to the trimetaphosphoric acid as shown in the Lewis structures (Fig. 4.20).

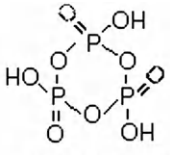
Three orthophosphoric acid molecules can condense in a line to obtain **tripolyphosphoric acid** ($H_5P_3O_{10}$), as shown in the illustration. This condensation process can continue with additional orthophosphoric acid units to obtain **tetrapolyphosphoric acid** ($H_6P_4O_{13}$) and so on. Note that each extra phosphoric unit adds one extra H-atom, one extra P-atom, and three extra O-atoms. The "backbone" chain of these types of molecules consists of alternating P and O atoms covalently bonded together. Polyphosphoric acid molecules can have dozens of such phosphoric units bonded in a row. A general formula for such poly-acid compounds is $HO(PO_2OH)_xH$, where x = number of phosphoric units in the molecule. The four oxygen atoms bonded to each phosphorus atom are in a tetrahedral configuration with the phosphorus in the center of the tetrahedron and the oxygens in each of the four corners. While the diagrams show the linkage of the tetrahedral $[P(=O)\text{-}O_2\text{-}OH]_n$ units as linear, they can also form branched units in the tetrapolyphosphate.



Tripolyphosphoric Acid



Tetrapolyphosphoric Acid



Trimetaphosphoric Acid

FIGURE 4.20

For the alkaline earths, we shall be interested in the following acids and their products:

HYPOPHOSPHOROUS ACID

$H_3PO_2 = HO\text{-}P(=O)(OH)$, a monobasic acid in valence state +1. One (1) salt is possible with the alkaline earths that form hypophosphites.

PHOSPHOROUS ACID

$H_3PO_2 = H\text{-}P(=O)(OH)_2$, a dibasic acid in valence state +3. Two (2) salts are possible with the alkaline earths that form phosphates.

PHOSPHORIC ACID

$H_3PO_4 = HO\text{-}P(=O)(OH)_2$, a dibasic acid in valence state +5. Three (3) salts are possible with the alkaline earths that form phosphates.

METAPHOSPHORIC ACID

$HPO_3 = HOP(=O)O$, the trimetaphosphoric state= $H_2(HPO_3)_3$, is a dibasic acid in valence state +5. One (1) salt is possible with the alkaline earths that form such compounds. The hexametaphosphoric state = $H_4(HPO_3)_6$ forms two salts with certain alkaline earths.

PYROPHOSPHORIC ACID

$H_4P_2O_7 = (HO)_2(O=)P\text{-}O\text{-}P(=O)(OH)_2$ is a tetrabasic acid in valence state +5. Two (2) salts are possible with the alkaline earths.

HYPOPHOSPHORIC ACID

$H_4P_2O_6 = (HO)_2P(=O)\text{-}P(=O)\text{-}(OH)_2$ is a tetrabasic acid with P in the +5 valence state. Two (2) salts are possible with the alkaline earths.

PEROXOPHOSPHORIC ACID

H_3PO_5 or $H_4P_2O_8 = HO\text{-}P(=O)\text{-}O\text{-}OH$ or $(HO)P(=O)\text{-}O\text{-}OP(=O)\text{-}OH$ is a monobasic acid with P in the +5 valence state. One or two compounds are possible with the alkaline earths.

TRIPOLYPHOSPHORIC ACID

$H_5P_3O_{10}$ or $H_6P_4O_{12} = (HO)_2\text{-}P(=O)\text{-}O\text{-}P(=O)(OH)\text{-}O\text{-}P(=O)(OH)\text{-}O\text{-}P(=O)\text{-}(OH)_2$ is a hexabasic acid with P in the +5 valence state. Three (3) compounds are possible with the alkaline earths.

4.2.2. Alkaline Earth Phosphides

Although there are a number of ways to prepare phosphides, the most general method is to heat stoichiometric amounts of the metal and red phosphorus to high temperature in an inert atmosphere or a vacuum. Alkali and alkaline earth metal phosphides are inert metallic-looking solids with high melting points and electrical conductivities. Many are semiconductors.

There are many metal phosphides, M_3P_2, which can be considered Zintl phases with phosphorus as a negative anion, P^{-3}. Zintl phases are ionic in contrast to covalent P to P bonding. They can be made by reaction of red or white phosphorus at high temperature in the absence of air. They can also be made using solvents such as tetrahydrofuran (C_4H_8O), monoglyme (1,2-Dimethoxyethane) or dimethylformamide (C_3H_7NO). Such phosphides can include: P^{3-}, P_2^{4-}, P_3^{4-}, P_3^{4-}, P_5^{4-}, P_6^{4-}, P_7^{4-}, P_{11}^{4-}, P_{14}^{6-}, P_{16}^{4-}, P_{19}^{4-}, P_{21}^{4-}, P_{26}^{4-}, $[P^-]_x$, $[P_5^-]_x$, $[P_6^{4-}]_x$, $[P_7^-]_x$, and $[P_{15}^-]_x$. The structure of Sr_3P_{14} and Ba_3P_{14} features discrete P_7^{3-} cages.

Monophosphides = P^{3-} which are formed by Mg, Ca, Sr and Ba (M_3P_2)

Diphosphides = P_2^{4-} which are formed by Ca and Sr (M_2P_4) as Zintl phases

Triphosphides = P_3^{5-} which are not known with the alkaline earths

Tetraphosphides = P_4^{6-} which is formed by Ba (Ba_3P_4)

Beryllium Phosphide

Beryllium phosphide has the formula of Be_3P_2 and the molecular weight of 88.9841 g/mol. It can be prepared by reaction of the elements, but not from aqueous solution:

$$12Be + 2P_4 \Rightarrow 4Be_3P_2$$

Red phosphorus melts at 317.3 °C and the boiling point is 553 °C so that addition of Be metal serves to form the phosphide. By adding Be to P_4 at about 350 °C, but less than the phosphorus sublimation temperature of 415 °C in an inert atmosphere, the melt readily forms the phosphide. A better way is to sublime the P_4 at 450 °C in an inert gas stream and react it with Be metal at 750 °C. Be_3P_2 has the CAS number 58127-61-0. It is a brown powder having a slight odor of garlic. Once formed, Be_3P_2 is very stable. However, it reacts slowly with moisture to form phosphine, PH_3 (which is toxic and flammable), and must be stored under dry conditions.

Beryllium phosphide is a semiconductor and has been studied by XRD methods using powder or a crystal, and by neutron diffraction from powder. The cell is tetragonal with $a = 10.22$ Å, $c = 20.39$ Å, Group I_{41}/a, $Z = 32$. The structure is like a superstructure of anti-fluorite with an ordering of vacancies and beryllium atoms.

Be_3P_2 is a direct band gap material with an eV of about 1.60. This is centered at about 775 nm which is too small to be of use in formulating semiconductors for LEDs or the like. The band gap of Mg_3P_2, for

example, is 160% wider. It is for this reason that beryllium phosphide films or composites have found little usage in the industry.

Furthermore, it has been shown that Be_3P_2 microcrystals are formed preferentially when Be was used as a dopant in phosphorus-based semiconductor compounds grown by chemical beam epitaxy. An example is an epilayer of $In0_{0.53}Ga_{0.47}As$ sandwiched between undoped InP epilayers to form InGaAs/InP interfaces. When Be was added as an electronic doping agent, the results showed that microcrystal formation occurs when high Be concentrations ($>10^{18}/cm^3$) and temperatures higher than 500 °C are used for crystal growth. The main consequence of Be_3P_2 formation is a high phosphorus consumption close to these microcrystals that causes a large density of P vacancies in the semiconductor layer. Experimental data shows that neutral Be interstitials in InGaAs and singly positively charged Be interstitials in InP result. This creates reduced electrical mobility, lattice parameter reduction, and poor crystallinity of the film in general.

A novel beryllium phosphide has been reported when a Au/AuBe/Au/p-GaP(111) thin-film system was rapidly annealed at 500 °C. The beryllium phosphide appeared having the crystal structure of a fcc lattice. The lattice constant of this beryllium phosphide is about 4.996 Å. The formation of beryllium phosphide was confined to the cubic-to-cubic orientation of GaP as a relationship with this cubic compound. The crystal structure of this beryllium phosphide does not pertain to those of any known binary beryllium phosphide systems. Thus, it was concluded that this cubic beryllium phosphide, was a new discovery.

Beryllium phosphide is offered by several manufacturers commercially for sale. Since it reacts slowly with water, it must be stored under dry conditions until usage.

Magnesium Phosphide

Magnesium phosphide has the formula of Mg_3P_2 and the molecular weight of 134.9456 g/mol. It can be prepared by reaction of the elements, but not from solution:

$$12Mg + 2P_4 \Rightarrow 4Mg_3P_2$$

Red phosphorus melts at 317.3 °C and the boiling point is 553 °C so that addition of Mg metal serves to form the phosphide. By adding Mg to P_4 at about 350 °C, but less than the sublimation temperature of 415 °C in an inert atmosphere, the melt readily forms the phosphide. A better way is to sublime the P_4 at 450 °C in an inert gas stream and react it with Mg metal at 750 °C. Mg_3P_2 has the CAS number of 12057-74-8 and is marketed as magnesium phosphide. It is a yellow cubic crystal having a density of 2.06 g/cm. It reacts violently with water and may ignite upon contact with air. It is toxic by ingestion. It has a slight odor of garlic. It is not combustible but forms a flammable gas on contact with water or damp air:

$$Mg_3P_2\,(solid) + 6H_2O\,(liq) \Rightarrow 3Mg(OH)_2\,(solid) + 2PH_3\,(gas)$$

Mg_3P_2 burns in air or oxygen at a dull red heat to form a phosphate, and reacts with chlorine gas to form:

$$Mg_3P_2\,(solid) + Cl_2 \Rightarrow MgCl_2 + PCl_3$$

The cubic structure of Mg_3P_2 has a D_{3h} symmetry and trigonal bipyramidal geometry. The antibixbyite structure of Mg_3P_2 is derived from the cubic bixbyite structure of the metal sesquioxide by switching the metal and nonmetal positions. The lattice constant is 6.06 Å.

A systematic study of the Mg–P system has revealed that only two compounds exist in the phase diagram: Mg_3P_2 and MgP_4. The latter compound was prepared using the former plus an excess of phosphorus:

$$2Mg_3P_2\,(solid) + 5P_4\,(gas) \Rightarrow 6MgP_4$$

The preparation of MgP_4 occurred from the reaction of gaseous P with Mg_3P_2 at 600 °C in a sealed silica tube. Powder XRD methods found that the structure of the MgP_4 to be isostructural with CdP_4. The crystal structure refinement from X-ray data produced the lattice constants: $a = 5.141$ Å, $b = 5.079$ Å, $c = 7.518$ Å,= 98.64°; $Z = 2$; space group $P2_1/c$. Among the distances between the P-atoms, there are three distinctly smaller ones than the others in the unit cell. Two of them are 2.18 Å and 2.19 Å in size between the P(1) and P(2) atoms and form a helical chain around a screw axis at $[x = 1/2, z = 1/4]$ and $[x = 1/2, z = 3/4]$ in the unit cell. These helices are joined with P to P bonds of 2.24 Å and the P-atoms are tetrahedrally distorted. The Mg atoms, which are all in centers of symmetry, have a distorted octahedral coordination.

The ^{31}P solid-state NMR spectra of Mg_3P_2 and MgP_4 were reported. Static and magic angle spinning (MAS) spectra were obtained for each compound. In all cases, chemical shift anisotropy and the effects of dipolar broadening were sufficiently reduced by the MAS method to reveal the isotropic chemical shifts for each crystallographically distinct phosphorus atom. The observed resonances were assigned to the different types of phosphorus by considering the structural details of each compound. In Mg_3P_2, two chemical resonance shifts from the 24*d* and 8*a* site P atoms were observed at −262.3 and −239.6 ppm, respectively. In MgP_4, two types of phosphorus, one type coordinated to two Mg and two P and the other to three P and one Mg, gave chemical shifts of −109.2 and −6.1 ppm, respectively.

Magnesium phosphide has found several uses in industry. It reacts with moisture in the atmosphere to produce phosphine gas which is the substance that is

active as a pesticide to control insects and rodents. It is primarily used for indoor fumigation of raw agricultural commodities, animal feeds, processed food commodities, and nonfood commodities in sealed containers or structures, and for outdoor fumigation of burrows to control rodents and moles in nondomestic areas, noncropland, and agricultural areas. Aluminum and magnesium phosphide are formulated as tablets, pellets, impregnated materials and dusts. Aluminum and magnesium phosphide are restricted use chemicals.

Tobacco was fumigated to control the cigarette beetle "*Lasioderma serricorne*" with a fumigant based on magnesium phosphide (Detiaphos-R™) in hogsheads and cartons at temperatures held almost constantly below freezing point and alternatively at temperatures which increased or decreased very slowly in the course of the fumigation. The dosage was 1.0 g PH_3/m^3 and the fumigation lasted 96 h in all cases. Gas concentration measurements in the tobacco and under sheeting showed that PH_3 developed rapidly in lethal concentrations from magnesium phosphide at low temperatures. Complete mortality of the interred test insects was registered after 96 h of the fumigation period. With magnesium phosphide, a fumigant is available which can be used for fumigating tobacco even at low temperatures.

Magnesium phosphide treatment of dried-fig stacks at 600 and 1000 ppm phosphine for 3 days under tarpaulin were compared with the standard method of control, Methyl bromide. The tested concentrations and exposure periods for Mg_3P_2 provided 100% mortality in test insects and no negative effect on fruit quality for 9 months in storage under ambient conditions. In contrast, fruit quality with CH_3Br did not match that of PH_3-treated fruit.

Magnesium phosphide has also been used to control insects in stored almonds, barley, brazil nuts, cashews, cocoa beans, coffee beans, corn, cottonseed, dates, filberts, flower seed, grass seed, millet, oats, peanuts, pecans, pistachio nuts, popcorn, rice, rye, sorghum, soybeans, sunflower seed, triticale, walnuts, wheat, vegetable seed, animal feed or feed ingredients.

Electronic structure calculations for Mg_3P_2 have been performed. Mg_3P_2 is predicted to be a direct semiconductor with the gap value of about 2.55 eV. The band gap widens in the alkaline earth series:

$$Be_3P_2 = 1.60 \text{ eV}; Mg_3P_2 = 2.55 \text{ eV}; Ca_3P_2 = 1.73 \text{ eV}$$

Whereas the complex polymeric structures of the Ca, Sr and Ba **polyphosphides** have received considerable attention in the literature, that of the Mg complex is almost nonexistent.

Magnesium phosphide is readily available from a number of manufacturers worldwide but is a restricted usage chemical and its importation is controlled in the U.S.

Calcium Phosphide

Calcium phosphide has the molecular formula of Ca_3P_2 and the molecular weight of 182.1825 g/mol. Its CAS number is 1305-99-3. It is a red-brown crystalline material with a melting point of 1605 °C. Its density is 2.51 g/cm^3. It readily reacts with water to form phosphine, PH_3, but is insoluble in ethanol.

It is easily prepared by reacting the metal with red phosphorus at high temperature. The best way is to sublime the P_4 at 450 °C in an inert gas stream and react it with Mg metal at 750 °C:

$$6Ca + 2P_4 \Rightarrow 2Ca_3P_4$$

Metal phosphides, primarily Ca_3P_2, have been used as rodenticides. Calcium phosphide baits have strong, pungent garlic-like odor characteristic for phosphine liberated by hydrolysis. The odor attracts rodents, but has a repulsive effect on other animals, who are not receptive to the smell. This salt has uses in incendiary bombs and other explosives. On contact with acids or water, calcium phosphide releases phosphine, which ignites spontaneously. It is also used in fireworks, torpedoes, self-igniting naval pyrotechnic flares, and various water-activated ammunition.

Early work (1845) separated diphosphine from phosphine that had been generated from Ca_3P_2, thereby demonstrating that P_2H_4 is responsible for the spontaneous flammability associated with PH_3, and also for the characteristic orange/brown color that can form on surfaces, which is a polymerization product. Ca_3P_2 produces more P_2H_4 than other phosphides because of the preponderance of P–P bonds in the starting material.

It has been established that CaO and P_4 react stoichiometrically at the temperature of 1100 °C to form the phosphide and orthophosphate:

$$24CaO + 4P_4 \Rightarrow 5Ca_3P_2 + 3Ca_3(PO_4)_2$$

Although the complete phase diagram for Ca–P has not been completely established, the reaction of excess P with calcium phosphide is sufficient to form the compound, CaP:

$$Ca_3P_2 + P_4 \Rightarrow 3Ca_2P_2 \text{ (CaP)}$$

or "calcium monophosphide". The term "calcium phosphide" describes the composition Ca_3P_2. CaP and Ca_3P_2 are completely different materials. CaP is black, but Ca_3P_2 is red-brown. The monophosphide is unstable and decomposes to Ca_3P_2 at about 600 °C.

$$12CaP \Rightarrow 4Ca_3P_2 + P_4$$

The structures of CaP and sodium peroxide (Na_2O_2) are very similar. The solid is described as a salt: $(Ca^{2+})_2P_2^{4-}$, or Ca_2P_2. Since the bonding is ionic (as a Zintl phase), the diphosphide centers carry a negative

charge and are easily protonated. Upon hydrolysis, this material releases diphosphine (P_2H_4):

$$Ca_2P_2 + 4H_2O \Rightarrow 2Ca(OH)_2 + P_2H_4$$

In this case, diphosphine spontaneously ignites in air. Thus, CaP must be protected from air or moisture. The thermal decomposition of calcium phosphohydride, $Ca(PH_2)_2$, prepared in liquid ammonia from calcium hydride and PH_3, was shown by X-ray analysis to decompose to first form Ca_2P_2 at 650 °C and then at 800 °C to form Ca_3P_2 plus P_4.

CaP and SrP, crystallize with the Na_2O_2 structure type, characterized by groups of P_2^{4-}. The magnetic susceptibility and the lattice constants of CaP show that P is divalent in this compound. The corresponding phase, BaP, is said not to exist. Calcium also forms a dicalcium hexaphosphide. The structure of Ca_2P_6 has been shown to consist of the P_6^{4-} groups bonded together to form a specific pattern (Fig. 4.21).

This is a polyphosphide which is a member of the polyphosphides referred to at the beginning of this section. In some of these positions in the structure, some of the P-atoms have only 2-bonds plus a negative charge. This accounts for the alkaline earth bonds that make up the total charge and bonding in the structure. This compound has been predicted to be a semiconductor with the direct band gap of 2.62 eV (473.3 nm).

A salt with the formula, $Na_{22}Ca_{13}P_{16}$ is said to exist but corroborating data is scanty.

A Knudsen-effusion technique in combination with a mass spectral analysis of the vapor phase has been applied to study thermodynamic properties of $(Ca_x + P_{1-x})$ alloys $(0.5 \leq x \leq 1)$ over the temperature range 650 K to 1537 K (377 °C to 1264 °C). The compound CaP was found to be unstable and to decompose at low temperatures (~600 °C) into Ca_3P_2 and gaseous phosphorus. Evaporation of the phosphide

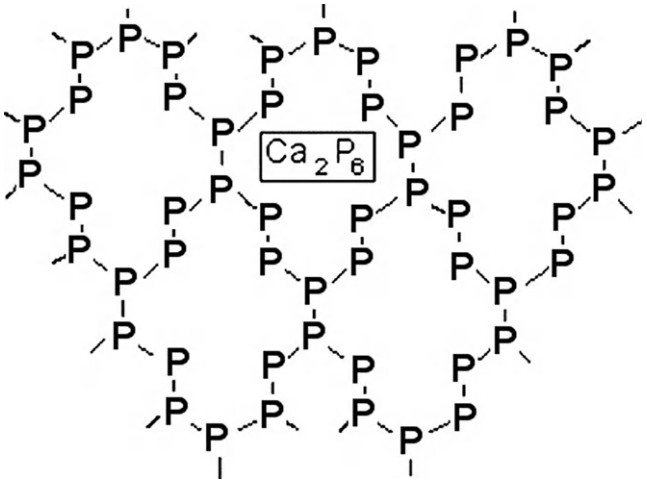


FIGURE 4.21

Ca_3P_2 was followed by congruent decomposition. The standard molar Gibbs energy of formation of Ca_3P_2 from red phosphorus and solid calcium, over the range of 1000 to 1300 °C, has been expressed by the equation:

$$3Ca(liq) + P_2(gas) = Ca_3P_2(solid) \quad \Delta G^\circ = -653{,}460 + 144.01T \text{ (J/mol)}$$

Thermodynamic functions of $[x\ Ca + (1-x)\ P]$ have been estimated with help of $\Delta_f G_m$ (Ca_3P_2) values and the coordinates of a point on the line of the two-phase equilibrium $(Ca_3P_2 + 1)$. It has been shown that the liquid solution can be described by the ideal associated solution model if complexes of the Ca_3P_2 type are assumed to exist.

Calcium phosphide is readily available as a fumigant and insecticide from many manufacturers worldwide commercially.

Strontium Phosphide

Strontium phosphide has the molecular formula of Sr_3P_2 and the molecular weight of 324.8075 g/mol. Its CAS number is 12504-13-1. It is a black crystalline material with a melting point of 1205 °C. Its density is 2.71 g/cm^3. It readily reacts with water to form phosphine, PH_3, but is insoluble in ethanol.

It is easily prepared by reacting the metal with red phosphorus at high temperature. The best way is to sublime the P_4 at 450 °C in an inert gas stream and react it with Sr metal at 650 °C:

$$6Sr + 2P_4 \Rightarrow 2Sr_3P_4$$

Strontium phosphide is a solid which will evolve flammable and toxic gases on contact with water. It also can react vigorously with oxidizing materials. In general, materials in this group are incompatible with oxidizers such as atmospheric oxygen. They are violently incompatible with acids, particularly oxidizing acids.

Strontium phosphide has not been utilized in industry due to cost and the fact that the calcium salt is just as efficacious.

Strontium also forms polyphosphides such as Sr_2P_6 which has been shown to have a structure similar to that of Ca_2P_6 except that a cyclic P_6^{2-} group is situated between the P_{13}^{4-} groups (Fig. 4.22).

In some of these positions in the structure, the P-atoms have only 2-bonds plus a negative charge. This accounts for the alkaline earth bonds that make up the total charge and bonding in the structure.

The compounds $CaFe_2P_2$, $SrFe_2P_2$ and $BaFe_2P_2$ have been studied because of their magnetic properties. They crystallize in the $ThCr_2Si_2$ structure that is a ternary variant of the $BaAl_4$ structure. For the three compounds, densities of states (DOS), local partial DOS and electron

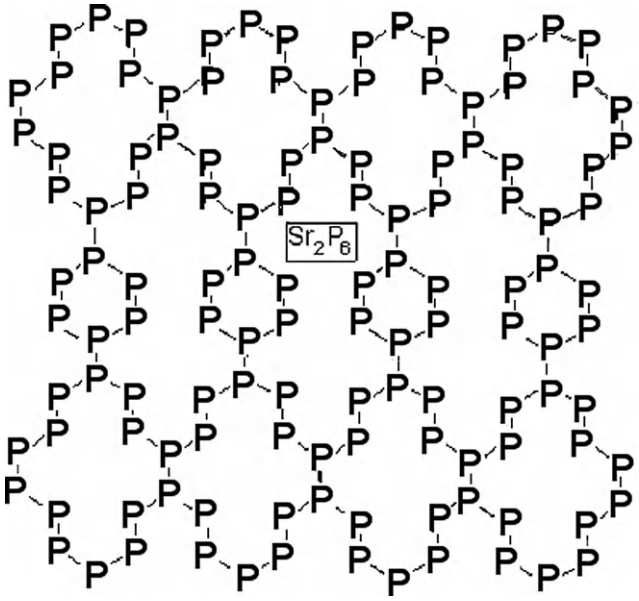

FIGURE 4.22

densities have been calculated. Compared to $CaNi_2P_2$ with a P–P distance of 2.30 Å (a value very close to that for a P–P single bond), the distance found for is 2.71 Å for $CaFe_2P_2$. While in this compound one still observes pronounced P–P (s–s and p–p) σ-bonds, this is not the case for $SrFe_2P_2$ and $BaFe_2P_2$ (P–P distances: 3.43 Å and 3.84 Å, respectively). Despite their different c/a ratios, the Sr and Ba compounds show fairly similar bonding properties, in particular as far as the Fe–Fe and Fe–P interactions are concerned. In $BaFe_2P_2$, however, non-negligible interactions of the semicore [Ba(5p)] states with the P(3s) states are found.

Strontium phosphide is available in limited quantities from domestic manufacturers. It is a restricted usage chemical, monitored by the EPA.

Barium Phosphide

Barium phosphide has the molecular formula of Ba_3P_2 and the molecular weight of 182.1825 g/mol. Its CAS number is 12380-72-2. It is a red-brown crystalline material with a melting point of 1585 °C. Its density is 2.51 g/cm^3. It readily reacts with water to form phosphine, PH_3, but is insoluble in ethanol.

It is easily prepared by reacting the metal with red phosphorus at high temperature. The best way is to sublime the P_4 at 450 °C in an inert gas stream and react it with Ba metal at 600 °C:

$$6Ba + 2P_4 \Rightarrow 2Ba_3P_4$$

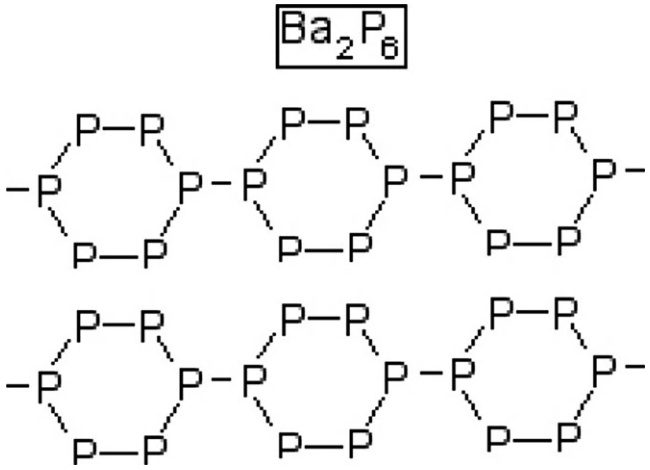

FIGURE 4.24

Barium Phosphide is a semiconductor used in high-power, high-frequency applications and in laser diodes. It crystallizes in the body-centered cubic mode.

The standard Gibbs energies of formation of barium phosphide was determined by a chemical equilibration technique yielding the following results:

$$3Ba(1iq) + P_2(gas) \Rightarrow Ba_3P_2(solid) \quad \Delta G^\circ = -732{,}000 + 156.1\,T(\pm 12{,}800)\ (J/mol)$$

This relates to the stability and the thermodynamic behavior of barium compounds as reaction products of dephosphorous reactions with steel.

Stoichiometric compounds BaP and Ba_3P_2 as well as alloys with compositions belonging to the two-phase equilibrium region ($BaP + Ba_3P_2$) were studied. The standard molar Gibbs energies of formation of BaP and Ba_3P_2 from gaseous phosphorus and liquid barium in the temperature range investigated have been expressed by the equations (Fig. 4.23).

Barium also forms one or more polyphosphide whose structure consists of a type of cage consisting of P_6^{4-} units as shown in the following diagram. This structure is linear in contrast to the cages shown for the calcium and strontium polyphosphide structures that are actually three-dimensional cages (Fig. 4.24).

In some of these positions in the structure, the P-atoms have only 2-bonds plus a negative charge. This accounts for the alkaline earth bonds that make up the total charge and bonding in the structure.

The Zintl phases Ba_3P_2 with isolated P^{3-} ions or Ba_4P_3 which contains P^{3-} ions and P_2^{4-} dumbbells, react

$$\Delta_f G_m^\circ(BaP)/(J \cdot mol^{-1}) = -(306804 \pm 1180) + (79.42 \pm 0.89) \cdot (T/K),$$

$$\Delta_f G_m^\circ(Ba_3P_2)/(J \cdot mol^{-1}) = -(736708 \pm 3014) + (171.43 \pm 2.21) \cdot (T/K).$$

FIGURE 4.23

with iodine in a direct way to **$Ba_3P_3I_2$** and BaI_2 (Eqns 1 and 2). A characteristic detail of the new compound is P_3 chains; therefore, an oxidation of the anionic partial structure results. The consequence is a P–P bonding formation and an enlargement of the phosphorus chains. The reaction was carried out at 1050 K, which is obviously below the melting points of the binary phosphides. Thus, the planned oxidation of a Zintl anion in the solid phase could be successfully realized. To avoid the formation of BaI_2 as a by-product, a mixture with the composition "BaP", containing Ba_3P_2, Ba_4P_3 and Ba_3P_4 can be used, too (Eqn 3). The use of P_2I_4 as an oxidation reagent is also possible (Eqn 4).

$$3Ba_3P_2 + 5I_2 \Rightarrow 2Ba_3P_3I_2 + 3BaI_2 \quad (1)$$

$$Ba_4P_3 + 2I_2 \Rightarrow Ba_3P_3I_2 + BaI_2 \quad (2)$$

$$3BaP + I_2 \Rightarrow Ba_3P_3I_2 \quad (3)$$

$$2Ba_3P_2 + P_2I_4 \Rightarrow 2Ba_3P_3I_2 \quad (4)$$

Reducing the amount of iodine has a direct influence on the anionic partial structure. Therefore one obtains, when using the composition $Ba_3P_3I_{1.8}$ the new compound **$Ba_5P_5I_3$**, which contains additional P_4 chains besides P_3.

The new compounds $Ba_3P_3I_2$ and $Ba_5P_5I_3$ are sensitive to air and moisture. They crystallize in new structure types: $Ba_3P_3I_2$ (*oP*32; *Pnma*; $a = 1719.5(5)$ pm; $b = 462.4(2)$ pm; $c = 1427.2(4)$ pm; $Z = 4$, $Ba_5P_5I_3$ (*mC*52; *C*2/*m*; $a = 4266.4(13)$ pm; $b = 456.3(2)$ pm; $c = 943.1(3)$ pm; $b = 92.20(3)°$; $Z = 4$). Both can be described as double salts of hypothetic Zintl phases ('Ba_2P_3" or "Ba_7P_{10}") and a halide (BaI_2). Characteristic structural features are P_3 and P_4 chains, corresponding to $Ba_3[P_3]I_2$ and $Ba_{10}[P_3]_2[P_4]I_6$, respectively (Figs. 4.25 and 4.26).

Barium phosphide is offered commercially in limited quantities for use as a target for deposition to form various semiconductor configurations.

Radium Phosphide

Radium phosphide would have the molecular formula of Ra_3P_2 and the molecular weight of

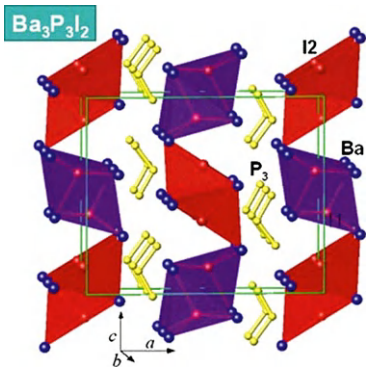

FIGURE 4.25

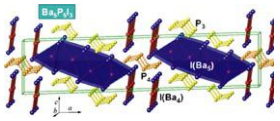

FIGURE 4.26

740.0237 g/mol. It has no CAS number. It has never been prepared but could be formed by reacting the metal with red phosphorus at high temperature. The best way is to sublime the P_4 at 450 °C in an inert gas stream and react it with Ra metal at 600 °C:

$$6Ra + 2P_4 \Rightarrow 2Ra_3P_4$$

It is expected to be a red–brown crystalline material with a high melting point and to readily react with water to form phosphine, PH_3. There is absolutely no demand for such a compound and it is likely that it will never be prepared and its physical properties measured.

4.2.3. Alkaline Earth Hypophosphites

Hypophosphorous acid is a powerful reducing agent with a molecular formula of H_3PO_2. Inorganic chemists refer to the free acid by this name although its IUPAC name is dihydridohydroxidooxidophosphorus, or the acceptable name of phosphinic acid. It is a colorless low-melting compound, which is soluble in water, dioxane, and alcohols. The formula for hypophosphorous acid is generally written H_3PO_2, but a more descriptive presentation is $HOP(O)H_2$ which highlights its monoprotic character. Salts derived from this acid are called **phosphinates** (hypophosphites).

Beryllium Hypophosphite

Beryllium hypophosphite has the molecular structure of $Be(H_2PO_2)_2$ or $Be(OH)H_2PO_2$, depending upon how the crystal is prepared. If an aqueous method is used, the latter is the result. The use of "monoglyme = 1,2 dimethoxy-ethane" or dimethylformamide (DMF) as a solvent allows the usage of an organic compound (such as acetylacetonate = Pentane-2,4-dione = $C_5H_8O_2$ = Acac) of Be to react with hypophosphorous acid to form the desired compound:

$$BeCl_2(aq) + H_3PO_2(aq) \Rightarrow Be(OH)H_2PO_2(solid)$$

$$Be(Acac)_2(DMF) + H_3PO_2(DMF) \Rightarrow Be(H_2PO_2)_2(solid)$$

The product is an anhydride and hydrates apparently do not exist.

The structure of tetragonal ($P4_12_12$) beryllium bis(dihydrogen phosphite), $Be(H_2PO_2)_2$, has been determined by single-crystal XRD. The method of preparation was

not presented. The structure consists of layers of hypophosphite anions and metal cations held in tetrahedral coordination by O atoms. Within the layers, the anions bridge two Be^{2+} cations. This structure is related to LiH_2PO_2, in which the Li atom lies on a twofold axis and the $H_2PO_2^-$ anion has the PO_2 atoms on a mirror plane. In $Be(H_2PO_2)_2$, the Be atom lies on a twofold axis and the $H_2PO_2^-$ anion is in a general position.

Polymers are frequently rendered flame resistive by adding phosphorus and halogen compounds or mixtures thereof to them. Some polymers are processed at high temperatures, for example at 250 °C or higher. For this reason, many known flame retardants are unsuitable for such applications, since they are too volatile or are not sufficiently heat resistant.

Beryllium forms a great number of organo-phosphinates which have been studied extensively. Such materials have potential as a catalyst in controlling the growth and size of polymers in general and in the production of fire-resistant polymers by incorporation of a metallic cation like Be^{2+}. An example is the preparation and measurement of the physical properties of such materials using infrared, DTA, and TGA methods of analysis. Data have been given for beryllium dimethyl-, tetramethylene-, di-*n*-butyl-, di-*n*-pentyl-, di-*n*-heptyl-, methylphenyl-, diphenyl-, and bis-pentafluorophenylphosphinates. Synthesis of dimeric beryllium acetylacetonyl phenyl-[*o*-methylcarboranyl phosphinate is reported. The beryllium phosphinates were prepared by the reaction of beryllium acetylacetonate with the appropriate hypophosphorus acid in dimethylformamide.

The general structure of these organo-phosphinates has been proposed to be a linear but three-dimensional cyclic structure of phosphinate groups to which "R groups = dimethyl, tetramethylene, di-*n*-butyl, etc." are attached (Fig. 4.27).

The characterization of beryllium phosphinates of stoichiometry, $Be(Bu_2^nPO_2)_2$ and $Be(Ph_2PO_2)_2$, and of some mixed-ligand species $Be[(Bu_2^nPO_2)_{2-2x}(Ph_2PO_2)_{2x}]$ has also been reported. The compounds richer in alkyl groups give stable solutions in hydrocarbon and halogenated solvents. Solution properties indicate that these compounds are linear polymers which undergo a reversible degradation influenced by the nature of the solvent, concentration, and temperature. The mixed-ligand species can be crystallized and are formulated as random copolymers. Isomorphous replacement of the two kinds of phosphinate groups within the crystal lattice of the related homopolymers is observed. The XRD fiber photographs indicate that the homopolymer $[Be(Bu_2^nPO_2)_2]_n$ and the copolymers $\{Be[(Be_2^nPO_2)_{2-x}(Ph_2PO_2)_{2x}]\}_n$ ($x = 0{\cdot}20$ or $0{\cdot}33$) have a backbone structure with alternate single and triple bridging phosphinate groups between tetrahedral metal atoms. The same chain-type structure is proposed for the homopolymer $[Be(Ph_2PO_2)_2]_n$ and the copolymers richer in diphenylphosphinate groups. It has been discovered that the phenyl type of beryllium phenylphosphinate (i.e.- R = phenyl) is sensitive to water vapor and decomposes. Thus, magnesium salts of a similar composition have not been used for this same usage.

Beryllium hypophosphite is available commercially but only from a few manufacturers and in limited quantities.

Magnesium Hypophosphite

Magnesium hypophosphite or phosphinate has the molecular formula of $Mg(H_2PO_2)_2$ and the molecular weight of 154.2546 g/mol. Its CAS number is 10377-57-8. This salt can be prepared by the aqueous reaction of the carbonate or oxide with H_3PO_2:

$$MgO + 2H_3PO_2 \Rightarrow Mg(H_2PO_2)_2$$

The salt is soluble in water (20 g/100 ml at 20 °C) so that the solution must be evaporated to obtain the hexahydrate crystals. $Mg(H_2PO_2)_2{\cdot}6H_2O$ has the CAS number of 26264-58-4 and the density of 1.59 g/cm^3. It is composed of white square crystals that are water soluble. It is insoluble in alcohol or ether. If heated to about 101 °C, five (5) waters of crystallization are lost, leaving the monohydrate. This decomposes at 182 °C to form the anhydrate. Further heating to about 345 °C causes decomposition to phosphine, PH_3, and $MgHPO_3$:

$$Mg(H_2PO_2)_2 + \text{heat} \Rightarrow PH_3 + MgHPO_3$$

If mixed with strong oxidants, a fire may result. It decomposes into H_3P, H_3PO_4, H_3PO_3 and H_2:

$$Mg(H_2PO_2)_2 + 2HNO_3 \Rightarrow PH_3 + MgHPO_3 + H_2 + N_2O_4$$

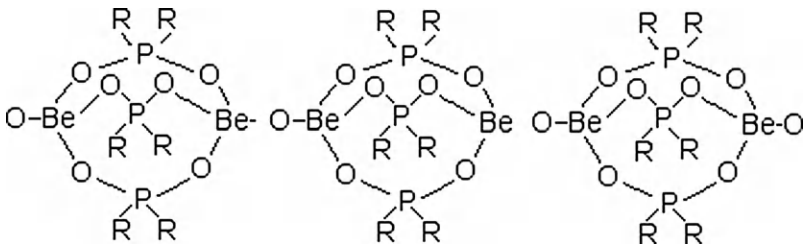

FIGURE 4.27

Two modifications of hexaaquamagnesium hypophosphite $[Mg(H_2O)_6](H_2PO_2)_2$ have been synthesized and structurally characterized. One of these forms is tetragonal with $a = 6.789$ Å and $c = 9.873$ Å. The geometrical characteristics of hexaaqua cations, hypophosphite anions, and nets of hydrogen bonds between the hypophosphite anions and the coordinated water molecules are analyzed. The packing motif of the structure-forming fragments was found to be the same for the two structures, except that modification of the inner structure of the complex cation leads to different nets of hydrogen-bonded cations and anions.

This salt has found several industrial applications. It is used as a reducing agent in the plating of polymers and in the preparation of finely supported catalysts in the production of oxide ceramics. A process for treating paper to prevent discoloration when exposed to light which comprises adding 1% to 10% by weight of magnesium hypophosphite to prevent discoloration when exposed to light. This addition can be added to the paper at any stage during or after papermaking.

However, the major use of magnesium phosphinate has been for the treatment of calcium and magnesium deficiency in cattle, swine, goats and sheep. This salt has been approved by numerous Agencies, including the FDA and Veterinary Association for this purpose. It is injected as a pure solution along with a sugar, calcium gluconate.

There are over 1 million registered importers–exporters in the world and this salt is readily available commercially.

Calcium Hypophosphite

Calcium hypophosphite has the molecular formula of $Ca(H_2PO_2)_2$ and the molecular weight of 170.0631 g/mol. This salt can be prepared by the aqueous reaction of the carbonate or oxide with H_3PO_2:

$$CaO + 2H_3PO_2 \Rightarrow Ca(H_2PO_2)_2$$

The salt is soluble in water (20 g/100 ml at 20 °C) so that the solution must be evaporated to obtain crystals. $Ca(H_2PO_2)_2$ has the CAS number of 7789-79-9 and the density of 1.59 g/cm^3. It is composed of white square monoclinic crystals which are water soluble. It is insoluble in alcohol or ether. When heated to about 305 °C, it disproportionates, forming calcium phosphate and phosphine:

$$Ca(H_2PO_2)_2 + \text{heat} \Rightarrow CaHPO_3 + PH_3$$

This salt is used in electroplating and protecting metals from corrosion (because it is a strong reducing agent). Its Lewis structure is shown in Fig. 4.28.

Recent patent and technical publications indicate a growing interest in halogen-free solutions with the predominance of the literature focusing on phosphorus-based flame retardants. Patents published on

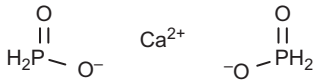

FIGURE 4.28

the flame retardancy of polycarbonate and its blends significantly exceed the number of patents on flame retardancy of any other polymer. Bridged aromatic diphenyl calcium phosphinates, especially as resorcinol bis(diphenyl phosphinate) and bisphenol A bis(diphenyl calcium phosphinate) have found broad application because of their good thermal stability, high efficiency, and low volatility.

Another actively reported group of compounds are the metal salts of dialkylphosphonic acid as well as calcium hypophosphite, which have recently been found to be particularly effective in poly(utylenes terephthalate) and polycarbonate. These products are synergistic with a number of phosphorus and nitrogen-containing compounds, such as melamine salts, which seem to be very efficient and commercially useful as fire retardants in nylons.

Calcium hypophosphite is relatively soluble in water, and when added to a solution of sodium hypophosphite, forms a double salt. Crystals were obtained by slow evaporation of the solution to form dodecahedra with well-developed {110} faces. The crystal structure of $CaNa(H_2PO_2)_3$ belongs to the cubic system with space group, $P2_13$, $Z = 4$ and $a = 9.721$ Å. The structure consists of two kinds of octahedral groups, one with a calcium atom and the other with a sodium atom. Each atom of the hypophosphite ions is coordinated to each one of the calcium and sodium atoms to form the octahedral. This structure is, in general, typical of the salts of hypophosphorous acid.

Calcium hypophosphite is readily available commercially since its main usage, both industrially and in Research, has proven to be as a source of hypophosphite anions to form other hypophosphites.

Strontium Hypophosphite

Strontium hypophosphite has the molecular formula of $Sr(H_2PO_2)_2$ and the molecular weight of 170.0631 g/mol. This salt can be prepared by the aqueous reaction of the carbonate or oxide with H_3PO_2:

$$SrO + 2H_3PO_2 \Rightarrow Sr(H_2PO_2)_2$$

The salt is soluble in water (16 g/100 ml at 20 °C) so that the solution must be evaporated to obtain crystals.

The structure of monoclinic strontium dihydrogenphosphinate, $Sr(H_2PO_2)_2$ consists of layers of hypophosphite anions and metal cations exhibiting square

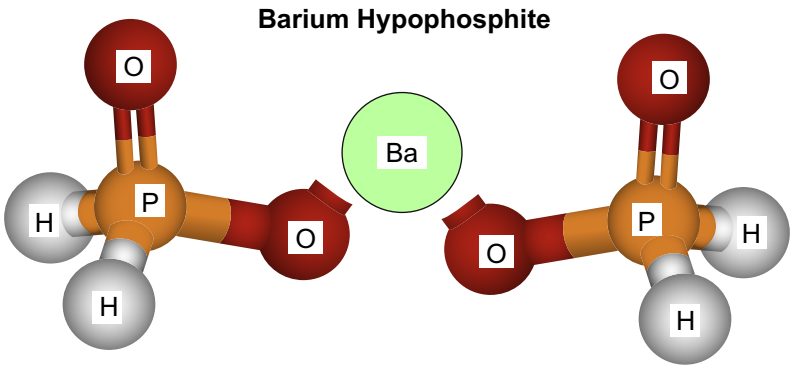

FIGURE 4.29

antiprismatic coordination by O atoms. The Sr atoms are located on sites with point symmetry 2_1. Within the layers, each anion bridges four metal cations.

Although strontium hypophosphite is mentioned in many patents concerning metal surface finishing, electroplating, chemical intermediates and as a source of hypophosphite anions, it is the calcium salt that is preferred since it is lower in cost and easier to use.

$Sr(H_2PO_2)_2$ is available in limited quantities commercially.

Barium Hypophosphite

Barium hypophosphite has the formula, $Ba(H_2PO_2)_2$, and the molecular weight of 267.30388 g/mol. This salt can be prepared by the aqueous reaction of the carbonate or oxide with H_3PO_2:

$$BaO + 2H_3PO_2 \Rightarrow Ba(H_2PO_2)_2$$

The salt is slightly soluble in water (3.62 g/100 ml at 20 °C) so that the solution must be evaporated to obtain crystals. This procedure forms barium hypophosphite monohydrate, $Ba(H_2PO_2)_2 \cdot H_2O$, whose CAS number is 14871-79-5. Its molecular weight is 285.320 g/mol. It occurs as monoclinic plates with a density of 2.94 g/cm^3. It is soluble in water but insoluble in alcohol. Therefore, the addition of alcohol during evaporation serves to hasten the crystallization process from aqueous solution. Heating to about 110 °C causes the loss of the water of hydration to form the anhydrate. The anhydrate is soluble in water at about 35 g/100 ml at 20 °C but only 30 g/100 ml at 100 °C.

The structure of orthorhombic barium bis(dihydrogenphosphinate), $Ba(H_2PO_2)_2$, consist of layers of hypophosphite anions and metal cations exhibiting square antiprismatic coordination by O atoms. The Ba atoms are on sites with point symmetry 222. Within the layers, each anion bridges four metal cations. A "ball and stick" model (like a Lewis structure) is shown in Fig. 4.29.

The major usage of barium hypophosphite has been as a source of hypophosphorous acid because the addition of H_3PO_4 to a solution allows the separation of the very insoluble $BaSO_4$. Although this salt is mentioned in a few patents concerning metal surface finishing, electroplating, chemical intermediates and as a source of hypophosphite anions, it is the calcium salt that is preferred since it is lower in cost and easier to use.

However, a number of Chinese manufacturers offer "barium phosphinate" as BaP_2O_4. This would have the Lewis structure shown in Fig. 4.30.

This is likely a mistake since the Lewis dot-structure formulation does not show a full complement of electrons for the phosphorus atoms.

Barium hypophosphite is readily available commercially from a number of manufacturers, notably Chinese.

Radium Hypophosphite

Radium hypophosphite would have the molecular formula of $Ra(H_2PO_2)_2$ and the molecular weight of 740.0237 g/mol. It has no CAS number. It has never been prepared but could be formed by reacting the oxide with hypophosphorous acid:

$$RaO + 2H_3PO_2 \Rightarrow Ra(H_2PO_2)_2 + H_2O$$

It would expected to be water soluble and would have strong reducing properties. In view of the intense radioactivity of ^{226}Ra, it is unlikely that this compound will ever be synthesized.

4.2.4. Alkaline Earth Phosphites

Phosphorous acid is a diprotic acid, since the hydrogen bonded directly to the central phosphorus

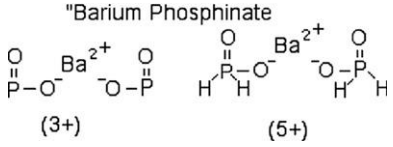

FIGURE 4.30

atom is not readily ionizable. $HP(O)_2(OH)$ is moderately a strong acid:

$$HP(O)(OH)_2 \Leftrightarrow HP(O)_2(OH)^- + H^+ \quad pK_a = 1.3$$
$$HP(O)_2(OH)^- \Leftrightarrow HPO_3^{2-} + H^+ \quad pK_a = 6.7$$

The $HP(O)_2(OH)^-$ species is called the hydrogen phosphite, and the HPO_3^{2-} the phosphite ion. Thus, two species are possible with the alkaline earths but only one, the hydrogen phosphite, is usually prevalent.

Beryllium Phosphite

Beryllium phosphite can have the formulas of either $Be(OH)HPO_3$ or $Be(OH)(H_2PO_3)_2$. It is the former that appears when phosphorous acid is reacted with the oxide, hydroxide or carbonate:

$$BeO\,(s) + H_3PO_3\,(aq) \Rightarrow [Be(OH)]_2HPO_3$$

The product is the hydrogen phosphite. If the sodium salt is employed, then the product is likely to be the phosphite:

$$BeO\,(s) + Na_3PO_3 \Rightarrow [Be(OH)]_3PO_3$$

On heating, it decomposes around 400 °C to form the pyrophosphite:

$$3[Be(OH)]_3PO_3 + \text{heat} \Rightarrow Be_3(PO_3)_2 = \{Be_3P_2O_6\} + 3H_2 + PH_3$$

It would also be possible to form a dihydrogen phosphite:

$$BeO\,(s) + H_3PO_3\,(aq) \Rightarrow [Be(OH)]H_2PO_3$$

However, there is no defining literature showing the properties of any of these possible salts of Be. Very little information is available in the literature regarding beryllium phosphite salts. The actual structure of beryllium hydrogen phosphite is not known. Nor has the structure of the phosphite or pyrophosphite been examined. The effect of pH in solution on the formation of these salts also remains unknown.

However, a mixed organophosphite has been studied. An organically templated beryllophosphite, $[H_3N(CH_2)_3NH_3]\cdot[Be_3(HPO_3)_4]$ **1**, was synthesized under mild hydrothermal conditions and characterized by single-crystal XRD. It is the first beryllophosphite formed using an organic amine as a structure-direction agent. Compound **1** crystallizes in a monoclinic system, space group $P2_1/c$ with cell parameters: $a = 8.5983$ Å, $b = 13.1561$ Å, $c = 13.460$ Å, $\beta = 92.470°$, and $Z = 4$. The three-dimensional framework is built up from strictly alternating (BeOH) tetrahedra and $[HPO_3^{2-}]$ pseudopyramids by sharing vertices. A new type of network containing 4-, 6-, 8-, 10-, 12-membered rings makes up the inorganic framework. The 1,3-diammonium propane template molecules are located in 8-membered ring windows. The compound was characterized by IR spectroscopy, inductively coupled plasma (ICP), and differential thermal and thermogravimetric analyses.

Beryllium phosphite has no CAS number and it is not offered for sale by a registered manufacturer. However, it is offered commercially by a few Chinese firms. Its quality remains questionable.

Magnesium Phosphite

Magnesium phosphite can have the molecular formula of the hydrogen phosphite, $MgHPO_3$ or the dihydrogen phosphite, $Mg(H_2PO_3)_2$. It is the former that appears when a solution of phosphorous acid is reacted with the oxide, hydroxide or carbonate:

$$MgO + H_3PO_3 \Rightarrow MgHPO_3 + H_2O$$

The product is a hexahydrate. It can also be prepared by the action of ammonium phosphite on magnesium chloride:

$$MgCl_2\,(aq) + NH_4HPO_3\,(aq) \Rightarrow MgHPO_3\cdot 6H_2O + NH_4Cl_2\,(aq)$$

If a sodium phosphite is used in the preparation, then the dihydrogen phosphite, $Mg(H_2PO_3)_2$, is produced. However, the full effect of pH during the formation of these phosphite salts of magnesium has not been fully defined in the scientific literature.

The nature of the hydrates of these hydrogen-phosphite salts is controlled, to some extent, by the solution temperature employed. The hexahydrate, $MgHPO_3\cdot 6H_2O$, is obtained at room temperature (15–25 °C). At 30–50 °C, the tri-hydrate occurs whereas at >85 °C, the monohydrate is most stable. This is due in part to the solubilities of these three salts. The hexahydrate is rather soluble at 16.4 g/100 ml of water (20 °C) whereas the trihydrate is most stable at 50 °C. It has been shown that at reaction temperatures less than about 60 °C a crystalline magnesium hydrogen phosphite trihydrate, $MgHPO_3\cdot 3H_2O$, whose solubility increased from 8.9 at 20 °C to 11.2 g/100 ml at 50 °C and then to 6.5 at 95 °C temperature. If formed at >85 °C, a magnesium hydrogen phosphite with about 0.5 waters of hydration, $MgHPO_3\cdot 0.5H_2O$, is produced. The CAS number of the trihydrate is 7757-86-0.

If heated to about 85 °C, the hexahydrate loses two water molecules to form the trihydrate. Further heating causes the trihydrate to decompose to the hemihydrate at about 110 °C and then the anhydrate at 185 °C. The anhydrate is stable in air up to about 300 °C where it decomposes:

$$3MgHPO_3 + \text{heat} \Rightarrow PH_3 + Mg(PO_3)_2$$

The anhydrate has a molecular weight of 103.2769 g/mol.

The crystal structure of magnesium hydrogen phosphite hexahydrate has been determined to be rhombohedral (Trigonal class) with $a, b, c = 5.96$ Å, $\alpha, \beta, \gamma = 96°24'$. The space group is R3 and the Mg, P and H atoms lie on the unique linear axis. The structure is built from discrete tetrahedral $(HPO_3)^{2-}$ ions and octahedral $\{Mg^{2+}(H_2O)_6\}$ groups that are linked together in three dimensions by a continuous system of hydrogen bonds.

It also forms a series of double salts. One example is that of the sodium–magnesium hydrogen phosphite. The structure of $NaMg(H_2PO_3)_3 \cdot H_2O$ belongs to the isotypic dihydrogen phosphite monohydrate series $NaMg(H_2PO_3)_3 \cdot H_2O$ with alternating NaO_6 [d_{av}(Na–O) = 2.466 (2) Å] and MgO_6 [d_{av}(Mg–O) = 2.086 (2) Å] octahedra, cross-linked by H_2PO_3 pseudo-pyramids [d_{av}(P–OMg) = 1.530 (2) Å and d_{av}(P–OH) = 1.575 (2) Å].

Magnesium apparently forms only the $MgHPO_3$ type of compounds (magnesium hydrogen phosphite) and the $Mg(H_2PO_3)_2$ type has not been studied. Although the hexahydrate as a crystal is known to be strongly pyroelectric, it has not found any usage in industry and has received little to no attention in the scientific literature.

The hexahydrate is available commercially as a powder from a few manufacturers.

Calcium Phosphite

Calcium phosphite can have the molecular formula of $CaHPO_3$ or $Ca(H_2PO_3)_2$. It is the former that appears when a solution of phosphorous acid is reacted with the oxide, hydroxide or carbonate:

$$CaO + H_3PO_3 \Rightarrow CaHPO_3 \cdot H_2O + H_2O$$

The product is a monohydrate. It can also be prepared by the action of ammonium phosphite on calcium chloride:

$$CaCl_2\,(aq) + NH_4HPO_3\,(aq) \Rightarrow CaHPO_3 \cdot H_2O + NH_4Cl_2\,(aq)$$

A white, crystalline powder is obtained. The solubility of $CaHPO_3 \cdot H_2O$ has apparently not been determined exactly. If heated to about 250 °C, the anhydrate results. This is stable when heated further up to about 320 °C where it decomposes to form phosphine and hydrogen:

$$3CaHPO_3 + \text{heat} \Rightarrow 2PH_3 + 3Ca(PO_3)_2 + H_2$$

$CaHPO_3 \cdot H_2O$ has the CAS number of 25232-60-4 and a molecular weight of 138.073 g/mol. It is a colorless, monoclinic crystal which loses water at about 150 °C and is slightly soluble in water but insoluble in alcohol. The anhydrate, calcium phosphite ($CaHPO_3$), is stable in air even when heated at 95 °C for 2 months. The CAS number of $CaHPO_3$ is 21056-98-4 and its molecular weight is 119.0479 g/mol.

The dihydrogen phosphite compound is prepared by reaction of calcium carbonate and sodium phosphite:

$$CaCO_3 + 2NaH_2PO_3\,(aq) \Rightarrow Ca(H_2PO_3)_2\,(aq) + 2NaOH\,(aq) + CO_2$$

The solution is evaporated via vacuum. This water-soluble dihydrogen phosphite monohydrate, $Ca(H_2PO_3)_2 \cdot H_2O$, loses its water of crystallization at about 150 °C.

This salt has been used to provide a coating composition useful for increasing the corrosion resistance of a surface. The final layer comprises the anticorrosive agent, calcium phosphite. The composition may also include fillers and other conventional additives. A process for protecting a surface from corrosion is also provided.

The crystal structures of two-layered metal phosphites $M(HPO_3) \cdot H_2O$ where M = Ca and Sr have been reported. These compounds are the first examples of inorganic phosphates, structurally related to metal phosphonates, with the general formula of $M(HPO_3) \cdot H_2O$. They crystallize in a monoclinic system with space group $P2_1/c$ and are isostructural with $a = 6.778$ Å, $b = 7.928$ Å, $c = 8.097$ Å, $\alpha = 67.9°$, $\beta = 84.8°$, $\gamma = 84.2°$, $V = 354.99$ Å^3 The structures consist of two-dimensional sheets formed by linked metal and phosphorus polyhedra, which are held together by O–H···O hydrogen bonds.

The crystal structure of the dihydrogen compound, $Ca(H_2PO_3)_2 \cdot H_2O$, exhibits two-dimensional sheets formed by linked Ca and P polyhedra. The layers are held together by O–H–O hydrogen bonds (Fig. 4.31).

Neither of the two types of calcium phosphite compounds have been utilized extensively in industry. Nor have they been studied academically except in general terms. The literature concerning them is exceptionally sparse.

Both the hydrogen and dihydrogen phosphite of calcium are available commercially. They are made in small quantities for sale.

Strontium Phosphite

Strontium phosphite can have the molecular formula of $SrHPO_3$ or $Sr(H_2PO_3)_2$. It is the former that appears when a solution of phosphorous acid is reacted with the oxide, hydroxide or carbonate:

$$SrO + H_3PO_3 \Rightarrow SrHPO_3 + H_2O$$

The product is a hemimonohydrate, i.e. $SrHPO_3 \cdot 1.5H_2O$. It can also be prepared by the action of ammonium phosphite on strontium chloride:

$$SrCl_2\,(aq) + NH_4HPO_3\,(aq) \Rightarrow SrHPO_3 \cdot 1.5H_2O + NH_4Cl_2\,(aq)$$

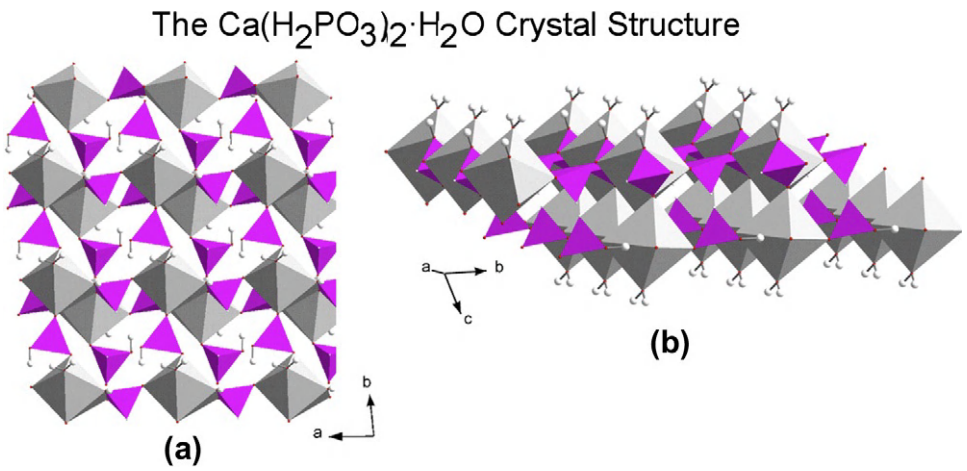

FIGURE 4.31

A white, crystalline powder is obtained. The dihydrogen phosphite compound is prepared by reaction of strontium carbonate and sodium phosphite:

$$SrCO_3 + 2NaH_2PO_3\ (aq) \Rightarrow Sr(H_2PO_3)_2\ (aq) + 2NaOH\ (aq) + CO_2$$

The salt is soluble in solution and is evaporated via vacuum. In contrast, the monohydrogen compound is relatively insoluble in water.

Very little information on these compounds is available in the scientific or technical literature. Papers dealing directly with strontium phosphite or similar salts are few and far between. Strontium phosphite is not used in industry although it is mentioned in several patents which generally employ the magnesium or calcium salt but cite the strontium salt as possibly functional in the usage

$Sr(H_2PO_3)_2$ has been characterized by means of single-crystal XRD and FT-IR absorption spectroscopy. The IR spectra exhibit split AB band systems in the OH stretching mode region due to Fermi resonance interactions of the (OH) with the in-plane bending modes of the hydroxyl groups. The compounds crystallize in a new structure type and are isotypic, if the P-bonded hydrogen atoms of $Sr(H_2PO_3)_2$ and the lone electron pairs are considered to be equivalent. The coordination of Sr is that of a distorted square antiprism. These SrO_8 polyhedra share three common edges and are additionally connected via O–X–O bonds of the isolable XO_2OH^- ions ($X = HP^{IV}$) of tetrahedral configuration. The resulting layers $^2[Sr(XO_2OH)_2]$ are connected via circular hydrogen bond systems of tetrameric $[XO_2OH^-]_4$ groups of a cyclooctane-like chair topology. Both the P-bonded hydrogen atoms and the lone electron pairs of the $HP^{IV}O_2OH^-$ form channels along [001] and induce the same crystal structure. This is a new configuration for acid salts of the type $M^{II}(XO_2OH)_2 \cdot nH_2O$ with $X = HP^{IV}$.

$Sr(HPO_3) \cdot H_2O$ crystallizes in a monoclinic system with space group $P2_1/c$ with $a = 6.778$ Å, $b = 7.928$ Å, $c = 8.097$ Å, $\alpha = 67.9°$, $\beta = 84.8°$, $\gamma = 84.2°$, $V = 354.99$ Å^3. The structure consists of two-dimensional sheets formed by linked metal and phosphorus polyhedra, which are held together by O–H···O hydrogen bonds, similar to the ca-compound.

Strontium phosphite has no CAS number and is not offered for sale by any registered manufacturer.

Barium Phosphite

Barium phosphite can have the molecular formula of $BaHPO_3$ or $Ba(H_2PO_3)_2$ with molecular weights of 216.3021 and 296.2739 g/mol, respectively. It is the latter that appears when a solution of phosphorous acid is reacted with the carbonate:

$$BaCO_3 + H_3PO_3 \Rightarrow Ba(H_2PO_3)_2 + H_2O + CO_2$$

The product is soluble in water so that a vacuum evaporation is needed to form the hemihydrate, $Ba(H_2PO_3)_2 \cdot 0.5H_2O$. It can also be prepared by the action of ammonium phosphite on barium chloride:

$$BaCl_2\ (aq) + 2NH_4HPO_3\ (aq) \Rightarrow Ba(H_2PO_3)_2 \cdot 0.5H_2O + 2NH_4Cl\ (aq)$$

After evaporation, a white, crystalline powder is obtained. The solubility of $Ba(H_2PO_3)_2 \cdot 0.5H_2O$ has apparently not been determined exactly. If heated to about 130 °C, the anhydrate results. This is stable when heated further up to about 320 °C where it decomposes:

$$6Ba(H_2PO_3)_2 + \text{heat} \Rightarrow 2PH_3 + 2Ba_3(PO_3)_2 + 10H_2$$

$Ba(H_2PO_3)_2 \cdot 0.5H_2O$ contains ninefold-coordinated Ba^{2+} ions connected by dihydrogen phosphite anions to form a three-dimensional network. The asymmetric unit contains two Ba^{2+} ions, four $[H_2PO_3]^-$ ions and

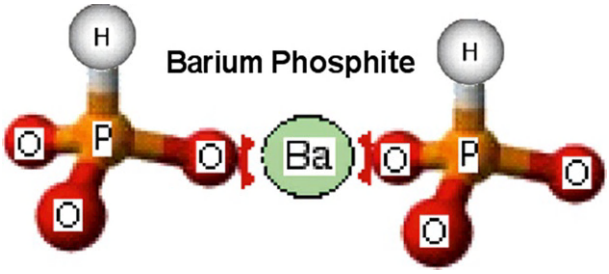

FIGURE 4.32

one water molecule. A ball and stick molecule are presented as follows. This may be compared to that of barium hypophosphite (Fig. 4.32).

The hydrogen phosphite compound is prepared by reaction of barium chloride and sodium phosphite:

$$BaCl_2 + 2NaHPO_3\,(aq) \Rightarrow Ba(HPO_3)\cdot H_2O\,(s) + 2NaOH\,(aq) + CO_2$$

The salt is substantially insoluble in water at 0.687 g/100 ml at 20 °C. This salt decomposes in boiling water to form phosphorous acid:

$$BaHPO_3\,(s) + 2H_2O\,(100\,^\circ C) \Rightarrow H_2PHO_3 + Ba(OH)_2$$

The literature regarding these barium phosphite salts is scarce and they have found little to no use in industry. Barium phosphite has no CAS number and is not offered for sale by a registered manufacturer. A few Chinese manufacturers state that they have a limited quantity available.

Radium Phosphite

Radium hypophosphite would have the molecular formula of $Ra(H_2PO_3)_2$ and $Ra(HPO_3)$ with the molecular weight of 383.6963 and 304.9974 g/mol, respectively. These salts have no CAS number and have never been prepared but could be formed by reacting the oxide with phosphorous acid:

$$RaO + 2H_3PO_3 \Rightarrow Ra(H_2PO_3)_2 + H_2O$$

In view of the intense radioactivity of ^{226}Ra, it is unlikely that these salts will ever be prepared.

Radium phosphite is not available commercially.

4.2.5. Alkaline Earth Phosphates

Alkaline earth orthophosphates are based upon phosphoric acid, H_3PO_4, in which the phosphorus atom has the oxidation state of +5. Orthophosphates are ubiquitous in Nature and "phosphate rock" is found in all parts of the world because the (PO_4^{3-}) cation is most stable of the phosphate species which includes hypo-ite, -ite, -ate, pyro-, meta- and poly- variations of -phosphates in which the P-atom is in the +1, +3, +5, +5, +5, +5 states, respectively.

If phosphoric acid is condensed to a solid by removing most of the water in which it is dissolved, it forms two solid hydrates. The thermal phase diagram shows two melting points, that of H_3PO_4 (40 °C) and that of $2H_3PO_4\cdot H_2O$ (28 °C), and two eutectics, that of H_8PO_4 (40 °C) and $2H_3PO_4\cdot H_2O$ (−85 °C) plus that of ice (0 °C). The heat of solution was found to be positive, +42.69 cals/mol of the crystalline acid dissolved. The heat of dilution in 11.4 mol of water/mol of acid was found to be +33.4 cals. Thus, it is clear that the acid, solid or liquid must be added to water and not the reverse.

The alkaline earths form three types of compounds based upon the number of hydrogen atoms in the phosphate complex, monobasic = $H_2PO_4^{3-}$, dibasic = HPO_4^{3-}, and tribasic = PO_4^{3-}. These arise dependant upon the pH and ionization constant of the acid in aqueous solution:

$$H_3PO_4\,(s) + H_2O\,(l) \Rightarrow H_3O^+\,(aq) + H_2PO_4^-\,(aq)$$
$$K_{a_1} = 7.25 \times 10^{-3}$$
$$H_2PO_4^-\,(aq) + H_2O_{(l)} \Rightarrow H_3O^+\,(aq) + H_2PO_4^{2-}\,(aq)$$
$$K_{a_2} = 6.31 \times 10^{-8}$$
$$HPO_4^{2-}\,(aq) + H_2O\,(l) \Rightarrow H_3O^+\,(aq) + PO_4^{3-}\,(aq)$$
$$K_{a_3} = 3.98 \times 10^{-13}$$

The regions of formation as a function of pH are shown in Fig. 4.33.

Thus, all of the monobasic salts are soluble and the solution must be evaporated to obtain the salt whereas the dibasic salts are insoluble and are easily separated from the solution. The ammonium dibasic salts generally provide the proper pH. The tribasic salts are insoluble in aqueous solution but the high pH demands the use of a soluble alkali salt. If a pure salt, free from the alkali cation, is desired, the best way is to sinter the dibasic salt with an oxide, hydroxide or carbonate.

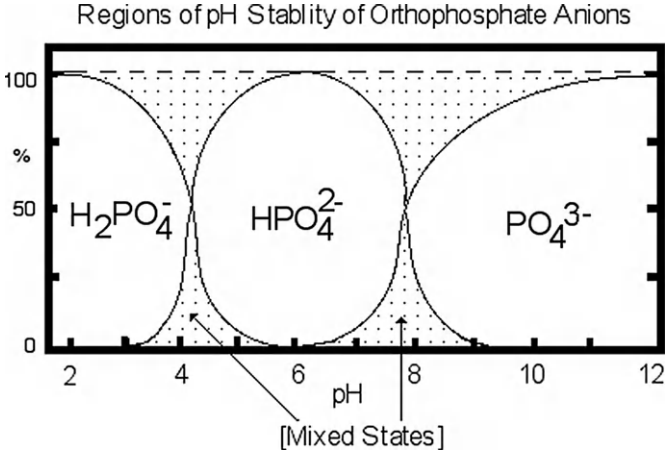

FIGURE 4.33

Beryllium Orthophosphates

The literature concerning the normal phosphates of beryllium is very far from clear. A few investigators who have taken up the subject have found the material they produced to be of a gelatinous nature very difficult to identify as an individual salt. The properties of the monobasic and dibasic salts have remained unknown. Their exact solubility in water is unknown. The formula for the monobasic salt ought to be $[Be(OH)]H_2PO_4$ while that of the dibasic salt should be $[Be(OH)]_2HPO_4$. However, it is listed and offered for sale as "Beryllium hydrogen phosphate—$BeHPO_4$—CAS number = 23598-15-7" with a molecular weight of 104.991 g/mol. It is described as insoluble in water.

The best-known phosphate is the compound $BeNH_4PO_4 \cdot 5H_2O$. It is prepared by adding diammonium phosphate to $BeCl_2$ at pH = 5.2–5.5. If the pH is lower than this, $Be(OH)HPO_4$ is also obtained. Heating $BeNH_4PO_4$ releases 4 waters of hydration at 60 °C and the final one at 250 °C. Ammonia is released at 400 °C and water of constitution at 500 °C to form the pyrophosphate at 700 °C. $BeNH_4PO_4$ crystallizes in the tetragonal system with $a = 12.96$ Å and $c = 9.65$ Å. $BeHPO_4$ is also tetragonal with $a = 9.05$ Å and $c = 9.65$ Å.

The only other salt identified and confirmed has been the tribasic salt, $[Be(OH)]_3PO_4$, which is described as a soluble salt. It is prepared by the reaction of trisodium phosphate and a soluble beryllium salt:

$$Be(OH)Cl_2\ (aq) + Na_3PO_4\ (aq) \Rightarrow [Be(OH)]_3PO_4$$

Upon evaporating the solution, a trihydrate is obtained as colorless crystals. $[Be(OH)]_3PO_4 \cdot 3H_2O$ loses one water of hydration at about 100 °C and the other two by 140 °C. Further heating presumably forms the pyrophosphate but there is no record of this in the literature.

Beryllium tribasic phosphate is said to form the heptahydrate, $[Be(OH)]_3PO_4 \cdot 7H_2O$ when alcohol was added to cause the formation of crystals. This preparation (1878) involved precipitating and growing crystals from a phosphoric acid solution of beryllium hydroxide with alcohol. However, this preparation and data obtained have never been confirmed. It is likely that the trihydrate dominates.

So-called "low-dimensional" beryllium phosphates have received some attention in the literature. They are composed of:

$$[C_5H_{14}N_2]_2[Be_3(HPO_4)_5] \cdot H_2O \quad \text{(I)}$$

and

$$[C_6H_{18}N_2]_{0.5}[Be_2(PO_4)(HPO_4)OH] \cdot 0.5H_2O \quad \text{(II)}$$

They were synthesized under mild hydrothermal/solvothermal conditions. The first is built up from strict alternation of BeO_4 and HPO_4 tetrahedra forming a unique one-dimensional double chains with 12-ring apertures. There are pseudo-10-ring apertures enclosed by two double chains through H-bonds. This compound can also be viewed as a pseudo two-dimensional layered structure stabilized by strong H-bonds. The diprotonated 2-methylpiperazium cations are located at three positions (i.e. inside the 12-ring aperture, inside the pseudo-10-ring aperture, and in the interlayer of the inorganic pseudo-layers.

The second is constructed by the alternation of Be-centered tetrahedra (including BeO_4 and $HBeO_4$) and P-centered tetrahedra (including PO_4 and HPO_4) resulting in a two-dimensional layered structure parallel to the (011) direction. The complex layer is composed of coupled 4.8 net-sheets. The diprotonated 1,6-hexandiamine cations and water molecules reside in the interlayer regions and interact with the inorganic layers through H-bonds.

Crystal data are shown in Table 4.15.

TABLE 4.15 Crystal Parameters of Two "Low-Dimensional" Beryllium Phosphates

			Angstroms				Degrees		
Type	Structure	Space Group	a	b	c	V (A^3)	α	β	γ

Beryllium phosphates are found as minerals in several parts of the world. These include:

$$\text{Beryllonite} = NaBePO_4$$
$$\text{Hurlbutite} = CaBe_2(PO_4)_2$$
$$\text{Hydroxylherderite} = CaBe[(OH,F)|PO_4]$$
$$\text{Glycine} = CaBe_4[(OH)_2|PO_4]_2\cdot 0.5H_2O$$
$$\text{Fransoletite} = Ca_3Be_2[HPO_4]_2\cdot 4H_2O$$
$$\text{Moraesite} = Be(OH)_2PO_4\cdot 3H_2O$$

Moraesite, a hydrous beryllium phosphate from the Sapucaia pegmatite mine, Minas Gerais, Brazil, has the composition $Be_2PO_4(OH)\cdot 4H_2O$. It occurs in spherulitic masses, as distinct crystals, and as crusts with a coarse fibrous structure. Crystals are singly terminated needles, acicular [001] with forms [100] and {130} and faces (131) and (131). Moraesite is monoclinic and prismatic (2/m, C_n) Lattice constants are: $a_0 = 8.55$ Å, $b_0 = 36.90$ Å, $c_0 = 7.13$ Å, $\beta = 97°41''$, $V = 2{,}229$ Å^3, $Z = 4$. It is biaxial negative, $2Y = 65''$; $\eta_\alpha = 1.462$, $\eta_\beta = 1.482$, $\eta_\gamma = 1.490$.

Beryllonite, $NaBePO_4$, is a rare beryllium mineral. It is found at only a few places around the world. It can be cut as gems, but lacks color, fire and hardness to be a popular gemstone. The first and some of the best specimens of beryllonite have come from McKean Mt., Stoneham, Maine. It forms from pegmatitic dikes and can be easily confused with more common pegmatite minerals. Crystals are colorless, white to pale yellow.

The mineral, **herderite**, $CaBePO_4(F,OH)$, calcium beryllium phosphate fluoride hydroxide is an attractive and, except in some mines in New England, a rather scarce phosphate mineral. It forms regular crystals and can have a nice yellow or light blue color. Its twinned crystals are its most noteworthy form although its simple prismatic crystals can have quite complex and interesting terminations

There is no demand for any of these compounds in industry. The tribasic salt has been given a CAS number of 35089-00-0. This salt is offered for sale by a few registered manufacturers. The dibasic salt, listed as $BeHPO_4$, has been assigned a CAS number of 23598-15-7. It is said to be insoluble in water. It is also offered for sale by few producers, notably Chinese. The actual constitution of this salt remians questionable and unknown.

Magnesium Orthophosphates

Magnesium forms all three of the orthophosphates salts rather easily. These are the monobasic, dibasic and tribasic varieties.

MONOBASIC SALT: $Mg(H_2PO_4)_2$

This is prepared by dissolving the oxide, the hydroxide or the carbonate in excess phosphoric acid. The best acid to cation ratio appears to be at least 2.5 to 1.0. If the pH is allowed to climb more than about 3.5, the insoluble dibasic salt begins to appear. Addition of acid causes it to redissolve. All alkaline earth monobasic salts are water soluble so that the solution must be evaporated to obtain the salt. The result is the monobasic salt, $Mg(H_2PO_4)_2\cdot 3H_2O$. Its molecular weight is 175.3025 g/mol while that of the anhydrate is 121.2563 g/mol. Its CAS number is 13092-66-5. It is also known as: magnesium biphosphate; primary magnesium phosphate; acid magnesium phosphate; magnesium tetrahydrogen phosphate.

Monobasic magnesium phosphate decomposes upon heating and loses waters of hydration at 145, 168 and 173 °C, respectively. The formation of the anhydrate is complete by 200 °C. The conversion to the acid pyrophosphate, $MgH_2P_2O_7$ is complete by 450 °C. This compound then forms a metaphosphate glass whose composition depends upon the cycle of heating.

Such glasses have been studied.[1] The XRD profile of magnesium glasses have been measured and the pair function distributions were calculated. Using the pair function method, distance and coordination numbers for the pairs of P–O, O–O, and Mg–O were determined. A fundamental unit of the structure in this phosphate glass is confirmed to be a PO_4 tetrahedron. It is found that in the structures of the abnormal-type magnesium phosphate glasses consist of long chains with many branches, and most of Mg^{2+} atoms are surrounded by four oxygens. Thus, the distinct structural difference for abnormal-type phosphate glasses was recognized by XRD results. However, an abrupt change of an oxygen coordination number around a metallic ion at the metaphosphate concentration was not observed, which is previously considered to be a main reason for the abnormal behavior of these abnormal-type phosphate glasses.

Monobasic magnesium phosphate has found limited usage in industry. It has been evaluated in fireproofing wood. As a food additive, it is used as an acidity regulator.

This salt is available commercially from several listed manufacturers.

DIBASIC SALT: $MgHPO_4$

Magnesium phosphate dibasic has the formula of $MgHPO_4$ and the molecular weight of 120.2626 g/mol. It is also called magnesium hydrogen phosphate; secondary magnesium phosphate. Its CAS number is 7757-86-0. It may be prepared by reacting the oxide,

[1]see "Inorganic Polymeric Glasses" by RC Ropp, ISBN 0-444-89500-0- Elsevier, 1992

hydroxide or carbonate in phosphoric acid at a pH of about 5.6–6.0. (Ammonia cannot be used to control the pH since it forms a double salt $MgNH_4PO_4$.) The result is a stable trihydrate, $MgHPO_4 \cdot 3H_2O$. Its density is 2.123 g/cm^3. It is slightly soluble in water, soluble in acid but insoluble in ethanol. The heptahydrate also forms at low solutions concentrations. $MgHPO_4 \cdot 7H_2O$ is a white monoclinic needlelike compound with a density of 1.728 g/cm^3 at 15 °C. It is also sparingly soluble in water (0.3 g/100 ml at 20 °C), soluble in acids but insoluble in ethanol.

If ammonia is used, the magnesium present is precipitated in highly alkaline solution as the hydrated crystal, $MgNH_4PO_4 \cdot 6H_2O$. When calcined at 1100 °C, it decomposes to the pyrophosphate $Mg_2P_2O_7$. Various mechanisms have been proposed for the course of decomposition of the magnesium-ammonium salt. It has been shown that a loss of 5 mols of water but no ammonia occurs at about 105 °C. The simultaneous decomposition and loss of the monohydrate and the ammonium radical itself occurs above 250 °C.

The dibasic magnesium phosphate trihydrate is a white crystalline powder with an orthorhombic structure. Its refractive index is 1.514 and density is 2.123 g/cm^3 at 15 °C. When heated, it loses a molecule of water at 105 °C and one more at 165 °C. The anhydrate is formed at 205 °C by losing the last molecule of water. It is stable to about 650 °C where it reacts to form the pyrophosphate:

$$2MgHPO_4 + \text{heat} \Rightarrow Mg_2P_2O_7 + H_2O$$

The pyrophosphate is stable at least to 1200 °C.

The dibasic magnesium phosphate trihydrate crystal is Orthorhombic with the space group = *mmm* (2/*m* 2/*m* 2/*m*)—Dipyramidal. The cell parameters are: $a = 10.23$ Å, $b = 10.68$ Å, $c = 10.01$ Å, $V = 1090.45$ Å^3, $Z = 6$. It is a biaxial (+) crystal with refractive indices of $\eta_\alpha = 1.514$, $\eta_\beta = 1.517$, $\eta_\gamma = 1.533$. Another source gave the cell parameters as: $a = 10.203$ Å, $b = 10.678$ Å, $c = 10.015$ Å, $Z = 8$, space group Pbca.

The trihydrate is found in nature as the mineral, "Newberyite" ($Mg(PO_3OH) \cdot 3H_2O$)—found in caves, formed directly from bat guano and as "Phosphoroesleriite" ($MgHPO_4 \cdot 7H_2O$). The latter mineral has a density of 1.721–1.729 g/cm^3. It is Monoclinic with the space group 2/m—prismatic.

A number of magnesium phosphate dibasic minerals have been found throughout the world. They are quite numerous. Some of these are:

$$\text{Dittmarite} = MgNH_4PO_4 \cdot H_2O$$
$$\text{Struvite} = MgNH_4PO_4 \cdot 6H_2O$$
$$\text{Hannayite} = Mg_3(NH_4)_2(PO_4) \cdot 8H_2O$$

Note that these are double salts. Dibasic magnesium phosphate is used as a food additive and also as a laxative. It also has been used as a stabilizer in certain plastics.

This salt is available commercially from several manufacturers, both domestically and foreign.

TRIBASIC SALT: $Mg_3(PO_4)_2$

This salt can be formed by the addition of a soluble salt like magnesium chloride to a solution of sodium phosphate:

$$3MgCl_2\ (aq) + 2Na_3PO_4\ (aq) \Rightarrow Mg_3(PO_4)_2 + 3NaCl$$

This forms the stable hydrate, $Mg_3(PO_4)_2 \cdot 4H_2O$ whose CAS number is 7757-87-1 and molecular weight is 239.6124 g/mol. Other hydrates have been formed by varying the solution concentration before precipitation. Those that have been studied include $Mg_3(PO_4)_2 \cdot 8H_2O$ and $Mg_3(PO_4)_2 \cdot 22H_2O$. The octahydrate occurs naturally as the mineral "Bobierrite", $Mg_3(PO_4)_2 \cdot 8H_2O$. The tribasic salt is also known as "magnesium orthophosphate", "neutral magnesium phosphate", and "tri-magnesium phosphate".

All basic magnesium phosphates find applications in plastics as stabilizers. The tribasic phosphate is an antacid and a nutritional food supplement. The compound also is an adsorbent and a polishing agent in dental work.

The tetrahydrate of the tribasic phosphate, $Mg_3(PO_4)_2 \cdot 4H_2O$ is a bulky and soft white powdery material. It forms monoclinic crystals with a density of 1.64 g/cm^3 at 15 °C. It is slightly soluble in water (0.02 g/100 ml at 20 °C) and soluble in acids. The naturally occurring octahydrate, "Bobierite", is a white crystalline solid, containing monoclinic plates with a refractive index of 1.510, has a density of 2.195 g/cm^3 at 15 °C. When heated, it loses two molecules of water of crystallization at 150 °C and loses all water at 400 °C. This salt is insoluble in water but soluble in dilute mineral acids.

The crystal structure was solved from powder XRD data. $Mg_3(PO_4)_2 \cdot 4H_2O$ crystallizes in the orthorhombic space group $Cmc2_1$ (No. 36) with $a = 8.41087(9)$ Å, $b = 17.3850(2)$ Å, $c = 12.8034(1)$ Å, $V = 1872.15(4)$ Å^3 and $Z = 8$. The structure consists of sheets stacked along [010], which are linked by edge-sharing octahedral $Mg_2O_6(H_2O)_4$ dimers. Within the sheets, there are infinite edge-sharing chains of Mg octahedra along [100]. The compound has been further characterized by ^{31}P MAS-NMR spectroscopy and TGA. The crystal structure of two dehydrated variants existing around 200 °C ($Mg_3(PO_4)_2 \cdot 2.5H_2O$) and 275 °C ($Mg_3(PO_4)_2 \cdot 2H_2O$) remains unknown.

The anhydrate, magnesium orthophosphate $Mg_3(PO_4)_2$ forms rhombic crystals; melts at 1184 °C, is insoluble in water but soluble in ammonium salt solution.

THERMOCHEMICAL PROPERTIES [$Mg_3(PO_4)_2$]

$$\Delta H_f^0 = -903.6 \text{ kcal/mol}$$
$$\Delta G_f^0 = -845.8 \text{ kcal/mol}$$
$$S^0 = 45.2 \text{ cal/degree mol}$$
$$C_P = 51.0 \text{ cal/degree mol}$$

The basic phosphates that occur naturally may be extracted from their respective minerals. They are formed by reactions of phosphoric acid with intrinsic magnesium oxide and/or hydroxide followed by crystallization from solution. Tribasic magnesium phosphate can be prepared by treating magnesium ores with phosphoric acid at high temperature. Some of these natural phosphates include:

$$\text{Farringtonite} = Mg_3(PO_4)_2$$
$$\text{Holtedahlite} = Mg_2(OH)PO_4$$
$$\text{Althausite} = Mg_2[(OH,F)|PO_4]_2$$

Tribasic magnesium phosphate is available as an impure salt from a number of commercial suppliers as well as the pure salt used as a food supplement and additive to dental pastes.

APATITES OF MAGNESIUM

Magnesium does not form the usual haloapatite formulation of 5:3 cation to anion ratio. Instead, the compound, $Mg_4O(PO_4)_2$ is known. This is not an apatite per se but is related in structure. The mineral, "Althausite" = $Mg_2(PO_4)(OH, F, O)$" is orthorhombic with Point Group: 2/m 2/m 2/m. It was found at Tingelstadtjern Quarry, Norway, its Space Group is Pnma and lattice parameters of: $a = 8.258$ Å, $b = 6.054$ Å, $c = 14.383$ Å, $Z = 8$, $V = 719.06$ Å^3, density = 2.98 g/cm^3.

A similar mineral, "Raadeite" = $Mg_7(PO_4)_2(OH)_8$ was found within the Tingelstadtjern serpentinite body, Norway. It is colorless, transparent, biaxial (−) [for = 589 nm], with refractive indices of $\eta_x = 1.5945$, $\eta_y = 1.6069$, $\eta_z = 1.6088$, $2V_{meas} = 45.6°$, $2V_{calc} = 43°$; strong dispersion $r > v$. The infrared spectrum shows prominent OH stretching bands at 3375, 3475, 3540 and 3580/cm. Raadeite is monoclinic, space group $P2_1/n$, $a = 5.250(1)$, $b = 11.647(2)$, $c = 9.655(2)$ Å, $\beta = 95.94(1)°$, $Z = 2$.

Magnesium can be incorporated into the structures of calcium or strontium haloapatites. Magnesium was incorporated in the compound according to the formula $(Ca_{10-x}Mg_x)_{10}(PO_4)_6(OH)_2$, where $x = 0$, 0.50, 1.00, 1.50 and 2.00. The magnesium hydroxyapatite should be described as $(Ca_{0.86}Mg_{0.14})_{10}(PO_4)_6(OH)_2$.

0.01w?>Ionic activity data were used to determine the phase relationships existing under aqueous conditions along the $Mg_5F(PO_4)_3 \cdot Mg_5OH(PO_4)_3$ join of the system $MgOP_2O_5 \cdot MgF_2 \cdot H_2O$. The results indicated that magnesium analog of fluoroapatite $Ca_5F(PO_4)_3$ and hydroxyapatite $Ca_5OH(PO_4)_3$ are unlikely to be found under aqueous conditions.

Magnesium does form a series of similar compounds with the sodium salt. The $MgO–Mg_3(PO_4)_2–Mg_4Na(PO_4)_3–Na_4P_2O_7$ subsystem of the ternary system $MgO–Na_2O–P_2O_5$ was investigated using thermal analysis (heating and cooling), XRD techniques and microscopy in reflected light. Three intermediate compounds: $Mg_4Na(PO_4)_3$, $MgNaPO_4$ and $MgNa_4(PO_4)_2$ occur in the partial system. $Mg_4Na(PO_4)_3$ melts incongruently at 1155 °C, $MgNa_4(PO_4)_2$ melts congruently at 1655 °C, whereas $MgNaPO_4$ exists only in the solid phase and decomposes at 950–960 °C. A phase diagram for the partial system was proposed. It has been established that the $MgNa_4(PO_4)_2$ phosphate forms a binary system with $Na_4P_2O_7$. A phase diagram of this specific system has been constructed. It was found that a ternary peritectic ($t_P = 1145 \pm 3.0$ °C) and two ternary eutectics ($t_{E1} = 984 \pm 3.0$ °C, $t_{E2} = 732 \pm 1.5$ °C) occur in the $MgO–Mg_3(PO_4)_2–Mg_4Na(PO_4)_3–Na_4P_2O_7$ system.

In another study, the partial system $Mg_3(PO_4)_2–Mg_4Na(PO_4)_3–Na_4P_2O_7–Mg_2P_2O_7$ in the ternary system $MgO–Na_2O–P_2O_5$ was investigated using thermal and XRD analyses and microscopy, and its phase diagram has been determined. In this range of composition, two binary phosphates occur: $Mg_4Na(PO_4)_3$ and $Mg_6Na_8(P_2O_7)_5$. The former melts incongruently (at 1155 °C) and the latter does so congruently (at 808 °C). In the partial system of interest, the two sections $Mg_4Na(PO_4)_3–Mg_2P_2O_7$ and $Mg_4Na(PO_4)_3–Mg_6Na_8(P_2O_7)_5$ were studied, and their phase diagrams were established. The partial system is divided into three partial ternary systems in which two ternary eutectics and one ternary peritectic occur.

None of these compounds are offered for sale commercially. The only interest in their properties has been academic, not industrial. No CAS numbers are available.

Calcium Orthophosphates

All of the possible calcium phosphates are known and can be prepared from phosphoric acid and calcium carbonate.

CALCIUM PHOSPHATE, MONOBASIC

This salt has the formula, $Ca(H_2PO_4)_2$ and the molecular weight of 137.0293 g/mol. Its CAS number is 3358-23-8. It is easily prepared by dissolving calcium carbonate in an excess of H_3PO_4. A ratio of at least 3:1 mol of acid is required:

$$CaCO_3 + 2H_3PO_4 \Rightarrow Ca(H_2PO_4)_2 + CO_2 + H_2O$$

If the pH exceeds about 3.8, the dibasic salt begins to precipitate. The monobasic salt is soluble so that the

solution must be evaporated, usually at high temperature, >80–90 °C. A monohydrate, $Ca(H_2PO_4)_2 \cdot H_2O$, readily forms acicular crystals.

The CAS numbers are: anhydrous: 7758-23-8, monohydrate: 10031-30-8. Their molecular weight is: anhydrous: 238.0122 g/mol, monohydrate: 256.0264 g/mol. Synonyms are: monocalcium orthophosphate; calcium biphosphate; primary calcium phosphate, calcium dihydrogen phosphate.

The monohydrate occurs as colorless shiny crystals, granules or powder. The impure material is hygroscopic due to the presence of traces of phosphoric acid and other impurities. The density of the monohydrate is 2.22 g/cm^3. It is moderately soluble in water (1.82 g/100 ml at 20 °C) and more so in dilute acids. The monohydrate loses water at 191 °C to form the anhydrate. Upon further heating, the acid pyrophosphate is formed at 291 °C and a series of metaphosphates are formed at 342, 361, 383, 400 and 553 °C before the final stage at 637 °C to form a polymeric metaphosphate, $[Ca(PO_3)_2]_n$.

$Ca(H_2PO_4)_2 \cdot H_2O$ crystallizes in the space group PI with the triclinic unit cell parameters of $a = 5.6261$ Å, $b = 11.8891$ Å, $c = 6.473$ Å, β = 98"633, $V = 118.262$ $Å^3$, and $\beta = 83.344$ ° at 25 °C with $Z = 2$. The hydrogen positions have been determined by neutron diffraction and no evidence of disorder was found. The two crystallographically distinct $H_2PO_4^-$ ions are hydrogen bonded to each other and to the water molecule. The distances of Ca···O and H···O bonds are 2.479 and 1.679 Å, respectively.

$Ca(H_2PO_4)_2$ crystallizes in the triclinic unit cell with $a = 7.5577$ Å, $b = 8.2561$ Å, $c = 5.5504$ Å, $\alpha = 109.87°$, $\beta = 93.68°$, $\gamma = 109.15°$, $V = 302.5$ $Å^3$ with $Z = 2$. The structure consists of rudimentary chains of Ca–$[P_{(1)}O_4]$-$H_{(1)}$)–$[P_{(2)}O_4]$… that run parallel to the (110) direction. Adjacent chains are joined by Ca···O bonds on one side and by $O_{(8)}$–$H_{(5)}$···$O_{(8')}$ hydrogen bonds on the other. These layers are held together by hydrogen bonds on one side and Ca···O bonds on the other. There are two very strong bonds in the structure: $O_{(7)}$–$H_{(4)}$–$O_{(7')}$ and $O_{(8)}$–$H_{(5)}$–$O_{(8')}$. These very strong hydrogen bonds join the $(P_{(2)}O_4)$ groups together to form an infinite chain and are centers of symmetry.

Monobasic calcium phosphate is primarily used in fertilizers. It has been called "superphosphate" since it is slightly soluble and more easily available to plants in the soil. It is also used in baking powders and as a mineral supplement in food. It is a buffer for pH control and as a stabilizer for plastics. A fertilizer grade product can be obtained by dissolving pulverized phosphate rock (tricalcium phosphate) in phosphoric or sulfuric acid and then evaporating the solution.

Calcium dihydrogen phosphate is also used in the food industry as a leavening agent to cause baked goods to rise. Because it is acidic, when combined with an alkali ingredient—commonly $NaHCO_3$ (baking soda)—it reacts to produce CO_2 and a salt. The carbon dioxide gas is what leavens the baked goods. When combined in a ready-made baking powder, the acid and alkali ingredients are included in the right proportions such that they will exactly neutralize each other. Apart from acting as leavening agent, it also inhibits microbial activity because of the phosphate ions present in the molecule.

Calcium dihydrogen phosphate is readily available commercially in tonnage quantities. There are 22 suppliers in the U.S. alone and over 3 million exporters and importers worldwide.

CALCIUM PHOSPHATE, DIBASIC

Dibasic calcium has the formula $CaHPO_4$ and the CAS number 7757-93-9. Its molecular weight is 136.0658 g/mol. It also occurs as the dihydrate, $CaHPO_4 \cdot 2H_2O$, known as "Brushite" (CAS number = 7789-77-7). The anhydrate is "Monetite"—$CaHPO_4$. Synonyms are: calcium hydrogen phosphate; secondary calcium phosphate; bicalcium phosphate. The most prevalent use of dibasic calcium phosphate has been in the manufacture of "Halophosphate" phosphors, $Ca_5(F,Cl)(PO_4)_3$:$Sb^{3=}$:Mn^{2+}, used as the main ingredient in all fluorescent lamps. Halophosphate phosphors were introduced about 1940 to replace zinc beryllium orthosilicate phosphors which were found to induce "Berylliosis" in Humans who handled it during the manufacture of fluorescent lamps.

It was determined that brushite could be converted to Monetite (both are slightly soluble in water) after the brushite had been formed by the addition of diammonium phosphate to a calcium chloride solution:

$$CaCl_2 + (NH_4)_2HPO_4 \Rightarrow CaHPO_4 \cdot 2H_2O$$

This is usually accomplished at room temperature. Dicalcium Phosphate Dihydrate (DCPD), also known as Brushite, is a hydrated calcium phosphate mineral with the composition $CaHPO_4 \cdot 2H_2O$. The structure of DCPD is almost identical to that of gypsum with their respective unit cell dimensions very similar. The phosphate of DCPD is isomorphous with arsenate, which forms instead, the mineral Pharmacolite. The backbone of DCPD is made up of alternating calcium and phosphorus atoms which form chains via the sharing of oxygens (the four phosphate oxygens). These chains run perpendicular to the ***b***-axis in the plane formed by the ***a*** and ***c*** axes (Fig. 4.34).

The phosphorus atoms have fourfold coordination forming phosphate tetrahedra while the calcium atoms have eightfold coordination. Four of calcium's bonds are with these phosphate tetrahedra, forming the backbone chains, while two more of the calcium bonds are

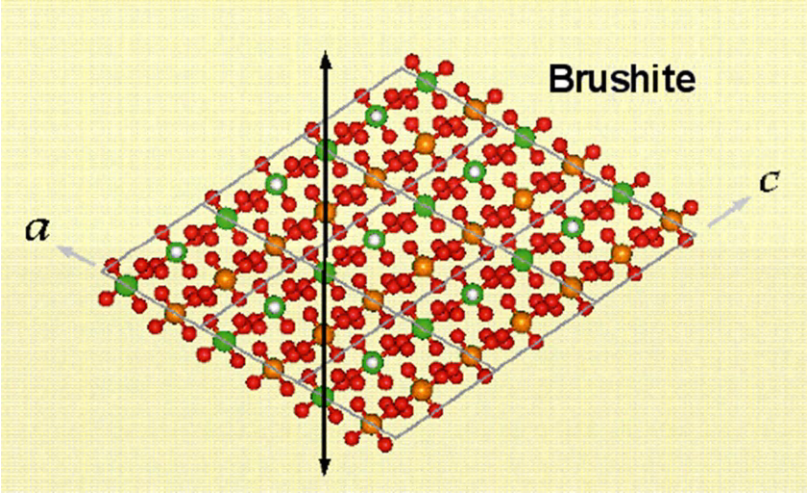

FIGURE 4.34

with oxygens from neighboring chains. These last bonds which link the chains together result in a zigzag pattern or corrugated sheet. The last two calcium bonds are with the water molecules. These water molecules are what hold the sheets together.

A continuous process has arisen in industry to convert brushite to Monetite. The equipment used to manufacture $CaHPO_4$ is shown in Fig. 4.35.

CONTINUOUS PROCESS FOR $CaHPO_4$

1. This process is used to manufacture the halophosphate phosphor and is made in tonnage quantities each month. $CaHPO_4$ is dimorphic in that it forms "brushite", i.e. $CaHPO_4 \cdot 2H_2O$ at precipitation temperatures below about 35 °C and "Monetite", i.e. $CaHPO_4$, above about 65–70 °C. The brushite crystals, formed at 25 °C, are "poorly-crystalline" to amorphous while the monetize crystals, formed at 65 °C are also not very crystalline. By a separate conversion in solution, brushite is first formed and then redissolved to form Monetite, a very crystalline product.
2. Brushite is converted to Monetite from a slurry suspension by reheating the suspension. Brushite crystals are of indeterminate size and crystallinity.

   The conversion produces flat plates or diamond-shaped crystals. Since the solubility product of $CaHPO_4$ is $K_{SP} = 3.4 \times 10^{-14}$, the solution equilibrium is a dynamic one:

$$Ca^{2+} + HPO_4^{=} \Leftrightarrow CaHPO_4 \Downarrow$$

3. In this process, a series of processing and holding tanks are used to purify both the $CaCl_2$ and the $(NH_4)_2HPO_4$ solutions, whereupon each solution stored is ready for use. Sulfide is added on a continuous basis.
4. These solutions are then pumped into a precipitation tank to form the $CaHPO_4 \cdot 2H_2O$ on a continuous basis. Then, the slurry is fed to a drum filter where the mother liquor is separated. The wet cake is then reslurried at a specific ratio of solid to water (sometimes containing a small amount of soluble phosphate) and the pH of the slurry is adjusted.
5. Thereupon, it is pumped to a conversion tank wherein the particles undergo a change from brushite to Monetite of predetermined size and proportions via the reaction:

$$[CaHPO_4]_{\text{brushite}} \Rightarrow Ca^{2=} + HPO_4^{2-} \Rightarrow [CaHPO_4]_{\text{Monetite}}$$

6. As stated above, a thick slurry will form the diamond-shaped crystals, whereas a thinner slurry forms the square crystals. The same general precipitation procedure is then followed. The type of crystals being formed during conversion is important. Increasing the solid content of the slurry gives diamond-shaped crystals while decreasing it tends to form elongated cubes rather than flat square crystals.
7. Product desired = flat, platy diamond-like crystals of about 7–9 μ (microns) in size. If a truly diamond-shaped crystal is desired, i.e. the procedure for making $CaHPO_4$ is modified (since crystal habit forms basis for final shape of phosphor crystals; Fig. 4.36).
8. Particle size should be about 8.0 μ. Most manufacturers have chosen to prepare flat square platy crystals to form the particulate film. This is referred to as "covering power". It is now well established that particles less than about 3.0 μ and greater than 35–40 scatter the ultraviolet and generated visible light within the film to such

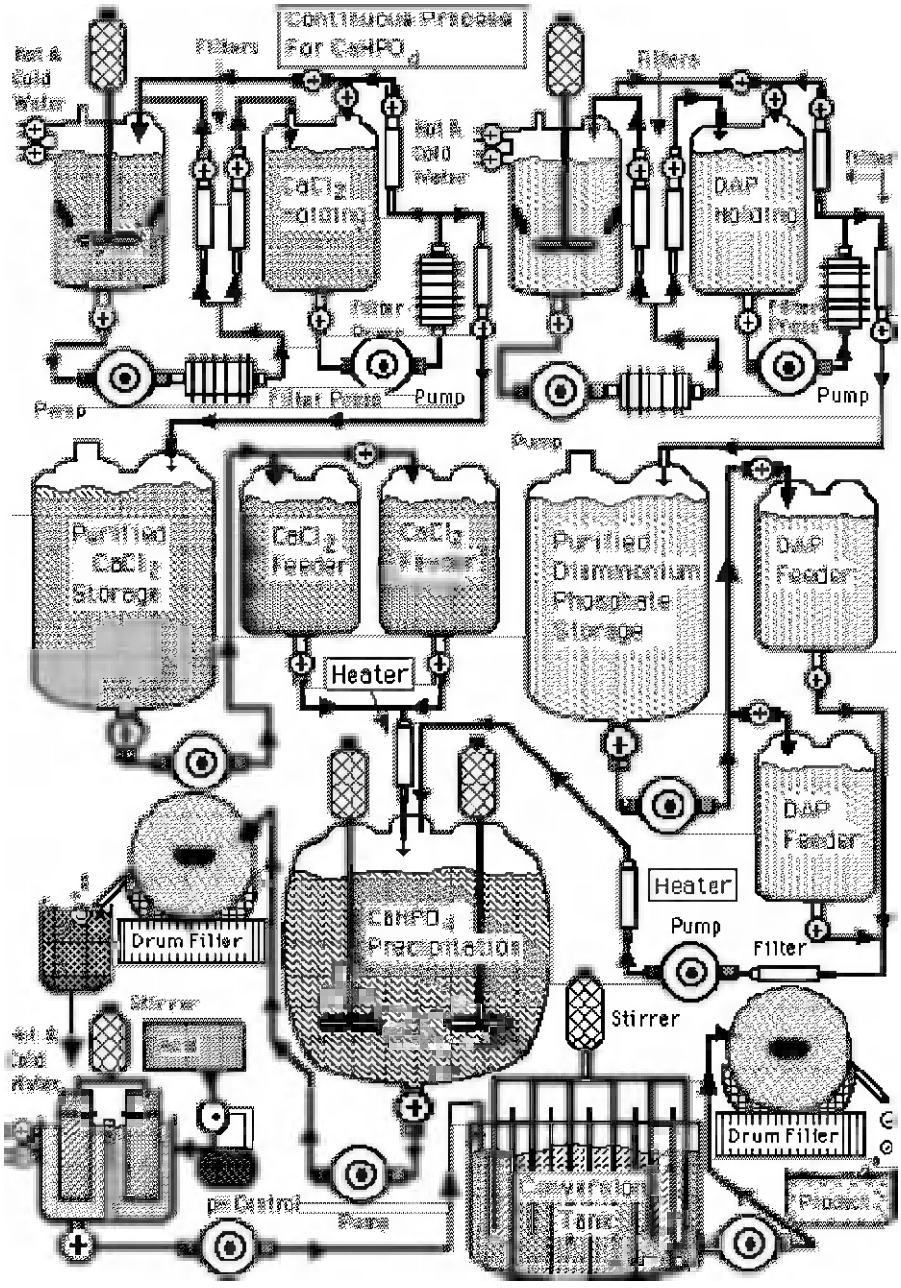

FIGURE 4.35

a degree that a loss of output of the fluorescent lamp results. Thus, the optimum particle size has been determined to be:

$$3.0\ \mu < \text{optimal particle size} < 35\text{–}40\ \mu$$

Dibasic calcium phosphate is found in nature as the mineral "Monetite". This mineral is triclinic (pinacoidal) and has the lattice parameters of: $a = 6.92$ Å, $b = 7.12$ Å, $c = 6.65$ Å, $Z = 4$; $\alpha = 96.35°$, $\beta = 91.267°$, $\gamma = 76.1°$, $V = 309.80$ Å^{33} and a density of 2.92 g/cm^3.

Dibasic calcium phosphate is also used as a food supplement and source of calcium, both in human food and animal feed. It is used in dough conditioner; in several dental products and in medicine.

Calcium hydrogen phosphate crystallizes as a double salt, $CaNaPO_4$. This salt has found some application in Dentistry and as a Medical bone graft. The use of biodegradable bone substitutes is advantageous in Dentistry for alveolar ridge augmentation, since it avoids second-site surgery for autograft harvesting. This study examines the effect of novel, rapidly resorbable calcium

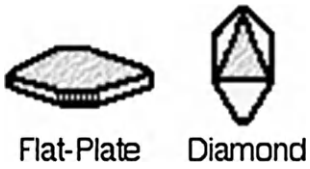

FIGURE 4.36

phosphates on the expression of bone-related genes and proteins by human bone-derived cells (HBDCs) and compares this behavior to that of tricalcium phosphate (TCP). Test materials were α-TCP, and four materials which were created from α-Rhenanite and its derivatives: R_1-α-Rhenanite ($CaNaPO_4$); R_1/M_2 composed of $CaNaPO_4$ and $MgNaPO_4$; $R_1 + SiO_2$ composed of $CaNaPO_4$ and 9% SiO_2 (wt%); and R_{17}-$Ca_2KNa(PO_4)_2$. HBDC were grown on the substrata for 3, 5, 7, 14 and 21 days, counted and probed for various mRNAs and proteins (Type I collagen, osteocalcin, osteopontin, osteonectin, alkaline phosphatase and bone sialoprotein). All substrata supported continuous cellular growth for 21 days. At day 21, surfaces of $R_1 + SiO_2$ and R_{17} had the highest number of HBDC. At 14 and 21 days, cells on R_1 and on $R_1 + SiO_2$ displayed significantly enhanced expression of all osteogenic proteins. Since all novel calcium phosphates supported cellular proliferation together with expression of bone-related proteins at least as much as TCP, these ceramics can be regarded as potential bone substitutes. R_1 and $R_1 + SiO_2$ had the most effect on osteoblastic differentiation, thus suggesting that these materials may possess a higher potency to enhance osteogenesis than TCP.

Other applications are in fertilizers, plastics and in the manufacture of glass. The salt used is less pure than those employed directly for human or animal consumption.

$CaHPO_4$, synthetic monetite, crystallizes in the triclinic unit cell $a = 6$–910 Å, $b = 6.627$ Å, $c = 6''998$ Å, $\alpha = 96'34°$, $\beta = 103''82°$, $\gamma = 88.33$ ° at 25 °C with cell contents of 4[$CaHPO_4$]. This structure may be regarded as $CaHPO_4$ chains bonded together by Ca···O bonds and three types of hydrogen bonds. These vary across the "normal" range, 2.565–2.669 Å. The P···O bond is about 2.567 Å. Ca(1) is coordinated to seven oxygen atoms with distances ranging from 2.2951 to 2.763 Å and Ca(2)–O distances are 2.379–2.5718 Å. Monetite is a white triclinic crystal; density 2.31 g/cm^3 (dihydrate). It is soft (3.5 Moh) and decomposes on heating to form the pyrophosphate.

Dibasic calcium phosphate can also be prepared by the reaction of phosphoric acid with tribasic calcium phosphate:

$$\underset{\text{Sl.Sol.}}{Ca_3(PO_4)_2} + \underset{\text{Sol.}}{Ca(H_2PO_4)_2} \Leftrightarrow \underset{\text{Insol.}}{4CaHPO_4}$$

This salt is readily available commercially in tonnage quantities from many manufacturers worldwide.

Both Monetite and Brushite are available in tonnage quantities from numerous sources, worldwide.

CALCIUM PHOSPHATE, TRIBASIC

Tricalcium phosphate has the formula $Ca_3(PO_4)_2$. It is also known as *tribasic calcium phosphate* or *"bone ash"* (calcium phosphate being one of the main products when bone is heated). It has an alpha and a beta crystal form, the alpha state being formed at high temperatures. As a mineral, it is found in "Whitlockite", which is a complex hydroxyapatite = $Ca_9(Mg,Fe)(PO_4)_6(PO_3OH)$. Its CAS number is 7758–87–4. Its molecular weight is 310.2045 g/cm^3. It is also known as "calcium orthophosphate; calcium phosphate; tricalcium phosphate; tertiary calcium phosphate; precipitated calcium phosphate; bone ash (technical product).

Tribasic calcium phosphate can be prepared by the reaction of calcium chloride added to a solution of trisodium phosphate. However, it is very difficult to obtain a pure product since this combination of solutions tends to form the hydroxyapatite, $Ca_5OH(PO_4)_3$ rather than the tribasic compound, $Ca_3(PO_4)_2$:

$$8CaCl_2\ (aq) + 5Na_3PO_4\ (aq) + H_2O \Rightarrow Ca_5OH(PO_4)_3\ (solid) + Ca_3(PO_4)_2 + 15NaCl_2 + HCl$$

The best way to prepare a pure product is to react monetite with calcium carbonate via a solid-state reaction:

$$2CaHPO_4 + CaCO_3 + heat \Rightarrow Ca_3(PO_4)_2 + CO_2$$

Calcium phosphate, tribasic, has the CAS number of 7758-87-4 and the molecular weight of 310.3346 g/mol. Its solubility in water is 0.00012 g/100 ml at 20 °C. It is a whiter, amorphous powder with a density of 3.14 g/cm^3 and a melting point of 1670 °C. Its solubility product is: $K_{sol} = 2.07 \times 10^{-33}$. The following thermodynamic constants of $Ca_3(PO_4)_2$ are known:

Enthalpy of formation: −4120.8 kJ/mol	Entropy: 236.0 J/mol K
Gibbs energy of formation: −3884.7 kJ/mol	Heat capacity: 227.8 J/mol K

It has been determined that the formation of tribasic calcium phosphate in solution is somewhat dependant upon the presence of $Ca(OH)_2$. If the monobasic salt is reacted with calcium hydroxide, the product is substantially the tribasic salt:

$$Ca(H_2PO_4)_2\ (aq) + 2Ca(OH)_2\ (solid) \Rightarrow Ca_3(PO_3)_2\ (solid) + 4H_2O$$

The solution is initially acidic but is shifted to just slightly alkaline as the calcium hydroxide dissolves and the tribasic salt forms as a precipitate. Nonetheless, it is possible to obtain a small fraction of hydroxyapatite as well.

The formation of tricalcium phosphate (TCP) from thermal reaction of dicalcium phosphate and calcium carbonate has been investigated using DTA, TGA, and powder XRD. DTA showed three distinct thermal events attributed to dehydration of DCPD (brushite) to dicalcium phosphate anhydrous (monetite, DCPA), the formation of beta-calcium pyrophosphate (β-$Ca_2P_2O_7$), and the calcination of calcium carbonate. TGA showed three weight losses corresponding to the three thermal events, respectively. XRD analysis showed that β-TCP formed, beginning at about 900 °C, by the reaction of β-$Ca_2P_2O_7$ with CaO and β-TCP changed to α-TCP above 1200 °C. Further examination of the formation of TCP from calcium hydroxide ($Ca(OH)_2$) and DCPA showed that β-TCP would form only after the decomposition of $Ca(OH)_2$ to CaO and from the reaction of CaO with β-$Ca_2P_2O_7$ at a fairly low temperature of 800 °C. In addition, by naturally cooling α-TCP, formed at 1300 °C within the heating furnace, to room temperature, it was difficult to obtain a pure phase of β-TCP. The proposed mechanism of the reaction to form TCP may include the dehydration of brushite to monetite, dehydration of monetite to beta-calcium pyrophosphate, decomposition of calcium carbonate, the formation of β-TCP, and phase transition.

The phase, α-$Ca_3(PO_4)_2$, is thermodynamically stable between the temperature range of 1120 and 1470 °C but is metastable at room temperature. It crystallizes in the monoclinic space group $P2_1/a$ with $a = 12.887$ Å, $b = 27.280$ Å, $c = 15.219$ Å, $\beta = 126.2°$ and $Z = 24$. The structure consists of columns of cations plus columns of anions and cations with compensating cation vacancies, and is closely related to the mineral "Glasserite", $K_3Na(SO_4)_2$. The calcium ions in α-$Ca_3(PO_4)_2$ exhibit a wide range of coordination numbers and geometries.

A related salt, an oxotetracalcium diphosphate, $Ca_4O(PO_4)_2$, is also known and is related to calcium hydroxyapatite. It crystallizes in the monoclinic unit cell of $a = 7.023$ Å, $b = 11.986$ Å, $c = 9.473$ Å, $\beta = 90.90°$ and space group of $P2_1$. The unit-cell dimensions of this salt and hydroxyapatite are similar and related. Although this three-dimensional relationship in the unit-cell shapes is not carried over in the details of the actual structures, $Ca_4O(PO_4)_2$ does contain a layer which is similar to that of hydroxyapatite. In this structural relationship, the oxide ions are "extra". One is weakly coordinated to the face of a PO_4-group, a feature that has been only observed in the β-$Ca_3(PO_4)_2$ structure as a distorted cation site. The two crystallographically discrete oxide ions are surrounded by tetrahedra of Ca^{2+} ions with Ca···O distances in the range of 2.136–2.277 Å. Thus, the oxide ions do not lie in the channel formed by cations in the structure and $Ca_4O(PO_4)_2$ cannot be considered to be an oxyapatite. The positions of the P atoms and those of the Ca atoms lie close to those required by the space group Pmcn. This explains the appreciable twinning exhibited by $Ca_4O(PO_4)_2$.

Tribasic calcium phosphate occurs in nature as the minerals:

$$\text{Oxyapatite} = Ca_{10}O(PO_4)_6$$
$$\text{Whitlockite} = Ca_9(Mg,Fe)(PO_4)_6(PO_3OH)$$
$$\text{Voelicherite} = (Ca,Mg,Fe)_{10}O(PO_4)_6$$
$$\text{Apatite} = Ca_5(PO_4)_3(OH,F,Cl)$$
$$\text{Phosphorite} = Ca_5(OH,F,Cl)(PO_4)_3\text{—amorphous}$$

The tribasic salt has many industrial applications. Some are similar to the monobasic and dibasic salts. It is used in fertilizers, dental products, ceramics and polishing powder. Some other important applications are in plastics as a stabilizer; as an anticaking agent; as a nutrient supplement in cattle food; for clarifying sugar syrup; as a mordant in dyeing textiles; and as a buffer to control pH.

Tricalcium phosphate is used in powdered spices as an anticaking agent. Calcium phosphate is an important raw material for the production of H_3PO_4 and fertilizers. In 1927, a process was invented wherein phosphate rock was processed to form a mixed fertilizer. The process involves acidifying the rock with nitric acid to produce a mixture of phosphoric acid and calcium nitrate:

$$Ca_3(PO_4)_2 + 6HNO_3 + 12H_2O \Rightarrow 2H_3PO_4 + 3Ca(NO_3)_2 + 12H_2O$$

The mixture is cooled to below 0 °C, where the calcium nitrate crystallizes and can be separated from the phosphoric acid:

$$2H_3PO_4 + 3Ca(NO_3)_2 + 12H_2O \Rightarrow 2H_3PO_4 + 3Ca(NO_3)_2 \cdot 4H_2O$$

The resulting calcium nitrate produces nitrogen fertilizer. The filtrate is composed mainly of phosphoric acid with some nitric acid and traces of calcium nitrate, and this is neutralized with NH_3 gas to produce a compound fertilizer:

$$Ca(NO_3)_2 + 4H_3PO_4 + 8NH_3 \Rightarrow CaHPO_4 + 2NH_4NO_3 + 3(NH_4)_2HPO_4$$

This method is now obsolete but was called the "ODDA Process".

Calcium phosphate is also a raising agent (food additives). It is a mineral salt found in rocks and bones. It is

used in cheese products. It is also a nutritional supplement and occurs naturally in cow's milk.

It is commonly used in porcelain and dental powders, and medically as an antacid or calcium supplement. It has been tried as a bony defect tissue replacement for repairing bony defects when autogenous bone graft is not possible.

Another practical application of the compound is its use in gene transfection. Calcium ions can make a cell porous to exogenous genes that can then enter the cell by diffusion. A heat shock afterward then invokes the cell to repair itself.

Thermochemical properties

$$\Delta H_f^0 = -984.9 \text{ kcal/mol}$$
$$\Delta G_f^0 = -928.5 \text{ kcal/mol}$$
$$S^0 = 56.4 \text{ cal/degree mol}$$
$$C_p = 54.4 \text{ cal/degree mol}$$

Tribasic calcium phosphate is available from many manufacturers worldwide. However, many of these actually supply the hydroxyapatite or a mixture of the two compounds.

CALCIUM APATITE COMPOUNDS

Calcium forms all of the apatite compounds possible, including the fluoro-, chloro-, hydroxy-, bromoapatites and iodoapatites. They all have the same composition, namely $Ca_5X(PO_4)_3$ where X is one of the halogens. They cannot, with the exception of the hydroxyapatite, be prepared from an aqueous solution but must be made by solid-state reaction. The overall enthalpy of formation of these apatite compounds has been determined. The standard ($p = 0.1$ MPa) molar enthalpies of formation in the crystalline state of hydroxyapatite, chlorapatite and a preliminary value for bromapatite, at $T = 298.15$ K, were determined by reaction-solution calorimetry as:

$$Ca_5OH(PO_4)_3 = -12{,}969 \text{ kcal/mol}$$
$$Ca_5Cl(PO_4)_3 = -13{,}231 \text{ kcal/mol}$$
$$Ca_5Br(PO_4)_3 = -13{,}063 \text{ kcal/mol}$$
$$Ca_5I(PO_4)_3 = -12{,}969 \text{ kcal/mol}$$

Those of Sr and Ba are similar. What this means is that the formation by solid-state reaction is energetically and thermodynamically driven and occurs rather easily under the right conditions. The general structure of haloapatites is hexagonal. The following diagram shows the two sites for the metal cations as well as the halogen sites in the lattice (Fig. 4.37).

This structure is indigenous to the apatite compounds and is found as a general composition, $M_{10}X_2(PO_4)_6$, where M is any of the alkaline earths (except Mg^{2+}) and X is any of the halogens including OH^-.

It is possible to estimate the lattice energy of these haloapatites. Experimentally based lattice energies are calculated for the apatite family of double salts $M_5X(PO_4)_3$, where M is a divalent metal cation (Ca, Sr, Ba) and X is hydroxide or a halide. These values are also shown to be estimable, generally to within 4%, using the recently derived Glasser-Jenkins equation:

$$U_{pot} = A \cdot I_{ion}/(2I_{ion}/V_m)^{1/3}$$

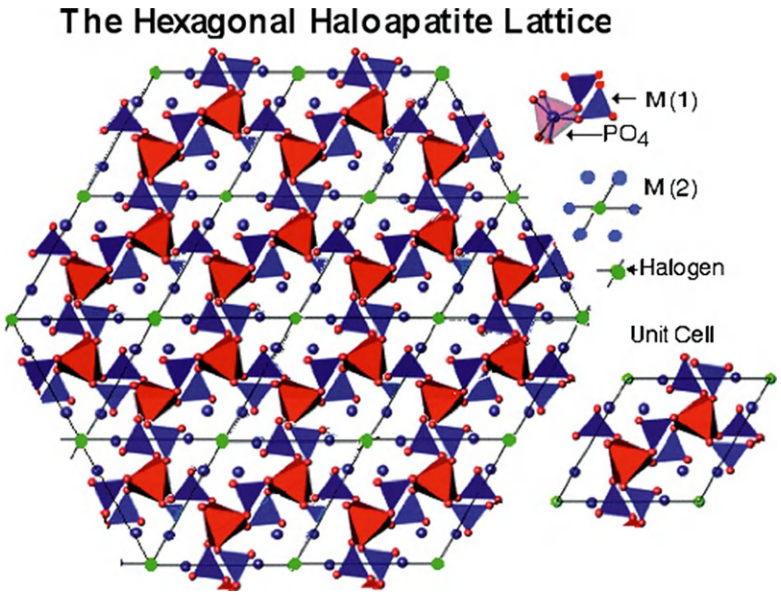

FIGURE 4.37

where A = 121.39 kJ/mol and M = Pb, Cd, etc. are less well reproduced but are within 8% of the experimentally based value. The lattice energy for ionic apatites (having identical lattice ionic strengths, I_{ion}) takes the particularly simple form which reproduces cycle values of U_{pot} well when V_m is estimated by ion volume summation and employing a volume for the PO_4^{3-} ion (not previously quantified with an associated error) of $0.063 \pm 0.003\ nm^3$.

$$U_{pot}/kJ/mol = 26680/(V_m/nm^3)^{1/3}$$

This allows one to compare the lattice stability of the various haloapatites. Because of the extensive usage of haloapatite phosphors in the lamp industry, the practical and theoretical knowledge of these compounds are broad. For example, the reactions that form apatites in general are:

Overall reaction:

$$6CaHPO_4 + 3CaCO_3 + CaF_2 + CaCl_2 \Rightarrow Ca_{10}(F,Cl)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Partial reactions:

a. $2CaHPO_4 \Rightarrow$ ß-$Ca_2P_2O_7$ (monoclinic) + H_2O
b. $CaCO_3 \Rightarrow CaO + CO_2$
c. $Ca_2P_2O_7 + CaO \Rightarrow$ ß-$Ca_3(PO_4)_2$ (triclinic)
d. ß-$Ca_3(PO_4)_2 + CaF_2 + CaCl_2 \Rightarrow Ca_5(F,Cl)(PO_4)_3$ (Hexagonal)

Probably, the most important fact concerning calcium apatite is that the hydroxyapatite is the dominant crystallite in human and animal bones.

Calcium Hydroxyapatite

This compound, also called hydroxylapatite, is a naturally occurring mineral form of calcium apatite with the formula $Ca_5(PO_4)_3(OH)$, but is usually written $Ca_{10}(PO_4)_6(OH)_2$ to denote that the crystal unit cell comprises two molecules. Pure hydroxyapatite powder is white. Naturally occurring hydoxyapatites can, however, also have brown, yellow, or green colorations, comparable to the discolorations of "dental-fluorosis".

Up to 50% of human bone is made up of a modified form of the inorganic mineral hydroxylapatite (known as bone mineral). Carbonated calcium-deficient hydroxylapatite is the main mineral of which dental enamel and dentin are comprised. Hydroxyapatite crystals are also found in the small calcifications (within the pineal gland and other structures) known as corpora arenacea or "brain sand". Hydroxyapatite is commonly used as a filler to replace amputated bone or as a coating to promote bone ingrowth into prosthetic implants. It has been suggested that this may promote osseointegration.

$Ca_{10}(PO_4)_6(OH)_2$ has the molecular weight of 502.3145 g/mol and the density of $3.16\ g/cm^3$. It has a hexagonal structure and the refractive index of $\eta_\omega = 1.651$, $\eta_\varepsilon = 1.644$. Birefringence, $\delta = 0.007$. It has been prepared by reaction of calcium chloride and trisodium phosphate:

$$CaCl_2\ (aq) + Na_3PO_4\ (aq) \Rightarrow Ca_5(PO_4)_3OH\ (solid) + NaCl\ (aq)$$

The chloride (45 °C) is added to the phosphate solution at 95 °C and the precipitate is allowed to recrystallize while stirring. It is then filtered, washed with water and dried. The system needs to be protected from the atmosphere since CO_2 will form a "carbonato-hydroxyapatite". Hydroxyapatites containing two levels of sodium and carbonate have been investigated by IR absorption spectroscopy and X-ray powder pattern fitting methods. Results confirm that both compounds relate to the apatite family crystallizing in a hexagonal system, space group $P6_3/m$. The cell parameters of the lower carbonate content apatite are $a = 9.3892$ Å and $c = 6.9019$ Å, while those of the higher one are $a = 9.3249$ Å and $c = 6.9213$ Å. Occupancy factors show that sodium is localized mainly in a 6h cationic site. Furthermore, carbonate ions occupy phosphate sites leading to a B-type carbonate apatite. These simultaneous substitutions affect the OH^- position in the channel, as well as the metal–oxygen interatomic distances. The substitution mechanism can be described using two of the six known elementary reaction mechanisms.

If the exactly pure hydroxyapatite is desired, $Ca(OH)_2$ is suspended in 100 °C water, protected from CO_2 by a NaOH trap, and 2.5 molar H_2PO_4 is added until the hydroxide disappears. The slurry of precipitate is then boiled until the pH exceeds 6.0 where any traces of $CaHPO_4$ are converted to hydroxyapatite. This apatite is hexagonal with $a = 9.424$ Å, $c = 6.885$ Å, $V = 446.73$ Å^3, $Z = 2$.

In another route of hydroxyapatite synthesis, a solution of calcium nitrate tetrahydrate ($Ca(NO_3)_2 \cdot 4H_2O$) and dibasic ammonium phosphate ($(NH_4)_2HPO_4$), of proper concentrations, were reacted with each other at high pH values in the presence of ammonium hydroxide (NH_4OH). The solution was held at 25 °C to prevent loss of the hydroxide during precipitation. The solution was protected, as before from CO_2 from the air. The solubility constant is *K*sp $(HA) = (2.03 \pm 0.04) \times 10^{-59}$.

Since hydroxyapatite has an affinity for proteins and other organic compounds, it can be used in combination with TiO_2 as an adsorbent. The TiO_2 regions and hydroxyapatite regions can function as photocatalysts and adsorbents for organic contaminants, respectively,

allowing simultaneous decomposition of organic contaminants by the photocatalysis of TiO_2 under irradiation. Therefore, the TiO_2coated hydroxyapatite crystals can favorably be applied for antibacterial applications and environmental purification.

DTA and TG data indicate that the presence of one water molecule in $Ca_5(PO_4)_3OH$ which, when heated, is lost at 110 °C:

$$2Ca_5(PO_4)_3OH + \text{heat} \Rightarrow Ca_{10}O(PO_4)_6 + H_2O$$

Calcium hydroxyapatite has a unique structure in that it is conductive along the hydroxide channels. OH^- ions lie at (1/4/,1/4,1/4) and (3/4/,3/4,3/4) on the *c*-axis and charge-carrying protons are responsible for the observed conductivities in $M_{10}(PO_4)_6(OH)_2$. The H^+ migration between the electroattractive ion (O^{2-}) to give molecular H_2O in matrix channels carries charge and the resulting conductivity. The structure of this salt is shown in the following Fig. 4.38.

The unit cell consists of two triangular prismatic subcells forming a rhombic prism with vertical sides. There are two horizontal mirror planes at the OH levels of 1/4 and 3/4 of the *c*-axis. In addition, there is a center of inversion exactly in the center of each vertical face of each subcell.

In a study of the high-temperature behavior of hydroxyapatite (HAp), it was found in relation to its ionic conduction properties that HAp underwent partial dehydration of its lattice hydroxide ions. Considering that HAp ceramics are sintered above 1200 °C without destruction of the apatitic structure, the dehydration was reflected in the time-dependent characteristics of conductivity, which exhibited up-and-down change of 10^3 S/cm above 700 °C.

The conduction was proved purely protonic by measurements of a hydrogen concentration cell, and it was noted that the protonic conductivity was increased to a high value of 10^{-3} S/cm at the initial stage of the dehydration. This phenomenon was demonstrated to be reversible in that the deuteration of fully dehydrated Hap could be accomplished; the uptake of OD^- inside the specimen was confirmed by infrared spectroscopic analysis after exposure to deuterium oxide vapor. Based on those results, a conduction model was proposed consistent with the dehydration phenomenon. This study also showed the importance of the supply of H_2O vapor to the ambient during sintering, for the lattice hydroxide ions of ceramic HAp were considerably dehydrated in sintering in air at high temperatures.

In the 1970s, it was found that sintered calcium hydroxyapatite, $(Ca_{10}(PO_4)_6(OH)_2$ (abbreviated as CaHap), possessed excellent biocompatibility and nontoxicity with femur and mandible bones. Since then, CaHap has been used as a biomaterial for artificial teeth and bones and as a filler for cements and polymers. Today, bone fillers made of CaHap are widely used in the medical and dental fields. In the 1980s, it was found that sintered CaHap has a good compatibility with skin tissues. Hence, percutaneous devices based on CaHap have been developed and applications have included continuous ambulatory peritoneal dialysis and intravenous hyperalimentation systems, blood pressure measurement and blood access for nutrition. Recently, many researchers have studied the chemistry of apatites, particularly CaHap, and have found various applications, such as artificial teeth and bones, ion exchangers, adsorbents for chromatography to separate proteins and enzymes, catalysts, ionic conductors, temperature and gas sensors, etc. In many of the applications, HA is applied by coating replacement hip joints with this chemical, so that the body may be more likely to accept the artificial joint, forming new bone that bonds the joint to the original leg bone. CaHA deposited by laser ablation in vacuum adheres to the substrate better at high temperatures of up to 700 °C.

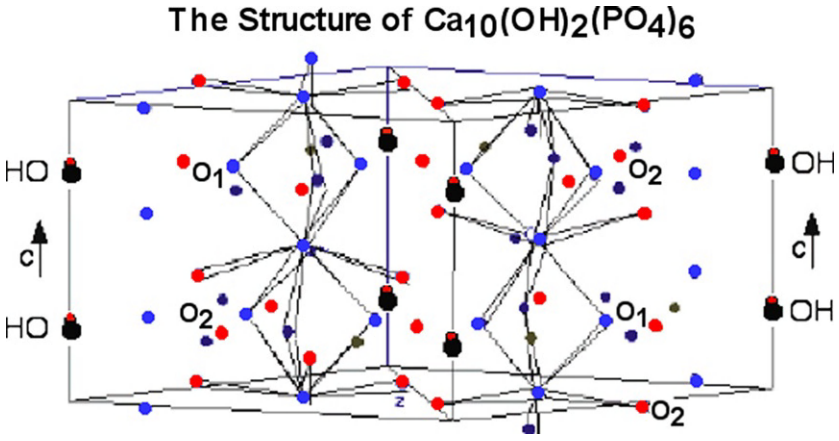

FIGURE 4.38

Calcium Fluoroapatite

This compound crystallizes in a hexagonal crystal system. It is often combined as a solid solution with hydroxyapatite ($Ca_5(PO_4)_3OH$) in biological matrices. Calcium fluorapatite is the most common phosphate mineral. It occurs widely as an accessory mineral in igneous rocks and in calcium-rich metamorphic rocks. It commonly occurs as a detritus mineral in sedimentary rocks and is an essential component of "Phosphorite" ore deposits. It occurs as a residual mineral in lateritic (clayey) soils. $Ca_5F(PO_4)_3$ is hexagonal with lattice parameters of $a = 9.367$, $c = 6.884$, $Z = 2$; $V = 523.09$ Å^3, its density $= 3.20$ g/cm^3. It is bipyramidal with point group 6/m and space group = P6/m. Single crystals are Uniaxial (−), $\varepsilon = 1.6325$, $\omega = 1.63$, birefringence = 0.0025. The most common source of fluoride (F^-) in the environment is the natural mineral fluorapatite.

Carbonate-fluorapatite ("Francolite") is the principal mineral of "Phosphorites", the sedimentary rock phosphates. The nature of the carbonate content, (whether it is part of the apatite, or adsorbed on the surface of the mineral, or even due to admixture with $CaCO_3$), and its structural position, or if it is part of the apatite lattice, has been a subject of considerable controversy in the past. This now appears to be resolved. The CO_3^- group is now considered to be a part of the fluorapatite structure, substituting for PO_4^- groups in the naturally occurring mineral.

The structure of carbonate-fluorapatite is probably triclinic (pseudohexagonal), and upon heating it decomposes according to the following reaction:

$$\underset{\text{(carbonate-fluroapatite)}}{Ca_{5-1/2x}\{(PO_4)_{3-x}(CO_3)_x(F,OH)\}} + \text{heat}$$
$$\Rightarrow \underset{\text{(fluroapatite)}}{Ca_5(OH,F)(PO_4)_3} + xCO_2 + CaO$$

The presence of CaO as a separate phase in the product has been confirmed by the X-ray powder pattern of CaO in the heated sample.

In the 1940s, calcium fluorapatite ($Ca_{10}(PO_4)_6F_2$) was the sole industrial resource for the production of phosphorus, phosphorus compounds, and fertilizers.

Calcium Chloroapatite

This has the empirical formula of $Ca_5(PO_4)_3Cl$ and the molecular weight of 520.7645 g/mol. It is formed by the same methods given for the fluoroapatite and is wholly soluble with it in solid-state solution:

$$[Ca_5(PO_4)_3F]_{1-x} \cdot [Ca_5(PO_4)_3Cl]_x$$

where x can vary from 0 to 100. When this series of compounds was activated with Sb^{3+} and Mn^{2+}, the resulting phosphors were used extensively in fluorescent lamps until about 1990 when the so-called "three-line emitting" rare-earth activated alkaline earth aluminates replaced them. Thus, the "broadband" emitting phosphors were replaced by line-emitting phosphors which could withstand high-energy discharge in lamps. This resulted in thinner fluorescent lamps that could be operated at much higher wattages.

Calcium chlorapatite has the following crystal parameters. Crystal system = hexagonal, bipyramidal with point group 6/m and space group $P6_3/m$. Lattice constants are: $a = 9.598$ Å, $c = 6.776$ Å, $Z = 2$; $V = 540.59$ Å^3, Density $= 3.20$ g/cm^3.

Calcium chlorapatite, as a mineral, is relatively much rarer than fluorapatite or hydroxylapatite, and is formed primarily in F-deficient environments. It is found as a mineral in calcium silicate marble, is an accessory mineral in layered mafic intrusions, occurs in veins such as "Diabase" and replaces "Triphylite" in some granite pegmatites. Such deposits are found in the USA, Quebec in Canada, in the Bushveld complex of Transvaal, South Africa, at the Angarf-Sud Tazenakht Plain of Morocco, at Rajagarh, India, at Kurokura in Japan, and from Snarum, Norway.

The values of the free energy of formation ΔG_f^0 of $Ca_5Cl(PO_4)_3$ has been calculated as $-1483 \cdot 2$ kcal/mol utilizing ionization activity data obtained from the hydrolysis of $CaHPO_4 \cdot 2H_2O$ in water. The concentration was 10^{-3} M for both F^- and Cl^-. The activity data was used to obtain the variation of ΔG_f^0 with composition along the $Ca_5F(PO_4)_3$–$Ca_5Cl(PO_4)_3$ and Ca_5OH–$(PO_4)_3$–$Ca_5Cl(PO_4)_3$ joins of the system CaO–$CaCl_2 \cdot CaF_2$–P_2O_5–H_2O. The phase relationships of solid solutions along these joins under aqueous conditions relative to pH and to either (a_{Ca}^{2+}), ($aH_2PO_4^-$) or (a_{Cl}^- was determined for equilibrium at 25 °C). It was then suggested that the $Ca_5Cl(PO_4)_3$–$Ca_5F(PO_4)_3$ solid solution shows considerable departure from ideal behavior. However, details are not available.

Normally, calcium apatites are expected to be hexagonal. However, a nearly stoichiometric synthetic chloroapatite has been found to be pseudo-hexagonal with a monoclinic space group of $P2_1/b$ and lattices parameters of $a = 9.628$ Å, $b = 19.256$ Å, $c = 6.754$ Å, $\gamma = 120°$. The monoclinic and hexagonal forms are very similar, the most significant feature of the monoclinic structure being an ordered arrangements of the Cl^- ions above and below $Z = 1/2$ on the pseudo-hexagonal axis with the doubling of one cell dimension. The Cl^- ion lies above and below the ordered oxygen triangle along the vertical planes, thus tilting the associated phosphate tetrahedral and resulting in a distortion throughout the structure.

Calcium Bromoapatite

This compound can be formed by the same methods of the chloro compound, namely:

$$6CaHPO_4 + 3CaCO_3 + CaBr_2 + \text{heat} \Rightarrow Ca_{10}(Br)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

The bromoapatite has been of academic interest because, if it is stoichiometric, it must contain two Br^- ions of 1.98 Å along the *z*-axis which would produce an elongated *c*-axis greater than that measured. The bromoapatite is hexagonal with space group $P6_3/m$ and $a = 9.761$ Å, $c = 6.739$ Å, $V = 556.06$ Å^3, $Z = 2$ and has a density of 3.374 g/cm^3. Calcium bromoapatite has the typical hexagonal structure with most of the Br^- ions at (0,0,0) but about 2% at (0,0,0–1,0,3) positions. The packing of Br^- ions requires an apparent radius of 1.68 Å, which is appreciably smaller than the traditional free-ion radius of 1.98 Å.

The value found for $\Delta G^{\circ}_{(Ca_5Br(PO_4)_3)}$ was –1475.2 kcal/mol. Calcium bromoapatite is a soft crystal and has not found much usage in industry or commercially. It does not have a CAS number and is not offered for sale commercially. It is mentioned in a few patents but usually in conjunction with the chloroapatite.

Calcium Iodoapatite

Calcium iodoapatite, $Ca_5\ I\ (PO_4)_3$, does not exist as a separate phase but as an "oxoapatite". Iodo-oxyapatite [pentadecacalcium iodide oxide nonaphosphate, $Ca_{15}(PO_4)_9(I,O)$] was synthesized by a flux method and the structure was solved from single-crystal X-ray data. The crystal structure was refined in the space group $P6_3/m$ with lattices parameters of: $a = 9.567$ Å, $c = 20.754$ Å and $Z = 2$. Iodo-oxyapatite has a typical hexagonal apatite structure but the unit cell is tripled along the hexad direction owing to the size and ordering of the iodide and oxide ions along this direction.

Strontium Orthophosphates

All of the possible strontium compounds have been prepared.

STRONTIUM PHOSPHATE, MONOBASIC

This salt has the formula, $Sr(H_2PO_4)_2$ and the molecular weight of 137.0293 g/mol. Its CAS number is 3358-23-8. It is easily prepared by dissolving strontium carbonate in an excess of H_3PO_4. A ratio of at least 3:1 moles of acid is required:

$$SrCO_3 + 2H_3PO_4 \Rightarrow Sr(H_2PO_4)_2 + CO_2 + H_2O$$

If the pH exceeds about 3.8, the dibasic salt begins to precipitate. The monobasic salt is soluble so that the solution must be evaporated, usually at high temperature, >80–90 °C. An anhydrate, $Sr(H_2PO_4)_2$, readily forms acicular crystals. Its molecular weight is 164.5713 g/mol. Substantially pure **strontium dihydrogen phosphate** was found to act as a catalyst for the production and conversion of hydroxyethylpiperazine to triethylenediamine (Fig. 4.39).

N-(2-Hydroxyethyl)piperazine) is used in the synthesis of triethylenediamine which is an important catalyst in the production of polyurethane foams.

Monobasic strontium phosphate has not found usage in industry due to the fact that it is very similar in physical and chemical properties to the calcium analog but is more expensive. It has been used to make a polymeric glass which is almost as stable to atmospheric moisture and dissolution in boiling water as sodalime plate glass. The hydrolysis stability of sodalime glass is 5.7×10^{-5} g/cm^2/h in boiling water (96 h) while that of the $(SrPO_3)_n$ glass was 13.0×10^{-5} g/cm^2/h in boiling water. However, the calcium glass had a value of 8.3×10^{-5} g/cm^2/h in boiling water (96 h) while that of the magnesium glass was 5.5×10^{-5} g/cm^2/h in boiling water (96 h). The corresponding ratios to sodalime glass were: Sr = 2.28 X, Ca = 1.48 X and Mg = 1.04 X.

Strontium phosphate, monobasic is available commercially from several manufacturers.

STRONTIUM PHOSPHATE, DIBASIC

Owing to similarity in both ionic size and polarity, strontium (Sr^{2+}) is known to behave in a comparable way to calcium (Ca^{2+}), and its role in bone metabolism has been well documented as both antiresorptive and bone forming. Dibasic strontium phosphate, or strontium hydrogen phosphate as it is sometimes known, can easily be prepared by the addition of diammonium orthophosphate to a soluble strontium solution:

$$SrCl_2 + (NH_4)_2HPO_4 \Rightarrow SrHPO_4 + 2NH_4Cl$$

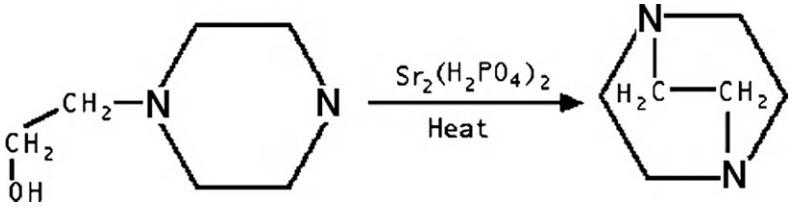

FIGURE 4.39

There is one of two dimorphs formed, α-$SrHPO_4$ and β-$SrHPO_4$, depending upon the temperature of precipitation. The beta salt is obtained below 25 °C and the alpha salt above about 40 °C. Between the two temperatures, a mixture is obtained. Both are anhydrates. α-$SrHPO_4$ has the CAS number of 250716-88-3 while that of β-$SrHPO_4$ is 13450-99-2. In addition, a new hydrogen orthophosphate has been reported.

"The hydrothermal synthesis, initial characterization (EDX analysis, IR, X-ray powder pattern), and X-ray single-crystal structure are reported for a new form of strontium hydrogen phosphate (γ-$SrHPO_4$). The cell is orthorhombic, space group Pbca (No. 61) with $a = 8.131$ Å, $b = 9.258$ Å, $c = 18.084$ Å, $V = 1361.31$ Å^3, and $Z = 16$. The structure was determined from 1272 observed reflections to a final R value of 0.039. The atomic arrangement consists of two kinds of anionic layers (P(1) and P(2)) lying parallel to (001), formed by closed dimers and infinite chains of H-bonded HPO_4^{2-} groups, respectively. These sheets are linked to each other via Sr^{2+} cations".

In addition, a compound, $SrNaPO_4$, has been reported. The crystal structure of $SrNaPO_4 \cdot 9H_2O$ is cubic with $a = 10.554$ Å, space group = P_23 and $Z = 4$. All cations and anions are surrounded by water molecules. All nine H_2O molecules are coordinated to the same Sr^{2+} cation, forming a tricapped trigonal prism. The Na^+ ion is coordinated to six water molecules forming a distorted octahedron. Extensive edge sharing of $Sr(H_2O)_9$ and $Na(H_2O)_6$ polyhedra exists. The environment of the PO_4^{3-} ion consists of 15 water molecules, all of which are hydrogen bonded to PO_4^{3-} oxygen atoms. There is considerable disordering of the phosphate-oxygen atoms, somewhat similar to those of SO_4^{2-} groups in Alums.

The main usage of the dibasic strontium phosphate salt has been to form various phosphors used in fluorescent lamps. $Sr_2P_2O_7$:Sn^{2+} is a blue-emitting phosphor as is $Sr_5(F)(PO_4)_3$:Sb^{3+}. The advent of LED lighting fixtures promises to eliminate the usage of these phosphors from the marketplace.

Strontium phosphate, dibasic is available commercially from many manufacturers worldwide.

STRONTIUM PHOSPHATE, TRIBASIC

The tribasic salt, $Sr_3(PO_4)_2$, can be prepared in a number of ways. If the tribasic sodium phosphate salt is used, the product is likely to be the hydroxyapatite, $Sr_5OH(PO_4)_3$ (which will be contaminated with sodium ion). The best method of preparation seems to be the use of the hydroxide with the monobasic salt in solution to carefully control the solution pH to about 7.5:

$$Sr(H_2PO_4)_2\ (aq) + 2Sr(OH)_2\ (s) \Rightarrow Sr_3(PO_4)_2\ (s) + 4H_2O$$

Since the monobasic salt is acidic, the hydroxide slowly dissolves into solution, and the pH must be monitored. Strontium phosphate, tribasic has the CAS number of 847870-28-4, and the molecular weight of 452.8027 g/mol. This type of preparation has been studied in detail.

Strontium phosphate precipitates were formed by mixing different amounts of $Sr(OH)_2$ and H_3PO_4. A solubility diagram was prepared from the analysis of the supernatant in equilibrium with the precipitate. XRD patterns indicated that there were two other compounds formed, $SrHPO_4$ and $Sr_{10}(PO)_6(OH)_2$. From the solubility diagram, it is estimated that the K_{sp} of $SrHPO_4$ is 4.2×10^{-7}. At high ratios of $Sr(OH)_2$ to H_2PO_4, the initial precipitate is $Sr_3(PO_4)_2 \cdot 4H_2O$, which then converts to a phase having the XRD pattern of strontium hydroxyapatite, but having a strontium: phosphorus ratio that depends somewhat on the initial ratio of $Sr(OH)_2$ to H_3PO_4 used in the precipitation.

Anhydrous $Sr_3(PO_4)_2$ is rhombohedral and the unit cell contains one molecule. The space group is R3m with $a = b = c = 7.280$ Å and $\alpha = 42°35'$. Its density is 5.25 g/cm^3. The atomic positions are; one Sr^{2+} in (0,0,0), 2 Sr^{2+} in ± (u_1, u_1, u_1), 2 P in ± (u_2, u_2, u_2), 2 O in ± (u_3, u_3, u_3), 6 O in ± (x, x, z) (x, z, x) (z, x, x), with parameters of $u_1 = 0.218$, $u_2 = 0.412$, $x = 0.285$ and $z = 0.742$.

The salt, "distrontium triphosphate", CAS number = 14414-90-5, is offered for sale by several manufacturers (notably overseas) but it is not likely that it is the tribasic salt since the formulation, $Sr_2(PO_4)_3$ is both energetically and Lewis electron charge-compensation impossible as a formula.

The tetrahydrate, $Sr_3(PO_4)_3 \cdot 4H_2O$, has been reported if strontium nitrate, $Sr(NO_3)_2$ is added to a large excess of K_2HPO_4 at 10 °C and then made basic with KOH to pH = 7.7 prevent hydrolysis to the hydroxyapatite:

$$Sr(NO_3)_2\ (aq) + K_3HPO_4\ (xs\text{-}aq) \Rightarrow Sr_3(PO_4)_2 \cdot 4H_2O + 3KNO_3$$

This product loses waters of hydration around 175 °C and 280 °C to form the anhydrate which is stable to >900 °C.

$M_3(PO_4)_2$ phosphates of divalent elements with a larger radius (M = Sr, Ba, Pb) are known to crystallize in the $K_2Pb(SO_4)_2$ or palmierite structure. The palmierite- and whitlockite-type structures are very similar and are made up of isolated PO_4^{3-} tetrahedra, which connect the Mon polyhedra into a three-dimensional framework via common vertices.

The following figure shows the [1120] projections of the palmierite-type $Sr_3(PO_4)_2$ (d) structure (Fig. 4.40).

Along the c-axis in these structures, it is possible to differentiate two types of columns: A and B. In the

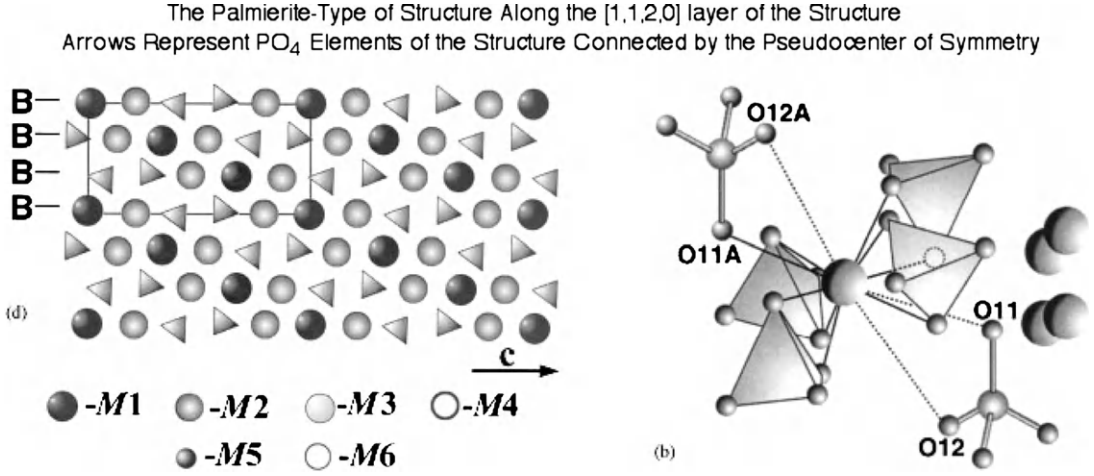

FIGURE 4.40

B-type column, three MOn polyhedra and two tetrahedra PO3 alternate. The A-type column consists of a sequence of polyhedra and cavities. All layers in the palmierite-type structure are built up by B columns. Sr^{2+} cations occupy two crystallographically different positions and B columns can be presented as [–$M2O_{10}$–$M1O_{12}$–$M2O_{10}$–PO_4–PO_4–].

$Sr_3(PO_4)_2$ has not found any uses in industry except as a matrix for phosphors. A thermoluminescence (TL) investigation has been reported for $Sr_3(PO_4)_2$:Eu^{2+}, which is a commercially available X-ray phosphor. Its TL emission spectrum is dominated by a single-emission band centered at 420 nm, that is characteristic of Eu^{2+}. The glow curve of the Eu^{2+} band has two well-separated peaks, a feature which rarely occurs in dosimetric materials. Owing to the above properties, $Sr_3(PO_4)_2$:Eu^{2+} seems to be the best choice for studying TL kinetics and the relation between radioluminescence and TL.

Sb^{3+}-doped $Sr_3(PO_4)_2$ crystals have been synthesized and the phosphor exhibits excitation peaks at 250 and 215 nm and an emission peak at 396 nm. The emission is attributed to $^3P_1$-$^1S_0$ transition and the excitation is attributed to $^1S_0$-$^3P_1$ and $^1S_0$-$^1P_1$ transition (as is usual for this activator). It was also observed that the intensity of PL is thermally stable up to 673 K (400 °C).

Tribasic strontium phosphate is available commercially in limited quantities from several manufacturers worldwide.

STRONTIUM APATITES

The strontium halophosphates or strontium apatites comprise the compound, $Sr_5X(PO_4)_3$ where X is OH, F, Cl Br or I. All can be formed (with the exception of the hydroxyapatite which must be formed in solution) by solid-state reaction:

$$6SrHPO_4 + 3SrCO_3 + SrX_2 + \text{heat} \Rightarrow Sr_{10}X_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Hydroxyapatite

This salt is prepared by the aqueous reaction of a soluble strontium salt with trisodium phosphate:

$$10SrCl_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Sr_{10}(OH)_2(PO_4)_6\ (solid) + 18NaCl\ (aq) + 2HCl$$

Alternately, it can be prepared by the aqueous reaction of the monobasic salt and the hydroxide at about 60–80 °C with addition of NaOH to control pH to a minimum of 10–11.

$$3Sr(H_2PO_4)_2\ (aq) + 2Sr(OH)_2\ (solid) \Rightarrow Sr_5OH(PO_3)_3\ (solid) + 8H_2O$$

Its molecular weight is 1479.8162 g/mol. Strontium readily forms mixed hydroxyapatites with both calcium and barium hydroxyapatites. The strontium hydroxyapatite crystal is hexagonal with $a = 9.745$ Å, $c = 7.265$ Å, $Z = 2$. The phosphate tetrahedra are less distorted than in the isostructural calcium hydroxyapatite ($a = 9.23$ Å, $c = 6.875$ Å). These hydroxyapatites can be OH deficient, with the charge balance maintained by Sr^{2+} or Ca^{2+} vacancies.

This salt can also be prepared by a series of solid-state reaction in an atmosphere of steam (Fig. 4.41).

Strontium hydroxyapatite has not found extensive usage in industry since the calcium analog is just as useful and is less expensive. It has been intensively studied since it will form nanosized particles via the sol-gel method. Nevertheless, it does not have a CAS number and is not offered for sale commercially.

Fluorapatite

This apatite is formed by the same methods as the calcium apatite analog. The solid-state reaction required is:

$$6SrHPO_4 + 3SrCO_3 + SrF_2 + \text{heat} \Rightarrow Sr_{10}F_2(PO_4)_6 + 3CO_2 + 3H_2O$$

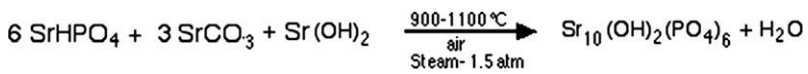

FIGURE 4.41

It has also been prepared by the solution method:

$$10SrF_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Sr_{10}(F)_2(PO_4)_6\ (solid) + 18NaF\ (aq) + 2HCl$$

However, the product is contaminated by Na^+ ions and must be washed thoroughly to obtain a pure product. A small amount of hydroxyapatite may also be present.

Strontium fluoroapatite is hexagonal with the space group = P6/m and unit-cell parameters of $a = 9.415$ Å and $c = 6.924$ Å, $Z = 2$ with the point group of $\underline{P3}$. Optical properties are: transparent, colorless, with the optical class = Uniaxial (–). $\omega = 1.651$, $\varepsilon = 1.637$.

It readily forms solid solutions with all of the calcium apatite analog and so is found as a partial substitute in those materials used in industry. This includes some formulations from various manufacturers of "Halophosphate" phosphors (while others only use the unadulterated calcium apatite). $Sr_5F(PO_4)_3{:}Sb^{3+}$ is a widely used phosphor employed for many years in fluorescent lamps. $Sb_5F(PO_4)_3$ has been stated as "an ideal substrate to demonstrate the emission characteristics of all of the Rare Earths, including, Ce^{3+}, Pr^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}, and Yb^{3+}. These trivalent cations are large but seem to fit into the Sr^{2+} sites with a minimum of energy, including a negative vacancy, $V_{\overline{Sr}}$ or an associated F^- ion. The exact combination has not been exactly determined.

A number of fluoroapatite glass ceramics have been studied for medical and dental applications. These bioceramics have consist of both calcium–strontium fluoroapatites as well as those based upon strontium apatite glass crystal combination themselves. Such glass ceramics have consisted of an aluminum silicate in which the apatite is suspended as a ceramic. The influence of substituting strontium for calcium in a glass of the following composition: $4.5SiO_2 3Al_2O_3 1.5P_2O_5$ 3CaO2CaF$_2$, having a Ca:P ratio of 1.67 corresponding to calcium fluorapatite ($Ca_5(PO_4)_3F$) has been studied. The glasses were characterized by magic angle spinning-nuclear magnetic resonance (MAS-NMR), by DSC and X-ray powder diffraction (XRD). The ^{29}Si, ^{27}Al and ^{31}P NMR spectra for the glasses with different strontium contents were identical. The ^{19}F spectra indicated the presence of F–Ca(n) and Al–F–Ca(n) species in the calcium glasses and F–Sr(n) and Al–F–Sr(n) in the strontium glasses. It can be concluded that strontium substitutes for calcium with little change in the glass structure as a result of their similar charge to size ratio.

Strontium fluorapatite has been shown to be one of the best hosts for Nd^{3+} doping among apatite crystals. Neodymium-doped strontium fluorapatite crystal has been grown by the Czochralski method. The data of thermal expansion and specific heat of the crystal have been measured. The thermal expansion coefficients along X and Z direction are $\alpha_1 = 11.4 \times 10^{-6}/K$ and $\alpha_3 = 12.3 \times 10^{-6}/K$, respectively. The specific heat is 110 cal/mol K at 330 K. The measured absorption spectra from 400 to 850 nm showed that the crystal has absorption peaks around 805.5 nm, and the absorption coefficients at 805.5 nm are 16.05/cm and 5.59/cm for π and α-polarization, respectively. The polarization fluorescence spectra at room temperature showed that the strongest fluorescence is centered at 1058.8 nm. The lifetime of $^4F_{3/2}$ is 175 μs for 1 atom% Nd^{3+} doped in the crystal. The laser at 1058.8 nm was demonstrated pumped by a 3 W CW laser diode at 805.5 nm, and the slope efficiency was 31.7%.

Strontium occurs in several minerals but never as the major cation in these apatites:

$$\text{Belovite} = (LaSr_3NaCe)_5(PO_4)_3(F,OH)$$
$$\text{Deloneite} = (NaCa_2SrCe)_5(PO_4)_3F$$
$$\text{Fluorcaphite} = (CaSrCeNa)_5(PO_4)_3F$$

Strontium fluoroapatite does not have a CAS number even though it is still used as a phosphor for compact and standard fluorescent lamps. It has been the subject of numerous academic studies but has found little or no usage in industry except those already mentioned.

Strontium Chloroapatite

This salt is prepared by the solid-state reaction of:

$$6SrHPO_4 + 3SrCO_3 + SrCl_2 + heat \Rightarrow Sr_{10}Cl_2(PO_4)_6 + 3CO_2 + 3H_2O$$

It has the molecular weight of 1516.7183 g/mol. It is hexagonal, as expected, with $a = 9.859$ Å and $c = 7.205$ Å. The general features of the structure are the same as the fluoroapatite or hydroxyapatite except the Cl^- atoms are at the (0,0,1/2) point along the c-axis between the two Sr triangles on the mirror planes at $z = 1/4$ and $z = 3/4$. This structure is almost identically the same as the calcium analog.

The major use of strontium chloroapatite has been as a matrix for forming "SCAP" which is a phosphor having the formula of $Sr_5Cl(PO_4)_3{:}\ Eu^{2+}$ in which the divalent

europium activator emits a blue band peaking at 450 nm. It is used extensively in "Tri-Color" fluorescent lamps. This phosphor is imported from Japan and China.

This salt has a CAS number of 68784-77-0 as the phosphor or luminophor. It is offered for sale as the phosphor but not as the compound, $Sr_5Cl(PO_4)_3$.

Strontium Bromoapatite

This apatite is formed by the same methods as the chloroapatite analog. The solid-state reaction required is:

$$6SrHPO_4 + 3SrCO_3 + SrBr_2 + \text{heat} \Rightarrow Sr_{10}Br_2(PO_4)_6 + 3CO_2 + 3H_2O$$

It has also been prepared by the solution method:

$$10SrBr_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Sr_{10}(Br)_2(PO_4)_6\ (solid) + 18NaCl\ (aq) + 2HCl$$

However, the product is contaminated by Na^+ ions and must be washed thoroughly to obtain a pure product. A small amount of hydroxyapatite may also be present.

Strontium bromoapatite is a softer crystal than the fluorapatites or chloroapatites of strontium and has not been used in forming phosphors for use in the lighting industry as it is not stable under the mercury-vapor discharge in fluorescent lamps. It has no CAS number.

It is not offered for sale commercially by many suppliers but is available in small quantities from a few manufacturers, notably Chinese.

Strontium Iodoapatite

Strontium iodoapatite is of academic interest because of the large size of the I^- ion compared to the other halide ions. However, the thermodynamic functions determined for the alkaline earth apatite series preclude the formation of a stable iodoapatite because of the cationic size of Sr^{2+} or Ba^{2+} is too small relative to that of the iodide ion which must fit upon the *c*-axis of the structure next to the triads of Sr^{2+} or Ba^{2+} at (000), (010), (011), and (001) positions in the lattice. Such crystals relevant to radioactive waste management include fluorapatite, and, in the end, iodoapatite, which should be able to immobilize the radioactive species, ^{129}I.

However, a lead vanado-iodoapatite $Pb_{10}(VO_4)_6I_2$ has been synthesized as a potential waste form to immobilize radioactive iodine and some thermal, mechanical and chemical properties were measured. TG–DTA showed that the apatite was stable up to about 800 K.

Barium Orthophosphates

Barium forms all of the normal orthophosphates, including the mono-, di-, tribasic compounds and the apatites.

MONOBASIC BARIUM PHOSPHATE

This salt has the formula, $Ba(H_2PO_4)_2$ and the molecular weight of 137.0293 g/mol. Its CAS number is 10048-98-3. It is easily prepared by dissolving barium carbonate in an excess of H_3PO_4. A ratio of at least 3:1 mol of acid is required:

$$BaCO_3 + 2H_3PO_4 \Rightarrow Ba(H_2PO_4)_2 + CO_2 + H_2O$$

If the pH exceeds about 3.8, the dibasic salt begins to precipitate. The monobasic salt is soluble so that the solution must be evaporated, usually at high temperature, >80–90 °C. An anhydrate, $Ba(H_2PO_4)_2$, readily forms acicular crystals. Its molecular weight is 331.3057 g/mol and its CAS number is 13517-08-3.

Monobasic barium phosphate forms two related crystalline dimorphs. One is monoclinic and the other orthorhombic. The monoclinic structure has the cell parameters of: $a = 7.0335$ Å, $b = 8.043$ Å, $c = 7.2158$ Å, $\alpha = \beta = 90°$, $\gamma = 96.02°$, $Z = 2$, density $= 2.99$ g/cm^3. The orthorhombic cell has the parameters of $a = 7.7926$ Å, $b = 10.2574$ Å, $c = 8.5653$ Å, $\alpha = \beta = \gamma = 90°$. The space group is Pccn and density is 3.03 g/cm^3. In both of these polymorphs, a corrugated network of hydrogen-bonded phosphate groups lies parallel to the *a*–*c* plane with Ba···O coordination bonds running between the phosphate layers. The eight Ba···O distances range from 2.579 Å to 2.903 Å. The phosphate distances are: P···OH = 1.579 Å and 1.576 Å and P···O = 1.495 Å and 1.490 Å.

The anhydrate, when heated, decomposes to form the acid pyrophosphate ($Ba(H_2P_2O_7)_2$ at 350 °C and the metaphosphate, $Ba(PO_3)_2$ at about 430 °C. These dehydrations occur in two distinct stages as shown in the following Fig. 4.42.

Further heating results in three internal rearrangements of the metaphosphate groups to final form of the polymerized phase, $\{Ba(PO_3)_2\}_n$ which melts at 830 °C. The glass, once formed and cooled, melts at 743 °C. The polymerized glass phase has several interesting characteristics among which is the existence of two thermal expansion coefficients, a lower one and an upper one, having a value of 115 and 127×10^{-7} in/in/°C, respectively.

Although monobasic barium phosphate has received considerable academic attention, little has occurred in industry.

It is available in moderate quantities commercially from a number of manufacturers worldwide.

BARIUM ORTHOPHOSPHATE, DIBASIC

Dibasic barium phosphate has the formula of $BaHPO_4$ and the molecular weight of 233.30933 g/mol and the CAS number of 10048-98-3. It is sometimes

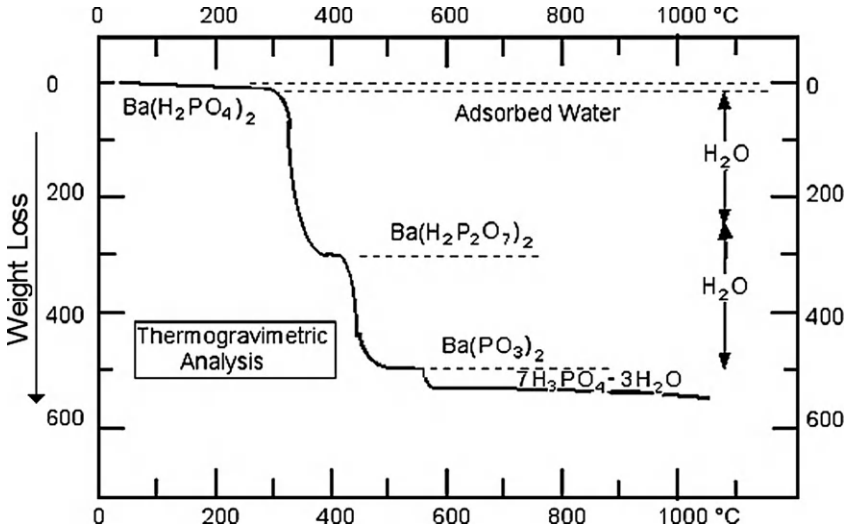

FIGURE 4.42

referred to as "barium hydrogen phosphate (BHP)". It is easily prepared by reacting diammonium phosphate with a soluble solution of barium, such as the chloride:

$$BaCl_2 + (NH_4)_2PO_4 \Rightarrow BaHPO_4 + 2NH_4Cl$$

To obtain a pure salt, the phosphate is always added to the barium solution.

Otherwise, one obtains a salt contaminated with a slight excess of phosphate. The solubility of $BaHPO_4$ is 0.013 g/100 ml at 20 °C. It is important to monitor the pH as the precipitation proceeds, as shown in the following diagram, in order to obtain the pure product (Fig. 4.43).

It has been shown that the size and shape of the product produced can be controlled by the use of an organic soluble polymer. By the use of a double-hydrophilic copolymer, poly(ethylene glycol)-acrylate-copoly(methacrylic acid), the morphology of BHP crystals produced can be controlled. This gives different shapes at different pH values: hexagon (pH = 7.26), sphere cluster (pH = 8), sphere with rough surface (pH = 9), sphere with relatively smooth surface (pH = 10), and small sphere (pH = 11). The results of XRD indicate that the morphology of the particles, as controlled by copolymers, contain mainly $BaHPO_4$ when pH < 11. Weak diffraction peaks of $Ba_5(PO_4)_3OH$ (112) and (211) appear when pH = 11, which means that precipitates are also mainly $BaHPO_4$ but with minor amounts of $Ba_5(PO_4)_3OH$.

The X-ray single-crystal structure of $BaHPO_4$ was refined in the centric space group Pbnm (No. 62) with $a = 4.609$ Å, $b = 14.195$ Å, $c = 17.214$ Å, $V = 1126.3$ Å^3, $Z = 12$ and a final R value of 0.036 for 1261 independent

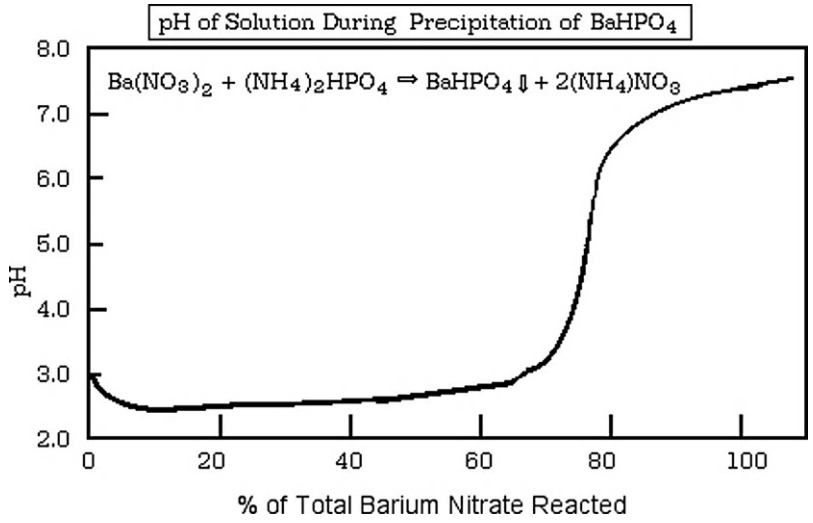

FIGURE 4.43

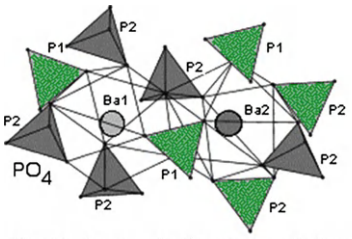
reflections. The atomic arrangement consists of anionic linear chains lying parallel to the a-direction and strongly linked by hydrogen bonds. Two successive chains are separated by Ba^{2+} cations. A comparison of the anionic networks for some similar compounds is also given. The polarized Raman and infrared absorption spectra are investigated. A factor group analysis leads to determination of internal modes of the PO_4^{3-} anions. The vibrational study confirmed the strong H–OP hydrogen bonds to the phosphate groups and indicated notably strong hydrogen bridges in the $BaHPO_4$ compound. The arrangement of the phosphate groups around the Ba^{2+} cations has been determined to be a dodecaheadral cage as shown in the following Fig. 4.44.

In addition, it has been determined that $BaHPO_4$ is dimorphic, the high-temperature phase being formed at precipitation temperatures <95–100 °C. This phase, α-$BaHPO_4$, was synthesized as a single-phase crystalline powder starting from an aqueous solution of barium hydroxide and phosphorus pentoxide at 373 K. α-$BaHPO_4$ crystallizes in a new structure type in which the Ba^{2+} ions form a distorted body-centered arrangement with the HPO_4^- anions in the quasi-octahedral voids ($BaHPO_4$, space group = Aem2, $Z = 16$, $a = 4.5996$ Å, $b = 22.809$ Å, $c = 14.081$ Å). The crystal structures of α-$BaHPO_4$ and β-$BaHPO_4$ are related. The infrared spectrum and a thermal and TGA of α-$BaHPO_4$ has also been reported.

Hydrothermal synthesis, IR characterization and X-ray single-crystal structure is reported for $CaBa(HPO_4)_2$. It crystallizes in the monoclinic system, space group $P2_1/a$ (N14) with $a = 9.470$ Å, $b = 7.930$ Å, $c = 9.865(1)$ Å, $\beta = 115.78°$, $V = 667.1$Å^3 and $Z = 4$. The crystal structure of $CaBa(HPO_4)_2$ is built up from corner-and/or edge-sharing BaO_9 polyhedra, CaO_7 pentagonal bipyramids and $(H)PO_4$ tetrahedra giving rise to a three-dimensional network. The HPO_4^{2-} groups are located in layers parallel to the a and b plane at $z \sim 0$ and $z \sim 1/2$. Interleaved barium and calcium cations ensure the cohesion between these sheets. Hydrogen bonds contribute to the stability of the structure.

BHP single crystals have gained considerable interest on account of their ferroelectric, dielectric and electro-optical properties. $BaHPO_4$ is ferroelectric and also shows intrinsic conductivity due to the hydrogen atom. The DC conductivity of the ferroelectric, $BaHPO_4$, was measured and found to lie between usual conductivities of semiconductor and insulator. Its temperature dependence shows intrinsic conduction in defective crystals due to H^+ ions. The AC conductivity calculated from the measured dielectric constant follows a power law. A frequency of 20 kHz was used to resolve the resistivity peak of AC conduction into two Gaussians. The ln σ vs f plots at different temperatures show an exponential dependence and existence of a focal point. An infrared spectroscopic study on pelletized BHP has been made. The distinct bands observed seem to be related with the P=O bond of PO_4 group. Around the ferroelectric transition at 315 K (32 °C), the interionic band at 2650/cm disappears on account of BaO ionic bond being broken. For the sample prepared at 500 K (227 °C), the bands around 2000 and 2500/cm appear intense, while broadening of bands due to various deformations like P=O and P=O–H takes place.

Barium hydrogen orthophosphate was first used for phosphor preparation, notably barium titanium phosphate, $Ba_2P_2O_7$:$TiFO_2$, by Ropp and first made commercially at Sylvania Electric Products, Inc at Towanda, Pa. because it was not available commercially in 1955. Since that time, a number of suppliers offer this chemical commercially in large lots.



The Environment of the Barium Cations in the Barium Hydrogen Orthophosphate Structure

FIGURE 4.44

BARIUM ORTHOPHOSHATE, TRIBASIC

Tribasic barium orthophosphate has the molecular formula of $Ba_3(PO_4)_2$ and the molecular weight of 601.9327 g/mol. Its CAS number is 13517-08-3. It can be prepared by a number of methods including solution and solid-state methods. The best way to prepare a pure salt is to react the dibasic salt with the carbonate:

$$2BaHPO_4 + BaCO_3 + \text{heat} \Rightarrow Ba_3(PO_4)_2 + CO_2 + H_2O$$

If a solution method is desired, the reaction of the soluble monobasic salt with the hydroxide seems to be superior to any other method:

$$Ba(H_2PO_4)_2\,(aq) + 2Ba(OH)_2\,(s) \Rightarrow Ba_3(PO_4)_2\,(s) + 4H_2O$$

Since the monobasic salt is acidic, the hydroxide slowly dissolves into solution, but the pH must be monitored so that it does not exceed pH = 9.5. Otherwise, the hydroxyapatite begins to appear.

The crystal structure refinement of rhombohedral $Ba_3(PO_4)_2$ [$a = 7.698$ Å, $\alpha = 42°35'$ and space group R-3m] have been carried out by means of the single-crystal diffraction data. The rod sequence of coordination polyhedra,

$$PO_4–M(2)O_{10}–M(1)O_{12}–M(2)O_{10}–PO_4,$$

where M = Sr or Ba, is characteristic in these structures. The $M(1)O_{12}$ and $M(2)O_{10}$ polyhedra show smaller distortion with increase in the ionic radius of the constituent elements. Atomic positions are: one Ba in (000), 2 Ba in ± (u_1, u_1, u_1), 2P in ± (u_2, u_2, u_2), 2 O in ± (u_3, u_3, u_3), and 6 O in (x, x, z) (x, z, x) (z, x, x) with $u_1 = 0.208$, $u_2 = 0.412$, $u_3 = 0.337$, $x = 0.285$, $z = 0.742$.

PL and electroluminescence (EL) in blue-violet emission were observed in newly developed phosphate phosphor thin films such as $Ba_3(PO_4)_2$:Eu and $Ba_3(PO_4)_2$:Ti. These phosphate phosphor thin films were first deposited on thick $BaTiO_3$ ceramic sheets by RF magnetron sputtering using powder targets and then post-annealed in various atmospheres. Blue-violet PL and EL emissions were obtained in $Ba_3(PO_4)_2$:Eu and $Ba_3(PO_4)_2$:Ti phosphor thin films that were deposited in an $Ar + H_2$ (10%) gas atmosphere and then post-annealed above about 900 °C in an $Ar + H_2$ (10%) gas atmosphere. In particular, the EL observed in $Ba_3(PO_4)_2$:Eu thin films exhibited two peaks, a red emission peaking at about 615 nm and a blue-violet emission peaking at about 420 nm. A luminance of 2.0 cd/m^2 in blue-violet emission was obtained in a thin film EL device using a two-step post-annealed $Ba_3(PO_4)_2$:Eu thin film emitting layer: step 1, post-annealing at 1000 °C in air for 1 h, and step 2, post-annealing at 1000 °C in an $Ar + H_2$ atmosphere.

Barium orthophosphate doped with Ce^{3+}, Pr^{3+}, Gd^{3+}, or Tb^{3+} acts as an efficient X-ray storage phosphor. The four compositions have different thermal stimulation properties; the thermally stimulated luminescence (TSL) occurs at higher temperatures than in $Ba_3(PO_4)_2$:La^{3+}. Similar to this latter compound, atomic hydrogen is present after irradiation in $Ba_3(PO_4)_2$:Ce^{3+} and $Ba_3(PO_4)_2$:Gd^{3+}, but its electron paramagnetic resonance signal disappears before the TSL takes place. In $Ba_3(PO_4)_2$:Pr^{3+} and $Ba_3(PO_4)_2$:Tb^{3+}, no H^0 is found. In the four cases studied, codoping with Eu^{2+} changes the TSL properties. In view of these results, it is concluded that the storage mechanism is different for barium phosphate doped with luminescent trivalent rare earth ions on the one hand, and barium phosphate with La^{3+} or Y^{3+} on the other.

Tribasic barium phosphate is offered for sale by several manufacturers worldwide. The CAS number of one may be 182259-25-2 while another is 13463-10-0. These materials vary according to the method of preparation (which is not disclosed). The former material is said to involve the use of H_3PO_4 and may be a barium hydroxyapatite.

BARIUM APATITES

All but the iodoapatite have been prepared. The barium halophosphates or barium apatites comprise the compound, $Ba_5X(PO_4)_3$ where X is OH, F, Cl Br or I. All can be formed (with the exception of the hydroxyapatite which must be formed in solution) by solid-state reaction:

$$6BaHPO_4 + 3BaCO_3 + BaX_2 + \text{heat} \Rightarrow Ba_{10}X_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Barium Hydroxyapatite

This salt is prepared by the aqueous reaction of a soluble barium salt with trisodium phosphate:

$$10BaCl_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Ba_{10}(OH)_2(PO_4)_6\ (s) + 18NaCl\ (aq) + 2HCl$$

Alternately, it can be prepared by the aqueous reaction of the monobasic salt and the hydroxide at about 60–80 °C with addition of NaOH to control pH to a minimum of 10–11.

$$3Ba(H_2PO_4)_2\ (aq) + 2Ba(OH)_2\ (solid) \Rightarrow Ba_5OH(PO_4)_3\ (solid) + 8H_2O$$

Its molecular weight is 1728.3662 g/mol and the CAS number of 12356-34-2. Barium readily forms mixed hydroxyapatties with both calcium and strontium hydroxyapatites. These hydroxyapatites can be OH deficient, with the charge balance maintained by Ba^{2+}, Sr^{2+} or Ca^{2+} vacancies. It has been found that Ba^{2+} ions are more difficult to be incorporated into hydroxyapatite crystals compared to Sr^{2+}ions. In a mixture with increasing Ba^{2+}content, the particles grew and finally turned into pure rod-shaped barium hydroxyapatite particles with a size of ca. 0.2 μ.

When barium hydroxyapatite, $(Ba_{10}(PO_4)_6(OH)_2$, (abbreviated-BaHAp) was synthesized by a wet method using $Ba(OH)_2 \cdot 8H_2O$ and $(NH_4)_2HPO_4$ as starting materials, the Ba-HAp obtained had a Ba/P atomic ratio of 1.76 and contained CO_3 groups. Thus, any solution method to prepare this compound must be protected from the ambient atmosphere in order to obtain a pure salt.

Carbonated barium hydroxyapatite $Ba_{10}(PO_4)_6(OH)_{2-2x}(CO_3)_x$, where $X = 0.30$–0.57, produced BaHAP particles with different Ba/P molar ratios. These were prepared by a wet method and CO_3^{2-} ions were incorporated into OH^- sites of a BaHAP lattice during the preparation at high pH solution. The obtained BaHAP particles were well crystallized and showed a high thermostability. On elevating the mixing temperature of the H_3PO_4 and $Ba(OH)_2$ solutions, the mean particle size of BaHAP particles decreased and their specific surface area increased. The amount of CO_2 adsorbed irreversibly on BaHAP particles increased as their Ba/P molar ratio increased.

In another study, carbonate-containing barium hydroxyapatite was prepared by solid-state reactions

in air at 950 °C. Obtained samples were investigated by X-ray powder diffraction and IR spectroscopy. The stoichiometry of these samples conforms to $Ba_5(PO_4)_{3-x}(CO_3)_x(OH)_{1-x}O_x$ as the result of CO_3^{2-} and O_{2-} substitution for PO_4^{3-} and OH_- in the hydroxyapatite lattice under the scheme:

$$PO_4^{3-} + OH^- \Rightarrow CO_3^{2-} + O^-$$

The crystal structure of some carbonated barium hydroxyapatite patterns were refined by the Rietveld method using X-ray powder diffraction data. The analysis of the crystallographic site occupation has shown that the single-phase range of $Ba_5(PO_4)_{3-x}(CO_3)_x(OH)_{1-x}O_x$ is limited by $x = 0.32$.

The properties of barium hydroxyapatite (BaHAp) as an ion-exchange medium with Pb^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Co^{2+} in solution have been investigated, with particular emphasis on the former two cations. Under similar conditions, the exchange capacities followed the order $Cu^{2+} > Pb^{2+} > Zn^{2+} > Cd^{2+} > Co^{2+}$. After exchange with Pb^{2+}, lead hydroxyapatite was identified in the solid phase but with Cu^{2+} no copper analog of BaHAp was found, although $Ba_3(PO_4)_2$ was formed. With solutions containing either Pb^{2+} or Cu^{2+}, only the former exchanged into BaHAp. With HCl in the exchanging solutions, the capacity of BaHAp for both Pb^{2+} and Cu^{2+} was enhanced, while copper hydroxyapatite was not found in the solid.

Barium hydroxyapatite is hexagonal with the point group of 6/m. The space group is P_63/m, $a = 10.1327(3)$ Å and $c = 7.7526(3)$ Å. The ionic conductivity measurement of $Ba_5(PO_4)_3OH$ showed its ionic conductivity reached the maximum of 2.0×10^{-6} S/cm at 400 °C with an activation energy as low as 0.43 eV due to the activity of OH groups along the channels.

Although barium hydroxyapatite has received considerable attention in the literature, it has not found many applications in industry. It is offered for sale by several manufacturers worldwide.

Barium Fluorapatite

This salt is generally prepared by solid-state reaction:

$$2BaHPO_4 + BaCO_3 + BaF_2 \Rightarrow Ba_{10}(F)_2(PO_4)_6$$

It is hexagonal with space group P63/m and $a = 10.153$ Å, $c = 7.733$ Å with $V = 607.142$ Å^3 and $Z = 2$.

Recently, neodymium-doped barium fluorapatite (Nd: B-FAP) of laser quality and dimension has been synthesized and has been shown to possess excellent qualities as a laser. High-quality single crystals of neodymium-doped barium fluorapatite have been grown by the Czochralski technique and evaluated as an optical gain medium. A product of the emission cross-section and lifetime of Nd^{3+} luminescence of more than 1.8×10^{-22}/cm^2/sex at 1055 nm, and laser performance with slope efficiency up to 65% have been obtained.

The vibrations of phosphate (PO_4^{-3}) ions in single crystals of hexagonal $Ba_5(PO_4)_3F$ (B-FAP) have been investigated by means of polarized Raman scattering and compared to Raman frequencies observed in fluorapatite analogs $Sr_5(PO_4)_3F$ (S-FAP) and $Ca_5(PO_4)_3F$ (FAP). The Raman vibrational frequencies decrease upon substitution of Ba^{2+} for Sr^{2+} or Ca^{2+} in the lattice, asymptotically approaching the Raman frequencies for vibrations of the free ion. The observed splitting is in accord with predictions made by a group theory analysis of the factor group of the unit cell. The effects of the host lattice environment on the magnitude of the Davydov splittings and frequency shifts of phosphate ions within different crystals with the fluorapatite structure are demonstrated to be inversely proportional to the unit cell volume.

Ultrafine $M_5(PO_4)_3F{:}Dy^{3+}$ (M = Ca, Ba) phosphors were prepared via a combustion process using metal nitrates as precursors. The formation of the crystalline phosphate was confirmed by XRD pattern. The PL excitation spectra show the excitation peaks observed at 250–400 nm due to $f \Rightarrow f$ transition of Dy^{3+} ion, which are useful for solid-state lighting purpose (mercury-free excitation). The PL emission of Dy^{3+} ion by 348 nm excitation gave an emission at 489 nm (blue), 582 nm (yellow) and 675 nm (red). All the characteristics of BYR emissions like BGR indicate that Dy doped $Ca_5(PO_4)_3F$ and $Ba_5(PO_4)_3F$ phosphors are good candidates that can be applied as solid-state lighting phosphors (mercury-free excited lamp phosphor) and white light LED.

The phosphors, fluorapatites $M_5(PO_4)_3F$ (M = Sr, Ba) activated with Dy^{3+} ions, were prepared by a high-temperature solid-state reaction technique. The VUV–UV excitation spectra and emission spectra under VUV/UV excitation were measured. The phosphors show broad and strong absorption near 172 nm and intensive emission with the chromaticity coordinates entering the white light region. Hence, the phosphors may be considered as suitable candidates for LED's and Hg-free lamps.

Additionally, barium fluoroapatite activated by Ce^{3+}, $Ba_5F(PO_4)_3{:}Ce^{3+}$ has been determined to be a good scintillator. Its luminosity is 450 photons/Mev with a decay time of 24 ns and an emission band peaking at 358 nm.

Other than its use as a phosphor for solid-state lighting, barium fluoroapatite has received little attention in industry. Whether these phosphors will receive actual usage remains to be seen. It is offered for sale commercially.

Barium Chloroapatite

This salt is easily prepared by the solid-state reaction:

$$6BaHPO_4 + 3BaCO_3 + BaCl_2 + \text{heat} \Rightarrow Ba_{10}(Cl)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Barium chloroapatite is hexagonal with space group of P63/m and $a = 10.284$ Å, $c = 7.651$ Å, $V = 602.003$ Å^3, $Z = 2$ and point group of 6/m. The following table shows the position of the various ions in the hexagonal structure. Thus, the Cl^- ion is located at (000) and (1/2, 1/2, 1/2) while the others lie at points in between. Ba_1 lies at (0.3333, 0.6667, 0.6667) while Ba_2 is at (0.2445, 0.2606, 0.2500).

This salt occurs as a natural mineral having the same composition, except the ore is contaminated by other metallic minerals as well. "Alforsite", ideally $Ba_5(PO_4)_3CI$ is a new member of the apatite group occurring in contact with metamorphosed vaporitic rocks from Fresno and Mariposa Counties, California, associated with fluorapatite and many other rare barium minerals previously described by Alfors et al (1965). It is optically uniaxial, negative, with $\omega, \varepsilon = 1.70$. The density is calculated to be 4.83 g/cm^3 for the end member composition. It is hexagonal, space group = p63/m, with $a = 10.25$ Å and $c = 7.64$ Å.

Single crystals of neodymium-doped barium chloroapatite have been grown by the Czochralski technique and evaluated as a laser medium. Among the known Nd-doped apatites, the material studied is characterized by the longest luminescence lifetime, $\tau = 0.375$ ms, and one of the largest emission cross-sections known, $\chi = 6 \times 10^{-19}$/cm^2. The product $\tau\chi$ in this crystal, which is equal to 2.3×10^{-22}/cm^2/s, is apparently the largest of those of all Nd-doped laser crystals. Laser operation at 1053.8 nm with a slope efficiency of 25% and an intrinsic slope efficiency of 49% was obtained.

It has been determined that this compound exhibits strong luminescence when excited by X-rays. $Ba_5Cl(PO_4)_3$ and the bromoapatite showed a broad emission band with the emission peak centered at about 400 nm while no luminescence from $Ba_5(PO_4)_3OH$ has been observed.

Yb^{2+} ion-doped $Ba_5(PO_4)_3Cl$ phosphor was synthesized by solid-state reaction. Four distinct absorption bands were observed in the UV light region due to the electronic transitions of Yb^{2+} ion from the $^1S_0$ ground state to $2F_5/2(t_{2g})$, $2F_5/2(eg)$, $2F_7/2(t_{2g})$, and $2F_7/2(eg)$ excited states. The main emission wavelength of the phosphor was around 630 nm. The optimized Yb^{2+} ion concentration was 0.2 mol% ($k_{exc} = 400$ nm). The calculated critical distance was about 8.729 Å and concentration quenching was observed above 0.2 mol% due to an electric dipole–dipole interaction of the adjacent activator sites.

Other than its potential uses as a matrix for phosphors and solid-state lasers, barium chloroapatite has received little attention in the literature or in academia. Industrially, it is used as a low-power but efficient laser for various purposes. It is available commercially.

Barium Bromoapatite

This salt can be prepared by the solid-state reaction:

$$6BaHPO_4 + 3BaCO_3 + BaBr_2 + \text{heat} \Rightarrow Ba_{10}(Br)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

It has also been prepared by the solution method:

$$10BaBr_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Ba_{10}(Br)_2(PO_4)_6\ (solid) + 18NaCl\ (aq) + 2HCl$$

However, the product is contaminated by Na^+ ions and must be washed thoroughly to obtain a pure product. A small amount of hydroxyapatite may also be present.

Barium bromoapatite is a softer crystal than the fluorapatites or chloroapatites of barium and has not been used in forming phosphors for use in the lighting industry as it is not stable under the mercury-vapor discharge in fluorescent lamps.

This salt has received little attention academically except as an adjunct to study of other haloapatites. It has no CAS number but is offered for sale commercially.

Barium Iodoapatite

Barium iodoapatite would have the formula, $Ba_5(PO_4)_5I$ if it could be formed. Barium iodoapatite, which has not been prepared, would have a small positive Gibbs energy of dissolution, and a small enthalpy of formation. This is probably due to the large size of the I^- ion as it would enter the lattice. Speculations on the existence of a possible fifth member of the alkaline earth apatite family, Iodoapatite, have been withdrawn due to energetic considerations. Whether an oxy-iodo-apatite, similar to the calcium analogue exists remains speculative.

Radium Orthophosphates

The main concern about radium as a phosphate has been its intense radioactivity (^{226}Ra) as a component of phosphate-rock minerals. Little or no description of these phosphate compounds can be found in the scientific literature. Yet, the chemistry of Ra should closely resemble that of the corresponding barium salts. Therefore, the following descriptions are those which will form the desired radium phosphate compound, even though these salts have apparently not been prepared heretofore nor have their physical and chemical properties been described.

MONOBASIC RADIUM PHOSPHATE

This salt could be easily prepared by dissolving radium carbonate in an excess of H_3PO_4. A ratio of at least 3:1 mol of acid is required:

$$RaCO_3 + 2H_3PO_4 \Rightarrow Ra(H_2PO_4)_2 + CO_2 + H_2O$$

If the pH exceeds about 3.8, the dibasic salt begins to precipitate. The monobasic salt is expected to be soluble so that the solution must be evaporated, usually at high temperature, >80–90 °C. An anhydrate, $Ra(H_2PO_4)_2$, readily forms acicular crystals. Its molecular weight would be 422.0011 g/mol. If heated, it should form a metaphosphate, then a polymeric radioactive glass.

RADIUM ORTHOPHOSPHATE, DIBASIC

Dibasic radium phosphate would have the formula of $RaHPO_4$ and the molecular weight of 322.0047 g/mol. It is sometimes referred to as "radium hydrogen phosphate". It would be easily prepared by reacting diammonium phosphate in solution with a soluble solution of radium, such as the chloride:

$$RaCl_2 + (NH_4)_2PO_4 \Rightarrow RaHPO_4 + 2NH_4Cl$$

To obtain a pure salt, the phosphate is always added to the radium solution. Otherwise, one obtains a salt contaminated with a slight excess of phosphate. Whether radium hydrogen phosphate is dimorphic or not remains speculative. It may be ferroelectric in the crystalline state as well as intrinsically conductive.

RADIUM ORTHOPHOSHATE, TRIBASIC

Tribasic radium orthophosphate would have the molecular formula of $Ra_3(PO_4)_2$ and the molecular weight of 690.6281 g/mol. It could be prepared by a number of methods including solution and solid-state methods. The best way to prepare a pure salt would be to react the dibasic salt with the carbonate:

$$2RaHPO_4 + RaCO_3 + \text{heat} \Rightarrow Ra_3(PO_4)_2 + CO_2 + H_2O$$

If a solution method is desired, the reaction of the soluble monobasic salt with the hydroxide seems to be superior to any other method:

$$Ra(H_2PO_4)_2\ (aq) + 2Ra(OH)_2\ (solid) \Rightarrow Ra_3(PO_4)_2\ (solid) + 4H_2O$$

Since the monobasic salt is expected to be acidic, the hydroxide slowly dissolves into solution, but the pH must be monitored so that it does not exceed pH = 9.5. Otherwise, the hydroxyapatite begins to appear. The crystal structure is expected to be rhombohedral $Ra_3(PO_4)_2$ with the space group *R*-3*m*.

RADIUM APATITES

None of these compounds have been prepared. The radium halophosphates or radium apatites comprise the compounds, $Ra_5X(PO_4)_3$ where X is OH, F, Cl Br or I. All of these should be easily formed (with the exception of the hydroxyapatite which must be formed in solution) by solid-state reaction:

$$6RaHPO_4 + 3RaCO_3 + RaX_2 + \text{heat} \Rightarrow Ra_{10}X_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Radium Hydroxyapatite

This salt is expected to be obtained by the aqueous reaction of a soluble barium salt with trisodium phosphate:

$$10RaCl_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Ra_{10}(OH)_2(PO_4)_6\ (solid) + 18NaCl\ (aq) + 2HCl$$

Alternately, it should be easily prepared by the aqueous reaction of the monobasic salt and the hydroxide at about 60–80 °C with addition of NaOH to control pH to a minimum of 10–11.

$$3Ra(H_2PO_4)_2\ (aq) + 2Ra(OH)_2\ (solid) \Rightarrow Ra_5OH(PO_4)_3\ (solid) + 8H_2O$$

Its molecular weight would be 1817.0616 g/mol.

Radium Fluorapatite

This salt is probably best prepared by solid-state reaction:

$$6RaHPO_4 + 3RaCO_3 + RaF_2 \Rightarrow Ra_{10}(F)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

It is expected to be hexagonal with space group P63/m.

Radium Chloroapatite

This salt should be easily prepared by the solid-state reaction:

$$6RaHPO_4 + 3RaCO_3 + RaCl_2 + \text{heat} \Rightarrow Ra_{10}(Cl)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Radium chloroapatite is expected to be hexagonal with a space group of P63/m and point group of 6/m.

Radium Bromoapatite

This salt could be prepared by the solid-state reaction:

$$6RaHPO_4 + 3RaCO_3 + RaBr_2 + \text{heat} \Rightarrow Ra_{10}(Br)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

It could also be prepared by the solution method:

$$10RaBr_2\ (aq) + 6Na_3PO_4\ (aq) \Rightarrow Ra_{10}(Br)_2(PO_4)_6\ (solid) + 18NaCl\ (aq) + 2HCl$$

However, the product is expected to be contaminated by Na^+ ions and must be washed thoroughly to obtain a pure product.

Radium Iodoapatite

Radium iodoapatite would have the formula, $Ra_5(PO_4)_5I$ if it could be formed. Radium iodoapatite, which has not been prepared, has great interest in academia since the size of the lattice may be sufficient to allow the formation of the iodoapatite phase. This salt is probably best prepared by solid-state reaction:

$$6RaHPO_4 + 3RaCO_3 + RaI_2 \Rightarrow Ra_{10}(I)_2(PO_4)_6 + 3CO_2 + 3H_2O$$

Whether this compound can be formed remains speculative.

4.2.6. Related Alkaline Earth Chalcogen Apatites

Four new apatitic phases have been prepared and their structures determined. The structure of $Ca_{10}(PO_4)_6S$ was refined from single-crystal X-ray data and the structures of $Sr_{10}(PO_4)_6S$, $Ba_{10}(PO_4)_6S$ and $Ca_{10}(PO_4)_6Se$ from powder X-ray data using the Rietveld method. The four apatites are isostructural and crystallize in the trigonal space group P3 with the chalcogenide ion positioned at (000) in the structure. The sulfoapatites show no ability to absorb H_2S in the way that oxyapatite absorbs H_2O at elevated temperatures. This can be attributed to the position of the sulfide ion and the way it influences the crystal structure around the vacant chalcogenide position at (000).

4.2.7. Alkaline Earth Pyrophosphates

The alkaline earths form at least two pyrophosphates, based on the acid, $H_4P_2O_7$. These are the acid pyrophosphate, $M(HP_2O_7)_2$ and the basic salt, $M_2P_2O_7$. The former salt is rare and it is the latter most often seen.

Beryllium Pyrophosphate

This salt has the formula, $Be_2P_2O_7$ or $(BeOH)_4P_2O_7$ depending upon the method of preparation. The compound, $(BeOH)_2H_2P_2O_7$, is also possible if a solution method is employed:

$$4(BeOH)Cl\ (aq) + Na_4P_2O_7 \Rightarrow (BeOH)_4P_2O_7 + 4NaCl$$

It is said to occur as the pentahydrate but more likely it is the monohydrate, $(BeOH)_4P_2O_7 \cdot H_2O$. If BeO is calcined with solid pyrophosphoric acid, the result is:

$$2BeO + H_4P_2O_7 + heat \Rightarrow Be_2P_2O_7 + 2H_2O$$

By precipitating a solution of sodium pyrophosphate with a basic solution of beryllium nitrate, a white pulverable precipitate was obtained, $(BeOH)_2H_2P_2O_7$. On analysis, this salt yielded results close to the theoretical formula for the pyrophosphate. However, the salt was completely dissolved for analysis and did not take into account the hydroxy-groups attached to the Be atom.

Once formed, $Be_2P_2O_7$ has been found to be dimorphic, the high-temperature form, α-$Be_2P_2O_7$ being stable above about 68 °C.

Beryllium dihydrogen pyrophosphate is unknown. There is absolutely no mention of use of these salts in industry and the number of papers dealing with them is very sparse in the scientific literature. Beryllium pyrophosphate has no CAS number and is not offered for sale commercially.

Magnesium Pyrophosphate

Magnesium pyrophosphate has the molecular formula of $Mg_2P_2O_7$ and the molecular weight of grams per mole. It may be prepared by the solid-state reaction of the dibasic orthophosphate, or alternately by the precipitation of a soluble Mg salt with aqueous pyrophosphoric acid:

$$2MgHPO_4\ (\text{or } MgNH_4PO_4) + heat \Rightarrow Mg_2P_2O_7 + H_2O\ (+NH_3)$$

$$MgCl_2\ (aq) + H_4P_2O_7\ (aq) \Rightarrow Mg_2P_2O_7\ (solid) + 2HCl\ (aq)$$

In the solution method, the result is the hexahydrate, $Mg_2P_2O_7 \cdot 6H_2O$. This is a white powder with a CAS number of 13478-16-5 and a molecular weight of 245.4073 g/mol. Its density is 1.71 g/cm^3 and it is relatively insoluble in water or ethanol but soluble in acids. Its structure may be visualized as in Fig. 4.45.

The angle between the tetrahedra is about 120°. The compound, $Mg_2P_2O_7$, has long been used for the quantitative determination of magnesium in the field of analytical chemistry. The magnesium is precipitated in highly alkaline solution as the hydrated crystal, $MgNH_4PO_4 \cdot 6H_2O$, calcined at 1100 °C, and weighed as $Mg_2P_2O_7$. It is for

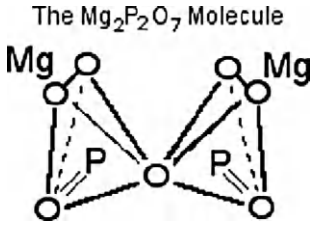


FIGURE 4.45

this reason that the decomposition of magnesium ammonium orthophosphate has been studied intensely.

Various mechanisms have been proposed for the course of decomposition of the magnesium-ammonium salt. It has been shown that $MgNH_4PO_4 \cdot 6H_2O$ loses 5 mols of water at about 105 °C but no ammonia below 150 °C. The simultaneous decomposition of the monohydrate and of the ammonium salt itself occurs above 250 °C. Rapid heating will destroy this sequence of the decomposition due to the formation of primary ammonium salts, which volatilize slowly at these temperatures. Once formed, the ignited compound $Mg_2P_2O_7$ first showed a contraction slightly above room temperature before the normal positive movement due to reversible thermal expansion took place. This unusual behavior showed that an inversion temperature took place. By means of thermal analyses, thermal expansions, and X-ray data, a solid-phase inversion of $Mg_2P_2O_7$ has been placed at approximately 68 °C. X-ray data indicate an accuracy of ±2 °C for the rapid low to high inversion, i.e.

$$\beta\text{-}Mg_2P_2O_7 \Leftrightarrow \alpha\text{-}Mg_2P_2O_7$$

The melting point of α-$Mg_2P_2O_7$ is 1668 K (1395 °C) ± 5 K with a heat of fusion of 32.1 kcal/mol. The transition at 342.2 K (69.2 °C) due to the change in crystal structure requires 729 cal/mol. The Raman spectra were measured and analyzed for both β- and α-$Mg_2P_2O_7$. The IR and Raman spectra were interpreted for both phases using factor-group analyses. The spectral features predicted with factor groups arising from the X-ray crystallographic space groups $P2_1/c$-c_{2h}^5 and $C2/m$-C_{2h}^3 for α-$Mg_2P_2O_7$ and β-$Mg_2P_2O_7$, respectively, fit the observed results. Bands observed in the Raman spectrum for β-$Mg_2P_2O_7$ are consistent with a linear bond angle while those for α-$Mg_2P_2O_7$ are consistent with a bent P–O–P bond angle. No soft modes were observed in the Raman spectra indicating that the phase transition between the two phases is not a second-order process.

The lattice parameters of the low temperature phase, β-$Mg_2P_2O_7$, are $a = 13.198$ Å, $b = 8.295$ Å, $c = 9.072$ Å, $\beta = 104.9°$ and $Z = 8$. The space group, $C2_1/c$ allows an easy comparison of the α- and β-phases of this compound. A primitive cell with the same space group could be chosen with cell parameters of $a = 6.981$ Å, $b = 8.295$ Å, $c = 9.072$ Å, $\beta = 113.0°$ and $Z = 2$. In contrast to with the apparently linear P···O···P group found for the α-phase, stable above 70 °C, the β-phase P···O···P group is bent at an angle of 144°. The $P_2O_7^{4-}$ ion has nearly C_2 symmetry with an average inner and outer P···O bond distances of 1.59 and 1.52 Å, respectively. The phase-diffuse transition appears to be related to the fact that the cations show both five and six coordination in the β-phase whereas in the α-phase, all cations are equivalent and sixfold coordinated.

The crystal structures of various hydrates of magnesium pyrophosphate have been studied. The thermal dehydration of $Mg_2P_2O_7 \cdot 6H_2O$ were studied, in the range 25–800 °C, by TGA (TG-DSC), XRD, and infrared spectroscopy. According to the TG-DSC curves, the dehydration of this salt takes place in two stages. The results of thermal analysis, X-ray patterns, and infrared spectra of this compound heated at different temperatures showed that, after dehydration, $Mg_2P_2O_7 \cdot 6H_2O$ decomposes into dihydrate $Mg_2P_2O_7 \cdot 2H_2O$ then to an amorphous $Mg_2P_2O_7$ product which crystallizes at 665 °C to give anhydrous diphosphate $Mg_2P_2O_7$. The enthalpy of the dehydration of $Mg_2P_2O_7 \cdot 6H_2O$ and of the formation of $Mg_2P_2O_7$ have been calculated from thermogravimetric data. An infrared spectroscopic study of $Mg_2P_2O_7 \cdot 6H_2O$ and of its heated products, revealed the existence of the characteristic bands of the P_2O_7 group and showed that the P···O···P angle is bent in these salts.

The crystal structure of the hexahydrate has been determined and is compared with the known structures of the dihydrate and two forms of the anhydrous compound. Comparisons among the structures provide some insight as to the structural role of Mg^{2+} as a cofactor in the ATP-ADP hydrolysis reactions of bioenergetics. Crystal data for dimagnesium pyrophosphate hexahydrate: $Mg_2P_2O_7 \cdot 6H_2O$, M(r) = 330.66, monoclinic, P2(1)/n, $a = 7.189$ (2) Å, $b = 18.309$ (8) Å, $c = 7.665$ (5) Å, $\beta = 92.360$ (14) degrees, $V = 1008.1$ A^3, $Z = 4$. "Struvite" is the name for the mineral with the same composition.

The room temperature variant with composition $Mg_2P_2O_7 \cdot 3.5H_2O$ crystallizes in the monoclinic space group $P2_1/c$ (No. 14) with $a = 10.9317(1)$, $b = 8.05578(9)$, $c = 9.2774(1)$ Å, $\beta = 90.201(1)°$, $V = 816.99(2)$ $Å^3$ and $Z = 4$. The structure consists of sheets stacked along [100] which are linked through $MgO_2(H_2O)_4$ pillars into a three-dimensional framework with cavities containing water molecules. Within the sheets, there are infinite edge-sharing chains of Mg octahedra along [010] which are cross-linked by $P_2O_7^{4-}$ groups. A high-temperature variant exists around 200 °C. The crystal structure of this compound with composition $Mg_2P_2O_7 \cdot H_2O$ was solved and refined in the monoclinic space group $C2/c$ (No. 15) with $a = 18.6596$ Å, $b = 7.9769$ Å, $c = 8.9757$ Å, $\beta = 107.378°$, $V = 1275.01$ $Å^3$, $Z = 8$. The transformation to $Mg_2P_2O_7 \cdot H_2O$ involves removal of the water molecules in the cavities and the water molecules of the Mg octahedral pillars in $Mg_2P_2O_7 \cdot 3.5H_2O$. The sheets in $Mg_2P_2O_7 \cdot 3.5H_2O$ however remain unchanged during the transformation as the water molecule coordinating Mg here is retained. These sheets are linked through tetrahedral MgO_4 pillars into a three-dimensional structure containing infinite 10-membered ring channels along [001]. Both compounds have been further

characterized by ^{31}P MAS-NMR spectroscopy, TGA and high-temperature powder XRD.

The dihydrate, $Mg_2P_2O_7 \cdot 2H_2O$, has the space group of $P2_1/n$ with $a = 7.367$, $b = 13.906$ Å, $c = 6.277$ Å, $\beta = 94°34'$, $Z = 4$, with a density of 2.66 g/cm^3. The structure consists of $P_2O_7^{4-}$ radicals linked by two kinds of Mg atoms. The Mg atoms have six nearest neighbors and share edges of the coordination octahedral to form infinite chains. One of the H atoms makes an O–H···O defined hydrogen bond. The other three form bifurcated hydrogen bonds.

Although the various magnesium pyrophosphate hydrates have received considerable attention in the literature, this has arisen because this compound is formed in the human body. This salt is also a plant virus inhibitor and has been used in industry as such. The only other usage has been as a matrix for forming phosphors. For example, Magnesium pyrophosphate, double activated with cerium and thorium, has been developed as an ultraviolet-emitting phosphor. However, magnesium is generally used as a minor ingredient in phosphors such as $(Sr,Mg)_3(PO_4)_2{:}Sn^{2+}$.

Magnesium pyrophosphate is available commercially in two varieties. It is offered for sale as $Mg_2P_2O_7 \cdot 2H_2O$ with the CAS number of 10102-34-8. The CAS number of 13446-24-7 refers to the hexahydrate.

Calcium Pyrophosphate

Calcium pyrophosphate has the molecular formula of $Ca_2P_2O_7$ and the molecular weight of 254.1378 g/mol. It has the CAS number of 7790-76-3. It may be prepared by the solid-state reaction of the dibasic orthophosphate, or alternately by the precipitation of a soluble Ca salt with aqueous pyrophosphoric acid:

$$2CaHPO_4 + \text{heat} \Rightarrow Ca_2P_2O_7 + H_2O$$

$$CaCl_2\,(aq) + H_4P_2O_7\,(aq) \Rightarrow Ca_2P_2O_7\,(solid) + 2HCl\,(aq)$$

The solid-state reaction produces an amorphous crystal at 240–500 °C. β-$Ca_2P_2O_7$ forms >750 °C and α-$Ca_2P_2O_7$ forms in the temperature range of 1140 to 1350 °C. The free energy of formation, $\Delta G_f = -3132$ kcal/mol.

The product of the aqueous method is the dihydrate, $Ca_2P_2O_7 \cdot 2H_2O$. It is a white powder and has the CAS number of 7790-76-3. It is insoluble in water but soluble in dilute acids. The anhydrate decomposes at 1353 °C to form a metaphosphate:

$$Ca_2P_2O_7 + \text{heat} \Rightarrow Ca(PO_3)_2 + CaO$$

The dihydrate is triclinic with $a = 7.365$ Å, $b = 8.287$ Å, $c = 6.691$ Å, $\alpha = 102.96°$, $\beta = 72.73°$, $\gamma = 95.01°$ with a space group of $P\underline{1}$. There are two units per unit cell. The six P···O_T (terminal) bond lengths range from 1.499 to 1.538 Å. The two bridge lengths, P···O_B, are equal to 1.623 Å. Average angles are O_B···P···$O_T = 107°$, O_T···P···$O_T = 112.1°$ and the P···O_B···P angle = 123.1°. The two water molecules form one interwater hydrogen bond and three hydrogen bonds to the pyrophosphate-oxygen atoms. Both calcium atoms are seven-coordinated at Ca…O distances less than 2.71 Å.

Calcium pyrophosphate is dimorphic. The phase transformation and sintering behaviors of $Ca_2P_2O_7$ with different phase composition has been investigated by using X-ray powder diffraction (XRD), dilatometery and SEM techniques. It was found that although α-$Ca_2P_2O_7$ (high-temperature form) could be maintained during its cooling process, it was metastable and retransformed into β-$Ca_2P_2O_7$ (low-temperature form) at about 950 °C during its reheating process. This reversible phase transformation was discussed from the point view of polyhedral distortion. The sample from β-$Ca_2P_2O_7$ calcined at 1000 °C/2 h densifies much faster than that from α-$Ca_2P_2O_7$ or the β + α mixture, and bulk density as high as 98% TD can be obtained as it is sintered at 1150 °C. A dense α-$Ca_2P_2O_7$ free of microcracks could not be obtained whatever using a powder of α-$Ca_2P_2O_7$, or of β-$Ca_2P_2O_7$, or of β + α mixture. Such different sintering behavior was explained in relation to the reversible phase transformation between the two forms, α- and β-$Ca_2P_2O_7$.

β-$Ca_2P_2O_7$ is composed of $P_2O_7^{4-}$ groups linked through Ca^{2+} cations. The P···O_B bonds involving the bridging O atoms are longer (average—1.650 Å) than the others (average—1.517 Å). As the PO_4 tetrahedra are almost regular, the displacement of the P-atoms involves two sets of O···P···O angles: O···P···O = 112.7° and O···P···O_B = 106°.

Raman spectra and middle infrared absorption spectra (4000–200/cm) were measured for α-$Ca_2P_2O_7$. No coincidences in the infrared and Raman spectra of α-$Ca_2P_2O_7$ indicated that this material possesses the centrosymmetric space group D_{2h}^{16}-Pnma rather than the noncentrosymmetric space group, C_{2v}^{9}-Pna2$_1$. Differences were noted in the vibrational spectra of monoclinic α-$Ca_2P_2O_7$ and the two orthorhombic α-phases, α-$Sr_2P_2O_7$ and α-$Ba_2P_2O_7$, which were related to differences in their crystal structures. The $P_2O_7^{4-}$-anions of both compounds contained nonlinear P–O–P bond angles. Microwave dielectric properties of β- and α-$Ca_2P_2O_7$ ceramic materials were investigated, using a network analyzer at the frequency of 10 GHz. It was found that β-$Ca_2P_2O_7$ could be sintered at 1150 °C for 2 h to produce a high-bulk density (98% TD) and α-$Ca_2P_2O_7$ could be sintered at 1290 °C/4 h with bulk density of 95.8% TD. The dielectric constant (ε_r) of β-$Ca_2P_2O_7$ sintered at 1150 °C/2 h is 8.4, the temperature coefficient of resonant frequency (τ_f) is −53 ppm/°C, and the *Qxf* value is 53,500 GHz. α-$Ca_2P_2O_7$ sintered at 1290 °C/4 h has ε_r of 7.8, τ_f of −97 ppm/°C and *Qxf* value of 14,115 GHz.

The Raman and IR spectra of triclinic $Ca_2P_2O_7 \cdot 2H_2O$ was interpreted using factor group analysis. Solid-state

effects, factor group splitting and two-site splitting, must be considered to explain the spectra; site group or free ion group models are inadequate. The simple unit cell of this pyrophosphate allows unambiguous assignment of the eight P–O stretching modes in order of decreasing energy: $4\,v^{a}_{PO} > v^{s}_{PO} > v^{a}_{PO} > v^{a}_{POP} > v^{s}_{POP}$. Comparison of these spectra with those for pyrophosphates such as Sr or Ba exhibiting larger unit cells demonstrates that the number of factor group split symmetric P–O stretching modes, v^{s}_{PO}, in the Raman spectra is proportional to the unit cell size. These spectra uniquely characterize this medically interesting material which can cause in vivo crystal-induced inflammation in tissues.

β-$Ca_2P_2O_7\cdot 4H_2O$ is monoclinic, $P2_1/c$, $a = 12.287$ Å, $b = 7.511$ Å, $c = 10.775$ Å, and $\beta = 112.54°$. Five of the terminal O atoms from a pyrophosphate group bind to Ca atoms, together with O atoms from three of the water molecules. The fourth H_2O forms only hydrogen bonds. Both Ca atoms have coordination number 7 and show characteristics between those of a capped octahedron and a pentagonal bipyramid. The analysis of coordination distortions suggests that regularity and volume efficiency of a Ca coordination polyhedron increases with the number of bound water O atoms. The structure is layered after {100}, reflected also in the morphology of crystals which are formed as extremely thin plates. The central parts of the layers are formed by chains of Ca coordination polyhedra that run along the *b*-axis and are interconnected by pyrophosphate groups. Water molecules form the surfaces of the layers. A peculiar auto-inhibition of growth from supersaturated solutions is supposed to be caused by a direct attachment of $CaP_2O_7^{2-}$ and $P_2O_7^{4-}$ to the water molecules on the surfaces of layers. $Ca_2P_2O_7\cdot 4H_2O$ is known in two polymorphs. The unit cell volume of the β-form compared with that of the α-form suggests that the former is a low-temperature modification.

The high-temperature form of calcium pyrophosphate, α-$Ca_2P_2O_7$, crystallizes in the monoclinic space group P2(1)/n. The structure is closely related to that of β-$Sr_2P_2O_7$, although the latter has orthorhombic symmetry. Both cations show coordination numbers of eight with average cation-oxygen atom bond lengths of 2.54 and 2.51 Å for the individual cation sites. The diffraction pattern shows a marked orthorhombic character suggesting a high-temperature phase with Pbnm symmetry.

The ultimate goal of implantation of biomaterials in the skeleton is to reach full integration of the nonliving implant with the living bone. The biomaterial can be used much as a bone graft, resorbing or dissolving as bone growth occurs, and the end result is a new remolded bone. Calcium pyrophosphate, $Ca_2P_2O_7$, is one of the intermediate products of bone mineralization. β-Dicalcium pyrophosphate (β-CP) doped with certain amounts of $Na_4P_2O_7\cdot 10H_2O$ was prepared as the developed material. $Na_4P_2O_7\cdot 10H_2O$ was used as a liquid-phase additive to improve the sintering process and promote physiological bioresorbability. Compressive strength and four-point bending strength were measured by the Bionix test system 858. The mechanical strength of the sintered β-CP increased with the addition of $Na_4P_2O_7\cdot 10H_2O$ up to 5 wt%, but thereafter decreased. The microstructure and crystal structure were analyzed by the techniques of SEM, EPMA, transmission electron microscopy (TEM) and XRD. The relationship between the mechanical strength of the sintered bioceramics and the $Na_4P_2O_7\cdot 10H_2O$ dopant was examined in terms of the presence of $NaCa(PO_3)_3$ (which is the fired product of the mixture), grain growth and abnormal grain coalescence while the dopant increased. A newly produced bioceramic, β-$Ca_2P_2O_7$ with addition of $Na_4P_2O_7\cdot 10H_2O$ (SCP), was implanted into the femoral condyle of rabbits. Within 6 weeks after implantation, most of the bioceramic is replaced by new woven bone. On the contrary, block form hydroxyapatite (HA) and β-tricalcium phosphate (β-TCP), which are osteoconductible, do not resorb within a short period of time. It appears that the biodegradable behavior of SCP may occur in two steps. The first and most important step is the digestion of particles and migration of the particles by phagocytosis. The object of this study was to examine the change in morphologies, chemical compositions and crystal structure of SCP after soaking in distilled water for a certain period of time. The SCP ceramic was also cocultured with leucocytes to observe how the SDCP particles were digested by the leucocytes, so that the mechanism of biodegradable behavior of SCP ceramic *in vivo* might be clarified. Four types of sintered calcium phosphate ceramics were tested in the experiment: SCP, pure α-$Ca_2P_2O_7$ (CP), HA and β-TCP. They were soaked in distilled water at 37 °C for up to 30 days. The microstructure and morphology of crystals deposited on the surface were observed using SEM. Sodium, calcium and phosphorus ion contents in the supernatant solution were detected by atomic absorption analysis and ion-coupled plasma. In summary, HA and DCP showed no significant evidence of dissolution in distilled water. In static distilled water, calcium ions may be released from β-TCP into solution during the initial 7 days and then converted into HA by reprecipitation. The results showed that the SCP was firstly dissolved into small grains or fragments by the solution.

A single-phased β-$Ca_2P_2O_7$:Eu^{2+}:Mn^{2+} phosphor has been synthesized for application to white-emitting LEDs. The enhancive orange emission of Mn^{2+} observed in α-$Ca_2P_2O_7$:Eu^{2+}:Mn^{2+} upon UV excitation is due to the energy transfer of $Eu^{2+} \Rightarrow Mn^{2+}$. The energy transfer efficiency can be as high as 65%. The white LED is formed by integrating the 400 nm emission of the blue-emitting chip with that of the phosphor

β-$Ca_2P_2O_7$:$Eu_{0.04}$:$Mn_{0.12}$ blue-orange phosphor and a Ba_2SiO_4:0.03Eu^{2+} green phosphor. The results show a color rendering index of 78 and a good luminescent efficiency of 9 lm/W. β-$Ca_2P_2O_7$:Eu^{2+}:Mn^{2+} appears to be a promising candidate phosphor for the production of white LEDs.

A new pyrophosphate long-lasting (phosphorescent) phosphor (LLP) with the composition of $Ca_{1.96}P_2O_7$:0.02Eu^{2+}:0.02Y^{3+} was synthesized via a high-temperature solid-state reaction method. The phosphor emits blue light that is related to the characteristic emission of Eu^{2+} due to 5d–4f transitions. For the optimized sample, bright-blue long-lasting phosphorescence could be observed by naked eyes even 8 h after the excitation source is removed. The TL spectra showed that the doping of Y^{3+} ions greatly enhanced the intensity of 335 K peak and created new TL peak at about 373 K that is also responsible for the blue LLP.

$Ca_2P_2O_7$ is an important product finding applications in the manufacture of oral care products like toothpaste and the like. Calcium pyrophosphate is available commercially from several manufacturers.

Strontium Pyrophosphate

Strontium pyrophosphate has the molecular formula of $Sr_2P_2O_7$ and the molecular weight of 349.1833 g/mol. Its CAS number is 765305-66-6. It may be prepared by the solid-state reaction of the dibasic orthophosphate, or alternately by the precipitation of a soluble Mg salt with aqueous pyrophosphoric acid:

$$2SrHPO_4 + \text{heat} \Rightarrow Sr_2P_2O_7 + H_2O$$

$$SrCl_2\ (aq) + H_4P_2O_7\ (aq) \Rightarrow Sr_2P_2O_7\ (solid) + 2HCl\ (aq)$$

The solution method produces a hemihydrate, $Sr_2P_2O_7 \cdot 1/2H_2O$. This salt decomposes at 575 °C to form β-$Sr_2P_2O_7$. The transition to the high temperature form, α-$Sr_2P_2O_7$ takes place at about 760–780 °C.

In the $Sr_2P_2O_7$ system, the unit-cell parameters of orthorhombic β-$Sr_2P_2O_7$ are: $a = 8.9839$ Å, $b = 13.163$ Å, and $c = 5.403$ Å. The crystallographic data of $Sr_2P_2O_7$ are reported to contain two types of sites for Sr^{2+} ions in the unit cell.

Single crystals in the $Sr_2P_2O_7 \cdot Mg_2P_2O_7$ system have been prepared in conjunction with crystallographic and electron spin resonance studies of α-$Ca_2P_2O_7$ and α-$Sr_2P_2O_7$. In an attempt to resolve the site of preferred solubility for Mn^{2+}, $(Sr,Mn)_2P_2O_7$ was prepared. When this phase was found to be triclinic, emphasis was then directed toward the $Sr_2P_2O_7 \cdot Mg_2P_2O_7$ system. $(Sr,Mg)_2P_2O_7$ was prepared and found to have the α-$Ca_2P_2O_7$ structure. The results of a study of the single-crystal diffraction patterns were reported

Raman spectra and middle infrared absorption spectra (4000–200/cm) were measured for α-$Ca_2P_2O_7$, α-$Sr_2P_2O_7$, and α-$Ba_2P_2O_7$. These spectra were interpreted using factor group analyses, and band assignments were made. Noncoincidences in the infrared and Raman spectra of α-$Sr_2P_2O_7$ indicated that this material possesses the centrosymmetric space group D_{2h}^{16} Pnma rather than the noncentrosymmetric space group, C_{2v}^{9}-Pna2$_1$. The similarities between the vibrational spectra of α-$Ba_2P_2O_7$ and α-$Sr_2P_2O_7$ suggested that α-$Ba_2P_2O_7$ is isostructural with α-$Sr_2P_2O_7$. Differences were noted in the vibrational spectra of monoclinic α-$Ca_2P_2O_7$ and the two orthorhombic α-phases, α-$Sr_2P_2O_7$ and α-$Ba_2P_2O_7$, which were related to differences in their crystal structures. The $P_2O_7^{4-}$-anions of all three compounds contained nonlinear P–O–P bond angles.

α-$Sr_2P_2O_7$ has an orthorhombic unit cell that contains four molecules per cell with space group = Pnma and cell parameters of: $a = 8.9104$ Å, $b = 5.4035$ Å, $c = 13.1054$ Å, $V = 631.1$ Å^3, the structure contains ecliptic diphosphate groups of m-symmetry with a P···O_{bridge}···P angle of 130.7°, the average bond distances are: P···$O_{Bridge} = 1.60$ Å and P···$O_{Terminal} =$ 1.50 Å. The Sr^{2+} atoms have nine oxygen neighbors.

Strontium pyrophosphate has long been used as a matrix for phosphors used in fluorescent lamps in the lamp industry. Tin-activated $Sr_2P_2O_7$ was introduced by Ropp in 1957. This same matrix has been used to incorporate divalent Eu^{2+} as a phosphor useful in producing white-emitting LED lamps. Such lamps promise to completely replace fluorescent lamps in the near future.

The phosphors in the system $Sr_2P_2O_7$:$x$$Eu^{2+}$:$y$$Mn^{2+}$ were synthesized by solid-state reactions and their PL properties were investigated. These phosphors have strong absorption in the near UV region, which is suitable for excitation of ultraviolet light-emitting diodes (UV-LEDs). The orange-reddish emission of Mn^{2+} in these phosphors can be used as a red component in the tri-color system and may be enhanced by adjusting the Mn^{2+}/Eu^{2+} ratio. The energy transfer from Eu^{2+} to Mn^{2+} is observed with a transfer efficiency of 0.45 and a critical distance of 10 Å. The results reveal that $Sr_2P_2O_7$:$x$$Eu^{2+}$,$y$$Mn^{2+}$ phosphors could be used in white light UV-LEDs.

By introducing the Y^{3+} cation into $Sr_2P_2O_7$:Eu^{2+} (which has divalent cation sites in the lattice), a kind of new phosphor with blue long-lasting phosphorescence was successfully prepared by a high-temperature solid-state reaction method. The properties of $Sr_2P_2O_7$:Eu^{2+}:Y^{3+} were investigated utilizing XRD, PL, luminescence decay, long-lasting phosphorescence and TL spectra. The phosphor emitted blue light that was related to the $4f^6 5d1–8S_{7/2}$ transition of Eu^{2+}. The bright blue phosphorescence could be observed by naked eyes even 8 h after the excitation source was removed. Two

TL peaks at 317 and 378 K related to two types of defects appeared in the TL spectrum. By analyzing the TL curve, the depths of traps were calculated to be 0.61 and 0.66 eV.

Strontium pyrophosphate activated by divalent europium has been used in fluorescent lamps for photocopying and has enabled higher reproduction rates to be achieved.

Other than the applications mentioned above, the literature concerning strontium pyrophosphate is sparse indeed. Few papers concerning this salt can be found in the scientific literature and little is available from industry, perhaps due to the higher cost of this salt, compared to the calcium variety.

It is commercially available from a number of suppliers both in the U.S. and other countries.

Barium Pyrophosphate

Barium pyrophosphate has the molecular formula of $Ba_2P_2O_7$ and the molecular weight of 448.5973 g/mol. It has the CAS number of 13466-21-2 and may be prepared by the solid-state reaction of the dibasic orthophosphate, or alternately by the precipitation of a soluble Ba salt with aqueous pyrophosphoric acid:

$$2Ba\ HPO_4 + \text{heat} \Rightarrow Ba_2P_2O_7 + H_2O$$

$$BaCl_2\ (aq) + H_4P_2O_7\ (aq) \Rightarrow Ba_2P_2O_7\ (s) + 2HCl\ (aq)$$

The solution method produces a dihydrate, $Ba_2P_2O_7 \cdot 2H_2O$.

The thermal dehydration in air of this hydrate and α-$Ba^2P^2O^7$ crystallization in air, vacuum, and a water vapor atmosphere was studied using thermal analysis, X-ray powder diffraction, IR spectroscopy, and low-temperature air adsorption. In vacuum, α-$Ba_2P_2O_7$ crystallizes at higher temperatures, and in a water vapor atmosphere, at lower temperatures than in air. The specific surface area of samples decreases systematically, because of caking, as the temperature was elevated. The applicability of the Kolmogorov model with $n = 4$ is an evidence of a three-dimensional growth of α-$Ba^2P^2O^7$ nuclei and their steady-state generation during growth. The appearance of crystallization centers within the induction period requires a relatively high value of the activation energy (387.1 kJ/mol). No experimental evidence of the existence of the low-temperature phase β-$Ba_2P_2O_7$ was found.

Anhydrous barium pyrophosphate is a white powder with a density of 3.91 g/cm^3. It is not very soluble in water at 0.008820 g/100 ml but is soluble in dilute acids. It melts at 1430 °C.

Raman spectra and middle infrared absorption spectra (4000–200/cm) were measured for α-$Ba_2P_2O_7$. These spectra were interpreted using factor group analyses, and band assignments were made. Noncoincidences in the infrared and Raman spectra of α-$Ba_2P_2O_7$ indicated that this material possesses the centrosymmetric space group D_{2h}^{16}-Pnma rather than the noncentrosymmetric space group, C_{2v}^{9}-Pna2$_1$. Differences were noted in the vibrational spectra of monoclinic α-$Ca_2P_2O_7$ and the two orthorhombic α-phases, α-$Sr_2P_2O_7$ and α-$Ba_2P_2O_7$, which were related to differences in their crystal structures. The $P_2O_7^{4-}$-anions of this compound contained nonlinear P–O–P bond angles. The structure of α-$Ba_2P_2O_7$ is shown in Fig. 4.46.

Parameters of the monoclinic cell of $BaMgP_2O_7$ are $a = 5.483$ Å, $b = 8.561$ Å, $c = 12.626$ Å and $\beta = 91.32°$ space group is P2$_1$/n, $Z = 4$. Although $Mg_2P_2O_7$, cannot be activated by tin, combination with $Ba_2P_2O_7$ (Ba < 25 mol%) produces a very efficient phosphor, $(Mg,Ba)_2P_2O_7$:Sn, emitting at 3970 Å. This last phase, combined with δ-$Ba_2P_2O_7$, forms a solid solution of limited stability, $(Ba,Mg)_2P_2O_7$:Sn, whose emission band appears at 5120 Å when excited by 2537 Å. A ternary phase can be formed $(Mg_{1.5}Ba_{0.5-x}Srx)P_2O_7$:Sn, whose ultraviolet emission peak changes with composition.

Titanium-activated barium pyrophosphate has long been used in fluorescent lamps as a wideband emitting bluish phosphor. It was introduced to the lighting industry by Ropp in 1953. Other than this application, barium pyrophosphate has found little usage in the lighting industry.

Few papers concerning this salt can be found in the scientific literature. It is available from a number of suppliers commercially, worldwide.

Radium Pyrophosphate

Radium pyrophosphate would have the molecular formula of $Ra_2P_2O_7$ and the molecular weight of 448.5973 g/mol. It has no CAS number. It may be prepared by the solid-state reaction of the dibasic

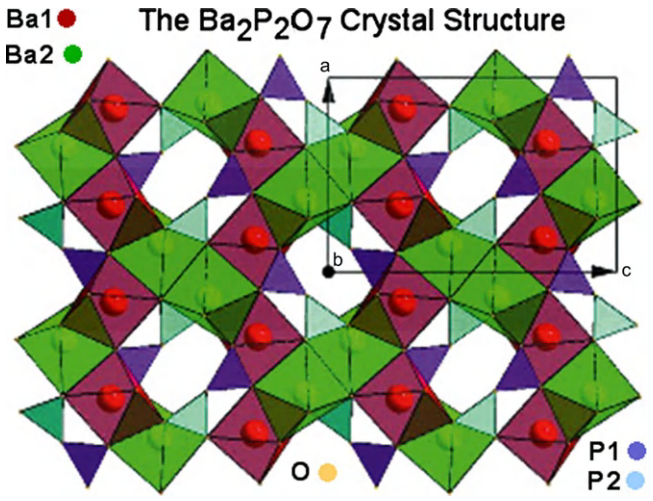

FIGURE 4.46

orthophosphate, or alternately by the precipitation of a soluble Ba salt with aqueous pyrophosphoric acid:

$$2RaHPO_4 + \text{heat} \Rightarrow Ra_2P_2O_7 + H_2O$$

$$RaCl_2\,(aq) + H_4P_2O_7\,(aq) \Rightarrow Ra_2P_2O_7\,(\text{solid}) + 2HCl\,(aq)$$

Radium coprecipitates with all barium compounds (and to a lesser extent with most strontium and lead compounds) even though the solubility product of the radium compound itself may not be exceeded. Because radium was one of the first radioactive elements utilized in tracer research, it was used in the development of the coprecipitation laws. Thus, in view of the intense radioactivity of ^{226}Ra, the formation of $(Ba,Ra)_2P_2O_7$ is probably the best method of forming the pyrophosphate.

The only usage of radium pyrophosphate has been in the medical field as a radioactive tracer and catalyst. Removal of ADP ribose from the iron protein of nitrogenase by activating enzyme resulted in the activation of the inactive iron protein. A radioassay that directly measured the initial velocity of the activation was developed using iron protein radiolabeled with radium pyrophosphate and either [8-3H]- or [G-3ZP]ADP-ribose. The release of radiolabeled ADP ribose by activating enzyme was linearly correlated with the increase in specific activity of the iron protein as measured by acetylene reduction.

The physical properties of radium pyrophosphate remain unknown. Whether a hydrate can be formed remains unknown. Furthermore, whether this salt is monomeric like the Ba salt or dimorphic like the Ca and SR salts remains to be determined.

Radium pyrophosphate is available in small lots commercially from several suppliers.

4.2.8. Alkaline Earth Metaphosphates and Polyphosphates

Metaphosphoric acid, HPO_3, is a singularly anhydrous version of orthophosphoric acid and is sometimes used as a water- or moisture-absorbing reagent. Metaphosphoric acid has phosphorus in the formal oxidation state of +5. Although it has several CAS numbers: 10343-62-1, 135306-83-1, 13566-25-1, and 37267-86-0, only the last two are associated with the IUPAC name **phosphenic acid**. The salts are called "metaphosphates" or "phosphenates". The phosphoric acid units can be bonded together in rings (cyclic structures) forming **metaphosphoric acid** molecules. The simplest such compound is **trimetaphosphoric acid** or **cyclo-triphosphoric acid** having the formula $H_3P_3O_9$. Its structure is shown in the following illustration. Since the ends are condensed, its formula has one less H_2O (water) than tripolyphosphoric acid. A general formula for such cyclic

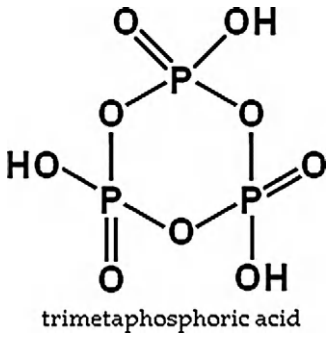

FIGURE 4.47

compounds is $(HPO_3)_x$ where x = number of phosphoric units in the molecule (Fig. 4.47).

One of the main differences in "metaphosphates" and "tripolyphosphates" lies in the fact that the former is cyclic whereas the latter is a linear structure. That is, there are 3-OH groups present in the above Lewis presentation while 6-OH groups are present in the tripolyphosphate. Yet many authors call one salt a polyphosphate when it actually is a metaphosphate and vice versa.

In a pyrophosphoric acid molecule, there are four hydrogens bonded to oxygens, and one, two, three, or all four can be lost as H^+ ions. When all four are lost from pyrophosphoric acid, a **pyrophosphate** ion is formed. The situation with higher order polyphosphoric acids and polyphosphates continues in a similar way. Tripolyphosphoric acid can lose up to five H^+ ions to form a **tripolyphosphate** ion, tetrapolyphosphoric acid can lose up to six H^+ ions to form **tetrapolyphosphate**, etc. As more dissociations per molecule are possible, the intervals between individual pK_a and pK_b values now start becoming smaller on the pH scale. As the polyphosphoric molecules grow increasingly larger and more complex, practically any number of the somewhat acidic −OH groups in them can dissociate to become negatively charged oxygens, forming numerous combinations of multiple-charged polyphosphoric/polyphosphate anions. Generally, in an aqueous solution, the degree or percentage of dissociation depends on the pH of the solution. Tripolyphosphoric acid has two more hydroxy groups in its molecule than the trimetaphosphate. A comparison of the two Lewis structures is shown in Fig. 4.48.

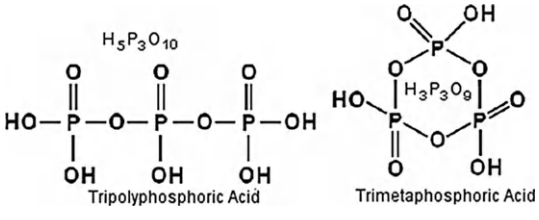

FIGURE 4.48

Tripolyphosphate compounds, especially alkali-based compounds, have been commonly used in detergents (i.e. cleaners) formulations. Sometimes pyrophosphate, tripolyphosphate, tetrapolyphosphate, etc. are called **diphosphate**, **triphosphate**, **tetraphosphate**, etc. especially when they are part of phosphate esters in biochemistry.

Beryllium Metaphosphates and Polyphosphates

Beryllium metaphosphate can be prepared by the solid-state reaction of metaphosphoric acid and the hydroxide, oxide or carbonate of calcium:

$$BeCO_3\ (s) + HPO_3\ (s) + \text{heat} \Rightarrow Be(PO_3)_2\ (s) + H_2O + CO_2$$

The best temperature to use is about 700 °C. It can also be prepared by the aqueous reactions:

$$NaPO_3\ (aq) + (BeO)Cl\ (aq) \Rightarrow (BeOH)(PO_3)\ (s) + NaCl\ (aq)$$

or

$$Be(OH)_2\ (s) + HPO_3\ (aq) \Rightarrow (BeOH)(PO_3)\ (s) + H_2O$$

The dissolution and reaction involving HPO_3 is slow and should be carried out in a hot solution. Evaporation at a low temperature (<15 °C) serves to form the crystals. The product is a monohydrate, $(BeOH)(PO_3)\cdot H_2O$. This salt loses its water of hydration at about 105 °C. Anhydrous beryllium metaphosphate is a white porous powder or granular material that is insoluble in water. If it is heated above about 450 °C, it forms a polymeric glass:

$$nBe(PO_3)_2 + \text{heat} \Rightarrow \{Be(PO_3)_2\}_n$$

If the cooled glass is then reheated, it devitrifies to form a high-temperature form, β-$Be(PO_3)_2$ (II) above 600 °C. This transformation is reversible. The so-called low-temperature form, γ-$Be(PO_3)_2$ (I) never appears but can be formed from the monohydrate, heated to above 250 °C.

The glassy and crystalline β-$Be(PO_3)_2$ (II) has a highly polymerized quartz-like structure with a mixed Be-metaphosphate skeleton where the Be-modifier also plays the role of the vitrifier. In this metaphosphate matrix, Be atoms merge into the quartz-like matrix with threefold coordinated oxygen atoms. Analogous elements are well known in "Phenacite"-orthosilicate lattices.

Four crystalline forms of $Be(PO_3)_2$ are known to date. The first form γ-(I) can be prepared at temperatures lower than 400 °C and β-(II) occurs above this temperature. The unit cell and space group have been determined. A third form α-(III), it was determined that this form has two modifications with a transition temperature of 96 °C. That is, one cooled the stable α-$Be(PO_3)_2$ form undergoes a further transformation when reheated to 96 °C. The stable higher temperature form of α-$Be(PO_3)_2$ (III) has an atomic arrangement closely related to that of "Keatite" which is an allotropic form of silica.

The major difference in these phases lies in the differences in bond lengths and bond angles of the various phases that results in differences in their crystal structure.

The following measurements have been made: (Table 4.16).

β-$Be(PO_3)_2$ (II) is a tetrapolyphosphate with a monoclinic cell: $a = 6.959$ Å, $b = 12.853$ Å, $c = 4.839$ Å, $\beta = 106.79°$, $Z = 4$, and space group = P2. Infinite PO_3 chains, with a period of four tetrahedra, run along the *a*-direction. BeO_4 tetrahedra link the different chains to form a three-dimensional network of tetrahedra.

Single crystals of γ-$Be(PO_3)_2$ (I) have been grown from a $BeCO_3 + (NH_4)_2HPO_4$ mixture, heated to about 600 °C. Its IR absorption spectrum is characteristic of linear polyphosphate. This beryllium polyphosphate variety crystallizes with a tetragonal unit cell, $a = b =$ 9.217 Å, $b = 21.082$ Å, $V = 1790.98$ Å^3, $Z = 16$, space group $P4/nnc$ and *density* = 2.48 g/cm^3.

Beryllium metaphosphate has limited use as a raw material in special ceramic compositions and as a catalyst carrier. It has been used as a component in a mixed-glass element used as a dosimeter. The combination of 80% ($Be(PO_3)_2 + LiPO_3$) and 20% $AgPO_3$ is melted to form a glass. The glass element, when exposed to radiation and excited by UV radiation, emits fluorescence directly proportional to the dose of the applied radiation. The dose is measured by the intensity of the emission.

Beryllium metaphosphate is available in limited quantities from selected suppliers. No polyphosphates of beryllium are listed.

Magnesium Metaphosphates and Polyphosphates

Magnesum metaphosphate can be prepared by the solid-state reaction of metaphosphoric acid and the hydroxide, oxide or carbonate of magnesium:

$$MgCO_3 + HPO_3 + \text{heat} \Rightarrow Mg(PO_3)_2 + H_2O + CO_2$$

TABLE 4.16

Phase	P–P (Å)	P–O–P (°)	P–P–P (°)	Period	Fs
β-$Be(PO_3)_2$ (II)	2.957	129.6	98.7	4	0.702
	2.887	139.9	108.1		
α-$Be(PO_3)_2$ (III)	2.933	139.8	105.2	8	1.000
	2.951	137.4	103.5		

Fs, Stretching coefficient.

The best temperature to use is about 700 °C. It can also be prepared by the aqueous reactions:

$$2NaPO3\ (aq) + MgCl_2\ (aq) \Rightarrow Mg(P_3O_9)_2 \cdot xH_2O\ (s) + 2NaCl$$

or

$$Mg(OH)_2\ (s) + 6\ HPO_3\ (aq) \Rightarrow Mg(P_3O_9)_2 \cdot xH_2O\ (s)$$

The reaction involving HPO_3 is slow and should be carried out in a hot solution. Evaporation at a low temperature (<15 °C) serves to form the crystals. The exact degree of hydration is not known. Magnesium trimetaphosphate is used as a coronary perfusing agent in Medicine (at a concentration of 15 mM) as a standard to estimate the absolute value of the phosphate-containing metabolites. The amounts of inorganic phosphate (Pi), phosphocreatinine (PCr) and ATP in the myocardium were determined by planimetry of the areas under individual peaks and were corrected for saturation factors.

A previously unreported metastable intermediate phase during the crystallization of magnesium metaphosphate ($Mg(PO_3)_2$) glasses to the equilibrium ring phase, $Mg_2P_4O_{12}$. It appears that the metastable phase contains polyphosphate chains, as in other crystalline alkaline earth polyphosphates. This type of phase appears to form by low-energy rearrangement of the polyphosphate chains in the glass structure to form the cyclic metaphosphate.

An investigation into the structure of glasses made from $Mg(PO_3)_2$ metaphosphate has been made. The phosphate network was found to consist of long linear chains of PO_4 tetrahedral units. This type of structure exists in many polyphosphate glasses, indicating that the cation modifier has little effect on the structure of the phosphate backbone. A study of the Mg^{2+} networks revealed that the modifier's field strength plays a significant role in determining the short-range order of the metal ions.

One paper reports a systematic structure investigation of alkaline earth metaphosphate glasses $Me(PO_3)_2$ with Me = Zn, Mg, Ca, Sr, Ba by neutron diffraction. The total structure factor S(Q) was measured up to Q = 170/nm. The total atomic distribution functions of most of the glasses show well-defined maxima for short distances which can be attributed to distinct atomic pairs. By a peak separation procedure, partial coordination numbers and mean distances for the atomic pairs P–O, O–O, Me–O, and P–P as well as the distribution of bond angles P–O–P were determined. The experimental data are compatible with the following model of the glass structure. The basic elements are PO_4 tetrahedra that are interconnected via two oxygens in chains. The chains are not straight. Metal ions are located between the chains and have oxygens in the first coordination shell. The metal-oxygen coordination number is 4 for Mg, Ca and 8 for Ba.

Binary magnesium phosphate glasses have been investigated by XRD to extract information on their short- and intermediate-range order. In these glasses, the Mg^{2+}/PO_4^{2-} ratio was varied. In order to study the intermediate-range order primarily, the main diffraction peak of the structure factors, S(s), was examined. The metaphosphate glass and crystalline compound, MgP_4O_{11}, exhibits a remarkably different structure from that of the related crystal $Mg_2P_4O_{13}$ which is a polyphosphate. Comparison of the X-ray scattering structure factors of the glasses experimentally obtained and calculated from the related crystal structures supports these findings. Thus, one is a metaphosphate and the other is a polyphosphate.

Magnesium polyphosphate glasses have been examined using X-ray and neutron scattering and ^{31}P MAS-NMR spectroscopy to extract information on their short-range, intermediate-range and submicroscopic structure. The depolymerization of the PO_4 chains with rising MgO content is quantitatively described by the increasing concentration of Q^1 and Q^0 groups determined by NMR. In the pyrophosphate region, the Q^1 sites disproportionate to Q^0 and Q^2 groups, whereas there is no disproportionation of the Q^2 sites at metaphosphate composition. The shortening of the real-space distances, r_m, indicates that the structure of the glasses becomes more compact with progressive depolymerization which is due to the increasing connection of the MgO_n polyhedra by the sharing the nonbridging oxygen atoms. The Mg–O coordination sphere was found to change insignificantly as composition changed.

The crystal structure of $Mg_2P_4O_{12}$ has been determined. This salt crystallizes in the monoclinic space group, C2/c with: $a = 11.756$ Å, $b = 8.285$ Å, $c = 9.917$ Å, $\beta = 118.96°$, $Z = 4$, $V = 845$ Å^3. The PO_4 tetrahedra in the structure are linked together in a ring to form $P_4O_{12}^{4-}$ ions with P···O···P angles of 134.2° and 138.8°. The Mg^{2+} ions are always 6-coordinated. Most "metaphosphate" compounds have previously been thought to be linked together in infinite chains (technically making them polyphosphates). Only a few "metaphosphates" with such anions have been found to date. The Mg^{2+} ions in $Mg_2P_4O_{12}$ are always surrounded by regular MgO_6 octahedra of two differing types: one with 2-point symmetry (around Mg_1) and the other with $\bar{1}$ symmetry (around Mg_2). The Mg···O distances range from 1.990 to 2.161 Å.

Magnesium metaphosphate and magnesium polyphosphate salts have listed no manufacturer or supplier. These salts have no CAS numbers listed.

Calcium Metaphosphates and Polyphosphates

Calcium metaphosphate (CMP) has the molecular formula of $Ca(PO_3)_2$ and the molecular weight of 198.0219 g/mol. Its CAS number is 13477-39-9.

This salt is also offered commercially as Calcium dimetaphosphate ($Ca(PO_3)_2$) with the CAS number of 53801-86-8. Another manufacturer has a calcium bismetaphosphate with the CAS number 53806-80-7. It is not clear what differences may exist, if any, between these salts or the method of their preparation. CMP can be prepared by the solid-state reaction of metaphosphoric acid and the hydroxide, oxide or carbonate of calcium:

$$CaCO_3 + HPO_3 + \text{heat} \Rightarrow Ca(PO_3)_2 + H_2O + CO_2$$

The best temperature to use is about 700 °C. Anhydrous β-$Ca(PO_3)_2$ is monoclinic, space group = $P2_1/a$ with $a = 16.960$ Å, $b = 7.7144$ Å, $c = 6.9963$ Å, $\beta = 90.394°$, $V = 915.40$ Å^3, $Z = 8$. The density is 2.874 g/cm^3. The crystal structure of $Ca(PO_3)_2$ consists of meandering chains of PO_4 tetrahedra along the [001] direction, connected by Ca atoms. Thus, it is a polyphosphate. P···O distances average 1.584 Å for bridging and 1.487 Å for terminal atoms. $Ca(O_1)$ has coördination number 8 with Ca···O distances ranging from 2.381 to 2.696 Å; the polyhedron is close to a tetragonal antiprism. $Ca(O_2)$ has coördination number 7 with Ca···O distances from 2.339 to 2.638 Å; the polyhedron is a capped trigonal prism (Fig. 4.49).

This salt can also be obtained by the thermal degradation of the monobasic phosphate:

$$Ca(H_2PO_4)_2 + \text{heat} \Rightarrow \beta\text{-}Ca(PO_3)_2 + 2H_2O$$

The monobasic firing product has been tested for biocompatibility using alkali salts additions. The purpose of this study was to investigate biocompatibility, osteoconduction capacity and biodegradability of Na_2O and/or K_2O-added CMP. Biodegradability of CMP, Na_2O–CMP and K_2O–CMP in Tris-buffer solution and simulated body fluid (SBF) for 30 days was measured. Graft materials were placed in rabbit parietal bone defects and sacrificed at 3 and 6 months. The amount of new bone formation was measured under LM. Biodegradability of Na_2O–CMP and K_2O–CMP was greater than that of CMP. All CMP grafts were biocompatible and osteoconductive. Histomorphometric data showed that there was no significant difference in new bone formation between all the CMP groups and Bio-Oss group. It was concluded that 5% Na_2O–CMP and 5% K_2O–CMP would be good candidates for bone substitution materials.

Chemical preparation, thermal behavior, kinetic and IR studies have been presented for the cyclotriphosphate $Ca_3(P_3O_9)_2 \cdot 10H_2O$. It is prepared by an aqueous method:

$$2NaPO_3\ (aq) + CaCl_2\ (aq) \Rightarrow Ca(P_3O_9)_2 \cdot 10H_2O(\text{solid}) + 2NaCl$$

or

$$Ca(OH)_2\ (\text{solid}) + 6\ HPO_3\ (aq) \Rightarrow Ca(P_3O_9)_2 \cdot 10H_2O\ (\text{solid})$$

The reaction involving HPO_3 is slow and should be carried out in a hot solution. Evaporation at a low temperature (<15 °C) serves to form the hydrate crystals. $Ca_3(P_3O_9)_2 \cdot 10H_2O$ is monoclinic $P2_1/n$ with the

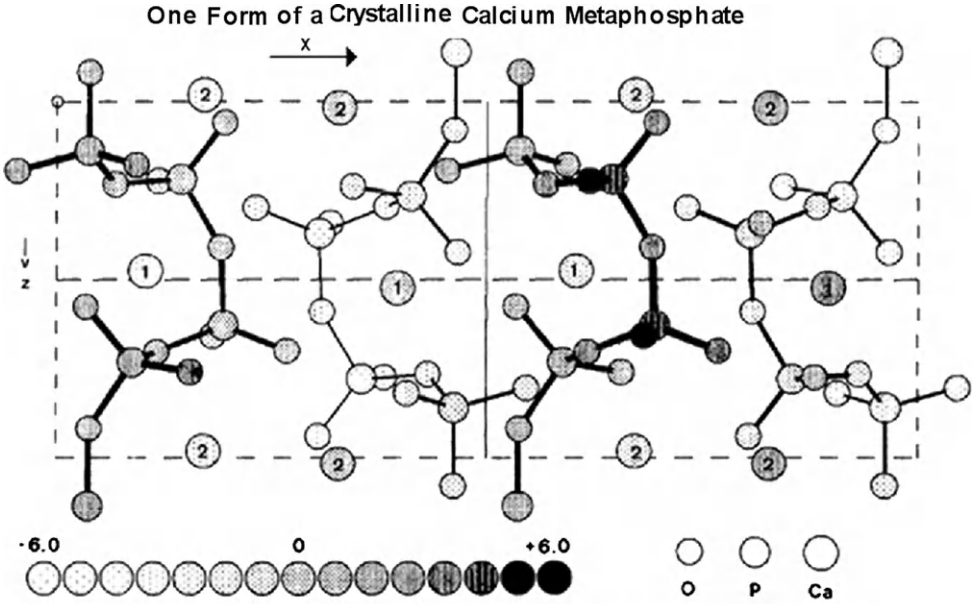

FIGURE 4.49

following unit-cell dimensions: $a = 9.332$ Å, $b = 18.132$ Å, $c = 7.841$ Å, $\beta = 106.69°$ and $Z = 2$. $Ca_3(P_3O_9)_2 \cdot 10H_2O$ has never been studied except for its crystallographic characterization. The thermal behavior of $Ca_3(P_3O_9)_2 \cdot 10H_2O$ has been studied and interpreted by comparison with IR absorption spectrometry, XRD experiments, chemical analyses, thermal analyses (TGA-DTA) and DSC. $Ca_3(P_3O_9)_2 \cdot 10H_2O$ is stable, under standard conditions of temperature and pressure, until 80 °C. It is impossible to dehydrate $Ca_3(P_3O_9)_2 \cdot 10H_2O$ without breaking its rings $P_3O_9^{3-}$ into chains that leads to amorphous compounds according to XRD and IR absorption spectrometry. The final product of the dehydration and calcination of $Ca_3(P_3O_9)_2 \cdot 10H_2O$, under atmospheric pressure is its long-chain polyphosphate form, β $[Ca(PO_3)_2]_8$. β$[Ca(PO_3)_2]_8$ is stable until its melting point at 1097 °C. On the other hand, α$[Ca(PO_3)_2]_8$ is prepared in a dry way. α$[Ca(PO_3)_2]_8$ has many applications in industry such as a humidity sensor and corrosion inhibitor. Also, quantum chemical calculations have been performed for the P_3O_9 rings.

$Ca_2[P_4O_{12}] \cdot 4H_2O$ crystallizes in the monoclinic space group $P2_1/n$, $a = 7.668$ Å, $b = 12.895$ Å, $c = 7.144$ Å, 107.00°, $D_x = 2.28$ g/cm^3, $Z = 2$. In the structure, there are ring-like anions, which are composed of $4PO_4^{3-}$ tetrahedra connected by oxygen bridges. The Ca^{2+} are surrounded by seven oxygen atoms. Each two-cation polyhedra are connected by a common edge to pairs which are isolated from one another. The water molecules form hydrogen bridges with one another and with the anion rings. The H_2O molecules of hydration are lost at about 120–140 °C.

If anhydrous CMP, $(Ca(PO_3)_2$, is heated to about 1150 °C, a glass is formed. Glasses were prepared with water content between 0.005 and 0.16 mol/l. Properties measured vary in a characteristic way in dependence on the water content. An interpretation for the shift of the absorption edge to shorter wavelength with increasing OH-group concentration, which also explains the change of the glass transition and the recrystallization temperature, is proposed. Dispersion calculations for the wavelength dependence of the refractive index refer to an additional absorption band caused by the OH-groups on the short wavelength side of the absorption determining the UV edge.

The short range structure of $Ca(PO_3)_2$ glass has been studied using X-ray and neutron diffraction and modeled using the reverse Monte Carlo method. Using this, combination of techniques has allowed six interatomic correlations to be distinguished and fitted to obtain a set of bond lengths and coordination numbers that describe the structure of the glass. The glass consists of metaphosphate chains of phosphate tetrahedra and each phosphate unit has two nonbridging oxygen atoms available for coordination with Ca. The Ca···O correlation was fitted with two peaks at 2.35 and 2.86 Å, representing a broad distribution of bond lengths. The total Ca···O coordination is 6.9 and is consistent with distorted polyhedral units such as capped octahedra or capped trigonal prisms. It is found that most nonbridging oxygen atoms are bonded to two calcium atoms. All of these observations are consistent with Hoppe's model for phosphate glasses. Furthermore, the medium-range order is revealed to consist of phosphate chains intertwined with apparently elongated clusters of Ca ions, and the Ca–O and Ca–P correlations contributed significantly to the first sharp diffraction peak in XRD.

CMP is trimorphic. The following table shows some of the differences determined for the bond lengths and bond angles for two of these phases (Table 4.17).

Unidirectionally crystallized $CaO–P_2O_5$ glass ceramics were produced by reheating glass rods between 450 and 580 °C (glass transition temperature = 500 °C) under a temperature gradient of 30 °C/cm. These glass ceramics exhibit high-bending strength (~650 MN/m^2) and toughness. Sample preparation is described and compared with conventional unidirectional solidification of melts. The characteristic mechanical properties were discussed in terms of the texture of the glass ceramics.

The facile synthesis and structural characterization of γ-$Ca(PO_3)_2$, a novel polymorph of CMP was reported. The single-step synthesis of this potential biomaterial was achieved using flux methods at 250 °C, yielding a single-phase product stable at room temperature. Single-crystal XRD determined the structure to be of monoclinic symmetry ($a = 9.5669$ Å, $b = 9.5023$ Å, $c = 10.3717$ Å, and $\beta = 93.474°$, space group = Cc), with layers of helical polyphosphate chains directed alternately along the [110] and [−110] unit cell directions to produce a unique arrangement of criss-cross polyphosphate layers separated by calcium ions. Further structural characterization by MAS-NMR and FT-IR was found to be consistent with this structure. Thermal studies indicated that γ-$Ca(PO_3)_2$ is stable up to 690 °C, whereupon it irreversibly converts to the β-$Ca(PO_3)_2$ polymorph. The actual arrangement of the PO_4 tetrahedra are shown in the following Fig. 4.50.

TABLE 4.17

Phase	P—P (Å)	P—O—P (°)	P—P—P (°)	Period	Fs
β-$Ca(PO_3)_2$	2.947	140.6	111.6	4	0.705
	2.978	135.9	93.1		
	2.939	135.9	88.2		
	2.980	141.5	116.7		
γ-$Ca(PO_3)_2$	2.898	124.6 133.9	102.2	2	0.909

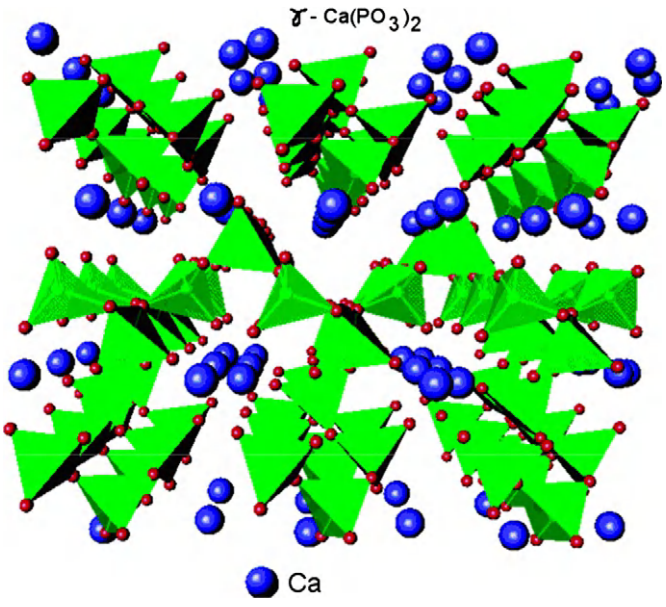

FIGURE 4.50

CMP has been prepared by reaction of CaO and gaseous white phosphorus, P_2O_5. The CaO/P_2O_5 ratio of starting materials was changed from 5.06 to 0.64, and the reaction was carried out at 400–1100 °C. These calcium phosphates were investigated using X-ray diffractometry and scanning electron microscope. By gas–solid reaction of $CaO–P_2O_5$, β-CMP was only synthesized at 400–500 °C, β-CMP, hydroxyapatite, and β- pyrophosphate at 600–700 °C, and α-CMP, hydroxyapatite, α-pyrophosphate, and α-tricalcium phosphate above 800 °C. Synthesized calcium phosphates were independent of the CaO/P_2O_5 ratio of starting materials but highly dependent on the reaction temperature. Nevertheless, a pure salt was never achieved in any of these preparations.

Although pure glassy compounds, that are colorless transparent polymers $[Ca(PO_3)_2]_n$, can be prepared, they remain hygroscopic and atmospheric moisture decomposes them over a period of time. The presence of water vapor can cause them to rapidly break down into calcium dihydrogen phosphate. Ropp has solved this problem and has samples that have remained stable for over 40 years. Their resistance to boiling water is equal or surpasses that of "window glass". They have many physical properties not found in "ordinary" glasses.

The porosity and slow solubility of "ordinary" calcium polyphosphates (CPPs) has led to its testing as a bone substitute. Porous structures were formed by gravity sintering CPP particles of either 106–150 or 150–250 μ size to form samples with 30–45 vol% porosity with pore sizes in the range of 100 micron (40–140 μ). Tensile strength of the samples assessed by diametric compression testing indicated relatively high values for porous ceramics with a maximum strength of 24.1 MPa for samples made using the finer particles (106–150 μ). XRD studies of the sintered samples indicated the formation of crystalline β-CPP from the starting amorphous powders. In vitro aging in 0.1 M tris-buffered solution (pH 7.4) or 0.05 M potassium hydrogen phthalate buffered solution (pH 4.0) at 37 °C for periods up to 30 days indicated an initial rapid loss of strength. Elution of P over 14 days was followed by a more gradual continuing strength but P loss resulted in strengths at 30 days equal to about one-third the initial value. The observed structures, strengths and in vitro degradation characteristics of the porous CPP samples suggested their potential usefulness as bone substitute materials. Subsequent in-vivo behavior assessment was not reported.

Further studies revealed that CPP bone substitutes could be prepared by gravity sintering crystal transformations. The crystalline structure of CPP was analyzed by Raman spectroscopy and in situ variable temperature XRD. In addition, the variation of CPP in SBF considered as degradation was characterized by monitoring the changes of its compressive strength and weight loss. The results revealed that CPP was inorganic condensed phosphate with a linear long-chain structure. Amorphous CPP (γ-CPP) was initially transformed to crystalline β-CPP, then crystalline α-CPP with the increase of sintering temperature. The transformation of β-CPP to α-CPP occurred from 650 to 670 °C. Compressive strength decreased quickly at initial stage for all specimens after immersed in SBF, and thereafter, continued to decrease at a slower rate subsequently. After immersion for 15 and 30 days, the compressive strength of β-CPP decreased from 13.5 to 7.6 and 4.8 MPa, while α-CPP decreased from 16 to 12 and 8 MPa, respectively. The degradation rate of γ-CPP, β-CPP and α-CPP decreased with time after immersed in SBF. γ-CPP had highest degradation rate, which would have been completely degraded in 10 days, and the weight loss ratio of β-CPP was 28% for 15 days and 35% for 30 days, but the weight loss of α-CPP was only 11% for 30 days. The results therefore revealed that CPPs with different degradation rates could be obtained by controlling the crystalline structure.

A novel biodegradable nanocomposite porous scaffold, comprising a β-TCP matrix and hydroxylapatite (HA) nanofibers, was developed and studied for load-bearing bone tissue engineering. HA nanofibers were prepared with a biomimetic precipitation method. The composite scaffolds were fabricated by a method combining the gel casting and polymer sponge techniques. The role of HA nanofibers in enhancing the mechanical properties of the scaffold was investigated. Compression tests were performed to measure the compressive strength, modulus and toughness of the

porous scaffolds. The identification and morphology of HA nanofibers were determined by XRD and TEM, respectively. SEM was used to examine the morphology of porous scaffolds and fracture surfaces to reveal the dominant toughening mechanisms. The results showed that the mechanical property of the scaffold was significantly enhanced by the inclusion of HA nanofibers. The porous composite scaffold attained a compressive strength of 9.870.3 MPa, comparable to the high-end value (2–10 MPa) of cancellous bone. The toughness of the scaffold increased from 1.0070 ± 0.04 to 1.7270 ± 0.02 kN/m, as the concentration of HA nanofibers increased from 0 to 5 wt%.

CMP is used as a mild abrasive and as neutralizing agent in toothpastes.

A galvanic cell-type humidity sensor has been constructed from sintered β-$Ca(PO_3)_2$ which is a proton conductive solid. The e.m.f. response as a function of the logarithm of water vapor is linear, reversible, reproducible, and very fast over a wide range of vapor pressure measured at 578, 678 and 776 °C, respectively. The variation of observed e.m.f. versus logarithm of water vapor is in good agreement with the theoretical e.m.f. expected from the Nernst equation. Experimental results of steam-oxygen and steam-hydrogen concentration cells, respectively, employing β-$Ca(PO_3)_2$ as an electrolyte confirm proton conductivity and suggest the potential application of this material for high-temperature galvanic cell-type humidity sensing.

CPP has been used as a food additive. Among the many direct uses are as an Acidity regulator, Emulsifier (emulsifier), Emulsifying salt (sequestrant), Raising agent (in Bakeries) and Stabilizer (moisture/water retention agent). Calcium tripolyphosphate was proven to inhibit steel corrosion when incorporated in a paint film. Good protection was achieved by employing only 10% volume of the pigment, instead of 30%, as was suggested in the case of phosphates. Calcium tetrapolyphosphate, $Ca_3P_4O_{13}$, has also been proven to be a good detergent. Upon heating, it decomposes to the tripolyphosphate plus orthophosphate and pyrophosphate:

$$3Ca_3P_4O_{13} + \text{heat} \Rightarrow 2Ca_2HP_3O_{10} + Ca_3(PO_4)_2 + Ca_2P_2O_7$$

Calcium metaphosphates and polyphosphates are available from many suppliers and manufacturers worldwide.

Strontium Metaphosphate or Polyphosphates

Strontium metaphosphate can be prepared by the solid-state reaction of metaphosphoric acid and the hydroxide, oxide or carbonate of strontium:

$$SrCO_3 + HPO_3 + \text{heat} \Rightarrow Sr(PO_3)_2 + H_2O + CO_2$$

The best temperature to use is about 600 °C. Strontium metaphosphate has the CAS number of 13762-75-9 and a density of 2.61 g/cm^3. It melts at 757 °C and its boiling point is 1384 °C. It is somewhat soluble in water.

It can also be prepared by the aqueous reactions:

$$2NaPO_3\,(aq) + SrCl_2\,(aq) \Rightarrow Sr(PO_3)_2\,(solid) + 2NaCl\,(aq)$$

or

$$Sr(OH)_2\,(solid) + HPO_3\,(aq) \Rightarrow Sr(PO_3)_2\,(solid) + H_2O$$

The dissolution and reaction involving HPO_3 are slow and should be carried out in a hot solution. Evaporation at a low temperature (<15 °C) serves to form the crystals. Hydrated alkaline earth cyclo-octaphosphates were made by adding an aqueous solution of alkaline earth chlorides into an aqueous solution of sodium cyclo-octaphosphate. Thermal properties of the compounds were studied by TG-DTA analysis. The water of crystallization was removed below 200 °C. The cyclo-octaphosphates decomposed to produce many phosphate species up to about 500 °C, and they finally reorganized to metaphosphates. The overall thermal reaction of alkaline earth cyclo-octaphosphates can be written by the equation:

$$Sr_4(PO_3)_8 \cdot nH2O \Rightarrow 4Sr(PO_3)_2 + nH_2O$$

Strontium trimetaphosphate heptahydrate, $Sr_3(P_3O_9)_2 \cdot 7H_2O$, is orthorhombic. The unit cell, with $a = 16.05$ Å, $b = 12.33$ Å, $c = 10.87$ Å, contains four formula units with the space group Pnma. It is a cyclic metaphosphate in structure. Strontium cyclotetraphosphate $Sr_2(P_4O_{12}) \cdot 6H_2O$ has also been successfully characterized. This hydrate was synthesized as a single-phase crystalline powder starting from an aqueous solution of barium hydroxide and phosphorus pentoxide at 300 K. $Sr_2(P_4O_{12}) \cdot 6H_2O$ crystallizes in a new structure type in which the Sr^{2+} ions form a distorted hexagonal diamond-like arrangement with the $(P_4O_{12})^{4-}$ anions in the trigonal prismatic voids with the point group, $C2/c$, $Z = 4$, $a = 7.773$ Å, $b = 12.976$ Å, $c = 13.461$ Å, $\beta = 95.38°$.

Three forms of $Sr(PO_3)_2$ have been observed. The low-temperature form, γ-$Sr(PO_3)_2$ (originally formed at 583 °C) is transformed to the β-crystal at 400 °C and finally to the high temperature form α-$Sr(PO_3)_2$ at 850 °C. The low temperature form is possibly a cyclotriphosphate. The β-form is the only one well characterized.

Two polymorphic phases of strontium polyphosphate were prepared by solid-state reactions. The structure of β-$Sr(PO_3)_2$ is a redetermination. The structure of γ-$Sr(PO_3)_2$ was solved and contains $(PO_3)_n$ chains and SrO_8 polyhedra. $(PO_3)_n$ chains cross the cell along the a direction. Their repeat unit is two PO_4 tetrahedra. SrO_8 polyhedra are connected by edge sharing to form

infinite chains, which are further interconnected by edge sharing to form double chains parallel to a. The $(PO_3)_n$ groups link these double chains to build three-dimensional networks. This, it is a polyphosphate.

The phosphate α-$Sr(PO_3)_2$ was synthesized as a single-phase crystalline powder starting from strontium carbonate and phosphorous acid at a temperature of 1150 °C. α-$Sr(PO_3)_2$ crystallizes in a novel structure type in which helical *catena*-polyphosphate ions interpenetrate a substructure of Sr^{2+} closely related to cubic diamond ($Sr_4(PO_3)_8$, $P2_1$, $Z = 2$, $a = 7.354$ Å, $b = 7.354$ Å, $\beta = 90.02°$. The catena-polyphosphate chains form helices running along [010]. Their chain periodicity is 16 and the length of the repeating unit complies with $b = 18.68$ Å, the chain stretching factor amounts to $f_s = 0.48$ and the pitch to radius ratio is $\xi = 2.49$. The vibrational spectra of α-$Sr(PO_3)_2$ are also reported. The structure of α-$Sr(PO_3)_2$ is shown in the following Fig. 4.51.

The coordination of the Sr^{2+} ions can be clearly seen as well as those of the PO_3^- tetrahedral which form chains. The structure of γ-$Sr(PO_3)_2$ consists of $(Sr_4O_{22})_n$ double chains and infinite $(PO_3)_n$ chains linked together by polyphosphate sharing edges and corners. The structure of β-$Sr(PO_3)_2$ has been redetermined.

The polyphosphates β-$Sr(PO_3)_2$ and $BaCa(PO_3)_4$ have been doped with Eu^{2+}. $BaCa(PO_3)_4$ was structurally characterized for the first time. Both phosphors were analyzed by fluorescence spectroscopy. β-$Sr(PO_3)_2$:Eu and $BaCa(PO_3)_4$:Eu were found to emit blue light at 424 nm and 418 nm, respectively, with a broader emission band compared with α-$Sr(PO_3)_2$:Eu. Both phosphors can be excited at 330 nm, i.e. an UV-LED emission. The crystal structure of $BaCa(PO_3)_4$ has been determined based on single-crystal data [$P2_1/n$, $Z = 4$, $a = 7.230$ Å, $b = 9.171$ Å, $c = 15.247$ Å, $\beta = 90.995(12)°$, $R_1 = 0.050$, $wR_2 = 0.099$, 1748 reflections, 164 parameters]. $BaCa(PO_3)_4$ is not homeotypic with β-$Sr(PO_3)_2$ and α-$Sr(PO_3)_2$ but isotypic with $BaCd(PO_3)_4$. The vibrational spectra of $Sr_2(PO_3)_4$ are also presented and discussed.

Strontium metaphosphates and polyphosphates are readily available commercially, even though only one CAS number is available. Whether the salt purchased is a metatype or polytype depends upon the method of manufacture.

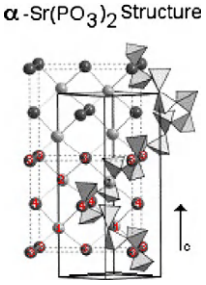

FIGURE 4.51

Barium Metaphosphate or Polyphosphates

Barium metaphosphate can be prepared by the solid-state reaction of metaphosphoric acid and the hydroxide, oxide or carbonate of barium:

$$BaCO_3 + HPO_3 + \text{heat} \Rightarrow Ba(PO_3)_2 + H_2O + CO_2$$

The best temperature to use is about 700 °C. It has the CAS number of 13762-83-9 and the molecular weight of 295.2709 g/mol. If diammonium phosphate is used instead of solid metaphosphoric acid, the product is not pure. Colored glasses are obtained caused by the reduction of P-atoms in the phosphate anion by hydrogen released from NH_3 to form colloidal dispersions of P_4 which produce various colors in the glass. β-$Ba(PO_3)_2$ is the final product. This compound can also be prepared by the aqueous reactions:

$$NaPO_3\,(aq) + BaCl_2\,(aq) \Rightarrow Ba(PO_3)_2\,(solid) + NaCl\,(aq)$$

or

$$Ba(OH)_2\,(solid) + 2HPO_3\,(aq) \Rightarrow Ba(PO_3)_2\,(solid) + 2H_2O$$

The dissolution and reaction involving HPO_3 are slow and should be carried out in a hot solution. Evaporation at a low temperature (<15 °C) serves to form the crystals. The product involves several hydrates depending upon the conditions of precipitation. Anhydrous barium metaphosphate is a white porous powder or granular material that is insoluble in water. If it is heated to about 950 °C, it forms a polymeric glass:

$$nBa(PO_3)_2 + \text{heat} \Rightarrow \{Ba(PO_3)_2\}_n$$

If the cooled glass is then reheated, it devitrifies to form α-$Ba(PO_3)_2$ above 600 °C. This transformation is reversible.

There are three form of $Ba(PO_3)_2$, a γ-form, a β-form and an α-form (Fig. 4.52).

The major difference between these phases lies in the P···P distances and P···O···P angles of the bonds. For example, the γ-phase and β-phase have the following parameters in the crystal where the bending angles are shown in Table 4.18.

Most of these compounds are true cyclic metaphosphates. This includes the trimeta- and tetrameta salts which form hydrates.

FIGURE 4.52

TABLE 4.18

Phase	P–P (Å)	P–O–P (°)	P–P–P (°)	Period	Fs
γ-$Ba(PO_3)_2$	2.818	120.7	127.3	4	0.695
	3.022	143.4	93.0		
β-$Ba(PO_3)_2$	2.898	124.6	102.2	2	0.909
		133.9			

(Fs = Stretching Coefficient)

Barium tetrametaphosphate hydrate $Ba_2(P_4O_{12})\cdot 3.5H_2O$ was synthesized as a single-phase crystalline powder starting from an aqueous solution of barium hydroxide and metaphosphoric acid at 30 °C. $Ba_2(P_4O_{12})\cdot 3.5H_2O$ crystallizes in a new structure type in which the Ba^{2+} ions form a distorted hexagonal diamond-like arrangement with the $(P_4O_{12})^{4-}$ anions in the trigonal prismatic voids. The ubit cell parameters are: $C2/c$, $Z = 4$, $a = 7.773$ Å, $b = 12.976$ Å, $c = 13.461$ Å, $\beta = 95.38°$, ($wR_2 = 0.071$, $R_1 = 0.018$, 1180 reflections, 118 parameters). The vibrational spectra of $Ba_2(P_4O_{12})\cdot 3.5H_2O$ and its thermal behavior up to 720 K have been reported.

The salt, barium cyclotriphosphate hexahydrate, $Ba_3(P_3O_9)_2\cdot 6H_2O$, is triclinic with the space group P-1 and the following unit-cell dimensions: $a = 7.547$ Å, $b = 11.975$ Å, $c = 13.068$ Å, $\alpha = 108.58°$, $\beta = 100.35°$, $\gamma = 95.54°$, $Z = 2$. $Ba_3(P_3O_9)_2\cdot 6H_2O$ is stable in the air and moisture until heated to about 80 °C. It is impossible to dehydrate $Ba_3(P_3O_9)_2\cdot 6H_2O$ without breaking its rings. $P_3O_9^{3-}$ a condition leading an amorphous compound. The final product of the dehydration and calcination of $Ba_3(P_3O_9)_2\cdot 6H_2O$, under atmospheric pressure, is its long chain polyphosphate form β-$Ba(PO_3)_2$. This compound is stable until it reaches its melting point of 870 °C.

The dehydration of the cyclotriphosphate hexahydrate of barium, $Ba_3(P_3O_9)_2\cdot 6H_2O$, occurs in two steps in two temperature ranges 69–198 °C and 274–456 °C. In the thermogravimetric (TG) curve, the first stage between 69 and 198 °C corresponds to the elimination of 5.5 water molecules and the second stage from 274 to 456 °C is due to the elimination of 0.5 water molecule. The derivative of the TG curve, DTG, of $Ba_3(P_3O_9)_2\cdot 6H_2O$ under atmospheric pressure and at a heating rate of 10 °C/min contains two peaks due to the dehydration of $Ba_3(P_3O_9)_2\cdot 6H_2O$. The first intensive peak in the domain 69–198 °C, at 165 °C is due to the departure of 5.5 water molecules. The second weak peak in the range of 274–456 °C, at 403 °C is due to the evolution of 0.5 remaining water molecules.

The preparation and determination of the crystalline structure of $Ba_3(P_3O_9)_2\cdot 4H_2O$ has been made. It has the space group of C2/m and is monoclinic. There is a mirror-plane symmetry of the anions P_3O_9 stretched along the c-axis and a localization of all Ba^{2+} in the mirror planes. Two of them are located in the mirror plane while the other two are distributed statistically within the entire cavity in a centrosystematic manner.

A systematic structure investigation of alkaline earth metaphosphate glasses, using $Me(PO_3)_2$ including Mg, Ca, Sr and Ba, was carried out using neutron diffraction. The total structure factor $S(Q)$ was measured up to $Q = 170/nm$. The total atomic distribution functions of most of the glasses show well-defined maxima for short distances which can be attributed to distinct atomic pairs. By a peak separation procedure, partial coordination numbers and mean distances for the atomic pairs P–O, O–O, Me–O, and P–P as well as the distribution of bond angles P–O–P were determined. The experimental data are compatible with the following model of the glass structure. The basic elements are PO_4 tetrahedra which are interconnected via two oxygens in chains. The chains are not straight. Metal ions are located between the chains and have oxygens in the first coordination shell. The metal–oxygen coordination number is 4 for Mg, Ca and 8 for Sr and Ba.

The salt, tribarium hexametaphosphate octahydrate, $Ba_3P_6O_{18}\cdot 8H_2O$, is monoclinic: space group = C2/c, $a = 20.98$ Å, $b = 7.227$ Å, $c = 17.44$ Å, $V = 2300.1$ Å^3, $Z = 4$ and density = 2.974 g/cm^3. The atomic arrangement can be described as being built of two layers of BaO_8 and BaO_{10} polyhedra approximately centered at the planes, $z = 1/4$ and 3/4, interconnected through the external O-atoms of the large $P_6O_{18}^{6-}$ groups. Inside a given layer, the Ba polyhedra assemble to form rings of 8-polyhedra which cover the available space as tiles. The phosphoric ring anions have a twofold internal symmetry rarely observed in the crystal chemistry of cyclophosphates. Other than the alkali compounds, the only other known cyclophosphates are $Cd_3P_6O_{18}\cdot 16H_2O$ $Mn_3P_6O_{18}\cdot 9H_2O$ and $Cu_3P_6O_{18}\cdot 14H_2O$.

Uses for barium metaphosphates or polyphosphates are few in industry. A few phosphors utilizing $Ba(PO_3)_2$ have been tried but this compound is usually a minor component. The polyphosphate glasses of barium, when activated by various rare earth cations have not proven to be as efficient as those of the other alkaline earths. $Ba(PO_3)_2$ has also been combined with BaF_2 to form optical glasses with a high refractive index (nD) 1.67–1.70, high transmission in the near infrared part of the spectra (to 6 micron) and a wide glass-forming domain. However, these glasses have not become commercial.

$Ba(PO_3)_2$ is available commercially from a few suppliers in limited quantities.

Radium Metaphosphates and Polyphosphates

Radium metaphosphate would have the formula of $Ra(PO_3)_2$ and the molecular weight of gm/mol. There is no record of either of these salts ever having been

prepared, although they could be made by several methods. The best one would be to react metaphosphoric acid and the hydroxide, oxide or carbonate of radium in the solid state:

$$RaCO_3 + HPO_3 + \text{heat} \Rightarrow Ra(PO_3)_2 + H_2O + CO_2$$

The best temperature to use is about 700 °C. It has no CAS number. The molecular weight is expected to be 383.9663 g/mol. This compound can also be prepared by the aqueous reactions:

$$NaPO_3\,(aq) + RaCl_2\,(aq) \Rightarrow Ra(PO_3)_2\,(solid) + NaCl\,(aq)$$

or

$$Ra(OH)_2\,(solid) + 2HPO_3\,(aq) \Rightarrow Ra(PO_3)_2\,(solid) + 2H_2O$$

Whether hydrates form remains unknown at this date. The only reference in the scientific literature concerns the removal of radioactive ^{226}Ra from drinking water by the addition of sodium polyphosphate. Radium polyphosphate is sufficiently insoluble so that all of the radium polyphosphate could be filtered out and subjected to proper disposal.

4.2.9. Alkaline Earth Hypophosphates

Hypophosphoric acid has the general formula of $H_4P_2O_6$ and differs from the other oxy-phosphorous acids. Lead and barium hypophosphates are insoluble, and the free acid can be obtained from them by means of hydrogen sulfide or sulfuric acid. It forms a hydrate $H_4P_2O_6 \cdot 2H_2O$. All alkaline earths hypophosphates are insoluble. Hypophosphoric acid has far less reducing power than phosphorous acid, and it is hydrolyzed in strong acid solution at elevated temperature to phosphorous and phosphoric acid:

$$H_4P_2O_6 + H_3O^+ \Rightarrow H_3PO_4 + H_3PO_3$$

The double formula $H_4P_2O_6$ was established by molecular weight determinations by the freezing point of solutions in water of the free acid and of the salt $Na_2H_2P_2O_6 \cdot 6H_2O$. Also the rate of hydrolysis of the acid by hydrogen ion to $H_3PO_4 + H_3PO_3$ is strictly monomolecular for $H_4P_2O_6$. It is thus clear that the acid is $H_4P_2O_6$, and the probable Lewis structure for this acid is shown in Fig. 4.53.

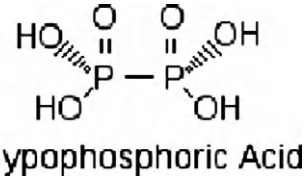

FIGURE 4.53

Where a direct bond between the two P-atoms is evident.

Beryllium Hypophosphate

Beryllium hypophosphate should have the molecular formula of $Be_2P_2O_6$ if it were to be formed by a solid-state reaction between hypophosphoric acid and BeO:

$$BeO + H_4P_2O_6 + \text{heat} \Rightarrow Be_2P_2O_6 + 2H_2O$$

However, there is no record that the preparation of this salt has ever been attempted. It could also be formed via an aqueous solution of hypophosphorus acid and a soluble beryllium salt:

$$2(BeOH)Cl\,(aq) + H_4P_2O_4\,(aq) \Rightarrow (BeOH)_2P_2O_4\,(solid) + 2HCl\,(aq)$$

Alternatively, sodium hypophosphate could be used to produce a basic solution instead of an acidic pH. A product from a basic solution, prepared in 1916, was said to have the formula, $Be_2P_2O_6 \cdot 1.5H_2O$ but this has never been confirmed. This compound was stated to lose its waters of hydration between 230 and 240 °C.

The formation of an "acid" salt-like $BeH_2P_2O_6$ or $(BeOH)H_2P_2O_6$ remains speculative. The formation of hydrates is not known nor has the structure of such compounds been delineated.

There are absolutely no academic studies concerning beryllium hypophosphate in the scientific literature nor is it mentioned in industrial circles. It has no CAS number nor is it offered for sale commercially by any manufacturer.

Magnesium Hypophosphate

Magnesium hypophosphate has the molecular formula of $Mg_2P_2O_4$. It can be formed by an aqueous solution of hypophosphorus acid and a soluble magnesium salt:

$$2MgCl_2\,(aq) + H_4P_2O_4\,(aq) \Rightarrow Mg_2P_2O_4\,(solid) + 2HCl\,(aq)$$

The magnesium salt solution is added until no precipitate results. Alternatively, sodium hypophosphate can be used to produce a basic solution instead of acidic. The acidic product is a magnesium hydrogen hypophosphate, $MgH_2P_2O_6 \cdot 4H_2O$. This salt is much more soluble in water (~0.05 g/100 ml) than the basic product that is a decahydrate, $Mg_2P_2O_4 \cdot 12H_2O$. The latter compound is much less soluble at 0.00072 g/100 ml. Neither of these salts has a CAS number.

The crystal structure of the anhydrate or the hydrates has not been determined. The thermal decomposition of either of these two salts has not been determined.

Only a few manufacturers and sellers of this salt are known. Whether the acid and/or basic salt is readily available remains to be determined by the buyer.

Calcium Hypophosphate

Calcium hypophosphate has the molecular formula of $Ca_2P_2O_4$. It can be formed by an aqueous solution of hypophosphorus acid and a soluble calcium salt:

$$2CaCl_2\ (aq) + H_4P_2O_4\ (aq) \Rightarrow Ca_2P_2O_4\ (solid) + 2HCl\ (aq)$$

The calcium salt solution is added until no precipitate results. Alternatively, sodium hypophosphate can be used to produce a basic solution instead of acidic. The basic product is a hexahydrate, $Ca_2P_2O_4 \cdot 6H_2O$. The acidic product is a dihydrate, $CaH_2P_2O_4 \cdot 2H_2O$. The former salt is insoluble in water but slightly soluble in acetic acid. It redissolves in excess hypophosphoric acid. Its CAS number is 75499-50-2. The acidic salt is more soluble in water at 16.8 g/100 ml at 20 °C. If this salt is heated, it loses the two waters of hydration at about 125–130 °C. The crystal structure of the anhydrate or the hydrate has not been determined.

Calcium hypophosphate has been used as a root-desensitizing agent in Dentistry. It has been prescribed as a source of calcium and phosphorus in the human body by Homopathic practioners until it was discovered that this compound crystallizes in tissues and may add to kidney stones and gall stones.

The literature concerning this salt is almost nonexistent and little attention from academia has occurred. It is available commercially in modest quantities.

Strontium Hypophosphate

Strontium hypophosphate would have the molecular formula of $Sr_2P_2O_4$, if it were to be produced. It can be formed by an aqueous solution of hypophosphorus acid and a soluble strontium salt:

$$2MgCl_2\ (aq) + H_4P_2O_4\ (aq) \Rightarrow Mg_2P_2O_4\ (solid) + 2HCl\ (aq)$$

The strontium salt solution is added until no precipitate results. Alternatively, sodium hypophosphate can be used to produce a basic solution instead of acidic.

However, there is categorically no record of preparation of this salt, unlike that of barium. It would be expected to mimic the properties of the homologous barium salts but no such descriptions can be found in any of the textbooks or scientific literature concerning the properties of this salt. Whether it forms hydrates or an acid salt remains unknown. It is expected to be rather insoluble in water but soluble in acids. It does not have a CAS number.

The crystal structure of the anhydrate or the possible hydrates has not been determined. It is not offered for sale commercially.

Barium Hypophosphate

Barium Magnesium hypophosphate has the molecular formula of $Ba_2P_2O_4$ and the molecular weight of 432.8235 g/mol. It can be formed by an aqueous solution of hypophosphorus acid and a soluble barium salt:

$$2BaCl_2\ (aq) + H_4P_2O_4\ (aq) \Rightarrow Ba_2P_2O_4\ (solid) + 2HCl\ (aq)$$

The barium salt solution is added until no precipitate results. Alternatively, sodium hypophosphate can be used to produce a basic solution instead of acidic. The basic product apparently is anhydrous since no record of a hydrate is known. The acidic product is a barium hydrogen hypophosphate, $BaH_2P_2O_6 \cdot 2H_2O$. This salt is slightly soluble in water at 1.1 g/100 ml at 20 °C. The basic salt is much less soluble at 0.00067 g/100 ml. Neither of these salts have a CAS number.

The crystal structure of the anhydrate or the hydrates has not been determined. The thermal decomposition of either of these two salts has not been determined.

No usage of either of these salts has appeared in industry. There are no commercial sources for these salts.

Radium Hypophosphate

Radium hypophosphate has the molecular formula of $Ra_2P_2O_4$. It can be formed by an aqueous solution of hypophosphorus acid and a soluble radium salt:

$$2RaCl_2\ (aq) + H_4P_2O_4\ (aq) \Rightarrow Ra_2P_2O_4\ (solid) + 2HCl\ (aq)$$

Alternatively, sodium hypophosphate can be used to produce a basic solution instead of acidic. The acidic product is expected to be a radium hydrogen hypophosphate, $RaH_2P_2O_6$. Neither of these salts have a CAS number. Whether hydrates form or not remains unknown.

The crystal structure of the anhydrate or the hydrates has not been determined. The thermal decomposition of either of these two salts has not been determined.

4.2.10. Alkaline Earth Peroxyphosphates

Two of these acids have been prepared, a peroxymonophosphoric acid H_3PO_5 and a peroxydiphosphoric acid $H_4P_2O_8$. Note that the latter is related to pyrophosphoric acid. Both are formed with 30% hydrogen peroxide, the first with phosphorous pentoxide:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$2H_3PO_5 + (P_2O_5 + H_2O_2) \Rightarrow 2H_4P_2O_8$$

The latter is the stronger oxidizing agent of the two acids. In aqueous solution, monoperoxyphosphoric

acid exists as H_3PO_5, $H_2PO_5^-$, HPO_5^{2-} and PO^{3-} at different pH values.

$$K_1 = H_3PO_5 \Leftrightarrow H_2PO_5^- + H^+ \quad (1)$$

$$K_2 = H_2PO_5^- \Leftrightarrow H_2PO_5^{2-} + H^+ \quad (2)$$

$$K_3 = HPO_5^{2-} \Leftrightarrow PO^{3-} + H^+ \quad (3)$$

The dissociation constants K_1, K_2, and K_3 are 8.0×10^{-2}, 4.2×10^{-6}, 1.6×10^{-13}, respectively at 298 K and $\mu = 0.2$ mol/dm^3.

Beryllium Peroxyphosphate

The chemistry of beryllium phosphates is far from complete. Beryllium peroxyphosphate has never been prepared. The chemistry involved and the physical properties of these compounds remain little known. Only a few references in the literature are available and most of these are dated before 1900. The compounds were identified by analysis, i.e. %Be, %P and %O as an oxidant. Parsons wrote a monograph "The Chemistry of Beryllium and Its Compounds" in 1910 but had little to add to what was already known.

Beryllium peroxyphosphates could be prepared by both solid-state or solution methods. However, it is likely that the two sets of compounds would differ. For the monoperoxyphosphates, one would get $Be(HPO_5)_2$ for the former method and $(BeOH)(HPO_5)$ for an aqueous solution. The question of hydrates remains unknown.

In the solution method, one could use the acid, H_3PO_5 or the potassium salt K_2HPO_5. Whether the solution should be acidic or basic is not known. Like the other alkaline earths, it is probably best to prepare the acid in a nonaqueous solution like carbon tetrachloride and ;then add the potassium compound for the basic solution:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$2H_3PO_5 + KOH \Rightarrow K_2HPO_5$$

To either of these is added to the beryllium compound to form the monoperoxyphosphate. Note that an aqueous solution could be used but the reaction product will undoubtedly differ in overall composition.

For the diperoxy compounds, the potassium monoperoxyphosphate compound is transformed to the diperoxyphosphate compound, in a nonaqueous solution at low temperature:

$$K_2HPO_5 + P_2O_5 \Rightarrow K_2P_2O_8$$

For beryllium, the probable compounds that will be formed are:

$$BeHPO_5 \text{ (or } (BeOH)HPO_5)$$
$$Be_2P_2O_8 \text{ (or } (BeOH)_2P_2O_8)$$

The nature of these compounds has never been explored. Beryllium peroxyphosphate has no CAS number and no listed manufacturers offer it for sale.

Magnesium Peroxyphosphate

Magnesium peroxyphosphate has remained unknown and little to no publications concerning this salt are available on the scientific literature. Like the other alkaline earths, magnesium peroxyphosphates could be prepared by both solid-state or solution methods. The two sets of compounds would likely differ. For the monoperoxyphosphates, one would get $MgHPO_5$ for the former method and perhaps a hydrate for an aqueous solution. The question of degree of hydration remains unknown.

In the solution method, one could use the acid, H_3PO_5 or the potassium salt K_2HPO_5. Whether the solution should be acidic or basic is not known. Like the other alkaline earths, it is probably best to prepare the acid in a nonaqueous solution like carbon tetrachloride and then add the potassium compound for the basic solution:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$2H_3PO_5 + KOH \Rightarrow K_2HPO_5$$

To either of these is added the magnesium compound to form the monoperoxyphosphate:

$$Mg(OH)_2 + K_2PO_5 \Rightarrow MgHPO_5 + H_2O$$

For the diperoxy compounds, the potassium monoperoxyphosphate compound is transformed to the diperoxyphosphate compound, in a nonaqueous solution at low temperature:

$$K_2HPO_5 + P_2O_5 \Rightarrow K_2P_2O_8$$

For magnesium, the probable compounds that will be formed are:

$$MgHPO_5 \text{ or } Mg_2P_2O_8$$

Other possible compounds are:

$$Mg(H_2PO_5)_2$$
$$Mg(H_2P_2O_8)_2$$

The nature of these compounds has never been explored. Magnesium peroxyphosphate has no CAS number and no listed manufacturers offer it for sale.

Calcium Peroxyphosphate

Calcium peroxyphosphate has the formula of $CaHPO_5$ as the monooxyphosphate or $Ca_2P_2O_8$ as the dioxyphosphate. For preparation of the monooxyphosphate, the acid is first prepared by adding P_2O_5 to 30%

hydrogen peroxide and then adding the hydroxide or carbonate to the acid:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$Ca(OH)_2 + H_3PO_5 \Rightarrow CaHPO_5 + H_2O$$

The phosphorus pentoxide powder was suspended in carbon tetrachloride under stirring while cooled in an ice bath. Aqueous hydrogen peroxide was added drop wise to this suspension to form H_3PO_5. Calcium carbonate or calcium hydroxide slurry was added slowly to the formed inorganic concentrated peroxymonophosphoric acid layer in an ice bath. The precipitate was then filtered. The result is a dihydrate, $CaHPO_5 \cdot 2H_2O$.

In an alternate Preparation of Calcium Peroxymonophosphate, the following recipe was given:

> "Suspend 2.22 g of calcium hydroxide in 50 ml of water. To this suspension, slowly add 2.28 g of concentrated peroxymonophosphoric acid, to be prepared as described in Example 1, in order to precipitate calcium peroxymonophosphate. Filter the resulting slurry and wash it with distilled water. The solid to be recovered is a basic calcium peroxymonophosphate, possibly also containing one or more calcium phosphate compounds."
>
> "To prepare diperoxyphosphate, dissolve 3.46 g of potassium peroxydiphosphate in 10 ml of water. To this solution, add 2.94 g of calcium chloride dihydrate under stirring, in order to precipitate calcium peroxydiphosphate. Filter the resulting slurry and wash it with distilled water. The solid to be recovered contains calcium peroxydiphosphate".

Note that the diperoxy compound is prepared from a monoperoxy compound. Still another method has been given:

> "To Prepare diperoxymonophosphoric acid by the action of hydrogen peroxide on pyrophosphoryl chloride. Maintain this inorganic diperoxy-phosphoric acid in an ice bath under stirring and slowly add a calcium carbonate slurry until the pH of the resulting solution is 3.3 and calcium diperoxyphosphate precipitates. Filter the resulting slurry and then wash it with distilled water. The solid to be recovered contains calcium diperoxymonophosphates and possibly also contains one or more calcium phosphate compounds".

The industrial interest stems from its use as a "dental whitener" in toothpaste and the like. Calcium peroxyphosphate compounds and dental compositions combine both whitening/stain removal of teeth with remineralization. The calcium peroxyphosphate compounds are capable of releasing, in an aqueous environment, whitening and reminiralization effective amounts of calcium ion, phosphate ion, and active oxygen. Preferred compounds are calcium peroxymonophosphate or calcium diperoxymonophosphate compounds. These compounds may be used in humans and other animals, including other mammals.

Yet, the only mention of calcium monoperoxy- or diperoxy-phosphate to be found in the technical literature is in patents several years old. These patents list a number of compounds as products of such preparations, as shown in the following:

Calcium monoperoxyphosphate
$CaHPO_5$
$Ca_3(PO_5)_2$
$Ca(H_2PO_5)_2$
$Ca_5(PO_5)_3OH$
Calcium diperoxyphosphate
$CaH_2(P_2O_8)$
$Ca_2P_2O_8$

Of these, only the physical properties of $CaHPO_5$ and $Ca_2P_2O_8$ have been documented. The scientific literature has been particularly devoid and publications from those in industry are exceedingly sparse, except for patents.

Diperoxyphosphoric acid, $H_4P_2O_8$, a starting material in the preparation of calcium diperoxymonophosphate, is less well known than H_2PO_5. However, this peroxy acid may be prepared, for example, in a manner similar to that for preparation of H_2PO_5, namely by the action of hydrogen peroxide on either P_2O_5 or pyrophosphoryl chloride ($P_2O_3Cl_2$). In general, the use of a peroxygenated phosphoric acid starting material allows for the preparation of various types of calcium peroxyphosphate compounds described herein. While the above procedures may generate a single calcium peroxyphosphate compound, generally a mixture of compounds is obtained. For example, a mixture of the peroxygenated forms $Ca(H_2\ PO_5)_2$ and $CaHPO_5$ may be obtained in the preparation of calcium peroxymonophosphates. Any of the calcium peroxyphosphates and calcium diperoxyphosphates described above may be in their respective hydrated or peroxyhydrated forms without adversely affecting their ability to release calcium ions, phosphate ions, and peroxide. Thus, as an example, a hydrated form of calcium peroxymonophosphate may be represented as $CaHPO_5 \cdot nH_2O$, indicating the association of "n" water molecules per molecule of calcium peroxymonophosphate.

Strontium Peroxyphosphate

Strontium peroxyphosphate has remained unknown and little to no publications concerning this salt are available on the scientific literature. Like the other alkaline earths, strontium peroxyphosphates could be prepared by both solid-state or solution methods. The two sets of compounds would likely differ. For the monoperoxyphosphates, one would get $SrHPO_5$ for the former method and perhaps a hydrate for an aqueous solution. The question of degree of hydration remains unknown.

In the solution method, one could use the acid, H_3PO_5 or the potassium salt K_2HPO_5. Whether the solution should be acidic or basic is not known. Like the other alkaline earths, it is probably best to prepare the acid in a nonaqueous solution like carbon tetrachloride and then add the potassium compound for the basic solution:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$2H_3PO_5 + KOH \Rightarrow K_2HPO_5$$

To either of these is added a soluble strontium compound to form the monoperoxyphosphate:

$$Sr(OH)_2 + K_2PO_5 \Rightarrow SrHPO_5 + H_2O$$

For the diperoxy compounds, the potassium monoperoxyphosphate compound is transformed to the diperoxyphosphate substance in a nonaqueous solution at low temperature:

$$K_2HPO_5 + P_2O_5 \Rightarrow K_2P_2O_8$$

For strontium, the probable compounds that will be formed are:

$$SrHPO_5$$
$$Sr_2P_2O_8$$

Other possible compounds are:

$$Sr(H_2PO_5)_2$$
$$Sr(H_2P_2O_8)_2$$

The nature of these compounds has never been explored. Strontium peroxyphosphate has no CAS number and no listed manufacturers offer it for sale.

Barium Peroxyphosphate

Barium peroxyphosphate has remained unknown and little to no publications concerning this salt are available on the scientific literature. Like the other alkaline earths, Barium peroxyphosphates could be prepared by both solid-state or solution methods. The two sets of compounds would likely differ. For the monoperoxyphosphates, one would get $BaHPO_5$ for the former method and perhaps a hydrate for an aqueous solution. The question of degree of hydration remains unknown.

In the solution method, one could use either the acid, H_3PO_5 or the potassium salt K_2HPO_5. Whether the solution should be acidic or basic is not known. Like the other alkaline earths, it is probably best to prepare the acid in a nonaqueous solution like carbon tetrachloride and then add the potassium compound for the basic solution:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$2H_3PO_5 + KOH \Rightarrow K_2HPO_5$$

To either of these is added a barium compound to form the monoperoxyphosphate:

$$Ba(OH)_2 + K_2PO_5 \Rightarrow BaHPO_5 + H_2O$$

For the diperoxy compounds, the potassium monoperoxyphosphate compound is transformed to the diperoxyphosphate compound, in a nonaqueous solution at low temperature:

$$K_2HPO_5 + P_2O_5 \Rightarrow K_2P_2O_8$$

For barium, the probable compounds that will be formed are:

$$BaHPO_5$$
$$Ba_2P_2O_8$$

Other possible compounds are:

$$Ba(H_2PO_5)_2$$
$$Ba(H_2P_2O_8)_2$$

The nature of these compounds has never been explored. Barium peroxyphosphate has no CAS number and no listed manufacturers offer it for sale.

Radium Peroxyphosphate

Radium peroxyphosphate has remained unknown and no publications concerning this salt are available in the scientific literature. This is not surprising in view of the intense radioactivity of ^{226}Ra. Like the other alkaline earths, radium peroxyphosphates could be prepared by both solid-state or solution methods. For the monoperoxyphosphates, one would get $RaHPO_5$ for the former method. The question of degree of hydration remains unknown.

In the solution method, one could use the acid, H_3PO_5 or the potassium salt K_2HPO_5. Whether the solution should be acidic or basic is not known. Like the other alkaline earths, it is probably best to prepare the acid in a nonaqueous solution like carbon tetrachloride and then add the potassium compound for the basic solution:

$$P_2O_5 + 2H_2O_2 + H_2O \Rightarrow 2H_3PO_5$$
$$2H_3PO_5 + KOH \Rightarrow K_2HPO_5$$

To either of these is added the radium compound to form the monoperoxyphosphate:

$$Ra(OH)_2 + K_2PO_5 \Rightarrow RaHPO_5 + H_2O$$

To prepare radium diperoxy compounds, the potassium monoperoxyphosphate compound is transformed to the diperoxyphosphate compound, in a nonaqueous solution at low temperature:

$$K_2HPO_5 + P_2O_5 \Rightarrow K_2P_2O_8$$

For radium, the probable compounds that will be formed are:

$$RaHPO_5$$

$$Ra_2P_2O_8$$

Other possible compounds are:

$$Ra(H_2PO_5)_2$$

$$Ra(H_2P_2O_8)_2$$

The nature of these compounds has never been explored. Radium peroxyphosphate has no CAS number and no listed manufacturers offer it for sale.

4.3. ALKALINE EARTH METAL OXO-ARSENIC COMPOUNDS

The alkaline earths form a series of compounds based upon the arsenic acids. The element, Arsenic, with the symbol As, forms a limited series of compounds called "arsenides" with the alkaline earth metals. The reason for this lies in the fact that arsenic is on the border line between those elements that are purely cationic (metallic in nature) and those that form anionic compounds. Even though the alkali metals have the highest degree of cationic behavior and form ionic bonds easily, arsenic exhibits both ionic and covalent character in its compounds and is classified as one of the "metalloids". There are two major forms of the acids, one having As either in the +3 state, i.e. H_3AsO_3, or the +5 valence state, H_3AsO_4 plus the arsenides in which the arsenic atom is in a trivalent state, i.e. As^{3+}.

4.3.1. Arsenic Acids

The following acids of Arsenic are known.

Arsenous Acid

This compound, also known as **arsenious acid**, is the hydrolyzed form of As_2O_3 and has the formula $As(OH)_3$. $As(OH)_3$ occurs in aqueous solutions and has not been isolated as a pure material, although this fact does not detract from the significance of $As(OH)_3$. This compound is essentially the "hydroxide" of the arsenic ion but is not basic in character. The molecular weight of arsenous acid is 125.94 g/mol. $As(OH)_3$ is a pyramidal molecule consisting of three hydroxyl groups connected by single bonds to arsenic. In contrast, the nominally related phosphorous species H_3PO_3 mainly adopts the structure $HPO(OH)_2$ in which $P(OH)_3$ is a very minor equilibrium component of such solutions (if it exists at all). The differing behaviors of the As and P compounds reflect a trend whereby high oxidation states are more stable for lighter members of main group elements than their heavier congeners like As where the +3 valance state dominates.

Arsenous acid [13464-58-9], AsH_3O_3, is known to exist only in solution. It is a weak acid with a dissociation constant of 8×10^{-16} at 25 °C. The free acid apparently has three OH groups attached directly to the arsenic atom and hence is not analogous to phosphorous acid. A number of complex arsenites are known, among which are copper acetate arsenite [12002-03-8], $Cu_2(C_2H_3O_2)(AsO_3)$, Paris green, and cupric hydrogen arsenite [10290-12-7], $CuHAsO_3$, Scheele's green. These have been used mainly as insecticides in the past.

$As(OH)_3$ is a weak acid with a pK_a of 9.2. The preparation of $As(OH)_3$ involves a slow hydrolysis of hydolysis of arsenic trioxide in water. Addition of a base such as one of the alkali cations converts arsenous acid to the arsenite ions $[AsO(OH)_2]^-$, $[AsO_2(OH)]^{2-}$, and $[AsO_3]^{3-}$. In other words, arsenous acid is "amphoteric" and easily forms anions in the presence of more cationic species like the alkali metals. Note that these anions are analogous to the mono, di and tri-basic anions of phosphate. Reactions attributed to aqueous arsenic trioxide are due to arsenous acid and its conjugate bases.

Arsenic acid has the molecular formula H_3AsO_4. More descriptively written as $AsO(OH)_3$, this colorless acid is the arsenic analog of phosphoric acid. Arsenate and phosphate salts behave very similarly. Arsenic acid as such has not been isolated, but only found in solution where it is largely ionized. Its hemihydrate form ($H_3AsO_4 \cdot 1/2H_2O$) does form stable crystals. Crystalline samples dehydrate with condensation at 100 °C. The difference in molecular structure between arsenous and arsenic acids is shown in Fig. 4.54.

Arsenic acid is a tetrahedral species of idealized symmetry C_{3v} with As–O bonds lengths ranging from 1.66 to 1.71 Å. Being a triprotic acid, its acidity is described by three equilibria:

$$H_3AsO_4 \Leftrightarrow H_2AsO_4^- + H^+ \quad (pk_1 = 10^{-2.19})$$

$$H_2AsO_4^- \Leftrightarrow HasO_4^{2-} + H^+ \quad (pk_2 = 10^{-6.94})$$

$$HasO_4^{2-} \Leftrightarrow AsO_4^{3-} + H^+ \quad (pk_3 = 10^{-11.5})$$

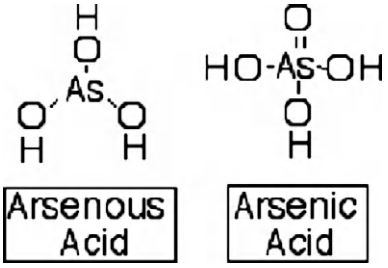

FIGURE 4.54

These K_a values are close to those for phosphoric acid. The highly basic arsenate ion (AsO_4^{3-}) is the product of the third ionization. Unlike phosphoric acid, arsenic acid is **strongly oxidizing**, illustrated by its ability to convert iodide to iodine. Thus, some compounds with the alkali metal ions are not stable.

Arsenic acid is prepared by treating arsenic trioxide with concentrated nitric acid or by combination of arsenic acid with water. The latter reaction is very slow. It is also formed when metaarsenic or pyroarsenic acid is treated with cold water.

4.3.2. Alkaline Earth Arsenides

Elemental arsenic combines with electropositive metals to form their arsenides, i.e. Mg_3As_2. It also combines with hydrogen to form arsine, a colorless gas; garlic-like unpleasant odor; liquefies at –55 °C; solidifies at –116.3 °C; heavier than air; gas density 2.695 (air = 1). Arsenic sublimes at 887 K, (615 °C, 1139 F) but does not melt. Thus, reaction with the liquid alkaline earths in an inert atmosphere serves to form the arsenides.

Beryllium Arsenide

Beryllium arsenide should have the molecular formula of Be_3As_2 and the molecular weight of 176.8801 g/mol. However, this is a doubtful compound that has never been prepared. Be melts at 1287 °C and the reaction at that temperature apparently does not occur:

$$3Be + 2As + \text{heat} \not\longrightarrow Be_3As_2$$

The reason for this is not clear but may lie in the difference in atomic radii of the two species (Be = 1.05 Å; As = 1.15 Å = ±10%). This behavior remains a mystery since the other alkaline earths all form arsenide compounds. However, a compound having a Be···As bond has been found. This compound was described as:

> "The compound (η^5-C_5Me_5)BeAs(*t*-Bu)$_2$ (**1**) was prepared by the reaction of (η^5-C_5Me_5)BeCl with LiAs(*t*-Bu)$_2$ in diethyl ether at 0 °C. The structure of **1** has been determined by X-ray crystallography and is the first structurally characterized diorganoarsenide derivative of beryllium. It is monomeric in the solid state with the As-*t*-Bu$_2$ ligand acting as a one electron donor".

This anomaly has been studied theoretically. The electronic structure and spectroscopic properties of a manifold of states of a new molecular species, Be···As, have been investigated theoretically using the "complete active space self-consistent field/multireference single and double excitations configuration interaction (CASSCF/MRSDCI)" approach, using the aug-cc-pV5Z-PP basis set for arsenic, which includes a relativistic effective core potential, and the cc-pV5Z set for beryllium. Potential energy curves of five quartet and eight doublet (L + S) states correlating with the five lowest-lying dissociation limits were constructed. The effect of spin–orbit coupling was also included in the description of the ground state, and of the doublet states correlating with the second dissociation channel. Dipole moment functions and vibrationally averaged dipole moments are also evaluated. The similarities and differences between BeAs, BeP, and BeN were analyzed. Spin–orbit effects are small for the ground state close to the equilibrium distance, but avoided crossings between $\Omega = 1/2$ states, and between $\Omega = 3/2$ states which changes significantly the L + S curves for the lowest-lying doublets.

Beryllium arsenide is not well known in either academic circles or industry. It is not available commercially and does not have a CAS number.

Magnesium Arsenide

Magnesium arsenide has the molecular formula of Mg_3As_2 and the molecular weight of 223.6592 g/mol. It may be prepared by direct reaction between the elements. Since As sublimes at 614 °C and Mg melts at 650 °C, the latter is melted at about 675 °C in an inert atmosphere like argon (not N_2 which would form nitrides) and arsenic vapors are carried into the reaction zone by a stream of Ar gas:

$$3Mg + 2As + \text{heat} \Rightarrow Mg_3As_2$$

Mg_3As_2 is obtained by this method as a deep-brown, X-ray amorphous powder. Magnesium arsenide has the CAS number of 12044-49-4. This compound decomposes in contact with water:

$$Mg_3As_2 + 3H_2O \Rightarrow 2AsH_3 + 3Mg(OH)_2$$

Thus, it must be stored under dry conditions. Its density is 3.15 g/cm^3. This compound is dimorphic with the low temperature form, β-Mg_3As_2 being cubic ($a = 12.33$ Å) and the high-temperature form, α-Mg_3As_2 being hexagonal. It crystallizes in the anti-La_2O_3 crystal structure, with unit-cell parameters of: $a = 4.264$ Å, $c = 6.738$ Å, c/a = 1.580. Both of these compounds are semiconductors. The latter has a band gap, E_g, of 2.2 eV (564 nm).

The phase diagram for the Mg–As system has been presented and is shown in the following Fig. 4.55.

In addition to the α- and β-phases, a compound, $MgAs_4$, is known to form. Paar first reported the existence of the Mg_3As_2 compound in 1867. It is a deep-red color when crystalline. The low-temperature form undergoes an allotropic transformation between 1000 and 1100 °C to form α-Mg_3As_2 (whose melting point is above 1200 °C.

These magnesium arsenide compounds have a narrow stability and homogeneity range (just like Mg_3Bi_2 and Mg_3Sb_2). The $MgAs_4$ compound was first

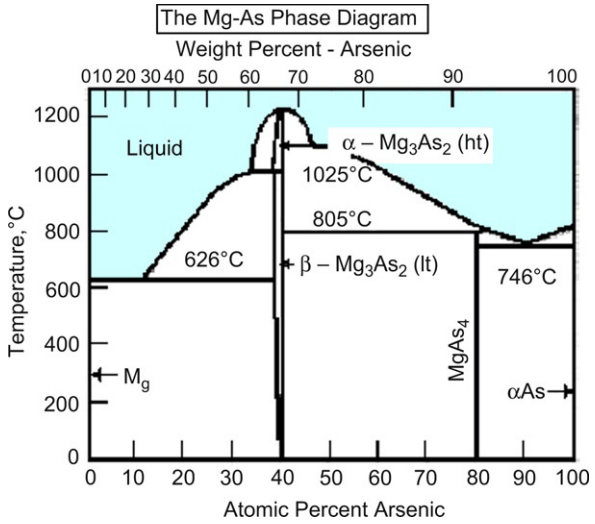

FIGURE 4.55

reported in 1874. Upon heating, it decomposes to Mg_3As_2 and As:

$$6MgAs_4 + \text{heat} \Rightarrow 2Mg_3As_2 + 5As_4$$

$MgAs_4$ crystallizes in the tetragonal space group $P4_12_12$ with $a = b = 5.385$ Å, $c = 15.798$ Å and $Z = 4$. The Mg atoms are octahedrally coordinated by six As atoms and the two types of As atoms are tetrahedrally bonded to two Mg and two As atoms or one Mg and three As atoms, respectively. The coordination of MgP_4 and $MgAs_4$ is similar in these structures.

Electronic structure calculations for Mg_3As_2 (low and high temperature modifications) have been performed. Mg_3As_2 with a high temperature modification is predicted to be a semiconductor with the gap value of about 1.1 eV (1127 nm), and Mg_3As_2 (low-temperature phase) is a semiconductor with 1.57 eV (790 nm).

Magnesium arsenide decomposes rapidly on exposure to air. It reacts with ethyl alcohol at the boiling point and at 180′ to 205 °C ethyl- and diethyl-arsines, with a trace of triethylarsine, are formed. The crystal structure of the arsenide has been investigated by the X-ray powder method. It resembles the corresponding zinc arsenide and has a cubic, lattice containing two molecules of Mg_3As_2 in the unit cell, the side of which is 6.10 Å, the calculated density being 3.26 g/cm^3. The structure of magnesium arsenide is not ionic but covalent.

Magnesium arsenide was used as a rodenticide and insecticide. Its toxicity to humans has led to its prohibition in the US and Europe. Yet, it is available commercially from a number of suppliers worldwide.

Calcium Arsenide

Calcium arsenide has the molecular formula of Ca_3As_2 and the molecular weight of 270.0772 g/mol. It may be prepared by reacting the elements together. Since As sublimes at 614 °C and Ca melts at 839 °C, the latter is melted at about 875 °C in an inert atmosphere like argon (not N_2 which would form nitrides) and arsenic vapors are carried into the reaction zone by a stream of Ar gas:

$$3Ca + 2As + \text{heat} \Rightarrow Ca_3As_2$$

Its CAS number is 12255-53-7. The standard Gibbs energies of formation of Ca_3As_2 was determined by a chemical equilibration technique yielding the following results:

$$3Ca + 2As \Rightarrow Ca_3As_2 \text{ (solid)}$$
$$\Delta G^\circ = -723{,}800 + 172.8T \text{ (J/mol)}$$
$$(T = 1273 \text{ to } 1573 \text{ K})$$

Calcium arsenide has the zinc-blende (cubic) structure with $a = 6.751$ Å. It can also be prepared by the reduction of calcium arsenate by carbon:

$$2Ca_3AsO_4 + 5C + \text{heat} \Rightarrow Ca_3As_2 + 2CaO + 3CO_2$$

When a mixture of hydrogen and arsenic vapor is passed over heated quicklime the product is mainly arsenite, only a little arsenide being formed. It has been shown that calcium arsenate is reduced by carbon slowly at 800 °C and rapidly at 850 °C, the arsenite being first produced and finally calcium oxide and arsenic; in order to obtain the arsenide, rapid heating to 1500 to 1600 °C is necessary. If the heating is slow, loss of arsenic occurs.

The arsenide is obtained as a crystalline mass, small fragments of which are transparent or reddish-brown in color. Its density is 2.54 g/cm^3, and it is harder than calcite. It is readily attacked by the halogens, but the higher the atomic number of the latter, the higher the temperature necessary for reaction to occur. It remains unchanged in dry air or oxygen at room temperature, but when heated in the latter it burns brilliantly to form a calcium arsenate. Hydrogen does not attack the arsenide, even at 700 to 800 °C. Water decomposes it in the cold with formation of calcium hydroxide and evolution of arsine; it is consequently unstable in moist air. It is also soluble in acids:

$$Ca_3As_2 + 6HCl \Rightarrow 2AsH_3 + 3\ CaCl_2$$

It is attacked by sulfur or hydrogen sulfide at dull red heat. Cold concentrated sulfuric acid is reduced to sulfurous acid. The gaseous halogen acids react at red heat giving arsenic and a calcium salt. Fuming nitric acid does not attack it in the cold, but there is a rapid reaction on heating. Carbon and boron are without action at 1000 °C, but the former can decompose it completely at the temperature of the electric furnace. Many metallic salts are decomposed when heated with the arsenide.

Calcium arsenide also forms several types of compounds, some of which are "Zintl" compounds (Zintl compounds consist of anionic elements which bind first to each other to form complex geometries like hexagonal bipyramids and then to the cations present). The compound, $Ca_{14}GaAs_{11}$ is such a compound. It is tetragonal with the space group $I4_1/acd$ and the lattice parameters of $a = 15.642$ Å, $c = 21.138$ Å. Its structure is composed of isolated $GaAs_4$ tetrahedra that are separated by As_3 linear units and isolated As and Ca atoms. The As_3 units are situated between the tetrahedral and alternate by 90° down the *c*-axis. This unit has essentially a –7 charge (similar to the isoelectronic hypervalent I_3^- anion). That is, there are seven bonds associated with the bonding of this unit to the other atoms in the structure. This compound is a semiconductor as well.

Another, similar compound is Ca_3AsCl_3, prepared as a grayish white, microcrystalline powder by the reaction of Ca, As, and $CaCl_2$ in the molar ratio 3:2:3 or by the reaction of Ca_3As_2 and $CaCl_2$ in the molar ratio 1:3. Colorless single crystals of the compound were obtained. Ca_3AsCl_3 begins to decompose reversibly at 1025 °C by forming the phase $Ca_{2x}As_{1x}Cl_{1+x}$, where x is about 0.1, and the second product is $CaCl_2$. Single crystal investigations show that Ca_3AsCl_3 is isotypic with Mg_3NF_3.

Calcium arsenide will also combine with CaO to form Ca_4As_2O (yellow). It was prepared by reaction of "Ca_3As_2" with CaO in a molar ratio 1:1 in steel ampoules under argon. This compound was obtained as a well-crystallized, easily hydrolyzed powder. It crystallizes in the anti-K_2NiF_4 tetragonal structure.

In industrial settings, arsine poisoning generally results from the accidental formation of arsine gas. Most reported cases of exposure to arsine have occurred during the smelting and refining of metals. However, there are many other situations where exposures to lethal concentrations of the gas have been reported including galvanizing, soldering, etching and lead plating operations. Arsine can be produced by Fungi (especially in sewage) when arsenic is present. The renewed interest in coal as a source of energy causes concern for a possible increase in the number of exposures to arsine, because coal contains considerable quantities of arsenic. The processes for converting coal to gas and other by-products should include preventative measures aimed at reducing the chance of transformation of the arsenic impurities into arsine.

Calcium arsenide has been used as a fungicide as well as a rodenticide. Ca_3As_2, treated with water gives a 14% yield of arsine. Better yields (60–90%) are obtained by decomposing a solution of acid. However, its toxicity has precluded extensive usage in the U.S. and less poisonous compounds are now being used. It is used in Research to develop new types of semiconductors but not in industry.

Calcium arsenide is still available commercially as crushed chunks and flakes from a number of suppliers worldwide.

Strontium Arsenide

Strontium Arsenide, Sr_3As_2, may be prepared by the reaction of the elements or by the reduction of strontium arsenate. The latter method is best accomplished by rapidly heating with carbon to 1500 to 1600 °C. If the heating is slow, reduction begins at about 800 °C yielding first the arsenite, arsenic then being lost and strontium oxide formed:

$$3Sr + 2As + \text{heat} \Rightarrow Sr_3As_2$$

$$2Sr_3AsO_4 + 4C + \text{heat} \Rightarrow Sr_3As_2 + 3SrO + 3CO + CO_2$$

Strontium arsenide forms reddish-brown crystals, transparent in thin sections, with a density of 3.23 g/cm^3. It has the CAS number 39297-24-0. Its molecular weight is 1167.9668 g/mol. It decomposes in contact with water, forming strontium hydroxide with liberation of arsine. It burns brilliantly when heated in oxygen or sulfur vapor. It reacts with fluorine at room temperature with incandescence and formation of arsenic trifluoride. Similar reactions occur with chlorine at 160 °C, with bromine at 200 °C, and with iodine vapor at a higher temperature. It is a powerful reducing agent and attacks most metallic oxides and oxidizing agents.

It is considered as a "Dangerous Substance for the Environment" and is prohibited in Europe by the EEC. Only one or two research papers exist in the scientific literature concerning this salt. The structure of strontium arsenide remains to be determined. Whether it is cubic like the calcium homologue remains unknown. It well may be hexagonal because of the size difference of the Sr^{2+} cation.

There are no uses listed in industry and the calcium and magnesium arsenides have found favor over this salt because of cost. Nevertheless, strontium arsenide is offered for sale commercially by a number of suppliers worldwide.

Barium Arsenide

Barium arsenide has the molecular formula of Ba_3As_2. By passing arsine over barium oxide, at red heat, a mixture of arsenide and arsenite is obtained. The best way is to react the elements together at red heat:

$$3Ba + 2Ar \Rightarrow Ba_3As_2$$

Since Ba metal melts at 729 °C, the metal is melted at 750 °C and vapors of As are passed over it in a stream of argon gas. Crystals of Ba_3As_2 slowly form in cooler parts of the enclosed tube furnace. It can also be prepared in

a pure form by reduction of barium arsenate with carbon in an electric furnace:

$$2Ba_3AsO_4 + 3C + \text{heat} \Rightarrow Ba_3As_2 + 3BaO + 2CO_2 + CO$$

The oxide produced may be removed by washing in an acid like HCl to solubilize it. The crystals obtained are deep brown with a density of 4.16 g/cm^3. Its molecular weight is 561.9324 g/mol.

Barium arsenide is very similar in chemical properties to the arsenides of calcium and strontium. Its CAS number is 12255-50-4. It is slightly darker in color, more readily fusible and more reactive chemically. It burns spontaneously in fluorine, chlorine or bromine vapor. In oxygen, it burns at about 300 °C to form the orthoarsenate and in sulfur vapor at dull red heat to form thioarsenates. Ba_3As_2 has the body-centered cubic structure with $a = 9.846$ Å, where 1/9 of the anion sites are empty.

Barium arsenide also forms double salts such as $Li_4Ba_3As_4$ (Orthorhombic space group = *Immm*) which is isostructural with $Li_4Sr_3Sb_4$ and $Li_4Ba_3Sb_4$. It contains two anionic moieties, namely As_2^{4-} dumbbells and As^{3-}, and consists of planes of $BaAs_6$ octahedra separated by corrugated sheets of Li and Ba atoms.

The ternary iron arsenide $BaFe_2As_2$ becomes superconducting by hole doping, which was achieved by partial substitution of the barium site with potassium. Bulk superconductivity has been discovered at $T_c = 38$ K in $(Ba_{1-x}K_x)Fe_2As_2$ with $x \approx 0.4$. The parent compound $BaFe_2As_2$ crystallizes in the tetragonal $ThCr_2Si_2$-type structure, which consists of $(FeAs)^-$ iron arsenide layers separated by Ba^{2+} ions. $BaFe_2As_2$ is a poor metal and exhibits a spin density wave anomaly at 140 K. Substituting Ba^{2+} for K^+ ions introduces holes in the $(FeAs)^-$ layers, which suppress the anomaly and induces superconductivity. The T_c of 38 K in $(Ba_{0.6}K_{0.4})Fe_2As_2$ is the highest in hole-doped iron arsenide superconductors known to date.

The barium–scandium–iron arsenide oxide, Ba_2ScO_3FeAs was synthesized by high-temperature solid-state reactions and its crystal structure determined by X-ray powder diffraction. Its structure is tetragonal (*P*4/*nmm*; Ba_2ScO_3FeAs: $a = 4.1266$ Å, $c = 16.800$ Å, $Z = 2$) and isotypic to Sr_2GaO_3CuS. This compound is vaguely similar to barium arsenide. Iron arsenide layers are sandwiched between perovskite-like metal oxide layers and separated by ~16.00 Å, which is much larger compared to the ZrCuSiAs-type "1111" iron arsenide superconductors. The structure is shown in the following Fig. 4.56.

The bond lengths and angles within the FeAs layers are adapted to the space requirements of the oxide blocks. Measurements of the magnetic susceptibility, electrical resistivity and temperature-dependent crystal structure show no hint for a structural phase transition

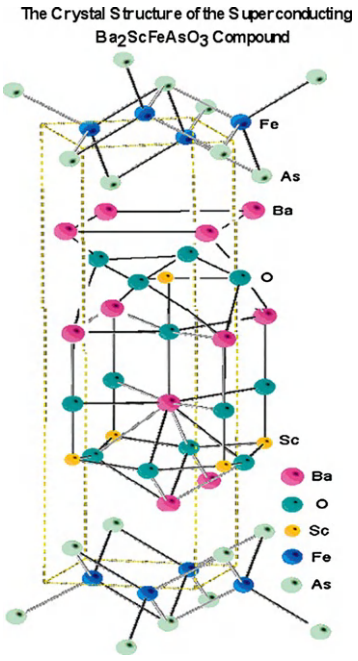

FIGURE 4.56

or magnetic anomaly in this compound. Ba_2ScO_3FeAs shows Curie–Weiss paramagnetism above 160 K with an effective magnetic moment of 3.83 KB in good agreement with the theoretical value of 3.87 KB for Cr3+ ($S = 3/2$). Antiferromagnetic ordering was detected below $T_N \sim 31$ K. ^{57}Fe-Mossbauer spectra of Ba_2ScO_3FeAs show single signals which are only subject to weak quadrupole splitting.

Barium arsenide itself has not been the subject of investigation of its physical properties of late. This compound was discovered in the 1800s and was well scrutinized in the twentieth century. However, the physical properties such as melting point and boiling point have not been documented. This salt is available in pure form commercially for use in the sputtering and vapor formation of mixed arsenides.

Radium Arsenide

Radium arsenide has not been prepared. It could be prepared by reaction of the elements. Ra melts at 700 °C (973 K) and the vapors of As could be carried into a reaction zone of 750 °C to form the compound. Yet, no record of this salt is available in the literature. Perhaps this is due the radioactive decay of ^{226}Ra and the fact that no demand in industry exists. The reaction would be:

$$3Ra + 2As + \text{heat} \Rightarrow Ra_3As_2$$

However, whether this compound exists and could be prepared remains unknown. It has no CAS number and there are no listed manufacturers of this salt.

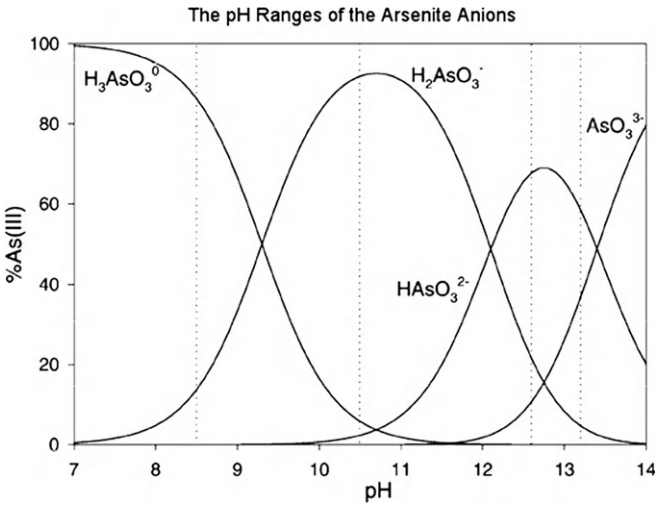

FIGURE 4.57

4.3.3. Alkaline Earth Arsenites

The alkaline earth arsenites can be prepared by precipitation from arsenous acid or from an alkali metaarsenite salt such as potassium arsenite. Above pH 9.0, As(III)behaves like a weak acid and its speciation is the result of the following equilibria:

$$As(OH)_3 \Leftrightarrow H^+ + AsO(OH)_2^- \quad pKa_1 = 9.32 \quad (1)$$

$$As(OH)_2^- \Leftrightarrow H^+ + AsO_2(OH)^{2-} \quad pKa_2 = 12.10 \quad (2)$$

$$AsO_2(OH)^{2-} \Leftrightarrow H^+ + AsO_3^{3-}(OH)^{2-} \quad pKa_3 = 13.41 \quad (3)$$

At pH 7.5, the neutral $As(OH)_3^\circ$ species predominates. The others appear as a function of pH. Thus, all arsenites must be prepared at a basic pH.

The pH ranges at which various arsenites appear is shown in the following Fig. 4.57.

The structures of all alkaline earth arsenites are based upon a triangular molecule as shown in the following Lewis structure (Fig. 4.58).

Berylium Arsenite

Beryllium Arsenite could be prepared by the solid-state reactions of the oxide and solid arsenous acid:

$$BeO + H_3AsO_3 + \text{heat} \Rightarrow BeHAsO_3 + H_2O$$

At a 2:1 ratio and a pH of 13.5, one would expect to obtain $Be_3(AsO_3)_2$. However, there is no record of this having been attempted. Attempts to prepare definite compounds of beryllium with arsenious acid in aqueous solution have not been successful. When beryllium hydroxide is precipitated from solutions containing arsenious oxide, much of the latter is adsorbed but a product has never been isolated and identified. The literature is devoid of any references and the only citations are dated in the 1860–1880s. Perhaps this is due to the fact that beryllium cations in aqueous solution are dominated by hydroxy groups which attach themselves to Be^{2+} to form species like $Be(OH)^+$. These do not react the same in solution as the other alkaline earths do.

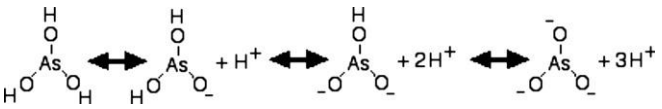

FIGURE 4.58

There are no uses that have developed for beryllium arsenites and they do not have any CAS numbers.

Magnesium Arsenites

Magnesium forms a series of compounds with arsenious acid similar to those of phosphorous acid. These include the monobasic, dibasic and tribasic forms as well as a pyro- and tetraärsenite. The Lewis structural formula for these compounds included in Fig. 4.59.

Note that these structures are based upon a linear triangular AsO_3^{3-} anion.

Basic magnesium arsenite cannot be prepared by reacting the oxides together either in a solid-state reaction in an inert atmosphere or in an aqueous reaction. An investigation of the system $MgO–As_2O_3–H_2O$ at 25 °C gave no evidence of chemical combination, but considerable adsorption of arsenious oxide by the magnesium hydroxide occurred. The key to forming this compound lies in controlling the pH around 7.5–8.0. Combination of the two oxides occurs at higher solution temperatures where some of the MgO dissolved to form the hydroxide and some basic metarsenite was formed.

However, the composition was mostly a basic arsenite of composition, $MgHAsO_3 \cdot 3H_2O$. This has the Lewis structure shown in Fig. 4.60.

A solution of soluble magnesium chloride and arsenious acid forms a dibasic salt which then results in an insoluble hexahydrate, $MgHPO_3 \cdot 6H_2O$. The pH then needs to be around 12.5 to maximize the formation of the compound. The dimensions of the hexagonal cell are $a = 8.88$ Å, $c = 9.10$ Å. The corresponding rhombohedral structure unit-cell parameters are $a_R = 5.96$ Å, $\alpha = 96°24'$. The space group is R3 and the Mg, P and H-atoms lie on the unique axis. The structure is built from discrete tetrahedral $(HPO_3)^{2-}$ ions and octahedral $Mg(H_2O)_6^{2+}$ groups which are linked together in three dimensions by a continuous system of hydrogen bonds. This compound is isomorphous with $MgSO_3 \cdot 6H_2O$. Its CAS number is 14332-25-3. Its molecular weight is 188.1007 g/mol. A trihydrate is also known which can be formed by heating the hexahydrate to 100 °C. This salt has few references in the scientific literature. The physical properties have not been studied.

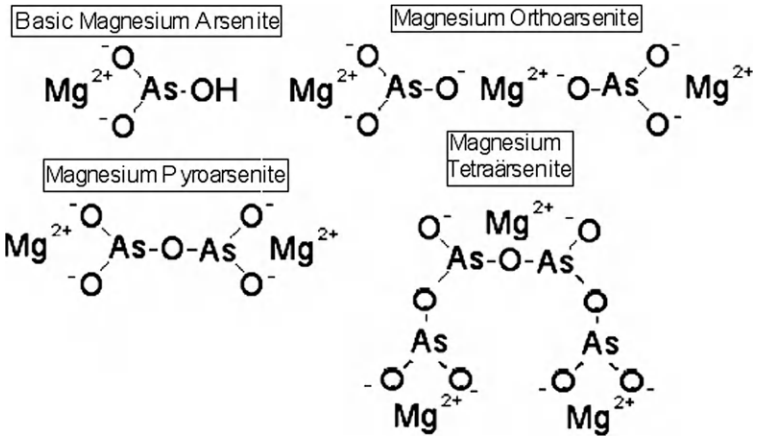

FIGURE 4.59

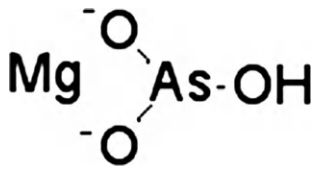

FIGURE 4.60

The monobasic salt, $Mg(H_2AsO_3)_2$ can be formed by the addition of $MgCl_2$ to an excess of arsenious acid or potassium arsenite and the evaporating the solution. The pH needs to around 10.5. Monobasic magnesium arsenite is soluble at 25 °C at 20 g/100 ml of water. Evaporation of the solution at low temperature (preferably vacuum evaporation) serves to form the hexahydrate. This salt, $Mg(H_2AsO_3)_2 \cdot 6H_2O$, when heated loses 5 waters of hydration at 105 °C and the other at 115 °C. Very little information is available concerning this salt. It is not listed in any textbooks and, with the exception of a few papers, the only references to it date back to the 1900s. Even Remi and Sidgewick do not categorize it. It has no CAS number and is not listed by any manufacturers for sale. Perhaps, this is due to the lack of knowledge regarding the requirement that the pH needs to be controlled. The pH data was not obtained and published until 2002.

Magnesium hydrogen arsenite forms a hydrate, $MgHPO_3 \cdot 0.5H_2O$ when precipitated from aqueous solution:

$$MgCl_2 + H_3AsO_3 \Rightarrow (MgHAsO_3)_2 \cdot H_2O + 2HCl$$

The solution is made neutral with sodium acetate. Ammonium arsenite forms the ammonium salt, $MgNH_4AsO_3$. Dibasic magnesium arsenite hemihydrate is essentially insoluble in water. Other hydrates include $MgHAsO_3 \cdot 5H_2O$ and $MgHAsO_3 \cdot 6.5H_2O$. Thus, the temperature of precipitation plays a large part in determining which hydrate forms. $(MgHAsO_3)_2 \cdot 13H_2O$ is formed at temperatures close to or less than 15 °C while the hemihydrate is obtained at 85 °C. If this salt is heated, it loses waters of hydration at about 85 °C and then at 120 °C. The exact sequence has not been studied intensively.

Magnesium orthoarsenite, $Mg_3(AsO_3)_2$, can be obtained as a white precipitate, easily soluble in water and in dilute acids, by adding a solution of magnesium chloride in 50% alcohol to a solution of potassium orthoarsenite made just neutral with acetic acid. The pH is around 13.5. Its molecular weight is 383.1666 g/mol. It is also formed when a solution of potassium tetraärsenite is added slowly to an aqueous solution of a magnesium salt. When heated in an inert atmosphere, the salt decomposes forming arsenious oxide and magnesium oxide:

$$Mg_3(AsO_3)_2 + \text{heat} \Rightarrow 3MgO + As_2O_3$$

Yet, this reaction is not reversible and the arsenite cannot be formed by reheating these ingredients together, either in an inert atmosphere or in air. However, if the mixture is heated in steam, then the reaction does occur. The mechanism of this reaction has not been studied in detail. This salt has found little usage in industry but is offered for sale by a number of manufacturers and suppliers, notably Chinese. It has no CAS number. There are few to no scientific publications that deal with this compound. Its physical properties like melting point have not been documented. This salt was described in the early work in the 1800s concerning inorganic salts. Since that time, the orthoarsenite of magnesium has received little attention for industry or academia. Very little information is available concerning this salt. It is not listed in any textbooks and, with the exception of a few papers, the only references to it date back to the 1900s. Even Remi and Sidgewick do not categorize it. It has no CAS number and is not listed by any manufacturers for sale.

Magnesium pyroarsenitc, $Mg_2As_2O_5 \cdot 4H_2O$, is a white, granular, hygroscopic, amorphous powder, soluble in water and dilute acids; on heating it undergoes decomposition and darkens in color. It is produced by the double decomposition between barium pyroarsenite and magnesium sulfate:

$$Ba_2As_2O_5\ (aq) + MgSO_4\ (aq) \Rightarrow Mg_2As_2O_5\ (aq) + BaSO_4\ (solid)$$

Crystals are formed when the filtered solution is evaporated. At low temperature, i.e. $<15\,^{\circ}C$, the 18-hydrate is obtained. At higher temperatures, the 13-hydrate and the 3-hydrate are also known, each a product of the crystallization temperature used. Like most of the magnesium arsenites, this salt has found little usage in industry but is offered for sale by a small number of manufacturers and suppliers, notably Chinese. It has no CAS number. There are few to no scientific papers which deal with this compound. Its physical properties like melting point have not been documented. This salt was described in the early work in the 1800s concerning inorganic salts. Since that time, the orthoarsenite of magnesium has received little attention for industry or academia.

Magnesium tetraärsenite, $Mg_3As_4O_9 \cdot 3H_2O$, is formed when a solution of magnesium sulfate or magnesia mixture is added to an aqueous solution of arsenious oxide or acid:

$$3MgSO_4\ (aq) + 4H_3AsO_3\ (aq) \Rightarrow Mg_3As_4O_9 \cdot 3H_2O\ (solid) + 3H_2SO_4$$

Very little information is available concerning this salt. It is not listed in any textbooks and, with the exception of a few papers, the only references to it date back to the 1900s. Even Remi and Sidgewick do not categorize it. It has no CAS number and is not listed by any manufacturers for sale. The metaarsenite can also be formed by adding a chloride slurry to sodium trimeta- or tetrameta-arsenite:

$$2MgCl_2 + Na_3(H_3AsO_{2n+1})_3 \Rightarrow 2Mg(H_3AsO_{2n+1})_3 + 6NaCl$$

Little is known in the literature or reference books concerning these salts. $MgHAsO_3$ is insoluble but whether it forms a hydrate remains unknown. The metaarsenites have not been studied extensively.

The above five salts of magnesium and arsenite ions have received little attention from academia and even less from industry. None of these compounds have found usage even though some of them are offered for sale commercially.

Calcium Arsenites

Divalent calcium forms the same type of arsenite compounds as its homologue, magnesium. The basic salt

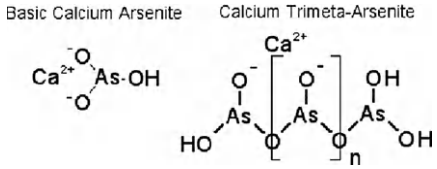

FIGURE 4.61

is $CaHAsO_3$ or $CaAsO_2(OH)$. It is referred to as a "metaarsenite" even though it is not polymeric (Fig. 4.61).

It is also known as: "calcium hydrogen arsonite" and **CAS Registry Number:** 52740-16-6. Synonyms: Calcium arsonite, Calcarin arsenicosa, Calcium arsenicosum, Calcium metaarsenite, Monocalcium arsenite, CALCIUM ARSENITE, Calcium arsenite (1:1), Calcium arsonate (1:1)".

Basic calcium arsenite can be prepared by adding a slurry of calcium hydroxide (slaked lime) to a solution of arsenious acid. The hydroxide dissolves and is basic enough to form the rather insoluble basic arsenite. The metaarsenite is formed by adding the same slurry to sodium trimeta- or tetrameta-arsenite:

$$CaCl_2 + H_3AsO_3 \Rightarrow CaHAsO_3$$

$$2CaCl_2 + Na_3(H_3AsO_{2n+1})_3 \Rightarrow 2Ca(H_3AsO_{2n+1})_3 + 6NaCl$$

Little is known in the literature or reference books concerning these salts. $CaHAsO_3$ is insoluble but whether it forms a hydrate remains unknown. The metaarsenites have not been studied extensively.

Calcium dihydrogen arsenite, $Ca(H_2AsO_3)_2$, is formed when excess of $Ca(OH)_2$ is added to an ammoniac solution of arsenious oxide, or when a solution of calcium chloride, is added to aqueous ammonium metarsenite, keeping the latter in excess. It is obtained as a white powder or as a gelatinous mass, and contains 5 to 11 waters of hydration. It is fairly soluble in water so that the solution must be evaporated to obtain crystals. The degree of hydration depends upon the temperature used during evaporation, the lower temperatures producing the highest degree of hydration. The pH should be slightly basic but if it becomes strongly acidic, no crystals will result during evaporation. A gelatinous mass results if the solution is strongly alkaline. It is insoluble in absolute alcohol and addition of ethyl alcohol aids in the crystallization process. Monobasic calcium arsenite has been used as an insecticide. It is soluble in water and can be sprayed onto plants. If sprayed on apricot, cherry or pear trees, it retards the ripening of the fruit. It has also been used in the manufacture of latex products. Its CAS number is 15194-98-6.

The ternary system $CaO–As_2O_3–H_2O$ was investigated at 0, 25, and 99 °C by the method wherein the

components were suspended in water and then heated. The pH was not controlled. The results indicated the formation of two arsenites, $CaHAsO_3$ and $Ca(H_2AsO_3)_2$. The former is a dibasic compound, calcium hydrogen arsenite, $CaHPO_3$, having the molecular weight of 120.0579 g/mol. It is slightly soluble in water (~1.2 g/100 ml), and practically insoluble in alcohol. It can also be prepared by adding H_3AsO_3 to a suspension of $Ca(OH)_2$ in water. It is well known that $CaHAsO_3$ is very stable under the high pH (12–13) values provided by lime water. The product is calcium arsenite monohydrate ($CaHPO_3 \cdot H_2O$). The CAS number of the $CaHAsO_3$ salt is 21056-98-4. That of the monohydrate is 138.073 g/mol. It is a colorless monoclinic crystal. Heating this salt to 150 °C causes the loss of the water of hydration. Its CAS number is 52740-16-6.

Calcium Metaärsenite, $Ca(H_2AsO_3)_2$, is an amorphous white powder, anhydrous at 100 °C, obtained by precipitation of calcium chloride with ammonium arsenite in ammoniac solution. It is also produced as a commercial preparation by the interaction of milk of lime and arsenious oxide with vigorous stirring at 100 °C, or by heating together at 60 to 70 °C arsenious oxide and slaked lime. The product produced is somewhat impure, containing calcium arsenate and a trace of free lime. Its solubility in water at 15 °C is about 0.044 to 0.051/100 ml. When strongly heated in an inert gas it decomposes, forming calcium and arsenious oxides and a little arsenic. This salt is best prepared by adding milk of lime to a sodium tri- or tetra-metaarsenite. The tetrameta salt may be considered to be a basic calcium metaarsenite polymer having the Lewis structure of Fig. 4.62.

Note that this compound is not the "monobasic" one but is related and differs in the number of hydroxyl groups present in the compounds structure. The general formula is $Ca_{n-2}(H_{2n}As_nO_{2n+1})_{2n-2}$.

Tribasic calcium arsenite can be formed by a solid-state reaction in which steam acts as a catalyst:

$$3CaO\ (solid) + As_2O_3\ (solid) + steam \Rightarrow Ca_3(AsO_3)_2\ (solid)$$

Apparently, the steam causes the formation of the hydroxide which is basic enough to cause the formation of the compound. If aqueous conditions are used where the concentrations of the reactants and the pH are much lower, then the dibasic salt, $CaHPO_3$ results.

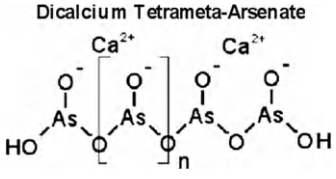

FIGURE 4.62

When mixtures of solid arsenious oxide and CaO are heated, reaction commences at about 300 °C and at 465 °C considerable heat is evolved and calcium orthoarsenite, $Ca_3(AsO_3)_2$, is formed. An industrial process for the manufacture of this compound consists of treating a dry mixture of quicklime (3 mol) and arsenious oxide (1 mol) with dry steam. It may also be obtained by precipitation of dilute calcium chloride solution with potassium orthoarsenite, 3 or of lime water (i.e. $CaCl_2$) with boiling aqueous arsenious acid. It is a white amorphous powder, which may be dried at 100 °C. It is only slightly soluble in water, but dissolves in acids. At red heat, it decomposes with volatilization of arsenic, leaving calcium arsenate. The latter is also formed when the arsenite is heated in oxygen. Its major usage in the past has been as an insecticide. Calcium arsenite ($Ca_3As_2O_6$) has a CAS number of 27152-57-4. Another is listed as 7778-44-1 while a third CAS number 52740-16-6 also exists. These CAS numbers may exist due to the method used to prepare the salt. Its molecular weight is 366.0748 g/mol.

Calcium Pyroarsenite, $Ca_2As_2O_5$, is a white powder obtained by slowly precipitating a solution of arsenious acid with excess of lime water, or by adding calcium chloride or sulfate to aqueous ammonia in the air at room temperature. The monohydrate is obtained. The pyroarscnite is only slightly soluble in water at 0.025 g/100 ml. It is more soluble in the presence of alkali chlorides and some ammonium salts, such as the nitrate, sulfate, acetate and succinate. It also dissolves in dilute acids. It has the CAS number of 13765-19-0. The pyroarsenite can also be prepared by firing arsenic trioxide with calcium hydroxide:

$$2Ca(OH)_2 + As_2O_3 + heat \Rightarrow Ca_2As_2O_5 + 2H_2O$$

A salt of composition $Ca_3As_4O_9 \cdot 3H_2O$, which may be regarded as consisting of three molecules of metaarsenite, $Ca\{AsO_2(OH)_2\}_2$, or as a derivative of a hypothetical tetraärsenous acid derived thus:

$$2As_2O_3\ (solid) + 6NH_4OH\ (solid) \Rightarrow H_6As_4O_9\ (solid) + 6NH_3\ (gas)$$

has been prepared by adding a solution of the corresponding potassium salt, $K_4H_2As_4O_9$, to a concentrated solution of calcium chloride. The white precipitate, after washing with alcohol, was dried in the air. At 100 °C, it loses one molecule of water. It is somewhat soluble in water. Very little is available in the literature concerning this salt. No description of its physical or chemical properties has been presented.

The above five salts of calcium and arsenite ions have received little attention from academia and even less

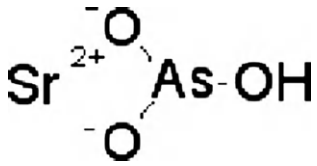

FIGURE 4.63

from industry. None of these compounds have found usage even though some of them are offered for sale commercially.

Strontium Arsenites

Strontium forms the same type of compounds expected for arsenious acid derivatives. The basic meta-arsenite has the formula, $Sr(As(OH)O_2)$ and the molecular weight of gm/mol. Its CAS number is 15195-06-9. It has the Lewis structure of Fig. 4.63.

Monobasic strontium arsenite can be prepared by heating a slurry of strontium hydroxide and adding a solution of arsenious acid:

$$Sr(OH)_2 + 2H_3AsO_3 \Rightarrow Sr(H_2PO_3)_2 + 2H_2O$$

The pH needs to be about 9.5–10.0. Strontium arsenite tetrahydrate, $Sr(H_2AsO_3)_2 \cdot 4H_2O$, has a molecular weight of 373.5234 g/mol and a CAS number of 10378-48-0. It is a white powder that is slightly soluble in H_2O but insoluble in EtOH. It is soluble in dilute acids. When heated, it loses two waters of hydration at 105 °C and the other two at 155 °C. The crystal structure of strontium dihydrogen phosphite, $Sr(H_2PO_3)_2$, contains eightfold-coordinated Sr ions connected by dihydrogenphosphite anions so that a layer structure is formed.

Tribasic strontium arsenite has the CAS number of 10378-48-0. Strontium arsenite is a white powder. It is slightly soluble in water. It is toxic by inhalation and by ingestion. Strontium arsenite is a white powder. It is slightly soluble in water. It is toxic by inhalation and by ingestion. An impure strontium orthoarsenite, containing more strontium that corresponds to the formula $Sr_3(AsO_3)_2$, was obtained as a white flocculent precipitate by treating strontium chloride solution with potassium orthoarsenite in the cold. The pH needs to be maintained around 13.5. Little is known about tribasic strontium arsenite. It is probably the most stable of this family of compounds. Yet, its physical properties have not been properly documented.

If the precipitate is dissolved in a dilute solution of acetic acid, on evaporation strontium hydrogen orthoarsenite, $SrHAsO_3 \cdot H_2O$, is obtained. Its CAS number is 15195-06-9.

Strontium Pyroarsenite. $Sr_2As_2O_5 \cdot 2H_2O$, may be prepared by adding an aqueous arsenious acid solution to strontium chloride dissolved in alcohol. The solution is filtered after standing for a time, and the white flocculent precipitate is dried at 100 °C. It is easily soluble in water and in acids. A better method is to fire the dibasic salt, $SrHAsO_3$ in a solid-state reaction under an inert gas atmosphere:

$$2SrHAsO_3 + \text{heat} \Rightarrow Sr_2As_2O_5 + H_2O$$

Little is known concerning this salt in the literature. It has not been studied extensively and is rarely mentioned for sale commercially. Although it is known to be rather insoluble, its physical properties have not been studied in detail.

Strontium dimetaärsenite, $Sr(H_3AsO_5)_{n=2}$, may be obtained as the tetrahydrate by the action of ammonium arsenite on a cold solution of a strontium salt. This salt has three hydroxy groups present and thus is a basic strontium arsenite. The precipitation is helped by the addition of alcohol, since the arsenite is fairly soluble in water. When dried at 100 °C it has the composition $Sr(H_3AsO_5)_{n=2} \cdot 3H_2O$. Further heating causes loss of hydrate water molecules at 120 and 150 °C. At higher temperatures, it decomposes to form strontium oxide, arsenious oxide and a little arsenic. Its CAS number is 91724-16-2. A salt, $Sr(HAsO_{2.5})_{n=2}$ (or $SrH_2As_2O_5$) is also possible but has not been documented. The trimeta- and tetrameta-salts, similar to those of Mg or Ca are not known.

The above five salts of strontium and arsenite ions have received little attention from academia and even less from industry. None of these compounds have found usage even though some of them are offered for sale commercially.

Barium Arsenites

Barium forms the same type of compounds with arsenite anions as the other alkaline earths. The most stable compounds are the dibasic and tribasic species, $BaHAsO_3$ and $Ba_3(AsO_3)_2$, respectively. In an investigation of the ternary system $BaO–As_2O_3–H_2O$ in which the two oxides in varying proportions were shaken with water at the temperatures 25 and 50 °C, the solution and solid phases were subsequently analyzed. Evidence of the formation of only two arsenites was obtained: a dibasic arsenite, $BaHAsO_3 \cdot 2H_2O$, and an arsenite of composition $3BaO \cdot 2As_2O_3 \cdot 4H_2O$ or $Ba_3(AsO_3)_2 \cdot 4H_2O$.

Tribasic barium arsenite, $Ba_3(AsO_3)_2$, has been prepared by the addition of potassium orthoarsenite to an aqueous solution of barium chloride and drying the precipitate at 100 °C in a current of hydrogen gas. The pH needs to at least 13.5. It is obtained as a white amorphous powder, readily soluble in hot water and in dilute

acids. When heated rapidly to about 730 °C in an inert atmosphere, it decomposed into arsenic and the arsenate. This is a double oxidation–reduction reaction in which part of the tribasic arsenite is oxidized and part reduced:

$$4Ba_3(AsO_3)_2 + \text{heat} \Rightarrow 12BaO + 4As_2O_3 + 4As$$
$$4As_2O_3 \Rightarrow 2As_2O_5 + 4As + 2O_2$$
$$4Ba_3(AsO_3)_2 + \text{heat} \Rightarrow 12BaO + 2As_2O_5 + 8As + 2O_2$$

Slow heating below 300 °C causes loss of arsenious oxide if heated in hydrogen or arsenic pentoxide if heated in air:

$$Ba_3(AsO_3)_2 + \text{Heat } (H_2) \Rightarrow 3BaO + As_2O_3$$

The monobasic salt, barium dihydrogen arsenite, $Ba(H_2AsO_3)_2$, can be obtained:

(1) by adding an excess of barium hydroxide to aqueous arsenious acid,
(2) by treating an ammonical solution of arsenious oxide with excess of barium chloride,
(3) by adding potassium pyroarsenite to a barium chloride solution and adjusting the solution pH to around pH = 10.5. The solution is then evaporated at a low temperature to recrystallize the salt.

This salt has the CAS number of 125687-68-5 and the molecular weight of 657.82 g/mol. In (1), the hydroxide is basic enough to afford the formation of the monobasic salt that is then obtained by low temperature evaporation of the solution. Very little is known concerning this salt and few papers are available in the literature. Even the contemporary reference books like Remy or Sidgwick do not mention it. The only references known date back to the middle 1800s and the data found there are probably not reliable. Barium dihydrogen arsenite is said to form a dihydrate when it is prepared from aqueous solution. It was observed to lose waters of hydration when exposed to air. The loss of water from this compound has never been studied. It is slightly soluble in cold water, more readily in hot water, the solution having a slightly alkaline reaction.

The dibasic salt is to be regarded as $BaHAsO_3$. It is best prepared from a solution of arsenious acid whose pH has been adjusted to about 12.5 with potassium acetate. If the precipitate is dried at low temperature, it has been determined that an octahydrate results. If dried at 100 °C, the dihydrate, $BaHAsO_3 \cdot 2H_2O$, is the stable compound. This salt has no CAS number and there is no registered supplier or manufacturer of this salt. The molecular weight is 261.2577 g/mol.

Barium pyroarsenite, $Ba_2As_2O_5$, is best prepared by heating barium hydrogen arsenite in an inert atmosphere at about 450 °C:

$$2BaHAsO_3 + \text{heat} \Rightarrow Ba_2As_2O_5 + H_2O$$

Very little is known concerning this salt and few papers are available in the literature. Even the current reference books like Remy or Sidgwick do not mention it. The only known references date back to the middle 1800s and the data found there is probably not reliable.

Barium metaärsenite, $Ba(H_3AsO_3)_{n=2}$, may be obtained as the tetrahydrate by the action of ammonium arsenite on a cold solution of a barium salt. This salt has three hydroxy groups present and thus is a basic barium arsenite. The precipitation is helped by the addition of alcohol, since the arsenite is fairly soluble in water. When dried at 100 °C it has the composition $Ba(H_3AsO_3)_{n=2} \cdot 3H_2O$. Further heating causes loss of hydrate water molecules at 105 and 130 °C. At higher temperatures, it decomposes to form barium oxide, arsenious oxide and a little arsenic. It has no CAS number.

The tetrameta-arsenite would have the Lewis structure of Fig. 4.64.

Where $n = 4$. The dimeta salt (which is the beginning of the series) would have the formula: $Ba(AsO_3(OH)_2)$. Early work (1844–1850) tried to prepare barium metaarsenite by warming barium chloride with a solution ammonium arsenite to which acetic acid had been added until arsenious acid was on the point of precipitation. The precipitate was then dried at 100 °C. It was said to be a white powder, easily soluble in water, but it was also obtained as a gelatinous mass when a mixture of barium chloride and potassium trimetaarsenite in solution was left to stand for a few hours. It is not clear what the degree of polymerization was in these preparations and they deserve further study.

The above five salts of barium and arsenite ions have received little attention from academia and even less from industry. None of these compounds have found usage in industry even though some of them are offered for sale commercially.

Radium Arsenites

Radium is expected to form the same type of compounds as the Sr and Ba homologues. That is, the monobasic-, dibasic- and tribasic compounds could be prepared using arsenious acid and radium hydroxide or oxide. The solution pH would have to be adjusted to: pH = 10.5, 12.5 or pH = 13.5 with potassium acetate and ammonia to obtain the corresponding arsenites.

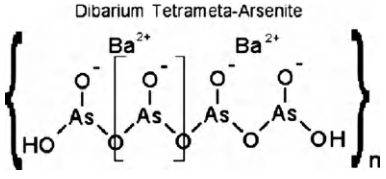

FIGURE 4.64

The pyroarsenite could be obtained by firing the dibasic salt, radium hydrogen arsenite in a solid-state reaction. The metaarsenite compounds could be obtained using the potassium metaarsenite compounds. However, there is absolutely no record of such work to be found in the scientific literature. Even the notable references books such as the CRC "Handbook of Chemistry and Physics" do not list such compounds. Of course, no early work exists since radium was not discovered until after the year 1900.

4.3.4. Alkaline Earth Orthoarsenates

Arsenious acid, H_3AsO_3, [As(III)] behaves as a monobasic acid and arsenic acid [As(V)] behaves as a tribasic acid. It is for this reason that arsenious acid shows quite different areas of pH stability than the corresponding phosphorous acid, H_2PO_3. Arsenic acid has ionization constants in aqueous solution very close to that of phosphoric acid, H_3PO_4:

$$H_3AsO_4 \Rightarrow H_2AsO_4^- + H^+ \ (pK_1 = 10^{-2.19})$$

$$H_2AsO_4^- \Rightarrow HAsO_4^{2-} + H^+ \ (pK_2 = 10^{-6.94})$$

$$HAsO_4^{2-} \Rightarrow AsO_4^{3-} + H^+ \ (pK_3 = 10^{-11.5})$$

These K_a values are close to those for phosphoric acid. Thus, the areas of pH stability are shown in the following Fig. 4.65.

The dotted lines show the area of greatest stability for the three states of ionization.

Beryllium Arsenates

Beryllium arsenate salts are less stable than those of magnesium and readily form basic salts. This is due to the fact that Be^{2+} preferentially forms hydroxy complexes of the type, $Be(OH)^+$ in association with water molecules. Species such as $Be_2(OH)^{3+}$ and $Be_3(OH)_3^{2+}$ are known to exist. The hydroxylation reaction has been given as:

$$xBe^{2+} + yH_2O \Rightarrow Be_x(OH)_y^{(2x-y)+} + yH^+$$

where x and y can vary from 1 to 8. Species such as $Be_3(OH)_7^{3+}$ and $Be_4(OH)_8^{4+}$ are known. Thus, the prior literature may be in doubt as to exact formulas for beryllium compounds prepared from aqueous solutions.

Beryllium orthoarsenate, $Be_3(AsO_4)_2 \cdot 15H_2O$, is obtained by drying in air the precipitate formed on mixing aqueous solutions of sodium monohydrogen arsenate and beryllium sulfate. The pH is maintained at 13.5. The precipitate itself is probably beryllium monohydrogen ortho-arsenate, $BeHAsO_4$, but this is readily hydrolyzed and unless immediately removed from the solution forms the tribasic salt, $Be_3(AsO_4)_2 \cdot 15H_2O$.

Dibasic beryllium arsenate has been obtained in the form of a dihydrate, $BeHAsO_4 \cdot 2H_2O$, as a viscous solid by dissolving beryllium hydroxide in arsenic acid and then precipitating with alcohol, and in the anhydrous form by heating arsenic pentoxide and beryllium hydroxide together in a sealed tube at 220 °C.

Beryllium dihydrogen orthoarsenate, $Be(H_2AsO_4)_2$, is obtained as colorless hygroscopic platelets by the action of a hot saturated solution of arsenic acid on beryllium hydroxide and vacuum evaporation.

By stirring beryllium oxide or carbonate with aqueous arsenic acid under carefully regulated conditions of concentration, acidity and temperature, two arsenates of definite composition have been isolated in a crystalline state, namely, $Be_4As_2O_9 \cdot 9H_2O$ and $Be_4As_2O_9 \cdot 10H_2O$. These are probably pyro-beryllium arsenates containing the hydroxy-Be cation (Fig. 4.66).

Thus, the correct formula is probably $(BeOH)_4As_2O_7 \cdot 6H_2O$ (hexahydrate or heptahydrate). The physical properties of this compound have never been documented or examined systematically.

The high-temperature/high-pressure hydrothermal synthesis and X-ray single-crystal structure of $Be_3(AsO_4)_2 \cdot 2H_2O$ has been described. The compound contains a three-dimensional network of BeO_4− and AsO_4-tetrahedra. Its structural motif includes infinite layers of "bridged" tetrahedral 3- and 4-rings. ^{9}Be NMR data are consistent with those derived from Be atom environments in the crystal structure (lattice parameters are: $Be_3(AsO_4)_2 \cdot 2H_2O$, molecular weight = 170.4528 g/mol), monoclinic, space group = C2/c,

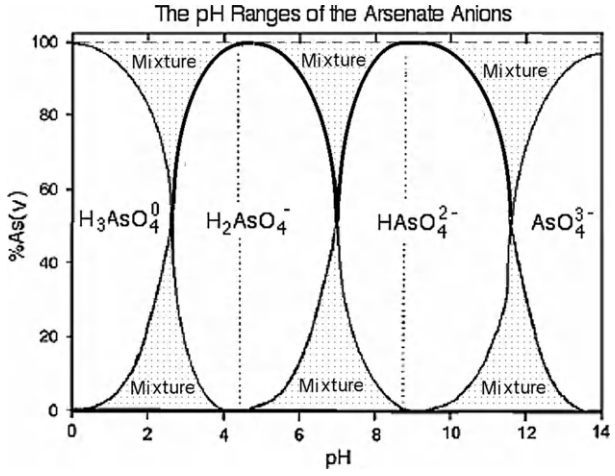

FIGURE 4.65

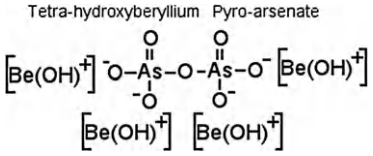

FIGURE 4.66

$a = 16.318$ Å, $b = 4.6664$ Å, $c = 9.8755$ Å, $\beta = 93.777°$, $V = 750.37$ Å^3, $Z = 4$).

This compound was prepared by a high-temperature/high-pressure hydrothermal reaction. $Be(OH)_2$, H_2O and H_3AsO_4 solution were sealed in a gold tube and heated to 550 °C for 135 h. Upon cooling, numerous needle- and shard-like crystals were recovered from the mother liquor (pH = 2) by vacuum filtration. $Be_3(AsO_4)_2 \cdot 2H_2O$ is built up from BeO_4 and AsO_4 subunits. This connectivity of tetrahedral nodes in $Be_3(AsO_4)_2 \cdot 2H_2O$ leads to a three-dimensional network, built up from infinite b···c plane layers of As(l) and Be(2) tetrahedral groups, which are linked together by the Be(1) groups. The As(1)/Be(2) layers are built up from infinite tetrahedral "bridged" 3- and 4-rings. The "backbone" of the layer is an edge-sharing chain of 4-rings, each of configuration L-[Be(2)–As(1)–Be(2)–As(l)]-J, which propagates in the *b*-direction. Adjacent 4-ring chains are fused together by 3-rings (configuration L-[Be(2)–As(1)–Be(2)]-J), which are fused edge-to-edge themselves, resulting in an infinite sheet structure. A notable feature of this connectivity is the fact that each Be(2) atom makes contact with *six* nearest-neighbor tetrahedral atoms [four distinct As(1)'s and two distinct Be(2)'s], and each As(l) atom bonds to six different Be(2) atoms.

The following diagram does not show the water molecules (for the sake of simplicity) (Fig. 4.67).

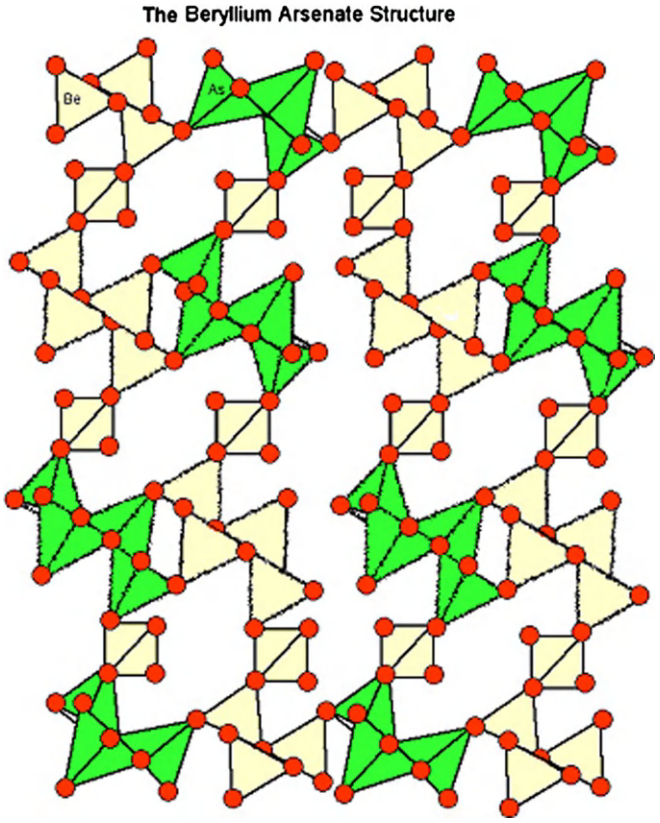

FIGURE 4.67

In another paper, $(BeOH)_2(AsO_4)_2OH \cdot 3H_2O$ was found to contain 3-ring groupings of tetrahedra as part of a one-dimensional chain of $(BeOH)AsO_4$ groups. Crystal data for this compound were: MW = 246.0124 g/mol, monoclinic, space group = $P2_1/a$, Unit cell: $a = 7.2349$ Å, $b = 12.6861$ Å, $c = 8.6545$ Å, $\beta = 98.439°$, $Z = 4$. The compound contains 1-dimensional stacks of interconnected BeO_4 and AsO_4 tetrahedra, including alternating 3-ring and 4-ring groups, the former containing Be···OH···Be bonds. The tetrahedral columns are connected by water molecules via a network of H-bonds.

Although studies of the tribasic beryllium orthoarsenate compound have been conducted, there has been no systematic investigation of the other arsenates of Be, including the basic-, monobasic-, dibasic, pyro- and metaarsenates. No data exists except that of early work whose results are subject to interpretation.

None of these compounds have CAS numbers and there is no record of them having been recently prepared. Little interest has resulted in industry or academia and they are not offered for sale commercially.

Magnesium Arsenates

Magnesium forms the same sequence of ortho-arsenates as the ortho-phosphates. Tribasic magnesium arsenate ($As_2Mg_3O_8$), has the CAS number 13464-38-5 while that of dibasic magnesium arsenate trihydrate, $MgHAsO_4 \cdot 3H_2O$, is 7757-86-0.

Magnesium forms a dibasic salt, $MgHAsO_4 \cdot H_2O$, that is insoluble in water:

$$MgCl_2\ (aq) + Na_2HAsO_4\ (aq) \Rightarrow MgHAsO_4 \cdot H_2O\ (solid)$$

The pH needs to be about 9.0. Other hydrates include $MgHAsO_4 \cdot 5H_2O$. Thus, the temperature of precipitation plays a large part in determining which hydrate forms. $(MgHAsO_3)_2 \cdot 8H_2O$ is formed at a temperature close to or less than 15 °C while the monohydrate is obtained at 85 °C. If this salt is heated in air, it loses waters of hydration at about 85 °C and then at 120 °C. The mode of dehydration of the octa-hydrate salt has never been documented.

In another method, magnesium monohydrogen orthoarsenate, $MgHAsO_4 \cdot 7H_2O$, was said to have been prepared by adding a calculated amount of magnesium sulfate to a solution of sodium monohydrogen arsenate neutralized with acetic acid. The amorphous precipitate was kept in contact with the solution for some days, during which time it became crystalline. It loses water when heated. The hepta-hydrate occurs in Nature as "Rösslerite" or "Roesslerite", a fibrous mineral consisting of monoclinic crystals with $a : b : c = 0–4473:1:0.2598$ and $\beta = 94°\ 26'$. A hemihiydrate, $(MgHAsO_4)_2 \cdot H_2O$ is obtained in the form of prismatic crystals by heating

Rösslerite
("Im Lochborn") Copper
mine, Bieber, Gelnhausen,
Spessart, Hesse, Germany

FIGURE 4.68

a solution of magnesium carbonate in excess of arsenic acid at 225 °C in a sealed tube (Fig. 4.68).

$MgHAsO_4 \cdot 4H_2O$ or "Brassite", which may occur as a dehydration product of "Rösslerite", crystallizes in the monoclinic system with Space Group C2/c and $a = 6.6918$ Å, $b = 25.744$a, $c = 11.538$ Å, $\beta = 95.15°$, $Z = 8$. The two crystallographically independent Mg-atoms are coordinated by 6 water molecules. The seventh water molecule is linked by hydrogen bonds only. No oxygen atoms are shared by coordination polyhedra and the crystal structure can be described in terms of layers parallel to (010) or to (001) lattice directions.

$MgAsO_3(OH) \cdot 4H_2O$ may recrystallize in the orthorhombic system with $a = 7.47$ Å, $b = 10.89$ Å, $c = 16.58$ Å, Space Group = Pbca, point group = 2m 2m 2m, $Z = 8$, Unit cell volume: V =1348.75 Å^3 and density = 2.326 g/cm^3. The structure is built up with $AsO_3(OH)$ tetrahedral linked together with $MgO_2(H_2O)_4$ octahedra to make chains parallel to (010). A two-dimensional net of hydrogen bonds between tetrahedral and octahedral belonging to different chains exists. They include O···O and O···H_2O bonds define layers parallel to (001).

Tribasic magnesium orthoarsenate may be obtained in various hydrated forms. When solutions containing equivalent quantities of magnesium sulfate and normal sodium ortho-arsenate are mixed, an amorphous precipitate forms which, on prolonged keeping in contact with the solution, becomes crystalline. Upon drying at 100 °C, the composition $Mg_3(AsO_4)_2 \cdot 2H_2O$ results:

$$MgSO_4\ (aq) + Na_3AsO_4\ (aq) \Rightarrow Mg_3(AsO_4)_2 \cdot 2H_2O\ (solid)$$

The crystals are monoclinic and isomorphic with the corresponding phosphate. The density at 15 °C is 1.788 g/mol, and the indices of refraction along the three axes $x = 1.548$ to 1–563, $z = 1.556$ to 1.571 and $y = 1.574$ to 1.596. The octahydrate, $Mg_3(AsO_4)_2 \cdot 8H_2O$, is obtained by mixing aqueous solutions of magnesium sulfate, sodium monohydrogcn arsenate and sodium bicarbonate and keeping the amorphous precipitate in contact with the solution for 24 h, when it becomes crystalline:

$$MgSO_4\ (aq) + Na_2HAsO_4\ (aq) \Rightarrow Mg_3(AsO_4)_2 \cdot 8H_2O\ (solid) + Na_2SO_4\ (aq)$$

$Mg_3(AsO_4)_2 \cdot 8H_2O$ has the molecular mass of 494.9458 g/mol and the CAS number of 10103-50-1. This hydrate is found in Nature as the mineral "Hornesite", the crystals of which are monoclinic and probably isomorphic with "Vivianite". The density of the mineral is 2.474 g/cm^3; that of the artificially prepared product is 2.609 g/cm^3. The mineral, "Roselite", $Ca_2(Co,Mg)(AsO_4)_2 \cdot 2H_2O$, is a beautifully colored mineral and varies from rose-red to pink. It would be a misguided assumption that its name came from its color. In fact it is named for a Germany eighteenth century mineralogist, Gustav Rose. The color of Roselite comes from the same coloring agent of many different colorful minerals, namely cobalt. Hoernesite [$Mg_3(AsO_4)_2 \cdot 8H_2O$] was originally found in arsenic-contaminated soils and in toxic waste sites. The solubility of this mineral is poorly known, but it must be not much different from the value determined for tribasic compound.

The heptahydrate, $Mg_3(AsO_4)_2 \cdot 7H_2O$, is obtained if sodium dihydrogen arsenate is substituted for the monohydrogen salt in the above preparation. The decahydrate, $Mg_3(AsO_4)_2 \cdot 10H_2O$ is formed when potassium or ammonium magnesium orthoarsenate is digested with water for several hours. On dehydration, hydrates containing 6. 5, 3, 2 and 2 can be obtained. The anhydrous salt decomposes when heated above 1100 °C in a vacuum, MgO, As_2O_3 and O_2 being formed.

A light form of magnesium arsenate may be obtained by heating a slurry of magnesium hydroxide with the theoretical quantity of arsenic acid and 15% of the equivalent amount of sodium hydroxide in an autoclave at 180 °C until the filtrate contains less than 0.2% of arsenic pentoxide. The solubility of magnesium arsenate is 5×10^{-5} mol/l. The solubility product constant is: $K_{SP} = 2 \times 10^{-20}$ for $Mg_3(AsO_4)_2$. The crystal structure of the anhydrate, $Mg_3(AsO_4)_2$, has been solved. It is tetragonal with: $a = 6.783$ Å, $c = 18.963$ Å, $V = 842.7$ Å^3, $Z = 6$ and space group = I $\bar{4}$ 2d. Crystals were obtained from a melt of $MgCO_3$ and As_2O_5 at 1450 °C. The structure contains two distinct AsO_4 groups with average bond lengths of 1.678 and 1.690 Å, respectively. Two of the three Mg ions are octahedrally coordinated and it is the third that occupies a site of $\bar{4}$ symmetry.

Atomic parameters for $Mg_3As_2O_8$

U_{ij}'s in Å² are computed from $\beta_{ij}=2\pi^2 b_i b_j U_{ij}$ where $T=\exp\{-[\beta_{11}h^2+2\beta_{12}hk+\ldots]\}$ appears in the structure-factor expression and b_j are reciprocal-lattice cell vectors.

FIGURE 4.69

The coordinates of the Mg, As and O atoms in the unit cell are shown in the following table labeled "Atomic parameters for $Mg_3As_2O_8$" (Fig. 4.69).

Stability diagrams derived for $Ca_3(AsO_4)_2$ and $Mg_3(AsO_4)_2$ show the comparatively high solubility of such compounds. The presence of CO_2 in the air has a pronounced effect in greatly increasing the water solubility of $Ca_3(AsO_4)_2$ and significantly affecting that of $Mg_3(AsO_4)_2$.

The relative stabilities of solid Ca and Mg arsenates were established by solubility experiments from the pH range and total aqueous Ca, Mg and As concentrations. The experimental data were consistent with the following solid phases defined as a function of the pH range:

$$Ca_3(AsO_4)_2\cdot 10H_2O \quad (7 < pH < 10)$$
$$CaNaAsO_4\cdot 7.5H_2O \quad (10 < pH < 12)$$
$$MgHAsO_4\cdot 4H_2O \quad (6.5 < pH < 7.1)$$
$$Mg_3(AsO_4)_2\cdot 8H_2O \quad (7.2 < pH < 9)$$

All the experimentation was performed at constant ionic strength in aqueous $NaClO_4$ solutions and at 25 °C, where the stoichiometric solubility products of the different solids were calculated. The corresponding thermodynamic solubility products of all the precipitates were computed by means of the Modified Bromley's Methodology that considers the variation of the activity coefficients of the ions involved in the precipitation equilibria with the medium and ionic strength. Moreover, all the solid arsenates obtained were characterized by FT-IR and FT-Raman spectroscopy and the hydration of each precipitate was confirmed by XRD data.

Several double arsenates of magnesium and the alkali metals, ammonium and calcium are known. The most important of these is magnesium ammonium ortho-arsenate, $MgNH_4AsO_4\cdot 6H_2O$ that is obtained as a crystalline precipitate when ammonium ortho-arsenate is added to a solution of a magnesium salt. It may be dried over sulfuric acid. It is also formed when an alkali arsenate is added to a solution of a magnesium salt in the presence of an ammonium salt and ammonia. When heated above 40 °C it loses ammonia and water. It is doubtful if any lower hydrate can be formed, although such are described in the literature. If heated above about 450 °C, it forms the pyroarsenate:

$$2MgNH_4AsO_4\cdot 6H_2O + \text{Heat} \Rightarrow Mg_2As_2O_7 + 2\,NH_3 + 14H_2O$$

Magnesium pyroarsenate, $Mg_2As_2O_7$, is monoclinic with space group C2/m.

It also forms a double salt with Ba^{2+}, as $BaMgAs_2O_7$ having the crystal structure parameters of: $a = 5.620$ Å, $b = 8.629$ Å, $c = 13.344$ Å, $\beta = 90.20°$, $V = 647.1$ Å^3, space group $P2_1/n$, $Z = 4$.

A number of magnesium ortho-arsenate minerals are known. Among these are:

$$\text{Manganberzeliite (TL)} = (Ca,Na)_3(Mn^{2+},Mg)_2[AsO_4]_3$$
$$\text{Manganohörnesite (TL)} = (Mn,Mg)_3(AsO_4)_2\cdot 8H_2O$$
$$\text{Guanacoite} = (Cu_{0.85}Mg_{0.15})_2Mg_2\,(Mg_{0.83}Cu_{0.17})(OH)_4(H_2O)_4(AsO_4)_2$$
$$\text{Arsenostruvite} = MgNH_4AsO_4\cdot 6H_2O$$

Magnesium dihydrogen orthoarsenate, $Mg(H_2AsO_4)_2$, has been described as a very deliquescent crystalline mass obtained by dissolving magnesium oxide in aqueous arsenic acid. The pH is set at 4.5 by the addition of ammonium acetate. A monohydrate results. It is soluble in water. To prepare the pyroarsenate, the dibasic compound is calcined at about 450 °C. If it is fired in air, it first decomposes to form the anhydrate at 150 °C and then the dimeta-arsenate between 200 and 206 °C and finally the pyro-arsenate at >600 °C.

A di-hydrate of the pyroarsenates, $Mg_2As_2O_7\cdot 2H_2O$ (dimagnesium diarsenic heptaoxide dihydrate) and $Zn_2As_2O_7\cdot 2H_2O$ (dizinc diarsenic heptaoxide dihydrate), have been synthesized. The two compounds are isotypic. Their frameworks are characterized by zigzag

infinite chains of edge-sharing MO_6 octahedra linked by As_2O_7 groups to form a three-dimensional architecture with intersecting tunnels. Water O-atoms are tightly bound to the Mg or Zn atoms with the H atoms directed into the tunnels. Both the MO_6 octahedra and the AsO_4 tetrahedra are more distorted in the zinc compound than in the magnesium compound.

To prepare the metaarsenate compounds, the monobasic compound is calcined at about 550 °C:

$$2Mg(H_2AsO_4)_2 + \text{heat} \Rightarrow Mg_2(AsO_3)_2 + 2H_2O$$

A tetrameric compound is said to be obtained, $Mg_2As_4O_{12}$ or a higher polymeric species such as $Mg_2(AsO_3)_6$. Very little is known concerning the metaarsenate compounds. Three different forms of condensed magnesium arsenatophosphates have been described but not that of the pure magnesium metaärsenates. One of these was the (As,P) analog of high-molecular magnesium polyarsenate, $[Mg(AsO_3)_2]_x \cdot H_2O$. A second form resembles the cyclic magnesium tetrametaphosphate, and a third one is either another modification of this tetrameta-arsenatophosphate or a salt with chain-like anions having an approximately regular As–P distribution. The Lewis structure of the magnesium tetrameta salt has been given as a cyclic one, rather than a linear chain as described for the calcium metaärsenate salt (Fig. 4.70).

Obviously, the exact formula depends upon the Mg/As ratio found in the metaarsenate compound. The only papers to be found date back to the 1950s.

A new compound, hepta-magnesium bis(arsenate) tetrakis(hydrogenarsenate), $Mg_7(AsO_4)_2(HAsO_4)_4$, was synthesized by a hydrothermal method. The structure is based on a three-dimensional framework of edge- and corner-sharing MgO_6, $MgO_4(OH)_2$, MgO_5, $AsO_3(OH)$ and AsO_4 polyhedra. Average Mg–O and As–O bond lengths are in the ranges 2.056–2.154 and 1.680–1.688 Å, respectively. Each of the two nonequivalent OH groups is bonded to both an Mg and an As atom. One OH group is involved in a very short hydrogen bond [OO = 2.468 (3) Å]. The formula unit is centro-symmetric, with all atoms in general positions except for one Mg atom, which has site symmetry. The compound is isotypic with $Mn_7(AsO_4)_2(HAsO_4)_4$ and $M_7(PO_4)_2(HPO_4)_4$, where M is Fe, Co or Mn. **Formula:** $Mg_7(AsO_4)_2(HAsO_4)_4$.

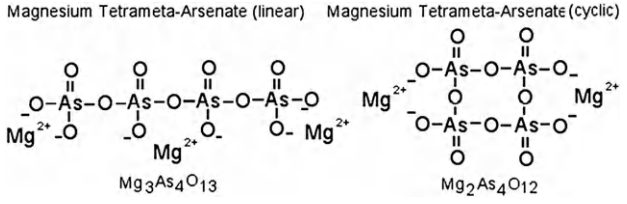

FIGURE 4.70

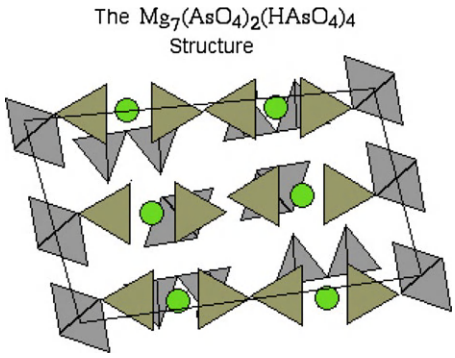

FIGURE 4.71

The structure is shown in (Fig. 4.71).

Single crystals of magnesium arsenate have been grown from a PbO–As_2O_5 eutectic by flux crystallization of a ceramic preparation having an initial composition of $6MgO \cdot As_2O_5$. The crystals are rhombohedral, space group P2/a, with hexagonal unit-cell parameters $a = 6.0278$ Å and $c = 27.600$ Å. The structure analysis indicated that magnesium arsenate has the composition $Mg_{8.5}As_3O_{16}$ and is isostructural with the previously reported $Co_8As_3O_{16}$. The structure is based upon a cubic close-packed oxygen array with charge balance achieved in magnesium arsenate through partial occupancy of a unique magnesium site occurring in an arsenic-substituted MgO-type layer.

In the system MgO–As_2O_5, there is a compound of the composition $6MgO \cdot 1As_2O_5$ or $Mg_6As_2O_{11}$. Products containing small concentrations of manganese show fluorescence upon excitation by cathode rays or by ultra-violet radiation. The band emitted depends on the valence of the manganese. Divalent manganese causes fluorescence in a broadband in the green, with a maximum at 5050 Å. Tetravalent manganese causes a red fluorescence in a band consisting of five narrow subbands at 6200, 6300, 6400, 6500 and 6580 Å. Both bands decay exponentially; the time constant at room temperature is 130/ms for the green band and 360/ms for the red band. For the red luminescent systems, the spectral distributions of the absorption, excitation and fluorescence and the temperature dependence of the intensity of the fluorescence, the fluorescence spectrum and the decay constant have been determined and a quantitative representation of several of these quantities has been given. This system has been studied intensively in a number of publications.

A number of United States patents cover processes for the manufacture of magnesium arsenates for use as insecticides. The magnesium arsenates tested as insecticides consisted generally of the dibasic magnesium arsenate, $MgHAsO_4$, the tribasic magnesium arsenate, $Mg_3(AsO_4)_2$, or the pyro-arsenate, $Mg_2As_2O_7$, with varying amounts of water of crystallization and excess

magnesium oxide or hydroxide. These magnesium arsenates have been tested against a large number of insects affecting fruits and vegetables and at one time were recommended for the control of the Mexican Bean Beetle but their use has declined due to the toxicity of As.

Various magnesium arsenates are available commercially but it is the dibasic and tribasic salts that are used in industry because of their relative stability.

Calcium Arsenates

In a basic form, calcium arsenate is an important commercial product and is used in the form of a spray or dust as an insecticide for plants. The commercial arsenates are usually mixtures and exhibit a wide variation in chemical and physical characteristics. The system $CaO–As_2O_5–H_2O$ has been investigated at various temperatures, and under various equilibrium data.

Microscopic and X-ray examination show that the following compounds are the most stable in water:

$$CaHAsO_4$$
$$Ca_5OH(AsO_4)_4\cdot 5H_2O$$
$$Ca_3(AsO_4)_2\cdot 2H_2O$$

The phase diagram for the ternary system $CaO–As_2O_5–H_2O$ at $23\pm1\,^{\circ}C$ has been determined. The calcium arsenates represented therein are:

$$Ca(H_2AsO_4)$$
$$CaHAsO_4\cdot H_2O$$
$$Ca_5H_2(AsO_4)_4\cdot 9H_2O$$
$$Ca_3(AsO_4)_2\cdot xH_2O\ (x=2/3 \text{ and } 3/4)$$
$$Ca_5(AsO_4)_3OH \text{ (apatite)}$$
$$Ca_4(OH)_2(AsO_4)_2\cdot 4H_2O$$

The solubility data indicate the following invariant points:

$$Ca(H_2AsO_4)_2–CaHAsO_4\cdot H_2O—\text{solution}$$
$$CaHAsO_4\cdot H_2O–Ca_5H_2(AsO_4)_4\cdot 9H_2O—\text{solution}$$
$$Ca_5H_2(AsO_4)_4\cdot 9H_2O–Ca_3(AsO_4)_2\cdot 41/4H_2O—\text{solution}$$
$$Ca_3(AsO_4)_2\cdot 31/3H_2O–Ca_4(OH)_2(AsO_4)_2\cdot 4H_2O—\text{solution}$$
$$Ca4(OH)_2(AsO_4)_2\cdot 4H_2O–Ca(OH)_2–\text{solution}.$$

The tricalcium arsenate, $Ca_3(AsO_4)_2\cdot 31/3H_2O$, or $[Ca_3(AsO_4)_2]_3\cdot 4H_2O$ was shown to be the only hydrate to dissolve congruently. The solubility of tribasic calcium arsenate dihydrate, precipitated at pH 7.0 and its dissolution in aqueous solutions at temperatures of 35, 40, 45 and 50 °C and a pH of between 3.0 and 8.0 was investigated. Temperature dependence of solubility is obtained by the equation:

$$-\log K_{TCA} = 9078.138/T - 34.0468 + 0.0821421\,T$$

where T is K. At 20 °C, its solubility is 0.0756 g/100 ml.

The normal salt, calcium orthoarsenate, $Ca_3(AsO_4)_2$, may be obtained by the action of lime water or milk of lime, $(Ca(OH)_2)$, on arsenic acid, or by addition of aqueous calcium chloride to aqueous sodium monohydrogen arsenate. In the latter case, if the solutions are alkaline (~pH = 9.0), a product of a high degree of purity is obtained. Drying at 100 °C gives the dihydrate, $CaHAsO_4\cdot 2H_2O$, which loses its water of crystallization at 175 °C. The anhydrous salt melts at 1455 °C. It is reduced by hydrogen at 400–450 °C to calcium oxide, arsenic and water. The density of the dihydrate is 3.28 g/cm^3, and of the anhydrous salt 3.62 g/cm^3. The solubility of the latter at 25 °C is 0.0133 g/100 ml of water. A mineral, "Adelite" [$CaMgAsO_4(OH)$] is known.

The commercial product made in the past was usually obtained either by adding arsenic acid to partly slaked lime containing sufficient quicklime to combine with the free water, thus yielding a dry product, or by heating a mixture of lime and white arsenic in the presence of an oxidizing medium, such as oxygen, chlorine or nitrates. It is essential that the product should contain a minimum of soluble arsenic and that the presence of the more soluble acid arsenates should be avoided. The commercial arsenate is generally slightly basic. Its actual composition is generally not known and varies from manufacturer to manufacturer. The results of analyses of 16 samples showed that the total As_2O_5 ranged only from 40.3 to 44.4% [As_2O_5 in $Ca_3(AsO_4)_2 = 57.7\%$], and the average molecular quotient CaO/As_2O_5 was 3/4. The average commercial product contains 80–85% of what is probably a mixture of the normal tribasic arsenate and a basic arsenate, probably $4CaO\cdot As_2O_5$, together with about 6.5% each of calcium hydroxide and calcium carbonate, and small quantities of other impurities. If varying quantities of arsenic acid are added to a saturated solution of lime, the ratio of $CaO:As_2O_5$ in the precipitate shows a continuous variation according to the quantity of arsenic acid added. Under these conditions, there is no evidence of the real existence or formation of tribasic calcium arsenate, $Ca_3(AsO_4)_2$.

The calcium arsenate that is sold commercially today as an insecticide is not a single chemical compound but a complex mixture of several calcium arsenates and an excess of calcium hydroxide. The material is made from arsenic trioxide by first oxidizing it to arsenic pentoxide with nitric acid and then reacting the solution of arsenic pentoxide or arsenic acid with a slurry of calcium hydroxide. The conditions of temperature,

concentration, and duration of reaction are important because of their influence on the physical nature of the product.

Commercial calcium arsenate generally is colored pink and is alkaline in reaction. It is a finely divided powder. It has been used extensively against certain insects affecting field crops, especially cotton. It cannot be used safely on apples, peaches, beans, and some other crops because of its burning effect on the foliage and fruit. It is banned by a number of countries.

A number of calcium orthoarsenate minerals are known. Some of these are shown in Table 4.19.

Groatite is isostructural with O'Danielite. The presence of the rare calcium arsenate minerals Weilite, Pharmacolite, Haidingerite, and Phaunouxite indicate that these minerals formed in locations where high concentrations of total dissolved arsenate existed. These minerals are isotypic and homologous: Phaunouxite, $Ca_3(AsO_4)_2\cdot 11H_2O$, is triclinic with $a = 12.563$ Å, $b = 12.181$ Å, $c = 6.205$ Å, $\alpha = 88.94°$, $\beta = 91.67°$, $\gamma = 113.44°$, $V = 807.77$ Å^3, MW = 596.2413 g/mol and $d = 2.28$ g/cm^3. Rauenthalite, $Ca_3(AsO_4)_2\cdot 10H_2O$, is triclinic with $a = 12.564$ Å, $b = 12.169$ Å, $c = 6.195$ Å, $\alpha = 89.09°$, $\beta = 79.69°$, $\gamma = 118.54°$, $V = 812.65$ Å^3, MW = 578.2264 g/mol and $d = 2.36$ g/cm^3. Space group for both is P1.

Raman and infrared (IR) spectroscopy have been used to study the mineral Pharmacolite $Ca(AsO_3OH)\cdot 2H_2O$. The mineral is characterized by an intense Raman band at 865/cm, assigned to the $(AsO_3)^{2-}$ symmetric stretching mode. The equivalent IR band is found at 864/cm. The low-intensity Raman bands is in the range from 844 to 886/cm provide evidence for 3 (AsO_3) antisymmetric stretching vibrations. A series of overlapping bands in the 300–450/cm region are attributed to 2- and 4(AsO_3)-bending modes. Prominent Raman bands at around 3187/cm are assigned to the OH stretching vibrations of hydrogen-bonded water molecules and the two sharp bands at 3425 and 3526/cm to the OH stretching vibrations of only weakly hydrogen-bonded hydroxyls in $(AsO_3OH)^{2-}$ units.

TABLE 4.19

Svabite = $Ca_5(AsO_4)_3F$

Tilasite (TL) = $CaMg[F|AsO_4]$

Turneaureite (TL) = $Ca_5(AsO_4)_3Cl$

O'Danielite = $Na(Zn,Mg)_3(AsO_4)[AsO_3(OH)]_2$

Weilite = $CaHAsO_4$

Pharmacolite = $CaHAsO_4\cdot 2H_2O$

Haidingerite = $CaHAsO_4\cdot H_2O$

Phaunouxite = $Ca_3(AsO_4)_2\cdot 11H_2O$

An old method involving electrolysis in solution for the manufacture of calcium arsenate is as follows. A solution of arsenious oxide in caustic soda (As_2O_3:NaOH = 198:250) is electrolyzed between iron electrodes. Hydrogen and a small quantity of metallic arsenic are liberated at the cathode and very little oxygen at the anode, the basic arsenite in solution being oxidized to arsenate. When this oxidation is complete, any arsenic is filtered off and the solution treated with milk of lime. A basic arsenate of extremely low solubility is precipitated and after removal, is washed and dried.

Calcium hydrogen orthoarsenate, $CaHAsO_4$, may be prepared by treating calcium carbonate with arsenic acid, or by precipitation from solutions of calcium salts with sodium monohydrogcn arsenate. Both solutions should be acidified to around pH = 9.0. When dried at 100 °C the monohydrate, $CaHAsO_4\cdot H_2O$, is obtained, but the water of crystallization is lost before the temperature of 175 °C is reached. By very slow addition of sodium monohydrogen arsenate solution to a vessel containing aqueous calcium nitrate, so that the two salts were able to mix by diffusion, well-defined monoclinic prisms of the dihydrate, $CaHAsO_4\cdot 2H_2O$ have been obtained. These two hydrates occur in Nature, the monohydrate as Haidingerite and the dihydrate as Pharmacolite. Calcium arsenate is a constituent of many other minerals. A saturated solution at 25 °C of calcium monohydrogen arsenate contains 0.3108 g, of the anhydrous salt per 100 ml of solution.

Calcium hydrogen arsenate trihydrate crystallizes in the orthorhombic system with space group = Pbca. Unit-cell parameters are: $a = 11.185$ Å, $b = 10.713$ Å, $c = 11.179$ Å, $Z = 8$. The hydrogen atoms were located and one of the three water molecules appears to be very weakly bonded. The structure is built from isolated Ca-octahedra sandwiched between As-tetrahedra. The resulting layers, parallel to (100), are connected by infinite zigzag chains of H-bonds along (100).

$CaHAsO_4\cdot 3H_2O$ is the most highly hydrated member of the group that includes:

$$CaHAsO_4\cdot 2H_2O = \text{Pharmacolite}$$
$$CaHAsO_4\cdot H_2O = \text{Haidingerite}$$
$$CaHAsO_4 = \text{Weilite}.$$

These hydrated species all form the same type of lattice structures except for the location of the water molecules and the ensuing point group. The tri-hydrate is probably D_{2h}^{14} while that of the monohydrate is C_{2v}^{6}. Weilite, the anhydrate, crystallizes in the triclinic system with space group P1 and unit-cell parameters of: $a = 7.0591$ Å, $b = 6.8906$ Å, $c = 7.2006$ Å, $\alpha = 97°26'$, $\beta = 103°33'$, $\gamma = 87°45'$, $Z = 4$. The structure has layers parallel to the (001) plane in which the two Ca atoms are crystallographically independent and coordinate

7- and 8-O atoms, respectively. The AsO_4 tetrahedra are on the layer surface. A series of hydrogen bonds exist between the tetrahedral and the Ca-positions.

The dihydrogen arsenate, $Ca(H_2AsO_4)_2$ is sparingly soluble in cold water and is decomposed by hot water, yielding the monohydrogen salt and arsenic acid. Calcium dihydrogen orthoarsenate has been obtained in the form of a monohydrate by adding nitric acid to a mixture containing equal proportions of calcium carbonate and arsenious oxide and allowing the solution to crystallize. It may also be prepared by adding excess of arsenic acid to calcium carbonate or to the normal or monohydrogen orthoarsenate. It forms colorless plates which lose their water at 180 and at 360 °C to yield calcium metaärsenate, $Ca(AsO_3)_2$, as a crystalline mass, insoluble in hydrochloric acid. Its molecular weight is 319.93 g/mol. It occurs in Nature as "Svenekite".

Calcium Pyroarsenate, $Ca_2As_2O_7$, as orthorhombic prisms, may be obtained by fusing calcium oxide with potassium monohydrogen arsenate at an elevated temperature or with a mixture of the latter with less than 40% of calcium chloride. When treated with cold water, the prisms break up into minute crystals of the hexahydrate, $Ca_2As_2O_7 \cdot 6H_2O$. By leaving it in contact with water, the salt is gradually transformed into calcium monohydrogen orthoarsenate, $CaHAsO_4 \cdot 2H_2O$. The pyroarsenate undergoes reduction when heated in hydrogen to above 400 °C to form arsenic and CaO. The best way to prepare the pyroarsenate is to calcine the dibasic salt, $CaHAsO_4 \cdot 2H_2O$, at about 650 °C.

Tribasic calcium arsenate was used extensively in the early 1900s as an insecticide on farm crops. In 1919, 1360 tons were manufactured, and 7270 tons (16 million lbs) were manufactured in 1922. Magnesium salts are used to a much lesser extent to promote arsenic fixation in soils, sediments, and wastes. In spite of magnesium arsenates being considered extremely insoluble solids, their solubilities are similar to the calcium arsenates.

The solubilities of some calcium arsenates are shown in the following Table 4.20.

TABLE 4.20

Solid phase	T/K	pH[a]	$Arsenate_{total}$/(mol/L)[a]
$CaHAsO_4 \cdot H_2O$	308	Acid	0.12–1.2
$Ca_3(AsO_4)_2$	293	6.90–8.35	1.5×10^{-2}–3.5×10^{-3}
$Ca_3(AsO_4)_2 \cdot 4.25H_2O$	296	7.32–7.55	1.1×10^{-2}–6.5×10^{-3}
$Ca_{10}(AsO_4)_6(OH)_2$	310	5.56–7.16	7.5×10^{-3}–4.4×10^{-4}
$Ca_{10}(AsO_4)_6Cl_2$	293	6.50–7.40	1.9×10^{-3}–3.7×10^{-5}

[a] *pH and total arsenate values are the highest and lowest numbers presented in the references, but a direct relation does not exist between the values of the two columns.*

The structure of the calcium arsenate compounds, precipitated from the mixing of soluble arsenic solutions with $Ca(OH)_2$ slurry was studied. The nature of the compounds formed depended on the pH and the Ca/As molar ratio. Three types of calcium arsenates, i.e. $Ca_3(AsO_4)_2 \cdot xH_2O$, $Ca_5(AsO_4)_3(OH)$ and $Ca_4(OH)_2(AsO_4)_2 \cdot 4H_2O$, were identified over a wide range of pH and for Ca/As molar ratios between 1.25 and 4.0.

The mixture of $Ca_3(AsO_4)_2 \cdot xH_2O$ and $Ca_4(OH)_2(AsO_4)_2 \cdot 4H_2O$ was observed to form at pH 3 to 7 and at Ca/As ratios of 1.0 and 1.25. The XRD and SEM analysis of 11 separate precipitation experiments for the Ca/As = 1.5 confirmed that four solid samples, precipitated at low initial pH values (3.06, 4.06, 4.75, 5.45) and low final pH (3.70, 4.13, 5.94, 5.54) were pure $Ca_3(AsO_4)_2 \cdot xH_2O$. Seven solids precipitated at initial pH values between pH = 6.84 to 12.94 and final pH values between 7.14 and 7.50 were mainly $Ca_3(AsO_4)_2 \cdot xH_2O$ with hydroxyarseanate apatite, $Ca_5(AsO_4)_3(OH)$, appearing as the solutions were in the process of precipitating. However, at equilibrium, the $Ca_3(AsO_4)_2 \cdot xH_2O$ solid appeared to be the most dominant at the final pH of 7.14 to 7.50.

At the Ca/As ratios of 1.67 and 4.0, the precipitated solids were comprised mainly $Ca_5(AsO_4)_3(OH)$ and some $Ca_3(AsO_4)_2 \cdot xH_2O$. The predominant compound formed at ratios of Ca/As = 2.0 was $Ca_4(OH)_2(AsO_4)_2 \cdot 4H_2O$, which appeared in conjunction with $Ca_5(AsO_4)_3(OH)$ and $Ca_3(AsO_4)_2 \cdot xH_2O$ but in minor amount. The XRD and SEM analysis indicated that the $Ca_3(AsO_4)_2 \cdot xH_2O$ compound found in all precipitates was independent on the Ca/As ratio and the pH of the mixing solution. These compounds were crystalline and had the distinct XRD pattern of $Ca_3(AsO_4)_2 \cdot xH_2O$. However, the structure and the grain size were related to the forming pH. For example, at the Ca/As = 1.25 and the initial pH = 4.09, and at the Ca/As = 1.5 and the initial pH = 3.04 and 4.06, the precipitated $Ca_3(AsO_4)_2 \cdot xH_2O$ was granular or platy. At the Ca/As = 1.5 and the initial pH = 4.75, the precipitated compound was equigranular and had a grain size of 5.40 μm. At the ratio Ca/As = 1.5 and the initial pH = 5.45, the small platy or leafy $Ca_3(AsO_4)_2 \cdot xH_2O$ with a grain size of 2.10 μm formed. In a word, the $Ca_3(AsO_4)_2 \cdot xH_2O$ solids precipitated at lower pH were more crystalline and had relatively larger grain size than those formed at higher pH.

Various calcium arsenates are still available commercially worldwide in spite of their toxicity. They are used mostly as insecticides.

Strontium Arsenates

Strontium forms several orthoarsenates of various degrees of ionization from arsenic acid.

Crystals of $M(AsO_3OH)$ (M = Sr and Ba) were synthesized under hydrothermal conditions. Single-crystal

X-ray structure investigations were performed. The average structure of $Sr(AsO_3OH)$ exhibits three crystallographically different hydrogen bonds; two of them are related by -1 symmetry [space group P-1, $a = 7.349(2)$ Å, $b = 7.057(2)$ Å, $c = 7.460(2)$ Å, $\alpha = 95.20(3)°$, $\beta = 104.78(3)°$, $\gamma = 88.11(3)°$, $Z = 4$]. Weak superstructure reflections were detected which are responsible for a larger cell volume [space group P-1, $a = 9.038(2)$ Å, $b = 11.732(2)$ Å, $c = 15.356(3)$ Å, $\alpha = 71.66(3)°$, $\beta = 75.16(3)°$, $\gamma = 89.11(3)°$, $Z = 16$]. All inversion centers restricting the hydrogen bonds are avoided in the supercell. As a result, a completely ordered atomic arrangement is obtained. The arsenate tetrahedra are linked by hydrogen bonds to polar chains with branches in [110] and [110], respectively. They are linked by the Sr atoms. The compounds $CaHPO_4$ (Monetite), $CaHAsO_4$ (Weilite), α-$SrHPO_4$ α-$NaHSO_4$, and $HgHPO_4$ have roughly the same arrangements of the cation and anion atoms. However, their hydrogen-bonding schemes are principally different. For the detailed comparison, the nonstandard unit cell was chosen for $Sr(AsO_3OH)$ [space group $F\bar{1}$, $a = 14.697$ Å, $b = 28.230$ Å, $c = 14.920$ Å, $\alpha = 95.20(3)°$, $\beta = 104.78(3)°$, $\gamma = 88.11(3)°$, $Z = 64$]. The structural refinement of $Ba(AsO_3OH)$ confirmed it as isotypic with γ-$Sr(PO_3OH)$, $K(SO_3OH)$, and $K(SeO_3OH)$ [space group Pbca $a = 8.581(2)$, $b = 9.896(2)$, $c = 19.417(4)$ Å, $Z = 16$]. $Sr(AsO_3OH)$ and $Ba(AsO_3OH)$ are characterized by short (strong) hydrogen bonds.

Strontium Orthoarsenate, $Sr_3(AsO_4)_2$, may be prepared by neutralizing aqueous arsenic acid with strontium hydroxide water slurry, or by adding ammonia to a solution of strontium monohydrogen arsenate in dilute hydrochloric acid. In either case, the precipitate is separated and well washed with water. The salt may also be obtained by fusing together at 450 °C equal quantities of sodium chloride and sodium orthoarsenate and adding the required proportion of strontium oxide. After cooling, the sodium salts are removed by washing with water. Colorless rhombic crystals, of density 4.601 g/cm^3, are obtained that are readily soluble in dilute acids. The salt melts at 1635 °C. When heated at 400–450 °C in hydrogen, reduction occurs to give strontium oxide, arsenic trioxide and water.

The previously uninvestigated atomic arrangements of six strontium arsenate(V) phases in the systems Sr–As–O–X (X = H, Cl) have been determined. These included in Table 4.21.

Single crystals of $Sr_3(AsO_4)_2$ and $Sr_5(AsO_4)_3Cl$ were grown from a borate and NaCl melt, respectively, whereas single crystals of α- and β-$SrAs_2O_6$ and of $Sr_5(AsO_4)_3OH$ were obtained under hydrothermal conditions. Microcrystalline samples of $Sr_2As_2O_7$ were prepared by solid-state reaction of As_2O_5 with $SrCO_3$ and, alternatively, by thermolysis of $SrHAsO_4$. Crystal structure determinations based on powder XRD data using the Rietveld method ($Sr_2As_2O_7$), and from single-crystal XRD data (all other phases) revealed isotypism with known structure types (except β-$SrAs_2O_6$ which represents a new structure type). $Sr_3(AsO_4)_2$ crystallizes in the $K_2Pb(SO_4)_2$ structure type. $Sr_2As_2O_7$ is isotypic with the high-temperature polymorphs of $Ca_2P_2O_7$ and $Sr_2V_2O_7$, but itself shows no polymorphism. $Sr_5(AsO_4)_3OH$ and $Sr_5(AsO_4)_3Cl$ crystallize with the hydroxylapatite and chloroapatite structure, respectively; $SrAs_2O_6$ is dimorphic. Like all other known $M^{II}As_2O_6$ metaärsenates (M = Mn, Co, Ni, Sr, Pd, Cd, Hg, Pb), the α-polymorph crystallizes in the $PbSb_2O_6$ structure type, whereas the novel β-polymorph is the first example of a $M^{II}As_2O_6$ superstructure with a doubled *c*-axis. Additional analytical methods using Raman spectroscopy and thermal analyses support the results of the X-ray structure work.

TABLE 4.21

$Sr_2As_2O_7$
$Sr_5(AsO_4)_3OH$
$Sr_5(AsO_4)_3Cl$
α-$SrAs_2O_6$
β-$SrAs_2O_6$

In an early method, the following recipe was given: "Strontium Monohydrogen Arsenate, $SrHAsO_4$, may be prepared as follows: Strontium hydroxide is added slowly and with stirring to a solution of arsenic acid (containing 75 g As_2O_5 in 1.5 l H_2O) until a slight turbidity appears. Sodium hydroxide, free from carbonate, is then added to bring the pH to about 5.4, and the faintly turbid solution is heated and stirred until the monohydrogen orthoarsenate separates in fine crystals. The supernatant liquid is removed, again treated with sodium hydroxide and heated to give a further yield. The crystals are washed with alcohol and dried in air. They usually contain a slight excess of arsenic acid".

The salt, $SrHAsO_4$, may also be obtained by the action of hot water on strontium dihydrogen ortho-arsenate or on the pyroarsenate, where these salts hydrolyze to the more stable dibasic compound. It may also be obtained by mixing solutions of strontium chloride and sodium monohydrogen ortho-arsenate, adding HCl, heating the resulting solution and then adding ammonia to form the insoluble dibasic precipitate. In the last case, the anhydrous salt crystallizes out, but if the mother liquor is kept in an atmosphere of ammonia, the monohydrate, $SrHAsO_4 \cdot H_2O$, appears. The density of the latter is

3.606 g/cm^3 at 15 °C and of the anhydrous salt 4.035 g/cm^3. The monohydrate becomes anhydrous at 130 °C and at a higher temperature yields the pyroarsenate.

Strontium dihydrogen orthoarsenate, $Sr(H_2AsO_4)_2$, may be prepared by adding strontium hydroxide to an aqueous solution of arsenic acid and heating until a clear solution is obtained. On prolonged boiling, much of the monohydrogen salt crystallizes out and, after filtration, a further crop may be obtained from the mother liquor. The crystals should be washed with alcohol and dried.

The dihydrate, $Sr(H_2AsO_4)_2 \cdot 2H_2O$, may be obtained by treating strontium carbonate with an excess of arsenic acid. The crystals lose their water of crystallization at 240 to 250 °C and on further heating yields strontium meta-ärsenate, $Sr(AsO_3)_2$.

Monobasic strontium arsenate is triclinic with space group P1 and $a = 8.558$ Å, $b = 7.697$ Å, $c = 5.721$ Å, $\alpha = 92°35'$, $\beta = 109°59'$, $\gamma = 109°52'$, $V = 327.2$ Å^3, MW = 321.9321 g/mol, $d = 3.195$ g/cm^3, Z = 4. No piezoelectric effect has been noted. The four H-atoms were located. In one anion, two half-hydrogens, located at centers of symmetry, for symmetrical hydrogen bonds. The bond lengths of these O(H)–O(H) species vary between 2.436–2.444 Å. The other is relatively long at 2.875 Å. The angles between these hydrogen bonds is about 150° and the As···O bonds carrying the half-hydrogen species are 1.667 Å while the full hydrogen bonds are 1.727 Å.

Strontium pyroarsenate, $Sr_2As_2O_7$, is formed when the monohydrogen ortho-arsenate is heated above 360 °C or when potassium monohydrogen ortho-arsenate is fused with strontium oxide or carbonate. It is slightly soluble in mineral acids. A new related compound $Sr_5(As_2O_7)_2(AsO_3OH)$ was synthesized under hydrothermal conditions. It represents a previously unknown structure type and belongs to a group of a few compounds in the system $SrO–As_2O_5–H_2O$ $(As_2O_7)^{4-}$ besides $(AsO_3OH)^{2-}$ groups have not been described yet. The crystal structure of $Sr_5(As_2O_7)_2(AsO_3OH)$ was determined by single-crystal XRD (space group $P2_1/n$, $a = 7.146$ Å, $b = 7.142$ Å, $\beta = 93.67°$, $Z = 4$). One of the five symmetrically unique Sr atoms is in a trigonal antiprismatic coördination, whereas the other Sr atoms adopt the commonly observed coordination. The position of the hydrogen atom was located in a difference Fourier Map and subsequently refined with an isotropic displacement parameter. A very short hydrogen bond length O_h–HO(1) of 2.494 Å was noted. It belongs to the shortest known examples where the donor and acceptor atoms are crystallographically different. This hydrogen bond was confirmed by IR spectroscopy.

A basic arsenate of composition $Sr_3(AsO_4)_2 \cdot Sr(OH)_2$ has been obtained as a fine flaky precipitate by the action of sodium hydroxide and strontium hydroxide slurry water on an acidified solution of sodium monohydrogen orthoarsenate, care being taken to ensure the absence of carbonate. This salt is apparently not apatitic in nature since it does not have the molecular formula of $Sr_5(As)_4)_3OH$ but that of $\{Sr_2HAsO_4)_2$.

The crystal structure of the double salt, strontium potassium arsenate octahydrate, $SrKAsO_4 \cdot 8H_2O$, has been determined by single crystal XRD. The crystals are tetragonal, $a = 7.144$ Å, $c = 23.613$ Å, space group $I4_1/md$ (No. 109), $Z = 4$, $V = 1205.1$ Å^3, and $d = 2.258$ g/cm^3. All cations and anions in this compound are completely surrounded by water molecules. Sr^{2+} and K^+ ions are each coordinated to eight water molecules arranged in an approximately square antiprism. The $[Sr(H_2O)_8]^{2+}$ polyhedron shares one face of four water molecules with a $[K(H_2O)_8]^+$ polyhedron forming $O_4–Sr–O_4–K–O_4$ polyhedra. The $O_4–Sr–O_4–K–O_4$ units are linked together through a pair of edge-sharing linkages of the outer water molecules, alternating along the *a*-axis and *b*-axis. The hydrated-cation polyhedra define the host lattice, which accommodates the AsO_4^{3-} ion in the interstitial space. The environment of the AsO_4^{3-} ion consists of 16 water molecules; each oxygen atom is the acceptor in hydrogen bonds from four water molecules. Each water molecule is coordinated to one Sr and one K, and hydrogen bonded to two O atoms of two different AsO_4^{3-} ions. There is no hydrogen bonding between water molecules.

Very little is known concerning the metaarsenate compounds. If the monobasic compound is heated, a number of "meta"-compounds are formed but these have not been characterized:

$$nSr(H_2AsO_4)_2 + \text{heat} \Rightarrow Sr(AsO_3)_{2n} + H_2O$$

Whether strontium forms a cyclic or linear metaarsenate is still not known. The reaction can be used to form a pure glass $\Rightarrow [Sr(AsO_3)_2]_n$ whose physical properties have been described by Ropp but its molecular structure remains to be elucidated.

Although a considerable amount of attention has ensued concerning these five types of strontium orthoarsenates in the literature and academia, little awareness of them has resulted in industrial circles. None of them have found usage in products. The dibasic and tribasic salts are readily available commercially but only in small quantities.

Barium Arsenates

Tribasic barium orthoarsenate, $Ba_3(AsO_4)_2$, is formed as large colorless plates when a mixture of barium oxide, alkali chloride and alkali hydrogen orthoarsenate is fused at about 750 °C and allowed to cool. Early work concerning barium arsenates and their formation from solution did not control the pH of the solution (If the pH is controlled around 9.0, the dibasic compound results but

the tribasic compound is obtained at pH > 11.0). As a result, mixtures of compounds usually resulted. In one work, the following description was given:

> "The tribasic compound was formed by the action of ammonia on an aqueous solution of barium hydrogen arsenate. The product, however, varied in composition, barium ammonium arsenate sometimes being formed and barium orthoarsenate rarely. The latter salt retains water which may be lost at 150 °C. Definite hydrates were not obtained. The tribasic compound was found to be only slightly soluble in cold water. The anhydrous orthoarsenate had a density of 5.086 g/cm^3 and melted at 1605 °C. It was reduced by hydrogen at 400–450 °C to barium oxide, arsenic and water".

A study of the acid section of the system As_2O_5–BaO–H_2O at 30 °C suggested that the stable solid phases are barium monohydrogen orthoarsenate, $BaHAsO_4 \cdot H_2O$, barium dihydrogen orthoarsenate, $Ba(H_2AsO_4)_2 \cdot 2H_2O$, and the (3, 5)-hydrate of arsenic pentoxide, $3As_2O_5 \cdot 5H_2O$. Current thermodynamic data advocate barium arsenate $Ba_3(AsO_4)_2$ to be the highly stable phase. However, sufficient evidence is available to question the validity of the current data. In order to determine the solubility (pK_{sp}) and calculate the standard free energy of formation (ΔG_f) of $Ba_3(AsO_4)_2$, an equilibrium solubility study was conducted. The equilibrium experiments were carried out under three different ionic strength conditions for reaction times up to 45 days. Equilibrium was approached from both undersaturated and supersaturated initial conditions. The pK_{sp} for the dissolution of $Ba_3(AsO_4)_2$ was calculated to be 21.62. Correspondingly, a ΔG_f of -3101.2 ± 2.0 kJ/mol was calculated. This value is 166.9 kJ/mol more positive than the current literature value. Reevaluation of the solubility data from a previous work suggests that the pK_{sp} for the dissolution of $BaHAsO_4 \cdot H_2O$ is 24.64 and the corresponding ΔG_f is -1587.0 ± 2.5 kJ/mol. Tribasic barium arsenate has the CAS number of 56997-31-0.

Barium dihydrogen orthoarsenate, the monobasic salt, $Ba(H_2AsO_4)_2$, can be prepared by adjusting a solution of arsenic acid with sodium acetate to about 4.5 and then adding barium carbonate to precipitate the arsenate:

$$BaCO_3\ (\text{solid}) + 2H_3AsO_4\ (\text{aq}) \Rightarrow Ba(H_2PO_4)_2 \cdot 2H_2O\ (\text{solid}) + CO_2 + H_2O$$

The best way to form the monobasic barium arsenate is to dissolve the carbonate in an excess of arsenic acid and then to evaporate the solution at a low temperature to form the crystals. Both triclinic and orthorhombic barium dihydrogen arsenates are known. The triclinic form has the following unit-cell parameters: Space group = $\overline{1}$, $a = 7.0334$ Å, $b = 8.0437$ Å, $c = 7.2158$ Å, $\alpha = 104.45°$, $\beta = 109.46°$, $\gamma = 96.09°$, $Z = 2$, $d = 2.99$ g/cm^3. The crystal is built up of BaO_8 square antiprisms linked together along the axis, c. The AsO_4 tetrahedra are connected to the BaO_8 groups to constitute layers parallel to the (100) plane.

Two related arsenates with the general formula $Ba(ZnAsO_4)_2$ and $Ba(ZnPO_4)_2$ were synthesized by solid-state reaction. The divalent Zn^{2+} ions replace the two H^+ ions in the structures. X-ray structures of these compounds were indexed with a monoclinic unit cell, and their structures were refined by the Riewelt method, using reported atomic coordinates of Paracelsian, $Ba(AlSiO_4)_2$. The synthesis of the compounds was carried out by high-temperature sintering of stoichiometric amounts of $BaCO_3$, ZnO (first dried at 700 °C), NH_4HPO_4 and $As_2O_5 \cdot 0.6H_2O$ (a hygroscopic compound determined to be 3/5 by TGA analysis). The powder mixtures were thoroughly mixed, placed in a platinum crucible, and heated to 400 °C (with loss of H_2O, NH_3, CO_2). They were then reground and fired at 900 °C for 72 h with intermediate remixing. Finally, the samples were slowly cooled to room temperature.

Crystal parameters were shown in Table 4.22.

Phosphorus and arsenic are totally ordered in the tetrahedra. Each ZnO_4 tetrahedron shares its oxygen atoms with four PO_4 or AsO_4 and vice versa. The resulting structure may be described as a (100) pseudo-layered framework of 4- and 8-membered rings. One layer of the 4- and 8-membered rings of AsO_4 and ZnO_4 is shown in the following Fig. 4.72.

This structure is typical of the ortho-arsenates in general where the AsO_4 tetrahedra are coordinated with other MO_4 tetrahedra in any given structure.

The case of $Ba(ZnPO_4)_2$ seems very different in that the Paracelsian form was only obtained under hydrothermal conditions. The crystal form resulting from heating the initial mixture under atmospheric pressure is trigonal ($a = 5.32$ Å, $c = 8.02$ Å), with space group $P3m_1$, and may be related to the hexagonal form of Paracelsian by introducing complete Zn–P order among the tetrahedra.

TABLE 4.22

$Ba(ZnPO_4)_2$	$Ba(ZnAsO_4)_2$	
Crystal system	Monoclinic	Monoclinic
Space group	$P2_1/c$	$P2_1/c$
a in Å	8.5783	8.0883
b in Å	9.7383	9.9821
c in Å	9.1446	9.4089
β in degrees	91.394	91.465
V in cubic Å	763.69	827.00
Formula weight	458.024 g/mol	545.92 g/mol

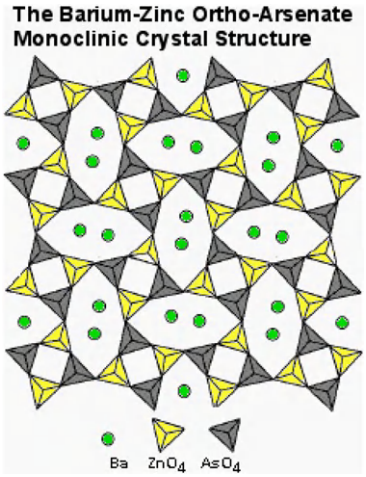

FIGURE 4.72

The change from one allotropic form to the other may be achieved either by pressure or temperature modification in agreement as shown in Fig. 4.73.

Barium Monohydrogen Orthoarsenate may be obtained as a gelatinous precipitate by adding barium hydroxide water slurry drop by drop to aqueous arsenic acid until the solution is alkaline to phenolphthalein (pH = 9.0). On shaking, the precipitate becomes crystalline. This salt can also be obtained in the form of small crystalline flakes by adding sodium hydrogen arsenate drop by drop to excess of barium chloride solution. The precipitate, $BaHAsO_4 \cdot H_2O$, is then dried at 100 °C. The crystals are transparent rhombic plates of density 3.926 g/cm^3 at 15 °C. If acetic acid is used, the crystals take the form of octahedra. When heated at 120 °C the salt loses its water of crystallization, and at 320 °C it loses constitutional water and forms barium pyroarsenate:

$$2\ BaHAsO_4 \cdot H_2O + \text{heat} \Rightarrow Ba_2As_2O_7 + 2\ H_2O$$

The monobasic salt, barium dihydrogen orthoarsenate, crystallizes as the dihydrate when tribasic barium orthoarsenate or barium monohydrogen orthoarsenate is dissolved in aqueous arsenic acid:

$$BaHAsO_4 \cdot H_2O\ (\text{solid}) + H_3AsO_4\ (\text{aq}) \Rightarrow Ba(H_2AsO_4)_2 \cdot 2H_2O\ (\text{solid})$$

This reaction was used in the past but was difficult to control. A better way to prepare the monobasic salt is to dissolve a $Ba(OH)_2$ or $BaCO_3$ slurry in excess arsenic acid solution. The crystals are monoclinic, with axial ratios $a{:}b{:}c = 1.100{:}1{:}0.625$ and $\beta = 108°34'$. The salt is only slightly soluble in water and in the presence of excess water changes to the monohydrogen arsenate:

$$Ba(H_2AsO_4)_2 + \text{x's } H_2O \Rightarrow BaHAsO_4\ (\text{solid}) + H_3AsO_4\ (\text{aq})$$

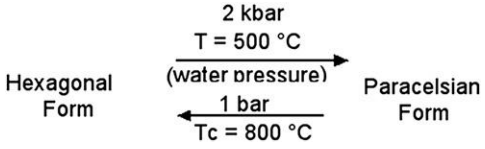

FIGURE 4.73

The solid product is readily soluble in hydrochloric acid but less soluble in acetic acid. When heated, it loses water, and above 230 °C barium metaärsenate, $Ba(AsO_3)_2$ remains. The latter may also be obtained by evaporation of a solution of the pyro-arsenate and calcination of the residue.

The anhydrate, $BaHAsO_4$ or $Ba(AsO_3OH)$ was synthesized under hydrothermal conditions and single-crystal X-ray structure investigations were performed. The average structure of $Ba(AsO_3OH)$ exhibits three crystallographically different hydrogen bonds. Two of them are related by $\bar{1}$ symmetry [space group $P\bar{1}$, $a = 7.349$ Å, $b = 7.057$ Å, $c = 7.460$ Å, $\alpha = 95.20°$, $\beta = 104.78°$, $\gamma = 88.11°$, $Z = 4$]. Weak superstructure reflections were detected which are responsible for a larger cell volume [space group $P\bar{1}$, $a = 9.038$ Å, $b = 11.732$ Å, $c = 15.356$ Å, $\alpha = 71.66°$, $\beta = 75.16°$, $\gamma = 89.11°$, $Z = 16$]. All inversion centers restricting the hydrogen bonds are avoided in the supercell. As a result, a completely ordered atomic arrangement is obtained. The arsenate tetrahedra are linked by hydrogen bonds to polar chains with branches in [110] and [110], respectively; they are linked by the Ba atoms. The compounds $CaHPO_4$ (monetite), $CaHAsO_4$ (weilite), β-$SrHPO_4$ β-$NaHSO_4$, and $HgHPO_4$ have roughly the same arrangements of the cation and anion atoms. However, their hydrogen-bonding schematics are predominantly different. For the detailed comparison, the nonstandard unit cell was chosen for $Sr(AsO_3OH)$ [space group F-1, $a = 14.697(3)$, $b = 28.230(5)$, $c = 14.920(3)$ Å, $\alpha = 95.20(3)°$, $\beta = 104.78(3)°$, $\gamma = 88.11(3)°$, $Z = 64$]. The structural refinement of $Ba(AsO_3OH)$ was confirmed isotropic with β-$Sr(PO_3OH)$, $K(SO_3OH)$, $K(SeO_3OH)$, and $Sr(AsO_3OH)$ and is characterized by short (strong) hydrogen bonds.

Barium Pyroarsenate, $Ba_2As_2O_7$, is formed when barium monohydrogen orthoarsenate is ignited, or when barium oxide is fused with an alkali hydrogen arsenate. In the latter case, it may be extracted with anhydrous glycerol. In contact with cold water, the hexahydrate, $Ba_2As_2O_7 \cdot 6H_2O$, is formed. Boiling water converts it to the ortho-arsenate.

Very little is known concerning the metaarsenate compounds. If the monobasic compound is heated, a number of "meta"-compounds are formed but these have not been characterized:

$$n\ Ba(H_2AsO_4)_2 + \text{heat} \Rightarrow Ba(AsO_3)_{2n} + H_2O$$

Whether barium forms a cyclic or linear metaarsenate is still not known. The reaction can be used to form a pure glass ⇒ $[Ba(AsO_3)_2]_n$ whose probable properties have been described by Ropp but its molecular structure remains to be elucidated.

Although the five above compounds have been described in the technical literature, they have not been well received from those in industry. There are no usages found for barium arsenates or for products that use any of these compounds. One of these compounds is offered for sale commercially but only from a few manufacturers worldwide.

Radium Arsenates

No radium arsenate compounds are known. This is likely due to the scarcity and high price of radioactive ^{222}Ra compounds and to the lack of interest in industry.

4.4. ALKALINE EARTH ANTIMONY COMPOUNDS

Antimony forms a limited number of compounds with the alkaline earths. This is due primarily to the fact that antimony, as Sb^{3+}, is almost as electropositive as any of the alkaline earth cations. The compounds that are stable are based upon the acids. Antimony is sufficiently electropositive in nature that acids such as "antimonous acid" ($H_3Sb^{3+}O_3$) or "antimonic acid" ($H_3Sb^{5+}O_4$) do not exist, or cannot be isolated from solution. In chemistry, an **antimonite** refers to salts of antimony(III), such as $NaSb(OH)_4$ (a double-salt) and $NaSbO_2$ (metaantimonite). Formally, these are salts of antimonous acid (antimonious acid—"$Sb(OH)_3$") whose existence in solution is dubious. Attempts to isolate it generally form $Sb_2O_3 \cdot xH_2O$, antimony(III) oxide hydrate, which slowly transforms into Sb_2O_3 (which is the more stable form).

The **antimonate** ion is $Sb(OH)^{6-}$ and an **antimonate** (compound) refers to a substance that contains the antimony(V) ion. In acid conditions, this forms antimony pentoxide, Sb_2O_5; in basic conditions, the antimonate ion, $Sb(OH)_6^-$ ion exists.

Like its horizontal neighbor in the periodic table, tellurium, Te and unlike the other elements in this Group, antimony(V) is commonly hexa-coordinate, for example in the unit $Sb(OH)_6^-$. Tetra-coordinate units, $Sb(OH)_4^-$, are not common. Thus, the known "antimonates" are usually prepared by solid-state reaction of Sb_2O_5 and the corresponding alkaline earth hydroxide. Even though many varying ratios of the two reactants have been attempted in an effort to form compounds similar to the phosphates and arsenates, only certain compositions of the individual alkaline earths have proven to be stable. Because antimony eschews aqueous solutions (due to the observed fact that the oxides, Sb_2O_3 and Sb_2O_5), are more stable than the acids themselves when contacted by water, it is the oxides that appear in many cases. Thus, antimonites and antimonates tend to decompose in contact with water to form the oxides, respectively. However, the alkali antimonates are stable in water and can be used to prepare some of these salts.

In addition, antimony metal forms a series of compounds with the alkaline earth metals, called antimonides.

4.4.1. Alkaline Earth Antimonites

Beryllium Antimonite

Beryllium antimonite can be prepared by firing BeO and Sb_2O_3 together in an inert atmosphere such as argon at about 1000 °C. However, this system has not been studied at all. The basic compounds that can be formed have not yet been identified. There is no description of the solution chemistry of beryllium antimonites in which sodium antimonite is reacted with a soluble beryllium salt like the chloride. Perhaps this is due to the fact that Be forms hydroxl complexes like $Be_x(OH)_y^{(2x-y)+}$ in solution. The technical literature is completely devoid of any description either by academia or industry in the form of structure determinations or products involving such compounds. Be is used but mostly in the form of the metal.

The beryllium antimonites, if they exist, have no CAS number nor are they offered for sale commercially.

Magnesium Antimonite

Magnesium antimonite can be prepared by the solid-state reaction of Sb_2O_3 and MgO or $MgCO_4$ wherein the reaction is carried out in an inert atmosphere like argon at about 1100 °C:

$$MgO + Sb_2O_3 \Rightarrow MgSb_2O_4$$

By varying the molecular ratio of MgO to Sb_2O_3, a number of compounds is expected to result. However, there is no record of this ever having been accomplished. The early work in the 1800s used an aqueous method to define the now known magnesium antimonites in which sodium or potassium antimonite, $K_2Sb_2O_4$, reacted to form the stable compound, $MgSb_2O_4$. This compound was reported in 1889 as the precipitation product, $Mg(SbO_2)_2 \cdot 12H_2O = MgO \cdot Sb_2O_3 \cdot 12H_2O$, but no corroborating evidence has since emerged.

The only available reference to magnesium antimonite identified the product of a 1:1 ratio of MgO and Sb_2O_3 as $MgSb_2O_4$. This compound was synthesized by a phase-equilibration technique and identified by XRD to be $MgSb_2O_4$. To determine the standard Gibbs energies of formation of this antimonite, the

e.m.f. values of the following galvanic cells were measured:

$$\text{Pt, Re/Sb (solid, liq), } Sb_2O_3 \text{ (solid, liq)/} ZrO_2 + \text{MgO(or } Y_2O_3\text{)/air, Pt,}$$

$$\text{Pt, Re/Sb (liq), } MgSb_2O_4 \text{ (solid), MgO (solid)/} ZrO_2 + \text{CaO/air, Pt,}$$

The resulting free energies of formation were determined:

$$\Delta G^0/\text{kJ/mol} = -687.7 + 0.2425\ T \text{ (773–904 K),}$$
$$[\text{for 2 Sb (solid)} + O_2 \text{ (gas)} \Rightarrow Sb_2O_3 \text{ (solid)}]$$
$$\Delta G^0/\text{kJ/mol} = -730.2 + 0.2895\ T \text{ (904–929 K),}$$
$$[\text{for 2 Sb (liq)} + O_2 \text{ (gas)} \Rightarrow Sb_2O_3 \text{ (solid)}]$$
$$\Delta G^0/\text{kJ/mol} = -683.1 + 0.2385\ T \text{ (929–1095 K),}$$
$$[\text{for 2 Sb (liq)} + O_2 \text{ (gas)} \Rightarrow Sb_2O_3 \text{ (liq)}]$$
$$\Delta G^0/\text{kJ/mol} = -78.9 + 0.0495\ T \text{ (929–1101 K),}$$
$$[\text{for } Sb_2O_3 \text{ (liq)} + \text{MgO (solid)} \Rightarrow MgSb_2O_4 \text{ (solid)}]$$

There are no publications that directly address the formation and properties of any magnesium antimonites in the scientific literature and no mention can be found in the current reference books. No products have found their way into industry and no CAS numbers exist at this time.

Calcium Antimonite

There are three calcium antimonites that have been established in the CaO–Sb_2O_3 system. These are: $CaSb_2O_4$, Ca_2SbO_5 and $Ca_4Sb_2O_7$. These compounds can be prepared by firing the carbonate or oxide with the appropriate ratio of CaO/Sb_2O_3 in argon at about 1000 °C:

$$\text{CaO} + Sb_2O_3 \Rightarrow CaSb_2O_4 \text{ (1:1)}$$

To determine the standard Gibbs energies of formation of this antimonite, e.m.f. values of the following galvanic cells have been measured:

$$\text{Pt, Re/Sb (solid, liq), } Sb_2O_3 \text{ (solid, liq)/} ZrO_2 + \text{CaO(or } Y_2O_3\text{)/air, Pt,}$$

$$\text{Pt, Re/Sb (liq), } Ca_4Sb_2O_7 \text{ (solid), CaO (solid)/} ZrO_2 + \text{CaO/air, Pt.}$$

Standard Gibbs free energies of formation of double oxides coexisting with liquid antimony from CaO (s) and Sb_2O_3 are derived as follows:

$$4\text{CaO(solid)} + Sb_2O_3\text{(liq)} = 4\text{CaO}\cdot Sb_2O_3\text{(solid);}$$
$$\Delta G^\circ/\text{kJ} = -130.3 \text{ to } 0.0031\ \text{T/K}$$
$$2\text{CaO(solid)} + Sb_2O_3\text{(l)} = 2\text{CaO}\cdot Sb_2O_3\text{(solid);}$$
$$\Delta G^\circ/\text{kJ} = -121.7 \text{ to } 0.00005\ \text{T/K}$$
$$\text{CaO(solid)} + Sb_2O_3\text{(l)} = \text{CaO}\cdot Sb_2O_3\text{(solid);}$$
$$\Delta G^\circ/\text{kJ} = -98.3 + 0.0197\ \text{T/K.}$$

The activities of Sb_2O_3 and CaO in the two-phase regions at 1000 and 1100 K were derived and the most stable double oxide was determined to be CaO·Sb_2O_3 in this system. By X-ray diffractometry, it was found that 3CaO·Sb_2O_3 (s) cannot coexist with Sb_2O_3.

In another work, the phase composition of crystalline mechanochemical synthesis products in the CaO–Sb_2O_3–Bi_2O_3 system was determined (Mechanochemical reactions consists of using a Rotary-Mill, equipped with "mill-stones", to grind the reactants together and cause a solid-state reaction to occur). Of the known phases in this system, only three could be prepared mechanochemically: $Ca_2Sb_2O_5$, $CaSb_2O_4$, and $Ca_2Bi_2O_5$ (all-fcc). A new metastable phase, "γ-Bi_2O_3", with an orthorhombic structure close to that of the high-temperature, fluorite phase α-Bi_2O_3, was obtained by mechanical processing at 30 °C. The mechanochemical yield of primary crystalline products was shown to be several times higher than that of secondary products. A broad composition range was found in which perovskite and fluorite phases are in mechanochemical equilibrium. The composition dependence of the lattice parameter of the metastable fluorite phase $Bi_{2-x}Sb_xO_3$ was found to be the opposite of the one predicted by Vegard's law. Metastable-mixed oxides undergo phase transformations during heating (starting at 280 °C in the case of the ternary perovskite phase). The compound, $Bi_{2\text{-}x}Ca_xO_{3-0.5x}$ (fluorite structure) experiences a transformation at 400 °C, accompanied by oxygen loss. During heating in air, Sb_2O_3-containing fluorite phases partially stabilize owing to oxidation but, nevertheless, undergo structural transformations above 480 °C. The transformation of $Sb_{2-x}Ca_xO_{3-0.5x}$ metastable fluorite solid solutions near 500 °C in air is accompanied by the formation of needle-like Sb_2O_3 crystals. A mechanism was proposed for the extremely rapid growth of such crystals. Extrusion of the Sb_2O_3 results from the fluorite decomposition in agglomerates through triple junctions of aggregates and through cracks in the surface layer of agglomerates.

Opacifiers, such as tin oxide and calcium antimonite, can be added to create opal-like or opalescent glass. Antimony reacts with the lime in the glass matrix to precipitate **calcium antimonite** crystals creating a white with high opacity. Indeed, there is evidence that early Egyptian craftsmen (1570–1292 BC), could have produced $Ca_2Sb_2O_5$ by using mixtures of Sb_2O_3 with calcium carbonates (atomic ratio Sb/Ca = 1) heat treated between 1000 and 1100 °C. This method has since been used to produce glass items for decorative items used in the home. A very opalescent glass can be produced. Since the glass making is usually done in air, there

is some question concerning whether the Sb is in the +3-state or the +5 state.

Calcium antimonite has no CAS number and is not used directly in industry. A paucity of technical papers concerning this compound(s) exists in the literature. It has only been described in conjunction with other antimonites, as detailed above (never by itself). Perhaps, this is due to its lack of stability in air. It is not offered for sale commercially.

Strontium Antimonite

Strontium antimonite can be prepared by the solid-state reaction of the oxides of Sr and Sb in an inert atmosphere at a temperature about 850 °C:

$$SrO + Sb_2O_3 \Rightarrow SrSb_2O_4$$

A detailed investigation of the $SrO–Sb_2O_3$ binary system was reported. The samples were prepared at 1200 °C under ambient inert gas pressure, and the binary compounds, $Sr_2Sb_2O_7$ and $SrSb_2O_4$, were confirmed. The former contains Sb(V) whereas the latter contains Sb(III), the stable compounds in this binary oxide system. A new mixed oxide, $Sr(Sr_{0.5}Sb_{0.5})O_{3-y}$, showing a double perovskite-related structure was described. It gives rise to $Sr_{(1.5-x)}Sb_{(0.5+x)}O_{3-y}$ solid solution ($0 \le x \le 0.64$), the lattice parameter of which was determined as a function of x by means of XRD.

The synthesis, structural and microstructural characterization of a strontium antimonite, $Sr_{1.5}Sb_{0.5}O_{3-y}$ (where $y = 0.25$), results in a cubic, double-perovskite structure and a large concentration of oxygen vacancies with no apparent long-range order. High-resolution electron microscopy indicates, however, that short-range ordering phenomena may occur. Electrical conductivity in this solid-state compound is independent of oxygen partial pressure (pO_2) for $pO_2 < 10^{-1.25}$ atmosphere, typical of ionic transport ($\sigma \sim 10^{-4}$ S/cm at 600 °C), whereas the conductivity is dominated by p-type charge carriers at higher pO_2 pressures. A number of substitutions have been made in this double-perovskite composition.

Several compositions in the system $Sr_{(1.45-x)}Ca_xSb_{0.55}O_{3-y}$ ($0 < x < 1.45$) have been synthesized by solid-state reaction at 1000 °C and investigated by powder XRD and EDS microanalysis. They exhibit good thermal stability up to 1200 °C. The solid solution range was delimited at the composition $0 < x < 1.1$. For quantities of Ca^{2+} higher than 1.1, the amount of solid solution decreases and another phase, $Ca_6Sb_2O_{10}$, appears.

A new phase, $Sr(Sr_{0.5}Sb_{0.5})O_{3-y}$ perovskite structure was discovered. This phase is the origin of a solid solution of SrO and $SrSb_2O_4 = Sr_{(1.5-x)}Sb_{(0.5+x)}O_{3-y}$, where x ranges between 0.00 and 0.64 ($0 \le x \le 0.64$) with the lattice parameter of a "double-perovskite", as determined by XRD. This is essentially a "strontium antimonite-strontiate". This oxygen-deficient and ordered perovskite-type structure was synthesized readily by a solid-state reaction in air at 1200 °C. The structure of the $Sr(Sr_{0.5}Sb_{0.5})O_{3-y}$ phase as determined by Rietveld analysis using XRD data, corresponds to an ordered perovskite with face-centered cubic symmetry, space group $Fm3m$ (No. 225) and lattice parameters, $a = 8.3136$ Å, $V = 574.602$ Å^3 and $Z = 8$. An important structural feature of $Sr(Sr_{0.5}Sb_{0.5})O_{3-y}$ is the oxygen deficiency and the displacements of oxygen atoms from their ideal positions toward the Sb^{5+} cations. This fact leads to an alternating arrangement of larger $[SrO_6]$ and smaller $[SbO_6]$ octahedra (B-sites), the remaining Sr^{2+} being in the larger 12-fold coordinated A-sites. The thermal stability of the $Sr(Sr_{0.5}Sb_{0.5})O_{3-y}$ phase was revealed because its melting point is 1480 °C, and it does not decompose at that point. Subsequent quenching of the liquid phase gives rise to a glassy material.

These double perovskites, as solid electrolytes at elevated temperature, are of interest for use in solid oxide fuel cells.

In another study, a penta-fluoroantimonite, $Sr_2Sb_2F_{10}$, in which all of the oxygen atoms (O^{2-}) have been replaced by (F^-) atoms has been synthesized. Strontium pentafluoroantimonite has the molecular weight of 354.8026 g/mol, and is orthorhombic with space group = Pbcm and $a = 4.378$ Å, $b = 8.853$ Å, $c = 11.233$ Å, $V = 435.3$ Å^3, $Z = 4$. The three-dimensional network consists of isolated SbF_5^{2-} units which are interconnected by ten-coordinated Sr^{2+} ions. The geometry of these pentafluoroantimonite ions is approximately square pyramidal with the Sr atom outside of the pyramid, below the four F^-atoms constituting the basal plane. Thus, $SrSbF_5$ is essentially an "Antimonite" in structure if not in chemical composition.

The literature is inadequate in terms of description of the physical and chemical properties of these strontium antimonites. No CAS numbers can be found. This class of salts has received little attention from academia and none from industry. No commercial suppliers offer these salts for sale.

Barium Antimonite

Barium antimonite can be prepared by firing the oxide with trivalent antimony oxide in an inert atmosphere at about 800–850 °C:

$$BaO + Sb_2O_3 \Rightarrow BaSb_2O_4$$

The system, $BaO \cdot Sb_3O_3$ has been investigated. The stable compounds are: $Ba_3Sb_2O_6$ and $Ba_2Sb_2O_5$. These compounds have been found to be triclinic and orthorhombic, respectively. The X-ray data are: barium antimonite(III)–$Ba_3[SbO_3]_2$, (triclinic, $P\bar{1}$, $a = 6.152$ Å,

$b = 9.814$ Å, $c = 12.154$ Å, $\alpha = 74.683°$, $\beta = 89.710°$, $\gamma = 71.464°$, $Z = 2$, $R_1 = 0.0802$) and $Ba_2[Sb_2O_5]$ (orthorhombic, Cmcm, $a = 4.010$ Å, $b = 14.506$ Å, $c = 6.366$ Å, $Z = 4$, $R_1 = 0.0589$). These compounds have been synthesized from melts of elemental barium and antimony oxide Sb_2O_3 at a temperature of 800 °C. Their oxoantimonite building units are strongly influenced by the stereochemically active lone pair electrons of the trivalent Sb(III) element. In the Ba-rich compound $Ba_3[SbO_3]_2$, isolated α-tetrahedra units, $[SbO_3]^{3-}$, are present; in $Ba_2[Sb_2O_5]$ which crystallizes with the $Sr_2Bi_2O_5$ structure type, two of these α-tetrahedra are condensed to form nuclear units $[Sb_2O_5]^{4-}$. The two compounds were compared in terms of structure and bonding with the alkali antimonites on one hand and with the alkaline earth bismutates on the other.

In another study, a penta-fluoroantimonite, $Ba_2Sb_2F_{10}$, in which all of the oxygen atoms (O^{2-}) have been replaced by (F^-) atoms has been synthesized. Barium pentafluoroantimonite has the molecular weight of 354.8026 g/mol, and is orthorhombic with space group = Pbcm and $a = 4.676$ Å, $b = 9.313$ Å, $c = 11.213$ Å, $V = 488.3$ Å^3, $Z = 4$. The three-dimensional network consists of isolated SbF_5^{2-} units which are interconnected by ten-coördinated Ba^{2+} ions. The geometry of these pentafluoroantimonite ions is approximately square pyramidal with the Ba atom outside of the pyramid, below the four F^-atoms constituting the basal plane. Thus, $BaSbF_5$ is essentially an "Antimonite" in structure if not in chemical composition.

The scientific literature concerning the barium antimonite salts are scarce indeed and no CAS numbers have been assigned to a commercial or academic product. None of these salts have been investigated in any detail other than those documented herein. There are no industrial products that use such antimonite salts and no patents concerning them.

Radium Antimonite

Radium antimonite could be prepared by firing the oxide with antimony trioxide in an inert atmosphere around 750–800 °C:

$$RaO + Sb_2O_3 \Rightarrow RaSb_2O_4$$

However, there is no record of anyone having done so. There is no demand for any of the possible or probable radium antimonites and the likelihood that they will ever be prepared is little to none because of the instability of such compounds in air and the intense radioactivity of ^{226}Ra atom.

4.4.2. Alkaline Earth Antimonates

These salts are generally prepared by reacting the oxides together in air.

Beryllium Antimonate

Beryllium antimonate can be prepared by firing BeO with Sb_2O_5:

$$BeO + Sb_2O_5 \Rightarrow BeSb_2O_6$$

The system, BeO/Sb_2O_5 has not been studied in any detail. Beryllium forms a mixed salt, $Na_2O{\cdot}8BeO{\cdot}Sb_2O_5 = Be_8Na_2Sb_2O_{14}$, which is a colorless, cubic compound with a density of 6.98 g/cc and a molecular weight of 585.6742 g/mol. Few papers are available describing the various salts of beryllium antimonate compositions.

Swedenborgite is a sodium-beryllium antimonate containing small amounts of Ca^{2+} ions which have been incorporated into the structure via the charge-compensation scheme:

$$Ca^{2+} + V^+ \Leftrightarrow 2Na^+$$

where "V" is a cation vacancy. Thus the molecular formula for Swedenborgite is:

$$(Na_{1-3x}Ca_xV_{2x})Be_4SbO_7$$

This mineral $[(Na_{0.88}Ca_{0.04}V_{0.08})Be_4SbO_7]$ is hexagonal, with unit-cell parameters: $a = 5.4317$ Å, $c = 8.8571$ Å, $V = 226.31$ Å^3, space group P63mc, $Z = 2$. The crystal structure was refined to an R index of 1.2. There is one *Sb* site occupied by Sb^{5+} and coordinated by an octahedron of O atoms, with a <Sb–O> distance of 1.97 Å. There are two *Be* sites that are each occupied by Be^{2+} and coordinated by a tetrahedron of O atoms, with a grand <Be–O> distance of 1.64 Å. There is one *Na* site, coordinated by 12 O atoms and occupied primarily by Na. The structure consists of layers of corner-sharing (BeO_4) tetrahedra and (SbO_6) octahedra that link together to form a dense framework. The resulting arrangement consists of (SbO_6) octahedra alternating with $[Be_4O_{13}]$ clusters that are fragments of the bromellite (BeO) structure. Small amounts of Ca are incorporated into the structure via the substitution $Ca + V_{Be} \Rightarrow 2Na$. The actual structure is shown in the following Fig. 4.74.

The structure can also be described as $[Be_4O_{13}]$ clusters and (SbO_6) octahedra placed at the vertices of a 6^3 net, and linked by sharing polyhedron vertices. Significant in this description is the fact that the $[Be_4O_{13}]$ cluster is a fragment of the bromellite (BeO) structure. Bromellite has the wurtzite structure and consists of identical layers of corner-sharing (BeO_4) tetrahedra that occupy the vertices of a 3^6-net. If we remove three Be and one O atoms per unit cell for such a layer, we obtain the pattern of (BeO_4) in the A layer of Swedenborgite. If we remove one Be atom per unit cell from a BeO layer, we obtain the B layer of Swedenborgite. Addition of Sb^{5+} and Na^+

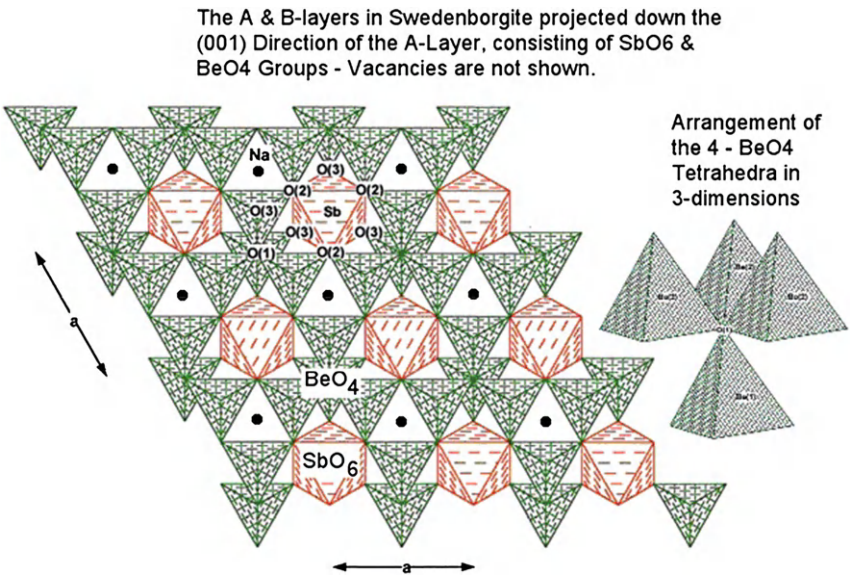

FIGURE 4.74

to the interstices of these layers results in the Swedenborgite structure:

$$Be_8O_8{-}Be_4{-}O + Sb_{5+} + Na \Rightarrow NaBe_4Sb^{5+}O_7.$$

Although several beryllium antimonate minerals have been studied, the system $BeO{\cdot}Sb_2O_5$ has not been studied in detail. No CAS number has been assigned and the papers dealing with beryllium antimonates are exceedingly rare. Even the early work of the 1880s do not list such compounds. No interest in industry has been shown in these compositions, due mainly to a lack of chemical and physical information concerning them. They are not available commercially.

Magnesium Antimonate

Magnesium antimonate can be prepared by firing MgO and antimony pentoxide in air at 1000 °C for 18 h:

$$MgO + Sb_2O_5 \Rightarrow MgSb_2O_6$$

The system $MgO{-}Sb_2O_5$ has not been studied in detail to establish the most stable antimonates. Indeed, the early literature cited compounds prepared in aqueous solution. The following compound was presented (1889), but no corroborating evidence has since emerged: $Mg(SbO_3)_2{\cdot}12H_2O$. It was said to be soluble in hot water.

In another preparation, $MgSb_2O_6$ samples were synthesized by a solution method, using Sb_2O_3 and H_2O_2 added to water and kept at 90 °C with stirring for 1.0 h to form Sb_2O_5. Stoichiometric $MgCl_2$ in aqueous solution was poured into the antimony pentoxide solution slowly and heated until evaporation of the solvent was achieved. After drying, the samples were pressed into pellets and sintered at 1320 K.

Single crystals of the compound, tetramagnesium diantimonate(V) $\{(MgO)_4[(Sb_2O_5)_2]$ or $Mg_4Sb_4O_{14}\}$, were obtained by a slow cooling method using K_2CO_3. The structure is isotypic with ilmenite, whose structure comprises the alternate stacking of layers consisting of metal–oxygen coordination octahedra. In each layer, the octahedra are connected by edge sharing so as to produce holes. One of the two nonequivalent metal sites is fully occupied by Mg (3-symmetry), while the second metal site (3-symmetry) is disordered and occupied by Mg and Sb with occupation factors of 1/3 and 2/3, respectively.

Other than this tetramagnesium diantimonate compound, no description of other Mg-antimonates has ensued to date. However, several antimonate minerals have been described.

"Bystromite" occurs in the antimony deposits of El Antimonio district as a tetragonal (ditetragonal dipyramidal) compound with lattice parameters of: $a = 4.68$ Å, $c = 9.21$ Å, $Z = 2$; $V = 201.72$ Å^3, $d = 5.9$ g/cc, Tetragonal-Bi-tetragonal Di-pyramidal, Point Group: (4/m,2/m,2/m), Space Group: $P4_1/mnm$, with two formula groups in the unit cell. The structure is of the trirutile type, and the mineral is isomorphous with the mineral, Tapiolite.

"Brandholzite", a magnesium antimony hydroxide hydrate mineral, $Mg(H_2O)_6[Sb(OH)_6]_2$, has been discovered in Au–Sb–Quartz veins of the former mining district of Brandholz-Goldkronach, Fichtelgebirge, Germany. This mineral is associated with stibnite and antimony ochers and forms colorless, plate-like crystals

up to ~1 mm in size. Natural as well as synthetic samples obtained by slow evaporation of an aqueous solution exhibit {100} twinning, leading to a pronounced I_m pseudo-symmetry. The crystal structures of Brandholzite and its synthetic analogue were investigated using single-crystal X-ray CCD data. It is trigonal, space group $P3$, $Z = 6$, $a = 16.119$ Å, $c = 9.868$ Å, (Brandholzite), and $a = 16.113$ Å, $c = 9.868$ Å, (synthetic analog). The structures are isotypic with "Bottinoite", $Ni(H_2O)_6[Sb(OH)_6]_2$, and are built up by nearly regularly shaped, isolated $Mg(H_2O)_6$ and $Sb(OH)_6$ octahedra which are interconnected by hydrogen bonds only.

Other than the above described compounds, no other combinations of $MgO \cdot Sb_2O_5$ have been found. No CAS numbers have been issued for any of these compounds and none of them is available commercially.

Calcium Antimonate

Calcium antimonite can be prepared by the solid-state reaction in air of the oxides. **A major study of the $CaO \cdot Sb_2O_5$ system had led to a seminal discovery**, namely that the stable phases obtained depend upon the firing temperature employed and less upon the ratio of CaO/Sb_2O_5 used. For the 1Ca:1Sb composition, a calcination at 1300 °C led to a pure $Ca_2Sb_2O_7$ weberite phase as the stable compound. Thus, the stable products obtained were: $1Ca:1Sb = CaSb_2O_4$ at 873 K (600 °C), $2Ca:1Sb = Ca_2Sb_2O_7$ at1073 K (800 °C) that is stable at 1573 K(1300 °C).

A study of the preparation of these two compounds has been made and it has been established that $Ca_2Sb_2O_7$ is orthorhombic. Calcium fluoantimonate was also synthesized for the first time and found to have the cubic structure of the mineral "Romeite". The probable formula is $Ca_4Sb_4O_{11}F_2$.

Actually, the early literature cited compounds prepared in aqueous solution. The following compounds were presented (1889), but no corroborating evidence has since emerged: $Ca(SbO_3)_2 \cdot 5H_2O$. Sodium meta-antimonate was used as the source but no mention of the pH or concentrations used was forthcoming.

Metastable antimony(V) oxide compounds were prepared via mechanochemical reactions in mixtures of CaO and the antimonite, Sb_2O_3, followed by mild oxidizing heat treatment and calcium leaching in a hydrochloric acid solution. They were characterized by XRD and thermal analysis. The synthesized compounds have the pyrochlore structure or a monoclinic pyrochlore-like structure ($Ca_{16}Sb_8^{3+}Sb_8^{5+}O_{48}$).

During the eighteenth Egyptian dynasty (1570–1292 BC), opaque white, blue and turquoise glasses were opacified by calcium antimonate crystals dispersed in a vitreous matrix. The technological processes as well as the antimony sources used to manufacture these crystals remain unknown. A new light on glass making history has been demonstrated in that, contrary to what was thought, Egyptian glassmakers did not use in situ crystallization but first synthesized calcium antimonate opacifiers, which do not exist in nature, and then added them to the molten glass. By using TEM for the first time in the study of Egyptian opaque glasses, it was shown that these opacifiers were nanocrystals. Prior to this research, such a process for glassmaking had not been suggested for any kind of ancient opaque glass production. Studying various preparation methods for calcium antimonate, it is supposed that Egyptian craftsmen (1570–1292 B.C.), could have produced $Ca_2Sb_2O_7$ by using mixtures of Sb_2O_3 or Sb_2O_5 with calcium carbonates (atomic ratio $Sb/Ca = 1$) heat treated between 1000 and 1100 °C.

Nonetheless, the literature is sparse and few papers dealing directly with calcium antimonates, their physical and chemical properties and uses in industry are rare.

Calcium antimonate as $CaSb_2O_4$ has the CAS number of 55200-87-8 and is offered for sale commercially.

Strontium Antimonate

Strontium antimonite can be prepared by the reaction of the oxides in proper proportion: For the 1:1:compound, the reaction takes place at 850 °C:

$$SrO + Sb_2O_5 \Rightarrow SrSb_2O_6 = Sr(SbO_3)_2$$

The system, SrO/Sb_2O_5 has not been thoroughly explored. Several different samples were prepared in the open air at a temperature of 1200 °C by varying the SrO/Sb_2O_5 ratio. The binary compounds $Sr_2Sb_2O_7$ and $SrSb_2O_6$ have been found and appear to be the most stable of those likely to form. Indeed, the early literature cited compounds prepared in aqueous solution. The following compound was presented (1889), but no corroborating evidence has since emerged of the existence of a hydrate, $Sr(SbO_3)_2 \cdot 6H_2O$. $SrSb_2O_6$ was synthesized by solid-state reactions between $Sr(NO_3)_2$ and Sb_2O_3 in air at 1150 °C for 24 h. This compound is essentially a meta-antimonate.

The Weberite, $Sr_2Sb_2O_7$ has been synthesized by reacting 2 mols of SrO to 1 mol of Sb_2O_5 at 1000 °C. Its molecular weight is 530.7432 g/mol. It is orthorhombic with space group = Imma and unit-cell parameters of $a = 7.4557$ Å, $b = 10.3708$ Å, $c = 7.6860$ Å, $V = 594.289$ Å^3, $Z = 4$. Although the Ca and Cd-salts form both the pyrochlore and weberite structure, Sr forms only the weberite modification. This compound shows high "photo-catalytic" activity in the presence of certain organic compounds like benzene and has been used to destroy such compounds when the mixture is exposed to UV light such as quartz-mercury lamps that emit 254 nm radiation.

This solid-state-prepared $Sr_2Sb_2O_7$ showed high photo-catalytic activity for benzene degradation under 254 nm UV irradiations, and no deactivation was observed during the prolonged photo-catalytic reaction. However, the photo-catalytic performance of a hydrothermally synthesized $Sr_2Sb_2O_7$ was superior to both P25 and the $Sr_2Sb_2O_7$ prepared by the conventional solid-state reaction. In the presence of the surfactant, cetyltrimethyl ammonium bromide (CTAB) or poly (vinyl pyrrolidone) (PVP), different three-dimensional hierarchical flower-like architectures of $Sr_2Sb_2O_7$, $Sr_2Sb_2O_7$ (CTAB) and $Sr_2Sb_2O_7$ (PVP) were successfully synthesized via a facile hydrothermal process using Sb_2O_5 as the starting material. The obtained samples were characterized by XRD, N_2-sorption BET surface area, UV-Visible diffuse reflectance spectroscopy, SEM, TEM, high-resolution transmission electron microscopy, and FT-IR spectroscopy. These are shown in Fig. 4.75.

"a" shows one form in which the micelles direct the antimonate "rods" into a loosely held particle while "b" shows another form in which the nanoparticles grow into a larger state before the particles agglomerate. The formation mechanisms for $Sr_2Sb_2O_7$ (CTAB) and $Sr_2Sb_2O_7$ (PVP) were proposed. Both $Sr_2Sb_2O_{7(CTAB)}$ and $Sr_2Sb_2O_{7(PVP)}$ show obvious photo-catalytic activity for the decomposition of salicylic acid under UV light illumination. $Sr_2Sb_2O_7$ (PVP) shows the best photo-catalytic activity for the degradation of salicylic acid due to its higher band gap energy and larger BET-specific surface area. Compared to samples prepared without the surfactant, both $Sr_2Sb_2O_7$ (CTAB) and $Sr_2Sb_2O_7$ (PVP) can be more readily separated from the slurry system by filtration or sedimentation after the photo-catalytic reaction and reused. This makes them ideal photo-catalysts for aqueous phase photo-catalytic reactions (Table 4.23).

It was shown that the light absorbance starts at about 350 nm for all these antimonate samples, while a uniform red shift of absorbance edge is observed in the order of $CaSb_2O_6$ ($\lambda = 346$ nm), $SrSb_2O_6$ ($\lambda = 349$ nm), and $BaSb_2O_6$ ($\lambda = 358$ nm). So the intrinsic band gaps of $CaSb_2O_6$, $SrSb_2O_6$ and $BaSb_2O_6$ are estimated at 3.59, 3.55 and 3.46 eV, respectively, using the widely applied equation: $Eg\ (eV) = 1241/\lambda\ (nm)$.

In spite of the potential uses of strontium antimonates as solid-state aqueous phase photo-catalytic reactants to destroy organic contaminants in soils and mixtures of organic compounds, these

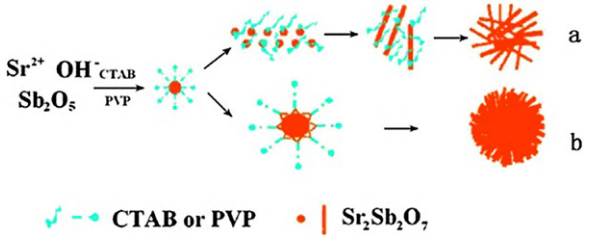

FIGURE 4.75

antimonates have not had a CAS number assigned. Little attention has ensued in industry and they are not being used in any capacity at this moment. The advent of fuel cells in the near future may change all of that. Certain types of Stand-Alone electrical-power generators, based on Fuel Cells, have been installed in certain manufacturing facilities. However, the solid-state conductance layer is not based upon strontium antimonates.

Barium Antimonate

Barium antimonate can be prepared by the solid-state reaction of BaO or $BaCO_3$ with Sb_2O_5 in air at about 1200 °C.

$$BaO + Sb_2O_5 \Rightarrow BaSb_2O_6$$

By changing the ratio of BaO/Sb_2O_5 during firing, a series of compounds is expected to result. However, there is no record in the literature concerning this possibility or even probability. No recent work is available although certain textbooks and reference books do cite $BaSb_2O_6$ as a stable compound. Indeed, the early literature cited compounds prepared in aqueous solution. The following compounds were presented (1889), but no corroborating evidence has since emerged:

$$Ba(SbO_3)_2 = BaO{\cdot}Sb_2O_5\text{—sl. soluble.}$$

$$Ba(SbO_3)_2{\cdot}2H_2O\text{—somewhat soluble (soluble in HCl)}$$

$$BaSb_4O_{11}{\cdot}5H_2O = BaO{\cdot}2Sb_2O_5\text{ (soluble in HCl)}$$

$$BaO{\cdot}3Sb_2O_5\text{ (insoluble in water–soluble in HCl)}$$

$$BaO{\cdot}4Sb_2O_5{\cdot}15H_2O$$

$$9BaO{\cdot}10Sb_2O_5{\cdot}18H_2O\text{ (insoluble in HCl)}$$

The salt, $Ba(SbO_3)_2$ or $BaSb_2O_6$ is offered for sale with the CAS number of 15600-59-6.

TABLE 4.23

Space	Catalyst	*Eg* (eV)	Crystal system	PF (%)	Method	Activity	Reference	Group

Nanoparticles of barium gadolinium antimonate, (Ba_2GdSbO_6), a complex perovskite-type oxide, have been synthesized using an autoignition combustion process. The nanoparticles thus obtained were characterized by powder XRD, TGA, DTA, Fourier transform infrared spectroscopy and TEM. The XRD studies showed that the as-prepared powder is phase-pure Ba_2GdSbO_6 and has a complex cubic perovskite crystalline structure with a lattice constant, $a = 8.449$ Å. The TEM image revealed that the particle size of the as-prepared nanopowder was in the range 30–60 nm. The nanocrystals of Ba_2GdSbO_6, synthesized by the combustion technique, could be sintered to 96% of the theoretical density by heating at a temperature of 1560 °C for a short duration of 3 h. The surface morphology of the sintered pellet was studied by use of a SEM. The dielectric constant ($\sigma_{\mu r}$) was 20 and the loss factor (tan θ) was ≈ 0.03 at 3 MHz. Using the present combustion technique, a phase-pure nanopowder of Ba_2GdSbO_6 could be obtained by a single-step process without the need of any calcination step.

Other rare-earth combinations studied include the Sm^{3+} ion. Nanoparticles of samarium barium antimonate (Ba_2SmSbO_6), a complex perovskite were also synthesized by the autoignition combustion process. The nanoparticles thus obtained were characterized in a similar manner. The XRD studies showed that the as-prepared powder is a phase-pure Ba_2SmSbO_6 and has the complex cubic perovskite ($A_2BB'O_6$) crystalline structure with a lattice constant of $a = 8.491$ Å. The particle size of the as-prepared powder was in the range 20–50 nm. The nanocrystals of Ba_2SmSbO_6 synthesized by the combustion technique could be sintered to 97% of the theoretical density by heating at a temperature of 1550 °C for 2 h. A similar study showed that Yttrium could also be incorporated into a powder which was phase pure Ba_2YSbO_6 with the complex cubic perovskite ($A_2BB'O_6$) crystalline structure and the lattice constant of $a = 8.402$ Å.

In another similar study, the crystal structure of the ordered perovskites $Ba_2(R,Sb)O_6$ (R = Y, Ho) was refined from neutron powder diffraction data in the space group *Fmm*(No. 225), $Z = 4$, with Ba at 8(*c*), R at 4(*b*), Sb at 4(*a*), oxygen at 24(*e*), oxygen positional parameter $x = 0.2636$ for R = Y and Ho, and unit-cell dimensions of $a = 8.4240$ Å and 8.4170 Å for R = Y and Ho, respectively. Bond valence analysis explains how the highly covalent Sb–O bonds determine the overall structure of these perovskites in which R–O and Ba–O bonds are under compressive and tensile stresses, respectively. The magnetic susceptibility of $Ba_2(HoSb)O_6$ has been measured in the temperature range 2–350 K. From an apriori estimation of the crystal-field parameters corresponding to the point site symmetry of the rare earth, O_h, and using the wave functions associated with the energy levels obtained, the paramagnetic susceptibility and its evolution vs temperature is simulated according to the van Vleck formalism. The observed deviation from the Curie–Weiss behavior at low temperature, very well reproduced, reflects the splitting of the ground state of this type of cation under the influence of the crystal field. These compositions were studied in relation to their possible superconducting properties relative to the copper-based compound, yttrium barium copper oxide = $YBa_2Cu_3O_7$.

Barium antimonate, $BaSb_2O_6$, has been tested as an opacifier in enamels used on cast iron. Antimonates of potassium, lithium, barium, calcium, magnesium, strontium, zinc, aluminum, lead, and tin were substituted for sodium antimonate in an acid-resisting dry process enamel for cast iron. The sodium antimonate content of this high-lead enamel was also varied to permit comparisons of all antimonates with sodium antimonate, as a standard, on an equivalent antimony pentoxide basis. In acid-resisting enamels, antimonates of potassium and barium compared reasonably well with sodium antimonate in opacifying power without introducing objectionable colors. Barium antimonate also produced improved acid resistance. Barium antimonate most closely approaches sodium antimonate in effectiveness. The behavior of the antimonates suggests an explanation for the variations often encountered with antimony oxide enamels.

Barium antimonate has been found to be a useful additive to varistor-ceramic compositions. When BaO was added to the usual $ZnO–Bi_2O_3–Sb_2O_3$ mixture and then fired, it was found that a new grain-boundary phase was formed consisting of $BaSb_2O_6$ besides the known Bi_2O_3 and $Zn_{2.33}Sb_{0.67}O_4$ grain-boundary phases. The barium antimonite phase was thermally stable and markedly improved the degradation tendencies of the varistor ceramic. The long-duration load voltage and surge current stability of the varistor were enhanced by this addition which improved the antidegradation properties (longer life).

The above five salts of barium and antimonate ions have received little attention from academia and even less from industry. None of these compounds have found marketable usage even though some of them are offered for sale commercially.

Radium Antimonate

Radium antimonate could be prepared by firing the oxide with antimony pentoxide in an air atmosphere around 750–800 °C:

$$RaO + Sb_2O_5 \Rightarrow RaSb_2O_6$$

However, there is no record of anyone having done so. There is no demand for any of the possible or probable radium antimonates and the likelihood that they

will ever be prepared is essentially zero because of the instability of such compounds in air and the intense radioactivity of ^{226}Ra atom.

4.4.3. Alkaline Earth Antimonides

Antimonides are generally prepared by solid-state reaction of the elements in an inert atmosphere. Whereas Be and Mg obey the basic electronic charge rules when reacted with Sb to form an alloy, i.e. $Mg_2^{2+}Sb_2^{3-}$, the heavier alkaline earths, Ca, Sr and Ba, form what appear to be "fractional-charge" compounds. They are, in reality, "Zintl phases" and obey the Zintl-Klemm electron counting rules and concept of covalent bonding in one-, two- or three-dimensions. The alkali and alkaline earth metals combine with the semimetals to form not only compounds with salt-like stoichiometries but also numerous compounds in which clustering of the semimetals occurs. Chains, rings, and cages of different lengths and sizes, as well as infinite sheets and porous frameworks are encountered. Such compounds as $Ca_{11}Sb_{10}$ and Ba_2Sb have been explained in terms of ionicity and charge assignment to each atom in the compound alloy. Zintl phases are a subgroup of brittle, high-melting point intermetallic compounds which are diamagnetic or exhibit temperature-independent paramagnetism, are poor conductors or are semiconductors. Zintl (1931) noted that there was an atomic volume contraction when these compounds were formed and realized this could indicate cation formation. He suggested that the structures of Zintl phases were ionic, where there was complete electron transfer from the more electropositive element. The structure of the anion (nowadays called the **Zintl ion**) should then be considered on the basis of the resulting electronic state. These ideas were further developed to become the **Zintl rules** or **Zintl-Klemm concept**, where the polyanion structure should be similar to an isoelectronic element.

Beryllium Antimonide

Beryllium antimonide has been prepared by the reaction of Be and Sb metals. Be melts at 1287 °C and is stable in an inert atmosphere until its boiling point of 2469 °C. Since Sb melts at 630.6 °C and is stable in an inert atmosphere until its boiling point of 1587 °C, the reaction is best carried out by evaporating Sb metal at about 1600 °C onto Be metal:

$$3Be + 2Sb \Rightarrow Be_3Sb_2$$

Although this is the expected reaction of these elements, it apparently does not always occur. Geach, Knapton and West (1958) observed no reaction between Be and Sb, but evaporation and electrical-resistivity measurements made by Ugai, Gordin and Anokhin (1964) indicated the existence of a compound with the formula Be_3Sb_2. Another study was undertaken to clarify the actual condition of beryllium antimonide and found that the stable form was $SbBe_{13}$, a material with space group = Fm3c, cubic with $a = 10.046$ Å, $Z = 8$, density = 3.13 g/cc, and $V = 1013$ Å^3. This compound has the $NaZn_{13}$ type of structure. Apparently, the Be^{3+} cation is too small to fit into a viable structure but requires 13-ions to form a stable one.

However, a patent (1968) stated that if Sb metal powder is "hot-pressed" with a large excess of Be-metal powder at about 1075 °C, a compound believed to be Be_3Sb_2 is formed. This cubic phase readily undergoes ordering which creates a distorted cubic structure, possibly tetragonal, with the *a*-axis only slightly different than the *b*-axis. Based upon X-ray examination, Be_2Sb_3 appeared to be the only compound in the binary Sb–Be system. The disordered structure is face-centered cubic with $a = 11.82$ Å. The point group was found to be T_h^7 with a density of 6.71 g/cc. Its melting point was stated to be 630 °C. Nonetheless, the pure compound could not be obtained but only as $(Be_3Sb_3)_{0.178} \cdot Be_{0.822}$ since the maximum content of Sb that could be incorporated was 0.16 of the weight of Be. However, the use of antimony to form the "beryllide" markedly improved the physical and mechanical properties of the Be metal so-treated and remains in use for some applications involving beryllium metal.

Although a phase diagram has been published, it is incomplete and is not included here.

Be_3Sb_2 has no CAS number and is not offered for sale by any manufacturer or supplier of beryllium or its compounds.

Magnesium Antimonide

Magnesium antimonide has been prepared by the reaction of Mg and Sb metals. Mg melts at 652 °C and is stable in an inert atmosphere until its boiling point of 1091 °C is reached. Since Sb melts at 630.6 °C and is stable in an inert atmosphere until its boiling point of 1587 °C, the reaction is best carried out by evaporating Mg metal at about 680 °C onto molten Sb metal:

$$3Mg + 2Sb \Rightarrow Mg_3Sb_2$$

Its molecular weight is 316.4351 g/mol and its CAS number is 12057-75-9. Mg_3Sb_2 melts at 1245 °C. Structural stabilities elastic properties and electronic structures have been determined from first-principles calculation by using Castep and Dmol computer programs based on the density functional theory given for the Mg_3Sb_2 phase. The calculation results of heat of formation and cohesive energy indicate that Mg_3Sb_2 has a strong alloying ability as well as the highest

structural stability of those compounds studied. The calculations of thermodynamic properties show that the Gibbs free energy of Mg_3Sb_2 changes with elevated temperature when the temperature is below 423 K (150 °C).

β-Mg_3Sb_2 crystallizes with an anti-La_2O_3-type structure with a space group of $P\bar{3}\,m1$. There is one formula unit in a hexagonal cell of $a = 4.558$ Å, $c = 7.229$ Å and a density of 4.02 g/cc. The existence of a polymorphic transition of β-Mg_3Sb_2 to cubic α-Mg_3Sb_2 has been suggested wherein the latter is isotypic La_2O_3. A phase diagram has been established (Fig. 4.76).

Layers of Mg_3Sb_2 evaporated in vacuo were found to exhibit semiconducting properties, although both constituents are normally metals. Under suitable conditions, the layers are photosensitive. Measurements were carried out on the spectral distribution of sensitivity, and showed bands with long wavelength edges at 1.5, 2.6 and 3.5 μ. The former is identified with intrinsic conductivity, and the two latter with impurity levels. Activation energies found from resistance-temperature measurements are very similar to the optical activation energies corresponding to the above wavelengths. Single-phase samples of Mg_3Sb_2 were prepared and found to contain oxygen at the grain boundaries. This compound was found to lose Mg and oxidize at temperatures above 900 K. Thermoelectric properties were characterized by Seebeck, electrical resistivity, and thermal conductivity measurements from 300 to 1023 K, and the maximum zT was found to be 0.21 at 875 K. Dimensionless figure of merit for Mg_3Sb_2 hot pressed and sintered at 873 K. The inset illustrates the crystal structure of Mg_3Sb_2 along the [100] direction (white = Mg, black = Sb).

In contrast, when zinc is added to Mg_3Sb_2, the result is a compound with metal-like conductivity. The $Mg_{3-x}Zn_xSb_2$ phases with $x = 0.00$–1.34 were prepared by direct reactions of the elements in tantalum tubes (Fig. 4.77).

According to the X-ray single crystal and powder diffraction, the $Mg_{3-x}Zn_xSb_2$ phases crystallize in the same $P\bar{3}m1$ space group as the parent Mg_3Sb_2 phase. The $Mg_{3-x}Zn_xSb_2$ structure is different from the other substituted structures of Mg_3Sb_2, such as (Ca, Sr, Ba) Mg_2Sb_2 or $Mg_{5.23}Sm_{0.77}Sb_4$. That is, in $Mg_{3-x}Zn_xSb_2$, it is the Mg_{tetr} atoms on the tetrahedral sites that are replaced, while in the other structures the Mg_{octa} on the octahedral sites is replaced. Thermoelectric performance for the two members of the series, Mg_3Sb_2 and $Mg_{2.36}Zn_{0.64}Sb_2$, was evaluated from low to room temperatures through the measurements of resistivity, Seebeck coefficient and thermal conductivity. In contrast to Mg_3Sb_2 which is a semiconductor, $Mg_{2.36}Zn_{0.64}Sb_2$ is metallic and exhibits an 18-times larger dimensionless figure-of-merit, ZT, at 20 °C. However, thermoelectric performance of $Mg_{2.36}Zn_{0.64}Sb_2$ is still poor and it is mostly due to its development of increased electrical resistivity at the higher temperatures.

In another study, the results of near infrared and visible optical studies on thin amorphous Mg–Sb alloy films were briefly reported. Excess Sb in the amorphous semiconductor Mg_3Sb_2 is found to change the band gap

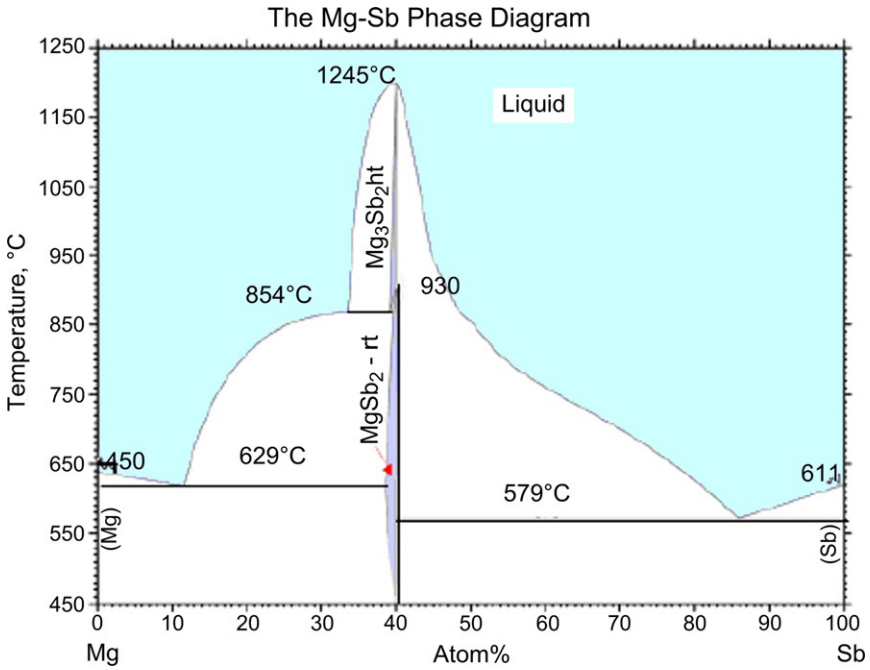

FIGURE 4.76

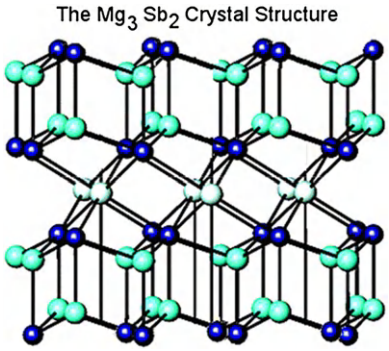

FIGURE 4.77

smoothly from about 1.05 for Mg_3Sb_2 to 0.24 eV for amorphous Sb. In contrast, excess Mg contributes localized states to Mg_3Sb_2 that fill in the band gap. The electrical properties of amorphous Mg–Sb alloys are discussed in terms of a model of a pseudogap containing localized states with the electrons moving by thermally activated hopping. However, in the Mg–Sb alloys on the Sb-rich side of the intermetallic compound, it appears that the density of states in the pseudogap is too low for hopping between localized states to be of importance, and the alloy behaves more like an extrinsic semiconductor with electrons being excited into acceptor states a few tenths of an electron volt above the valence band.

Mechanical alloying plus hot pressing was employed to prepare nanocrystalline Mg_3X_2 (X = Bi, Sb) compounds that were characterized by microstructural examinations and DC electrical resistance measurements. The results indicated that Mg_3Sb_{2+y} compounds with mean grain size 30 nm and with solute Sb atoms as much as 5 atom % in the powder specimens were successfully prepared. By comparison, $Mg_{3+x}Bi_2$ compound with solute Mg atoms as much as 13 atom% could be fabricated with similar grain sizes. Hot pressing at 673 K (400 °C for 20–50 min) only led to a limited grain growth (<10 nm) for both compound systems. However, experiments showed that hot pressing could further facilitate alloying of the elements in Mg–Bi system. In contrast, an elementary Sb phase formed gradually in the Mg_3Sb_{2+y} system with supersaturated solute Sb atoms incorporated during hot pressing, presumably due to its high ionicity and a large number of intragranular imperfections, as revealed by large lattice strain. DC-resistance measurements indicated that a semimetal–metal transition occurred in $Mg_{3+x}Bi_2$ system as solute $3+x$ reached 3.72; while in Mg_3Sb_{2+y} system a transition of its conduction behavior from logarithmic law to Mott's $T^{1/4}$ law was observed at $T < 190$ K (−83 °C) as solute Sb-content y exceeded 0.097, suggesting that phonon-assisted hopping occurred in the Mg_3Sb_{2+y} at the low temperatures.

The ternary polar intermetallic phase, $Mg_{5.231}Sm_{0.769}Sb_4$ has been obtained from solid-state reactions at 700–850 °C in sealed Ta or Nb containers wherein the synthetic conditions took into account its characteristic incongruent melting point. The compound crystallizes in the trigonal space group P ($Z = 1$) with $a = 4.618$ Å and $c = 14.902$ Å in a structure that derives from that of Mg_3Sb_2 (anti-La_2O_3 type). This composition appears to be near the lower limit of the Sm content, and solutions with appreciably higher Sm contents are also stable ($Mg_{6-x}Sm_xSb_4$ with $x \leq 1$). The structure has been presented in the literature, shown in Fig. 4.78.

The result provides the first example of a superstructure of a Mg_3Sb_2-like structure with a doubled c-axis induced by ordering a mixture of the larger trivalent and divalent Sm and Mg ions separately within alternate layers of octahedral sites of Sb^{3+} ions. Still larger proportions of Sm also give rise to a second solid solution region in the parent Mg_3Sb_2-type structure ($Pm1$), $Mg_{6-x}Sm_ySb_4$, ($0 \leq y \leq 1$). Retention of the same $3e^-$ valence electron counts per antimony in all of these phases suggests that the compounds remain electron precise and Zintl phases. Analogous compounds with Ca, Sr, or Ba substitution have evidently not been investigated.

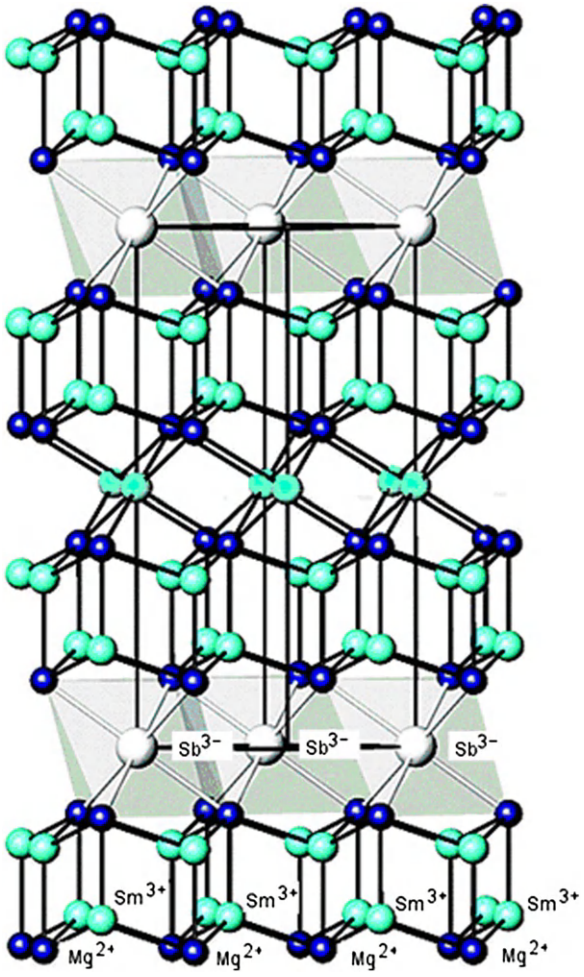

FIGURE 4.78

Magnesium and calcium antimonites, which can coexist with MgO and CaO, respectively, were synthesized by a phase-equilibration technique and identified by XRD to be $MgSb_2O_4$ and $Ca_4Sb_2O_7$. To determine the standard Gibbs energies of formation of those antimonites, e.m.f. values of the following galvanic cells have been measured:

$$\text{Pt, Re/Sb (solid,liq), } Sb_2O_3\text{(solid,liq)/}ZrO_2 + \text{CaO(or } Y_2O_3\text{)/air, Pt}$$

$$\text{Pt, Re/Sb (liq), } MgSb_2O_4 \text{ (solid), MgO (solid)/}ZrO_2 + \text{CaO/air, Pt}$$

$$\text{Pt, Re/Sb (liq), } Ca_4Sb_2O_7 \text{ (solid), CaOA(solid)/}ZrO_2 + \text{CaO/air, Pt.}$$

The following free energies of formation were determined:

$$\Delta G^0/\text{kJ/mol} \pm 0.4 = -687.7 + 0.2425\ T \text{ (773–904 K),}$$
$$\text{for 2Sb (solid)} + 3/2O_2 \text{ (gas)} = Sb_2O_3 \text{ (solid)}$$
$$\Delta G^0/\text{kJ/mol} \pm 0.3 = -730.2 + 0.2895\ T \text{ (904–929 K),}$$
$$\text{for 2Sb (solid)} + 3/2O_2 \text{ (gas)} = Sb_2O_3 \text{ (solid)}$$
$$\Delta G^0/\text{kJ/mol} \pm 0.2 = -683.1 + 0.2385\ T \text{ (929–1095 K),}$$
$$\text{for 2Sb (liq)} + 3/2O_2\text{(gas)} = Sb_2O_3 \text{ (ℓ)}$$
$$\Delta G^0/\text{kJ/mol} \pm 0.7 = -78.9 + 0.0495\ T \text{ (929–1101 K),}$$
$$\text{for } Sb_2O_3 \text{ (liq)} + \text{MgO (solid)} = MgSb_2O_4 \text{ (solid)}$$
$$\Delta G^0/\text{kJ/mol} \pm 0.7 = -134.7 + 0.0017\ T \text{ (972–1101 K),}$$
$$\text{for } Sb_2O_3 \text{ (liq)} + 4\text{CaO (solid)} = Ca_4Sb_2O_7 \text{ (solid).}$$

Magnesium antimonide has also been used in an electrochemical and device apparatus for high-amperage electrical energy storage. It features a high-temperature, all-liquid chemistry. The batteries are simply tanks filled with three separate layers of liquid that float on top of one another at 700 °C: the top layer is molten magnesium, the bottom is antimony, and the middle layer is a salt containing magnesium antimonide, a dissolved compound of the two metals. When the battery is being charged, magnesium antimonide in the middle layer breaks down into the pure elements and so the upper and lower layers deepen. Discharging the battery reverses the process and releases electrons to provide power. Once heated up to its operating temperature, the battery generates enough heat on its own to keep the liquids molten. The reaction products created during charging remain part of the electrodes during storage for discharge on demand.

In a simultaneous ambipolar electrodeposition cell, a reaction compound is electrolyzed to effect transfer from an external power source; the electrode elements are electro-dissolved during discharge. A cell containing molten metal layer of: magnesium (density 1.5 g/ml, melting point 650 °C), a liquid metalloid layer of antimony (density 6.5 g/ml, melting point 630 °C) and an appropriate electrolyte containing magnesium antimonide (density 4.1 g/ml, melting point 1245 °C) was found to be a system of immiscible liquids having the requisite conductivity modes that could self-assemble into the layers shown in the following figure. These, upon melting, provided for simple manufacture and assembly of a cell from billets. A cell containing these constituents preferably operates around 700 °C. The design of such a cell is shown in Fig. 4.79.

With reference to this cell, an energy storage cell **10** of the invention houses three liquid constituents: a molten metal layer **14** that serves as negative electrode; a liquid metalloid layer **16** that serves as positive electrode; and an intervening ionically conductive electrolyte **20**. The liquid constituents are housed in a conductive container **22** which provides mechanical support to an inner sheath **24**. The sheath **24** prevents shorting by electronic conduction between the negative electrode **14** and the positive electrode **16** through the container **22**. The sheath **24** also protects the conductive container **22** from chemical attack by corrosive salts in the electrolyte **20**. The cell is covered by a conductive lid **26**. An insulating seal **29** electrically insulates the lid **26** from the container **22** and confines molten constituents and vapors to the container **22**. The portion of the lid **26** in contact with the negative electrode **14** functions as a negative current collector **27**, through which electrons pass between the molten electrode **14** and an external source or sink by way of a negative terminal **28**. The portion of the container **22** in contact with the positive electrode **16** functions as a positive current collector **23**, through which electrons pass between the molten electrode **16** and an external source or sink by way of a positive terminal **30**. The placement of the

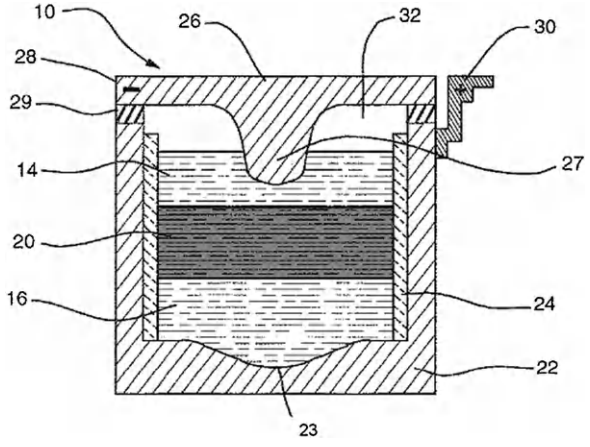

FIGURE 4.79

negative terminal **28** and the positive terminal **30** facilitates arranging individual cells in series by connecting the positive terminal of one cell to the negative terminal of another cell. An inert gas layer **32** overlaying the negative electrode **14** accommodates volume changes in the three-constituent system during charging and discharging. Optionally, the lid **26** or seal **29** incorporates a safety pressure valve.

In the case of the magnesium–antimony cell system, a lower melting supporting electrolyte was needed to bring the liquid range of the electrolyte **20** down from the melting point of magnesium antimonide and within the liquid range of magnesium, which boils at 1090 °C. Preferably, the liquid electrolyte **20** has a liquid range permitting a cell operating temperature close the melting temperatures of the electrode elements. Prime candidates for supporting electrolyte in a magnesium–antimony magnesium–antimonide system are sodium sulfide, lithium sulfide, calcium sulfide, magnesium sulfide and potassium sulfide. Other additives may include sodium selenide, lithium selenide, sodium antimonide and small amounts of other selenides, tellurides and/or halides.

Structural stabilities, elastic properties and electronic structures have been determined from first-principles calculation by using Castep and Dmol computer programs based on the density functional theory for the aluminum alloy, $Mg_{17}Al_{12}$ as well as those of Mg_3Bi_2 and Mg_3Sb_2 phases. The calculation results of heat of formation and cohesive energy indicated that Mg_3Sb_2 has the strongest alloying ability as well as the highest structural stability. The calculations of thermodynamic properties showed that the Gibbs free energy of formation for $Mg_{17}Al_{12}$, Mg_3Bi_2 and Mg_3Sb_2 change with elevated temperature. When the temperature is below 423 K (150 °C), Mg_3Sb_2 and Mg_3Bi_2 are more stable than the $Mg_{17}Al_{12}$ phase and Sb or Bi addition to the Mg–Al-based alloys can improve the heat resistance. The elastic parameters were calculated, then the bulk modulus, shear modulus, Young's modulus and Poisson ratio value were derived. All the results of the analysis indicate that adding Sb to Mg–Al alloy could improve the ductility and plasticity by forming Mg_3Sb_2 phases.

Laboratory experiments to test Mg_3Sb_2 as a reagent to disperse thick fog by condensation of water have shown that when this substance sublimes in a supercooled fog, the upper temperature limit for the occurrence of the ice phase is about −10–11 °C. The temperature limit increases to −8 or –9 °C when Mg_3Sb_2 in aqueous suspension is sprayed into the fog. Hence, Mg_3Sb_2 is, basically, an effective reagent for crystallizing a supercooled fog. However, there are some practical difficulties involved in employing this substance, e.g the instability of the substance and the difficulty of producing and dispersing it.

There are no vendors are listed for this material even though it has been assigned a CAS number. There are several potential commercial usages for this compound that have not materialized as yet. This includes high-amperage electrical energy storage.

Calcium Antimonide

Calcium antimonide can be prepared by the reaction of Ca and Sb metals. Ca melts at 842 °C and is stable in an inert atmosphere until its boiling point of 1484 °C is reached. Since Sb melts at 630.6 °C and is stable in an inert atmosphere until its boiling point of 1587 °C, the reaction is best carried out by evaporating Ca metal at about 880 °C onto molten Sb metal:

$$3Ca + 2Sb \Rightarrow Ca_3Sb_2$$

However, the product(s) is not the expected 3:2 compound but a series of Zintl products whose composition is dependent upon the initial Ca:Sb atomic ratio. Ca_3Sb_2 itself does not exist but Ca_5Sb_3 does. The most stable compound was determined to be $Ca_{11}Sb_{10}$. It was only after the Zintl-Klemm electron counting rules and concept of covalent bonding in one-, two- or three-dimensions became a reality that such compounds could be explained in terms of ionicity and charge assignment to each Atom in the compound alloy. A phase diagram has been established (Fig. 4.80).

The early work on calcium antimonides as intermetallic compounds involved determination of standard Gibbs energies of formation of Ca_3Sb_2, and Ca_3Bi_2 by a chemical equilibration technique yielding the following results:

$$3Ca\ (liq) + 2Sb\ (liq) = Ca_3Sb_2\ (solid)$$

$$\Delta G^\circ = -726{,}300 + 159.3\ T\ (\pm 24{,}600)\ (J/mol)$$

$$(1273\ to\ 1573\ K)$$

$$3Ca\ (liq) + 2Bi\ (liq) = Ca_3Bi_2\ (solid)$$

$$\Delta G^\circ = -696{,}400 + 195.6\ T\ (\pm 23{,}200)\ (J/mol)$$

$$(1148\ to\ 1323\ K)$$

The stabilities of these compounds were also discussed by using the critical oxygen partial pressures calculated from the above equations.

A Knudsen effusion technique combined with mass-spectrometric analysis of the evaporated species was used to investigate the gaseous phase and to determine the thermodynamic properties of alloys of calcium with antimony in the temperature range from 933 to 1669 K (660–1396 °C). Concentration of antimony varied from 50.2 to 63.5 mol%. The thermodynamic properties of the liquid phase were approximated by

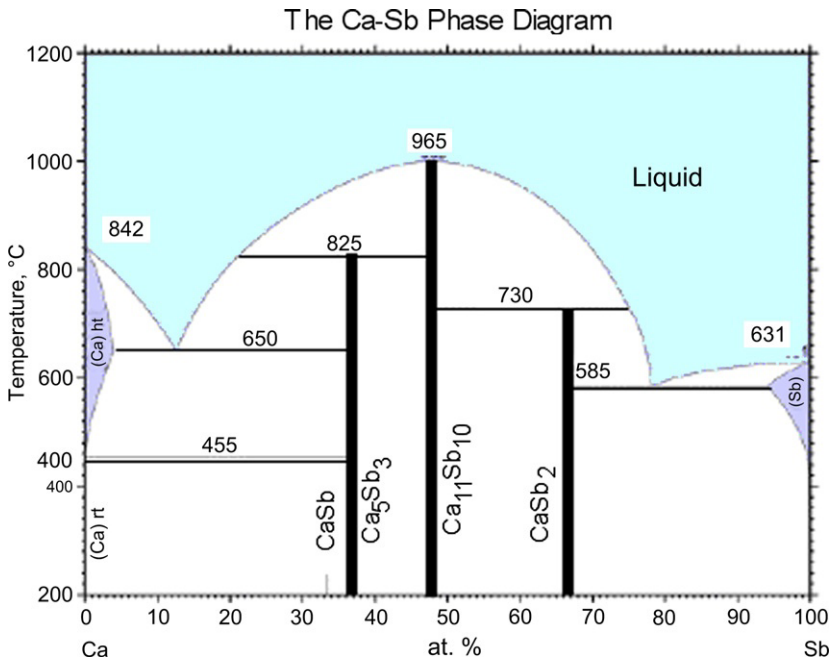

FIGURE 4.80

the association solution model, assuming that four types of associates Ca_3Sb_2, Ca_3Sb, Ca_2Sb and CaSb can exist in the melt. The Gibbs energies of formation of compounds from solid components were expressed by the equations:

$$\Delta_f G\ (Ca_{11}Sb_{10}) = (218{,}844 \pm 14595) - (43.47 \pm 12.34)\ T, \text{J/mol}$$

$$\Delta_f G(Ca_5Sb_3) = -(919{,}276 \pm 5110) + (34.24 \pm 4.75)\ T, \text{J/mol}$$

The obtained data were used for the computation of the part of the Ca–Sb phase diagram, corresponding to the composition range studied.

The latest data are shown in the above phase diagram where the congruently melting compound is $Ca_{11}Sb_{10}$, which melts at 965 °C. The other three compounds, Ca_2Sb, Ca_5Sb_3 and $CaSb_2$ all melt incongruently with corresponding horizontal eutectics of 455, 825 and 730 °C.

Data concerning the compositions forming in the Ca–Sb system have been controversial. CaSb was reported to melt congruently (985 °C) while the compounds Ca_3Sb_2 and $CaSb_3$ were reported to melt with decomposition. The corresponding horizontal peritectics were reported as 825 and 730 °C, respectively. The corresponding thermodynamic constants have not always been consistent. The standard enthalpy of formation, $\Delta H_{f(298)}$, has been given as 728 kJ/mol and the standard entropy, S^0_{298} as 157.3 J/mol. In the range of 1000–1300 °C, the Gibbs free energy of formation for the reaction to form Ca_3Sb_2 has been given as:

$$\Delta G^0_f = -726{,}300 + 159.6\ T \pm 24{,}000$$

However, this stoichiometric compound is not stable and is supplanted by the compound, Ca_2Sb. Furthermore, the most stable compound is $Ca_{11}Sb_{10}$, not the conventional Ca_3Sb_2 where the ionic charges on the latter are Ca^{2+} and Sb^{3-} whereas the formal charges on the former appear to be Ca^{2+} and $Sb^{2.2-}$. This relates to the fact that the stable compounds in the Ca–Sb system adhere to the Zintl-Klemm electron counting rules and concept of covalent bonding in one-, two- or three-dimensions. That is, linear chains, square two-dimensional boxes or three-dimensional networks are the norm. Thus, the optimal electron count for a linear chain is seven electrons per atom, six electrons per atom for a square lattice and five electrons per atom for a simple cubic lattice.

The basic concept behind the Zintl-Klemm concept is the transfer of electrons from more electropositive elements to more electronegative elements like Sb. This protocol usually works well with the alkaline earths as electron donors but as the atomic weight and number of electrons increase, as in Ca, Sr and Ba, things are not so simple. Thus, a "fractional-valence" seems to appear as in $Ca_{11}Sb_{10}$. Isolated Sb_4 squares are quite common within antimony phases. If the electron-octet is completed around the Sb_4 squares, then this leads to

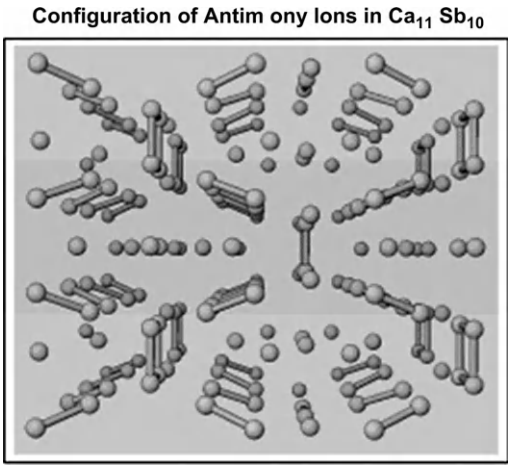

FIGURE 4.81

a –1 charge on each Sb atom in the square. $Ca_{11}Sb_{10}$ contains one isolated Sb_4 square, four Sb_2 pairs and eight Sb atoms per two formula units. This is shown in the following Fig. 4.81.

This gives the following assignment of charge to this Zintl phase:

$$(Ca_{22})^{44+}(Sb_4^{square})^{4-}(Sb_8^{pair})^{16-}.$$

In contrast, $CaSb_2$ consists of planar zigzag helical chains as shown in the following Fig. 4.82.

Thus, the charge assignment is:

$$Ca^{2+}(Sb^{atom})^{-}(Sb^{helix})^{-}.$$

The lattice parameters for CaS_2 are: $a = 4.746$ Å, $b = 4.177$ Å, $c = 9.084$ Å, $\beta = 106.3°$, Space Group = $P2_1/m$, $Z = 2$. In the helix, the Sb···Sb bond distances vary from 2.92 and 2.94 Å.

The compound, Ca_5Sb_3, appears to have two modifications. Hexagonal Ca_5Sb_3 and Ba_5Bi_3 belong to the hexagonal Mn_5Si_3 type; Sr_5Bi_3 is isostructural with orthorhombic β-Yb_5Sb_3. The orthorhombic form of

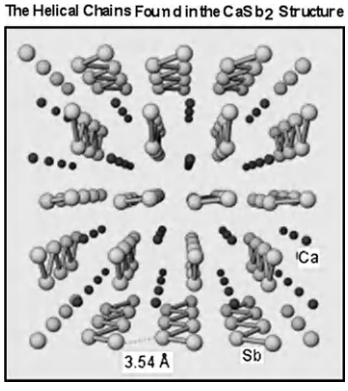

FIGURE 4.82

Ca_5Sb_3 (β-Yb_5Sb_3 type) has already been reported in the literature as stable at room temperature. It crystallizes as: Space Group = Pnma, with four formula units in a cell of: $a = 12.502$ Å, $b = 9.512$ Å, $c = 8.287$ Å, $d = 3.81$ g/cc, $Z = 4$. The Zintl-Klemm charge assignment is:

$$Ca_5^{10+}(Sb_2^{pair})^{4-}(Sb^{atom})^{2-}$$

Ca_2Sb can be obtained by the thermal decomposition of $Ca_2Sb_{1-x}I_x$. It crystallizes in the tetragonal system with $a = 4.69$ Å, $C = 16.39$ Å and Space group = 14 mm. The structure can be described as an arrangement of cubes with Sb atoms at each corner. The faces are centered by Ca atoms. These cubes build infinite layers along the x- and y-axes. A glide plane appears along the sequence of these layers along the z-axis. The corners of the upper cubes project at the center of the faces of the lower cubes. The Zintl-Klemm charge assignment for this compound is thus:

$$Ca_4^{8+}(Sb_2^{cube})^{8-}$$

The relation of these calcium antimonates has been somewhat elucidated by a study involving the addition of iron to this Ca–Sb system. This is shown in the following phase Fig. 4.83.

Samples of $Ca_{11}Sb_{10}$ have been synthesized using a high-temperature (1075–1275 °C) flux method. This compound is iso-structural to $Ho_{11}Ge_{10}$, crystallizing in the body-centered, tetragonal unit cell, space group I4/mmm, with $Z = 4$. The structure consists of antimony dumbbells and squares, reminiscent of Zn_4Sb_3 and filled "Skutterudite" (e.g. $LaFe_4Sb_{12}$) structures. In addition, this structure can be considered a Zintl compound and are valence precise semiconductors with ionic contributions to the bonding. DSC, thermogravimetry (TG),

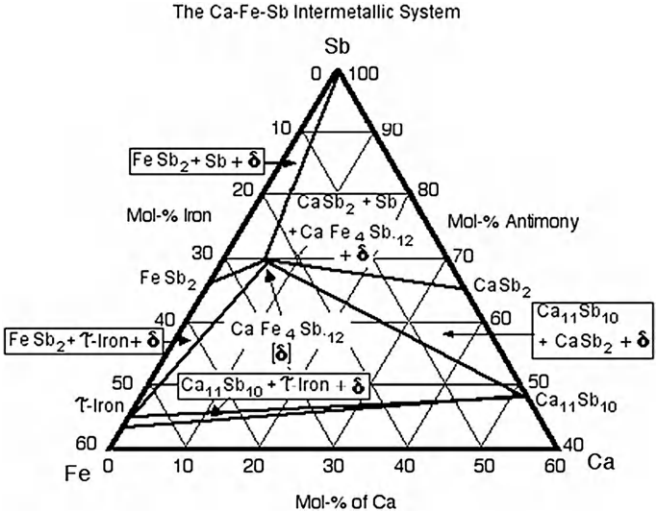

FIGURE 4.83

resistivity ([ρ]), Seebeck coefficient ([α]), thermal conductivity ([κ]), and thermoelectric figure of merit (zT) from room temperature to a minimum of 700 °C are presented for $Ca_{11}Sb_{10}$. DSC/TG were measured to 1250 °C and reveal the stability of these compounds. This compound exhibits remarkably low-lattice thermal conductivity (~10 mW/cm K) for $Ca_{11}Sb_{10}$ that can be attributed to the complex crystal structure. $Ca_{11}Sb_{10}$ is a semiconductor suggesting that a gradual metal–insulator transition may be possible upon the addition of a trivalent ion like Yb^{3+} or Y^{3+}. The low values and the temperature dependence of the Seebeck coefficients for this compound suggest that bipolar conduction produces a compensated Seebeck coefficient and consequently a low zT.

Calcium antimonide is particularly unstable in the presence of water and releases the volatile Stibine gas (Ayhan et al. 1982):

$$Ca_{11}Sb_{10} + 6H_2O \Rightarrow 2SbH_3\ (gas) + 3Ca(OH)_2$$

Perhaps this is the reason that no calcium antimonides have found usage in industry. None of these compounds have received CAS numbers and there are no listed suppliers commercially.

Strontium Antimonide

The compounds formed by solid-state reaction of strontium and antimony are lesser known than those of Ca or Ba. Perhaps this is due to the higher cost of Sr. Nonetheless, Sr forms the same type of Zintl phases and these compounds have been mentioned in conjunction with discussion of the Ca and Ba Zintl-Klemm analyses. The known strontium intermetallic phases include:

$$Sr_{11}Sb_{10}\quad Sr_2Sb\quad Sr_5Sb_4\quad Sr_2Sb_3\quad SrSb_3$$

Thus, the conventional Sr_3Sb_2 compound, where the ionic charges are Sr^{2+} and Sb^{3-} is not known. Since Sr melts at 777 °C and is stable in an inert atmosphere until its boiling point of 1382 °C is reached. Since Sb melts at 630.6 °C and is stable in an inert atmosphere until its boiling point of 1587 °C, the reaction is best carried out by evaporating Sr-metal at about 787 °C onto molten Sb metal in an inert atmosphere:

$$xSr + yBe \Rightarrow Sr_xSb_y$$

where x can vary from 1 to 11 and y varies from 1 to 10.

$SrSb_3$, $Sr_{11}Sb_{10}$, Sr_3Sb_2 and Sr_2Sb have melting points of 680 °C, 935 °C, 880 °C and 840 °C. All except $Sr_{11}Sb_{10}$ melt incongruently. Thus, the phase diagram is quite similar to that of calcium and its antimonides, as shown in the following Fig. 4.84.

Sr_2Sb crystallizes in the tetragonal system, space group I4/mmm, with four formula units in a cell of dimensions of $a = 5.002$ Å and $c = 17.405$ Å. The point group is tP_t6 and the space group is P4/nmm with atoms in the positions of 2 (*a*) O,O,O; 2(c_i) (0, 1/2, z_i) and 2(z_2) (O, 1/2, Zn).*i*. There are uncommonly short

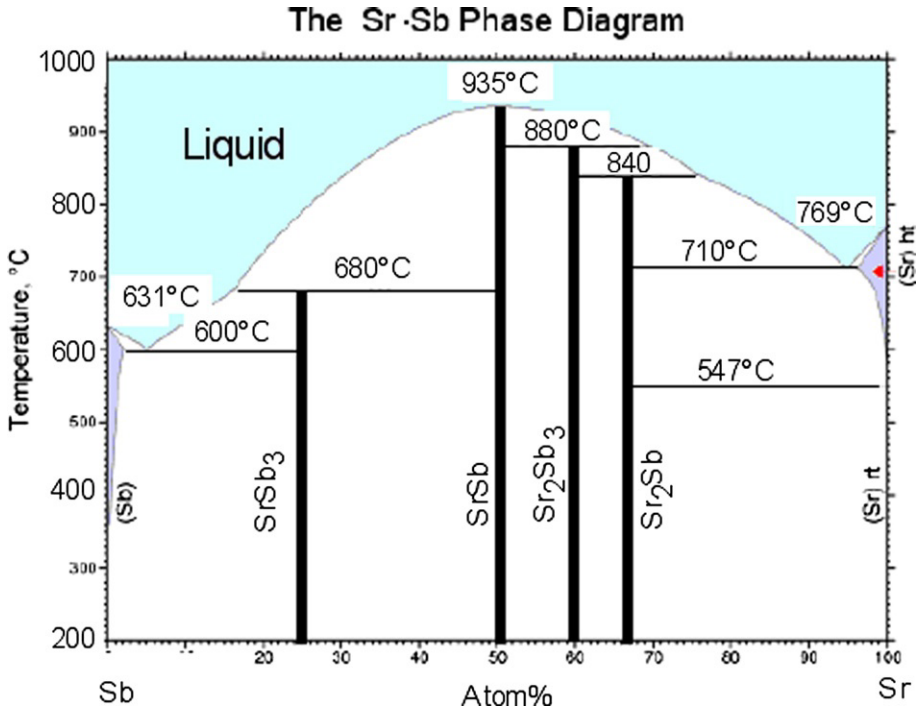

FIGURE 4.84

Sr···Sr distances in layers perpendicular to the *x*-axis. The positional cell coordinates of these are: Sr(1) at (0,1.2,)-($B = 0.85$ Å^2), Sr(2) at (0,0,0.328)-($B = 1.24$ Å^2), and Sr(3) at (0,0,0.137)-($B = 0.94$ Å^2). Single crystals can be prepared using a 2:1 ratio of these are crystallographically important points in the crystal lattice Sr:Sb. The crystals are black and have a laminar shape, the *c*-axis being perpendicular to the length. Because of their extreme sensitivity to air, they have to be kept under argon atmosphere.

Sr_2Sb_3 crystallizes in the monoclinic system with lattice parameters $a = 6.670$ Å, $b = 12.973$ Å, and $c = 15.208$ Å, with $\beta = 90.03°$, space group P21/c. The structure is characterized by Sb_6^{chains} and the compound belongs to the Zintl phases. The empirical formula is Sr_4Sb_6 and the Zintl charge-density formula is $Sr_4^{8+}(Sb_6^{chains})^{8-}$.

Sr_5Sb_3 crystallizes both in a tetragonal and orthorhombic phase. Single crystals of Sr_5Sb_3 can be prepared by cooling a melt of 3 Sr/2Sb from 1350 °C to room temperature. Isolated crystals are black and unstable to air. It crystallizes as a Mn_5Si_3 type (tetragonal) with space group $P6_3/mcm$ and two formula units per cell with dimensions of: $a = 9.496$ Å, $c = 7.422$ Å. The density is 4.602 gm/cc. This compound has a chain-structure like Ba_2Sb_3 except that the chains are linear, not zigzag. The assigned electrical Zintl-Klemm charge is:

$$(Sr5)^{10+}(Sb)^{3-}(Sb)^{4-}(Sb)^{3-}$$

There is one unusually-short Sr···Sr bond distance in the crystal.

Both tetragonal and orthorhombic phases have been identified. The tetragonal phase has the unit-cell constants of: $a = 5.002$ Å, $c = 17.405$ Å with density = 1.740 g/cc and Sr(1) at (0,0,0.137) and Sr(2) at (0,0,0.328).

In another study (1990), four phases were synthesized and their crystal structures determined by powder diffraction methods. $Sr_{11}Sb_{10}$ ($a = 12.581$ Å, $c = 18.098$ Å) and $Sr_{11}Bi_{10}$ ($a = 12.801$ Å, $c = 18.451$ Å), space group = I4/mmm, are of the $Ho_{11}Ge_{10}$ type. Relatively few compounds crystallize with this structure type. The structure consists of square-planar Sb_4 rings which are interconnected three-dimensionally by Sb_2 dumbbells. Therefore, the Zintl-Klemm designation is:

$$(Sr_{11})^{22+}(Sb_4^{square})_2^{8-}(Sb_6^{pair})^{12-}(Sb_2^{single})^{2-}.$$

Thus, the structure resembles that of the barium compound. The crystal structure of a fifth compound Sr_2Bi_3 was determined by single-crystal diffractometry: $M_r = 802.18$, orthorhombic, *Pnna*, $a = 15.631$ Å, $b = 6.793$ Å, $c = 6.599$ Å, $V = 700.4$ Å^3, $Z = 4$, $d_x = 7.60$ g/cm^3, Sr_2Bi_3 is of a new type and is closely related to the monoclinic Sr_2Sb_3 and Ca_2As_3 structures.

A new Zintl compound strontium tin antimonide, $SrSn_3Sb_4$, has been synthesized, and its structure has been determined by single-crystal XRD methods. It crystallizes in the orthorhombic space group—Pnma with $a = 10.060(2)$ Å, $b = 4.361(1)$ Å, $c = 22.934(4)$ Å, and $Z = 4$ at 22 °C. The structure of $SrSn_3Sb_4$ may be described as consisting of large, narrow channels running along [010] defined by 30-membered rings constructed from an anionic framework of linked $SnSb_4$ tetrahedra, $SnSb_3$ trigonal pyramids, and zigzag Sb–Sb chains. Sr^{2+} cations are situated within these channels. The channel structures of $SrSn_3Sb_4$ and $Ba_2Sn_3Sb_6$ are closely related. The relation of these strontium antimonides has been somewhat elucidated by a study involving the addition of iron to this Sr–Sb system. This is shown in the following phase Fig. 4.85.

Although $Sr_{11}Sb_{10}$ melts congruently and is featured prominently in the Ca–Sb–Fe phase diagram, it does not appear in the Sr–Sb–Fe phase diagram. The reason for this remains unknown. The stable phases are: Sr_2Sb_3, $SrSb_2$, and $FeSb_2$. Strontium antimonite is not listed for sale in general although $SrSb_2$ is offered for sale commercially. None of these Sr–Sb compounds have CAS numbers.

Barium Antimonide

Barium antimonide can be prepared by the reaction of Ba and Sb metals. Ba melts at 727 °C and is stable in an inert atmosphere until its boiling point of 1897 °C is reached. Since Sb melts at 630.6 °C and is stable in an inert atmosphere until its boiling point of 1587 °C, the reaction is best carried out by evaporating Ba-metal at about 780 °C onto molten Be metal:

$$xBa + ySb \Rightarrow Ba_xSb_y$$

where $0 < x < 12$ and $0 < y < 12$. Its CAS number is 12057-75-9.

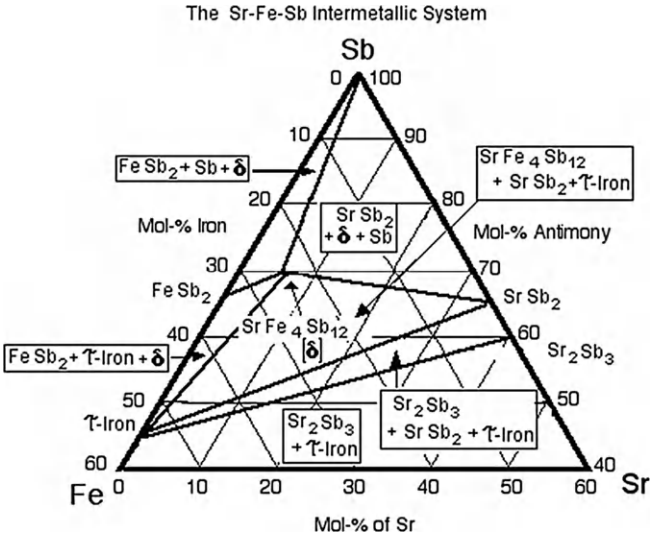

FIGURE 4.85

The $Ba_{11}Sb_{10}$ compound melts at 945 °C. $BaGa_2Sb_2$ was obtained from a direct element combination reaction in a sealed graphite tube at 950 °C, and its structure was determined by single-crystal XRD methods. It crystallizes in the orthorhombic space group Pnma (No. 62) with $a = 25.454(5)$ Å, $b = 4.4421(9)$ Å, $c = 10.273(6)$ Å, and $Z = 8$. The anionic $[Ga_2Sb_{6/3}]^{2-}$ framework is assembled by the ethane-like dimeric $[Sb_3Ga–GaSb_3]$ units sharing Sb atoms, forming parallel tunnels with a 26-membered ring cross section. These tunnels are filled with Ba atoms. The three-dimensional $[Ga_2Sb_{6/3}]^{2-}$ framework features a new structure type. The compound satisfies the classical Zintl concept. Band structure calculations indicate that the material is a semiconductor, and this is confirmed by spectroscopic experiments which show $E(g)$ approximately 0.35 eV. The calculations also suggest that the structure is stabilized by strong Ga–Ga covalent bonding interactions. Polycrystalline ingots of $BaGa_2Sb_2$ show room-temperature electrical conductivity of approximately 65 S/cm and a Seebeck coefficient of +65 μV/K.

Barium antimonides are Zintl complexes involving a numbers of types of Ba···Ba bond configurations. For example, Ba_5Sb_4 forms a series of one-dimensional pairs (dumbbells) plus isolated atoms. $BaSb_3$ on the other hand forms two-dimensional nets which are interconnected (2,3-connected nets). Still another configuration involves Ba_2Sb_3 with linear Ba_6 zigzag units (also Sb_2Sb_3). $Ba_{11}Sb_{10}$ forms a series of linear Sb_4 squares, plus pairs, and separated atoms.

The most commonly occurring in barium antimonides is a Sb substructure with an Sb···Sb bond involving an Sb_2 pair, or dumbbell. In theory, the pair can have 7, 6 or 5 electrons per Sb atom that would formally be consistent to single, double or triple bonds. In Ba_5Sb_4, the charges can be assigned as $(Ba_5)^{10+}(Sb_2^{atom})^{6-}(Sb_2^{pair})^{4-}$.

The crystal structure of Ba_2Sb_3 contains isolated zigzag chains as shown in the following Fig. 4.86.

Thus, the charges in Ba_2Sb_3 can be assigned as $(Ba_2)^{4+}(Sb^{2-})(Sb^{-})(Sb^{-})$. These are isolated Sb_3 units in a zigzag chain. There is also a form with Sb_6^{8-} chains having the empirical formula Ba_4Sb_6 and the charge formula of $Ba_4^{8+}(Sb_6^{chain})^{8-}$ where chain consists of the zigzag chain pictured above.

$BaSb_3$ consists of a 2-dimensional 2,3-connected Sb-net, shown in Fig. 4.87.

The charges may be assigned as $Ba^{2+}Sb^0Sb_2^{2-}$.

Barium also forms an antimonide with Zn as $BaZnSb_2$. This is shown in the following Fig. 4.88.

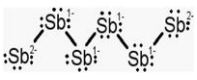

FIGURE 4.86

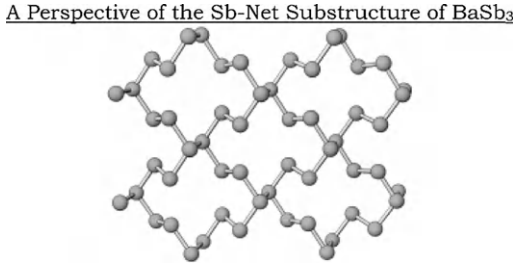

FIGURE 4.87

This structure has a 3-dimensional sheet-like structure in which the Zn ions are in a tetrahedral conformation, $ZnSb_4$. In the $(Ba,Zn)Sb_2$ compound, Ba ions are the small dark spheres, Zn is within the tetraheda setup by the Sb atoms and Sb-nets are the light large spheres. Perfectly square Sb sheets are present and the Zn atoms are surrounded by isolated Sb atoms forming the tetrahedral complex. This gives rise to the assignment: $Ba^{2+}Zn^{2+}(Sb^{sheet})^{-}(Sb^{atom})^{3-}$.

Ba_2Sb is tetragonal with $a = 5.22$ Å, $c = 18.46$ Å and a space group of I4mm. Ba(1) atoms are at (0,0,0), Sb atoms are at (0,0,0.136) and Ba(2) atoms are at (0,0,0.327) positions within the unit cell. The structure can be described as an arrangement of cubes with Sb atoms at each corner. The faces are centered by Ca atoms. These cubes build infinite layers along the x- and y axes. A glide plane appears along the sequence of these layers along the z-axis. The corners of the upper cubes project at the center of the faces of the lower cubes.

The Zintl-Klemm charge assignment for this compound is thus: $Ba_4^{8+}(Sb_2^{cube})^{8-}$.

The relation of barium antimonates has been somewhat elucidated by a study involving the addition of

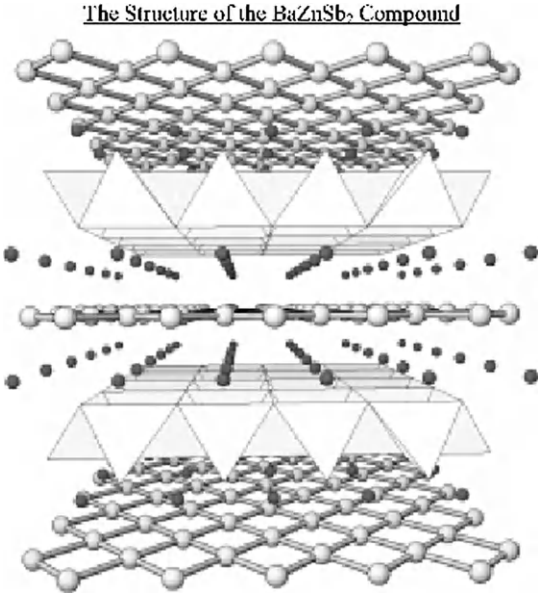

FIGURE 4.88

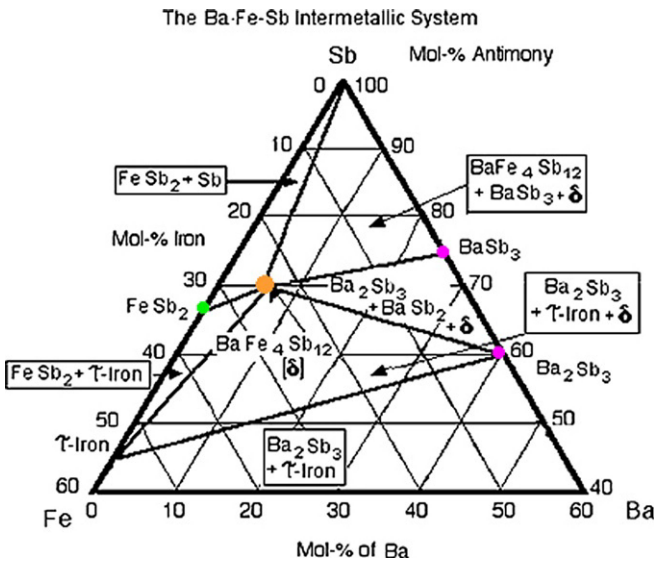

FIGURE 4.89

iron to this Ba–Sb system. This is shown in the following phase Fig. 4.89.

In the Ba–Fe system, the two metals do not dissolve or react with one another. Only when Sb is present is there a reaction to form specific compounds. Only Ba_2Sb_3 and $BaSb_3$ appear in this phase diagram of Ba–Fe–Antimonides. The other known phases do not. The reason for this behavior is not known.

$Ba_{11}Sb_{10}$ contains non electron-precise isolated dumbbells statistically composed of $(Sb_2^{pair})^{4+}$ charges, containing pentelide dumbbells among isolated Zintl anions. A redetermination of the structure of $Ba_{11}Sb_{10}$ has been made: Orthorhombic, Immm, $a = 12.653$ Å, $b = 13.161$ Å, $c = 19.472$ Å, $Z = 4$, $R_1 = 0.0724$, shows, that it represents a distorted variant of the tetragonal $Ho_{11}Ge_{10}$ structure type. This distortion is not only of crystallographic importance, as it results in a major change in the nature of the anions and their bonding, which is supported by DFT band-structure calculations. Likewise, the Zintl phase $BaSb_2$ is monoclinic, P21/m, $a = 11.679$ Å, $b = 4.381$ Å, $c = 12.571$ Å, $\beta = 100.53°$, $Z = 6$, $R_1 = 0.0648$. It crystallizes with a superstructure of the $CaSb_2$ type previously reported.

Ba_5Sb_4 crystallizes in the orthorhombic space group Cmca and is isostructural with Eu_5As_4 reported in the Ccmb alternate setting. β-$Ba_5Sb_4$is a new arrangement which is more symmetrical than α-Ba_5Sb_4 (1981) with space group Pnma, and isostructural with Sm_5Ge_4. The structure contains two anionic moieties, i.e. $(Sb_2^{pair})^{4-}$ dumbbells [Sb···Sb = 2.886 Å] and $(Sb_3^{atom})^{3-}$. The Sb(l) atom [$(Sb_3^{atom})^{3-}$] lies inside a monocapped distorted trigonal prism (6 × Ba(l) and 1 × Ba(2). The Sb(2) atom, which forms the $(Sb_2^{pair})^{4-}$dumbbells, sits inside a tricapped trigonal prism (6 × Ba(l), 2 × Ba(2) and 1 × Sb(2). β-Ba_5Sb_4 displays a more symmetrical arrangement than α-Ba_5Sb_4 (*Pnma*). It contains two anionic moieties, which are Zintl phases lying in tri-capped and distorted monocapped trigonal prisms of Ba atoms, respectively.

The antimonide oxide Ba_3Sb_2O consists of discrete $(Sb_2^{pair})^{4-}$ dumbbells and O^{2-} anions, and crystallizes with a new structure type. The Sb–Sb distances are comparable to those known from electron-precise Zintl phases and the tetrahedral coordination of the O^{2-} anion is also observed in some other Ba-rich metallide oxides.

A Zintl phase, dibarium-tritin-hexaantimonide, $Ba_2Sn_3Sb_6$ has been synthesized, and its structure has been determined by single-crystal XRD methods. It crystallizes in the orthorhombic space group—Pnma with $a = 13.351(1)$ Å, $b = 4.4100(5)$ Å, $c = 24.449(3)$ Å, and $Z = 4$ ($T = -50$ °C). The structure of $Ba_2Sn_3Sb_6$ comprises large channels [010] defined by 30-membered rings constructed from an anionic framework. This framework is built up from Sn-centered trigonal pyramids and tetrahedra, as well as zigzag chains of Sb atoms. Within the channels reside the Ba^{2+} cations and additional isolated zigzag Sb–Sb chains. The simultaneous presence of Sn trigonal pyramids and tetrahedra implies that $Ba_2Sn_3Sb_6$ is a mixed-valence compound whose oxidation state notation can be best represented as $(Ba^{2+})_2[(Sn^{II})_2(Sn^{IV})(Sb^{-III})_3(Sb^{-I})]^{2-}[(Sb^{-I})_2]^{2-}$. The structure has been given in Fig. 4.90.

Resistivity and AC magnetic susceptibility measurements on $Ba_2Sn_3Sb_6$ and $SrSn_3Sb_4$ indicate that these Zintl compounds display a transition to a superconducting phase at $T_C = 3.9$ K. The Meissner effect was observed for $Ba_2Sn_3Sb_6$ under an applied field of 25 Oe. The signatures for superconductivity, such as high- and low-velocity conduction electrons and lone pairs, are present for both of these compounds.

Only a few of these barium antimonides are offered for sale commercially. Ba_2Sb_3 has one supplier and has

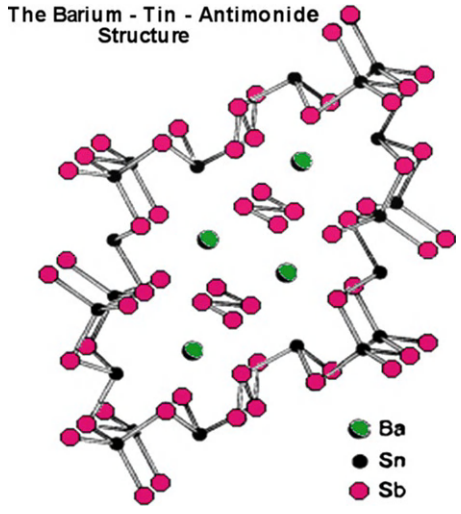

FIGURE 4.90

the CAS number of 55576-04-0. $BaSb_2$ is offered for sale by one or two Chinese manufacturers (CAS number = 12057-75-9).

Radium Antimonide

Radium antimonide could probably be prepared by the reaction of Ra and Sb metals. Ra melts at 700 °C and is stable in an inert atmosphere until its boiling point of 1737 °C is reached. Since Sb melts at 630.6 °C and is stable in an inert atmosphere until its boiling point of 1587 °C, the reaction is best carried out by evaporating Ra metal at about 680 °C onto molten Sb metal:

$$3Ra + 2Be \Rightarrow Ra_3Sb_2$$

However, this reaction has never been carried out due, perhaps, to the intense radioactivity of ^{226}Ra atom. It is probable that Ra forms the same type of antimonide compounds as Ba but there is no industrial or commercial interest and no academic interest in these compounds due to the care required in handling such compounds.

4.5. ALKALINE EARTH BISMUTHATE COMPOUNDS

According to some early sources, bismuth (either as Bi^{3+} or Bi^{5+}) is too electropositive to form "bismuthates" with the alkaline earths. However, this observation undoubtedly applied to solution chemistry. Even then, there were exceptions, notably that of barium, where soluble alkali bimuthates were used to form barium bismuthates. In recent years, bismuthates have been prepared by solid-state reaction and evaluated for various applications. The possible oxy-complexes include BiO_2^{1-} or $Bi_2O_4^{2-}$ (bismuthites), and BiO_3^{1-} or $Bi_2O_6^{2-}$ (bismuthates) and combinations like $Bi_2O_7^{4-}$. The major driving force has been the discovery of "high-temperature" superconducting compounds (1989) where liquid N_2 at 77 K is sufficient to maintain the superconducting state of these Sr or Ba bismuthate–cuprate compounds with a critical temperature of 113 K.

Bismuth has unusually low toxicity for a heavy metal. Bismuth is stable to both dry and moist air at ordinary temperatures. When red hot, it reacts with water to make bismuth(III) oxide. Bismuth forms trivalent and pentavalent compounds. The trivalent compounds are more common. Many of its chemical properties are similar to those of As and Sb, although they are less toxic than derivatives of those lighter elements. At elevated temperatures, the vapors of the metal combine rapidly with oxygen, forming the yellow trioxide, Bi_2O_3. On reaction with base, this oxide forms two series of oxy-anions: BiO_2^-, which is polymeric and forms linear chains, and BiO_3^{3-}. The anion in Li_3BiO_3 is actually a cubic octameric anion, $Bi_8O_{24}^{24-}$, whereas the anion in Na_3BiO_3 is tetrameric. The dark red bismuth(V) oxide, Bi_2O_5, is unstable, liberating oxygen gas upon heating. In aqueous solution, Bi^{3+}, as an anion, exists in various states of hydration, depending on the pH (Table 4.24).

Thus, in order to describe the alkaline earth bismuthate system, it is necessary to consider solution methods as well as solid-state reaction methods of combining the oxides. The valence state of Bi in the final solid will depend upon the nature of the alkaline earth whereas the trivalent Bi atom is almost always present in compounds formed from solution.

In general, the phase diagrams of the various AeO–Bi_2O_3 or AeO–Bi_2O_5 systems are not available and have not been thoroughly studied.

4.5.1. Alkaline Earth Bismuthate Compounds

Beryllium Bismuthates

There are no reports that deal with beryllium–bismuth compounds. None of the reference books like Remy, Sidgwick or Lange's Handbook of Chemistry list such compounds and their properties. It is highly probable that they do not exist. The literature is devoid of such references unlike the other alkaline earths.

Magnesium Bismuthate

Of the possible magnesium bismuthate (-ite) compounds, only $MgBi_2O_6$ has been reported. No phase diagram for the MgO–Bi_2O_3 or MgO–Bi_2O_5 systems are available. This compound is semiconducting and is employed in small batteries used in portable electronic devices. Magnesium bismuthate is prepared by the reaction of sodium bismuthate with a soluble Mg salt:

$$MgCl_2\ (aq) + 2NaBiO_3\ (aq) \Rightarrow MgBi_2O_6\ (solid) + 2NaCl\ (aq)$$

The preparation of magnesium bismuthate, $MgBi_2O_6$, was accomplished in a sealed PTFE-lined pressure

TABLE 4.24

pH range	Species
<3	$Bi(H_2O)^{3+}$
0–4	$Bi(H_2O)_5(OH)^{2+}$
1–5	$Bi(H_2O)_4(OH)_2^+$
5–14	$Bi(H_2O)_3(OH)_3$
>11	$Bi(H_2O)_2(OH)_4^-$

vessel. The pressure vessel and contents were heated to and held at 135 °C for 2.5 days. The pressure vessel was cooled to room temperature before opening. After separation of the solid by filtration and drying at 60 °C for 24 h, a dark brown powder was obtained. The powder was characterized using X-ray powder diffraction, chemical analysis, and thermal analysis. The X-ray powder diffraction pattern was consistent with that reported for trirutile $MgBi_2O_6$. The lattice parameters were refined in the tetragonal space group P42/mnm. The values obtained ($a = 4.82168$ Å and $c = 9.70194$ Å) corresponded closely to the reported values in the literature. The density of 7.51 g/cm^3 was determined by displacement of helium gas using a null-pycnometer. A Mg:Bi atom ratio of 1.02:2.00 was determined by ICP spectroscopy which is consistent with that expected for a trirutile structure. Thermal analysis of $MgBi_2O_6$ by DTA/TGA at a heating rate of 10 °C/min to 550 °C revealed a loss in weight starting below about 400 °C in flowing air. This was caused by the decomposition of $MgBi_2O_6$ to MgO and Bi_2O_3 accompanied by oxygen loss. The experimentally observed weight loss of 5.91 wt% is consistent with the calculated weight loss of 5.94 wt%.

$MgBi_2O_6$ can be classified as a transparent conducting oxide (TCO) that possess an unusual combination of properties; high transparency across most of the visible spectrum, coupled with high-electrical conductivity. TCO's have a wide variety of applications, including use in flat panel displays, solar cells, energy-efficient windows, gas sensors, antistatic coatings, and heating elements. $MgBi_2O_6$ reveals temperature-independent conductivity (0.01 S/cm^2), a negative Seebeck coefficient (20.025 mV/K), and an optical band gap that falls at the low-energy end of visible region (1.8 eV). This combination of attributes, indicating that this compound is a degenerate *n*-type semiconductor, a trait that has not previously been reported in a Bi^{5+} oxide.

The crystal structure is shown in the following Fig. 4.91.

It consists of a ring structure of octahedral BiO_6^{2-} octagonal units with interspersed Mg^{2+} cations. Characterization of polycrystalline samples of the trirutile oxide $MgBi_2O_6$ revealed temperature-independent conductivity (0.4 and 0.01 S/cm), a negative Seebeck coefficient (−0.035 and −0.025 mV/K), and an optical band gap that falls at the low-energy end of visible region (1.7 and 1.8 eV). This combination of attributes indicates that this compound is a degenerate *n*-type semiconductor, a property that has not previously been observed in a Bi^{5+} oxide.

Although this compound is thoroughly described in the scientific literature, it has no CAS number and is not offered for sale commercially.

Crystal Structure of Magnesium Bismuthate

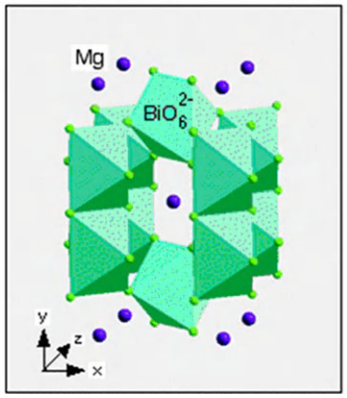

FIGURE 4.91

Calcium Bismuthate

Calcium forms a series of compounds with Bi_2O_3. Four stable phases with stoichiometric molar ratio, $Ca_6Bi_6O_{15}$, $Ca_4Bi_6O_{13}$, $CaBi_2O_4$ and $Ca_5Bi_{14}O_{26}$ have been prepared by conventional solid-state reaction methods. The reactions are:

$$x\mathrm{CaCO_3} + y\mathrm{Bi_2O_3} + \text{heat} \Rightarrow \mathrm{Ca}_x(\mathrm{Bi}_{2y}\,\mathrm{O}_{3y+5}) + x\mathrm{CO_2}$$

where x varies from 1 to 4 and y varies from 2 to 7. Thus, the above stable compounds are essentially variations of 6:3, 4:3, 1:1 and 5:7 mol ratios.

The details of the reaction processes have been investigated and the different intermediate products were identified by XRD before the pure phases were obtained. In the four phases, the valence of Bi was +3 and the lone-pair electrons of Bi^{3+} led to the formation of the Bi–O sheet structures. Bi–O polyhedrons with different coordination numbers and bond lengths were discussed. The optical properties of the four samples were also investigated. The band gaps of $Ca_6Bi_6O_{15}$, $CaBi_2O_4$, $Ca_4Bi_6O_{13}$ and $Ca_5Bi_{14}O_{26}$ were estimated from the absorption spectra as 3.34 (372 nm), 3.08 (402 nm), 2.76 (450 nm) and 2.60 eV (477 nm), respectively, and they were all direct transition semiconductors. Moreover, the Raman spectra of $Ca_6Bi_6O_{15}$, $Ca_4Bi_6O_{13}$ and $CaBi_2O_4$ were also investigated and the results suggested that some high-frequency phonon modes (Raman shift more than 450/cm) appeared in the crystals when Ca was being introduced into the three complex oxides.

Single crystals and powdered samples of the bismuth(III) calcium oxide $Ca_6Bi_6O_{15}$ have been synthesized and studied using both X-ray and neutron diffractometry. The compound crystallizes in the space group P with $Z = 2$. Cell parameters, obtained with the single-crystal X-ray diffractometer, were $a = 10.101$ Å, $b = 10.130$ Å, $c = 10.466$ Å, and $\alpha = 116.86°$, $\beta = 107.18$ Å, $\gamma = 92.90°$.

As with other materials in the series M–Bi–O (M = Ca, Sr) studied thus far, at least some Bi is found in threefold coordination with oxygen; the remaining Bi are fourfold coordinated. The structure is related to that of $Ca_4Bi_6O_{13}$, which has been studied using neutron powder diffraction. Both compounds are composed of layers containing alternating Bi- and Ca-rich segments. These layers stack to form Bi-rich slabs containing tunnels accommodating the Bi-$6s^2$ lone pairs.

$Ca_4Bi_6O_{13}$ has both a high-temperature (HT) and low temperature (LT) phase. The HT phase forms at 820 °C while the LT phase is stable up to 700 °C. The HT phase is a defect type with oxygen vacancies comprising a body-centered cubic structure ($a = 4.26$ Å) γ-type solid solution (ss-γ) phase as $(1-x)Bi_2O_3{\cdot}CaO_x$ ($0.50 < x < 0.60$) was investigated by electron diffraction. Instead of finding evidence for additional Bragg reflections at G_n^o as previously assumed in attempting to interpret powder neutron diffraction data, localized diffuse scattering was detected and described by G_q^0, where $q \sim 0.2$ <211>*gamma as a (diffuse) modulation wave vector. A crystal structural relationship between the cation arrays in the ssγ phase and the low-temperature (LT) line phase, $Ca_4Bi_6O_{13}$, was established. The unit cell of the LT phase can be expressed as $a_{LT} = a_\gamma - c_\gamma$, $b_{LT} = 5/3(a_\gamma - 2b_\gamma + c_\gamma)$ and $c_{LT} = \cong (a_\gamma + b_\gamma + c_\gamma)$. From the cation ordering in the LT phase and the reciprocal space relation $2b \times LT = 0.2$<121>*γ ≅ q, the localized diffuse scattering in the ssγ phase was linked to cation ordering into layers perpendicular to <121>γ.

The crystal structure of the 1:1 CaO–Bi_2O_3 compound ($CaBi_2O_4$) has been determined by single-crystal X-ray and neutron powder diffraction techniques. The compound crystallizes with the symmetry of the monoclinic space group C2/c and lattice parameters $a = 16.6130$ Å, $b = 11.5900$ Å, $c = 13.9939$ Å, $\beta = 134.048°$ (Fig. 4.92).

The structure consists of sheets parallel to the b–c plane and connected by Ca–O bonds. There is a structural unit in each layer consisting of four Bi atoms, ten oxygen atoms, and two calcium atoms. The Bi atoms are fourfold coordinated and the coordination polyhedron may be described as a short distorted pyramid, open on one end to accommodate the lone-pair electrons of the bismuth atoms. Calcium is seven-coordinated and the coordination polyhedron may be described as a monocapped trigonal prism.

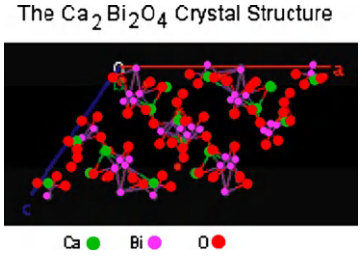

FIGURE 4.92

The electronic structure of $CaBi_2O_4$ was calculated by a GGA approach. The valence-band maximum is approximately located at the Γ-point or the *Y*-point and the conduction band minimum at the *V*-point. This means that $CaBi_2O_4$ is an indirect energy gap material. The conduction band is composed of Bi 6p–O 2p interaction. On the other hand, the valence band can be divided into two energy regions ranging from −9.92 to −7.40 eV (lower valence band) and −4.69 to 0 eV (upper valence band). The former is mainly constructed from Bi-6s states interacting slightly with O-2s and O-2p states, and the latter consists of O-2p states hybridizing with Bi-6s and Bi-6p states. The states near the valence band maximum are strongly localized and the mobility of holes generated by band gap excitation is predicted to be fairly low.

Organic contaminants such as volatile organic compounds and dyes (e.g. acetaldehyde and methylene blue (MB)) can be photo-catalytically degraded over a novel $CaBi_2O_4$ catalyst. The reaction is environmentally friendly (O_2 oxidant) and proceeds at room temperature under visible-light irradiation of wide-ranging wavelengths. An example is the conversion of CH_3CHO into CO_2.

Lithium forms a series of glasses with Bi_2O_3 in which electrical conductivity is supported by transmission of Li^+ cations. The addition of Ca^{2+} improves and stabilizes the conductivity. Ion transport in Li_2O–CaO–Bi_2O_3 glasses has been studied in the frequency range from 10 Hz to 2 MHz and in the temperature range from 293 to 543 K. The variation of the DC conductivity and the activation energy of these glasses with composition have been compared with those of binary lithium bismuthate glasses. It has been observed that the introduction of CaO in small amounts does not effect the DC conductivity and the corresponding activation energy, but a larger amount of CaO changes them to some extent. The frequency-dependent conductivity has been studied using both conductivity and modulus formalisms. The values of the nonexponential parameter and frequency exponent are found to differ for the Li_2O–CaO–Bi_2O_3 glasses from those for the binary Li_2O–Bi_2O_3 glasses. Mobile Li^+ ion concentration does not change appreciably with a change in the Li_2O content or the CaO content in the compositions. The increasing amount of CaO in the glass compositions for fixed Li_2O content shows that it is the fact that CaO dilates the glass network, thus enhancing the rate and migration of Li^+ ions.

Calcium bismuthates have no CAS numbers and they are not offered for sale commercially.

Strontium Bismuthates

The known data for the phases $Sr_6Bi_2O_9$, $Sr_3Bi_2O_6$, $Sr_2Bi_2O_5$, $Sr_{18}Bi_{22}O_{51}$, $Sr_6Bi_{14}O_{27}$, $SrBi_4O_7$, $Sr_2Bi_6O_{11}$, $SrBi_2O_4$, $Sr_8Bi_{10}O_{23}$, $Sr_8Bi_2O_{11}$, $Sr_5Bi_6O_{14}$, $Sr_6Bi_2O_{11}$, $Sr_6Bi_4O_{15}$ and $Sr_{24}Bi_{14}O_{52}$ have been revised, corrected, and unknown data have been estimated. The values of ΔH^0_{298}, S^0_{298}, H^0_{297}-H^0_0, the T and ΔH values for the phase transformations, $Cp(T)$ for the crystalline state, Cp at $T > T_{ph,tr}$, and also the polynomial approximating a reduced Gibbs have been presented (G. Moseev et al—1996). In the phase diagram of SrO and Bi_2O_3, four compounds are known. These are:

$SrBiO_4$—monoclinic

$Sr_2Bi_2O_5$—tetragonal

$Sr_3Bi_2O_6$—orthorhombic

$Sr_6Bi_2O_9$—type not known

Note that the tribasic compound, Bi_2O_3 is specified. Strontium bismuthate can be prepared by firing the oxides, SrO and Bi_2O_5, in air. The reaction is:

$$2SrCO_3 + Bi_2O_5 + \text{heat} \Rightarrow 2SrBiO_3$$

where the bismuth oxide is in reality the acid salt, $Bi_2O_5 \cdot 3.67H_2O$ (or $3Bi_2O_5 \cdot 11H_2O$). $SrBiO_3$ is a mixed-valence type of compound where the actual formula is $Sr(Bi^{3+},Bi^{5+})O_{3-x}$ signifies an oxygen deficiency. Varying the Sr:Bi(V) ratio always results in the formation of this mixed-valence perovskite salt and the pyrochlore salts never appear. It is for this reason that many preparations have used sealed ampoules where the contents are under pressure when heated and in many cases employ an oxidizing agent such as $KClO_4$ to ensure that the oxidized form results. However, the preparation is not always successful. It is this fact that accounts for the scarcity of data concerning both strontium and barium bismuthates.

According to another paper, new cubic pyrochlore oxides of the type $(RM)(Bi)_2O_7$ (M = Ba, Sr, R = rare earth) could be prepared by solid-state reactions at 850 °C under 3 kbar pressure, starting from Bi_2O_3, R_2O_3 and peroxides of Ba, Sr or Ca in sealed gold ampoules. In the case of Sr, attempts to synthesize $Sr_2Bi_2O_7$ pyrochlores under high-oxygen pressure always resulted in the formation of the perovskite $SrBiO_{3-x}$ where Bi(III&V) is always the resultant.

Interest in these types of compounds stems from the fact that a copper–Sr (or Ba) bismuthate is a superconductor with a transition temperature, T_c, of 113 K. The general formula of the "2212" phase is $Sr_2Ca_{n-1}Cu_nBi_2O_{2-n}+4$, where n is the number of copper-oxide planes in the structure. The above diagram shows such a structure. In this diagram, Sr is shown but the composition with Ba has a higher critical temperature, T_c, number (Fig. 4.93).

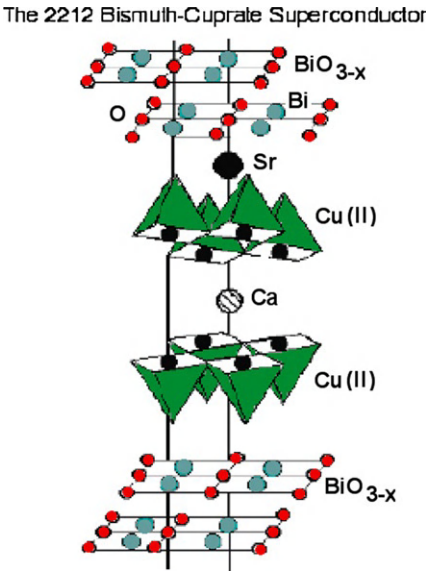

FIGURE 4.93

In this diagram, layers of $Cu(II)O_6$ are bordered by layers of bismuthates, BiO_{3-x} and interspersed with isolated Sr^{2+} (Ba^{2+}) or Ca^{2+} cations.

The "pyrobismuthate" has been difficult to obtain owing to the difficulty of bismuth to form stable Bi^{5+} compounds. The brownish-orange product obtained by heating an intimate mixture of $SrBiO_{3-x}$ and $KClO_4$, for 15 min at 730 °C and 60 kbar was a mixture of KC1 and a relatively well-crystallized phase whose XRD pattern could be indexed on an orthorhombic unit cell with $a = 7.70$ Å, $b = 7.91$ Å, and $c = 10.58$ Å. There is little doubt that this phase was the weberite $Sr_2Bi_2O_7$. Its "a-value", 5.44 Å, is about 2.6% larger than that of the perovskite phase, $Sr_2Sb_2O_7$. The loss of as much as one oxygen per $Sr_2Bi_2O_7$ (corresponding to $Sr_2Bi(III)Bi(V)O_7$) would amount to a weight loss of only 2.3%. The $Sr_2Bi_2O_7$ weberite appears to be one of the few genuinely stoichiometric oxygen compounds of Bi(V). It is noted that barium forms a mixed-valence compounds related to $Sr_2Bi_2O_7$, the golden $Ba_4Bi(III)Bi(V)O_{13}$.

The compound, $SrBi_2O_4$, has the following lattice parameters: $M_w = 569.58$ g/mol, monoclinic space group = C2/m, $a = 19.300$ Å, $b = 4.358$ Å, $c = 6.106$ Å, $\beta = 94.801(4)°$, $V = 511.7$ Å^3, $Z = 4$, $d_x = 7.39$ g/cm^3. The structure has been refined by Rietveld analyses of XRD data recorded at room temperature.

The $Ca_2Sb_2O_7$ compound crystallizes with a structure of both the pyrochlore (P) and the weberite (W) type, but $Sr_2Sb_2O_7$ is only known as a weberite. Its orthorhombic unit-cell parameters are: $a = 7.452$ Å, $b = 7.687$ Å, $c = 10.381$ Å, $Z = 4$. It is pseudo-cubic with "$a = 8.297$ Å". The structures are given in Fig. 4.94.

In the SrO–Bi_2O_3 system, several compounds were found to adopt an unusual structure. For example, in the structure of $Sr_2Bi_2O_5$, all Bi atoms are in unusual

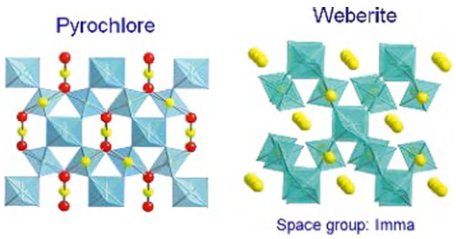

FIGURE 4.94

threefold coordination with respect to oxygen. The compound crystallizes with the space group *Amam*, and with cell parameters of $a = 6.1715(6)$ Å, $b = 14.3066(13)$ Å, $c = 3.8261(4)$ Å, $V = 338.1$ Å^3 and $Z = 2$.

The basic structure consists of the intergrowth of two simple structural elements. The first element is the anti-nickel arsenide structure. Each Sr atom is surrounded by six nearest neighbors in a trigonal prismatic arrangement. The second structural element can be regarded as $Bi_2O_4^{4+}$ chains which are inserted between the anti-NiAs slabs, Bi in 3-coordination with oxygen appears to exist only in systems containing the electropositive alkaline earth cations Ca and Sr. These Sr and Ca atoms appear to allow the Bi–O bonds to be more covalent in nature and therefore more directional. Ordering of oxygen and vacancies is also visible along the *c*-direction and results in displacements of the Bi atoms along *c*. The lone-pair electrons associated with the Bi can be envisioned as being directed toward the vacant site. The unit cell of $Sr_2Bi_2O_5$ showing the SrO_6 trigonal prisms and the position of $[Sr_2O_4]^{4+}$ groups is given in Fig. 4.95.

The Sr^{2+}(I) positions in the lattice are occupied by the $Sr_2O_4^{4+}$ groups while the Sr^{2+}(II) positions are occupied by the SrO_6 trigonal prisms. The two layers are separated by a channel caused by the $6s^2$ electrons of the $Bi_2O_4^{2-}$ groups.

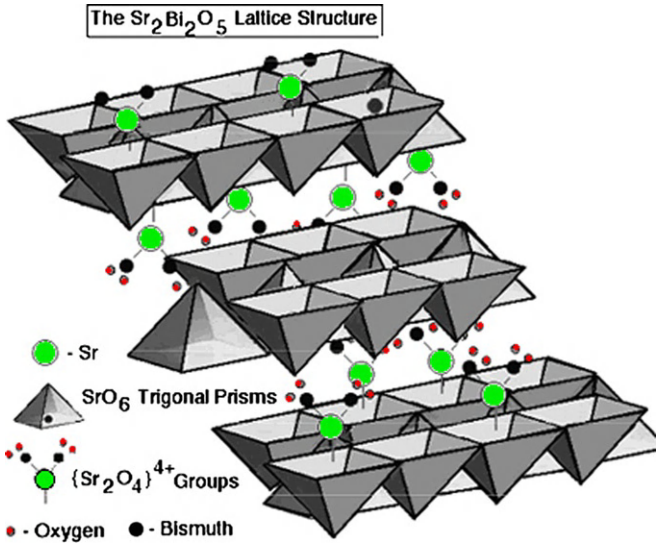

FIGURE 4.95

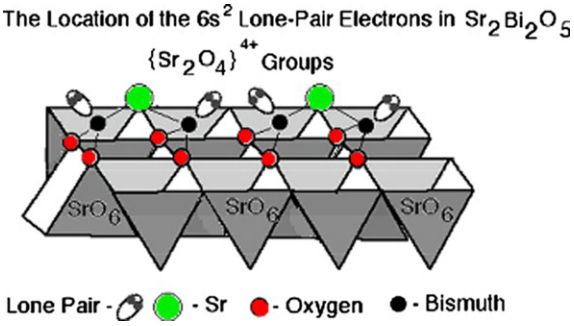

FIGURE 4.96

A better detail is shown in the following diagram showing the bond attachments and the two-electron lone-pairs of Bi^{3+} (Fig. 4.96).

The lone pairs, $6s^2$ of Bi^{3+} dominate all of the bismuthite compounds and cause noticeable channels within the structure of these compounds wherein they are coordinated. Perhaps it is this factor that makes pentavalent bismuth compounds so hard to achieve since the $6s^2$ electrons must be transferred to the relevant anion in order to achieve the pentavalent degree of ionization.

Ion transport in Li_2O–Bi_2O_3–SrO glasses has been studied in the frequency range 10 Hz–2 MHz and in the temperature range 263–483 K. The variation of the DC conductivity and the activation energy of these glasses with composition have been compared with those of bismuthate and lead bismuthate glasses. The frequency-dependent conductivity has also been studied using both modulus and conductivity formalisms. In the strontium glasses, Li_2O–Bi_2O_3–SrO, the variation of the power law exponent with Li_2O content is in contrast to that for the Li_2O–Bi_2O_3 and Li_2O–Bi_2O_3–PbO glasses. The values of the nonexponential parameter for the Li_2O–Bi_2O_3–SrO glasses are lower than those for the binary Li_2O–Bi_2O_3 glasses.

The conductivity increases and the activation energy decreases with the increase of SrO content in the glass compositions with fixed Li_2O content. The estimated mobile ion concentration is almost independent of temperature and SrO content in the compositions. The results have been interpreted on the basis of the modification of the bismuthate network by the addition of SrO, which enhances the mobility of Li ions, without altering the mobile Li+ ion concentration. It has also been shown that the conductivity relaxation in these glasses is independent of temperature and composition, and the non-exponential parameter is less than that for the lithium bismuthate glasses without SrO.

A new bismuth-based oxide, (Sr,K)BiO_3, was synthesized. Superconductivity was induced by the K-doping of $SrBiO_{3-x}$, performed under high pressure. The maximum T_c achieved was about 12 K (for 45–60% of K). This new compound has a distorted perovskite-based

structure. Powder synchrotron and neutron diffraction studies have shown that, as a function of K doping, the symmetry changes from monoclinic (space group $P2_1/n$) to tetragonal (space group I4/mcm) and remains the same down to 4 K. Above room temperature, $SrBiO_3$ keeps the same structure until decomposition around 700 °C, whereas the K-doped phases decompose around 300 °C with a progressive loss of oxygen until the $(Sr,K)BiO_{2.5}$ stoichiometry is reached. The oxygen loss is accompanied by a decrease of T_c. An increase of T_c was observed when resistivity was measured as a function of pressure. Powder synchrotron studies indicated that, for K-doped samples, pressure induces an increase of the tetragonal distortion, as well as a change of the tilt angle of the octahedra until the pressure corresponding to T_{cmax} is reached. The (Sr,K) site is more affected by the pressure effect than the Bi one. In the case of $SrBiO_3$, no noticeable change was observed under pressure.

The compound, $Sr_3Bi_2O_6$, has been studied because it is related to a superconducting compound, Bi_3O_3–PbO–SrO–CaO–CuO. Phase equilibria of the quasi-quinary system were studied between 650 and 900 °C in air with emphasis on the high-temperature superconducting phase ($T_c = 110$ K). $(Bi,Pb)_{2+x}Sr_2Ca_2Cu_3O_{10+d}$ (2223). The 2223 phase lies in equilibrium with a number of non-superconducting phases and also with the superconducting phase $(Bi,Pb)_2Sr_2CaCu_2O_{8+d}$ (2212). The single-phase region was found to be very limited. The Pb solubility of the 2223 phase is strongly temperature dependent. The phase relations are very sensitive to variations of the cation concentration and temperature. This effect significantly influences the preparation of 2223 ceramics.

In another paper, the compound $Sr_2Bi_2CuO_6$ should nominally be the phase with $n = 1$ of the high T_c superconducting series $Sr_2Bi_2Ca_nO_{4+2n}$. However, the superconducting phase with $n = 1$ (with no CaO) occurs only with a gross deficiency in SrO content. Instead, at the composition $Sr_2Bi_2CuO_6$, a different phase is formed with an XRD pattern considerably different from that expected for the $n - 1$ member of the series. This phase has been found, by a combination of electron diffraction and single-crystal and powder XRD, to have a commensurate lattice with monoclinic symmetry, space group $C2/m$ or Cm, $a = 24.473$ Å, $b = 5.4223$ Å, $c = 21.959$ Å, and $ß = 105.40°$. The actual composition of this phase may be deficient in CuO by as much as 1.0 mol%.

The phase equilibria of the systems SrO–CuO and $SrO\text{-}1/2Bi_2O_3$ were studied by XRD analysis of quenched powder samples. The compounds $SrCuO_2$ and Sr_2CuO_3 melt incongruently at 1085 and 1225 °C, respectively. The newly found compound $Sr_6Bi_2O_9$ decomposes at 965 °C into SrO and $Sr_3Bi_2O_6$ melts incongruently into SrO and liquid at 1210 °C. $SrBi_2O_4$ undergoes a phase transition at 825 °C, and although both are nonstoichiometric, the low-temperature phase is slightly poorer in SrO with 33.5 mol% SrO than the high-temperature phase. The decomposition of $SrBi_2O_4$ into $Sr_5Bi_2O_9$ at 780 °C for the $SrBi_2O_4$ composition has to be associated to the decomposition into two solid solutions. The $Sr_6Bi_2O_9$ compound is not part of the Bi_2O_3–SrO system but, due to a necessary stabilizing Bi^{III}–Bi^{V} oxidation phenomenon, it must be formulated $Sr_6Bi^{V}_yBi^{III}_{2-y}O_{9+y}$ with $y > 0$.

Another reported compound was designated $SrBi_3O_{5.5}$ or $Sr_2Bi_6O_{11}$. The crystal structure of the rhombohedral (R/m) $Bi_{0.75}Sr_{0.25}O_{1.375}$ phase has been determined at room and high temperature using single-crystal neutron diffraction. It can be described at all temperatures as the regular repetition of three fluorite-like sheets shifted with respect to one another by a vector $\gamma = 2\,(a/3 + b/3 + c/3)$ and thus separated by an intersheet space free of anions. Interstitial anions partially occupy delocalized sites in the vicinity of the unsubstituted interface Bi-layers and are responsible for the high ionic conductivity of this phase. They are mainly located on the fluorite-like sheet side of this Bi-layer at room temperature. At high temperature, they partly migrate to the opposite side, i.e. the intersheet side, a phenomenon which results in the $\gamma_2 \Rightarrow \gamma_1$ transition and a sudden increase of the conductivity. In light of these and previous results, the different behavior of various alkaline earth-doped rhombohedral phases (Ca, Sr, Ba) and of the La-doped homologue is analyzed and rationalized.

Strontium bismuthates have no CAS numbers and they are not offered for sale commercially.

Barium Bismuthate

Metal oxides containing Bi^{5+} are relatively rare. Those of $BaO \cdot Bi_2O_5$ are not easily formed due to the same restrictions already mentioned for $SrO \cdot Bi_2O_5$. Thus, those of $BaO \cdot Bi_2O_3$ are much more stable due to the presence of the $6s^2$ lone pairs of the ion, Bi^{3+}. $BaBiO_3$ is a mixed-valency type of compound where the actual formula is $Ba(Bi^{3+},Bi^{5+})O_{3-x}$ signifies an oxygen deficiency. Varying the Ba:Bi(V) ratio always results in the formation of this mixed-valency perovskite salt and the pyrochlore salts never appear under usual chemical conditions. It is for this reason that many preparations have used sealed ampoules where the contents are under pressure when heated and in many cases employ an oxidizing agent such as $KClO_4$ to ensure that the oxidized form results. However, the preparation is not always successful. It is this fact that accounts for the scarcity of data concerning barium bismuthates. The correct formulation for $BaBiO_3$ is believed to be:

$$Ba{Bi^{3+}}_{0.5+x}{Bi^{5+}}_{0.5-x}O_{3-x}$$

which is accurately a "Bismuthite". $BaBiO_{3-x}$ occurs as a distorted monoclinic type of structure with a breathing- and a tilting-mode lattice distortion of

BiO_6 octahedra, and it shows semiconducting behavior despite the theoretical calculation predicting metallic behavior. The compound crystallizes monoclinic in the space group I2/m, with $a = 6.181$ Å, $b = 6.136$ Å, $c = 8.670$ Å, $\beta = 90.17°$, and $Z = 4$. The calculated density of the valence electrons is 0.3041 electrons per $Å^3$. The compound undergoes two structural phase transitions, a first-order transition to a rhombohedral structure near 425 K (152 °C) and a second-order transition to a cubic structure, the transition temperature being estimated as 893 K (620 °C).

In order to clarify the effect of oxide ion vacancy on electronic structure of $BaBiO_{3-x}$, the electrical conduction property at high temperature under various oxygen partial pressures, $P(O_2)$, was investigated. At 775 °C, in dependence of electrical conductivity on log $P(O_2)$, three phases were observed. This behavior shows agreement with oxygen nonstoichiometry data measured by thermogravimetry. Under log P (O_2) higher than −1.75, *n*-type semiconducting property was observed which could be attributed to charge density waves originating from two kinds of Bi sites in crystal structure. In the log $P(O_2)$ region between −1.75 and −2.45, electrical conductivity almost independent of log $P(O_2)$ was observed. This suggested semimetallic electronic structure with itinerant electrons that could originate from single Bi site in $BaBiO_{3-x}$ with ideal perovskite structure (as clarified by neutron diffraction). Below log $P(O_2)$ of −2.45, abrupt decrease of electrical conductivity was observed, suggesting localization of electron in Bi orbitals, which could also be speculated from low symmetry around the Bi site in $BaBiO_{2.5}$.

If a ratio of $2BaO:Bi_2O_3$ is used, a compound, $Ba_2(BiO_3)_2$ or $(BaBiO_3)_2$ results. This identical compound shows that the most stable configuration of the $Bi^{3+}Bi^{5+}$ complex is an ordered supercell, but there are no big variations in energy between different $Ba_2Bi^{3+}Bi^{5+}O_{6-x}$ configurations. If divalent or trivalent cations are added to $BaBi^{3+}Bi^{5+}O_{3-x}$, it has been reported that the results are quite different. With the aid of infrared spectroscopy, it was shown that the bismuth ions in $BaBiO_{3-x}$ are equivalent and that the charge distribution is $Ba_2Bi^{3+}Bi^{5+}O_6$. In addition, it was demonstrated that the bismuth ions are pentavalent in Ba_2TbBiO_6, but tetravalent in $Ba_3PbBi_2O_9$.

Doping $BaBiO_{3-x}$ with alkali ions transforms the larger monoclinic parent lattice into a more compact cubic or nearly cubic lattice. This lattice contraction favors the transition from semiconductor to metal. It also leads to superconductivity. Doping $BaBiO_3$ with both K and Rb raises the onset resistivity T_c above those obtained by doping with either K or Rb alone. $BaBiO_{3=x}$ keeps the same structure until decomposition around 750 °C, whereas the K-doped phases decompose around 300 °C with a progressive loss of oxygen until the (Ba, K, Rb)$BiO_{2.5}$ stoichiometry is reached. The oxygen loss is accompanied by a decrease of T_c. An increase of T_c was observed when resistivity was measured as a function of pressure. Both, Bismuth and Barium have a distorted coordination sphere. Bismuth and oxygen occupy two different crystallographic positions, the 2(a)- and 2(c)-positions and the 4(i)- and 8(j)-positions.

Following the initial discovery, $BaBiO_{3-x}$ has been doped with a variety of cations in efforts to increase the T_c of the product. Two such examples were:

> "The structure, nonstoichiometry, and electrical conductivity of compositions in the $BaBiO_{3-x} \Rightarrow Ba(Ce_{1-x}Gd_x)O_{3-x/2}$ system have been investigated in an attempt to prepare new mixed (ionic-electronic) conducting oxides. The substitution of Bi into $Ba(Ce_{1-x}Gd_x)O_{3-x/2}$ decreases the concentration of oxygen-ion vacancies, and the effective negative charge of the Gd dopant is compensated by the mixed valence of Bi (3+, 5+). For low Bi contents, a decrease in ionic conductivity decreases the overall conductivity; however, higher levels of Bi introduce significant electronic conductivity, and for $Ba(Bi_{0.5}Ce_{0.5})O_3$, $<> s_{total}$ at 1 S/cm^2 at 800 °C in air was observed. Compositions in the $Ba(Bi_{0.5}Ce_{0.5-x}Gd_x)O_3$ pseudobinary system undergo a B-cation site order-disorder transformation at 1300–1350 °C for $x = 0.5$ and at 1250 °C for $x = 0.4$; all other compositions retain a disordered B-site arrangement. These disordered perovskites exhibit oxygen nonstoichiometry under reducing conditions at elevated temperatures, with the extent of reduction decreasing with increasing Gd content. However, their ordered counterparts remain close to stoichiometric proportion. The electronic conductivities of this nonstoichiometric pseudobinary could be fitted to a 3-band type-2 model, and, despite the presence of oxygen vacancies for the lower values of x, no significant ionic conductivity was observed".
>
> "Changes in the electronic states for $Ba_{1-y}K_yBiO_{3-x}$ ($y = 0$ and 0.5) due to various surface treatments (fracturing, scraping and ion sputtering) have been studied by X-ray photoelectron spectroscopy. It is found that marked spectral changes occur as a result of scraping and sputtering; the core levels are broadened and the intensity at the top of the valence bands is reduced. These results are discussed in terms of the reduction of elements and damage in the surface region. The above results cause the authors to conclude that fracturing these samples is suitable as a cleaning procedure for this system. The Bi-4f, Ba-4d and O-1s core levels have very low binding energies and are shifted by 0.2–0.4 eV to lower binding energies on 50% substitution of K for Ba. The Bi-4f line seems to contain a single chemical state for $BaBiO_{3-x}$, and more than one chemical state for $Ba_{0.5}K_{0.5}BiO_{3-x}$. The top of the valence band is found to be 0.5 eV below the Fermi level for $BaBiO_{3-x}$, while a clear Fermi edge appears for the K-doped material in the valence band spectra from both X-ray and ultraviolet photoelectron spectroscopy. The electronic states of $BaBiO_{3-x}$ and K doping effects are discussed and compared with band calculations".

The compound $Ba_{1-y}K_yBiO_{3-x}$ shows superconductivity at $T_c \approx 30$ K (−243 °C). One such study shows that in $BaBiO_3$, Bi^{3+} sites can trap two holes from the valence band to form Bi^{5+} cations. The trapping is accompanied by large local lattice distortions; therefore the composite particle consisting of the electronic hole and the local lattice phonon field forms a polaron. This study clearly shows that even "sp" elements can trap carriers at

lattice sites, if the local lattice relaxations are sufficiently large to screen the localized hole. The derived model describes all relevant experimental results, and settles the issue of why hole-doped $BaBiO_{3-x}$ remains semiconducting upon moderate hole doping.

The structure of the valence ordered perovskite-like compound $BaBiO_{3-x}$ has been studied at five temperature intervals between room temperature and 923 K (650 °C) using high-resolution synchrotron X-ray powder diffraction methods. The compound undergoes two structural phase transitions, a first-order transition to a rhombohedral structure near 425 K (152 °C) and a second-order transition to a cubic structure, the transition temperature being estimated as 893 K (620 °C). The perovskite-like compound $BaBiO_{3-x}$ system has been studied by first-principles molecular dynamics and the relation between phase-transition properties and different valence of bismuth has been discussed. A successful match between theoretical and experimental results has been achieved. It is found that irrespective of which bismuth valence, $Bi^{4+}Bi^{4+}$ or $Bi^{3+}Bi^{5+}$, is used, the structural transformation is present and is basically a size effect. The calculation also shows that the most stable configuration of the $Bi^{3+}Bi^{5+}$, is an ordered supercell, but there are no big variations in energy between different $Ba_2Bi^{3+}Bi^{5+}O_6$ configurations.

In an effort to study the effect of reduction on the oxygen content in $BaBiO_{3-x}$, the following observations have been made. The reduction isobar T vs x ($pO_2 = 0.21$ atm) of $BaBiO_{3-x}$ between 750 and 1050 °C shows a trend with three near linear sections in the ranges 750–850 °C, 850–1000 °C, and 1000–1045 °C, respectively. The quenching in liquid N_2 of first-section solids (phase I) does not prevent the transformations $Fm\bar{3}\,m \Rightarrow R3 \Rightarrow I2/m$ (which are typical of the stoichiometric compound) and their XRD patterns at room temperature are not different from that of the stoichiometric $BaBiO_3$. The quenching of the cubic structure $Pm\bar{3}\,m$ of solids in the second section (phase II) still originates a monoclinic structure, but one strongly perturbed by the high concentration of oxygen vacancies. As determined by neutron diffraction at high temperatures, the phase II to phase III transition (third section of the isobar) occurs unusually in a gradual way, and it is nearly complete as the melting temperature (1045 °C) is approached. The close resemblance of the XRD patterns of the terms of the Aurivillius series with those of $BaBiO_{2.56}$ (phase III) leads to the conclusion that this last phase is the term limit of the above series. Its structure would therefore be characterized by a random distribution of Ba and Bi ions in the perovskite A and B sites. The reduction of $BaBiO_3$ in high purity N_2 ($pO_2 \approx 10^{-6}$ atm) yields the polymorphous solid $BaBiO_{2.50}$. At 1000 °C, it still shows a structure with the tetragonal symmetry of phase III. Between 1000 and 800 °C, this bright red solid shows a pseudocubic perovskite-type structure, while for lower temperatures it assumes a bright yellow color and a structure with monoclinic "no-longer-perovskite"-type symmetry. The equilibria between the solids of the examined system were also studied through annealing and quenching in water of solids with $x = 0.2$, 0.3, and 0.44, sealed in silica glass tubes. The eutectoid decomposition of phase II ($x = 0.2$) to phase I and phase III (at $T = 668 \pm 2$ °C) and the subsequent decomposition of phase III to phase I plus the yellow phase $BaBiO_{2.5}$ (at 663 ± 2 °C) disagrees with the results of other authors. The results of the simultaneous DTA, TG, and DTG analyses on the stoichiometric $BaBiO_3$ at $pO_2 = 0.21$ and 1 atm leads to the conclusion that the monophasic region II ($Pm\bar{3}\,m$) for adequate pO_2 ($pO_2 > 1$ atm) extends as far as the stoichiometric solid itself ($x = 0$).

Barium bismuthate, $BaBiO_3$, has a CAS number of 12785-50-1 and a molecular weight of 394.305 g/mol. It is a bronze crystal which decomposes at 1040 °C. It has found usage in industry in alkaline batteries. The incorporation of small amounts (1–5 wt%) of semiconducting $BaBiO_{3-x}$ and metallic $Ba_{0.6}K_{0.4}BiO_3$ additives on the rechargeability of electrolytic manganese dioxide cathodes in alkaline cells in the one-electron regime has been investigated. Both the $BaBiO_3$ and $Ba_{0.6}K_{0.4}BiO_3$ additives lead to better recyclability compared to the previously known binary oxide additive Bi_2O_3. XRD patterns recorded before and after 30 cycles as well as cyclic voltammograms recorded after first and 30 cycles reveal that the better recyclability in the presence of $BaBiO_3$ and $Ba_{0.6}K_{0.4}BiO_3$ additives is due to the suppression of the formation of unwanted, electrochemically inactive "Birnessite" and "Hausmannite" phases and a shifting of the second-electron capacity of Mn to higher potentials.

The synthesized oxide $BaBiO_{3-x}$ can absorb light with wavelength below 650 nm, which almost covers the region from UV through all strong visible light in the sunlight, as well as that of an indoor lamp. The material demonstrates highly photocatalytic properties for the decompositions of hazardous chemicals such as gaseous acetaldehyde and methylene-blue dye even under light irradiation with wavelength longer than 600 nm. These optical effects have been explained in terms of "excitons". The energy splitting due to Charge Density Wave formation in the 6s band of Bi is found to be very large (2.0 eV), whereas, the minimum gap is much smaller (0.55 eV) than it. This large optical gap appears in the visible region as a dominant peak of the optical conductivity, and it is mainly due to the direct formations of excitons. The smaller gap appears in the infrared region, and is due to an indirect exciton mechanism. This theory well agrees with the results of recent optical experiments on $BaBiO_{3-x}$.

A Bi-based photocatalyst ($BaBiO_{3-x}$) was prepared by the solid-state reaction of BaO and $Bi_2O_3 \cdot (OH)_4$ and its

optical absorption properties were determined by UV-visible diffuse reflectance spectrum. The photocatalytic properties of the oxide for decomposition of acetaldehydes were investigated. The results show that this Bi-based material is very active in photocatalytic organic decomposition under visible light irradiation.

$BaBiO_{3-x}$ and modifications thereof are now being used as solid-state ceramic conducting membranes for the separation of oxygen from air. These membranes are heated to about 700 °C and involves transport of O^{2-} atoms across the membrane to form O_2 atoms. They can deliver oxygen fluxes in excess of 5 ml/min/cm^2.

$BaBiO_3$ is a semiconducting material and shows a good negative temperature coefficient (NTC) effect. NTC thermistors are thermally sensitive resistors whose resistance decreases with increasing temperature. They are mainly used in electronics for the suppression of in-rush current, for temperature measurement and control, and for compensation for other circuit elements.

Although $BaBiO_{3-x}$ remains the most studied compound in the $BaO \cdot Bi_2O_3$ series, other compounds have been discovered. $BaBi_2O_6 \cdot 4H_2O$ is an orange crystal which can be precipitated from solution by the reaction:

$$BaCl_2\ (aq) + NaBiO_3\ (aq) \Rightarrow Ba(BiO_3)_2 \cdot 4H_2O\ (s)$$

This compound, when heated to about 80 °C, loses two waters of hydration and the other two at 180 °C. Further heating to about 420 °C then causes loss of oxygen and formation of the compound, $BaBiO_{3-x}$.

$Ba_2Bi_2O_5$ actually has the formula of $Ba_2Bi_2O_{5+y}$ where an excess of oxygen is present. It has been found useful in the dehydrogenation of olefins where the double bond is changed from 2(C=C) to (C-C-C-C) a saturated hydrocarbon useful in fuels. Bi_2O_5 has traditionally been used in this context but $Ba_2Bi_2O_{5+y}$ has proven to be superior as a catalyst. To prepare this compound, the stoichiometric compound, $Ba_2Bi_2O_6$ is first prepared. A mixture of the nitrates are first fired together in air for 2 h at 400 °C, followed by regrinding and heating at 800 °C for 24 h. This compound was brownish-red in color. It was then reheated at 850 °C in flowing oxygen (100 ppm or 0.0001 atm) + argon. The product is magenta in color. It is sensitive to moisture in air. The product was analyzed as $Ba_2Bi_2O_{5.0 \pm 0.02}$. Its structure was pseudo-cubic with $a = 8.892$ Å. The actual formula is probably: $Ba_2Bi^{3+}Bi^{5+}O_{5+y}$.

To prepare other degrees of oxygen-rich barium bismuthate, $Ba_2Bi_2O_6$ is heated in a flowing oxygen argon at the following temperatures and oxygen concentrations (Table 4.25).

Further modifications have been made by the addition of Y^{3+} and Ln^{3+} ions which substitute for the Bi^{3+} ion in the structure. Such catalysts are used in Refinery processes for treating various fractions of crude oils, particularly "heavy crude". Such a process includes the heterogenetic-catalytic oxidative gaseous phase dehydrogenation of alkyl aromatics or aliphatics (educts) to form the corresponding alkenyl aromatics or olefins. In a first reaction step, the educt is dehydrogenated with a bismuth-containing redox catalyst (oxygen carrier) in the absence of molecular oxygen, and, in a second reaction step, the reduced catalyst is reoxidized with an oxidizing agent. The reaction steps are chronologically or spatially decoupled, and at least one reducible bismuthate like $Ba_2La^{3+}Bi^{5+}O_{5+y}$ on a basic or neutral carrier is used as the bismuth-containing catalyst. The process further concerns a Ba-bismuthate(5) having the composition $Ba_9Bi_3O_{14}$ as a novel substance.

$Ba_2Bi^{3+}Bi^{5+}O_6$ has been synthesized. High-resolution neutron powder diffraction has been used to investigate the structures and phase transitions in the double perovskites $Ba_2Bi^{3+}Bi^{5+}O_6$ (dibarium dibismuth hexaoxide) in the temperature ranges 4.2–973 K (−269 to 700 °C). The charge-ordered bismuthate adopts four structures in the temperature range—monoclinic in $P2_1/n$, monoclinic in I2/m, rhombohedral in $R\bar{3}$, and finally cubic in $\bar{b}$. The low-temperature monoclinic structure has been determined for the first time. The transitions from $P2_1/n \Rightarrow$ I2/m, at 132 K (−141 °C), and $R\bar{3} \Rightarrow Fm\bar{3}$ at 820 K (547 °C), are tricritical in nature; the transition from I2/m $\Rightarrow \bar{b}$ at ≈ 430 K (157 °C) is discontinuous. The behavior of Ba_2BiSbO_6 is very similar, except that the transition temperatures are lower at 250 K for I2/m $\Rightarrow R\bar{3}$ and 515 K for $R\bar{3} \Rightarrow Fm\bar{3}$ and the low-temperature structure is not formed at all.

Although $BaBiO_{3-x}$ has a CAS number, its availability is commercially limited to small quantities suitable for CVD studies. Only a few manufacturers offer it for sale.

Radium Bismuthate

There are no known publications concerning $RaBi_2O_4$- or $RaBi_2O_6$-type compounds. The most likely stable compound would be $RaBiO_{3-x}$ but even this composition has apparently not been synthesized. The systems, $xRaO \cdot yBi_2O_3$ or $xRaO \cdot yBi_2O_5$, remain unknown.

TABLE 4.25

$Ba_2Bi_2O_{5.10 \pm 0.04}$	Tetragonal, $a = 8.784$ Å; $c = 8.977$ Å	3 h at 765 °C	1000 ppm = 0.001 Atm	Black
$Ba_2Bi_2O_{5.62 \pm 0.04}$	Perovskite	58 h at 715 °C	1000 ppm = 0.001 Atm	Dark brown

The chemistry of Ra^{2+} ought to follow that of Ba^{2+}. However, in view of the difficulty in forming similar compounds of barium and the radioactivity of ^{226}Ra, it is apparent why this line of research has not been followed. If one were to initiate such a program, one would follow that of barium.

Metal oxides containing Bi^{5+} are relatively rare. Those of $RaO \cdot Bi_2O_5$ are not expected to be easily formed due to the same restrictions already mentioned for $SrO \cdot Bi_2O_5$. Thus, those of $RaO \cdot Bi_2O_3$ would be much more stable due to the presence of the $6s^2$ lone pairs of the ion, Bi^{3+}. $RaBiO_3$ would be a mixed-valency type of compound where the actual formula is $Ra(Bi^{3+},Bi^{5+})O_{3-x}$ signifies an oxygen deficiency. Varying the Ra:Bi(V) ratio would always result in the formation of this mixed-valency perovskite salt and the pyrochlore salts would never appear under usual chemical conditions. It is for this reason that many preparations would require sealed ampoules where the contents are under pressure when heated and in many cases employ an oxidizing agent such as $KClO_4$ to ensure that the oxidized form results. However, the preparation is not expected to always be successful. It is this fact that probably accounts for the scarcity of data concerning radium bismuthates. The correct formulation for $RaBiO_3$ is believed to be:

$$RaBi^{3+}_{0.5+x}Bi^{5+}{}_{0.5-x}O_{3-x}$$

which is accurately a "Bismuthite".

4.5.2. Alkaline Earth Bismuthides

Bi metal forms a series of alloy compounds with the alkaline earths. Various compositions have been studied and the phase diagrams have been established. Some of these have unique structures.

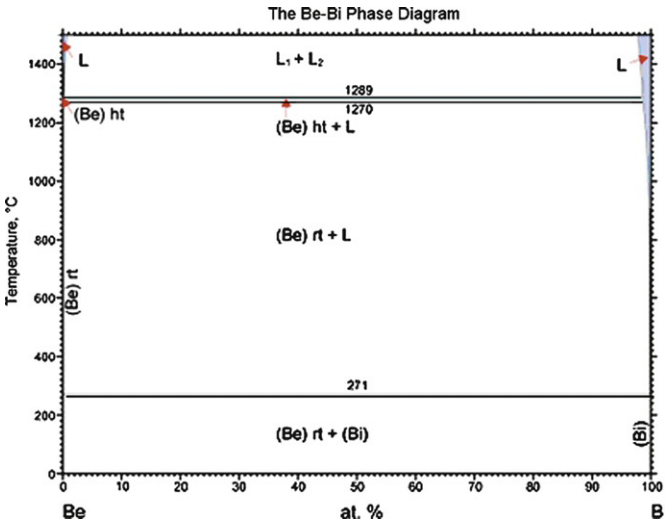

FIGURE 4.97

Beryllium Bismuthides

Be metal does not form any specific compounds with metallic Bi. The only phenomena found was the formation of alloys having the characteristics of Be metal itself, as shown in the following phase Fig. 4.97.

Magnesium Bismuthides

Mg metal forms a series of compounds with Bi metal, as shown in the following phase Fig. 4.98.

Only one compound has been established which is dimorphic. The crystal parameters of the system are: The crystal structure of Mg_3Bi_2 has the form shown as follows, which is a La_2O_3 type of structure (Fig. 4.99).

Cell parameters are: $a = 4.62$ Å, $b = 4.62$ Å, $c = 7.41$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 136.97 Å^3, $Z = 1$. Site occupancy is shown in Table 4.26.

In addition, the high-temperature phase changes and has the Ag_2S type of structure (Fig. 4.100).

TABLE 4.26

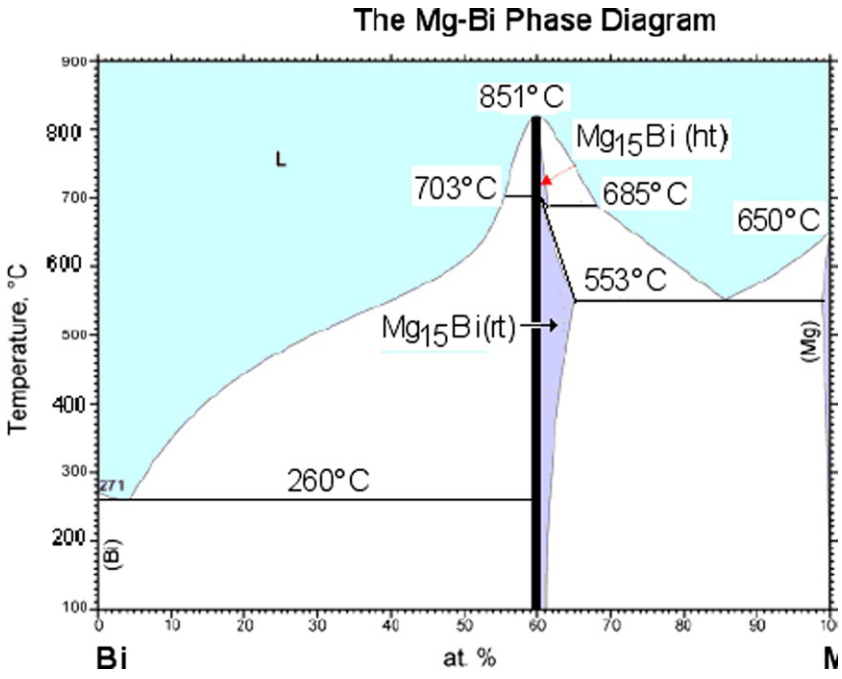

FIGURE 4.98

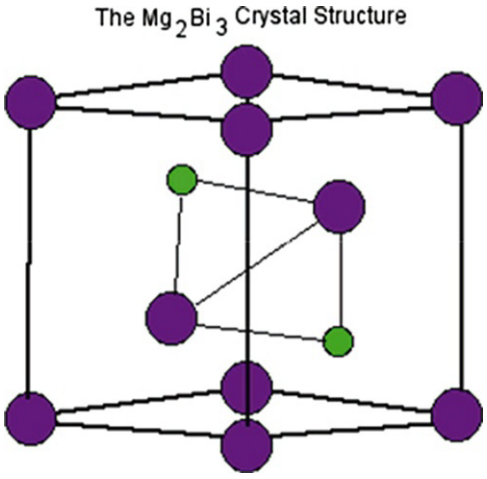

FIGURE 4.99

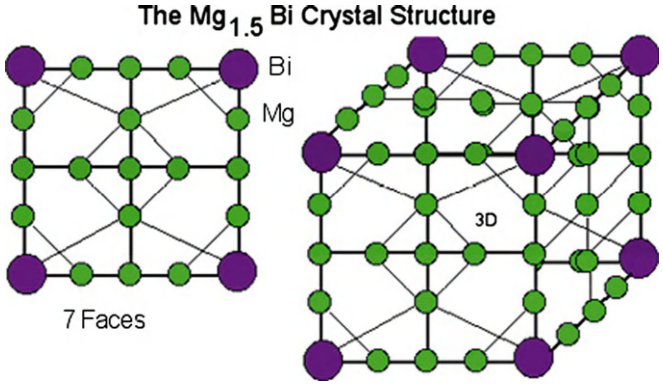

FIGURE 4.100

The $Mg_{1.5}Bi$ structure, actually α-Mg_3Bi_2, consists of seven (7) unilateral faces, one on each side of the cube and one hidden in the middle. The low-temperature phase, β-Mg_3Bi, shows a much simpler structural design. Cell parameters of α-Mg_3Bi_2 are: $a = b = c = 4.5673$ Å, $\alpha = \beta = \gamma = 109.471°$, cell volume $= 74.31$ Å^3, $Z = 2$. Cell occupancy is shown in Table 4.27.

The structure of β-Mg_3Bi_2 has been determined by neutron powder diffraction. The results show that it is a super-ionic phase, with a fixed body-centered cubic bismuth sublattice and mobile Mg^{2+} ions. From the analysis of the radial distribution function obtained from the diffraction pattern, it is concluded that the magnesium ions occupy the tetrahedral and triangular symmetry sites of the bismuth lattice in a similar way to the silver

ions in the anion lattices of α-AgI and α-Ag2Se. This material is an example of a new type of super-ionic conductor in which the metallic mobile ion is small and doubly charged.

Structural stabilities, elastic properties and electronic structures have been determined from first-principles calculation by using Castep and Dmol program based on the density functional theory for $Mg_{17}Al_{12}$, Mg_3Bi_2 and Mg_3Sb_2 phases. The calculation results of heat of formation and cohesive energy indicate that Mg_3Sb_2 has the strongest alloying ability as well as the highest structural stability. The calculations of thermodynamic properties show that the Gibbs free energy of $Mg_{17}Al_{12}$, Mg_3Bi_2 and Mg_3Sb_2 change with the elevated temperature, when the temperature is below 423 K, Mg_3Sb_2 and Mg_3Bi_2 are more stable than $Mg_{17}Al_{12}$ phases and Sb or Bi addition to the Mg–Al-based alloys can improve the heat resistance. The DOS of these compounds have been given. The elastic parameters are calculated, then the bulk modulus, shear modulus, Young's modulus and Poisson ratio value are derived. All the results of the analysis indicate that adding Sb or Bi to Mg–Al alloy could improve the ductility and plasticity by forming Mg_3Sb_2 and Mg_3Bi_2 phases.

Calcium Bismuthides

Calcium forms a number of compounds with Bi as can be seen by examination of the phase diagram shown in Fig. 4.101.

$CaBi_3$ does not appear in the phase diagram and has not been characterized separately. The reason for this remains unknown. Very little information concerning this compound is available in the literature and its structure has not been determined. Its physical properties are the only ones described (in one paper). It has no CAS number.

The other compounds are: Ca_2Bi, Ca_5Bi_3, and $Ca_{11}Bi_{10}$.

The system parameters are shown in Table 4.28.

The crystal structure of Ca_5Bi_3 is shown as follows where a view of the *c*-direction is shown. The cell parameters are: $a = 8.437$ Å, $b = 9.706$ Å, $c = 12.66$ Å, $\alpha = \beta = \gamma = 90°$, $Z = 4$, cell volume $= 104.640$ Å^3 (Fig. 4.102).

Cell occupancy by the 32 atoms in the unit cell is shown in Table 4.29.

The Mn_5Si_3 structure arrangement is virtually unique. The active component in this hexagonal structure ($P6_3/mcm$) is a confacial chain of $A_6/2B_6/2$ units; that is, a chain of A_6 trigonal antiprisms (octahedra) that are condensed with like units by sharing basal faces. The shared faces in these condensed units are then each bridged by three B atoms to give what can be described as $[A_{6/2}\text{-}B_{6/2}]$ chains. Each of these A atoms (crystallographically A_2) has six other A neighbors, two in the shared face and two in each of the two adjoining shared faces. The A atoms likewise have four B neighbors, two around the shared face plus one above and one below in the staggered planar A_5B_3 units. The active site for binding of an interstitial atom (Z) is the center of each trigonal antiprismatic A_6 unit. A better diagram shows the hexagonal network of the Ca_5Bi_3 structure that is endemic to all Yb_2Si_3-type of compounds (Fig. 4.103).

In contrast, the structure of Ca_2Bi is much simpler as shown in the following Fig. 4.104.

The unit-cell parameters are: $a = b = 4.722$ Å, $c = 8.918$ Å, $\alpha = \beta = 105.345°$, $\gamma = 90°$, cell volume $= 184.24$ Å^3. Cell occupancy of the 12 atoms is shown in Table 4.30.

This compound has been reported not to exist. Reported were the structure refinements and the electronic structure calculations for the ternary

compound Ca_4Bi_2O, up until now stated to have been erroneously known as the binary $Ca_2Bi.\cdot Ca_4Bi_2O$ crystallizes in the body-centered tetragonal space group $I4/mmm$ (no. 139), with cell parameters $a = 4.719(2)$ Å and $c = 16.505(9)$ Å at 120 K, and its structure can be regarded as built of oxygen-centered octahedra of Ca, forming infinite layers via corner sharing, i.e. as an antitype of the perovskite-related

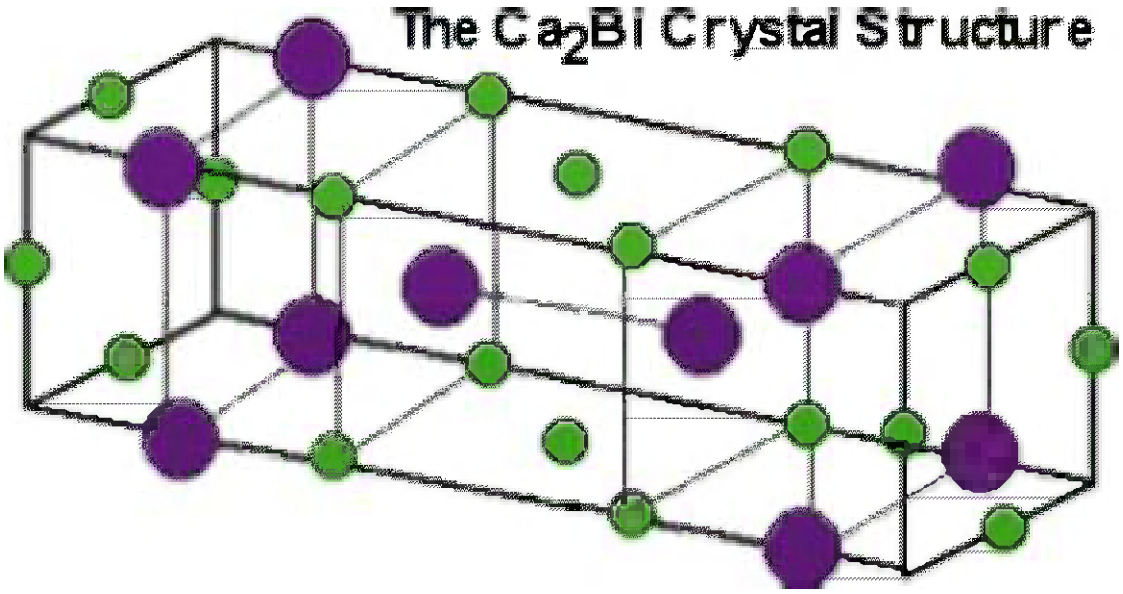

FIGURE 4.104

K_2NiF_4. The bonding in Ca_4Bi_2O has been further analyzed using electronic structure calculations (LMTO-ASA), which confirm that Ca_4Bi_2O and related phases, as expected, are closed-shell compounds. It is likely that both compounds exist, the latter being a product formed when the two metals are melted together in air.

The 11:10 compound has also been characterized. Its structure is shown in Fig. 4.105.

Lattice parameters are: $a = b = 12.22$ Å, $c = 12.40$ Å, $\alpha = \beta = 119.518°$, $\gamma = 90°$, cell volume $= 132.828$ Å^3, $Z = 4$. Cell parameters for the 84 atoms present in the unit cell are shown in Table 4.31.

In addition, a compound having the stoichiometry of $Ca_{16}Bi_{11}$ has been characterized. Its structure has the form shown in Fig. 4.106.

Cell parameters are: $a = 11.43$ Å, $b = \gamma = 12.495$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 175.448$ Å^3, $Z = 2$. Site occupancy of the 58 atoms in the unit cell is shown in Table 4.32.

Zintl phases of type $M_{16}X_{11}$ (M = Ca and Yb; X = Sb and Bi) have been synthesized by both the flux and the solid-state reaction methods. In order to evaluate the potential of these phases for thermoelectrics, the electrical resistivity (δ), thermopower (σ) and thermal conductivity (η) have been measured on hot pressed samples over a wide temperature range of 10–1000 K. The δ and σ trends are typical of a degenerate semiconductor. However, δ remains low (30 μV/K or less). Hall measurements indicate a low-charge carrier mobility 3–7 cm^2/V s, except for $Ca_{16}Sb_{11}$. It is notable that low-thermal conductivity values ranging from 2.5 to 0.8 W/m K are measured for these phases at higher

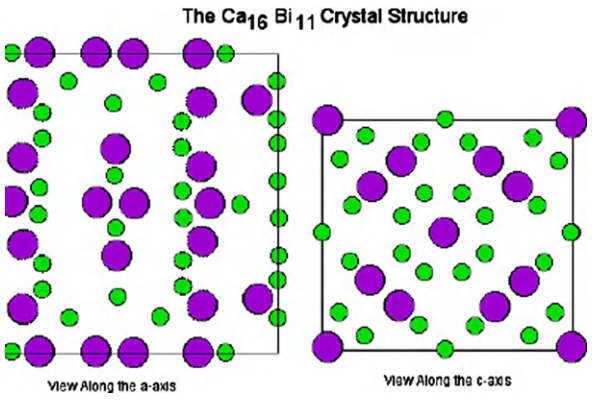

FIGURE 4.106

temperatures up to 1273 K. Particularly for $Yb_{16}Sb_{11}$, the lattice part of thermal conductivity is found to be between 0.5 and 0.7 W/m K. However, the challenge in this M16X11 system is to achieve high thermopower. In order to understand more fully the measured transport properties, band structure calculations have been performed. Consistent with experimental data, these calculations suggest that all the systems are indeed metallic. The electronic structures for Ca-based phases show one-dimensional metallic behavior with small and almost symmetric density of states around the Fermi level.

Calcium bismuthide compounds have not been developed sufficiently to warrant any usage in industry. This may be due to the fact that alkaline earth

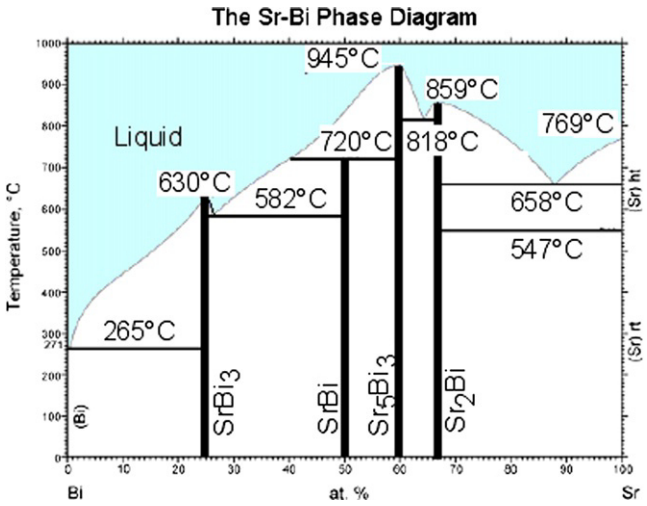

FIGURE 4.107

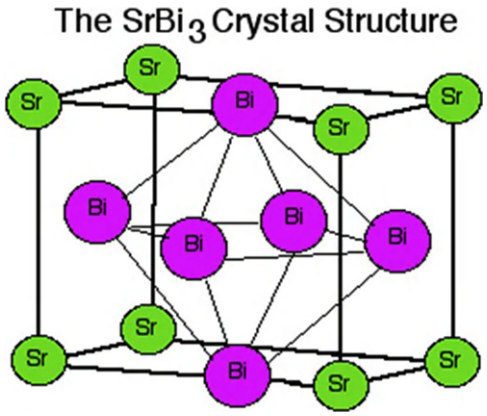

FIGURE 4.108

metals are not very stable in air or moisture and that the addition of Bismuth metal does not improve their instability.

Strontium Bismuthides

Sr metal also forms a number of compounds, as shown in Fig. 4.107.

Four compounds, $SrBi_3$, SrBi, Sr_5Bi_3 and Sr_2Bi are known.

The structure factors for these compounds are shown in Table 4.33.

The compound, $SrBi_3$, has the face-centered cubic structure, as shown on the next page. It has lattice parameters of: $a = b = c = 5.042$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 128.18$ Å^3 (Fig. 4.108).

Cell occupancy is shown in Table 4.34.

This compound is a superconductor with $T_c = \sim 3.6$ K.

The compound Sr_5Bi_3 has the Mn_5Si_3 structure with point Group hP16 and space group $P6_3/mcm$. Its structure can be represented as in Fig. 4.109.

Unit-cell parameters are: $a = 7.523$ Å, $b = c = 9.651$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 606.83$ Å^3. Site occupancy is shown in Table 4.35.

This compound is dimorphic and can assume the Yb_5Sb_3 structure with point group oP32 and space group Pnma (Fig. 4.110).

Cell parameters are: $a = 8.89$ Å, $b = 10.233$ Å, $c = 13.37$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 1216.29$ Å^3. Site occupancy is shown in Table 4.36.

The compound, Sr_2Bi_3 does not appear in the phase diagram. It has the structure as in Fig. 4.111.

Cell parameters are: $a = 6.599$ Å, $b = 6.793$ Å, $c = 15.631$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 700.69$ Å^3. Site occupancy is shown in Table 4.37.

If Ba is substituted for Sr in this structure, it changes to Fig. 4.112.

Crystals of the composition $Sr_{2-x}Ba_xBi_3$ $(0 \leq x \leq 1.3)$ were synthesized from the elements and were characterized by single-crystal and powder XRD methods. The compounds crystallize for $x = 0$, 0.45, 0.86, 1.08, 1.28 in the structure type of the parent compound Sr_2Bi_3 with

space group Pnna (No. 52) and $Z = 4$. Substitution of Sr by Ba leads to a site preference for Ba. The anionic Bi substructures in the pseudoternary system simultaneously distort under remarkable elongation of one distinct Bi–Bi contact. Magnetic measurements for samples with $x = 0$, 0.45 and 1.08 reveal superconducting transitions at low temperatures. Linear muffin-tin orbital band structure calculations of Sr_2Bi_3 show strong cation–anion interactions that greatly stabilize the structure. Besides showing characteristics of a typical metal, the band structure plot unveils the co-instantaneous

occurrence of flat and steep bands around the Fermi level indicative for superconductivity.

The compound, Sr_2Bi has the structure shown in the following Fig. 4.113.

The unit-cell parameters are: $a = b = 5.01$ Å, $c = 9.623$ Å, $\alpha = \beta = 105.25°$, $\gamma = 90°$, cell volume = 221.88 Å^3. Cell occupancy is shown in Table 4.38.

$Sr_{16}Bi_{11}$ has the same structure as the Ca-homologue (Fig. 4.114).

Cell parameters are: $a = 11.934$ Å, $b = 13.152$ Å, $c = 13.152$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 2064.29 Å^3. Cell occupancy is shown in Table 4.39.

When Sr metal and Bi metal in proper proportion is reacted in Ta containers at about 1100 °C and then annealed at 825–900 °C or slowly cooled, the $Sr_{16}Bi_{11}$ composition results. It is important to run particularly such reactions either under dynamic vacuum or to previously remove the pervasive hydrogen impurity from these metals. The complex structure is built of

pairs of confacial Sr_5Bi_3-like slabs intergrown with single square-prismatic slabs along c in which Sr atoms in both define the polyhedra centered by Bi (Fig. 4.115).

This structure is missing the $n = 2$ member of the homologous series $A_{5n+6}B_{3n+5}$ (Parthé) with n:1 ratios of intergrown slabs. Four of five $Ae_{16}(Sb,Bi)_{11}$ examples studied are diamagnetic ($Ba_{16}Sb_{11}$ excepted), and $Ca_{16}Sb_{11}$ is a poor semiconductor. Accommodation of these Zintl-phase characteristics in the $Sr_{16}Bi_{11}$ structure requires that 50% of the Bi atom pairs centering the confacial square antiprisms be bonded ($d = 3.40$ Å) on a random basis. Ellipsoids on these atoms are elongated along the proposed bonds.

Strontium bismuthides are not used in industry and do not have assigned CAS numbers.

Barium Bismuthides

The phase diagram of the Ba–Bi system has only been partly examined. The atom-ratio between 30 and 100 At % are shown in the following Fig. 4.116.

However, four compounds are known: $BaBi_3$, Ba_5Bi_3, Ba_2Bi and $Ba_{16}O_{11}$. All of these have the same structure as that of the Sr homologues.

$BaBi_3$ has the structure shown in Fig. 4.117.

Cell parameters are: $a = 5.157$ Å, $b = c = 5.188$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 138.80 Å^3. Cell occupancy is shown in Table 4.40.

$BaBi_3$ has the assigned CAS number 91648-92-9 and is available commercially.

The compound, Ba_5Bi_3, has the structure shown in Fig. 4.118.

A better diagram of the structure is shown in Fig. 4.119.

Ba_5Bi_3 belongs to the hexagonal Mn_5Si_3 type while Sr_5Bi_3 is isostructural with orthorhombic α-Yb_5Sb_3. Unit-cell parameters are: 7.768 Å, $b = c = 10.098$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 658.98 Å^3. Cell occupancy is shown in Table 4.41.

Resistivity measurements have been performed for electronic characterization of the compounds Ba_5Bi_3 with the Mn_5Si_3 structure type, along with Ca_5Bi_3 and

Ca_5Bi_3F, with the β-Yb_5Sb_3 structure type. Ba_5Bi_3 was found to be a semiconductor ($Eg = 0.30$ eV) with a larger band gap than its corresponding chloride ($Eg = 0.09$ eV).

A new ternary phase $Ba_5In_4Bi_5$ has been synthesized by direct reaction of the corresponding elements at high temperature. It crystallizes in a noncentrosymmetric space group and represents a new structure type (tetragonal, P4nc with $a = 10.620(2)$ and $c = 9.009(2)$ Å, $Z = 2$). The structure is built of interconnected heteroatomic clusters of In_4Bi_5, square pyramids with In_4-bases and four exo-bonded bismuth atoms (bonded to the In atoms). According to Wade's rule, the compound is electron deficient with one electron per cluster, that is, $[In_4Bi_5]_{10}$ instead of the expected $[In_4Bi_5]$ for a closed shell species. The clusters were discussed also in light of the known

heteroatomic deltahedral clusters with the same composition but different charge, $[In_4Bi_5]^{3-}$. Band structure calculations on the new compound suggested substantial participation of barium in the overall bonding of the structure that accounts for the electron shortage (Fig. 4.120).

Ba_2Bi has the structure shown in Fig. 4.121.

Cell parameters are: $a = b = 5.263$ Å, $c = 10.063$ Å, $\alpha = \beta = 105.16°$, $\gamma = 90°$, cell volume $= 256.99$ Å^3. Cell occupancy is shown in Table 4.42.

Single crystals of Ba_2Bi can be prepared by cooling a melt of stoichiometry $3Ba + 2Bi$ with a small excess of Ba from 1350 °C to room temperature. It is orthorhombic.

$Ba_{16}Bi_{11}$ has the structure shown in Fig. 4.122.

Cell parameters are: $a = 12.568$ Å, $b = 13744$ Å, $c = 13.744$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 2374.06$ Å^3. Cell occupancy is shown in Table 4.43.

Only $BaBi_3$ is offered for sale. The other compounds have not found usage in industry.

Radium Bismuthide

Radium bimuthide could probably be prepared by the reaction of Ra and Bi metals. Ra melts at 700 °C and is stable in an inert atmosphere until its boiling point of 1737 °C is reached. Since Bi melts at 272 °C and is stable in an inert atmosphere until its boiling point of 1564 °C, the reaction is best carried out by evaporating Ra metal at about 680 °C onto molten Bi metal:

$$3Ra + 2Bi \Rightarrow Ra_3Bi_2$$

However, this reaction has never been carried out due, perhaps, to the intense radioactivity of ^{226}Ra atom. It is probable that Ra forms the same type of antimonide compounds as Ba but there is no industrial or commercial interest and no academic interest in these compounds due to the care required in handling such compounds.

5.1. ALKALINE EARTH OXY-CARBON COMPOUNDS

Among the possible oxy-carbon compounds known are the carbides, carbonates and "bicarbonates". Carbonates are related to carbonic acid which in turn is related to carbon dioxide, CO_2.

5.1.1. Carbonic Acid

Carbonic acid has the formula H_2CO_3 (equivalently $OC(OH)_2$). It is also a name sometimes given to solutions of CO_2 in water, where it exists in equilibrium:

$$CO_2 + H_2O \Leftrightarrow H_2CO_3$$

At room temperature, only small amounts of carbonic acid are present. The salts of carbonic acids are called bicarbonates (or hydrogen carbonates) and carbonates. They are weak acids. The hydration equilibrium constant for carbonic acid at 25 °C is $K_h = [H_2CO_3]/[CO_2] = 1.70 \times 10^{-3}$. Hence, the majority of the carbon dioxide is not converted into carbonic acid, but remains as CO_2 molecules. In the absence of a catalyst, the equilibrium is reached quite slowly. The rate constants are 0.039/s for the forward reaction ($CO_2 + H_2O \Rightarrow H_2CO_3$) and 23/s for the reverse reaction ($H_2CO_3 \Rightarrow CO_2 + H_2O$). Carbonic acid is used in the manufacture of soft drinks, inexpensive and artificially carbonated sparkling wines, and other bubbly drinks. If two equivalents of water could add to CO_2, this would give orthocarbonic acid, $C(OH)_4$, which is virtually unimportant in aqueous solution.

Carbonic acid is diprotic in that it has two protons, which may dissociate from the molecule. Thus, there are two dissociation constants, the first one for the dissociation into the bicarbonate ion, HCO_3^-, (also called hydrogen carbonate):

$$H_2CO_3 \Rightarrow HCO_3^- + H^+$$

$$K_{a_1} = 2.5 \times 10^{-4};\ pK_{a_1} = 3.60 \text{ at } 25\ ^\circ C$$

This indicates that H_2CO_3 is a stronger acid than acetic acid or formic acid. Its high acidity reflects the influence of the electronegative oxygen constituent. The second constant for the dissociation of the bicarbonate ion into the carbonate ion is:

$$HCO_3^- \Rightarrow CO_3^{2-} + H^+$$

$$K_{a_2} = 5.61 \times 10^{-11};\ pK_{a_2} = 10.33 \text{ at } 25\ ^\circ C \text{ and ionic strength} = 0.0$$

Care must be taken when quoting and using the first dissociation constant of carbonic acid. In aqueous solution, carbonic acid only exists in equilibrium with carbon dioxide, and the concentration of H_2CO_3 is much lower than the dissolved CO_2 concentration. Since it is not possible to distinguish between H_2CO_3 and dissolved CO_2 (referred to as CO_2 (aq) by conventional methods), $H_2CO_3^-$ is used to represent the two species when writing the aqueous chemical equilibrium equation. The equation may be rewritten as follows:

$$H_2CO_3^- \Rightarrow HCO_3^- + H^+$$

$$K_a = 4.6 \times 10^{-7};\ pK_a = 6.352 \text{ at } 25\ ^\circ C \text{ and ionic strength} = 0.0$$

Whereas this is the pK_a quoted as the dissociation constant of carbonic acid, it is ambiguous. It might better be referred to as the acidity constant of dissolved carbon dioxide, as it is particularly useful for calculating the pH of CO_2–containing solutions. At a given temperature, the composition of a pure carbonic acid solution (or of a pure CO_2 solution) is completely determined by the partial pressure of carbon dioxide above the solution. To calculate this composition, account must be taken of the above equilibria between the three different carbonate forms (H_2CO_3, HCO_3^- and CO_3^{2-}) as well as of the hydration equilibrium between dissolved CO_2 and H_2CO_3 with the constant:

$$K_h = H_2CO_3/CO_2$$

and of the following equilibrium between the dissolved CO_2 and the gaseous CO_2 above the solution:

$$CO_2(\text{gas}) \Leftrightarrow CO_2(\text{dissolved}) \text{ where the Henry constant, } k_H = 29.76 \text{ atm/(mol/l) at } 25\ ^\circ\text{C}$$

The corresponding equilibrium equations together with the relation and the charge neutrality condition result in six equations for the six unknowns $[CO_2]$, $[H_2CO_3]$, $[H^+]$, $[OH^-]$, $[HCO_3^-]$ and $[CO_3^{2-}]$, showing that the composition of the solution is fully determined by these. The equation obtained for $[H^+]$ is a cubic whose numerical solution yields the following values for the pH and the different species concentrations (Table 5.1).

- We see that in the total range of pressure, the pH is always largely lower than pK_{a_2} so that the CO_3^{2-} concentration is always negligible with respect to HCO_3^- concentration. In fact CO_3^{2-} plays no quantitative role in the present calculation.
- For vanishing PCO_2, the pH is close to the one of pure water (pH = 7) and the dissolved carbon is essentially in the HCO_3^- form.
- For normal atmospheric conditions ($PCO_2 = 3.5 \times 10^{-4}$ atm), we get a slightly acid solution (pH = 5.7) and the dissolved carbon is now essentially in the CO_2 form. From this pressure on, $[OH^-]$ becomes also negligible so that the ionized part of the solution is now an equimolar mixture of H^+ and HCO_3^-.
- For a CO_2 pressure typical of the one in soda drink bottles ($PCO_2 \sim 2.5$ atm), we get a relatively acid medium (pH = 3.7) with a high concentration of dissolved CO_2. These features contribute to the sour and sparkling taste of these drinks.
- Between 2.5 and 10 atm, the pH crosses the pK_{a_1} value (3.60) giving a dominant H_2CO_3 concentration (with respect to HCO_3^-) at high pressures.
- CO_2 gas solidifies at –78 °C and boils at –57 °C.

5.1.2. Alkaline Earth Carbides

These compounds are generally prepared by the high-temperature sintering of the alkaline earth metals (AEMs) with an excess of carbon. These compounds can be classified according to the type of hydrocarbon that appears when the carbide compound is hydrolyzed:

$$\text{Methanides} = C^{4-} = CH_4$$

$$\text{Acetylides} = C_2^{4-} = HC{\equiv}CH$$

$$\text{Sesquicarbides} = C_3^{4-} = CH_3C{\equiv}CH$$

These are essentially "salt-like" carbides in contrast to covalent carbides like SiC or B_4C.

Beryllium Carbides

This compound has the molecular formula of Be_2C and the molecular weight of 30.0351 g/mol. It is a very hard compound. Beryllium carbide is prepared by heating the elements at elevated temperatures (above 900 °C). It also may be prepared by reduction of BeO with carbon at a temperature above 1500 °C:

$$2BeO + 3C \Rightarrow Be_2C + 2CO$$

TABLE 5.1

Beryllium oxide (BeO) and carbon react at 2000 °C (3600 F) to produce the brick-red beryllium carbide. Beryllium carbide has a CAS number of 506-66-1 and a density of 1.91 g/cc (15 °C). Its melting point is 2110 °C. It is a yellow to brick-red crystal whose color depends upon the amount of excess carbon present. Be_2C has the anti-CaF_2 cubic structure with $a = 4.341$ Å, $Z = 2$ and $V = 81.7$ Å^3. It decomposes very slowly in water, but is stable in air if it is compacted:

$$Be_2C + 2H_2O \Rightarrow 2BeO + CH_4\ (gas)$$

The rate of decomposition and evolution of methane are faster in mineral acids:

$$Be_2C + 4H^+ \Rightarrow 2Be^{2+} + CH_4\ (gas)$$

However, in hot concentrated alkali, the reaction is very rapid, forming alkali metal beryllates and methane:

$$Be_2C + 4OH^- \Rightarrow 2\ BeO_2^{2-} + CH_4\ (gas)$$

Beryllium carbide is hard (Knoop = 2410) and compares favorably with tungsten carbide (Knoop = 1800) and silicon carbide (Knoop = 2480). As a refractory, beryllium carbide has several disadvantages. It tends to hydrolyze in atmospheric moisture and to react with both oxygen and nitrogen when heated. Because of its refractory nature and chemical instability in the presence of moisture, methods of fabricating beryllium carbide are definitely limited. Considerable success has, however, been achieved by hot-pressing techniques, and by means of cold-pressing followed by sintering under controlled conditions. Additions of graphite or of beryllium oxide to the carbide considerably facilitate fabrication. BeC_2 has no value as a ceramic since it is attacked by N_2 above 1100 °C, by oxygen above 800 °C and by sulfur above 1000 °C. When stored under ambient conditions in air, it loses its crystallinity and cannot be identified by X-ray diffraction (XRD).

The vapor pressure of beryllium carbide has been measured over the temperature range 1388–1763 K (1115–1490 °C) using Knudsen-effusion mass spectrometry. Vaporization occurs incongruently according to the reaction:

$$Be_2C\ (solid) \Rightarrow 2Be\ (gas) + C\ (solid)$$

The equilibrium vapor pressure above the mixture of Be_2C and C over the experimental temperature range is:

$$(R/J/K\ mol)\ Ln(p/Pa) = -(3.610 \pm 0.009) \times 10^5 (K/T) + (221.43 \pm 1.06)$$

The third-law enthalpy change for the above reaction obtained from the vapor pressures present is $\Delta H^o(298\ K) = (740.5 \pm 0.1)$ kJ/mol. The corresponding second-law result is $\Delta H^o(298\ K) = (732.0 \pm 1.8)$ kJ/mol. The enthalpy of formation for Be_2C (solid) is $\Delta H_f^o(298\ K) = -(92.5 \pm 15.7)$ kJ/mol [calculated from the third-law vaporization enthalpy and the enthalpy of formation of Be (gas)].

The kinetics of the oxidation of electrolytic flake beryllium in carbon dioxide, in carbon monoxide and in carbon monoxide–carbon dioxide mixtures have been measured at temperatures from 500 to 750 °C. In carbon dioxide, at temperatures up to 700 °C, the rate of oxidation continuously decreases with time to reach a very small value (e.g. at 700 °C, 0.13 μg/cm^2 h after 300 h). This is due to formation of a protective oxide layer on the metal. At 750 °C, the rate first decreases and then increases, indicating that a breakaway occurs. If the carbon dioxide is admitted to the preheated sample, the oxidation is very rapid at first and most of the carbon deposition occurs over this initial period. In carbon monoxide, the oxidation is nonprotective above 550 °C, and the rate of oxidation being considerably greater than in carbon dioxide. When beryllium is heated at 650 °C in carbon monoxide–carbon dioxide mixtures containing up to 7.5% of carbon monoxide, the kinetics are the same as in pure carbon dioxide.

Preparation of a beryllium dicarbide, BeC_2, has been reported. It is formed by passing acetylene over Be metal powder at 450–550 °C in an inert atmosphere:

$$Be + HC{\equiv}CH \Rightarrow BeC_2 + H_2$$

This carbide is offered for sale as "beryllium carbide" with a CAS number of 12070-28-9. Other manufacturers list Be_2C for sale with the CAS number of 506-66-1.

Magnesium Carbides

There are two known carbides of magnesium, MgC_2 and the sesquicarbide, Mg_2C_3. The sesquicarbide ion is linear and is isoelectronic with CO_2. The C≡C distance in Mg_2C_3 is 1.333 Å. Mg_2C_3 yields methylacetylene, $CH_3C{\equiv}CH$, on hydrolysis which, when it was first synthesized, was the first indication that it may contain the ion, C_3^{4-}. This salt can be prepared by the reaction of methane with the oxide at temperatures above 2100 °C:

$$5\ CH_4 + 2MgO \Rightarrow Mg_2C_3 + 6H_2 + CO$$

The sesquicarbide reaction has potential for upgrading natural gas by using the solid metal carbide to generate useful acetylenes for manufacture of olefins and subsequent plastics. The acetylene can also be converted into a useful fuel. This potential is based, of course, upon relative costs of the process.

A similar reaction at 450–600 °C produces the acetylide, MgC_2, which has a fcc cubic structure. The reaction is endothermic with $\Delta G_f = +15$ kJ/mol. Most of the reactions between carbon and the metals to form carbides are exothermic. Thus, the difficulty in forming a stable MgC_2 stems from the fact that the structure is not thermodynamically stable as a solid. Even the Mg_2C_3

compound is not thermodynamically inclined and its free energy of formation is only $\Delta G_f = -15$ kJ/mol. However, it is the more stable of the two salts that form in this system.

If MgC_2 is heated to about 1100 °C, it decomposes to form the sesquicarbide:

$$2MgC_2 + \text{heat} \Rightarrow Mg_2C_3 + C$$

Carbon crystals having high structural order, of macrocrystalline size (>0.25 μm) and monocrystalline character were prepared by decomposition of this magnesium carbide between 950 and 1200 °C. CaC_2 was the source of carbon; this was dissolved in and reacted with $MgCl_2$. Crystalline carbon was formed by conversion of MgC_2 to Mg_2C_3 and subsequent decomposition of the latter to its elements. Magnesium metal formed in situ appeared to catalyze rearrangement of carbon atoms to a higher degree of order. The maximum yield of graphite was 86% of the carbon present.

The self-hydrogenation of propyne and propadiene to propene on evaporated magnesium films has been studied at 100 and 150 °C. The species retained in the solid state in the course of the reaction were then desorbed by deuterium oxide and characterized as deuterated hydrocarbons. The structures of these hydrocarbons (mainly propyne = HC≡CH and propene = H_2C=CH_2) and the variations in their deuterium distributions with temperature and contact time of the previous self-hydrogenation reaction are consistent with a mechanism involving two parallel processes:

(a) Dehydrogenation of propyne and propadiene into methylated propyne CH_3C≡CH–Mg (or deuterolyzed to [$^2H_1$]-propyne), that was stable at 373 K but rapidly further dehydrogenated at 423 K to the magnesium carbide Mg_2C_3 (or deuterolyzed to [$^2H_4$]propyne).

(b) Two-step hydrogenation of the reagent to propene, via half-hydrogenated intermediates, stable at 373 K and deuterolyzed to [$^2H_1$]-propene.

In an AC type of plasma-display panel, "PDP", an electrode for the main discharge is generally covered with a dielectric layer, and performs memory driving to reduce a driving voltage. When the dielectric layer deteriorates due to an impact of ions generated by the discharge and hitting the layer, the driving voltage may increase. To prevent this from increasing, a protective layer for protecting the dielectric layer is formed on a surface of the dielectric layer. The protective layer, made of MgO and magnesium carbide, reduces a variation of the discharge delay time against temperature. Thus, the protective layer has excellent electron emission ability hardly changing against temperature. This allows the PDP to preferably display images regardless of environmental temperature.

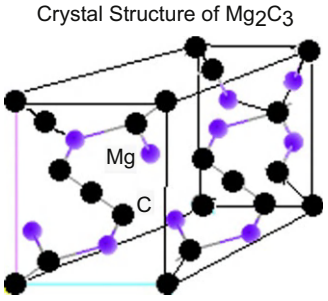

FIGURE 5.1

Magnesium carbide, Mg_2C_3 has the CAS number of 12151-74-5 and is also offered for sale commercially. It has a quasi-cubic structure, distorted along the *c*-axis with unit-cell parameters of: $a = 3.7283$ Å, $b = 5.2786$ Å, $c = 6.4108$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 126.17 Å^3, $Z = 2$.

MgC_2 has the CAS number of 12122-46-2 and is offered for sale commercially. Its crystal parameters are: $a = 3.9342$ Å, $b = 3.9342$ Å, $c = 5.021$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, $V = 77.71$ Å^3, $Z = 2$.

The structure of Mg_2C_3 is shown in the above diagram. The structure is quasi-cubic (rhombohedral) with a distortion in the *c*-direction (Fig. 5.1).

Under pressure, this compound reverts to the acetylide, Mg_2C_2 (designated MgC in the literature). It is known that Mg reacts with hydrocarbons in the temperature range of 450–700 °C at atmospheric pressure, producing the known magnesium carbides, MgC_2 and Mg_2C_3. The interaction of Mg and graphite was studied under pressures up to 7.7 Gpa and temperatures up to 1800 °C. Differential thermal analysis (DTA) was used, under pressure, to determine what reactions were taking place as the carbon content was changed. With C-concentrations above 15% by weight, the acetylide Mg_2C_2 was formed. This compound was cubic (FFC) with $a = 5.635$ Å. As the C was increased, the rhombic lattice of Mg_2C_3 appeared at C-concentrations of 50–67% by weight.

Magnesium carbides are available commercially but calcium carbides remain the leader in industrial usage.

Calcium Carbides

Calcium carbide has the nominal formula of CaC_2 and the molecular weight of 64.0992 g/mol. The pure material is colorless, but most samples have a color ranging from black to grayish-white, depending on the grade. Its density is 2.22 g/cc and it melts at 2160 °C with a boiling point (under an inert atmosphere) of 2300 °C, where it decomposes. Its main use industrially is in the production of acetylene and calcium cyanamide, $CaCN_2$. Calcium carbide is produced industrially in an electric-arc furnace from a mixture of $CaCO_3$ and

coke (carbon) at approximately 2000 °C. This method has not changed since its invention in 1888:

$$CaCO_3 + 3C \Rightarrow CaC_2 + CO + CO_2$$

The high temperature required for this reaction is not practically achievable by traditional combustion, so the reaction is performed in an electric-arc furnace where the electrodes are graphite. The carbide product produced generally contains around 80–85% calcium carbide by weight. The carbide is crushed to produce small lumps that can range a few millimeters up to 50 mm. The impurities are concentrated in the finer fractions. The CaC_2 content of the product is assayed by measuring the amount of acetylene produced on hydrolysis. As an example, the U.S. standard for the content of the coarser fractions is 295–300 l/kg. Impurities present in the carbide include phosphide, which produces PH_3 (a poisonous gas) when hydrolyzed to produce HC≡CH, i.e. acetylene.

This reaction was an important part of the industrial revolution in chemistry, and was made possible in the U.S. as a product of massive amounts of cheap hydroelectric power generated at Niagara falls before the turn of the twentieth century. The method for the production of CaC_2 in an electric-arc furnace was discovered independently by two researchers in Europe in 1888 and 1892. The following diagram is an illustration of how CaC_2 has been manufactured (Fig. 5.2).

The common crystalline form at room temperature is a distorted rock salt structure with the C_2^{4-} units lying parallel. The structure is tetragonal with point group $= D_{4h}^{17}$ and space group = I4/mmm. Actually, there are several forms of calcium carbide (Table 5.2).

TABLE 5.2

Number	Composition	Space group	Point group	SG #
1	Ca_6C_{60}	cP	—	—
2	CaC_2	aP12	P-1	2
3	CaC_2	mS12	C2/c	15
4	CaC_2	tI6	I4/mmm	139
5	CaC_2	cF36	Fm-3m	225
6	CaC_6	hR21	R-3m	166

In the following diagram, the a ⇒ c vector plane of the structures of calcium carbides are shown as a function of the space groups that form due to differences in how the CaC_2 was created (Fig. 5.3).

In calcium carbide, CaC_2, the C≡C triple bond length is about 1.092 Å (similar to ethyne).

$$CaC_2 + 2\,H_2O \Rightarrow HC{\equiv}CH + Ca(OH)_2$$

This reaction is the basis of the industrial manufacture of acetylene, and is the major industrial use of calcium carbide in industrial circles.

In China, acetylene derived from calcium carbide remains a raw material for their chemical industry, in particular for the production of polyvinyl chloride. Locally produced acetylene is more economical than using imported oil. Production of calcium carbide in

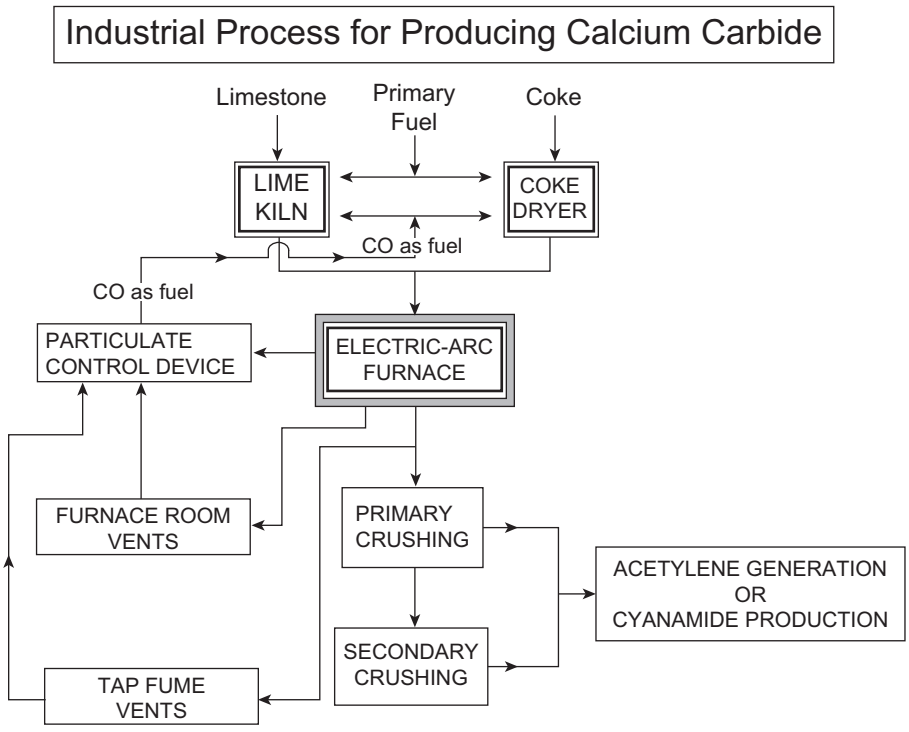

FIGURE 5.2

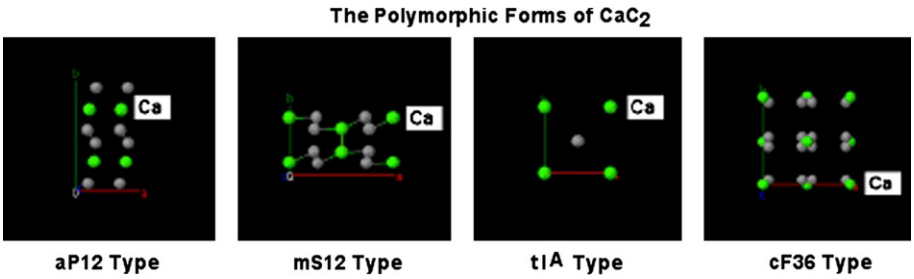

FIGURE 5.3

China has been increasing. In 2005, output was 8.94 million tons, with the capacity to produce 17 million tons. In the USA, Europe and Japan consumption is generally declining. Production levels in the USA in 1990s were 236,000 tons per year.

Calcium carbide reacts with nitrogen at high temperature to form calcium cyanamide:

$$CaC_2 + N_2 \Rightarrow CaCN_2 + C$$

Calcium cyanamide is used as fertilizer. It is hydrolyzed to cyanamide, $H_2N{=}C{=}N$, in the soil and is readily available to plants as a nitrogen plant food.

Calcium carbide has been used:

- in the "desulfurization" of iron (pig iron, cast iron and steel).
- as a fuel in steelmaking to extend the scrap ratio to liquid iron, depending on economics.
- as a powerful deoxidizer in steel at ladle treatment facilities.
- was used in carbide lamps, in which water drips on the carbide and the acetylene formed is ignited. These lamps were usable but dangerous in coal mines, where the presence of the flammable gas methane made them a serious hazard. The presence of flammable gases in coal mines led to the miner "safety lamp". However, carbide lamps were used extensively in slate, copper and tin mines, but most have now been replaced by electric lamps. Carbide lamps are still used for mining in some less wealthy countries, such as in the silver mines near Potosi, Bolivia. Carbide lamps are also still used by some in exploring caves and other underground areas, though they are increasingly being replaced in this use by the new LED lamps. They were also used extensively as headlights in early automobiles, motorcycles and bicycles, although in this application they are also obsolete, having been replaced entirely by electric lamps, and in some cases, by LED lamps.
- in the ripening of fruit. Calcium carbide is used as source of acetylene gas, which is a ripening agent.
- in toy cannons where the acetylene is set off by an applied spark to create a loud "boom".
- as floating, self-igniting naval flares for use as signals.

Thermodynamic constants for CaC_2 are:

$$\Delta H_f^\circ = -14.29 \text{ kcal/mol}$$

$$\Delta G_f^\circ = -15.51 \text{ kcal/mol}$$

$$S^\circ = 16.73 \text{ cal/degree mol}$$

$$C_p = 14.99 \text{ cal/degree mol}$$

The standard Gibbs energies of formation of CaC_2 was determined by an equilibration technique at temperatures ranging from 1223 to 1673 K, yielding the following results:

$$\text{Ca (liq)} + 2\text{C (solid)} \Rightarrow CaC_2 \text{ (solid)},$$
$$\Delta G^\circ = -90,100 - 11.0\,T \text{ [J/mol]}$$

Calcium carbides are available commercially in tonnage lots.

Strontium Carbides

Strontium carbide has the molecular formula of SrC_2 and the molecular weight of 111.644 g/mol. It is obtained by heating strontium carbonate with carbon in the electric furnace. It resembles calcium carbide, decomposing rapidly in the presence of water or moisture, producing acetylene. SrC_2 has the CAS number of 12071-29-3. It is a black, tetragonal crystal whose melting point is in excess of 1700 °C. Its density is 3.19 g/cc. A number of polymorphs exist as shown in the following Fig. 5.4.

The a ⇒ c vector plane is shown for these polymorphs. SrC_2 has been used in a metathetical reaction to produce transition elements carbides. These carbides are difficult to produce by any other means. Examples of such reactions are:

$$NaVO_3 + SrC_2 \Rightarrow V_8C_7 \ (a = 4.165 \text{ Å})$$

$$Nb_2O_5 + SrC_2 \Rightarrow Nb_2C_2 \ (a = 4.462 \text{ Å})$$

$$Ta_2O_5 + SrC_2 \Rightarrow Ta_2C_2 \ (a = 4.446 \text{ Å})$$

The standard Gibbs energy of formation of SrC_2 was determined by an equilibration technique at

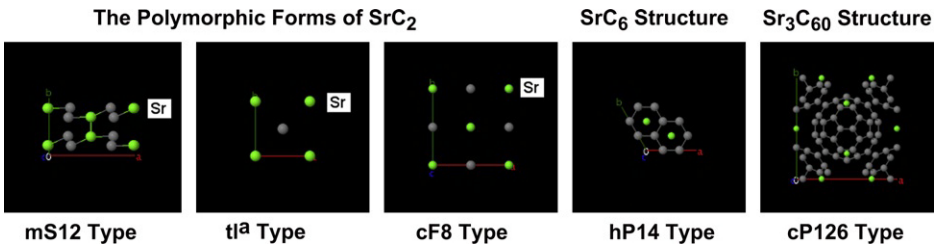

FIGURE 5.4

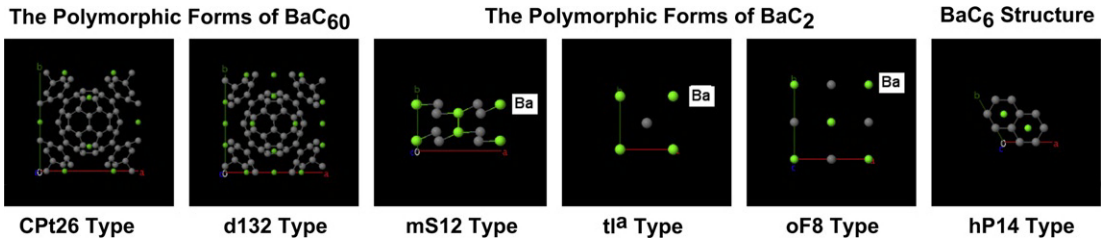

FIGURE 5.5

temperatures ranging from 1223 to 1673 K, yielding the following results:

$$\mathrm{Sr\ (Liq) + 2\,C\ (solid) = SrC_2\ (solid)},$$
$$\Delta G_f^\circ = -104{,}000 - 8.04\,T\ \ [\mathrm{J/mol}]$$

Its CAS number is 12071-29-3. Strontium carbide is available in numerous forms and custom shapes including ingot, rod, plate and sputtering target. High-purity forms also include carbide powder, submicron powder and nanoscale, single crystal or polycrystalline forms. Strontium carbide is generally immediately available in most manufactured volumes.

Barium Carbides

In the system, Ba–C, seven barium carbides are known. These have the following crystal parameters (Table 5.3).

These have the form as shown in Fig. 5.5.

The a ⇒ c plane is shown for these polymorphs that arise due to differences in how they were formed. The difference for BaC_2 is due to stability at a given temperature. The face-centered cubic form is stable above 150 °C while the face-centered tetragonal (rhombohedral) form is stable below 150 °C. BaC_2 has the molecular weight of 161.348 g/mol and the CAS number of 50813-65-5. It is a gray cubic to rhombohedral crystal with a density of 3.74 g/cc. Only two types of barium carbide appears in the phase diagram of Ba–C, that of BaC_2 and BaC_6. The BaC_2 compound melts incongruently at about 1065 °C.

The standard Gibbs energy of formation of BaC_2 was determined by an equilibration technique at temperatures ranging from 1223 to 1673 K, yielding the following results:

$$\mathrm{Ba\ (Liq) + 2C\ (solid) \Rightarrow BaC_2\ (solid)},$$
$$\Delta G_f^\circ = -115{,}000 + 3.53\mathrm{T}\ [\mathrm{J/mol}]$$

TABLE 5.3

Number	Composition	Type	Space group	Point group	SG #
1	Ba_3C_{60}	Ba_3C_{60}	cP126	Pm-3b	223
2	Ba_3C_{60}	Ba_3C_{60}	oL	Immm	71
3	Ba_3C_{60}	Cs_3C_{60}	cL132	Im-3	204
4	BaC_2	ThC_2	mS12	C2/c	15
5	BaC_2	CaC_2	tI6	I4/mmm	139
6	BaC_2	NaCl	cF8	Fm-3m	225
7	BaC_6	BaC_6	hP14	$P6_3/mmc$	194

An intercalated compound of Ba metal and graphite has been reported. Ba metal was evaporated and diffused into well-oriented pyrolytic graphite (PG) and formed the compound, BaC_8. This material was shiny gold in color, brittle and had a hardness about five times that of graphite. Resistivity and thermoelectric power measurements indicated that it is metallic in nature. However, it could not be separated from the bulk graphite in a pure form.

Data concerning the barium carbides are scarce in the scientific literature. Little work concerning potential compounds can be found. The binary phase diagram is not to be found although a ternary phase diagram of Ba–C–The is available.

Barium carbide, BaC_2, is available commercially for sale but not in the quantities that CaC_2 is offered. BaC_6 is offered for sale as CAS #50813-65-5.

Radium Carbide

Radium carbide is not listed in the literature. No published report for the preparation of radium carbides can be found. This is probably due to difficulties in handling the ^{226}Ra radioactivity as well as lack of interest. Because of the closeness of the chemistry of Ba and Ra, and the fact that it is the end-member of the alkaline earth series (Group 2), an acetylide having the formula RaC_2 is expected. Carbides of elements in the radioactive actinide series, The, Pa, U, Nap and Up, are known and have been discussed in the literature. Thus, the absence of data concerning radium carbide compounds is probably due to lack of interest.

5.1.3. Alkaline Earth Carbonates and Bicarbonates

Alkaline earth carbonates are based upon carbonic acid, H_2CO_3 whose properties have been discussed above. Since this acid is dipodic, bicarbonates, i.e. HCO_3^-, are also possible salts.

Beryllium Carbonates

Beryllium carbonate has the molecular formula of $BeCO_3$ and the molecular weight of 69.0211 g/mol. Beryllium carbonates are less stable than those of magnesium and readily form basic salts. This is due to the fact that Be^{2+} preferentially forms hydroxyl-complexes of the type, $Be(OH)^+$ in association with water molecules. Species such as $Be_2(OH)^{3+}$ and $Be_3(OH)_3^{2+}$ are known to exist. The hydroxylation reaction has been given as:

$$xBe^{2+} + yH_2O \Rightarrow Be_x(OH)_y^{(2x-y)+} + hype^+$$

where x and y can vary from 1 to 8. Species such as $Be_3(OH)_7^{3+}$ and $Be_4(OH)_8^{4+}$ are also known. Thus, the prior literature listing of the formulation, $BeCO_3$, may be in doubt concerning exact formulas for beryllium carbonate compounds prepared from aqueous solutions.

The preparation of beryllium carbonate can be accomplished by heating BeO at about 1000 °C in a current of CO_2 gas. The reaction is slow and requires several hours:

$$BeO\ (solid) + CO_2\ (gas) + heat \Rightarrow BeCO_3(solid)$$

There are three forms reported in the literature, an anhydrous, a tetra hydrate and a "basic" beryllium carbonate. The anhydrous form is reported to be unstable, decomposing to BeO and CO_2 in air, and requiring storage under CO_2 for stability. It is not clear whether "basic" refers to the bicarbonate or not. The anhydrous form, $BeCO_3$, is said to have a "melting point" of 54 °C and a "boiling point" of 100 °C where it decomposes to the oxide and carbon dioxide. The enthalpy of formation, ΔH_f^0, is —14.85 kJ/mol and the specific heat capacity, C_p, is 0.9417 J/K. The tetra hydrate is said to be formed when CO_2 is bubbled through a solution of $Be(OH)_2$ and is also reported to be similarly unstable.

Basic beryllium carbonate is a mixed salt that can be prepared by the reaction of beryllium sulfate and ammonium carbonate, and contains both carbonate and hydroxide ions, with a formula said to be $Be_2CO_3(OH)_2$. In the older literature, this is probably what was referred to as beryllium carbonate. However, in view of more recent work, the most likely formula is $(BeOH)_2CO_3$. This is not a basic carbonate but a "hydroxyl-based" beryllium carbonate. This compound is offered for sale as CAS #66104-24-3. $BeCO_3$, formed by dehydration of the hydroxyl-salt, is offered as CAS #1319-43-3.

Soluble beryllium carbonate complexes can be produced by dissolving $BeCO_3$ in ammonium carbonate solutions. This solution has the stoichiometry of $(NH_4)_4Be(CO_3)_2$. This salt can be separated from solution by vacuum evaporation at a low temperature. Hydrolysis of the salt by heating the solution produces:

$$BeCO_3 + (NH_4)_2CO_3\ (aq) \Rightarrow (NH_4)_4Be(CO_3)_2\ (aq) + Evap \Rightarrow (NH_4)_4Be(CO_3)_2\ (solid)$$

$$(NH_4)_4Be(CO_3)_2\ (aq) + heat \Rightarrow (BeOH)_2CO_3\ (solid)$$

Heating this salt at about 400 °C then produces BeO. Note that when the pH of the solution is greater than about pH = 9.5–10, beryllates compounds tend to form. These are based upon the acid, beryllic acid:

$$H_4BeO_4 \Leftrightarrow H^+ + H_3BeO_4^- \Leftrightarrow H^+ + H_2BeO_4^{-2} \Leftrightarrow H^+ + HBeO_4^{-3} \Leftrightarrow H^+ + BeO_4^{-4}$$

The major usage in industry for beryllium carbonate has been as an intermediate in processing beryllium ores to obtain Be metal. This is due to the instability of the various Be carbonates that tend to decompose to

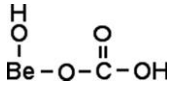

FIGURE 5.6

the oxide when stored in air over long periods of time. Thus, it is the hydroxide which forms by a second hydrolysis of the carbonate while still in solution. The hydroxide is more soluble than the carbonate (basic carbonate = 0.00036 g/100 ml vs hydroxide = 0.029 g/100 ml at 20 °C).

Beryllium carbonate occurs in nature as the mineral, "niveolinite", with the formula, $NaBe(CO_3)(OH)\cdot 2H_2O$. It is tetragonal with $a = 13.087$ Å, $c = 5.404$ Å, $V = 925.54$ Å^3, $Z = 8$, space group = P4/mmc, density = 2.09 g/cc. The crystals are fibrous and snow white or pearl white. They are deliquescent—when removed from their natural habitat, these crystals absorb water from the air and melt or otherwise deteriorate. Its structure includes isolated, infinite chains of $BeO_2(OH)_2$ tetrahedra linked via common OH^- groups; two other vertices of each Be tetrahedron are shared with (CO_3) groups, and Na cations occupy sevenfold polyhedra $[NaO_6(H_2O)]$, forming columns. Chains of Be tetrahedra and columns of Na polyhedra are aligned along the *c*-axis, as broad channels in which H_2O molecules are located. The structural formula is: $\{(Na_{0.9}Ca_{0.1})[(H_2O)_{0.9}(OH)_{0.1}]\}\{Be(OH)\}(CO_3)\cdot 0.1H_2O$. The idealized formula is: $NaBe(CO_3)(OH)\cdot 2H_2O$.

Beryllium bicarbonate, $Be(OH)(HCO_3)$ remains unknown but would have the Lewis structure shown in Fig. 5.6.

This structure is apparently not stable as well.

Beryllium carbonate compounds are not generally available commercially because of their instability in air and moisture.

Magnesium Carbonates

Magnesium carbonate has the molecular formula of $MgCO_3$ and the molecular weight of 84.3145 g/mol. For the most part, Mg^{2+} forms several hydrated and basic carbonates that are stable and occur in nature. The types, names, formulas and CAS numbers of anhydrous, hydrated and basic magnesium carbonates are tabulated as in Table 5.4.

These compounds are also available commercially, and, in many cases, directly extracted from the minerals themselves. The two principal minerals are magnesite, $MgCO_3$ and dolomite, a double salt, $CaCO_3\cdot MgCO_3$. Both minerals are used as source materials in the production of magnesium metal. Also, they are calcined to produce basic refractory bricks for use in furnaces and the like.

There are two main branches of sedimentary petrology. One branch deals with carbonate rocks, namely limestones and dolomites, composed principally of calcium carbonate (calcite) and calcium magnesium carbonate (dolomite). Much of the complexity in classifying carbonate rocks stems partly from the fact that many limestones and dolomites have similar properties. Both are used extensively as a secondary fertilizer to "sweeten acid-soils". Dolomite has been used as a building material for centuries.

In 1701, M. B. Valentine prepared "heavy" magnesium carbonate from mother liquors obtained in the manufacture of potassium nitrate. Magnesia was confused with lime until 1754 when J. Black showed that the two substances were entirely different. Deposits of natural magnesium carbonate were discovered in Moravia in 1803 and were described by C. F. Ludwig as "talcum carbonatum". The term "magnesite" was first restricted to the natural carbonate in 1808 by Dr L. G. Karsten and was generally accepted gradually although the term "globertite" was used in France for some time thereafter.

The most common magnesium carbonate forms available on the open market are the anhydrous salt magnesite ($MgCO_3$) and the di, tri, and pentahydrate minerals known as barringtonite ($MgCO_3\cdot 2H_2O$), nesquehonite ($MgCO_3\cdot 3H_2O$), and lansfordite ($MgCO_3\cdot 5H_2O$),

TABLE 5.4

Compound	Mineral	Formula	CAS No.
Anhydrous salt	Magnesite	$MgCO_3$	[13717-00-5]
Dihydrate	Barringtonite	$MgCO_3\cdot 2H_2O$	[5145-48-2]
Trihydrate	Nesquehonite	$MgCO_3\cdot 3H_2O$	[14457-83-1]
Pentahydrate	Lansfordite	$MgCO_3\cdot 5H_2O$	[61042-72-6]
Basic carbonate	Artinite	$MgCO_3\cdot Mg(OH)_2\cdot 3H_2O$	[12143-96-3]
Basic carbonate	Hydromagnesite	$4MgCO_3\cdot Mg(OH)_2\cdot 4H_2O$	[12072-90-1]
Basic carbonate	Dypingite	$4MgCO_3\cdot Mg(OH)_2\cdot 5H_2O$	[12544-02-4]
Basic carbonate	—	$4MgCO_3\cdot Mg(OH)_2\cdot 8H_2O$	[75300-49-1]

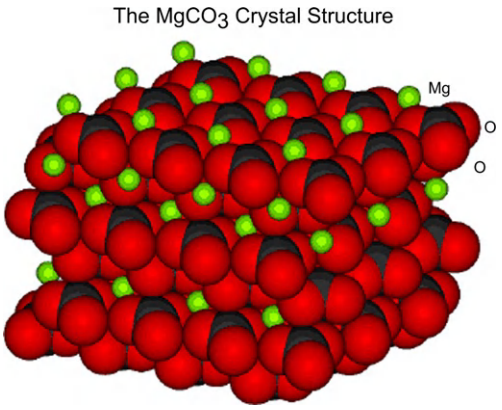

FIGURE 5.7

respectively. All forms of magnesium carbonate react with acids. The calcite structure of magnesium carbonate has the form wherein Mg^{2+} is surrounded by six O^{2-} atoms. The dihydrate composition has a triclinic structure, while the trihydrate has a monoclinic structure. References to "light" and "heavy" magnesium carbonates actually refer to the magnesium hydroxycarbonates. A space-filling structure of the anhydrous salt is seen in the above diagram where the triangular CO_3^{2-} groups are clearly visible (Fig. 5.7).

This anhydrous salt consists of white trigonal crystals with a refractive index of 1.717 and a density 2.958 g/cm^3. It decomposes at 540 °C to form the oxide. It is practically insoluble in water (0.0106 g/100 ml at room temperature) with a K_{sp} of 1.1×10^{-5}. Under partial pressure of CO_2 in water, it has an increased solubility (3.5 and 5.9 g $MgCO_3$/100 g of saturated solution at CO_2 pressures of 2 and 10 atm, respectively). It is insoluble in acetone and ammonia but dissolves in acids.

The di- and trihydrates, $MgCO_3 \cdot 2H_2O$ and $MgCO_3 \cdot 3H_2O$ are colorless crystals having triclinic and monoclinic structures, respectively; the refractive index of 1.458 and 1.412, respectively; and their densities are 2.825 and 1.837 g/cm^3.

The pentahydrate, $MgCO_3 \cdot 5H_2O$, occurring naturally as the mineral "lansfordite", is a white crystalline solid consisting of monoclinic crystals. Its refractive index is 1.456 and has a density of 1.73 g/cc. It is not stable and decomposes in air to the trihydrate. The pentahydrate is slightly soluble in water (0.375 g/100 ml at 20 °C). Its density is 1.73 g/cc. The K_{SP} of magnesium carbonate trihydrate, $MgCO_3 \cdot 3H_2O$, is 2.38×10^{-6} while that of magnesium carbonate pentahydrate, $MgCO_3 \cdot 5H_2O$, is 3.79×10^{-6}.

All three basic carbonates, artinite, hydromagnesite and dypingite, are white crystalline substances having monoclinic crystal structures and refractive indices of 1.488, 1.523 and 1.508, respectively. The index of refraction for the basic carbonate octahydrate is 1.515 while the densities are 2.02 and 2.16 g/cc for artinite and hydromagnesite. These basic carbonates are all practically insoluble in water.

Thermochemical properties

$$\Delta H_f^0\ (MgCO_3) = -261.9\ \text{kcal/mol}$$

$$\Delta G_f^0\ (MgCO_3) = -241.9\ \text{kcal/mol}$$

$$\Delta G_f^0\ (MgCO_3 \cdot 3H_2O) = -412.6\ \text{kcal/mol}$$

$$\Delta G_f^0\ (MgCO_3 \cdot 5H_2O) = -525.7\ \text{kcal/mol}$$

$$S^0\ (MgCO_3) = 15.7\ \text{cal/degree mol}$$

$$C_p\ (MgCO_3) = 18.05\ \text{cal/degree mol}$$

Magnesium carbonate is obtained mainly by mining the natural mineral magnesite. The trihydrate salt, $MgCO_3 \cdot 3H_2O$, is prepared by mixing solutions of magnesium and carbonate ions in the presence of carbon dioxide. Alternatively, it may be produced by carbonation of magnesium hydroxide slurry with carbon dioxide under pressure (3.5 to 5 atm) and at a temperature below 50 °C which yields soluble magnesium bicarbonate:

$$Mg(OH)_2 + 2CO_2 \Rightarrow Mg(HCO_3)_2$$

The solution is filtered to remove impurities and the filtrate is subjected to vacuum or aeration to yield insoluble magnesium carbonate as a hydrated salt:

$$Mg^{2+}\,(aq) + 2HCO_3^-\,(aq) \Rightarrow MgCO_3\,(solid) + CO_2\,(gas) + H_2O$$

Under ordinary conditions, anhydrous magnesium carbonate cannot be prepared in aqueous systems. The anhydrous salt, however, can be made under very high partial pressures of carbon dioxide.

Basic magnesium carbonate occurs in nature as the mineral, "Hydromagnesite". The basic salt is obtained by mining the ore followed by purification. The basic carbonates also can be made by drying the magnesium carbonate trihydrate at about 100 °C. Alternatively, it can be prepared by simply boiling a solution of magnesium bicarbonate. The bicarbonate is obtained by carbonation of a magnesium hydroxide slurry below 50 °C and under a CO_2 partial pressure of 3.5 to 5 atm. Composition of the basic carbonate produced by the above methods is $4MgCO_3 \cdot Mg(OH)_2 \cdot 4H_2O$.

Another basic salt, $MgCO_3 \cdot Mg(OH)_3 \cdot 3H_2O$ is precipitated when magnesium salt solution is treated with sodium carbonate solution. The reactions are:

$$CO_3^{2-} + H_2O \Rightarrow HCO^{3-} + OH^-$$

$$2Mg^{2+} + CO_3^{2-} + 2OH^- \Rightarrow MgCO_3 \cdot Mg(OH)_2$$

When magnesium carbonate dissolves in dilute mineral acids, it evolves carbon dioxide:

$$MgCO_3 + HCl \Rightarrow MgCl_2 + CO_2\,(gas) + H_2O$$

$$MgCO_3 + H_2SO_4 \Rightarrow MgSO_4 + CO_2\,(gas) + H_2O$$

When heated above 360 °C, CO_2 and magnesium oxide are formed:

$$MgCO_3 \Rightarrow MgO + CO_2$$

The trihydrate, $MgCO_3 \cdot 3H_2O$ or other hydrates when heated form basic magnesium carbonates, the product compositions depending on degree of water of crystallization and the temperature employed. At a temperature range between 250 and 800 °C, $MgCO_3$ decomposes with a reaction enthalpy of 118 kJ/mol. Above 540 °C, the process reaches a decomposition rate of 100% MgO.

Magnesium carbonate forms several double salts with salts of alkali and AEMs and ammonium ion. Some examples are:

$$MgCO_3 \cdot Na_2CO_3$$

$$MgCO_3 \cdot K_2CO_3 \cdot 8H_2O$$

$$MgCO_3 \cdot KHCO_3 \cdot 4H_2O \text{ (Engle's salt)}$$

$$MgCO_3 \cdot (NH_4)_2CO_3 \cdot 4H_2O$$

$$MgCO_3 \cdot MgCl_2 \cdot 7H_2O$$

$$MgCO_3 \cdot MgBr_2 \cdot 7H_2O$$

Ammonium magnesium carbonate tetrahydrate, $MgCO_3 \cdot (NH_4)_2CO_3 \cdot 4H_2O$, crystallizes with an orthorhombic unit cell, $a = 7.697$, $b = 10.287$, $c = 6.639$ Å, $Z = 2$; $D_x = 1.595$, $D_M = 1.61$ mg/m^3.

Some applications of magnesium carbonate are uses in flooring, fireproofing and fire-extinguishing compositions; as a filler material and smoke suppressant in plastics; as a reinforcing agent in neoprene rubber; as a drying agent and for color retention in foods; in cosmetics. Magnesium carbonate is used as an antacid in medicine and as an additive to table salt. Another important application of magnesium carbonate is as a starting material in producing a number of magnesium compounds.

Because of its water-insoluble, hygroscopic properties, $MgCO_3$ was first added to salt in 1911 to make the salt flow more freely. Magnesium carbonate, most often referred to as "chalk", is used as a drying agent for hands in gymnastics, weight lifting and rock climbing. Magnesium carbonate is also used in taxidermy for whitening skulls. It can be mixed with hydrogen peroxide to create a paste, which is then spread on the skull to give it a white finish. Basic magnesium carbonate is used as a clay in face masks and it has mild astringent properties and helps to smooth and soften skin. It is recommended for use on normal to dry skins.

Magnesium carbonate is readily available commercially from a large number of suppliers worldwide.

Calcium Carbonate

Calcium carbonate has the molecular formula of $CaCO_3$ and the molecular weight of 100.0924 g/mol. It is a common substance found in rock in all parts of the world, and is the main component of the shells of many marine organisms such as snails and conches. It is the main ingredient in eggshells of birds and pearls obtained from oysters. Calcium carbonate is the active ingredient in "limestone" used as "agricultural lime" and is the principal cause of "hard water" since most subterranean streams used for fresh water come from wells where underground water flows through limestone beds which are eroded due to its passage.

Calcium carbonate occurs in nature as limestone in various forms, such as marble, chalk, and coral. It is probably the most widely used raw material in the chemical industry. It has numerous applications, primarily to produce cement, mortars, plasters, refractories, and glass as building materials. It is also used to produce quicklime, hydrated lime and a number of calcium compounds. Calcium carbonate is found naturally as the following polymorphs:

Aragonite
Calcite
Vaterite (μ-$CaCO_3$).

The trigonal crystal structure of calcite is the most common mineral. A transparent variety of calcite called "Iceland Spar" exhibits a "double refraction" wherein light is broken into two parts as it passes through the crystal. This double-refraction occurrence is one of the strongest of all minerals. The difference in refractive index of the ordinary part ($\eta_0 = 1.658$) and that of the extraordinary part ($\eta_0 = 1.4860$) is 0.172 (Fig. 5.8).

Few minerals can be found which approach this distinction.

In addition, this type of calcite crystal polarizes the light rays vertically as they pass through. This phenomenon was exploited in 1828 by the Englishman, William Nicol, who bisected an Iceland double-spar crystal, realigned them and cemented the two parts together with Canada balsam. He thus obtained a simple polarization

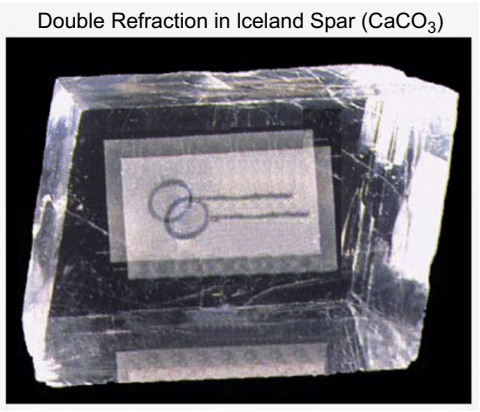

FIGURE 5.8

optical filter that we call today a "Nicol Prism". Large transparent calcite crystals can also be used for this purpose.

The following rocks are composed primarily of $CaCO_3$:

Calcite
Chalk
Limestone
Carbonatite
Marble
Tufa
Travertine.

These minerals have been mined extensively over the eons and used by man.

Calcite, which gets its name from "*chalix*" the Greek word for lime, is a most amazing and yet, most common mineral. The structure of cubic calcite is shown in the following Fig. 5.9.

It is one of the most common minerals on the face of the earth, comprising about 4% by weight of the earth's crust and is formed in many different geological environments. Calcite can form rocks of considerable mass and constitutes a significant part of all three major rock classification types. It forms oolitic, fossiliferous and massive limestones in sedimentary environments and even serves as the internal cement for many sandstones and shales. Calcite is even a major component in the igneous rock called carbonatite and forms the major portion of many hydrothermal veins. Not necessarily a variety of calcite, cave formations are certainly a unique aspect of calcite's story. Calcite is the primary mineral component in cave formations. Stalactites and stalagmites, cave veils, cave pearls, "soda straws" and the many other different cave formations that millions of visitors to underground caverns enjoy are made of calcite. It is the fact that calcite is readily dissolved or worn away by water that these formations occur. Overlying limestones or marbles are dissolved away by years and years of slightly acidic ground water that percolates into the caverns below. In fact, the caverns themselves may have been the result of water dissolving away the calcite-rich rock. As the calcite-enriched water enters a relatively dry cavern, the water starts to evaporate and thus reprecipitate as the calcite. The resulting accumulations of calcite are generally extremely pure and are colored, if at all, by very small amounts of iron or other impurities. Mexican onyx is a variety of calcite that is used extensively for ornamental purposes. It is easily carved into figurines and is so popular that almost every child in the USA owns a small onyx animal or two. Carvings such as vases, bookends, plates, eggs, obelisks, pyramids and statues are all popular. It is not the same onyx as the quartz variety of onyx which is a little more precious (it is used in jewelry) and is banded white and black. To avoid confusion, it is best to refer to it as *Mexican* onyx. Mexican onyx is banded with multiple orange, yellow, red, tan, brown and white colors that have marble-like texture. The carvings are quite attractive and affordable; a rare combination!

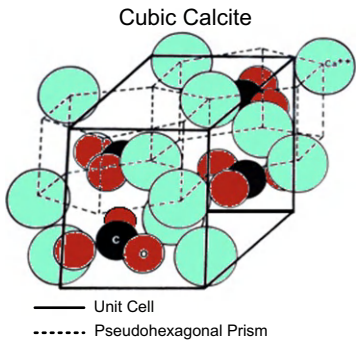

FIGURE 5.9

Chalk is a sedimentary rock of biochemical origin. It is soft, white and porous.

It formed in the deep ocean far from land via the gradual accumulation of the calcite shells of coccolithophores. Layers of chalk are known that are hundreds of feet thick, indicating extremely long periods of accumulation. This mineral of $CaCO_3$, is similar in composition to limestone, but softer. It is characteristically a marine formation and sometimes occurs in great thickness; the chief constituents of these chalk deposits are the shells of minute animals called "Foraminiferans". Chalk has been laid down in all periods of geologic time, but most of the best-known deposits, e.g. the cliffs of the English channel (known as "The Cliffs of Dover") date from the Cretaceous period of geological time. Chalk is used directly in the manufacture of putty, plaster, cement, quicklime, mortar, and also for blackboard chalk. Harder forms are used as building stones. Poor soils containing an excessive proportion of clay are frequently improved and "sweetened" by mixing chalk into them. Extensive deposits occur in Western Europe south of Sweden and in England, notably in the chalk cliffs of Dover along the English Channel. Other extensive deposits occur in the U.S. from South Dakota to Texas and eastward to Alabama. Chalk is used for making lime and Portland cement and as a soil additive. Finely ground and purified chalk is known as whiting and is used as a filler, extender, or pigment in a wide variety of materials, including ceramics, putty, cosmetics, crayons, plastics, rubber, paper, paints, and linoleum.

Limestone is a very common sedimentary rock of biochemical origin. It is composed mostly of the mineral calcite. Sometimes it is almost pure calcite, but most limestones are filled with lots of other minerals and sand and as such are called dirty limestones. The calcite

present is derived mostly from the remains of organisms such as clams, brachiopods, bryozoa, crinoids and corals. These animals live on the bottom of the sea and when they die their shells accumulate into piles of shelly debris. This debris can then form beds of limestone. Some limestones may have been derived from nonbiogenic calcite formation. Although some limestones can be nearly pure calcite, there is often a large amount or sand or silt that is included in the shelly debris. Limestones are important rocks. They can be used for building materials but are not quite as strong as sandstone and are easily weathered by acidic conditions. Limestones are the primary source of lime for cements. Cement is considered one of the most important construction materials ever invented by man. Limestone can be crushed and used as road ballast. Significant quantities of limestone are quarried around the world for these purposes. Limestone is usually the type of rock that gives us caves. Most caves are the result of dissolution of calcite by acidic waters. Ground water can dissolve portions of massive limestone formations and yield extremely large caverns. Large caves and numerous sinkholes are often found in areas that have significant limestone formations.

Carbonatite is an igneous rock that may be either intrusive or extrusive and is composed of at least 20% carbonate minerals. The rock known as "Natrocarbonatite" primarily consists of two carbonate minerals, nyerereite and gregoryite. Carbonatites are defined by mineralogic composition consisting of greater than 50% carbonate minerals. Carbonatites may be confused with marble, and may require geochemical verification. Carbonatites usually occur as small plugs within zoned alkali-like intrusive complexes, or as dikes, sills, breccias and veins. They are, almost exclusively, associated with continental rift-related tectonic settings. The majority of carbonatites are Proterozoic or Phanerozoic in age. It seems that there has been a steady increase in the carbonatitic igneous activity throughout the Earth's history, from Archean to present. Nearly, all carbonatite occurrences are intrusives or subvolcanic intrusives. This occurs because carbonatite lava flows are unstable and react quickly in the atmosphere. Carbonatite lavas may be more common than has been thought, but have been poorly preserved through weathering throughout the Earth's history.

Marble is a rock resulting from the metamorphism of sedimentary rocks such as limestone or dolemite rocks. Metamorphism causes variable recrystallization of the original carbonate mineral grains. The resulting marble rock is typically composed of an interlocking mosaic of carbonate crystals. Primary sedimentary textures and structures of the original carbonate rock (protolith) have typically been modified or destroyed. Pure white marble is the result of metamorphism of a very pure (silicate-poor) limestone or dolomite protolith. The characteristic swirls and veins of many colored marble varieties are usually due to various mineral impurities such as clay, silt, sand, iron oxides, or chert which were originally present as grains or layers in the limestone. Green coloration is often due to serpentine resulting from initial contamination of high magnesium limestone or "dolostone" with silica impurities. These various impurities may have been mobilized and recrystallized by the intense pressure and heat of the metamorphism mechanism. White marble has been valued for its use in creating sculptures since classical times. This preference has to do with the softness and relative isotropy and homogeneity, and a relative resistance to shattering of marble. Also, the low index of refraction of modified calcite within marble allows light to penetrate several millimeters into the stone before being scattered out, resulting in the characteristic "waxy" look which gives "life" to marble sculptures of the human body. The word "marble" derives from the Greek mármaron (mármaros), "crystalline rock", "shining stone", perhaps from the verb (marmaír), "to flash, sparkle, gleam". This linguistic stem is also the basis for the English word *marmoreal*, meaning "marble-like." Colorless or light-colored marbles are a very pure source of calcium carbonate, which is used in a wide variety of industries. Finely ground marble or calcium carbonate powder is a component in paper, and in consumer products such as toothpaste, plastics and paints. Ground calcium carbonate can be made from limestone, chalk, and marble; about three-quarters of the ground calcium carbonate worldwide is made from marble. Ground calcium carbonate is used as a coating pigment for paper because of its high brightness and as a paper filler because it strengthens the sheet and imparts high brightness. Ground calcium carbonate is used in consumer products such as a food additive, in toothpaste, and as an inert filler in pills. It is used in plastics because it imparts stiffness, impact strength, dimensional stability, and thermal conductivity. It is used in paints because it is a good filler and extender, has high brightness, and is weather resistant. However, the growth in demand for ground calcium carbonate in the last decade has mostly been for a coating pigment in paper. U.S. dimension marble production in 2006 was 46,400 tons valued at $18.1 million, compared to 72,300 tons valued at $18.9 million in 2005. Crushed marble production (for aggregate and industrial uses) in 2006 was 11.8 million tons valued at $116 million, of which 6.5 million tons was finely ground marble. As the favorite medium for Greek and Roman sculptors and architects, marble has become a cultural symbol of tradition and refined taste. Its extremely varied and colorful patterns make it a favorite decorative material. Sculptures of marble

FIGURE 5.10

are shown below that are typical of the type of detail that can be obtained with marble forms.

Pure white marble is the result of metamorphism of a very pure (silicate-poor) limestone or dolomite protolith. The characteristic swirls and veins of many colored marble varieties are usually due to various mineral impurities which were originally present as grains or layers in the limestone (Fig. 5.10).

Tufa is a variety of limestone, which is formed by carbonate mineral precipitation from ambient temperature water bodies. One example is from geothermally heated hot springs where such mechanisms sometimes produce similar (but less porous) carbonate deposits known as **travertine**. Tufa is sometimes referred to as (meteogene) travertine. Care must be taken when searching through literature to prevent confusion with hot spring (thermogene) travertine. Calcareous tufa should not be confused with Tuff, a porous volcanic rock with similar etymological origins. Modern and fossil tufa deposits abound in areas with wetland plants. As such many tufa deposits are characterized by their large macrobiological components and are highly porous. Tufa forms either in fluvial channels or in lacustrine settings. Tufa columns are an unusual form of tufa typically associated with saline lakes. It is generally thought that such features form from $CaCO_3$ precipitated when carbonate-rich source waters emerge into alkaline soda lakes. They have also been found in marine settings.

Calcium carbonate is produced commercially either as powdered or precipitated calcium carbonate. The latter consists of finer particles of greater purity and more uniform size. They also have many important commercial applications. Various grades of precipitated calcium carbonate are used in several products, such as textiles, papers, paints, plastics, adhesives, sealants, and cosmetics. The industrial equipment used to make pure $CaCO_3$ is shown in Fig. 5.11.

This diagram shows an array of equipment that has been used commercially for preparing salts such as calcium carbonate. The aim is to produce very high-purity $CaCO_3$ using ordinary purity commercial-grade $CaCl_2$ and ammonium carbonate. Both are dissolved and additives such as sodium sulfide and/or heavy-metal complexing agents like ammonium dithiocarbamate and the like are added to remove heavy metals so as to obtain pure $CaCO_3$ containing only a few parts per million of impurities. The crystal sizes required for various commercial applications can be controlled by regulation of temperature, pH, concentrations, and mixing rate.

Calcium carbonate may also be produced by mixing solutions of calcium chloride and sodium carbonate. In some cases, the presence of sodium is objectionable so that the ammonium carbonate salt is preferable.

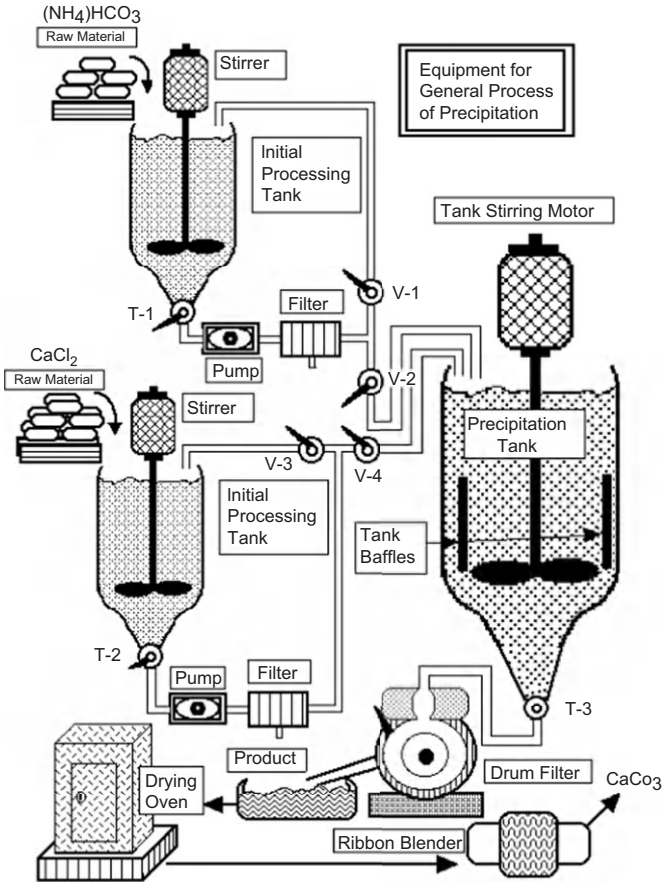

FIGURE 5.11

Calcium carbonate occurs in two main forms—the hexagonal crystal known as calcite, and the orthorhombic form, aragonite. Calcite decomposes on heating at 825 °C, aragonite melts at 1339 °C (at 102.5 atm. pressure). A comparison of the two structures is seen in the following diagram shown below (Fig. 5.12).

Densities are:

2.71 g/cc (calcite)
2.83 g/cc (aragonite).

Both are insoluble in water (0.0015 g/100 ml at 25 °C); $K_{sp} = 4.8 \times 10^{-9}$. Both forms are soluble in dilute mineral acids. It has already been found that calcium carbonate exists in one stable form, β-$CaCO_3$ (calcite), and two less stable forms, λ-$CaCO_3$ (aragonite) and μ-$CaCO_3$ (or vaterite), in the ordinary temperature range. Aragonite is formed if precipitation is carried out at a temperature approaching the boiling point of water (higher than 85 °C), whereas when precipitation is carried out at room temperature only calcite results. The third form of calcium carbonate, μ-$CaCO_3$, is formed by precipitation at 60 °C.

Thermochemical properties

$$\Delta H_f^\circ = -288.6 \text{ kcal/mol}$$
$$\Delta G_f^\circ = -269.9 \text{ kcal/mol}$$
$$S^\circ = 21.92 \text{ cal/degree mol}$$
$$C_p = 19.9 \text{ cal/degree mol}$$

Calcium carbonate is obtained from natural limestone deposits. The purified compound, known as precipitated calcium carbonate, is synthesized from limestone. Limestone is calcined to calcium oxide and carbon dioxide in a kiln. The products are recombined after purification. Calcium oxide is hydrated with water to give a slurry called milk of lime, which is then carbonated by bubbling CO_2 through it. The reactions involved in the process are as follows:

$$CaCO_3 + \text{heat} \Rightarrow CaO + CO_2$$

$$CaO + H_2O \Rightarrow Ca(OH)_2$$

$$Ca(OH)_2 + CO_2 \Rightarrow CaCO_3 + H_2O$$

Calcium carbonate is used to produce other calcium compounds. Treatment with dilute mineral acids produces corresponding calcium salts with liberation of CO_2 gas:

$$CaCO_3 \text{ (solid)} + 2HCl \text{ (aq)} \Rightarrow CaCl_2 \text{ (aq)} + H_2O + CO_2 \text{ (gas)}$$

$$CaCO_3 \text{ (solid)} + 2H_2SO_4 \text{ (aq)} \Rightarrow CaSO_4 \text{ (aq)} + H_2O + CO_2 \text{ (gas)}$$

$$CaCO_3 \text{ (solid)} + 2HNO_3 \text{ (aq)} \Rightarrow Ca(NO_3)_2 \text{ (aq)} + H_2O + CO_2 \text{ (gas)}$$

In the presence of CO_2, it dissolves in water with the formation of bicarbonate:

$$CaCO_3 \text{ (solid)} + H_2O + CO_2 \text{ (gas)} \Rightarrow Ca^{2+} + 2HCO_3^-$$

Limestone has been used by man since ancient times. Calcination of limestone using charcoal fires to produce "quicklime" or CaO has been practiced since antiquity by cultures all over the world. The quicklime is generally slaked to form what is called "whitewash" or $Ca(OH)_2$ as a slurry in water (see alkaline earth hydroxides presented above). Some of the earliest known examples of lime use for building purposes are in early Egyptian buildings (primarily monuments). Some of these examples in the chambers of the pyramids, which date back to around 2000 BC, are still hard and intact.

Calcium bicarbonate ($Ca(HCO_3)_2$), also known as calcium hydrogen carbonate, does not refer to a known solid compound. It exists only in aqueous solution containing the ions calcium (Ca^{2+}), dissolved carbon dioxide (CO_2), bicarbonate (HCO_3^-), and carbonate (CO_3^{2-}). It cannot be separated from solution in a stable form. The relative concentrations of these carbon-containing species depend on the pH. Bicarbonate anions predominate within the range 6.36–10.25 in fresh water. Attempts to prepare compounds such as calcium bicarbonate by evaporating its solution to dryness invariably yield the solid carbonate instead:

$$Ca(HCO_3)_2 \text{ (aq)} \Rightarrow CO_2 \text{ (gas)} + H_2O \text{ (Liq)} + CaCO_3 \text{ (solid)}$$

Very few solid bicarbonates other than those of the alkalis and ammonium ions are known to exist. This is due to the fact that bicarbonate is stable at basic pH values in solution. Calcium bicarbonate is moderately soluble in water with the following values:

16.1 g/100 ml (0 °C)
16.6 g/100 ml (20 °C)
18.4 g/100 ml (100 °C)

Calcium carbonate has the CAS number of 471-34-1. It is available commercially all over the world in large quantities.

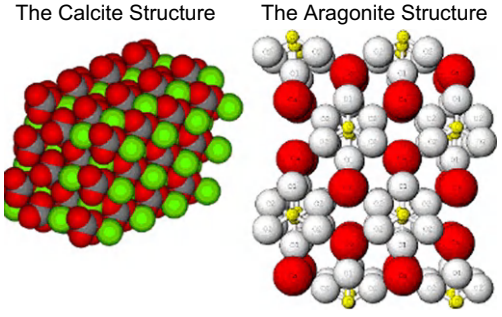

FIGURE 5.12

Strontium Carbonate

Strontium carbonate has the formula of $SrCO_3$ and the molecular weight of 147.6326 g/mol. Its CAS

number is 1633-05-2. Strontium carbonate occurs in nature as the mineral "strontianite". The name strontianite comes from a famous location for the mineral, Strontian, Scotland. Strontianite is strontium carbonate as found naturally. Significant deposits are found in Germany, Scotland and the US at Strontium Hills, California. It occurs as white or slightly gray orthorhombic crystals with a refractive index of 1.518. The unit-cell parameters are: $a = 5.107$ Å, $b = 8.414$ Å, $c = 6.029$ Å, $Z = 4$; $V = 259.07$ Å^3, Den(Calc) = 3.78. The crystal system is orthorhombic with space group Pmcn and point group 2/m, 2/m, 2/m. Strontium carbonate has only one stable form (aragonite-type structure) and temperature of precipitation has no effect on crystal form, unlike that of calcium or magnesium carbonates. However, it undergoes transitions as it is heated, before it decomposes at 1290 °C. Thermal decomposition studies (TG, DTG and DTA) in air showed $SrCO_3$ was formed at ca. 500 °C through the formation of transient intermediate of a mixture of $SrCO_3$ and SrC_2O_4 around 455 °C. A sharp phase transition from γ-$SrCO_3$ to β-$SrCO_3$ was indicated by a distinct endothermic peak at 900 °C in DTA.

The aragonite structure is shown in the following Fig. 5.13.

Aragonite, in contrast to calcite, has strontium ions coordinated by nine oxygen atoms and each oxygen is bonded to three strontium atoms. Aragonite has a more compact atomic arrangement than calcite and is the stable phase at high pressures and low temperatures.

$SrCO_3$ is slightly hygroscopic with a hardness of 3.5 Mohs and a density of 3.5 g/cc. It is almost insoluble in water (0.0011 g/100 ml at 18 °C) but soluble in dilute acids with liberation of carbon dioxide. It is stable in air but when heated decomposes at 1290 °C.

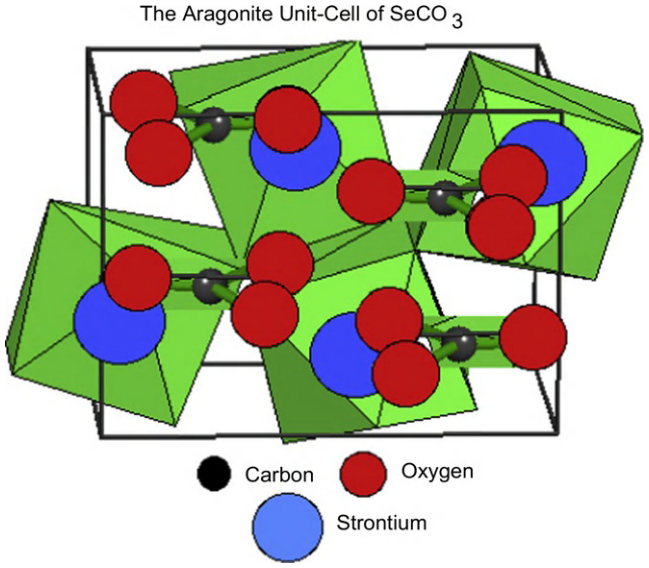

FIGURE 5.13

Thermochemical properties

$$\Delta H_f^0 = -291.6 \text{ kcal/mol}$$
$$\Delta G_f^0 = -272.5 \text{ kcal/mol}$$
$$S^0 = 23.2 \text{ cal/deg mol}$$
$$C_p = 19.5 \text{ cal/deg mol}$$

The solubility is increased if $SrCO_3$ is suspended in water and CO_2 gas is introduced. Such measurements of the solubility of strontianite were used to evaluate the equilibrium constant for the reaction:

$$SrCO_3 \text{ (solid)} \Rightarrow Sr^{2+} \text{ (aq)} + CO_2^{3-} \text{ (aq)}$$

between 2 and 91 °C. The temperature dependence of the equilibrium constant is given by the expression: $\log K = 155.0305 - 7239.594/T - 56.58638 \log T$ where T is in degrees Kelvin. The log K of strontianite, the Gibbs energy, and enthalpy of the reaction at 25 °C are:

$$\log K = -9.271 \pm 0.020,\ 52.919 \pm 0.08 \text{ kJ/mol}$$
$$\Delta G_f^0 = -1.67 \pm 1.30 \text{ kJ/mol}$$
$$\Delta H_f^0 = -183.1 \pm 4.0 \text{J/mol/K}$$

The equilibrium constants are consistent with an aqueous model that includes the ion pairs $SrHCO_3^+$ (aq) and $SrCO_3^0$ (aq) which were evaluated by potentiometric methods between 5 and 80 °C. The equilibrium constant for the association reaction:

$$Sr^{2+} \text{ (aq)} + HCO_3^- \text{ (aq)} \Rightarrow SrHCO_3^+ \text{ (aq)}$$

is given by the expression: $\log K\ (SrHCO_3^+) = -3.248 + 0.014867\ T$. The log of the association constant, the Gibbs energy, enthalpy and entropy of the reaction at 25 °C are:

$$\log K = 1.18$$
$$\Delta G_f^0 = -6.76 \text{ kJ/mol}$$
$$\Delta H_f^0 = 25.30 \text{ J/mol}$$
$$C_p = 107.5 \text{ J/mol/K}$$

The equilibrium constant for the association reaction:

$$Sr^{2+} \text{ (aq)} + CO_3^{-2} \text{ (aq)} \Rightarrow SrCO_3^0 \text{ (aq)}$$

is given by the expression: $\log K\ (SrCO_3^0) = -1.019 + 0.012826\ T$. The log of the association constant, the Gibbs energy, enthalpy, and entropy of the reaction at 25 °C are:

$$\log K = 2.81$$
$$\Delta G_f^0 = -16.01 \text{ kJ/mol}$$
$$\Delta H^0 = 21.83 \text{ J/mol}$$
$$C_p = 126.9 \text{ J/mol/K}$$

These results lead to reliable calculation of the aqueous speciation and solubility of strontianite in the system $SrCO_3$–CO_2–H_2O from 0 °C to more than 90 °C.

Strontium carbonate occurs in nature as strontianite and can be mined from its deposit. It is, however, usually made commercially from the mineral "celestite". Celestite is fused with sodium carbonate at elevated temperatures or boiled with a solution of ammonium carbonate:

$$SrSO_4\,(aq) + Na_2CO_3\,(aq) \Rightarrow SrCO_3\,(solid) + Na_2SO_4\,(aq)$$

$$SrSO_4\,(aq) + (NH_4)_2CO_3\,(aq) \Rightarrow SrCO_3\,(solid) + 2NH_3\,(gas) + CO_2\,(gas) + H_2O$$

Strontium carbonate is insoluble in water. It precipitates from the product mixture in the second reaction. If fused with sodium carbonate, the product mixture is leached with water. Insoluble carbonate separates from the water-soluble sodium sulfate.

Crystal structures of the so-called "triple carbonates" of Ba, Sr and Ca were studied where co-precipitated powders were studied by the X-ray powder method, using an X-ray Geiger counter spectrometer. There exist three kinds of solid solutions: aragonite type crystal (l-carbonate), calcite type crystal (β-carbonate) and vaterite type crystal (μ-carbonate); in the $BaCO_3$–$SrCO_3$–$CaCO_3$ system. The phase domains of these three crystal forms are affected somewhat by the temperature at which the precipitation is carried out. The triple diagrams are obtained at two stages of precipitation temperatures.

The compound, $SrCO_3$, is used in pyrotechnics and ceramic ferrites. It is also used in making iridescent glass for color television tubes. Other uses are in refining sugar and preparing other strontium salts. The most common use is as an inexpensive fireworks colorant. Strontium and its salts emit a brilliant red color in flame. Unlike other strontium salts, the carbonate salt is generally preferred because of its cost and the fact that it is not hygroscopic. Its ability to neutralize acid is also very helpful in pyrotechnics. Another similar application is in road flares. Strontium carbonate is used for electronic applications. It is used for manufacturing glass color-television tubes to absorb X-rays resulting from the bombardment of the cathode rays on the glass enclosure of the cathode-ray gun. With the advent of PDP and LCD panels as TV displays, this application is not so important anymore. $SrCO_3$ is used in the preparation of iridescent glass, luminous paints such as $SrS{:}Ce^{3+}$, strontium oxide or strontium salts and in refining sugar. It is widely used in the ceramics industry as an ingredient in glazes. It acts as a flux and also modifies the color of certain metallic oxides. It is also used in the manufacturing of strontium ferrites for permanent magnets that are used in loudspeakers and door-magnets. Strontium carbonate can be used to produce many different strontium compounds by simply dissolving it in the corresponding acid.

Strontium bicarbonate has not been isolated. It exists only in aqueous solution containing the ions strontium (Sr^{2+}), dissolved carbon dioxide (CO_2), bicarbonate (HCO_3^-), and carbonate (CO_3^{2-}). It cannot be separated from solution in a stable form. The relative concentrations of these carbon-containing species depend on the pH. Bicarbonate anions predominate within the range 6.36–10.25 in fresh water. Attempts to prepare compounds such as strontium bicarbonate by evaporating its solution to dryness invariably yield the solid carbonate instead. Ammonium or sodium bicarbonates can be used to prepare $Sr(HCO_3)_2$ as a solid only if the pH is >9.5.

Strontium carbonate is readily commercially available worldwide.

Barium Carbonate

Barium carbonate has the molecular formula of $BaCO_3$ and the molecular weight of 197.3359 g/mol. Its CAS number is 513-77-9. Barium carbonate has only one stable form (aragonite-type structure) and temperature of precipitation has no effect on crystal form, unlike that of calcium or magnesium carbonates. Barium carbonate is made commercially from barium sulfide either by treatment with sodium carbonate or ammonium carbonate at 60 to 70 °C or by passing CO_2 gas through a soluble Ba^{2+} solution at 40 to 90 °C:

$$BaS + Na_2CO_3 \Rightarrow BaCO_3\,(solid) + Na_2S$$

$$BaS\,(aq) + CO_2\,(gas) + H_2O \Rightarrow BaCO_3\,(solid) + 2H_2S$$

In the soda ash process, solid or dissolved sodium carbonate is added to barium sulfide solution, and the barium carbonate precipitate is filtered, washed to remove sodium nitrate, and dried. A barium sulfide solution is reacted with sodium carbonate in a suitable vessel in which barium carbonate is precipitated. The precipitate is then separated from the sodium sulfide solution except that greater difficulty is qualified in washing the precipitate free of the sodium salt. For the process to be economical, it is also necessary to work up the by-product, sodium sulfide, into a salable product. It is frequently sold as crystals containing 30% sodium sulfide or as a fused, broken mass. The Na_2S solution can be treated with nitric acid to oxidize the H_2S released to sulfur:

$$Na_2S\,(aq) + HNO_3\,(aq) \Rightarrow NaNO_3\,(aq) + S\,(solid)$$

A precipitated barium carbonate can be made from a barium sulfide solution, by precipitation with carbon

dioxide or with soda ash. The barium sulfide is made on the same premises by the high-temperature reduction of barites, $BaSO_4$ with coke in rotary kilns. The product commonly known as black ash is lixiviated or leached with water to form an impure barium sulfide solution. The solution may be evaporated to yield a crude technical grade product in the form of a brownish to grayish product and contains 80% to 90% barium sulfide.

Either the solution from the black ash leaching or the redissolved solid barium carbonate is then treated with carbon dioxide, often from the black-ash kiln, by bubbling the gas through the barium sulfide solution in a suitable vessel. The resulting slurry of barium carbonate is sent to a filter, where it is separated from the mother liquor and washed free of soluble salts. Then it is dried and ground to the required size. The mother liquor may be used as makeup in the next batch. In this process, only one-half of the barium is converted to barium carbonate. If desired, the reaction may be carried further by application of either of the reactions. In both cases, a higher conversion of barium ion to barium carbonate is effected, but a by-product disposal problem arises.

A similar process has been proposed to treat "mine-tailings". Mining is a significant contributor to water pollution. Effluents need to be treated to remove sulfate to less than 200 mg/l and for metal removal. The use of barium carbonate as a process can meet these requirements. A study was conducted to demonstrate the performance of an integrated barium carbonate process, consisting of the following stages:

(a) Sulfate precipitation as $BaSO_4$ by treatment of sulfate-rich water with $BaCO_3$.
(b) Thermal reduction of $BaSO_4$ to BaS.
(c) Conversion of BaS to $BaCO_3$ and H_2S by passing CO_2 through a solution of BaS.
(d) The stripped H_2S is converted to elemental sulfur.

A major constituent of mine tailings is pyrites. When pyrites (FeS_2) is exposed to air, it is oxidized by a biologically catalyzed reaction mediated by bacteria *Thiobacillus ferrooxidans*. The primary pollutants of acid mine drainage are the hydrogen ion (acidity), iron, sulfate, manganese, magnesium and sometimes aluminum. Sulfate needs to be removed from effluents to prevent or reduce salination of surface water, gypsum scaling, biocorrosion and acid corrosion. The proposed equipment consisted of a series of tanks in which the acidic mine tailings are treated in stages to reduce soluble sulfate from sulfide ores, using CO_2 derived from limestone, and barium carbonate to form $BaSO_4$ and then BaS and finally sulfur.

Barium carbonate is a white powder with an orthorhombic crystal structure. Its density is 4.286 g/cc and has a refractive index of 1.603. Its hardness is 3.50 Mohs. It is almost insoluble in water (0.00141 g/100 ml at 25 °C) and its K_{sp} is 2.04×10^{-9}. Its melts at 811 °C with subsequent decomposition to the oxide plus CO_2.

Barium carbonate decomposes to barium oxide and carbon dioxide when heated at 1300 °C. In the presence of carbon, decomposition occurs at lower temperatures. Barium carbonate dissolves in dilute HCl and HNO_3 liberating CO_2. A similar reaction occurs in acetic acid. The solid salts, chloride, nitrate and acetate that are water soluble may be obtained by evaporation of the solution. Dissolution in HF, followed by evaporation to dryness, and then heating to red heat, yields barium fluoride.

Barium carbonate forms barium iodide on treatment with ferrous iodide solution:

$$BaCO_3 + FeI_2 \Rightarrow BaI_2 + FeCO_3$$

Barium carbonate produces barium potassium chromate, a pale yellow pigment, known as pigment E, when heated with potassium dichromate. Calcination at 1300 °C with titanium dioxide yields barium metatitanate, $BaTiO_3$:

$$BaCO_3 + TiO_2 \Rightarrow BaTiO_3 + CO_2$$

Barium carbonate is found in nature as the mineral "witherite". The mineral is named after William Withering, who in 1784 recognized it to be chemically distinct from "barites". It occurs in lead-ore veins in Northumberland, England and in Lancaster, England and a few other localities there. It was also reported in Tsumeb, Namibia. There is only one region in North America that is a good producer of this mineral. That is the area of the Fluorite mines in Hardin Co., Illinois. Small deposits also exist in El Portal, Mariposa Co., California, Castle Dome District, Yuma Co., Arizona, and in Canada at Thunder Bay, Ontario.

Natural witherite ($Ba_{0.99}Sr_{0.01}CO_3$) has been studied by single-crystal XRD in a diamond anvil cell at eight pressures up to 8 GPa. At ambient pressure, cell dimensions are $a = 5.3164$ Å, $b = 8.8921$ Å, $c = 6.4279$ Å. The structure was refined to space group Pmcn with $R(F) = 0.020$ from 2972 line-intensity data. The unit-cell and atom position parameters for the orthorhombic cell were refined at pressures of 1.2, 2.0, 2.9, 3.9, 4.6, 5.5, 6.2, and 7.0 GPa. At approximately 7.2 GPa, a first-order transformation to space group $P\bar{3}/c$ was observed. Cell dimensions of the high-pressure phase at 7.2 GPa are $a_1 = 5.258$ Å, $c_1 = 5.64$ Å. The high-pressure structure was determined and refined to $R(F) = -0.06$ using 83 intensity data, of which 15 were unique. This high-pressure phase appears to be more compressible than the orthorhombic phase with an estimated initial bulk modulus ($K = 7.2$ GPa) of 10 GPa.

Barium carbonate has many major commercial applications in brick, glass, ceramics, oil-drilling, photographic and chemical industries. It is mixed with wet clay to immobilize many water-soluble salts in making uniform red bricks. In the glass industry, barium is added to glass as barium carbonate or barium oxide to improve the refractive index of optical glass and also to promote sintering and lower the viscosity of melted glass to make glass bead formation easy. It is used in the manufacture of television picture tubes and photographic paper. Another important application involves its use as a fluxing ingredient in ceramic industry for enamels, glazes and ceramic bodies. Barium carbonate is used in oil well drilling to insolubilize gypsum and inhibit coagulation; in ferrous metallurgy for steel carburizing; in chlor-alkali cells for treating salt brines to remove sulfates; and to make ferrites, and barium titanate. Many barium salts are prepared from barium carbonate.

The so-called "triple carbonates" of Ba, Sr and Ca have long been used to lower the work function of a variety of heated electrodes used in television tube guns and the like. Upon heating (breakdown), the carbonate coatings are converted to semiconductor oxides of Ba, Sr, and Ca. These oxides are characteristically *n*-type and exhibit high-electron conductivity paralleling the high-functional activity of the hot cathodes. The electron emissivity is multiplied many times and lower voltages on the electrodes can be used, resulting in multiplying the lifetimes of such electrodes in TV tubes, fluorescent lamps and other electronic equipment. Crystal structures of Ba, Sr and Ca carbonates were co-precipitated and studied by X-ray powder method using an X-ray Geiger counter spectrometer. There exist three kinds of solid solutions: aragonite type crystal (l-carbonate), calcite type crystal (β-carbonate) and vaterite type crystal (μ-carbonate); in the $BaCO_3$–$SrCO_3$–$CaCO_3$ system. The phase domains of these three crystal forms are affected somewhat by the temperature at which the precipitation is carried out. The triple diagrams are obtained at two stages of precipitation temperatures.

Barium carbonate ($BaCO_3$) was examined in a diamond anvil cell up to a pressure of 73 GPa using an in situ angle-dispersive XRD technique. Three new phases of $BaCO_3$ were observed at pressures >10 GPa. From 10 to 24 GPa, $BaCO_3$-IV had a post-aragonite structure with space group *Pmmn*. There are two molecules in a single unit cell ($Z = 2$) of the orthorhombic phase, which is same as the high-pressure phases of $CaCO_3$ and $SrCO_3$. The isothermal bulk modulus of $BaCO_3$-IV is $K_0 = 84$ GPa, with $V_0 = 129.0$ Å^3 when $K_0 = 4$. The *c* axis of the unit-cell parameter is less compressible than the *a* and *b* axes. The relative change in volume that accompanies the transformation between $BaCO_3$-III and $BaCO_3$-IV is −6%. $BaCO_3$-V, which has an orthorhombic symmetry, was synthesized at 50 GPa. As the pressure increases, $BaCO_3$-V is transformed into tetragonal $BaCO_3$-VI. This transformation is likely to be second order, because the diffraction pattern of $BaCO_3$-V is similar to that of $BaCO_3$-VI, and some single peaks in $BaCO_3$-VI become doublets in $BaCO_3$-V. After decompression, the new high-pressure phases transform into $BaCO_3$-II. These findings resolve a dispute regarding the stable high-pressure phases of $BaCO_3$

Only a few research papers concerning $BaCO_3$ are available in the current scientific literature. This salt is used primarily to make other barium compounds and in glazes for pottery.

Barium bicarbonate is a compound, $Ba(HCO_3)_2$, which is stable only in solution. It can be formed by the action of carbon dioxide on a suspension of barium carbonate in cold water:

$$BaCO_3\,(\text{solid}) + CO_2\,(\text{gas}) + H_2O\,(\text{liq}) \Rightarrow Ba(HCO_3)_2\,(\text{aq})$$

On heating, this reaction is reversed.

Barium carbonate is readily available commercially, both in an impure form and as a highly purified compound.

Radium Carbonate

Radium carbonate has the molecular formula of $RaCO_3$ and the molecular weight of grams per mole. Most of the compounds of radium are more insoluble than the corresponding barium compounds and concentrate in the precipitate upon fractional precipitation of barium–radium mixtures. One notable exception is radium carbonate, which is more soluble than barium carbonate and, hence, concentrates in the soluble fraction (filtrate) when barium–radium carbonate mixtures are fractionally separated.

Radium carbonate is soluble in dilute acids, and more soluble in concentrated ammonium carbonate solution than $BaCO_3$. In general, $RaCO_3$ is prepared in conjunction with $BaCO_3$ and then separated. Radium sulfate is the most insoluble of the alkaline earth sulfates and probably the most insoluble radium compound known. Its volubility is 2.1×10^{-4} g/100 ml of water at 18 °C. For this reason, precipitation as the sulfate is a common practice for the recovery of radium, particularly with the addition of barium carrier. Precipitation is readily accomplished by adding dilute sulfuric acid to a solution of a soluble radium compound. Radium sulfate may be dehydrated completely by heating it in dry air at 300 °C. The compound is soluble in concentrated sulfuric acid, but precipitates upon dilution of the acid. It is converted to radium carbonate by fusion with sodium carbonate (a technique frequently used for the dissolution of radiferous barium sulfate because the resulting barium–radium carbonates are soluble in any dilute mineral acid).

Radium carbonate may also be prepared by precipitation from neutral or weakly alkaline solutions of radium salts with a solution of ammonium carbonate. Gram quantities of radium have been recovered from a concentrated solution of radium nitrate by precipitation as the carbonate. The radium nitrate solution was adjusted to pH 9.2–9.5 with concentrated ammonium hydroxide. Carbon dioxide gas was bubbled into the solution until the pH was just slightly above 7.0. To insure complete precipitation of radium carbonate, ethyl alcohol and some additional ammonium hydroxide solution were added. The radium carbonate was filtered and washed with 90% ethyl alcohol. It was first dried at 110 °C to remove the alcohol and weighed as $RaCO_3$. Mixtures of radium and barium have been separated by fractional precipitation from homogeneous solution as carbonates.

When a mixture of chemically similar cations such as radium and barium is present in the solution, the one which forms the least soluble carbonate concentrate in the precipitate. Consequently, a radium–barium mixture radium is concentrated in the liquor and barium in the precipitate. It appears that the separation of radium and barium by fractional carbonate precipitation is more efficient at higher temperatures. The logarithmic distribution coefficient at 90 °C is 0.1830, whereas at 20 °C, it is about 0.51. Radium and barium carbonates probably show an increasing volubility differential with increasing temperature.

The principal use of radium carbonate has been in medicine and to prepare other radium compounds. Research papers concerning the properties of $RaCO_3$ are scarce and the physical data are scanty. Radium occurs in the mineral "davidite", $La_{0.7}Ce_{0.2}Ra_{0.02}Ca_{0.1}Y_{0.75}U_{0.25}Ti_{15}Fe^{3+}{}_5O_{38}$, which occurs at the Radium-Hill mine in Southern Australia. ^{226}Ra is separated via a $RaSO_4 \Rightarrow RaCO_3$ method. The latter finds employment in medicine.

5.2. ALKALINE EARTH OXY-SILICON COMPOUNDS

Silicon has but one electronic state, that of Si^{4+} in compounds. With the alkaline earths, it forms silicides, M_2Si and "silicates" based on various "silicic acids", composed of oxygen, silicon and the alkaline earth.

5.2.1. Acids Based on Silicon

Silicic acid is a general name for a family of chemical compounds of the elements, Si, H and O, with the general formula $[SiO_x(OH)_{4-2x}]_n$. Some simple silicic acids have been identified in very dilute aqueous solution, such as *metasilicic acid* (H_2SiO_3), *orthosilicic acid* (H_4SiO_4, $pK_{a1} = 9.84$, $pK_{a2} = 13.2$ at 25 °C), *disilicic acid* ($H_2Si_2O_5$), and *pyrosilicic acid* ($H_6Si_2O_7$). However, in the solid state, these forms are not generally stable and condense to form polymeric silicic acids of complex structure. Silicic acids may be obtained by acidifying certain silicate salts like sodium silicate in aqueous solution. When heated they lose water to form silica gel.

In the oceans, silicon exists primarily as orthosilicic acid (H_4SiO_4), and its biogeochemical cycle is regulated by the group of algae known as "diatoms". These algae polymerize the silicic acid to so-called "biogenic silica", used to construct their cell walls (called "frustules").

Orthosilicic acid is the form predominantly absorbed by humans and is found in numerous tissues including bone, tendons, aorta, liver and kidney. Persuasive data suggest that silica is essential for health although no RDI has been established. However, a deficiency of silica induces deformities in skull and peripheral bones, causes poorly formed joints, reduced contents of cartilage, collagen, and disruption of mineral balance in the femur and vertebrae.

5.2.2. Silicides of the Alkaline Earths

Similar to borides and carbides, the composition of silicides cannot be easily specified as covalent molecules. The chemical bonds in silicides range from conductive metal-like structures to ionic or covalent. Silicides of all nontransition metals, with exception of beryllium, have been described. Group 1 and 2 silicides, e.g. Na_2Si and Ca_2Si, react with water to yield hydrogen and/or silanes.

Electronic structures and densities of states of the following AEM silicides have been calculated using a first-principle pseudopotential method: Mg_2Si, $BaSi_2$, Ca_2Si, and Sr_2Si. Mg_2Si and $BaSi_2$ were predicted to be indirect semiconductors while Ca_2Si and Sr_2Si were predicted to be direct semiconductors. Estimated band gaps are about 50% or less of the observed values. The valence bands of these are composed of Si (3s,3p) as well as of Mg (3s,3p), Ca (4s,4p,3d), Sr (5s,5p,4d) or Ba (6s,6p,5d) electrons. The conduction bands are mainly composed of AEM s, p, d states and the contributions of Si(3s,3p) were relatively small. Formation energy of stoichiometric Mg_2Si was successfully foretold.

Beryllium Silicides

Beryllium silicide has the molecular formula of Be_2Si and the molecular weight of 46.1094 g/mol. Be_2Si has never been identified and its existence remains questionable. Although Si has a melting point of 1414 °C and a boiling point of 3265 °C, the melting and boiling points

of Be are nearly as high at 1287 °C and 2469 °C, respectively. Thus, fusion of the elements is not feasible because of lack of equipment that will withstand such temperatures during fusion. Thus, the system Be–Si has never been studied and it is not known whether Be_2Si exists or not. It may be that this compound is not stable thermodynamically due to the sizes of the Be^{2+} and Si^{4-} ions. The reaction of SiC with the oxide was studied:

$$SiC + 2BeO \Rightarrow Be_2Si + CO_2$$

But no beryllium silicide formation was observed.

Although the existence of beryllium silicide has never been reported, a paper describing the evaporation of Be metal upon the surface of silicon has resulted in the formation of "rings" during the growth of epitaxial single-crystal (0001) hcp Be on (111) Si substrates using molecular beam epitaxy. The ring structure is believed to be constructed from 4-Be atoms arranged in a square on the surface of the Si substrate arranged at a distance commensurate with that of 2-Si atoms, i.e. Be_4Si_2, as determined from scanning tunneling microscopy and photoelectron spectroscopy. These methods showed that the nucleation, growth, and structure of beryllium on Si (111) by a chemical reaction that occurs at temperatures as low as 120 K, resulting in a nano-cluster of Be_4Si_2 on the surface. The Be is oriented with Be[1010] parallel to Si[110] and Be[1120] parallel to Si[211]. Crystalline quality of the layer improved with increasing deposition temperature T, where $T = 100$, 200, 300, 400, and 500 °C for the results reported. The films deposited at $T \leq 300$ °C are smooth while those deposited at $T \geq 400$ °C are rough. A superstructure was observed on the surface, probably $\sqrt{3} - \sqrt{3}$, $R30°$, for films grown at $T = 300$ °C.

The physical properties of beryllium silicide remain unknown and it is unavailable commercially due to lack of demand for such a material.

Magnesium Silicide

Magnesium silicide has the molecular formula of Mg_2Si and the molecular weight of 76.6955 g/mol. Its CAS number is 22861-39-6. Its density is 1.998 g/cc and its melting point is 1102 °C. It is a black powder. Since the melting and boiling points of Mg metal are 651 °C and 1091 °C, respectively, this salt can be formed by the reaction of Mg, mixed with Si, at 800 °C in an inert atmosphere:

$$2Mg\ (gas) + Si\ (solid) \Rightarrow Mg_2Si\ (gas)$$

Magnesium silicide is unstable in air and reacts with moisture to form silane. When magnesium silicide is placed into aqueous HCl, the gas silane, SiH_4, is produced. This gas is the silicon analogue of methane, CH_4, but is more reactive. Silane is pyrophoric, that is due to the presence of O_2 in the air, i.e. it spontaneously combusts in air:

$$Mg_2Si\ (solid) + 4HCl\ (aq) \Rightarrow SiH_4\ (gas) + 2MgCl_2\ (solid)$$

$$SiH_4 + 2O_2 \Rightarrow SiO_2 + 2H_2O$$

These reactions are typical of a Group-2 silicide. Mg_2Si reacts similarly with sulfuric acid.

As a powder, magnesium silicide is dark blue or slightly purple in color. SiO_2, found in sand and glass, when heated with Mg metal forms magnesium silicide. The first product in this reaction is silicon, which then reacts further with magnesium to produce Mg_2Si:

$$SiO_2 + 2Mg \Rightarrow 2MgO + Si$$

$$Si + 2Mg \Rightarrow Mg_2Si$$

Magnesium silicide can also be formed by the reaction between magnesium hydride and silicon with the evolution of hydrogen gas at temperatures above 250 °C:

$$2MgH_2 + Si \Rightarrow Mg_2Si + 2H_2$$

Magnesium silicide is dimorphic and has the following cell parameters:

Cubic—cF12 type

$a = b = c = 4.4908$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 64.04 Å^3, cell occupancy is shown in Table 5.5.

Tetragonal—hP18 type

$a = 6.422$ Å, $b = c = 12.453$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 961.80 Å^3, cell occupancy is shown in Table 5.6.

Mg_2Si crystallizes in a cubic CaF_2 (fluorspar)-type lattice with $a = 4.49$ Å. The centers of this lattice are analogous to that of diamond. Each Si atom forms four covalent sp^3 bonds. The Mg subshells are only half-filled. There is no bonding between the two Mg atom sites. The distance between the Mg and Si atoms is 2.77 Å. Bonding in this compound is essentially covalent. The heat of formation ΔH_f^0 is –6380 cal/g atom. Mg_2Si is an n-type semiconductor with a forbidden band gap of 0.78 eV at 0 °C. Its conductivity can be expressed by:

Extrinsic: $Q_E = [13 \times 10^3] \exp [0.011/2KT]$
Intrinsic: $Q_I = [10^4/3150] \exp [0.48/2KT]$

A three-dimensional crystal model is shown in the following diagram presented below. Mg_2Si is an ionic crystal composed of Mg^{2+} and Si^{4-} ions that have very different ionic radii, 0.6 Å and 2.1 Å, respectively. This compound exhibits n-type electric conductivity which originates from formations of positively charged Mg ions at interstitial sites, regardless of the chemical composition in crystal growth. Thus, the vacancy model includes V_{Mg}^{2+} and $Mg_{Interstit}^{2+}$ (Fig. 5.14), a Frenkel type.

Magnesium silicide (Mg_2Si) undergoes a transformation from a cubic (fluorite)-type lattice to a hexagonal lattice at pressures above about 25 kilobars and

temperatures above 900 °C. There is an increase of density of about 15% associated with this structure change. Both the parent and product substances are semiconductors, but of different resistivities. The high-pressure phase may be recovered and is indefinitely metastable at normal ambient conditions.

Mg_2Si is not attached by alkali solutions but reacts vigorously with acids to form silanes. This substance also slowly reacts with ammonium chloride solution:

$$2Mg_2Si\ (\text{solid}) + 8NH_4Cl + 3H_2O \Rightarrow 4MgCl_2 + H_2Si_2O_3 + 8NH_3\ (\text{gas}) + 6H_2\ (\text{gas})$$

In a hydrogen atmosphere at 1000–1220 °C, magnesium silicide decomposes with the vaporization of Mg metal. Heating this compound in a N_2 stream forms a black mass which is unstable in air and moisture, forming ammonia, NH_3, as a result of the formation of magnesium nitride.

This compound is a thermoelectric material. That is, upon exposure to heat, it converts heat energy to an electric current. Efficient, inexpensive and nontoxic thermoelectric elements such as silicides are being developed for large-scale applications such as recovering the combustion heat of municipal solid waste, that are well suited for thermoelectric power generation. The characterization and thermoelectric properties of undoped and doped *n*-type magnesium silicide processed by the powdered elements spark plasma sintering (SPS) method were investigated. The patterns by powder X-ray diffractometry showed that it had typical polycrystalline phase. The temperature dependence of thermoelectric properties such as the Seebeck coefficient and electrical conductivity were measured for the temperature range from 300 to 773 K. As a result, a power factor value of $6.0 \times 10^{-4}\ W/(m\ K)^2$ was obtained at 773 K for a doped sample. Mg_2Si demonstrates semiconductor conductivity *n*-type character with an energy band gap $E_g = 0.78$ eV and a solid solution based on the Mg_2Si–Mg_2Sn composition has a figure of merit of $ZT > 1$. The magnesium silicide films grown on a silicon substrate by reactive diffusion method and their thermoelectric properties were also investigated.

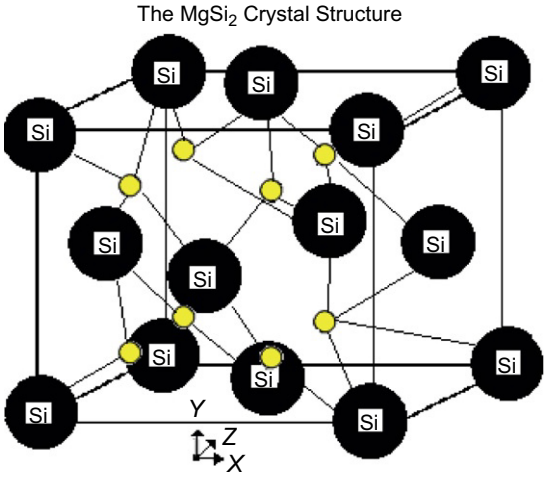

FIGURE 5.14

Bulk Mg_2Si crystals can be grown using a vertical Bridgman melt growth method. The *n*-type and *p*-type dopants, bismuth (Bi) and silver (Ag), respectively, were incorporated during the growth. X-ray powder diffraction analysis revealed clear peaks of Mg_2Si with no peaks associated with the metallic Mg and Si phases. Residual impurities and process-induced contaminants were explored by using glow discharge mass spectrometry (GDMS). A comparison between the results of GDMS and Hall effect measurements indicated that electrical activation of the Bi doping in the Mg_2Si was sufficient, while activation of the Ag doping was relatively smaller. It was shown that an undoped *n*-type specimen contained a certain amount of aluminum (Al), which was due either to residual impurities in the

Mg source or the incorporation of process-induced impurities. Thermoelectric properties such as the Seebeck coefficient and the electrical and thermal conductivities were measured as a function of temperature up to 850 K. The dimensionless figures of merit for Bi-doped and Ag-doped samples were 0.65 at 840 K and 0.1 at 566 K, respectively. Temperature dependence of the observed Seebeck coefficient was well fitted by the two-carrier model. First-principles calculations were carried out, using the all-electron band structure calculation package (ABCAP) in which the full-potential linearized augmented plane-wave method was employed. The ABCAP calculation adequately presents characteristics of the Seebeck coefficients for the undoped and heavily Bi-doped samples over the whole measured temperature range from room temperature to 850 K. The agreement between theory and experiment is poorer for the Ag-doped *p*-type samples.

Vacancies play a great part in the thermoelectric properties of Mg_2Si. The formation energy of vacancies in Mg_2Si has been studied. The calculation of the formation energy for vacancies on different sublattices using the ab initio method SIESTA have yielded specific values. While the values for the silicon (1.04 eV) and the magnesium vacancy (1.74 eV) lie in the expected range, the formation energy of the di-vacancy and the stoichiometric tri-vacancy turns out to be just 0.68 and 0.78 eV, respectively. This is smaller than the value for both mono-vacancies. Thus, this type of vacancies is preferred.

Polycrystalline, 10-μ size magnesium silicide was prepared by alloying 99.9% purity polycrystalline silicon obtained from rice husk ash and a high-purity magnesium metal powder. The material in sintered pellet form was characterized for its structural, electrical, thermal, thermoelectric and other properties. A typical sintered pellet exhibited a room temperature (30 °C) thermoelectric power of 565 μV/K and an electrical resistivity of 35 Ω cm. On the other hand, the material was found to be thermally quite stable up to 650 °C with a room temperature thermal conductivity of 6.3×10^{-3}/cals/cm/K (2.6 J/s/m/K). These properties of the material indicate that the material can find potential applications as a thermoelectric generator and in other semiconductor devices. Furthermore, an indigenous technology for large-scale production of silanes (SiH_4) can be developed using the Mg_2Si that could be prepared in large quantities by a simple and low-cost process.

In another paper, magnesium silicide has been regarded as a candidate for an advanced thermoelectric material used in the temperature range of 500–800 K that corresponds to that of vehicle exhaust emission. It is also a nontoxic substance, compared with other thermoelectric materials, such as PbTe and $CoSb_n$ that operate in the same conversion temperature range. The efficiency of a thermoelectric device is characterized by measurement of the dimensionless figure of merit, $ZT = S^2 \cdot \alpha / {}^\circ T / \hat{U}$, of its constituent thermoelectric material, where S is the Seebeck coefficient, α is the electrical conductivity, $\hat{U}$ is the thermal conductivity, and T is the absolute temperature.

For thermoelectric device operation, the use of a material with ZT more than unity is needed to realize a conversion efficiency of $\geq$10%. The optimization of doping in Mg_2Si is required in order to realize a value of unity for ZT. Mg_2Si single crystals have been grown (along with doping elements of Bi and Al) using a vertical Bridgman method. Mg (99.99%) and Si (99.99999%) with a stoichiometric Mg: Si ratio of 67:33 were mixed and melted to form Mg_2Si. Prior to the growth, Bi (99.999%) powder at the ratio from 0.5 to 3 at-% for Mg_2Si and the presynthesized polycrystalline Mg_2Si powder were mixed, and Mg_2Si crystals were grown at a rate of 3 mm/h by the vertical Bridgman method. Grown samples were characterized by XRD patterns and electron-probe microanalysis. Both analyses indicated that Mg_2Si crystals result. Hall carrier concentrations were evaluated at room temperature. The electrical conductivity, the Seebeck coefficient, and the thermal conductivity were estimated in the temperature range from RT to 850 K. The grown crystals exhibited *n*-type conductivity in undoped and all Bi-doped conditions. All the Bi-doped crystals showed high electrical conductivity and high carrier concentration compared with that of the undoped crystal. On the other hand, the thermal conductivity was lowered as the amount of Bi increased. Consequently, the thermal conductivity for the crystal that was Bi doped at 3 at-% was 0.021 W/cm/K at 842 K, and its ZT reached 0.99 at 842 K, which is near the unity of ZT that is regarded as a standard of practical use for thermoelectric materials. The solid solubility limit of Bi to Mg_2Si was determined to be around 3 at-%.

The development of advanced rechargeable batteries for efficient energy storage finds one of its keys in the lithium-ion concept. The optimization of the Li-ion technology urgently needs improvement for the active material of the negative electrode, and many recent papers in the field support this tendency. Mg_2Si was synthesized by mechanically activated annealing and evaluated as a negative electrode material. A maximum discharge capacity of 830 mA h/g was observed by cycling over a wide voltage window of 5–650 mV versus Li, but capacity fade was rapid. Cycling over the range 50–225 mV versus Li produced a stable discharge capacity of approximately 100 mA h/g. XRD experiments showed that lithium insertion converts Mg_2Si into Li_2MgSi after lithium intercalation into Mg_2Si. Electrochemical evidence of Li–Si reactions indicated

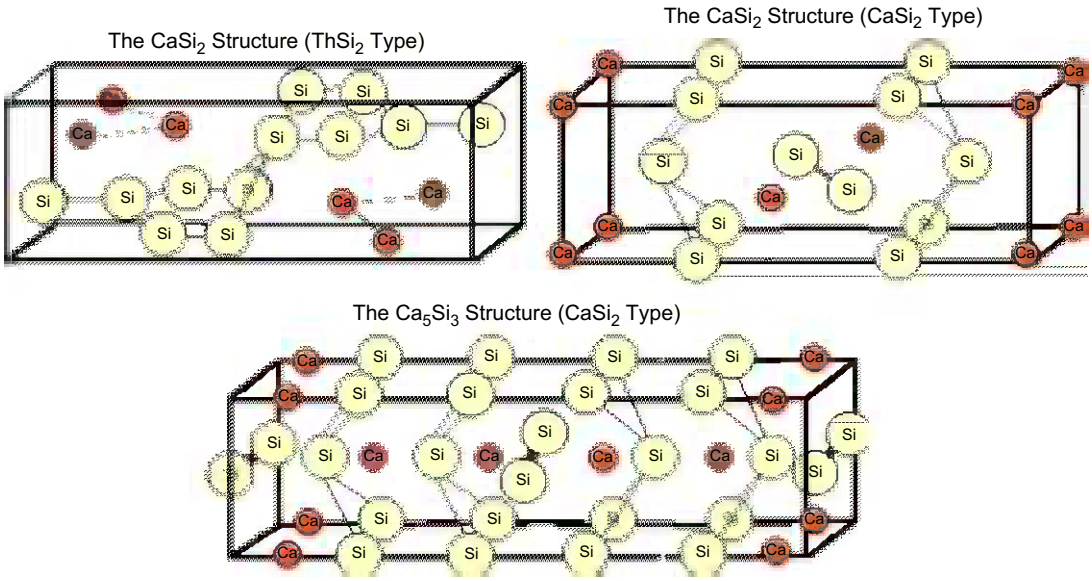

FIGURE 5.15

that the Li_2MgSi structure could be converted to binary lithium alloys with extensive charging.

Magnesium silicide is available commercially in small lots worldwide.

Calcium Silicides

Calcium silicide has the molecular formula of Ca_2Si and the molecular weight of 96.2514 g/mol. It has the CAS number of 12013-56-8. This salt can be formed by the reaction of Ca metal, mixed with Si, at 850 °C in an inert atmosphere:

$$2Ca\ (gas) + Si\ (solid) \Rightarrow Ca_2Si\ (gas)$$

The metal, Ca has a normal melting point of 842 °C and a normal boiling point of 1484 °C. Calcium silicide, also called calcium disilicide, is an inorganic compound, a silicide of calcium. It is a whitish or dark gray to black solid matter with melting point between 700 and 935 °C. It is insoluble in water, but may decompose when subjected to moisture, evolving hydrogen and producing calcium hydroxide. It decomposes in hot water. It is flammable and may ignite in air by producing silane that spontaneously ignites.

Calcium hydride and silicon react with the evolution of hydrogen gas at temperatures above 250 °C:

$$2CaH_2 + Si \Rightarrow Ca_2Si + 2H_2$$

This reaction can also produce a hydro-silicide, $CaSiH_2$, that has been assigned a CAS number of 12013-55-7.

The reaction of silica with excess Ca metal also produces the disilicide:

$$SiO_2 + 2Ca \Rightarrow 2CaO + Si$$

$$Si + 2Ca \Rightarrow Ca_2Si$$

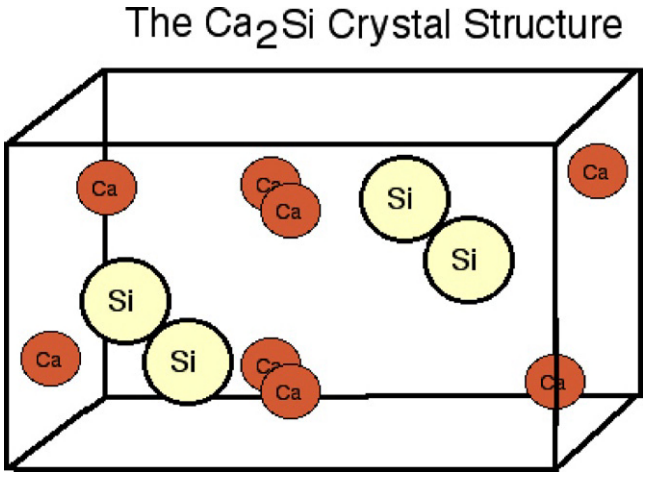

FIGURE 5.16

Calcium di-silicide is tri-morphic and the three structures are compared in the Fig. 5.15 given above.

Dicalcium silicide is dimorphic and readily forms two compounds, Ca_2Si as well as Ca_3Si_5. However, other forms have also been discovered. The cubic phase Ca_2Si film and the tetragonal phase Ca_5Si_3 film can be grown directly and individually on the different Si(100) substrates.

The Ca_2Si structure has the form shown in Fig. 5.16.

The phase diagram of the Ca–Si system has been investigated across almost the whole composition range (0 to 70 at% Si) using DTA, metallographic analysis, XRD and electron microscopy. Six intermediate phases have been found: $CaSi_2$ ($CaSi_2$-type), $Ca_{14}Si_{19}$ ($Ca_{14}Si_{19}$-type), Ca_3Si_4 (Ca_3Si_4-type), CaSi (CrB-type), Ca_5Si_3 (Cr_5B_3-type) and Ca_2Si (anti-$PbCl_2$-type). Ca_3Si_4, not

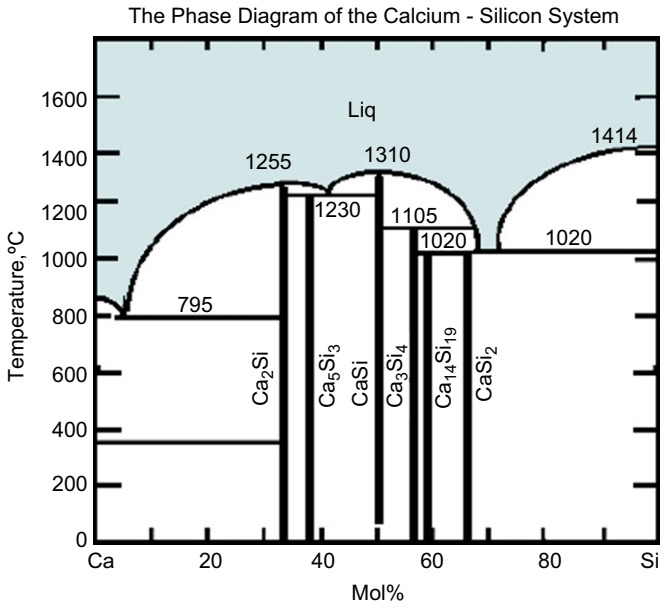

FIGURE 5.17

previously known, is a Zintl phase representative of a new structural type: hexagonal $hP42$, $a = 8.541$, $c = 14.906$ Å, space group $P6_3/m$. Three eutectics occur in this system: at about 3.5 at% Si and 795 °C, 42.5 at% Si and 1230 °C, 72.0 at% Si and 1020 °C.

The phase diagram is shown in Fig. 5.17.

Vaporization thermodynamics in this binary system of calcium–silicon has been studied by Knudsen effusion mass spectrometry and vacuum microbalance techniques. The equilibrium partial pressure of Ca (g) over the two-phase regions in the composition range 20–75 at.% Si has been measured and the standard enthalpy changes for the appropriate vaporization reactions were determined from the temperature dependence of the measured vapor pressures. The standard reaction enthalpy changes were also evaluated by the third-law method using the pressure data in conjunction with estimated Gibbs energy functions.

Standard enthalpies of formation of the calcium silicides were derived from the standard reaction enthalpy values at room temperature. The results obtained for $\Delta_f H^\circ_{298}$ were the following:

$$Ca_2Si = -56.1,\ Ca_5Si_3 = -55.3,\ CaSi = -49.6,$$

$$Ca_3Si_4 = -40.6,\ Ca_{14}Si_{19} = -44.4,\ CaSi_2 = -37.8$$

(all in kJ/mol atoms).

The results for Ca_2Si, CaSi and $CaSi_2$ may be compared with previous measurements. All other results were first determinations.

Trigonal/rhombohedral $CaSi_2$(I) ($CaSi_2$-type structure) with corrugated layers of three-connected Si atoms can be transformed by a high-pressure high-temperature treatment into a tetragonal $CaSi_2$(II) (α-$ThSi_2$-type structure) with a three-dimensional net of three-connected Si atoms. The silicon net of $CaSi_2$(II) is slightly distorted from the topologically simplest tetragonal three-dimensional three-connected net derived on a geometrical basis. In order to correlate crystal chemical with thermochemical data, the transformation between both polymorphs of $CaSi_2$ has been studied at equilibrium and nonequilibrium conditions. The pressure–temperature phase diagram of $CaSi_2$ has been investigated by X-ray technique in quenched samples. From the slope of the equilibrium line and the change in molar volume, the approximate values of the entropy and energy of transformation $CaSi_2(I \Rightarrow II)$ have been determined $\Delta S = 3.2$ e.u., $\Delta U = 4.9$ kcal/mol. Under nonequilibrium conditions, the transformation $CaSi_2(II \Rightarrow I)$ yielded $\Delta H = -4.2$ kcal/mol at 500 °C and ambient pressure in a DTA apparatus. Complete transformation of metastable $CaSi_2$(II) can be achieved within 5 min at a heating rate of 20 °C/min. Due to the relatively high speed of transformation, simple structural relations between both polymorphs of $CaSi_2$ were discussed.

The structure and phase variation of Ca_5Si_3 upon hydrogenation were systematically investigated using combined neutron powder diffraction (NPD), neutron vibrational spectroscopy, and first-principles calculations. The hydrogen absorption equilibrium was first attained with formation of $Ca_5Si_3{\cdot}H(D)_{0.53}$ ($I4/mcm$) with H exclusively located in Ca_4-tetrahedral sites. More hydrogen absorbed into the system under higher pressure leads to dissociations into CaH_2 (an amorphous hydride at higher pressures) and CaSi. The hydrogen-induced formation of an amorphous phase under higher pressures is very unusual in Cr_5B_3-type compounds and the observed formation of CaH_2 upon hydrogen absorption confirmed the proposed composition equilibrium. Ca_2Si was found to reversibly absorb and desorb hydrogen in a moderate temperature range of 473–573 K. Ca_2Si showed even more rapid absorption kinetics with the formation of a reversible amorphous hydride phase in the temperature range of 473–523 K. Further studies led to investigation of hydrogen storage properties of Ca_5Si_3 and structural variations upon the hydrogenation/dehydrogenation of Ca_5Si_3, another important intermetallic phase in the Ca–Si system. The crystal structure of Ca_5Si_3, belongs to the frequently encountered tetragonal Cr_5B_3-type structure, which features an equal number of monomeric and dimeric hydride anions so that the divalent cations formally meet the structure criterion for Zintl phases, in terms of oxidation states. The presence of a significant Ca_4-tetrahedral cavity in this structure type allows a ready incorporation of small quantities of hydrogen or fluorine into the structure, resulting in oxidation of the substrate.

A [1,0,0] view of the tetragonal structures of Ca_5Si_3 and $Ca_5Si_3{\cdot}D_{0.53}$ with empty and filled Ca_4-tetrahedral cavities.

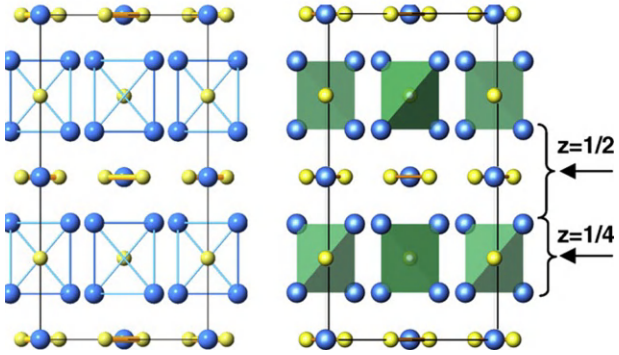

FIGURE 5.18

A representation of this phenomenon is shown in Fig. 5.18.

This compound has considerable potential for storing hydrogen at ambient temperatures for release thereof by heating. It would be used in automobiles or buses in lieu of natural or synthetic gas. Another possible usage is as the source for fuel-cell electrical generators in "electric-automobiles".

A newly discovered Ca_3Si_4 compound is said to be a semiconductor. It is characterized by an indirect transition of 0.35 eV. In fact, the phase diagram of the Ca–Si system was reinvestigated by Manfrinetti et al and a new compound—Ca_3Si_4—was found. It crystallizes in the hexagonal structure (space group $P63/m$) and has the following lattice constants: $a = 8.541$ Å and $c = 14.906$ Å. The unit cell consists of six formula units where Ca and Si atoms are grouped, respectively, into four inequivalent sites.

A peculiar dispersion of the last valence band and the first conduction band, displaying a loop of extrema, has been found. This feature leads to large anisotropy of the mobility of holes and electrons. A comparison of the dielectric function of this material was made with data for another semiconducting calcium silicide Ca_2Si.

Industrial calcium silicide usually contains iron and aluminum as the primary contaminants, and low amounts of carbon and sulfur. Calcium silicide is used for manufacture of special metal alloys, e.g. for removing phosphorus and as a deoxidizer. In pyrotechnics, it is used as fuel to make special mixtures, e.g. for production of smokes, in flash compositions, and in percussion caps. Specification for pyrotechnic calcium silicide is MIL-C-324C. In some mixtures, it may be substituted by ferrosilicon. Silicon-based fuels are used in some time-delay mixtures, e.g. for controlling of explosive bolts, hand grenades, and infrared decoys. Smoke compositions often contain hexachloroethane. During burning they produce silicon tetrachloride, It, like titanium tetrachloride used in smoke screens, reacts with air moisture and produces a dense white fog. Gum arabic is used in some mixtures to inhibit calcium silicide decomposition.

Self-heating cans of military food rations developed during the World War II used a thermite-like mixture of 1:1 of Fe(II,III) oxide and calcium silicide. Such mixture, when ignited, generates a moderate amount of heat and no gaseous products. There is also a calcium silicide CaH_2Si, CAS number 12013-55-7.

The uses of calcium silicide are many. Some of these include:

- Calcium silicide is used for manufacture of special metal alloys, e.g. for removing phosphorus and as a deoxidizer.
- In pyrotechnics, it is used as fuel to make special mixtures, e.g. for production of smokes, in flash compositions, and in percussion caps.
- Calcium silicide is used in the manufacture of certain initiatory, pyrotechnic and smoke compositions.
- The silicon and calcium alloy is mainly used as desulfurizing agent and deoxidizer for steel industry and casting industry.
- Calcium silicide has been found to be extremely corrosive to all metals including the refractory metals. It has been successfully contained in boron nitride for 36 h.
- The formation of calcium silicide ($CaSi_2$) intermetallic through the simultaneous reduction of calcium oxide from the electrolyte and of the silica pellet and reduction of dissolved carbon dioxide.

China has increased the selling price of calcium silicide continuously, especially in the products manufactured in Shaanxi, Shanxi and Inner Mongolia provinces within the past 2 years. The annual production of silicon and calcium alloy is about 130,000 tons all over world and international market demand is about 160,000 tons. Calcium silicon is made in shaft-type electric furnaces.

The "Calcium Silicide Manufacturers Directory" lists over 3,000,000 registered importers and exporters

Strontium Silicide

Strontium silicide has the molecular formula of Sr_2Si and the molecular weight of gm/mol. This salt can be prepared by the reaction of the elements in an inert atmosphere at about 850 °C:

$$2Sr + Si \Rightarrow Sr_2Si$$

Its CAS number is 12138-28-2. Di-strontium silicide has the structure shown below and that of mono-strontium silicide is shown next to it. Up to four other strontium silicides are known.

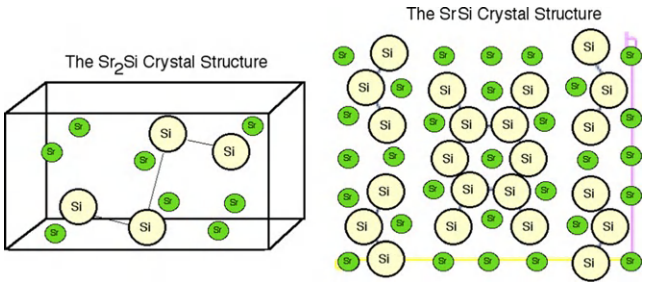

FIGURE 5.19

Thermodynamic modeling of the Si–Sr system was carried out using the CALPHAD method (Fig. 5.19).

Crystal parameters are given in Table 5.7.

The unit-cell parameters are:

Sr_2Si

$a = 5.162$ Å, $b = 8.133$ Å, $c = 9.544$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 400.21$ Å^3, cell occupancy is shown in Table 5.8.

Sr_5Si_3

$a = b = 8.089$ Å, $c = 9.726$ Å, $\alpha = \beta = 114.72°$, $\gamma = 90°$, cell volume $= 513.72$ Å^3, cell occupancy is shown in Table 5.9.

SrSi—oP12 type

$a = 4.042$ Å, $b = 4.826$ Å, $c = 6.138$ Å, $\alpha = 113.15°$, $\beta = \gamma = 90°$, cell volume $= 110.09$ Å^3, cell occupancy is shown in Table 5.10.

SrSi—oI40 type

$a = 4.892$ Å, $b = c = 11.374$ Å, $\alpha = 69.584°$, $\beta = \gamma = 77.587°$, cell volume $= 572.20$ Å^3, cell occupancy is shown in Table 5.11.

$SrSi_2$—$ThSi_2$-type

$a = 4.438$ Å, $b = 4.438$ Å, $c = 7.594$ Å, $\alpha = \beta = 106.99°$, $\gamma = 90°$, cell volume $= 136.20$ Å^3, cell occupancy is shown in Table 5.12.

$SrSi_2$—$SrSi_2$ type

$a = b = c = 6.715$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 302.79$ Å^3, cell occupancy is shown in Table 5.13.

In this system, three of the intermetallic compounds, Sr_2Si, Sr_5Si_3, SrSi, were considered to be stoichiometric

and $SrSi_2$ was modeled as a nonstoichiometric phase. For the liquid phase, two different models were used. In one case, Sr and Si were assumed to constitute a random solution, with its excess Gibbs energy being described through the Redlich–Kister polynomial. In the second case, the liquid phase was described through the associate model, considering the species Si, Sr and SrSi. The terminal solid solutions, (β-Sr), (α-Sr) and (Si), are treated as having negligible solubility. A set of self-consistent thermodynamic parameters were obtained by considering experimental phase equilibria, measurements of the mixing enthalpy in the liquid phase, as well as measured and calculated–via first-principles methods based on density functional theory–formation enthalpies of the intermetallic compounds.

The phase diagram determined is shown in Fig. 5.20.

Four intermediate phases exist: Sr_2Si ($PbCl_2$-type), Sr_5Si_3 (Cr_5B_3-type), SrSi (CrB-type) and the dimorphic $SrSi_2$ compound (for a total of five known forms).

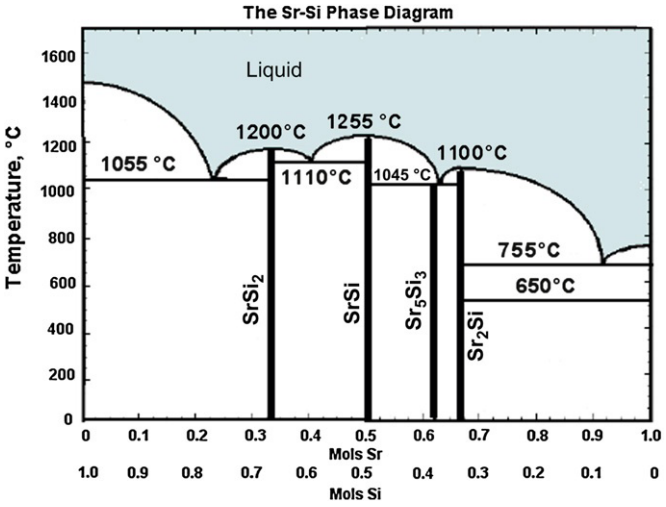

FIGURE 5.20

The low-temperature form α-$SrSi_2$ is cubic, $SrSi_2$-type, and the high-temperature form β-$SrSi_2$ is tetragonal with the α-$ThSi_2$ structure type. For this last phase, a solid solubility range, from about 62.0 to 66.7 at.% Si, has also been found. Four eutectics occur in the system: at about 3 at.% Si and 745 °C, 44 at.% Si and 1110 °C, 61 at.% Si and 1055 °C, 74 at.% Si and 1045 °C.

Strontium silicides have recently been found to have potential applications in electronic devices. Renewed research efforts have led to a reevaluation of the phase equilibria in this system, resulting in the discovery of previously undetected stable intermetallic compounds.

Dimorphic $SrSi_2$ is the first compound found that has the two simplest three-dimensional three-connected nets in its polymorphs. The cubic net of three-connected silicon atoms ($SrSi_2$ type of structure) can be transformed into the tetragonal one (α-$ThSi_2$ type of structure) by a high-pressure and high-temperature treatment. The tetragonal phase is quenchable. Heating of this phase to 600–700 °C at ambient pressure results in transformation into the cubic one. At a heating rate of 20 °C/min, complete transformation can be achieved within 5 min in a DTA apparatus. The energy of transformation, Δh_{Trans}, has been obtained from the peak areas of the DTA curves to be -1.6 ± 0.3 kcal/mol. Although the transformation between the three-dimensional three-connected sets in $SrSi_2$ must be formally classified as a reconstructive one, a relatively small entropy change ($\Delta S = 1.2$ cal/deg mol) has been calculated from the change in molar volume and *p-T* equilibrium conditions. The two structures look like in Fig. 5.21.

The pressure–temperature phase diagram of dimorphic $SrSi_2$ was investigated in the pressure range 10–40 kbar and temperature range 600–1200 °C in a belt-type apparatus. The phase boundary between cubic $SrSi_2$I ($SrSi_2$-type) and tetragonal $SrSi_2$II (α-$ThSi_2$-type) was studied by X-ray techniques in quenched samples. The curvature of the equilibrium line was not resolved. Molar volumes of both polymorphs have been measured in the temperature range 20–400 °C at ambient pressure. From the slope of the equilibrium line in the pressure–temperature diagram and the change in molar volume, approximate values of the entropy and heat of transition $SrSi_2$(I–II) have been calculated. In the silicon sublattice of both polymorphs of $SrSi_2$, the topologically simplest three-dimensional three-connected nets are found to be slightly distorted from their ideal configurations. The ideal $SrSi_2$-type net represents the three-connected analogy to the four-connected diamond net. The Sr_2Si, Sr_5Si_3 and SrSi phases have been predicted to undergo high-pressure transitions. The lattice transitions shown here have been calculated to occur at 5.5, 19.9, 11.8 and 60 GPa, respectively:

$$Sr_2Si\ (oP12 \Rightarrow hP6)$$

$$Sr_5Si_3\ (tI32\text{-}Cr_5B_3 \Rightarrow tI32\text{-}Mo_5Si_3)$$

$$SrSi(oC8 \Rightarrow oP8 \Rightarrow tP2)$$

Electronic structure of the computed ground states and the predicted four new high-pressure polymorphs of Sr_2Si, Sr_5Si_3 and SrSi phases are calculated and discussed in relation with their corresponding crystal structures and heats of formation.

The high-temperature vaporization processes of strontium silicides were studied by means of the Knudsen effusion mass spectrometry and Knudsen effusion

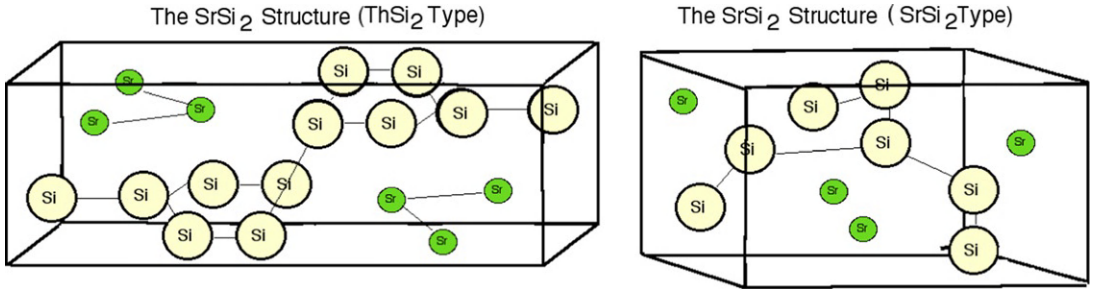

FIGURE 5.21

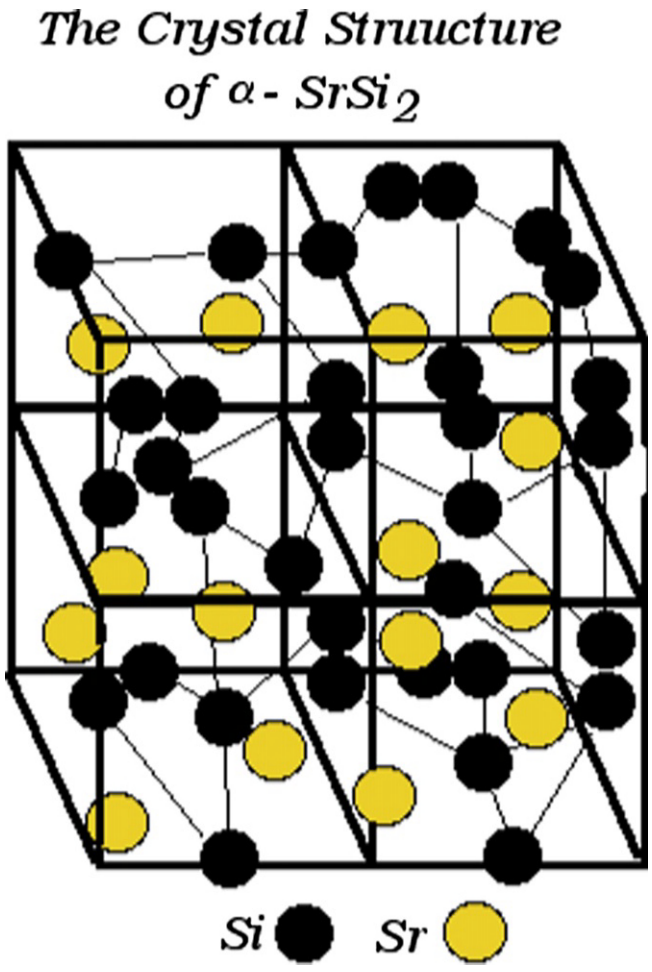

FIGURE 5.22

weight loss techniques in the temperature range 665–1300 K, with reference to the recent reinvestigation of the Sr–Si phase diagram. The only species detected in the vapor phase equilibrated with two-phase solid mixtures was monoatomic gaseous strontium. The vapor pressure of Sr (g) was measured as a function of the temperature, and the enthalpy changes associated with the decomposition processes were thereafter derived. The enthalpies of formation of the strontium silicide phases reported in the Palenzona reference (namely Sr_2Si, Sr_5Si_3, SrSi and α-$SrSi_2$), were finally obtained as, respectively (values in kJ/mol atoms, ($T = 298$ K): $\Delta H_f^0 = -39.7 \pm 3.2$; -43.8 ± 3.6; -51.7 ± 4.1; -40.3 ± 3.7). These results are definitely at variance with the scattered, strongly exothermic calorimetric data reported for some phases in the old literature, while they are in satisfactory agreement with recent density functional theory calculations. The crystal structure of α-$SrSi_2$ is shown in Fig. 5.22.

Strontium silicide has been explored as a possible thermoelectric material because it is a semiconductor. A study of the thermoelectric properties of $BaSi_2$, $SrSi_2$, and LaSi was conducted. The polycrystalline samples were prepared by SPS. The electrical resistivity (ρ), Seebeck coefficient (S), and thermal conductivity (κ) were measured above room temperature. The power factor (S^2/ρ) is quite low (below 10^{-5}/Wm/κ^2) over the whole temperature range for $BaSi_2$ and LaSi, while relatively high (1.19×10^{-3} Wm^{-1}/κ^2 at 331 K) for $SrSi_2$. $BaSi_2$ exhibits quite low κ. The κ values at room temperature are 1.56, 5.25, and 6.71/Wm/κ for $BaSi_2$, and $SrSi_2$, respectively. The maximum values of the dimensionless figure of merit, $ZT = S^2T/\rho/\kappa$, are 0.01 at 954 K for $BaSi_2$, and 0.09 at 417 K for $SrSi_2$.

Strontium silicide is available in all grades ranging from commercial to 99.999% purity. A large number of suppliers are available commercially.

Barium Silicide

Barium silicide has the molecular formula of Ba_2Si and the molecular weight of gm/mol. Its CAS number is 1304-40-1. This salt has been prepared by the reaction of the elements in an inert atmosphere at 850 °C:

$$2Ba + Si + \text{heat} \Rightarrow Ba_2Si$$

The reaction is slow. Melt growth of $BaSi_2$ by the vertical Bridgman (VB) technique is difficult, particularly when the elements are melted together. Because Ba is highly reactive at the growth temperature (≈1500 K), the crucible materials were chosen to avoid chemical reactions and sticking between the crucibles and the molten and vapor phases of Ba. Crucibles made of molybdenum, quartz, alumina, SiNx-coated quartz, chemical vapor deposition (CVD), PG, and CVD SiC-coated graphite were examined, and the semiconductor, orthorhombic $BaSi_2$, was obtained in quartz, alumina, and molybdenum crucibles. The crystalline forms of the grown crystals depend on the crucible materials and growth conditions.

Ba_2Si is a semiconductor that has been studied as a thermoelectric element for use in converting waste heat into electricity. To date, measurements have shown that $BaSi_2$ exhibits quite low-thermal conductivity and a comparative value of 0.01 when compared to conventional thermoelectrics which exhibit values of >0.10 in conversion efficiency.

Its structure is identical to that of Ca_2Si (Fig. 5.23).

The crystal parameters are given in Table 5.14.

The unit-cell parameters are:

Ba_2Si

$a = 5.214$ Å, $b = 8.443$ Å, $c = 9.634$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 422.21 Å^3, cell occupancy is shown in Table 5.15.

Ba_3Si_4

$a = b = 8.523$ Å, $c = 11.824$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 859.47 Å^3, cell occupancy is shown in Table 5.16.

Ba_4Si_{23}

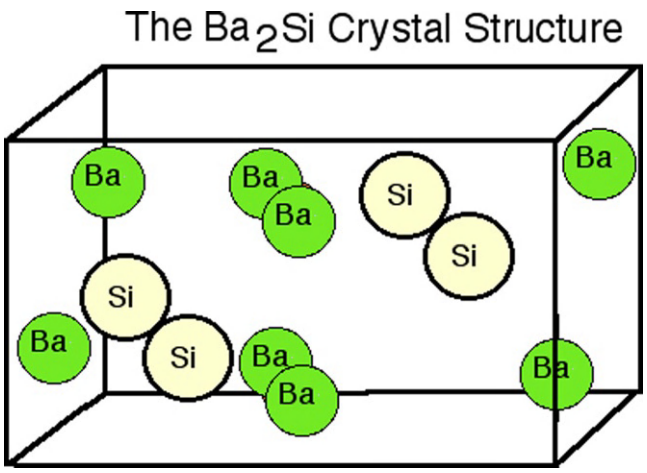

FIGURE 5.23

$BaSi_2$—$SrSi_2$type

$a = b = c = 6.535$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 279.09$ Å^3, cell occupancy is shown in Table 5.22.

These structures are compared in the following a ⇒ c vector diagrams (Fig. 5.24).

The high-temperature decomposition of the intermediate phases of the Ba–Si system (namely, Ba_2Si, Ba_5Si_3, BaSi, Ba_3Si_4 and $BaSi_2$) has been investigated by means of Knudsen effusion mass spectrometry and Knudsen effusion weight loss techniques. All barium silicides decompose at high temperature by loss of monatomic gaseous barium. The standard enthalpy changes of the decomposition reactions were derived from vapor pressure measurements by the second- and third-law methods of analysis. From these values, the heats of formation of all the barium silicides were calculated. First-principles electronic structure calculations for the same compounds were also performed by the density functional theory approach, in the generalized gradient approximation, using plane wave basis functions and Vanderbilt ultrasoft pseudopotentials. The experimental ground state lattices of the barium silicides have been studied: structures have been relaxed and total energy values derived. These were used in combination with calculated total energies of diamond–silicon and fcc-barium to derive the heats of formation of the barium silicides. First-principles predictions and experimental heats of formation are in satisfactory agreement. The selected values of the heats of formation of the intermediate phases of the Ba–Si system, ΔH_f^0, are (in kJ mol-at.$^{-1}$): $Ba_2Si = -35.8 \pm 7.0$; $Ba_5Si_3 = -42.4 \pm 5.2$; $BaSi = -50.1 \pm 2.9$; $Ba_3Si_4 = -50.7 \pm 3.1$; and $BaSi_2 = -46.7 \pm 3.5$.

The phase diagram is presented as shown in Fig. 5.25.

The phase diagram of the Ba–Si system has been completely revised from a thermal point of view. All the already-known intermediate phases have been confirmed: Ba_2Si (Co_2Si type), Ba_5Si_3 (Ba_5Si_3 type), BaSi (CrB type), Ba_3Si_4 (Ba_3Si_4 type) and $BaSi_2$ ($BaSi_2$ type). Save for Ba_5Si_3, which forms peritectically, all other compounds melt congruently. The five eutectic compositions occurring in the system are at 11, 40, 52.5, 60 and 83 at.% Si, respectively.

$BaSi_2$ crystals were grown from a near-stoichiometric melt containing mixtures of Ba (99.9%) and Si (99.99999%) with Ba:Si at.% ratios of 36:64 (Ba-rich) and 30:70 (Si-rich) by the vertical Bridgman growth method. XRD analysis revealed that the grown crystals were semiconducting orthorhombic $BaSi_2$. The samples produced were polycrystalline consisting of single-crystal grains. Optical absorption measurements were carried out to identify the different types of optical transition at room temperature. All of the bulk orthorhombic $BaSi_2$ grown exhibited an indirect transition with an indirect band gap energy ($E_G^{Indirect}$) of 1.13 eV.

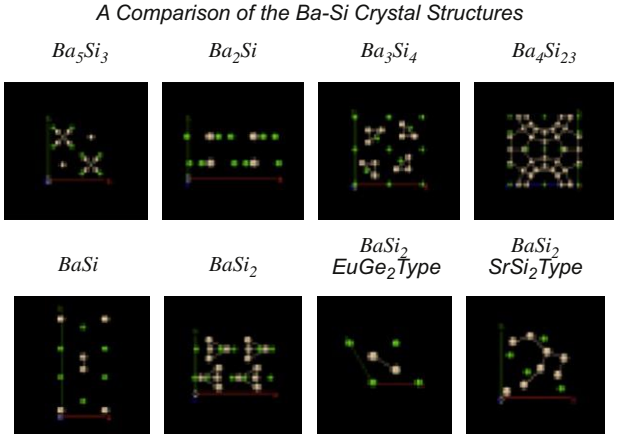

FIGURE 5.24

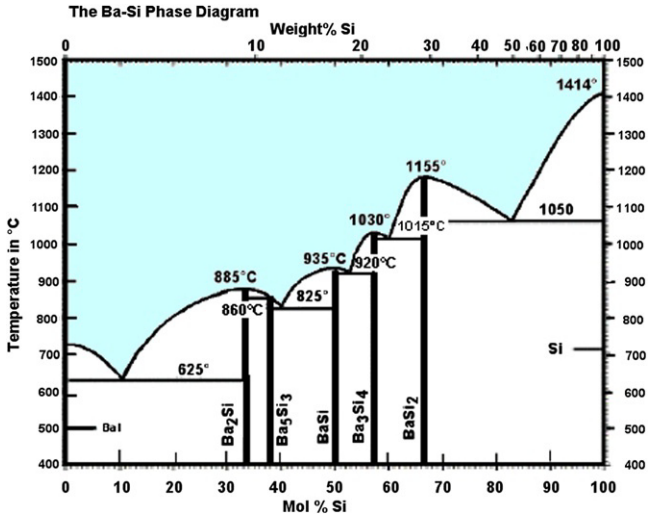

FIGURE 5.25

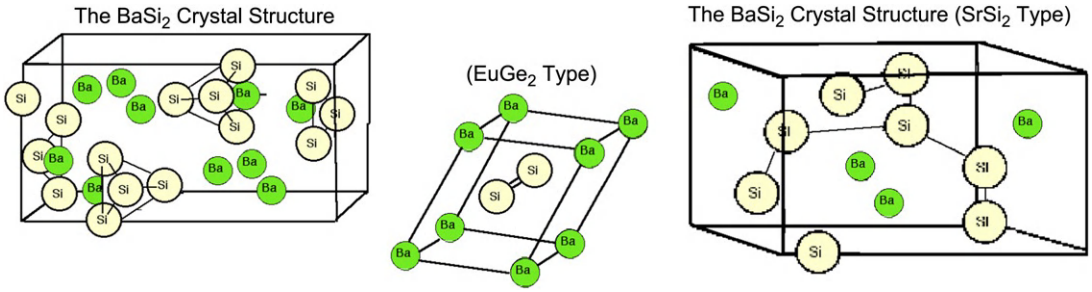

FIGURE 5.26

The structure of barium di-silicide may be represented as shown in Fig. 5.26.

Emission from photoluminescence measurements made at 15 K, seemed to be due to indirect transitions, and revealed that there were probably impurities and crystal defects present. To understand the experimental results, the electronic band structure from first principles using a local density approximation in the all-electron full potential linearized augmented plane wave method was calculated. The calculation is consistent with the experimental indirect band gap results giving an indirect band gap of 0.72 eV and a direct gap of 0.81 eV. The band gap arises from the Si-3p orbitals, while Ba-5d orbitals are strongly hybridized with the Si-3p orbitals in the conduction band.

In situ XRD measurements revealed the transition sequence of cubic and trigonal $BaSi_2$ from orthorhombic $BaSi_2$ at high pressures and high temperatures. The electrical resistivity measurements of three polymorphs show that the electrical properties depend on the crystal structure: orthorhombic $BaSi_2$ is an *n*-type semiconductor as previously reported; cubic $BaSi_2$ is an *n*-type semiconductor; trigonal $BaSi_2$ is a "hole-metal" conductor that shows superconductivity with an onset temperature of 6.8 K. $BaSi_2$ has three high-pressure, high-temperature phases: a trigonal, a cubic, and an additional phase, at pressures up to 7 GPa and temperatures up to 1300 K. All transformations between orthorhombic $BaSi_2$I with isolated Si-tetrahedra, trigonal $BaSi_2$II with corrugated Si-layers, and cubic $BaSi_2$III with a three-dimensional three-connected Si-net can be performed in approximately 5 min at high-pressure and high-temperature conditions. At ambient conditions, the difference in molar volume between $BaSI_2$I and $BaSi_2$III is relatively large ($\Delta V_{\text{I-III}} = -6.79\ \text{cm}^3/\text{mol}$) and that between $BaSi_2$III and $BaSi_2$II very small ($\Delta V_{\text{III-II}} = -0.05\ \text{cm}^3/\text{mol}$). Consequently, in the pressure–temperature phase diagram, the boundary (I-III) shows a strong pressure dependence contrary to that of (III-II) which is less dependent on variation of pressure. The triple point between the three solid phases is near 11 kbar and 925 °C. Substitution of divalent metal and quadrivalent metalloid can easily influence the phase relations in $BaSi_2$.

Over the past few years, compounds with clathrate structures have been the focus of much attention due to their good thermoelectric properties, their promising mechanical properties, their potential for optoelectronic applications correlated to their wide band gap [and the recent discovery of superconductivity in type I Ba intercalated Si clathrates, with a maximum superconducting critical temperature obtained for pure Ba_8Si_{46} ($T_c = -9$ K)]. The discovery of a superconducting transition in these doped column-IV sp^3 semiconductors bears much analogy with the superconducting transition in boron-doped diamond. Only recently, the full intercalation of Ba in type I Si-based clathrate compounds has been achieved under high pressure (3 GPa) and high temperature (HP-HT) conditions (800 °C). At lower pressure, around 1.5 GPa and high temperature, a new type of clathrate (type III), $Ba_{24}Si_{100}$, was also obtained [14], which is isotypic with $Ba_{24}Ge_{100}$.

This new type of clathrate structure is closely related to the type I structure. The unit cell contains three different kinds of cages surrounding the Ba guest atoms: eight "closed" Si_{20} cages, 12 "open" Si_{20} cages and four cages composed of eight silicon atoms. It should be noted that the Si atoms forming this last class of cages have sp^2 bonding. Therefore, in each unit cell, 68 Si atoms have sp^3 bonding while 32 Si atoms have sp^2 bonding. Thus, contrary to the type I clathrate which is only composed of sp^3 silicon atoms, this type III clathrate structure possesses both sp^2 and sp^3 bondings.

Because superconductivity with strong covalent bonding is atypical, the study of such kinds of superconducting compounds is of great interest. Within this class of compounds, the alkali-doped fullerenes, MgB_2 or the highly B-doped diamond and Si-based superconductors are found. Among the Ba-based silicide compounds, it should be noted that only type I Ba-based clathrate compounds and the metastable trigonal phase of $BaSi_2$ (synthesized under high-temperature and high-pressure conditions) have been found to be superconducting and both possess a sp^3 Si lattice. The two other forms of $BaSi_2$, the orthorhombic and the cubic ones, have sp^2 type Si bonds, are *n*-type semiconductors and do not superconduct. The compound, Ba_3Si_4, has the structure shown in Fig. 5.27.

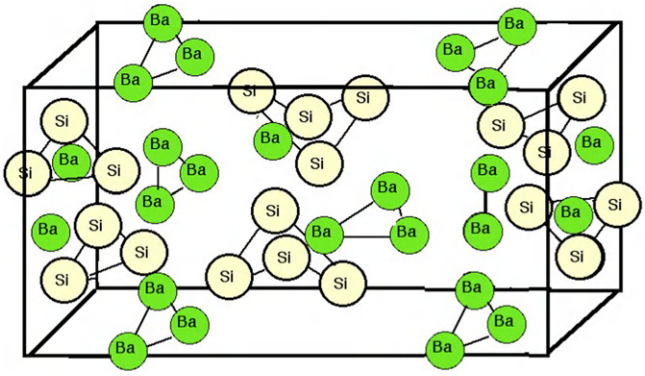

FIGURE 5.27

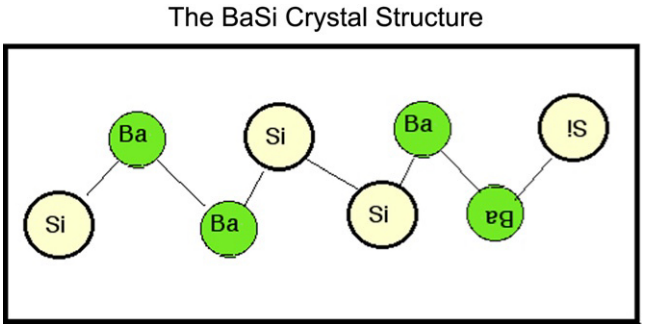

FIGURE 5.28

In addition, it is superconducting. In contrast, the compound, BaSi, is not superconducting and has the structure shown in Fig. 5.28.

The superconductivity of the type III helical cubic clathrate $Ba_{24}Si_{100}$ was investigated. The onset of the superconducting transition is observed at $T_c = 1.55 \pm 0.05$ K. This is the first observation of a Si-based superconductor having both sp^2 and sp^3 bondings. The magnetic superconducting state is investigated from the determination of the critical fields H_{c1} and H_{c2} by AC susceptibility measurements. It was determined that $Ba_{24}Si_{100}$ is a type II superconductor with moderate electron–phonon coupling. The comparison with the other superconducting clathrate Ba_8Si_{46}, based only on sp^3 silicon atoms and which superconducts at 8 K, points out that the presence of sp^2 Si bondings in $Ba_{24}Si_{100}$ is an important parameter to take into account for explaining the moderate electron–phonon coupling and the lower superconducting critical temperature in $Ba_{24}Si_{100}$ (Table 5.23).

Single crystals of the Ba-containing silicon clathrate superconductor $Ba_{7.76}Si_{46}$ were prepared using a high-pressure and high-temperature condition (3 GPa, 1300 °C). It crystallized in the cubic space group *Pm*-3*n* with $a = 10.3141(7)$ Å and $Z = 1$. There are two crystallographically different types of Ba sites, at the centers of Si dodecahederal (Ba at Si_2O) and Si tetrakaidecahedral (Ba at Si24) cages. On evacuation at 527 °C, a part of Ba atoms were removed from the Ba at Si_2O sites. The superconducting transition temperature (T_c) decreased from 9.0 to 6.0 K with the decrease of the Ba content from 7.76 to 6.63 Ba/Si_{46}. The Ba-deficient sites and the deficiency were determined by the structural refinement in the single-crystal X-ray analyses. The structure is shown in Fig. 5.29.

Although barium silicides have many interesting physical properties, their usage in industry has not yet materialized. Perhaps this is due to the higher cost and the fact that no superior aspect of quality has emerged over the other alkaline earth silicides. Nevertheless, barium silicides, in high purity, are offered for sale commercially.

Radium Silicides

Radium silicide has the molecular formula of Ra_2Si and the molecular weight of gm/mol. There have been no reports on the preparation of radium silicide. A variety of alkaline earth silicides has been prepared but there is insufficient evidence that any of the possible radium silicides have ever been synthesized. The expected compounds would include:

Ra_2Si(Co_2Si type) Ra_5Si_3(Ba_5Si type)
RaSi(CrB type)
Ra_3Si_4(Ba_3Si_4 type)
$RaSi_2$($BaSi_2$ type)

However, in view of the radioactive nature of ^{226}Ra, and the lack of demand for such a salt, the likelihood that they will ever be prepared is nil to none.

5.2.3. Alkaline Earth Silicates

The alkaline earths form an enormous number of compounds with oxy-silicon anions, i.e. Si_xO_y

TABLE 5.23 Fundamental Superconducting Parameters of Barium-based Type III and Type I Group IV Clathrates

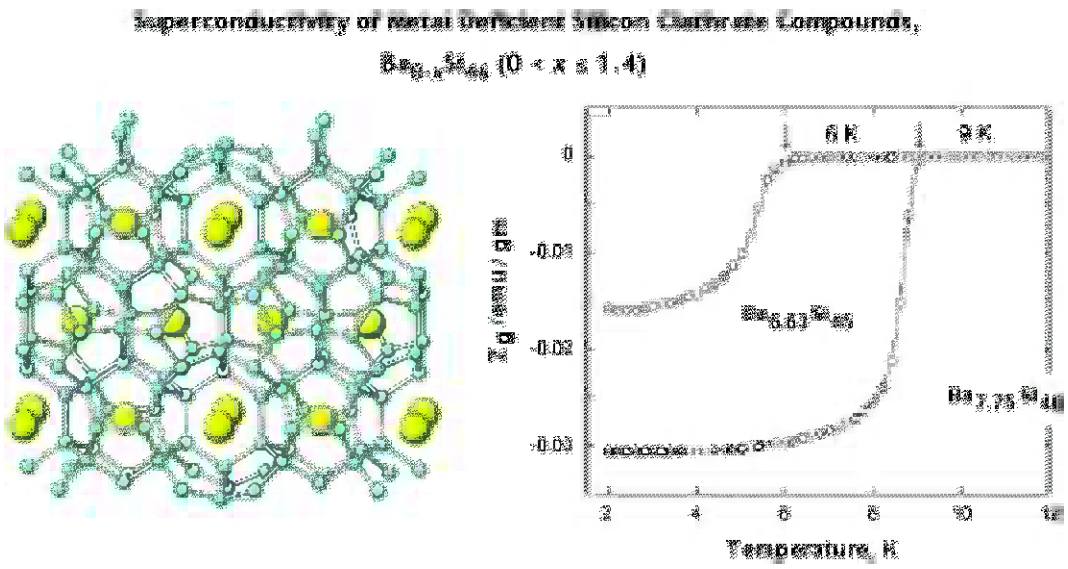

FIGURE 5.29

compounds (where x and/or y can range from 1 to 25 or more). In some silicates, the Si atoms clearly show an amphoteric character so that some Si atoms act as donors (bases) adopting an octahedral coordination, whereas most of the others behave as acceptors (acid), adopting a tetrahedral coordination. The chemistry of silica and silicates has been widely studied. Silicates are the most interesting and the most complicated class of all minerals. Approximately, 30% of all minerals are silicates and some geoscientists estimate that 90% of the earth's crust is made up of silicates. They also play an important role in daily life. Thus, silicates are present in raw materials and many industrial products such as glass, concrete and many ceramic materials. Their widespread application is due to the large variability of their properties and this, in turn, is due to the very large number of different silicate phases and the diversity of their structures.

Concerning the structural chemistry of silicates, the Inorganic Crystal Structure Database (ICSD), Release 2004, contains 3192 entries of binary, ternary and quaternary silicates. Silicates have often been described on the basis of an ionic model, i.e. a dense packing of O^{2-} anions in which Si^{4+} cations seem to fit into interstitial tetrahedral voids. However, several experimental studies of the electron density distribution clearly indicate that the Si–O bond has a considerable covalent character. Thus, a model that considers silicates as formed by either isolated or condensated [SiO_4] tetrahedra seems to be more appropriate. Thus, following this descriptive model, silicates have been classified into monosilicates, oligosilicates, ring silicates, chain silicates, layer silicates and tectosilicates according to the type of polyanion present in the structure. One of the major problems (from our viewpoint) is that most of the alkalis and transition elements cations readily substitute into these structures and are major contributors to their physical and chemical properties. Thus, any given formula can be quite lengthy.

In view of this difficulty in describing the alkaline earth silicates, we shall limit the current discussion to **"Binary"** silicates like Ca_2SiO_4 ($2CaO{\cdot}SiO_2$) or $CaSiO_3$ ($CaO{\cdot}SiO_2$), that is—the so-called "ortho-" or "meta-" silicates, etc.

The book "*Structural Chemistry of Silicates*" is an ornately and profusely illustrated survey of the structures of crystalline silicates which contains an extensive study of the bonding and structures of these compounds [Friedrich Liebau, (1985) *Structural Chemistry of Silicates*. Springer Publ. Co., Berlin, Heidelberg, New York—Library of Congress #- QD181.S6 L614 1985]. In it, the structures are classified and described following a criterion of increasing complexity of the silicate polyanions. However, it should be pointed out that the reasons why these polyanions adopt a given structure are far from being explained. This is the reason why the so-called "rich variety" of condensated silicate polyanions has been considered, in many instances, as "capricious".

The structures of monosilicates, oligosilicates, ring silicates, chain silicates, layer silicates and tectosilicates are shown in the following Fig. 5.30.

The mineral wadsleyite is a high-pressure phase having the composition, Mg_2SiO_4, a monosilicate. Disilicates are characterized by isolated $[Si_2O_7]^{6-}$ anions. $Ca_3Si_2O_7$ (the mineral rankinite) is such a compound.

Oligosilicates consist of "bound" $Si_2O_7^{6-}$ groups within an overall structure of "oxy-" groups such as belkovite = $Ba_3Nb_6[Si_2O_7]_2{\cdot}O_{12}$, or baghdadite = Ca_3Zr

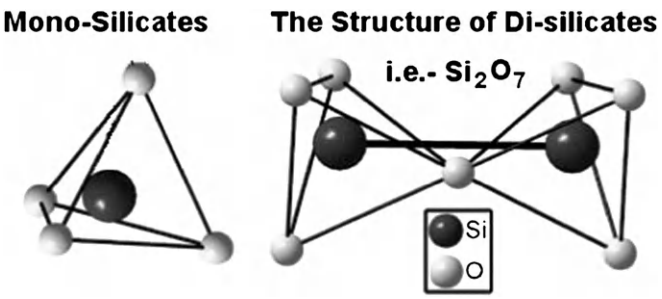

FIGURE 5.30

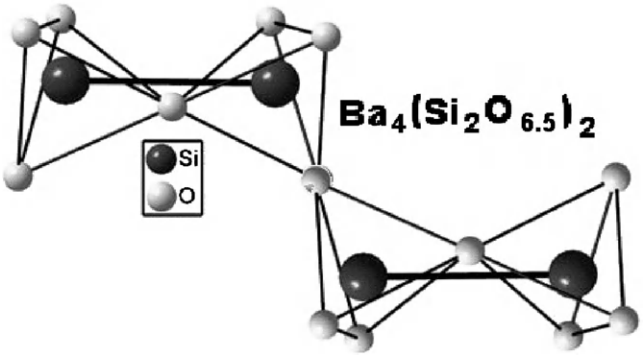

FIGURE 5.31

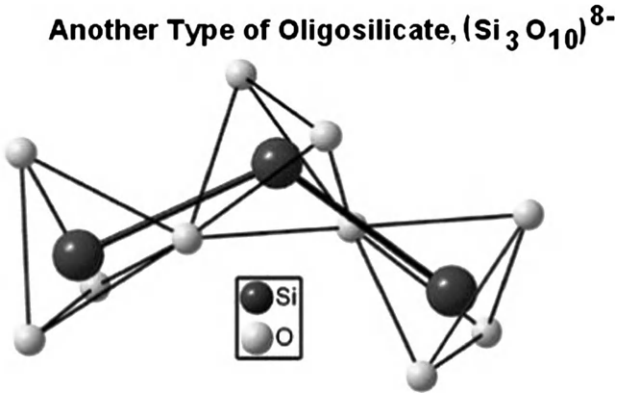

FIGURE 5.32

$[Si_2O_7]\cdot O_2$ while other disilicates consist of isolated $[Si_2O_7]^{6-}$ anions within the structure. Another oligosilicate has the formula of $Ba_4[Si_4O_{13}]$ wherein the two $[Si_2O_7]$ groups are connected by an oxygen atom (Fig. 5.31).

Still another type of oligosilicate is shown in Fig. 5.32.

Ring silicates are illustrated as shown. The structures of the ring silicate anions $[Si_3O_9]^{6-}$, $[Si_4O_{12}]^{8-}$, $[Si_6O_{18}]^{12-}$ and $[Si_{12}O_{36}]^{24-}$ are shown in Fig. 5.33.

The mineral "papagoite", $Sr_4[Si_4O_{12}]$, has such a structure. Double-ring structures such as $Si_6O_{15}^{6-}$ are also known.

Chain structures are illustrated by wollastonite, $Ca_3[Si_3O_9]$. Both "chain-branched" and "loop-branched" silicate structures have been established.

The following diagram shows the internal structure of such SiO_4^{4-} chain-tetrahedra (Fig. 5.34).

In addition, chain silicates are compiled according to their chain multiplicity into single-, double-, triple-, quadruple- and quintuple-chain silicates. Within each of these groups, the tetrahedra are arranged with regard to "branchedness" (unbranched, open-branched and loop-branched), and further classified according to their chain periodicity. The mineral, "tremolite" has the molecular structure of $Ca_2Mg_5Si_8O_{22}(OH)_2$ and this "double-looped single-chain" structure.

"Layered" structures are just what the word implies. A layered structure is seen in the following Fig. 5.35.

An example is the mineral "sanbornite"—$Ba[Si_2O_5]$. A whole variety of "layered silicates" are known which we will not elaborate upon. All silicates in which $[XO_4]$ tetrahedra form 3D tetrahedron frameworks by sharing oxygen atoms are called tectosilicates. The vast majority of tectosilicates contain only four-connected tetrahedra so that each framework oxygen atom is linked to two X atoms and is, therefore, two-connected. As a consequence, the ratio between X atoms and framework O (or more generally T) atoms in the unit cell is $z = \sum n(O)/\sum n(X) = 2$. For such tectosilicates, the term "fully linked" tectosilicates has been suggested. There is relatively small number of tectosilicates which contain $[XO_4]$ tetrahedra that are linked to less than four others, i.e. which contain, exclusively or in addition to three-connected Q3 units, also Q4 units and, very rarely, also Q2 and Q1 tetrahedra. These silicates necessarily contain nonbridging framework O atoms and their atomic ratio z is higher than 2.

To summarize, the principal types of arrangement of silicon–oxygen radicals that we will address are:

(a) isolated tetrahedrons of $[SiO_4]^{4-}$ with octahedrons of Mg and Ca
(b) $[Si_2O_7]^{6-}$ groups formed from two tetrahedrons
(c) hexagonal rings of $[Si_3O_9]^{6-}$
(d) chains of $[SiO_3]^{2-}$
(e) double chains of $[Si_4O_{11}]^{6-}$
(f) sheets of hexagonal rings of $[Si_4O_{10}]^{4-}$

These are illustrated in the following Fig. 5.36.

Therefore, the type of compounds that we will address here are the binary silicates based upon the acids:

Metasilicic acid (H_2SiO_3) = metasilicates (monosilicates)

Orthosilicic acid (H_4SiO_4) = orthosilicates (monosilicates)

Disilicic acid $(H_2Si_2O_5)$ = phyllosilicates

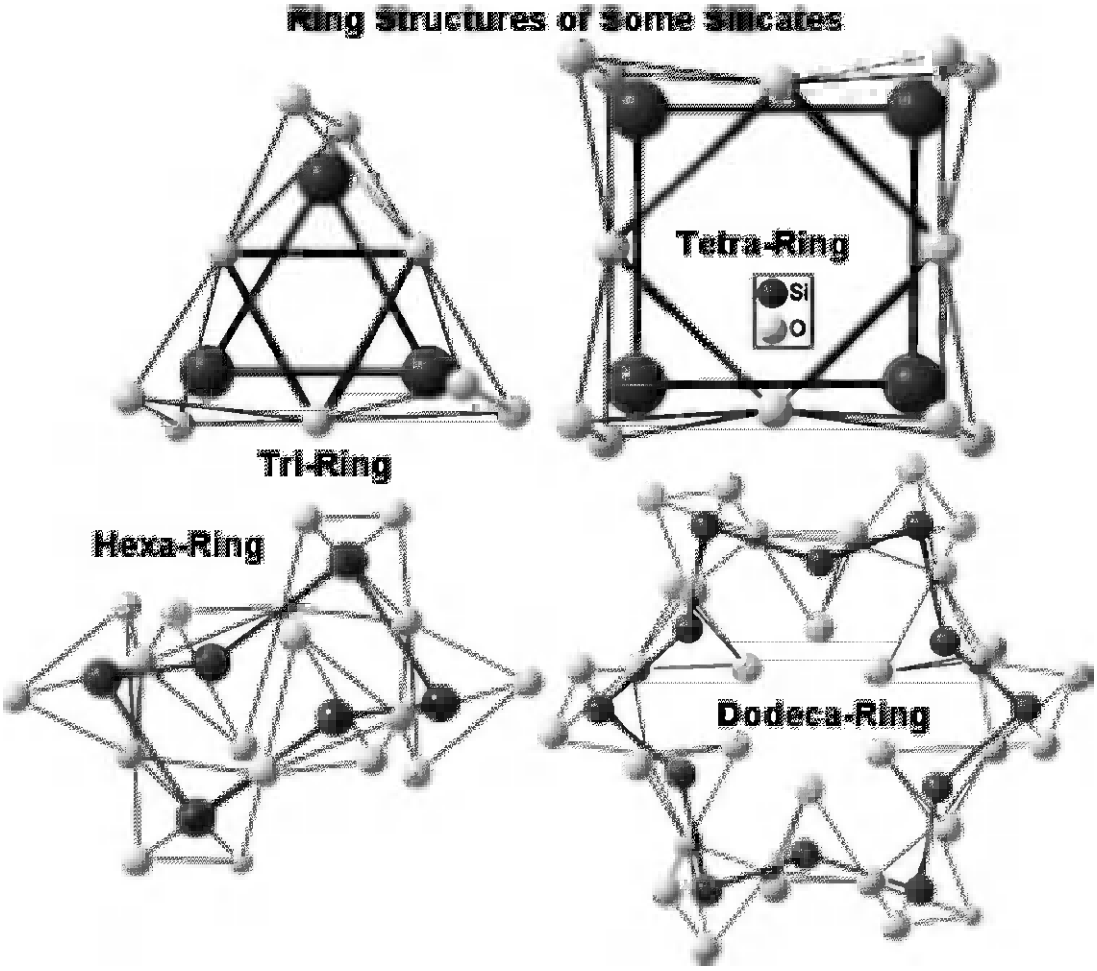

FIGURE 5.33

Pyrosilicic acid ($H_6Si_2O_7$) = pyrosilicates (disilicates)

$$Tri-ring\ structures\ =\ Si_3O_9{}^{6-}\ \text{etc.}$$

In addition, where known alkaline earth chain structures have been utilized in industry and/or studied in Academia, these types of compounds are included in this survey (but only if they conform to the binary $MO{\cdot}SiO_2$ motif).

In general, the alkaline earths form a number of silicates including the "orthosilicates = $M_2SiO_4 = 2MO{\cdot}SiO_2$" and the "metasilicates = $MSiO_3 = MO{\cdot}SiO_2$". The terms "meta-" and "ortho-" are now regarded as obsolete. The following diagram, presented on a following page, summarizes the types of known silicates (which are numerous). These silicates are synthesized by varying the ratio of MO to SiO_2 in a solid-state reaction (SSR) (Fig. 5.37).

$$x\text{MO} + y\text{SiO}_2 + \text{heat} \Rightarrow \text{M}_x(\text{SiO}_3)_y$$

Mg is anomalous and is plotted separately as part of the diagram (making it a ternary one). Melting points of some of the calcium silicates are given to show the range of melting points of these compounds. Not all of these possible silicates are formed by either Ca or Sr. Only Ba forms all of these (plus one more—1:3).

Beryllium Silicates

Beryllium silicate can be prepared by calcining the oxide with silica, SiO_2, at an elevated temperature:

$$\text{BeO} + \text{SiO}_2 + \text{heat} \Rightarrow \text{BeSiO}_3$$

The so-called "metasilicate" results. This compound appears in nature as beryl, $(BeSiO_3)_3{\cdot}Al_2(SiO_3)_3 = Be_3Al_2(SiO_3)_6$, which is a double salt. This is a chain silicate related to a ring-silicate structure. When two oxygen of SiO_4^{4-} units share bonds with other SiO_4^{4-} units, the silicates form a ring or an infinite chain. The stoichiometry of the silicate becomes $(SiO_3)_n^{2n-}$. Single-chain structures have the empirical formula $MSiO_3$ and were often called "metasilicates" in the older literature, a term that lingers in industrial usage but should now be regarded as obsolete. In natural minerals, these chains are ionically bound together by interstitial metal ions such as Be^{2+}, Mg^{2+}, Fe^{2+}, or Al^{3+}.

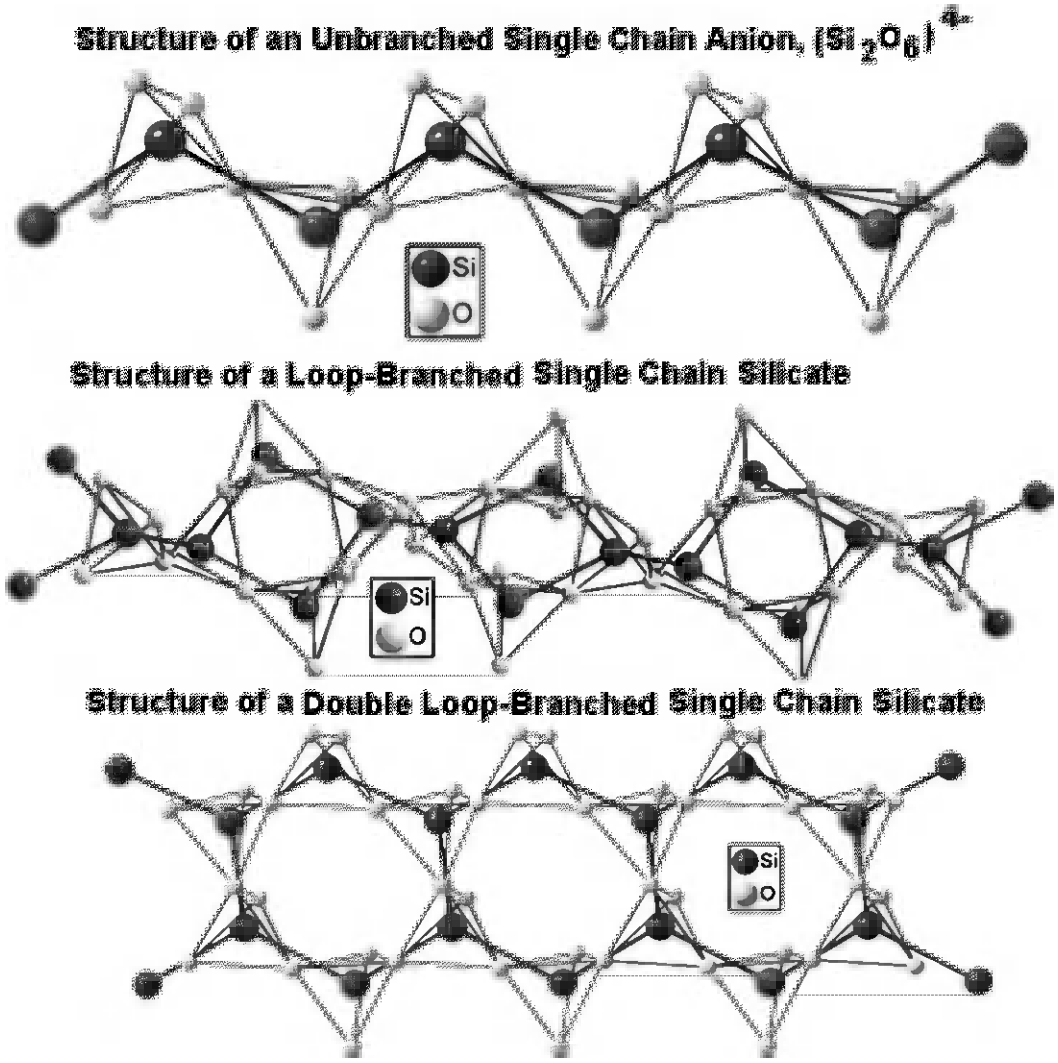

FIGURE 5.34

Beryllium used in industry begins as a silicate ($BeSiO_3$) in beryl and bertrandite ores. More than 20 minerals containing beryllium are known but most of them are rare. The most important are bertrandite ($Be_4Si_2O_7(OH)_2$), Beryl ($3BeO{\cdot}Al_2O_3{\cdot}6SiO_2$), phenacite ($2BeO{\cdot}SiO_2 = Be_2SiO_4$), and chrysoberyl ($BeO{\cdot}Al_2O_3 = BeAl_2O_4$), of which beryl is the most abundant and in fact is the only one of commercial importance. The beryllium aluminate, chrysoberyl, which can be obtained directly from the ore, has interesting possibilities because of its high-melting temperature (about 1880 °C). In a very pure crystalline form, beryl occurs as gems such as blue-green aquamarine and green emerald.

In the system, $BeO–SiO_2$, only two compounds appear in the phase diagram shown here. Both melt congruently (Fig. 5.38).

Phenacite is a fairly rare nesosilicate mineral consisting of beryllium orthosilicate, Be_2SiO_4. The name "phenacite", or the alternate spelling, "phenakite", was named in 1833 by Nordenskiold from the Greek for "deceiver" because it was often mistaken for quartz. In 1811, 20 years before, it was recognized as a new mineral, phenacite was identified as "White Tourmaline". Phenacite is trigonal–rhombohedral in structure with the point group, $\bar{3}$, space group = R $\bar{3}$ and unit-cell parameters of: $a = 12.472$, $c = 8.252$, $Z = 18$; $V = 1111.63$ Å^3, Den(Calc) = 2.96. Occasionally, used as a gemstone, phenacite occurs as isolated crystals, which are rhombohedral in structure with parallel-faced hemihedrism, and are either lenticular or prismatic in habit. The hardness is high, being 7.5–8 Mohs; the specific gravity is 2.96 g/cc. The crystals are sometimes perfectly colorless and transparent, but more often they are grayish or yellowish and only translucent; occasionally they are pale rose-red (Fig. 5.39).

Phenacite is found in high-temperature pegmatite veins and is associated with quartz, chrysoberyl and

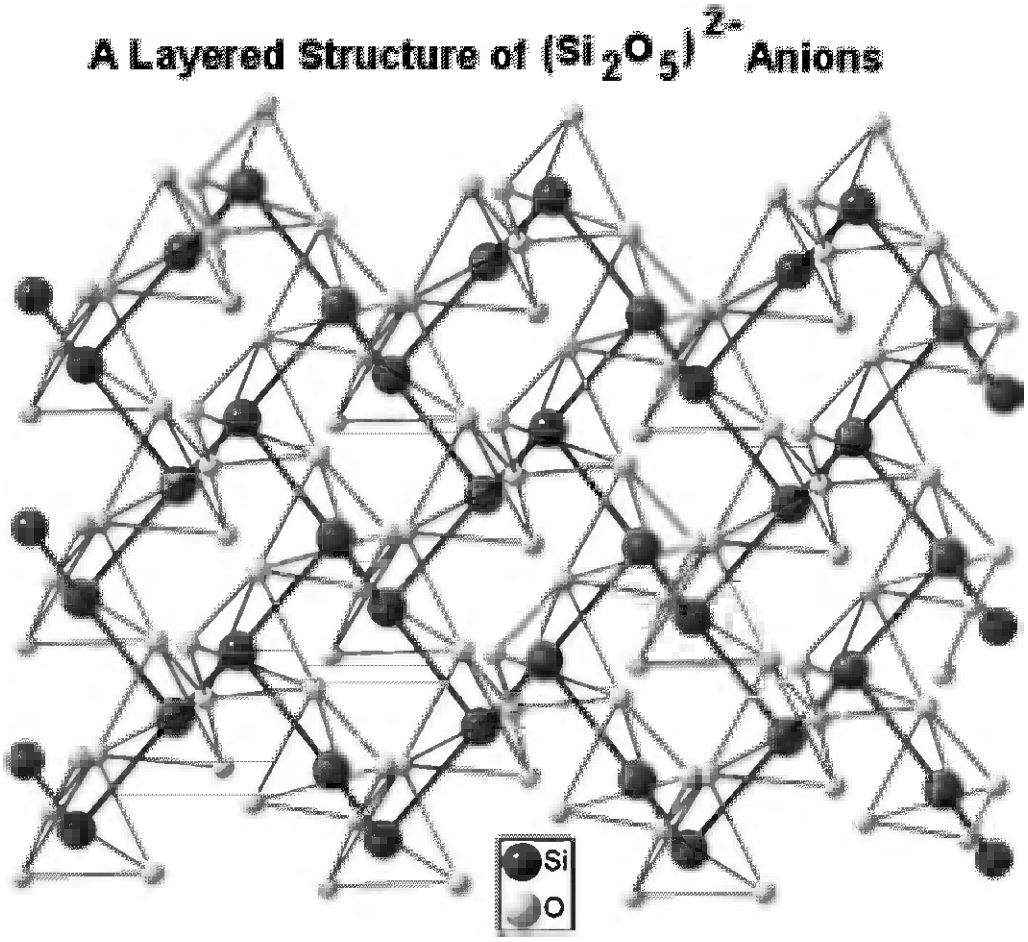

FIGURE 5-35

topaz. It has long been known from the Chrysoberyl mine on the Takovaya stream in Russia, where large crystals occur in mica-schist. It is also found with topaz and amazon stone in Colorado and Maine, USA. Large crystals of prismatic habit have been found in a Norway. The structure of phenacite is illustrated in the following diagram, presented below. The structure consists of a three-dimensional network of corner-linked, slightly distorted BeO_4 and fairly regular SiO_4 tetrahedra. The lattice of these materials consists of SiO_4 and BeO_4 tetrahedra, which are bound to each other and form chains oriented along the principal crystallo-graphic axis C_3. The chains form voids in the form of wide channels ~4.5 Å in diameter. In this diagram, the lighter tetrahedrons are oriented upward while the darker ones are oriented downward. A specific feature of phenacite-structure crystals is that the [SiO_4] tetrahedra are separated, i.e. they do not touch each other. All oxygen atoms on the phenacite lattice are three-coordinated, and each of them is shared by three tetrahedra, namely, two [BeO_4] and one [SiO_4].

The compound, Be_2GeO_4, has a similar structure. The heat of formation for Be_2SiO_4 has been found to be: $\Delta H_f^0 = -497.57$ kcal/mol and $\Delta G_f^0 = -470.22$ kcal/mol at 298 K. When heated above 700 °C, phenacite decomposes to BeO and SiO_2. Thermal expansion and high-temperature crystal structures of phenakite and chrysoberyl have been determined by X-ray methods at several temperatures to 690 °C. Phenakite (hexagonal, space group $R\bar{3}$) has a slightly anisotropic thermal expansion and average expansions between 25 and 690 °C perpendicular and parallel to the c axis are $\eta_1 = 5.2 \times 10^{-6}/°C$ and $\eta_2 = 6.4 \times 10^{-6}/°C$, respectively. The unit-cell volume of phenakite over this temperature range is given by the polynomial expression: $V = 1102.9 + 0.010\,T + 1.1 \times 10^{-5}\,T^2$. Chrysoberyl (orthorhombic, space group Pbnm) has nearly isotropic thermal expansion, with maximum expansivity of $8.5 \times 10^{-6}/°C$ parallel to the b axis, and minimum expansivity $7.4 \times 10^{-6}/°C$ parallel to a axis. The c axis expansivity is $8.3 \times 10^{-6}/°C$. Chrysoberyl volume between 25 and 690 °C may be represented by: $V = 227.1 + 0.003\,T + 4 \times 10^{-6}\,T^2$. The thermal expansion of beryllium, aluminum, and silicon cation coordination polyhedra in phenakite and chrysoberyl are similar to values found in previous studies of minerals

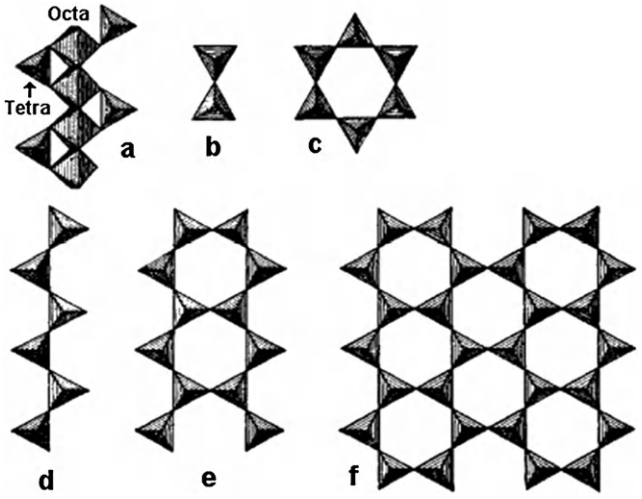

FIGURE 5.36

in the $BeO–Al_2O_3–SiO_2$ system. High-temperature structure studies of bromellite (BeO), beryl ($Be_3Al_2Si_6O_{18}$), phenakite and chrysoberyl all have beryllium tetrahedra that display the same near-zero expansion at room temperature, but increasing expansion at higher temperatures.

Beryllium silicates are available commercially but are usually processed to obtain the oxide and metal.

Magnesium Silicates

Magnesium silicate is very important in the earth sciences because it is the material that makes up most of the volume of the Earth. Magnesium silicate can be prepared by calcining the oxide with silica, SiO_2, at an elevated temperature:

$$MgO + SiO_2 + \text{heat} \Rightarrow MgSiO_3$$

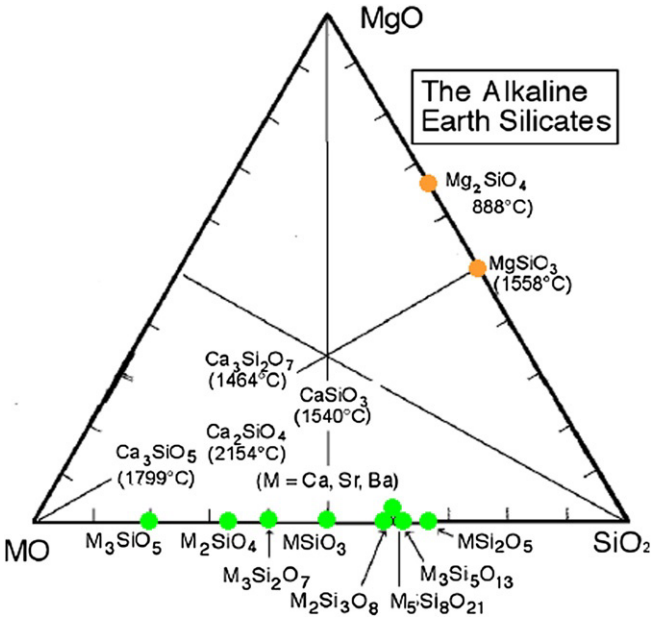

FIGURE 5.37

The so-called "metasilicate" results. In the phase diagram of $MgO–SiO_2$, only two compounds are seen whereas in the $CaO–SiO_2$ phase system, five compounds are apparent.

Magnesium is a major and ubiquitous "rock-forming" entity and magnesium silicates and expanded silicates are found in a majority of rocks and minerals. The relationships in the ternary diagram of $CaO–MgO–SiO_2$ are shown in the following Fig. 5.40.

The optimized $CaO–MgO–SiO_2$ system at 1 bar (Jung, 2003) is shown. Temperatures in parentheses are congruent melting points. The other temperatures are critical points in the ternary system. The abbreviations used include: Ak = Akermanite; Crs = Cristobalite;

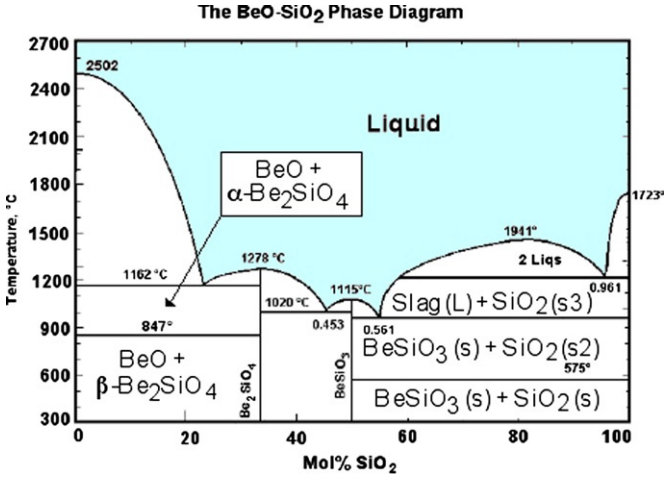

FIGURE 5.38

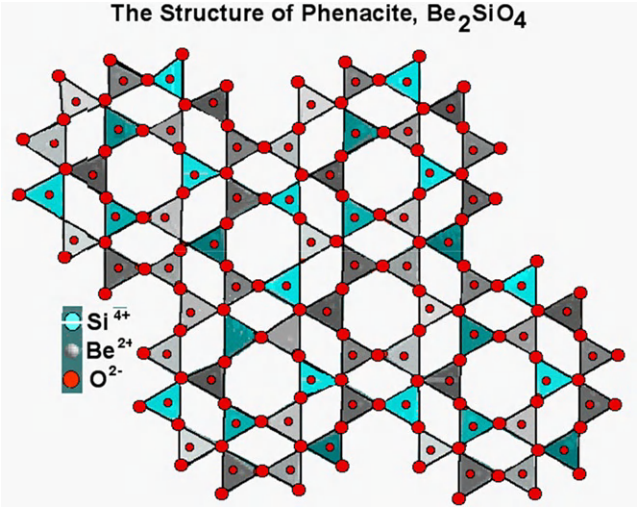

FIGURE 5.39

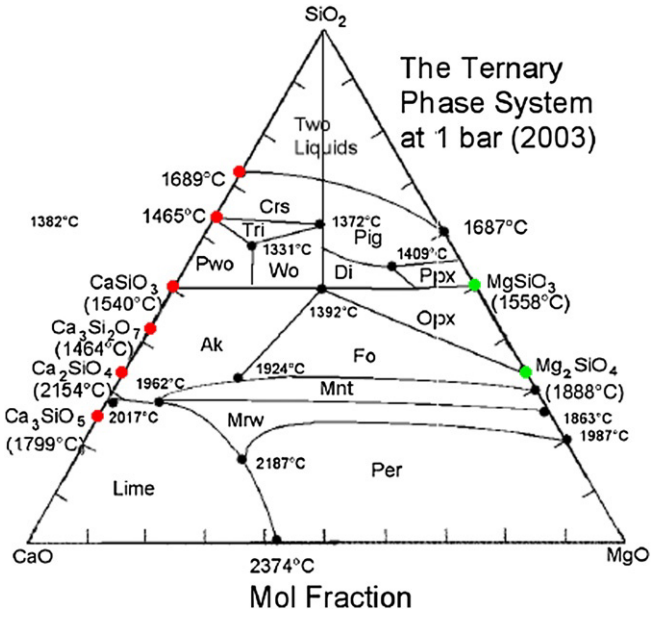

FIGURE 5.40

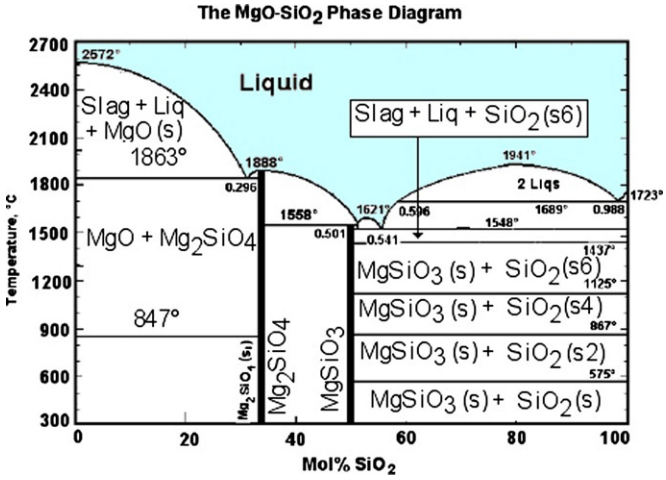

FIGURE 5.41

Di = Diopside; Fo = Forsterite; Mnt = Monticellite; Mrw = Merwinite; Opx = Orthopyroxene; Per = Periclase; Pig = Pigeonite; Ppx = Protopyroxene; Pwo = Pseudowollastonite; Tri = Tridymite; Wo = Wollastonite.

This diagram covers most of the known minerals found within the earth's crust. The system CaO–MgO–SiO_2 has been extensively studied in the past at low (Bowen, 1914; Schairer and Yoder, 1962; Kushiro, 1972; Longhi and Boudreau, 1980) and high pressures (Kushiro, 1969) because it includes forsterite, enstatite and diopside, which are major constituents of peridotitic (85%) and basaltic rocks.

The subsystem diopside–forsterite–silica has been very useful in providing a framework for the understanding of complex phase equilibria of natural basaltic rocks. The recognition that silica-saturated liquids may be generated by partial melting of peridotites at pressures up to 2.0 GPa pH_2O (Kushiro, 1969) is an excellent example of how experiments in this subsystem (dry and wet) have provided insight into the petrogenesis of igneous rocks.

Only two magnesium silicates appear in the binary phase diagram. These are $MgSiO_3$ and Mg_2SiO_4. This phase diagram is shown in Fig. 5.41.

Forsterite (Mg_2SiO_4) is the magnesium-rich end-member of the Olivine solid solution series. Forsterite crystallizes in the orthorhombic system (space group = Pbnm) with cell parameters $a = 4.75$ Å (0.475 nm), $b = 10.20$ Å (1.020 nm) and $c = 5.98$ Å (0.598 nm).

Forsterite is associated with igneous and metamorphic rocks and has also been found in meteorites. In 2005, it was also found in cometary dust returned by the "Stardust" probe in space. Experimental studies have shown that a number of dense hydrous magnesium silicates are stable at mantle pressures, corresponding to depths greater than 200 km: e.g. phase A, phase B, phase E, super hydrous phase B but also hydrous Wadsleyite and Ringwoodite, the high-pressure modifications of forsterite.

Two polymorphs of forsterite are known: "Wadsleyite" (also orthorhombic) and "Ringwoodite" (isometric). Both are mainly known from meteorites. Peridot is the Forsterite gemstone found in the mineral "olivine". Forsterite reacts with silica to form the orthopyroxene mineral "enastite" as shown in the following reaction:

$$Mg_2SiO_4 + SiO_2 + \text{heat} \Rightarrow 2MgSiO_3$$

The structure of Forsterite involves both octahedral and tetrahedral sites, as shown in the following Fig. 5.42.

In the diagram, the SiO_4^{2-} groups are clearly shown as well as the two Mg octahedral sites in green colors. The cations occupy two different octahedral sites generally labeled as and form isolated ionic bonds with the silicate

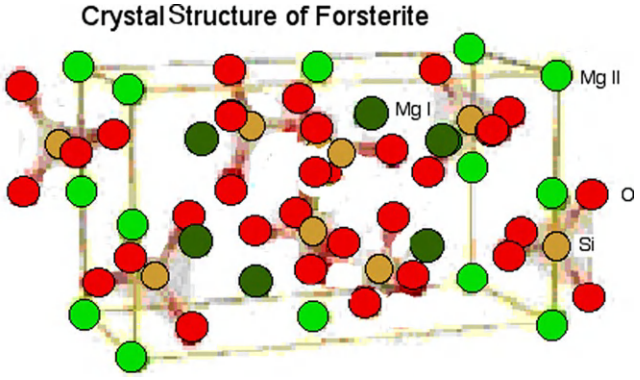

FIGURE 5.42

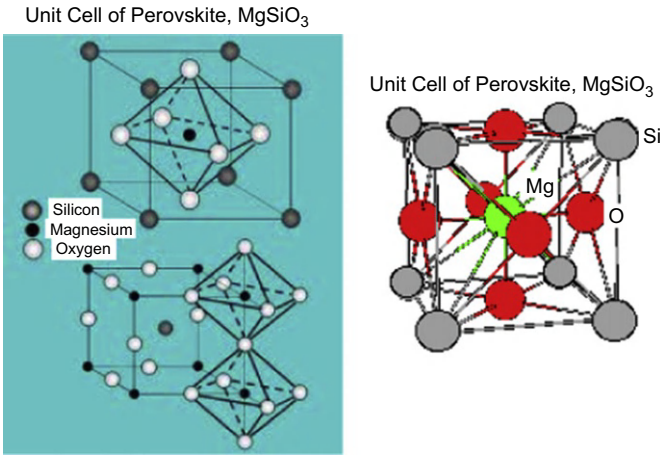

FIGURE 5.43

anions. MgI and MgII are slightly different. The MgII site is larger and more regular than MgI. The packing in forsterite structure is dense. The space group of this structure is Pbnm and the point group is 2/m, 2/m, 2/m which is an orthorhombic crystal structure.

Magnesium silicate perovskite ($MgSiO_3$) is thought to be the major phase in the earth's lower mantle (660–2900 km depth). It is orthorhombic. The structure is presented in the following Fig. 5.43.

The MgO_6 octahedra are shown both in the unit cell and in the environments of the SiO_4 tetrahedra. The Forsterite and Perovskite structures are related. A molecular dynamics simulation of the perovskite $MgSiO_3$ gave evidence for a phase transition from the orthorhombic to a tetragonal phase at about 2600 K on heating the crystal under a constant pressure of 310 kbar. Enstatite (orthorhombic—$a = 18.228$ Å, $b = 8.805$ Å, $c = 5.185$ Å, $Z = 8$; $V = 832.18$ Å^3, Den(Calc) = 3.20 g/cc) is the magnesium end-member of the pyroxene silicate mineral series "enstatite" ($MgSiO_3$)—"ferrosilite" ($FeSiO_3$).

The magnesium-rich members of the solid-solution series are common rock-forming minerals found in igneous and metamorphic rocks. The intermediate composition, $(Mg,Fe)SiO_3$, has historically been known as "hypersthene", although this name has been formally abandoned and replaced by "orthopyroxene". When determined petrographically or chemically, the composition is given as relative proportions of enstatite (En) and ferrosilite (Fs) (e.g. $En_{80}Fs_{20}$). Most natural crystals are orthorhombic (space group = Pbca) although four polymorphs are known. The high-temperature, low-pressure polymorphs are protoenstatite and protoferrosilite (also orthorhombic, space group = Pbcn) while the low-temperature, low-pressure forms, clinoenstatite and clinoferrosilite, are monoclinic (space group = P21/c).

Glasses made from the magnesium silicate minerals enstatite ($MgSiO_3$) and forsterite (Mg_2SiO_4) and three intermediate compositions can be considered as analogues of quenched melts from the earth and lunar mantle. Combined neutron and XRD data show an abrupt change in glass structure in the narrow compositional range 38% SiO_2 to 33% SiO_2 (Mg_2SiO_4). These structural changes reflect a change from a glass characterized by corner-shared SiO_4 tetrahedra and an approximately equal mixture of MgO_4 and MgO_5 polyhedra, to one in which the average coordination of magnesium by oxygen is increased from 4.5 ± 0.1 to 5.0 ± 0.1. Both these local environments are very different from that of their crystalline counterparts. The change in structure is associated with a discontinuous change in the rheological properties of these glass-forming liquids close to the forsterite composition.

Diopside is a monoclinic pyroxene mineral with composition $MgCaSi_2O_6$. It is an important rock-forming mineral in several metamorphic and basic to ultrabasic igneous rocks, and is also found in meteorites. It forms complete solid-solution series with "hedenbergite" ($FeCaSi_2O_6$) and "augite" $[(Ca,Na)(Mg,Fe,Al)(Si,Al)_2O_6]$ and partial solid solutions with "orthopyroxene" $[(Mg,Ca)(Si,Al)_2O_6]$ and "pigeonite" $[(Ca,Mg,Fe)(Mg,Fe)Si_2O_6)]$. The diopside–hedenbergite series is analogous to the amphibole series. Diopside has several varieties, including a chromium-rich gem variety called chrome diopside. Diopside forms variably colored, but typically dull green crystals in the monoclinic prismatic class. It has two distinct prismatic cleavages at 87 and 93° typical of the pyroxene series. It has a Mohs hardness of six, a Vickers hardness of 7.7 GPa at a load of 0.98 N, and a density of 3.25 to 3.55 g/cc. It is transparent to translucent with indices of refraction of $\eta_1 = 1.663–1.699$, $\eta_2 = 1.671–1.705$, and $\eta_3 = 1.693–1.728$. Violan is a rare blue variety found in some localities in Italy. There is also a green "cat's-eye" variety that contains minute inclusions, that reflect light in such a way as to produce a lively linear luminescence within the crystal.

Magnesium forms a series of phyllosilicates (from the Greek *phyllon*, leaf), or sheet silicates, and forms parallel sheets of silicate tetrahedra with Si_2O_5 of a 2:5 ratio. Hydroxy silicates are known. These minerals have the formula of $Mg_3Si_2O_5(OH)_4$ but differ in the actual lattice construction. "Antogorite" $[(Mg, Fe)_3Si_2O_5(OH)_4]$, lizardite $\{Mg_3[(OH)_4Si_2O_5]\}$ and "crysotile" all belong to the "serpentine" group of minerals. It is not clear whether these compositions are actually double salts of $2Mg(OH)_2 \cdot MgSi_2O_5$ or not. They definitely are not hydrates. Most of these minerals form as rocks. Rock composed primarily of these minerals is called "serpentinites".

Serpentines find use in industry for a number of purposes, such as railway ballast, building materials, and the asbestos-form types find use as thermal and

electrical insulation (chrysotile asbestos). The asbestos content can be released to the air when serpentine is excavated from the mine and if it is used as a road surface, forms a long-term health hazard to humans by breathing. Asbestos from serpentine can also appear at low levels in water supplies through normal weathering processes, but there is as yet no identified health hazard associated with use or ingestion. In its natural state, some forms of serpentine react with carbon dioxide and re-release oxygen into the atmosphere. Antigorite is the polymorph of serpentine that most commonly arises during metamorphism of wet ultramafic rocks and is stable at the highest temperatures—to over 600 °C at depths of 60 km or so in the earth. In contrast, lizardite and chrysotile typically form near the earth's surface and break down at relatively low temperatures, probably well below 400 °C. It has been suggested that chrysotile is never stable relative to either of the other two serpentine polymorphs.

Talc (derived from the Persian word for talk) is a mineral composed of hydroxy magnesium silicate with the chemical formula of $H_2Mg_3(SiO_3)_4$ or $Mg_3Si_4O_{10}(OH)_2$. In loose form, it is the widely used substance known as "talcum powder". It occurs in nature as foliated to fibrous masses. It is monoclinic but so rare that as to be almost unknown. It is very soft and can be easily cut with a knife. As the defining mineral for the value of 1,0 on the Mohs-hardness scale, it can be easily scratched by a fingernail. It has a density of 2.5–2.8 g/cc, a clear or dusty "luster", and is translucent to opaque. Talc is not soluble in water, but it is slightly soluble in dilute mineral acids. Its color ranges from white to gray and it has a distinctly greasy feel. Soapstone is a metamorphic rock composed predominantly of talc.

A hydrated magnesium silicate has been examined at 20 GPa and 1200 °C. The single crystal has composition $Mg_{1.11}Si_{1.89}H_{2.22}O_6$ (ideal formula: $MgSi_2H_2O_6$ or $MgSiO_5 \cdot H_2O$), trigonal, cell parameters $a = 4.7453$, $c = 54.3450$ Å, and $V = 5\ \ 84.74$ Å^3, and space group = P31m. The crystal structure is relatively simple with all the Si-occupying octahedral sites in a layer similar to that of brucite, but with one of every three Mg octahedra vacant. The MgO_6 octahedra are located above and below each vacant octahedral site. All O–H bonding occurs between SiO_6 octahedral layers. This is the only high-pressure hydrous magnesium silicate structure reported to date that contains all octahedrally coordinated Si. The calculated density of phase D ($d_{cal} = 5\ \ 3.50$ g/cm^3) is substantially greater than any other high-pressure hydrous magnesium silicate phase.

A synthetic magnesium silicate adsorbent is offered for sale as a white fine powder, amorphous, with vesicular structure and huge specific area. It is an amphoteric compound capable of absorbing either acid or alkali metal catalyst. It is an efficient refining and purifying agent in the production of polyols for its excellent depicking, deodorizing, potassium ion absorbing effects and function as a filter medium.

Magnesium silicate is offered for sale with a CAS number of 1343-88-0 but the actual composition has not been forthcoming. A number of differing compositions have been listed. Asbestos is a fibrous silicate of magnesium and calcium. However, the "extender", known as "asbestine", that has come to the forefront in paint making, is really a ring silicate of magnesia and slightly alkaline, but without the fibrous texture of asbestos or amianth. Asbestine pulp (as a certain variety of the material mined at the foot of the Adirondack mountains is known to the trade), although it is sold in the dry powdered form, belongs really to the soapstone or talc variety. But it is not as unctuous as either of those, has a harder texture, and is of whiter color than either soapstone or talc.

Soapstone or talc is used for toilet powder and as a lubricant by shoemakers, also on dancing floors, in fillers, Putties and cements, but not as a rule in paints for general usage. Asbestine pulp or asbestine in its various varieties has been used for many years by manufacturers of paints, not so much as an adulterant, but rather to make the paint more buoyant in order to keep it from settling to any extent, as this compound is of very low-specific gravity and a great oil absorber. This feature, however, depends on the location where it is mined, as there is a wide divergence in that respect. Its specific gravity varies between 2.3 and 2.7 and its oil absorption is between 30 and 36%, or in other words, to make a paste in oil will require 70 pounds of the heavier asbestine to 30 pounds of oil or 64 of the lighter asbestine pulp to 36 pounds of oil. Asbestine is used to some extent in making liquid fillers for soft wood, and certainly much better than silica. Mixed with silicate of soda (water glass) it makes a very good fireproof coating. Asbestine is as inert as barytes or silica, and does not undergo a chemical combination with oil or water, but will be found sometimes more or less alkaline, and while it may be safely used as an extender with almost any color.

A number of magnesium silicates are offered for sale commercially, worldwide from many manufacturers.

Calcium Silicates

The term, calcium silicate, is often used to refer to a group of chemical compounds formed from CaO and silica, SiO_2. In general, calcium silicates are not prepared by dissolving a soluble calcium salt and adding a solution of sodium silicate. One of the reasons is that sodium silicate is not well defined and contains a variety of silicate chains and structures. A hydrate is known and is the product formed when Portland cement "cures" as

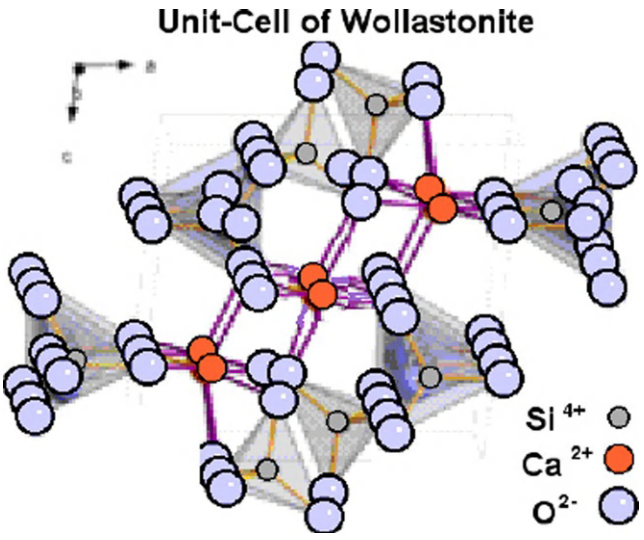

FIGURE 5.44

a result of the reaction between the contained silicate phases and water. This reaction typically is expressed as:

$$2Ca_3SiO_5 + 7H_2O \Rightarrow 3CaO{\cdot}2SiO_2{\cdot}4H_2O + 3Ca(OH)_2 + 173.6\ kJ$$

The stoichiometry of the hydrate in cement paste is variable and the state of the chemically and physically bound water in its structure is not clear.

Thus, calcium silicate can be prepared by calcining the oxide with silica, SiO_2, at an elevated temperature:

$$CaO + SiO_2 + heat \Rightarrow CaSiO_3$$

At a molar ration of 1:1, the metasilicate, $CaSiO_3$ results. "Wollastonite" occurs as a calcium inosilicate mineral that may contain small amounts of Fe, Mg and Mn substituting for calcium. An "inosilicate" is a chain silicate (from the Greek, Inos = fiber). The structure involves interlocking chains of silicate tetrahedra with either SiO_3, 1:3 ratio, for single chains or Si_4O_{11}, 4:11 ratio, for double chains. The manufactured salt is usually white. It forms within the earth when impure limestone is subjected to high temperature and pressure, sometimes in the presence of silica-bearing fluids as in metamorphic rocks. It is named after the English chemist and mineralogist William Wollaston (1766–1828). The structure is shown above in Fig. 5.44.

Some of the properties that make wollastonite so useful are its high brightness and whiteness, low moisture and oil absorption, and low-volatile content. Wollastonite is used primarily in ceramics, friction products (brakes and clutches), metalmaking, paint filler, and plastics. Despite its chemical similarity to the compositional spectrum of the Pyroxene group of minerals, it is structurally very different, with a third SiO_4 tetrahedron in the linked chain (as opposed to two in the pyroxenes). Wollastonite crystallizes as a triclinic crystal with

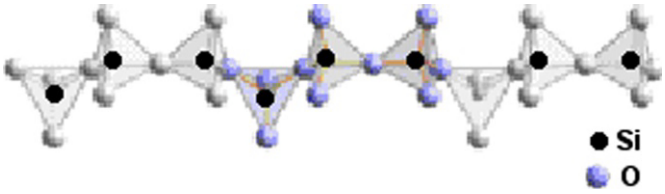

FIGURE 5.45

the space group, 1, and the lattice constants: $a = 7.94$ Å, $b = 7.32$ Å, $c = 7.07$ Å; $\alpha = 90.03°$, $\beta = 95.37°$, $\gamma = 103.43°$ and six formula units per cell (Fig. 5.44).

This is a chain structure and the arrangement of the SiO_4^{4-} tetrahedral are shown in Fig. 5.45.

Wollastonite was once classed structurally among the pyroxene group, because both of these groups have a ratio of Si:O = 1:3. In 1931, Warren and Biscoe showed that the crystal structure of wollastonite differs from minerals of the pyroxene group, and they classified this mineral within a group known as the pyroxenoids. It has been shown that the pyroxenoid chains are more kinked than those of pyroxene group, and exhibit longer repeat distance. The structure of wollastonite contains infinite chains of $[SiO_4]$ tetrahedra sharing common vertices, running parallel to the *b*-axis. The chain motif in wollastonite repeats after three tetrahedra, whereas in pyroxenes only two are needed. The repeat distance in the wollastonite chains is 7.32 Å and equals the length of the crystallographic *b*-axis. Wollastonite occurs as bladed crystal masses, single crystals can show an acicular particle shape and usually it exhibits a white color, but sometimes cream, gray or very pale green. The melting point of wollastonite is about 1540 °C.

In 2005, China was the top producer of wollastonite with at least 50% world share followed by India and the USA. In the United States, wollastonite is mined in New York state. Deposits have also been mined commercially in Northwestern Mexico. Wollastonite has industrial importance worldwide. It is used in many industries, mostly by tile factories that have incorporated it into the manufacturing of ceramic to improve many aspects, and this is due to its fluxing properties, freedom from volatile constituents, whiteness, and acicular particle shape. It can also be used in paint, paper, and vinyl tile manufacture. In some industries, it is used in different percentages of impurities such as its use as, a fabricator of mineral wool insulation, or as an ornamental building material. Wollastonite usually occurs as a common constituent of a thermally metamorphosed impure limestone, it also could occur when the silicon is due to metamorphism in contact altered calcareous sediments, or to contamination in the invading igneous rock. In most of these occurrences, it is the result

of the following reaction between calcite and silica with the loss of carbon dioxide:

$$CaCO_3 + SiO_2 \rightarrow CaSiO_3 + CO_2$$

Wollastonite may also be produced in a diffusion reaction in "skarn". It develops when limestone within a sandstone is metamorphosed by a "dyke", which results in the formation of wollastonite in the sandstone as a result of outward migration of Ca.

The chemical compound, Ca_2SiO_4, is also known as calcium orthosilicate and sometimes formulated $2CaO \cdot SiO_2$. Calcium orthosilicate is a white powder with a low-bulk density and absorbs water freely. It is used as an anticaking agent and an antacid. A free-flowing powder derived from limestone and silica, calcium silicate has no known adverse effects to health. It is used in roads, insulation, bricks, roof tiles, table salt and occurs in cements. Calcium orthosilicate is commonly used as a safe alternative to asbestos for high-temperature insulation materials. Industrial grade piping and equipment insulation are often fabricated from calcium orthosilicate. This compound has the CAS number of 1344-95-2 and the molecular weight of 116.1578 g/mol.

The phase diagram of this binary system is shown in the following Fig. 5.46.

Four compounds are relatively stable:

1:1 = $CaSiO_3$ = monosilicate
3:2 = $Ca_3Si_2O_7$ = disilicate
2:1 = Ca_2SiO_4 = orthosilicate
3:1 = Ca_3SiO_5 = layered structure

The compound, $Ca_2Si_3O_7$, is unstable and is not shown here. $CaSiO_3$ melts congruently at 1540 °C while $Ca_3Si_2O_7$ melts incongruently at 1464 °C. The compound, Ca_2SiO_4 is trimorphic and undergoes structural transformations at 847°, 1300°, and 1437°. It melts congruently at 2154 °C. At 25 mol% with CaO, the compound, Ca_3SiO_5, forms but only if the temperature reaches >1300 °C. It melts incongruently and decomposes into CaO and Ca_2SiO_4 at 1799 °C. $Ca_3Si_2O_7$ appears in nature as the mineral "rankinite". It is monoclinic with unit-cell constants of: space group: P21/, $a = 10.557$ Å, $b = 8.885$ Å, $c = 7.858$ Å, $V = 1195.86$ Å^3, $Z = 4$. Point Group = 2/m. It is found in Scawt Hill, near Larne, Co. Antrim, Ireland, found near Kilchoan, Ardamurchan, Argyllshire, and Camas Mor, Isle of Muck, Scotland. It appears in Golden Gully, Tokatoka district, Auckland, New Zealand at Fuka, near Bicchu, Okayama Prefecture, Japan. In the Christmas Mountains, Brewster Co., Texas, USA, in the Hatrurim Formation, at Hatrurim and Ma'aleh Adumim, Israel and in the Lower Tunguska River basin, central Siberia, Russia. Another variant, Kilchoanite, is orthorhombic with cell constants of: space group: Imam or Ima2: $a = 11.42$ Å, $b = 5.09$ Å, $c = 21.95$ Å, $Z = 8$, point group: 2/m 2/m 2/m or mm2. It is found solely in Kilchoan, Scotland and is isomorphous with rankinite. It has apparently formed in limestones, thermally metamorphosed by invasion of gabbro and is thought to have formed during retrograde metamorphism following decarbonation of limestone and thus under low pressure of CO_2. It is a retrograde replacement of rankinite that is a disilicate and has the structure shown in Fig. 5.47.

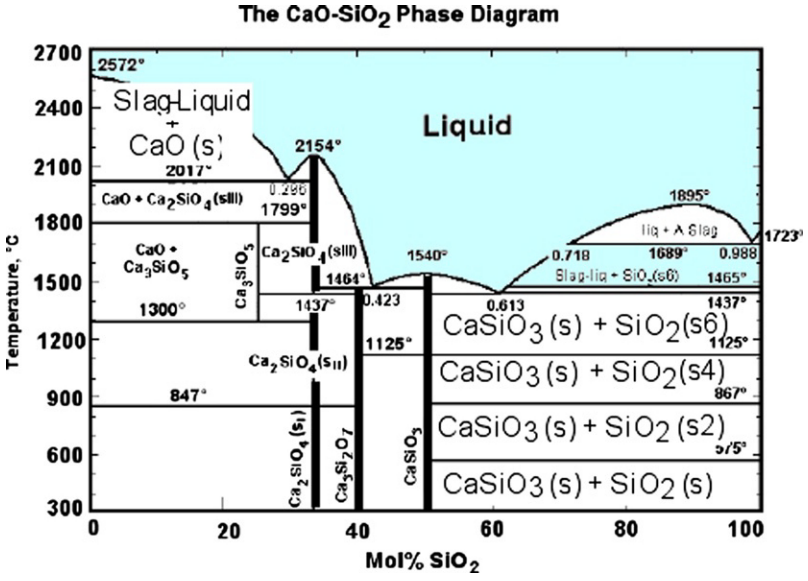

FIGURE 5.46

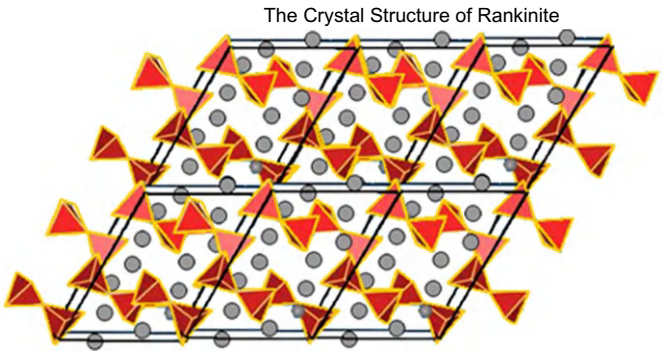

FIGURE 5.47

In this structure involving dimers, a series of disilicate chains interspersed with calcium atoms exists. Rankinite is unstable at the temperature 1510 °C and dissociates through diffusion mechanisms[1] according to the formula:

$$Ca_3Si_2O_7 + \text{heat} \Rightarrow 2CaSiO_3 + CaO$$

Thus, it is clear that wollastonite ($CaSiO_3$) is more thermodynamically stable than rankinite ($Ca_3Si_2O_7$).

A green emitting phosphor was prepared by SSR and its structure was confirmed to be $Ca_3Si_2O_7$:Eu^{2+} by XRD. The photoluminescence (PL) results showed that this phosphor is efficiently excited by ultraviolet (UV)–visible light in the wavelength range from 250 to 450 nm and emits intensely green light with a broad peak at around 521 nm, causing it to exhibit a bright green emission.

Ca_3SiO_5 occurs in nature as "Hatrurite". It contains small amounts of Al^{3+} and Ti^{4+} as cations. The structure is trigonal–ditrigonal pyramidal with point group (3m) and space group: R 3m. Unit cell dimensions are: $a = 7.151$ Å, $c = 25.562$ Å, $Z = 9$; $V = 1131.63$ Å^3, Den(Calc) = 3.02 g/cc. It is a brownish-red to colorless crystal with a hardness of 6 Mohs.

The thermal decomposition of pure Ca_3SiO_5 has been studied at temperatures between 1025 and 1210°. The results show that decomposition is initiated by formation of nuclei of Ca_2SiO_4 and CaO at the surface of Ca_3SiO_5 grains. The presence of CaO or Ca_2SiO_4 increases the apparent rate of decomposition, largely by eliminating the need for a separate nucleation period. A Ca_3SiO_5:Eu^{2+} phosphor was synthesized by the sol-gel reaction method. The emission spectrum exhibits one asymmetric band centered at 505 nm, under 365 nm excitation, and the excitation spectrum for 505 nm indicates two bands centered at 374 and 397 nm, respectively. The effect of synthesis condition, such as synthesis temperature, synthesis time and Eu^{2+} concentration, on the emission spectrum of Ca_3SiO_5:Eu^{2+} phosphor was investigated. The results show that the emission peak intensity of Eu^{2+} first increases, then decreases with the increase in synthesis temperature or synthesis time or Eu^{2+} concentration, and reaches the maximum value at 1100 °C, for 4 h and 0.5 mol% Eu^{2+}. Ca_3SiO_5 has the CAS number of 71396-54-8.

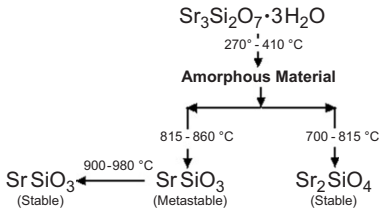

FIGURE 5.48

Calcium silicates are readily available commercially in several forms on a worldwide basis.

Strontium Silicates

Strontium silicate can be prepared by calcining the oxide with silica, SiO_2, at an elevated temperature:

$$SrO + SiO_2 + \text{heat} \Rightarrow SrSiO_3$$

The metasilicate composition results. Three forms of strontium silicate are known: $SrSiO_3$ (monoclinic), the ortho-salt, Sr_2SiO_4 (monoclinic) and the phyllo-salt, Sr_3SiO_5 (tetragonal) that has a layered structure. Only the ortho-salt has a CAS number = 12712-63-9.

Very few studies of strontium silicate hydrate precipitations have been reported. A hydrate can be prepared through an "alkoxy-process". Therein, Si–OC_2H_5 and Sr–OCH_3 were mixed together at a 2:3 molar ratio in an aqueous ammonia solution and heated to 85 °C. The resulting precipitate consisted of $Sr_3SiO_5 \cdot 3H_2O$. This compound was then heated and the products were identified as $SrSiO_3$ and Sr_2SiO_4. A diagram showing the preparation steps involved in heating the pyrosilicate compound to form the metasilicate and/or orthosilicate compound is shown above in Fig. 5.48.

In the SrO–SiO_2 binary system, there are three transition compounds including: $SrSiO_3$, Sr_2SiO_4 and Sr_3SiO_5. The phase diagram is presented as shown in Fig. 5.49.

The pyrosilicate is not seen in the solid-state preparation method. The melting temperature of the Sr_2SiO_4 compound is 2325 °C. The eutectic temperature between Sr_2SiO_4 and Sr_3SiO_5 is 2150 °C at 27 mol% SiO_2. The phase diagrams of the systems Sr_2SiO_4–$SrSiO_3$ and $SrSiO_3$–SiO_2 have been determined experimentally using DTA. The eutectic compositions and temperatures of the Sr_2SiO_4–$SrSiO_3$ and $SrSiO_2$ subsystems are estimated to be 49.3 mol% SiO_2, 1567 °C and 65.8 mol% SiO_2, 1342 °C, respectively. The known compounds,

[1]For a discussion of diffusion mechanisms in silicates, see "Solid-State Chemistry" by RC Ropp, Elsevier (2003), pp 161–168.

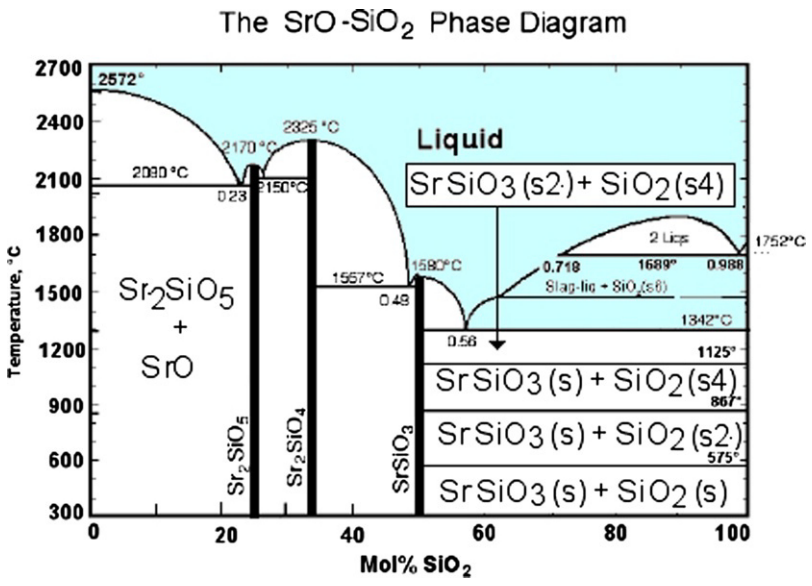

FIGURE 5.49

$SrSiO_3$, Sr_2SiO_4, and Sr_3SiO_3, melt congruently at 1580 ± 15 °C, 2325 ± 15 °C, and 2170 ± 15 °C, respectively. Simple binary eutectics exist between (1) Sr_2SiO_4 and Sr_3SiO_5 at 2150 ± 15 °C and 27 mol% SiO_2 and (2) Sr_3SiO_5, and SrO at 2080 ± 15 °C and 23 mol% SiO_2.

A new type of strontium silicate has been discovered. High-pressure synthesis of the new $SrSi_2O_5$ phase was performed at 16 GPa and 900 °C by using a Kawai-type multianvil apparatus. The powder XRD pattern of the compound was analyzed by Rietveld refinement based on the structure of a high-pressure polymorph of $BaGe_2O_5$, as $BaGe_2O_5$ III. The structure is orthorhombic with space group *Cmca* and cell parameters of $a = 5.2389$ Å, $b = 9.2803$ Å, $c = 13.4406$ Å, $V = 653.46(2)$ Å^3, $Z = 8$, dens $= 4.549$ g/cm^3. The structure consists of layers containing SiO_6 octahedra and SiO_4 tetrahedra. In a unit layer, oxygen and strontium atoms are arranged in an approximation to hexagonal close packing. The strontium atom is accommodated in a 12-coordinated site. Each SiO_6 octahedron shares four corners with SiO_4 tetrahedra and the other two corners with another SiO_6 octahedra. The SiO_6 octahedra are linked to each other to form SiO_6 chains along the *a*-axis. This is the first known example of a silicate with a $BaGe_2O_5$ III-type structure.

A Eu^{2+}-activated strontium silicate (Sr_3SiO_5:Eu^{2+}) yellow-emitting phosphor was prepared by conventional SSR (solid state reaction) techniques in a reducing atmosphere with starting materials of $SrCO_3$, SiO_2 and Eu_2O_3. The phase, morphology and luminescence properties of the samples were analyzed. XRD analysis showed the main phase in all samples to be tetragonal Sr_3SiO_5. With Eu^{2+} ions doped into the host lattice, the Sr_3SiO_5:Eu^{2+} phosphors absorb light energy in the near-UV–visible spectrum region and show an intense broad emission band in the yellow color range (around 570 nm) and a weak band in the blue region (around 470 nm). The excitation and the emission bands originate from the 4f ⇒ 5d transition of Eu^{2+} ions. As the concentration of Eu^{2+} ions increases, the emission peaks of phosphors shift to longer wavelengths. The effective emission in the yellow color indicates that the phosphor has potential usage for preparation of white light-emitting diodes.

The enthalpies of solution, ΔH_{sol}, of $SrSiO_3$ and Sr_2SiO_4 in 3.035 mol/dm^3 HF (aq) + 3.019 mol/dm^3 HCl (aq) have been measured.

From these results, the standard molar enthalpies of formation of $SrSiO_3$(s) and Sr_2SiO_4(s) have been calculated. The values obtained are −1635.3 kJ/mol and −2305.7 kJ/mol, respectively.

The aqueous phase interaction of divalent Sr with silicate-containing solutions was studied over a range of pH values, as a function of dissolved silica, Sr concentrations, and extended to basic solution (0.2 M NaOH) at room temperature (22–23 °C). Formation of an amorphous Sr silicate phase of variable composition was observed, beginning at approximately pH 10. The precipitate became quasi-crystalline at higher base concentrations and with aging time. The phase that formed at high-base concentration (beginning at pH 11.5–12.0) was identified by total chemical analysis, XRD, and thermogravimetric analysis to have a chemical formula of $Sr_5Si_6O_{16}(OH)_2 \cdot 5H_2O$, with a tobermorite-like structure. The $Sr_5Si_6O_{16}(OH)_2 \cdot 5H_2O$ phase has not been previously reported.

In another case, light-brown crystals were discovered growing from the interface of a strontium silicate melt and the containing platinum crucible. The compound turned out to be $Sr_4(PtO_6)\cdot 2Sr_2SiO_4$ with a molecular weight of 1176.21 g/mol. It is monoclinic with $a = 18.830$ Å, $b = 5.744$ Å, $c = 7.172$ Å, $\beta = 110.72°$, $V = 725.547$ Å^3, $Z = 2$ and density = 5.383 g/cc. The structure involves isolated SiO_4 tetrahedra and PtO_6 octahedra. Three of the four nonequivalent Sr atoms are coordinated by o-atoms in distorted trigonal prisms. The fourth is located in a square antiprism that has one small and one large face, i.e. 1/2 of a cubooctahedron. Two of the small faces are shared which produces a short Sr–Sr distance of 3.28 Å.

Strontium silicate is offered for sale as STRONTIUM METASILICATE; strontium silicate(1:1); CAS = 13451-00-8 by several suppliers, notably Chinese. Another type, CAS = 12712-63-9, is offered as "strontium silicate" but is probably the orthosilicate Sr_2SiO_4 (2:1).

Barium Silicates

Barium silicate can be prepared by calcining the oxide with silica, SiO_2, at an elevated temperature:

$$BaO + SiO_2 + \text{heat} \Rightarrow BaSiO_3$$

The so-called "metasilicate" results. Barium silicate has been given the CAS number of 13255-26-0.

The phase diagram of the system BaO–SiO_2 has been studied as shown in the following Fig. 5.50.

Whereas three compounds have been reported in most of the other alkaline earth silicate systems, seven (7) separate compounds were found in this system. The compounds were prepared by varying the molar ratio of BaO to SiO_2 as the 3:1, 2:1, 1:1, 2:3, 5:8, 3:5, and 1:2 before the calcination step.

Ba_3SiO_5 is tetragonal with the space group I4/mcm (D) isotypical with Cs_3CoCl_5. The unit-cell parameters are: $a = 7.3068$ Å, $c = 11.2275$ Å. It is a disilicate. It is stable up to 1800 °C where it decomposes to the orthosilicate:

$$Ba_3SiO_5 + \text{heat} \Rightarrow Ba_2SiO_4 + BaO$$

Ba_3SiO_5 has been used as a host to prepare a yellow-emitting phosphor using the activator, Eu^{2+}. It is easily activated by blue-light of an LED diode to produce a white-emitting LED lamp. The phosphor is formed at 1050 °C but the emission becomes green due to the formation of the Ba_2SiO_4:Eu^{2+} phosphor.

In general, barium containing silicate compounds are of great interest for practical luminescent materials due to higher luminous efficiency of Eu^{2+} in this kind of host lattices. Under UV excitation, Eu^{2+}-doped barium silicates can be roughly classified into two groups according to the emitting color: bluish-green emission, i.e. Ba_2SiO_4:Eu^{2+} ($\lambda_{em} = 504$ and 510 nm), $BaSi_2O_5$:Eu^{2+} ($\lambda_{em} \sim 520$ nm), and $Ba_2Si_3O_8$:Eu^{2+} ($\lambda_{em} \sim 485$ nm); and greenish-yellow emission, i.e.$BaSiO_3$:Eu^{2+} ($\lambda_{em} \sim 550$ nm) and Ba_3SiO_5:Eu^{2+} ($\lambda_{em} = 504$ and 566 nm or 560 and 590 nm). The position of the emission band mainly depends on the chemical composition and crystal structure.

Ba_2SiO_4, the orthosilicate, has the orthorhombic structure, Pnam (62), $Z = 4$, isostructural with α-K_2SO_4, and the unit-cell dimensions of $a = 7.508$ Å, $b = 10.214$ Å, $c = 5.8091$ Å.

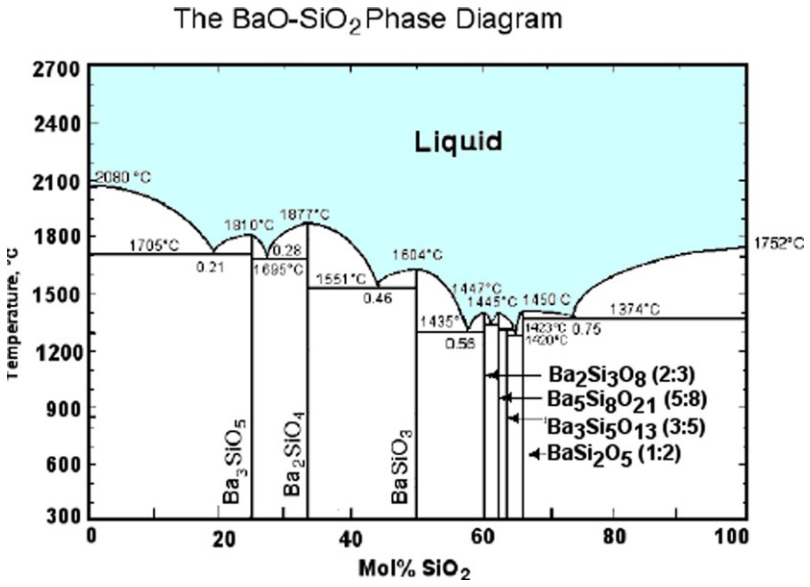

FIGURE 5.50

The enthalpy of solution of Ba_2SiO_4 in 3.15 mol/dm^3 HF + 8.13 mol/dm^3 HCl has been measured. From the results, the standard molar enthalpy of formation of Ba_2SiO_4(s) was been calculated. The value obtained was -2292.2 ± 4.2 kJ/mol.

The system Ba_2SiO_4–Ca_2SiO_4 was studied by heating mixtures of Ba_2SiO_4 and Ca_2SiO_4 at 1723 K. Six distinct phases resulted; they were examined by both XRD and DTA. The phases α-$(Ba_{0.05}Ca_{1.95})SiO_4$ and β-$(Ba_{0.15}Ca_{1.85})SiO_4$ are isostructural with corresponding high-temperature modifications of Ca_2SiO_4. The X phase ($Ba_{0.48}Ca_{1.52}SiO_4$) is orthorhombic and is a pure phase rather than a solid solution. The phase ($Ba_{1.31}Ca_{0.69}SiO_4$) is hexagonal and interpreted in terms of a unit cell with a doubled c parameter, in contrast with literature data.

This salt also forms a double salt with BaO, as $Ba_2SiO_4 \cdot BaO$. It is tetragonal with space group I4/mcm and $a = 7.3023$ Å, $c = 11.2178$ Å, $Z = 4$. Ba_3O-SiO_4 is isostructural with $Cs_3ClCoCl_4$. The SiO_4 tetrahedra are slightly distorted with O–Si–O angles of 110.6° and 107.6°, respectively and a distance of 1.639 Å for the Si–O bonds. The two crystallographically different Ba atoms are coordinated by ten Ba(I) and eight O-atoms at Ba(II) with mean Ba–O distances of 2.988 Å and 2.81 Å, respectively. The structure looks like in Fig. 5.51.

Numerous studies of Eu^{2+}-activated Ba_2SiO_4 have been performed. In one study, Eu^{2+}-activated Ba_2SiO_4 phosphors were synthesized at 1300 °C by SSRs under a weak reductive atmosphere and systematically investigated by photoluminescence excitation and emission spectra, diffuse reflectance spectra, concentration quenching process and lifetime. The intensive green LEDs were fabricated by combining the synthesized phosphors with near-ultraviolet InGaN chips ($\lambda_{em} = 395$ nm). The Commission Internationale de I'Eclairage color coordinate of the fabricated LEDs was calculated to be $x = 0.1904$, $y = 0.4751$ under 20 mA forward-bias current. The dependence of the green LEDs on forward-bias current shows that as the current increases, the relative intensity simultaneously increases and the color coordinates maintain excellent stability, falling in the standard area of the Institute of Transportation Engineers for traffic lights and the Society of Automotive Engineers for automotive displays. These results indicate that the fabricated phosphor-converted green LEDs show great potential for traffic lights and automotive display applications.

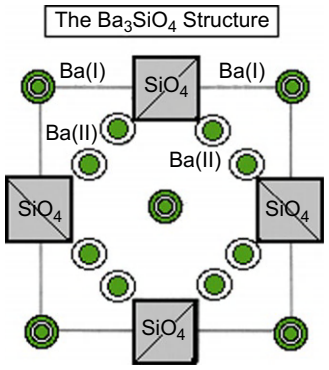

FIGURE 5.51

$BaSiO_3$ is orthorhombic with unit-cell dimensions of $a = 5.6182(5)$ Å, $b = 12.445(1)$, $c = 4.5816$ Å. It is dimorphic with α-$BaSiO_3$ stable below about 990 °C but forms β-$BaSiO_3$ above 1000 °C. A 1:1 mol ratio of BaO–SiO_2 fired at 850 °C and 1050 °C serves to form the two dimorphs.

The enthalpy of solution of $BaSiO_3$ in (3.15 mol/dm^3 HF + 8.13 mol/dm^3 HCl) has been measured. From the results, the standard molar enthalpy of formation of $BaSiO_3$ (s) was calculated. The value obtained was -1606.4 ± 2.6 kJ/mol.

$Ba_5Si_8O_{21}$ is not listed as to structure in the NBS Standard XRD powder patterns monograph.

β-$Ba_2Si_3O_8$ is monoclinic with space group P2i/a (14), $Z = 4$ and lattice constants of $a = 13.960$ Å, $b = 4.6895$ Å, $c = 12.486$ Å, $\beta = 93.54°$. A reversible transformation of β-$Ba_2Si_3O_8$ occurs when heated above 1009 °C to form α-$Ba_2Si_3O_8$.

$Ba_3Si_5O_{13}$ is monoclinic, P2j/c (14), $Z = 4$, with lattice parameters of: $a = 20.208$ Å, $b = 4.7106$ Å, $c = 13.854$ Å, $\beta = 98.62°$.

Sanbornite, **β-$BaSi_2O_5$**, previously described in the literature as triclinic, is orthorhombic with space group Pmmm. The unit cell is: $a_o = 4.6336$ Å, $b_o = 7.6922$ Å, $c = 13.525$ Å, $Z = 4$. There is a high-temperature phase, α-$BaSi_2O_5$, that is stable above 1350 °C. The unit-cell contains four $BaSi_2O_5$ molecules. The structure is a silicate sheet structure with two Si + oro-a sheets per unit cell lying parallel to (001) at 7/4 and 3/4, and two barium ions lying roughly half-way between each successive pair of sheets. Each sheet consists of continuously linked, distorted, six-membered rings of SiO_4 tetrahedra. Unshared vertices of tetrahedra lie on both sides of each sheet. Each barium ion is surrounded by seven near-oxygen ions. Interionic distances are of expected magnitude. The structure is shown in the following Fig. 5.52.

The mineral sanbornite, $BaSi_2O_5$, was first described by Rogers (1932). Only one occurrence in the U.S. is known, near Incline, Mariposa County, California, where it is found with the rare mineral gillespite ($BaFeSi_4O_{10}$) and other minerals. It is known from only one other locality. Sanbornite occurs as white to colorless, translucent to transparent, anhedral plates. The sanbornite deposits at Big Creek and Rush Creek, Fresno County, California are host to many rare barium silicates, including "bigcreekite", UK6, "walstromite" and "verplanckite". Bigcreekite, ideally $BaSi_2O_5 \cdot 4H_2O$, is

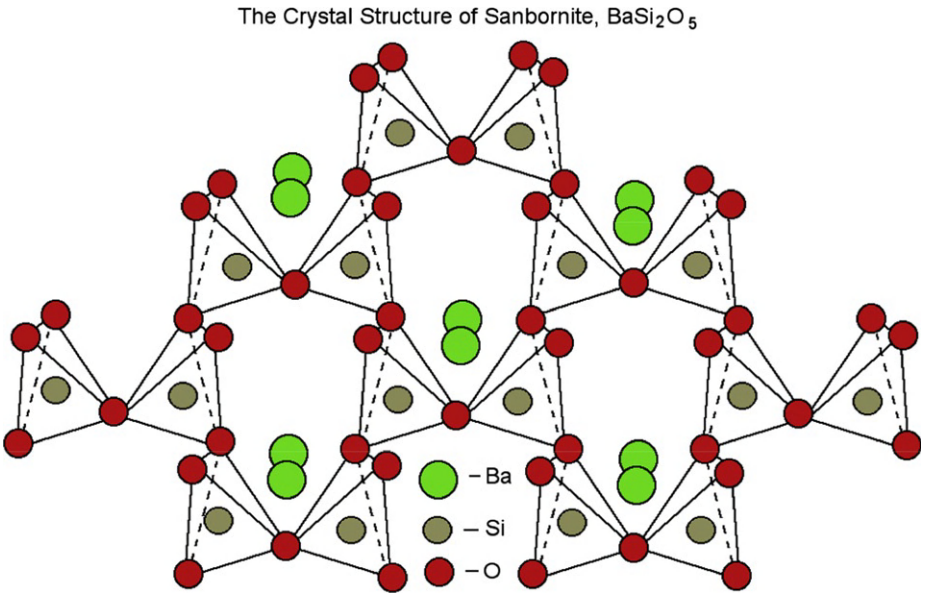

FIGURE 5.52

a newly identified mineral species that occurs along very thin transverse fractures in fairly well-laminated quartz-rich sanbornite portions of the rock.

Bigcreekite is biaxial negative, with indices of refraction $\eta_1 = 1.537(2)$, $\eta_2 = 1.538(2)$, $\eta_3 = 1.541(2)$; $X = b$, $Y = a$, $Z = c$ and $2V_{[submeas]} = 59.2°$, $2V_{[sub\ calc]} = 60.1°$. The crystal structure of bigcreekite was solved as space group Pnma, with cell parameters $a = 5.038$ Å, $b = 9.024$ Å, $c = 18.321$ Å, and $Z = 4$. Bigcreekite is a hydrous chain silicate containing four-membered rings which form chains of silica tetrahedra, parallel to [100] and staggered in the [001] direction. Water molecules fill the large spaces between the rows of silicon tetrahedra. The structure of "bigcreekite" has been solved and is shown in the following diagram shown as Figure 5.53. BigCreekite is a hydrous sheet silicate containing four-membered rings that form chains of silica tetrahedra, $Si_2O_5^{2-}$, parallel to the *a*-axis and staggered along the *c*-axis, with a repeat distance of two tetrahedra. The tetrahedra are connected to the Ba-polyhedra, BaO_9, which form sheets along the (001) direction, resulting in perfect cleavage of the mineral in that direction. The BaO_9 polyhedra are joined together by four-oxygen atoms at the corners. Parts of the O-atoms are those associated with water molecules (Fig. 5.53).

Bigcreekite has similarities to sanbornite and gillespite. Bigcreekite was named for Big Creek, California, its typical locality. Krauskopfite, $BaSi_2O_4(OH)_2 \cdot 2H_2O$, one of the rarer species at the deposits, is restricted to a single site above Rush Creek, where it occurs with macdonaldite in white veinlets up to 5-mm thick (Site 3). Krauskopfite is opaque to translucent white, and occurs as cleavage masses and occasional elongated tabular cleavages on fracture surfaces. Sanbornite is the most abundant of the barium silicates at Big Creek and Rush Creek. Bodies of this mineral host many of the other species. Walstromite, $BaCa_2Si_3O_9$, is the coarsest-grained mineral in the deposits, and is second only to sanbornite in abundance. It occurs widely as clots and layers of interlocking masses and also as isolated anhedral crystals in sanbornite-quartz rock, more frequently within the

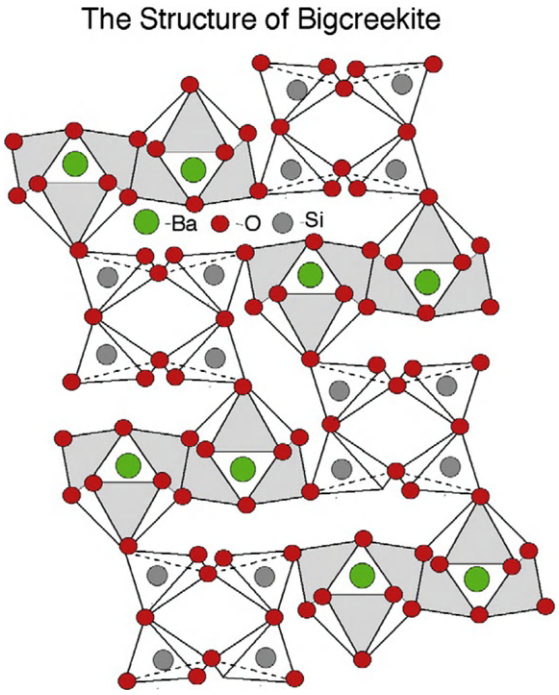

FIGURE 5.53

quartz-rich zones. Walstromite is white to gray with three perfect cleavages, but otherwise is similar in appearance to sanbornite. Twenty-three barium species have been identified from the sanbornite deposits at Big Creek and Rush Creek. Ten are type-locality minerals; the others occur elsewhere and are common to extremely rare. In addition, seven potentially new species are currently known and several are under study.

Barium and strontium silicates have nearly identical physical and chemical characteristics. Thus, studies have been conducted concerning the ternary system: $BaO–SrO–SiO_2$. Phase equilibria in the system $BaO–SrO–SiO_2$ in air were established using conventional solid-state techniques. The phase relations in the boundary system $SrO–SiO_2$ were completed by determining the liquidus temperatures for the SrO-rich portion of the diagram. The known compounds, $SrSiO_3$, Sr_2SiO_4, and Sr_3SiO_3, melted congruently at 1580 ± 15, 2325 ± 15, and 2170 ± 15 °C, respectively. Simple binary eutectics exist between (1) Sr_2SiO_4 and Sr_3SiO_5 at 2150 ± 15 °C and ~27 mol% SiO_2 and (2) Sr_3SiO_5, and SrO at 2080 ± 15 °C and ~23 mol% SiO_2. All alkemade lines were established for the ternary system; two of these joins were examined in detail because of extensive solid-solution regions. On the $Ba_2SiO_4–Sr_2SiO_4$ join, a maximum solubility of ~70 mol% Sr_2SiO_4 in Ba_2SiO_4 appears to exist at 2100 ± 15 °C, the eutectic reaction temperature. A two-phase region apparently connects the eutectic reaction isotherm with a high-temperature polymorphic transition ($\alpha \Rightarrow \beta$) of Sr_2SiO_4. Below this transition temperature, a complete solid-solution series exists between Ba_2SiO_4 and β-Sr_2SiO_4. The $BaSiO_3–SrSiO_3$, join contains limited solid-solution regions at the extremities which arise from the solid solubility of 40 mol% $SrSiO_3$ in the high-temperature (α) polymorph of $BaSiOs_3$ and 20 mol% $BaSiO_3$ in $SrSiO_3$ at 1210 ± 15 °C. The only ternary compound isolated, $BaSrSi_3O_8$, has a lower limit of stability at 1220 ± 3 °C and melts incongruently at 1275 ± 3 °C.

Barium silicates are readily available for sale commercially.

Radium Silicates

Radium silicate can be prepared by calcining the oxide with silica, SiO_2, at an elevated temperature:

$$RaO + SiO_2 + \text{heat} \Rightarrow RaSiO_3$$

The so-called "metasilicate" results. There have been no reports on the preparation of radium silicate. A variety of alkaline earth silicates has been prepared but there is insufficient evidence that any of the possible radium silicates have ever been synthesized. The most likely compound would be the $RaSiO_3$ composition but this synthesis and the physical and chemical properties remain unknown. Perhaps this is due to the lack of interest industrially since the oxide, carbonate and chloride salts are adequate for the purposes to which ^{226}Ra is employed.

5.3. ALKALINE EARTH OXY-GERMANIUM COMPOUNDS

In general, germanium is too electropositive in nature to form anions, i.e. "germanates", in solution. It is possible to fire the oxides together to form a germanate-like $CaGeO_3$ but the possibility of formation of alkaline earth germanates by a solution method is essentially zero. Germanium has but one valence state, that of Ge^{4+} so that GeO_3^{2-} and GeO_4^{4-} anions are possible. However, germanium does not form extensive anions in solution as silicon does.

5.3.1. Alkaline Earth Oxo-Germanium Compounds

Beryllium Germanates

Beryllium germanate can be formed by firing the oxides together at about 650–700 °C:

$$BeO + GeO_2 + \text{heat} \Rightarrow BeGeO_3$$

This is the metagermanate. Three beryllium germanate compounds appear in the phase diagram. They are: $BeGeO_3 = 1{:}1$, $Be_2GeO_4 = 2{:}1$, and $BeGe_2O_5 = 1{:}2$. They all mimic the corresponding silicate in structure. The metagermanate has the perovskite structure shown in Fig. 5.54.

The lattice parameters for the phyllo-compound, $BeGe_2O_5$ (as a type-3 $SrSi_2O_5$ structure), were found to be: $a = 5.2376$ Å, $b = 9.2751$ Å and $c = 13.4352$ Å, orthorhombic, space group: Cmca.

The complex oxide Be_2GeO_4 is a wide band gap insulator crystallizing in the phenacite structure ($BeSiO_4$).

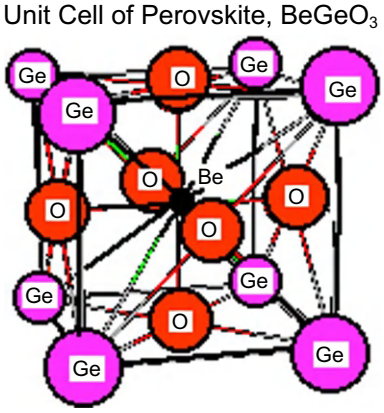

FIGURE 5.54

These compounds are crystallochemical analogs and belong to the nesosilicate class (germanates). The crystal lattice of these materials consists of [SiO_4/GeO_4] or [BeO_4] tetrahedra, which are bound to each other and form chains oriented along the principal crystallographic axis C_3. The chains form voids in the form of wide channels ~4.5 Å in diameter. A specific feature of phenacite-structure crystals is that the [SiO_4] tetrahedra (or [GeO_4] in the case of Be_2GeO_4) are separated, i.e. they do not touch each other. All oxygen atoms on the phenacite lattice are three-coordinated, and each of them is shared by three tetrahedra, namely, two [BeO_4] and one [Si(Ge)O_4]. Be_2GeO_4 is a trigonal phenakite structural analog. It relates to a class of island silicates which feature separated tetrahedrons, GeO_4 and BeO_4. Polycrystalline Be2GeO_4 can be prepared by reacting 2 mol of BeO and 1 mol of GeO_2 by a high-temperature SSR like that given above for the metagermanate. Be_2GeO_4 is hexagonal with $a = 12.79$ Å, $c = 8.42$ Å.

The luminescence emission of $(Zn,Be)_2GeO_4$:Mn phosphors at room temperature and near liquid nitrogen temperature is qualitatively similar to that of the $(Zn,Be)_2SiO_4$:Mn phosphors (which were used extensively for fluorescent lamps in the 1940s). In both the silicate and germanate, a green emission band is observed with low manganese content and beryllium concentrations. Increase in the concentration of either of these two constituents causes the growth of a new band in the red region of the spectrum. Certain differences in properties are noted, however, between the germanate and the silicate. The most important of these is the absence of any clear-cut "red" band in the low-temperature emission of Zn_2GeO_4 containing large manganese concentrations. Corresponding Zn_2SiO_4 phosphors clearly show the red band. The results of the emission measurements have been discussed in the light of two hypotheses that have been proposed to explain the dependence of the luminescence of manganese on the nature and composition of the host crystal.

Be_2GeO_4 polycrystalline samples preliminarily irradiated by fast neutrons ($E \sim 1.0$ MeV, $\phi = 4.5 \times 10^{17}/cm^2$) were studied by photoluminescence spectroscopy using synchrotron radiation pulses for excitation. The neutron-induced luminescence band observed at 1.7 eV (1033 nm) in the spectra of the irradiated samples is assigned to the radiative relaxation of a molecular ion O^{2-}. The luminescence of these point defects in the Be_2GeO_4 structure is effectively excited by 4.7 eV (263 nm) and 5.2 eV (238 nm) photons. It is most likely that, in the Be_2GeO_4 structure, the center is located in hollow channels oriented parallel to the C_3 axis. Thus, the vibrational structure of the point-defect O^{2-} center PL spectra in Be_2GeO_4 reflects the presence of predominantly intramolecular interactions. In other words, the O^{2-} defect center can be considered, in a certain sense, an almost free ion whose intrinsic vibrations are disturbed by the interaction with the Be_2GeO_4 lattice.

The possibilities of exoelectron spectroscopy to investigate defects in dielectrics have been demonstrated for the phenakite, Be_2SiO_4, and its structural analog Be_2GeO_4, and the solid solution, $Be_2Si_{1-x}Ge_xO_4$ ($0 < x < 1$). The optical sensitivity of BeO-based luminophores is well known for many years. Thermoluminescent emission maxima at 330 (57 °C) and 670 K (397 °C) in phenakite solid solution have been found to be due to $[GeO_4]^{5-}$ and E′ centers, respectively.

Beryllium germinates are not generally available commercially since the demand is not great. They do not have assigned CAS numbers but are considered hazardous due to the Be content in these salts.

Magnesium Germanates

Magnesium germanate can be formed by firing the oxides together at about 900 °C.

$$MgO + GeO_2 \Rightarrow MgGeO_3$$

This salt has the perovskite structure. The lattice parameters are: $a = 4.9375$ Å, $c = 13.743$ Å, $V = 290.15$ Å^3. It occurs as the mineral, "majorite", with lattice parameters of: $a = 11.051$ Å, $b = 11.051$ Å, $c = 11.480$ Å, $\alpha = \beta = \gamma = 90°$, space group = $I4_1/A$. There are four (4) magnesium germanates known as shown in the following phase diagram of the system, MgO–GeO_2 where each compound can be obtained by varying the MgO/GeO_2 mol ratios before firing (Fig. 5.55).

$MgGeO_3$ is polymorphic. It forms several types of pyroxenes. Pyroxene is one of the important constituent minerals of the earth's crust and upper mantle. Three kinds of $MgGeO_3$ pyroxene single crystals of l–10 mm size were grown by the flux method: an orthopyroxene, a clinopyroxene and a "clino-form-proto" phase. The lattice parameters and the space groups for the three are:

(1) Orthopyroxene: $a = 18.8099$ Å, $b = 8.9484$ Å, $c = 5.3451$ Å, $V = 899.69$ Å^3, orthorhombic, Pbca, $Z = 16$.

(2) Clinopyroxene: $a = 9.6010$ Å, $b = 8.9323$ Å, $c = 5.1592$ Å, $\beta = 101.034°$, $V = 434.27$ Å^3, $Z = 8$, monoclinic, C2/c.

The phase relationships of $MgGeO_3$ were studied in the temperature range 655–1030 °C and in the pressure range 0–55 kbar. The boundary between orthopyroxene and clinopyroxene was determined as 1810 °C + 3.8 P (in kbar), where both the high-pressure and low-temperature phase is monoclinic. Single crystals of ilmenite-type $MgGeO_3$ were also grown in association with the pyroxene–ilmenite transformation at 55 kbar, using the flux-grown millimeter-size orthopyroxene or

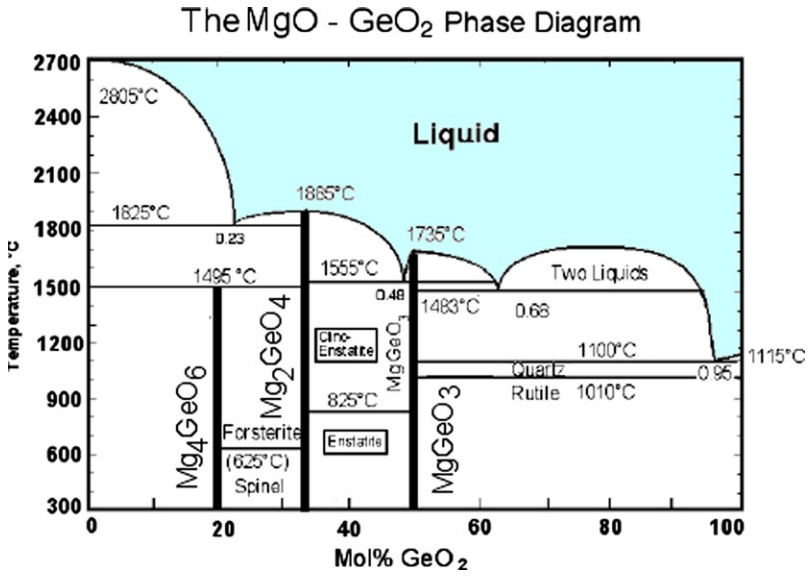

FIGURE 5.55

clinopyroxene $MgGeO_3$ single crystals as starting materials.

The orthogermanate, Mg_2GeO_4, has the molecular weight of 185.2476 g/mol and the CAS number of 12025-13-7. Study of the olivine-like compound, magnesium germanate, Mg_2GeO_4, showed that it has polymorphs that have both olivine and spinel structures. The free energies of transformation from the olivine to the spinel structure at 1200 °C are estimated to be +1.6 kcal/mol for Mg_2GeO_4. In the spinel structure, $a = 8.2496$ Å and the oxygen atoms are arranged in cubic closest packing (in which the position of every third layer repeats that of the initial layer) instead of hexagonal closest packing (in which the position of every second layer repeats that of the initial layer of the olivine structure).

Synthetic polycrystals of α-Mg_2GeO_4 (with the olivine structure) and γ-Mg_2GeO_4 (with the spinel structure) that deformed at high temperature and pressure in their respective stability fields were investigated by analytical transmission electron microscopy. Specimens with a mean grain size of 20–30 μm deform by dislocation glide and/or climb. The predominance of glide versus climb depends on stress and grain orientation. The defect microstructures of both polymorphs are very similar to those observed in their respective silicate analogues, α- and γ-$(Mg,Fe)_2SiO_4$, and, in the case of the spinel phase, very similar to those observed in magnesium aluminate spinels. These observations suggest that Mg_2GeO_4 is a good rheological analogue for the earth's upper mantle. A spinel specimen deformed under the same conditions of temperature and strain rate as an olivine specimen was approximately three times stronger than olivine. In specimens of both phases deformed at or above 1400 K, a thin amorphous film composed of Mg, Ge, and O was detected along some grain boundaries. Grains ≤ 10-μm diameter surrounded by a film of amorphous phase (>10-nm thick) exhibited low dislocation densities, and deformation appeared to have occurred by grain boundary sliding.

Magnesium germanate, when activated by manganese has long been used in fluorescent lamps. The emission spectrum of Mg_4GeO_6:0.01Mn^{2+} has been found to depend on the temperature of preparation. The spectrum of the sample prepared at 1275 °C shows four narrow bands at 6200 Å to 6600 Å; the spectrum of the sample prepared at 1475 °C consists of a broadband centered at 6150 Å. XRD patterns of the powders indicate the presence of an intermediate phase in the sample prepared at 127 °C. It was concluded that the valence of the manganese activator is different in the two samples. The emission of Mn^{4+} shows four brilliant narrow peaks in the red region of the spectrum (6200–6600 Å) whereas the Mn^{2+} ion emits in a broadband centered at about 6150 Å. Single crystals of magnesium germanate were obtained from a lead oxide flux crystallization of a ceramic preparation from an initial charge of $4MgO \cdot GeO_2$. The crystals are orthorhombic with $a = 14.512$ Å, $b = 10.219$ Å, and $c = 5.944$ Å and the unit-cell contents, $Mg_{28}Ge_{10}O_{48}$, conform to the symmetry requirements of the space group *Pbam*. The crystal structure was accurately determined by XRD analysis with a final residual $R = 0.044$. The structure, which is based upon a closest packed oxygen anion array, (*ABACBC*)*n*, involves a unique stacking of an olivine-type layer with a substituted MgO-type layer.

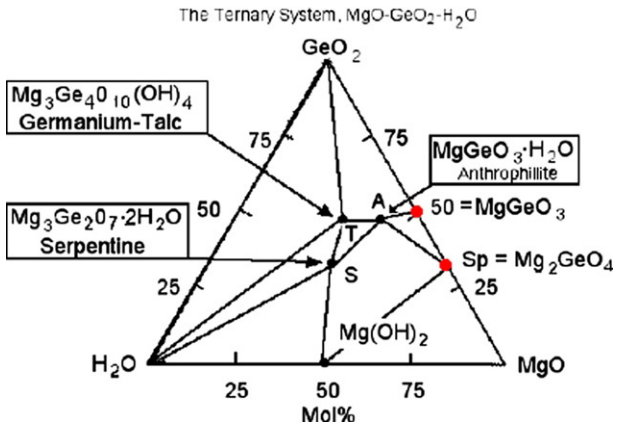

FIGURE 5.56

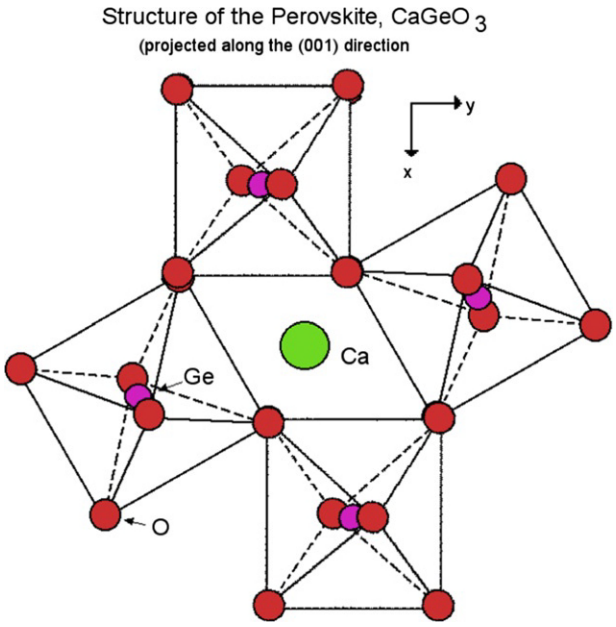

FIGURE 5.57

The germanium serpentine, $3MgO \cdot 2GeO_2 \cdot 2H_2O$ is formed easily from intimate mixtures of very fine MgO and the quartz form of GeO_2 under conditions similar to those under which the silicon analogue grows. The decomposition temperature was found to be 520 ± 15 °C at 10,000 psi. This phase gives a well-defined powder X-ray pattern not showing the diffuseness of the chrysotile pattern, and has a basal spacing of 7.47 Å and a mean refractive index for the basal section of 1.600. Above the decomposition temperature, the phases which appeared were $Mg_3Ge_4O_{10}(OH)_4$ (germanium talc) and Mg_2GeO_4. The ternary system phase diagram of $MgO–GeO_2–H_2O$ is shown as shown in Fig. 5.56.

This diagram summarizes all that is known concerning the hydrates of magnesium germanates. These salts are rare in nature and are only used to obtain the oxide, GeO_2, which is used in various electronic components manufactured in industry. Since Ge is a rare element, its costs prohibit extensive usage in industry and it is only used when its electrical properties are superior to any other combination of components.

Magnesium germanates are available commercially worldwide.

Calcium Germanates

Calcium germanate can be formed by firing the oxides together at about 750–800 °C:

$$CaO + GeO_2 \Rightarrow CaGeO_3$$

The result is a perovskite. This salt is polymorphic and exhibits three polymorphs. Phase boundaries for the reactions **$CaGeO_3$** (wollastonite ⇒ garnet) and $CaGeO_3$ (garnet ⇒ perovskite) were determined at high pressure and temperature. The enthalpies of these transitions were measured by high-temperature calorimetry. These studies indicate a positive dP/dT for the wollastonite ⇒ garnet transition and a negative dP/dT for the garnet ⇒ perovskite transition. These PT slopes are further supported by calculations of lattice vibrational entropies based on Kieffer's model and the infrared and Raman spectra of the three polymorphs. A single-crystal X-ray study indicates that the perovskite form of $CaGeO_3$ is orthorhombic (Pbnm) and isotypic with $GdFeO_3$. The cell dimensions are: $a = 5.2608$ Å, $b = 6.2688$ Å, $c = 7.4452$ Å, $V = 366.43$ Å^3, $Z = 4$, $d_{calc} = 5.17$ g/cc. The crystal structure is close to that of $SmAlO_3$. Although the unit cell of $CaGeO_3$ is pseudocubic, the structure itself is very distorted through the tilting and distortion of polyhedra. The oxygen polyhedra are less tilted and less distorted than those of other $GdFeO_3$-type perovskites. The structural deformation of the $GdFeO_3$ type of perovskite is determined primarily by the size ratio of two kinds of cation occupying A and B sites. Some structural characteristics such as O(2)-O(2F(2)) and A-O(1)-B angles and bond-length distortions exhibit systematic relationships as a function of the observed tolerance factor. The structure is shown in Fig. 5.57.

The GeO_6 octahedra are clearly seen and the CaO_{12} dodecahedra are indicated if one stacks this two-dimensional representation in the z-direction.

Single crystals of $CaGeO_3$ garnet were synthesized and the crystal structure was refined from single-crystal XRD data. This garnet is tetragonal with lattice parameters of $a = 12.535(2)$ Å, $c = 12.370(2)$ Å, $V = 1943.5(5)$ Å^3 and belongs to space group $I4_1/a$. The two dodecahedral sites are occupied only by Ca with mean Ca–O bond lengths of 2.480(4) and 2.467(4) Å. The Ca and Ge cations are completely ordered at two octahedral sites with mean Ca–O = 2.301(3) Å and mean Ge–O = 1.910(3) Å.

Three tetrahedral sites are occupied only by Ge, and their mean Ge–O bond lengths are 1.753(3), 1.787(4), and 1.764(4) Å. Furthermore, the present tetragonal garnet has an unusual feature in that the mean value [2.704 Å] of the shared edge lengths of GeO_6 octahedron is larger than that [2.699 Å] of the unshared ones, as has also been observed for other tetragonal garnets with $I4_1/a$. The equilibrium phase boundary between the garnet and perovskite phases was determined as P(GPa) = 6.9–0.0008T(°C). The negative P and T slope definitely established in the present study is in reasonable agreement with the value, −0.0023 GPa/°C, that was calculated from the thermochemical data on the enthalpy of transition. The molar volume change accompanied with this transformation was estimated to be about 13%.

The polymorphic transformation of pure $2CaO{\cdot}GeO_2$ (**Ca_2GeO_4**) and $3CaO{\cdot}GeO_2$ (**Ca_3GeO_5**) which are the nearest crystal chemical analogous with the main cement minerals $2CaO{\cdot}SiO_2$ and $3CaO{\cdot}SiO_2$ has been studied extensively by XRD. X-ray patterns of the polymorphic forms of Ca_3GeO_5 (2-layer and 24-layer) were obtained at ambient temperature, 820 °C and 1410 °C. The fragments of X-ray pattern of unstable modification were obtained at 1060 °C.

The binary system Ca_2SiO_4–Ca_2GeO_4 has been studied by means of XRD and DTA. For dicalcium silicate, Ca_2SiO_4, five modifications are known (α, α'_H, α'_L, γ and β); for dicalcium germanate, Ca_2GeO_4, only two (α and γ) were found at room temperature. Limited solubility has been found for α and for the metastable γ form, both of which occur only in the Si-rich part of the system. From single-crystal investigations, a new hexagonal structure with space group $P6_3mc$ was derived for the α form. These two modifications have a phase transition temperature of 1453 °C. The low-temperature phase (γ) is isostructural with forsterite and has the olivine structure with space group Pbnmn. The lattice parameters are: $a = 5.240$ Å, $b = 11.400$ Å, $c = 6790$ Å, $V = 670.32$ Å^3, $Z = 2$, $d = 3.53$ g/cc. Transition into phase-I forms the high-temperature phase (α) at 1470 °C which has a hexagonal structure ($P2_12_12_1$). Lattice parameters at 20 °C are: $a = 5.52$ Å, $c = 7.162$ Å, $V = 687.2$ Å^3, $Z = 2$. The melting point is 1901 °C.

Application of pressure and variation of temperature causes the formation of three more isotypes, labeled in the following diagram as II, III and IV. At $P = 11.3$ GPa and $T = 940$ °C, the triple point for the three isomers was found. Ca_2GeO_4 III is tetragonal with $a = 3.700$ Å, $c = 11.882$ Å. Ca_2GeO_4 IV is tetragonal as well (Fig. 5.58).

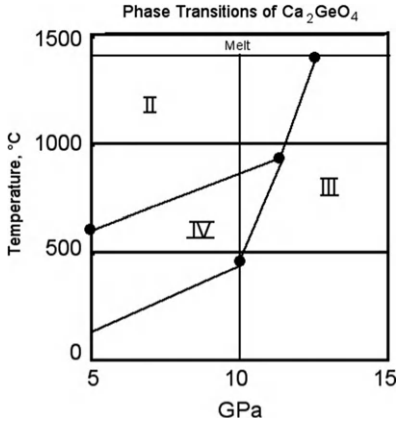

FIGURE 5.58

Ca_2GeO_4 has been tested as a host for lasers, using Nd^{3+} as the activator. Large crystals of highly doped Ca_2GeO_4:Cr^{4+} were grown by a top-seeded melt-solution growth method. Absorption and emission measurements for various crystal orientations have been performed. From the spectroscopic measurements, the only optically active center was identified as tetrahedrally coordinated Cr^{4+}. Gain switched, tunable laser operation of Ca_2GeO_4:Cr^{4+} crystal was demonstrated. Pulse energies of 0.4 mJ at 1.4 μm have been generated at a repetition rate of 100 Hz. Tunability over the 1348- to 1482-nm spectral range has been demonstrated.

A novel red phosphor Ca_2GeO_4:Eu^{3+} was prepared by the traditional SSR. X-ray powder diffraction (XRD) analysis suggested that there was no impurity phase. The study on the diffusion reflection spectra of the undoped and Eu^{3+}-doped Ca_2GeO_4 phosphors revealed an absorption band superposed of that of the host material and the Eu^{3+} ions. The excitation spectrum presented a dominating broadband at 250–300 nm which was attributed to both the host material absorption and the charge transfer band of the Eu^{3+} ions. The investigation on the excitation and diffusion spectra showed that there was an effective energy transfer from the host material to the Eu^{3+} ions. This was favorable to the red emission of the phosphor. Photoluminescence measurements indicated that the phosphor presents bright red emission at 611 nm under UV excitation. In addition, the Al^{3+} or Li^+ codoping enhanced the red emission from Ca_2GeO_4:Eu^{3+} by about 3 and 2 times, respectively under UV excitation.

Ce^{3+}-activated Ca_2GeO_4 phosphors were synthesized by a SSR method, and their photoluminescence properties were characterized. The excitation band of Ca_2GeO_4:Ce^{3+}:Li^+ ranges from 380 to 520 nm with a maximum intensity appearing at about 465 nm, which matches well with the emission of blue light-emitting diode chips. Through transitions from 5d to 4f ($^2F_{5/2}$ and $^2F_{7/2}$) in Ce^{3+}, Ca_2GeO_4:Ce^{3+}:Li^+ exhibits a broad yellow emission band in the wavelength range of 480–750 nm under 465-nm excitation. Compared to $Y_3Al_5O_{12}$:Ce^{3+} garnet, Ca_2GeO_4:Ce^{3+}:Li^+ shows a broader bandwidth (140 nm) and more saturation in

red, which is favorable for white light-emitting diode conversion phosphors.

By using a diamond anvil pressure cell coupled with laser heating, Ca_2GeO_4 has been found to decompose into the mixture $Ca_3Ge_2O_7$ plus CaO at pressures greater than 200 kbar and at about 1000 °C. The decomposition product, **$Ca_3Ge_2O_7$**, is a new compound which is isostructural with $Sr_3Ti_2O_7$ and has the lattice parameters of: hexagonal $a = 3.72 \pm 0.01$ and $c = 19.32 \pm 0.05$ Å at room temperature and 1 bar pressure.

$$2Ca_2GeO_4 + \text{heat (pressure)} \Rightarrow Ca_3Ge_2O_7 + CaO$$

Ca_3GeO_5 has the crystal structure of a 24-layer polytype with a molecular weight of 272.8 g/mol. It is rhombohedral, R3m, with $a = 7.228$ Å, $c = 76.72$ Å, $V = 3050$ Å^3, $Z = 24$. The structure consists of *two kinds of subunits*: one related to the structure of a two-layer polytype and the other to that of the nine-layer polytype. These alternate in the structure to form the 24-layered structure. Half of the eight independent GeO_4 tetrahedra show nearly perfect orientation disorder along the *c*-axis. The coordination numbers of the Ca atoms are in the range of 6.0 to 6.6, giving mean bond lengths of 2.34 to 2.51 Å. Slabs of CaO_6 and GeO_4 form a triangle mesh with single GeO_4 tetrahedra (partial orientation disorder) in $(h_2ch_4c)_3$ stacking. The formula may be represented as $Ca_3(GeO_4)O$. The two-layer polymorph is hexagonal ($P6_3mc$) with: $a = 7.223$ Å, $c = 5681$ Å, $V = 256.7$ Å^3, $Z = 2$, $d = 3.38$ g/cc. The structure may be regarded as a two-layer variant of the rhombohedral structure. It consists of isolated GeO_4 tetrahedra located on the threefold axes and separate anions on the mirror planes. Each tetrahedron takes a statistical orientation: 62% of the tetrahedra point in one *c*-direction while the other 38% point in the other. The separate cation sites, which are not coordinated to Ge sites.

Determination of the crystal structure of two polymorphic modifications of Ca_3GeO_5, one marked monoclinic C_3-G-3M (space group $P6_3mc$) and one rhombohedral denoted C_3-G-9R (space group R3m) was conducted. The relationships of atomic arrangements in both structures are closely the same. The deformations of polyhedra in C_3-G-3M are larger than in C_3-G-9R. The crystal structure of these 24-layer polytypes C3-G are: rhombohedral, $a = 7.228$ Å, $c = 76.42$ Å, $V = 3050$ Å^3, $Z = 24$. The structure consists of two kinds of subunits, one is related to the structure of the two-layer polytype and the other to that of the nine-layer polytype. These occur alternately in the structure. Half of the eight independent germanate tetrahedra are split, the separations being in the range of 0.34 to 0.69 Å. The coordination number of Ca is 8, each calculated as the sum of occupancy of the Ca–O bonds are in the range of 6.0–6.56 Å, giving a mean bond length of 2.34 to 2.51 Å.

If fluoride is substituted for oxygen in these structures (by substituting a small amount of CaF_2 for CaO in the oxide mixture before firing), the composition, $Ca_{3-x}GeO_4)(O_{1-2x}F_{2x})$ results. Instead of a 24-layer structure, a two-layer structure results. This salt is hexagonal with space group = $P6_3mc$, $a = 7.223$ Å, $c = 5.681$ Å, $V = 256.72$ Å^3, $Z = 2$. It is a variant of the rhombohedral structure of tribalism silicate (germanate) that has the nine-layer type of structure. It consists of isolated GeO_4 tetrahedra located on threefold axes and separate anions on the mirror planes. Each GeO_3 tetrahedron takes a statistical orientation—62% points in one *c*-direction while 38% point in the other direction. The separate anion sites that are not connected to the Ge were occupied by O–F complexed atoms 40.5% O–59.5% F). The resultant deficiency of minus charge is compensated by a distribution of vacancies at the Ca sites.

$CaGe_2O_5$, a new polymorph has been discovered via high-pressure experiments (above 8 GPa). The phase is orthorhombic, space group Pbam, with $a = 7.306$ Å, $b = 8.268$ Å, $c = 5.714$ Å, $V = 345.2$ Å^3, and $Z = 4$. This new phase, $CaGe_2O_5$, is the high-pressure polymorph of titanite $CaSi_2O_5$. The structure of this new polymorph is based on a network of 5- and 6-coordinated Ge polyhedra and 8-coordinated Ca atoms. Following the germanate analog to silicate, post-titanite $CaSi_2O_5$ could be expected to form at high-pressure conditions and thus might exist in earth's mantle.

The structure of $CaGe_2O_5$ between room temperature and 923 K has been determined by X-ray powder diffraction. A continuous phase transition from triclinic $C\bar{1}$ to monoclinic C2/c symmetry at $T_c = 714$ K was observed. The transition is accompanied by a weak heat capacity anomaly. This anomaly and the strain analysis based on the measured lattice parameters indicate a classical second-order phase transition. The order parameter, as measured by the strain component ε_{23}, is associated with the displacement of the Ca cation. Electronic structure optimization by density functional methods is used to verify the centric space group of the low-temperature structure of $CaGe_2O_5$.

Another new compound, octacalcium pentagermanium octadecaoxide **$Ca_8Ge_5O_{18}$**, represents a new intermediate phase between CaO and GeO_2, and had not previously been reported in the literature. The structure consists of three different Ge sites, two of them on general 8d positions, site symmetry 1, one on special position 4d, site symmetry 2. Three of the five Ca sites occur on 8d positions, site symmetry 1, one Ca is on 4b with site symmetry and one Ca is on 4c with site symmetry 2. All nine O atoms have symmetry 1 (8d position). By sharing common edges, the Ca sites form infinite bands parallel to the *c* axis. These bands are interconnected by isolated GeO_4 and Ge_3O_{10} units.

The (100) layers are stacked along *a* in an ABAB… sequence, with the B layer being inverted and displaced along b/2.

Although Ca_2GeO_4 is now being used commercially, there do not seem to be any suppliers offering these salts commercially. Primarily, the laser crystals are made from a melt of the oxides. No CAS numbers have been issued.

Strontium Germanates

Strontium germanate can be formed by firing the oxides together at about 850 °C:

$$SrO + GeO_2 + \text{heat} \Rightarrow SrGeO_3$$

The result is the metagermanate, β-$SrGeO_3$. The reaction of an equimolar mixture of SrO and GeO_2 at 1150 °C proceeds in five stages,

(1) $2SrO + GeO_2 \Rightarrow Sr_2GeO_4$
(2) $SrO + 4GeO_2 \Rightarrow SrGe_4O_9$
(3) $SrO + GeO_2 \Rightarrow$ β-$SrGeO_3$
(4) β-$SrGeO_3 \Rightarrow$ α-$SrGeO_3$
(5) $3Sr_2GeO_4 + SrGe_4O_9 \Rightarrow 7$ (α-$SrGeO_3$)

The overall reaction of [1], [2], and [3] forms ortho- and then the tetrameta- and finally the β-strontium metagermanate is formed directly at lower temperatures from amorphous material prepared by the simultaneous hydrolysis of strontium and germanium alkoxides which is the stable form at that temperature. This form has monoclinic rather than hexagonal symmetry. Two forms of $SrGeO_3$ are known at present: this monoclinic form and a triclinic form. β-$SrGeO_3$ transforms to α-$SrGeO_3$ at about 955 °C. The monoclinic structure has alternate stacking of ternary rings of GeO_4 groups and close-packed Sr atoms along [001], and is a six-layer polytype. The low-temperature form has the perovskite structure while the high-temperature form has the wollastonite form.

The $SrGeO_3$ perovskite crystal structure is formed by the Ge cations filling 25% of the octahedral holes in the cubic close-packed SrO_3 array as an octahedron. In the ideal cubic structure, each Sr cation is coordinated to 12 O-anions and each GE cation is coordinated to six O-anions. An example of this cubic structure is shown in Fig. 5.59.

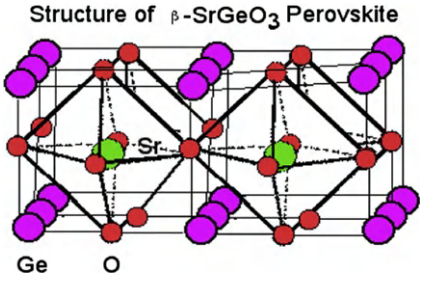

FIGURE 5.59

$SrGeO_3$ perovskite, like $CaSiO_3$ perovskite, forms at high pressure from a framework structure composed of vertex-sharing tetrahedra. It appears that when these frameworks condense with dramatic decreases in volume to form perovskite structures, the phase that is formed has quite a different nature than an ambient-pressure ideal perovskite such as $SrTiO_3$. Among the most important differences is the wide disparity in the covalency of the Ge–O and Ti–O bonds. While the octahedra themselves remain essentially intact and undistorted through the tilting and twisting motions required to form the distorted perovskite structures, the vertex-linking topology of the perovskite provides a flexible linkage whose resistance to bending varies widely with its covalency. In the silicate and germanate perovskites, high-pressure transformations to lower symmetry structures must overcome the significantly enhanced covalency of the vertex-linked octahedral chain, a process that makes observable phase transformations unlikely, particularly in the mantle of the earth.

In addition to the metagermanate, the orthogermanate, **Sr_2GeO_4** and the phyllo-germanate. **$SrGe_2O_5$**, have also been characterized. A stable monoclinic low-temperature (β) form of Sr_2GeO_4 was found which converts reversibly to the high-temperature α′ modification at 85 °C. The enthalpy of the β-α′ transition is 51 cal/mol. The high-temperature phases of Sr_2GeO_4 have been compared to those of the better-known $CaGeO_4$ homologues as shown in the following phase diagram shown on the next page as Fig. 5.60.

Sr_2GeO_4 melts at about 1800 °C but undergoes similar transitions from beta- to alpha-structures at about the same temperatures of the calcium homologues. However, the number of known polytypes is not as numerous as those of Ca_2GeO_4. Crystals of the orthorhombic phase of strontium germanate, Sr_2GeO_4, showing superstructure have been obtained. Crystal data are: $a = 5.8520$ Å, $b = 14.2991$ Å, $c = 9.9165$ Å, space group $Pbn2_1$ and $Z = 8$. The superstructure of this crystal was twice as large as the average structure ($a = 5.85$ Å, $b = 7.15$ Å, $c = 9.92$ Å). The dominant rule of differentiating two-layers superstructure type like this crystal and three-layers type like other crystals of the compounds α-Ca,Sr_2SiO_4 is the size effect of cations at the tetrahedral positions. This rule leads to the results that the two-layers type shows the space group $Pbn2_1$ and the three-layers type shows the space group $P2_1nb$ on account of the geometrical restriction.

Sr_3SiO_5 has the tetragonal structure and space group of P4/nnc with lattice parameters of: $a = 6.934$ Å, $c = 10.721$ Å, $Z = 4$. Systematic absences in hk0 for h + k-odd, in 0kl for l-odd, and in hkl for l-odd were seen. There is, in addition, a pronounced systemic flaw among the hkl reflections with h + k + l-odd, which makes it an approximately body-centered lattice.

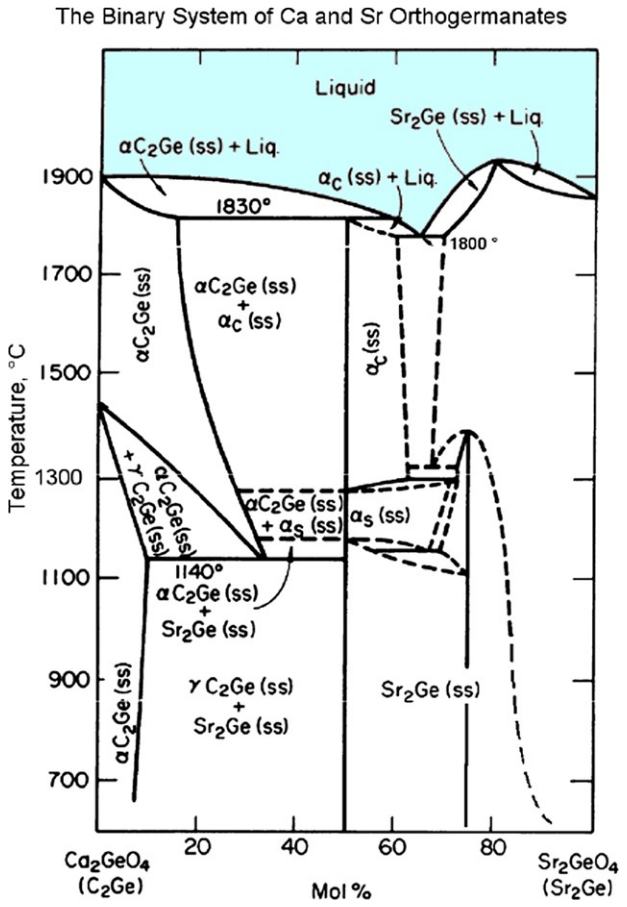

FIGURE 5.60

The devitrification behavior of strontium germanate glasses, examined by DTA, Fourier transform infrared spectroscopy (FTIR) and XRD, has been reported. The glass compositions are expressed by the general formula: $x\text{SrO}(1-x)\text{GeO}_2$ with $x = 0.050$, 0.125, 0.200 and 0.250. The glasses with $x = 0.050$ and 0.125 exhibit two glass transition temperatures due to a phase separation. The phases crystallizing during DTA runs were identified and devitrification mechanisms proposed. In all glasses, $SrGe_4O_9$ crystals grow from bulk nuclei.

Strontium also forms a 1:2 salt. The structure of tetragermanium strontium nonaoxide, $SrGe_4O_9$, comprises two different types of sheet structure stacked alternately along the c axis. One sheet comprises the GeO_6 octahedra and the SrO_8 polyhedra while the other sheet contains three-membered rings of GeO_4 tetrahedra.

Although other compounds like $SrSi_2O_5$, $Sr_3Si_2O_7$, $SrSi_3O_7$, $Sr_2Si_3O_8$, and $SrSi_2O_5$, are possible, the scientific literature and references make no mention of them. The phases possible in the SrO–GeO_2 system are: 1:1, 1;2, 1:3, 2:1, 3:1, 2:3 3:2, and 3:5, but only the 1:1 ($SrGeO_3$), 2:1 (Sr_2SiO_4) and 3:1 (Sr_3SiO_5) phases have been reported.

No CAS numbers have been assigned to strontium germanates, probably because they are primarily prepared from the oxides by the users and are not available as separate compounds commercially.

Barium Germanates

Phase equilibria in the system BaO–GeO_2 were studied using several complementary methods and a number of modifications made to the previously published phase Fig. 5.61.

The system contains four compounds, Ba_3GeO_5, Ba_2GeO_4, $BaGeO_3$ and $BaGe_4O_9$. Evidence was presented to show that the previously reported compounds $Ba_3Ge_2O_7$ and $BaGe_{19}O_{39}$ do not exist. However, other investigators have determined the structural

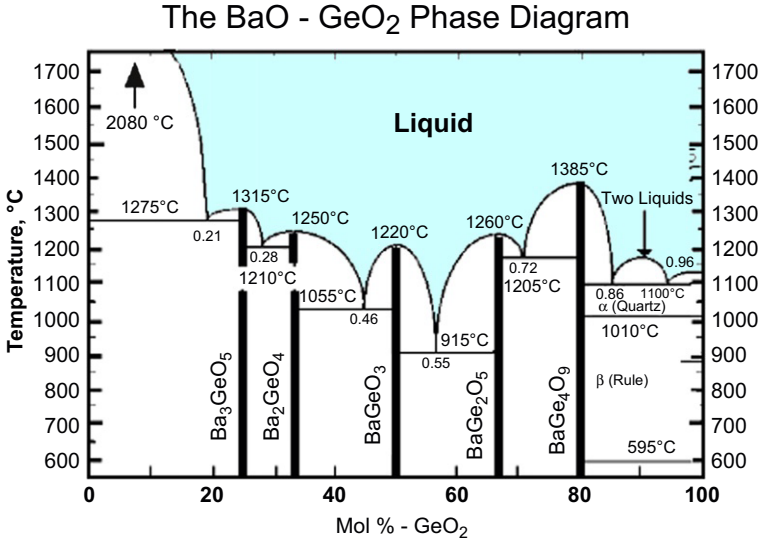

FIGURE 5.61

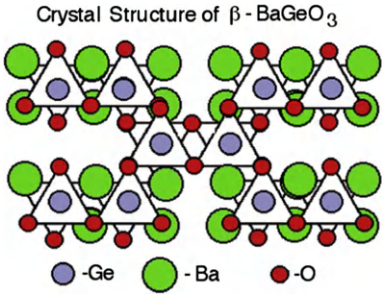

FIGURE 5.62

characteristics of the former but not the latter. Five invariant points were established in the system and defined as simple eutectics at: 1275 °C, 1210 °C, 1055 °C, 915 °C and 1205 °C at 0.21, 0.28, 0.46, 0.56, 0.72 and 0.80 mol of GeO_2.

Barium germanate can be formed by firing the oxides together at about 750–800 °C:

$$BaO + GeO_2 \Rightarrow BaGeO_3$$

The metagermanate results. This salt is dimorphic and forms both β- and α-$BaGeO_3$. β-$BaGeO_3$ is a pseudo-wollastonite which transforms at 1225 °C to α-$BaGeO_3$. The former consists of digermanate groups arranged in a chain structure. The packing is pseudo-cubic (Fig. 5.62).

The structure consists of alternating layers of Ba cations and triangular $[GeO_3]_3$ rings, and is closely related to pseudo-wollastonite. The rings show a twofold positional disorder owing to stacking faults. The stacking is not random, but can be rationalized by a twinning mechanism mapping the two noncongruent enantiomorphic polytypes of the structure onto each other. The compound is monoclinic with space group C2/c and unit-cell parameters of $a = 13.1877$ Å, $b = 7.6222$ Å, $c = 11.7190$ Å, $\beta = 112.295°$, $V = 1089.9$ Å^3 and $Z = 12$. The structure was found to consist of alternating layers of barium atoms and three-membered $[GeO_3]_3$ rings showing a twofold positional disorder. Apart from the disorder, the structure is very similar to the one of $SrGeO_3$; both are six-layer structures build from the same type of layers. The same structure type also appears in pseudo-wollastonite, forming four- or six-layer polytypes. Careful studies of possible structural variations using simulated annealing [did not reveal any deviation from symmetry C2/c]. The disorder of the ternary rings can be summarized as follows: ternary $[GeO_3]_3$ rings appear in only one out of two possible orientations and occupy only 2/3 of the positions compatible with this orientation. For six-layered structures of this type, there is only one distinct polytype with the inherent symmetry C2/c. There are, however, two noncongruent enantiomorphs of this structure. The disorder observed in $BaGeO_3$ can be

FIGURE 5.63

described as the simultaneous appearance of both possibilities.

In another study, $BaGeO_3$, was found to undergo a reversible phase transformation at 1100° from a low-temperature hexagonal polymorph to a medium-temperature polymorph. This had an unknown crystal structure, which experiences a further reversible transformation at 1200° to a high-temperature orthorhombic polymorph found to be stable up to the melting temperature of 1287°. On cooling from the melt, the high-temperature form can be retained as a metastable material at room temperature, but transforms to the low-temperature form at 900°. The structure of α-$BaGeO_3$ differs from that of β-$BaGeO_3$ in that the cubic form becomes a series of chains of triangular GeO_3 units, stacked in an orthorhombic fashion wherein 2 GeO_3—groups alternate with a single group in the structure.

α-Barium metagermanate ($BaGeO_3$), in its high-temperature form, was formed metastabely at 630–660 °C from an amorphous material prepared by the simultaneous hydrolysis of barium and germanium alkoxides. The transformation of $BaGeO_3$ was studied by thermal analysis and high-temperature XRD. The transformation of $BaGeO_3$ can be summarized as shown in Fig. 5.63.

On cooling from the melt, α- $BaGeO_3$ can be retained at room temperature.

A hydrate of barium metagermanate can also be obtained by the use of soluble compounds:

$$BaCl_2\ (aq) + Na_2GeO_3\ (aq) \Rightarrow BaGeO_3 \cdot 5H_2O\ (s) + 2NaCl$$

This salt, when heated to 100 °C loses three waters of hydration and then forms the β-$BaGeO_3$ composition at 460 °C. The hydrate has the structure of: monoclinic, space group = 2C/2, $a = 15.677$ Å, $b = 8.404$ Å, $c = 11.368$ Å, $\beta = 97.60°$, $V = 465.4$ Å^3, $Z = 4$.

The orthogermanate can be obtained by firing 2.0 mol of BaO with 1.0 mol of GeO_2. Ba_2GeO_4 is orthorhombic with space group: Pnma (62), crystal system: orthogonal unit cell parameters: $a = 7.585$, $b = 5.985$, $c = 10.43$.

Phase relations in the system BaO–GeO_2 were investigated in the pressure range 20–70 kbar in the temperature range 750–1200 °C. Several new phases were identified in this system which were modifications of $BaGe_2O_5$:

(a) An atmospheric phase of $BaGe_2O_5$ (monoclinic $BaGe_2O_5$ I)
(b) Two high-pressure phases of $BaGe_2O_5$ (monoclinic $BaGe_2O_5$ II and tetragonal $BaGe_2O_5$ III)
(c) A high-pressure phase of $Ba_2Ge_5O_{12}$.

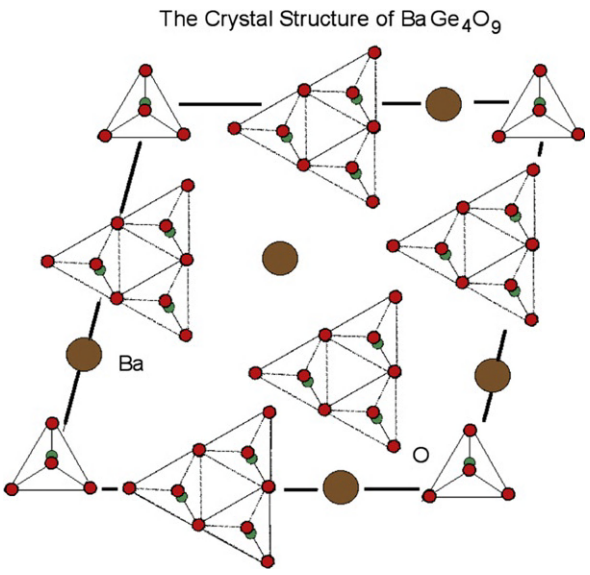

FIGURE 5.64

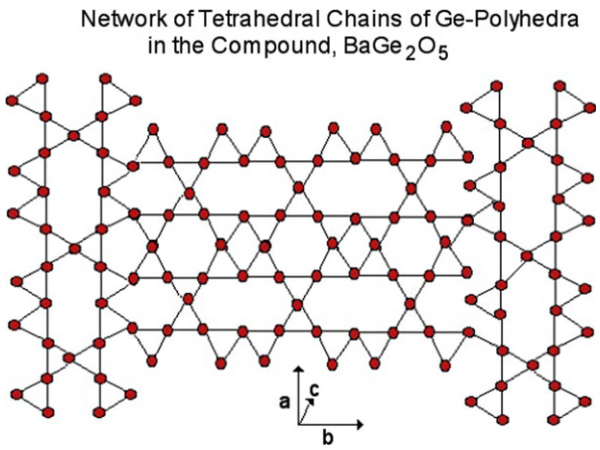

FIGURE 5.65

The phase boundary curve between $BaGe_2O_5$-II and $BaGe_2O_5$-III was preliminarily determined as P(kbar) = 7.7 + 0.047*T* (°C). The high-pressure phases of $BaGeO_3$, which were previously reported by Y. Shimizu et al (1970) in the pressure range 15–95 kbar, were interpreted to be not single-phase materials but complicated mixtures of more than two phases in the system BaO–GeO_2. X-ray powder diffraction data for the new compounds synthesized in this study are given. **$BaGe_3O_7$** does not exist as a single phase.

The compound, $BaGe_4O_9$ has the extraordinary structure shown in Fig. 5.64.

It consists of a tri-ring structure of GeO_4 tetrahedra arranged on a tetragonal lattice. There is a separated tetrahedron at the corners of the unit cell so that the formula should be designated as: $BaGeO_3(GeO_3)_3$. This is analogous to the compound $BaTi(SiO_3)_3$. BaGe $[Ge_3O_9]$ is trigonal, space group P3, with lattice constants $a = 11.61$, $c = 4.74$ Å, $V = 489.3$ Å^3 and $Z = 3$. The previously proposed structural relationship of this compound with benitoite, $BaTiSi_3O_9$, has been confirmed. The structure can be considered as composed of Ge_3O_9 rings, in which the Ge is tetrahedrally coordinated, linked through octahedrally coordinated Ge atoms to form a three-dimensional Ge–O network. All Ge polyhedra are linked by corner sharing. The Ba ions occupy positions in channels of the network.

The compound, $BaGe_2O_5$, has a molecular weight of 362.564 g/mol. It is monoclinic with space group = $P2_1/a$, the unit-cell parameters are: $a = 13.214$ Å, $b = 13.043$ Å, $c = 9.5501$ Å, $\beta = 94.006°$, $V = 1642.4$ Å^3 and $Z = 4$. There are three kinds of infinite chains of Ge polyhedra. One type, parallel to the *b*-axis, is connected to another chain of the same type by two other chains, parallel to the *a*-axis, so that two ladder-like sheets, parallel to the (201) and (201) directions, are formed. These are stacked in the *c*-direction (Fig. 5.65).

In this diagram, the Ba and Ge atoms have been omitted for clarity.

In the following diagram, they are shown in the unit cell of the compound (Fig. 5.66).

The compound, Ba_3GeO_5 is also known. It crystallizes in the tetragonal space group I4/mcm (D_{4h}^{18}) and is isostructural with Cs_3CoCl_5. Lattice constants of these compounds have been given. Sr_3SiO_5 shows a slight modification of the Cs_3CoCl_5 type of structure which causes a deviation from body centering; the space group is therefore P4/ncc (D).

In general, barium germanates are not offered for sale except as high-purity targets for sputtering and the like.

Radium Germanate

Radium germanate can be formed by firing the oxides together at about 750–800 °C:

$$RaO + GeO_2 + \text{heat} \Rightarrow RaGeO_3$$

In general, radium is expected to form the same type of compounds as its barium analogue. However, there is no record of the preparation of such compounds or

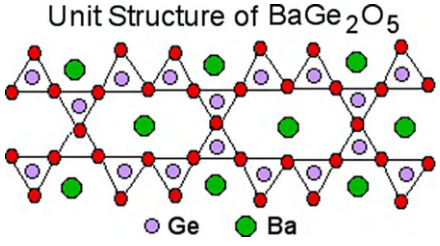

FIGURE 5.66

measurements of their properties, both physical and chemical. Perhaps this is due to the difficulty in handling radioactive ^{226}Ra compounds but more likely is due to the lack of interest in industry and academia.

5.3.2. Other Related Oxo-Germanium Compounds, Including Bismuth

In order to illustrate the concept of electronegativity as applied to the problem of whether a compound can be formed, the following discussion is presented. In this case, Bi^{3+} is sufficiently electropositive to be able to form a bismuth germanate. Bismuth germanate is a cubic crystal with the formula, $Bi_4Ge_3O_{12}$. It has the "evlitine" structure. A less common composition is $Bi_{12}GeO_{20}$ (Fig. 5.67).

The unit cell consists of three GeO_3 tetraheda arranged in a building block. These units are arranged in a cubic close-packed structure as shown in the above diagram.

The crystal structure of tetrabismuth tris(germanate), $Bi_4Ge_3O_{12}$ ($I3d$, $Z = 4$), is stable to at least 7.30 GPa, as demonstrated by hydrostatic single-crystal XRD measurements in a diamond anvil cell at room temperature. The highest pressure reached in this study was close to the onset of amorphous character at about 8 GPa. The Bi and Ge atoms are located at the 16*c* (3) and 12*a* (2) Wyckoff positions, respectively. The compression mainly affects the distorted BiO_6 octahedra, while the GeO_4 tetrahedra are relatively rigid. When compared with the values obtained under ambient conditions, the long Bi–O distances decrease with increasing pressure, while the short Bi–O distances do not change.

Its main use is as a scintillator crystal wherein it functions to absorb gamma rays (γ rays) and emit photons. Its emission band occurs at 480 nm with a band spread of 375–650 nm. It produces about 8500 photons per meV of the high-energy radiation absorbed. Thus, it can be used to count gamma-ray bursts, which are flashes of γ rays associated with extremely energetic explosions in distant galaxies. It has good "radiation hardness" (its parameters remaining stable up to 5×10^4 years) and a high "scintillation efficiency". It is mechanically strong, is not hygroscopic, and has a high density of 7.13 g/cc and a high "Z-value" (the *z*-value relates the resistance of a crystal to withstand differing temperatures without losing its scintillation efficiency). Its melting point is 1052 °C.

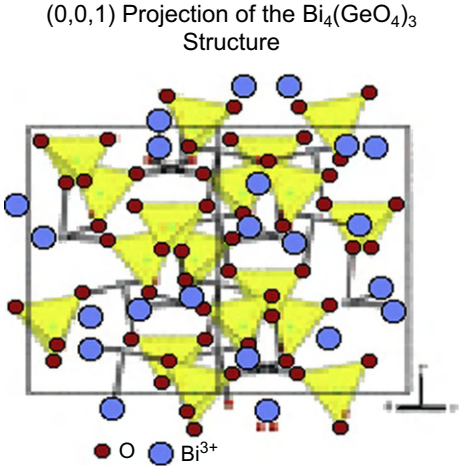

FIGURE 5.67

Bismuth germanate is used in detectors in particle physics, aerospace physics, nuclear medicine, geology exploration, and other industries. Bismuth germanate arrays are used for gamma pulse spectroscopy. BGO crystals are also used in detectors for positron emission tomography. Bismuth germanate has a high "electro-optic coefficient" (3.3 pm/V for $Bi_{12}GeO_{20}$) making it useful in nonlinear optics for building "Pockel cells". It can also be used for photorefractive elements useful in the ultraviolet part of the electromagnetic spectrum.

Commercially available crystals are grown by the Czochralski method and usually supplied in the form of cubes or cylinders. Large crystals are also available.

5.3.3. Alkaline Earth Germanides

In addition of forming oxy-germanate compounds with the alkaline earths, a series of "germanide" compounds have also been studied.

Beryllium Germanides

Beryllium does not form any compounds with germanium as shown in the following phase diagram shown as Fig. 5.68.

The structural factors are given in Table 5.24.

Perhaps, the lack of many compounds in this system is caused by the large disparity of atom sizes between the two metals.

Magnesium Germanides

Magnesium forms just one compound as shown in the following phase diagram shown as Fig. 5.69.

The structural factors are given in Table 5.25.

The dimagnesium germanide compound, Mg_2Ge, has the form shown as in Fig. 5.70.

The structure is cubic and has the fluorite arrangement. The unit-cell parameters are: $a = b = c = 4.5148$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 65.07 Å^3. Cell occupancy is shown in Table 5.26.

Two other structures have been presented that gave differing point groups and space groups:

$$Mg_2Ge\ (II) = cF12 = Fm\text{-}3m$$

$$Mg_2Ge\ (III) = hP45$$

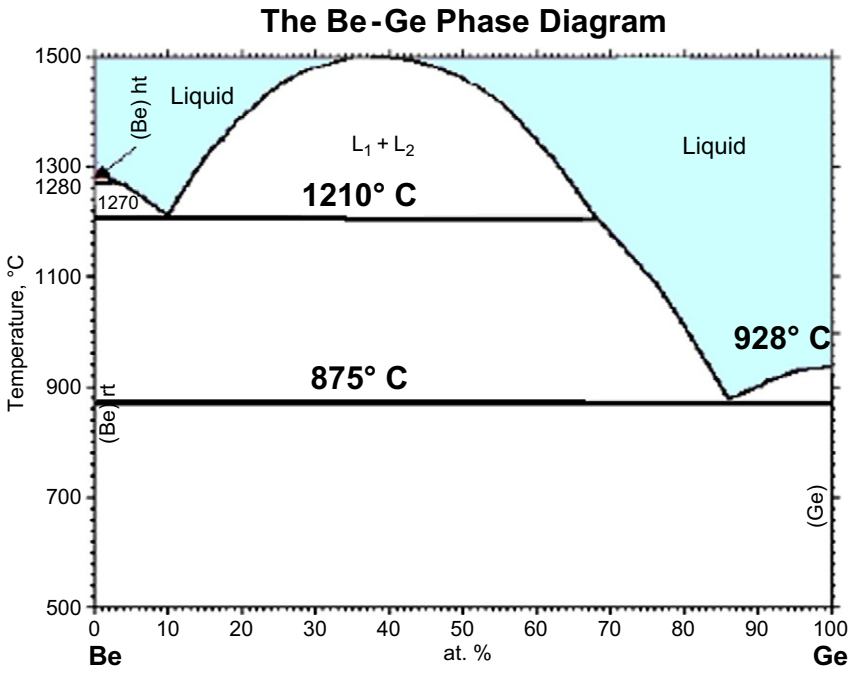

FIGURE 5.68

Large high-purity single crystals of the semiconductor Mg_2Ge have been grown by a modified Bridgman method. Crystals grown from stoichiometric melts were *p*-type with carrier concentrations at 77 K of about $10^{16}/cm^3$ and Hall mobilities near 1100 cm^5/V s. Excess magnesium placed in the melt acted as a donor and produced *n*-type material. Carrier concentrations of the compensated *n*-type material could be obtained ranging from 5×10^{14} to $5 \times 10^{17}/cm^3$ at 77 K. Mobilities for the *n*-type material were somewhat higher at about 1600 cm^5/V s than for the *p*-type crystals.

Infrared absorption spectra of several *n*-type Mg_2Ge single crystals were obtained in the wavelength regions from 1 to 13 μ and 1 to 7 μ, respectively, over the temperature range from 85–370 K. Free carrier absorption occurred in Mg_2Ge at the longer wavelengths. The absorption edges appeared to be due to indirect transitions and the shift of the optical energy gap with temperature is estimated to be ~6.5×10^{-4} eV/K for Mg_2Ge.

Magnesium germanide is readily available as Mg_2Ge and has a CAS number of 1310-52-7.

Calcium Germanides

Calcium metal readily forms a number of compounds with germanium metal, as can be seen in the phase diagram for the Ca–Ge system (Fig. 5.71).

Thermodynamic modeling of the Ca–Ge system has been carried out by means of the CALPHAD (calculation of phase diagrams) method and new experimental phase diagram data. The liquid phase and the intermetallic compounds Ca_2Ge, Ca_5Ge_3, Ca_7Ge_6 (new compound), CaGe and $CaGe_2$ are taken into consideration in this optimization. The substitutional solution model was used to describe the liquid phase. The five compounds were treated as stoichiometric phases. A consistent set of thermodynamic parameters has been obtained. The optimized phase diagram and thermodynamic properties were presented and compared with other calculated and experimental data obtained from the literature.

Associated structure factors are shown in Fig. 5.72.

TABLE 5.24

Compound	Structure type	Point group	Space group	Melting point, °C	Physical data
(Be) ht	W	cI2	229	1289	No data

(Ge)	C	cF8	227	928	No data

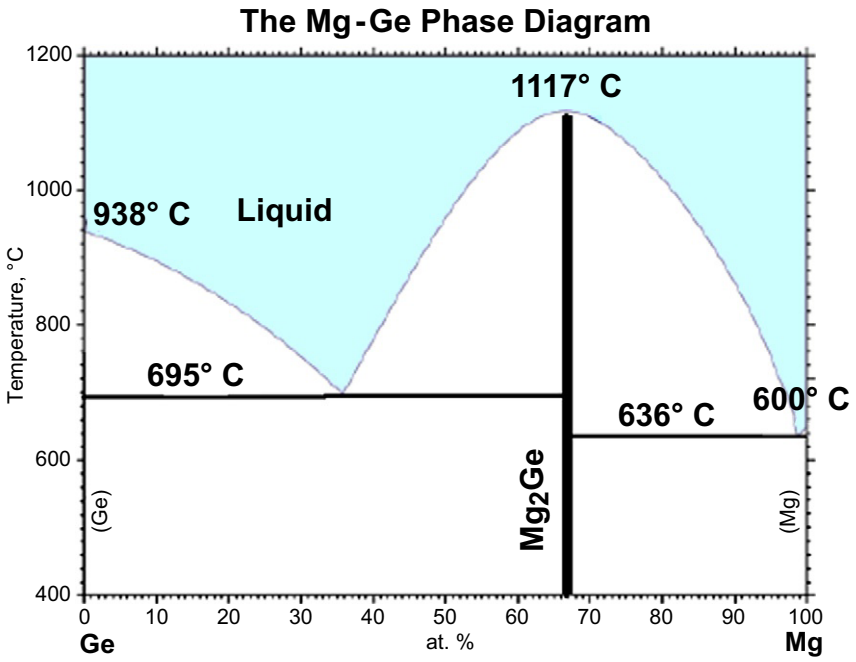

FIGURE 5.69

It was also found that CaGe is a mechanically unstable phase. Ca_2Ge is a direct band gap semiconductor with a band gap of 0.07 eV. In addition, it is found that the absolute values of heats of formation for all Ca–X intermetallics are larger than 30 kJ/mol-atom.

Dicalcium germanide, Ca_2Ge, has the structure shown in Fig. 5.73.

Cell parameters are: $a = 4.834$ Å, $b = 7.734$ Å, $c = 9.069$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 339.06$ Å^3. Cell occupancy is: shown in Table 5.27.

The compound, CaGe, has the structure shown in Fig. 5.74.

Cell parameters are: $a = 4.005$ Å, $b = 4.565$ Å, $c = 5.880$ Å, $\alpha = 112.84°$, $\beta = \gamma = 90°$, cell volume $=$ 99.07 Å^3.

Cell occupancy is shown in Table 5.28.

Very little data is available for this compound. It has been stated that it is not stable and tends to decompose when subjected to moisture and/or oxygen in air.

Calcium digermanide has the structure shown in Fig. 5.75.

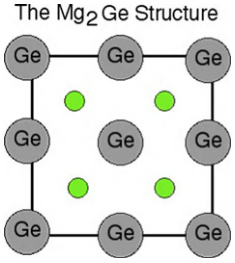

FIGURE 5.70

Cell parameters are: $a = b = 3.9492$ Å, $c = 10.493$ Å, $\alpha = \beta = 79.15°$, $\gamma = 60°$, cell volume $= 138.30$ Å^3. Cell occupancy is shown in Table 5.29.

The epitaxial growth of thin $CaGe_2$ films with reactive deposition epitaxy on Ge(1,1,1) substrates has been described. The films consisted in general of a mixture of the known trigonal rhombohedral tR6 modification and a hexagonal hR2 modification of $CaGe_2$ containing two Ca and two buckled Ge layers per unit cell in a twofold stacking sequence whose formation appears

to be favored by strain. Epitaxial layers of both polytypes show remarkably higher crystalline quality compared to epitaxial $CaSi_2$ films grown on silicon substrates. The tr-6 modification is found to be unstable in air in contrast to the hR-2 modification.

This novel polymorph of $CaGe_2$, which crystallizes with the hexagonal space group $P6_3mc$ (no. 186) with cell parameters of $a = 3.9966$ and $c = 10.211$ Å ($Z = 2$; Pearson's code *hP6*) has been reported when formed by flux synthesis. The structure can be viewed as

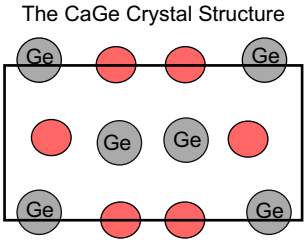

FIGURE 5.74

puckered layers of three-bonded germanium atoms, $^2{}_\infty[Ge_2]^{2-}$, which are stacked along the direction of the *c*-axis in an *ABAB*-fashion. The germanium polyanionic layers are separated by the Ca cations. As such, this structure is closely related to the structure of the other $CaGe_2$ polymorph, which crystallizes with the rhombohedral $CaSi_2$ type in the $R\bar{3}m$ space group (no. 166), where the $^2{}_\infty[Ge_2]^{2-}$ layers are arranged in an *AA'-BB'-CC'*-fashion, and are also interspaced by Ca^{2+} cations. LMTO calculations suggest that in spite of the formal closed-shell configuration for all atoms and the apparent adherence to the Zintl rules for electron counting, i.e. $Ca^{2+}[3b\text{-}^2{}_\infty[Ge_2]^{2-}]$, the phase will be a poor metal due to a small Ca-3*d*–Ge-4*p* band overlap. Magnetic susceptibility measurements as a function of the temperature indicate that the new $CaGe_2$ polymorph exhibits weak, temperature independent, Pauli paramagnetism. The hP6 structure can also be represented by Fig. 5.76.

The electrical resistivity of high-purity $CaGe_2$, $SrGe_2$, and $BaGe_2$ was measured in the temperature range from 20 to 800 °C by a four-point technique. $CaGe_2$ shows metallic behavior, while $SrGe_2$, and $BaGe_2$ are semiconducting. This difference can be explained by the change of the structure of the "anion" sublattices and the change of the metal distances in the metal sublattices.

Penta-calcium tri-germanide has the structure shown in Fig. 5.77.

Cell parameters are: $a = b = 7.74$ Å, $c = 9.148$ Å, $\alpha = \beta = 115.03°$, $\gamma = 90°$, cell volume $= 439.12$ Å^3. Cell occupancy is: Table 5.30.

Another view of the Ca_5Ge_3 structure may be seen in the following Fig. 5.78.

The electronic structure of Ca_5Ge_3 (Cr_5B_3 type), which can be formulated $(Ca^{+2})_5(Ge_2^{-6})Ge^{-4}$ in oxidation states, has been explored comparatively by means of semiempirical and first-principles density functional methods. The FP-APW calculations show that alkaline earth metal and germanium orbitals, particularly the d-orbitals on the cations and the p-π^* orbitals of the halogen-like dimeric Ge_2-6, mix considerably to form a conduction band. This covalency perfectly explains the unusual metallic properties of the nominally electron-precise Zintl phase Ca_5Ge_3 and its numerous relatives. Similar calculation results are obtained for Sr_5Ge_3, Ba_5Ge_3, and Ca_5Sn_3. Cation d-orbitals appear to be a common theme among Zintl phases that are also metallic.

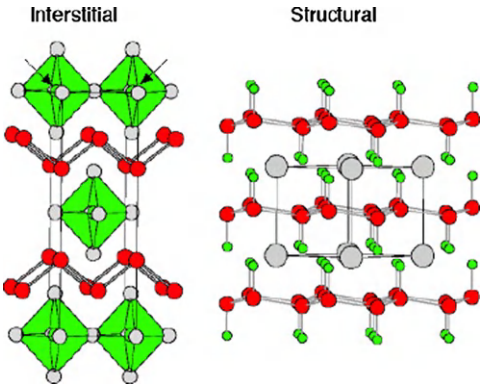

FIGURE 5.79

Hydrogen may be incorporated in Zintl phases in two different ways: either hydridic where H is exclusively coordinated by electropositive metals (interstitial hydrides), or as part of the polyanion where it acts as a covalently bonded ligand (polyanionic hydride). Both scenarios provide novel coordination environments and bonding scenarios for the atoms involved. This makes hydrogenous Zintl phases important model systems for fundamental studies of hydrogen–metal interactions. Simultaneously, hydrogen-induced chemical structure and physical property changes provide exciting prospects for materials science. In hydrogenous Zintl phases, hydrogen may occur hydridic or be part of the polymeric anion where it acts as a covalently bonded terminating ligand. This gives rise to the following structure types (Fig. 5.79).

Ca_5Ge_3 forms a structural type of hydride.

The compound, Ca_7Ge_6, is also known. It is isomorphous with Ca_7Sn_6 and melts at 1170 °C. However, little data concerning this compound has emerged in the open literature.

Calcium germanides, in general, have not been offered for sale commercially. They do not have an assigned CAS number. Stability in air and moisture is a critical factor for most of the compositions.

Strontium Germanides

Strontium metal forms a series of compounds with germanium metal as can be seen by examination of the phase Fig. 5.80.

The phase diagram of the Sr–Ge system has been investigated across almost the whole composition range (0–85 at.% Ge) using DTA and XRD. Four intermediate phases exist: Sr_2Ge ($PbCl_2$-type, orthorhombic oP12-Pnma), Sr_5Ge_3 (Cr_5B_3-type, tetragonal tI32-I4/mcm), SrGe (CrB-type, orthorhombic oC8-Cmcm) and $SrGe_2$ ($BaSi_2$-type, orthorhombic oP24-Pnma). A further intermediate phase, observed only at high temperature above 985 °C, crystallizes with a defective AlB_2-type structure. Four eutectics occur in the system: about 5 at.% Ge at 740 °C, 42 at.% Ge at 1100 °C, 61 at.% Ge at 965 °C and 85 at.% Ge at 755 °C. As a whole, the Sr–Ge system appears very similar to the Sr–Si one. The structure factors for the Sr–Ge system are given in Table 5.31.

Distrontium germanide has the structure shown in Fig. 5.81.

Lattice parameters are: $a = 5.166$ Å, $b = 8.153$ Å, $c = 9.593$ Å, $\alpha = \beta = \gamma = 90°$. Cell volume = 404.04 Å^3. Site occupancy is:

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy

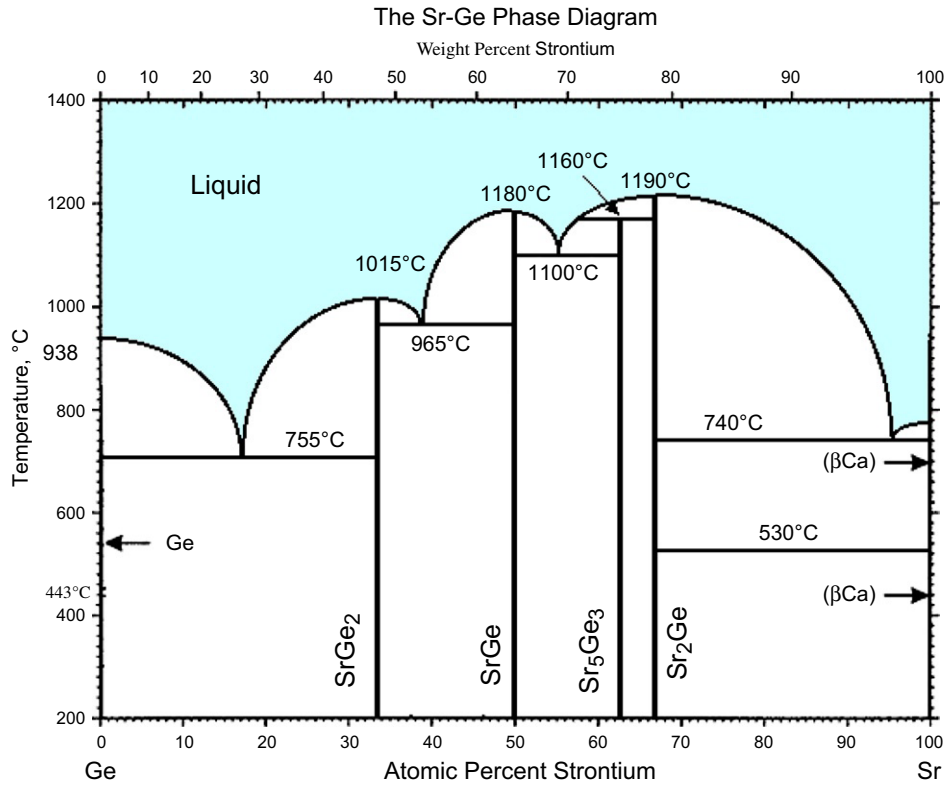

FIGURE 5.80

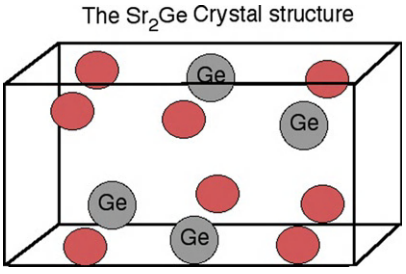

FIGURE 5.81

There is a dearth of information in literature concerning its physical properties.

The crystal **strontium monogermanide**, SrGe, has the structure shown in Fig. 5.82.

Lattice parameters are: $a = 4.17$ Å, $b = 4.82$ Å, $c = 6.18$ Å, $\alpha = 112.94°$, $\beta = \gamma = 90°$, cell volume $= 114.38$ Å^3. Site occupancy is shown in Table 5.32.

Other than structure data, little information concerning the physical properties of SrGe can be found.

Penta-strontium tri-germanide, Sr_5Ge_3, is dimorphic. One form has the same structure as that of its calcium homologue and is shown below. The other is orthorhombic and its structure is shown in Fig. 5.83.

Lattice parameters are: $a = b = 8.134$ Å, $c = 9.760$ Å, $\alpha = \beta = 114.626°$, $\gamma = 90°$, cell volume $= 521.172$ Å^3 (Table 5.33).

The orthorhombic form of Sr_5Ge_3 has the structure shown in Fig. 5.84.

Cell parameters are: $a = 8.134$ Å, $c = 9.7602$ Å, $\alpha = \beta = 114.626°$, $\gamma = 90°$, cell volume $= 521.72$ Å^3. Site occupancy is shown in Table 5.33.

Strontium di-germanide, $SrGe_2$, has the structure shown in Fig. 5.85.

Another form of the compound, $SrGe_2$, has the structure shown in Fig. 5.86.

Cell parameters are: $a = 6.82$ Å, $b = 8/63$ Å, $c = 11.15$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 654.33$ Å^3. Site occupation is shown in Table 5.34.

A number of similar $SrGe_2$ compounds have been investigated by means of different ab initio methods. All materials are found to be indirect band gap semiconductors displaying almost equal dispersion of bands close to the gap region. The energy gaps of 0.83, 0.57

and 0.44 eV are estimated for $BaSi_2$, $BaGe_2$ and $SrGe_2$, respectively.

A new germanide, $SrGe_{6-\delta}$ ($\delta = 0.5$), was synthesized by the reaction of Sr and Ge mixtures under a pressure of 5 GPa at 1200 °C. It crystallized in the orthorhombic space group Cmcm (no. 63) with $a = 4.0981(6)$ Å, $b = 11.159(1)$ Å, $c = 12.6825(8)$ Å, $V = 580.0(1)$ Å^3, and $Z = 4$. $SrGe_{6-\delta}$ is composed of a Ge covalent network having a cage-like structure and Sr atoms situated in the cages. Each Ge atom is coordinated by four neighboring Ge atoms. The coordination polyhedra are fairly distorted from an ideal tetrahedron, and the Ge network contains vacancies and disordering. The resistivity shows metallic behavior down to 2 K, and the positive thermoelectric power indicates that the dominant carriers to be holes. The structure has been determined to be in Fig. 5.87.

In contrast, the compound, $SrGe_{0.76}$, has the structure shown in Fig. 5.88.

This structure appears to be related to the $SrGe_{6-\delta}$ compound in structure.

In addition to the compounds described above, Sr forms a differing set of materials if Mg is added to the mix. Synthetic investigations of the $Sr_xMg_{2-x}Ge$ section have been carried out in sealed Ta containers. These reveal, in addition to the known Mg_2Ge, MgSrGe, and Sr_2Ge, two new phases with the nominal compositions $Sr_2Mg_{12}Ge_7$ and $Sr_5Mg_{19}Ge_{12}$. The first is a line compound that is isostructural with $Zr_2Fe_{12}P_7$ (P6,

$Z = 1$, $a = 11.064$ Å, $c = 4.356$ Å, and has the refined composition $Sr_{2.17}Mg_{11.83}Ge_7$. About 6% strontium substitutes in the larger, five-coordinate magnesium site. The other phase is isostructural with $Ho_5Ni_{19}P_{12}$ or the very similar $Sc_5Co_{19}P_{12}$ according to Guinier powder diffraction and is nonstoichiometric, viz. $Sr_{5+y}Mg_{19-y}Ge_{12}$ with an approximate range of $-0.7 \leq y \leq 2.7$. Both structures feature tricapped trigonal prismatic units of metal about isolated germanium atoms, these prisms being condensed by sharing some prismatic edges and faces. The new compounds are the first valence (Zintl) examples of structures previously known only for metallic transition metal phosphides and arsenides.

Although a considerable amount of investigation concerning the strontium germanide intermetallic compounds has been published, little usage in industry has resulted. These compounds have not been assigned CAS numbers although a few are available commercially for sale in limited quantities.

Barium Germanides

Barium forms a number of compounds with Ge as can be seen in the above phase diagram shown as Fig. 5.89.

Structure factors are listed in Table 5.35.

Dibarium germanide, Ba_2Ge, has the structure shown in Fig. 5.90.

Unit cell parameters are: $a = 5.48$ Å, $b = 8.38$ Å, $c = 10.04$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 461.06 Å^3. Site occupancy is shown in Table 5.36.

The compound, Ba_2Ge, has not been studied thoroughly except for its structural relationship to other barium germanide compositions.

Barium digermanide, $BaGe_2$, is dimorphic. One form has the structure shown in Fig. 5.91.

This structure may be compared to the Ba_2Ge composition where an excess of Ba atoms is present. Unit cell parameters are: $a = b = 44.769$ Å, $c = 8.1035$ Å, $\alpha = \beta = 107.113$ Å, $\gamma = 90°$, cell volume = 167.58 Å^3. Site occupancy is shown in Table 5.37.

The alternative structure has the form shown in Fig. 5.92.

Tetrahedral units, Ge_4^{2-}, are present as well as triangular units, Ge_3^{2-} in the structure. Unit-cell parameters are: $a = 6.83$ Å, $b = 9.05$ Å, $c = 11.65$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 720.10 Å^3. Site occupancy is shown in Table 5.38.

Barium monogermanide, BaGe, has the crystal structure shown in Fig. 5.93.

The cell parameters are: $a = 4.341$ Å, $b = 5.058$ Å, $c = 6.502$ Å, $\alpha = 112{,}89°$, $\beta = \gamma = 90°$, cell volume = 130.28 Å^3. Cell occupancy is shown in Table 5.39.

This compound has not been thoroughly researched and its physical properties remain unknown, except for structure.

Penta-barium tri-germanide has the structure shown in Fig. 5.94.

Unit-cell parameters are: $a = b = 8.529$ Å, $c = 16.554$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 1201.38$ Å^3. Site occupancy is shown in Table 5.40.

Barium also forms a tribarium tetragermanide that is dimorphic. One version has the form shown in Fig. 5.95.

Cell parameters are: $a = 11/799$ Å, $b = 12.21$ Å, $c = 12.097$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 1742.76$ Å^3. Site occupancy is shown in Table 5.41.

The other has the form shown in Fig. 5.96.

Cell parameters are: $a = 8.621$ Å, $b = 8.624$ Å, $c = 12.031$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 894.16$ Å^3. Site occupancy is shown in Table 5.42.

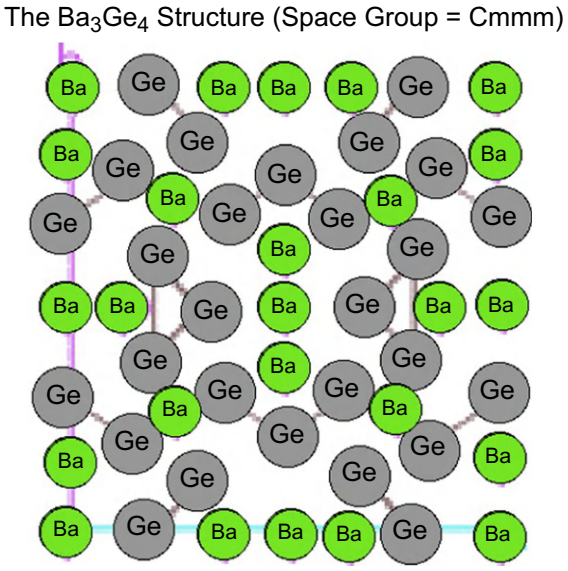

FIGURE 5.95

The composition, barium pentagermanide, $BaGe_5$, has been found to be semiconducting. $BaGe_5$ constitutes a new type of intermetallic clathrate obtained by decomposition of clathrate-I Ba_8Ge_{43}-3 at low temperatures. The crystal structure consists of characteristic layers interconnected by covalent bonds. $BaGe_5$ is a semiconducting Zintl phase (Fig. 5.97).

The reinvestigation of the crystal structure of $Ba_8Ge_{43\Delta 3}$ (space group, no. 230; $a = 21.3123(5)$ Å; $Z = 8$; Pearson symbol *cI*408) shows a full ordering of the vacancies (Δ) in the germanium framework. This ordered crystal structure can be considered as a derivative of an ideal "Ba_8Ge_{46}" clathrate-I-type structure (Pm3n, $a' = a/2$) in which three Ge vacancies (per formula unit) are allowed to order in a cubic superstructure with a doubled unit-cell parameter (Δ at the 24*c* site, space group Pm3n). In the resulting Ge framework, each vacancy Δ is surrounded by four three-bonded (3b)Ge^- species. The ordering in crystals of as-cast samples

(cooled in argon atmosphere, nonannealed) is partially disrupted. For the "as-cast" crystals, a short-range model is proposed based on the partial distribution of Ge on the 24*c* and 24*d* sites. From the electron balance, Ba_8Ge_{43} can be considered as a metallic Zintl phase with four excess electrons per formula unit. The Ba_8Ge_{43} phase is stable in the temperature range 770–810 °C and exists in equilibrium with Ba_6Ge_{25} and Ge. By decomposition of under cooled (metastable) Ba_8Ge_{43}, a new metastable binary $BaGe_5$ phase is formed.

Further work has resulted in another Zintl-type semiconductor based upon the Ba–Cu–Ge system. Eight

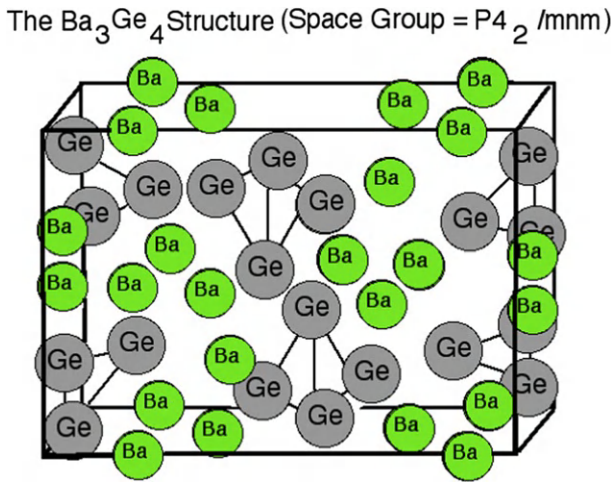

FIGURE 5.96

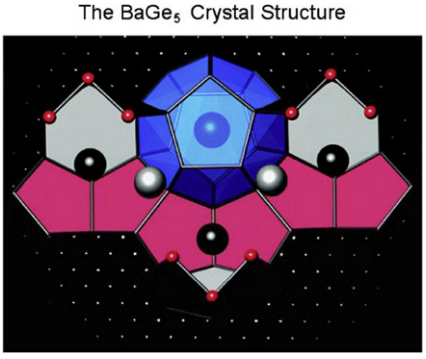

FIGURE 5.97

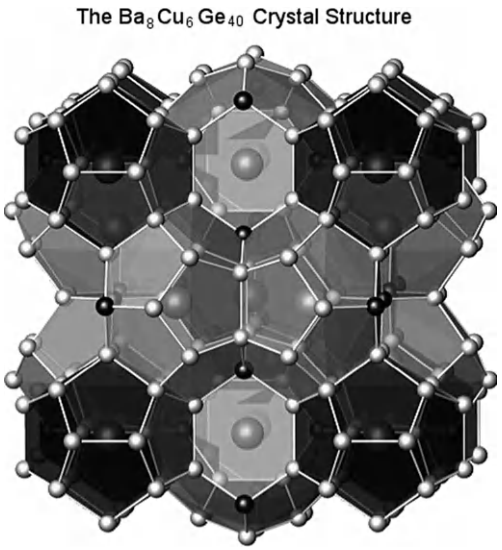

FIGURE 5.98

samples with nominal stoichiometry $Ba_8Cu_{6-x}Ge_{40+x}$ ($x = 0$ to 0.7) have been synthesized with a new method involving Ba_6Ge_{25} as an intermediate step. The new route provides fine control of the Cu:Ge ratio and allows systematic studies of the changes in the transport properties as a function of x. Resistivity, thermopower, and Hall carrier concentration all show systematic changes upon altering the Cu:Ge ratio. On the basis of density functional theory, we have calculated the electrical transport properties for fully ordered $Ba_8Cu_6Ge_{40}$. An optimal power factor is predicted for a Fermi level in the top of the valence band. Contrary to expectation, *n*-type behavior is observed in all samples, which appears to be due to small amounts of vacancies. Relatively low mobilities result in moderate thermoelectric properties with ZT = 0.07 at 400 K for the $x = 0.2$ sample. The structure determined was shown in Fig. 5.98.

Radium Germanides

Although radium germanides undoubtedly could be formed into the same type of compounds produced by the system Ba–Ge, there is no record of any work in the past or recent literature that has tried to characterize them. Without a doubt, this is due to the high cost of Ra metal as well as the high radioactive exposure level encountered.

5.4. ALKALINE EARTH OXY-TIN (STANNUM) COMPOUNDS

As a metal, tin forms alloys with a number of other elements. Alloys can be amorphous or crystalline. With the alkaline earths, it has been determined that there are a few crystalline alloy compounds of specific compositions. However, tin remains as a cation in these states, although it is not as electropositive as the alkaline earths. In both cases, both Sn and M (M = Be, Mg, Ca, Sr, Ba, Ra) remain in an elemental state, i.e. Sn^0 and M^0.

Tin has two valence states, Sn^{2+} and Sn^{4+}. Tin oxides are amphoteric and dissolve in aqueous solution under both acidic and basic conditions. As cations, they are sometimes called "Stannous" and "Stannic". As anions, chemical combination with any given cation is designated as a "stannite" or "stannate". These compounds are also called "metastannate" and "orthostannate", although this designation is not strictly correct. Stannic oxide, SnO_2, although insoluble in water, occurs in nature as the "Cassiterite" ore. It has been described as difficult to dissolve in acids and alkalis. "Stannic acid" refers to hydrated tin dioxide, $SnO_2 \cdot xH_2O$, which is also called "stannic hydroxide".

5.4.1. Stannides of the Alkaline Earths

The alkaline earths form a series of "Stannides" of the general formula "M_xSn_y, where both x and y can vary form 1 to 6, and combinations thereof.

Beryllium Stannides

The metal, Be, melts at 1287 °C while the metal, Sn, melts at 232 °C. However, the reaction:

$$Be(solid) + Sn(liq) \Rightarrow Be_xSn_y(solid)$$

does not occur. No beryllium stannides are known and there are no references in the literature that describe the physical or chemical properties of any possible compounds.

Magnesium Stannides

The metal, Mg, melts at 651 °C while the metal, Sn, melts at 232 °C.

The reaction:

$$Mg(solid) + Sn(liq) \Rightarrow Mg_xSn_y(solid)$$

forms a limited series of compounds like Mg_2Sn. However, combining the two metals above their melting temperatures usually results in an amorphous alloy combination, not a compound or series of compounds. The observed asymmetry in the properties of mixing of Mg–Sn alloy in molten state has been successfully explained on basis of the quasi-lattice model. This method has been utilized to determine the free energy of mixing, entropy of mixing, heat of mixing, the concentration–concentration structure factor in long wave length limit [Scc(0)] and the Warren Cowley short-range order parameter (α1) of the Mg_2Sn alloy in a molten state

at 1073 K (800 °C). The analysis suggests that hetero-coordination leading to the formation of a chemical complex-like Mg_2Sn is likely to exist in the melt but is weakly interacting in nature. The interaction energies between the species of the melt are found to depend considerably on temperature and the alloy is more ordered toward Mg-rich region. Only one compound can be formed from the melt as shown in the following phase Fig. 5.99.

Only one compound is shown, Mg_2Sn, but the compound, Mg_9Sn_5 has also been documented. The crystal parameters are given in Table 5.43.

A comparison of these structures can be seen in the following Fig. 5.100.

Cell parameters are:

Mg_2Sn

$a = b = c = 4.7496$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 77.21 Å^3, cell occupancy is shown in Table 5.44.

Mg_9Sn_5

$a = b = c = 8.8027$ Å, $\alpha = \beta = \gamma = 97.358°$, cell volume = 663.64 Å^3, cell occupancy is shown in Table 5.45.

$Mg_{0.974}Sn_{0.026}$

$a = b = 3.2058$ Å, $c = 5.2194$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 46.44 Å^3, cell occupancy is:

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	M	$Mg_{0.974} + Sn_{0.026}$	2	c	-6m2	1/3	2/3	1/4	1.0

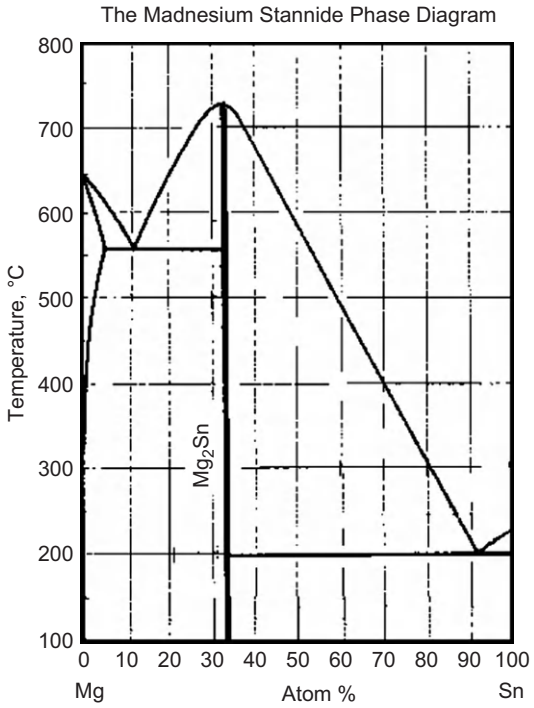

FIGURE 5.99

$Mg_{0.15}Sn_{0.85}$

$a = 3.011$ Å, $b = c = 3.189$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 26.47 Å^3, cell occupancy is shown in Table 5.46.

Single crystals of Mg_9Sn_5, a supposed high-pressure modification of Mg_2Sn, have been obtained from the elements by high-pressure and high-temperature reaction in a modified Belt-type apparatus (Ta capsule, 50 kbar, cooling = 1400 °C ⇒ 500 °C, and subsequent quenching to ambient conditions). The compound crystallizes trigonally, space group R3d, with $a = 13.222$, $c = 13.150$ Å, $c/a = 0.9946$ and $Z = 6$. Final residuals after refinement against F_2 were R1 = 0.0297, wR2 = 0.0811 and $S = 0.927$ for 85 refined parameters and 975 unique reflections. The crystal investigated showed obverse–reverse twinning and a pronounced pseudo-symmetry.

The crystal structure of Mg_9Sn_5 comprises a framework of magnesium atoms with an arrangement similar to that found in Fe_2P. The tin atoms are accommodated in tunnels running along the c-axis. Mg_9Sn_5 is at least very similar, perhaps even identical, with the "dense form of Mg_2Si", described by Cannon and Conlin (1964).

However, most of the published work has involved the Mg_2Sn type of compound. By varying the ratio of

Mg/Sn in the Mg_2Sn melt, it is possible to obtain crystals with either *n*-type or *p*-type semiconducting properties. Resistivity and Hall measurements were carried out on Mg_2Sn crystals in the temperature range 300–60 K (−215 to 25 °C). Single crystals were grown by a modified Bridgman technique from stoichiometric melts and from melts containing 1, 2, 10, and 18 at.% excess Sn and 3 at.% excess Mg. In the mixed conduction and

extrinsic ranges, it was found possible to describe the calculated temperature dependence of the conduction mobility based on a combination of lattice vibration (acoustic mode) and ionized impurity scattering. A stoichiometry effect was observed. The Mg_2Sn crystals appear to dissolve the excess constituent producing *n*-type crystals (excess Sn) and *p*-type crystals (excess Mg). The observed effect corresponds to a solubility of 10^{-5} to 10^{-6} action excess constituent. This result was briefly discussed in terms of bonding in Mg_2Sn that has been found to consist of weak covalent bonds (Fig. 5.101).

By ball milling, a mixture of Mg–Sn metals, the mechanical alloying (MT) of a mixture of pure metals under argon or hydrogen atmosphere initially leads to the formation of the stable cubic structure of Mg_2Sn. Its transformation into the high-pressure and high-temperature phase of Mg_2Sn is produced during the course of milling. This metastable hexagonal structure transforms into the stable phase at 440 °C.

With the discovery of the MT method that produces stable compounds at room temperature, interest in industry has revived. Mg_2Sn has two relevant physical properties. It is an *n*-type semiconductor and it is a thermoelectric compound with a Seebeck coefficient that exceeds any other known compound, particularly when combined with Mg_2Si. Samples based on Mg_2Si–Mg_2Sn solid solutions, with a density exceeding 95% of theoretical density, have been prepared. The thermoelectric properties (Seebeck coefficient, electrical and thermal conductivities) have been measured in the temperature range 300–850 K (25–575 °C). Measurements of the thermoelectric properties from about 80 to 700 K show that the presence of excess Sn or Mg in the Mg_2Sn crystal decreases the absolute values of the Seebeck coefficient but causes the electrical conductivity to increase. The net effect of a small amount of finely dispersed inclusions leads to enhancement of the power factor, while larger amounts of free Mg or Sn or $Mg_2Sn + Mg$ eutectic can form interconnected microstructures which, while causing the electrical conductivity to increase, also lower the Seebeck coefficient and thus lead to a lower power factor. However, it is possible to disperse these coarse inclusions by powder metallurgy followed by hot pressing to produce bulk materials with nanoscale grain size and containing a large concentration of submicron inclusions of metal-like and semiconducting secondary phases which are effective in scattering phonons, i.e. decreasing the thermal conductivity, thus greatly enhancing the figure of merit.

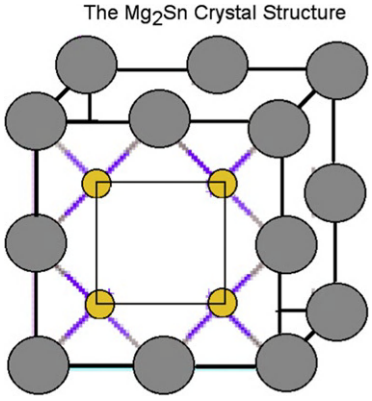

FIGURE 5.101

Phase relations in the Mg_2Sn–Sn system were studied by DTA at a pressure of 5.8 GPa and temperatures up to 1100 °C. A schematic *p*,*T* diagram for Mg_2Sn has been presented. Single crystals of the high-pressure phase of Mg_2Sn were obtained by growth from a molten solution under high pressure. Crystal data for Mg_2Sn(II) were determined using a Berger precession X-ray camera. The phase Mg_2Sn(II) crystallizes with a hexagonal unit cell, $a = 13.19 \pm 0.01$ Å, $c = 13.28 \pm 0.01$ Å, $c/a = 1.006$, $D_m = 4.1 \pm 0.2$ g/cm^3, $Z = 30$, $D_c = 4.17$ g/cm^3, space group $P3c1$ (no. 158) or (no. 163).

Positive electrodes for Li-ion and lithium batteries (also termed "cathodes") have been under intense scrutiny since the advent of the Li-ion cell in 1991. This is especially true in the past decade when Mg_2Sn came to the forefront. The electrochemical properties of Mg_2Sn were investigated to evaluate a new anode material for a lithium battery. A Mg_2Sn intermetallic compound was synthesized by the mechanical alloying (MA) method. As a result, it was found that the reversible insertion–extraction of a large amount of lithium can be electrochemically inserted in a mechanically alloyed Mg_2Sn. The Mg_2Sn changed its own crystal structure from cubic to orthorhombic with increasing MA time. The compound exhibiting a good performance as an anode had a mixture of cubic and orthorhombic phases. The discharge capacity of the Mg_2Sn electrode was still maintained at 250–300 mA h/g even after a 20 times charge–discharge cycle. The reaction proceeded without any phase separation and/or decomposition of the compound. Mg_2Sn is regarded as a promising anode material for lithium secondary batteries.

Further work has shown that the reversibility of alloying of lithium with the cubic phase of Mg_2Sn can be faulty in a lithium battery. Through in situ XRD measurements, the reactivity mechanisms of cubic Mg_2Sn toward lithium were deduced. It entails first a monophasic insertion of about one lithium per formula unit into the fcc Sn framework without extrusion of either Mg or Sn, then a biphasic process leading to the formation of cubic Li_2MgSn concomitant with a progressive expulsion of Mg, and finally the formation of

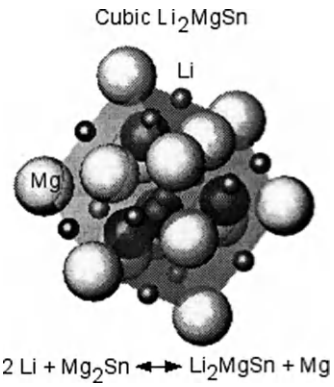

FIGURE 5.102

Li–Mg solid-solution alloys. Upon charging, the poor reversibility of the alloying reaction of Li with Mg leads to a deficit in free Mg, resulting in the formation of a $Mg_2Sn + Sn$ mixture, and accounting for the poor cyclability of Mg_2Sn/Li cells over the 0.0–1.5 V voltage window. Limiting the cycling to the monophasic process was shown to improve the cycling behavior. Finally, it was found that the electrochemical reaction of high-pressure Mg_2Sn(II) with Li leads to the same Li_2MgSn intermediate and the same subsequent sequence of transformations, resulting in similarly poor capacity retention upon cycling. The structure determined is shown in the following Fig. 5.102.

It is for this reason that Ag and/or Mg_2Si has been added to Mg_2Sn to improve this type of performance.

Mg_2Sn ingots, doped *p*-type by the addition of 0–1.0 at.% Ag, were prepared by the vertical Bridgman method at growth rates ~0.1 mm/min. The crystalline quality and microstructure of ingots were analyzed by XRD, scanning electron microscopy and energy-dispersive X-ray spectroscopy. The single-phase Mg_2Sn ingots consist of highly oriented large grains. Measurements of the Hall coefficient, Seebeck coefficient a, and electrical conductivity s in the temperature range 80–700 K were conducted to study the dependence on the silver content, and to determine the thermoelectric power factor a^2s which reached a maximum value 2.4×10^{-3} W/m/K^2 at 410 K (207 °C) for 1.0 at-% Ag content.

In another paper, $Mg_2Si_{1-x}Sn_x$ ($x = 0.2$, 0.4, 0.6 and 0.8) thermoelectric materials have been prepared by vacuum melting and melting/hot-pressing methods. The phase structures and electrical transport properties were measured. The relationships between electronic structures and electronic properties are discussed. XRD showed that the hot-pressed compounds were better formed. The electrical conductivity and Seebeck coefficient measurements showed that the properties of the compounds were dramatically affected by solid solubility. When $x = 0.2$, the highest electrical conductivity resulted in the highest power factor of 1.32×10^{-3}/Wm/K^2 at about 500 K, while the highest value of Seebeck coefficient of -459 μvk^{-1} was obtained at about 450 K for $x = 0.6$.

Mg_2Sn has the CAS number of 1313-08-2 and is available commercially.

Calcium Stannides

The metal, Ca, melts at 842 °C while Sn melts at 232 °C. The SSR of the metals produces:

$$2Ca + Sn \Rightarrow Ca_xSn_y$$

as a product, where x or y can vary from 1 to 30. The phase diagram of the Ca–Sn system has been investigated in the whole composition range using DTA, metallographic analysis, single-crystal and powder XRD. Seven intermediate phases have been found. Four of them have been confirmed: $CaSn_3$ ($AuCu_3$-type), CaSn (CrB-type), $Ca_{31}Sn_{20}$ ($Pu_{31}Rh_{20}$-type) and Ca_2Sn (Co_2Si-type). They melt congruently while Ca_7Sn_6 (Ca_7Sn_6-type), $Ca_{36}Sn_{23}$ ($Yb_{36}Sn_{23}$-type) and Ca_5Sn_3 (Cr_5B_3-type) have been identified and characterized as melting incongruently, as shown in the following phase Fig. 5.103.

Four eutectic points occur in this system: at about 5 at.% Sn and 780 °C, 48 at.% Sn and 995 °C, 68 at.% Sn and 610 °C, and at less than 1 at.% Ca and 225 °C. It was also found that $Ca_{36}Sn_{23}$ is a mechanically unstable phase. Results on the electronic energy band and densities of states also indicated that Ca_2Sn, is a direct band gap semiconductor with a band gap of 0.07 eV. In addition, it is found that the absolute values of heats of formation for all Ca–Sn intermetallics are larger than 30 kJ/mol atom.

The crystal structure data is shown in the following Table 5.47.

The following shows a comparison along the a ⇒ c vector plane of the structures (Fig. 5.104).

Unit-cell parameters for these compounds are:

$Ca_{0.15}Sn_{0.85}$

$a = 2.994$ Å, $b = c = 3.151$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 25.74 Å^3, cell occupancy is shown in Table 5.48.

$Ca_{31}Sn_{20}$

$a = b = 12.5422$ Å, $c = 21.8781$ Å, $\alpha = \beta = 106.66°$, $\gamma = 90°$, cell volume = 3146.02 Å^3, cell occupancy is shown in Table 5.49.

CaSn

$a = 4.349$ Å, $b = 4.841$ Å, $c = 6.244$ Å, $\alpha = 112.71°$, $\beta = \gamma = 90°$, cell volume = 120.77 Å^3, cell occupancy is shown in Table 5.50.

Ca_3Sn

$a = b = c = 4.732$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 105.96 Å^3, cell occupancy is shown in Table 5.51.

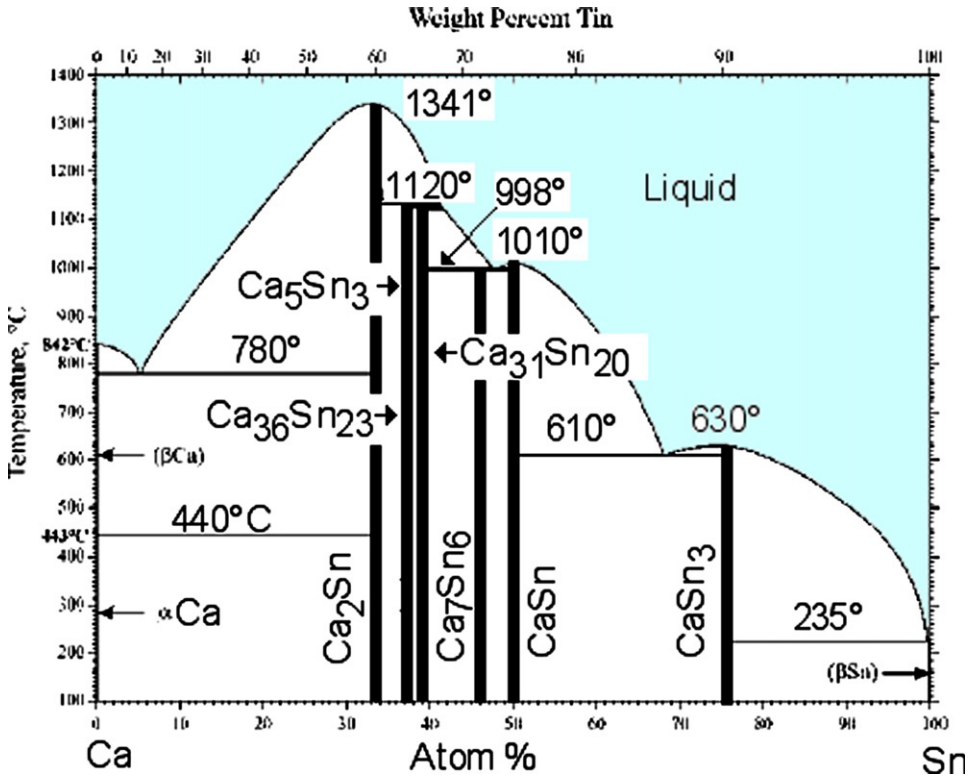

FIGURE 5.103

Ca_2Sn

$a = 5.044$, $b = 7.975$ Å, $c = 9.562$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 384.64$ Å^3, cell occupancy is shown in Table 5.52.

The standard free energies of formation of dicalcium stannide were determined by a chemical equilibration technique, yielding the following results:

$$2Ca(liq) + Sn(liq) = Ca_2Sn(solid):$$

$$\Delta G° = -353{,}970 + 79.28\,T\ (J/mol)\ 1000\ °C \text{ to } 1300\ °C.$$

Dicalcium stannide is a thermoelectric material. Approximate room temperature values for the figures of merit of stoichiometric calcium stannide, and strontium stannide have been determined. The highest value obtained was about 7×10^{-5} (K), for the latter compound.

X-ray investigations have shown that Ca_2Sn is an isotype with Ca_2Si and Ca_2Ge ($PbCl_2$-structure, C23-type). Lattice constants, space group, and point parameters are: Ca_2Sn: $a = 9.562 \pm 0{,}004$; $b = 7.975 \pm 0.004$;

3	Sn	Sn	4	c	.m.	0.253	1/4	0.389	1.0

$c = 5.044 \pm 0.003$ Å. The point group is D_{2h}^{14} and the space group is D-Pbnm; the atoms lie at:

$$4c \pm (x,y,1/4) \text{ and } (1/2 - x,1/2 + y,1/4)$$

The phase, $Ca_{31}Sn_{20}$, has a tetrahedral symmetry with: $a = 12.542$ Å, $c = 40.00$ Å, space group = I4/mcm, $V = 6292$ Å^3, $Z = 4$ and $d = 3.74$ g/cc.

Calcium distannide, $CaSn_2$ is not known.

The compound, **calcium tristannide**, $CaSn_3$, once formed, is immediately decomposed by air at room temperature. It has been observed to possess a pronounced singularity of orbital magnetic susceptibility. The degeneracy points of the electronic energy bands close to the Fermi level are found to be responsible for the anomalous diamagnetism in $CaSn_3$ alloys. The appearance and smearing of this anomaly with temperature and impurities were analyzed, and corresponding band structure and scattering parameters were determined. This compound, in argon gas atmosphere, melts congruently with:

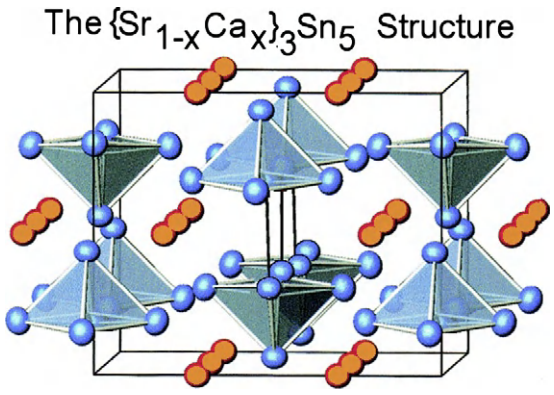

FIGURE 5.105

$$\Delta S \text{ melting } (Ca_{0.25}Sn_{0.75}) = 14.6 + 0.1 \text{ J/mol degree;}$$
$$T_{melting} = 891 \pm 1 \text{ K}$$

All attempts to obtain the pure Ca phase of **tricalcium pentastannide**, Ca_3Sn_5, have been unsuccessful. However, the compound, Sr_2CaSn_5, has been prepared. It was found to crystallize in the Pu_3Pd_5 structure type (SG = Cmcm) with cell dimensions of $a = 10.5179(9)$ Å, $b = 8.4789(8)$ Å, and $c = 10.7623(10)$ Å (Fig. 5.105).

The structure consists of isolated Sn_5^{6-} square-pyramidal units surrounded by cations that seem to play a crucial role in stabilizing the Zintl polyanions. The square pyramids contract at low temperatures (100 K = −173 °C) leading to the shortening of the basal intracluster Sn–Sn bond (2.74 Å), while the intercluster bonds become very large, indicating that features of bond-stretching isomerism are known for both Sr_3Sn_5 and Ba_3Ge_4. Study of different crystals shows a slight variation in the lattice parameters, suggesting the presence of a definite phase width which was substantiated by the successful synthesis of monophasic samples of $Sr_{3-x}Ca_xSn_5$ ($0.5 \le x \le 2.5$). The structure is shown in the following diagram which depicts the alkaline earth positions as "reddish-orange". The atom coordinates for this structure are given in Table 5.53.

The phase, $Ca_{31}Sn_{20}$ (which is related to Ca_3Sn_2—**tricalcium distannide**), can be obtained by allowing the pure elements to react in sealed Ta containers at 1100–1180 °C followed by slow cooling. It is isostructural with $Pu_{31}Pt_{20}$. The structure of $Ca_{31}Sn_{20}$ was redetermined (I4/mcm, $Z = 4$, $a = 12.5267$ Å, $c = 39.912$ Å). A description of the structure is given in terms of isolated tin atoms plus well-bonded tin dimers and linear pentamers (d(Sn–Sn) = 3.06–3.16 Å) in proportions of 5:5:1 within a rather distorted W_5Si_3-like framework. It was also found that $Ca_{36}Sn_{23}$ is a mechanically unstable phase.

The addition of hydrogen to these stannides forms a series of Zintl phases. The electronic structure of three recently discovered Zintl-phase hydrides: $SrAl_2H_2$, Ca_3SnH_2, and Ca_5Sn_3H have been analyzed. The energy bands and the total and partial densities of states were computed by means of the full-potential linearized augmented plane wave method. It was found that $SrAl_2H_2$ and Ca_5Sn_3H hydrides are metallic and Ca_3SnH_2 is a small-gap semiconductor.

Calcium stannides have no CAS number and are not offered for sale commercially.

Strontium Stannides

The metal, Sr, melts at 776 °C while Sn melts at 232 °C. The SSR of the two at 900 °C produces a compound with atomic ratios according to those of Sr/Sn used in the original mixture:

$$2Sr + Sn \Rightarrow Sr_2Sn$$

The phase diagram of the Sr–Sn system was investigated over the complete compositional range by means of DTA, XRD, optical microscopy (LOM). All the already known intermediate phases: Sr_2Sn ($PbCl_2$-type), Sr_5Sn_3 (Cr_5B_3-type), SrSn (CrB-type), Sr_3Sn_5 (Pu_3Pd_5-type), $SrSn_3$ ($PuGa_3$-type) have been confirmed. Also the very new compound, $SrSn_4$, recently determined, could be confirmed in this work. Three eutectics occur in the system: at about 2.5 at.% Sn and 752 °C, 45.5 at.% Sn and 1100 °C and about 99.0 at.% Sn and 230 °C (Fig. 5.106).

A part of the Sn–Sr phase diagram was investigated in 1981 and later by other investigators (1981). The entire phase diagram was reinvestigated in 2004 by means of DTA, XRD and optical microscopy. The result is shown below. The associated crystal structure data is shown in Table 5.54.

One paper reported that SnSr and SnSr2 were dimorphic. However, the 2004 investigation found no phase transitions in these compounds. The Sn_5Sr_3 phase was unknown.

Only two compounds, Sr_2Sn and SrSn, melt congruently. The other three melt incongruently, decomposing to the adjacent compound. For example, Sr_5Sn_3 decomposes to form Sr_2Sn and SrSn:

$$Sr_5Sn_3 + \text{heat} \Rightarrow 2Sr_2Sn + SrSn$$

$$Sr_3Sn_5 + \text{heat} \Rightarrow SrSn + SrSn_3$$

$$4SrSn_3 + \text{heat} \Rightarrow Sr_3Sn_5 + SrSn_4 + 3Sn$$

$$SrSn_4 + \text{heat} \Rightarrow SrSn_3 + Sn$$

A comparison of the a ⇒ c vector plane of four of these structures is shown in the following Fig. 5.107.

Unit-cell parameters are:

Sr_2Sn

$a = 5.378$, $b = 8.402$ Å, $c = 10.078$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 455.38 $Å^3$, cell occupancy is shown in Table 5.55.

Sr_2Sn

$a = b = 8.565$ Å, $c = 10.138$ Å, $\alpha = \beta = 114.99°$, $\gamma = 90°$, cell volume = 596.45 $Å^3$, cell occupancy is shown in Table 5.56.

SrSn

$a = 4.495$ Å, $b = 5.045$ Å, $c = 6.527$ Å, $\alpha = 112.74°$, $\beta = \gamma = 60°$, cell volume = 136.49 $Å^3$. Cell occupancy is shown in Table 5.57.

$SrSn_3$

$a = b = 6.945$ Å, $c = 11.710$ Å, $\alpha = \beta = 72.76°$, $\gamma = 60°$, cell volume = 458.96 $Å^3$. Cell occupancy is shown in Table 5.58.

Strontium tetrastannide, $SrSn_4$, is a superconducting stannide with localized and delocalized bond character.

This compound is the tin-richest phase in the system Sr–Sn and is obtained by stoichiometric combination of the elements. $SrSn_4$ decomposes in a peritectic manner with formation of $SrSn_3$ and Sn at 340 °C. The structure determined from a single crystal shows a new structure type with a novel structure motive in tin chemistry. It can be described by a corrugated, distorted quadratic net of tin atoms as the only building unit. The nets intersect at common Sn atoms, and the resulting channels host the Sr atoms (Fig. 5.108).

The structure can alternatively be described as an intergrowth structure of the AlB_2-type and W-type. The atoms that are connected by the two shortest Sn–Sn distances (2.900 and 3.044 Å) form a two-dimensional net consisting of hexagons of tin atoms. The hexagons have boat conformation in contrast to the rather similar alpha-As structure type, where hexagons have a chair conformation. Further tin atoms connect the two-dimensional net of Sn hexagons. Temperature-dependent magnetic susceptibility measurements show that $SrSn_4$ is superconducting with $T(c) = 4.8$ K at 10 G. LMTO band structure and density of states (DOS) calculations verify the metallic behavior of $SrSn_4$. An analysis of the electronic structure with the help of the electron localization function (ELF) shows that localized covalent bonds beside delocalized bonds

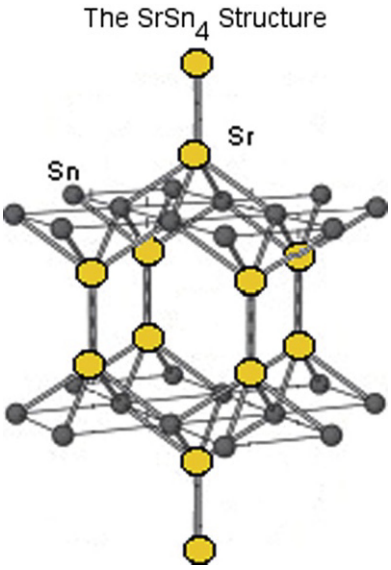

FIGURE 5.108

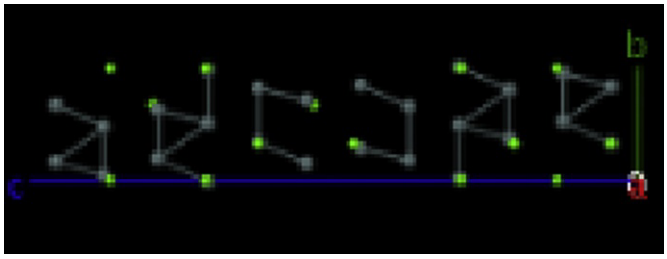

FIGURE 5.109

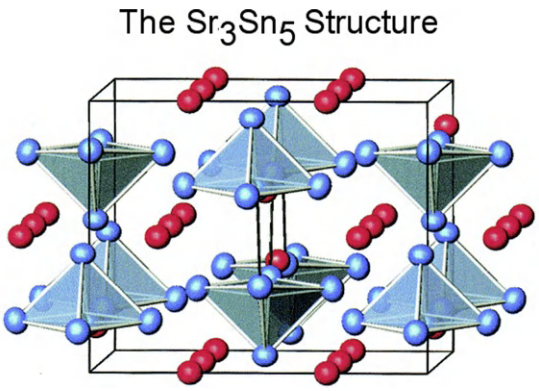

FIGURE 5.110

coexist in $SrSn_4$. The structure of $SrSn_4$ is characterized by regions, which can be described by covalent bonds between the Sn atoms and regions with higher coordination numbers for Sn, which are typical for intermetallic compounds. Therefore, $SrSn_4$ is an example for the structural transition between Zintl phases and intermetallics.

Strontium tristannide, $SrSn_3$, shows a transition to the superconducting state at 5.4 K and $SrSn_4$ at 4.8 K. $SrSn_3$ crystallizes in the Mg_3In-type, which consists of distorted hexagonal layers with AB_3 composition, similar to the above structure. In addition, a Zintl compound composed of $SrSn_3 \cdot SrSb_4$ has been synthesized and its structure has been determined by single-crystal XRD methods. It crystallizes in the orthorhombic space group—Pnma with $a = 10.060$ Å, $b = 4.361$ Å, $c = 22.934$ Å, and $Z = 4$ at 22 °C. The structure of $Sr_2Sn_3Sb_4$ may be described as consisting of large, narrow channels running along [010] defined by 30-membered rings constructed from an anionic framework of linked $SnSb_4$ tetrahedra, $SnSb_3$ trigonal pyramids, and zigzag Sb–Sb chains. Sr^{2+} cations are situated within these channels. This structure has the following symmetry where the coordination along the *a*-axis is shown in Fig. 5.109.

The atom coordinates for this structure are given in Table 5.59.

The structure of **tristrontium pentastannide**, Sr_3Sn_5 is isotypic to one of Pu_3Pd_5. The basic structural unit is a distorted square pyramid of Sn atoms. Those $[Sn_5]^{6-}$ anions can be regarded as a Wades cluster of the arachno type. The strontium and tin atoms are clearly seen in the above diagram, as shown in Fig. 5.110.

The electronic structure of the pyramidal Zintl anions and the influence of the number of skeletal electrons of these clusters were investigated using the ELF. The structural relationship between Sr_3Sn_5 and the Zintl phases Ba_3Si_4 and Ba_3Ge_4 are analyzed. Additionally, two new Zintl phases $Ba_3Ge_{2.82}Sn_{2.18}$ and $Ba_3Ge_{3.94}Sn_{0.06}$, have been synthesized and their structures are reported, which directly show that the exchange of tin against germanium leads to a change from the $M_{3\times5}$ to the $M_{3\times4}$ structure type. This effect

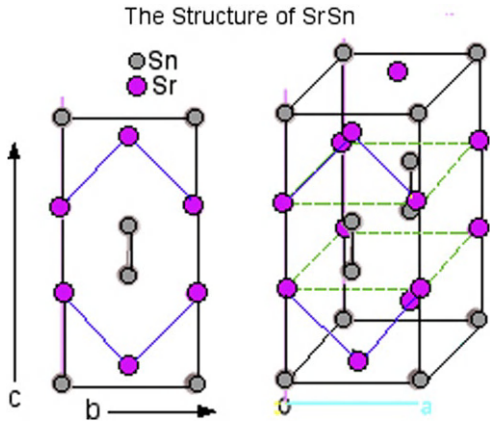

FIGURE 5.111

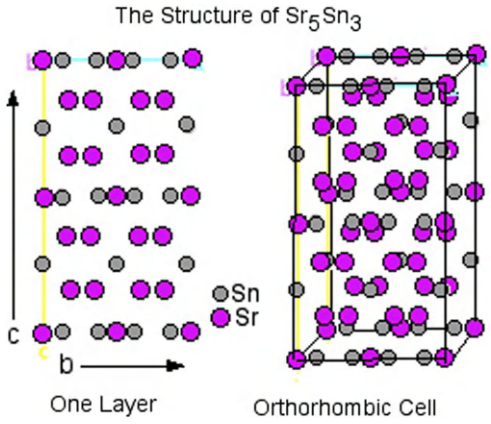

FIGURE 5.112

is traced back to the maximal charge acquisition property of the Zintl anions of heavier and lighter tetralides.

This compound contains square pyramidal Sn_5^{6-} polyanions and was been obtained by direct fusion of the elements at 570 °C, followed by slow cooling or annealing. The crystal structure was refined in the Pu_3Pd_5 structure type (orthorhombic, *Cmcm*, $Z = 4$) with cell dimensions of $a = 10.644$ Å, $b = 8.588$ Å, and $c = 10.895$ Å. Square pyramidal clusters of the tetrel elements are weakly interlinked into chains via two types of longer intercluster interactions that are mediated by bridging cations and substantially influenced by cation size and the free electron count. The new compounds are all metallic, in agreement with simple valence considerations that predict two and five extra electrons per formula unit. Extended Hückel tight-binding calculations on this compound reveal that bonding in the regions below and around the Fermi energies are dominated by general cation–anion interactions, that is, lattice covalency.

In another paper, the two binary Zintl phases, Sr_3Sn_5 and Ba_3Sn_5, have been synthesized and structurally characterized. The revised structure of Ba_3Pb_5 is also reported. All of these compounds are isotypic and crystallize with a modified Pu_3Pd_5 structure type. The anionic substructure is composed of Sn_5^{6-} square pyramidal clusters, which are described as arachno clusters according to the Wade–Mingos electron counting rules. The electronic structure of the pyramidal Zintl anions and the influence of the number of skeletal electrons of these clusters have been investigated using the ELF.

Although **strontium monostannide**, SrSn, has been synthesized, it has not been studied intensely. SrSn is a thermoelectric material but its Seebeck coefficient is lower than other known thermoelectrics. The highest value obtained was about 7×10^{-5}/K. The structure is presented shown in Fig. 5.111.

SrSn is orthorhombic with cell parameters of: $a = 5.045$ Å, $b = 12.04$ Å, $c = 4.494$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume $= 272.97$ Å^3, $d = 5.02$ g/cc, $Z = 4$. The atom coordinates for this structure are given in Table 5.60.

Pentastrontium tristannide, Sr_5Sn_3, also has not been the object of intense study academically. The phases Sr_5Sn_3 and Ba_5Sn_3 crystallize with the tetragonal Cr_5B_5 structure type and Sr_5Bi_3 is isostructural with orthorhombic β-Yb_5Sb_3. Single crystals of Sr_5Sb_3 in the orthorhombic form (β-Yb_5Sb_3 structure type) were obtained as a minor product of a reaction of the elements and Mn in a welded Nb container. To date only the hexagonal form (Mn_5Si_3-structure type) of Sr_5Sb_3 has been reported. The orthorhombic phase of Sr_5Sb_3 has synthesized in high yield by the reaction of stoichiometric amounts of the elements in an alumina crucible, sealed in a quartz tube. The structure is shown in the following Fig. 5.112.

The atom coordinates for this structure are given in Table 5.61.

Distrontium stannide, Sr_2Sn, also is orthorhombic but with differing cell parameters, as might be suspected. They are: $a = 8.402$ Å, $b = 5.378$ Å, $c = 10.078$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume $= 455.38$ Å^3. The structure is given in Fig. 5.113.

These three compounds may be compared to each other. Strontium stannides have no CAS number and are not available commercially.

Barium Stannides

Barium stannides can be formed through the reaction of the melted metals, provided that air is excluded from the reaction zone. The reaction that is used is:

$$x\mathrm{Ba} + y\mathrm{Sn} + \text{heat} \Rightarrow \mathrm{Ba}_x\mathrm{Sn}_y$$

where x and y usually varies from 1 to 6. In the phase diagram of the Ba/Sn system, the compounds Ba_2Sn, Ba_5Sn_3, Ba_3Sn_5, BaSn, $BaSn_2$, $BaSn_3$ and $BaSn_5$ have been recognized. The conditions for the synthesis of Ba_3Sn_5, $BaSn_3$, and $BaSn_5$ were optimized by DTA experiments of the corresponding stoichiometries of the binary phase system. Magnetic measurements showed that $BaSn_3$ and $BaSn_5$ become superconducting at 2.4 and 4.4 K, respectively. A partial substitution of Ba atoms by Sr atoms causes for $BaSn_3$ no significant change of the critical temperature. A higher transition temperature is observed in $BaSn_5$ if a part of Ba is replaced by Sr. The structural relationship between Ba_3Sn_5 and the Zintl phases, Ba_3Si_4 and Ba_3Ge_4, were analyzed. Additionally, two novel Zintl phases, $Ba_3Ge_{2.82}Sn_{2.18}$ and $Ba_3Ge_{3.94}Sn_{0.06}$, have been synthesized and their structures reported, which directly show that the exchange of tin against germanium leads to a change from the $M_{3\times5}$ to the $M_{3\times4}$ structure type. This effect is traced back to the maximal charge acquisition property of the Zintl anions of heavier and lighter tetralides. Although a number of barium stannide

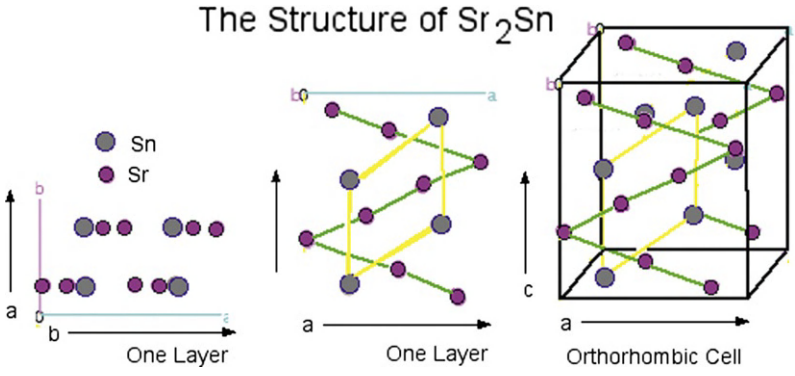

FIGURE 5.113

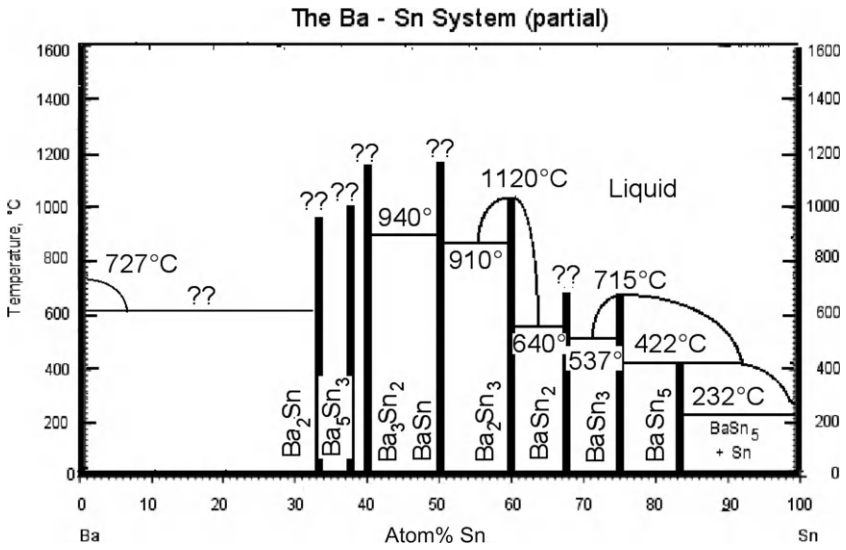

FIGURE 5.114

compounds are known, no complete phase diagram has been published. A partial phase diagram is shown in the following Fig. 5.114.

Instead of $BaSn_4$, the compound, $BaSn_5$, appears. Dibarium stannide, Ba_2Sn, is also known. The lack of melting-point data seems to be the reason why the full diagram has not been documented. All of the compounds that have been studied in regard to their crystal structure are included. However, melting points and mode of melting, as well as eutectics, are generally not available. Those compounds which have well-defined melting points are indicated in this diagram. It is clear that the high-barium compounds have not been studied in a thorough manner.

Barium monostannide, BaSn, contains zigzag chains of Sn^{2-} ions, along with Ba^{2+} ions. It is a Zintl compound. BaSn is orthorhombic with cell parameters of: $a = 7.065$ Å, $b = 14.041$ Å, $c = 4.484$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 444.81 Å^3, $d = 6.02$ g/cc, $Z = 4$. The structure is shown in Fig. 5.115.

Only a two-dimensional layout is shown so as to illustrate the Zintl layers which predominate in this structure. BaSn is metallic in electrical conductivity rather than being a semiconductor like many of the other Ba–Sn compounds. This may be the reason why BaSn has not received much attention in the scientific literature.

The atom coordinates for this structure are:

The compound, **barium distannide**, $BaSn_2$, is trigonal with space group $P3m1$ (no. 164), and lattice parameters of: $a = 4.652(2)$ Å, $c = 5.546(4)$ Å, $V = 103.9$ Å^3, $Z = 1$. $BaSn_2$ crystallizes in the $EuGe_2$ structure type ($c/a = 1.22$) with a c/a ratio of 1.19. The structure is shown in two-dimensions as in Fig. 5.116.

The structure is composed of 36 planar nets of Ba at $z = 0.5$ and corrugated 63 nets of three-bonded (3b) Sn atoms $\{[(3b)Sn]^{2-})_\infty\}$ with a Sn–Sn distance of 2.919(1) Å, which is slightly longer than the covalent bonds found in Sn (II) (2.80 Å). Such layers with 3b atoms are reminiscent of the element structure of (gray, rhombohedral) two-arsenic. The tin layers are made of condensed $\{Sn_6\}$ rings in chair conformation, which are arranged like in *trans*-decalin, and are primitively stacked along [001]. This is a contrast to the arsenic structure where the layers are displaced. Another difference is their clear separation with a shortest Sn–Sn interlayer contact of ca. 4.4 Å by Ba atoms. Another way of describing the Sn substructure is deriving it from the AlB_2 structure type by strong corrugation of the planar Ba-atom layers built of hexagons in AlB_2. The intralayer Sn–Sn distance is comparable to separations found in other Zintl phases, such as in Na_7Sn_{12} (2.83–3.09 Å). The valence angle of 105.7° in the layers is close to the ideal tetrahedral angle. The coordination by the six nearest Sn atoms (up to 4 Å) shows Ba residing in the center of a distorted $\{BaSn_6\}$

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy

2	Ba	Ba	4	c	m2m	0	0.362	1/4	1.0

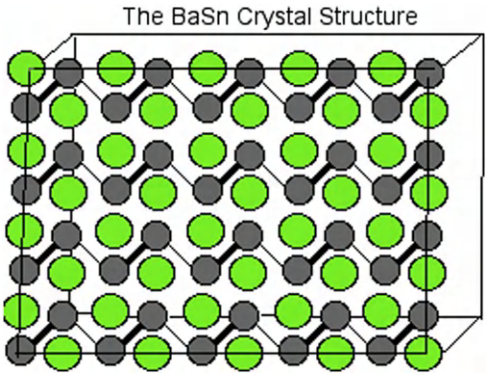

FIGURE 5.115

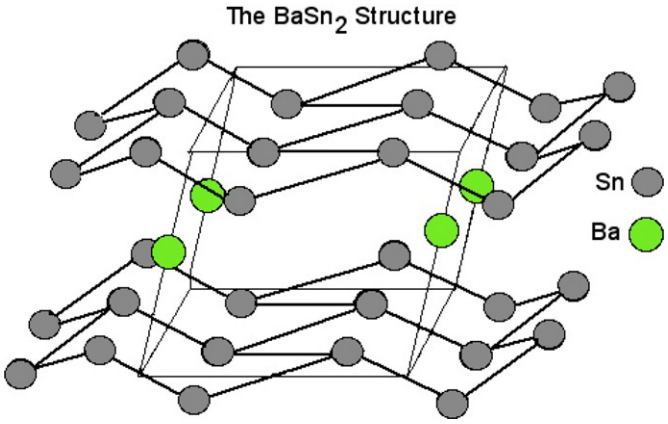

FIGURE 5.116

octahedron with a Ba–Sn distance of 3.473(2) Å. The latter description is consistent with Ba atoms populating the octahedral holes between two hexagonal Sn layers. Each octahedron shares six edges with its neighbors, resulting in edge-sharing layers of octahedra in the (001) plane. The tetrahedral holes are empty.

In the Ba/Sn system, **barium tristannide**, $BaSn_3$, could be isolated (Pearson symbol: hP6, space group: P63/mmc, $a = b = 7.253$ Å, $c = 5.496$ Å, $\beta = 120°$). $BaSn_3$ crystallizes in the structure of Ni_3Sn. The structure is shown in the following Fig. 5.117.

It is characterized by a chain of fused octahedra in which Sn_3 groups predominate. It contains linear chains of face sharing Sn octahedra. In between the octahedral chains, the Ba atoms can be found. The formula can be written as: Ba^{2+} $[Sn_3^{2-}]$. The atom coordinates for this structure are given in Table 5.63.

EH and LMTO investigations show that $BaSn_3$ is at the borderline of Zintl phases and intermetallic phases. Magnetometric investigations show that $BaSn_3$ becomes a superconductor at $T_C = 3.7$ K. Resistivity measurements reveal the metallic character of the compound. The electronic structure is shown in Fig. 5.118.

Molecular wires **2** are formed by the stacking of Sn triangles **1** in $BaSn_3$. The balanced interplay of interactions between localized and delocalized structural components is responsible for the superconductivity of **2**. The "fingerprint" in the band structure of this superconductor was discussed with the help of partial electron density introduced here as well as the ELF.

Barium pentastannide, $BaSn_5$, is the second compound obtained in the Ba/Sn system (Pearson symbol: hP5; space group: P6/mmm, $a = b = 5.357$ Å, $c = 7.065$ Å, $\beta = 120°$). The compound represents a new structure type. Its structure is shown in Fig. 5.119.

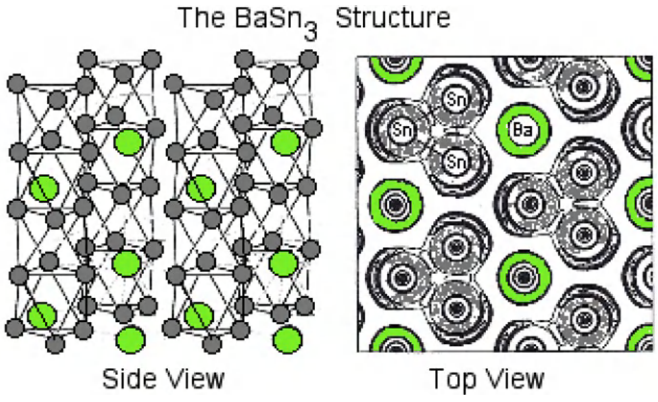

FIGURE 5.117

In this structure, a double layer of tin atoms can be found building hexagonal networks. The resulting hexagonal prisms are centered by tin atoms. The Ba atoms can be found between two double layers. $BaSn_5$ shows a two-dimensional slab of face-sharing hexagonal prisms which are formed by two superimposed graphite-like layers of Sn_6^{2-} clusters.

Tribarium pentastannide, Ba_3Sn_5, is a binary Zintl phase, not found in the phase diagram presented above. Sr_3Sn_5 and Ba_3Sn_5 were synthesized and structurally characterized. All compounds are isotypic and crystallize with a modified Pu_3Pd_5 structure type. The anionic substructure is composed of Sn_5^{6-} square pyramidal clusters, which are described as arachno clusters according

TABLE 5.63

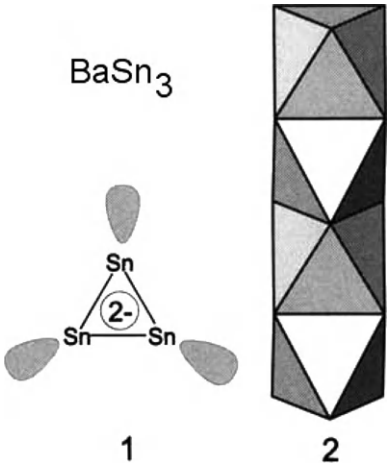

FIGURE 5.118

to the Wade–Mingos electron counting rules. The electronic structure of the pyramidal Zintl anions and the influence of the number of skeletal electrons of these clusters were investigated using the ELF. The structural relationship between Ba_3Sn_5 and the Zintl phases Ba_3Si_4 and Ba_3Ge_4 was also analyzed. Additionally, two new Zintl phases $Ba_3Ge_{2.82}Sn_{2.18}$ and $Ba_3Ge_{3.94}Sn_{0.06}$, have been synthesized and their structures were reported, which directly show that the exchange of tin against germanium leads to a change from the $M_{3\times5}$ to the $M_{3\times4}$ structure type. This effect is traced back to the maximal charge acquisition property of the Zintl anions of heavier and lighter tetralides.

The polar intermetallic compound, Ba_3Sn_5, has the crystal structure of Eu_3Sn_5 and crystallizes in an orthorhombic lattice, with a space group Cmcm and $a = 10.466$, $b = 8.445$, $c = 10.662$ Å, $V = 942.4$ Å^3, $Z = 4$, MW = 1049.33 g/mol, $D_{calc} = 7.396$ g/cc. Its structure belongs to the modified Pu_3Pd_5 type (Fig. 5.120).

It is isostructural with Sr_3Sn_5, featuring [Sn_5] square pyramidal clusters described as "arachno" according to the Wade–Mingos electron counting rules. The europium cations are located at the voids between the square pyramidal clusters. Results of the extended Hückel band structure calculations indicate that Ba_3Sn_5 is metallic. The structure is presented where the square pyramidal clusters are clearly evident.

The atom coordinates for this structure are given in Table 5.64.

Dibarium stannide, Ba_2Sn, is not well known in the technical literature. In contrast, interest in a like compound, dibarium tritin hexaantimonide, $Ba_2Sn_3Sb_6$, has been extensive because it is a superconductor. The novel Zintl phase dibarium tritin hexaantimonide, Ba_2Sn, has been synthesized, and its structure has been determined by single-crystal XRD methods. It crystallizes in the orthorhombic space group—*Pnma* with $a = 13.351(1)$ Å, $b = 4.4100(5)$ Å, $c = 24.449(3)$ Å, and $Z = 4$ ($T_c \cong 50$ °C). The structure can be represented as in Fig. 5.121. Where the arrangement of atoms in the *b*-direction of the lattice is shown. The atomic coordinates for this structure are given in Table 5.65.

The structure of $Ba_2Sn_3Sb_6$ comprises large channels [010] defined by 30-membered rings constructed from an anionic framework. This framework is built up from Sn-centered trigonal pyramids and tetrahedra, as well as zigzag chains of Sb atoms. Within the channels reside the Ba^{2+} cations and additional isolated zigzag Sb–Sb chains. The simultaneous presence of Sn trigonal pyramids and tetrahedra implies that $Ba_2Sn_3Sb_6$ is a mixed valence compound whose oxidation state notation can be best represented as $(Ba^{2+})_2[(Sn^{II})_2(Sn^{IV})$

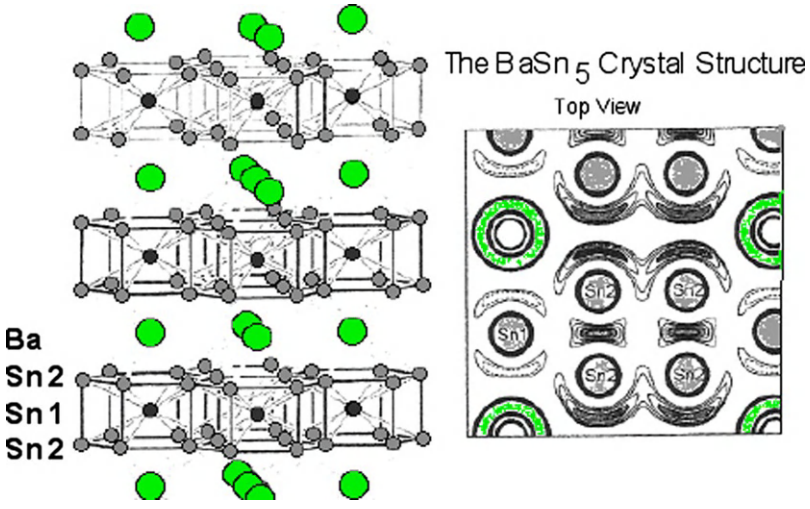

FIGURE 5.119

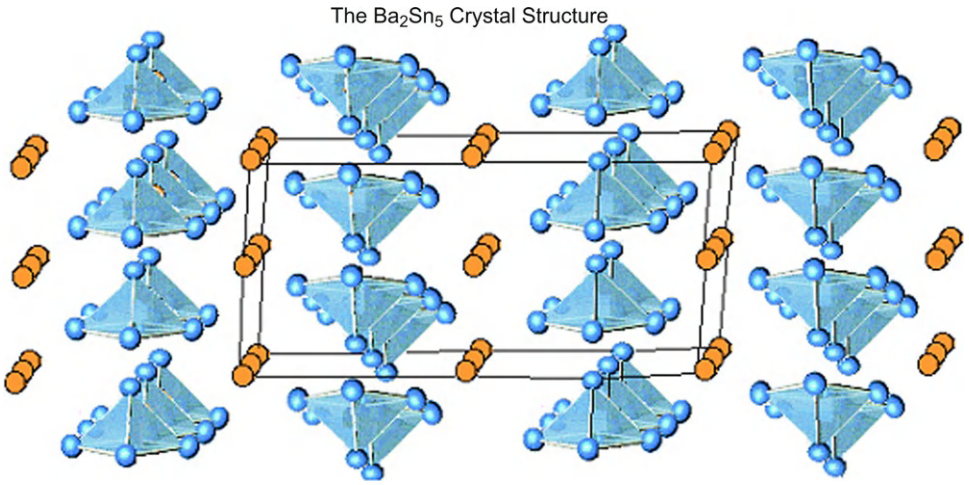

FIGURE 5.120

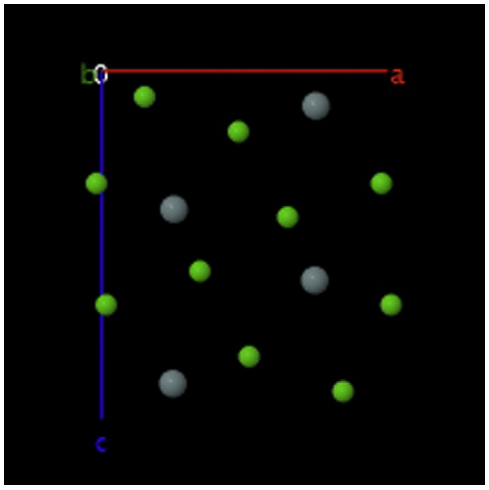

FIGURE 5.121

$(Sb^{-III})_3(Sb^{-I})]^{2-}[(Sb^{-I})_2]^{2-}$. The structure is shown in Fig. 5.122.

Resistivity and AC magnetic susceptibility measurements on $Ba_2Sn_3Sb_6$ and $SrSn_3Sb_4$ indicate that these Zintl compounds display a transition to a superconducting phase at $T_C = 3.9$ K. The Meissner effect was observed for $Ba_2Sn_3Sb_6$ under an applied field of 25 Oe. The signatures for superconductivity, such as high- and low-velocity conduction electrons and lone pairs, are present for both of these compounds.

Although **dibarium tristannide**, Ba_2Sn_3, is listed as a stable compound melting congruently at 1120 °C, the scientific literature is devoid of any mention of this compound except as already mentioned. Although it is crystalline, its unit-cell parameters are not listed nor is there any discussion of its physical or chemical properties.

Tribarium distannide, Ba_3Sn_2, is also listed as a crystalline component of the Ba–Sn series of compounds. However, its melting point and mode of melting (incongruent or congruent) have not been thoroughly investigated.

The lack of thermal behavior of the barium-rich series of compounds in the Ba–Sn system is the main reason why a description of these series of compounds cannot be provided. Since most of the Ba–Sn compounds are not stable to moisture and many are pyrophoric, the experimental conditions needed to investigate their physical and chemical properties have not been forthcoming. The work described above stems from the fact that several of these barium stannides are superconducting, even though their usage would be impractical due to their instability in air.

There are no CAS numbers for any barium stannides and they are not available commercially.

Radium Stannides

Although the likelihood of forming a series of compounds like:

Ra_2Sn
Ra_5Sn_3
RaSn
Ra_3Sn_5
$RaSn_3$
$RaSn_5$

is likely, no description of such work can be found in the technical literature. This may be due to the fact that ^{226}Ra is highly radioactive and not easy to work with chemically.

5.4.2. Acids and Bases of the Stannite or Stannic Anions

Tin oxides dissolve in acids. Certain halogen acids attack SnO_2 to give hexahalostannates, such as $[SnI_6]^{2-}$. One report describes reacting a sample in refluxing HI (hydroiodic acid) for many hours:

$$SnO_2 + 6HI \Rightarrow H_2SnI_6 + 2H_2O$$

HI is a colorless gas that reacts with oxygen to give water and iodine. With moist air, HI gives a mist (or fumes) of hydroiodic acid. It is exceptionally soluble in water. One liter of water will dissolve 425 l of HI gas, the final solution having only four water molecules per molecule of HI.

Similarly, SnO_2 dissolves in sulfuric acid to give the sulfate:

$$SnO_2 + 2H_2SO_4 \Rightarrow Sn(SO_4)_2 + 2H_2O$$

SnO_2 dissolves in strong base to give "stannates," with the nominal formula Na_2SnO_3. Dissolving the solidified SnO_2/NaOH melt in water gives $Na_2[Sn(OH)_6]_2$, "preparing salt," which is used in the dyeing industry. Blue-black SnO can be prepared by heating the tin(II) oxide hydrate, $SnO{\cdot}xH_2O$ $(x < 1)$ precipitated when a tin(II) salt is reacted with an alkali hydroxide such as NaOH. Metastable, red SnO can be prepared by gentle heating of the precipitate produced by the action of aqueous ammonia on a tin(II) salt. SnO may be prepared as a pure substance in the laboratory, by controlled heating of tin(II) oxalate (stannous oxalate) in the absence of air:

$$SnC_2O_4 \Rightarrow SnO + CO_2 + CO$$

Tin(II) oxide burns in air to form SnO_2. When heated in an inert atmosphere, a disproportion initially occurs giving Sn metal and Sn_3O_4 which further reacts to give SnO_2 and Sn metal:

$$4SnO \Rightarrow Sn_3O_4 + Sn$$

$$Sn_3O_4 \Rightarrow 2SnO_2 + Sn$$

SnO is amphoteric, dissolving in strong acid to give tin(II) salts and in strong base to give stannites containing $Sn(OH)_3^-$. It also dissolves in strong acid solutions to give the ionic complexes $Sn(OH_2)_3^{2+}$ and $Sn(OH)(OH_2)_2^+$, and in less acid solutions to give $Sn_3(OH)_4^{2+}$. Thus, the number of alkaline earth compounds formed in solution is strictly limited. Note that anhydrous stannites, e.g. $K_2Sn_2O_3$, K_2SnO_2, are also known. SnO is a reducing

agent and this appears to be its role in the manufacture of so-called "copper ruby glass".

The term **stannate** can refer to compounds:

- *orthostannates* which contain discrete SnO_4^{4-} units (e.g. K_4SnO_4) or have a "Spinel" structure (e.g. Mg_2SnO_4).
- *metastannates* with a stoichiometry $M^{II}Sn^{IV}O_3$ or $M^{I}{}_2Sn^{IV}O_3$ which may contain polymeric anions or may be sometimes better described as mixed oxides.

Note that stannic acid, the formal precursor to stannates, does not exist and is actually a hydrate of SnO_2. The term is also used as a suffix in naming conventions. For example, the hexachlorostannate ion is $SnCl_6^{2-}$.

In contrast, **stannite** is a mineral, a sulfide of copper, iron, zinc and tin with the chemical formula of Cu_2FeSnS_4. Zn commonly occurs and iron plus a trace of Ge may be present. Stannite is used as a source of tin, consisting of approximately 28% tin, 13% iron, 30% copper, 30% sulfur by mass.

Thus, "stannous" or "stannite" compounds of the alkaline earths are exceedingly rare.

5.4.3. Alkaline Earth Orthostannates, Metastannates and Stannites

Beryllium Stannates

The literature concerning beryllium and its oxy-tin compounds is not extensive. A description of the combination of a Be compound with a tin compound is completely lacking in the past or present technical literature. It should be possible to use the "peroxide method" to form these compounds but there is no record of anyone having done so. Thus, the physical and chemical properties of $BeSnO_3$ and Be_2SnO_4 have remained unknown.

The reactions for the peroxide method would be:

$$BeCl_2 + HCl(aq) \Rightarrow BeCl_3^- + H^+$$

$$SnCl_4 + 2HCl(aq) \Rightarrow SnCl_6^{2-} + 2H^+$$

$$BeCl_3^- + SnCl_6^{2-} + 3H^+ + NH_4OH + H_2O_2 \Rightarrow Be_2SnO_4 \text{ (or } BeSnO_3) + NH_3 + 3H_2O$$

In view of the propensity of beryllium to form hydroxy-compounds in solution, the Be precursor may actually be $(BeOH)Cl_2^-$. This propensity may actually depend upon the temperature and concentration of the solutions before the precipitation takes place. Thus, the likely composition of these compounds would be:

$(BeOH)_2SnO_3$—beryllium metastannate

$(BeOH)_4SnO_4$—beryllium orthostannate

These compounds would have the Lewis structure (Fig. 5.123).

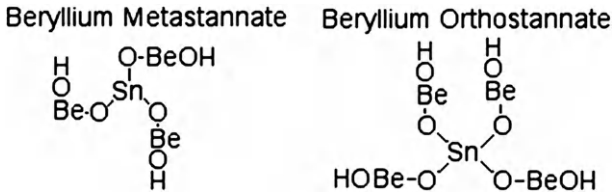

FIGURE 5.123

Since the SnO_4^{4-} anion is a tetrahedron in $(BeOH)_4SnO_4$, this compound is expected to have cubic close-packed perovskite structure containing SnO_6 octahedrons, similar to the barium compound. The metastannate is expected to consist of a network of SnO_3^{2-} trigonal prisms similar to that of the germanates. Alternatively, the cubic structure could form a series of chains of triangular SnO_3 units, stacked in an orthorhombic fashion wherein two SnO_3^{2-} groups alternate with a single group in the structure.

Beryllium stannates are not available commercially and no CAS numbers have been assigned.

Magnesium Stannates

Magnesium orthostannate Mg_2SnO_4 has the CAS number of 12032-29-0 and a molecular weight of 191.0145 g/mol. It can be synthesized at 900 °C with high purity using the peroxide route:

$$MgO_2 + SnO_2 + \text{heat} \Rightarrow MgSnO_4$$

The method involves mixed cation precursors, derived using magnesium chloride, tin tetrachloride and aqueous HCl. They are added to a basic solution of ammonia and hydrogen peroxide and the light-yellow precipitate is filtered, dried and calcined at relatively low temperatures of about 700–1200 °C to form homogeneous crystalline $MgSnO_3$ and Mg_2SnO_4. The powder produced shows a large specific surface area and small grain size, leading to a high sinterability. A peroxo-precursor is formed during the synthesis by a precipitation step from aqueous solution. The thermal decomposition of the X-ray amorphous precursor leads directly to Mg_2SnO_4. Magnesium metastannate, $MgSnO_3$, is formed after thermal degradation of a corresponding peroxo-precursor at temperatures below 700 °C. Further thermal treatment at temperatures above 700 °C leads to the decomposition of $MgSnO_3$ to Mg_2SnO_4 and SnO_2.

The above reaction, if the MgO compound is used, results in a "metastannate", $MgSnO_3$. Thus, these SSRs are dependent upon the molecular ratio of the oxides employed:

$$MgO + SnO_3 \Rightarrow MgSnO_3$$

$$2MgO + SnO_2 \Rightarrow Mg_2SnO_4$$

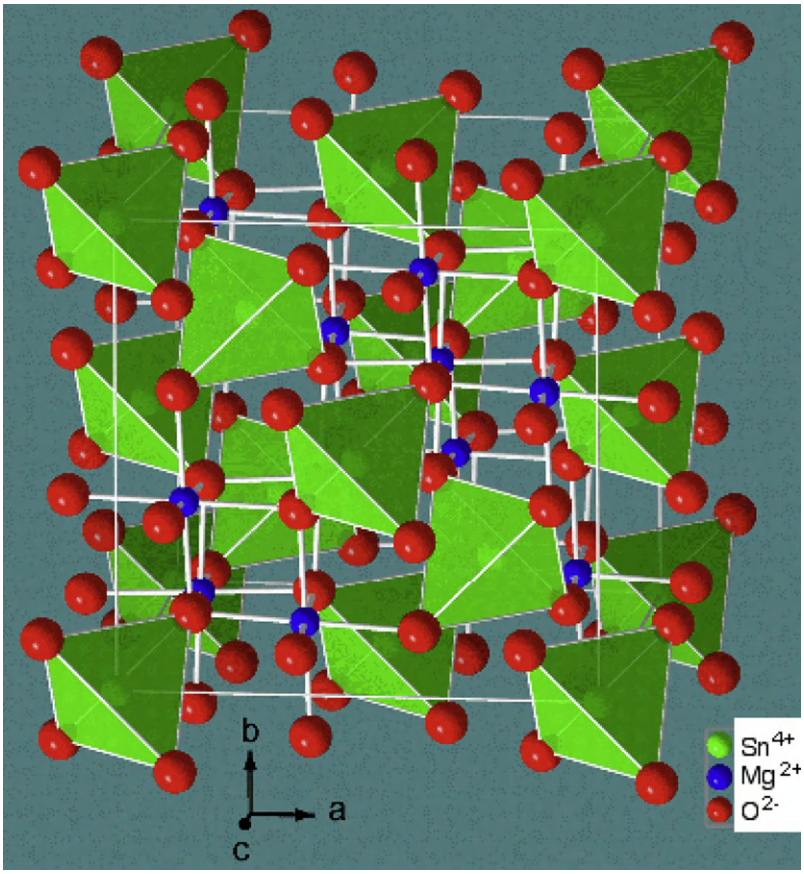

FIGURE 5.124

In the reaction, it is the chlorides, $MgCl_2$ and $SnCl_6^{2-}$, that are added to the basic hydrogen peroxide solution and MgO_2 is a fleeting prototype which forms the amorphous precursor. The cubic spinel structure of Mg_2SnO_4 is shown in Fig. 5.124.

It is easily seen that SnO_4 tetrahedra dominate with octahedra of MgO_6 arranged in a cubic unit cell with $a = 8.611$ Å. The dimensions of individual sites have also been measured (Fig. 5.125).

Interestingly, the behavior of magnesium metastannate ($MgSnO_3$) and orthostannate (Mg_2SnO_4) is very

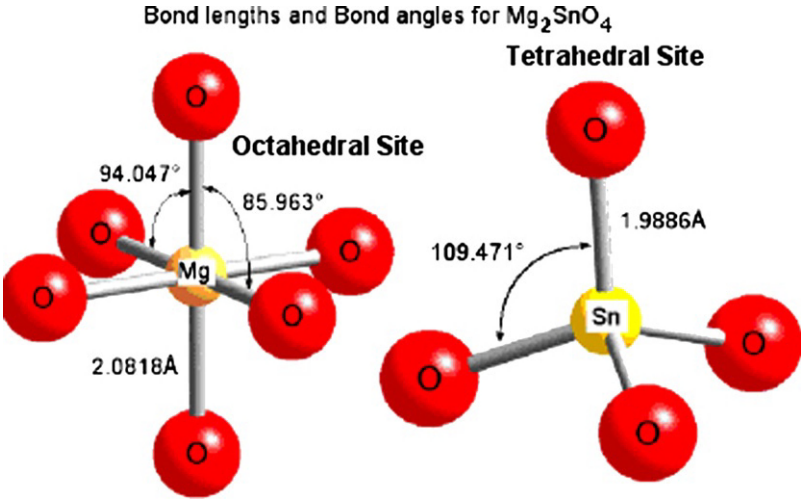

FIGURE 5.125

different from the corresponding Ca, Sr and Ba counterparts. The metastannates and orthostannates of calcium, strontium and barium are known to be stable independently up to very high temperatures without degradation. $MgSnO_3$ is unstable and disproportionates into orthostannate and tin oxide upon heating above 700 °C. In some cases, even the orthostannate cannot be synthesized as a single phase.

Phase stability of magnesium metastannate and orthostannate has been examined in samples synthesized via the traditional SSR and a novel self-heat-sustained (SHS) technique using 2 mol ratios of magnesium to tin (1:1 and 2:1). The powder mixtures were calcined over a wide temperature–time (*T*–*t*) span ranging from 600 to 1300 °C and 3 to 72 h. The powders obtained from the two preparative methods were processed and sintered under identical conditions. In the 2:1 molar mixtures, Mg_2SnO_4 was formed as a single phase upon calcination in both SRR and SHS methods. This phase remained the only compound in the sintered bodies as well. In the 1:1 composition, the ultimate reaction product was a mixture of Mg_2SnO_4 and SnO_2. Both SSR and SHS techniques with 2:1 molar mixture yielded a single phase, Mg_2SnO_4, in the sintered compacts. Compacts with near-zero porosity could be achieved in SSR-derived samples upon sintering up to 1600 °C, while significant porosity was an interesting feature of the SHS-derived samples.

Systematic microstructural evolution with the variation of sintering conditions has been discussed.

Magnesium orthostannate, Mg_2SnO_4, a potential candidate for applications in high-temperature and high-frequency domain as a ceramic capacitor element, was synthesized from metallic tin and magnesium powders. An alloy of composition Mg_2Sn was prepared by the conventional powder metallurgy route. This compound, upon heating in air under carefully designed ordinary and mild experimental conditions, yielded single-phase inverse spinel-type Mg_2SnO_4.

Uniform crystalline $MgSn(OH)_6$ nanocubes have been synthesized by a hydrothermal method. The influences of reaction conditions were investigated and the results showed that the solvent constituents significantly affected the shape and size of $MgSn(OH)_6 \cdot SnO_2$ crystals. Mg_2SnO_4 was obtained by thermal treatment at 850 °C for 8 h under a nitrogen atmosphere using $MgSn(OH)_6$ as the precursor. The electrochemical tests of SnO_2/Mg_2SnO_4 revealed that SnO_2/Mg_2SnO_4 has a higher capacity and better cyclability compared to pure SnO_2 or Mg_2SnO_4. The electrochemical performance of SnO_2/Mg_2SnO_4 was sensitive to the size of the nanoparticles. The lithium-driven structural and morphological changes of the electrode after cycling were also studied by the ex-situ XRD pattern and TEM tests. This work indicates that SnO_2/Mg_2SnO_4 is a promising anode material candidate for application in Li-ion batteries.

The thermodynamic properties of the spinel, Mg_2SnO_4, have been determined by e.m.f. measurements on the solid oxide galvanic cell:

$$\text{Pt, W, MgO} + \text{Mg}_2\text{SnO}_4 + \text{Sn}/\text{Y}_2\text{O}_3 - \text{ThO}_2/\text{Sn} + \text{SnO}_2, \text{ W, Pt}$$

in the temperature range 600 to 1000 °C. The Gibbs' free energy of formation of Mg_2SnO_4 from the component oxides can be expressed as:

$$2\text{MgO } (r.s) + \text{SnO}_2 \text{ (rut)} \rightarrow \text{Mg}_2\text{SnO}_4 \text{ (sp)},$$

$$\Delta G^\circ = 1420 - 2.96T \ (\pm 100) \text{ cal/mol}$$

These values are in good agreement with the information obtained by Jackson *et al.* (1974) concerning the high-pressure decomposition of magnesium stannate into component oxides at different temperatures. The thermodynamic data suggest that the spinel phase is entropy stabilized, and would be unstable below 207 (±25) °C at atmospheric pressure. Based on the information obtained in this study and trends in the stability of aluminate and chromite spinels, it was deduced that the stannates of nickel and copper(II) are unstable.

A new tin mineral named "schoenfliesite", magnesium hexahydroxostannate, $MgSn(OH)_6$, occurs as a late-stage hydrothermal alteration product in a contact metamorphic zone on Brooks Mountain, Seward Peninsula, Alaska. The chemical formula was derived from the analysis of a mixture, and electron microprobe study confirms the assigned composition. The mineral is soluble in HCl and slowly soluble in NaOH. The symmetry is cubic, space group Th^2–$Pn3$, $a = 7.759 \pm 0.006$ Å, $Z = 4$, density (calc.) $= 3.483$ g/cm^3. The four strongest lines in the XRD powder pattern are 3.88 Å (100), 4.48 Å (50), 2.74 Å (25), and 1.733 Å (25). Differential thermal analyses of natural and synthetic material are in agreement. The name is given in honor of the mathematical crystallographer, Artur Moritz Schoenflies. Some crystallographic data and the densities of magnesium orthostannate and magnesium metastannate are also presented.

The spinel phosphor, Mg_2SnO_4:Mn^{2+}, has been the object of intense study over the past 80 years. It was first described in 1935 and documented by Kröger in 1948. A number of current papers have appeared in the literature. One paper stated:

> "The photoluminescent (PL) spectrum of Mg_2SnO_4:Mn^{2+} at room temperature is dominated by a green band peaking at 500 nm, suggesting the existence of tetrahedral Mn^{2+} sites. When the phosphors are formed by a millimeter-wave heating method, the 500-nm band is very much more intense compared to that obtained by the electric furnace heating method. To clarify the origin of the PL enhancement, measurements of scanning electron microscope (SEM) and electron spin

resonance (ESR) were made. The SEM image reveals the growth of small round particles with an average size of 1.6 μm. Such well-grown micron-sized particles were not observed under the electric furnace heating. The ESR spectra exhibit six prominent lines, the intensity of which becomes greater for the phosphors obtained by the millimeter-wave heating method. From this observation, it is presumed that the PL enhancement is mainly due to the increase in the number of tetrahedral Mn^{2+} sites. Therefore, the millimeter-wave heating has an important advantage over the electric furnace heating in the synthesis of Mg_2SnO_4:Mn phosphors".

"Various stannate phosphors were prepared and some of their emissions were determined. Stannate phosphors based upon Mg_2SnO_4, Ca_2SnO_4, Sr_2SnO_4, emit green, blue or yellowish white light when activated by Mn^{2+}, blue, violet or red by Bi^{3+}, orange, green or blue by Pb^{2+}, while those activated by Ce^{3+} show blue or red emission. It is suspected that the activation by tin (Sn^{2+}) also occurs in some cases. This is supported by the fact that the emission of magnesium stannate activated by titanium changes as the flux is varied".

The latest work involves evaluation of Mg_2SnO_4:Mn^{2+} phosphor for use in "plasma-display" panels where very short UV is generated as an excitation medium. The Mg_2SnO_4:Mn phosphor exhibited green luminescence with the emission spectrum centered at 500 nm due to spin flip transition of the d-orbital electron associated with the Mn^{2+} ion. Optimum Mn concentration of Mg_2SnO_4:Mn under VUV excitation of 147 nm and electron beam excitation (with 800 V excitation voltage) are 0.25 and 0.6 mol%, respectively. The emission intensities of Mg_2SnO_4:Mn phosphors under the two excitation sources are higher than those of Zn_2SiO_4:Mn or $ZnGa_2O_4$:Mn phosphors. At 0.25 mol% of Mn concentration, the decay time is shorter than 10 ms, which makes it usable in plasma-display panels.

However, the same phosphor composition, i.e. Mg_2SnO_4:Mn, prepared in a different manner exhibits a long decay (phosphorescence). A novel long-lasting phosphorescence phosphor, Mn^{2+}-activated Mg_2SnO_4, was synthesized and its optical properties have been investigated. The Mg_2SnO_4:Mn^{2+}, upon UV irradiation, emits green light with high luminance centered at 499 nm from the spin forbidden transitions of the d-electrons in Mn^{2+} ions. The CIE chromaticity coordinates of the Mg_2SnO_4:Mn^{2+} phosphor are $x = 0.0875$ and $y = 0.6083$ under 254-nm UV excitation. The phosphorescence can be observed by the naked eyes (0.32 mcd/m^2) in the dark clearly for over 5 h after the 5-min UV irradiation. Its thermoluminescence has been studied and the mechanism of the long-lasting phosphorescence has been discussed.

Mg_2SnO_4 has recently been studied for use as a potential electronic ceramic for applications in the high-temperature and high-frequency domain such as thermally stable capacitors with low permittivity and small loss tangent. Uniform crystalline $MgSn(OH)_6$ nanocubes were synthesized by a hydrothermal method. The influences of reaction conditions were investigated and the results showed that the solvent constituents significantly affected the shape and size of $MgSn(OH)_6$/SnO_2. Mg_2SnO_4 was obtained by thermal treatment at 850 °C for 8 h under a nitrogen atmosphere using $MgSn(OH)_6$ as the precursor. The electrochemical tests of SnO_2/Mg_2SnO_4 revealed that SnO_2/Mg_2SnO_4 has a higher capacity and better cyclability compared to pure SnO_2 or Mg_2SnO_4. The electrochemical performance of SnO_2/Mg_2SnO_4 was sensitive to the size of the nanoparticles. The lithium-driven structural and morphological changes of the electrode after cycling were also studied by the ex-situ XRD pattern and TEM tests. This work indicates that SnO_2/Mg_2SnO_4 is a promising anode material candidate for application in Li-ion batteries.

Magnesium stannate is offered commercially in small lots by a number of manufacturers worldwide.

Calcium Stannates

A chemical route for the low-temperature synthesis of the calcium stannates, $CaSnO_3$ and Ca_2SnO_4, potential materials for dielectric applications, has been reported. Mixed cation precursor powders, derived using calcium chloride, tin tetrachloride and hydrogen peroxide, were calcined at relatively low temperatures of about 700–1200 °C to form homogeneous crystalline $CaSnO_3$ and Ca_2SnO_4. The reactions involved:

$$CaCl_2\,(HCl) + SnCl_6^{2-}(HCl) + H_2O_2(NH_4OH) \Rightarrow CaSnO_3 + 2HCl$$

This takes place in two stages involving the peroxide, CaO_2, as an intermediate. The structural evolution of the crystalline phases was studied using XRD, DTA, thermogravimetric analysis, scanning electron microscopy, Brunauer–Emmett–Teller (BET) measurements and chemical analysis. The thermal degradation of the X-ray amorphous peroxo precursors to the single-phase stannates occurs in two steps for the formation of $CaSnO_3$ and in three steps for the formation of Ca_2SnO_4. $CaSnO_3$ is one of the intermediate products formed during the final thermal decomposition to Ca_2SnO_4. The ultrafine powders resulting after the thermal degradation of the precursors contain a small amount of impurities. They show a high degree of sinterability at temperatures above 1000 °C which increases as Ca_2SnO_4 is formed from $CaSnO_3$. The highest densities reached for ceramic samples were about 97% of the theoretical value for $CaSnO_3$ and 95% for Ca_2SnO_4 by sintering at 1400 °C for 4 h.

In another method, a precursor $CaSn(OH)_6$ was prepared using tin tetrachloride, calcium chloride and sodium hydroxide at room temperature. Then the precursor was annealed at relatively low temperature

of 600 °C to obtain $CaSnO_3$. This compound has the CAS number of CAS 12013-46-6. Its molecular weight is 206.7218 g/mol.

The cubic compounds, denoted by $ASnO_3$ (A = Sr, Ba), adopt the cubic perovskite structure whereas Ca_2SnO_4 has the Sr_2PbO_4 structure.

The compounds $SrSnO_3$, $BaSnO_3$ and Ca_2SnO_4 were synthesized by solid-state and/or sol–gel methods, and characterized by XRD, X-ray photoelectron spectroscopy and SEM. Their electrochemical properties were studied as cathodes versus Li metal in the range 0.005–1.0 V for use in lithium batteries. The discharge capacities (mA-h/g) (moles of equivalent Li) on the 20th cycle at a current rate of 30 mA/g were found to be: $SrSnO_3$ (solid-state) (144 (1.4)), $SrSnO_3$ (sol–gel) (222 (2.1)), $BaSnO_3$ (solid-state) (190 (2.2)), $BaSnO_3$ (sol–gel) (156 (1.8)) and Ca_2SnO_4 (247 (2.4)). The $SrSnO_3$ (sol–gel) with nanoparticle morphology displays better galvanostatic cycling performance than $SrSnO_3$ (solid-state). The cycling behavior of $SrSnO_3$ and $BaSnO_3$ is inferior to that of Ca_2SnO_4 and $CaSnO_3$, which demonstrates that calcium is superior as a matrix element than Sr or Ba. The inferior electrochemical performance of Ca_2SnO_4 in comparison to $CaSnO_3$ reveals that the higher Ca:Sn ratio in the former is not advantageous and the perovskite structure is preferable to that of Sr_2PbO_4 structure. The coulombic efficiencies are >98% in all cases. Cyclic voltammetry (CV) results compliment the observed cycling behavior.

An ordered ilmenite phase of the stannate composition, $CaSnO_3$, was demonstrated from powder patterns. Two crystal forms were discovered. The hexagonal and rhombohedral unit-cell parameters are respectively: $a = 5.487$ (1), $c = 15.287$ (6) Å, $Z = 6$ and $a = 6.000$ (2) Å, $c = 54.42$ (3)°, $Z = 2$, $D_m = 5.16$, $D_x = 5.17$ g/cm^3.

The alkaline earth stannates having the general chemical formula $MSnO_3$ (M = Ca, Sr and Ba), have been projected as potential electronic ceramics (thermally stable capacitors, humidity sensors, carbon dioxide sensors, etc.). The nanocomposite "$CaO{\cdot}SnO_2$" and nano-$CaSnO_3$ were prepared by the thermal decomposition of $CaSn(OH)_6$ precursor and characterized by XRD, SEM, and high-resolution transmission electron microscopy (HR-TEM) along with selected area electron diffraction (SAED) and density measurements. Nanosize (3 to 6 nm) grains of CaO and SnO_2 in the X-ray amorphous $CaO{\cdot}SnO_3$ and particles of 60-nm size in nano-$CaSnO_3$ were obtained. Galvanostatic cycling of both phases vs Li metal was performed in the voltage ranges 0.005−1.0 V and 0.005−1.3 V at the current rate, 60 mA/g (0.12 °C). Stable and reversible capacities of 490 (±5) and 550 (±5) mA h/g was observed for nano-$CaO{\cdot}SnO_2$, respectively up to 50 cycles in the above voltage windows. These values correspond to 3.8 and 4.2 mol of cyclable Li per mole of $CaO{\cdot}SnO_2$ in comparison to the theoretical value of 4.4 mol of Li. A capacity of 420 (±5) mA h/g was observed at a rate of 0.4 °C. Nano-$CaSnO_3$ showed a stable capacity of 445 (±5) mA h/g (3.4 mol of Li) up to 50 cycles when cycled in the voltage window, 0.005 to 1.0 V. The average discharge and charge potentials are 0.2 and 0.5 V, respectively, for both the phases. The reasons for the superior Li-cycling performance of nano-$CaO{\cdot}SnO_2$ in comparison to nano-$CaSnO_3$ were discussed. Ex situ XRD, TEM, and SAED studies are carried out to support the reaction mechanism. Cyclic voltammetry and electrochemical impedance spectroscopy (EIS) data as a function of voltage were presented and discussed to complement the galvanostatic results. The "apparent" Li-ion diffusion coefficient (D^+_{Li}) estimated from EIS is 1.0×10^{-14} cm^2/s at $V \leq 1.0$ V during the first cycle and 11th discharge cycle. Thus, $CaSnO_3$ has been proven to be superior for use in lithium batteries over all of the alkaline earth metastannates and is being used commercially. The latest usage is a large rechargeable battery in electrically driven automobiles.

"Burtite", a calcium hexahydroxostannate, occurs as a latent mineral in a tin-rich garnet skarn in the vicinity of the El Hamman fluorite deposit. The surface of the altered "octahedral" crystal (up to 2 mm) is composed of pale yellow varlamoffite; the core is colorless and shows an apparently cubic cleavage. This unaltered core material has hardness 3; its density is 3.28 g/cc (meas.). It has a cubic symmetry with space group Pn3 or Pn3m, $a = 8.128$ Å and $Z = 4$. The optical orientation implies a rhombohedral departure from this symmetry. This leads to the most probable space group R3 with $a = 8.128$ Å, $\alpha = 90°$ and $Z = 4$. The mineral is colorless with a good cubic cleavage. It is very brittle and the hardness is about 3. The luster is vitreous, and there is no fluorescence under shortwave or longwave UV light. It is slowly soluble in cold, dilute HCl. In thin section, burtite is colorless, with the cubic cleavage traces visible. $CaSn(OH)_6$ is readily synthesized at room temperature by the reaction of $Na_2Sn(OH)_6$ or $K_2Sn(OH)_6$ with calcium chloride or nitrate in aqueous solution. It was found to be stable at 150 °C at 7 bar and 298 °C at 82 bar in the presence of H_2O; at a higher temperature, it converts to anhydrous calcium stannate (Christensen and Hazell 1969). The dehydration temperature at atmospheric pressure was 355 °C, according to the DTA data obtained by these authors.

Uniform and cubic-structured RE^{3+} (RE = Pr,Tb)-doped $CaSnO_3$ phosphors have been successfully synthesized by a two-step approach including the room-temperature synthesis of $CaSn(OH)_6$ precursors with the help of cetyltrimethylammoniumbromide surfactant and then converted to $CaSnO_3$ by calcination at 750 °C. The decomposition process of the $CaSn(OH)_6$ precursor, crystallization, and morphology of the

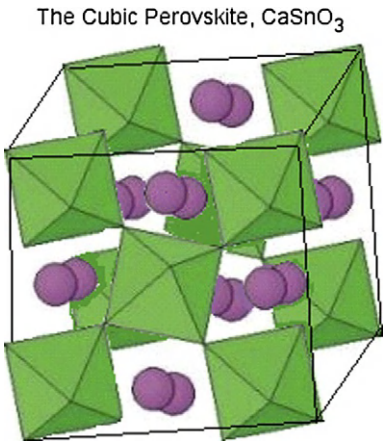

FIGURE 5.126

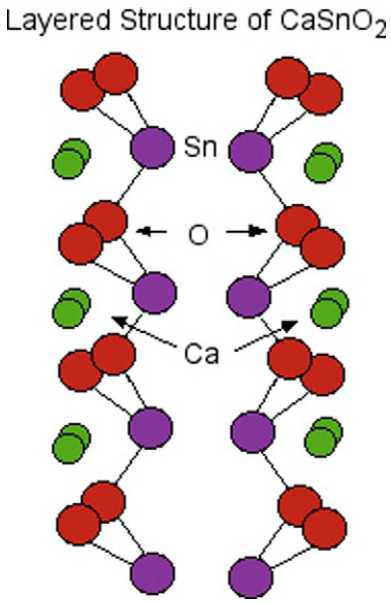

FIGURE 5.127

as-synthesized $CaSnO_3$ phosphors have been investigated using thermal analysis, XRD, and SEM. Furthermore, luminescence properties of $CaSnO_3/RE^{3+}$ (where RE = Pr or Tb) phosphors, including photoluminescence, fluorescence lifetime, afterglow decay, and thermoluminescence, were also systematically discussed in this paper. The as-synthesized Pr^{3+} and Tb^{3+}-doped $CaSnO_3$ phosphors show intense luminescence under ultraviolet excitation. Moreover, the afterglow emission from $CaSnO_3/RE^{3+}$ (RE = Pr,Tb) phosphors lasts for more than 3 h after the ultraviolet irradiation source has been removed. Both the fluorescence and afterglow decay curves of the $CaSnO_3/RE^{3+}$ (RE = Pr,Tb) phosphors contain one fast-decay component and another slow-decay process. Thermoluminescence spectra indicate that the incorporation of RE^{3+} ions into the $CaSnO_3$ host produces suitable trapping centers, which are the origin of the long-lasting phosphorescence phenomenon in this kind of material at room temperature.

The effect of high pressure upon phase stabilities of the $CaSnO_3$ system was investigated using density functional theory static lattice energy calculations. Six phase changes in this system were discovered:

Perovskite ⇒ post-perovskite,
Post-perovskite ⇒ B2 + cotunnite in $CaSiO_3$,
B1 ⇒ B2 in CaO,
Cassiterite ⇒ pyrite,
Pyrite ⇒ orthorhombic-I,
and orthorhombic ⇒ I-Cotunnite in SnO_2.

These results demonstrate a new high-pressure phase sequence of perovskite ⇒ post-perovskite ⇒ B2 + cotunnite. The post-perovskite transformation occurs at ~12 GPa with ~2.5% volume reduction and then it decomposes into the oxide mixture of B2 CaO and cotunnite SnO_2 at ~70 GPa with 8.1% volume reduction. The results also predict a few percent bulk velocity variations across these phase changes. The cubic structure of $CaSnO_3$ is shown in the following Fig. 5.126.

It is dominated by octahedrons of SnO_6^{2-} where Z = 10.

Calcium stannite, $CaSnO_2$, where tin is in the +2 state, i.e. Sn^{2+}, has been reported. It is believed that $CaSnO_2$ adopts a layered structure of SnO_2^{2-} groups but the crystallographic data only relates to the better known orthorhombic Na_2PbO_2. The probable structure is shown in Fig. 5.127.

The calcium stannates, $CaSnO_3$ and Ca_2SnO_4, are available commercially in small quantities. Hundred grams of $CaSnO_3$ is priced at $125.00 but the orthostannate price has not been given.

Strontium Stannates

Strontium tin oxide ($SrSnO_3$) is also known as strontium stannate or strontium tin trioxide. The strontium stannates, $SrSnO_3$ and Sr_2SnO_4, can be synthesized by the wet chemical peroxide route:

$$SrO_2(aq) + SnO(solid) \Rightarrow SrSnO_3$$

$$SrO_2(aq) + SnO_2(solid) \Rightarrow SrSnO_4$$

The first step of the preparation is the precipitation of stoichiometric peroxo precursors which can be transformed into the corresponding stannates by thermal degradation. The resulting very fine, single-phase strontium stannate powders have extremely small impurity contents. They show a very fast densification behavior during sintering at temperatures above 1200 °C. The phase, $Sr_3Sn_2O_7$, could not be prepared using the

peroxide route. This method involves dissolving $SrCl_2$ and $SnCl_4$ in dilute HCl and adding this to a solution of H_2O_2 and NH_4OH in water. Molar ratios used were 1:1:2.5 as $SrCl_2$, $SnCl_4$, and H_2O_2 and NH_4OH, respectively for $SrSnO_3$ and 2:1:2.5 for Sr_2SnO_4. Light yellow precipitates are formed. The ratios, 3:2:7, for $Sr_3Sn_2O_7$ did not produce a product. The precipitates were filtered and dried. The metastannate is first obtained as a trihydrate, $SrSnO_3 \cdot 3H_2O$ which can be calcined at 430 °C to obtain the anhydrate.

$SrSnO_3$ has the CAS number of 12143-34-9.

Alkaline earth stannates have received more and more attention in recent years as components of ceramic dielectric elements. $SrSnO_3$ has been employed in humidity sensors. Solid solutions of alkaline earth titanates plus stannates have been used in the fabrication of ceramic "boundary-layer" capacitors. The phase diagram shows the existence of two stable phases, $SrSnO_3$ and Sr_2SnO_4. $Sr_3Sn_2O_7$ is metastable at 1350 °C, decomposing to Sr_2SnO_4 and SrO. $SrSnO_3$, the most important of these compositions, is a dielectric of technological importance. It can be synthesized by a solid-state reaction between SrO and SnO_2 at 1000 °C. It is a cubic perovskite. Sr_2SnO_4 is a stable tetragonal K_2NiF_4 structure and forms a solid solution with Ba_2SnO_4. This compound decomposes to SrO and SnO_2 at >1250 °C. $Sr_3Sn_2O_7$ can be formed at <1150 °C by the reaction of 3SrO and $2SnO_2$. The phase diagram is similar to that of the barium analogues except for temperatures.

Strontium stannate is under study as an ultra-stable dielectric material for microelectronic applications at low temperatures. It is known to have a remarkably temperature-independent dielectric constant from 27 K to room temperature. However, anomalies in the Raman spectra, dielectric response, and DTA of strontium stannate exist, compatible with a structural phase transition at 160 K. Further anomalies are seen in calorimetric and Raman data (but not dielectric data) that suggest another phase transition at 270 K (−3 °C). An X-ray powder diffraction study confirms a small change in the pseudo-cubic lattice constant α (T) at the lower transition.

Hydroxide perovskites of $MSn(OH)_6$ (M = Ba, Sr, Ca, Mg) were synthesized by coprecipitation and sonochemical reaction routes. Some of the compounds were also prepared by the hydrothermal method. These were characterized by XRD, TGA/DTA, TEM and IR studies. The hydroxide perovskites are stable up to 523 K (250 °C) and all the compounds stabilize in cubic crystal system (SG = $Pn3m$) at 298–523 K except $BaSn(OH)_6$. The as-prepared powders of the above compositions show cubic square net in the reciprocal lattice of their electron diffraction patterns. Among these perovskites, $MgSn(OH)_6$ exhibits proton conduction at 298–500 K. Above 523 K, solid solutions of SnO_2 and the corresponding MO components were observed. On heat treatment at 850–950 K (577–677 °C) a defective $M_{2-x}(V_M)_xSnO_4$ (M-deficient spinel, $x \leq 1$) along with SnO_2 was observed. On further sintering to 1773 K (1500 °C) for a duration of 6–7 h, the $M_{2-x}(V_M)_xSnO_4$ phase was stabilized. The electrical properties of these compounds were measured by four-probe DC method. $SrSn(OH)_6$ does not show any type of electrical conduction at 298–850 K (25–577 °C). The loss of proton conduction above 523 K (250 °C) may be ascribed to dehydroxylation and subsequent decomposition to $SnO_2 + Mg_{2-x}SnO_4$ (defect spinel, or $MSnO_3$ (M = Ba, Sr, Ca).

The electrical conduction of rare earth-doped $SrSnO_3$ and $SrSnO_4$ has been ascribed to the formation of an oxygen vacancy, $V_{\bar{O}}^{\bar{=}}$. This shows that conduction occurs by hopping of charge carriers among localized sites. These sites are associated with Sn^{2+} and Sn^{4+} ions. Traces of divalent Sn^{2+} ions are probably present due to loss of oxygen during sintering in accordance with the reaction:

$$2O_O \Rightarrow O_2\,(\text{gas}) + V_{\bar{O}}^{\bar{=}} + 2e^-$$

the electrons released during the high-temperature sintering of these materials may be captured by the reaction:

$$Sn^{4+} + 2e^- \Rightarrow Sn^{2+}$$

Electrical conduction therefore seems to occur by hopping of charge carriers among the two tin sites.

Transparent and conductive oxide (TCO) films with a cubic perovskite structure, i.e. lanthanum-doped strontium stannate, $La_xSr_{1-x}SnO_3$ ($x = 0$–0.15) (LSSO), have been grown epitaxially on $SrTiO_3$ (001) substrates by a pulsed laser deposition method. The doping concentration and growth parameters were optimized based on the high-resolution XRD and electric transport measurements. It was found that the optimum doping level is around $x = 0.07$, and the epitaxial films can be grown at temperatures as low as 600 °C and in atmospheres compatible with many other perovskite oxide films. They are n-type TCO films, showing high optical transmittance in the visible range with a direct allowed band gap of 4.65 eV. They possess a weak metallic transport behavior with a low resistivity of ~4.0 mΩ cm within 10–300 K. Due to a very close lattice match with the ferroelectric $Pb(Zr_{0.52}Ti_{0.48})O_3$ (PZT) and multiferroic $BiFeO_3$ (BFO), all-perovskite LSSO(Pt)PZT(BFO)/LSSO capacitors and p-PZT($\leq$20 nm)/n-LSSO [p-BFO (100 nm)/n-LSSO] p–n junctions have also been fabricated and characterized. The square polarization versus electric field hysteresis loops, good rectifying characteristics, high optical transmittance, as well as the epitaxial growth exhibited by the heterostructures, strongly

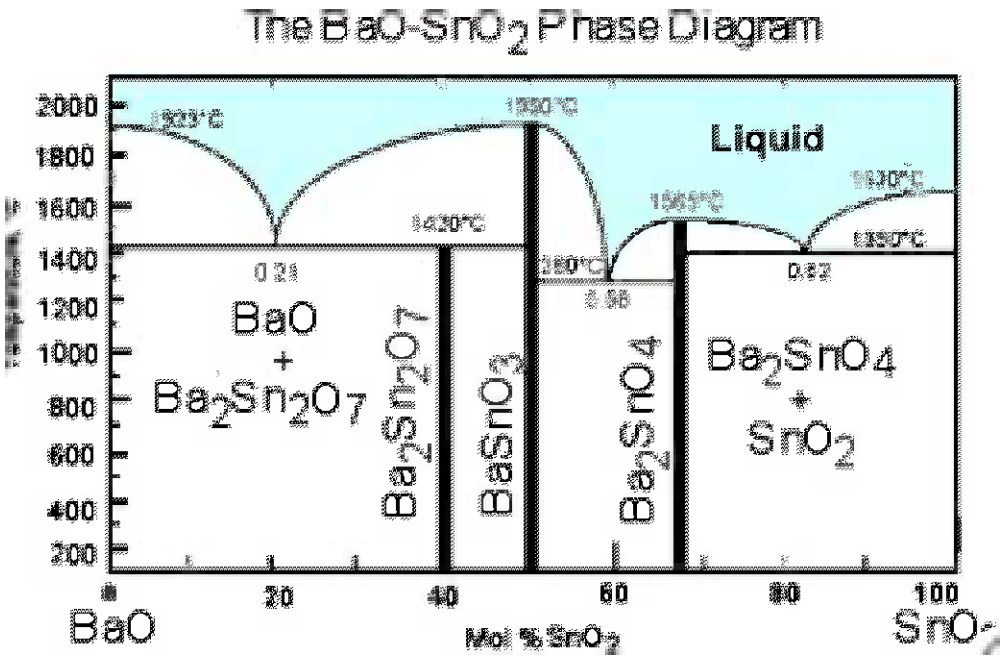

FIGURE 5.128

suggest that the LSSO films are potential candidates for use in transparent thin-film devices.

Intense green, orange or magenta luminescence was observed in rare-earth-doped alkaline earth (Ca, Sr, and Ba) stannates, particularly strontium stannates with perovskite-related structures. Tb–Mg codoped $SrSnO_3$ showed sharp emission lines corresponding to Tb ions as a green phosphor. Sm^{3+}-doped $Sr_3Sn_2O_7$ exhibited sharp pairs of emission lines corresponding to Sm ions as an orange phosphor. Eu–Ti codoped Sr_2SnO_4 as a magenta phosphor showed sharp red luminescent lines corresponding to Eu^{3+} ions as well as a broad blue emission band corresponding to Ti-related complexes. It was suggested that codoping and/or layered structures in these phosphors are closely related to the increase in luminescence intensity from these rare-earth ions.

Strontium stannates are available commercially from a number of suppliers worldwide.

Barium Stannates

There exist three oxostannate(IV) compounds in the BaO–SnO_2 binary system, $BaSnO_3$, $Ba_3Sn_2O_7$ and Ba_2SnO_4, but barium stannate is normally referred to as $BaSnO_3$ because $BaSnO_3$ is the best known among these, the most thoroughly investigated and the most useful compound. The phase diagram, shows the melting points and areas of temperature stability of these three compounds (Fig. 5.128).

$Ba_3Sn_2O_7$ melts incongruently, forming $BaSnO_3$ and BaO. The other two compounds are stable but $BaSnO_3$ is the preferred compound as a ceramic.

$BaSnO_3$ crystallizes in a cubic perovskite structure as shown in the following Fig. 5.129.

In this cubic structure, the Ba^{2+} ions (1.34 Å) occupy the corners of the Sn^{4+} ions (0.71 Å), the volume center, and the O^{2-} ions (1.40 Å), the surface center.

In this structure, the larger Ba^{2+} ions and the O^{2-} ions build a cubic, dense, ball by packing together. A quarter of the octahedral holes is filled with small Sn^{4+} ions. Each Ba^{2+} ion is coordinated with 12 O^{2-} ions and each O^{2-} ion is surrounded by four Ba^{2+} ions and two Sn^{4+} ions. Thus, the crystallochemical formula is $Ba^{[12]}Sn^{[6]}O_3^{[4+2]}$. The octahedrons of $[SnO_6]$ are linked by sharing corners to form a three-dimensional framework. It should be understood that this high-symmetry cubic structure can distort and deform under specific conditions so that the structure symmetry degree is lowered. The lattice constant of $BaSnO_3$ is $a = 4.1163$ Å.

The barium stannates, $BaSnO_3$ and Ba_2SnO_4, can be synthesized by the wet chemical peroxide route. The first step of the preparation is the precipitation of stoichiometric peroxo precursors which are transformable into the corresponding stannates by thermal decomposition. The resulting ultrafine, phase-pure barium stannate powders are generally very pure, >99.9%. They are very sinterable above 1200 °C. $BaSnO_3$ shows a better densification behavior than Ba_2SnO_4 during sintering. However, the phase, $Ba_3Sn_2O_7$, could not be synthesized using the peroxide method.

$BaSnO_3$ with cubic perovskite structure exhibits good dielectric properties. Because of these characteristic properties, $BaSnO_3$ ceramic is becoming more and more important in material technology. It can be

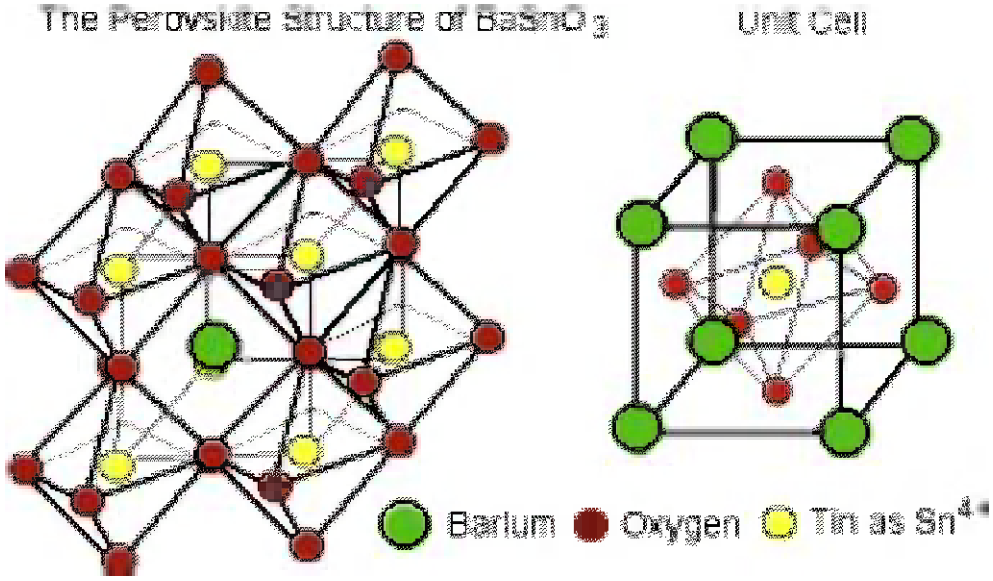

FIGURE 5.129

used to prepare thermally stable capacitors and to fabricate ceramic boundary layer capacitors. In recent years, $BaSnO_3$ has been found to be a very promising sensor material and has therefore received the most attention. In pure as well as doped forms, stannates have been investigated as potential solid-state sensor materials for many gases, including CO, NO_x, H_2 and CO_2. $BaSnO_3$ has also been used in the preparation of multifunctional temperature–humidity–gas sensors by combining it with $BaTiO_3$. Detection of gas in $BaSnO_3$ sensors is achieved by measurement of the electrical properties changes such as resistance and conductivity. The changes are induced in the semiconducting oxide form of $BaSnO_3$ following adsorption of any given gases on the solid surface. The gas sensitivity of this semiconducting oxide is related to the surface reaction process. Thus, a large surface area of the semiconducting oxide is of importance to its gas sensor devices.

Attempts to prepare $BaSnO_3$ by the hydrothermal method starting from $SnO_2 \cdot xH_2O$ gel and $Ba(OH)_2$ solution in Teflon-lined autoclaves at 150–260 °C invariably lead to the formation of a hydrated phase, $BaSn(OH)_6 \cdot 3H_2O$. On heating in air or on releasing the pressure at about 260 °C, $BaSn(OH)_6 \cdot 3H_2O$ converts to $BaSnO_3$ as a fine powder which involves the formation of an intermediate oxyhydroxide, $BaSnO(OH)_4$. TEM studies show that particle size of the resulting $BaSnO_3$ ranges from 0.2 to 0.6 μm. Solid solutions of Ba(Ti,Sn)O_3 were prepared from $(TiO_2 + SnO_2) \cdot xH_2O$ mixed gel and $Ba(OH)_2$ solutions. Single-phase perovskite Ba(Ti,Sn)O_3 was obtained up to 35 atom% Sn. Above this composition, the hydrothermal products are mixtures of $BaTiO_3$ (cubic) and $BaSn(OH)_6 \cdot 3H_2O$ which on heating at 260 °C give rise to $BaTiO_3 + BaSnO_3$. Annealing at 1000 °C results in monophasic Ba(Ti,Sn)O_3, in the complete range of Sn/Ti. Formation of the hydrated phase is attributed to the amphoteric nature of $SnO_2 \cdot xH_2O$ gel which stabilizes $Sn(OH)_6^{2-}$ anions under higher water pressures and elevated temperatures. The sintering characteristics and dielectric properties of ceramics prepared from these fine powders were also studied.

The electrical and optical properties of Ge-doped $BaSnO_3$ ceramics sintered at various temperatures have been investigated to determine their semiconductor behavior. The electrical conductivity of Ge-doped $BaSnO_3$ samples increases with increase in temperature, confirming that the samples exhibit a semiconductor behavior. A maximum conductivity value of 6.31×10^{-9} S/cm was observed for a sample sintered at 1200 °C. The optical band gaps of the Ge-doped $BaSnO_3$ samples were determined by means of reflectance spectra. The variation with optical band gap was analyzed using the $E_g(T) = Eg_o + \beta T$ equation. The rate of change of the band gap, β, of $BaSn_{0.99}Ge_{0.01}O_3$ was found to be 7.6×10^{-4} eV/°C. A minimum optical band gap value of 2.95 eV was observed for the sample sintered at 1400 °C. It was concluded that $BaSn_{0.99}Ge_{0.01}O_3$ is a wide band gap semiconductor and its semiconducting properties change with sintering temperature.

Nanocrystalline $BaSnO_3$ with a primary particle size of 40–60 nm was prepared through hydrolysis of a barium tin isopropoxide and a following crystallization. The thermal decomposition, the crystallization and the microstructure of the obtained powders were investigated with the help of TG-DTA, IR, XRD, HRSEM and HRTEM analytical methods. The organic groups in

the as-prepared powder decompose thermally at 350 °C, and is accompanied by the formation of $BaCO_3$ that disappears again at 600 °C. The crystallization of $BaSnO_3$ takes place at 500–600 °C. Single-phase $BaSnO_3$ powders have been obtained at a temperature as low as 600 °C. The amorphous as-prepared powder shows a cluster structure. Nucleation of $BaSnO_3$ beginning at 350 °C was observed under HRTEM, and the spherical nanoparticles of $BaSnO_3$ calcined at 760 °C crystallize well and are strongly aggregated. The presented results indicate a heterogeneous nucleation and growth mechanism as $BaSnO_3$ is formed.

The formation of solid solutions of the type $[Ba(HOC_2H_4OH)_4][Sn_{1-x}Ge_x\ (OC_2H_4O)_3]$ as a $BaSn_{1x}/Ge_xO_3$ precursor and the phase evolution during its thermal decomposition are described in this paper. The 1,2-ethanediolato complexes can be decomposed to nanosized $BaSn_{1-x}/Ge_xO_3$ pre-ceramic powders. Samples with $x = 0.05$ consist of only a $Ba(Sn,Ge)O_3$ phase, whereas powders with $x = 0.15$ and 0.25 show diffraction patterns of both the $Ba(Sn,Ge)O_3$ and $BaGeO_3$ phase. The sintering behavior on powders with a $BaGeO_3$ content of 5 and 15 mol% was investigated. These powders show a specific surface area of 15.4–15.9 m^2/g and were obtained from calcination temperatures above 800 °C. The addition of $BaGeO_3$ reduced the sintering temperature of the ceramics drastically. $BaSn_{0.95}Ge_{0.05}O_3$ ceramics with a relative density of at least 90% can be obtained by sintering at 1150 °C for 1.0 h. The ceramic bodies produced reveal a fine microstructure with cubical-shaped grains between 0.25 and 0.6 μm. To produce dense ceramics, the sintering temperature could be lowered down to 1090 °C, if the soaking time was extended up to 10 h.

In another paper, the same preparation of a nanometer-sized $BaSnO_3$ powder by calcination of a barium tin 1,2-ethanediolato complex precursor—$[Ba(HOC_2H_4OH)_4][Sn_{1-x}Ge_x(OC_2H_4O)_3]$ was employed. Its sintering behavior was studied. A linear rate-controlled calcination process to 820 °C led to a nanometer-sized $BaSnO_3$ powder with a BET-specific surface area of 15.1 m^2/g and a BET equivalent diameter of 55 nm. Crystallite-size measurements by XRD line broadening reveal a value of about 26 nm. The powder produced had a slightly larger cell parameter of $a = 4.1222$ Å compared to the single-crystal value, 4.1170 Å, that was caused by OH groups inside the lattice. The lattice parameter decreases with increasing calcination temperature and reaches the reference value above 1000 °C. The nanometer-sized powder consists of cubical-shaped particles. Corresponding powder compacts of the nano-sized $BaSnO_3$ achieve a relative density of 90% after sintering at 1600 °C for 1 h (grain size: 1.3–4 μm). At 1500 °C and a soaking time of 30 h, a grain size of 3–13 μm was observed, whereas coarse-grained powder compacts reach only 80% of the relative density at 1650 °C (10 h).

In another method, $BaSnO_3$ powder with a crystallite size of 27.6 nm was prepared through a hydrothermal reaction of a peptized $SnO_2 \cdot xH_2O$ and $Ba(OH)_2$ at 250 °C. This was followed by crystallization of this hydrothermal product at 330 °C. The peptization of the $SnO_2 \cdot xH_2O$ gel is dependent on the pH value. Through peptization, the mean particle size of $SnO_2 \cdot xH_2O$ in the aqueous solution has been decreased by a factor of 100 to 8 nm. A limited agglomeration in the sol-prepared powder was observed under the microscope. The structure evolution and crystallization behaviors of the sol-prepared powders were investigated by TG-DTA, IR and XRD. The $BaSn(OH)_6$ phase in the as-prepared powder transforms into an amorphous phase at 260 °C, from which the $BaSnO_3$ particles nucleate and grow with an increase in temperature. The single-phase $BaSnO_3$ powder has been obtained at a temperature as low as 330 °C. This sol-prepared powder is more sinterable than the gel-prepared powder and can be sintered to a ceramic at 340 °C with 90.7% of the theoretic density.

Because of its characteristic dielectric properties, $BaSnO_3$, has been used as a component of ceramic dielectric bodies to prepare thermally stable capacitors, and to fabricate ceramic boundary layer capacitors when combined with $BaTiO_3$. In recent years, more and more attention has been shifted to study of the application of barium metastannate as a sensor material. It has been found that the electrical properties of barium metastannate such as conductivity, resistance, capacitance or impedance are dependent on temperature, oxygen partial pressure, the nature of the measured gases and their concentrations. Based on these results, many gas sensor devices made from $BaSnO_3$ powder have been developed. $BaSnO_3$ and $BaSn_{1-x}Zr_xO_3$ ($x = 0.05$, 0.10 and 0.20) are also sensor materials for H_2S gas in ambient conditions. $BaSnO_3$ can also be used for fabricating a CO sensor. It is thought that the mechanism of CO detection sensitivity of this metal oxide is a surface reaction process. Thus, to achieve a high gas sensitivity, $BaSnO_3$ is fabricated as a thin film. The CO sensitivity shows a maximum in the temperature range of 600 to 700 °C under dry conditions. Humidity has a different influence on the CO sensitivity, which depends on the oxygen concentration. A gas sensor for detecting the presence of CO in polluted air, comprising a perovskite compound such as $Ba_{0.9}Gd_{0.1}SnO_3$, has been reported. $BaSnO_3$ as a semiconducting oxide is also a very promising sensor material for detecting nitric oxide. The sensitivity of the $BaSnO_3$ thin films to NO depends on the temperature and the oxygen concentration. The NO sensitivity, under dry conditions, shows a maximum in the range of 450 to 550 °C. A sensor comprising $BaSnO_3$ is found to be selectively sensitive to NO_2. Oxygen sensors used for

controlling air–fuel ratio in boilers or engines (sometimes called exhaust gas sensor or air–fuel ratio sensor) have been fabricated from sintered $BaSnO_3$. The application of $BaSnO_3$ to detect humidity has also been reported. The humidity sensitivity of $BaSnO_3$ is enhanced slightly by calcining barium tin hydroxides, which are prepared by a coprecipitation method. The partial substitution of the A-site element of the perovskite-type oxides with La produced an enhancement of the sensitivity.

Barium stannate behaves as a pure, *n*-type semiconductor below 900 °C. The measured band gap of $BaSnO_3$ is 3.4 eV. The behavior of this semiconducting oxide material can be controlled by manipulation of the crystallite size and specific surface area of the material exposed to the gas and of the concentration of electrically active donor species present in the lattice. This give characteristic changes either of *n*-type materials (resistance decreases in reducing gases and increases in oxidizing gases), or of *p*-type materials (resistance increases in reducing gases and decreases in oxidizing gases), or of a mixed behavior.

A ferroelectric ceramic based on Te-modified $BaSnO_3$ with a general formula $BaSn_{1-x}Te_xO_3$ ($x = 0$, 0.05, 0.10, 0.15) has been synthesized by a high-temperature SSR technique. Thermal analysis (DTA, TGA and DTG) was carried out to optimize the calcination temperature and other experimental conditions of material formation required. Preliminary structural analysis indicated that crystal structure of the material is basically cubic and remains unaffected even on Te doping. Microstructural analysis of the sample reveals polycrystalline nature and substantial modification of the surface properties of these materials on Te doping. Detailed studies of dielectric properties of the compounds produced as a function of temperature showed a ferroelectric to paraelectric phase transition. It has been observed that the value of peak dielectric constant (max) and Curie temperature are strongly dependent on frequency and dopant concentration. An evidence of a relaxation property has also been noticed for each concentration of the Te dopant. Studies of electrical conductivity of the Te-doped $BaSnO_3$ show a substantial improvement in its value at elevated temperatures.

The synthesis of $BaSn(OH)_6$ acicular crystals by precipitation at 100 °C from aqueous solutions and their transformation into the perovskite-like compound, $BaSnO_3$, has also been investigated. Single-acicular crystals 100–200 μm in length were obtained from a 0.05 M solution, whereas bundle-like aggregates of 20 to 40 μm were precipitated from 0.2 to 0.6 M solutions. The XRD pattern of barium hexahydroxostannate was indexed according to a monoclinic symmetry with cell parameters, $a = 11.029$ Å, $b = 6.340$ Å, $c = 10.563$ Å, $\beta = 128.51°$, $\alpha = \gamma = 90°$. The $BaSn(OH)_6$ particles decomposed to $BaSnO_3$ and water at approximately 270 °C and the original morphology was retained. The resulting product had a specific surface area of up to 30–40 m^2/g and consisted of 10- to 20-nm crystallites. The larger unit-cell edge in comparison to the single-crystal value and the continuous weight loss up to 1200 °C indicate that water is not completely released during decomposition and a substantial amount of proton defects (up to 0.4 mol per mole of $BaSnO_3$ is incorporated in the perovskite lattice as OH^- groups) remains. Normal crystallographic properties of $BaSnO_3$ are restored only after calcination at 1300 °C.

In still another paper, hydroxide perovskites of $BaSn(OH)_6$ were synthesized by coprecipitation and sono-chemical reaction routes. Some of the compounds were also prepared by the hydrothermal method. These were characterized by XRD, TGA/DTA, TEM and IR studies. The hydroxide perovskites are stable up to 523 K (300 °C) and all the compounds stabilize in cubic crystal system (space group = *Pn*3*m*) at 298–523 K (20–250 °C) except $BaSn(OH)_6$. The as-prepared powders of the above compositions show a cubic square net in the reciprocal lattice of their electron diffraction patterns. Among these perovskites, $BaSn(OH)_6$ exhibits proton conduction at 298–500 K (20–227 °C). Above 250 °C, solid solutions of SnO_2 and BaO components were observed. On heat treatment at 850–950 K (577–677 °C), an oxygen-deficient $Ba_{2-x}(V_M)_xSnO_4$ spinel, ($x < 1$) along with SnO_2 are observed. On further sintering to 1773 K (1500 °C) for a duration of 6–7 h, $M_{2-x}(V_M)_xSnO_4$ phase is stabilized. The electrical properties of these compounds were measured by four-probe DC method. The loss of proton conduction above 523 K may be ascribed to dehydroxylation and subsequent decomposition to $SnO_2 + Ba_{2-x}(V_M)_xSnO_4$.

Since $BaSnO_3$ crystallizes in a cubic perovskite structure and exhibits insulating behavior, the transformation into a semiconducting compound has been studied. It can be made conducting by reducing a small fraction of Sn^{4+} into Sn^{2+} under an O_2-free atmosphere. This can be achieved through the solid solution. $Ba_{1-x}La_xSnO_3$ is a mixed phase for $x > 0.02$ wherein a trivalent ion, La^{3+} substitutes for a divalent ion, Ba^{2+}. This behavior is readily understood in terms of the lone pair cation Sn^{2+}. The magnetic susceptibility was measured down to 4.2 K and is less than 1.7×10^{-5} emu cgs/mol consistent with a collective electron behavior. The Mössbauer spectrum exhibits a wide unsplit peak with a quadrupole doublet of 3.18 mm/s and an isomer shift of 0.12 mm/s characteristic of Sn^{4+} that corroborates the delocalization of the stereo chemical pair $5s^2$. The band gap, E_g, was found to be 3.12 eV with a further indirectly allowed interband transition occurring at 2.85 eV. The transport properties of $Ba_{0.98}La_{0.02}SnO_3$ indicate *n*-type conductivity ($\sigma_{300\ K} = 4.03$ Ω-cm), and little temperature dependence, with an activation energy ΔE of ~1 meV and an

electron mobility $\sigma_{300\ K} \sim 0.1\ cm^2/V/s$, thermally activated. The conduction occurs by small polaron hopping between mixed valence Sn^{4+}/Sn^{2+} ions. The observed conductivity is greater than that originating from La substitution, with one-electron doping implying the existence of oxygen vacancies. The electrons are believed to travel in the Sn-5s conduction band with an effective mass of $m(e,l) = 3.7m_{(0)}$ [where $m_{(0)} = 9.11 \times 10^{-31}$ kg]. The nonlinear dependence of ln σ versus T^{-1} at low temperatures could result from a predominant variable range hopping as suggested by the linear variation of log σ versus $T^{-0.25}$. The electron localization may be attributed to the random distribution of lanthanum as well as oxygen vacancies.

The AC conductivity, η_{ac} of $BaSnO_3$ has been measured in the temperature range 310–520 K (37–247 °C) and frequency range 100 Hz–1.0 MHz. Below 420 K (147 °C), the conductivity is almost independent of temperature while between 420 and 520 K, it is temperature dependent. At 100 kHz, the activation energy of these two regions is 0.08 and 0.35 eV, respectively. It has been proposed that in the low-temperature region, conduction is due to hopping of charge carriers among the Sn^{+2} and Sn^{+4} sites. In the high-temperature region, conduction is due to excitation of charge carriers at the edges of the conduction band and hopping at energies close to it.

The compound, barium stannite = $BaSnO_2$(II) remains unknown.

Barium stannate is available as $BaSnO_3$ commercially in small to medium lots worldwide.

Radium Stannates

There is no record of the preparation of any of these compounds. They could be prepared by the same methods used for the barium compounds, namely:

$$Ra^{2+}(HCl) + SnCl_6^{2-} \text{—the wet proxide method}$$

$$RaSn(OH)_6 \cdot 3H_2O \text{ method}$$

$$[Ra(HOC_2H_4OH)_4][Sn(OC_2H_4O)_3]$$

$$RaSn(OH)_6 \text{ method}$$

Three compounds are expected to be formed: $RaSnO_3$, Ra_2SnO_4 and $Ra_3Sn_2O_7$. Nonetheless, the reference books and chemical literature are devoid of any mention of any of these due, perhaps, to the intense radioactivity and danger of handling of ^{227}Ra compounds.

5.5. ALKALINE EARTH OXY-PLUMBATE COMPOUNDS

Plumbides can be formed when lead forms a Zintl phase compound with a more metallic element. The alkaline earths form a limited number of such compounds due to the large size of the lead ion. The structure of Pb_5^{2-} is presented as Fig. 5.130

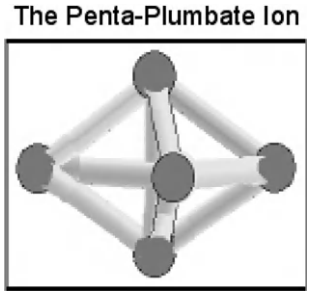

FIGURE 5.130

5.5.1. Oxides of Lead, Pb_xO_y

There are two valence states for the element, Pb^{2+} and Pb^{4+}. Lead oxides are amphoteric and dissolve in aqueous solution under both acidic and basic conditions. As cations, they are sometimes called "Plumbous" and "Plumbic". As anions, chemical combination with any given cation is designated as a "plumbite" or "plumbate". These compounds are also called "metaplumbate" and "orthoplumbate", although this designation is not strictly correct.

Divalent lead oxide has the formula PbO. Lead(II) oxide occurs in two polymorphs, red, having a tetragonal crystal structure and yellow, having an orthorhombic crystal structure. Both forms occur naturally as rare minerals. The red form is known as "Litharge" and the yellow form is known as "Massico".

Lead dioxide, PbO_2, also plumbic oxide, is an odorless dark-brown crystalline powder which is nearly insoluble in water. It exists in two crystalline forms. The α phase has orthorhombic symmetry, lattice constants $a = 0.497$ nm, $b = 0.596$ nm, $c = 0.544$ nm, $Z = 4$ (four formula units per unit cell). It was first synthesized in 1941 and identified in nature as a rare mineral "scrutinyite" in 1988. The prevailing, tetragonal β phase was first identified as the mineral "plattnerite" around 1845 and later produced synthetically. Its lattice parameters are: $P4_2/mnm$ (no. 136), tP6, $a = 0.491$ nm, $c = 0.3385$ nm, $Z = 2$. Lead dioxide is a strong oxidizing agent that is used in the manufacture of matches, pyrotechnics, dyes and other chemicals. It also has several important applications in the electrochemical industry, in particular as a component of lead–acid batteries used in almost all types of vehicles. Lead dioxide decomposes upon heating in air as follows:

$$PbO_2 \Rightarrow Pb_{12}O_{19} \Rightarrow Pb_{12}O_{17} \Rightarrow Pb_3O_4 \Rightarrow PbO$$

The stoichiometry of the end product can be controlled by changing the temperature—for example,

in the above reaction, the first step occurs at 290 °C, second at 350 °C, third at 375 °C and fourth at 600 °C. In addition, Pb_2O_3 can be obtained by decomposing PbO_2 at 580–620 °C under oxygen pressure of 1.4 kbar. Therefore, thermal decomposition of lead dioxide is a common industrial way of producing the various lead oxides.

Lead tetroxide, also called "minium", red lead or triplumbic tetroxide, is a bright red or orange crystalline pigment. Chemically, red lead is lead tetroxide, Pb_3O_4, or $2PbO \cdot PbO_2$. This compound's Latin name *Minium* originates from the Minius river in northwest Spain where it was first mined. Natural minium is uncommon, forming only in extreme oxidizing conditions of lead ore bodies. The best specimens known come from Broken Hill, New South Wales, Australia, where they were formed as the result of a mine fire.

Lead dioxide is an amphoteric compound with dominant acidic properties. It dissolves in strong bases to form the hydroxy-plumbate ion, $Pb(OH)_6^2$.

$$PbO_2 + 2NaOH + 2H_2O \Rightarrow Na_2[Pb(OH)_6]$$

It also reacts with basic oxides in the melt yielding orthoplumbates such as $K_4[PbO_4]$. Because of the instability of its Pb^{4+} cation, lead dioxide reacts with warm acids, converting to the more stable Pb^{2+} state and liberating oxygen:

$$2PbO_2 + 2H_2SO_4 \Rightarrow 2PbSO_4 + H_2O + O_2$$

$$2PbO_2 + 4HNO_3 \Rightarrow 2Pb(NO_3)_2 + H_2O + O_2$$

$$PbO_2 + 4HCl \Rightarrow PbCl_2 + 2H_2O + Cl_2$$

Plumbous acid, H_2PbO_3, does not exist per se. The divalent ion, Pb^{2+}, forms under weakly acidic conditions (~pH = 6.0–6.5) as $Pb(OH)_2$. In solution, lead(II) hydroxide is a somewhat weak base, forming the lead(II) cation, Pb^{2+}, under weakly acidic conditions. This cation hydrolyzes and, under progressively increasing alkaline conditions, forms $Pb(OH)^+$, $Pb(OH)_2$(aqueous), $Pb(OH)_3^-$, and $Pb(OH)_4^{2-}$.

Thus, the number of "plumbides", "plumbites" and "plumbates" of the alkaline earths is strictly limited and depends upon the nature of the alkaline earth. This is probably due to the large size of the lead atom which, when combined with the alkaline earths, limits the number of stable compounds. Thus, we would not expect to find many stable beryllium–lead compounds but barium would exhibit the greatest number of stable compounds.

5.5.2. Plumbides of the Alkaline Earths

Beryllium Plumbides

No beryllium plumbides are known to exist. It is not clear whether this is due to the fact that they are not stable or to the fact that preparation of such alloys have never been attempted experimentally. Be melts at 1287 °C while Pb melts at 232 °C. This disparity may be the reason why the Be–Pb phase system has not been explored. The lack of interest in industry to their physical or electrical properties is probably the primary reason why the Be–Pb system has not been explored.

Magnesium Plumbides

Magnesium (MP = 643 °C) and lead (MP = 232 °C) react to form but one compound:

$$2Mg + Pb + \text{heat} \Rightarrow Mg_2Pb$$

The stability and elastic properties of Mg_2Pb have been investigated by the first-principles method, using the method of ultrasoft pseudopotential within the generalized gradient approximation based on density functional theory. Cohesive energy and formation enthalpy show that Mg_2Pb is stable. Similar result is also obtained by the energy band structure and DOS analysis. The thermal data of Mg_2Pb have also been calculated using Debye's quasi-harmonic approximation, such as heat capacity and Gibbs free energy. Based on the C_V, it was found that the Debye temperature of Mg_2Pb is 247.2 K. Young's modulus and shear modulus for Mg_2Pb are 68.6 and 27.9 GPa calculated from the theoretical elastic constants by Voigt-Reuss-Hill averaging scheme. The phase diagram is shown in Fig. 5.131.

Following this work, the liquidus curve for the Mg–Pb system was redetermined, and its slope was used to assess phase transformations in the β′ + Pb-rich liquid phase field. A peritectic reaction occurred at 538.7 °C when Mg_2Pb decomposed into a Mg-rich liquid and β′ (a Mg–Pb compound containing 35.15 at% Pb, or 0.3515 N_{Pb}, the atomic fraction of Pb) which melted congruently at 548.5 °C, confirming the work of Eldridge et al. When β' was cooled, a series of reactions occurred with the progressive rejection of Pb, this catatectic reaction terminated at 249 °C, 4 °C below the temperature of the Pb-rich eutectic at 83.88 at% Pb and 252.6 °C. This finding was contrary to that of Eldridge et al [1967] as they reported that the catatectic reaction terminated at 291 ± 5 °C. The rejection of Pb from an ingot of β' was recorded as a time-lapse series of photographs. The phase transformations resulting from the catatectic reaction and several polymorphic transformations of the intermediate products have been identified in the temperature range 548.5 to 249 °C.

The identification of the reactions at 252.6 and 249 °C has clarified this region of the phase diagram, as both of these values have been reported as the eutectic temperature. Finally, two polymorphic transformations of Mg_2Pb at 229 and 208 °C were identified and provided a basis for the identification of the final stage of the

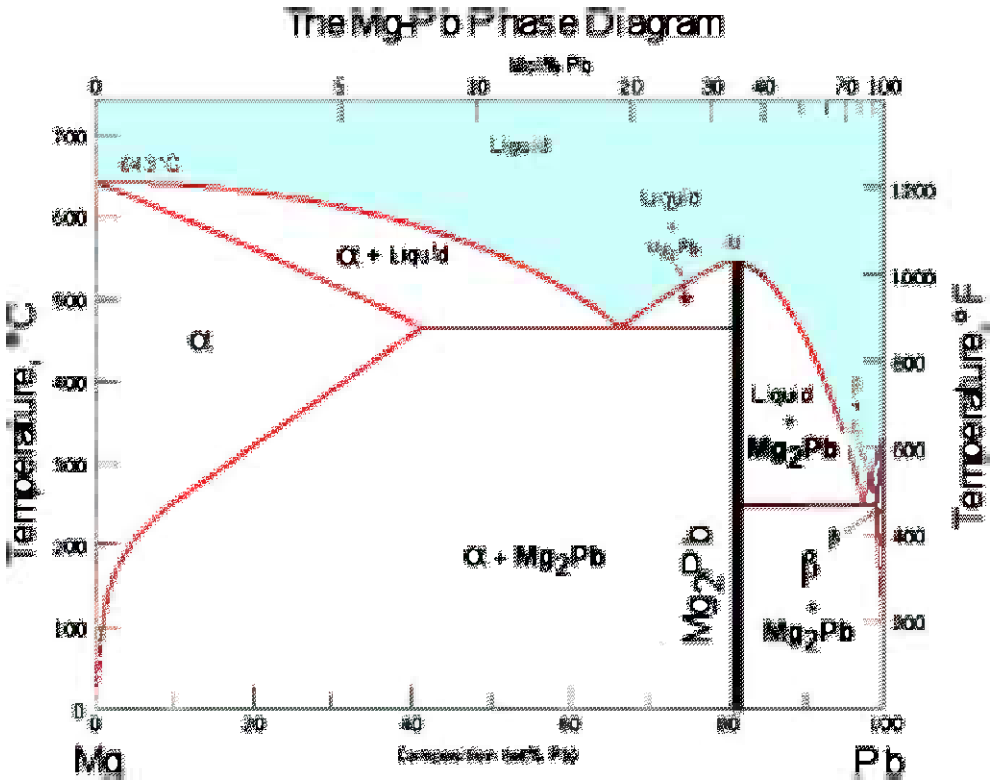

FIGURE 5.131

catatectic reaction at 249 °C. Mg_2Pb crystallizes in the "anti-fluorite" cubic structure with $a = 8.456$ Å (Fig. 5.132).

The thermal conductivity of a semimetal Mg_2Pb single crystal has been measured from 2 to 200 K (−271 to −73 °C). At low temperatures, thermal conduction is by phonons, but limited by phonon scattering from the heavy hole Fermi surface. At higher temperatures, the thermal conductivity contains both electronic and phonon contributions. A comparison of the thermal conductivity of Mg_2Pb with the thermal conductivities of the related semiconductors, Mg_2Si, Mg_2Ge, and Mg_2Sn, indicates that there is a significant bipolar contribution to the electronic thermal conductivity.

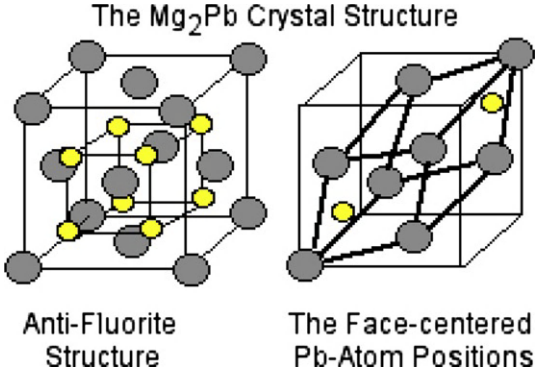

FIGURE 5.132

The sublimation of Mg_2Si, Mg_2Ge, Mg_2Sn and Mg_2Pb was studied by mass spectrometric observation of the vapor effusing from a Knudsen cell. Analysis of the temperature dependence of the partial pressure of Mg was used to obtain ΔH_{Mg}. The values of ΔH_{Mg} reported in this work are shown to correlate with the known melting points of the various compounds and to support metallic interpretation of the high conductivity of Mg_2Pb.

When Mg bismuthide and Mg plumbide react, the peritectic reaction changed from an even to odd reaction at 310 °C (0.14 wt% Bi and 4 wt% Mg). This was caused by the incorporation of 1.6 wt% Bi into Mg plumbide. This value was calculated from material balances of equilibrium studies of this reaction and confirmed by direct analysis of crystals using a "Cameca Microbeam" electron probe microanalyzer. A model was presented in which an atom of Pb in the unit cell, Mg_2Pb Mg_2Pb_5, was replaced by an atom of Bi which gives a concentration of 1.63 to 1.71 wt% Bi depending on the actual species of Mg plumbide present.

The phase boundary for double saturation of Pb and Mg plumbide has been established from the data of equilibrium tests. This shows a minimum temperature of 251.8 °C at 0.008 wt% Bi and 2.2 wt% Mg. Alloys in

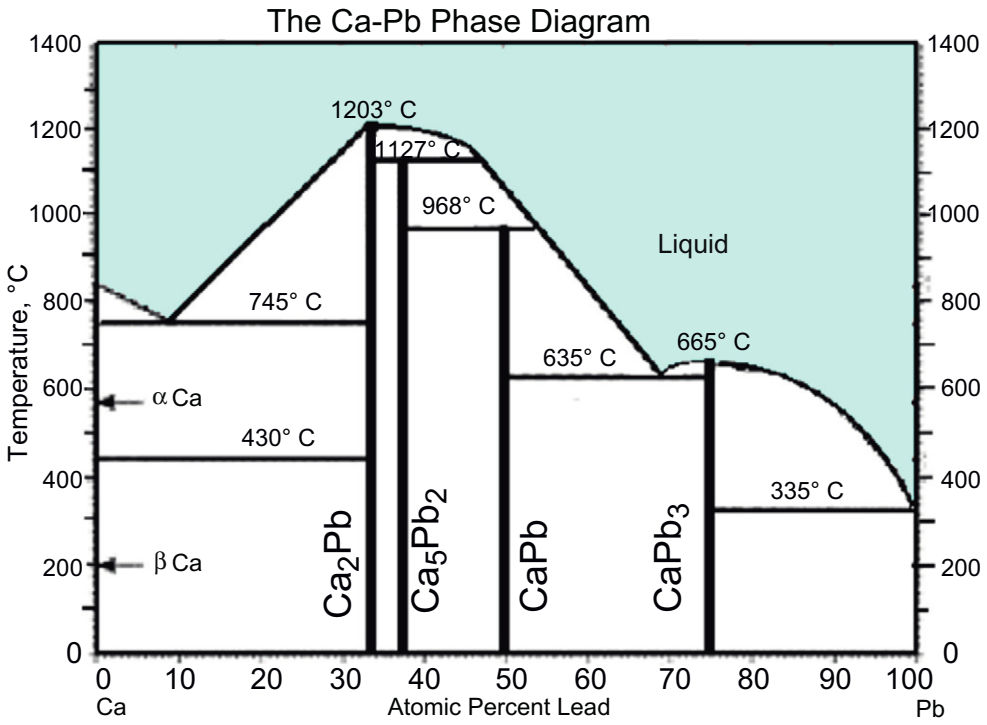

FIGURE 5.133

the primary Pb phase field adjacent to this boundary show undercooling to less than 248.5 °C, followed by one or two sharp temperature increases to 250.5 °C, with the initiation of the removal of Bi when the double saturation occurs, producing a final liquid phase containing less than 0.001 wt% Bi. Crystallization paths for alloys in the Mg plumbide phase field show a catatectic reaction and polymorphic transformations in the intermetallic compound. The removal of Bi is dependent on the concentration of Bi and Mg in the initial alloy. In systems containing sufficient Mg, a final alloy, containing less than 0.001 wt% Bi can be produced. These conditions have been used as the starting point for the development of a process for the removal of Bi from Pb. In addition, the crystallization paths show that there is a change in the thermal properties of the liquid alloy at 0.008 wt% Bi that is independent of the temperature and concentration of Mg. Further work is required to resolve this finding.

Mg_2Pb is offered for sale commercially even though no CAS number has apparently been assigned.

Calcium Plumbides

Calcium, Ca^0, melts at 842 °C and Pb^0 at 317 °C. Several compounds form from the melt. The reaction is:

$$xCa + yPb \Rightarrow Ca_xPb_y$$

where x and y can be 1 to 5.

The calcium–lead system has been investigated by thermal and X-ray methods. The Ca–Pb phase diagram, established as of 2004, is shown in Fig. 5.133.

Two compounds melt congruently: Ca_2Pb (1203 °C) and $CaPb_3$ (667 °C); two compounds form peritectically: Ca_5Pb_3 (1127 °C) and CaPb (968 °C).

Two eutectics occur at 90.5 at.% Ca (750 °C) and 36.5 at.% Ca (638 °C), respectively. The crystal structures of Ca_2Pb, Ca_5Pb_3 and $CaPb_3$ were confirmed. The compound CaPb was found to crystallize with the AuCu I-type structure ($a = 5.118$ Å, $c = 4.491$ Å). The same structure type was found for the phases EuPb ($a = 5.226$ Å, $c = 4.586$ Å) and YbPb ($a = 5.085$ Å, $c = 4.443$ Å), in which Eu and Yb behave as divalent elements similar to the alkaline earths. Crystal parameters are presented in the following Table 5.66.

Calcium triplumbide, $CaPb_3$, has been determined to be diamagnetic.

Diamagnetism is the property of an object which causes it to create a magnetic field in opposition to an externally applied magnetic field, thus causing a repulsive effect. Specifically, an external magnetic field alters the orbital velocity of electrons around their nuclei, thus changing the magnetic dipole moment. According to Lenz's Law, this opposes the external field. Diamagnetic materials cause lines of magnetic flux to curve away from the material, and superconductors can exclude them completely (except for a very thin layer at the

TABLE 5.66

surface). The features of the band structure and orbital magnetic susceptibility of the intermetallic compound $CaPb_3$ have shown that the anomalous, strongly temperature-dependent diamagnetism observed earlier in experiments on these compounds is of an interband origin and is due to the presence of degenerate electronic states in the immediate vicinity of the Fermi level.

Ternary mixed Ca/Sr–Ba triplumbides of overall composition $M_{1.0}Pb_{3.0}$ were synthesized from stoichiometric mixtures of the elements. The structures of the compounds have been determined by means of single-crystal X-ray data. All structures exhibit close-packed ordered APb_3 layers containing Pb Kagomë nets, which are stacked in different orientations. Depending on the stacking sequences, the resulting lead polyanion resembles the oxygen nets of the hexagonal (face sharing octahedra, *h*-stacking, Ni_3Sn-type structure) or the cubic perovskites (corner-sharing octahedra, *c* stacking, Cu_3Au-type structure). The known binary compound, $BaPb_3$, the structure of which has been redetermined from single-crystal data (trigonal, space group $\bar{R}3m$, $a = 7.2906$ Å, $c = 25.6443$ Å, $Z = 9$), shows a $(hhc)_3$ stacking ($TaCo_3$-type structure). A small partial substitution of barium against calcium ($Ca_{0.03}Ba_{0.97}Pb_3$: trigonal, space group $\bar{R}3m$, $a = 7.260$ Å, $c = 34.43$ Å, $Z = 12$), or strontium ($Sr_{0.11}Ba_{0.89}Pb_3$: $a = 7.273$ Å, $c = 34.21$ Å, $Z = 12$) causes a structural change to the HT-$PuGa_3$ structure type with a $(hhcc)_3$-stacking sequence. At an approximate 1:1 ratio (35 to 53% Sr) of strontium and barium ($Sr_{0.56}Ba_{0.44}Pb_3$: trigonal, space group $P63/mmc$, $a = 7.1582$ Å, $c = 17.1791$ Å, $Z = 6$), the $PuAl_3$ structure type [$(hcc)_2$-stacking] has a distinct homogeneity range. The composition, $(Ba_{0.95},Sr_{0.05})Pb_3$ has a rhombohedral unit cell ($a = 12.80$ Å, $\alpha = 34.43°$). The series is terminated with the pure *cubic* stacking of $SrPb_3$ and $CaPb_3$. As already noted from the above series, the stacking of the closely-packed layers is influenced by the ratio of the atomic radii of the contributing elements. The electronic stability ranges, which are discussed on the basis of the results of FP-LAPW band structure calculations and in comparison to further compounds known from the literature, can be explained using Zintl/Wade rules. Still, due to the presence of only partially occupied steep Pb-*p* bands of σ-bonding characteristic, the compounds are metals exhibiting pseudo band gaps at or near the Fermi level. Thus, this structure family represents an instructive case of transition from polar ionic/covalent toward (inter)metallic chemistry.

The enthalpies of formation of liquid or solid Ca–Pb alloys have been measured by direct and indirect calorimetry, for example: DTA gave diagram lines. In particular, the peritectic invariant temperature of low-calcium alloys has been confirmed. The melting entropy of $CaPb_3$ (12.6 J/K/(mol at.)) was obtained by anisothermal calorimetry. All the enthalpy information and diagram lines have been included in a computer calculation. Numeric representation of the thermodynamic properties of the Ca–Pb system is given. The heat of formation of $CaPb_3$ is:

$$\Delta H_f\ (1/4\ CaPb_3\ (910\ K = 637\ °C)\ Ca(s)Pb\ (liq) = -35.1\ kJ/mol$$

Pentacalcium triplumbide, Ca_5Pb_3, has the Mn_5Si_3 structure. The many A_5B_3 phases that exhibit hexagonal Mn_5Si_3-type structures by and large have a nearly unique abilities to bind diverse heteratoms Z in a preformed cavity within a chain of confacial trigonal antiprisms of A. The historical development of this chemistry as interstitially stabilized Nowotny phases and recent research to clarify the necessity for Z and the range of Z possible in certain hosts are described. Some hosts may bind as many as 20 different interstitial Z. Structures, stoichiometric relationships, volume effects electronic guidelines, anomalies, Nowotny phases that require Z for stability, and a few band calculations are described. The special cases of hosts composed of divalent cations with pnictogens (As–Bi) and tetrels (Si–Pb) are complex cases of Nowotny phases.

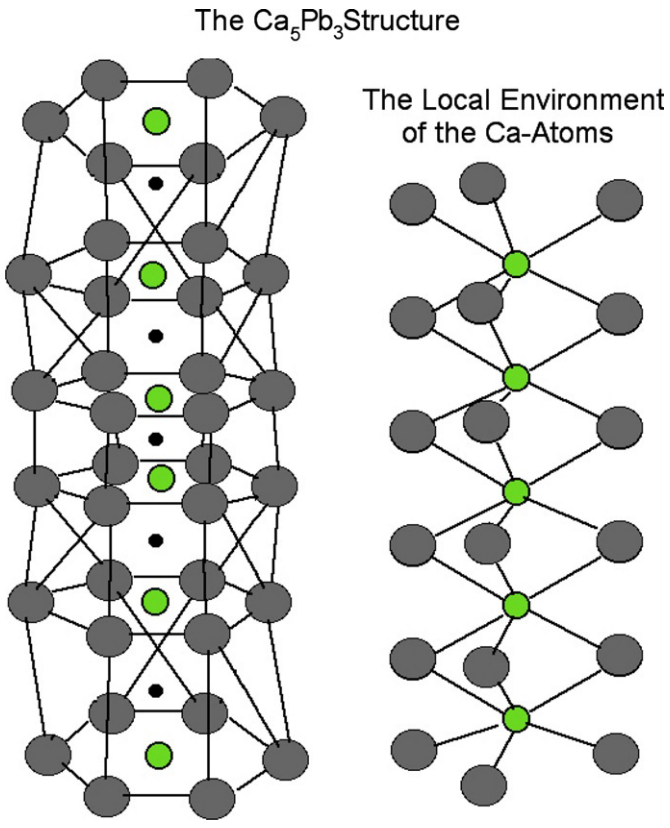

FIGURE 5.134

The structure of Ca_5Pb_3 is shown in Fig. 5.134.

The interstitial positions, referred to above, are shown as the black dots. Although the crystal structure and lattice constants have been measured, little data, other than its melting point, have been presented in the literature. It does form solid solutions with its Sr and Ba homologues but is only mentioned in passing when descriptions of those compounds are presented. The technical literature is almost devoid of mention of this compound except for structure.

The compound, **Monocalcium plumbide,** CaPb, was found to crystallize with the AuCu I-type structure. The Au–Cu system is one of the earliest systems for which several order–disorder-type transformations have been established. Much of the theory of order–disorder phenomenon has grown from an extensive study of these phases. In the case of CaPb, the structure is usually I-type which is a face-centered cubic structure where the Ca atoms are at the corners of the cube and Pb atoms lie at part of the face-centered positions. However, the occupartition can shift as shown in the accompanying diagram in which one row of the infinite structure is shown in Fig. 5.135.

The atom coordinates for this structure are presented in the following Table 5.67.

Although CaPb has been studied intensively concerning it structural abnormalities, little interest has been shown in industry due to the lack of interesting electrical properties.

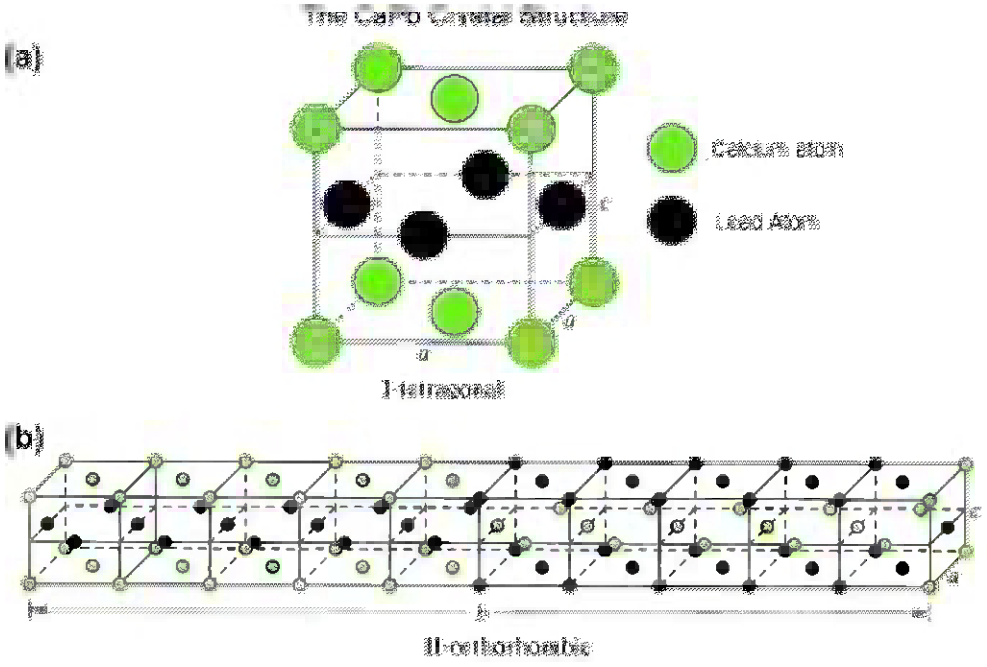

FIGURE 5.135

TABLE 5.67

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	Pb	Pb	1	d	4/mmm	1/2	1/2	1/2	1.0
2	Ca	Ca	1	a	4/mmm	0	0	0	1.0

Dicalcium plumbide, Ca_2Pb, is isotypic with Ca_2Si and Ca_2Ge ($PbCl_2$-structure, C-23-type). The lattice constants, space group, and point parameters are similar. The structure is shown in Fig. 5.136.

The lattices parameters are: Ca_2Pb: $a = 9.647 \pm 0.004$; $b = 8.072 \pm 0.004$; $c = 5.100 \pm 0.003$ Å, space group $= D_{2h}^{16}$.

The atoms occupy the point positions:

$$4(c) \pm (x, y, 1/4),\ (1/2 + y,\ 1/4).$$

The found parameters are the y values of the heavy metal atoms in both compounds and the same amount except: $x = x_{Pb} = 0.111$, $x = 0.067_{Ca1,Ca2} = 0.683$, $y_{Pb} = 0.250$, $y = 0.655_{Ca1}$, $y = 0.513_{Ca2}$.

Although Ca_2Pb has been studied concerning its structural properties, little interest has been shown in industry due to the lack of interesting electrical properties.

The **tricalcium plumbide** compound, Ca_3Pb, has been observed to be unstable yet it forms a hydride Zintl phase. Shiny crystals of the isotypic title compounds are obtained in high yield from suitable proportions of CaH_2, metal Ca, and Pb in welded Ta containers slowly cooled from 1100 °C. These were characterized by single-crystal XRD for Ca_3SnH_2 and Ca_3PbH_2 (orthorhombic, *Cmcm* (no. 63), $Z = 4$, $a = 8.866(1)$, 8.937(1) Å, $b = 11.371(2)$, 11.470(2) Å, $c = 5.220(1)$, 5.2551(7) Å, respectively). The structure is shown in Fig. 5.137.

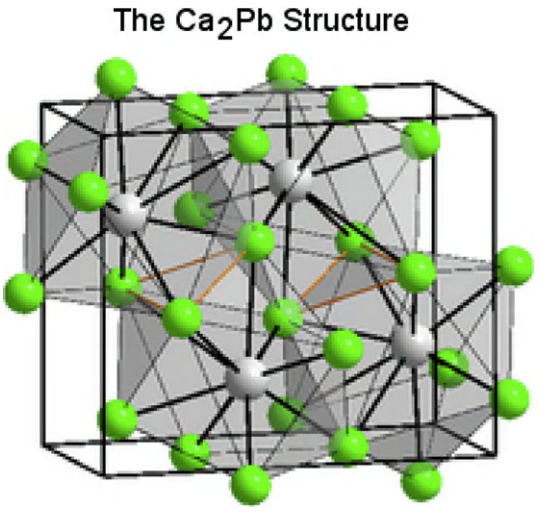

FIGURE 5.136

The structure contains distorted hcp layers of Ca_3Pb between which hydrogen occupies all tetrahedral voids formed by Ca atoms. These tetrahedra share three edges to form double chains along the c axis that are separated by Tt atoms. Both calcium compounds are diamagnetic semiconductors, and the family can all be formulated in terms of oxidation states as Zintl phases $(A^{+2})_3Tt^{-4}(H^-)_2$. Their structure may be derived from the hexagonal version of the cubic perovskite Ca_3SnO by distortions that split the octahedral site in the oxide into edge-sharing tetrahedral pairs shown below. Thus, although Ca_3Pb is not stable and does not form in a Ca–Pb melt, it is stable if CaH_2 is added to the melt.

In general, calcium plumbides are not available commercially and no CAS numbers have been assigned to any of these compounds.

Strontium Plumbides

Strontium, as a metal, forms a series of crystalline compounds with Pb. The Sr–Pb system was studied by thermal analysis and X-ray analysis. The phase diagram is shown in Fig. 5.138.

Seven intermediate phases were found to exist. Two of these phases melt congruently: Sr_2Pb (1155 °C); $SrPb_3$ (675 °C). The remaining five phases form peritectically: Sr_5Pb_3 (1054 °C); Sr_5Pb_4 (943 °C); SrPb (785 °C); Sr_2Pb_3 (717 °C); Sr_3Pb_5 (645 °C). Two eutectics are formed, at 87.5 at.% Sr (725 °C) and at 30.5 at.% Sr (627 °C). The crystal structures of the compounds Sr_2Pb (anti-$PbCl_2$ type), Sr_5Pb_3 (Cr_5B_3 type), SrPb (CrB type) and $SrPb_3$ (Ti_3Cu type) are confirmed; Sr_5Pb_4 crystallizes with the Gd_5Si_4-type structure.

Distrontium plumbide, Sr_2Pb, crystallizes in the "ordered" anti-$PbCl_2$ type and is therefore related to the binary compound Ca_2Pb, which forms the anti-$PbCl_2$ type as well.

The structure is given as follows. Lattice parameters are: $a = 8.445$ Å, $b = 5.391$ Å, $c = 10.139$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume $= 461.60$ Å^3, space group = Pnma, point group = oP12, $Z = 4$ (Fig. 5.139).

Little use has been found for this material in industry.

Strontium monoplumbide, SrPb, is tetragonal and has the lattice parameters of $a = 4.648$ Å, $b = 5.018$ Å, $c = 6.6097$ Å, $\alpha = 112.31°$, $\beta = 90°$, $\gamma = 90°$, cell

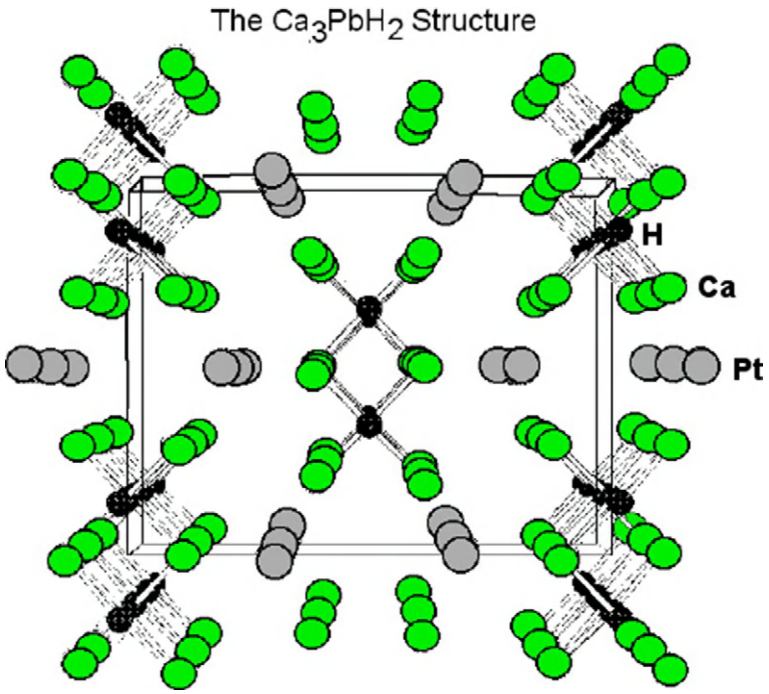

FIGURE 5.137

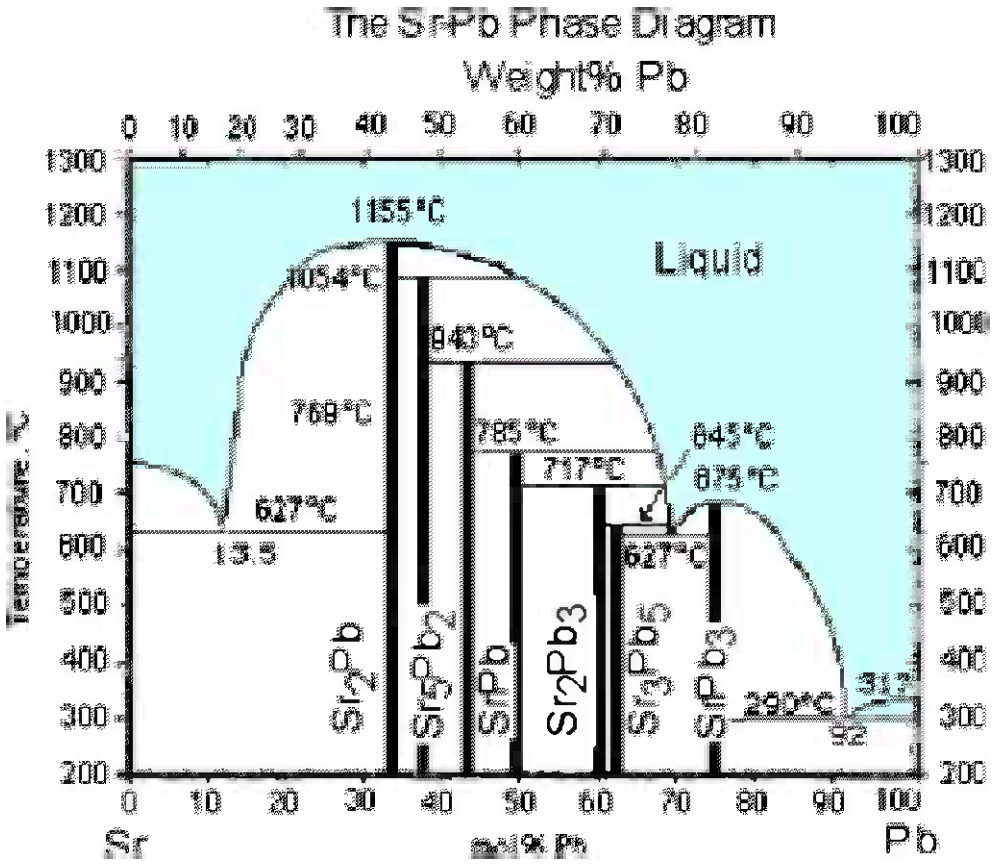

FIGURE 5.138

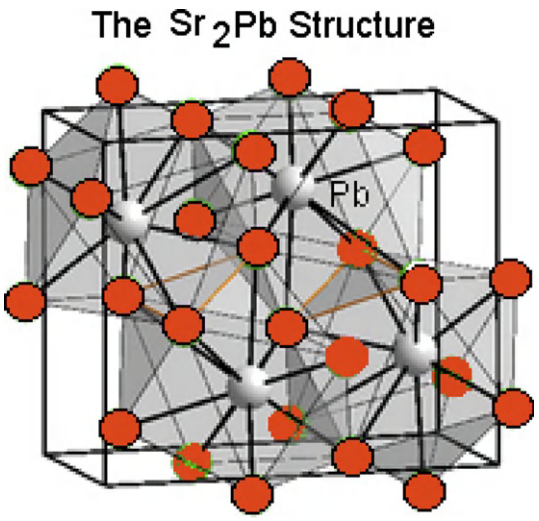

FIGURE 5.139

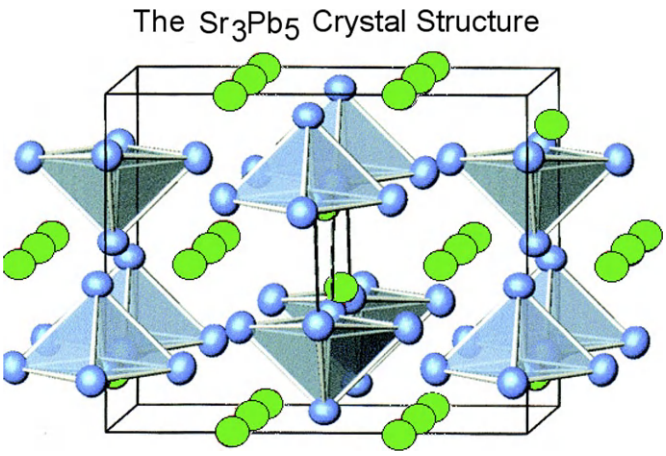

FIGURE 5.141

volume = 142.6 Å^3, $Z = 4$, space group = Cmcm, point group = oS8. Little usage for this compound has been found in industry. Hence, the technical literature is sparse. The structure of SrPb is shown in Fig. 5.140.

Tristrontium pentaplumbide, Sr_3Pb_5, has the same structure as its Ba homologue, and is shown in Fig. 5.141.

The cell parameters are: $a = 4.883$ Å, $b = 8.367$ Å, $c = 8.367$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 341.84 Å^3, $Z = 4$. It is orthorhombic with space group P4/mbm and point group tP10. In another modification, Sr_3Pb_5, is reported to be tetragonal with space group = P4/mbm, $a = 8.367$ Å, $c = 4.883$ Å, $Z = 2$.

Both binary Zintl phases, Sr_3Pb_5 and Ba_3Pb_5, were synthesized and structurally characterized. The revised structure of Ba_3Pb_5 is also reported. Both compounds are isotypic and crystallize with a modified Pu_3Pd_5 structure type. The anionic substructure is composed of Pb_5^{6-} square pyramidal clusters, which are described as arachno clusters according to the Wade–Mingos electron counting rules. The electronic structure of these pyramidal Zintl anions and the influence of the number of skeletal electrons of these clusters were investigated using the ELF.

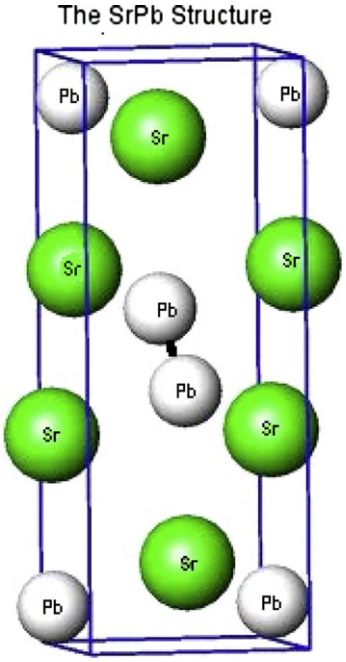

FIGURE 5.140

These compounds that contain square pyramidal polyanions of lead has been obtained in alkaline earth tetrel systems by direct fusion of the elements at 570 °C (Sr_3Pb_5), 1000 °C (Ba_3Pb_5), followed by slow cooling or annealing. The crystal structures have been refined in the Pu_3Pd_5 structure type (orthorhombic, *Cmcm*, $Z = 4$) with cell dimensions of $a = 10.644$, and 11.154 Å, $b = 8.588$ and 9.049 Å, and $c = 10.895$ and 11.370 Å, for Sr_3Pb_5 and Ba_3Pb_5, respectively. Square pyramidal clusters of the tetrel elements are weakly interlinked into chains via two types of longer intercluster interactions that are mediated by bridging cations and substantially influenced by cation size and the free electron count. The new compounds are all metallic ($\lambda_{298} = 10$ (Sr_3Pb_5) to 25 (Ba_3Pb_5) Ω cm), in agreement with simple valence considerations that predict two and five extra electrons per formula unit, respectively, beyond that necessary for closed-shell *nido*-Tt_5^{4-} anions. Extended Hückel tight-binding calculations on these new compounds reveal that bonding in the regions below and around the Fermi energies are dominated by general cation–anion interactions, that is, lattice covalency.

Strontium triplumbide, $SrPb_3$, [13c] crystallizes in the $AuCu_3$ type of structure with cell parameters of

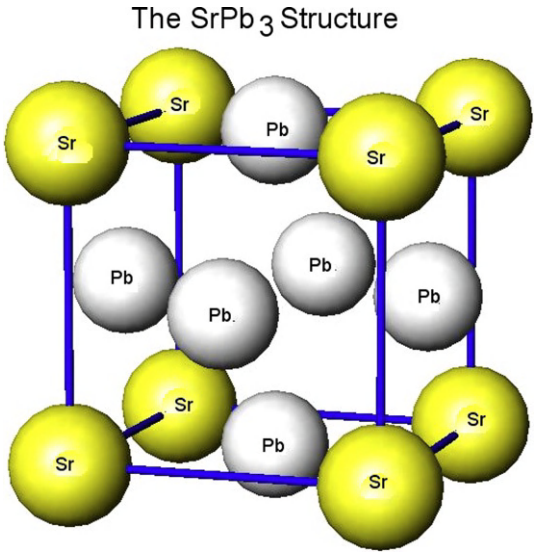

FIGURE 5.142

$a = 4.966$ Å, $b = 4.966$ Å, $c = 5.025$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90$ °, cell volume = 123.92 Å^3, $Z = 2$, $d = 9.50$ g/cc, point group = tP4, space group = P4/mmm.

The structure is shown in Fig. 5.142.

Ternary mixed Sr/Ca–Ba triplumbides of overall composition $A^{II}Pb_3$ were synthesized from stoichiometric mixtures of the elements. The structures of the compounds have been determined by means of single-crystal X-ray data. All structures exhibit close-packed-ordered APb_3 layers containing Pb Kagomë nets, which are stacked in different orientations. Depending on the stacking sequences, the resulting lead polyanion resembles the oxygen nets of the hexagonal (face sharing octahedra, *h* stacking, Ni_3Sn-type structure) or the cubic perovskites (corner-sharing octahedra, *c* stacking, Cu_3Au-type structure). $SrPb_3$ is cubic but modification with barium causes change to a different structure: ($Sr_{0.11}Ba_{0.89}Pb_3$: $a = 7.273(2)$, $c = 3.421(2)$ Å, $Z = 12$, $R1 = 0.0424$) having the HT-PuGa3 structure type with a (*hhcc*)3-stacking sequence. At an approximate 1:1 ratio (35 to 53% Sr) of strontium and barium ($Sr_{0.56}Ba_{0.44}Pb_3$: trigonal, space group *P63/mmc*, $a = 7.1582(2)$, $c = 17.1791(7)$ Å, $Z = 6$, $R1 = 0.0309$) with the $PuAl_3$-structure type [(*hcc*)2-stacking] over a distinct homogeneity range.

Distrontium triplumbide, Sr_2Pb_3, crystallizes in the tetragonal system, P4/mbm group. This structure is highlighted by trigonal prismatic coordination and octahedral cubo atoms around the Pb atoms. Cell parameters are: $a = 4.883$ Å, $b = 8.367$ Å, $c = 8.367$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 341.84. The structure is shown in Fig. 5.143.

It consists of columns of 2 and 3 Pb atoms coordinated in a spiral fashion. A three-dimensional cell is shown along with a (100) plane and the positions of the columns along the *c*-axis [(001) plane]. This structure is unique among the alkaline earth plumbides. Little data exists concerning its physical properties and it has found no usage in industry at this moment.

Penta-strontium triplumbide, Sr_5Pb_3, crystallizes in the Cr_5B_3 type with point group of tl32 and space group of I4/mcm. Cell parameters are: $a = 8.67$ Å, $b = 8.67$ Å, $c = 10.0551$ Å, $\alpha = 115.539°$, $\beta = 115.539°$, $\gamma = 90°$, cell volume = 599.1 Å^3. The structure is shown in the following diagram. It consists of Zintl dumbbells of Pb, ⊙—⊙ which are interspersed among Sr-Pb_2 triangles along the (001) direction in the lattice (Fig. 5.144).

Both a three-dimensional view is shown along with an arrangement along the (100) plane (for simplicity). Little usage has developed for this Zintl phase whose conductivity is metallic in nature. The various Pb_2 dumbbells are slightly tilted away from the 90° angle in many of their positions in the lattice. Some of the Pb atoms form a localized $PbSr_4$ arrangement which is actually a *nido*-Tt_5^{4-} anion. This structure has the arrangement shown in Fig. 5.145.

Pentastrontium quadro-plumbide, Sr_5Pb_4, crystallizes in the Sm_5Ge_4 type of orthorhombic structure with cell parameters of: $a = 8.480$ Å, $b = 9.011$ Å,

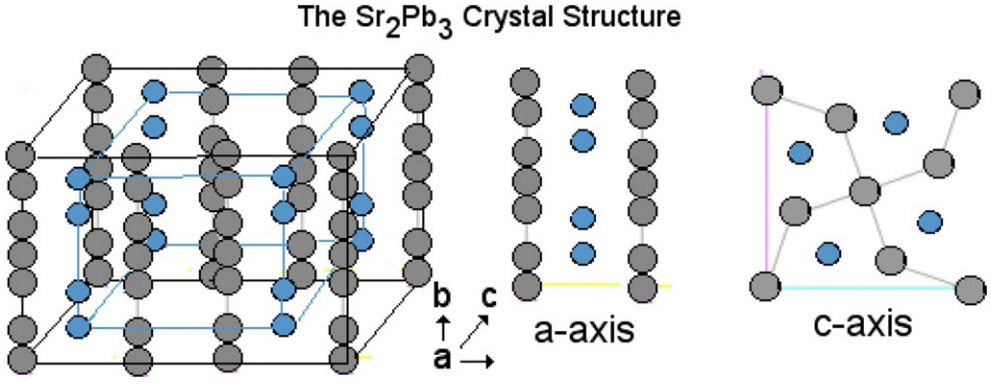

FIGURE 5.143

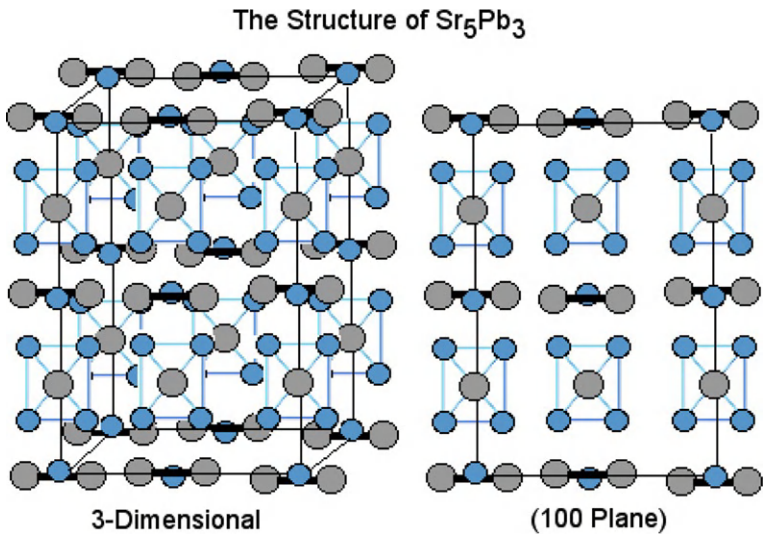

FIGURE 5.144

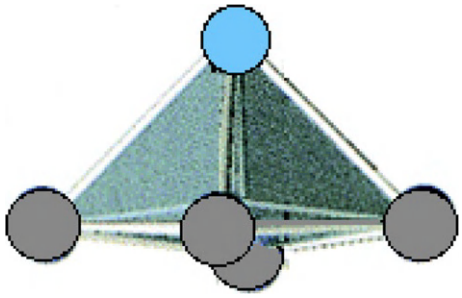

FIGURE 5.145

$c = 17.272$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 131.951 Å^3, point group = oP36, space group = Pnmna. There are six atoms in the asymmetric unit, one Sr in Wyckoff site 4*c*, two Sr in 8*d*, two Pb in 4*c* and one Pb in 8*d*. Two of the Pb sites are statistically occupied, with a lack of long-range ordering.

The arrangement of the individual atoms to each other in the slabs present are shown in Fig. 5.146.

The three-dimensional structure is shown with the three types of Sr atom symmetries (Fig. 5.147).

In addition to the seven compounds shown in the phase diagram, another composition has been found. Sr_7Pb_{12} has a unique crystal formation with cell parameters of: $a = 0.4.886$ nm, $b = 1.6.17$ nm, $c = 1.6.17$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 127.754 Å^3. The structure was determined as follows. Only the (100) plane is shown in the Fig. 5.148.

There are two kinds of Pb atoms, Pb1 forms a series of pentagonal nets while Pb2 forms triangles within the structure. Little is known concerning its physical properties. Only the structure has been determined.

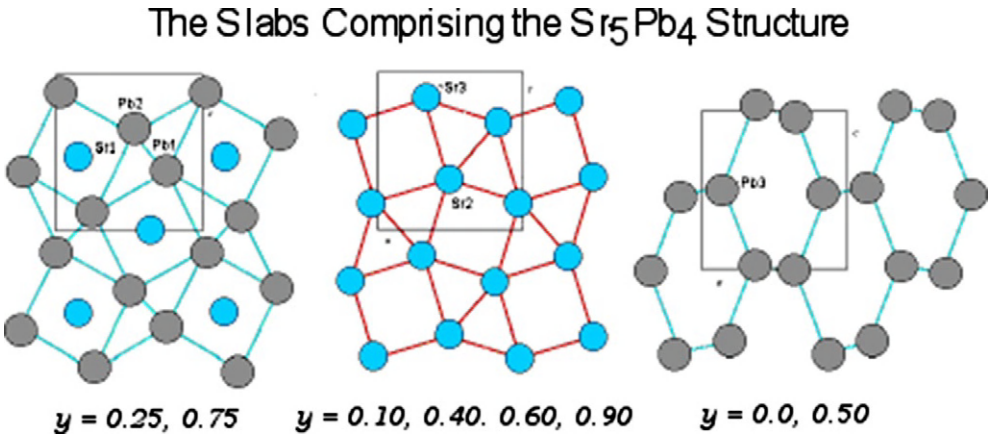

FIGURE 5.146

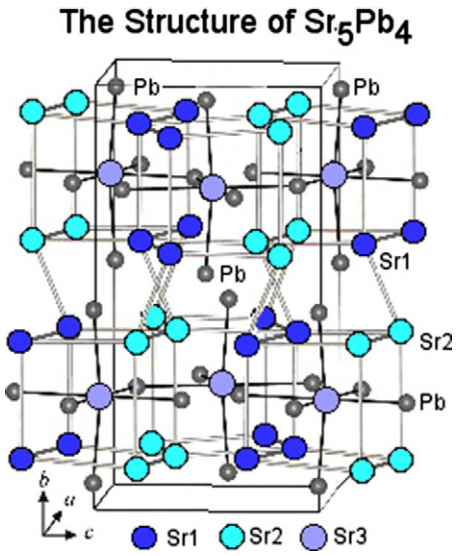

FIGURE 5.147

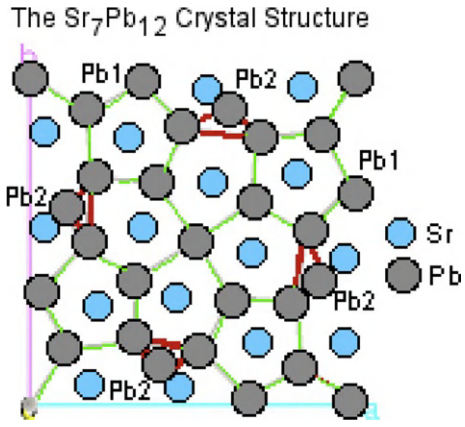

FIGURE 5.148

The strontium plumbides have not found usage in industry and they are not offered for sale commercially. No CAS numbers have been issued at this time.

Barium Plumbides

Barium forms a series of crystalline compounds with Pb. The complete phase diagram is shown in Fig. 5.149.

The structures of the compounds, Ba_5Pb_3, BaPb, and $BaPb_3$ have been determined. Ba_5Pb_3 has the body-centered tetragonal $D8_4$ structure with $a = 9.038$ Å, $c = 16.843$ Å, space group = I4/mcm, $Z = 4$. The room temperature modification of BaPb has the orthorhombic R_f structure with $a = 5.29$ Å, $b = 12.60$ Å, $c = 4.78$ Å, space group = Cmcm, $Z = 4$. $BaPb_3$ is rhombohedral with $a = 9.565°$, $\alpha = 44.78°$, $Z = 3$. Two other phases have been identified: Ba_3Pb_5 and Ba_2Pb. The former crystallizes in the Pu_3Pd_5-type structure

($a = 11.148$ Å, $b = 9.049$ Å, $c = 11.368$ Å) and the latter in the anti-$PbCl_2$-type structure ($a = 10.61$ Å, $b = 5.71$ Å, $c = 8.64$ Å). Crystal data for these compounds are shown in Fig. 5.150.

The barium plumbides have structures similar to those of calcium and strontium.

Dibarium plumbide, Ba_2Pb, has lattice unit-cell parameters of: $a = 5.71$ Å, $b = 8.64$ Å, $c = 10.61$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 823.44 Å^3, $Z = 4$. The lattice is of the Co_2Si type and is shown in Fig. 5.151.

Little information is available concerning this compound other than its crystal structure. It has found no usage in industry nor has its electrical properties been measured.

Tribarium pentaplumbide, Ba_3Pb_5, has the unit-cell parameters of: $a = 7.1792$ Å, $b = 7.1792$ Å, $c = 11.368$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 101.866°$, cell volume = 573.40 Å^3, $Z = 4$. It has the Pu_3Pd_5 type of structure shown in Fig. 5.152.

A series of compounds that contain square pyramidal Tt_5 polyanions of lead has been obtained in alkaline earth tetrel systems by direct fusion of the elements at 1000 °C (Ba_3Pb_5), followed by slow cooling or annealing.

The Ba_3Pb_5 Crystal Structure

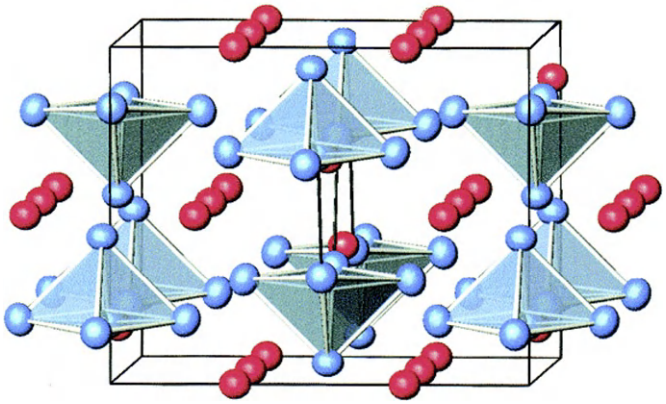

FIGURE 5.152

The crystal structures for all three have been refined in the Pu_3Pd_5 structure type (orthorhombic, Cmcm, $Z = 4$) with cell dimensions given above. Square pyramidal clusters of the tetrel elements are weakly interlinked into chains via two types of longer intercluster interactions that are mediated by bridging cations and substantially influenced by cation size and the free electron count. This new compound is all metallic in conductivity (~15–25 Ω cm), in agreement with simple valence considerations that predict two and five extra electrons per formula unit, respectively, beyond that necessary for closed-shell nido-Tt_5^{4-} anions. Extended Hückel tight-binding calculations reveals that bonding in the regions below and around the Fermi energies are dominated by general cation–anion interactions, that is, lattice covalency. Closed-shell bonding features for the classical PB_5^{4-} ion is also obvious but subsidiary to the heteroatomic interactions with the cations. The intercluster contacts are relatively unimportant in bonding.

Pentabarium triplumbide, Ba_5Pb_3, has the cell parameters of: $a = 9.04$ Å, $b = 9.04$ Å, $c = 10.562$ Å, $\alpha = 115.338°$, $\beta = 115.338°$, $\gamma = 90°$, cell volume = 687.11 Å^3, $Z = 6$. It is of the Cr_5B_3 type of structure shown in Fig. 5.153.

It consists of Zintl dumbbells of Pb, ⬬ which are interspersed among the Ba-Pb_2 triangles along the (001) direction in the lattice. There are four Ba_5Pb_3 groups per unit cell in a calculated density of 6.31 g/cc. General *hkl* reflections were observed only when $h + k + l = 2n$. Very little data is available for this compound other than its structure.

Barium monoplumbide, BaPb, has the cell parameters: $a = 4.822$ Å, $b = 5.289$ Å, $c = 6.8371$ Å, $\alpha = 112.755°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 160.80 Å^3, $Z = 4$.

It has the CrB type of structure shown in Fig. 5.154.

This compound, BaPb, is stated to possess "incipient" ferroelectric properties but has not been researched

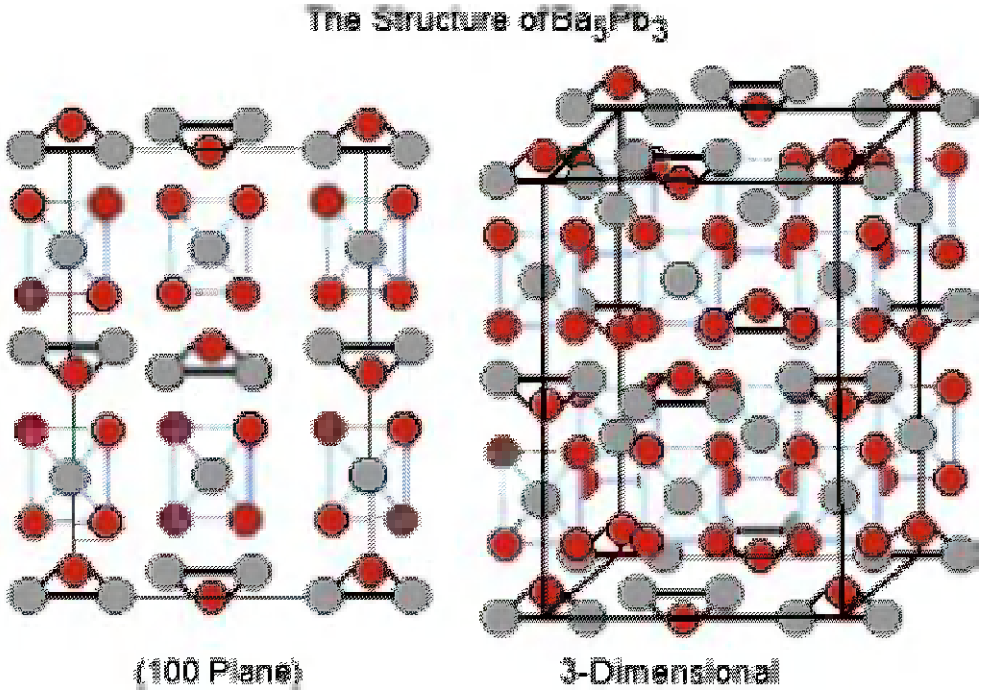

FIGURE 5.153

FIGURE 5.154

thoroughly. The only well-established property has been its structure. Its electrical properties remain unknown.

Barium triplumbide, $BaPb_3$, has the cell parameters of: $a = 7.298$ nm, $b = 7.298$ nm, $c = 9.5662$ nm, $\alpha = 67.577°$, $\beta = 67.577°$, $\gamma = 60°$, cell volume $= 396.14$ Å^3, $Z = 4$, space group = R3m. $BaPb_3$ is rhombohedral and has the Nb_3Sn type of structure as shown in Fig. 5.155.

Ternary-mixed Ca/Sr–Ba triplumbides of overall composition APb_3 were synthesized from stoichiometric mixtures of the elements. The structures of the compounds have been determined by means of single-crystal X-ray data. All structures exhibit closely-packed ordered APb_3 layers containing Pb Kagøme nets, which are stacked in different orientations. Depending on the stacking sequences, the resulting lead polyanion resembles the oxygen nets of the hexagonal (face-sharing octahedra, hexagonal (h) stacking, Ni_3Sn-type structure) or the cubic perovskites (corner-sharing octahedra, cubic (c) stacking, Cu_3Au-type structure). The known binary compound $BaPb_3$, the structure of which has been redetermined from single-crystal data (trigonal, space group R3m, shows a $(hhc)_3$ stacking, $TaCo_3$-type structure). A small partial substitution of barium against calcium ($Ca_{0.03}Ba_{0.97}Pb_3$: trigonal, space group R3m, $a = 7.260$ Å, $c = 34.43$ Å, $Z = 12$, $R_1 = 0.0542$) or strontium ($Sr_{0.11}Ba_{0.89}Pb_3$: $a = 7.273$ Å, $c = 34.21$ Å, $Z = 12$, $R_1 = 0.0424$) causes a structural change to the HT-$PuGa_3$ structure type with a $(hhcc)_3$ stacking sequence. At an approximate 1:1 ratio (35 to 53 % Sr) of strontium and barium ($Sr_{0.56}Ba_{0.44}Pb_3$: trigonal, space group P63/mmc, $a = 7.1582$ Å, $c = 17.1791$ Å, $Z = 6$, $R_1 = 0.0309$), the $PuAl_3$ structure type [$(hcc)_2$ stacking] has a distinct homogeneity range. The series is terminated with the pure c stacking of $SrPb_3$ and $CaPb_3$. As already noted from the above series, the stacking of the close-packed layers is influenced by the ratio of the atomic radii of the contributing elements. The electronic stability ranges, which are discussed on the basis of the results of FP-LAPW band structure calculations and in

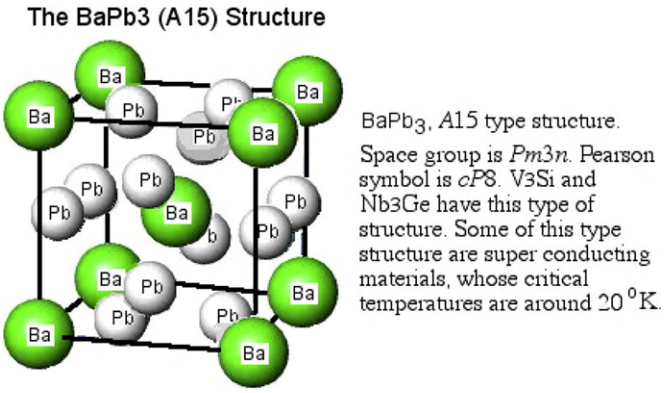

FIGURE 5.155

comparison to further compounds known from the literature, can be explained using Zintl/Wade rules. Still, due to the presence of only partially occupied steep Pb-p bands of σ bonding characteristic, the compounds are metals exhibiting pseudo band gaps at or near the Fermi level. Thus, this structure family represents an instructive case of transition from polar ionic/covalent toward (inter)metallic chemistry.

Tribarum pentaplumbide has been identified as a Zintl phase and the anionic substructure is composed of X_5^{6-} square pyramidal clusters (X = Pb), which are described as arachno clusters according to the Wade–Mingos electron counting rules. The electronic structure of the pyramidal Zintl anions and the influence of the number of skeletal electrons of these clusters are investigated using the ELF. The structural relationship between Ba_3Sn_5 and the Zintl phases Ba_3Si_4 and Ba_3Ge_4 were analyzed. Additionally, two new Zintl phases, $Ba_3Ge_{2.82}Sn_{2.18}$ and $Ba_3Ge_{3.94}Sn_{0.06}$, have been synthesized and their structures are reported, which directly show that the exchange of tin against germanium leads to a change from the $M_{3\times5}$ to the $M_{3\times4}$ structure type. This effect is traced back to the maximal charge acquisition property of the Zintl anions of heavier and lighter tetralides.

A series of compounds that contain square pyramidal Tt_5 polyanions of tin and lead has been obtained in alkaline earth or rare-earth metal tetrel systems by direct fusion of the elements at 1000 °C (Ba_3Pb_5), followed by slow cooling or annealing. The crystal structure has been refined in the Pu_3Pd_5 structure type (orthorhombic, Cmcm, $Z = 4$) with cell dimensions of $a = 11.154$ Å, $b = 9.049$ Å, and $c = 11.370$ Å. Square pyramidal clusters of the tetrel elements are weakly interlinked into chains via two types of longer intercluster interactions that are mediated by bridging cations and substantially influenced by cation size and the free electron count. This compound is all metallic in agreement with simple valence considerations that predict two and five extra electrons per formula unit, respectively, beyond that necessary for closed-shell nido-Tt_5^{4-} anions. Extended Hückel tight-binding calculations on the compound reveal that bonding in the regions below and around the Fermi energies are dominated by general cation–anion interactions, that is, lattice covalency.

Barium plumbide compounds have found little usage in industry and have no CAS numbers. They have received some attention in the technical literature but no specific usages have yet been found for these compounds.

Radium Plumbides

It is not surprising that no mention of any radium plumbide compounds can be found in the scientific literature because lead is the final decay product (^{208}Pb) of radium (^{228}Ra). It should be possible to form compounds similar to those of barium, namely:

RaPb
Ra_2Pb
Ra_5Pb_3
Ra_3Pb_5
$RaPb_3$

However, this has never been recorded in the literature to date. Nor it is likely that these compounds will ever be studied because of the radioactivity and long life of ^{226}Ra.

5.5.3. Oxy-Plumbates of the Alkaline Earths

Beryllium Plumbates

The technical literature concerning beryllium and its oxy-lead compounds is completely lacking. A description of any combination of a Be compound with a lead oxide compound is completely lacking in the past or present technical literature. It should be possible to use the thermal-heating method to form these compounds but there is no record of anyone having done so. Thus, the physical and chemical properties of $BePbO_3$ and Be_2PbO_4 have remained unknown. The reactions should involve:

$$BeO + PbO_2 \Rightarrow BePbO_3$$

$$2BeO + PbO_2 \Rightarrow Be_2PbO_4$$

A temperature of at least 1000 °C would be required. It is not certain whether these compounds are stable. The divalent Be^{2+} ion has a radius of 0.44 Å (0.31 Å in some references) whereas the size of the Pb^{4+} ion in PbO_3^{2-} is 1.19 Å. Thus, while the corresponding Ca (Ca^{2+} = 1.02 Å), Sr and Ba compounds have been well established ($Sr^{2+} = 1.18$ Å and $Ba^{2+} = 1.35$ Å), those of Be have not.

There are no CAS numbers assigned and these compounds are not available commercially.

Magnesium Plumbates

The technical literature concerning magnesium and its oxy-lead compounds is completely lacking. A description of any combination of a Mg compound with a lead oxide compound is completely lacking in the past or present technical literature. It should be possible to use the thermal-heating method to form these compounds but there is no record of anyone having done so. Thus, the physical and chemical properties of $MgPbO_3$ and Mg_2PbO_4 have remained unknown. The reactions should involve:

$$MgO + PbO_2 \Rightarrow MgPbO_3$$

$$2MgO + PbO_2 \Rightarrow Mg_2PbO_4$$

A temperature of at least 1000 °C would be required. $MgPbO_3$ would be expected to have the perovskite structure. It is not certain whether these compounds are stable. The divalent Mg^{2+} ion has a radius of 0.72 Å whereas the size of the Pb^{4+} ion in PbO_3^{2-} is 1.19 Å. That of Sr^{2+} is almost identical and the corresponding compounds have been well studied. If $MgPbO_3$ or Mg_2PbO_4 exists, either or both compounds would be expected to possess semiconducting or metallic-conducting properties due to the $Pb^{2+} \Leftrightarrow Pb^{4+}$ electron-exchange mechanism induced by a proper formation mechanism within the crystal.

Recent (2000) experimental investigations of phase equilibria and thermodynamic properties of the systems M–Pb–O, where M = Mg, Ca, Sr or Ba, indicate a regular increase in thermodynamic stability of ternary oxides, $MPbO_3$ and M_2PbO_4, with increasing basicity of the oxide of the alkaline earth metal. Number of stable interoxide compounds at 1100 K (827 °C) in the systems M–Pb–O (M = Mg, Ca, Sr, Ba) increases in unit increments from Mg to Ba. In this paper, experimentally determined standard Gibbs energies of formation of M_2PbO_4 (M = Ca, Sr, Ba) and $MPbO_3$ (M = Ca, Sr, Ba) from their component binary monoxides and oxygen gas are combined with an estimated value for $MgPbO_3$ to delineate systematic trends in thermodynamic stability of the ternary oxides. The trends are interpreted using concepts of tolerance factor and acid–base interactions. All the ternary oxides in these systems contain lead in the tetravalent state. The small Pb^{4+} ions polarize the surrounding oxygen ions and cause the formation of oxy-anions which are acidic in character. Hence, the higher oxidation state of lead is stabilized in the presence of basic oxides of alkaline earth group. A schematic subsolidus temperature-composition phase diagram is presented for the system BaO–PbO–O_2 to illustrate the change in oxidation states in binary and ternary oxides with temperature.

No CAS numbers have been assigned to any magnesium plumbates and they are not available commercially.

Calcium Plumbates

Phase relations in the system CaO–PbO at 1100 K (827 °C) in air and oxygen have been determined by equilibrating 18 compositions of varying ratios of these oxides and identifying the phases present in quenched samples by XRD and energy dispersive X-ray analysis (EDX). Only one binary compound, Ca_2PbO_4, was found to be present ($CaPbO_3$ was absent as was any other possible compounds). The compound coexists with CaO and PbO. The standard Gibbs energies of formation of Ca_2PbO_4 (880–1100 K) was determined using solid-state cells based on yttria-stabilized zirconia as the solid electrolyte. Pure oxygen gas at 0.1 MPa was used as the reference electrode. For measurements on Ca_2PbO_4, a novel cell design with three electrodes in series, separated by solid electrolyte membranes, was used to avoid polarization of the electrode containing three solid phases. Two three-phase electrodes were used. The first absorbs the electrochemical flux of oxygen from the reference electrode to the measuring electrode. The other three-phase electrode, which is unaffected by the oxygen flux through the solid electrolyte, is used for electromotive force (e.m.f.) measurement. The results from EMF studies were cross checked using thermogravimetry (TG) under controlled oxygen partial pressures. The results can be summarized by the following equations:

$$2CaO + PbO + 1/2O_2 \Rightarrow Ca_2PbO_4$$

$$\Delta G^0\,(\mathrm{J/mol}) = -128{,}340 + 93.21\,T/\mathrm{K} \pm 200$$

Single crystals of Ca_2PbO_4 were prepared by a flux technique and investigated by X-ray methods. It crystallizes with orthorhombic symmetry, space group D-Pbam ($a = 5.832$; $b = 9.766$; $c = 3.375$ Å, $Z = 2$). Ca_2PbO_4 belongs to the Sr_2PbO_4 type. It shows Ca^{2+} in a sevenfold and Pb^{4+} in octahedral coordination, as shown in the following Fig. 5.156.

Calcium orthoplumbate can be obtained by reaction of a homogeneous mixture of powdered oxides at 600–800° in the presence of air, or by heating compounds of calcium and lead which yield oxides and volatile products by dissociation. In the presence of excess oxygen, the kinetics of reaction between CaO and PbO to form calcium plumbate has been found to be governed by a diffusion process related to a specific kinetic model (Jander's model).

The energy of activation of the process, as calculated from the Arrhenius equation, was found to be 50 kcal/mol. In an air and nitrogen atmosphere (ratio 1:16), the reaction rate is 4–5 times slower than that obtained in a pure oxygen atmosphere:

$$2CaO + PbO + 1/2O_2 \Rightarrow Ca_2PbO_4$$

It has been shown that formation of calcium plumbate from pure CaO and PbO_2 occurs without formation of intermediate compounds between 600 and 800 °C.

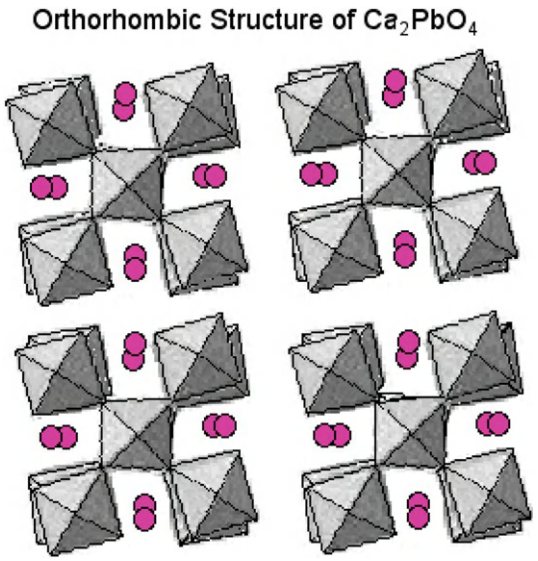

FIGURE 5.156

Calcium orthoplumbate, Ca_2PbO_4, can also be prepared by sol–gel methods (two varieties of the Pechini complex route and a water soluble polymer method) and by solid-state reaction. The sol–gel-prepared samples contained calcium orthoplumbate as the only phase as early as after 2 h annealing at 800 °C. Phase composition was detected by XRD measurement and by Raman spectroscopy. Annealing at 800 °C for 24 h induced small losses of Pb^{2+}, as confirmed by XRF measurement. The Pb losses were smaller for the sol–gel-prepared samples probably due to earlier formation of Ca_2PbO_4 as the samples were being heated. Microstructure and grain size were also established. Sol–gel-prepared samples had regularly distributed grains with a small distribution coefficient with a median value in order of 1 μm. Differences in microstructure of solid state and sol–gel samples were compared using SEM micrographs.

Calcium orthoplumbate is a powerful oxidizing agent that also prevents corrosion on iron and steel surfaces when added to paints. Its corrosion-inhibiting effect is a result of the pigment's capacity to oxidize soluble iron compounds formed in anodic areas, which then form an insoluble film of iron compounds at the anode. This neutralizes that element of the corrosion cell and restricts any further corrosion. In the meantime, calcium carbonate is formed at the cathodic region of the "corrosion cell".

Calcium orthoplumbate, like red lead, provides protection by a combination of basic and oxidizing characteristics, as well as film-forming properties by interaction with linseed oil. It is believed to pacify both cathodic and anodic areas on iron and steel, and in this respect differs from other rust-inhibitive pigments. In practice, it shows the behavior which on theoretical grounds might be expected to be associated with this type of inhibition. Linseed oil paints based on calcium plumbate have been found to be remarkably free from any tendency to crack, and their adhesion on galvanized iron and timber suggests the value of suck paints as primers with a wide variety of applications.

The metaplumbate, $CaPbO_3$, can be prepared by direct reaction at 800 °C of CaO and PbO_2. Its molecular weight is 295.2835 g/mol and its CAS number is 12744-29-7. The orthorhombic modification of $CaPbO_3$ can also be synthesized from a mixture of Ca_2PbO_4 and PbO_2 at high temperature and high pressure. Its structure was analyzed by Rietveld analysis of neutron diffraction data on the basis of space group Pbnm. It has a distorted perovskite structure of the $GdFeO_3$ type and a unit cell with dimensions of $a = 5.6710$ Å, $b = 5.8875$ Å, and $c = 8.1495$ Å. The Pb–O bond lengths in each PbO_6^{2-} octahedron are comparable to each other, whereas the PbO_6^{2-} octahedron tilts around [110]p and [001]p axes (p: perovskite subcell) by 18.50° and 20.28°, respectively. These tilt angles, which show great structural distortion in $CaPbO_3$ containing the smaller Ca^{2+} ion, are much larger than corresponding ones in crystal chemically isotypic $SrPbO_3$. The electric resistivity of $CaPbO_3$ at room temperature was as high as $3 \times 10^3\ \Omega$ cm, which is in sharp contrast to low resistivities observed in other perovskite-type oxides $BaPbO_3$ and $SrPbO_3$. The high resistivity of $CaPbO_3$ is explained as gap formation between 2p(O) nonbonding and 6s(Pb)-2p(O) sp-antibonding bands, which overlap with each other in $BaPbO_3$. Solid solutions, where Sr^{2+}, La^{3+}, Nd^{3+}, and Y^{3+} ions were partially substituted for Ca^{2+} ions, were also prepared to examine structural and electrical properties in perovskites based on $CaPbO_3$. Substitution of Sr^{2+} for Ca^{2+} led to reductions in the distortion and gap energy, whereas that of La^{3+}, Nd^{3+}, and Y^{3+} induced metallic conductivity owing to doping of electron carriers into the antibonding band, i.e. charged oxygen vacancies, V_O^+, causes electron hopping mechanisms to dominate.

A new structure type can be obtained under pressure. A new perovskite-type compound with nominal composition $CaPbO_3$ under about 6 GPa using a cubic-anvil-type apparatus from a mixed powder of high-purity CaO and PbO_2 was formed. The XRD pattern was indexed on the basis of an orthorhombic unit cell with $a = 5.667$ Å, $b = 5.879$ Å and $c = 8.147$ Å. This compound has a distorted perovskite-type structure, while two previously reported types of $CaPbO_3$ have a cubic fluorite-type structure and an ilmenite-type structure. EDX analysis and the unit-cell parameters suggest a deficiency in the Ca site. The electrical resistivity of this compound at room temperature was very high (>105 Ω cm) in contrast to the metallic and

semiconducting conductivity of $BaPbO_3$ and $SrPbO_3$, respectively.

Partial substitutions of La for alkaline earth elements of perovskite-type $CaPbO_3$ was studied in order to examine carrier-doping effects on the $CaPbO_3$ system. The solubility limit of La^{3+} was found to be about 10% for every alkaline earth element. The temperature dependencies of electrical resistivity and the Seebeck coefficient for the $Ca_{0.9}La_{0.1}PbO_3$ samples indicated that they were metallic conductors. This is in good contrast with the resistivity of $APbO_3$ (where A = Ca, Sr and Ba), which is strongly influenced by the ionic size of A, via the distortion of PbO_6 octahedra. The Seebeck coefficients (in V/K) for the $Ca_{1-x}La_xPbO_{3-\delta}$ ($x = 0$ and 0.1) samples were negative, and absolute values were reduced by the La^{3+} substitution, which implies that electron carriers were introduced into the conduction band. Superconductivity was not observed in these compounds down to 1.8 K, although the carrier density expected, based on the Seebeck coefficient, was comparable to the value for the superconducting $BaPb_{1-x}Bi_xO_3$.

Attempts to form calcium plumbite, $CaPbO_2$, have failed. If $CaCl_2$ (aq) is reacted with Na_2PbO_2 in solution, a precipitate is obtained. But upon separation from solution (by filtration and the like), it rapidly transforms in air to the metaplumbate:

$$2CaPbO_2 \Rightarrow CaPbO_3 + CaO$$

Ca_2PbO_4 has the CAS number of 12013-69-3. Both compounds, Ca_2PbO_4 and $CaPbO_3$, are available commercially.

Strontium Plumbates

The system SrO–PbO_2 has been shown to contain two compounds, $SrPbO_3$ and Sr_2PbO_4. $SrPbO_3$ is an orthorhombic distortion of the perovskite structure. Sr_2PbO_4 is considered in the literature, the type example of a newly described structure type. Precise unit cell and powder data have been presented for these phases. High-temperature diffractometry shows a transition from orthorhombic to tetragonal $SrPbO_3$ at 450 °C. This transition is not reflected in the dielectric constant. IR spectra for the compounds have been described. $SrPbO_3$ is orthorhombic with $a = 5.8595$ Å, $b = 5.9568$ Å, and $c = 8.3253$ Å. The probable space group is Pbnm.

To obtain $\Delta_f H^0$ of $SrPbO_3$ and Sr_2PbO_4, the enthalpies of solution of SrO, PbO_2, $SrPbO_3$, and Sr_2PbO_4 in 6 mol/dm^{-3} HCl were measured by isoperibolic solution calorimetry and the values of $\Delta_f H^0$ for the strontium plumbates were derived from Hess cycles. The values obtained were:

$$\Delta_f H^0_m(SrPbO_3 \text{ at } 298.15 \text{ K}) = -949.3 \pm 3.5 \text{ kJ/mol}$$

$$\Delta_f H^0_m(Sr_2PbO_4 \text{ at } 298.15 \text{ K}) = -1565.1 \pm 6.9 \text{ kJ/mol}$$

Strontium metaplumbate, $SrPbO_3$, samples were obtained by means of high-pressure synthesis and studied by means of the temperature (T) dependences of the resistivity δ and differential thermoelectric power, S. Thus, prepared samples were found to demonstrate a much steeper increase of δ for low T than those synthesized without high-pressure application. Moreover, the δ minimum observed earlier which indicated a proximity to the metal state completely disappeared. The sign of S (T) is positive in the whole T range, contrary to what has been observed earlier. Tunnel measurements were carried out using the in situ break-junction technique, revealing a correlation dielectric gap of 1.5 to 2 eV. The data can be explained if one assumes the existence of both holes (oxygen vacancies) and electrons in this oxide. The high-pressure application during synthesis leads to higher sample disorder, most probably inducing current carrier localization and a Coulomb gap emergence in the quasi-particle spectrum. Electrons do not survive this process, whereas the former minority holes reveal themselves in thermoelectric measurements. Meanwhile, the overall transport behavior loses its semimetallic features, characteristic of more conventionally produced lead oxide ceramics. Our results show how fragile the electron spectrum of this oxide is, being near the metal–semiconductor phase transition boundary.

$SrPbO_{3-\delta}$ is n-type, narrow band gap semiconductor crystallizing in a distorted perovskite structure (similar to that of its calcium homologue). The electrical conductivity varies with temperature but in a nonmonotonic manner. At high temperatures, the thermal evolution of the conductivity follows an Arrhenius-type law with an activation energy of 0.11 eV, which can be attributed to mixed valence states, Pb^{4+}/Pb^{2+}, and leads to a dielectric constant of 13.6. The sign of its thermopower, S, is negative, indicating that the mobile carriers are electrons, which is ascribed to oxygen extraction. The electron hopping occurs between similar electronic localized states in the vicinity of the mobility edge with an electron mobility of $2 \times 10^{-2}/cm^2/V/s$ that is thermally activated. The variation of $S(T)$ suggests a finite density of states at the Fermi level. At low temperatures, the conduction mechanism changes to a variable-range hopping. The weak hybridization of the Pb–O bond, due to the tilting of PbO_6 octahedra, lowers the energy of the antibonding conduction band resulting in a small optical gap E_g. The E_g value was found to be 1.76 eV and the transition is directly allowed; a further indirect transition occurs at 0.79 eV. The flat potential $V_f b$ measured from the Mott–Schottky plot was equal to –0.38 VSCE. The upper valence band edge, located at 6.8 eV below vacuum, is made from mainly the O:2p orbital, whereas the conduction band consists of empty 6s levels.
