The transport properties of oxygen-deficient perovskite $SrPbO_{3-\delta}$ with mixed lead valence were investigated down to 4.2 K. The small δ-value (0.059), determined from iodometry, is due to the inert lone pair of Pb^{2+} that does not enjoy regular octahedral coordination in spite of collective electron behavior. The oxide exhibits a temperature-independent magnetic susceptibility consistent with itinerant electrons. The sign of carriers like polarons is that of *n*-type conductivity coming from the balance charge caused by oxygen extraction. The thermal variation of conductivity and thermopower reveal the existence of an energy gap. The conduction mechanism occurs by polaron hopping in conformity with a small activation energy. The metal-insulating transition seems to be of Anderson type, resulting from the disorder of oxygen vacancies. At low temperature, the conductivity was fitted to a variable hopping range, $\ln(1-p)\ T^{-1}$. A comparison with $SrSnO_{3-\delta}$ was reported. The covalency of the Sn–O bond raises the antibonding conduction state of its 5s parentage and increases the forbidden gap from 1.78 to 3.30 eV.

The subsolidus phase relationships of the PbO–SrO–CaO system in air were investigated at 830 to 835 °C. Complete solid solution exists between Ca_2PbO_4 and Sr_2PbO_4. Compatibility between $SrPbO_3$ and the $(Ca,Sr)_2PbO_4$ solid solution terminates at approximately $(Ca_{0.80}Sr_{0.20})_2PbO_4$. Tie-line relationships between $(Ca,Sr)_2PbO_4$ and PbO, $SrPbO_3$, and the solid solutions (Ca,Sr)O and (Sr,Ca)O were also determined. At 830 to 835 °C, SrO and CaO do not form a complete solid solution. Tie-lines were found to extend from the Ca-rich solid solution (CaO to $Ca_{0.89}Sr_{0.11}O$) to nearly the entire range of $(Ca,Sr)_2PbO_4$. Tie-lines were also found between $(Sr,Ca)_2PbO_4$ (from Sr_2PbO_4 to $Sr_{1.95}Ca_{0.5}PbO_4$) and (Sr,Ca)O (from SrO to $Sr_{0.83}Ca_{0.17}O$). No other ternary oxide phases were found in this system.

A comparative structural study of the tetravalent plumbates, $BaPbO_3$ and $SrPbO_3$, has been carried out by using a NPD technique. Both compounds are an orthorhombic distortion of the perovskite structure, with the lattice parameters related to that of the ideal cubic perovskite (ap) by $a \approx \sqrt{2}ap$, $b \approx \sqrt{2}ap$ and $c \approx \sqrt{2}ap$. The structure of $BaPbO_3$ (Ibmm) consists of the PbO_6 octahedra tilted around the primitive [110]p axis, whereas the tilts of the PbO_6 octahedra in $SrPbO_3$ (Pbnm) are about the [110]p and [001]p axis, respectively. These different tilts, necessary to keep the stable perovskite structure, are discussed and the influence of octahedral distortions on the physical properties of the relevant compounds are considered.

Strontium plumbates, both $SrPbO_3$ and Sr_2PbO_4, are available commercially in small lots.

Barium Plumbates

$BaPbO_3$ was prepared from high-purity powders of $BaCO_3$ and PbO_2 by a conventional solid-state procedure. Temperatures of 500–780 °C were used for the thermal treatment. Subsequent annealing was accomplished within a range of 530–1120 °C. The phase purity of $BaPbO_3$ was monitored by X-ray analysis. The data obtained by a full chemical analysis of samples showed this phase to have a barium deficit, and the composition of the phase was found to be $Ba_{0.80\pm0.03}PbO_{3.10\pm0.02}$. The structure is of rhombic perovskite type having the following unit-cell parameters: $a = 6.024$, $b = 6.065$ and $c = 8.506$ Å. The structure belongs to space group Imma and not to Pbnm ($GdFeO_3$) found for many other orthorhombic perovskite systems.

The structure of $BaPbO_3$ has been refined from powder neutron and synchrotron XRD data at both room temperature and 15 K. At room temperature, the structure is orthorhombic, space group = Imma and $a = 6.0299$ Å, $b = 8.5094$ Å, $c = 6.6094$ Å. On cooling, the structure transforms to a monoclinic form, space group C2/m, $a = 8.5548$ Å, $b = 8.4808$ Å, $c = 6.0118$ Å, $\beta = 134.806°$. $BaPbO_3$, which is a perovskite with a "pseudocubic [orthorhombic] symmetry". It is a true metal (its electrical conductivity at room temperature is 3448/ohm/cm, and at liquid helium temperature, 4.2 K, is 13,514/ohm/cm) with a bilayer metallic bond, so it has properties desirable for the layered composites.

A suggested electronic structure of BaPbO3, according to picture VB, is presented in the following Fig. 5.157.

The bilayer metallic bond in the compound would appear to be the lead $7p_{(y,z)}$ - oxygen $2P_{(y,z)}$ $2p_{(x,y)}$ $P_{(XO)}$ by this analysis. The $d_{(z)}2p_{(z)}$ lobes of the sp3ds octahedral hybrid orbital might be more voluminous and "bulge out" more than the sp-type lobes, thereby lengthening the *z*-axis of the cubic unit cell and making it orthorhombic, as is observed experimentally.

High-resolution X-ray powder diffraction studies have shown $BaPbO_3$ to transform from an orthorhombic Imma structure at room temperature, through an intermediate I4/mcm phase, to a cubic Pm3/m structure above 500 °C. The Imma to I4/mcm transition is first order and the I4/mcm–Pm3/m transition for $BaPbO_3$ is tricritical in nature. No evidence for any phase transitions in $SrPbO_3$ up to 760 °C was found, the structure remaining in Pnma from room temperature to 760 °C.

The preparation, structure and electrical properties of $Ba_{1-x}Sr_xPbO_{3-\delta}$ compounds have been reported. These phases all have orthorhombic perovskite structure whose space group, however, changes at around

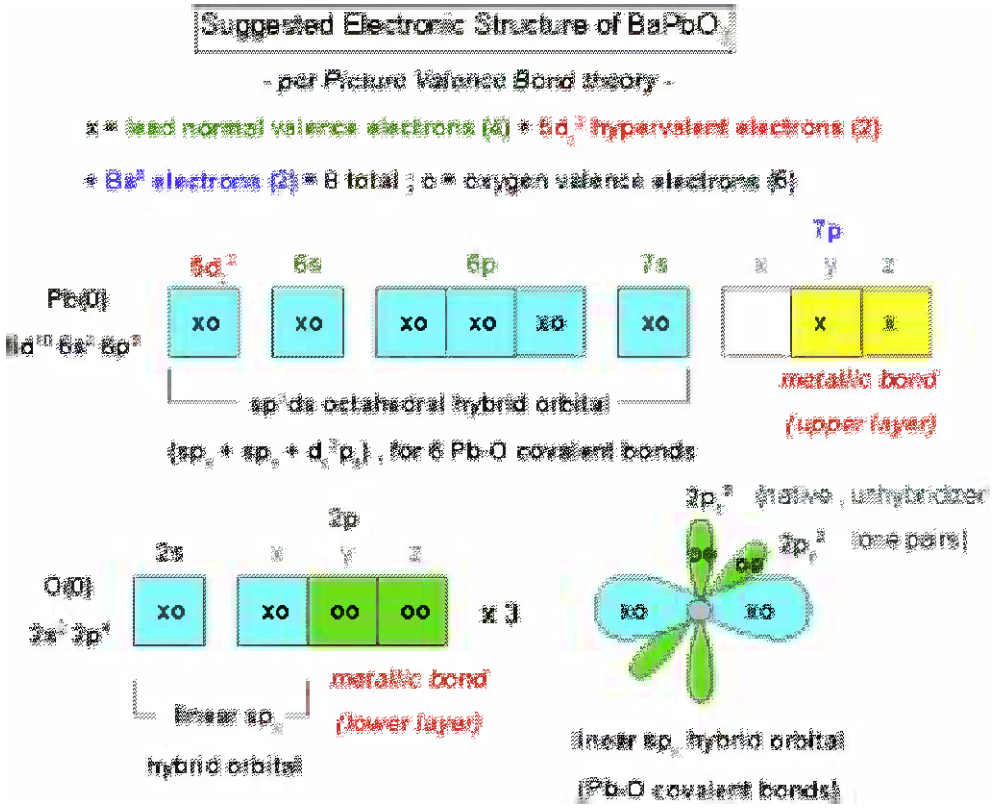

FIGURE 5.157

$x = 0.3$–0.4 from Inma ($BaPbO_3$ side) to Pnma ($SrPbO_3$ side). The transport property also changes from metallic (Inma) to semiconductive (Pnma) at this point. A wide range of oxygen deficiency was realized in this system by changing the synthetic oxygen pressure. With the increase of oxygen deficiency, the metallic conductivity region expanded to the Sr-rich side. The doping of La^{3+} into the A site was also effective to change the system to metallic conductivity.

$BaPbO_3$ ceramics were also fabricated using $BaCO_3$ and PbO powders. Phase transitions and the physical properties of $BaPbO_3$ fabricated with different Pb/Ba mol ratios were studied. The metallic conduction behavior of $BaPbO_3$ can be understood by either the unfilled d-orbital of Pb^{4+} or the substitution of Ba by Pb. However, the model of a unit-cell structure with PbO_2 layers "inserted" between BaO layers together with unfilled d orbital of Pb^{4+} seems to be the more appropriate mechanism. $BaPbO_3$ was also shown to be stable in water, but not so stable in the presence of both water and air (moisture). Increasing the Pb content can improve the resistance of $BaPbO_3$ to moisture.

Phase relations in the ternary system Ba–Pb–O have been studied by equilibrating 18 samples in the ternary in pure oxygen, inert gas or evacuated capsules at 1100 K. Phase identification of quenched samples was performed using optical and electron microscopy, XRD and energy dispersive analysis of X-rays. Three interoxide compounds, Ba_2PbO_4, $Ba_4Pb_3O_{10}$ and $BaPbO_3$ were found to be stable: tie-lines connect each of these compounds with PbO and oxygen gas. Lead is present in a tetravalent state in all the three interoxide compounds. All alloys and intermetallics (Ba_2Pb, Ba_5Pb_3 and BaPb) are in equilibrium with BaO. The oxygen chemical potential corresponding to the three-phase fields:

$$BaO + PbO + Ba_2PbO_4$$

$$PbO + Ba_2PbO_4 + Ba_4Pb_3O_{10}$$

$$PbO + Ba_4Pb_3O_{10} + BaPbO_3$$

These were measured using solid-state cells incorporating $(Y_2O_3)ZrO_2$ as the solid electrolyte in the temperature range 750–1080 K. A special cell design, with a buffer electrode in addition to the normal reference and measuring electrodes, was used to avoid polarization of the three-phase electrode. The standard Gibbs free energies of formation of the three ternary oxides were derived from the e.m.f. of three solid oxide

galvanic cells. The results were cross-checked by measuring the chemical potential of BaO in the three-phase field $PbO + BaPbO_3 + O_2$ (26.2 Pa) and Gibbs energy of formation of $BaPbO_3$ using a cell based on BaF_2 as the electrolyte. The following equations summarize the results:

$$2BaO + PbO + 1/2O_2 \Rightarrow Ba_2PbO_4;\ \Delta G^\circ = -202\,640 + 91.67\,T\ (J/mol)$$

$$4BaO + 3PbO + 3/2O_2 \Rightarrow Ba_4Pb_3O_{10};\ \Delta G^\circ = -556\,835 + 283.12\,T\ (J/mol)$$

$$BaO + PbO + 1/2O_2 \Rightarrow BaPbO_3;\ \Delta G^\circ = -165\,970 + 87.45\,T\ (J/mol)$$

The results obtained in this study differ significantly from data reported in the literature. The earlier investigators incorrectly assumed that BaO exists at unit activity under pure oxygen in the temperature range 700–875 K.

In another study, the phases, $BaPbO_3$ and Ba_2PbO_4, were produced using the sol–gel method, a method based around that described by Fan Wang. Precursors, $Pb(CH_3COO)_2 \cdot 3H_2O$ and $Ba(CH_3COO)_2$ were mixed and dissolved in water in stoichiometric amounts, and maintained at a temperature of 90 °C with stirring. A solution of PVA, a chelating agent, was added to the acetate solution in the ratio Ba: PVA = 0.01 mol:1 g. The resulting solution was heated, with stirring, at a temperature of 90 °C so as to allow partial evaporation of the water. The remaining gel was then dried at a temperature of 400 °C for 60 min before being fired at 500, 600 and 700 °C for 4 h at each temperature (with a heating and cooling rate of 5 °C/min), with intermediate grindings. For Ba_2PbO_4, final phase formation was observed at 1000 °C. For Sc-doped $BaPbO_3$, final phase formation was observed at 900 °C. Phase purity was confirmed by XRD.

Partial substitutions of La for alkaline earth elements of the type, $APbO_{3-\delta}$ (A = Ba, Sr, and Ca) were studied in order to examine carrier-doping effects on the $APbO_{3-\delta}$ system. The solubility limit of La was found to be about 10% for every alkaline earth element. The temperature dependencies of electrical resistivity and the Seebeck coefficient for $A_{0.9}La_{0.1}PbO_{3-\delta}$ samples indicated that they were metallic conductors, irrespective of the ionic size of the alkaline earth elements. This is in good contrast with the resistivity of $APbO_{3-\delta}$, which is strongly influenced by the ionic size of A, via the distortion of PbO_6 octahedra. The Seebeck coefficients for the $A_{1-x}La_xPbO_{3-\delta}$ ($x = 0$ and 0.1) samples were negative, and absolute values were reduced by the La substitution, which implies that electron carriers were introduced into the conduction band. Superconductivity was not observed in these compounds down to 1.8 K, although the carrier density expected, based on the Seebeck coefficient, was comparable to the value for the superconducting $BaPb_{1-x}Bi_xO_3$.

The perovskite-type compound $BaPbO_3$ in the Ba–PbO–O system is of considerable interest in materials science and technology owing to its wide-ranging electronic and chemical applications. To determine the thermodynamic stabilities of this compound and related plumbates, the e.m.f. of the galvanic cells using both oxide and fluoride solid electrolytes and with (a) $BaPbO_3$–$Ba_4Pb_3O_{10}$–PbO, (b) $Ba_4Pb_3O_{10}$–Ba_2PbO_4–PbO and (c) $BaPbO_3$–Pb_3O_4–Pb_3O_4–BaF_2 as the test electrodes have been studied over the temperature ranges 756–968, 797–1097 and 695–880 K, respectively. The least-squares analysis and further processing of the e.m.f data together with the standard Gibbs energies ΔG_f of formation of binary oxides from the literature have yielded the expressions:

$$\Delta G_f\ (BaPbO_3(s)\ (kJ/mol) = -901.56 + 0.26596\,T\ (K)$$

$$\Delta G_f\ (Ba_4Pb_3O_{10}(s)\ (kJ/mol) = -3278.95 + 0.89356\,T\ (K)$$

$$\Delta G_f\ (Ba_2PbO_4(s)\ (kJ/mol) = -1482.10 + 0.37421\,T\ (K)$$

These data together with phase equilibrium studies have been made use of in constructing the Ba–Pb–O phase diagram at 800 K.

The perovskite-type compound $BaPbO_3$ in the Ba–Pb–O system is of considerable interest in materials science and technology owing to its wide-ranging electronic and chemical applications. Barium plumbates have been studied extensively in recent years because of such interesting properties. $BaPbO_3$ is known to exhibit room temperature metallic conductivity, due to an overlap (~2 eV) of the O-2p nonbonding band with the (Pb-O)-sp antibonding band at the Fermi level. Another phase in the Ba–Pb–O system, Ba_2PbO_4, is known to adopt the K_2NiF_4 structure and behaves as a large-gap semiconductor (valence bands are separated by a ~1.7 eV semiconductor gap). The structures are shown in Fig. 5.158.

$BaPbO_3$ has a distorted perovskite structure, deviating from the normal cubic perovskite; it is an orthorhombic distortion of the perovskite structure with the space group Imma. This is only one of the possible structures that can result from a perovskite. The type of distortion seen is related to the radii of the cations and anions involved and while the 12-coordination of A is easily distorted, the 6 coordination octahedra is harder to distort. $BaPbO_3$ possesses lattice parameters related to that of the ideal cubic perovskite structure by $a \propto 2ap$, $b \propto 2ap$, $c \propto 2ap$ where ap is the lattice parameter of the ideal perovskite. The structure of $BaPbO_3$ consists of the PbO_6 octahedra tilted around the primitive [110]p axis. It is noted that the octahedra tilt differently when replacing the A site with Sr or Ca.

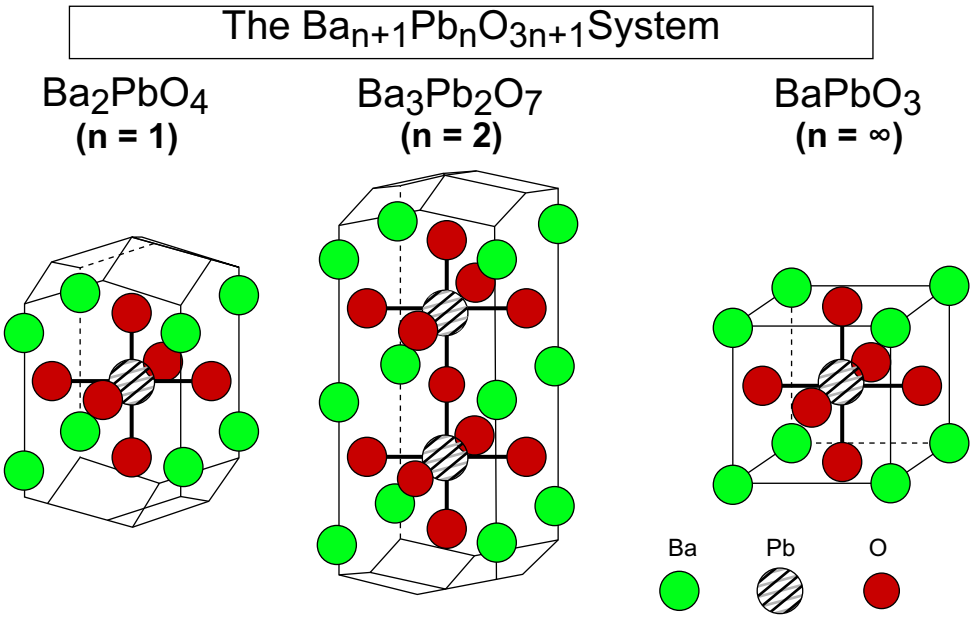

FIGURE 5.158

It is widely recognized that barium plumbate's room temperature metallic conductivity may be attributed to the overlap of the Pb-6s and O-2p orbitals at the Fermi level. Band structure calculations have shown the presence of such a strongly hybridized band at the Fermi level involving the energetic overlap of the previously mentioned orbitals. This broadband is only partially occupied by the available electrons and therefore metallic conductivity can occur. Thus, $BaPbO_3$ is not really a normal valence compound like its ionic insulating neighbor $BaSnO_3$, where such cation-oxygen hybridization apparently does not occur. The results of such a band structure calculation is shown in Fig. 5.159.

The overlap of the valence and conduction bands is clearly evident.

Unlike $BaPbO_3$ (which is a metallic conductor at room temperature), even though the valence state (4+) and coordination geometry around the Pb atom are the same (PbO_6 octahedra), the K_2NiF_4-type (tetragonal) Ba_2PbO_4 compound is a semiconductor with a band gap of ~1.7 eV. Band structure calculations have shown that a shortened axial Pb–O distance which induces sp interactions between Pb-6s and O-2p orbitals is instrumental in opening the band gap. $Ba_2Pb_{1-x}Bi_xO_{4-y}F_y$ compositions have been produced, aimed at modifying the coordination geometry around Pb in an attempt to induce metallic and/or superconducting properties in the system by possibly modifying the Pb–O/F orbital overlaps. However, the results were disappointing.

A new type of barrier layer capacitor was described utilizing thin glass layers on highly conducting ceramics of barium plumbate and barium bismuth plumbate. Barium metaplumbate ($BaPbO_3$) thin films were prepared using a chemical solution method. Films with different thicknesses, ranging from 100 nm to 1 μm, were deposited by a spin coating technique. After drying at 300 °C and firing between 600 and 700 °C in air, a room-temperature resistivity about 1 mΩ-cm was obtained, which is comparable to that of the ceramic bulk resistivity. The chemical reaction sequence during

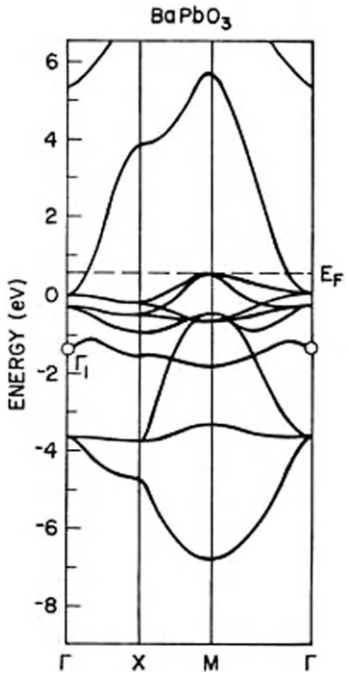

FIGURE 5.159

heating was investigated using XRD and thermal analysis. It was found that several reactions were involved in the temperature range from 200 to 600 °C. The crystallized films tended to decompose upon subsequent depositions, which resulted in the loss of conductivity of the films. However, the conductivity could be recovered by firing at higher temperatures than 600 °C. In addition, a thickness threshold about 1200 Å was observed to be required below which the resistivity of the films increased rapidly.

Barium plumbates are available commercially in small to medium-sized lots.

Radium Plumbates

The scientific literature is devoid of any description of radium plumbates. They could be prepared by the same methods as those used for barium but there is no record of anyone having done so. The expected, stable, compounds would be $RaPbO_3$ and Ra_2PbO_4. In addition, since barium forms a stable $Ba_3Pb_2O_{10}$ compound, there is a strong possibility that radium should also do so.

Perhaps the lack of any description of such salts can be ascribed to the intense radioactivity of the ^{226}Ra atom and the dangers of handling it improperly. Nonetheless, the chemistry of other radioactive cations have been reported so that this explanation does not seem valid. Little interest has been shown in industry or academia for radium plumbates and the corresponding alkaline earth plumbates are much cheaper and easier to handle than the radium salts.

6.1. GROUP 13 ACIDS AND BASES

A number of acids and bases of the Group 13 elements are known.

6.1.1. Boron, Boron Acids and Borates

Boron was not recognized as an element until it was isolated by Sir Humphrey Davy, Joseph Gay-Lussac and Louis Thénard in 1808 through the reaction of boric acid and potassium. Davy called the element boracium. Jöns Jacob Berzelius identified boron as an element in 1824. The first pure boron was arguably produced by the American chemist W. Weintraub in 1909. The alkaline earths form a number of compounds with boron, including borates as well as borides.

Boric acid, also called boracic acid or orthoboric acid or acidum boricum, is a weak acid often used as an antiseptic, insecticide, flame retardant, in nuclear power plants to control the fission rate of uranium, and as a precursor of other chemical compounds. It exists in the form of colorless crystals or as a white powder and is soluble in water. It has the chemical formula H_3BO_3, sometimes written $B(OH)_3$. As a mineral, it is called "sassolite".

Boric acid was first prepared by William Homberg (1652–1715) from borax, by the action of mineral acids, and was given the name "Sal Sedativum Hombergi" (sedative salt of Homberg). The presence of boric acid or its salts has been noted in seawater. It is also said to exist in plants and especially in almost all fruits. The free acid is found native in certain volcanic districts such as Tuscany, the Lipari Islands and Nevada, issuing mixed with steam from fissures in the ground. It is also found as a constituent of many minerals such as "borax", "boracite", "boronatrocaicite" and "colemanite".

Boric acid is soluble in boiling water. Its solubility in water is shown in Table 6.1:

Boric acid does not dissociate in aqueous solution, but is acidic due to its interaction with water molecules to form the tetrahydroxyborate ion:

$$B(OH)_3 + H_2O \Rightarrow B(OH)_4^- + H^+$$
$$(K_a = 5.8 \times 10^{-10}\ \text{mol/l};\ pK_a = 9.24)$$

Polyborate anions are formed at pH 7–10 if the boron concentration is higher than about 0.025 mol/l. The best known of these is the **tetraborate** ion, found in the mineral borax:

$$4B(OH)_4^- + 2H^+ \Rightarrow B_4O_7^{2-} + 9H_2O$$

Boric acid makes an important contribution to the absorption of low-frequency sound in seawater.

Colloidal suspensions of nanoparticles of boric acid dissolved in petroleum or vegetable oil can form a remarkable lubricant on ceramic or metal surfaces with a coefficient of sliding friction that decreases with increasing pressure to a value ranging from 0.1 to 0.02.

The primary industrial use of boric acid is in the manufacture of monofilament fiberglass usually referred to as "textile fiberglass". Textile fiberglass is used to reinforce plastics in applications that range from boats, to industrial piping to computer circuit boards.

Boric acid is used in nuclear power plants to slow-down the rate at which fission is occurring. Fission chain reactions are generally driven by the amount of neutrons present (as products from previous fissions). Natural boron is 20% boron-10 and about 80% boron-11. Boron-10 has a high cross-section for absorption of

TABLE 6.1

		G/100 ml of water								
Substance	**Formula**	**0 °C**	**10 °C**	**20 °C**	**30 °C**	**40 °C**	**50 °C**	**60 °C**	**80 °C**	**100 °C**

low-energy (thermal) neutrons. By adding more boric acid to the reactor coolant which circulates through the reactor, the probability that a neutron can survive to cause fission is reduced. Therefore, boric acid concentration changes effectively regulate the rate of fissions taking place in the reactor. Boron is also dissolved into the spent fuel pools containing used uranium rods. The concentration is high enough to keep neutron multiplication at a minimum.

In the jewelry industry, boric acid is often used in combination with denatured alcohol to reduce surface oxidation and fire scale from forming on metals during annealing and soldering operations.

Boric acid is used in producing the glass faceplates of LCD flat panel displays.

In electroplating, boric acid is used as part of some proprietary formulas. It is also used in the manufacturing of "remming mass", a fine silica-containing powder used for producing induction furnace linings.

Borates including boric acid have been used since the time of the Greeks for cleaning, preserving food, and other activities. It is used in pyrotechnics to prevent the amide-forming reaction between aluminum and nitrates. A small amount of boric acid is added to the composition to neutralize alkaline amides that can react with the aluminum.

Boric acid dissolved in methane is popularly used among fire jugglers and fire spinners to create a deep green flame. Boric acid is added to salt in the curing of cattle hides, calfskins and sheepskins. Used in that way it helps to control bacteria development and also aids in the control of insects.

The alkaline earths form various types of borates as well as "borides". These include:

Metaborates—BO_2^-

Orthoborates—BO_3^{3-}

Pyroborates—$B_2O_5^{4-}$

Perborates—$B_2O_6^{6-}$

Diborates—$B_2O_5^{4-}$

Triborates—$B_3O_7^{5-}$

Tetraborates—$B_4O_9^{6-}$

The last three are examples of polymeric boron species. It should be recognized that species like "borites" do not exist (in deference to phosphorous species).

6.1.2. Aluminates

Aluminum forms intermetallic compounds known as aluminides. It does not form any acids. It is polymeric. Alumina exists as the phases, γ, δ, η, θ and χ. Each has a unique crystal structure and properties. The so-called β-alumina proved to be $NaAl_{11}O_{17}$. Since Al_2O_3 is amphoteric, it dissolves in a strong basic solution:

$$2NaOH + Al_2O_3 \Rightarrow Na_2Al_2O_4 + H_2O$$

This formula is also given as $NaAlO_2$ but the more exact one is $\{NaAlO_2\}_2$. The alkaline earths thus form aluminates as MAl_2O_4. There are other types of soluble "aluminates" such as discrete AlO_4^{5-} anions, or $Al_3O_8^{7-}$ and $Al_5O_{16}^{17-}$which contain complex polymeric anions. Whether a specific combination appears will depend upon the size and electropositivity of the alkaline earth.

6.1.3. Gallates

Gallium is found primarily in the +3 valence state. The +1 oxidation is also attested in some compounds, although they are known to disproportionate into elemental gallium and gallium(III) compounds. What are sometimes referred to as gallium(II) compounds are actually mixed-oxidation state compounds containing both gallium(I) and gallium(III). Gallium is amphoteric:

- β-Ga_2O_3 is prepared by heating nitrate, acetate, oxalate or other organic derivatives above 1000 °C.
- α-Ga_2O_3 can be obtained by heating β-Ga_2O_3 at 65 kbars and 1100 °C for 1 h giving a crystalline structure. The hydrated form can be prepared by decomposing precipitated and "aged" gallium hydroxide at 500 °C.
- γ-Ga_2O_3 is prepared by rapidly heating the hydroxide gel at 400–500 °C.
- δ-Ga_2O_3 is obtained by heating $Ga(NO_3)_3$ at 250 °C.
- ε-Ga_2O_3 is prepared by briefly heating δ-Ga_2O_3 at 550 °C for 30 min.

Strong acids dissolve gallium metal, forming gallium(III) salts such as $Ga_2(SO_4)_3$ and $Ga(NO_3)_3$. Aqueous solutions of gallium(III) salts contain the hydrated gallium ion, $[Ga(H_2O)_6]^{3+}$. $Ga(OH)_3$ may be precipitated from gallium(III) solutions by adding NH_4OH. Dehydrating $Ga(OH)_3$ at 100 °C produces gallium oxide hydroxide, GaO(OH).

Alkaline hydroxides such as NaOH solutions dissolve gallium, forming gallate salts containing the $Ga(OH)_4^-$ anion. Amphoteric gallium hydroxide also dissolves in alkali solutions to form alkaline earth gallate salts. Although earlier work had suggested $Ga(OH)_6^{3-}$ as a possible anion, later work has discredited this finding.

6.1.4. Indates

Indium is also amphoteric but less so than its homologues, Al^{3+} and Ga^{3+}. The oxide dissolves in NaOH to form the indate, $Na_2In_2O_4$, like its Al- or Ga-homologue.

There are no known acids containing the indate anion, $In_2O_4^{2-}$. Although indium is listed to possess a monovalent cationic state, In^+, it has been found that this valence state is unstable and it decomposes to In^0 and In^{3+}. Thus, no "indous" or "indite" compounds are known.

6.1.5. Thallates

The two main oxidation states of thallium are +1 and +3. In the oxidation state +1, most compounds closely resemble the K^+ compounds (the ionic radius of thallium(I) is 1.47 Å while that of potassium is 1.33 Å). For example, the water-soluble and very basic TlOH reacts with CO_2 forming water-soluble thallium carbonate, Tl_2CO_3. This carbonate is the only known water-soluble heavy metal carbonate.

The amphoteric nature of thallium oxide has been demonstrated. However, the reaction in solution does not follow the same rules as those for Al_2O_3 or Ga_2O_3. At 25 °C, it was established that the components, Na_2O, H_2O and Tl_2O_3, only react in systems containing thallium(I) and sodium hydroxides. They form with thallium(I) orthothallate with restricted solid solutions between thallium oxide and the orthothallate based on thallium oxide and sodium hydroxythallate $Na_3Tl(OH)_6$.

At elevated temperatures of 150 and 200 °C, it was established that potassium metathallate is formed in the K_2O–Tl_2O_3–H_2O system while sodium metathallate $Na_2Tl_2O_4$ and a hydrated thallate of the composition $4Na_2O{\cdot}Tl_2O_3{\cdot}(3–4)H_2O$ are formed in the Na_2O–Tl_2O_3–H_2O system at 150 °C. The thallates, Tl_3TlO_3, $Na_3Tl(OH)_6$, $Na_2Tl_2O_4$ and $K_2Tl_2O_4$ have been isolated in pure forms and identified by X-ray analysis.

6.2. ALKALINE EARTH BORON COMPOUNDS

In addition to forming borates, boron also forms borides with the alkaline earths.

6.2.1. Alkaline Earth Borides

Beryllium Boride

Beryllium forms a number of borides among which is BeB_2. This compound is copper-red in color and has a cubic fluorite structure with $a = 4.661$ Å. BeB_2 is readily hydrolyzed by dilute acids to produce beryllium hydrides. BeB_2 has the CAS number of 12429-94-6 and a molecular weight of 73.878 g/mol. This red solid melts at >1970 °C. The other beryllium borides are insoluble in acids. They do not melt below 1500 °C. Hydrochloric acid, when reacted with beryllium boride, was found to give higher yields of tetraborane (B_4H_{10}) than the corresponding reaction with magnesium boride.

There are four stable compounds in the Be–B system: Be_4Be, Be_2B, BeB_2 and BeB_6. They are prepared by heating the elements together at about 1400 °C. The BeB_6 compound has a salt structure in which the B_6^{2-} octahedra occupy the Cl^- sites and the Be^{2+} cations are on the Na^+ sites. Each octahedron is linked to six neighboring octahedra at a distance of 1.72 Å, which is also the interatomic distance within each octahedron.

Be_4B is a refractory solid with a melting point of 1160 °C, a molecular weight of 40.8601 g/mol, and a CAS number of 12536-52-6. At atmospheric pressure, Be_4B has a tetragonal structure with a space group of P4/nmm. It undergoes a polymorphic transformation to a rhombohedral structure at >50 GPa, but details of the lattice parameters have not been documented.

The following lists are some physical characteristics of these beryllium borides (Table 6.2).

Be_2B is a pink crystal with a melting point of 1560 °C, a molecular weight of 28.8351 g/mol, and a CAS number of 12536-51-5.

BeB_2 is a refractory copper-red solid with a melting point >1970 °C, a molecular weight of 30.3641 g/mol, and a CAS number of 12228-40-9.

BeB_6 is a red solid with a melting point >2070 °C, a molecular weight of 73.8782 g/mol, and a CAS number of 12429-94-6.

Though beryllium diboride has been known and studied for more than 40 years, there has been no firm evidence that this phase exists with stoichiometry

TABLE 6.2

Compound	Density	Structure	Melting temperature,°C	Hardness
Be_4B	1.94 g/cc	Tetragonal	1160 °C	1370 (HK_{100})
Be_2B	1.89	Cubic	1504	1300
BeB_2	2.42	Hexagonal	>1970	3180
BeB_3	2.35	Tetragonal	2020	2580
BeB_6	2.42	Hexagonal	—	—

BeB_2. The space group of a compound reported to be BeB_2 was hexagonal P6/mmm with lattice constants $a = 5.0979$ Å and $c = 5.0955$ Å, but a full structure determination was not carried out.

The actual composition of BeB_2 has been reported to be $Be_{29.5}B_{81}$. The space group of the unit cell is P-62m. In the unit cell, there are 12 inequivalent B sites and seven inequivalent Be sites, one of the latter being only half occupied. The refined structure produced a stoichiometry of $Be_{1.23}B_{3.38}$, i.e. $BeB_{2.75}$ with $a = 5.097738$ Å and $c = 5.095467$ Å. The structure has 81 B atoms and 29.5 Be atoms per unit cell. $BeB_{2.75}$ is a superconductor with a $T_c(^{10.8}B)$ of 0.72 K and that the ^{10}B sample has a slightly enhanced $T_c(^{10.0}B)$ of 0.79 K. This result can be explained in terms of "nanostructures". Small $(BeB_2)_n$ clusters ($n = 1$–6 and 8) as well as BeB_2 nanotubes and cages $(BeB_2)_n$, with $n = 10$, 12, 15, 18, and up to 30, have been studied using density functional theory. These nanostructures strongly resemble the ones formed by carbon, with ring-like geometries for very small clusters and closed cages for medium-sized clusters. The energetics for distortion and closure of planar sheets into cages and nanotubes prove favorable in comparison with carbon systems (Fig. 6.1).

However, by the time that the B atoms reach 80 (2×40) in the structure, the number of Be ions has shrunk to about 30 because of overlap of the wave functions.

Diberyllium boride, Be_2B, was prepared, and its crystal structure was studied. The structure of Be_8Be_5 was considered to be a compromise between a tendency for Be to adopt the fluorite arrangement and the tendency for B to form some sort of network containing B–B bonds. Be_8B_5 in contrast to Be_8B_4 had almost an identical number of valence electrons per unit cell as Be_8C_4. Thus, this series of compounds are subject to the same restraints as BeB_2 in that the actual compounds formed have the general formula, $(Be_2B)_n$, where n can vary from 2 to 10 (but the Be/B ratio does not remain at 2/1 at the higher numbers of n, i.e. $Be/B \leq 2/1$).

Both Be_2B and Be_4B have been of interest in the formation of light-weight armor. In general, the material selection should be a balance between low density, high incompressibility (high yield strength and impedance), and ability to dissipate tensile stresses without fracturing (ductility). Several ceramics (B_4C, $A1_2O_3$, B itself, etc.) possess the first two qualities, i.e. low density and high incompressibility, but ductility has been observed in only a few low-density ceramics (BeC, Be_2B,Be_4B, and MgO), even under high hydrostatic pressures. Exposure to moisture during handling and storage had little or no adverse effect on the Be_4B or Be_2B powders. Be_4B and Be_2B decompose below their melting points, 1165 and 1370 °C, respectively. The low-melting point of the Be_4B suggests the possibility of preparing a two-phase (~30 vol% Be_4B–Be_2B) armor material by casting. A method of casting lightweight armor material of Be_4B dispersed in a Be matrix was developed. This comprised the melting of a mixture of Be_4B and Be powder, cooling to induce a temperature gradient in the molten material, and recovering the solidified cermet. A phase diagram comprising these three compounds was prepared as a guide to forming lightweight armor by liquid casting (Fig. 6.2).

The phase equilibria of B from 70% to 100% are not shown here. Only BeB_2 melts congruently and Be_2B was determined to exist only above 950 °C and decomposes to BeB_2 and Be_4B below that temperature:

$$7Be_2B \Rightarrow 2BeB_2 + 3Be_4B$$

In order to obtain a compound stable at room temperature, the mixture was heated, $1400\,°C > T > 950\,°C$, and then rapidly quenched. Because of the toxicity of Be, the armor fittings are not used today, particularly with the advent of Kelvar™ body armor for use in military and police work.

Beryllium borides are available in limited quantities worldwide.

Magnesium Boride

Magnesium boride can be formed directly from the elements. Mg melts at 650 °C and boron melts at 2076 °C. Therefore, if a vapor of Mg metal at >750 °C (red-heat) is passed over crystals of boron, reaction forms the desired boride. However, to obtain a stoichiometric compositions, it is better to heat the well-mixed powders of Mg and B to obtain specific compounds:

$$Mg + 2B \Rightarrow MgB_2$$

Magnesium diboride (MgB_2) is a simple ionic binary compound that has proven to be an inexpensive and useful superconducting material. Its superconductivity was announced in March 2001 with a critical temperature of 39 K (−234 °C). This is the highest T_C found among conventional superconductors. This material was first synthesized and its structure confirmed in 1953, but its superconducting properties were not discovered until 2001. The discovery caused great

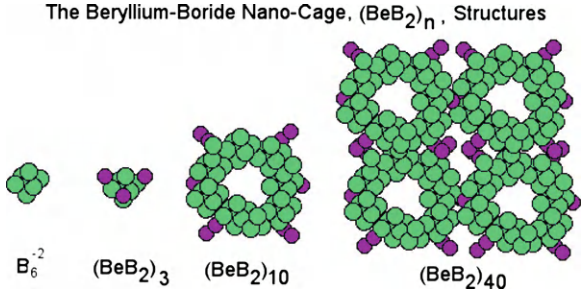

FIGURE 6.1

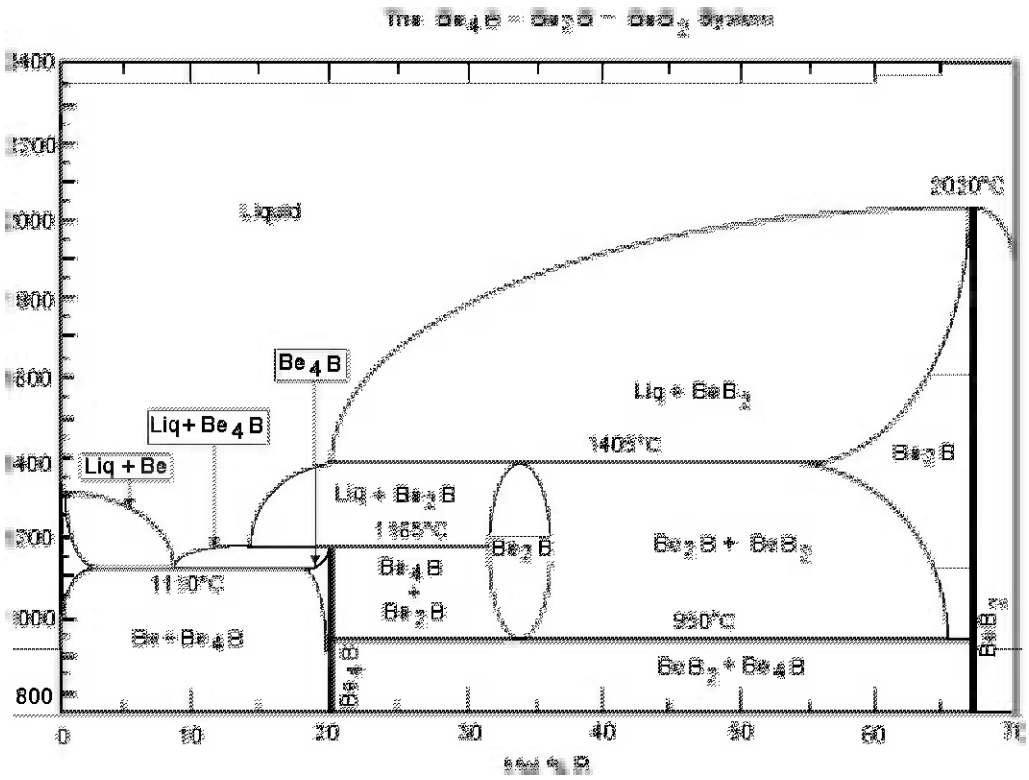

FIGURE 6.2

excitement. A large number of papers appeared in the scientific literature concerned with the physical and chemical properties of MgB_2 and its homologues. Its molecular weight is 45.9325 g/mol. It melts at 830 °C and is hexagonal with space group P6/mmm and lattice constants of $a = 3.0864$ Å, $c = 3.5215$ Å. The density is 2.625 g/cm^3 and the hardness is 1260 kg/mm^2. MgB_2 has the CAS number of 12007-25-9.

MgB_2 is a layered hexagonal crystal as shown in the following diagram. In this diagram, both Mg and B atoms are in a hexagonal coordination within the structure (Fig. 6.3).

The compounds of magnesium boride, such as the diboride MgB_2, are very promising materials for superconductivity applications. They represent a new class of low-cost and high-performance superconductors that are not oxides or fullerenes, but are characterized by relatively high Curie temperature. In addition to MgB_2, that has a honeycomb structure very similar to graphite, other thermodynamically stable borides such as MgB_4, MgB_7, MgB_{12} and MgB_{20} have been observed.

If Mg metal is heated with boric acid under a reducing (hydrogen) atmosphere, the product is:

$$Mg + 2H_3BO_3 + (\text{Heat} + H_2) \Rightarrow MgB_2 + 3H_2O$$

This compound appears even if the ratio of Mg/B approximates 3:2 (which is the stoichiometric composition expected between these two elements). In the Mg–B system, four boride phases were established in 1952: MgB_2, MgB_4, MgB_6 and MgB_{12}. More recent work found that the stable phases were MgB_2, MgB_4, and MgB_7. The diboride is hexagonal while the

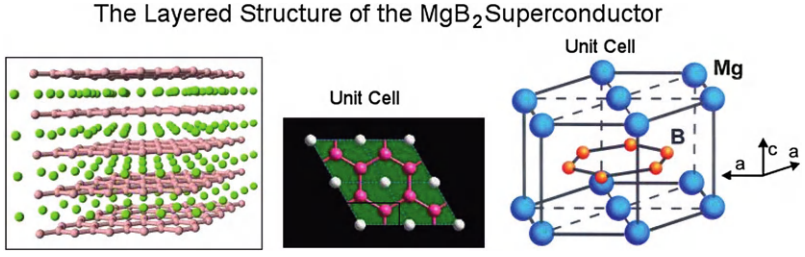

FIGURE 6.3

tetraboride is orthorhombic. At 800 °C, MgB_2 decomposes to the tetraboride:

$$2MgB_2 + \text{heat } (>800\ ^\circ C) \Rightarrow MgB_4 + Mg\ (gas)$$

$$3MgB_2 + \text{heat } (>1000\ ^\circ C) \Rightarrow MgB_6 + 2Mg\ (gas)$$

The vaporization behavior of MgB_2 and MgB_4 under thermodynamic conditions has been studied by the Knudsen effusion mass spectrometry technique. In the temperature range explored (883–1154 K or 610–887 °C), magnesium borides are observed to decompose by loss of gaseous Mg only. Above 1200 °C, both MgB_4 and MgB_6 decompose to form the decaboride:

$$3MgB_4 + \text{heat } (>1200\ ^\circ C) \Rightarrow MgB_{12} + 2Mg\ (gas)$$

$$2MgB_6 + \text{heat } (>1200\ ^\circ C) \Rightarrow MgB_{12} + Mg\ (gas)$$

At higher temperatures (>1700 °C), MgB_{12} decomposes to form gaseous Mg and B vapors which condense on a cool surface. A "normal" phase diagram cannot be presented as such since all of these magnesium borides decompose incongruently with a gas, Mg vapor, as the product. The temperature of decomposition of MgB_2 can be delayed up to >1500 °C by the application of an external, inert, atmosphere. The following diagram shows a type of phase diagram depicting this kind of behavior (Fig. 6.4).

The decomposition temperature of MgB_2 is dependant upon the external pressure present, whether it is air or an inert gas pressure. It is Mg metal gas that forms and the gaseous phase is retarded at higher external pressures.

The effect of external pressure on the formation of the various magnesium boride compositions is shown in Fig. 6.5.

It should be clear that the "melting temperatures" of these phases are dependant upon the external pressures used to formulate them. It is the volatility of Mg as the vapor which controls the apparent melting temperatures observed. This phenomenon appears to be the dominant

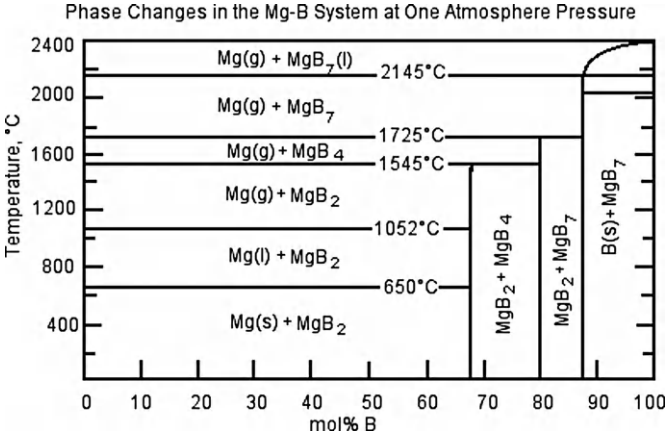

FIGURE 6.4

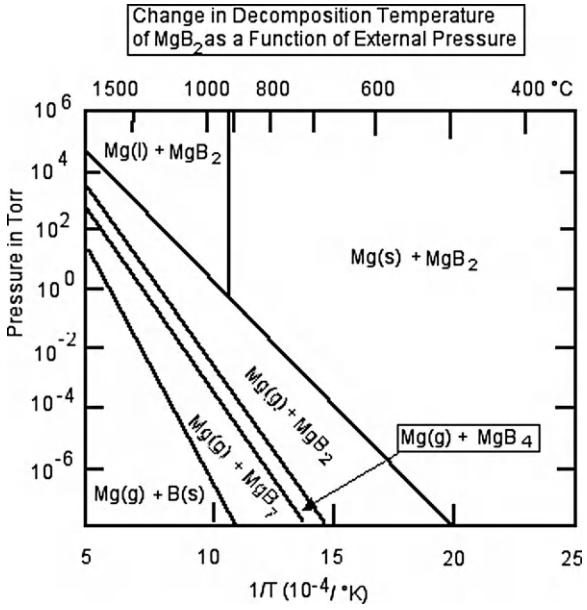

FIGURE 6.5

factor in the formation of all of the alkaline earths, but more so for magnesium borides.

A novel complex magnesium boride, Mg_2B_{25}, has been prepared and its crystal structure determined from laboratory X-ray powder diffraction data. It is an R-centered trigonal lattice (with $a = 11.0402$ Å, $c = 24.198$ Å, hexagonal setting), space group R-3m, which is isomorphous with β-boron and with the rhombohedral compounds of the boron-rich metal boride family. The magnesium atoms occupy interstitial sites with partial occupancies. The Mg atom in one site is vicariant with the B(4) atom and lies in a pseudo-metallic environmental site surrounded by the 10 nearest-neighbor B atoms. All other magnesium atoms are found in lattice cavities within the corrugated slabs normal to c, with Mg occupying two sites in the lattice that are similar to those populated in other metal borides. In addition, Mg also exists in a new type of site that has a different type of coordination not seen in other metal borides. Thus, a total of four interstitial sites of Mg exist. These slabs present two equiprobable, but self-excluding, configurations of ordered Mg atoms, which randomly stack along the *c*-axis. Mg_2B_{25} shows a significant increase in the *c*-axis of the rhombohedral lattice with respect to the other members of the family. This was attributed to both to the larger metallic radius and the anisotropic stacking of the Mg atoms, caused by the presence of the over-stuffed Mg sublattices.

MgB_2 reacts vigorously with acids, forming boron hydrides (like B_4H_{10}) and MgB_2 remains the chief source for preparing such compounds:

$$5MgB_2\ (s) + 14HCl\ (aq) \Rightarrow B_{10}H_{14}\ (\text{solid}) + 5MgCl_2\ (aq) + 2Cl_2\ (gas)$$

This borane is the final product of hydrolysis since diborane, tetraborane, are gases which are explosive in water and/or air and pentaborane and decaborane are liquids which are unstable in water and form explosive mixtures in air. Dodecaborane, $B_{12}H_{16}$, is also another possible product. The higher magnesium borides like the tetraboride are more stable and their hydrolysis is not accompanied by formation of boranes.

Magnesium aluminum boride ($MgAlB_{14}$), also known as BAM, is a ceramic alloy that is highly resistive to wear with a low coefficient of sliding friction. First reported in 1970, it has an orthorhombic structure with four icosahedral B12 units per unit cell. This ultra-hard material is also characterized by its high hardness and coefficient of thermal expansion comparable to other widely used materials. BAM alone is among the hardest nondiamond materials.

Magnesium diboride is available commercially worldwide.

Calcium Boride

Calcium boride can be formed directly from the elements. Ca melts at 842 °C and boron melts at 2076 °C. Therefore, if a vapor of Ca metal at >850 °C (red-heat) is passed over crystals of boron, a gas–solid reaction forms the desired boride. However, to obtain stoichiometric compositions, it is better to heat the well-mixed powders of Ca and B to obtain specific compounds:

$$Ca + 6B \Rightarrow CaB_6$$

The phase system of calcium and boron compounds is shown in the diagram as follows. Only one compound is known, CaB_6, which melts at 3162 °C (Fig. 6.6).

The intermediate fields in this diagram consist of various crystal states of Ca plus CaB_6. On the boron side, β-B changes to α-B at 2075 °C.

Other methods used to prepare calcium hexaboride **commercially** include high-temperature reactions of:

Reaction of calcium and boron at 1000 °C.
$Ca(OH)_2$ and boron in vacuum at about 1700 °C.
$CaCO_3$ and boron as B_4C in vacuum above 1600 °C.
Boron with calcium or calcium oxide (CaO) at 800–1800 °C.
CaO and H_3BO_3 and Mg at 1100 °C.

Calcium hexaboride (sometimes calcium boride) is a compound of calcium and boron with the chemical formula CaB_6.

Typical samples of CaB_6 are nonstoichiometric, i.e. the ratio of boron to calcium is not exactly 6:1, for example the ultra-fine powders of CaB_6 produced by some researchers had B:Ca ratio of 5.91:1. It is an important material due to its high electrical conductivity, hardness, chemical stability, and melting point. It is a black, lustrous, chemically inert powder with a low density. Calcium hexaboride is insoluble in H_2O, MeOH (methanol), and EtOH (ethanol) and dissolves slowly in acids. It has the cubic structure typical for metal hexaborides, with octahedral units of six boron atoms combined with calcium atoms. Lanthanum-doped CaB_6 show weak ferromagnetic properties, which is a remarkable fact because calcium and boron are neither magnetic, nor have inner 3d or 4f electronic shells, which are usually required for ferromagnetism. This structure is shown in the Fig. 6.7.

The crystal structure of calcium hexaboride is a cubic lattice with calcium at the cell centers and compact,

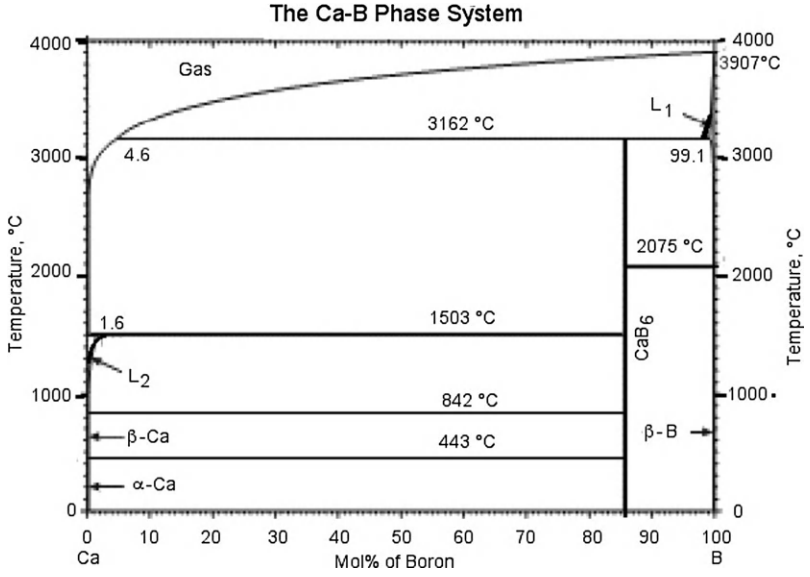

FIGURE 6.6

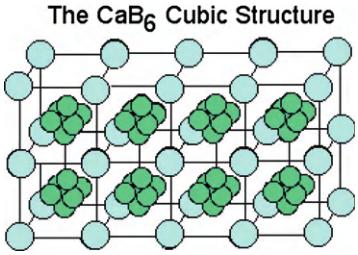

FIGURE 6.7

regular octahedrons of boron atoms linked at the vertices by B–B bonds to give a three-dimensional boron network.

The above diagram does not show this so that the relation of Ca^{2+} and B_6^{2-} ions could be shown simply. The B_6 ions should be linked three dimensionally. Each calcium has 24 nearest-neighbor boron atoms. The calcium atoms are arranged in simple cubic packing so that there are holes between groups of eight calcium atoms situated at the vertices of a cube. The simple cubic structure is expanded by the introduction of the octahedral B_6 groups and the structure is a CsCl-like packing of the calcium and hexaboride groups. Another way of describing calcium hexaboride is that a metal and a B_6^{2-} octahedral polymeric anions occupy a CsCl-type structure where the calcium atoms occupy the Cs sites and the B_6 octahedra in the Cl sites. The Ca–B bond length is 3.05 Å and the B–B bond length is 1.7 Å. The predicted lattice constant varies between 4.08 and 4.105 Å while it has been experimentally measured from 4.145 to 4.153 Å. The space group is P"m$\overline{3}$ m" and the point group is O_h. It is a semiconductor with an energy gap of 0.48 eV and a band gap of about 1.0 eV.

^{43}Ca NMR data contains a δ_{peak} at −56.0 ppm and δ_{iso} at −41.3 ppm where δ_{iso} is taken as peak max of +0.85 bandwidth and the negative shift is due to the high-coordination number.

Calcium hexaboride has three Raman peaks at 754.3, 1121.8, and 1246.9/cm due to the active modes A_{1g}, E_g, and T_{2g}, respectively.

Observed infrared vibration frequencies (in cm^{-1}) include: 1270 (strong) from A_{1g} stretch, 1154 (medium) and 1125 (shoulder) from E_g stretch, 526, 520, 485, and 470 from F_{1g} rotation, 775 (strong) and 762 (shoulder) from F_{2g} bend, 1125 (strong) and 1095 (weak) from F_{1u} bend, 330 and 250 from F_{1u} translation, and 880 (medium) and 779 from F_{2u} bend.

The microhardness is 27 GPa, $\Delta H_f = -120$ kJ/mol, and the resistivity is greater than 200 Ωm × 10^8. The magnetic moment is less than or equal to 0.07 μB per atom. The Curie temperature is ~600 K.

The ferromagnetic transition temperature of calcium hexaboride is around 900 K which is high for a molecule without partially filled d- or f-shell orbitals. It is a semiconductor with an energy gap of 0.48 eV and a band gap of about 1.0 eV. Ferromagnetic order (FM) have been observed at unexpectedly high temperatures in La-doped alkaline earth hexaboride compounds including calcium hexaboride. The origin of this high-temperature FM is the FM phase of a dilute electron gas, linkage to the presumed excitonic state in calcium boride, or external impurities on the surface of the sample. In fact, the impurities include iron and nickel probably coming from boron in sample preparation.

Hexaborides in general show a low work function, around 2.5 eV. They are also resistant to poisoning. Calcium hexaboride, as well as SrB_6 and BaB_6, has been used in this capacity. Boride cathodes are about 10 times as "bright" as the tungsten ones and have 10–15 times longer lifetime. For example, they are used in electron microscopes, microwave tubes, electron beam welding apparatus, X-ray tubes and free-electron lasers. However, these materials tend to be expensive.

The oxidation of CaB_6 powders at high temperatures was investigated. The sample oxidized at 873 to 973 K (600 to 700 °C) for 25 h exhibited weight gain with increasing oxidation temperature; the oxidation proceeded in accordance with the parabolic law during the initial oxidation stage. On the other hand, the weight gain of the sample oxidized at and above 1073 K for 4 h was approximately 80%; however, even if the oxidation time was prolonged, an additional weight change did not occur. Based on the results of the X-ray diffraction (XRD) analysis, calcium borate (CaB_4O_7) was found to be present on the surface of the sample oxidized at 1073 K (800 °C). The sample showed a good oxidation resistance at 1273 to 1373 K (1000 to 1100 °C), because the surface film of calcium borate (CaB_2O_4) formed by oxidation acted as an oxidation resistant layer:

$$CaB_6 + 5O_2 \Rightarrow CaB_4O_7 + B_2O_3$$

The optimum conditions for the preparation of pure calcium hexaboride by the borothermic and boroncarbide techniques are at temperature of 1600 °C and a holding time of 60 min; the charge should contain a 10% excess of calcium oxide.

A different calcium boride, CaB_3, was epitaxially grown on Al_2O_3 crystal on the (0001) lattice direction with a substrate temperature of 500 °C. Structural characterization by RHEED (Reflection high-energy electron diffraction) and XRD indicated that CaB_3 has a hexagonal cell with lattice parameters of $a = 4.008$ Å and $c = 4.098$ Å. No evidence for superconductivity was found down to 2 K.

Carbon hexaboride is used in the manufacturing of boron-alloyed steel. Also, calcium hexaboride is used as a deoxidation agent in production of oxygen-free copper, which results in higher conductivity than conventionally phosphorus-deoxidized copper owing to the low solubility of boron in copper. Also, it can serve

as a high temperature material, surface protection, abrasives, tools, and wear-resistant material. When used at elevated temperature, calcium hexaboride will oxidize degrading its properties and shortening its usable lifespan.

Calcium hexaboride is irritating to the eyes, skin, and respiratory system. This product should be handled with proper protective eyewear and clothing. Never put calcium hexaboride down the drain or add water to it.

Calcium hexaboride is available commercially in small to medium quantities worldwide.

Strontium Boride

Strontium boride can be formed directly from the elements. Sr melts at 777 °C and boron melts at 2076 °C. Therefore, if a vapor of Sr metal at >850 °C (red-heat) is passed over crystals of boron, reaction forms the desired boride. However, to obtain stoichiometric compositions, it is better to heat the well-mixed powders of Sr and B to obtain specific compounds:

$$Sr + 6B \Rightarrow SrB_6$$

Strontium boride appears as a crystalline black powder. Closer examination reveals slightly translucent dark red crystals capable of scratching quartz. It is very stable and has a high melting point and density. Although not thought to be toxic, it is an irritant to the skin, eyes, and respiratory tract. It has the formula of SrB_6, with a molecular weight of 152.49 g/mol. It is a black crystalline solid (15.0 °C) with a density of 3.39 g/cm^3, and a melting point of 2235.0 °C. Its CAS number is 12046-54-7.

Strontium boride, along with other alkali earth metal borides, has been shown to exhibit weak ferromagnetism at low temperatures. This is thought by some to be caused by slight impurities or aberrations in the crystal lattice, while others suggest different explanations are needed. Strontium boride has also been examined for semiconducting properties at lower temperatures. Strontium boride is used in insulation and nuclear control rods. A recent patent filed for aircraft windows uses SrB_6 nanoparticles in a transparent acrylic sheet. The IR-absorbing properties of these nanoparticles prevent the transmittance of infrared wavelengths while still allowing the transmittance of visible light. Strontium boride has the same cubic structure as CaB_6 except that the lattice parameters differ due to the larger size of the Sr^{2+} ion (Fig. 6.8).

Here, the interatomic bonding of the octagonal B_6^{2-} groups are shown. Only SrB_6 appears in the phase diagram which is similar to that of the calcium system except for the melting point of SrB_6 (Sr = 2235 °C and Ca = 3162 °C). It is a semiconductor at normal temperatures.

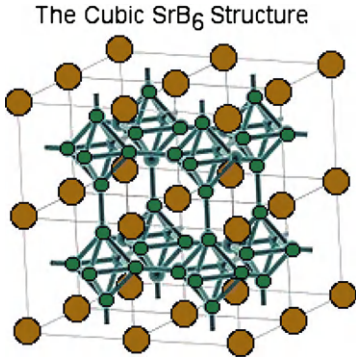

FIGURE 6.8

The NMR of this compound has been reported. Below 30 K, the NMR spectrum is temperature independent but the spin–lattice relaxation rate T_1^{-1} exhibits different features in two different temperature regimes. At high temperatures, between 30 K and a field-dependent crossover temperature T_B between 0.5 and 2 K, T_1^{-1} is almost temperature independent. For T in the crossover temperature range, the magnitude of T_1^{-1} of SrB_6 is distinctly larger than for LaB_6, a metal with a charge carrier concentration at least two orders of magnitude higher than that of SrB_6. A possible cause for this behavior may be the very weak itinerant ferromagnetism that has subsequently been established to occur in nominally pure SrB_6. At low temperatures, below T_B, T_1^{-1} decreases substantially with decreasing temperature confirming a crossover or phase transition phenomenon as observed by measurements of thermal and transport properties. It has been suggested that the ferromagnetism is due to a small amount of intrinsic defects in the lattice.

Growth of single-crystal strontium hexaboride (SrB_6) nanowires was achieved by pyrolysis of diborane (B_2H_6) over SrO powders at 760–800 °C and 400 mTorr in a quartz tube furnace. Raman spectra demonstrate that the nanowires are SrB_6, and transmission electron microscopy (TEM) along with selected area diffraction indicate that the nanowires consist of single crystals with a preferred [001] growth direction. Electron energy loss data combined with the TEM images indicate that the nanowires consist of crystalline SrB_6 cores with a thin (1 to 2 nm) amorphous oxide shell. The nanowires have diameters of 10–50 nm and lengths of 1–10 μm.

SrB_6 has been tested as a component in low-temperature emissive electron gun electrodes. LaB_6 has an emissive power of 29 A/cm^2/°C and a work function of 2.66 eV. The corresponding emissive power for SrB_6 is 0.14 A/cm^2/°C and a work function of 2.67 eV. In contrast, that for BaB_6 is 16 A/cm^2/°C and a work function of 3.45 eV. At 1700 °C, the currents obtained were: La = 1.0 A/cm^2; Sr = 140 mA/cm^2; Ba = 18 A/cm^2.

Strontium hexaboride is available commercially from a number of suppliers worldwide.

Barium Borides

Barium boride can be formed directly from the elements. Ba melts at 727 °C and boron melts at 2076 °C. Therefore, if a vapor of Ba metal at >750 °C (red-heat) is passed over crystals of boron, a chemical reaction forms the desired boride. However, to obtain stoichiometric compositions, it is better to heat the well-mixed powders of Ba and B to obtain specific compounds:

$$Ba + 6B \Rightarrow BaB_6$$

BaB_6 has the CAS number of 12046-08-1. It was established that a barium hexaboride with a composition approaching theoretical can be obtained by a so-called borothermic technique at a temperature of 1600 °C from a charge with a 40% excess of barium oxide. It is more economical to prepare BaB_6 by the reaction of barium carbonate with boron in two stages (30 min at 900 °C and 60 min at 1500 °C).

Barium hexaboride has the same cubic structure as Ca^{2+} and Sr^{2+} hexaborides. The following diagram shows two unit cells in the structure (Fig. 6.9).

Its melting point is 2543 °C and its density is 2.543 g/cc. Its molecular weight is 202.1973 g/mol. Barium hexaboride, BaB_6, has been obtained in the form of single crystals. Its crystal structure was refined in space group *Pmm* (no. 221), $a = 4.2615$ Å. The

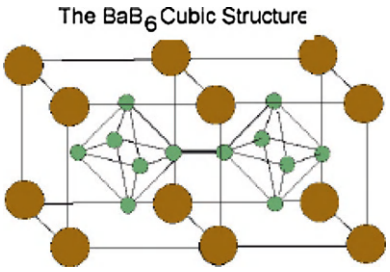

FIGURE 6.9

electronic situation of BaB_6 was discussed on the basis of different band structure calculations performed within the density functional theory (LMTO, plane wave). A comparison with CaB_6 and the molecular anion $[B_6H_6]^{2-}$ shows a similar band ordering. The different orbital contributions are strongly mixed and the inter-octahedral bonds are lower in energy than some of the intra-octahedral framework interactions.

Barium hexaboride has been considered as a candidate for manufacture of a "hot-cathode" electron gun for use in various instruments. The following diagram shows some of the results of their usage in this application (Fig. 6.10).

Note that lanthanum hexaboride can function up to 2200 °C and deliver a current as high as 75 A/cm^2. SrB_6 has been measured as limited to 0.14 A/cm^2 and BaB_6 has a limit of 18 A/cm^2 because of losses as they approach their melting point (see diagram). Only CaB_6

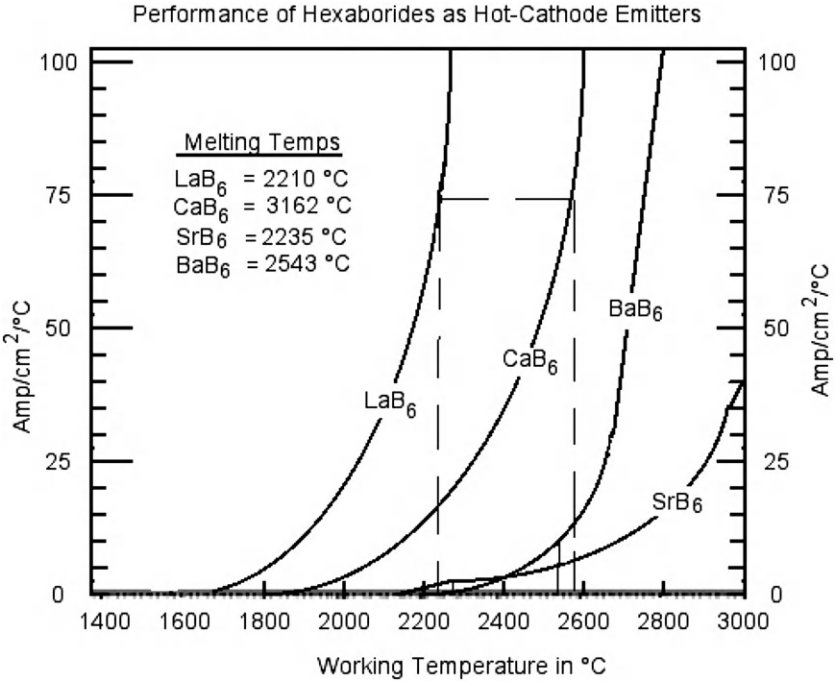

FIGURE 6.10

with a melting point of 3162 °C can approach and exceed the performance of LaB_6. However, to reach the same level of amperage output, the CaB_6 cathode gun must reach a temperature of 2580 °C whereas LaB_6 needs only a temperature of 2230 °C to do so. Thus, the CaB_6 electrode is not as efficient as the LaB_6 one. The difference lies in the fact that the LaB_6 crystal exhibits metallic conduction properties whereas the alkaline earths are semiconductors. The LaB_6 brightness is of the order of 15 to 20 times that of tungsten operated at 40-h life conditions, and it was stated that single-crystal cathodes are more reliable for producing high brightnesses of these electrodes.

The synthesis and formation mechanism of BaB_6 powder by the reaction of $BaCO_3$ with B_4C and carbon were investigated systematically. The influences of heating temperature and holding time on the reaction products were studied by X-ray diffractometry, and the morphologies of BaB_6 were investigated by scanning electron microscopy (SEM). The interaction in the $BaCO_3$–B_4C–C system by which BaB_6 is formed was found to be a solid-phase diffusion process that passes through $Ba_3B_2O_5$ and BaB_2O_4 transition phases. The optimal conditions for BaB_6 synthesis are a holding time of 2 h at 1400 °C, under a vacuum of 10^{-2} Pa of pressure.

Barium hexaboride (BaB_6) crystals can also be synthesized electrochemically using a molten salt technique. Barium carbonate ($BaCO_3$) and boron trioxide (B_2O_3) were used as reactants. Lithium fluoride (LiF) was used as the supporting electrolyte. Small single crystals could be separated from the molten mixture.

Single crystals of alkaline earth hexaborides, CaB_6, SrB_6 and BaB_6, have been grown from a molten aluminum metal flux. The size of crystals produced was up to 5 mm for CaB_6, 3 mm for SrB_6 and 1 mm for BaB_6 in the longest dimension. The color of single crystals is black for CaB_6, dark blue for SrB_6 and dark green for BaB_6. The optical reflectance of single crystals was measured over 1.5–5.5 eV photon energy range.

Barium hexaboride is available in small to medium lots commercially worldwide. It is also offered as single-crystal "whiskers" for sale for research into its properties.

Radium Boride

The scientific literature is devoid of any description of radium borides. The expected compound is RaB_6, the hexaboride. It could be prepared by the same methods as those used for barium but there is no record of anyone having done so. Perhaps the lack of any description of such salts can be ascribed to the intense radioactivity of the ^{226}Ra atom and the dangers of handling it improperly.

6.3. ALKALINE EARTH OXY-BORON COMPOUNDS

The alkaline earths form a series of compounds with the borate anions. These include:

Metaborites—$BO_2^- = M(BO_2)_2$

Orthoborates—$BO_3^{3-} = M_3(BO_3)_2$

Pyroborates—$B_2O_5^{4-} = M_2B_2O_5$

Perborates—$B_2O_6^{6-} = M_3B_2O_6$

Diborates—$B_2O_7^{8-} = M_4B_2O_7$

Triborates—$B_3O_7^{5-} = M_5(B_3O_7)_2$

Tetraborates—$B_4O_7^{2-} = M(B_4O_7)$

Not all of these compounds exist with any given alkaline earth. For example, the Be^{2+} ion is too small and perborates either do not exist or have never been explored. The last three types of compounds are polymeric in BO_3 groups and are stable with the larger alkaline earths like Sr^{2+} and Ba^{2+}. In that case, the valence of the group changes from −8 to −4 or −2, depending upon the nature of the corresponding alkaline earth. This stems from the fact that triangular BO_3^{3-} groups form bonds with tetrahedral BO_4^{5-} groups in the B_3O_7 structure by O to O sharing, as shown in the following Fig. 6.11.

These condensed polyanions have the Lewis structure shown in Fig. 6.12.

However, these BO_3 groups should not be confused with the $(BO_4)_2^{6-}$ groups of perborate. Unlike the percarbonate, and perphosphate, the sodium perborate compound is not simply an adduct with hydrogen peroxide, but contains a cyclic anion ($B_2O_4(OH)_4^{2-}$) with two peroxo bridges and does not contain the BO_3^- ion. This makes the substance more stable, and safer for handling and storage. The formulas of the monohydrates and tetrahydrates can therefore be written as

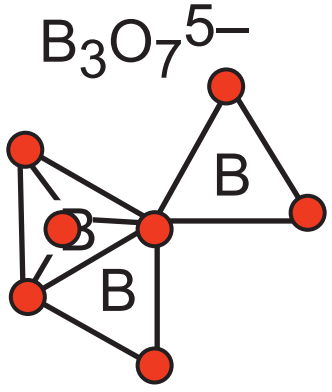

FIGURE 6.11

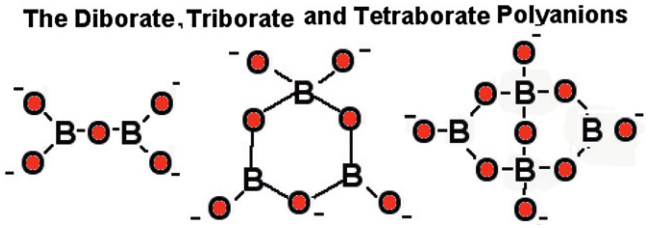

FIGURE 6.12

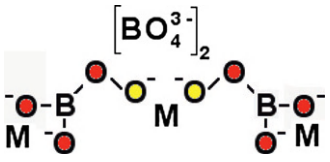

FIGURE 6.13

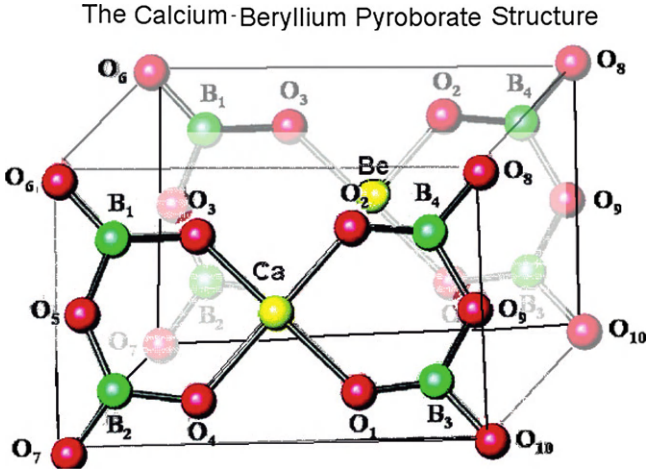

FIGURE 6.14

$H_4B_2O_6^{2-}$ (anhydrous) and $[H_2B_2O_8]^{4-}\cdot 4H_2O$, respectively. The Lewis structure is shown in Fig. 6.13.

The two types of oxygen atoms are clearly depicted.

6.3.1. Beryllium Borates

Beryllium borate can be synthesized by the reaction of the oxide with boric oxide:

$$BeO + B_2O_3 \Rightarrow Be(BO_2)_2$$

The metaborate is shown but a change in the molar ratio from 1:1 to 2:1, etc. produces other compositions. The **metaborate**, $Be(BO_2)_2$ or BeB_2O_4, is offered for sale with the CAS number of 14720-43-5. Another metaborate, $BeBO_2$, is offered for sale with the CAS number of 10682-18-3. It is actually a hydroxy compound with the composition $(BeOH)BO_2$ and was prepared by a solution method:

$$Be(OH)_2\ (aq) + NaBO_2\ (aq) \Rightarrow (BeOH)BO_2\ (solid)$$

A monohydrate is formed. The water of hydration is lost at 120 °C. In addition, the **orthoborate** has been prepared by a solid-state reaction (SSR):

$$3BeO + B_2O_3 + heat \Rightarrow Be_3(BO_3)_2$$

Its CAS number is 13701-63-8. Orthoborates have been used in the passivation of steel products but those containing Be have been shunned because of the potential toxicity.

In combination with other alkaline earths, beryllium forms a **pyroborate**, e.g. (Ca, Be)B_2O_5. Beryllium calcium diborate has the molecular weight of 150.7146 g/mol. It is monoclinic with: space group = $P2_1/n$; cell parameters of: $a = 5.167$ Å, $b = 3.756$ Å, $c = 17.161$ Å, $\beta = 98.12°$, $V = 329.7$ Å^3, $Z = 4$. The structure is formed from two intermingled networks—a CaO_9 polyhedral system and a Be complex constructed from 3- and 4-coordinate Be atoms. The extended coordinate complex results from a unique condensation of six-membered rings containing the triangular BO_3 and distorted tetrahedral BeO_4 groups. Although the formula would indicate a pyroborate group, i.e.  , a mixture of 3- and 4-coordinate boron atoms exists in a complex beryllium borate network. Crystals of (Ca,Be)B_2O_5 were grown from a melt of $Ca(BO_2)_2$ and BeO at 925 °C, as the melt was cooled slowly to 425 °C. The crystals were then washed in water to remove the excess flux. Similar compounds, such as (Sr,Be)B_2O_5 and (Ba,Be)B_2O_5 were also obtained. Part of the structure of the (Ca,Be)B_2O_5 is shown in Fig. 6.14.

Two layers are shown. These layers alternate to form the complete structure, as described above, to form the monoclinic structure where the cations exist in two differing, distorted, coordination states. This combination of $B_2O_5^{4-}$ with Sr and Ba to form mixed compounds has been studied for use as frequency-doubling crystals. Three new alkaline earth beryllium borates, built from unique two- and three-dimensional networks and frameworks, have been identified. $CaBeB_2O_5$ is constructed from a CaO_9 polyhedral network and a beryllium borate network.

The structure of $(Sr,Be)_3(BO_3)_2$ consists of layers of composition $(Be_2(BO_3))^{2-}$ interleaved by Sr atoms.

In $(BaBe)_2(BO_3)_2$, the structure is composed of a beryllium borate framework intermingled with a Ba-centered dodecahedral framework. While the work is not complete at this point in time, the barium beryllium borate is believed to be very useful as a frequency converter for YAG:Nd lasers to produce a collimated beam containing 155-nm photons used in the manufacturing of integrated circuits on silicon substrates.

Gaseous beryllium metaborate, $Be(BO_2)_2$, was identified mass spectrometrically in the vapor above the

beryllium–boron–oxygen system. A study of this system by differential thermal analysis (DTA) and Knudsen effusion using a vacuum balance and mass spectrometer, showed solid $Be_3B_2O_6$ to be the only condensed mixed oxide phase present with a melting point of 1495 ± 5 °C. The following thermodynamic values were obtained for the formation of gaseous beryllium metaborate from beryllium oxide and gaseous boron oxide:

$$BeO\ (solid) + B_2O_3\ (gas) = Be(BO_2)_2\ (gas);$$

$$\text{enthalpy, } \Delta H_f \text{ at } 1500\ ^\circ C = -22.5\ \text{kcal/mol};$$

$$\text{entropy, } S^0 \text{ at } 1500\ ^\circ C = 6.1\ \text{eu/mol}.$$

For the formation of solid $Be_3(BO_3)_2$ from the condensed oxides:

$$3BeO(solid) + B_2O_3\ (gas) \Rightarrow Be_3B_2O_6\ (gas);$$

$$\text{enthalpy } \Delta H_f = -23.5\ \text{kcal/mol};$$

$$\text{entropy, } S^0 = -13 = 2\ \text{eu/mol}.$$

The metal–anion bond strengths in the gaseous beryllium metaborates show the same relation to each other as the bond strengths in the corresponding chlorides, thus further confirming the pseudohalide character of the gaseous metaborates.

Only two beryllium borate minerals are known in which Be^{2+} is the major cation. They are:

Berborite (hydrated beryllium borate hydroxide fluoride),

Hambergite (beryllium borate hydroxide) $= (Be)_4B_4O_7(OH)_4$.

Beryllium perborate, $(BeOH)BO_3$, remains unknown. Presumably, it could be made by the reaction of:

$$Be(OH)_2\ (aq) + Na_4B_2O_8\ (aq) \Rightarrow (BeOH)_4B_2O_8\ (aq)$$

The solution is then evaporated to obtain crystals. The question of the hydrate(s) produced remains unknown. There is no record of anyone actually trying to prepare this compound.

Beryllium forms a beryllodiborate with sodium, $Na_2[BeB_2O_5]$. Single crystals of disodium beryllodiborate have been obtained by spontaneous nucleation from a high-temperature melt. $Na_2[BeB_2O_5]$ adopts a new structure type and contains $[BeB_2O_7]^{6-}$ rings as building units that are made up from one BeO_4 tetrahedron and two BO_3 triangles. These rings are further condensed and form $\{[BeB_2O_5]^{2-}\}_\infty$ two-dimensional layers extending parallel to the *ab* plane with the Na^+ cations in a $[6+1]$ coordination located between the layers. All atoms except Be and an O atom (both with site symmetry P.2) are in general positions.

The diborate, $Be_4B_2O_7$, has been said to have been prepared as a monohydrate by the reaction of the sodium salt in solution:

$$BeCl_2\ (aq) + Na_8B_2O_7\ (aq) \Rightarrow [Be(OH)]_8B_2O_7 \cdot H_2O + 6NaOH + 2NaCl$$

However, no specific data is available concerning this compound other than the statement that it had been prepared. In view of the fact that the **triborate**, $B_3O_7^{5-}$ and tetraborate, $B_4O_7^{2-}$ are known to be unstable, it is unlikely that this compound has ever been synthesized. The only known **tetraborate** of beryllium is the mineral "hambergite" which is described as a hydroxyborate. More likely, its actual formula is $(BeOH)_8B_4O_7 \cdot H_2O$.

A few beryllium borates are available commercially in small lots. The usage of these compounds in industry is nil to none. They have been of scientific interest only in Academia.

Magnesium Borates

Magnesium borate can be prepared by the SSR of boric oxide with MgO:

$$MgO + B_2O_3 \Rightarrow Mg(BO_2)_2$$

The metaborate is shown but the actual product obtained depends upon the molar ratio of the two components. If a solution method is used, then a hydrate results which is difficult to dehydrate by normal methods. The comparative effects of high-energy milling on solid-state thermal syntheses of different magnesium borate compounds from $MgO–B_2O_3$ and $MgO–B(OH)_3$ mixtures have been investigated using initial $MgO:B_2O_3$ mole ratios of 1:0.125, 1:0.25, 1:0.5, 1:1, 1:2 at temperatures between 500 and 900 °C. It was observed that magnesium oxide–boric acid mixtures react only by high-energy milling to form hydrous magnesium borates. Following high-energy milling of the initial solid mixtures, anhydrous magnesium borate compounds started to form at temperatures as low as 500 °C, and purer and more crystalline phases were obtained at higher temperatures compared to compositions that had not been milled.

Magnesium metaborate, $MgO \cdot B_2O_3{:}nH_2O$ was synthesized at 25 °C in solutions of the chlorides of sodium, potassium and magnesium in the presence of 3% boric acid and potassium hydroxide to a ratio $B_2O_3{:}K_2O{=}1$. The noncrystalline sediment which first precipitates is converted over the course of several weeks to crystalline magnesium metaborate, $Mg(BO_2)_2 \cdot nH_2O$, where *n* depends upon the temperature of the solution during this process.

Equilibrium in the system has been investigated for compositions from 0.6 to 75 wt% MgO. Three intermediate compounds were found. $MgO \cdot B_2O_3$ melts incongruently at 988 °C to form $2MgO \cdot B_2O_3$ and a liquid

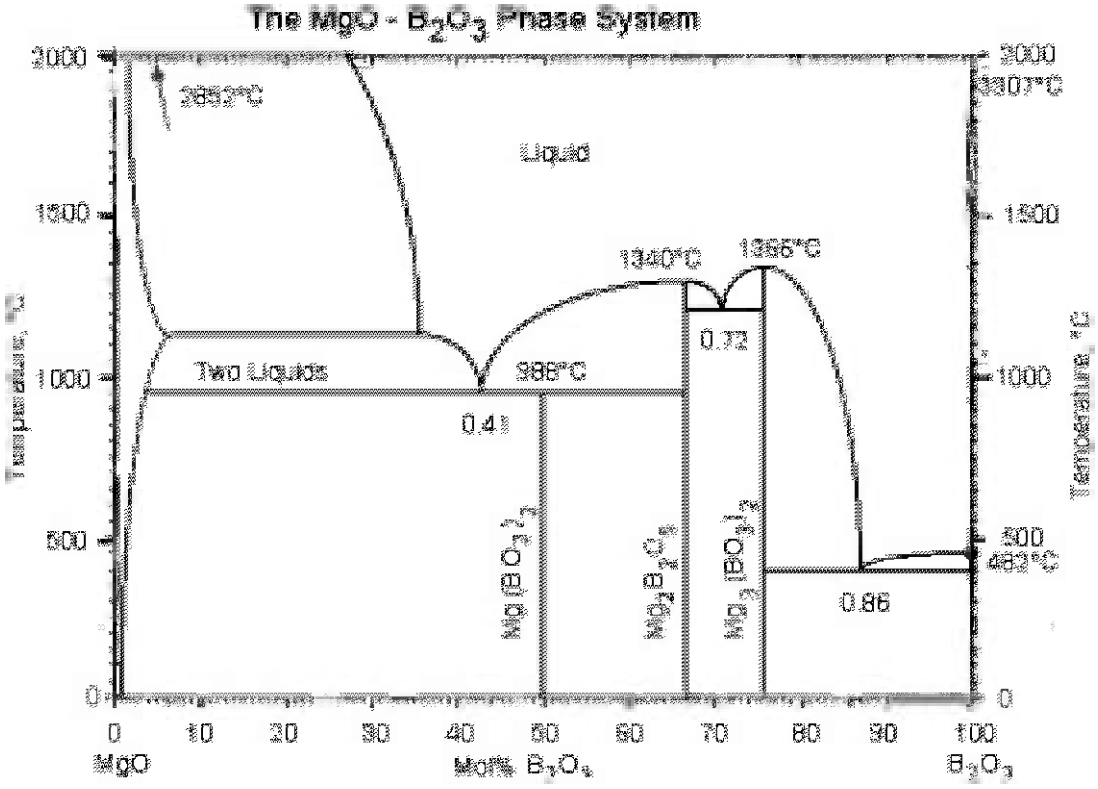

FIGURE 6.15

containing more than 99% B_2O_3. The other two compounds melt congruently: $2MgO \cdot B_2O_3$ at 1340 °C and $3MgO \cdot B_2O_3$ at 1366 °C. At 1142 °C, a region of liquid immiscibility extends from 0.6 to 36.0% MgO. The phase diagram is shown in Fig. 6.15.

Thus, at 1:1 molar ratio, a metaborate forms whereas at 3:1, an orthoborate is obtained. At a molar ratio of 2:1, the pyroborate forms. Thus, at 1:1 molar ratio, a metaborate forms whereas at 3:1, an orthoborate is obtained. At a molar ratio of 2:1, the pyroborate forms. The chemical properties of these three compounds differ from each other. The pyroborate anion, $B_2O_5^{4-}$, occurs in nature as the mineral "suanite" and has the formula, $Mg_2B_2O_5 \cdot xH_2O$.

If the metaborate is heated, single-crystalline magnesium borate nanowires of the form $Mg_2B_2O_5$ with typical diameter about 120–180 nm and length about 0.2 mm have been successfully synthesized by a new and simple method of heating the mixed tablet of $Mg(BO_2)_2$ and graphite directly in vacuum at 1200 °C for 1 h:

$$4Mg(BO_2)_2 + \text{heat (Vac)} \Rightarrow 2Mg_2B_2O_5 + 3O_2\ (\text{gas})$$

A number of magnesium borate minerals are known:

Hydroboracite, $CaMgB_6O_{11} \cdot 6H_2O$, is an uncommon borate mineral. It is one of the borate minerals that form silky, fibrous crystal clusters. Ulexite is another more common borate that forms similar fibrous aggregates and thus the two minerals are not easy to distinguish. Hydroboracite's silky luster is quite attractive.

"Ulexite" ($NaCaB_5O_6(OH)_6 \cdot 5(H_2O)$) (hydrated sodium calcium borate hydroxide) a.k.a. TV rock, is a mineral occurring in silky white rounded crystalline masses or in parallel fibers. The natural fibers of ulexite conduct light along their long axes, by internal reflection.

"Boracite" is a magnesium borate mineral with formula: $Mg_3B_7O_{13}Cl$. It occurs as blue green, colorless, gray, yellow to white crystals in the orthorhombic–pyramidal crystal system.

"Admontite" is a magnesium borate mineral with formula: $MgB_6O_{10} \cdot 7H_2O$. It is named after Admont, Austria. An alternate formula is $MgB_6O_7(OH)_6 \cdot 4H_2O$. Its crystal parameters are: space group: P21/c, $a = 12.68$ Å, $b = 10.07$ Å, $c = 11.32$ Å, $\beta = 109.68(10)$, $Z = 4$. It is generally found in gypsum deposits.

"Ludwigite" is a magnesium–iron borate mineral: Mg_2FeBO_5. Ludwigite typically occurs in magnesium–iron skarn and other metamorphic deposits. It occurs in association with magnetite, forsterite, clinohumite and the borates vonsenite and szaibelyite.

"**Warwickite"** is an iron magnesium titanium borate mineral with formula: $(Mg,Fe)_3Ti(O,BO_3)_2$ or $Mg(Ti,Fe^{3+},Al)(BO_3)O$. It occurs as brown to black prismatic orthorhombic crystals which are vitreous and transparent. It has a Mohs hardness of 3 to 4 and a density of 3.36 g/cc.

"**Teruggite"** is a mineral with the chemical formula of $Ca_4MgAs_2B_{12}O_{22}(OH)_{12}\cdot 12(H_2O)$. It is colorless. Its crystals are monoclinic prismatic. It is transparent. It is not radioactive. It has vitreous luster. Cell dimensions are: $a = 15.68$, $b = 19.9$, $c = 6.25$, $Z = 2$; $\beta = 100.083°$, $V = 1.920.08$, Den(Calc) $= 2.14$.

"**Chambersite**", a member of the borate mineral series that includes other minerals such as "ericacite", $Fe_3B_7O_{13}Cl$, and "boracite", $Mg_3B_7O_{13}Cl$. When chambersite was first discovered, it was the second chemical analog of boracite to be found in nature.

"**Admontite**" (hydrated magnesium borate) has the formula $MgB_6O_{10}\cdot 7H_2O$. Crystal data: monoclini, point group: 2/m; cell data: space group: P21/c, $a = 12.68$ Å, $b = 10.07$ Å, $c = 11.32$ Å, $\beta = 109.68°$, $Z = 4$.

"**Inderite**" or "kurnakovite" has the formula, $Mg_2B_6O_{11}\cdot 15H_2O$. It is monoclinic.

"**Macallisterite**", $2MgO\cdot 6B_2O_3\cdot 15H_2O$ [or $Mg_2(B_3O_5)_4\cdot 15H_2O$] is trigonal; the space group is R3c (nonpiezoelectric); hexagonal with $a = 11.546$ Å, $c = 35.562$ Å, c/a: 3.080; rhombohedral $a_{RH} = 13.600$ Å, $V = 4105$ Å^3, $Z = 6$.

Additional known minerals include:

Aksaite (hydrated magnesium borate hydroxide)
Boracite (magnesium borate chloride)
Fluoborite (magnesium borate fluoride hydroxide)
Halurgite (hydrated magnesium borate hydroxide)
Hungchaoite (hydrated magnesium borate hydroxide)
Kotoite (magnesium borate)
Inderite (hydrated magnesium borate hydroxide)
Mcallisterite (hydrated magnesium borate hydroxide)
Preobrazhenskite (magnesium borate hydroxide)
Pinnoite (hydrated magnesium borate)
Suanite (magnesium borate)
Wightmanite (hydrated magnesium borate oxide hydroxide)

If the metaborate, $Mg(BO_2)_2$, is dissolved in a solution of boric acid, a series of complex compounds, as hydrates, can be obtained. Conductivity and depression in freezing point of a series of solutions containing a fixed amount of boric acid and varying quantities of magnesium metaborate have been determined. The values obtained indicated the formation of three possible hydrated compounds:

$$MgO\cdot 4B_2O_3\cdot 9H_2O = MgB_4O_7\cdot 2B_2O_3\cdot 9H_2O$$

$$MgO\cdot 3B_2O_3\cdot 6H_2O = MgB_4O_7\cdot B_2O_3\cdot 6H_2O$$

$$2MgO\cdot 3B_2O_3\cdot 3H_2O = Mg_2B_2O_5\cdot 2B_2O_3\cdot 3H_2O$$

The first two are **tetraborates** and the last is a **pyroborate**. The results have been confirmed by quantitative estimation of magnesium and B_2O_3 in the precipitates obtained from solution. Thus, compounds corresponding to the above mentioned complexes have been formed in which a metaborate is transformed in solution to a tetraborate or pyroborate. In other words, the most stable compounds are the pyroborate and the tetraborate.

Magnesium borate of the **pyroborate** form, $Mg_2B_2O_5$, has been prepared and its structural and thermal properties were studied using XRD and DTA. An investigation of the electrical and optical properties of $Mg_2B_2O_5$ system has been carried out. The electrical resistivity of the sample was measured in the temperature range of 170–400 K. The data analysis revealed an extrinsic nature of the conductivity with two impurity levels located at 0.13 and 0.71 eV in the temperature ranges of 170–230 K and 240–400 K, respectively. The optical transmission and reflection were recorded at 300 K in the incident photon energy range of 3.0–6.0 eV. The absorption coefficient data analysis revealed an indirect optical energy band gap of 4.73 eV. In addition, two impurity levels located at 3.43 and 4.49 eV were observed in the absorption spectra.

Single-crystal triclinic $Mg_2B_2O_5$ and orthorhombic $Mg_3(BO_3)_2$ "nano-rods" were formed by a solvothermal method under supercritical conditions. Detailed microstructures of as-synthesized products were characterized by XRD, SEM, TEM, and X-ray photoelectron spectroscopy. It was found that the morphology and phase of the products were strongly dependent on the reaction conditions, such as the ratio of Mg/B, temperature, reaction time, and solvent media. The formation process of $Mg_2B_2O_5$ nano-rods was illustrated based on SEM observations of the different reaction stages. This technique may also have great potential in realizing other nanostructured materials. The following diagram shows the methods used to synthesize these "nano-rods" (Fig. 6.16).

In another method, magnesium borate "nano-belts" have been prepared by heating mixed powders of boron and MgO under flowing Ar/H_2O gases at 1100 °C. Typical widths with the nano-belts are in the range of 100–300 nm and lengths are up to tens of micrometers. XRD and selected area electron diffraction patterns show the nano-belts are of orthorhombic $Mg_3B_2O_6$ structure, having the **orthoborate** composition. Furthermore, high-resolution TEM identifies that the magnesium borate nano-belts are single crystal in nature.

A flux-assisted thermal conversion route to the pore-free high-crystallinity magnesium pyroborate ($Mg_2B_2O_5$) "nano-whiskers" with a length of 0.47–3.0 μm, diameter of 50–240 nm, and aspect ratio of 5/36 at a relatively low temperature of 650–700 °C (200–350 °C lower than that needed via the traditional method) was developed. Magnesium borate hydroxide [$MgBO_2(OH)$] nano-whiskers were first prepared by a coprecipitation–hydrothermal approach at 240 °C for 18 h by using $MgCl_2\cdot 6H_2O$, H_3BO_3 and NaOH (or

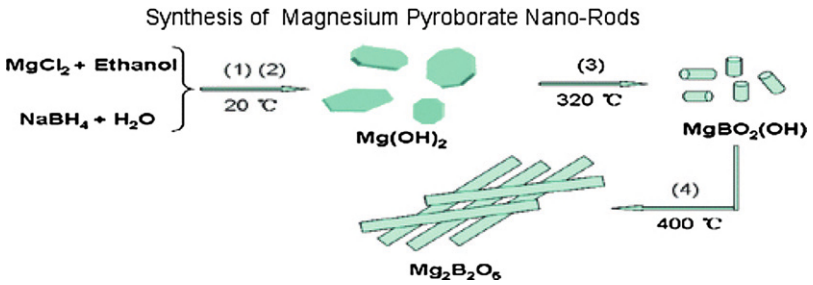

FIGURE 6.16

KOH) as the raw materials and the hydroxyborate was then calcined to produce $Mg_2B_2O_5$ nano-whiskers. The resultant NaCl (or KCl) in the coprecipitation served as the flux and played a key role in the thermal conversion of $MgBO_2(OH)$ nano-whiskers as the transport medium for the rearrangement of structural units of $Mg_2B_2O_5$, leading to the final formation of the pore-free $Mg_2B_2O_5$ nano-whiskers with uniform one-dimensional morphology, high-crystallinity, and twinned crystal structures.

It has been determined that a magnesium dibarium orthoborate, $MgBa_2(BO_3)_2$, is useful as an unconventional birefringent material with high transparency in the visible region and predicted that it is comparable to α-BBO in terms of the magnitude of birefringence. It usage as a frequency-doubling crystal for use with lasers is currently under investigation in that industry.

Magnesium pyroborate, $Mg_2B_2O_5$, when activated by trivalent dysprosium, has been studied as a phosphor for detection of radiation dosage. This thermoluminescent phosphor, $(Mg,V_{Mg}^{+})_2B_2O_5:Dy_{Mg}^{3+}$, has almost the same human-tissue equivalence and sensitivity to γ-rays but has the property of "fading" during usage as the vacancy defect is "repaired" in the lattice. If the tetraborate, MgB_4O_7, prepared from $Mg(NO_3)_2$ and ammonium tetraborate, $(NH_4)_2B_4O_7$, is activated by the addition of the Dy^{3+} ion, a phosphor, $(Mg,V_{Mg}^{+})B_4O_7:Dy_{Mg}^{3+}$, results that does not fade during multiple usages. The following figure shows the linear response obtained as a function of dosage (Fig. 6.17).

Magnesium perborate, $Mg(BO_3)_2$, can also be prepared by a solution method:

$$MgCl_2\ (aq) + Na_2BO_3\ (aq) \Rightarrow Mg(BO_3)_2 \cdot 7H_2O$$

The usual form is the heptahydrate and its CAS number is 17097-11-9. It is a bulky, white powder which gradually decomposes in air with loss of active oxygen. It is slightly soluble in water, with partial decomposition, so that it has been used in medicine as an oxidizing agent, antiseptic and antibacterial agent. It is soluble in dilute acids. The CAS number of the monohydrate is 14635-87-1. Its molecular weight is 141.9244 g/mol. Both of these salts are available commercially.

The perborates of magnesium were studied intensively in the early 1900s. There is little current work being accomplished on these salts. However, they are available in tonnage quantities worldwide. Their main usage has been in dental preparations and in laundry detergents as cleaning and bleaching agents.

Solid–liquid phase equilibria of the compound, $2MgO \cdot 2B_2O_3 \cdot MgCl_2 \cdot 14H_2O = Mg_2B_4O_7 \cdot 7H_2O$, when added to an aqueous 3.0% $H_3BO_3 + H_2O$ system have

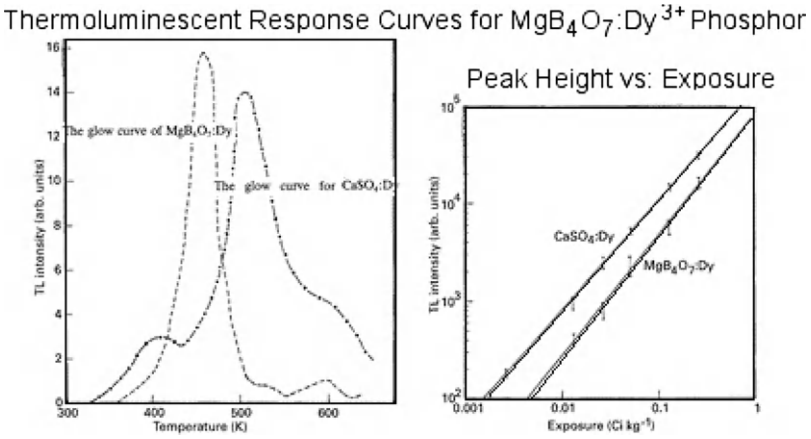

FIGURE 6.17

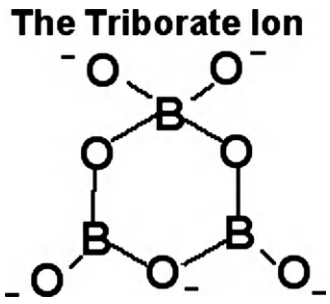

FIGURE 6.18

been studied at various temperatures of 0 to 200 °C. The solid phase equilibria identified by infrared spectra and X-ray powder diffraction were $MgB_4O_7 \cdot 9H_2O$ (a diborate) at 0 to 27 °C, $Mg_5(B_3O_7)_2 \cdot 15H_2O$ (a triborate) at 27 to 50 °C, $Mg_2B_6O_{11} \cdot 15H_2O$ (inderite) at 50 to 72 °C, $Mg(BO)_2 \cdot 3H_2O$ (a metaborate) at 72 to 98.5 °C, $Mg_2B_2O_5 \cdot 2H_2O$ (a pyroborate) at 98.5 to 190 °C, and $Mg_2B_2O_5 \cdot 1.5\ H_2O$ (a pyroborate) at 190 to 200 °C, respectively. The Lewis structure of the triborate ion is shown in Fig. 6.18.

The fundamental unit of these polyanionic structures is a trimeric ring containing both trigonal and tetrahedral boron atoms. The formation of the tetramer, pentamers, etc. and long-chain polyanions results from the fusion of two or more rings at the tetrahedral boron atoms, or from dehydration.

The structural mechanism of the thermal decomposition of "kaliborite", $HKMg_2B_{12}O_{16}(OH)_{10} \cdot 4H_2O$ has also been investigated. Kaliborite decomposition is an internal structural reconstitution process occurring in the whole volume of the crystal. The following stages of the process have been distinguished: (1) dehydroxylation; (2) dehydration; (3) recrystallization of the anhydrous amorphous substance and formation in succession of MgB_4O_7, $Mg_2B_2O_5$ and KB_5O_8. Dehydration precedes dehydroxylation and both of them consist of two independent stages: formation of free water molecules localized into the structural framework, and their release.

Magnesium borates are available commercially as several types of compounds.

Calcium Borates

Calcium forms all of the possible compounds based on "borates". This is based upon combination of CaO with B_2O_3. These two oxides are fired together at varying molecular ratios to obtain the various compounds. The phase diagram shows four separate compositions (Fig. 6.19).

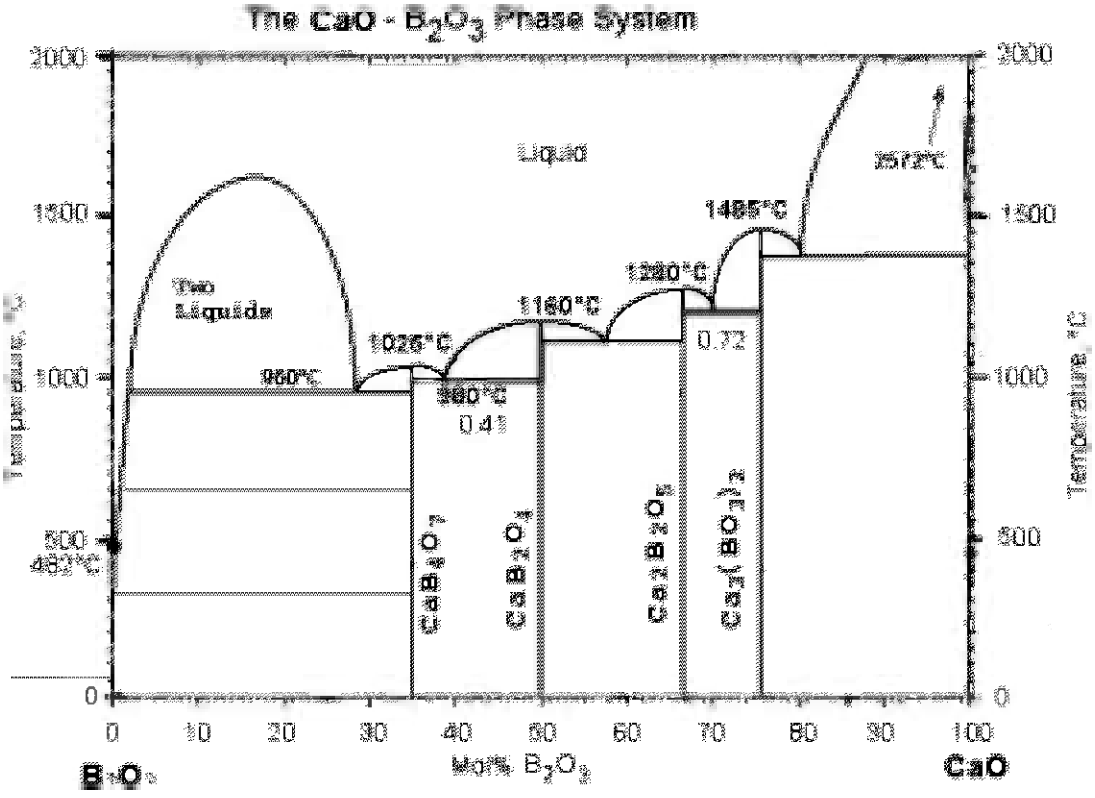

FIGURE 6.19

The tetraborate appears here in addition to the other compounds, meta-, pyro- and orthoborate that are also found in the Mg system. The melting points of these anhydrate compounds are given in the diagram. Additionally, a number of hydroxylated calcium borates have also been discovered. A great number of these occur as minerals throughout the world.

Calcium metaborate has the molecular formula of $Ca(BO_2)_2$ and the molecular weight of 125.7038 g/mol. It can be prepared by the aqueous reaction of sodium metaborate and a soluble calcium compound:

$$CaCl_2(aq) + Na_2BO_2\ (aq) \Rightarrow CaB_2O_4 \cdot xH_2O\ (aq)$$

where $x = 2$, 4 and 6. The solution is evaporated to obtain the salt. The most usual salt suppliers by manufacturers is $Ca(BO_2)_2 \cdot 2H_2O$ (whose CAS number is 13701-64-9). Some manufacturers supply the tetrahydrate, $CaB_2O_4 \cdot 4H_2O$ as white crystals. This hydrate, upon heating, loses two water molecules at 101 °C and lost two more water molecules at 120 °C. It changes from four water molecules at 300 °C when it is transformed into the dihydrate. In another method, a "fructoborate" complex is formed. The synthesis of calcium fructoborate was performed according to Miljkovic's procedure using boric acid, d-fructose, $CaCO_3$ and acetone. D-fructose was dissolved in distilled water at room temperature and boric acid was then added to this solution. Finally, calcium carbonate was added in small portions, under constant stirring. After the CO_2 evolution has ceased, 40 ml of acetone was added to the reaction mixture, whereupon a colorless oil was separated at the bottom of the reaction vessel. The two layers were separated and the lower oily layer, containing the crude boron complex was treated again with 40 ml of acetone. Upon standing for 1 h, crystallization was induced with a glass rod, and the oil slowly turned into a white crystalline solid. The product was filtered off, washed with small portions of acetone and air dried. Upon firing the product, $Ca(C_6H_{10}O_6BO)_2 \cdot 3.5H_2O$, a very pure $Ca(BO_2)_2$ product was obtained.

The anhydrate has the Lewis structure shown in Fig. 6.20.

Where a "double-bond" oxygen atom is present. The formula is sometimes written as: $Ca(BO_2)_2$. Its CAS number is 13701-64-9. This compound consists of infinite chains of $B_2O_4^{2-}$ ions held together by Ca^{2+} ions. Crystals of calcium metaborate are orthorhombic. The unit cell containing four molecules CaB_2O_4 was found to have the dimensions $a = 6.214$ Å, $b = 11.604$ Å, $c = 4.285$ Å. The space group is Pnca and the point group is V_h^{14}. The atoms are distributed among the available positions as:

$4Ca^{2+}$ on fold-axes: $\pm(1/4O_u)(1/4, 1/2, 1/2 + u)$

8 B. 8 O_1 and O_2: $\pm(x, y, z)(x, 1/2 - y, z + 1/2)(x + 1/2, 1/2 - y, 1.2 - z)(x + 1/2, y, z)$

In the lattice, each Ca^{2+} ion is surrounded by eight-oxygen atoms, two O_1 at 2.46 Å, two O_2 at 2.48 Å and two O_2 at 2.58 Å. Three oxygen atoms (two O_1 and one O_2) form an almost equilateral triangle around each boron atom. The B–O distances are: 1.35 Å, 1.35 Å and 1.38 Å. The edges of the oxygen triangle are 2.35 Å and 2.36 Å whereas each O_2 atom is linked to one boron and three calcium atoms. The following diagram shows one layer of the B_2O_4 chains which are linked three dimensionally (Fig. 6.21).

Each O_1 atom is linked to two boron atoms and one calcium atom, whereas each O_2 atom is linked to one boron and three calcium atoms. As all the BO_3 groups are oriented parallel to the *a*-face, strong negative birefringence has been found, the *a*-axis being the acute bisectrix. The observed perfect cleavage parallel to the *a*-face is accounted for by the structure; there is only one Ca–O bond per 12.5 A^2 crossing the *a*-face. The most interesting feature of the structure is the presence of endless strings of BO_3 groups parallel to the *c*-axis. The average composition of each string is BO_2.

Calcium metaborate has been evaluated as a wood preservative. Water-saturated wood specimens were first impregnated by a saturated borax solution and then diffuse-penetrated with Ca^{2+}, or Pb^{2+} solution. The precipitates of these metaborates in the wood proved to be insoluble or hardly soluble in water by a leaching test. A decay test was performed using a brown-rot fungus (*Fomitopsis palustris*) and a white-rot fungus (*Trametes versicolor*) and with the termite test using a virulent subterranean termite (*Coptotermes formosanus*). The metaborate-treated woods showed generally good decay and termite resistance with negligible mass loss of the specimens. Particularly, the lead metaborate formed in the wood provided superb biological resistance against decay and termite attacks.

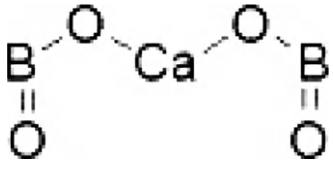

FIGURE 6.20

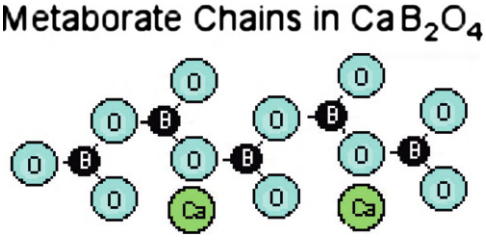

FIGURE 6.21

The tetrahydrate is soluble in water, acid and alkaline aqueous solutions. It is used in E-glass as a coating and is a new use for this industrial raw material. It is also used for antirust coatings, fire retardants, and in the fungicide and pharmaceutical industries.

Borate glasses present an absorption coefficient very close to that of human tissue. This fact makes some borate glasses ideal materials to develop medical and environmental dosimeters. Glass compositions with calcium tetraborate (CaB_4O_7) and calcium metaborate, such as the $(CaB_4O_7)_x \cdot (CaB_2O_4)_{100-x}$ system (0.6 to 100 wt%) were obtained by the traditional melting/quenching method. A phenomenon widely known as the "boron anomaly" was observed in thermal analysis measurements, as indicated by the increase of Tg (glass transition temperature) and the appearance of a maximum value in the composition with 40 wt% of CaB_2O_4. The Dy^{3+}-doped and Li co-doped 80 CaB_4O_7–20 CaB_2O_4 (wt%) glass samples were studied by the thermoluminescence technique. The addition of Dy improved the signal sensitivity in about three times with respect to the undoped glass sample. The addition of Li as a co-dopant in this glass caused a shift to a lower temperature of about 20 °C in the main glow peak.

Coatings of calcium metaborate have been found to protect iron against oxidation in the temperature range 750–1050 °C in oxygen. Protection is due to the compound iron boroferrite ($4FeO \cdot Fe_2O_3 \cdot B_2O_3$) that forms as a noncoherent, granular, blocking layer along the scale/metal interface, which effectively decreases the interfacial area for iron ion diffusion.

Calcium orthoborate, ($Ca_3(BO_3)_2$), also called Gerstley borate, is a bluish white crystal with a very defined structure. It can be prepared by reacting sodium borate in solution or by reacting Ca metal with boric acid. The resulting product is calcium orthoborate. A hydrate is obtained from the solution method.

Single crystals of $Ca_3(BO_3)_2$ have been obtained from the melt. The compound crystallizes in the rhombohedral system, space group R'3c, with six formula units in the hexagonal cell of dimensions $a = 8.6377$ Å and $c = 11\text{-}849$ Å. The BO_3 group appears as a nonplanar triangle with an O–B–O angle of 119.95° and a B–O distance of 1.3836 Å. The Ca^{2+} ions are surrounded by eight O-atoms, forming a distorted square antiprism. Analysis of calcium orthoborate, $Ca_3(BO_3)_2$, and recognize that the energy difference between oxygen nonbonding lone pair and B analysis on calcium orthoborate, $Ca_3(BO_3)_2$, and recognize that the energy difference between oxygen nonbonding lone pair and B–V_{Ca}–O–π bond states plays a crucial role in the origin of the large birefringence. With the aid of this mechanism, dibarium magnesium orthoborate, $Ba_2Mg(BO_3)_2$, has been proposed as an unconventional birefringent material with high transparency in the visible region and predicted that it will be comparable to α-BBO in terms of the magnitude of birefringence. O–π bond states play a crucial role in the origin of the large birefringence.

The luminescence properties of calcium orthoborate, $Ca_3(BO_3)_2$, doped with cerium (Ce^{3+}) were studied upon X-ray (~30 keV) and VUV (3.5–15 eV) synchrotron excitation. The emission bands peaked at 392 and 420 nm were attributed to interconfigurational transitions of Ce^{3+} ions. The short-wavelength emission band at 340 nm was said to be caused by radiative decay of exciton-like states. The fundamental absorption edge of $Ca_3(BO_3)_2$ was found to be near 7.1 eV. The introduction of a trivalent impurity into a divalent site causes formation of a positively charged vacancy, V^{+}_{Ca}. Based on thermoluminescence data and other information, the behavior of defects in the performance of $Ca_3(BO_3)_2$:Ce^{3+} as a thermoluminescent radiation detector was studied.

Calcium pyroborate has the molecular formula of $Ca_2B_2O_5$, it can be prepared by the reaction of:

$$2CaCl_2\ (\text{solid}) + 2H_2BO_3\ (\text{solid}) + \text{heat} \Rightarrow Ca_2B_2O_5 + 4HCl\ (\text{gas})$$

The structure consists of stacked double chains containing $Ca(1)O_7$ and $Ca(2)O_6$ polyhedra are linked to form a three-dimensional framework by B_2O_5 groups. The structure is shown in the following Fig. 6.22.

The structure in a unit cell contains four formula units or $[Ca_2B_2O_5]_4$. The structure contains Ca_4O_{19} tetramers which form double chains extending along the *a*-direction. The double chains are linked to form layers and the B_2O_5 groups bridge these adjacent chains and adjacent layers through O-atoms to form a three-dimensional network.

A hydrated calcium pyroborate has also been synthesized. A pure calcium borate, $Ca_2[B_2O_4(OH)_2] \cdot 0.5H_2O$, has been synthesized under hydrothermal condition and characterized by XRD, FT-IR and TG as well as by chemical analysis. The molar enthalpy of solution of $Ca_2[B_2O_4(OH)_2] \cdot 0.5H_2O$ in $HC1 \cdot 54.582H_2O$ was determined. From a combination of this result with measured

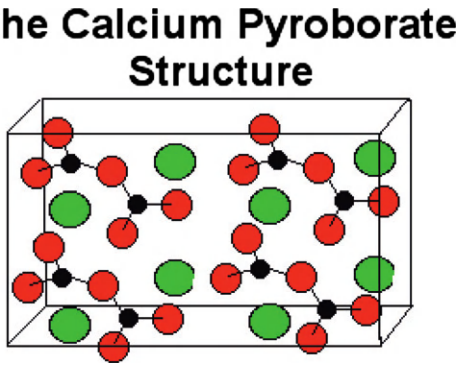

FIGURE 6.22

enthalpies of solution of H_3BO_3 in $HC1 \cdot 54.561H_2O$ and of CaO in $(HCl + H_3BO_3)$ solution, together with the standard molar enthalpies of formation of CaO(s), H_3BO_3(s) and H_2O(l), the standard molar enthalpy of formation of -3172.5 kJ/mol of $Ca_2[B_2O_4(OH)_2] \cdot 0.5H_2O$ was obtained. The thermal decomposition has revealed that it is a multistage internal process. The following stages have been distinguished: (1) a two-step release of interlayer water; (2) internal structure reconstruction; (3) dehydroxylation and amorphization of crystal structure; (4) recrystallization of amorphous solid and successive formation of CaB_2O_4 and then CaB_4O_7.

Microbiological fouling of plastic materials is an unwanted nuisance and a problem in many household and industrial environments. The humid and high-moisture environments where plastic materials are often used provide excellent growth environments for unwanted microorganisms such as mold, fungi, and mildew. In addition to degrading and fouling plastic materials, these microorganisms can cause unsightly stains and unpleasant odors. Calcium pyroborate has been employed in various plastic materials that contain a microbicidally effective amount of calcium pyroborate that protects plastic materials from microbiological attack. It is also used in fungicidal and corrosion inhibiting paint pigments.

Calcium perborate, CaB_2O_6, has the CAS number of 54630-47-6. Its Lewis formula is shown in Fig. 6.23.

It has been prepared by the reaction:

$$CaCl_2\ (aq) + Na_2B_4O_5 + H_2O_2 \Rightarrow Ca(BO_3)_2 \cdot 2H_2O + 2NaCl$$

This mixture was stirred, and the temperature was maintained at 20–25 °C. The solids were then filtered out, and the filter cake was reslurried with water and filtered again. Finally, the solids were dried overnight in a vacuum oven at 50 °C. The product thus obtained was a calcium perborate, $Ca(BO_3)_2$, containing the equivalent of 27.9% calcium oxide [CaO] and 10.0% active oxygen [O].

Calcium perborate has been used as an oxidizing and teeth-whitening agent in dentistry and in some applications in polyolefin polymer preparation.

Calcium triborate has been found to have the formulation of $CaB_3O_7(OH)_3$ and the Lewis structure of is shown in Fig. 6.24.

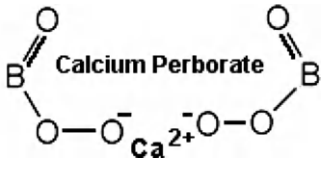

FIGURE 6.23

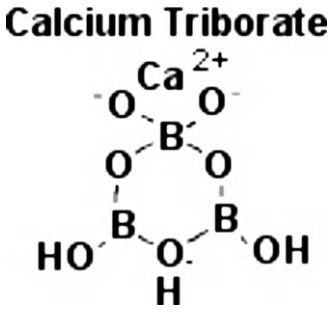

FIGURE 6.24

A monohydrate and a tetrahydrate are known.

Pentacalcium triborate fluoride has been studied in its relationship to fluoroapatite. $Ca_5F(BO_3)_3$ has the molecular weight of 395.8346 g/mol and is monoclinic with space group—Cm. Lattice parameters are: $a = 8.125$ Å, $b = 16.051$ Å, $c = 3.538$ Å, $\beta = 100.90°$, $V = 453.1$ Å^3, $Z = 2$.

Calcium tetraborate, CaB_4O_7, has the CAS number 27676-48-8. The monohydrate has the CAS number of 12007-56-6. Calcium tetraborate has been formed from the thermal decomposition of the mineral, "pandermite" $= Ca_2B_5O_8 \cdot 2H_2O$. Investigation has revealed that it is a multistage internal process, realized by gradual reconstitution of the mineral structure. The following stages have been distinguished: (1) a two-step release of interlayer water; (2) internal structure reconstruction; (3) dehydroxylation and amorphization of crystal structure; (4) recrystallization of amorphous solid and successive formation of CaB_2O_4 and then CaB_4O_7, the tetraborate. It has the monoclinic structure shown in Fig. 6.25.

Here, the calcium cations are in a face-centered position.

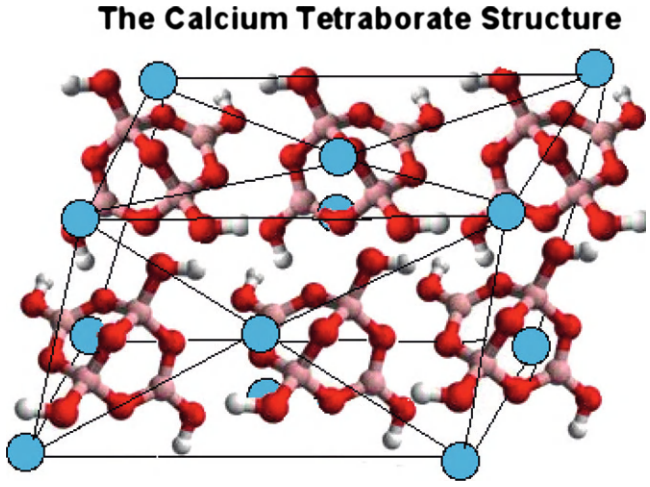

FIGURE 6.25

Thermal decomposition of "colemanite", Ca $[B_3O_4(OH)_3]H_2O$, monohydrate has been found to form calcium tetraborate when it is heated to high temperatures. The mode of decomposition was explored by thermal, X-ray, IR and optical microscopy methods at normal as well as at elevated temperatures. Investigation has revealed that thermal decomposition of colemanite occurs in the whole volume of the crystal and is divided into two independent stages: (1) formation of H_2O from OH groups and (2) breaking of H_2O and borate chains bonds and then removal of both kinds of water from the anhydrous phase of the preserved borate structure. Each process corresponds to a separate DTA peak, the second being accompanied also by loss of weight due to explosive water escape. This represents a rare event of dehydroxylation with distinct separation of H_2O formation and removal of water molecules from the parent substance.

The effect of mechanical treatment on the thermal decomposition of calcium borate, "colemanite"—$[CaB_3O_4(OH)_3]_2 \cdot H_2O$, a tetraborate, was studied by means of XRD, FTIR, SEM and thermal analysis methods. Grinding of colemanite causes the solid-state amorphization of this mineral, as a result of the destruction of its structure along the cleavage plane. The decrease in the particle size of the original material and the increase in its internal structural disorder affect the temperature and the magnitudes of the thermal effects accompanying the processes of dehydration and dehydroxylation. The diminishing values of the enthalpies of these processes may be a quantitative measure of the degree of amorphism of colemanite. This mineral is built of borate chains which are comprised of two tetrahedra and one triangle. Thermal decomposition proceeds within the temperature range of 300–370 °C by splitting off the hydroxy groups (−OH) to form water molecules at 320 °C. Next, the molecular water is removed at ca. 363 °C. This is accompanied by a gradual amorphism of the structure. "Pandermite", $Ca_2B_5O_8(OH)_3 \cdot 2H_2O$ belongs to the pentaborate group, which has a layered structure. The thermal decomposition of pandermite follows the same two-stage decomposition pattern. The first stage involves 3.5 mol of water at 438 °C, following by 0.5 mol of water at 438 °C. A rearrangement then takes place at 525 °C to form a tetraborate.

A pure calcium tetraborate, $Ca_2[B_2O_4(OH)_2] \cdot 0.5H_2O$, has been synthesized under hydrothermal conditions and characterized by XRD, FT-IR and TG as well as by chemical analysis. The molar enthalpy of solution of $Ca_2[B_2O_4(OH)_2] \cdot 0.5H_2O$ in $HC1 \cdot 54.582H_2O$ was determined. From a combination of this result with measured enthalpies of solution of H_3BO_3 in $HC1 \cdot 54.561H_2O$ and of CaO in $(HCl + H_3BO_3)$ solution, together with the standard molar enthalpies of formation of CaO(s), H_3BO_3(s) and H_2O(l), the standard molar enthalpy of formation of $Ca_2[B_2O_4(OH)_2] \cdot 0.5H_2O$ was obtained as −3,172.5 kJ/mol.

$(NH_4)_2Ca[H_4B_4O_9]_2 \cdot 8H_2O$ contains alternate layers of tetraborate anions and two of the water molecules. The structure is completed by the cations and the remaining water molecules. The space group and number of water molecules of hydration depend on the nature of the cation.

Calcium forms a number of borate minerals throughout the world. A hydrated form occurs naturally as the minerals:

"Ulexite" ($NaCaB_5O_6(OH)_6 \cdot 5H_2O$)
"Colemanite" ($CaB_3O_4(OH)_3 \cdot H_2O$)
"Nobleite" ($CaB_6O_9(OH)_2 \cdot 3H_2O$)
"Ginorite" [$Ca_2B_{14}O_{23} \cdot 8H_2O$]
"Fabianite" (CaB_3O_5OH)
"Calciborite" (CaB_2O_4)
and "priceite".

In addition, there are a large number of hydrolylated minerals containing calcium and borates. Some of these include:

Calciborite (calcium borate)
Chelkarite (hydrated calcium magnesium borate chloride)
Colemanite (hydrated calcium borate hydroxide)
Ekaterinite (hydrated calcium borate chloride hydroxide)
Fabianite (calcium borate hydroxide)
Frolovite (calcium hydroborate)
Ginorite (hydrated calcium borate)
Gowerite (hydrated calcium borate)
Hexahydroborite (hydrated calcium hydroborate)
Hilgardite (hydrated calcium borate chloride)
Hydroboracite (hydrated calcium magnesium borate hydroxide)
Hydrochlorborite (hydrated calcium borate chloride hydroxide)
Inderborite (hydrated calcium magnesium borate hydroxide)
Inyoite (hydrated calcium borate hydroxide)
Korzhinskite (hydrated calcium borate)
Kurnakovite (hydrated magnesium borate hydroxide)
Meyerhofferite (hydrated calcium borate hydroxide)
Nifontovite (hydrated calcium borate hydroxide)
Nobleite (hydrated calcium borate hydroxide)
Olshanskyite (calcium hydroborate)
Pentahydroborite (hydrated calcium hydroborate)
Priceite (calcium borate hydroxide)
Pringleite (hydrated calcium borate hydroxide chloride)
Probertite (hydrated sodium calcium borate hydroxide)

Ruitenbergite (hydrated calcium borate hydroxide chloride)
Shabynite (hydrated magnesium borate chloride hydroxide)
Sibirskite (calcium borate hydroxide)
Solongoite (calcium borate hydroxide chloride)
Takedaite (calcium borate)
Tertschite (hydrated calcium borate)
Tyretskite (hydrated calcium borate hydroxide)
Uralborite (calcium borate hydroxide)
Vimsite (calcium borate hydroxide)
Wardsmithite (hydrated calcium magnesium borate)
Vimsite—CaB_2O_2OH
Sibirskite—$Ca_2[(OH)(B_2O_4)(OH)]$
Parasibirskite—$Ca_2[B_2O_5]\cdot H_2O$
Fabianite—CaB_3O_5OH
Uralborite—$Ca_2[B_3O_3(OH)_5\cdot OB(OH)_3]$
Olshanskyite—$Ca_3\{(OH)(B[OH]_4])_2\}_2$
Frolovite—$Ca[B(OH)_4]_2$

Ulexite contains chains of sodium, water and hydroxide octahedrons linked in endless chains. The chains are linked together by calcium, water, hydroxide and oxygen polyhedra and massive boron units. The basic boron unit has a formula of $B_5O_6(OH)_6$ and a charge of -3. It is composed of three borate tetrahedrons and two borate triangular groups. The crystal system is triclinic and space group $\bar{1}$.

Colemanite, like other borates, is a complex mineral, that is found in playa lakes and other evaporite deposits. The basic structure of colemanite contains endless chains of interlocking $BO_2(OH)$ triangles and $BO_3(OH)$ tetrahedrons with the calcium ions, water molecules and extra hydroxides interspersed between the chains. The crystal system is monoclinic; 2/m.

Nobleite is monoclinic; space group is $P2_1/a$; lattice parameters are: $a = 14.56$ Å, $b = 8.01$ Å, $c = 9.83$ Å, $\beta = 111.75°$, $V = 1064.81$ Å^3 (calculated from unit cell) density = 2.095 g/cc.

Ginorite is monoclinic with $a = 13.37$ Å, $b = 14.36$ Å, $c = 12.26$ Å, $V = 2309.01$ Å^3, $\beta = 101.2°$.

Calcioborite is orthorhombic with $a = 8.38$ Å, $b = 13.82$ Å, $c = 5$ Å and $V = 579.06$ Å^3.

Takedaite has been proven to be a natural analog of synthetic $Ca_3B_2O_6$. The diffraction photographs showed takedaite to be trigonal with the possible space group of R3c or R3c. The unit-cell dimensions were $a = 8.638$ Å and $c = 11.850$ Å. Optically, the mineral was uniaxial negative with refractive indices omega = 1.726, $E = 1.630$, and the Vickers microhardness was 478 kg/mm^2.

Johachidolite, $CaAl[B_3O_7]$, (Cmma, $a = 9.767(2)$, $b = 11.723(3)$, $c = 4.3718(5)$ Å, $V = 408.3(1)$ Å^3, $Z = 4$) has been refined from a light-green gem-quality crystal from the Mogok gem-mining district in Myanmar. A fragment from the same gem was measured by electron microprobe and laser ablation inductively coupled plasma mass spectrometry, and is almost end-member composition with ca. 0.3 wt% ThO_2 and ca. 1000 ppm La^{3+} probably replacing Ca. Johachidolite has a very dense structure with all cations in maximum oxygen coordination. Boron is tetrahedrally coordinated and the tetrahedra form four- and six-membered rings that link to give a sheet, the only borate layer structure among minerals with only BO_4 tetrahedra. The interlayer space is filled by octahedrally coordinated Al and 10-coordinated Ca. Johachidolite, forming in boron-rich skarn or pegmatite, has never been synthesized. Other ternary compounds, synthesized from corresponding glass compositions, $CaAlBO_4$ and $CaAl_2B_2O_7$, are unknown as minerals and have B (three-coordinate), Al (tetrahedral), and Ca (octahedral) in their lowest known oxygen coordination. Johachidolite displays the structural characteristics of a mineral with high-pressure stability and has the triborate anion. $B_3O_7^{5-}$, as part of its structure.

Dirubidium calcium tetraborate octahydrate, $Rb_2Ca[B_4O_5(OH)_4]_2\cdot 8H_2O$, was prepared by reaction of Rb-borate aqueous solution with $CaCl_2$ and it's structure has been determined by single-crystal XRD data. It crystallizes in the orthorhombic system, space group $P2_12_12^1$ with unit-cell parameters, $a = 11.536$ Å, $b = 12.639$ Å, $c = 16.690$ Å; $Z = 4$, $V = 2433.5(8)$ Å^3. The structure contains alternate layers of $[B_4O_5(OH)_4]^{2-}$ polyanions separated by water molecules and Rb, Ca cations. The isolated $[B_4O_5(OH)_4]^{2-}$ is constructed from two $BO_3(OH)$ tetrahedron groups and two $BO_2(OH)$ triangular groups joined at common oxygen atoms. The two $BO_3(OH)$ tetrahedron groups are further linked by means of an oxygen bridge across the ring. The Ca^{2+} ion displays a coordination of seven, while the two nonequivalent Rb^+ ions display nine and seven coordination, respectively. Infrared and Raman (4000–400/cm) spectra of $Rb_2Ca[B_4O_5(OH)_4]_2\cdot 8H_2O$ were recorded at room temperature and analyzed. Fundamental vibration modes were identified and band assignments were made. The dehydration of this hydrated-mixed borate occurs in one step and leads to an amorphous phase which undergoes a crystallization at higher temperatures.

Calcium borates are available commercially in various sized lots. Most of the borates in the world are supplied by Rio Tinto Borax from the southern United States. The company was established by Francis Marion Smith in 1883 which was then known as The Harmony Borax Works. In 1872, Mr Smith found borates in the Nevada desert. Death Valley in California is famous for borate mining. The Atacama desert in Chile also contains mineable borate concentrations. Calcium borate's various forms are used as wood preservatives.

Strontium Borates

A number of various strontium borates are known. In general, alkaline earth metal borates exhibit framework structures made up of BO_4 tetrahedra and BO_3 triangles. Only a few compounds show isolated islands, and layered structural features and chain arrangements are generally absent. The structures of strontium and barium borates have been addressed in the past. Among the few strontium borates known are SrB_2O_4, the metaborate consisting of slightly puckered anionic layers with the composition $(B_2O_4)_n^{2n-}$, the tetraborate, SrB_4O_7, with a three-dimensional network structure, the pyroborate, $Sr_2B_2O_5$, composed of SrO_7 and SrO_6 polyhedra and isolated B_2O_5 groups, and the hexaborate, $Sr_3B_6O_9(OH)_6$, with infinite chains of composition $n[B_6O_9(OH)_6]^{6-}$.

Strontium metaborate can be synthesized by firing the oxides at 600 °C:

$$SrO + B_2O_3 + \text{heat} \Rightarrow Sr(BO_2)_2$$

The product has been assigned the CAS number of 13703-84-9. Its molecular weight is 173.2396 g/mol. Single crystals of strontium metaborate, SrB_2O_4, have been grown from the melt by the Czochralski method and a detailed structure analysis was carried out. The Sr atom is coordinated in a dodecahedral fashion by eight O atoms from the neighboring infinite planes consisting of borate molecules so that all O atoms in the borate molecules participate in the coordination with SrO distances ranging from 2.522 (7) to 2.728 (5) Å. It is orthorhombic with all boron atoms triangularly coordinated and the strontium atoms surrounded by eight oxygen polyhedra. The BO_3 groups lie in an infinite series of layers as shown in the following diagram shown on the next page. Here, the Sr atoms are dodecahedrally coordinated by eight O atoms from neighboring planes of borate molecules so that all of the O atoms in the BO_3 groups participate in the coordination (Fig. 6.26).

Sr–O distances range from 2.522 to 2.728 Å. Each B atom in the infinite chains is surrounded by three O atoms whose bond lengths vary from 1.328 to 1.395 Å. The BO_3 groups have an almost planar structure with B–O–B angles of 115.8 to 126.9°. The mean value is 120.0°. The BO_3 groups have almost a perfectly planar structure. The dihedral angle between planes is 161.1° so that the layers are slightly puckered. Thus, the strontium metaborate structure may be described as consisting of slightly puckered layers of $(B_2O_4)_n^{n2-}$ groups and Sr^{2+} atoms coordinated by eight neighboring O atoms from the $(B_2O_4)_n^{n2-}$ layers. The shortest Sr–Sr (x, $1-y$, $1.2+z$) distance is 3.8864 Å. The calcium homologue has the same structure except for distances.

This structure can be modified by application of pressure and temperature. SrB_2O_4 (III) and SrB_2O_4 (IV) are two high-pressure phases. The polycrystalline phase III was prepared at 15 kbar and 600 °C. It is orthorhombic with $a = 12.426$ Å, $b = 6.418$ Å and $c = 11.412$ Å, $d = 3.77$ g/cc, $Z = 12$ and has a symmetry of $Pna2_1$. It is isostructural with CaB_2O_4. The IV-phase, formed at 20 kbar and 600 °C, is cubic with $a = 8.222$ Å, $Z = 12$, $d = 4.38$ g/cc, and has the symmetry of Pa3. It, too, is isostructural with the Ca homologue. Further application of pressure causes decomposition to the tetraborate:

$$2\,SrB_2O_4 + \text{Pressure (600 °C)} \Rightarrow SrB_4O_7 + SrO$$

Both the III and IV-analogues could be reconverted to the low-pressure starting material by annealing them overnight at 750 °C in air. Crystals of the III-analog are birefringent whereas those of the IV-modification are isotropic.

The Raman spectra of these crystals, built solely of metaborate triangles, provide fingerprint identification of three distinct network types. Classified according to increasing cation field strength these are: rings with degenerate intra-annular bonds and D_3h symmetry, distorted rings with alternating intra-annular bonds and C_3h symmetry, as well as chains. The occurrence of

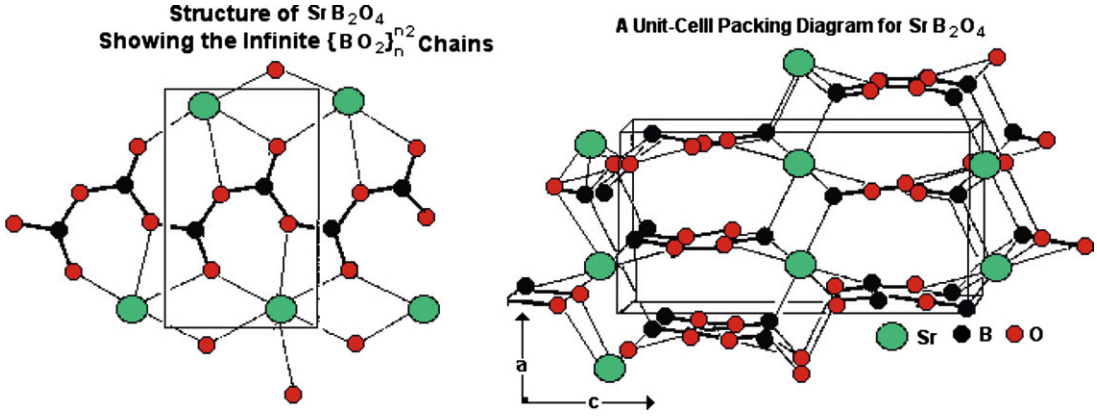

FIGURE 6.26

each network type has been associated with a characteristic range of cationic field strength. This approach led to the discovery of a hitherto unknown C_3h ring strontium metaborate crystal, with Sr^{2+} cations in 9- or 10-fold coordination to oxygen atoms. The Raman spectra of the mixed cation metaborates like $Ba_2Ca(B_2O_4)_3$ and $Ba_2Mg(B_2O_4)_3$ confirm their C_3h ring structure and clearly point to the fact that the synergetic effect of dissimilar cations to the metaborate network cannot be predicted by the additivity of their field strengths.

In another study, single crystals of strontium metaborate, SrB_2O_4, were obtained and their electrical and optical properties were studied. The wide optical transparency range of SrB_2O_4 extends from 100 to 3250 nm. The result of dielectric and thermal measurements confirms that no structural phase transition is exhibited in the temperature range from 50 to 1200 K (−223 to 927 °C). The dielectric dispersion above 600 K (327 °C) and a pronounced dielectric anomaly at 1136 K (863 °C), analyzed, using an equivalent circuit model, are a result of a low-frequency dielectric relaxation observed that gives rise to super ionic conduction at high temperature and by the space charge incurred by the softening, respectively.

Knudsen effusion mass spectrometry has been used to study the vaporization behavior of SrB_2O_4 (s or l) in the temperature range 1310 to 1442 K. Vapors of Sr(g), $SrBO_2$(g), BO(g), B_2O_2(g), and B_2O_3(g) have been identified. On the basis of their partial pressures, the molar enthalpies of formation and dissociation for $SrBO_2$(g) have been determined to be: $\Delta_f H_m$ ($SrBO_2$, gas, 298 K) = −(636 ± 19) kJ/mol and $\Delta_f H^0_m$ (Sr, gas, 298 K) + $\Delta_f H^o_m$ (BO_2, gas, 298 K) − $\Delta_f H^0_m$ ($SrBO_2$, gas, K) = (516 ± 17) kJ/mol, respectively. The molar enthalpies of formation for SrB_2O_4(s) formed from elements and from constituent oxides were found to be: $\Delta_f H^0_m$ ($SrBO_2$, s, 298.15 K) = −(2017 ± 29) kJ/mol and $\Delta_f H^0_m$ (SrB_2O_4, s, 298 K) − $\Delta_f H^0_m$ (SrO, s, 298 K) − $\Delta_f H^0_m$ (B_2O_3, s, 298 K) = −(153 ± 29) kJ/mol, respectively.

Two hydrated strontium borates, $SrB_2O_4 \cdot 4H_2O$ and $SrB_6O_{10} \cdot 5H_2O$, were synthesized by a liquid–phase precipitation method, and pure phase strontium tetraborate (SrB_4O_7) was obtained by high-temperature calcination. The phase compositions, morphology and the high-temperature sintering process of products were characterized by XRD, SEM, TG-DTA and chemical composition analysis. The effects of calcining temperature and holding time were investigated. The results showed that a process of dehydration, amorphization and crystallization exists in the calcination of these hydrated strontium metaborates. SrB_6O_{10} was unstable at 800 °C, and decomposed into SrB_4O_7 and liquid boric trioxide. Pure strontium tetraborate was obtained with $SrB_2O_4 \cdot 4H_2O$ and $SrB_6O_{10} \cdot 5H_2O$ compounds as raw materials, which were calcined for 4 h. With the increasing of reaction time, the degree of crystallization was improved at 900 °C, while the crystal structures were essentially unaffected.

Strontium orthoborate crystallizes in the rhombohedral system with two formula units in a cell of dimensions, $a = 6.695$ Å and $\alpha_R = 85.00°$ for $Sr_3B_2O_6$. The equivalent hexagonal lattice parameters are $a_H = 9.046$, $c_H = 12.566$ Å. In another study, the crystal parameters were determined as follows. The Rietveld refinement method was used to determine the structure of the compound $Sr_3(BO_3)_2$ and found it to be calcium orthoborate structure. The cell parameters are determined to be $a = b = 9.0405$ Å, $c = 12.5665$ Å, and Sr, B, and O occupy the 18e, 12c, 36f positions, respectively. It represents a new orthoborate structure type built of complex layers formed by BO_3 triangles sharing corners with Ga_2O_7 tetrahedral dimers and GaO_4OH square pyramids. The Sr atoms occupy both interlayer and intralayer sites (Fig. 6.27).

If a mixed crystal of Ba^{2+} and Sr^{2+} orthoborates is grown, the composition then varies from the normal orthoborate composition. Single crystals of strontium barium orthoborate, $(Sr_{1.36}Ba_{1.64})_3(B_3O_6)_2$, were grown by a high-temperature solution growth technique, and a detailed structure analysis was carried out. The orthoborate $(B_3O_6)^{3-}$ anion planar groups in this compound form infinite layers parallel to (001) plane, and Sr and Ba atoms are alternatively placed between the layers

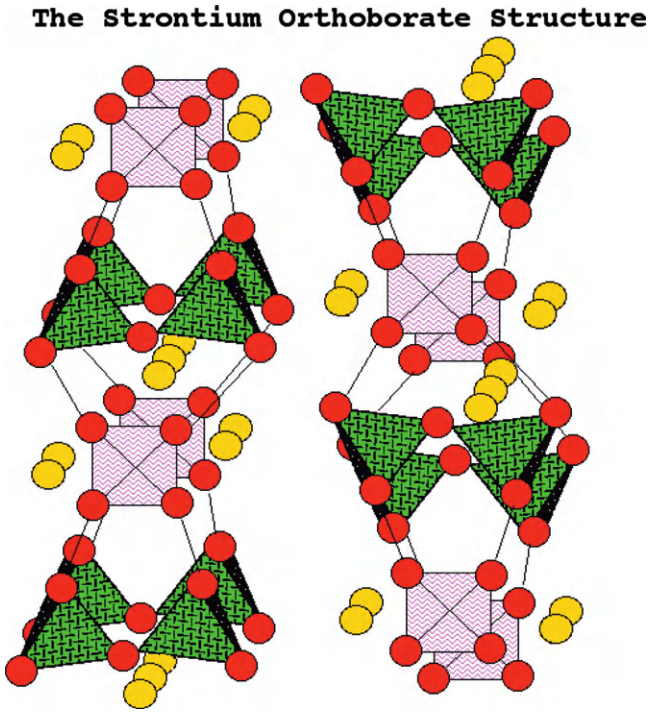

FIGURE 6.27

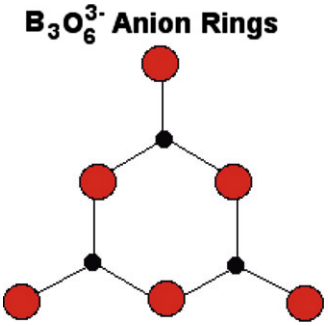

FIGURE 6.28

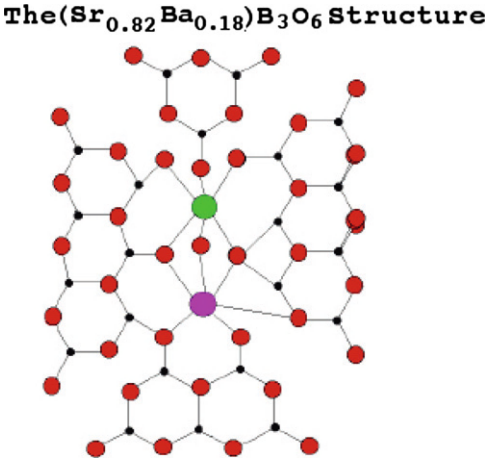

FIGURE 6.29

and are octahedrally coordinated by six O(2) atoms in the neighboring anion rings. This is shown in Fig. 6.28.

If a mixed crystal of Ba^{2+} and Sr^{2+} orthoborates is grown, the composition then varies from the normal orthoborate composition. Single crystals of strontium barium orthoborate, $(Sr_{1.36}Ba_{1.64})_3(B_3O_6)_2$, were grown by a high-temperature solution growth technique, and a detailed structure analysis was carried out. The orthoborate $(B_3O_6)^{3-}$ anion planar groups in this compound form infinite layers parallel to (001) plane, and Sr and Ba atoms are alternatively placed between the layers and are octahedrally coordinated by six O(2) atoms in the neighboring anion rings (Fig. 6.29).

In this structure, a metaborate molecule, $(B_3O_6)^{3-}$ anion ring, is completed by three BO_2 groups related by threefold rotation symmetry along the *c*-axis perpendicularly passing through the center of the molecular plane. The ring plane is planar within 0.078 Å with O_1-B = 1.410 Å, O_1-B_{ix} = 1.397 Å, and O_2-B = 1.306 Å showing double-bond character, whose geometry is very similar to that of $Sr_xBa_{3-x}(B_3O_6)_2$. The strontium atom is octahedrally coordinated by two O atoms in the anion groups with a $Sr\cdots O_2 = 2.5100$ Å, and the barium atom is also octahedrally coordinated by the same two O atoms but with two different coordination bond lengths $Ba\cdots O_2 = 2.7964$ Å and $Ba\cdots O_{2vi} = 2.738$ Å so that the two O atoms are participating in three coordinations with $Sr\cdots O_2\cdots Ba = 90.39°$, $Sr\cdots O_2\cdots Ba_{viii} = 131.05°$, $Ba\cdots O_2\cdots Ba_{viii} = 103°$. The sixfold coordination bond lengths of SrO_2 and $Ba\cdots O_2$ are very close to the respective 2.5801 Å and 2.76 Å bond lengths shown in international tables for X-Ray Crystallography (Vol III, Section 7). Therefore, the three-dimensional infinite molecular network is formed by the O_2 atom in the $(B_3O_6)^{3-}$ anion ring which plays a bridging role among Sr, Ba atoms, and the metaborate molecule.

Nonlinear optical crystals that enable to generate third and fourth harmonic generation of 1.064-mm wavelength of an Nd: YAG laser have become very important in providing UV light sources for the fabrication of very large scale integrated circuits by lithographic technique. For this purpose, much effort has been paid to develop borate crystals because the borates that are composed of BO_3 or BO_4 units are not only highly transparent in the UV spectral region, but also possess relatively large second-order nonlinear optical coefficients. A metaborate crystal containing $(B_3O_6)^{3-}$ anion-rings is one of such borates and is expected to show large second- and third-order nonlinear optical effects because of high nonlinearity of $(B_3O_6)^{3-}$ rings.

The physical and X-ray data of the $(Sr,Ba)_3(B_2O_3)_2$ compound as a crystal are given in the following Table 6.3.

Strontium pyroborate, $Sr_2B_2O_5$, has been synthesized by a high-temperature solution reaction. Crystals were grown from a mixture containing appropriate amounts of $SrCO_3$ and H_3BO_3, using KFB_4 as a flux. The mixture was thoroughly milled, heated in a platinum crucible in air to 1193 K (920 °C), and kept at that temperature for 15 h. The temperature was quickly quenched to 1053 K (880 °C) and slowly cooled from 1053 to 973 K (700 °C) at a rate of 0.011 K/h and then air quenched to room temperature. Colorless crystals were obtained.

Strontium pyroborate crystallizes in the monoclinic space group $P21/c$ with cell dimensions $a = 7.719$ Å, $b = 5.341$ Å, $c = 11.873$ Å, $\beta = 92.71°$, $V = 488.9$ Å^3, and $Z = 4$, $D_{calc} = 3.76$ g/cm^3. The structure comprises SrO_7 and SrO_6 polyhedra and B_2O_5 groups, as shown in the following Fig. 6.30.

The structure is based on Sr_4O_{19} tetramers and is composed of two $Sr(1)O_7$ and two $Sr(2)O_6$ polyhedra. These two polyhedra link by four shared O–O edges to form a double-chain extending along the *a*-direction. The double-chains link together to form sheets parallel to the *ac* plane by sharing O(4) atoms. These sheets stack along the *b*-direction to form the three-dimensional

framework by sharing O(1), O(2), and O(3) atoms. The $[B_2O_5]$ group bridges the adjacent double chains and adjacent sheets together. A similar structure to this compound is $Mg_2B_2O_5$. It is built from the Mg_4O_{18} tetramer sharing three edges and connected by the B atom to form chains extending along [010]. However, the tetramer itself is discrete and forms an infinite chain only by B atoms.

The electronic structure of $Sr_2B_2O_5$ has been calculated by the ZINDO/S (Zerner's Intermediate Neglect of Differential Overlap) method for this compound, and the dynamic refractive indices have been obtained in terms of INDO/SCI following combination with the sum-over-states method. The calculated energy gap is 4.26 eV between the upper valence band and lower conduction band, and the calculated average refractive index is 1.791 at a wavelength of 1.065 lm. The charge transfers from O^{2-} anion orbitals to Sr^{2+} cation orbitals make the significant contributions to linear polarizability in terms of analyses of atomic state density contributing to the valence and conduction bands.

Strontium perborate can be made by the reaction of sodium perborate on strontium chloride in solution:

$$SrCl_2\ (aq) + Na_2BO_3\ (aq) \Rightarrow Sr(BO_3)_2 \cdot 2H_2O + 2NaCl$$

It has the probable Lewis structure shown in Fig. 6.31.

However, in view of its Mg and Ca homologues and its higher costs, little interest in this compound has been shown by industry. Hence, little effort by academia has been forthcoming. Thus, the physical and chemical properties of strontium perborate have not been thoroughly explored. The above formula shows boron having a double-bonded oxygen atom and a linear structure. It is clear that the BO_3^- anion is not an orthoborate, BO_3^{3-}, since the B atom would have to be in a +5 state. Nor is it a BO_3^- triangular species since two of the oxygen atoms are available as oxidizing agents. Perhaps it has a cyclic or linear structure shown in Fig. 6.32.

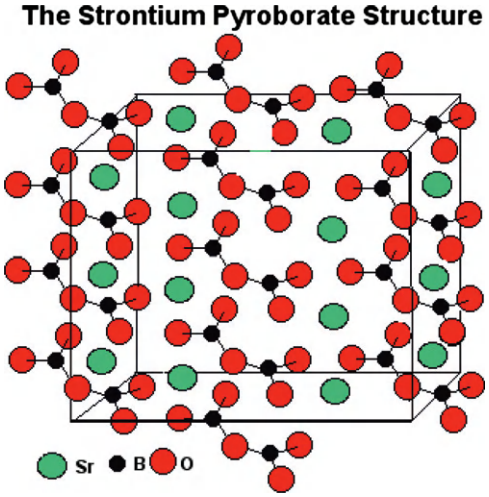

FIGURE 6.30

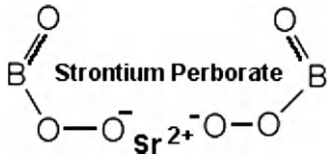

FIGURE 6.31

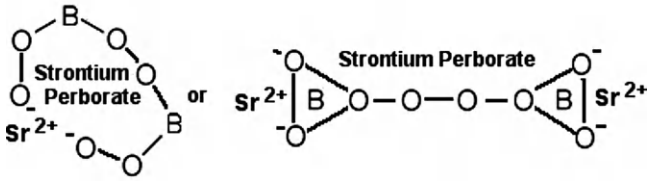

FIGURE 6.32

The actual formula would be $(SrBO_4)_2$, but this has not been firmly established.

Strontium tetraborate, SrB_4O_7, (SBO) has been investigated as a potential nonlinear optical material with excellent mechanical and optical properties such as a high power second harmonic generation (SHG) coefficient, high optical damage threshold, high hardness, etc. Additionally, the SBO crystals possess high UV transmittance at wavelengths down to about 130 nm. SrB_4O_7 congruently melts at 994 °C. The structure appears as a series of tetrahedrons (Fig. 6.33).

The structure consists of a three-dimensional borate network with channels parallel to the *a*- and *b*-axis with Sr ions located in these channels. All the boron atoms are tetrahedrally coordinated and all the tetrahedra are connected to each other by sharing corners. Four independent O atoms can be divided into two groups: O(1), O(2) and O(3) are linked to two B atoms with shorter O–B bonds (1.416–1.458 Å), while O(4) is linked to three B-atoms with longer O–B bonds (1.536–1.560 Å). The Sr atom is surrounded by nine oxygen atoms to form a capped cube-coordination environment (see Fig. 6.33). Although there are six-membered B–O rings in the borate network parallel to the *b*-axis, the rings do not belong to the "conjugated group" type. SBO crystals were not found to be hygroscopic.

SrB_4O_7 occurs in two polymorphs. The α-phase, $SrO{\cdot}2B_2O_3$ crystallizes below 1000 °C from a melt of the same composition. The orthorhombic crystals belong to the space group $Pmn2_1$ and have unit-cell dimensions $a = 10.711$ Å, $b = 4.427$ Å, $c = 4.235$ Å. The calculated density with two formula units in the cell is 4.02 g/cc. The asymmetric unit of β-SrB_4O_7, contains five Sr atoms (three located on a threefold rotation axis), 12 B and 21 O atoms. The structure is made up from BO_3 triangles and BO_4 tetrahedra in a 1:1 ratio. Pairs of BO_3 triangles are linked to BO_4 tetrahedra via common corners, forming chains. These chains are further linked to adjacent chains through corner sharing, leading to a three-dimensional framework with channels running parallel to [001]. The Sr^{2+} ions reside in the channels and exhibit strongly distorted polyhedra. The density of the β-polymorph is considerably lower than that of α-SrB_4O_7, which is constructed solely from BO_4 tetrahedra β-SrB_4O_7 has the molecular weight of 242.86 g/mol, it is trigonal with space group = P3, $a = 17.145$ Å, $c = 4.2527$ Å, $V = 1082.61$ Å^3, $Z = 9$. Strontium tetraborate is transparent across the far UV to far infra-red spectrum (Fig. 6.34).

Thus, it has great potential for use as lens components in optical devices such as those used for the fabrication of very large scale integrated circuits by a lithographic technique.

The luminescence properties of Ce^{3+} ions in strontium hexaborate $Sr(B_3O_5)_2$, excited in the 3.5- to 18-eV (68–365 nm) region, has been studied. At least two types of luminescent Ce^{3+} centers are observed in solid solutions of composition $Sr_{1-x}Ce_xB_6O_{10}$ ($x < 0.01$). One of them is formed by direct replacement of strontium ions without local charge compensation, and the second center is an associate of a Ce^{3+} cerium ion and a strontium vacancy, V_{Sr}^{+}. It is shown that the dominant charge-compensation mechanism on the cation sublattice includes the formation of one strontium vacancy for each two Ce^{3+} ions introduced into the lattice.

Strontium tetraborate compounds have been prepared by pouring slowly a concentrated solution of $Sr(NO_3)_2$ in water into another concentrated solution in water of $Na_2B_4O_7{\cdot}10H_2O$. The reaction brings about white flakes which precipitate. After vacuum filtration, the material has been dried in an oven at 100 °C for 12 h and afterward baked at 900 °C for 20 h. XRD experiments indicates that the final product is crystalline strontium tetraborate.

A number of phosphors based upon the matrix, SrB_4O_7, have been investigated. Strontium tetraborate when activated by Eu^{2+}, is used as a phosphor in "black-light" lamps for tanning salons. Its emission band is very narrow (~20 nm) as shown in the following Fig. 6.35.

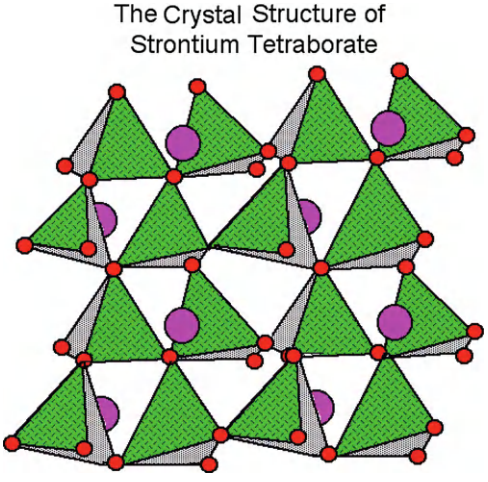

FIGURE 6.33

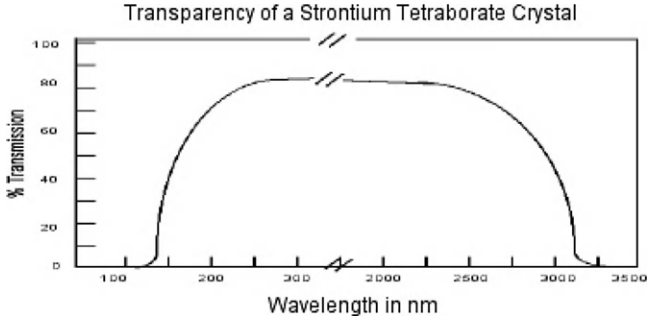

FIGURE 6.34

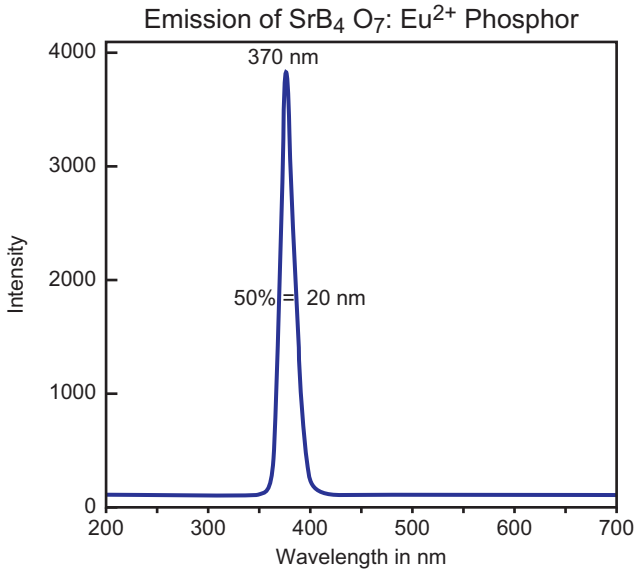

FIGURE 6.35

The luminescence properties of Eu(II) borates and Eu^{2+}-activated Sr borates have been studied, e.g. $Sr_{1-x}Eu_xB_2O_4$, $Sr_{1-x}Eu_xB_4O_7$ and $Sr_{1-x}Eu_xB_6O_{10}$. It was found that $Sr_{1-x}Eu_xB_4O_7$ consisting of a three-dimensional network of BO_4 tetrahedra gave a remarkably stronger emission than the other compounds consisting of BO_3^{3-} ions, $B_2O_5^{4-}$ ions, $(BO_2)\infty$ chains or a $(B_3O_5)\infty$ network. This was understood by considering their crystallographic properties and with help of the Dexter theory. The band emissions of the high-pressure phases of EuB_2O_4 and $SrB_2O_4Eu^{2+}$ are assigned to $(4f)^7$-$(4f)^6(5d)$ transitions of the Eu^{2+} ions.

The phosphor typically used for a near 368- to 371-nm UV emission peak is either europium-doped strontium fluoroborate ($SrB_4O_7F:Eu^{2+}$) or europium-doped strontium tetraborate ($SrB_4O_7:Eu^{2+}$) while the phosphor used to produce a peak at around 350–353 nm is lead-activated barium disilicate ($BaSi_2O_5:Pb^+$), sometimes called "Blacklight Blue" lamps that peak at 365 nm.

Bi^{2+}-doped SrB_4O_7 and SrB_6O_{10} for use as orange and red phosphors in white light-emitting diodes has been studied. In both compounds, absorption due to $^2P_{1/2}$–>$^2S_{1/2}$ in Bi^{2+} could be observed and quantified. The emission redshift from SrB_4O_7 to SrB_6O_{10} and their different phonon satellite spectra are attributed to the enhancement of phonon–electron interaction. Investigation of the reduction mechanism of Bi^{3+} to Bi^{2+} suggests that in oxidizing atmosphere, Bi^{2+} can only be stabilized on Sr^{2+} sites only in such lattices that are dominated by tetrahedrally coordinated boron.

A number of strontium borate minerals are known. Most of these are hydroxylated and/or hydrated.

Strontioborite (strontium borate hydroxide)
Strontioginorite (hydrated strontium calcium borate)
Sussexite (magnesium borate hydroxide)
Szaibelyite (magnesium borate hydroxide)
Tunellite (hydrated strontium borate hydroxide)
Veatchite (hydrated strontium borate hydroxide)

Tunellite, $(SrB_6O_9(OH)_2\cdot 3H_2O)$, is monoclinic with lattice parameters: space group = $P2_11a$; $a = 14.415(3)$ Å, $b = 8.213(1)$ Å, $c = 9.951(2)$ Å, $\beta = 114.05°$, $V = 1075.83$ Å^3. The crystal structure contains infinite sheets composed of polymerized borate polyanions, with Sr^{2+} cations and water molecules filling available spaces in and near the sheets. Each Sr^{2+} is coordinated by 10 oxygen atoms at an average distance of 2.74 Å. Adjacent sheets are held together solely by bonds to water molecules. The polymerized borate polyanions are composed of individual borate groups, each group containing three B–O tetrahedra and three B–O triangles. These polyhedra link at corners so that one oxygen is shared by all three tetrahedra, and three six-membered B–O rings result, each made up of two tetrahedra and one triangle. This compound has the same structure as that of the Ba analog (shown below).

Strontioborite has the empirical formula of $(SrB_8O_{11}(OH))_4$.

Strontioginorite has the empirical formula of $([Sr,Ca]B_{14}O_{23}\cdot 8H_2O)$.

Veatchite is an unusual strontium borate, with the chemical formula $Sr_2B_{11}O_{16}(OH)_5\cdot H_2O$. There are two known polymorphs, Veatchite-A and Veatchite-p. Veatchite was discovered in 1938, at the Sterling Borax mine in Tick Canyon, in California. Veatchite is named to honor John Veatch the first person to detect boron in the mineral waters of California.

A new compound, $Sr_4B_{14}O_{25}$ $(4SrO\cdot 7B_2O_3)$, corresponding to an oxide ratio of 4: 7 has been identified and synthesized in the $SrO–B_2O_3$ system. The crystal structure of the compound has been determined (space group $Cmc21$, $a = 7.734(5)$ Å, $b = 16.332(5)$ Å, $c = 14.556(5)$ Å, $Z = 4$). The borate anions form a three-dimensional framework consisting of borate groups of two types: three-ring structures (3B,6O) and BO_3 triangles (Fig. 6.36).

Layers formed by 14-membered rings composed of boron-oxygen tetrahedra and triangles packed within the layer according to the herringbone pattern can be distinguished in the framework. The strontium atoms

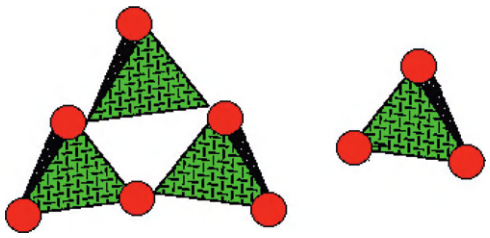

FIGURE 6.36

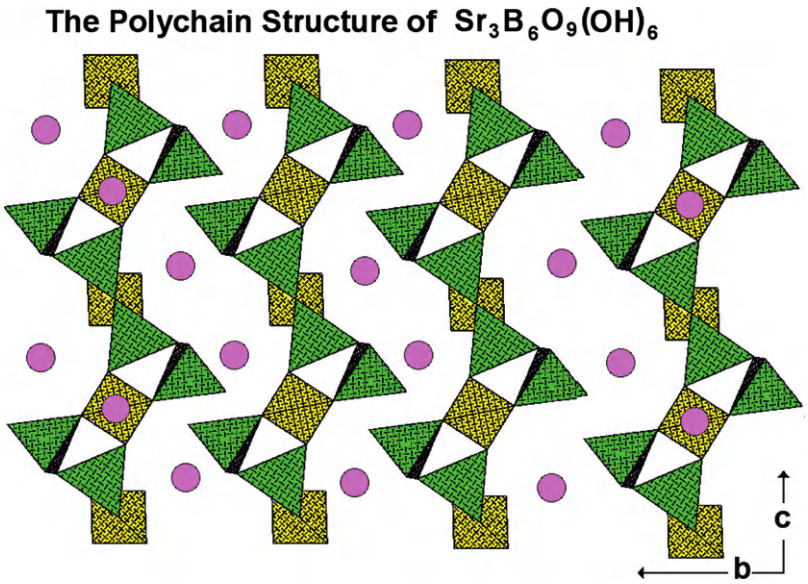

FIGURE 6.37

are located on the mirror symmetry planes between these layers. The compound is metastable and decomposes, on long-term storage, into strontium diborate and metaborate.

The compound, $(SrBe)_2B_2O_5$, (SBBO) has been reported to be transparent below 200 nm, and exhibits a large SHG coefficient. Significant difficulties in the flux growth of large, high-quality crystals have prevented this material from further development. Recently, large crystals of SBBO have been grown by a hydrothermal synthetic method for the first time, and their physical properties have been characterized. SBBO remains the best material found to date for this purpose.

Strontium also forms a number of hydrated borates. Among these is $Sr_3B_6O_9(OH)_6$, which is a polychain (Fig. 6.37).

This structure and composition has no analogues among the other alkaline earths except that of Ba which is identical. It is not a hydrate but is hydoxylated. The BO_3 triangles are actually $[BO_2(OH)]$ groups.

The following shows the arrangement of the individual borate anions $[BO_2(OH)]_2$ in $SrBO_2(OH)$ groups (Fig. 6.38).

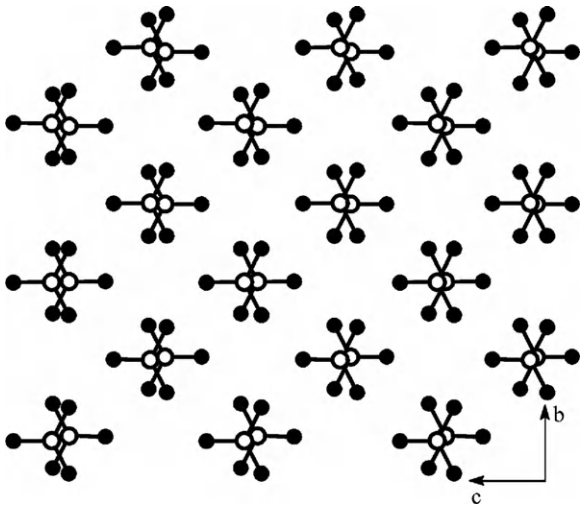

FIGURE 6.38

The open circles are boron atoms, the solid ones are oxygen atoms. Hydrogen atoms are not shown. The eightfold-coordinated Sr atom presents regular Sr–O bond distances between 2.557 and 2.862 Å (mean, 2.645 Å). Comparable values have been encountered in other Sr oxide structures. The B triangles are connected by common edges or corners to SrO_8 polyhedra. Each Sr shares only one edge of its coordination polyhedron with a neighboring BO_3 triangle, while all other O atoms of this particular SrO_8 polyhedron are corner shared with other BO_3 units. The structure of compound 2 contains anionic infinite chains extending along the *a*-direction, with a composition of $[B_6O_9(OH)_6]^{n6-}$ built up from nonplanar six-membered B_3O_3 rings, which are found to join together by sharing B atoms (Fig. 6.4). In each B_3O_3 ring, all the three B atoms are bonded to four oxygen atoms. The B–O bond distances range from 1.444(4) to 1.523(5) Å (average, 1.479 Å), comparable with the normal average tetrahedral B–O distance observed in the literature.

The crystallization of strontium borate glasses containing 16.7–43.0 mol% SrO was investigated. New crystalline compounds of the hypothetical compositions $2SrO{\cdot}3B_2O_3$ (metastable) and $SrO{\cdot}5B_2O_3$ (stable below

750 °C), as well as the metastable diborate modification β-$SrO \cdot 2B_2O_3$, were discovered, and their X-ray powder diffraction data are obtained. It was demonstrated that, with a deficit of strontium oxide, the $4SrO \cdot 7B_2O_3$ compound forms solid solutions. Strontium triborate $SrO \cdot 3B_2O_3$, which was previously prepared only through the dehydration of crystal hydrates, was produced by crystallizing certain glasses. The thermal stability of this compound was studied. The influence of the ease of dispersion on the stability of different crystalline phases was discussed. Variants of the phase diagram for the $SrO \cdot B_2O_3$ system in the case of monolithic and dispersed samples were proposed from analyzing the experimental results and data available in the literature.

Various strontium borates are available commercially from a number of suppliers worldwide.

Barium Borates

In general, alkaline earth metal borates exhibit framework structures made up of BO_4 tetrahedra and BO_3 triangles. Only a few compounds show isolated islands, and layered structural features and chain arrangements are usually absent. Previously reported barium borates include:

BaB_2O_4 containing isolated borate anions $(B_3O_6)^{3-}$
BaB_4O_7 and BaB_8O_{13}, with a framework structure
$Ba[B(OH)_4]2H_2O$
$Ba[B(OH)_4]_2$ containing discrete tetrahedral $B(OH)_4$ groups,
$Ba_2[B_5O_8(OH)_2](OH)$,
sheet structures of $Ba[B_5O_8(OH)](OH) \cdot H_2O$
$Ba_5[B_{20}O_{33}(OH)_4] \cdot H_2O$
Barium borate $Ba_3(B_6O_9)(OH)_6$, containing polyborate chains.

If BaO and B_2O_3 are heated together at various mol-ratios, four compounds are obtained. The phase diagram is shown in Fig. 6.39.

One compound is described as BaB_8O_{13} but appears to be a ditetraborate, $Ba(B_4O_7)_2$.

Barium metaborate, also called barium diborate, barium boron oxide, or (as an optical crystal) BBO (BaB_2O_4 or $Ba(BO_2)_2$) is available as a hydrate or dehydrated. Its molecular weight is 222.9526 g/mol and its density is 3.85 g/cc. Its melting point is 1051 °C and it is soluble in water. Barium diborate is a biocide registered in USA since 1960 as a broad-spectrum bactericide and fungicide. It is added to paints, coatings, adhesives, plastics, and paper and paper products. Barium metaborate can be prepared by reaction of an aqueous solution of boric acid with $Ba(OH)_2$. The prepared γ-BBO contains water of crystallization that cannot be completely removed by drying at 120 °C. Dehydrated γ-BBO can be prepared by heating to 300–400 °C. Further heating at about

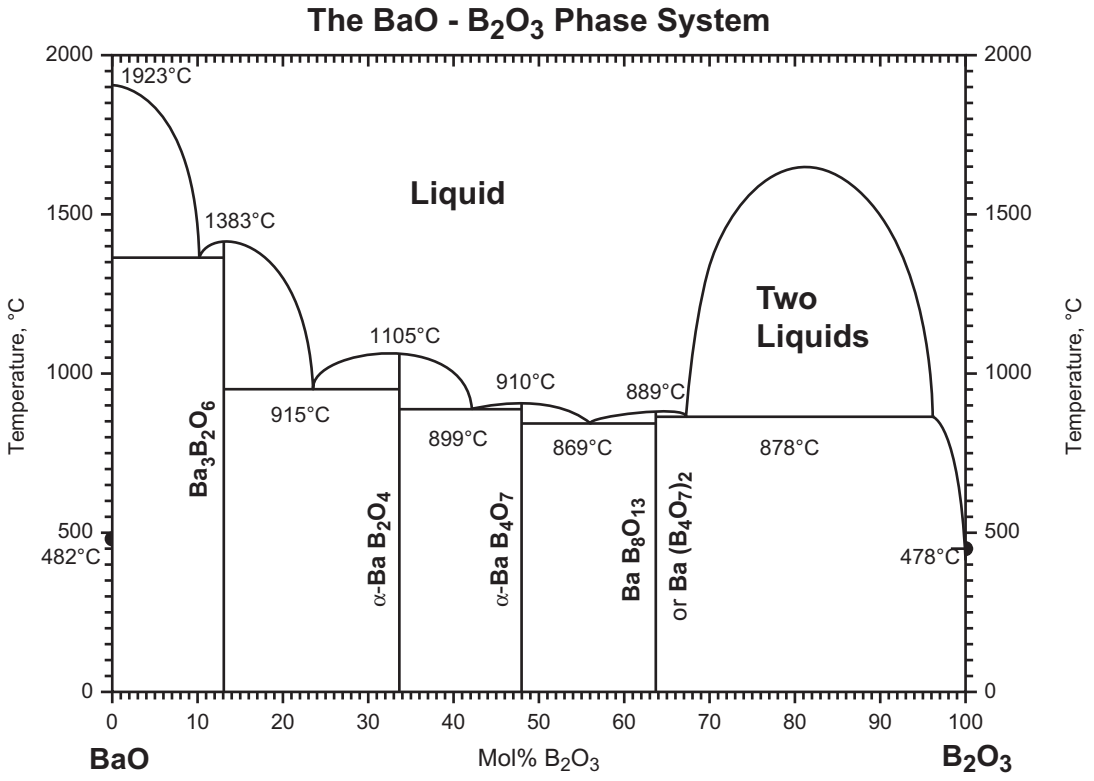

FIGURE 6.39

600–800 °C causes complete conversion to β-BBO. BBO prepared by this method does not contain trace amounts of BaB_2O_2. β-BBO is a nonlinear optical material which is used as a crystal to double the frequency of many lasers.

Barium metaborate can also be prepared by a soluble barium compound and sodium metaborate. Barium borate monohydrate is prepared at 20 °C from the solution of $BaCl_2$ and $Na_2B_2O_4$. The solution is evaporated to obtain crystals. It is a white powder. It is used as an additive to paints as a flame retardant, mold inhibitor and corrosion inhibitor. It is also used as a white pigment. The solubility of barium borate is a disadvantage when used as a pigment. Silica-coated powders are available. The alkaline properties and the anodic passivity properties of the borate ion enhance the anticorrosion performance. Commonly available barium metaborate pigment comes in three grades; Grade I is a barium metaborate itself, grade II is compounded with 27% zinc oxide, and grade III is compounded with 18% of zinc oxide and 29% calcium sulfate. Barium borate shows synergistic performance with zinc borate as a pigment.

Alpha barium metaborate, α-BaB_2O_4, the high-temperature phase, is an optical material with high birefringence and very wide optical transmission window from about 189 to 3500 nm. It has good mechanical properties and is a suitable material for high-power UV polarization optics. It has, in many cases, replaced calcite, TiO_2, $LiNbO_3$ in Glan–Taylor prisms, beam splitters and other similar optical elements. It is not hygroscopic and its MOHs hardness is 4.5. Its damage threshold is high at 1 GW/cm^2 at 1064 nm and 500 MW/cm^2 at 355 nm. Its density is 3.85 g/cm^3.

The low-temperature form of BaB_2O_4 crystallizes in the trigonal crystal system, space group R3c, with six formula units in the cell of dimensions $a = 8.380(4)$ Å and $\alpha = 96.65(4)^\circ$ (hexagonal cell: $a = 12.519$ Å, $c = 12.723$ Å). The structure is closely related to the high-temperature form, α-BaB_2O_4, containing nearly planar $[B_3O_6]^{3-}$ anions. Different is the coordination of the barium atom. In this case, it is surrounded by eight oxygen atoms in an irregular polyhedron.

Barium metaborate dihydrate can be prepared from the solution of $BaCl_2$ and $Na_2B_2O_4$ at 90–95 °C. After cooling to room temperature, a white powder is precipitated. Barium metaborate dihydrate loses water at above 140 °C. It is used as a flame retardant for paints, textiles, and paper.

Vapor formation in the BaO–B_2O_3 system was studied by high-temperature mass spectrometry. The equilibrium reactions with participation of gaseous barium metaborates were determined. The standard enthalpies of formation of gaseous BaB_2O_4(gas) and $BaBO_2$(gas) of -1424 ± 28 and 598 ± 15 kJ/mol, respectively, were evaluated.

Thin films of BBO can be prepared by MOCVD (Metal oxide-chemical vapor deposition) from barium(II) hydro-tri(1-pyrazolyl)borate. Different phases can be obtained depending on deposition temperatures. Thin films of β-barium metaborate can be prepared by a sol–gel synthesis. Alpha (and to less degree beta) barium metaborate crystals can be used as radiative neutron detectors.

Barium metaborate is used as a flux in some $BaTiO_3$ and $PbZrO_3$ EIA-Class 2 dielectric ceramic formulations for ceramic capacitors in an amount of about 2%. The barium–boron ratio is critical for flux performance; BaB_2O_2 content adversely affects the performance of the flux.

Transparent crystalline crystal materials can exhibit different kinds of optical nonlinearities that are associated with a nonlinear polarization. Such media with a nonlinearity are mainly used for parametric optical frequency conversion and other electro-optic modulators, including those which exhibit the Kerr effect, the Raman effect and four-wave mixing. In essentially all cases, artificial (rather than naturally occurring) crystals are used. There are a number of borates, the most important ones being lithium triborate (LiB_3O_5 = LBO), cesium lithium borate (CLBO, $CsLiB_6O_{10}$), β-barium borate (β-BaB_2O_4 = BBO), strongly hygroscopic, often used in Pockels cells. These can be used for generating and frequency-converting laser light. Less frequently used are strontium beryllium borate ($Sr_2Be_2B_2O_7$ = SBBO) and $K_2Al_2B_2O_7$ (KAB), because their band gap energy is relatively high, the crystals are relatively resistant to UV light, and there are suitable phase-matching options. Borates such as LBO and BBO also work well in broadly tunable optical parametric oscillators and optical parametric chirped pulse amplification.

DTA and visual polythermal analysis are used to study phase equilibria in the BaO–BaB_2O_4 system. The following compounds are formed in the system: $Ba_5B_4O_{11} = 5BaO \cdot 2B_2O_3$ (which melts peritectically at 1170 ± 10 °C), $Ba_3(BO_3)_2$ (which melts congruently at 1390 ± 10 °C), and $Ba_4B_2O_7 = 4BaO \cdot B_2O_3$ (which decomposes in the solid state at 1190 ± 10 °C).

Barium orthoborate has the formula of $Ba_3(BO_3)_2$. A mass spectrometric Knudsen effusion method has been used for the study of the vaporization behavior of $Ba_3B_2O_6$(solid) in the temperature range 1434 to 1630 K. Vapor species of Ba(gas), $BaBO_2$(gas), BO(gas), B_2O_2(gas), and B_2O_3(gas) have been found. From their partial pressures, the molar enthalpies of formation and dissociation for $BaBO_2$(gas) have been determined to be:

$$\Delta_f H^0_m(BaBO_2,\ \text{gas},\ 298.15\ \text{K}) = -(633 \pm 21)\text{KJ/mol}$$

$$\Delta_f H^0_m(\text{Ba, gas, } 298.15\ \text{K}) + \Delta_f H^0_m(BO_2, \text{gas}, 298.15\ \text{K}) -$$

$$\Delta_f H^0_m(BaBO_2, \text{ gas}, 298.15\ \text{K}) = (524 \pm 18)\text{KJ/mol},$$

The molar enthalpies of formation for $Ba_3B_2O_6$(s) from the elements and from the constituent oxides were found to be:

$$\Delta_f H^0_m(Ba_3B_2O_6,\ \text{solid}, 298.15\ \text{K}) = -(3469 \pm 50)\text{KJ/mol}$$

$$\Delta_f H^0_m\{(\text{BaO}, \text{solid}, 298.15\ \text{K}) - \Delta_f H^0_m(B_2O_3, \text{solid}, 298.15\ \text{K})\} = -(552 \pm 50)\text{KJ/mol},$$

A novel anhydrous, noncentrosymmetric orthoborate, $Ba_3(BO_3)_2$, has been prepared and its crystal structure determined by XRD of a single crystal (Fig. 6.40).

The material crystallizes in the orthorhombic system with $a = 15.068(2)$, $b = 8.720(2)$, and $Z = 8$; the space group is $Pca2_1$. The structure is composed of layers of BaO_4 tetrahedra and BO_3 triangles connected through shared oxygen vertices; these layers are connected by additional interleaving BO_3 triangles and barium atoms. This structure is identical to that of strontium orthoborate.

If a mixed crystal of Ba^{2+} and Sr^{2+} orthoborates is grown, the composition then varies from the normal orthoborate composition. Single crystals of barium strontium orthoborate, $(Ba_{1.64},Sr_{1.36})_3(B_3O_6)_2$, were grown by a high-temperature solution growth technique, and a detailed structure analysis was carried out. The orthoborate, $(B_3O_6)^{3-}$ anion planar groups in this compound form infinite layers parallel to (001) plane, and Sr and Ba atoms are alternatively placed between the layers and are octahedrally coordinated by six O(2) atoms in the neighboring anion rings. In this structure, a metaborate molecule, $(B_3O_6)^{3-}$ anion ring, is completed by three BO_2 groups related by threefold rotation symmetry along the *c*-axis perpendicularly passing through the center of the molecular plane. The ring plane is planar within 0.078 Å with O_1-B = 1.410 Å, O_1-B_{ix} = 1.397 Å, and O_2-B = 1.306 Å showing double-bond character, whose geometry is very similar to that of $Sr_xBa_{3-x}(B_3O_6)_2$. The strontium atom is octahedrally coordinated by two O atoms in the anion groups with a $Sr\cdots O_2 = 2.5100$ Å, and the barium atom is also octahedrally coordinated by the same two O atoms but with two different coordination bond lengths $Ba\cdots O_2 = 2.7964$ Å and $Ba\cdots O_{2vi} = 2.738$ Å so that the two O atoms are participating in three coordinations with $Sr\cdots O_2\cdots Ba = 90.39°$, $Sr\cdots O_2\cdots Ba_{viii} = 131.05°$, $Ba\cdots O_2\cdots Ba_{viii} = 103°$ (Fig. 6.41).

The sixfold coordination bond lengths of SrO_2 and $Ba\cdots O_2$ are very close to the respective 2.5801 Å and 2.76 Å lengths shown in International tables for X-Ray Crystallography Vol. III.7). Therefore, the three-dimensional infinite molecular network is formed by the O_2 atom in the $(B_3O_6)^{3-}$ anion ring which plays a bridging role among Sr, Ba atoms, and the metaborate molecule.

Barium pyroborate can be prepared by the reaction of the oxides at high temperature:

$$2\text{BaO} + B_2O_3 + \text{heat} \Rightarrow Ba_2B_2O_5$$

Crystals can be grown from a mixture containing appropriate amounts of $BaCO_3$ and H_3BO_3, using KFB_4 as a flux. The mixture is thoroughly milled, heated in a platinum crucible in air to 1193 K (920 °C), and kept at that temperature for 15 h. The temperature is then

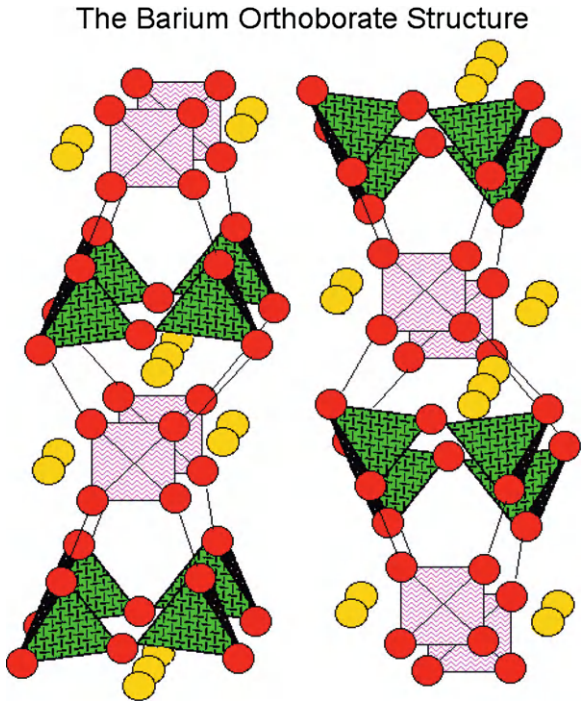

FIGURE 6.40

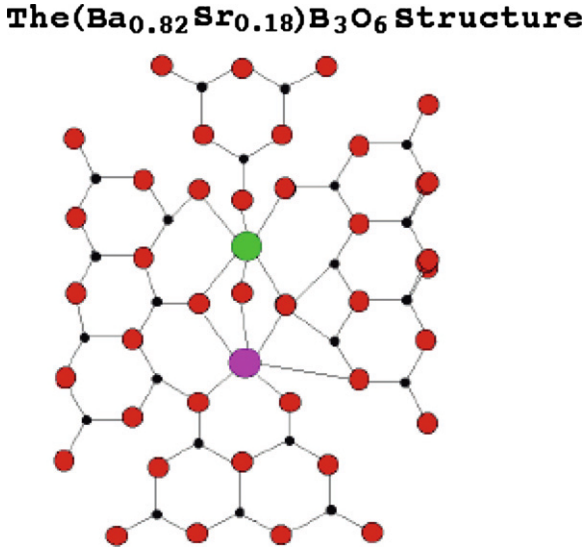

FIGURE 6.41

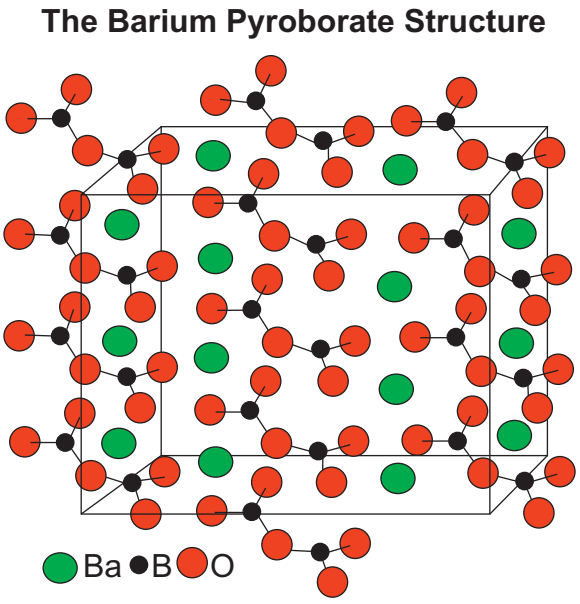

FIGURE 6.42

quickly quenched to 1053 K (880 °C) and slowly cooled from 1053 to 973 K (700 °C) at a rate of 0.011 K/h and then air quenched to room temperature. Colorless crystals are obtained. The structure is monoclinic (Fig. 6.42).

This structure is identical to that of the Sr-homologue. The noncentrosymmetric pyroborate $Ba_2B_2O_5$ crystallizes in the monoclinic space group C2 with a cell of dimensions $a = 6.485$ Å, $b = 9.165$ Å, $c = 3.971$ Å, and $\beta = 96.14°$. It is composed of highly distorted $[BaO_4]$ squares and double-triangular $[B_2O_5]$ groups that are connected to form infinite two-dimensional layers. The layers are stacked parallel to (001), and the Ba atoms interleave successive layers. Parallel alignment of the pyroborate groups is conductive to high efficiency for optical frequency conversion. The magnetic moment at 22 °C is $1.69 \pm 0.03\ \mu_B$.

Barium perborate was prepared by the reaction of boric acid in solution with barium peroxide as early as 1875:

$$BaO_2\ (aq) + H_2BO_3\ (aq) \Rightarrow BaB_2O_6 \cdot 3H_2O\ (solid)$$

The heptahydrate was also reported in 1898. Undoubtedly, the difference is in the solution temperature used to prepare this salt. It is unstable and decomposes to the metaborate plus oxygen gas:

$$BaB_2O_6 \cdot 3H_2O \Rightarrow BaB_2O_4 + 3H_2O\ (gas) + O_2\ (gas)$$

In order to obtain a usable product that is stable and not subject to slow degradation, it is necessary to maintain a reaction temperature not lower than 40 °C or over 60 °C. At lower temperatures, the product tends to decompose readily whereas at higher temperatures,

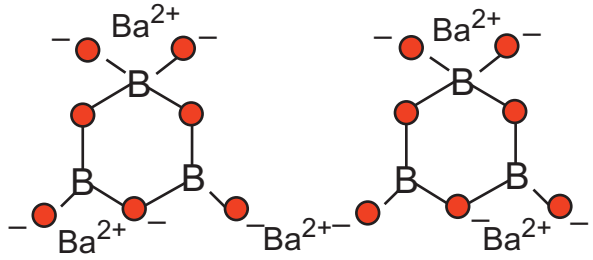

FIGURE 6.43

the peroxide grouping, $(BO_3)_2^{2-}$ tends to decompose in solution. Thus, at $T > 60$ °C, it is difficult to obtain a product having a suitable amount of active oxygen.

Perhaps this is the reason why barium perborate has not found usage as an oxidizing agent in industry. Both the Mg- and Ca-homologues are much more stable, are cheaper, and have found various niches of usage.

The compound, barium triborate, involves the anion $B_3O_7^{5-}$ and would have the formula, $5BaO \cdot 3B_2O_3 = Ba_5B_6O_{14}$ or $Ba_5(B_3O_7)_2$. This would have the Lewis structure shown in Fig. 6.43.

Single crystals of the noncentrosymmetric barium borate, $Ba_2B_{10}O_{17}$, have been grown by slowly cooling a stoichiometric melt. The material crystallizes in the triclinic space group P1 with cell parameters $a = 9.858(1)$, $b = 9.990(1)$, $c = 6.706(1)$ Å, $\alpha = 96.79°$, $\beta = 106.64°$, and $\gamma = 76.89°$. The structure is a new type characterized by a condensation of B_3O_7 rings and BO_3 triangles. A calculation of the second-order nonlinear susceptibility coefficients on the basis of the orientations of the tetrahedral and triangular borate groups in the rings and triangles has yielded a maximum coefficient of $d_{11} = 0.2$ pm/V. This result is consistent with the measured second-harmonic signal—0.5 × KDP. A partial solid solubility of Sr in the host—$Ba_{2-x}Sr_xB_{10}O_{17}(0 < x \leq 0.25)$—has also been observed.

$B_3O_7^{5-}$ rings are also noted in bismuth-containing barium borate compositions. Bismuth, Bi^{3+}, is present as a "bismuthate". Single crystals of a the compound, $BaBi_2B_4O_{10}$, were grown by cooling a melt having a stoichiometric composition. The crystal structure of the compound has been solved by direct methods. It is monoclinic, space group $P2_1/c$, $a = 10.150$ Å, $b = 6.362$ Å, $c = 12.485$ Å, $\beta = 102.87°$, $V = 786.0$ Å^3, $Z = 4$. The structure is based upon anionic thick layers that are parallel to (001). The layers can be described as built from alternating novel borate $[B_4O_{10}]_\infty^{8-}$ chains and bismuthate $[Bi_2O_5]_\infty^{4-}$ chains extended along *b*-axis. The borate chains are composed of $[B_3O_7]^{5-}$ triborate groups of three tetrahedra and single triangles with a $[BO_2]^-$ radical. The borate chains are interleaved along the *c*-axis with rows of the Ba^{2+} cations so that the Ba atoms are located within the layers. The layers are connected by two nonequivalent Ba–O bonds as well as

by two equivalent Bi–O bonds with bond valences in the range of 0.2–0.3 e.u.

Thermal expansion of $BaBi_2B_4O_{10}$, studied by high-temperature X-ray powder diffraction in the temperature range of 20–700 °C (temperature step 30–35 °C), shows that it is highly anisotropic. While the *b* and *c* unit-cell parameters increase almost linearly on heating, temperature dependencies of α parameter and β monoclinic angles show nonlinear behavior. As a result, on heating, orientation of the thermal expansion tensor changes, and bulk thermal expansion increases from $20 \times 10^{-6}/°C$ at the first heating stage up to $57 \times 10^{-6}/°C$ at 700 °C that can be attributed to the increase of thermal mobility of heavy Bi^{3+} and Ba^{2+} ions.

Barium tetraborate has been studied extensively. The structure of BaB_4O_7 has been determined from the use of three-dimensional X-ray data (Fig. 6.44).

The structure contains two separate interlocking three-dimensional networks, each of which consists of alternating triborate and pentaborate groups as building blocks. This structure is quite similar to those found in other tetraborates The two kinds of oxygen atoms linked in the triborate and pentaborate groups are clearly delineated. This is a projection along the pseudo-tetragonal axis of one of the networks in barium tetraborate. The four types of atoms are shown. The pentaborate groups are at the corners of the unit cell whereas the triborate groups are at the center. Unit-cell parameters are: $a = 8.562$ Å, $b = 5.78$ Å, $c = 13.201$ Å, space group = $P4_122$. Positional parameters for the lattice are shown in Fig. 6.45.

The unit-cell parameters are: $a = 10.56$ Å, $b = 8.20$ Å, $c = 13.01$ Å, $\beta = 104°$, and $Z = 8$, space group = $P2_1/c$. The borate network can also be described as a three-dimensional linkage of alternating six-membered single rings containing two tetrahedral B atoms and one triangular B atom, and double rings containing two tetrahedral B atoms, one of them being common to both rings, and three triangular B atoms. Each single ring is directly linked only to double rings and each double ring directly links to only to single rings. The Ba atoms fit into channels of this network. Another view of barium tetraborate is shown in the following Fig. 6.46.

This is a view showing the relation of the triborate groups to each other, as shown in the middle of the above view of the structure. In barium tetraborate, two different bond valence sums of the two crystallographic different barium positions are observed.

The thermal behavior of BaB_4O_7 was investigated using high-temperature X-ray powder diffraction analysis. The components of the thermal expansion tensor and the tensor orientation with respect to the crystallographic axes are calculated. Thermal deformation was analyzed in relation to the crystal structure. The thermal expansion of the BaB_4O_7 borate was studied in three high-temperature XRD experiments (two experiments with heating and one experiment with cooling). The thermal expansion of this compound is strongly anisotropic; the expansion is maximum in the *ac* monoclinic plane, whereas a contraction is observed along the *b*-axis.

Activation of barium tetraborate by divalent Europium has been studied. A phosphor peaking at 350 nm was obtained whose spectrum is shown in the following diagram. Although the wavelength is suitable for use in "black-light" lamps, the intensity of the Sr homologue is

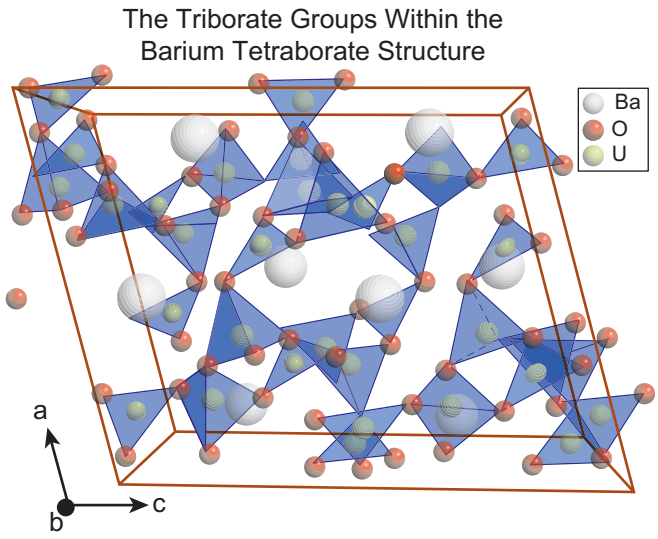

FIGURE 6.46

greater at 370 nm. Thus, this composition has not found use in the lamp industry. Barium tetraborate has the CAS number of 12007-55-5 (Fig. 6.47).

Bismuth-containing barium borates have been studied as frequency-converting crystals. Phase equilibria in the $BaO–Bi_2O_3–B_2O_3$ system have been investigated by X-ray powder diffraction analysis and DTA. Quasi-binary sections have been determined, and an isothermal section of the system in the subsolidus region has been constructed. The $BaO–Bi_2O_3–B_2O_3$ ternary system has been divided into 22 triangles of coexisting phases. It has been found that four bismuth barium borates exist, namely, $Ba_3BiB_3O_9$, $BaBi_2B_4O_{10}$, $BaBiB_{11}O_{19}$, and $BaBiBO_4$. $Ba_3BiB_3O_9$ undergoes a phase transition at 850 °C and exists up to 885 °C, where it decomposes in the solid state. $BaBiB_{11}O_{19}$ and $BaBi_2B_4O_{10}$ melt congruently at 807 and 730 °C, respectively. $BaBiBO_4$ melts incongruently at 780 °C. X-ray powder diffraction data for the low-temperature polymorph of $Ba_3BiB_3O_9$ were presented. $BaBiBO_4$, or $BaBi(BO_3)O$, is a novel borate oxide which has been synthesized by SSR at temperatures below 650 °C and 1 atmosphere pressure. Its crystal structure has been determined from powder XRD data and refined from powder neutron diffraction data (noncentrosymmetric Pna21 space group, $a = 8.5817$ Å, $b = 9.6802$ Å, $c = 5.1505$ Å, $Z = 4$). The structure is built of [001] chains of edge-sharing BO_3 and BiO_5 groups interleaved with Ba^{2+} cations. The measurement of the nonlinear optical properties of the powder sample by the Kurtz–Perry method yielded an efficiency for second-harmonic generation equal to five times that of KH_2PO_4.

A **hydroxylated barium borate**, $Ba_3B_6O_9(OH)_6$, consists of infinite chains of composition of $[B_6O_9(OH)_6]_n^{n6-}$ and Ba^{2+} cations residing between the negatively charged chains. This compound is the first reported chain borate in which the boron atoms are all tetrahedrally coordinated by oxygen atoms (Fig. 6.48).

The structure of this compound contains anionic infinite chains extending along the *a*-direction, with a composition of $[B_6O_9(OH)_6]^{n6-}$ built up from nonplanar six-membered B_3O_6 rings, which are found to join together by sharing B atoms. In each B_3O_6 ring, all the three B atoms are bonded to four oxygen atoms. The B–O bond distances range from 1.444 to 1.523 Å (average—1.479 Å), comparable with the normal average tetrahedral B–O distance observed in many works The negative charges of the polyborate chains are compensated for by the Ba^{2+} cations residing between adjacent chains. Two new borate compounds have been prepared in the presence of amines by

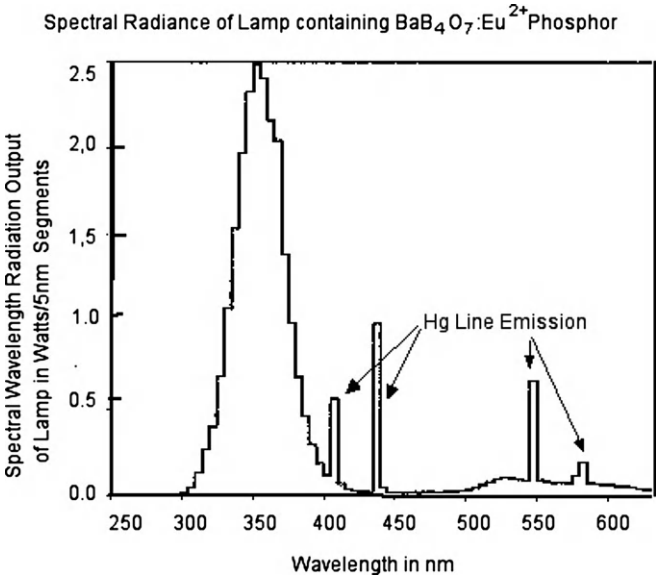

FIGURE 6.47

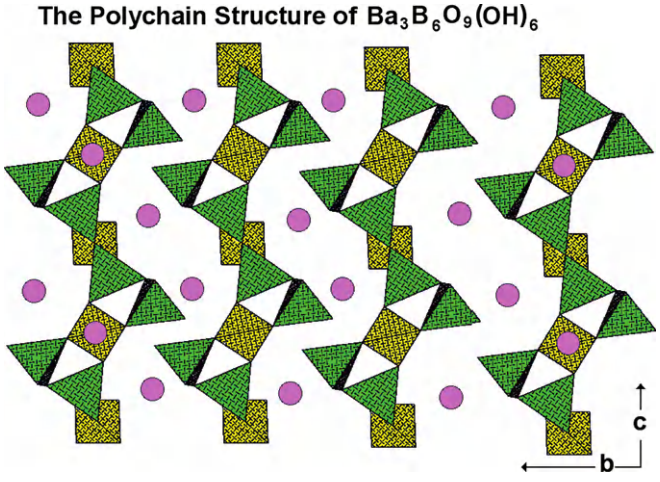

FIGURE 6.48

employing hydrothermal techniques. $Ba_3B_6O_9(OH)_6$ consists of infinite chains of composition of $[B_6O_9(OH)_6]^{n6-}$ and Ba^{2+} cations residing between the negatively charged chains. This compound is the first reported chain borate in which the boron atoms are all tetrahedrally coordinated by oxygen atoms. The SR compound has an identical structure.

The successful synthesis of these two compounds may help in the search for new ways of synthesizing borate crystals with interesting structural features.

Barium borates are widely used in industry and are readily available commercially.

Radium Borates

The scientific literature is devoid of any description of radium borates. They could be prepared by the same methods as those used for barium but there is no record of anyone having done so. The expected, stable, compounds would be RaB_2O_4, $Ra_3(BO_3)_2$, $Ra_2B_2O_5$ and RaB_4O_7. In addition, since barium forms a stable $Ba_3B_6O_9(OH)_6$ compound, there is a strong possibility that radium should also do so.

Perhaps the lack of any description of such salts can be ascribed to the intense radioactivity of the ^{226}Ra atom and the dangers of handling it improperly. Nonetheless, the chemistry of other radioactive cations have been reported so that this explanation does not seem valid. Little interest has been shown in industry or academia for radium plumbates and the corresponding alkaline earth plumbates are much cheaper and easier to handle than the radium salts.

6.4. ALUMINUM COMPOUNDS OF THE ALKALINE EARTHS

Since aluminum is close to the nonmetals in the periodic table, it has some nonmetal characteristics and some metal characteristics. Its oxide is amphoteric. It dissolves in both bases and acids. When dissolved in bases, it forms the aluminate ion. An aluminate can be considered as the neutralization of aluminum oxide with a base, or an adduct of aluminum oxide with the base. The generally accepted form of the aluminate is a mononuclear tetrahedral complex that is negatively charged, $Al(OH)_4^-$ or AlO_2^-. Aluminate can also refer to the polyatomic ion AlO_3^{3-}. Aluminum also forms a series of "aluminides" where the group Al_x^{y-} varies, depending upon the nature of the alkaline earth.

6.4.1. Alkaline Earth Aluminides

An aluminide contains aluminum and one or more electropositive elements. Since aluminum is similar to the nonmetals, it forms compounds with properties intermediate between a metal alloy and an ionic compound. Aluminides have found applications in hydrogen storage technology, the aeronautical industry, and in coatings for furnaces and other high-temperature applications. Many of the alkaline earth aluminides crystallize in the Laves type of cubic to hexagonal lattices. These phases, which form the largest group of intermetallics (with more than 1400 representatives), have the ideal composition AB_2. An intermetallic compound is classified as a Laves phase purely on the basis of the geometry of the crystal structure. The Laves phases crystallize in three structure types, which are named after the representative cubic $MgCu_2$ (C15), hexagonal $MgZn_2$ (C14) and hexagonal $MgNi_2$ (C36). These are represented as shown in Fig. 6.49.

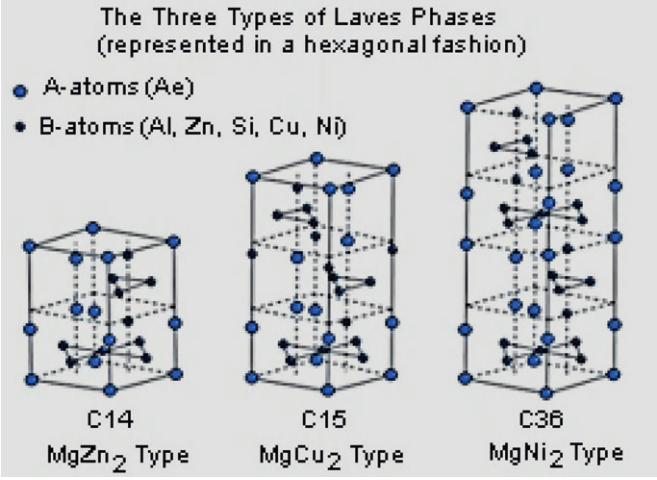

FIGURE 6.49

The B atoms form a series of networks that are distinctive (Fig. 6.50).

Beryllium Aluminides

Beryllium does not form any compounds with aluminum. Instead, it forms a series of alloys whose melting points vary from the melting point of Be (1283 °C) to that of Al (654 °C). However, the melting point line of $Be_{1-x}Al_x$ is not linear but is an "s-shaped" curve as shown in the following diagram. There is a eutectic at 3.1 mol% Be ($Be_{0.031}Al_{0.969}$) of 644 °C so that it is clear that a synergy exists in these alloys (Fig. 6.51).

Al–Be alloys possess physical and mechanical properties that exceed those of standard aluminum alloys in such areas as mechanical stability, dampening, thermal management and reduced weight. "AlBeMet™" combines the high modulus and low density of beryllium with the strength, ductility and fabrication characteristic of aluminum. The use of AlBeMet-AM162,

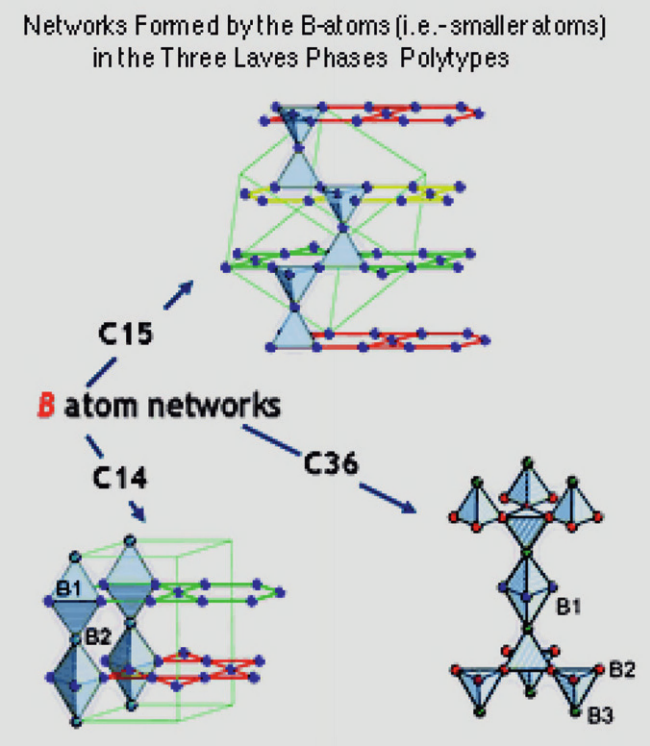

FIGURE 6.50

an aluminum–beryllium metal matrix composite, is an effective way to reduce the size and weight of many structural aerospace components that are currently made out of aluminum and titanium alloys. These savings, which are essential for today's technologies, are primarily due to the material's high modulus and low density combined with its better than average specific strength. The raw material costs are significantly higher than they are for traditional engineering alloys, and the available billet sizes are more limited than they are for aluminum and titanium alloys. Although the material costs are higher for the aluminum–beryllium composite, ease of machining makes it financially competitive when compared to equivalent parts made out of titanium alloys. Due to toxic nature of beryllium, however, debris-generating operations must be strictly regulated to limit worker's exposure to the material and protect them from potentially fatal diseases.

An aluminum–beryllium alloy with a high modulus-to-density ratio (3.8 times that of aluminum or steel) greatly reduces the chance of flexure and mechanical failure (Table 6.4).

These alloys have the following CAS numbers: aluminum–beryllium (Al–Be) alloy CAS number: aluminum = 7429-90-5; beryllium = 7440-41-7.

Magnesium Aluminide

Magnesium aluminide is an intermetallic compound of Mg and Al. Common phases (molecular structures) include the beta phase (Mg_2Al_3) and the gamma phase ($Mg_{17}Al_{12}$). Both have cubic crystal structures. Magnesium aluminides are important constituents of 99.999% aluminum alloys (aluminum–magnesium) and magnesium–aluminum alloys, determining many of their engineering properties. The compound, Mg_2Al_2, has also been investigated for use as a basis for producing metal hydrides for hydrogen storage. Like many

intermetallics, MgAl compounds often have unusual stoichiometries with large and complex unit cells. The phase diagram is given in Fig. 6.52.

Four compounds are formed: Mg_5Al_8, Mg_2Al_3, MgAl, and $Mg_{17}Al_{12}$. Both the 5:8 and the 17:12 compositions melt congruently. The others melt incongruently.

Additionally, there is a compound that forms above 322 °C and is stable only in a very limited range up to 372 °C where it decomposes. This compound, labeled "R", likely has the composition Mg_7Al_9. Thus, the reaction mixture of Mg + Al between the mole ratios of 40.0 and 50.0 At% Mg produces a mixture of Mg_2Al_3 and MgAl. But if the mixture is heated to >322 °C, Mg_7Al_9 becomes stable.

Further heating then forms:

$$3Mg_7Al_3 \Rightarrow 2Mg_2Al_3 + Mg_{17}Al_{12}$$

If an exact mixture containing 42.75 atom% Mg is present, the reaction is:

$$2Mg_2Al_3 + 3Mg_2Al_2 \Rightarrow Mg_7Al_9$$

It is this compound that is stable up to 372 °C where it decomposes to:

$$3Mg_7Al_9 \Rightarrow Mg_{17}Al_{12} + 5Mg_2Al_3$$

However, since the structure of "R" has not been determined, the only basis for its formation has been a change in diffraction pattern at the 42.75 At% composition.

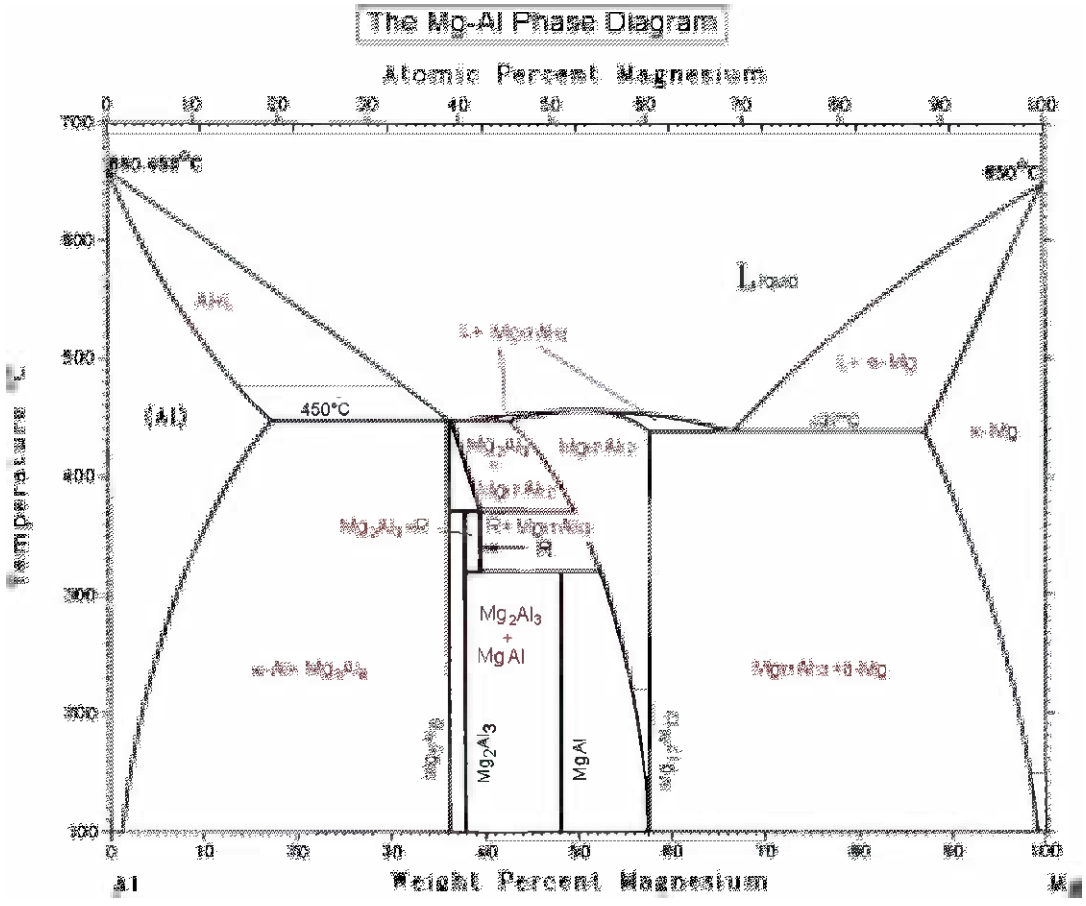

FIGURE 6.52

Pentamagnesium octaaluminide, Mg_5Al_8, is a component of Mg–Al alloys. In Al–Mg alloys with high Mg content (>3% Mg), solid solution is supersaturated with Mg solute atoms, because the Mg content is higher than 1.9% Mg, which is the equilibrium solubility of Mg in Al matrix at room temperature. In that case, Mg solute atoms tend to precipitate out as an equilibrium β-phase (Mg_5Al_8) along the grain boundaries or randomly distributed in the structure. Precipitation sequences of the decomposition of supersaturated solid solution have been reported as follows:

α-Al matrix ⇒ GP zones (β′-phase) ⇒ (β-phase(Mg_5Al_8))

This process occurs slowly even at room temperature, and is significantly accelerated at high temperatures (>65 °C). Since the corrosion potential of β-phase (−1.24 V), is more negative than the potential of Al matrix (−0.87 V), dissolution of anodic (β-phase particles occur in an appropriate solution, such as seawater). Other second phase particles, such as $MnAl_6$, have no influence on the corrosion behavior of Al–Mg alloys, since the corrosion potential of $MnAI_6$ particles (−0.85 V) is as much as the potential of Al matrix.

The presence of Mg_5Al_8 in Mg–Al alloys seriously weakens the strength of low Mg-containing alloys. However, if the alloying step is properly controlled, a major increase in strength and other properties occurs. The generic aluminum alloys derive most of their strength from solution hardening. The Al–Mg phase diagram shows why. At room temperature, aluminum can dissolve up to 1.8 wt% magnesium at equilibrium conditions. In practice, Al–Mg alloys can contain as much as 5.5 wt% Mg in solid solution at room temperature—a super saturation of $5.5 - 1.8 = 3.7$ wt%. In order to obtain this super saturation, the alloy is given the following schedule of heat treatments:

(a) Hold at 450 °C (solution heat treat)

This puts the 5.5% alloy into the single phase (α) field and all the Mg will dissolve in the Al to give a random substitutional solid solution.

(b) Cool moderately quickly to room temperature.

The phase diagram shows that, below 275 °C, the 5.5% alloy has an *equilibrium* structure, that is two phase, $\alpha Al + Mg_5Al_8$. If, then, the alloy is *slowly cooled* below 275 °C, Al and Mg atoms will diffuse together to form precipitates of the intermetallic compound, Mg_5Al_8. However, below 275 °C, diffusion is slow and the C-curve for the precipitation reaction is well over to the right. If the 5.5% alloy is cooled moderately, none of the Mg will be removed from solution as Mg_5Al_8, and the final result will be a supersaturated solid solution at room temperature. This supersaturated Mg gives a substantial increase in yield strength:

Yield strengths of (Al−Mg) alloys

Wt% Mg	Strength in MPa
0.80	40
1.50	55
2.50	90
2.70	120 (SS)
4.50	145 (SS)
5.10	160 (SS)

[SS = superstaurated]

Dimagnesium trialuminide, Mg_2Al_3, has two dimers, each having a unique structure. These have been labeled β-Mg_2Al_3 and β″-Mg_2Al_3. The former is cubic and the latter rhombohedral. A determination of the crystal structure of the phase commonly referred to as β-Mg_2A1_3 has been carried out and the structure has been refined by three-dimensional, least-squares techniques. The final agreement index R is 0.061 for 1215 reflections. The crystals are cubic, space group Fd3m (07) with $a_0 = 28.239$ Å. There are approximately 1168 atoms in the unit cell. These are distributed over 23 crystallographically different positions that, as a result of partial disorder, describe 41 different polyhedra. An interesting feature of the disorder is that it results in an increase in the number of icosahedra in the unit of structure, over that found in the idealized ordered model. The unit cube contains 672 icosahedra, 252 Friauf polyhedra, and 244 miscellaneous, more or less irregular polyhedra of ligancy of 10–16.

An analysis of cross-sections perpendicular to the main diagonal of a cubic elementary cell of a Samson structure such as β-Mg_2Al_3 has been conducted. It has been proven that all skeleton atoms, i.e. which occupy their positions with probability of 100%, form a framework of hexagonal planes. These planes are a part of three domains shifted with respect to each other by one-third of the length of cube's diagonal. Space between domains is filled up by clusters with partially occupied atomic positions. For hexagonal domains, the elementary cell and positions of decorating atoms have been determined. Thus, a specific arrangement of the atoms comprising the structure cannot be given since the disorder is so great. However, the general shape of these structural units have been defined.

The Samson structure of β-Mg_2Al_3 occurs as a cubic elementary cell (Fd-3m, no. 227 space group) that contains 1168 atoms which are distributed over 1832 atomic positions. About 75% of atoms (879 to be exact) form the framework of the structure (skeleton atoms). The framework is made up of Samson's positions which are occupied by atoms with SOF equal to 1. The remaining 289 (25%) atoms partially occupy 953 positions with the average

occupation probability of 30%. They form clusters arranged in an elementary cell in a hexagonal lattice. Their structure can be illustrated as shown in Fig. 6.53.

The lattice constant of the Samson structure is gigantic: $a = 28.242(1)$ Å. At a temperature of 214 °C, the structure undergoes a phase transformation to the rhombohedral β′-Mg_2Al_3 (space group R3m, no. 160, which is a subgroup of the Fd-3m group—index 4) with $a = 19.968(1)$ Å, $c = 48.9114(8)$ Å. It should be pointed out that the constant c of a rhombohedral structure is practically equal to the length of the diagonal of the cubic structure cubic rhomb $a_{cubic}\sqrt{3} = 48.9166$ Å $\approx c_{rhomb}$. The near equivalence in length between the c-axis of the rhombohedral β′-Mg_2Al_3 structure and the diagonal of the cubic β-Mg_2Al_3 is a consequence of lattice transformation connecting the hR cell of the β′-phase to the F cell of the β-phase. Comparison of two different types of Mg_2Al_3 structure, i.e. the β–cubic phase and rhombohedral β′ one, leads to the conclusion that all skeleton atoms of a Samson structure do not change their position during the phase transformation. The skeleton atoms of a Samson phase lie within hexagonal layers.

These layers form three structural domains shifted with respect to each other by 1/3 of the length of the main diagonal of the cubic unit structure. Besides within a hexagonal layer the length of every shift vector is a multiple of about 1/7 of the distances characteristic for hexagonal structures. Once the shift vectors were found, one could then describe the structure as

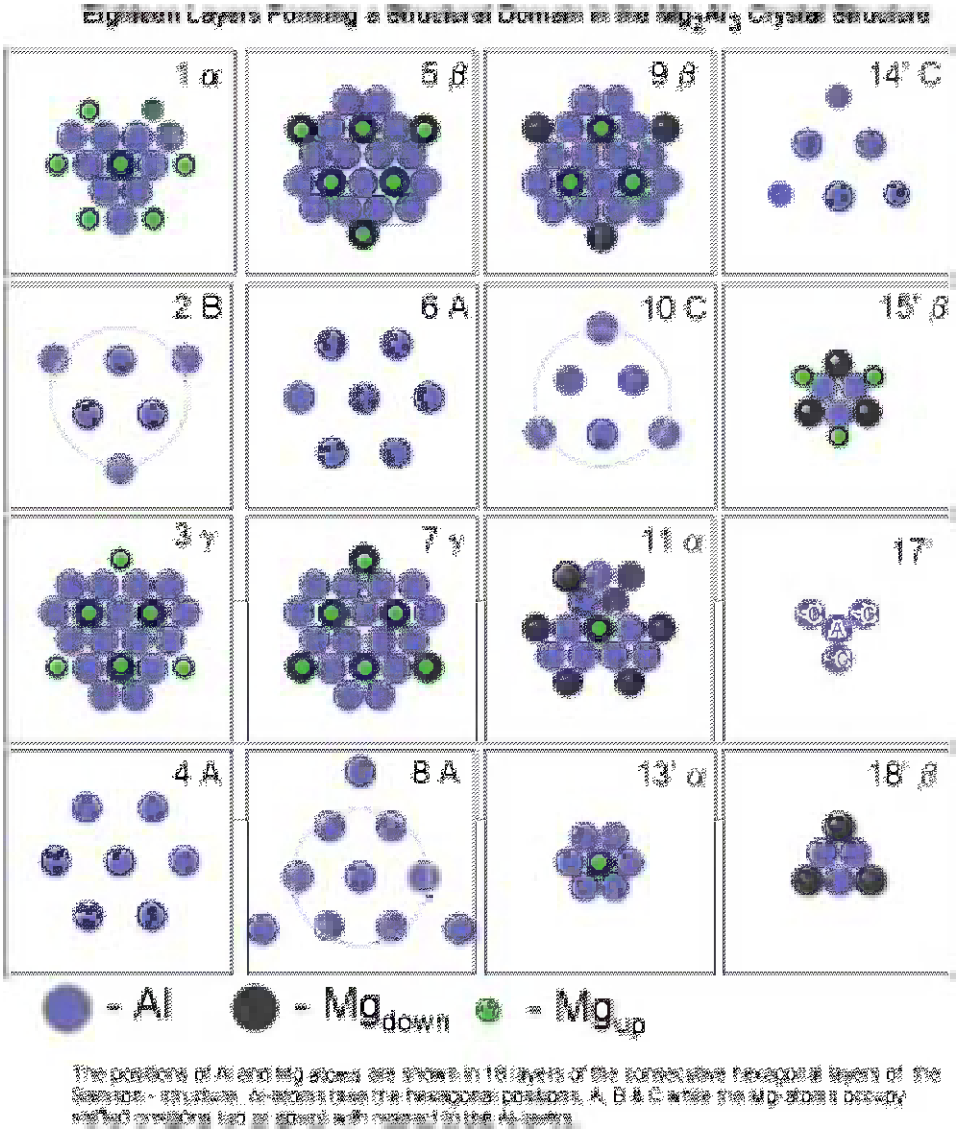

FIGURE 6.53

a modulated one. Thus, the stability range of the Samson phase, β-Mg_2Al_3 can be summarized as:

> "For the composition $Mg_{38.5}Al_{61.5}$, the cubic phase, space group *Fd*-3*m* (no 227), $a = 28.242(1)$ Å, $V = 22526(2)$ Å^3, undergoes at 214 °C a first-order phase transition to rhombohedral β′-Mg_2Al_3, $a = 19.968(1)$ Å, $c = 48.9114(8)$ Å, $V = 16{,}889(2)$ Å^3 (i.e. 22519 Å^3 for the equivalent cubic unit cell), with a space group *R*3*m* (no 160), a subgroup of index 4 of *Fd*-3*m*. The structure of the β-phase has been redetermined at ambient temperature as well as in situ at 400 °C. It essentially agrees with Samson's model, even in most of the many partially occupied and split positions. The structure of β′-Mg2Al3 is closely related to that of the β-phase. Its atomic sites can be derived from those of the β-phase by group-theoretical considerations. The main difference between the two structures is that all atomic sites are fully occupied in case of the β′-phase".

Unusual electronic transport properties have been found in the rhombohedral β′-phase of the complex metallic alloy Mg_2Al_3. The magnetoresistance (MR) is 2 orders of magnitude larger than in the related cubic β-Mg_2Al_3-phase and Kohler's rule is strongly violated in the β′-phase at higher temperatures. Above about 100 K, the Hall coefficient R_H of the β- and β′-phases are similar and free-electron-like, while in the β′-phase, R_H changes sign with decreasing temperature at low fields. These transport anomalies have not been clearly identified. Several conventional mechanisms for a large MR have been examined, and found not to be applicable. The different properties in the β- and the β′-phases are puzzling since the magnitudes of the electrical resistivities are similar and cyclotron frequency-scattering time is equally small in both phases. The similar temperature range in which anomalies occur in the β′-phase in the resistivity, the Hall effect, and the MR indicates an electronic transition or a change of the electron structure in this phase below about 100 K.

Magnesium monoaluminide, MgAl, has been investigated as a storage medium for liquid hydrogen with little success. It is available for sale commercially but does not have a CAS number. The structure remains unknown. The interaction of hydrogen with a 50:50 Mg–Al alloy pre-exposed to air has been studied with in situ time resolved X-ray powder diffraction. The experimental setup allowed recording of full diffraction patterns within 150 s, allowing the study of structural changes during kinetic investigations. Phase fractions as a function of time were derived from series of consecutive diffraction patterns. The apparent activation energy for dehydrogenation of the Mg–Al alloy is found to be approximately 160 kJ/mol. This is not significantly higher than for pure and fully activated Mg. It is suggested that the addition of Al improves the resistance toward oxygen contamination. Furthermore, it was found that Mg–Al is hydrogenated to $MgH_2 + Al$ and upon dehydrogenation an Mg–Al alloy is reformed. Pure Mg is not observed during dehydrogenation, suggesting that the formation of Mg–Al is fast compared to the liberation of hydrogen from MgH_2. From thermodynamical calculations using the semiempirical Miedema model, a slight lowering of the heat of hydride formation is found compared to that of pure Mg.

Heptadeca-magnesium dodeca-aluminide, $Mg_{17}Al_{12}$, is probably the most stable compound of the Mg–Al series of compounds. The γ-phase is an intermetallic compound with a stoichiometric composition of $Mg_{17}Al_{12}$ (at 43.95 wt.% Al) and an α-Mn–type cubic unit cell. The electronic structure of γ phase in the system $Mg_{17}Al_{12}$ contains 58 atoms per unit cell with space group I43m. Magnesium alloys are light metallic structural materials with a unique combination of properties, which are very attractive in applications such as the automobile, aerospace and electronic industries. The use of magnesium alloys has become significant due to a one-third lower density of magnesium compared with aluminum, improved damping ability, a higher resistance to corrosion and better mechanical properties. The presence of γ-$Mg_{17}Al_{12}$ contributes significantly o improved properties over the usage of aluminum alloys in these applications. Young's modulus of the γ-phase is about 80 GPa whereas for magnesium only 45 GPa. The maximum solid solubility of aluminum in magnesium is reasonably high at 12.9 wt.% Al at an eutectic temperature of 710 K (437 °C) whereas the equilibrium concentration at 473 K (200 °C) is about 2.9 wt.% Al. The volume diffusion coefficient (DV) for aluminum in magnesium can be determined using Fig. 6.54.

Precipitates with the Burgers OR [Burgers method of order (or disorder)] in the structure show such order parallel to the basal plane of the matrix, i.e. $(0001)_\alpha$ whereas precipitates with optional ORs lie on the prism plane of the magnesium, i.e. $(1\bar{1}00)_\alpha$ and they are perpendicular to the basal plane of the matrix. The strain caused by the γ phase, $Mg_{17}Al_{12}$ precipitate may be seen clearly from its eigenstrain matrix. In this case, the hcp α phase must be transformed to a regular cubic γ-phase. During transformation, the coordinates system of matrix x^α_1-x^α_2-x^α_3 must be changed to the coordinates of precipitate, ξ^γ_1-ξ^γ_2-ξ^γ_3. The following figure shows a scheme of the transformation of the α phase to the γ precipitate according to the Burgers OR and the Crawley OR methods of disorganization (Fig. 6.55).

In a "as-cast", microstructure of a magnesium alloy, the γ-phase, is the main constituent of the more or less divorced eutectic, but it should also be noted that in slow cooled castings, it may also create discontinuous

$$D_V = 12 \times 10^{-4} \exp\left\{\frac{144 \times 10^3}{RT}\right\} m^2/sec$$

FIGURE 6.54

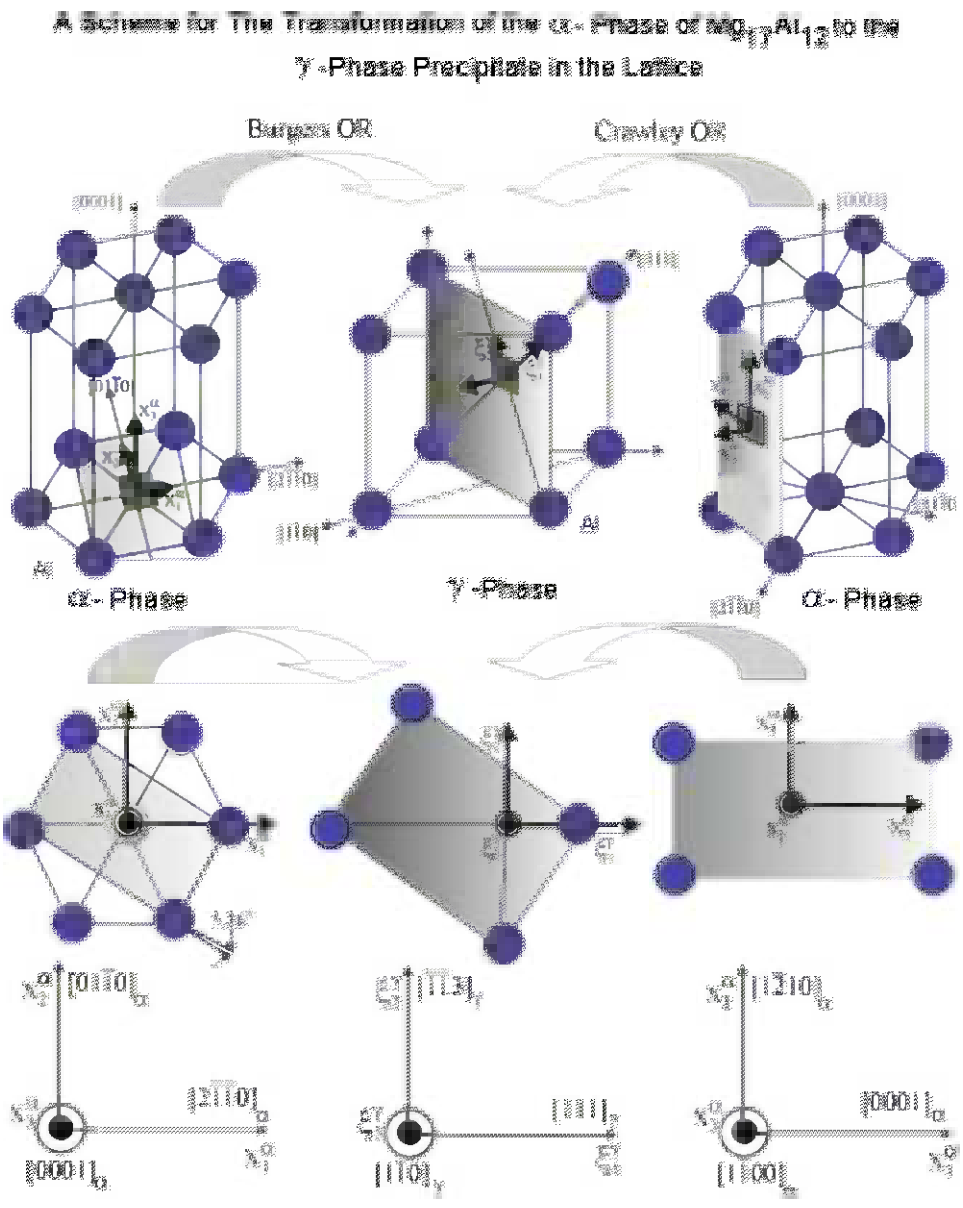

FIGURE 6.55

precipitates. After ageing of a supersaturated solid solution at 423 K, only discontinuous precipitates have been observed whereas at 623 K only continuous ones are were revealed in the microstructure. At intermediate ageing temperatures, both discontinuous and continuous precipitates of the γ-phase occur. The spherical shape of γ-precipitates can be obtained if the correct precipitation and magnesium matrix deformation processes are carefully controlled. The following illustrates the entire process to obtain spherical precipitates of $Mg_{17}Al_{12}$ particles in a metal matrix of magnesium alloys (Fig. 6.56).

The hydriding behavior of the $Mg_{17}Al_{12}$ intermetallic compound was studied in detail. It was found that the $Mg_{17}Al_{12}$ compound can initially react with hydrogen to form Mg_2Al_3, MgH_2 and Al at 573 K (300 °C). Increasing the hydrogenation temperature to 623 K (350 °C), further hydriding leads to the decomposition of Mg_2Al_3 into the hydride MgH_2 and the Al-based solid solution $Al_{0.9}Mg_{0.1}$.

The reactions are:

$$2Mg_{17}Al_{12} + H_2 \Rightarrow 8Mg_2Al_3 + MgH_2 + 2Al$$

$$3Mg_2Al_3 + H_2 \Rightarrow MgH_2 + MgAl_9$$

$$2Mg_{17}Al_{12} + 2H_2 \Rightarrow 5Mg_2Al_3 + 2MgH_2 + 2Al$$

Heating the hydrided mixture to about 650 °C causes the reverse reactions to occur.

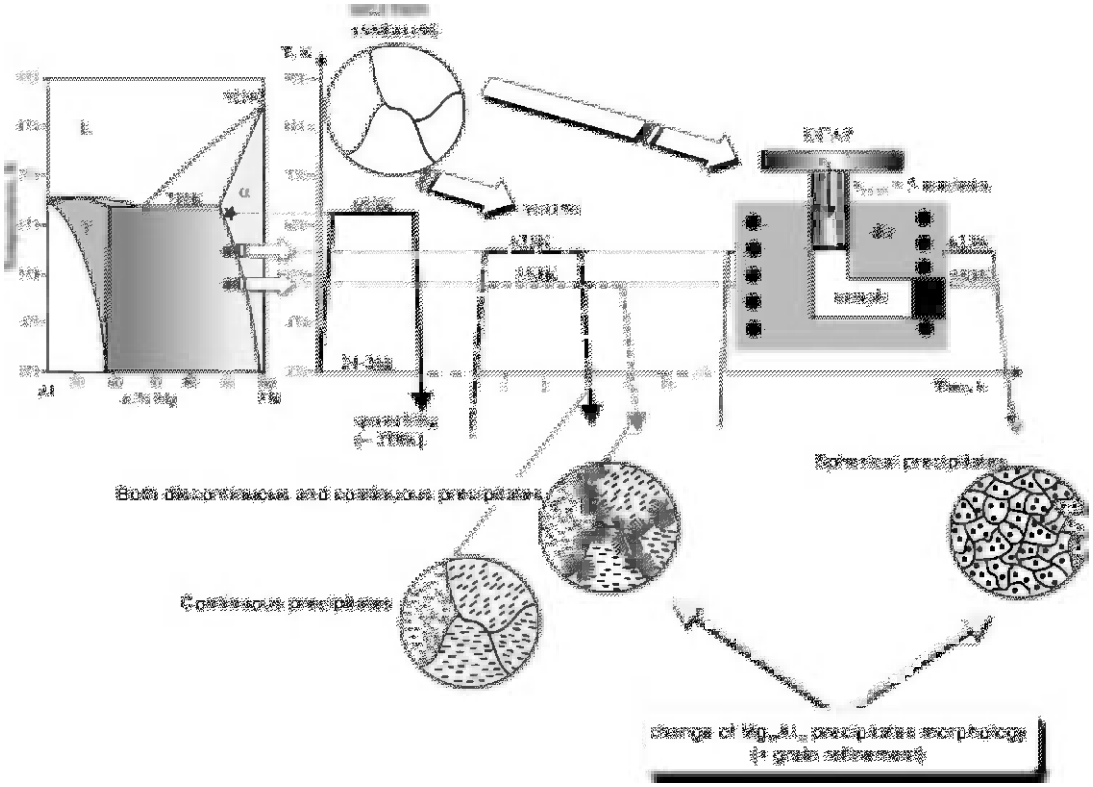

FIGURE 6.56

The crystallization behavior of the Mg–Al alloy (initial ratio Mg:Al = 17:12) prepared by ball milling (BM) was studied by means of XRD, differential scanning calorimetry (DSC), SEM and TEM. In the case of a short BM time (18 ks), we could prepare the mixture of nano-sized Mg and Al grains and the post annealing of the mixtures at even $T < 373$ K yielded formation of the fine and low-strained $Mg_{17}Al_{12}$ phase. In fact, the DSC analysis showed that only the sample after 18 ks of BM had a distinct exothermic peak at 373 K, corresponding to the formation of the $Mg_{17}Al_{12}$ and consisted of the compound from nano Mg and Al grains. The samples prepared for longer BM (144 ks) did not show equivalent the formation peak time. These samples were composed of nano-sized $Mg_{17}Al_{12}$ phase with heavy strained due to mechanical energy. In addition, the $Mg_{17}Al_{12}$ synthesized from the sample after 18 ks of BM is superior in hydrogen properties to the sample after 144 ks of BM. The synthesis of $Mg_{17}Al_{12}$, an intermetallic compound, by both mechanical alloying based on the high-energy BM, and bulk mechanical alloying based on the repeated forging process has been studied. These two processing techniques resulted in alloys with different crystal structures. After MA of up to 20 h, XRD peaks from the intermetallic $Mg_{17}Al_{12}$ with unalloyed Mg and Al were observed. On the other hand, the elemental Mg and Al powders were completely mechanically alloyed resulting in $Mg_{17}Al_{12}$ after 2000 cycles of BMA. (It should be emphasized that 2000 BMA cycles correspond to 4.4 h of processing time.) Compared with MA, BMA has a great advantage on processing time. From the pressure–composition (*P*–*C*) isotherm of BMA powder at 523 K, a plateau corresponding to the hydride formation clearly appeared at 0.06 and 0.04 MPa during absorption and desorption, respectively. It was confirmed that the alloy is able to absorb hydrogen up to 3.2 wt.% at 5.3 MPa, and is also able to desorb hydrogen at 523 K. When the hydriding starts, $Mg_{17}Al_{12}$ decomposed into $Mg_2Al_3 + MgH_2 + Al$. This reaction proceeds to $MgH_2 + Al$, as reported earlier. Then, these separated phases were recombined to $Mg_{17}Al_{12}$ phase upon dehydriding.

Magnesium aluminides are not generally available in the commercial marketplace.

Calcium Aluminides

Calcium forms four compounds in the Ca–Al system when the two elements are heated together. These are $CaAl_4$, $CaAl_2$, CaAl, and Ca_8Al_3. The phase diagram is presented as shown in Fig. 6.57.

Crystal structure data are given in the following table shown below. Only $CaAl_4$ and Ca_8 melt congruently with eutectics at 5.5, 66.3 and 79.8 atom% calcium. The other two melt incongruently (Table 6.5).

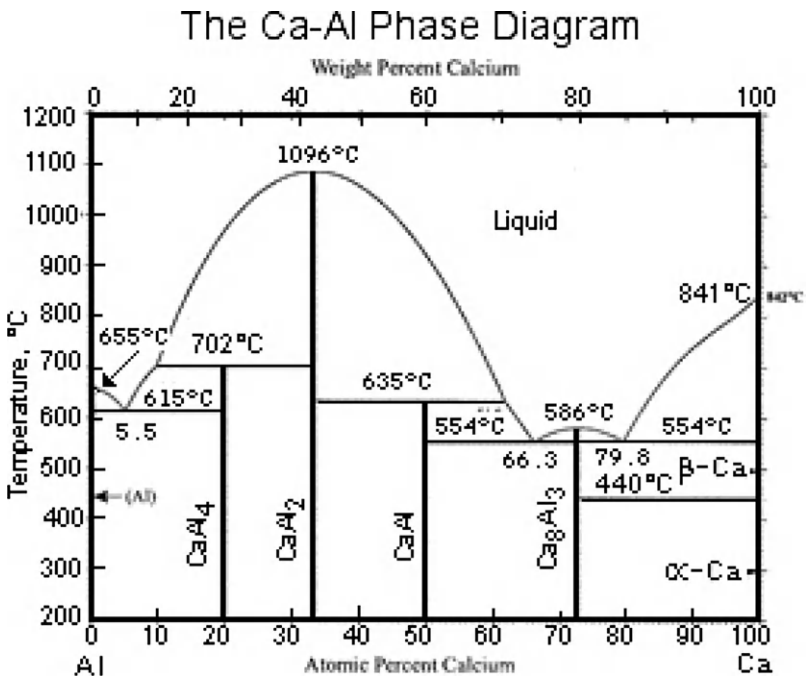

FIGURE 6.57

Calcium tetra-aluminide is dimorphic. The transition from the high-temperature tetragonal $CaAl_4$ structure (space group I4/mmm) to the low-temperature monoclinic (C2/m, $Z = 2$) phase is a slow process at room temperature. This compound has the structure shown in Fig. 6.58.

This is a top and side view of the monoclinically distorted body-centered tetragonal unit cell of $CaAl_4$ containing two formula units. This compound has been investigated as an electron-emitting electrode for a cathode in various devices. Cathodes are used in many devices ranging from microwave ovens, CRTs, to organic light-emitting diodes (OLEDs). Crucial materials properties are a low work function (Φ) and a (relatively) stable surface. In CRTs, a thin layer of a low-Φ metal is often present on top of a cathode made from a structurally stable material to enhance its electron-emitting properties. Electron injection into OLEDs strongly depends on the cathode work function. The lifetime of the device, on the other hand, derives from a subtle interplay between high voltages and reaction of the cathode with the organic material. OLEDs with single-element cathodes can be greatly improved, in terms of lifetime and luminosity, by first evaporating a small layer of a low-Φ metal on the polymer. The work function is defined as the amount of energy it takes to extract electrons from a metal, i.e. bring them from the Fermi level (E_F) to the vacuum V_{vac}.

$$\Phi = V_{Fermi} - V_{vac}$$

At locations that are microscopically far from the material, but macroscopically near it, Φ is surface dependent. $CaAl_4$ has been found to possess one of the lowest work functions known to date and is increasingly being used as a coating on emissive cathodes.

Reactions in the SrH_2–Al–H_2 system were studied by hydrogenation $\Leftrightarrow$ dehydrogenation of a $2SrH_2 + Al$ mixture prepared by BM of SrH_2 alloy under hydrogen. It was found that SrH_2 and Al can react with hydrogen to form Sr_2AlH_7 at 553 K (280 °C) when

TABLE 6.5

Cpd.	At% Ca	Entalpy-ΔH_f kJ/mol	Space group	Crystal structure	Prototype

Ca_8Al_3	72.7	−13.7	P**1**	triclinic	Ca_8In_3

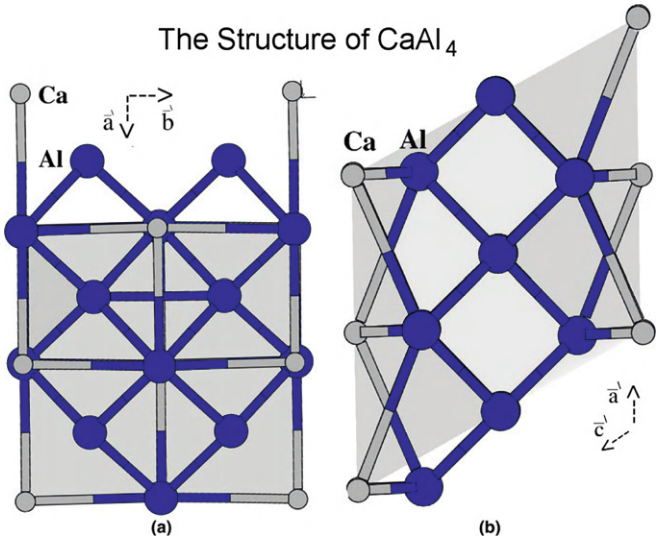

FIGURE 6.58

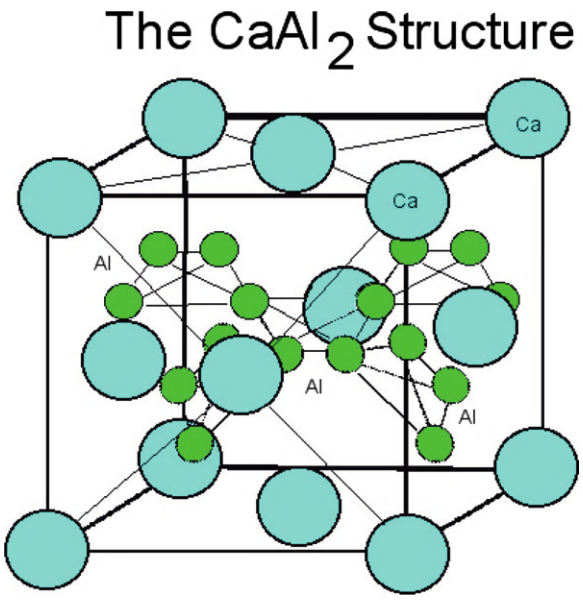

FIGURE 6.59

the hydrogen pressure is above 2.93 MPa. This reaction is reversible. The enthalpy change for the formation of Sr_2AlH_7 from $SrH_2 + Al + H_2$ is about -51 kJ/mol H_2. When the hydrogen pressure is below 1.76 MPa and the temperature is 553 K, $SrAl_2$ reacts with Al to form $SrAl_4$ and H_2 with an enthalpy change of 48 kJ/mol H_2. This reaction is irreversible. Similarly, Sr_2AlH_7 also decomposes into SrH_2, $SrAl_4$ and H_2 when the hydrogen pressure is below the equilibrium pressure of the irreversible reaction.

Calcium dialuminide, $CaAl_2$, has a cubic structure with $a_0 = 8.03$ Å and $Z = 4$. The structure is shown in the following Fig. 6.59.

The Ca atoms are located at (0,0,0) and in face-centered positions while the four Al_4 groups are located at $(\frac{5}{8},\frac{5}{8},\frac{5}{8})$ positions. $CaAl_2$ offers the possibility of high hydrogen storage capacity with extraordinary low material cost. However, $CaAl_2$ does not absorb as much hydrogen at near room temperatures, probably because, according to the Westlakeís empirical law, the distance between interstitial sites (T_{sites}) atoms is too large for simultaneous occupation of hydrogen to form an unstable hydride.

The addition of Si to $CaAl_2$ to form $CaAl_{1-x}Si_x$ produces a compound with superconductivity at $T_c = 7.7$ K. The $CaAl_{1-x}Si_x$ alloy, has been recently synthesized in the C_{32} structure in a wide composition range (x), and shown to be superconducting at all values of x. It has been shown that superconductivity is of electron–phonon type, and that the lower critical temperature with respect to MgB_2 can be understood because the electronic and vibrational states involved in the superconducting pairing are different. $CaAl_2$ is isoelectronic and isostructural to MgB_2, and thus represents an ideal candidate for the observation of superconductivity.

The hydriding behavior of pseudobinary $CaAl_{2-x}M_x$ (M = B, Si) where $0 < x < 1$ alloys with the C_{15} Laves phase structure was examined in the search for new metal hydrides for hydrogen storage. The initial activation for hydriding proceeded at an H_2 pressure of 3 MPa and at temperatures between 300 and 400 °C without changing their phase structure or decomposing thermally. The $CaAl_{1.8}B_{0.2}$ alloy absorbed the largest amount of hydrogen among these alloys, forming $CaAl_{1.8}B_{0.2}H_{0.6}$ at an H_2 pressure of 1 MPa at 60 °C.

Trideca-calcium tetradeca-aluminide, $Ca_{13}Al_{14}$, can be obtained by fusion of the appropriate mixture of the elements in Ta containers at 1100 °C followed by annealing at 600 °C or slow cooling. The structure was determined by single-crystal X-ray means. $Ca_{13}Al_{14}$ crystallizes with monoclinic symmetry (space group C2/m (no. 12), $Z = 2$, $a = 15.551$ Å, $b = 9.873$ Å, $c = 9.726$ Å, $\beta = 108.09°$), $Ca_{13}Al_{14}$ contains a two-dimensional Al network structure composed of planar hexagonal six-membered rings, planar rhombus (four-membered) rings, and trigonal three-membered rings. An electron count on the basis of the simple Zintl–Klemm formalism for three- and four-bonded Al in $Ca_{13}Al_{14}$ suggests that the phase is closed shell. However, full band structure calculations within the extended Huckel formalism indicate that it is metallic, with considerable Ca–Al covalency and, characterically, with all the Al–Al bonding states just filled at EF. The descriptor "metallic Zintl phase" is apt (Fig. 6.60).

The ladder-like structure of the Al atoms is clearly evident.

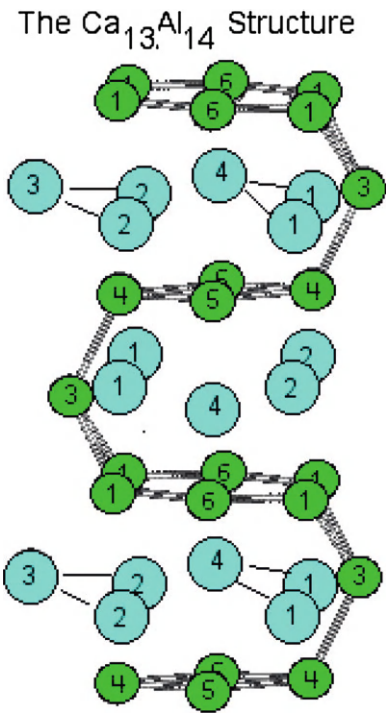

FIGURE 6.60

Octa-calcium tri-aluminide, Ca_8Al_3, can be prepared as the pure Ca_8Al_3 intermetallic compound by induction melting of appropriate amounts of pure metals and subsequent annealing. Ca_8Al_3 has the triclinic Ca_8In_3-type structure (Pi (no. 2), $Z = 2$, $a = 9.484$ Å, $b = 9.592$ Å, $c = 9.671$ Å, $\alpha = 99.02°$, $\beta = 101.13°$, $\gamma = 119.55°$). Ca_8Al_3 contains isolated Ca and Al atoms and is slightly electron rich relative to classical valence rules. This compound is a good metallic conductors with Pauli-paramagnetic-like properties.

The hydrogenation behavior of the Ca_8Al_3 compound was studied in detail. It was found that the Ca_8Al_3 compound can react with hydrogen to form CaH_2 and Al starting from 373 °K, but the process is very sluggish at this low temperature. Prior to the decomposition, the lattice parameters of Ca_8Al_3 do not change, indicating that the compound does not absorb hydrogen to form a solid solution. By increasing the hydrogenation temperature to 523 °K, the hydrogen-induced decomposition of Ca_8Al_3 occurs entirely.

Calcium aluminides are not generally available commercially. There have been no CAS numbers assigned.

Strontium Aluminides

The strontium aluminum and barium–aluminum systems have been examined by thermal, micrographic and X-ray methods. Compounds corresponding to the following compositions were observed: $SrAl_2$ (936 °C), $SrAl_4$ (1040 °C); Sr_8Al_7 (667 °C). Only $SrAl_4$ melts congruently. Eutectic points occur at 81.75 atom% Sr (590 °C) in this system (Fig. 6.61).

The crystal parameters are shown in Table 6.6.

Strontium tetra-aluminide, $SrAl_4$, has the $BaAl_4$ type of structure shown in Fig. 6.62.

Two types of this Zintl structure are shown in which cubic Al_4^{-2} or pentagonal Al_5^{2-} clusters predominate. In this structure, four groups are present in the unit cell.

The synthesis, structural characterization and the properties of the Zintl hydrides, AeE_2H_2 and AeAlSiH (Ae = Ba, Ca, Sr; E = Al, Ga, In), have been reported. The first hydride in this class of compounds is $SrAl_2H_2$ that was discovered under an experiment by Gingl, who hydrogenated $SrAl_2$ at various temperatures (Gingl et al. 2000). The intention was to form alanates, e.g. AlH_4, by terminating the three-dimensional four-connected aluminum network in $SrAl_2$. The new hydride, $SrAl_2H_2$, has a partially conserved aluminum network. The three-dimensional anionic network in $SrAl_2$ is reduced to two dimensions in the hydride, with aluminum bonded to both aluminum and hydrogen. This type of bonding configuration has not been observed before.

Strontium dialuminide, $SrAl_2$, has the structure shown as follows. In $SrAl_2$, the aluminum atoms are arranged three dimensionally in a negatively charged net. When Gingl did an in situ X-ray measurement while heating a sample of strontium aluminide under hydrogen pressure, he discovered a new type of hydride with most of the aluminum structure conserved (Fig. 6.63).

The three-dimensional network had been reduced to a two dimensional one with hydrogen atoms attached in the vacant positions. Orthorhombic $SrAl_2$, $SrZn_2$ and $BaIn_2$ crystallizes in the space group *Imma* ($CeCu_2$ structure type). Their structure consists of puckered hexagon layers of Al atoms, which are stacked on top of each other. The Al atoms have a distorted tetrahedral environment: they are linked to three neighbors within a puckered layer and to a fourth one in the adjacent layer either above or below, thus forming a three-dimensional polymer Zintl anion. The Al–Al atom distances within a layer are considerably shorter than the one linking layers. The difference is about 0.1 Å for $SrAl_2$ and $BaIn_2$. The positive ions are located between the nets, slightly displaced from the centers of the hexagons. According to the Zintl concept, Al atoms are formally reduced by electropositive Sr. In- and Al-atoms isolectronic to Si and, thus, the formation of a polyanionic three-dimensional four-connected network in these compounds is reasonable. However, the Al–Al distances in $SrAl_2$ are rather large (2.78 and 2.88 Å) and much closer to the Al–Al nearest neighbor distance in fcc-Al (2.86 Å) than to the distance expected

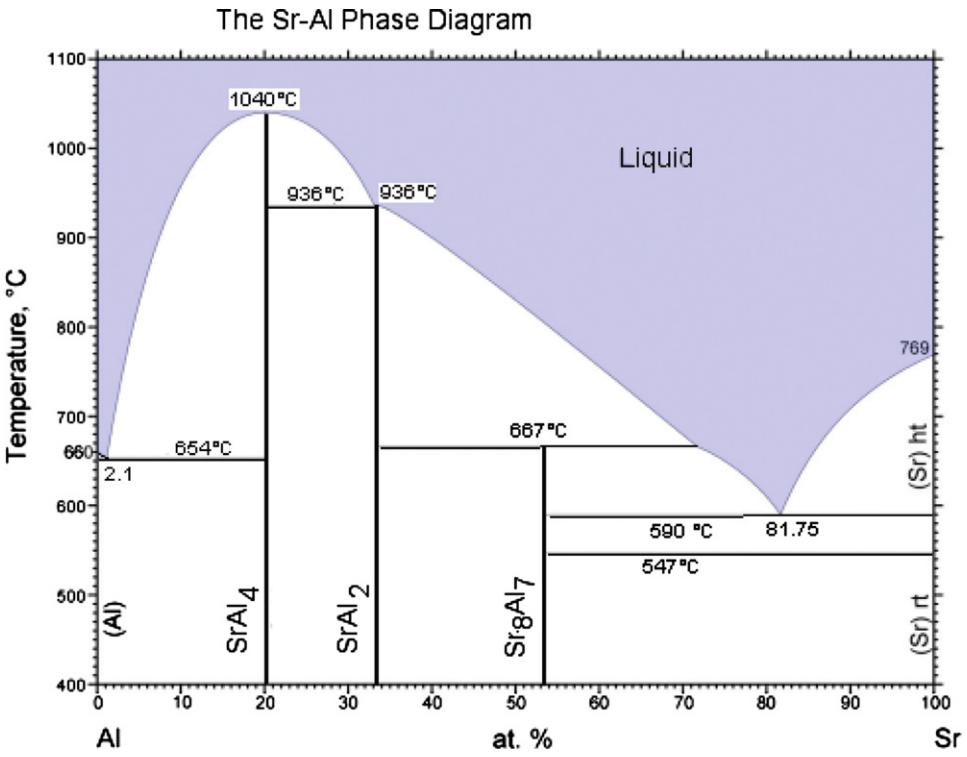

FIGURE 6.61

for a pair of two-electron two-center-bonded Al atoms (around 2.6 Å).

The hydrogenation of $SrAl_2$ is clear-cut, 190 °C and 50 bar, compared to the difficult synthesis of alanates and alane, AlH_3. The latter synthesis uses aluminum in its zero oxidation state in contrast to the synthesis of $SrAl_2H_2$ from $SrAl_2$. (In the $SrAl_2$ precursor, aluminum is reduced by the electropositive metal to −1.) Hence, this discovery shows a different route to alanates by using precursors with aluminum in a reduced state. If $SrAl_2H_2$ is further hydrogenated at 250 °C, the two-dimensional network breaks and Sr_2AlH_7 forms. The hydride, $SrAl_2H_2$, decomposes around 300 °C at 1 atm (Fig. 6.64).

The hydride, Sr_2AlH_7, decomposes into SrH_2, $SrAl_4$, and H_2 when the H_2 pressure is below the equilibrium pressure of the irreversible reaction. Sr_2AlH_7 has a very interesting structure (Fig. 6.65).

The monoclinic structure consists of isolated $[AlH_6^{3-}]$ octahedra and $[HSr_4]^{7+}$ units. The $[HSr_4]^{7+}$ tetrahedra are connected via shared edges and form infinite one-dimensional twisted chains. The heavy atom structure and hydrogen positions were determined, respectively, by X-ray powder diffraction and time-of-flight neutron powder diffraction. They crystallize with a new monoclinic structure in space group I2 (No. 5); cell parameters: $a = 12.575$ Å, $b = 9.799$ Å, $c = 7.991$ Å, $\beta = 100.270(4)°$ (hydride), $a = 12.552$ Å, $b = 9.7826$ Å, $c = 7.9816$ Å, $\beta = 100.286°$ (deuteride), $Z = 8$. Sr_2AlH_7 is the first example that consists of isolated $[AlH_6]$ units and infinite one-dimensional twisted chains of edge-sharing $[HSr_4]$ tetrahedra along the crystallographic c-axis.

Octa-strontium Hepta-Aluminide, Sr_8Al_7, is cubic and has the cell parameters of: $a = 12.76$ Å and a cell volume of 207.755 $Å^3$, $Z = 8$ (Fig. 6.66).

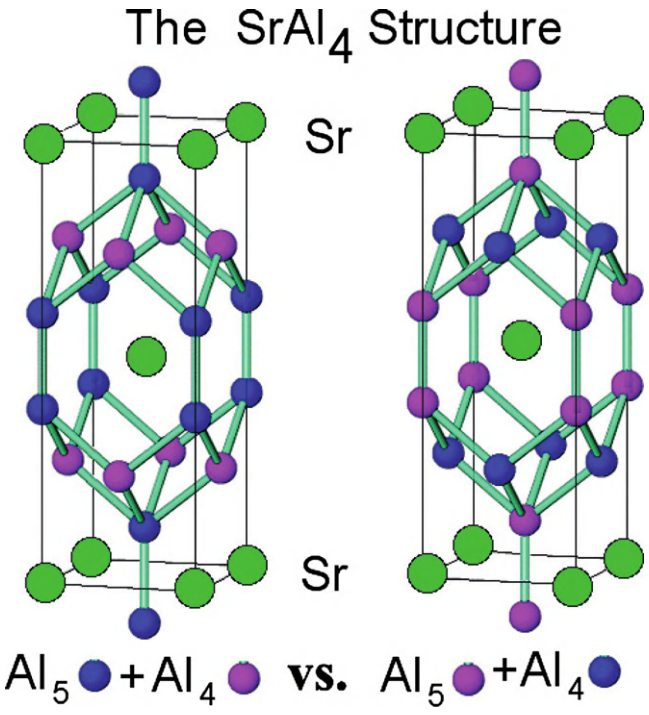

FIGURE 6.62

The structure is composed of Al_7^{16-} units, surrounded by eight Sr^{2+} atoms. The atom coördinates for this structure is shown in Table 6.7.

The Al-building block consists of a tetragonal unit attached to a triangular unit (Fig. 6.67).

Little usage has been found for this compound.

In addition to the above described compounds shown in the phase diagram, the compound, **pentastrontium nona-aluminide**, Sr_5Al_9, has been characterized. It is rhombohedral with: $a = 5.88$ Å, $c = 35.71$ Å, space group = R**3**m, $Z = 4$ and melts at 835 °C. The structure can be visualized as being composed of two building blocks as shown in the following Fig. 6.68.

The structure is composed of Sr_4Al_6 and Sr_6Al_9 building blocks, arranged in an alternating fashion. Little research has been accomplished on the physical properties of this compound other than its melting point that is congruent.

Strontium aluminides are not generally available commercially. However, a "strontium aluminide" is offered for sale with the assigned CAS number of 53169-53-2. No details concerning its composition were forthcoming.

Barium Aluminides

Barium and aluminum can form several compounds as can be determined from examination of the phase diagram. A CAS number of 12253-23-5 has been assigned for a "barium aluminide" product but the specific composition is not generally specified. The phase diagram shows five compounds formed when the two elements are melted together. The specific composition of the compound depends upon the atom ratio used to form the melt (Fig. 6.69).

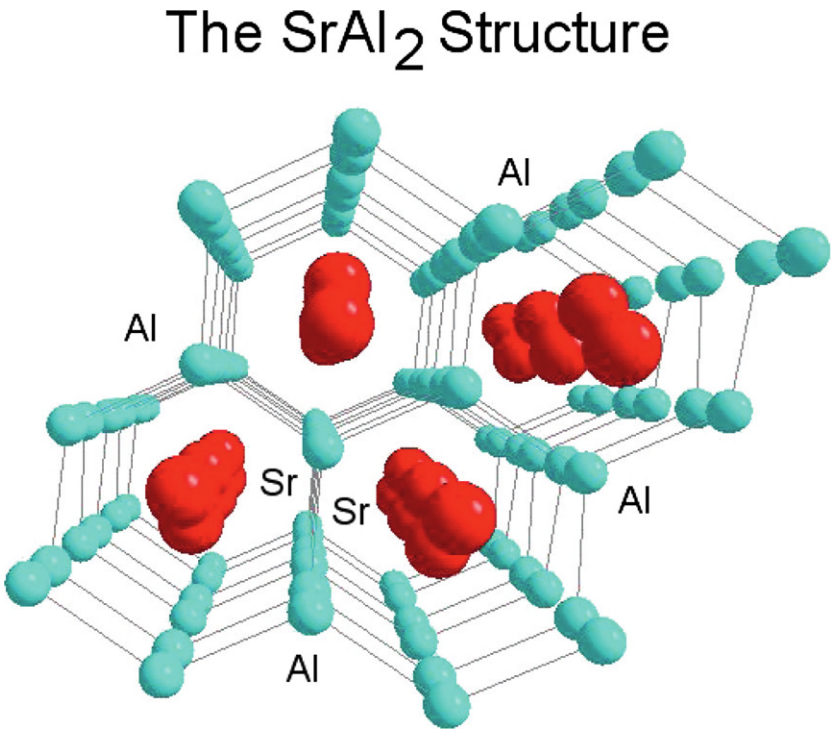

FIGURE 6.63

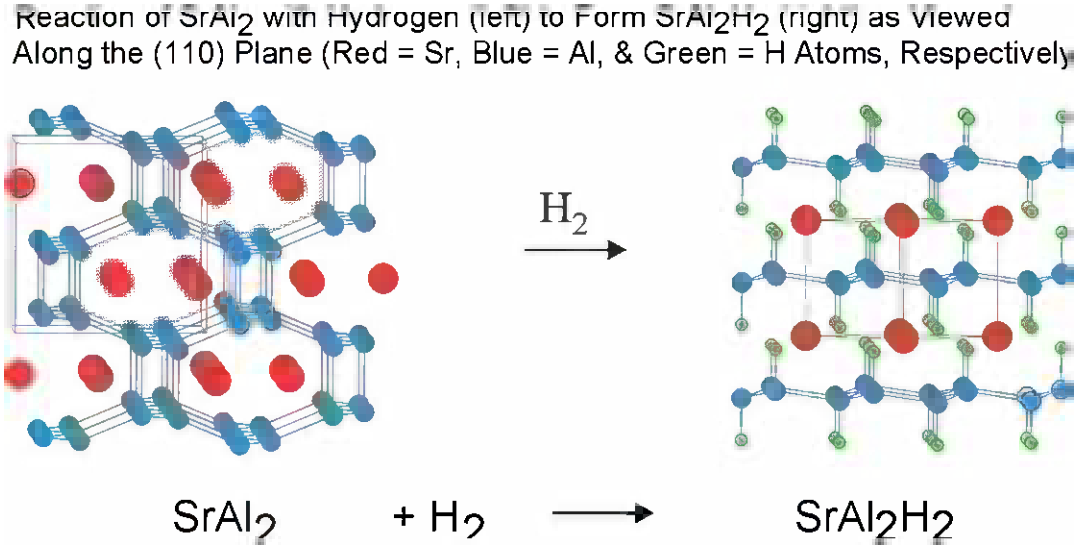

FIGURE 6.64

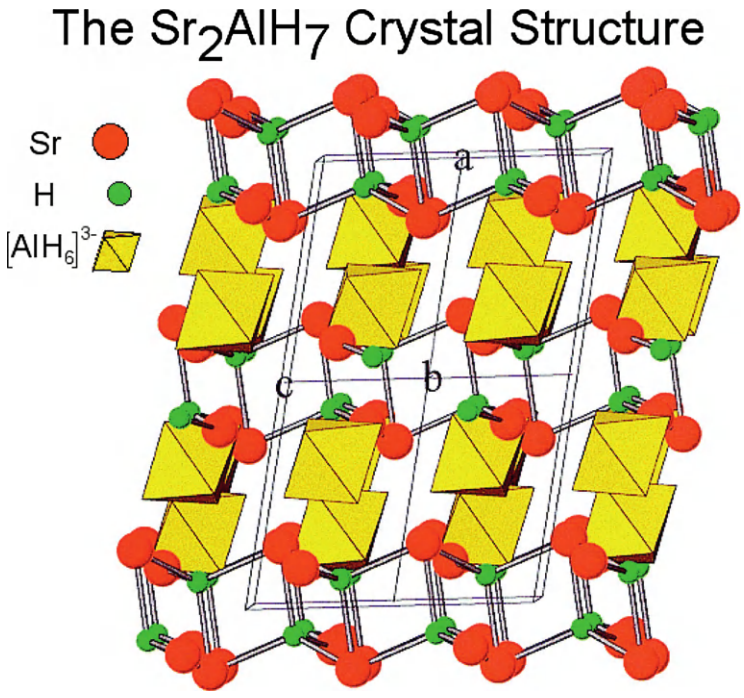

FIGURE 6.65

The unit-cell parameters of these compounds are shown in Table 6.8.

Ba_7Al_{13} was originally mistaken for $Ba_{21}Al_{40}$ but a comparison is given in the table.

Barium tetraaluminide, $BaAl_4$, has a unique structure adopted by many other compounds. It was the first of its kind to have the structure elucidated (Fig. 6.70).

Two types of this Zintl structure are shown in which cubic Al_4^{-2} or pentagonal Al_5^{2-} clusters predominate. In this structure, four groups are present in the unit cell. The Al atoms form groups of two different types of clusters.

These clusters can alternate in succession as shown in the Fig. 6.71 diagram:

Six unit cells are shown along with the possible alternate packing schemes. Ternary $BaAl_4$-type derivative structures are frequently found with silicide and germanide compounds.

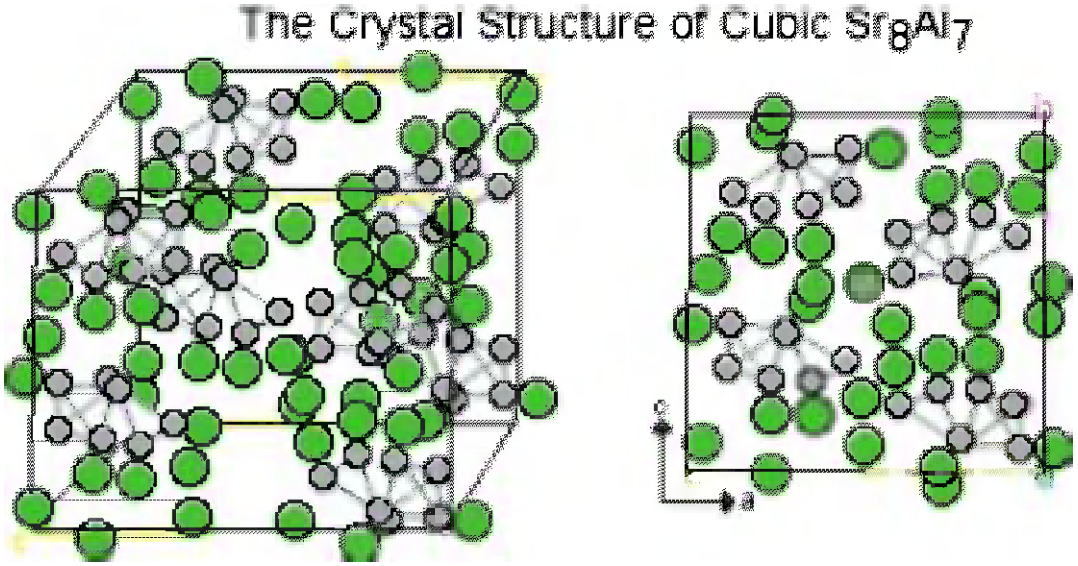

FIGURE 6.66

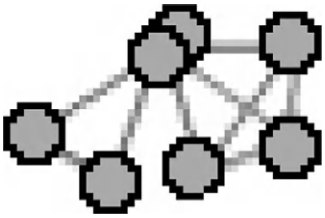

FIGURE 6.67

The Ba atoms occupy two kinds of sites at the center of an almost regular 16-atom coordination polyhedron. All Ba atoms on the tetrahedral site are surrounded by a tetrahedron of Al atoms while those on the pyramidal site are surrounded by five Al atoms in the form of a square pyramid. Another view of this structure is shown in Fig. 6.72.

The $BaAl_4$–tI10 structure, having a general composition MN_2X_2, is not only the most populous of all known structure types, being adopted by some 400 phases, but is representative of a new group of metallurgically important structures that do not adhere to classifications of Cu-type close packings or tetrahedral close packings. The structure can be described by a square pyramidal framework of N and X atoms which by edge-sharing from slabs in (001) planes, the slabs being interconnected by X–X bonds along [001] (in perhaps 10% of the phases no [001] X–X bonds exist). This framework creates tetragonal hexagonal prismatic voids, that enclose the large M atoms. The average observed distances of N–X and [001] X–X can be interpreted in a model that shows that the framework, that is responsible for structural stability, accounts for almost all of the valency electrons provided by N and X. The M atoms (diameters 3.1–5.1 Å) are accommodated in the voids of the framework according to the principles of geometrical packing, apparently without size restriction. In some cases, M–N or M–X interactions are shown to control the variable a, c, and z_X structural parameters, but they only very

modestly influence the N–X distances of the framework. A comparison with the Cu_2Sb–tP6 structure was made.

A recent work (2002) has presented a detailed, combined experimental and theoretical study on the structural stability of s–p bonded compounds with the $BaAl_4$ structure type (space group I4/mmm, $Z = 2$) as part of a broad program to investigate the complex questions of structure formation and atomic arrangements in polar intermetallics. From ab initio calculations employing pseudo-potentials and a plane wave basis set,

extracted optimized structural parameters, binding energies, and the electronic structure of the systems $AeX(III)_4$, $AeX(II)_2X(IV)_2$, $AeX(II)_2X(III)_2$ (Ae = Ca, Sr, Ba; X(II) = Mg, Zn; X(III) = Al, Ga; X(IV) = Si, Ge) were determined. For all systems, a pronounced pseudo-gap in the density of states separating network X_{42}- bonding from antibonding electronic states that coincides with the Fermi level for an electron count of 14 electrons per formula unit, the optimum value for stable $BaAl_4$-type polar intermetallics. However, the synthesis and structural characterization (from X-ray single-crystal and powder diffraction data) of the new compounds $AeZn_2$–Al^{2+}, $AeZn_2$–$\delta Ga_{2+\delta}$ (Ae = Ca, Sr, Ba; $\delta = 0$–0.2) and $AeMg_{0.9}Al_{3.1}$, $AeMg_{1.7}Ga_{2.3}$.

(Ae = Sr, Ba) manifested that electron deficiency is quite frequent for $BaAl_4$-type polar intermetallics. The site preference for different "X" elements in the ternary systems was quantified by calculating "coloring energies", which, for some systems, was strongly dependent on the size of the electropositive Ae component. The Ae^{2+} cations decisively influence the nearest neighbor distances in the encapsulating polyanionic networks X_4^{2-} and the structures of these networks are surprisingly flexible to the size of the Ae component without changing the overall bonding picture. A monoclinically distorted variant of the $BaAl_4$ structure occurs when the

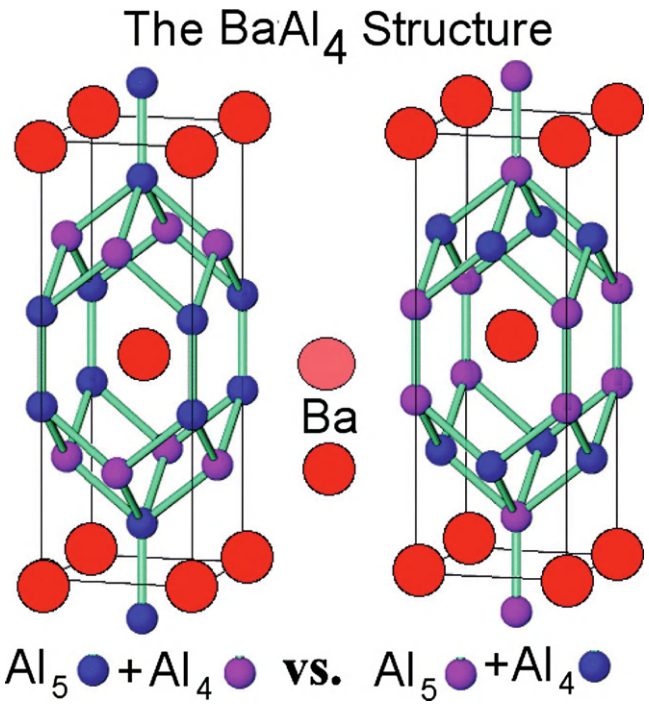

FIGURE 6.70

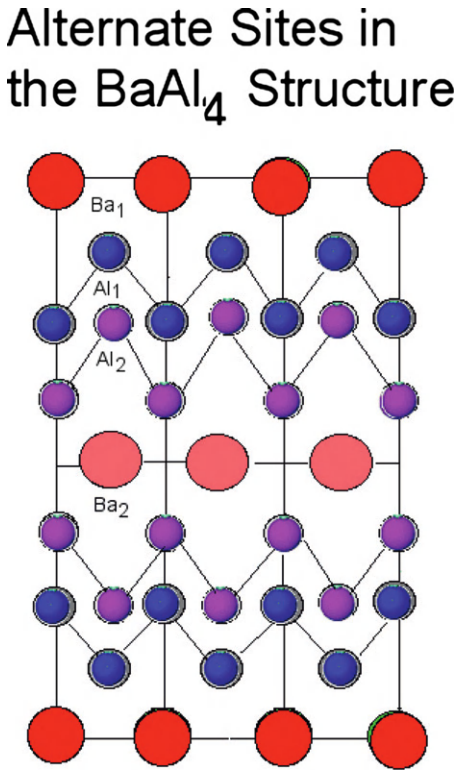

FIGURE 6.71

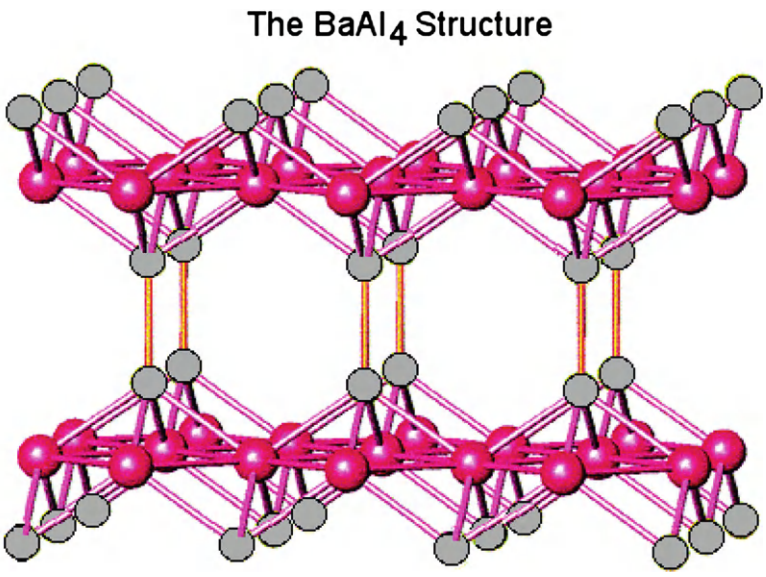

FIGURE 6.72

cations become too small for matching the size of encapsulating X_4^{2-} cages. An even larger size mismatch leads to the formation of the $EuIn_4$ structure type.

$BaAl_4$ has been studied in regard to its work function. The relationship between the work function (Φ) and the surface stability of compounds is not exactly known but is very important for applications such as OLEDs. This relation was studied using first-principles calculations on various surfaces of crystal $BaAl_4$. The most stable surface [Ba-terminated (001)] has the lowest Φ (1.95 eV), which is lower than that of any elemental metal including the metal, Ba. Adding barium to this surface neither increases its stability nor lowers its work function. $BaAl_4$ is also strongly bound. These results run counter to the common perception that stability and a low Φ are incompatible. In addition, a large anisotropy and a stable low-work function surface has been predicted for intermetallic compounds with polar surfaces.

Barium dialuminide, $BaAl_2$, is cubic and crystallizes in the Laves $MgCu_2$ (C15) face-centered structure (Fig. 6.73).

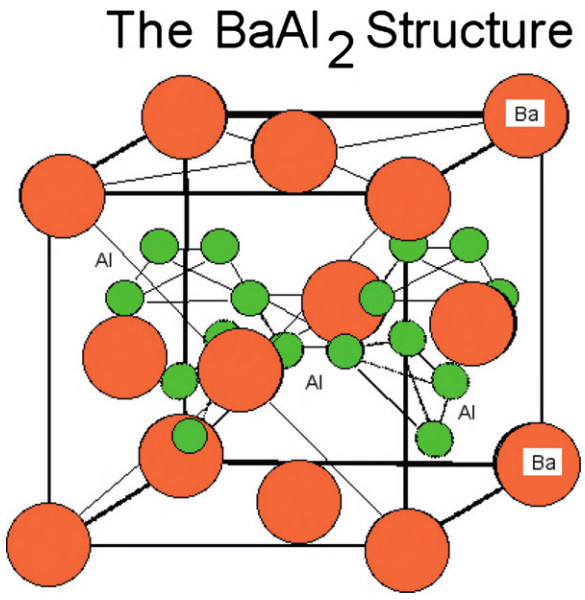

FIGURE 6.73

The Ba atoms are located at (0,0,0) and in face-centered positions while the four Al_4-groups are located at $(\frac{5}{8},\frac{5}{8},\frac{5}{8})$ positions. These Al_4 groups have the configuration shown in Fig. 6.74.

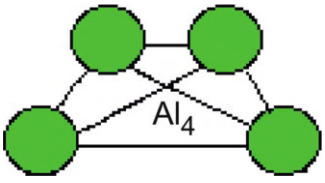

FIGURE 6.74

The atom arrangement in the structure is shown in Table 6.9.

$BaAl_2$ offers the possibility of high hydrogen storage capacity with extraordinary low material cost. However, $BaAl_2$ does not absorb as much hydrogen at near room temperatures, probably because, according to the Westlakeís empirical law, the distance between interstitial

TABLE 6.9

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy

2	Ba	Ba	8	b	-43m	3/8	3/8	3/8	1.0

sites (T_{sites}) atoms is too large for simultaneous occupation of hydrogen to form an unstable hydride. According to one source, Ba does not form $BaAl_2$ with Al but forms Ba_7Al_{13}. A new type of hydride, $BaAlH_5$, was formed by hydrogenation of Ba_7Al_{13} under a hydrogen pressure of 7 MPa at 513 K for 5 days (Fig. 6.75).

It crystallizes with a novel orthorhombic structure in the space group Pna21, cell parameters: $a = 9.194$ Å, $b = 7.0403$ Å and $c = 5.1061$ Å.

The crystal structure of $BaAlH_5$ contains Al-centered hydride octahedra [AlH_6], which share one-corner and form one-dimensional zigzag chains along the crystallographic *c*-axis. Because of this interesting arrangement of hydrogen atoms, $BaAlH_5$ has a larger H/M ratio than $NaAlH_4$ and Na_3AlH_6. If some light elements can be used as substitutes for Ba, the weight percent of hydrogen will increase considerably.

$BaAlH_5$ and Ba_2AlH_7 were successfully synthesized through reactive BM commercially available BaH_2 and Al powders for the first time. The effects of the mole ratios of BaH_2/Al on the phase formation and structural properties were investigated by means of an x-ray diffraction method and a subsequent Rietveld refinement. For different BaH_2/Al mole ratios (0.5, 1.0 and 2.0), the main phases were $BaAlH_5$, Ba_2AlH_7 and BaH_2, respectively. Ba_2AlH_7 can also be prepared by

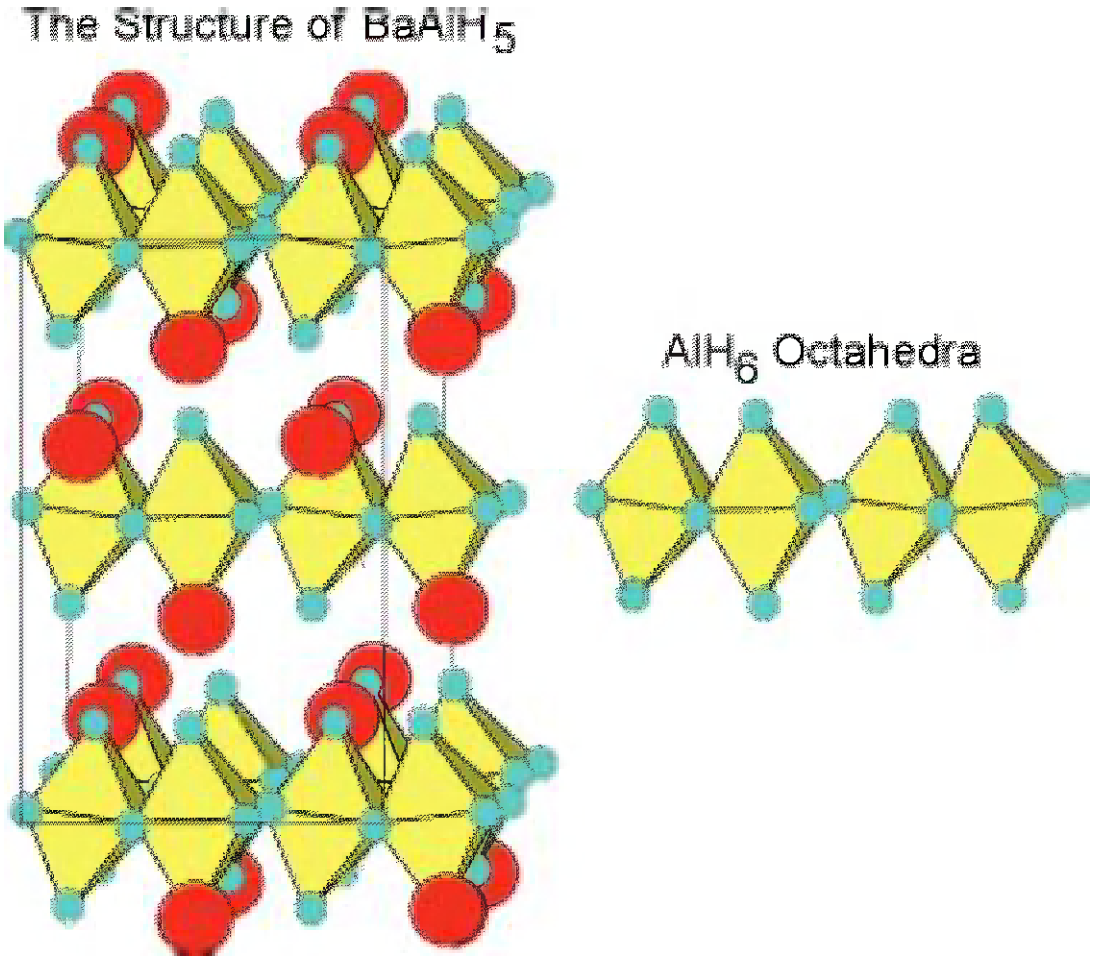

FIGURE 6.75

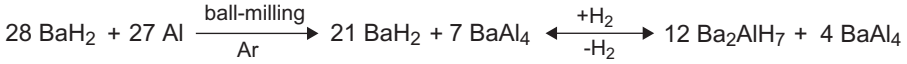

FIGURE 6.76

BM BaH_2/Al (1:1) under Ar and a subsequent hydrogenation. The phase transition and hydriding/dehydriding characteristics of the ball-milled BaH_2/Al (1:1) system under Ar were investigated using in situ DSC under H_2 atmosphere and pressure–composition isotherms (PCI). The mechanochemistry-induced phase transformation of the BaH_2/Al (1:1) mixture to a BaH_2/$BaAl_4$ (3:1) mixture during BM under Ar was first observed. The hydrogenation enthalpy of BaH_2/$BaAl_4$ (3:1) to form Ba_2AlH_7 was determined to be −20.0 kJ/mol from a van't Hoff plot. The phase transitions during BM under Ar and PCT measurements were proposed as shown in Fig. 6.76.

High-pressure forms of intermetallic compounds with the composition $CaZn_2$, $SrZn_2$, $SrAl_2$, and $BaAl_2$ were synthesized from $CeCu_2$-type precursors ($CaZn_2$, $SrZn_2$, $SrAl_2$) and $Ba_{21}Al_{40}$ by multianvil techniques and investigated by X-ray powder diffraction ($SrAl_2$ and $BaAl_2$), X-ray single-crystal diffraction ($CaZn_2$), and electron microscopy ($SrZn_2$). Their structures correspond to that of Laves phases. Whereas the dialuminides crystallize in the cubic $MgCu_2$ (C15) structure, the dizincides adopt the hexagonal $MgZn_2$ (C14) structure. This trend is in agreement with the structural relationship displayed by *sp*-bonded Laves phase systems (face-centered cubic) at ambient conditions.

Tribarium pentaaluminide, Ba_3Al_5, is cubic. The structure has a sequence of layers similar to that of the $MgZn_2$ type of Laves phases, but with a slightly different arrangement of the Al_4 tetrahedra. In Ba_3Al_5, isolated pairs of tetrahedra are joined, instead of the infinite columns present in many Laves phases. Segments of the Ba_3Al_5 are also present in the Ba_4Al_5 phase. The Laves phases crystallize in three structure types, which are named after the representatives cubic $MgCu_2$ (*C15*), hexagonal $MgZn_2$ (*C14*) and hexagonal $MgNi_2$ (*C36*). The "A" and "B" parts (Ae = Mg, Ca, Sr and Ba) (B = Al, Si and others) exhibit distinctive structures as shown in the following Fig. 6.77.

They are polytypes with a common underlying structure principle. In the first half of the last century, it was shown by J.B. Friauf, F. Laves, G.E.R. Schulze, F.C. Frank and J.S. Kasper that the Laves phases can be regarded as tetrahedrally close-packed structures from atoms A and B with ideal ratio of the radii of rA/rB = (3/2)1/2. The A atoms are surrounded by a Z16 Frank–Kasper polyhedron (16 vertices decorated with 12 B atoms and 4 A atoms) and the smaller B atoms are surrounded by an icosahedron formed by six A atoms and six B atoms. Many ternary and multiparty representatives of the Laves phases have been observed with A or B in excess. In addition, ternary Laves phases are known in systems with no corresponding binary Laves phases. Laves phases can be formed by main group metallic elements, transition metals as well as by lanthanides and actinides. The large variety of possible components for both A and B as well as the large interval of experimentally observed enthalpies of formation (0 down to −350 kJ/mol) indicate a considerable diversity in the chemical bonding situation.

The structure of the C15 phase of Ba_3Al_5 is shown in Fig. 6.78.

Only one sheet of the arrangement is shown. The barium atoms form a ladder-like structure along the *c*-axis. The two types of Al atoms are shown. One is above the plane of the Ba atom sheet while the other is slight below. The unit-cell arrangement in the structure is presented in Table 6.10.

A three-dimensional structure, showing the arrangement of the Al_5 groups is shown in the following Fig. 6.79.

Tetrabarium penta-aluminide, Ba_4Al_5, has a similar structure to Ba_3Al_5 as shown in the single sheet Fig. 6.80.

The unit-cell arrangement in the structure is shown in Table 6.11.

Again the "up" and "down" Al atoms are clearly shown. Three aluminides of the series Ba_xAl_5($x = 3$, 3.5, 4) were synthesized from stoichiometric ratios of the elements in Ta crucibles. The crystal structure of the new compound Ba_7Al_{10} was determined using single-crystal X-ray data (space group R**3**m, $a = 6.0423$ Å, $c = 4.8790$ Å, $Z = 3$, $R_1 = 0.0325$). The compound exhibits Al-Kagomé (3.6.3.6.) nets in which half of the triangles form the basis of trigonal bipyramids Al_5. The apical Al are thus three bonded assuming a charge of −2 (^{27}Al-NMR chemical shift $\delta = 660$ pm), whereas the Al atoms of the basal triangle (i.e. of the Kagomé net) are four bonded and thus of formal charge −1($\delta = 490$ ppm). The total charge of the anion is thus exactly compensated by the Ba cations, i.e. the compound can be interpreted as an electron-precise Zintl phase, exhibiting a distinct pseudo-band gap at the Fermi level of the calculated tDOS. According to the total formula, the structure displays a combination of the stacking sequences of Ba_3Al_5 and Ba_4Al_5, the structures of which have been redetermined with current methods (both hexagonal with space group P6/mmc; Ba_3Al_5: $a = 6.0655$ Å, $c = 14.618$ Å, $Z = 2$, $R_1 = 0.0239$; Ba_4Al_5: $a = 6.0921$ Å, $c = 17.758$ Å, $Z = 2$, $R_1 = 0.0300$). These three compounds with slightly different electron counts but similar polyanions allows

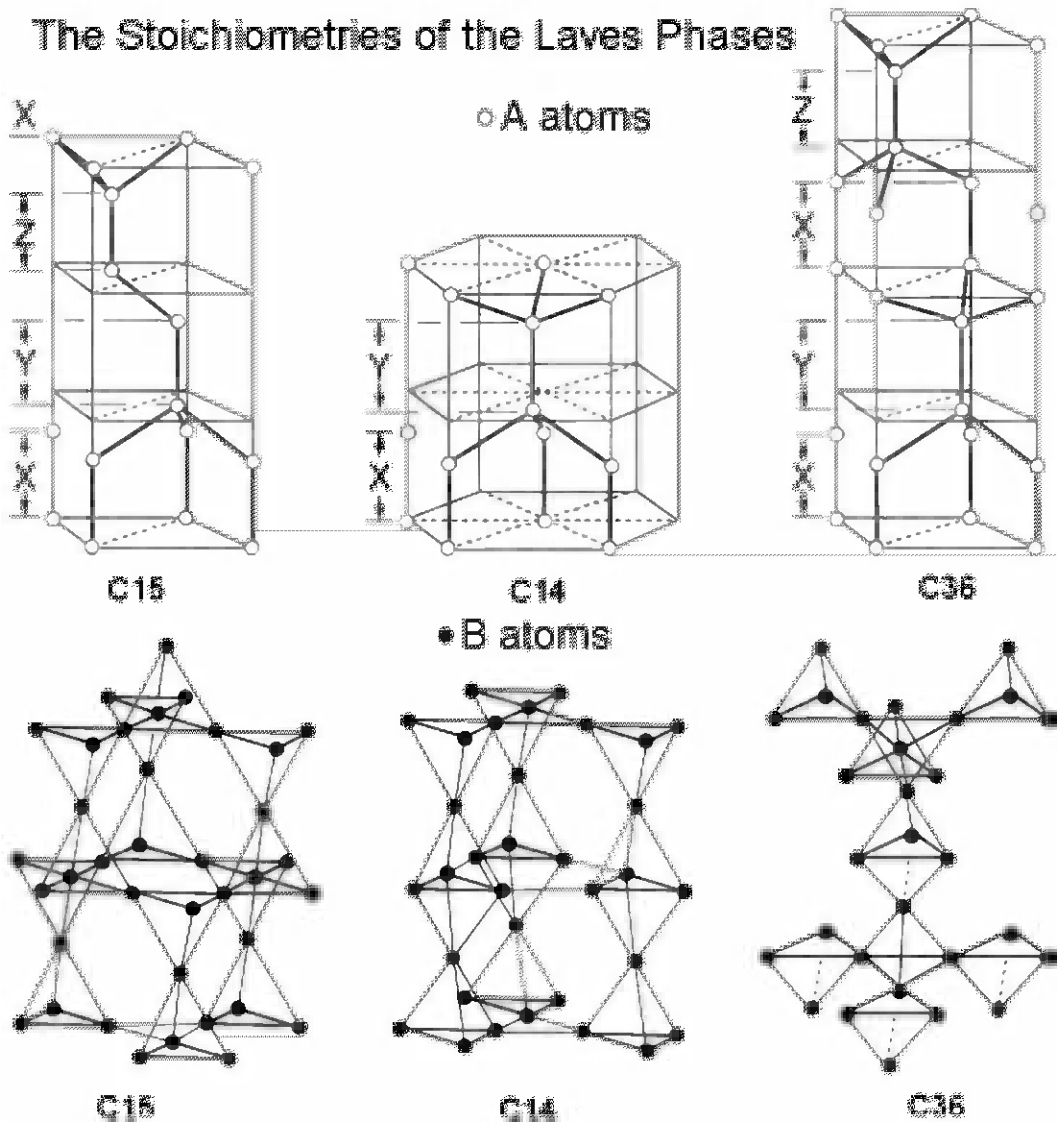

FIGURE 6.77

one to compare the bond lengths, the electronic structures and the overall bonding situation in dependence of positive or negative deviation of the electron count in relation to the novel formally electron-precise Zintl compound Ba_7Al_{10}.

Tetrabarium pentaaluminide, Ba_4Al_5, has been studied as a hydrogen-storing agent. The formation and decomposition behaviors of $BaAlH_5$ and Ba_2AlH_7 were investigated by means of XRD and pressure–composition isotherms (PCT). The phase transitions, phase compositions, and lattice parameters were determined by Rietveld refinement. Significantly pure $BaAlH_5$ with a purity of 99.1% was obtained through hydriding of Ba_4Al_5 alloy at 100 °C under 5 MPa H_2. When the hydrogenation temperature increased to 250 °C, the main phase became Ba_2AlH_7 with some impurity phases of $BaAl_4$ and BaH_2. PCT measurements of Ba_4Al_5 showed that the plateau pressure at 150 °C was about 0.5 MPa, and the maximum absorption H_2 content was 2.15 wt%. The final products obtained after PCT measurements of Ba_4Al_5 at 150 °C, 280 and 350 °C were $BaAlH_5$, a mixture of Ba_2AlH_7, BaH_2 and $BaAl_4$, a mixture of BaH_2 and $BaAl_4$, respectively. Independent decomposition experiments showed that $BaAlH_5$ partly desorbed H_2 to form a mixture of $BaAlH_5$, Ba_2AlH_7, BaH_2, and $BaAl_4$ at 280 °C, whereas both $BaAlH_5$ and Ba_2AlH_7 completely decomposed into BaH_2 and $BaAl_4$ at 350 °C. In addition, a new binary electron-precise *Zintl* compound, $Ba_{3.5}Al_5$, was found to contain Al_5 layers of Kagomé nets, that are also found in Ba_3Al_5 and Ba_4Al_5.

Undodecabarium tetradeca-aluminide, $Ba_{21}Al_{40}$, is a Zintl structure derived from Laves phases. The

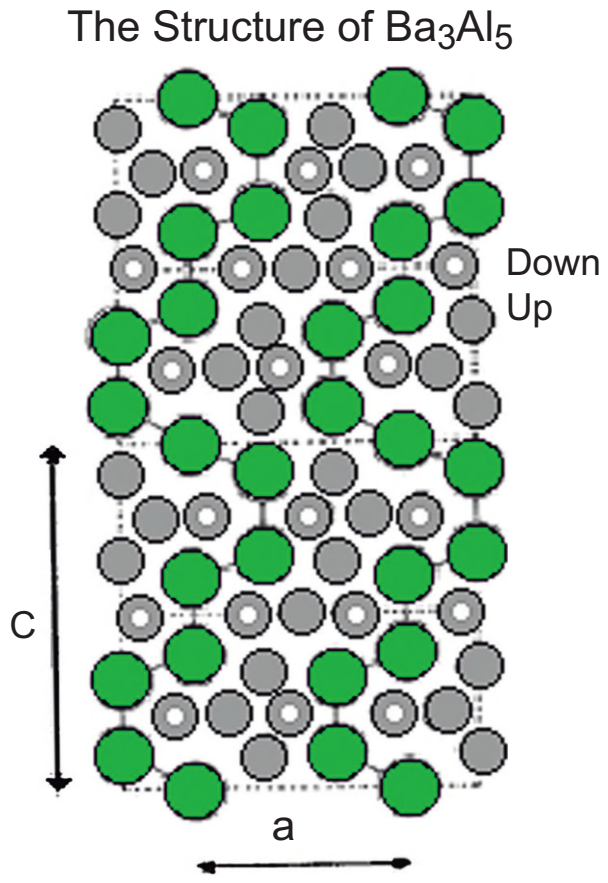

FIGURE 6.78

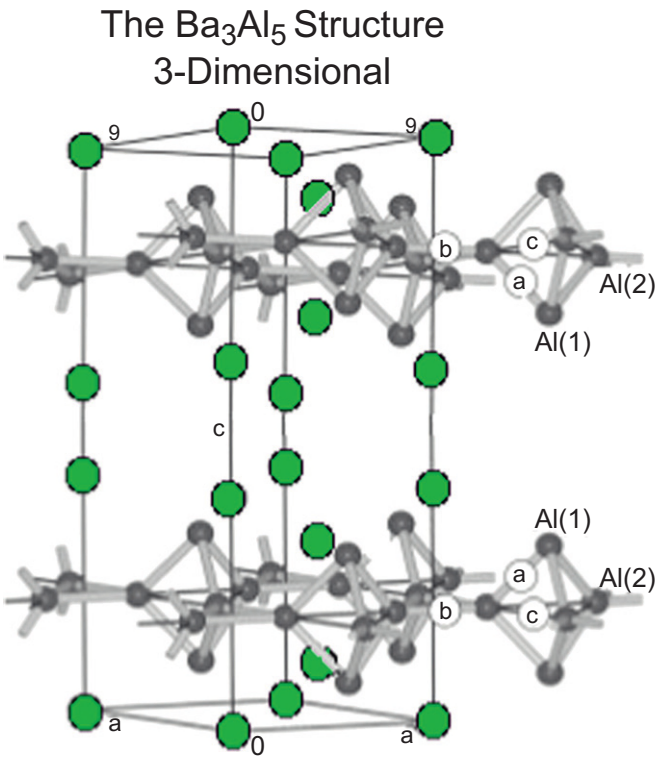

FIGURE 6.79

compound, Ba_7Al_{13}, has been mistaken for $Ba_{21}Al_{40}$. For Ae = Ba in AeB_2 Laves phases, the binary compound $BaAl_2$ does not exist, but the more Ba-rich compound, $Ba_{21}Al_{40}$, forms. The reinvestigation of the crystal structure of $Ba_{21}Al_{40}$ by selected area and convergent beam electron diffraction in a transmission electron microscope revealed a superstructure, which subsequently could be refined from single XRD data. The formula unit of the superstructure is $Ba_{21}Al_{40}$ (space group P31m, $Z = 1$, $a = 10.568$ Å, $c = 17.205$ Å). In $Ba_{21}Al_{40}$, a size match problem between Ba and Al present in Ba_7Al_{13} is resolved. The structure of $Ba_{21}Al_{40}$ can be considered as a Ba excess variant of the hexagonal $MgNi_2$ Laves phase-type structure. An incommensurately modulated variant of the $MgNi_2$ structure is obtained for phases $BaAl_2$–xMg_x with $x = 0.8$–1. At even higher Mg concentrations, a structural change to the proper $MgZn_2$-type structure takes place.

The idealized structure is shown as a C36 Laves structure in the following Fig. 6.81.

The atom arrangement in the structure is shown in Table 6.12.

The difference manifests itself in the Kagomé network of the Al_{40}^{42-} groups (Fig. 6.82).

Convergent-beam electron diffraction in combination with selected-area diffraction has been used to determine uniquely the space group symmetry of the respective phases formed. The crystal structure of $Ba_{21}Al_{40}$ and $Ba_{14}Al_{22+x}Zn_{5-x}$ are derived from Laves-type structures by omitting and modifying some of the triangular and Kagomé layers. In the case of $Ba_{21}Al_{40}$, intergrowth of motifs from the crystal structures of Ba_3Al_5 and Ba_4Al_5 were observed, whereas for $Ba_{14}Al_{22+x}Zn_{5-x}$ the bulk phase displays a domain structure. Adjacent domains are misoriented by −120°, the specific angle resulting from the pseudo-trigonal symmetry of the Ba net. Therefore, only the (Al, Zn)-net is disordered.

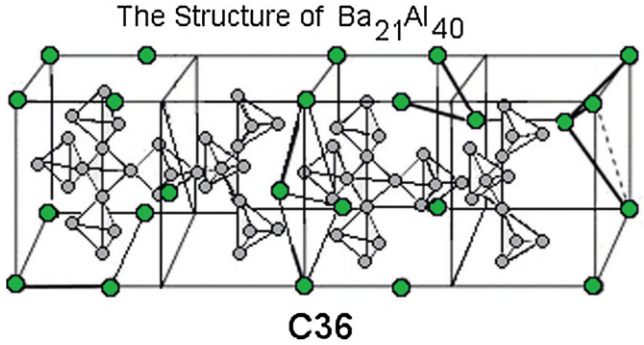

FIGURE 6.81

The hydrogenation characteristics of $Ba_{21}Al_{40}$ have been studied under a hydrogen pressure of 7 MPa at different temperatures for 5 days. $Ba_{21}Al_{40}$ reacts with hydrogen to form $BaAlH_5$ and Al between 373 and 553 K. When the temperature is in the range from 553 to 603 K, $Ba_{21}Al_{40}$ is hydrogenated to Ba_2AlH_7 and Al. However, further increasing the temperature leads to the hydrogen-induced decomposition of $Ba_{21}Al_{40}$ into

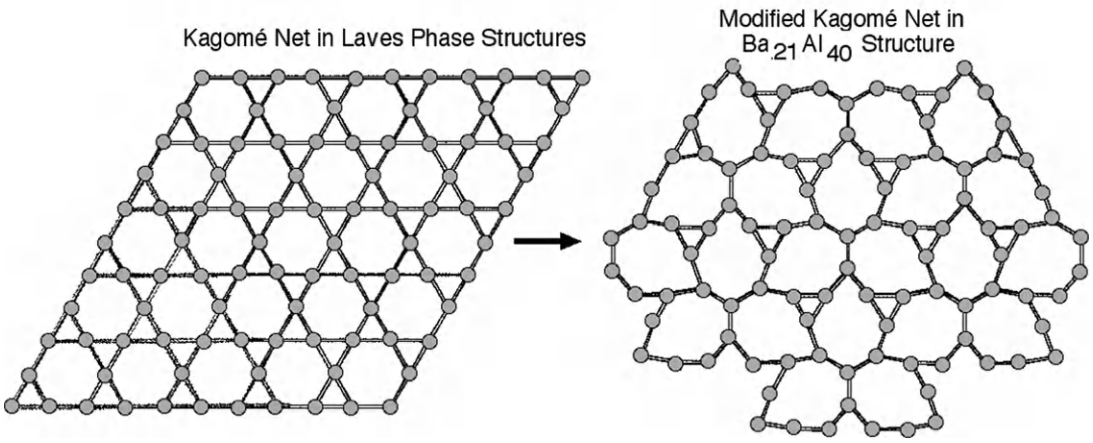

FIGURE 6.82

Ba_2AlH_7 and $BaAl_4$. The crystal structure of Ba_2AlD_7 was also studied by neutron powder diffraction. Ba_2AlD_7 is isostructural to Sr_2AlD_7, crystallizing with a monoclinic structure in space group $I2/a$. The lattice parameters were determined as $a = 13.197$ Å, $b = 10.237$ Å, $c = 8.509$ Å, $\beta = 101.290°$.

The only barium aluminide that has been assigned a CAS number is $BaAl_4$ (CAS 12672-79-6). It is available commercially.

Radium Aluminides

The literature is devoid of any mention of radium aluminides. Apparently, there have been no attempts to characterize such compounds as:

$RaAl_4$
Ra_3Al_5
Ra_3Al_5

This may be due to lack of demand for these compounds in industry and lack of interest in academia because of the intense radioactivity of ^{226}Ra.

6.4.2. Oxy-Aluminum Compounds of the Alkaline Earths

Beryllium Aluminates

Beryllium aluminate is readily formed by heating the oxides together at about 900 °C:

$$BeO + Al_2O_3 + \text{heat} \Rightarrow BeAl_2O_4$$

Three compounds appear in the phase diagram, the 3:1, 1:1 and 1:3 $BeO \cdot Al_2O_3$ combinations (Fig. 6.83).

Note that the 3:1 compound melts incongruently. The $BeAl_2O_4$ compound exists in nature as "crysoberyl" and is used as a gemstone. The thermodynamic constants determined for the above reaction are shown in Table 6.13.

Its CAS number is 120041-06-7 and it melts at 1873 °C. Beryllium aluminate, $BeAl_2O_4$, has the molecular weight of 126.9734 g/mol and it has a density of 3.65 g/cc. Chrysoberyl is orthorhombic with space group Pnma. The gemstone "chrysoberyl", not to be confused with "beryl" (which is an "alumino-silicate"), is an aluminate of Be with the formula $BeAl_2O_4$. The name chrysoberyl is derived from the Greek words Χρυσζ—*chrysos* and βηρνλλοç-*beryllos*, meaning "a gold-white spar". Despite the similarity of their names, chrysoberyl and beryl are two completely different gemstones. Chrysoberyl is the third-hardest frequently encountered natural gemstone and lies at 8.5 on the hardness scale. Only diamond and sapphire are harder.

"Alexandrite", a strongly pleochroic (trichroic) gem, will exhibit emerald green, red and orange-yellow colors depending on the viewing direction in partially polarized light. However, its most distinctive property is that it also changes color in artificial (tungsten/halogen) light compared to daylight. The color change from red to green is due to strong absorption of light in a narrow yellow portion of the spectrum, while allowing large bands of blue-green and red wavelengths to be transmitted. It, too, has the chemical formulation of $BeAl_2O_4$, is orthorhombic but has the space group of Pca2. The colors displayed by alexandrite are the result of impurities in its crystal structure. They are Cr^{3+} and Cu^{2+}, chromium and copper. The alexandrite unit cell can be visualized as being approximately hexagonal close packed (hcp) and composed of four molecules, with eight Al^{3+} ions occupying distorted octahedral sites, and four Be^{2+} ions, located at tetrahedral distorted sites, in addition to oxygen ions located in planes perpendicular to *c*-axis. Distortions from a precise hcp structure of oxygen ions originate from two sites of distinct symmetries: one is called Al_1, located at an inversion site and the other is called

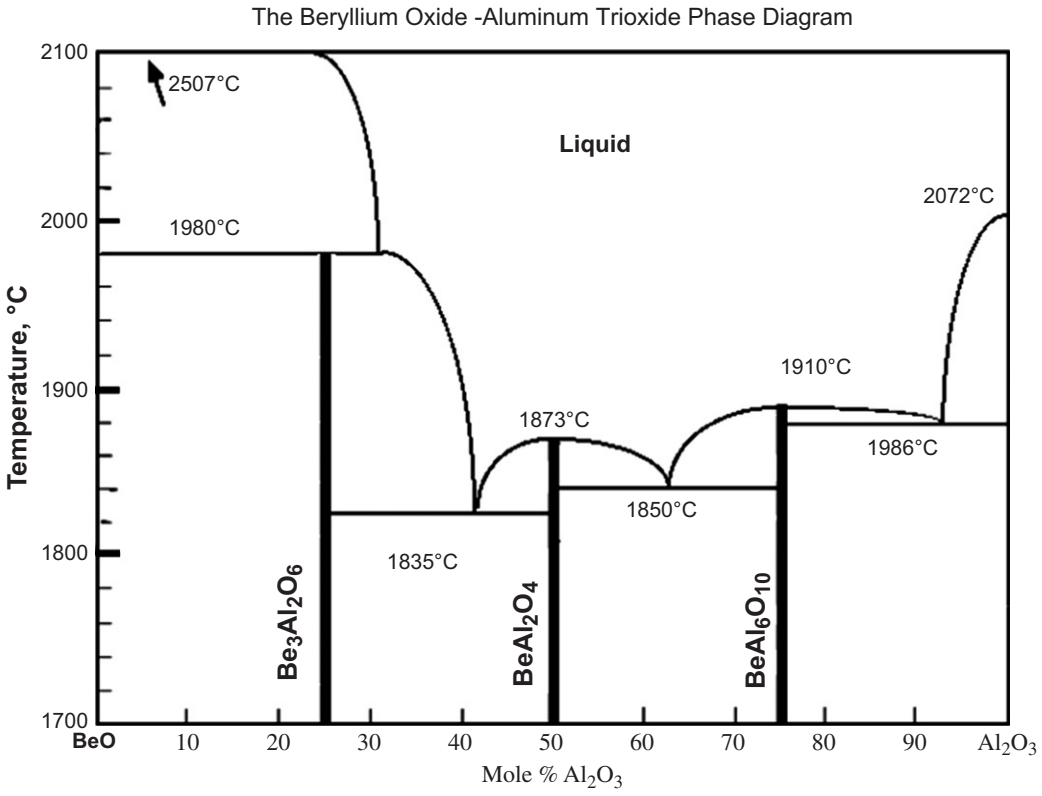

FIGURE 6.83

TABLE 6.13

Enthalpy of formation		Entropy of formation		Gibbs free energy	
(kcal/mol)	(kJ/mol)	(cal/K)	(J/K)	(kcal/mol)	(kJ/mol)
−549.9	−2300.7816	15.84	66.27456	−520.7	−2178.6088

Al_2, located at a reflection site. Both Al sites are octahedrally coordinated. The Al_2 coordination octahedron has a larger Al–O average bond length (1.938 Å) when compared to the Al1 octahedron (1.890 Å) resulting in a larger polyhedral volume.

Another gemstone, "taffeite", has the formulation: $BeMg_3Al_8O_{16}$ (which is a solid solution: $Mg_3Al_2O_6 \cdot BeAl_6O_{10}$). It is hexagonal but the unit-cell dimensions have not been recorded.

The major use in industry for these compounds has been as laser crystals.

Because $Be_3Al_2O_6$ melts incongruently, little use has evolved for this composition. Both $BeAl_2O_4$:Cr^{3+} and $BeAl_6O_{10}$:Cr^{3+} have been grown by Czochralski techniques for use as "tunable" lasers. It was determined that only crystals of $BeAl_2O_4$:Cr^{3+}, grown along the *a*- and *c*-axis showed laser activity. Later work then formed $BeAl_6O_{10}$:Cr^{3+} which was not subject to this limitation. The optical absorption–emission properties of these two crystals is shown in the Fig. 6.84 and the crystal structure of $MgAl_2O_4$ is shown in Fig. 6.85.

The major difference noted was in the tunability of the laser output, the $BeAl_6O_{10}$:Cr^{3+} being superior in this aspect. Comparative studies were performed for "alexandrite" crystals, Al_2BeO_4:Cr^{3+}, employed in solid-state lasers and grown by the horizontal-oriented crystallization (HOC) technique (one-dimensional) and alexandrite crystals grown by the Czochralski (Cz) method (two-dimensional). It was shown that the structural quality and possibilities of generation of stimulated emission for HOC crystals are similar to Cz crystals, and that their damage threshold is about three times higher.

The obtained results and considerably lower cost of HOC-alexandrite crystals proved their advantageous application in powerful laser systems, which require large laser rods with a higher resistance to internal heating caused by generation of the laser beam. It was

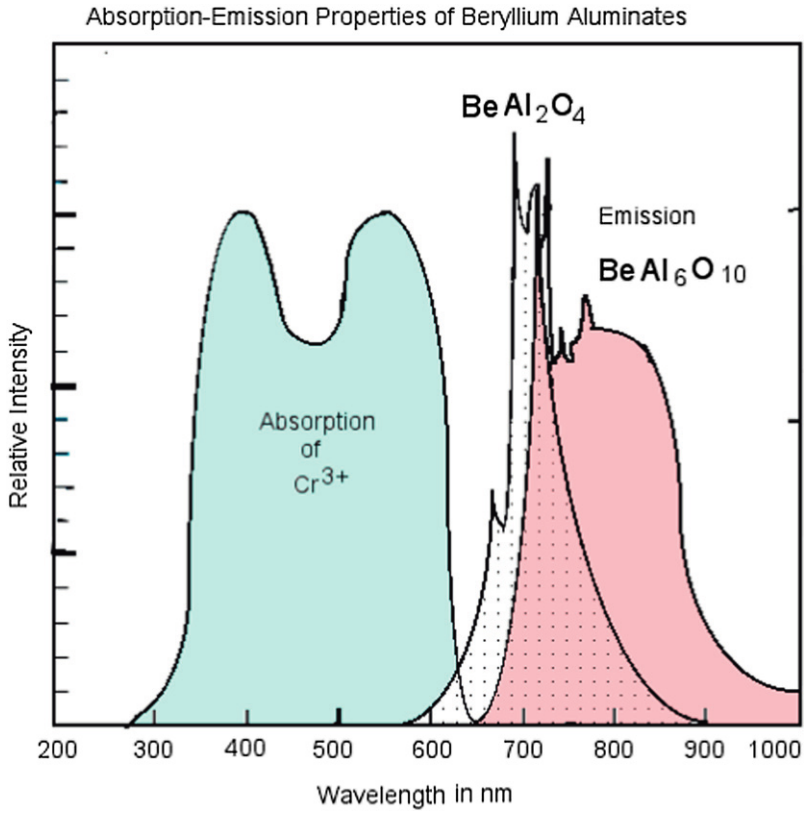

FIGURE 6.84

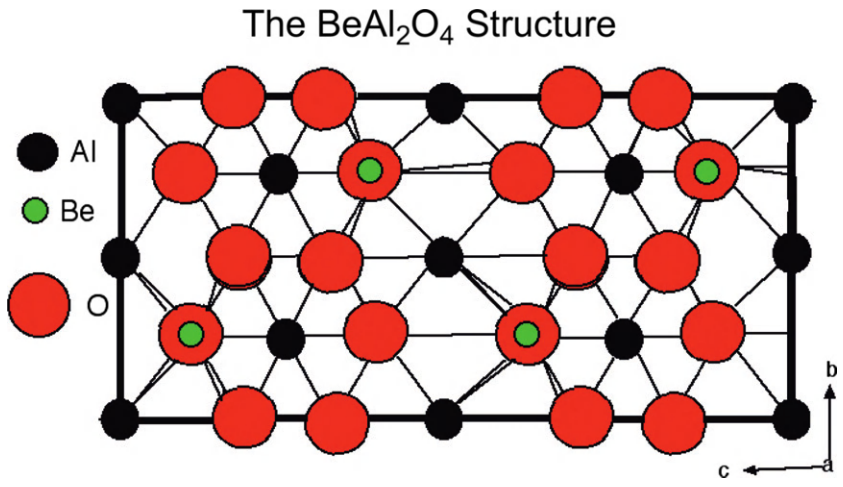

FIGURE 6.85

emphasized that application of HOC technique is promising for growth of laser crystals of other high-temperature oxide compounds. These crystals have a density of 3.74 g/cc, a Mohs hardness of 7.5, a thermal capacity of 0.8 J/kg K, a thermal conductivity of 12.5 W/m K, a Young's modulus of 109 N/m^2 and a Poisson modulus of 0.24.

The stratified hydrodynamic structure of melt in the boat-like crystallization container that predetermines major features of crystal growth was revealed by model experiments. Patterns of (120), (130), and (100) growth sectors of crystal volume and zones of preferred entrapment of gas–melt inclusions as well as efficient distribution coefficient of chrome on crystallization (inversion

included) and distribution behavior of dopant along the grown crystals was shown to be superior to Cz crystals. Occurrence of metal microinclusions of crystallization from the molybenum container (Mo) in grown alexandrite crystals was also analyzed.

A comparison of these two crystals as lasers is shown in Table 6.14.

The absorption spectra of $BeAl_6O_{10}$ are shifted toward the IR range as compared with the alexandrite spectra to be, consequently, superior for using diode pumping as the excitation medium for crystal lasers. $BeAl_6O_{10}$ absorbs 70% at $\lambda = 650$ nm of the maximum, whereas alexandrite is only 35% at the same wavelength.

The structure of alexandrite (crysoberyl) is shown in the following diagram. Only one layer of the three-dimensional structure is shown in Fig. 6.86.

Crystals of alexandrite (crysoberyl) and the beryllium hexa-aluminate are readily available commercially.

Magnesium Aluminates

Spinel is the magnesium aluminum member of the larger spinel group of minerals. It has the formula $MgAl_2O_4$. The cubic spinel structure is very flexible with respect to the cations it can incorporate. There are over 100 known compounds. The formula can be written as $Mg^{2+}(Al_2^{3+})O_4$. This compound can be formed by the SSR of the oxides at ca. 700–1200 °C:

$$MgO + Al_2O_3 + \text{heat} \Rightarrow MgAl_2O_4$$

Magnesium aluminate, $Mg(AlO_2)_2$, has the CAS number of 12068-51-8, a molecular weight of 142.2664 g/mol and a density of 3.55 g/cc. It is

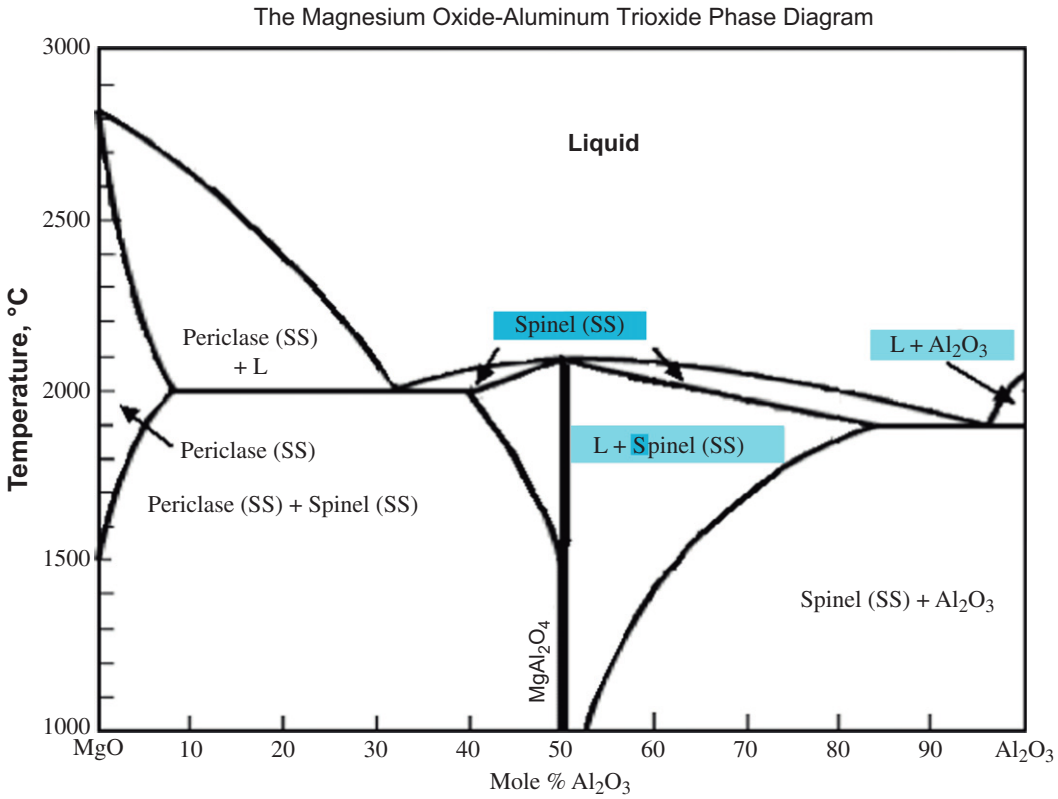

FIGURE 6.86

a colorless, cubic crystal that melts at 2105 °C. The Gibbs free energy involved in this process is:

$$MgO(solid) + Al_2O_3(solid) = MgAl_2O_4(solid)$$

$$\Delta G_{973\ K}^{\circ} = -7.69\ Kcal/mol$$

Most spinel structures can be formed in this way. In general, the use of soluble sodium aluminate, Na_3AlO_3, cannot be used to form the metaaluminate because it forms a double salt, $MgO{\cdot}Na_2O{\cdot}5Al_2O_3$. This compound is sometimes called "β-alumina". Formation of the salt $(Mg, Na)_3(AlO_3)_2{\cdot}xH_2O$, can also occur. In addition, this salt is hydrated and can contain up to 10 water molecules.

The use of several Mg compounds that decompose to form the oxide so as to react with Al_2O_3 has been studied. Little or no difference was noted in the product produced, the initial temperature required, or the rate of reaction that occurred. The exception was γ-Al_2O_3, a compound with a high-specific surface area that reacted much faster with the MgO produced by the decomposition of the various compounds tried.

The phase diagram, shown as follows, presents but one compound, the Spinel. In contrast, the other alkaline earths exhibit a number of other stoichiometries. Spinels have a number of applications in industry. Spinels crystallize in the cubic system, forming octahedral crystals. Owing to its high-melting point (2100 °C), high hardness (16.1 GPa), resistance to chemical attack, and chemical compatibility with alumina, zirconia, and mullite, spinel ($MgAl_2O_4$) is an attractive matrix material for ceramic matrix composites (Fig. 6.86).

A selection of spinels is also presented in Table 6.15.

Monolithic, transparent spinel is also used in optical applications, such as windows for pressure vessels and bulletproof vehicles. The structure of $MgAl_2O_4$ is shown in the following Fig. 6.87.

Among the crystalline compounds, the spinel oxides present a large range of interesting electrical, magnetic and optical properties. The magnesium–aluminum spinel, $MgAl_2O_4$, in particular has been comprehensively studied and previous works point out a high melting point (2135 °C), a high hardness (7.5–8 Mohs), and interesting thermal and optical properties. $MgAl_2O_4$ can crystallize in the "normal" or "inverse" spinel structure. This structure may be described as a cubic closest-packed array of oxygen atoms, with one-eighth of the tetrahedral sites and one-half of the octahedral sites filled. The space group is $Fd\bar{3}$ m (O_H^7) and the lattice parameter "*a*" is equal to 8.08435 Å. In the case of a "normal" spinel structure, Mg^{2+} ions are located in tetrahedral sites and the Al^{3+} ions are in octahedral sites.

As $MgAl_2O_4$ is one of major components of both the spinel phase and the calcium ferrite phase in the Earth's mantle, many researchers have studied its high-pressure phase relations. However, the high-pressure, high-temperature phase relation has been unclear at temperatures higher than 2000 °C. By performing high-pressure experiments, it was determined that $MgAl_2O_4$ spinel decomposes to $Mg_2Al_2O_5$ and Al_2O_3 at 20–25 GPa and temperatures higher than 2000 °C:

$$2\ MgAl_2O_4 + (Heat\ and\ Pressure) \Rightarrow Mg_2Al_2O_5 + Al_2O_3$$

This is the first report of a compound with the composition of $Mg_2Al_2O_5$. The powder XRD pattern cannot be explained by the crystal structures of already known high-pressure phases like the "Brownmillerite"-type $Ca_2Al_2O_5$. In this study, a crystal structure model of this $Mg_2Al_2O_5$ phase was constructed. The obtained structure model was used for structure refinement by a Rietveld analysis. In addition, the $Mg_2Al_2O_5$ phase for a powder XRD measurement was synthesized using a Kawai-type multianvil high-pressure apparatus. The starting material of a mixture of $MgO{:}Al_2O_3 = 2{:}1$ (in molar ratio) was held at 23 GPa and 2500 °C for 10 min. After quenching, the sample was recovered at ambient pressure. The sintered polycrystalline sample was crushed by a die and ground into powder. The powder XRD profile

Compound	Characteristics
$MgAl_2O_4$	Spinel itself, base for natural gemstones
$ZnAl_2O_4$	Gahnite, a transparent diamagnetic spinel
$FeAl_2O_4$	Hercynite, a classical paramagnet
γ-Fe_2O_3	Maghemite, a natural material for magnetic recording
$FeCr_2O_4$	Chromite, the chrome ore of Rhodesia
Mn_3O_4	Hausmannite, a natural tetragonal spinel
Fe_3O_4	Magnetite, the ancient navigator's lodestone
Fe_3S_4	Greigite, a ferrimagnetic semimetal
$NiFe_2O_4$	Trevorite, a ferrimagnetic semiconductor
$ZnFe_2O_4$	Franklinite, the paramagnetic ferrite
$CuCo_2S_4$	Carrollite, a natural metallic spinel
Fe_2TiO_4	Ulvùspinel, with giant magnetostrictive properties
Mg_2SiO_4	The high-pressure spinel polymorph of forsterite (olivine) thought to comprise the Earth's inner mantle
LiV_2O_4	A heavy fermion transition metal oxide
$Fe_{1-x}Cu_xCr_2S_4$	A chalcogenide with colossal magnetoresistive properties

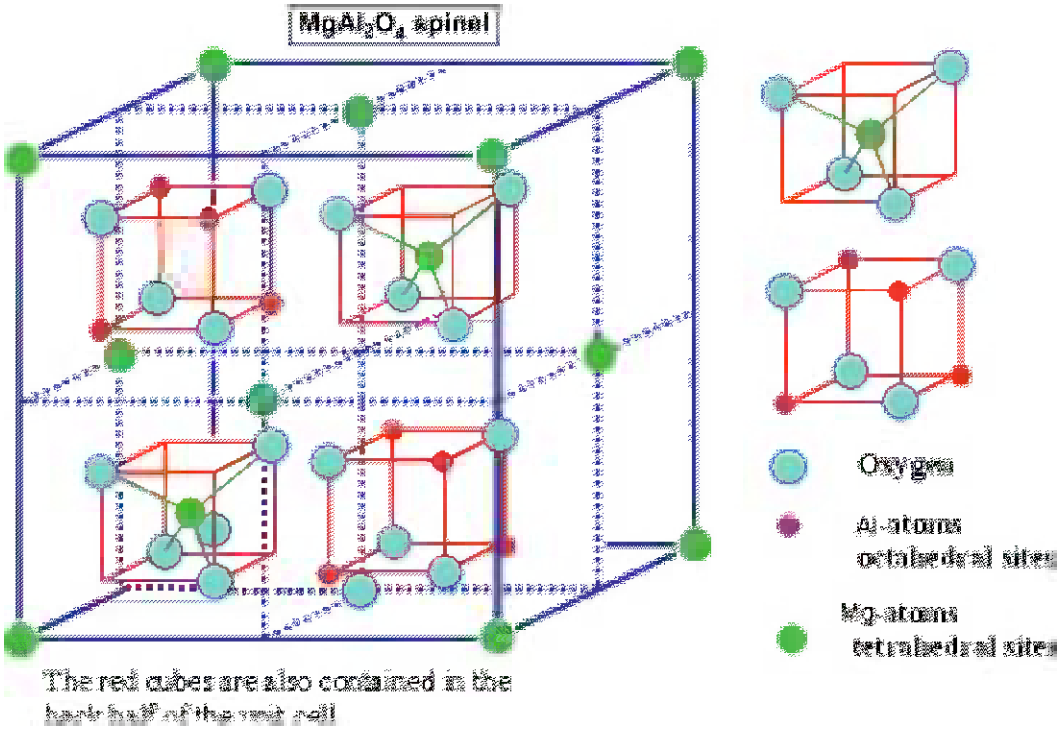

FIGURE 6.87

was measured, showing that crystal symmetry of the $Mg_2Al_2O_5$ phase is orthorhombic. The extinction rules of the powder XRD peaks suggested the space group of Pba2 or Pbam. Since it was found that the XRD pattern is close to that of (Mg, Fe^{2+})$_2$(Fe^{3+}, Al)(BO_3)O_2 (Ludwigite), a structure model of the $Mg_2Al_2O_5$ phase, based on it, was constructed. It should be noted that planar three-coordinated sites in this quasi-Ludwigite was adapted by moving the boron sites by 0.50 Å in atomic coordinate along *c*-axis, because interatomic distances between cation and oxygen in the planar three-coordinated sites are too short for Mg^{2+} and Al^{3+} ions. In this structure model, (Mg,Al)O_6 octahedra were connected by edge sharing and corner sharing to form triangular tunnels along the *c*-axis. Cation sites occupied by only Mg^{2+} are placed in the tunnels. The sites have a coordination environment of trigonal prism-type MgO_6. By the Rietveld analysis, lattice parameters were determined as $a = 9.3710(6)$ Å, $b = 12.1952(6)$ Å, $c = 2.7916(2)$ Å. The calculated density of 3.801(1) g/cm^3 is consistent with the high-pressure phase relations. The *R* factor by adopting the space group of Pbam is smaller than that by Pba2. Therefore, it is suggested that the space group of the $Mg_2Al_2O_5$ phase is Pbam.

In another study, phase transitions in $MgAl_2O_4$ were examined at 21–27 GPa and 1400–2500 °C using a multi-anvil apparatus. A mixture of MgO and Al_2O_3 (corundum), that are high-pressure dissociation products of $MgAl_2O_4$ spinel, was found to combine into calcium ferrite-type $MgAl_2O_4$ at 26–27 GPa and 1400–2000 °C. Below 2000 °C, the calcium ferrite-type $MgAl_2O_4$ is stable above about 26 GPa, and below that pressure a mixture of MgO, periclase and Al_2O_3 corundum is stable. At temperature above 2000 °C and at pressure below 25.5 GPa, a mixture of Al_2O_3 and a new phase with $Mg_2Al_2O_5$ composition is stable. The transition boundary between the two fields has a strong negative pressure–temperature slope. Structure analysis and Rietveld refinement on the basis of the powder XRD profile of the $Mg_2Al_2O_5$ phase indicated that the phase represented a new structure type with orthorhombic symmetry (Pbam), and the lattice parameters were determined as $a = 9.3710$ Å, $b = 12.1952$ Å, $c = 2.7916$ Å, $V = 319.03$ Å^3, $Z = 4$. The structure consists of edge-sharing and corner-sharing (Mg,Al)O_6 octahedra, and contains chains of edge-sharing octahedra running along the *c*-axis. A part of Mg atoms are accommodated in six-coordinated trigonal prism sites in tunnels surrounded by the chains of edge-sharing (Mg,Al)O_6 octahedra. The structure is related with that of Ludwigite (Mg,Fe^{2+})$_2$(Fe^{3+},Al)(BO_3)O_2. The molar volume of the $Mg_2Al_2O_5$ phase is smaller by 0.18% than sum of molar volumes of 2MgO and Al_2O_3 corundum. High-pressure dissociation to the mixture of corundum-type phase and the phase with ludwigite-related structure has been found only in $MgAl_2O_4$ among various $A^{2+}B_3 + 2O_4$ compounds.

Metal matrix composites have been extensively studied, in particular, Spinel and Al metal. If Al_2O_3 particles are introduced into a metal melt consisting of 96%Al–4 wt% Mg by the "vortex" method, aluminum oxide plus a metal matrix results. After being cast, Al_2O_3-(Al–4 wt% Mg) composites were remelted at 700, 750, 800 and 850 °C for different residence times to investigate the formation of $MgAl_2O_4$ (spinel). The results showed that $MgAl_2O_4$ is the unique interface of the Al_2O_3-(Al–Mg) composites held at 700–850 °C. Fine $MgAl_2O_4$ crystals grew on the surface of the Al_2O_3 particle but, as the holding temperature and the residence time increase, some spinels grew into a pyramidal shape. The $MgAl_2O_4$ grew not only at the matrix–particle interface but also on the surface of the composite specimens. The formation reactions of interfacial $MgAl_2O_4$ are as follows:

$$Mg(liq) + 2Al(liq) + 2O_2(gas) \Rightarrow MgAl_2O_4(solid)$$

$$3Mg(liq) + 4Al_2O_3(solid) = 3MgAl_2O_4(solid) + 2Al(liq)$$

Both reactions are equally important. The mechanism of reaction was determined to be governed by diffusion of Al and Mg ions through the layers of reaction products composed of $MgAl_2O_4$ and Al_2O_3 phases. It was found that during the process, the composition of the reaction products changed as the concentration of Mg in the boundary layer diminished.

In another study, the interfacial reactions between Al_2O_3 particles and 50:83 Al–Mg alloys during fabrication by compo-casting and subsequent remelting at 800 °C for 0.5 and 4 h have been studied using analytical TEM and SEM. It was found that the reaction product was changed with increasing remelting time. MgO was the main reaction product after casting and remelting for 0.5 h. The MgO crystals are then very small (about 5–20 nm in size) and the reaction zone is about 50–80 nm thick for the as-cast material and about 100–150 nm after remelting for 0.5 h. However, after remelting for 4 h, MgO is transformed into $MgAl_2O_4$ and the interfacial region is then constituted of large $MgAl_2O_4$ crystals of about 1 μm in size. This transformation indicates that the nature of the reaction products is controlled by the Mg content in the matrix.

The feasibility of fabricating near net-shaped spinel, $MgAl_2O_4$, by the oxidation of solid Mg–Al_2O_3-bearing precursors has been demonstrated. Porous Al_2O_3 preforms were fabricated by uniaxial pressing of Al_2O_3 powder having a mean particle size of 7 microns. The alumina disks and bars were then sintered in air at 1500 °C for 5–12 h so as to produce 65–70% dense preforms. Dense disk-shaped and bar-shaped precursors were fabricated by the pressure-less infiltration of molten Mg into the porous (65–70% dense) Al_2O_3 preforms at 680–700 °C. The shaped, solid MgO–Al_2O_3-bearing precursors were then oxidized in pure, flowing oxygen at 430 °C/40 h to 700 °C/6 h. The resulting mixtures of MgO and Al_2O_3 were converted into $MgAl_2O_4$ within 15 h of annealing in oxygen at 1200 °C. A subsequent 10-h sintering treatment at 1700 °C in flowing Ar yielded shaped spinel-bearing bodies with densities of 92.5% of theoretical. Various shapes could be fabricated.

As a refractory material, $MgAl_2O_4$ spinel has some unique applications in the form of sintered ceramics or coatings. It is considerably more resistant to slags and fluxes, especially alkalis, than alumina. This spinel, including various chemical variations, can be used to coat crucibles and dish nozzles for improved resistance to molten metals and slag. It is usable as an impact resistant optical window and as an infrared radiation lens. As this oxide is practically inert to cold concentrated mineral acids and even boiling acids of moderate concentration, it would be serviceable as a dense coating for chemical reactors. Some variants of this oxide include $MgAl_2O_4/Al_2O_3$ and $MgAl_2O_4$/MgO composites and $MgAl_2O_4/MgCr_2O_4$ solid solutions. Such chemical alterations permit modification of properties such as thermal expansion and corrosion resistance. These materials can be thermally sprayed using flowable, fully reacted powders to give thick dense coatings having properties near to that of bulk ceramics.

Optical absorption of magnesium aluminate spinel single crystals of different compositions $MgO \cdot nAl_2O_3$ ($n = 1.0$ and 2.5) were investigated after irradiation with neutrons, X-rays and the UV light to elucidate existence of specific absorption bands related to lattice defects. The radiation-induced absorption envelope is shifted to higher energy and is larger in intensity in nonstoichiometric spinel in comparison with the stoichiometric one at the same irradiation conditions. Deconvolution of different optical spectra of irradiated crystals shows the shift of the F-type centers from 4.75 and 5.3 eV in stoichiometric crystals to 5.08 and 5.63 eV in $MgO \cdot 2.5Al_2O_3$ for F^+ and F^- centers, respectively. The absorption bands at 3.1 (400 nm) and 3.78 eV (328 nm) are present in both stoichiometric and nonstoichiometric crystals and are identified as V-type centers. By changing the irradiation time and using isochronal annealing, it was revealed that additional bands appear in optical absorption spectra at 4.15 eV (299 nm) for $MgO \cdot 1.0Al_2O_3$ crystals and at 4.46 eV (278 nm) for $MgO \cdot 2.5Al_2O_3$ crystals. From the shift of the band energy position and the high intensity of this band in nonstoichiometric spinel crystals, these wavelengths could be identified with electronic centers related to lattice defects.

Recent studies have demonstrated that cerium containing magnesium aluminate spinels such as $MgAl_2O_4$ and $Mg_2Al_2O_5$ are very effective SO_x reduction catalysts for Fluid catalytic cracking (FCC) units in oil refineries. These magnesium aluminate spinels can be prepared

by three different techniques: (i) thermal co-condensation (ii) coprecipitation and (iii) co-gel formation. Some of the important physical and chemical properties of a spinel, synthesized for this purpose, were found to depend on the preparative route used. The preparation methods and characterization techniques utilized for these spinels were discussed concerning how the SOx abatement activity of these spinels were related to the preparative route employed.

Refractory oxide melts of the binary system MgO–Al_2O_3 have been studied by a molecular dynamics simulation using an advanced ionic interaction model derived from first principles. The simulations reproduced values close to experimental densities, structure factors, and transport properties. Anomalous behavior of the latter was observed as a function of melt composition. The minimum in the Al self-diffusion and the respective maximum in the shear viscosity around the $MgAl_4O_7$ composition were explained by structural changes in the melt. It was concluded that when $MgAl_2O_4$ is melted and excess Al_2O_3 is added, a structural change occurs in the melt:

$$MgAl_2O_4\ (liq) + Al_2O_3(solid) \Leftrightarrow MgAl_4O_7 + (liq)$$
$$+ Al_2O_3(solid) \Leftrightarrow MgAl_6O_{10}\ (liq)$$

However, as the melt cools, the reaction reverted to a mixture of the spinel plus Al_2O_3.

It was found possible to grow a good crystal of $MgAl_6O_{10}$ by a Czochralski method. $Mg_{0.4}Al_{2.4}O_4$ single crystals with good optical quality were successfully grown. The transmission spectrum indicated that the absorption edge of the crystal was at 220 nm, while no apparent absorption peaks were found. The XRD and DSC curve analysis showed that the $MgAl_6O_{10}$ crystal was stable at room temperature. However, after annealing in the air and hydrogen atmosphere at about 1200 °C, $MgAl_6O_{10}$ decomposed into Al_2O_3 and $MgAl_4O_7$. The reaction mainly occurred on the crystal surface, barely inside.

Magnesium aluminate (spinel) is available commercially worldwide in large quantities.

Calcium Aluminates

Calcium aluminate can be formed by heating the oxides together at about 900–1250 °C:

$$CaO + Al_2O_3 + \text{heat} \Rightarrow CaAl_2O_4$$

Calcium aluminate as $CaAl_2O_4$ has the CAS number of 12042-68-1 and a molecular weight of 158.0392 g/mol. It is a white powder and exhibits a monoclinic crystalline form. Its density is 2.98 g/cc and its melting point is 1605 °C. The formation of $CaAl_2O_4$ from $CaCO_3 \cdot Al_2O_3$ powder mixtures has been intensely studied by varying holding times between 1.0 and 40 h and temperatures between 1300 and 1500 °C. Phase formation was studied in samples both quenched from the holding temperatures and in samples slowly cooled. Samples were characterized by X-ray powder diffraction (XRPD), using Guinier-Hägg film data and the Rietveld method, and SEM and TEM. Samples for TEM with very high-site accuracy were produced using focused ion beam microscopy.

In addition to $CaAl_2O_4$, (CA), the samples contained major amounts of CA_2 ($CaAl_4O_7$), $C_{12}A_7$ ($Ca_{12}Al_{14}O_{33}$) and minor amounts of unreacted A (Al_2O_3). Trace amounts of C_3A ($Ca_3Al_2O_6$) were observed only for samples heated to 1500 °C. The amount of the Ca-rich phase $C_{12}A_7$ was found to decrease with time as it reacts with A and, to a less degree, CA_2 to form CA, the most stable phase. In agreement with previous studies, the amount of CA_2 formed decreases comparatively slowly with time. Its unreactivity is due to the fact that it is concentrated in isolated porous regions of sizes up to 100 μm. The formation of the Ca aluminates is found to be in response to local equilibriums within small inhomogeneous regions, with no specific phase acting as an intermediate phase. Samples quenched from 1500 °C were found to contain smaller amounts of poorly crystallized phases. A reaction between C and A takes place as low as 900 °C, forming a metastable orthorhombic modification of CA. The orthorhombic unit cell with $a = 8.732(2)$ Å, $b = 8.078(2)$ Å, $c = \sqrt{3}, \cdot a = 15.124(4)$ Å was verified by electron diffraction, revealing frequent twinning and disorder of the crystallites.

The phase diagram contains five compounds as shown in Fig. 6.88.

The stable phases shown in the phase diagram (formed at atmospheric pressure under an atmosphere of normal humidity) are:

- Tricalcium aluminate, $3CaO \cdot Al_2O_3$ (C3A) = 3:1
- Dodeca-calcium hepta-aluminate, $12CaO \cdot 7Al_2O_3$ (C12A7) = 12:7

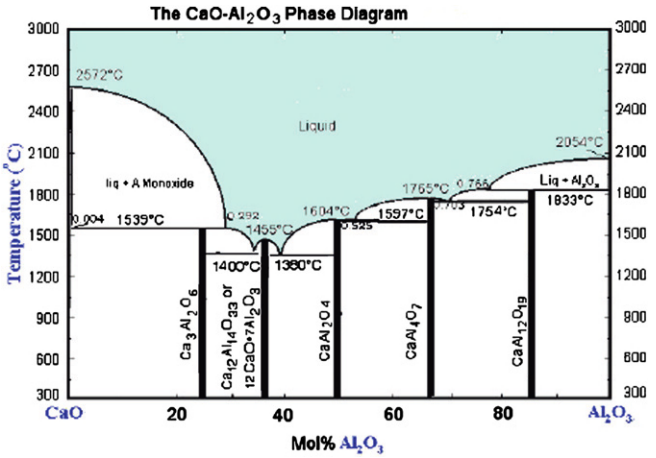

FIGURE 6.88

- Monocalcium aluminate, $CaO \cdot Al_2O_3$ (CA) = 1:1
- Monocalcium dialuminate, $CaO \cdot 2Al_2O_3$ (CA2) = 1:2
- Monocalcium hexa-aluminate, $CaO \cdot 6Al_2O_3$ (CA6) = 1:6

In addition, other phases include:

- Dicalcium aluminate, $2CaO \cdot Al_2O_3$ (C2A) = 2:1, which exists only at pressures above 2500 Mpa. The crystal is orthorhombic, with density 3.480 g/cc.
- Penta-calcium tri-aluminate, $5CaO \cdot 3Al_2O_3$ (C5A3) = 5:3, that forms only under an anhydrous and oxygen-free atmosphere. The crystal is orthorhombic, with a density of 3.067 g/cc. It reacts rapidly with water.
- Tetra-calcium tri-aluminate, $4CaO \cdot 3Al_2O_3$ = 4:3, is a metastable phase formed by dehydrating $4CaO \cdot 3Al_2O_3 \cdot 3H_2O$ (C4A3H3).

The major use found for $CaAl_2O_4$ has been as a hydrous cement. Alternative names are "aluminous cement", "high-alumina cement" (HAC) and "Ciment fondu". They are used in a number of small-scale, specialized applications. The method of making cement from limestone and bauxite was patented in France in 1908 by J. Bied of the Pavin de Lafarge Co. The initial development was as a result of the search for a cement offering sulfate resistance. The cement was called in the French "Ciment fondu". Subsequently, its other special properties were discovered, and these guaranteed its future in niche applications. The main active constituent of calcium aluminate cements is $CaAl_2O_4$, or $CaO \cdot Al_2O_3$, or CA (in the parlance of "cement-chemists"). The cement is prepared by fusing together a mixture of a calcium-bearing material (normally limestone) and an aluminum-bearing material (normally bauxite for general purposes, or refined alumina for white and refractory cements). The liquefied mixture cools to a basalt-like clinker that is ground to produce the finished product. Because complete melting usually takes place, raw materials in lump form can be used. The calcined material drops into the "cool-end" of the melt bath. The melt overflows the hot end of the furnace into molds in which it cools and solidifies. The hydration reactions of calcium aluminate cements are very complex. The strength-developing phases are monocalcium aluminate (CA), dodeca-calcium hepta-aluminate (12C7A) and "belite" = dicalcium silicate, Ca_2SiO_4. A typical composition is $Ca_{0.93}Al_{1.94}Fe_{0.11}Si_{0.02}O_4$. It reacts rapidly with water, forming the metastable hydrate $CaO \cdot Al_2O_3 \cdot 10H_2O$, or a mixture of $2CaO \cdot Al_2O_3 \cdot 8H_2O$, $3CaO \cdot Al_2O_3 \cdot 6H_2O$ and $Al(OH)_3$ gel. These reactions form the first stage of strength development in calcium aluminate cements. The reactive aluminates react with water initially to form a mixture of:

$$CaO \cdot Al_2O_3 \cdot 10H_2O$$

$$2\ CaO \cdot Al_2O_3 \cdot 8\ H_2O,$$

$$3CaO \cdot Al_2O_3 \cdot 6H_2O,$$

$$Al(OH)_3\ \text{gel}$$

The amounts of each present depends upon the curing temperature. The first two hydrates subsequently decompose to a mixture of 3 $CaO \cdot Al_2O_3 \cdot 6H_2O$, $Al(OH)_3$ gel and water, this process being called "conversion". Because of the loss of water, conversion causes an increase in porosity, which can be accompanied by a decrease in strength. This need not be a problem in structural concrete provided that a sufficiently high cement content and a sufficiently low water/cement ratio are employed.

The structures of these compounds and their hydrates have been investigated because of their involvement in the "setting" of Portland cement as well as HAC. There are three fundamental calcium aluminate hydrates that are formed during the course of hydration of HAC. These involve two metastable phases, CAH_{10} ($CaAl_2O_4 \cdot 10H_2O$) and C_2AH_8 ($Ca_2Al_2O_6 \cdot 8H_2O$). Additionally, the stable phase C_3AH_6 ($Ca_3Al_2O_6 \cdot 6H_2O$ = hydrogarnet or Katoite) appears. Further to these species, alumina trihydrate phases often occur during the course of hydration, these being either as an amorphous gel or the crystalline phase Gibbsite.

The major compounds found in these hydrous cements are shown in the following Fig. 6.89.

The purple-tetrahedra are AlO_4 groups but only a part of the red-oxygen atoms are shown (for clarity). The blue spheres are Ca^{2+} cations.

Calcium monoaluminate (CA) is the principal hydraulic mineral present in calcium alumina cement. Its hydration contributes to the high early strength of CA cements. Calcium monoaluminate is a monoclinic phase, pseudo-hexagonal, and its space group is $P2_1/n$, with $Z = 12$ and $D_x = 2.945$ g/cc. It resembles the structure of β-tridymite with an infinite three-dimensional framework of AlO_4 tetrahedra-sharing corners. However, the large ionic radius of the Ca^{2+} cation distorts the tridymite network and a section of the calcium atoms has an irregular coordination polyhedra with oxygen. Under the optical microscope, CA appears as irregular colorless grains, with interference colors less than that of CA2. Some of the Al^{3+} ions in the AlO_4^+ tetrahedra can be partially replaced by iron. CA has a monoclinic unit cell. Figure 1 shows a model of its crystal structure. In calcium aluminate cements, it exists as a solid solution in which the amount of minor elements depends upon the bulk composition of the cement. A typical cement composition is $Ca_{0.93}Al_{1.94}Fe_{0.11}Si_{0.02}O_4$. It reacts rapidly with water, forming the metastable hydrate $CaO \cdot Al_2O_3 \cdot 10H_2O$, or a mixture of $2CaO \cdot Al_2O_3 \cdot 8H_2O$, $3CaO \cdot Al_2O_3 \cdot 6H_2O$ and $Al(OH)_3$

gel. These reactions form the first stage of strength development in calcium aluminate cements.

Grossite or calcium di-aluminate (CA2) has a monoclinic structure with the space group C2/c, $Z = 4$ and $D_x = 2.920$ g/cc. Its structure is based upon a framework of AlO_4 tetrahedra. Some of the oxygen atoms are shared between two tetrahedra and the rest distributed between the other three. The CA2 phase tends to be more refractory in nature than CA. However, it is less reactive, chemocally. CA2, hydrating on its own, will impart a lower strength than CA to the cement after 24 h of curing. However, the hydration of CA2 has been reported to be accelerated by higher temperatures and also by the presence of CA. Grossite's crystal structure is shown in Fig. 2 (presented below).

Dodeca-calcium hepta-aluminate (C12A7) or "Mayenite", $Ca_{12}Al_{14}O_{33}$, is a rare mineral of cubic symmetry, originally reported from the Eifel volcanic complex in Germany. It is also found at pyrometamorphic sites: e.g. in the Hatrurim Formation (Israel) and in some burned coal dumps. Mayenite is also found as an aluminate in aluminate cement where its formula is also written as $12CaO{\cdot}7Al_2O_3$, or C12A7 in the "cement-chemist notation". It has the space group $I_4\bar{3}d$. Its respective crystal structure is composed of Ca^{2+} ions with irregular sixfold coordination with oxygen, which has an incomplete framework of corner-sharing AlO_4 tetrahedra that has the empirical composition, $Al_7O_{16}^{11-}$. In each formula unit, one of the O^{2-} ions is distributed between 12 sites, which increases two of the AlO_4 groups to AlO_5. The calcium ions in mayenite have a highly balanced shell of oxygen atoms, that are roughly distributed on the surface of a hemisphere. These coordinating hemispheres occur in pairs along the axes of crystal symmetry, so that the planar faces are defined by vacancies among the 12-fold positions. Mayenite is the most reactive of all calcium aluminate species occurring in "high-alumina cements" (HACs), and will hydrate very rapidly in contrast to CA. Due to this fact, the amount of mayenite contained in calcium aluminate is very carefully regulated by manufacturers. Its structure is shown in Fig. 3.

Calcium hexa-aluminate (CA6) forms as a result of the sintering of CA2. It is nonhydraulic and more refractory than the other phases, having a melting point of 1870 °C. CA6 is formed in refractory castable products when they are heated to high temperatures. The C3A phase is very reactive and is only present in Portland cements.

Tricalcium aluminate, $Ca_3Al_2O_6$, often formulated as $3CaO{\cdot}Al_2O_3$ to highlight the proportions of the oxides from which it is made, is the most basic of the calcium aluminates. It does not occur in nature, but is an important mineral phase in Portland cement. Pure tricalcium aluminate is formed when the appropriate proportions of finely-divided calcium oxide and aluminum oxide are heated together above 1300 °C. The pure form is cubic, with unit-cell dimension 15.263 Å and has density 3.064 g/cc. It melts with decomposition at 1542 °C. The unit cell contains eight cyclic $Al_6O_{18}^{18-}$ anions, which can be considered to consist of six corner-sharing AlO_4 tetrahedra.

In Portland cement clinker, tricalcium aluminate occurs as an "interstitial phase", crystallizing from the melt. Its presence in clinker is solely due to the need to obtain liquid at the peak kiln processing temperature (1400–1450 °C), facilitating the formation of the desired silicate phases. Apart from this benefit, its effects on cement properties are mostly undesirable. It forms an impure solid-solution phase, with 15–20% of the aluminum atoms replaced by silicon and iron, and with variable amounts of alkali metal atoms replacing calcium, depending upon the availability of alkali oxides in the melt. The impure form has at least four polymorphs whose structure depend upon the amount of impurities present: two types of cubic, one-orthorhombic and one monoclinic crystal form. In keeping with its high basicity, tricalcium aluminate reacts most

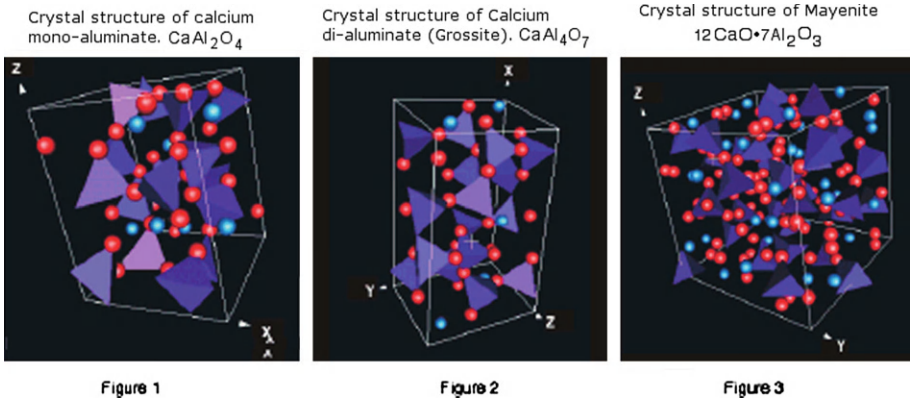

FIGURE 6.89

strongly with water of all the calcium aluminates, and it is also the most reactive of the Portland clinker phases. Its hydration to phases of the form $Ca_2AlO_3(OH)\cdot nH_2O$ leads to the phenomenon of "flash set" (instantaneous set), and a large amount of heat is generated. To avoid this, Portland-type cements include a small addition of calcium sulfate (typically 4–8%). Sulfate ions in solution lead to the formation of an insoluble layer of Ettringite ($3CaO\cdot Al_2O_3\cdot 3CaSO_4\cdot 32H_2O$) over the surface of the aluminate crystals, passivating them. The aluminate then reacts slowly to form the AFm phase, $3CaO\cdot Al_2O_3\cdot CaSO_4\cdot 12H_2O$. These hydrates contribute little to strength development.

Tricalcium aluminate is associated with three important effects that can reduce the durability of concrete: heat release, which can cause spontaneous overheating in large masses of concrete. Where necessary, tricalcium aluminate levels are reduced to control this effect. Sulfate attack, in which sulfate solutions to which the concrete is exposed react with the AFm phase to form Ettringite. This reaction is expansive, and can disrupt mature concrete. Where concrete is to be placed in contact with, for example, sulfate-laden ground waters, either a "sulfate-resisting" cement (with low levels of tricalcium aluminate) is used, or slag is added to the cement or to the concrete mix. The slag contributes sufficient aluminum to suppress formation of Ettringite. Delayed formation, where concrete is cured at temperatures above the decomposition temperature of Ettringite (about 65 °C) has also been employed to obtain stable concrete formations. On cooling, expansive Ettringite formation takes place, which strengthens the cured concrete.

Dodecacalcium hepta-aluminate ($12CaO\cdot 7Al_2O_3$) occurs rarely in nature as the mineral "mayenite" (see above for its structure). It is an important mineral phase in calcium aluminate cements and is an intermediate in the manufacture of "Portland" cement. Its composition and properties have been the subject of much debate, because of variations in composition that can arise during its high-temperature formation. The mineral as normally encountered is a solid-solution series with end-members $Ca_{12}Al_{14}O_{33}$ and $Ca_6Al_7O_{16}(OH)$. The latter composition loses water only at high temperature, and has lost most of it by the melting point (around 1400 °C). If material heated to this temperature is rapidly cooled to room temperature, the anhydrous composition is obtained. The rate of reabsorption of water to form the hydrous composition is negligible below 930 °C. The mineral is cubic. The crystal of $Ca_{12}Al_{14}O_{33}$ has cell dimension 11.983 Å and a density of 2.680 g/cc, while that of $Ca_6Al_7O_{16}(OH)$ has a cell dimension of 1.1976 nm and 2716 kg/m^3. A confusion regarding composition contributed to the mistaken assignment of the composition $Ca_5Al_3O_{33}$. Studies of the system have shown that the solid solution series extends also to the accommodation of other species in place of the hydroxyl group, including halides, sulfide and oxide ions. The mineral as normally encountered is a solid solution series with end-members $Ca_{12}Al_{14}O_{33}$ and $Ca_6Al_7O_{16}(OH)$. The latter composition loses water only at high temperature, and has lost most of it by the melting point (around 1400 °C). If material heated to this temperature is rapidly cooled to room temperature, the anhydrous composition is obtained. The rate of reabsorption of water during cooling to form the hydrous composition is negligible below 930 °C. The mineral is cubic. The crystal of $Ca_{12}Al_{14}O_{33}$ has cell dimension 1.1983 nm and density 2680 kg/m^3 while that of $Ca_6Al_7O_{16}(OH)$ has 1.1976 nm and 2716 kg/m^3. The confusion regarding composition contributed to the mistaken assignment of the composition $Ca_5Al_3O_{33}$. Studies of the system have shown that the solid solution series extends also to the accommodation of other species in place of the hydroxyl group, including halides, sulfide and oxide ions.

Dicalcium aluminate, $2CaO\cdot Al_2O_3$ or $Ca_2Al_2O_5$, was prepared in a piston cylinder apparatus at 1250 °C and 2.5 GPa. The compound is orthorhombic with space group symmetry I2*mb*, $a = 5.2281(1)$ Å, $b = 14.4686(2)$ Å, $c = 5.4004(1)$ Å ($Z = 4$, $D_{calc} = 3.481$ g/cm^3), and belongs to the "Brownmillerite" structure family. Main building units of this structure are (1) layers of perovskite type corner-connected AlO_6 octahedra lying perpendicular to [010], and (2) Zweier single chains of AlO_4 tetrahedra running parallel to the [100] plane. The alternate stacking of the layers and sheets of single chains results in a three-dimensional network in which the calcium ions are incorporated for charge compensation. This structure is the first known example for an alkaline earth aluminate with Zweier single chains of tetrahedra.

Penta-calcium tri-aluminate, $5CaO\cdot 3Al_2O_3$ or $Ca_5Al_6O_{14}$, (C5A3), forms only under an anhydrous and oxygen-free atmosphere. The crystal is orthorhombic, with a density of 3.067 g/cc. It reacts rapidly with water. This unstable form has the space group Cmc2 with $a = 11.253$ Å, $b = 10.996$ Å, $c = 10.290$ Å, $Z = 4$. It consists of alternating sheets of distorted AlO_4 tetrahedra and layers of Ca^{2+} atoms which lie parallel to the (001) plane. The tetrahedra are linked through corners to form a network of five-membered rings. The arrangement of the Ca atoms is unusual in that very short distances of Ca–Ca (~3.200 to 3.267 Å) result in face sharing of the Ca polyhedra.

Tetra-calcium tri-aluminate, $4CaO\cdot 3Al_2O_3$ (C4A3) or $Ca_4Al_6O_{13}$, is a metastable phase formed by dehydrating $4CaO\cdot 3Al_2O_3\cdot 3H_2O$ (C4A3H3). The crystal structure of tetracalcium trialuminate ($Ca_4Al_6O_{13}$), synthesized at 1250 °C and 2.5 GPa, has been determined from single-crystal X-ray data by direct methods [space group

Pcan, $Z = 8$, $a = 5.3002(2)$ Å, $b = 17.7610(5)$, $c = 21.0887(9)$ Å] and refined to $R1 = 6.42\%$. The unit-cell parameters of $Ca_4Al_6O_{13}$ exhibit a relationship to those of perovskite: $a \approx \sqrt{2}\, a_P$, $b \approx 5a_{Pv.}$ and $c \approx 4\sqrt{2}\, a_{Pv}$. The diffraction data showed the typical features of a pseudo-translational symmetry: all reflections (*hkl*) with *l* equal to 4*n* (*n* is an integer) had significantly higher intensity than the reflections with $l \neq 4n$. Furthermore, diffuse streaks parallel to *b** were observed. This compound exhibits Al^{3+} in three different kinds of coordination polyhedra: octahedra, tetrahedra, and trigonal bipyramids. One of the two main building units involves slightly corrugated sheets of perovskite-type corner-sharing AlO_6 octahedra perpendicular to the [010] direction. The octahedral sheets are connected by layers containing tetrahedral Zweier single chains. Within these layers, the tetrahedral chains are linked by two different kinds of rods containing distorted trigonal bipyramids sharing common corners and edges, respectively. The tetrahedral chains and the bipyramidal rods are parallel to [100]. Charge compensation is achieved by the Ca ions, which are coordinated by 9 or 10 oxygen cations.

If $CaSO_4$ (Gypsum) is added to the mix, the mineral, "ettringite" results. It is a hexacalcium aluminate trisulfate hydrate, of general formula:

$$(CaO)_6(Al_2O_3)(SO_3)_3 \cdot 32H_2O,$$

or;

$$(CaO)_3(Al_2O_3)(CaSO_4)_3 \cdot 32H_2O.$$

"Rapid Set® Cement" is an advanced, high-performance, hydraulic cement, that provides structural strength in 1 h, reduced shrinkage, and superior resistance to chemical attack. The chemistry of Rapid Set® Cement is primarily composed of hydraulic tetracalcium trialuminate sulfate (C4A3) and dicalcium silicate (C2S). The C4A3 compound, often referred to as calcium sulfoaluminate, hydrates to form beneficial "ettringite". Ettringite is a strong, needle-like crystal that forms very quickly to give Rapid Set® its high performance. Another significant aspect of the chemistry is the absence of tricalcium aluminate (C3A). C3A is present in Portland cement and makes it susceptible to sulfate attack. The fact that Rapid Set® has little or no C3A makes it very durable in sulfate environments.

Ettringite, a naturally occurring mineral, is formed in the hydrated Portland cement system as a result of the reaction of tricalcium aluminate with calcium sulfate, both present in Portland cement:

$$Ca_3Al_2O_6 + 3CaSO_4 \rightarrow \text{Ettringite}$$

In the cement system, the presence of Ettringite depends on the ratio of calcium sulfate to tri-calcium aluminate (C3A). When this ratio is low, ettringite forms during early hydration and then converts to the calcium aluminate monosulfate (AFm phase or (Al_2O_3–Fe_2O_3–monoaluminate)). When the ratio is intermediate, only a portion of the Ettringite converts to AFm and both can coexist, while ettringite is unlikely to convert to AFm at high ratios. Ettringite is named after Ettringen, Germany, the place where it was discovered in 1874.

Another mineral, Mayenite (after Mayen, Germany), $Ca_{12}Al_{14}O_{33}$, is a rare cubic mineral of cubic symmetry, originally reported from Eifel volcanic complex (Germany). It is also found at pyrometamorphic sites: e.g. in the Hatrurim Formation (Israel) and in some burned coal dumps as "Mayenite". The formula can be written as $[Ca_{12}Al_{14}O_{32}]O$, which refers to the unique feature: anion diffusion process. Mayenite is also found as calcium aluminate in cement where its formula is also written as $12CaO \cdot 7Al_2O_3$, or C12A7 in the "cement-chemist" notation.

The hydrates involved in the setting of these cements are:

Calcium aluminate decahydrate (CAH_{10}) is a metastable hydrate, which is typically formed when calcium aluminates are mixed with water at temperatures below 20 °C. CAH_{10} forms hexagonal platelets of poorly crystallized material making its interrogation by XRD often difficult. Upon heating, CAH_{10} will dehydrate at between 120 and 130 °C with an endothermic reaction which can easily be detected using DTA. CAH_{10} has a unit cell that is deformed orthorhombic. Its structure is shown in Figure 4, shown above in Fig 6.90.

Dicalcium aluminate octahydrate (C_2AH_8) is another metastable calcium aluminate hydrate. It tends to precipitate out of solution as a thin hexagonal platelet similar to CAH_{10}. C_2AH_8 occurs in the temperature range 21–30 °C. It dehydrates in the region of 210–230 °C with a characteristic endothermic peak.

Tri-calcium aluminate hexahydrate (C_3AH_6) or hydrogarnet (Katoite) is the most stable of all calcium

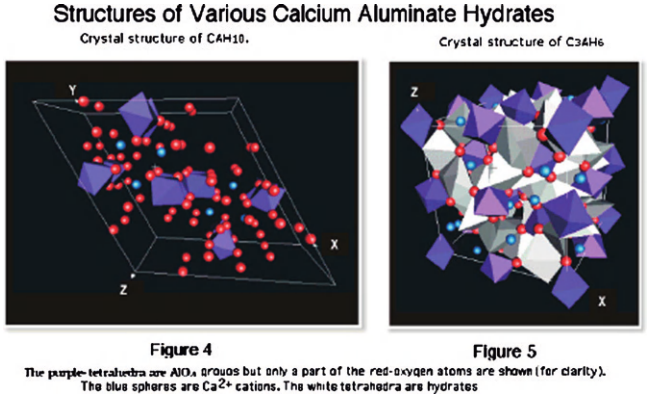

FIGURE 6.90

aluminate hydrates. It has a cubic unit cell. It is formed at higher ambient temperatures. It will not undergo transformation into other hydrates as with CAH_{10} and C_2AH_8. It dehydrates at between 300 and 350 °C forming first of all $C_3AH_{1.5}$ before undergoing complete dehydration around 500 °C. Its crystal structure is shown as shown in Figure 5 of Fig. 6.90.

In addition, several other hydrates have been discovered. Several modifications of the "hexagonal" tetracalcium and dicalcium aluminate hydrates have been obtained. Only a newly established $4CaO \cdot Al_2O_3 \cdot 19H_2O$ hydrate, and an α-form and a β-form of a $2CaO \cdot Al_2O_3 \cdot 8H_2O$ hydrate have been found to occur in the aqueous system at 25 °C. Other modifications are produced on drying under various conditions.

The $4CaO \cdot Al_2O_3 \cdot 19H_2O$ hydrate, characterized in the X-ray patterns by a long basal spacing of 10.62 Å, is dehydrated relatively easily to give a mixture of α-and β-forms of a $13H_2O$ hydrate, characterized by the basal spacings of 8·224 Å and 7·926 Å, respectively (basal here means the longest spacing between the two positions in the crystal structure).

There is little difference in stability between the two forms and it appears to be a matter of chance as to the relative amount of each that may be formed.

Two other tetracalcium aluminate hydrates have been obtained with water contents of $11H_2O$ and $7H_2O$, both of which give basal spacings of 7·42 Å. The α- and β-forms of $2CaO \cdot Al_2O_3 \cdot 8H_2O$ are characterized by basal spacings of 10·728 Å and 10·447 Å, respectively. The α-form appears to be more stable than the β-form. Three other states of hydration of the dicalcium compound exist, having water contents of $7.5H_2O$, $5H_2O$ and $4H_2O$, with basal spacings of 10.642 Å, 8.714 Å, and 7.443 Å, respectively. With various preparations of the compound $3CaO \cdot Al_2O_3 \cdot CaSO_4$,aq., basal spacings of 10·332 Å, 9·621 Å, 8·943 Å, 8·234 Å, and 8·034 Å have also been observed.

The basic nature of "concrete" formed from $CaAl_2O_4$ (CA) in Portland cement has also been elucidated. For CA, the anhydrous grains react immediately upon their addition to water, dissolving congruently to yield calcium ions and aluminate ions. As a consequence of this, the resulting solution appears to increase in both conductivity and pH until a point of super saturation is attained. The dissolution process is typically thought of as being congruent, yet there is often more lime than alumina present in solution:

$$CaAl_2O_4\ (\text{solid}) + 4\,H_2O \Rightarrow Ca^{2+}\ (\text{aq}) + 2\,Al(OH)^-\ (\text{aq})$$

It was reported that this observation is due to the fact that small quantities of alumina gel precipitate out of solution during hydration via the equation:

$$Al(OH)^- \Rightarrow Al(OH)_3\ (\text{gel}) + OH^-$$

This initial stage in the hydration reaction is exothermic and associated heat evolution can be detected easily by calorimetric methods. Once a state of super saturation of Ca^{2+} and $Al(OH)^{4-}$ (aq) species is reached, the reaction reaches a dormant stage prior to the nucleation stage.

In the second stage of the hydration reaction (nucleation), the solution remains supersaturated with ions. Dissolution and hydrate formation occur at a very slow rate, wherein a very high concentration of Ca^{2+} and $Al(OH)^{4-}$ (aq) species is maintained. Thus, the pH and conductivity of the solution will remain constant.

At the end of the nucleation phase of the reaction, massive precipitation and growth of the hydrate species will occur. This immediately results in a reduction in the amount of ions present in the solution, so that if any reacted CA is present, it will quickly be redissolved to attain super saturation once again. However, this will precipitate almost instantaneously to yield hydrated species. Dissolution and hydrate reprecipitation now proceeds simultaneously, though eventually the rate of the reaction will become infinitely large as the anhydrous CA diminishes. At this point, the conductivity will drop sharply corresponding to the drop of inorganic ionic species present in solution. Mass precipitation of species of this nature in the hydration reaction is accompanied by a considerably large exotherm (which can be detected to determine the end-point of the hardening reaction).

The hydration pathway for CA (monocalcium aluminate) in the hardening sequence of chemical reactions for this cement is shown as shown in Fig. 6.91.

Thus, it should be apparent that the hydration of the CA phase is temperature dependent. At lower temperatures, CAH_{10} will form (typically below 20 °C). In the intermediate temperature ranges between 21 and 30 °C, C_2AH_8 will form. Under conditions of elevated temperature C_3AH_6 will form, which is the most thermodynamically stable and the least soluble of the calcium aluminate hydrates. In addition to the hydrates

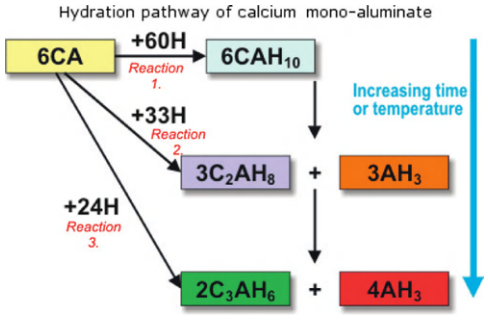

FIGURE 6.91

formed at intermediate temperatures, crystalline Gibbsite (AH_3) will form. Due to the metastable nature of CAH_{10} and C_2AH_8 over long periods of time or at elevated temperatures, both phases will undergo a transformation into the hydrogarnet phase (C_3AH_6.) This reaction is known as *"conversion"*. Conversion is initiated by the nucleation of C_3AH_6 and takes place in solution. As well as obvious changes in the chemistry during conversion, there are accompanying changes in the physical properties. In the transformation from CAH_{10} to C_3AH_6, a 52.5% reduction takes place, and during the change from C_2AH_8 to C_3AH_6 there is a 33.7% reduction in size. This results in an increase in the porosity of the concrete. Another effect of conversion is the release of water from the hydrates. A major impact of this increase in porosity and shrinkage is a decrease in mechanical strength. Conversion is a very topical subject in the field of calcium aluminate cements and the phenomena has been responsible for the failure of many buildings and bridges.

Because of their relatively high cost, calcium aluminate cements are used in a number of restricted applications:

- in construction concretes, rapid strength development is achieved, even at low temperatures.
- in construction concretes, high chemical resistance is possible.
- in refractory concretes, strength is maintained at high temperatures.
- as a component in blended cement formulations, various properties such as ultrarapid strength development and controlled expansion can be obtained.

However, calcium aluminates cements are no longer widely used in building construction because they are not stable enough over time. Incorrect use of calcium aluminate cements has led to widespread construction problems, especially during the third quarter of the twentieth century when this type of cement was used because of its faster hardening properties. After several years, some of the buildings and structures collapsed due to degradation of the cement and many had to be torn down or reinforced. Heat and humidity accelerate the degradation process called "conversion"; the roof of a swimming pool was one of the first structures to collapse in Britain. In Madrid, Spain, a large housing block nicknamed Korea (because it was built to house Americans during the Korean war), built 1951~1954 was affected and had to be torn down in 2006. Also in Madrid, the Vicente Calderón soccer stadium was affected and had to be partially rebuilt and reinforced.

Calcium aluminates are readily available commercially worldwide.

Strontium Aluminates

Strontium aluminate can be prepared by reaction of the oxides at about 700–900 °C:

$$SrO + Al_2O_3 + \text{heat} \Rightarrow SrAl_2O_4$$

The crystals of $SrAl_2O_4$ are monoclinic, with unit-cell parameters: $a = 5.1497$ Å, $b = 8.836$ Å, $c = 8.442$ Å, $\beta = 93.43°$; space group $P2_1$ or $P2_1/m$.

The $SrO \cdot Al_2O_3$ system is of interest in industry because of the use of the intermediate compounds for hydraulic cements, laser matrices, and long-duration photoluminescence or thermoluminescence pigments. But, compared to the information developed for the magnesium and calcium counterparts, the knowledge of the phase diagram of strontium aluminates has been quite limited. The only complete phase diagram of this system was reported in 1979. However, differences in melting and eutectic temperatures have found their way into the literature. The compounds and phase relations are essentially the same as shown by Massazza (1959), except for the differences in the various melting and inversion temperatures reported. The metastable compound, $Sr_4Al_2O_7$, was synthesized by several authors, but was not shown in any of the earlier phase diagrams. The following phase diagram is that which is believed to be the most representative of this phase system (Fig. 6.92).

The $SrO–Al_2O_3$ system shown has five binary phases: $3SrO \cdot Al_2O_3$, $SrO \cdot Al_2O_3$, $SrO \cdot 2Al_2O_3$, $4SrO \cdot Al_2O_3$ and $SrO \cdot 6Al_2O_3$. Liquidus temperatures drop rapidly upon addition of Al_2O_3 to SrO. Thus, $SrO \cdot 6Al_2O_3$ melts incongruently to Al_2O_3 at 1690 °C.

The minimum melting compositions are the eutectics between:

(i) $SrO \cdot 2Al_2O_3$ and $SrO \cdot 6Al_2O_3$ located at 1780 °C.
(ii) $SrO \cdot Al_2O_3$ and $SrO \cdot 2Al_2O_3$ located at 1760 °C.

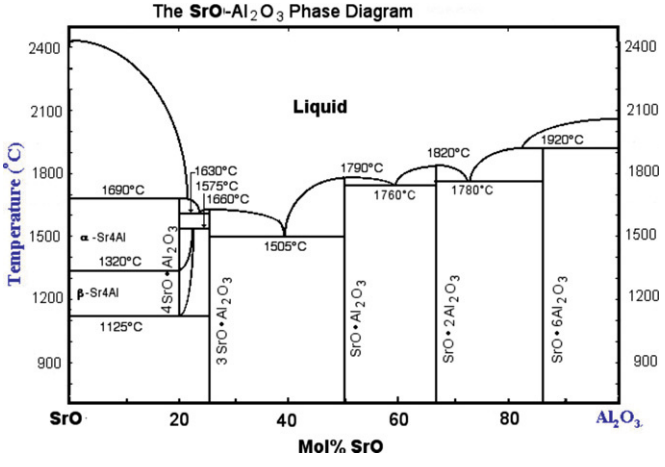

FIGURE 6.92

(iii) 3 SrO Al_2O_3 and SrO·Al_2O_3 located at 1505 °C.
(iv) 4 SrO Al_2O_3 and 3SrO Al_2O_3 located at 1630 °C.

Several of these compounds are difficult to synthesize. Up to about 1999, strontium dialuminate, $SrAl_4O_7$ (SA2), could be synthesized only by solidification from the high-temperature liquid state.

Strontium hexa-aluminate, $SrAl_{12}O_{19}$, has the magnetoplumbite structure. The magnetoplumbite-structured $SrAl_{12}O_{19}$ may be expected to accommodate a diverse chemistry because of the variety of crystallographic sites within the unit cell (Fig. 6.93).

It has a hexagonal structure, with space group *P*63/*mmc*. There are three types of Al^{3+} ions in the lattice. The unit cell is composed of spinel-structured slabs containing Al^{3+} cations separated by mirror planes which contain one Sr^{2+} and three oxygen ions per unit cell. The spinel blocks have the usual IV and VI coordinated sites for cations, whereas the interspinel layers have rather unusual V-fold sites for small cations. The interspinel layers also provide XII-fold sites to accommodate large cations, which may be monovalent, divalent, or trivalent with balancing charge substituents either in the interspinel layer (i.e. $Na_{0.5}$+ $La_{0.5}$) or in both the interspinel layer and the spinel block (e.g. La and Mg replacing Sr and Al, respectively). The latter reaction can be expressed as:

$$SrAl_{12}O_{19} + (x/2)\ La_2O_3 + x\ MgO \Rightarrow Sr_{1-x}La_xAl_{12-x}Mg_xO_{19} + x\ SrO + (x/2)\ Al_2O_3$$

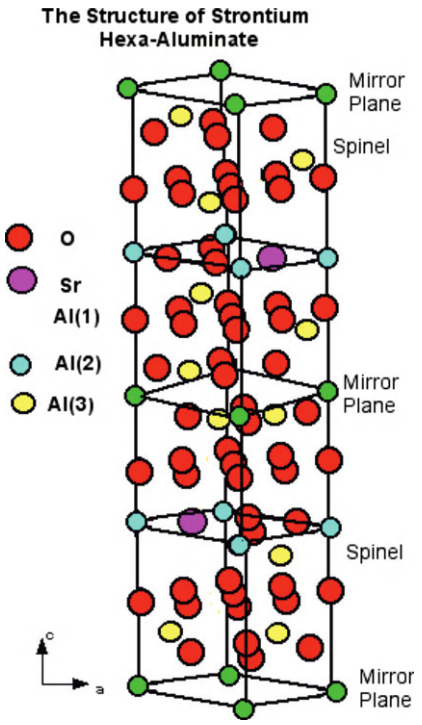

FIGURE 6.93

The defect reaction energy for this process is:

$$E = E(La_{Sr}) + E(Mg_{Al}) + E_{lat}(SrO) + 0.5E_{lat}(Al_2O_3) - 0.5E_{lat}(La_2O_3) - E_{lat}(MgO)$$

Some lattice energies and defect energies related to this question have been calculated and are given in Table 6.16.

"Frenkel" and "Schottsky" lattice defects are: Fr = interstitual + vacancy and Sch = cation vacancy + anion vacancy, respectively. For a comprehensive discussion of lattice defects in solids, see "Chapter 2—The Point Defect" in "Luminescence and the Solid State"—2nd Ed. by R. C. Ropp, Elsevier (2004) ISBN-0-444-51661-1.

The reaction enthalpy is calculated to be −1.02 eV when the binding energy of the two point defects is considered. This negative enthalpy indicates that the defect process is energetically favorable. This results in the following lattice energies (Table 6.17).

Strontium dialuminate, $SrAl_4O_7$ (SA_2), could only be synthesized in the past by solidification from the high-temperature liquid state. However, its synthesis from

a spray-dried amorphous precursor can be obtained if its stability domains are maintained during synthesis. Its kinetics of formation is very low. It can be crystallized in the 900–1000 °C temperature range either directly with a low heating rate or via two metastable solid solutions [hexagonal strontium monoaluminate, $SrAl_2O_4$ (SA) and β-alumina] by annealing at 950–1000 °C. As the temperature is raised beyond 1100 °C, SA_2 becomes metastable, its formation is no longer possible, and the crystallization of $Sr_4Al_{14}O_{25}$ (S_4A_7) is favored. The latter compound, whose composition is close to that of SA_2, is stable up to 1500 °C. At higher temperature, it decomposes into SA and SA_2, which in its turn decomposes into SA and SA_6 ($SrAl_{12}O_{19}$). There is again another stability domain for SA_2, restricted to a narrow temperature scale close to its melting point (~1800 °C). The behaviors at crystallization from amorphous precursors at low temperature and from liquid at very high temperature are symmetrical: low heating or cooling rates produce pure SA_2 while too rapid kinetics result in mixtures of phases. Strontium dialuminate ($SrAl_4O_7$) can also be synthesized by crystallization of amorphous spray-dried precursors via the ethylenediaminetetraacetic acid precursor route. Differential thermal analysis, thermogravimetric, Fourier transform infrared spectroscopy, and XRD were used to characterize the precursors and the oxide powders derived. XRD analysis showed that single-phase $SrAl_4O_7$ was obtained from pulverized resin at a temperature of 1050 °C for 2 h and $SrAl_4O_7$ can be stable at least up to 1200 °C. Single-phase $SrAl_4O_7$ was not obtained from the citrate acid route.

Strontium dialuminate has two polymorphs, the α-phase being stable at STP but the β-phase can only be prepared at a high pressure and temperature. A mixture of α-$SrAl_4O_7$ and water was used in a cubic anvil type apparatus to prepare β-$SrAl_4O_7$. Pressure was maintained at 5.0 MPa and temperature at 1473 K (1200 °C) for 60 min. If water was not present, unknown phases were obtained. Upon cooling to 800 °C, single crystals of β-$SrAl_4O_7$ were obtained. This crystal is orthorhombic with space group Cmma, $a = 8.085$ Å, $b = 11845$ Å, $c = 4.407$ Å, Dens = 4.84 (calc) and $Z = 2$. The lattice consists of a three-dimensional (Al_4O_7) network of $Al(1)O_6$ octahedra and $Al(2)O_4$ and $Al(3)O_4$ tetrahedra. The bond lengths for the octahedra were 1.795 to 1.968° for the octahedra and 1.449 to 1.537 Å for the tetrahedra. The structure has certain similarities to that of the tetrastrontium aluminate structure. Each Sr atom is surrounded by 10 O atoms with distances ranging from 2.503 to 2.664 Å.

Tetrastrontium aluminate is also very unstable and can only be formed in a narrow temperature range. This can be determined from the phase diagram given above. It does not form at temperatures <1125 °C and when mixtures of $4SrO \cdot Al_2O_3$ are calcined, $Sr_3Al_2O_6$ results. If the mixture is heated above 1100 °C, S3A becomes metastable, and its formation is no longer possible since the crystallization of $Sr_4Al_2O_7$ (Sr4A) is favored. The latter compound, whose composition is close to that of SA2, is stable up to 1690 °C. At higher temperature, it decomposes into SA and SA2, which in its turn decomposes into SA and SA6 ($SrAl_{12}O_{19}$). The behaviors at crystallization from amorphous precursors at low temperature and from liquid at very high temperature are symmetrical: low heating or cooling rates produce pure SA_2 while too rapid kinetics result in mixtures of phases. The phase [$Sr_3Al_2O_6$] has been observed at 1000 °C as a stable phase. This phase was found to be transformed into [$SrAl_2O_4$] at 1250 °C. All of this thermal behavior is the result of the instability of S4A.

The reactions observed were shown in Table 6.18.

Thus, it should be clear that the stable compounds in this system are SA ($SrAl_2O_4$) and SA6 ($SrAl_{12}O_{13}$). X-ray powder diffraction data for $SrAl_2O_4$ have been obtained from the pure synthesized compound. The crystals of $SrAl_2O_4$ are monoclinic, with unit-cell parameters: $a = 5.1497$ Å, $b = 8.836$ Å, $c = 8.442$ Å, $\beta = 93.43°$; space group $P2_1$ or $P2_1/m$.

The major use for **strontium aluminate** (SA) has been as a long-term phosphorescent material when activated by Eu^{2+}. It is labeled as $SrAl_2O_4$:Eu^{2+}. It acts as a photoluminescent phosphor with long persistence of phosphorescence. Its CAS number is 12004-37-4. Strontium aluminate is a vastly superior phosphor than its predecessor, copper-activated zinc sulfide; it is about 10 times brighter, 10 times longer glowing, and 10 times more expensive than ZnS:Cu. It is frequently used in "glow-in-the-dark" toys, where it displaces the cheaper and less efficient ZnS:Cu and it is less toxic. However, the material has high hardness, causing abrasion to the machinery handling it; coating the particles with a suitable lubricant is usually used when strontium aluminate is added to plastics. Strontium aluminate (SA) phosphors produce green and aqua hues, where green gives the highest brightness and aqua the longest glow time. The excitation wavelengths for strontium aluminate range from 200 to 450 nm, i.e. it is "daylight" excited. The emission wavelength for its green formulation is 520 nm, its blue-green version emits at 505 nm, and the blue one emits at 490 nm. Colors with longer

TABLE 6.18

$$S3A + S \xrightarrow{1100°C} Sr4A\{Sr_3Al_2O_6 + SrO \Rightarrow Sr_4Al_2O_7\}$$

$$Sr4A + 4A \xrightarrow{1690°C} 3SA + SA2$$

$$4SA2 + A \xrightarrow{>1690°C} 3SA + SA6$$

$$S3A \xrightarrow{>1690°C} SA + 2S$$

wavelengths can be obtained from the strontium aluminate as well, though at the cost of some loss of brightness. The wavelengths produced depend on the internal crystal structure of the material. Slight modifications in the manufacturing process (the type of reducing atmosphere, small variations of stoichiometry of the reagents, addition of carbon or rare earth halides) can significantly influence the emission wavelengths.

Strontium aluminate phosphor is fired at about 1250 °C. Subjecting it to temperatures above 1090 °C is likely to cause loss of its phosphorescent properties. The glow intensity depends on the particle size; generally, the bigger the particles, the better the glow.

All of the possible phase compositions of the strontium aluminates have been explored for this application. Among them, $Sr_3Al_2O_6$, $SrAl_2O_4$, $SrAl_4O_7$, and $SrAl_{12}O_{19}$ crystals that have been doped with Eu^{2+} and Dy^{3+} ions were found worthy of investigation for determining the phosphorescence mechanism and the development of a new phosphor with a variety of colors. It is noteworthy that the addition of a trivalent cation like Dy^{3+} promotes the formation of electron traps in the lattice via formation of a cation vacancy:

$$DySr^{3+} + VSr^{+} \Leftrightarrow 2Sr_{Sr}^{2+}$$

Dy^{3+} is routinely added to the lattice composition because it causes a loss of photoluminescence and promotes phosphorescence. The luminescent properties of $SrAl_2O_4$ doped with Eu^{2+} and codoped with the rare earths ($Ln^{3+} = Eu^{3+}$, Er^{3+}, Sm^{3+} and Dy^{3+}) have been studied. The materials were synthesized by a reflux method and fired up to 900 °C for 16 h. The XRD pattern confirmed that the synthesized material consists of $SrAl_2O_4$ as main phase. The photoluminescence study gives a clear evidence of europium stabilizing in trivalent form and surprisingly with a lack of presence of europium in the divalent state. The addition of Dy^{3+} as co-dopant in the $Sr_3Al_2O_6$:Eu^{3+} matrix shows a quenching effect in the photoluminescence (PL) spectra. The photoluminescence intensity of Eu^{3+} falls gradually on increasing the concentration of the co-dopant in the range from 0.1 to 2.0 mol%. A significantly intense thermoluminescence (TL) glow peak was obtained for $Sr_3Al_2O_6$:Eu^{3+}:Dy^{3+} (1% and 0.1%) at around 194 °C when irradiated with 10 kGy dose from Sr-90 β-source.

A long-decay strontium aluminate (SrA)-based phosphor has been prepared by a solid state reaction technique. The dependence of initial brightness and observed afterglow characteristics on various thermal processing parameters such as heating rates, time of constant heating and cooling rates have been investigated. It has been found that heating rates (>625 °C/h), time of constant heating (<2 h at around 1200 °C) and cooling rates (>250 °C/h) resulted in nonuniform luminescent samples which are not excited under daylight but were excited under UV (365 nm). When proper heating rates (<300 °C/h), time of constant heating (>4 h at 1200 °C) and cooling rates (<100 °C/h) were employed, high-density ceramic compact (3100 kg/m^3) samples resulted. These phosphors had very low initial brightness but a quite long afterglow under room light and UV excitation. An optimum of both fast rise and long afterglow under room light excitation was been achieved for the SrA samples fired with the heating rates of 300–625 °C/h, time of constant heating of 2–4 h at around 1200 °C and cooling rates of about 100–250 °C/h. The decay characteristics of SrA were much superior to the established ZnS:Cu long-decay phosphor.

The mechanoluminescence (ML) of Eu,Dy co-doped strontium aluminates has been studied (ML is luminescence induced by force or stress on the crystal lattice). The compositions, $SrAl_2O_4$ and $Sr_3Al_2O_6$, showed a high degree of ML capacity, which is clearly visible to the naked eye in the air (One merely presses on the powder to obtain emission.). $SrAl_2O_4$:Eu:Dy shows the highest ML intensity and has many filled traps, high-quantum efficiency and moderate stiffness. On the other hand, $Sr_3Al_2O_6$:Eu:Dy does not have many filled traps and has a high relative quantum efficiency. But it does show a relatively high ML intensity. It has many filled traps and high relative quantum efficiency, but $SrAl_4O_7$:Eu,Dy shows very little ML capacity. The ML properties of $SrAl_2O_4$:Eu,Dy indicates that the lattice is capable of promoting high thermoluminescence because of the stiffness of the lattice. This suggests that "stiffness" is an important factor for obtaining ML intensity within the Eu,Dy co-doped strontium aluminate system.

Discussion of the applicability of long-duration (phosphorescent) phosphors has been based on optical measurements. $Sr_3Al_2O_6$, $SrAl_2O_4$, $SrAl_4O_7$, and $SrAl_{12}O19$ crystals were grown by a floating-zone technique for application as long-duration phosphors. Long-duration phosphorescence with a variety of colors has been observed in $Sr_3Al_2O_6$, $SrAl_2O_4$, $SrAl_4O_7$, and $SrAl_{12}O_{19}$ crystals. The peak wavelength of the phosphorescence is 520 nm for $SrAl_2O_4$, 480 nm for $SrAl_4O_7$, and 400 nm for $SrAl_{12}O_{19}$. The phosphorescence is characterized by decay times that have been analyzed by a curve-fitting technique. It is the green-emitting phosphor, $SrAl_2O_4$:Eu^{2+}:Dy^{3+} that has found the most usage commercially.

As is well-known, the effect of crystal-field symmetry upon the excitation state of the activator is the main cause of differences in the wavelength position of the emission of any phosphor. A variety of different compositions have been tried in an effort to improve both emission intensity (brightness) and decay time (persistence) of the strontium aluminate phosphorescence. The

following table summarizes some of these attempts in terms of crystal structure (Table 6.19).

Divalent europium, Eu^{2+}, emits mostly in the blue region of the spectrum in most lattices. The following is a summary of the peak wavelength of the strontium aluminate phosphors:

$$\text{Sr2A3} = 4600\ \text{Å} \qquad \text{SrA6} = 3950\ \text{Å}$$
$$\text{BaMgAl5} = 4500\ \text{Å} \qquad \text{SrMgA5} = 4650\ \text{Å}$$
$$\text{BaA} = 5050\ \text{Å} \qquad \text{SrA} = 5200\ \text{Å}$$

These structures can be described as "stuffed tridymite" lattices. In $BaAl_2O_4$, there are two different Ba^{2+}-sites, one occurring three times more frequently than the other. Both Ba sites are coordinated by nine oxygen ions. One Ba site is less regular than the other. The structure of $SrAl_2O_4$, which is the monoclinic low-temperature form, has two sites available for Sr^{2+} cations. Both occur in equal amounts in the lattice and are coordinated by nine oxygen ions. The coordination of Sr by oxygen is less regular than that of Ba in these monoaluminates. Due to the existence of the hexagonal form of $SrAl_2O_4$ at higher temperatures, mixed crystals of $Sr_{1-x}Ba_xAl_2O_4$ can be obtained.

In recent years, the **tetrastrontium hepta-aluminate**, $Sr_4Al_{14}O_{25}$, doped with divalent europium, has been regarded as another excellent phosphor host and has attracted considerable research efforts. This compound has been prepared by a solid-state method in which excess alumina was added to the 4:1 mix. Eu^{2+}, Dy^{3+} co-doped strontium aluminate ($Sr_4Al_{14}O_{25}$) phosphor with high brightness and persistent luminescence was also prepared via a combustion process using $SrAl_2O_4$ as a precursor, followed by heating the precursor at 1300 °C in a protective atmosphere of N_2. The result showed that the single-phase $Sr_4Al_{14}O_{25}$ was formed at 1300 °C. The phosphor powders have two main peaks near 403 and 482 nm, respectively, which are ascribed to two types of Eu^{2+} that exist in the $Sr_4Al_{14}O_{25}$ matrix crystal. The average particle size of the $Sr_4Al_{14}O_{25}:Eu^{2+},Dy^{3+}$ phosphor nanoparticles ranges from 20 to 40 nm. These nanometer phosphors exhibit a bright luminescence and a long duration of phosphorescence. The main excitation peak of the samples occurred at 360 nm and the main emission peak at 490 nm, respectively. The material heat treated at a rate of 10 °C/min and soaked at 920 °C for 10 min in an active carbon atmosphere possessed the best performance of luminescence and longest afterglow. The afterglow time allowed it to be visually recognized for over 20 h at darkness after removal of the excited light source. Compared with sulfide long-decay phosphors, $Sr_4Al_{14}O_{25}:Eu^{2+},Dy^{3+}$ phosphors possess safe, chemically stable, very bright and long-lasting phosphorescence in addition to not requiring external radiation from radioactive agents like that used for the sulfide phosphors. Note that a vacancy will exist in the crystal due to the trivalent ion, Dy^{3+}, i.e. $Dy^{3+}_{Sr} + V^{+}_{Sr} \Leftrightarrow 2Sr^{2+}_{Sr}$. This has resulted in a wide field of applications, such as luminous paints in highway, airport, building and ceramics, as well as in textile, dial plate of glowing watch, warning signs and escaping routeway applications.

The effect of trap level in the europium-doped strontium aluminate ($SrAl_2O_3:Eu^{2+}$) phosphors has been evaluated for a fiber-optic thermometer application. Sensitivity and temperature range of the $SrAl_2O_3:Eu^{2+}$ phosphor sensor head vary strongly with the trap depth and the trap density of the phosphors. In the temperature range of 273 to 353 K, $SrAl_2O_3:Eu^{2+}$ co-doped with Dy^{3+} or Nd^{3+}, which has a trap depth at around $E_t = 0.5$ eV, was found to be a powerful sensor

** Mp, magnetoplumbite block; Sp, spinel block; bA, β-alumina block.*

material having a large temperature coefficient. Persistent luminescence of Eu^{2+}-doped calcium aluminate, $CaAl_2O_4$: Eu^{2+}, was studied under UV and visible illumination. Broadband luminescence was observed in the blue region ($\lambda_{max} = 440$ nm) due to the $4f^6 5d^1 \Rightarrow 4f^7$ transition of Eu^{2+}. The threshold for the visible excitation was found at about 530 nm, which is not high enough in energy to create the monovalent Eu^+ ion required by the mechanisms presented by various authors previously. A new mechanism proposed involves the excited state absorption of two 530-nm photons via deep traps followed by trapping of electrons in shallow traps. The persistent luminescence is observed after a temperature-controlled electron–hole recombination and subsequent energy transfer to the Eu^{2+} luminescent center

Tristrontium aluminate, $Sr_3Al_2O_6$, has also been studied as a long-persistence phosphor. A detailed preparation process involving Eu^{2+} and Dy^{3+} ion co-doped $Sr_3Al_2O_6$ phosphor powders with red long afterglow by sol–gel combustion method in a reducing atmosphere was reported. XRD, SEM and photoluminescence spectroscopy were used to investigate the effects of synthesis temperature on the crystal characteristics, morphology and luminescent properties of the as-synthesized $Sr_3Al_2O_6$:Eu^{2+}:Dy^{3+} phosphors. The results revealed that $Sr_3Al_2O_6$ crystallizes completely when the combustion ash was sintered at 1200 °C. The excitation and the emission spectra indicated that the excitation broadband lies chiefly in visible range and the phosphor powders emit strong light at 618 nm under the excitation of 472 nm. The light intensity and the duration time of $Sr_3Al_2O_6$:Eu^{2+}:Dy^{3+} phosphors were increased when the calcination temperature was increased from 1050 to 1200 °C. The afterglow of $Sr_3Al_2O_6$:Eu^{2+}:Dy^{3+} phosphors sintered at 1200 °C lasts for over 600 s when the excited source is cut off. The red emission mechanism was discussed in terms of the effect of nephelauxetic and crystal field on the $4f^6 5d^1 \Rightarrow 4f^7$ transition of the Eu^{2+} ions.

In another report, a red luminescent $Sr_3Al_2O_6$:Eu^{2+} phosphor was synthesized via a sol–gel route assisted by microwave irradiation in a reducing atmosphere. The phosphor powders were characterized by XRD, SEM and a fluorescence spectrophotometer. The results reveal that the $Sr_3Al_2O_6$:Eu^{2+} phosphor powders calcined above 1150 °C possessed a $Sr_3Al_2O_6$ single cubic phase. The $Sr_3Al_2O_6$:Eu^{2+} particles at 1100 °C showed primarily rod-like morphology. However, the particles at 1150 to 1200 °C showed a flower-like and diffuse morphology. The average flower-like crystallite sizes were between 0.5 and 3 μm. The $Sr_3Al_2O_6$:Eu^{2+} powders exhibited a broad excitation band chiefly in visible range and a red abroad emission band of main peak at 612 nm under the excitation of 472 nm. Particularly, the $Sr_3Al_2O_6$:Eu^{2+} powders prepared at 1200 °C exhibited the strongest luminescent and phosphorescent intensity, which was due to the higher crystallinity and homogeneous flower-like particle morphology.

The luminescent properties of $Sr_3Al_2O_6$:Ln^{3+} doped and co-doped with the rare earths ($Ln^{3+} = Eu^{2+}$ and/or Dy^{3+}) have been studied. The material was synthesized by reflux method and fired up to 900 °C for 16 h. The XRD pattern confirms that the synthesized material consists of $Sr_3Al_2O_6$ as main phase. The photoluminescence study gives a clear evidence of europium stabilizing in trivalent form and surprisingly with no presence of europium in the divalent state. The addition of Dy^{3+} as co-dopant in the $Sr_3Al_2O_6$:Eu^{3+} matrix shows the quenching effect in the photoluminescence (PL) spectra. The photoluminescence intensity of Eu^{3+} falls gradually on increasing the concentration of the co-dopant in the range from 0.1 to 2.0 mol%. The significantly intense thermoluminescence (TL) glow peak was obtained for $Sr_3Al_2O_6$:Eu^{2+}:Dy^{3+} (1% and 0.1%) at around 194 °C when irradiated with 10 kGy dose from Sr-90 β source.

Tri-strontium aluminate has a "stuffed-tridimite" structure as shown in the following diagram. The structure, shown as follows, is based upon $(AlO_3)_6$ rings. It is cubic with a space group of Pa3. The noteworthy feature of this structure is the puckered six-membered tetrahedral AlO_4 rings. There is a front layer and a back layer in this structure, each running parallel to the other. This structure is typical of the strontium aluminates where either tetrahedral, AlO_4, or octahedral AlO_6 groups are present (or sometimes both). The lattice parameters are: $a = 15.8556$ Å, $V = 3986.3$ Å^3, $Z = 24$, $d_{calc} = 4.126$ g/cc (Fig. 6.94).

Only one layer within the cubic structure is shown, for the sake of clarity. Two layers are actually present in the unit cell.

Because of the red emission of trivalent chromium in Al_2O_3 as a laser, the ion, Cr^{3+}, has been added to the mix in long-decay aluminate phosphors. Cr^{3+} activated, red-emitting, long-persistence phosphorescence through

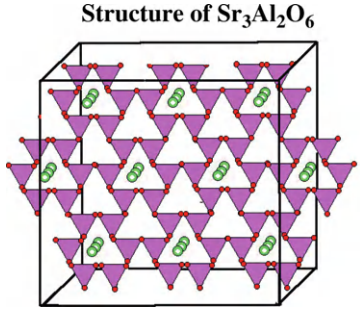

FIGURE 6.94

energy transfer from Eu^{2+} to Cr^{3+} has been reported in strontium aluminates co-doped with Cr^{3+}, Eu^{2+} and Dy^{3+}. The decay processes of the red long-persistent phosphorescence at 693-nm emission show signs of the f–d band of Eu^{2+}, indicating the occurrence of energy transfer from Eu^{2+} to Cr^{3+}. Lifetime measurements of the blue band show that the energy transfer rates increase with increase in Cr^{3+} concentration. There are several phases observed in the strontium aluminates. Energy transfer occurs only for the Eu^{2+} and Cr^{3+} ions that located in the same phase in the host. In $SrAl_{12}O_{19}$ phase, the Eu^{2+} ions emit blue light centered at 400 nm but prefer to transfer energy to the Cr^{3+} site that yields 688-nm emission. In the $Sr_2Al_6O_{11}$ and $Sr_4Al_{14}O_{25}$ phases, the Eu^{2+} ions emit at 460 and 490 nm, respectively, and transfer energy to the Cr^{3+} ions that produce emission at 693 nm. Persistent phosphorescence only occurred in the 490 and 693 nm bands, indicating that efficient phosphorescence comes from the $Sr_4Al_{14}O_{25}$ phase. It is possible to synthesize this phosphor by a cheap, easy and efficient combustion method. Persistent phosphorescence in blue–green (495 nm) by Eu^{2+} and in red (695 nm) by Cr^{3+} was observed in this phosphor. The persistence time for blue–green emission is over 10 h but for red emission, it was comparatively short. Red phosphorescence can be obtained through the persistent energy transfer from Eu^{2+} to Cr^{3+}, converting the blue–green to red. The energy transfer rate increases when the Cr^{3+} ions concentration increases and reaches maximum at 4 at%. The comparative results revealed that the relatively regular morphology, smaller particle size and narrow size distribution can be achieved for the phosphor synthesized by this combustion method but the emission intensity is somewhat less, probably due to lower crystallinity. However, the phosphor after post annealing at 1300 °C showed a higher emission intensity.

In another paper, Cr^{3+} activated red long-persistence phosphorescence through continuous energy transfer from Eu^{2+} to Cr^{3+} has been reported in strontium aluminates co-doped with Cr^{3+}, Eu^{2+} and Dy^{3+}. The decay processes of the red long-persistent phosphorescence at 693-nm emission show the same strong phosphorescence behavior of f–d band of Eu^{2+}, indicating the occurrence of energy transfer from Eu^{2+} to Cr^{3+}. Lifetime measurements of the blue band showed that the energy transfer rates increased with increase of the Cr^{3+} concentration. There are several phases observed in the strontium aluminates. Energy transfer occurs only for the Eu^{2+} and Cr^{3+} ions that located in the same phase in the host. In the $SrAl_{12}O_{19}$ phase, the Eu^{2+} ions emit blue light centered at 400 nm and prefer to transfer energy to the Cr^{3+} sites that yields 688-nm emission. In the $Sr_2Al_6O_{11}$ and $Sr_4Al_{14}O_{25}$ phases, the Eu^{2+} ions emit at 460 and 490 nm, respectively, and transfer the energy to the Cr^{3+} ions that produce emission at 693 nm. It was found that the efficient phosphorescence only occurs in the 490 and 693 nm bands, indicating the best phosphorescent matrix is that based on ions in the $Sr_4Al_{14}O_{25}$ phase.

A novel compound, $12SrO{\cdot}7Al_2O_3$, can be formed from an amorphous material prepared by the simultaneous hydrolysis of strontium and aluminum alkoxides. It has a cubic unit cell with $a = 12.325$ Å. The structure contains tetrahedral AlO_4 groups and octahedral AlO_6 groups. This compound decomposes into $3SrO{\cdot}Al_2O_3$ and $SrO{\cdot}Al_2O_3$ at higher temperatures. A new crystal structure of an aluminate having the formula, $Sr_6[Al_{12}O_{24}]{\cdot}Bi_2O_3$, was obtained as a side phase in the study of Bi–Ca–Sr–Cu–O system. This occurred as a result of a melt interaction with the Al_2O_3 crucible material. This aluminate has a trigonal unit cell with $a = 17.720$ Å, $c = 7.107$ Å, $V = 1933$ Å^3, space group $R3$, $Z = 3$, $d_{calc} = 4.38$ g/cm^3. In the framework of AlO_4 tetrahedra, a 12-atomic block of a new 3-6-3 type as a secondary building unit was found. The block consists of a corrugated sixfold ring and six triple rings. The blocks are stacked according to the rhombohedral law to form elongated sixfold and eightfold rings. A distinctive feature of the structure was the presence of a trigonal-bipyramidal "molecular" Bi_1O_3 group not observed before.

In another application to produce a cement, a strontium monoaluminate was produced by firing the oxides together in air. Some $SrAl_{12}O_{19}$ may be present. When formulated as a high-temperature cement, it hydrates slowly to produce $SrO{\cdot}Al_2O_3{\cdot}7–10H_2O$. In the later course of its hydration, it slowly transforms to $SrAl_6O_{10}{\cdot}6H_2O$, with a loss of strength. The cement can be used in the production of refractory cement that is useful in temperatures up to 2000 °C.

Strontium aluminates are readily available commercially as powders or as long-persistence paints.

Barium Aluminates

Barium aluminate (BA) has the formulation $BaAl_2O_4$, and the CAS number of 12004-04-5. Its molecular weight is 255.2884 g/cc. It is hexagonal in structure and melts at 1827 °C. Various barium aluminates can be synthesized by varying the BaO/Al_2O_3 molar ratio and firing the oxides at elevated temperatures of 800–1200 °C. The phase diagram of the $BaO–Al_2O_3$ system is shown in the following diagram, presented as shown in Fig. 6.95.

Four compounds are evident, $Ba_4Al_2O_7$, $Ba_3Al_2O_6$, $BaAl_2O_4$, and $BaAl_{12}O_{10}$. Barium hexa-aluminate ($BaO{\cdot}6Al_2O_3$) is the most refractory aluminate in the series and melts at 1915 °C. Three compounds melt congruently but the tetra-barium aluminate melts incongruently at 1425 °C to form the tribarium aluminate plus BaO.

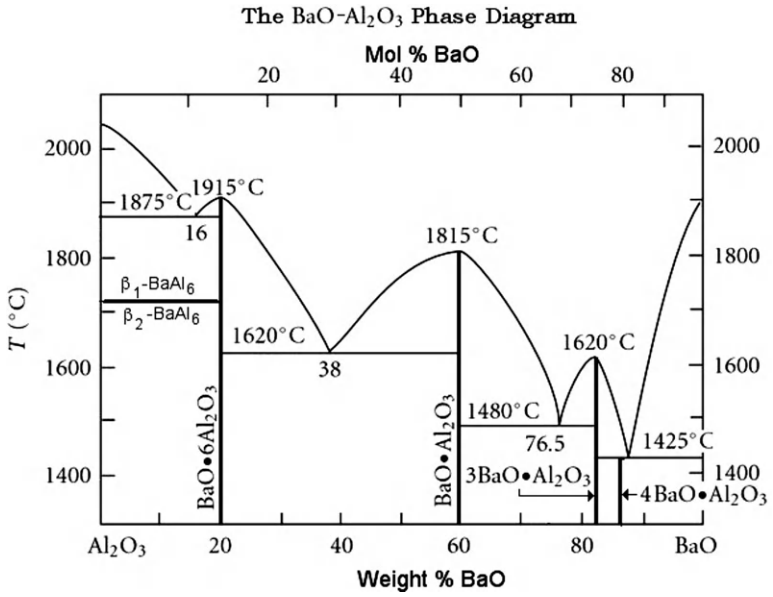

FIGURE 6.95

Barium aluminate, $BaAl_2O_4$ (BA), synthesis by solid–solid reaction at 900 °C between powdered reactants of barium carbonate and alumina in stoichiometric proportions has been studied. During the synthesis and under particular gaseous atmospheres, the aluminate BA, as it forms, reacts with the carbonate to form an intermediate product $Ba_3Al_2O_6$ (B_3A). When the barium carbonate has completely disappeared, B_3A and remaining alumina lead to the barium aluminate, BA. The mechanisms for this reaction synthesis at 900 °C, using pellets made of each reactant $BaCO_3$ and Al_2O_3 as starting materials, involve diffusion of Ba^{2+} through the Al_2O_3 matrix and the diffusion of Al^{3+} through the BaO matrix in opposite directions. The rate of "hopping" of Ba^{2+} ions is much faster than that of Al^{3+} so that the reaction: $3Ba^{3+} + Al_2O_3 \Rightarrow Ba_3Al_2O_6$ builds up first. The later reaction involves $Ba_3Al_2O_6 + 2Al^{3+} \Rightarrow 3BaAl_2O_4$. The ionic diffusion mechanisms described include two kinds of oxygen transfer, either in the solid state, or from the gaseous atmosphere. Kinetic developments corresponding to the most probable rate determining steps in each case were carried out and summarized. The importance of the various chemical parameters that modify the reaction process was discussed and the influence of the gaseous atmosphere was particularly followed. In addition, diffusion experiments using BaO and alumina were studied. This work follows up a kinetic study previously published on the synthesis of $BaAl_2O_4$ from stoichiometric $BaCO_3 + \beta\text{-}Al_2O_3$ powder mixtures, with formation of an intermediate compound. In that study, the formation of other barium aluminates was shown, as the distances of diffusion greatly increase in the lattice. Isothermal sintering of monobarium aluminate ($BaAl_2O_4$) was carried out by measuring shrinkage on firing of compacted pellets of ~45 micron size powder samples at temperature of 1300, 1350, 1400 and 1450 °C. The time dependence of linear shrinkage reveals volume diffusion as dominant mechanism of sintering. The apparent diffusion coefficient (D) of sintering was calculated and its temperature dependence can be represented by the equation:

$$D = 8.04 \times 10^{-9}\ (-188{,}000/\mathrm{RT})/\mathrm{cm}^2/\mathrm{s}$$

In another study, nanosized (10–30 nm particle size) hexagonal barium monoaluminate, having a high surface area of ~30 m^2/g, was synthesized by calcination of hydrothermally prepared precursors. The precursors were obtained by hydrolytic precipitation, using a mixed solution of barium and aluminum nitrates in the presence of aqueous urea at 180 °C. Based on the results of XRD, FTIR, SEM/EDS, TEM, and TG-DTA studies, the most probable sequence of reactions leading to the formation of barium monoaluminate was:

- Conversion of aqueous barium and aluminum nitrates in the presence of urea by hydrothermal precipitation to crystalline orthorhombic barium carbonate and boehmite,
- Formation of an interim form consisting of amorphous fibrillar aluminum oxide(s) interlaced with crystalline barium carbonate in the calcination temperature range of 500–800 °C,
- Initiation of formation of barium monoaluminate at 1000 °C, and
- Formation of a near monophase nanosized barium monoaluminate at 1200 °C.

In another study, pure barium monoaluminate and β_1-β_2-barium hexa-aluminate were prepared by keeping Ba/Al ratio as 1:2 and 1:12, respectively. Similar to the strontium system, these were found to be the most stable phases in the $BaO–Al_2O_3$ system.

The effect of varying Ba/Al ratio from 1:4 to 1:10 on the formation of barium aluminates was also studied. The samples obtained during hydrothermal precipitation contained mixtures of $BaCO_3$ and γ-AlOOH. The mean crystallite diameter (MCD) values along (1 1 1) plane corresponding to $BaCO_3$ phase for these precursors were in the range of 70–99 nm whereas the MCD values along (0 2 0) plane corresponding to γ-AlOOH were in the range of 10–12 nm. The precursors, when calcined at 400 °C, did not show any crystalline phases of alumina and most of the peaks corresponded to barium carbonate with diminished peaks of γ-AlOOH when compared to the precursor. At 800 °C, some peaks for $(Al_2O_3)\underline{O}$ were observed along with major phase of $BaCO_3$. At 1200 °C, irrespective of the Ba/Al ratio, formation of major phase of $BaAl_2O_4$ along with minor phases of α-Al_2O_3 and Ba-$\beta_1\beta_2$-$Al_{12}O_{19}$ were observed. At 1400 °C, $BaAl_2O_4$ remained the major phase at all Ba/Al ratios along with crystalline phase of α-Al_2O_3. Typical peaks corresponding to Ba-$\beta_1\beta_2$-$Al_{12}O_{19}$ aluminate became more prominent when the Ba/Al ratio was ≥1:6. No other intermediate phases such as tri-barium mono-aluminate, barium tetra aluminate or nonstoichiometric barium aluminates were formed.

The effect of high-energy BM and subsequent annealing on a mixture of Al_2O_3 and $BaCO_3$ was also investigated. DTA results show that the initiatory decomposition temperature of $BaCO_3$ decreases with increase of ball milling time duration. XRD measurement indicated that a nanocrystalline powder mixture was produced and that no $BaAl_2O_4$ is formed during a high-energy BM process after milling for 30 h. Significant crystallization of $BaAl_2O_4$ from the nanocrystalline powder mixture milled for 5, 15 and 30 hwas observed after annealing at 900 °C, although a trace of $BaCO_3$ remained at this temperature. Single-phase $BaAl_2O_4$ can be obtained for the sample milled for 5 h at 1000 °C, which is at least 200 °C lower than that used in the traditional solid-state method, while the secondary crystalline phases, $Ba_5Al_2O_8$ and $BaCO_3$, exist within the physical mixture at 1000 °C. No significant gain was observed when the milled powders were annealed at 1000 °C with different milling times and the average size of the particles produced was about 0.3–0.5 μm.

Barium monoluminate is also easily hydrated. A number of studies have been made because of the potential of using barium aluminates in a "fast-setting" cement. A new layered barium aluminate hydrate was synthesized from a hydrothermal system. γ-$BaAl_2O_3(OH)_2\cdot H_2O$ is orthorhombic, Fdd2, with $a = 20.70$ Å, $b = 8.977$ Å, $c = 6.426$ Å, $Z = 8$. It contains chains of composition $[AlO(OH)_2^{-1}]_\infty$, made-up of tetrahedra-sharing corners. Its formula is therefore better written as γ-$Ba[AlO(OH)_2]_2$.

A hydrolysis study was made of the following compounds:

$BaO\cdot Al_2O_3$,
$3BaO\cdot Al_2O_3$,
$BaO\cdot Al_2O_3\cdot H_2O$
$BaO\cdot Al_2O_3\cdot 2H_2O$,
$BaO\cdot Al_2O_3\cdot 4H_2O$,
$BaO\cdot Al_2O_3\cdot 7H_2O$,
$7BaO\cdot 6Al_2O_3\cdot 36H_2O$
$2BaO\cdot Al_2O_3\cdot 5H_2O$
$A1_2O_3\cdot 3H_2O$

From this, together with a study of precipitation from supersaturated barium aluminate solutions, a diagram of phase equilibria (stable and metastable) at 30 °C was drawn. All the barium aluminates are hydrolyzed by water. The stable solid phases in the system $BaO–Al_2O_3–H_2O$ at 30 °C are $A1_2O_3\cdot 3H_2O$ (gibbsite), $Ba(OH)_2\cdot 8H_2O$, and, over a narrow range, probably $2BaO\cdot Al_2O\cdot 5H_2O$. On the basis of the experiments performed and subject to the experimental conditions, the following conclusions were presented:

1. Monobarium aluminate is hydrolyzed by water, with **precipitation of** hydrated alumina.
2. Monobarium aluminate dissolves in barium hydroxide solutions with precipitation first of $7BaO\cdot 6Al_2O_3\cdot 36H_2O$, which subsequently forms $BaO\cdot Al_2O_3\cdot 7HO$ in less basic and $BaO\cdot Al_2O_3\cdot 4H_2O$ in the more basic solutions.
3. Tribarium aluminate is rapidly hydrolyzed by water, with precipitation of $Ba(OH)_2\cdot 8H_2O$, $BaO\cdot Al_2O_3\cdot 7H_2O$, and, subsequently, $2BaO\cdot Al_2O_3\cdot 5H_2O$.
4. All the hydrated barium aluminates dissolve in water and are hydrolyzed, with precipitation of hydrated alumina.
5. The hydrated barium aluminates dissolve in barium hydroxide solutions with eventual precipitation of the equilibrium solid phases, but frequently with preliminary separation of metastable intermediate solid phases.
6. The stable phases in the system $BaO–Al_2O_3–H_2O$ at 30 °C are: (a) gibbsite ($Al_2O_3\cdot 3H_2O$) over a range from approximately zero concentration to about 52 g of BaO and 2.8 g of Al_2O_3 per liter; (b) $Ba(OH)_2\cdot 8H_2O$ from 52.9 g of BaO and zero Al_2O_3 to about 55.5 g of BaO and 2.7 g of Al_2O_3 per liter; (c) probably 2BaO. $Al_2O_3\cdot 5H_2O$ (but possibly $BaO\cdot Al_2O_3\cdot 4H_2O$ or gibbsite) over the short range from 52BaO and $2.8Al_2O_3$ to 55.5BaO and $2.7Al_2O_3$.

7. $7BaO \cdot 6Al_2O_3 \cdot 36H_2O$ is a metastable phase, not sufficiently stable to permit an accurate determination of its solubility.
8. $BaO \cdot Al_2O_3 \cdot 7H_2O$ is also metastable, but it may exist in contact with solution for several months.
9. $BaO \cdot Al_2O_3 \cdot 4H_2O$ is likewise metastable over the **greater** part, if not **all**, of its range. Its stability is greater than that of the higher hydrates.

Supersaturated solutions of alumina in barium hydroxide were prepared and allowed to stand, with occasional shaking, at 30 °C. The precipitates were observed under the microscope from time to time, and changes in concentration of the solutions were determined by analysis. Various methods were used for preparation of the supersaturated solutions. The most satisfactory treatment of anhydrous barium aluminate was to add sufficient water to cause practically complete hydrolysis and precipitation of hydrated alumina, followed by boiling the mixture with barium hydroxide solution to dissolve the alumina. The solution was then filtered promptly while still hot. The anhydrous aluminate used for the purpose was either $BaO \cdot Al_2O_3$ or $3BaO \cdot Al_2O_3$ or a mixture of the two, as desired, prepared by heating a mixture of barium carbonate and gibbsite ($Al_2O_3 \cdot 3H_2O$), in the desired proportions, at about 1300 °C. The final compound, $3BaO \cdot Al_2O_3$, crystallizes in the orthorhombic space group $Pna2_1$ with $M = 291.33$ g/mol, $a = 5.642$ Å, $b = 9.887$ Å, $c = 10.449$ Å, $V = 582.9$ Å^3, $Z = 4$, $R = 0.0288$. The structure of the compound consists of aluminate sheets stacked in an ABAB sequence. Each individual sheet contains six-membered rings formed by corner-sharing $AlO_2(OH)_2$ tetrahedral units with the terminal OH groups pointing toward the interlayer region in one direction. There are Ba^{2+} cations and water molecules located between the adjacent aluminate sheets. On the basis of powder XRD, the as-synthesized compound converts to the $BaAl_2O_4$ phase by thermal treatment at elevated temperatures. The phase transition was also been monitored by infrared spectroscopy.

Formation of $CaAl_2O_4$ in a 1:1 molar mix of CaO and Al_2O_3 occurs at higher temperature through formation of mainly lime-rich phases such as C_3A and $C_{12}A_7$. In the $BaO–Al_2O_3$ mix, however stoichiometric formation of $BaAl_2O_4$ occurs at relatively higher temperatures due to larger ionic size of barium ions. The rate of $BaAl_2O_4$ formation is faster and the interdiffusion coefficient values calculated for $BaO–Al_2O_3$ system were found to be much higher than in $CaO–Al_2O_3$ system. Sintering studies showed a slower rate of densification in $BaAl_2O_4$ powder compacts and were thought to be due to the higher molecular weight of $BaAl_2O_4$ though the values of apparent diffusion coefficients calculated were found to be comparable in both the systems.

In another study, the Ba system was compared to the Mg system. The formation kinetics of monobarium aluminate, $BaO \cdot Al_2O_3$, (BA) in the temperature range of 1100–1380 °C was studied. Activation energy of its formation from barium and aluminum oxide was calculated to be 68.6 Kcal/mol. In the presence of MgO, its formation is accelerated and the activation energy of reaction is found to be 47.3 Kcal/mol. The activation free energies of the reaction were found to increase in the presence of MgO (1.5% by weight). Diffusion coefficients (D) of these reactions have also been calculated and the temperature dependence obeys the relationships:

$$D = 9.596 \times 10^{-4}(-24{,}800/\mathrm{RT})/\mathrm{cm}^2/\mathrm{s}$$

$$D = 9.552 \times 10^{-4}(-20{,}900/\mathrm{RT})/\mathrm{cm}^2/\mathrm{s}$$

without and with MgO, respectively.

Methods of preparation, optical properties, and XRD data were also reported for six barium aluminate hydrates. Three of these were obtained successively by precipitation from supersaturated barium aluminate solutions at 30 °C. The first, designated by the empirical formula $BaO \cdot Al_2O_3 \cdot 6H_2O$, is metastable with respect to the second, $BaO \cdot Al_2O_3 \cdot 7H_2O$, which in turn is metastable with respect to $BaO \cdot Al_2O_3 \cdot 4H_2O$. Two lower hydrates, $BaO \cdot Al_2O_3 \cdot 2H_2O$ and $BaO \cdot Al_2O_3 \cdot H_2O$, were also prepared hydrothermally. $2BaO \cdot Al_2O_3 \cdot 5H_2O$ was obtained from boiling the barium aluminate solutions.

If a molar ratio of 2:5 $Ba(OH)_2$ and AlO(OH) is held under hydrothermal conditions at 618 K (°C) for 3 weeks, well-formed hexagonal prisms form. These have the chemical formula of barium aluminate hydrate, $2BaO \cdot 5Al_2O_3 \cdot H_2O$ or $Ba_2Al_{10}O_{16}(OH)_2$, $[BaAl_5O_8(OH)]$. This compound is hexagonal with space group $P6_3mmc$. Lattice parameters determined were: $a = 5.635$ Å, $c = 13.489$ Å, $V = 371.0$ Å^3, $Z = 4$, $D_{calc} = 3.773$ g/cc. Its structure is related to the well-known β-alumina compound, $Na_2O \cdot 11Al_2O_3$. The only difference is the absence of two oxygen layers from the spinel block.

The density and the ferroelectric, ferrielectric and pyroelectric properties of ceramics derived from $BaAl_2O_4$ have been investigated. The XRD patterns and the variation of the density are consistent with the presence at 300 K of nonstoichiometric materials in the 44.4–50.0 mol% BaO range. They appear to be ferrielectric like $BaAl_2O_4$. The Curie temperature varies from 396 (50% BaO) to 275 K (44.4% BaO) due to the composition change of the solid solution. The value of the spontaneous polarization, P_s, is relatively small and shows anomalous behavior: the thermal variation presents a maximum but there is no structural change. The unit-cell volume increases with decreasing BaO content. A substitution mechanism based on the

replacement of two Ba^{2+} for an $[Al–O–Al]^{4+}$ link, and a model accounting for the ferrielectricity was proposed.

The paraelectric–ferroelectric (PE-FE) phase transition in stuffed tridymite $BaAl_2O_4$ was studied in situ by TEM. Electron diffraction revealed that the PE and FE phases have hexagonal symmetry. The PE-FE phase transition is accompanied by a doubling of the cell dimensions in the *a–b* plane. The transition is reversible, takes place over a wide temperature range (400–670 K) and the interfaces related to the transition have a fluctuating character. The crystal structure of the high-temperature PE phase was determined by high-resolution electron microscopy (HREM). The structures of the PE phase (space group $P6_322$, $a = 5.224$ Å, $c = 8.843$ Å) and of the FE phase (space group $P6_3$, $a = 10.447$ Å, $c = 8.793$ Å) differ mainly by the configuration of the Al–O strings oriented along the *c*-axis. In the PE phase, all the strings are equivalent whereas straight and corrugated strings alternate in an ordered manner in the FE phase resulting in doubling of the *a* and *b* cell parameters. Translation and orientation domains due to the decrease of the translation and point symmetry were frequently observed. $BaAl_2O_4$ has the same structure as that of its Sr homologue and is shown in the following Fig. 6.96.

The structure consists mostly of isolated AlO_4 tetrahedra offset by the large Ba^{2+} ions. Not all of the oxygen atoms are shown, for the sake of clarity.

Tetra-barium aluminate has a unique structure that involves AlO_4 tetrahedra and two types of BaO_6 octahedra, as shown on the next page. This type of structure is common among the alkaline earth aluminates and involves mixed tetrahedra and octachedra. But here, the octahedra are connected and tilted away from each other. Crystal growth experiments in the system $BaO–Al_2O_3$ yielded single crystals of an oxo-aluminate with composition $Ba_4Al_2O_7$. **Tetra-barium aluminate** is orthorhombic, with cell parameters of: $a = 11.3126(5)$, $b = 11.7045(9)$, $c = 27.1850(14)$ Å , space group *Cmca*. The crystal structure is shown in Fig. 6.97.

The structure was solved by direct methods followed by difference Fourier synthesis from X-ray single-crystal diffraction data ($R1 = 0.048$ for 1213 independent observed reflections and 135 parameters). The main building units of tetrabarium aluminate are Al_3O_{10} trimers and isolated AlO_4 tetrahedra. Seven crystallographically different Ba sites crosslink between the tetrahedral groups and are coordinated by six to nine oxygen ligands. The structure is closely related to the mineral "kilchoanite" ($Ca_6[SiO_4][Si_3O_{10}]$) and is the first known alkaline earth representative of an unbranched oligoaluminate with triple tetrahedra.

Tetrabarium aluminate is not very stable, due, perhaps, to the size of the Ba^{2+} cation. It readily decomposes to the tribarium aluminate compound upon heating to elevated temperatures.

It forms a series of solid solutions with its calcium homologues as shown in the following ternary phase Fig. 6.98.

In addition to the solid solutions like $Ba_3A–Ca_3A$, two separate compounds are formed: $BaCaAl_2O_4$ and $BaCaAl_8O_{14}$. Although some authors include Ba_8A, the instabliity of $Ba_4Al_2O_7$ precludes the physical and chemical stability of a compound having a stoichiometry like $Ba_8Al_2O_{11}$.

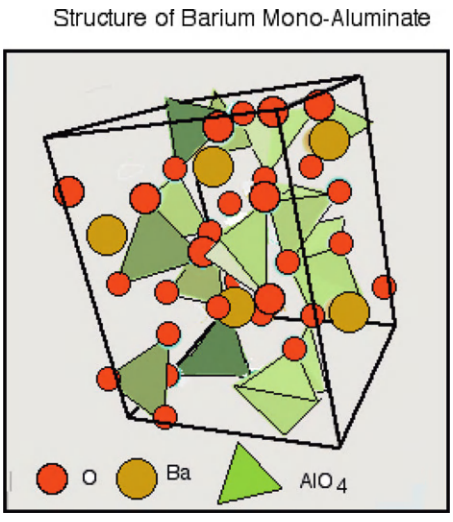

FIGURE 6.96

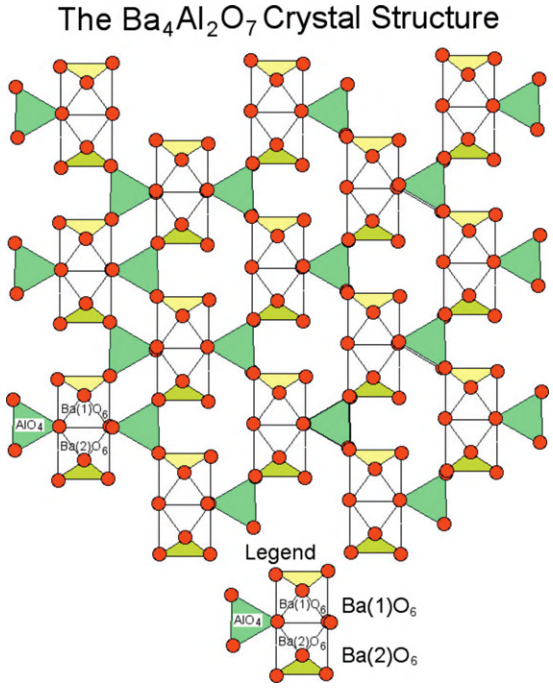

FIGURE 6.97

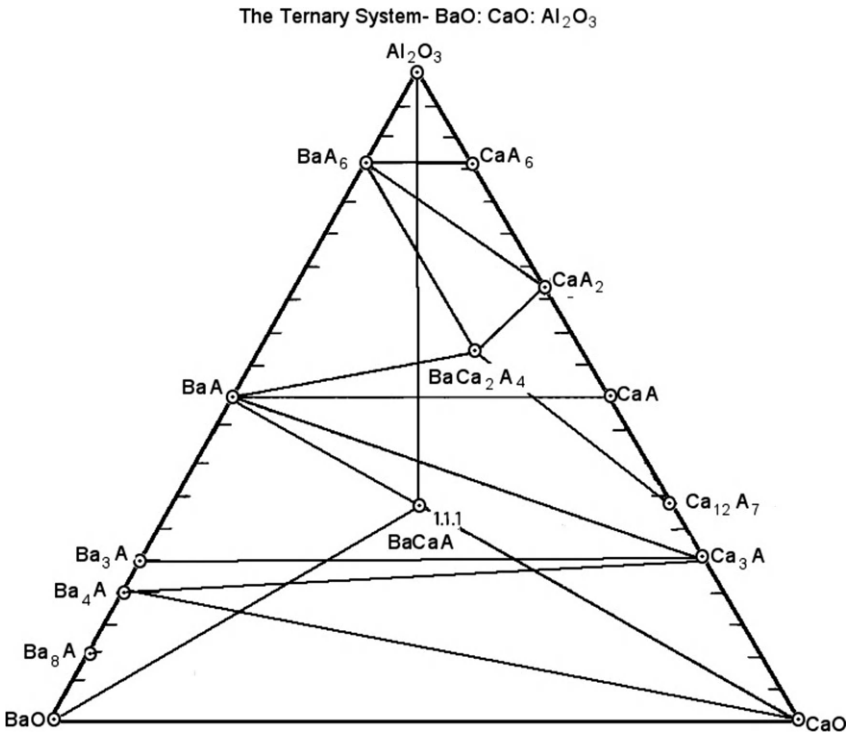

FIGURE 6.98

Single crystals of **tribarium aluminate** have been synthesized from the melt at 1480 °C. The compound adopts a space group $P2_13$, with $a = 16.4984$ Å and $Z = 24$ formula units per unit cell. The principal building units of $Ba_3Al_2O_6$ are highly corrugated 12-membered rings of AlO_4 tetrahedra that are cross-linked via Ba cations. Alternatively, the compound can be derived from the ABO_3 perovskite-type, representing a defect structure with vacancies on the B- and the O-positions. The relationship with perovskite can be expressed by the following formula: $Ba(Al_{3/4}Ba_{1/8}V_{1/8})(O_{3/4}V_{1/4})_3$. The structure shows a pronounced degree of pseudo-symmetry. Apart from one Ba position, all atoms in the structure approximately conform to the symmetry requirements of a perovskite. Nevertheless, the whole structure adopts the cubic subgroup $P2_13$. This investigation was said to correct earlier studies describing $Ba_3Al_2O_6$ in either too low or too high symmetry. The characterization of tribarium aluminate was completed by Raman spectroscopy.

Tri-barium aluminate, $Ba_3Al_2O_6$, has the structure shown in Fig. 6.99.

Where the AlO_4 tetrahedra are tied together in a puckered 12-membered rings. The barium ions surround each tetrahedron in an ordered pattern.

The compound, **barium di-aluminate**, $BaAl_4O_7$, apparently cannot be formed. A simple process, based on the solvothermal reaction of alkaline earth precursors

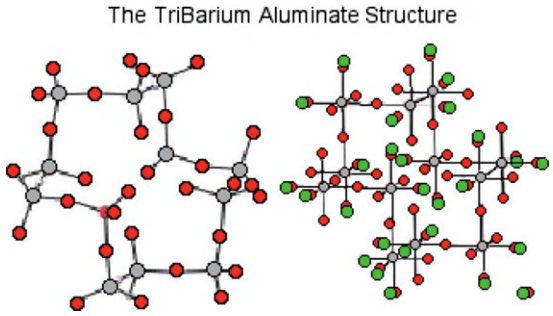

FIGURE 6.99

with aluminum isopropoxide in benzyl alcohol, leads to crystalline complex nanostructures of alkaline earth aluminates, which, up to now, could only be obtained by SSR at temperatures above 1100 °C or by sol–gel and further calcination at temperatures only slightly lower (800 °C). When this nonaqueous route was used, it led to crystalline complex nanostructures of $BaAl_2O_4$, $CaAl_4O_7$, and $SrAl_4O_7$ but $BaAl_4O_7$ could not be obtained.

Barium hexa-aluminate powder with a high surface area (22 m^2/g) and micro-sized (0.3–2 μm) particles was prepared by the calcination (at 1400 °C, for 2 h) of hydrothermally prepared precursors of orthorhombic barium carbonate and boehmite. The precursors were obtained by a hydrothermal treatment (at 180 °C, for

1 h) of aqueous solutions of barium and aluminum nitrates of appropriate compositions in the presence of aqueous urea as the neutralizing precipitant. Results of XRD, TG-DTA and SEM measurements suggested that the most probable reaction sequence for the preparation of barium hexa-aluminate ceramic powder was:

(i) The hydrothermal precipitation of orthorhombic $BaCO_3$ and boehmite (γ-AlOOH) precursors from the aqueous Ba and Al nitrates in the presence of urea,

(ii) The formation of an interim mixture of β-Al_2O_3, $BaCO_3$ and Ba–β_1-β_2- alumina in the temperature range of 800–1200 °C,

(iii) The formation of a ceramic powder corresponding to the composition $BaO{\cdot}6Al_2O_3$ having a –β_1-β_2-alumina type structure at 1400 °C.

The final material did not show presence of any other crystalline phases like alumina, baria, barium mono-aluminate and tri-barium mono-aluminate phases.

In another study, barium hexa-aluminate ($BaO{\cdot}6Al_2O_3$) aerogels were prepared using a supercritical drying method and their properties examined. A barium hexa-aluminate aerogel prepared from a double alkoxide of barium and aluminum showed a high specific surface area of 421 m^2/g. Monolithic barium hexa-aluminate formed. No $BaO{\cdot}Al_2O_3$ or alumina was observed, as is often the case in powder processing. The specific surface area of the monolithic barium hexa-aluminate fired at 1400 °C for 2 h was 12 m^2/g, while that of the barium hexa-aluminate xerogel was only 0.8 m^2/g. A barium hexa-aluminate aerogel was also prepared using barium by using a chelating agent. This aerogel showed a specific surface area of 454 m^2/g, as-dried. In the case of the chelating agent, $BaO{\cdot}Al_2O_3$ was also detected along with barium hexa-aluminate after firing.

The crystal structure of barium hexa-aluminate phase I ($BaAl_{12}O_{19}$) was determined by single-crystal X-ray reflection data. The refinements were carried out by the least-square method to give a final *R*-value of 0.023. The structure was revealed to be essentially of a β-alumina type and the Ba ion was detected only at the 6*h* site near the Beevers-Ross site (2*d* site). The charge compensation for nonstoichiometry was found to be principally effected by the interstitial oxygen due to Frenkel defects of Al^{3+} ions. From the structural point of view, phase-I was referred to as "barium β_1-aluminate." This compound has the same structure as its strontium homologue (Fig. 6.100).

Three types of Al^{3+} ions are present, dividing the structure into mirror planes and a spinel block. Upon calcination at 1200 °C, a marked drop in surface area value was observed associated with the formation of the final $BaO{\cdot}6Al_2O_3$ phase. This compound is hexagonal

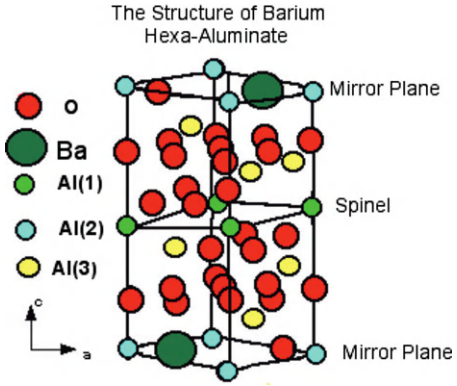

FIGURE 6.100

with $a = 5.582$ Å, $c = 22.715$ Å, $V = 612.9$ Å^3, $Z = 2$ and $D_{calc} = 3.662$ g/cc. The space group is $P6_3/mmc$.

Barium hexa-aluminate is a well-defined refractory compound. Barium hexa-aluminate refactories are strong (MOR ~ 600 MPa). Possible industrial uses are in the glass and metallurgical industries, and also as molds and cores for metal casting. A gel precursor of barium hexaaluminate can be prepared from a solution of a barium salt mixed with a solution of an aluminum salt, to give the oxide stoichiometry $BaO{\cdot}6Al_2O_3$. This is followed by heating to remove volatiles or by adding a separate gelling agent such as ammonium acetate. The gelling agent can also be a salt already present, for instance barium acetate, which gives better control of gelation. The gel is dried and fired to form barium hexaaluminate. Filaments which convert on firing to a barium hexa-aluminate ceramic fiber can be drawn as the gel is forming or extruded from a semi-rigid gel. Refractory components can be prepared from a suitably graded refractory grain mix bonded with the gel. The aluminum salt may be replaced by an aluminum alkoxide. Alkaline gelation is desirable to obtain a rigid coherent gel or a ceramic fiber. FT-IR, XRD and Al-NMR studies showed that barium was not incorporated directly into the gel structure, no barium aluminum oxides being formed before the barium species liquefy. A powder mixture suitable for firing to form barium hexa-aluminate was prepared from alumina and barium carbonate or barium hydroxide. Strong ceramic shapes have been made from a sintered powder mix. XRD studies showed that rapid firing to 1600–1700 °C gives barium hexaaluminate directly. Slow firing to 1600-1700 °C gives barium mono-aluminate as one intermediate phase. Chromium (III) addition reduces the temperature required to form an aluminum–barium oxide, and ultimately, the temperature of formation of barium hexaaluminate.

Although **dodeca-barium hepta-aluminate**, $12BaO{\cdot}7Al_2O_3 = Ba_{12}Al_{14}O_{33}$, does not appear in the phase diagram, it has been prepared via a sol–gel process. Optical and electrical properties of B12A7 films were

investigated. The films were coated on soda lime float glass by a dip coating process, and annealed in air and hydrogen (H_2) at 450 °C for 2 h. The UV absorption edge was red shifted for films annealed in H_2 atmosphere. The B12A7 films had a high transparency of about 90% over a wide visible range with maximum of 95% at 575-nm wavelength. The sheet resistance of the 300-nm films corresponding to 90.57 and 0.974 kΩ per cm^2 has been observed for air and H_2-annealed films, respectively. Such thin films have been tested thermoluminescent dosimeter. A thermoluminescent dosimeter in the form of reusable solid chip was prepared using an acid-catalyzed sol-gel process, with tetramethoxysilane (TMOS) and $BaAl_2O_4$ powder as precursors. In comparison with the manufacturing process of typical lithium fluoride-based dosimeters, the method optimizes the manufacturing process. The new dosimeter has a dose response over a dose range varying from 0.1 to ~160 Gy and can be used to detect higher doses using the typical commercial TLD readers without special adjustments. Furthermore, the process may be used for the preparation of other TLDs using a simple chemical processing. However, the literature is devoid of any other supposed usages of this compound.

Dibarium aluminate, $Ba_2Al_2O_5$, does not exist, in spite of several attempts to synthesize it from the oxides or by a sol–gel synthesis.

Oxides containing aluminum and barium, optionally with chromium, are refractories with several possible industrial uses. A gel precursor of an oxide having the formula $BaO{\cdot}n(Al_{2x}Cr_{2y}O_3)$, where $1 < n < 6.6$, $(x + y = 1)$ and $0 < y < 0.5$ was prepared by mixing a solution of a barium salt with a solution of an aluminum salt or a solution of an aluminum salt and a chromium III salt, then forming a gel which was fired to obtain the desired oxide. Filaments could be drawn as the gel was forming or extruded from a semi-rigid gel. FT-lR, XRD and ^{27}Al NMR studies showed that barium is not incorporated directly into the gel structure. Barium aluminum oxides were obtained only after liquefaction of barium species. A powder mixture suitable for firing to an oxide of the formula $BaO{\cdot}m\ [Al_{2x}Cr_{2y}\ O_3]$ where $4.6 < m < 6.6$, $(x + y) = 1$ and $0 < y < 0.5$ was prepared from source materials barium hydroxide, barium oxide, barium carbonate and barium monoaluminate, alumina and/or a hydrated alumina and chromium III oxide, the relative amounts being varied to give the desired values of m and y on firing. A preferred oxide has the formula $BaO{\cdot}6Al_2O_3$ ($m = 6$ and $y = 0$). Strong ceramic shapes have been prepared from this. XRD studies of oxide compositions (n or $m = 6$ and $y = 0$) sintered at high temperature showed that barium monoaluminate is a low-temperature intermediate phase. Chromium III reduces the temperature required to form a barium aluminum oxide.

$BaAl_{12}O_{19}$–$BaAl_2O_4$ doped with Eu^{2+}, Cr^{3+} and $(Eu^{2+} + Cr^{3+})$ are prepared by SSR. The spectra of $BaAl_{12}O_{19}$–$BaAl_2O_4$:Eu^{2+}, Cr^{3+} shows that the f–d emission bands from Eu^{2+} are centered at 442 and 495 nm and the Cr^{3+} yields the emission lines at 694 and 700 nm. Photoluminescence study demonstrates that the red photoluminescence and energy transfer occurs only in the phase of $BaAl_{12}O_{19}$ not $BaAl_2O_4$ though the samples are mixed phases. The fluorescence lifetime measurements indicate efficient energy transfer from Eu^{2+} to Cr^{3+} in $BaAl_{12}O_{19}$: Eu^{2+}, Cr^{3+}. The energy transfer rate and efficiency are calculated. The results show that the energy transfer rate and efficiency increase following the increase in Cr^{3+} concentration.

$BaMgAl_{10}O_{17}$:Eu^{2+} (BAM) is currently used as the blue-emitting phosphor in most display devices, including color television and computer screens. It is not very stable over time and degrades much faster than the green or red-emitting phosphors. The effect is much sooner in cathode ray tubes or plasma-discharges tubes. The thermal degradation was investigated by forcibly annealing BAM particles in air at temperatures of 500–1300 °C. Rietveld analysis with powder XRD revealed novel lattice deformations in the thermally degraded BAM. The lattice constants c and a changed monotonically as annealing temperature increased, while the unit-cell volume V showed no change with annealing up to 900 °C, then abruptly expanded at 1100 °C annealing. In addition, peak profile analysis revealed increasing lattice strain being induced in the host lattice. The main cause of the thermal degradation of BAM appears to be due to generation of a lattice vacancy like the Schottky defect.

Barium aluminate cements have been synthesized by using barium carbonate, alumina, kaolin and colloidal silica as starting materials. The effects of the source of SiO_2 and of firing temperature on phase formation and physical properties of the fired cements have been studied. Cement samples were characterized using XRD, SEM, EDX. The setting time and heat of hydration of cements were also evaluated. The barium aluminate cements were mixed in castables. Cold crushing strengths evaluated, and values compared to those obtained using calcium aluminate cement (Secar 71). Mixtures of $BaCO_3$ and Al_2O_3 were targeted to produce $BaAl_2O_4$ which had a fast set-time, expansive behavior and lower strength compared to samples with SiO_2 additions. SiO_2 additions, regardless of source, resulted in $BaAl_2Si_2O_8$ (celsian) formation. The prepared samples had short setting times and higher mechanical properties in comparison with standard calcium aluminate cement.

Radium Aluminates

The scientific literature is lacking in any references to radium aluminates. Perhaps this is due to the intense

radioactivity of the isomer ^{226}Ra but is more likely due to lack of interest of those in industry who have usage of such compounds. It is anticipated that various radium aluminates could be prepared, using the same methods as those developed for the barium aluminate series of compounds. Thus, one would expect to be able to obtain:

$RaO \cdot Al_2O_3$,
$3RaO \cdot Al_2O_3$,
$RaO \cdot 6Al_2O_3$
$2RaO \cdot Al_2O_3$,
$RaO \cdot Al_2O_3 \cdot 4H_2O$
$RaO \cdot Al_2O_3 \cdot 7H_2O$,
$7RaO \cdot 6Al_2O_3 \cdot 36H_2O$,
$2RaO \cdot Al_2O_3 \cdot 5H_2O$,
$RaO \cdot Al_2O_3 \cdot H_2O$,
$RaO \cdot Al_2O_3 \cdot 2H_2O$,
$RaO \cdot Al_2O_3 \cdot 4H_2O$
$RaO \cdot Al_2O_3 \cdot 7H_2O$,
$7RaO \cdot 6Al_2O_3 \cdot 36H_2O$,
$2RaO \cdot Al_2O_3 \cdot 5H_2O$.

However, there is no record of such syntheses in the literature.

6.5. ALKALINE EARTH GALLIUM COMPOUNDS

Gallium does not exist in free form in nature, and the few high-gallium minerals such as "gallite" ($CuGaS_2$) are too rare to serve as a primary source of the element or its compounds. Its abundance in the Earth's crust is approximately 16.9 ppm. It has but one stable valence state: Ga^{3+}. The +1 oxidation has also been attested in some compounds, but they tend to disproportionate into elemental gallium and gallium(III) compounds. What is sometimes referred to as gallium(II) compounds may actually be mixed-oxidation state compounds containing both gallium(I) and gallium(III).

Gallium is amphoteric. Strong acids dissolve gallium, forming gallium(III) salts such as $Ga_2(SO_4)_3$ and $Ga(NO_3)_3$. Aqueous solutions of gallium(III) salts contain the hydrated gallium ion, $[Ga(H_2O)_n]^{3+}$, where n is usually 6 because gallium prefers an octahedral coordination. Gallium hydroxide, $Ga(OH)_3$, may be precipitated from gallium(III) solutions by adding NH_4OH or NH_3 (gas) to a solution containing Ga^{3+} ions. Dehydrating $Ga(OH)_3$ at 100 °C produces gallium oxide hydroxide, GaO(OH).

Additionally, it forms anionic species with oxygen. Alkaline solutions dissolve gallium, forming *gallate* salts containing the $Ga(OH)_4^-$ anion. Gallium hydroxide, which is amphoteric, also dissolves in alkali to form gallate salts. Although earlier work suggested $Ga(OH)_6^{3-}$ as another possible gallate anion, this species has not been confirmed in later works.

In general, alkaline earth gallates are prepared by a SSR of the oxides rather than by solution methods because of the formation of hydroxy-dominated compounds and/or hydrated compounds.

6.5.1. Alkaline Earth Gallide Compounds

The alkaline earths form "gallide" compounds with specific lattice structures when the elements are melted together in the proper atomic ratios.

Beryllium Gallide

Beryllium does not form any compounds with gallium. Instead, it forms a continuous solid solution as shown in Fig. 6.101.

The structural characteristics are shown in the following table:

Compound	Structure type	Point group	Space group	Melting point
(Be) rt	Mg	hP2	194	1270 °C
(Be) ht	W	cI2	229	30 °C
(Ga)	Ga	oS8	64	30 °C

Gallium is not used to alloy beryllium in industry because of lack of useful properties over that of Be metal alone.

Magnesium Gallide

The metal, Mg, forms a series of compounds with gallium as shown in Fig. 6.102.

Five compounds are known and their structural characteristics are presented in the following table, along with their melting temperatures (Table 6.20).

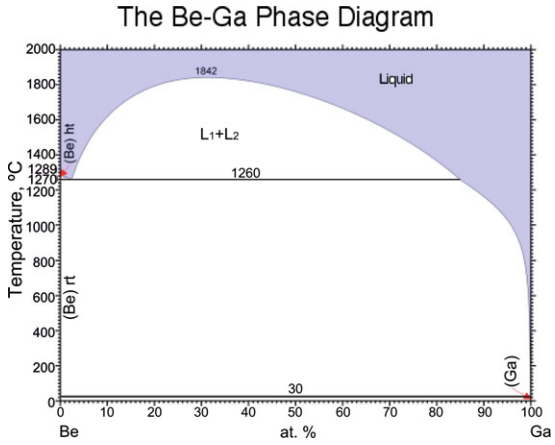

FIGURE 6.101

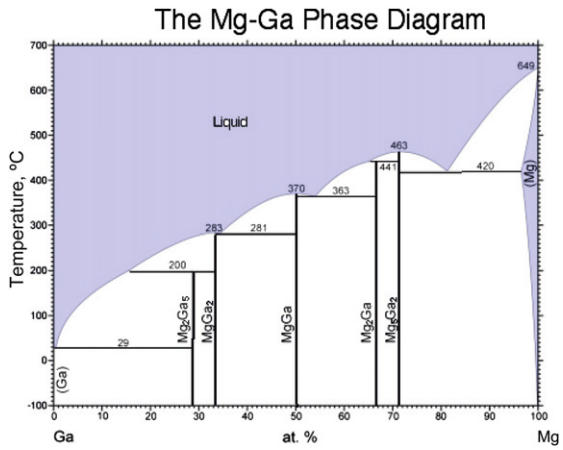

FIGURE 6.102

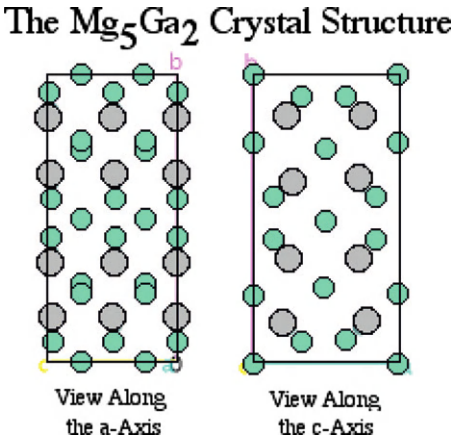

FIGURE 6.103

$MgGa_2$, MgGa, and Mg_5Ga_2 melt congruently, and the others melt incongruently. Note that the crystal types are all distinctive and are "one-of-a-kind".

Penta-magnesium di-gallide, Mg_5Ga_2, is orthorhombic and has the unit-cell parameters of: $a = 6.02$ Å, $b = 7.04$ Å, $c = 8.27$ Å, $\alpha = 115.042°$, $\beta = 111.348°$, $\gamma = 90°$, cell volume $= 289.08$ Å^3. The three-dimensional structure is difficult to depict on a flat surface so that the following structure is shown in two views, one along the *a*-axis of the structure and the other along the *c*-axis[1] (Fig. 6.103).

If these two views are placed at 90° to each other, then the three-dimensional character of the structure can be visualized. This structure is not formed by any other species other than Mg_5Ga_2. The location of the 28 atoms in the unit-cell lattice is shown in Table 6.21.

This compound can be prepared by reaction of a 5:3 mixture of the elements. It has been used to prepare base-free trimethylgallium by reaction of methyl iodide with the intermetallic compound [Mg_5Ga_2] in a high-boiling ether. If Mg_5Ga_2 is hydrided, microparticles of MgH_2 grow at the expense of the compound:

$$Mg_5Ga_2 + 5H_2 \Rightarrow 5MgH_2 + 2Ga$$

TABLE 6.20

Compound	Crystal type	Point group	Space group	Melting temperature	Crystal type
(Mg)	Mg	hP2	194	469 °C	—

[1]For a three-dimensional view, controllable by mouse, visit "NIMS Data Base.com" to observe these structures.

One of the most interesting characteristics of the Mg–Ga system is the existence of a glass-forming concentration range around the eutectic of 70–80 mol% Ga. This encompasses the Mg_5Ga_2 compound which has been studied as a "glassy-metal" and its physical properties examined.

Very little usage of this compound has resulted in industry and the only interest in academia has been the determination of its crystal structure.

It has been assigned the CAS number of 12064-14-1.

Dimagnesium gallide, Mg_2Ga, is hexagonal with cell parameters of: $a = 0.7.794$ nm, $b = 0.7.794$ nm, $c = 0.6.893$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume = 362.63 Å^3. The structure is shown in Fig. 6.104.

The location of the 18 atoms in the unit-cell lattice is shown in the following Table 6.22.

This compound has been assigned the CAS number of 12422-88-7. Although this compound has been assessed as a hydrogen-storage media, it did not compare in such properties with other, more efficient materials.

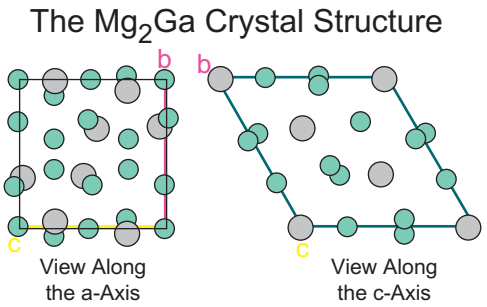

FIGURE 6.104

Magnesium digallide, $MgGa_2$, has the cell parameters of: $a = 0.4.111$ Å, $b = 6.802$ Å, $c = 16.346$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 457.08 Å^3. The structure is shown in Fig. 6.105.

Again, the three-dimensional structure can be visualized by placing the *c*-axis at 90° to the *a*-axis. The location of the 24 atoms in the unit-cell lattice is shown in the following Table 6.23.

No data can be found in the technical literature concerning its properties except that of structure.

Magnesium gallide, MgGa, has the cell parameters of: $a = 5.5331$ Å, $b = 7.9426$ Å, $c = 7.9426$ Å, $\alpha = 83.039°$, $\beta = 69.628°$, $\beta = 69.628°$, cell volume = 306.58 Å^3. The structure is orthorhombic as shown in the following Fig. 6.106.

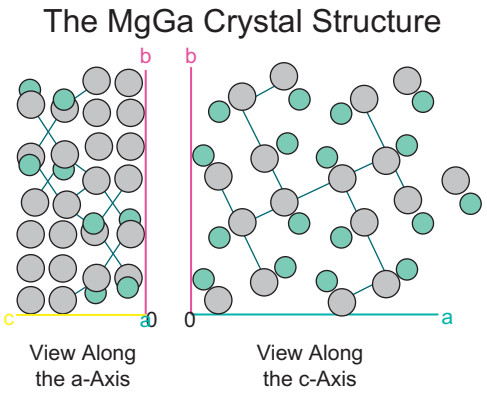

FIGURE 6.106

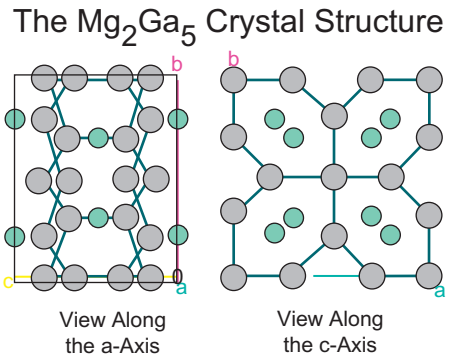

FIGURE 6.107

A three-dimensional structure may be visualized by placing the *c*-axis at 90° to the *a*-axis.

The location of the 32 atoms in the unit-cell lattice is shown in the following Table 6.24.

No data or usage of this compound has arisen in industry or the technical literature.

Dimagnesium penta-gallide, Mg_2Ga_5, crystallizes in an orthorhombic cell with the space group Ibam. The unit-cell parameters are: $a = 0.7.0607$ Å, $b = 7.0607$ Å, $c = 7.0607$ Å, $\alpha = 104.689°$, $\beta = 104.689°$, $\gamma = 119.529°$, cell volume $= 264.61$ Å^3, $Z = 4$. The structure is presented as shown in Fig. 6.107.

Again, this structure can be visualized in three dimensions by placing the *c*-axis at 90° to the *a*-axis. It consists of Ga_2 dumbbells, spaced within the orthorhombic lattice.

The arrangement of the 28 atoms in the unit-cell lattice is shown in Table 6.25.

Commercial usage of these compounds is virtually nil because of their instability to heating a prime requisite for stable and reversible hydrogen-storage purposes.

Calcium Gallides

Calcium forms a number of compounds with gallium metal, even though Ga melts around 30 °C and Ca metal melts at 842 °C. The phase diagram is shown as shown in Fig. 6.108.

Nine compounds are apparent in this diagram. The system, Ca–Ga, forms the most numerous crystalline compounds of any of the alkaline earths.

The lattice parameters are given in the Table 6.26.

The gallium-rich region of the Ca–Ga system (64.9–84.6 atom% Ga) was examined by X-ray methods. In addition to the $CaGa_2$ phase with the $CaIn_2$ structure

type, another phase, $CaGa_{2+x}$, was found in a limited homogeneity range, being $0.1 < x < 0.4$, with crystal structure derived from the AlB_2 type. The mechanism of solid solubility formation was clarified by single-crystal refinement. A new phase Ca_3Ga_8 was identified by powder diffraction data as isotypic with Eu_3Ga_8. The structure of $CaGa_4$, determined by single-crystal methods, can be described as a new monoclinic distortion of the $BaAl_4$ type, related to the low temperature form of $CaAl_4$.

By focusing on the alkaline earth metal Ca, a high flexibility of Ga with respect to the chemical bonding situation was observed. In the Ga-rich part of the systems Ca–Ga, the intermetallic phase $Ca_{1-x}Ga_{2+3x}$ was described. This compound crystallizes in a substitution variant of the AlB_2 type of structure. Due to a substitution of the cations by triangular Ga_3 units, three types of Ga atoms in nonequivalent chemical environments can be assigned using single-crystal X-ray investigation methods. With respect to the first coordination sphere three-bonded Ga atoms form the AlB_2 typical honeycomb-like six-membered rings and are labeled as Ga(3b). Throughout the formation of a chemical bond between the substituting Ga3 units with the atoms of the hexagonal Ga layers, these atoms have to be assigned as Ga(4b) and Ga(4b'), respectively. This structure is shown in Fig. 6.109.

The cation substitution leads to a formation of a homogeneity range between $0.056 \le x \le 0.115$ ($T = 880$ °C) for $Ca_{1-x}Ga_{2+3x}$ and $0 \le x \le 0.056$ ($T = 400$ °C) for $Sr_{1-x}Ga_{2+3x}$, respectively. For $x = 0.115$, the formation of a $Ca_{1-x}Ga_{2+3x}$ super lattice structure was also revealed.

Another view shows the Zintl structure of the Ga atoms (Fig. 6.110).

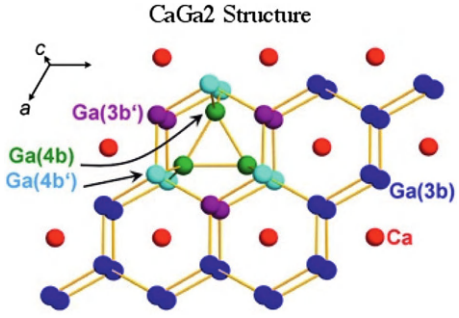

FIGURE 6.109

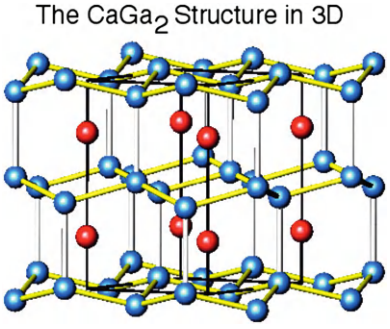

FIGURE 6.110

This structure is fairly simple in composition and arrangement of atoms in three-dimensional space and can be illustrated in two dimension as well. However, the more complicated structures are nearly impossible to decipher. It is for this reason that the structures of the Ca–Ga compounds have been shown as "views along the *a*-axis" which show the first sheet of atom

arrangements and those "views along the *c*-axis" which show the number of sheets within the three-dimensional volume and the arrangement of atoms on each sheet. Where the three-dimensional atom arrangement can be illustrated in two dimension adequately, the diagram will be included. In the more complicated structures, a table, showing the locations of the various atoms, is included.

Calcium digallide, $CaGa_2$, has the $CaIn_2$ structure. It has the unit-cell parameters of: $a = 4.467$ Å, $b = 4.467$ Å, $c = 7.393$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume = 127.76 Å. The structure is shown in Fig. 6.111.

The *c*-axis diagram shows four layers present but does not show the hexagonal arrangement of the Ga atoms relative to the Ca atoms. A three-dimensional structure shows this in a much better fashion (Fig. 6.112).

The "yellow" flags show the arrangement of the Zintl dumbbells. The arrangement of the atoms in this structure is shown in the following Table 6.27.

Calcium digallide is a superconductor at 4.3 K. The electronic states of the intermetallic compound $CaGa_2$ were investigated with the empirical local pseudopotential method. The band structure shows the existence of interlayer states which are similar to those recently found in graphite, hexagonal boron nitride, and LiC_6. The chemical binding in the Ga planes consists of strong σ bonds between Ga sp^2 hybrids while the interlayer cohesion mostly results from the overlap between Ga $4p_z$ orbitals.

Calcium mono-gallide, CaGa, has been synthesized by either arc melting or direct reactions in sealed Ta containers. The CrB structures of this binary phase have been identified by Guinier powder diffraction, and the MoB-type structure of the new ternary line phase $Y(Ga_{0.8}Zn_{0.2})$ has been refined by single-crystal means: $I4_1/amd$, $Z = 8$, $a = 4.1787$ Å, $c = 21.856$ Å. Resistivity and magnetic susceptibility measurements on the CrB-type CaGa compound demonstrates its metallic properties and the nonapplicability of a literal Zintl phase assignment of oxidation states. CaGa has the unit-cell parameters of: $a = 4.191$ Å, $b = 4.387$ Å, $c = 6.0997$ Å, $\alpha = 90°$, $\beta = 110.093°$, $\gamma = 90°$, cell volume = 105.32 $Å^3$. The structure is illustrated as shown in Fig. 6.113.

The arrangement of the eight atoms in the structure is shown in Table 6.28.

A better view of this structure can be seen in a three-dimensional view (Fig. 6.114).

No physical data concerning the CaGa compound is available in the literature other than structural data.

Calcium tetra-gallide, $CaGa_4$, is one of the least complicated of the species. It has the lattice parameters of: $a = 4.3544$ Å, $b = 4.3544$ Å, $c = 6.1223$ Å, $\alpha = 69.93°$, $\beta = 69.93°$, $\gamma = 89.516°$, cell volume = 101.59 $Å^3$.

The lattice structure is illustrated as a two- and a three-dimensional model in the following diagram. The three-dimensional lattice model does not

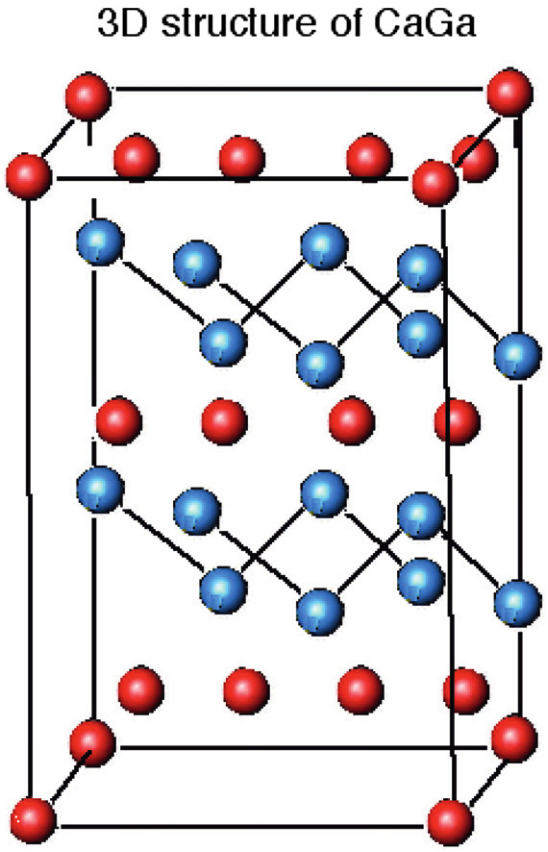

FIGURE 6.114

adequately show the three layers shown along the *c*-axis. The structure is trigonal, not cubic (Fig. 6.115).

The arrangement of the 10 atoms in the structure is shown in Table 6.29.

The structure of $CaGa_4$, determined by single-crystal methods, can be described as a new monoclinic distortion of the $BaAl_4$ type, related to the low temperature form of $CaAl_4$. A better representation is shown as shown in Fig. 6.116.

Here, the Zintl structure is clearly evident.

The enthalpies of formation of $CaGa_4$ at 988 K was determined, using precipitation calorimetry, to be -28.2 ± 1.7 kJ/(g-atom). The integral enthalpy of mixing of the (Ca–Ga) liquid alloys (ΔH_0) measured at 1309 K are described by the following Redlich–Kister equation:

$$\Delta H_0 = x_{Ca}(1 - x_{Ca})\, f(y)$$

$$f(y) = 48y^2 - 8.34y - 161.16$$

$$y = x_{Ca} - x_{Ga}$$

$$\Delta H^0_{Ca} = -104.8 \pm 1.7 \text{ kJ (g-at\%)}^{-1}$$

Calcium di-gallide, $CaGa_{2.25}$, is a much more complicated structure which is a variant of $Ca_{1-x}Ga_{2+x}$. $CaGa_{2.25}$ has the cell parameters of: $a = 4.315$ Å, $b = 4.315$ Å, $c = 4.315$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume $= 69.58$ Å^3.

The structure is illustrated as shown in Fig. 6.117.

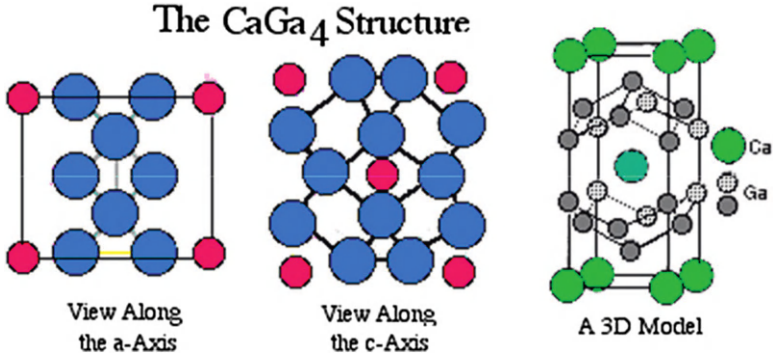

FIGURE 6.115

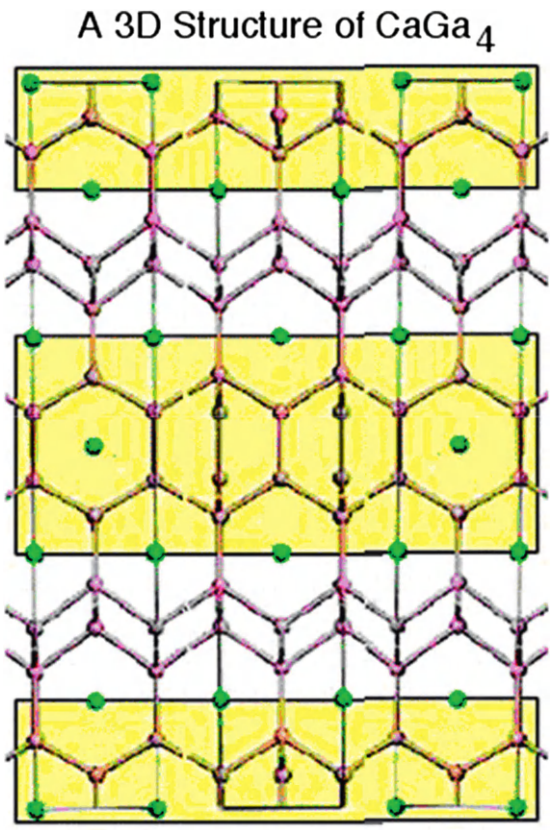

FIGURE 6.116

There are two Ga atoms that are hidden in this representation.

The location of the nine individual atoms in this structure is shown in Table 6.30.

A better representation shows the two hidden Ga atoms in the following Fig. 6.118.

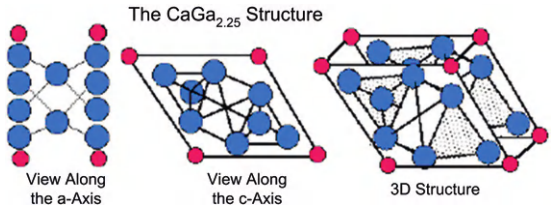

FIGURE 6.117

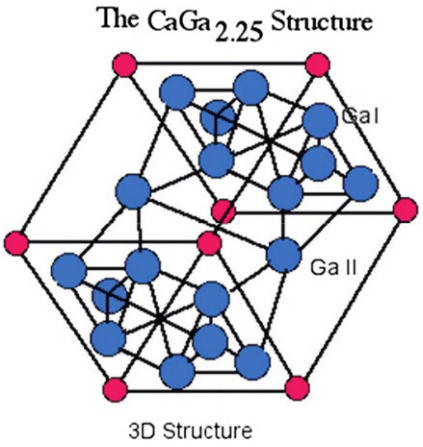

FIGURE 6.118

Undeca-calcium hepta-gallide, $Ca_{11}Ga_7$, has the cell parameters of: $a = 11.3908$ nm, $b = 11.3908$ nm, $c = 11.3908$ nm, $\alpha = 60°$, $\beta = 60°$, $\gamma = 60°$, cell volume $= 104.508$ Å^3, $Z = 8$. Its structure may be represented as shown in Fig. 6.119.

The locations of the various 144 atoms in the lattice are shown in the following Table 6.31.

The actual structure has 25 of these plates of Ca–Ga atoms, with the actual arrangement of Ca and Ga atoms

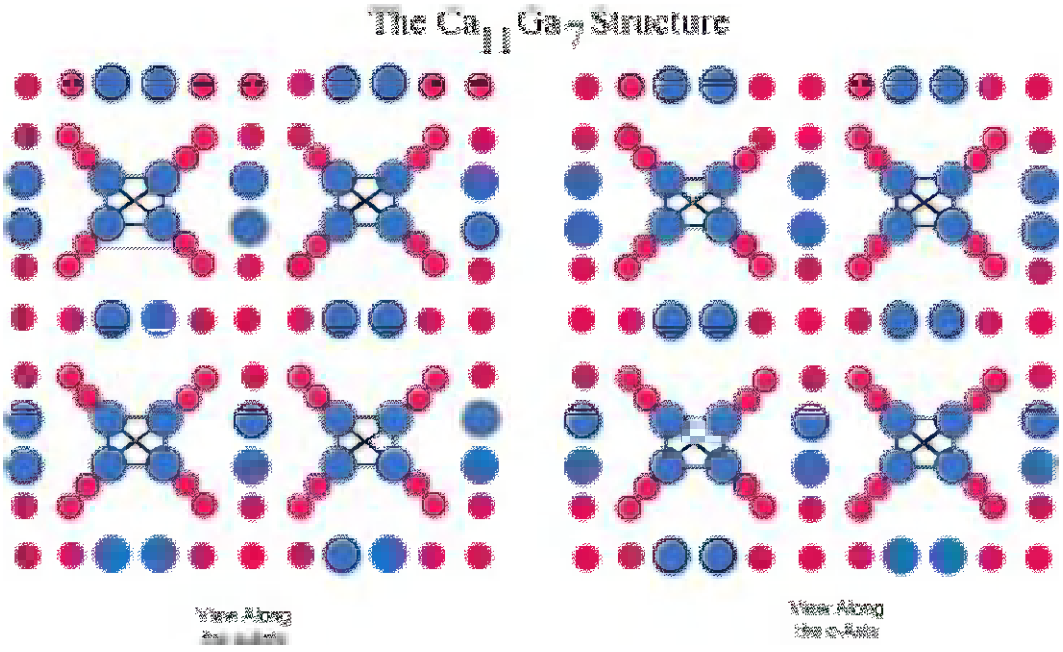

FIGURE 6.119

as shown here. There are five plates in the *b*-direction and five in the *c*-direction. In one unit cell, there are 88 Ca atoms and 56 Ga atoms for a total of 144. Thus, this structure encompasses 1152 atoms in eight unit cells.

The binary alkaline earth triclides $Ca_{11}Ga_7$ and $Sr_{11}In_7$ crystallize with a singular structure type (cubic, space group, Fm3m, $Z = 8$). The Ca- and Sr-mixed triclides forming this structure type were synthesized from stoichiometric mixtures of the elements and were characterized by single-crystal XRD. The structures exhibit isolated M(1) atoms (M(2) = Al, Ga, In, Sn, Pb) together with tetrahedral units $[M(1)_4]$, which are formed by the triel elements exclusively. Remarkably, one of the four crystallographically independent A^{II} positions is—as in the pure element—coordinated by A^{II} partners in a cuboctahedral arrangement. In the mixed M^{III}/M^{IV} compounds, a maximum phase range up to a maximum composition limit: $Ca_{11}[Ga_1^{3-}]_4[Ga_2^{4-}]_3$ is observed, which nearly corresponds to an ionic description according to the Zintl concept (tetrahedral anions isoelectronic to white phosphorus P_4 besides isolated noble gas isosteric tetra-elide anions $[Ga^{IV}]^{4-}$). Thus, this structure encompasses triangular Ga_3^{3-} units tied to tetrahedral Ga_4^{4-} units in a regular fashion.

Dodeca-octa calcium undeca-gallide, $Ca_{28}Ga_{11}$, has the cell parameters of: $a = 5.324$ Å, $b = 7.488$ Å, $c = 31.0641$ Å, $\alpha = 96.922°$, $\beta = 94.916°$, $\gamma = 90°$, cell volume = 1224.79 Å^3. The structure is depicted as shown in Fig. 6.120.

The actual structure has about 78 atoms. The locations of the different Ca and Ga atoms in the lattice are shown in the following Table 6.32.

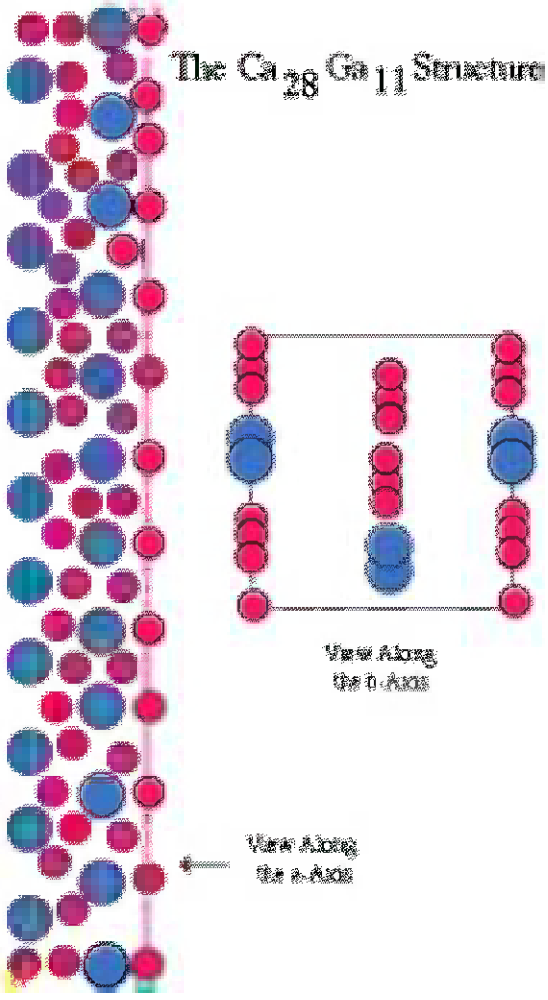

FIGURE 6.120

The structure of $Ca_{28}Ga_{11}$ is characterized by three types of calcium polyhedra surrounding the Ga atoms: tri-capped trigonal prisms, distorted cubes and distorted cuboicosahedra (10-vertex polyhedra similar to those found around Si in CO_2Si). The linkage of these polyhedra give rise to columns or slabs that alternate along the greatest axis of the cell. No Ga–Ga contacts are present.

No other data is available concerning the physical properties of this compound or its potential usage in industry.

Tricalcium penta-gallide, Ca_3Ga_5, has the unit-cell parameters of: $a = 4.463$ Å, $b = 5.8424$ Å, $c = 15.025$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 112.454°$, cell volume $= 362.07$ Å. The structure may be represented as shown where a unit of 10 Ga atoms are joined in a unique structure, surrounded by six Ca atoms (Fig. 6.121).

This unit is then inverted to form the full structure (Fig. 6.122).

The 32 atoms are located in the lattice in Table 6.33.

A better view of the lattice can be seen in the following diagram. Here, the Zintl arrangement of the Ga atoms is more readily apparent (Fig. 6.123).

Tricalcium octa-gallide, Ca_3Ga_8, has the unit-cell parameters of: $a = 4.323$ Å, $b = 4.323$ Å, $c = 13.2782$ Å, $\alpha = 99.369°$, $\beta = 99.369°$, $\gamma = 90°$, cell volume = 241.48 Å^3. The structure is shown in Fig. 6.124.

The enthalpies of formation of the intermetallic compounds $CaGa_4$, Ca_3Ga_8, and $CaGa_2$, at 298.15 K, were determined by high-temperature liquid gallium solution calorimetric measurements to be -24.9 ± 4.9 kJ/(g-atom), -25.4 ± 2.4 kJ/(g-atom), and -38.8 ± 4.8 kJ/(g-atom), respectively.

The 22 atoms in the lattice are located in Table 6.34.

There are three layers of the atom arrangement of the a-axis to form the three-dimensional structure (Fig. 6.125).

Penta-calcium tri-gallide, Ca_5Ga_3, has the unit-cell parameters of: $a = 7.954$ Å, $b = 7.954$ Å, $c = 9.4082$ Å, $\alpha = 115.006°$, $\beta = 115.006°$, $\gamma = 90°$, cell volume = 477.15 Å^3. The structure is illustrated as shown in Fig. 6.126.

The location of the 32 individual atoms in this structure is shown in Table 6.35.

A three-dimensional structure is shown in the following Fig. 6.127.

The unit-cell consists of gallium dumbbells surrounding calcium atoms, as well as two skewed octahedron of Ca atoms opposite the center of the cell. Calcium gallides are available in limited quantities commercially. No specific usage of any of them has arisen in industry.

Strontium Gallides

Strontium metal and gallium metal, when melted together, forms a limited number of compounds as can be seen in the following Fig. 6.128.

The crystal parameters are shown in the following Table 6.36.

Strontium digallide, $SrGa_2$, has the AlB_2 structure. The unit-cell structure parameters are: $a = 4.345$ Å, $b = 4.345$ Å, $c = 4737$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume = 77.45 Å^3. The structure can be represented by Fig. 6.129.

An analysis of the electron localization function (ELF) shows honeycomb-like 6_3 nets of the Ga atoms as the

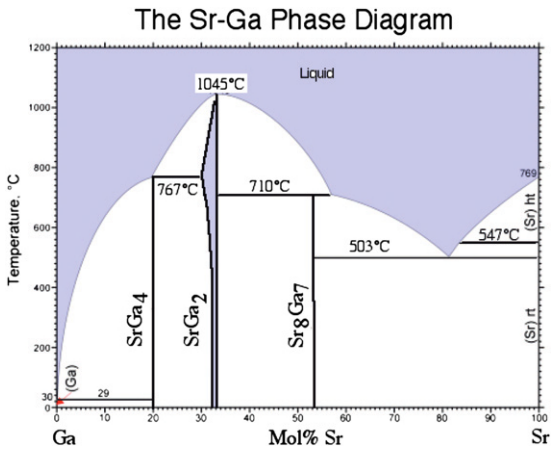

FIGURE 6.128

most prominent structural features in $SrGa_2$ and $BaGa_2$. The location of the individual atoms in this structure is shown in the following Table 6.37.

The layered structure is readily seen in the following Fig. 6.130.

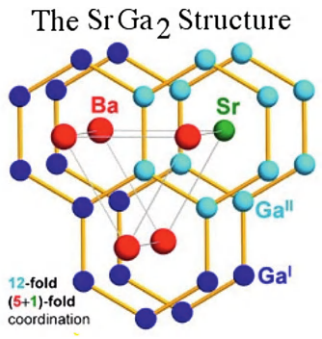

FIGURE 6.129

The hydrogenation behavior of the polar intermetallic systems AeE_2 (Ae = Ca, Sr, Ba; E = Al, Ga, In) has been investigated systematically and afforded the new hydrides $SrGa_2H_2$ and $BaGa_2H_2$. The structure of these hydrides was characterized by X-ray powder diffraction and neutron diffraction of the corresponding deuterides.

Both compounds are isostructural to previously discovered $SrAl_2H_2$ (space-group Pm1, Z = 1, $SrGa_2H_2$/

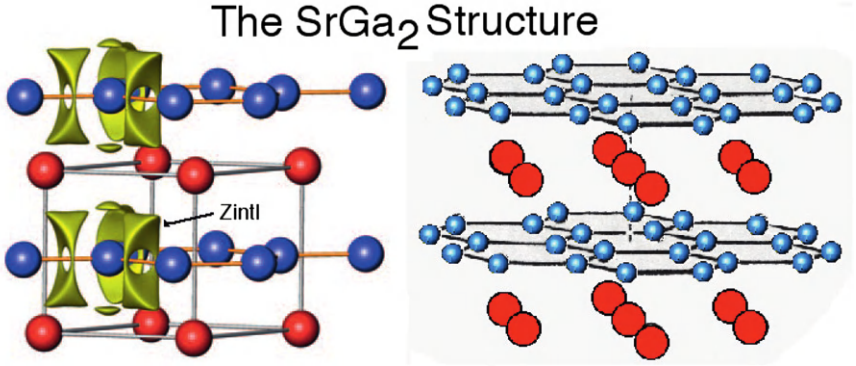

FIGURE 6.130

D_2: $a = 4.4010/4.3932$ Å, $c = 4.7109/4.699$ Å; $BaGa_2H_2/D_2$: $a = 4.5334/4.5286$ Å, $c = 4.9069/4.8991$ Å). The two hydrides, $SrGa_2H_2$ and $BaGa_2H_2$, decompose at around 300 °C at atmospheric pressure. First-principles electronic structure calculations reveal that H is unambiguously part of a two-dimensional polyanion $[E_2H_2]^{2-}$ in which each E atom is tetrahedrally coordinated by three additional E atoms and H. The compounds AeE_2H_2 are classified as polyanionic hydrides. The peculiar feature of polyanionic hydrides is the incorporation of H in a polymeric anion where it acts as a terminating ligand. Polyanionic hydrides provide unprecedented arrangements with both E–E and E–H bonds. The hydrogenation of AeE_2 to AeE_2H_2 takes place at low-reaction temperatures (around 200 °C), which suggests that the polyanion of the polar intermetallics ([E2]2-) is employed as precursor. The structure of these hydrides is shown in Fig. 6.131.

Octa-strontium hepta-gallide, Sr_8Ga_7, has a unique structure similar to that of its Ba homologue (Fig. 6.132).

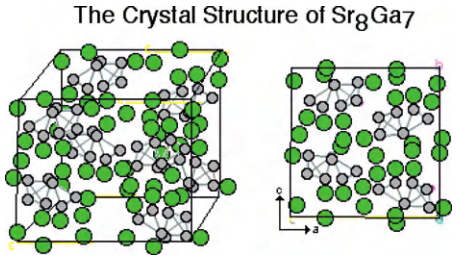

FIGURE 6.132

The structure is composed of Al_7^{16-} units, surrounded by eight Sr^{2+} atoms. It is cubic. Cell parameters are: $a = 12.484$ Å, $b = 12.484$ Å, $c = 12.484$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 194.64 Å^3. The various atoms are located in Table 6.38.

Two- and three-bonded Ga atoms forming molecular units are observed in Sr_8Ga_7 and Ba_8Ga_7. Three-dimensional frameworks are formed by four- and five-bonded Ga atoms in $SrGa_4$, or $BaGa_4$.

Strontium tetra-gallide, $SrGa_4$, has the cell parameters of: $a = 4.43$ nm, $b = 4.43$ nm, $c = 6.2039$ nm, $\alpha = 110.918°$, $\beta = 110.918°$, $\gamma = 90°$, cell volume = 105.09 Å^3. The structure can be represented as shown in Fig. 6.133.

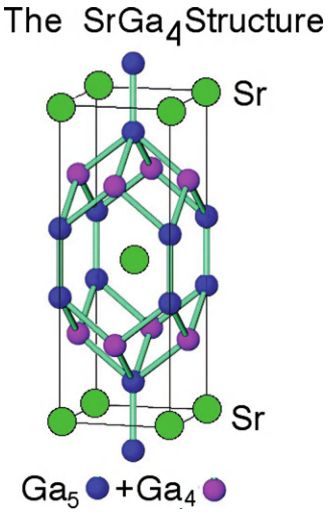

FIGURE 6.133

TABLE 6.38

7	Sr(3)	Sr	4	a	.3.	0.6859	0.6859	0.6859	1.0

The various atoms are located in Table 6.39.

Single crystals of $SrGa_4$, were synthesized from the corresponding elements using molten Sn metal as a solvent. The structure determination showed the product to be a binary phase with composition $SrGa_4$, which crystallizes with the $BaAl_4$ type in the body-centered tetragonal space group I4/mmm (No. 139). The three atoms in the asymmetric unit lie on special positions with Wyckoff symbols 2a (Sr), 4d and 4e for the Ga atoms.

Strontium gallides are not generally available commercially.

Barium Gallides

Barium gallides can be prepared by heating the metals in proper atom ratios to form various compounds. The phase diagram shows four compounds, as shown in the Fig. 6.134.

Two- and three-bonded Ga atoms forming molecular units are observed in Sr_8Ga_7 and Ba_8Ga_7. Three-dimensional frameworks are formed by four- and five-bonded Ga atoms in MGa_4 with M = Ca, Sr, or Ba.

The crystal parameters are shown in the following Table 6.40.

Barium tetra-gallide, $BaGa_4$, has the cell parameters of: $a = 4.5661$ Å, $b = 4.5661$ Å, $c = 6.2822$ Å, $\alpha = 111.31°$, $\beta = 111.31°$, $\gamma = 90°$, cell volume = 112.36.

Its structure is unique but identical to that of its Sr homologue (Fig. 6.135).

The positions of the various atoms in the structure is given in the following Table 6.41.

This compound has been studied extensively as to its physical properties. $BaGa_4$ possesses the most popular structure type in solid-state chemistry. More

than 600 compounds crystallize in this structure. Many compounds of this family exhibit interesting physical properties such as superconductivity, unusual magnetic behavior, valence fluctuation and heavy fermion phenomena.

Barium digallide, $BaGa_2$, has the cell parameters of: $a = 4.429$ Å, $b = 4.429$ Å, $c = 5.076$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume $= 86.23$ Å^3. The structure can be represented as shown in Fig. 6.136.

The alternating layers of Ba and Ga are readily seen. The individual atoms in the unit cell are located in Table 6.42.

An analysis of the ELF shows honeycomb-like 6_3 nets of the Ga atoms as the most prominent structural features in $SrGa_2$ and $BaGa_2$. A three-dimensional structure is shown in the following Fig. 6.137.

Octa-barium hepta-gallide, Ba_8Ga_7, has the $P2_13$ space group and the cell parameters of: $a = 1.2.99$ nm, $b = 1.2.99$ nm, $c = 1.2.99$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume $= 219.93$ Å^3. Its structure can be represented by Fig. 6.138.

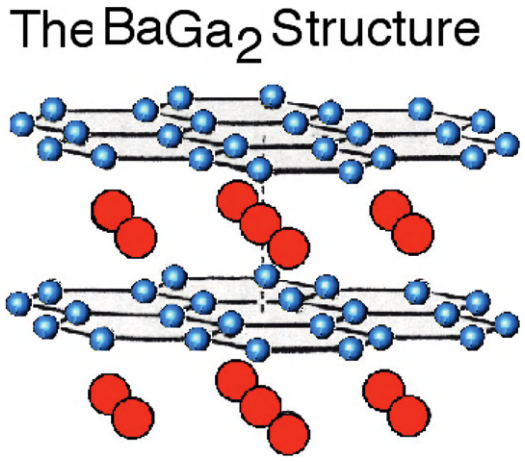

FIGURE 6.136

This compound is isotypic with the Ca and Sr compounds and is characterized by the presence of isolated tetrahedral and triangular clusters of Ga atoms included in cages of 16 Ba atoms. The location of the Ba and Ga atoms in the unit cell is shown in the following Table 6.43.

Penta-barium hexagallide, Ba_5Ga_6, has the cell parameters: $a = 7.771$ Å, $b = 7.771$ nm, $c = 14.376$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume $= 751.83$ Å^3.

This compound does not appear in the phase diagram. The crystal structure of Ba_5Ga_6 was determined by single-crystal diffractometry. It is hexagonal, hP22, space group P6c2 (n.188), and contains a disordered Ba position with partial occupation. The structure is characterized by octahedral Ga_6 clusters, isolated and surrounded by a cuboctahedron of 12 Ba atoms. The barium cubo-octahedra, by sharing of edges and faces, are condensed in a tridimensional framework. Application of Wade's rules to the Ga_6-naked cluster gives an excess of two electrons per formula unit.

The compound Ba_5Ga_6 replaces the phase "BaGa" given in the original Ba–Ga phase diagram that was later refined to exclude the BaGa compound. Its structure can be represented by Fig. 6.139.

The atoms are located in Table 6.44.

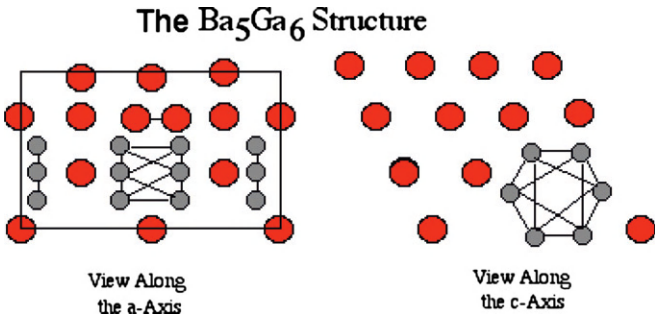

FIGURE 6.139

A unique structure of Ga atoms is shown within the unit cell. This dodecahedron has the general form has shown in Fig. 6.140, and is located at approximately 1/3 of the *c*-direction in the unit cell. There are three of these entities present.

Deca-barium gallide, $Ba_{10}Ga$, has the cell parameters: $a = 14.5098$ nm, $b = 14.5098$ nm, $c = 14.5098$ nm, $\alpha = 60°$, $\beta = 60°$, $\gamma = 60°$, cell volume $= 216.01$ Å^3. It is cubic but has a unique structure consisting of 40 Ba atoms, combined with a tetrahedron of Ga_4 atoms. The structure may be represented by Fig. 6.141.

The locations of the various atoms are shown in Table 6.45.

No data or research appears to exist concerning this compound.

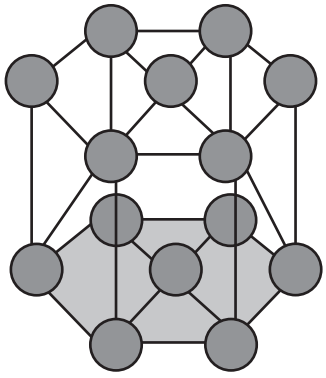

FIGURE 6.140

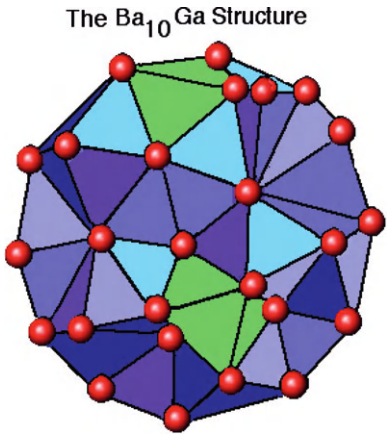

FIGURE 6.141

Barium gallides are available commercially in limited quantities for selected compositions.

Radium Gallides

The scientific literature is lacking in any references to radium gallides. Perhaps this is due to the intense radioactivity of the isomer ^{226}Ra but is more likely due to lack of interest of those in industry who have usage of such compounds. It is anticipated that various radium gallides could be prepared, using the same methods as those developed for the barium gallides series of compounds. Thus, one would expect to be able to obtain:

RaGa,
$RaGa_4$,
$RaGa_2$,
$RaGa_2$.

However, there is no record of such syntheses in the literature.

6.5.2. Alkaline Earth Gallate Compounds

Beryllium Gallates

Beryllium gallate, $BeO{\cdot}Ga_2O_3 = BeGa_2O_4$, can be formed by the SSR of the oxides at about 900 °C.

$$BeO + Ga_2O_3 + \text{heat} \Rightarrow BeGa_2O_4$$

X-ray powder diffraction data for $BeGa_2O_4$ have been obtained from the synthesized compound. The space group was determined by using a hexagonal prismatic single crystal obtained from a lead pyrophosphate flux by slow cooling. The crystal of $BeGa_2O_4$ belongs to the hexagonal system, with unit-cell parameters: $a = 7.7525$ Å, $c = 2.9817$ Å, $V = 155.19$ Å^3; space group $P6_3$ or $P6_3/m$, $Z = 2$. The crystal lattice is isomorphous with β-Si_3N_4. $BeGa_2O_4$ melts at 2013 K and has fairly small thermal expansion coefficients: $\alpha_{//}a = 3.29 \times 10^{-6}$/K, $\alpha_{//}c = 2.95 \times 10^{-6}$/K (298–1173 K average). $D_m = 4.511$ g/cm^3 (323 K) and $D_x = 4.546$ g/cm^3 (298 K).

High-pressure phase transformation of beryllium gallium oxide ($BeGa_2O_4$) has been studied. Applying high pressure at elevated temperatures to the original hexagonal $BeGa_2O_4$ (β–Si_3N_4-type structure), results in a high-pressure modification with orthorhombic structure (olivine-type structure), i.e. o-$BeGa_2O_4$. Lattice parameters of the new phase were determined to be $a = 0.5698$, $b = 0.9759$, and $c = 0.4551$ nm. The pressure and temperature ranges of the stable high-pressure phase observed were 3.5 to 7.5 GPa and 800 to 1600 °C, respectively. A tentative pressure–temperature phase diagram for $BeGa_2O_4$ was proposed. The transformation was not straightforward. Decomposition of the original phase into single oxides and their recombination to form o-$BeGa_2O_4$ was observed to be necessary. This process seems to apply to both formation and decomposition of the high-pressure phase. The stability of the high-pressure phase was explained in terms of the total molar volume for the phase, i.e. the result of summing up molar volumes of constituent compounds. This was said to be the first known report on transformation of the β–Si_3N_4 type structure into a denser structure.

$BeGa_2O_4$ is unique in that it can coexist with the oxides that are used to form it. Thus, the phase diagram exhibits only the beryllium monogallate (Fig. 6.142).

Beryllium gallate has been used as a flux to form high-strength sintered articles of chemical substances having the β-silicon nitride-type crystal structure. Sintered articles formed preponderantly of Si_3N_4 enjoy the properties of high thermal resistance, high strength, and a low thermal expansion coefficient but have proven very difficult to manufacture. Owing to these properties, they have drawn keen interest and have found utility in applications to automobile engine parts, gas turbine parts, cutting tools, etc. Such compositions can be

TABLE 6.45

more easily formed by blending 50 to 99.9 wt% of a β-silicon nitride and/or β′-sialon and 50 to 0.1 wt% of a mixture, as a sintering aid, consisting of $BeGa_2O_4$, and Al_2O_3 in respective amounts so as to have a Ga_2O_3 / BeO ratio in the range of from 2.8 to 9.4, an Al_2O_3/BeO ratio in the range of from 0.0 to 2.6, and an Al_2O_3 /Ga_2O_3 ratio in the range of from 0.0 to 1.1, all ratios being ratios by weight and sintering the resultant blend.

Beryllium monogallate is available in limited quantities commercially. It has no CAS number.

Magnesium Gallates

Although Ca, Sr and Ba form a number of compounds when the molar ratios of MO to Ga_2O_3 are varied in the SSR:

$$xMO + yGa_2O_3 \Rightarrow M_x(Ga_2O_3)_y = M_xGa_{2y}O_{3y}$$

the magnesium cation, Mg^{2+}, forms only the magnesium monogallate, $MgGa_2O_4$. This compound, $MgO{\cdot}Ga_2O_3 = MgGa_2O_4$, can be formed by the SSR of the oxides at about 1200 °C:

$$MgO + Ga_2O_3 + \text{heat} \Rightarrow MgGa_2O_4$$

It has the molecular weight of 227.764 g/mol. Its density is 5.298 g/cc. It has a modified Spinel structure. The phase diagram is similar to that of the BeO–Ga_2O_3 system, except that MgO melts at 2852 °C.

The diffusion of trivalent gallium into the rock salt lattice of MgO has been investigated. This study concerned a diffusion process, with a moving interface, which involves both defect formation and the formation of a new phase, $MgGa_2O_4$. The study was performed on presintered MgO and β-Ga_2O_3 pellets. The Wagner treatment of Fick's second law was used in the analysis and it was subjected to certain boundary conditions and approximations. The diffusion coefficient was determined from the slope of the linear region of the inverse complementary error function of the concentration as a function of penetration. The departure from linearity in the region of greatest penetration indicates that, initially, diffusion takes place in the grain boundaries. The region of linear dependence takes place in the later states of diffusion when bulk diffusion predominates. The mean diffusion coefficient as determined from three different anneal times at 1500 °C was $7.53 \pm 0.25 \times 10^{-10}$ cm^2/s.

In another study, the SSR of single crystals of MgO and β-Ga_2O_3 to form the spinel $MgGa_2O_4$ at 1600 °C was investigated. Three sets of reaction couples consisting of the (100), (110) and (111) planes of MgO contacting the (001) plane of β-Ga_2O_3 were studied. All the reaction products were $MgGa_2O_4$ in single-crystal form. The Wagner mechanism of counter diffusion across the reaction interface was verified. In each instant where Spinel was formed, it adhered strongly to the host crystal. Spinel formed by vapor transport was also observed on the MgO crystal.

Spinelloid phases (which are mixed solid solutions of two differing compositions) of germanate–gallate have been observed and characterized by powder XRD and HREM. $Mg_3Ga_2GeO_3$(III), with a narrow composition range of approximately 3 mol% Mg_2GeO_4, is stable at atmospheric pressure up to about 1420° C, and is isostructural with β-Mg_2SiO_4 and the spinelloid Phase III of the $NiAl_2O_4$–Ni_2SiO_4 system. This represents the first occurrence of a β-phase structure stable at 1 atm pressure. Above 1420 °C (1 atm), $Mg_3Ga_2GeO_8$ (III) decomposes reversibly into a mixture of spinel and olivine. At high pressures (around 30 kbar at 1100 °C), it transforms into another spinelloid phase, $Mg_3Ga_2GeO_8$ (IV), isostructural with Phase IV of the $NiAl_2O_4$–Ni_2SiO_4 system. In terms of crystal structures and phase relations, there exists a close analogy between the magnesium gallo-germanate and nickel alumino-silicate systems, the former being a lower pressure analog of the latter. The results of investigation of a number of other pseudo-binary spinel–olivine oxide systems suggests that the formation of spinelloid phases can be associated with the inverse character of the spinel component.

Magnesium gallate, when activated by divalent manganese, Mn^{2+}, is a phosphor that has a cubic spinel structure and was used in electrostatic copy machines. The spectral properties of the fluorescent lamp were shown in Fig. 6.143.

The characterization and optical properties of luminescent $MgGa_2O_4$:Eu^{3+} powders has also been investigated. Nanograined phosphors of Eu^{3+}-activated $MgGa_2O_4$ crystallites were prepared by a sol–gel technique. The dried sol–gel powders were calcined in air at different temperature from 600 to 1000 °C for 5 h. The XRD profiles showed that the $MgGa_2O_4$:Eu^{3+} powders began to crystallize around 600 °C and formed a stable $MgGa_2O_4$ phase in the temperature range of 600–900 °C. The TEM morphology observations

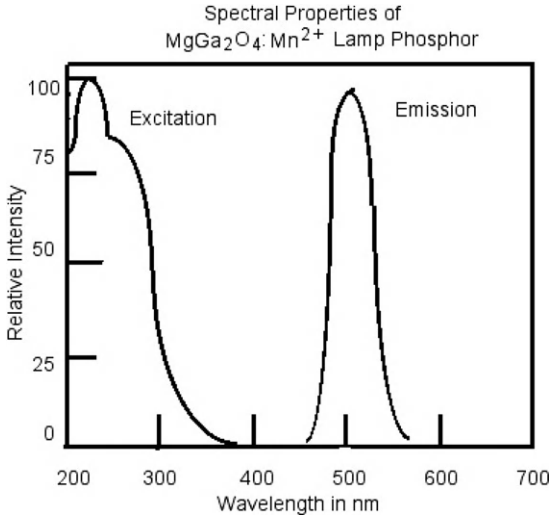

FIGURE 6.143

revealed that the fired powders exhibit small grain size less than 20 nm. In the PL studies, under ultraviolet (394 nm) excitation, the calcined powders emitted bright red luminescence (615 nm, $5D_0 \Rightarrow 7F_2$), and the powders fired at 900 °C were found to have the maximum photoluminescence intensity. The quenching concentration of Eu^{3+} in $MgGa_2O_4$ crystallites was also indicated to be about 5~6 mol%.

Magnesium monogallate is a partially inverted spinel with space group Fdpm and $a = 8.286$ Å. There are two possible sites in the lattice for metal ions, the A and B sites. Because magnesium is divalent and gallium is trivalent, these ions distribute themselves among these sites unequally. Mg^{2+} ions are distributed in about 16% in a tetragonal site and 84% in an octahedral site in the lattice, as shown in the following Fig. 6.144.

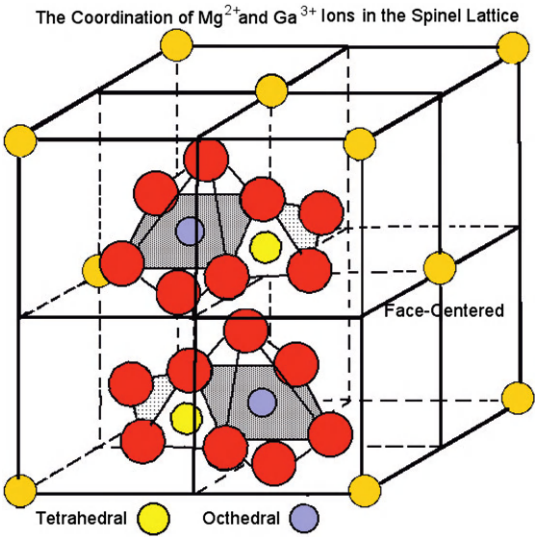

FIGURE 6.144

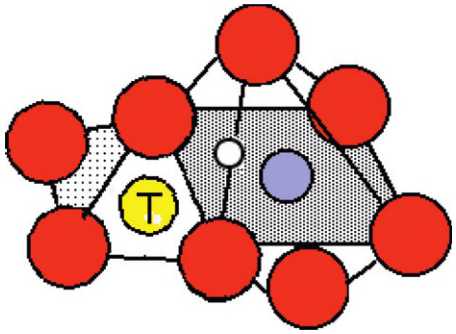

FIGURE 6.145

The oxygen atoms occupy a set of special positions. One or the other of the O- or T-Mg^{2+} or Ga^{3+} atoms is in a face-centered position between four unit cells. The separate tetrahedral and octahedral positions are better seen in the following Fig. 6.145.

Thus, there are two special positions for the Mg^{2+} and Ga^{3+} ions. There are 14 face-centered Ga^{3+} or Mg^{2+} sites that are shared in eight unit cells. The front faces of tetrahedral and octahedral positions of the Mg^{2+} and Ga^{3+} ions in two of the eight unit cells are clearly shown. The Mg^{3+} ions occupy the other positions in these lattice cells. The tetrahedral and octahedral groups are joined by a central oxygen atom in the structure. This structure is unique among the known cubic spinel compounds.

Other gallates of magnesium have not been discovered. Magnesium monogallate is available commercially in limited quantities. It has no CAS number.

Calcium Gallates

Monocalcium gallate can be prepared by firing the oxides together at 1200 °C for 8 h. The reaction is:

$$CaO + Ga_2O_3 + \text{heat} \Rightarrow CaGa_2O_4$$

Its structure has been described as a "stuffed-tridymite" which is a modification of silica. The phase diagram at room temperature is shown in the following Fig. 6.146.

The phase diagram has been determined as consisting of four compounds, although it is possible to form other stoichiometries by varying the formation conditions.

The system, $CaO–Ga_2O_3$, forms four compounds: $Ca_3Ga_2O_6$, $Ca_3Ga_4O_9$, $CaGa_2O_4$ and $CaGa_4O_7$. $3CaO–Ga_2O_3$ melts incongruently to CaO plus liquid at 1263 °C; $CaO·Ga_2O_3$ and $CaO·2Ga_2O_3$ melt congruently at 1369 and 1504 °C, respectively. Eutectics are located at the following temperatures and compositions (in mol% Ga_2O_3): between $3CaO·Ga_2O_3$ and $CaO·Ga_2O_3$, 1245 °C and 37.5%; between $CaO·Ga_2O_3$ and $CaO·2Ga_2O_3$, 1323 °C and 57.0%; and between $CaO·2Ga_2O_3$ and β-Ga_2O_3, 1457 °C and 68.0%. There is

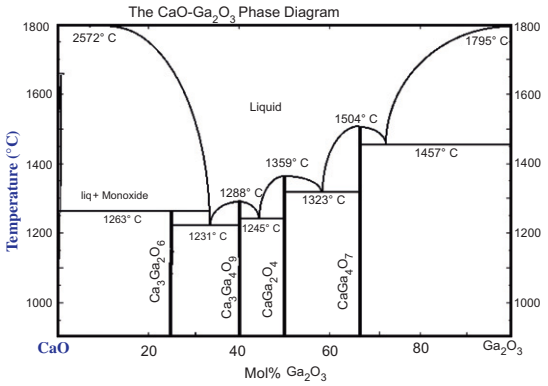

FIGURE 6.146

a peritectic at 1263 °C and 36.0%. Three polymorphs of $CaO{\cdot}Ga_2O_3$ have been described. Compositions from approximately 35 to 70 mol% Ga_2O_3 can be quenched to yield homogeneous glasses.

In another report, this system was reexamined using the methods of X-ray and differential thermal analysis. Four compounds $Ca_3Ga_2O_6$, $Ca_3Ga_4O_9$, $CaGa_2O_4$, and $CaGa_4O_7$ were found in the subsolidus region of the phase diagram of the $CaO–Ga_2O_3$ system. The existence of the gallate, $Ca_3Ga_4O_9$, discovered for the first time, was confirmed by measuring the e.m.f.'s of galvanic cells. Changes in Gibbs energy, enthalpy, and entropy for the reactions of formation of all four calcium gallates from oxides have been determined by the e.m.f. method with a solid $|F^-|$-ionic electrolyte in the range of 1100–1400 K (825–1125 °C). On the basis of the data obtained, the relative stabilities of the compounds were analyzed and the activity of calcium oxide in the system was calculated.

Monocalcium gallate ($CaO{\cdot}Ga_2O_3$) is polymorphic. Single crystals of the three polymorphs of $CaGa_2O_4$ have been studied. $CaGa_2O_4$-I is orthorhombic, with $a = 7.73$, $b = 9.14$, $c = 10.36$ Å; $CaGa_2O_4$-II is orthorhombic with $a = 5.32$, $b = 14.38$, $c = 16.82$ Å; *m*-$CaGa_2O_4$ is monoclinic with $a = 7.86$, $b = 8.90$, $c = 10.55$ Å, $\beta = 93°$. These cell dimensions do not resemble any of those previously reported for other $MO{\cdot}Ga_2O_3$ compounds.

The structure of calcium monogallate involves a series of tetrahedra–octahedra which share both corners and edges of octathedra. A high-pressure modification of calcium monogallate ($CaGa_2O_4$) has been prepared in a piston cylinder apparatus at 700 °C and 4.0 GPa. The compound is orthorhombic (space group *Pnam*, $a =$ 9.12476 Å, $b = 10.56093$ Å, $c = 2.98547$ Å, $V = 287.70$ Å^3, $Z = 4$, $D_{calc} = 5.62$ g/cm^3) and belongs to the $CaFe_2O_4$-type structure family. The structure was refined by the Rietveld method using laboratory X-ray powder diffraction data. Two crystallographically-independent GaO_6 octahedra forming edge-sharing double chains could be distinguished. The shared edges exhibit a considerable shortening. The chains are running parallel to the *c*-axis and are linked by corner sharing. They enclose tunnels in which the calcium atoms are located for charge compensation. Each calcium cation has eight nearest oxygen neighbors. The coordination environment can be described as a bicapped trigonal prism.

The SSRs (solid-state reactions) and the phase relations in the $CaAl_2O_4{\cdot}CaGa_2O_4$ system, of which both end-members have the stuffed tridymite structure, were examined by using three kinds of starting materials:

$$A = CaCO_3 + (Al,Ga)_2O_3$$

$$B = CaAl_2O_4 + CaGa_2O_4$$

$$C = CaCO_3 + Al_2O_3 + Ga_2O_3$$

When using the starting material B, a very low rate of SSR between $CaAl_2O_4$ and $CaGa_2O_4$ was found, which seemed to be due to very slow interchange of Al^{3+} and Ga^{3+} ions located in the tetrahedra of this structure. In order to obtain the probable equilibrium phase relations, it was necessary to use the starting material A. In using the A system, a new stable phase was found over a wide range of composition, which was proposed to have the same structure as so-called metastable phase of $CaGa_2O_4$ but a different array of tetrahedra from either $CaAl_2O_4$ or $CaGa_2O_4$.

In another paper, the modifications of $CaAl_2O_4$ and $CaGa_2O_4$ with the stuffed tridymite structure were examined under high temperatures (600 to 1500 °C) and high pressures (10 to 40 kbar). Calcium monoaluminate $CaAl_2O_4$ was found to transform to three kinds of high-pressure modifications. The original $CaAl_2O_4$ (CA-I) changed to the phase CA-II that had an m-$CaGa_2O_4$ type of structure with a different array of tetrahedra in the six-membered rings of the tetrahedron. The phase CA-II transformed either to the phase CA-IV with $CaFe_2O_4$-type structure or to an unknown phase (CA-III) under high pressures. The phase CA-IV was obtained under the pressures above 30 kb and at the temperatures above 1000 °C. In contrast, calcium monogallate, $CaGa_2O_4$, transformed to the $CaFe_2O_4$-type structure above 30 kb and 700 °C. No phases such as CA-II and CA-III were found. The structural relations among these modifications were discussed.

Dicalcium monogallate, $2CaO{\cdot}Ga_2O_3 = Ca_2Ga_2O_5$, was synthesized as a single crystal in a piston cylinder apparatus at 1250 °C/2.5 GPa from precursors prepared by SSRs. The crystal structure was investigated by XRD methods. The compound crystallizes in the orthorhombic space group *I*2*mb* ($a = 5.3525$ Å, $b = 14.6666$ Å, $c = 5.5651$ Å, $V = 436.88$ Å^3, $Z = 4$, $D_{calc} = 4.56$ g/cm^3)

and is isotypic with Ca_2FeAlO_5 (Brownmillerite) and $Ca_2Al_2O_5$. Basic building units of $Ca_2Ga_2O_5$ are:

(1) Layers of perovskite type corner-connected GaO_6 octahedra.
(2) Sheets comprised of Zweier single chains of GaO_4 tetrahedra (Fig. 6.147).

The alternate stacking of the two building units results in a three-dimensional framework in which the calcium cations are incorporated for charge compensation. Dicalcium gallate is the first structurally characterized representative of a double oxide in the system $CaO{\cdot}Ga_2O_3$ showing a sixfold coordination of Ga^{3+}. The stacking pattern is perhaps better seen in the following diagram where two layers are shown in Fig. 6.148.

A high-temperature XRD study revealed that Brownmillerite-type $Ca_2Al_2O_5$ transforms to an incommensurately modulated structure at elevated temperatures. Single crystals of $Ca_2Al_2O_5$ were synthesized in an end-loaded piston cylinder press at 2.5 GPa and 1273 K. The diffraction pattern observed at 1090 K by in situ single-crystal diffraction experiments was indexed by an *I*-centered orthorhombic cell and a modulation wave vector of $\mathbf{q} = 0.595\ \mathbf{c}$. A $(3+1)$ dimensional model in superspace group *Imma*(00)*s*00 was used to refine the modulated structure. The structure is assembled from two building units: (i) layers of corner-sharing $[AlO_6]$ octahedra, stacked along **b** alternate with (ii) layers of *Zweier* single chains of $[AlO_4]$ tetrahedra running along **a**. The modulated structure arises from an aperiodic sequence of two different configurations of the chains within the tetrahedral layers. The modulated high-temperature phase of $Ca_2Al_2O_5$ is isotypic to the modulated high-temperature modification of $Ca_2Fe_2O_5$. A large hysteresis was found in the phase-transition temperature. On heating, the transition occurs at ca. 1075 K (800 °C); on cooling, satellite reflections can be observed down to 975 K (700 °C). The characterization of $Ca_2Al_2O_5$ was completed by Raman spectroscopy, including a partial interpretation of the spectra.

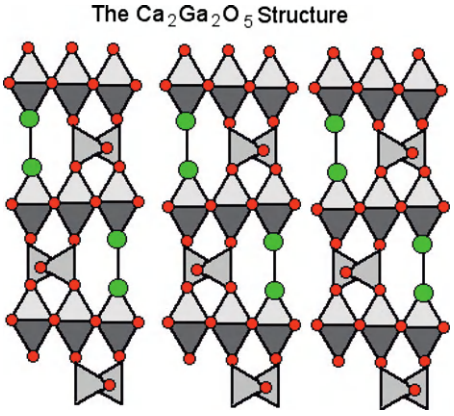

FIGURE 6.147

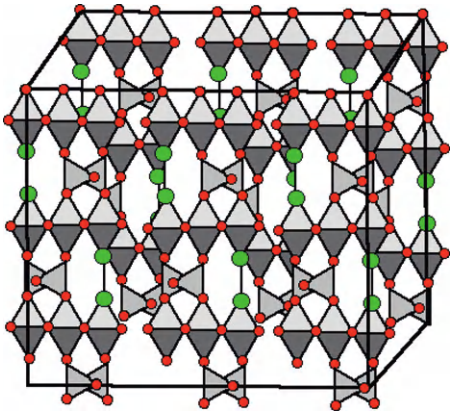

FIGURE 6.148

The compound, **mono-calcium digallate**, $CaGa_4O_7 = CaO{\cdot}2Ga_2O_3$, was prepared and its structure determined by single-crystal X-ray investigations. $CaGa_4O_7$ crystallizes as a monoclinic structure in the space group C_6^2/c with the lattice constants $a = 13.065$, $b = 9.079$, $c = 5.600$ Å; $\beta = 105.15°$. Calcium has an unusual coordination, which can be regarded as a distorted trigonal bipyramid. Its five nearest oxygen neighbors form a trigonal bipyramid. The gallium, however, is tetrahedrally coordinated. Four compounds were found to give significant Mn^{2+}-activated luminescence; $MgO{\cdot}Ga_2O_3$, $ZnO{\cdot}Ga_2O_3$, $K_2O{\cdot}5Ga_2O_3$, and $CaO{\cdot}2Ga_2O_3$. These have characteristic peak emissions at 512, 513·5, 507 and 587 nm, respectively.

Penta-calcium trigallate can be prepared by heating the oxides in the proper molar proportions at 1200 °C:

$$5CaO + 3Ga_2O_3 + \text{heat} \Rightarrow Ca_5Ga_6O_{14}$$

A direct current ($j = 20$ to $80\ mA/cm^2$) passing in vacuum ($P = 0.1$ Pa) at 1275 K (1002 °C) through $Ca_5Ga_6O_{14}$ single crystals led to a change of electrophysical and luminescent properties of samples. Specifically, this procedure induces the ionic component of electrical conductivity of $Ca_5Ga_6O_{14}$ and the red (1.83 eV = 678 nm) luminescence of F-centers. Using the obtained results, it was predicted that the ionic conduction is due to the transport of Ca^{2+} ions.

A novel $Ca_6Mn_3(Ga_{0.80}Al_{0.20})_5O_{18}$ compound was discovered in the Ca–Mn–Al–Ga–O system as a product of the reduction of the $Ca_2Mn(Ga_{0.8}Al_{0.2})O_5$, "Brownmillerite" and then prepared as a single-phase material. The structure consists of a tetrahedral $[(Ga_{0.59}Mn_{0.24}Al_{0.17})_{15}O_{30}]^{18-}$ framework stabilized with the embedded $[(Ca_{0.9}Mn_{0.1})_{14}MnO_6]^{18.24+}$ polycations. A high degree of disorder in the structure can be attributed to the random orientation of the tetrahedra around the Ga3 and Ga4 atoms in order to achieve proper bonding

conditions for the O2 atoms placed at the centers of the tetrahedral clusters. The joint occupation of the tetrahedrally coordinated positions in the framework by Ga and Al is not a necessary condition for the stability of this structure type. This indicates a large ability of this structure type in adapting to changes in the chemical composition.

The structure, in terms of octahedra and tetrahedra is shown in the following Fig. 6.149.

Here, the Ca^{2+} atoms, Ca1, Ca2, Mn and O3 atoms are omitted for clarity. Ga1, Ga2, Ga3 and Ga4 atoms are located at the yellow, brown, green and blue tetrahedra, respectively. The O3 atoms do not participate in the tetrahedral framework and form octahedra around the Mn atoms. The Mn–O3 octahedra together with the Ca1 and Ca2 atoms fill the cages in the tetrahedral framework. The MnO_6 octahedra are isolated from each other and from the tetrahedral framework. The $Ca_{6.3}Mn_3Ga_{4.4}Al_{1.3}O_{18}$ compound exhibits an onion skin-like structure where the Mn atom, chosen as a central point, is surrounded by the enclosed O_6,(Ca, $Mn)_{14}$ and (Ga, Al, $Mn)_{42}O_{104}$ shells (Fig. 6.150).

The full structure is shown in the following where positions of the MnO6 octahedra (red), Ca1 and Ca2 atoms (brown spheres) in the unit cell. The F23-ordered structure is shown for simplicity (Fig. 6.151).

From this point of view, the $Ca_6Mn_3(Ga_{0.80},Al_{0.20})_5O_{18}$ compound demonstrates a certain similarity to the structural organization of the ''Fullerenoid'' $Sr_{33}Bi_{24+d}Al_{48}O_{141+3d/2}$ oxide, where the onion skin-like structure is also present, and the largest sphere in this structure has a geometry virtually identical to that of D2d isomer of the C84 fullerene. However, the analogy with fullerene is based on pure geometrical resemblance since the bonding in complex oxides is essentially more ionic than that in carbon materials. The tetrahedral framework of the $Ca_6Mn_3(Ga_{0.80},Al_{0.20})_5O_{18}$ structure can be described as a three-dimensional $[(Ga_{0.59}Mn_{0.24}Al_{0.17})_{15}O_{30}]^{18-}$ anion stabilized with the embedded $[(Ca_{0.9}Mn_{0.1})14\ MnO_6]^{18+}$ polycations.

Another complex oxide $Ca_7Mn_2Ga_6O_{18}$ was synthesized by the SSR in a sealed evacuated quartz tube at 1000 °C. Its crystal structure was determined by electron diffraction and X-ray powder diffraction. The structure can be represented as a tetrahedral framework, viz., the polyanion $[(Mn_{0.285},Ga_{0.715})_{15}O_{30}]^{19-}$ stabilized by the incorporated cation $[Ca_{14}GaO_6]^{19+}$. The polycation consists of the GaO6 octahedra surrounded by the Ca atoms, which are arranged to form a cube capped at all places. The tetrahedral framework is partially

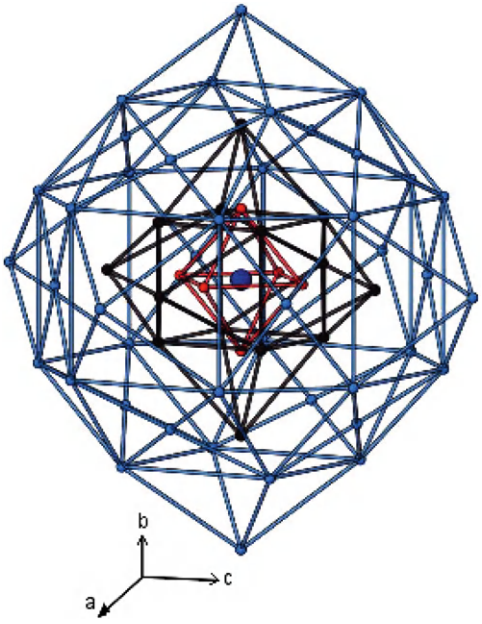

FIGURE 6.150

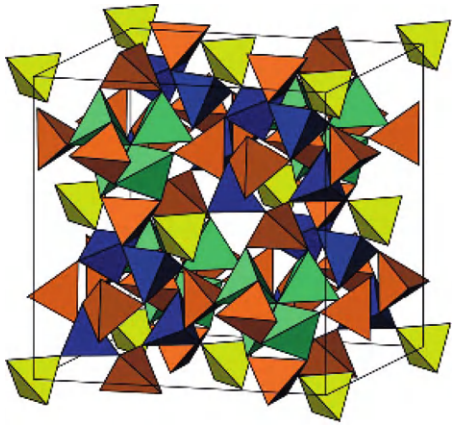

FIGURE 6.149

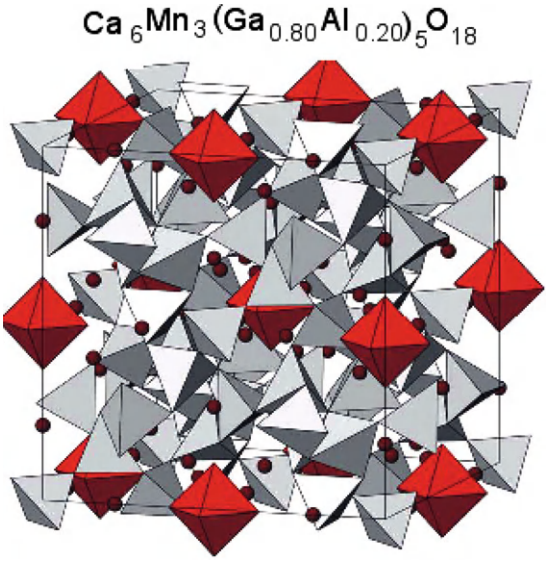

FIGURE 6.151

disordered due to the presence of tetrahedra with two possible orientations in the positions (0, 0, 0) and (x, x, x) with $x \approx 0.15$ and 0.17. The relationship between the $Ca_7Mn_2Ga_6O_{18}$ structures and related-ordered phases with the symmetry $F2_3$, as well as the influence of the oxygen content on the ordering in the tetrahedral framework, was discussed.

The magnetoplumbite family of materials exhibit properties that make them suitable to be used as substrates materials for microwave or luminescent applications. Four members of the family studied in this work are $LaMgAl_{11}O_{19}$, $NdGaMgAl_{10}O_{19}$, $CaGa_6Al_6O_{19}$ and $CaGa_{12}O_{19}$. Dielectric studies have been carried out over a temperature range of 4–300 K (−269 to 27 °C) and a wide frequency range. All four exhibit a low dielectric constant with good temperature stability, low dielectric loss and favorable frequency dependence characteristics.

The luminescence of $Sr(Ga_{12-x}Al_x)_{12}O_{19-y}:Eu^{2+}$ phosphors can be quenched by substitution of a small amount of Mg for Al, or by preparing samples with excess Al_2O_3. It is most probable that oxygen vacancies near the Eu^{2+} activator ions act as the radiationless sinks of the excitation energy. In $CaAl_{12}O_{19}:Eu^{2+}$, the quenching of the luminescence by the introduction of defects is much less effective, so that less oxygen vacancies are supposed to be formed. In view of the fact that the stability of $CaAl_{12}O_{19}$, with respect to less oxygen-containing phases, is higher than that of $Sr(Ga_{12-x}Al_x)_{12}O_{19-y}$, this is a reasonable assumption. The homogeneity range of $La_{1-x}A1_{11+x}0_{19}$: Eu^{2+} is at such values of x that a large number of Al vacancies exist. Quenching of its luminescence by the introduction of oxygen vacancies was not observed. In $LaMgAl_{11}O_{19}:Eu^{2+}$ phosphors, Al^{3+} interstitials, rather than oxygen defects, seem to play a dominate role in achieving charge neutrality.

Calcium gallates are available in limited quantities commercially.

Strontium Gallates

The strontium gallates may be formed by a SSR of the oxides:

$$x\mathrm{SrO} + y\mathrm{Ga_2O_3} + \text{heat} \Rightarrow \mathrm{Sr}_x\mathrm{Ga}_{2y}\mathrm{O}_{3y+x}$$

where x or y can vary from 1, 2, 3, 4, 6 and 7.

In the early literature, it was stated that the system, $SrO{\cdot}Ga_2O_3$, forms three compounds in the SSR of SrO and Ga_2O_3 ($4SrO{\cdot}Ga_2O_3$, $3SrO{\cdot}Ga_2O_3$, and $SrO{\cdot}Ga_2O_3$).

A phase diagram was published in 1969 that shows four compounds (Fig. 6.152).

These are: 1:1 = $SrGa_2O_4$, 4:1 = $Sr_4Ga_2O_7$, 3:2 = $Sr_3Ga_4O_9$, 1:2 = $SrGa_4O_7$, 1:6 = $SrGa_{12}O_{19}$. All were said to melt incongruently except $SrGa_2O_4$ which melts congruently at 1580 °C.

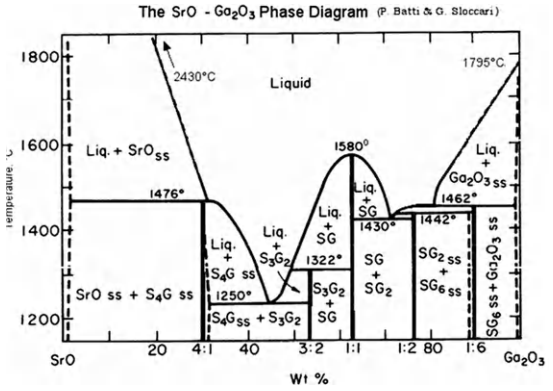

FIGURE 6.152

According to later phase equilibrium studies, at least seven different strontium gallates have to be distinguished: $Sr_4Ga_2O_7$, $Sr_7Ga_4O_{13}$, $Sr_3Ga_2O_6$, $Sr_3Ga_4O_9$, $SrGa_2O_4$, $SrGa_4O_7$ and $SrGa_{12}O_{19}$. In contrast, the $CaO{\cdot}Ga_2O_3$ system shows but four compounds. Furthermore, for strontium monogallate, different polymorphic forms have been reported. However, the space groups and the crystal structures of many of these compounds remain to be solved; to date only the more gallium-rich compounds $SrGa_{12}O_{19}$, $SrGa_2O_4$ and $SrGa_4O_7$ have been completely characterized by structure analysis. $SrGa_{12}O_{19}$ is isotypic with magnetoplumbite. The different polymorphs of $SrGa_2O_4$ belong to the group of stuffed tetrahedral frameworks (similar to the calcium monogallate isotypes). $SrGa_4O_7$ also belongs to the group of framework structures with sixfold tetrahedral rings, though the structure is more complex and not a simple derivative of high tridymite. For $Sr_3Ga_2O_6$, an indexed X-ray powder diffraction pattern based on a cubic unit cell with $a = 16.095$ Å has been published, indicating that this phase may be isostructural with $Ca_3Al_2O_6$. However, there may exist a second tetragonal polymorphic form for this compound. In the case of $Sr_3Ga_4O_9$, only an unindexed powder pattern has been reported by Kobzareva et al. so that the existence of a phase having this composition has remained uncertain. In addition, a compound having a 10:3 molar ratio has recently been discovered in this phase system so that the phase diagram for the strontium gallates remains to be firmly established.

Strontium monogallate has two isomorphs that have been investigated by single-crystal XRD. A β-phase corresponding to the stable modification at room temperature and γ-$SrGa_2O_4$, a quenched high-pressure polymorph prepared at 1250 °C and 2.5 GPa. β-$SrGa_2O_4$ is monoclinic, space group $P12_1/c1$, $a = 8.3770$ Å, $b = 8.9940$ Å, $c = 10.6800$ Å, $\beta = 93.932°$, $V = 802.8$ Å^3, $Z = 8$, $D_{calc} = 4.82$ g/cm^3; γ-$SrGa_2O_4$ is monoclinic as well, space group $P12_1/n1$, $a = 8.1100$ Å, $b = 10.7610$ Å, $c = 9.0570$ Å, $\beta = 91.569°$, $V = 790.1$ Å^3, $Z = 8$,

$D_{calc} = 4.89\ g/cm^3$. The structures of both phases are characterized by layers of six-membered rings of GaO_4 tetrahedra perpendicular to the *a*-axis. The stacking of the layers parallel to the *a*-axis results in a three-dimensional framework containing channels that are occupied by the Sr cations for charge compensation. The two modifications differ with respect to the relative orientation of up (U) and down (D) pointing apices of adjacent tetrahedra within a single ring. The sequence of directedness is UUUDDD for γ-$SrGa_2O_4$ and UUDUDD for β-$SrGa_2O_4$, respectively. γ-$SrGa_2O_4$ belongs to the zeolite ABW-type structures and is apparently the only member with space group symmetry $P12_1/n1$ in combination with a doubled *b*-axis compared to the ABW-aristotype (space group *Jmma*). It is the first member of this structure family with exclusively trivalent tetrahedral ions of only one chemical species and divalent nonframework cations within the channels. The compound is isotypic with the monoclinic modification of $CaGa_2O_4$. The structure is shown in the following diagram. The main structural features of γ-$SrGa_2O_4$ are layers of GaO_4 tetrahedra perpendicular to the *a*-axis (Fig. 6.153).

The stacking of the layers parallel to [100] results in a three-dimensional framework containing tunnels, where the strontium cations are located. Individual layers can be described as being built by the condensation of ditrigonally-shaped six-membered tetrahedral rings. The sequence of up (U) and down (D) pointing apices within a single ring is UUUDDD. This structure of γ-$SrGaO_4$ belongs to the family of the zeolite ABW-type structures and is the first zeolite-type compound with exclusively gallium occupying the tetrahedral positions of the framework.

Strontium monogallate can be made as a "self-activated" phosphor. Gallium has the electron configuration of: Ar $3d^{10}$ $4s^2$ $4p^1$. The trivalent state is thus a closed-shell and can function as an activator (see "Luminescence and the Solid State" by R.C. Ropp (2004—Elsevier, NY) for a more complete explanation in Chapter 6—Design of Phosphors—p. 462).

A tunable blue to blue-white $SrGa_2O_4$ phosphor was prepared with a SSR method by varying the composition concentration of source materials. The decomposition temperature and weight loss of Ga_2O_3 and $SrCO_3$ were evaluated by thermogravimetric analysis. Gallium trioxide has a tendency to sublime so that a slight deficiency of Ga^{3+} ions may occur in the final product. The deficiency of Ga^{3+} in the $SrGa_2O_4$ phosphor is attributed to this sublimation and may be compensated by increasing the molar ratio of $Ga_2O_3/SrCO_3$ in the reaction. Photoluminescence measurements show that Ga^{3+} is the luminescent center of this strontium monogallate phosphor. When the molar ratio of $Ga_2O_3/SrCO_3$ is 1, the emission wavelength of $SrGa_2O_4$:Ga^{3+} phosphor is ~402 nm, which is caused by the $^4T_1 \Rightarrow {}^4A_2$ transition of electrons in Ga^{3+} d-orbits. Crystallization of $SrGa_4O_7$ was observed as the phosphor was prepared at a higher molar ratio of $Ga_2O_3/SrCO_3$. The ligand field and the electron-transferring mechanism in Ga was observed to be modulated by the development of the crystal, $SrGa_4O_7$. Thus, the emission wavelength of phosphor is altered from 402 to 430 nm where the electron is transferred from $^4T_{2A}$ exciting state to the emitting state, $^4T_1$ to the $^4A_2$ ground state and the emission spectrum is broadened in the latter crystal.

If Ce^{3+} is added to $SrGa_2O_4$, the self-activation is restricted. Ce^{3+}-activated $SrGa_2O_4$ phosphor was synthesized by a method of citric gel, wherein citric acid served as the chelate agent, and the as-synthesized powder was calcined in a slightly reduced ambient. The crystallization characteristics of the sample varied with the calcining temperature. Compared with the phosphor prepared by the SSR, the phosphor synthesized by citric gel was calcined at a relatively lower temperature. Consequently, the volatilization of Ga_2O_3 during high-temperature calcining process was avoided. The typical

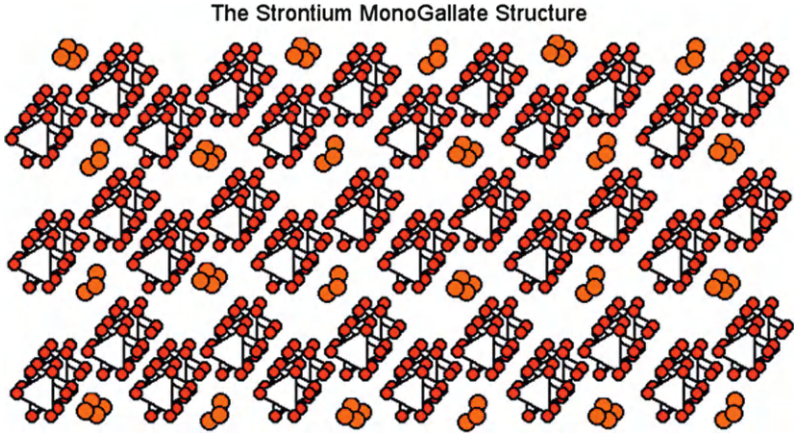

FIGURE 6.153

double-peak emission of Ce^{3+} originated from $^2D(5d) \Rightarrow {}^4F_{5/2}(4f)$, and $^2D(5d) \Rightarrow {}^4F_{7/2}(4f)$ was observed, and the intrinsic emission of $SrGa_2O_4$ host was much restricted. The emission intensity varied with the calcining temperature because the different crystallinity and the optimal concentration of Ce dopant was determined at 3 mol%. Charge compensation was employed, using Li^+ cations:

$$(Ce^{3+} + Li^+)_{Sr} \Leftrightarrow (2Sr^{2+})_{Sr}$$

A bright-blue luminescence was observed with the double-peaks characteristic of Ce^{3+} emission.

Distrontium gallate, $Sr_2Ga_2O_5$, has been prepared by reaction of strontium carbonate with gallium trioxide for 1 hour at 1200 °C:

$$2\,SrCO_3 + Ga_2O_3 + \text{heat} \Rightarrow Sr_2Ga_2O_5 + 2\,CO_2\ (\text{gas})$$

The reaction of the oxides is extremely slow and since $Sr_2Ga_2O_5$ melts as low as 1230 °C, the "oxide reaction" cannot be used effectively. This compound has not appeared in the phase diagrams published to date because of the very slow reaction rates of the oxides. The main usage for this compound has been as a sintering aid. When ceramics with a high melting point (>1500 °C) need to be joined (such as sealing of "end-caps" to form a high-pressure sodium lamp for street lighting), it is not practical to melt the ends together, particularly if they are metallic and do not wet the edges of the ceramic. Furthermore, the lattice parameters do not match, leading to an imperfect join and a weak joint. Distrontium gallate performs admirably in this aspect.

Ceria-based ceramics have been considered as one of the most promising electrolytes for intermediate temperature solid-oxide fuel cells, because its electrical conductivity is higher than that of yttria-stabilized zirconia (YSZ) (ZrO_2:Y^{3+}). The densification behavior and grain growth of $Ce_{0.8}Gd_{0.2}O_{1.9}$ ceramics were investigated with the strontium gallate concentration ranging from 0 to 5 mol%. Both the sintered density and grain size were found to increase rapidly up to 0.5 mol% $Sr_2Ga_2O_5$, and then to decrease with further addition. Dense $Ce_{0.8}Gd_{0.2}O_{1.9}$ ceramics with 97% of the theoretical density could be obtained for a 0.5 mol% $Sr_2Ga_2O_5$-added specimen sintered at 1250 °C for 5 h, whereas pure $Ce_{0.8}Gd_{0.2}O_{1.9}$ ceramics needed to be sintered at 1550 °C in order to obtain an equivalent theoretical density. The addition of $Sr_2Ga_2O_5$ was found to promote the sintering properties of Gd_2O_3-doped CeO_2. Other ceramics that have been sintered and/or joined by the use of $Sr_2Ge_2O_5$ include: $Ce_{0.8}Sm_{0.2}O_{1.9}$ ceramics and $La_{0.8}Sr_{0.2}Ga_{0.83}Mg_{0.17}O_3$ ceramics.

Strontium di-gallate, $SrGa_4O_7$ was prepared, and studied by single-crystal X-ray investigations. It is isotypic with $CaAl_4O_7$ and $CaGa_4O_7$; space group C^6_{2h} – C2/c ($a = 13.46$, $b = 9.19$, $c = 5.69$ Å, $\beta = 105.8°$). Sr^{2+} as well as Ca^{2+} is surrounded by five oxygen ions in a trigonal bipyramidal array.

Strontium digallate ($SrGa_4O_7$) can be synthesized by crystallization of amorphous spray-dried precursors or solidification from the liquid. $SrGa_4O_7$ was prepared via the ethylenediaminetetraacetic acid precursor route. Differential thermal analysis, thermogravimetric, Fourier transform infrared spectroscopy, and XRD were used to characterize the precursors and the oxide powders derived. XRD analysis showed that single-phase $SrGa_4O_7$ was obtained from pulverized resin at a temperature of 1050 °C for 2 h and $SrGa_4O_7$ can be stable at least up to 1200 °C. Single-phase $SrGa_4O_7$ was not obtained from the citrate acid route.

Boron may be substituted into the $SrGa_4O_7$ lattice. A novel borogallate, $SrGa_2B_2O_7$ (M = Sr, Ba), has been synthesized and structurally characterized. The structure of $SrGa_2B_2O_7$ (*Cmcm*, $a = 11.7260$ Å, $b = 8.3745$ Å, $c = 5.7062$ Å, $Z = 4$) has been determined by single-crystal XRD. $BaGa_2B_2O_7$ (*Cmcm*, $a = 11.7434(6)$ Å, $b = 8.7076(4)$ Å, $c = 5.8038(3)$ Å, $Z = 4$) has been shown to be isostructural by ab initio structure determination and Rietveld refinement using powder X-ray data. The $SrGa_2B_2O_7$ structure, formulated as $SrGa_2(B_2O_5)O_2$, consists of a framework of corner-sharing tetrahedral (GaO_4) chains and pyroborate (B_2O_5) groups with the Sr atoms filling eight-coordinated framework cavities. It represents a new structure type for anhydrous borogallates and, in particular, is structurally distinct from the $SrAl_2B_2O_7$ aluminoborate analogs.

Tristrontium monogallate = $Sr_3Ga_2O_6$, a perovskite-related Ga oxide, was synthesized and characterized in order to design new diluted magnetic perovskites for spin electronics. The crystal structure was investigated by powder XRD and Rietveld analysis. Strontium gallate, $Sr_3Ga_2O_6$ (SGO) is a novel cubic structure with a GaO_4 tetrahedral unit, space group P3a, and $a = 16.095$ Å.

In another study, the cubic structure of Tristrontium monogallate, $Sr_3Ga_2O_6$, has been refined from powder diffraction data using the Rietveld method (space group *P3a*, $a = 16.1049$ Å, $V = 4177.1$ Å^3, $Z = 24$, $D_{calc} = 4.75$ g/cm^3). The compound is isostructural with tricalcium aluminate and contains highly puckered, six-membered $[Ga_6O_{18}]^{18-}$ rings. The rings are linked by nine strontium cations having six to nine nearest oxygen neighbors. The structure of the rings is shown in the following diagram presented on the next page.

Thus, the overall formulation can be written as: $Sr_9Ga_6O_{18}$. This may be contrasted to the $(Ga_6O_{19})^{19-}$ rings found in the $Sr_{10}Ga_6O_{19}$ compounds as shown in Fig. 6.154.

The nine Sr^{3+} atoms are arranged in groups of three along the *b*-axis.

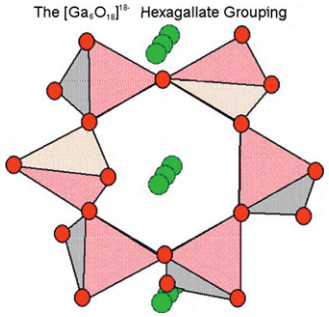

FIGURE 6.154

A novel compound $Sr_3(Al_{0.36}Ga_{0.64})_2O_6$ can be synthesized and was studied by single-crystal XRD. The material crystallizes in the cubic space group Pa3 (No. 205) with $Z = 24$ and a lattice constant $a = 16.0195$ Å. The structure is isotypic with $Ca_3Al_2O_6$ and is characterized by isolated, highly puckered, six-membered $(Al,Ga)O_6$ rings. The rings are linked by strontium cations which are coordinated by six to nine oxygen ligands. Alternatively, the structure can be regarded as an example for a defect ABO_3-perovskite with 12.5% vacancies in the A-sublattice and 25% oxygen vacancies:

$$(Sr_{7/8\text{-}1/8})((Al,Ga)_{3/4}Sr_{1/4})(O_{9/4\text{-}3/4})$$

The ternary systems La_2O_3–SrO–Ga_2O_3, La_2O_3–MgO–Ga_2O_3, and the quaternary system La_2O_3–SrO–Ga_2O_3–MgO were studied at 1350–1400 °C in air with emphasis on the solid solubility of Sr and Mg in $LaGaO_3$. In both ternary systems, the solid solubility of Sr substituting for La and that of Mg substituting for Ga, respectively, is rather small. However, when Sr and Mg are present simultaneously, the solid solubility of Sr and Mg in $LaGaO_3$ increases significantly. In addition, several phases of the quaternary system exhibit a pronounced variation of their La:Sr ratio and a high solid solubility of Mg, as for example $LaSrGa_3O_7$ and $LaSrGaO_4$. The structure $LaGaO_3$ containing Sr and Mg has been determined to be orthorhombic, space group *Pbnm*, $a = 5.53443$ Å, $b = 5.49523$ Å, and $c = 7.78320$ Å. In the quaternary system, extended four phase regions exist between $LaGaO_3$, MgO and the La–Sr–Ga–O compounds. Quaternary phases were not observed.

Tristrontium digallate, $Sr_3Ga_4O_9$, is triclinic, space group $P1_c$ ($a = 6.7490$ Å, $b = 8.0494$ Å, $c = 9.7295$ Å, $\alpha = 85.01(2)$o, $\beta = 72.71(2)$o, $\gamma = 74.24(2)$o, $V = 485.7$ Å^3, $Z = 2$, $D_{calc} = 4.69$ g/cm^3). The compound belongs to the group of tetrahedral single-layer structures. Individual sheets are parallel to (100), thus producing a prominent cleavage. The stepped layers can be described as being built by the condensation of six tetrahedra-wide bands. The bands in turn consist of two open-branched Dreier single chains connected via common corners and they contain tertiary and quaternary tetrahedra Q^3 and Q^4 in the ratio 1:1. The stacking of the layers containing four-, six- and eight-membered rings results in a three-dimensional structure in which the strontium cations reside in the voids between the layers and are coordinated by six to seven oxygen neighbors. The structure is shown in the following Fig. 6.155.

$Sr_3Ga_4O_9$ belongs to the group of tetrahedral single-layer structures. Individual sheets containing GaO_4 tetrahedra extend along (100). The main building unit of the layers are chains of corner-connected tetrahedra that can be classified as open-branched Dreier single chains. These chains run parallel to [010] (see Fig. 6.156a).

Therefore, the translation period along the direction of the chains is about 8.1 Å. Condensation of two neighboring chains, which are related by inversion centers, produces a six tetrahedra-wide band, see Fig. 6.156b.

This ribbon is characterized by the presence of four- and six-membered rings of corner-connected tetrahedra.

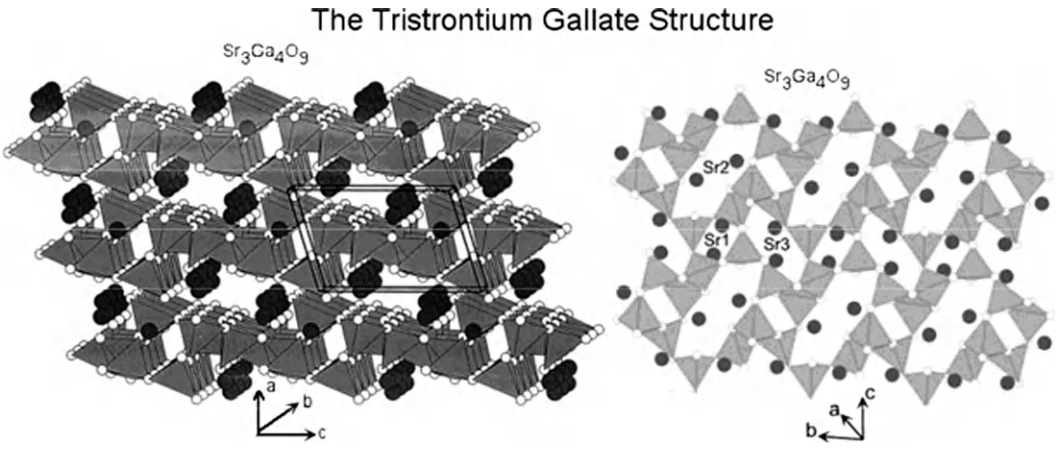

FIGURE 6.155

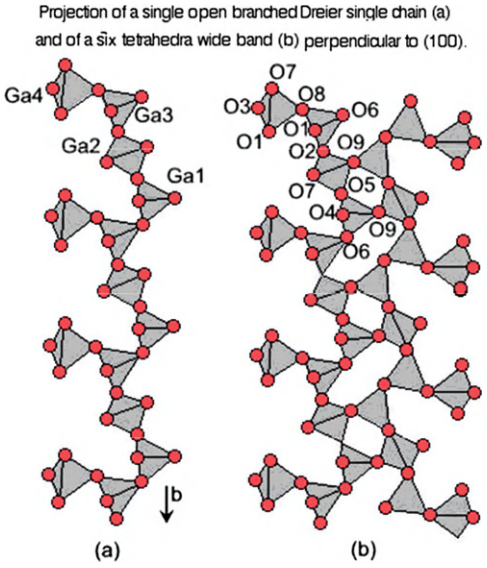

FIGURE 6.156

Further condensation of the bands via the bridging oxygen atoms O1 and O7 results in the stepped sheets mentioned above. Three of the four crystallographically different Ga tetrahedra provide linkage between the neighboring bands: Ga2, Ga3 and Ga4. The Ga2- and Ga3 sites belong to the linear part of the chain whereas Ga4 represents the branched tetrahedron. The tetrahedron around Ga1 is only connected to tetrahedra within the same band. At the interface between two adjacent bands, puckered eight-membered rings are formed containing four tetrahedra of each ribbon.

In a study of **tetrastrontium gallate**, crystal growth experiments yielded single crystals of $Sr_4Ga_2O_7$. This compound is monoclinic, space group $P1c1$, $a = 13.0822$ Å, $b = 15.7967$ Å, $c = 15.8586$ Å, $\beta = 90.643°$, $Z = 16$. The crystals showed twinning by pseudo-merohedry. Furthermore, the diffraction data exhibited the typical features of a superstructure. $Sr_4Ga_2O_7$ can be classified as a mixed anion gallate comprising insular $[GaO_4]$ groups and $[Ga_3O_{10}]$ trimers. Both anion groups are located in layers perpendicular to [100]. There are 32 symmetrically independent Sr cations that cross-link between the tetrahedral anion groups. Alternatively, the compound can be described as a 3-4-4 superstructure of ABO_3 perovskite, with 22.2% vacancies in the oxygen sublattice. The relationship with perovskite can be expressed in the following crystal chemical formula: $Sr(Ga_{2/3}Sr_{1/3})(O_{7/9\text{-}2/9})_3$. A discussion of the structure in the context with other similar defect perovskites is presented.

Decastrontium trigallate, $Sr_{10}Ga_6O_{19}$, occurs in two similar but distinct modifications: a monoclinic as well as an orthorhombic phase. Both compounds are based on noncyclic tetrahedral $[Ga_6O_{19}]$ units. From a structural point of view, the two polymorphs differ with respect to the conformation of these groups as well as their packing. The crystal structures of $Sr_{10}Ga_6O_{19}$, have been characterized using XRD techniques. The structure was determined from a single-crystal diffraction data set. Two phase transitions were identified: (1) between 453 and 503 K, the incommensurate superstructure is replaced by a doubling of the a and b lattice constant, and (2) between 503 and 673 K, a phase with the basic cell is formed, identical to α-$Sr_{10}Ga_6O_{19}$. The compound is monoclinic with space group $C12/c1$ ($a = 34.973$ Å, $b = 7.934$ Å, $c = 15.943$ Å, $\beta = 103.55°$, $V = 4300.7$ Å^3, $Z = 8$, D_{calc}=4.94 g/cm^3) and can be classified as an oligogallate (Fig. 6.157).

It is the first example of an inorganic compound where six $[GaO_4]$ tetrahedra of only one chemical species occupy the tetrahedral centers that are linked via bridging oxygen atoms to form $[Ga_6O_{19}]$ groups. The hexamers are not linear, but are highly puckered. Eleven symmetrically different Sr cations located in planes parallel to (100) cross-link between the oligo groups. They are coordinated by six to eight oxygen ligands.

The early phase diagram studies of the system SrO–Ga_2O_3 do not show a phase of the composition $Sr_{10}Ga_6O_{19}$. The diagram published by Kobzareva et al. contains three phases which are close to $Sr_{10}Ga_6O_{19}$: they are listed as (I) $Sr_4Ga_2O_7$ (20 mol% Ga_2O_3), (II) $Sr_7Ga_4O_{13}$ (22.2 mol% Ga_2O_3) and (III) $Sr_3Ga_2O_6$ (25 mol% Ga_2O_3). The structures of I and III have been resolved. As already mentioned by Kobzareva et al., the structures show a perovskite-related subcell. Phase II has not been determined yet, which leaves room for speculation as to whether it exists at all.

Crystal data are included in the following Table 6.46.

The composition of $Sr_{10}Ga_6O_{19}$ (23.1 mol% Ga_2O_3) is very close to the proposed phase of $Sr_7Ga_4O_{13}$. Possibly, decastrontium hexagallate was misinterpreted as heptastrontium tetragallate. The same assumption was made in a more recent work. However, we cannot exclude that both of them are stable phases. Including the results of this work, at least four polymorphs are known for $Sr_{10}Ga_6O_{19}$: α and β[5] as well as the presented superstructures.

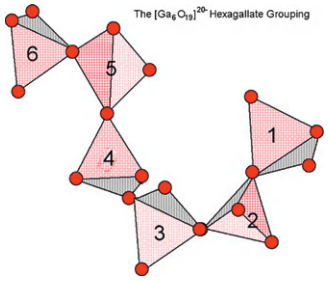

FIGURE 6.157

TABLE 6.46

Chemical formula	α-$Sr_{10}Ga_6O_{19}$	$Sr_{10}Ga_6O_{19}$
Molecular weight	271.847 g/mol	271.847 g/mol
Space group	C2 = c(0βO)	C2 = c
a (Å)	34.9145	35.0481
b (Å)	7.9369	7.9732
c (Å)	15.9450	16.0077
β	103.551°	103.492°
V (Å^3)	4287.5	4349.8

In another study, the crystal structure of $Sr_{10}Ga_6O_{19}$ was investigated by in situ single-crystal XRD in the temperature range 298–673 K. At ambient conditions, the compound shows a (3 + 1)-dimensional modulated structure in the superspace group $C2/c(00)s0$ [a = 34.9145 Å, b = 7.9369 Å, c = 15.9150 Å and = 103.551°] with a modulation wave vector of $\mathbf{q} = 0.4288\ (2)\mathbf{b}^*$. Whereas the presented structural model uses first-order harmonic modulation functions only, some features of the modulations are discussed utilizing an electron density derived by the maximum entropy method. Furthermore, two phase transitions were identified: between 453 and 503 K, the incommensurate superstructure is replaced by a doubling of the a and b lattice constants, and between 503 and 673 K, a phase with the basic cell is formed, identical to α-$Sr_{10}Ga_6O_{19}$. Under some cooling conditions, crystals showing a combined diffraction pattern of both superstructures can be obtained.

Mono-strontium hexagallate, $SrGa_{12}O_{19}$, is triclinic with cell parameters of: a = 5.794 Å, b = 5.794 Å, c = 22.816°, α = 90°, β = 90°, γ = 120°, V = 663.3 Å^3, $D_{(calc)}$ = 6.15 g/cc, Z = 2. The structure is unique in that it is composed of a network of $Ga_6O_{18}^{-2}$ units charge compensated by a single Sr^{2+} cation (Fig. 6.158).

These units are arranged in a triclinic pattern. Two directions along the lattice axes are shown. Structures of magnetoplumbite-type crystals $SrGa_{12}O_{19}$ (M = Al, Fe, Ga) have been refined by the single-crystal XRD method. The space group is $P6_3/mmc$ with Z = 2. The cell dimensions are a = 5.7929 Å and c = 22.8123 Å for $SrGa_{12}O_{19}$ at 22 °C. Four structural models were tested with respect to the states of gallium atoms at trigonal bipyramidal sites: central atom and split atom models with and without anharmonic thermal vibrations. The simple split atom model gave lower R_w values than the central atom model with anharmonic thermal vibrations $SrGa_{12}O_{19}$, whereas it gave an R_w value approximately equal to that given by the central atom model with anharmonic vibration for $SrFe_{12}O_{19}$. The present study suggested that the potential around the Ga atom with trigonal bipyramidal coordination has double minima in all the magnetoplumbite-type crystals at lower temperatures.

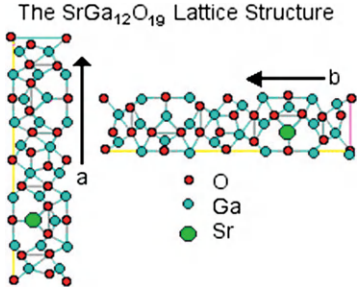

FIGURE 6.158

Hepta-strontium digallate, $Sr_7Ga_4O_9$, has no homologues in the other alkaline earth gallates. It is difficult to prepare and the SSR of the oxides takes >45 h to form a stable compound. However, if the tristrontium gallate is reacted with the tetragallate, the reaction proceeds rapidly:

$$7SrO + 2Ga_2O_3 \Rightarrow Sr_7Ga_4O_{13}\ (46\ h\ at\ 1100\ ^\circ C)$$

$$Sr_4Ga_2O_7 + Sr_3Ga_2O_6 \Rightarrow Sr_7Ga_4O_{13}\ (1.0\ h\ at\ 950\ ^\circ C)$$

It is for this reason that this compound has not been studied as extensively as the other strontium gallates and its structure remains unknown.

A number of red-emitting phosphors have been developed, based upon various strontium gallates for use as electroluminescent (EL) display materials. Bright red EL has been obtained in amorphous and crystalline alkaline earth gallates doped with Eu^{3+}. Powder targets of compositions, $Sr_4Ga_2O_7$, $Sr_7Ga_4O_{13}$, $Sr_3Ga_2O_6$, $Sr_3Ga_4O_9$, $SrGa_4O_7$, $SrGa_{12}O_{19}$, doped with 1–2% Eu, were RF magnetron sputtered onto $BaTiO_3$ substrates. Both annealed and as-deposited films yielded bright EL emission in the red part of the visible spectrum with peaks characteristic of the Eu^{3+} ion. Relative outputs of EL emission are shown as follows:

Compound	fL at 400 VDC
$Sr_4Ga_2O_7$ =	40.0
$Sr_7Ga_4O_{13}$ =	15.0
$Sr_3Ga_2O_6$ =	80.0
$Sr_3Ga_4O_9$ =	0.0 (45.0 at 650 VDC)
$SrGa_4O_7$ =	17.0
$SrGa_{12}O_{19}$ =	0.0 (6.5 at 500 VDC)

Strontium gallates have no CAS number and are not offered for sale commercially.

Barium Gallates

The system, $BaO \cdot Ga_2O_3$, forms at least three compounds—the $4BaO \cdot Ga_2O_3 = Ba_4Ga_2O_7$, $3BaO \cdot Ga_2O_3 = Ba_3Ga_2O_6$, and $BaO \cdot Ga_2O_3 = BaGa_2O_4$ compositions. The SSR is:

$$xBaO + yGa_2O_3 \Rightarrow Ba_xGa_{2y}O_{3y+x}$$

This system is subject to oxygen deficiencies so that the formula,

$$Ba_xGa_{2y}O_{(3y+x)-\delta}$$

sometimes applies. The phase diagram of $BaO–Ga_2O_3$ has not been published and is not available in the current technical literature.

Barium monogallate, $BaGa_2O_4$, belongs to the group of stuffed tetrahedral framework structures AB_2O_4 (A = Ca, Sr, Ba; B = Al, Ga), which are known to show interesting ferroelectric properties and a great variety of different polymorphic forms. They consist of a three-dimensional framework of corner-sharing BO_4 tetrahedra, the cavities of which are filled with alkaline earth metal atoms. $BaGa_2O_4$ is known to have at least four polymorphs, three of which (β-, γ- and δ-phases) are ferroelectric because of the symmetry properties. The paraelectric α-phase is reported to be stable above the ferroelectric–paraelectric phase transition temperature of 770 °C. The three polymorphs of $BaGa_2O_4$ (α-, β- and δ-phases) have a hexagonal structure and one (δ-phase) has a monoclinic structure.

Polymorphism in barium gallate, $BaGa_2O_4$, was studied using electron diffraction and HREM. Three modifications of $BaGa_2O_4$ with structures closely related to the high-temperature γ-form were observed. The phase transitions from α-$BaGa_2O_4$ ($a_\gamma = 18.6143$ Å $= \sqrt{2}\sqrt{3}a$, $c_\gamma = 8.6544$ Å $= c_\alpha$, S.G. $P6_3$) to β-$BaGa_2O_4$ ($\mathbf{a}_\beta = 2\mathbf{a}_\alpha$, $\mathbf{c}_\alpha = \mathbf{c}_\alpha$, S.G. $P6_3$) and to the new δ-polymorph having a monoclinic structure ($\mathbf{a}_\delta = \mathbf{c}_\alpha$, $\mathbf{b}_\delta = 2\mathbf{a}_\alpha + \mathbf{b}_\alpha$, $\mathbf{c}_\delta = 2\mathbf{b}_\alpha$ and $\beta = 92°$, S.G. $P2_1/c$) were induced by electron beam irradiation. HREM observations allow one to establish the close similarity between the structures of δ-$BaGa_2O_4$ and β-$SrGa_2O_4$. The γ ⇒ β and β ⇒ δ transitions involve a rearrangement of oxygen atoms in the BaO layers together with a tilting distortion of the tetrahedral framework. The microstructure of the δ-phase is characterized by the presence of numerous translation and orientation domains. The structure is shown in Fig. 6.159.

This structure is isotypic with the other alkaline earth monogallates, except for the unit-cell dimensions. However, $BaGa_2O_4$ and $SrGa_2O_4$ do not form solid solutions. If these compounds are heated together, they form an entirely different structure from the SSR:

$$BaGa_2O_4 + SrGa_2O_4 + \text{heat} \Rightarrow BaSrGa_4O_8$$

The structure is entirely different from either of the components, as shown in the diagram presented on the next page. A Rietveld refinement of the $BaSrGa_4O_8$ reveals that GaO_4 tetrahedra form the six-membered rings with sharing corners and the Ba and Sr atoms lie at the large cavities of the six-membered rings. The structure has space group $P6_3$ (No. 173) with cell parameters $a = 9.196$ Å, $c = 8.6465$ Å. One of the positions of O atoms splits to the O4 and O5 sites (Fig. 6.160).

In these projections, there are two layers of connected tetrahedra that form the six-membered rings.

In another study, crystals of barium monogallate were obtained by growth from a stoichiometric melt at 1350 °C. The hexagonal crystals belong to space group $P6_3$, $a = 18.6403$ Å and $c = 8.6801$ Å, $V = 2611.9$ Å^3, $Z = 24$, $D_{calc.} = 5.20$ g/cm^3. The structure was solved by Patterson techniques using a single-crystal diffraction data set. Merohedral twinning of the crystal (twin element $2_{[110]}$) was accounted for in the refinement calculations. The main structural features of $BaGa_2O_4$ are layers of six-membered rings of GaO_4 tetrahedra perpendicular to the *c*-axis. The stacking of the layers parallel to *c* results in a three-dimensional framework containing tunnels, where the barium cations are located. Within a single layer, two different types of ditrigonal-shaped six-membered rings are

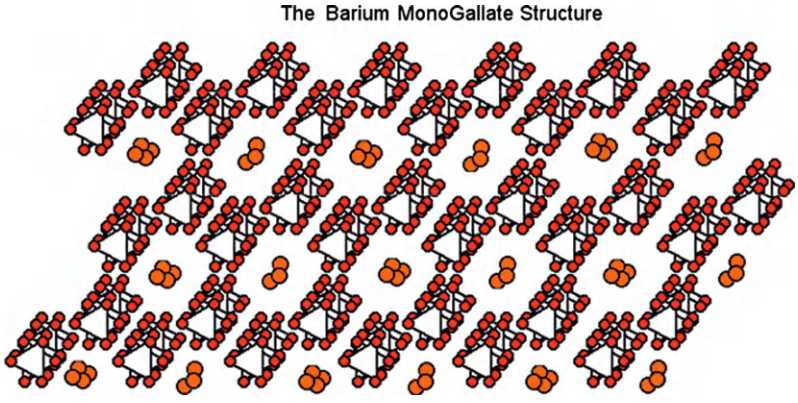

FIGURE 6.159

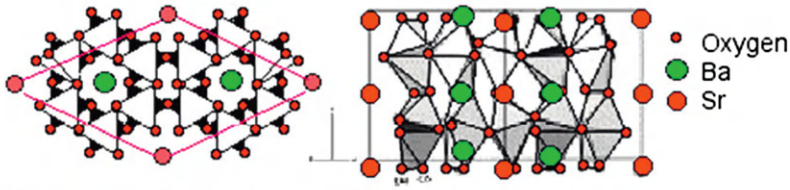

(a) [001] projection of the structure of $BaSrGa_4O_8$. (b) [110] projection of the structure of $BaSrGa_4O_8$

FIGURE 6.160

distinguished on the basis of relative orientation of up (U) and down (D) pointing apices of adjacent tetrahedra: one-fourth of the rings have an UDUDUD topology, whereas the sequences of directedness of the remaining rings is UUUDDD. The structure is isotypic with $KAlGeO_4$. It is the first member of this structure family containing exclusively trivalent tetrahedral ions of only one chemical species and divalent nonframework cations within the channels.

Differential thermal analysis and high-temperature single-crystal diffraction of monobarium gallate indicate that there is a reversible paraelectric–ferroelectric phase transition at about $T_c = 770$ °C. The crystal structure of the previously unknown paraelectric high-temperature modification α-$BaGa_2O_4$ was solved from a single-crystal data set collected at 800 °C. The compound is isotypic with β-$BaAl_2O_4$ and closely related with hexagonal high-Kalsilite, adopting a space group $P6_322$ ($a = 5.3925$, $c = 8.9739$ Å, $V = 226.0$ Å^3, $Z = 2$, $D_{calc} = 5.01$ g/cm^3). The main building elements of the structure are GaO_4^{5-}tetrahedra which are corner linked to form sheets normal to the *c*-axis. These layers are in turn connected to build up a three-dimensional framework enclosing cavities that are occupied by Ba^{2+}. The bridging oxygen atoms between the layers are statistically distributed over three positions displaced 0.56 Å from the ideal position on the threefold axis. The off-centering reduces the Ga–O–Ga bond angle from an energetically unfavorable 180 to 145.0°. Within a single layer of the high-temperature phase, the tetrahedra are arranged in six-membered rings with an UDUDUD conformation. A different framework topology is found in the low-temperature modification β-$BaGa_2O_4$ which is based on two different ring configurations, UUUDDD and UDUDUD. Due to the differences between the sequences of upward and downward pointing tetrahedra in both phases, the α–β transformation is a first-order transition showing a pronounced thermal hysteresis between heating and cooling. The transition is also reflected in the evolution of the lattice parameters where significant discontinuities are observed at T_c.

Dibarium gallate, $Ba_2Ga_2O_5$, apparently does not exist. There are no references to this substance in the available literature and no structure determinations, if it exists at all, have been made. In contrast, distrontium has been prepared and used as a "sintering aid" in lowering the temperature of densification required in the preparation of intermediate temperature solid oxide fuel cells. The possibility that the dibarium gallate has a lower melting point than that of the strontium analog makes it a promising candidate for the sealing and densification of many ceramic devices.

Single crystals of **tribarium gallate** ($Ba_3Ga_2O_6$) have been synthesized from a melt with composition 70 mol % BaO and 30 mol.% Ga_2O_3 in the temperature range between 1200 and 1400 °C. The compound adopts space group *Pa* with $a = 16.746(9)$ Å and $Z = 24$ formula units per unit cell. $Ba_3Ga_2O_6$ belongs to the group of cyclogallates and is closely related to $K_4SrGe_3O_9$. Main building elements are isolated, highly puckered, 12-membered rings built by $[GaO_4]^{5-}$ tetrahedra. Charge balance is achieved by incorporation of Ba ions in the voids between the rings. The coordination number of the alkaline earth atoms is six, eight and nine, respectively.

Preparation of a $Ba_3Ga_2O_6$ powder and its sintering characteristics were investigated in Ar or air. This sintered body with perovskite-related structure was synthesized by reaction sintering, using mixed powders in the atomic ratios of Ba/Ga = 1.5. The order–disorder transition temperatures of the $Ba_3Ga_2O_6$-sintered bodies was 1230 °C. By comparison to other sintered compositional bodies, it was found that the order–disorder transition temperatures were influenced by the ionic radius of cations in B sites, and the transition temperatures decreased with increasing ionic radius.

Tribarium gallate has been investigated as a solid-state ionic conductor for use in high-temperature fuel cells. Oxide ion conductivity of Ga-based perovskite-type oxides, $LnGaO_3$ (Ln = Nd, La) and its related oxide, $A_3Ga_2O_6$ (A = Ba and Sr) was investigated. Oxide ion transference number t_{ion} is almost 1.0 for $Ba_3Ga_2O_6$. However, electrical conductivity of this system of oxides was lower than log σS/cm of −3 of the doped perovskite-type oxide of $NdGaO_3$ and $LaGaO_3$, due to the low solubility of the aliovalent cations. The latter compounds exhibited a high electrical conductivity and the transference number of oxide ion was higher

than 0.9 in the oxygen partial pressure range from $P_{O2} = 1$ to 10 atm. In particular, Ca and Mg doped $NdGaO_3$, exhibited a high oxide ion conductivity similar to the $LaGaO_3$-based oxide.

Single crystals of **tetrabarium gallate**, $Ba_4Ga_2O_7$, were obtained by growth from a melt at 1500 °C. The compound is monoclinic, with cell parameters $a = 17.7447$ Å, $b = 10.6719$ Å, $c = 7.2828$ Å, $\beta = 98.962°$, $V = 1362.3$ Å^3. The diffraction pattern shows systematic absences corresponding to the space group $P12_1/c1$. The structure was solved by direct methods followed by Fourier syntheses. The chemical composition derived from structure solution is $Ba_4Ga_2O_7$, with a unit-cell content of $Z = 6$. Main building units of the structure are GaO_4 tetrahedra sharing one oxygen atom to form Ga_2O_7 groups. The Ga–O–Ga bridging angle of one of the two symmetrically independent groups is linear by symmetry. The dimers are cross-linked by barium cations coordinated by six to eight oxygen ligands.

Single crystals of **barium hexagallate**, $BaGa_{12}O_{19}$, have been grown in a Na_2O–Ga_2O_3 flux. The compound is hexagonal: $a = 5.859$ Å, $c = 23.192$ Å. The crystal structure was determined by single-crystal X-ray reflection data and refined to a final R-value of 0.018. The structure was revealed to be of β-alumina type, with a formula $Ba_{0.65}Ga_{10.80}O_{16.84}$ ($BaGa_{16.7}O_{26}$), and not of magnetoplumbite type as it was conventionally considered. The Ba^{2+} ion is located only in a 6h site, near the Beevers-Ross one. The charge compensation mechanism is that of gallium vacancies in the tetrahedra of the middle of the spinel block instead of that of Frenkel defects. In another study, the following unit-cell parameters were derived. Single-crystal X-ray analysis verified preparation of an ideal magnetoplumbite-type phase in the ternary barium hexagallate system. X-ray refinement was carried out by the full-matrix least squares on F^2 method. Microanalysis data yielded a composition of $Ba_{1.07}Ga_{11.95}O_{19}$. The crystal chemistries of the barium hexagallate and barium hexaaluminate systems were compared and discussed. Crystal data for $BaGa_{12}O_{19}$: $M = 1277.98$, space group $P6_3/mmc$ (No.194), $a = 5.8140$ Å, $c = 23.038$ Å, $V = 674.4$ Å^3, $Z = 2$, $D_{calc} = 6.293$ g/cm^3.

An X-ray-induced F^+ center was used as a paramagnetic probe to study sintered powders of barium hexaaluminates phases I and II (referred to as Ba(ϕ_I) and Ba(ϕ_{II})) and mixed barium-lanthanum hexaaluminate (referred to as BLA). This F^+ center was previously shown to exist only in β-alumina-type mirror planes containing interstitial oxygen ions as charge-compensating defects, so that its study yields information about the local structure of this type of mirror plane. By comparison of the EPR spectra of Ba(ϕ_I) and Ba(ϕ_{II}), it is shown that the latter contains only one type of F^+ center with a reduced hf interaction. This indicates that there is only one type of mirror plane containing interstitial oxygen in Ba(ϕ_{II}) and that the separation between spinel blocks is larger in Ba(ϕ_{II}) than in Ba(ϕ_I). This result agrees with models proposed by other authors for barium-lead hexaaluminate and barium hexagallate. Investigation of the F^+ center in mixed barium-lanthanum hexaaluminate ceramics clearly supports the hypothesis of segregation of Ba^{2+} ions in β-alumina-type mirror planes. It is also shown that the structure of these planes is very similar to that of Ba(ϕ_{II}) defect planes.

Crystallographic data of aluminate and gallate β-aluminas and magnetoplumbites are reviewed. For the $XAl_{11}O_{17}$ and $XGa_{11}O_{17}$ compounds (X = Ba, Sr, Ca), c/a increases as the cationic size increases. The magnetoplumbites have c/a values ranging between 3.915 and 3.954 with the exception of $BaAl_{12}O_{19}$ and $BaGa_{12}O_{19}$. These compounds seem to have strongly distorted magnetoplumbite-derived structures. Upon activation of the $MeAl_{12}O_{19}$ (Me = Ca, Sr or Ba) lattices with Eu^{2+} and Ce^{3+}, the luminescence properties of Ba-containing compounds deviate from the other compounds. This seems to be due to different coordinations of the activator ions. Substitution of Mg^{2+} for Al^{3+} in magnetoplumbite phases results in the case of $SrAl_2O_{19}$ in changes of the c/a ratio, of diffraction intensities and of the luminescence properties. The various data suggest a close similarity of this type of phases and $BaAl_{12}O_{19}$. In the $MeGa_{12}O_{19}$ series (Me = Sr or Ba), the quantum efficiency of $BaGa_{12}O_{19}$: Mn^{2+} was found to be anomalously low.

$BaAl_{12}O_{19}$–$BaAl_2O_4$ doped with Eu^{2+}, Cr^{3+} and ($Eu^{2+} + Cr^{3+}$) were prepared by SSR. The spectra of $BaAl_{12}O_{19}$–$BaAl_2O_4$:Eu^{2+}:Cr^{3+} shows that the f ⇒ d emission bands from Eu^{2+} are centered at 442 and 495 nm and the Cr^{3+} yields the emission lines at 694 and 700 nm. Photoluminescence study demonstrates that the red photoluminescence and energy transfer occurs only in the phase of $BaAl_{12}O_{19}$ not $BaAl_2O_4$ though the samples are mixed phases. The fluorescence lifetime measurements indicate efficient energy transfer from Eu^{2+} to Cr^{3+} in $BaAl_{12}O_{19}$: Eu^{2+}, Cr^{3+}. The energy transfer rate and efficiency are calculated. The results show that the energy transfer rate and efficiency increase following the increase in Cr^{3+} concentration.

Dibarium trigallate, $Ba_2Ga_6O_{11}$, has been investigated as a phosphor for fluorescent lamps. When activated by both Eu^{2+} and Cr^{3+}, it emits both deep-red and blue-green emission bands as shown in the following diagram. When combined with a green-emitting phosphor, a "white" lamp was obtained (Fig. 6.161).

Barium gallates do not have an assigned CAS number and are not offered for sale commercially.

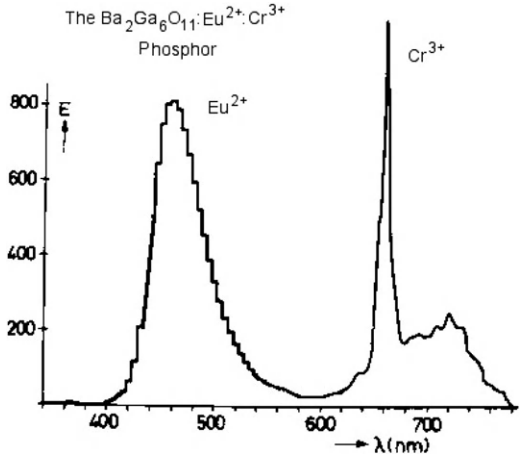

FIGURE 6.161

Radium Gallates

The scientific literature is lacking in any references to radium gallates. Perhaps this is due to the intense radioactivity of the isomer ^{226}Ra but is more likely due to lack of interest of those in industry who may have usage of such compounds. It is anticipated that various radium gallates could be prepared, using the same methods as those developed for the barium gallate series of compounds. Thus, one would expect to be able to obtain:

$RaO \cdot Al_2O_3$,
$3RaO \cdot Al_2O_3$,
$RaO \cdot 6Al_2O_3$,
$2RaO \cdot Al_2O_3$.

However, there is no record of such syntheses in the literature.

6.6. ALKALINE EARTH INDIUM-COMPOUNDS

Indium has but one valence state—In^{3+}. As such, indium is too electropositive and forms a limited number of "indates", i.e. $In_xO_{3x}^{2x-}$. One example is $MgIn_2O_4$ which is a 1:1 compound. For the most part, In^{3+} tends to form cationic species rather than anionic ones. These indium-containing compounds are more like "solid-solutions" in which InO_3^{2-} has a degree of electronegative character. In the case of the alkaline earths, the number of compounds formed goes from zero to five. That is the $MO–In_2O_3$ system forms shown in Table 6.47.

TABLE 6.47

Cation	Be	Mg	Ca	Sr	Ba
# of Cpds	0	1	1	2	5

Additionally, forms a series of "indides" as separate crystalline compounds, M_xIn_y, where x and y can vary from 1 to as many as 28 in the unit cell.

6.6.1. Alkaline Earth Indides

The term "indides" is not used generally in the scientific literature but indicates a binary compound of indium metal with certain alkaline earth metals.

Beryllium Indides

Beryllium does not form any compounds with In metal as shown in the following phase Fig. 6.162.

Indium metal melts at 157 °C and forms an alloy if the two metals are "ball milled" together at room temperature. The room-temperature form of Be (Be_{rt}) appears and is stable at all compositions until 1270 °C where the high-temperature form (Be_{rt}) appears. The latter melts at 1285 °C to form two separate liquids, L_{Be} and L_{In}.

No alloy of Be–In has found usage in industry because of lack of interesting properties other than the appearance of liquid indium combined with particles of Be metal. No CAS number has been assigned.

Magnesium Indides

Magnesium metal forms several compounds with In metal as may be seen in the following phase Fig. 6.163.

The crystal parameters are shown in the following Table 6.48.

For the most part, Mg and In form solid solutions of a specific composition with each other. The melting points of the compositions, like $Mg_{0.1}In_{0.9}$, varies according to its indium content. It has been found that the direct transition of one phase (called β_1) to another phase (called β' phase), as the Mg/In atom ratio is varied, is prevented by the two-phase regions of the whole composition range. The location of the unstable Mg_5In_3 phase, called β_3, has been finally established in

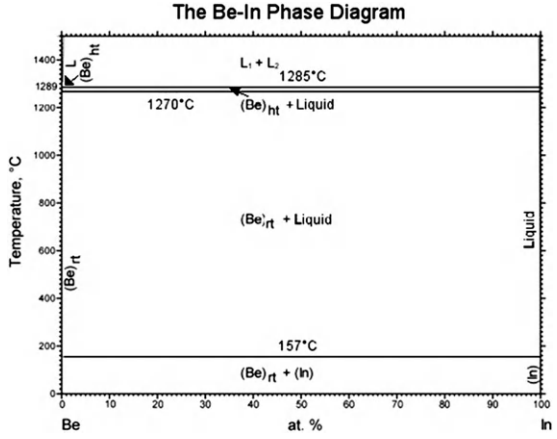

FIGURE 6.162

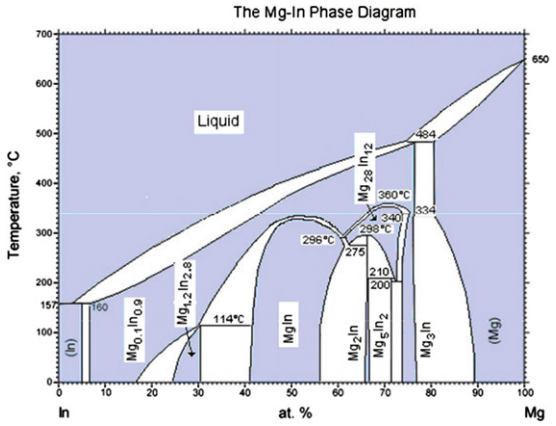

FIGURE 6.163

the phase diagram. β_3-phase is stable only below 210 °C and decomposes into β′ and β_2 phases above this temperature. In addition to this, Mg_3In changes its structure from an ordered 12R symmetry to a disordered f.c.c. structure through an ordered 3R symmetry as the temperature increases. The transformation energy associated with the change in the stacking sequence (12R ⇒3R) and that associated with the order–disorder phase change has been estimated to be ~120 cal/mol and ~340 cal/mol, respectively. Thus, the phase diagram presented above is accurate to the limits of estimation of the phase changes that occur with temperature at any given mole-ratio of Mg/In. These factors account for the departure of the Mg–In phase diagram from the standard phase diagrams of other binary metal systems.

The equilibrium phase diagram of the indium–magnesium system in the range up to 40 atom% Mg has been established by XRD and thermal analysis. The solid solubility of magnesium in indium does not exceed about 5 atom%. An intermediate solid solution, β_1, with a face-centered cubic structure exists over a wide range of composition. An ordered phase, β′, with the superstructure of Cu_3Au type, is formed near 28 atom% Mg at temperatures below 114 °C.

These compounds are not stable and have found little usage in industry. The corrosion process of InMg alloy and the conversion of corrosion products by annealing in vacuum have been investigated by X-ray powder diffraction and energy-dispersive spectroscopy methods. The crystalline indium phase and an amorphous phase with a composition corresponding to the formula of the mineral perovskite ($Mg(OH)_2MgCO_3 \cdot 0.5H_2O$) were found as corrosion products. Their further conversion during annealing in vacuum at various temperatures was examined. Nevertheless, the crystal structure of the various Mg–In compounds have been thoroughly examined.

Dimagnesium indide, Mg_2In, has the unit-cell parameters of: $a = 3.42$ Å, $b = 8.27$ Å, $c = 8.27$ Å, $\alpha = 120°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 202.57 Å^3. The structure can be represented by Fig. 6.164.

The two types of In atoms are shown. In2 is in the center of the unit cell at (1/3, 2/3, 13) and is connected to all of the Mg atoms.

The location of the atoms in the unit cell is shown in Table 6.49.

Mg_2In crystallizes in the orthorhombic space group Pnma ($Z = 4$; Co_2Si-type structure). This indide, Mg_2In, has the lattice parameters of: $a = 7.275$, $b = 5.371$, $c = 9.990$ Å, $Z = 4$, $R1 = 0.0252$). It was synthesized from stoichiometric melts of the elements. The crystal structure exhibits isolated In atoms coordinated by seven to 10 alkaline earth atoms. The electronic structures of the less elaborate compound, Mg_2In, was discussed in comparison with those of the closely related, nominally electron precise Zintl compounds Ca_2Sn and Sr_5Sn_3.

Trimagnesium indide, Mg_3In, has the cell parameters of: $a = 6.323$ Å, $b = 6.323$ Å, $c = 10.9781$ Å, $\alpha = 73.263°$, $\beta = 73.263°$, $\gamma = 60°$, cell volume = 258.47 Å^3. The structure can be represented as shown in Fig. 6.165.

A unit cell is composed of the unit seen in the "*c*-direction" view. As shown in the "diagonal vsiew" part of the diagram, these 18-atom units

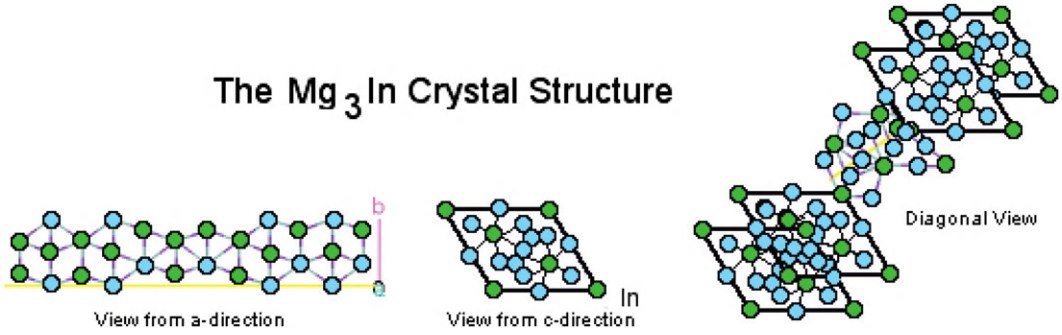

FIGURE 6.165

form two connected units at each end of the lattice, separated by an eight-unit configuration. The location of the atoms in the lattice structure is shown in Table 6.50.

The volume of the primitive cell of Mg_3In increases when pressure is applied. Samples of the alloy Mg_3In were annealed at 200–250 °C in the Bridgman anvil-type press under pressures between 20 and 100 kbar.

After being quenched to ambient pressure and temperature, the crystal structure was studied by XRD. The number of close-packed layers in one repeating unit of the alloy structure is 12 with the stacking sequence (3) 3 when annealed under the atmospheric pressure, but at 20, 35 and 55 kbar it increases to 18 with the sequence (31)3, and at 75 and 100 kbar a 24-layered structure with the sequence (311)3 has been found to form. The pressure-induced change in the layer-stacking sequence in Mg3In is similar to the change with the decrease in the electron-atom ratio previously observed for the ternary alloys $Mg_3(In_{1-x},Cd_x)$. The change is about 13.7%.

Pentamagnesium tri-indide, Mg_5In_3, has the crystal cell parameters of: $a = 6.19$ Å, $b = 7.36$ Å, $c = 8.59$ Å, $\alpha = 115.374°$, $\beta = 111.125°$, $\gamma = 90°$, cell volume = 324.15 Å^3. The structure can be represented by Fig. 6.166.

The locations of the various atoms in the lattice are shown in Table 6.51.

This structure is tetragonal in nature. Mg_5In_3 is not stable above 210 °C and no literature describing its physical properties (other than structure) is available in the literature.

Magnesium indide, MgIn, has the unit-cell parameters of: $a = 3.2555$ Å, $b = 3.2555$ Å, $c = 4.413$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 46.77 Å^3. The structure is body-centered cubic (Fig. 6.167).

The locations of the individual atoms are shown in Table 6.52.

A pressure dependence of the lattice parameters of MgIn having the tetragonal Ll_0-type structure has been measured by an XRD method using a diamond anvil-type squeezer up to 14 GPa. The rate of decrease in the *a* parameter is larger than that of the *c* parameter and, consequently, the axial ratio increases from the value 0.957 at atmospheric pressure to 0.97 at about 8 GPa. On further increasing pressure, however, it remains almost constant. Change in the volume can be described by a Birch–Murnaghan equation with an initial bulk modulus of 38 GPa. Experimental results were discussed taking into account the theory of lattice stability of alloys developed by Mrosan, John and Eschrig.

Magnesium tri-indide, $MgIn_3$, has cell parameters of: $a = 4.589$ Å, $b = 4.589$ Å, $c = 4.589$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 96.64 Å^3. The structure is face-centered cubic (Fig. 6.168).

The locations of the atoms in this structure are shown in Table 6.53.

The **composition**, $Mg_{0.04}In_{0.96}$, has the cell parameters of: $a = 3.2718$ Å, $b = 3.2718$ Å, $c = 3.3498$ Å, $\alpha = 119.233°$,

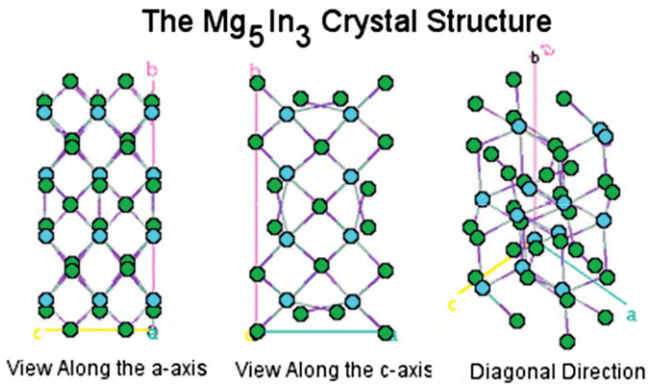

FIGURE 6.166

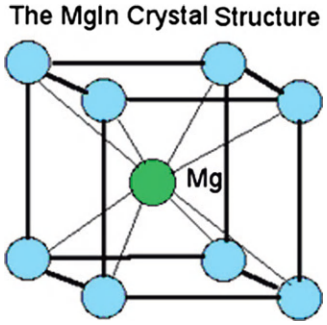

FIGURE 6.167

TABLE 6.53

1	In	In	3	c	4/mm.m	0	1/2	1/2	1.0
2	Mg	Mg	1	a	m-3m	0	0	0	1.0

$\beta = 119.233°$, $\gamma = 90°$, cell volume = 25.93 Å^3. The structure may be represented by the following, where a hypothetical view is presented. Nevertheless, the structure is not that of solid indium metal but is a specific structure when Mg metal is allowed to diffuse into In. The **composition**, $Mg_{0.928}In_{0.072}$, has a similar structure with cell parameters of: $a = 3.2003$ Å, $b = 3.2003$ Å, $c = 5.2128$ Å, $\alpha = 90°$, $\beta = 90$ °, $\gamma = 120°$, cell volume = 46.24 Å^3 (Fig. 6.169).

The substitution of Mg for In can be random in this face-centered lattice up to about $Mg_{0.75}In_{0.25}$ which had the lattice parameters of: $a = 3.1912$ Å, $b = 3.1912$ Å, $c = 3.1912$ Å, $\alpha = 60°$, $\beta = 60°$, $\gamma = 60°$, cell volume = 22.98 Å^3. The structure can be illustrated as shown in Fig. 6.170.

This behavior is a singular aspect of the Mg–In crystal system.

The occupation of the atoms in such structures is given in the following Table 6.54.

Calcium Indides

Calcium forms at least three compounds with In metal as may be seen in the following phase Fig. 6.171.

Crystal parameters are shown in Table 6.55.

Calcium diIndide, $CaIn_2$, is known to crystallize in the orthorhombic space group Pnma ($Z = 4$; Co_2Si-type structure). The structure is shown in Fig. 6.172.

The crystal structures of the known di-indides $A^{II}In_2$ (A^{II} = Ca/Sr: hexagonal, space group $P6_3/mmc$, $a = 4.892/5.009$, $c = 7.739/8.03.6$ Å, $Z = 2$, $R1 = 0.0254/0.0277$, $CaGa_2$ type; A^{II} = Ba: orthorhombic, space group *Imma*, $a = 5.220$, $b = 8.504$, $c = 8.520$ Å, $Z = 4$, $R1 = 0.0265$, KHg_2 type) contain three-dimensional indium tetrahedral networks. In accordance with their interpretation as classical Zintl compounds, the calculated density of states show pseudo band gaps. Among the tetraindides, only $BaIn_4$ (tetragonal, space group $I4/mmm$, $a = 4.970$, $c = 11.983$ Å, $Z = 2$, $R1 = 0.0187$, $BaAl_4$ type) can be explained with the extended Zintl concept. The electron-deficient isotypic alkaline metal indides, KIn_4 and $RbIn_4$ ($a = 4.928$, $c = 12.575$ Å, $R1 = 0.0289$) show the structural consequences of the depopulation of the highest occupied states.

$CaIn_2$ has also observed to have the tetragonal structure with cell parameters of: $a = 4.895$ Å, $b = 4.895$ Å, $c = 7.75$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume = 160.82 $Å^3$ (Fig. 6.173).

The site occupancy is shown in Table 6.56.

Additionally, the binary alkaline earth-rich indide compound, **dicalcium indide**, Ca_2In, has the Co_2Si structure type that is orthorhombic, space group Pnma, with $a = 7.275$ Å, $b = 5.371$ Å, $c = 9.990$ Å, $Z = 4$,

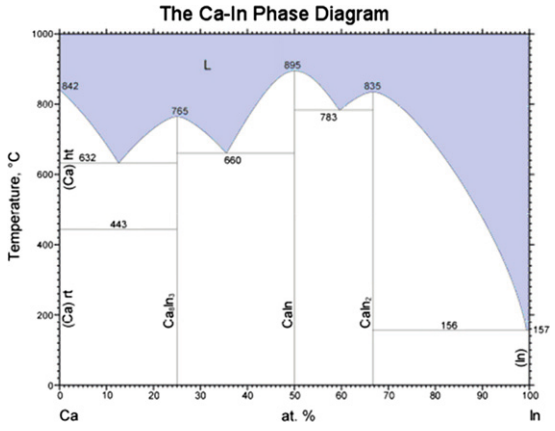

FIGURE 6.171

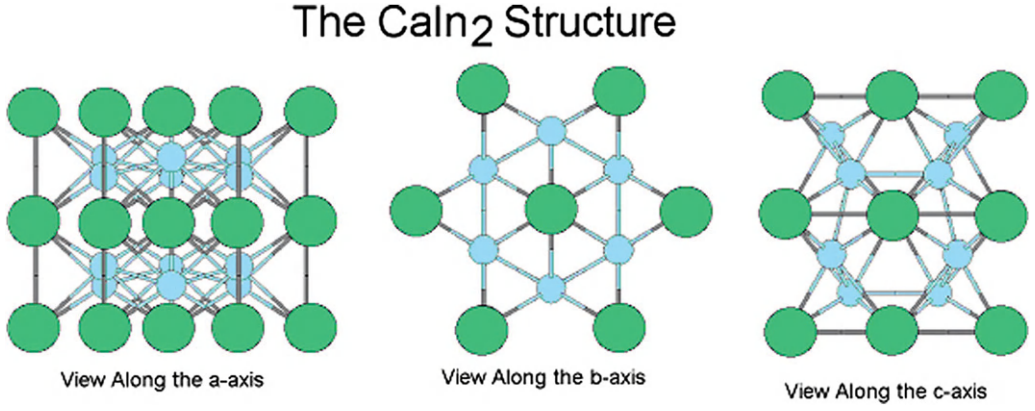

FIGURE 6.172

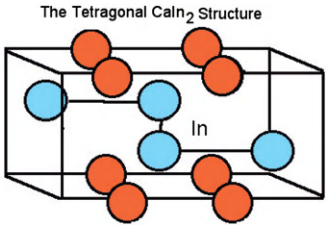

FIGURE 6.173

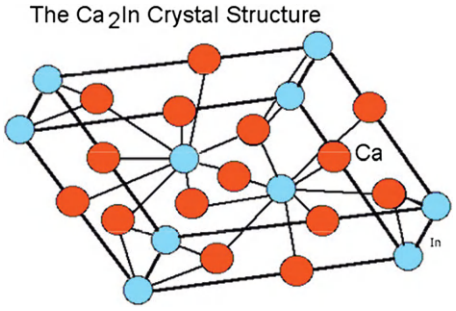

FIGURE 6.174

$R1 = 0.0252$. The structure may be represented as shown in Fig. 6.174.

The coördinates in the lattice are shown in Table 6.57.

Octa-**calcium tri-Indide**, Ca_8In_3, has the triclinic structure with cell parameters of: $a = 9.606$ Å, $b = 9.712$ Å, $c = 9.782$ Å, $\alpha = 99.01°$, $\beta = 101.15°$, $\gamma = 119.6°$, cell volume $= 742.74$ Å^3. The structure can be represented by Fig. 6.175.

The site occupancy is shown in Table 6.58.

The Ca_8In_3 structure is derived by distortion of the face-centered cubic type-like BiF_3. It can be described as a three-layered structure along the *a*-axis, the atoms being located at (0, 1/3, 2/3). Three different coördination polyhedra are found around the In atoms: distorted cubicoahedra (10 vertex polyhedra) for In1, In2, In4,and In6, cubes for In3, and icosahedra for In5. Distorted cubicohedra centered by In at $x = 0$ and $x = 1/3$ are alternately joined by an edge and by a face to form parallel rows. Cubes and icosahedra centered by In at $x = 2/3$ are joined by an edge and also form parallel rows.

Calcium mono-indide, CaIn, has the cell parameters of: $a = 0.3.8191$ nm, $b = 0.3.8191$ nm, $c = 0.3.8991$ nm, $\alpha = \beta = \gamma = 90°$, cell volume $= 55.70$ Å^3. The structure is tetragonal (Fig. 6.176).

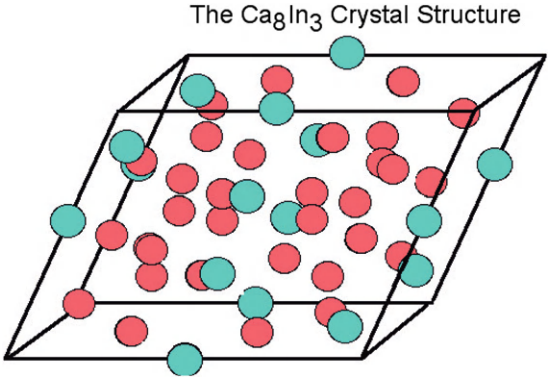

FIGURE 6.175

The mono-indides, AIn, of Ca, Sr and Ba crystallize with three different new structure types: In CaIn (tetragonal, space group $I4/mmm$, $a = 7.37$, $c = 8.40.1$ Å, $Z = 8$, $R1 = 0.0825$), isolated squares of In_4 are present. In contrast, SrIn (orthorhombic, space group $Fdd2$, $a = 10.23$, $b = 26.14$, $c = 8.40$ Å, $Z = 32$, $R1 = 0.1185$) and

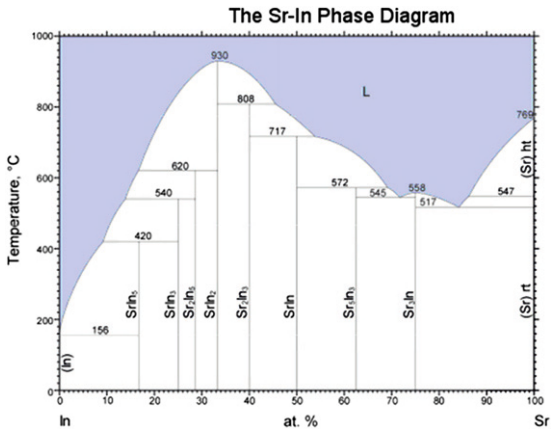

FIGURE 6.177

BaIn (orthorhombic, space group *Cmcm*, $a = 8.158$, $b = 12.481$, $c = 5.578$ Å, $Z = 8$, $R1 = 0.0623$) show—in accordance with the Zintl counting rules—three-bonded In^{2-} atoms, which are connected to form layers (SrIn) and ladders (BaIn), respectively. Both compounds can be structurally regarded as reduced $BaIn_2$, their total density of states like those of the diindide, exhibit pseudo band gaps.

Calcium indides are not very stable in the air or in moisture and are not used.

Commercially, no CAS numbers have been issued for any of them.

Strontium Indides

Strontium forms a number of compounds with In metal as may be seen in Fig. 6.177.

The crystal parameters are shown in Table 6.59.

Eight compounds are shown in the phase diagram but only six are listed in the structural diagrams. The two lists may be compared (Table 6.60).

In one paper, the binary system strontium–indium was investigated using thermal, metallographic and X-ray analysis. The compounds Sr_3In, Sr_3In_2, SrIn, Sr_2In_3, $SrIn_2$, $SrIn_3$, $SrIn_5$ were found. However, the existence of Sr_2In_5 is doubtful and it has not been discussed in the scientific literature.

Strontium indide, SrIn, has the cell parameters of: $a = 3.8191$ Å, $b = 3.8191$ Å, $c = 3.8191$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 56.75$ Å^3. The structure is a body-centered cubic lattice (Fig. 6.178).

Site occupancy in this structure is given in the following Table 6.61.

SrIn has found little usage in industry and is regarded as a novelty compound.

Strontium di-indide, $SrIn_2$, has the cell parameters of: $a = 5.001$ Å, $b = 5.001$ Å, $c = 8.021$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume $= 173.66$ Å^3, $Z = 2$. The structure can be illustrated as shown in Fig. 6.179.

Here, the In atoms adopt a "chair pattern". The site occupation is shown in Table 6.62.

$SrIn_2$, has the $CaIn_2$ structure. In $SrIn_2$, the In-bond distances are increased to 2.98 Å (3) and 3.30 Å. As the cation radius increases from Ca^{2+} (0.99 Å) to Sr^{2+} (1.12 Å), the long In–In bond in the net expands from 3.13 Å ($CaIn_2$) to 3.30 Å ($SrIn_2$). Therefore, one can

estimate (taking $Ba^{2+} = 1.34$ Å) a value of at least 3.40 Å for the long bond distance of $BaIn_2$ in the $CaIn_2$ type of structure. This bond distance is too long for a In–In single bond and $BaIn_2$ apparently does not form.

Strontium tri-indide, $SrIn_3$, has the cell parameters of: $a = 5.481$ Å, $b = 6.769$ Å, $c = 6.769$ Å, $\alpha = 120°$, $\beta = 90°$, $\beta = 90°$, cell volume $= 217.49$ Å^3, $Z = 2$. The structure may be represented as shown in Fig. 6.180.

The locations of the atoms in the lattice is shown in Table 6.63.

Strontium penta-indide, has the cell parameters of: $a = 4.827$ Å, $b = 5.937$ Å, $c = 5.937$ Å, $\alpha = 120°$, $\beta = 90°$, $\gamma = 90°$, cell volume $= 147.35$ Å^3, $Z = 2$. The structure can be represented as shown in Fig. 6.181.

Site occupancy in this structure is shown in Table 6.64.

Penta-strontium tri-indide, Sr_5In_3, has the cell parameters of: $a = 8.738$ Å, $b = 8.738$ Å, $c = 10.284$ Å, $\alpha = 115.14°$, $\beta = 115.14°$, $\gamma = 90°$, cell volume $= 627.69$ Å^3. The structure has the form shown in Fig. 6.182.

Site occupancy in this structure is shown in Table 6.65.

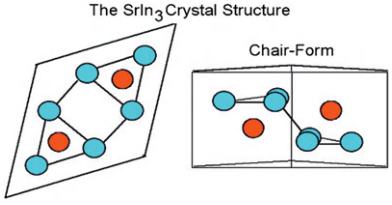

FIGURE 6.180

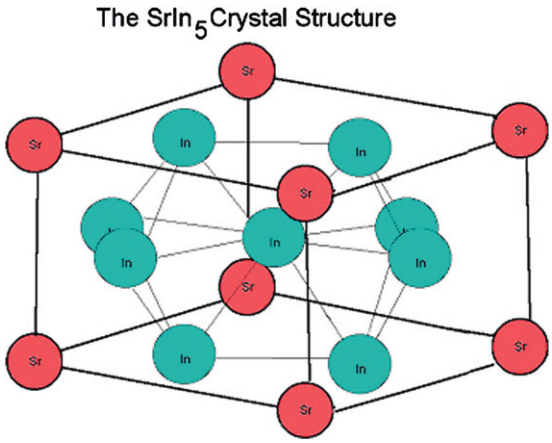

FIGURE 6.181

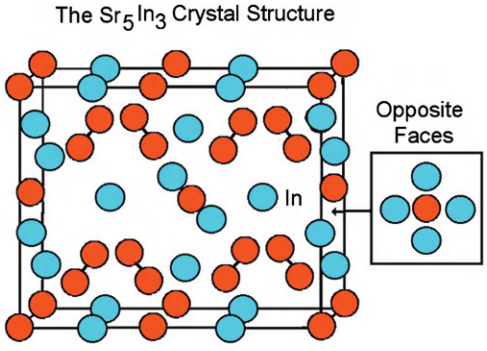

FIGURE 6.182

In the crystal structure of Sr_5In_3 (tetragonal, space group 14/mcm, $a = 8.744$, $c = 16.429$ Å, $Z = 4$, $R1 = 0.0347$, Cr^5B^3 structure type), isolated In atoms coexist with In_2 dumbbells exhibiting short In–In contacts (2.844 Å). The electronic structures of the less elaborate compounds Ca^2In and Sr^5In^3 are discussed in comparison with those of the closely related, nominally electron precise Zintl compounds Ca^2Sn and Sr_5Sn_3.

Octadodeca-strontium undeca-indide, $Sr_{28}In_{11}$, crystallizes in the ortho-rhombic space group Imm2 ($Z = 24$). The cell parameters are: $a = 8.36$ Å, $b = 8.36$ Å, $c = 8.36$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 581.28 Å^3.

Another paper found that the binary alkaline earth-rich indide, $Sr_{28}In_{11}$, has the orthorhombic, space group Imm2, with $a = 5.826$ Å, $b = 66.878$ Å, $c = 8.235$ Å, $Z = 2$, $R1 = 0.0571$. It was said to have the $Ca^{28}Ga^{11}$ structure type when synthesized from stoichiometric melts of the elements. The crystal structure displays isolated In atoms coordinated by seven to 10 alkaline earth atoms. The compound exhibits a complex three-dimensional network built of four- and five-bonded indium atoms in fused and interbonded pentagons that sandwich the strontium atoms. Both electronic band structure calculations and property measurements show that the compound is metallic. A detailed band structure analysis indicates that the compound is hypoelectronic with a one-electron deficiency, but the In–In bonding is effectively optimized in the structure.

Binary alkaline earth (A^{II}) triclides, **undeca-Ae hepta-indides**, $Ca_{11}Ga_7$ and $Sr_{11}In_7$ have been stated to crystallize with a singular structure type (cubic, space group, $a = 16.02$ Å ($A^{II} = Ca$) and 17.06 Å ($A^{II} = Sr$), $Z = 8$). They were synthesized from stoichiometric mixtures of the elements and characterized by single-crystal XRD. The structures exhibit isolated $A^{II}(1)$ atoms with B(2) atoms = In, together with tetrahedral units $[B(2)]_4$, which are formed by the triel elements exclusively. Remarkably, one of the four crystallographically independent A^{II} positions is—as in the pure element—coordinated by A^{II} partners in a cuboctahedral arrangement. The stabilities and phase ranges of the compounds, which are influenced by geometric and electronic factors (investigated by FP-LAPW band structure calculations), are discussed.

The binary compound, **tri-strontium undeca-indide**, Sr_3In_{11}, was synthesized and structurally characterized by XRD experiments. It crystallizes in the orthorhombic La_3Al_{11} structure type (space group Immm, $Z = 2$; $a = 4.9257$, $b = 14.247$, $c = 11.212$ Å).

The crystal structure of Sr_3In_{11} bears features of the monoclinic $EuIn_4$ structure, which is adopted by $SrIn_4$, and the prominent tetragonal $BaAl_4$ structure, as shown in the Fig. 6.183.

Two types of Sr atoms ($Sr_{I\ and\ II}$) are shown as well as three types of In atoms ($In_{I,II\ and\ III}$) in the structure. Sr_3In_{11} is stable until 550 °C. At higher temperatures, it decomposes peritectically into $SrIn_2$ and In. Structural stability and bonding properties of Sr_3In_{11} were

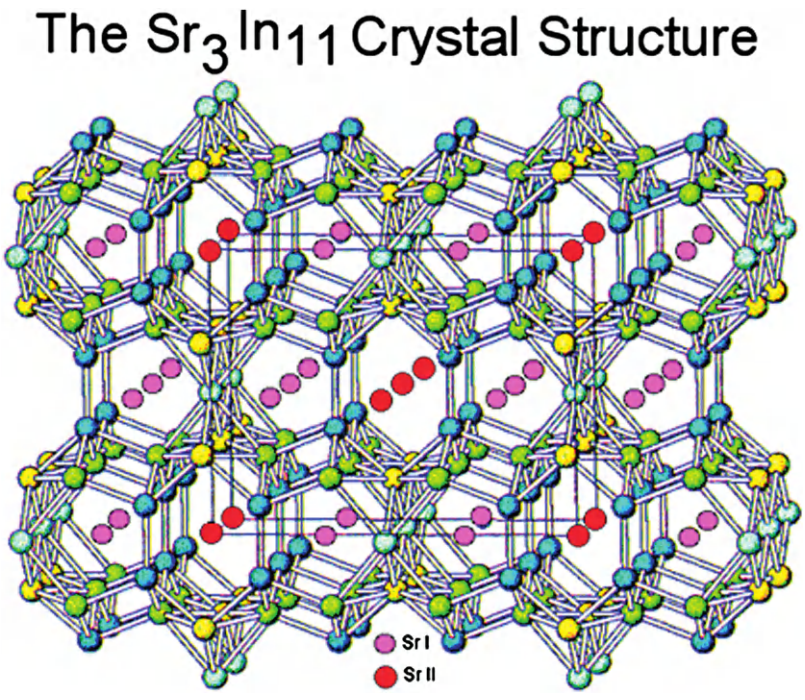

FIGURE 6.183

investigated by first-principles calculations and compared to $SrIn_4$ in the monoclinic $EuIn_4$ and the tetragonal $BaAl_4$ structure. All three structures consist of a three-dimensional, polyanionic, network formed by In atoms and Sr cations encapsulated in cages. The crystal structure of Sr_3In_{11}, isomorphous with the La_3Al_{11} structure, features two types of tunnels along the *a*-axis that are formed by indium pentagons and hexagons.

Strontium tetra-indide, $SrIn_4$, In–In network bonding is perfectly optimized. In contrast, the networks of $EuIn_4$-type $SrIn_4$ and Sr_3In_{11} appear hypo- and hyperelectronic, respectively. The formation of Sr_3In_{11} with a composition close to 1:4 and the nonexistence of $BaAl_4$-type $SrIn_4$ is explained by a delicate interplay of size and electronic factors governing structural stability in the In-rich part of the Sr–In system.

In the **tri-strontium penta-indide** structure, Sr_3In_5 (Cmcm), 4- and 2-bonded indium atoms in a 4:1 ratio form a three-dimensional classical network that encapsulates strontium atoms in its narrow channels. The electrical conductivity of the compound shows typical metallic behavior. The detailed electronic structure analysis suggests that the electron hole is mainly localized on a nonbonding p-orbital on the 2-bonded indium atoms, and that these orbitals, stacked in a σ-type way along the *a*-axis (4.97 Å), interact only weakly with each other to form highly one-dimensional bands.

The compounds, Sr_2In_3 and Sr_3In, have not been studied in the scientific literature. Although the structures of Sr_3In_5, $SrIn_4$, $Sr_{11}In_7$, and $Sr_{28}In_{11}$ have been reported with some detail, no crystal structure diagrams are presented herein.

Strontium indides have found no usage in industry and have no CAS numbers assigned.

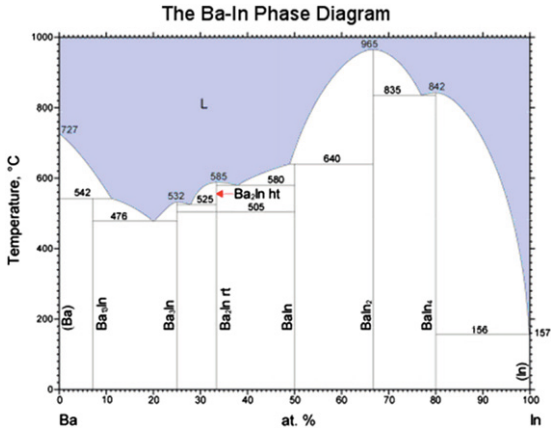

FIGURE 6.184

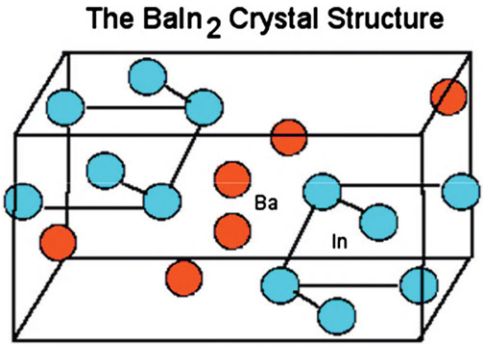

FIGURE 6.185

points of these compounds, the technical literature has few references to any of the properties of these compounds (and certainly not of their structures). Thus, the known crystal parameters are:

Compound	Number of elements	Type	Pearson symbol	Space group	Group #	Melting point, °C
$BaIn_2$	2	KHg_2	oI12	Imma	74	965
$BaIn_4$	2	$BaAl_4$	tI10	I4/mmm	139	842

Barium Indides

Barium forms a number of compounds with In metal as may be seen in the following phase Fig. 6.184.

The binary system of barium–indium has been investigated using thermal, metallographic and X-ray analysis. The six compounds, $Ba_{13}In$, Ba_3In, Ba_2In (two modifications), BaIn, $BaIn_2$ and $BaIn_4$ have been found. Note that the combinations of Ba:In atom ratios, Ba_xIn_y, vary from $x = 3$, 2, 1 (+13) (for $y = 1$) and $y = 1$, 2, 4 for $x = 1$. Although the phase diagram shows the melting

Barium di-indide, $BaIn_2$, has more than one structure. The cell parameters of one form is: $a = 5.225$ Å, $b = 6.5141$ Å, $c = 6.5141$ Å, $\alpha = 80.744°$, $\beta = 66.356°$, $\beta = 66.356°$, cell volume $= 186.05$ Å^3. One structure has the form shown in Fig. 6.185.

The cell occupancy is given in the following Table 6.66.

Barium dilndide, $BaIn_2$, also forms the $CeCu_2$ structure. Following the Zintl concept, the In ions in $BaIn_2$ are isoelectronic with group IV tin and should adopt

TABLE 6.66

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	In	In	8	h	m..	0	0.07	0.17	1.0
2	Ba	Ba	4	e	mm2	0	1/4	0.55	1.0

a four-connected structure. In contrast to R-tin, which has a cubic diamond structure, the indium ions in $BaIn_2$ build up an orthorhombic three-dimensional four-connected net containing distorted tetrahedra and ladder polymers of four-membered rings. In the $CeCu_2$ structure (space group Imma), two bond angles in these distorted tetrahedra are fixed at 90°. $BaIn_2$ abandons the $CaIn_2$ structure and favors the orthorhombic 3D4C net of the $CeCu_2$ structure. The structure has been presented as shown in Fig. 6.186.

Here, the In–In bonds are shorter than those in $SrIn_2$ ($CaIn_2$ structure): 2.97 Å (1), 3.03 Å (2), and 3.12 Å (1). However, the bond angles within the "tetrahedra" are distorted to 118.1°, 118.5°, 112.8°, and 90°. At the price of creating two 90° bond angles, relatively short In–In bonds and large cavities for the Ba^{2+} ions are formed in the four-connected net. In comparison to black phosphorus, the puckering of the indium layers in the orthorhombic 3D4C net of $BaIn_2$ is reduced. Otherwise the cavities in the net would be too small for two Ba^{2+} counter ions to be well accommodated.

The indium ions in $BaIn_2$ build up an orthorhombic three-dimensional four-connected net containing distorted tetrahedra and ladder polymers of four-membered rings. In the $CeCu_2$ structure (space group Imma), two bond angles in these distorted tetrahedra are fixed at 90°. The four-connected net in the $CeCu_2$ structure is topologically related to the layers in black phosphorus (space group Cmca). The ladder structure has the form shown in Fig. 6.187.

In CaPtSn (TiNiSi structure), the orthorhombic four-connected net is formed by $(PtSn)^{2-}$ ions in an ordered arrangement. Calculations on $BaIn_2$ and CaPtSn show that the four-connected nets are increasingly stabilized as the valence electron count is increased from 16 to 30 valence electrons per four formula units. For more

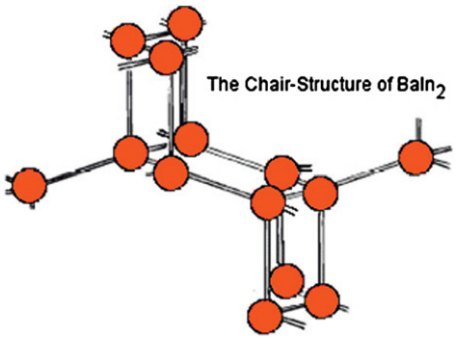

FIGURE 6.187

than 30e, the nets are destabilized due to filling of M⇒E antibonding states. Structural data obtained by precise single-crystal investigations for the TiNiSi series CaPdIn (20e), CaPdSn (24e), CaPdSb (28e), and CaAgSb (32e), confirm the results of the extended Hückel calculations. An interesting and understandable angular asymmetry of the tetrahedral sites in these ternary compounds is apparent.

Barium tetra-indide, $BaIn_4$, has the cell parameters of: $a = 0.4.93$ nm, $b = 0.4.93$ nm, $c = 0.6.896$ nm, $\alpha = 110.944°$, $\beta = 110.944°$, $\gamma = 90°$, cell volume = 144.61 $Å^3$. The structure has the form shown in Fig. 6.188.

Cell occupancy is shown in Table 6.67.

The important role of cation size in the structure choice has been noted in a comparative study of $BaIn_4$, which has the closely related $BaAl_4$-type structure in which barium atoms are sandwiched by six-membered rings.

A novel binary compound, **nona-barium tetra-indide** in the system Ba–In has been synthesized and structurally characterized. According to single-crystal XRD data, Ba_9In_4 crystallizes with the tetragonal symmetry

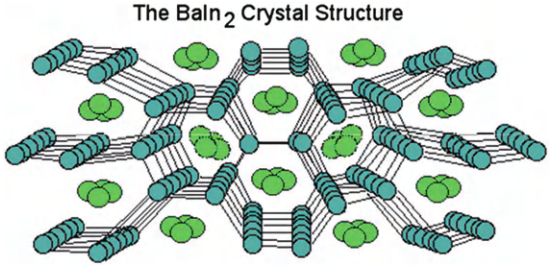

FIGURE 6.186

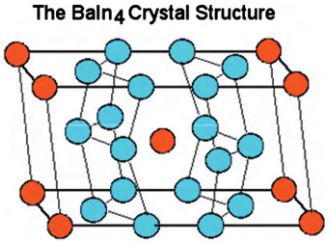

FIGURE 6.188

TABLE 6.67

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	In2	In	4	e	4mm	0	0	0.382	1.0
2	In1	In	4	d	-4m2	0	1/2	1/4	1.0
3	Ba	Ba	2	a	4/mmm	0	0	0	1.0

(I4/m, $a = 13.948$, $c = 5.888$ A°, $V = 1145.5$ Å^3, $Z = 2$, $R1 = 0.037$, w$R2 = 0.071$). This very moisture-sensitive compound could only be obtained as a single phase by reaction of metallic barium and indium at 350 °C. Thus, it was not reported in the phase diagram, as presented above.

A new indide hydride, $Ba_9[In]_4[H]$, was synthesized from the elements in stoichiometric proportions using the inherent hydrogen content of commercial elemental barium as hydrogen source. Its structure, constituting a new type, was determined using single-crystal X-ray data (tetragonal, space group $I4/m$, $a = 13.973$ Å, $c = 5.918$ Å, $Z = 2$) in sufficient quality ($R1 = 0.0261$) to allow identification and location of the hydride ion as well as the refinement of its thermal parameter. The crystal structure of $Ba_9[In]_4[H]$ exhibits isolated indium atoms, which are coordinated by 10 barium cations in a cubicosahedral arrangement. The hydride anions are octahedrally surrounded by six Ba^{2+} cations. According to $[HBa_4Ba_{2/2}]$, these octahedra are connected by opposite corners to form chains running along the *c*-axis. The presence of the hydride ion was determined by solid-state NMR spectroscopy, where the chemical shift of the ^{1}H-MAS-NMR signal of –9.0 ppm nicely corresponds to the values in BaH_2 and other metallic hydrides. As in the other binary alkaline earth indides, the band structure calculated using the frame of the FP-LAPW methods shows a pseudo band gap slightly above the Fermi level, associated with the electron-precise valence-electron count of Zintl-type (isolated In^{5-}) components. This compound was compared to other hydrides and indides, both according to the structural as well as the bonding features.

A series of ternary barium triel(M^{III})/tetrel(M^{IV})-ides have been prepared from melts of the elements. They all crystallize with the Pu_3Pd_5-type structure (orthorhombic, space group *Cmcm*) and exhibit isolated M_5 clusters of slightly distorted *nido* shape components (square pyramids). A comparable situation is found for the corresponding germanides, where 0.7 atoms of In ($Ba_3In_{0.7}Ge_{4.3}$: $a = 10.513$ Å, $b = 8.6405$ Å, $c = 10.547$ Å, $R1 = 0.0248$) or Ga ($Ba_3Ga_xGe_{5-x}$: $a = 10.351$ Å, $b = 8.615$ Å, $c = 10.368$ Å, $R1 = 0.0148$) are necessary to stabilize a Ge-rich compound of this structure type. For the stannides, the situation is somewhat different, because the binary phase Ba_3Sn_5 itself forms the Pu_3Pd_5 type. In this case, the structure type remains stable up to a Ga content of 0.5 Ga/f.u. ($Ba_3Ga_{0.5}Sn_{4.5}$: $a = 11.0041$ Å, $b = 8.9619$ Å, $c = 11.1182$ Å, $R1 = 0.0169$) and also with a substantial In content ($Ba_3In_xSn_{5-x}$: $x \approx 0.9$; $a = 11.105$ Å, $b = 9.000$ Å, $c = 11.207$ Å, $R1 = 0.0262$). As the five-atom *nido* cluster requires only 24 valence electrons per formula unit according to *Zintl* and *Wade*, an excess of electrons can be assumed for the binary tetrelides such as Ba_3Sn_5 (26 v.e./f.u.) that even the maximal amount of triel substitution 0.7 M^{III}/f.u. attained in the title compounds cannot sufficiently compensate for. An assessment of the geometric influence of varied valence electron counts however, coupled with a detailed analysis of the calculated electron densities and the partial densities of states in the energy region above the pseudo band gap at 24 v.e./f.u. clearly shows that these excess electrons populate π-bonding M-*p*/Ba-*d* states and actually contribute to a stabilization of the structure. In the range above 25.3 v.e./f.u. predominantly antibonding M-*p* states are populated, resulting in a widening of the base of the cluster.

Barium indides have not found usage in industry due to primarily their instability in the presence of moisture and air.

Radium Indides

The chemistry of radium indides should follow the solid-state chemistry of the Ca, Sr and Ba indides. However, there is absolutely no mention of such compounds in the scientific literature up to the present time.

6.6.2. Alkaline Earth Oxy-Indium Compounds

Indium has but one oxidation state, In^{3+}, and so does not form any other compounds except that of "indates".

Beryllium Indates

It would appear, at first glance, that beryllium indate could be prepared by the reaction of the oxides:

$$BeO + In_2O_3 + \text{heat} \Rightarrow BeIn_2O_4$$

However, there are no reports of the properties of this compound or of any other beryllium indate compounds. No CAS numbers exist. It is likely that the system

$BeO–In_2O_3$ has never been studied in any detail. Only one reference to $BeIn_2O_4$ is to be found, that of "Physical Properties of Adsorbants" by Marek Kosmulski (© 2001 Marcel Dekker, Inc.). This compendium is a listing of known crystallographic data. However, this compound is listed but no unit-cell data are given. Thus, the final conclusion is that $BeIn_2O_4$ does not exist per se.

Magnesium Indates

Magnesium indate can be prepared by the reaction of the oxides at 1100 °C:

$$MgO + In_2O_3 + \text{heat} \Rightarrow MgIn_2O_4$$

However, the reaction is very slow and as long as 10 days of heating is required for complete reaction of these oxides. A much better method, which has been used in general to prepare the alkaline earth indate compounds, is the so-called "combustion synthesis" (CS) method. In the CS method, the nitrates of Mg and In are mixed in proper proportion and a calculated amount of urea ($(NH_2)_2CO$) is added to the solution as a fuel. The solution is placed in a furnace at 500 °C. An exothermic reaction occurs, producing a fluffy white powder. This is then heated for 36 h at 900 °C and then reheated at 1050 °C for 36 h to form a highly crystalline material.

$MgIn_2O_4$ is a transparent conducting oxide. Such materials, due to their high transparency in the visible region of the electromagnetic spectrum and conductivity in the order of 10^2 S/cm, are candidates for a variety of technologically important devices such as liquid-crystal displays, computer monitors, iPods, iPhones, "Blackberries", etc. It has been reported that $MgIn_2O_4$ has a high electrical conductivity and is capable of higher UV transmission than indium tin oxide (ITO). It is a cubic spinel with space group Fd3m and $a = 0.8864$ Å. The spinel structure is basically constituted of closed-packed oxygen ions forming NO_4 or NO_6 polyhedra that run parallel to the (110) direction. The chains are connected to each other by cations like Mg^{2+} in tetrahedral sites. There are 64 equivalent tetrahedral cation sites and 32 octahedral sites in the unit cell. Out of these, 7/8 of the tetrahedral and 1/2 of the octahedral sites are not occupied. A $MgIn_2O_4$ film prepared by a magnetron-sputtering technique, was found to have a resistivity of 3.9×10^{-4} Ω cm. The structure of $MgIn_2O_4$ is shown in the above diagram. It consists of isolated MgO_4 tetrahedra and isolated InO_6 octahedra (Fig. 6.189).

Magnesium ions are distributed over the tetrahedral and octahedral sites of the inverted spinel structure with preferential orientation along (3,1,1) Miller plane. The possible mechanism that promotes conductivity in this system is the charge transfer between the resident divalent (Mg^{2+}) and trivalent (In^{3+}) cations in addition to the available oxygen vacancies in the lattice. A room

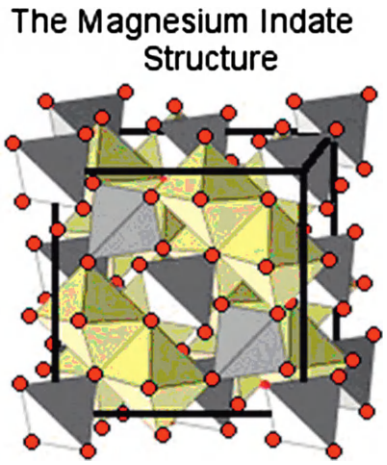

FIGURE 6.189

temperature electrical conductivity of 1.59×10^{-5} S/cm and an average optical transmittance >75% have been achieved. Hall measurements showed *n*-type conductivity with electron mobility value 0.95×10^{-2} $cm^2/V/s$ and carrier concentration $2.7 \times 10^{19}/cm^3$. Smoothness of the film surface observed through atomic force microscope measurements favors this material for gas sensing and opto-electronic device development.

$MgIn_2O_4$ has been adopted as the primary transparent material in optoelectronic device fabrication due to its high optical transparency and electrical conductivity. Such a technologically important material was prepared by the spray pyrolysis technique. Precursors prepared for the cationic ratio $Mg/In = 0.5$ were thermally sprayed onto glass substrates at 400 and 450 °C. The films were characterized by XRD, energy-dispersive absorption X-ray spectroscopy (EDAX), and atomic force microscopy. The XRD results showed the single-phase formation of the material that revealed the presence of Mg^{2+} and In^{3+} in the inverse spinel-related structure. The FTIR and EDAX results further confirmed that the nanocrystalline films were mainly composed of magnesium, indium, and oxygen, in agreement with XRD analysis. For a 423-nm thick magnesium indium oxide films grown at 400 °C, the electrical conductivity was 1.56×10^{-3} S/cm and the average optical transmittance was 63% in the visible range (400–700 nm). Similar $MgIn_2O_4$ films deposited at 450 °C have a conductivity value of 0.95×10^{-3} S/cm and an average transmittance of 75%. Hall coefficient observations showed *n*-type electrical conductivity and high-electron carrier concentration of $2.7 \times 10^{19}/cm^3$. From the diffuse reflectance spectral measurement of $MgIn_2O_4$, the band gap was found to be 4.3 eV which is higher than that of ITO. The conductivity of as-prepared sample and that of the H_2-annealed sample of $MgIn_2O_4$ was and 5.57×10^0 S/cm.

Magnesium indium oxide films ($MgIn_2O_4$), manifesting high transparency were prepared by metal organic chemical spray pyrolysis technique. Precursors prepared for various cationic ratios of $Mg/In = 0.35$, 0.40, 0.45 and 0.50 were thermally sprayed onto quartz substrates, decomposed at 450 °C and the spinel phase evolution was studied. XRD, Rutherford backscattering and X-ray photoelectron spectroscopy studies have been conducted to confirm the formation of single-phase $MgIn_2O_4$ films with Mg/In ratio 0.50. From optical transmission studies, the observed optical band gaps varied from 3.18 to 3.86 eV (321–389 nm) ($0.35 < Mg/In < 0.5$). The electrical conductivity variations of these films were measured in the temperature range between 30 and 150 °C by four-probe technique ($34.07–1.44 \times 10^{-5}$ S/cm) and the Hall coefficient showed *n*-type electrical conduction and high carrier concentration (0.16×10^{20}–$0.89 \times 10^{17}/cm^3$).

Magnesium forms a series of spinels with Al^{3+}, Ga^{3+} and In^{3+}, namely normal magnesium aluminate, $MgAl_2O_4$, half-inverse magnesium gallate, $MgGa_2O_4$, and inverse magnesium indate, $MgIn_2O_4$. The response of each of these oxides for energies of up to 10 keV for the initial knock-on event was analyzed and compared. Defect production was characterized mainly by split interstitials/crowd ions and cation antisite or disorder defects. The results show that cation interstitials preferentially occupy octahedral sites in all three materials. In the normal spinel, subcascade branching occurs and the defects at the end of the cascade are generally isolated, whereas in the half-inverse spinel, the higher energy cascades show a core damage region some of which consists of a partial rearrangement of atoms to the normal spinel structure and a partial transformation to a disordered rock salt structure. In the fully inverse spinel, a more connected region of the disordered rock salt structure with the cascade core is evident. Temperature accelerated dynamics (TAD) was used to characterize the kinetics of defects in these three spinel oxides: magnesium aluminate $MgAl_2O_4$, magnesium gallate $MgGa_2O_4$, and magnesium indate $MgIn_2O_4$. These materials have varying tendencies to disorder on the cation sublattices. In order to understand chemical composition effects, defect kinetics in perfectly ordered, or normal, spinels were studied, focusing on point defects on each sublattice so as to examine the role that cation disorder has on defect mobility. Using TAD, it was found that disorder creates local environments that strongly trap point defects, effectively reducing their mobility. The consequences of this trapping via kinetic Monte Carlo simulations on the oxygen vacancy (V_O) in $MgGa_2O_4$, shows that V_O mobility is directly related to the degree of inversion in the system. Thus, the indate compound is likely to be the best material to replace ITO as a transparent conductive film.

An epitaxially grown magnesium indium oxide ($MgIn_2O_4$) thin film was prepared by pulsed laser deposition (PLD) on an YSZ-buffered Si substrate at 300 °C. Although there is a large lattice mismatch exists (72.5%) between $MgIn_2O_4$[100] and YSZ[100], epitaxial growth, with cube-on-cube relations, was achieved. A room-temperature electrical conductivity of 29.0 S/cm and a transmittance >80% were achieved above 530 nm. The optical band gap measured for a $MgIn_2O_4$ thin film deposited on a glass substrate showed 4.2 eV. On this $MgIn_2O_4$/YSZ/Si(001) substrate, a $BaTiO_3$-$NiFe_2O_4$ composite film was deposited at 700 and 750 °C by PLD. Although the partial decomposition of $MgIn_2O_4$ into In_2O_3 was observed, both $BaTiO_3$ and $NiFe_2O_4$ were simultaneously epitaxially grown on $MgIn_2O_4$ with cube-on-cube relationship. These findings indicate that $MgIn_2O_4$ can be used as a bottom electrode for multiferroic composite films such as $BaTiO_3$ and $NiFe_2O_4$.

Magnesium indate has no CAS number and is not offered for sale commercially.

Calcium Indates

Calium indate may be prepared by the reaction of the oxides:

$$CaO + In_2O_3 + \text{heat} \Rightarrow CaIn_2O_4$$

However, the reaction is slow at 950 °C and may take up to 10 days to obtain a complete reaction. Calcium indate melts above 1500° C. It is more easily prepared by a CS method. In the CS method, the nitrates of Ca and In are mixed in proper proportion and a calculated amount of urea ($(NH_2)_2CO$) is added to the solution as a fuel. The solution is placed in a furnace at 500 °C. An exothermic reaction occurs, producing a fluffy white powder. This is then heated for 36 h at 900 °C and then reheated at 1050 °C for 36 h to form a highly crystalline material.

Employing the following solid oxide galvanic cells with a zirconia electrolyte, i.e. [Ni, NiO-O^{2-}-$In + In_2O_3$] and [Ni, NiO-O^{2-}, +In, CaO, $CaIn_2O_4$], the Gibbs free energies of formation of solid In_2O_3, and $CaIn_2O_4$ were determined to have the form $\Delta G^0_{\text{f, } In_2O_3} = -909.425 + 307.49T$ kJ/mol and $\Delta G^0_{\text{f, } CaIn_2O_4} = -952.550 + 342.797T$ kJ/mol. Consequently, the Gibbs free energy change for the formation of $CaIn_2O_4$ from the respective oxides $CaO + In_2O_3 \Rightarrow CaIn_2O_4$ was established as $\Delta G^0_{\text{f,oxides}} = -43.126 + 35.3T$ kJ/mol over the temperature range 923–1123 K (650–850 °C).

The development of visible light-induced photocatalysts has been found to be of great importance for the efficient utilization of solar energy or indoor artificial light in the photocatalytic degradation of organic pollutants and splitting of water. It has been demonstrated that the metal oxides of MIn_2O_4 (M = Ca, Sr, Ba) have

good photocatalytic activity for degrading organic pollutants such as methylene blue (MB) under visible light irradiation or the splitting of water into hydrogen and oxygen by dispersion of RuO_2 under UV irradiation. These p-block metal oxides are electronically composed of octahedrally coordinated metal ions having the d^{10} configuration. Among these oxides, $CaIn_2O_4$ shows the highest photocatalytic activity. Because Ca^{2+} has the smallest ionic radii, combined with a similar InO_6 octahedra network structure, it probably is more efficient in the photoelectronic transfer of electrons. The activity order under visible light irradiation was $CaIn_2O_4 > SrIn_2O_4 > BaIn_2O_4$. The general structure of these indates is shown in the following Fig. 6.190.

Two types are known. In one, the structure consists of a series of joined tetrahedra–octahedra to form a tetragonal structure with: $a = 5.0348$, $c = 14.0688$ Å, unit cell with *I4cm* (#108) space group symmetry. In the other, a series of edge-joined octahedra are the major feature. $CaIn_2O_4$, $CdIn_2O_4$, $SrIn_2O_4$ and $BaIn_2O_4$ can be prepared by heating the mixed metal oxides in the temperature range 880–1400 °C. These compounds have been reported to be distorted spinels; however, powder and single-crystal X-ray photographs show that they are related to $CaFe_2O_4$ and contain six-coordinated In^{3+}. The general occurrence of spinel, stuffed silica and ferrite-type AB_2O_4 compounds can be correlated with the radius ratio of the cations. Originally, it was thought that all of the alkaline earth monoindates adopted a tetragonal structure but it has been shown that the Sr and Ba compounds differ markedly in structure. Perhaps, this accounts for the enhanced activity of calcium monoindate as a photocatalytic compound. Note that the structure of $CaIn_2O_4$ differs from those of the analogous compounds, $SrIn_2O_4$ and $BaIn_2O_4$. Perhaps it is this difference that accounts for the increased capacity of the calcium compound toward the highest photocatalytic activity (Fig. 6.191).

SSR is the conventional method widely used for preparing these materials, during which the oxides of the starting materials are mixed together, followed by being calcined at high temperature for a sufficient length of time. Due to the evaporation of In_2O_3 above 1273 K (1000 °C), it is difficult to synthesize and obtain pure-phase $CaIn_2O_4$ using the SSR method. Furthermore, this method does not mix the various components at the molecular level so that agglomeration and formation of a pure phase may occur. This more often produce large particles with an extremely low-surface area and a higher degree of lattice defects. These effects are deleterious to the photocatalylitic activity. Using a coprecipitation method, Inoue et al. synthesized a kind of $CaIn_2O_4$ particles with better photocatalytic activity than that of a sample prepared by the SSR method.

The CS method was found to be successful in preparing many metastable phases and also conventional materials at low temperature. A mixed composition of $CaIn_2O_4$ was prepared by a combustion method using the urea as fuel. However, the resulting $CaIn_2O_4$

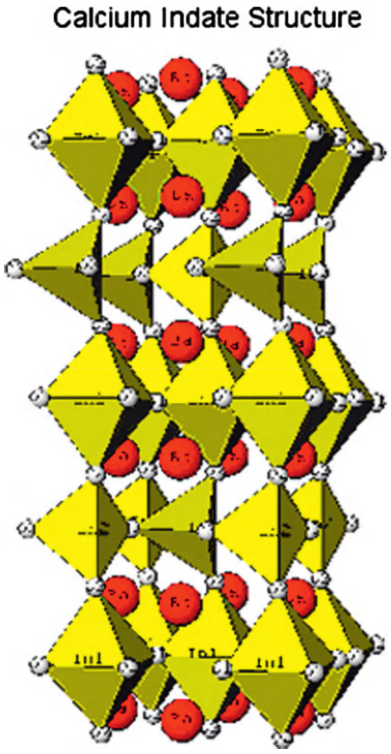

FIGURE 6.190

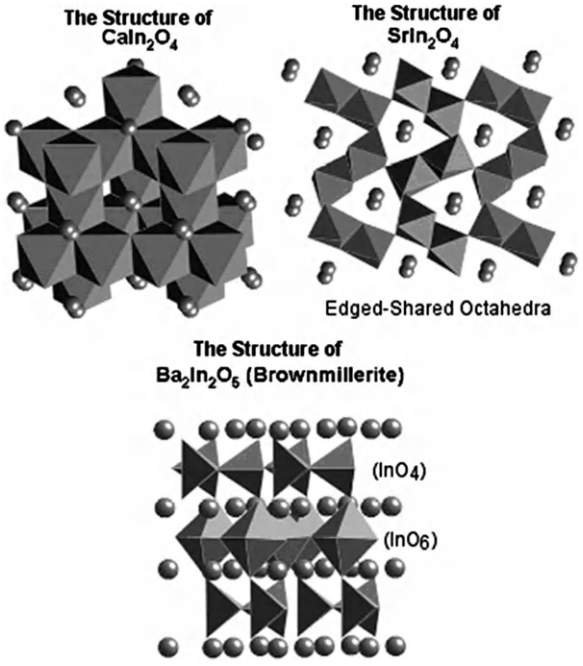

FIGURE 6.191

was impure with a small amount of CaO and In_2O_3 still remaining after calcination at 1323 K (1200 °C) for 6 h (likely due to decomposition of In_2O_3 at that temperature). In another study, a pure $CaIn_2O_4$ particle was prepared at a relatively low temperature by a modified solution–combustion method in which the nitrates were dissolved in water with ethyl nitrate. The mixed solution was kept at 473 K (200 °C) for 30 min to form a solid, which was then slowly heated to 573 K (300 °C) in 30 min (3.3°/min). During this period, a spontaneous combustion took place and a fluffy powder was formed. A following high-temperature treatment made the nanometric particles grow into regular $CaIn_2O_4$ rods. Due to the high crystallization, low impurity level and large surface area, the $CaIn_2O_4$ rods showed significantly higher photocatalytic activity for MB degradation and toluene oxidation under visible light irradiation compared with the sample synthesized by the conventional SSR method. Furthermore, with the dispersion of Pt, the $CaIn_2O_4$ rods exhibited an excellent photocatalytic activity for water decomposition under visible light and UV irradiation.

In the process of preparing a visible light photocatalyst $CaIn_2O_4$, a novel core shell-like composite In_2O_3 at $CaIn_2O_4$ was observed at intermediate calcination temperatures, during the SSR between ball-milled powders of $CaCO_3$ and In_2O_3. The composition, crystallinity and photo absorption of the coupled phases obtained in the temperature range 873–1323 K (600–1050 °C), were characterized by powder XRD, TEM and UV–Vis diffused reflectance spectroscopy. The coupled composite phases In_2O_3 at $CaIn_2O_4$ showed superior visible light-induced photocatalytic degradation of MB compared to single-phase $CaIn_2O_4$. Selective charge separation and efficient charge transport at the interface when illuminated are considered to be the possible reasons for the enhanced photocatalytic performance of this composite catalyst.

The photocatalytic activities of In_2O_3 at $CaIn_2O_4$ composite photocatalysts were investigated based on the decomposition of methyl orange under visible light irradiation ($\lambda > 400$ nm). Different In_2O_3 at $CaIn_2O_4$ contents can be obtained by controlling the synthesis temperature. The photocatalytic tests indicated that the composite samples demonstrated high visible light activity for decomposition of methyl orange. The significant enhancement of the In_2O_3 at $CaIn_2O_4$ photoactivity under visible light irradiation can be ascribed to the efficient separation of photo-generated carriers in the In_2O_3- and $CaIn_2O_4$-coupled semiconductors.

In another study, the photocatalytic properties for water decomposition of RuO_2-dispersed alkaline earth metal and lanthanum indates with an octahedrally coordinated In^{3+} ion of d^{10} configuration were studied. The influences of preparation methods, calcination temperature, and the amount of RuO_2 on the activity of RuO_2-dispersed $CaIn_2O_4$ were examined, and it was shown that the combination of well-crystallized $CaIn_2O_4$ with highly dispersed RuO_2 particles led to the highest photocatalytic performance: hydrogen and oxygen were stably produced at nearly the stoichiometric ratio under UV irradiation. The photocatalytic activity of RuO_2-dispersed $Sr_{1-x}Ca_xIn_2O_4$ ($x = 0.25$, 0.50, 0.75) increased monotonically with increasing x. The activity of RuO_2-dispersed Sr_{1-x} $Ba_xIn_2O_4$ was similar to that of RuO_2-dispersed $SrIn_2O_4$, whereas RuO_2-dispersed $LaInO_3$ had much lower activity. The photocatalytic properties of different kinds of indates were compared.

Terbium-activated $(M_{1-x}Tb_x)In_2O_4$ (M = Ca and Sr, $x = 0.12$, 0.5, 1.0, 1.5 and 2.0 mol%) phosphors have been synthesized by combustion route using urea as a fuel in a pre-heated furnace at 500 °C. The characteristics of the phosphors, such as photoluminescence, crystallinity and particle morphology, were investigated with different levels of Tb^{3+} doping. The green luminescence was attributed to the transition from the $^5D_4$ excited state to $^7F_5$ ground state of Tb^{3+} ions. Qualitative analysis of the phosphors has been performed by energy-dispersive analysis (EDAX). The powder XRD of the phosphor was also studied and reported.

In a like manner, $CaIn_2O_4$:Eu^{3+} phosphors were prepared by a Pechini sol–gel process. XRD, field emission scanning electron microscopy (FE-SEM), photoluminescence (PL), cathodoluminescence (CL) spectra as well as lifetimes were utilized to characterize the samples. The XRD results reveal that the samples begin to crystallize at 800 °C, and the crystallinity increases upon raising the annealing temperature. The FE-SEM images indicate that the $CaIn_2O_4$:Eu^{3+} samples consist of fine and spherical grains with size around 200–400 nm. Under the excitation of ultraviolet light and low-voltage electron beams, the $CaIn_2O_4$:Eu^{3+} phosphors show the characteristic emissions of Eu^{3+} ($^5D \Rightarrow {}^7F_J$ $J, J' = 0, 1, 2, 3$ transitions). The luminescence color can be tuned from white to orange to red by adjusting the doping concentration of Eu^{3+}.

The hitherto unknown compound, **tricalcium monoindate**, $Ca_3In_2O_6$ was prepared and investigated by X-ray single-crystal methods. $Ca_3In_2O_6$ is orthorhombic ($a = 10.908$, $b = 16.45$, $c = 3.228$ Å, space group D^9_{2h}-Pbam) and has a partial statistically distribution of Ca and In. One of the metal positions is occupied only by Ca. The crystal structure of $Ca_3In_2O_6$ is similar to the $CaFe_2O_4$ type which occurs as a mineral, "delafossite". The structure is shown in the following Fig. 6.192.

This structure is characterized by a layer of linearly coordinated Ca^{2+} ions, stacked between edge-shared octahedral layers (InO_6).

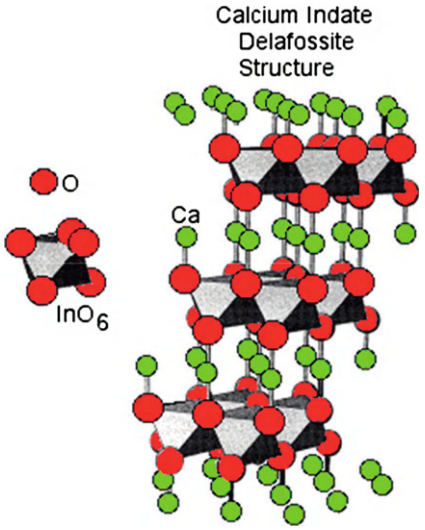

FIGURE 6.192

Four calcium indate compounds are said to be known:

Calcium mono-indate = $CaIn_2O_4$ = 1:1 = 50 mol% indate
Dicalcium tri-indate = $Ca_3In_6O_{11}$ = 2:3 = 60 mol% indate
Tricalcium indate = $Ca_3In_2O_6$ = 3:1 = 25 mol% indate
Tricalcium tetra-indate = $Ca_3In_8O_{15}$ = 3:557 mol% indate

However, the scientific literature is practically devoid of any mention of the properties of these materials other than about one or two authors. Other than the 1:1 and 3:1 compounds, no melting points or other characteristics for the other two have been recorded.

Calcium indate has no CAS numbers and is not offered for sale commercially.

Strontium Indates

Strontium indate, $SrIn_2O_4$, can be prepared by reaction of the oxides at about 1200 °C:

$$SrO + In_2O_3 + \text{heat} \Rightarrow SrIn_2O_{4\neq}$$

Strontium monoindate melts only above 1600° C. $SrIn_2O_4$ was investigated by X-Ray single-crystal methods (space group $D^{16}{}_{2h}$-Pnam; $a = 9.809$, $b = 11.449$, $c = 3.265$). The similarity of the crystal structure of $SrIn_2O_4$ with $Ca_3In_2O_6$ was discussed (see above for the unit-cell structure).

The sintered indate $(Sr,Ca)In_2O_4$ is outstandingly suitable as a crucible material for the SSR of the oxides of bismuth, strontium, calcium and copper to form phases having HT superconductivity, and generally for producing ceramics having a content of Bi, In or Tl. This is of interest in as much as the formation of the superconductive phase in the Bi–Sr–Ca–Cu–O system, which has a transition temperature of 110 K, takes place only at temperatures just below the melting point of the mixture. When such sintering experiments are carried out in crucibles or on carrier plates of Al_2O_3, the latter are strongly attacked and contaminated products of unsatisfactory quality, i.e. a low content of the 110 K phase, are obtained. If, however, the reaction is carried out on a substrate of sintered strontium indate, calcium indate or a Sr–Ca indate, the content of the desired 110 K phase is increased, under otherwise identical conditions. Furthermore, it becomes possible to work at higher sintering temperatures. It is not necessary for the carrier to be composed of solid indate. Preferably, it is composed of a ceramic, for example, Al_2O_3, to which a thin layer of indate has been applied, for example by plasma spraying or by screen printing.

$SrIn_2O_4$ can be prepared by heating the mixed metal oxides in the temperature range 880–1400 °C. These compounds have been reported to be distorted spinels; however, powder and single-crystal X-ray photographs show that they are related to $CaFe_2O_4$ and contain six-coordinated In^{3+}. The general occurrence of spinel, stuffed silica and ferrite-type AB_2O_4 compounds can be correlated with the radius ratio of the cations. $SrIn_2O_4$ was investigated by X-ray single-crystal methods (space group D^{16}_{2h}-Pnam; $a = 9.809$, $b = 11.449$, $c = 3.265$ Å). The similarity of the crystal structure of $SrIn_2O_4$ with $Ca_3In_2O_6$ was striking. In an effort to explain the photoelectric activity of $CaIn_2O_4$, the geometric structures of InO_6 octahedral units were compared among the indates, and it was shown that the photocatalytically active indates possessed distorted InO_6 octahedra having a dipole moment, and that there was a correlation between the photocatalytic activities and the dipole moment. A plane wave density function theory was applied to calculate the density-of-state and band energy diagram for $CaIn_2O_4$. The valence band was composed of the O-2p orbital, whereas the conduction band consisted of the hybridized indium 5s5p orbitals having a large dispersion, indicative of a substantial mobility of photoexcited electrons in the conduction band. The electronic feature of $SrIn_2O_4$ was compared with that of a representative transition metal oxide of $BaTi_4O_9$ with an octahedrally coordinated d^0 metal ion. On the basis of the electronic and geometric consideration, a mechanism was proposed: "Internal fields due to the dipole moment promote the charge separation, while the broad sp conduction bands with large dispersion permit photoexcited electrons to move to RuO_2 particles dispersed as a promoter."

The green-emitting phosphors, $SrIn_2O_4$:xTb ($x = 0.125$, 0.5 and 2%), have been prepared by SSR at 1200 °C. With different levels of Tb^{3+} doping, the XRD, photoluminescent properties, integrated fluorescence

intensity, fluorescence decay lifetime and chromatic characteristics of the phosphors have been systematically investigated.

In another reference, a single-crystal investigation of strontium monoindate, $SrIn_2O_4$, indicated that it had a structure similar to $Ca_3In_2O_6$, the tricalcium monoindate. The space group was Pnam (D^{16}_{2h}) with $a = 9.809$, $b = 11.449$, $c = 3.265$ Å.

Distrontium indate, $Sr_2In_2O_5$, on the other hand, belongs to the orthorhombic space group, Ibm2 (C^{22}_{2v}) with $a = 6.049$, $b = 15.84$, $c = 3.265$ Å and is isostructural with "Brownmillerite", Ca_2FeAlO_5. Half of the In^{3+} atoms are tetrahedrally and half octahedrally coordinated (as in the $CaIn_2O_4$ structure). The ability of trivalent indium to adopt various coordinations—tetrahedral, octahedral, pyramidal—is an interesting feature for the generation of oxygen-deficient perovskites and relatives. In the indates $Sr_2In_2O_5$ and $Ba_2In_2O_5$, the ordering of the oxygen vacancies leads to a Brownmillerite structure with alternating sheets of InO_6 octahedra and InO_4 tetrahedra. A sheet-like element of the Brownmillerite structure is shown in the following Fig. 6.193.

Note that the tetrahedra are isolated from each other but attached to the octahedra. The trivalent In^{3+} ions are half in octahedral and half in tetrahedral coordination.

Only the two compounds listed above are known in the SrO–In_2O_3 system. They do not have a CAS number and are not listed for sale commercially. No uses have arisen in industry, a fact that may explain the lack of interest for such compounds in academia.

The Perovskite-Brownmillerite Structure contains two Octahedra and one Tetrahedra Layers. These Polyhedra contain Indium Coordinated to Oxygen atoms which are tied to the Stountium Atoms in the Structure

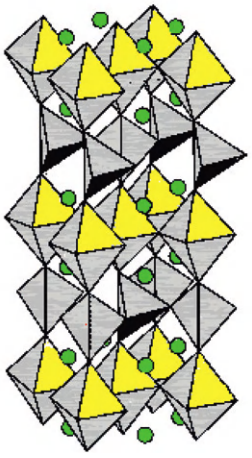

FIGURE 6.193

Barium Indates

The general occurrence of spinel-, stuffed silica- and ferrite-type AB_2O_4 compounds can be correlated with the radius ratio of the cations. Such compounds as $CaIn_2O_4$, $CdIn_2O_4$, $SrIn_2O_4$ and $BaIn_2O_4$ have been reported to be distorted spinels. However, powder and single-crystal X-ray patterns show that they are related to $CaFe_2O_4$ and contain six-coordinated In^{3+} ions. They can be prepared by heating the mixed metal oxides in the temperature range 880–1400 °C. In the BaO–In_2O_3 system, there are five reported compounds. In addition to the known compounds, $BaIn_2O_4$ and $Ba_4In_6O_{13}$, three other compounds have been found: $Ba_2In_2O_5$, $Ba_3In_2O_6$ and $Ba_5In_2O_8$. $Ba_2In_2O_5$ has a simple, perovskite-like X-ray structure, which was not indexed. $Ba_3In_2O_6$ and $Ba_5In_2O_8$ have tetragonal body-centered unit cells with $a = 4.1913$ Å, $c = 21.6693$ Å and $a = 4.1741$ Å, $c = 29.431$ Å, respectively. $Ba_3In_2O_6$ reacts with most air to form a hydrogarnet: $Ba_3In_2(OH)_{12}$. Of the five compounds, only $BaIn_2O_4$ and $Ba_2In_2O_5$ melt congruently, as shown in the following phase Fig. 6.194.

Most of these compounds melt or decompose between 1400 and 1500 °C. Of the binary and ternary compounds in this system, as reported in the literature, only a few of them have been confirmed as stable at 930 °C, namely; $Ba_5In_2O_8$ and $Ba_4In_2O_7$. These two have been identified as a single phase of variable composition $Ba_{5-x}In_{2+x}O_{8+0.5x}$ (α-phase) with $0 \leq x \leq 0.45$, and $Ba_2In_3O_{6.5}$, the latter denoted as $Ba_{1.6}In_{2.4}O_{5.2}$ to reflect its "doubled" perovskite structure (which is different from that reported to date for the $Ba_2In_3O_{6.5}$ compound and identical to the already described series of $Ba_2In_{2-x}Cu_xO_{4+\delta}$ type).

Barium indium oxides ($BaIn_2O_4$, $Ba_4In_6O_{13}$, $Ba_2In_2O_5$, $Ba_3In_2O_6$, and $Ba_5In_2O_8$) were synthesized by a citric process and characterized by powder XRD. The optical absorption properties of these compounds were investigated by UV-visible diffuse reflectance spectroscopy. It was found that, with the increase of the mole ratio of In_2O_3 in the formula, the optical absorption edges of

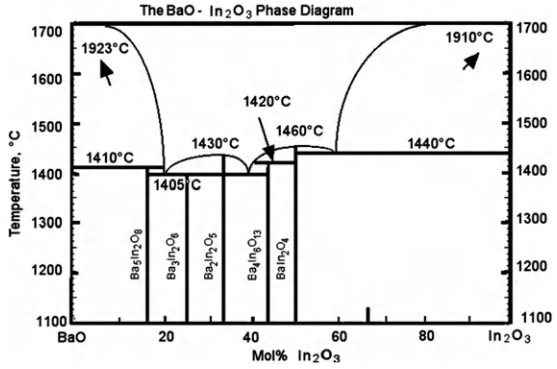

FIGURE 6.194

these oxides shift to the longer wavelength side monotonically. The photocatalytic H_2 and O_2 evolutions under visible light irradiation ($\lambda > 420$ nm) from aqueous CH_3OH/H_2O and $AgNO_3/H_2O$ solutions were performed. Among these oxides, $BaIn_2O_4$ was the most stable compound. The other compounds were not stable chemically in the case of water and visible light irradiation. The structure of $BaIn_2O_4$ is shown in the following Fig. 6.195.

Barium monoindate, $BaIn_2O_4$, has the unit-cell parameters of: monoclinic symmetry; space group C^5_{2h}-$P2_1/a$; $a = 14.432$ Å, $b = 5.833$ Å, $c = 20.792$ Å, $\beta = 110.02°$, $Z = 16$. $BaIn_2O_4$ represents a new structure type with relationships to $BaSc_2O_4$. The crystal structure of $BaIn_2O_4$ is clearly different from $CaIn_2O_4$ and $SrIn_2O_4$.

A variation of barium monoindate is also formed in which the lattice parameters are doubled. $Ba_3In_6O_{12}$ is not very stable but the addition of Ca forms a stable $(Ba,Ca)_3In_6O_{12}$ compound. The tunnel structure of the oxide $(Ba_{0.85}Ca_{2.15})_3In_6O_{12}$ has been revisited. A mono-incommensurate modulation was evidenced by electron diffraction. The simultaneous refinement of X-ray and neutron powder diffraction patterns has allowed a complete determination of the incommensurate structure [$P3_1$]. The existence of a modulated disorder, affecting Ba and Ca atoms, has been pointed out. The occupancy modulation concerning Ba and Ca atoms located on the hexagonal tunnel axis induces a modulation of the Ba–O bond lengths. The HREM study has shown the existence of twinning domains and of crystal regions possessing a defective arrangement of the modulation.

Dibarium indate, $Ba_2In_2O_5$, is a high-temperature semiconductor. At 700 °C, its conductivity, σ, was measured at 5.1×10^{-3} S/cm while that at 900 °C was 1.2×10^{-1} S/cm. This one of the highest oxygen-ion transport conductivities measured for this type of compound. The structure is shown in the following diagram. In situ neutron and XRD experiments were used to determine the crystal structure of $Ba_2In_2O_5$ as related to temperature. $Ba_2In_2O_5$ has a Brownmillerite-type crystal structure from room temperature to 900 °C, consisting of an orthorhombic unit cell with lattice parameters $a = 6.0864(3)$, $b = 16.7903(7)$, $c = 5.9697(3)$ Å and *Icmm* (74) space group symmetry (Fig. 6.196).

At 900 °C, oxygen vacancies begin to disorder. By 925 °C, barium indate recrystallizes in a tetragonal, $a = 6.0348(4)$, $c = 17.0688(22)$ Å, unit cell with *I4cm* (108) space group symmetry. This oxygen vacancy order–disorder transition is associated with an evolution to fast oxide-ion conduction. At 1040 °C, $Ba_2In_2O_5$ becomes a cubic oxygen-deficient perovskite, $a = 4.2743$ Å, in the *Pm3m* space group. At 1080 °C, $Ba_2In_2O_5$ begins to decompose.

The oxygen and proton conductor $Ba_2In_2O_5$ is known to undergo a structural transformation in humid atmosphere at about 300 °C. The resulting phase, $Ba_2In_2O_5 \cdot H_2O$, was investigated by in situ high-temperature XRD. During the transformation, a transient structure existing near 320 °C in a narrow temperature interval is formed. $Ba_2In_2O_5 \cdot H_2O$ is stable from ≈300 °C down to room temperature and may be characterized by S.G. P4/mmm, No. 123, tetragonal, with $a = 4.1827$ Å, $b = 4.1827$ Å and $c = 8.9617$ Å. The atomic rearrangement during the transformation together with the change of the coordination of one-half of the In atoms from tetrahedral to octahedral symmetry reduces the unit-cell volume of $Ba_2In_2O_5 \cdot H_2O$ to one-quarter of the initial value. Linear thermal expansion coefficients of both phases show a strong anisotropy. The interactions among H_2O vapor, CO_2 and $Ba_2In_2O_5$ solid were investigated by thermogravimetry–mass spectroscopy (TG-MS) and XRD measurements. XRD revealed that the crystal structure of as-prepared $Ba_2In_2O_5$ was Brownmillerite-type orthorhombic. However, incorporation of H_2O and CO_2 into the specimen was also confirmed by TG-MS measurement. Weight decrease observed at around 100 and 300 °C in TG curve of as-prepared $Ba_2In_2O_5$ could be attributed to the secession of H_2O by using mass spectroscopy. It

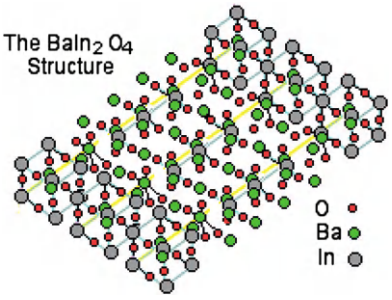

FIGURE 6.195

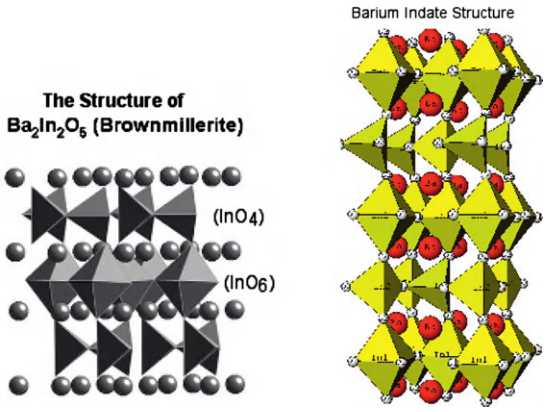

FIGURE 6.196

was suggested that H_2O adsorbed on the surface of the specimen was released at around 100 °C, whereas H_2O incorporated in the crystal was released from the specimen at around 300 °C. The weight of the specimen also decreased at around 700 °C, at which temperature CO_2 secession was confirmed. By annealing the specimen in humid Ar at 250 °C, the amount of H_2O incorporated in the crystal increased from $Ba_2In_2O_5 \cdot 0.34H_2O$ to $Ba_2In_2O_5 \cdot 0.98H_2O$ involving structural transformation from Brownmillerite-type orthorhombic system to tetragonal one other than Brownmillerite.

$Ba_2In_2O_5$ exhibits a dramatic increase in electrical conductivity as the "trapped" oxygen vacancies become partially disordered. On further heating, the vacancies become completely disordered so that the structure reverts to that of a highly defective cubic perovskite. The following diagram illustrates this factor (Fig. 6.197).

Oxygen Frenkel pairs were found to be the most energetically favorable intrinsic defects and are responsible for oxide ion conductivity in the orthorhombic structure. Formation energies of electronic species suggest that $Ba_2In_2O_5$ will oxidize readily to produce positive holes. Energies of proton incorporation reveal that $Ba_2In_2O_5$ should also exhibit reasonable proton conductivity in moist atmospheres.

Network of Oxygen Octahedra and Tetrahedra in $Ba_2In_2O_5$ Showing Interstitial Sites (Squares) and Crystallographically Distinct Oxygen Sites. Indium Ions sit at the Centers of the Octahedra and Tetrahedra, while the Larger Barium Cations Occupy the Open Spaces between the O(2) Ions.

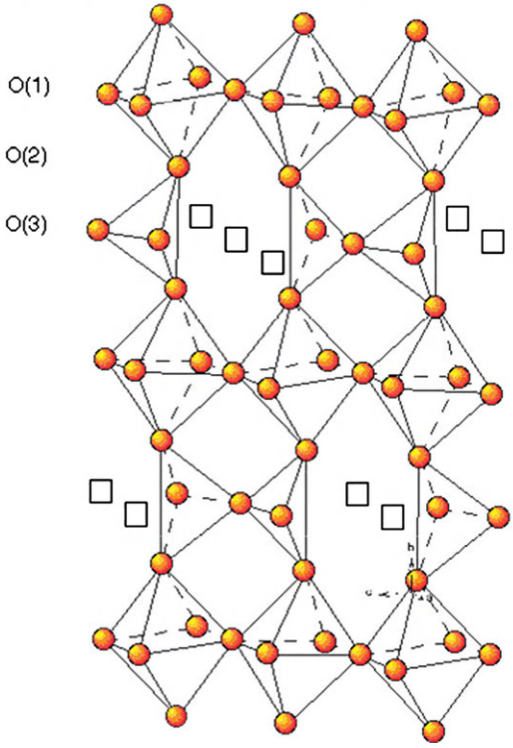

FIGURE 6.197

Attempts to stabilize the disordered phase at lower temperatures by selective doping of A and/or B sites have met with some success, but oxide ion conductivities are not significantly improved compared to fluorite-structured oxides such as YSZ.

In addition, $Ba_2In_2O_5$ has been reported to display both electronic conductivity under variable redox conditions [and proton conductivity due to water incorporation in its low temperature form].

A review of results of experimental studies of ionic conductivity in Brownmillerite and related oxides has been compiled by Kendall et al. The positions found is shown in the following Fig. 6.198.

The 3:1 compounds based on **tribarium indate**, (I) $Ba_2SrIn_2O_6$ and (II) $Sr_{0.93}Ba_{0.07}In_2O_4$, were prepared and investigated by single-crystal X-ray technique. I crystallizes with tetragonal symmetry, space group D–I4/mmm, $a = 4.168$; $c = 21.290$ Å; $Z = 2$; II belongs to the orthorhombic space group D–Pnma, $a = 9.858$; $b = 3.273$; $c = 11.520$ Å; $Z = 4$. I shows in respect to the formerly investigated compound $BaSr_2In_2O_6$ an unexpected statistically distribution of Ba^{2+} and Sr^{2+} with the $La_2SrCu_2O_6$ type. II marks the range of existence of the calcium ferrite type within the alkaline earth oxoindates in direction of large radii of M^{2+} ions.

The proton compounds $Ba_2In_{2(1-x)}Ti_{2x}O_{4+2x}(OH)_y$ $[0 \le x \le 1;\ y \le 2(1-x)]$ were prepared by reacting $Ba_2In_{2(1-x)}Ti_{2x}O_{5+x(1-x)}$ $(0 \le x \le 1)$ phases with water vapor at 200 °C. For $0 \le x \le 0.20$, the filling of oxygen vacancies by protons is almost complete. For larger x values, it decreases significantly down to 30% at $x = 0.7$. The crystal structure of the end-member $Ba_2In_2O_4(OH)_2$ $(x = 0)$ was reinvestigated by a combination of techniques including ^1H and ^2D NMR and electron, X-ray and neutron diffraction. The actual cell is eight

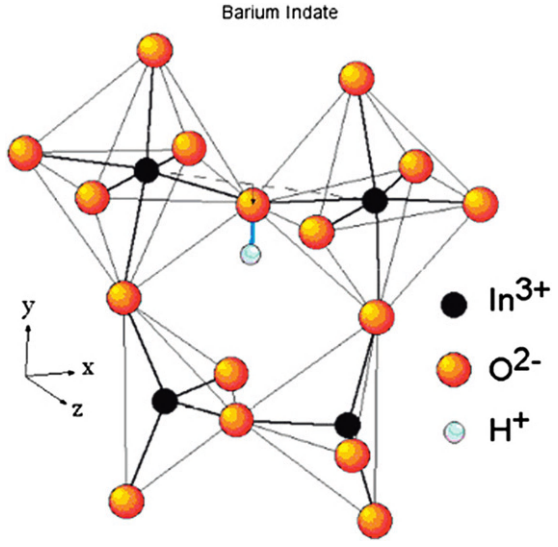

FIGURE 6.198

times larger than that previously published. The structure analysis confirms that the sheet consisting of parallel chains of $In(2)O_4$ tetrahedra and parallel rows of oxygen vacancies in the parent structure of $Ba_2In_2O_5$ has been converted into a $In(2)O_6$ octahedral perovskite-like sheet. It demonstrates that the protons are bonded only to the O atoms around this In(2) site. When x increases, the change in reduced perovskite cell volume, concomitant with the water uptake, remains small for $x < 0.25$ and negligible for larger x values.

The proton conductivity was measured between room temperature and 180 °C. The highest conductivity at 180 °C, $\sigma_{180} \approx 10^{-6}$ S/cm, is observed for $x = 0.3$.

The compound, **tetrabarium triïndate**, $Ba_4In_6O_{13}$, has had limited coverage in the open scientific literature. The crystal structure of $Ba_4In_6O_{13}$ was determined by the single-crystal XRD method using a single crystal grown by the floating zone method. $Ba_4In_6O_{13}$ is isostructural with $Sr_4Fe_6O_{13}$ and crystallizes in the noncentrosymmetric space group *Iba2* with the unit-cell parameters $a = 11.460(6)$, $b = 20.95(3)$, $c = 5.944(2)$ Å. The structure is classified as one of the perovskite derivatives consisted of $Ba_2In_2O_6$- and $Ba_2In_4O_7$-slabs arranged perpendicular to the *b*-axis, as shown in the following Fig. 6.199.

The In(3)-polyhedron in the perovskite-type $Ba_2In_2O_6$-slab is a distorted octahedron, whereas In(1)- and In(2) polyhedra in the $Ba_2In_4O_7$-slab are described as strongly distorted square pyramids. Each polyhedron of In(1) and In(2) shares edges with each other. The sharing scheme of the In(1) polyhedra is similar to the cases for V atoms in CaV_3O_7 and CaV_4O_9, whereas that of the In(2) polyhedra is uncommon.

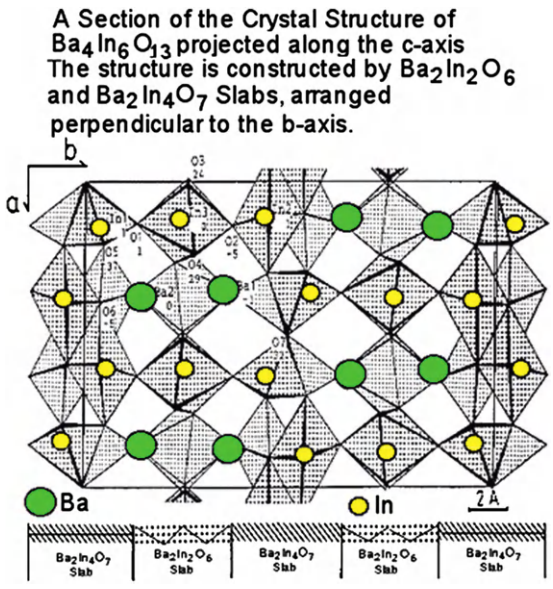

FIGURE 6.199

Although **penta-barium indate** ($Ba_5In_2O_8$) has been prepared, little work has been accomplished concerning its structure or usage either academically or industrially. It melts incongruently at 1410 °C.

Barium indates have no CAS numbers and are not available commercially.

Radium Indates

The scientific literature is lacking in any references to radium indates. Perhaps this is due to the intense radioactivity of the isomer ^{226}Ra but is more likely due to lack of interest of those in industry who may have usage of such compounds. It is anticipated that various radium indates could be prepared, using the same methods as those developed for the barium indate series of compounds. Thus, one would expect to be able to obtain:

$RaO \cdot In_2O_3$,
$3RaO \cdot In_2O_3$,
$5RaO \cdot In_2O_3$,
$2RaO \cdot In_2O_3$,
$3RaO \cdot 3In_2O_3$.

However, there is no record of such syntheses in the literature.

6.7. ALKALINE EARTH THALLIUM COMPOUNDS

The two main oxidation states of thallium are +1 and +3. In the oxidation state +1, most compounds closely resemble the K or Ag compounds. (The ionic radius of thallium(I) is 1.47 Å while that of potassium is 1.33 Å and that of silver is 1.26 Å.). For example, the water-soluble and very basic thallium(I) hydroxide reacts with CO_{2+} forming water-soluble thallium carbonate. This carbonate is the only water-soluble heavy metal carbonate known. The similarity with silver compounds is observed with the halide, oxide, and sulfide compounds. TlBr is a photosensitive yellow compound very similar to the AgBr, while the black TlO and TlS are very similar to AgO and AgS. Tl(I) does not form compounds with the alkaline earths. The compounds with oxidation state +3 resemble the aluminum(III) compounds. They are moderately strong oxidizing agents, as illustrated by the reduction potential of +0.72 V for $Tl^{3+} + 3\ e^- \Rightarrow Tl(s)$. Thallium(III) oxide is a black solid which decomposes above 800 °C, forming thallous(I) oxide and oxygen. In general, thallium is too electropositive to form oxy-thalium compounds in solution. However, for the Ca, Sr and Ba compounds, they can be prepared by solid-state methods.

Thallium also forms a series of intermetallic compounds with the alkaline earths.

6.7.1. Alkaline Earth Thallide Compounds

A series of crystalline compounds can be formed when the various alkaline earth metals are melted together with thallium metal. By varying the atomic ratios of the two components, specific compositions are attained.

Beryllium Thallides

Beryllium metal does not form any compounds with thallium metal. In contrast to the Be–In system where a phase diagram exists showing that Be and In for a solid solution of alloys, no phase diagram for the Be–Tl system exists. If such a diagram exists, it undoubtedly would appear as shown in Fig. 6.200.

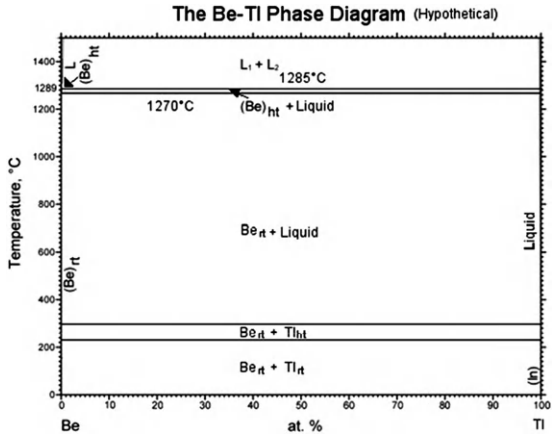

FIGURE 6.200

Magnesium Thallides

Mg metal forms a series of compounds as shown in the phase diagram for the Mg–Tl system (Fig. 6.201).

The crystal parameters are shown in Table 6.68.

Dimagnesium thallide, Mg_2Tl, has a unique crystal structure as shown in the following Fig. 6.202.

The cell parameters are: $a = 3.6796$ Å, $b = c = 8.0828$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 208.19$ Å^3, $Z = 4$. The cell occupancy is shown in Table 6.69.

Magnesium mono-thallide, MgTl, has the CsCl type of structure as shown in the following Fig. 6.203.

The cell parameters are: $a = b = c = 3.628$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 47.75$ Å^3 and $Z = 1$. The cell occupancy is shown in Table 6.70.

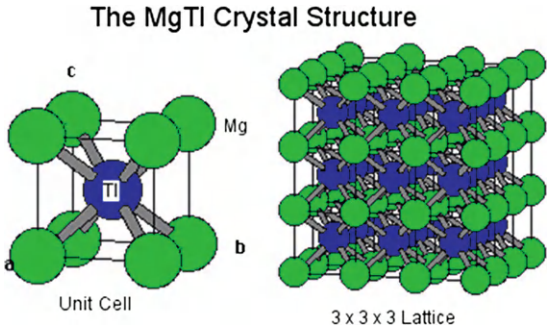

FIGURE 6.203

Penta-magnesium di-thallide, Mg_5Tl_2, has the structure shown in Fig. 6.204.

Cell parameters are: $a = 6.197$ Å, $b = 7.328$ Å, $c = 8.605$ Å, $\alpha = 115.202°$, $\beta = 111.11°$, $\gamma = 90°$, cell volume $= 324.35$ Å^3, $Z = 4$. Cell occupancy is shown in Table 6.71.

The compound, $Mg_{0.995}Tl_{0.005}$, has been found to have a hexagonal structure. Tl atoms are allowed to diffuse

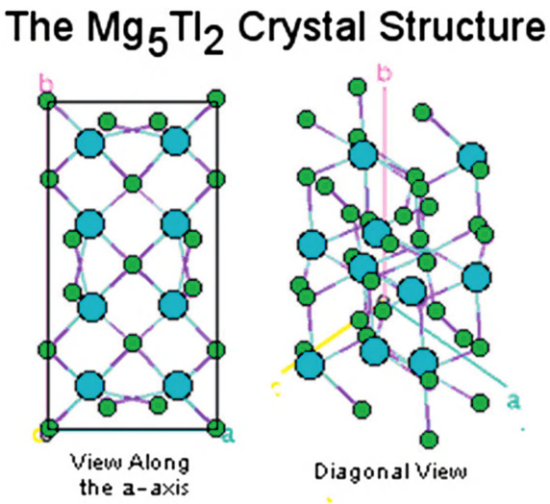

FIGURE 6.204

within the Mg metal structure to change the crystal lattice. A hypothetical structure is thought to consist of Fig. 6.205.

The larger Tl atom substitutes on a Mg atom site, changing the local structure. This mechanism has certain advantages in "hardening" of Mg alloys and is used in Mg metallurgy. The cell parameters are: $a = b = 3.2057$ Å, $c = 5.2122$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 46.93$ Å^3.

Magnesium thallides are not used in industry due, in part, to the toxicity of Tl metal in the human body. They are not available commercially.

Calcium Thallides

This series of compounds can be formed by melting the metals under an inert atmosphere. A series of compounds has been obtained as shown in the phase

TABLE 6.70

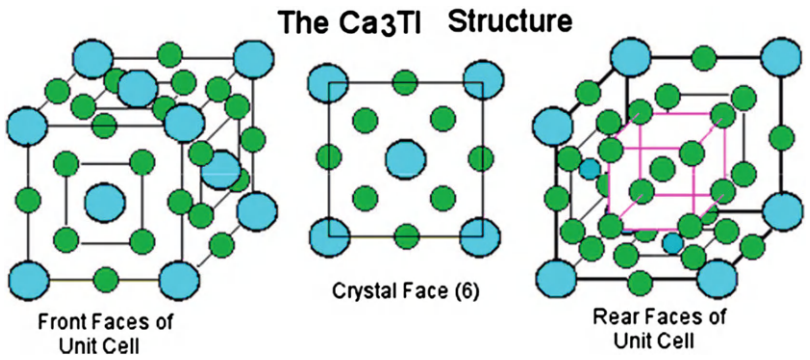

FIGURE 6.208

The structure is cubic and the cell parameters are: $a = b = c = 3.8522$ Å, $\alpha = \beta = \gamma = 90°$, $Z = 57.14$ Å^3, $Z = 1$. Site occupation of the atoms in the structure is shown in Table 6.72.

Tri-calcium thallide, Ca_3Tl, has the BiF_3 type of structure (Fig. 6.208).

The structure consists of Tl atoms at the corners of the unit cell with a face-centered configuration. There are Ca atoms are located in a tilted square at specific locations on any given face (of which there are six for a total of five per face). Many of the Tl atoms are hidden within the lattice. There is a body-centered configuration of nine Tl atoms within the unit cell. Site occupancy is shown in Table 6.73.

Cell parameters for this lattice are: $a = b = c = 5.5508$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 120.93$ Å^3, $Z = 10$.

Calcium tri-thallide, $CaTl_3$, has the lattice structure of the Cu_3Au type of crystal (Fig. 6.209).

This structure is identical to that of $MgIn_3$. The structure is a face-centered cubic with cell parameters of: $a = b = c = 4.803$ Å, $\alpha = \beta = \gamma = 90°$, cell volume is 110.80 Å^3 (Site occupation is shown in Table 6.74).

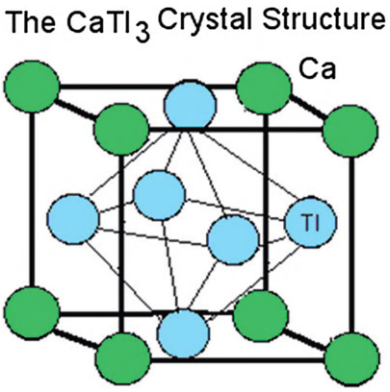

FIGURE 6.209

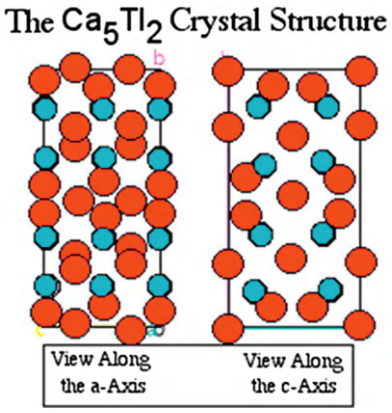

FIGURE 6.210

The compound, **penta-calcium di-thallide**, Ca_5Tl_2, is known to have the Mg_5Ga_2 structure as shown in the following Fig. 6.210.

This structure contains a number of Ca atoms that lie within the center of the lattice. The structure has not been finalized and no lattice parameters are available. Site occupancy is shown in Table 6.75.

Tri-calcium tetra-thallide, Ca_3Tl_4, is almost unknown. Very little data are available for this compound and its discovery was not assessed by determination of its crystal structure. The following is a description of the manner of its discovery:

"When Tl metal was melted and Ca metal added to the melt, a small series of crystals separated. Then, the compound, $CaTl_3$, was formed (deduced by the prolongation of the eutectic at 310 °C). Further addition of Ca metal causes the intermediate melt temperature to rise until 556 °C is reached where Ca_3Tl_4 is formed as crystals at 43.7 atom% Ca. Further addition of Ca metal causes the intermediate melt temperature to rise to 969 °C where the compound CaTl is dominant".

All of these alloys are unstable in air. It is this fact that no usage has arisen for any of the compounds established in the Ca–Tl system. No CAS numbers have been issued. They are not available commercially.

Strontium Thallides

Strontium thallides can be formed by melting the metals together under an inert atmosphere. A series of compounds can be formed by varying the atom ratios in the original melt as shown in the following phase diagram of Fig. 6.211.

At least six compounds are known. Strontium thallides resemble those of the Ca analogues but also form 5:3, 2:3 and 1:2 compounds.

The structure parameters are shown in Table 6.76.

Strontium mono-thallide, SrTl, has the CsCl structure as shown in the following Fig. 6.212.

It is body centered with the Tl atom at the center of the lattice. Cell occupancy is shown in Table 6.77.

Lattice parameters are: $a = b = c = 4.038$ Å and $\alpha = \beta = \gamma = 90°$, cell volume = 65.48 Å^3.

Tri-strontium thallide, Sr_3Tl, has the structure shown in the following diagram. Cell parameters are: $a = 5.771$ Å, $b = 8.073$ Å, $c = 23.723$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 110.524 Å^3 (Fig. 6.213).

This structure is almost identical to its homologue, Ca_3Tl, except for the lengths of the lattice parameters. Cell occupancy is shown in Table 6.78.

Strontium tri-thallide, $SrTl_3$, has the face-centered cubic type of structure as shown in the following Fig. 6.214.

Cell parameters are: $a = b = c = 4.992$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 115.43 Å^3. Cell occupation is shown in Table 6.79.

Penta-strontium tri-thallide, Sr_5Tl_3, has the Mg_5In_2 structure and the lattice parameters of: $a = 8.635$ Å, $c = 10.210$ Å, $\alpha = \beta = 114.99°$, $\gamma = 90$ °, cell

volume = 611.01 Å^3, $Z = 4$. It is a Zintl structure with Tl–Tl dumbbells predominating in the structure. Each face of the *a*-axis and *c*-axis consists of alternating Sr and Tl atoms and the opposite end faces have a distinctive arrangement of atoms (Fig. 6.215).

Strontium di-thallide, $SrTl_2$, has the structure shown in Fig. 6.216.

It is tetragonal with cell parameters of: $a = b =$ 5.076 Å, $c = 8.231$ Å, $\alpha = \beta = 90°$, $c = 120°$, $Z = 2$, cell volume = 183.26 Å^3. Cell occupancy is shown in Table 6.80.

The compounds, Ca_3Tl_5 (**III**), and Sr_3Tl_5 (**IV**), have been obtained by direct fusion of the elements in sealed

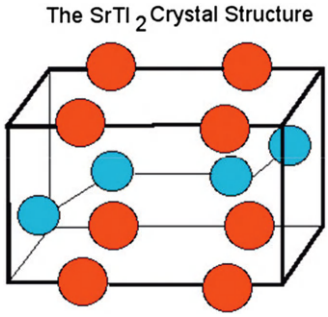

FIGURE 6.216

Nb ampoules at high temperature. Their structures were determined by single-crystal X-ray diffraction studies and the bonding was investigated by *TB–LMTO–ASA* calculations. These binary compounds **III** and **IV** crystallize in the Pu3Pd5-structure type; space group *Cmcm* (No. 63); $Z = 4$ with $a = 10.231(2)$, $b = 8.362(2)$, $c = 10.623(2)$ Å for **III** and $a = 10.592(5)$, $b = 8.667(5)$, $c = 10.973(6)$ Å for **IV**. The structure is shown in the following Fig. 6.217.

Both structure types consist of zigzag chains of distorted square pyramidal clusters, Tl_5^{6-}. In the these structures, the clusters are aligned parallel and show a considerably high degree of polymerization. The electronic band structure for Sr_3Tl_5 and Ca_3Tl_5 show metallic properties and strong participation of the cations in the bonding.

Strontium thallides have not found a usage in industry due, in part, to the toxicity of Tl metal in the human body. No CAS numbers has been assigned. They are not available commercially.

Barium Thallides

Barium forms a series of thallide compounds with Tl as shown in the following phase Fig. 6.218.

Six compounds are seen when the atom ratio of Ba:Tl is varied 13:1, 2:1, 1:1, 1:2, 1:3, and 1:4. The structure factors are partially known (Table 6.81).

Barium tri-thallide, $BaTl_3$, has the structure shown in Fig. 6.219.

This compound was synthesized and characterized by physical property measurements and electronic structure calculations. Its structure (Cmcm) is a new intermediate in the Ni_3Sn family (P63/mmc), and consists of thallium layers formed from two-center bond formation between the parallel chains of face-sharing octahedral clusters. The valence electron concentration (VEC) of the thallium layers is consistent with their two-dimensional nature, in comparison with those in other AX_3-type compounds with one- or three-dimensional anionic networks with the same building blocks and different VECs. The unique geometric features of the anionic thallium layers bring on an unusual competition between inter- and intra-cluster bonds. Detailed studies of the energetics of $BaTl_3$ reveal for the first time the important role of cation–anion interactions in the bonding competition in such an anionic substructure.

Barium di-thallide, $BaTl_2$, has the tetragonal structure shown in Fig. 6.220.

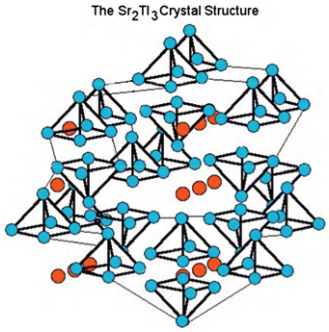

FIGURE 6.217

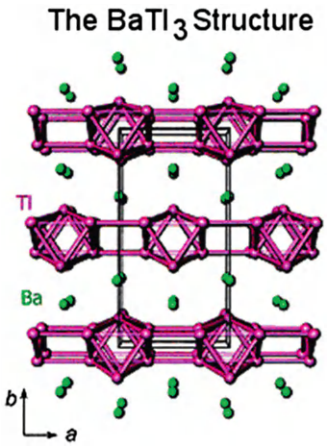

FIGURE 6.219

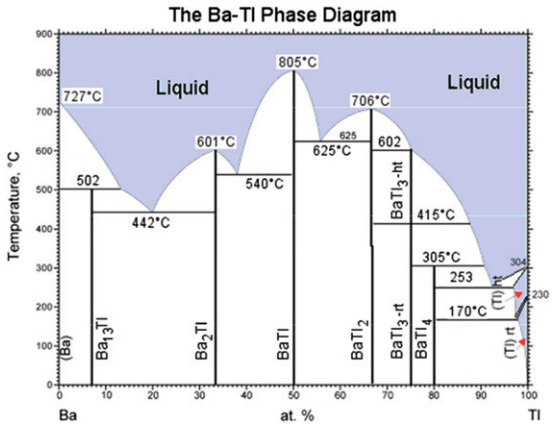

FIGURE 6.218

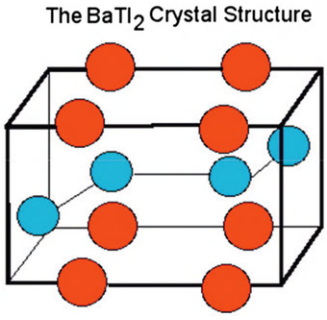

FIGURE 6.220

This is identical to $SrTl_2$ compound except for lattice parameters: $a = b = 5.217$ Å, $\alpha = \beta = 90°$, $c = 120°$, cell volume = 198.82 Å^3. Cell occupancy is shown in Table 6.82.

Barium tetra-thallide, $BaTl_4$, has the following structure shown in Fig. 6.221.

The synthesis and bonding of $BaTl_4$ can be described as: space group = C2/m, $Z = 4$, $a = 12.408$, $b = 5.351$, $c = 10.383$ Å, $\beta = 116.00°$. Pairs of edge-sharing Tl pentagons are condensed to generate a network of pentagonal biprisms along b that encapsulate Ba atoms. Alternating levels of prisms along c afford six more bifunctional Tl atoms about the waists of the biprisms, giving Ba a coordination number of 16. Each Tl atom is bonded to five to seven other Tl atoms and to three to five Ba atoms. There is also strong evidence that Hg substitutes preferentially in the shared edges of the Tl biprisms in $BaHg_{0.8}0Tl_{3.20}$ to generate more strongly bound Hg_2 dimers. Cations that are too small relative to the dimensions of the surrounding polyanionic network make this $BaTl_4$ structure (and for $SrIn_4$ and perhaps $EuIn_4$ as well) one stable alternative to tetragonal $BaAl_4$-type structures in which cations are bound in larger hexagon-faced nets, as for $BaIn_4$ and $SrGa_4$. Characteristic condensation and augmentation of cation-centered prismatic units are common among many relatively cation- and electron-poor, polar derivatives of Zintl phases gain stability. At the other extreme, the large family of Frank–Kasper phases in which the elements exhibit larger numbers of bonded neighbors are sometimes referred to as "orbitally rich".

Barium mono-thallide has the structure (Fig. 6.222).

Lattice parameters are: $a = b = c = 4.341$ Å and $\alpha = \beta = \gamma = 90°$, cell volume = 81.82 Å^3. Site occupancy is shown in Table 6.83.

Di-barium thallide, Ba_2In, is known from phase diagram surveys but has not been studied extensively as to structure. Both Ca and Sr do not form such compounds and the existence of Ba_2Tl remains uncertain.

The major usage of Ba, combined with Tl, has been in the formation of superconducting compounds. A general formula is $Tl_2Ba_2CuO_6$, whose critical temperature, T_c, is 82 K. The formula, $Tl_2Ba_2Ca_2Cu_3O_{10}$, has a T_c of 122 K, one of the highest known for these "high-temperature" superconductors.

Superconducting materials conduct electricity with little or no resistance. Apart from the potential use of such materials in applications such as magnetic propulsion and the storage of magnetic energy, being able to distribute energy along power lines without energy loss through resistance is one of the holy grails of efficient power transmission. Since 1986, when the superconductivity of lanthanum–barium–copper oxide at

35 K (−396.67 F) was discovered by Bednorz and Müller, research has continued in the development of HTS materials, particularly in places like Oak Ridge National Laboratory, as part of the U.S. Department of Energy's national effort on HTS' electrical power applications. In 1993, researchers discovered the superconductivity of thallium-doped mercury-barium-calcium-copper oxide at the even higher temperature of 138 K (−211.27 F), a temperature higher even than that for the compound thallium-barium-calcium-copper oxide.

HTS materials are now used in electronic filters for cell phones and in a few superconductor power cables.

In summary, thallium metal forms a number of compounds with the alkaline earths. The atom ratios vary with the nature of the Ae atom and its atomic radius, as shown in the following Table 6.84.

Radium Thallides

The scientific literature is lacking in any references to radium thallides. Perhaps this is due to the intense radioactivity of the isomer ^{226}Ra but is more likely due to lack of interest of those in industry who may have usage of such compounds. It is anticipated that various radium thallides could be prepared, using the same methods as those developed for the barium thallide series of compounds. Thus, one would expect to be able to obtain:

Ra·Tl
3Ra·Tl
5Ra·Tl
2Ra Tl
3Ra·2Tl

However, there is no record of such syntheses in the literature.

6.7.2. Alkaline Earth Thallates

Thallium forms a number of oxygen-dominated compounds with certain of the alkaline earths. The exceptions are beryllium and magnesium.

Beryllium Thallates

A perusal of the literature reveals that no references to beryllium thallates exist. There are no reports of the properties of such compounds or that any beryllium thallate compounds exist. No CAS numbers exist. It is likely that the system BeO–Tl_2O_3 has never been studied in any detail. Both of these elements are harmful and poisonous to the human body and no incentive to discover the properties of such compounds exists.

Magnesium Thallates

Although it might appear, at first glance, that magnesium thallate could be prepared by the reaction of the oxides:

$$MgO + Tl_2O_3 + \text{heat} \Rightarrow MgTl_2O_4$$

However, there are no reports of the properties of this compound or of any other magnesium thallate compounds. No CAS numbers exist. It is likely that the system MgO–In_2O_3 has never been studied in any detail. This is surprising since CaO, SrO and BaO form a number of compounds with Tl_2O_3. One concludes that, in view of the large ionic size of Tl^{3+} in thallate anions, the Mg^{2+} cation is too small to form stable compounds. A search of the available scientific literature concerning the various 1:1, 1:2, 2:1 MgO/Tl_2O_3, etc compounds revealed that a description does not exist. Therefore, one concludes that no such compounds can be formed.

TABLE 6.84

13:1	—	—	—	—	X

The trends, already described above, that certain compositions do not form, because of size prohibitions in stable crystal lattices, is carried out here where no beryllium gallate is stable but one magnesium **gallate** can be formed (five gallates in the CaO–, SrO–, and $BaO–Ga_2O_3$ systems) as compared to the thallate system, $MO–Tl_2O_3$, where no BeO– or $MgO–Tl_2O_3$ compounds have been obtained or characterized.

Calcium Thallates

The phases present in the Tl_2O_3–CaO system have been synthesized and characterized using powder neutron diffraction data. The structures of the phases known to exist in the $Ca_nTl_2O_{3+n}$ system with n =1, 1.5, 2 and 3 have been refined and the oxycarbonate phase with composition $Ca_4Tl_2O_6CO_3$ has been identified. Four compounds are found in the phase Fig. 6.223.

The only stable compound with a congruent melting point is $Ca_3Tl_2O_6$ (3:1). The others, $Ca_2Tl_2O_5$ (2:1), $Ca_3Tl_4O_9$ (3:2), and $CaTl_2O_4$ (1:1) all have incongruent melting points and decompose to the oxides.

The $Ca_nTl_2O_{3+n}$ phases with $n = 1$ or 3 are related to the lillianite structure while the $n = 2$ compound is an oxycarbonate that has been found to crystallize in $I4/mmm$ symmetry for M = Ca. The relationships between these structures have been discussed and comparisons were made to the previously published structures determined from X-ray powder diffraction data.

The structure of **tri-calcium thallate**, $Ca_3Tl_2O_6$, is shown in the following diagram. It consists of alternating chains of TlO_6 octahedra which form channels in which the Ca^{2+} cations reside. Two layers of chains are shown but not all of the oxygen atoms are visible. The structure consists of Tl_6^{6-} octahedra in which Ca^{2+} ions fit into channels between the thallate groupings (Fig. 6.224).

The salt, tricalcium thallate, $Ca_3Tl_2O_6$ (3:1) has been found to crystallize in the space group *Pbam* with

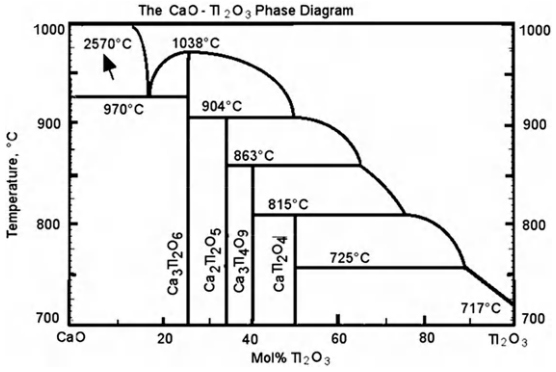

FIGURE 6.223

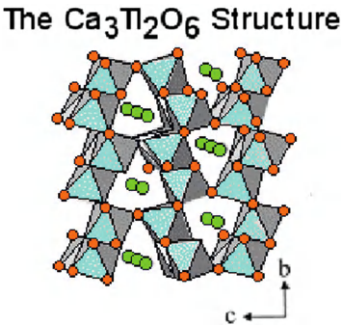

FIGURE 6.224

$a = 11.248$ Å, $b = 16.513$ Å, and $c = 3.333$ Å. The ab initio determination of its structure from powder X-ray data shows that it consists of zigzag rock salt-type layers $[Ca_4Tl_4O_{14}]_\infty$ parallel to (010), built up from quadruple ribbons of TlO_6 octahedra running along c, interconnected with single and double ribbons of CaO_6 octahedra. Along b, these rock salt-type layers share the corners of their octahedra forming tunnels approximately similar to those observed in $CaTi_2O_4$, where calcium ions are located with a monocapped trigonal prismatic coordination. This oxide represents the third member of the series $CanTl_2On_{+3}$; its relationships with the two $n = 1$ and 2 members $CaTl_2O_4$ and $Ca_2Tl_2O_5$, that correspond to a chemical twinning of the rock salt structure, are discussed. In fact, $Ca_3Tl_2O_6$ is isostructural with $Ca_3In_2O_6$.

A **tricalcium dithallate**, $Ca_3Tl_4O_9$ (3:2) has been isolated. It crystallizes in a monoclinic cell, space group $C2/m$, with $a = 11.118(3)$ Å, $b = 3.341(1)$ Å, $c = 12.287(3)$ Å, and $\gamma = 102.88(2)°$. The ab initio determination of this structure shows that it consists of a regular intergrowth of the first two members of the calcium thallate family $CanTl_2O_{3+n}$: $CaTl_2O_4$ ($n = 1$) and $Ca_2Tl_2O_5$ ($n = 2$). Intergrowth defects have been characterized by electron microscopy. Among all oxides and sulfides that belong to the lillianite family, $Ca_3Tl_4O_9$ is the only one that exhibits the ^{2,3}L structure, i.e. where layers are built up from ribbons of two and three edge-sharing octahedra alternately. The ab initio determination of this structure shows that it consists of a regular intergrowth of the first two members of the calcium thallate family $CanTl_2O_{3+n}$: $CaTl_2O_4$ ($n = 1$) and $Ca_2Tl_2O_5$ ($n = 2$). Intergrowth defects have been characterized by electron microscopy. Among all oxides and sulfides that belong to the lillianite family, $Ca_3Tl_4O_9$ is the only one that exhibits the ^{2,3}L structure, i.e. where layers are built up from ribbons of two and three edge-sharing octahedra alternately.

Two calcium thallates, $CaTl_2O_4$ and $Ca_2Tl_2O_5$, i.e. (1:1 and 2:1) have been isolated that crystallize in the *Cmcm* space group with $a = 3.3255$ Å, $b = 11.022$ Å,

and $c = 10.479$ Å for the first and $a = 3.3431$ Å, $b = 11.159$ Å, and $c = 13.499$ Å for the second. The ab initio determination of their structure from powder X-ray data shows that they are closely related and that they represent the first two members of a series with the generic formula $Can Tl_2O_{n+3}$. In fact, the first member, $CaTl_2O_4$, is isotypic to $CaTi_2O_4$ and can be described as a chemical twin of $[Tl_2O_4]_\infty$ rock salt layers, whereas the second member, $Ca_2Tl_2O_5$, is derived from the first by increasing the thickness of the rock salt layers, i.e. by replacing double ribbons of edge-sharing octahedra by triple ribbons. In both structures, the chemical twinning is induced by the ability of calcium to adopt the trigonal prismatic coordination in prismatic tunnels; the direction of rock salt layer is invariable, i.e. parallel to the (113) plane of the cubic rock salt structure.

No calcium thallates have found usage in industry and no CAS numbers have been issued.

Strontium Thallates

The reaction of SrO with Tl_2O_3 is expected to form strontium mono-thallate:

$$SrO + Tl_2O_3 + \text{heat} \Rightarrow SrTl_2O_4$$

In the $Sr_nTl_2O_{3+n}$ system, the structures of the phases with $n = 1$, 2 and 3 have also been refined. Three different modifications have been found with space groups $P4/mmm$, $I4/mmm$ and $Pmmm$ for M = Sr, depending on the ordering of the thallium groups. However, a detailed phase diagram for the SrO–Tl_2O_3 system is not available.

The crystal structure of the **strontium mono-thallate**, $SrTl_2O_4$, has been determined using powder XRD. This oxide is isostructural with $CaFe_2O_4$, i.e. it crystallizes in the space group Pnam with $a = 10.041$ Å, $b = 11.697$ Å and $c = 3.409$ Å (Fig. 6.225).

The $[Tl_2O_4]\infty$ framework is built up from double rutile chains of TlO_6 octahedra forming five-sided tunnels where the strontium cations are located. The semimetallic properties of this phase are once more in favor of the existence of a proximity effect-induced superconductivity in the $[TlO]\infty$ layers of layered thallium cuprates.

A new thallium oxide and strontium compound, **di-strontium thallate**, was prepared by direct interaction in the solid state of SrO with Tl_2O_3 at 900 ° C. Its composition, $Sr_2Tl_2O_5$, was determined by combining chemical analysis and physical methods. The microscopic studies and XRD show that the symmetry of the lattice is orthorhombic with the parameters: $a = 3.502$ (2) Å, $b = 11.506$ (9) Å, $c = 13.798$ (9) Å. Three space groups are compatible with the results: $CMC2_1$, Cc2m, or Cmcm.

The compound, **tetra-strontium thallate**, $Sr_4Tl_2O_7$, was prepared and investigated by X-ray single-crystal methods. $Sr_4Tl_2O_7$ crystallizes in the tetragonal space group $CP4_2nm$ ($a = 5.006$, $c = 18.73$ Å). Sr^{2+} has a trigonal prismatic surrounding whereas Tl^{3+} shows 2 + 2 oxygen neighbors. The crystal structure is completely described as a tetragonal lattice. The golden yellow $Sr_4Tl_2O_7$ appears to be an insulator.

The system, SrO–Tl_2O_3, has not been thoroughly studied as evidenced by lack of a reliable phase diagram. Mention of several compounds has been available in the literature but structure reports are not widely available.

Strontium thallates are not available commercially, due in part to the toxic nature of thallium in the human body.

Barium Thallates

Thallium oxide, Tl_2O_3, forms several compounds with BaO as may be seen in the phase diagram for this system that is shown in Fig. 6.226.

FIGURE 6.225

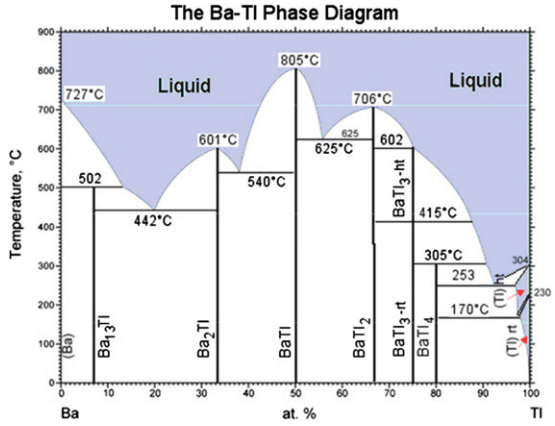

FIGURE 6.226

TABLE 6.85

Cell parameters				
Compound	**Crystal**	***a***	***b***	***c***
$BaTl_2O_4$	Orthorhombic	10.45	11.93	3.476
$Ba_4Tl_6O_{13}$	Orthorhombic	5.748	7.164	9.572
$Ba_2Tl_2O_5$	Orthorhombic	6.264	17.258	6.05
$Ba_4Tl_2O_7$	Tetragonal	5.33		23.04

Crystal cell parameters for this system are given in the Table 6.85.

The 1:1 compound melts incongruently at 840 °C as does the 4:3 compound at 865 °C and the 4:1 compound at 1050 °C. Only the 2:1 compound melts congruently at 1110 °C.

Di-barium thallate, $Ba_2Tl_2O_5$, has been investigated by a combination of XRD, electron diffraction, and energy dispersive X-ray spectroscopy. A monoclinic unit cell was observed with $a = 5.836$, $b = 6.226$, $c = 17.342$ Å, and $\gamma = 91.34°$, cell volume = 651.02 Å^3. The impurity phase coexisting with $Ba_2Tl_2O_5$ was determined to be $Ba_4Tl_6O_{13}$, having an orthorhombic unit cell with $a = 5.748$, $b = 7.221$, and $c = 9.361$ Å.

The structure may be represented by Fig. 6.227.

An oxygen-deficient perovskite, **di-barium thallate**, $Ba_2Tl_2O_{5-x}$, was successfully prepared by a SSR technique. Orthorhombic unit-cell dimensions refined from a powder diffraction pattern are $a = 6.257 \pm 0.0001$, $b = 6.038 \pm 0.0001$, and $c = 17.232 \pm 0.0003$ Å, $\alpha = \beta = \gamma = 90$ °, cell volume = 651.02 Å^3, Pearson symbol = oP36, space group = Pnma.

The perovskite, $Ba_2Tl_2O_5$, was found to be a semiconductor. $Ba_2Tl_2O_5$ was reinvestigated by a combination of XRD, electron diffraction, and energy dispersive X-ray spectroscopy. A new monoclinic unit cell was observed with $a = 5.736$, $b = 6.126$, $c = 17.342$ Å, and $\gamma = 91.34°$. The impurity phase coexisting with $Ba_2Tl_2O_{5-x}$ was determined to be **tetra-barium tri-thallate**, $Ba_4Tl_6O_{13}$, having an orthorhombic unit cell with $a = 5.748$, $b = 7.221$, and $c = 9.361$ Å. The possible mechanism of solid–solid reaction of Ba, Tl oxides was discussed.

The structure of barium monothallate has been determined as shown in the following Fig. 6.228.

In another paper, the same two perovskite-related phases in the Tl_2O_3–BaO system have been synthesized and investigated by X-ray powder diffraction and high-resolution electron microscopy. A solid solution phase was found to exists with the compositions between $BaTl_2O_4$ and $Ba_4Tl_{10}O_{19}$. The typical composition, $Ba_6Tl_{14}O_{27}$, has an orthorhombic unit cell with $a = 17.724$, $b = 6.890$, and $c = 10.235$ Å. The compound $Ba_2Tl_{10}O_{17}$ has a $1 \times 3.5 \times 1$ superstructure derived from the $Ba_6Tl_{14}O_{27}$ phase, being also orthorhombic with unit-cell dimensions of $a = 17.676$, $b = 24.167$, and $c = 10.110$ Å. The relationships between both these new structures, the recently discovered $Ba_4Tl_6O_{13}$ and the perovskite-like basic structures, are discussed. Cell parameters for this composition were found to be: $a = 5.748$ Å, $b = 7.221$ Å, $c = 9/361$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 388.54 Å^3.

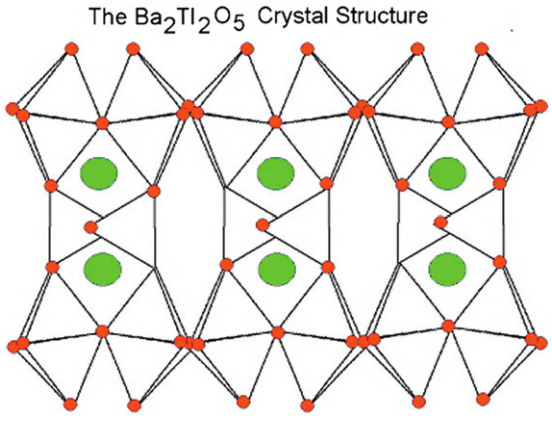

FIGURE 6.227

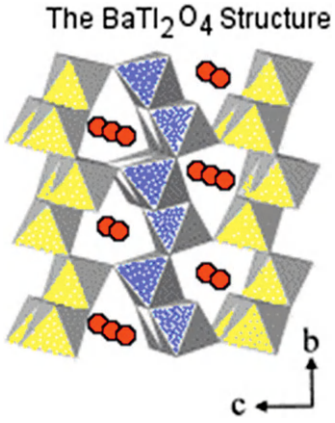

FIGURE 6.228

Barium thallates have not found any uses in industry and are not available commercially. No CAS numbers have been issued, due in part to the toxic nature of thallium in the human body.

Radium Thallates

The scientific literature is lacking in any references to radium thallates. Perhaps this is due to the intense radioactivity of the isomer ^{226}Ra but is more likely due to lack of interest of those in industry who may have usage of such compounds. It is anticipated that various radium thallates could be prepared, using the same methods as those developed for the barium thallate series of compounds. Thus, one would expect to be able to obtain:

$RaO \cdot Tl_2O_3$,
$3RaO\ Tl_2O_3$,
$5RaO \cdot Tl_2O_3$,
$2RaO\ Tl_2O_3$,
$3RaO \cdot 3Tl_2O_3$.

However, there is no record of such syntheses in the present literature.

Group 3 (Sc, Y, and La) Alkaline Earth Compounds

OUTLINE

7.1. Group 3 Transition Metals and Alkaline Earth Compounds **637**
7.1.1. Alkaline Earth—Scandium Compounds 638
Beryllium—Scandium System 638
Magnesium—Scandium System 639
Calcium—Scandium System 640
Strontium—Scandium System 641
Barium—Scandium System 641
Radium—Scandium System 643
7.1.2. Alkaline Earth—Yttrium Compounds 643
Beryllium—Yttrium System 643
Magnesium—Yttrium Compounds 643
Calcium—Yttrium Compounds 645
Strontium—Yttrium Compounds 649
Barium—Yttrium Compounds 650
Radium—Yttrium Compounds 652
7.1.3. Alkaline Earth—Rare Earth Compounds 652

7.1. GROUP 3 TRANSITION METALS AND ALKALINE EARTH COMPOUNDS

This is the first chapter in which the compounds formed from the d-shell elements and the alkaline earths are described. More specifically, these elements involve d-electron shells that are not filled. We have already described the compounds formed from Groups 13 to 17 (Periods 2 to 6) that contain p-electron shells and possess a degree of electronegativity. The modern IUPAC definition of such transition elements states that a transition metal is "an element whose atom has an incomplete d subshell, or which can give rise to cations with an incomplete d subshell". Thus, Group 12 elements within this definition are not transition metals within this definition. All elements in the d-block are metals. Y, Sc and La do not easily form compounds like "yttrides or yttrates $[YO_n^{(2n-1)-}]^{n-}$" because they exhibit significant electropositive characteristics, i.e. they are too metallic. This includes the Lanthanides and Actinides. The number of compounds formed are few and far between as shown in the following table:

Be^{2+}	Mg^{2+}	Ca^{2+}	Sr^{2+}	Ba^{2+}
-	$MgSc_2O_4$	$CaSc_2O_4$	$SrSc_2O_4$	$Ba_3Sc_4O_9$
Y_2BeO	-	$Ca_3Y_2O_6$	SrY_2O_4	$Ba_3Y_4O_9$
$La_2Be_2O_5$	-	-	$Sr_3La_4O_9$	$BaLa_2O_4$
-	-	$CaGd_4O_7$	-	$BaGd_2O_4$
-	-	$Ca_3Yb_2O_6$	-	-
-	-	$CaLu_2O_4$	-	$Ba_3Lu_4O_9$

Note that only the larger of the alkaline earths form a series of compounds. Such compounds cannot be considered as a "barium scandate" nor as a "scandium barate", since the actual composition is a mixed oxide solid-solution arrangement, i.e. $BaO{\cdot}Sc_2O_3$. Thus, the occurrence of compounds in the system $BaO–Sc_2O_3$ has not been thoroughly investigated. It is for this reason that this chapter is short. Although lanthanides (represented by La here) do form a series of compounds, including mixed lanthanide compounds, we will not describe them here because they are not truly relevant to the intent of this book.

Encyclopedia of the Alkaline Earth Compounds

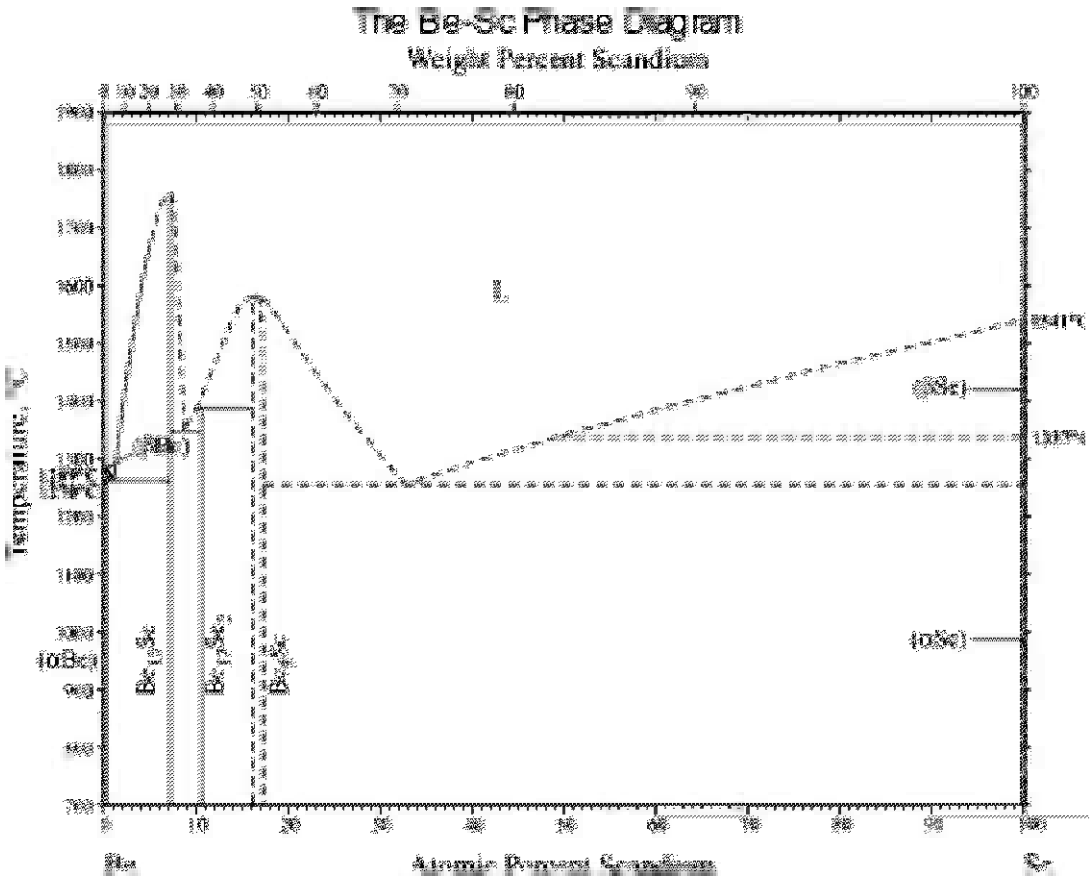

FIGURE 7.1

7.1.1. Alkaline Earth—Scandium Compounds

Since scandium is more expensive than gold, lack of data generated by Academia or Industry perhaps accounts for the scarcity of information concerning these compounds.

The phase diagrams of the **intermetallic** series, Ae–Sc (where Ae is one of the alkaline earths) have been studied. Excluding Be, only one compound is known in this series, that of MgSc. All of the other phase diagrams exhibit a continuous intermetallic solid solution and the larger alkaline earths, when combined with Sc metal, melt to form two liquids. Thus, the only significant feature is that of the polymorphic changes of the alkaline earths, i.e. $\alpha\text{-Ae}_0 \Rightarrow \beta\text{-Ae}_0 \Rightarrow \gamma\text{-Ae}_0$ (where Ae represents any or all of the alkaline earths). It is for this reason that the phase diagrams, in general, are not presented here.

Beryllium–Scandium System

The system, Be^0–Sc^0, forms a few intermetallic compounds, as shown in Fig. 7.1

These intermetallic compounds have the following structural characteristics, shown as follows. Very little data concerning beryllium–scandium compounds have appeared in the technical literature until about 2008 when this data became available (Fig. 7.2).

Be-Sc Crystal Structure Data

Phase	Composition, at % Sc	Point Group	Space Group	Structure Prototype
β Be	0	c/2	Im3m	W
α Be	0	hP2	$P6_1/mmc$	Mg
$Be_{13}Sc$	7.2	cF12	Fm-3c	$NaZn_{7.2}$
$Be_{17}Sc_2$	16.5	hP38 hP19	$P6_1/mmc$ R3m	$Ni_{17}Th_2$ Th_2Zn_{17}
Be_5Sc	16.7	hP6	$P6_1/mmc$	CaCu5
β Sc	100	c/2	Im3m	W
α Sc	100	hP2	$P6_1/mmc$	Mg

FIGURE 7.2

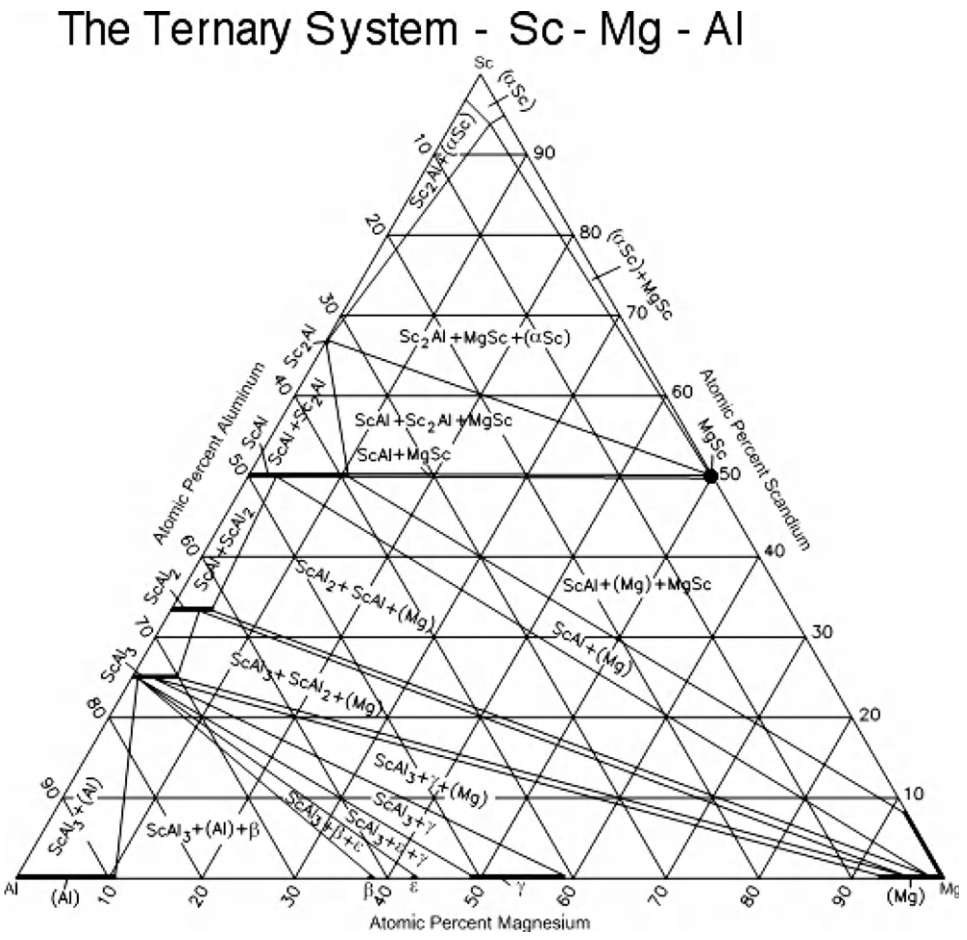

FIGURE 7.3

The oxy-system, $BeO \cdot Sc_2O_3$, does not form any compounds.

There are no uses that have appeared in the Industry and none of these compounds appear to be destined for further consideration.

Magnesium–Scandium System

The intermetallic system, Mg·Sc, has been studied. Whereas, Sc forms many compounds with the metal, Al, it only forms one as shown in the ternary system (Mg-Sc-Al) of Fig. 7.3.

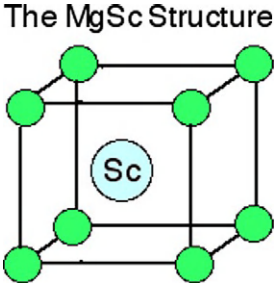

FIGURE 7.4

The one compound, MgSc, has the cubic CsCl structure with $a = 3.436$ Å. It is a body-centered structure with a cell volume of 40.57 Å^3. The Sc atom is located at (1/2/,1/2,1/2) in the unit cell as shown in Fig. 7.4.

It is a body-centered structure with a cell volume of 40.57 Å^3.

The only known binary system is shown in Fig. 7.5. The same compound, MgSc is indicated but the scope and width of the peritectics remain questionable. However, the eutectic points are clearly visible.

As of this date, no complete phase diagram of the system, $MgO–Sc_2O_3$, has been created. The Sc_2O_3–MgO system has been partially studied and found to consist of one liquid and two solid solutions. A relatively simple approach was used to model the solution phases, which were treated as the regular and the subregular solutions of the end-members. The solution parameters were derived from the phase equilibrium data. The thermodynamic calculations using the model allowed the determination of the liquidus, solidus, solvus, and metastable liquid miscibility gaps. Also the lattice stabilities of the components were evaluated.

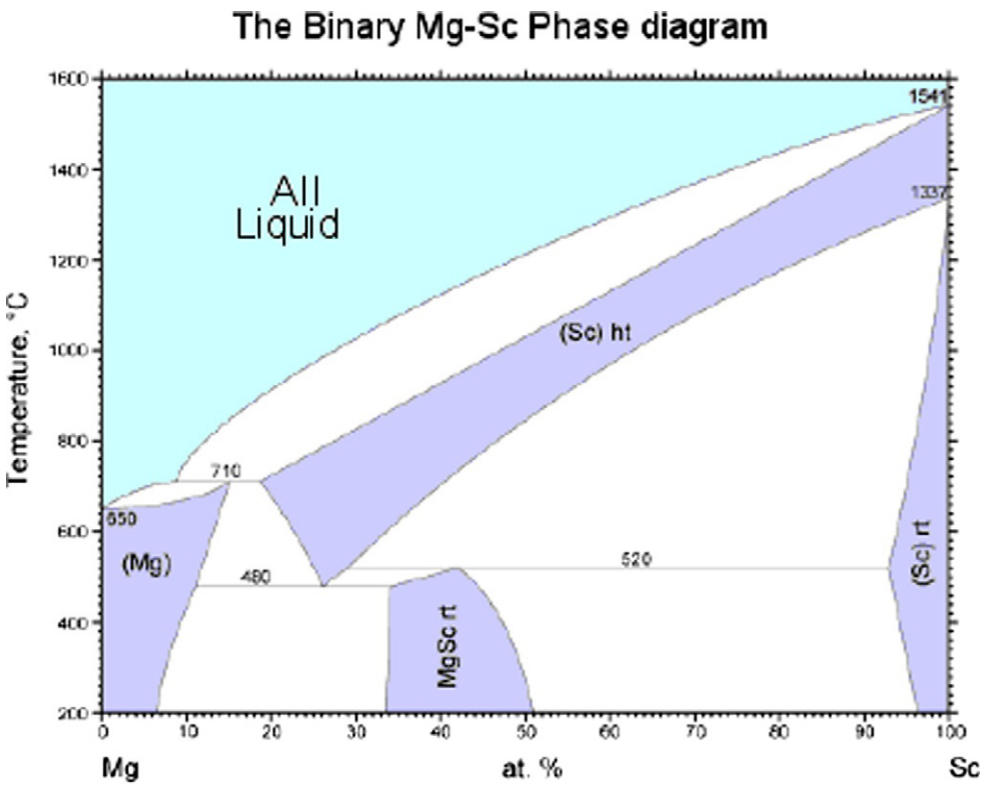

FIGURE 7.5

The hitherto unknown compound $MgSc_2O_4$ was prepared at temperatures above 2000 °C. It crystallizes orthorhombic with the space group D_{2h}^{16}-*Pnam* and is isotypic with $CaSe_2O_4$ and $CaFe_2O_4$. A statistical distribution of Mg^{2+} and Sc^{3+} was found to occupy the metal positions. This is confirmed regarding the distances occurring with the trigonal prismatic coordination (Me^{2+} positions) and with the octahedral coordination (Me^{3+} positions). The $(Sc_2O_4)^{2-}$ framework is rigid as can be shown in the case of the scandates of alkaline earth metals. Thus, analogous compounds with large Me cations cannot be prepared.

The oxy-scandium compound, magnesium scandate, $MgSc_2O_4$, has the CAS number of 12032-33-6 and is offered for sale commercially.

Calcium–Scandium System

The intermetallic system, Ca^0–Sc^0, does not form any compounds but forms intermetallic solid solutions at all compositions (0–100%).

The system, $CaO{\cdot}Sc_2O_3$, has not been studied intensively. A paper describing the 1:1 compounds of $CaO{\cdot}Sc_2O_3$ was published. Therein, it was stated that the compounds $CaSc_2O_4$ and $SrSc_2O_4$ were synthesized by solid-state reaction of the component oxides at temperatures ranging from 950 to 1400 °C. Both calcium and strontium monoscandates are orthorhombic and analogous to $CaFe_2O_4$. Lattice parameters for $CaSc_2O_4$ are: $a_o = 9.461$, $b_o = 11.122$, $c_o = 3.143$ Å and for $SrSc_2O_4$, $a_o = 9.698$, $b_o = 11.302$, $c_o = 3.185$ Å. Based on four molecules per unit cell, the X-ray density for $CaSc_2O_4$ was determined to be 3.89 g/cm^3 and that for $SrSc_2O_4$ is 4.59 g/cm^3. The structure consists of face-shared tetrahedra of ScO_6^{3-} octahedra joined to form rigid $(ScO_6)_2^{6-}$ units. These are arranged in a zigzag pattern in the crystal (see Fig. 7.6).

Both $CaSc_2O_4$ and $SrSc_2O_4$ are isostructural with $CaFe_2O_4$ and have the space group of *Pnam*. Cell parameters are listed in Table 7.1.

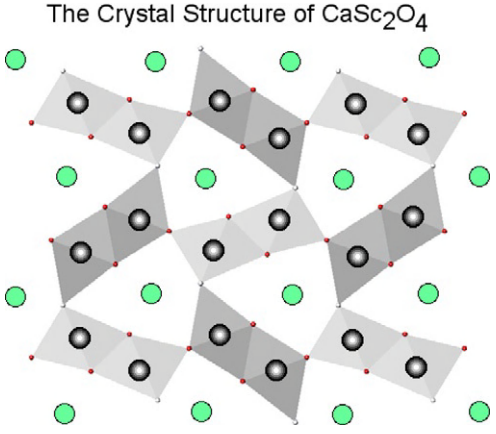

FIGURE 7.6

TABLE 7.1

Pnam	$CaSc_2O_4$	$SrSc_2O_4$
a(Å)	9.461	9.698
b(Å)	11.122	11.302
c(Å)	3.143	3.185
V(Å^3)	330.6	349.1
Z	4	4
MW (g/mol)	193.99	241.53
Density (g/cm^3)	3.90	4.60

In this structure, the octahedra form a rigid three-dimensional (3D) structure with two distinct Sc sites as part of the structure. This organization allows the alkaline earths to occupy the long cavities that exist in the *ab*-plane of the structure.

None of these compounds are available commercially.

Strontium–Scandium System

The system, SrO–Sc_2O_3, has not been studied intensively. Although $Ba_3Sc_2O_5$ is known, the corresponding strontium compound has not been documented. This suggests that the compound, tri-strontium scandate, is not very stable. There are no reports of its synthesis or of its physical properties.

The compound, $SrSc_2O_4$, has the same structure as its homologue, $CaSc_2O_4$, whose structure is presented above.

However, a layered oxysulfide, $Sr_3Cu_2Sc_2O_5S_2$, has been formulated as $Sr_3Sc_2O_5{\cdot}Cu_2S_2$. It is composed of anti-PbO-like Cu_2S_2 slabs alternating with perovskite-like $Sr_3Sc_2O_5$ slabs, and was systematically studied as a p-type transparent conducting material. This material has a wide energy gap of 3.1 eV and a p-type electrical conductivity of 2.8 S/cm at room temperature. A hole mobility of $+150\ cm^{-2}/V/S$ at room temperature was found, which is much higher than the typical value of 10^{-1} to $10\ cm^{-2}/V/S$ found in other copper compounds. The performance of bulk undoped $Sr_3Cu_2Sc_2O_5S_2$ shows the promise of copper oxysulfides as a class of p-type transparent conductive materials that could be essential for optoelectronic applications.

Although a study of the barium scandate (BaO–Sc_2O_3) system has been published, the literature concerning SrO–Sc_2O_3 is almost nonexistent. No compounds are offered for sale commercially and no CAS numbers have been issued to date.

Barium–Scandium System

Information concerning the BaO–Sc_2O_3 system has been scanty in the scientific literature. Compound formation in the BaO–Sc_2O_3 binary system has been examined. Early work established the existence of the compounds $Ba_3Sc_4O_9$ and $BaSc_2O_4$. A later worker then studied compositions ranging from 3–30 mol% of Sc_2O_3 (with the balance consisting of BaO) and then with Sc_2O_3 ranging up to 66% in the temperature range of 900–1400 °C. This resulted in the discovery of a low temperature barium-rich phase, $BaSc_2O_5$. This worker determined that BaO was soluble in $BaSc_2O_5$. Above 1000 °C, excess BaO reacted and the $BaSc_2O_5$ appeared to decompose to form $Ba_3Sc_4O_9$. The compounds were noted to be relatively stable in the ambient atmosphere. The most accurate phase diagram was presented in 1988. This is presented in Fig. 7.7.

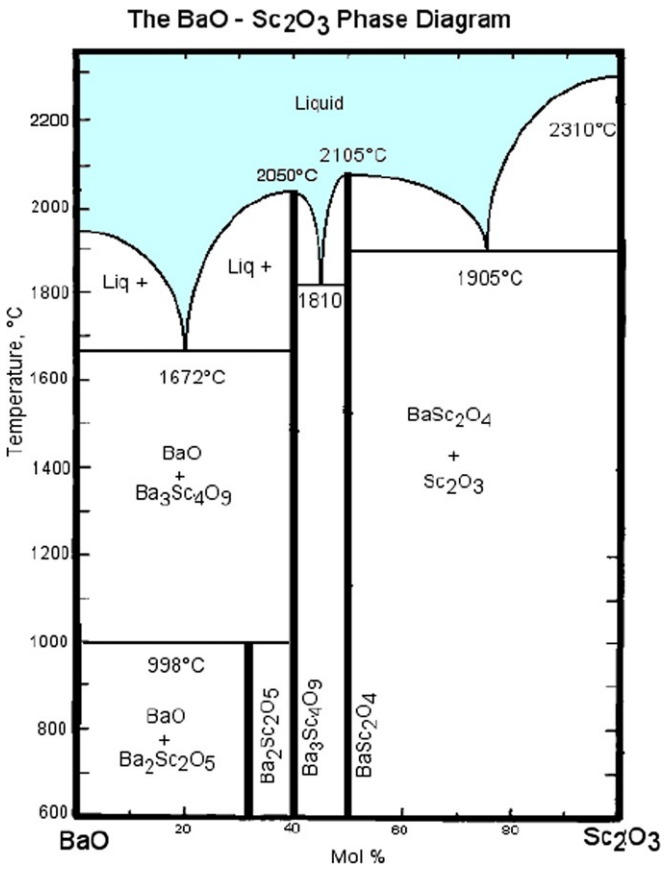

FIGURE 7.7

$Ba_2Sc_2O_5$ decomposes into $Ba_3Sc_4O_9$ and BaO at temperatures greater than 1000 °C. $Ba_3Sc_4O_9$ and $BaSc_2O_4$ were reported to melt congruently at 2050 and 2100 °C, respectively. Another discrepancy between two prior reports involved the low temperature range. It was reported that $Ba_3Sc_4O_9$ and $BaSc_2O_4$ were not stable below 1200 °C whereas others reported that both of these compounds were stable to 900 °C. In addition, some experiments were undertaken utilizing aqueous salts of barium and scandium as starting materials.

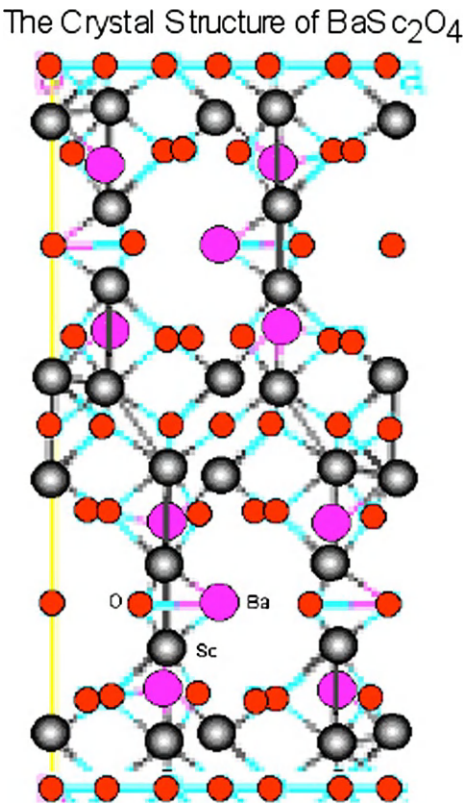

FIGURE 7.8

(Other experiments were conducted using scandium oxide and barium carbonate as the raw materials.) At 1000 °C a different compound was observed, having a composition close to $Ba_3Sc_4O_9$ but with a unit cell dimension decreased along the *c*-axis by a factor of 6. This led others to suggest the existence of yet another barium scandate phase, $Ba_6Sc_6O_{15}$. The results of this investigation provided a somewhat incomplete description for the stability of compounds in the subsolidus region.

The $BaSc_2O_4$ compound was observed to crystallize as a perovskite type structure, in the tetragonal system, with lattice constants $a = 4.160$ Å and $c = 3.994$ Å, The crystal structure of the $Ba_3Sc_4O_9$ compound was determined to be hexagonal with lattice constants of $a = 5.873$ Å and $c = 23.69$ Å. Finally, the crystal structure of the $BaSc_2O_4$ compound was identified as monoclinic, with lattice parameters $a = 9.836$ Å, $b = 20.578$ Å, $c = 5.187$ Å and $\gamma = 89°$. The structure has the form shown in Fig. 7.8.

It consists of a series of ScO_4 tetrahedra, corner-attached to form a series of chains parallel to the *c*-axis The associated cell parameters are: $a = b = 5.7136$ Å, $c = 20.563$Å, $\alpha = \beta = 90°$, $\gamma = 118.881°$, cell volume = 587.71 Å^3, $Z = 4$. Cell occupancy is shown in Table 7.2.

After considerable deliberation, it has been agreed that the structure of $BaSc_2O_4$ is a type between that of calcium ferrite and a "filled" tridymite. The "filled" tridymite structure was thought to be the stable structure formed when only tetrahedral coordination of the R^{+3} ion was possible, usually due to the large ionic size. The crystal structure of $BaSc_2O_4$ has been confirmed using single crystals. The crystal symmetry is monoclinic ($C2/c$, $Z = 12$) with a pseudo-orthorhombic unit cell. The relationship with parent perovskite structure was discussed in terms of coordination polyhedra and bond lengths.

The hydration behavior of the barium scandates with oxygen-deficient perovskite-related structures of tetragonal $Ba_2Sc_2O_5$ and cubic $BaScO_{3-\delta}$ ($\delta = 0.5$) was studied. Both the tetragonal $Ba_2Sc_2O_5$ and cubic $BaScO_{3-\delta}$ absorbed water and formed $Ba_2Sc_2O_5 \cdot 0.60H_2O$ and

TABLE 7.2

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O3	O	8	f	1	0.065	0.339	0.123	1.0
2	O4	O	8	f	1	0.103	0.144	0.621	1.0
3	O6	O	8	f	1	0.153	0.443	0.0025	1.0
4	Sc2	Sc	8	f	1	0.164	0.119	0.053	1.0
5	Ba2	Ba	8	f	1	0.1656	0.109	0.3615	1.0
6	Sc1	Sc	8	f	1	0.1662	0.108	0.1969	1.0
7	O2	O	8	f	1	0.236	0.373	0.252	1.0
8	O5	O	8	f	1	0.336	0.153	0.121	1.0
9	Sc3	Sc	8	f	1	0.5028	0.117	0.0697	1.0
10	O1	O	4	e	2	0	0.07	1/4	1.0
11	Ba1	Ba	4	e	2	0	0.609	1/4	1.0

$BaScO_{3-\delta}\cdot 0.37H_2O$, respectively, during cooling in a humidified atmosphere. The hydration and the dehydration temperatures for the barium scandates were ~533 and 553 K, respectively; these temperatures were 30–70 K lower than that for $Ba_2In_2O_5$. A distinct difference in the hydration behavior of the structurally different tetragonal $Ba_2Sc_2O_5$ and cubic $BaScO_{3-\delta}$ was not observed. The $Ba_2Sc_2O_5$ types of compounds show protonic conduction below 673 K and p-type conduction above 773 K in a humidified atmosphere.

$Ba_3Sc_4O_9$ has a structure similar to perovskite with cell parameters of: $a = b = 6.873$ Å, $c = 8.5939$ Å, $\alpha = \beta = 70.2°$, $\gamma = 80°$, $Z = 2$, cell volume = 235.88 Å^3.

In addition, it has been determined that the systems (CaO–SrO–BaO)ScO_4 can form mixed cation compounds. In the CaO···SrO···Sc_2O_3 and BaO···SrO···Sc_2O_3 systems, complete series of mixed crystals were found for (Ca,Sr)Sc_2O_4 and (Sr,Ba)$_3Sc_4O_9$, respectively. In the BaO···CaO···Sc_2O_3 system a new ternary phase with composition $Ba_x(Ca_{2x}Sc_{2-2x})Sc_6O_{12}$ was detected having an incommensurate structure which may be described with a basic hexagonal unit cell ($a = 9.739$ Å, $c = 3.1274$ Å) and a second hexagonal cell having the same basic a-axis. The c-axis of the second cell is x-dependent: $c^x = 3.13/x$, x varying from 0.782 to 0.736, corresponding to the region from $BaCa_2Sc_8O_{15}$ with $c^x = 4.00$ Å, to $BaCa_2Sc_9O_{16.5}$ with $c^x = 4.25$ Å.

Radium–Scandium System

Both Ra and Sc, as metals, are too expensive {^{226}Ra = >$1 million/oz and Sc = $1250/oz} and it is unlikely that any radium–scandium compounds will ever be investigated.

7.1.2. Alkaline Earth—Yttrium Compounds

The same limitations exist for the Ae–Y intermetallic and oxy-yttrium dominated compounds of the alkaline earths, as for the Ae–Sc system (Ae = alkaline earths). Thus, Y metal only forms one intermetallic compound with Be metal. Y metal forms three compounds with Mg metal but no compounds are known for the systems: Y–Ca, Y–Sr or Y–Ba. All of these latter combinations show an intermetallic solid solution from >0 to <100% of the alkaline earth combinations. These solid solutions then melt to form two liquids. Although the phase diagrams have been published and are available for the Ca–Y, Sr–Y and Ba–Y systems, only one is shown here.

Beryllium–Yttrium System

The system, Be–Y, as metals, forms just one compound, $Be_{13}Y$, as shown in the following phase diagram (Fig. 7.9).

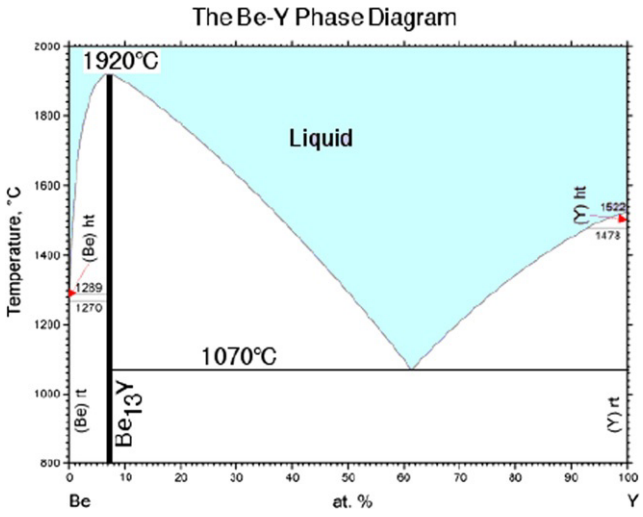

FIGURE 7.9

It melts at 1920 °C, which is about 50% higher than either of its components. Studies were made on the Be–Y system in order to establish the existence of intermetallics in it and to systematize the compounds of type Ae–Be_{13} according to their formula volumes. The existence of a cubic phase YBe_{13}, isomorphous with $NaZn_{13}$ and with a lattice period $a = 10.238$ Å, was established. It was concluded that the known ABe_{13} beryllides can be divided into three groups according to their volume relationships to the volume of the A component:

Sc, Hf, Zr
Mg, Er, Y, Ca, Am
Np, U, Pu, Th, Ce, La

BeO forms but one oxy-dominated compound with Y_2O_3. No other compounds in this system are known.

BeY_2O_4 has the structure shown in Fig. 7.10.

It consists of YO_4 tetrahedra, attached in a zigzag chain with Be^{2+} atoms interspersed along the chains.

Cell parameters are: $a = 3.5315$ Å, $b = 9.8989$ Å, $c = 1.0443$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 363.56 Å^3, $Z = 4$. Cell occupancy is shown in Table 7.3.

Although $Be_2Y_2O_5$ is listed in one reference as an oxy-yttrate compound of Be, there are no further references that address this composition. Its existence remains in doubt.

No uses for any of these compounds have arisen in Industry and they are not available commercially.

Magnesium–Yttrium Compounds

Mg metal forms three compounds with yttrium metal as shown in the following phase diagram in Fig. 7.11.

The structure of MgY is body-centered cubic as shown in the following diagram in Fig. 7.12.

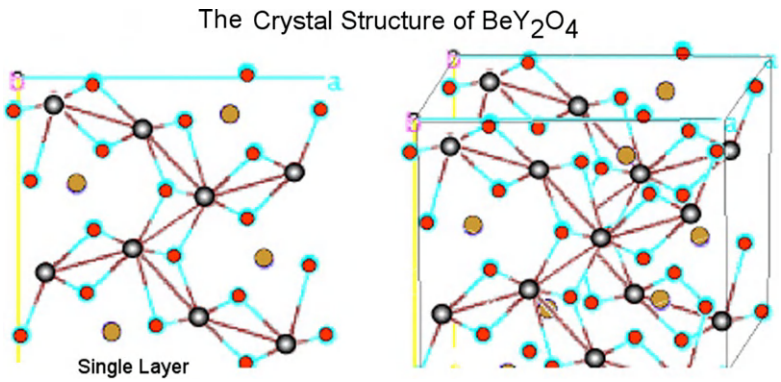

FIGURE 7.10

TABLE 7.3

6	O1	O	4	c	.m.	0.27699	1/4	0.24361	1.0
7	O3	O	4	c	.m.	0.51297	1/4	0.61518	1.0

TABLE 7.4

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	Y	Y	1	b	m-3m	1/2	1/2	1/2	1.0
2	Mg	Mg	1	a	m-3m	0	0	0	1.0

The cell parameters are: $a = b = c = 3.797$ Å and $\alpha = \beta = \gamma = 90°$. Cell volume is 74.64 Å^3. The cell occupancy is shown in Table 7.4.

The compound, Mg_2Y, has the structure shown in Fig. 7.13.

Cell parameters are: $a = b = 6.018$ Å, $c = 9.734$ Å, $\alpha = \beta = 90°$, $c = 120°$, cell volume = 305.30 Å^3. Cell occupancy is shown in Table 7.5.

These two compounds are the only structures known. The structure of MgY_5 has not been published. However, an additional compound, $Mg_{24}Y_5$, has been discovered and has the structure shown in Fig. 7.14.

Cell parameters are: $a = b = c = 9.7434$ Å, $\alpha = \beta = \gamma = 109.71°$, cell volume = 712.05 Å^3, $Z = 4$. Cell occupancy is shown in Table 7.6.

In addition, it has been found that Ce^{3+} is able to substitute for Y^0 in these compounds. The structural and magnetic properties of a series of novel compounds in the ternary Ce–Mg–Y system have been studied by X-ray diffraction, SQUID magnetometry and XAS spectroscopy. The crystal structures of the compounds $Ce_{0.34}Y_{0.67}Mg_2$ and $Ce_{0.49}Y_{0.51}Mg_{4.7}$ have been refined. Magnetic data are consistent with a tri-positive ground state $^2F_{5/2}$ for the cerium atom (not tetrapositive). The XAS measurements confirm this result. Crystal field effects are apparent in the magnetic data at temperatures below about 50 K in the compounds with higher Ce concentration.

However, substitution of Zn^0 for Mg^0 in the Mg_2Y compound results in a complete change in crystal structure (Fig. 7.15).

MgO forms oxy-dominated compounds with Y_2O_3. The structure of MgY_2O_4 has the form shown in Fig. 7.16.

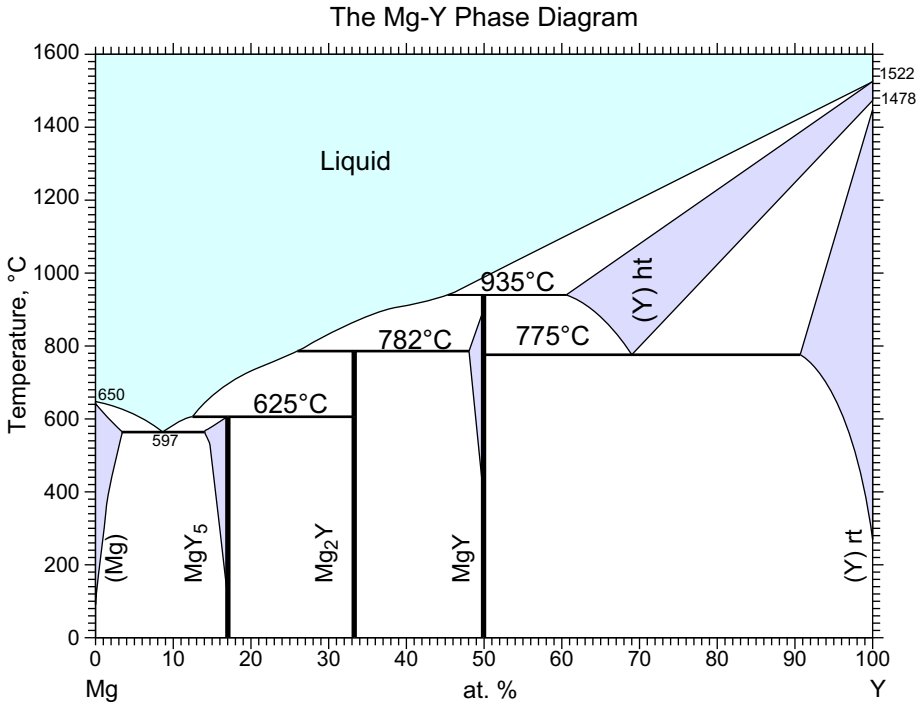

FIGURE 7.11

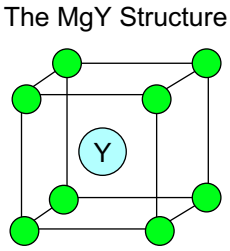

FIGURE 7.12

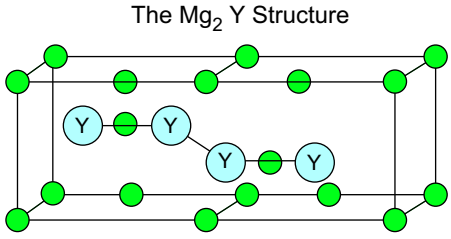

FIGURE 7.13

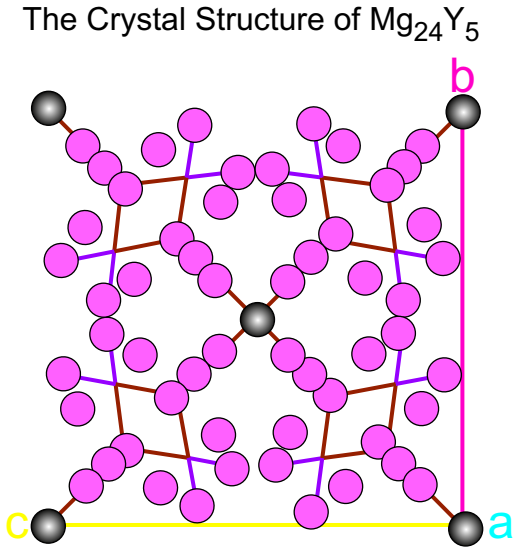

FIGURE 7.14

It is nearly identical to the Be homologue. Cell parameters are: $a = 3.5315$ Å, $b = 9.799$ Å, $c = 10.452$ Å, $\alpha = \beta = \gamma = 90°$. Cell occupancy is shown in Table 7.7.

Other than structure, little is known concerning this compound.

No uses have appeared for these compounds in the Industry and little interest in Academia has been forthcoming at this date and time.

Calcium–Yttrium Compounds

Calcium metal does not form any specific **intermetallic** compounds with yttrium metal. The phase diagram

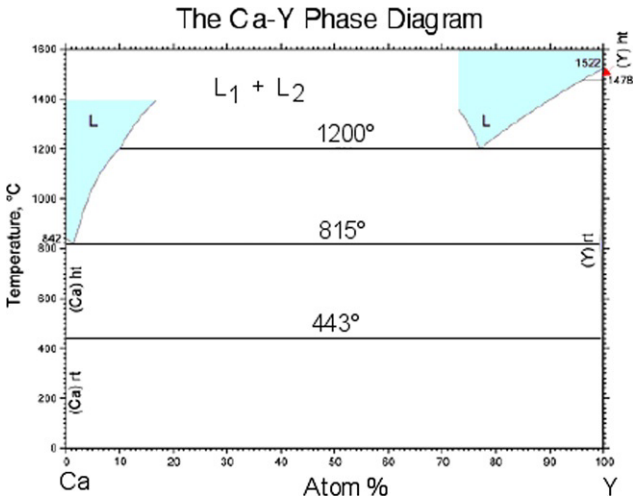

FIGURE 7.17

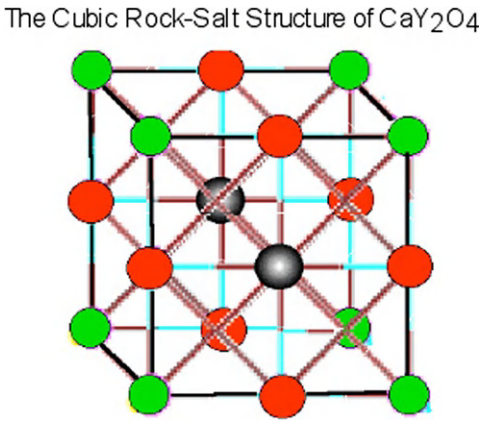

FIGURE 7.18

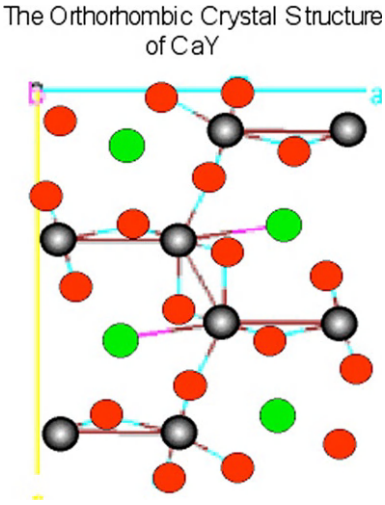

FIGURE 7.19

is devoid of any compounds and shows only the polymorphic transformation of the individual metals. A sample phase diagram has been presented in Fig. 7.17.

The system, $CaO–Y_2O_3$, forms few compounds as well. CaY_2O_4 is a 1:1 compound with the rock salt structure. 0.11 atom% of the cation positions are occupied by Y and 0.89% atom% by Ca in the $Ca_{0.89}Y_{0.11}O_2$ structure (Fig. 7.18).

Cell parameters of $Ca_{0.89}Y_{0.11}O_2$ are: $a = b = c =$ 3.3976 Å, $\alpha = \beta = \gamma = 60°$, cell volume is 27.73 Å^3, $Z = 4$. Cell occupancy is shown in Table 7.8.

Although it may appear that this compound could be related to the CaY_2O_4 composition, the CaY_2O_4 compound has a completely different structure (Fig. 7.19).

It is closely related to that of BeY_2O_4. Cell parameters are: $a = 3.38$ Å, $b = 10.09$ Å, $c = 11.96$ Å, $\alpha = \beta = \gamma = 90°$, cell volume is 407.89 Å^3, $z = 2$. Cell occupancy is shown in Table 7.9.

A $CaO–Y_2O_3$ phase diagram was first made in 1964. This researcher who stated that a eutectic type was prevalent. Later work (1987) also showed the same lack of crystalline compounds. A diagram illustrating this shown in Fig. 7.20.

Both of these authors claimed that only mixtures and a solid solution existed in this system. Yet, others had already reported three compounds to be present in this system, CaY_2O_4, CaY_4O_7 and $Ca_3Y_2O_7$. Later work (1991) also indicated that no compounds exist in the $CaO–Y_2O_3$ system, only separate oxides up to the eutectic temperature. These researchers:

> "The degree of solid solubility between yttria and calcia was measured, in the yttria-rich region, over the temperature range 1200 to 2000 °C. X-ray diffraction results indicate that as much as 12.4 mol% calcia can be dissolved in yttria at 2000 °C. No solid solution between the two oxides was observed below 1400 °C. In addition, ex-solution kinetics was measured. Kinetic data were compared to a number of solid

state models with the 3D nucleation model providing the best correlation. The Hulbert model was further used to characterize the growth mechanism. It suggested that growth is phase-boundary controlled between 1200 and 1500 °C and that the nucleation rate either drops to zero or that growth becomes two-dimensional above 1600 °C. Although undoped yttria is both a p- and n-type semiconductor, yttria-calcia solutions are ionic conductors below about 10^{-10} atm oxygen (t_i >0.99) with no trace of n-type conductivity being observed. The activation energy for ionic conduction in yttria-5 mol% calcia is 125 kJ/mol". The only caveat was that the temperature may have not been high enough in their experiments.

It has been observed that the compound, CaY_4O_7, is obtained as a decomposition product from CaY_2O_4:

$$2\ CaY_2O_4 + \text{heat} \Rightarrow CaY_4O_7 + CaO$$

CaY_4O_7, CaY_2O_4, and $Ca_3Y_2O_6$ compounds were found to be stable above temperatures of 1200 °C and could not be quenched to room temperature. $Ca_3Y_2O_6$, CaY_2O_4, and CaY_4O_7 exist up to 1960, 1760 but 2140 °C, respectively. In view of this observation and other results (see above), the phase diagram has been modified to the diagram shown in Fig. 7.21.

No CAS numbers have ever been assigned and no calcium–yttrium compounds are offered for sale commercially. Although the possibility of sulfur-dominated compounds like $CaS{\cdot}Y_2S_3$ exists, no studies of such compounds are available in the scientific literature as well.

In view of the instability of these compounds (which were measured using high temperature XRD equipment), coupled with the fact that they have not been obtained as stable compounds at room temperature, it

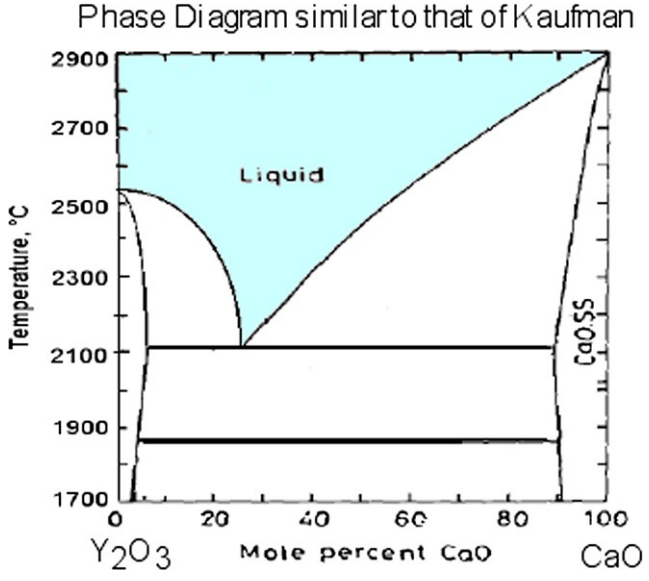

FIGURE 7.20

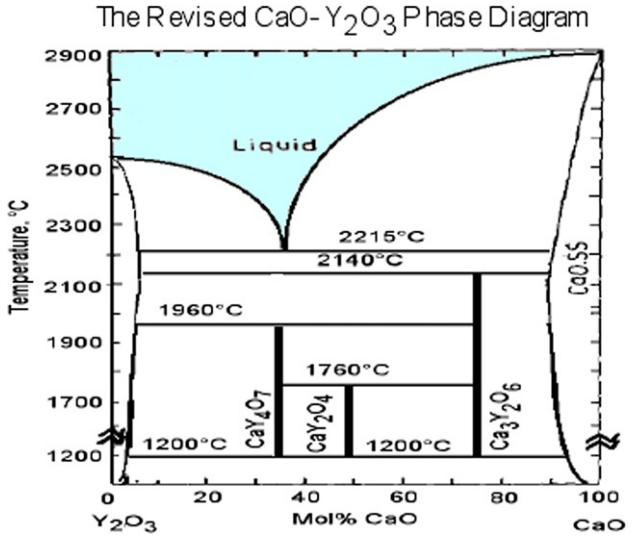

FIGURE 7.21

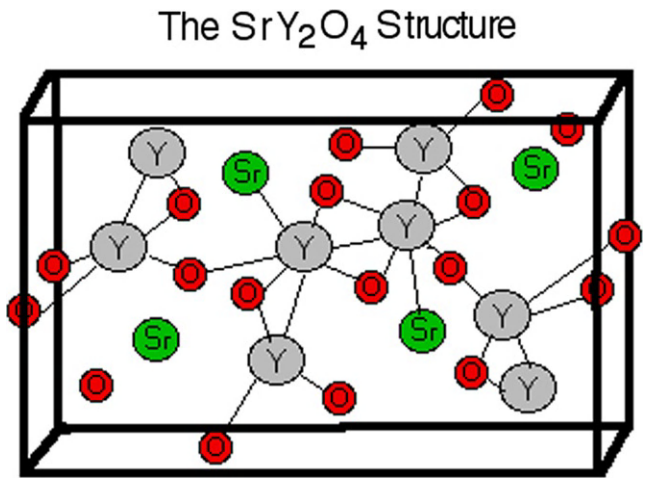

FIGURE 7.22

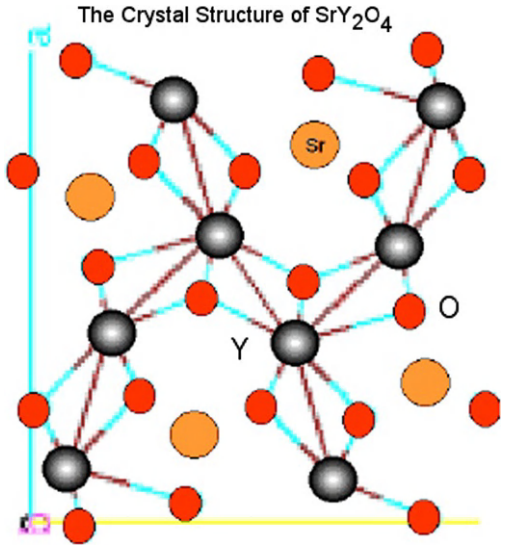

FIGURE 7.23

is not surprising that the scientific literature is very limited. Few papers concerning data relating to these compounds can be found and they present little interest to those in the Industry. They are not offered for sale commercially.

Strontium–Yttrium Compounds

Strontium metal does not form any specific **intermetallic** compounds with Yttrium metal. The phase diagram is devoid of any compounds and shows only the polymorphic transformation of the individual metals (like that shown above for MgO–Y_2O_3).

The system, SrO–Y_2O_3, has not been thoroughly investigated. It was originally stated that no compounds exist. Nonetheless, a recent patent (2009) has described novel red emitting phosphors for use in fluorescent lamps resulting in superior color rendering index values compared to conventional red phosphors. Also disclosed is a fluorescent lamp including a phosphor layer comprising blends of one or more of a blue phosphor, a blue-green phosphor, a green phosphor and a red phosphor selected from the group consisting of SrY_2O_4:Eu^{3+}. This compound has the structure shown in Fig. 7.22.

It is tetragonal with cell parameters of: $a = 3.38$ Å, $b = 10.09$ Å, $c = 11.96$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 407.89 $Å^3$. Cell occupancy is shown in Table 7.10.

Another view of the same structure is shown in Fig. 7.23.

The applicability of SrY_2O_4 as a thermal barrier coating was investigated. A polycrystalline sample of SrY_2O_4 was prepared and measured concerning its thermophysical properties. The melting temperature (T_m) of SrY_2O_4 is 2413 K (2140 °C). The longitudinal and shear sound velocities were measured by an ultrasonic pulse-echo method at room temperature in air. This enabled the evaluation of the elastic moduli and Debye temperature. The heat capacity (C_P) was measured by using a differential scanning calorimeter in high purity argon atmosphere. The relationships between the

TABLE 7.10

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	O1	O	4	c	.m.	0.071	1/4	0.078	1.0
2	Y1	Y	4	c	.m.	0.077	1/4	0.394	1.0
3	Sr1	Sr	4	c	.m.	0.242	1/4	0.65	1.0
4	O2	O	4	c	.m.	0.289	1/4	0.352	1.0
5	O3	O	4	c	.m.	0.387	1/4	0.016	1.0
6	O4	O	4	c	.m.	0.47	1/4	0.775	1.0
7	Y2	Y	4	c	.m.	0.568	1/4	0.609	1.0

thermophysical properties of SrY_2O_4 were studied. It was concluded that this compound was suitable as a thermal barrier material.

The only interoxide, SrY_2O_4 in the Y_2O_3–SrO system was synthesized at a low temperature of 1120 K (850 °C) by a hybrid polymeric gel cum auto-combustion method. For determining the high temperature stability of SrY_2O_4 the emf of the galvanic cell:

$$\text{-Pt, SrO, } SrF_2\text{, } O_2 \,|SrF_2|\, O_2\text{, } SrF_2\text{, } Y_2O_3\text{, } SrY_2O_4\text{, Pt-}$$

was studied over the temperature range from 935 to 1080 K (660–810 °C) which yielded the least squares expression:

$$E \pm 0.76(\text{mV}) = 236.46 - 0.16198T\ (\text{K})$$

From this, the standard Gibbs energy of formation $\Delta G^{o}_{f,ox}$ of SrY_2O_4 from its constituent binary oxides Y_2O_3 and SrO was derived to be:

$$\Delta G_{f,ox^o}(\text{kJ/mol}) = -45.63 + 0.03126T\ (\text{K})$$

A value of 0.58 could be derived for the activity of SrO, a_{SrO}, in the SrY_2O_4/Y_2O_3 mixture at an extrapolated temperature of 1273 K, which was used for assessing the compatibility of 15 mol% $YO_{1.5}$ stabilized zirconia (YSZ) electrolyte with SrO-bearing components of solid oxide fuel cells.

In the last few years, a growing interest for luminescent-doped nanoparticles has arisen because of the observed modification of their significant properties as compared to the bulk materials. Small crystalline particles exhibit many novel physical properties not found in bulk materials. The nanocrystals are of considerable importance for both technological applications and fundamental studies. Oxide-based luminescent materials have been widely used due to their thermal and chemical stability. SrY_2O_4 is a good host material because it has a wide band gap. In one work, attention was focused on their structural and electronic properties and the calculated results by chemical bond method and density functional method were reported within the scheme due to Perdew–Burke–Ernzerhof. SrY_2O_4 was predicted to be a direct-gap material because the top of the valence band and the bottom of the conduction band are to be along the same direction at G. The bond length and bond covalency were also calculated by chemical bond method. Compared with the SrY_2O_4 bulk crystal, the bond covalency of nanocrystal has a decreasing trend; its band gap also is narrower; the bond lengths of SrY_2O_4 nanocrystal become longer, which is responsible for the change of the covalency and band gap.

Crystals of SrY_2O_4 (space group *Pnam*) were examined by high-temperature powder X-ray diffractometry to determine the changes in unit-cell dimensions with temperature. The individual cell dimensions linearly increased with increasing temperature up to 1473 K. The expansion coefficients (K^{-1}) were 1.263×10^{-5} along the *a*-axis, 7.46×10^{-6} along the *b*-axis, and 9.93×10^{-6} along the *c*-axis. The coefficient of mean linear expansion was 1.001×10^{-5}/K.

No other compounds involving combinations of SrO-Y_2O_3 are known at this time. There are no strontium–yttrium compounds available commercially and none are offered for sale.

Barium–Yttrium Compounds

Barium metal does not form any **intermetallic** specific compounds with yttrium metal. The phase diagram is devoid of any compounds and shows only the polymorphic transformation of the individual metals. The situation differs in the BaO–Y_2O_3 system.

Starting with BaO and Y_2O_3, four compounds have been found in the BaO–Y_2O_3 system. At high temperatures (above 1200 °C) two compounds, mentioned in the literature, are found: $Ba_3Y_4O_9$ and BaY_2O_4. Heating the oxide mixtures at 900 °C results in the formation of a new compound $Ba_2Y_2O_5$. This compound is transformed at 1000 °C into another new compound: $Ba_4Y_2O_7$. X-ray data of the four compounds have been given in detail. The reactions are:

$$\text{BaO} + Y_2O_3 + \text{heat} \Rightarrow BaY_2O_4 (>1200\ ^\circ\text{C})$$

$$3\ \text{BaO} + 2\ Y_2O_3 + \text{heat} \Rightarrow Ba_3Y_4O_9 (>1200\ ^\circ\text{C})$$

$$\text{BaO} + Y_2O_3 + \text{heat} \Rightarrow Ba_2Y_2O_5 (<1000\ ^\circ\text{C})$$

$$2\ Ba_2Y_2O_5 + \text{heat} (>1000\ ^\circ\text{C}) \Rightarrow Ba_4Y_2O_7 + Y_2O_3$$

Although the system, BaO–Y_2O_3–CuO–O, has been evaluated as to its phase diagram because it is a superconductor at 90 K, little work has been accomplished on the system, BaO–Y_2O_3. The final phase diagram has not yet been established. The problem is similar to that of the CaO–Y_2O_3 system where the relevant compounds are stable only over a limited temperature range. The lower limit for a-BaO·and b-Y_2O_3 compounds seems to be 800 °C. However, since the melting points of these compounds are not available, a phase diagram cannot be constructed.

BaY_2O_4 has the same structure as its strontium homologue with cell parameters of: $a = 3.452$ Å, $b = 10.404$ Å, $c = 12.121$ Å. $\alpha = \beta = \gamma = 90^\circ$, cell volume $= 435.12$ Å^3. Cell occupancy is shown in Table 7.11.

The structure of $Ba_3Y_4O_9$ has not been completely established. It has the cell parameters of: $a = b = 6.114$ Å, $c = 9.115$ Å, $\alpha = \beta = 70.403^\circ$, $\gamma = 60^\circ$, cell volume $= 272.04$ Å^3.

In the binary system BaO–Y_2O_3 it has been stated that the compounds "$Ba_4Y_2O_7$" and "$Ba_2Y_2O_5$" are

TABLE 7.11

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	O1	O	4	c	.m.	0.071	1/4	0.078	1.0

3	Ba1	Ba	4	c	.m.	0.242	1/4	0.65	1.0
4	O2	O	4	c	.m.	0.289	1/4	0.352	1.0
5	O3	O	4	c	.m.	0.387	1/4	0.016	1.0
6	O4	O	4	c	.m.	0.47	1/4	0.775	1.0
7	Y2	Y	4	c	.m.	0.568	1/4	0.609	1.0

oxycarbonates with composition $Ba_4Y_2O_7{\cdot}CO_2$ and $Ba_2Y_2O_5{\cdot}2CO_2$. Thus, their existence remains in doubt.

In another study, the coexisting phases in the pseudo-binary system $BaO–Y_2O_3$ have been identified by equilibrating samples containing different amounts of component oxides at 1173, 1273 and 1373 K (900, 1000 and 1100 °C). Only two ternary oxides, BaY_2O_4 and $Ba_3Y_4O_9$, have been found to be stable in the temperature range of investigation. Solid-state galvanic cells:

$$\mathrm{Pt}, O_2 + BaO + BaF_2 || BaF_2 + 2\ \text{mol\%}\ Al_2O_3 || BaF_2 + BaY_2O_4 + Y_2O_3 + O_2, \mathrm{Pt}$$

$$\mathrm{Pt}, O_2 + BaO + BaF_2 || BaF_2 + 2\ \text{mol\%}\ Al_2O_3 || BaF_2 + BaY_2O_4 + Ba_3Y_4O_9 + O_2, \mathrm{Pt}$$

have been employed for determining the Gibbs' energies of formation of BaY_2O_4 and $Ba_3Y_4O_9$ from the component oxides in the range 850–1250 K. A composite solid electrolyte incorporating Al_2O_3-dispersed BaF_2 was used in the cells. To prevent interaction between the Al_2O_3 powder and electrode materials, the solid electrolyte was coated with pure BaF_2. The Gibbs' energies of formation of BaY_2O_4 and $Ba_3Y_4O_9$ from component oxides are given by: ΔG_f^0 (BaY_2O_4, s) = −128,310 +5.211T (±580) J/mol, (850 ≤ /T ≤ /1250 K) and ΔG_f^o ($Ba_3Y_4O_9$, solid) = −317,490 − 24.704T J/mol, (850 ≤ T ≤ 1250 K).

Proton conducting ion transport membranes are required to extract absolutely pure hydrogen from mixed gas streams in the processing of fossil fuels and other petroleum and petrochemical processes. Ceramic materials are required to withstand these high-temperature processes. Yttrium-doped barium cerate ($BaCe_{0.80}Y_{0.20}O_{3-\delta}$) is currently one of the best materials when considering only proton conductivity. However, this material is very sensitive to the carbon dioxide (CO_2) and sulfur (e.g. H_2S) contamination found in the fossil fuel process stream. Barium cerate will decompose into barium carbonate ($BaCO_3$) and ceria (CeO_2) in the presence of CO_2; and CeO_2 reacts with H_2S to produce a sulfide phase, particularly in the highly reducing fuel environment. Two approaches for improving the stability of barium cerate are examined: manipulation of the A- to B-site (in this case, Ba and Ce/Y/Zr, respectively).

Recent work shows, through both experimental results and thermodynamic modeling, that $Ba(Ce,Y)O_{3-\delta}$ is ill-suited for use in environments containing CO_2. Despite efforts to improve the stability of $Ba(Ce,Y)O_{3-\delta}$ through partial ZrCe substitution and adjusting the A-site to B-site cation ratio, the perovskite phase is shown to be unstable in the presence of CO_2 at temperatures below ca. 1000 °C.

It should be noted that the reaction time for the $BaCO_3 + Y_2O_3$ mixture to come to completion is much longer than that of the $BaO–Y_2O_3$ mixture. Thus, the $Ba_4Y_2O_7$ and $Ba_2Y_2O_5$ compounds have proved to be carboxy compounds. Even those compounds annealed in oxygen gas proved to be identical. The stability of these compounds proved to be poor in air containing moisture, with the exception of BaY_2O_4. All compounds, with the exception of BaY_2O_4 decomposed immediately. Only $Ba_3Y_4O_9$ exists at a high temperature but cannot be quenched for measurement at room temperature. This accounts for the fact that these two compounds are the only ones for which ΔG_f^0 has been measured. The temperature ranges of stability for these compounds are shown in Fig. 7.24.

The $BaO–Y_2O_3$ system has been studied more often than any other of the alkaline earth systems. The major interest in the $BaO–Y_2O_3$ system stems from the fact that these two components are the chief oxide components in the high-temperature superconductor series of compounds like $Ba_2YCu_3O_{6+x}$. However, there are no separate commercial uses of these compounds and they are not offered for sale. No CAS numbers have been issued.

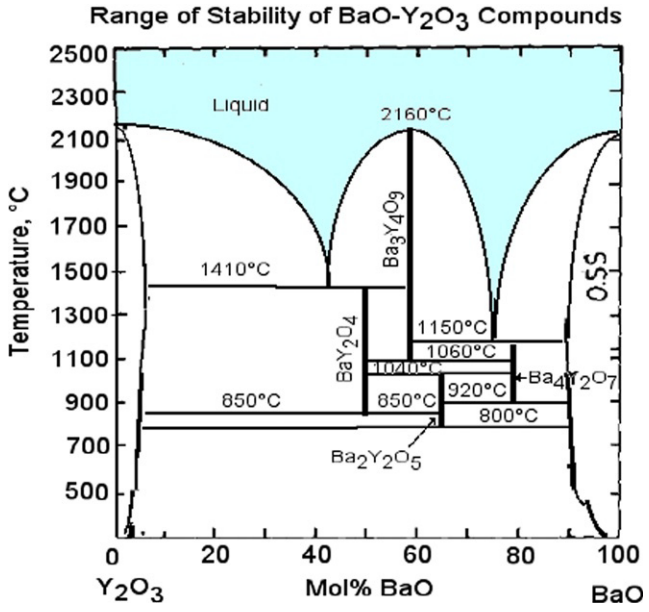

FIGURE 7.24

Radium–Yttrium Compounds

Although compounds similar to those of the barium precursor could be studied, there is no record on any such research papers. Nor are there any examinations of Ra–Y intermetallic compounds available in the published literature. This is probably due to the high cost of Ra metal.

7.1.3. Alkaline Earth—Rare Earth Compounds

The rare earths comprise 14 elements, La to Lu. All of these elements, as oxides, form compounds with the oxides of the alkaline earths. As shown in a recent paper, the type of compounds formed include AeO–Ln_2O_3 in various mole ratios, similar to the Ae–Y_2O_3 system.

The paper describes the interactions of rare earth element (REE) oxides with magnesium, calcium, strontium, and barium oxides in a wide range of concentrations and temperatures from 1000 to 2450 °C. The most typical binary phase diagrams found for these oxide systems are illustrated in the paper. The existence of six types of compounds, i.e. $MeLn_4O_7$, $MeLn_2O_4$, $Me_5Ln_8O_{17}$, $Me_3Ln_4O_9$, $Me_2Ln_2O_5$, has been established. It has been shown that the compounds formed resemble other classes of compounds with REE oxide participation; this is demonstrated by spasmodic property changes in a given series of compounds of a single type (process of formation, X-ray and petrographic characteristics) and by changes of the composition of the compounds. These facts indicate an appreciable role of the 4f electrons of the REE atoms resulting in changes in the nearest environment of the REE atoms; in turn this leads to property and compositional changes of the compounds formed and, hence, to variations of the type of phase diagrams in the La–Lu series. Phase transformations in REE oxides (1800 °C) have been investigated and the regularities observed in the effects of oxides of elements of the IIA subgroup on the transformations are discussed.

The nature and kinetics of decomposition of magnesium oxide-based solid solutions have been studied in the $Sc_2O_3 \cdots MgO$ system. It is suggested that the regularities observed may be valid for other oxide systems having a eutectic type of liquids where the decomposition of the solid solution occurs into the starting components or into solid solutions on their base, without the formation of intermediate compounds. Theoretical calculations of the phase-field boundaries of some types of phase diagrams of the systems studied have been carried out, assuming ideal or regular solution models.

No further description of these compounds will be presented here.

8.1. ALKALINE EARTH TITANIUM COMPOUNDS

8.1.1. Beryllium Titanates

Available data on the system BeO–TiO_2 are contradictory and the question as to the existence of any beryllium titanates is still open. In 1960, a paper stated:

"Mixtures of BeO-TiO_2 with stoichiometric ratios of 1:1, 2:1, and 3:1 were heated at temperatures of 450 to 1750 °C. Whether using oxides or hydroxides as starting materials, no evidence of interaction could be observed to indicate the formation of beryllium titanate. X-ray analysis showed only the lines of the starting components. The densities of the calcined product were close to the densities of the corresponding mixtures of BeO-TiO_2. Selective leaching with HCl (1:1) and H_2SO_4 (1:5) left a residue in which only BeO and TiO_2 could be detected by x-ray analysis. The results of thermographic

Copyright © 2013 Elsevier B.V. All rights reserved.

analysis indicated the absence of any interaction between the oxides. Microscopic analysis showed only the presence of two phases, one of which (BeO) fluoresced in ultraviolet light. Additions of up to 5% of Li_2O, Na_2O, MgO, ZnO, Al_2O_3, Fe_2O_3, B_2O_3, SiO_2 and P_2O_5 showed up only the starting components on x-ray analysis. It must be concluded that beryllium titanate is not formed in the system BeO-TiO_2".

However, by 1986, it was concluded that:

> "Be_2TiO_4 (mol weight 129.92) can be obtained by sintering a mixture of beryllium hydroxide and titanium dioxide, using a molar ratio of 2:1. This orthotitanate of beryllium is a light yellow crystalline powder. When heated to 1780 °C, it melts congruently. Permittivity 30. It decomposes in boiling hydrochloric acid. $BeTiO_3$ (mol weight 104.91) is formed in the system BeO-TiO_2. It is a yellowish crystalline powder. It melts at 1720 °C congruently. The powder is water insoluble, but decomposes in boiling hydrochloric acid".

A so-called "beryllium titanate" was found to be piezoelectric. However, a 1993 paper stated:

> "A mixed BeO:TiO_2 ceramic showing a high electrical conductivity has been the subject of preliminary investigation with respect to its application in TSEE and TL dosimetry. The results clearly indicate that the two oxides involved do construct independent substructures in the mixed ceramic. The TiO_2 substructure provides electrical conductivity, and is passive from the TL and TSEE point of view, whereas the BeO substructure is fully responsible for the dosimetric signals. Although the title question cannot be definitely answered yet the results encourage further studies".

Further work has shown that, although Wartenburg et al. included two congruently melting compounds—$2BeO \cdot TiO_2$ at about 1800 °C and BeO–TiO_2 at about 1720 °C, the results were faulty. They concluded that the system contained no compounds. They also concluded that a single eutectic exists at about 85 wt% of TiO_2 and 1670 ± 3 °C and that a narrow region of TiO_2 mixed crystals (an area of solid solution) extends from just beyond the eutectic to pure titania. Early in the study, seven mixtures, ranging in composition from about 55 to 94% of TiO_2, were specially heat treated for X-ray diffraction (XRD) examination. Each of the mixtures was heated to about 10–15 °C above the melting point of the mixture as given by Wartenburg, cooled to the reported solidus temperatures, that temperature maintained for about 2 h, and the mixture then cooled fairly rapidly (about 400 °C/h to about 1000 °C). A phase diagram was presented as shown in Fig. 8.1.

Thus, the current understanding is that BeO does not form any "titanates" when reacted with TiO_2 at high temperatures.

8.1.2. Beryllium Titanides

Be metal does form a series in intermetallic alloys with Ti metal that have distinctive structures. The phase diagram is shown in Fig. 8.2.

The crystal parameters are listed in Table 8.1.

$Be_{12}Ti$ has the structure shown in Fig. 8.3.

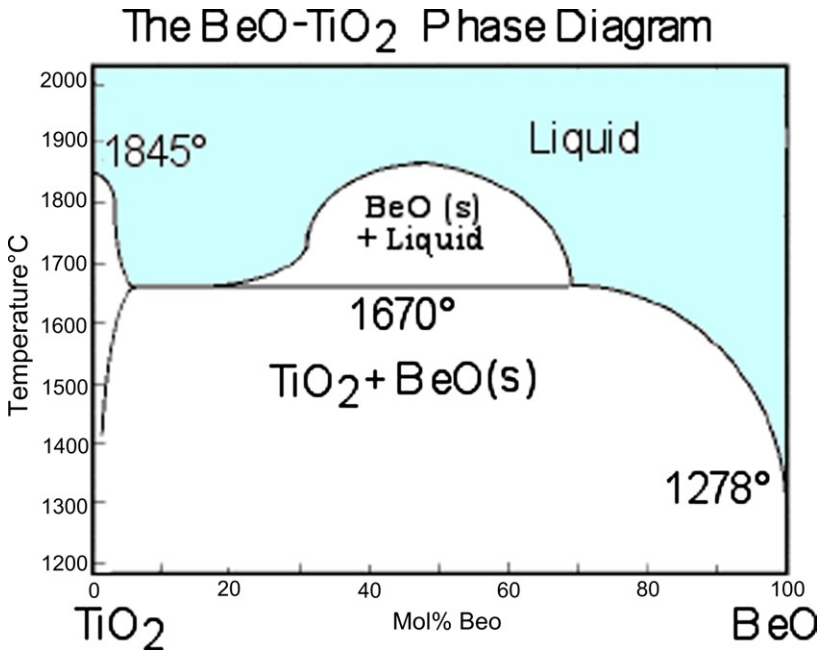

FIGURE 8.1

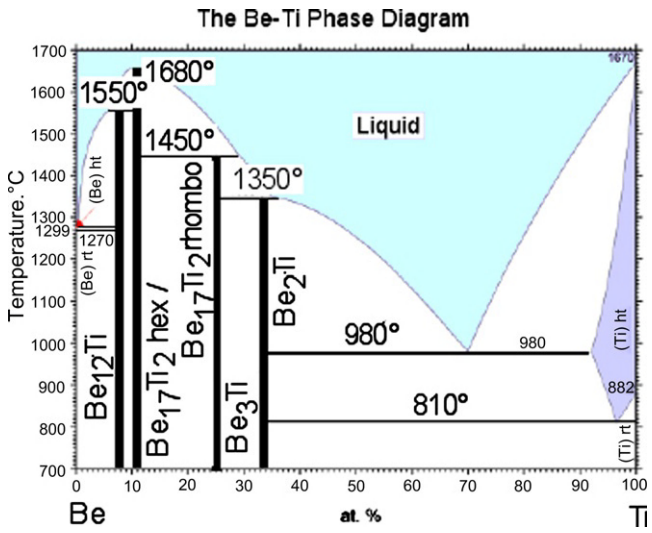

FIGURE 8.2

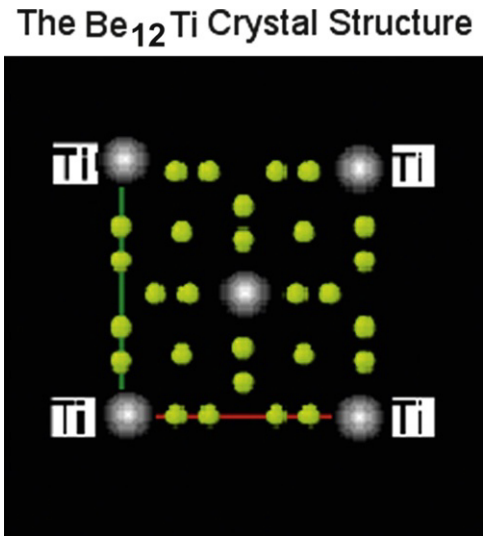

FIGURE 8.3

Unit cell parameters are: $a = 4.195$ Å, $b = 5.6111$ Å, $c = 5.6111$ Å, $\alpha = 81.967°$, $\beta = 68.049°$, $\gamma = 68.049°$, cell volume = 113.62 Å^3. Cell occupancy is listed in Table 8.2.

$Be_{17}Ti_2$ has the structure shown in Fig. 8.4.

Cell parameters are: $a = b = c = 5.5812$ Å, $\alpha = \beta = \gamma = 82.939°$, cell volume = 170.020 Å^3. Cell occupancy is listed in Table 8.3.

Be_2Ti has the structure shown as follows. It consists of a double layer of interconnected Ti tetrahedra, surrounded by cubic patterns of Be atoms. The unit cell contains eight formula units (Fig. 8.5).

Cell parameters are: $a = b = c = 4.5635$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 67.20 Å^3. Cell occupancy is listed in Table 8.4.

Be_3Ti has the structure shown in Fig. 8.6.

It consists of a series of "Ti ladders" that are connected three-dimensionally. Unit cell parameters are: $a =$

BeTi has the structure shown in Fig. 8.7, presented on a following page.

Unit cell parameters are: $a = b = c = 2.941$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 25.41$ Å^3. Cell occupancy is listed in Table 8.6.

None of these compounds has found usage in Industry and they have not evolved any interest in Academia due to unusual physical or chemical properties. They are not available commercially.

8.1.3. Magnesium Titanides

There are no known intermetallic compounds found in the system, Mg–Ti. A phase diagram has been published but shows only polymorphic transitions of the two metals.

8.1.4. Magnesium Titanates

In the oxygen-dominated system MgO–TiO_2, several compounds are known such as $MgTi_2O_5$, Mg_2TiO_4 and $MgTiO_3$. $MgTi_2O_5$ (Armalcolite) has a pseudobrookite structure with cell parameters of $a = 9.72$ Å, $b = 1.04$ Å and $c = 3.73$ Å (space group *Bbmm*), while Mg_2TiO_4 (Quandilite) has either a cubic structure with $a = 8.40$ Å at 700 °C (space group *Fd3m*, spinel) or

a tetragonal structure with $a = 5.94$ Å and $c = 8.42$ Å (space group $P4122$, spinel) at 500 °C. $MgTiO_3$ (Geikielite) has a rhombohedral ilmenite structure with $a = 5.05$ Å and $c = 13.89$ (space group $R3$).

Mg_2TiO_4 has attracted attention because of its optical properties to be used in integrated optics and as a dielectric material. Epitaxial layers of Mg_2TiO_4 grown by solid-state reaction between (001) MgO single crystals and TiO_2 have been used as buffer layers for growing high-temperature superconducting thin films. In contrast, $MgTiO_3$ is known as a dielectric material that has good dielectric properties at high frequencies as well as a high thermal stability. Bulk $MgTiO_3$ is used to construct microwave (MW) ceramic capacitors and resonators. $MgTiO_3$ has a refractive index of 1.95, a value that lies between that of $LiNbO_3$ (2.2) and Al_2O_3 (1.7). Thus, $MgTiO_3$ thin films can be used as a cladding layer. For the most part, $MgTiO_3$ has been produced and studied in bulk ceramic form. However, there have been some reports on fabrication and properties of $MgTiO_3$ thin films. Spinel-forming topotaxial solid-state reactions like:

$$2AO + BO_2 \Rightarrow A_2BO_4 \text{ or } AO + B_2O_3 \Rightarrow AB_2O_4$$

are prototypes of chemical reactions in complex oxides. Previously, a series of topotaxial reactions with (100) MgO single crystals were studied. Different spinels, such as Mg_2TiO_4, Mg_2SnO_4, $MgIn_2O_4$, $MgAl_2O_4$, $MgCr_2O_4$ and $MgFe_2O_4$, with different values of spinel/MgO lattice misfit were considered. In such cases of cube-on-cube orientation, the structure of the reaction fronts and the mechanism of the interfacial reaction were determined by the sign and amount of the lattice misfit. At positive misfit, the Burgers vector of the misfit dislocations present at the reaction front points out of the interface, enabling the dislocations to glide, when coping with the movement of the advancing reaction front. At negative misfit, the Burgers vector lies in the interface plane, so that a climb process is required for the movement of the dislocations. At very low misfit (<0.2%/Å), no misfit (interfacial) dislocations form and the misfit is accommodated by point defects and antiphase boundaries.

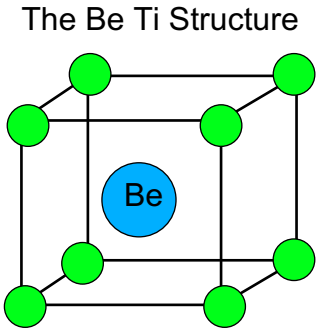

FIGURE 8.7

Three compounds have been established in the phase diagram of MgO–TiO_2, as shown in Fig. 8.8.

These include the orthotitanate, the metatitanate and the dititanate. Thermochemical and crystallographic properties of $MgTi_2O_5$, $MgTiO_3$, and Mg_2TiO_4 have been studied to characterize stability relations, structural variations, and order–disorder phenomena.

Enthalpies of formation, decomposition, and order–disorder transitions were determined by high-temperature solution calorimetry and transposed-temperature-drop calorimetry on synthetic powders.

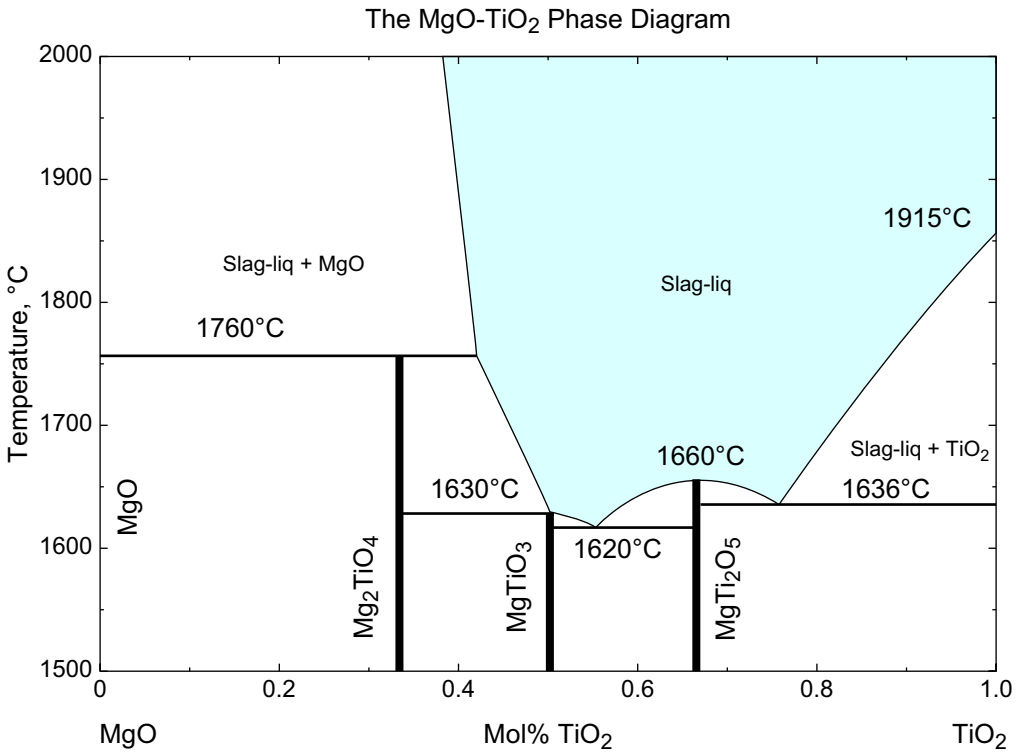

FIGURE 8.8

X-ray lattice parameter measurements and Rietveld refinements of neutron diffraction data were used to evaluate intracrystalline cation distributions and their variation with quenching temperature. $MgTiO_3$ is the most stable phase and apparently retains a fully ordered Mg···Ti distribution to at least 1673 K. Both $MgTi_2O_5$ and Mg_2TiO_4 are stable only at high temperature because of the configurational entropy arising from cation disorder. The disorder in $MgTi_2O_5$ appeared to vary continuously throughout the range of 773–1373 K and was accompanied by changes in lattice parameters. Mg_2TiO_4 undergoes a cubic tetragonal transition at 933 ± 20 K involving the appearance of long-range order on octahedral sites. However, thermochemical evidence suggests that Mg···Ti octahedral short-range order changes gradually, perhaps over an interval of several hundred degrees.

Ilmenite is a weakly magnetic titanium–iron oxide mineral which is iron black or steel gray. It is a crystalline iron titanium oxide ($FeTiO_3$). It crystallizes in the trigonal system, and it has the same crystal structure as corundum and hematite. $MgTiO_3$ has the same structure shown in Fig. 8.9.

Another view of the octahedra is shown in Fig. 8.10.

The compound, Mg_2TiO_4, crystallizes in the cubic system, with a $[Mg(MgTi)O_4]$ inverse structure, where Mg^{2+} occupies part of the Ti^{4+} sites in the lattice.

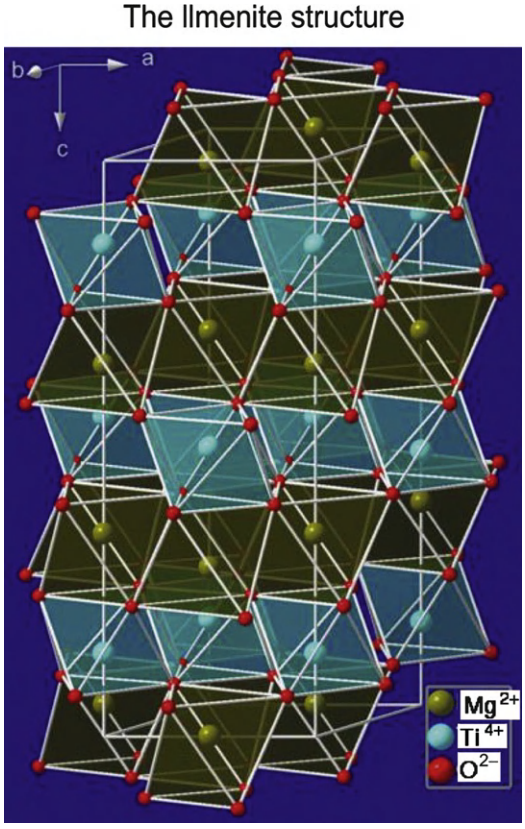

FIGURE 8.9

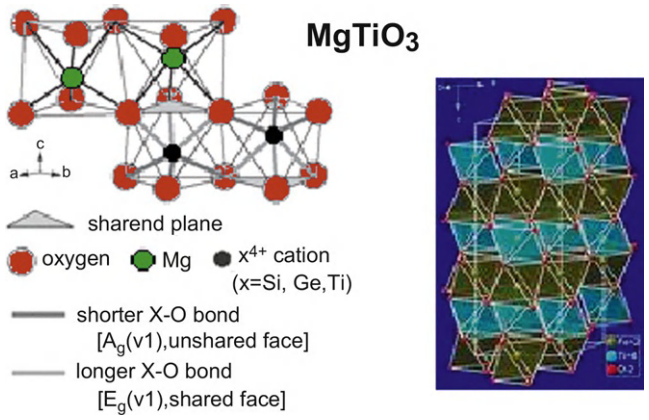

FIGURE 8.10

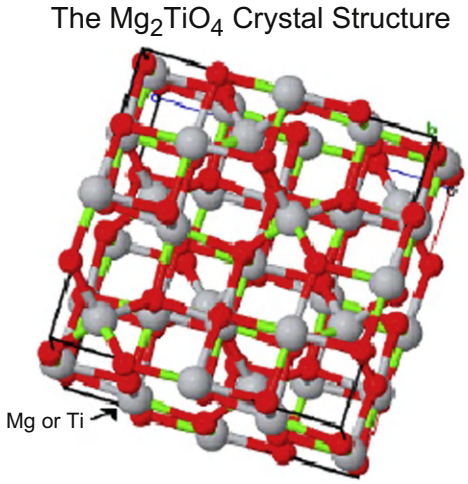

Polyhedra · Edge · Sharing MgO_6 and TiO_6 Octahedra, combined with MgO_4 Tetrahedra, are joined Through Neighboring Octahedra through Vertices

FIGURE 8.11

Synthetic Qandilite (Mg_2TiO_4) is an inverse spinel in which random mixing of Mg and Ti on the octahedral site should give rise to a configurational entropy of 11.5 J/K/mol. The structure can be represented as shown in Fig. 8.11.

The free energy of formation of Mg_2TiO_4 has been determined from the location of the univariant reaction $MgTiO_3 + MgO \Rightarrow Mg_2TiO_4$ in pressure–temperature space between 0 and 20 kbar. The use of literature data for $MgTiO_3$ and MgO, together with the results gave S_o (298 K) = 111.2 ± 0.6 J/K/mol for Mg_2TiO_4. This entropy is only 7.6 ± 0.9 J/K/mol more than the calorimetrically determined value of 103.6 ± 0.7 J/K/mol. The discrepancy implies either considerable short-range order of Mg and Ti in Mg_2TiO_4, or perhaps an error in the high-temperature heat-capacity data for $MgTiO_3$ caused by disordering in this substance. The transformation ranges as a function of pressure are shown in Fig. 8.12.

The electron density distribution in magnesium titanium oxide spinel [composition Mg_2TiO_4 tetrahedral site T = Mg, octahedral site X = Mg, Ti (equal amounts) for general formula TX_2O_4] has been studied with single-crystal XRD methods through scattering factor refinement procedures. In the refinement with harmonic parameters, a positive residual region up to +0.25 e/Å^3 in height encircles oxygen in the hemisphere directed toward the T-site, along with weak residuals assuming octahedral arrangements around the X-site. These

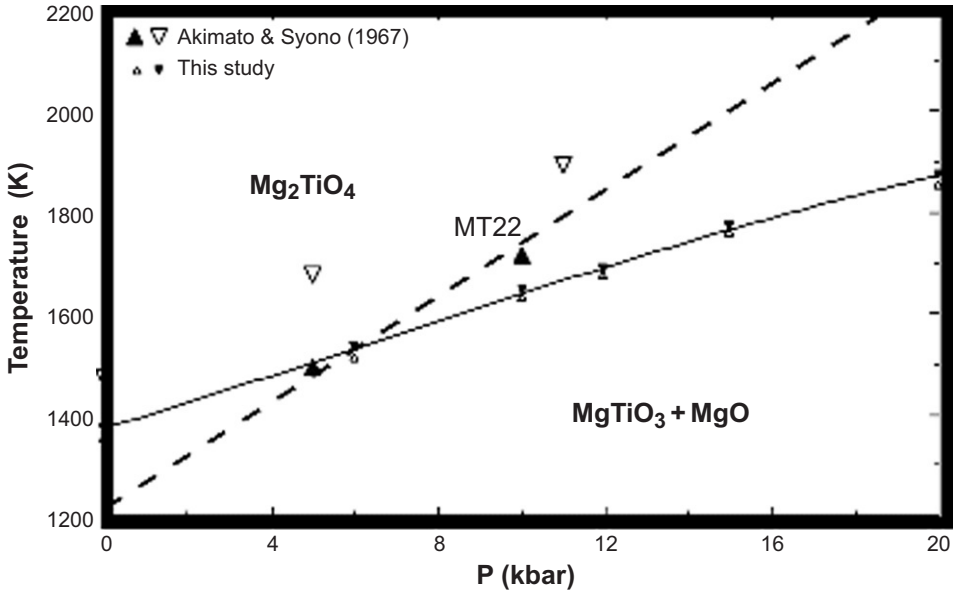

FIGURE 8.12

residuals almost completely disappear with anharmonic refinement. Another residual $+0.20\,e/Å^3$ in height is situated near the X_4O_4 cuboidal unit. [153 equivalent-averaged reflexions, $R = 0.0077$ (harmonic refinement), $R = 0.0059$ (anharmonic refinement).]

In relation to modern telecommunication systems, much attention has been paid to the dielectric properties of materials at MW and millimeter frequencies for wireless communication technologies such as mobile phones, intelligent transport systems, and wireless LAN. Also, the utilized frequency has increased from the MW to millimeter-wave range due to the large quantities of information being relayed and the demand for high-speed transportation in telecommunication systems. Dielectric materials applicable to millimeter-wave frequencies should have a high-quality factor (Q_f) and relatively low dielectric constant (K), as these properties affect the broadness and stability of the resonant frequency. Magnesium metatitanate ($MgTiO_3$) ceramics have been investigated due to their excellent dielectric properties, that is, a high-quality factor ($Q_f = 110{,}000$ GHz) and low dielectric constant ($K = 17$), which are applicable to millimeter-wave frequencies. It has been reported that the origin of the high Q_f value of $MgTiO_3$ specimens is related to the sharing type of MgO_6 and TiO_6 octahedra as well as the absence of 3d electrons which induce electrical conductivity. However, secondary phases such as inverse spinel Mg_2TiO_4 and pseudobrookite $MgTi_2O_5$ are detected during the conventional sintering process of ilmenite, $MgTiO_3$, due to the low solidus limit of the $MgTiO_3$ system. Moreover, these secondary phases affect the MW dielectric properties of $MgTiO_3$ ceramics. A single phase of $MgTiO_3$ showed a dielectric constant (K) of 18.2, a quality factor (Q_f) of 198,000 GHz, and a temperature coefficient of resonant frequency (TCF) of -51 ppm/°C. However, the dielectric properties of the specimens with a secondary phase of $MgTi_2O_5$ ($K = 19.9$, $Q_f = 48{,}000$ GHz) and/or Mg_2TiO_4 ($K = 15.6$, $Q_f = 56{,}000$ GHz) were worsened. Dependence of the MW dielectric properties on the secondary phase of the MgO–TiO_2 system was also discussed in terms of dielectric mixing rules.

Nanocrystalline magnesium titanate materials were synthesized at low temperatures by the sol–gel method, using butyl titanate and magnesium nitrate as precursors. Thermal decomposition behavior of the gel was analyzed by thermogravimetry (TG)–differential thermal analysis (DTA). Crystallinity of $MgTiO_3$ powders was examined by transmission electron microscopy (TEM). The surface morphology was observed by scanning electron microscopy (SEM). The average grain size of $MgTiO_3$ crystals was between 10 and 30 nm at 600 °C and $MgTi_2O_5$ disappeared completely at 700 °C. At the sintering temperature of 1200 °C, the $MgTiO_3$ ceramics which made from the nanopowders calcined at 600 °C achieved excellent dielectric properties: $K_r = 16.6$, $Q_f = 42{,}600$ GHz ($f = 7$ GHz), $\Delta f = -41$ ppm/°C.

Pseudobrookite-type $MgTi_2O_5$ (Karroite) is a synthetic crystalline phase with the *Bbmm* structure and a component in orthorhombic oxide solid solutions, $R^{2+}Ti_2O_5$–$R_2^{3+}TiO_5$, which are present as accessory minerals in lunar and terrestrial rocks. $MgTi_2O_5$ (Karroite) exhibits cation exchange between the two nonequivalent octahedral M1 and M2 sites. The temperature dependence of Ti–Mg disorder has been determined using in situ time-of-flight powder neutron diffraction to establish the cation population of each site. The equilibrium Ti–Mg exchange commences above 700–800 °C, and continues up to 1300 °C. At ~1350 °C, $MgTi_2O_5$ appears to undergo a reversible, displacement phase transition, although the structure can still be refined in space group 63. This transition shows discontinuities in the degree of order, the c cell parameter, and in the M–O bond lengths, quadratic elongation, and bond angle variance for the M1 octahedron, which becomes pseudo-tetrahedral. In contrast, the M2 octahedron shows no significant change. An Arrhenius plot, exhibiting linear behavior from 750 to 1300 °C, gives an exchange enthalpy of ordering of 33.6 kJ/mol, and a value of 10.7 kJ/mol for the entropy of disordering. A value of 5.92 cm^3/mol was deduced for the V of the high-temperature reaction of Geikielite ($MgTiO_3$) + Rutile (TiO_2) to form fully disordered $MgTi_2O_5$ at an extrapolated temperature of 1860 °C.

The crystal structure of $MgTi_2O_5$ projected upon [001] is shown in Fig. 8.13.

All atoms lie in the a–b plane at either c or $c/2$. All MO_6 octahedra share edges in the pseudobrookite-type structure. M1 (2*mm*) and M2 (*m*) sites are labeled.

The magnesium titanates $MgTiO_3$, Mg_2TiO_4 and $MgTi_2O_5$ can be synthesized by the wet chemical peroxide route at low temperatures. The first step of the preparation is the precipitation of peroxo-precursors of definite stoichiometry which are transformable into the corresponding titanates by thermal decomposition. The resulting ultrafine, phase-pure magnesium titanate powders have only a low impurity content. They are very easily sintered above 1200 °C. The rate of densification during sintering of compacts is improved in the order $MgTi_2O_5 < Mg_2TiO_4 < MgTiO_3$, including the green densities, the densities at a given time and the theoretical densities of the titanates for the calculations. The Mg_2TiO_4 formation occurs via the inverse spinel phase of Mg_2TiO_4 in a metastable state at low temperatures and $MgTiO_3$ and MgO as intermediates.

In addition to the Ti^{4+} compounds described above, a compound based on Ti^{3+} is known. The structure has the form shown in Fig. 8.14.

At room temperature, $MgTi_2O_4$ has a cubic ($Fd\bar{3}m$) spinel structure, based on corner-sharing distorted

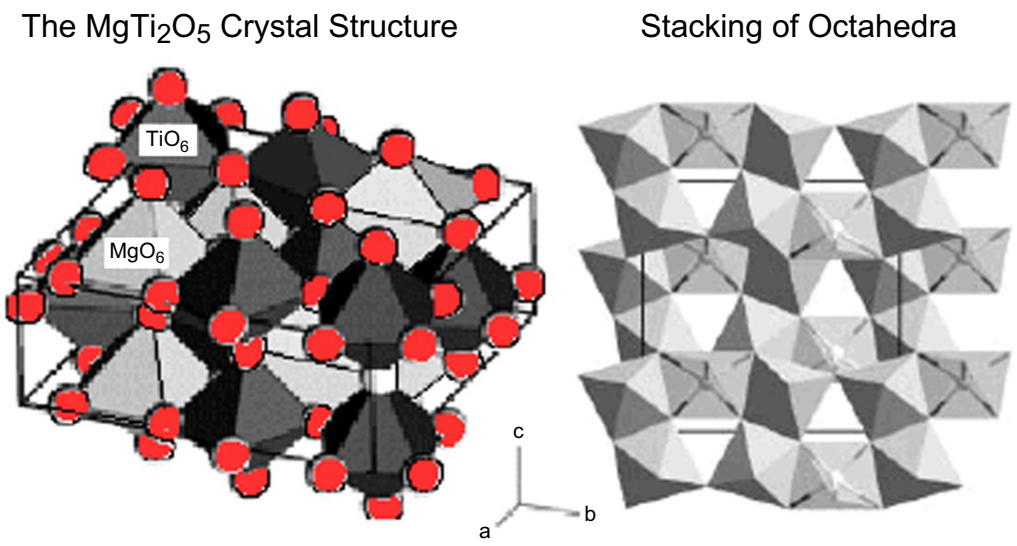

FIGURE 8.13

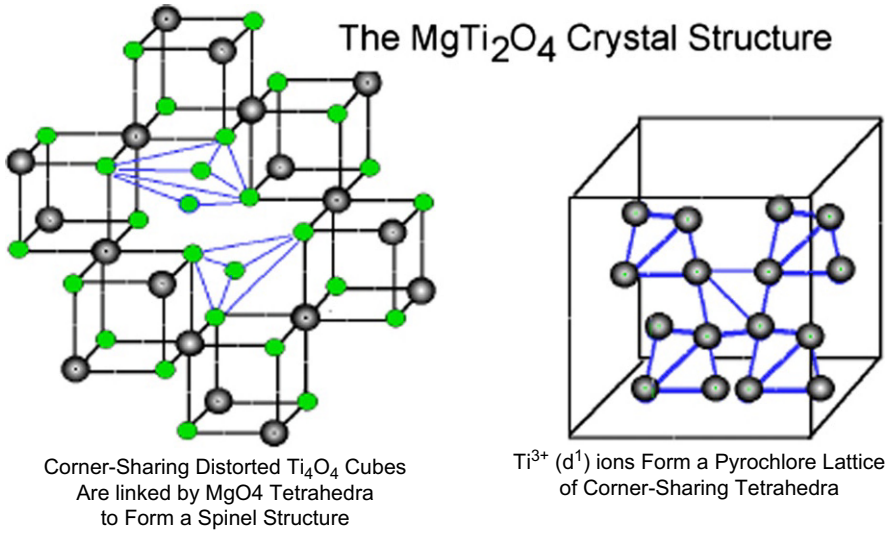

FIGURE 8.14

Ti_4O_4 cubes are linked by MgO_4 tetrahedra. Ti^{3+} (d1) ions form a pyrochlore lattice of corner-sharing tetrahedra. Only a highly reductive sintering atmosphere gives a possibility for the preparation of stoichiometric $MgTi_2O_4$, based on Ti^{3+}. $MgTi_2O_4$ thus obtained shows a metal to spin singlet insulator transition accompanied by the structural change from cubic to tetragonal. Introduction of Ti^{3+} (d^1, $S = 1/2$) to the nonmagnetic insulator $Mg_2Ti^{4+}O_4$ acts partly as doping of carrier dopants and partly as a source of localized electrons. Increasing content of Ti^{3+} leads to their delocalization, resulting in the metallic $MgTi_2O_4$ at $x = 1.0$. The Peierls-like transition observed in the stoichiometric $MgTi_2O_4$ rapidly smears out with the content of Ti^{3+} ion decrease, suggesting an important role of orbital degree of freedom as an effective mechanism for the transition, which seems to be significantly influenced by the randomness associated with the appearance of Ti^{4+} ions.

The transition metal spinel $MgTi_2O_4$ undergoes a metal–insulator transition on cooling below *TM-I* = 260 K. A sharp reduction of the magnetic susceptibility below *TM-I* suggests the onset of a magnetic singlet state. This phenomenon, typically observed in one-dimensional systems, is very rare in cubic compounds, such as the spinels, and is thought to arise because of the interplay between the "frustrated" geometry of the lattice and the orbital occupancy of the Ti sites. Using high-resolution synchrotron and neutron powder diffraction, the low-temperature crystal structure of $MgTi_2O_4$ has been solved. It was found to contain

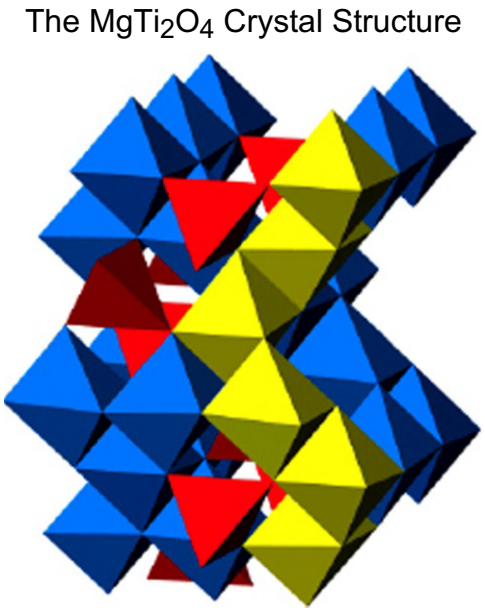

FIGURE 8.15

dimers with short Ti–Ti distances (the locations of the spin singlets) alternating with long bonds to form helices. Band structure calculations based on hybrid exchange density functional theory show that, at low temperatures, $MgTi_2O_4$ is an orbitally ordered band insulator. This structure is shown in Fig. 8.15.

This figure shows one such helix in the context of the spinel structure. Band structure calculations based on hybrid exchange density functional theory show that, at low temperatures, $MgTi_2O_4$ is an orbitally ordered band insulator, whereby the short bonds are associated with doubly occupied *xz* or *yz t2g* orbitals. This interpretation provides an excellent explanation of the structural, transport and magnetic properties.

In general, magnesium titanates are available commercially in limited quantities. $MgTiO_3$ is the composition that is advertised for sale most often. However, no CAS numbers have been assigned to date.

8.1.5. Calcium Titanides

There are no known intermetallic compounds to be found in the system, Ca–Ti. A phase diagram has been published but shows only the polymorphic transitions of the two metals.

8.1.6. Calcium Titanates

The Ti^{4+} system, $CaO–TiO_2$, has been studied intensely. In one study, phase relations in the system Ca–Ti–O were established by equilibration of several samples at 1200 K for prolonged periods and identification of phases in quenched samples by optical and Scanning Electron Microscope (SEM), X-Ray Diffraction (XRD) and Energy-Dispersive X-ray Spectroscopy (EDS). Samples

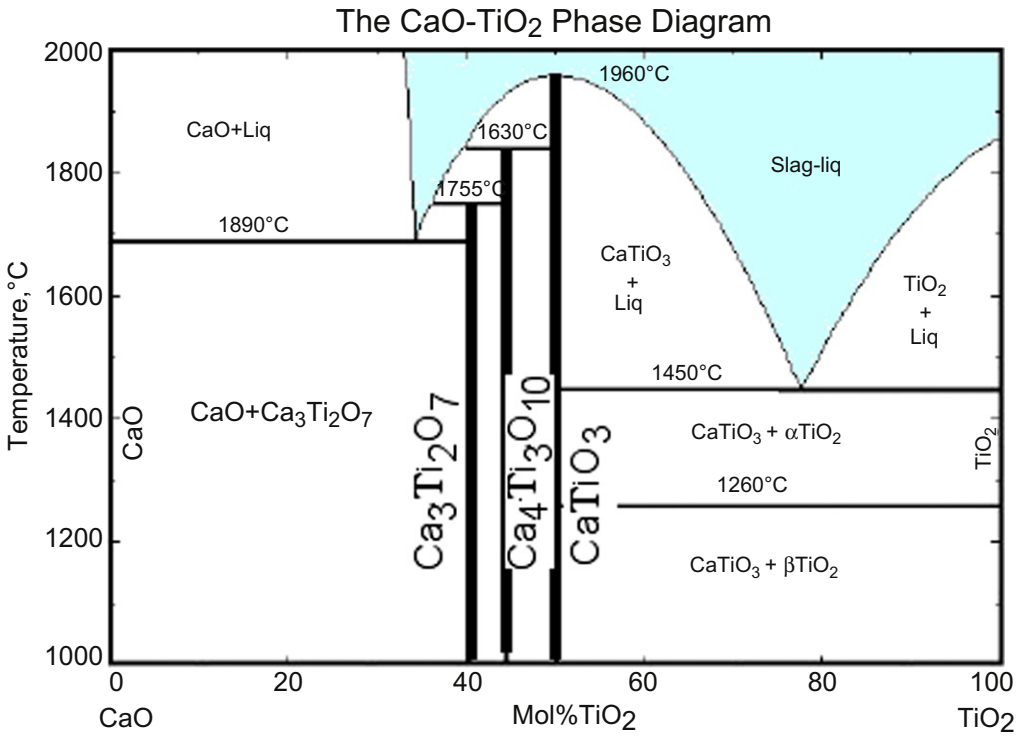

FIGURE 8.16

representing 20 compositions in the ternary system were analyzed, resulting shown in Fig. 8.16.

There was negligible solid solubility of Ca in the phases along the binary Ti–O, and of Ti^{4+} in CaO. Four ternary oxides were identified: $CaTiO_3$, $Ca_4Ti_3O_{10}$ and $Ca_3Ti_2O_7$ containing tetravalent titanium, and $CaTi_2O_4$ containing trivalent titanium. Tie-lines link calcium titanite ($CaTi_2O_4$) with the three calcium titanates ($CaTiO_3$, $Ca_4Ti_3O_{10}$ and $Ca_3Ti_2O_7$), CaO, oxygen excess $TiO_{1+\delta}$ and stoichiometric TiO_2. Tie-lines connect $CaTiO_3$ with TiO_{2-x}, Magneli phases Ti_nO_{2n-1} ($28 \geq n \geq 4$), Ti_3O_5, Ti_2O_3 and $TiO_{1+\delta}$.

CaO was found to coexist with TiO, and Ti–O solid solutions α and β. This phase diagram was found useful for understanding the mechanisms and kinetics of direct calciothermic reduction of TiO_2 to metal and electrochemical reduction of TiO_2 using a graphite anode and molten $CaCl_2$ electrolyte.

A study of mixtures of CaO and TiO_2 fired at 1773 K (1500 °C) with various heating rates confirmed the presence of three binary compounds in the system as: CaO–TiO_2, $CaTiO_3$, $Ca_3Ti_2O_7$, and $Ca_4Ti_3O_{10}$. Mixtures of CaO and TiO_2 of the same composition but fired at different rates were found to develop calcium titanates that are stoichiometrically different. With a heating rate of 50 K/h, Ca_3TiO_7 and $Ca_4Ti_3O_{10}$ are formed and at 300 K/h, mainly calcium monotitanate, $CaTiO_3$, was found, with a small amount of $Ca_3Ti_2O_7$ also present.

All of these calcium titanate compositions may be regarded as variations of the basic perovskite layer in which CaO may be interleaved, as shown in Fig. 8.17.

The features of the crystallochemical structure of calcium titanate indicates that the structure of $Ca_3Ti_2O_7$ and $Ca_4Ti_3O_{10}$ can be perceived as consisting of alternating layers of the perovskite, $CaTiO_3$, and CaO. This means that it can be assumed that the first crystal phase developing in the solid-phase sintering in mixtures

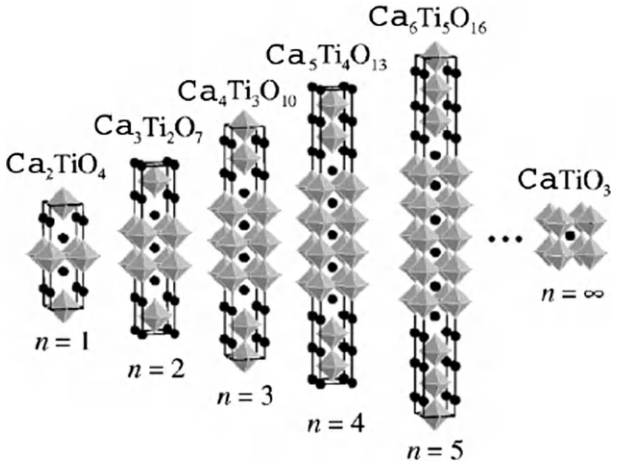

FIGURE 8.17

$CaO–TiO_2$ is $CaTiO_3$. Subsequently, during a slow heating rate, a gradual ordering of the structure of calcium trititanates and tetratitanates occurs, leading to an equilibrium wherein a high concentration of CaO (>88%) is in association with $Ca_3Ti_2O_7$ and $Ca_4Ti_3O_{10}$. With increase in the CaO content in calcium monotitanate, there should be an increase in the resistance of lime refractories to atmospheric hydrolysis. The sintering schedule of lime refractories and especially lime clinker should therefore ensure the formation of titanates and solid solutions most highly enriched with CaO. This has resulted in an increase in hydrolysis resistance for refractory forms based upon lime.

The chemical potentials of CaO in two-phase field ($TiO_2 + CaTiO_3$), ($CaTiO_3 + Ca_4Ti_3O_{10}$), and ($Ca_4Ti_3O_{10} + Ca_3Ti_2O_7$) of the pseudo-binary system ($CaO + TiO_2$) have been measured in the temperature range (900–1250 K), relative to pure CaO as the reference state, using solid-state galvanic cells incorporating single-crystal CaF_2 as the solid electrolyte. The cells were operated under pure oxygen at ambient pressure. The standard Gibbs free energies of formation of calcium titanates, $CaTiO_3$, $Ca_4Ti_3O_{10}$, and $Ca_3Ti_2O_7$, from their component binary oxides were derived from the reversible e.m.f.s. The results can be summarized by the following equations:

$$CaO(solid) + TiO_2(solid) \Rightarrow CaTiO_3(solid)$$

$$\{\Delta G^\circ \pm 85/(J/mol) = -80{,}140 \text{ to } 6.302(T/K)\}$$

$$4CaO(solid) + 3TiO_2(solid) \Rightarrow Ca_4Ti_3O_{10}(solid)$$

$$\{\Delta G^\circ \pm 275/(J/mol) = -243{,}473 \text{ to } 25.758(T/K)\}$$

$$3CaO(solid) + 2TiO_2(solid) \Rightarrow Ca_3Ti_2O_7(solid)$$

$$\{\Delta G^\circ \pm 185/(J/mol) = -164{,}217 \text{ to } 16{,}838(T/^\circ K)\}$$

The reference state for solid TiO_2 is the rutile form. The results of this study were in good agreement with thermodynamic data for $CaTiO_3$ reported in the literature. For $Ca_4Ti_3O_{10}$, Gibbs free energy of formation obtained in this study differed significantly from that reported by Taylor and Schmalzried at $T = 873$ K. For $Ca_3Ti_2O_7$, experimental measurements are not available in the literature for direct comparison with the results obtained in this study. Nevertheless, the standard entropy for $Ca_3Ti_2O_7$ at $T = 298.15$ °K estimated from the results of this study using the Neumann–Koop rule is in fair agreement with the value obtained from low-temperature heat-capacity measurements.

Several investigations of the bulk phase diagram of the system CaO–TiO_2 predicted the existence of three stable compounds such as $Ca_3Ti_2O_7$, $Ca_4Ti_3O_{10}$ and $CaTiO_3$. The first two phases peritectically decompose at 1750 and 1840 °C, respectively, whereas the $CaTiO_3$ phase melts congruently at 1960 °C. There is also a eutectic at 1450 °C between $CaTiO_3$ and TiO_2. $Ca_3Ti_2O_7$ has an

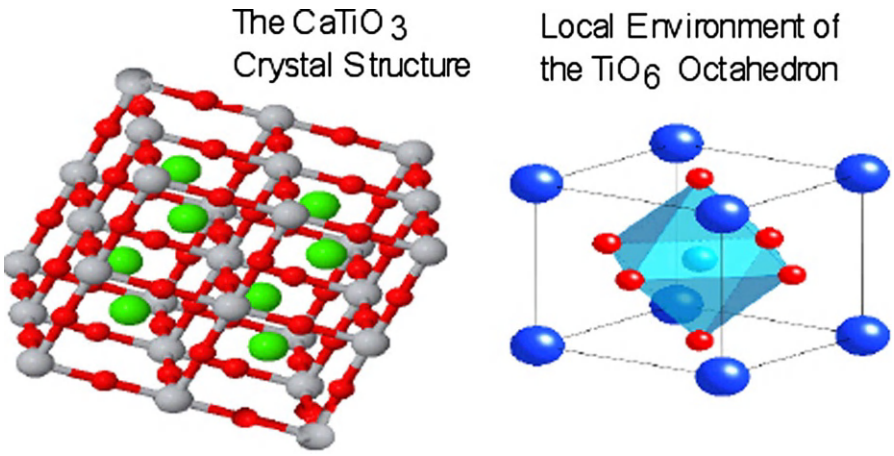

FIGURE 8.18

orthorhombic structure with $a = 5.41$ Å, $b = 19.42$ Å and $c = 5.42$ Å (space group $Ccm21$), while $Ca_4Ti_3O_{10}$ has also an orthorhombic structure with $a = 5.43$ Å, $b = 27.14$ Å and $c = 5.43$ Å (space group $Pcab$). The mineral, perovskite = $CaTiO_3$, has an orthorhombic structure at room temperature with $a = 5.38$ Å, $b = 5.44$ Å and $c = 7.654$ Å (space group $Pbnm$). The orthorhombic distortion of $CaTiO_3$ decreases with increasing temperature. The phase transitions from the room temperature orthorhombic structure to a tetragonal ($a = b = 5.49$ Å and $c = 7.78$ Å, space group $I4/mcm$) polymorph occur at temperatures between 1373 and 1423 K, followed by transformation to the cubic phase ($a = 3.83$ Å, space group $Pm\bar{3}m$) at 1523 K.

$CaTiO_3$ is mostly prepared by a solid-state reaction of CaO or $CaCO_3$ with TiO_2 at high temperatures. The undoped $CaTiO_3$ is an incipient ferroelectric with potential applications in MW-tunable devices. Upon doping with Pb^{2+}, it becomes a true ferroelectric. The versatility of calcium titanate extends to its suitability as a material for the immobilization of radioactive waste and as a biocompatible coating for medical Ti implants. Calcium metatitanate, $CaTiO_3$ has a cubic perovskite structure with $a = 3.795$ Å and $\alpha = \beta = \gamma = 90°$, as shown in Fig. 8.18.

The cell parameters are listed in Table 8.7.

Ceramic solid solutions involving $CaTiO_3$ are among the candidate systems for high-quality MW dielectric materials. Pure $CaTiO_3$ has a dielectric constant of about 180 at room temperature. The dielectric constant increases monotonically as temperature decreases over the measured range from 4.2 to 430 K, and extrapolates to a value greater than 300 at zero temperature. Associated with the trends in dielectric constant is a large positive TCF ($\gamma_f = \partial f/\partial T$) for dielectric resonators made from $CaTiO_3$.

Calcium metatitanate is also orthorhombic with: $CaTiO_3$: SG = $Pbnm$ (No. 62): $a = 5.380$ Å, $b = 5.440$ Å, $c = 7.639$ Å. The structure can be represented as shown in Fig. 8.19.

In order to make this distinction, the following diagram is presented as shown in Fig. 8.20.

TABLE 8.7

Atom	Wyckoff	x	y	z
Ca	4c	0.0065	0.0356	1/4
Ti	4b	0	1/2	0
O1	4b	0.5711	−0.0161	1/4
O2	8d	0.2897	0.2888	0.0373

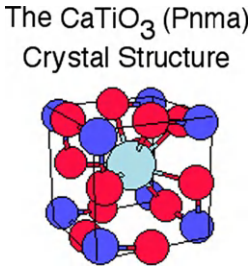

FIGURE 8.19

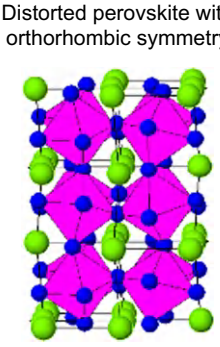

FIGURE 8.20

The distorted octahedra are clearly present and cause the cubic form to disappear entirely. Once formed, the orthorhombic form remains stable, even if high pressure is applied.

Some other unique properties that set perovskites apart and make them ideal for technological applications include:

(1) it is the only crystal structure that is ferroelectric (spontaneous alignment of the electric dipoles caused by interactions between them) not because of an external magnetic field but due to its crystal structure,

(2) it has unique ferro-, pyro-, and piezoelectric properties, and structural properties such as durability and chemical flexibility.

In the $CaTiO_3$–CaO system, two polytypic phases have been reported, $Ca_3Ti_2O_7$ ($n = 2$) and $Ca_4Ti_3O_7$ ($n = 3$). Due to a different Ca/Ti ratio, the phase, Ca_2TiO_4 is not stable. $Ca_3Ti_2O_7$ and $Ca_4Ti_3O_{10}$ consist of coherent intergrowths of **n** perovskite blocks with a single CaO layer having a distorted rock salt configuration. In both structures, the TiO_6 octahedra are tilted and distorted in a fashion like that of $CaTiO_3$. In $Ca_4Ti_3O_{10}$, there are two types of octahedra. Those in the middle of perovskite blocks are designated as "type 1" and those at the edges of the block as "type 2". The mean Ca–O bond lengths in this compound indicate that there are two distinct Ca^{2+} sites in this polytype structure where the Ca_1 sites are larger in the middle of the $CaTiO_3$ blocks and the Ca_2 sites are smaller in the CaO layers (Fig. 8.21).

The calcium titanates, $CaTiO_3$, $Ca_3Ti_2O_7$ and $Ca_4Ti_3O_{10}$, can be synthesized by the wet chemical peroxide route. The first step of the preparation is the precipitation of peroxo-precursors of definite stoichiometry which are transformable into the corresponding titanates by thermal decomposition. The resulting ultrafine, phase-pure calcium titanate powders have only a small impurity content. They are very sinter active above 1200 °C. The rate of densification during sintering of compacts is improved in the sequence $Ca_3Ti_2O_7 < Ca_4Ti_3O_{10} < CaTiO_3$, considering the green densities, the densities at a given time and the theoretical densities of the titanates for the calculations. The phase $CaTi_4O_9$ can be obtained after thermal degradation of a corresponding peroxo-precursor at temperatures below 700 °C. There are also indications of the formation of the phase $CaTi_2O_5$ below 700 °C. A phase in which titanium appears as Ti^{3+} in Ca_2TiO_4 cannot be synthesized using the peroxide route.

Calcium titanate is supplied in large quantities commercially as $CaTiO_3$ with a CAS number of 12049-50-2.

A symmetry analysis of the zero temperature instabilities of the tetragonal phase of tricalcium dititanate, $Ca_3Ti_2O_7$, which is stable at high temperature, has been performed. Order parameters were used to characterize each of the possible lattice distortions in order to construct a Landau free energy that elucidates the proposed group–subgroup relations for structural transitions in these systems. The coupling between the unstable distortion modes and the macroscopic strain tensor was also included. It was shown that in this phase the weak ferromagnetic moment and the spontaneous ferroelectric polarization are coupled, so that rotating one of these ordering by applying an external electric or magnetic field one can rotate the other ordering. A number of different domains (including phase domains) exist in each of the phases and indicate how these may be observed. The structure is shown in Fig. 8.22.

Ruddlesden–Popper (RP) systems are compounds of the form $A_{2+n}B_{1+n}C_{4+3n}$, where n is an integer, and the

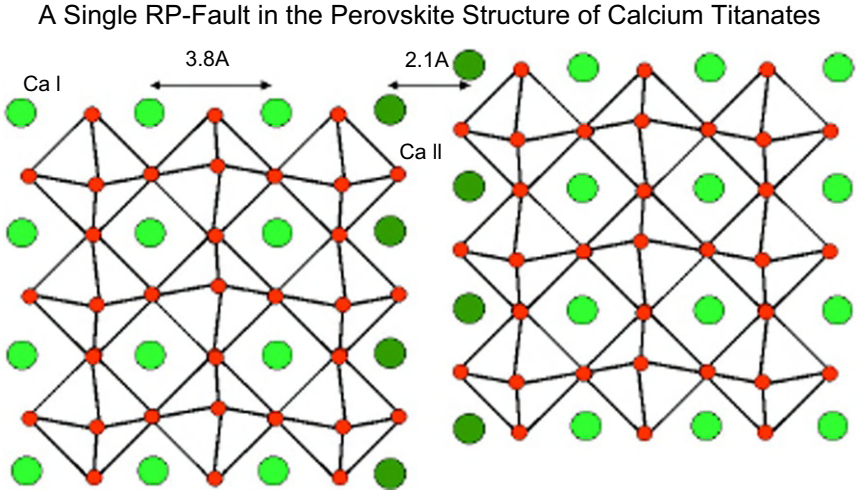

FIGURE 8.21

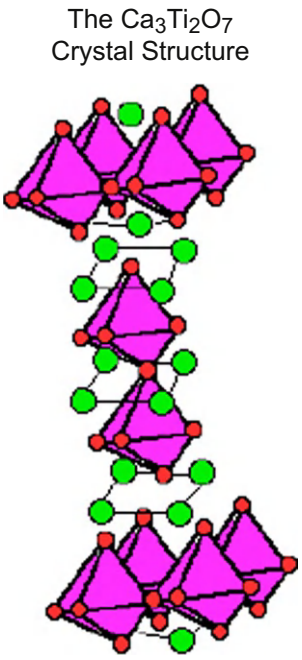

FIGURE 8.22

valences of the ions are usually $A = +2$, $B = +4$ and C (oxygen) $= -2$. They are essentially a series of tetragonal or hexagonal conformations.

Systems like $CaTiO_3$ can be regarded as being $n = \infty$. At high temperatures $T \geq 800$ K, their crystal structure is tetragonal, consisting of n-layer units, each layer consisting of vertex sharing oxygen octahedra at whose center sit a B ion, as shown in Fig. 8.22. As the temperature is lowered, these systems can undergo structural phase transitions into orthorhombic structures. These structural transitions usually involve reorientation of oxygen octahedra. One reason for the continuing interest in octahedral reorientations lies in the fact that they are important for many interesting electronic properties such as high-Tc superconductivity, colossal magnetoresistance, metal–insulator transitions and magnetic ordering.

Compounds concerning Ti^{2+} are also known. In an academic study of a "defect perovskite" structure of stoichiometry $AeTiO_2$ (AE = alkaline earth metal, Be, Mg, Ca, Sr, and Ba), we find substantial Ti–Ti bonding tuned by the size of the Ae^{2+} cation. The bonding is one-dimensional, partially σ, partially π. These formal d2 systems are expected to be nonmagnetic and metallic. A competing (for same Ae) structural alternative, an ordered rock salt structure, is magnetic shown in Fig. 8.23.

The photoactivity of this catalyst, containing Ti^{2+} ions, was evaluated by photocatalytic degradation of an azo dye, acid red 1 (AR1), using UV light irradiation. The results of the investigations revealed that the

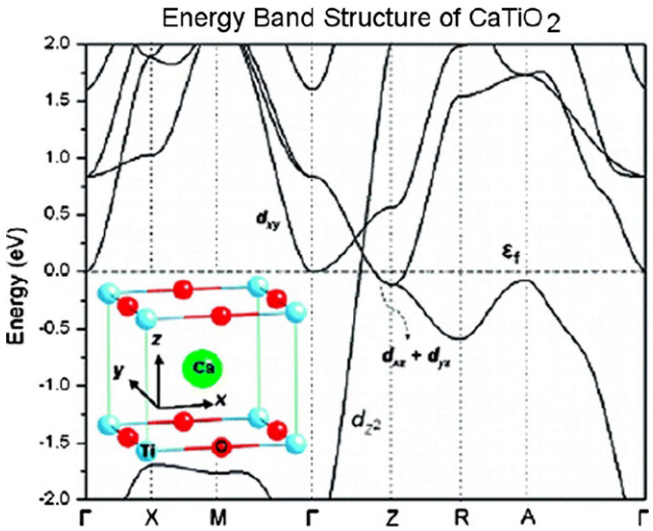

FIGURE 8.23

samples calcined at 300 °C for 3.6 h in a cyclic (2 cycles) mode had the best performance. Lower percentage dopant, 0.3–1.0 wt%, enhanced the photocatalytic activity of TiO_2, with the best at 0.5 wt% $CaTiO_2$. The performance of 0.5 wt% $CaTiO_2$ in the degradation of AR1 was far superior to that of a commercial Anatase TiO_2 Sigma product CAS No. 1317-70-0. The effect of pH on the degradation of AR1 was studied, and the pH of the dye solution exerted a great influence on the degradation of the dye. In contrast, the 2:1 compound, Ca_2TiO_3, was not photocatalytic at all.

Both 1:1 and 1:2 compounds in the $CaO–Ti_2O_3$ system occur as minerals, either Kassite, $CaTi_2O_4(OH)_2$ or Cafetite, $CaTi_2O_5(H_2O)$. The structure of Kassite is shown in Fig. 8.24.

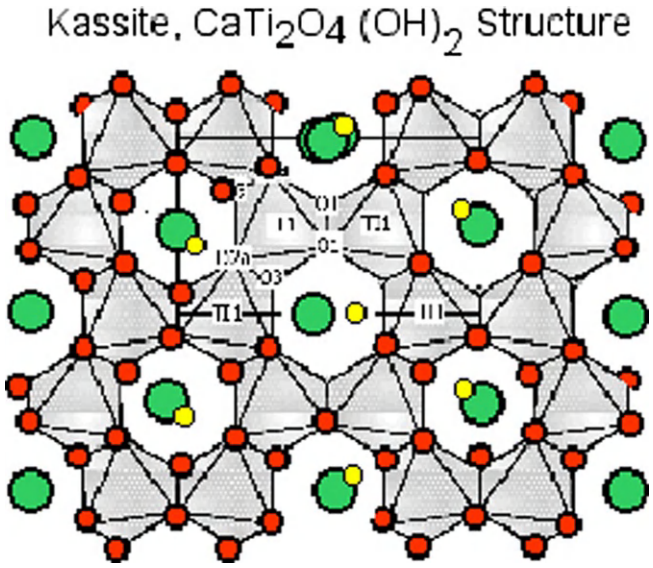

FIGURE 8.24

A related homologue, $Ca_2Ti_2O_6$ has also been studied. Ca–Ti–O films were prepared on quartz substrates by MoCVD (Metal oxide-chemical vapor deposition) using the precursors of $Ti(O\text{-}i\text{-}Pr)_2(dpm)_2$ and $Ca(dpm)_2$. The effects of deposition conditions on the crystal structure and microstructure of Ca–Ti–O films were investigated. The deposition temperatures (T_{dep}) were changed from 787 to 1187 K and the total pressure in the reaction chamber (P_{tot}) was kept at 0.8 kPa. The molar ratio of Ca to Ti precursors ($R_{Ca/Ti}$) was changed from 0.34 to 0.95. At temperatures higher than 1073 K (800 °C), $CaTiO_3$ perovskite films in a single phase were obtained. Mixtures of $Ca_2Ti_2O_6$ in a pyrochlore structure and $CaTiO_3$ in a perovskite structure were obtained at 787–1073 K and the content of $Ca_2Ti_2O_6$ phase increased with decreasing $R_{Ca/Ti}$. $Ca_2Ti_2O_6$ pyrochlore films in a single phase were obtained at $T_{dep} = 1073$ K and $R_{Ca/Ti} = 0.38$. $Ca_2Ti_2O_6$ is a face-centered cubic structure with $a = 9.90$ Å. Pyrochlore showed a granular microstructure about 500 nm in grain size. The transmittance of the $Ca_2Ti_2O_6$ films in a single phase was 50–70% in the wavelength range of 500–2500 nm. The band gap of pyrochlore was about 3.3 eV that calculated by the transmittance. The permittivity of $Ca_2Ti_2O_6$ films was about 100 from room temperature to 700 K.

Calcium titanates are readily available commercially.

8.1.7. Strontium Titanides

There are no known intermetallic compounds in the system, Sr–Ti. A phase diagram has been published but shows only the polymorphic transitions of the two metals.

8.1.8. Strontium Titanates

In the bulk phase diagram of the system SrO–TiO_2, several compounds are known and include compositions such as Sr_2TiO_4, $Sr_3Ti_2O_7$ and $SrTiO_3$. There is a eutectic at 1440 °C between $SrTiO_3$ and TiO_2, as shown in Fig. 8.25.

In the Ti^{4+} system of SrO–TiO_2, Sr_2TiO_4 has a tetragonal structure with $a = b = 3.88$ Å and $c = 12.62$ Å (space group $I4/mmm$), while $Sr_3Ti_2O_7$ has also a tetragonal structure with $a = b = 3.94$ Å and $c = 20.38$ Å (space group $I4/mmm$). $SrTiO_3$ has a cubic perovskite structure with $a = 3.91$ Å (space group $Pm3m$) at room temperature and higher, as shown in Fig. 8.26.

Strontium titanate is commonly produced by a solid-state reaction of $SrCO_3$ with TiO_2 at high temperatures (>1000 °C):

$$SrCO_3(solid) + TiO_2(solid) \Rightarrow SrTiO_3(solid) + CO_2(gas)$$

No intermediate products were observed during $SrTiO_3$ synthesis by Tagawa and Igarashi as well as by Chang and Liu. However, further investigation has suggested that the above reaction resulted via an intermediate Sr_2TiO_4 compound. $SrTiO_3$ is of technical significance. Owing to its high dielectric constant and large dielectric breakdown field, $SrTiO_3$ is a potential candidate for storage capacitor cells in dynamic random access memories. $SrTiO_3$ single crystals and thin films are extensively used as substrates for high-Tc superconducting, ferroelectric and multiferroic thin films. Suitably doped $SrTiO_3$ single crystals have been considered for nonvolatile memories based on resistive switching. Strontium titanate or $SrTiO_3$ single crystal provides a good lattice match to most materials with perovskite structure. At room temperature it exists in the cubic form, but transforms into the tetragonal structure at temperatures less than 105 K. At very low temperatures, $SrTiO_3$ exhibits piezoelectric and superconducting characteristics. It also exhibits a very large dielectric constant.

Strontium titanate ($SrTiO_3$) is currently the most widely used high-temperature superconducting

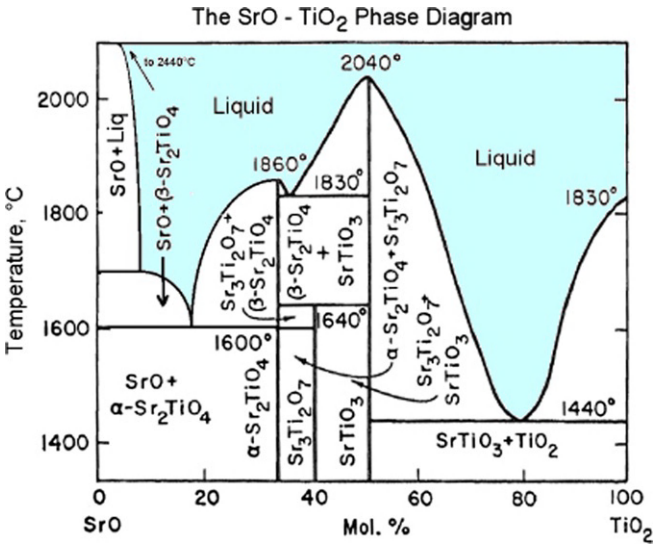

FIGURE 8.25

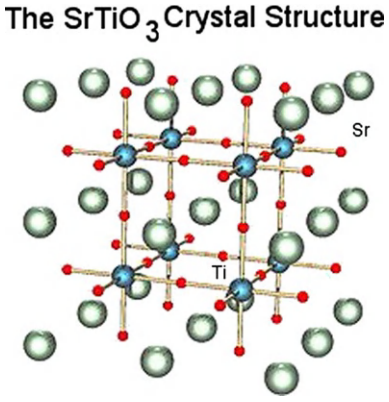

FIGURE 8.26

single-crystal substrate and is superior in this regard. It is compatible with $YBaCuO_3$ high-temperature superconducting materials with advantages such as lattice matching, and lack of twin structure, physical and mechanical properties when the film is formed. Film technology using a variety of systems (such as magnetic sputtering, pulsed laser deposition, laser molecular beam epitaxy, etc.) produced by a variety of high-temperature superconducting thin films (Y-system, Bi-system, La-system, etc.) can be TCO $\geq$ 90 K, JCO $\geq$ 106 A/cm^2 and other indicators. $SrTiO_3$ is also used in high-temperature superconducting junction technology (using double-crystal substrate or the step-like substrate) and is the preferred single-crystal material at the level of substrate (at a specific point of the miter and heat treatment).

In the $SrTiO_3$–SrO system, three polytypic phases have been reported, Sr_2TiO_4 ($n = 1$), $Sr_3Ti_2O_7$ ($n = 2$) and $Sr_4Ti_3O_7$ ($n = 3$). The phase, Sr_2TiO_4 can be described as the ordered sequence of a single SrO fault and a single $SrTiO_3$ perovskite block, while the $Sr_4Ti_3O_{10}$ structure is a sequence of one planar fault and three perovskite layers. These RP phases are completely ordered only when an exact stoichiometry is achieved. For this phase, the Sr/Ti ratio should be 1.33 of coherent intergrowths of **n** perovskite blocks with a single SrO layer having a distorted rock salt configuration. In both structures, the TiO_6 octahedra are tilted and distorted in a fashion like that of $SrTiO_3$. In $Sr_4Ti_3O_{10}$, there are two types of octahedra. Those in the middle of perovskite blocks are designated as "type 1" and those at the edges of the block as "type 2". The mean Sr–O bond lengths in this compound indicated that there are two distinct Sr^{2+} sites in this polytype structure wherein the Ca_1 sites are larger in the middle of the $SrTiO_3$ blocks and the Sr_2 sites are smaller in the SrO layers. An RP defect in the perovskite type of structure was given for the Ca homologue.

Although a 1:2 compound in the CaO–TiO_2 system has been reported, there are no reports of an equivalent $SrTi_2O_5$ phase.

Figure 8.27 shows the structures of the unit cells of the artificially layered phases ($m = 1$–5).

Only $SrTiO_3$ appears in the phase diagram. The strontium (light- and dark-green spheres), titanium (centered in the octahedra), and oxygen (apices of the octahedra) ions are assumed to arrange in the same manner as in the related $SrTiO_3$, Sr_2TiO_4, and SrO ($m = 1, 2, \infty$) phases. Based on these principles, the c lattice parameter of the unit cells for the odd m phases was made equal to the spacing between TiO_2 planes, whereas c is twice for the even m phases owing to a body-centering translation.

Although these phases are easily envisioned, the question was asked as to whether or not they can be formed and whether or not they are stable with respect to large-scale phase separation into the equilibrium

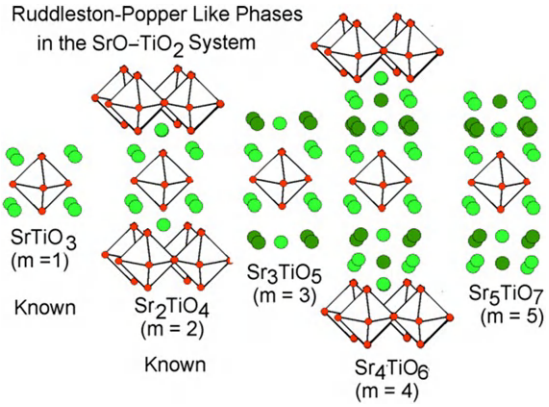

FIGURE 8.27

bulk phases Sr_2TiO_4 and SrO. The epitaxial films were grown on $LaAlO_3$(001) substrates using a molecular beam epitaxy (MBE) system for crystal growth system. The single-crystal substrates were etched in 3:1 HCl:HNO_3 ultrasonically cleaned in acetone and ethanol and annealed prior to the growth of films. Growth was controlled to the monolayer level by first calibrating the flux rates of both sources ex situ. Deposition was carried out by alternating the open elemental source between Sr and Ti (while the other was shuttered) in a manner to deposit m monolayers of SrO followed by a single TiO_2 monolayer. These layers have been valuated as dielectric films for MW applications.

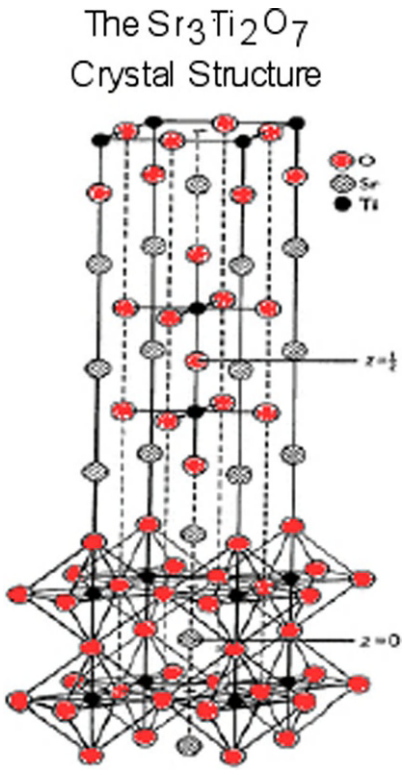

FIGURE 8.28

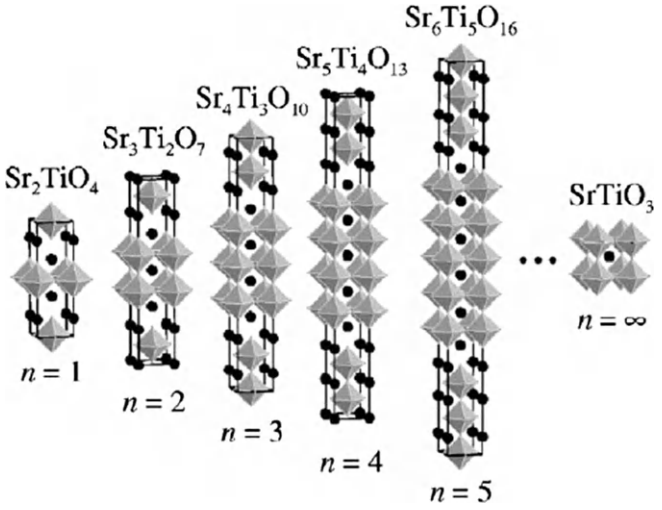

FIGURE 8.29

The compound, tristrontium dititanate, $Sr_3Ti_2O_7$, has the structure shown in Fig. 8.28. It is tetragonal but related to the cubic perovskites, as may be seen by closer examination of the structure diagram shown in Fig. 8.28.

It was formed by firing a mixture of $SrCO_3$ and TiO_2 at a molar ration of 3:2. Its structure is intermediate to Sr_2TiO_4 (K_3NiF_4 type) and perovskite, $SrTiO_3$. Whereas in Sr_2TiO_4, perovskite layers are interleaved with SrO layers, forming a tetragonal, body-centered unit with an axial ratio of about 3:2, double perovskite layers are interleaved with SrO layers in $Sr_3Ti_2O_7$, the axial ratio being increased to about 5:2. The unit cell contains about two formula units. This is better illustrated as shown in Fig. 8.29. The increase in layers for various strontium titanate compositions is more easily seen in Fig. 8.29.

The main usage for $SrTiO_3$ has been as a gemstone. A sample is shown in Fig. 8.30.

Strontium titanate is both much denser (space group = 4.88 for natural, 5.13 for synthetic) and much softer (Mohs hardness = 6–6.5 for natural, 5.5 for synthetic) than diamond. Its refractive index (2.41—as measured by sodium light, 589.3 nm) is nearly identical to that of diamond, but the dispersion (the optical property responsible for the "fire" of the cut stones) of strontium titanate is over four times higher, at 0.19 (B–G interval). This results in an excess of "fire" when compared to diamond.

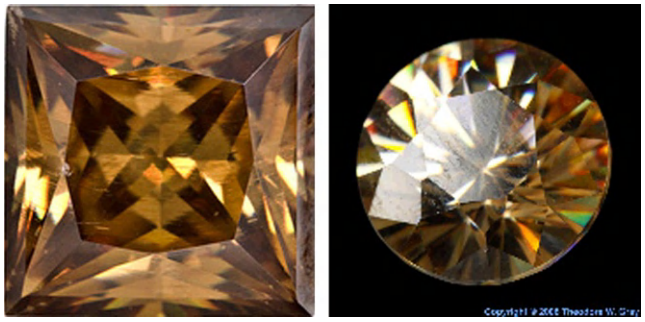

FIGURE 8.30

The strontium titanates $SrTiO_3$, Sr_2TiO_4, $Sr_3Ti_2O_7$ and $Sr_4Ti_3O_{10}$ can be synthesized to a good quality by a wet chemical peroxide route. At first, peroxo-precursors of definite stoichiometry are formed during the preparation. These are then transformed into the titanates by thermal decomposition. The resulting strontium titanate powders are of ultrafine nature and have a high purity. They show high sintering activity at temperatures >1200 °C. The densification behavior during sintering improved in the sequence $Sr_2TiO_4 < Sr_3Ti_2O_7 < Sr_4Ti_3O_{10} < SrTiO_3$.

Vacancy-ordered $Sr_2Ti_2O_5$ (110) epitaxial films in situ deposited on $YBa_2Cu_3O_{7-\delta}$ (YBCO) (103) epitaxial films were studied for insulating layers in high-Tc superconducting heterostructures. The ordered structure is interpreted by a $2 \times 2 \times 2$ superstructure with a long-range ordered arrangement of oxygen vacancies in the film and a 2:1 surface superstructure with an ordered arrangement of surface oxygen vacancies on it. The resistivity of the $Sr_2Ti_2O_5$ film sandwiched between Au and YBCO films was measured as a function of the thickness and temperature, and discussed with respect to electron scattering induced by a deficiency of oxygen in the film and at the film boundary.

In the Ti^{3+} system of SrO–Ti_2O_3, the crystal structure of the strontium thallate $SrTl_2O_4$ was determined using powder XRD. This oxide is isostructural with $CaFe_2O_4$, i.e. it crystallizes in the space group *Pnam* with $a = 10.041$ Å, $b = 11.697$ Å and $c = 3.49$ Å. The $[Tl_2O_4]\infty$ framework is built up from double rutile chains of TlO_6 octahedra forming five-sided tunnels where the strontium cations are located. The semimetallic properties of this phase are once more in favor of the existence of proximity effect induced superconductivity in the $[TlO]\infty$ layers of layered thallium cuprates.

Strontium titanates are available commercially, in the form of gemstones, single-crystal slices and powders.

8.1.9. Barium Titanides

There are no known intermetallic compounds that occur in the system, Ba–Ti. A phase diagram has been published but shows only the polymorphic transition temperatures of the two metals.

8.1.10. Barium Titanates

A number of compounds form by reaction between BaO and TiO_2 at elevated temperatures. Some of these compounds are of great interest and technological importance. Statton first tried to establish phase relations in the BaO–TiO_2 system. Later, this phase diagram was restudied and improved by many other workers.

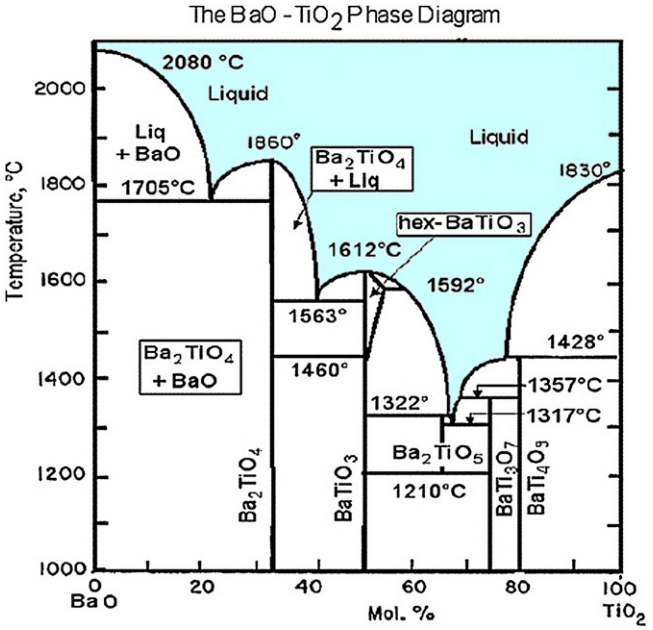

FIGURE 8.31

A high-temperature phase diagram constructed for the system BaO–TiO_2 is shown in Fig. 8.31.

The determination of the phase relationships was based on XRD and microscopic visual analyses of the samples quenched from high temperature. In the Ti-rich region, the results of Kirby et al. are in general agreement with those of Negas et al. and O'Bryan et al. As can be seen from the phase diagram, the formation of Ti-rich barium titanates depends on the ratio of Ba to Ti as well as temperature. The stable Ti-rich barium titanates which exist at high temperatures are: $Ba_6Ti_{17}O_{40}$, $Ba_4Ti_{13}O_{30}$, $BaTi_4O_9$ and $Ba_2Ti_9O_{20}$. The latter two Ti-rich phases are used in MW industry. Other supposedly possible Ti-rich barium titanates such as $BaTi_5O_{11}$ and $BaTi_6O_{13}$ have not been observed in these studies. A compound, $BaTi_2O_5$, was found in a sample containing 65 mol% TiO_2, when quenched from the liquid state. However, heating of this sample at 1320 °C for 64 h resulted in a mixture of $BaTiO_3$ and $Ba_6Ti_{17}O_{40}$ with no evidence of any remaining $BaTi_2O_5$.

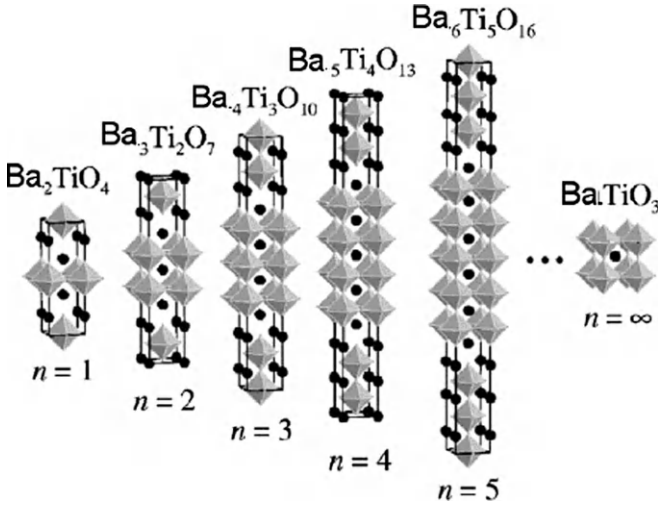

FIGURE 8.32

It was noted that these three Ti-rich barium titanates form only through a liquid intermediate. However, Ritter et al. obtained $BaTi_2O_5$ and $BaTi_5O_{11}$ phases by using low-temperature alkoxide synthesis techniques. In this diagram, both $BaTi_2O_5$ and $BaTi_5O_{11}$ phases crystallize at ~700 °C. $BaTi_2O_5$ decomposes into $Ba_6Ti_{17}O_{40}$ and $BaTiO_3$ at ~1150 °C, while $BaTi_5O_{11}$ decomposes to TiO_2, $Ba_2Ti_9O_{20}$ and/or $BaTi_4O_9$ at ~1200 °C. Thus, we can conclude that both these phases ($BaTi_2O_5$ and $BaTi_5O_{11}$) are either low-temperature stable phases or metastable phases obtained by crystallization of an amorphous precursor. This can be better appreciated by perusal of the following diagram that shows such phases originate from the cubic perovskite phase and are di-, tri-, tetra-, penta- or hexa-perovskites (Fig. 8.32).

The types of barium titanate compounds investigated and their crystalline parameters are shown in Table 8.8 ("*n*" is the number of layers present).

TABLE 8.8

Phase	Space group	*a* (Å)	*b* (Å)	*c* (Å)	*α* (°)	*β*	*γ*	*n*
$BaTi_2O_5$	*A*2/*m*—monoclinic	9.409	3.93	16.92	90	103.5	90	—

$Ba_6Ti_{17}O_{40}$	*C*2/*c*—monoclinic	9.88	17.08	18.92	90	98.42	90	8

These crystal structures of Ti-rich barium titanates have been extensively studied. $BaTi_4O_9$ and $BaTi_2O_5$ have structures which can be described as cubic close-packed arrangements of Ba and O atoms. Both these compounds have one short cell constant of about 4.0 Å. These structures have often been referred to as Wadsley–Andersson type phases (also called tunnel structures). The structures of other Ti-rich barium titanates, i.e. $BaTi_6O_{13}$, $BaTi_5O_{11}$, $Ba_4Ti_{13}O_{30}$, $Ba_2Ti_9O_{20}$, $Ba_2Ti_{13}O_{22}$ and $Ba_6Ti_{17}O_{40}$, are more complex but can be described as close packing of Ba and O atoms in which some of the octahedral O_6 interstices are occupied by Ti atoms. These structures can be illustrated as being made up of Ba–O close-packed layers with 4, 6, 8 or 10 layers per unit cell. The unit cell dimensions of Ti-rich barium titanates as well the number of layers per unit cell are given in Table 8.8.

The mean thickness of each close-packed layer of the Ti-rich barium titanates is ≈0.234 nm which is similar to the (111) interplanar spacing of $BaTiO_3$. The orientation of the close-packed layer is usually derived from the morphology of the crystals or from the diffraction pattern. For example, in the case of $Ba_6Ti_{17}O_{40}$, the lattice constant $c = 18.92$ Å (≈8 Å ~ 0.234 nm) leads to the conclusion that the unit cell contains eight close-packed layers perpendicular to the *c*-axis. Despite one unit cell repeating itself after 8 layers, the real crystallographic identity period of the packing of the complete structure is 24 layers. This arises because the direction of packing is [103]. The angle between the [103] direction and the (001) plane in $Ba_6Ti_{17}O_{40}$ is ≈1.3. The compositions of other Ti-rich barium titanates can be derived by analogy to the layers in $Ba_6Ti_{17}O_{40}$ and $Ba_4Ti_{13}O_{30}$ as was shown by Roth et al. for the phases $Ba_6Ti_{14}Nb_2O_{39}$, $Ba_{14}Ti_{40}Nb_2O_{99}$ and $Ba_{18}Ti_{54}Nb_2O_{132}$. Recently, a topotaxial orientation relationship between $BaTiO_3$ and $Ba_6Ti_{17}O_{40}$ as well as between $BaTiO_3$ and $Ba_4Ti_{13}O_{30}$ has been established. Despite the different procedure of sample preparation (solid-state reaction of $BaCO_3$ and TiO_2 at high temperatures in air or chemical reaction of SiO_2 film with $BaTiO_3$ single crystals). Thus, the close-packed planes of $Ba_6Ti_{17}O_{40}$ and $Ba_4Ti_{13}O_{30}$ lie parallel to the close-packed planes of $BaTiO_3$. Crystallographically, Krasevec et al. explained the orientation relationship between $Ba_6Ti_{17}O_{40}$ and $BaTiO_3$ phases by the similarity of the stacking sequence of (111) planes of $BaTiO_3$ and (001) planes of $Ba_6Ti_{17}O_{40}$, if the larger unit cell of the monoclinic $Ba_6Ti_{17}O_{40}$ phase was appropriately cut. On the base of the above relationship, a model of a topotactic boundary between $Ba_6Ti_{17}O_{40}$ and $BaTiO_3$ phases was constructed.

In the preparation of $BaTiO_3$ from $BaCO_3$ and TiO_2, it was noted that formation of pseudo-cubic $BaTiO_3$ free from $BaCO_3$ and TiO_2 occurred when the barium–titanium polymeric precursor was heat treated in air at 500 °C for 8 h or at 600 °C for 2 h. However, the Raman spectra of the same powders indicated the formation of tetragonal (rather than cubic) $BaTiO_3$, with traces of high-temperature hexagonal $BaTiO_3$ stabilized at room temperature, XRD of a pyrolyzed product at 500 °C for 2 h revealed a simple mixture of $BaTiO_3$ and an intermediate phase, $Ba_2Ti_2O_5 \cdot CO_3$. The solid-state reaction between $BaCO_3$ and TiO_2 was concluded as not being responsible for the $BaTiO_3$ formation; rather, $BaTiO_3$ formed directly by thermal decomposition of the intermediate $Ba_2Ti_2O_5 \cdot CO_3$ phase at temperatures >500 °C. In addition, by Raman scattering measurements, the intermediate $Ba_2Ti_2O_5 \cdot CO_3$ phase was found to be unstable in ambient air, yielding $BaCO_3$ as one of the decomposed products.

Barium titanate ($BaTiO_3$) is well known to have several phase transitions, depending on temperature. Above the Curie temperature (≈120 °C), it has the cubic perovskite structure (with Ba^{2+} as A and Ti^{4+} as B, $a \approx 4.01$ Å, space group $Pm3m$). This is a centrosymmetric cubic structure with Ba at the corners, Ti at the center and the oxygen atoms at the face centers (Fig. 8.33).

The ions are in the following positions: Ba at (0,0,0), Ti at (1/2,1/2,1/2) and three oxygen ions at (1/2,1/2,0), (1/2,0,1/2), (0,1/2,1/2). The titanium ion is surrounded by six oxygen ions in octahedral configuration and lies in octahedral holes of the Ba–O packing. Each barium ion has 12 oxygen neighbors. However, there are two high-temperature forms of $BaTiO_3$: cubic and hexagonal ($a = 5.74$ Å and $c = 14.05$ Å, space group $C6/mmc$). At temperatures above 1432 °C, the cubic form of $BaTiO_3$ transforms into the hexagonal form. These two modifications are built from close-packed (111) layers of composition BaO_3. In cubic $BaTiO_3$, there is repetition after every third layer as ABC … in the hexagonal form repetition occurs along the *c*-axis after every sixth layer as ABCACB …. As the temperature is lowered, cubic $BaTiO_3$ goes through phase transitions to three different ferroelectric phases: cubic to tetragonal at 393 K, tetragonal to

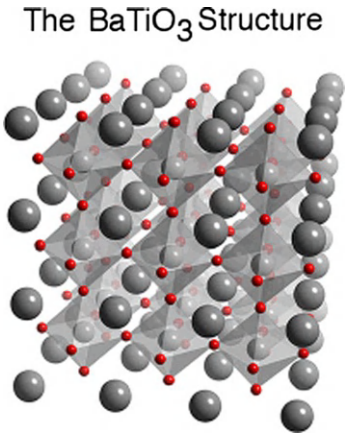

FIGURE 8.33

orthorhombic at 278 K, and orthorhombic to rhombohedral at 183 K. These three phases involve small distortions from the cubic symmetry. At room temperature, $BaTiO_3$ is usually considered as tetragonal with $a = 3.994$ Å, and $c = 4.038$ Å (space group $P4mm$).

The electrical properties of titania and its compounds indicate the suitability of these materials not only as substitutes for condenser grade mica but also for a number of other electrical applications where it is not possible or convenient to use other dielectrics. Of these, barium titanate is far superior. The oxides and carbonates of beryllium, magnesium, cerium, zinc, strontium, cadmium and barium were heated with titanium oxide to a temperature of about 1500 °C. The dielectric constants of the orthotitanates thus obtained were: for beryllium titanate 70, for magnesium 17, for calcium 115, for zinc 30, for strontium 155, for cadmium 62, >1000 for barium. The measurements were carried out at room temperature at a frequency of 1 MHz.

Barium strontium titanate (BST) powders of the formula $Ba_{1-x}Sr_xTiO_3$ ($0 \le x \le 1$) have been prepared by the polymeric precursor route using citric acid and ethylene glycol. Pure BSTs were obtained at 500 °C. These oxides were found to have the cubic structure, which is retained even after heating at 800 °C. Detailed X-ray studies on samples sintered at 1100 °C show weak tetragonal distortion for $BaTiO_3$, while the other BSTs retain their cubic structure. The particle size of the sintered oxides increases from 55 nm for $BaTiO_3$ to 88 nm for $SrTiO_3$, from X-ray line-broadening studies. The nano-sized grains are reasonably stable to sintering (the particle size for $BaTiO_3$ changes from 25 nm at 500 °C to 55 nm at 1100 C). The dielectric constant of the sintered oxides decreases from 510 for $BaTiO_3$ ($x = 0$) to 190 for $SrTiO_3$ ($x = 1$) at 100 kHz. The dielectric loss decreases from 0.05 for $BaTiO_3$ to 0.001 for $SrTiO_3$ at 100 kHz. No ferroelectric transition was observed either in the dielectric studies or by differential scanning calorimetry (Fig. 8.34).

Ba_2TiO_4 (barium orthotitanate) is the most Ba-rich compound in the system $BaO–TiO_2$. It is formed as an intermediate phase during the synthesis of $BaTiO_3$ by solid-state reaction between $BaCO_3$ and TiO_2. Ba_2TiO_4 exists in monoclinic and orthorhombic modifications. The orthorhombic form is stable at high temperatures, while the monoclinic phase is stable at room temperature. The orthorhombic Ba_2TiO_4 was observed to be a chemically unstable compound and it decomposed when exposed to air. Monoclinic Ba_2TiO_4 has a β-Ca_2SiO_4 type structure. Its unit cell has the dimensions: $a = 6.12$ Å, $b = 7.72$ Å, $c = 10.53$ Å and $\beta = 92.99°$. The orthorhombic modification of Ba_2TiO_4 has a distorted β-K_2SO_4 structure. Its unit cell has the dimensions: $a = 7.65$ Å, $b = 10.55$ Å, $c = 0.6.11$ Å (space group $Pnam$). The orthorhombic structure consists of tetravalent titanium cations in an unusual tetrahedral coordination.

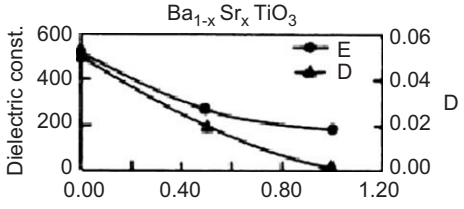

FIGURE 8.34

In the Ti^{3+} system of $BaO–Ti_2O_3$, the compound, $BaTi_2O_4$, remains unknown.

Barium titanates are readily available commercially in several forms.

8.1.11. Radium Titanates

There are no references the study of radium titanates. It is doubtful whether any such compounds can be formed. The literature is devoid of any mention of such compounds similar to those of the barium titanate series of compounds.

The high cost of radium is also a significant deterrent to work in Academia.

8.2. ALKALINE EARTH ZIRCONIUM COMPOUNDS

In contrast to titanium, only a few zirconate compounds of the alkaline earths are known. Additionally, only Be metal forms any intermetallic compounds with Zr metal.

8.2.1. Beryllium–Zirconium Compounds

There are no known compounds based on the $BeO–ZrO_2$ system. A phase diagram is available but shows only polymorphic temperature transitions of the individual oxide components.

8.2.2. Beryllium Zirconides

The intermetallic system, Be–Zr, has been studied and a phase diagram has been published (Fig. 8.35).

At least four compounds are known. With the exception of Be_2Zr, nearly all of the compounds are formed in the Be-rich part of the phase diagram.

$Be_{13}Zr$ has the structure shown in Fig. 8.36.

This lattice consists mostly that of the Be metal as modified by a few Zr atoms. The lattice structure changes in the vicinity of the Zr atoms. Cell parameters are: $a = b = c = 7.102$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 253.30 $Å^3$, $Z = 8$. Cell occupancy is listed in Table 8.9.

The compound, $Be_{17}Zr_2$, has similar features and the crystal structure shown in Fig. 8.37.

Cell parameters are: $a = b = c = 5.694$ Å, $\alpha = \beta = \gamma = 82.894°$, cell volume = 180.68 Å^3. Cell occupancy is listed in Table 8.10.

Be_2Zr has the crystal structure shown as follows. Cell parameters are: $a = 3.23$ Å, $b = c = 3.814$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 40.69 Å (Fig. 8.38).

Cell occupancy is listed in Table 8.11.

Be_5Zr has the crystal structure shown in Fig. 8.39.

Cell parameters are: $a = 3.485$ Å, $b = c = 4.584$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 62.87 Å^3. Cell occupancy is listed in Table 8.12.

These intermetallic compounds are not available commercially nor have any uses developed in Industry. No CAS numbers have been assigned.

8.2.3. Magnesium Zirconide Compounds

There were no known intermetallic compounds established in the system, Mg–Zr. A phase diagram has been published but showed only the polymorphic transition temperatures of the two metals.

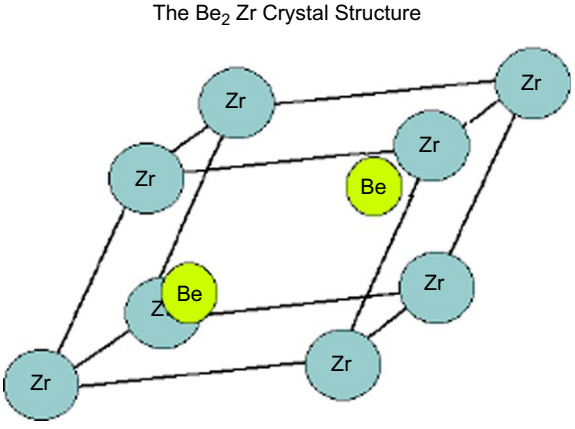

FIGURE 8.38

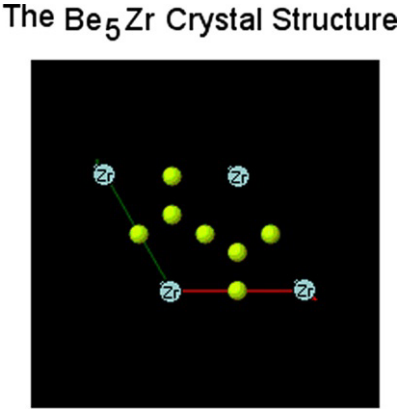

FIGURE 8.39

8.2.4. Magnesium Zirconate Compounds

The system, $MgO–ZrO_2$, has also been studied. A phase diagram is available but shows only the polymorphic temperature transitions of the individual oxide components.

It has been determined that the probable perovskite structure of $MgO–ZrO_2$, i.e. $MgZrO_3$, is difficult to prepare. $MgZrO_3$ melts at 2060 °C. The heat of formation is:

$$\Delta_f H = -3.34 \times 10^2 \text{ kJ/mol, 298 K, MgZrO}$$

This low value accounts for the lack of interest in this compound since it is difficult to create.

$MgZrO_3$ has been used as a thermal barrier material. Because of difficulty in formation of this material from the oxides, a plasma-spray technique has been used. Functionally gradient coatings are widely used at high temperatures in order to improve performances of materials in automotive, aircraft and aerospace industries, etc. These coating systems contain a steel substrate, bonding layer, cermet layer and ceramic coating, respectively. Furthermore, the composition and morphology of the coatings change gradually from ceramic to metal. In a recent work, 304 L stainless steel substrates were coated by functionally gradient coatings consisting of bond coat NiCrAl, 70% NiCrAl + 30% $MgZrO_3$, 50% NiCrAl + 50% $MgZrO_3$, 30% NiCrAl + 70% $MgZrO_3$ as the cermet layer and 100% $MgZrO_3$ as the top coat.

No other known compounds occur in this system. Although the other alkaline earths form a 1:1 compound having a perovskite-like structure, $MgZrO_3$ has the CAS number of 12032-31-4.

8.2.5. Calcium Zirconide Compounds

No known intermetallic compounds have been discovered in the system, Ca–Zr. A phase diagram has been published but showed only the polymorphic transition temperatures of the two metals.

8.2.6. Calcium Zirconate Compounds

The system, $CaO–ZrO_2$, has been studied and a phase diagram has been published. It has the form shown in Fig. 8.40.

Originally, only the 1:1 compound, $CaZrO_3$, was known but later work showed the existence of $CaZr_4O_9$ to be present. However, the existence of the $CaZr_4O_9$ compound remains contentious. Calcium zirconate, $CaZrO_3$, has at least two polymorphs. One structure

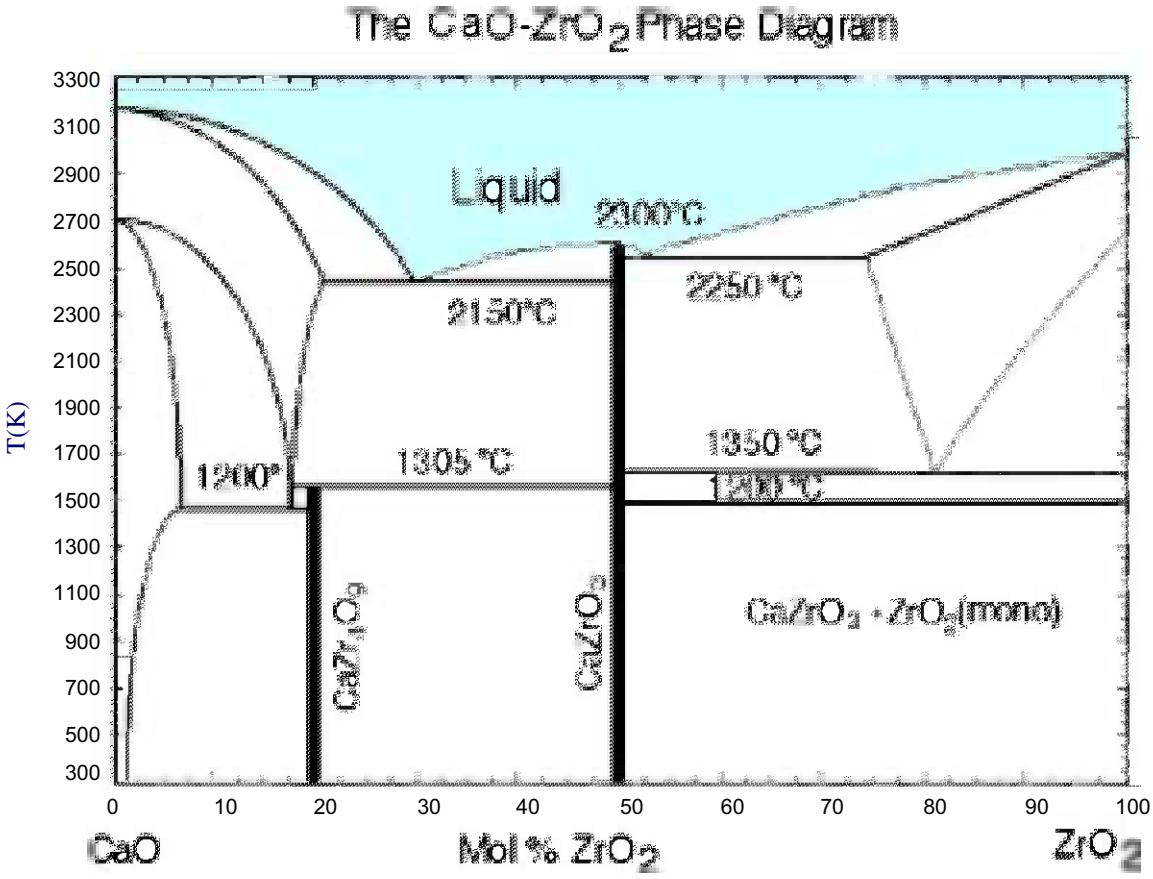

FIGURE 8.40

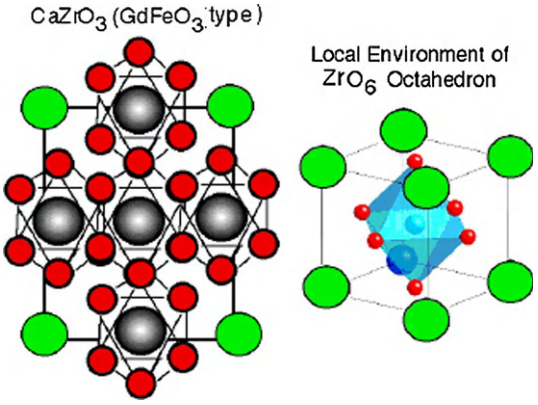

FIGURE 8.41

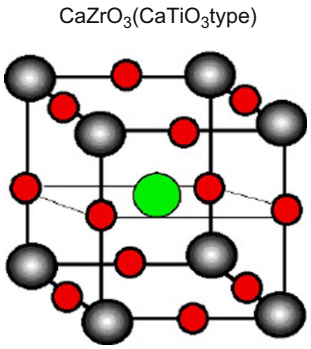

FIGURE 8.42

has the $GdFeO_3$ structure and the cell parameters of $a = b = 5.736$ Å, $c = 8.052$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 248.62 Å^3. The three-dimensional $GdFeO_3$ polymorph consists of ZrO_6 octahedra (one per cell) interspersed with Ca^{2+} cations. The structure is shown in Fig. 8.41.

Cell occupancy is listed in Table 8.13.

The other polymorph has the structure of $CaTiO_3$ and the cell parameters are: $a = b = c = 4.12$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 69.93 Å^3 (Fig. 8.42).

Cell occupancy is listed in Table 8.14.

Two other structures have been reported. One form has a cubic structure with point group = hP30, $a = b = c = 5.774$ Å, $\alpha = \beta = \gamma = 60.6°$, cell volume = 137.96 Å^3, while the other was stated to have cell parameters of: $a = b = 4.039$ Å, $c = 4.098$ Å, $\alpha = \beta = \gamma = 90°$. However, no corroborating evidence has emerged and these structures remain doubtful.

Calcium zirconate is readily available commercially and has the CAS number of 12013-47-7. It occurs as a mineral, Lakargiite, $CaZrO_3$—the zirconium analog of perovskite [*Pbnm*, $a = 5.556(1)$, $b = 5.715(1)$, $c = 7.960(1)$ Å, $V = 252.7(1)$ Å^3, $Z = 4$]. Lakargiite was discovered as an accessory mineral in high-temperature skarns in carbonate–silicate rocks occurring as xenoliths in ignimbrites of the Upper Chegem (Verkhniy Chegem) volcanic structure, the North Caucasus, Kabardino-Balkaria, Russia. Lakargiite forms pseudocubic crystals up to 30–35 μm in size and aggregates up to 200 μm. Lakargiite is associated with spurrite, larnite, calcio-olivine, calcite, cuspidine, rondorfite, reinhard-braunsite, wadalite, perovskite, and minerals of the ellestadite group.

$CaZrO_3$ has been studied as a thermal blanket for corrosion resistance to extreme agents like liquid lithium metal. Mixed oxide phases as candidates for a magneto-hydrodynamics-coating material in a liquid lithium blanket concept were investigated by immersing in liquid lithium. $CaZrO_3$ showed a better compatibility than $MgTiO_3$, $MgZrO_3$ and $CaTiO_3$ with respect to mass and thickness changes and electrical resistance. With increasing density of $CaZrO_3$ sample, better compatibility at 823 K was observed. In case of a low-density sample, Li introduced inside of the sample through the opening channel removed the grains itself

to increase the corrosion rate to 30 μm/year, while the rate was 11 μm/year in the case of a high-density sample. $CaZrO_3$ samples containing excess of ZrO_2 showed significant decrease of their compatibility at 673 K. The micro-ZrO_2 phase, which is unstable in lithium, may be corroded selectively. Thus, the fabrication of high-density coating, with a Ca to Zr composition ratio 1:1, is considered the key ingredient for the corrosion–resistance in this instance.

Two oxide systems, yttria and calcium zirconate ($CaZrO_3$), have been systematically studied for their potential use as thermistor materials, usable above 1000 °C. Both oxides have a sensitivity (temperature coefficient of resistance) of about 1.5%/°C or higher. Doping yttria with zirconia results in a slight decrease in sensitivity, but enables the system to be used in a humid environment without a protective coating. The electrical response of calcium zirconate was found to be sensitive to methane, but was practically unaffected by humidity and carbon monoxide. The use of a calcium zirconate-based thermistor is, therefore, limited to atmospheres without methane and/or possibly other hydrocarbon gases. The results of feasibility tests of a.c.-powered thermistors based on yttria and calcium zirconate suggest that an excitation circuitry can be used for designing a thermistor display device.

There is a growing interest in calcium–zirconium-based oxides for potential sensor/device applications at elevated temperatures. In particular, several studies have been reported on the use of calcium zirconate-based systems for monitoring oxygen, humidity and hydrogen. $CaZrO_3$ has also been studied for its potential use as high-temperature thermistor material. The electrical response of calcium zirconate (prepared by the solid-state firing of $CaCO_3$ and ZrO_2 powders at 1400 °C) was found to be sensitive to methane, but was practically unaffected by humidity and carbon monoxide.

Stoichiometric calcium zirconate and calcium zirconate with calcia or zirconia excess sintered bodies have been prepared. Electrical properties of these materials were investigated at 950 °C using the dc four-probe and ac impedance spectroscopy methods. XRD analysis was used to determine the changes of cell parameters. The Rietveld method was used to refine the calcium zirconate structure. The e.m.f. measurements of galvanic cells were used to determine the ionic transference numbers in the selected samples. Stoichiometric calcium zirconate appeared to be a rather poor and mixed electron–oxygen ion conductor, whereas calcium zirconate samples with excess of calcia or zirconia exhibit purely oxygen ion conductivity. In both cases, introduction of a respective cation excess led to the significant enhancement in conductivity. A simple point defect model for calcium zirconate with calcia or zirconia excess was proposed.

The preparation of perovskite-based calcium zirconate titanates ($Ca[Zr_xTi_{1-x}]O_3$) via an acetic acid-modified sol–gel process, two different alkoxide sol–gel routes, and the direct reaction of oxides and carbonates was explored. X-ray absorption spectroscopy measurements on xerogels prepared using alkoxides indicated the presence of zirconium and titanium with coordination numbers >6 and <6, respectively. The use of acetic acid as a modifier changes the local structure around zirconium in the xerogel. A calcium-rich phase was observed at low heat treatment temperatures regardless of the sample preparation route. Many of the initially prepared xerogels contained perovskite and the higher titanium content samples more readily crystallized to perovskite upon heating. None of the processing routes led to a clean formation of perovskite at low temperatures. At intermediate temperatures, a fluorite-related phase was always formed in addition to perovskite, and the fluorite-like material transformed to perovskite at higher temperatures. The average composition of the perovskite present in the fluorite–perovskite mixture did not change as more of the fluorite was converted to perovskite by heating, suggesting that the two phases have the same zirconium-to-titanium ratio. The EXAFS analyses indicated that the average Zr–O and Ti–O bond lengths are only weakly dependent upon solid solution composition, even though the average M–O bond length depends strongly on composition. The EXAFS data also suggest that the cation distribution in the solid solution is to some extent dependent upon the sample preparation method.

The wet chemical synthesis of $CaZr_{0.9}In_{0.1}O_3$ powders via a peroxo-oxalate complexation method has been studied in detail using different techniques, i.e. TG-DTA, XRD, FT-IR, BET, SEM, EDX, and non-isothermal densification. Using these techniques, the different reaction steps in the calcination process have been clarified. After drying the precipitated complex at 150 °C for 3 h, a mixture of calcium oxalate and an amorphous zirconia phase was found. Between 200 and 450 °C, the calcium oxalate decomposes into calcium carbonate. In the temperature range 450–800 °C, the calcium carbonate decomposes into CaO, while a crystalline zirconia phase appears ($CaZr_4O_9$). In this temperature range, the formation of $CaZrO_3$ is already observed. Further increasing the calcination temperature to 1000 °C leads to a binary mixture of $CaZrO_3$ and $CaIn_2O_4$. When the calcination temperature is increased to around 1500 °C, the $CaIn_2O_4$ phase dissolves into the calcium zirconate to form the desired $CaZr_{0.9}In_{0.1}O_{3-2\delta}$. All compacts sintered at 1550 °C for 10 h show single-phase $CaZr_{0.9}In_{0.1}O_{3-2\delta}$, independent of the calcination temperature. The morphology of the sintered compacts, however, varies with the calcination temperature, due to the presence or absence of a reactive sintering step around 1300 °C. Powders calcined at 1000 °C show

The $CaZr_4O_9$ Structure

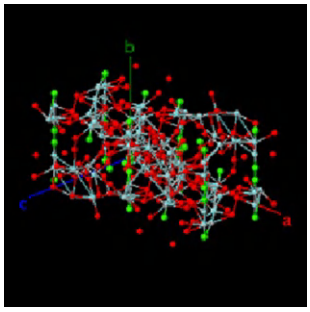

FIGURE 8.43

a larger grain size in the sintered compact than powders calcined at 1450 or 1550 °C.

The precise crystal structure of $CaZr_4O_9$ has not been reported in the literature. The compound, $CaZr_4O_9$, has the cell parameters of: $a = b = 11.5685$ Å, $c = 12.127$ Å, $\alpha = \beta = 86.29°$, $\gamma = 79.141°$, cell volume = 1339.17 $Å^3$.

Cell occupation consists of 30 locations as shown on the next page. Thus, a three-dimensional structure is too complicated to show here. A two-dimensional representation of the structure is shown in Fig. 8.43.

Site symmetry reinforces this observation as listed in Table 8.15.

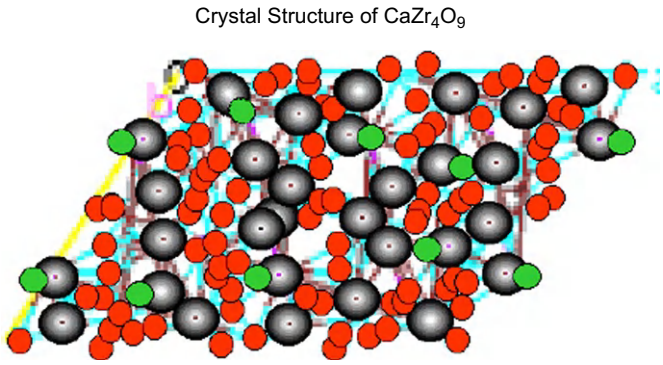

FIGURE 8.44

Vacancy and cation ordering in the δ_1-phase $CaZr_4O_9$ in ZrO_2–CaO system has been investigated. A sample with precipitates of the δ_1 phase has been prepared by annealing a cubic stabilized zirconia single crystal ($Zr_{0.85}Ca_{0.15}O_{1.85}$) at 1300 K for 1 month in air.

Another view of the same structure is shown in Fig. 8.44.

Using powdered material, the structure has been determined by analyzing X-ray and neutron diffraction data by the Rietveld method. The δ_1 phase has the monoclinic space group, $C2/c$. The relation of its lattice parameters to the lattice parameter of the cubic phase was confirmed. The ordering of the calcium ions along the fluorite (110) direction and the ordering of the vacancies separated by δ along the fluorite (111) direction were obtained from the X-ray and neutron data, respectively. All calcium ions are 8-fold coordinated by oxygen ions, while 12 zirconium ions are 6-, 40 zirconium ions 7-, and 12 zirconium ions 8-fold coordinated. The high B-factors (up to 0.18 nm^2) and some anomalous small Zr···O distances (down to 0.169 nm) indicate incomplete order of the δ_1 phase. The chemical equilibrium for the system ZrO_2–CaO was redetermined for temperatures above 1000 °C by heating the reactive powders for extended periods of time. The eutectoid decomposition of the cubic solid solution was found to occur at 1140 ± 40 °C and 17.0 ± 0.5 mol% CaO. Decomposition reactions in sintered cubic solid solutions were studied using electron diffraction and transmission techniques. Decomposition follows metastable extensions of the boundary lines which separate two-phase region from the adjacent cubic solid solution region. The appearance of the diffuse diffraction features in the electron-diffraction patterns of cubic solid solutions seems to be associated with short-range ordering of oxygen vacancies. "Duo-ordered" phases, $CaZr_4O_9$ and $Ca_6Zr_{19}O_{44}$, were synthesized and their upper limits of stability were determined to be 1235 ± 15 and 1355 ± 15 °C, respectively.

The point group and space group symmetry of the controversial fluorite-based stoichiometric superlath phase of $ø_1$ ($CaZr_4O_9$: $Z = 16$), considered to be

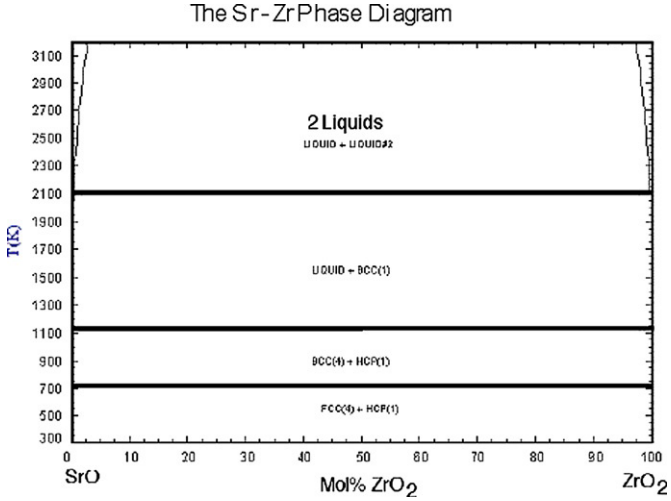

FIGURE 8.45

a coherently intergrown subphase of lime-stabilized zirconia, was examined. Using convergent-beam and selected-area electron diffraction, it was determined that the space group of $ø_1$ is $C2/c$, in apparent agreement with earlier studies utilizing other diffraction techniques.

In view of the fact that the tetrazirconate, $CaZr_4O_9$, is the stable phase, it is not surprising that information concerning the dizirconate, $CaZr_2O_5$, is lacking in the technical literature.

Calcium zirconate, as $CaZrO_3$, is readily available commercially in large quantities.

8.2.7. Strontium Zirconides

There were no known intermetallic compounds determined in the system, Sr–Zr. A phase diagram has been published but showed only the polymorphic transition temperatures of the two metals. This is representative of the Ae–Zr intermetallic forms determined for all of the alkaline earth systems (Fig. 8.45).

8.2.8. Strontium Zirconates

In the oxide system, SrO–ZrO_2, four compounds are known: $SrZrO_3$, Sr_2ZrO_4, $Sr_3Zr_2O_7$, and $Sr_4Zr_3O_{10}$. The formation at 1450 °C of the strontium zirconates, $SrZrO_3$, $Sr_4Zr_3O_{10}$, $Sr_3Zr_2O_7$ and Sr_2ZrO_4, was investigated by X-ray powder diffraction and DTA. Three different routes of synthesis were tested. In the Sr zirconate system, single-phase orthorhombic $SrZrO_3$ and somewhat impure, tetragonal Sr_2ZrO_4 were observed, whereas the formation of ordered RP phases, $Sr_nZr_{n-1}O_{3n-2}$, where $n = 4$ and 3, was not verified. The conductivity of the Sr zirconates increases with increasing Sr/Zr ratio. Samples with a nominal composition corresponding to Sr_2ZrO_4 have a conductivity of 7.5×10^{-5} and 5.9×10^{-4} S/cm^2 at 750 and 1000 °C, respectively. For

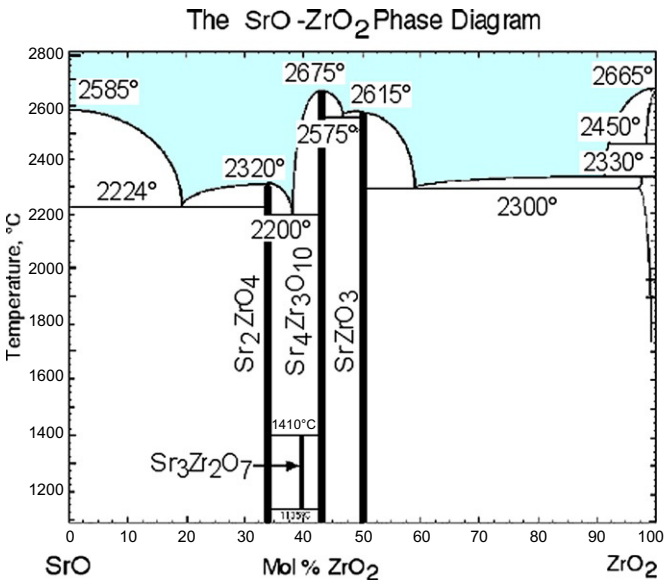

FIGURE 8.46

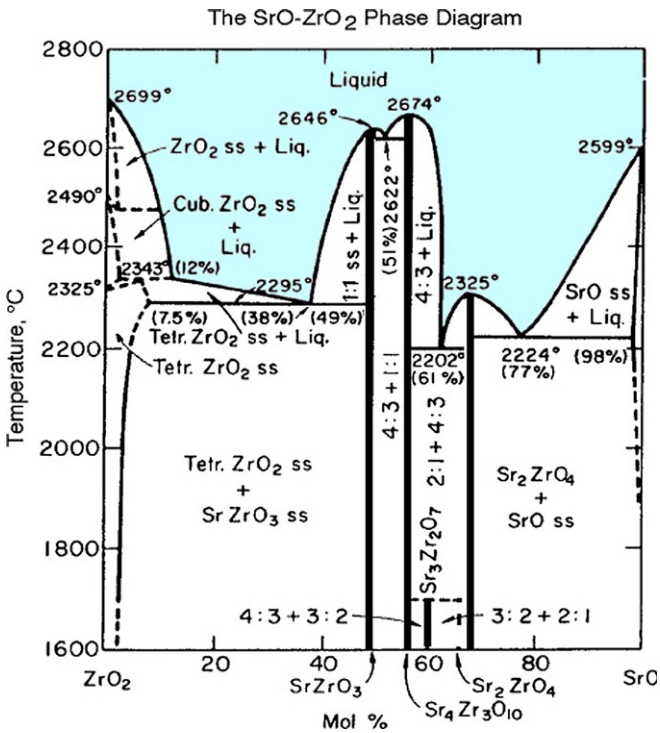

FIGURE 8.47

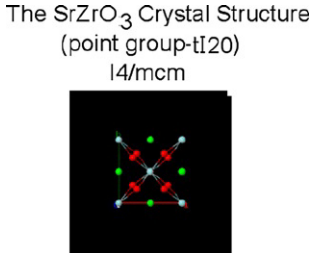

FIGURE 8.48

all samples one observes low activation energies for ionic conduction (~0.5 to 0.65 eV).

The phase diagram of SrO–ZrO_2 is shown in Fig. 8.46.

Another view of the SrO–ZrO_2 system is shown in Fig. 8.47.

In this diagram (dated 1989), more detail is available but the data concerning $Sr_3Zr_2O_7$ has since been modified. Thus, this diagram is regarded as the more accurate of the two diagrams.

In general, it is better to prepare these zirconate compounds by a solid-state reaction of the oxides (or compounds that decompose to form oxides while being heated), then to employ a hydrothermal method. Zirconium compounds, in solution, tend to form hydroxylated gels that are very difficult to decompose to form anhydrates, free of water. Furthermore, alkali ions tend to be incorporated in the product as well. The use of nitrates, i.e. the precursors $Sr(NO_3)_2$ and $ZrO(NO_3)_2 \cdot xH_2O$, has been reported as a superior method. However, disposal of NO_x gases is a problem in this process.

$SrZrO_3$ is dimorphic. One isomer has the point group—tI20 point group and the other cP40 (both with space group = *I*4/*mcm*). The structures of $SrZrO_3$ have been studied in five temperature steps, from room temperature to 1230 °C, by very high-resolution neutron powder diffraction. It was concluded that orthorhombic $SrZrO_3$, with space group *Pnma* at room temperature, changes by a continuous transition to a pseudo-tetragonal structure with space group *Imma* at about 750 °C. It further changes by a discontinuous transformation to tetragonal *I*4/*mcm* at about 840 °C, and finally, continuously, to cubic at 1070 °C. Unit cell parameters are: $a = b = c = 5.8506$ Å, $\alpha = \beta = 119.955°$, $\gamma = 90°$, cell volume = 141.99 $Å^3$ (Fig. 8.48).

Cell occupancy is listed in Table 8.16.

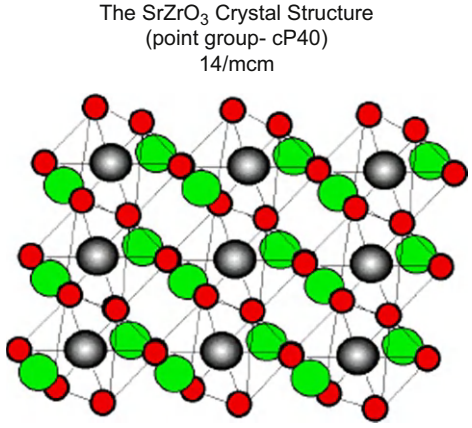

FIGURE 8.49

For the point group structure, cP40 (space group = *I*4/*mcm*), the cell parameters are: $a = b = c = 5.513$ Å, $\alpha = 90°$, $\beta = \gamma = 119.978°$, cell volume = 118.52 Å^3 (Fig. 8.49).

Site occupancy is listed in Table 8.17.

The differences in these two polymorphs may be more discernable shown in Fig. 8.50.

A large number of compounds adopt these $SrZrO_3$ structures as shown in Table 8.18.

The perovskite type of $SrZrO_3$ was investigated as an alternative to yttria-stabilized zirconia (YSZ) material for thermal barrier coating (TBC) applications. Three-phase transformations (orthorhombic ⇔ pseudo-tetragonal ⇔ tetragonal ⇔ cubic) were found only by

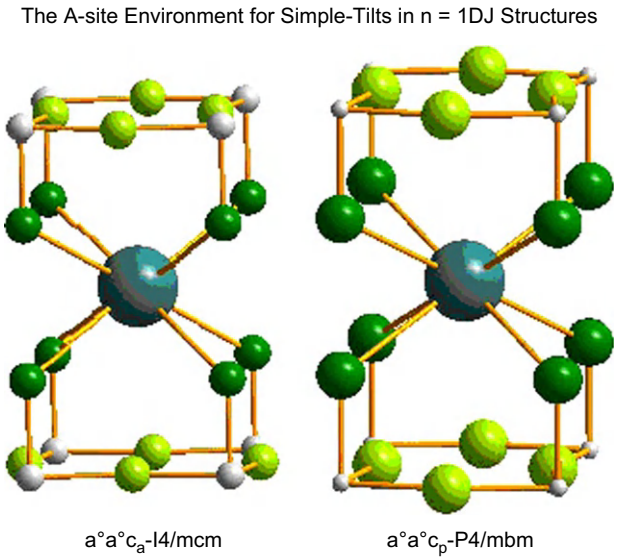

FIGURE 8.50

heat-capacity measurement, whereas the phase transformation from orthorhombic to pseudo-tetragonal was found using thermal expansion measurements. The thermal expansion coefficients (TECs) of $SrZrO_3$ coatings were at least 4.5% larger than YSZ coatings up to 1200 °C. Mechanical properties (Young's modulus, hardness, and fracture toughness) of dense $SrZrO_3$ showed lower Young's modulus, hardness, and comparable fracture toughness with respect to YSZ. The "steady-state" sintering rate of a $SrZrO_3$ coating at 1200 °C was 1.04×10^{-9}/s, which was less than half that of YSZ coating at 1200 °C. Plasma-sprayed coatings were produced and characterized. Thermal cycling with a gas burner showed that at operating temperatures ~1250 °C the cycling lifetime of $SrZrO_3$/YSZ double-layer coating (DLC) was more than twice as long as $SrZrO_3$ coating and comparable to YSZ coating. However, at operating temperatures >1300 °C, the cycling lifetime of $SrZrO_3$/YSZ DLC was comparable to the optimized YSZ coating, indicating $SrZrO_3$ might be a promising material for TBC applications at higher temperatures compared with YSZ.

Elastic behavior associated with the hierarchy of tilting transitions in $SrZrO_3$ has been examined using resonant ultrasound spectroscopy on a ceramic sample at temperatures between 153 and 1533 K (−120 and 1250 °C). Changes in slope of the evolution of resonance frequencies with temperature indicate that phase transitions occur at 1038 K (*Pnma* ⇔ *Imma*), 1122 K (*Imma* ⇔ *I4/mcm*), and 1367 K (*I4/mcm* ⇔ *Pm3m*). Strain analysis of previously recorded neutron diffraction data shows that the *I4/mcm* ⇔ *Pm3m* and *Imma* ⇔ *I4/mcm* transitions are close to triacritical in character, and that *Imma* ⇔ *I4/mcm* is first order.

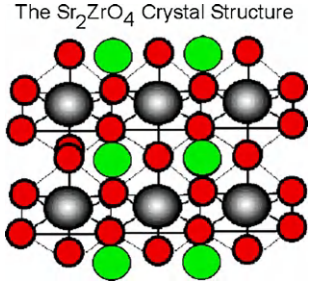

FIGURE 8.51

Deviations from the form of the elastic behavior predicted by Landau theory are found. In particular, elastic softening in the vicinity of the transition suggests that local dynamical fluctuations between individual tilt systems occur rather than a discontinuous switch from one phase to another. Determinations of the mechanical quality factor, *Q*, show that SrZrO3 in the *Pm3m* phase is a classically high-*Q* (i.e. non-dissipating) cubic material. *I4/mcm* and *Imma* phases both have much greater dissipation (low *Q*), which is tentatively attributed to the mobility of twin walls. The room temperature *Pnma* phase is unexpectedly much stiffer than both *I4/mcm* and *Imma* phases and has high *Q*. It appears that when two separate tilt systems operate, as in *Pnma*, they can interact to reduce strain/order parameter relaxations.

The composition Sr_2ZrO_4 has been reported to be in the tetragonal crystal system in space group *I4/mmm* with all parameters $a = 4.103$, $c = 12.82$ and has the K2NiF4 structure. It has the CAS number 12036-39-4. It consists of a series of ZrO_6 octahedra, interspersed with Sr^{2+} cations (Fig. 8.51).

However, it most likely has the structure of Sr_2CeO_4. Whereas, the phosphor, Sr_2ZrO_4 is an efficient phosphor like $MgWO_4$, with an excitation peak at 354 nm and a broad emission peak at about 385 nm, $SrZrO_3$ shows no luminescence at all at room temperature. The luminescence of other Zr compounds is too weak to be seen at room temperature. The reason is that the octahedra of Zr^{4+} in the host lattice, i.e. ZrO_6, are isolated from each other. In the case of Sr2ZrO4, they share oxygen ions along an edge and form a linear chain structure, so that efficient charge-transfer luminescence appears, i.e. it is "self-activated".

The formation of the compound, $Sr_3Zr_2O_7$, is difficult when reactions between the oxides are employed because it is stable only in the temperature range of 1180–1430 °C. Its structure may be represented as shown in Fig. 8.52.

Cell parameters are: $a = b = 4.103$ Å, $c = 10.865$ Å, $\alpha = \beta = 100.848°$, $\gamma = 90.188°$, cell volume = 175.28 Å^3. Cell occupancy is listed in Table 8.19.

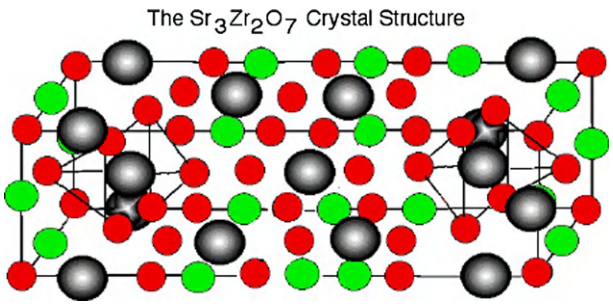

FIGURE 8.52

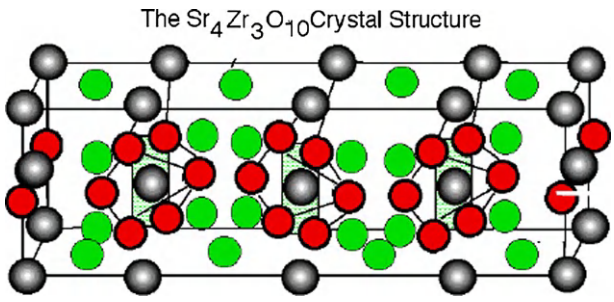

FIGURE 8.53

The compound $Sr_3Zr_2O_7$ is not stable and dissociates in the solid state at about 2300 °C to form $Sr_4Zr_3O_{10}$ and Sr_2ZrO_4:

$$2\,Sr_3Zr_2O_7 + \text{heat} \Rightarrow Sr_4Zr_3O_{10} + Sr_2ZrO_4$$

The Standard molar Gibbs energies of formation of $Sr_3Zr_2O_7$(s) have been determined by measuring Sr(g) pressures over the three-phase system: $\{x_1Sr_4Zr_3O_{10}(s) + x_2Sr_3Zr_2O_7(s) + (1 - x_1 - x_2)Zr_{1-x}O_x(s)\}$ using a Knudsen effusion mass-loss technique employing a Sartorius® microbalance model 4410. The values of the mole fractions x_1 and x_2 in the three-phase mixture are 0.3795 and 0.5391, respectively. The value of $\Delta_fG^0_m(Sr_3Zr_2O_7,s,T)$ has been calculated and is given by:

$$\Delta_fG^0_m(Sr_3Zr_2O_7,s,T)/(kJ/mol) = \{-4229 + 0.7357(T/K)\} \pm 15,$$

where $(1349° \leq K/T \leq 1466°)$.

The $\Delta_fH^0_m(Sr_3Zr_2O_7,s,298.15\,K)$ value was calculated from the known values of $\Delta_fG^0_m(Sr_3Zr_2O_7,s,T)$, and molar heat capacities of Sr(s,l), Zr(s), and O_2(g) as taken from the literature using the values of $Sr_4Zr_3O_{10}$(s) from previously published work. The resulting value was:

$$\Delta_fH^0_m(Sr_3Zr_2O_7),s = -(4186 \pm 38)\ kJ/mol.$$

A corresponding value of $\Delta_fH^0_m(Sr_3Zr_2O_7,s,298.15\,K) = -(4163 \pm 42)$ kJ/mol has also been calculated using the third law. In this method, $\Delta G^0_m = (\delta^T{}_0S^0_m - \eta^T{}_{298.15K}H^0_m/T)$ values for $Sr_4Zr_3O_{10}$(s), Sr(g), $Zr_{0.72}O_{0.26}$(s), $Sr_3Zr_2O_7$(s), and Sr(g) pressure over the three-phase system have been used for the calculation of $\Delta_fH^0_m(Sr_3Zr_2O_7,s,298.15\,K)$ at each experimental temperature.

The compound, $Sr_4Zr_3O_{10}$, has the structure as follows. It is related to the $Sr_3Zr_2O_7$ structure. Cell parameters are: $a = b = 5.812$ Å, $c = 29.361$ Å^3, $\alpha = \beta = \gamma = 90°$, cell volume = 901.52 Å^3 (Fig. 8.53).

Cell occupancy is listed in Table 8.20 and Table 8.21.

Enthalpy increment measurements on $Sr_3Zr_2O_7$(s) and $Sr_4Zr_3O_{10}$(s) were carried out using a Calvet microcalorimeter. The enthalpy increment values were least squares analyzed with the constraints that $H^0(T) - H^0(298.15\,K)$ at 298.15 K equals to 0 and $C^0_p(298.15\,K)$ equals to the estimated value. The dependence of enthalpy increment with temperature can be given as:

$$\Delta H_0(T) - H^0\ (25\ °C)\ (J/mol) = 427.85\ T\ (°C) + 36.502 \times 10^{-3}T^2\ (°C) + 81.67 \times 10^5/T\ (°C) - 158{,}203\ (Sr_4Zr_3O_{10}(s),\ [365.4 \leq T\ (°C) \leq 980.6]$$

$$\Delta H_0(T) - H^0\ (25\ °C)(J/mol) = 349.62\ T\ (°C) + 7.621 \times 10^{-3}T^2\ (°C) + 89.814 \times 10^5/T\ (°C) - 135{,}041\ (Sr_3Zr_2O_7(s),\ [365.4 \leq T\ (°C) \leq 980.6]$$

The first differential of the above equations with respect to temperature gives $C^0_p(T)$. Gibb's functions were evaluated using estimated S^0 (298.15 K) values.

Standard molar Gibbs energies of formation of $Sr_4Zr_3O_{10}$(s) have been determined by measuring Sr(g) pressures over the three-phase mixture: $\{Sr_4Zr_3O_{10}(s) +$

$SrZrO_3(s) + Zr_{1-}xOx(s)\}$ using the Knudsen effusion mass-loss technique employing a Sartorius microbalance, model 4410, and are given as:

$$\Delta_f G_m(Sr_4Zr_3O_{10},s,T) \pm 20(kJ/mol) = -5946.8 + 1.0076(T/K),\ (1157.5 \le T/K \le 1370.5).$$

Using the molar heat capacities for Sr(s,l), Zr(s), and O_2(g) from literature and that for $SrZrO_3$(s) from previous work, $\Delta_f H^0_m(Sr_4Zr_3O_{10},s,298.15\ K)$ has been calculated as $-(5985.4 \pm 49)$ kJ/mol. A value of $\Delta_f H^0_m(Sr_4Zr_3O_{10},s,298.15\ K) = -(5972.8 \pm 44)$ kJ/mol has also been calculated using the values for the function: $\delta = (\eta^\circ TS_m - \eta^T_{298.15K}H_m/T)$ for $SrZrO_3$(s), Sr(g), $Zr_{0.72}O_{0.28}$(s), and $Sr_4Zr_3O_{10}$(s) from literature. The value of $-(5972.8 \pm 44)$ kJ/mol (the third-law value) is recommended for $\Delta_f H^0_m(Sr_4Zr_3O_{10},s,298.15\ K)$.

Strontium zirconates are readily available commercially in small to large quantities worldwide.

8.2.9. Barium Zirconides

The intermetallic system Ba^0–Zr^0 does not form any compounds. Only the polymorphic changes with temperature are apparent in the phase diagram.

8.2.10. Barium Zirconates

In contrast to the Ca and Sr homologues, the system, BaO–ZrO_2, does not form many compounds. The phases formed have not been well researched and the only phase diagram known to date shows only the cubic perovskite, $BaZrO_3$ (Fig. 8.54).

$BaZrO_3$ has the perovskite structure shown in Fig. 8.55.

Cell parameters are: $a = b = c = 4.182$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 73.14$ Å^3. Cell occupancy is listed in Table 8.22.

A thermodynamic description of the ZrO_2–BaO system was developed using all available experimental

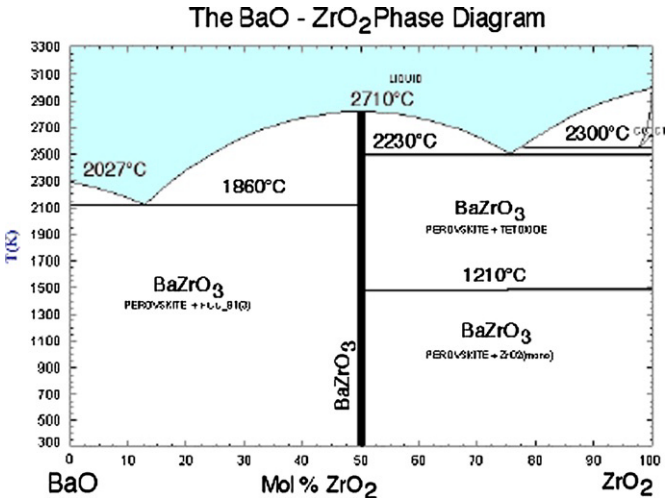

FIGURE 8.54

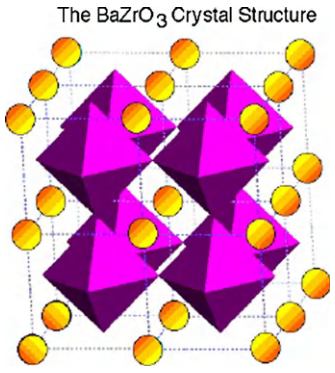

FIGURE 8.55

information. Special attention was paid to the modeling of the perovskite phase $BaZrO_3$ by a temperature-dependent polynomial to fit the experimental thermodynamic properties. The liquid phases, Css (cubic ZrO_2 solid solution) and Tss (tetragonal ZrO_2 solid solution), were modeled by use of the Redlich–Kister formula. The hypothetical compounds Ba_2ZrO_4 and $Ba_3Zr_2O_7$ were treated as stoichiometric phases and the BaOss and Mss (halite BaO and monoclinic ZrO_2 solid solutions) were treated as pure compounds. Comparisons between the calculated and the measured phase diagram as well as the thermodynamic quantities indicate that the most reliable experimental information is satisfactorily accounted for by the present thermodynamic calculation.

The formation of $BaZrO_3$ from very fine (70–90 nm) ZrO_2 powders and coarser (~1 μm) $BaCO_3$ powders has been studied in dry and humid air up to 1300 °C using TGA/DTA, XRD, SEM, TEM, and EDS microanalysis. In the temperature range 900–1100 °C, barium is rapidly transported at the surface of the ZrO_2 particles and reacts, forming $BaZrO_3$. The compound grows as a concentric layer with gradual consumption of the central ZrO_2 particle. The overall formation kinetics of $BaZrO_3$ is well described by a diminishing core model, and the most likely rate-determining step is a phase-boundary process at the ZrO_2–$BaZrO_3$ moving interface. The size and shape of the final particles is generally determined by the morphology of the starting ZrO_2 particles and not by that of the $BaCO_3$. The reaction is faster in humid air than in dry air, and the activation energy decreases from 294 kJ/mol (dry air) to 220 kJ/mol (humid air). When the fraction reacted is >80–90 mol%, the reaction rate rapidly decreases.

In another paper, zirconia–baria solid solutions were obtained by sintering powders produced by coprecipitation from solutions of zirconyl chloride hydrate and barium nitrate. The fired materials had monoclinic, cubic or tetragonal structure depending of composition which ranged from 4 to 16 mol% BaO. The pure cubic phase could be retained at room temperature for compositions from 10 to 12, whereas materials containing 16 mol% BaO were tetragonal; for lower baria content a mixture of monoclinic and cubic phase was detected. The double-phased materials can be fully transformed into the monoclinic form by grinding while for pure cubic or tetragonal samples the transformation is not full. Samples fired at 1450 °C had coarse microstructures and the grains dimension is of several microns just after 1 h of sintering, but materials containing 10, 12 and 16 mol% BaO remain cubic or tetragonal, their transformability being the same as that of materials sintered at lower temperature. The grains growth kinetic during the sintering process is similar to that of the $BaZrO_3$, and the resulting microstructures showed coarser grains than those observed in sintered tetragonal zirconia materials stabilized with other oxides. The crystal structures of cubic or tetragonal BaO stabilized zirconia seem to be isostructural to $BaZrO_3$ as they have similar cell parameters.

Solid oxide fuel cells (SOFCs) are particularly attractive because of their high efficiencies (especially when integrated with thermal energy conversion devices that utilize the high-quality waste heat available from SOFCs), their fuel flexibility, and their operability in the absence of precious metal catalysts. One of the most promising such alternatives is the family of proton conducting perovskites. These materials have particularly high conductivity, but the most promising compositions in terms of electrical properties, Y-doped $BaCeO_3$, readily react with CO_2 and suffer from other long-term stability problems. A promising candidate for proton ceramic SOFC (PC-SOFC) applications is Y-doped $BaZrO_3$ (BYZ). It has desirable properties such as high protonic conductivity and excellent chemical and mechanical stability. The current limitation for application of BYZ in PC-SOFCs is the extremely high grain boundary resistance, which leads to the relatively poor

TABLE 8.22

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O	O	3	d	4/mm.m	1/2	0	0	1.0
2	Ba	Ba	1	b	m-3m	1/2	1/2	1/2	1.0
3	Zr	Zr	1	a	m-3m	0	0	0	1.0

total conductivity. The key to obtaining high conductivity in BYZ is to enhance grain growth and/or increase conductivity across grain boundaries. While these challenges are not directly amenable to theoretical approaches, computational studies of proton transport through bulk perovskites might help to solve the above-mentioned problem and/or to develop alternative materials that may not suffer from the same microstructural drawbacks.

Barium mono-zirconate has been used in the solution growth of single crystals of $YBa_2Cu_3O_{7-\delta}$ and $PrBa_2Cu_3O_{7-\delta}$ in a new type of homemade crucible, namely made of $BaZrO_3$, which has the advantage that it does not react with the occurring melts which are commonly used as a flux. These new crucibles have several advantages: not only the crystals obtained after the growth experiment contain no impurities from the crucible material, but also an important problem is solved, e.g. the corrosion of the crucible does no longer change the composition of the melt during the growth experiment, thus avoiding uncontrollable growth conditions. Hence, due to this novel inert crucible material the use of more sophisticated crystal growth techniques such as top seeded solution growth are now possible.

Polycrystalline perovskite type oxides, $BaZrO_3$ and $BaCeO_3$, have been prepared by mixing the appropriate amounts of ZrO_2, CeO_2, and $BaCO_3$ followed by reacting at 1273 K and sintering at 1773 K. The thermophysical properties, viz. the TEC, melting point, elastic moduli, Debye temperature, and Vickers hardness, of $BaZrO_3$ and $BaCeO_3$ have been measured. The harmonic and dilatational terms of the heat capacity have been evaluated by using the values of the TEC, compressibility, and Debye temperature measured. The relationships between several properties of $BaZrO_3$ and $BaCeO_3$ show the typical characteristics of the perovskite type oxides.

Specific heat capacities (C_p) of polycrystalline samples of $BaCeO_3$ and $BaZrO_3$ have been measured from about 1.6 K up to room temperature by means of adiabatic calorimetry. Experimental data for the heat capacity of $BaCeO_3$ in the range $T < 10$ K were given and experimental data below 53 K for $BaZrO_3$ were provided. Applying Debye's T^3 law for $T \Rightarrow 0$ K, thermodynamic functions as molar entropy and enthalpy were derived by integration. The values obtained were:

$$Cp = 114.8\ (\pm 1.0)\ \text{J/mol/K}^1;\ S^0 = 145.8\ (\pm 0.7)\ \text{J/mol/K for } BaCeO_3$$

$$Cp = 107.0\ (\pm 1.0)\ \text{J/mol/K};\ S^0 = 125.5\ (\pm 0.6)\ \text{J/mol/K for } BaZrO_3$$

at 298.15 K. These results are in overall agreement with previously reported studies but slightly deviating, in both cases. Evaluations of $C_p(T)$ yield Debye temperatures and identify deviations from the simple Debye theory due to extra vibrational modes as well as anharmonicity. The anharmonicity turns out to be more pronounced at elevated temperatures for $BaCeO_3$. The characteristic Debye temperatures determined at $T = 0$ K are $\delta_0 = 365$ (± 6) K for $BaCeO_3$ and $\delta_0 = 402$ (± 9) K for $BaZrO_3$.

The formation of solid solution composition $BaTi_{0.6}Zr_{0.4}O_3$, from $BaCO_3$, TiO_2 and ZrO_2 powders has been studied through solid oxide reaction using TGA/DSC, XRD. $BaCO_3$ decomposes at much lower temperature in the mixture due to the presence of TiO_2. $BaTiO_3$ and $BaZrO_3$ start forming from the temperature range 700–800 °C without intermediate formation of BaO or other titanate/zirconate phases. The rate of $BaTiO_3$ formation is higher than $BaZrO_3$ formation due to the lower activation energy (34.3 kcal/mol) required for titanate formation than zirconate (48.4 kcal/mol). Solid solution then forms by diffusion of $BaTiO_3$ into $BaZrO_3$ from 1300 °C onwards. Lattice parameter of initial SS phase is higher, indicating the phase has a coherent interface with zirconate and higher in Zr concentration than final product. Activation energy for the SS formation (133 kcal/mol) indicates that Ba and/or O diffusion through SS layer may limit the reaction.

Although it does not appear in the phase diagram, the di-barium zirconate, Ba_2ZrO_4, has been characterized (Fig. 8.56).

It has the K_2NiF_4 structure with cell parameters of: $a = b = 4.182$ Å, $c = 7.3451$ Å, $\alpha = \beta = 106.5°$, $c = 90°$, $Z = 4$. Cell volume is: 117.59 Å^3. Cell occupancy is listed in Table 8.23.

This structure contains a body-centered ZrO_6 octahedra with 1/2 of an octahedra at both ends of the tetragonal unit cell. Barium ions are interspersed on the edges of the tetrahedral unit.

With the exception of structural parameters, no other information is available concerning d-barium zirconate. As of 2011, the formation of other phases like Ba_2ZrO_4 and $Ba_3Zr_2O_7$ has not been observed.

Barium zirconate is available commercially in small quantities but no CAS number has been issued.

8.2.11. Radium Zirconates

In view of the high cost and strong radioactivity of ^{226}Ra metal, it is not surprising that the formation of

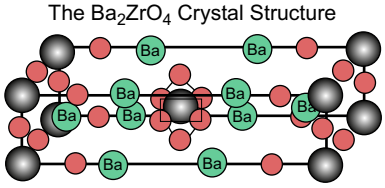

FIGURE 8.56

radium zirconates by reaction of the oxides, RaO and ZrO_2, has not been documented in the technical literature. It is not likely that any possible compounds like $RaZrO_3$ will ever be studied.

8.3. ALKALINE EARTH HAFNIUM COMPOUNDS

Hafnium and zirconium form a nearly identical sequence of chemical compounds. Its major valence state is Hf^{4+}, but Hf^{2+} is also known. The white hafnium oxide (HfO_2), with a melting point of 2812 °C and a boiling point of roughly 5100 °C, is very similar to zirconia, but slightly more basic. Hafnium(IV) oxide is quite inert. It reacts with strong acids such as concentrated H_2SO_4 and with strong bases like NaOH. It dissolves slowly in HF to give fluorohafnate anions.

Of all of the alkaline earths, only Be^0 forms intermetallic compounds with Hf^0.

A phase diagram of the system Mg–Hf has been published and is representative of the systems, Mg–Hf, Ca–Hf, Sr–Hf and Ba-Hf.

The oxide-based compounds based on the system, AeO–HfO_2, are few and resemble those found in the AeO–ZrO_2 system. In addition to the great analogy between binary systems with hafnia and zirconia, the main interest in hafnium-containing compounds has been prompted by their higher melting temperatures compared with those of zirconia-based compounds and by several peculiar physicochemical properties characteristic of hafnia-based compounds and solid solutions. Early work in the HfO_2–AeO systems has shown that strontium forms the greatest number of compounds: $SrHfO_3$, Sr_2HfO_4, $Sr_3Hf_2O_7$ and $Sr_4Hf_3O_{10}$; calcium forms two compounds: $CaHfO_3$ and $CaHf_4O_9$; barium and magnesium each produce one compound: $BaHfO_3$ and $Mg_2Hf_5O_{12}$, respectively. Beryllium forms none. Most of these compounds are stable only over a certain temperature range and transform into disordered F-type cubic solid solutions at elevated temperatures. In addition, there exist limited regions of solid solutions based on the monoclinic (M) and tetragonal (T) modifications of HfO_2. Later work has shown that some quite complicated compounds like $Ca_6Hf_{19}O_{44}$ and $Ca_2Hf_7O_{16}$ also exist.

8.3.1. Beryllium Hafnate Compounds

There are no known compounds based on the BeO–HfO_2 system. A phase diagram is available but shows only polymorphic temperature transitions of the individual oxide components.

8.3.2. Beryllium Hafnide Compounds

A phase diagram of the intermetallic compounds formed when Be metal is heated with Hf metal is shown in Fig. 8.57. Both metals are high melting with melting points of 1821 °C for Hf and 1289 °C for Be.

By comparison of the Be–Zr and Be–Hf phase diagrams, it is easily seen that the same type of compounds occurs for Hf as for Zr (Fig. 8.57).

Five compounds are shown, Be_2Hf, Be_5Hf, $Be_{17}Hf_2$, $Be_{13}Hf$ and BeHf. The only compound that melts congruently is $Be_{17}Hf_2$. It is trimorphic. The compound, $Be_{13}Hf$, is only stable between the temperatures of 1400 and 1620 °C, and was difficult to establish in terms of crystal structure, i.e. it is "metastable". It is, however,

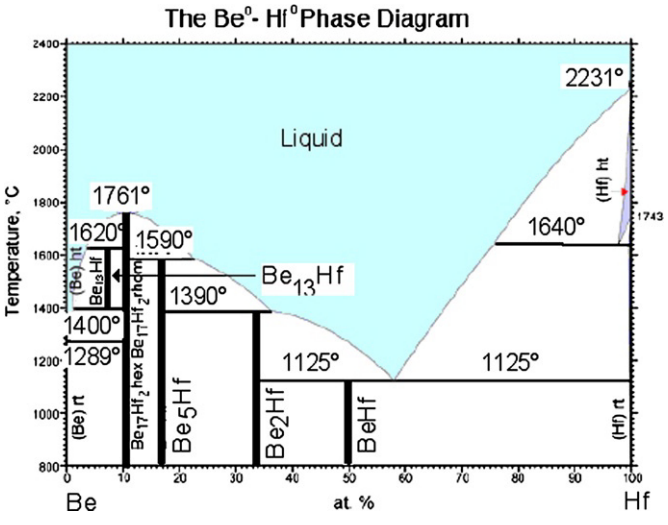

FIGURE 8.57

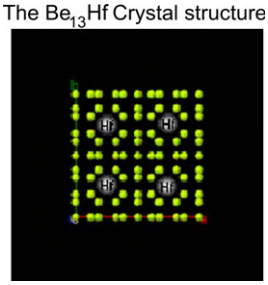

FIGURE 8.58

stable at room temperature once it has been formed. Nonetheless, any applied heat causes it to decompose into the two metal forms.

The crystal data are shown in Table 8.24.

The compound, $Be_{13}Hf$ has the same structure as its Zr counterpart. Cell parameters are: $a = b = c = 7.0711$ Å, $\alpha = \beta = \gamma = 80°$, cell volume = 250.00 Å^3.

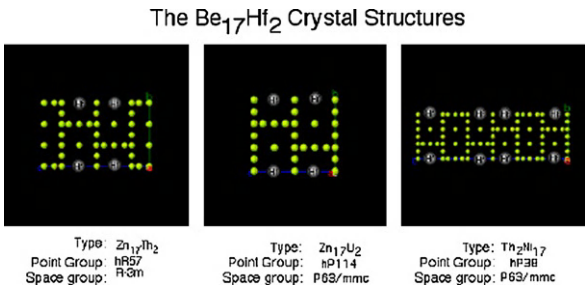

FIGURE 8.59

Cell occupancy of the 112 atoms is also given in Fig. 8.58. The unit cell contains eight formula units, i.e. $Z = 8$.

Cell occupancy is listed in Table 8.25.

The two-dimensional structure shown here can be morphed into a three-dimensional structure by extending 3 units in the "c-direction" of the lattice.

The compound, $Be_{17}Hf_2$, is trimorphic (Fig. 8.59).

The difference lies in the local arrangement of the Hf atoms as surrounded by Be atoms in each structure. Cell parameters are presented as follows:

Type: $Zn_{17}Th_2 - hR57 - R\text{-}3m$: $a = b = c = 5.6563$ Å, $\alpha = \beta = \gamma = 82.973°$, cell volume = 177.20 Å^3. Cell occupancy is listed in Table 8.26.

Type: $Zn_{17}Th_2 - hP38 - P6_3/mmc$: $a = b = c = 7.44$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 353.78 Å^3. Cell occupancy is listed in Table 8.27.

Type: $Zn_{17}Th_2 - hP114 - P6_3/mmc$: $a = b = c = 7.499$ Å, $\alpha = \beta = 90°$, $c = 120°$, cell volume = 1066.79 Å^3. Cell occupancy is listed in Table 8.28.

The compound, Be_2Hf, has the same crystal structure as Be_2Zr as shown in Fig. 8.60.

Cell parameters are: $a = b = c = 3.159$ Å, $\alpha = 120°$, $\beta = \gamma = 90$, cell volume $= 39.23$ Å^3. Cell occupancy is listed in Table 8.29.

The compound, Be_5Hf, has the same crystal structure as Be_5Zr (Fig. 8.61).

Cell parameters are: $a = 3.465$ Å, $b = c = 4.519$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 61.28$ Å^3. Cell occupancy is listed in Table 8.30.

The compound, BeHf, has the structure shown in Fig. 8.62.

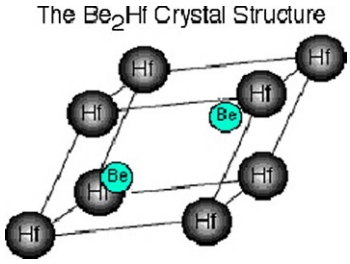

FIGURE 8.60

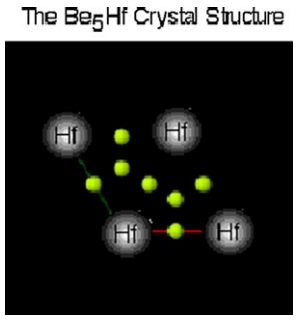

FIGURE 8.61

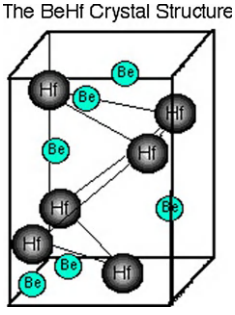

FIGURE 8.62

Unit cell parameters are: $a = 3.34$ Å, $b = 3.72$ Å, $c = 5.27$ Å, $\alpha = \gamma = 90°$, $\beta = 108.45°$, cell volume $= 62.12$ Å^3. Cell occupancy is listed in Table 8.31.

The technical literature is devoid of any papers concerning beryllium–hafnium intermetallic or oxy-hafnium compounds. None of these compounds are commercially available.

8.3.3. Magnesium Hafnide Compounds

The system, Mg–Hf, does not form any intermetallic compounds. A phase diagram has, however, been presented which is typical of the alkaline earths. The only difference in the Ca–Hf, Sr–Hf and BaHf systems lies in the transition temperatures of the individual metals (Fig. 8.63).

8.3.4. Magnesium Hafnate Compounds

The oxy-hafnium system, $MgO–HfO_2$, has been said to form but one compound. The HfO_2–MgO quasi-binary system has been assessed thermodynamically by means of the CALPHAD method. A phase diagram consistent with experimental information was obtained with an optimized set of 10 parameters for different phases. Further information is necessary on the lower limit of fluorite-type solid solution as well as the stability

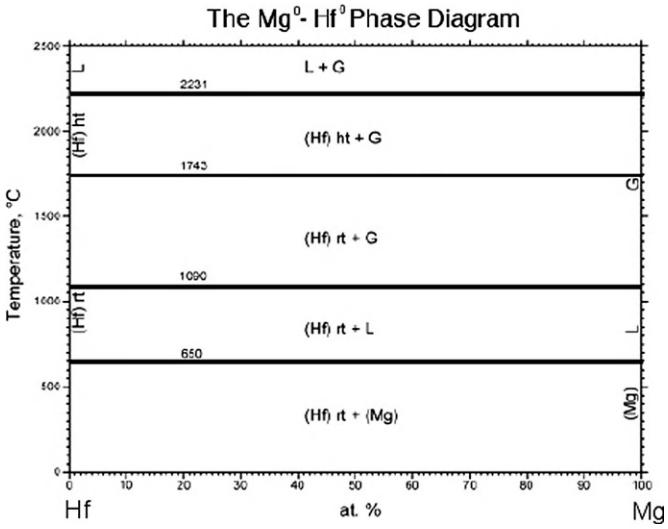

FIGURE 8.63

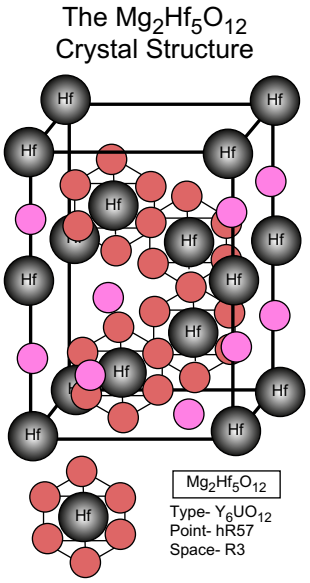

FIGURE 8.64

range of the ordered phase $Mg_2Hf_5O_{12}$ in order to present the full diagram.

This compound has the structure shown in Fig. 8.64.

Cell parameters are: $a = b = c = 6.1494$ Å, $\alpha = \beta = \gamma = 99.651°$, cell volume = 221.59 Å^3. It has the Y_6UO_{12} type structure with point group hR57 and space group = *R*-3.

Cell occupancy is listed in Table 8.32.

This structure consists of 3-HfO_6 octahedra interspersed within the unit cell with Mg^{2+} cations along the edges of the unit cell, which contains three formula units on the average. Two-thirds of the Hf atoms reside on the M1 site and 1/3 is occupied by the Mg atoms.

One study reported on the dielectric and leakage current properties of $Mg_2Hf_5O_{12}$ thin films deposited at room temperature by radio frequency magnetron sputtering. Polycrystalline $Mg_2Hf_5O_{12}$ thin films showed a reasonably high dielectric constant ($\varepsilon_r = 22$) and greatly enhanced leakage current characteristics ($<2 \times 10^{-7}$ A/cm^2) compared to the leakage current ($<2 \times 10^{-5}$ A/cm^2) of HfO_2 thin films at 0.4 MV/cm. A band-edge spectroscopic analysis revealed lower conduction band-edge defect states and a greater p-type-like Fermi energy level of $Mg_2Hf_5O_{12}$ compared to the HfO_2 thin films. The suitability of $Mg_2Hf_5O_{12}$ films as gate insulators for low-voltage operating $InGaZnO_4$ thin film transistors (TFTs) was investigated. All room temperature processed $InGaZnO_4$ TFTs on plastic substrates exhibited a high-field effect mobility of 27.32 cm^2/Vs and a current on/off ratio of 4.01×10^6. The threshold voltage and subthreshold swing were 2 V and 440 mV/dec, respectively. The fabrication and compositional manipulation method of the $Mg_2Hf_5O_{12}$ films described in this work was simple and versatile, providing fascinating opportunities for new high-*k* gate dielectrics.

Another compound, $Mg_{0.2}Hf_{0.6}O_{1.8}$, has been reported to possess the CaF_2 (cubic) structure (Fig. 8.65).

Cell parameters are: $a = b = c = 3.2638$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 32.01 Å^3. Site occupancy is listed in Table 8.33.

However, this compound can also be regarded as a "mixed oxide".

Although one paper stated that, the decomposition of magnesium hafnyl oxalate, $MgHfO(C_2O_4)_2 \cdot 7H_2O$, when heated formed $MgHfO_3$, there is no corroborating evidence that such a compound exists. According to these authors, the thermal decomposition of these oxalates was investigated employing TGA, DTA,

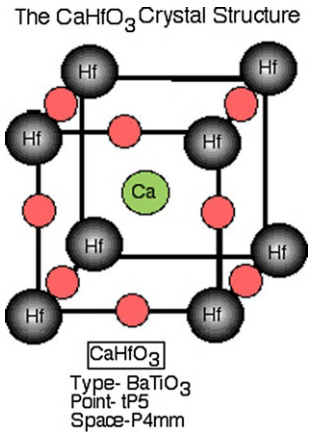

FIGURE 8.66

infrared spectral and chemical analysis techniques. The decomposition proceeds through three major steps, viz. the dehydration of the hydrated oxalate, the decomposition of the anhydrous oxalate to the carbonate and, finally, the decomposition of the carbonate to the oxide. Pure hafnium oxide, HfO_2, was the product in the thermal decomposition of simple hafnyl oxalate and ammonium hafnyl oxalate, while for magnesium hafnyl oxalate, $MgHfO_3$ was isolated as the final decomposition product.

Magnesium hafnates have been found to be unstable when used in high-temperature applications and have not found usage in Industry. They are not available commercially.

8.3.5. Calcium Hafnide Compounds

The intermetallic system, Ca–Hf does not form any compounds.

8.3.6. Calcium Hafnate Compounds

The complete phase diagram of the system, CaO–HfO_2, has not been thoroughly studied. It is known that two compounds are formed from these oxides: $CaHfO_3$ and $CaHf_4O_9$ However, a complete phase diagram has not been published.

The chemical equilibrium for the system HfO_2–$CaHfO_3$ was determined for temperatures above 1200 °C by heating reactive powders for extended periods. The eutectoid decomposition of the cubic solid solution was found to occur at 19.0 ± 0.5 m/o CaO and 1415 ± 7 °C. The solid solubility of CaO in tetragonal hafnia is very low. The tetragonal solid solution was shown to form from monoclinic hafnia solid solution at a eutectoid temperature of 1775 ± 50 °C. Three ordered compounds exist in this system. The ordered compound $CaHf_4O_9(\Phi_1)$ was found to be unstable at all temperatures investigated. It does, however, form metastably. The compound $Ca_2Hf_7O_{16}(\Phi)$ is stable with an upper limit of 1473 ± 5 °C. No lower limit of stability for this compound could be determined. The compound $Ca_6Hf_{19}O_{44}(\Phi_2)$ is stable from 1350 ± 50 °C to its upper limit of 1463 ± 5 °C.

The compound, $CaHfO_3$, crystallizes in several polymorphous modifications, including the cubic and rhombic perovskite type of structures.

$BaTiO_3$ Type

This form has the structure shown in Fig. 8.66.

This is a simple cubic structure with hafnium occupying the corners of the unit cell. The cell is unique in that it contains only 1/2 of the possible oxygen sites filled.

Cell parameters are: $a = b = c = 4.0496$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 67.15$ Å^3. Site occupancy is listed in Table 8.34.

TABLE 8.34

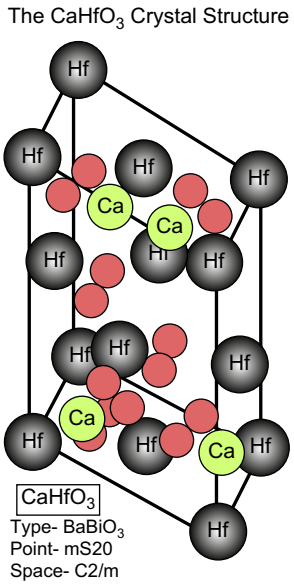

FIGURE 8.68

A three-dimensional structure is also shown as follows, where just the Hf and O ions are shown in Fig. 8.67.

$BaBiO_3$ Type

This structure can be represented as shown in Fig. 8.68. Cell parameters are: $a = 7.998$ Å, $b = 8.001$ Å, $c = 9.038$ Å, $\alpha = 91.52°$, $\beta = \gamma = 90°$, cell volume = 578.16 Å^3. Site occupancy has not been documented.

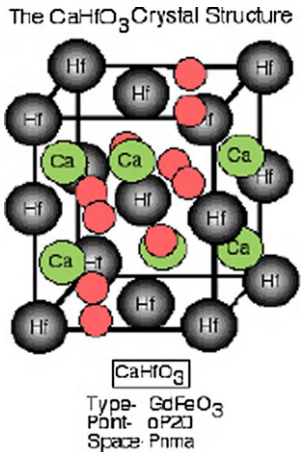

FIGURE 8.69

$GdFeO_3$ Type

This form has the structure shown in Fig. 8.69. Cell parameters are: $a = 5.631$ Å, $b = 5.737$ Å, $c = 8.066$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 260.57 Å^3.

Site occupancy is listed in Table 8.35.

$LaAlO_3$ Type

This form has the structure shown in Fig. 8.70.

Cell parameters are: $a = b = c = 5.788$ Å, $\alpha = \beta = \gamma = 60.6°$, cell volume = 138.97 Å^3. Site occupancy has not been documented.

This structure consists of 4 HfO_6 octahedra which are joined on an edge and occupy the center of the unit cell. They are surrounded by Ca^{2+} cations located on the edges of the unit cell.

$CaTiO_3$ Type

This structure has the form shown in Fig. 8.71. Cell parameters are: $a = b = c = 4.091$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 68.47 Å^3.

Site occupancy is listed in Table 8.36.

The three-dimensional structure shown in Fig. 8.72 may be compared to the $BaTiO_3$ type shown above.

Other calcium hafnate compositions have been studied. Three ordered fluorite-related phases occurred in the system CaO–HfO_2 and their crystal structures

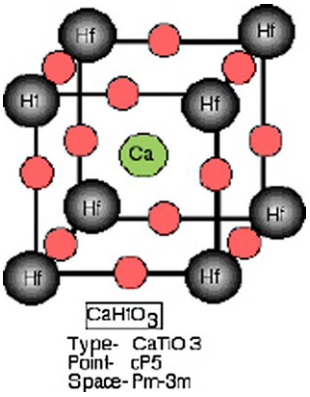

FIGURE 8.71

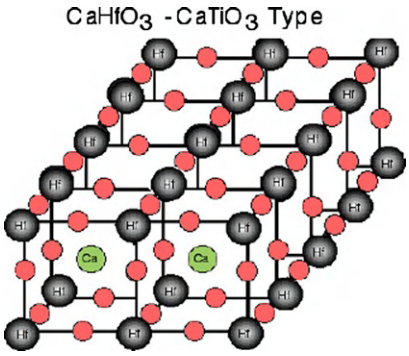

FIGURE 8.72

have been described. $Ca_2Hf_7O_{16}$ (Φ) is rhombohedral, with $a = b = c = 9.527$ Å, $\alpha = \beta = \gamma = 38.80°$. $CaHf_4O_9$ (Φ_1) is monoclinic, with $a = 17.698$ Å, $b = 14.500$ Å, $c = 12.021$ Å, $\beta = 199.47°$. $Ca_6Hf_{19}O_{44}$ (Φ_2) is rhombohedral, with $a = b = c = 12.059$ Å, $\alpha = \beta = \gamma = 98.31°$.

The chemical equilibrium for the system HfO_2-$CaHfO_3$ was determined for temperatures above 1200 °C by heating reactive powders for extended periods. The eutectoid decomposition of the cubic solid solution was found to occur at 19.0 ± 0.5 m/o CaO and 1415 ± 7 °C. The solid solubility of CaO in tetragonal hafnia is very low. The tetragonal solid solution was shown to form from monoclinic hafnia solid solution at a eutectoid temperature of 1775 ± 50 °C. Three ordered compounds exist in this system. The ordered compound $CaHf_4O_9(\Phi_1)$ was found to be unstable at all temperatures investigated. It does, however, form metastably. The compound $Ca_2Hf_7O_{16}(\Phi)$ is stable with an upper limit of 1473 ± 5 °C. No lower limit of stability for this compound could be determined. The compound $Ca_6Hf_{19}O_{44}(\Phi_2)$ is stable from 1350 ± 50 °C to its upper limit of 1463 ± 5 °C.

The atomic arrangement in the fluorite-related phase, $Ca_2Hf_7O_{16}$, has been determined by powder XRD. The unit cell is rhombohedral, R3, with $a = 9.5273$ Å, $\alpha = 38.801°$, and $Z = 1$, and its volume is 2.5 times that of the fluorite subcell from which it is derived. The cations are ordered on the cation sites of the fluorite structure with the calcium ions segregated into discrete layers parallel to the (111) fluorite plane: there is some evidence that the formal anion vacancies are also ordered.

Crystal structures for the fluorite-related phases $CaHf_4O_9$ (Φ_1) and $Ca_6Hf_{19}O_{44}$ (Φ_2) have been determined from X-ray powder diffraction data. Φf_1 is monoclinic, $C2/c$, with $a = 17.698$ Å, $b = 14.500$ Å, $c = 12.021$ Å, $\beta = 119.47°$ and $Z = 16$. Φf_2 is rhombohedral, with $a = 12.058$ Å, $\alpha = 98.31°$ and $Z = 2$.

Both phases are superstructures derived from the defect fluorite structure by ordering of the cations and of the anion vacancies. The ordering is such that the

TABLE 8.36

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O	O	3	d	4/mm.m	1/2	0	0	1.0
2	Ca	Ca	1	b	m-3m	1/2	1/2	1/2	1.0
3	Hf	Hf	1	a	m-3m	0	0	0	1.0

calcium ions are always 8-coordinated by oxygen ions, while the hafnium ions may be 6-, 7-, or 8-coordinated. The closest approach of anion vacancies is a 1/2(111) fluorite subcell vector, and in each structure vacancies with this separation form strings.

Luminescence of Pr from two sites was observed. About 85% of Pr ions occupy on Ca site (A site of perovskite ABO_3) and 15% of Pr ions stay on Hf site (B site). Pr(A) shows an excitation band at 240 nm from the 4f5d state, and gives strong UV emission bands peaking at 294 and 337 nm. Emission at 490 nm from $^3P_0$ is dominant. In contrast, Pr(B) shows 5d excitation band at 275 nm, and gives a weak and broad emission band near 390 nm. Emission from its $^1D_2$ at 610 nm is stronger than the emission from $^3P_0$ state (484 nm). Codoping with Na^+, In^{3+}, or Al^{3+} for the purpose of charge compensation could change distribution of Pr on both sites. Na^+ tends to reduce, but In and Al tend to increase the population of Pr on Hf (B) site.

Calcium hafnates are not very stable at high temperatures, a factor that has led Industry to abandon any potential uses of these compounds. No CAS numbers have been issued to date.

8.3.7. Strontium Hafnide Compounds

The system, Sr–Hf, does not form any intermetallic compounds.

8.3.8. Strontium Hafnate Compounds

In the SrO–HfO_2 system, four compounds, $SrHfO_3$, Sr_2HfO_4, $Sr_3Hf_2O_7$ and $Sr_4Hf_3O_{10}$, are known and their crystal structures have been described. However, the phase diagram is not available.

Studies were made of the synthesis and sintering of strontium hafnate. Ceramics were obtained from $SrHfO_3$ with a density of about 95% of the theoretical, and characterization was made of its basic properties, which suggest the possibility of using $SrHfO_3$ ceramics at elevated temperatures in air and in inert gas. Ceramics made from $SrHfO_3$ cannot be used at high temperatures over a prolonged period in vacuum because of the marked volatilization and change in their phase composition and basic properties.

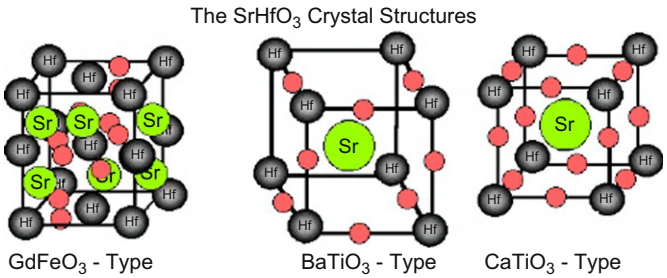

FIGURE 8.73

$SrHfO_3$ is trimorphic. Crystal structures are the same as those for $CaHfO_3$, except for cell parameters. The following diagram compares these structures shown in Fig. 8.73.

The cell parameters and cell occupancies are as follows:

$GdFeO_3$ Type

Unit cell parameters are: $a = 5.7569$ Å, $b = 5.780$ Å, $c = 9.130$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 271.43 Å^3.

Cell occupancy is listed in Table 8.37.

$BaTiO_3$ Type

Cell parameters are: $a = 4.105$ Å, $b = c = 4.114$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 69.4 Å^3.

Cell occupancy is listed in Table 8.38.

$CaTiO_3$ Type

Cell parameters are: $a = b = c = 4.121$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 69.93 Å^3.

Cell occupancy is listed in Table 8.39.

Sr_2HfO_4 has the K_2NiF_4 structure and the form shown in Fig. 8.74.

This structure contains a body-centered HfO_6 octahedra with 1/2 of an octahedra at both ends of the tetragonal unit cell. Strontium ions are interspersed on the edges of the tetrahedral unit. Cell parameters are: $a = b = c = 4.079$ Å, $\alpha = \beta = 107.03°$, $\gamma = 90°$, cell volume = 105.65 Å^3. Cell occupancy is listed in Table 8.40.

The compound, $Sr_3Hf_2O_7$, has the same form as the Sr_2HfO_4 compound except that two HfO_6 octahedra are present in the unit cell (Fig. 8.75).

3	O2	O	4	c	mmm.	0	1/2	0	1.0
4	Hf1	Hf	2	a	4/mmm	0	0	0	1.0

Cell parameters are: $a = b = 4.083$ Å, $c = 10.856$ Å, $\alpha = \beta = 100.839°$, $\gamma = 90°$m cell volume $= 174.46$ Å^3. Cell occupancy is listed in Table 8.41.

The compound, $Sr_4Hf_3O_{10}$, has the structure shown in Fig. 8.76. It has the structure type of $Ca_4Ti_3O_{10}$, point group = oP68, space group = *Pcba*.

Unit cell parameters are: $a = b = 6.783$ Å, $c = 29.235$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 974.33 Å^3.

Cell occupancy is listed in Table 8.42.

Another structure type of this compound has the structure type of $Sr_4Ti_3O_{10}$, point group = tl34, space group = *I*4/*mmm*, and is shown in Fig. 8.77.

Cell parameters are: $a = b = 4.088$ Å, $c = 14.923$ Å, $\alpha = \beta = 97.873°$, $\gamma = 90°$, cell volume = 244.36 Å^3. Cell occupancy is listed in Table 8.43.

The compound, $SrHfO_3$, has been used as a base for fast-decay phosphors. Luminescence spectra of $SrHfO_3$:Ce^{3+} and $BaHfO_3$:Ce^{3+} consist of a broad band due to Ce^{3+} emission peaking at 410 and 400 nm, respectively. The light yield of $BaHfO_3$:Ce^{3+} and $SrHfO_3$:Ce^{3+}, as a transparent optical ceramic, is approximately 40,000 photons/MeV when compared to a crystal of BGO. The principal decay time constant for $SrHfO_3$:Ce^{3+} and $BaHfO_3$:Ce^{3+} is 15 and 16 ns, respectively. A timing resolution of 276 ps (FWHM) was obtained with a transparent optical ceramic of $SrHfO_3$:Ce^{3+}.

There are only few published studies regarding dielectric properties of the $SrHfO_3$. Most recently, epitaxial $SrHfO_3$ was investigated on Si(100) substrates. There

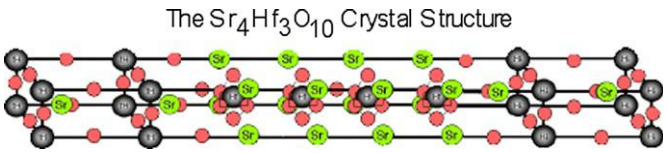

FIGURE 8.77

are, however, no reports on thin $SrHfO_3$ layers deposited onto metal electrodes inevitable in storage capacitors. In this work, $SrHfO_3$ was deposited onto 20 nm layers of magnetron sputtered TiN on Si wafers. The dielectric films were formed by coevaporation of HfO_2 and SrO in a molecular beam deposition chamber. Substrate temperature during evaporation was kept at 400 °C. It was found that "As-deposited" layers are amorphous and show a dielectric constant of $\kappa = 21$. During RTA, the amorphous material crystallizes in the cubic $SrHfO_3$ perovskite phase and the dielectric constant increases to around 35. Low leakage currents, 10^{-7} A/cm^2 at 1.0 V were measured down to CETs of 1.2 nm. $SrHfO_3$ layers have similar properties to $BaHfO_3$ films. In both cases, postdeposition RTA at 800 °C was necessary to convert 10- to 15-nm-thick As-deposited amorphous layers into polycrystalline films with improved κ. The measured dielectric constant of polycrystalline $BaHfO_3$ films is slightly higher than those of $SrHfO_3$. Breakdown fields are also similar: 3.3 and 2.8 MV/cm for amorphous and crystalline films. This is significantly lower than for pure HfO_2 (5.8 MV/cm). For both materials, leakage currents below 10^{-7} A/cm^2 at 1 V were measured for 1.2 nm CET. They are due to point defects, possibly associated with Ti contamination.

Strontium hafnates have not found usage in Industry because their physical and electrical properties have not been found to be superior to the materials presently being used in specific applications.

8.3.9. Barium Hafnide Compounds

The system, Ba–Hf, does not form any intermetallic compounds.

8.3.10. Barium Hafnate Compounds

In the $BaO–HfO_2$ system, one compound is known ($BaHfO_3$). $BaHfO_3$ has the same structure as $BaZrO_3$, as shown in Fig. 8.78.

Cell parameters are: $a = b = c = 4.161$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 72.00 Å^3. Cell occupancy is listed in Table 8.44.

Barium hafnate ($BaHfO_3$) precursor can be prepared by mixed barium nitrate and hafnium (IV) chloride

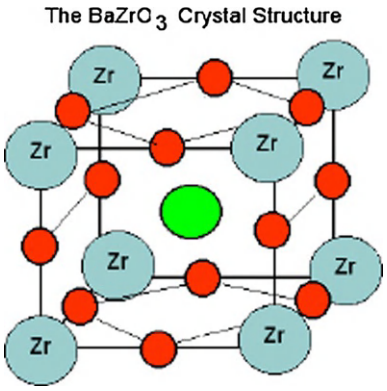

FIGURE 8.78

with ammonium oxalate aqueous solution. Barium hafnate powders were obtained by decomposition of the precipitate precursor at 800 °C for 2 h. As a dispersant, polyethylene glycol (PEG6000) was used in the precipitation reaction and the influence of dispersant dosage on particle size was studied. XRD analysis showed the powders was pure cubic $BaHfO_3$ without impurities. SEM and TEM demonstrated that the size distribution was uniform, and the average grain size was about 50 nm.

The crystal structure and MW dielectric properties of $BaHfO_3$ ceramics prepared by the solid-state route have been investigated. X-ray and electron diffraction show $BaHfO_3$ to be an untilted cubic perovskite ($a^0a^0a^0$, space group), whereas $SrHfO_3$ and $CaHfO_3$ are both orthorhombic-distorted perovskites ($a^-b^+a^-$, space group *Pnma*). $AeHfO_3$ ceramics with a relative density ~90% of the theoretical X-ray density and microstructures were prepared by firing at 1750 °C for 6 hrs. The product consisted of randomly oriented equiaxial grains. Conventional TEM revealed the occurrence of long parallel ferroelastic domains in the subgrain microstructure of $CaHfO_3$ and $SrHfO_3$. At room temperature and MW frequencies, $AeHfO_3$ ceramics, where Ae = Ba, Sr, and Ca, have $\varepsilon_r \sim 24.2$, $Qxf_r \sim 14{,}250$ GHz (at 8.9 GHz) and $\tau_f \sim +111$ ppm/K; $\varepsilon_r \sim 23.5$, $Qxf_r \sim 33{,}534$ GHz (at 9.3 GHz), and $\tau_f \sim 63$ ppm/K; and $\varepsilon_r \sim 21.4$, $Qxf_r \sim 15{,}950$ GHz (at 8.9 GHz), and $\tau_f \sim 33$ ppm/K, respectively. The ion polarizability for Hf^{4+} in a cubic perovskite environment was calculated to be 3.32 Å^3, whereas in a noncubic environment it increased to

TABLE 8.44

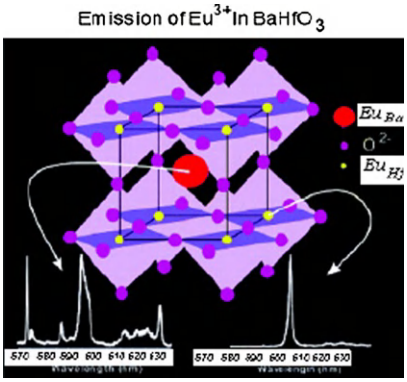

FIGURE 8.79

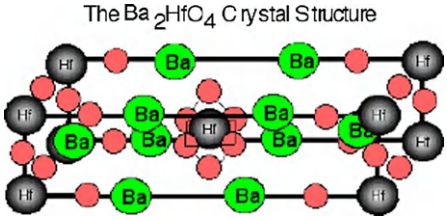

FIGURE 8.80

4.36–4.47 Å^3. The dielectric properties of $AeHfO_3$ (Ae = Ba, Sr, and Ca) were compared with their titanate and zirconate counterparts.

$BaHfO_3$ is a scintillator. The emission properties of $BaHfO_3$:Ce^{3+} consist of a broad band due to Ce^{3+} emission peaking at 400 nm. The light yield of $BaHfO_3$:Ce^{3+} is approximately 40,000 photons/MeV when compared to a crystal of BGO. The principal decay time constant for $BaHfO_3$:Ce^{3+} is 25 ns. A timing resolution of 276 ps (FWHM) was obtained with transparent optical ceramic of $BaHfO_3$:Ce^{3+}. Analysis of the band structure showed that perovskite-type $BaHfO_3$ is a wide gap indirect semiconductor. The band gap was predicted to be 3.94 eV within the screened exchange local density approximation (sX-LDA). The calculated equilibrium lattice constant of this compound was in good agreement with the available experimental and theoretical data reported in the literatures. The independent elastic constants (C_{11}, C_{12}, and C_{44}), bulk modulus B and its pressure derivatives, B', compressibility, β, shear modulus G, Young's modulus Y, Poisson's ratio, Y, and Lamé constants (μ, Å) were obtained and analyzed in comparison with the available theoretical and experimental data for both the single-crystalline and polycrystalline $BaHfO_3$. The bonding-charge density calculation made it clear that the covalent bonds exist between the Hf and O atoms and that ionic bonds exist between the Ba atoms and HfO_3 ionic groups in $BaHfO_3$.

Barium hafnate, $BaHfO_3$ is a valuable host lattice for X-ray phosphors, especially due to its high absorption for ionizing radiation, which results mainly from the presence of two heavy ions, Ba^{2+} and Hf^{4+} in the lattice and density reaches 8.5 g/cm^3. What is also advantageous is that $BaHfO_3$ crystallizes in cubic structure, which allows for transparent ceramics fabrication. These are potentially attractive replacements for monocrystalline materials.

Most of the research on $BaHfO_3$ was has been concentrated on Ce-doped powders, because of its fast luminescence decay, so important in dynamic medical techniques. Doping with Eu^{3+} as its red luminescence fits perfectly the region of the highest efficiency of CCDs, and is presently considered a detector of choice for digital planar X-ray imaging (Fig. 8.79).

In this technique the relatively slow decay of the Eu^{3+} luminescence is not an obstacle. Two series of $BaHfO_3$ powders activated with Eu^{3+} ions were prepared with a ceramic method. By stoichiometric variations, the dopant was forced to enter either Ba^{2+} or Hf(IV) sites. XRD analysis proved that Eu^{3+} ions preferred substitution of Hf(IV) in $BaHfO_3$, while replacement of Ba^{2+} encountered difficulties and led finally to separation of a foreign phase, $Eu_2Hf_2O_7$. Yet, it was shown that the host always incorporated the activator both into Hf(IV) and Ba^{2+} positions, and the two sites, $Eu_{Hf\cdot}$ and $Eu_{Ba\cdot}$, were spectroscopically characterized. From photoluminescence spectra, it appeared that $Eu_{Ba\cdot}$ gave emissions at 573.6, 595, and 626.0 nm, while luminescence from $Eu_{Hf\cdot}$ was practically limited to just one line peaking at 595.6 nm.

Luminescence and excitation spectra taken under synchrotron radiation showed that energy from the excited host is preferentially transferred to Eu_{Hf} compared to $Eu_{Ba\cdot}$. At 10 K, the latter was not capable of intercepting any energy upon excitation above the fundamental absorption of $BaHfO_3$, which limited

TABLE 8.45

4	Hf1	Hf	2	a	4/mmm	0	0	0	1.0

the luminescence in such conditions to a single line peaking at 595.6 nm. Also, under excitation with X-rays, practically only the Eu_{Hf}^{-} was able to produce luminescence.

The compound, Ba_2HfO_4, has the same structure as its Sr counterpart shown in Fig. 8.80.

Cell parameters are: $a = b = 4.191$ Å, $\alpha = \beta = 107.631°$, $\gamma = 90°$. Cell occupancy is listed in Table 8.45.

Although the crystal structure of this compound has been elucidated, it has found little usage in Industry and does not have a CAS number. The usage of $BaHfO_3$ is just beginning to be used in Industrial applications but it does not have a CAS number. These are the only two barium hafnate compounds known to date.

8.3.11. Radium Hafnium Compounds

Although radium could be used to form at least two compounds, $RaHfO_3$ and Ra_2HfO_4, the high cost and radioactive nature of ^{228}Ra has precluded any investigations of this system. Nor is it likely that Ra^0 forms any intermetallic compounds with Hf^0.

9.1. ALKALINE EARTH VANADIUM COMPOUNDS

The relation of ion-types of vanadium oxy-ions in solution with pH is shown in the following diagram: Fig. 9.1.

The decavanadate ion is shown in the following Fig. 9.2.

The major valence state is +5 and V_2O_5 is an oxide with slightly basic tendencies.

Vanadium forms a number of different compounds with the alkaline earths. Due to the amphoteric nature of vanadium, these compounds can be formed by either a solution method or solid-state reaction of the oxides. Most often, the latter method is employed.

9.1.1. Beryllium Vanadium Compounds

Be^0 forms only two intermetallic compounds with V^0. A phase diagram has been presented in Fig. 9.3.

Structure parameters are shown in Table 9.1.

Be_2V has the $MgZn_2$ structure with space group $P6_3/mmc$ as shown in Fig. 9.4.

Unit cell parameters are: $a = b = 4.384$ Å, $c = 7.131$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 118.73 Å^3. Cell occupancy is shown in Table 9.2.

In addition, the compound, $Be_{12}V$, has the structure of the $ThMn_{12}$ type where the V-atoms are arranged on the corners of the cubic cell, and is body-centered (as shown in the following diagram and the *a*-axis diagram): Fig. 9.5.

The Be-atoms are arranged in five internal-layers as shown in the *c*-axis diagram. The point group is tl26, and the space group is $I4/mmm$. The unit cell parameters are: $a = 4.212$ Å, $b = c = 5.5606$ Å, $\alpha = 81.75°$, $\beta = \gamma = 67.744°$, cell volume = 111.55 Å^3.

Note that layers one and five have only two atoms in them. Site occupancy is shown in Table 9.3.

The structure of the $Be_{17}V_2$ compound has not been elucidated. These are the only known Be–V compounds.

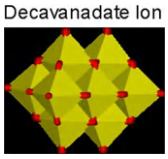

FIGURE 9.2

Beryllium (Be) metal is used as a reference material for a neutron multiplier in the fusion blanket design. However, Be metal may have problems such as high reactivity and large swelling at high temperature-high neutron dose in the DEMO fusion blanket. Beryllium alloys such as Be–Ti and Be–V are promising candidates for advanced neutron multipliers from the viewpoints of high melting point, high beryllium content, low radioactivation, and good chemical stability. In one study, the compatibility between structural material F82H steel and Be-7 atom%/V that included a Be^0 phase was investigated. After annealing, reaction products, at the surface of a F82H steel and Be-7 atom%/V specimen, were analyzed by X-ray diffraction (XRD) analysis and EPMA/SEM (electron probe micro analyzer/scanning electron microscopy) analysis. The thickness and rate constant of reaction layer at the surface of the F82H steel was evaluated and good compatibility between Be–V and F82H was clearly identifiable.

There are no known oxy-vanadium compounds of Be. As early as 1916, it was stated, "It was evident that a normal **beryllium vanadate** was not to be obtained … It has been shown that basic mixtures and not compounds are obtained by the addition of soluble vanadates to solutions of beryllium salts". Note that this involved aqueous solutions. However, the results of heating the oxides together have not been reported in the literature.

No beryllium–vanadium compounds are available commercially and no CAS numbers have been issued.

9.1.2. Magnesium Vanadium Compounds

Magnesium metal, Mg^0, does not form any intermetallic compounds with V^0. A phase diagram has been

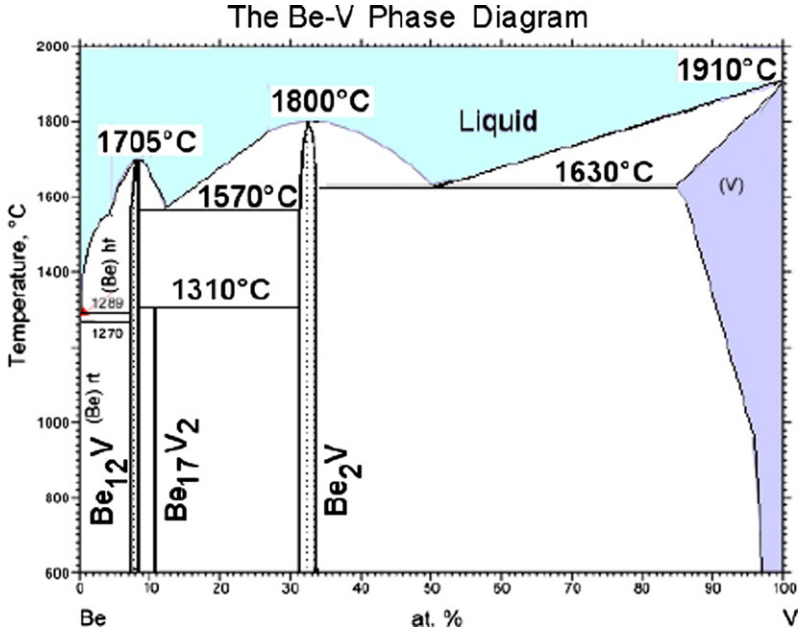

FIGURE 9.3

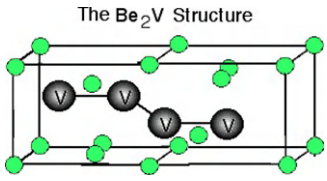

FIGURE 9.4

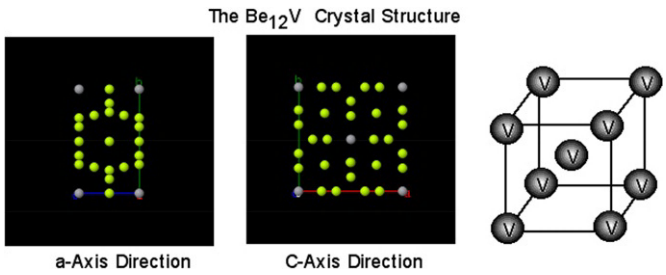

FIGURE 9.5

published showing the various polymorphic stages of both metals as a function of temperature as shown in Fig. 9.6.

This diagram is typical of all of the other alkaline earths (Ca, Sr and Ba) with V-metal and those phase diagrams will not be presented herein.

MgO forms a series of compounds with V_2O_5 when those oxides are heated at high temperatures at various molecular ratios. The solution method is almost unknown. An investigation was made of solid–solid reactions in MgO/V_2O_5 mixtures of various stoichiometric ratios. Three compounds were obtained, viz., $Mg_3V_2O_8$, $Mg_2V_2O_7$, and MgV_2O_6; no evidence was obtained to indicate the formation of other $MgO–V_2O_5$ compounds, as reported in the early literature. DTA data were listed for the three compounds and some observations were made on the mechanism of formation of the compounds. A new polymorph of $Mg_2V_2O_7$ was prepared, and its space group and cell parameters were deduced from the powder XRD pattern. This polymorph undergoes

a transition, reversible with difficulty, at 980–990 K. (700–790 °C).

The above figure presents the phase diagram of this system: Fig. 9.7.

The compound, MgV_4O_5, contains V^{2+} as the vanadium ion. The structure is of the rock-salt type with lattice parameters of: $a = b = c = 4.128$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 7.03 Å^3, $Z = 4$. Cell occupancy is shown in Table 9.4.

The $MgVO_2$, Mg_2VO_3, and Mg_3VO_4 compounds remain unknown.

In the V^{3+} containing compounds in the $MgO–V_2O_3$ series of compounds, the MgV_2O_4 compound has been studied. The structure has a cubic form, described as a "stuffed trigonal" structure, shown as follows in Fig. 9.8.

The unit cell is usually taken to be cubic with eight molecules of MgV_2O_4 and the space group is $Fd\bar{3}$Å.

VO6 octahedra along the chain direction in both the cubic and tetragonal phases (distortions have been exaggerated). The trigonal distortion slightly splits the t_{2g} levels in the cubic phase. In the tetragonal phase, the oxygen octahedra are compressed causing large splitting of the t_{2g} levels

FIGURE 9.9

The Mg and V ions are located at the oxygen tetrahedral A(8*a*) and octahedral B(16*d*) sites, respectively. The VO_6 octahedra share edges and three arrays of the V ions cross at each site. Each V ion has six neighboring ones. MgV_2O_4 possesses highly coupled spin, lattice, and orbital degrees of freedom and a distortion from spinel at room temperature (space group $F\bar{4}3m$), which allows for a greater trigonal distortion of the VO_6 octahedra and a low-temperature space group ($I\bar{4}m2$) that maintains the mirror plane symmetry.

In one study of this compound, a unique report of the frustrated spinel, MgV_2O_4, (which possesses highly coupled spin, lattice and orbital degrees of freedom) was presented. Using large single-crystal and powder samples, a distortion from spinel at room temperature (space group *F*-43*m*), which allows for a greater trigonal distortion of the VO_6 octahedra and a low-temperature space group (*I*-4*m*2) that maintains the mirror plane symmetry was discovered.

The magnetic structure that develops below 42 K consists of antiferromagnetic (AFM) chains with a strongly reduced moment while inelastic neutron scattering reveals one-dimensional behavior and a single band of excitations. The implications of these results were discussed in terms of various orbital ordering scenarios. It was concluded that although spin-orbit coupling must be significant to maintain the mirror plane symmetry, the trigonal distortion is large enough to mix the 3d levels leading to a wave function of mixed real and complex orbitals as shown in Fig. 9.9.

The electronic configuration of V^{3+} is $3d^2$, leading to a single-ion spin $S = 1$. Each V^{3+} ion is located at the center of edge sharing VO_6 octahedra which creates a crystal field that splits the d-orbitals and lowers the energy of the three-t_{2g} orbitals by approximately 2:5 eV. These levels are usually assumed to be degenerated (ignoring the small trigonal distortion) so that the two d-electrons of V^{3+} randomly occupy the three-t_{2g} orbitals, thereby introducing an orbital degree of freedom. This class of compounds undergoes a structural transition (TS) from cubic to tetragonal, which partially lifts the orbital degeneracy. A magnetic transition to long-rangeAFM order occurs at a lower temperature (T_N).

The magnetic properties MgV_2O_4 and $Mg(V_{0.85}Al_{0.15})_2O_4$ were also studied. Both compounds are normal cubic spinels having a highly frustrated magnetic lattice. Around $T_2 = 65$ K, MgV_2O_4 has a magnetic order associated with the cubic-tetragonal transition. Below T_2, the susceptibility shows complex behavior. In $Mg(V_{0.85}Al_{0.15})_2O_4$, the spin-glasslike state appears. The ^{51}V-Knight shift of MgV_2O_4 has anomalous temperature dependence. MgV_2O_4 occurs as a mineral called "Magnesiumcoulsonite".

In the V^{4+} system of MgO–VO_2, the compound, $MgVO_3$ has been studied. Its structure is shown in Fig. 9.10.

Cell parameters are: $a = 5.239$ Å, $b = 5.291$ Å, $c = 5.665$ Å, $\alpha = 117.84°$, $\beta = \gamma = 90°$, cell volume = 138.85 Å^3, $Z = 4$. Cell occupancy is shown in Table 9.5.

The magnetic susceptibility and the electron spin resonance in the X-band of the transition metal oxide

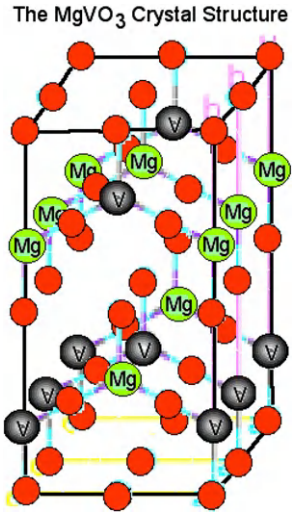

FIGURE 9.10

compound $MgVO_3$ showed that this compound, made of weakly coupled infinite chains of VO_5 pyramids, behaves as a $S = 1/2$ one-dimensional Heisenberg AFM.

In the V^{4+} system of MgO–VO_2, two phases have been investigated at 900 °C. $MgVO_3$ crystallizes in the orthorhombic system, space group $Cmc2_1$, with $a = 5.243$ Å, $b = 10.028$ Å, and $c = 5.290$ Å. The structure is built up from square pyramids VO_5 and MgO_5 sharing edges and forming sheets connected through oxygen atoms. Its structure is related to the ReO_3 and Mg_2NF structures. MgV_2O_5 is orthorhombic with $a = 3.696$ Å, $b = 9.965$ Å, and $c = 11.019$ Å, the space group is $Cmc2_1$, $Cmcm$, or $C2cm$.

The preparation of a high-pressure form of $MgVO_3$ has been accomplished utilizing two independent synthesis methods. The triclinic, ilmenite-type phase has been characterized by its crystallographic, magnetic, and electrical properties. Its structure is believed to be similar to that previously observed for other ilmenite-type AVO_3 derivatives ($CoVO_3$, $NiVO_3$, and $MnVO_3$). The properties of $MgVO_3$ appear to be intermediate between the localized electron model found in $MnVO_3$, $CoVO_3$, and $NiVO_3$, and the delocalized electron regime observed in $CuVO_3$. Related structures, ilmenite and perovskite type $Mg^{2+}V^{4+}O_3$ were newly synthesized at high pressures and high temperatures. The low-pressure form of $MgVO_3$ I is supposed to have a triclinic symmetry and to be isomorphous with the vanadate type of ilmenites $MnVO_3$ I and $CuVO_3$ I. Unit cell dimensions determined were: $a = 5.072$ Å, $b = 5.550$ Å, $c = 5.023$ Å, $\alpha = 90°0'$, $\beta = 118°38$, $\gamma = 63°4$ and $V = 106.3$ Å^3. The high-pressure form of $MgVO_3$ II, stabilized above about 45 kbar, has the orthorhombic perovskite structure with the possible space group of D_{2h}^{16}-$Pbnm$ or C_{2v}^{9}-$Pbn2_1$. Unit cell dimensions were $a = 5.106$ Å, $b = 5.265$ Å, $c = 7.387$ Å and $V = 198.6$ Å^3. It was stated that $MgVO_3$ II is the first perovskite containing Mg^{2+} ions in the larger cationic sites in the ilmenite structure.

In another study, the magnetic susceptibility and the electron spin resonance in the X-band of the transition metal oxide compound $MgVO_3$ was reported. This compound, made of weakly coupled infinite chains of VO_5 pyramids, behaves as an $S = 1/2$ one-dimensional Heisenberg AFM. From the ESR and magnetic experiments it was deduced that the Néel temperature K, the in-chain coupling constant K and the g-factor values $gx = gz = 1.972(2)$, $gy = 1.946(1)$ for V^{4+} ions in $MgVO_3$.

Powder samples of MgV_2O_5, which has a structure similar to the spin ladder compound CaV_2O_5, were synthesized and the magnetic properties were investigated. The magnetic susceptibility shows a broad maximum around 100 K and below about 15 K, it decreases more rapidly with decreasing temperature. The magnetization curves in high fields up to 17 T at 1.5 K and 30 T at 1.7 K show a change of slope around $H_c \sim 12.5$ T, which can be considered to be a transition from a singlet ground state to a gapless magnetic state. The excitation gap Δ was evaluated as $\Delta/k_B \sim 17$ K in agreement with the energy gap of about 2 meV from the inelastic neutron scattering. The results strongly suggest that MgV_2O_5 is a spin ladder system with a spin gap. Magnetic-susceptibility measurements on MgV_2O_5, a compound in which the vanadium oxide planes has the same topology as in CaV_2O_5. The most striking property is that there is an energy gap of about

15 K, much smaller than in CaV_2O_5, where the values reported are of the order of 500 K. It was shown that this might be understood naturally in terms of the phase diagram of the frustrated coupled ladder system. This analysis led to the prediction that MgV_2O_5 should have incommensurate dynamic spin fluctuations. The compound, MgV_3O_7, is not known.

The liquidus–solidus regions of the V^{5+} system MgO–V_2O_5 were investigated over the entire composition range, with the following principal findings: There are two congruently melting compounds: $2MgO \cdot V_2O_5$ melting at 1128 °C, and $3MgO \cdot V_2O_5$ melting at 1210 °C. A third compound, $MgO \cdot V_2O_5$, is thought to have an incongruent melting point at 762 °C. There are three eutectics: one at approximately 15 mol% V_2O_5 melting at 1192 °C, one at approximately 30 mol% V_2O_5 melting at 1122 °C, and one at approximately 75 mol% V_2O_5 melting at 658 °C. These compounds are sometimes called "metavanadate = MgV_2O_6", "pyrovanadate = $Mg_2V_2O_7$" and "orthovanadate = $Mg_3(VO_4)_2$".

The crystal structure of the low-temperature form of magnesium pyrovanadate (α-$Mg_2V_2O_7$) has been determined from synchrotron powder XRD data using Rietveld refinement as shown in Fig. 9.11.

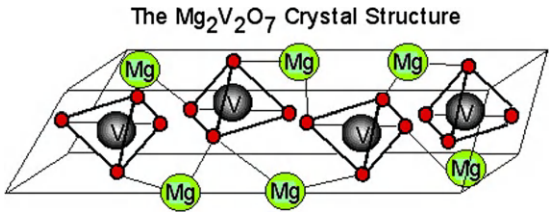

FIGURE 9.12

α-$Mg_2V_2O_7$, grown from a melt of MgO and V_2O_5, is triclinic with space group = $P1$. Another view of this structure is shown in Fig. 9.12.

Cell parameters are: $a = 13.767$ Å, $b = 5.414$ Å, $c = 4.912$ Å, $\alpha = 81.42°$, $\beta = 106.83°$, $\gamma = 130.33°$, $Z = 2$. The structure has chains of $V_2O_7^{4-}$-groups with long V–O bridges between these groups. The average terminal V–O bond length is 1.694 Å. Cell occupancy is shown in Table 9.6.

α-$Mg_2V_2O_7$ is isostructural with $Co_2V_2O_7$ and $Ni_2V_2O_7$. The Mg^{2+} ions are octahedrally coordinated to oxygen atoms in a distorted arrangement while the pyrovanadate anion has an approximately eclipsed conformation of non-bridging oxygen atoms. The ^{51}V MAS NMR spectra of the central and satellite transitions for the two distinct ^{51}V sites in α-$Mg_2V_2O_7$ allow determination of the magnitudes and relative orientations of the ^{51}V quadrupole coupling and chemical shift tensors. The crystal structure data are used to calculate the principal elements of the ^{51}V electric field gradient tensors employing the point-monopole approach. A good correlation between these elements and the experimental ^{51}V quadrupole tensor elements is observed, which allows assignment of the quadrupole coupling constants of $C_Q = 4.80$ MHz and $C_Q = 3.33$ MHz to the crystallographic V(1) and V(2) sites, respectively.

The formation process and microwave dielectric properties of the $Mg_2V_2O_7$ ceramics have been investigated. The MgV_2O_6 phase that was formed at around 450 °C interacted with remnant MgO above 590 °C to form a homogeneous monoclinic $Mg_2V_2O_7$ phase. Finally, this monoclinic $Mg_2V_2O_7$ phase was changed to a triclinic $Mg_2V_2O_7$ phase for the specimen fired at 800 °C. Sintering at 950 °C for more than 5 h produced high-density triclinic $Mg_2V_2O_7$ ceramics. In particular, the $Mg_2V_2O_7$ ceramics sintered at 950 °C for 10 h exhibited good microwave dielectric properties of $\varepsilon_r = 10.5$, $Q \times f = 58\ 275$ GHz, and $\tau_f = -26.9$ ppm/°C. Thus, it was concluded that magnesium pyrovanadate is trimorphic.

Propene is an important chemical that can be used to produce polypropylene, acrolein, acrylic acid, propylene oxide, etc. The oxidative dehydrogenation of propane (ODP) to propene is being intensively investigated to produce olefins. The ODP reaction is an exothermic process favored by thermodynamics. Among these catalysts, the V–Mg–O catalyst system is one of the most important. The catalytic oxidation of ethane, propane, 2-methylpropane, butane, pentane, and cyclohexane has been studied using $Mg_3(VO_4)_2$–MgO, $Mg_2V_2O_7$, and $(VO)_2P_2O_7$ as catalysts. These reactions produced a wide range of products ranging from alkenes, dienes, anhydrides, acids, and carbon oxides. Broadly speaking, the major products were dehydrogenation products over $Mg_3(VO_4)_2$, combustion products over $Mg_2V_2O_7$, and oxygen-containing organic products over $(VO)_2P_2O_7$, although there are exceptions to this broad generalization. From the product selectivity, the moles of oxygen consumed per mole of alkane reacted could be calculated. These were the average oxygen stoichiometries for the reactions. They had values of about unity for ethane oxidation over VPO, about two when oxidative dehydrogenation was the predominant reaction, and about four for the other reactions studied. The selectivity patterns in terms of the formation of dehydrogenation products versus oxygen-containing products including carbon oxides were explained by assuming that there existed a selectivity-determining step, which could be the reaction of the surface alkyl species or the adsorbed alkene before its desorption. The formation of oxygen-containing products would be facilitated if the surface alkyl or adsorbed alkene could interact with the vanadium ions in two adjacent VO_x units such that it could easily react with the reactive oxygen in the V–O–V bridge. The results of ethane oxidation, however, could not be explained simply by this model, and other factors, not elucidated, were considered to be affective.

In another paper, the three meta-, pyro-, and ortho-magnesium vanadate phases were synthesized, characterized, and tested as catalysts in the oxy-dehydrogenation of propane. *In situ* electrical conductivity measurements have clearly indicated that these solids behave as intrinsic semiconductors in oxygen at the reaction temperature (520 °C), with band gap energies equal to twice the corresponding activation energies of conduction, in good agreement with the values determined by UV–visible spectroscopy. In the presence of propane, the electrical conductivity of the samples increased instantaneously at a variation rate and to an extent which both changed in the following order: pyro-$Mg_2V_2O_7$ > meta-MgV_2O_6 > ortho-$Mg_3V_2O_8$. The increase in conductivity observed has been attributed to the consumption of surface lattice oxygen anions by propane, leading to the formation of propene, water, and ionized anionic vacancies. The existence of these vacancies were supported by the study of their filling, using either dioxygen, O_2 or nitric oxide, NO, as sources of dissociated oxygen species. It was proposed that pure magnesium vanadates act as redox relays in the oxy-dehydrogenation of propane according to the Mars and van Krevelen mechanism. The higher catalytic activity of pyrovanadate, $Mg_2V_2O_7$, was directly connected with the lability of its surface O^{2-} ions, as detected by conductivity. The high reoxidation rate implied that the solids are working in a surface state close to stoichiometry, i.e. close to the oxidized state. This could explain why the reaction kinetic order with respect to oxygen was equal to zero. The electrical properties of the three V–Mg–O phases could explain why pyrovanadate $Mg_2V_2O_7$ was the most active and the most selective phase for oxidative dehydrogenation of propane into propene.

In another paper, periodic oscillations of oxygen activity of a $Mg_2V_2O_7$ catalyst during the oxidative dehydrogenation of propane were investigated by solid electrolyte potentiometry (SEP). Among the catalysts tested, $Mg_3(VO_4)_2$, prepared with a (Mg + V)/citric acid molar ratio of 1:1.2 and calcined at 823 K for 6 h, exhibited the best catalytic performance and had an excellent thermal stability. The catalytic active-phase was identified as containing $Mg_3(VO_4)_2$, $Mg_2V_2O_7$ and MgV_2O_6 as pure magnesium vanadates. The results of characterization and evaluation showed that $Mg_2V_2O_7$ had the isolated active sites, weakly basic surface and best reducibility of these compositions, and could be recognized as the catalytic active phase.

In another study, two pure magnesium vanadate phases, $Mg_2V_2O_7$ and $Mg_3V_2O_8$, were prepared and tested in the dehydrogenation of n-pentane in the presence of oxygen. Both magnesium vanadates are effective catalysts, with $Mg_3V_2O_8$ exhibiting higher selectivity to form dehydrogenation products. Testing of mechanical mixtures, consisting of each one of the magnesium vanadates and antimony oxides, indicated that the latter had a positive effect especially on the selectivity to dehydrogenation with the $Mg_3V_2O_8$ containing samples. The main products of the reaction were pentenes,

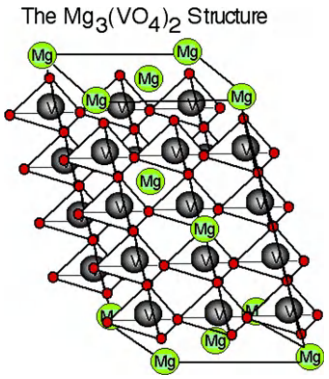

FIGURE 9.13

pentadienes and carbon oxides. Characterization of the samples prior to and after catalytic tests revealed that all catalysts remained practically unchanged during the reaction. The mixtures consisted of separate magnesium vanadate and antimony oxide phases and no formation of new phases was detected. The study of oxidative dehydrogenation of propane was carried out over V–Mg–O catalysts. The citrate method was used to prepare catalysts with the Mg/V atomic ratio varying from 1/4 to 9/1. Three pure Mg vanadates and the corresponding biphasic catalysts were obtained from very homogeneous Mg–V–citrate precursors after calcination at 550 °C.

Among the three pure Mg vanadates, α-$Mg_2V_2O_7$ (pyrovanadate) was found to be the most selective, while MgV_2O_6 (metavanadate) was the worst one. Interestingly, the catalytic behavior of biphasic catalysts is quite different from that of pure Mg vanadate phases. For example, the selectivity of $Mg_3V_2O_8$ (orthovanadate) can be promoted by a coexisting pyrovanadate phase or excess magnesium oxide in intimate contact. These differences were discussed in terms of the different specific activities of phases and possible synergy effects between the phases.

An unusual MgV_2O_6 phase having a Brannerite ($ThTi_2O_6$) related structure was obtained by solid-state reaction and its powder XRD and thermal studies were discussed. Those studies confirmed a structural transition at 833 K (560 °C) for non-stoichiometric magnesium metavanadate.

Magnesium ortho-vanadate has the structure shown in Fig. 9.13.

Cell Parameters are: $a = 6.953$ Å, $b = 11.428$ Å, $c = 8.318$ Å, $\alpha = \beta = \gamma = 80°$, $Z = 57.54$ Å^3. Cell occupancy is shown in Table 9.7.

Reduction of polycrystalline and crystalline magnesium orthovanadate $Mg_3V_2O_8$ by hydrogen was investigated in the temperature range of 560–920 °C. A single crystal of orthorhombic $Mg_3V_2O_8$ with a cation-deficient-spinel structure (25% of the magnesium atoms on octahedral sites are vacant) was transformed into cubic $Mg_3V_2O_6$ which has a cation-stuffed-spinel structure (8*a* and 16*c* sites were partially occupied by magnesium and 16d sites were fully occupied by magnesium and vanadium) at 560 °C in 7% H_2 in N_2. This cubic phase, $Mg_3(VO_3)_2$, has the space group $Fd3m/2$ and the cell parameters of: $a = b = c = 8.409$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 594.61 Å^3.

Single-crystals of the polar compound, magnesium hydrogen vanadate(V), $Mg_{13.4}(OH)_6(HVO_4)_2(H_{0.2}VO_4)_6$, were synthesized hydrothermally. It represents the first hydrogen vanadate(V) among inorganic compounds. Its structure was determined by single-crystal XRD [space group $P\ 6_3mc$, $a = 12.9096(2)$, $c = 5.0755(1)$ Å, $V = 732.55(2)$ Å, $Z = 1$]. The crystal structure of $Mg_{13.4}(OH)_6(HVO_4)_2(H_{0.2}VO_4)_6$ consists of well separated, vacancy-interrupted chains of face sharing Mg_2O_6 octahedra, with short Mg_2–Mg_2 distances of 2.537(1) Å, embedded in a porous magnesium vanadate 3D framework having the topology of the zeolite, "Cancrinite". All three hydrogen positions in the structure were confirmed by FTIR spectroscopy.

Magnesium vanadate is offered for sale as the metavanadate composition. Its CAS number is 210909-46-9.

9.1.3. Calcium Vanadium Compounds

The metal, Ca^0, does not form any intermetallic compounds with V^0. The system, CaO–V_2O_5, forms

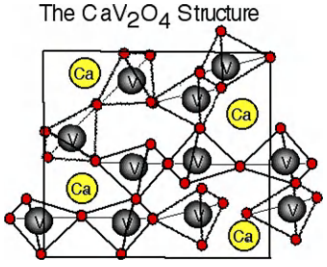

FIGURE 9.15

a series of compounds. The only published phase diagram shows the meta-, pyro- and ortho-vanadate compositions as shown in Fig. 9.14.

However, other compositions have been reported. All three compounds shown in the phase diagram melt incongruently.

In the V^{2+} system of CaO–VO, the compound, $CaVO_2$ is unknown, as is Ca_2VO_3 and Ca_3VO_4.

In the V^{3+} system of CaO–V_2O_3, the compound, CaV_2O_4 has the structure shown on the next page. The lattice parameters are: $a = 6.053$ Å, $b = 6.466$ Å, $c = 8.318$ Å, $\alpha = \beta = 90°$, $\gamma = 83.18°$, cell volume $= 287.69$ Å^3 as shown in Fig. 9.15.

Cell occupancy is shown in Table 9.8.

In the V^{4+} system of CaO–VO_2, the compound, $CaVO_3$ is known to be dimorphic. In the $3d(t2g)^1$ perovskites series, $SrVO_3$–$CaVO_3$–$LaTiO_3$–$YTiO_3$, the transition-metal *d* electron becomes increasingly localized and undergoes a Mott transition between $CaVO_3$ and $LaTiO_3$. By defining a low-energy Hubbard Hamiltonian in the basis of Wannier functions for the *t2g* LDA band and solving it in the single-site dynamical mean-field

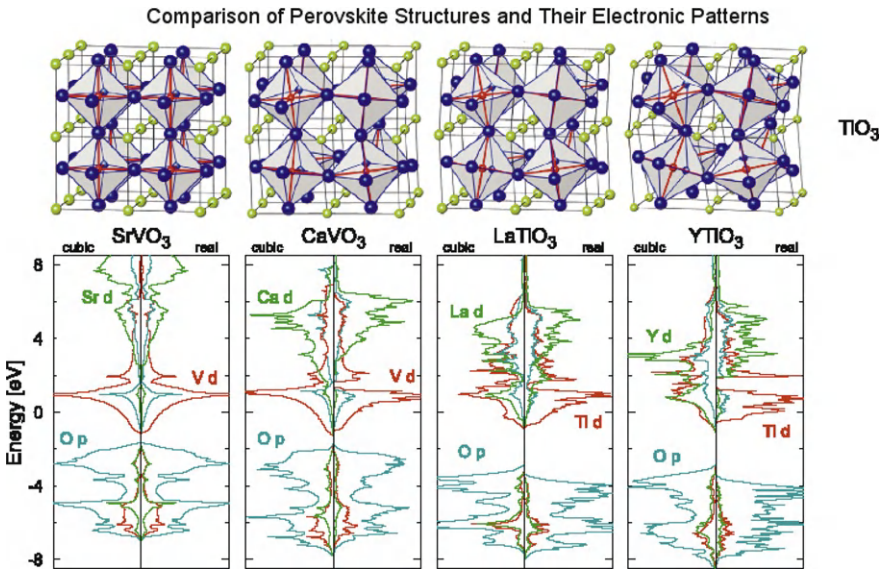

FIGURE 9.16

(DMFT) approximation, it has been shown that together with the Mott transition there occurs a strong suppression of orbital fluctuations due to splitting of the *t*2*g* levels.

A comparison of structures including $CaVO_3$ is shown in the diagram: Fig. 9.16.

A stoichiometric calcium vanadium (IV) oxide with formula $CaVO_3$ has been prepared by soft-chemistry procedures, followed by annealing under reducing conditions (H_2/N_2 flow). This material has been studied by XRD and neutron powder diffraction (NPD), thermal analysis, magnetic and magneto-transport measurements. $CaVO_{3.0}$ perovskite crystallizes in the orthorhombic *Pbnm* (No. 57) space group, with the $GdFeO_3$-type structure. The unit-cell parameters are $a = 5.3219$ Å, $b = 5.3427$ Å and $c = 7.5472$ Å. In this distorted perovskite the VO_6 octahedra are tilted by 10.1° in order to optimize the Ca–O bond-lengths. A bond valence study from NPD data confirms the tetravalent oxidation state for V cations. The perovskite is fully oxygen stoichiometric, as demonstrated from thermal analysis and the refinement of the oxygen occupancy factors. The magnetic susceptibility is predominantly Pauli paramagnetic-like, although a non-negligible temperature-dependent component due to isolated V^{4+} spins is patent at low temperatures. The transport measurements show a metallic behavior between 2 and 300 K; at low temperatures a positive magneto-resistance as large as 14% for $H = 9$ T is interpreted as the result of quantum interference effects.

Four vanadates (IV) have been synthesized by solid-state reactions and characterized in the $CaO–VO_2$ systems as: $CaVO_3$, CaV_2O_5, CaV_3O_7, and CaV_4O_9 (1:1, 1:2, 1:3, 1:4). Structural data have been given. The structural evolution of the series CaV_nO_{2n+1} is described as follows. As n increases from $n = 1$ to $n = 4$, the vanadium +4 compounds show only a five-fold square pyramid coordination. As the Ca/V ratio increases, the Ca_2VO_4 and Ca_3VO_4 compounds can be formed. A chemical potential diagram of the V–Ca–O system was constructed. A V–Ca–O catalyst used in the oxidative dehydrogenation of n-butane was prepared by the impregnation method and was characterized by in-situ XRD. $Ca_3V_2O_8$ and CaO were detected on the in-situ XRD pattern under the oxygen pretreatment at 600 °C, and the XRD measurements under working conditions showed that $Ca_3V_2O_8$ is reduced to CaV_2O_4, having a cubic spinel structure with a lattice constant of $a = 8.427$ Å. The observed reduction of V^{5+} in $Ca_3V_2O_8$ to V^{3+} in CaV_2O_4 under the working conditions were well characterized through the use of the chemical potential diagram.

Among perovskite-type light-3d oxides, $CaVO_3$ has attracted considerable attention because of its metallic conductivity. This behavior is opposed to the insulating one observed in $LaTiO_3$. It was reported for $CaVO_3$ that oxygen defects induced insulating conductivity, while oxygen excess induced metallic conductivity. Another important point concerning CaVO3 is that the magneto-resistance is positive in the stoichiometric samples and is negative in non-stoichiometric samples. In addition, there has been no report on the anisotropic properties of $CaVO_3$. The magnetic properties of perovskite $CaVO_3$ single crystals have been studied by means of magneto-resistance $p(T, H)$ and magnetization $M(H)$ measurements in fields up to 18 T. At 2 K, the magneto-resistance is positive and a maximum value of $\Delta p((18\text{ T})/p_0) = 16.5\%$ is found for $H//a$. The

magnetization exhibits a smooth increase at 2 K, reaching values of $M(18\ \mathrm{T}) = 0.03, 0.05, 0.17\ \mu\mathrm{B/f.u.}$ for $H//a$, $H//b$, and $H//c$, respectively. This anisotropy found in $M(H)$ is consistent with that observed for $\Delta p(H//a) > \Delta p(H//b) > \Delta p(H//c)$. These results can be interpreted in terms of the field-dependent scattering mechanism of $CaVO_3$.

Non-stoichiometric $CaVO_{3-\delta}$ with a well-controlled oxygen content was synthesized at a $\delta = 0.01$ step by reducing stoichiometric $CaVO_{3.00}$ using a Zr sheet. The relations between oxygen deficiency and structure were investigated. Three new phases, phase A ($0.04 < \delta < 0.08$), phase B ($\delta = 0.14$), and phase C ($\delta = 0.2$), appear in the sequence of δ's. Each phase has a vacancy-ordered structure with a much larger unit cell than the primitive one. These oxygen-deficient phases are unstable in air at room temperature and are easily oxidized to stoichiometric $CaVO_{3.00}$. All of the phases are metallic but magnetic susceptibilities of phases B and C with high oxygen deficiencies show Curie–Weiss behaviors, while stoichiometric $CaVO_{3.00}$ and phase A are Pauli paramagnets. In phases B and C there exist at least two distinct V sites in electronic state, that is, localized V sites with $S^{=}$ and itinerant V sites. There are two structures in the photoemission spectra of $CaVO_{3-\delta}$ and $SrVO_{3-\delta\delta}$ in the d-band region. One peak is within ~1 eV of the Fermi level and has a sharp Fermi cutoff. The other is a broad peak centered at ~1.6 eV. From our photoemission spectra of $CaVO_{3-\delta}$ and $SrVO_{3-\delta}$ both with oxygen vacancies ($\delta = \sim 0.1$) and without vacancies ($\delta = 0$), it is shown that the relative intensity of the peak near the Fermi level for $CaVO_{3=\delta}$ drastically decreases with decreasing oxygen vacancy concentration (δ). In contrast, no such drastic change in intensity is observed for $SrVO_{3-\delta}$. This difference in the effect of oxygen vacancies between $SrVO_{3-\delta}$ and $CaVO_{3-\delta}$ reflects the fact that a metal-insulator phase transition induced by bulk oxygen vacancies takes place in $CaVO_{3-\delta}$ but not in $SrVO_{3-\delta}$.

Cavoite, CaV_3O_7 occurs at the Gambatesa mine (Liguria, Italy) filling micro-cavities in massive bands of caryopilite + calcium rhodochrosite and quartz. Cavoite has been found as very rare radiated-aggregates of strongly elongated prismatic to acicular crystals. The crystals vary in color from colorless to olive green-brown. The powder-diffraction data give the refined cell parameters $a = 10.42$ Å, $b = 5.28$ Å, $c = 10.34$ Å and $V = 568.2$ Å^3 in the space group *Pnam*. Cavoite is the natural analog of the synthetic CaV_3O_7, whose structural study is reported in literature together with that of the isostructural phases SrV_3O_7 and CdV_3O_7. A discontinuous change of muon-spin precession frequencies in CaV_3O_7 is observed at $T \sim 0.2$ K, indicating a possible spin reorientation. These results suggest that CaV_3O_7 possesses the identical spin direction as isostructural

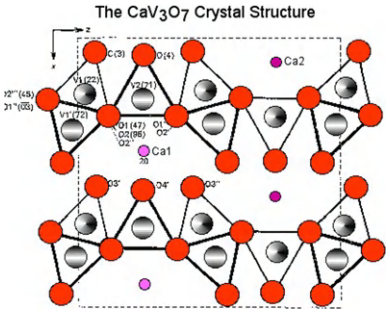

FIGURE 9.17

SrV_3O_7 below ~0.2 K, although the spin directions in the two compounds are different at higher temperatures as determined by elastic neutron scattering. The structure of CaV_3O_7 is shown as Fig. 9.17.

The layered vanadates, CaV_2O_5, MgV_2O_5, CaV_3O_7, and CaV_4O_9, have been thoroughly studied. The uniform susceptibility of the Heisenberg model with these exchange couplings was calculated by the quantum Monte Carlo method; it agrees well with the experimental measurements. These results were stated to naturally explain the unusual magnetic properties of these materials, especially the huge difference in spin gap between CaV_2O_5 and MgV_2O_5, the unusual long range order in CaV_3O_7, and the "plaquette resonating valence bond" spin gap in CaV_4O_9. Muon spin relaxation measurements of CaV_4O_9, CaV_3O_7 and CaV_2O_5 have been made. The sub-lattice magnetization in the AFM state of CaV_3O_7 agrees well with spin wave theory. In CaV_4O_9 and CaV_2O_5, it was observed that spin-freezing occurred below 15 and 50 K, respectively, which indicates that a substantial fraction of the vanadium magnetic moment is not in a spin-singlet state at low temperatures in either materials.

In the $CaO–V_2O_5$ system containing V^{5+}, CaV_2O_6, has the structure shown in Fig. 9.18.

The VO_4 tetrahedra form a series of chains along the a-axis of the unit cell. The unit cell parameters are: $a = 3.671$ Å, $b = 5.3502$ Å, $c = 7.025$ Å, $\alpha = 103.32°$, $\beta = 90°$, $\gamma = 110.06°$, cell volume $= 125.64$ Å^3. In another

4	O3	O	4	i	m	0.4126	0	0.2781	1.0
5	Ca1	Ca	2	b	2/m	0	1/2	0	1.0

study, MgV_2O_6 was found to crystallize in the monoclinic space group $C2/m$ with lattice parameters $a = 9.279$ Å, $b = 3.502$ Å, $c = 6.731$ Å and $\beta = 111.77°$ with $Z = 2$. The structure was refined, at room temperature, utilizing 593 symmetry independent reflections, by full matrix least squares to a final R-value of 0.032.

The structure consists of Ca^{2+} lying at a site of $2/m$ symmetry octahedrally coordinated to oxygen atoms with a mean separation of 2.140 Å. All the remaining atoms lie in crystallographic mirror planes with the V ion coordinated to six oxygen atoms with bond distances ranging from 1.666 to 2.671 Å. Site occupancy in the unit cell is shown in Table 9.9.

The crystal structure of a high-pressure modification of calcium divanadium (V^{+5}) hexoxide, CaV_2O_6, was refined from X-ray single-crystal data. It contains zigzag chains of corner-sharing VO_4 tetrahedra. Tetrahedra in adjacent chains share corners and form corrugated layers. Tetrahedrally coordinated Ca atoms, which lie on two-fold axes, are situated between the layers. The columbite-like structure results in a strong distortion of the CaO_6 octahedra, which may be stabilized only at high pressure.

If the metavanadate compound, CaV_2O_6, is heated in a hydrogen atmosphere, a loss of oxygen occurs:

$$CaV_2O_6 + 2H_2 \Rightarrow CaV_2O_4 + 2H_2O$$

However, instead of the formation of $O^{=}$ vacancies to form $CaV_2O_{6-\delta}$, a change in the valence state from V^{5+} to V^{3+} occurs. This results in a "vanadite" compound that is stoichiometric and has the formula of CaV_2O_4. Another V^{5+} containing composition, the ortho-vanadate, $Ca_3(VO_4)_2$ has the structure as shown in Fig. 9.19.

Unit-cell parameters are: $a = b = 10.817$ Å, $c = 59.36$ Å, $\alpha = \beta = 67.492°$, $\gamma = 60°$, cell volume $= 1284.20$ Å^3. The crystal structure of $Ca_3(VO_4)_2$ is rhombohedral with space group $R3c$ and with equivalent hexagonal axis lengths of $a = 10.809(1)$ and $c = 38.028(9)$ Å. The rhombohedral cell contains seven formula units. Cell occupancy is shown in Table 9.10.

It is isomorphous with $Ca_3(AsO_4)_2$. The structure was refined by full-matrix least squares utilizing 1252 symmetry-independent reflections to a final R-value of 0.049. One formula unit lies on the three-fold axis with one of the calcium-ion sites on this axis half-occupied and another site octahedrally coordinated to oxygen atoms. The remaining calcium ions are coordinated to 8, 7 and 8 oxygen atoms with Ca–O bond lengths of 2.525, 2.442 and 2.570 Å respectively. The mean V–O bond length for the three crystallographically independent VO_4 groups are within 0.01 Å of 1.69 Å. The structure is related to that of $Ba_3(VO_4)_2$ but with a formula-unit density 7/8 as large, due to the loss of one formula unit per cell from chains along the threefold axis. This change in structure follows from the smaller average cation-oxygen bond length in the calcium salt. R-values as low as 0.041 can be obtained with models that allow for differences in the environment of the half-occupied cation site, presumably dependent upon whether it is filled or empty.

A novel polymorph of calcium orthovanadate $Ca_3(VO_4)_2$ was synthesized at 11 GPa and 1373 K and

recovered to ambient conditions. It crystallizes in a monoclinic cell (space group $C2/m$, $Z=2$) with $a=9.6715(2)$, $b=5.43276(7)$, $c=7.0713(1)$ Å, $\beta=116.949(1)^\circ$. The crystal structure was solved by ab initio methods from powder XRD data using direct categorization. The oxygen atoms form a hexagonal close packing. The VO_4^{3-} tetrahedra are radially and angularly distorted. The two crystallographically independent Ca atoms are in deformed octahedral and 10-fold coordinations. Unlike in the palmierite-derived parent $Ba_3(VO_4)_2$ (Rm, $Z=1$) and $Ca_3(VO_4)_2$ ($R3c$, $Z=7$), this network is three-dimensional. The new monoclinic structure of calcium orthovanadate was discussed in relation to those of related orthophosphates and orthovanadates. It was suggested that the pressure-induced amorphously-formed $Ca_3(VO_4)_2$ ($R3c$, $Z=7$) at 10 GPa and room temperature could be due to kinetically inhibited changes in the dimensionality of the crystal structure.

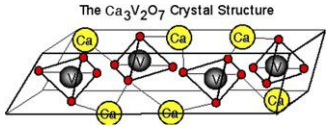

FIGURE 9.20

The pyrovanadate, $Ca_2V_2O_7$, is homologous to $Mg_2V_2O_7$ and has the same structure as shown in the following diagram: Fig. 9.20.

The unit cell parameters are: $a=6.667$ Å, $b=6.921$ Å, $c=7.018$ Å, $\alpha=96.39\cdot$, $\beta=63.84^\circ$, $\gamma=83.64^\circ$, cell volume $=288.83$ Å^3. Cell occupancy is shown in Table 9.11.

Investigations of the CaO–V_2O_3–VO_2–V_2O_5 system under various oxygen pressures and with addition of sodium in starting mixture have been described. A diagram of CaV_4O_9 and CaV_3O_7 stability and the reaction:

$$CaV_3O_7 + VO_2 \Rightarrow CaV_4O_9$$

was studied by variation of temperature and oxygen partial pressure. In this case, the vanadium ion is in the V^{4+} valence state. As a result, single-phase CaV_4O_9 and CaV_3O_7 ceramics were prepared, and plate-like single crystals of CaV_4O_9 were grown. Magnetic susceptibility data confirmed the existence of a disordered spin liquid state with spin gap $\beta=100\pm15$ K in CaV_4O_9 and of an AFM order below $T_N=22$ K in CaV_3O_7.

Muon spin relaxation measurements of CaV_4O_9, CaV_3O_7 and CaV_2O_5 were performed. The sub-lattice magnetization in the AFM state of CaV_3O_7 agrees well with spin wave theory. In CaV_4O_9 and CaV_2O_5, spin

TABLE 9.11

freezing below 15 and 50 K, respectively was observed, which indicated that a substantial fraction of the vanadium magnetic moment is not in a spin-singlet state at low temperatures in either material.

Another compound, $Ca_{0.6}V_2O_5$, has been discovered. It was prepared by heating the metavanadate with VO_2 in a hydrogen atmosphere. The structure is shown in Fig. 9.21 as follows:

The formula may be construed, as $Ca_3V_5O_{25}$ but is actually composed of three molecular units: $CaV_2O_4 \cdot CaVO_3 \cdot CaV_2O_6$ in which the vanadium atom has the +3, +4 and +5 valence states, respectively. The structure is actually composed of VO_3 triangles, a double tetrahedra and a triangle-tetrahedra unit. Cell parameters are: $a = 3.709$ Å, $b = 6.187$ Å, $c = 9.27$ Å, $\alpha = \gamma = 101.317°$, $\beta = 90°$, cell volume $= 198.60$ Å^3.

The $CaO–V_2O_5$ system has not received the attention that other compounds in the $MgO–V_2O_5$ system have found and calcium vanadate compounds are not used in industry. Certain compounds are available commercially. No CAS numbers have been assigned to date.

9.1.4. Strontium Vanadium Compounds

The metal, Sr^0, does not form any intermetallic compounds with V^0.

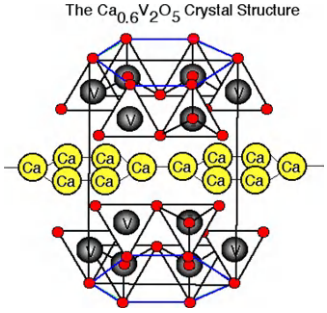

FIGURE 9.21

The system, $SrO–V_2O_5$, forms a series of compounds. The structure of many binary oxides can be predicted on the basis of the relative sizes of the metal and oxide ions and filling of holes in a close packed oxide lattice. Such predictions of structure are more difficult for ternary phases. The combination of two or more metals in an oxide generates a wealth of structural possibilities dependent on the relative sizes of the two metal ions and the oxide ion. In addition the stoichiometry of the ternary oxide may be changed by varying the proportions of the two component oxides and, for transition and lanthanide elements, the oxidation state. For example, at least twenty ternary oxide phases are formed between strontium and vanadium including $Sr_2V_2O_5$, (V-III) & (V-IV), $SrVO_3$ (V^{4+}) Sr_2VO_4 (V^{4+}) and SrV_2O_6 (V^{5+}). The structural chemistry of ternary and more complex oxides is, thus, an extensive subject, there are, however, a few structures which are widely adopted by ternary oxides and many materials from these structural classes have important technological applications. These ternary oxide structures are also used as units in building more complex oxides, such as the high-temperature superconductors.

In the V^{2+} system of SrO–VO, no compounds are known. A modification of Sr_2VO_3 has been found to be a super-conductor. The new superconducting system $Sr_2VO_{3-\delta}$–FeAs has been fabricated at different oxygen contents. It is found that the superconducting transition temperature drops monotonically with the increase of oxygen deficiency and the residual resistivity, indicating an anomalous pair breaking effect by disorders. Magneto-transport measurements reveal that the superconducting transition evolves from one-step-like at low field to two-step-like at high field. The first step corresponds to the upper critical field, while the second one is related to the irreversibility line. A vortex phase diagram is thus derived, which shows a large area of vortex liquid state. This indicates a high anisotropy of

the system. To conclude, the specific heat of the optimally doped sample ($\delta \approx 0.1$) with $T_c = 40$ K was presented. A high residual specific heat coefficient appeared in the superconducting state, suggesting the existence of large amount of unpaired electrons, which may derive from the V-band. Superconductivity at 33 K in $Sr_2VO_{3-\delta}$–FeAs is completely suppressed by small amounts of V-doping in $Sr_2VO_3[Fe_{0.93}(+/-0.01)V_{0.07}(+/-0.01)]As$. The crystal structures and exact stoichiometries are determined by combined NPD and powder XRD. $Sr_2VO_{3-\delta}$–FeAs is shown to be very sensitive to Fe/V mixing, which interferes with or even suppresses superconductivity. This inhomogeneity may be intrinsic and explains scattered reports regarding T_c and reduced superconducting phase fractions in $Sr_2VO_{3-\delta}$–FeAs. Neutron diffraction (ND) data collected at 4 K indicates incommensurate magnetic ordering of the V-sub-lattice with a propagation vector $q = (0,0,0.306)$ suggests that strongly correlated vanadium does not contribute significantly to the Fermi surface of $Sr_2VO_{3-\delta}$–FeAs.

In another study, $(Sr_2ScO_3)_2Fe_2As_2$ and $(Sr_2VO_3)_2Fe_2As_2$ with the spacing distance between FeAs layers as large as 15.66 Å was synthesized and a T_c of 37.2 K was found in the latter compound. Density-functional calculations indicated that the ground states of $(Sr_2ScO_3)_2Fe_2As_2$ and $(Sr_2VO_3)_2Fe_2As_2$ were stripe AFM and checkerboard AFM, respectively. The band structure and Fermi surface of $(Sr_2ScO_3)_2Fe_2As_2$ are similar to those of LaOFeAs, while those of $(Sr_2VO_3)_2Fe_2As_2$ show a significant difference. In $(Sr_2VO_3)_2Fe_2As_2$, both Fe 3*d* and V 3*d* states contribute to the Fermi surfaces, which implies that the V 3*d* states may play important roles in the superconductivity.

The superconducting Fe pnictide, $Sr_2VFeAsO_3$, has been found to be composed of alternating stacks of FeAs and Sr_2VO_3 perovskite-like block layers. The superconducting transition temperature T_c is 37 K. For this system, several band calculations have pointed out that both FeAs and V layers seem to have conduction electrons, and that the Fermi surfaces (FS's) do not have a significant nesting feature. This implies that $Sr_2VFeAsO_3$ gives an opportunity to examine whether Fermi-surface nesting is important for the occurrence of superconductivity of Fe pnictides. On this point, it has been reported that, because the FS's are constructed only by the Fe orbitals of $Sr_2VFeAsO_3$ are similar to those expected in other Fe pnictides; the nesting condition is also satisfied in this system.

In the V^{3+}-containing system, $SrO–V_2O_3$, the compound, SrV_2O_4 is unknown. The phase relationship of Sr–V–O system that contains low-valent V^{3+} oxide has been investigated. The phase identification was performed by XRD. The resistivities of constituent phases were measured by standard four-probe technique at 100–1000 K. The results indicate that low-valent V compounds in the system exist as hexagonal $Sr_8V_8O_{25}$ and cubic $Sr_2V_2O_5$ as well as V_2O_3, which show an electronic resistivity of <100–101 Ω cm at >150 K. The V_2O_3 phase exhibits a steep enhancement in resistivity with a magnitude of order of 105 Ω cm at <150 K, showing a transition from electronic conductor to insulator. These materials are useful for battery cathodes. The structure of $Sr_2V_2O_5$ is one of the "rock-salt" structure types where the Sr^{2+} and V^{3+} ions (as $V_2O_{6-\delta}$) are substituted on the cation and anion sites. Cell parameters are: $a = b = c = 7.656$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 777.64 Å^3. Cell occupancy has not been given.

In the V^{4+} system of $SrO–VO_2$, the $SrVO_3$ has the structure as shown in Fig. 9.22.

Lattice parameters are: $a = b = c = 3.842$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 56.71 Å^3, $Z = 1$.

Cell occupancy is shown in Table 9.12.

$SrVO_3$ is a metal-insulator compound. The changes occurring in the electronic structure of digitally controlled $SrVO_3$ ultra-thin films across the metal-insulator transition (MIT) by control of the film thickness using in situ photoemission spectroscopy was investigated. With decreasing film thickness, a pseudogap is formed at E_F through spectral weight transfer from the coherent part to the incoherent part. The pseudogap finally evolves into an energy gap that is

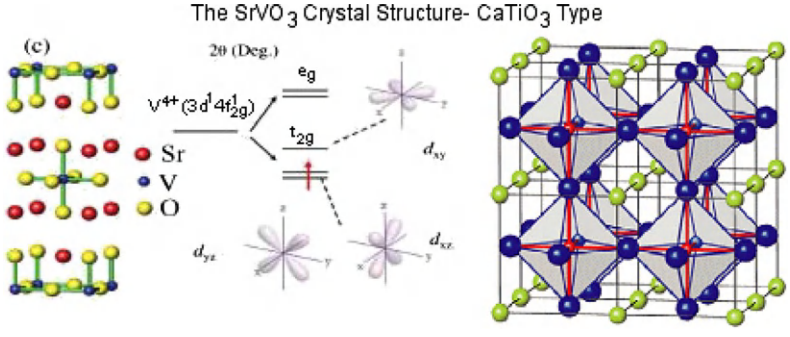

FIGURE 9.22

TABLE 9.12

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	O	O	3	d	4/mm.m	1/2	0	0	1.0
2	Sr	Sr	1	b	m-3m	1/2	1/2	1/2	1.0
3	V	V	1	a	m-3m	0	0	0	1.0

indicative of the MIT in an $SrVO_3$ ultra-thin film. The observed spectral behavior is reproduced by layer dynamical-mean-field-theory calculations, and it indicates that the observed MIT is caused by the reduction in the bandwidth due to the dimensional crossover. LDA + DMFT (local density approximation + dynamical mean field theory) results for the many-body spectra of cubic $SrVO_3$ and orthorhombic $CaVO_3$ were measured. Both systems are found to be strongly correlated metals, but not on the verge of a metal-insulator transition. In spite of the considerably smaller V–O–V bonding angle in $CaVO_3$, the LDA + DMFT photoemission spectra of the two systems are very similar, their quasi-particle parts being almost identical. The calculated X-ray absorption spectra show more pronounced, albeit still small, differences. This is in contrast to earlier theoretical and experimental conclusions, but in agreement with recent bulk-sensitive photoemission and X-ray absorption experiments.

Physical properties of the MVO_3 (M = Sr and Ca) perovskite systems and the related compound $Sr_8V_8O_{25}$ have been studied by electrical resistivity, magnetic susceptibility and NMR measurements. It has been pointed out that the magnetic properties of $SrVO_3$ are almost explained with a free electron model, where the electron–electron correlation seems to be small, and the electron transport is possibly due to the orbital mixing between the d^1 and oxygen $p\pi$.

In another study, the influence of local Coulomb correlations on the surface electronic structure of $SrVO_3$, a strongly-correlated metal in a perovskite structure, is investigated for both the SrO-layer and VO_2-layer-terminated (001) surfaces. The electronic structure within the local density approximation of a semi-infinite surface is determined using the embedded Green-function approach, and the resultant density of states projected on the V t_{2g} orbitals is used as an input to a subsequent many-body calculation within the DMFT and the multi-orbital quantum Monte Carlo technique. Qualitatively, the present study confirms the conclusion of recent photoemission experiments and tight-binding DMFT calculations which both indicate that the electronic structure at the surface is more strongly correlated than in the bulk. On a quantitative level significant differences are obtained as a function of orbital polarization at the surface, surface layer relaxation, and SrO vs VO_2 surface termination.

The Mott–Hubbard series $SrVO_3$–$CaVO_3$–$LaVO_3$–YVO_3 present a distinct metal-insulator transition. The microscopic origin of this transition can be related to the correlation effects in the electronic structure. The valence band photoemission results show very interesting trends across these Mott–Hubbard series. These results suggest that the O 2*p* states play an important role in the Mott–Hubbard transition. Some of the changes in the spectra are unexpected and cannot be explained by the current Mott–Hubbard theories as shown in Fig. 9.23.

Another compound containing the V^{4+} ion, $Sr_3V_2O_7$, has the structure as shown in Fig. 9.24.

The cell parameters are: $a = b = 3.8399$ Å, $c = 10.4765$ Å, $\alpha = \beta = 100.56°$, $c = 90°$, cell volume = 149.20 Å^3, $Z = 2$. Cell occupancy is shown in Table 9.13.

Synthesis, electrical, and magnetic properties of a layered perovskite-related compound, $Sr_3V_2O_7$, has been reported. Powder XRD analysis confirmed the body-centered tetragonal ($I4/mmm$) structure as proposed earlier. The electrical resistivity of the sample is 0.054 Ω cm at room temperature and decreases with temperature down to 15 K, with T^2 dependence in the range 15–150 K. The temperature-dependent magnetic susceptibility shows a small cusp at 110 K. Spin-glass-like behavior is observed in the temperature range 5–26 K as evidenced by irreversibility of the zero-field-cooled and field-cooled magnetization curves. The spin-glass dynamics of the sample was confirmed via the measurement of the AC susceptibility. The observed electrical and magnetic properties suggest disorder-induced localization of the defects at low temperatures. Two types of metal-insulator transitions in $Sr_3V_2O_7$ have been observed. A transition from the metallic state to the insulating state took place by substituting Cr for V, and this transition was interpreted as the result of the band splitting from the XPS data. The other transition occurred when the oxygen content was decreased in $Sr_3V_2O_{7-\delta}$, and the insulator exhibits variable range hopping conduction and spin freezing properties, which denotes that this transition is considered as the disorder-induced Anderson localization. The electrical and magnetic properties of the $Sr_3V_2O_{7-\delta}$ system have been studied in detail. Electrical resistivity changes from metallic to semiconducting with decreasing oxygen content. Transport is governed by variable-range hopping of the electrons since the resistivity obeys the $\exp(AT^{-1/4})$ law at low temperature. Oxygen-deficient $Sr_3V_2O_{7-\delta}$ exhibits different temperature magnetic susceptibility curves for zero-field-cooled and field-cooled measurements below about 15 K. A measurement of the field dependence of the magnetic susceptibility and the long-time relaxation of thermo-remanent magnetization, which obeys the relationship $M_{TRM} = At^{-\alpha}$. The magnetic properties in the $Sr_3V_2O_7$-d system was therefore interpreted to be spin-glass-like caused by the localized V spins introduced by the disorder-induced localization.

The presence of intergrowths in the $Sr_3V_2O_7$ compound has been elucidated by means of high resolution transmission electron microscopy (HRTEM) and several types of atomic stacking sequence of the intergrowths, i.e. a stacking irregularity along the *c* direction of $Sr_3V_2O_7$, have been clarified. The intergrowths were composed of the $Sr_4V_3O_{10}$ phase, i.e. one of the related compounds $Sr_{n+1}V_nO_{3n+1}$. The presence of such intergrowths are considered to be produced by matrix compositional fluctuations.

The layered perovskite compound, $Sr_3V_2O_{7.01}$, was synthesized by heating mixtures of the constituent oxides at 1110 °C in flowing hydrogen atmosphere. Rietveld analysis based on powder XRD data shows that the compound has a tetragonal structure ($I4/mmm$). The resistivity of the compound is 4.8 mΩ cm at room temperature (300 K) and decreases with decreasing temperature down to 2 K. The magnetic susceptibility can be represented by a summation of temperature-independent and Curie–Weiss terms. The effective number of Bohr magnetons per vanadium atom is 0.37, which is considerably smaller than the free-ion value of 1.73 for V^{4+}.

The V^{4+} containing compound, Sr_2VO_4, shows a temperature-dependent DC susceptibility. Powder XRD on a pure tetragonal sample of Sr_2VO_4 shows an AFM orbital-ordering transition at $T_{OO} = 97$ K, in which the occupied orbitals lie along the *c* axis. The unusual broadening of the X-ray Bragg peaks throughout the orbital-ordering transition temperature region indicates that this process occurs in stages, and the onset of short-range orbital ordering occurs at $T_1 \approx 122$ K. The study of the order parameter associated with this transition by analyzing the spontaneous strain results in a critical exponent $\beta = 0.35$ consistent with 3D Heisenberg behavior. These results experimentally confirm the orbital-ordering state in Sr_2VO_4 predicted by first-principles calculations using combinations of the local-density approximation and the *GW* method.

A sample $Sr_4V_2O_9$ was first prepared by solid-state reaction in air of the appropriate mixture of $SrCO_3$ and

V_2O_5 at 1073 K (800 °C) for 60 h. Polycrystalline Sr_2VO_4 compound was made by reduction of $Sr_4V_2O_9$ under a H_2 flow at 1323 K for 100 h, with several grindings of the sample. The resulting compound contains V^{4+} ions. It has the structure shown in Fig. 9.25 as follows:

Temperature-dependent dc susceptibility and powder XRD on a pure tetragonal sample of Sr_2VO_4 show an antiferromagnetic orbital-ordering transition at $T_\infty = 97$ K, in which the occupied orbitals lie along the c axis. The unusual broadening of the X-ray Bragg peaks throughout the orbital ordering transition temperature region indicates that this process occurs in stages, and the onset of short-range orbital ordering occurs at $T_1 = 122$ K.

Strontium Vanadite, or Sr_2VO_4, is an interesting compound in the family of layered perovskites. A perovskite is a class of materials which generally form in a cubic structure and in most often contain oxygen as a major chemical component. Perovskite materials exhibit lot of interesting and intriguing properties both from theoretical point of view as well as in its applications. Some of these are colossal magnetoresistance, charge ordering, spin dependent transport, interplay of structural, as well as magnetic and transport properties. These compounds are used as catalyst electrodes in certain types of fuel cells and are candidates for memory devices and spintronics applications. In this specific case however, Sr_2VO_4 is of interest because it is similar to La_2CuO_4, i.e.lanthanum cuprate. La_2CuO_4 is a parent compound to high T_c superconductors, and has many correlations with Sr_2VO_4. Both have spin $= 1/2$ layered magnetic atoms, but the La_2CuO_4 case orders antiferromagnetically. Sr_2VO_4 on the other hand, has an unusual orbital ordering. This strange electronic state is not well understood and may be related to the superconductivity in the parent compound.

Neutron powder diffraction experiments were performed for SrV_3O_7, which is characterized by the 1/4 depleted $V^{4+}(S = 1/2)$ square lattice model. An AFM 3D long-range order was observed below $T_N = 34.3$ K. The 'Stripe Order' spin structure, which is not expected from a classical Heisenberg model, is realized. This spin structure is the same as found in CaV_3O_7, but the spin direction here is parallel to the a(stacking)-axis, instead of the c-axis for CaV_3O_7 as shown in Fig. 9.26.

In addition to the four compounds listed above, a mixed valence compound of strontium vanadate has been found. The compound $Sr_2V_3O_9$ contains three kinds of vanadium ions in the unit cell. Two of them are nonmagnetic V^{5+} ions located in VO_4 tetrahedra, and the rest is V^{4+} ions with $S = 1/2$ located in VO_6 octahedra. The VO_6 octahedra are connected with each other by sharing oxygen at the corner along the [101] direction, as shown in the following Fig. 9.27.

The magnetic properties of these mixed valence-state vanadium compounds have been intensely studied. If $Sr_2V_2O_7$ is fired with VO_2, a new compound is obtained:

$$Sr_2V_2O_7 + 5V_2O_3 \Rightarrow 2\,SrV_6O_{11}$$

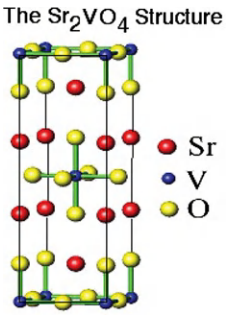

FIGURE 9.25

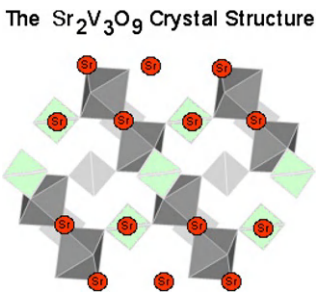

FIGURE 9.27

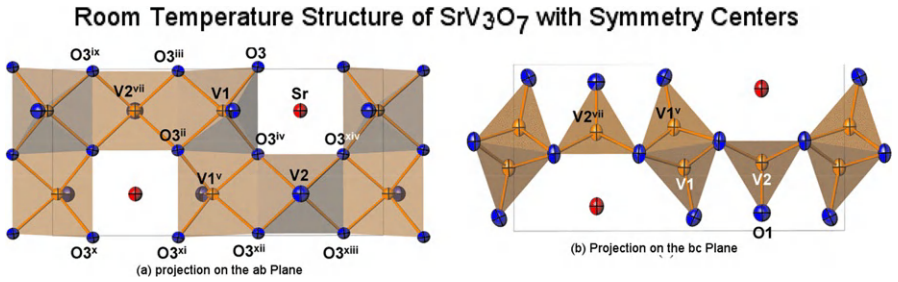

FIGURE 9.26

Single crystals and polycrystals of this compound were synthesized by a solid-state reaction. Four-circle X-ray structural analysis discovered a structural transition at a temperature range between room temperature and 353 K. This transition corresponds to that of NaV_6O_{11} at 245 K. Specific heat measurement of SrV_6O_{11} was performed between 20 and 150 K and two anomalies were observed at 42 and 73 K. These anomalies are consistent with the two peaks in the temperature dependence of magnetization. Below 42 K, SrV_6O_{11} shows metamagnetism and its critical field is about 4 T at 5 K. Its basic magnetic structure at 73 K is considered to be an AFM state formed by the localized electron system.

The *ac*-plane with the magnetic network is weakly stacked along the *b*-axis. The magnetic properties are understood in terms of the $S = 1/2$ 1D-AF chain model with the exchange interaction between the nearest spins, $J = 82$ K, estimated from the susceptibility measurements. However, it has been suggested from ESR measurements and a theory by Koo and Whangbo that the spin-chain direction is not the [101] direction but the [101] direction, along which VO_6 octahedra are connected via a VO_4 tetrahedron. Note that V^{5+} ions and V^{4+} ions are located in VO_4 tetrahedra and VO_6 octahedra, respectively.

The V^{5+}-containing $SrO–V_2O_5$ boundary system contains 4 compounds at SrO to V_2O_5 molar ratios of 4:1, 3:1, 2:1, and 1:1. A fifth compound with a molar composition of 10:3 with the apatite crystal structure was also found. The phase diagram is shown as follows in Fig. 9.28.

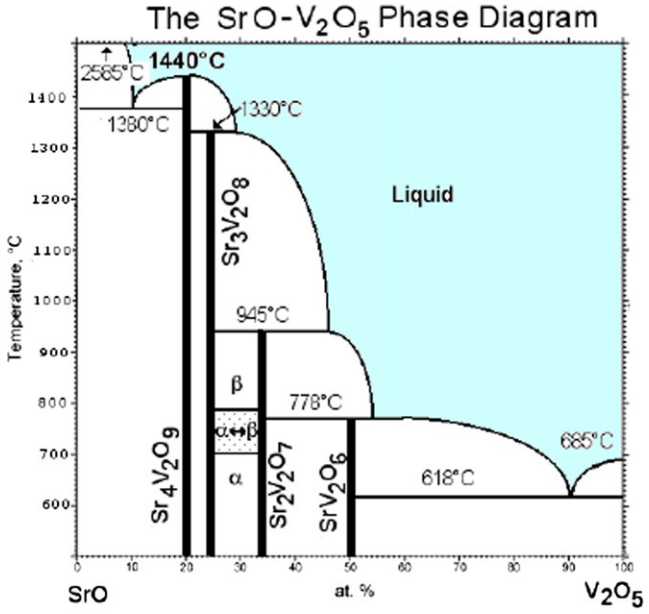

FIGURE 9.28

The phase evolution and properties of the **strontium orthovanadate**, $Sr_3V_2O_8$, were investigated using different methods of preparation: solid-state reaction and two wet-route techniques (colloidal route and sol-gel method-polymerized complex route). DTA/TG study showed decomposition temperatures of starting materials and helped to choose processing temperatures. XRD analysis was used to determine phase evolution. Solid-state reaction sample contained a small amount of $Sr_3V_2O_8$ as soon as after the first calcinations, but 100% of $Sr_3V_2O_8$ did not appear until whole procedure was finished. The colloidal route turned out as an inconvenient method for preparation of pure phase. The final colloidal route sample contained 80% of $Sr_3V_2O_8$, and the residual volume corresponded to $Sr_{10}V_6O_{25}$, which is related to apatite. The most progressive phase evolution was detected in the sol-gel route. Raman and FTIR spectroscopy detected evolution of the first amount of $Sr_3V_2O_8$ after gel heating at 250 °C for 2 h. The pure strontium orthovanadate was prepared after heating at 800 °C for 2 h. The structure is identical to its calcium isomorph as shown in Fig. 9.29.

Cell parameters are: $a = b = 5.619$ Å, $c = 7.4441$ Å, $\alpha = \beta = 67.83°$, $\gamma = 60.0°$, cell volume = 1832.05 Å^3.

Cell occupancy is shown in Table 9.14.

The **pyrovanadate**, $Sr_2V_2O_7$, has the same structure as its calcium homolog as shown in Fig. 9.30.

Cell parameters are: $a = 7.051$ Å, $b = 7.099$ Å, $c = 12.983$ Å, $\alpha = 99.97°$, $\beta = 96.77°$, $\gamma = 90.89°$, cell volume = 636.45 Å^3.

This compound is dimorphic. Single crystals of the high-temperature phase of strontium pyrovanadate, α-$Sr_2V_2O_7$, were grown from a melt. The structure can be described as the packing of four $Sr_2V_2O_7$ layers that are approximately normal to the *b* axis or as the stacking of two zigzag chains. Two different types of $(V_2O_7)^{4-}$ anions are present. Three reported X-ray powder

5	Sr1	Sr	3	a	-3m	0	0	0	1.0

patterns are indexed with the cell parameters from this work. The α to β polymorphic transition temperature is about 645 °C. β-$Sr_2V_2O_7$ is tetragonal, space group $P4_1$ with eight formula units per unit cell and $a = 7.055$ Å, $c = 25.64$ Å. The compound is isomorphous with β-$Ca_2P_2O_7$. The structure was determined from three-dimensional data collected on an automatic diffractometer with both Cu$K\alpha$ and Mo$K\alpha$ radiation. It was solved by comparing a Patterson section with a difference Fourier map. The phases for the latter were calculated from the Ca and P coordinates of β-$Ca_2P_2O_7$. The oxygen atoms were subsequently located from successive difference Fourier maps, and the structure was refined by full-matrix least squares with isotropic temperature factors. The two different sets of data were refined separately, and the final *R* is 0.058 and 0.046 for data using Cu and Mo radiation, respectively. The compound has the dichromate-type structure with nearly eclipsed V_2O_7 groups. The bond distances for the two independent pyrovanadate anions are separable into two sets: the bridging bonds whose lengths are 1.81 Å and the non-bridging bonds whose lengths range between 1.63–1.77 Å. The bond angles are 123°. The coordination number of strontium ranges from 7 to 9.

The formation process and microwave dielectric properties of the $R_2V_2O_7$ (R = Ba, Sr, and Ca) ceramics were investigated. Transient RV_2O_6 phases, which were formed at 300 °C similar to 500 °C by the reaction of RCO_3 and V_2O_5, interacted with remnant RCO_3 to form the homogeneous triclinic $R_2V_2O_7$ phases at 600 °C –700 °C . The $Sr_2V_2O_7$ and $Ca_2V_2O_7$ ceramics sintered at 1000 °C and 950 °C, respectively, for 10 h showed a dense microstructure with the microwave dielectric properties of $\varepsilon_r = 10.4$–12.1, $Q \times f = 15{,}200$–19,520 GHz, and $\tau_f = -30.9$–34.8 ppm/°C. However, the $Ba_2V_2O_7$ ceramic was well sintered at 900 °C for 10 h and it showed good microwave dielectric properties of $\varepsilon_r = 10.1$, $Q \times f = 51{,}630$ GHz, and $\tau_f = -26.5$ ppm/°C.

The addition of Li_2CO_3 to $Sr_2V_2O_7$ ceramics decreased their sintering temperature and time. A dense microstructure was developed for the specimens sintered at 750°–850 °C due to the melting of Li_2CO_3 during the sintering. For the specimens sintered at 800 °C, the grain size was considerably increased when the Li_2CO_3 content exceeded 1.0 mol%. The $Q \times f$ value was increased by the Li_2CO_3 addition due to the increased density and grain size. In particular, a high $Q \times f$ value of 73,800 GHz with ε_r and τ_f values of 9.94 and −28.8 ppm/°C, respectively, was obtained for the specimen containing 3.0 mol% Li_2CO_3 sintered at 800 °C for 2 h.

The compound, **tetrastrontium vanadate**, $Sr_4V_2O_9$, has not been studied thoroughly due, in part, to the tendency of the compound to vaporize or possibly to decompose above its optimal temperature of preparation. There is quite a series of alkaline-earth compounds having the same general formula as tetracalcium vanadate. The phosphate, $4CaO \cdot P_2O_5$, and tetracalcium arsenate, $4CaO \cdot As_2O_5$, are not well known. The preparation of these and the compounds $4CaO \cdot V_2O_5$, $4SrO \cdot P_2O_5$, $4SrO \cdot As_2O_5$, $4BaO \cdot V_2O_5$, and $4BaO \cdot As_2O_5$ by thermal synthesis has been described. Being metastable at room temperature, most of these compounds must be quenched. X-ray powder diagrams show that all these compounds are isostructural and the dimensions of their orthorhombic unit cells have been tabulated.

The **metavanadate**, SrV_2O_6, has a structure similar to the calcium analog. Cell parameters are: $a = 7.656$ Å, $b = 8.26$ Å, $c = 12.297$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 777.46 Å^3 as shown in Fig. 9.31.

The structure involves VO_4 octahedra that are connected with each other along the [101] direction by

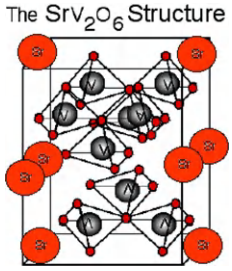

FIGURE 9.31

sharing oxygen at the corner and are also connected via a VO_4 tetrahedron along the [101] direction.

In the V^{6+} system of SrO–VO_3, the compound, $Sr_2VO_{5-\delta}$ has been synthesized. The effects of the oxygen deficiency on the electrical and magnetic properties of $Sr_2VO_{4-\delta}$ were investigated. Single-phase samples of polycrystalline $Sr_2VO_{5-\delta}$ with $\delta = 0.18$, 0.29 and 0.38 were synthesized by the solid-state reaction in flowing hydrogen atmosphere. The crystal structure was determined by Rietveld analysis of XRD data. All the samples were tetragonal at 298 K. With increase of δ, the lattice constant 'a' decreased and the lattice constant 'c' increased. Electrical resistivity measurements showed that all the samples were semiconductive with resistivity of about 1 Ω cm at 298 K. Magnetic measurements showed that the magnetic properties of $Sr_2VO_{5-\delta}$ system were strongly dependent on the oxygen deficiency δ. It was suggested that the non oxygen-deficient compound Sr_2VO_5 ($\delta = 0$) had no magnetic long-range order. As δ was increased, spin-glass-like behavior became evident at low temperatures and was overlapped by a long-range magnetic order with a transition temperature of 35 K for $\delta = 0.2$. It was suggested that the long-range magnetic order was a canted antiferromagnetism with a small net magnetization.

Strontium vanadates are offered commercially in small quantities for research purposes. No Industry uses have yet emerged.

9.1.5. Barium Vanadium Compounds

The metal, Ba^0, does not form any intermetallic compounds with V^0. Like the other alkaline earths, barium forms a number of compounds with vanadium. However, these are limited to the oxo-vanadate types of compounds since intermetallic compounds of Ba^0 and V^0 do not exist.

In the V^{2+} system of BaO–VO, no compounds like $BaVO_2$, Ba_2VO_3 or BaV_2O_3 have been reported.

In the V^{3+} system of BaO–V_2O_3, in contrast to the other alkaline earth MV_2O_4 compounds, Ba does not form BaV_2O_4 when the oxides are heated together in a reducing atmosphere. Apparently, the radius of Ba^{2+} is too large to accommodate it in a perovskite lattice. No other BaO–V_2O_3 compounds have been reported in the current literature.

In the V^{4+} system of BaO–VO_2, the vanadite compound, $BaVO_3$, has been studied. A 5-layer mixed valence oxide, $BaVO_{2.8}$, has been synthesized by reducing $Ba_2V_2O_7$ in high-purity hydrogen gas at 1350 °C. $BaVO_{2.9}$ has been obtained by room temperature oxidation of $BaVO_{2.8}$ in air and $BaVO_{3.0}$ obtained by annealing $BaVO_{2.8}$ or $BaVO_{2.9}$ at 200 °C in air. The structures of this series of novel compounds have been refined by the Rietveld method using ND and XRD data. Magnetic and electrical properties were examined down to 5 K. All three compounds crystallize in the hexagonal system, space group $P\bar{3}m1$ and $Z = 5$. Lattice parameters (Å) derived from Si-calibrated Guinier XRD data are: $BaVO_{2.8}$, $a = 5.7800(2)$, $c = 11.8969(6)$; $BaVO_{2.9}$, $a = 5.7215(5)$, $c = 11.685(2)$; and $BaVO_{3.0}$, $a = 5.6650(3)$, $c = 11.4629(6)$. The $BaVO_{2.8}$ structure consists of face-sharing VO_6^{8-} and VO_6^{9-} octahedra that form VO_{12}^{14-} trimers and of VO_4^{4-} tetrahedra that share corners with the trimers. The $BaVO_{2.9}$ and $BaVO_{3.0}$ structures are similar to $BaVO_{2.8}$, except that the VO_4^{4-} tetrahedra in the latter are replaced by VO_6 octahedra in the former compounds. The previously reported 24R $Ba_8V_7O_{22}$ was found to be an intergrowth product of 5H $BaVO_{2.8}$ ($Ba_5V_5O_{14}$) and 9R $Ba_3V_2O_8$. The hydrogen reduction mechanism of $Ba_2V_2O_7$ is examined and the initial formation of $Ba_3V_2O_8$ in the temperature range 650 to 1200 °C has been proven by ND. The low stability of $BaVO_{2.8}$ is analyzed in terms of stress relief of the face-sharing octahedra and the mobility of the unshared tetrahedron corner oxygen atoms. The electrical conductivity increases dramatically with increasing oxygen content in the $BaVO_{3-\delta}$ series ($\delta = 0.2$, 0.1, and 0.0). $BaVO_{2.8}$ and $BaVO_{2.9}$ are semiconductors with room temperature resistivities of about 30 and 0.14 Ω cm, respectively. $BaVO_{3.0}$ is metallic with a room temperature resistivity of 0.013 Ω cm. The magnetic susceptibility of $BaVO_{2.8}$ shows a broad maximum at about 20 K, indicative of short-range order. The susceptibility of $BaVO_{2.9}$ has both temperature-independent and Curie–Weiss type paramagnetic contributions, and $BaVO_{3.0}$ primarily exhibits Pauli paramagnetism.

A comparison of the alkaline earth vanadites was presented. AVO_3 ($A = Ba^{2+}$, Sr^{2+}, La^{3+}, Gd^{3+}) oxides have been prepared by hydrogen reduction of suitable vanadium(V) ternary oxides. The oxidation state of vanadium in the reduction products seems to be controlled by the nature of other cations. In the presence of strongly basic alkaline-earth metal ions, Ba^{2+} and Sr^{2+} as in $Ba_2V_2O_7$ and $Sr_2V_2O_7$, vanadium is reduced to +4 state. But when A is a trivalent lanthanide ion, as in $LnVO_4$ (Ln = La or Gd), the reduction of vanadium proceeds to the +3 state to yield $LnVO_3$ phases. The products have been characterized by XRD. $BaVO_3$ crystallizes in a hexagonal structure related to $Ba_3V_2O_8$ while $SrVO_3$, $LaVO_3$ and $GdVO_3$ crystallize in $GdFeO_3$ type structure. Electrical transport measurements indicate that $BaVO_3$, $LaVO_3$ and $GdVO_3$ are p-type semiconductors while $SrVO_3$ is metallic.

Another V^{4+} containing vanadite, Ba_2VO_4 has been produced. Phase-pure Ba_2VO_4 has been synthesized by hydrogen reduction of a mixture of $Ba_3V_2O_8$ and 20% excess $BaCO_3$ at 1200–1250 °C, and its crystal structure, designated as β-Ba_2VO_4, refined using a combination

of NPD and XRD data. It is monoclinic, space group $P2_1/n$ (no. 14), with $a = 6.0191$ Å, $b = 7.6494$ Å, $c = 10.465$ Å, $\beta = 92.39(1)°$, and $V = 481.4$ Å^3 from Guinier XRD data. β-Ba_2VO_4 is isostructural with β-Ca_2SiO_4. The structure is closely related to β-K_2SO_4 and consists of isolated VO_4^{4-} tetrahedra and loosely bonded Ba(1)O_{10} and Ba(2)O_9 polyhedra. Its magnetic behavior can be approximated as an $S =$ infinite Heisenberg linear chain. The crystal structure and magnetic properties of the β-Ba_2VO_4 are compared with those of the structurally related high-temperature form of Sr_2VO_4 (β-Sr_2VO_4). Reexamination of the crystal structure of the latter discloses that one of the V^{4+} atoms has rare trigonal bipyramidal coordination and that this atom is weakly bonded to a VO_4^{4-} tetrahedron forming a $V_2O_8^{8-}$ dimer. The formation mechanism of β-Ba_2VO_4 and the possible existence of an orthorhombic form isostructural with β-K_2SO_4 are also discussed.

A new spin 1/2-V^{4+} barium oxovanadate BaV_4O_9 was synthesized and studied by means of single-crystal XRD. Its room-temperature structure is monoclinic, space group $P2/c$. The temperature evolution of the crystal structure and thermal expansion tensor of the material between 293 and 100 K was measured and discussed.

The crystal structure at room temperature is shown in the following Fig. 9.32.

A new preparation route has been developed for 5H $BaVO_{2.8}$ using an induction furnace. It was determined that addition of 4% to 8% molar excess of vanadium in the reaction produced a pure material. In a study of $BaVO_{2.8}$ using NPD, peaks due to long-range magnetic order were not detected. The possibilities of either a spin-glass or super-paramagnetic ground state remain. Transport property measurements on BaVO2.8 suggest that two-dimensional variable range hopping is occurring at low temperatures. With oxidation, the dominant carrier type changes from holes ($BaVO_{2.8}$) to electrons ($BaVO_{3.0}$).

A novel vanadium arsenate $BaAsVO_6$ has been synthesized hydrothermally and structurally characterized by single-crystal XRD, IR spectroscopy, and magnetic susceptibility measurements. It crystallizes in the monoclinic system, space group $P21/c$ with unit cell parameters $a = 5.645(1)$ Å, $b = 10.243(1)$ Å, $c = 8.945(1)$ Å, $\beta = 90.60(1)°$, and $Z = 2$. The layered structure is built up from $V_2O_4^{2+}$ units and AsO_4^{3-} anions, the AsO_4^{3-} ligands being coordinated to two $(V_2O_4^{2+})$ units in both, terminal and bridging μ_2−AsO_4^{3-} fashion. The $[VO_2(AsO_4)]^{2-}$ layers are separated by Ba^{2+} cations. The $V_2O_4^{2+}$ unit has no precedence in oxo-vanadium chemistry.

In the V^{5+} containing sub-solidus region of the BaO–V_2O_5 system, the phase diagram has been determined. Previously reported binary phases of $Ba_3V_2O_8$, $Ba_2V_2O_7$, $Ba_3V_4O_{13}$ and BaV_2O_6 have all been confirmed. (Fig. 9.33).

The metavanadate, BaV_2O_6, has been studied. Single crystals of barium metavanadate BaV_2O_6 have been grown in a hydrothermal system of $VO(OH)_2 + Ba(NO_3)_2$ at 280 °C. The heat of formation is −440 kcal/mol. The compound crystallizes in the orthorhombic system, $C222$, $a = 8.482$ (1), $b = 12.610$ (1), $c = 7.916$ (2) Å, $\alpha = \beta = \gamma = 90°$, $Z = 6$. The structure has since been re-investigated and refined to $R/R_w = 0.029/0.041$ using 1458 unique reflections. An identical structure was derived but the atomic positions were greatly improved. The structure consists of chains of vertex-shared VO_4 tetrahedra running along the (120) directions and Ba atoms located interstitially between the chains.

Soluble barium and strontium bromides, when treated with ammonium metavanadate, precipitate barium or strontium as the metavanadate is shown in Fig. 9.34.

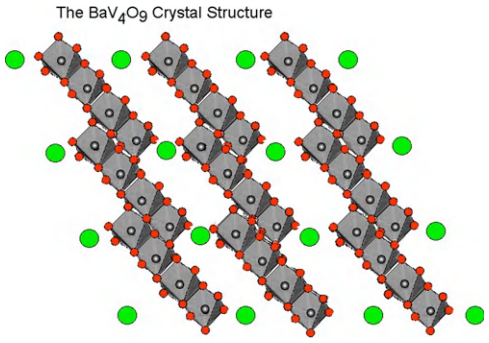

FIGURE 9.32

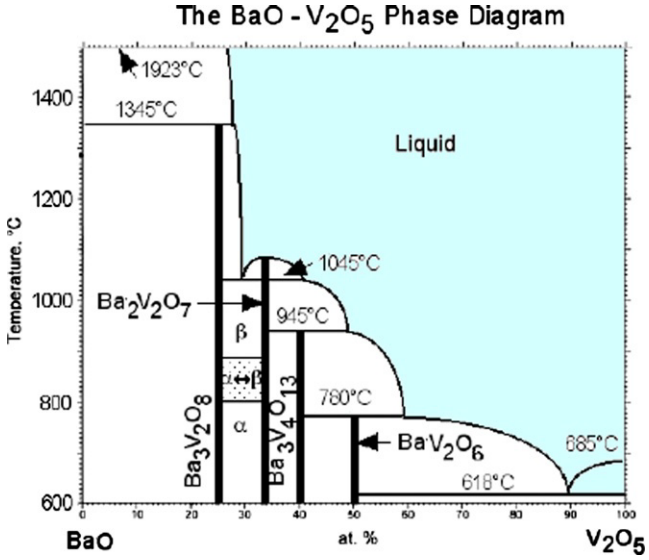

FIGURE 9.33

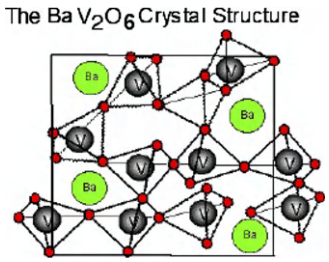

FIGURE 9.34

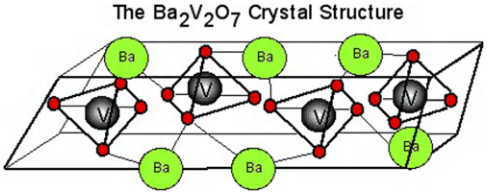

FIGURE 9.35

$Ba(VO_3)_2 \cdot H_2O$ is orthorhombic with $a = 8.997$ Å, $b = 9.728$ Å, $c = 7.409$ Å, $V = 648.7$ Å^3, $Z = 4$. Each V-atom is coordinated by four O atoms to form a tetrahedron. Each atom is connected to the others to form a twisted spiral parallel to the *c*-direction. The Ba atom is coordinated by nine O atoms and one water molecule and the whole is very similar to the diagram given above.

Very little data concerning the metavanadate is available in the literature other than structural data. Most of the research papers are concerned with the pyrovanadate or the orthovanadate. The pyrovanadate, $Ba_2V_2O_7$, has the same structure as the strontium homolog as shown in Fig. 9.35.

$Ba_2V_2O_7$ is triclinic with $a = 13.571$, $b = 7.320$, $c = 7.306$ Å, $\alpha = 90.09(1)$, $\beta = 99.48(1)$, $\gamma = 87.32°$, $V = 715.12$ Å^3, $Z = 4$, and space group *P*1. The crystal structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares analysis to a R_w of 0.034 ($R = 0.034$) using 2484 reflections measured on a Syntex P1 automatic four-circle diffractometer. The structure has two unique divanadate groups that are repeated by the *b* and *c* lattice translations to form sheets of divanadate groups parallel to (100). These sheets are linked by four unique Ba atoms that lie between these sheets. Ba(1) and Ba(3) are coordinated by eight oxygen atoms arranged in a distorted biaugmented triangular prism and a distorted cubic antiprism, respectively. Ba(2) is coordinated by 10 oxygen atoms arranged in a distorted gyro-elongated square dipyramid and Ba(4) is coordinated by nine oxygen atoms arranged in a distorted triaugmented triangular prism. These coordination numbers are substantiated by a bond strength analysis of the structure, and the variation in <Ba–O> distances are compatible with the assigned cation and anion coordination numbers. Both divanadate groups are in the eclipsed configuration with <V–O(br)> bond lengths of 1.821 and 1.824 Å and V–O(br)-V angles of 125.6 and 123.7°, respectively. Examination of the divanadate groups in a series of structures allows certain generalizations to be made. Longer <V–O(br)> (br = bridge) bond lengths are generally associated with smaller V–O(br)–V angles. When V–O(br)–V <140°, the divanadate group is generally in an eclipsed configuration; when V–O(br)–V >140°, the divanadate group is generally in a staggered configuration. Non-tetrahedral cations with large coordination numbers require more oxygen atoms with which they bond, and hence O(br) is more likely to have three coordinates, with the divanadate group in the eclipsed configuration. In the eclipsed configuration, decrease in V–O(br)–V promotes bonding between O(br) and non-tetrahedral cations, and hence smaller non-tetrahedral cations are generally associated with smaller V–O–(br)–V angles.

Li_2CO_3 was added to $Ba_2V_2O_7$ ceramics at various contents up to 20 mol% to decrease their sintering time and temperature. The Li_2CO_3-added $Ba_2V_2O_7$ ceramics sintered at 750 °C for 2 h had a dense microstructure with a high density. A liquid phase, which existed as an amorphous phase after cooling, was formed during the sintering due to the melting of Li_2CO_3 and aided the densification of the specimens. The 6.0 mol% Li_2CO_3-added ceramic sintered at 750 °C showed good microwave dielectric properties of $\varepsilon_r = 10.93$, $Q \times f = 74{,}513$ GHz, and $\tau_f = -19.86$ ppm/°C, indicating that the Li_2CO_3-added $Ba_2V_2O_7$ ceramic is a good candidate material for low-temperature cofired ceramics.

The **orthovanadate**, $Ba_3(VO_4)_2$, has the structure as shown in Fig. 9.36.

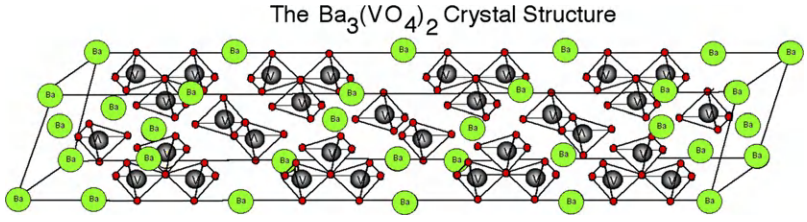

FIGURE 9.36

TABLE 9.15

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy

3	O1	O	6	c	3m	0	0	0.328	1.0
4	V1	V	6	c	3m	0	0	0.4076	1.0
5	Ba1	Ba	3	a	-3m	0	0	0	1.0

Cell parameters are: $a = 5.7842$ Å, $b = 5.7842$ Å, $c = 7.8519$ Å, $\alpha = 68.387°$, $\beta = 68.387°$, $\gamma = 60°$, cell volume $= 205.90$ Å^3. Site occupancy is shown in Table 9.15.

The vanadium is tetrahedrally surrounded by oxygen atoms. There are two kinds of barium atoms, one with distorted octahedral coordination, and the other with 10-fold coordination. Pairs of three barium atoms, Ba(2), Ba(1), Ba(2), share a common triangular face of their respective coordination polyhedra; these three thus form a connected linear cluster. There are two kinds of oxygen atoms; one has two-fold linear coordination, the other, five-fold trigonal-dipyramidal coordination. Pauling's electrostatic-valence rule is perfectly satisfied but some of the bond strengths are unexpected.

The pressure-induced transitions and structural changes in isostructural strontium and barium orthovanadates, $Sr_3(VO_4)_2$ and $Ba_3(VO_4)_2$, via Raman spectroscopy (RS) has been studied. The spectral changes in $Ba_3(VO_4)_2$ can be interpreted as being due to condensation of VO_4^{3-} units into edge- or corner-shared octahedra with little or no hysteresis on decompression. For $Sr_3(VO_4)_2$, there is a pressure-induced first-order phase change at about 150 kbar, with large hysteresis on decompression, which can be rationalized as a transition into a spinelloid series of structures, retaining the tetrahedral coordination of the V atoms.

$Ba_3(VO_4)_2$ and $Ba_3(VO_4)_2$:Nd^{3+} crystals were grown successfully by the Czochralski technique. Powder XRD and transmission spectrum of $Ba_3(VO_4)_2$ crystal were measured at room temperature. Spontaneous Raman scattering spectra of $Ba_3(VO_4)_2$ and $SrWO_4$ crystals were presented, and both larger integral Raman scattering cross-section and stronger peak line intensity were observed in $Ba_3(VO_4)_2$ crystal. In addition, polarized absorption spectra of Nd^{3+}:$Ba_3(VO_4)_2$ crystals were measured at room temperature.

A flower-shaped nano-crystalline barium vanadate has been obtained by the composite hydroxide mediated (CHM) method from V_2O_5 and $BaCl_2$ at 200 °C for 13 h. XRD and XPS spectrum of the as-synthesized sample indicate it is hexagonal $Ba_3V_2O_8$ with a small amount of $Ba_3VO_{4.8}$ coexisting. SEM and TEM display that the flower-shaped crystals are composed of nanosheets with thickness of 20 nm. The UV–Visible spectrum shows that the barium vanadate sample has two optical gaps (3.85 eV and 3.12 eV). Photoluminescence spectrum of the barium vanadate flowers exhibits a visible light emission centered at 492 and 525 nm, which might be attributed to VO_4 tetrahedron with T_d symmetry in $Ba_3V_2O_8$.

Ferromagnetic behavior of the barium vanadate nanoflowers has been determined with a saturation magnetization of about 83.50×10^{-3} emu/g, coercivity of 18.89 Oe and remnant magnetization of 4.63×10^{-3} emu/g, which is mainly due to the presence of a non-orthovanadate phase with spin $S = 1/2$.

Reactions of the alkaline earth metal vanadates such as $Ba_2V_2O_7$ and $Ba_3V_2O_8$ with hydrogen and ammonia have been investigated by TG analysis and in a flow reactor. Reactions in ammonia do not lead to the formation of oxynitride phases, in contrast with the formation of $LaVO_{3-x}N_x$ from $LaVO_4$ under similar conditions as shown in Fig. 9.37.

Both hydrogen reduction and ammonia reactions of the $Ba_2V_2O_7$ compounds are dominated by the formation of the corresponding $A_3V_2O_8$ phases. $Ba_3V_2O_8$ and $Sr_3V_2O_8$ do not react easily in ammonia at temperatures below 1000 °C and $Ca_3V_2O_8$ converts to CaO and VN or to CaO, VN and $CaVO_3$. In contrast, reaction with hydrogen at elevated temperatures produces $BaVO_3$. Reduction of $Ba_2V_2O_7$ by hydrogen yields the compounds $Ba_6V_6O_{19}$ and $BaVO_3$. Their x-ray diagrams show relations to the structure of $Ba_3V_2O_8$. Measurements of the density, electrical conductivity and NMR-spectra in comparison to other corresponding compounds result to a coordination number 4 for the vanadium atoms of $BaVO_3$. The structure of $BaVO_3$ differs widely form the perovskite-type. The relation to the $Ba_3V_2O_8$-structure was discussed.

The syntheses and the results of unit-cell determinations of $Ba_3V_4O_{13}$ and the two forms (low- and high-temperature) of $Ba_3P_4O_{13}$ have been presented. $Ba_3V_4O_{13}$ crystallizes in the monoclinic system, space group Cc or $C2/c$ with unit-cell dimensions $a = 16.087$, $b = 8.948$, $c = 10.159$ Å, $\beta = 114.52°$ Low-$Ba_3P_4O_{13}$ crystallizes in the triclinic system, space group $P1$ or $P\bar{1}$ with unit-cell dimensions $a = 5.757$, $b = 7.243$, $c = 8.104$ Å, $\alpha = 82.75°$, $\beta = 73.94°$, $\gamma = 70.71°$. Low-$Ba_3V_4O_{13}$

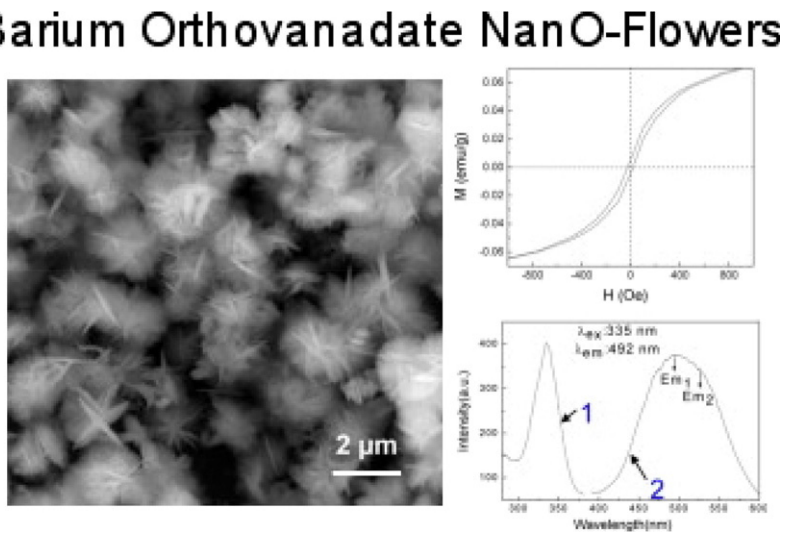

FIGURE 9.37

transforms at 870 °C into high-$Ba_3V_4O_{13}$ which crystallizes in the orthorhombic system, space group *Pbcm* (No. 57) (or *Pbc*2, No. 29) with unit-cell dimensions $a = 7.107$, $b = 13.883$, $c = 19.219$ Å. No relations have been found between the structures of the tribarium tetravanadate and the tribarium tetraphosphate. The compound, $Ba_3V_4O_{13}$ (3:2 $BaO \cdot V_2O_5$) and related compounds, $Ba_5V_5O_{14}$, $Ba_8V_7O_{22}$ have been synthesized. A comparison of their structures is given in the following Fig. 9.38.

Cell parameters are:

$Ba_3V_4O_{13}$-mS80-C2/*m* typex

$a = 8.9418$ Å, $b = 9.2053$ Å, $c = 10.1622$ Å, $\alpha = 111.16°$, $\beta = \gamma = 90°$, $c = 119.06$ Å, cell volume $= 666.94$ Å^3, cell occupancy is shown in Table 9.16.

$Ba_5V_5O_{14}$-hP24-*P*-3m*l* type

$a = b = 5.78$ Å, $c = 11.897$ Å, cell volume $= 344.21$ Å^3, cell occupancy is shown in Table 9.17.

$Ba_8V_7O_{22}$-hR111-*R*-3*m* type

$a = b = 5.784$ Å, $c = 19.316$ Å, $\alpha = \beta = 81.389°$, $\gamma = 60°$, cell volume $= 551.21$ Å^3. Cell occupancy is shown in Table 9.18.

A similar compound, $BaV_{10}O_{15}$ exhibits a first-order structural phase transition in the temperature range 105 K–135 K, depending upon the sample. The variation in transition temperature has been correlated with the variation in the lattice parameters and degree of sample oxidation. Crystal symmetry decreases from *Cmca* in the high-temperature phase, to *Pbca* in the low-temperature phase. Single crystal work has shown a decrease in certain V–V distance, which has been attributed to metal–metal bond formation. A cooperative magnetic transition occurs near 42 K that contains features of both spin glass behavior and long-range magnetic order. NPD has shown that the moment is much lower than the expected value of 2.2 μB. Furthermore, the magnetic entropy released below 70 K is less than 15% of the entropy release expected for this moment value.

In addition to the four compounds shown in the phase diagram, other compositions have been discovered as well. The crystal structure of $Ba_2V_3O_9$ has been determined and refined to final R and R_w values of 0.025 and 0.028 from 1562 independent single crystal reflections. It crystallizes in the space group $P2_1/m$

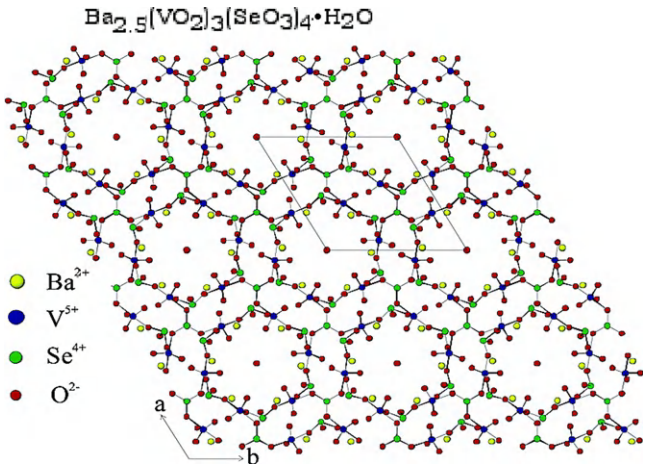

FIGURE 9.39

with $a = 9.302$ Å, $b = 5.969$ Å, $c = 8.118$ Å, and $\beta = 113.96°$. The structure consists of one-dimensional rutile-type chains of edge-sharing VO_6 octahedra parallel to the *b*-axis. The VO_4 tetrahedra share corners with VO_6 octahedra of a single rutile-type chain to form one-dimensional $[V_3O_9]^{4-}_{\infty}$ columns which are held together by Ba^{2+}ions. In this mixed valence compound, V^{4+} and V^{5+} ions are distributed in an ordered way in octahedra and tetrahedra, respectively. In the almost perfect O_6 octahedron, the vanadium atom is off-centered so that it forms a short vanadyl V=O bond of 1.686 Å, typical of a V^{4+} ion. This compound is a barium vanadyl vanadate $Ba_2(VO)(VO_4)_2$. It is the first example of isolated rutile-type chains found with V^{4+} ions. Magnetic susceptibility measurements show that this phase is an anti-ferromagnet with $T_N = 58$ K. At about 20 K. magnetic anisotropy causes a canted spin arrangement.

A novel vanadate, $Ba_{2.5}(VO_2)_3(SeO_3)4 \cdot H_2O$, has been synthesized by hydrothermal methods using $BaCO_3$, $Ba(OH)_2 \cdot H_2O$, V_2O_5, TeO_2, and H_2SeO_3 as reagents. The structure was determined by single-crystal XRD as shown in Fig. 9.39.

$Ba_{2.5}(VO_2)_3(SeO_3)_4 \cdot H_2O$ exhibits a two-dimensional layered structure consisting of VO_5 square pyramids and SeO_3 polyhedra. Infrared spectroscopy (IR) and RS, UV–Vis diffuse reflectance spectroscopy, and thermogravimetric (TG) analysis were also presented. Crystal data: $Ba_{2.5}(VO_2)_3(SeO_3)4 \cdot H_2O$, trigonal, space group *P* (No. 147) with $a = b = 12.8279$ Å, $c = 7.2631$ Å, $V = 1035.1$ Å^3, and $Z = 2$

Barium vanadate is available commercially as the orthovanadate. Its CAS number is 39416-30-3.

9.1.6. Radium Vanadates

Although some radium vanadates could undoubtedly be prepared and studied, no dissertations or papers have appeared in the scientific literature. According to R.T. Lawson (Environmental Science Division, Australian Atomic Energy Commission-1985): "There are no reports on the preparations of **radium vanadate** and no estimates have been reported for the thermodynamic properties of this compound". This is probably due to the high-cost of Ra salts as well as the intense radioactivity of ^{226}Ra itself.

9.2. ALKALINE EARTH NIOBIUM COMPOUNDS

Niobium forms oxides with the oxidation states +5 (Nb_2O_5), +4 (NbO_2), and +3 (Nb_2O_3). The most common state is +5, those of +4 are rare and those of +3 are almost non-existent. The list of alkaline earth niobates is similar to that of the vanadates. The compounds $BeNbO_3$, $CaNbO_3$, $Ca_2Nb_2O_7$, $SrNbO_3$, $BaNbO_2$, $BaNbO_3$ and $BaNb_2O_5$ have been discovered. The trend seems to be related to the size of the alkaline earth cation, zero (0) oxide compounds being formed by beryllium, four (4) definitive compounds by Mg^{2+} and Ca^{2+}, five (5) by Sr^{2+}, and nine (9) by Ba^{2+}. In addition, Nb-metal, Nb^0, forms a series of compounds with Be^0 but none with the other alkaline earths.

Niobium was originally called "Columbium" by Charles Hatchett (1801) who found a new element in a sample of mineral sent to England from Massachusetts in 1734 by John Winthrop. He named the mineral "Columbite" and the new element after "Columbia", the poetical name for "America". However, his results were subsequently disputed because the "element" that Hatchett separated was actually a mixture of Nb^0 and Ta^0. Heinrich Róse (1846) argued that the oxide from the mineral, originally named "Tantalite", actually contained Nb plus Ta. He therefore renamed the elemental metals after the children of Tantalus who were called "Niobe" and "Pelops". The former name remained but the latter became known as "Tantalum" (who was the ruler of a city in western Phrygia, located in Asia Minor or contemporary Turkey). This confusion arose because of the minimal observed chemical differences between tantalum and niobium. It was not until the early 20th century that niobium was first used commercially in incandescent-lamp filaments. This use quickly became obsolete through the replacement of niobium with tungsten, which has a higher melting point and thus is preferable for use in incandescent lamps. The discovery that niobium improves the strength of steel was made in the 1920s, and this application remains its predominant use today. Currently, a number of uses are emerging for alkaline earth niobates, notably the use of single-crystal calcium pyroniobate, $Ca_2Nb_2O_7$, as a frequency-doubler for high-power

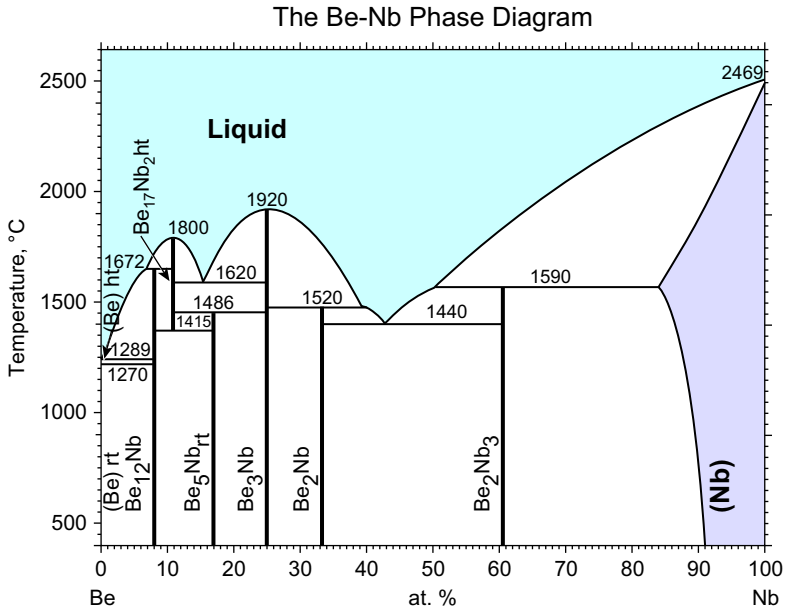

FIGURE 9.40

YAG-lasers. Its response is five (5) times that of KDP (KH_2PO_4) commonly used for second-harmonic generation of 1064 nm (Nd^{3+}) laser beams.

9.2.1. Beryllium Niobium Compounds

Beryllium metal, Be^0, forms a series of intermetallic compounds with Nb^0 as shown in the above phase diagram: Fig. 9.40.

Nearly all of the Be^0–Nb^0 compounds melt peritectically with the exception of Be_3Nb and $Be_{17}Nb_2$ (the latter is stable only between 1415 °C and 1800 °C). These compounds melt congruently. The crystal phase factors are shown in Table 9.19 as follows:

Be_2Nb has the crystal structure as shown in Fig. 9.41.

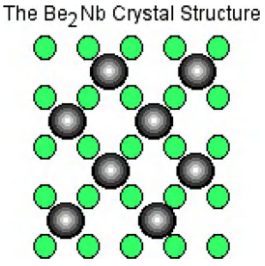

FIGURE 9.41

Here the Be_2Nb arrangement, is repeated in all three directions in the lattice. Cell parameters are: $a = b = c = 4.6259$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 70.01 Å^3, cell occupancy is shown in Table 9.20.

Be_3Nb has the structure shown as follows in Fig. 9.42.

Cell parameters are: $a = b = 4.561$ Å, $c = 7.4945$ Å, $\alpha = \beta = 72.285°$, $\gamma = 60°$, cell volume $= 125.41$ Å^3. Cell occupancy is shown in Table 9.21.

Be_2Nb_3 has the structure as shown in Fig. 9.43.

Cell parameters are: $a = 3.35$ Å, $b = 6.49$ Å, $c = 6.49$ Å, $\alpha = \beta = \gamma = 90°$, cell volume is 141.10 Å^3. Cell occupancy is shown in Table 9.22.

The compound, $Be_{12}Nb$, has the structure shown as follows in Fig. 9.44.

The cubic lattice contains a body-centered cube of Nb-atoms (see below) but there are three (3) inner layers of Be-atoms in the structure.

Cell parameters are: $a = 4.244$ Å, $b = c = 5.6209$ Å, $\alpha = 81.806°$, $\beta = \gamma = 67.52°$, cell volume = 114.68 Å^3.

Cell occupancy is shown in Table 9.23.

Another compound, described as $Be_{0.15}Nb_{0.85}$, has been discovered. In this intermetallic compound, 15% of the sites in a semi-cubic body-centered lattice are occupied by Be atoms while the other 85% are randomly occupied by Nb atoms. The structure is shown in Fig. 9.45.

This compound does not appear in the phase diagram. Cell parameters are: $a = b = c = 2.8484$ Å, $\alpha = \beta = \gamma = 109.471°$, cell volume = 17.79 Å^3. Site occupancy is shown in Table 9.24.

Sputter deposition of Be–Nb alloys at low temperatures (30 °C) produces an amorphous phase for compositions of greater than 5 atom% Nb. A metastable crystalline phase, which can be considered a highly faulted form of the $Be_{12}Nb$ occurs at higher deposition temperatures or by low temperature annealing of the amorphous phase. Because of structural similarities, this metastable phase is a precursor to the formation of either $Be_{12}Nb$ or $Be_{17}Nb_2$ upon high temperature annealing. There was no evidence of the Be_5Nb phase that has been postulated on some phase diagrams.

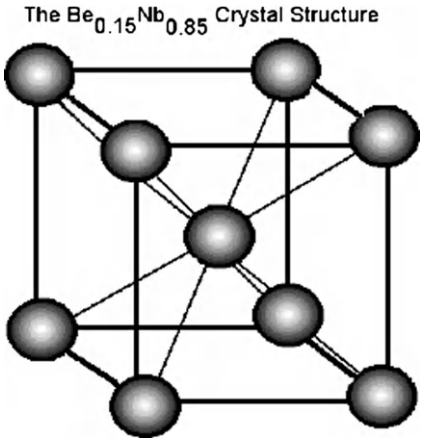

FIGURE 9.45

The system, BeO–Nb_2O_5, does not seem to form any compounds. Reference is made to $BeNb_2O_6$ in one or two papers but no description of its properties has been documented.

No Industrial uses for Be-Nb intermetalic compounds have yet emerged.

9.2.2. Magnesium Niobium Compounds

No intermetallic compounds are formed between Mg^0 and Nb^0 as metals.

In the Nb^{2+} system of MgO–NbO, no compounds like Mg_2NbO_2 have been found.

In the Nb^{3+} system of MgO–Nb_2O_3, no compounds like $MgNb_2O_4$ have been discovered. Nor have the possible compounds like $Mg_2Nb_2O_5$ or $MgNb_2O_7$ been revealed. Thus Nb^{3+} is not a viable valence-state for combination with MgO to form compounds. This behavior may be contrasted to that of MgO and vanadium oxides (which are easily formed).

In the Nb^{4+} system of MgO–NbO_2, the compound, $MgNbO_3$ has not been synthesized. Nor are the possible compounds, Mg_2NbO_4, Mg_3NbO_5, $MgNb_2O_5$, or $MgNb_3O_7$, known to date. Thus, Nb^{3+} is not a viable valence-state for combination with MgO to form compounds. This behavior may be contrasted to that of MgO and vanadium oxides (which readily do so).

In the Nb^{5+} system of MgO–Nb_2O_5, four compounds are thought to exist as shown in Fig. 9.46.

$MgNb_2O_6$ is said to be congruently melting at 1570°C while the compounds (Mg,Nb)$O_{2.42}$, $Mg_5Nb_4O_{15}$ and

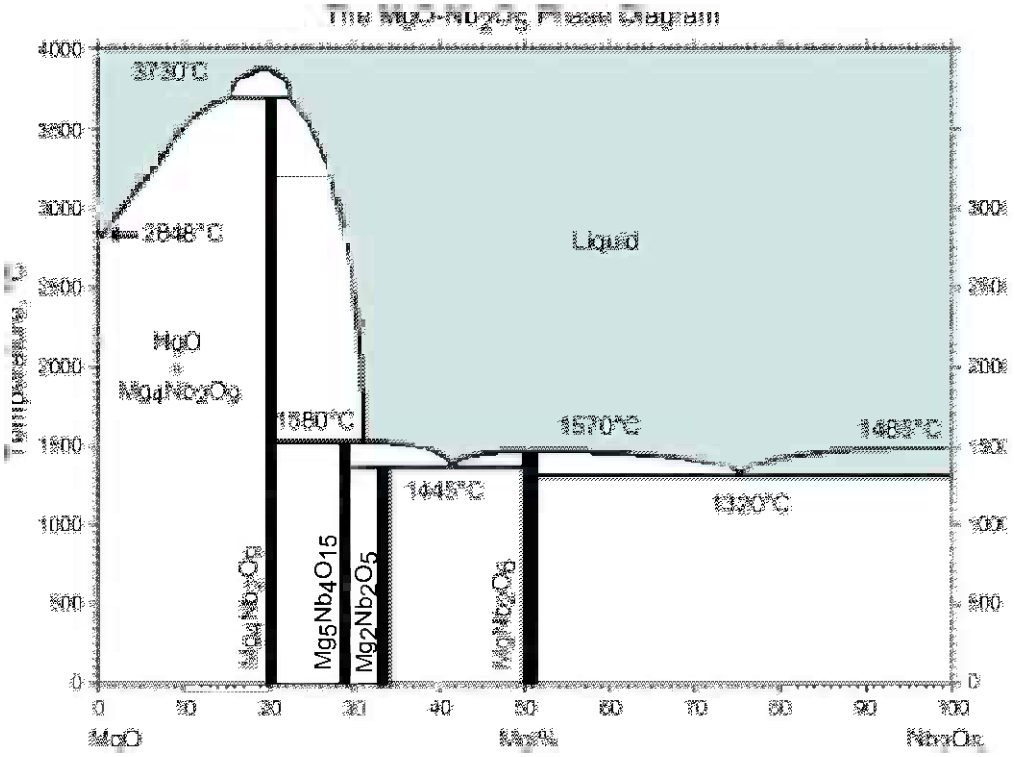

FIGURE 9.46

$Mg_4Nb_2O_9$ decompose peritectically at 1445, 1580 and 3730°C, respectively. Small crystals of all four compounds were grown by the laser-heated pedestal growth (LMPG) method. The Nb_2O_5-rich compounds showed some tendency to partial reduction of Nb^{5+} even when grown in an O_2 atmosphere, resulting in a bluish-black color in the as-grown crystals. In Figure 9.46 (Mg,Nb) $O_{2.42}$ is shown as $Mg_2Nb_2O_{5-\delta}$, where the more likely composition where δ is a small number >2.

The magnesium niobate system (MgO–Nb_2O_5) and its solid solutions have been studied. At least four possible magnesium niobate oxides have been studied: $MgNb_2O_6$, $Mg_4Nb_2O_9$, $Mg_5Nb_4O_{15}$, and $Mg_{0.66}Nb_{0.33}O_{2.9}$. It was reported that $MgNb_2O_6$ and $Mg_4Nb_2O_9$ are the only stable phases that can be found at room temperature. Although magnesium niobate $MgNb_2O_6$ was identified as a potential candidate to be used as a microwave dielectric material, it has not found such usage. However, it has been widely used as a precursor for the synthesis of single-phase relaxor perovskite $Pb(Mg_{0.66}Nb_{0.33}O_3)$ (PMN) since the success of the route, known as the "Columbite method" was proposed. $PbMg_{0.66}Nb_{0.33}O_3$ (PMN) is a relaxor whose dielectric constant can reach 25,000 at high frequencies (100 Hz) and decrease at lower frequencies. Its temperature of maximum dielectric constant (T_m) is −40°C and it loses its spontaneous polarization around −10°C (T_d). With the additions of about 28% of $PbTiO_3$, the T_m shifts to higher temperatures, allowing its use as a piezoelectric at room temperature. In general, production of single-phase $MgNb_2O_6$ is not straightforward, as minor concentrations of the phase $Mg_4Nb_2O_9$ and/or MgO are sometimes formed along side the major phase of $MgNb_2O_6$. The solid-state reaction among constituent oxides of MgO and Nb_2O_5 at an elevated temperature always results in inhomogeneous composition, irregular grain shape, and larger grain size with broad distribution. Moreover, the formation of magnesium niobate phases requires long heat treatment. Use of a niobium ethylate is one way to prepare pure $MgNb_2O_6$ by a sol-gel method:

$$Mg(NO_3)_2 + 2\,Nb(OC_2H_5)_5 \Rightarrow Mg(OC_2H_5)_{10} + 2\,NO_{3^-} + 2\,H^+$$

Addition of citric acid forms the gel, which is heated to 500–800 °C for 3 h to decompose the organic ethylate and form a crystalline $MgNb_2O_6$ compound.

The compounds $MgNb_2O_6$ and $Mg_4Nb_2O_9$ are known to exhibit luminescence in the blue-green region (self-activated). The excitation–emission spectra are shown in Fig. 9.47.

Layers of these compounds were grown by evaporating Nb_2O_5 on the heated surface of a crystal of MgO in order to establish the stability of these compounds. The following Table 9.25 shows typical samples in terms of their deposition temperature and identified phase.

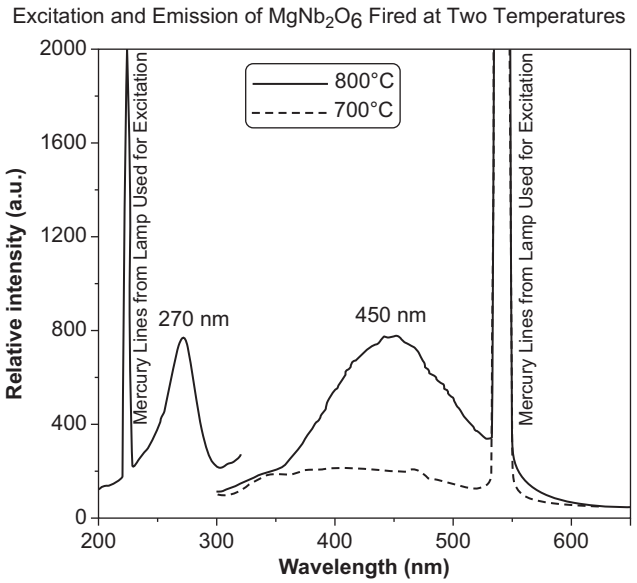

FIGURE 9.47

The reaction begins ~750 °C and both compounds are formed. Above 1050 °C, only $Mg_4Nb_2O_9$ is stable.

The lattice parameters found were:

$Mg_4Nb_2O_9$

$a = b = 5.1624$ Å, $c = 14.024$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$

$MgNb_2O_6$

$a = 5.71$ Å, $b = 14.19$ Å, $c = 5.03$ Å, $\alpha = \beta = \gamma = 90°$

Crystals of $MgNb_2O_6$ have the orthorhombic columbite-type structure. The compound $MgNb_2O_6$ melts congruently at about 1570 °C. $MgNb_2O_6$ has the crystal structure as shown in Fig. 9.48.

The groups are part of the NbO_6 octahedrons, which are distributed in three (3) dimensions in the

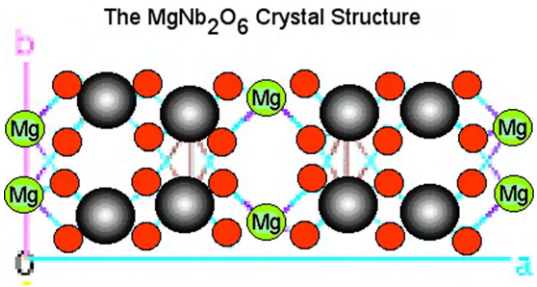

FIGURE 9.48

structure. The Mg^{2+} cations are tetrahedrally coordinated by the oxygen atoms of two (2) octahedra. Cell occupancy is shown in Table 9.26.

Magnesium niobate ($MgNb_2O_6$) powders in orthorhombic form have been successfully prepared via an oxalate synthetic route. Solutions of magnesium chloride hexahydrate and niobium pentachloride were used as the starting materials in the synthesis of $MgNb_2O_6$ powders. The formation mechanism of $MgNb_2O_6$ was clarified by TGA–DTA, FT-IR and XRD. Crystals of $MgNb_2O_6$ may also be grown from a $Na_2Mo_2O_7$ flux by a slow cooling method. The major advantage of this flux method is that crystals grow at a temperature well below the melting point. Another advantage is that well-formed crystals are obtained. The morphology, density and lattice parameters of the resulting crystals were examined. The morphology of the formed powders was examined by (SEM). The following Fig. 9.49 shows the morphology of such crystals as grown from the melt.

It was found that the second phases of MgO, Nb_2O_5 and $Mg_{0.66}Nb_{1.33}O_{2.9}$ tend to form together with $MgNb_2O_6$, depending on calcination conditions. However, single-phase $MgNb_2O_6$ powders consisting

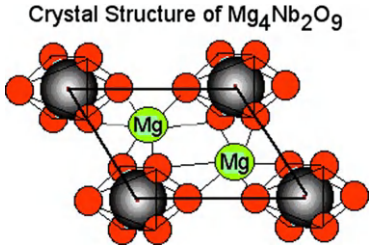

FIGURE 9.50

of nanoparticles ~100–300 nm were successfully obtained for a calcination temperature of 750 °C for 13 h with the introduction of pre-firing (750 °C/2 h) and remixing processes.

$MgNb_2O_6$ single crystals of several cubic centimeters have been grown by the Czochralski technique. The as-grown black crystals were annealed in oxygen at high temperature and became transparent. The process was reversible by high temperature vacuum annealing. The optical absorption observed in as-grown samples has been attributed to oxygen deficiency of the crystal. The grown crystals were resistant against strong mineral acids.

Mainly, two product phases were found in each of the two systems $MgO–Nb_2O_5$ and $MgO–Ta_2O_5$, viz. $Mg_4Nb_2O_9$ and $MgNb_2O_6$, and $Mg_4Ta_2O_9$ and $MgTa_2O_6$ phases, respectively. Details on phase formation and on the $MgNb_2O_6$ and $MgTa_2O_6$ phases have been published. $Mg_4Nb_2O_9$ and $Mg_4Ta_2O_9$ were stated to be hexagonal (space group $P3c1$, No. 165) with the lattice parameters $a = b = 5.1624$ Å and $c = 14.024$ Å for $Mg_4Nb_2O_9$ [JCPDS 38–1459], and $a = b = 5.1611$ Å and $c = 14.0435$ Å for $Mg_4Ta_2O_9$ [JCPDS 38–1458]. The crystal structure of $Mg_4Ta_2O_9$ has a distorted hexagonal close-packed stacking of oxygen ions along the c-axis. It is isotypic with the corundum-type (α-Al_2O_3) structure, with cations occupying two thirds of the octahedral interstices of the oxygen frame. The structure of $Mg_4Nb_2O_9$ is quite similar to that of $Mg_4Ta_2O_9$, with a very small difference in the lattice parameters. Due to this fact, the results obtained on $Mg_4Nb_2O_9$ and $Mg_4Ta_2O_9$ were most similar to each other. Thus the obtained results presented in this paper on the example of either one or the other of the two materials is nearly the same. The structure may be represented as shown in Fig. 9.50.

In another paper, magnesium niobate ($Mg_4Nb_2O_9$) powders have been prepared and characterized by TG–DTA, XRD, SEM and EDX techniques. The effect of calcination temperature, dwell time and heating/cooling rates on phase formation, morphology and chemical composition of the powders were examined. The calcination temperature and dwell time have been found to have a pronounced effect on the phase formation and morphology of the calcined magnesium niobate powders. It has been found that the minor phases of nano-sized MgO inclusion and the columbite-type $MgNb_2O_6$ phase tend to form together with the corundum-type $Mg_4Nb_2O_9$ phase, depending on calcination conditions. It is seen that optimization of calcination conditions can lead to a single-phase $Mg_4Nb_2O_9$ in a hexagonal phase.

Synthesis of $MgTiO_3$ and $Mg_4Nb_2O_9$ phases having an ordered corundum type structure by reacting MgO and TiO_2 or Nb_2O_5 together with the addition of excess MgO has been investigated. When MgO and TiO_2 or Nb_2O_5 are reacted with 1:1 and 4:1 stoichiometry, $MgTiO_3$ and $Mg_4Nb_2O_9$ phases having an ordered corundum type structure are formed. Moreover, a minor amount of $MgTi_2O_5$ and $MgNb_2O_6$ phases are frequently observed along with the ordered corundum type phases. It has been shown that the formation of these additional phases can be suppressed by the addition of stoichiometrically excess of MgO, which can subsequently be removed after the reaction by treating with dilute mineral acid, thus forming pure $MgTiO_3$ and $Mg_4Nb_2O_9$. Another representation of the structure is shown in Fig. 9.51.

Cell occupancy is shown in Table 9.27.

The sintering temperature of $Ba(Mg_{1/3}Nb_{2/3})O_3$ (BMN) ceramic occurs at about 1450 °C. When B_2O_3 was added, BMN sintered at 900 °C and it had a 1:2 ordered hexagonal structure. A liquid phase, which could be responsible for the decrease in sintering temperature, was observed in B_2O_3-added BMN. $Mg_4Nb_2O_9$ and $Ba_2B_2O_5$ second phases were found in

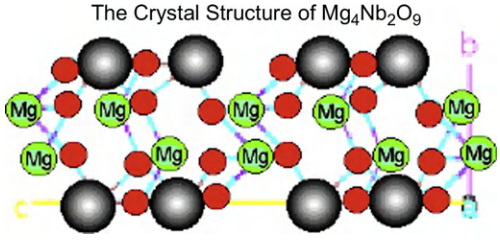

FIGURE 9.51

TABLE 9.27

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	O1	O	12	g	1	0.336	0.308	0.086	1.0
2	O2	O	6	f	.2.	0.276	0	1/4	1.0
3	Mg1	Mg	4	d	3..	1/3	2/3	0.019	1.0
4	Mg2	Mg	4	d	3..	1/3	2/3	0.3034	1.0
5	Nb1	Nb	4	c	3..	0	0	0.1426	1.0

the specimens and the $Ba_2B_2O_5$ second phase might be related to the liquid phase. The dielectric constant (ε_r) and Q value increased with increasing sintering temperature and it is due to the increase in bulk density. However, they decreased with increasing B_2O_3 content, which can be explained by the existence of the second phases. Good microwave dielectric properties of $Q \times f = 8500$ GHz, $\varepsilon_r = 27.5$ and temperature coefficient of resonance frequency $(\tau_f) = 27.0$ ppm/°C were obtained for BMN with 2.0 mol% B_2O_3 sintered at 930 °C for 2 h.

In another study, the columbites $MgNb_2O_6$, $MgTa_2O_6$ and corundum-type $Mg_4Nb_2O_9$ ceramics were prepared by a conventional solid-state ceramic route. The structure and microstructure of the sintered samples were investigated by XRD and SEM techniques. The microwave dielectric properties of the samples were measured by the resonance method in the frequency range 4–6 GHz. The dielectric properties were tailored by forming a solid solution between $MgNb_2O_6$ and $MgTa_2O_6$ and by the substitution of TiO_2 for Nb_2O_5 in both $MgNb_2O_6$ and $Mg_4Nb_2O_9$ ceramics. The $Mg(Nb_{0.7}Ta_{1.3})O_6$ composition has $\varepsilon_r = 29$, $Q_u \times f = 67{,}800$ GHz, and $\tau_f = 0.8$ ppm/°C and the $MgO\{(0.5)Nb_2O_5–(1.5)TiO_2\}$ composition has $\varepsilon_r = 34.5$, $Q_u \times f = 81{,}300$ GHz, and $\tau_f = -2$ ppm/°C.

The binary niobate ceramics, with the formula $M^{2+}Nb_2O_6$ where $M^{2+} = Ca$, Mg, or a transition metal (TM), have the orthorhombic columbite structure. The best-known members of this group are zinc niobate ($ZnNb_2O_6$) and magnesium niobate ($MgNb_2O_6$), but Ca, Co, Ni, Mn, Cu, Cd, and Fe $^{2+}$ cations can also be included in the columbite structure. The TM columbite niobates have been found to sinter at temperatures of 1100 °–1200 °C, much lower than the complex perovskites, and this can be lowered even more when Cu^{2+} is used. The best columbite niobates have $Q \times f$ values similar to those of $BaZn_{0.33}Nb_{0.67}O_3$, and all have ε_r between 17 and 25 and negative τ_f values of <-80 ppm/°C. There is a growing interest in the columbites as microwave dielectric ceramics, due to their lower processing temperatures, less complicated processing due to the simple chemistry of the binary compounds, and the lower cost of niobium compared with tantalum, and with incorporation of Cu^{2+} they are approaching low-temperature co-fired ceramics (LTCC) temperatures. They have also been investigated combined with other dielectric ceramics (to compensate for the negative τ_f values), and with additives to lower sintering for LTCC. Furthermore, $MgNb_2O_6$ is in wide use as a precursor to synthesize single phase PMN ($Pb(Mg_{1/3}Nb_{2/3})O_3$) in the "columbite" process, and $NiNb_2O_6$ is being increasingly investigated as a catalyst for splitting water and organic compounds. $CoNb_2O_6$ and other columbites have interesting magnetic properties, and $CaNb_2O_6$ and $CdNb_2O_6$ have useful optical properties.

In another study, single crystals of a magnesium niobium oxide $Mg_5Nb_4O_{15}$ were prepared at 1673 K (1400 °C). This compound has an orthorhombic pseudo-brookite-type structure (space group *Cmcm*). The single-crystal structure refinement was carried out in the temperature range from 293 to 1173 K. The final *R*-factors were $R = 0.025$–0.038 and $R_w = 0.031$–0.044. The lattice parameters were $a = 3.806$, $b = 10.057$ and $c = 10.260$ Å at 293 K and $a = 3.810$, $b = 10.188$ and $c = 10.398$ Å at 1117 K. The linear thermal expansion coefficients were $ß_a = 1.28 \times 10^{-6}$, $ß_b = 15.8 \times 10^{-6}$ and $ß_c = 16.3 \times 10^{-6}$/K. Thermal expansion anisotropy in the bond distances and angles is consistent with the thermal expansion anisotropy in the lattice parameters. $Mg_5Nb_4O_{15}$ in the $MgO–Nb_2O_5$ system and is stable between 1200°C and its incongruent melting point at 1580°C. In an analyysis of the structure of both compounds with the help of ND, it was determined that the compounds are isostructural with pseudo-brookite Fe_2TiO_5, and the presence of any superstructure could not be noticed. The compounds crystallize with the orthorhombic structure within the space group D_2-*Cmcm* with $Z = 4$. The structure consists of double chains of (Mg, Nb)0_6 units, sharing edges of the plane, interconnected through common oxygen along the *a*-axis to give a three dimensional array. Because of the instability of this compound, no applications in Industry have emerged.

$MgNb_2O_6$ has the CAS number of 12163-26-7 and is available commercially.

9.2.3. Calcium Niobium Compounds

No intermetallic compounds are known in the Ca^0–Nb^0 system.

In the Nb^{2+} system of CaO–NbO, no compounds are known.

In the Nb^{3+} system of CaO–Nb_2O_3, the $CaNb_2O_4$ compound has been synthesized. Single crystals of a new reduced calcium niobium oxide, $CaNb_2O_4$, were prepared in an evacuated quartz tube at 1100 °C. The calcium niobium oxide crystallizes in the orthorhombic space group *Pbcm* with $a = 5.054$ Å, $b = 11.904$ Å, and $c = 5.839$ Å, $Z = 4$, and the final R factors are $R = 0.027$ and $R_w = 0.029$ for 799 unique reflections. The crystal structure has the layer built up by edge-sharing of NbO_6 trigonal prisms to form infinite metal–metal bonding as seen in $ANbO_2$ (A = Li, Na). The Ca^{2+} ion is located at the trigonal prism site in the interlayer. No evidence for superconductivity was found down to 2.0 K.

In the Nb^{4+} system of CaO–NbO_2, electrically conducting ABO_x titanates and niobates of the $A_nB_nO_{3n+2}$ type have been synthesized and investigated with respect to their physical and structural properties. Work was initiated on the $LaTiO_x$, $SrNbO_x$ and $CaNbO_x$ systems (where the value of x was found to be variable and controllable, depending upon the synthesis conditions). $CaNbO_3$ belongs to the perovskite-related title compounds of the $A_nB_nO_{3n+2}$ type but their crystal structures were not well known. They belong to the so-called Ruddlesden–Popper phases $A_{m+1}B_mO_{3m+1}$ series. A large number of compositions can be prepared by varying both the cation molecular ratios and the anion ones as well. The thickness of the layers rises with m. For $m = \infty$, the three-dimensional perovskite structure ABO_3 is realized. It has the structure shown on the next page. The $m = 1$ member is also known as the K_2NiF_4 crystal structure type. The metaniobite, $CaNbO_3$, has the structure as shown in Fig. 9.52.

Cell parameters are: $a = 5.56$ Å, $b = 5.77$ Å, $c = 8.016$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 257.16 Å^3, $Z = 2$. Cell occupancy is shown in Table 9.28.

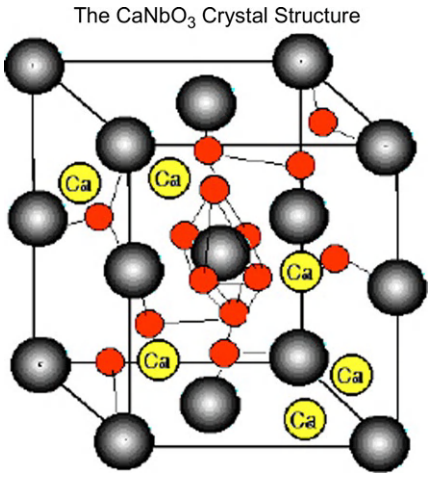

FIGURE 9.52

$CaNbO_x$ system involves a mixed valence Nb^{4+}/Nb^{5+} for $x = 3.5$ and therefore a high electrical conductivity can be expected. The physical properties were not investigated. Among the fully oxidized insulating titanates and niobates there are compounds with remarkable structural and physical properties. Some fully oxidized $n = 4$ type compounds such as $CaNbO_{3.50}$, $SrNbO_{3.50}$ and $LaTiO_{3.50}$ display extraordinary dielectric properties. They are ferroelectric up to extremely high temperatures. Their ferroelectric transition temperatures T_c lie in the range of 1615 K to 1850 K (1342 and 1577 °C). No other ferroelectric materials with such high T_c are known.

Three-dimensional titanium and niobium oxides are superconducting at temperatures considerably lower than layered copper oxides. Single crystals of isostructural niobium oxides, $CaNbO_x$ and $SrNbO_x$ were prepared with the floating zone melting technique. In common with $LaTiO_x$ they have the following properties. For $x \leq 3.4$, its layered perovskite-related structure of a known type is derived from the layered highest-T_c (>1600 K) ferroelectrics, $CaNbO_{3.5}$ and $SrNbO_{3.5}$. In the range $3.42 \leq x \leq 3.50$ well- ordered-intergrowth takes place between the $x = 3.5$ structure and the $x = 3.4$ structure. This intergrowth was found to be representative of the bulk and the stacking sequence is

dependent on x. For x <3.5, magnetic and resistivity measurements were performed between room temperature and 4.2 K. The temperature dependence of the magnetic susceptibility along the layers displays a minimum. Semiconducting behavior was found along the c-axis and perpendicular to the layers. At low temperatures, the resistivity exhibits thermally activated behavior with unexpectedly small activation energies in MeV range. It consists of layers of inter-locking NbO_6 octahedra as shown in Fig. 9.53.

ABO_x niobates and titanates belonging to the homologous series $A_nB_nO_{3n+2}$ are a special group of perovskite-related layered materials. These oxides comprise the highest-T_c ferroelectrics such as $CaNbO_{3.50}$ and $LaTiO_{3.50}$, as well as thermodynamically stable bulk compounds involving well-ordered stacking sequences of layers with different thickness such as $SrNbO_{3.45}$. These belong to the so-called Ruddlesden–Popper phases $A_{m+1}B_mO_{3m+1}$. The thickness of the layers rises with m, for $m = \infty$, the three-dimensional perovskite structure ABO_3 is realized. The $m = 1$ member is also known as the K_2NiF_4 crystal structure type. A crystallographic study on $CaNbO_x$ ($3.4 \leq x \leq 3.5$) was made. This $CaNbO_x$ system involves a mixed valence Nb^{4+}/Nb^{5+} for x <3.5 and therefore a high electrical conductivity was to be expected. However, the physical properties were not investigated.

A related compound, Ca_2NbO_4 is a superconductor. From DC magnetization and powder XRD measurements of the defect-perovskitc-type reduced niobate $Ca_2Nb_{1+x}O_y$, at least two kinds of broad superconducting phases with the critical temperatures of about 9.2 K (for $0 \leq x \leq 1.0$) and 8.3 K (for $1.2–1.5 \leq x \leq 5.0$) were found that covered almost the whole valence state of Nb from Nb^{1+} to Nb^{5+} in the Ca system. The highest shielding effect in this phase is attained for samples prepared from the starting mixtures having the initial mean Nb valence between 1+ and 2+.

In the binary system containing Nb^{5+}, $CaO–Nb_2O_5$ has been shown to include three compounds: $CaO \cdot Nb_2O_5$, which melts congruently at 1560 °C; $2CaO \cdot Nb_2O_5$, which melts congruently at 1576 °C; and $3CaO–Nb_2O_5$, which melts incongruently at 1560 °C. Three eutectic compositions occur at 6% CaO (1362 °C), 23% CaO (1492 °C), and 34% CaO (1535 °C).

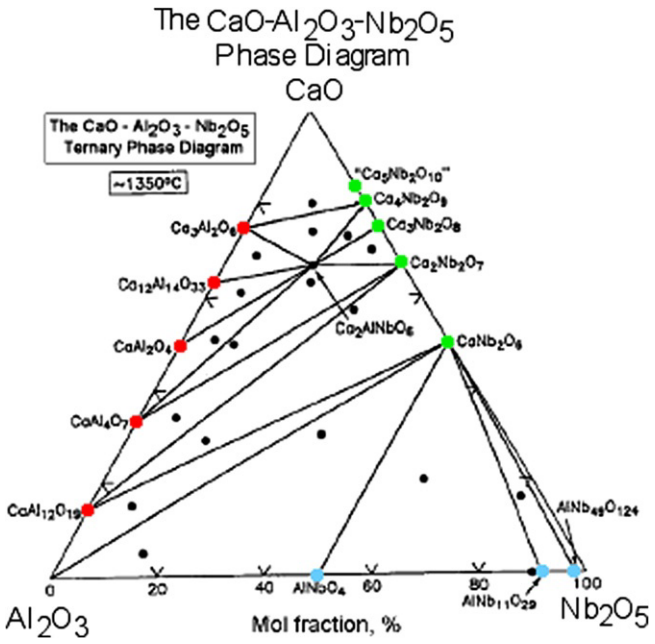

FIGURE 9.54

In addition, $4CaO–Nb_2O_5$ and what was described as "$5CaO–Nb_2O_5$" have been included in a ternary diagram of $CaO–Nb_2O_5$ and Al_2O_3. This is shown as follows in Fig. 9.54.

The binary phase diagram is shown as follows. Note that the compounds formed are based on the molar ratio of x CaO:1.0 Nb_2O_5, where x varies from one (1) to five (5) as shown in Fig. 9.55.

Subsolidus phase equilibria in the $CaO:Al_2O_3:Nb_2O_5$ system at 1325 °C in air have been determined. Only one ternary phase forms, Ca_2AlNbO_6 that exhibits a perovskite-related structure with 1:1 or NaCl-type ordering of Al^{3+} and Nb^{5+} on the B sites. Indexed powder XRD data for this monoclinic compound were given: ($P2_1/n$ (No. 11); $a = 5.3780(1)$, $b = 5.4154(1)$, $c = 7.6248(2)$ Å, $\beta = 89.968(2)°$). The subsystem $CaO–Nb_2O_5$ was reexamined at CaO contents above 70 mol % to clarify inconsistencies in the literature. Two phases were confirmed to form in this region: the polymorphic-ordered perovskite, $Ca_4Nb_2O_9$, with solid solution ranging from approximately 17 to 20.5 mol% Nb_2O_5, and the compound referred to as $Ca_3Nb_2O_8$, which was shown at this time to occur as essentially a point compound at the composition 75.25:24.75 $CaO:Nb_2O_5$.

The perovskite-related structure of the $Ca_3Nb_2O_8$-type phase was shown to be non-cubic. Capacitance methods at 1 MHz were used to determine the dielectric constants and associated temperature coefficients for eleven compounds in the $CaO:Al_2O_3:Nb_2O_5$ system. It was determined that Ca_2AlNbO_6 and $Ca_3Nb_2O_8$ coexist in equilibria and exhibit temperature coefficients of permittivity with opposite signs. Five compositions in

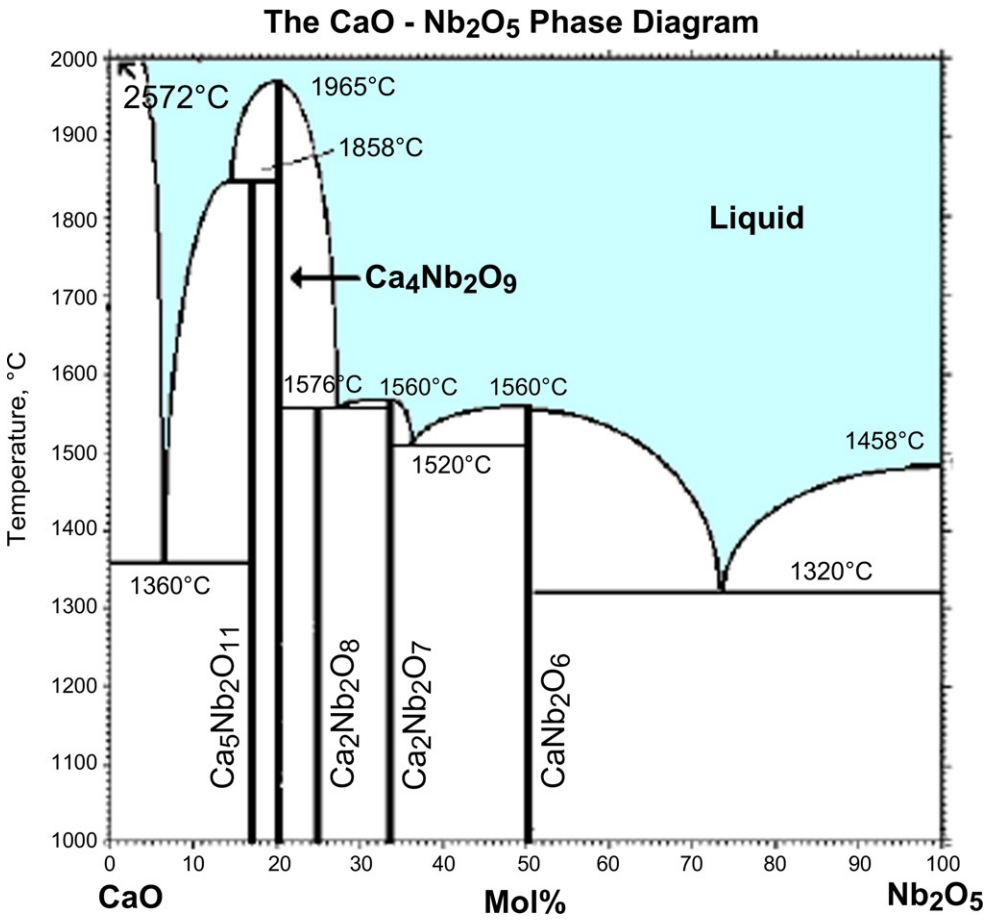

FIGURE 9.55

the $x Ca_2AlNbO_6$:$(1-x)Ca_3Nb_2O_8$ system were prepared and their dielectric properties measured by dielectric resonator methods at 5–7 GHz. The relative permittivities and temperature coefficients of resonant frequency obtained for the end members Ca_2AlNbO_6 and $Ca_3Nb_2O_8$ were 30, −88 ppm/°C, and 45, +113 ppm/°C, respectively. Temperature compensation of the resonant frequency was obtained near $x = 0.67$ with a permittivity of 32; no solid solution was detected by powder XRD.

Liquidus temperatures have been determined in the high-lime part of the system CaO–Nb_2O_5 with the high-temperature hot-stage microscope. The existence of a compound having the composition, $11CaO \cdot 2Nb_2O_5$, and melting congruently at 2105 °C was indicated. The probable existence of a compound with the composition $5CaO \cdot Nb_2O_5$, melting incongruently at 2065°C was announced. Phase relations below 1600°C of compositions near $4CaO \cdot Nb_2O_5$ were interpreted from the results of differential thermal analyses and XRD patterns of samples quenched from various temperatures.

Calcium niobate has the formula of $CaNb_2O_6$ and the structure is shown in Fig. 9.56.

It consists of interconnected niobate octahedrons and the cell constants: $a = 5.219$ Å, $b = 5.752$ Å, $c = 14.96$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 449.09 $Å^3$. Cell occupancy is shown in Table 9.29.

The pyro-niobate, $Ca_2Nb_2O_7$, is trimorphic. A comparison of the three forms is shown in the following diagram: Fig. 9.57.

Cell parameters are:

These structures consist of a series of connected NbO_6 octahedra as partially shown in the above diagram. This arrangement of Ca–Nb–O atoms is identical in the a ⇒ b and a ⇒ c direction in the unit cell. Minus the oxygen-atoms, each face consists of the above arrangement of Ca–Nb atoms, as shown in the following diagram. Only one octahedron is shown in Fig. 9.58.

This structure is the prototype for 441 compounds such as: $Ce_2Zr_2O_7$, $Cd_2Sb_2O_7$, $Ce_2Zr_2O_7$, $Ca_2Os_2O_7$, $La_2Hf_2O_7$, $Mn_2In_2O_7$, $Sr_2Mn_2O_7$, $Sr_2V_2O_7$, $Ce_2Zr_2O_7$, $Ce_2Zr_2O_7$, $Ce_2Zr_2O_7$, $Ce_2Zr_2O_7$, and the like. A complete list is available on NIMS Materials Database (MatNavi).com.

Calcium pyroniobate ($Ca_2Nb_2O_7$) has been discovered as a new nonlinear optical crystal by the Kurtz power method, and the intensity of second harmonic

of a Nd:YAG laser generated by this crystal is 5.2 times that of KDP crystal. Following this discovery, attempts to obtain large $Ca_2Nb_2O_7$ single crystals of improved optical quality have been undertaken. A reasonably good quality crystal of 25 mm diameter and 35 mm length has been grown by the Czochralski method. Its optical transparency range has been measured and found to span from 370 to 5500 nm.

The **tricalcium niobate** compound, $Ca_3Nb_2O_8 = 3CaO–Nb_2O_5$, has been shown to exist in two forms: type I, face-centered cubic with $a = 7.978$ Å, having a superlattice with $a = 23.934$ Å, and type II, orthorhombic (pseudo-tetragonal, distorted cubic) with $a = 11.51$ Å, $b = 11.10$ Å, $c = 15.98$ Å, having a pseudocell with $a = 5.754$ Å, $b = 5.551$ Å, and $c = 7.990$ Å. The perovskite-related phase, $Ca_3Nb_2O_8$, when grown as single crystals from a calcium vanadate flux, incorporates a small amount of vanadium from the flux to form the composition $Ca_3Nb_{2-x}V_xO_8$ with $x = 0.025$. The crystals have pseudo-cubic symmetry with $a = 6a_c$ (perovskite). The actual symmetry is rhombohedral, space group $R3$, with $a_h = 16.910(1)$ Å, $c_h = 41.500(2)$ Å. The structure was solved using a combination of single-crystal methods together with constrained refinements of powder X-ray and neutron powder data. The unit-cell composition is $[Ca_{138}\square_{24}]_A\,[Ca_{42}Nb_{117}V_3]_B[O_{480}\square_6]$, with vacancies (indicated by the boxes in the formula) in both the anion sites and *A*-cation sites. The Ca and Nb atoms are fully ordered in the *B*-sites such that (001) layers containing only Nb-centered octahedra alternate with layers containing both Nb-centered and Ca-centered octahedra. At the origin *B*-site, ordered oxygen vacancies result in the octahedron being transformed to a tetrahedron, which, in the single crystals, is occupied by vanadium. The structure displays a new type of octahedral tilt system in which $3 \times 3 \times 3$ blocks of $(a^+a^+a^+)$ tilts are periodically twinned on the pseudo-cubic $\{100\}_c$ planes.

The tetracalcium niobate, $Ca_4Nb_2O_9$, is polymorphic. Four $Ca_4Nb_2O_9$ polymorphs with perovskite-related $A(B'_{1/3}B'_{2/3})O_3$ structures and different arrangements of *B*-site cations were identified and characterized by powder XRD and TEM. The *B*-cation ordering in three of these phases is combined with $b^-b^-c^+$ octahedral tilting. Two high-temperature forms of $Ca_4Nb_2O_9$ are separated by a displacement phase transition which involves octahedral tilting and occurs between 1500 and 1600 °C. Above this transition, the structure is either disordered or exhibits chemical 1:1 ordering (ordering vector $1/2[111]^*_c$) of Ca and Nb cations on the *B*-sites; the correct structural model has yet to be determined. Below the transition, the structure exhibits 1:1 ordering combined with octahedral tilting. Upon cooling, the 1:1 ordered structure transforms to a metastable P1 triclinic structure with lattice parameters $\sqrt{6}a_c \times \sqrt{2}a_c \times 2\sqrt{2}a_c$, $\alpha \sim \gamma \sim 90°$, $\beta \sim 125°$ (a_c refers to cubic perovskite) and ordering vector $1/4[111]^*_c$. This transformation occurs by reordering of cations on (111) planes.

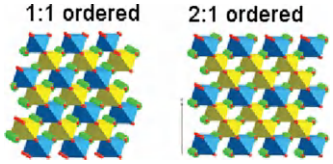

FIGURE 9.59

The metastable P1 structure transforms upon annealing to a stable 2:1 ordered $P2_1/c$ structure with lattice parameters $\sqrt{6}a_c \times \sqrt{2}a_c \times 3\sqrt{2}a_c$, $\beta = 125°$ (ordering vector $1/3[1,1,1]^*_c$). This first-order transition occurs by precipitation and growth of the 2:1 ordered phase, which is stable below 1400 °C.

The related structures are shown as follows. For $Ca_3Nb_2O_9$, the cell parameters are; $a = 5.538$ Å, $b = 9.816$ Å, $c = 14.115$ Å, $\alpha = 91.03°$, $\beta = \gamma = 90°$, cell volume $= 767.18$ Å^3. (Fig. 9.59).

These octahedra are tilted in the disordered phases.

The pentacalcium niobate, $Ca_5Nb_2O_{10}$, has been postulated and the melting temperature has been given (see phase diagram). However, there is no substantiating data in the literature for its actual existence.

Calcium niobates are not offered for sale commercially. No CAS numbers have been assigned.

9.2.4. Strontium Niobium Compounds

No intermetallic compounds of Sr^0 and Nb^0 are known. However, a number of oxide compounds are known.

No compounds are known where niobium has the +2 valence state.

In the Nb^{3+} system of $SrO–Nb_2O_3$, the compound, $SrNb_2O_4$, has never been synthesized. No compounds containing Nb^{3+} have been reported.

In the Nb^{4+} containing system of $SrO–NbO_2$, the compound, $SrNbO_3$, has the perovskite structure shown on the next page. Stoichiometric $SrNbO_3$, with a $GdFeO_3$ type structure, was synthesized between 1300 and 1550 °C in Ar-filled and sealed niobium ampoules. Its crystal structure was refined using time-of-flight ND data. Space group *Pnma*: $a = \sqrt{2}\cdot a_p = 5.6894$ Å; $b = 2\cdot a_p = 8.0684$ Å; $c = \sqrt{2}\cdot a_p = 5.6944$ Å; $R_F^2 = 0.020$; and $R_P = 0.034$. High-resolution electron microscopy (HREM) and ED studies frequently revealed structural defects in $SrNbO_3$. XRD and ED studies showed cubic symmetry for $SrNbO_3$ synthesized below 1300 °C and for compounds with nominal composition $Sr_{0.8}NbO_3$ synthesized between 1200 and 1550 °C. $SrNbO_3$ was found to be temperature independently paramagnetic. No other Nb^{4+} compounds are known. (Fig. 9.60).

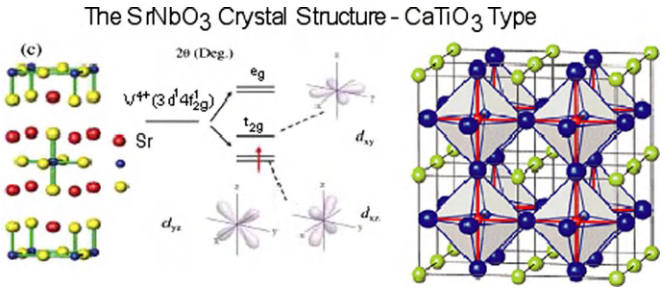

FIGURE 9.60

The Nb^{5+} containing system of $SrO–Nb_2O_5$ forms a number of compounds. The following ternary diagram shows that at least six (6) compounds have been discovered. The binary diagram, based on $SrO–Nb_2O_5$ is also shown as follows on the next page. Of the six (6) compounds displayed only two melt congruently. The 6:1 compound is stable only at high temperatures (>1260 °C) and the 4:1 compound is stable only up to 1260 °C. (Fig. 9.61).

$SrNb_2O_6$ is a potential candidate for ferroelectric and electro-optic applications. It has been prepared at low temperatures from hydroxide precursors.

The simple procedure of mixing commercially purchased strontium hydroxide and niobium (or tantalum) hydroxide thoroughly together and heating at a low temperature (<400 °C) produced pure $SrNb_2O_6$ in a powder form. This is the lowest temperature so far reported for the formation of these phases. The reaction sequence and evolution of the phase formation were investigated by X-ray methods. The phase diagram has the form as shown in Fig. 9.62.

Strontium niobate, $SrNb_2O_6$, has a crystal structure consisting of a series of interconnected NbO_6 octahedra. The structure is shown in Fig. 9.63.

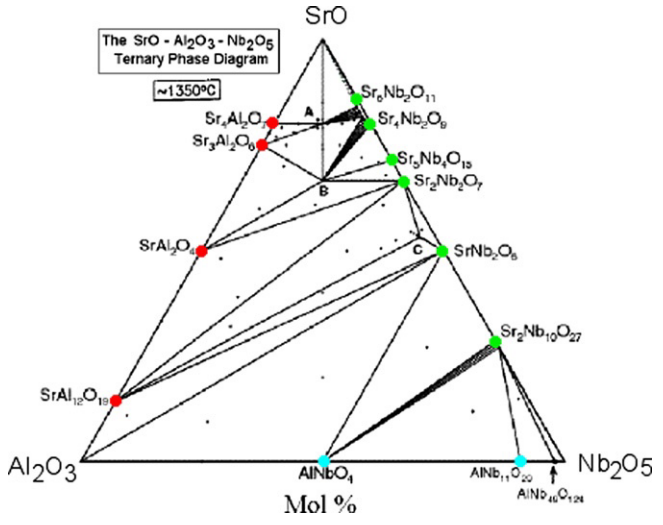

FIGURE 9.61

Cell parameters are: $a = 5.592$ Å, $b = 7.722$ Å, $c = 10.989$ Å, $\alpha = 90.36°$, $\beta = \gamma = 90°$, cell volume = 474.31 $Å^3$. Cell occupancy is shown in Table 9.33.

A general approach to synthesize niobium-containing nano-structured photo-catalysts such as $SrNb_2O_6$, via a facile hydrothermal-electrolytic process has also been demonstrated. This method is based on reactions between soluble/insoluble metallic compounds and metallic oxides in the aqueous solution without using any organic dispersants or capping agents. The one-step technique is controllable and provides a simple, convenient, and innovative strategy for the preparation of niobate nanostructures and basically can be easily expanded to synthesize other materials of a similar structure.

Nanocrystalline rods of $SrNb_2O_6$ powders were successfully prepared by this simple electrochemical method, and the influences of electrolytic solution ingredients, electrolyte concentration, and applied electric current intensity on the electrochemical process and products were systemically studied as shown in Fig. 9.64.

It was found that the formation of strontium niobates is strongly determined by the basic or acidic condition of the electrolytic solution. When $Sr(OH)_2 \cdot 8H_2O$ or the mixed solution, $Sr(OH)_2 \cdot 8H_2O$ plus $SrCl_2 \cdot 6H_2O$, was used as an electrolyte, $Sr_5Nb_4O_{15}$ and $SrNb_2O_6$ phases would simultaneously form, and the relative ratio of $Sr_5Nb_4O_{15}$ to $SrNb_2O_6$ declined with increase of the $SrCl_2 \cdot 6H_2O$ content in electrolytic solution. The higher the basicity of electrolytic solution, the more favored was the crystallization and development of the $Sr_5Nb_4O_{15}$ phase. Only the monoclinic phase $SrNb_2O_6$ was obtained in neutral $SrCl_2 \cdot 6H_2O$ solution or acidic solution of $SrCl_2 \cdot 6H_2O$ with the addition of hydrochloric acid. A lower concentration of $SrCl_2 \cdot 6H_2O$ ($\leq$0.50 M) was beneficial to the formation of the $SrNb_2O_6$ phase and stable anodic sparks could be observed. Moreover, the crystallization and development of the nanocrystalline $SrNb_2O_6$ powders are not sensitive to the applied electric current intensity, and their similar particle size and morphology ultimately result in the loss of UV–Vis absorption and subsequent photo degradation. They show a slight red shift of light absorption onset and better photocatalytic performance compared with that prepared by the solid-state reaction.

It has been shown that these as-synthesized one-dimensional niobate nanostructures with larger BET surface areas possess higher photocatalytic activities for splitting pure water under UV light irradiation than those samples from the solid-state route as shown in Fig. 9.65.

$SrNb_2O_6$ having a rhombic nanotubular structure with a diameter of 300 nm, average length of 3 μm and wall thickness of 50 nm was synthesized via a facile

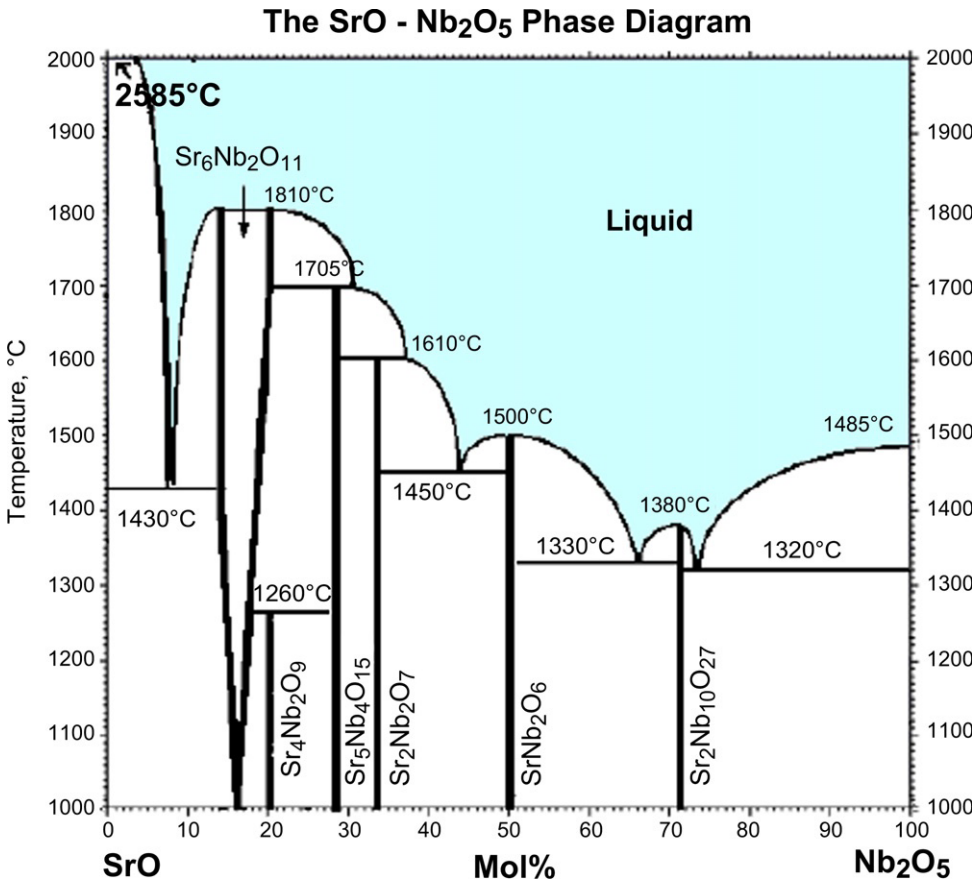

FIGURE 9.62

hydrothermal route. Compared to the same material prepared by the solid-state reaction method, the rhombic nanotubes of $SrNb_2O_6$ exhibited enhanced photocatalytic activity for the production of H_2 from pure water, which was mainly attributed to their higher surface area. The following results shown on the next page were obtained. Thus, $SrNb_2O_6$ is 60 times more effective as TiO_2 in the catalytic splitting of water into O_2 and $2H_2$ gases at room temperature. Moreover, the increased optical absorption properties resulting from the variation of the crystal structure are also attributed to their higher photo-catalytic activity.

The heat capacity and the enthalpy increments of strontium metaniobate $SrNb_2O_6$ were measured by the relaxation method (2–276 K), micro DSC calorimetry (260–320 K) and drop calorimetry (723–1472 K). The

temperature dependence of the molar heat capacity in the form $C_{pm} = (200.47 \pm 5.51) + (0.02937 \pm 0.0760)T - (3.4728 \pm 0.3115) \cdot 106/T^2$ J/K/mol (298–1500 K) was derived by the least-squares method from the experimental data. The standard molar entropy at 298.15 K as Sm^0 (298.15 K) = 173.88 ± 0.39 J/K/mol was evaluated from the low temperature heat capacity measurements. The standard enthalpy of formation ΔH_f (298.15 K) = −2826.78 kJ/mol was derived from total energies obtained by full potential LAPW electronic structure calculations within density functional theory.

Ultrathin strontium niobate films were processed by water-based chemical solution deposition, an approach that offers significant environmental benefits. $SrNb_2O_6$ shows high-k values, a factor that is important for applications such as alternative gate dielectrics in integrated circuits. The study of ultra-thin films (thickness <30 nm) is crucial as this is the thickness range for the application envisaged, and as film properties depend strongly on the film thickness. $SrNb_2O_6$ had a lower crystallization temperature, less interfacial silicate, lower carbonate content, and higher roughness compared to other dielectrics used. The k values of amorphous films were limited (k = 12–14). Crystallization and complete removal of organics or carbonates was accomplished by high-temperature annealing, but increased the roughness and leakage current in the composite.

A novel solution-phase route using $Nb_2O_5 \cdot nH_2O$ as precursor was developed to selectively synthesize single-crystalline $Sr_{0.4}H_{1.2}Nb_2O_6 \cdot H_2O$ nanopolyhedrons and $SrNb_2O_6$ nanorods as photocatalysts via simply adjusting pH values of the reactive solutions as shown in Fig. 9.66.

Strontium barium niobate ($Sr_xBa_{1-x}Nb_2O_6$ = SBN), where ($0.25 \leq x \leq 0.75$) is currently being investigated as a potential ferroelectric material for many micro-device applications, such as pyroelectric infrared detectors, electro-optic modulators, holographic storage, and beam steering, because of its large pyroelectric coefficient, excellent piezoelectric and electro-optic properties, and photorefractive sensitivity. Compared with other well-known ferroelectric materials, SBN has an extremely high electro-optic coefficient. For example, the figure of merit is more than 50 times higher than that of $LiNbO_3$,

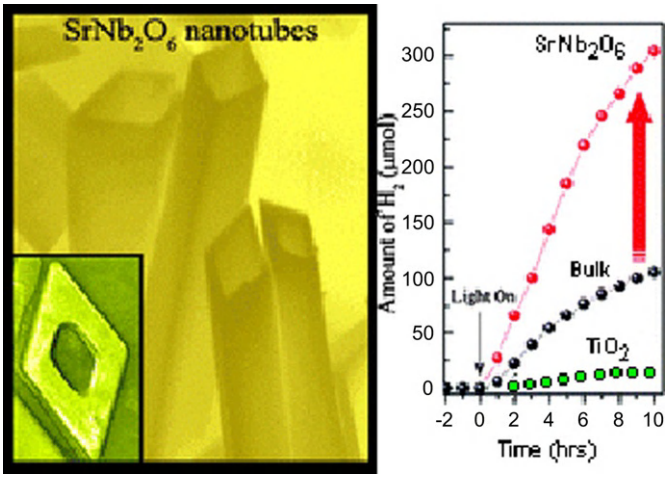

FIGURE 9.65

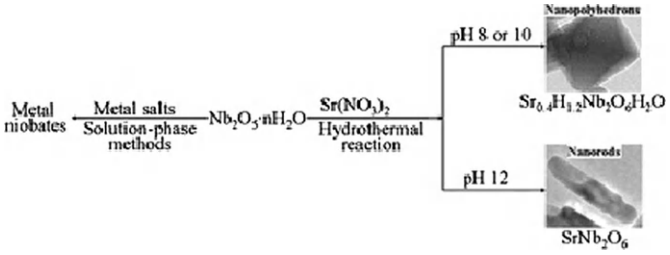

FIGURE 9.66

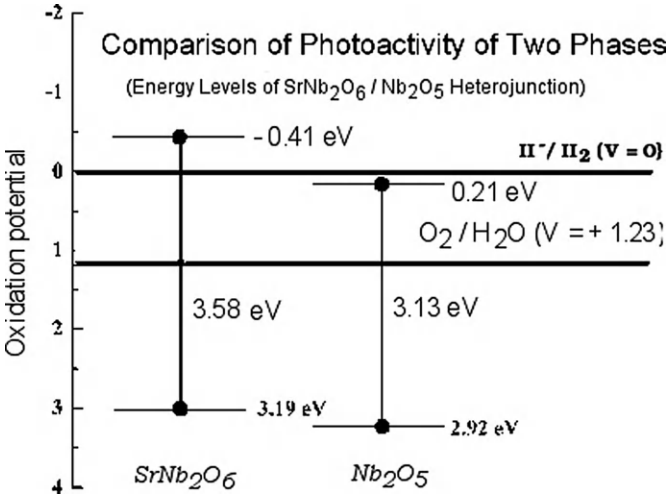

FIGURE 9.67

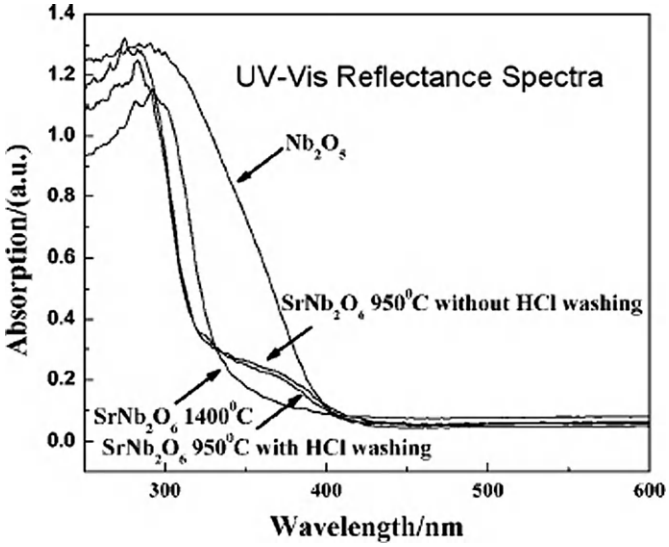

FIGURE 9.68

offering the possibility of much smaller devices. 3 SBN is a solid solution between $BaNb_2O_6$ and $SrNb_2O_6$ phases with a tetragonal tungsten bronze (TTB) structure, wherein its physical properties vary with its composition. These properties and their applications have been investigated mainly for both single crystals and polycrystalline ceramics. Moreover, the demand for thin film processing has increased due to the development of electronic and optical integrated devices. SBN thin films, especially highly *c*-axis-oriented SBN thin films, are desired for optical applications, such as electro-optic properties, photorefractive, and nonlinear optical applications because these applications can take full advantage of the high ferroelectricity of the fabricated SBN films.

$SrNb_2O_6$ powders were prepared by a conventional solid-state method and characterized by powder XRD and UV-Vis diffuse reflection spectra. Their photocatalytic activities were investigated on the degradation of methyl orange. The results show that the photocatalytic activity of pure phase $SrNb_2O_6$ calcined at 1400 °C is lower than that of the impure phase $SrNb_2O_6$ calcined at 950 °C. The hetero-junction model is used to explain that the impure sample can improve the photocatalytic activity due to the interface interaction of Nb_2O_5 and $SrNb_2O_6$ as shown in Fig. 9.67.

Nb_2O_5 has a differing UV-Vis reflectance spectrum than $SrNb_2O_6$ and is believed to contribute electrons to the hole-conductivity of the latter so that the overall photocatalytic efficiency is vastly improved as shown in Fig. 9.68.

The **pyroniobate**, $Sr_2Nb_2O_7$, exhibits at least two separate types of structures. One is that of the calcium homolog (Point group = oP88, space group = $Pna2_1$) and the other is distinctive to the $Sr_2Nb_2O_7$ composition (Point group = oS44, space group = $Cmc2_1$) as shown in Fig. 9.69.

Another view of the Ca-type is presented in the following diagram: Fig. 9.70.

Cell parameters for the Ca-type are: $a = 5.64$ Å, $b = 7.91$ Å, $c = 26.18$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 1166.48 Å^3.

Cell occupancy is shown in Table 9.34.

Cell parameters for the Sr-type are: $a = 3.958$ Å, $b = 5.704$ Å, $c = 13.540$ Å, $\alpha = \gamma = 90°$, $\beta = 98.04°$, cell volume = 302.41 Å^3. Cell occupancy is shown in Table 9.35.

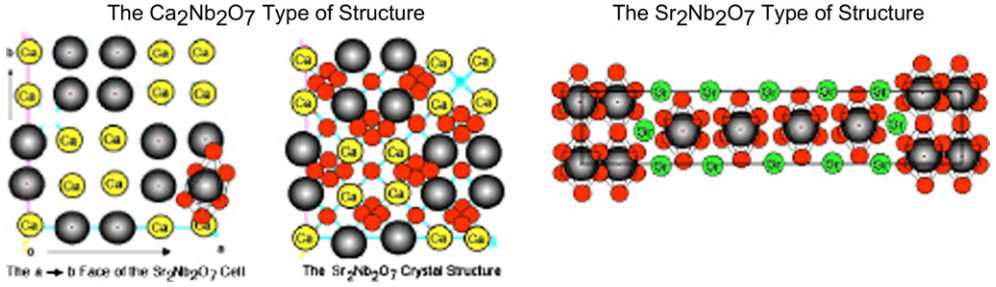

FIGURE 9.69

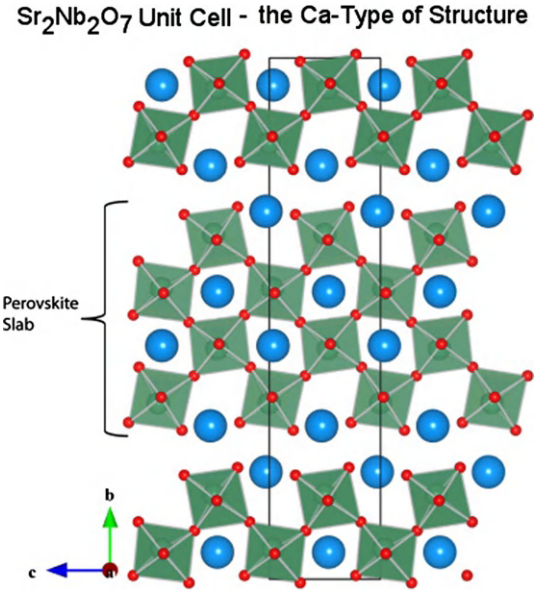

FIGURE 9.70

$Sr_2Nb_2O_7$ belongs to the homologous series of $A_nB_nO_{3n+2}$ type of compounds with A = Sr, B = Nb and $n = 4$. Its Curie temperature is 1342 °C, below which it is ferroelectric and possesses interesting piezoelectric and electro-optic properties. $Sr_2Nb_2O_7$ with certain substitutions, e.g. in the form of important solid solutions such as, $Sr_2(Nb,Ta)_2O_7$ and $(Sr,Ba)_2Nb_2O_7$, is used for ferroelectric memory storage devices based on field effect transistors (FET) and capacitors . The structure of $Sr_2Nb_2O_7$ comprises slabs, each slab extending parallel to {010} planes and consisting of $4NbO_6$ octahedra with Sr atoms occupying the space between them. These NbO_6 octahedra are known to distort and tilt upon cooling and consequently $Sr_2Nb_2O_7$ undergoes three phase transitions from $Cmcm \Leftrightarrow Cmc21 \Leftrightarrow Pbn21 \Leftrightarrow Pb11$ at 1342 °C, 215 °C and −156 °C respectively.

The $Sr_2Nb_2O_7$ (SNO) compound has been determined to be suitable for use as a ferroelectric material for ferroelectric memory FETs, because this substance has a low

dielectric constant, low coercive field and high heat resistance. In one study, operation was successful for $Sr_2(Ta,Nb)_2O_7$ (STN) capacitors on polycrystalline silicon (poly-Si). Using secondary ion mass spectroscopy (SIMS) profiles, the lack of interdiffusion of ions in the STN metal ferroelectric metal insulator semiconductor (MFMIS) structure was confirmed. C–V and I_D–V_G hysteresis curves, dependent on ferro-electric polarization, were obtained. These capacitors were applied to floating gate type ferroelectric random access memory (FFRAM) cells. The degradation in ferroelectric properties of STN capacitors during FFRAM cell fabrication process was not observed. These FFRAM cells can be operated with a lower voltage than that required for PZT.

The lattice images of oxygen-deficient $SrNbO_{3.5-x}$ have been studied by HRTEM observations. The results indicate that loss of oxygen from $SrNbO_{3.5-x}$ eventually results in the formation of an intergrowth of $Sr_5Nb_5O_{17}$, a member of $n=5$ in the perovskite-related family $A_nB_nO_{3n+2}$. The microstructure of $SrNbO_{3.5-x}$ can be considered as a disordered intergrowth between $Sr_2Nb_2O_7$ and $Sr_5Nb_5O_{17}$.

Pulsed laser deposited films (from a $Sr_2Nb_2O_7$ target) obtained in both oxygen and nitrogen atmospheres upon various substrates were characterized with XRD, EDX, atomic force microscopy(AFM), and TEM. In oxygen atmospheres, films adopted the (110)-layered perovskite structure of the target. Higher temperatures, lower pressures of oxygen, and the use of (110)-oriented $SrTiO_3$ substrates lead to highly crystalline, epitaxial films of $Sr_2Nb_2O_7$. The use of nitrogen atmospheres resulted in cubic perovskite $SrNbO_3$ formation: epitaxial, textured, or polycrystalline films were obtained depending on the substrate; no nitrogen incorporation could be observed on the anion sub-lattice. On $SrTiO_3$, the cubic perovskite films followed a cube-on-cube epitaxy and planar defects were observed to occur on the (110) perovskite planes. In oxygen, films adopt the $Sr_2Nb_2O_7$ (110)-layered perovskite structure (left). In nitrogen, films adopt the cubic perovskite $SrNbO_3$ structure (right), as shown in the following diagram: Fig. 9.71.

The films' microstructure depends, however, on the substrate type and temperature. Recently, a number of ternary transition metal oxide catalysts have been discovered to dissociate water more efficiently than conventional materials such as titania. These new materials all have anisotropic structures made up of layers or tunnels. It has been hypothesized that these materials have high efficiencies because the layers and tunnels somehow separate the photo generated charge carriers and, therefore, the locations of the oxidation and reduction half reactions. If such a separation were to occur, it

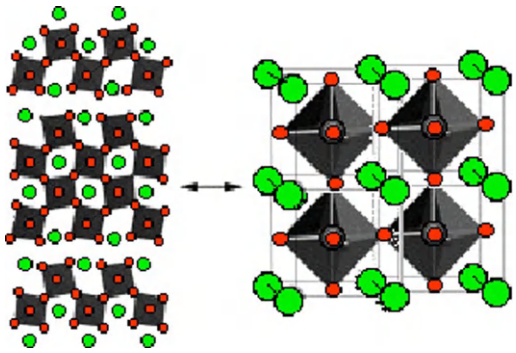

FIGURE 9.71

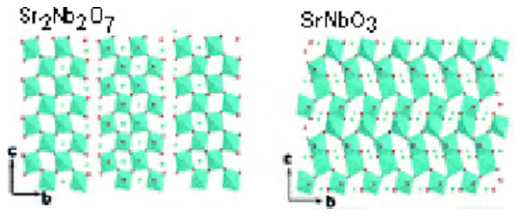

FIGURE 9.72

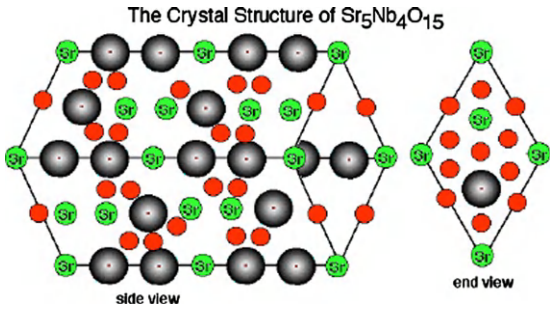

FIGURE 9.73

would suppress carrier recombination and the rate of the back reaction. Two such materials are $Sr_2Ta_2O_7$ and $Sr_2Nb_2O_7$. Both of the structures are made up of corner sharing MO_6 octahedra that are arranged in (110) perovskite type slabs parallel to (010), and separated by Sr_2O layers. The main difference between these materials is the distortion of the NbO_6 octahedra in $Sr_2Nb_2O_7$, which makes it ferroelectric ($Ps \| c$-axis). The role that the layer structure plays in the superior photochemical properties of these compounds is currently unclear.

A comparison between the octahedra structure of in $SrNb_2O_6$ and $Sr_2Nb_2O_7$ shows that the somewhat disordered arrangement of the former becomes ordered as a molecule of SrO is added to former the latter is shown in Fig. 9.72.

The thermal properties of highly textured and polycrystalline samples of 0.5 mol% La-doped $Sr_2Nb_2O_7$ have been measured from just above room temperature 351 °C to 1000 °C. The thermal conductivity was found to be very low (~1 W/mK), temperature independent, and strongly anisotropic parallel and perpendicular to the layered structure up to 1000 °C. The phase transition between the room temperature *IC* orthorhombic phase and the normal orthorhombic phase above 215 °C has a negligible effect on thermal conductivity.

Nanostructured $Sr_2Nb_2O_7$ powders with different morphologies were synthesized via a hydrothermal reaction at 200 °C for 24 h in an Sr^{2+}–$Nb_2O_5 \cdot nH_2O$–KOH system. Powder XRD characterization indicated that 0.3–5 M KOH solutions favored the formation of an $Sr_2Nb_2O_7$ pure phase. On increasing the concentration of KOH from 0.3 to 5 M, the morphology of $Sr_2Nb_2O_7$ samples changed from nanoneedles to nanorods, nanosheets, and finally nano-sized flakes, and their aspect ratios gradually reduced. Ultraviolet–Visible diffuse reflectance spectra analyses showed that the nanostructured $Sr_2Nb_2O_7$ powders had good light absorption properties in the ultraviolet light region.

The ortho-niobate, $Sr_3(NbO_4)_2$, has never been synthesized. However, more complex compounds like $Sr_5Nb_4O_{15}$, $Sr_5Nb_5O_{16}$ and $Sr_3Nb_5O_{15}$ have been discovered.

The compound, $Sr_5Nb_4O_{15}$, has the structure shown as follows: Fig. 9.73.

Cell parameters are: $a = b = 5.659$ Å, $c = 11.459$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 317.80 Å^3. Cell occupancy is shown in Table 9.36

The strontium niobate compounds $Sr_4Nb_2O_9$ and $Sr_5Nb_4O_{15}$ were prepared by solid-state reactions and studied by high-resolution powder XRD measurements. The structures of the two systems $Sr_4Nb_2O_9$ and $Sr_5Nb_4O_{15}$ were obtained by Rietveld analysis, indicating triclinic and monoclinic unit cell parameters, respectively. Both structures reveal a layering of Sr···O planes. The Nb ions are located in octahedral holes between the Sr···O layers. Another view of the $Sr_5Nb_4O_{15}$ crystal structure is shown in Fig. 9.74.

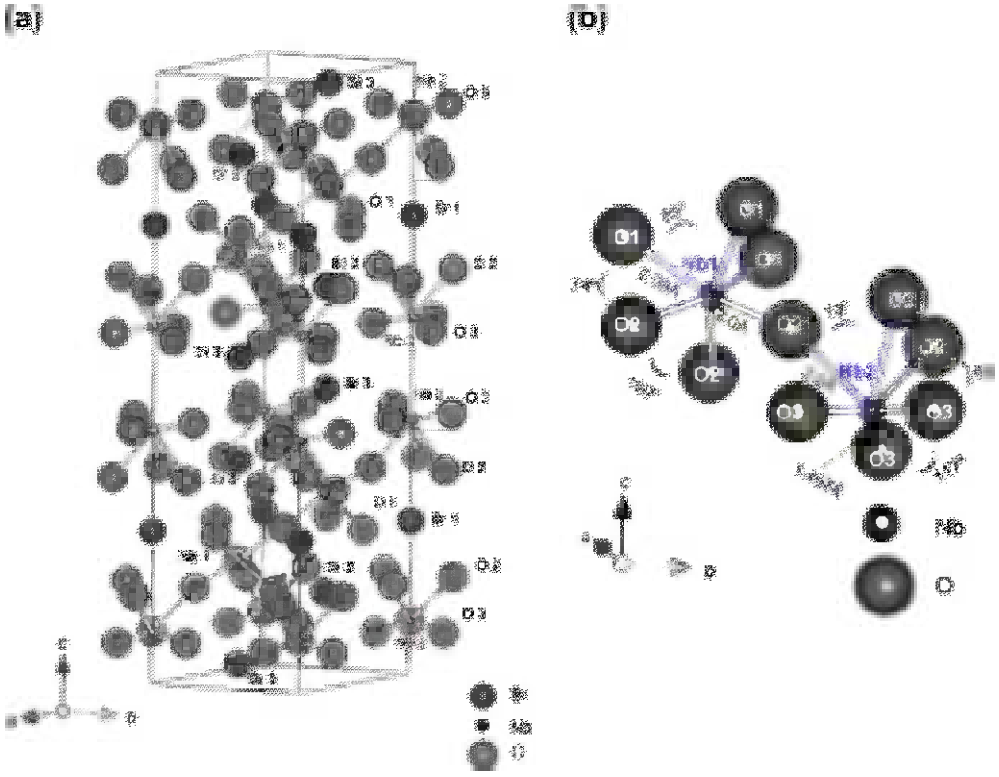

FIGURE 9.74

In the phase diagram, strontium niobate $Sr_4Nb_2O_9$ has a perovskite derivative structure, as well as its neighboring phase $Sr_6Nb_2O_{11}$. At least two researchers, one Russian and the other French, considered the part of the $SrO–Nb_2O_5$ phase diagram between $Sr_4Nb_2O_9$ and $Sr_6Nb_2O_{11}$ as a continuous $Sr_4Nb_2O_9$ base solid solution whose end member is $Sr_6Nb_2O_{11}$. However, one found the $Sr_4Nb_2O_9$ phase to be stable as a solid at room temperature while the other did not. A final conclusion was finally agreed upon. Accordingly, there is a very narrow two-phase field within 1–3 mol between the $Sr_4Nb_2O_9$ and $Sr_6Nb_2O_{11}$ phases.

$Sr_5Nb_4O_{15}$ (SN) and $Ba_5Nb_4O_{15}$ (BN) microwave ceramics prepared by a reaction-sintering process were investigated. Without any calcination involved, the Nb_2O_5 mixture of $BaCO_3$ and $SrCO_3$ was pressed and sintered directly. BN and SN ceramics could be obtained after 2–6 h sintering at 1350–1500 °C. A density 6.13 g/cm^3 (97.3% of theoretical value) was obtained in BN for 4 and 6 h sintering at 1450 °C. The sintering temperature was 200 °C lowered with the addition of 1 wt.% CuO. For SN, low densification 86.9% was obtained at 1500 °C and became dense with 96% of the theoretical density at 1430 °C after 1 wt.% CuO was added. Dielectric constants 39.5 and 38.1 could be obtained in BN and SN. $Q \times f$ values 22,700 GHz at 7.2 GHz and 10,500 GHz at 7.47 GHz are observed in BN and SN.

The investigation of the electrical properties of metal rich alkaline earth niobates was pioneered as early as the 1980's. Even then, the high conductivity of these niobates was related to oxygen ion migration by means of exchange of positions between an ion residing in a regular position of the oxygen sub-lattice and structural oxygen vacancies, as:

$$O^{x_0} + (V^{s_0}) \Leftrightarrow (V^{s_0})^{x} + O^{x_0}(V^{s_0})$$

In parallel to publications of Russian researchers, French workers published a set of works concerning electrical conductivity measurements as a function of temperature and oxygen partial pressure. They chose to study samples containing 81–85 mol% SrO and considered these samples as solid solutions of general formula $Sr(Sr_{1/3+x}Nb_{2/3-x})O_{3-3/2x}$ $(0 \leq x \leq 1/6)$. Discussion was in terms of the point defect model. Later studies of samples of these compositions involved the comparison of the measured (pycnometer) density with densities calculated for various dissolution models. These later studies showed that the model of $Sr_6Nb_2O_{11}$ base solid solution is characterized by the general formula $Sr_{6-2x}Nb_{2+2x}$ O_{11+3x} $(0 \leq x \leq 0.28)$; this formula suggests partial substitution of niobium ions for octahedrally coordinated Sr^{2+} ions. The $Sr_6Nb_2O_{11}$ phase and the related $Sr_4Nb_2O_9$ phase both have dominant oxygen conductivity. The phase $Sr_4Nb_2O_9$ is a non-stoichiometric phase with a disordered perovskite structure.

The complex structural behavior of the perovskite-related compound $Sr_4Nb_2O_9$ ($Sr(Sr_{1/3}Nb_{2/3})O_3$) has been investigated using ED, XRD, and NPD. Analysis of well-equilibrated specimens annealed at various temperatures indicated that two thermodynamically stable polymorphs occur above and below $T = 1250\,^{\circ}C$. The high-temperature (HT) polymorph exhibits an average cubic structure (*Fm* 3*m*, *a* 2*ac*, where 'c' refers to the cubic ~4 perovskite unit cell) with 1:1 (NaCl-type) partial ordering of Sr^{2+} and Nb^{5+} on the *B*-sites. The low-temperature (LT) phase is monoclinic (*P*21/*n*, *a* 6*ac* 3, *b* 2*ac* 2, *c ac* 6, *b* 90) with a distant, yet unknown, *B*-cation arrangement. Examination of the HT cubic polymorph using ED revealed diffuse intensity contours that were consistent with additional local ordering/cluster formation on the sites of the mixed (Sr/Nb) fcc cubic sublattice of the 1:1 ordered *B*-cation array. Concentration of intensity observed at certain points within the diffuse intensity contours was attributed to superstructure formation. Additionally, refinements of the HT structure using XRD and NPD data indicated local displacements of both oxygen and *A*-site Sr atoms, which resembled those associated with octahedral tilting. HT-$Sr_4Nb_2O_9$ specimens subsequently annealed at 900 °C exhibited remarkably complex chemical and structural behavior: The contours of diffuse intensity were replaced by arrays of sharp superlattice reflections corresponding to at least four distinct metastable superstructures, all derived from the 1:1 *B*-cation arrangement. Compositional analysis indicated that these phases exhibit Sr/Nb ratios slightly different from 2/1; that is, they are not true polymorphs, but rather a series of structurally distinct phases with compositions near $Sr_4Nb_2O_9$. The metastable superstructures were attributed to ordering of Sr and Nb on the mixed *B*-sites in the 1:1 ordered array, possibly combined with either *A*-site or oxygen vacancy ordering, depending on the Sr/Nb ratio in the particular phase. The metastable phases transform to the stable LT-$Sr_4Nb_2O_9$ phase upon annealing in the 1100 °C–1200 °C temperature range. The dielectric properties of HT- and LT-$Sr_4Nb_2O_9$ were measured by capacitive methods at 1 MHz. HT-$Sr_4Nb_2O_9$ exhibited an ambient permittivity of 40 with a non-monotonic temperature dependence, while that for LT-$Sr_4Nb_2O_9$ was 30 with near-linear temperature dependence. The peculiar dielectric behavior of HT-$Sr_4Nb_2O_9$ was ascribed to the competitive responses of nanodomains having somewhat different structures and compositions.

Barium and strontium niobates have been prepared by means of an economic and ecologic aqueous solution-gel route with high compositional flexibility. The synthesis of precursor solutions and gels, and thermal analysis of the gels are presented. The crystallization of the different oxides was studied in situ using high-temperature X-ray diffraction measurements (HT-XRD). The crystallization behavior of strontium niobates was strongly dependent on the Sr:Nb ratios, as observed in HT-XRD. Phase pure $SrNb_2O_6$ was obtained at low temperature (600 °C). $Sr_2Nb_2O_7$ and $Sr_5Nb_4O_{15}$ were formed at 900 °C from an intermediate phase, with a minor secondary phase. $Nb_2Sr_4O_9$ crystallized at 600 °C, but transformed to a mixture of phases at high temperature (1000 °C). By off-line furnace annealing, phase pure strontium niobates of all four compositions were obtained. The presented work demonstrated the high compositional flexibility of the aqueous solution-gel route, allowing fast synthesis of different multi metal oxides with high purity.

The possibility that the structure of the novel semiconducting perovskite-related material strontium niobium oxide, $Sr_5Nb_5O_{17}$, refined in space group *Pnn*2, might instead belong to space group *Pnnm* has been investigated. This followed an analysis of the atomic coordinates that indicated the latter space group to be more likely. All I_{obs} were carefully remeasured, first those within a hemisphere containing *c**, then all that lay within the full sphere of reflection. Refinement was undertaken, with each of two different sets of weights, in each space group. Each data set was used under three limiting intensity conditions: $I_{obs} > 4(I_{obs})$, $I_{obs} > 2(I_{obs})$ and finally with *all* reflections, but setting magnitudes with I_{obs} 0 equal to 0. Fourteen separate tests based only upon the XRD data may be used to distinguish between *Pnn*2 and *Pnnm*. Nine tests favored the latter choice, four were indeterminate and one was not used. Seven further tests were made on the basis of physical measurement; of these, three strongly indicated *Pnnm*, one was indeterminate and three could not be used. The evidence clearly suggests the space group is *Pnnm*. The use of all reflections, including those with negative magnitude set equal to zero, is essential to avoid ambiguity in the XRD tests and achieve the highest reliability. Refinement with weights based on variances of Type *A* and Type *B* resulted in improved reliability compared with that obtained from a popular empirical weighting scheme. The revised structure differs in several respects from that published previously.

New oxide compounds with large thermal expansion coefficients and low thermal conductivities are being sought by means of a material calculation technique. Among the thousands of compounds in the databases, there are some materials with low thermal conductivities and large thermal expansion coefficients in the group of strontium–niobium oxides. For example, $Sr_4Nb_2O_9$ has a thermal expansion coefficient of 14.5×10^{-6} /°C and a thermal conductivity of 1.0 W/mK, although a slight amount of other phases appear during long-term annealing. These thermal properties are better than those of yttria-stabilized zirconia, which is the standard material for thermal barrier coatings.

TABLE 9.37

Mol Ratio of Component oxides

$Sr_6Nb_2O_{11}$	6	1		
$Sr_5Nb_5O_{16}$	5	2		1
$Sr_6Nb_{34}O_{91}$	6	16		2
$Sr_7Nb_6O_{21}$	7	1	3	1

Phase relations have been investigated within the $Sr_4Nb_4O_{14}$–$Sr_5Nb_4O_{15}$–$SrTiO_3$ region of the SrO–Nb_2O_5–TiO_2 system with a view to clarifying the occurrence of perovskite-related phases. Most samples were prepared from oxide or carbonate powders heated in air at 1350 °C but some samples were also prepared by argon arc melting. The overall phase analysis was carried out by powder XRD. Two-phase lines contain a homologous series of layered perovskite phases. These are the $Sr_n(Nb,Ti)_nO_{3n+2}$ $(4 \leq n \leq 7)$ series on the $Sr_4Nb_4O_{14}$–$SrTiO_3$ line and $Sr_n(Nb,Ti)_{n-1}O_{3n}$ $(5 \leq n \leq 7)$ on the $Sr_5Nb_4O_{15}$–$SrTiO_3$ line. The microstructures in these homologous series were clarified by TEM. This revealed both ordered and disordered intergrowths of the perovskite homologs and allowed the defect microstructure of $SrTiO_3$ in contact with the layered perovskites to be determined.

In addition to the compounds described above, a series of stable compounds has been synthesized. The composition can only be described as a combination of niobium oxides in which various states of oxidation of the Nb-atom appear. These compositions are all part of the layered perovskite type of compound but with varying stages of oxidation state of the Nb = atom in the structure. The above Table 9.37 lists strontium niobate compounds whose composition is made up of various niobium oxides.

All of these compounds belong to the Ruddlesden–Popper series of layered compounds. Their structures have been solved and are available. It is notable that only the strontium and barium analogs of these alkaline earth niobates form such compounds with Nb^{4+}, Nb^{5+} and Nb^{6+} states of ionization in the same compound. A comparison of such structures is presented in the following diagram: Fig. 9.75.

The green spheres show the Sr^{2+}atom positions in the lattice, the gray spheres are those of the Nb^{5+} atoms and the red spheres are those of the oxygen atoms. For the

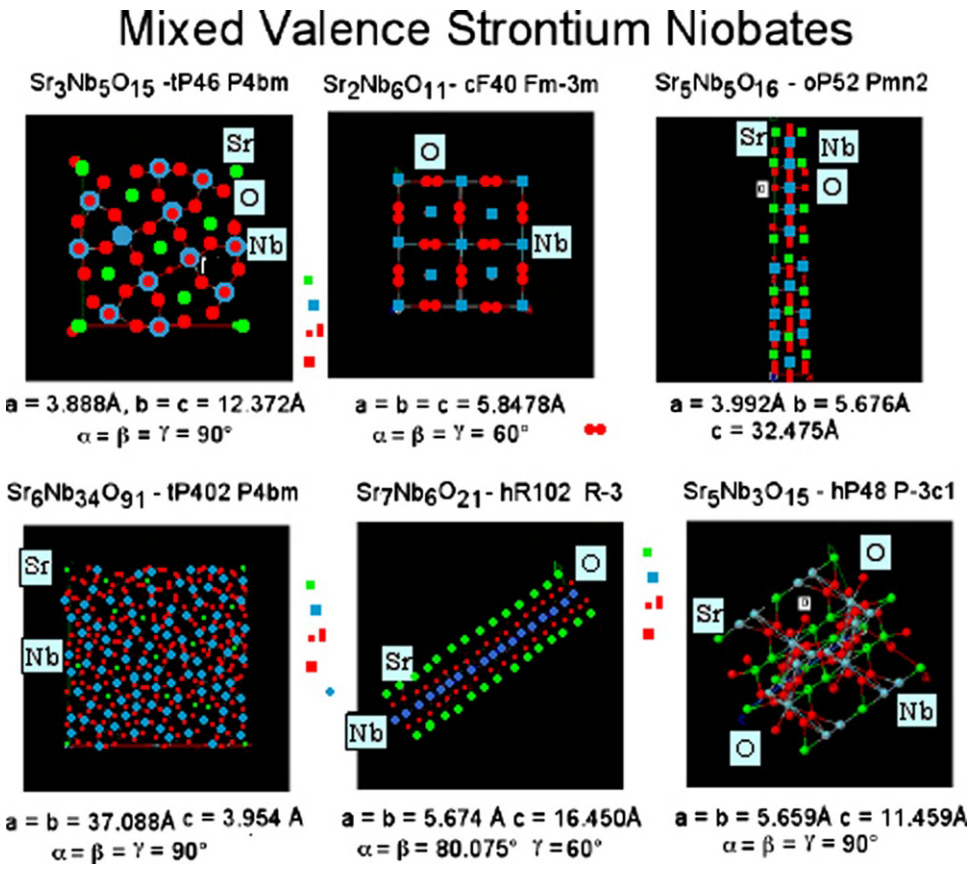

FIGURE 9.75

most part, a view along the *c*-axis is shown, i.e. the *a*–*c* plane of the unit cell. A number of atoms are only partially visible. To visualize a three dimensional view of each lattice, the *a*–*c* plane is doubled and set at the corresponding plane at the angles specified.

Strontium niobate is available commercially as the $SrNb_2O_6$ composition with the CAS number of 12034-89-8.

9.2.5. Barium Niobium Compounds

The system, BaO–Nb_2O_5, resembles the SrO–Nb_2O_5 system in many ways. The structures of many compounds are isomorphic. However, BaO forms up to 16 compounds compared to the eight (8) seen in the SrO family of compounds.

Similar to the SrO family of niobates, no compounds are known where niobium has the +2 valence state.

In the Nb^{3+} system of BaO–Nb_2O_3, the compound, $SrNb_2O_4$ has never been synthesized. No compounds containing Nb^{3+} have been reported.

In the Nb^{4+} system of BaO–NbO_2, the compound $BaNbO_3$ is known. Heating a mixture of NbO_2 and $BaO{\cdot}3B_2O_3$ to 1100 °C (10^{-6}–10^{-7} Torr), followed by slow cooling (8 °C/h) produces golden crystals of the niobate $Ba_2Nb_{15}O_{32}$ (average Nb oxidation state 4+), as well as crystals of $Ba_3Nb_5O_{15}$ ($Nb^{4.8+}$) and $BaNb_8O_{14}$ [8] ($Nb^{3.25+}$) which form in a disproportionate side-reaction. The structure of $Ba_2Nb_{15}O_{32}$ contains a layer (A) of isolated octahedral $[Nb_6O_{12}]O_6$ metal–metal bound clusters, interconnected by Nb-atoms in octahedral holes in the lattice. These layers are separated by layers of Nb_3O_{13} groups (B), and layers with Ba-ions and isolated NbO_6 octahedra (C). Single crystal resistivity measurements indicate semiconducting behavior, with a semiconductor-to-semiconductor transition at 170 K. This coincides with a magnetic transition from a weakly paramagnetic state to diamagnetism below the transition temperature.

In another reference, single crystals of the reduced niobate $Ba_2Nb_{15}O_{32}$ were produced by heating NbO_2 in $BaO{\cdot}3B_2O_3$ under high-vacuum conditions. The borate acts both as a source of BaO and as a flux for crystallization. The compound $Ba_2Nb_{15}O_{32}$ crystallizes in space group *R*3 ($a = 7.777$ Å, $c = 35.518$ Å) and contains isolated $[Nb_6O_{12}]O_6$ clusters arranged in layers. As side products, single crystals of the following phases were observed to be formed:

$Ba_3Nb_5O_{15}$ (space group $P4/mbm$), $a = 12.598$ Å, $c = 3.9774$ Å with a tetragonal tungsten bronze-type structure.

$BaNb_8O_{14}$ (space group *Pcab*, $a = 9.4222$ Å, $b = 10.3649$ Å, $c = 23.716$ Å).

These contain $[Nb_6O_{12}]O_6$ clusters in a three-dimensional arrangement, interconnected by three different modes of oxygen sharing. This compound, $Ba_2Nb_{15}O_{32}$, exhibits a semiconductor-to-semiconductor transition at 170 K, coinciding with a transition from a weakly paramagnetic state to diamagnetism. Single-crystal resistivity measurements on $Ba_3Nb_5O_{15}$ indicate a significant anisotropy ($\rho \perp c = 55$, $\rho \| c$ at 300 K) and small band gap semiconducting behavior.

The phase diagram is shown as follows in Fig. 9.76.

Of the nine (9) compounds shown, only three (3) melt congruently. The other six (6) melt incongruently. The 4:1, 3:1, 5:2, 5:6 and 1:2 compounds have not been studied very extensively. These incongruently melting compounds, $Ba_4Nb_2O_9$, $Ba_3Nb_2O_8$, $Ba_5Nb_4O_{15}$, $Ba_5Nb_{12}O_{35}$, and $BaNb_4O_{11}$, have been documented through study of their crystal structures but only $Ba_5Nb_4O_{15}$ has received any commercial attention.

The **metaniobate**, $BaNb_2O_6$, is polymorphic and has five differing crystal structures. Three (3) are unique to the metaniobate and the others are isomorphous to a ferrate, $NdFeO_6$ and a tantalate, $BaTa_2O_6$, as shown in the following Fig. 9.77.

These three isomorphic structures are shown as the low temperature α-type, and the β-type or γ-type. They are merely specific arrangements of NbO_6 octahedra and can be transposed one into the other by temperature changes as shown in Table 9.38.

Cell parameters and cell occupancies are given as follows:

α-type

$a = 3.952$ Å, $b = 6.059$ Å, $c = 10.434$ Å, $\alpha = \gamma = 90°$, $\beta = 90.35°$, Cell volume = 149.43 Å^3. Cell occupancy is shown in Table 9.39.

β-type

$a = \beta = 7.268$ Å, $\gamma = 10.292$ Å, $\alpha = \beta = 90°$, $\gamma = 114.35°$, cell volume = 495.33 Å^3. Cell occupancy is shown in Table 9.40.

γ-type

$a = 3.946$ Å, $b = 6.034$ Å, $c = 10.461$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 248.91 Å^3.

Cell occupancy is shown in Table 9.41.

The metaniobate also has the Nd_2FeO_6-type of structure as shown in the Fig. 9.78.

Cell parameters are: $a = 5.12$ Å, $b = 5.84$ Å, $c = 13.82$ Å, $\alpha = \beta = \gamma = 90°$, Cell volume = 413.23 Å^3. Cell occupancy is shown in Table 9.42.

$BaTa_2O_6$ type

This compound has the structure shown in Fig. 9.79. Unit cell parameters are: $a = 3.94$ Å, $b = c = 12.05$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 495.45 Å^3. Cell occupancy has not been given.

Crystals of the high-temperature form of $BaNb_2O_6$ were grown from a BaB_2O_4 flux. The symmetry of the crystals is orthorhombic and the structure consists of a zigzag pattern of edge-sharing pairs of NbO_6-octahedra joined at corners at nearly 60° and 120°

angles to produce rings of six octahedra. The barium atoms are situated in the cages formed by the rings. Pure hexagonal $BaNb_2O_6$ crystallizes at 640° to 700 °C from an amorphous material prepared by simultaneous hydrolysis of barium and niobium alkoxides. This structure is characterized by layer networks of NbO_6 octahedra. Crystallization isotherms are described by the Avrami equation: $\ln(1-f) = -kt^n$ with $n = 2$; the activation energy is

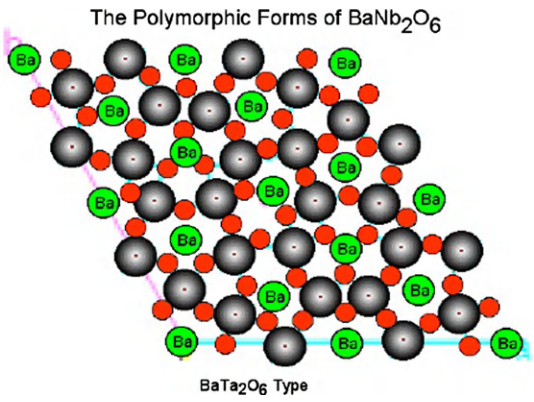

FIGURE 9.79

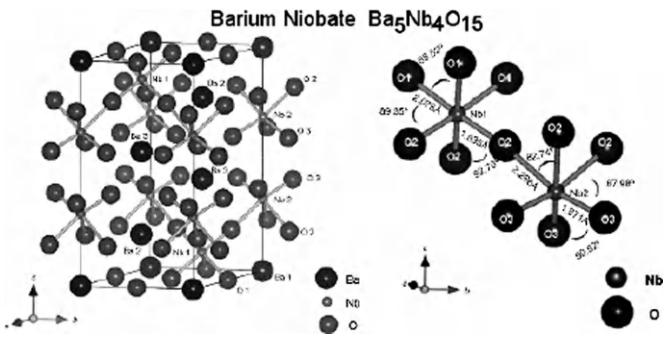

FIGURE 9.80

268 kJ/mol. Hexagonal $BaNb_2O_6$ transforms to the orthorhombic modification at 1250° to 1310 °C.

Barium metaniobate, $BaNb_2O_6$ with polymorphic orthorhombic and hexagonal forms was also prepared by solid-state reaction. Hexagonal α-$BaNb_2O_6$ is the low temperature phase, and can be transformed to the orthorhombic phase over a broad temperature range above 1150 °C. It was observed that the hexagonal-to-orthorhombic phase transition is reversible due to the structural similarity of these two polymorphs. The difference in transition kinetics and associated mechanisms could be confirmed from the analysis of time dependence of transformed phase. It was also found the dielectric properties of each phase was significantly different. In particular, orthorhombic β-$BaNb_2O_6$ has good microwave dielectric properties:

$$Q \times f = 43,000\ \text{GHz}, \quad \varepsilon_r = 30, \quad \tau_f = -45\ \text{ppm/°C}.$$

$Ba_{1-x}Sr_xNb_2O_6$ ceramics, where $0.25 \le x \le 0.75$, are ferroelectric materials with tungsten bronze structures, and have excellent electro-optic, pyroelectric, photorefractive, and piezoelectric properties.

The compound, **penta-barium di-niobate**, $Ba_5Nb_4O_{15}$, its structures and properties, has been well studied. This compound has a hexagonal structure and crystallizes in the $P3m1$ space group with one formula unit per cell ($Z = 1$). The compound has a five-layer closest packing of oxygen and barium ions. The niobium ions are located in the octahedral holes between layers with one layer of octahedral holes are missing niobium ions to accommodate the charge neutrality. The $Ba_5Nb_4O_{15}$ compound is a hexagonal polytype i.e., the (5H) member of a series of polytypes containing 4, 5, 6, 8, 10 and 12 layered (4H, 5H, 6H, 8H, 10H, and 12H) species. The structure has the form as shown in Fig. 9.80

Cell parameters are; $a = 3.878$ Å, $b = 20.86$ Å, $c = 36.27$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 2934.06 Å^3.

The addition of B_2O_3 to a mixture of $Ba_5Nb_4O_{15}$-$BaNb_2O_6$ significantly lowered the sintering temperature to about 900 °C in comparison to about 1250 °C for B_2O_3-free samples. A B_2O_3-rich intra-granular phase in the sample was attributed to the presence of a liquid phase during sintering. This barium metaniobate, $BaNb_2O_6$ has five polymorphs, with orthorhombic and hexagonal forms. A major contributor to good microwave dielectric properties of low-fired samples is the low-temperature phase, hexagonal $BaNb_2O_6$. A small amount of hexagonal $BaNb_2O_6$ apparently tunes the temperature coefficient of resonant frequency (τ_f) of $Ba_5Nb_4O_{15}$. Therefore the mixture, $Ba_5Nb_4O_{15}$–$BaNb_2O_6$ with B_2O_3 is suitable for preparation of a low-temperature co-fired ceramic (LTCC), due to its reduced sintering temperature and good microwave dielectric properties: $Q \times f = 28{,}000$ GHz; ε_r and τ_f are 42 and 0 ppm/°C, respectively.

A barium niobium oxide displaying bronze characteristics was found by the reaction of niobium metal with mixtures of barium and niobium oxides to form $Ba_5Nb_4O_{15}$. It is a red compound with the cubic perovskite-type structure $a_0 = 4.080$ Å, a good electrical metallic conductor and paramagnetic with Curie–Weiss behavior.

The low-temperature, far-infrared reflectivity, and Raman-scattering measurements for the layered compound, $Ba_5Nb_4O_{15}$, was reported. This material is characterized by a strong anharmonic lattice where the symmetric stretching vibration of the empty octahedra, a singular feature of this layer compound, splits into two narrow Raman-active bands. These differences were assigned to the same phonon in a slightly different environment, and suggested the existence of a small local departure from the reported centro-symmetric $D^3_{3d} - P3m1$ space group. It was concluded that the infrared and mainly the Raman band profiles indicated that the lattice of $Ba_5Nb_4O_{15}$ is close to collapsing into a lower symmetry structure.

A study was carried out of the microwave dielectric properties of the five-layered compound $Ba_5Nb_4O_{15}$ prepared by conventional solid-state synthesis. Results show that $Ba_5Nb_4O_{15}$ has excellent microwave dielectric characteristics; $\varepsilon_r = 38$, $Q \times f = 7500$ at 10 GHz, and $\tau_f = +50$ ppm/K. Since this compound has a high dielectric constant, high Q and sufficiently stable

characteristics, it is perceived as useful for applications at microwave frequencies.

The effect of B_2O_3 on the sintering temperature and microwave dielectric properties of $Ba_5Nb_4O_{15}$ was reinvestigated using powder XRD, SEM, and a network analyzer. Interactions between $Ba_5Nb_4O_{15}$ and B_2O_3 led to the formation of second phases, $BaNb_2O_6$ and BaB_2O_4. The addition of B_2O_3 to $Ba_5Nb_4O_{15}$ resulted in lowering the sintering temperature from 1400° to 925 °C. Low-fired $Ba_5Nb_4O_{15}$ could be interpreted by measuring changes in the quality factor ($Q \times f$), the relative dielectric constant (ε_r), and the temperature coefficient of resonant frequency (τ_f) as a function of B_2O_3 additions. More importantly, the formation of $BaNb_2O_6$ provided temperature compensation. The microwave dielectric properties of low-fired $Ba_5Nb_4O_{15}$ had good dielectric properties: $Q \times f = 18700$ GHz, $\varepsilon_r = 39$, and $\tau_f = 0$ ppm/°C.

$Ba_5Nb_4O_{15}$ ultrafine powders were prepared by a hydrothermal method using $Ba(NO_3)_2$ and Nb_2O_5 precursors. The synthesis characteristics were influenced by the chemical form of precursors, reaction temperature, mole ratio of Ba/Nb and pH value. The chemical form of the precursors has a strong influence on the products of $Ba_5Nb_4O_{15}$. There was no requisite compound in the final product when Nb_2O_5 powder was used as Nb-precursor. In addition, the reaction completeness was also dependent on the synthesis temperature. The best single-phase $Ba_5Nb_4O_{15}$ ultrafine powders were obtained at a temperature of 230 °C. The most appreciate Ba/Nb molar ratio was 3/2. The reactions were only carried out in a solution with pH value between 12 and 14. When pH was equal or larger than 14, there was no product of $Ba_5Nb_4O_{15}$ powder in the reactor.

The effects of a forming atmosphere on the stability, the sintering and the dielectric properties of $Ba_5Nb_4O_{15}$, $BaNb_2O_6$, $ZnNb_2O_6$ and $Zn_3Nb_2O_8$ ceramics were investigated, because of the primary importance of the sintering atmosphere in relation to copper sintering. These Nb-based materials were sintered in air and in Ar/H_2 (10%). Zn-containing samples are very sensitive to the reductive atmosphere. ZnO volatilizes at 800–850 °C and the resulting compound does not exhibit the expected properties. $BaNb_2O_6$ and $Ba_5Nb_4O_{15}$ are more stable in terms of relative weight loss. A phase analysis revealed that a modification of the $BaNb_2O_6$ phase was formed during reduction that induced degradation of the dielectric property stability as a function of temperature. In contrast, the properties of $Ba_5Nb_4O_{15}$ are not modified by a sintering in a reductive atmosphere. A relative permittivity of 38.8, a permittivity temperature coefficient of −150 ppm/°C and an insulating resistivity of $10^{10.9}$ V/cm were obtained for the latter.

A related compound, $Ba_3Nb_5O_{15}$, has the structure as shown in Fig. 9.81

Lattice parameters are: $a = 3.945$ Å, $b = c = 12.362$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 595.99 Å^3, $Z = 4$. Cell occupancy is shown in Table 9.43.

Little is known concerning this compound other than its crystal structure.

Two related compounds, tribarium niobate and tetrabarium niobate, $Ba_3Nb_2O_8$ and $Ba_4Nb_2O_9$, have received

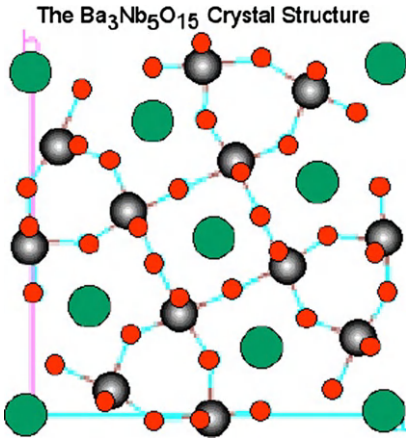

FIGURE 9.81

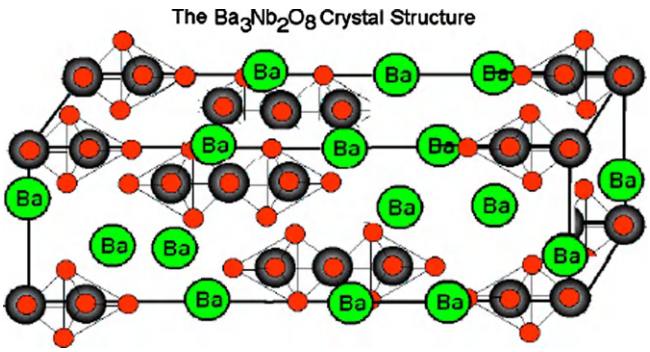

FIGURE 9.82

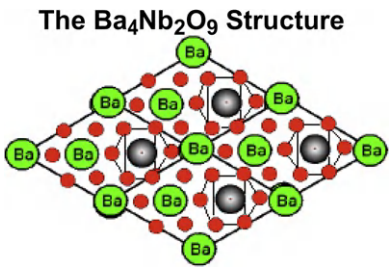

FIGURE 9.83

extensive attention in the literature. They differ by one BaO molecule but have quite differing structures. The **tribarium niobate** compound, $Ba_3Nb_2O_8$, has the structure as shown in Fig. 9.82.

Cell parameters are: $a = b = 6.045$ Å, $c = 7.903$ Å. $\alpha = \beta = 67.513°$, $\gamma = 60°$. Cell volume $= 224.37$ Å^3. Cell occupancy is shown in Table 9.44.

According to one study, the structural investigations performed by powder XRD, selected area ED, and high-resolution electron microscopy(HREM) on $Ba_3Nb_2O_8$ clearly showed that the palmierite structure previously reported for this compound is not adopted. The presence of Nb in the *B* sub-lattice induces a change in symmetry from rhombohedral to hexagonal, and a 9H unit cell is formed. The two possible layer stacking sequences, (*ccchhhhhh*) (*Pm*1) and (*cchhchhhh*) (*Pm*1), was discussed in terms of ordering of both anionic and cationic vacancies.

The crystal structure given above is that which is regarded as most relevant to the actual structure of this compound. Very little information or studies of this 3:1 compound have appeared in the literature and it is clearly inferior in dielectric properties, compared to other barium niobate compositions.

The addition of another BaO molecule to form the compound $Ba_4Nb_2O_9$ changes the NbO_4 tetragonal unit of $Ba_3Nb_2O_8$ to an octagonal unit, NbO_6, in the crystal structure, shown in Fig. 9.83.

Cell parameters are: $a = b = 6.11$ Å, $c = 8.04$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 257.80$ Å^3. Cell occupancy is shown in Table 9.45.

Polymorphic phase transitions in $Ba_4Nb_2O_9$ were studied by thermal analyses, HTTEM and powder XRD. Two stable polymorphs were isolated, a low-temperature α-modification and a high-temperature γ-modification, with an endothermic phase transition at 1176 °C. The alpha ⇔ gamma transformation is accompanied by the formation of a 120° domain structure, which is a consequence of the hexagonal ⇔ orthorhombic unit cell reconstruction. Reheating the pre-sintered γ-$Ba_4Nb_2O_9$ results in the formation of a metastable γ′-modification (formerly known as β-polymorph) in the temperature range between 360 °C and 585 °C, before the α ⇒ γ transformation above 800 °C occurs. Above about 1490 °C, $Ba_4Nb_2O_9$ becomes moderately sensitive to a loss of BaO. In air, the surface of the $Ba_4Nb_2O_9$ grains decomposes to nano-crystalline $Ba_5Nb_4O_{15}$ and BaO, which instantly reacts with atmospheric CO_2 to form $BaCO_3$. Surface reaction delays the α ⇒ γ transformation up to 866 °C in air. In vacuum the loss of BaO is even more enhanced and consequently the formation of minor $Ba_3Nb_2O_8$ phase is observed above 1150 °C.

In another study, $Ba_4Nb_2O_9$ was shown to have two basic polymorphs: a high-temperature γ phase, which represents a differing structure type and a low-temperature α phase, which has the rare $Sr_4Ru_2O_9$ structure type. The phases can be rearranged into one or the other by a reconstructive phase transition close to 1370 K. The kinetics is sufficiently slow that the γ phase can easily be quenched to room temperature. Below 950 K, both α and γ phases absorb significant amounts of water. In the case of the γ phase, protons from absorbed water occupy ordered positions in the structure, giving rise to a stoichiometric phase, γ-III-$Ba_4Nb_2O_9 \cdot 1/3H_2O$, at room temperature. γ-III-$Ba_4Nb_2O_9 \cdot 1/3H_2O$ partially dehydrates close to 760 K to give another stoichiometric phase γ-II-$Ba_4Nb_2O_9 \cdot 1/3H_2O$, which completely dehydrates at 950 K to γ-I-$Ba_4Nb_2O_9$. The hydrated γ phases exhibit faster protonic and oxide ionic transport than the hydrated α phases because of the presence in the γ phases of 2D layers containing Nb^{5+} cations with unusually low oxygen coordination numbers (4 or 5) separated by discrete OH groups. Hydration appears to play an important role in stabilizing the γ phases at low temperatures, and the γ ⇔ α transition caused by reheating a quenched sample occurring at a higher temperature in humid atmospheres.

The structure of γ-$Ba_4Nb_2O_9$, having the $Sr_4Ru_2O_9$ structure is shown in the following diagram Fig. 9.84.

In addition to being sensitive to moisture adsorption, this compound also absorbs CO_2. Powder XRD, HRTEM, ED, IR, TG and mass spectroscopy (MS) were performed to investigate the composition and the crystal structure of tetra-barium niobate (V) $Ba_4Nb_2O_9$. The TG, MS and IR studies revealed that the compound is a hydrated oxycarbonate. Assuming that the carbonate

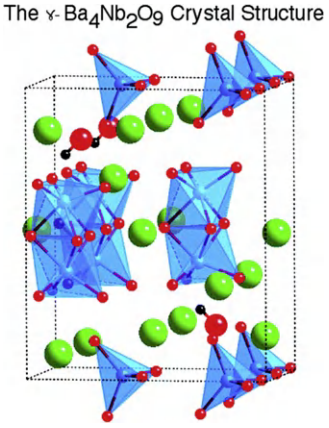

FIGURE 9.84

stoichiometrically replaces oxygen, it was found that the composition of the low-temperature α-modification, obtained by slow cooling from 1100 °C, corresponds to $Ba_4Nb_2O_{8.8}(CO_3)_{0.2} \cdot 0.1H_2O$, while the quenched high-temperature γ-modification has the $Ba_4Nb_2O_{8.42}(CO_3)_{0.58} \cdot 0.38H_2O$ composition. The α-phase has an incommensurately composite-modulated structure consisting of two mutually interacting $[Ba]_\infty$ and the $[(Nb,)O_3]_\infty$ subsystems (where the vacancy is clearly seen). The composite-modulated crystal structure of the α-phase can be described with the lattice parameters $a = 10.2688$ Å, $c = 2.82426$ Å, $q = 0.66774c^*$ and a superspace group $R\bar{3}m(00\gamma)0s$. The HRTEM analysis demonstrates the nanoscale twinning of the trigonal domains parallel to the {100} crystallographic planes. The twinning introduces a one-dimensional disorder into the $[(Nb,)O_3]_\infty$ subsystem, which results in an average $P62c$ crystal structure of the α-phase. Possible places for the carbonate group in the structure were discussed using a comparison with other hexagonal perovskite-based oxycarbonates. It has been concluded that the preparation of $Ba_4Nb_2O_9$ from the oxides in air does not result in the anhydrous compound but cools to a perovskite-based hydroxy-carbonate.

The polymorphic phase transitions and the stability of the individual polymorphs of tetra-barium niobate ($Ba_4Nb_2O_9$) were studied at different temperatures. $Ba_4Nb_2O_9$ ceramics were prepared via a conventional solid-state reaction route. Three $Ba_4Nb_2O_9$ polymorphs were isolated. These include a hexagonal (α) and two orthorhombic (β, γ) modifications. TEM revealed an intergranular BaO-rich amorphous phase and nano-crystalline $Ba_5Nb_4O_{15}$ in all the polymorphs, most abundantly in the α-modification. Superstructure ordering in the γ-modification was confirmed by ED methods. The α-$Ba_4Nb_2O_9$ was observed to be stable in the temperature range 560–1160 °C; below 560 °C the stable polymorph is β-$Ba_4Nb_2O_9$, while above 1160 °C the only stable polymorph is γ-$Ba_4Nb_2O_9$.

Other than phase-transitions and structural data, little information concerning these compounds has appeared in the scientific or technical literature.

The structure of the compound, **barium tri-niobate**, $BaNb_6O_{16}$, has the cell parameters of: $a = 3.98$ Å, $b = 12.47$ Å, $c = 19.72$ Å, $\alpha = 107.44°$, $\beta = \gamma = 90°$, cell volume $= 92.74$ Å^3. An exact structure has not been published. This compound appears as a reaction product of the oxides at high temperatures but does not appear to be stable at room temperature. When the sintering temperature was 1400 °C, a homogeneous phase with a 1:3 ordered structure was found in the specimens. At lower temperatures, a disordered structure and $BaNb_6O_{16}$ second phase were found. The main phase of this system was a cubic perovskite with a small quantity of a second phase like $Ba_5Nb_4O_{15}$, as determined by XRD analysis.

The 5:6 compound, **penta-barium hexa-niobate**, $Ba_5Nb_{12}O_{35}$, has the cell parameters of: $a = 3.878$ Å, $b = 20.86$ Å, $c = 36.27$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 2{,}934.04$ Å^3. As with other compounds in this series, the exact structure published is subject to question and is not included here. It is cubic with a complicated structure.

The existence of the compound, **tri-barium penta-niobate**, $Ba_3Nb_{10}O_{28}$, is doubtful. No structural data is available nor are any descriptions of its chemical or physical properties appeared in the scientific literature. Yet, this compound is listed as a component in a ternary phase diagram. The only known compound similar to this composition is $BaNb_4O_6$, which contains Nb^{3+} and Nb^{4+}ions. Although the compound, $Ba_3Nb_{10}O_{28}$, is listed in the phase diagram, no information is available in the scientific or technical literature. It is said to be tetragonal and have the tetragonal tungsten–bronze structure. However, specific data is not available in the scientific or technical literature.

The compound, barium di-niobate, $BaNb_4O_{11}$ has the structure shown as follows in Fig. 9.85.

Cell parameters are: $a = b = 3.182$ Å, $c = 8.212$ Å, $\alpha = \beta = \gamma = 90°$, cell volume is 143.62 Å^3.

Cell occupancy is shown in Table 9.46.

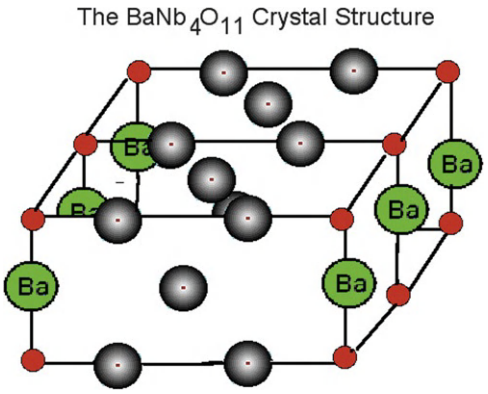

FIGURE 9.85

Little information is available for this compound other than its structure. $BaNb_4O_{11}$ has not been thoroughly studied and little to no data can be found in the open literature.

The compound, **hexa-barium niobate**, $Ba_6Nb_2O_{11}$, has been found to form oxygen-vacancy lattices as well as stoichiometric ones. The perovskite-related phases, $Ba_6Nb_2O_{11}(V_o^s)_1$ and $Ba_4Ca_2Nb_2O_{11}$, where V_o^s stands for "oxygen structural vacancies", have been studied by TG, AC-conductivity and IR and/or RS. A correlation between water uptake and nominal V_o^s concentrations was established, but it was determined that the nature of the alkaline earth metal atom influences the oxygen sub-lattice: $Ba_6Nb_2O_{11}(V_o^s)_1$ has zero water uptake. The relationship between short-range disorder and water uptake is clear; only compounds having a strong oxygen and cation lattice disorder exhibit maximal water uptake. In $Ba_4Ca_2Nb_2O_{11}$, the protonic species change during cooling–heating.

Single crystals of $BaNb_4O_6$ (I) and $Ba_2Nb_5O_9$ (II), containing Nb in various valence states, have been prepared by heating pellets containing $Ba_5Nb_4O_{15}$, NbO_2, Nb_2O_3 Nb (Ba:Nb:O = 1:7:9 for I and 4:14:23 for II) together with 10% BaF_2 as a mineralizer for 24 h in a sealed niobium ampoule at 1600 °C. The crystal structures of I and II were refined using single-crystal data (CAD 4: I, 128 unique reflections, $R = 1.91\%$, $R_w = 1.70\%$, **II**, 223

TABLE 9.46

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O(2)	O	4	i	2mm.	0	1/2	0.2431	1.0
2	Nb(2)	Nb	2	g	4mm	0	0	0.2531	1.0
3	Nb(1)	Nb	2	e	mmm.	0	1/2	1/2	1.0
4	O(1)	O	1	d	4/mmm	1/2	1/2	1/2	1.0
5	Ba	Ba	1	c	4/mmm	1/2	1/2	0	1.0
6	O(3)	O	1	a	4/mmm	0	0	0	1.0

unique reflections, $R = 2.75\%$, $R_w = 2.55\%$). I crystallizes in space group $P4/mmm$ with $a = 4.182$ Å and $c = 8.212$ Å and II in $P4/mmm$ with $a = 4.172$ Å and $c = 12.224$ Å. The atomic positions are slightly different from those previously obtained from powder data. The structures of I and II contain Nb_6O_{12} clusters linked to two-dimensional sheets and can be ascribed to terms of an intergrowth between slabs of perovskite- and NbO-type structures. I and II are metallic in conductivity and exhibit a weak temperature-independent paramagnetism.

A reduced barium niobate, $Ba_2Nb_5O_9$, has been found in the course of an investigation of the Ba–Nb–O system. It has been characterized by means of XRD and high resolution electron microscopy(HREM). The space group is $P4/mmm$ and its unit cell parameters are $a = 4.1696(2)$ and $c = 12.228$ Å. The structure that has been refined by profile fitting of XRD data is an ordered intergrowth between $BaNbO_3$ and NbO, giving rise to two-dimensional layers of corner-sharing octahedral Nb_6-clusters.

A new crystalline form, hitherto unsuspected in the $Ba_xSr_{1-x}Nb_2O_6$ solid-solution zone, has been found to exist for $x = 0.15$, 0.20, 0.25 and 0.29. It has a monoclinic symmetry and belongs to the $P21/a$ space-group. For $x = 0.29$ its lattice parameters are: $a = 10.997$ Å, $c = 5.666$ Å and $\gamma = 90°$ 30/100.

$Ba_{3-x}Sr_xLaNb_3O_{12}$ ($x = 0$ to 3) ceramics were prepared by the conventional solid-state reaction route. All of them adopt $A_4B_3O_{12}$ cation-deficient hexagonal perovskite structure. The substitution of Sr for Ba effectively enhances quality factor and modifies τ_f of $Ba_3LaNb_3O_{12}$. The $Q \times f$ value increases significantly from 16 000 to 45 327 GHz, τ_f improves from −96 to −9 ppm/°C and the dielectric constant (ε_r) varies gradually from 44.8 to 35.8 with the increase of Sr content.

Barium niobates are not used commercially and most of the scientific studies have concentrated upon mixed alkaline earth niobates, including addition of selected rare earths like La^{3+} and Ce^{3+}. Cobalt as Co^{3+} is also another additive that has received intense study in efforts designed to improve the dielectric properties of barium niobates for use in electrical-insulating layer structures in high-frequency capacitors and insulating layers in the construction of integrated circuits.

9.2.6. Radium Niobates

The high cost of Ra-metal and its intense radioactivity has precluded any investigation of any radium niobate compounds. Undoubtedly, the same type of compounds could be formed from RaO and Nb_2O_5 as those that exist in the BaO–Nb_2O_5 system. However, no data is known nor is any expected because of the lack of interest in Academia and Industry in such compounds.

9.3. ALKALINE EARTH TANTALUM COMPOUNDS

Tantalum has the valence states: 5, 4, 3, 2, −1, with the most important one being Ta^{5+}. Only the Ta^{4+} ion appears in the solid-state, the others appear in solution chemistry. Thus, the major system with the alkaline earths involves AeO–Ta_2O_5. Tantalum forms the same type of compounds, with almost identical crystal structures, as the niobates. Indeed, many of the published papers involve both the same type of compositions and the solid-state solution compositions that are formed.

9.3.1. Beryllium Tantalum Compounds

Beryllium does not form any oxygen-dominated tantalate compounds. But, it does form a series of intermetallic compounds similar to that of the Be–Nb system. The intermetallic phase diagram shows six (6) compounds, all of which melt congruently as shown in Fig. 9.86.

The structure factors are shown as follows in Table 9.47.

The structure types are varied. The $BeTa_2$ structure has the form as shown in Fig. 9.87.

The Ta-atoms form a distinctive pattern in the unit-cell. Cell parameters are: $a = 4.89$ Å, $b = c = 4.902$ Å, $\alpha = 75.6°$, $\beta = \gamma = 60.087°$, cell volume = 88.32 Å^3. Cell occupancy is shown in Table 9.48.

In contrast, the Be_2Ta structure has a different form as shown in Fig. 9.88.

A two-dimensional layer is shown. The three dimensional form is shown as well as the arrangement of the individual Be and Ta atoms along one plane of the structure. Here, the four (4) Ta-atoms have adopted a slightly different pattern in the cell, almost akin to an octahedral pattern. Cell parameters are: $a = b = c = 4.6011$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 68.88 Å^3.

Site occupancy is shown in Table 9.49.

The next compound in the series, Be_3Ta, has the structure as shown in Fig. 9.89.

Here, the Ta-atoms have adopted a slightly distorted Ta_5 pattern. Cell parameters are: $a = b = 4.53$ Å, $c = 7.457$ Å, $\alpha = \beta = 72.318°$, $\gamma = 80°$, cell volume = 124.11 Å^3. Cell occupancy is shown in Table 9.50.

The 2:3 compound, Be_2Ta_3, has the structure as shown in Fig. 9.90.

Where the Ta-atoms dominate the unit cell. Cell parameters are: $a = 3.32$ Å, $b = c = 6.52$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 140.27 Å^3. Cell occupancy is shown in Table 9.51.

When the Ta-atom content is low, as in $Be_{17}Ta_2$, the following structure results as shown in Fig. 9.91.

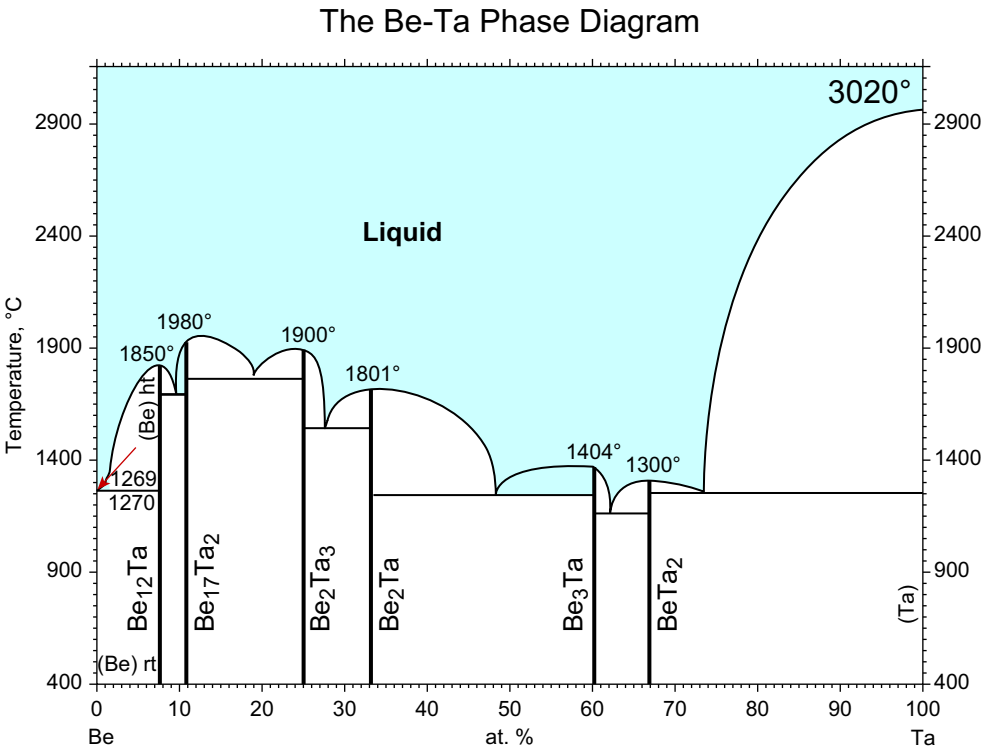

FIGURE 9.86

Note that the Ta-atoms are no longer connected in the unit cell. Cell parameters are: $a = b = c = 5.5687$ Å, $\alpha = \beta = \gamma = 83.112°$, cell volume = 169.23 Å^3. Cell occupation is shown in Table 9.52.

The final composition in the series is $Be_{12}Ta$, which has the structure as shown in Fig. 9.92.

Cell parameters are: $a = 4243$ Å, $b = c = 5.6129$ Å, $\alpha = 81.787°$, $\beta = \gamma = 67.792$ Å, cell volume = 114.58 Å^3. Cell occupancy is shown in Table 9.53.

There are no compounds formed within the BeO–Ta_2O_5 system.

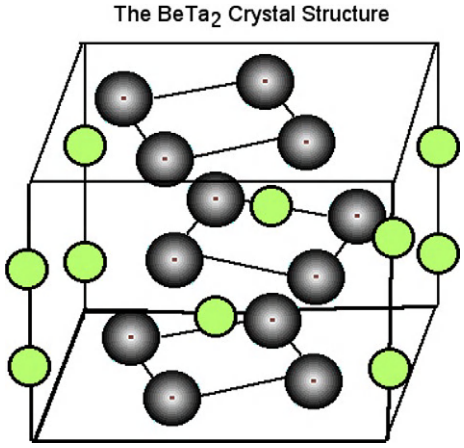

FIGURE 9.87

9.3.2. Magnesium Tantalum Compounds

The system Mg^0–Ta^0 does not form any intermetallic compounds.

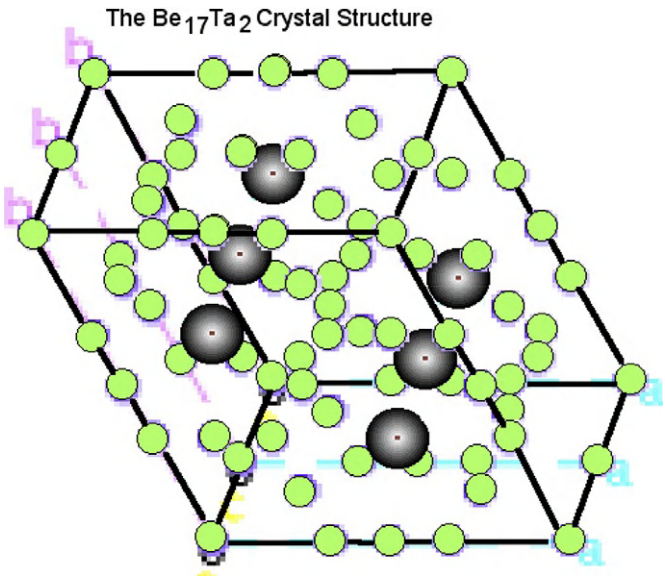

FIGURE 9.91

As stated above, the valence states of $Ta^{2+}$and Ta^{3+} are found only in solution.

The valence state of Ta^{4+} is extremely limited and no studies of synthesis have resulted in a xMgO-yTaO$_2$ compound of any sort.

The Ta^{5+} containing system MgO–Ta_2O_5 shows that MgO and Ta_2O_5 form three compounds: $Mg_4Ta_2O_9$, $Mg_3Ta_2O_8$, and $MgTa_2O_6$. $Mg_4Ta_2O_9$ and $MgTa_2O_6$ are stable up to their melting points, whereas $Mg_3Ta_2O_8$ is stable only between 1475° and about 1675 °C. XRD and density data have been presented for the three compounds as shown in Fig. 9.93.

The structure factors are shown in the following Table 9.54.

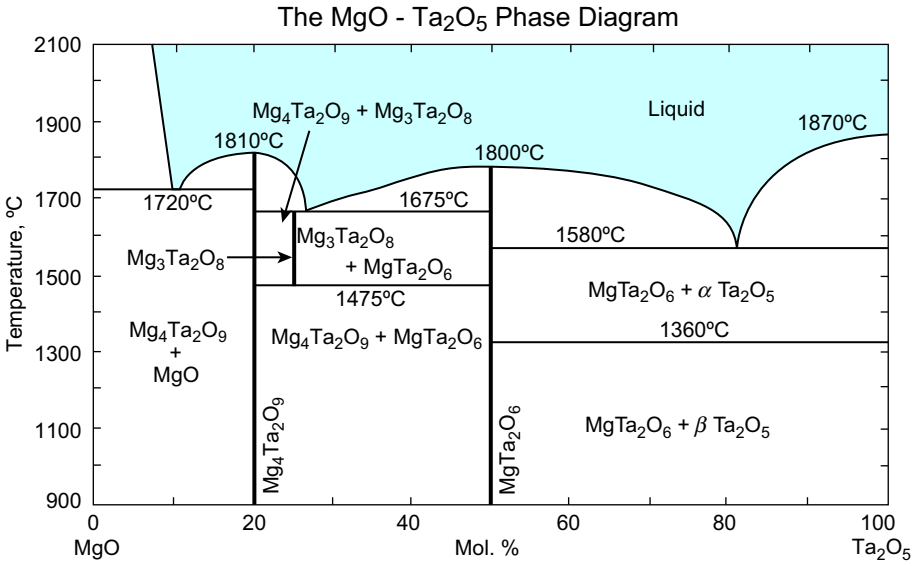

FIGURE 9.93

In one investigation, vapor-phase reactions were investigated using a solid MgO surface and thin-film solid-state reactions. In the system MgO–Nb_2O_5, MgO (001) substrates were subjected to Nb–O vapor at different temperatures in high vacuum. Thin films containing the phases $Mg_4Nb_2O_9$ and $MgNb_2O_6$ were formed by a vapor–solid reaction between the Nb–O vapor and the substrate. The crystallographic orientations of these phases were studied by XRD including pole figure analysis. $Mg_4Nb_2O_9$ grows (114)-, (116)-, and (119)-oriented, whereas $MgNb_2O_6$ grows with a preferential (241) orientation.

The **tetramagnesium tantalate**, hP30 type, has the structure as shown in Fig. 9.94.

The positions of Mg^{2+} in the structure are shown as well as the positions of the octahedra and the tilting of each to the other. Cell parameters are: $a = b = 5.1611$ Å, $c = 14.0435$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 323.96 Å^3. Cell occupancy is shown in Table 9.55.

Its dielectric behavior is shown in the following diagram, presented on the next page as Fig. 9.95.

Another view of the tetra-magnesium tantalate structure is shown in Fig. 9.96.

Single crystals of (A) $Mg_4Ta_2O_9$ and (B) $Mg_2Ni_2Ta_2O_9$ were prepared by recrystallization of a CO_2-Laser-beam heated flux. Single crystal X-ray structure analysis lead to a trigonal symmetry, space group *D-P3c*1 with: $a = 5.1654$; $c = 14.0463$ Å; B: $a = 5.1362$; $c = 14.0577$ Å; $Z = 2$. Both compounds crystallize with a corundum related structure type. In B, the metal positions are occupied statistically by Mg^{2+} and Ni^{2+}.

$MgTa_2O_6$ has the structure as shown in Fig. 9.97.

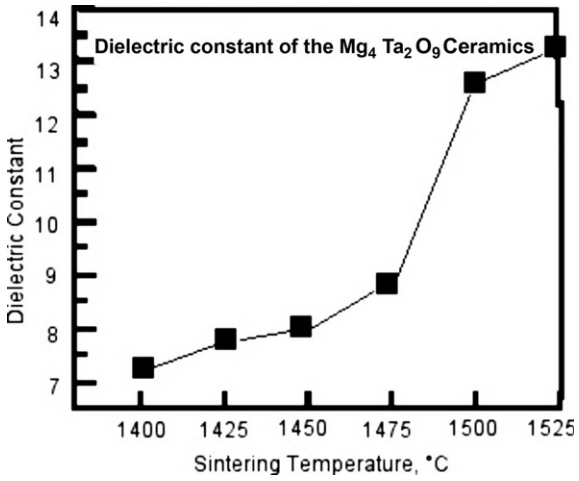

FIGURE 9.95

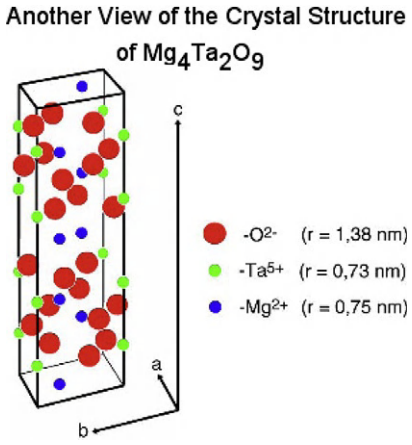

FIGURE 9.96

This is a layered structure. Cell parameters are: $a = b = 4.72$ Å, $c = 9.22$ Å, $\alpha = \beta = \gamma = 90\pm°$, cell volume = 205.71 Å^3. Cell occupancy is shown in Table 9.56.

Two different chemical methods have been applied to prepare $MgTa_2O_6$ (MT_2) and $Mg_4Ta_2O_9$ (M_4T_2) powders. A gel was formed when an aqueous solution of $Mg(NO_3)_2$, TaF_5 and citric acid in stoichiometric ratio is heated on a water bath. This gel on decomposition at 750 °C produced the fine crystallites of a binary oxide, M_4T_2. A simple co-precipitation technique was also successfully applied for the preparation of pure ultrafine single phase MT_2. Ammonium hydroxide was used to precipitate Mg^{2+} and Ta^{5+} cations as hydroxides simultaneously. This precursor, on heating at 750 °C, produces MT_2 powders.

$MgTa_2O_6$ is an interesting dielectric material and has uses in the microwave frequency range. It has been reported to crystallize in the trirutile structure with space group of $P42/mnm$ and tetragonal lattice parameters of $a = 4.7189$ Å and $c = 9.2003$ Å. The structure is made up of strings of edge-shared octahedra, extending along the 'c' direction and these strings are linked to

TABLE 9.55

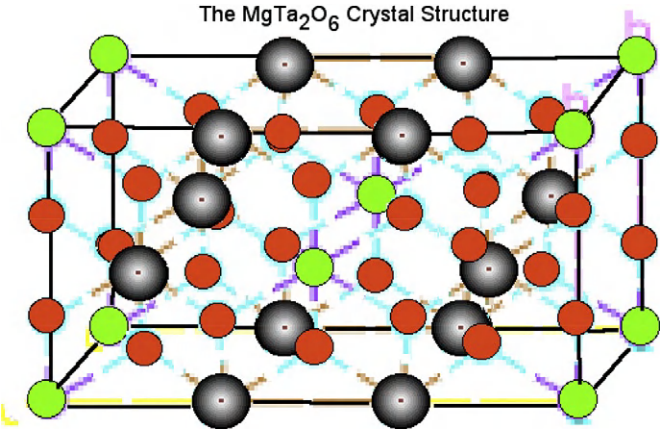

FIGURE 9.97

each other by sharing corners. The edge-sharing occurs at opposite edges in each octahedron and leads to linear octahedral strings in the trirutile structure. Normally the synthesis of $MgTa_2O_6$ by the ceramic route is carried out at high temperatures of 1200 °C to 1400 °C. This structure can be obtained by the ceramic route by heating $Mg(NO_3)_2 \cdot 6H_2O$ and Ta_2O_5 at temperatures of 1200 °C. It may be noted that using MgO as the starting material leads to a biphasic mixtures of $MgTa_2O_6$ and Ta_2O_5 at 1200 °C. The trirutile structure of tetragonal $MgTa_2O_6$ is made up of strings of edge-shared octahedra, extending along the '*c*' direction and these strings are linked to one another by sharing corners. Edge-sharing occurs at opposite edges in each octahedron and leads to linear octahedral strings extending infinitely.

The phase relation in the BaO–MgO–Ta_2O_5 system equilibrated at 1450 °C was reported. Three ternary phases, namely 3:1:1 perovskite $Ba_3MgTa_2O_9$, 9:1:7 TTB (tetragonal tungsten bronze)-type $Ba_9MgTa_{14}O_{45}$ and 4:1:5 $Ba_4MgTa_{10}O_{30}$ closely related to the tungsten bronze structure. Another ternary phase, $Ba_{10}Mg_{0.25}Ta_{7.9}O_{30}$, with a 10 layer hexagonal perovskite structure can be only obtained after equilibration at 1600 °C. MgO solubility in the TTB-like $Ba_4Ta_{10}O_{29}$, $BaTa_4O_{11}$ and $Ba_{6.63}Ta_{34.95}O_{95}$ does not exceed 2.0 mol%. Only the hexagonal polymorph of the $BaTa_2O_6$ phase was found along the $Mg_4Ta_2O_9$–$BaTa_2O_6$ join. Measurements of dielectric properties in the 20 Hz–2 MHz range revealed that $Ba_9MgTa_{14}O_{45}$ has a dielectric constant of 99 with no frequency dispersion and low dielectric loss. The authors also claimed that they had clarified several contradictory reports related to the ternary and binary phases in the BaO–MgO–Ta_2O_5 composition field.

A compound with the formula, $Mg_4Ta_6O_{19} \cdot 9H_2O$, reported in 1893, was obtained by precipitation from solution, using $Na_8Ta_6O_{19}$ and $MgCl_2$. The material was said to be amorphous and gelatinous but has never been confirmed.

The compound, $Mg_5Ta_4O_{15}$, does not appear in the phase diagram but has been studied extensively. The crystal structure of the isomorphous phases $Mg_5Nb_4O_{15}$ and $Mg_5Ta_4O_{15}$ was refined from neutron powder diffraction data. These compounds are isostructural with pseudobrookite, Fe_2TiO_5. The two kinds of metal sites of this structure are randomly occupied by Mg(II) and Nb(V) or Ta(V). The structure consists of double chains of $(Mg,M)O_6$ units (where M = Nb or Ta), sharing edges on the *bc* plane, interconnected through common oxygen atoms along the *a* axis to give a three-dimensional array. The $(Mg, M)O_6$ polyhedra at both metal positions can be described as exceptionally distorted octahedra, with (Mg, M)–O distances ranging from 1.93 to 2.22 Å. The crystallographic formulas can be written as $(Mg_{0.73(2)}Nb_{0.27(2)})_{4c}(Mg_{0.94(2)}Nb_{1.06(2)})_{8f}O$ and $(Mg_{0.66(2)}Ta_{0.34(2)})_{4c}(Mg_{1.01(2)}Ta_{0.99(2)})_{8f}O_5$ respectively, where 4*c* and 8*f* are the Wyckoff sites of the two metal positions of the structure. The space group is *Cmcm* (orthorhombic) and $Z = 4$. Unit cell parameters, cell volume, R_{wp} and *R*, values obtained were $a = 3.8068$ Å, $b = 10.0561$ Å, $c = 10.2566$ Å, $V = 392.64$ Å^3, and 6.72% and 2.94% for the niobium compound; and $a = 3.81884$ Å, $b = 10.0574$ Å, $c = 10.2343$ Å, $V = 393.07$ Å^3, and 4.46%, and 2.36% for the tantalum compound, third and the fourth layers. The crystal structure of $Mg_5Ta_4O_{15}$ is completely different from similar Ca, Sr or Ba compounds and is isostructural with pseudobrookite Fe_2TiO_5. The space group is orthorhombic D_{2h}, *Cmcm* with $Z = 4$. The structure consists of double chains of $(Mg,Ta)O_6$ units, sharing edges of the *bc* plane,

TABLE 9.56

No	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O1	O	8	j	..m	0.297	0.297	0.322	1.0

interconnected through common oxygen along the *a* axis to give a three-dimensional array.

In another study, the structural and microwave dielectric properties of the various $Mg_5Ta_4O_{15}$ ceramics were investigated. The ceramics were prepared by the solid-state ceramic route. Specimens sintered at a temperature of 1400° ~ 1450 °C formed both the $Mg_4Ta_2O_9$ phase and $MgTa_2O_6$ phase. In another range of sintering temperatures, the $Mg_5Ta_4O_{15}$ phase appeared. Bulk density and quality factor were increased with sintering temperature in 1400° ~ 1450 °C, but these were decreased in the range of 1475° ~ 1500 °C. Dielectric constant was increased continuously by increasing the sintering temperature. In the case of the $Mg_5Ta_4O_{15}$ ceramics sintered at 1450 °C for 5 h, the dielectric constant, ε_r, quality factor, τ_f, and temperature coefficient, $Q \times f$, of the resonant frequency were 8.2, 259,473 GHz and −10.91 ppm/°C, respectively. $MgTa_2O_6$ as a secondary phase in $Mg_5Ta_4O_{15}$ caused an increase in ε_r and the positive τ_f of $MgTa_2O_6$ favorably shifts the τ_f of the nonhomogeneous $Mg_5Ta_4O_{15}$ to 17 ppm/°C according to the mixing rule. $MgTa_2O_6$ has $\varepsilon_r = 21.4$, $Q \times f = 93{,}800$ GHz, and $\tau_f = 70$ ppm/°C. Again, the presence of $MgTa_2O_6$ as the secondary phase in $Mg_5Ta_4O_{15}$ is the reason for the increased ε_r, $Q \times f$, and τ_f of the $Mg_5Ta_4O_{15}$ prepared using the raw MgO. $Mg_5Nb_4O_{15}$ is stable above 1400 °C and $Mg_5Ta_4O_{15}$ above 1475 °C.

The compound, di-magnesium tantalate, $Mg_2Ta_2O_7$, is also known. $Mg_2Ta_2O_7$ crystallizes in the cubic pyrochlore structure and is stable in the temperature range from 1400 °C to its melting point. The phase formation in the $Mg_2Ta_2O_7$–Nd_3TaO_7 system in the temperature range from 1300 °C to the melting point has been studied. The formation of $Mg_2Ta_2O_7$-based cubic solid solutions extending to 35-mol% Nd_3TaO_7 has been established. A phase of varying composition with a fluorite-like structure stable to 1500–1550 °C in the concentration range of 43 to 67 mol% Nd_3TaO_7 has also been identified.

Magnesium tantalate is available commercially with the CAS number of 206991-05-1. However, it is described as $Mg_2Ta_2O_7$, even though such a compound has not been characterized crystallographically.

9.3.3. Calcium Tantalum Compounds

Calcium (Ca^0) does not form any metallographic compounds with the metal Ta^0.

No compounds are known in the Ta^{2+} or Ta^{3+} containing systems of CaO–TaO_2 or CaO–Ta_2O_3.

In the Ta^{4+} system of CaO–TaO_2, the compound, $CaTa_2O_5$ has been observed. The reduction of Ta_2O_5 in molten $CaCl_2$ at about 950 °C first forms the stable compounds, $CaTa_2O_4$ and $CaTa_4O_{11}$ during the reaction of the reduced phase, TaO_2 and the Ca^{2+} ion. These compounds are then further reduced to TaO or δ-TaO to form metal particles of ~300 nm in size. The current efficiency and energy consumption was ~78% and ~2.4 kWh/kg of Ta produced. Oxygen content was about 1200 ppm. The specific capacitance of the Ta-powder was about 40 kμFV/g. No attempt was made to isolate these compounds and no structural determinations have been made.

The Ta^{5+}-containing system, CaO–Ta_2O_5, is known to form four (4) compounds. A phase diagram for the CaO–Ta_2O_5 binary system has been plotted from results obtained using sub-solidus sintering, DTA, hot-stage microscopy and an iridium-strip furnace. The compound $CaO \cdot 2Ta_2O_5$ melts incongruently at 1730 °C and the compounds β-CaO Ta_2O_5 and $2CaO \cdot Ta_2O_5$ melt congruently at 1958° and 1896 °C, respectively. The $\alpha \Rightarrow$ β-$CaO \cdot Ta_2O_5$ polymorphic transition occurs at 1558 ± 5 °C. X-ray data were given for two previously unreported calcium tantalates having the stoichiometric compositions $4CaO \cdot Ta_2O_5$ and $5CaO \cdot Ta_2O_5$, respectively. These two compounds formed a solid-solution area in the phase diagram at temperatures above 1590 °C and this single-phase region is postulated to terminate at 1990 °C, i.e., the incongruent melting point of $4CaO \cdot Ta_2O_5$. The phase diagram is shown as follows in Fig. 9.98.

Structure factors are shown in Table 9.57.

Calcium di-tantalate, $CaTa_4O_{11}$, has the structure as shown in Fig. 9.99.

Cell parameters are: $a = b = 6.215$ Å, $c = 12.226$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 401.31 Å^3. Cell occupancy is shown in Table 9.58.

Very little information is available concerning this compound other than its structure. It has not found usage in Industry nor has it been studied to any great extent.

Dicalcium tantalate, $Ca_2Ta_2O_7$, is polymorphic with existence of four modifications with slightly distorted pyrochlore structures and a high-temperature modification with a perovskite-type layer structure. The high temperature form has the structure as shown in Fig. 9.100.

Unit cell parameters are; $a = 3.86$ Å, $b = 5.52$ Å, $c = 13.51$ Å, $\alpha = \gamma = 90°$, $\beta = 98.16°$, cell volume = 283.22 Å^3. Cell occupancy is shown in Table 9.59.

One view of the low-temperature form of the structure is shown in Fig. 9.101, shown on the next page. It consists of TaO_6 octahedra attached at the corners to form an ordered three-dimensional structure in which the Ca^{2+} ions fit into the channels made by the rows of octahedra.

A better view of the high and low types of Weberite structures of $Ca_2Ta_2O_7$ is afforded in the Fig. 9.101.

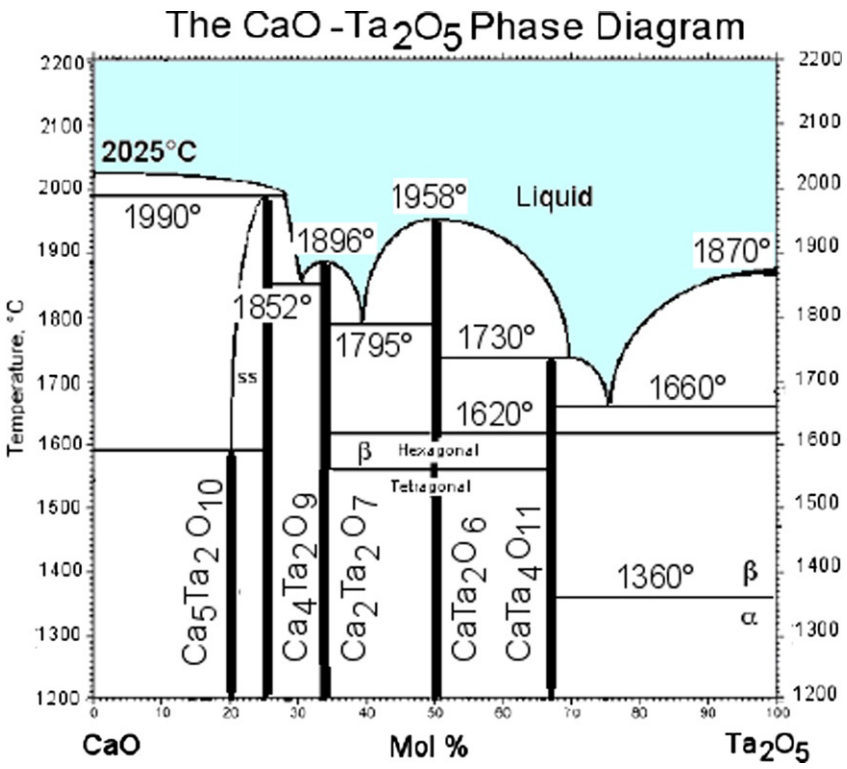

FIGURE 9.98

The main difference is that the niobate-type octahedra are tilted in respect to one-another whereas the tantalate octahedra are aligned perfectly as shown in Fig. 9.102.

Single crystals of the 8O hexagonal modification of $Ca_2Ta_2O_7$ were grown by an optical floating zone melting and their structure was solved by XRD. 8O-$Ca_2Ta_2O_7$ crystallizes in space group $C222_1$ with $a = 7.3690$ Å, $b = 12.7296$ Å, $c = 48.263$ Å. The structure is related to the weberite structure type and can be described as a stacking of 8 basic building units per unit cell. Each building unit consists of one Ta_3Ca and one Ca_3Ta layer with a cubic close packed arrangement.

Transmission measurements in the UV–Vis and IR regions of the spectrum revealed a high transparency in a wide energy range from 0.2–3.5 eV. Dielectric measurements yielded a high ε_r value of 60 at room temperature.

Two calcium tantalate polytypes have also been prepared in the system $Ca_2Ta_2O_7$–$Ca_2Nb_2O_7$. Their structures have been determined and refined using single-crystal XRD data and NPD data, and their dielectric properties have been measured in the 100 kHz to 10 GHz frequency range. The 7M polytype of pure $Ca_2Ta_2O_7$ has monoclinic symmetry with $a = 12.726$, $b = 7.380$, $c = 42.538$ Å, $\beta = 95.771°$, $Z = 28$, space group $C2$. The 7M $Ca_2Ta_{1.9}Nb_{0.1}O_7$ is isostructural, with $a = 12.7170$, $b = 7.3728$, $c = 42.464$ Å, $\beta = 95.755°$. The 5M $Ca_2Ta_{1.8}Nb_{0.2}O_7$ is monoclinic with $a = 12.7528$, $b = 7.3492$, $c = 30.2442$ Å, $\beta = 94.245°$, $Z = 20$, space group $C2$. The two polytypes have in common the closest packing of (001) metal atom layers that alternately have the composition Ca_3Ta and Ta_3Ca. The polytypes have mixed hexagonal-cubic stacking sequences of the metal atom layers: 7M = *hccccchccccccch*…, 5M = *hccchccccch*… The cubic-stacked blocks have weberite-type structures in both polytypes, in which

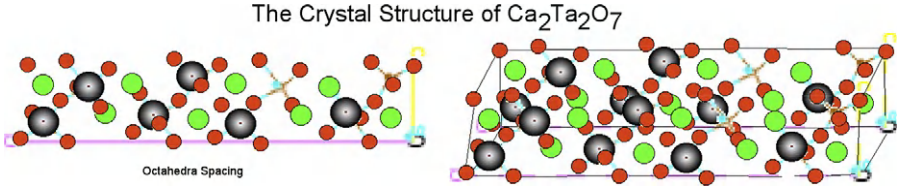

FIGURE 9.100

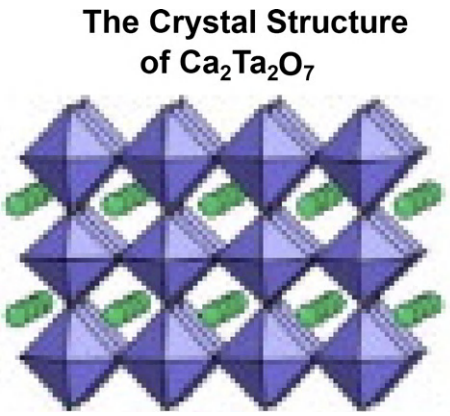

FIGURE 9.101

hexagonal tungsten bronze type layers of corner-connected octahedra are interconnected via corner linking to isolated TaO_6 octahedra in the Ca_3Ta layers to give a $[Ta_2O_7]^{4-}$ framework within which the eight-coordinated calcium atoms are distributed. The polytypes display a broad resonance at about 8 GHz, with relative permittivities of 25 and with $Q \times f$ values of about 200.

The weberite structure ($A_2B_2X_7$) is an anion-deficient fluorite related superstructure. Compared with fluorites, the reduction in the number of anions leads to a decrease in the coordination number of the B cations (VI coordination) with respect to the *A* cations (VIII coordination), thus allowing the accommodation of diverse cations. As a result, weberite compounds have a broad range of chemical and physical properties and great technological potential. $Ca_2Ta_2O_7$-based compounds are important in the weberite family since for N >4, only $Ca_2Ta_2O_7$-based compounds have been reported.

The "B-chains" are illustrated in the diagram shown in Fig. 9.103.

It has been shown that $Ca_2Ta_2O_7$ compounds can crystallize into 3T, 4M, 5M, 6T, 6M and 7M forms by using different doping or synthesis methods. It was also shown that an 8ϕ $Ca_2Ta_2O_7$ single crystal could be grown by using the optical floating zone method.

It is important to note that the close-packed cation layers are stacked the same as fcc (face-centered cubic) stacking in which the stacking sequence is ABCABC… in 2ϕ, 2M, 3T, 4M and 6T polytypes. The cation layers in 5M, 6M, 7M and 8ϕ polytypes ($Ca_2Ta_2O_7$-based compounds) are a mixture of cubic stacking and hexagonal stacking. The hexagonal stacking layers act as mirror glide planes for the cations, for example, the stacking sequence of 5M is *ABCACBACAB* in a unit cell (the underline letters indicate a hexagonal stacking). Therefore, 5M, 6M, 7M and 8ϕ polytypes are not pure weberite. The weberite-blocks are separated by h-stacking layers. A simpler approach is to describe the stacking of *c* as cubic and *h* as hexagonal. The stacking sequence is *ccchccchcc* for 5M [simplified as (3*c*)*h*(3*c*) *h*(2*c*), the integers indicating the number of *c* stacking layers], (5*c*)*h*(5*c*)*h* for 6M, (5*c*)*h*(7*c*)h for 7M and (4*c*) *h*(7*c*)*h*(3*c*) for 8ϕ.

A significant difference between 2ϕ and non-2ϕ weberites is that the AB3 and A3B layers are parallel to the (011) planes for 2ϕ and parallel to the (001) planes for other weberites, The lattice parameter difference between 2M, 4M, 5M, 6M and 7M is mainly on the c axis. The lattice parameters for *n*M ($n = 2$, 4, 5 and 7) are approximately $6_{1/2}$a, $2_{1/2}$a and $[n(6)_{1/2}/2]$a and they are nearly $2_{1/2}$a, $6_{1/2}$a and $3(6)_{1/2}$/a for 6M. The 8ϕ weberite is closely related to a monoclinic variant rather than 2ϕ in both the orientations of the AB_3 and A_3B layers and the lattice parameters. The lattice parameters are nearly $2_{1/2}$a, $6_{1/2}$a and $4(6)_{1/2}$/a. As for 3T, the [100], [0.5, 0.5, 0.5] and [012] vectors in 2ϕ are transformed into the basal vectors. The resulting lattice parameters are approximately $2_{1/2}$a, $2_{1/2}$a and $2(3)_{1/2}$a.

The 7M polytype of pure $Ca_2Ta_2O_7$ has monoclinic symmetry with $a = 12.726$, $b = 7.380$, $c = 42.538$ Å, $\beta = 95.77°$, $Z = 28$, space group *C*2. The 5M $Ca_2Ta_2O_7$ is monoclinic with $a = 12.7528(4)$, $b = 7.3492(2)$, $c = 30.2442(8)$ Å, $\beta = 94.245(2)°$, $Z = 20$, space group *C*2. The two polytypes have in common a close packing of

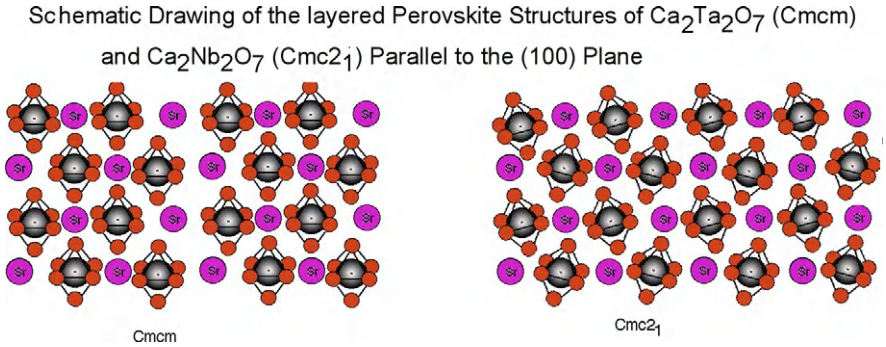

FIGURE 9.102

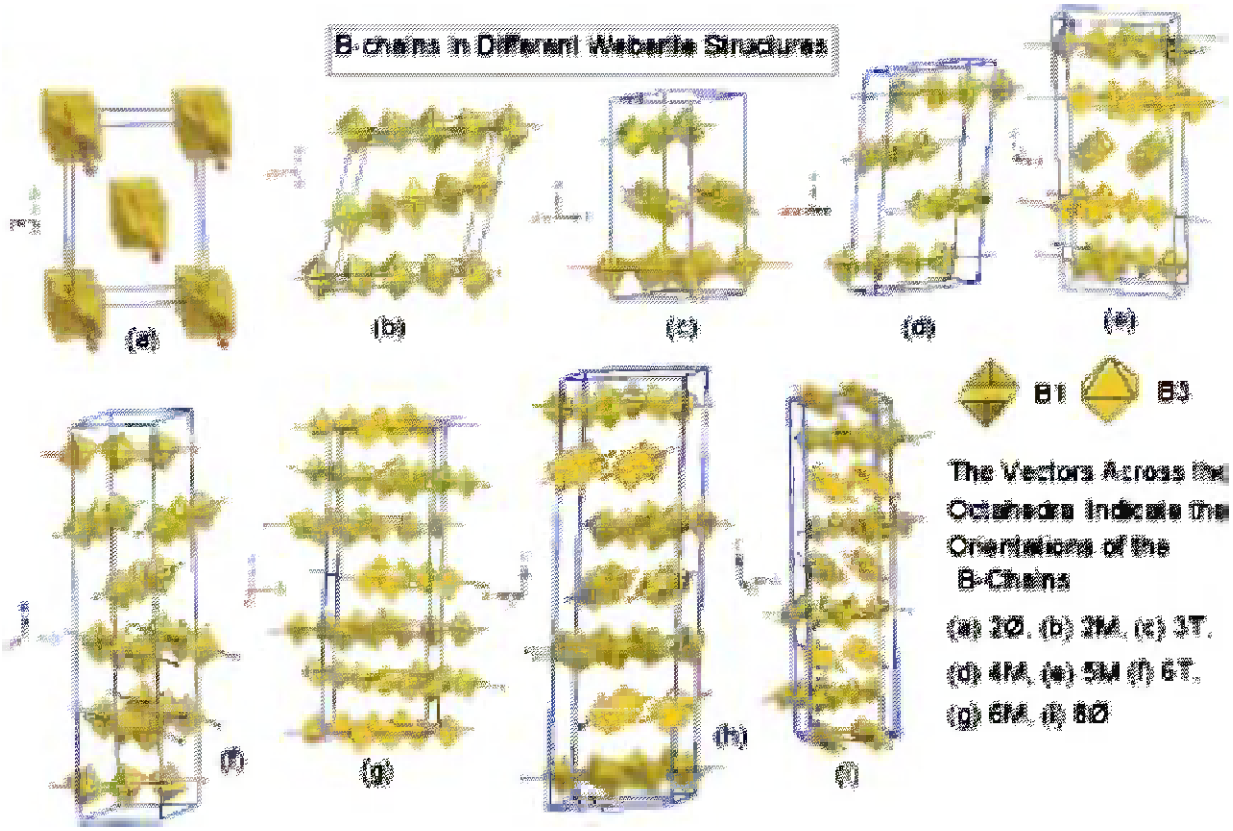

FIGURE 9.103

(001) metal atom layers that alternately have the composition Ca_3Ta and Ta_3Ca. These polytypes have mixed hexagonal-cubic stacking sequences of the metal atom layers: 7M = *hccccchccccccch*…, 5M = *hccchccccch*…. The cubic-stacked blocks have weberite-type structures in both polytypes, in which hexagonal tungsten bronze type layers of corner-connected octahedra are interconnected via corner linking to isolated TaO_6 octahedra in the Ca_3Ta layers to give a $[Ta_2O_7]^{4-}$ framework within which the eight-coordinated calcium atoms are distributed. The polytypes display a broad resonance at about 8 GHz, with relative permittivities of 25 and with Q values of about 200.

The mixed metal oxides $Ca_2B_2O_7$ (B = Nb, Ta) have been synthesized with the pyrochlore structure. The oxides were prepared by hydrolysis of Nb and Ta alkoxides and subsequent crystallization in the presence of the divalent cation in alkaline solution at temperatures up to 100 °C. The reactions yield crystalline phases directly, though with small particle size and high-surface area. The pyrochlore oxide $Ca_2B_2O_7$ was also found to undergo ion exchange in acid under mild conditions to form the hydrated oxide $HnbO_3 \cdot xH_2O$, also with small particle size and high-surface area. Confirmation of the structures of $Ca_2Nb_2O_7$ and $HnbO_3 \cdot xH_2O$ was obtained by Rietveld analysis of the XRD data.

New calcium tantalate polytypes with weberite-related structures have been prepared by doping $Ca_2Ta_2O_7$ with $Sm_2Ti_2O_7$. Trigonal 6-layer (6T) and monoclinic 5-layer (5M) polytypes containing 6 and 10 mol%, respectively of the $Sm_2Ti_2O_7$ component were prepared and the structures were determined and refined using X-ray data on flux-grown single crystals. The 6T phase, $Ca_{1.89}Ta_{1.86}Sm_{0.16}Ti_{0.10}O_7$, has $a = 7.353(1)$, $c = 36.264(1)$ Å, $Z = 12$, space group $P3_1$, and the 5M phase, $Ca_{1.80}Ta_{1.80}Sm_{0.24}Ti_{0.17}O_7$, has $a = 12.763$, $b = 7.310$, $c = 30.190$ Å, $\beta = 94.09°$, $Z = 20$, space group $C2$. The 6T structure is related to the 3T weberite structure, having a cubic close packed metal atom array as in fluorite and a stacking of (001) metal atom layers ($\{111\}_f$) that alternately have the composition Ta_3Ca and Ca_3Ta. Hexagonal tungsten bronze type layers of corner-connected octahedra are interconnected by isolated TaO_6 octahedra in the Ca_3Ta layers, giving an octahedral framework of composition $[Ta_2O_7]^{4-}$ in which the eight-coordinated calcium atoms are distributed. The octahedra in the Ca_3Ta layers have only four anions involved in corner sharing. The different weberite polytypes are distinguished by the geometry of the

two terminal anions, cis- or trans. In the 6T structure there is an alternation of cis- and trans- octahedra in successive Ca_3Ta layers. The 5M polytype differs from the weberite polytypes in having regular twinning of the metal atom lattice on (001), giving a stacking sequence *hccchccccc*…. The *c*-stacked blocks alternatively have the weberite and pyrochlore structures, with ordering of Sm into the Ca sites in the pyrochlore blocks.

In another study, single crystals of the 8O modification of $Ca_2Ta_2O_7$ were grown by an optical floating zone melting and their structure was solved by XRD. 8O $Ca_2Ta_2O_7$ crystallizes in space group $C222_1$ with $a = 7.3690$ Å, $b = 12.7296$ Å, $c = 48.263$ Å. The structure is related to the weberite structure type and can be described as a stacking of eight basic building units per unit cell. Each building unit consists of one Ta_3Ca and one Ca_3Ta layer with a cubic close packed arrangement. Transmission measurements in the UV–Vis and IR region reveal a high transparency in a wide energy range from 0.2–3.5 eV. Dielectric measurements yield a high ε_r value of 60 at room temperature.

New weberite-type $Ca_2Ta_2O_7$ polytypes have been prepared by doping with Nd/Zr respectively. Their structures have been refined using single crystal XRD intensity data. The 4M $Ca_2Ta_2O_7$ polytype has approximately the same composition, from microprobe analyses, as the 3T polytype, with the refined formula of $Ca_{l.92}Ta^{Nd}_{l.92O.08}Zr_{O.08}0_7$ The cell parameters are $a = 12.761$, $b = 7.358$, $c = 24.565$ Å, $\beta = 100.17°$, space group = $C2$, $Z = 16$. $Ca_2Ta_2O_7$ weberite-type polytypes maintain a fluorite-like fcc packing of metal atoms; the fluorite-type topology of edge-shared OM_4 tetrahedra is not maintained. One of the oxygen atoms moves from a tetrahedral Ta_3Ca interstice to an adjacent Ta_2Ca_4 octahedral interstice.

It has been determined that the structure of pure $Ca_2Ta_2O_7$ is 3T weberite up to 1673 K, where it transforms to the 7M polytype. The structure can be easily modified by doping different synthesis routines. One of the most interesting dielectric properties of $Ca_2Ta_2O_7$ is that the temperature coefficient of the dielectric constant (TC″r) is 0 when mixing with 18-mol% of $Ca_2Ta_2O_7$, meeting the requirement for the application of microwave dielectrics. TC″r′ 0 can be easily understood because TC″r is negative for $Ca_2Ta_2O_7$ (444 ppm/K at 295 K) and positive for $Ca_2Nb_2O_7$ (231 ppm/K at 295 K). Extensive studies on the structure of the $(1-x)$ $Ca_2Ta_2O_7 \cdot xCa_2Nb_2O_7$ system have been performed by powder and single-crystal XRD, and NPD. The system forms 7M weberite solid solutions up to $x = 0.1$ and $Ca_2Nb_2O_7$-type solid solutions from $x = 0.2$–1. When $x = 0.1$, the structure transforms into 5M. The solubility limit is reached when the substitution of $Ca_2Nb_2O_7$ increases to 15 mol% and $Ca_2Nb_2O_7$ forms as a second phase. The presence of $Ca_2Nb_2O_7$ thus results in TC″r compensation, making it approximately zero. Another interesting aspect is that most of the $(1-x)Ca_2Ta_2O_7 \cdot xCa_2Nb_2O_7$ compounds have higher dielectric constants (above 30) than pure $Ca_2Ta_2O_7$ and $Ca_2Nb_2O_7$ at 1 MHz. However, another set of published dielectric constants of 5M $Ca_2Ta_{1.8}Nb_{0.2}O_7$ and 7M $Ca_2Ta_{1.9}Nb_{0.1}O_7$ are approximately 18 and 20 at 1 MHz, respectively, which are lower than the previous publication. It is not clear what causes the discrepancy in dielectric constant measurement. It may be due to different firing conditions and measurement methods. Dielectric properties at radio frequency have also been investigated. The dielectric constants of 3T $Ca_{1.6}Nd_{0.4}Ta_{1.6}Zr_{0.4}O_7$, 5M $Ca_2Ta_{1.8}Nb_{0.2}O_7$ and 7M $Ca_2Ta_{1.9}Nb_{0.1}O_7$ are approximately stable (18–19) from 100 kHz up to 5 GHz and reach a maximum (22, 24.5 and 26.1, respectively) at 8 GHz. The dielectric constant is comparable for some important microwave dielectrics, such as $BaMg_{1/3}Ta_{2/3}O_3$ (~24). However, the problem with these systems is that they have low quality factors ($Q \times f \sim 200$) for technical applications. It is interesting to see that 8O $Ca_2Ta_2O_7$, which is synthesized by the optical floating zone melting method from 3T $Ca_2Ta_2O_7$ powder, has a relatively high dielectric constant (~60) at room temperature. And ε_r increases to 90 at 50 K. The high dielectric constant may result from a net dipole created by the off-center Ta^{5+} in the TaO_6 octahedra of the Ca_3Ta layers. The shifting of Ta^{5+} also produces two short Ta–O bonds and two long Ta–O bonds, leading to the distortion of TaO_6 octahedra. The high dielectric constant and the ability to tailor it are interesting for scientific study and possible electronic applications. In addition, the crystallographic study of $Nd_2Zr_2O_7$ and $Sm_2Ti_2O_7$ doping $Ca_2Ta_2O_7$ has been conducted. The resulting phases include 3T, 4M, 5M and 6T weberites. The great structural flexibility of $Ca_2Ta_2O_7$-based compounds is interesting in a crystallographic study and may have potentials in several technical applications.

Mono-calcium tantalate, $CaTa_2O_6$, is dimorphic. The high temperature form, β-$CaTa_2O_6$ has the structure shown as follows. Cell parameters are: $a = 5.37$ Å, $b = 7.501$ Å, $c = 11.071$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 445.94 Å^3 as shown in Fig. 9.104.

Cell occupancy is shown in Table 9.60.

Single crystals of cubic-$CaTa_2O_6$ were prepared with a CO_2-Laser-technique. X-ray investigations lead to a cubic symmetry (space group $Pm3T^1_h$, $a = 7.78$ Å, $Z = 4$). Ta^{5+} and O^{2-} occupy nearly the positions of these ions in the Perovskite structure. For this reason there is a similarity to $Ca_{0.5}TaO_3$. The decisive difference to the $Ca_{0.5}TaO_3$ is an ordered distribution of Ca^{2+} ions.

The low-temperature form, α-$CaTa_2O_6$, has the cubic perovskite structure with $a = b = c = 3.88$ Å. It exists

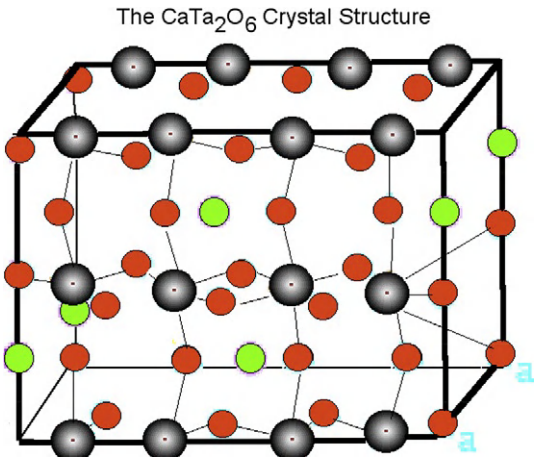

FIGURE 9.104

up to 1558 °C. Above this temperature, the β-form exists with the orthorhombic structure as shown above. The structure of this modification has been studied in detail and it is not perovskite. It has been concluded that $MgTa_2O_6$ has the trirutile structure while $CaTa_2O_6$ has the Eschynite structure as shown in Fig. 9.105.

A similar view of the arrangement of the octahedra is afforded in the following diagram: Fig. 9.106.

Transparent, colorless 30 mm long, (705 ± 11) μm diameter $CaTa_2O_6$, single crystal fibers with a cubic crystalline structure ($Pm3$) were grown by the Laser Heated Pedestal Growth (LHPD) technique. The lattice parameter determined was: $a = 7.757 \pm 0.002$ Å, as obtained from the Rietveld refinement. The fiber growth direction was determined to be [101] by XRD. The growth temperature was 2040 °C and the axial temperature gradient measured at the crystallization interface was 7.5×10^3 C/cm. The fiber/pedestal-pulling ratio was equal to 1.20. Undoped samples were characterized by optical microscopy, XRD patterns, infrared transmission and Raman scattering methods. The structural and spectroscopic results indicate that this crystal may have potential as a host for photo-active ions such as neodymium and erbium that have interesting emissions in the near-infrared region for use in cable and telephonic applications.

The successful growth of undoped and neodymium doped $CaTa_2O_6$ single crystal fibers by the LHPG technique, as well as the fibers' structural and spectroscopic characterizations, has been studied. The 700-μm diameter and 3-cm length fibers present high optical quality and excellent transparency, and XRD measurements indicate that they crystallize in the cubic structure ($Pm3$). The extensive transmission window of the host crystal fibers enables the study of rare-earth ion emission in the near-infrared region with several technological applications. Neodymium doped fibers (0.5–2.5 mol%) were characterized by ground and excited state absorptions, luminescence and lifetime measurements. Stimulated emissions were measured at 1.06 μm ($^4F_{3/2} \Rightarrow {}^4I_{11/2}$ transition) and around 1.34 μm ($^4F_{3/2} \Rightarrow {}^4I_{13/2}$ transition). Because $CaTa_2O_6$:Nd^{3+} fibers can be grown with excellent optical quality at low cost and in processes that are much faster than those usually used to grow bulk crystals, they might become an interesting material for the construction of compact optical devices such as diode pumped miniature lasers.

High optical quality Er^{3+}-doped $CaNb_2O_6$ and $CaTa_2O_6$ single crystal fibers having a 700-mm diameter and 1–2-cm length were grown by the LHPG technique. The fibers present the respective single-phase orthorhombic and cubic structures, and successful incorporation of the dopant ions, as confirmed by their light pink coloration, and characteristic absorption and luminescence spectra. Intense emission was observed at 1550 nm for both compositions, with slightly larger inhomogeneous spectral broadening for Er:CT fibers. These results associated with the fairly low phonon energies, and extensive transmission windows of the fibers, indicate they are potential laser active media for compact optical devices, in the near-infrared, or even in the green and red spectral regions, via up conversion processes.

A rare mineral occurrence of orange-brown manganotantalite lamellae (visible in a hand specimen), intergrown with microlite $[(Ca,Na)_2(Ta,Nb)_2(O,OH,F)_7]$,

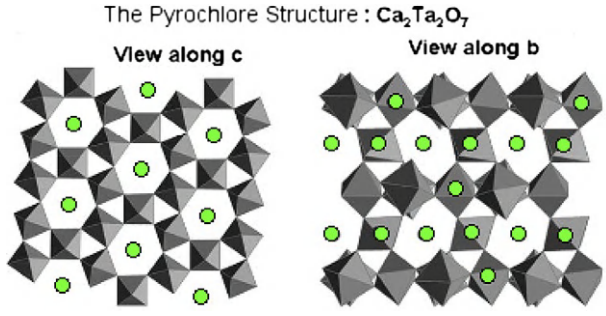

FIGURE 9.106

aggregates of ferrotapiolite, bismuth minerals and apatite was analyzed to understand more about the mechanisms of crystal growth and secondary modification in Ta-rich minerals. The intergrowth occurs within amblygonite/montebrasite nodules near the quartz core of the highly fractionated rare-metal Li/Be/Ta pegmatite that is found at Rubicon, Karibib, Namibia. Electron microprobe analysis showed that manganotantalite lamellae are variable in composition. Primary microlite (Ta_2O_5 82%, 1.97 Ta a.p.f.u.) forms the matrix mineral between the lamellae. In this context, Nb always equals 2 but Ta is in terms of Atoms per formula unit (a.p.f.u.) but less than 2. Textural relations suggest an ex-solution origin for the lamellae. Manganotantalite is represented by three generations in geology: (1) primary late magmatic; (2) disequilibrium ex-solution lamellae; and (3) sub-solidus replacement. Crystallization commenced with primary microlite and likely simultaneous intergrowth between ferrotapiolite and a first generation of late-magmatic primary manganotantalite with low Ta (1.1–1.5 a.p.f.u.). On cooling this was followed by ex-solution of manganotantalite lamellae, generation (2) with low–medium Ta (1.27–1.7 a.p.f.u.). The replacement of microlite by a highly fractionated late-stage melt rich in Mn^{2+}, Ca^{2+} with low Na^{+} finally produces a third generation (3) of manganotantalite with high Ta (1.72–1.99 a.p.f.u.) at the contact with microlite. Native bismuth and bismutite cut across microlite and pseudomorph lamellae as a final hydrothermal replacement. Apatite is ubiquitous at the contact with amblygonite. The stability field of microlite may be extended by incorporation of $CaTa_2O_6$–rynersonite and $Ca_2Ta_2O_7$ -idealized, components in solid solution. However, Rynersonite–$CaTa_2O_6$ with distorted octahedra has some structural templates, which are similar to the structure of pyrochlore (microlite). Hence, via the perovskite/pyrochlore analogy, hypothetical ex-solution of manganotantalite-type structures may occur from a microlite (pyrochlore) host by solid-state diffusion via metastable Rynersonite-type intermediates. Such a mechanism has the potential to explain the crystallographically controlled intergrowth textures and the compositional heterogeneity.

The compound, **tricalcium tantalate**, $Ca_3Ta_2O_8$, has been used as a matrix to develop a green-emitting phosphor for cold-cathode fluorescent lamps used as a backlight in display applications. The purpose of this study was to develop green phosphors with high stability, high luminescent efficiency, excellent color purity and optimum color gamut. The solid-state reaction method was used to synthesize Tb^{3+} activated tantalate phosphors, which are regarded as potential CCFL green phosphors. In Tb^{3+} activated tantalate, $Ca_{3-y}Tb_yTa_2O_8$, the optimum Tb^{3+} content is $y = 0.05$. It emitted green

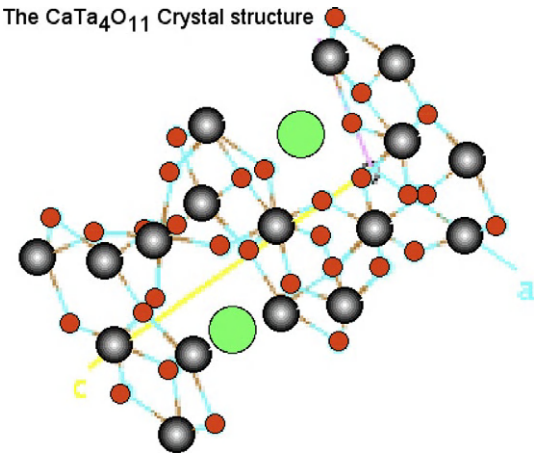

FIGURE 9.107

light due to the $^5D_4 \Rightarrow {}^7F_5$ transition of Tb^{3+} at 548 and 542 nm under excitation with 254 nm light. The emission intensity was higher than that of $Zn_{2.997}Tb_{0.002}Ta_2O_8$ phosphor (which has been reported before) but not for $La_{0.95}Tb_{0.05}TaO_4$ phosphor, which was the brightest in the series. The optimum calcining temperature was 1450 °C for the phosphor. The cross-relaxation and non-radiative relaxation which is related to the $^5D_3$ and $^5D_4$ energy level in Tb^{3+} ions was also discussed.

The compound, **tetra-calcium tantalate**, $Ca_4Ta_2O_9$, has been shown in the phase diagram and one structure has been published. One version gave the unit cell dimensions as: $a = 5.545$ Å, $b = 9.812$ Å, $c = 14.116$ Å, $\alpha = 90.00°$, $\beta = \gamma = 90.0°$. The penta-calcium tantalate, $Ca_5Ta_2O_{10}$, is unknown in structure. The analogous compounds, $Ca_5Nb_4O_{15}$ and $Ca_5Ta_4O_{15}$ are not known as well.

However, the calcium di-tantalate, $CaTa_4O_{11}$, has the structure as shown in Fig. 9.107.

Cell parameters are: $a = b = 6.215$ Å, $c = 12.266$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, $Z = 2$, cell volume is 410.23 Å^3. Cell occupancy is shown in Table 9.61.

Calcium tantalate is offered commercially as the pyro-tantalate, $Ca_2Ta_2O_7$, and its CAS number is 12049-50-2.

9.3.4. Strontium Tantalum Compounds

Strontium metal does not form any intermetallic compounds with Ta-metal.

No compounds are known in the SrO–TaO system or SrO–Ta_2O_3 system.

In the Ta^{4+}-containing system of SrO–TaO_2, the only reference to a strontium tantalite is a mixed strontium bismuth tantalite (SBT), $SrBi_2Ta_2O_9$. A number of these materials are useful in a broad range of device applications. Various factors that influence the material properties such as particle size, stresses, stoichiometry, compositional homogeneity and their effects on phase transition were investigated. The processing conditions, A- and B-site substitution, size-dependent Raman spectra and the structure-property correlations are discussed in the bulk, thin film and nano-crystalline forms of these materials. Film thickness dependence stress study on lead titanate (PT) and lead zirconate titanate (PZT) films indicated that the nature of stress depends strongly on the lattice parameters of the film and substrate. The size effect was found to decrease the ferroelectric transition temperature in lead-based perovskite materials. Both ionic charge and radii induced changes in the Raman spectra of A- and B-site substituted perovskites and layered compounds were studied. A-site substitution in strontium bismuth tantalite (SBT) was found to induce a relatively linear variation of transition temperature compared with the B-site substituted SBT.

The system, SrO–Ta_2O_5 is known to form five compounds. All are dimorphic except $SrTa_2O_6$, $Sr_3Ta_6O_{16}$ and $Sr_5Ta_5O_{15}$. The phase diagram is shown as follows in Fig. 9.108.

Structure factors are shown in Table 9.62.

$SrTa_2O_6$ is trimorphic while $Sr_2Ta_2O_7$ is dimorphic. Other known strontium tantalates not included in the phase diagram are $Sr_4Ta_2O_9$, and $Sr_6Ta_2O_{11}$.

Three polymorphic forms of **mono-strontium tantalate**, $SrTa_2O_6$ have been recognized. The monoclinic form has also been prepared and studied by powder XRD techniques and DTA. The sequence of formation

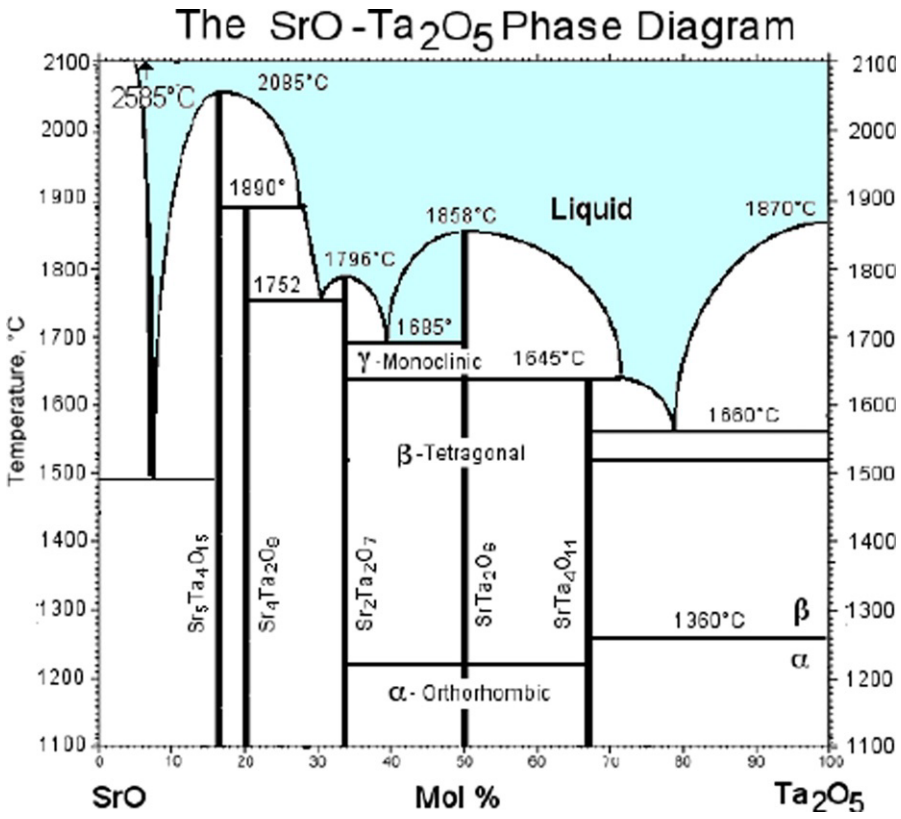

FIGURE 9.108

of these polymorphs has been found to follow a series of temperature changes:

α-Orthogonal (1220 °C) ⇒ β-tetragonal (1645 °C) ⇒ γ-monoclinic

The results of X-ray analysis show that α-$SrTa_2O_6$ crystallizes in a pseudo-orthorhombic unit cell with $a = 5.621$ Å, $b = 7.632$, $c = 5.621$ Å, $\alpha = \beta = \gamma = 90°$.

The structure is identical to the Ca-homolog except for lattice parameters as shown in Fig. 9.109.

Cell occupancy is shown in Table 9.63.

Orthorhombic $SrTa_2O_6$ is a low temperature modification related to orthorhombic $CaTa_2O_6$. $SrTa_2O_6$(orth.) was obtained when the well known modification $SrTa_2O_6$(TTB) which is related to the tetragonal tungsten bronzes was heated in the presence of a transporting agent (chlorine) or a mineralizer (melt of B_2O_3) at temperatures below 1150 °C. It could be prepared by the reaction of a 1:1 mixture of $Sr(NO_3)_2$ or $SrCO_3$ with Ta_2O_5 in a sealed quartz glass tube as well. $SrTa_2O_6$(orth.) also occurred as an intermediate phase

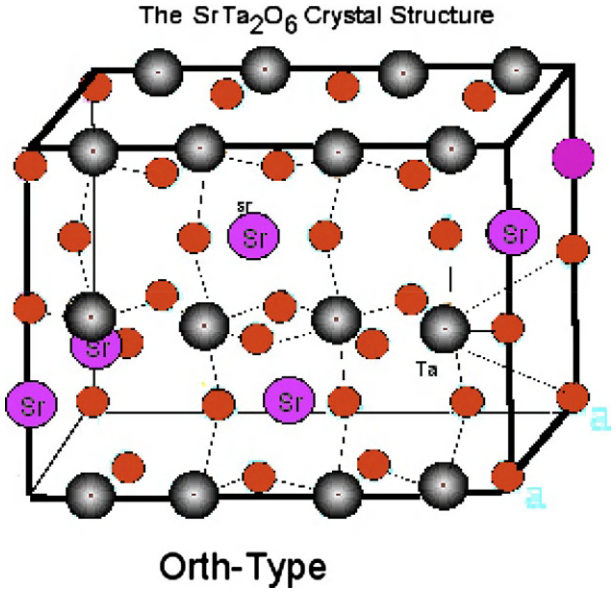

FIGURE 9.109

of the reaction of the corresponding 1:2 mixture at temperatures below 900 °C (e.g. 840 °C). Indexing of Guinier powder patterns led to the following unit cell: $a = 11.006$ Å, $b = 7.638$ Å, $c = 5.622$ Å. At temperatures above 1220 °C, $SrTa_2O_6$(orth.) changes (in air) to $SrTa_2O_6$(TTB). A reversal of this transition could not be achieved without the presence of a mineralizer or a transporting agent. $Ca_xSr_{1-x}Ta_2O_6$ solid solutions of the low temperature form could not definitely be established. However, at 1300 °C solid TTB solutions of $Ca_xSr_{1-x}Ta_2O_6$ were formed. For $x > 0.05$ the TTB unit cells are orthorhombically distorted. For $x \geq 0.85$ the X-ray powder patterns of the solid solutions looked like the one of $CaTa_2O_6$(orth.) and no TTB-structure was observed at 1300 °C. Above 1645 °C, the monoclinic (γ-form) was obtained.

These forms are related to the well-known transition involving the Ruddlesden–Popper change of perovskite to TTB phases, as shown in the following diagram where the original compound was isostructural $K_2SrTa_2O_7$ that is first ion-exchanged to the corresponding acid form and then topo-chemically dehydrated to yield metastable perovskite phase, $SrTa_2O_6$as shown in Fig. 9.110.

The β-form has the structure as shown in Fig. 9.111.

The two lattices may be better compared by the following diagram as shown in Fig. 9.112.

$SrTa_2O_6$ is a promising candidate for gate oxide applications because of its high dielectric constant and low leakage current. The structural and electrical properties of a MOS-derived $SrTa_2O_6$(SrTaO)/n-$In_{0.53}GaAs_{0.47}$(InGaAs)/InP structure, where the SrTaO was grown by atomic vapor deposition, was investigated.

The MOS structure has the form as shown in Fig. 9.113.

A study using TEM (transmission microscopic microscope) revealed a uniform, amorphous SrTaO film having an atomically flat interface with the InGaAs substrate with an SrTaO film thickness of 11.2 nm. The amorphous SrTaO films (11.2 nm) exhibit a dielectric constant of 20, and a breakdown field of >8 MV/cm. A capacitance equivalent thickness of 1 nm is obtained for an SrTaO thickness of 3.4 nm, demonstrating the scaling potential of the SrTaO/InGaAs MOS system. Thinner SrTaO films (3.4 nm) exhibited increased nonuniformity in thickness. From the capacitance–voltage response of the SrTaO (3.4 nm)/n-InGaAs/InP structure, prior to any post deposition annealing, a peak interface state density of $2.3 \times 10^{13}/cm^2$ eV is obtained located at 0.28 eV (±0.05 eV) above the valence band energy (E_v) and the integrated interface state density in range $E_v + 0.2$ to $E_v + 0.7$ eV is $6.8 \times 10^{12}/cm^2$. The peak energy position (0.28 ± 0.05 eV) and the energy distribution of the interface states are similar to other high-k layers on InGaAs, such as Al_2O_3 and $LaAlO_3$, providing further evidence that the interface defects in the high-k/InGaAs system are intrinsic defects related to the InGaAs surface.

$SrTa_2O_6$ thin films with thickness between 6 and 150 nm were also deposited by metal-organic chemical vapor deposition in a multiwafer planetary reactor. The monomolecular precursor, strontium-tantalum-(methoxyethoxy)-ethoxide, was dissolved in toluene

TABLE 9.63

and injected by a liquid delivery system. A rather narrow process window for the deposition of stoichiometric $SrTa_2O_6$ was found for this precursor at low pressures and a susceptor temperature around 500 °C. Films were grown on $Pt/TiO_2/SiO_2/Si$, TiN_x/Si, and SiO_2/Si substrates. The as-deposited films were X-ray amorphous but could be crystallized by post-annealing at a temperature $\geq$700 °C. The distorted tetragonal tungsten bronze phase of $SrTa_2O_6$ dominated within a broad range of compositions (Sr/Ta: 0.4–0.7) and a perovskite-type phase was additionally observed for Sr/Ta~0.7 and predominated for Sr/Ta~1. The electrical properties have been investigated with metal-insulator-metal and metal-insulator-semiconductor capacitors after sputter

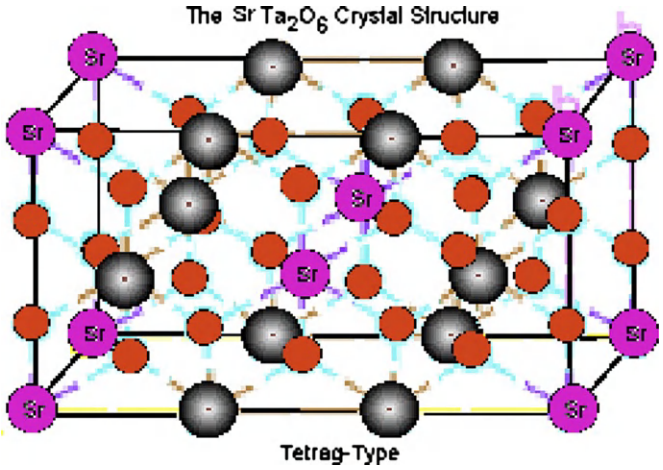

FIGURE 9.111

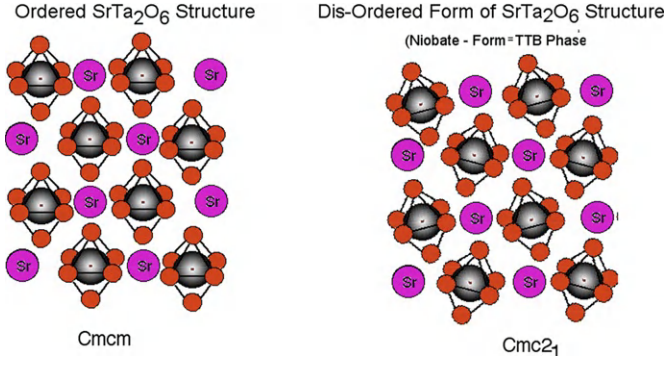

FIGURE 9.112

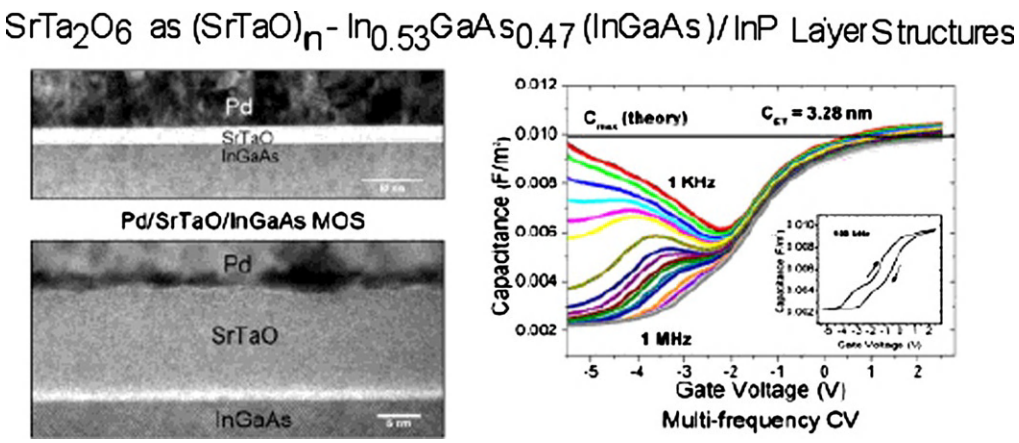

FIGURE 9.113

deposition of Pt top electrodes. The amorphous films had a dielectric constant K in the range of 35–45 and low leakage currents. For stoichiometric $SrTa_2O_6$ the dielectric permittivity reached values of $K = 100$–110, but the leakage currents were increased. Remarkably, the permittivity is not very sensitive to deviations from the exact stoichiometry of the $SrTa_2O_6$ phase (Sr/Ta: 0.4–0.7), but a decrease to values of $K = 30$–40 is observed along with the transition to the perovskite phase at high Sr contents.

$SrNb_2O_6$ (SN) or $SrTa_2O_6$ (ST) compounds can also be prepared at low temperatures from hydroxide precursors. A simple procedure of mixing commercially purchased strontium hydroxide and niobium (or tantalum) hydroxide thoroughly together and heating at a low temperature (<400 °C) produced $SrNb_2O_6$ (SN) or $SrTa_2O_6$ (ST) powders. This is the lowest temperature so far reported for the formation of these phases. These materials are potential candidates for ferroelectric and electro–optic applications.

The compound, **strontium tetra-tantalate**, $SrTa_4O_{11}$, has received some attention in the literature. It has the structure shown as follows in Fig. 9.114.

The structure consists of layers of TaO_7 pentagonal bipyramids, sharing edges as found in U_3O_8. Between the layers lie Sr atoms with distorted cubic coordination geometry and Ta(1) atoms with distorted octahedral coordination geometry. The dimorphism of $SrTa_4O_{11}$ may be described as a step from the tetragonal structure of bronzes to the structure of $CaTa_4O_{11}$. Hexagonal $SrTa_4O_{11}$ is a new modification and isostructural with $CaTa_4O_{11}$. It was obtained by heating the already known $SrTa_4O_{11}$ in a chlorine atmosphere at 1000–1100 °C.

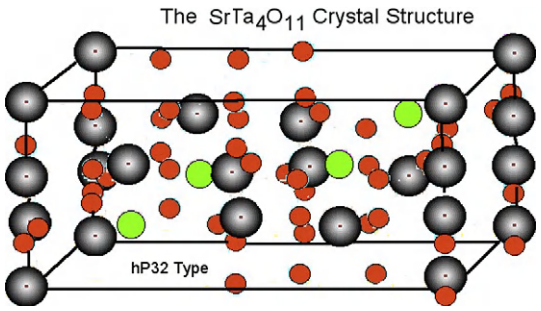

FIGURE 9.114

The Guinier powder pattern could be indexed with the following hexagonal unit cell: $a = 6.25$ Å; $c = 12.33$ Å. In air at 1180 °C, $SrTa_4O_{11}$ (hex.) changes into the well-known TTB-modification (corresponding to the tetragonal tungsten bronzes). The transition of $SrTa_4O_{11}$ (TTB) to $SrTa_4O_{11}$ (hex.) was only observed in the presence of a transporting agent (Cl_2) or a mineralizer (melt of B_2O_3) at temperatures below 1100 °C. This transition could not be achieved by means of a solid-state reaction. In a (Ca, Sr)Ta_4O_{11} solid solution, with at least 78 At% Ca, the hexagonal form could be stabilized even at temperatures where otherwise the TTB-modification occurred.

Very little information is available for this compound other than the structural data. No uses for it have evolved in Industry.

The **pyro-tantalate** compound, $Sr_2Ta_2O_7$, has the structure as shown in Fig. 9.115.

Cell parameters are: $a = 3.95$ Å, $b = 5.68$ Å, $c = 13.76$ Å, $\alpha = \gamma = 90°$, $\beta = 98.251°$. Cell volume = 305.58 Å^3. Cell occupancy is shown in Table 9.64.

The other polymorph is related to the niobate structure as shown in Fig. 9.116.

The cell parameters are: $a = 3.94$ Å, $b = 5.692$ Å, $c = 13.717$ Å, $\alpha = \gamma = 90°$, $\beta = 98.27°$, cell volume = 304.44 Å^3. Cell occupancy is shown in Table 9.65.

The arrangement of the octahedra is more easily seen in the following diagram where the pyro-antimonate is shown in Fig. 9.117.

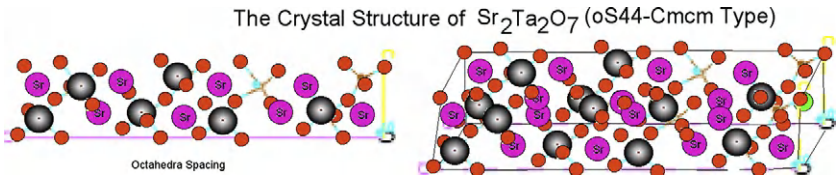

FIGURE 9.115

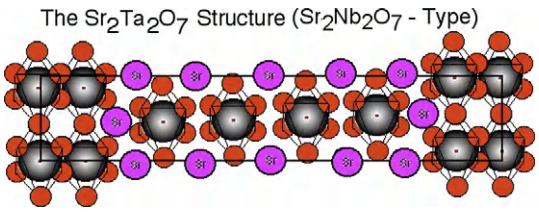

FIGURE 9.116

Recently, a number of ternary transition metal oxide catalysts have been discovered to dissociate water more efficiently than conventional materials such as Titania. These materials all have anisotropic structures made up of layers or tunnels. It has been hypothesized that these materials have high efficiencies because the layers and tunnels somehow separate the photo generated charge carriers and, therefore, the locations of the

FIGURE 9.117

oxidation and reduction half reactions. If such a separation were to occur, it would suppress carrier recombination and the rate of the back reaction. Two such materials are $Sr_2Ta_2O_7$ (*Cmcm*, $a = 3.937$ Å, $b = 27.198$ Å, $c = 5.692$ Å) and $Sr_2Nb_2O_7$ (*Cmc*21, $a = 3.933$ Å, $b = 26.726$ Å, $c = 5.683$ Å). Both of the structures are made up of corner sharing MO_6 octahedra that are arranged in (110) perovskite type slabs parallel to (010), and separated by Sr_2O layers. The main difference between these materials is the distortion of the NbO_6 octahedra in $Sr_2Nb_2O_7$ that makes it ferroelectric (Ps||*c*-axis). The role that the layer structure plays in the superior photochemical properties of these compounds is currently unclear.

Three compounds, $SrTa_2O_6$, $Sr_4Ta_2O_9$, and $Sr_5Ta_4O_{15}$, were synthesized by a polymerizable complex method. Their photocatalytic activities for water splitting into H_2 and O_2 were tested and compared against previously published results for $Sr_2Ta_2O_7$. It was found that the efficiency of the catalysts decreases in the following order:

$$Sr_2Ta_2O_7 > Sr_5Ta_4O_{15} > SrTa_2O_6 > Sr_4Ta_2O_9$$

The relationship between photocatalytic activities and crystal structures was discussed in this paper.

Strontium tantalate, $Sr_2Ta_2O_7$, and strontium niobate, $Sr_2Nb_2O_7$, are ferroelectric crystals with a layered perovskite structure. The space group of the prototype structure is *Cmcm*. The ferroelectric phase transition temperature, T_2, of $Sr_2Ta_2O_7$ is 155 °C and that of $Sr_2Nb_2O_7$ is 1615 °C. The spontaneous polarization of each crystal appears along the *c*-axis in the layer. The transition temperature T_2 of the mixed solid-solution niobate-tantalate crystals, i.e.- $Sr_2(Ta_{1-x}Nb_x)_2O_7$, changes steeply with Nb concentration. The mixed crystals exhibit a superlattice phase transition with twice the lattice constant along the *a*-axis around $T_1 = 443$ °C in the region $x < 0.4$. It has an incommensurate phase transition around 488 °C in the region $x > 0.6$. The transition temperature T_1 of the mixed crystal changes continuously with x from 443 °C to 488 °C. The dielectric anomaly of the single crystals along the *c*-axis around T_1 and T_2 in the mixed crystals reveal the characteristics of the phase transitions of the layered perovskite ferroelectrics. Additionally, the low-frequency dielectric dispersion in $Sr_2Ta_2O_7$ observed at the temperatures from 60 K to 150 K was reported. The dielectric dispersion in the mixed crystal may relate to the dynamical properties of Nb center. The ferroelectric phase transition temperature was found to change sensitively with the Nb concentration from 155 °C for $x = 0$ to 480 °C for $x = 0.081$. A cusp-like dielectric anomaly appears in each sample around 443 °C. The low frequency dielectric dispersion is observed in the temperature range from 60 °C to 150 °C in each sample. The soft mode frequency for the ferroelectric phase transition at 20 °C increases with x.

$Sr_2Ta_2O_7$ and $Sr_2Nb_2O_7$ have a (110) layered perovskite structure and are efficient photolysis catalysts. Aqueous silver and lead cations were photo-chemically reduced and oxidized, respectively, on the surfaces of $Sr_2Ta_2O_7$ and $Sr_2Nb_2O_7$ crystals with a wide range of orientations. AFM has been used to observe the distribution of photo chemically reduced and oxidized products and determine the orientation dependence of the reactivity. On surfaces with the same orientation, reaction products frequently had a non-uniform distribution. The reactivity of both compounds proved to be only weakly anisotropic, with the highest relative reactivity for both oxidation and reduction occurring for surfaces oriented between (010), (110), and (011). These low index orientations have structures similar to the ideal {110} and {100} planes in the perovskite structure, respectively.

$Sr_2Ta_2O_7$ nanosheets have been synthesized by a hydrothermal method without using any template. The thickness, widths, and lengths of $Sr_2Ta_2O_7$ nanosheets are about 10–50 nm, 50–150 nm, and 500 nm, respectively. The optimum conditions for the formation of the nanosheets are maintaining the reactants at 260 °C for 7 days. On basis of the experimental data, a possible formation mechanism of the nanosheets under the hydrothermal conditions was proposed. The photocatalytic activity for water splitting was investigated under ultraviolet irradiation. It has been found that $Sr_2Ta_2O_7$ nanosheets, compared to the bulk $Sr_2Ta_2O_7$ sample, showed a higher photocatalytic activity even in the absence of a co-catalyst. The higher activity of the hydrothermally synthesized sample is attributed to its larger surface areas and nanoscale structure.

Thin films of nanoscale ribbons derived from the layer perovskite $H_2SrTa_2O_7$ were grown and characterized as solid-state proton conductors. The ribbons, made by exfoliation of the parent solid with tetra(n-butyl)ammonium hydroxide, were typically 500 nm long, 40 nm wide, and 3 nm thick, with the short axis corresponding to the layer axis of $H_2SrTa_2O_7$. Powder XRD and HRTEM confirmed that the ribbons had similar *a*-axis unit cell

parameters (3.98 ± 0.05 Å) to $H_2SrTa_2O_7$ (3.87 Å) and the defect perovskite $CaTa_2O_6$ (3.92 Å) which is the dehydration product of $H_2SrTa_2O_7$. By using inductively coupled plasma atomic emission spectroscopy, X-ray photoelectron spectroscopy, and EDX spectroscopy, the ribbons were found to have a lower Sr/Ta ratio than $H_2SrTa_2O_7$. Thin films of these ribbons were grown by layer-by-layer assembly and by spin-coating, and in both cases the long axis had a preferred orientation parallel to the substrate. Electrochemical impedance measurements were done on pellets of $H_2SrTa_2O_7$ and $CaTa_2O_6$ and on films of oriented ribbons measured perpendicular and parallel to the plane of their long axis. At 25 °C, the proton conductivities in humidified air were 1.5×10^{-4} and 1.7×10^{-5} S/cm^2 for pellets containing randomly oriented grains of $H_2SrTa_2O_7$ and $CaTa_2O_6$. The measured conductivities of oriented films of the ribbons were 1.3×10^{-9} and 2.4×10^{-2} S/cm^2 in the perpendicular and parallel directions, respectively, indicating a high proton conductivity along the ribbon axis and very high conductivity anisotropy.

The structural phase transition in $Sr_2Ta_2O_7$ at 170 °C has been investigated by Raman scattering measurements. A low-lying mode of the *Ag* symmetry softens significantly toward T_{tr}. Anomalous increase in the damping constant of this mode has been observed in the vicinity of T_{tr}. The structural phase transitions of $Sr_2Ta_2O_7$ single crystals have also been studied by the modulated temperature differential scanning calorimetry (MDSC), Brillouin scattering and dielectric spectroscopy. The specific heat (C_p) was measured over a wide temperature range from −150 °C to 25 °C and from 100 °C to 210 °C. The C_p curve showed an anomaly at $T_0 = 166.7$ °C, indicating the phase transition $Cmcm \Rightarrow P21/m$. The transition enthalpy ΔH, the transition entropy ΔS and specific heat jump ΔC_p at T_0 were estimated to be 0.465 J/g, 1.01 mJ/g/K and 9.78 mJ/g/K, respectively. The C_p anomaly associated with the ferroelectric phase transition at $T_c = -107$ °C has not been detected. However, both Brillouin and dielectric data showed the anomalies corresponding to the ferroelectric phase transition from $P21/m$ to $P21$.

$Sr_2Ta_2O_7$ nanosheets have been synthesized by a hydrothermal method without using any template. The thickness, widths, and lengths of $Sr_2Ta_2O_7$ nanosheets are about 10–50 nm, 50–150 nm, and 500 nm, respectively. The optimum conditions for the formation of the nanosheets are maintaining the reactants at 260 °C for 7 days. On basis of the experimental data, a possible formation mechanism of the nanosheets under the hydrothermal conditions was proposed. The photocatalytic activity for water splitting was investigated under ultraviolet irradiation. It has been found that $Sr_2Ta_2O_7$ nanosheets, compared to the bulk $Sr_2Ta_2O_7$ sample, showed a higher photocatalytic activity even in the absence of a co-catalyst. The higher activity of the hydrothermally synthesized sample is attributed to its larger surface areas and nanoscale structure.

A comparison of the catalyst activity of some compounds that split water into hydrogen and oxygen under photo-activity of UV light is shown in the following Table 9.66. The conditions used were: room temperature; catalyst 0.3 gm; water 500 cc; 450 W medium-pressure Hg lamp. Work continues in the investigation of this aspect.

A single-source $Sr[Ta(OEt)_5(Me)]_2$ precursor was utilized to form dielectric layers on 200-mm Si(100)/TiN substrates within a thermal budget of BEOL (400 °C). The Sr/Ta ratio in the products was controlled by varying the process pressure. Two stoichiometries, namely, $Sr_2Ta_2O_{7-\delta}$ and $Sr_5Ta_4O_{15-\delta}$, were intensively characterized, to show that $Sr_2Ta_2O_{7-\delta}$ based MIM capacitors offer better electrical performance. The best results, achieved at an $Sr_2Ta_2O_{7-\delta}$ layer thickness of 30 nm, have a capacitive density of 5.5 fF/μm^2 in combination with a linearity coefficient of 80 ppm/V^2 and quality factor of 52 at 10 kHz. The corresponding leakage current density at 2 V is 7×10^{-9} A/cm^2, and the determined breakdown strength is 3.2 MV/cm.

The **penta-strontium di-tantalate** compound, $Sr_5Ta_4O_{15}$, has been well studied. This compound has a hexagonal structure and crystallizes in the $P\bar{3}m1$ space group with one formula unit per cell ($Z = 1$). The compound has a five-layer closest packing of oxygen and strontium ions. The tantalum or niobium ions are located in the octahedral holes between layers with one layer of octahedral holes missing tantalum or niobium ions to accommodate the charge neutrality. The $Sr_5Ta_4O_{15}$ structure is a hexagonal polytype i.e., the (5H) member of a series of polytypes characterized by Hutchison and co-workers containing 4, 5, 6, 8, 10 and 12 layered (4H, 5H, 6H, 8H, 10H, and 12H) species. Whiston and Smith have reported the existence of $Sr_5Ta_4O_{15}$ isostructural with the niobium analog. Two structures have been reported for $Sr_5Nb_4O_{15}$, monoclinic and trigonal.

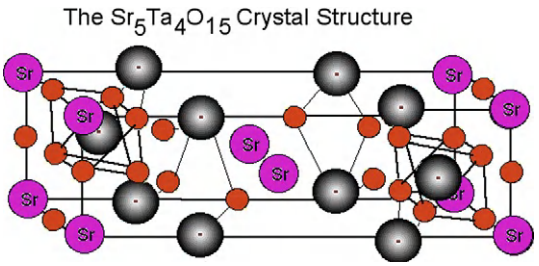

FIGURE 9.118

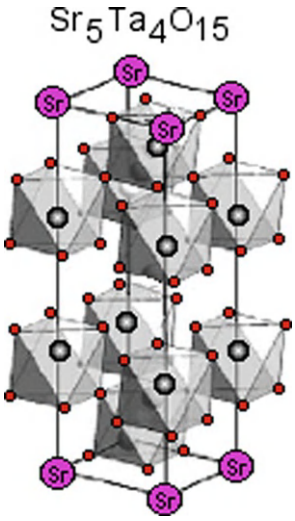

FIGURE 9.119

The trigonal $Sr_5Ta_4O_{15}$ has the structure as shown in Fig. 9.118.

Cell parameters are: $a = b = 5.66$ Å, $c = 11.47$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 318.12$ Å^3. Cell occupation is shown in Table 9.67.

The arrangement of the octahedra in the monoclinic form may be more easily seen in the following diagram shown in Fig. 9.119.

Recent progress in microwave (MW) telecommunications has demanded the need for good quality ceramic dielectric resonators. The important characteristics required for dielectric resonators are high permittivity, ε_r (the size of resonators is proportional to $1/\sqrt{\varepsilon_r}$), a high quality factor $Q = \varepsilon_r'/\varepsilon_r''$, and a low temperature coefficient of resonant frequency τ_f. $Sr_5Ta_4O_{15}$ exhibits unusual low frequency heavily damped excitation at 15 cm. This mode is partially seen in the reflectivity and is very well evident in both THz and FTIR transmission spectra. The low frequency excitation observed at 15 /cm in $Sr_5Ta_4O_{15}$ suggests a ferroelectric soft mode; however, more low temperature measurements are needed. The IR spectrum of $Sr_5Nb_4O_{15}$ does not support the previously published report of monoclinic symmetry with $Z = 2$. The spectrum is similar to that for the three related samples with trigonal symmetry and $Z = 1$.

Due to the drive for miniaturization of devices, B-site deficient hexagonal perovskites like $Sr_5Ta_4O_{15}$ have become an area of growing research for their dielectric properties and application in this area, as they display promising properties. The following Table 9.68 shows the measured dielectric properties.

Current work continues on this compound and its homologs concerning improvement in dielectric and photoactive properties.

The mechanism and kinetics of water incorporation into the double perovskite, **hexa-strontium tantalate**, $Sr_6Ta_2O_{11}$, has been investigated in the range 300 to 500 °C and $H_2O = (1 \times 10^{-3}$ atm.). The formation of hydration products $Sr_6Ta_2O_{11}$ xH_2O $(0.2 < x < 0.50)$ was limited by the diffusion of H_2O. It has been found that the concentration dependences of D_2O are the same. With increasing x, the temperature dependences of the chemical diffusion coefficients of water for a composition of $Sr_6Ta_2O_{11} \cdot 0.35H_2O$ could be described with an activation energy of $E_a = 0.49 \pm 0.03$ eV. The chemical diffusion coefficients of water are nearly one order of magnitude lower for the barium tantalate

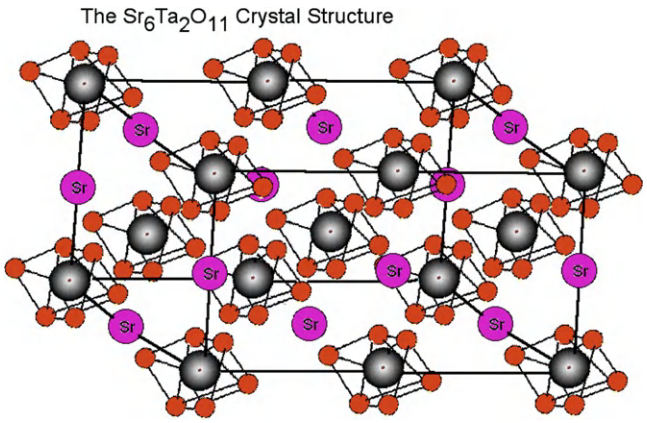

FIGURE 9.120

$Ba_6Ta_2O_{11}$. This result correlates with lower oxygen and proton conductivities in $Sr_6Ta_2O_{11}$ as the consequence of lower mobility. It has the structure as shown in Fig. 9.120.

Cell parameters are: $a = b = c = 5.8739$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 143.31 Å^3. Cell occupancy is shown in Table 9.69.

The structural transformations of $Sr_6Ta_2O_{11}$ and $Sr_{5.92}Ta_{2.08}O_{11.12}$ oxygen-deficient cryolites with variations in the partial pressures of oxygen $p(O_2)$ and water vapor $p(H_2O)$ have been investigated using XRD, TG, and electrical conductivity measurements. It was found that a change in the oxygen partial pressure leads to a phase transition accompanied by the transformation of the cubic cell into the tetragonal cell, most probably due to ordering of oxygen vacancies. The intercalation of water into the matrix of the complex oxides under investigation results in a structural-chemical transformation during which the solid solution undergoes a transition to an oxyhydrate phase of variable composition and the cubic cell transforms into the orthorhombic cell.

In another study, evolution of the structure and phase relations of the oxygen-deficient cryolite $Sr_6Ta_2O_{11}$ and phase $Sr_{5.92}Ta_{2.08}O_{11.12}$ from homogeneity range have been investigated during water intercalation by gravimetry, dilatometry and XRD measurements. Intercalation of H_2O up to 0.50 and 0.30 mol H_2O per formula units $Sr_6Ta_2O_{11}$ and $Sr_{5.92}Ta_{2.08}O_{11.12}$, respectively, takes place without change in the crystal structure, which could be described under the cubic space group *Fmm* with a cell parameter of approximately 8.32 Å. Further intercalation of water leads to structure transformation to the orthorhombic space group *Fmmm*. The temperature of phase transition increases with increasing pH_2O. It is around 475–450 °C in open air. ($pH_2O \approx 0.02$ atm.). This phase transition is induced by change in pH_2O (T = constant) and temperature (pH_2O = constant) and can be observed as a jump when TG curves are obtained vs. pH_2O or T. At 200 °C, the most hydrated phases correspond to the compositions $Sr_6Ta_2O_{11}\cdot 0.96H_2O$ (H_2O stoichiometry close to the theoretical value of 1.0) and $Sr_{5.92}Ta_{2.08}O_{11.12}\cdot 0.6H_2O$ (70% of the theoretical value).

The systems $Sr_6Ta_2O_{11}$–H_2O and $Sr_{5.92}Ta_{2.08}O_{11.12}$–$H_2O$ were investigated. At high temperatures, both compounds are normal proton conductors but at lower temperatures show the formation of hydrate phases (here labeled β-phases). The latter are deleterious if the above compounds were to be used in fuel cells, sensors and pumping devices. The phase diagrams of the 2 systems were determined using thermogravimetry. The solubility of water vapor in the α-phases was measured. Considering 2-phase mixtures of α and β, the plateau vapor pressures were determined as well as the pertinent thermodynamic parameters. The $\alpha \Rightarrow a + \beta$ solvus was also investigated.

Conductivity of the $Sr_{6-2x}\ Ta_{2+2x}O_{11+3x}$ ($0 \le x \le 0.33$) solid solutions with the cryolite structure was studied in an atmosphere with high content of water vapors with temperature and oxygen activity variation in the gas phase. Appearance of the protonic conductivity component was proved at the temperatures below

TABLE 9.68

700 °C. It was found that protonic conductivity increases when a decrease in the parameter x occurs in the composition series. This is related to an increase of both the concentration of protonic defects formed in the structure and their mobility. In the case of compositions with $x < 0.15$ at the temperatures below 550 °C, the protonic transport becomes predominant.

The mechanism and kinetics of water incorporation in the double perovskite $Sr_6Ta_2O_{11}$ has been investigated ($T = 300$–500 °C and $aH_2O = 1 \times 10^{-3}$ (300 °C) which varies up to 2.2×10^{-2} at 500 °C). The formation of hydration products $Sr_6Ta_2O_{11} \cdot xH_2O$ ($0.2 < x < 0.50$) was limited by the diffusion of H_2O. It has been found that the concentration dependences of $\tilde{D}_{H2O}$ are the same for both samples: small increasing of $\tilde{D}_{H2O}$ with increasing x. The temperature dependences of the chemical diffusion coefficients of water for compositions of $Ba_4Ca_2Nb_2O_{11} \cdot 0.35H_2O$ and $Sr_6Ta_2\ O_{11} \cdot 0.35H_2O$ could be described with close activation energies of $E_a = 0.38 \pm 0.03$ eV and $E_a = 0.49 \pm 0.03$ eV, respectively. The chemical diffusion coefficients of water are nearly one order of magnitude smaller for the tantalate, $Sr_6Ta_2O_{11}$. This result correlates with lower oxygen and proton conductivities in $Sr_6Ta_2O_{11}$ as the consequence of lower mobilities.

In another study, The perovskite-related phases $Sr_6Ta_2O_{11}$, $Sr_{5.92}Ta_{2.08}O_{11.12}$ (V-o(s))(0.88), and $Sr_{5.46}Ta_{2.54}O_{11.81}$(V-o(s))(0.19), where V-o(s) stands for 'oxygen structural vacancies', have been studied by TG, AC-conductivity and IR and RS. A correlation between water uptake and nominal V-o(s) concentration was established, but the nature of the alkaline earth metal atom influences the oxygen sub-lattice: The relationship between short-range disorder and water uptake is clear: only compounds having a strong oxygen and cation lattice disorder exhibit maximal water uptake: $Sr_6Ta_2O_{11}$. The protonic species were observed to change during cooling–heating.

The compound, **tetra-strontium tantalate**, $Sr_4Ta_2O_9$, has a phase with a completely occupied oxygen sublattice that also exhibits insignificant sensitivity to exposure to water. It has the general crystal structure related to the Ba-homolog in which two octahedra are tilted and surrounded by Sr^{2+} ions as shown in the following diagram: Fig. 9.121.

$Sr_4Ta_2O_9$ and HfO_2 films were prepared on 200 mm TiN/Si(100) substrates by Atomic Vapor Deposition (AVD). Depositions were carried out within a thermal budget of CMOS via back-end of line. Electrical properties have been investigated in metal-insulator-metal capacitors after sputter deposition of Au top electrodes. Both $Sr_4Ta_2O_9$ and HfO_2 dielectrics show excellent electrical performances. Oxides possess high capacitance densities of 3.5 fF/μm^2 (HfO_2) and 4.5 fF/μm^2 ($Sr_4Ta_2O_9$) in combination with high voltage linearity ($\leq$100ppm/V^2).

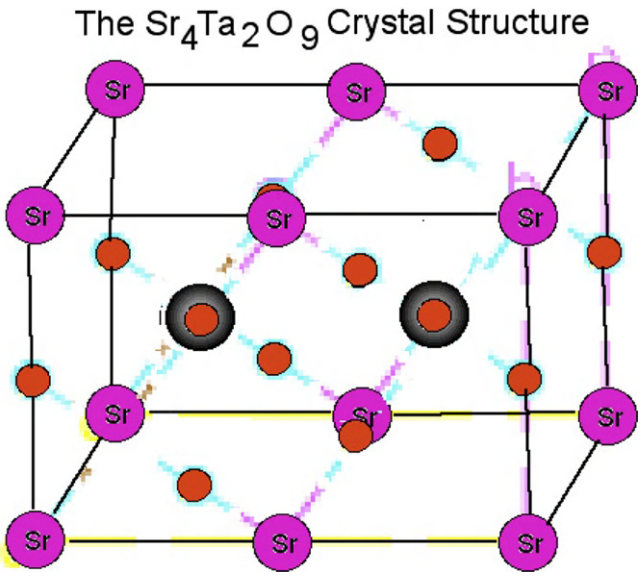

FIGURE 9.121

$Sr_4Ta_2O_9$ MIM capacitors provide lower leakage currents at 2 V, while HfO_2 MIMs offer higher operating voltage values for 10 years lifetime than $Sr_4Ta_2O_9$ based capacitors. The dielectric breakdown fields of HfO_2 (5.8 MV/cm) and $Sr_4Ta_2O_9$ (3.2 MV/cm) were obtained from IV-characteristics.

The conductivities of $Sr_2Ta_2O_7$, $Sr_6Ta_2O_{11}$, Sr_2LaTaO_6 and $Sr_3LaTa_3O_{12}$, both doped and undoped, were measured by the ac complex impedance technique over a temperature range of approximately 400–800 °C. The conductivity of $Sr_2Zr_{2x}Ta_{2-2x}O_{7-x}$ at 800 °C increased from 5.4×10^{-6} S/cm for the undoped compound to 3.0×10^{-4} S/cm at $x = 0.1$, and the activation energy correspondingly decreased from 0.98 to 0.63 eV. $Sr_3TaO_{5.5}$ and Sr_2LaTaO_6 were found to be the endpoints of a solid solution, which can be described by $Sr_{2+x}La_{1-x}TaO_{6-x/2}$ where x ranges from 0 to 1. It has the $(NH_4)_3FeF_6$-type fcc structure. There was a maximum in conductivity at $x = 0.75$ with an oxygen vacancy concentration of 6.25%. The corresponding conductivity at 800 °C was 6.2×10^{-3} S/cm, nearly identical to 15% CaO-stabilized ZrO_2. The conductivities at 800 °C of Sr_2LaTaO_6 and $Sr_3LaTa_3O_{12}$ were 3.6×10^{-5} and 1.0×10^{-6} S/cm, and the activation energies over the 400–800 °C temperature range were 1.41 and 0.84 eV, respectively.

Strontium tantalate is offered for sale commercially as the mono-strontium compound with the CAS number of 12065-74-6.

9.3.5. Barium Tantalum Compounds

The metal, Ba^0, does not form any intermetallic compounds with Ta^0.

Similar to the strontium system, no compounds are known in the Ta^{2+} or Ta^{3+} containing systems of BaO–TaO_2 or BaO–Ta_2O_3.

In the Ta^{4+} containing system of BaO–TaO_2, the compound, $BaTaO_3$ is not known. However, a mixed composition has been prepared and studied. Multiferroic super-lattice thin films of $BaFeO_3/BaTaO_3$ were fabricated by the pulsed laser deposition method for the first time. XRD and dielectric hysteresis measurements were carried out at room temperature. Temperature dependences of dielectric constant, magnetization and second harmonic generation intensities were also measured. Ferroelectricity and weak ferromagnetism were confirmed at room temperature.

In another publication, modeling of the system $A(B'_{1/3}B''_{2/3})O_3$ perovskites where B′ is Zn, B″ is Ta and A is Ba, was studied.

Ionic model (SSCAD) calculations were performed for 36 different cation ordered super cell configurations in the pseudo-binary perovskite related system $BaTaO_3$–$BaZnO_3$. $Ba(Zn_{1/3}Ta_{2/3})O_3$ (BZT) in a $P3m1$ ordered structure is the only single phase compound that is observed experimentally, and the one that SSCAD calculations predict as having lowest formation energy. It is therefore the presumed ground state at the BZT composition. The SSCAD results are supported by first principles VASP pseudo potential calculations which were performed for $BaTaO_3$, $BaZnO_3$, $Ba(Zn_{1/3}Ta_{2/3})O_3$, and $Ba(Zn_{1/2}Ta_{1/2})O_3$ with NaCl type ordering of Zn and Ta. Finite temperature calculations that are based on the SSCAD results, predict a strongly first-order $P3m1$–>$Pm3m$ transition, but the predicted T_C appears to be about an order of magnitude too high. The structure of $BaTaO_3$ is unknown since it is most likely unstable in bulk but probably stabilized by oxygen vacancies. It is likely a cubic perovskite with the formula of $BaTaO_{3-\delta}$ where δ is an array of scattered holes in the cubic lattice.

A similar compound, $BaTa_2O_5$ has been studied. A new lead-free ferroelectric material was developed. Ferroelectric materials are widely used for capacitors and piezoelectric devices. In those applications, "lead-free" is an important keyword due to environmental issues. The newly developed material is a Ba–Ta–O double oxide, $BaTa_2O_5$. The compound was synthesized in single crystal by a floating zone (FZ) method. Excellent ferro electricity was discovered in a particular direction of the crystal plane.

The Ta^{5+} containing system of BaO–Ta_2O_5 is known to form six (6) compounds as shown in the phase diagram: Fig. 9.122.

Three compounds melt congruently: $BaTa_2O_6$, $Ba_5Ta_4O_{15}$ and $Ba_6Ta_2O_{11}$. The others melt incongruently. A single report is available describing a systematic study of phase relations in the BaO–Ta_2O_5 system. Six binary phases were reported to form at 6:1, 4:1, 3:1, 5:2, 1:1, and 1:2 BaO:Ta_2O_5 molar ratios. The three latter compounds are well established: $Ba_5Ta_4O_{15}$ is isostructural with $Ba_5Nb_4O_{15}$ and exhibits a five-layer hexagonal structure derived from perovskite.

Structure factors included are shown in Table 9.70.

$BaTa_2O_6$ exhibits three polymorphs: a low-temperature orthorhombic form isostructural with $BaNb_2O_6$, an intermediate form with a tetragonal tungsten bronze type structure, and a high-temperature hexagonal form; all of the structures are of the framework type with octahedrally coordinated Ta^{5+} and channels accommodating barium. $BaTa_4O_{11}$ occurs with a tetragonal tungsten bronze related structure. The occurrence and crystal chemistry of the higher-BaO compounds at 3:1, 4:1, and 6:1 BaO:Ta_2O_5 have not been well established; however, $Ba_4Ta_2O_9$ has been reported to exist in polymorphic forms with perovskite-related structures. Ceramics have good microwave dielectric properties, including high relative permittivity (ε_r), high quality factor (Q), and low temperature coefficient of resonator frequency (τ_f). The ceramics show ε_r in the range of 11–51, $Q \times f = 2400$–$88{,}000$ GHz and τ_f in the range −73–+232 ppm/°C. This type of materials is called cation-deficient perovskites if written in the perovskite form (ABO_3), and $A_5B_4O_{15}$ is reduced to $AB_{0.8}O_3$. There is a vacancy of 0.2B cation per 1A cation, i.e., overall 1B cation vacancy per 5A cations. Galasso et al. showed that these compounds have hexagonal structure and crystallized them in the $P\bar{3}m1$ space group. They also have the closest packing of oxygen and barium ions into five layers. The tantalum or niobium ions are located in the octahedral holes between layers. One layer of the octahedral hole does not have tantalum or niobium ions to obtain the charge neutrality. Therefore, there is an empty octahedrum, which results in the loss of face sharing on the NbO_6 sub-lattice, and this structure implies strong anharmonicity. The $Ba_5Nb_4O_{15}$ shows a hexagonal structure where the dielectric values are: $\varepsilon_r = 39$, $Q \times f = 23{,}700$ and $\tau_f = 78$ ppm/°C. The $Ba_5Ta_4O_{15}$ has a lower $\varepsilon_r = 28$ than that of $Ba_5Nb_4O_{15}$, even though its tantalum has larger ionic polarizability. This arises because the lattice of $Ba_5Ta_4O_{15}$ is stable whereas that of $Ba_5Nb_4O_{15}$ could collapse to a lower symmetry. Lattice anharmonicity causes a relatively higher permittivity for $Ba_5Nb_4O_{15}$ compound.

Mono-barium tantalate is trimorphic. There are three space groups involved:

$C222_1$, $P3m_1$ and $P3m_1$

The polymorphism of $BaTa_2O_6$ has been described by Layden. Below about 1150 °C, a modification isostructural with orthorhombic $BaNb_2O_6$ forms, between ~1150 °C and 1300 °C a tetragonal tungsten bronze type structure forms, and above 1300 °C a hexagonal modification occurs. For the latter form, a structural

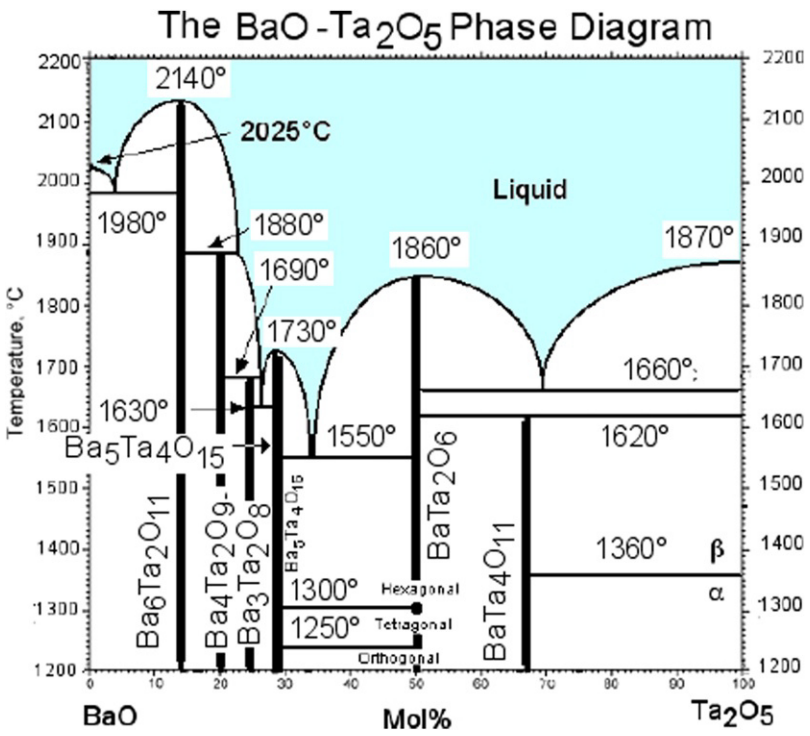

FIGURE 9.122

model has been proposed that was consistent with powder XRD data (*P6/mmm*; $a = 21.14$ Å, $c = 3.917$ Å; $Z = 12$). In the BaO–Nb_2O_5 system, the same hexagonal structure was found to form at the composition $Ba_{0.9}Nb_2O_{5.9}$. Single crystals of all three forms of $BaTa_2O_6$ have been obtained using a BaO:V_2O_5 flux. Completed structural refinements results indicate that: 1) for the hexagonal structure, one of the Ba sites originally placed at $Z = 0$ is actually at $Z = 0.28$, changing the coordination number from an unlikely 18 to a more reasonable 12; and 2) the tetragonal form crystallizes in the non-polar space group $P\bar{4}b2$ rather than the more commonly found *P4bm*. Mixtures prepared along the $BaTa_2O_6$ –$Ba_5Ta_4O_{15}$ join and annealed at temperatures above 1300 °C (e.g. 1550 °C) were found to contain the tetragonal tungsten bronze type form of $BaTa_2O_6$, indicating that this polymorph is kinetically stabilized in this region. The hexagonal form has the sub-lattice as shown in Fig. 9.123.

Lattice parameters are: $a = 6.14$ Å, $c = 8.05$ Å, $\alpha = 90°$, $\gamma = 120°$, cell volume = 259.41 Å^3. Site occupancy is shown in Table 9.71.

Phase equilibria studies in the compound, $BaTa_2O_6$, disclosed three modifications: a low temperature modification isomorphous with orthorhombic $BaNb_2O_6$ which forms below about 1150 °C, a tetragonal modification having the potassium tungsten bronze structure which forms between about 1150 °C and 1300 °C, and

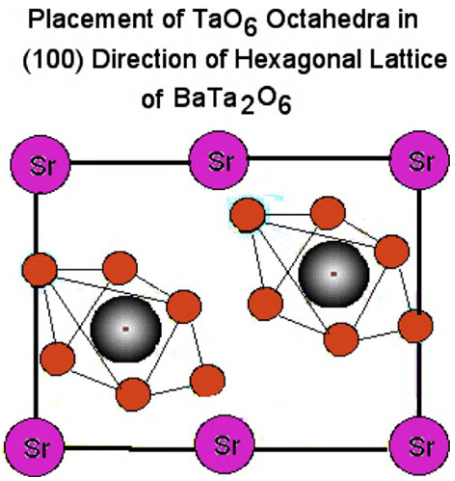

FIGURE 9.123

a hexagonal modification stable from 1300 °C to its melting point at about 1850–1900 °C. The high-temperature hexagonal form of $BaTa_2O_6$ has a *P6/mmm* symmetry with unit-cell parameters of $a = 21.116$ Å, and $c = 3.9157$ Å. Single crystal X-ray structure refinements for both phases are generally consistent with a previously proposed model, except for displacements of some Ba atoms from high-symmetry positions.

Another view of these three structures is presented in Fig. 9.124.

The orientation of the barium ions is better seen in Fig. 9.125

The structures are based on a framework of corner- and edge-connected Nb/Ta-centered octahedra, with barium atoms occupying sites in four different types of [001] channels with hexagonal, triangular, rectangular and pentagonal cross-sections. The refinements showed that the non-stoichiometry in the niobate phase is due to barium atom vacancies in the pentagonal channels and to extra niobium atoms occupying interstitial sites with tri-capped trigonal prismatic coordination. The origin of the non-stoichiometry is attributed to minimization of non-bonded Ba–Ba repulsions. The hexagonal structure is related to the structures of the low-temperature forms of $BaNb_2O_6$ and $BaTa_2O_6$, through a 30° rotation of the hexagonal rings of octahedra centered at the origin. Crystals of the orthorhombic and hexagonal modifications have been grown from this system by the slow-cooling technique.

The tetragonal form could only be obtained as a very fine precipitate. Attempts were made to grow the hexagonal modification from the melt using the Czochralski technique; it was found that not only the hexagonal, but the orthorhombic and tetragonal forms as well, could be grown in this fashion. The phase transformation of crystal fragments was investigated. Only transformations from the orthorhombic and tetragonal forms to the hexagonal form were observed to occur in times less than 100 h in the appropriate temperature ranges.

The hexagonal form of $BaTa_2O_6$ differs considerably from its Sr-homolog, as shown in Fig. 9.126. Yet, it readily forms solid solutions with the strontium homolog.

The proposed structure for hexagonal $BaTa_2O_6$ has one twelfth of the barium atoms located in tunnels, which run in the *c* direction through the Ta-oxygen framework. A relaxation polarization process is observed to occur when an alternating electric field is imposed across single crystal samples in the *c* direction, but is not observed when the field is perpendicular to the *c* direction. This is attributed to the motion of barium atoms in the tunnels.

This compound has been studied as a dielectric film for use in high-frequency capacitors. The characteristics of radio-frequency magnetron sputtered $BaTa_2O_6$ thin films with aluminum (Al) top and indium tin oxide (ITO) bottom electrodes have been investigated as a function of applied field and temperature. The optical transmittance in the visible range was in range of 80–90% regardless of the substrate temperature. The dielectric constant increased from 20 to 30 with increasing the substrate temperature and nearly independent of the frequency in the range of 0.3–100 kHz but the loss factors increased with increasing the substrate temperature at high frequency. The leakage currents of $BaTa_2O_6$

thin film are in the order of 10^{-6}–10^{-7} A/cm^2 at the applied field of 1 MV/cm and the charge storage capacitance ($E_{breakdown}$) are 5.64 (100 °C), 10.6 (200 °C) and 11.8 (300 °C) μC/cm^2. From the deposition temperature, voltage polarity and thickness dependence of leakage current, we can conclude that the dominant conduction mechanism is ascribed to Schottky emission at high electric field (>1 MV/cm) and hopping conduction at low electric field (<1 MV/cm). The Schottky barrier heights measured are 1.14 eV at Al(+) and 0.8 eV at Al(−).

Hexagonal barium tantalate ($BaTa_2O_6$) nanorods were synthesized by a hydrothermal method based on the reaction of concentrated $Ba(OH)_2$ solution and Ta_2O_5. $BaTa_2O_6$ samples show a uniform cylindrical structure with diameters of 5–30 nm and the lengths of 50–200 nm. The formation of $BaTa_2O_6$ nanorods follows a dissolution–recrystallization mechanism and is governed by hydrothermal temperature and time. $BaTa_2O_{6-\delta}$ nanorod samples prepared at 270 °C for 72 h have exhibited the highest photocatalytic activity in the degradation of Rhodamine B (RhB) in aqueous solution under UV radiation. Hydrogen-related defects were detected in $BaTa_2O_{6-\delta}$ nanorods, which originate from the oxygen octahedron. The number of defects was dependent on the hydrothermal temperature, and the photocatalytic activities of $BaTa_2O_{6-\delta}$ nanorods increase with the decrease of defect amounts. On the basis of the experiment results, the difference in photocatalytic activities for samples is mainly caused by lattice defects, which can act as inactivation centers.

Single crystal of a novel compound, $K_{1.83}Ba_{4.17}Nb_{12.18}O_{36}$, has been synthesized in the course of investigation on the K_2O–BaO–Nb_2O_5 system. The crystal structure was determined by single crystal XRD

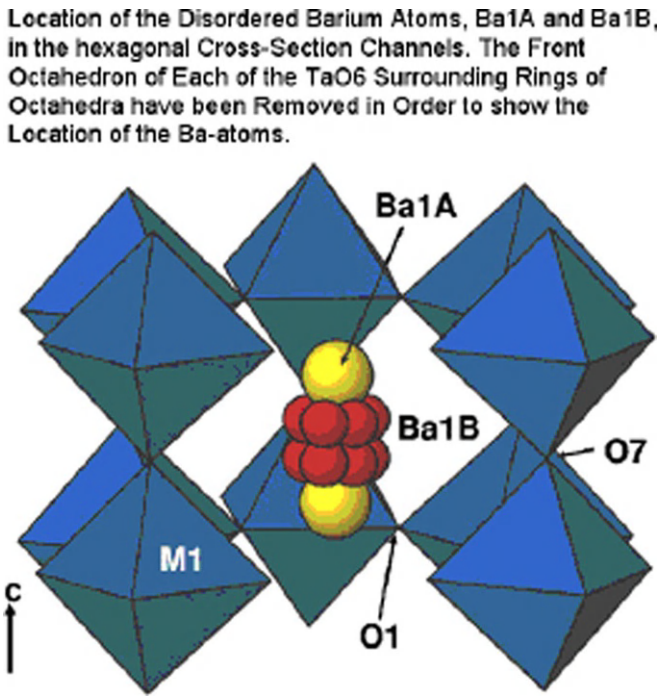

FIGURE 9.125

data. The space group of this compound was found to be $P6/mmm$ (#191) with the lattice parameters of $a = 21.109(4)$ and $c = 3.967(1)$ Å. The final R-factors were $R = 0.039$ and $R_w = 0.042$ for unique 508 reflections. The crystal structure had the same tunnel structure as that of hexagonal $BaTa_2O_6$ (H-$BaTa_2O_6$), which is the highest temperature form in three modifications of $BaTa_2O_6$. The chemical composition of $K_{1.83}Ba_{4.17}Nb_{12.18}O_{36}$ was close to that of the tetragonal tungsten bronze (TTB) type $KBa_2Nb_5O_{15}$ and the powder samples within this composition were prepared so as to clarify the boundary between H-$BaTa_2O_6$ and TTB-type structures. The H-$BaTa_2O_6$-type structure appears in $(K + Ba)/Nb \leq 0.500$ and the TTB-type structure is in $(K + Ba)/Nb \geq 0.575$. The dielectric constants of these samples were measured from room temperature to 500 °C for sintered body. The TTB-type compounds exhibited ferroelectric temperature dependence with the Curie points of 284–372 °C and the H-$BaTa_2O_6$-type compounds were not ferroelectrics as predicted from the crystal structure analysis.

The compound, **barium di-tantalate**, $BaTa_4O_{11}$, appears in the phase diagram as an incongruently melting structure. Although the TTB-type of $BaTa_4O_{11}$ (33 mol% BaO) was previously reported as a line compound, a recent study found an extensive solid solution in this region of the binary system. This solid solution is similar to that found in the BaO:Nb_2O_5 system, and again demonstrates the remarkable stability of tetragonal tungsten bronze related structures over a wide range of stoichiometry. In the region from 43 to 39 mol% BaO, no superstructure formation was observed and powder patterns could be indexed on the basis of tetragonal 12 Å × 4 Å TTB-type unit cells. Although the formula for the solid solution in this region can be written with oxygen-deficiency as $Ba_{5-y}Ta_{10}O_{30-y}$, with $1.2 \leq y \leq 1.8$, there is no logical crystal chemical model to account for the possible oxygen vacancies. Alternatively, and preferably, if one assumes that the strongly bonded octahedral framework (denoted in the following by square brackets) remains intact, the formula for the TTB-type solid solution from 43 to 39 mol% BaO can be expressed as $Ba_xTa_{(10-2x)/5}[Ta_{10}O_{30}]$, with $x = 3.93$ to 3.40. In this model, Ba and the excess Ta occupy disordered sites within the channels, with Ta^{5+} lowering its coordination number by moving from the centers of the channels. In the region from 38 to 31 mol% BaO, superstructures formed with a- and b-parameters related to those of the TTB structure by a factor of $\sqrt{2}$, yielding tetragonal or orthorhombic super cells similar to those observed in a number of other systems. If one assumes that the formation of a super cell with a doubled unit-cell

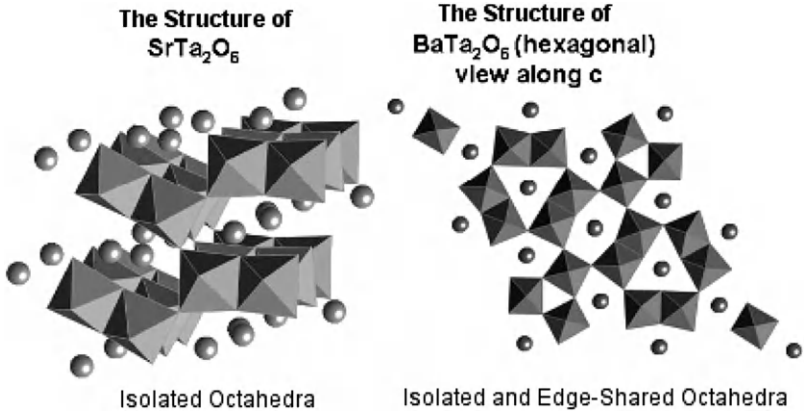

FIGURE 9.126

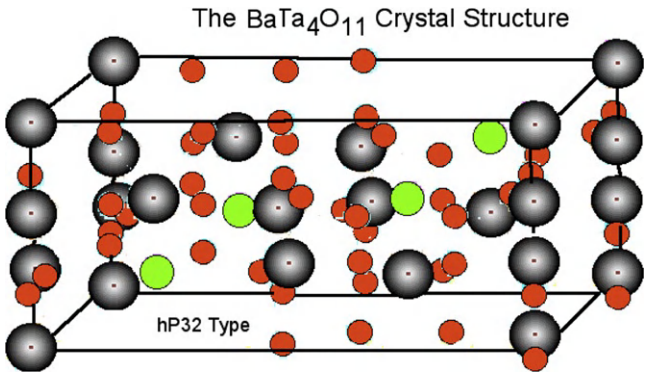

FIGURE 9.127

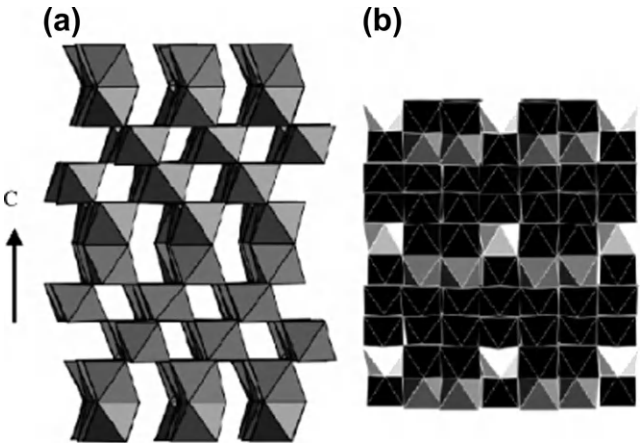

FIGURE 9.128

volume is caused by the ordering of 2[TaO_6] units per super cell in sites within the pentagonal channels, in a manner analogous to the formation of tripled superstructures in TTB-related $Nb_8W_9O_{47}$ or $Sr_2Nb_{10}O_{27}$, and $SrTa_4O_{11}$, then a possible general formula for the $\sqrt{2}$-type solid solution from 38 to 31 mol% BaO is $Ba_xTa_{(14-2x)/5}[Ta_{22}O_{62}]$, with $x = 6.77$ to 5.11, respectively. This model would not require the formation of oxygen vacancies; Ba and excess Ta not associated with the framework would occupy disordered sites within the channels. In the region from 30 to 26 mol% BaO, tripling of the TTB *b*-parameter was observed, resulting in a unit cell with a tripled cell volume. As in $Nb_8W_9O_{47}$ [42,38], the formula for the framework of the tripled TTB structure is [$M_{34}O_{94}$], which includes the 4 [MO] units occupying ordered pentagonal channel sites. Therefore, a possible general formula for the tripled-cell-type solid solution from 30 to 26 mol% BaO is $Ba_xTa_{(18-2x)/5}[Ta_{34}O_{94}]$, with $x = 7.42$–6.17, respectively. As above, this model does not require the formation of oxygen vacancies, and Ba and excess Ta not associated with the [$M_{34}O_{94}$] framework would occupy disordered sites within the channels. Detailed structural determinations have not yet been carried out to confirm these suggested mechanisms accommodating the variable stoichiometry and leading to the formation of the different superstructures.

The compound, barium di-tantalate, $BaTa_4O_{11}$, is believed to have the same structure as the strontium di-tantalate. It would then have the form as shown in Fig. 9.127.

However, the exact structure has not been published to date.

The **tri-barium tantalite** compound, $Ba_3Ta_2O_8$, is hexagonal. Cell parameters are: $a = b = 5.8445$ Å, $c = 7.3832$ Å, $\alpha = \beta = 67.388°$, $\gamma = 60.167°$, cell volume = 194.41 Å^3, $Z = 2$. Although this barium compound has not found usage in Industry, a modification of this structure is beginning to be used in the wireless communication sector. The complex perovskite compounds of barium-zinc tantalates, that exhibit a high relative permittivity, good quality factor (Q), and a near zero temperature coefficient of resonant frequency (τ_f), have been used in manufacturing dielectric resonators in the wireless communication system. A barium zinc niobate ($Ba(Zn_{1/3}Nb_{2/3})O_3$) (BZN) complex perovskite has been reported to have special microwave dielectric properties with close relation of its ordered structure. The tantalate modification has also been studied. The hexagonal perovskite, $Ba_8ZnTa_6O_{24}$, was prepared in single-phase form and was found to be a stable secondary phase, formed as a result of the loss of ZnO from $Ba(Zn_{1/3}Ta_{2/3})O_3$ microwave dielectrics. The experimental and calculated X-ray patterns of $Ba_8ZnTa_6O_{24}$ indicate it is isostructural with $Ba_8ZnNi_6O_{24}$ with an 8H $(CCHC)^2$ close-packed BaO_3 stacking sequence and the lattice parameters, $a = 5.100825$, $c = 5.190587$ Å . The structure has the form as shown in Fig. 9.128.

Here, the structure models of $Ba_8ZnTa_6O_{24}$ are projected along: (a) the (110) direction to highlight the corner and face-shared octahedra and (b) along the [110] direction to highlight the ordering of Ta, Ni, and vacancies in the face-shared octahedra (Ta = black, vacancy = white, Zn-rich = gray). In both the figures, Ba atoms are omitted for clarity.

High-density ceramics of $Ba_8ZnTa_6O_{24}$ could be prepared at temperatures considerably lower (1400 °C) than those used to sinter pure $Ba(Zn_{1/3}Ta_{2/3})O_3$, and exhibit very good microwave dielectric properties with $\varepsilon_r = 530.5$, $Q \times f = 562\ 300$, and $\tau_f = 5136$ ppm/°C at 8.9 GHz. Dense ceramic samples of B $Ba_8ZnTa_6O_{24}$, formed at 1400 °C via a two-stage sintering process, have excellent microwave dielectric properties with $\varepsilon_r = 30.5$, and $Q \times f = 62{,}300$ at 8.9 GHz; however, additives will be needed to lower the temperature coefficient $\tau_f = +36$ ppm/°C.

The **tetra-barium tantalite**, $Ba_4Ta_2O_9$, is dimorphic with space groups of o*S*240-*C*222$_1$ and *hP*15-*P*-3m_1. Cell parameters are: (1) low temperature phase: $a = 12.15$ Å, $b = 12.20$ Å, $c = 16.07$ Å, $\alpha = \beta = 90°$, $\gamma = 119.86°$, cell volume = 2065.76 Å^3, $Z = 16$. The other form (2) has the parameters: $a = 4.253°$, $b = c = 5.952$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 130.48 Å^3, $Z = 1$. The polymorphic phase transitions and the stability of the individual polymorphs of tetra-barium di-niobate (V) ($Ba_4Nb_2O_9$) were studied at different temperatures. $Ba_4Nb_2O_9$ ceramics were prepared via a conventional solid-state reaction route. Three $Ba_4Nb_2O_9$ polymorphs were isolated. These include a hexagonal (α) and two orthorhombic (γ, β) modifications. TEM revealed an intergranular BaO-rich amorphous phase and nano-crystalline $Ba_5Nb_4O_{15}$ in all the polymorphs, most abundantly in the α-modification. Superstructure ordering in the α-modification was confirmed by ED methods. The α-$Ba_4Nb_2O_9$ was observed to be stable in the temperature range 560–1160 °C; below 560 °C the stable polymorph is β-$Ba_4Nb_2O_9$, while above 1160 °C the only stable polymorph is γ-$Ba_4Nb_2O_9$.

Low-temperature α-$Ba_4Ta_2O_9$ is isostructural with β-$Ba_4Nb_2O_9$ ($Sr_4Ru_2O_9$ type), and it undergoes a reconstructive phase transition at approximately the same temperature (1400 K) to a γ-form that can easily be quenched to room temperature. However, the γ forms of the two compounds are completely different. Whereas γ-$Ba_4Nb_2O_9$ represents a unique structure type, γ-$Ba_4Ta_2O_9$ adopts a more conventional 6H-perovskite type. The α ⇒ γ transition is virtually irreversible in the tantalate, unlike the niobate, which can be converted back to the α form by annealing slightly below the transition temperature. Quenched γ-$Ba_4Ta_2O_9$ is highly strained due to the extreme size mismatch between Ba^{2+} (1.35 Å) and Ta^{5+} (0.64 Å) cations in the perovskite B-sites, and undergoes a series of symmetry-lowering distortions from $P63/mmc \Rightarrow P63/m \Rightarrow P21/c$; the second of these transitions has not previously been observed in a 6H perovskite. Below 950 K, both α-$Ba_4Ta_2O_9$ and γ-$Ba_4Ta_2O_9$ hydrate to a greater extent than the corresponding phases of $Ba_4Nb_2O_9$. Both hydrated forms show significant mixed proton and oxide ionic conductivity, and electronic conductivity upon dehydration.

The low-temperature form has the structure shown as follows. The low-temperature form of $Ba_4Ta_2O_9$ is isostructural with that of $Ba_4Nb_2O_9$ and undergoes a reconstructive phase transition at a similar temperature as shown in Fig. 9.129.

However, the high-temperature forms are different. The tantalates hydrate to a greater extent than the niobates, but show slightly lower protonic and oxide ionic conduction. The structure contains isolated Ta_2O_9 face-sharing octahedral dimers, separated by very large voids.

The compound, **hexa-barium tantalite**, $Ba_6Ta_2O_{11}$, has the highest melting point of all of the barium tantalites, as shown in the phase diagram presented above. It is said to possess a five-layered structure similar to the penta-barium di-tantalate which has a double-layer structure as shown in Fig. 9.130.

This diagram is expanded in order to show the octahedra in the internal structure. The actual structure is more compact. Very little information is available for this compound other than structure. It has proven difficult to prepare and is unstable at room temperature.

The compound penta-barium di-tantalate, $Ba_5Ta_4O_{15}$, has the structure as shown in Fig. 9.131.

Cell parameters are: $a = b = 5.783$ Å, $c = 11.81$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = $a = 0.5783$ nm, $b = 0.5783$ nm, $c = 1.182$ nm, cell volume = 342.34 Å^3, $Z = 1$. Cell occupancy is shown in Table 9.72.

Monomolecular-layer perovskite $Ba_5Ta_4O_{15}$ nanosheets with hexagonal structure have been synthesized by a hydrothermal method. The thickness of the nanosheets was about 1.1 nm, which corresponded to a monolayer of $Ba_5Ta_4O_{15}$ molecules, with the lateral size ranging from 50 to 200 nm. The optimal conditions for the formation of the nanosheets were found to be maintaining the reactants above 270 °C for 24 h. A dissolution recrystallization mechanism was suggested based on observations of the factors that influence nanosheet formation, such as reaction time, temperature, and basicity. Formation of $Ba_5Ta_4O_{15}$ nanosheets took precedence over other nanostructures under high

concentrations of OH^- because the hindering effect of OH^- ions on the *c*-axis growth is strong. Thus, the extended growth rate of polyhedrons on one monolayer was much faster than the superposition rate of the monolayer, and the crystal grows more easily along the *a*- and *b*-planes. The $Ba_5Ta_4O_{15}$ nanosheets showed a high photocatalytic activity in the degradation of Rhodamine B and gaseous formaldehyde. The layered perovskite probably affects the photocatalytic activity by promoting the charge separation and delocalization of photo generated electrons and holes. A better view of this crystal structure is shown in the following Fig. 9.132.

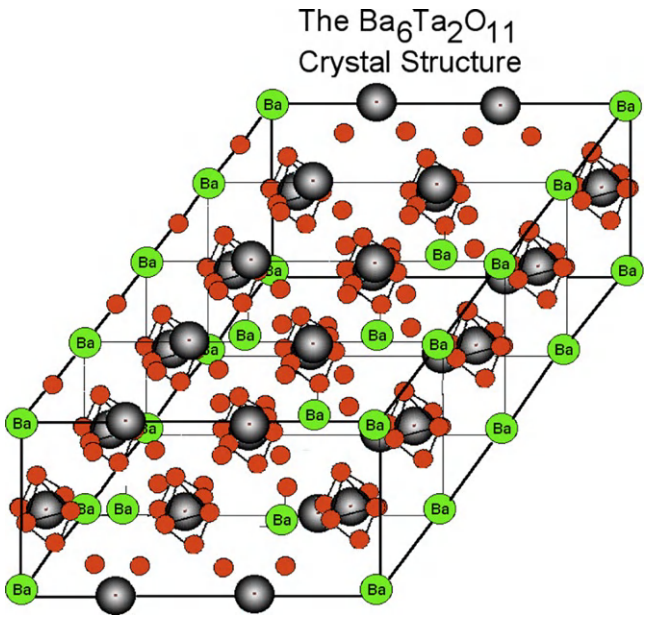

FIGURE 9.130

It is homologous with penta-strontium di-tantalate. Barium, as BaO, forms a number of distinct and unusual tantalate compounds with other members of the alkaline earth family including Mg, Ca, and Sr.

The phase relations in the BaO–MgO–Ta_2O_5 system equilibrated at 1450 °C were reported. Three ternary phases, namely 3:1:1 perovskite $Ba_3MgTa_2O_9$, 9:1:7 TTB (tetragonal tungsten bronze)-type $Ba_9MgTa_{14}O_{45}$ and 4:1:5 $Ba_4MgTa_{10}O_{30}$ closely related to the tungsten bronze structure were reported. Another ternary phase, $Ba_{10}Mg_{0.25}Ta_{7.9}O_{30}$, with a 10 layer hexagonal perovskite structure can be only obtained after equili bration at 1600 °C. MgO solubility in the TTB-like $Ba_4Ta_{10}O_{29}$,

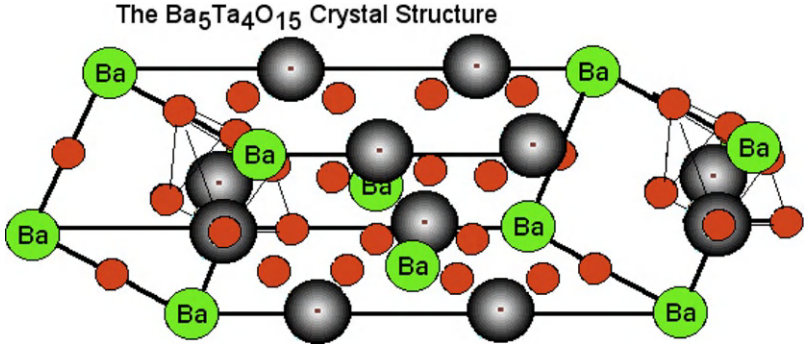

FIGURE 9.131

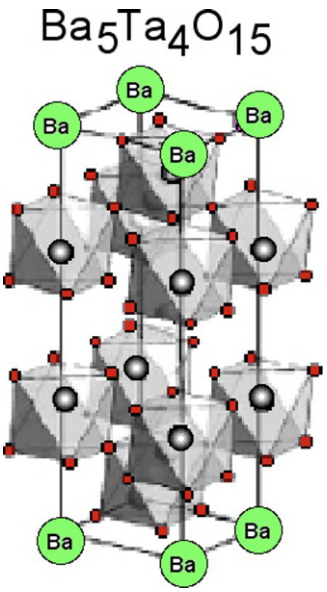

FIGURE 9.132

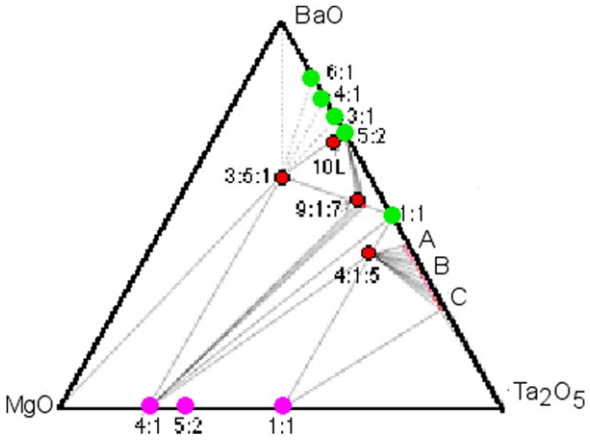

FIGURE 9.133

$BaTa_4O_{11}$ and $Ba_{6.63}Ta_{34.95}O_{95}$ does not exceed 2.0 mol%. Only the hexagonal polymorph of the $BaTa_2O_6$ phase was found along the $Mg_4Ta_2O_9$–$BaTa_2O_6$ join. Measurements of dielectric properties in the 20 Hz–2 MHz range revealed that $Ba_9MgTa_{14}O_{45}$ has a dielectric constant of 99 with no frequency dispersion and low dielectric loss.

The ternary diagram appears as shown in Fig. 9.133.

The photocatalytic activities of strontium pyrotantalate are improved by forming solid solutions with the barium compound, i.e.-$(Sr_{1-x}Ba_x)_2Ta_2O_7$. However, the detailed reason why such an increase in the photo catalytic performance by barium doping occurs has not yet been explained. In this study, Rietveld analysis of the powder XRD data was performed to reveal the structural changes induced by barium doping. The powder samples were prepared by the polymerized complex method with the molar ratio of Sr:Ba:Ta = 1−*X*:*X*:1. Existing phases in the prepared samples were identified and the mass fraction for each phase was estimated by the result of Rietveld analysis. The photocatalytic activity of a mixture of Sr:Ba increases up to $X = 0.2$, where the sample containing Ba-doped $Sr_2Ta_2O_7$ exhibits the highest photocatalytic performance, 5700 μmol/h, in the photolytic decomposition of H_2O into H_2. On the other hand, the sample of $X = 0.8$ composed of mainly Sr-doped $Ba_5Ta_4O_{15}$ shows the next highest activity, 4800 μmol/h. The high photocatalytic activities of strontium–barium tantalate solid solutions can be explained in terms of distortion in the crystal lattice, based on the result of Rietveld analysis.

Barium tantalate is offered for sale commercially as $BaTa_2O_6$ with the CAS Number: 12047-34-6.

9.3.6. Radium Tantalates

Although radium is expected to form the same type of compounds as its barium homolog, such as $RaTa_2O_6$, $Ra_5Ta_4O_{15}$ and $Ra_6Ta_2O_{11}$, the high cost of radium and the high level of radioactivity of ^{226}Ra have likely precluded any studies being made. It is unlikely that any examination of such compounds will occur in the future because of the non-existent demand in Industry for these materials.

10.1. ALKALINE EARTH CHROMIUM COMPOUNDS

In the important oxidation state of +3, chromium's extensive chemistry is dominated by the formation of stable complexes in which chromium is dodecahedrally six-coordinate. Dichromium trioxide [CAS 1308-3-91] (also chromium sesquioxide, chromium (+3) oxide), Cr_2O_3, is an important green pigment. Compounds of the type $Ae^{2+}Cr_2O_4$ are mixed oxides, with the chromium occupying the octahedral holes in a closed-packed lattice of oxide ions. The Ae^{2+} oxides are largely spinels and the ore, chromite, is an important example of the class.

Chromium(IV) oxide, chromium dioxide, CrO_2, is obtained by hydrothermal reaction of Cr(VI) or Cr(III) compounds in the presence of oxygen or hydrogen. The stability of chromium dioxide has been studied. It has a tetragonal lattice similar to rutile, TiO_2. Although Cr(IV) does not form anions in aqueous solution, compounds such as dibarium chromate (1:1) Ba_2CrO_4, prepared from the oxides and containing discrete CrO_2 groups, have been prepared (the other Ae_2CrO_4 compounds are unknown). The chemistry of chromium in oxidation state +5 is quite similar to that of the +4 state. There are more ionic chromium(V) compounds, but disproportionation in aqueous systems prevents their isolation from water solution.

Chromium pentoxide, chromium(V) oxide (2:5), Cr_20_5, like CrO_2 can be prepared by the decomposition of CrO_3. A nearly complete series of salts containing the $Cr0_4^{3-}$ ion has been prepared. They resemble the corresponding phosphates structurally and are generally green in color. The alkali metal salts M_3CrO_4 are hygroscopic and unstable in moist air. The barium, strontium, and calcium chromates(V) are also known. The calcium chromite–chromate, $Ca_{0.4}CrO_3 \cdot Cr_2O_3$, reported from the roasting of chromite with lime and

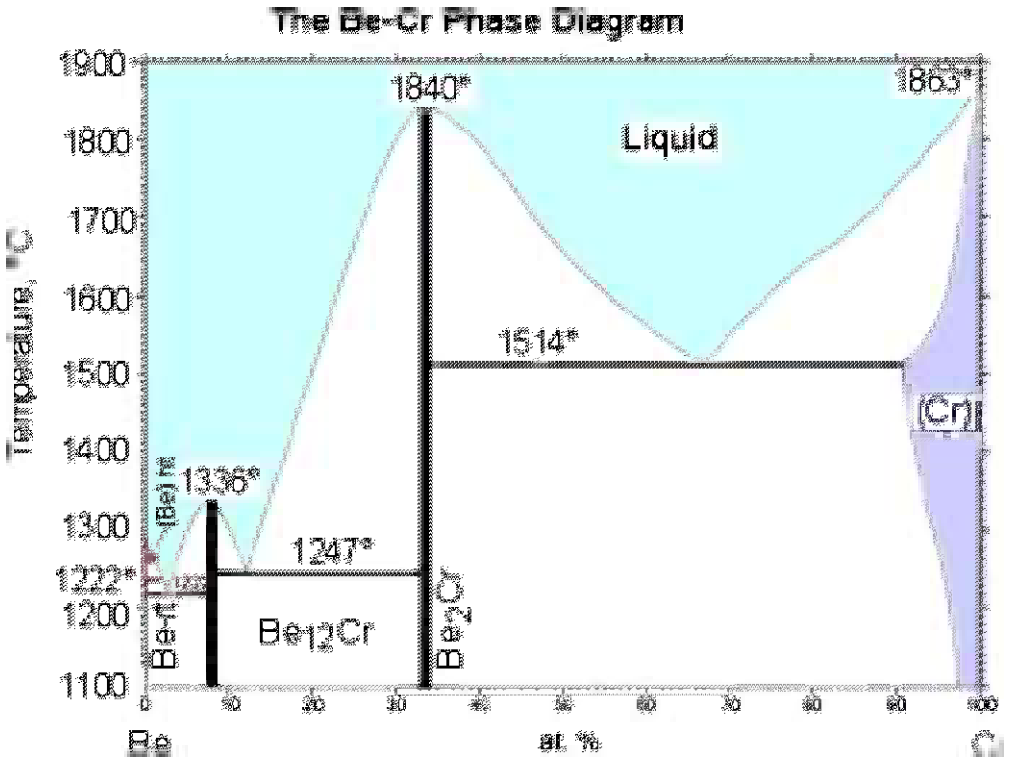

FIGURE 10.1

soda ash, is more properly formulated as $Ca_3(CrO_4)_2$. This compound is readily prepared by heating CaO and $CaCrO_4$ to about 1150 °C. Hydroxy-compounds, such as $Ba_5(CrO_4)_3(OH)$ analogous to apatite also exist.

Chromium(VI) bears a strong structural resemblance to hexavalent sulfur. The principal differences are to be found in the oxidizing nature of chromium(VI). The weaker acidity of H_2CrO_4, the nonexistence of solid dichromates containing the $HCrO_3^-$ ion, the existence of polychromates, particularly dichromates, and the much less energetic hydration of the oxide CrO_3 also contribute to this characteristic. The softer nature of the acid, e.g. the polarizabilty of the CrO_4^{2-} ion, is also a factor. In solution, at pH 6, the tetrahedral yellow CrO_4^{2-} ion is the principal species; at pH 2–6, the orange $HCrO_4^-$ and $Cr_2O_7^{2-}$ ions predominate at moderate concentrations. At very low pH, the principal species is $HCr_2O_7^{2-}$. In heavy concentrated solutions, $Cr_3O_{10}^{2-}$ and $Cr_4O_{13}^{2-}$ ions exist. Chromium trioxide (chromic anhydride, chromium(VI) oxide), CrO_3, is the chromic acid of commerce. It is a red solid, melting at 197 °C with slow decomposition. The decomposition becomes rapid and exothermic at about 220 °C, forming largely impure Cr_2O_5.

Thus, it is the +3 and +6 states of chromium that are most important in the chemical reaction of alkaline earth oxides with oxy-chromium compounds to form "chromites" and "chromates". The dichromates of the alkaline earths have also been characterized. In aqueous solution, chromate and dichromate anions can exist in a chemical equilibrium:

$$2CrO_4^{2-} + 2H^+ \Leftrightarrow Cr_2O_7^{2-} + H_2O$$

Further condensation reactions can occur in strongly acidic solutions with the formation of trichromates, $Cr_3O_{10}^{2-}$, and tetrachromates, $Cr_4O_{13}^{2-}$. All poly-oxyanions of chromium(VI) have structures made up of tetrahedral CrO_4 units sharing corners.

10.1.1. Alkaline Earth Chromide Compounds

The metal, Cr^0, forms a limited number of "chromides" with the alkaline earth metals. Only Be forms any specific compounds and these are limited to two. These intermetallic compounds have found no usage in industrial applications.

The phase diagram of the system, Cr–Be, is shown in Fig. 10.1.

The structural data are shown in Table 10.1.

The compound, Be_2Cr, has the structure shown in Fig. 10.2.

Cell parameters are: $a = b = 4.26$ Å, $c = 6.988$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 109.23 Å^3. Cell occupancy is shown in Table 10.2.

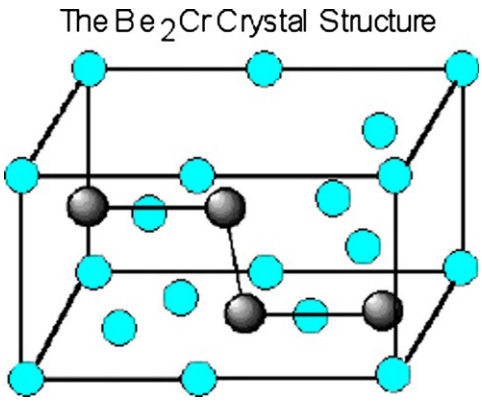

FIGURE 10.2

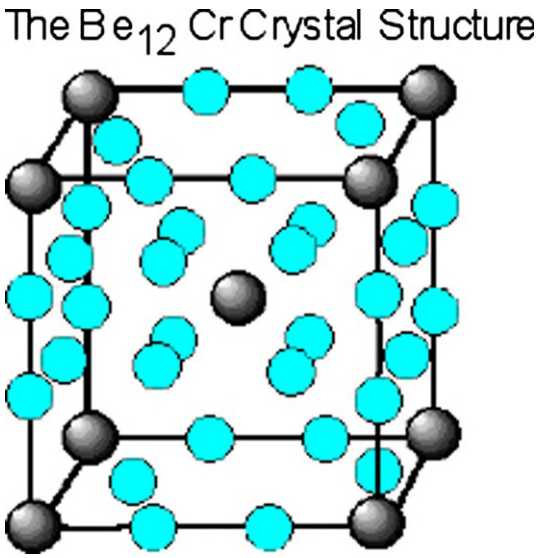

FIGURE 10.3

The compound, $Be_{12}Cr$, has the structure shown in Fig. 10.3.

Cell parameters are: $a = 4.174$ Å, $b = c = 5.5277$ Å, $\alpha = 81.803$ Å, $\beta = \gamma = 67.816$ Å, cell volume $= 109.34$ Å^3, $Z = 2$. Cell occupancy is shown in Table 10.3.

In Be–Cr alloys that are in equilibrium, there is a phase based on $CrBe_{12}$, which is formed by the peritectic reaction: $Liq + CrBe_2 \Leftrightarrow CrBe_{12}$. The composition of the compound is evidently close to the composition at the peritectic point on the phase diagram. Further work on the position of the eutectic point on the phase diagram determined more precisely its value from the beryllium side. Eutectic solidification occurs at 1240 ± 10 °C in the alloy containing 13.8% Cr. Binary beryllium alloys containing up to 13% Cr have relatively low strength, not

exceeding 10–11.6 kgf/mm^2. When nickel or vanadium is added to the alloy of beryllium with chromium, the strength rises to 14–17 kgf/mm^2. The ductility of these alloys is low. They have not found usage in industry.

The other alkaline earths, Mg, Ca, Sr, Ba and Ra do not form chromide-type compounds.

10.2. ALKALINE EARTH OXY-CHROMIUM COMPOUNDS

Based on the known stability of the oxygen-dominated chromium ions, we would expect to find: chromites, $Cr_2O_4^{2-}$, CrO_4^{4-}, CrO_3^{2-}, $Cr_2O_6^{2-}$, $Cr_2O_7^{4-}$, $CrO_4^{2-}$and $Cr_2O_7^{2-}$. These are based upon the oxides: Cr_2O_3, CrO_2, Cr_2O_5, and CrO_3.

10.2.1. Beryllium Chromates

Beryllium oxide forms a number of compounds with the chromium oxides. The exact composition depends, to a great extent, on the oxidation state of the chromium ion, $Cr^{3,\ 4,\ 5\ or\ 6+}$.

For the system of BeO–CrO, no compounds are known.

For the trivalent Cr(III) oxide system only $BeCr_2O_4$ is known. One form of this compound is the chrysoberyl ($BeAl_2O_4$) structure shown in Fig. 10.4.

The purple BeO_4 tetrahedra sit at the apex of groups of three edge-connected green Cr(III)O_6 octahedra. In the BeO/Cr_2O_3 system, besides $BeCr_2O_4$ and the starting oxides, only small amounts of $BeCr(VI)O_4$ occur which, however, is supposed to catalytically activate the formation of a spinel-like $MgCrO_4$.

$BeCr_2O_4$ also has the Mg_2SiO_4 structure shown in Fig. 10.5.

Cell parameters are: $a = 4.555$ Å, $b = 5.663$ Å, $c = 9.792$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 252.58$ Å^3, $Z = 4$. Cell occupancy is shown in Table 10.4.

The other valence states of chromium do not allow the formation of compounds with BeO. Neither of the compounds shown above has been used in Industry, perhaps due to the lack of interest in Academia concerning their physical and chemical properties.

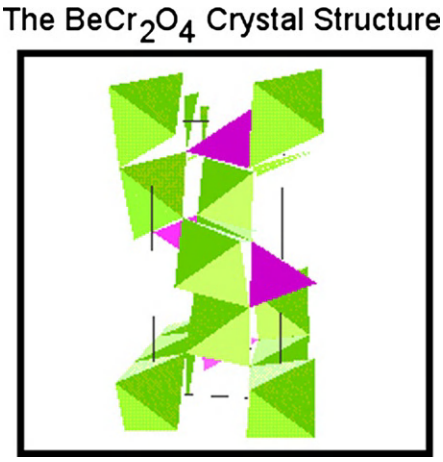

FIGURE 10.4

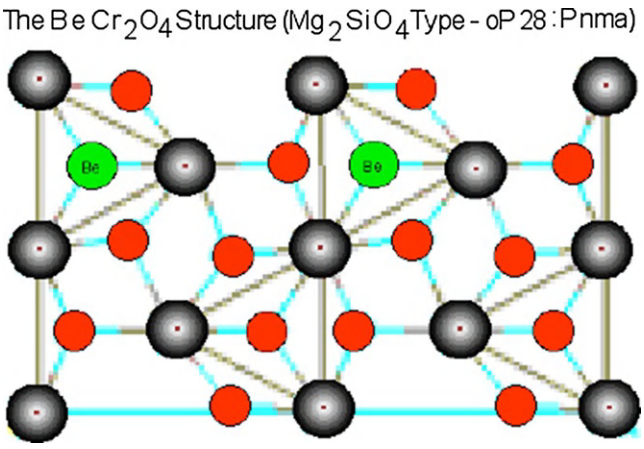

FIGURE 10.5

10.2.2. Magnesium Chromium Compounds

Magnesium oxide forms a limited number of compounds with the chromium oxides. The exact composition depends, to a great extent, on the oxidation state of the chromium ion, $Cr^{3,\ 4,\ 5\ or\ 6+}$.

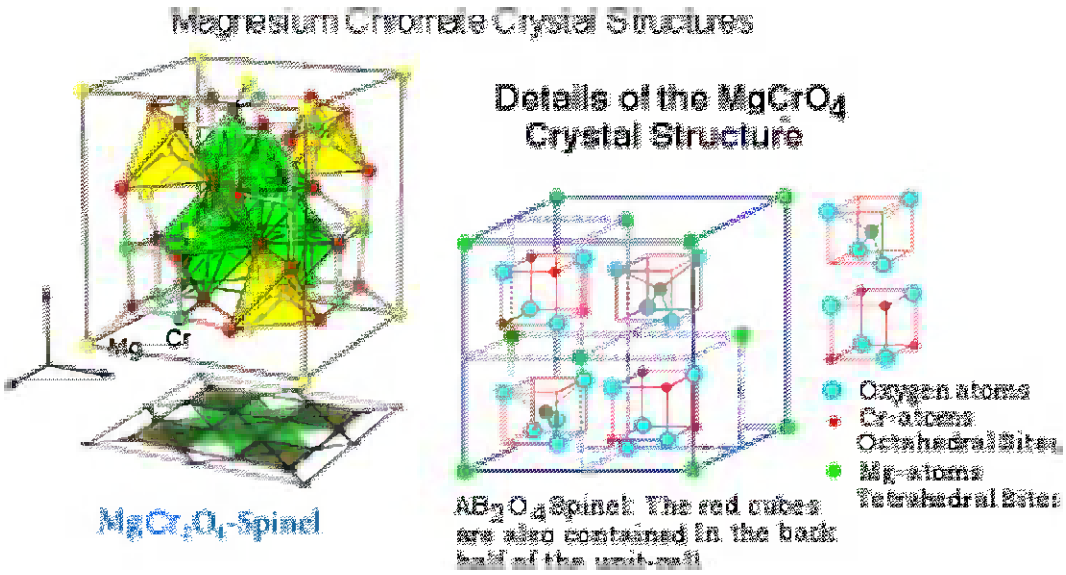

FIGURE 10.6

In the MgO–CrO system, no compounds are known.

In the Cr^{3+}-containing MgO–Cr_2O_3 system, only the compound, $MgCr_2O_4$ is known. The heat capacity of synthetic Eskolaite, Cr_2O_3, and of the synthetic spinel magnesiochromite, $MgCr_2O_4$, was measured from 1.5 K to 340 K. For $MgCr_2O_4$, a substantial magnetic contribution to the entropy is revealed by a sharp peak in the heat capacity curve at 12.55 ± 0.05 K, which indicates the transition to antiferromagnetic long-range order. Integration of the heat capacity curve yields a value of 118.3 ± 1.2 J/(mol K) for the standard entropy at 298.15 K, which is in excellent agreement with that calculated from phase equilibria studies on the reaction $MgCr_2O_4 + SiO_2 = Cr_2O_3 + MgSiO_3$. The new calorimetric results for Cr_2O_3 indicate standard entropy at 298.15 K of 82.8 ± 0.8 J/(mol K).

This compound has the cubic spinel structure as shown in Fig. 10.6.

Cell parameters are: $a = b = c = 5.8513$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 141.66$ Å^3, $Z = 8$. Cell occupancy is shown in Table 10.5.

The $MgCr_2O_4$ spinel belongs to the class of normal spinels and is the only compound in the MgO–Cr_2O_3 system that crystallizes in a face centered cubic structure (space group *Fd*3*m*). The unit cell parameter for this compound is equal to 8.329 Å, the melting temperature is 2350 °C, and the density amounts to 4.43 g/cm^3. The magnesium–chromium spinel is a chemically stable compound that does not decompose into oxides up to the melting temperature, but does react with concentrated mineral acids. The high melting temperature of the $MgCr_2O_4$ spinel compound allows one to use it as a refractory material.

The heat capacity of synthetic "Eskolaite", Cr_2O_3, that of the synthetic spinel magnesium chromite, $MgCr_2O_4$, and the chromite, $FeCr_2O_4$, was measured from 1.5 K to 340 K. For $MgCr_2O_4$, a substantial magnetic contribution to the entropy was revealed by a sharp peak in the heat capacity curve at 12.55 ± 0.05 K. This indicates a transition to antiferromagnetic long-range order. Integration of the heat capacity curve yields a value of 118.3 ± 1.2 J/molK for the standard entropy at 298.15 K, which is in excellent agreement with that calculated from phase equilibria studies on the reaction: $MgCr_2O_4 + SiO_2 = Cr_2O_3 + MgSiO_3$. The calorimetric results for Cr_2O_3 indicated standard entropy at 298.15 K of 82.8 ± 0.8 J/mo lK. The measurements for $FeCr_2O_4$ show three distinct heat capacity anomalies, one of which (peaking at 36.5 ± 0.2 K). This was missed by prior low-temperature heat capacity measurements, which only extended down to 53 K. Integration of the heat capacity curve yielded a value for the standard

TABLE 10.5

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O1	O	32	e	.3m	0.238	0.238	0.2378	1.0

entropy at 298.15 K of 152.2 ± 3.0 J/molK for $FeCr_2O_4$, some 6 J/molK greater than the previous calorimetric value.

Magnesium chromite, $MgCr_2O_4$, undergoes a structural transition from a cubic spinel structure [space group $Fd3^{-}m$, $a = 58.32768$ Å at 16 K] into a tetragonal distorted structure [space group $I41/amd$, $a = 55.89199$ Å, $c = 58.31677$ Å at 10 K], isotypic with Hausmannite, Mn_3O_4. This phase transition is unstable and takes place very close to or at the antiferromagnetic ordering temperature.

The vaporization of the system $MgO–Cr_2O_3$ was studied in a vacuum of 10^{-5} torr (10^{-3} N/m^2) at 1500–1700 °C using the Langmuir and Knudsen methods. It was found that the phases in the system vaporize nearly congruently and the logarithm of the vaporization coefficient, η_V, of $MgCr_2O_4$ increases linearly with increasing reciprocal temperature. The α-phase tends to unity at a temperature near the melting point (2525 ± 23 °C). The additivity rule can be applied to the Langmuir vaporization rates on the basis of the surface area ratios of the phases in the two-phase system $MgO–Cr_2O_3$. The enthalpies of vaporization of $MgCr_2O_4$ were 695.0 and 549.2 kcal/mol for the activated and equilibrium processes, respectively.

The rate of formation of single-crystal $MgCr_2O_4$ from single-crystal MgO and polycrystalline Cr_2O_3 in air can be described by the expression $k = 16.3 \exp(80{,}000 \pm 9000/RT)$ cm^2/s. The single crystal of $MgCr_2O_4$ grew by the advancement of (110) planes at the $MgCr_2O_4/Cr_2O_3$ interface. Two different methods were used for the calculation of interdiffusion coefficients of Cr^{3+} in MgO in the temperature range 1340–1640 °C. Wagner's analysis was applied for the calculation of interdiffusion coefficients in the $MgO–Cr_2O_3$ system where an intermediate spinel phase exists. A different mathematical treatment was derived for the calculation of interdiffusion coefficients at the saturation concentration of Cr_2O_3, in MgO single crystal.

In a similar study, the interdiffusion coefficients increased linearly with increasing mole fraction of Cr^{3+} cations and with increasing mole fraction of cation vacancies. For the concentration of 1-mol% Cr_2O_3 diffusing into MgO, the interdiffusion coefficient can be expressed as $D = 5 \cdot 50 \times 10^{-3} \exp(67{,}000 \pm 2000/RT)$ /cm^2/s. The enthalpy of activation was independent of cation vacancy concentration while the entropy of activation increased with increasing vacancy concentration. The measured interdiffusion coefficients were deduced to be the intrinsic diffusion coefficients for Cr^{3+} cations in MgO. Interdiffusion coefficients were in the range of $10^{-12} \times 10^{-9}$ /cm^2/s for the temperatures and concentrations studied. Theoretical formation energy of the Cr vacancy in $MgCr_2O_4$ showed negative values in the case of the oxidation limit of β-$MgCr_2O_4$, in good agreement with experimental results showing abundance of Cr vacancies when annealed in air. On the other hand, the formation energy of the Al vacancy in $MgAl_2O_4$ under the same condition is as large as 4.76 eV. This also corresponds well to the experimental fact that Al vacancy does not form alone when $MgAl_2O_4$ is processed in air.

Polycrystalline $MgCr_2O_4$ and $CuCr_2O_4$ samples were investigated by X-ray and neutron diffraction methods before and after irradiation by fast neutrons ($E_n \geq 1$ MeV) of effluence 2×10^{24}/m^2. It was found that, under irradiation of cubic magnesium and tetragonal copper chromites having the corresponding space groups O^7_h–$Fd3m$ and D^{19}_{4h}–$I4/amd$, different types of cations were redistributed over "allowed" and "forbidden" sites of the initial spinel lattice. As a result, the lattice periods and crystal symmetries were changed. The structures of the irradiated chromites may then be described in terms of the space group O^7_h–$Fm3m$. When annealed, the irradiated samples restored their initial crystal structures. The structural changes occurring on different stages of annealing were analyzed using X-rays.

This compound is a naturally occurring mineral and is found as black crystalline grains in Serpentinite (Fig. 10.7).

Small amounts of metal atom non-stoichiometry are possible in the $ZnCr_2O_4$ and $MgCr_2O_4$ spinels. The non-stoichiometry, though less than 2%, significantly impacts T_N and the nature of the magnetic correlations above T_N. The $Zn_{1+x}Cr_{2-x}O_4$ spinel is particularly sensitive. While stoichiometric $ZnCr_2O_4$ displays antiferromagnetic short-range correlations in the susceptibility above T_N, ferromagnetic correlations are observed in non-stoichiometric, hole-doped $Zn_{1+x}Cr_{2-x}O_4$. The $Mg_{1+x}Cr_{2-x}O_4$ spinels are less profoundly affected by non-stoichiometry, though significant changes are also observed. We contrast the magnetic properties of $Zn_{1+x}Cr_{2-x}O_4$ and $Mg_{1+x}Cr_{2-x}O_4$ ($x = 0$, 0.02, 0.04) with those of materials with the equivalent amounts of isovalent nonmagnetic Ga^{3+} substituted on the Cr^{3+} site to separate the effects of static site disorder and hole doping.

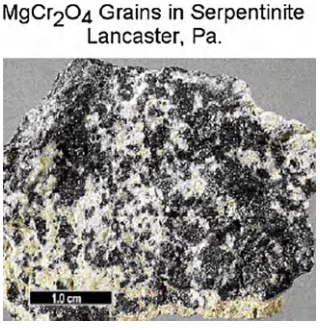

FIGURE 10.7

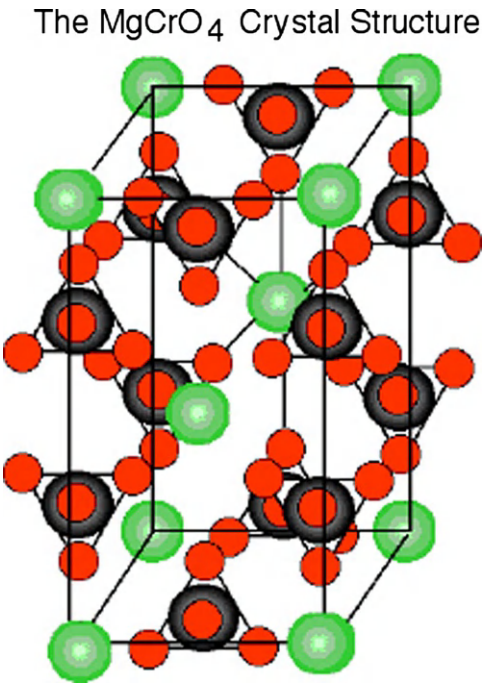

FIGURE 10.8

Magnesium chromite, $MgCr_2O_4$, undergoes a structural transition from a cubic spinel structure [space group $Fd\bar{3}m$, $a = 58.32768(4)$ Å at 16 K] into a tetragonal distorted structure [space group $I41/amd$, $a = 55.8919$ Å, $c = 58.31677$ Å at 10 K], isotypic with Hausmannite, Mn_3O_4. This phase transition takes place very close or at the antiferromagnetic ordering temperature. The structural and magnetic transitions are coincident and their order parameters (the tetragonal strain and Cr moment) scale with each other. The structural transition partially relieves magnetic frustration in the Cr network, although remaining frustration is evident from the low value (1.63 μbar) of the saturated Cr^{3+} moment.

No Cr^{4+}-containing compounds have been found in the $MgO–CrO_2$ system. It is expected that $MgCrO_3$ would have a perovskite structure, but this compound has never been synthesized. The possible +4 chromates, $MgCrO_3$, Mg_2CrO_4, Mg_3CrO_5, $MgCr_2O_5$, and the +5 chromates $MgCr_2O_6$, $Mg_2Cr_2O_7$ and $Mg_3Cr_2O_8$ remain unknown.

Magnesium chromate, $MgCrO_4$, containing Cr(VI) is dimorphic. Phase equilibria were determined for the systems $MgO–Cr_2O_3–O_2$, and $CdO–Cr_2O_3–O_2$ from 450 to above 850 °C and at oxygen pressures of from 2 to 3500 atm. The system, $MgO–CrO_3$, was not studied because of the low melting point of CrO_3. The magnesium and cadmium systems show three analogous phases: the low-temperature α-$MgCrO_4$ and α-$CdCrO_4$ (both with the $CrVO_4$ structure), the high-temperature β-$MgCrO_4$ and β-$CdCrO_4$ (both with the β-$MnMoO_4$ structure), and the spinels $MgCr_2O_4$ and $CdCr_2O_4$. The cadmium system contains an additional phase, Cd_2CrO_5, which is primitive monoclinic (Fig. 10.7).

This is a low-temperature form. The tetrahedra units are clearly seen. Cell parameters of α-$MgCrO_4$ are: $a = b = 5.0032$ Å, $c = 6.324$ Å, $\alpha = \beta = 90°$, $c = 113.396°$, cell volume = 145.28 Å^3, $Z = 4$. Cell occupancy is shown in Table 10.6.

IR spectra have been determined for $NiCrO_4$, α-$MgCrO_4$, α-$CdCrO_4$ (all crystallizing with the $CrVO_4$ structure); β-$MgCrO_4$, β-$CdCrO_4$ (both with the α-$MnMoO_4$, structure); and Cd_2CrO_5. The number of bands does not exceed the predictions of factor group analysis. It was shown that a dichromate-like spectrum can arise from chromate anions if the CrO_4 tetrahedron is sufficiently distorted.

β-$MgCrO_4$ is a high temperature dimorph with the structure of paramagnetic β-$MnMoO_4$, the stable phase at STP. It is monoclinic with lattice constants $a = 10.469 \pm 0.005$, $b = 9.516 \pm 0.005$, $c = 7.143 \pm 0.005$ Å, and $\beta = 106°17 \pm 6$, and space group $C2/m$. This crystal structure has been solved and refined by a combination of three-dimensional (3D) Patterson and Fourier series and by the method of least squares. Thousand eight hundred and seventy three independent integrated intensities were measured by PEXRAD; the final agreement factor between measured and calculated structure factors is 0.0574. Two crystallographically independent Mg atoms are surrounded by highly distorted oxygen octahedra; the Mg–O distance varies between 2.091 ± 0.006 and 2.252 ± 0.003 Å, with average length 2.164 Å. Two crystallographically independent Mg atoms are surrounded by slightly distorted oxygen tetrahedra, with Mg–O distances ranging from 1.724 ± 0.005 to 1.851 ± 0.004 Å, the average being 1.761 Å. The thermal vibrations were found to be significantly anisotropic.

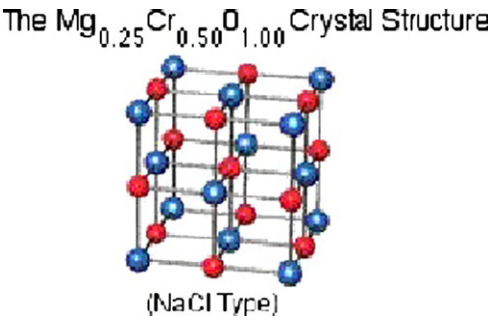

FIGURE 10.9

Another form of $MgCrO_4$ has the NaCl structure where a portion of the Mg^{2+} sites is occupied by divalent Mg-ions and the rest of the metal sites are occupied by $Cr^{6+} + Mg^{2+}$ ions.

The structure is shown in Fig. 10.9.

Cell parameters are: $a = b = c = 2.9338$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 17.86 Å^3, $Z = 8$. Cell occupancy is shown in Table 10.7.

α-$MgCrO_4$ is not stable and decomposes at 525–645 °C to form magnesium chromite: $4MgCrO_4 \Rightarrow 2MgCr_2O_4 + 2MgO + 3O_2$. The conclusive phase diagram has not been presented in the literature.

The effects of cobalt and manganese oxide doping on the surface and catalytic properties of Cr_2O_3/MgO system have been reinvestigated. The dopant concentration was changed between 1 and 5 mol% cobalt and manganese oxides. Pure and variously doped solids were subjected to heat treatment at 400 and 700 °C. The analytical techniques employed were XRD, nitrogen adsorption at −196 °C, catalytic conversion of isopropanol at 200–400 °C using flow technique and catalytic decomposition of H_2O_2 at 20–40 °C. The results revealed that the doping process of the system, processed at 400 or 700 °C, enhanced the solid–solid reactions between the catalyst constituents, yielding α-$MgCrO_4$, β-$MgCrO_4$ and $MgCr_2O_4$, respectively. Additionally, manganese and cobalt oxide doping for Cr_2O_3/MgO system increased its catalytic activity significantly in the decomposition of H_2O_2. The increase was found to be more pronounced in the case of manganese doping. Opposite results were observed in the case of isopropanol conversion, a mechanism which proceeds via dehydrogenation and dehydration reactions. The S_{BET} of the investigated system was found to decrease by increasing the dopant concentration. The doping process did not modify the activation energy of the catalyzed reaction, but rather changed the concentration of the catalytically active constituents without changing their energetic nature.

These chromate compounds have not yet found usage in Industry. Magnesium chromate is available commercially with the CAS number of 13423-61-5.

10.2.3. Calcium Chromium Compounds

No intermetallic compounds are known. Calcium oxide forms a limited number of compounds with the chromium oxides. The exact composition depends, to a great extent, on the oxidation state of the chromium ion, $Cr^{3,\ 4,\ 5\ or\ 6+}$. For the calcium chromate system, CaO–Cr_nO_m, only three crystal structures are readily available (Table 10.8).

Only those based on CaO–Cr_2O_3 have been investigated. The reason is that the trivalent chromium oxide melts at 2435 °C whereas CrO_3 melts at 197 °C and boils at 251 °C. The phase diagram for the CaO–Cr_2O_3 system is shown in Fig. 10.10.

In the solid-state reaction between CaO and Cr_2O_3, only the $CaCrO_4$ and $Ca_5(CrO_4)_3$ compounds can be produced. The former melts incongruently at 1073 °C to form $CaCr_2O_4$ and the latter melts congruently at 1275 °C, respectively. Only the latter compound is stable

at room temperature while the other compounds (herein labeled as "a", "w" and "c") are metastable at rather low temperatures 776 ⇒ 959 °C, 882 ⇒ 1253 °C and 1143 ⇒ 1297 °C, respectively. Their structures have not been thoroughly investigated. (**N.B.**-these results have not been verified but are those of a specific investigation published in 1995).

Note that $CaCrO_4$ contains Cr^{6+} ions whereas $Ca_5(CrO_4)_3$ contains Cr^{3+} ions. The reactions that form these compounds are:

$$5CaO + 3Cr_2O_3 \Rightarrow Ca_5(CrO_4)_3 \text{ (neutral atmosphere)}$$

$$4CaO + 6Cr_2O_3 + 3O_2 \Rightarrow 4CaCrO_4 \text{ (oxidizing atmosphere)}$$

At 1073 °C, $CaCrO_4$ decomposes to form:

$$4CaCrO_4 + \text{heat} \Rightarrow 2\beta\text{-}CaCr_2O_4 + 2CaO + 3O_2$$

The high temperature form, β-$CaCr_2O_4$ contains the Cr^{3+} ion. For the trivalent Cr(III) oxide system, only **calcium chromite**, $CaCr_2O_4$, has been meticulously studied. It is dimorphic and the structure of the high temperature form, β-$CaCr_2O_4$ is shown in Fig. 10.11. Two unit cells are shown. It consists of four chromium tetrahedra, two of which are joined by face-sharing (edge-sharing) and the other two joined by point-sharing.

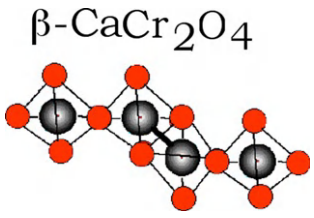

FIGURE 10.11

Cell constants are: $a = 2.99$ Å, $b = 9.07$ Å, $c = 10.61$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 287.74$ Å^3, $Z = 4$ (Fig. 10.12).

Cell occupancy is shown in Table 10.9.

In another study, single crystals of high temperature modification, β-$CaCr_2O_4$, were investigated by X-ray goniometer data ($a = 11.059$, $b = 5.836$, $c = 5.114$ Å, space group *D–Pmmn*). β-$CaCr_2O_4$ is isotypic with $SrCr_2O_4$. A mass of residue including needle-like β-$CaCr_2O_4$ crystals was obtained by heating a powder mixture consisting of $CaCO_3$ and Cr_2O_3 on graphite powder in an alumina crucible with holes. The needle-like β-$CaCr_2O_4$ crystals were separated from the mass by hydrochloric acid. The yield of the crystals increased with increasing temperature above 1500 °C and reached about 41 wt%

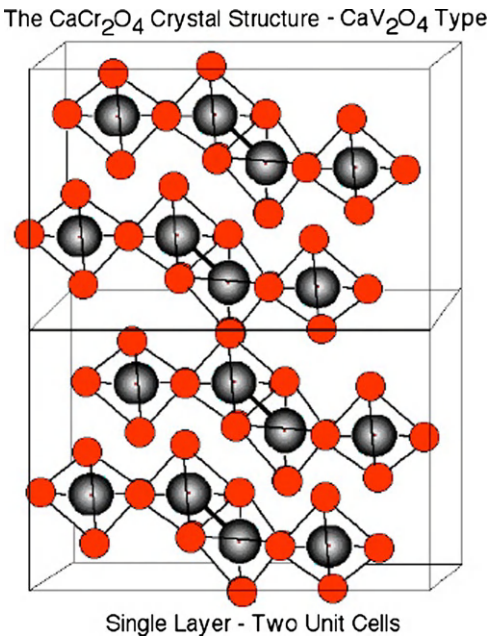

FIGURE 10.12

when heated at 1700 °C for 4 h. Then the average length and diameter of the crystals were 2.5 mm and 118 μm, respectively; the largest crystal was 3.8 mm in length and 187 μm in diameter. Needle axis of the crystals was the *c*-axis. The low temperature form, α-$CaCr_2O_4$, has the structure shown in Fig. 10.13.

CrO_6 octahedra are shown in blue and green colors for the inequivalent Cr1 and Cr2 sites. The Ca^{2+} ions are shown as light gray spheres. The red thin line marks the crystallographic unit-cell. The middle section shows the projection of the CrO_2 layer onto the *bc*-plane. Colored thick lines shows the connectivity between first-neighbor Cr ions. The corresponding interatomic distances are shown. On the right is a depiction of the face-sharing octahedra and their relationship in the structure.

In this compound, in which the unusual topology of the Cr^{3+} magnetic lattice can be described as a network of triangular "zigzag" ladders with legs parallel to *c*, a complex antiferromagnetic ordering with an unequal propagation vector $\mathbf{k} = (0, 0, q)$ ($q \sim 0.477$ at 1.5 K) is evidenced below $T_N = 21$ K. This complex magnetic ordering can be described as a honeycomb-like arrangement of cycloids, running along *c*, and presenting a unique pattern

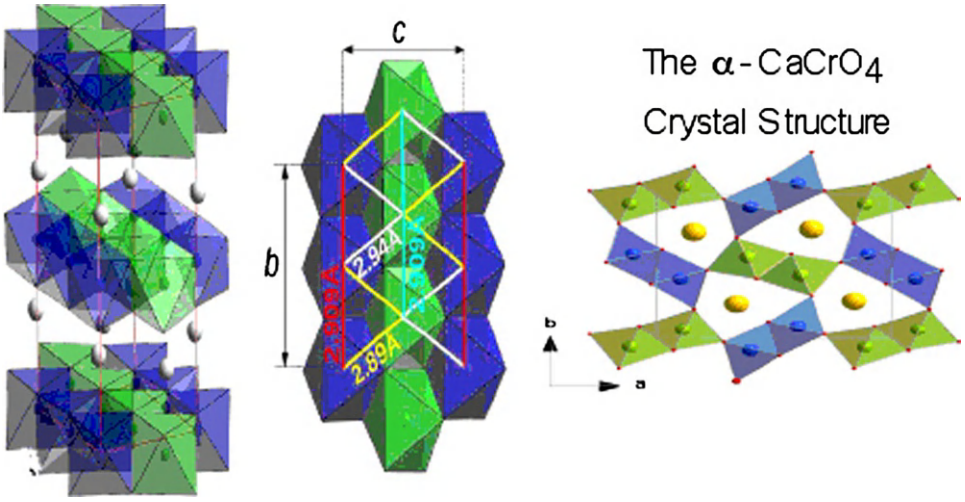

FIGURE 10.13

TABLE 10.9

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O1	O	4	c	.m.	0.071	1/4	0.078	1.0
2	Cr1	Cr	4	c	.m.	0.077	1/4	0.394	1.0
3	Ca1	Ca	4	c	.m.	0.242	1/4	0.65	1.0

of staggered chirality. The crystal structure of α-$CaCr_2O_4$ was first reported by Pausch et al. It crystallizes with orthorhombic symmetry, in the space group *Pmmn*. There are two inequivalent Cr sites, Cr1 located at (0,0,0), having a single symmetry and Cr2 at position (0.5047,0,0.497) located on a mirror plane, each site possessing a multiplicity of 4. The Cr ions are six-coordinated by oxygen in a distorted octahedral configuration. The octahedra share edges to form CrO_2 layers in the *bc*-plane, leaving a weakly distorted triangular lattice as shown by the different interatomic distances marked in Fig. 10.13. The CrO_2 layers, separated by Ca^{2+} ions, are stacked along the *a*-axis of the orthorhombic unit-cell. The in-plane magnetic interactions between Cr can be mediated either by direct exchange through the t_{2g} orbitals or by Cr–O–Cr superexchange interactions. The interactions between layers can be mediated by super–super exchange interactions through two oxygen atoms, but are expected to be much weaker due to the large interatomic Fe–Fe distance (5.52 Å at 1.5 K). This compound shows a weak inverse magnetic susceptibility with a quasi-linear regime above 250 K. A linear fit of the data with a Curie–Weiss law in the temperature range 250 K to 350 K under 3.0 T yields the following diagram (Fig. 10.14).

In another paper, the ferroelectricity of α-$CaCr_2O_4$ in the incommensurate helical magnetic phase (i.e. below T_N, 43 K) has been confirmed by pyroelectric measurements. Magnetoelectric and magnetodielectric coupling exist below T_N and are proportional to the square of magnetic field. From symmetry analysis, it was suggested that the presence of an external electric field destabilizes the symmetrical 2221′ phase and stabilizes 21′ symmetry. This provides a unique system in which the polarization varies as the *fourth-degree* of the order-parameter amplitude and exhibits a vanishingly small value below the first-order transition at T_N, as observed experimentally. This compound crystallizes in an orthorhombic-layered structure with triangular sheets of CrO_2 separated by Ca^{+2} and mostly resembles "Delafossite-$CuCrO_2$" with a small distortion.

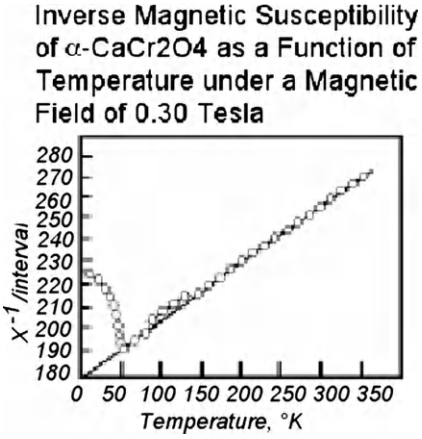

FIGURE 10.14

Recently, the magnetic properties of α-$CaCr_2O_4$ have been investigated in detail. It exhibits a long-range antiferromagnetic incommensurate helical magnetic phase below $T_N = 43$ K that has a magnetic propagation wave vector value of $q = (0,0.3317,0)$. Neutron diffraction data show that the plane of rotation of spins is perpendicular to the wave vector. In materials with incommensurate phases, the lattice modulation is generally connected with a spatially varying electric polarization (e.g. Rb_2ZnCl_4, $NH_4)_2BeF_4$ and K_2SeO_4). At low temperature, these materials exhibit a first-order phase transition to a ferroelectric phase. Similarly, ferroelectricity has been reported in $TbMnO_3$, $YBaCuFeO_5$ and $CuFeO_2$ in the incommensurate magnetic phase. It has been determined that α-$CaCr_2O_4$ fits into this category of quasi-magnetic materials.

In the CaO–CrO_2 system, compelling evidence that $CaCrO_3$ is a rare case of a metallic and antiferromagnetic transition-metal oxide with a 3D electronic structure was revealed. Local spin density approximation calculations correctly describe the metallic behavior as well as the anisotropic magnetic ordering pattern of *C* type. The high Cr valence state induces via sizable pd hybridization remarkably strong next-nearest-neighbor interactions stabilizing this ordering. The subtle balance of magnetic interactions gives rise to magnetoelastic coupling, explaining pronounced structural anomalies observed at the magnetic ordering transition. The electronic structure of the perovskite oxide $CaCrO_3$ using valence-band, core-level, and Cr 2p-3d resonant photoemission spectroscopy (PES) was examined. Despite its antiferromagnetic order, a clear Fermi edge characteristic of a metal with dominant Cr 3d character is observed in the valence-band spectrum. The Cr 3d single-particle density of states are spread over 2 eV, with the photoemission spectral weight distributed in two peaks centered at ~1.2 and 0.2 eV below *EF*, suggestive of the coherent and incoherent states resulting from strong electron–electron correlations. Resonant PES across the Cr 2p-3d threshold identifies a "two-hole" correlation satellite and yields an on-site Coulomb energy $U \sim 4.8$ eV. The metallic DOS at *EF* is also reflected through the presence of a well-screened feature at the low binding energy side of the Cr 2p core-level spectrum. X-ray-absorption spectroscopy at Cr $L_{3,2}$ and 0 K edges exhibits small temperature-dependent changes that point toward a small change in Cr–O hybridization. The Cr 2p core-level spectrum can be reproduced using cluster model calculations that include a charge transfer from the metallic screening channel at *EF*. The overall results indicate that $CaCrO_3$ is a strongly hybridized antiferromagnetic metal, lying

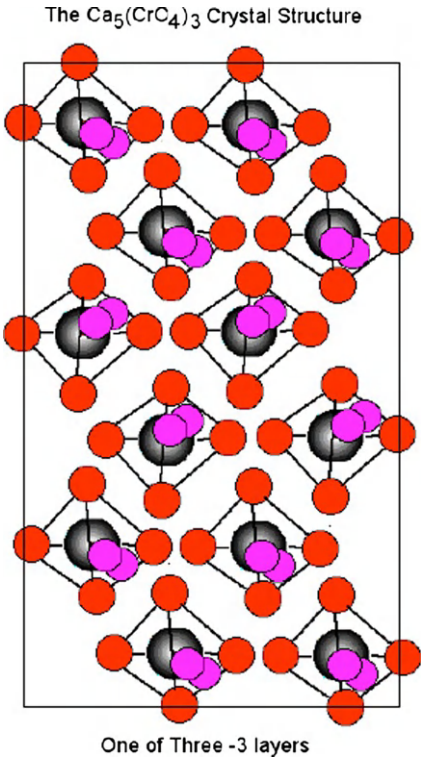

FIGURE 10.15

in the regime intermediate to Mott–Hubbard and charge-transfer systems.

The compound, penta-calcium tri-chromate, $Ca_5(CrO_4)_3$, has an apatite-like structure. The arrangement of atoms in the unit cell is shown in Fig. 10.15.

The structure consists of isolated CrO_4 tetrahedra associated with pairs of Ca^{2+} cations. Cell parameters are: $a = 6.733$ Å, $b = 10.334$ Å, $c = 16.097$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 1,120.01 Å^3, $Z = 4$.

Cell occupancy is shown in Table 10.10.

The crystal structures of similar compounds, $Ca_5Cr_3O_{12}$ and $Ca_5Cr_{1.8}Si_{1.2}O_{12}$, the chromium analogues of silicocarnotite, $Ca_5P_2SiO_{12}$, have been determined. Both compounds were grown at 1250 °C and analyzed by electron microprobe analysis. Diffraction data collection was accomplished on spherically ground crystals that were both orthorhombic with space group *Pnma*. The charge-balance requirements as well as site-occupancy refinement of the Si-containing compound pointed strongly to the presence of both tetravalent and hexavalent chromium in tetrahedral sites. The Si is located together with tetravalent Cr in a general position, whereas the hexavalent Cr ion is situated on a mirror plane. The calcium atoms are located in seven-, eight-, and nine-coordinated sites. The presence of vacant channels of 3.5 Å diameters perpendicular to (100) is a feature of this structural type. Its relation to the apatite and glaserite structures was also shown.

The system CaO–CrO, processed in air, has been reinvestigated and the existence of intermediate phases with chromium in the oxidation state $\geq 3^+$ (such as $Ca_5Cr_3O_{12}$, $Ca_3(CrO_4)_2$, and $Ca_5(CrO_4)_3$) were confirmed. Under reducing conditions these phases are not stable. A metastable, polymorphic form of calcium chromite, δ-$CaCr_2O_4$, has been observed.

In the CaO-rich section of the CaO–Al_2O_3–Cr_2O_3 system, a ternary intermediate phase, "Chromehaüyne", $Ca_4[(Al,Cr^{3+})_6O_{12}](Cr^{6+}O_4)$, coexists with the calcium chromate and calcium aluminate phases. In air, low melting temperatures are preserved in all assemblages containing the calcium chromate phases. Under

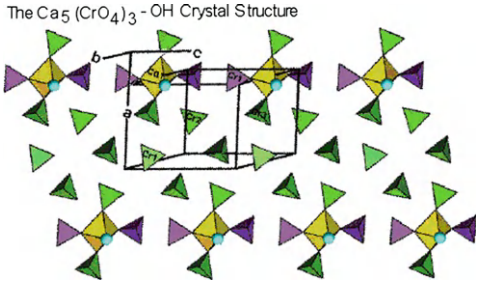

FIGURE 10.16

reducing conditions a new ternary phase, $Ca_6Al_4Cr_2O_{15}$, coexists with CaO, $CaCr_2O_4$, chrome-haüyne, and calcium aluminate phases. The influence of chromium oxide additions on the solidus temperatures of the $CaO–Al_2O_3$ system is insignificant.

The calcium chromate hydroxyl apatite, $Ca_5(CrO_4)_3OH$, was synthesized, and its electrical conductivity and chemical stability were investigated. It has the structure shown in Fig. 10.16.

Lanthanum chromite, $La_2Cr_2O_6$, has been used as a separator in solid oxide fuel cells.

Based on experimental results, detrimental effects of the apatite formation on the surface of lanthanum chromite separators in solid oxide fuel cells have been discussed. The mean Cr–O distance for tetrahedral coordination is 1.66 Å. In an attempt to replace the OH-group with chlorine, a new phase with the composition of Ca_2ClCrO_4 and the unit cell dimensions of $a = 6.237$ Å, $b = 7.122$ Å and $c = 11.045$ Å (orthorhombic) was found. Unit cell dimensions of $Sr_3(CrO_4)_2$, $Ba_3(CrO_4)_2$, $Sr_5Cl(CrO_4)_3$, $Ba_5Cl(CrO_4)_3$, and Sr_2ClCrO_4 were also given.

Calcium chromate ($CaCrO_4$) is a bright yellow solid. It normally occurs as the dihydrate. Calcium chromate loses water at 200 °C. Calcium chromate reacts with organic matter or reducing agents to form Cr(III). Calcium chromate will react explosively with hydrazine. If mixed with boron and ignited, calcium chromate will burn violently. It occurs naturally as the mineral "Chromatite". The compound, $CaCr(VI)O_4$ is metastable as shown in the above phase diagram which was constructed from studies of CaO and Cr_2O_3. No phase diagram for $CaO–CrO_3$ is known (CrO_3 melts at 197 °C). $CaCrO_4$ is an important cathode material in thermally activated electrochemical cells, and it is also often used in many industrial process as an intermediate compound formed in the system of Ca–Cr–O.

$CaCrO_4$ crystallizes into a zircon-type structure of tetragonal lattice with space group $I41/amd$ ($Z = 4$) at ambient conditions. The structure of zircon-type $CaCrO_4$ is built from isolated and slightly distorted CrO_4 tetrahedral units, which are connected with CaO_8 dodecahedra by edge- and corner-sharing. Both these units are shown in Fig. 10.17.

The infrared spectra of the chromates (V) of calcium, strontium and barium have been measured from 2000 to 400/cm. The results, and those for the corresponding chromates (VI), are interpreted in terms of the site symmetry of the anion. It has been shown that, in the chromates(VI), the anion is not strongly perturbed. For the chromate (V) ion, the stretching force constant of the chromium (V)—oxygen bond is 4·94 mdyn/Å and the stretch–stretch interaction constant is 0·22 mdyn/Å. The effect of the non-bonding d electron of chromium (V) on the metal to oxygen bonding was discussed. Pressure-related structural characteristics of $CaCrO_4$ with the zircon-type structure ($I41/amd$) were investigated at ambient pressure in a diamond anvil cell (DAC) up to 29.1 GPa at room temperature. The electromagnetic sources were synchrotron radiation and XRD in an energy-dispersive mode. A sluggish first-order structural phase transition to a scheelite-type phase ($I41/a$) was observed at 5.7 GPa. The lattice parameters of both phases at different pressures were calculated.

Heat capacities of calcium chromate ($CaCrO_4$) and calcium chromite (β-$CaCr_2O_4$) were measured at elevated temperatures using the differential scanning calorimetry. The measured heat capacities of $CaCrO_4$ and β-$CaCr_2O_4$ as a function of temperature (measured in J/mol K) are expressed as C_p ($CaCrO_4$) =

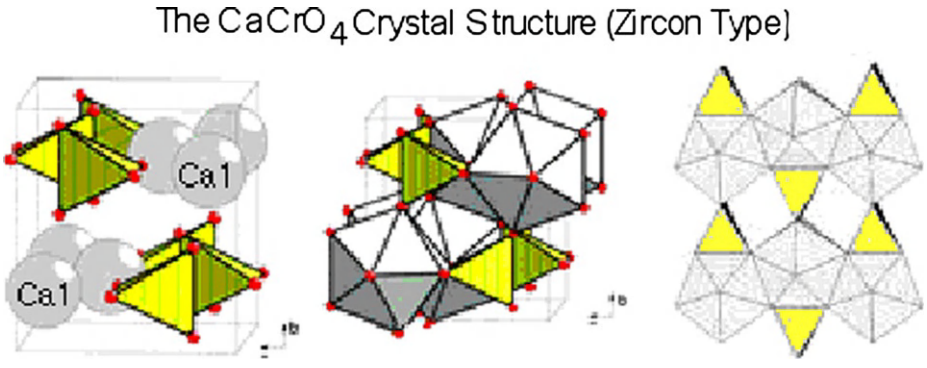

FIGURE 10.17

$127.92 + 35.73 \times 10^{-3}T - 2.257 \times 10^{6}/T^{-2}$ (298–1123 K), $C_p(\beta\text{-}CaCr_2O_4) = 166.69 + 18.33 \times 10^{-3}T - 2.92 \times 10^{6}T^{-2}$ (298–1203 K), respectively.

It is known, for example, that trivalent chromium Cr(III) compounds are generally insoluble, whereas hexavalent chromium Cr(VI) forms soluble compounds. The latter are extremely poisonous to the human body. It is also well established that the most damaging ingestion pathway for Cr(VI) is inhalation. Consequently, Cr(VI)-contaminated wastes should not be incinerated. Another method of disposing of such wastes would be to place them in landfills, but, in time, they are likely to leach and may contaminate ground water resources. A better solution is to contain the wastes in ordinary Portland cement, where heavy-atom contaminants are typically immobilized in a high-strength monolithic cement waste matrix. Depending on the type of the metal ions, stabilization can be through chemisorption, precipitation, chemical-incorporation in the hydrated cement phases, physical entrapment, or a combination of these. In an effort to dispose of such compounds, it was found that when Cr(VI) solution is added to the Portland cement, soluble $CaCrO_4 \cdot 2H_2O$ forms within the first day of reaction. However, as more calcium comes into the pore solution from dissolution of the tricalcium silicate component of the Portland cement, the new stable product formed is $Ca_2CrO_5 \cdot 3H_2O$. In the cement–Cr(VI) waste matrix, $Ca_2CrO_5 \cdot 3H_2O$ is formed according to:

$$Ca(OH)_2 + CaCrO_4 \cdot 2H_2O \Rightarrow Ca_2CrO_5 \cdot 3H_2O$$

The 3D structure is shown in Fig. 10.18.

It consists of double layers CrO_4 tetrahedra and CaO_8 polyhedra that run parallel to the (001) face of the unit cell. Within each double layer, the distance between the Ca and the Cr planes is 3.0858 Å. Each chromium atom is coordinated with four oxygen atoms, forming tetrahedra whose O1–O3–O1 base is oriented (quasi), parallel to the (001) face of the unit cell.

The coordination sphere of Ca, including the values of the Ca–O bond lengths, is shown in Fig. 10.19. Oxygen O4, O5, and O6 correspond to the water molecules and are coordinated with calcium atoms as hydroxyls, whose presence was previously verified by infrared OH stretching vibrations. The presence of Ca–O–H bonds might explain the incongruent dissolution of dicalcium chromate.

The fact that $CaCrO_4$ decomposes with loss of volatile CrO_3 if heated too high in temperature has been utilized to prepare interconnects [one of the key components for solid oxide fuel cells (SOFCs)]. The perovskite lanthanum chromite ($LaCrO_3$) substituted with alkaline earth metals (Ae = Ca or Sr) has been widely accepted as the major candidate for fabricating interconnect material in present generation SOFCs. It satisfies most of the requirements for construction of SOFC, such as high electronic and negligible ionic conductivity, chemical stability at both oxidizing and reducing atmospheres at high temperatures as well as chemical and thermomechanical compatibility with other cell components under operating conditions.

The compound, $La_{0.7}Ca_{0.3}Cr_{0.97}O_3$, with a slight Cr deficiency of 0.03 was prepared by an auto-ignition process. Relatively low-temperature (1150–1300 °C) sintering characteristics and electric conductivities were achieved. The material reached 94.3% relative density when heated at 1200 °C for 5 h in air, which is about 200 °C lower than that of with no Cr deficiency. XRD results indicated that a pure perovskite phase was formed after sintering within the temperature range of 1150–1300 °C. The sample sintered at 1250 °C had the maximum conductivity of 62.0 S/cm at 850 °C in air, which is about 2.6 times as high as that of $La_{0.7}Ca_{0.3}CrO_3$ with no Cr deficiency. When sintered in pure H_2, it achieved the maximum electrical conductivity of 3.3 S/cm at 850 °C compared to a sample sintered at >1200 °C. The TEC of the material was about 11.4×10^{-6} /K, which is very much

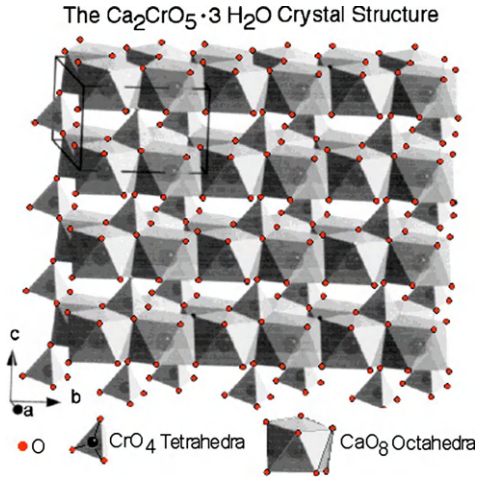

FIGURE 10.18

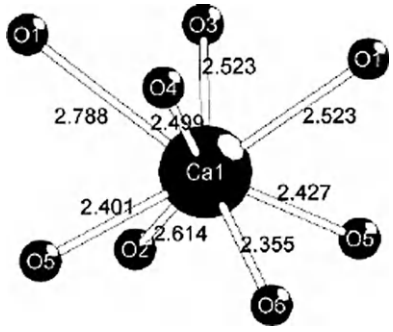

FIGURE 10.19

comparable to that of the other commonly used SOFC components.

Calcium chromate is supplied commercially with CAS No. 12013-31-9, calcium dichromium tetraoxide.

10.2.4. Strontium Chromium Compounds

Strontium oxide forms a number of compounds with the chromium oxides. The exact composition depends, to a great extent, on the oxidation state of the chromium ion, $Cr^{3,\ 4,\ 5\ or\ 6+}$. For the strontium chromite–chromate system, only two crystal structures are found as shown in Table 10.11.

For the trivalent Cr(III) oxide system, under neutral conditions, only $SrCr_2O_4$ is known.

For the $SrO–Cr_2O_3–O_2$ system, four compounds have been found to be stable in air at ambient temperature. However, a permanent phase diagram has not been established since these compounds are metastable and the melting points determined depend, to a great extent, upon the conditions under which they are being melted. However, several compositions involving the $SrO–CrO_2$ system are known. Some are antiferromagnetic.

The phase relations involving various oxides in the system Sr–Cr–O at 1250 K in air have been determined by equilibrating samples representing 17 compositions inside the ternary and subsequent phase identification in quenched samples. Optical and scanning electron microscopes (SEM) were used in conjunction with XRD to identify phases; the composition of each phase was verified using energy dispersive analysis of X-rays (EDX). Four stable ternary oxides, $SrCrO_4$, $Sr_3Cr_2O_8$, Sr_2CrO_4, and $SrCr_2O_4$, were identified. All the compounds, except $Sr_3Cr_2O_8$, were found to be stoichiometric within the accuracy of EDX. X-ray absorption near-edge structure (XANES) analysis showed that the average valence of Cr in $Sr_3Cr_2O_8$ is +5.2, suggesting the presence of mixed valence states in this compound. Only one of the ternary oxides, $SrCr_2O_4$, was found to coexist with Cr metal since it contains Cr^{3+}. The compounds containing Cr^{6+}, $SrCrO_4$ and $Sr_3Cr_2O_8$, were stable in pure oxygen.

The standard Gibbs energy of formation of $SrCrO_4$ was determined as a function of temperature in the range from 950 to 1280 K using a solid-state cell incorporating single-crystal SrF_2 as the electrolyte. The oxygen potential corresponding to the three-phase equilibria involving $SrCrO_4$, $Sr_3Cr_2O_8$, and Cr_2O_3 was measured from 1080 to 1380 K using a cell with yttria-stabilized zirconia as the solid electrolyte and pure oxygen gas at a pressure of 0.1 MPa as the reference electrode. The standard Gibbs energy of formation of $Sr_3Cr_2O_8$ was derived from the oxygen potential. The results can be represented by the following equations:

$$4SrO + 2Cr_2O_3 + O_2 \Rightarrow 4SrCr_2O_4$$

$$\Delta G^0\,(J/mol) = -273.825 + 131.57\,T/K$$

$$3SrO + Cr_2O_3 + O_2 \Rightarrow Sr_3Cr_2O_8$$

$$\Delta G^0\,(J/mol) = -472.345 + 184.20\,T/K$$

In another study, seven (7) compounds, $SrCrO_4$, $SrCr_2O_7$, $Sr_3Cr_2O_8$, $SrCrO_3$ Sr_2CrO_4, $Sr_2Cr_2O_5$, Sr_2CrO_4 and $SrCr_2O_4$ have been reported in the system Sr–Cr–O. The structure of $SrCrO_4$ belongs to the monoclinic system. Space group $= P2_1/n$ ($lt4$) with $a = 7.083$ Å, $b = 7.388$ Å, $c = 6.771$ Å, $\beta = 103.43°$. It is isostructural with $PbCrO_4$. The compound, $SrCr_2O_7$, is in isomorphism with $PbCr_2O_7$ and belongs to the tetragonal system, space group $P4_3/nmc$ (137), with $a = 11.193$ Å, and $c = 9.480$ Å. It is a low temperature phase in this system. The phase, $Sr_3Cr_2O_8$ is trigonal with space group $R\bar{3}m$ and has the hexagonal cell parameters of $a = 5.569$ Å, $c = 20.171$ Å. It is isostructural with $Ba_3(PO_4)_2$. It contains the unusual ion, Cr^{5+}. $SrCrO_3$ is a high-pressure phase formed from SrO and CrO_3 with Cr^{4+} in an octahedral coordination. The compound, Sr_2CrO_4, is orthorhombic, space group $P2_1nb$ (33) with $a = 10.007$ Å, $b = 14.194$ Å, $c = 5.809$ Å at ambient temperature. Under high pressure of 6.6×10^5 Pa and 1000 °C, this structure transforms to the K_2NiF_4 type with $a = 3.821$ Å and $c = 12.422$ Å. This transformation is accompanied by a 12% decrease in cell volume and a change in Cr-coordination of tetragonal to octahedral, i.e. $CrO_4 \Rightarrow CrO_6$. The reaction of Sr_2CrO_4 and CrO_3 at high pressure forms $Sr_2Cr_2O_7$. This compound has a body-centered tetragonal cell with $a = 3.822$ Å and $c = 20.124$ Å.

Strontium chromate ($SrCrO_4$) melts in pure oxygen (0.1 MPa) at 1556 K (1283 °C) and is of interest as an additive to $LaCrO_3$ for use in current-day SOFCs. The thermodynamic stabilities of $CaCrO_4$, $BaCrO_4$ and $SrCrO_4$ are of interest to materials scientists and also in nuclear technology because these are the possible compounds of fission product-cladding chemical interaction under conditions of accident in fast nuclear reactors. Though there are some reports on the thermodynamic stabilities of $CaCrO_4$ and $BaCrO_4$ obtained by the fluoride electrolyte electromotive force (e.m.f.)

TABLE 10.11

No.	Compound	No. of elements	Structure type	Point group	Space group

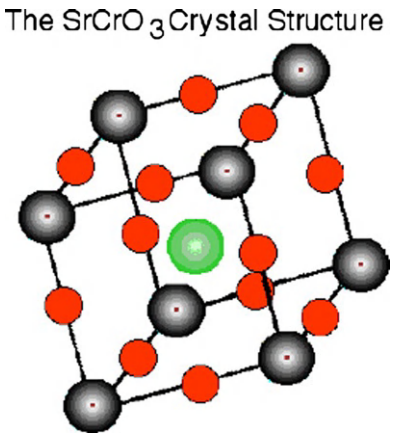

FIGURE 10.21

method, there is no reliable thermodynamic information on $SrCrO_4$. Hence the e.m.f. of the galvanic cells Pt, $O_2(g)/CaO$, $CaF_2/CaF_2/AF_2$, $ACrO_4$, Cr_2O_3/Pt, $O_2(g)$ was studied under an atmosphere of pure oxygen at a pressure of 0.1 MPa over the ranges 788–1070, 851–1116 and 850–1168 K where A is Ca, Sr and Ba, respectively. From the cell e.m.f. data, the standard Gibbs energies of formation ΔG_f^0 of the chromates, according to the reaction $AO(s) + Cr_2O_3(s) + O_2(g) \Rightarrow ACrO_4(s)$ were derived to be:

$$\Delta G_f^0(CaCrO_4) = -1356.6 + 0.31641T(\pm 0.63)\text{kJ/mol},$$
$$\Delta G_f^0(SrCrO_4) = -1359.1 + 0.32998T(\pm 0.30)\text{kJ/mol},$$
$$\Delta G_f^0(BaCrO_4) = -1323.7 + 0.31159T(\pm 0.34)\text{kJ/mol}$$

Both $SrCrO_4$ and $BaCrO_4$ have the structure shown in Fig. 10.20.

It consists of CrO_4 tetrahedra aligning in the "*ab*" direction of lattice (a single layer is shown here). Lattice parameters are: space group $P2_1/n$, $Z = 4$; $a = 7.065$ Å, $b = 7.375$ Å; $c = 6.741$ Å; $\beta = 103.08°$. In $SrCrO_4$ the average Cr–O bond is 1.626 Å. The largest bond length distortions within the XO_4 tetrahedra were found in $SrCrO_4$. α-$PbSeO_4$ (Rooseveltite), $BiPO_4$, $PbCrO_4$ (Crocoite), α-$PbSeO_4$, $SrCrO_4$, $SrSeO_4$, and $ThSiO_4$, exhibit a nine-coordination geometry. This geometric form is best described as a pentagonal interpenetrating tetrahedral polyhedron.

A number of compounds based upon the system SrO–CrO_2 are known in which the Cr^{4+} ion is involved. An overview of a series of experiments involving increasingly complex oxides synthesized from CrO_2, under high-pressure and high-temperature conditions, having a space group of Cl in octahedral coordination was published. Although the emphasis was on the structure and microstructure of the compounds as obtained from XRD and transmission electron microscopy (TEM) and diffraction, attention was also given to their interesting electronic and magnetic properties. The study was complemented with an electron energy loss spectroscopic analysis of the different phases. These are the cubic perovskite $SrCrO_3$, the orthorhombic perovskite $CaCrO_3$, the solid solution $Sr_{1-x}Ca_xCrO_3$, the Ruddlesden–Popper-type $Sr_3Cr_2O_7$, the family $CrSr_2RECu_2O_8$ (RE = rare earth), a compositionally modulated perovskite $PbCrO_3$, and the misfit layer oxide $Sr_2O_2[CrO_2]_{1.85}$. The compound, strontium chromite, $SrCrO_3$, containing tetravalent chromium, Cr^{4+}, has the $CaTiO_3$ structure shown in Fig. 10.21.

It contains Sr^{2+} cations in a body-centered cubic lattice, surrounded by CrO_3 units that are shared by other unit cells.

The structure and magnetic properties of Sr_2CrO_4 and Ba_2CrO_4 were compared with their vanadium analogues β-Sr_2VO_4 and β-Ba_2VO_4. Unlike isostructural β-Sr_2VO_4 that contains the $V_2O_8^{8-}$ dimer, Sr_2CrO_4 contains truly isolated CrO_4^{4-} tetrahedra and its magnetic behavior can be best described as a dimerized chain. Ba_2CrO_4 and Ba_3CrO_5 also contain isolated CrO_4^{4-} tetrahedra. Ba_2CrO_4 is paramagnetic down to 5 K. Ba_3CrO_5 undergoes long-range magnetic order at 8 K, a temperature range significantly higher than that of isostructural Rb_3CoCl_5 and Cs_3CoX_5 (X = Cl, Br).

The strontium chromium oxide $[Sr_2O_2][CrO_2]_{1.85}$ "misfit-layer" compound has been synthesized at high-pressure and high-temperature conditions. Electron diffraction (ED) patterns and high-resolution TEM images along [001] showed the misfit character of the different layers composing the structure with a super cell along the incommensurate parameter, as shown in Fig. 10.22.

In this figure, the average structure of $[Sr_2O_2][CrO_2]_{1.85}$ is shown as

(a) Projection along the common axis.
(b) Projection along the incommensurate *b*-axis.
(c) [010] projection of the Fourier map of the composite crystal summed up along the x_2 and x_4 coordinates.

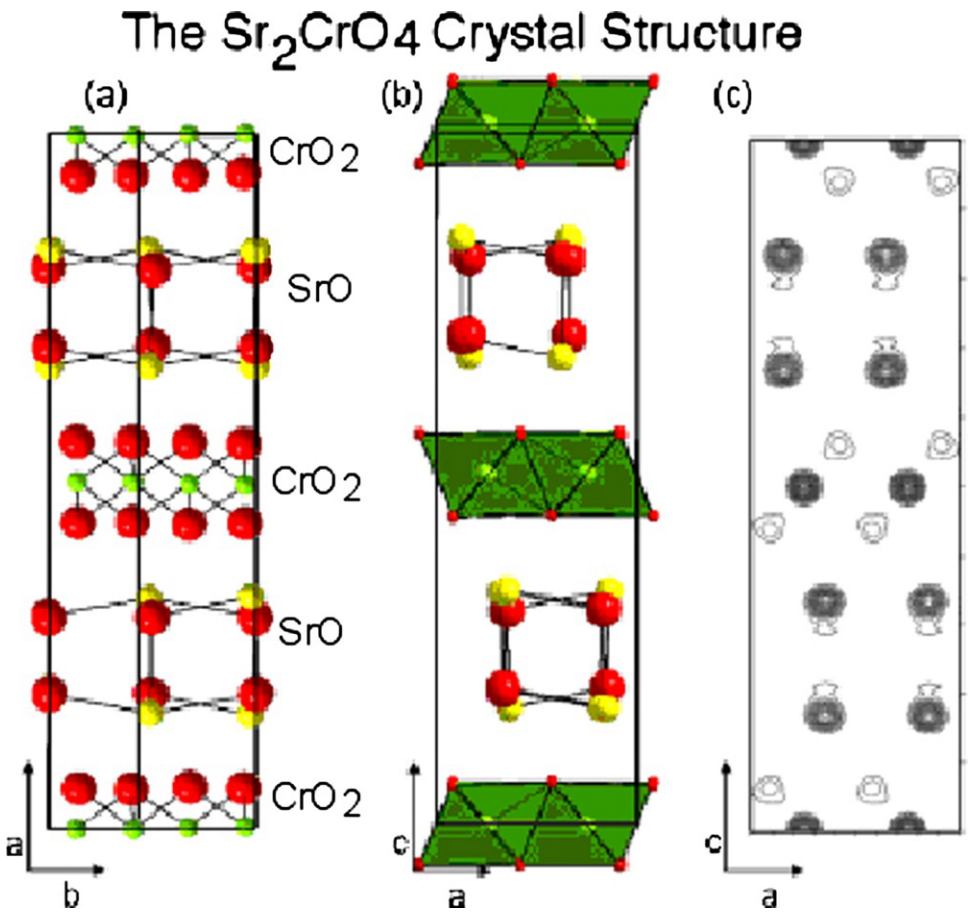

FIGURE 10.22

Yellow and green spheres represent strontium and chromium atoms, respectively, and red spheres for oxygen.

This incommensurately modulated structure has been successfully solved by means of single-crystal XRD with the super space group $C_0nmb(0s20)00s$. This orthorhombic structure corresponds to the stacking of two SrO and one CrO_2 layer and their mirror. The atoms of the Sr–O layer present the larger displacement modulation, especially the Sr atoms have the largest displacements, and are correlated with large modulations in the thermal parameters so as to accommodate the structural mismatch. The intersubsystem bond is particularly strong, in the whole system, which results in an underbonded Cr atom with an estimated valence of 3.48.

The compound, **tristrontium ortho-chromate**, $Sr_3(CrO_4)_2$, contains the Cr^{5+} ion. $Sr_3Cr_2O_8$ is an interesting structure for a number of reasons. It is a dimerized quantum magnet with gapped excitations and displays Bose–Einstein condensation in an applied magnetic field. Furthermore it displays substantial magnon phonon coupling at low temperatures. $Sr_3Cr_2O_8$ consists of triangular bilayers of chromium ions in the **ab** plane that are stacked along the **c** direction in an ABCABC sequence. The magnetic ions are paired into dimers by the dominant antiferromagnetic bilayer coupling and the system can therefore be viewed as a frustrated triangular network of dimers. The chromium ions are in the unusual 5^+ valence state resulting in one electron in the 3d shell and a spin value of 1/2 while the tetrahedral crystal field ensures that this electron occupies the doubly degenerate e_g orbitals. At 285 K, $Sr_3Cr_2O_8$ undergoes a cooperative Jahn–Teller distortion that lifts the orbital degeneracy so that only the $3z^2$-r^2 orbital is occupied. This low-temperature phase is characterized as having monoclinic crystal symmetry and antiferro-orbital ordering. Single crystals of $Sr_3Cr_2O_8$have been prepared. DC susceptibility measurements, high-field magnetization and powder and single-crystal inelastic neutron scattering were utilized. The data reveal a singlet ground state and gapped triplet excitations consisting of three modes arising from the three twins.

In another study, magnetic susceptibility, φ and specific heat C_p versus temperature T measurements on polycrystalline samples of $Sr_3Cr_2O_8$ and the isostructural, nonmagnetic compound $Sr_3V_2O_8$ were reported. A Curie–Wiess fit to the high-T $X(T)$ data for $Sr_3Cr_2O_8$ indicates that the Cr atoms are in the rare Cr^{5+} (spin $S = 1/2$)

valence state as expected from the compositional state. The ground state was found to be a spin singlet with an excitation gap $\Delta/k_B = 61.9$ K to the magnetic triplet states, and a weak interdimer coupling of 6.2 K was inferred.

The **distrontium chromite** compound, Sr_2CrO_4, plus Ba_2CrO_4, and Ba_3CrO_5, have been prepared. The characterization of these three Cr^{4+} compounds by X-ray and magnetic susceptibility experiments has been conducted. The magnetic moments for Sr_2CrO_4, Ba_2CrO_4, and Ba_3CrO_5 were determined to be in good agreement with the calculated value expected for a tetrahedral Cr^{4+} ion. Weak antiferromagnetic ordering for all three compounds is indicated from the small paramagnetic Weiss constants determined from the susceptibility data in the temperature region 80–300 K. Distortions of the tetrahedra from ideality, as determined from the structural features, further cause a reduction in the magnetic moments from the theoretical values.

The compound, **strontium dichromite**, $SrCr_2O_4$, has received moderate study. α-$SrCr_2O_4$ has a triangular planar lattice of d-containing Cr^{3+} made from edge-sharing CrO_6 octahedra. The plane shows a very small orthorhombic distortion from hexagonal symmetry. With a Curie–Weiss temperature of -596 K and a 3D magnetic ordering temperature of 43 K, the magnetic system is quasi two-dimensional and frustrated. Neutron powder diffraction shows that the ordered state is an incommensurate helical magnet, with an in-plane propagation vector of k = (0,0.3217,0). Temperature-dependent synchrotron powder diffraction characterization of the structure shows an increase in the inter-plane spacing on cooling below 100 K and an inflection in the cell parameters at the magnetic ordering temperature. These anomalies indicate the presence of a moderate degree of magneto-structural coupling. The structure has been presented in Fig. 10.23.

Here, the polyhedra are aligned in rows parallel to each other in the lattice.

Phase equilibria were determined in the complete composition range of the SrO–Cr_2O_3–La_2O_3 system in air at 1223 K and under low oxygen pressure (high vacuum, $p(O_2) \approx 10^{-9}$ bar). The (La, Sr)CrO_3 perovskite phase is the only quasi ternary oxide phase stable in air. The quasi ternary Ruddlesden–Popper phases $(La,Sr)_{n+1}Cr_nO_{3(n+1)}$ ($n = 1,2,3$) were identified in addition to the perovskite phase in the samples annealed under low oxygen pressure. The solubility limit of strontium in the $La_{1-x}Sr_xCrO_3$ phase was determined at 1223 K as $x = 0.10 \pm 0.02$ in air and at 1873 K as $x = 0.31 \pm 0.02$ under low oxygen pressure. The crystal lattice parameters of the Ruddlesden–Popper phase $LaSrCrO_4$ were obtained by the analysis of XRD patterns.

Solid-state reaction between $SrCO_3$, Cr_2O_3 and SrF_2 has produced the apatite phase $Sr_{10}(CrO_4)_6F_2$ and

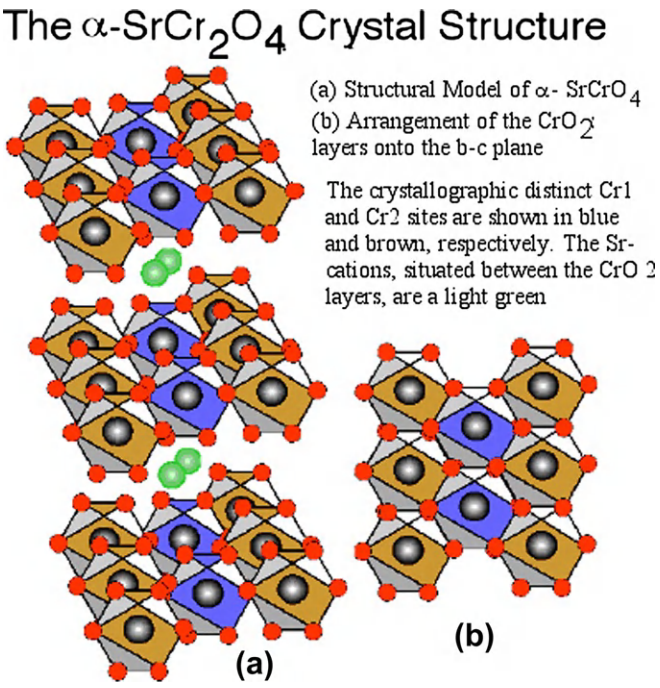

FIGURE 10.23

Sr_2CrO_4 which adopts the K_2NiF_4-type structure. The structure has the form as shown in Fig. 10.24.

The reaction outcome was very sensitive to the heating rate, with rapid rise times favoring the formation of Sr_2CrO_4, which has been synthesized at ambient pressure for the first time. Powder XRD (PXRD) and ED confirmed that Sr_2CrO_4 adopts a body-centered tetragonal cell (space group $I4/mmm$) with lattice parameters $a = 3.8357$ Å and $c = 12.7169$ Å, while a combination of neutron and XRD verified $Sr_{10}(CrO_4)_6F_2$ as hexagonal (space group $P6_3/m$) with lattice parameters: $a = 9.9570$ Å and $c = 7.4292$ Å. X-ray photo-electron spectroscopy (XPES)and magnetic measurements were used to characterize the oxidation states of chromium contained within these phases. PXRD and ED confirmed that Sr_2CrO_4 is body-centered tetragonal, while a combination of neutron and XRD verified $Sr_{10}(CrO_4)_6F_2$ is hexagonal. XPES and magnetic measurements identified the oxidation states of chromium in these phases.

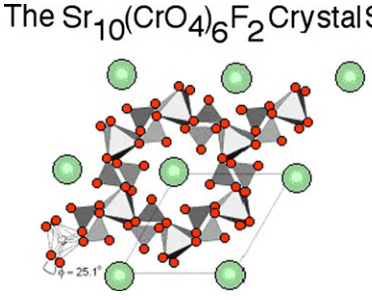

FIGURE 10.24

High pressure and temperature was used to synthesize perovskite-related phases in the Sr–Cr(IV)–O system. The $n = 1$, 2 and ∞ members of the $Sr_{n+1}Cr_nO_{3(n+1)}$ family have been obtained. Another new member, $n = 3$ as well as a hexagonal layered perovskite have also been observed by TEM and ED. The average structure of $Sr_3Cr_2O_7$ as determined by XRD has space group $I4/mmm$, whereas its microstructure includes a large amount of defects both in the layer stacking and within the layers. 2D magnetism and a large electrical resistance in $Sr_3Cr_2O_7$ are observed as opposed to the nonlocalized electronic behavior of $SrCrO_3$.

$SrCrO_4$ is offered for sale commercially with the CAS number of 7789-06-2.

10.2.5. Barium Chromium Compounds

No intermetallic compounds are known. Barium oxide forms a number of compounds with the chromium oxides. The exact composition depends, to a great extent, on the oxidation state of the chromium ion, $Cr^{3,\ 4,\ 5\ or\ 6+}$. In contrast to the other alkaline earth chromite–chromate systems, a number of barium chromate structures are known as shown in Table 10.12.

For the trivalent Cr(III) oxide system only $BaCr_2O_4$ and $Ba_3Cr_2O_6$ are known. The occurrence and products of solid/solid interactions in equimolar-mixed $BaCO_3$ and Cr_2O_3 powders were examined isothermally (700–1000 °C) and non-isothermally (25–1200 °C) under different gas atmospheres, employing thermogravimetry, X-ray diffractometry, infrared and Raman spectroscopy (RS), SEM, and energy dispersive X-ray spectroscopy (EDX). Irrespective of the gas atmosphere, a noncatalytic decomposition of the barium carbonate commenced at 570 °C, a temperature that is much less than the decomposition temperature (~970 °C) of $BaCO_3$ itself. The characteristics and distribution of the yielding products were found to be quite sensitive to the surrounding gas atmosphere. Under N_2 atmosphere, the interactions were thermochemical in nature, leading eventually to the formation of barium chromite ($BaCr_2O_4$) spinel as the sole detectable product. Under O_2 atmosphere, however, the oxygen molecules contributed oxidatively to the chromite thermal genesis course, thus imposing a topochemical nature to the reaction, leading to the formation of $BaCrO_4$, as the major product, and barium chromites ($BaCr_2O_4$ and $Ba_3Cr_2O_6$), as minor products. Proposed reaction pathways and characteristics of products have been presented and discussed. The phase diagram has the form as shown in Fig. 10.25.

Only the two phases appear in the diagram, both containing Cr^{3+}. The photophysical and photocatalytic properties of $BaCr_2O_4$ synthesized with normal spinel-type crystal structure were studied. It was found that H_2 could be photocatalytically evolved from the aqueous CH_3OH solution suspended with Pt(0.2 wt %)/$BaCr_2O_4$ powder under irradiation of both ultraviolet (UV) and visible lights. The wavelength dependence of H_2 evolution under visible light irradiation showed a maximum activity for $\lambda \geq 540$ nm. A possible electronic band structure and corresponding photoexcitation modes of $BaCr_2O_4$ under irradiation of UV and visible lights were proposed in regard to the complicated photophysical and photocatalytic properties.

It has the structure shown in Fig. 10.26.

The two types of Cr^{3+} are clearly shown. Chromium(III) oxide reverses the sequence of dehydration of barium perchlorate trihydrate (BP). Between 223 and 310 °C, the oxide reacts with anhydrous BP in a 1:1 molar ratio to give the yellow barium dichromite $BaCr_2O_4$. Between 350 and 430 °C, this material reacts in a 1:1 stoichiometry with BP, to give barium chromate $BaCrO_4$. The fact that $Ba_3Cr_20_6$ is only detected at low temperatures (<400 °C) has precluded any extensive determination of its physical characteristics.

Single crystals of $BaCr_2O_4$ were prepared as a high temperature compound of the $SrCr_2O_4$-type. It crystallizes with orthorhombic symmetry, space group $D—Pmmn$, $a = 12.286$ Å; $b = 5.921$ Å; $c = 5.146$ Å, $Z = 4$.

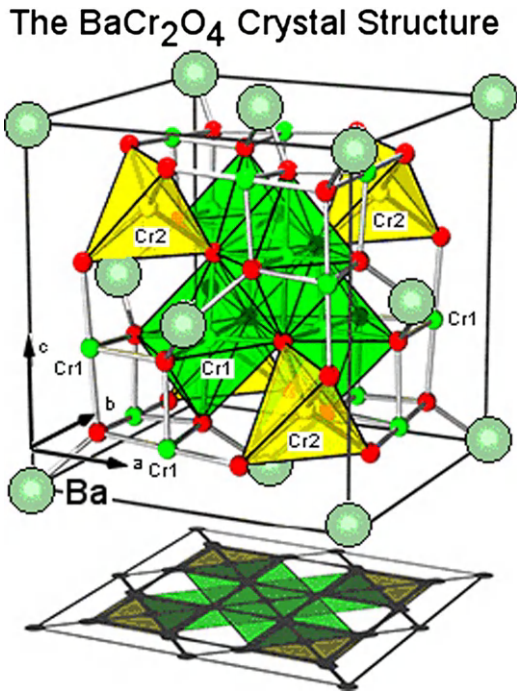

FIGURE 10.26

The crystal structure was described and the relationship to the metastable compounds α-$CaCr_2O_4$ and $SrCr_2O_4$ was discussed.

A number of compounds containing the Cr^{+4} ions are known as shown in Table 10.12 presented above. These include: $BaCrO_3$ (tetramorphic), Ba_2CrO_4, $Ba_4Cr_{13}O_{28}$, and $Ba_3Cr_2O_6$ (which contains +4 and +5 ions).

The structures determined for the four tetramorphic forms of $BaCrO_3$ are shown as follows. The first two forms are shown in Fig. 10.27.

$BaSO_4$ type: Cell parameters are: $a = 5.528$ Å, $b = 7.336$ Å, $c = 9.113$ Å, $\alpha = \alpha \Rightarrow \beta = \gamma = 90°$, cell volume is 369.56 $Å^3$, $Z = 4$.

Cell occupancy is shown in Table 10.13.

$BaCrO_3$ type (hP70): Cell parameters are: $a = b = 5.653$ Å, $c = 32.467$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 897.57 $Å^3$. Cell occupancy is shown in Table 10.14.

The other two types have the lattice form shown in Fig. 10.28.

$BaCrO_3$-hP20 type: Cell parameters are: $a = b = 5.66$ Å, $c = 9.357$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell

volume = 269.60 Å^3, $Z = 4$. Cell occupation is shown in Table 10.15.

$BaCrO_3$-hR144 type: Cell parameters are: $a = b = 5.652$ Å, $c = 21.1697$ Å, $\alpha = \beta = 82.329°$, $\gamma = 60°$, cell volume = 578.67 Å^3, $Z = 24$. Cell occupation is shown in Table 10.16.

The structure of the four-layer hexagonal $BaCrO_3$ polytype (hP20 type), prepared at high temperature and high pressure, was determined utilizing a Picker FACS-I diffractometer. The hexagonal black crystal was found to crystallize with a four-layer stacking sequence in space group $P6_3/mmc$ having unit cell parameters $a = 5.660(1)$ and $c = 9.357(1)$ Å. The structure was determined from 668 independent reflections of which 605 were considered observed. Equivalent reflections were averaged and this operation yielded 130 unique, observed reflections. Refinement of the structure by least-squares methods gave a conventional *R*-value of 3.0%. The structure consists of a four-layer stacking sequence of close-packed BaO_3 layers containing tetravalent chromium in all the octahedral oxygen interstices. The compound was found to be isostructural with β-$BaMnO_3$ and the recently reported $BaRhO_3$ and $SrMnO_3$.

In another study, a product from the reaction between CrO_2 and Ba_2CrO_4 at 900 °C under 60–65 kbar was found to be the six-layer polytype of $BaCrO_3$ from powder diffraction studies. A hexagonal black crystal obtained from this reaction was isolated for single-crystal studies and structure determination. The crystal

was found to possess a six-layer stacking sequence of BaO_3 layers with space group $P6_3/mmc$ and had unit cell parameters $a = 5.629(2)$, $c = 13.698(6)$ Å, and $Z = 6$. The structure was determined from 936 independent reflections of which 693 were considered observed. Averaging equivalent reflections yielded 163 unique, observed reflections. Refinement of the structure by least-squares methods gave a conventional R value of 4.8% ($R_w = 6.2\%$). The structure consists of a six-layer stacking sequence of close-packed BaO_3 layers containing tetravalent chromium in all the octahedral oxygen interstices. The compound was found to be isostructural with previously reported $BaMnO_3$ phases.

Twenty-seven-layer barium chromium oxide, $BaCrO_3$-hR144 type, was prepared at 1200 °C and 60–65 kbar by reaction of CrO_2 and Ba_2CrO_4. The compound crystallizes in space group $R3m$ with hexagonal cell dimensions $a = 5.652 \pm 0.002$ Å, $c = 62.75 \pm 0.02$ Å. The structure was determined from 1070 independent reflections, of which 811 were considered observed, collected by automated counter methods, and refined by least-squares methods to a conventional R-value of 4.1%. The structure consists of a 27-layer stacking sequence of close-packed BaO_3 layers. Zhdanov notation for the sequence is (3)2(2)2, with all of the O_6 octahedral sites occupied by Cr. Strings of four pairs of face-sharing octahedra in which the pairs are linked to each other by corner sharing are in turn joined to each other by octahedra sharing only corners. The structure is thus closely related to the four-layer and six-layer polytypes of $BaCrO_3$. Bariums in two of the five crystallographic positions showed large thermal anisotropy and are better described in terms of half atom occupancy in split sites.

Under the local-spin density approximation method plus on-site coulomb interaction U correction (LSDA+U), the $BaCrO_3$-hP70 type, in the perovskite structure is found to be half-metallic ferromagnet with an integral magnet moment of 2.000 Bohr magnetons (μ_B) per unit. The feasibility of constructing the $BaCr_{0.5}Ti_{0.5}O_3$ superlattice to stabilize the perovskite phase for the $BaCrO_3$ is theoretically explored. Additionally, the influence of screened parameters U on the electronic structures and magnet moments of the perovskite $BaCrO_3$ and $BaCr_{0.5}Ti_{0.5}O_3$ superlattice is expounded.

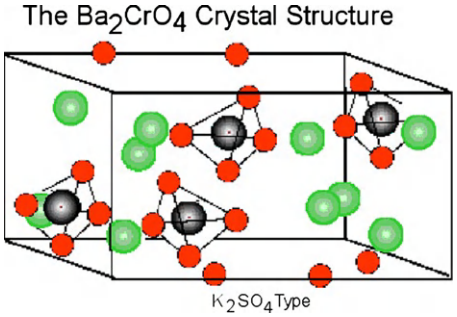

FIGURE 10.29

One of the products of the reaction of CrO_2 and Ba_2CrO_4 at 1300 °C is a 14-layer polytype of $BaCrO_3$. Cell parameters are space group = $P6_3/mmc$ with $a = 5.650$ Å and $c = 32.467$ Å, $Z = 14$. It consists of a 14-layer stacking sequence of closed-packed BaO_3 layers with all of the octahedral sites occupied by Cr^{4+} ions. The Zhdanov notation for the sequence is: {2(3)2|2(3)2}. In each cell, there are strings of three pairs of face-sharing octahedra in which pairs are linked to each other by corner-sharing. The strings are in turn joined to each other by octahedra-sharing-only corners. Thus, the structure is closely related to the four-layer, six-layer and twenty-seven layer polytypes of $BaCrO_3$. In order to clarify what is being discussed, consider the following diagram: Fig. 10.28

It shows the sequence of polytype layers from the aspect of the joined octahedra.

The compound, **dibarium chromite**, Ba_2CrO_4, contains the Cr^{4+} ion and has a structure related to $BaCrO_3$, except for the number of Ba^{2+} ions present in the unit cell. One form has the structure of K_2SO_4 while that of the other is of the $BaSO_4$ type as shown in Fig. 10.29.

The cell parameters are: $a = 5.967$ Å, $b = 7.611$ Å, $c = 10.496$ Å, $\alpha = \beta = \gamma = 90°$, $Z = 4$. Cell volume = 475.99 Å^3. Cell occupancy is shown in Table 10.17.

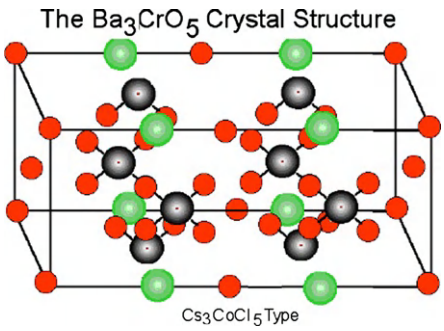

FIGURE 10.30

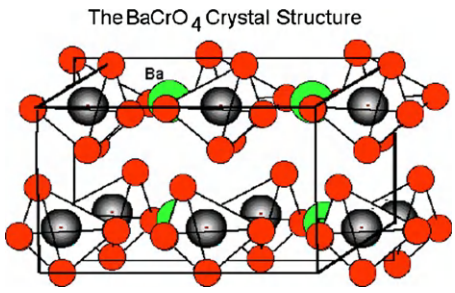

FIGURE 10.31

The preparation of the compounds Ba_2CrO_4, and Ba_3CrO_5 has been described. However, the exact structure of Ba_3CrO_5 has not been published except to state that it has the structure of Cs_3CoCl_5 with point group - = *tI*36 and space group = *I*4/*mcm*. The structure may be represented in Fig. 10.30.

Cell parameters are: $a = b = 9.123$ Å, $c = 9.7041$ Å, $\alpha = \beta = 118.038°$, $\gamma = 90°$, $Z = 4$, cell volume = 603.37 Å^3. Cell occupancy is shown in Table 10.18.

The characterization of these two Cr^{4+} compounds by X-ray and magnetic susceptibility experiments has been conducted. The magnetic moments for Ba_2CrO_4, and Ba_3CrO_5 were determined to be in good agreement with the calculated value expected for a tetrahedral Cr^{4+} ion. Weak antiferromagnetic ordering for both compounds was indicated from the small paramagnetic Weiss constants determined from the susceptibility data in the temperature region 80–300 K. Distortions of the tetrahedra from ideality, as determined from the structural features, further caused a reduction in the magnetic moments from the theoretical values.

The compound, **barium chromate**, $BaCrO_4$, contains the ion, Cr^{6+}, and has the CAS number of 10294-40-3 and the structure is shown in Fig. 10.31.

Cell parameters are: $a = 5.528$ Å, $b = 7.336$ Å, $c = 9.113$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 369.56 Å^3, $Z = 4$.

Cell occupancy is shown in Table 10.19.

$BaCrO_4$ was studied at high pressure up to 25 GPa in a diamond-anvil cell using both RS and XRD methods. The results showed that $BaCrO_4$ exhibits a phase transition near 9 GPa from both Raman and XRD measurements. The new high-pressure phase ($BaCrO_4$-II) is suggested as a monoclinic ($P2_1/m$) structure, different from other high-pressure forms of ABO_4-type compounds. Moreover, the high-pressure phase of $BaCrO_4$ is found to be reversible; the low-pressure phase is recovered at ~8 GPa upon decompression. The

pressure–volume data of $BaCrO_4$ fitted to a third-order Birch–Murnaghan equation of state yield a bulk modulus of 53(1) GPa and a pressure derivative of 6.8(5), in agreement with the theoretical prediction. For the high-pressure phase $BaCrO_4$-II, the bulk modulus is 117(10) GPa and the pressure derivative is 3(1).

Refinement of the crystal structures of Ba_2CrO_4 and Ba_3CrO_5 using powder neutron diffraction data has confirmed that the former is isostructural with β-K_2SO_4 and the latter is isostructural with Cs_3CoCl_5. Ba_2CrO_4 is orthorhombic, *Pnma* (No. 62), $Z=4$ with $a=7.6285(5)$ Å, $b=5.9136(5)$, $c=10.4639(8)$, and $V=472.04(5)$ Å^3. Ba_3CrO_5 is tetragonal, *I*4/*mcm* (No. 140), $Z=4$ with $a=7.3033(3)$ Å, $c=11.6704(6)$, $V=622.48(4)$ Å^3 from powder Guinier XRD data. Magnetic properties of Sr_2CrO_4, Ba_2CrO_4, and Ba_3CrO_5 were examined down to 2–5 K. The structures and magnetic properties of Sr_2CrO_4 and Ba_2CrO_4 are compared with their vanadium analogues β-Sr_2VO_4 and β-Ba_2VO_4. Unlike isostructural β-Sr_2VO_4, which contains the $V_2O_8^{8-}$ dimer, Sr_2CrO_4 contains truly isolated CrO_4^4 tetrahedra and its magnetic behavior can be best described as a dimerized chain. Ba_2CrO_4 and Ba_3CrO_5 also contain isolated CrO_4^{4-} tetrahedra. Ba_2CrO_4 is paramagnetic down to 5 K. Ba_3CrO_5 undergoes long-range magnetic order at 8 K, a temperature range significantly higher than that of isostructural Rb_3CoCl_5 and Cs_3CoX_5 (X = Cl, Br).

The compound, $Ba_4Cr_{13}O_{28}$ has the structure as shown in Fig. 10.32.

Cell parameters are: $a=b=5.652$ Å, $c=9.815$ Å, $\alpha=\beta=73.266°$, $\gamma=60°$, cell volume = 256.09 Å^3. Cell occupancy is shown in Table 10.20.

Little is known concerning this compound other than its structure, which is that of a 12-layered perovskite.

Barium chromate is offered for sale commercially as $BaCrO_4$ with the CAS number of 10294-40-3.

10.2.6. Radium Chromium Compounds

Although it is likely that radium chromite or chromate compounds could be prepared and studied by the same methods used to characterize the homologous barium compounds, no such information has appeared in the technical literature. This is likely due to the high cost of RaO and its high radioactive intensity.

10.3. ALKALINE EARTH MOLYBDENUM COMPOUNDS

Molybdenum occurs as two oxides MoO_2 and MoO_3 having the Mo^{4+} and Mo^{6+} valence states. Molybdenum trioxide forms *n*- and *p*-type semiconductor phases which are of technological interest. Molybdenum dioxide is produced by roasting molybdite ore (MoS_2). It is colorless to yellowish-white. It is quite soluble in hot water and slightly soluble in cold water. Comparative crystal structures are shown in Fig. 10.33.

Both the structures are composed of MoO_6 octahedra, the dioxide having a point-shared structure while the trioxide is composed of separated or point-coordinated octahedra in most cases.

10.3.1. Beryllium Molybdenum Compounds

Only Be forms intermetallic compounds with Mo metal. The phase diagram has been presented in Fig. 10.34.

Structure factors are shown in Table 10.21.

The other alkaline earth metals do not form intermetallic compounds with Mo metal.

The compound, Be_2Mo, has the structure. Cell parameters are: $a = 4.448$ Å, $c = 7.312$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 125.26$ Å^3, $Z = 4$.

The reaction between single crystal 99.99% Mo with YBe_{13} [CAS #-12010-31-0] was studied at 1000–1400 °C. A hexagonal-closed-packed Be_2Mo [CAS #-12232-43-8]

layer was formed in the contact zone. The activation energy for $MoBe_2$ formation was 42.5 kcal/mol. Cell occupancy is shown in Table 10.22.

The feasibility of producing composites containing nickel or molybdenum fibers in a beryllium matrix was investigated. The composites studied were fabricated by powder metallurgical techniques. The 1-mil-diameter nickel fibers reacted completely below 900 °C, converting the fibers from nickel to Ni_5Be_{21}. As the hot-pressing temperature was raised above 1100 °C, the nickel diffused outward from the beryllide fibers. The solid solubility of nickel in beryllium was about 20 wt% at the 1100 °C pressing temperature at the zone-fiber interface. The 1.5-mil-diameter molybdenum fibers showed no evidence of reaction and little evidence of diffusion after pressing at 900 °C. Between 1000 and 1050 °C pressing conditions, the fibers began to react, producing layers of $MoBe_2$ and $MoBe_{12}$, respectively, surrounding the molybdenum core. The structure remained the same at 1100 °C with no evidence of solid solubility of the molybdenum in the beryllium or vice versa.

The compound **Mo_3Be** was prepared and found to be isomorphous with Mo_3Si, a compound that is cubic. The compound, Be_3Mo, has the crystal structure as shown in Fig. 10.36.

This compound is a "Zintl" phase with Be atoms in body-centered positions and Mo–Mo barbells situated at face-centered positions. Cell parameters are: $a = b = c = 4.892$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 116.93 Å^3, $Z = 2$. Cell occupancy is shown in Table 10.23.

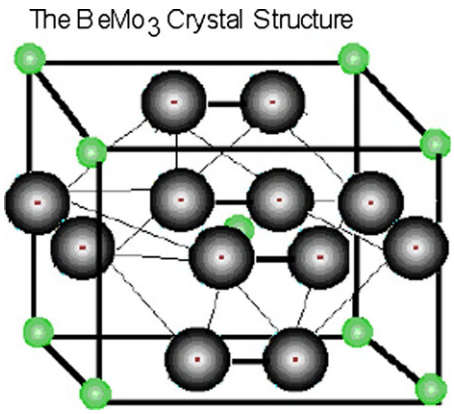

FIGURE 10.36

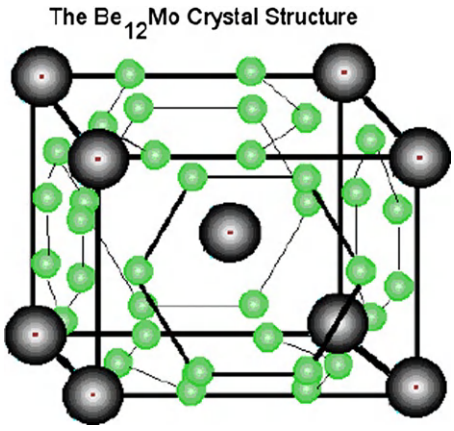

FIGURE 10.37

The compound, $Be_{12}Mo$, has the structure as shown in Fig. 10.37.

TABLE 10.22

1	Mo	Mo	6	c	4m.2	1/4	0	1/2	1.0
2	Be	Be	2	a	m-3.	0	0	0	1.0

It consists of two (2) sub-units: a body-centered lattice of Mo atoms and six (6) hexagonal units of Be (Be_6) arranged on the faces of the tetragonal lattice. The unit cell parameters are: $a = b = 5.5471$ Å, $c = 4.3342$ Å, $\alpha = \beta = 67.565°$, $\gamma = 81.625°$, $Z = 2$, cell volume $= 111.31$ Å^3. Cell occupancy is shown in Table 10.24.

The intermetallic compound $MoBe_{12}$ has been found to be ferromagnetic at low temperatures. The ferromagnetic and paramagnetic Curie temperatures are each about 50 K, and at 1.4 K; the saturation moment is approximately 0.2 Bohr magnetons per chromium atom. In contrast, the compounds Nb_2Be_{17}, $NbBe_{12}$, Ta_2Be_{17}, $TaBe_{12}$, $MoBe_{12}$, $ZrBe_{13}$, and $CaBe_{13}$ were found to be nonmagnetic and non-superconducting above 1.4 K.

Although the compound, $Be_{13}Mo$ has been reported, there is no corroborating evidence to confirm its existence in the Be–Mo system.

An intermetallic compound, $Be_{22}Mo$, is also known. It has the structure as shown in Fig. 10.38.

Unit cell parameters are: $a = b = c = 8.2265$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 393.67$ Å^3, $Z = 8$. Cell occupancy is shown in Table 10.25.

This compound, $Be_{22}Mo$, has been found to be superconducting with a critical temperature of $T_c = 4.14$ K. No other intermetallic compounds have been discovered to date. None of these compounds have found usage in Industry.

The only reference to beryllium molybdates has been the determination of the heat of formation when BeO was evaporated from Mo metal crucibles. When heated to a sufficiently high temperature, BeO evaporates as a BeO-molecule, $(BeO)_n$ where $n = 1$–5.

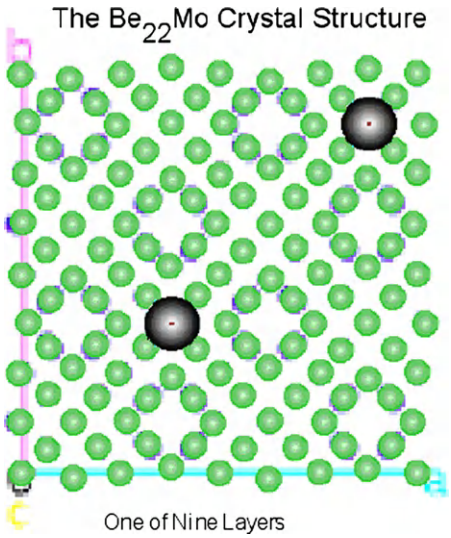

FIGURE 10.38

If a Mo metal crucible is used, then beryllium molybdate molecules are detected in the vapor phase. Gas-phase reactions involving beryllium molybdates and tungstates were studied by high-temperature mass spectrometry. The standard enthalpies of formation and atomization of $BeMoO_3$, $BeWO_3$, $BeWO_4$, and Be_2WO_4 were determined. The following values were determined:

Heat of formation (vapor phase): ΔH_f^0 (2175–2450 °C)

$$Be_3O_3 + 3\,MoO_2 \Rightarrow 3\,BeMoO_3, \quad \Delta H_f^0 = -432 \text{ kJ/mol}$$

$$Be_3O_3 + 3\,WO_2 \Rightarrow 3\,BeWO_3, \quad \Delta H_f^0 = -424 \text{ kJ/mol}$$

However, when the vapors were cooled to room temperature, only a mixture of oxides was obtained. No other Be–Mo compounds are known to date.

10.3.2. Magnesium Molybdenum Compounds

Magnesium does not form any intermetallic compounds with molybdenum. All of the Ae–Mo systems have been investigated and a typical phase diagram has the form as shown in Fig. 10.39.

Except for the temperatures, the other alkaline earths exhibit the same behavior with Mo metal in that no compounds or solid solutions are formed.

MgO forms a limited number of compounds with molybdenum oxides.

No compounds are known where the valence state of Mo is 3+. In the Mo^{4+} system of MgO–MoO_2, the compound, $MgMoO_3$ is expected to belong to the cubic perovskite structure, but this compound has never been synthesized. The possible +4 molybdates, $MgMoO_3$, Mg_2MoO_4, Mg_3MoO_5, $MgMo_2O_5$, and the +5 molybdates $MgMo_2O_6$, $Mg_2Mo_2O_7$ and $Mg_3Mo_2O_8$ remain unknown.

The solid-state reaction of MgO and MoO_3 produces three compounds as shown in Table 10.26.

The phase diagram of MgO–MoO_3 has been presented in Fig. 10.40.

$MgMoO_4$ is trimorphic. Although the compound, dimagnesium tri-molybdate, $Mg_2Mo_3O_{11}$, was identified in early works along with $MgMo_2O_7$, the pyromolybdate, subsequent work has established that this compound is actually the low temperature form of the pyromolybdate in the system, MgO–MoO_3. The

transition temperature was established at 840 °C, the point where the X-ray pattern changes into the α-$MgMo_2O_7$ pattern.

Magnesium molybdates, prepared from an aqueous solution of magnesium nitrate and ammonium paramolybdate under various pH conditions, produce the same compositions. The difference is that those compounds formed from solution are catalytic and have been used for the selective oxidation of propane and isobutane with gaseous oxygen under atmospheric pressure in the temperature range of 360–520 °C. The structure analyses by XRD and FT-IR showed the formation of three phases, α-$MgMoO_4$, β-$MgMoO_4$ and $Mg_2Mo_3O_8$, in the catalysts calcined below 550 °C. The catalyst prepared at pH = 5.7 showed the highest activity for the oxidative dehydrogenation of the alkanes as well as the strongest acidity. By XPES measurements, an excess amount of Mo compared to Mg was observed over the active catalysts. It is likely that the excess molybdenum species is present as molybdate and creates acidic sites over the catalyst surface. Low coordinated molybdates are present in $MgMo_2O_7$ (dimer of MoO_3 and $MgMoO_4$) and in $NaMo_2O_7$ (chain of alternating MoO_4 and MoO_6 units). Isolated MoO_4 coordination is, however, rather common for ortho-molybdates (e.g. K_2MoO_4, Na_2MoO_4, $CaMoO_4$, $MgMoO_4$, $MnMoO_4$, $CuMoO_4$, etc.).

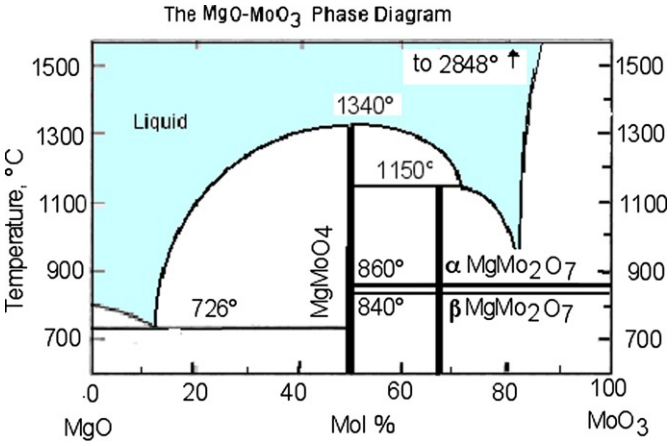

FIGURE 10.40

Note that $MgMoO_4$ is trimorphic, as shown in Fig. 10.41 and $MgMo_2O_7$ is dimorphic (see Fig. 10.42). The former melts congruently whereas the latter melts incongruently (see Fig. 10.40).

$MgWO_4$ type: Cell parameters are: $a = 4.964$ Å, $b = 4.900$ Å, $c = 5.689$ Å, $\alpha = \beta = 90°$, $\gamma = 90.35°$, cell volume = 130.85 Å^3, $Z = 2$. Cell occupancy is shown in Table 10.27.

$MnMoO_4$ type: Cell parameters are: $a = b = 6.9246$ Å, $c = 7.025$ Å, $\alpha = \beta = 77.504°$, $\gamma = 84.235°$, cell volume = 320.57 Å^3, $Z = 4$. Cell occupancy is shown in Table 10.28.

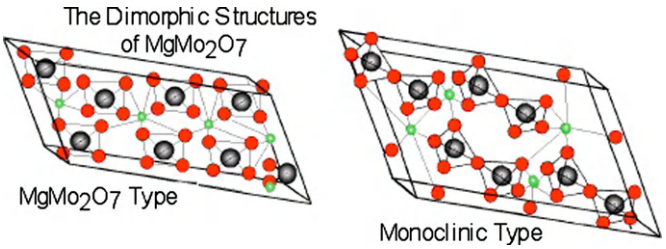

FIGURE 10.42

$MgMoO_4$ type: Cell parameters are: $a = 0.6.92$ Å, $b = 0.8.354$ Å, $c = 0.9.651$ Å, $\alpha = 96.48°$, $\beta = 106.9°$, $\gamma = 101.7°$, cell volume $= 513.87$ Å^3. Cell occupation has not been given.

The importance of luminescent tungstates and molybdates in several technological applications motivated the study of the structural, luminescence and scintillation properties of the $MgWO_4$–$MgMoO_4$ system. XRD studies allowed the identification of three main types of structures in the pseudo-binary system: $MgWO_4$–$MgMoO_4$ system (Sanmartinite = β-$MgMoO_4$, Cuproscheelite = α-$MgMoO_4$, and Wolframite = $MgWO_4$) and the refinement of the parameters of the crystal lattice. It was found that the single-phase solid solution $MgMo_{1-x}W_xO_4$ with the β-$MgMoO_4$ structure is created only at $x < 0.10$, while for higher tungsten content a mixture of different phases is formed. The X-ray luminescence spectra of a series of samples of the $MgWO_4$–$MgMoO_4$ system was measured at $T = 8$ K. The principal emission bands were assigned to the main structural phases as follows: β-$MgMoO_4$, 520 nm; α-$MgMoO_4$, 590 nm; $MgWO_4$ (Wolframite), 480 nm. The phase composition of the sample determined the actual shape of the observed spectra. Possible relations between the crystal structure and luminescence properties of different phases were discussed in terms of a configuration coordinate model. Of all the compounds under test, $MgWO_4$ was found to have the best scintillation response for particle excitation (0.90 ± 0.15 that of $ZnWO_4$ at $T = 295$ K). Further, the light yield also remained high with decreasing temperature, which makes this material potentially useful for cryogenic applications.

The dimorphic compound, magnesium dimolybdate, $MgMo_2O_7$, has the structure shown in Fig. 10.42.

One structure is monoclinic with space group $P2_1/c$ and $a = 8.111$ Å, $b = 5.700$ Å, $c = 15.002$ Å, $\beta = 115.32°$, $Z = 4$, $V = 627.54$ Å^3. The $Mo_2O_7^{2-}$ pyro-anion consists of two corner-sharing MoO_4 tetrahedra which are twisted from the ideal eclipsed configuration by an average of 12.3°. These Mo_2O_7−groups form anionic sheets parallel to the (100) plane. Mg^{2+} ions are situated between the anionic sheets in a distorted-octahedral arrangement of O atoms. The MgO_6 octahedra share one edge, forming Mg_2O_{10} units. The other structure consists of two MoO_4 tetrahedra arranged within the unit cell by 2 units and surrounded by MgO_8 octahedra. Cell parameters for this phase are: $a = 5.711$ Å, $b = 8.111$ Å, $c = 13.6748$ Å, $\alpha = 97.18°$, $\beta = \gamma = 90°$, cell volume $= 627.27$ Å^3, $Z = 4$. Cell occupancy is shown in Table 10.29.

The compound di-magnesium tri-molybdate, $Mg_2Mo_3O_8$, was obtained by solid-state reaction of MgI_2 and MoO_3 (1:1) at 200 °C and subsequent crystallization at 800 °C. Its formula is actually $MgO{\cdot}(MoO{\cdot}2MoO_3)$ where both Mo^{4+} and MoO^{6+} are present in the lattice structure. Under the same conditions, ZnI_2 and MoO_3 only yielded rather impure $Zn_2Mo_3O_8$; however, when ZnI_2 or CdI_2 and MoO_3 were taken in a molar ratio of 1:2, well-crystallized α-Mo_4O_{11} was obtained. The known crystal structures of $Mg_2Mo_3O_8$ and α-Mo_4O_{11} were refined

TABLE 10.29

with new XRD data ($R = 0.030$ and 0.059, respectively) (Fig. 10.43).

The compound, $MgMoO_3$, does not exist. The structures of the oxidized and reduced phases in the system $MgO–MoO_3$ were characterized by XRD. With $SrMoO_4$, reduction resulted in the formation of $SrMoO_3$; however, each of the other oxides underwent a reversible decomposition. $MgMoO_4$ formed a mixture of crystalline MgO and $Mg_2Mo_3O_8$. For $MgMoO_4$, removal of one O/Mo occurred at a $p(O_2)$ of 10^{-6} atm., corresponding to a ΔG of oxidation of -100 kJ/mol-O_2; however, the equilibrium between $SrMoO_4$ and $SrMoO_3$ occurred at 10^{-26} atm. of O_2, corresponding to a ΔG of oxidation equal to -375 kJ/mol of O_2. These thermodynamic properties differ significantly from oxidation of MoO_2 to MoO_3, for which ΔG is -220 kJ/mol-O_2 at 873 K. All of the mixed oxides were essentially inactive for the selective oxidation of methanol, with specific rates that were much lower than that observed for MoO_3.

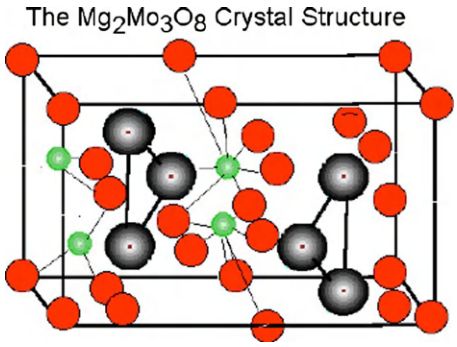

FIGURE 10.43

A compound of the formula $Fe_3Mg_2Mo_2V_3O_{20}$ has been obtained as a result of a reaction between $FeVO_4$ and $MgMoO_4$ taken at a molar ratio of 3:2. This compound crystallizes in the monoclinic system and its unit cell parameters are the following: $a = 6.971$ Å, $b = 9.055$ Å, $c = 1.2.542$ Å, $\gamma = 102.00°$, $Z = 2$.

There have been no uses developed in Industry for any of these magnesium molybdates. $MgMoO_4$ has the CAS number of 12013-21-7.

10.3.3. Calcium Molybdenum Compounds

Calcium oxide forms but few compounds with the molybdenum oxides. In the $CaO–Mo_2O_3$ system, a different strain-relaxation mechanism takes place in ultrathin CaO films grown on Mo(001). Whereas CaO films are amorphous at low growth temperature due to a substantial lattice mismatch with the support, a crystalline phase develops upon annealing to 1000 K. This phase is characterized by a sharp (2×2) pattern in low-energy ED and displays wide, atomically flat terraces in scanning tunneling microscopy (STM) images. The phase transition is initiated by the diffusion of Mo from the support into the film, where it replaces 25% of the Ca ions. The resulting rock salt-type Ca_3MoO_4 structure has a negligible lattice mismatch with the Mo(001), enabling the growth of extended, defect-free oxide patches. The oxidation of Mo atoms from the support provides a second, thermodynamic stimulus for the phase transition. For MgO films grown on the same Mo(001) surface, no relevant intermixing is revealed at the interface, most likely because of the smaller lattice mismatch between both systems.

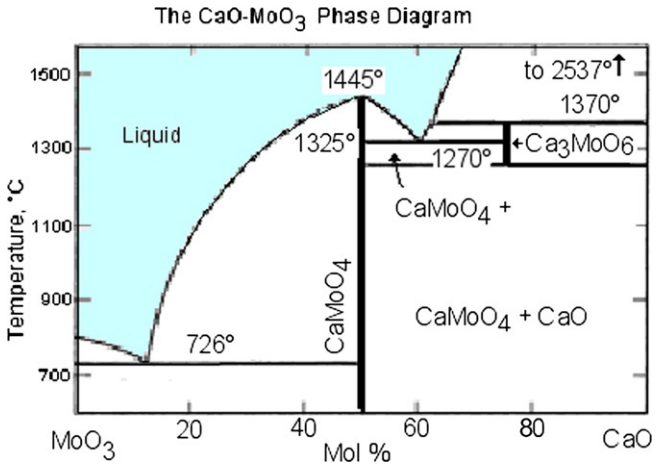

FIGURE 10.44

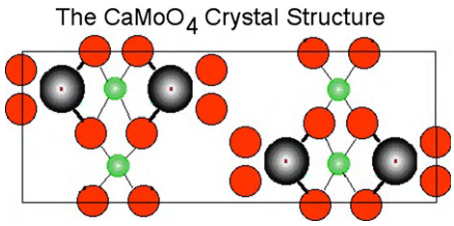

FIGURE 10.45

In the $CaO–Mo_2O_3$ system, no compounds like $CaMoO_4$ or $Ca_3Mo_2O_6$ are known.

The phase diagram is shown in Fig. 10.44.

Structure factors are shown in Table 10.30.

$CaMoO_3$ is the sole member of the $CaO–MoO_2$ family of compounds. The tri-calcium molybdate, Ca_3MoO_6 is meta-stable and only appears between the temperatures of 1270 and 1370 °C. It decomposes below 1270 °C into $CaMoO_4$:

$$Ca_3MoO_6 \Rightarrow CaMoO_4 + 2CaO$$

Calcium molybdate is a white tetragonal crystal with the CAS number of 7789-82-4. Its molecular weight is 200.02 g/mol. It melts at 1446 °C.

The compound, calcium molybdate, $CaMoO_4$, has the crystal structure shown in Fig. 10.45.

In this scheelite structure, the Ca^{2+} exists as a bisdisphenoid polyhedron with eight oxygen atoms forming a CaO_8 polyhedron, whereas the molybdenum (Mo) ions are surrounded by four oxygen atoms forming a tetrahedral unit. The CaO_8 polyhedron shares four of its edges with four other CaO_8 polyhedra extending in the *c*-directions. Each oxygen atom of the CaO_8 polyhedron is connected to one Mo atom. In particular, Mo-containing scheelite type ABO_4 compounds has been of interest for decades, not only because of its excellent optical properties suitable for phosphors, lasers, optical fibers, and electrochromic materials, but also due to its mixed conducting properties for negative electrode materials in Li-ion batteries. Single-phase tetragonal scheelite $CaMoO_4$ (space group, *Pmmm*) can be easily prepared via a conventional solid-state reaction method.

The refined unit cell parameters for $CaMoO_4$ at ambient temperature were: $a = 5.222$ Å, $b = 5.222$ Å, and $c = 11.425$ Å ($V = 311.55$ Å^3). The oxidation state of the transition metal species for the as-sintered $CaMoO_4$ was analyzed by XPS. The two well resolved spectral lines at 232.6 and 235.8 eV were assigned to the binding energies of an electron in Mo-$3d^{5/2}$ and Mo-$3d^{3/2}$, spin-orbit components, respectively. The average thermal expansion coefficient was about 11×10^{-6}/K over the temperature range 303–1273 K. This compound is not stable when heated to elevated temperatures because of the volatility of molybdenum trioxide:

$$CaMoO_4 + \text{heat} \Rightarrow CaO + MoO_3\Uparrow$$

It has been found that pure MoO_3 sublimes above 973 K, but the evaporation rate becomes much more significant beyond the melting point of MoO_3 at 1068 K. To investigate the relationship between evaporation rate and system composition changes, isothermal holding experiments were carried out in the case of $CaMoO_4$ at temperatures 1573, 1723, 1773 and 1823 K. All the mass decreases were assumed to be caused only by MoO_3 evaporation. The molar fraction of MoO_3 in the system was calculated for each time step based on the measured mass decrease. The following Fig. 10.46 shows the variation of evaporation rate as a function of MoO_3 remaining in the system, for $CaMoO_4$ at: (1) 1573 K, (2) 1723 K, (3) 1773 K, and (4)

TABLE 10.30

Compound	Structure type	Point group	Space group	Melting point, °C

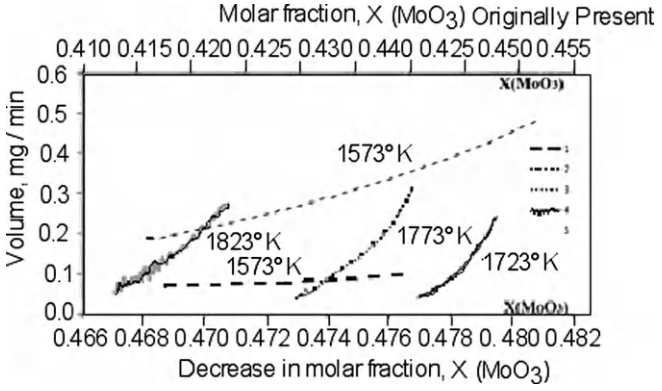

FIGURE 10.46

1823 K (lower *x*-axis) and (5) for $MgMoO_4$ at 1573 K (upper *x*-axis).

It can be seen from the figure that a considerable decrease in evaporation rate is observed for $CaMoO_4$ at each temperature (and to a lesser extent in the case of $MgMoO_4$) even after a small decrease in MoO_3 molar fraction. The X-ray studies showed that the calcium molybdate is formed from the oxide mixture in the temperature interval 773–873 K, which precedes the beginning of evaporation of MoO_3. Results of thermogravimetric (TG) studies with mixtures CaO and MgO with MoO_3 as well as the compounds $CaMoO_4$ and $MgMoO_4$ confirm the above results. In the vapor phase, MoO_3 is known to exist as a mixture of clusters like $(MoO_3)_2$, $(MoO_3)_3$, etc.

It was found, after TGA experiments with $CaMoO_4$ at 1573 and 1673 K were performed, that the substance remained solid and had a faint yellow color probably due to the partial evaporation of MoO_3 from the top of the layer. The sample was found, after the experiment at 1723 K, to have partially melted. In the case of the experiments at 1733, 1773 and 1823 °K, the formation of liquid phase seems to be complete. Hence, line 1 in the above Fig.10.46 should correspond to the evaporation from solid phase, while line 2 is for partially melted powder. These observations are in accordance with the results that reported that pure $CaMoO_4$ has melting point 1719 ± 5 K. Ca_3MoO_6 forms an eutectic with $CaMoO_4$ (60% of molar fraction of CaO with a melting temperature 1598 K). However, Ca_3MoO_6 is unstable below 1543 K and decomposes into CaO and $CaMoO_4$ which would result in only solid products on cooling. Considerable shrinkage and sintering were reported as a result of Ca_3MoO_6 formation from the solid mixture of CaO and MoO_3 above 1543 K. Even these are in accordance with the present results in the case of $CaMoO_4$ samples after treatment at 1573 and 1673 °K. It was found that MoO_3 can be stabilized by mixing with CaO, MgO or $CaCO_3$ and heating the mixtures as the result of appropriate molybdates formation. The formation of $CaMoO_4$ from the mixtures of MoO_3 with CaO or $CaCO_3$ starts after 773 K (as confirmed by high-temperature XRD studies) and is completed around 973 K. The structure of calcium molybdate was also studied by means of synchrotron-based high-resolution powder diffraction methods in the temperature range 12–300 K. The scheelite structure type was confirmed for $CaMoO_4$ in the temperature region investigated and no structural anomalies were observed.

A related compound, di-calcium molybdate, Ca_3MoO_6, can be formed at high temperatures. However, it is not stable below 1543 K and decomposes into $CaMoO_4$:

$$Ca_3MoO_6 \Rightarrow CaMoO_4 + CaO$$

The phase change is reversible. The reported transition appeared to be a ferroelastic second-order transformation producing a structure that is a monoclinic distortion of the low-pressure phase and was previously observed in compounds isostructural to $CaMoO_4$.

Single-crystalline thin films of $CaMoO_3$ and $SrMoO_3$ with a Mo^{4+} state perovskite structure have been epitaxially grown by pulsed-laser deposition from Mo^{6+} state ceramic targets. Phase-pure films were obtained on nearly lattice-matched perovskite substrates using argon gas flow during the deposition. Transport properties of the films are consistent with those of paramagnetic and metallic phases, whereas the residual resistivities are far lower than those reported previously for films and bulk polycrystals. These results indicate that this growth method can be useful for exploring the interfaces and junction properties of 4d and 5d transition metal oxides that are unstable in a conventional oxidative atmosphere.

The compound, **calcium molybdite**, $CaMoO_3$, has been prepared as a polycrystalline perovskite by soft-chemistry procedures, followed by controlled annealing under reducing conditions (H_2/N_2 flow). The crystal structure, studied from neutron powder diffraction data, can be described in an orthorhombic unit cell, space group *Pbnm* (No. 62). The lattice parameters were $a = 5.4510(1)$ Å, $b = 5.5821(1)$ Å and $c = 7.7803(2)$ Å. In the perovskite network, the MoO_6 octahedra are tilted by 13.5° in order to optimize the Ca–O bond lengths; the tilting scheme corresponds to a $GdFeO_3$-like superstructure. It has the form as shown in Fig. 10.47.

The perovskite is fully oxygen stoichiometric, as demonstrated from the refinement of the oxygen occupancy factors. Resistivity and transport measurements indicated that $CaMoO_3$ behaves as a metal; at low temperatures (5 K) a small positive magnetoresistance is observed, reaching a maximum value of

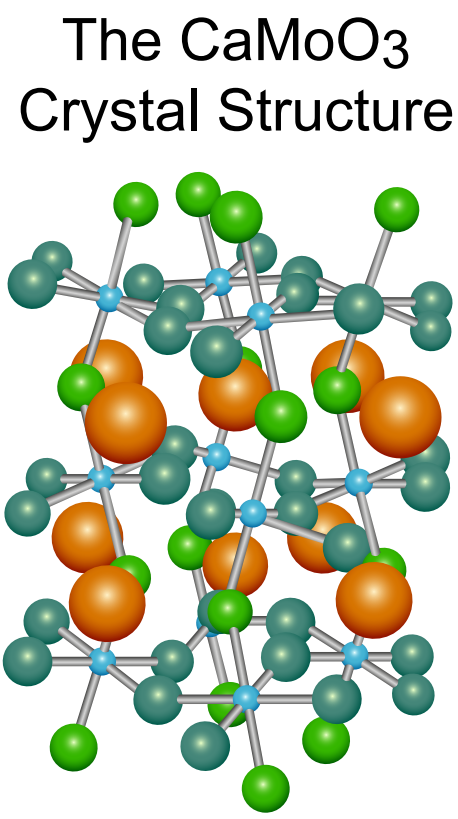

FIGURE 10.47

1.4% at 9 T. The magnetic susceptibility is predominantly Pauli paramagnetic-like, although a non-negligible temperature-dependent component due to isolated Mo^{4+} spins is patent at low temperatures. $CaMoO_3$ is an orthorhombic perovskite (*Pbnm*) where the MoO_6 octahedra are tilted by 13.5°. It was shown that:

(a) It is a Pauli paramagnet
(b) At low temperatures (5 K), it presents a small positive magnetoresistance

Reactions of $CaMoO_4$ and $CaMoO_3$ with ammonia were investigated at temperatures of $873\ K < T < 1123\ K$ with the particular intention to synthesize novel oxynitride perovskites of the general composition $AMo(O,N)_3$ and to study their crystal structure. $CaMo(O,N)_3$ and $BaMo(O,N)_3$ were prepared by thermal ammonolysis of the corresponding $CaMoO_3$ and $BaMoO_3$ precursors at $T = 898$ and 998 K, respectively. The structural parameters of the oxynitrides were obtained from Rietveld refinements of XRD and neutron powder diffraction data. $CaMo(O,N)_3$ crystallizes in the $GdFeO_3$ distorted perovskite structure with orthorhombic space group *Pbnm* and $a = 5.5029(1)$ Å, $b = 5.5546(1)$ Å, $c = 7.8248(1)$ Å as determined by XPRD. Its O/N content refined from the neutron diffraction data corresponds to the composition $CaMoO_{1.7(1)}N_{1.3(1)}$. $BaMo(O,N)_3$ crystallizes in the cubic perovskite structure with space group $Pm\bar{3}m$ and $a = 4.0657(1)$ Å as determined by XPRD. TEM reveals a complex microstructure for both $CaMoO_3$ and $CaMoO_{1.7}N_{1.3}$ represented by twin domains of different orientation.

Calcium molybdate, $CaMoO_4$, has the CAS number 7789-82-4. It is available commercially in tonnage lots.

10.3.4. Strontium Molybdenum Compounds

Strontium oxide forms a limited number compounds with the molybdenum oxides. The systems, SrO–MoO and Sro–Mo_2O_3 do not form any stable compounds.

In the system, SrO–MoO_2, single crystals of a highly conductive oxide $SrMoO_3$ have been grown by a floating-zone method under argon atmosphere with ultralow oxygen partial pressure $p(O_2) \sim 10^{-25}$ atm. The obtained single crystals of $SrMoO_3$ reveal quite low resistivity at 300 K $\rho(300\ K) = 5.1\ \mu\Omega\,cm$, which is the lowest to date in the values of $\rho(300\ K)$ of all the oxides. Resistivity and specific heat data suggest that electrons in $SrMoO_3$ behave as the Fermi liquid (correlated electron), and that its low resistivity is due to the extremely small electron–phonon interaction in $SrMoO_3$.

In another publication (2010) highly conductive $SrMoO_3$ thin films with a smooth surface were grown on $SrTiO_3$ substrates by pulsed-laser deposition. The substrate temperature ranged from 560 °C to 640 °C. Oxygen pressure below 10^{-3} Pa is necessary to obtain high-quality $SrMoO_3$ thin film. The film shows metal-like conducting behavior with low electrical resistivity on the order of 10 μΩ cm between 10 K and room temperature. The smooth surface, good conductivity and optical transparency in ultraviolet region suggest that $SrMoO_3$thin film can be used as a new electrode material and a favorable candidate in a variety of oxide device applications.

The compound, strontium molybdite, $SrMoO_3$, has the general structure as shown in Fig. 10.48.

An RF magnetron reactive sputtering method was used to prepare a $SrMoO_3$ thin film on a silica glass substrate so as to evaluate its optical properties. The reflectivity of the blue-colored film showed a cutoff due to plasmon at ~1.7 eV. From a Kramers–Kronig analysis of the reflectivity, the spectral dependence of dielectric constants and optical constants was obtained. They agreed in tendency with the constants determined by spectroscopic ellipsometry. The plasma frequency due to free carriers (4.5 eV) was obtained by application of a Drude model to reflectivity values, which showed that the effective mass of the

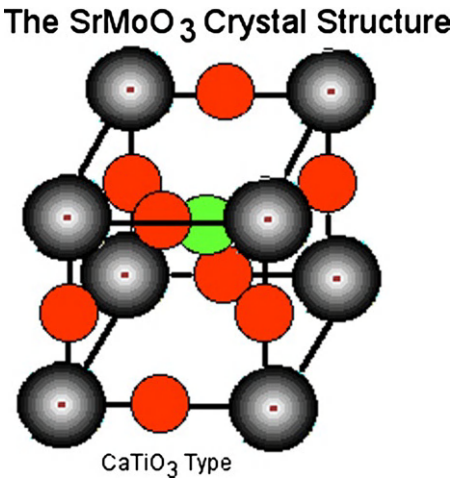

FIGURE 10.48

conduction carrier was $m^+ = 2.1m_0$, where m_0 is the free electron mass.

The structure of a polycrystalline sample of $SrMoO_3$ has been investigated using powder neutron diffraction from 5 to 300 K, to reveal two structural phase transitions, the first from the cubic structure with $a = 3.97629(3)$ Å to a tetragonal structure in *I4/mcm* near 266 K and the second to an orthorhombic *Imma* phase below 125 K. The average Mo–O distance is essentially independent of temperature. The temperature dependence of the octahedral tilting appears typical of a tri-critical phase transition (Fig. 10.49).

Variable temperature neutron diffraction measurements of $SrMoO_3$ from 5 K to room temperature show the presence of two-phase transitions associated with tilting of the octahedra. On cooling, the structure transforms from cubic to tetragonal (*I4/mcm*) and ultimately orthorhombic (*Imma*).

In addition, the enthalpy increment values ($HT^\circ\Delta H^\circ_{298.15\,K}$) of the compounds $SrMoO_3$(solid) and $BaMoO_3$(solid) were measured in the temperature range 426.2 to 1010.8 K (±0.1 K) and 477.8 to 1010.8 K (±0.1 K), respectively, using a high-temperature Calvet calorimeter. The data were least-square fitted with respect to temperature and are given by the following polynomials:

$$\underline{SrMoO_3(solid)}$$

$$\Delta H^\circ_{298.15\,K}\,(J/mol) = -29291 + 91.942\,T(K) + 0.0264\,T^2(K)$$

$$\underline{BaMoO_3(solid)}$$

$$\Delta H^\circ_{298.15\,K}\,(J/mol) = -31427 + 97.977\,T(K) + 0.0275\,T^2(K)$$

Heat capacities of the compounds calculated from the above equations were compared with estimated heat capacity values obtained by Neumann Kopp's rule. Standard entropy ($S_m^\circ(298.15\,K)$), standard enthalpy of formation ($\Delta_f H^\circ(298.15\,K)$) and free energy functions of the compounds were calculated using heat capacities obtained from present experiments, Gibbs free energy of formation of the compounds reported in the literature and elemental thermodynamic data.

In another work, it was determined that $SrMoO_4$ reduced to $SrMoO_3$ at ~800 °C in $4\%H_2/Ar$ and $SrMoO_3$ was found to oxidize to $SrMoO_4$ around 450 °C in air. After performing several redox cycles at 800 °C, no secondary phases were detected with XRD. Secondary phases were also not detected for SMO–YSZ composites sintered up to 1200 °C indicating good chemical compatibility. At 800 °C, the bulk conductivity of $SrMoO_4$ was of order 10^{-3} S/cm. Upon reduction to $SrMoO_3$ the bulk conductivity increased six orders of magnitude to ~103 S/cm. For the infiltrated SMO–YSZ composites, SMO appeared to reach the percolation threshold at loadings between 9% and 14%. An SMO loading of 20% resulted in a conductivity of 20 S/cm, which exceeds the electron conductivity requirement of SOFC anodes.

The system, $SrO–MoO_3$, when heated to elevated temperatures, forms two compounds, $SrMoO_4$ and Sr_3MoO_6. Structure factors for these known compounds are shown in Table 10.31.

Note that Sr_3MoO_6 is dimorphic. The phase diagram for the hexavalent compounds in the system, $SrO–MoO_3$ is shown in Fig. 10.50. The phase diagram of $SrO–MoO_2$ is not known.

Compound formation and compatibility relations have been studied for a portion of the system Sr···Mo···O at 1200 °C. The following binary compounds were prepared: $SrMoO_4$ with the tetragonal scheelite structure, $SrMoO_3$ with the cubic perovskite structure and Sr_3MoO_6. This last compound gave x-ray

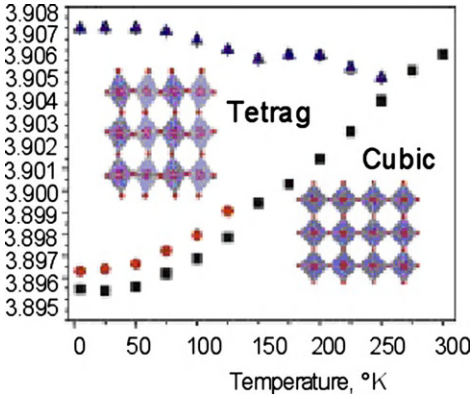

FIGURE 10.49

TABLE 10.31

powder data which could be indexed on a cubic unit cell with $a_0 = 16{\cdot}39(1)$ Å. It appeared to have a structure related to that of $(NH_4)_3FeF_6$. X-ray powder data have been determined for $SrMoO_3$ and Sr_3MoO_6. A previously reported fourth compound, Sr_2MoO_4, could not be prepared at 1000, 1200 or 1400 °C. The stable phase assemblage at its bulk composition was (Sr_3MoO_6 + Mo).

However, in later studies, this compound has been evaluated based upon its superconducting properties. In systematic study of polycrystalline Sr_2MoO_4 as an electronic analogue to the spin-triplet superconductor Sr_2RuO_4, the Pauli paramagnetic susceptibility and metallic behaviors of specific heat and electrical resistivity have been observed. The relevant structure has the form shown in Fig. 10.51.

The density of states at the Fermi level $D(E_F)$ deduced from the results is about three times smaller than that of Sr_2RuO_4. Any indication of superconductivity intrinsic to Sr_2MoO_4 has not been observed down to 25 mK, which may correspond to the smaller $D(E_F)$ used to discuss the origin of the difference in electronic states between Sr_2MoO_4 and Sr_2RuO_4.

The crystal structure of $SrMoO_4$ has the form shown in Fig. 10.52.

$SrMoO_4$ was studied under compression up to 25 GPa by angle-dispersive XRD. A phase transition was observed from the scheelite-structured ambient phase to a monoclinic fergusonite phase at 12.2 GPa that had cell parameters $a = 5.265$ Å, $b = 11.191$ Å, $c = 5.195$ Å, and $\beta = 90.9°$, $Z = 4$ at 13.1 GPa. There was no significant volume collapse at the phase transition. No additional phase transitions were observed and on release of pressure the initial phase was recovered, implying that the observed structural modifications are reversible. The reported transition appeared to be a ferroelastic second-order transformation producing a structure that is a monoclinic distortion of the low-pressure phase and was previously observed in compounds isostructural to $SrMoO_4$. The two types of structures are shown in Fig. 10.53.

This figure shows: (a) the scheelite structure of $SrMoO_4$ at 0.5 GPa and (b) the fergusonite structure of $SrMoO_4$ at 24 GPa. Large blue circles represent the Sr atoms, middle-size blue circles the Mo atoms and small black circles the O atoms. The unit cell, Sr–O bonds, and

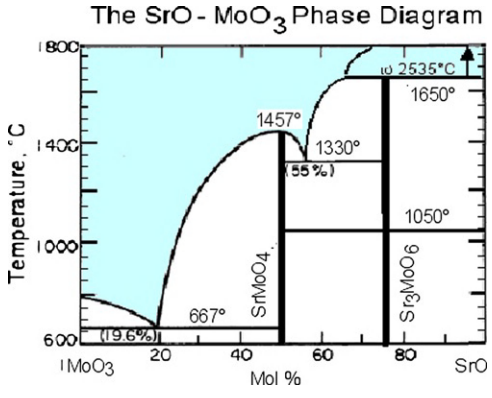

FIGURE 10.50

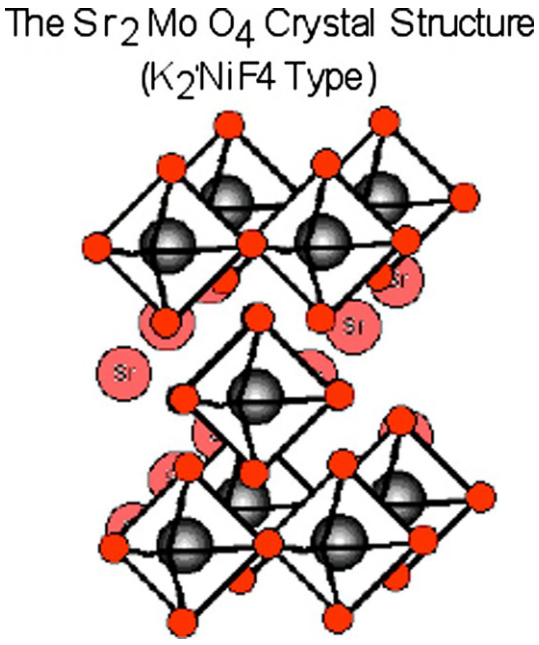

FIGURE 10.51

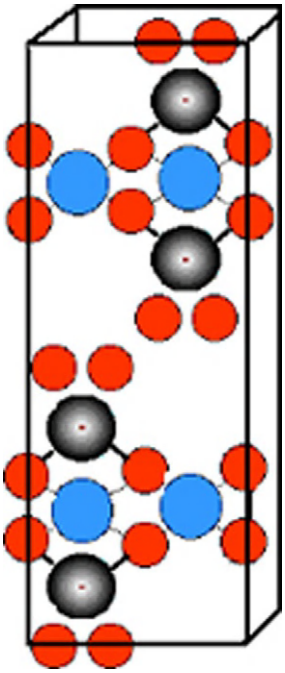

FIGURE 10.52

Mo–O bonds are also shown. In (b), it is illustrated that at high pressure the Mo coordination changes from 4 to 6 with two short bonds (gray), two middle-size bonds (red), and two large bonds (black).

A possible mechanism for the transition has been proposed and its character was discussed in terms of the present data and the Landau theory. Finally, the EOS was reported and the anisotropic compressibility of the studied crystal was discussed in terms of the compression of the Sr–O and Mo–O bonds.

High-temperature mass-spectrometric analysis was used to study the sublimation of $SrMoO_4$(s) at 1570–1800 K. SrMoO ≠ (g) molecules are found to be present in the vapor. The vapor pressure of the SrMoO ≠ (g) molecule was determined to be $\log p = -19980/T + 7.99$. The heat of sublimation ΔH^0_s, $(SrMoO_4(s)) = 480 \pm 40$ kJ/mol was determined using the third law of thermodynamics. The atomization energy of the $SrMoO_4$(g) molecules is calculated to be ΔH^0_{at}, $(SrMoO_4(g)) = 2860 \pm 40$ kJ/mol.

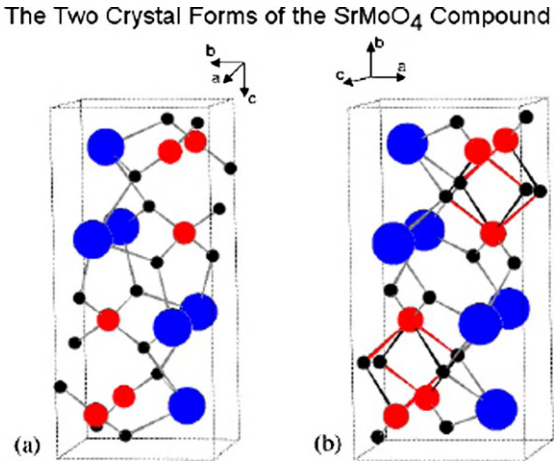

FIGURE 10.53

A fluorescent material for white light emitting diodes (LEDs) involving Eu^{3+} activated molybdate $SrMoO_4$ as a phosphor was fabricated by a solid-state method. XRD showed that the doping of trivalent europium ion reduced the lattice parameters. The excitation and emission spectra indicated that this phosphor could be excited effectively by visible light which then emitted red light with the peaks located at 616 and 624 nm. The influence of Eu^{3+} concentration on the luminescent properties of Eu^{3+} doped $SrMoO_4$ was investigated and the formulation, $(Sr_{0.75}Eu^{3+}_{0.25})$, i.e. 25% mole fraction, was found to be the appropriate molar concentration. The reaction time and temperature had an obvious effect on the luminescent properties. The luminescent intensity reached the strongest when it was sintered at 800 °C for 3 h.

The elemental and phase compositions during the solid-state synthesis of the promising solid oxide fuel cell (SOFC) anode material, Sr_2MgMoO_6, was investigated. It was demonstrated that molybdenum does not notably evaporate under the normal synthesis conditions with temperatures up to 1200 °C due to the formation of $SrMoO_4$ as an intermediate product that occurs at low temperatures, i.e. below 600 °C. However, partial decomposition of the Sr_2MgMoO_6 phase becomes evident at higher temperatures (1500 °C). The effect of $SrMoO_4$ on the electrical conductivity of Sr_2MgMoO_6 was evaluated by preparing a series of Sr_2MgMoO_6 samples with different amounts of additional $SrMoO_4$. Under the reducing operation conditions of an SOFC anode the insulating $SrMoO_4$ phase is apparently reduced to the highly conductive $SrMoO_3$ phase. Percolation takes place with 20–30 wt% of $SrMoO_4$ in an Sr_2MgMoO_6 matrix, with a notable increase in electrical conductivity after reduction. Conductivity values of 14, 60 and 160 S/cm are determined at 800 °C in 5% H_2/Ar for the Sr_2MgMoO_6 samples with 30, 40 and 50 wt% of added $SrMoO_4$, respectively.

For many years, there had been debates over the existence of the compound Sr_2MoO_4 until Lindblom demonstrated that it crystallizes in a K_2NiF_4 type of structure. However, what was actually obtained was a mixture of Sr_2MoO_4 and SrO, and the latter had to be washed away with methanol. Recently, interest in Sr_2MoO_4 has emerged in solid-state physics with the discovery of unconventional superconductivity in

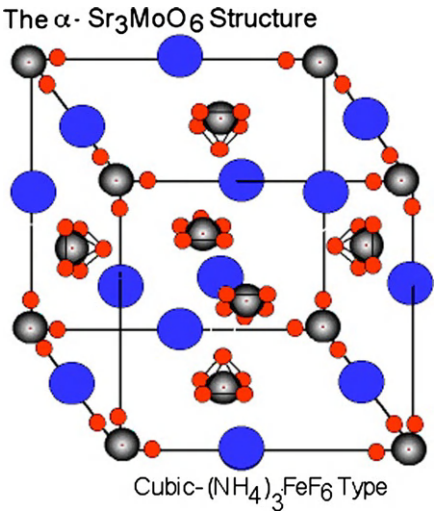

FIGURE 10.54

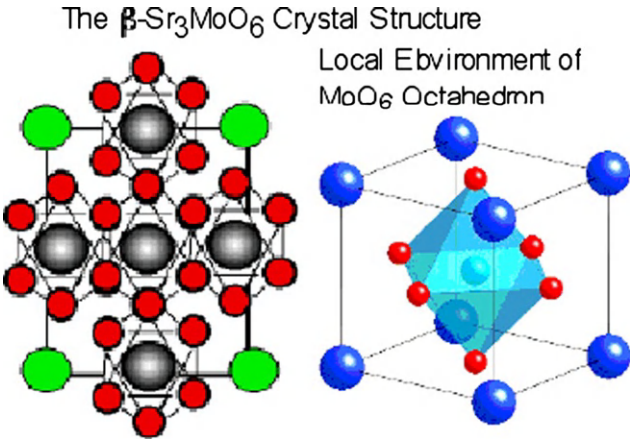

FIGURE 10.55

Sr_2RuO_4. This compound, Sr_2MoO_4, can be prepared using Ti_2O_3 as a catalyst for the reaction:

$$Sr_3MoO_6 + Ti_2O_3 \Rightarrow Sr_2MoO_4 + TiO_2$$

The reaction was first carried out at 840 °C under a flowing Ar atmosphere. The sealed tube was kept at 1150 °C for 1 week. Prior to this, Sr_3MoO_6 had been prepared according to the reaction:

$$3SrCO_3 + MoO_3 \Rightarrow Sr_3MoO_6 + 3CO_2(gas)$$

The mixture of $SrCO_3$ (99.99%) and MoO_3 (99.99%) was heated in flowing Ar atmosphere at 1000 °C for 24 h with two intermittent grindings. This compound is stable in air but if heated to 400 °C, it reverts to the $SrMoO_4$ structure. The layered compound Sr_2VO_4 is an antiferromagnetic insulator with $S = 1/2$, while the isostructural Sr_2MoO_4 is a Pauli paramagnetic metal.

The compound, **tristrontium molybdate**, Sr_3MoO_6, is unstable and melts incongruently. Sr_3MoO_6 was melted in Ar atmosphere under an ultralow oxygen partial pressure (ULOPP) of $p(O_2) = 10'–20'$ Pa by a lamp-image furnace at 1830–1900 K. Sr_3MoO_6 melted in Ar atmosphere was yellow, whereas Sr_3MoO_6 melted under ULOPP changed from yellow to metallic ash-gray luster. XPES analysis showed that the Sr in Sr_3MoO_6 was strongly reduced chemically to a metallic state and that the binding energy of Mo was shifted to the high-energy side. Its structure is shown in Fig. 10.54.

Cell parameters are: $a = b = c = 5.8266$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 139.87$ Å^3, $Z = 2$. Cell occupancy is shown in Table 10.32.

The other polymorphic form of Sr_3MoO_6 has the $GdFeO_3$ structure, as shown in Figure 10.55. The heat of formation, $\Delta fG^o_m(Sr_3MoO_6,solid,T)$, has been obtained by measuring equilibrium pressures of CO_2(gas) over the ternary mixture $SrMoO_4$(solid) + $SrCO_3$(solid) + Sr_3MoO_6(solid) in the temperature range 1040–1215 K, using a static manometric method (Fig. 10.55).

The heat of formation, $\Delta_f G^o_m(Sr_3MoO_6,solid,T)$, has been obtained by measuring equilibrium pressures of CO_2(gas) over the ternary mixture $SrMoO_4$(solid) + $SrCO_3$(solid) + Sr_3MoO_6(solid) in the temperature range 1040–1215 K, using a static manometric method. It was found to be given by the equation:

$$\Delta_f G^0_m(Sr_3MoO_6, solid, T)\ (kJ/mol) \pm 0.6 = -2837.9 + 0.6036\,T(K)$$

Using the heat capacity values of Sr(s,1), Mo(solid) and O_2(gas) from the literature, Sr_3MoO_6(solid) from

this work and the variation of $\Delta_f G^{o}_{m}(T)$ with temperature, the value of $\Delta_f H^{0}_{m}$ (at 298.15 K) was calculated as $-(2821.2 \pm 3.0)$ kJ/mol.

A related compound, $Sr_3Mo_2O_7$ has been found. $Sr_3Mo_2O_7$ is a member of the Ruddlesden–Popper type series of $Sr_{n+1}Mo_nO_{3n+1}$ with $n = 2$, a so-called double layered perovskite. This compound has been successfully synthesized to obtain polycrystalline samples of single-phase $Sr_3Mo_2O_7$ with the aid of Ti_2O_3 as $p(O_2)$ buffer. The phase-pure samples allowed us to perform measurements of the electrical resistivity and the magnetic susceptibility on $Sr_3Mo_2O_7$ for the first time. The resistivity revealed that $Sr_3Mo_2O_7$ is a metallic conductor from 300 K to 30 mK. The Pauli-paramagnetic behavior is observed in the susceptibility. This means that $Sr_{n+1}Mo_nO_{3n+1}$ compositions for $n = 1$, 2, and ∞ all show the Pauli-paramagnetic metal behavior, in contrast to $Sr_{n+1}Ru_nO_{3n+1}$ which involves an electronic analogue series.

The compound, strontium penta-molybdate, $SrMo_5O_8$, is a composition and structure unique among the alkaline earth molybdates. It contains Mo^{4+} ions arranged as $Mo_{10}O_{18}$ units so that the average valence is 3.6^{+}. There are 2 units per unit cell, one of which is shared by neighboring cells. The overall structure has the form shown in Fig. 10.56.

Unit cell parameters are: $a = 7.553$ Å, $b = 9.1556$ Å, $c = 9.966$ Å, $\alpha = \gamma = 90°$, $\beta = 109.301°$, cell volume = 650.44 Å^3, $Z = 3$. Cell occupancy is shown in Table 10.33.

This compound is isostructural with $LaMo_5O_8$ and contains bi-octahedral $Mo_{10}O_{18}$ cluster units, strongly linked by Mo···Mo intercluster bonds to form infinite molybdenum oxide chains. Each unit has the form shown in Fig. 10.57.

These chains are interconnected through Mo···O···Mo bonds to create four-sided channels in which the Sr^{2+} ions are located. Each Sr^{2+} cation is surrounded by 10 O atoms at distances ranging from 2.529–2.835 Å with the 11th O atom at 3.219 Å in the SrO_{11} cluster in the structure.

Strontium molybdate is available commercially with the CAS number of 13470-04-7. Both $SrMoO_4$ and Sr_3MoO_6 are offered for sale.

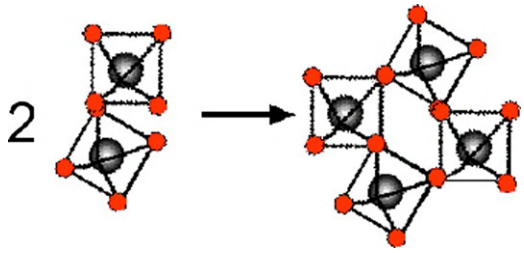

FIGURE 10.58

10.3.5. Barium Molybdates

Barium forms a number of compounds with molydenum oxides. The Mo^{3+}, Mo^{4+} and Mo^{6+} valance states are the most common.

In the BaO–MoO system, no compounds like Ba_2MoO_3 or Ba_3MoO_4 have been reported.

In the BaO–Mo_2O_3 system, the compound $BaMo_2O_4(C_2O_4)_2{\cdot}5H_2O$ was synthesized by the aqueous reaction of $H_2C_2O_4$ and $(NH_4)_2[MoOCl_5]$. This substance contains the binuclear anion, $[Mo_2O_4(C_2O_4)_2(H_2O)_2]^{2-}$ with two octahedrally-coordinated Mo atoms. The octahedra are canted in the middle of the central Mo_2O_2-rings which are formed from the union of two octahedra shown in Fig. 10.58.

However, this compound is not stable and the requisite $BaMo_2O_4$ compound has never been reported. In this Mo^{3+}-containing system, a novel ternary molybdenum oxide, $BaMo_6O_{10}$, was discovered and its crystal structure was determined from single-crystal XRD data. $BaMo_6O_{10}$ crystallizes in the orthorhombic space group *Pnma* with $a = 10.154$ Å, $b = 8.641$ Å, $c = 9.184$ Å, $V = 805.7$ Å^3, $Z = 4$, $R = 0.0438$, $R_w = 0.0401$ for 652 independent reflections with $I > 3.0\sigma(I)$. The structure contains infinite zigzag molybdenum oxide chains built up from M_6O_{12}-type clusters, cross-linked to form channels where Ba^{2+} cations reside. Bond distance analysis results indicate that $BaMo_6O_{10}$ is perfectly bonded with all valence electrons of the Mo atoms in either Mo···Mo or Mo···O bonding states.

In the BaO–MoO_2 system, a ternary oxide, $BaMoO_3$ (Scholder and Brixner, 1955) characterizes this system shown in Fig. 10.59.

$BaMoO_3$ has the $CaTiO_3$ cubic structure (space group *Pm3m*) with $a = 4.0404$ Å.

A polycrystalline sample of perovskite type barium molybdate, $BaMoO_3$, was prepared by a reduction of $BaMoO_4$ under 4% H_2–Ar atmosphere at 1523 K. The thermoelectric properties, viz. the electrical resistivity, Seebeck coefficient, and thermal conductivity of $BaMoO_3$ have been evaluated from room temperature to about 1000 K. The electrical resistivity of $BaMoO_3$ is slightly lower than that of state-of-the-art thermoelectric materials, and has a positive temperature dependence. The Seebeck coefficient of $BaMoO_3$ is negative in the whole temperature range. The thermal conductivity of $BaMoO_3$ at room temperature equals 30 W/m/K, which is very high compared with that of state-of-the-art thermoelectric

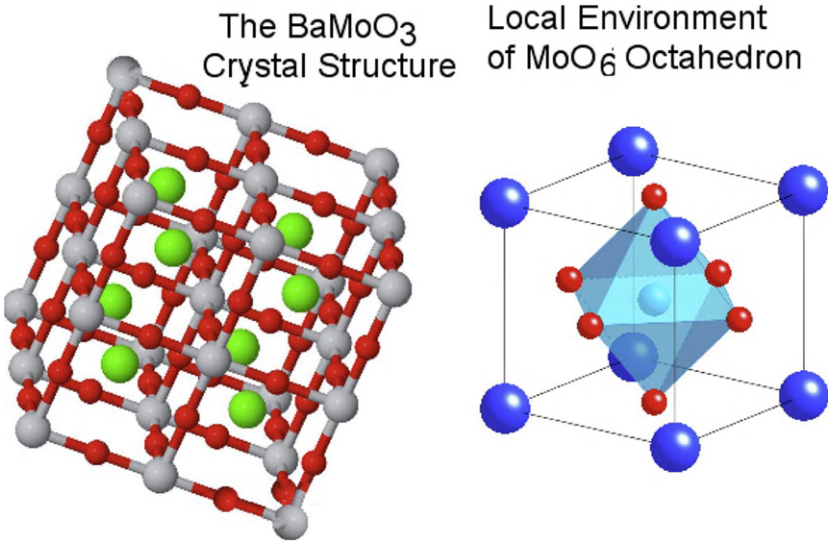

FIGURE 10.59

materials. The maximum value of the thermoelectric figure of merit ZT is 0.015 at around 470 K.

The thermal stability of $BaMoO_3$(solid) was determined by differential thermal analysis (DTA) (solid) and TG methods. A slight gain in weight in the TG curve was attributed to the oxidation of $BaMoO_3$(solid) to $BaMoO_4$(solid) in analytical reagent grade argon at 1050 K. However, the DTA curve did not show any exothermic or endothermic peaks. This confirms the absence of any solid-state phase change in $BaMoO_3$(solid) below 1050 K. It was found by DTA measurements under flowing argon and helium atmospheres that $BaMoO_3$(solid) decomposes at 1653 K into $BaMoO_4$(solid), Mo(solid), and BaO(gas). Mass spectrometric studies reported that barium molybdate salts mainly evaporate as molecular $BaMoO_4$(gas) and $BaMoO_3$(gas). This work identified ternary gaseous oxides, $BaMoO_3$(gas), from the mass spectra of vapor effusing from a molybdenum Knudsen cell containing $BaMoO_4$(solid) and MoO_3(l) at $T > 1900$ K. $BaMoO_3$(gas) was predicted to form as a result of the reaction:

$$BaMoO_4(gas) + MoO_2\ (gas) \Rightarrow BaMoO_3\ (gas) + MoO_3\ (gas)$$

Because the molecular species in this reaction were present in the vapor phase in concentrations of the same order. The enthalpy of formation for the reaction:

$$2BaMoO_3 + O_2 \Rightarrow 2BaMoO_4$$

was measured by oxygen bomb calorimetry, and the Gibbs energy change of the reaction was reported as: $\Delta H_f = -1228$ kcal/mol ($T = 1480$–1580 K).

Perovskite-type oxides, $BaMoO_3$ and $SrMoO_3$, were prepared by reduction of scheelite-type oxides, $BaMoO_4$ and $SrMoO_4$, in H_2 flow at 873 K and characterized by XRD, TG, SEM, TPR, NH_3-TPD, UV–Vis DRS and BET measurement. The catalytic activity of these alkaline earth molybdenum oxide catalysts was tested for oxidation of 2-propanol with gaseous oxygen under atmospheric pressure. Dehydration to propylene was mainly promoted over the scheelite-type with Mo^{6+} ions, while oxidative dehydrogenation to acetone was mainly promoted over the perovskite type with Mo^{4+} ions, and selectivity to acetone was much higher over $BaMoO_3$ than over $SrMoO_3$. Both perovskite-type oxide catalysts underwent oxidation to some degree during the catalytic reaction, so that they also contained some Mo^{6+}. It was concluded that the high selectivity to acetone resulting from oxidative dehydrogenation during 2-propanol conversion was related to the constantly changing oxidation state of the catalyst, resulting in coexistence of Mo^{6+} octahedra and Mo^{4+} octahedra on the $AMoO_3$ oxides.

This system was said to be characterized by nine ternary oxides. This is the only comprehensive listing of compounds available in the literature:

$BaMoO_3(Mo^{4+})$	$BaMoO_4(Mo^{6+})$
$BaMo_2O_7(Mo^{6+})$	$BaMo_3O_{10}(Mo^{6+})$
$BaMo_4O_{13}(Mo^{4+})$	$Ba_2MoO_5(Mo^{6+})$
$Ba_2Mo_5O_{17}(Mo^{6+})$	$Ba_3MoO_6(Mo^{6+})$
	$Ba_3Mo_7O_{24}(Mo^{6+})$

All but two has the 6+-valence state. Although the structure of many of these compounds is known, a finalized phase diagram has not been published. In Fig. 10.60, presented on the next page, the positions of each of these compounds are shown relative to one another along with known melting temperatures (where known). Only $BaMoO_4$ is known to melt congruently.

The exact melting points need to be established with more certainty. The phase diagram shows how these melting points would probably be arranged, given the melting points of the two components, BaO and MoO_3. Nevertheless, this is a representation of how the melting points of this series of compounds ought to appear, but these melting points shown have not yet been firmly established.

In the BaO–MoO_3 system, the system is characterized by these seven ternary oxides. $BaMoO_4$ has a tetragonal structure (space group $I4_1/a$) with $a = 5.56$ Å, $c = 12.76$ Å. Ba_2MoO_5 has an orthorhombic structure with $a = 7.4097$ Å, $b = 11.3906$ Å, $c = 5.7603$ Å and $\alpha = \beta = 65.04°$ and $\gamma = 50.67°$. Lattice parameters of the other barium molybdates have not yet been published in the open literature.

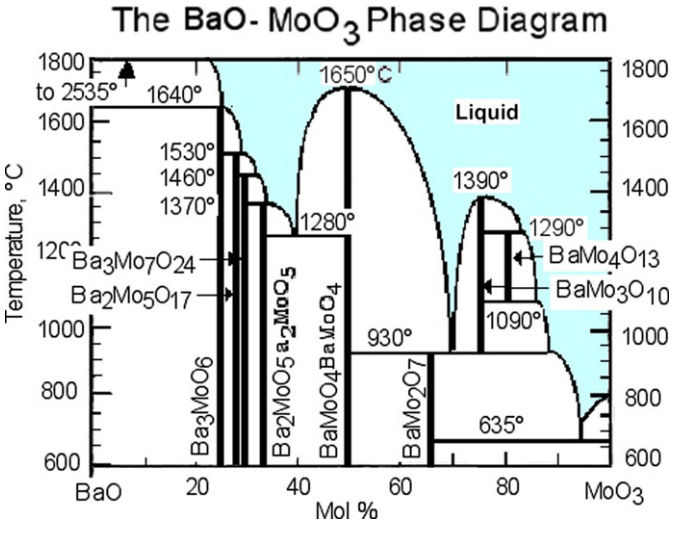

FIGURE 10.60

The structure factors (where known) are shown in Table 10.34.

The structure of barium ortho-molybdate, $BaMoO_4$, has the same structure as the $SrMoO_4$ composition, as shown in Fig. 10.61.

Cell parameters are: $a = b = 5.581$ Å, $c = 7.526$ Å, $\alpha = \beta = 111.76°$, $c = 90°$, cell volume = 199.60 Å^3, $Z = 2$. Cell occupancy is shown in Table 10.35.

Another view of the scheelite-like $BaMoO_4$ structure is shown in Fig. 10.62.

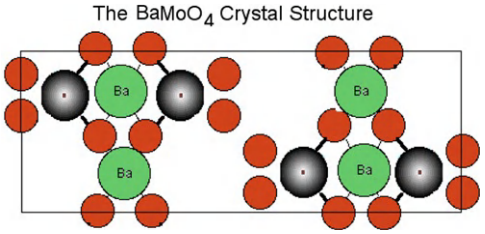

FIGURE 10.61

Scheelite-structured alkaline earth molybdates are technologically important materials as these are used as scintillators, laser host materials or cryogenic detectors for dark matter. These tungstates are also being considered for Raman lasers. $BaMoO_4$ can assume two structures, tetragonal distorted scheelite (b) and cubic (a), depending on the temperature applied during their synthesis. $BaMoO_4$ with a scheelite structure is an important material that has a high application potential in various fields. Recently, crystal structures based on the scheelite type have attracted much interest because of their applications as a scintillating medium and in other electro-optical devices (i.e. solid-state laser and optical fibers). In these scheelite-structured compounds (space group $I41/a$, $Z = 4$), oxygen atoms form a distorted simple cubic arrangement, while the two cations in this structure have fourfold and eightfold coordination with the oxygen atoms. XRD and Raman scattering studies on the scheelite structured barium molybdate show that, at ~5.8 GPa, it undergoes a first-order phase transition to the fergusonite structure ($I2/a$, $Z = 4$)—as also observed in iso-structural barium tungstate. At still higher pressures, barium molybdate transforms to another phase between ~7.2–9.5 GPa. On release of pressure from 15.8 GPa, the initial phase is recovered implying that the observed structural modifications are reversible. The form of the two phases is shown in the diagram as follows. $BaMoO_4$ undergoes structural transformations similar to its strontium homologue as shown in Fig. 10.63.

In the $BaCO_3 \cdot MoO_3$ system with an excess of barium carbonate, $BaMoO_4$ is the stable reaction product up to 1073 K. Above 1073 K, Ba_2MoO_5 and Ba_3MoO_6 can be formed. $BaMo_2O_7$ was formed with an excess of MoO_3. Ustinov et al. (1970) and Yanushkevich and Zhukovskii (1972) gave a partial phase diagram of this system. $BaMoO_4$(s) melts congruently at 1737 K. The compound, $BaMo_2O_7$, melts incongruently at 926 K.

SOFCs have attracted great attention in electrochemical devices because of their high-energy conversion efficiency, little pollution and widely flexible fuel choices. Scheelite type based oxide ion conducting materials like $PbWO_4$, $BaMoO_4$, $SrMoO_4$ possess more ion conductivity and can also be used as an electrolyte for intermediate temperature SOFC (ITSOFC) applications. The development of nanocrystalline Dy^{3+} doped $BaMoO_4$ was pursued in order to increase the ionic conductivity for ITSOFC applications. Nanocrystalline dysprosium doped $BaMoO_4$ samples were prepared by an acrylamide-assisted combustion process. All the samples were characterized by TG/DTA, XRD, FTIR and SEM-EDX techniques and studied concerning their grain and grain boundary conductivities through impedance measurements. XRD patterns of the Dy^{3+} doped $BaMoO_4$ samples and the formation of the crystalline $BaMoO_4$ phase and some mixed phases were

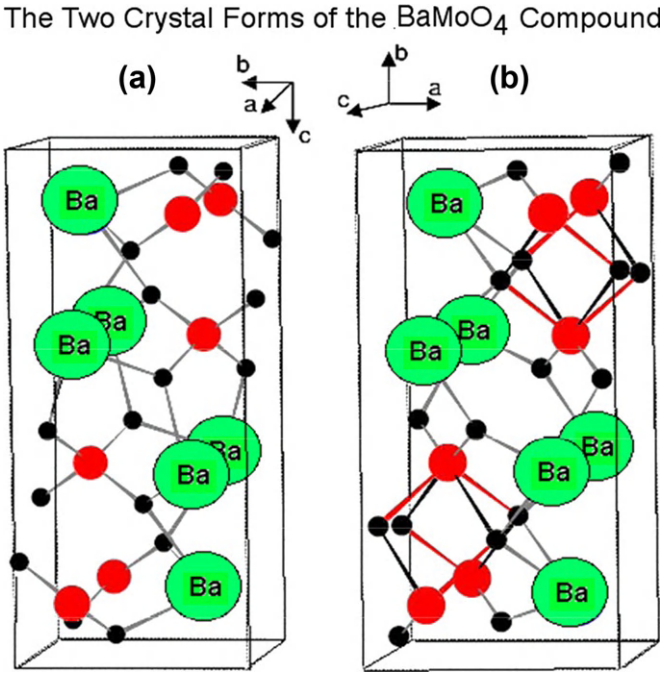

FIGURE 10.63

confirmed by comparing the ICDD data with the observed XRD peaks. The crystallite size was calculated using Scherrer's formula for all the compositions of compounds and found to be less than 100 nm. FTIR spectra results confirm the formation of the MoO_3 structure in Dy^{3+} doped $BaMoO_4$ samples. SEM image of a particular composition of Dy^{3+} doped $BaMoO_4$ sample (BDM4) showed agglomerated spherical particles.

The formation of barium monomolybdate ($BaMoO_4$) in equimolar powder mixtures of $BaCO_3$ and MoO_3 was examined under isothermal and nonisothermal conditions upon heating in air at 25–1200 °C, using thermogravimetry. Concurrence of the observed mass loss (due to the release of CO_2) to the occurrence of the formation reaction was evident. Accordingly, the extent of reaction (x) was determined as a function of time (t) or temperature (T). The x–t and x–T data thus obtained were processed using a well-established mathematical apparatus and methods to characterize the nature of the reaction rate-determining step and derive isothermal and nonisothermal kinetic parameters (rate constant, frequency factor, reaction order, and activation energy). Moreover, the reaction mixture quenched at various temperatures (450–575 °C) in the reaction course was

analyzed by various spectroscopic (X-ray diffractometry, infrared spectroscopy, and laser RS) and microscopic (SEM and XED) techniques for material characterization. The results obtained indicated that the reaction rate may be controlled by unidirectional diffusion of MoO_3 species through the product layer ($BaMoO_4$), which was implied to form on the barium carbonate particles. The nonisothermally determined activation energy (156 kJ/mol) was found to be close to the isothermally determined one (164–166 kJ/mol).

The compound, **barium di-molybdate**, $BaMo_2O_7$, has not been studied intensively. The complex Ba $[Mo_2O_5(C_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (BMO) was prepared and characterized by chemical analysis and IR spectral studies. TG and DTA techniques were used to study the thermal decomposition. The dehydration of BMO takes place in two steps between 115 and 230 °C, two moles of water being lost in each step. The decomposition of anhydrous BMO occurs between 230 and 360 °C in three steps. The first two steps occur in the temperature ranges 230–255 and 255–295 °C to give intermediates having the tentative compositions Ba $[Mo_2O_5(C_2O_4)(CO_3)]$ and $BaMo_2O_7\cdot CO_2$, respectively, the latter then decomposes between 295 and 360 °C to give the end product. The end product consists of $BaMoO_4$, $BaMo_2O_7$ and some other phase which could not be identified.

$\Delta_f G^\circ(BaMo_2O_7,s,T)$ has been determined for barium di-molybdate using the e.m.f. technique. The cell used was:

$$(-)Pt/(BaMo_2O_7(solid) + BaMoO_4(solid) + MoO_2(solid))\ //CSZ//air(p(O_2(gas) = 21.21\,kPa)/Pt(+)).$$

The observed e.m.f.s in the temperature range 828–985 °K could be represented by $E = 0.7663–4.953 \times 10^{-4}T$ *V*. The standard molar Gibbs energy of formation of $BaMo_2O_7$(solid) was evaluated from e.m.f. values and the $\Delta_f G^\circ(T)$ of $BaMoO_4$(solid) and MoO_2(solid). The corresponding expression is given as $\Delta_f G^\circ(BaMo_2O_7,solid,T) = -2269.7 + 0.6173T$ kJ/mol. Using the required literature values, the $\Delta_f H^\circ(BaMo_2O_7,solid,\ 298.15\,K)$ was calculated by the second law method and the corresponding value was found to be −2291.2 kJ/mol. The structure has not been documented but is presumably like that of $SrMo_2O_7$. This is illustrated in Fig. 10.64.

Two types of tetrahedra are shown in the structure. This compound melts incongruently at 655 °C to form $BaMoO_4$ and BaO:

$$BaMo_2O_7 \Rightarrow BaMoO_4 + BaO + O_2$$

Barium di-molybdate has not received much attention in the scientific literature and even less consideration in industry.

The compound, **barium tri-molybdate**, $BaMo_3O_{10}$, is not used in Industry. In Academia, its structure has been elucidated. The crystal structure of $BaMo_3O_{10}$ has been determined from X-ray and neutron powder diffraction data using no prior structural information. Direct methods and combined X-ray and neutron Rietveld refinements were used to solve the structure. There are two Ba, six Mo and 20 O atoms in the asymmetric unit. The crystal symmetry is monoclinic (space group $P2_1$; $Z = 4$), and the unit cell parameters are $a = 14.695$ Å, $b = 7.5704$ Å, $c = 6.9618$ Å, and $\beta = 100.381°$. In a combined Rietveld refinement with 124 variables, the *RF*-values 0.034 and 0.046 were obtained for neutron time-of-flight and X-ray data, respectively, although small oscillations in some parameters could not be avoided in the final refinement cycles. The structure, shown on the next page, is built of layers of $[Mo_3O_{10}^{2-}]$ linked to each other with barium ions. The Mo–O framework contains distorted MoO_6 octahedra interlinked by corner- and edge-sharing as shown in Fig. 10.65.

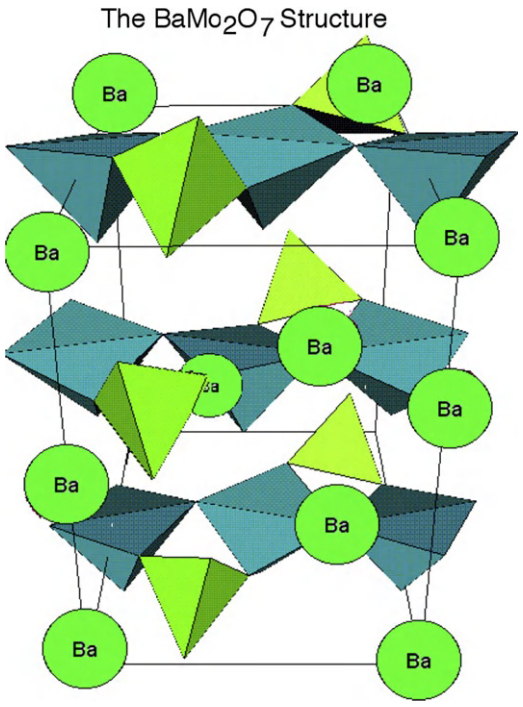

FIGURE 10.64

The compound, **barium tetra-molybdate**, $BaMo_4O_{13}$, has also been prepared hydrothermally as a hydrate. The hydrothermal synthesis, X-ray single-crystal structure, and some properties of the new-layered $BaMo_4O_{13}\cdot 2H_2O$ were described. (Crystal data: $BaMo_4O_{13}\cdot 2H_2O$, $M_\tau = 765.11$, orthorhombic, space group *Pbna* (No. 60), $a = 7.680$ (2) Å, $b = 15.756$ (3) Å, $c = 19.689$ (3) Å, $V = 2382.5$ Å^3, $Z = 8$, $R(F) = 4.00\%$ $R_w(F) = 4.39\%$ [3059 reflections with $I > 3\sigma(I)$]) (Fig. 10.66).

$BaMo_4O_{13}$ $2H_2O$ is the first well-characterized barium molybdate hydrate to be reported, and contains three

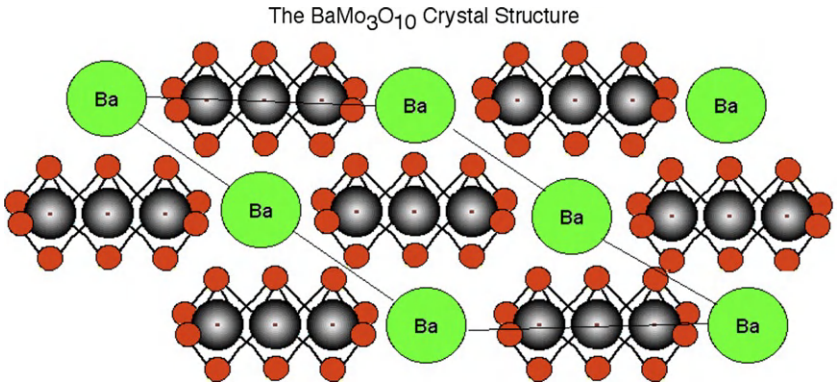

FIGURE 10.65

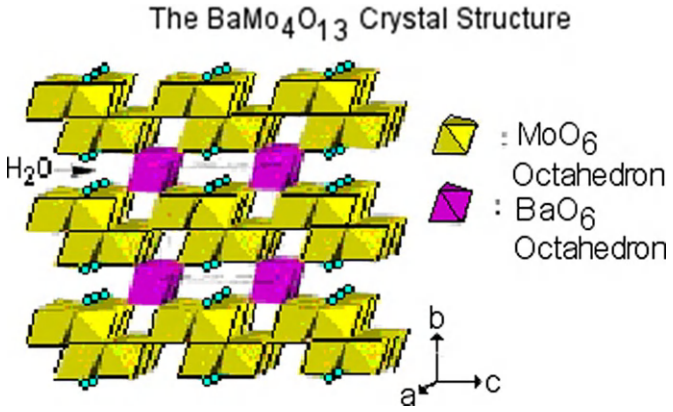

FIGURE 10.66

distinct MoO_6 units and an unusual, distorted, MoO_5 group in its layer structure. The nine-coordinate Ba^{2+} cations and water molecules provide the interlayer packing between the $[Mo_4O_{13}]^{2-}$ sheets. $SrMo_4O_{13}$ $2H_2O$ has also been prepared, and is isostructural with $BaMo_4O_{13}$ $2H_2O$, on the basis of powder X-ray, TGA, and IR data. $BaMo_4O_{13}2H_2O$ is built up from layers of edge- and vertex-sharing MoO_6 and MoO_5 groups. Inter-layer Ba^{2+} cations and water molecules complete the structure. Except for structure, little information has been published concerning this compound. It remains under current investigation as to its catalytic and electrical properties.

The compound, **dibarium molybdate**, Ba_2MoO_5, also has not been studied intensively. Its crystal parameters are: $a = 5.769$ Å, $b = 7.412$ Å, $c = 11.382$ Å, $\alpha = \beta = 65.04°$, $\gamma = 50.67°$, cell volume $= 486.61$ Å^3, $Z = 4$. The structure has the orthorhombic form as shown in Fig. 10.67.

The compound, tribarium molybdate, Ba_3MoO_6, has the structure as shown in Fig. 10.68.

This structure is characterized by MoO_6 groups that are close-packed in the cubic structure and are shared equally by neighboring unit cells. Cell parameters are: $a = b = c = 6.0811$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 159.01$ Å^3, $Z = 4$. Cell occupancy is shown in Table 10.36.

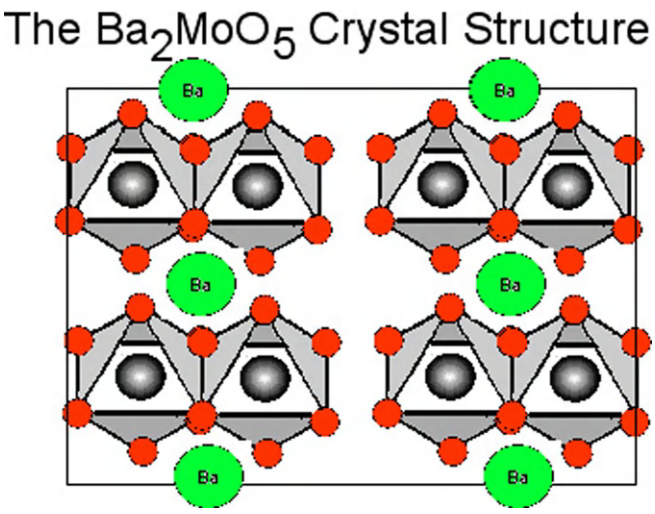

FIGURE 10.67

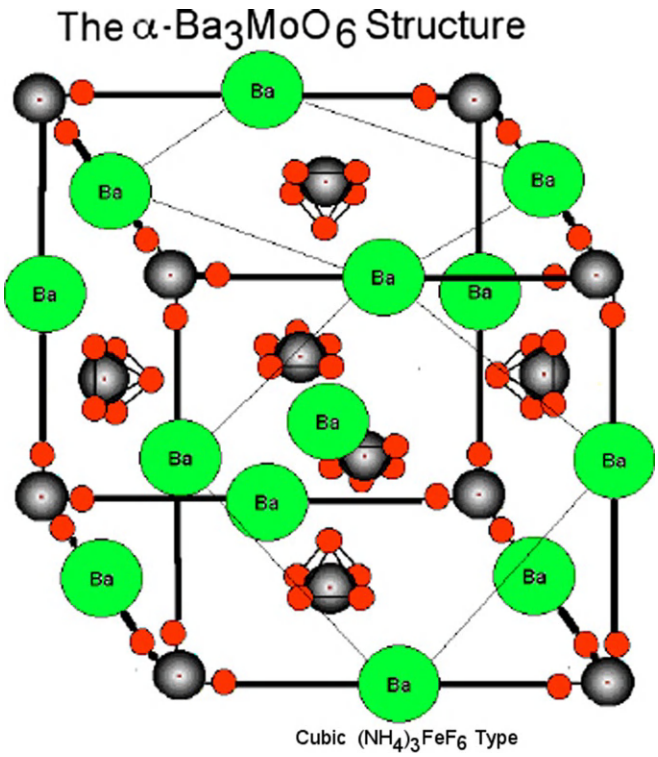

FIGURE 10.68

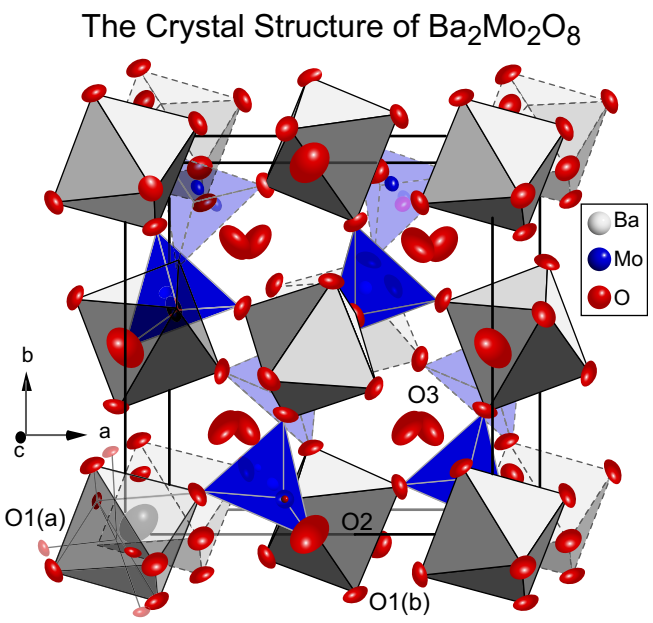

FIGURE 10.69

Neither of these compounds is considered stable at ambient conditions but have been prepared and measured at elevated temperatures.

Little is known concerning the compound, δ-barium di-molybdate, $Ba_2Mo_2O_8$, except for its structure as shown in Fig. 10.69.

Although dibarium penta-molybdate, $Ba_2Mo_5O_{17}$, has been described as a valid component within the family of barium molybdates, only one reference (Dash et al., 2000) lists this compound. No structural data are available nor has there been any description of its physical or chemical properties available in the current literature.

The same may be said concerning the compound, $Ba_3Mo_7O_{24}$. It is significant that reference to this compound (3:7:24) appears in the early literature (~1890–1910) but not in the current scientific sources.

Barium molybdate is offered commercially as $BaMoO_4$-CAS # 7787-37-3 and as Ba_3MoO_6-CAS # 13470-04-7.

10.3.6. Radium Molybdenum Compounds

Radium does not form any compounds with molybdenum or molybdenum oxides,

10.4. ALKALINE EARTH—TUNGSTEN COMPOUNDS

The tungsten-oxide system is mainly composed of three oxides, W_2O_3-tungsten trioxide (W^{3+}), WO_2-tungsten dioxide (W^{4+}), and WO_3-tungsten trioxide (W^{6+}), wherein the valence state of tungsten is indicated. In combination with the alkaline earths, the compounds, $AeWO_3$ and $AeWO_4$ have been termed as "tungstates" and "ortho-tungstates". Although the ammonium ion (NH_4^+) and the alkalis form "polytungstates", the alkaline earths do not.

Some examples of polytungstate ions that have been detected in the solution and/or solid state include:

polymeric $W_2O_7^{2-}$ ions

$[W_7O_{24}]^{6-}$ (paratungstate A)

Phase relations in the systems, alkaline earth oxide-orthotungstate (AeO–WO_3), and their stability with metallic tungsten have been investigated by the quenching technique using sealed capsules.

These tungsten oxides and polytungstates form several different types of compounds with the alkaline earths.

In the system BeO–WO_2, no intermediate compounds have been described. Binary mixtures resulted in a eutectic at 1185 °C and 37 mol% BeO.

In the system MgO–WO_3, the 1:1 compound was stable and melted congruently at 1358 °C. There are two crystalline modifications of this compound. The well-known wolframite-type form is stable below 1165 °C. Two eutectics were found: 1120 °C and 28.5 mol% MgO and 1318 °C and 55.0 mol% MgO. In the systems CaO–WO_3, SrO–WO_3, and BaO–WO_3, two binary compounds are stable. The 1:1 compounds with the scheelite-type structure melt, respectively, at 1580, 1535, and 1475 °C, and form eutectics with WO_3 at 1135, 1073, and 935 °C, all with a eutectic composition near 75 mol% WO_3. The 3:1 compounds, having the distorted $(NH_4)_3FeF_6$-type structure, melt at 2250, 2225, and 1795 °C. The eutectics between these two compounds are at 1490 °C and 56.5 mol% CaO, 1410 °C and 57.0 mol% SrO, and 1320 °C and 58.2 mol% BaO. Phase transformations to an ideal $(NH_4)_3FeF_6$-type structure in Sr_3WO_6 and Ba_3WO_6, were observed at 1100 ° and 805 °C, respectively, by application of both high-temperature XRD and DTA. At 1700 °C, metallic tungsten exists in equilibrium with liquid, the alkaline earth oxides, $W_{18}O_{49}$, the 3:1 ternary oxides, and with combinations thereof.

The structural inorganic chemistry of tungsten oxide closely mirrors that of molybdenum oxide. Many orthotungstate compounds possessing isolated WO_4 sites are known. Alkaline earth tungstates rarely form polymeric WO_4 compounds, but one such exception is MgW_2O_7 that consists of a pair of sharing WO_4 units. An isolated WO_5 coordinated site has been determined to be present in the $Ca_3(WO_5)Cl_2$ compound. Isolated WO_6 coordinated units are present in the Wolframite structure.

10.4.1. Beryllium Tungsten Compounds

BeO does not form any compounds with WO_2 or WO_3. However, it does form intermetallic compounds in the Be^0–W^0 system. This system is shown in Fig. 10.70.

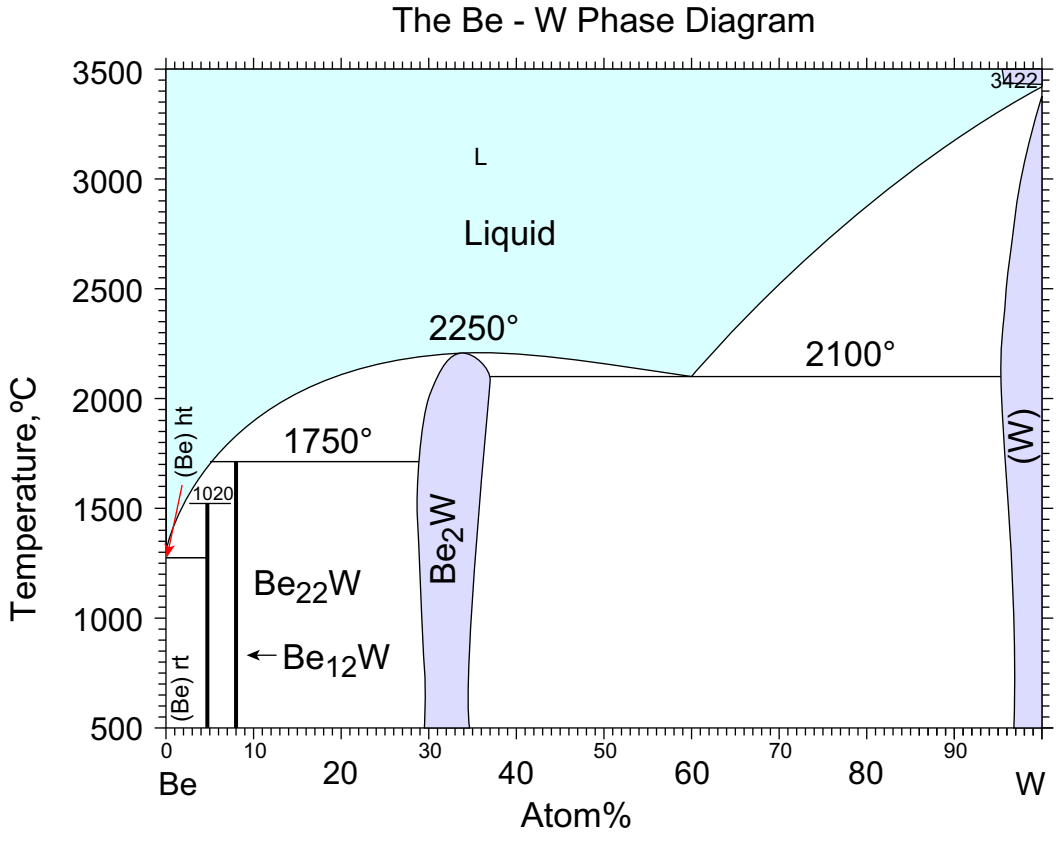

FIGURE 10.70

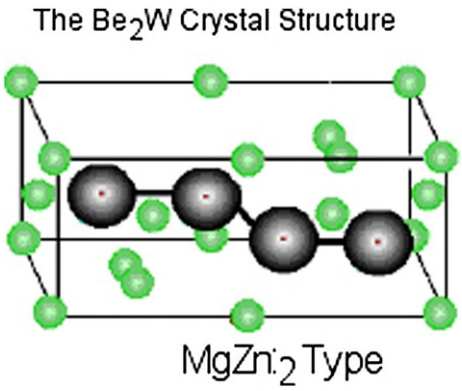

FIGURE 10.71

Only three compounds are known, two of which are modifications of the Be^0 crystal structure.

The structure factors are shown in Table 10.37.

The compound, Be_2W, has the structure shown in Fig. 10.71.

Cell parameters are: $a = b = 4.558$ Å, $c = 7.333$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 131.99$ Å^3, $Z = 4$. Cell occupancy is shown in Table 10.38.

The planned application of both metals beryllium and tungsten together as first wall materials of the next step fusion device "ITER" is based on the foreseen advantageous properties of these metals for the respective locations in the plasma vessel. ITER is an international project to design and build an experimental fusion reactor based on the "Tokamak" concept. Erosion, transport, and re-deposition of both materials during operation will lead to transport of elements onto surfaces of different materials. Due to kinetic energy of impinging particles and elevated wall temperatures, alloys and compounds consisting of the present elements will be formed. These "mixed materials" exhibit strongly altered physical and chemical properties compared to the intended properties of the pure elements which were originally installed.

Of all binary systems considered in previous studies, beryllium–tungsten received least attention although Be–W alloys bear the potential of drastically reduced melting temperatures compared to pure W. For the formation of a binary Be–W alloy, two possible scenarios can be envisaged in a fusion device: deposition of tungsten on beryllium surface or vice versa. The intermetallic Be–W system was investigated by analyzing both a W film on polycrystalline Be and the inverse system, Be films on polycrystalline W. The films were annealed up to 1070 K and the alloy formation was investigated by a combination of Rutherford backscattering spectroscopy (RBS) and XPES. For the structure analysis and identification of the formed alloys, XRD measurements were used. In the case of W films on Be, $Be_{12}W$ was identified within the diffusion depth (as expected), whereas Be films on W showed alloy formation restricted to the film–substrate interface. Both XPS and XRD measurements indicate the formation of Be_2W.

The compound, $Be_{12}Mo$, has the structure shown in Fig. 10.72.

Cell occupancy is:

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	Be(j)	Be	8	j	m2m.	0.291	1/2	0	1.0
2	Be(i)	Be	8	i	m2m.	0.351	0	0	1.0
3	Be(f)	Be	8	f	..2/m	1/4	1/4	1/4	1.0
4	Mo	Mo	2	a	4/mmm	0	0	0	1.0

This structure consists of two (2) sub-units: a body-centered lattice of W-atoms and six (6) hexagonal units of Be (Be_6) arranged on the faces of the tetragonal lattice. The unit cell parameters are: $a = b = 5.6163$ Å, $c = 4.216$ Å, $\alpha = \beta = 67.955°$, $\gamma = 81.901°$, $Z = 2$, cell volume $= 114.31$ Å^3.

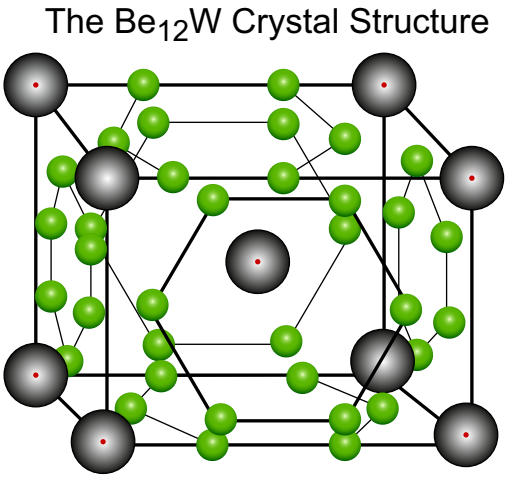

FIGURE 10.72

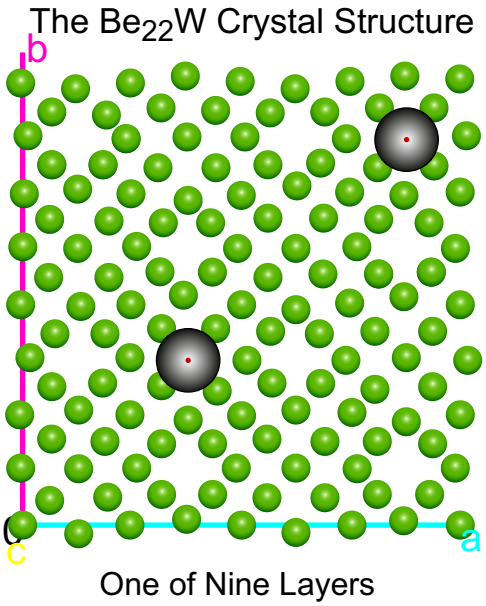

FIGURE 10.73

An intermetallic compound, $Be_{22}Mo$, is also known. It has the structure as shown in Fig. 10.73.

Unit cell parameters are: $a = b = c = 8.2244$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 393.37$ Å^3, $Z = 8$. Cell occupancy is shown in Table 10.39.

No other intermetallic compounds have been discovered to date. None of these compounds have found usage in industry at this date (2011).

10.4.2. Magnesium Tungsten Compounds

The system Mg^0–W^0 does not form any intermetallic compounds.

In the divalent WO system, no compounds like Mg_2WO_3 or Mg_3WO_4 have been reported.

In the trivalent system, MgO–W_2O_3, no compounds containing W^{3+} have been reported.

In the W^{4+} system of MgO–WO_2, the expected perovskite formula of $MgWO_3$ has not been reported.

Only one compound, $MgWO_4$, is known to be stable in the MgO–WO_3 system. The phase diagram has the form shown in Fig. 10.74.

The compound, magnesium mono-tungstate, $MgWO_4$, has been stated to be dimorphic. A powder with XRD patterns almost identical with those of the high-temperature phase of $MgWO_4$, reported to exist only above 1065 °C, has been prepared in the temperature range of 200 °C, either by dehydration of $MgWO_4 \cdot H_2O$ or hydrothermally. The unit cell has

TABLE 10.38

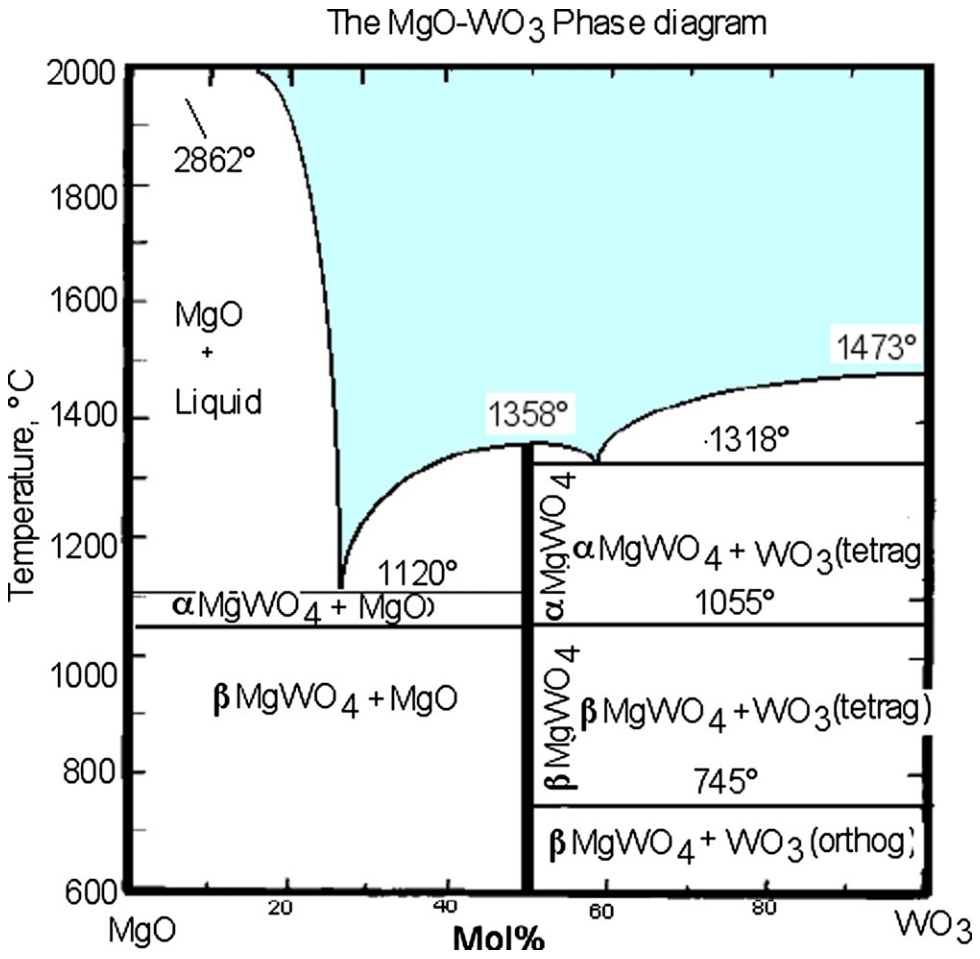

FIGURE 10.74

been determined to be triclinic, with $a = 5.60$ Å, $b = 5.58$ Å, $c = 8.84$ Å, $\alpha = 123.2°$, $\beta = 112.7°$, $\gamma = 101.4°$, $Z = 4$.

By means of results from X-ray powder and selected area ED, infrared spectroscopy and luminescence, and of arguments based on the topotactic nature of the dehydration reaction, as well as on structural relations of "HT"-$MgWO_4$ with both $MgWO_4 \cdot H_2O$ and the wolframite type monoclinic $MgWO_4$, a model for the crystal structure of "HT"-$MgWo_4$ has been derived. The crystal structure models have the form shown in Fig. 10.75. These two dimorphs exhibit similar aspects to their lattice structure as well as that of the hydrates.

The luminescence of $MgWO_4.2H_2O$ contains two emission bands, one due to the tungstate tetrahedron, and another one related to the hydrate group. The former has been compared with the tungstate luminescence of anhydrous $MgWO_4$.

The excitation-emission properties of the $MgWO_4$:W phosphor are shown in Fig. 10.76.

This phosphor is a "self-activated" composition in which the tungstate group is photo-active and probably involves a "charge-transfer" mechanism where a UV-photon is absorbed by the MgO_4 group and the energy is transported to the emitting group, WO_4. It has long been used in fluorescent lamps but not in any other display devices.

$MgWO_4 \cdot 2H_2O$ crystallizes in the monoclinic space group $P21/c$, $a = 5.917$, $b = 10.243$, $c = 8.566$ Å, $\beta = 90.05°$. Its crystal structure consists of individual layers built up from edge-sharing pairs of $MgO_4(H_2O)_2$ octahedra that are corner-linked with WO_4 tetrahedra. Thermal dehydration leads, in a first topotactic step, to

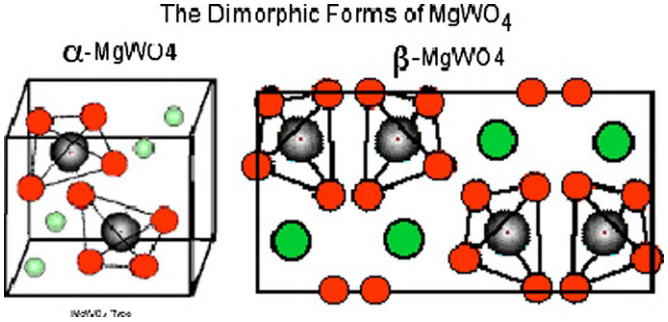

FIGURE 10.75

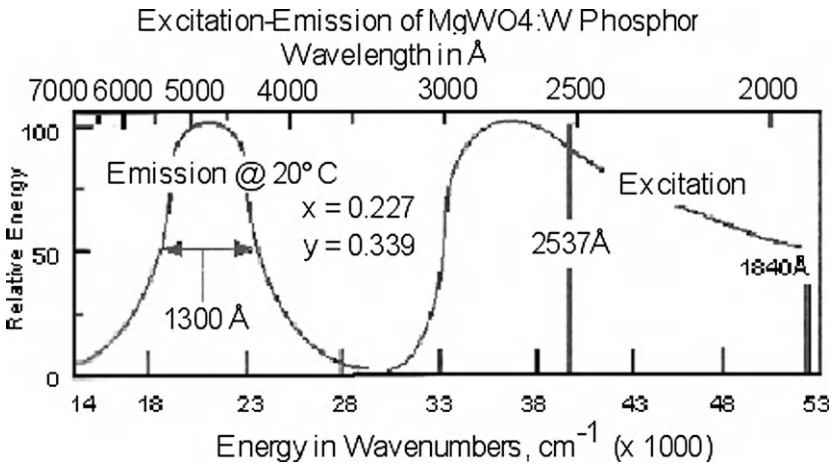

FIGURE 10.76

monoclinic (eventually triclinic) $MgWO_4 \cdot H_2O$, for which a structural model has been deduced, based on its unit cell ($a = 9.246$, $b = 10.773$, $c = 8.564$ Å, $\gamma = 92.43°$) and the relative orientation relations between the two lattices.

It corresponds to an unobserved atomic arrangement, predicted to exist by earlier authors on theoretical grounds. The loss of the remaining water is again topotactic, but leads to a multiple twinned product, which corresponds in its powder diffraction pattern closely to high-temperature $MgWO_4$, reported to exist above 1200 °C only, and is transformed into the stable wolframite structure at 650 °C. These observations are attributed to the topotactic nature of the dehydration process.

The luminescence of $MgWO_4 \cdot 2H_2O$ contains two emission bands, one due to the tungstate tetrahedron, and another one related to the hydrate group. The former is compared with the tungstate luminescence of anhydrous $MgWO_4$.

Magnesium orthotungstate is readily available commercially and has the CAS number of 13573-11-0.

10.4.3. Calcium Tungstates

Like the MgO–W_xO_{x+1} system, CaO does not form many compounds. No intermetallic Ca^0–W^0 compounds are known.

The system, CaO–WO, does not form any compounds nor does the W^{3+} system of CaO–W_2O_3. Compounds like CaW_2O_4, $Ca_2W_2O_5$ and CaW_4O_7 do not exist.

In the CaO–WO_2 system, the wolframite, $CaWO_3$ has not been thoroughly studied. Little work has appeared in the literature concerning this compound. Although, it might appear that $CaWO_3$ should have the perovskite type of lattice, which it does not.

Although the tetra-valent compounds, $Ca_6(WO_3)_5$, $Ca(WO_3)_{10}$, and $Ca_3(WO_3)_{10}$ have been studied in regard to their structure, no papers are available which develop knowledge concerning their physical or electrical properties. For example, $CaWO_3$, in which W^{4+} ions exist, is said to possess the $GdFeO_6$ structure. This is the same as the Sr_3MoO_6 structure where Mo^{6+} ions are present. The structure thus would have the general form, shown as follows. This is typical of perovskite-type compounds as shown in Fig. 10.77.

This may be a form of the so-called "tungsten–bronze" compounds in which the valence of the tungsten atom varies from 4+ to 6+.

However, the compound, $Ca_6(WO_3)_5$, is said to have the $CaTiO_3$ structure as shown in the diagram presented in Fig. 10.78.

These two structures do not seem to be compatible since the latter appears to be a condensation of WO_3^{2-} groups. It is likely that these groups follow the patterns

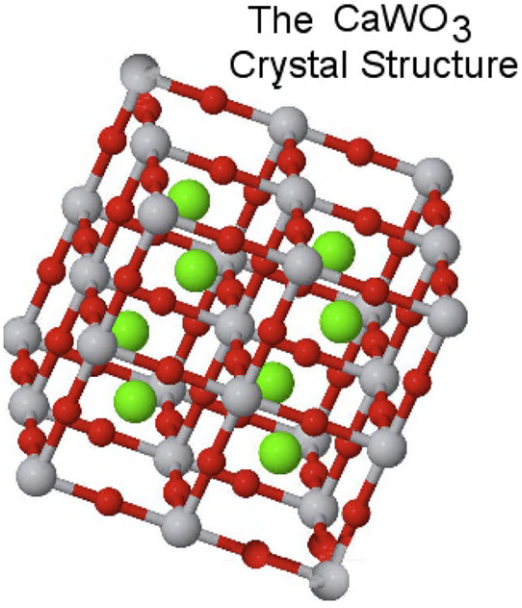

FIGURE 10.77

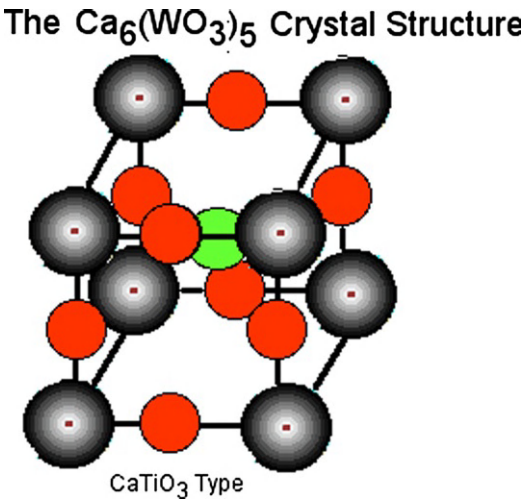

FIGURE 10.78

established by the titanate-group condensations which involve a compound like $Ca_6(WO_3)_5$. If so, then the structures shown for the compounds in the following diagram (Fig. 10.79) would be valid.

This aspect of the chemistry of calcium tungstite compounds needs to be further clarified.

The system, CaO–WO_3, forms two compounds as shown in Fig. 10.80.

Structure factors are shown in Table 10.40.

Alkaline earth tungsten and molybdenum oxides with a scheelite structure have been applied in the past as phosphors, laser hosts and scintillators.

A new field for the application of these materials has emerged a few years ago when a new generation of cryogenic detectors, offering the capability of discrimination between electron and nuclear recoils has been implemented in some particle physics experiments. The increasing interest in using $CaWO_4$ for rare event searches initiated research in the fundamental physical

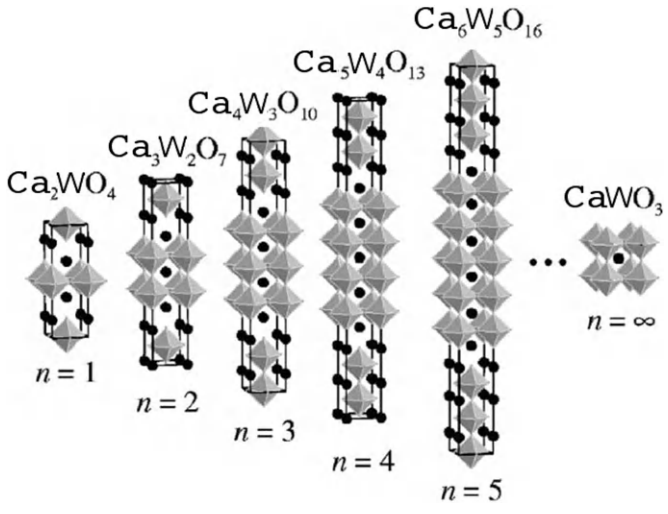

FIGURE 10.79

characteristics of this material over a wide temperature range. The compound, calcium tungstate has the structure shown on the next page. The scheelite structure consists of isolated tetrahedra that form non-touching, one-dimensional (1D) chains. There are two directions that the chains align themselves as shown in Fig. 10.81.

Cell parameters are: $a = b = 5.2444$ Å, $c = 6.7922$ Å, $\alpha = \beta = 112.71°$, $\gamma = 90°$, cell volume $= 156.71$ Å^3, $Z = 9$. Cell occupancy is shown in Table 10.41.

In addition to the scheelite structure, $CaWO_4$ also exhibits a "Fergusonite" structure. $CaWO_4$ is known to have two polymorphs. At high temperatures, it has a tetragonal structure with space group $I41{=}a$ [13] (number 88). This is the so-called the Scheelite structure, referring to the structure of the mineral Scheelite, $CaWO_4$, named in honor of the Swedish chemist, K. W. Scheele (1742–1786). The low-temperature phase is monoclinic with space group C_2/c [5] (number 15). This structure is often called Fergusonite after the Scottish mineral collector Robert Ferguson (1767–1840). The structure may be regarded as a monoclinic distortion of the tetragonal structure. The tetragonal *ct* axis corresponds to the monoclinic *bm* axis. The low temperature phase, β-$CaWO_4$, is sometimes stated to have the $LaNbO_4$ structure which is related to the Fergusonite structure.

The following diagram illustrates these structures (Fig. 10.82).

The (a) scheelite, (b) wolframite, and (c) fergusonite structures of $CaWO_4$ compounds are shown. Large circles represent the A (Ca, Sr) atoms, middle-size circles correspond to the W atoms, and the small circles are the O atoms. The unit cell, A–O bonds and W–O bonds are also shown. As a consequence of the scheelite-to-fergusonite transition two Ca–O and W–O bonds are enlarged; these bonds are showed as dark lines in (c). The CaO_8 and WO_4 polyhedra are also shown. By comparing (a) and (c), the polyhedra distortion caused by the scheelite-to-fergusonite transition is apparent.

(a) Structural site parameters of scheelite $CaWO_4$ at 1.4 GPa: $I41/a$, $Z = 4$, $a = 5.205(5)$ Å, $c = 11.275(7)$ Å (Table 10.42).

(b) Structural site parameters of fergusonite $CaWO_4$ at 11.3 GPa: $I2/a$, $Z = 4$, $a = 5.069$ Å, $b = 10.851$ Å, $c = 5.081$ Å, $b = 90.091$ as shown in Table 10.43.

$CaWO_4$ exhibits a weak luminescence at room temperature but is a very efficient emitter at liquid nitrogen temperatures where it operates as an efficient scintillator. The mechanism of luminescence involves a transition among charge-transfer states since $CaWO_4$ is a direct bandgap insulator. Vibronic coupling of the WO_4^{2-}-center occurs at room temperature but is minimized at LN_2 temperature. The electronic–vibronic

center of the WO_4^{2-} center has been clarified as shown in Fig. 10.83.

This diagram is a schematic representation of the crystal-field splitting and hybridization of the molecular orbitals of a tetrahedral WO_4^{2-} or MoO_4^{2-} ion with "$*$" indicating the anti-bonding (unoccupied) states. The numbers in parentheses indicate the degeneracy—including spin degeneracy—of each cluster state. The ordering of the molecular orbitals in the diagram approximates the partial density of states analyses. The shaded boxes are included to emphasize the fact that the discrete states are broadened by neighboring cluster interactions in the solid material. The relative positions of the Ca-3d states for $CaWO_4$ and $CaMoO_4$ are also indicated in this diagram.

$CaWO_4$ was selected as a detector for particle and electron detection in a WIMP (weakly interacting massive particle) apparatus because of its high light yield at low temperatures and the absence of a noticeable degradation of the light yield for events near the crystal surface. Such degradation, often found in coincident phonon-charge measurements with some scintillators, can cause difficulties as it may lead to a

misidentification of electron/photon surface events as nuclear recoils.

According to another paper, 1D $CaWO_4$ and $CaWO_4$:Tb^{3+} nanowires and nanotubes have been prepared by a combination method of sol–gel process and electro-spinning. A variety of methods were used to characterize the resulting samples. The results of XRD, FT-IR, TG-DTA indicate that the $CaWO_4$ and $CaWO_4$:Tb^{3+} samples begin to crystallize at 500 °C with the scheelite structure. Under ultraviolet excitation and low-voltage electron beams excitation, the $CaWO_4$ samples exhibit a blue emission band with a maximum at 416 nm originating from the WO_4^{2-} groups, while the $CaWO_4$:Tb^{3+} samples show the characteristic emission of Tb^{3+} corresponding to $^5D_4 \Rightarrow {}^7F_{6,5,4,3}$ transitions due to an efficient energy transfer from WO_4^{2-} to Tb^{3+}. The energy transfer process was further studied by the time-resolved emission spectra as well as kinetic decay curves of Tb^{3+} upon excitation into the WO_4^{2-} groups. Furthermore, the photoluminescence (PL) emission color of $CaWO_4$:x mol%Tb^{3+} can be tuned from blue to green by changing the concentrations (x) of the Tb^{3+} ion. These materials may have potential applications as fluorescent lamps and field emission displays (FEDs).

The compound, tricalcium tungstate, Ca_3WO_6, because of its high melting point, has been explored as a high-temperature resistant coating for space vehicles because of its very high melting point of 2250 °C.

Ca_3WO_6 is monoclinic, $a = 5.5430$ Å, $b = 5.806$ Å, $c = 7.9958$ Å, $\gamma = 90.205(3)°$. The space group $P21/n$ was confirmed by the systematic absences due to the n glide plane. The structure is of the double perovskite-type $A_2\acute{B}\acute{B}\acute{O}_6$ where $A = \acute{B} =$ Ca and $\acute{B}' =$ W. It presents a rock salt type B-cation sub-lattice with alternating CaO_6 and WO_6 octahedra. The tilt of the octahedra can be described as (*a*-*b*-*c*-), in accordance with the Glazer (1972) notation.

Cell occupation is shown in Table 10.44.

The structure has the form shown in Fig. 10.84.

The large octahedra are CaO_6 and small octahedra WO_6. The dark spheres represent Ca atoms, light ones are W and the vertices of the octahedra are O. This compound, Ca_3WO_6, is isostructural with Ca_3UO_6 (space group $P2_1$).

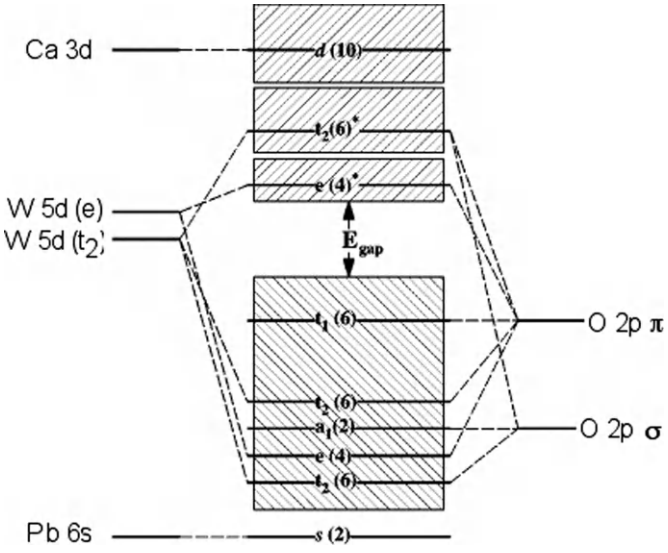

FIGURE 10.83

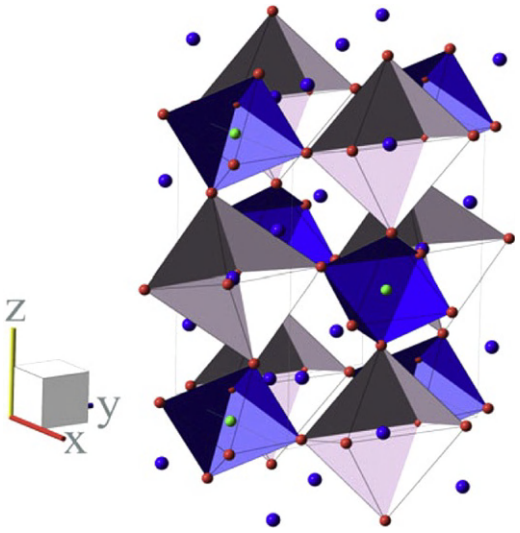

FIGURE 10.84

Thermogravimetry, XRD and SEM methods have been used to study the direct reduction–carburization of $CaWO_4$ with C at 1500 K. The reduction process was studied with solid carbon under an argon atmosphere and under vacuum. CaO, W, WC were the products of the process. Reduction under an atmosphere of CO was then studied and it was found that, compared to argon and vacuum, reduction under CO was very slow and the products were not fully carburized. This led to the conclusion that the first step in the reduction process is a solid–solid reduction reaction with carbon producing tricalcium tungstate (Ca_3WO_6) as an intermediate product. This tricalcium tungstate is then further reduced to W before carburization to WC. The overall rate of the process was found to be controlled by the W–WC stage.

The Ca_3WO_6 ceramic was prepared by solid-state reaction method and was well densified at 1260 °C, or above, for 2 h in air. The sharp Raman vibration mode at 810/cm suggested that long-range order exists in the Ca_3WO_6 structure. The best microwave dielectric properties were obtained in ceramic sample sintered at 1275 °C for 2 h with a permittivity ~15.3, a $Q \times f$ value ~ 29,200 GHz and a TCF value about −30 ppm/°C. Applying the oxide additivity rule, the calculated permittivity agrees well with the measured value. This kind of ceramic may have some potential value for microwave applications in its good microwave dielectric properties.

Calcium tungstate is available as $CaWO_4$ (scheelite) with a CAS number of 7790-75-2.

10.4.4. Strontium Tungsten Compounds

The system Sr^0–W^0 does not form any intermetallic compounds.

In the divalent WO system, no compounds like Sr_2WO_3 or Sr_3WO_4 have been reported.

In the trivalent system, SrO–W_2O_3, the expected compound, SrW_2O_4 has not been reported. There are no other compounds of interest, such as $Sr_2W_2O_5$ or SrW_4O_5, reported as well.

In the W^{4+} system of SrO–WO_2, the cubic perovskite formula of $SrWO_3$ has been reported. The compound, strontium tungstite, $SrWO_3$, has the same structure as the corresponding molybdite as shown in Fig. 10.85.

It is not certain whether these "tungstite or molybdite" compounds follow the trend of the cubic-stacked "perovskite " compounds like the titanates or $CaWO_3$ or whether they follow the "tungsten–bronze" structure motif. The difference is slight with the ratio W:O = 1:3 between perovskite and Sr_2 $(WO_3)_3$ based on the tungsten bronze-type crystal structure with 2×2 perovskite-like unit cells. However, the latter

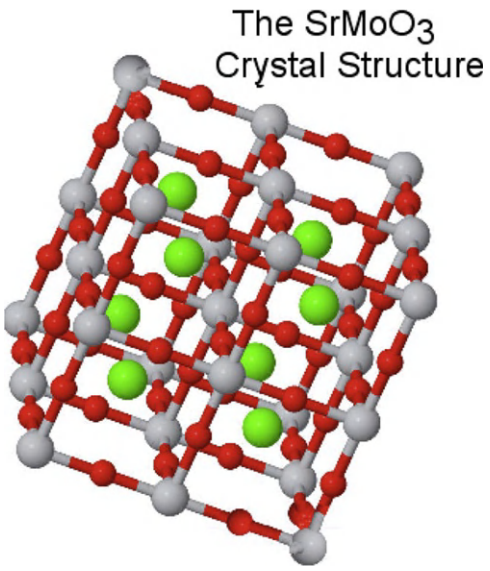

FIGURE 10.85

type of strontium tungstite has not been discovered to date.

The tungsten bronzes are an example of Class II mixed-valence compounds. They have the perovskite AMX_3 crystal structure, with WO_3 forming a supercube lattice, and with various large A cations trapped in the cage-like cavities. The addition of M^{3+} and N^+ ions (NH_4^+ and alkalis) makes an enormous number of tungsten–bronze-based structures possible.

With half of the cavities filled, the tungsten bronze above would have the empirical formula $A_{0.5}WO_3$. The family of tungsten bronzes is very large. Many metallic elements "A" have been inserted into WO_3, although the most widely studied have been the alkali metal tungsten bronzes. In fact, 10 elements are generally considered to form "bronzes": Ti, Zr, V, Nb, Ta, Cr, Mo, W, Re, and U, so the scope of these Class II compounds is very wide.

In contrast to magnetite, the tungsten bronzes can have remarkably high electrical conductivities, which are dependent on the doping level. For example, in the cubic Na_xWO_3 series, when "x" is below 0.3, the compounds are poor semiconductors. The $Na_{0.5}WO_3$ bronze has an ambient electrical conductivity of around 18,000/ohm/cm, and those with higher doping levels of $x > 0.8$ can have conductivities of up to 70,000/ohm/cm, well into the metallic range (Shanks et al., 1963). This arises because the "A" element enters the WO_3 lattice and donates its valence electrons to the tungsten–oxygen p orbitals, creating a π-XO (crystal orbital, metallic bond, conduction band) throughout the W–O lattice. The more "A" element is used to dope the WO_3 lattice, the richer the XO becomes in mobile free electrons and the higher is the compound's electrical

conductivity. The bronzes are all brightly colored solids with a noticeable metallic luster. In Classes I and II the metal cations are separated by anions or other ligands. In Classes IIIA and IIIB, there is direct metal–metal bonding between the cations.

In this system, the hexagonal compound $SrWO_3$, containing W^{4+}, has also been reported. The reaction between SrO(solid) and W(solid) at high temperatures was studied by mass-spectrographic thermal analysis. The vaporization and reactions proceed in three stages. In the first, the gaseous product, Sr(gas), appears above 1285 K:

$$4SrO(solid) + W(solid) \Rightarrow 3Sr(gas) + SrWO_4(solid)$$

In the second stage, vaporization of Sr(gas) is observed above 1580 K from the residual SrO(solid) that was unreacted with W(solid) during the course of the first stage. The third stage overlaps with that of the second stage, producing $SrWO_3$(gas), $SrWO_4$(gas) and a small amount of Sr(gas), all from the vaporization of $SrWO_4$(solid). The reaction is:

$$4SrWO_4(solid) \Rightarrow 2SrWO_3(gas) + SrWO_4(gas) + Sr(gas) + 3O_2(gas)$$

The apparent partial pressure of Sr(gas) and those of $SrWO_4$(gas) and $SrWO_3$(gas) in the third stage was determined from the curve of the mass-spectrometric thermal analysis by a modified integration method and a sensitivity calibration method, respectively. These show that the reactions given above are valid.

The hexagonal compound, $SrWO_3$, can be prepared by the reduction of $SrWO_4$:

$$SrWO_4 + H_2 \Rightarrow SrWO_3 + H_2O$$

The product is stable above 820 °C with $a = 3.842$ Å and $c = 12.623$ Å. However, it is not very stable at room temperature and tends to deoxidize to form the orthotungstate.

$SrWO_3$ has been formed as a thin film on a (100) Si surface. It is amorphous but exhibits intense luminescence under excitation of 433 nm wavelength light.

The emission characteristics are shown in the diagram as follows. Film thickness was of the order of 100–200 μm. This compound could be used in the manufacture of "white-emitting diodes" if its stability during operation can be maintained (Fig. 10.86).

The system, SrO–WO_3 forms two compounds, $SrWO_4$ and Sr_3WO_6. The phase diagram is very similar to the CaO–WO_3 system as shown in Fig. 10.87.

The compound, $SrWO_4$, has the scheelite structure as shown in Fig. 10.88.

It also undergoes structural conformations like the calcium system in which the scheelite ⇔ wolframite ⇔ fergusonite structures are in equilibrium as shown in Fig. 10.89.

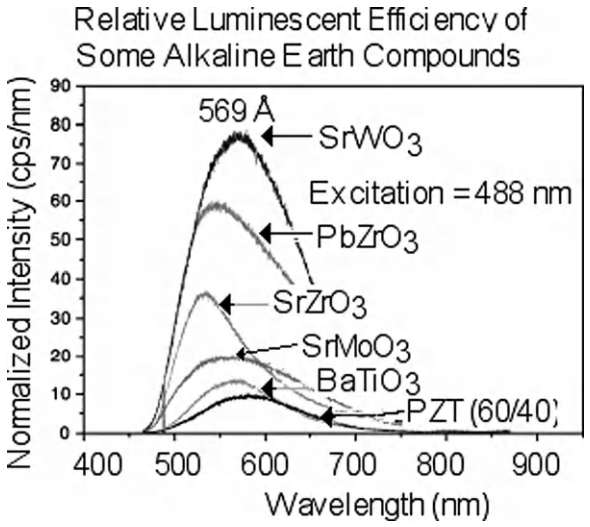

FIGURE 10.86

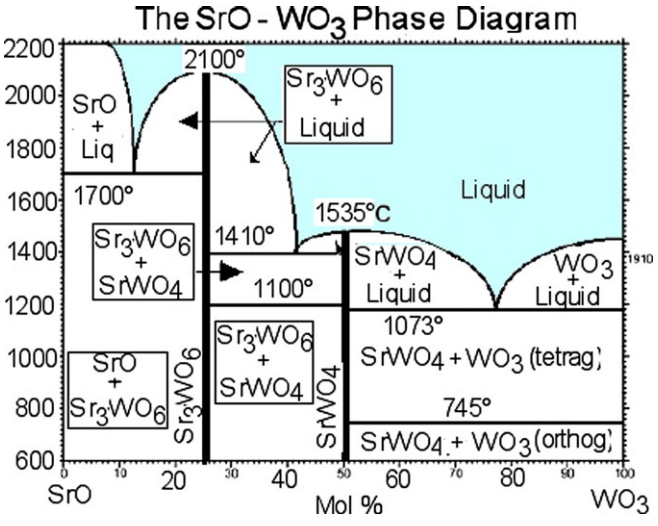

FIGURE 10.87

The (a) Scheelite, (b) Wolframite, and (c) Fergusonite structures of $SrWO_4$ are shown. Large circles represent the A (Ca, Sr) atoms, middle-size circles correspond to the W atoms, and the small circles are the O atoms. The unit-cell, Sr–O bonds and W–O bonds are also shown.

As a consequence of the scheelite-to-fergusonite transition, two Sr–O and W–O bonds are enlarged; these bonds are showed as dark lines in (c). The SrO_8 and WO_4 polyhedra are also shown. By comparing (a) and (c) the polyhedra distortion, caused by the scheelite-to-fergusonite transition, can be seen.

Structural parameters of scheelite $SrWO_4$ at 0.2 GPa are shown in Table 10.45.

Structural parameters of Fergusonite $SrWO_4$ at 10.1 GPa are shown in Table 10.46.

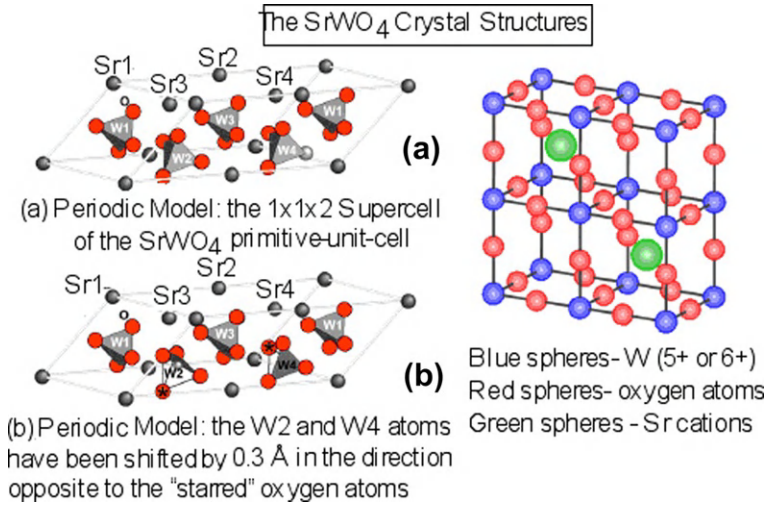

FIGURE 10.88

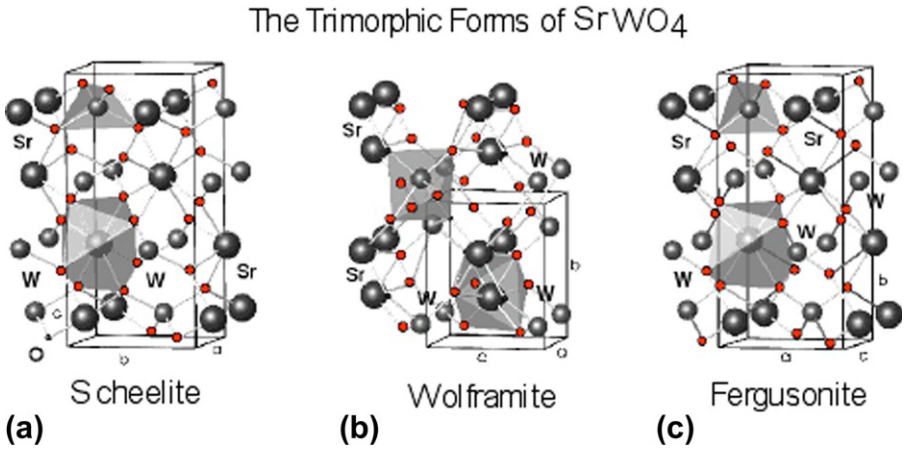

FIGURE 10.89

$SrWO_4$ undergoes a pressure-induced scheelite-to-fergusonite transition around 10 GPa. In particular, $SrWO_4$ has attracted considerable attention for the development of new electro-optics devices due to its efficient blue or green luminescence emission at room temperature. Large sized strontium tungstate ($SrWO_4$) single crystals were grown by a Czochralski method. Raman scattering and infrared absorbance spectra measurements showed that the characteristic lattice vibrational modes of $SrWO_4$ arise mainly from the internal vibrations of the WO_4 tetrahedra and partly by the external SrO_8 polyhedra modes. Thermal properties including thermal expansion, specific heat, thermal diffusion and conductivities of the crystal were investigated to evaluate the thermal properties of $SrWO_4$.

The anisotropy of thermal properties was explained by crystal structure and its correlation with the lattice vibration spectra. The vibronic-coupling and emission

spectra are similar to those given above for $CaWO_4$, except that $SrWO_4$ is more efficient of the two at room temperature. The emission peak for $CaWO_4$ occurs at 480 nm while that for $SrWO_4$ is situated at 560 nm as shown in Fig. 10.90.

Single crystals of calcium tungstate and strontium tungstate have been grown by double decomposition flux reaction technique using lithium chloride as flux. Growth conditions are optimized to synthesize well faceted crystals. Effect of primary and secondary flux density in the growth charge has been studied. TG study reveals that the grown crystals are highly stable in the temperature range 25–1000 °C. Analysis of optical absorption normal to the *ab*-plane in the spectral range of 200–800 nm reveals the true absorption edge, the nature of transition being the allowed indirect one at 4.56 eV for $SrWO_4$. Well-crystallized $SrWO_4$ products with kayak-like shapes were synthesized by a microemulsion method. In addition, various other morphologies including peanut, dumbbell, and notched sphere shapes were synthesized using a simple precipitation reaction. As the molar ratio of $[WO_4^{2-}]$ to $[Sr^{2+}]$ was increased, the morphology of the $SrWO_4$ crystals evolved from rods, through peanut-like structures and dumbbells, to notched spheres. This morphology evolution of $SrWO_4$ crystals was attributed to a fractal mechanism.

Pure and rare earth (Nd^{3+}, Tm^{3+} and Er^{3+})-doped strontium tungstates of good optical quality with sizes of about 20–50 mm were grown successfully by the Czochralski technique. The (001) orientation was found to be the favorable direction for crystal growth. XRPD, DTA and differential scanning calorimeter (DSC) of pure strontium tungstate were measured. The concentrations of Nd^{3+}, Tm^{3+} and Er^{3+} were measured and their segregation coefficients were also calculated. The absorption and emission spectra of rare earth-doped crystals as a function of the σ and π polarizations were presented and discussed. Favorable values of the absorption cross section centered at about 800 nm suggest that Nd^{3+}- and Tm^{3+}-doped strontium tungstates are promising candidates for laser diode (LD) pumping.

$SrWO_4$ crystals were grown from the melt by the Czochralski method with RF heating. The melting point of $SrWO_4$ is 1535 °C, so it is possible to use a platinum crucible in air atmosphere. A Pt screen was placed above the crucible to provide the needed thermal gradients. Vertical thermal gradient for $SrWO_4$ was less than 50 °C/cm to avoid overheating the crucible. The starting material was synthesized from $SrCO_3$ (purity 5N) and WO_3 (purity 8N). The crystals were grown along direction [100] perpendicular to the optical C4 axis that corresponded to maximal Raman scattering cross-section. Rotation rate was 30 rpm and pulling rate was up to 6 mm/h.

Typical defects observed in as-grown crystals were:

Microscopic scattering centers that caused opalescence due to the evaporation of WO_3 during the growth process

Cracking along the [001] direction, a cleavage plane specific for the crystals with the scheelite structure

These defects were observed in crystals grown with too high crystallization rate or wrong annealing conditions; the "central defect" seems to be bubbles and dendrites, formed due to facet growth on the convex solid–liquid interface. Growth striations are a result of slight deviations in ratio of main components or dopants because of the local variations in crystallization rate. It was shown that $SrWO_4$ crystals grown from the stoichiometric melt had scattering centers and introduction of some excess of WO_3 into the melt allows to decrease

FIGURE 10.91

the number of scattering centers and under definite conditions to eliminate this defect at all. It was determined that excess of 1.5 wt% WO_3 was optimal for the growth of $SrWO_4$:Nd^{3+} and $SrWO_4$:Nd^{3+}:Na^{+} composition series. Optimal excess of WO_3 for series $BaWO_4$:Nd_2O_3 and undoped crystals was 1 wt%. Single crystals of both $SrWO_4$ and $BaWO_4$ are shown in Fig. 10.91.

Raman measurement results on the growth technique, spectral and luminescence characteristics of Nd^{3+} ions in $SrWO_4$ crystals were presented. Optimal conditions to obtain optically homogeneous single crystals free of light scattering centers and growth striations were found. The values of effective segregation coefficients of active Nd and compensating Nb ions were determined. Strontium tungstate crystal exhibits one of the highest Raman gain values (5.0 cm/GW) among Nd-doped Raman host materials. Efficient intracavity Raman self-conversion in Nd^{3+}:$SrWO_4$ laser was demonstrated.

$SrWO_4$ powders were synthesized by co-precipitation method and processed at 140 °C for different times in a microwave hydrothermal (MH) system. XRD patterns revealed that these powders crystallize in a scheelite-type tetragonal structure with space group *I*41/*a*. The small deviations in the lattice parameter values were associated with the effect of microwave radiation. MR and FT-IR spectra showed characteristic modes of these powders. XRD patterns and MR spectra indicated that independent of the processing time in a MH system, $SrWO_4$ powders are ordered at long and short range. FEG-SEM micrographs showed that the processing time is an important factor in the growth mechanism of $SrWO_4$ powders. These micrographs also indicated that the PEG is a surfactant that favors the growth of $SrWO_4$ micro-octahedrons along the [001] direction. A possible growth mechanism for the formation of $SrWO_4$ micro-octahedrons was proposed. UV–Vis absorption spectra showed different optical band gap values, which were associated with the presence of intermediary energy levels within the band gap. PL behavior was explained through distortions on the [WO_4] tetrahedron groups by the microwave radiation. These observations are summarized in Fig. 10.92.

This is a schematic representation of a simple mechanism to explain the PL behavior of $SrWO_4$ powders processed in MH at 140 °C for different times.

(a) Interaction of the microwave radiation on the [WO_4] tetrahedron groups
(b) three possible distortions on [WO_4] tetrahedron groups by the displacement of tungsten atoms along the atomic coordinates (*x*, *y*, and *z*),
(c) proposed model with intermediary energy levels (oxygen 2p and tungsten 5d states) within the band gap,
(d, e) recombination of e and h·pair and
(f) PL spectrum of $SrWO_4$ powders processed in MH at 140 °C for 2 h.

The growth of such crystals was also carefully monitored as shown in Fig. 10.93.

This is a schematic representation of the synthesis and growth mechanism of $SrWO_4$ particles by MH.

The compound, tristrontium tungstate, Sr_3WO_6, has a double perovskite structure. It exhibits three polymorphs, α, β, and γ. The structure has the general form shown in Fig. 10.94.

The crystal structures of the β and γ polymorphs of Sr_3WO_6 and the γ ⇒ β phase transition have been investigated using ED, synchrotron XRPD, and neutron powder diffraction. The γ-Sr_3WO_6 polymorph is stable above $T_c \approx 470$ K and adopts a monoclinically distorted double perovskite $A_2BB'O_6 = Sr_2SrWO_6$ structure (space group Cc, $a = 10.2363$ Å, $b = 17.9007$ Å, $c = 11.9717$ Å, $\beta = 125.585°$ at $T = 1373$ K, $Z = 12$, ap, bp, cp, lattice vectors of the parent *Fmm* double perovskite structure). Upon cooling it undergoes a continuous phase transition into the triclinically distorted β-Sr_3WO_6 phase (space group $C1$, $a = 10.09497$ Å, $b = 17.64748$ Å, $c = 11.81400$ Å, $\alpha = 89.5470°$, $\beta = 125.4529°$, $\gamma = 90.2889°$ at $T = 300$ K).

Both crystal structures of Sr_3WO_6 belong to a family of double perovskites with broken corner-sharing connectivity of the octahedral framework. A remarkable feature of the γ-Sr_3WO_6 structure is a non-cooperative rotation of the WO_6 octahedra. One-third of the WO_6 octahedra are rotated by 45° about either the *bp* or the *cp* axis of the parent double perovskite structure. As a result, the WO_6 octahedra do not share corners but instead share edges with the coordination polyhedra of the Sr cations at the B positions increasing their coordination number from 6 to 7 or 8. The crystal structure of the β-phase is very close to the structure of the γ-phase; decreasing symmetry upon the γ ⇒ β transformation occurs because of unequal octahedral rotation angles about the *bp* and *cp* axes and increasing distortions of the WO_6 octahedra.

If the metal, W^0, is reacted in air with $SrCO_3$ at temperatures >850 °C, the result is a mixture of Sr_3WO_6 and $SrWO_4$. Metallic Sr then forms according to the equation:

$$2Sr_3WO_6 + W \Rightarrow 3SrWO_4 + 3Sr$$

Thus, it is $SrWO_4$ that is thermodynamically the more stable compound at the higher temperatures.

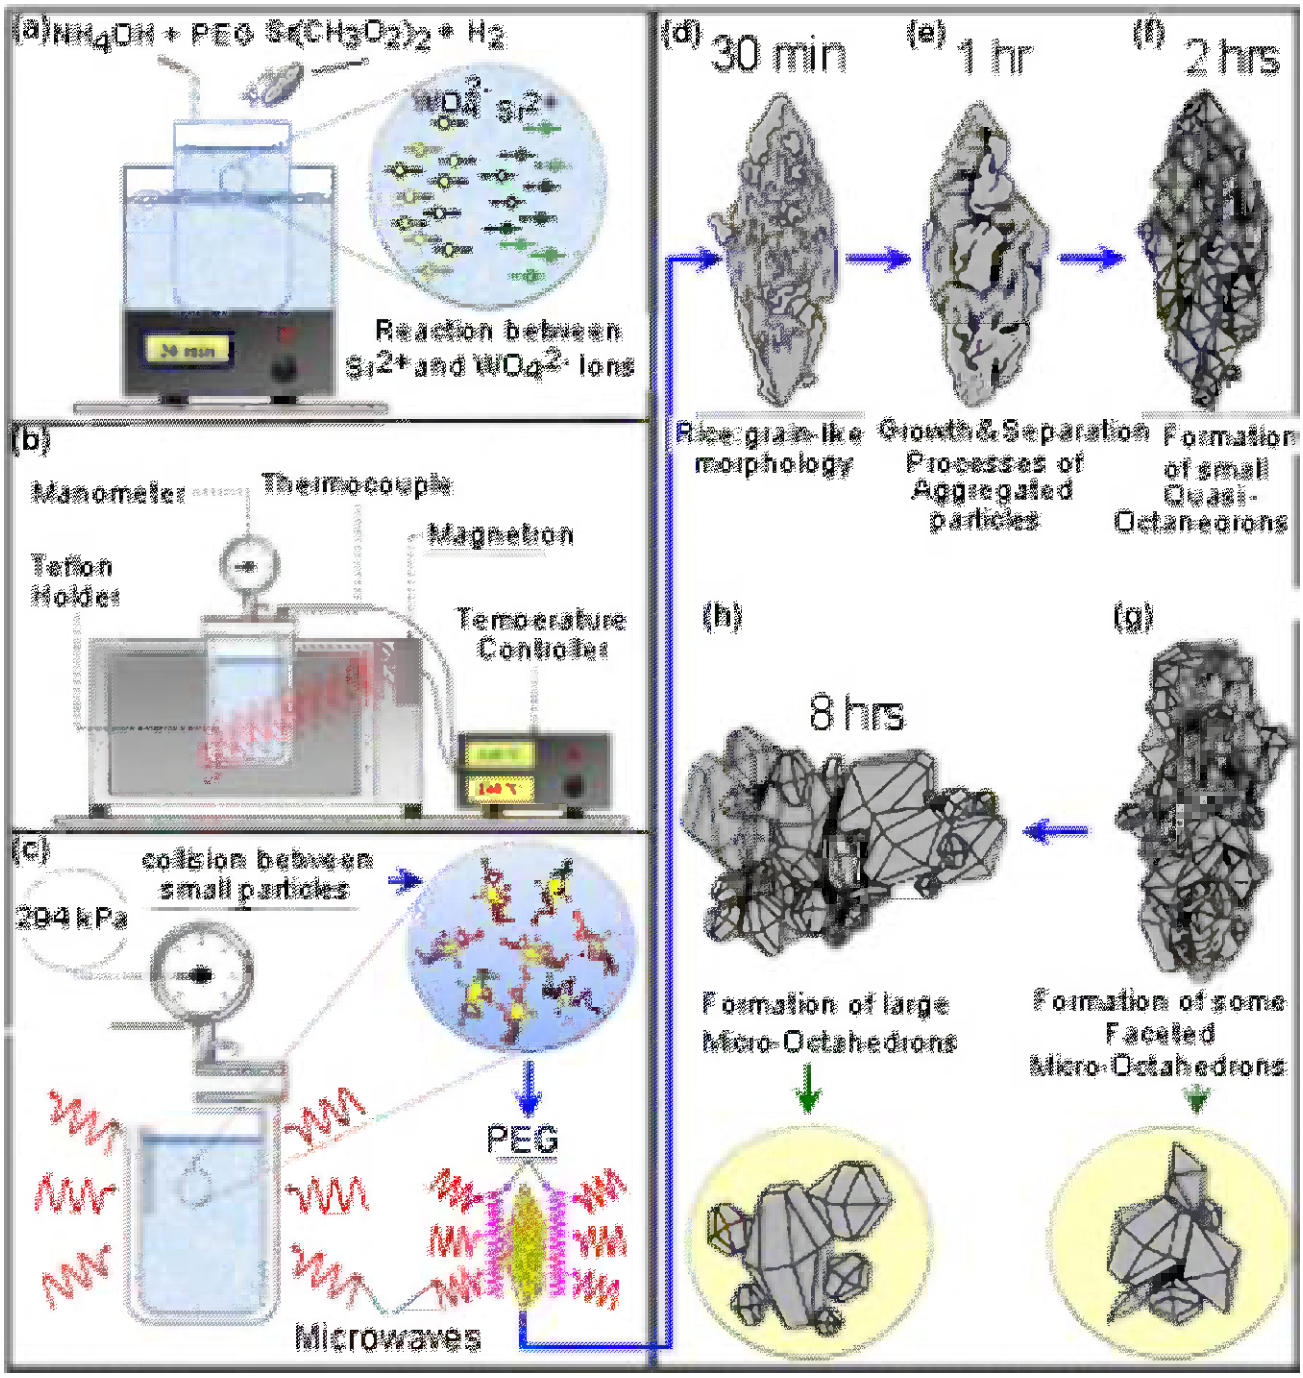

FIGURE 10.93

XRPD measurements of Sr_2CaWO_6 and Sr_2MgWO_6, at different temperatures have been reported. The crystal structures at room temperature of both compounds were determined and results showing the existence of phase transitions in them were presented. For the structure at room temperature of the Ca-containing compound, the space group $P2_1/n$ was obtained, which is different from that previously suggested. The evolution with temperature of the structure of this compound shows the presence of two phase transitions, a discontinuous one at 1130 K and a continuous one at 1250 K, with the following phase transition sequence: $P2_1/n \Rightarrow I4/\mathrm{m} \Rightarrow Fm3M$. The crystal structure of the Mg-containing compound at room temperature has the $I4/m$ space group. The temperature evolution of the structure has revealed a continuous phase transition at 570 K, changing the symmetry from tetragonal ($I4/m$) to cubic ($Fm3m$).

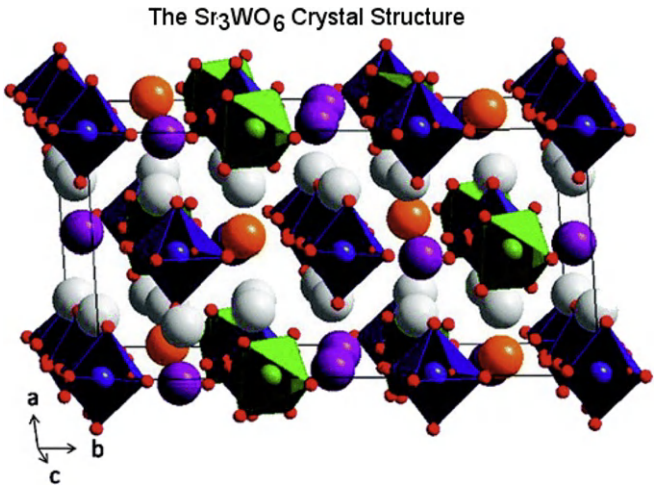

FIGURE 10.94

The compound, distrontium tungstate, Sr_2WO_5, does not appear in the phase diagram. It is tetragonal with unit-cell parameters of $a = 0.5547$ nm, $b = 0.7251$ nm, $c = 1.0896$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume = 438.24 Å^3. The structure of Sr_2MoO_5 is unknown, but the pattern of the impurity peaks looked much like those of Sr_2WO_5.

Efficient luminescence at relatively long wavelength was reported for Sr_2WO_5:U, Ba_2WO_5:U and Ba_2TeO_5:U. Excitation and emission bands shift to longer wavelength in this sequence. From vibrational spectroscopy, the hexavalent host lattice ions were shown to be in octahedral coordination. Evidence was given for the substitutional position of the emitting U^{6+} ions. The fine structure of the emission at low temperatures can be ascribed to vibronic interaction with UO_6^{6-} vibrational modes. Due to the presence of radiation-less decay processes in the tungstate group, it is impossible to excite these phosphors in the tungstate group.

Strontium tungstate is available as $SrWO_4$ commercially.

10.4.5. Barium Tungstates

No intermetallic compounds of Ba^0–W^0 are known. In the barium oxide–tungsten oxides series of compounds, a number of compounds have been studied.

In the divalent WO system, no compounds like Ba_2WO_3 or Ba_3WO_4 have been reported.

In the trivalent system, BaO–W_2O_3, the expected compound, BaW_2O_4 has not been reported. There are no other compounds of interest, such as Ba_2W_2O5 or BaW_4O_5, reported as well.

In the W^{4+} system of BaO–WO_2, the cubic perovskite formula of $SrWO_3$ has not been reported. There are no other compounds known to contain the W^{4+} ion.

In earlier work, it was found that the system BaO–WO_3 forms three (3) compounds as shown in a published phase diagram. This diagram indicated that Ba_3WO_6 melts congruently at 1790 °C while Ba_2WO_5 melts incongruently at 1645 °C. $BaWO_4$ melts congruently at 1475 °C. Both the 3:1 and 1:1 compounds are mono-morphic but the 2:1 compound was said to be tri-morphic. This is not consistent with later sources that stated it as the 3:1 compound that is tri-morphic. However, further and more accurate work determined that the trimorphic compound was actually Ba_3WO_6, not Ba_2WO_5. The phase diagram was then corrected and is shown in Fig. 10.95.

One dimorphic, one trimorphic and two other compounds are evident. The tribarium tetratungstate does not appear in the phase diagram, even though it can be formed from BaO and WO_3. It contains W^{5+} ions as part of a Ruddlesden–Popper series.

The structure factors are given in Table 10.47.

In another paper, the 1200 °C isothermal section of the system CaO–BaO–WO_3 was studied in detail. The system contains one ternary compound, Ba_2CaWO_6. It can exist in binary equilibrium with BaO, CaO, Ba_3WO_6, Ba_2WO_5, $BaWO_4$, and Ca_3WO_6. The composition range of solid solutions based on the ternary compound extends from Ba_2CaWO_6 to $Ba_{1.86}Ca_{1.14}WO_6$ at 1200 °C. Solid solubility along the binary join $BaWO_4$–$CaWO_4$ was studied in the interval 1000–1340 °C. Maximum solid solubilities occur at the eutectic temperature (1340 ± 10 °C) and are 18 mol% $CaWO_4$ in $BaWO_4$ and 3.5 mol% $BaWO_4$ in $CaWO_4$. A phase diagram was given for the $BaWO_4$–$CaWO_4$ system. Evidence was presented which shows that Ba_2WO_5 is a stable phase, and the BaO–WO_3 phase diagram was revised accordingly. There are three polymorphs of Ba_3WO_6 related by rapid reversible inversions at 1385 ± 5 and 1490 ± 10 °C. The low-temperature form of Ba_3WO_6 is tetragonal ($a = 8.652$ Å and $c = 16.434$ Å), not cubic as previously reported. The compounds Ca_6WO_9, BaW_2O_7, $BaCa_2WO_6$, $Ba_5CaW_2O_{12}$, and $Ba_{1.5}Ca_{1.5}WO_6$ reported in earlier studies were not confirmed.

The compound, **barium tungstate**, $BaWO_4$, has the same structure as $SrWO_4$, namely the perovskite structure with cell parameters of: $a = b = 5.62$ Å, $c = 7.5024$ Å, $\alpha = \beta = 111.996°$, $\gamma = 90°$, cell volume = 200.99 Å^3, $Z = 4$ as shown in Fig. 10.96.

Cell occupancy is shown in Table 10.48.

Another view of the same structure is shown in Fig. 10.97.

The structure exhibits tetragonal WO_4 units and BaO_6 octahedral units. In-situ high-pressure PXRD studies on $BaWO_4$ show that barium tungstate undergoes a first-order phase transition to a new phase at about 3 GPa.

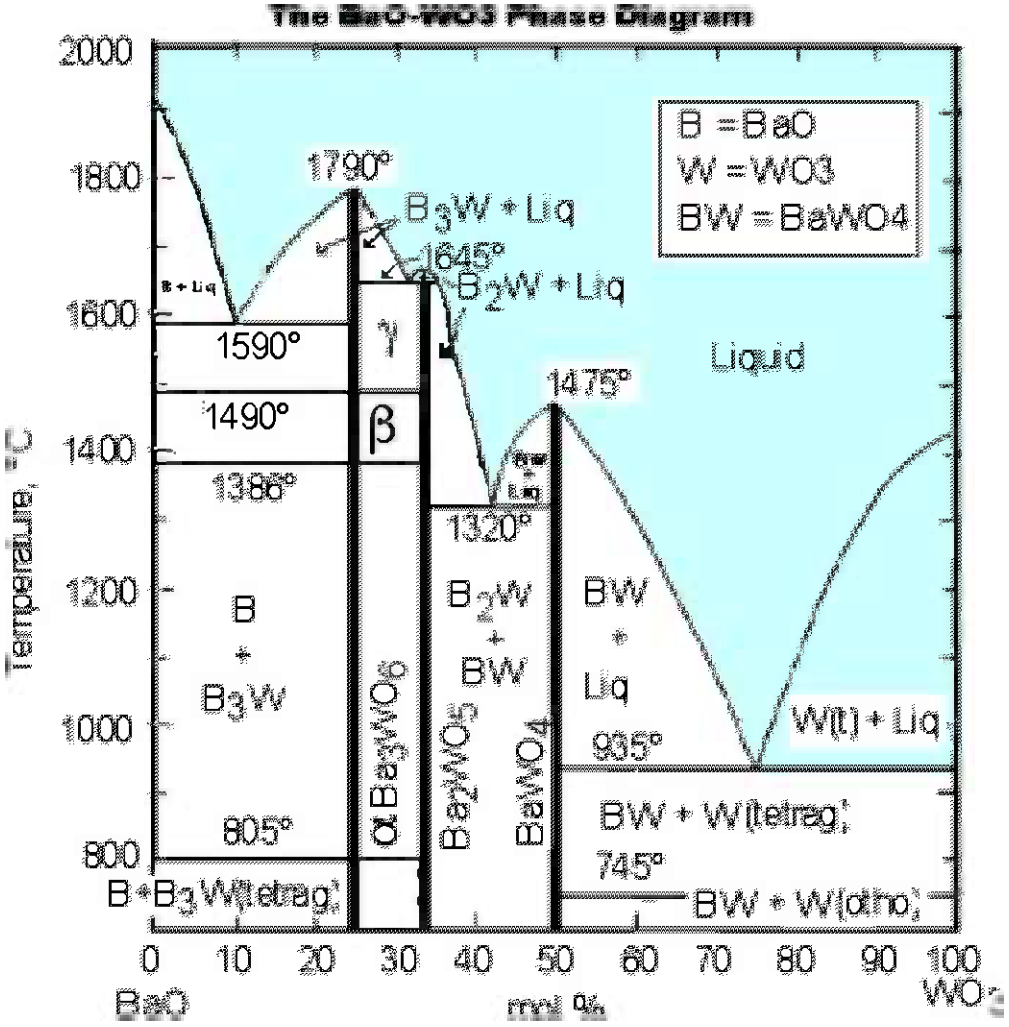

FIGURE 10.95

It has been shown that this new phase could have a structure similar to the monoclinic Fergusonite phase as shown in Fig. 10.98.

At 14 GPa, it further transforms to a new phase which becomes significantly disordered by ~20 GPa. On release of pressure from 20 GPa, the scheelite phase is recovered below 3 GPa, indicating reversible nature of both the transformations.

In another study, at room temperature Raman scattering was measured in barium tungstate ($BaWO_4$) up to 16 GPa. The pressure dependence of all the Raman active first-order phonons of the tetragonal scheelite phase ($BaWO_4$-I, space group $I4_1/a$), is stable at normal conditions. As pressure increases, the Raman spectrum undergoes significant changes around 6.9 GPa due to the onset of the structural phase transition to the monoclinic $BaWO_4$-II phase (space group $P2_1/n$). This transition is only completed above 9.5 GPa. A further change in the spectrum was observed at 7.5 GPa related to a scheelite-to-fergusonite transition. The scheelite, $BaWO_4$-II, and fergusonite phases coexist up to 9.0 GPa due to the sluggishness of I ⇒ II phase transition. Further to the experimental study, ab initio lattice dynamics calculations were performed that helped in

TABLE 10.47

Compound	Structure type	Point group	Space group	Melting point, °C

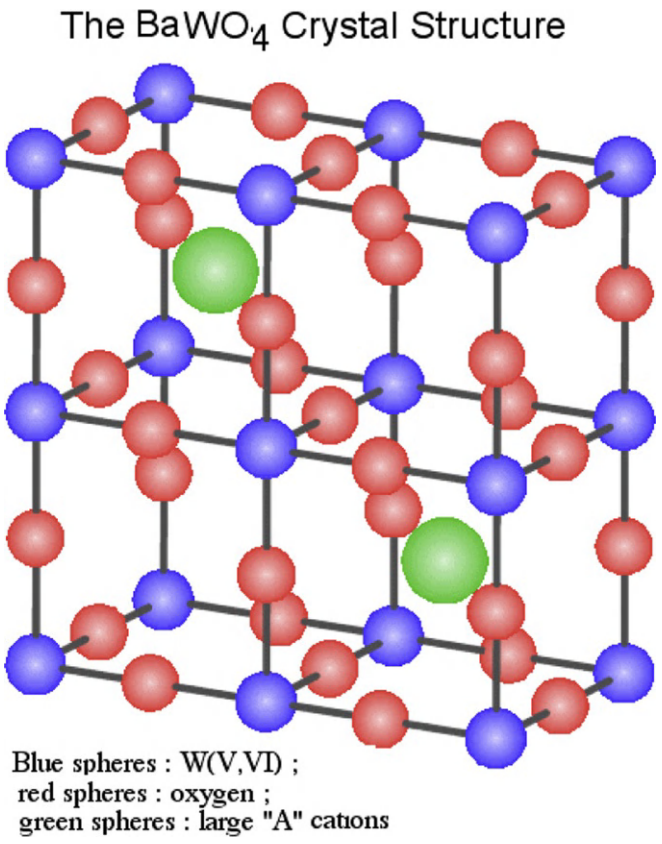

FIGURE 10.96

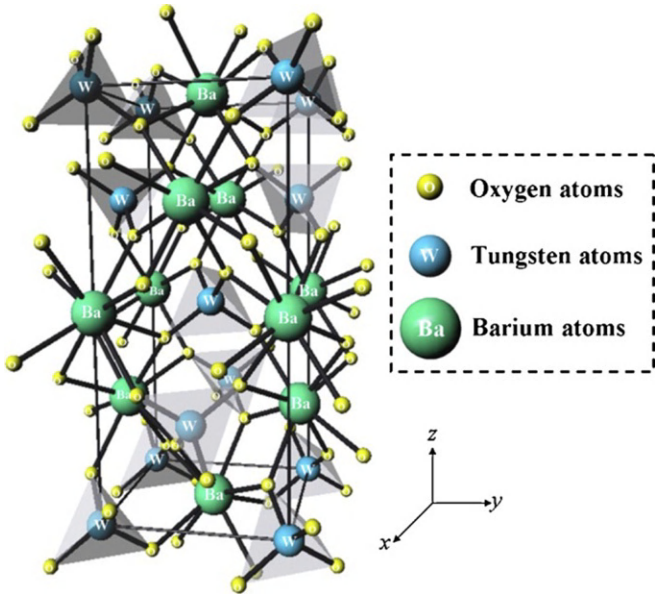

FIGURE 10.97

assigning and discussing the pressure behavior of the observed Raman modes of the three phases as shown in Table 10.49.

Beyond 14 GPa, this compound undergoes another phase transformation to a significantly disordered structure. Both the phase transitions were found to be reversible. This high-pressure phase, $BaWO_4$-II has been found to possess the structure shown Fig. 10.99.

It is monoclinic with $a = 13.159$ Å, $b = 7.161$ Å, $c = 7.499$ Å, $\beta = 93.76°$, $Z = 8$ and space group $= P2_1/n$. This structure has no direct resemblance to either the scheelite or wolframite structures. It consists of dense packed layers of WO_6 octahedra that are connected by edge- or corner-sharing. Barium ions are located between them. The coordination number of Ba^{2+} has increased in this compound, compared to the ordinary type of barium tungstate such as the scheelite structure.

Quantum-mechanical calculations indicated that the disorder at short range consists only of Ba atoms in the $Ba_{1-x}WO_{4-x}$ lattice. This has a very important role in the charge transfer mechanism involved in the intense green PL emission. This indication was detected and confirmed by means of FT RS measurements. The experimental and theoretical results are in good agreement, both demonstrating the specific type of structural disorder that is the best favorable condition for generating the most intense green PL emission in the scheelite lattice structure.

Mass spectrometric studies indicate that barium molybdate and barium tungstate salts evaporate mainly as molecular $BaMoO_4$(gas) and $BaWO_4$(gas), respectively. The importance of ion fragmentation processes occurring in the mass spectrometer was established from appearance potential measurements and the variations in relative ion intensities with condensed phase composition. Third law calculations give for the dissociation reactions:

$$BaMoO_4(gas) \Rightarrow BaO(gas) + MoO_3(gas),$$
$$\Delta G_0^0 = 129.7 \pm 4.0 \text{ kJ/mol}$$

The heats of vaporization of $BaMoO_4$(liq) and $BaWO_4$(liq) at 2000 K are 83.5 and 93.7 ± 4 kcal/mol, respectively.

$BaWO_4$ crystals were grown from the melt by the Czochralski method with RF heating. The melting point of $BaWO_4$ is 1475 °C, $SrWO_4$ is 1535 °C, so it is possible to use platinum crucibles and melt in an air atmosphere. A Pt screen was placed above the crucible to provide the needed thermal gradients. Vertical thermal gradient for $BaWO_4$ growth was 60–100 °C/cm; the thermal gradient for $SrWO_4$ was less than 50 °C/cm to avoid crucible overheating. The starting material was synthesized from $BaCO_3$ or $SrCO_3$ (purity 5N) and WO_3 (purity 8N). Crystals were grown along direction [100] perpendicular to the optical C_4 axis that corresponded to maximal Raman scattering cross-section. Rotation rate was 30 rpm and pulling rate was up to 6 mm/h. Typical defects observed in as-grown crystals were: microscopic scattering centers that cause opalescence, due to the evaporation of WO_3 during the growth process; cracking along [001] direction, caused by a cleavage plane specific for the crystals with scheelite structure. These defects were observed in crystals grown with too high crystallization rate or the wrong annealing conditions; the

"central defect" seems to be bubbles and dendrites that are formed due to facet growth on the convex solid–liquid interface. Growth striations are a result of slight deviations in ratio of main components or dopants because of the local variations in crystallization rate. It was shown that $BaWO_4$ crystals grown from a stoichiometric melt had scattering centers and introduction of some excess of WO_3 into the melt allows a decrease in the number of scattering centers obtained and, under certain conditions, to eliminate this defect entirely. It was determined that an excess of 1.5 wt.% WO_3 was optimal for growth of BaWO4:Nd^{3+}:Nb^{5+} and $BaWO_4$:Nd^{3+}:Na^{+}. Optimal excess of WO_3 for the series, $BaWO_4$:Nd_2O_3, and/or undoped crystals was 1.0 wt%. (See the strontium tungstate section above for pictures of some of the crystals).

Thin (~10 nm) BaO films on tungsten substrates (prepared at specific coverage from multilayer Langmuir–Blodgett precursor films) were heated at different temperatures between 200 and 1200 °C in a vacuum environment. The chemical changes occurring at the BaO/W interface were characterized by XPES, infrared reflection spectroscopy, spectroscopic ellipsometry, and XRD analyses. The results showed that a $BaWO_4$ phase forms above an approximate threshold temperature of 800 °C and, contrary to previous observations reported for heterogeneous reactions in powders, no evidence for a Ba_3WO_6 phase was seen. These data form a fundamental basis for understanding the regulation of the emission work function in the operation of an alkaline earth-coated tungsten cathode fluorescent lamp.

One explanation was expanded as follows:

> "Thermionic emitters, consisting of barium oxide dispersed throughout a body of porous tungsten, can be successfully made if suitable compounds of barium are employed as the source of the oxide. Compounds such as the carbonate, which can oxidize tungsten and react to form Ba_3WO_6: $3BaCO_3 + W \Rightarrow Ba_3WO_6 + 3CO$, are unsuitable. However, if by various means, BaO is dispersed in tungsten, reaction occurs at operating temperature of the cathode to slowly generate free barium: $6BaO + W \Rightarrow Ba_3WO_6 + 3Ba$, which diffuses to the surface and lowers the work function. Cathodes consisting of approximately 5 percent of BaO in W are capable of supplying continuous emission in excess of 100 amp/cm^2, give equivalent dc and pulsed emission, and are highly resistant to damage by arcing, temporary poor vacuum, ion bombardment, and high temperatures. Emission current of approximately 8 amp/cm^2 was obtained at an operating temperature of 1000 °C from a typical cathode of this type. The life of this cathode, at 1100 °C, was in excess of 650 h. Constants of the Richardson equation for a relatively inactive cathode were $\eta = 1.56$ eV, $A = 0.6$ amp/cm^2/deg^2".

Barium tungstate ($BaWO_4$) crystals were employed to achieve efficient stimulated Raman scattering conversion in a compact diode-pumped actively Q-switched Nd:YAG laser. With an incident pump power of 9.2 W, 1.56 W of 1181 nm first-Stokes average output power was generated at a pulse repetition rate of 20 kHz, corresponding to an optical-to-optical conversion efficiency of 16.9%.

The generation of multi-watt continuous-wave (CW) yellow (5865 Å) laser emission from an intra-cavity diode-pumped Nd:$GdVO_4$/$BaWO_4$ Raman laser was reported, utilizing a high-Q resonator (for fundamental and first-Stokes wavelengths) and intra-cavity frequency-doubling in LBO. CW output power of 2.9 W was achieved with a high overall diode-to-yellow conversion efficiency of 11% and with good beam quality (M^2 ~2.5).

Properties of the laser operation and simultaneously stimulated Raman scattering in SRS-active neodymium doped $SrWO_4$ and $BaWO_4$ crystals were studied. They were coherently end-pumped at wavelength 752 nm by a pulsed free-running alexandrite laser radiation. The Nd^{3+} ion emission at wavelength 1.065 μm corresponded to a $^4F_{3/2} \Rightarrow {}^4I_{11/2}$ transition. The shortest generated pulse (1.3 ns FWHM) and highest peak power (615 kW) was obtained with a Nd:$BaWO_4$ Raman laser, Q-switched by LiF crystal, with an initial transmission $T_0 = 60\%$. Up to 0.8 mJ was registered at the first-Stokes wavelength 1169 nm. The Q-switched Nd:$SrWO_4$ laser higher energy in Raman emission obtained (1.23 mJ) was longer (2.9 ns FWHM) but resulted in lower peak power (430 kW).

$BaWO_4$, prepared as a single crystal, has been widely used in electro-optical industry due to its emission of blue luminescence. Its intrinsic emission is due to transitions in the tetragonal $(WO4)^{2-}$ molecular ions. Phosphors formed from $BaWO_4$ doped with rare earth ions (RE = Eu, Tb, Tm) were prepared by the polyol method. The crystal structure and morphology of the powders were investigated using XRD, field emission SEM and Fourier transform spectroscopy. The as-prepared $BaWO_4$-based phosphors processed as low as 160 °C show mono-dispersive and crystalline nanostructures. The optical characteristics of the phosphors were investigated using low-voltage cathodoluminescence (CL). Efficient energy transfer between the host and RE ions was revealed in the spectra. No broad-band emission was seen. Red, green and blue CL was observed corresponding to sharp dominant emission peaks located at 616 nm, 545 nm and 473 nm for Eu^{3+}, Tb^{3+} and Tm^{3+} doped phosphors, respectively.

The low-voltage CL spectra obtained are shown in Fig. 10.100.

Although $BaWO_4$ and $CaWO_4$ crystal structures have been reported to be identical with similar optical properties, it is evident that they possess different emission behaviors.

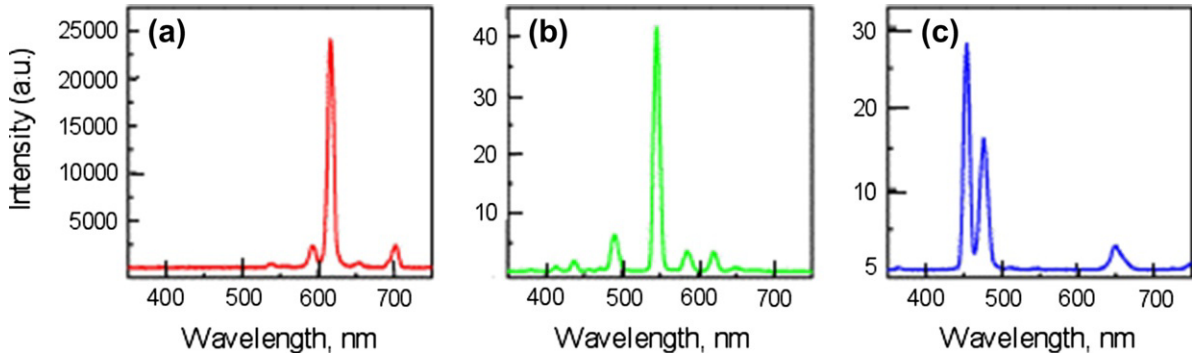

FIGURE 10.100

For $CaWO_4$: Eu^{3+} phosphors, both broad emission of $(WO_4)^{2-}$ ions and sharp line emissions correspond to Eu^{3+} ions were reported.

In $BaWO_4$:Ln^{3+} phosphors, only sharp line emissions were observed free from any broad emission. A recent result of Eu^{3+} doped $ZnWO_4$:Eu^{3+} phosphors also showed spectra similar to those of $CaWO_4$:Eu^{3+}. These differences can be explained by the symmetry of the sites (crystal field effect) in which the rare earth ions located there are significantly affected by changing the host structure cations even though the scheelite structure is maintained. This in turn affects the efficiency of energy transfer.

Since $BaWO_4$ is a weak emitter at room temperature, it was unforeseen that the $Ba_2WO_3F_4$ compound would turn out to be a strong emitter at room temperature. $Ba_2WO_3F_4$ crystallizes in an acentric monoclinic symmetry, space group *Ia* with $a = 9.281(2)$, $b = 9.361(2)$, $c = 7.183(1)$ Å and $\beta = 92.48(2)°$. It exhibits broad band fluorescent emission peaking at 475 nm both under UV and X-ray excitation.

TABLE 10.50

Compound	Luminescent peak produced when excited in short-wave excitation band (nm)	Luminescent peak produced when excited in long-wave excitation band (nm)
Ba_2MgWO_6	412	508
Sr_2MgWO_6	404	520
Ca_2MgWO_6	412	556
Ba_2CaWO_6	468	—
Sr_2CaWO_6	460, 580	—
Ca3WO6	440, 556	—
Ca_3WO_6	440, 556	—
Ba_3WO_6	518	—

The barium and mixed-barium tungstate compounds exhibit a number of interesting emission features, as shown in Table 10.50.

Two emission bands have been observed for the mixed cation compound, Ba_2MgWO_6, that are also present in the spectra of Sr_2MgWO_6 and Ca_2MgWO_6. By selective excitation it is possible to observe the two emission bands separately. The long wavelength emission is observed when the sample is excited by long wavelength UV radiation ($\lambda_{excit} = 320$ to 340 nm) while the short wavelength emission is observed when the sample is excited with radiation of 277 nm. The emission spectra of Ba_3WO_6, Ba_2SrWO_6 and Ba_2CaWO_6 show only one band, the excitation spectrum of which resembles that of the short wavelength emission of Ba_2MgWO_6.

Ce^{4+}-doped Ba_3WO_6 complex oxides were used as catalysts for methane oxidative coupling (MOC), and characterized by XPS and O_2-TPD-MS techniques. The results indicated that the ratio of electrophilic oxygen species O^- and O^{2-} to lattice oxygen on the surface was crucial for C_2 selectivity. By adjusting the relative amount of cations in Ba–W–Ce complex oxides with perovskite superstructure, interstitial oxygen species can be created which benefits C_2 selectivity by raising the relative amount of $(O^- + O^{2-})$ on the surface. The crystal structure of $Ba_3W_2O_9$ contains isolated $W_2O_9^{6-}$ groups. These are reported to luminescence efficiently. This observation shows that clusters of tungstate octahedra emit more efficiently than that of the isolated species.

The compound, dibarium tungstate, Ba_2WO_5, has a structure related to Ba_2ReO_5. Cell parameters are: $a = 5.742$ Å, $b = 7.412$ Å, $c = 11.486$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 488.84$ Å^3. The structure is composed of separate dumb-bell like units of $W_2O_{10}^{4-}$, tied together to produce a double-perovskite like structure as shown in Fig. 10.101.

Only one layer is shown here. The actual structure consists of infinite sheets of $Ba_4W_2O_{10}$, laid end-to-end. The Ba_2WO_5 compound is isostructural with Ba_2ReO_5

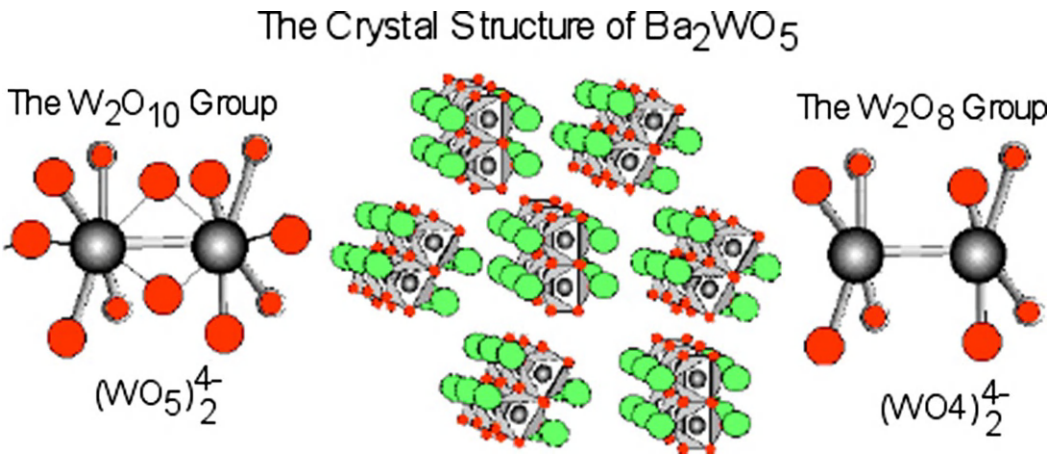

FIGURE 10.101

and contains WO_6 octahedra, which are linked by common corners and form infinite cis-bridged chains, separated by Ba atoms. The W_2O_{10} cluster is known for possessing the average oxidation state of tungstate atoms between +4 and +5.5. The W_2O_8 group on the contrary has been found only in the compounds containing W^{4+}.

NO_x sensing properties of Ba_2WO_5 were investigated in an effort to explore for a new sensor material operative at high temperature. Ba_2WO_5 was prepared from BaO and WO_3, and packed and sintered to fabricate disk-type sensor elements. It was found that the resistance of an element sintered at 800 °C decreased sharply upon exposure to NO_x in air at 500 °C, exhibiting the sensitivity values (defined as the ratio of the resistance in air to that in the sample gas) as large as 47 and 29 to 200 ppm NO and 80 ppm NO_2, respectively. The sensitivity was very dependent on the operating temperature, giving rise to a rather sharp maximum appearing at temperature around 500 °C. In addition, the elements sintered at the other temperatures (750, 850, or 900 °C) failed to exhibit significantly high sensitivity even at 500 °C. The NO_x sensing mechanism of Ba_2WO_5 was briefly discussed. From the response transient to NO and NO_2, a possible reaction occurring on the surface of Ba_2WO_5 in the presence of NO and NO_2 gases is believed to involve the reaction:

$$Ba_2WO_5 + NO(gas) + e^- \Rightarrow NO_2 + BaWO_4(solid) + BaO(solid)$$

Metal tungstates and their composites with carbonates have been investigated for application to semiconductor-type sensors capable of detecting nitrogen oxides at elevated temperatures. Among the metal

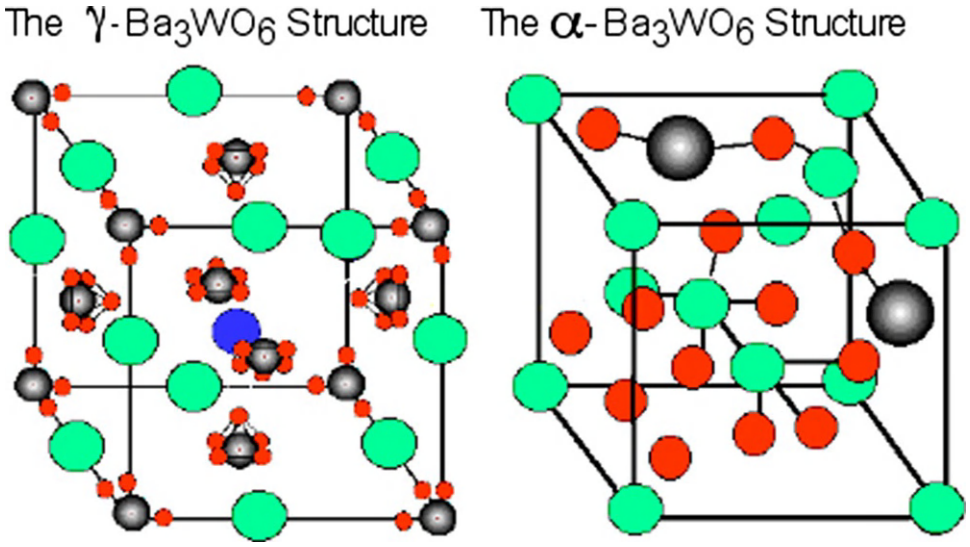

FIGURE 10.102

tungstates tested at 500 °C, $MgWO_4$ and $ZnWO_4$ are highly sensitive to NO_2 only, while $BaWO_4$ is remarkably sensitive to both NO and NO_2. The sensitivity to NO and NO_2 is greatly promoted when $BaWO_4$ is added to $BaCO_3$. The resulting composite, $BaWO_4$–$BaCO_3$ (2:1 in molar ratio) exhibits the most excellent sensing characteristics: its signal output is the same to both NO and NO_2 and increases almost linearly with increasing gas concentration in the range 0–400 ppm NO and 0–200 ppm NO_2 at 600 °C.

The double perovskite, $Ba(Zn_{1/2}W_{1/2})O_3$, is a potential microwave dielectric material. It was studied by using XRD, electron microscopy, and Knudsen effusion combined with mass spectrometry. The results show that above 1200 °C, the perovskite decomposes due to the sublimation of ZnO, which results in the formation of $BaWO_4$, Ba_2WO_5, and amorphous BaO-rich phases. Thus, the dibarium tungstate composition is one of the most stable compounds in this series. The simultaneous presence of $BaWO_4$ and Ba_2WO_5 causes the formation of a liquid phase above 1320 °C, which in the case of ceramics results in a progressive deterioration of the microstructure. As a consequence, the dielectric losses of $Ba(Zn_{1/2}W_{1/2})O_3$-based ceramics strongly depend on the processing parameters.

The structure of $Ba_3W_2O_9$ has been determined from PXRD data and found to be the same as in $Cs_3Tl_2Cl_9$. Two-thirds of the octahedral sites between hexagonal closest-packed BaO_3 layers (ABAB…) are filled by the tungsten atoms. The enneaoxo $W_2O_9^{6-}$ group represents the first crystal chemistry example of tungsten (VI) in a face-sharing arrangement. Infrared and Raman data are consistent with overall 32 (D_3) site symmetry. Crystallographic and spectroscopic evidence supports a covalent bonding model with oxygen pπ-metal dπ stabilization of this tungsten (VI) phase.

Two solid solutions have been obtained in the $Sr_{3-x}Ba_xWO_6$ system. One of them, with $0 \le x \le 0.75$, shows nonlinear behavior. Four transitions have been detected by X-ray, DTA, and dielectric measurements. The HT phase has the structure of cubic $(NH_4)_3FeF_6$, while the other ones are related. Raising x decreases the transition temperatures. At room temperature the obtained phase is piezoelectric and ferroelectric. Ba_3WO_6 is trimorphic. The intermediate structure, β-Ba_3WO_6, is not available. The high- and low-temperature polymorphs have the structure as shown in Fig. 10.102.

Cell parameters are:

HT phase = γ-Ba_3WO_6: $a = b = c = 6.1023$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 160.68 Å^3, $Z = 4$

β-Ba_3WO_6: $a = b = c = 17.1723$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 5061.68 Å^3, $Z = ?$

LT phase = α-Ba_3WO_6: $a = b = 6.1072$ Å, $c = 8.671$ Å, $\alpha = \beta = 89.91°$, $\gamma = 89.86°$, cell volume = 323.40 Å^3, $Z = 2$.

The HT-form, α-Ba_3WO_6, has the cell occupancy as shown in Table 10.52.

The cell occupancy of β-Ba_3WO_6 has not been given.

γ-Ba_3WO_6: Cell occupancy is shown in Table 10.53.

It has been known that in the system of BaO–WO_3, there are five compounds $BaWO_4$, $Ba_3W_2O_9$, Ba_2WO_5, Ba_3WO_6 and $Ba_{2.75}WO_{5.75}$. While cubic cryolite A_3BO_6 (or A_2ABO_6) is regarded as a $2 \times 2 \times 2$ superstructure of the simple cubic perovskite ABO_3 with unit cell dimension *ap*, the off-stoichiometric $Ba_{11}W_4O_{23}$ (or $Ba_{2.75}WO_{5.75}$) takes a $4 \times 4 \times 4$ superstructure with $4a_p$ (*Fd*-3*m*), $a = 17.1823$ Å, $Z = 8.23$ °C. (Note that $1X = Ba_3WO_6$ and $4X = Ba_{12}W_4O_{24}$).

The structure, $Ba_{11}W_4O_{23}$, was characterized by two types of asymmetric W ions: one in $W(1)O_6$ octahedra, typical of perovskite, and the other in polyhedra of oxygen and anionic vacancies that are statistically distributed over three divided sites to form 18 partially occupied oxide ions (~30% on average), thus, represented as $W(2)O_{18/3}$. While $W(1)O_6$ octahedra are isolated from each other by Ba1 and Ba2 ions, the W(2) $O_{18/3}$ polyhedra along the (110) direction exhibits a 1D alignment without blocking ions in between, but with the metal vacancies, indicated as V_u and V_d as shown in Fig. 10.103.

In this figure, two views are shown.

(a) A (110) view of $Ba_{11}W_4O_{23}$ unit cell: $W(1)O_6$ are shown as hatched octahedra, and $W(2)O_{18/3}$ as

white polyhedra. Ba1 and Ba2 are shown as gray spheres, and Ba3 as smaller darker spheres.

(b) Slab of the (001) plane around $Z = 0$ with a thickness of ~5.0 Å.

It has been found that this compound is an oxide ion conductor, over a wide oxygen activity range, but with a moderate ionic conductivity, compared with the conventional electrolyte oxides. The oxide also exhibits a proton conductivity at temperature below 800 °C.

The compound, tribarium di-tungstate, $Ba_3W_2O_9$, has been found to have a structure the same as in $Cs_3Tl_2Cl_9$. The structure of $Ba_3W_2O_9$ has been determined from PXRD data. Two-thirds of the octahedral sites between hexagonal closest-packed BaO_3 layers (ABAB…) are filled by the tungsten atoms. The ennea-oxo $W_2O_9^{6-}$ group represents the first crystal chemistry example of tungsten (VI) in a face-sharing arrangement. Infrared and Raman data are consistent with an overall 32 (D_3) site symmetry. Crystallographic and spectroscopic evidence supports a covalent bonding model with oxygen pπ ⇒ metal dπ stabilization of this tungsten (VI) phase. The structure of $Ba_3Te_2O_9$ has been determined from XPRD data and by profile refinement of neutron diffraction data. $Ba_3W_2O_9$ is octahedrally coordinated as expected and has the face-shared $[B_2O_9]^{6-}$ unit as observed in other similar compositions.

The compound, $Ba_3(WO_3)_4$, has the structure as shown in Fig. 10.104.

It is composed of two octahedra tied together in the *c*-direction (011-section) but two layers of octahedra tied by W–O bonds in the (110) direction. Although the structure of tri-barium tetra-tungstate has been published, there are no studies of its physical or electrical properties available. Nothing has been published concerning its chemical properties as well.

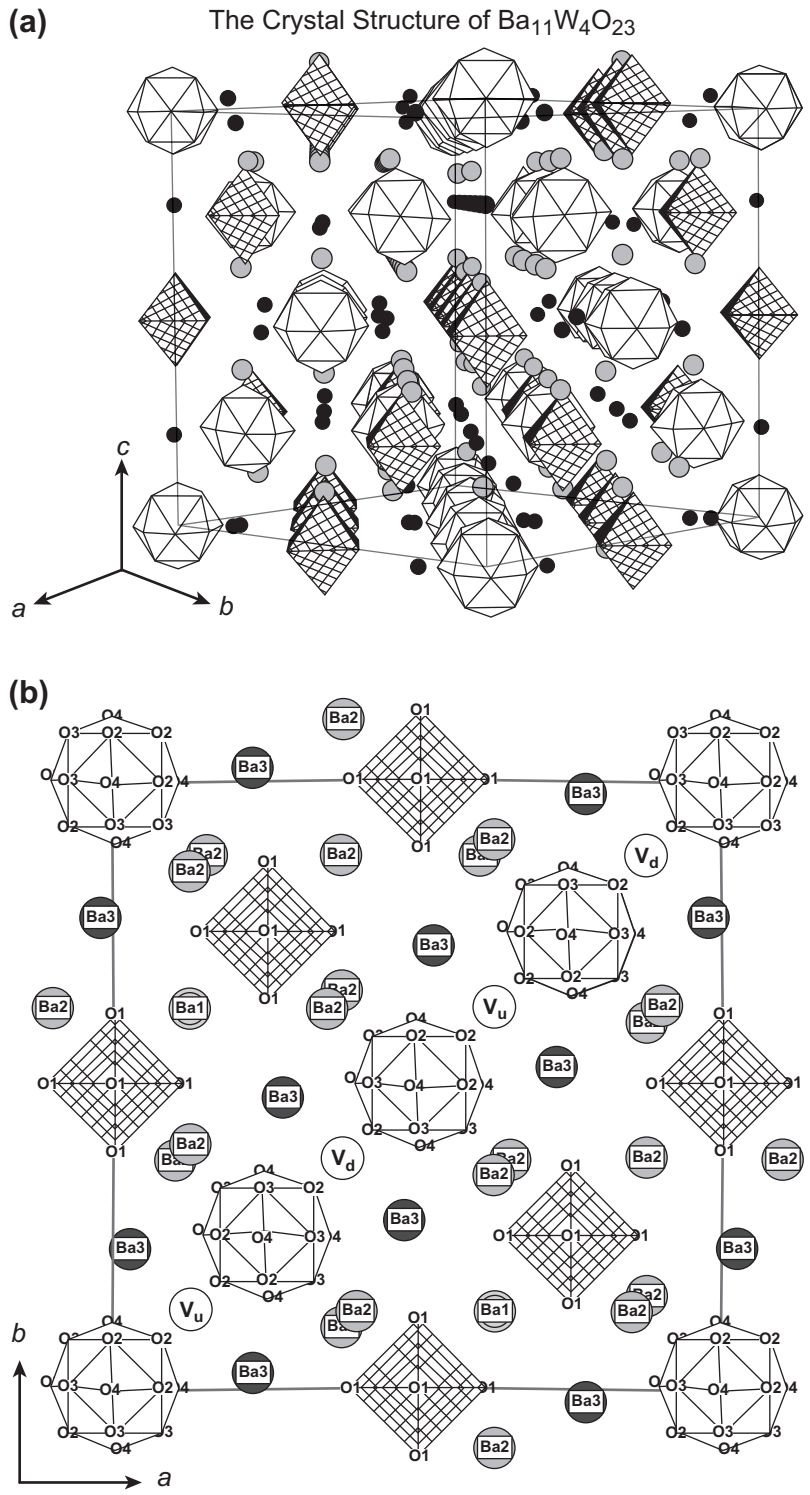

FIGURE 10.103

The compound, $BaWO_3$, barium tungstite, remains unknown, although it has been detected in the gaseous phase when a mixture of BaO and WO_3 are evaporated under neutral or reducing conditions. However, it was stated that measurement or prediction of the free energy of formation proved impossible due to its instability in the gaseous or solid state.

Barium tungstate (CAS 7787-42-0) is available commercially for proteomics research in a pure grade at $53/50 g.

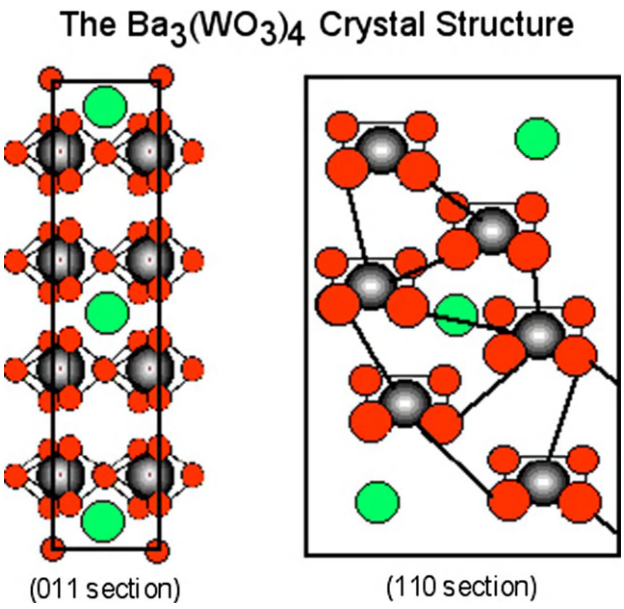

FIGURE 10.104

10.4.6. Radium Tungstates

Although radium tungstates are expected to take the same form as the homologous barium tungstates, the high cost of RaO (~1.0×10^6 USD) and its intense radioactivity have precluded any examination of compounds like $RaWO_4$, Ra_2WO_5 or Ra_3WO_6. It is unlikely these compounds will ever be examined.

11.1. ALKALINE EARTH—MANGANESE COMPOUNDS

Manganese forms a limited number of intermetallic compounds with the alkaline earths. In addition, a number of "manganites" and "manganates" are known. Many of the so-called "manganites" do not contain discrete oxo-anions, but are mixed oxides with perovskite ($LaMn^{III}O_3$, $CaMn^{IV}O_3$) structures.

Manganese with valence 2–4 enters a wide range of ternary alkaline earth oxides. Just as cuprates are intimately associated with high T_c superconductivity, ternary alkaline earth manganese oxides have attracted considerable attention in the last decade for their **giant-magnetoresistance** properties. Interestingly, this applies not only to the widely studied "manganites" (or rather manganates (III, IV), if we use chemical nomenclature rules), but also to pyrochlore-type $Tl_2Mn_2O_7$ with that has a quite different structures. Manganese ions with valence ≥ 5 form very short, highly covalent Mn–O bonds, resulting in stable, isolated tetrahedral MnO_4^- species. Mn^{5+} and Mn^{6+} are known only in few compounds with very basic cations such as Ba or K.

For manganese ions with valences of 5+, 6+ and 7+, the following names have been designated in Table 11.1.

The manganate(V) anion, MnO_4^{3-}, known trivially as hypomanganate and systematically as tetraoxidomanganate(3−), is a bright blue species with a visible absorption maximum of $\lambda_{max} = 670$ nm.

$$HMnO_4^- \Leftrightarrow MnO_4^{3-} + H;\ pK_a = 13.7 \pm 0.2$$

11.1.1. Beryllium–Manganese Compounds

Beryllium forms two compounds with Mn^0 metal. They are Be_2Mn and $Be_{12}Mn$. These compounds have the $MgZn_2$ and $ThMn_{12}$ structures, respectively. The point groups are tl26 and hP12 while the space groups are $I4/mmm$ and $P6_3/mmc$, respectively (Fig. 11.1).

The phase diagram remains unknown.

The cell parameters are:

Be_2Mn

$a = b = 4.231$ Å, $c = 6.909$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 107.11$ Å^3, $Z = 4$. Cell occupancy is shown in Table 11.2.

$Be_{12}Mn$

$a = b = c = 4.1649$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 51.09$ Å^3, $Z = 2$. Cell occupancy is shown in Table 11.3.

The only other known phase diagram involves Be–Mn–Al. A ternary phase diagram is shown as follows, illustrating what is known concerning this compound (Fig. 11.2).

The other alkaline earths do not form any intermetallic compounds. They form solid solutions as Ae^0–Mn^0 but no compounds as shown in the phase diagrams of Mg–Mn and Ba–Mn. The phase diagrams are shown in Fig. 11.3.

11.2. ALKALINE EARTH—OXO-MANGANESE COMPOUNDS

It has been observed that manganese, as one of the transition elements, does not form oxo-manganese compounds with the alkaline earths unless the alkaline

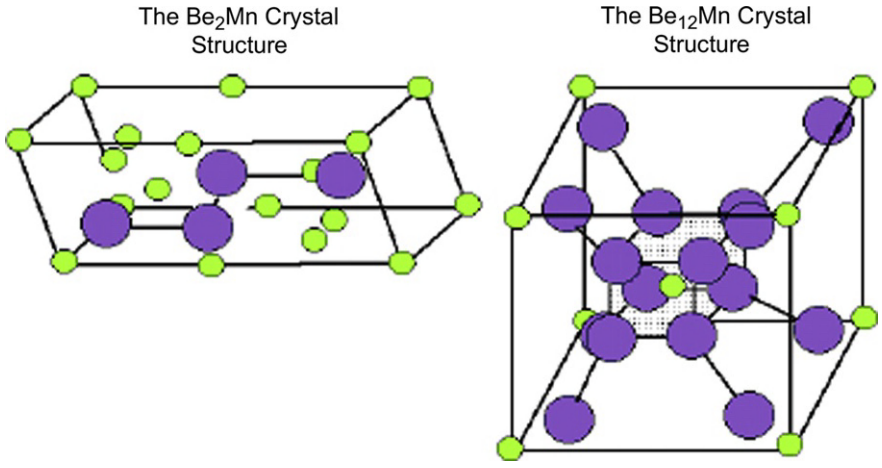

FIGURE 11.1

TABLE 11.3

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy

2	Mn	Mn	8	b	-43m	3/8	3/8	3/8	0.17

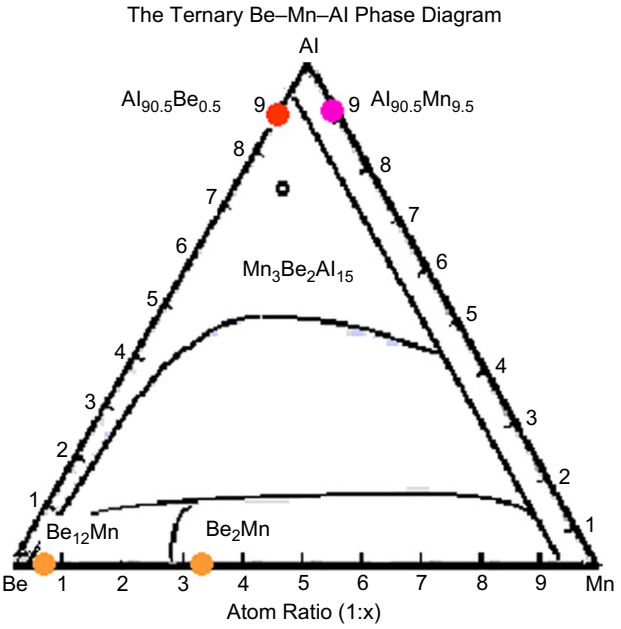

FIGURE 11.2

earth cation is large enough. This seems to be a general rule for all of the transition elements that have the anionic formula of $N_xO_{x+1}^{-x+1}$ for species where x can vary from 2 to 7. What this means in terms of manganese chemistry is that the Mn^{+2} ion in MnO_3^- (manganite) compounds has the largest atomic radius and thus can fit into a structure without undue strain. In contrast, alkaline earth compounds containing the smaller Mn^{6+}, i.e. $Mn_2O_7^{2-}$, are rare (if they exist at all). The ionic sizes of the various Mn ions are: $Mn^{2+} = 0.81$ Å, $Mn^{3+} = 0.72$ Å, $Mn^{4+} = 0.67$ Å, $Mn^{5+} = 0.47$ Å, $Mn^{6+} = 0.395$ Å, and $Mn^{7+} = 0.60$ Å. Thus, the solid-state chemistry of alkaline earth oxide–manganese oxide compounds is generally limited to those based on AeO–MnO, Mn_2O_3 and MnO_2. Seldom is a compound based on MnO_3 or Mn_2O_7 found. And these involve mostly CaO, SrO and BaO. No compounds based on BeO+(MnO, Mn_2O_3 or MnO_2) have been discovered to date. Some compounds based on MgO+(MnO, Mn_2O_3 or MnO_2) or CaO+(MnO, Mn_2O_3 or MnO_2) are very uncommon.

11.2.1. Beryllium Manganese Compounds

A search of the past and current literature does not reveal the existence of any compounds based on oxides of the manganese oxides and BeO.

11.2.2. Magnesium Manganese Compounds

In the MgO–MnO system, no specific compounds are formed from a direct reaction with manganese monooxide, MnO. In this system in air, a periclase-manganosite **solid solution** (approximate composition MgO–MnO) and spinel (approximate composition $MgMnO_2$–$MgMn_2O_4$) are the only phases present in equilibrium with liquids. Liquidus and solidus temperatures increase with increasing MgO content. A peritectic situation exists at 1587 ± 10 °C, with the two phases coexisting in equilibrium with liquid (1 wt% MgO, 99 wt% manganese oxide). This compound, (Mg, Mn)O_2 has

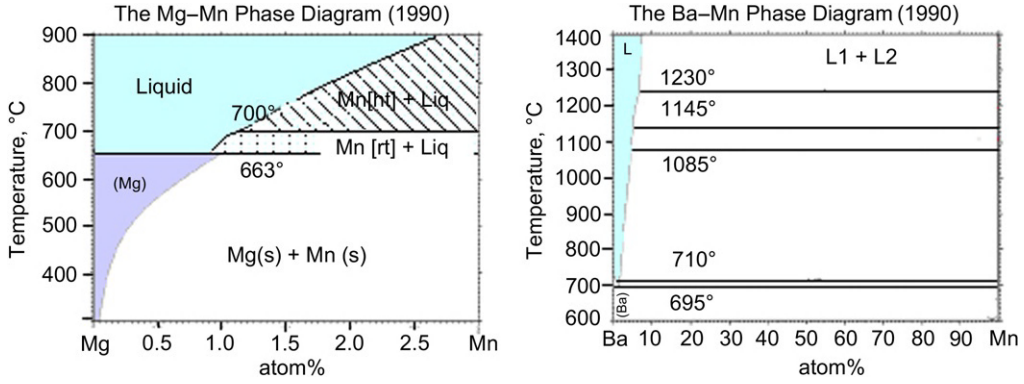

FIGURE 11.3

the NaCl crystal structure with Mg^{2+} and Mn^{2+} occupying 1/2 of the metal sites. The resistivity of $MgMnO_2$ was measured in the temperature range of 290–670 K and it was found to be *p*-type with a negative temperature coefficient of resistance.

In the manganite system, $MgO–Mn_2O_3$, a series of compounds can be formed by the use of Li_2O as a reaction catalyst. The solid–solid interactions between manganese and magnesium oxides in absence and in presence of small amounts of Li_2O have been investigated. The molar ratios between manganese and magnesium oxides in the form of Mn_2O_3 and MgO were varied between 0.05:1 and 0.5:1. The mixed solids were calcined in air at 400–1000 °C. The techniques employed were DTA (differential thermal analysis), X-ray diffraction (XRD) and H_2O_2 decomposition at 20–40 °C. The results obtained revealed that solid–solid interactions took place between the reacting solids at 600–1000 °C yielding magnesium manganates (Mg_2MnO_4, Mg_6MnO_8, $MgMnO_4$ besides unreacted portions of MgO, Mn_2O_3 and Mn_3O_4). Li_2O doping (0.75–6 mol%) of the investigated system followed by calcination at 600 and 800 °C decreased progressively the intensity of the diffraction lines of Mn_2O_3 (Bixbyite) with subsequent increase in the lattice parameter "*a*" of MgO to an extent proportional to the amount of Li_2O added. This finding appeared to suggest that the doping process enhanced the dissolution of Mn_2O_3 in MgO, forming a solid solution. This treatment led also to the formation of Li_2MnO_3. Furthermore, the doping with 3 and 6 mol% Li_2O conducted at 800 °C resulted in the conversion of Mn_2O_3 into Mn_3O_4, a process that took place at 1000 °C in the absence of Li_2O. The produced Li_2MnO_3 phase remained stable by heating at up to 1000 °C. Furthermore, Li_2O doping of the investigated system at 400–1000 °C resulted in a progressive measurable increase in the particle size of MgO. However, it is possible to obtain a pure manganate compound using Mn_2O_3.

Several ternary compounds and solid solutions of the system Mg–Mn–O have been investigated with regard to the dependence of their specific electrical conductivity on the oxygen partial pressure (10^{-19} PO_2–10^5 Pa) at 700–1000 °C. Below 1000 °C the compounds Mg_6MnO_8, Mg_2MnO_4 and $MgMn_2O_4$ are only stable at high-oxygen partial pressures, while the solid solutions $(Mg_{1-x}Mn_x)O$ are only stable at low-oxygen partial pressures ($PO_2 < 10^{-1}$ Pa). Only Mg_6MnO_8 and $Mg_{1-x}Mn_xO$ show a variation of the specific electrical conductivity, σ, with the change of PO_2. Considering the slopes of the plots of log σ versus log PO_2 and the stability of these two compounds, they may be considered as potentially good oxygen sensors.

Solid solutions of tetragonal $MgMn_2O_4$ and cubic $MgAl_2O_4$ have been synthesized and characterized using the XRD technique. Electrical conductivity (σ) and magnetic susceptibility (μ) have been measured over the temperature ranges 25–1000 °C and −195 to 60 °C, respectively. All the compounds were found to be monophasic and crystallized with either tetragonal ($c/a > 1$) or cubic symmetry. The critical concentration of $MgAl_2O_4$, required to stabilize the cubic structure, was found to be only 12.5%. This may be explained as due to migration of a considerable amount of Mn^{3+} to A sites. The values of energy of activation and free energy of activation obtained from $\ln\sigma - 1/T$ and $\ln(\sigma T) - 1/T$ plots were found to be almost identical. All the samples exhibited paramagnetism at $T \geq 195$ °C and indications of antiferromagnetic (AFM) ordering at lower temperatures.

The compound, di-magnesium manganate, Mg_2MnO_4, has the spinel structure shown in Fig. 11.4.

Cell parameters are: $a = b = c = 6.9164$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 146.44 Å^3, $Z = 4$. Cell occupancy is shown in Table 11.4.

In the $MgO–Mn_3O_3$ system, the compound, $MgMn_2O_4$, also has the magnesium aluminate spinel structure, but with the same positions for the Mg^{2+} and Mn^{4+} ions. This is shown in Fig. 11.5.

Cell parameters are: $a = b = c = 6.0245$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 154.61 Å^3, $Z = 8$.

Cell occupancy is shown in Table 11.5.

The catalytic activity measurements of these compounds showed that the increase in the molar ratio of Mn_2O_3 in the samples precalcined at 400–800 °C was accompanied by a significant increase in the catalytic activity of the treated solids. The maximum increase in the catalytic activity expressed as reaction rate constant measured at 20 °C attained 3.14-, 2.67- and 3.25-fold for the solids precalcined at 400, 600 and 800 °C, respectively. Li_2O doping of the samples having the formula 0.1 Mn_2O_3/MgO conducted at 400–600 °C brought a progressive significant increase in its catalytic activity. The maximum increase in the value of *k* 20 °C due to Li_2O attained 1.93- and 2.75-fold for the samples preheated at 400 and 600 °C, respectively and opposite effect was found for the doped samples preheated at 800 °C.

Single crystals of spinel and Hausmannite having seven different compositions in the $MgAl_2O_4$–$MgMn_2O_4$–$MnMn_2O_4$ system were synthesized and structurally and chemically characterized by XRD and electron microprobe techniques. As predicted, tetrahedral and octahedral bond lengths increased with increasing substitutions of Mn^{2+} for Mg and Mn^{3+} for Al, respectively. A transition from cubic to tetragonal symmetry occurs at a critical concentration of $Mn^{3+} > 1.4$ atoms per formula unit as a result of the Jahn–Teller distortion around octahedrally coordinated Mn^{3+}. The present data in conjunction with data from the literature provide a basis for quantitative analyses

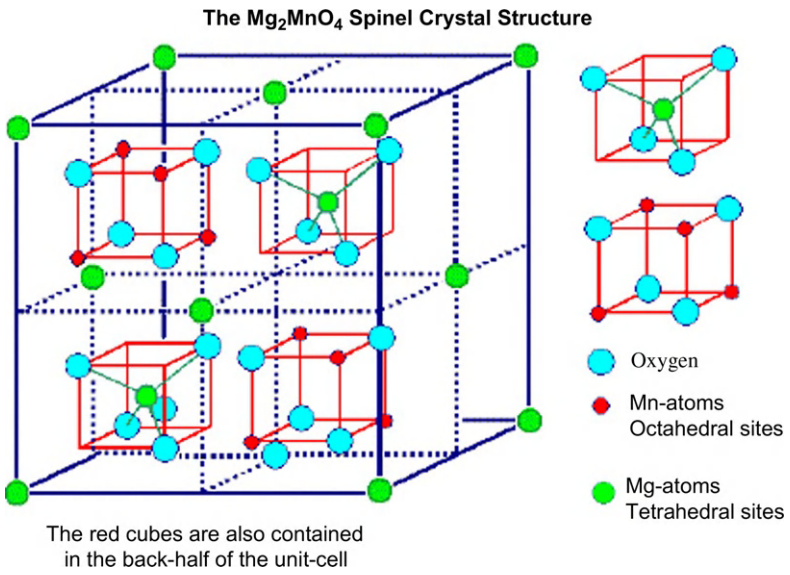

FIGURE 11.4

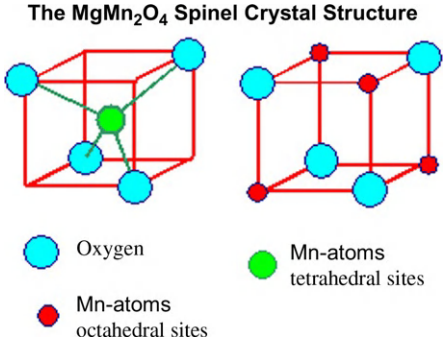

FIGURE 11.5

of the cation polyhedral-distortion parameters and their variations in spinel- and Hausmannite-type structures (*Fdm* and $I4_1/amd$, respectively). In contrast to the linear correlation between $<\sigma_M>$ (octahedral quadratic elongation) and δ^2_M (octahedral bond-angle variance) observed for many silicates and isomorphic structures, these two distortion parameters are not correlated in multiple oxides with spinel- and Hausmannite-type structures. By using a model of multiple linear regression, it was demonstrated that $<\eta_M>$ varies as a function of both δ^2_M and σ_M (octahedral bond-length distortion). The degree of octahedral distortion was significant in the spinel structures and was in fact comparable with that calculated for the Hausmannite-type structures. The degree of octahedral distortion was then related to

steric effects in both spinel- and Hausmannite-type structures, whereas the electronic effects caused by Mn^{3+} accounted for the transition from cubic to tetragonal symmetry.

A novel type of ion-sieve manganese oxide (HMnO(<2Mg)) was prepared by extracting magnesium from Mg_2MnO_4 with aqueous acid. The preparation conditions of HMnO(<2Mg) and its ion-exchange properties were examined. The extraction of magnesium from Mg_2MnO_4 caused a decrease in the lattice constant of a spinel structure. The HMnO(<2Mg) showed a selective adsorption of lithium from seawater when the Mg/Mn ratio of the sample was less than 1. The pH titration curve showed an affinity order of Cs: K < Li above pH 3.5. The lithium-ion uptake increased with increasing solution pH and reached 3 meq/g at pH 12. The selectivity sequence was Na < Li < K < Rb < Cs for alkali metal ions at pH 3.1, while it changed to Na < Rb:Cs < K < Li at pH 8. The selectivity sequences were Mg < Ca < Sr < Ba for alkaline earth metal ions and Ni < Zn < Cu < Co for transition metal ions at pH 3.1. The Li^+-selective property is discussed based on the ion-sieve effect of the protonated octahedral sites at the cubic closed-packed oxygen framework of HMnO(<2Mg).

The phase stability of the $MgMn_2O_4$ spinel has been studied by means of high-pressure XRD for pressures up to 30 GPa. Two samples with different inversion degrees have been considered. Both spinels undergo a phase transition toward an orthorhombic structure ($CaMn_2O_4$ type). As for the more inverted sample the transition pressure is at least 1 GPa lower than that of the less inverted spinel, and the volume contraction, relative compressibility, and density trends are different for the two samples, as well.

In another paper, the influence of the cation migration process on the electrical properties of $MgMn_2O_4$ was investigated. By measuring the temperature dependence of the electrical resistance and thermoelectric power, it is possible to study the migration process of the cations in the spinel lattice, and to establish the temperature range in which the tetragonal-cubic phase change occurs. By using the thermoelectric power data, it was possible to specify the valence formulas of samples that had been quenched or slow-cooled from high temperature. The electrical conduction occurs by a hopping mechanism between the octahedral-site Mn^{3+} and Mn^{4+} ions, and involves very low mobilities.

In the $MgO–MnO_2$ system, two new ilmenites of tetravalent manganese have been prepared at high pressures: $MgMnO_3$: $a = 4.945$ Å, $c = 13.73$ Å and $ZnMnO_3$: $a = 4.965$ Å, $c = 13.80$ Å. The compounds were found to be AFM, and $MgMnO_3$ possessed semiconducting electrical properties.

Synthesis and magnetic properties of nanocrystals (size = 22 nm) of cubic spinel $MgMnO_3$ with the defect structure $[Mg^{2+}][Mg^{2+}_{1/3}Mn^{4+}_{4/3[1/3]}]O_4$ are reported. Analysis of the magnetization M versus T (2–370 K) and M versus H (up to 65 kOe) data shows a blocking temperature $T_B \approx 11$ K and an estimated Néel temperature $T_N \approx 150$ K above which the Weiss temperature $\theta = -7$ K and $\mu = 3.91$ μbar/Mn^{4+}. For $T_B < T < T_N$, fit of the M versus H data to modified Langevin function yields 35 μbar as magnetic moment/particle, resulting from the defect structure.

In the $MgO–Mn_2O_5$ system, no compounds having a composition, $MgMn_2O_6$ or $Mg(MnO_3)_2$ are known. This is likely due to the instability of the Mn^{5+} ion.

In the $MgO–Mn_2O_7$ system, the permanganate is known. It can be prepared by:

$$MgCl_2\ (aq) + Na_2(MnO_4)_2 \cdot H_2O\ (aq) \Rightarrow Mg(MnO_4)_2 \cdot 6H_2O\ (s)$$

This compound has the structure shown in Fig. 11.6.

This compound can be prepared as a molecular sieve by careful control of the initial preparation conditions (Fig. 11.7).

Here, a facile single-step method was developed for synthesizing a Todorokite-type manganese oxide octahedral molecular sieves (OMS-1) and 2 × 4 tunnel-structured manganese oxide (OMS-5) materials. Selection of

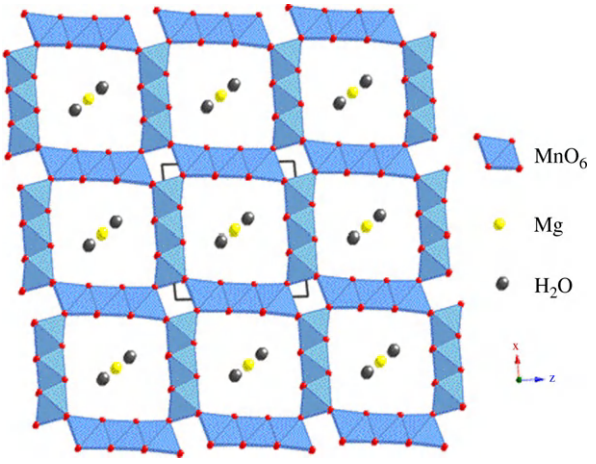

FIGURE 11.6

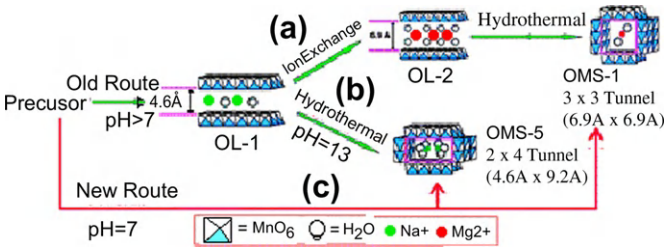

FIGURE 11.7

starting materials and initial pH conditions was crucial to a satisfactory synthesis.

In the $MgO–MnO_3$ system, no known compounds exist.

Magnesium permanganate is offered for sale as $Mg(MnO_4)_2 \cdot 6H_2O$ but little is available concerning its manufacture.

Magnesium permanganate hydrate (CAS 250578-91-7), is a specialty product for proteomics research. Magnesium permanganate (10377-62-5) is also offered for sale commercially.

11.2.3. Calcium Manganese Compounds

In the system, CaO–MnO, no compounds with MnO (hypomanganite) have been found as shown in Fig. 11.8.

This diagram is typical of the other alkaline earth—MnO systems. However, by the use of Li_2O as a molten flux, the crystal structure of $CaMnO_2$ has been determined to be that of the cubic NaCl arrangement.

In the Mn^{2+} system, CaO–MnO, the compound, dicalcium hypomanganite, Ca_2MnO_3, has been prepared. When the precursors $CaMnO_3$ and Ca_2MnO_4 are reduced with any one of a variety of inorganic (H_2, NH_3) or organic (C_2H_4, C_3H_6) reducing agents between 300 and 500 °C, topotactic reaction occurs to produce the ordered oxygen-defect phases $CaMnO_{2.5}$ and $Ca_2MnO_3.5$, respectively. Orthorhombic cell constants for $CaMnO_{2.5}$ are $a = 5.43(1)$, $b = 10.24(1)$, and $c = 3.74(1)$ Å, and for Ca_2MnO_3 are $a = 5.30$, $b = 10.05$, and $c = 12.24$ Å. These compounds were characterized by powder XRD, thermo-gravimetric analysis, magnetic susceptibility, and infrared spectroscopy. The reduced compounds reversibly oxidize to their respective precursor in oxygen at low temperatures.

In another study, an analysis of the electronic and magnetic properties of Ca_2MnO_3 was carried out within local-spin density functional theory using the augmented spherical wave method. From energy differences between the hypothetic magnetic configurations this system was found to be an insulating antiferromagnet in the ground state with a 1 eV gap. An intermediate half metallic ferromagnetic (FM) state was identified with the Hund's rule expected moments for Mn^{III} (4 μBar, high-spin HS configuration). This result of moment magnitude finds support in recent experimental evidence of Mn^{III} bismuth oxides as a ferromagnet in its ground state. This is characterized by a small density of states (DOS) magnitude of itinerant states in spin (⇑) channel pointing to a metallic-like behavior as it is experimentally evidenced.

The Mn^{3+} system, $CaO–Mn_2O_3$, contains the compound, $CaMn_2O_4$ whose structure consists of MO_4^{2-} tetrahedra interconnected facewise is shown in Fig. 11.9.

Cell parameters are: $a = 3.162$ Å, $b = 9.71$ Å, $c = 10.03$ Å, cell volume $= 307.95$ Å^3, $Z = 4$.

Cell occupancy is shown in Table 11.6.

Physical properties including magnetic susceptibility, room-temperature electrical resistivity, thermal conductivity, heat capacity, and thermal expansion have been reported for high-quality single-crystal samples of Marokite, $CaMn_2O_4$. It was determined that $CaMn_2O_4$ is highly electrically insulating and exhibits long-range AFM order below $T_N = 217$ K with easy axis along a. Anisotropic thermal expansion, similar to that of crystallographically layered materials, is observed, suggesting that the crystal structure of $CaMn_2O_4$ is also assembled from previously unexplained layers. An extensive thermodynamic study of the AFM transition was undertaken resulting in a heat-capacity critical exponent $\alpha = 0.082$ and calculated pressure derivative $dT_N/dP = 5.154$ K/GPa.

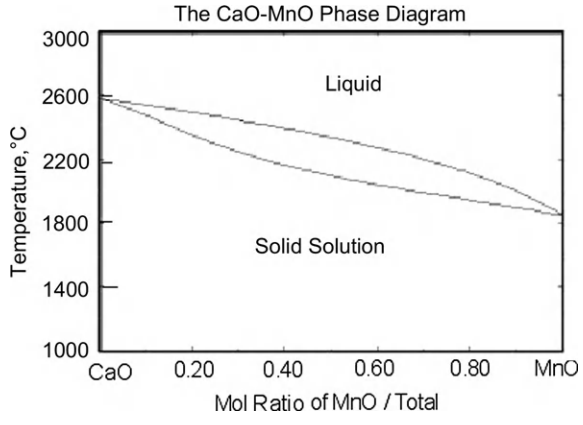

FIGURE 11.8

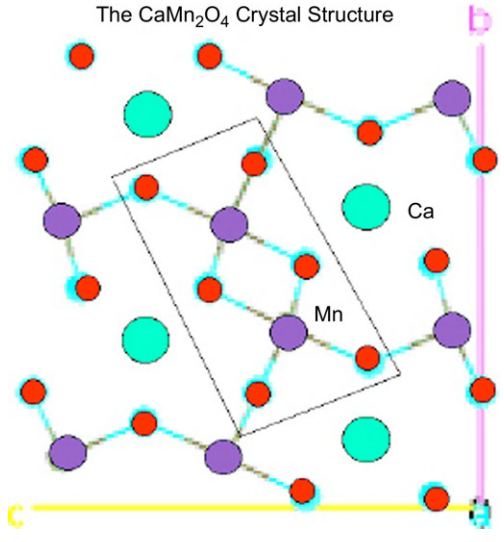

FIGURE 11.9

Centimeter-sized single crystals of $CaMn_2O_{4+\delta}$, commonly known as Marokite, were grown using the floating-zone method. The growth conditions are reported along with a discussion of a simple method for polycrystalline rod preparation, which differs from the typical cold isostatic pressure procedure. Crystal characterization was determined by powder XRD, back-reflection Laue diffraction, iodometric titration, energy-dispersive X-ray spectrometry, and vibrating sample magnetometry. Polycrystalline rods, composed of stoichiometric Marokite, were found to produce crystals with $CaMnO_3$ as a secondary impurity phase as revealed by magnetic measurements and powder diffraction. Crystals grown from polycrystalline rods with excess manganese oxide produced single crystals of high quality without impurity phases.

Three structures of $CaMn_2O_4$, $CaFe_2O_4$, and $CaTi_2O_4$ have been proposed as post-spinel phases. Because these structures are very similar, several ambiguities and inconsistencies appear in high-pressure studies, leading to many problems that are yet to be solved. Systematic powder diffraction studies related to these three phases were conducted under high pressure using synchrotron radiation. All three samples have further high-pressure polymorphs. $CaMn_2O_4$ transforms to the $CaTi_2O_4$-type structure at about 30 GPa. The MnO_6 octahedron in the lower pressure structure is distorted by the Jahn–Teller effect. A new phase was observed at pressures above 50 GPa during compression of $CaFe_2O_4$. Rietveld profile fitting analysis of diffraction data at 63.3 GPa demonstrated that the high-pressure structure, with space group *Pnam*, is produced via a martensitic transformation by displacing atoms in every third layer perpendicular to the *c*-axis. $CaTi_2O_4$ also has a new high-pressure polymorph above 39 GPa with space group *Bbmm*. The most probable post-spinel candidate in the mantle is the $CaTi_2O_4$-type structure. The $CaMn_2O_4$-type structure is only formed at high pressure from spinel phases with atoms susceptible to Jahn–Teller distortion.

Mixed calcium manganese(III) oxides (see structure; Ca-green, Mn-red, O-white) with elemental compositions and structures mimicking the active site of photosystem-II were found to be highly active catalysts for the oxidation of water to molecular oxygen. As for PS II, the presence of Ca^{2+} greatly enhances the catalyst performance in comparison to the related manganese-only system Mn_2O_3 (Fig. 11.10).

Calcium manganite $CaMn_2O_4$ is orthorhombic. Susceptibility measurements in weak fields and pulsed fields made on powder and on a single crystal show that this manganite is AFM below $T_N = 225 \pm 5$ K, the moments being parallel to [100]. Neutron diffraction measurements confirm these results and show that the magnetic unit cell is twice the chemical cell (2*a*, *b*, *c* instead of *a*, *b*, *c*). The magnetic ordering has also been determined.

In this Mn^{4+} system, another compound based on the 2:1 ratio, $Ca_2Mn_2O_5$ has been found. It has the structure shown in Fig. 11.11.

It has a layered structure as may ascertained in this figure. The *b*-*c* plane (011) shows the Ca^{2+} ions layered between the MnO_4^{3+} tetrahedra {*a*-*b* plane = (110)}.

Call parameters are: $a = b = 5.183$ Å, $c = 12.6031$ Å, $\alpha = \beta = 101.866°$, $\gamma = 90°$, cell volume = 323.93 Å^3, $Z = 4$. Cell occupancy is shown in Table 11.7.

In the following figure, the ordering of oxygen vacancies in Ca2Mn2O5 having [MnO5] square pyramids is shown (Fig. 11.12).

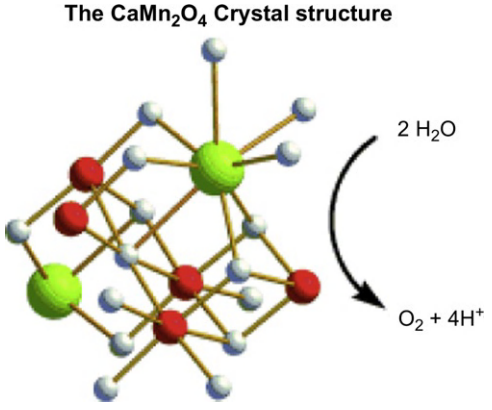

FIGURE 11.10

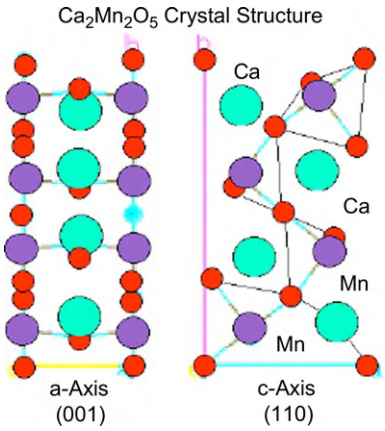

FIGURE 11.11

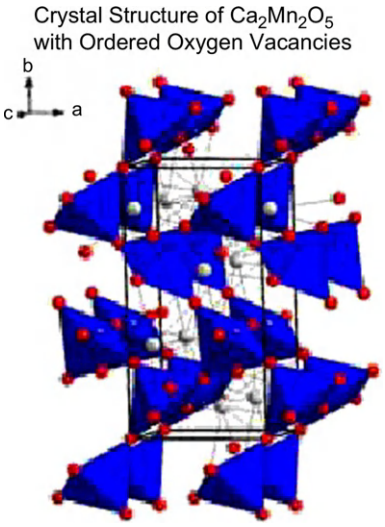

FIGURE 11.12

This is an example of a defect perovskite where the chemistry can be described according to the homologous series $A_nB_nO_{3n-1}$, $n = 2-\infty$. Several types of vacancy orderings are known, including the structure of $Ca_2Mn_2O_5$ having $n = 2$. This structure is related to "Brownmillerite" in which oxygen vacancies cause the perovskite structure to form ordered levels of defects (Fig. 11.13).

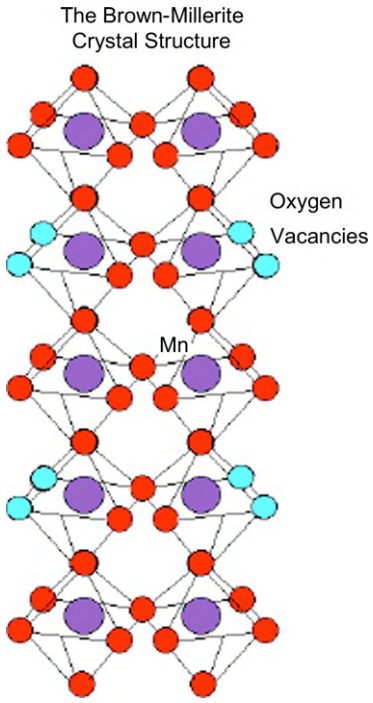

FIGURE 11.13

This is, perhaps more easily seen in the following diagram shown in Fig. 11.14.

This is a schematic representation of the ordered vacancy arrangement respect to (**a**) the perovskite cubic sublattice, (**b**) $Ca_2Mn_2O_5$ and (**c**) Brownmillerite structural types. It has been observed, generally speaking, that the FM fraction in oxygen deficient manganites decreases for high concentration of vacancies, since anionic vacancy introduction breaks the Mn_{4+}–O–Mn_{3+} double exchange interactions avoiding the FM ordering. On the basis of this description two situations can be attained (i) when vacancies are randomly distributed the magnetic behavior of the starting material is lost while (ii) it is partially kept when ordering between octahedral and tetrahedral layers happens. This is possible because the FM interactions remain at the octahedral layers. It is then clear that, together with the more conventional synthetic strategies, chemical

TABLE 11.7

doping and more recently cationic vacancy formation, the anion vacancies can also play an important role in the intriguing structure properties relationships in manganites.

In the Mn^{4+} system, CaO–MnO_2, the manganate compound, $CaMnO_3$, is known. $CaMnO_3$ and $SrMnO_3$ are canonical AF band insulators (Mn^{4+},$t_{2g}^3e_g^0$) with a simple, bi-partite spin arrangement and a small electron density ($\sim 5 \times 10^{18}\,cm^{-3}$) produced by native oxygen vacancies. Oxygen vacancies in transition-metal oxides produce shallow donor states within the band gap that can play a crucial role in determining electronic and magnetic properties through their binding of electrons, hybridization with cation d-states, mediation of exchange interactions, or overlap to form vacancy-derived impurity bands. Such effects are implicated in many novel and unexpected phenomena that are currently the focus of considerable attention within the condensed matter physics community: magnetic polaron formation in manganites and dilute magnetic semiconducting oxides, "d^0 ferromagnetism" in materials like HfO_2 and TiO_2, highly conducting and even magnetic 2D electron gas formation at interfaces between nonmagnetic perovskite insulators. The 3d transition-metal oxides exhibit amazing physical effects such as high-temperature superconductivity. Colossal responses, such as high-temperature superconductivity, colossal magnetoresistance (CMR) and ferroelectricity, have brought doped transition metal oxides into focus during the past two decades.

Two series of manganate phases have been prepared and their magnetic properties measured. The first series consists, in addition to $CaMnO_3$, of three phases having layered structures. In these, tetravalent manganese ions are contained in single or multiple perovskite layers which are separated from each other by nonmagnetic calcium-oxygen layers. Magnetic exchange of the type Mn^{4+}–O–Mn^{4+} is disrupted between layers, and decreased Néel temperatures were expected to result. In a second series of phases, the size of the $CaMnO_3$ unit cell was increased by partial substitution of strontium for calcium. Increased separation of manganese ions produced by this means was expected to reduce Néel temperatures. However, contrary to these expectations, Néel temperatures remained approximately constant for the first series of phases and increased for the second.

$CaMnO_3$ occurs as three forms, two of which are oxygen-defect (holes) compound. The crystal parameters are listed in Table 11.8.

Titration and Mn-K XAS indicate the reduction of Mn(IV) to Mn(III) with increasing δ in the $CaMnO_{3-\delta}$ system by the creation of two five-coordinate Mn(III) sites per O vacancy. The resistivity of the electron doped $CaMnO_{3-\delta}$ decreases as δ increases but remains semiconducting in the range 20–300 K. The superexchange interactions that lead to G-type AFM ordering in the $\delta = 0$, Mn(IV) material still dominate in the O-defect materials. However, the AF-domain canting appears hindered. Evidence of FM intra-cluster Mn(IV)–O–Mn(IV) interactions are found in the Curie constant enhancement with increasing δ. A large 40% MR is demonstrated in $CaMnO_{2.89}$. The difference in spins is illustrated in Fig. 11.15.

The magnetoresistive "electron"-doped materials $CaMnO_{3-\delta}$ ($\delta = 0.06,\ 0.11$) have been investigated by neutron diffraction. While both materials order at $T_N \sim 125$ K, they have unique yet related magnetic structures. The $CaMnO_{2.94}$ sample orders into a simple G-type AFM structure, shown on the left, which is also

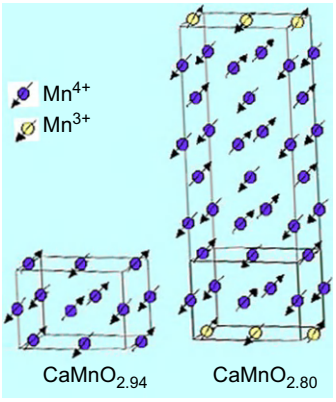

FIGURE 11.15

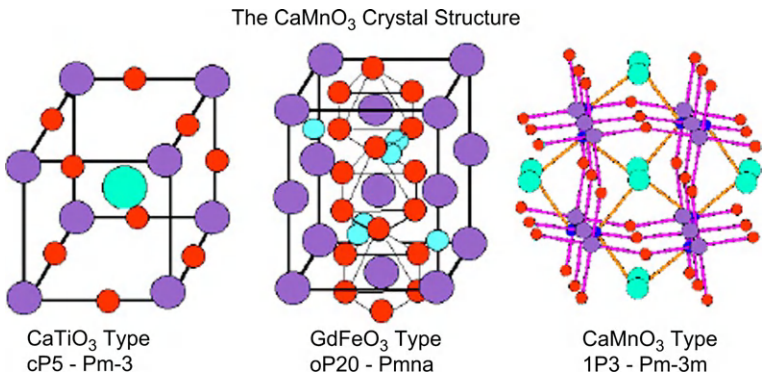

FIGURE 11.16

observed in $CaMnO_3$. The slightly more doped sample $CaMnO_{2.89}$, on the other hand, orders into a magnetic structure which is based upon the G-type, but also involves a Mn^{3+}/Mn^{4+} charge ordering over every four layers in the crystallographic *c* direction (shown on the right). The potential of these kinds of materials as new magnetic recording media is great, but the mechanism for such magnetoresistive behavior is poorly understood. Studies such as this demonstrate how subtle crystal chemistry effects can result in dramatic differences in the properties of materials.

The changes in structure as a function of oxygen defects have been studied. Polarized Raman spectra of oriented finely twinned $CaMnO_3$ thin films and nonpolarized Raman spectra of $CaMnO_3$ ceramics were studied at room temperature using several excitation laser wavelengths. The selection rules for the polarized Raman spectra, obtained from samples consisting of finely twinned orthorhombic domains, were calculated and the symmetry of all observed Raman lines was determined. The relationship between the intensity of the Raman lines and the distortions in the ABO_3 perovskites with $GdFeO_3$-type structure is discussed. These distortions can be described as superposition of four simple basic distortions: two MnO_6 octahedral tilts, Jahn–Teller deformation of $Mn^{3+}O_6$ octahedra, and shift of the A ions from their sites in the ideal perovskite. Twenty of the 24 Raman-allowed modes in the real $GdFeO_3$-type structure have counterparts in only one of the four simpler structures, obtained by a single basic distortion. The assignment of the Raman lines of $CaMnO_3$ to definite atomic vibrations, most of them activated by a single basic distortion, was made in close comparison with the results of lattice dynamical calculations and the Raman spectra of isostructural $LaMnO_3$ and $CaGeO_3$.

The three homologous crystal forms of $CaMnO_3$ are shown in Fig. 11.16.

The cell parameters are:

$GdFeO_3$ type

$a = 5.34$ Å, $b = 5.38$ Å, $c = 7.57$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 217.48$ Å^3, $Z = 4$.

Cell occupancy is shown in Table 11.9.

$CaTiO_3$ type

$a = b = c = 3.774$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 53.57$ Å^3, $Z = 1$. Cell occupancy is shown in Table 11.10.

$CaMnO_3$ type

$a = b = 5.333$ Å, $c = 7.534$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 214.27$ Å^3, $Z = 4$.

Cell occupancy has not been documented.

In addition to the 1:1 compound described above, the $2CaO–3MnO_2$ compound, dicalcium tri-manganate, $Ca_2Mn_3O_8$, is also known. $Ca_2Mn_3O_8$ and $Cd_2Mn_3O_8$, which contain Mn^{4+} monolayers, have also been

prepared and characterized. Their magnetic susceptibility and electron paramagnetic resonance behavior have been examined in detail. The Mn^{4+} moments in both $Ca_2Mn_3O_8$ and $Cd_2Mn_3O_8$ form an AFM order near 60 and 10 K, respectively. Although the Néel temperature in $Ca_2Mn_3O_8$ is in reasonable agreement with molecular-field theory, that in $Cd_2Mn_3O_8$ is well below its expected value. It is proposed that these results, as well as those in the calcium manganite series $CaMnO_3$–Ca_2MnO_4, may reflect the chemical influence of the divalent cation in modifying the Mn–O covalent mixing. It has the monoclinic structure shown in Fig. 11.17.

Cell parameters are: $a = 4.942$ Å, $b = 5.851$ Å, $c = 6.2358$ Å, $\alpha = 117.98°$, $\beta = 107.35°$, $\gamma = 90°$, $Z = 2$. Cell volume = 149.89 Å^3. Cell occupancy is listed in Table 11.11.

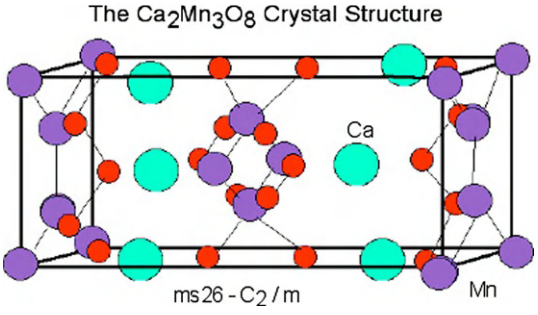

FIGURE 11.17

Another type of structure exists in this system. The dicalcium manganate compound, Ca_2MnO_4 has the structure shown in Fig. 11.18.

Cell parameters are: $a = b = 5.183$ Å, $c = 12.6031$ Å, $\alpha = \beta = 101.866°$, $\gamma = 90°$, cell volume = 323.93 Å^3, $Z = 4$. Cell occupancy is listed in Table 11.12.

The first member of the Ruddlesden–Popper (RP) family, Ca_2MnO_4, has two structures, as has been shown by electron microscopy at room temperature and neutron diffraction data. These are both AFM structures at low temperature. Two forms, with an orthorhombic

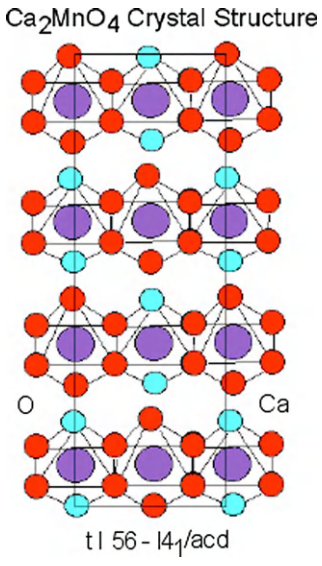

FIGURE 11.18

*Aba*2 ($a \approx b \approx \sqrt{2}$ and $c \approx 12$ Å) and a tetragonal $I4_1/cad$ ($a \approx a_p\sqrt{2}$ and $c \approx 24$ Å) symmetry, were found to coexist coherently within the same matrix.

In another study, an analysis of the electronic and magnetic properties of Ca_2MnO_4 and $Ca_2MnO_{3.5}$ was carried out within local-spin density functional theory using the augmented spherical wave method. From energy differences between the hypothetic magnetic configurations both systems were found to be insulating antiferromagnets in the ground state with a 1 eV gap. However, an intermediate half metallic FM state with the Hund's rule expected moments for Mn^{IV} (3 μBar) and Mn^{III} (4 μBar, high-spin HS configuration), respectively. The latter result of moment magnitude finds support in recent experimental evidence of Mn^{III} bismuth oxide as a ferromagnet in its ground state. This is characterized by a small DOS magnitude of itinerant states in spin (⇑) channel pointing to a metallic-like behavior as it is experimentally evidenced. For both Ca_2MnO_4 and $Ca_2MnO_{3.5}$ the chemical bonding characteristics are resolved for the two spin channels.

The enthalpies of oxidation of $Ca_2MnO_{4-\delta}$ have been determined by in situ oxidation in a high-temperature adiabatic calorimeter. Ca_2MnO_4, was synthesized by the EDTA precursor or the ceramic method, and partly reduced materials were prepared by topotactic reduction in diluted H_2 (5–10%) at 290–355 °C. Unit cell dimensions and oxygen stoichiometry of partly reduced and reoxidized materials were determined by powder XRD, thermogravimetry, and iodometric titration. The enthalpy of oxidation of $Ca_2MnO_{4-\delta}$ was more exothermic than for $CaMnO_{3-\delta}$. The enthalpy of oxidation was discussed in terms of basicity of oxides, the Goldschmidt tolerance factor, and the crystal structures of the oxidized and reduced materials.

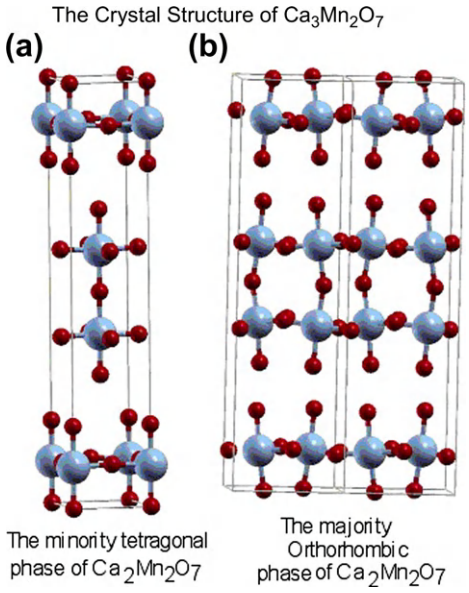

FIGURE 11.19

There is also a 3:1 compound in this system. Tricalcium di-manganate, $Ca_3Mn_2O_7$, is dimorphic. These homomorphs have the structure shown as follows. It consists of a tetragonal lattice and an orthorhombic phase (Fig. 11.19).

On the basis of density functional theory electronic band structure calculations using the augmented spherical wave method, the electronic and magnetic properties of the orthorhombic and tetragonal phases of $Ca_3Mn_2O_7$ were investigated and the spin exchange interactions of the orthorhombic phase were analyzed. The final calculations showed that the magnetic insulating states are more stable than the nonmagnetic metallic state for both polymorphs of $Ca_3Mn_2O_7$, the orthorhombic phase is more stable than the tetragonal phase, and the ground state of the orthorhombic phase is AFM. The total energies calculated for the three spin states of the orthorhombic phase of $Ca_3Mn_2O_7$ led to estimates of the spin exchange interactions $J_{nn} = -3.36$ meV and $J_{nnn} = -0.06$ meV. The accuracy of these estimates was tested by calculating the Curie–Weiss temperature within the mean-field approximation.

A compound, calcium hepta-manganate, $CaMn_7O_{12}$, contains the Mn^{3+} ion and has been found to have the structure as shown in Fig. 11.20.

Cell parameters are: $a = b = c = 5.206$ Å, $\alpha = \beta = \gamma = 60.406°$, cell volume $= 100.69$ Å^3, $Z = 2$. Cell occupancy is listed in Table 11.13.

The structural phase transition in $CaMn_7O_{12}$ has been investigated by using high-resolution synchrotron and neutron powder diffraction. Both measurements show

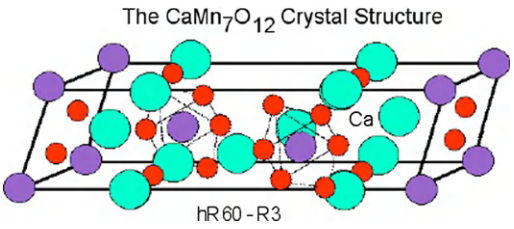

FIGURE 11.20

a phase coexistence phenomenon between 409 and 448 K and two different crystallographic phases coexist in the material. The first one is trigonal and it has a charge ordering (CO) of the Mn^{3+} and Mn^{4+} ions, while the second one is cubic and charge delocalized (CD). The volume fraction of the CD phase increases with temperature from 0 at 400 K up to 100% about 460 K. Both phases have domains of at least 150 nm at each temperature in the PS region. A percolation scenario assuming a growth of the volume of the highly conducting CD regions at the expense of the volume of the insulating CO matrix is discussed and it is found to be in agreement with literature data of the $CaMn_7O_{12}$ resistivity.

In the Mn^{3+} system, $CaO–M_2O_3$, the compound, tetra-calcium di-manganate, has the structure as shown in Fig. 11.21.

The structure encompasses the MnO_5^{5-} group coupled to a MnO_4^{4-} group. Cell parameters are: $a = 5.297$ Å, $b = 6.6598$ Å, $c = 10.053$ Å, $\alpha = \beta = 90°$, $\gamma = 113.434°$, cell volume $= 325.39$ Å^3, $Z = 4$. Cell occupancy is listed in Table 11.14.

In this type of compound, Mn^{2+} lies near the size borderline. It occupies the large site in $A_2Mn_2O_7$

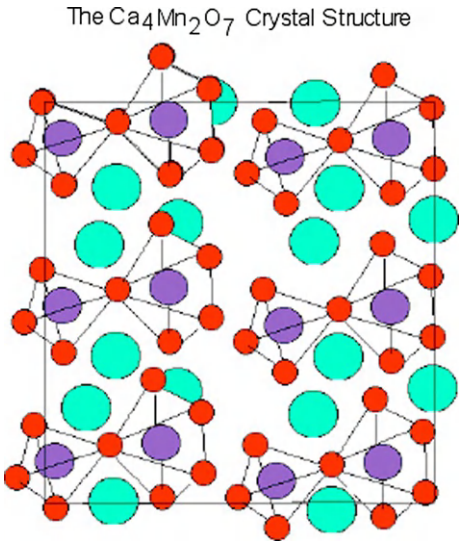

FIGURE 11.21

pyrochlores, contrary to Mn^{4+}, and occupies separate crystallographic sites in known mixed-valent $Mn^{2+}–Mn^{3+}$ or Mn^{4+} oxides. The bond distances, Mn–O–Mn bonding angles and Mn sublattice topology are given for the main Ae–Mn–O structures. Only the perovskite and K_2NiF_4 structures give Mn–O–Mn angles near 180°, while these are close to 90° in spinels, to 135° in pyrochlores and marokites. The magnetic properties of non-perovskite manganese oxides were briefly discussed in view of these structural features. The magnetic properties of oxides with intermediate superexchange angles are complex, especially when the manganese lattice is frustrated. This situation arises in two

important structural families, the spinels and the pyrochlores. As a result, mixed valence in spinels, which is easy to achieve, does not give rise to physical properties comparable to those of the so-called "manganites".

In the Mn^{5+} system of $CaO–Mn_2O_5$, the compound mono-calcium manganate is not known. The dicalcium and tricalcium compounds, $Ca_2Mn_2O_7$ and $Ca_3Mn_2O_8$, have not been discovered. The instability of the Mn^{5+} ion is probably the major contributor to lack of data concerning such compounds.

In the Mn^{6+} system of $CaO–MnO_3$, the electrical, physical and chemical properties of the manganate, $CaMnO_4$, are not described in the technical literature. The dicalcium and tricalcium manganates, Ca_2MnO_5 and Ca_3MnO_6, have never been prepared. It is doubtful if they actually exist.

In contrast, the calcium permanganate (VII) compound, $Ca(MnO_4)_2$ is offered for sale commercially in large lots as an oxidizer and as a bactericide with the CAS number of 10118-76-0. Because manganese is in the +7 state, the permanganate (VII) ion is a strong oxidizing agent. Permanganate solutions are purple in color and are stable in neutral or slightly alkaline media. Calcium permanganate can be prepared in solution by the reaction:

$$CaCl_2\ (aq) + 2NaMnO_4\ (aq) \Rightarrow CaMn_2O_8\ (solid) + 2NaCl$$

This compound is stable and is in common use in qualitative analysis that involves redox reactions (permanganometry). It is a useful reagent with organic compounds, but is not very selective. Manganates(VII) are not very stable thermally and decompose at low temperatures (180–280 °C), releasing oxygen gas.

Calcium manganates are readily available commercially. The calcium permanganate salt is thought to be a "tooth whitener".

11.2.4. Strontium Manganese Compounds

In the Mn^{2+} system of SrO–MnO, the compound, $SrMnO_3$, has not been described in the open scientific literature. The reason is that the stoichiometric compound is not stable while the defect compound, $SrMnO_{2.5+\delta}$, has been established as a stable compound. The compound, strontium hypomanganite, $SrMnO_{2.5}$ has been found to possess a defect structure (Fig. 11.22).

This phase crystallizes with orthorhombic symmetry in the space group *Bbcm* with lattice parameters, $a = 5.30$ Å, $b = 10.05$ Å, $c = 12.23$ Å. The oxygen vacancies form an ordered arrangement in the perovskite block layers to give an equivalent structure to the defect perovskites $SrMnO_{2.5}$ and $CaMnO_{2.5}$ consisting of corner connected MnO_5 square-based pyramids. In these isostructural phases, the manganese ions are in square pyramidal coordination, and are subject to AFM coupling with three neighboring Mn^{3+} ions, and FM coupling with two others. It is shown that the structure of $Sr_2MnO_{3.5-\delta}$ contains Mn–O layers with a different ordering pattern to that reported previously for layers with the same overall composition, $MnO_{1.5}$. As a result of the different packing of the square pyramidal MnO_5 units, a new magnetic structure is formed below the Neel temperature.

The related compounds, dicalcium- and tri-calcium-hypomanganite, Sr_2MnO_3 and Sr_3MnO_4, have also not been synthesized. Their existence remains in doubt.

In the Mn^{3+} system of $SrO–Mn_2O_3$, very little data concerning the compound, $SrMn_2O_4$ is available. The reason is that the stoichiometric compound is not stable while a defect state is more stable. Thus, a compound like $SrMn_2O_{3.5+\delta}$ has been thoroughly studied because it exhibits a large negative magnetoresistance effect while $SrMn_2O_4$ does not. The Mn^{3+} ion is so unstable that, in acidic solution, it disproportionates to Mn^{2+} and MnO_4^{4-} in solution.

However, the related compound, Sr_2MnO_5 has been reported. The crystal and magnetic structure of $SrMn_{0.5}O_{2.5}$ has been investigated by neutron power diffraction from 20 to 425 K. The compound has orthorhombic crystal structure with the unit cell dimensions $a = 5.5307$ Å, $b = 10.7829$ Å, $c = 3.8145$ Å at 425 K, where space group is *Pbam* and $Z = 4$ (Fig. 11.23).

The structure is related to $SrMnO_{2.5+\delta}$ except that the Sr^{2+} ions are ordered, not disordered. Below $T_N = 375$ K, an AFM ordering occurs and the magnetic unit cell is orthorhombic with the dimensions $am = ac$, $bm = bc$, $cm = 2cc$, where ac, bc and cc are the parameters of the crystallographic unit cell. The FM and AFM coupling coexist in the c-plane according to the difference of Mn–O–Mn angle and the coupling between adjacent planes is AFM. The direction of the magnetic moments

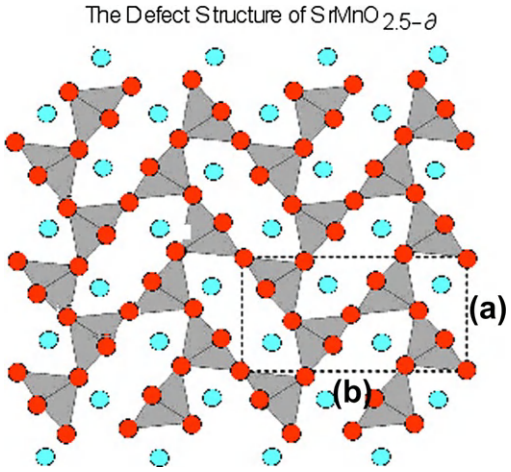

FIGURE 11.22

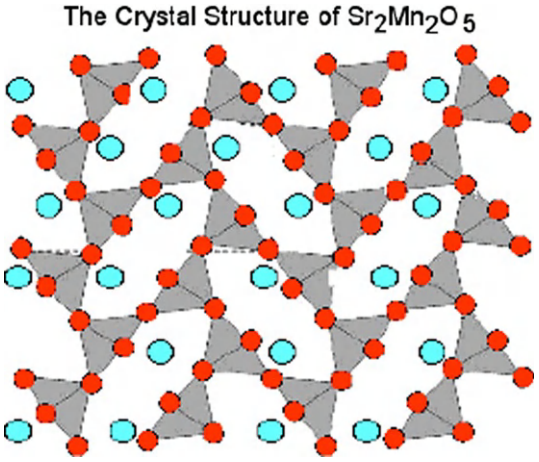

FIGURE 11.23

is along the crystallographic *b*-axis. The magnitude of magnetic moment at 20 K is 3.44 μbar per Mn. The resolution of the magnetic structure at room temperature and 4.2 K shows that the Mn^{+3} ions (d^4) order with a propagation vector $k = (0,0,1/2)$ and a magnetic moment of 3.2 μbar at 4.2 K. Each manganese ion is in square pyramidal coordination, and is coupled antiferromagnetically with three neighbors and ferromagnetically with two others.

Grossly non-stoichiometric perovskite-related $Sr_2Mn_2O_{5-\delta}$ oxide was used to exhibit the distribution of oxygen vacancies in this type of compound. The distribution remains even at high temperatures and is far from random. This behavior occurs with relatively few configurations and is associated with different arrangements of tetrahedral BO_4, square pyramidal BO_5 and octahedral BO_6 entities that are thermally accessible at most temperatures. A plot of this compound in terms of energy versus: degeneracy is given in the following diagram shown in Fig. 11.24.

Since the Sr^{2+} ions are evenly distributed, even at high temperature, the oxygen-vacancies remain evenly distributed as well. This behavior is rarely found in other alkaline earth compounds and most have a randomly distributed vacancy network. In this phase, oxygen vacancies are ordered in lines running along one of the (100) directions of the parent cubic perovskite system. Oxygen-vacancy ordering allows the charge and orbital ordering of the Mn^{3+} and Mn^{4+} cations.

A related compound, $Sr_3Mn_2O_6$, is known to exist. The oxygen-deficient RP phase $Sr_3Mn_2O_6$ crystallizes with an ordered array of oxygen vacancies to afford a structure in which the Mn^{3+} ions exist in a square-pyramidal environment. The MnO_5 polyhedra are linked through their corners to form a structure that is related to that observed for the single-layered material, $Sr_2MnO_{3.5}$. Due to the unique interlayer ordering, both phases have a magnetic structure that consists of FM clusters of four corner-sharing MnO_5 pyramids that are antiferromagnetically ordered relative to each other (Fig. 11.25).

The superstructure is due to the oxygen vacancies ordering in these compounds, an ordering which is different from that in the defect perovskites $SrMnO_{2.5}$ and $Ca_2MnO_{3.5}$. Both $Sr_2MnO_{3.5}$ and $Sr_3Mn_2O_{6+x}$ have an interlayer ordering of the same type of structure with elongated pseudo-hexagonal channels, formed by

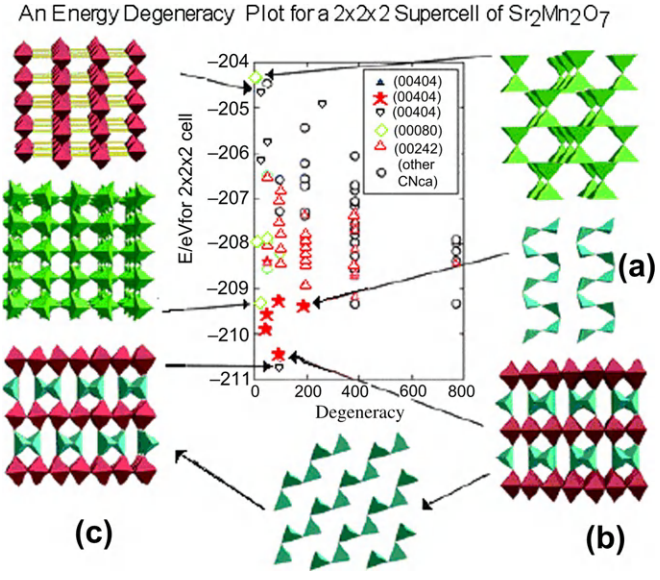

FIGURE 11.24

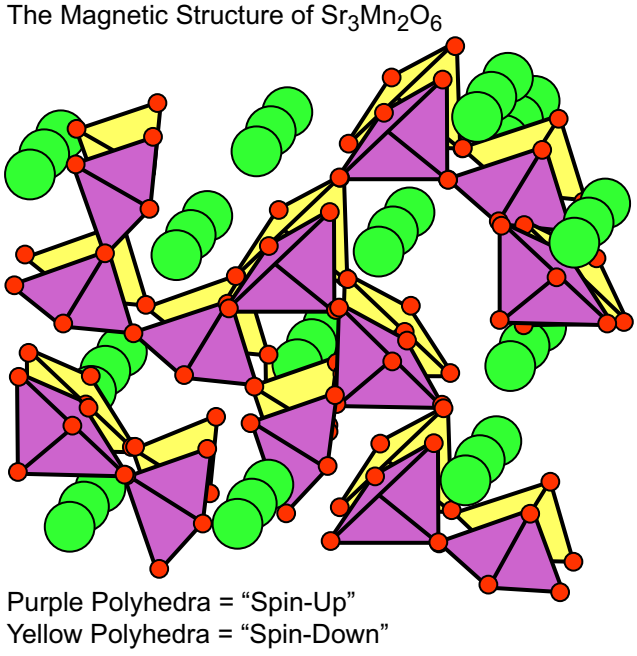

FIGURE 11.25

corner-connected MnO_5 square-based pyramids. The stacking in the two compounds, however, occurs in a different manner, leading to a monoclinic cell in the first case, and a tetragonal one in the second. Neutron powder diffraction refinements confirmed a unique model.

In another paper, the nuclear and magnetic structures of a polycrystalline sample of $Sr_3Mn_2O_6$ have been determined using Rietveld analysis of neutron powder diffraction data and electron diffraction (ED) techniques. The pure Mn^{3+} double-layered phase crystallizes in a superstructure of the simple RP subcell: tetragonal, $P4 = mbm$; $a = 10.8686$ Å and $c = 20.2051$ Å. Magnetic susceptibility studies suggest a transition at 250 K to a canted AFM ordered structure. The magnetic unit cell consists of FM clusters of corner-sharing MnO_5 units, which are antiferromagnetically aligned to other clusters within the layers. The double-layered RP phase $Sr_3Mn_2O_{6+x}$ crystallizes with the oxygen vacancies forming an ordered array in the "MnO_2" layers of the perovskite blocks. The vacancies order to give a similar layer structure to $Sr_2MnO_{3.5}$ consisting of corner connected Jahn–Teller distorted MnO_5 square-based pyramids. The primitive tetragonal structure shows complete oxygen vacancy ordering in the perovskite block layers at $z = 0$ and 1; whereas only partial order is observed in the middle layer at z 1/4 1 2: $Sr_3Mn_2O_{6+x}$ orders antiferromagnetically below ca. 250 K and the magnetic structure contains FM clusters aligned antiferromagnetically to each other within the perovskite block layers.

The Mn^{4+} system involving SrO–MnO_2 has been studied extensively because of its electrical properties. The compound, $SrMnO_3$, is a perovskite. The compound, Sr_2MnO_4, has a body-centered tetragonal structure and a reduced phase $Sr_2MnO_{3.84}$ is reported to contain the oxygen vacancies in the "MnO_2" layers (equatorial positions) in a disordered array. The magnetic structure of Sr_2MnO_4, is analogous to that of K_2NiF_4. The magnetic unit cell shows a doubling along the *a*-axis, with the magnetic moments parallel to the *c*-axis exhibiting AFM ordering with $T_N \approx 170$ K. This contrasts with the magnetic structure of Ca_2MnO_4 where the *c*-axis was doubled for the magnetic cell. A related double-layered oxygen-deficient strontium manganite, $Sr_3Mn_2O_{6.35}$ has also been reported. This RP structure also has the oxygen defects located in the equatorial "MnO_2" layers, but again, similar to $Sr_2MnO_{3.84}$, these vacancies are found to exist in a disordered manner.

Perovskites containing Mn in mixed $Mn^{3+/}Mn^{4+}$ oxidation states have been the focus of much attention owing to their ability to display large negative magnetoresistance effects upon application of magnetic fields of the order of several tesla. The study of these manganese oxides, widely known as manganites, that exhibit the CMR effect is among the main areas of research within the area of Strongly Correlated Electrons. After considerable theoretical effort in recent years, mainly guided by computational and mean-field studies of realistic models, considerable progress has been achieved in understanding the curious properties of these compounds. These recent studies suggest that the ground states of manganite models tend to be intrinsically inhomogeneous due to the presence of strong tendencies toward phase separation, typically involving FM metallic and AFM charge and orbital ordered insulating domains. Calculations of the resistivity versus temperature using mixed states lead to a good agreement with experiments. The mixed-phase tendencies have two origins: (i) electronic phase separation between phases with different densities that lead to nanometer scale coexisting clusters, and (ii) disorder-induced phase separation with percolative characteristics between equal-density phases, driven by disorder near first-order metal-insulator transitions. The coexisting clusters in the latter can be as large as a micrometer in size. In addition, the physics of manganites appears dominated by intrinsic inhomogeneities and its description is quite difficult in purely analytic frameworks that usually assume uniform states.

The field of manganites started with the seminal paper of Jonker and van Santen (1950) where the existence of ferromagnetism in mixed crystals of $LaMnO_3$–$CaMnO_3$, $LaMnO_3$–$SrMnO_3$, and $LaMnO_3$–$BaMnO_3$ was reported. Various types of structures are obtained as a function of preparation temperature. The following diagram illustrates this factor, obtained by ED techniques (Fig. 11.26).

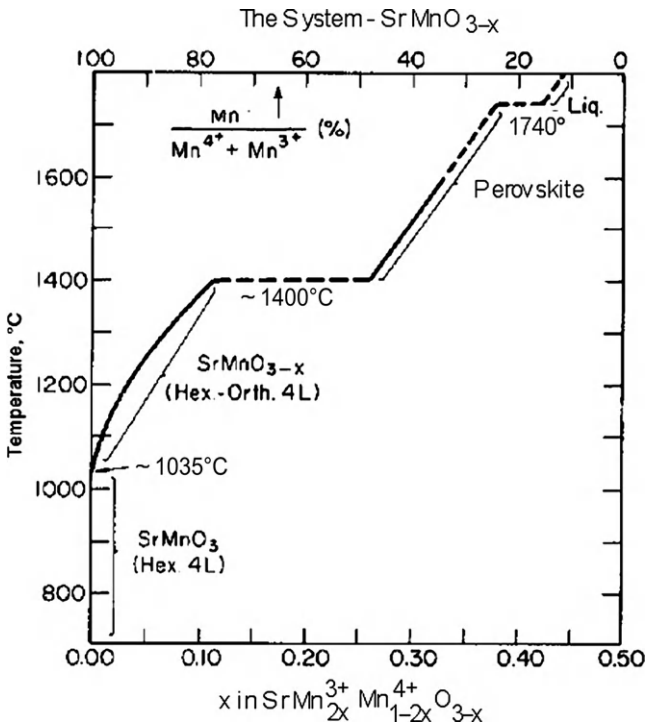

FIGURE 11.26

The pure Mn^{3+} single-layered phase crystallizes in the primitive monoclinic space group $P2_1/c$ with lattice constants $a = 6.8524$ Å, $b = 10.8131$ Å, $c = 10.8068(4)$ Å, $\beta = 113.247°$. The oxygen defects form an ordered superstructure within the perovskite block layers consisting of interconnected MnO_5 square pyramids, slightly different from those observed for the defect perovskites $SrMnO_{2.5}$ and $Ca_2MnO_{3.5}$. Magnetic susceptibility studies show a broad transition at 280 K, which is attributed to an overall AFM ordering of spins, which leads to doubling of the unit cell along [100]. The magnetic unit cell comprises FM clusters of four corner-sharing MnO_5 pyramids, which are antiferromagnetically aligned to other similar clusters within the perovskite block layers.

α-$SrMnO_{3.5-\delta}$ crystallizes in the hexagonal system with unit cell dimensions $a = 5.454$ Å, $c = 9.092$ Å, space group $P6_3/mmc$, $Z = 4$. The structure was solved by the heavy-atom method; of 404 unique reflections measured by counter method, 203 that obeyed the condition $|F_0| \geq 3\sigma$ ($|F_0|$) were used in the refinement to a conventional R value of 0.043. The structure consists of four close-packed SrO_3 layers in an $ABAC$ stacking sequence along the hexagonal c-axis. Oxygen octahedra containing Mn^{4+} are grouped into face-sharing pairs linked by corner sharing within the cubically stacked "A" layer.

Dilatometric measurements were used to determine phase transition temperatures and oxidation temperatures of $Sr_2MnO_{4-\delta}$ and several phases in the system $SrMnO_{3-\delta}$. The use of dilatometry is based on differences among the molar volume of the various phases determined by XRD. Oxidation of $SrMnO_{3-y}$ and $Sr_2MnO_{4-y'}$ proceeded without change in the basic structure of perovskite and K_2NiF_4 type, respectively. Anion vacancies produce lattice expansion in reduced Sr_2MnO_{4-y} and $SrMnO_{3-y}$ compared with $Sr_2MnO_{4.00}$ and β-$SrMnO_{3.00}$. In the case of $SrMnO_{2.58}$, the ratio of lattice constants indicates narrow structural relations to β-$SrMnO_3$.

The nuclear and magnetic structures of polycrystalline $Sr_2MnO_{3.5}$ have been determined by the Rietveld analysis of neutron powder diffraction data and ED techniques. The pure Mn^{3+} single-layered phase crystallizes in the primitive monoclinic space group $P2_1/c$ with lattice constants $a = 6.8524(3)$ Å, $b = 10.8131(4)$ Å, $c = 10.8068(4)$ Å, $\beta = 113.247(4)°$. The oxygen defects form an ordered superstructure within the perovskite block layers consisting of interconnected MnO_5 square pyramids, slightly different from those observed for the defect perovskites $SrMnO_{2.5}$ and $Ca_2MnO_{3.5}$. Magnetic susceptibility studies show a broad transition at ~280 K, which is attributed to an overall AFM ordering of spins, which leads to doubling of the unit cell along [100]. The magnetic unit cell comprises FM clusters of four corner-sharing MnO_5 pyramids, which

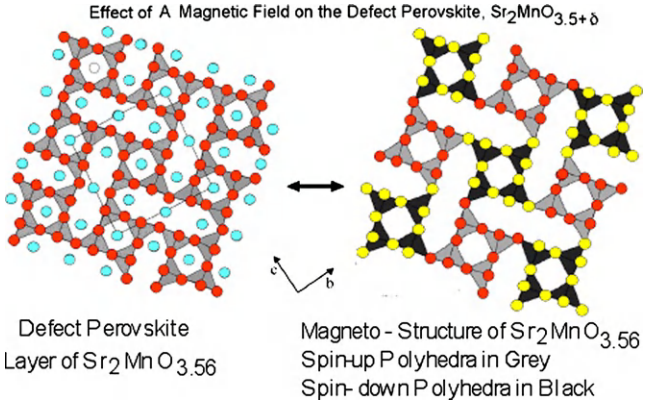

FIGURE 11.27

are antiferromagnetically aligned to other similar clusters within the perovskite block layers. The effect of a magnetic field upon the structure of the defect perovskite, $Sr_2MnO_{3.56}$ composition is shown in Fig. 11.27.

ED (electron diffraction) studies clearly revealed a superstructure implying an ordering of the oxygen vacancies to give a primitive monoclinic cell with $a = 6.85$ Å, $b = 10.28$ Å, $c = 10.26$ Å, $\beta = 104.61°$. Rietveld structure refinement based on various plausible distributions of the oxygen vacancies showed that only one arrangement appeared consistent with such a large unit cell in the bc plane, ca. 10×10 Å. The arrangement, which corresponds to $P2_1/c$ symmetry, is similar to that seen for the ordered perovskite $SrMnO_{2.5}$. The Mn^{3+} ions have the electronic configuration $t_{2g}^3 e_g(dz^2)^1$ and the magnetic exchange between adjacent square-based pyramids can be ascertained by the interactions between the singly occupied dz^2 orbitals, and the perpendicular, empty dx^2-y^2 orbitals. This leads to the prediction of FM exchange when a connecting oxygen anion links a dz^2 orbital with a vacant dx^2y^2 orbital, and an AFM alignment upon interaction of two dz^2 orbitals. Hence, the intralayer magnetic structure was deduced as clusters of four ferromagnetically aligned moments, which are arranged antiferromagnetically to other clusters within the perovskite block layers. This behavior may be summarized as:

> "The single-layered phase $Sr_2MnO_{3.5}$ crystallizes with the oxygen vacancies forming an ordered array in the "MnO_2" layers of the perovskite block. Although the defect structure formed can be compared with that found in the oxygen-deficient perovskite $SrMnO_{2.5}$ and the analogous $Ca_2MnO_{3.5}$, the vacancies order to give a new type of structure of corner connected Jahn–Teller distorted MnO_5 square-based pyramids. $Sr_2MnO_{3.5}$ orders antiferromagnetically below 280 K and the magnetic structure contains FM clusters aligned antiferromagnetically to each other within the perovskite block layers".

The tri-strontium di-manganate is also known. The structure is shown in Fig. 11.28.

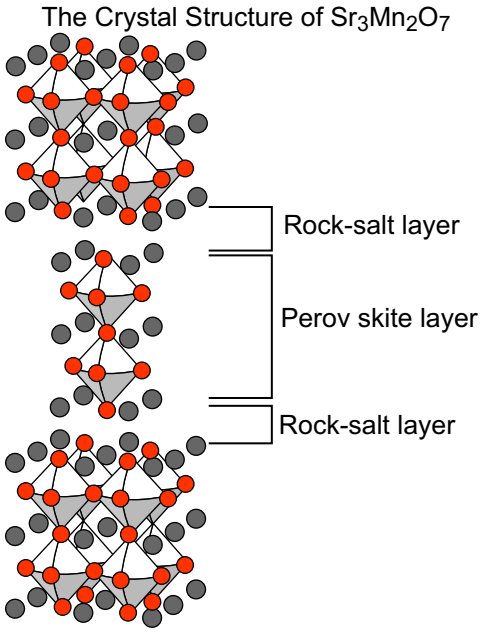

FIGURE 11.28

The crystal and magnetic structures of the bilayer RP phase $Sr_3Mn_2O_{7-\delta}$ ($\delta = 0.0,\ 0.45$). The $\delta = 0.45$ compound exhibits a large number of oxygen vacancies that are disordered in the MnO_2 planes and is a nonmagnetic insulator. $Sr_3Mn_2O_{7.0}(\delta = 0)$ in an AFM insulator whose magnetic structure is analogous to that of the related $SrMnO_3$ perovskite. The stoichiometric layered material has a small distortion of its exclusively $Mn^{4+}O_6$ octahedra as a result of steric influence of the surrounding cations. Thus, it provides a baseline for structural distortions related to electronic and/or magnetic transitions in doped materials.

Polycrystalline $Sr_3Mn_2O_{6.54}$ and $Sr_3Mn_2O_7$ layered manganites were studied at room temperature using Raman spectroscopy. While the phonon spectrum of the stoichiometric $Sr_3Mn_2O_7$ sample is consistent with the group theoretical analysis for the $I4/mm$ structure, three additional modes are observed in the phonon spectrum of the oxygen-deficient $Sr_3Mn_2O_{6.54}$ sample. Based on an analysis of the temperature dependence of the Raman spectrum of $Sr_3Mn_2O_{6.54}$ and a comparison with the Raman spectrum of $LaSr_2Mn_2O_7$, we conclude that the "extra" modes should be viewed as disorder-induced Raman scattering.

The electronic structure of the RP layered perovskite compound $Sr_3Mn_2O_7$ was studied from density functional calculations using the linear muffin-tin orbital method. An AFM, insulating solution is obtained in agreement with the experiments, with a magnetic moment of about 2.52 bar for each Mn atom. The magnetic interactions between the Mn atoms, both within the bilayer and between the bilayers, are shown to arise from superexchange. The intrabilayer interaction involves the three-site Mn–O–Mn superexchange much like the case of the well-known $CaMnO_3$, while the interbilayer exchange, mediated via the longer Mn–O–O–Mn superexchange path, is considerably weaker. Consistent with the layered nature of the compound, a strong out-of-plane to in-plane band-mass anisotropy for $Sr_3Mn_2O_7$ ($mz^*/mx,y^* = 10.9$ for electrons and -4.2 for holes) was found, while for the related compound $LaSr_3Mn_2O_7$, which is a FM metal, a strong anisotropy in the resistivity $\rho c/\rho_{ab}$-40 using kinetic transport theory, in qualitative argument with the experimental value of ~100 was obtained.

Transition metal oxides have been extensively studied due to the complex interactions between the different order parameters. The layered manganites have shown long-range magnetic, charge, orbital and correlated structural distortions. Such order parameters in the RP group, $(La,Sr)_{n+1}Mn_nO_{3n+1}$ have been studied with a variety of techniques. The resonant X-ray scattering results for the bilayer, $n = 2$ member, with $x = 0.7$ is shown in the following figure, Fig. 11.29. This overdoped system has a hole density provided by the doped strontium ions sufficient for the usual half doped CE checkerboard to become unstable. Indeed, this breakdown of the 1:1 checkerboard pattern and associated herringbone orbital order has been observed to collapse with $x \approx 0.575$. Further investigations have suggested that the orbital and charge order are caused to melt through the onset of AFM order. In contrast, no such long-range magnetic order has been observed in $La_{0.6}Sr_{2.4}Mn_2O_7$.

The phase diagram for the bilayer manganite series $La_{2-2x}Sr_{1+2x}Mn_2O_7$ ($0.35 < x < 0.75$) is shown in Fig. 11.30.

Data points marked by X show the onset of charge order (and JT) through the appearance of superlattice reflections, X data points mark the maxima in the intensity of the CO (or JT) reflections, interpreted as the onset of A-type AFM order. The data points marked by symbols are taken from prior publications. The phase diagram for the bilayer manganites, showed a general transition from a FM phase in the underdoped system, to an AFM phase around half doping, to a paramagnetic overdoped system as a function of increasing doping. Charge order and cooperative Jahn–Teller distortions are observed in the half doped and overdoped systems. It has been previously shown that the CE checker board charge order breaks down at $x \approx 0.575$, and through resonant XRD it is suggested that the formation of a charge density wave and associated orbital density wave in the $x = 0.7$ system becomes dominant.

In the Mn^{5+} system of $SrO–Mn_2O_5$, the compound, $SrMn_2O_6$, has been discovered. The structure is illustrated in Fig. 11.31.

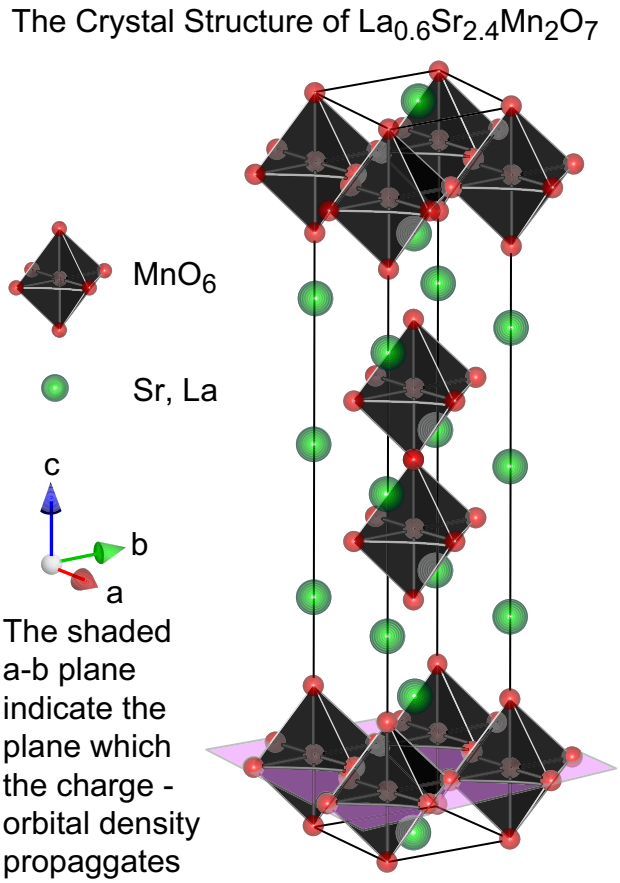

FIGURE 11.29

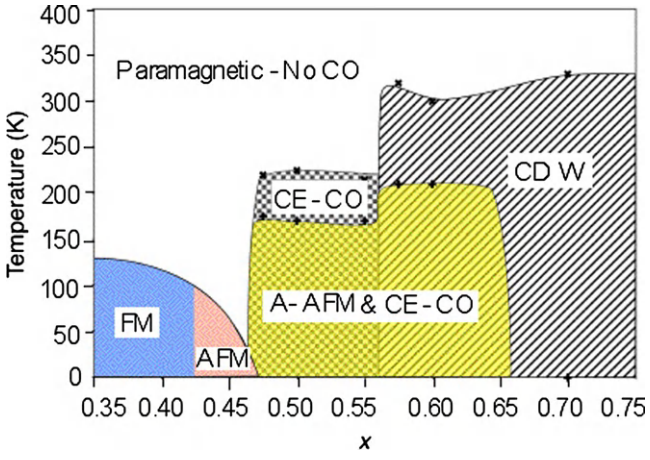

FIGURE 11.30

$SrMn_3O_6$ exhibits an incommensurately modulated structure. This strontium manganate phase has been synthesized and characterized by structural refinement of NPD data using a 4D formalism. The structure can be described by edge-sharing MnO_6 octahedra, which

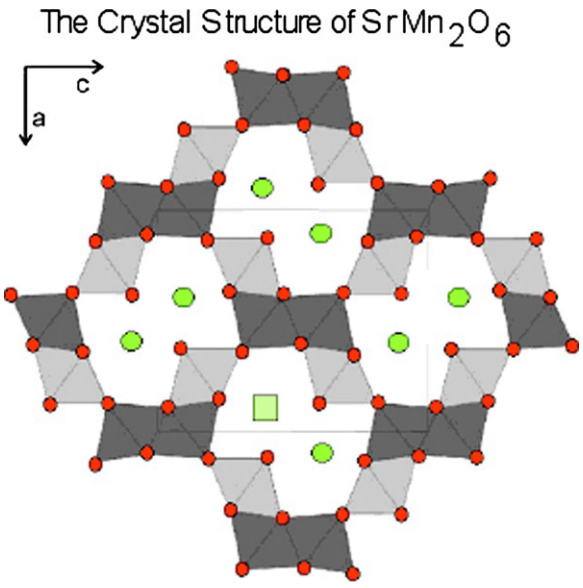

FIGURE 11.31

exist in groups of four, in a distorted z-shape. These z-shaped units form an infinite ribbon along the short *b*-axis of the unit cell, and are corner linked to four other z-shaped units to give double tunnels shaped like a figure of eight. The Sr cations are located in 67% of the available tunnel sites.

$SrMn_3O_6$ exhibits an average distorted tunnel structure with the same basic features as $Na_xFe_xTi_{2-x}O_4$ and $BaPb_{1.5}Mn_6Al_2O_{16}$, but a complicated incommensurate 1D modulation is present with modulation wave-vector components $\mathbf{q} = 0.52a + 0.31b$. The existence of ordered strontium vacancies is implied from the structural refinement and this constitutes the main driving force of the modulation in $SrMn_3O_6$; the slight distortion of the Mn–O framework can be attributed to this ordering of strontium and vacancies. It could therefore be proposed that the $BaPb_{1.5}Mn_6Al_2O_{16}$ may also exhibit a similar type of modulation since the tunnel sites are again only partially occupied. The most intense reflections are the basic reflections, which correspond to the Pnma subcell with $a = 9.1334$ Å, $b = 2.8219$ Å and $c = 12.0959$ Å.

The electronic structure of the RP layered perovskite compound $Sr_2Mn_2O_7$ has been studied from density functional calculations using the linear muffin-tin orbitals method. An AFM, insulating solution was obtained, with a magnetic moment of about 2.52 μbar for each Mn atom. The magnetic interactions between the Mn atoms, both within the bilayer and between the bilayers, were shown to arise from superexchange. The intrabilayer interaction involves the three-site Mn–O–Mn superexchange much like the case of the well-known $CaMnO_3$, while the interbilayer exchange, mediated via

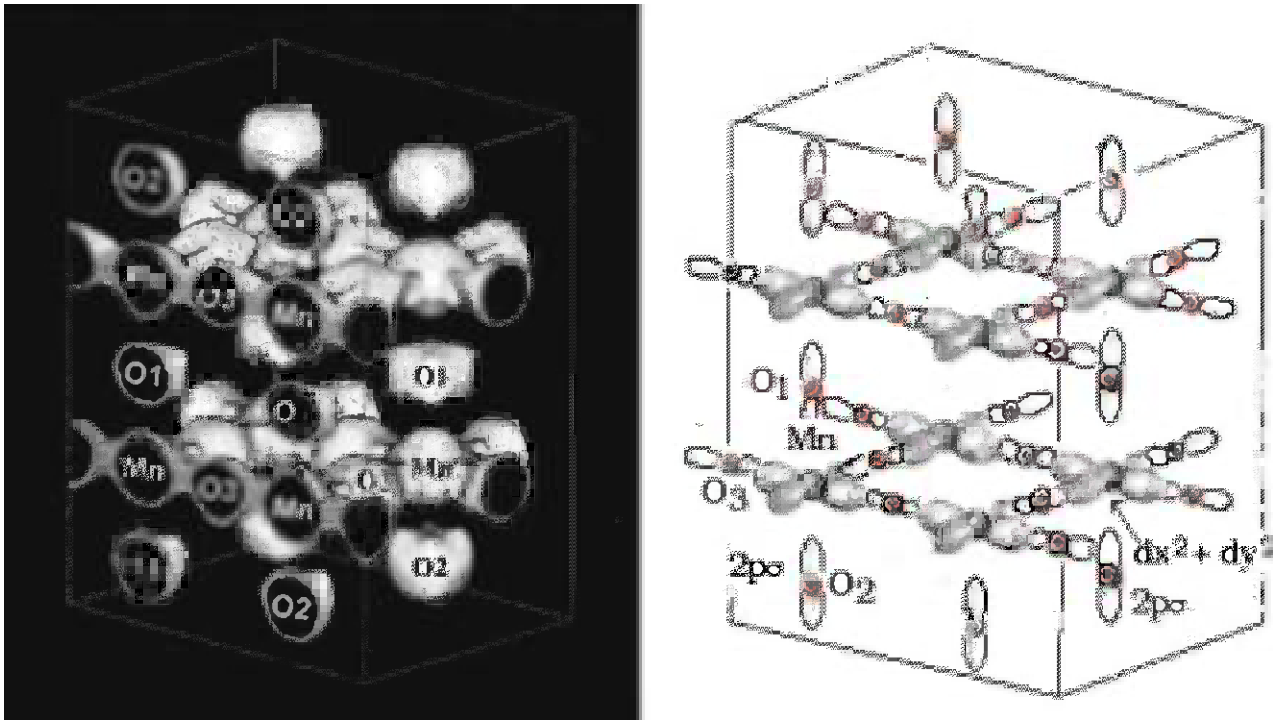

FIGURE 11.32

the longer Mn–O–O–Mn superexchange path, is considerably weaker. Consistent with the layered nature of the compound, a strong out-of-plane to in-plane band-mass anisotropy for $Sr_3Mn_2O_7$ ($mz^*/mx,y^* \sim 10.9$ for electrons and ~4.2 for holes) was seen, while for the related compound $LaSr_2Mn_2O_7$, which is a FM metal, a strong anisotropy in the resistivity $rc/rab \sim 40$, using kinetic transport theory, in qualitative agreement with the experimental value of ~100 was obtained. The following diagram shows contours containing a charge density of 0.4 eÅ^3, obtained by the maximum-entropy analysis of synchrotron-X-ray powder diffraction data for $NdSr_2Mn_2O_7$ at 19 K, showing the MnO_6 double layers. The schematic orbital structure is also shown in Fig. 11.32.

In a study of the composition, $(Nd_{12x}La_x)Sr_2Mn_2O_7$, researchers found a narrow, charge order CE AFM regime to exist on the La-rich end of the series, that dominates in a narrow temperature range between 110 and 220 K. On further cooling, the resistivity of $LaSr_2Mn_2O_7$ first increases sharply at the charge ordering transition, reaches a maximum, and then decreases to a minimum near 100 K. Single-crystal neutron-scattering data provide greater detail. A-type AFM order and CE-type charge order appear simultaneously at 210 K. This coincides with a decrease in diffuse magnetic scattering. Near 120 K, the CE-type charge ordering disappears and a weak, CE-type AFM peak appears.

In the Mn^{6+} system of SrO–MnO_4, the compound $SrMnO_4$ has been used for organic synthesis. Strontium manganate ($SrMnO_4$) in the presence of aluminum chloride ($AlCl_3$) is an efficient reagent for the high-yielding oxidative deprotection of aromatic and aliphatic silyl and pyranyl ethers into their corresponding carbonyl compounds, in solution and under solvent-free conditions (Fig. 11.33).

Yields are in excess of 95% for a great number of compounds.

The oxygen-deficient RP phase Sr_3MnO_6 is a double-layer manganite that crystallizes with an ordered array of oxygen vacancies to give a structure containing $Mn(VI)O_5^{4-}$ square-pyramidal polyhedra. The MnO_5 polyhedra are linked through their corners to form a structure that is related to that observed for the single-layered material, $Sr_2MnO_{3.5}$. At 250 K, there is a transition to a canted AFM ordered structure. The magnetic unit cell consists of FM clusters of corner-sharing MnO_5 units, which are antiferromagnetically aligned to other clusters within the layers.

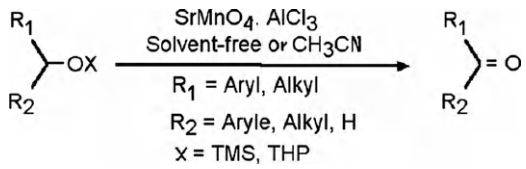

FIGURE 11.33

The crystal and magnetic structures of the bilayer RP phase $Sr_3Mn_2O_{7-\delta}$ ($\delta = 0,0.45$) were investigated. A correlation of these structures with their magnetic and transport properties was made. The $\delta = 0.45$ compound contains a large number of oxygen vacancies that are disordered in the MnO_2 planes. As a result of this disordered vacancy structure, $Sr_3Mn_2O_{6.55}$ is a nonmagnetic insulator. $Sr_3Mn_2O_{7-\delta}$ ($\delta = 0$) is an AFM insulator whose magnetic structure is related to that of the $SrMnO_3$ perovskite. Comparison of this end-member compound to its doped congeners in the $\gamma La_{2-2x}Sr_{1+2x}Mn_2O_7$ series highlights the extreme sensitivity of magnetic structure to dopant concentration in these layered materials.

The magnetic and structural properties of the layered manganite $Sr_7Mn_4O_{15}$ have been studied by powder neutron diffraction and magnetic susceptibility techniques between 5 and 300 K. The structure consists of pairs of face-sharing MnO_6 octahedra to form Mn_2O_9 dimers. The description of the crystal structure has been improved by employing a model in which some of the Sr and O ions are statistically distributed over two different sites. Three different magnetic phases can be distinguished in the temperature region studied. Below ~75 K, the Mn^{4+} sublattice is antiferromagnetically ordered with an antiparallel alignment between all nearest-neighbor manganese ions. Between ~75 and ~150 K extensive quasi two-dimensional (2D) magnetic clusters are present. At temperatures above ~150 K, one can observe correlations related to intradimer spin pairing. Truly paramagnetic behavior is not observed at any temperature below 300 K.

Low-temperature topotactic reduction reactions can exhibit remarkable selectivity. The reaction of the complex Mn(IV) oxide $Sr_7Mn_4O_{15}$ with CaH_2 selectively removes only oxide ions which link MnO_6 octahedra in a corner shared manner, leaving the rest of the anion lattice in place (Fig. 11.34).

The preparation of the Mn(III) phase $Sr_7Mn_4O_{13}$ and further reduction to form $Sr_7Mn_4O_{12}$ allows the controlled removal of all the 180° Mn–O–Mn superexchange pathways present in the material. Thus, we can directly and rationally influence the magnetic coupling interactions in complex oxides.

"Anion-doped" mixed valent Mn(III)/Mn(IV) phases can be prepared by the subsequent partial oxidation of $Sr_7Mn_4O_{13}$. Reaction with a limited stoichiometry of oxygen yields the highly metastable phase $Sr_7Mn_4O_{14}$. Reaction with fluorine gas allows the preparation of $Sr_7Mn_4O_{13}F_2$. Solid-state ^{19}F NMR confirms that the fluoride ions are located in the sites vacated by oxide ions on reduction. This shows that the oxide–fluoride ordering is patterned by the anion vacancy ordering in the reduced intermediate, allowing this feature of the structure to be controlled.

Reaction of $LaSrMnO_4$ with CaH_2 at 420 °C yields $LaSrMnO_{3.67(3)}$. Raising the temperature to 480 °C yields the Mn(II) phase $LaSrMnO_{3.50(2)}$. Neutron powder diffraction data show that both phases adopt body-centered orthorhombic crystal structures ($LaSrMnO_{3.67}$, Immm: $a = 3.7256$ Å, $b = 3.8227$ Å, $c = 13.3617$ Å; $LaSrMnO_{3.50}$, Immm: $a = 3.7810$ Å, $b = 3.7936$ Å, $c = 13.3974$ Å) with anion vacancies located within the equatorial MnO_{2-x} planes of the materials. The origin of the low-dimensional magnetic order and ordering of the anion vacancies in the reduced phases is shown in Fig. 11.35.

Analogous reactivity is observed between $LaBaMnO_4$ and CaH_2 to yield body-centered tetragonal reduced phases ($LaBaMnO_{3.53(3)}$, I4/mmm: $a = 3.8872(1)$ Å, $c = 13.6438(2)$ Å). Low-temperature neutron diffraction and magnetization data show that $LaSrMnO_{3.5}$ and $LaBaMnO_{3.5}$ exhibit three-dimensional (3D) AFM order below 155 K and 135 K, respectively. Above these temperatures, they exhibit 2D AFM order with paramagnetic behavior observed above 480 K in both phases.

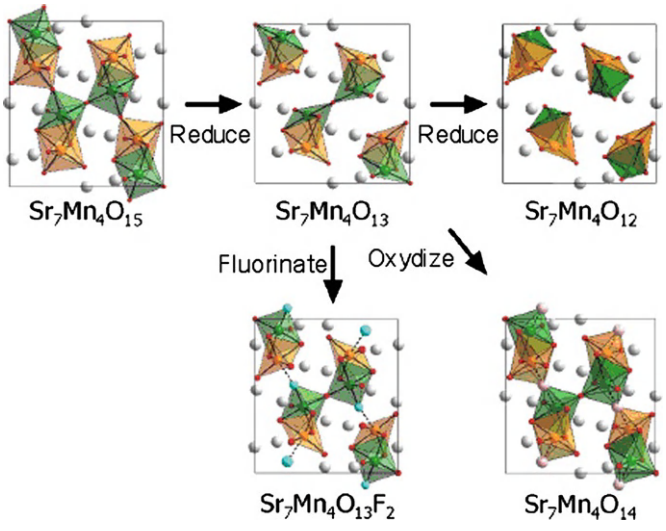

FIGURE 11.34

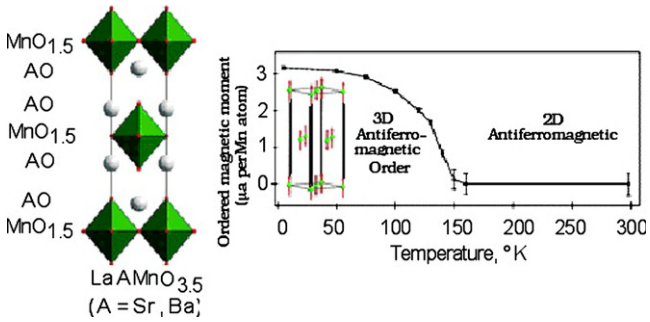

FIGURE 11.35

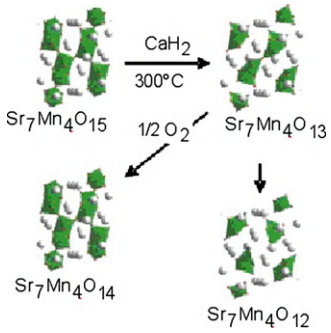

FIGURE 11.36

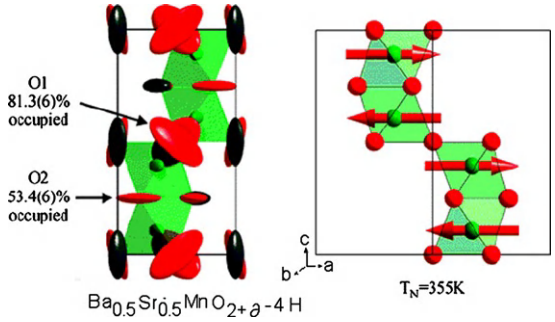

FIGURE 11.37

The synthesis of phases of composition $Sr_7Mn_4O_{15-x}$ $(0 < x < 3)$ is reported via the topotactic manipulation of the anion lattice of $Sr_7Mn_4O_{15}$. In addition the reduced cation substituted phases $BaSr_6Mn_4O_{13}$ and $Sr_6CaMn_4O_{13}$ are described. Structural characterization using powder X-ray and neutron diffraction data reveals that in all phases anions are selectively removed from sites which link the MnO_6 octahedra in the structure in an apex-sharing manner. An explanation based on the total lattice energy of the anion deficient phases is presented to account for this unusual selectivity. Topotactic reduction of $Sr_7Mn_4O_{15}$ selectively removes apex-linked oxide ions, as shown in Fig. 11.36.

Strontium manganate is offered for sale commercially as $SrMnO_4$.

11.2.5. Barium Manganese Compounds

It has been observed that MnO (hypomanganite) will form compounds with the alkaline earths if the cation, like Ba^{2+}, is sufficiently large. The anion-deficient perovskite 4H-$BaMnO_{2+x}$ has been obtained by a topotactic reduction, with LiH, of the hexagonal perovskite 4H-$BaMnO_{3-x}$. The crystal structure of 4H-$BaMnO_{2+x}$ was solved using electron diffraction and X-ray powder diffraction and further refined using neutron powder diffraction (space group—Pnma, $a = 10.375$ Å, $b = 9.466$ Å, $c = 11.276$ Å, at 373 K). The orthorhombic superstructure arises from the ordering of oxygen vacancies within a 4H (chch) stacking of close packed c-type $BaO_{2.5}$ and h-type $BaO_{1.5}$ layers. The ordering of the oxygen vacancies transforms the Mn_2O_9 units of face-sharing octahedra into Mn_2O_7 (two corner-sharing tetrahedra) and MnO_6 (two edge-sharing tetrahedra) groups. The Mn_2O_7 and MnO_6 groups are linked by corner sharing into a 3D framework. The structures of the $BaO_{2.5}$ and $BaO_{1.5}$ layers are different from those observed previously in anion-deficient perovskites providing a new type of order pattern of oxygen atoms and vacancies in close packed structures. Magnetization measurements and neutron diffraction data reveal 4H-$BaMnO_{2+x}$ adopts an antiferromagnetically ordered state below $T_N \sim 350$ K.

The synthesis of the Mn(II) phase 4H-$Ba_{0.5}Sr_{0.5}MnO_{2+\delta}$ via the topotactic reduction of 4H-$Ba_{0.5}Sr_{0.5}MnO_{3-x}$ with the novel reducing agent LiH, has been described. Neutron powder diffraction data show that oxide ions are de-intercalated from the host structure in a disordered manner to yield "tetrahedral" MnO_4 coordination sites. Magnetic susceptibility and neutron powder diffraction data show that the title phase adopts a canted antiferromagnetically ordered state below $T_N = 355$ K, consistent with the strong magnetic coupling expected between d^5 centers. The ordering of defects is shown in Fig. 11.37.

In this system of Mn^{2+} anions, MnO_2^{2-}, the compound, Ba_2MnO_3, could be prepared by solid-state reaction in hydrogen atmosphere. X-ray structure investigations gave a monoclinic unit cell $a = 5.84$ Å, $b = 11.57$ Å, $c = 12.70$ Å, $\beta = 93.74°$, space group CC_c. Mn^{2+} forms isolated tetrahedron chains connected by sevenfold coordinated Ba^{2+}. The crystal structure of Ba_2MnO_3 can be thought of as a heavily distorted rock salt structure.

In the Mn^{3+} system of BaO–Mn_2O_3, the compound, $BaMn_2O_4$, has not been prepared. No compounds based on the Mn^{3+} oxidation state are to be found including compounds like Ba_2MnO_5 and Ba_3MnO_6. As stated before, the Mn^{3+} state is too unstable and disproportionates into Mn^{2+} and Mn^{4+}.

In the Mn^{4+} system of BaO–MnO_2, the compound, barium manganite, $BaMnO_3$ has been studied intensely in regard to its "Gigantic Magnetoresistance" phenomenon. The crystal structure of the 2H perovskite $BaMnO_3$ has been refined from neutron powder diffraction data collected at room temperature and 80 and 1.7 K. The structure consists of chains of face-sharing MnO_6 octahedra, separated by Ba^{2+} cations. At room temperature, $a = 5.6991(2)$, $c = 4.8148(2)$ Å, space group $P63/mmc$. At 80 K, $a = 9.8467(1)$, $c = 4.8075(1)$ Å, space group $P63cm$. The structural phase transition introduces

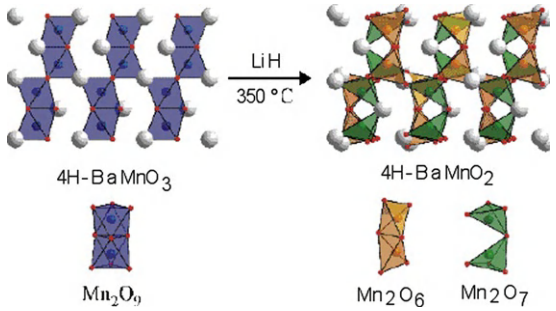

FIGURE 11.38

a displacement of neighboring chains and reduces the coordination number of Ba^{2+}. Long-range AFM ordering is apparent below $T_N = 59$ K, with a magnetic moment of 1.31 μbar per Mn^{4+} cation at 1.7 K. Neighboring spins within each chain are antiferromagnetically coupled and lie in a plane perpendicular to [001]. The spin directions associated with the chains at (1/3, 2/3, z) and (2/3, 1/3, z) are rotated by ±120° with respect to that of the chain at (0, 0, z).

Reaction of LiH with 4H-$BaMnO_3$ reductively deintercalates oxide ions from the host structure resulting in the Mn(II) phase $BaMnO_2$. The anion vacancies in the material are ordered in a complex manner, leading to the formation of Mn_2O_7 and Mn_2O_6 "dimer" units consisting of pairs of edge or corner sharing MnO_4 distorted tetrahedra. Further corner sharing of the dimer units leads to the formation of a novel 3D Mn(II)–O network. This is shown in the following diagram. Strong Mn–O–Mn superexchange coupling leads to the observation of AFM order at room temperature in 4H-$BaMnO_2$ and 4H-$Ba_{0.5}Sr_{0.5}MnO_2$ (Fig. 11.38).

The complex stacking sequences adopted by $BaMnO_{3-x}$ phases are driven by their anion nonstoichiometry. Neutron diffraction data indicate that the anion vacancies in $BaMnO_{3-x}$ phases are located almost exclusively on "hexagonal" sites which link MnO_6 octahedra in a face-sharing manner (Fig. 11.39).

As the vacancy concentration increases additional "cubic" corner-linked layers are incorporated into structures to accommodate the declining structural tolerance factor. Initially these cubic layers maximize their separation (15R, 8H, 9R), however as the anion vacancy concentration increases the stacking sequence changes to incorporate Mn_2O_{9-x} dimer units that specifically stabilize vacant anion sites.

The system $BaMnO_{3-x}$ ($0 \le x < 0.5$) in air has been investigated by gravimetric, quenching, single-crystal and powder XRD studies. Below 1150 °C hexagonal, two-layer $BaMnO_3$ ($a = 5.699$ Å, $c = 4.817$ Å) is stable. Above 1150 °C a series of anion-deficient $BaMnO_{3-x}$ phases exists. With increasing temperature, these include a rhombohedral 15-layer form ($a = 5.681$ Å, $c = 35.377$ Å; hexagonal indexing) and hexagonal 8-layer ($a = 5.699$ Å, $c = 18.767$ Å), 6-layer ($a = 5.683$ Å, $c = 14.096$ Å), 10-layer ($a = 5.680$ Å, $c = 23.373$ Å) and 4-layer ($a = 5.672$ Å, $c = 9.319$ Å) forms. The 6-layer modification is not of the hexagonal $BaTiO_3$-type. A simple orderly structural sequence involving a progressive increase of cubic-type layer stacking with increasing temperature characterizes the phases prepared.

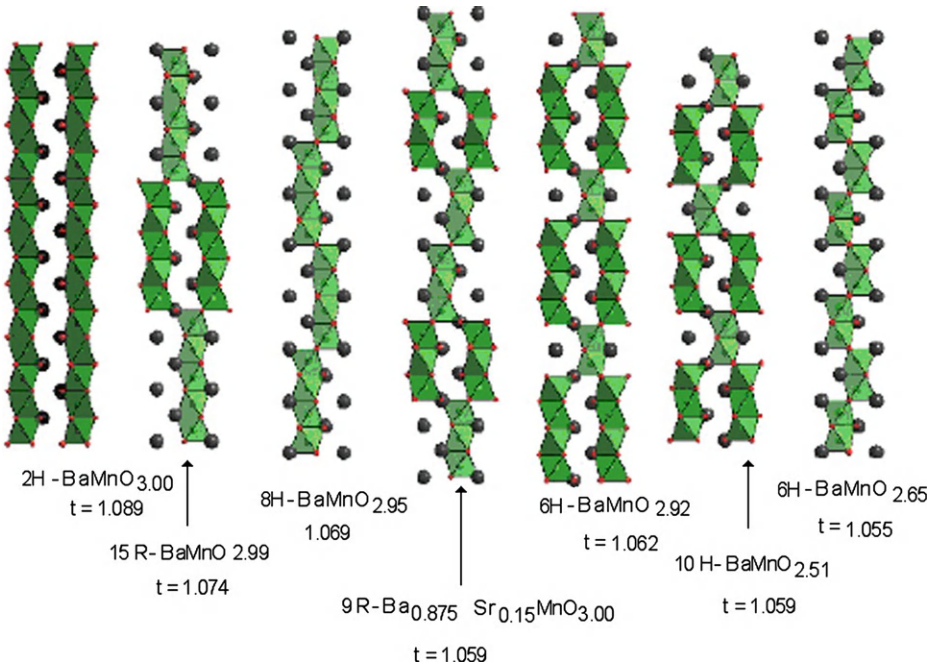

FIGURE 11.39

Influence of anion stoichiometry on phase formation is considered.

Mixed valence Mn(III)/Mn(IV) oxides exhibit strong coupling between charge, spin and lattice degrees of freedom. This leads to strongly correlated behavior and the observation of charge and orbital order, magnetoresistance and a variety of other complex behavior. A number of mixed valency, i.e. Mn(II)/Mn(III), complex oxides have been prepared to see if these phases exhibit analogous complex behavior. The diagram given as follows shows this factor (Fig. 11.40).

Topotactic reduction of cubic perovskite $La_{1-x}Ba_xMnO_3$ phases leads to the formation of the corresponding $La_{1-x}Ba_xMnO_{2.5}$ Brownmillerite phases. The Brownmillerite structure has a series of variants which exhibit different ordering patterns of the twisted tetrahedral chains. Detailed analysis of the structural parameters obtained from the $La_{1-x}Ba_xMnO_{2.5}$ phases has enabled us to construct a plot that rationalizes the different Brownmillerite structural variants as a function of the tetrahedral chain twist angle and tetrahedral layer separation. This plot can be extended to include a wide range of reported Brownmillerite phases enabling the structural variant a particular composition will adopt, to be predicted on the basis of simple structural parameters. In addition this structural analysis has allowed the identification of robust octahedral-site Mn(II)–Mn(III) charge order at room temperature in phases centered on $La_{0.75}Ba_{0.25}MnO_{2.5}$ compositions.

The synthesis and structure determination of 4H-$BaMnO_{3-x}$ ($0x0.35$) and 4H-$Ba_{0.5}Sr_{0.5}MnO_{3-x}$ ($0x0.21$) have been described in another paper. Neutron powder diffraction data unambiguously show the anion vacancies in the oxygen-deficient phases lie in the hexagonal BaO_{3-x} layers, rather than the cubic layers predicted by previous structural models. The localization of anion vacancies in the hexagonal layers is discussed on the basis of the local coordination polyhedra of the metal cations. Low-temperature neutron diffraction data show the oxidized materials adopt AFM ordered structures ($Ba_{0.5}Sr_{0.5}MnO_{2.99}$). Anion-deficient phases do not achieve magnetic order, suggesting that the Mn(III/IV) charge disorder suppresses long-range magnetic order. The following diagram illustrates the type of anion vacancy that occurs in these compounds (Fig. 11.41).

The synthesis and structural characterization of 15R-, 8H-, 6H′-, and 10H-$BaMnO_{3-x}$ and 9R-$Ba_{0.875}Sr_{0.125}MnO_3$ are also described. Neutron powder diffraction data reveal a strong preference for the location of anion vacancies within the face-shared hexagonal layers of these phases. At high-anion vacancy concentrations, Mn_2O_{9-x} dimer units become dominant. Magnetic characterization indicates AFM order in all these phases. Ordering temperatures are in the range $250\ K < T < 270\ K$ and show a dependence on the fraction of cubic layers present in the stacking sequence.

In a following paper, novel phases in the $BaMnO_{3-x}$ system were investigated by high-resolution electron microscopy. A hexagonal cell with two atomic layers (2H, $a = 5.72$ Å, $c = 4.84$ Å) was found to have an oxygen deficiency to some degree, though its X-ray powder pattern gave a single phase of a 2H crystal. Observed structure images showed that a 2H phase was transformed into a 10H (6L + 4L) phase under a low beam intensity and into a 6H (4L + 2L) phase under a very high beam intensity. A mechanism of phase transformation was proposed in that "oxygen deficiency in face-sharing octahedra induces the displacement of the Mn ions which reduce the coordination number and the disruption of face-sharing octahedra. In the reduction process of $BaMnO_3$, the oxygen loss is accompanied with structural changes related to the introduction of

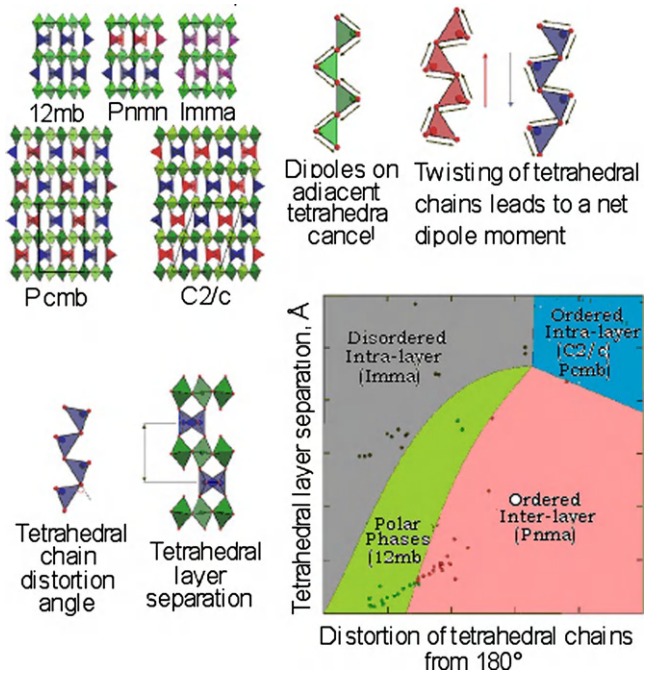

FIGURE 11.40

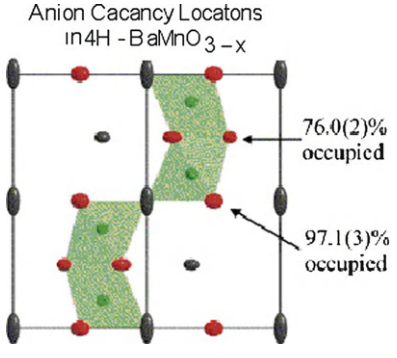

FIGURE 11.41

cubic layers in the starting hexagonal close packing". Several ordered hexagonal types (2H, 15H, 8H, 6H, 10H and 4H) can be obtained, for an explicit oxygen content, as a function of the synthetic route. The synthesis and structural characterization of the 6H type was also described.

The electronic structure and electrical transport properties of the cubic perovskite (E21) oxide barium manganese ($BaMnO_3$) and the $BaMnO_3/BaTiO_3$ superlattice was investigated by the density functional theory in this report. The results show that the cubic $BaMnO_3$ exhibits half-metallic properties with an integral magnetic moment of 3.000 μbar per unit cell in its metastable state, while the $BaMnO_3/BaTiO_3$ superlattice also shows a stable half-metallic ground state with an integral magnetic moment of 12.000 μbar per unit cell. The construction of a $BaMnO_3/BaTiO_3$ superlattice could stabilize the cubic metastable phase of the $BaMnO_3$ compound and provide a stable half-metallic material for potential applications in spintronic devices. In summary, $BaMnO_{3-\delta}$ and lightly Li- and K-doped $BaMnO_{3-\delta}$ possess strong magnetoelectric effects near room temperature. The large dielectric constants of these materials, comparable to those of well-known ferroelectrics, are closely associated with magnetic order and magnetic anisotropy that sensitively hinges on the cubic stacking ratio. These findings provide ***a new paradigm for developing novel, high-temperature magnetoelectrics and, eventually, multiferroic materials*** of technological importance.

Hypomanganate, MnO_4^{3-}, is a blue-colored ion of Mn(V) that forms when MnO_4^{2-} is treated with manganite MnO_4^{4-} at pH > 12. It has also been generated by treatment of $KMnO_4$ in 10 M KOH with H_2O_2. The pK_a of $HMnO_4^{2-}$ is 13.7, which indicates that solutions of hypomanganate contain significant amounts of the protonated form even at high pH's. Oxidations of alkenes by permanganate are proposed to proceed via the intermediacy of "esters" of hypomanganate, that is, species of the type $MnO_2(OR)_2^-$ where R is an alkyl group.

The Mn^{5+}-containing compound, $BaMn_2O_7$ has been reported. It is related to the $BaMnO_{3-\delta}$ type of compounds. The discovery of novel structural and physical properties in the A-site ordered manganite $RBaMn_2O_6$ (R = Y and rare earth elements) has demanded new comprehension about perovskite manganese oxides. In the present study, the A-site disordered form, $R_{0.5}Ba_{0.5}MnO_3$, was successfully synthesized and investigated concerning its structure and electromagnetic properties. $R_{0.5}Ba_{0.5}MnO_3$ has a primitive cubic perovskite cell. The magnetic glassy states are unexpectedly dominant as the ground state of $R_{0.5}Ba_{0.5}MnO_3$ in contrast to the ordinary disordered manganite $R_{0.5}A_{0.5}MnO_3$ (A = Sr and Ca). A peculiar behavior detected was the step-like ultrasharp magnetization and resistivity change observed in $Pr_{0.5}Ba_{0.5}MnO_3$.

The crystal structure and electromagnetic properties of the A-site ordered perovskite manganite, $TbBaMn_2O_6$, have been studied. $TbBaMn_2O_6$ has successive phase transitions; the structural transition at $T_t = 450$ K, the charge/orbital order transition at $T_{CO} = 430$ K and the AFM transitions on Mn ions at $T_N = 210$ K and on Tb ions at $T_N = 12$ K. At T_t, both *a*- and *b*-axis expand by 0.7%, and the *c*-axis shrinks by 1.3% in the low-temperature phase. The magnetic interaction changes from FM (the high-temperature triclinic phase) to AFM (the low-temperature monoclinic phase) across T_t. The electrical resistivity clearly shows anisotropic behaviors at T_t; an increase of resistivity along the *c*-axis and no change within the *ab*-plane. The obtained results strongly suggest the dx^2-y^2-type orbital order at T_t. Comparing to the metal-disordered manganites, two remarkable features are recognized in $RBaMn_2O_6$: (1) relatively high-charge order transition temperature and (2) the presence of structural transition without any charge and magnetic ordering. These features are closely related to the peculiar structure that the MnO_2 square lattice is sandwiched by the rock salt layers of two kinds; RO and BaO with different lattice sizes.

The compound, $Ba_2Mn_2O_7$, is unknown. However, the tri-barium di-manganate, $Ba_3Mn_2O_8$, has been reported. $Ba_3Mn_2O_8$ is a hexagonally coordinated Mn^{5+} $S = 1$ spin dimer system with small uniaxial single-ion anisotropy. [135,137]Ba NMR spectroscopy was used to establish the lower critical field Hc_1 of distinct field-induced phases for *H* parallel to c, *H* perpendicular to c, and to measure the longitudinal (Ml) and transverse (Mt) magnetizations in the vicinity of the quantum critical point (QCP). M_l-parallel (T, Hc_1), M_l-perpendicular (T, Hc_1) points were reproduced by solving a low-energy model for a dilute gas of interacting bosons. M_l-parallel (T goes to 0, $H = Hc_1$) (M_l-perpendicular (T goes to 0, $H = Hc_1$)) follows the expectation for a BEC (Ising-like) QCP.

Single crystals of $Ba_3Mn_2O_8$ were grown by a slow cooling flux method. $Ba_3Mn_2O_8$ is a spin dimer compound based on pairs of $S = 1$, $3d^2$, Mn^{5+} ions arranged on a triangular lattice. AFM intradimer exchange leads to a singlet ground state in zero-field. Specific heat, magnetocaloric effect, and torque magnetometry measurements were performed in magnetic fields up to 32 T and temperatures down to 20 mK. For fields above $H\{c_1\} \sim 8.7$ T, these measurements reveal a single magnetic phase for *H* parallel to c, but two distinct phases (approximately symmetric about the center of the phase diagram) for *H* perpendicular to c. Analysis of the simplest possible spin Hamiltonian describing this system yields candidates for these

ordered states corresponding to a simple spiral structure for *H* parallel to c, and to two distinct modulated phases for *H* perpendicular to c. Both single-ion anisotropy and geometric frustration play crucial roles in defining the phase diagram. The relation between the Ba^{2+} ions and the Mn^{5+} ions is shown in Fig. 11.42.

This schematic diagram shows the arrangement of MnO_4 tetrahedra in the *R*-3*m* structure of $Ba_3Mn_2O_8$. Intradimer (J_0), out-of-plane interdimer (J_1), in-plane direct interdimer (J_2) and in-plane crossed interdimer (J_3) exchange bonds are drawn as thick black, dotted black, thin black and dashed black lines, respectively. Only two of the in-plane crossed interdimer exchange bonds (J_3) were drawn for clarity. $Ba_3Mn_2O_8$ crystallizes in the rhombohedral *R*3*m* structure, and is comprised of pairs of Mn^{5+} $3d^2$ ($S = 1$) ions arranged vertically on hexagonal layers. Each Mn^{5+} ion is coordinated by distorted oxygen tetrahedra, which results in an orbitally non-degenerate ground state. Successive layers are stacked following an "ABC" sequence, such that the dimer units on adjacent planes are positioned in the center of the triangular plaques of the layers above and below. Pairs of ions on each dimer are coupled antiferromagnetically, resulting in a singlet ground state. Initial powder inelastic neutron scattering (INS) indicated an intradimer exchange energy $J_0 \approx 1.61(3)$ meV[14]. The same INS measurements revealed a spin gap of 1.05 meV and a hierarchy of additional exchange energies, in which interdimer coupling between Mn ions in the same plane is characterized by $J_2 - J_3 = 0.112^{+0.015}_{-0.003}$ meV and interdimer coupling between Mn ions residing on adjacent planes is characterized by $J_1 = -0.062^{+0.007}_{-0.006}$ meV.

In the Mn^{6+} system of BaO–MnO_3, the compound $BaMnO_4$ is known. Two convenient methods were developed to transform $KMnO_4$ into barium permanganate, $BaMn_2O_7$ and other permanganate salts via $BaMnO_4$ or Mn_2O_7 intermediates. Pure $BaMnO_4$ was prepared by the reaction of $KMnO_4$ with KI in the presence of $BaCl_2$ and NaOH. Hydrothermal reaction of barium manganate with excess carbon dioxide for 1.5 h at 100 °C led to barium permanganate with almost quantitative yield. $BaMnO_4$, is generated by the reduction of $KMnO_4$ with iodide in the presence of $BaCl_2$. Just like $BaSO_4$, $BaMnO_4$ exhibits low solubility in virtually all solvents. It has the CAS number of 7787-35-1 and is offered for sale commercially. Manganates, particularly the insoluble $BaMnO_4$, have been used as oxidizing agents in organic synthesis. They will oxidize primary alcohols to aldehydes and then to carboxylic acids. Secondary alcohols are easily oxidized to ketones. Barium manganate has also been used to oxidize hydrazones to diazo compounds.

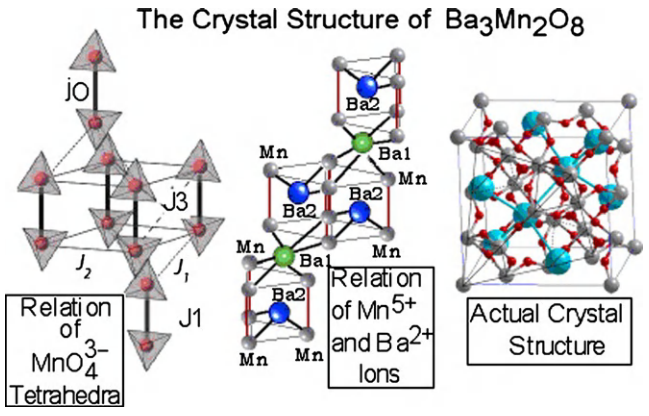

FIGURE 11.42

$BaMnO_4$ has a scheelite-like structure. XRD and Raman scattering studies on the scheelite structured barium molybdate show that, at ~5.8 GPa, it undergoes a first-order phase transition to the fergusonite structure ($I\,2/a, Z = 4$)—as also observed in iso-structural barium tungstate. At still higher pressures, barium molybdate transforms to another phase between ~7.2 and 9.5 GPa. On release of pressure from 15.8 GPa, the initial phase is recovered, implying that the observed structural modifications are reversible.

In the Mn^{7+} system of BaO–Mn_2O_7, the compound, barium permanganate, $BaMn_2O_8$, is known. It has the CAS number of 7787-36-2 and is offered for sale commercially. It is a strong oxidizer and i used in the manner described for $BaMnO_4$. Since this compound, $Ba(MnO_4)_2$ has the tendency to disproportionate into the insoluble $BaMnO_4$:

$$BaMn_2O_8 + \text{heat}\ (T > 280\ ^\circ\text{C}) \Rightarrow BaMnO_4 + MnO_2 + O_2$$

it has not found widespread use in the Industry and has not been extensively researched by Academia.

Barium Manganate (CAS = 7787-42-0) is readily available commercially on a worldwide basis.

11.2.6. Radium Manganese Compounds

No Compounds are known.

11.3. ALKALINE EARTH—TECHNETIUM COMPOUNDS

The element technetium, Tc, does not appear in nature and all of it used commercially is produced synthetically. It is the lowest atomic number element that does not have any stable isotopes. The most common isotope, technetium-99, i.e. $^{99}Tc_{43}$, is a weak beta emitter with a short half-life of $T_{1/2} = 6.0$ h. Because such radiation is blocked by the walls of laboratory glassware, Tc is employed in the medical profession to

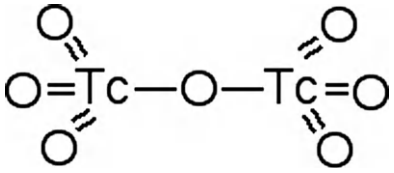

FIGURE 11.43

pinpoint blood flow blockage in the arterial–venous system of the human body.

All isotopes are radioactive. The only known stable oxide is **Technetium(VII) oxide** with the formula, Tc_2O_7. This yellow volatile solid is a rare example of a molecular binary metal oxide, the other examples being RuO_4, OsO_4 and the unstable Mn_2O_7. It adopts a centro-symmetric corner-shared bi-tetrahedral structure in which the terminal and bridging Tc–O bonds are 167 pm and 184 pm, respectively and the O–Tc–O angle is 180°. The Gibbs structure is shown in Fig. 11.43.

The vapor pressure of Tc_2O_7 is much higher than that of Re_2O_7 at low temperatures (e.g. 10^{-1} mm at 100 °C, compared to $\sim 3 \times 10^{-5}$ for Re_2O_7). In contrast to rhenium, technetium (VII) is therefore easily lost upon evaporation of acid solutions unless a reducing agent is present or the evaporation is conducted at a low temperature. This limits the number of alkaline earth—technetium compounds that have been synthesized. The solution chemistry is mostly based upon pertechnetic acid. Pertechnetic and perrhenic acids behave as very strong acids, Ka ~ 10^{-1} s. Their extensive dehydration to M_2O_7 in such media as 7.0 M sulfuric acid complicates a spectrophotometric comparison of acid strengths. Heptavalent technetium, present in aqueous solutions as pertechnetate ion, TcO_4^- can be extracted into a variety of organic liquids, including alcohols, ketones, ethers, organo-phosphorus, and tertiary and quaternary amines dissolved in nonpolar solvents. Good extraction from acid but not from neutral nor alkaline solution was observed with the alcohols, esters of phosphoric acid, and tertiary amines. Ketones and quaternary amines extracted technetium efficiently over a wide pH range. The technetium species transferred between phases was shown to be $HTcO_4$ from acid aqueous media, and to be $MTcO_4$ from neutral alkali metal salt solutions.

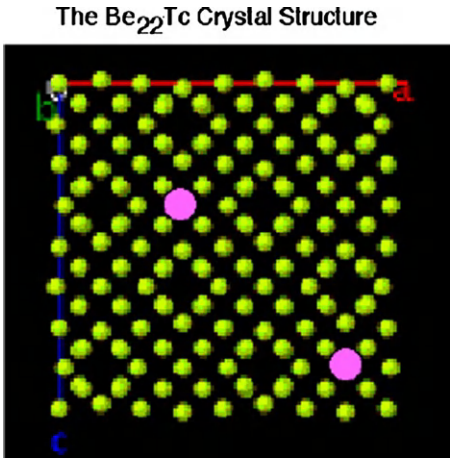

FIGURE 11.44

The crystal chemistry of technetium has been investigated as a series of simple binary and ternary oxide structures. An investigation of the system Tc–O under controlled conditions has revealed only one intermediate compound. Technetium-containing spinels can be synthesized in which technetium lies on the octahedral sites in the lattice. Technetium will enter the B-sites in ABO_3 compounds yielding perovskite, hexagonal $BaTiO_3$, and pyrochlore structures. The radius of the Tc^{4+} is shown to be 0·67 Å.

11.3.1. Beryllium–Technetium Compounds

Be^0 metal forms one known compound with Tc^0 metal. The structure has the $Zn_{22}Zr$-type of structure shown in Fig. 11.44.

Cell parameters are: $a = b = c = 8.1784$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 386.80 Å^3, $Z = 8$. Cell occupancy is shown in Table 11.15.

Be does not form any oxo-technetium compounds. No structures have been reported and the literature is devoid of any mention of such compounds.

11.3.2. Magnesium Technetium Compounds

Mg^0 metal does not form any intermetallic compounds with Tc^0 metal.

TABLE 11.15

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	Be1	Be	96	g	..m	0.0617	0.06174	0.3192	1.0
2	Be2	Be	48	f	2.mm	0.4867	1/8	1/8	1.0
3	Be3	Be	16	d	.-3m	1/2	1/2	1/2	1.0
4	Be4	Be	16	c	.-3m	0	0	0	1.0
5	Tc1	Tc	8	a	-43m	1/8	1/8	1/8	1.0

In the Mg–Tc–O system, the compound $MgTc_2O_8 \cdot 4H_2O$ has the unit cell dimensions of: $a = 6.46$ Å, $b = 7.03$ Å, $c = 7.195$ Å, $\alpha = 63.06°$, $\beta = 69.88°$, $\gamma = 71.99°$, cell volume = 268.87 Å^3, $Z = 4$. space group = P-1, point group of $aP15$. It is triclinic but no specific structural arrangement has been presented in the literature. It is readily soluble in water.

The compound, $Mg_2(TcO_4)_2$, has been described as a black powder that is cubic with $a = 8.498$ Å, having the spinel type of structure. $Mg_2(TcO_4)_2$ is offered for sale commercially, with the CAS number of 71683-38-0.

No other magnesium technetate compounds have been described in the literature.

11.3.3. Calcium Technetium Compounds

The metal, Ca^0, does not form any compounds with the Tc^0 metal.

In the Ca–Tc–O system, the technetium perovskite, $CaTcO_3$ has been synthesized. Combining synchrotron X-ray and neutron diffraction, it was found that $CaTcO_3$ is an AFM with a surprisingly high Neel temperature of ~800 K. The transition to the magnetic state does not involve a structural change, but there is obvious magnetostriction. Electronic structure calculations confirm the experimental results. The structure of $CaTcO_3$, $SrTcO_3$ and $BaTcO_3$ is shown in Fig. 11.45.

Side (a) and top (b) views of the *Pnma* structure of the distorted perovskite are shown. The Tc atoms (medium-light blue spheres) are surrounded by O_6 atoms to form an octahedron. $AeTcO_3$ compounds adopt the same distorted *Pnma* perovskite structure as $LaMnO_3$, characterized by a $GdFeO_3$-like (GFO) tilting of the TcO_6 octahedra caused by the Ae–O and Ae–Tc covalencies, and a concomitant Jahn–Teller (JT) Tc–O bond length disproportionation, with long (l) and short (s) Tc-O(2) in-plane distances and medium (m) Tc-O(1) vertical ones. When compared to $LaMnO_3$, the experimental values of the JT modes, $Q_2 = 2(l - s)/\sqrt{2}$ and $Q_3 = 2(2m - l - s)/\sqrt{2}$ in $CaTCO_3$ and $SrTCO_3$ are significantly smaller due to the intrinsically different electronic configuration of the transition metal ions. In $LaMnO_3$, the Mn^{3+} ions 3d states are in a $t^3_{2g}e^1_g$ configuration and a strong JT effect is required to release the degeneracy of the e_g orbitals and to form an orbitally ordered state. On the contrary in $AeTcO_3$, the Tc^{4+} ions ($4d^3$: $t^3_{2g}e^0_g$) have completely filled (empty) $t_{2g}(e_g)$ manifolds, similarly to Mn^{4+} ions in $CaMnO_3$, a configuration which inhibits the occurrence of electronic and structural JT instabilities, and leads to an insulating G-type AFM ground state (AFM-G). However, at variance with 3d transition metal (TM) ions in perovskites, where d^3 configurations unavoidably lead to fully polarized $m = 3$ μbar moments on TM (e.g. $CaMnO_3$), a much larger extension of the 4d electrons is observed That, in turn, forms much stronger hybridizations with Op states. A sizable amount of charge fills the 4d minority states as well, with a consequential reduction of magnetic moment and an overtly evident intraatomic violation of Hund's rule.

The structure of $CaTcO_3$ is shown in the following diagram. Cell parameters have not been given (Fig. 11.46).

In other papers, Avdeev et al. and Rodriguez et al. have reported the successful synthesis of the first ever fabricated Tc-based perovskites, namely $CaTcO_3$ and $SrTcO_3$. Furthermore they have shown that these compounds display the anomalously high Neel temperatures (T_N) of 800 K for $CaTcO_3$ and 1000 K for $SrTcO_3$, by far the highest among materials not incorporating 3d transition metals. These results are surprising and challenge the current understanding of the magnetic interaction in perovskites. In particular they pose three fundamental questions: i) Is the origin of such a large magnetic ordering temperature related to the strong Tc 4d-Op hybridization? ii) What is the role played by the structural degrees of freedom? and iii) Is the enhancement of T_N upon Ca/Sr substitution related to the observed increase in unit cell volume and the corresponding modification of the internal atomic positions? These questions remain to be answered.

No other calcium technetate compounds are known to date. No CAS numbers have been issued.

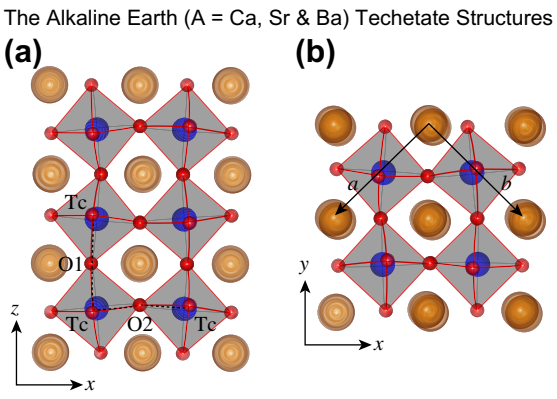

FIGURE 11.45

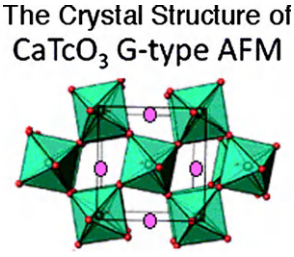

FIGURE 11.46

11.3.4. Strontium Technetium Compounds

The metal, Sr^0, does not form any compounds with the Tc^0 metal.

In the Sr–Tc–O system, the compound, Sr_2TcO_4, has been described as a black tetragonal material having the K_4NiF_4 type of structure with $a = 3.901$ Å, $c = 12.72$ Å.

The compound, $SrTcO_3$, is a perovskite. Strontium meta-technetiate exhibits the highest magnetic transition temperature outside of the first-row 3d-transition elements, as shown below. Magnetic scattering by the Tc cations is substantiated given that the peak intensity and thus magnetic ordering is retained to 750 °C, well above a crystallographic transition of $SrTcO_3$ to the highest possible symmetry group for a perovskite, *Pm*3 *m*, at 500 °C.

The structure of the perovskite $SrTcO_3$ has been investigated using both synchrotron X-ray and neutron powder diffraction. At room temperature $SrTcO_3$ is orthorhombic as a consequence of cooperative tilting of the corner sharing TcO_6 octahedra. The tilts are sequentially removed as the sample is heated with the oxide displaying the sequence of structures *Pnma* ⇒ *Imma* ⇒ *I*4/*mcm* ⇒ *Pmm*. Neutron powder diffraction data collected in the temperature range 4–1023 K indicate that $SrTcO_3$ has G-type AFM structure, in which each Tc moment is antiparallel to its six nearest neighbors, below 1000 K. The magnetic structure is collinear AFM with the technetium moments parallel to *c*-axis and can be described by the propagation vector $\mathbf{k} = [0,0,0]$ and the basis vector $(0,0,A_z)$. The same magnetic structure is observed in each of the four crystal structures. The arrangement of the octahedra is shown in Fig. 11.47.

The structure of $SrTcO_3$ has been presented above, except for the unit cell parameters. They are: $a = 5.543$ Å, $b = 7.854$ Å, $c = 5.576$ Å, cell volume $= 242.74$ Å^3, $\alpha = \beta = 164.74°$, $\gamma = 168.76°$. It is thus a distorted tetragonal structure composed of TcO_6 octahedra. It has been observed that the magnetism in the technetium perovskite, $SrTcO_3$, is unaffected by the phase transitions associated with tilting of the TcO_6 octahedra. The existence of the Tc(VII) compound, $Sr(TcO_4)_2$ has not been established.

No other strontium technetate compounds are known. These compounds are not available commercially and no CAS numbers have been issued.

11.3.5. Barium Technetium Compounds

The metal, Ba^0, does not form any compounds with the Tc^0 metal.

In the Ba–Tc–O system, the compound, Ba_2TcO_4, has been described as a black tetragonal material having the K_4NiF_4 type of structure with $a = 4.401$ Å, $c = 13.40$ Å. It decomposes at 630 °C.

Barium forms a perovskite, $BaTcO_3$, and its structure is isomorphous to the Ca and Sr perovskites as described above. The evolution of the magnetic ordering temperature of the $4d^3$ perovskites $RTcO_3$ (R = Ca, Sr, Ba) and its relation with its electronic and structural properties has been studied by means of hybrid density functional theory and Monte Carlo simulations. When compared to the most widely studied 3d perovskites the large spatial extent of the 4*d* shells and their relatively strong hybridization with oxygen weaken the tendency to form Jahn–Teller like orbital ordering. This strengthens

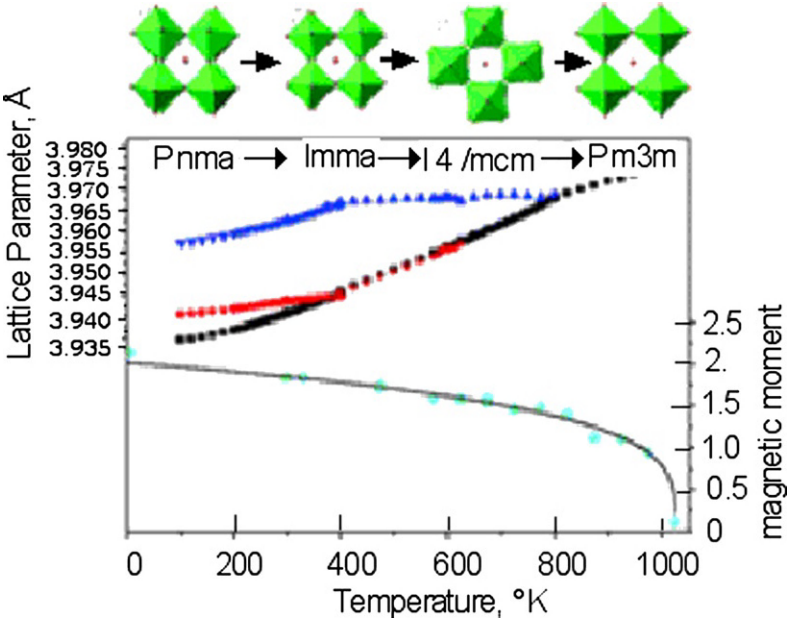

FIGURE 11.47

the superexchange interaction. The resulting insulating G-type AFM ground state is characterized by large superexchange coupling constants (26–35 meV) and Neél temperatures (750–1200 K). These monotonically increase as a function of the R ionic radius due to the progressive enhancement of the volume and the associated decrease of the cooperative rotation of the TcO_6 octahedra.

In the case of technetium, even TcO_3 is not well established. Gerlit claimed evidence for a Tc(VI) intermediate in the hydrazine reduction of alkaline pertechnetate. Rulfs et al. examined the growth of the intermediate spectrophotometrically in order to select an optimum time for precipitation of $BaTcO_4$. But small-scale preparations of this material were too high in Tc/Ba ratio, despite known contamination with $BaCO_3$. These peripheral objectives have led to significant new information, but a (VI) salt of technetium has not been obtained. The existence of the Tc (VII) compound, $Ba(TcO_4)_2$, has not been established.

No barium technetate compounds are offered for sale commercially.

11.3.6. Radium Technetium Compounds

Although radium–technetium compounds like $RaTcO_3$ could be synthesized, the likely of such a synthesis is nil. Both elements are radioactive and the demand for such compounds in the Industry is zero.

11.4. ALKALINE EARTH—RHENIUM INTERMETALLIC COMPOUNDS

The metal, Rhenium, does not form any compounds with the alkaline earth metals, with the exception of beryllium. According to the phase diagram of Be^0–Re^0, three compounds (3) exist shown in Fig. 11.48.

One of these is a slight adjustment of the basic metal, Be^0. Note that Be_2Re exists over a range of Br/Re atom ratios. The structure factors are listed in Table 11.16.

The compound, $Be_{22}Re$, has the following structure shown in Fig. 11.49.

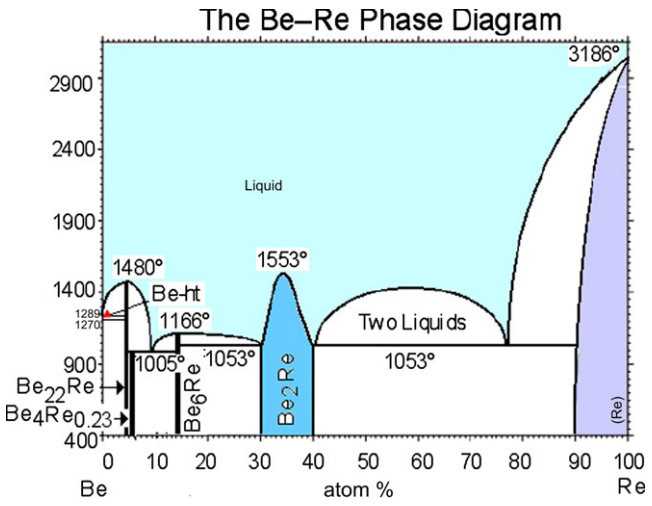

FIGURE 11.48

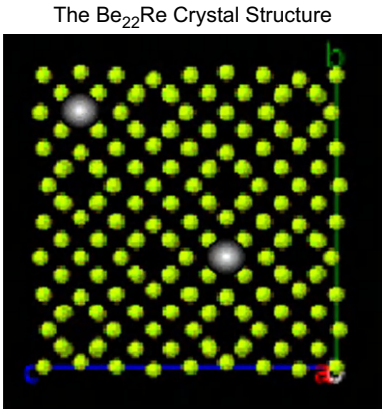

FIGURE 11.49

Cell parameters are: $a = b = c = 8.1742$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 386.21$ Å^3, $Z = 6$. Cell occupancy is shown in Table 11.17.

Cell parameters are: $a = b = c = 8.1742$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 386.21$ Å^3, $Z = 6$. Cell occupancy is shown in Table 11.18.

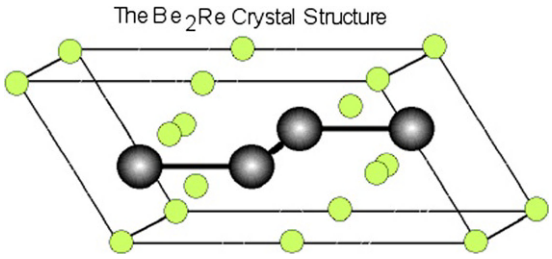

FIGURE 11.50

The structure of Be_2Re has the form shown in Fig. 11.50.

Cell parameters are: $a = b = 4.345$ Å, $c = 7.087$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 115.87$ Å^3, $Z = 3$. Cell occupancy is shown in Table 11.19.

The compound, $Be_{4.0}Re_{0.23}$, has the structure shown in Fig. 11.51.

Cell parameters are: $a = b = c = 4.1543$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 50.70$ Å^3. $Z = 2$. Cell occupancy is shown in Table 11.20.

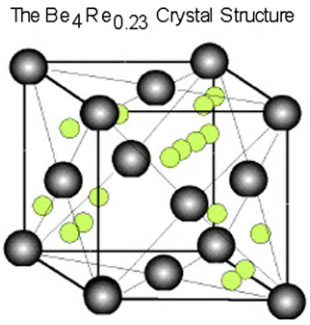

FIGURE 11.51

None of these compounds have found usage in the Industry and they are not offered for sale commercially.

11.5. ALKALINE EARTH—OXO-RHENIUM COMPOUNDS

These compounds are extremely rare and few in number. In fact, Re is reluctant to form any oxides at all. In a recent study of rhenium and its effect upon the Earth's mantle, the following comment was made:

> "Rhenium concentrations have been measured in eight samples from Volcan Alcedo in the Galapagos Archipelago—four basalts, an icelandite, a dacite and a rhyolite (all part of a fractionation trend), and a magnetite phenocryst-rich separate from a rhyolite. This study shows that Re concentrations increase (from 234 to 850 ppt) during the FeO and TiO_2 enrichment trend, and indicates that Re is incompatible in olivine, augite and plagioclase. Once magnetite stabilizes and fractionates, the iron and titanium enrichment trend in the melt reverses, and Re concentration drops from 610 ppt in the icelandite to 36 ppt in the rhyolite. The magnetite-rich separate has an extremely high Re content of 40 ppb–further evidence for compatibility of Re in magnetite. The paucity of sulfides in this suite suggests that magnetite is a significant host phase for Re. Re–SiO_2 trends in the Alcedo suite can be modeled with a magnetite–melt partition coefficient (D) of 20–50 for a sulfide-free system and D of 20–26 for a sulfide-bearing system. Compatibility of Re in magnetite suggests a valence of 3+ or 4+ for Re in terrestrial magmatic processes. The distribution of Re and Os in cubic oxides may be controlled by crystal chemistry".

The conclusion can be reached that Re forms oxides reluctantly.

11.5.1. Beryllium Oxo-Rhenium Compounds

Beryllium does not form any compounds with Rhenium oxide components.

11.5.2. Magnesium Oxo-Rhenium Compounds

No compounds are known in the MgO–ReO or MgO–Re_2O_3 systems.

In the MgO–ReO_2 system, attempts to prepare spinels of the type Mg_2ReO_4, $MgReO_3$ and $MgNiReO_3$ have similarly failed. In all three cases, the products consist of oxides and no diffraction peaks other than those resulting from the mixture of oxides were evident.

In the MgO–ReO_3 system, the compound, $MgReO_4$ apparently has the wolframite structure. But, the structure and crystal parameters have not been readily available. Only sixfold coordination is known for Re^{6+} in magnesium rhenium oxides. Conversely, the octahedral environment varies from the perfect octahedron in ReO_3 to the distorted one in Mg_3ReO_6.

In the MgO–Re_2O_7 system, the crystal structure of $Mg(ReO_4)_2 \cdot 4H_2O$ was determined from single-crystal X-ray diffractometer data. This compound was prepared from solution with $MgCl_2$ and $KreO_4$. The compound is triclinic, space group P1, with lattice parameters $a = 7.692$, $b = 7.026$, $c = 6.469$ Å, $\alpha = 108.279$, $\beta = 92.388$, $\gamma = 120.418°$, $Z = 1$, $dens_{calcd.} = 3.58\ g/cm^3$, $dens_{exp.} = 3.62\ g/cm^3$. The structure was solved in anisotropic approximation from 2990 observed reflections and refined to an index R of 7.4%. The rhenium atom is tetrahedrally coordinated, the magnesium atom octahedrally coordinated.

Magnesium rhenate compounds are not available commercially due, in part, to their very high cost.

11.5.3. Calcium Oxo-Rhenium Compounds

The Ca–Re–O system contains more compounds than the Mg system. This is due, in part, to the size factor where both Mg^{2+} and Be^{2+} are too small to form stable compounds.

No compounds are known in the CaO–ReO or CaO–Re_2O_3 systems.

In the CaO–ReO_2 system, the $CaReO_3$ compound has not been synthesized or described. An increase of the oxidation state of rhenium (>3) is expected to lead to the formation of structures containing cluster groups with different orders of metallic Re–Re bonds. The Re_2O_{10} cluster is known for the average oxidation state of rhenium atoms between +4 and +5.5. The Re_2O_8 group in contrast was found only in the compounds containing Re^{4+} (Fig. 11.52).

The oxidation state of rhenium in such double oxides will influence the charge carrier concentration and, consequently, the electrical and magnetic properties of these compounds. Nevertheless, there are only rare cases of careful structure-properties investigations in these systems. However, in a ternary system, magnetic and electrical properties of the sintered oxides belonging to the $CaIr_xRe_{1-x}O_3$ series were examined ($x = 0.25$; 0.33; 0.50; 0.66; 0.75). These compounds exhibit semiconducting ($x = 0.25$; 0.33) and metallic ($x = 0.66$; 0.75) properties over the temperature range from 77 to 600 K. The d^3 and

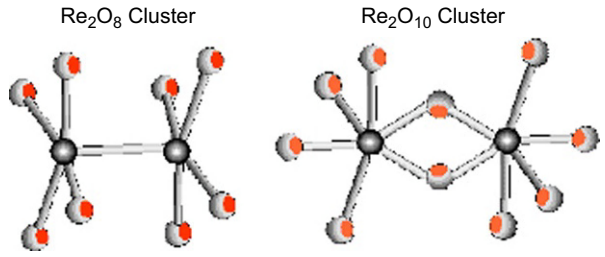

FIGURE 11.52

d^5 low-spin electron configurations for Re^{+4} and Ir^{+4} ions respectively, leads to the strong lowering of the magnetic moments, as the result of the superexchange interactions by the O^{2-} anions.

In the system CaO–Re_2O_5, single crystals of **$Ca_2Re_2O_7$** were synthesized using a flux method under 4 GPa at 973 K in a cubic-anvil type. It has a pyrochlore type of structure. $Ca_2Re_2O_7$ exhibits a unique structural transition characterized by a loss of the inversion symmetry as a metal. A novel effect has been predicted for conductors containing a broken mirror symmetry [e.g. polar metals and asymmetrical quantum well (QW) structures]. If such a conductor is under the direct current, $\mathbf{J}\cdot\mathbf{E}^{d}$, the circular polarized infrared radiation should induce an additional transverse current $\mathbf{J}_H\cdot\mathbf{E}^{d}\mathbf{x}\mathbf{c}$, where $\mathbf{E}^{d}$ is the driving electric field and **c** is a vector directed either along the polar axis or perpendicular to a QW. The sign of the current, $\mathbf{J}_H$, can be reversed by switching the helical nature of the light from right to left handed. Thus the phenomenon is, in fact, something like the Hall effect in which light acts as an external magnetic field. Competition between the FM double-exchange interaction and the superexchange AFM interaction was theoretically studied in the presence of geometrical frustration in the crystal. As the superexchange interaction increases, the FM metal becomes unstable and is taken over by a cooperative paramagnetic metal, in sharp contrast to a discontinuous transition to the AFM insulator in the absence of frustration. In the critical region, the system exhibits a peculiar temperature-independent behavior with highly incoherent transport, suggesting a large residual entropy at low temperatures in pyrochlore oxides.

In the system, CaO–ReO_3, only sixfold coordination is known for Re^{6+} in oxides. However, the octahedral environment varies from the perfect octahedron in ReO_3 to the distorted one in Ca_3ReO_6. The complex oxide Ca_3ReO_6 was synthesized and its crystal structure determined using X-ray powder analysis (space group $P2_1/n$; $a = 5.53664$ Å; $b = 8.80322$ Å; $c = 7.98492$ Å; $\beta = 90.073°$; $R_I = 0.032$, $R_P = 0.069$, $R_{wP} = 0.095$; $Z = 2$). The real symmetry is monoclinic due to a simultaneous tilt and rotation of the CaO_6 and ReO_6 octahedra. Electron diffraction and electron microscopy confirm the X-ray results. Ca_3ReO_6 is isostructural with A_2RRuO_6 oxides. Its structure has the form shown in Fig. 11.53.

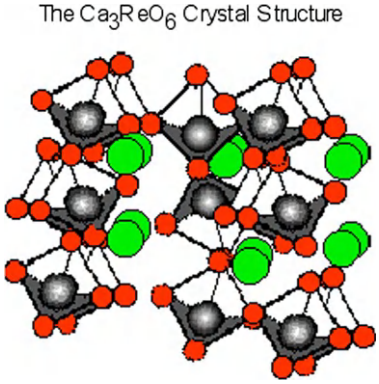

FIGURE 11.53

It consists of pairs of ReO_6 octahedra which are tilted relative to one another. The tilting and distortion of Re(Ca)O_6 octahedra together with B-cation ordering decrease the symmetry from orthorhombic to monoclinic with an angle close to 90°. One may well conclude that Rhenium is limited to different oxidation states from +4 to +7 in oxides. At the present time only compounds containing Re^{7+} are well studied, while the information about reduced Re-containing oxides (i.e. $V_{Re} < +7$) is very limited. In spite of the rich chemistry of rhenium in a low oxidation state, the synthetic problems encountered have discouraged the research in this field: Re cations with ($V_{Re} < +7$) are easily oxidized to Re^{7+} and they have the strong tendency to disproportionate. Such compounds have attracted the attention of many scientists in basic research because of their various interesting physical properties. For example, rhenium bronzes A_xReO_3 (A = Li, K) exhibit superconducting properties at low temperatures. Only one attempt to observe and build a phase diagram for the ternary rhenium oxides was carried out (BaO–Re–Re_2O_7). However, information and phase diagram data for other alkali earth—rhenium–oxygen systems is very scarce.

The $M_5Re_2O_{12}$ (M = Ca, Sr) oxides with Re in the formal oxidation state +7 also crystallizes in a hexagonal perovskite-like structure, where Re and M atoms are in a distorted octahedral oxygen coordination, d(Re–O) = 1.80–1.97 Å. The alkaline earth atoms are situated in the centers of eight- and ninefold polyhedra. The Ca_3ReO_6 compound belongs to the $A_2BB'O_6$ (Ca_2CaReO_6) perovskites with a "rock salt" type distribution of Re and Ca atoms over the B-cation sublattice. The tilting and distortion of Re(Ca)O_6 octahedra together with B-cation ordering decrease the symmetry from orthorhombic to monoclinic with an angle close to 90°.

The thermal decomposition of $Ca_5Re_2O_{12}$ in vacuo yielded single crystals of a perovskite-related phase having the composition $Ca_3ReO_{5.5}$. The $Ca_5Re_2O_{12}$ oxide with Re in the formal oxidation state +7 also crystallizes in a hexagonal perovskite-like structure, where Re and

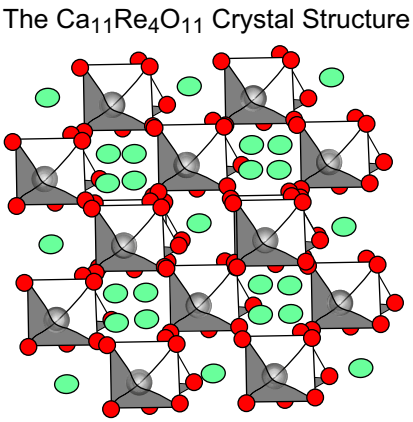

FIGURE 11.54

M atoms are in a distorted octahedral oxygen coordination, d(Re–O) = 1.80–1.97 Å. The alkaline earth atoms are situated in the centers of eight- and ninefold polyhedra. The structure has the form shown in Fig. 11.54.

The crystal structure of the $Ca_{11}Re_4O_{24}$ compound can also be derived from the perovskite structure. The rhenium atoms occupy two crystallographic sites, both with slightly distorted octahedral oxygen coordination. The averaged Re(1)–O distance of 1.931 Å and for Re(2)–O of 1.877 Å clearly reflects the two different oxidation states of rhenium in this compound. The formal oxidation state of $Re^{6.5+}$ in $Ca_{11}Re_4O_{24}$ is actually a consequence of one half Re^{6+} and the other half Re^{7+}. Four of eleven Ca atoms are distributed with Re atoms in the *B*-sublattice in a rock salt manner. The *A*-sublattice is not completely occupied and formally the $Ca_{11}Re_4O_{24}$ formula may be written as $Ca_7 \cdot (Ca_4Re_4)O_{24}$, which emphasizes the cation-deficient vacancies in the *A*-sublattice.

The magnetic susceptibility of $Ca_{11}Re_4O_{24}$ was determined with a Faraday balance in the temperature range between 138 and 296 K. The compound shows Curie–Weiss behavior with a magnetic moment of $\mu_{exp} = 1.2(1)$ μbar per Re(VI) ion. High-temperature treatment led to the formation of the most stable phases in this system, Ca_5ReO_{12} and $Ca(ReO_4)_2$, independent on the choice of precursors. The phases of primary interest are therefore unstable at temperatures above 950 °C.

The following table lists the most stable materials as well as the ranges and products of oxidation or reduction (Table 11.21).

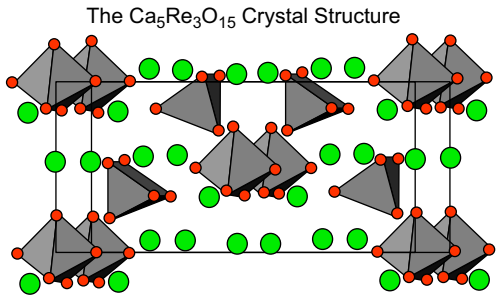

FIGURE 11.55

In the Ca–Re–O system, the stability of the Ca-rich phases was investigated. Two phases, $Ca_{11}Re_4O_{24}$ and $Ca_5Re_3O_{15}$, could be synthesized as single phase. The crystal structures of the complex oxides $Ca_{11}Re_4O_{24}$ and $Ca_5Re_3O_{15}$ were determined recently by X-ray single-crystal diffraction. Some discrepancies between the crystal structures revealed from powder diffraction data and single crystal ones were established. The structure of $Ca_5Re_3O_{15}$ is shown in Fig. 11.55.

Calcium rhenates are not available commercially and demand for these substances is almost nil. The high cost of Rhenium in general has precluded any usage in the Industry.

11.5.4. Strontium Rhenium Compounds

The literature describes many compounds concerning strontium oxy-rhenium compounds.

No compounds are known in the SrO–ReO system or the $SrO–Re_2O_3$ system.

In the $SrO–ReO_2$ system, it was claimed in a little known Czechoslovak thesis publication that a perovskite compound had been observed. However, the crystal parameters were not available. In a later thesis publication, the ternary compound, Sr_2CrReO_6, was studied. It is a double perovskite and the crystal parameters were given. It is dimorphic with the tetragonal form having $a_T = 5.5272$ Å, $c_T = 7.8091$ Å. The pseudo-cubic form has $a_c = b_c = c_c = 2 \cdot a_T/\sqrt{2} = 7.8166$ Å.

In the $SrO–ReO_3$ system, a number of compounds have been discovered. The Sr_3ReO_6 oxide has a monoclinic cell with $a = 8.1177(8)$ Å, $b = 5.9103(6)$ Å, $c = 5.9422(6)$ Å, $\beta = 90.47(1)°$ (space group I_2/m) and adopts a distorted

TABLE 11.21

Phase	Products of reduction	Lower $P(O_2)$ limit, bar	Upper $P(O_2)$ limit, bar	Products of oxidation
Ca_2ReO_6	$Re + CaO$	2.0×10^{-18}	1.0×10^{-3}	$Ca_5Re_2O_{12} + CaO$
$Ca_{11}Re_4O_{24}$	$Ca_3ReO_6 + Ca_5Re_3O_{15}$	5.0×10^{-11}	1.0×10^{-9}	$Ca_5ReO_{12} + CaO$
$Ca_5Re_3O_{15}$	$Re + Ca_3ReO_6 + Ca(ReO_4)_2$	5.0×10^{-11}	1.0×10^{-9}	$Ca_5Re_2O_{12} + CaO$

perovskite structure with Sr and Re ordered on the B-sites in a "rock salt" manner. Formally the Sr_3ReO_6 formula can be written as Sr_2SrReO_6. The Sr_3ReO_6 complex oxide could be considered as a Ba_2SbBiO_6 type of perovskite structure distortion. The ReO_6 and SrO_6 octahedra are cooperatively rotated about the [011] perovskite plane and are tilted with respect to a_0b-b-Glazer notation. The A-sites in a perovskite cell are occupied by the rest of Sr atoms. This compound is stable in the narrow range of partial oxygen pressure of 4.6×10^{-17} to 2.3×10^{-15} bar only. At the higher partial oxygen pressure the Sr_3ReO_6 oxide decomposes to a mixture of SrO and $Sr_{11}Re_4O_{24}$ compounds. The formal Re valence in the Sr_3ReO_6 increases from +6 to +6.5 due to a formation of cation vacancies in the A-sublattice, that leads to changing the coordination number of the Sr atoms in the B-sublattice from 6 to 8. The further increasing of a partial oxygen pressure to 1.1×10^{-3} bar leads to decomposition of the $Sr_{11}Re_4O_{24}$ compound to $Sr_5Re_2O_{12}$ and SrO. In this case the rest of the Re atoms with the oxidation state +6 in the $Sr_{11}Re_4O_{24}$ oxidizes to the Re^{+7} and vacancies in the B-sublattice are formed. This oxidation sequence could be considered as a stepwise increase of the amount of cation vacancies in the A- and B-sublattices from $Sr_6Re_2O_{12}$ through $Sr_{5.5}Re_2O_{12}$ to $Sr_5Re_2O_{12}$.

In the SrO–Re_2O_7 series of compounds, a novel oxide $Sr_2Ru_3O_{10}$ has been prepared under hydrothermal conditions (480–650 °C, 1800–2100 bar) and characterized by X-ray single-crystal diffraction data. The structure was refined in $C2/m$ space group with $a = 10.985(3)$ Å, $b = 5.635(1)$ Å, $c = 6.452(6)$ Å, and $\beta = 105.3(4)°$. The structure refinement converged to $R = 0.032$ and $R_w = 0.042$. The ruthenium atoms with a mean oxidation number of 5.33 occupy two sorts of octahedral sites. The first form infinite rutile-like chains parallel to the *b*-axis, while the second link these chains together to form layers parallel to (100) plane. The average Ru–O bond distance in the two types of octahedra does not allow assignment of an integral oxidation number to individual Ru ions. The Sr^{2+}cations are located in the interlayer space ensuring the stacking cohesion. The $Sr_2Ru_3O_{10}$ structure can also be described by the stacking of SrO_5 layers. The same stoichiometry is encountered in the barium fluorides $Ba_2M_3F_{10}$ (M = Ni, Cu, or Zn) but the stacking sequence is based on BaF_3 and BaF_7 layers. $Sr_2Ru_3O_{10}$ was the first example of strontium ruthenium oxide with Ru/Sr ratio higher than one. The Sr/Ru ratio is allowed by the existence of SrO_5 layers, which creates 1.5 octahedral sites per SrO_5 layer.

The X-ray powder diffraction patterns of annealed samples with $Sr_{2.75}ReO_{5.75}$ bulk composition was completely indexed based on a body-centered tetragonal cell with $a = 11.6779$ Å and $c = 16.1488$ Å (cell volume, $V = 2202.26$ Å^3). The indexing of the XRD pattern was confirmed by an electron diffraction study. The preliminary electron diffraction study did not reveal any superstructural spots corresponding to a decrease in symmetry or a unit cell expansion. Since the reflections with *hkl*: $h + k + l = 2n+1$, *hk*0: h, $k = 2n+1$ and 00*l*: $l = 4n+1$ were systematically absent, space group $I41/a$ was considered for further crystal structure determination The integral intensities of the reflections from the angular range 5°–70° for the diffraction pattern of $Sr_{11}Re_4O_{24}$ were extracted by profile fitting and further used for the calculation of the 3D Patterson distribution. The analysis revealed the positions of Re and for a part of the Sr atoms. The atomic coordinates of the other Sr and oxygen atoms were found by a subsequent Fourier and difference Fourier syntheses.

Re_2O_{10} clusters are connected with each other to form a 3D framework in Sr_xReO_3 ($0.5 \geq x \geq 0.4$) in the same way as in $La_4Re_6O_{19}$. The Sr_xReO_3 compound was synthesized by annealing under high pressure (50 kbar, 900 °C). The Re–Re distance in the Re_2O_{10} group for this structure is 2.429 Å. The only difference between these two structures is filling of the channels in the framework. The Sr atoms are situated in the interstices of the channels statistically (occupation number 0.3) on the 16f position of $Im3$ space group and have a ninefold coordination.

The $Sr_{2.4}Re_6O_{18}$ structure has the same cubic framework formed by the Re_2O_{10} group, and has a distribution of A-cations into the hexagonal channels. This formula can be written as $(Sr_{2.4})(Re_6O_{18})$ to distinguish between atoms belonging to the framework and those located inside the channels. Note that ordering of A-cations occurs with the increasing number of filled interstices and leads to a decrease of symmetry. Accordingly, as the Sr atoms fill the interstices statistically, the $Sr_{2.4}Re_6O_{18}$ structure has $Im\bar{3}$ symmetry and a body-centered cell similar to other compounds with 3D frameworks of Re_2O_{10} clusters.

Three new phases were prepared, Sr_3ReO_6, $Sr_{11}Re_4O_{24}$ and $Sr_7Re_4O_{19}$, and their crystal structures were solved and refined. Only one of these phases, $Sr_{11}Re_4O_{24}$ (the most stable in this system), could be prepared as a single phase without explicit control of the partial oxygen pressure in the sealed silica tube. The synthesis of the two other compounds requires a careful control of the partial oxygen pressure. The structure of $Sr_{11}Re_4O_{28}$ has the form shown in Fig. 11.56.

The following Table 11.22 lists the most stable materials as well as the ranges and products of oxidation or reduction. Formally the $M_{11}Re_4O_{24}$ formula (M = Sr or Ba) can be written as $M_7(M_4Re_4)O_{24}$, which allows the consideration of this compound as a cation-deficient perovskite with vacancies in the A-sublattice. This projection of the $Sr_{11}Re_4O_{24}$ crystal structure along the [001] shows that Re and M(4) atoms both occupy the *B*-position of the perovskite subcell in an ordered manner forming a "rock salt" type cation sublattice.

FIGURE 11.56

The remaining M atoms are placed in the channels of a 3D framework formed by ReO_6 and $M(4)O_8$ polyhedra, connected by corner sharing and edge sharing. Re(1) and Re(2) atoms are located in distorted octahedra ($d_{Re(1)–O} = 1.92–1.97$ Å, $d_{Re(2)–O} = 1.87–1.88$ Å). Since the octahedral coordination is not typical for Sr cations, the perovskite octahedral framework is significantly transformed. So, $Re(1)O_6$ octahedra are only slightly tilted along [110] whereas $Re(2)O_6$ ones are rotated along the same axis by $\approx 45°$. This changes the M(4) oxygen environment from an octahedron to an irregular eightfold polyhedron where Sr(4)–O distances vary in the range of 2.32–2.87 Å, and Ba(4)–O ones in the range of 2.40–2.85 Å. As a result, the $Re(2)O_6$ octahedron is edge shared by the equatorial oxygen atoms O(4) and O(6) to four $M(4)O_8$ polyhedra and connected with two $M(4)O_8$ ones by corner sharing via the apical oxygen atoms O(5). $Re(1)O_6$ octahedra are linked with the M(4) polyhedra only by corner sharing. The rotation of the ReO_6 octahedra leads to two kinds of nonequivalent channels filled by A-cations (see above diagram). In the first one only 3/4 of A-positions are occupied by M(1) and M(2) cations with 12-fold ($d_{Sr(1)–O} = 2.59–3.21$ Å) and 10-fold ($d_{Sr(2)–O} = 2.55–3.26$ Å) coordinations, respectively. The second one contains M(3) atoms surrounded by eight oxygen atoms ($d_{Sr(3)–O} = 2.50–2.97$ Å). The formal oxidation state of Re, calculated from the refined composition, is equal to +6.5. The Re atoms in the $M_{11}Re_4O_{24}$ structure are distributed over two nonequivalent positions and an ordered placement of Re_{+6} and Re_{+7} cations is expected.

The composition $Sr_{11}Re_4O_{24}$ ($Sr_{2.75}ReO_6$) is close to Sr_3ReO_6. An increase of the size of strontium atoms in comparison with the calcium ones in Ca_3ReO_6 results in an essential structural rearrangement of the anion framework and a formation of vacancies in the *A*-sublattice. The type of polyhedra sharing is different for these two structures in spite of the similar *B*-cation "rock salt" arrangement. In most cases the octahedral tilting distortion of the perovskite structure leads to a change of the first coordination sphere around A-cations. At the same time, the coordination environment of *B*-cations remains almost unchanged. The main reason for this distortion is the requirement to optimize the distances between A-cations and oxygen atoms. The geometrical relationship between *A*–O and *B*–O distances is determined by the Goldschmidt factor. In contrast the degree of octahedra tilting in the $M_{11}Re_4O_{24}$ structure significantly exceeds the usual tilt angles (which are approximately equal to 10°) and leads to dramatic changes in the first coordination sphere for half of the *B*-cations. This structural transformation is caused by the large size of M cations (M = Sr, Ba), which have to be surrounded by more than six oxygen atoms.

The crystal structure type of $M_{11}Re_4O_{24}$ (M = Sr, Ba) is closely related to two other structures of the already known compounds with the same stoichiometry, $Ca_{11}Re_4O_{24}$ and $Sr_{11}O_{s4}O_{24}$. The structure of $Sr_{11}O_{s4}O_{24}$ has been refined in the centrosymmetric, monoclinic space group $I2/a$, while for $Ca_{11}Re_4O_{24}$ noncentrosymmetric, the tetragonal space group $I41$ was unambiguously established. Both structures are considered to be derived from the common tetragonal, higher symmetry space group $I41/a$ of $M_{11}Re_4O_{24}$ (M = Sr, Ba) through a "translationengleiche" [(t) transformation]. These minor differences in the $M_{11}Re_4O_{24}$ structures for M = Ca and M = Sr, Ba can be traced to the different space requirements of the calcium and strontium atoms. In $Ca_{11}Re_4O_{24}$ the calcium atoms have coordination of 8 and 9. In contrast, the strontium atoms, occupying the *A*-sublattice, have coordination numbers of 10 and 12.

The compound, $Sr_7Re_6O_{19}$, has the crystal structure form shown as follows. There are two nonequivalent Re positions in the $Sr_7Re_4O_{19}$ crystal structure. The Re atoms are situated in the distorted octahedra. The average Re–O distance is 1.95 Å and 1.94 Å for Re(1) and Re(2) atoms, respectively, in good agreement with

TABLE 11.22

Phase	Products of reduction	Lower $P(O_2)$ limit, bar	Upper $P(O_2)$ limit, bar	Products of oxidation
Sr_3ReO_6	Re + SrO	4.5×10^{-17}	2.3×10^{-15}	$Sr_{11}Re_4O_{24} + SrO$
$Sr_{11}Re_4O_{24}$	Re + SrO	2.3×10^{-15}	1.1×10^{-3}	$Sr_5Re_2O_{12} + SrO$
$Sr_7Re_4O_{19}$	Re + SrO	2.3×10^{-15}	1.3×10^{-9}	$Sr_5Re_2O_{12} + Sr(ReO_4)_2$

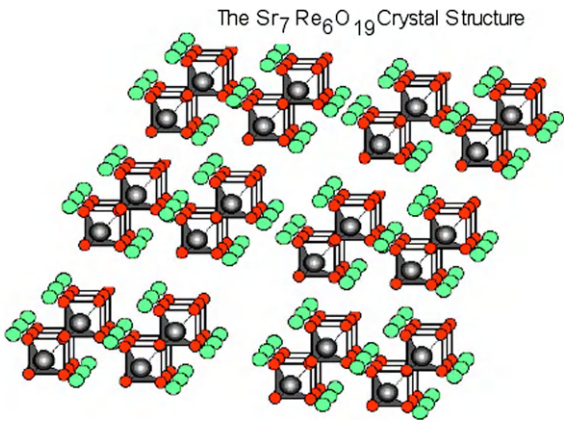

FIGURE 11.57

the ionic radius of Re_{6+} (0.52 Å) for CN = 6. Sr atoms have two different coordinations (Fig. 11.57).

Sr(1) and Sr(4) are 12-fold coordinated, Sr(2) and Sr(3) have 10 neighboring oxygen atoms each. The Sr(4) environment is regular in contrast to other Sr/O-polyhedra and can be described as a four capped cube . Other Sr atoms have irregular oxygen coordination. The $Sr_7Re_4O_{19}$ structure may be considered as an intermediate structure between Ba_2ReO_5 and $Ba_3Re_2O_9$ structures. The Ba_2ReO_5 compound contains ReO_6 octahedra linked by common corners and form infinite *cis*-bridged chains. In contrast, corner-sharing ReO_6 octahedra build infinite layers in the $Ba_3Re_2O_9$ structure. The $Sr_7Re_4O_{19}$ structure consists of two isolated, infinite chains of corner-sharing ReO_6 octahedra connected with each other. A new $Sr_7Re_4O_{19}$ double oxide could be considered as the fourth member of the $A_{4+n}Re_4O_{16+n}$ structure family ($n = 0, 1, 2,\ldots$), where A is an alkaline earth metal.

The compound, Sr_3ReO_6, has been synthesized by annealing in an evacuated silica tube under controlled partial oxygen pressure $p(O_2) = 4.6 \times 10^{-15}$ bar at 740 °C for 24 h. To control partial oxygen pressure a mixture of Ni and NiO was used. The structure investigation of the Sr_3ReO_6 complex oxide was carried out using X-ray powder diffraction. Its cation composition was determined by EDX analysis, Sr: Re = 3.00(4):1.00(4). The powder diffraction pattern of the Sr_3ReO_6 oxide was indexed, based on an *I*-centered monoclinic cell with $a = 8.1177$ Å, $b = 5.9103$ Å, $c = 5.9422$ Å, $\beta = 90.47°$. The structure has the form shown in Fig. 11.58.

The Sr_3ReO_6 complex oxide adopts a distorted perovskite structure with Sr and Re ordered on the *B*-sites in "rock salt" manner. Formally the Sr_3ReO_6 formula can be written as Sr_2SrReO_6. The Sr_3ReO_6 complex oxide could be considered as a Ba_2SbBiO_6 type of perovskite structure distortion. The ReO_6 and SrO_6 octahedra are cooperatively rotated about the [011] axis of the perovskite subcell and a_0b-b tilted with respect to Glazer's

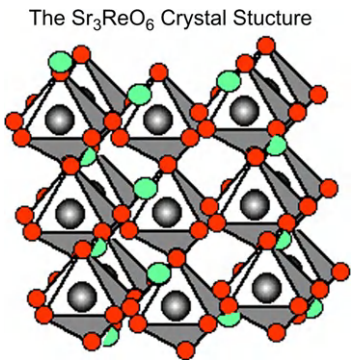

FIGURE 11.58

notation. The A-sites in a perovskite cell are occupied by the remaining Sr atoms. This compound is stable in the narrow range of partial oxygen pressure from 4.6×10^{-17} to 2.3×10^{-15} bar only. At a higher partial oxygen pressure the Sr_3ReO_6 oxide decomposes to a mixture of SrO and $Sr_{11}Re_4O_{24}$. The formal Re valence in Sr_3ReO_6 increases from +6 to +6.5 due to a formation of cation vacancies in the *A*-sublattice, that leads to a change in the coordination number of the Sr atoms in the *B*-sublattice from 6 to 8. A further increase of the partial oxygen pressure to 1.1×10^{-3} bar leads to decomposition of $Sr_{11}Re_4O_{24}$ to $Sr_5Re_2O_{12}$ and SrO. In this case all Re atoms with the oxidation state +6 in $Sr_{11}Re_4O_{24}$ are oxidized to Re_{+7}, and vacancies in the *B*-sublattice are formed. This oxidation sequence can be considered as a stepwise increase of the amount of cation vacancies in the *A*- and *B*-sublattices from $Sr_6Re_2O_{12}$ through $Sr_{5.5}Re_2O_{12}$ to $Sr_5Re_2O_{12}$, as shown in the following equations:

$$Sr_6Re_2O_{12} \Rightarrow Sr_{5.5}Re_2O_{12} + 1/2\ SrO$$
$$Sr_{5.5}Re_2O_{12} + 1/2\ SrO \Rightarrow Sr_5Re_2O_{12} + 1/2\ SrO$$

The compound, $Sr_5Re_2O_{12}$ has the structure form shown in Fig. 11.59.

The structural relations between Sr_3ReO_6 (a) $[A_2ABO_6]$, $Sr_{11}Re_4O_{24}$ (b) $[A_{1.75}ABO_6]$ and $Sr_5Re_2O_{12}$

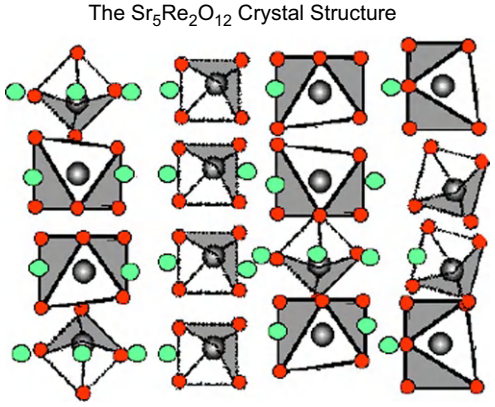

FIGURE 11.59

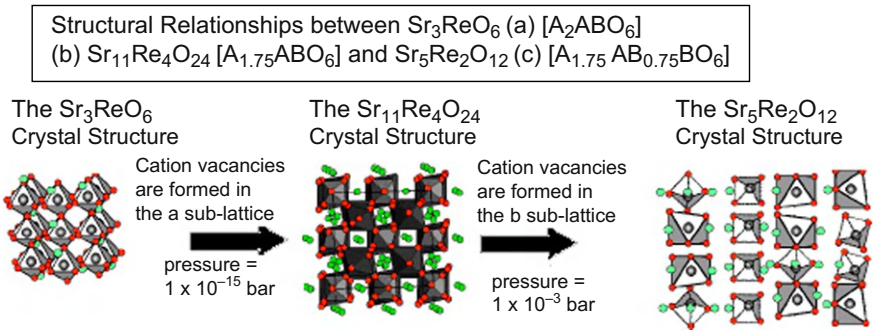

FIGURE 11.60

(c) $[A_{1.75}A_{0.75}BO_6]$ are shown in the following diagram in Fig. 11.60.

It should be clear that control of the oxygen partial pressure has a direct effect upon the nature of the strontium rhenate compound obtained and that cation vacancies and/or anion vacancies are the norm at specific synthesis conditions.

Strontium rhenates are not available commercially and no CAS numbers have been issued. No uses have emerged in the Industry, a fact that may be due to the high cost of Re metal that was $ 10.25/g in 2010.

11.5.5. Barium Rhenium Compounds

The Ba–Re–O system is very like that of the Sr–Re–O system and many of the comments and observations made for the Sr system are directly applicable to the Ba system. There is, however, at least one difference that exists between the systems. Whereas, three (3) compounds that are the most stable are listed in the Sr–Re–O system, only one (1) has been found in the Ba–Re–O system. That compound is $Ba_{11}Re_4O_{24}$. However at oxygen partial pressures of $PO_2 \geq 3 \times 10^{-3}$, it decomposes to $Ba_5Re_2O_{12}$ plus $Ba_3(ReO_5)_2$.

No compounds are known that involve the lower valence state of rhenium. The systems, BaO–ReO, $BaO–Re_2O_3$, $BaO–ReO_2$ and $BaO–Re_2O_5$ are nearly devoid of compounds. Most of the known compounds involve the $BaO–ReO_3$ and $BaO–Re_2O_7$ systems. The $Ba_3Re_2O_9$ oxide has hexagonal perovskite-like structures based on a 9R(*chh*)3 close-packed stacking of the BaO_3 layers where Re atoms are situated in the octahedral interstices. Units of three face-sharing octahedra are linked by corner sharing and form infinite chains along the [001] direction. The middle octahedron of these units is vacant to overcome the electrostatic repulsion between the highly charged neighboring Re^{6+} cations (Fig. 11.61).

For $Ba_3Re_2O_9$, the magnetic data, measured with a Faraday balance, suggest a Curie–Weiss behavior in the temperature region from 80 to 230 K, the magnetic moment is $\mu_{exp} = 1.55$ μbar per Re(VI) ion. Electrical resistivity measurements on $Ba_3Re_2O_9$ and Ba_2ReO_5 have revealed a high-room temperature resistivity ($\rho \sim 10^7$ Ωcm), which is doubtless a consequence of the orthogonality of the Re t_{2g} orbitals involved in the π–bonding to *cis* oxygen atoms.

The Ba_2ReO_5 compound is isostructural with Ba_2WO_5. The Ba_2ReO_5 compound contains ReO_6 octahedra linked by common corners and form infinite *cis*-bridged chains. In contrast, corner-sharing ReO_6 octahedra build infinite layers in the $Ba_3Re_2O_9$ structure shown in Fig. 11.62.

The existence of the compound, Ba_3ReO_6 remains in doubt. Syntheses of samples with controlled partial oxygen pressure and with BaO excess did not lead to a reproducible formation of the early observed compound, "Ba_3ReO_6". The conclusion can be made that the observed compound may be considered as a complex barium–rhenium oxycarbonate, where carbonate groups substitute BaO_6 octahedra partially in the 3D network of the corner-sharing octahedra BaO_6 like in the well-known case of barium–copper oxycarbonate, erroneously denoted as "$BaCuO_2$". This conclusion is supported by geometrical considerations

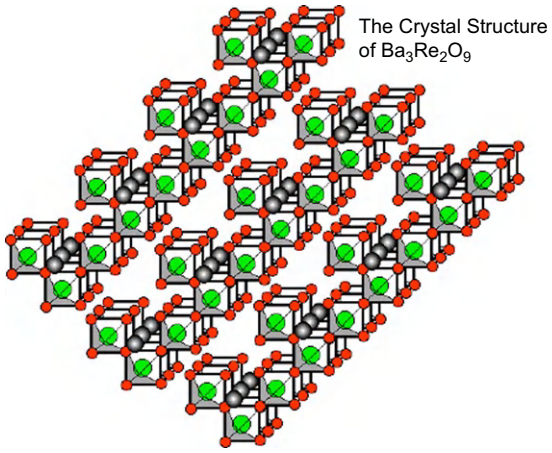

FIGURE 11.61

FIGURE 11.62

for the expected Ba_3ReO_6 complex oxide, which should crystallize in a perovskite-related structure with rock salt ordering of cations in the *B*-subcell, like in the Ca_3ReO_6 and the Sr_3ReO_6 structures. One-third of the Ba atoms would occupy the center of oxygen octahedra, but such an octahedral coordination would be very unusual for the big barium atoms, as the ionic radius of Ba^{2+} is 1.36 Å for sixfold coordination. Even in the case of the analogous strontium compound, Sr_3ReO_6, with $r_{Sr+2} = 1.16$ Å for a sixfold coordination, the occupancy of octahedral sites by Sr atoms results in a considerable restriction of the stability range in comparison to other observed phases in the Sr–Re–O system.

The crystal structure of the recently reported $Ba_{11}Re_4O_{24}$ compound can also be derived from the perovskite structure, designated a_{per} here. The crystal parameters are: $a = 12.2347$ Å and $c = 16.647$ Å ($V = 2496.65$ Å^3 for M = Ba). The cell parameters of $M_{11}Re_4O_{24}$ are clearly connected with the parameters of the perovskite subcell a_{per}: $a = 2\,a_{per}$, $c = 4\,a_{per}$. Formally the $M_{11}Re_4O_{24}$ formula can be written as $M_7(M_4Re_4)O_{24}$, which allows us to consider this compound as a cation-deficient perovskite with vacancies in the *A*-sublattice. This structure is shown in Fig. 11.63.

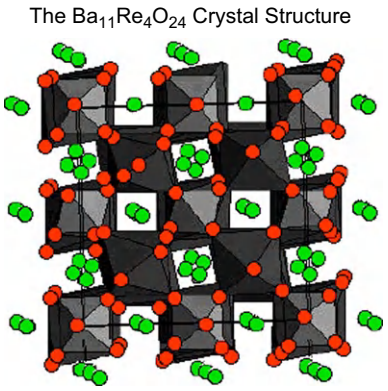

FIGURE 11.63

The rhenium atoms occupy two crystallographic sites, both with slightly distorted octahedral oxygen coordination. The averaged Re(1)–O distance of 1.931 Å and for Re(2)–O of 1.877 Å clearly reflects the two different oxidation states of rhenium in this compound. The formal oxidation state of $Re_{+6.5}$ in $Ca_{11}Re_4O_{24}$ is actually a consequence of one half Re_{+6} and the other half Re_{+7}. Four of eleven Ca atoms are distributed with Re atoms in the *B*-sublattice in a rock salt manner. The *A*-sublattice is not completely occupied and formally the $Ca_{11}Re_4O_{24}$ formula may be written as $Ca_7 \cdot (Ca_4Re_4)O_{24}$, which emphasizes the cation-deficient vacancies in the *A*-sublattice.

The crystal structure type of $Ba_{11}Re_4O_{24}$ is closely related to two other structures of the already known compounds with the same stoichiometry, $Ca_{11}Re_4O_{24}$ and $Sr_{11}O_{s4}O_{24}$. The structure of $Sr_{11}O_{s4}O_{24}$ has been refined in the centrosymmetric, monoclinic space group *I*2/*a*, while for $Ca_{11}Re_4O_{24}$ noncentrosymmetric, the tetragonal space group *I*41 was unambiguously established. Both structures may be deemed to be derived from the common tetragonal, higher symmetry space group *I*41/*a* of $Ba_{11}Re_4O_{24}$ through a translationengleiche (t) transformation.

A spectrophotometric study shows that less than 35% of normal perrhenate converts to a meso form in 15 M base, and $K_f \sim 0.1$. The species absorbs at 260 μm ($\delta = 6400$) and near 310 μm ($\delta \sim 1400$), overlapping the normal perrhenate features. Reflectance spectra on an isolable barium salt, $Ba_3(ReO_5)_2$, confirm this resolution of the curve components. Single crystals of two new barium rhenate compositions, $Ba_{16}Re_6O_{37}$ and $Ba_{10}Re_3O_{16}(OH)_3$, and of one new polymorph, orthorhombic $Ba_5Re_2O_{12}$, were grown out of a barium hydroxide flux in sealed silver tubes. $Ba_{16}Re_6O_{37}$ and $Ba_{10}Re_3O_{16}(OH)_3$ crystallize into the monoclinic *C*2/*m* system, with $a = 20.577$ Å, $b = 5.8897$ Å, $c = 15.438$ Å, $\beta = 92.255°$ and $a = 19.3834$ Å, $b = 5.8172$ Å, $c = 10.2925$ Å, $\beta = 91.7460°$, respectively. The orthorhombic polymorph of $Ba_5Re_2O_{12}$ crystallizes in the space group *Pnma*, with $a = 19.6728$ Å, $b = 5.8491$ Å and $c = 10.4648$ Å. All the three crystal structures are related and consist of a framework of BaO_x polyhedra (where *x* varies from 6 to 12) with inter-penetrating layers of ReO_6 octahedra. The arrangement of these octahedra is shown in Fig. 11.64.

A systematic survey of the BaO–Re–Re_2O_7 phase diagram was reported with emphasis on the reduced ternary oxides. At 800 °C, the previously reported compounds $Ba_3Re_2O_9$, Ba_2ReO_5, and Ba_3ReO_6 were observed, all of which contain Re(VI) in ReO_6 octahedra. The stability of these phases is apparently due to Re–O π-bonding in and between the octahedra.

The previously unknown structure of Ba_2ReO_5 was determined by powder neutron diffraction and found to be isotypic with that of $K_2VO_2F_3$ (space group

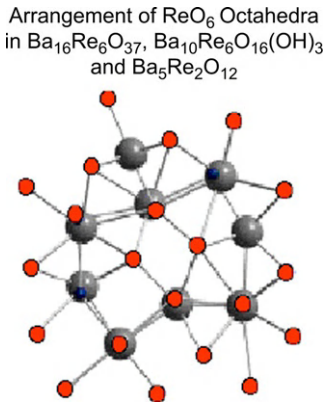

FIGURE 11.64

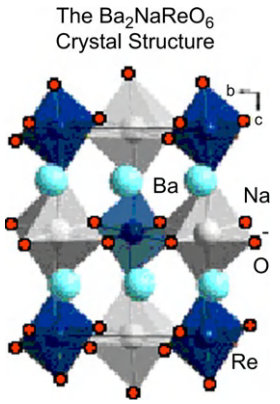

FIGURE 11.65

Pnma), with $a = 7.3233$, $b = 5.7745$, and $c = 11.4124$ Å. ReO_6 octahedra share adjacent corners to produce cis-chains which are held together by 10 coordinated Ba atoms.

Single crystals of the double perovskite rhenates A_2BReO_6 (A = Sr, Ba; B = Li, Na) were grown out of molten hydroxide fluxes. Single crystals of orange/yellow Ba_2LiReO_6, Ba_2NaReO_6 and Sr_2LiReO_6 were solved in the cubic, *Fm*-3*m* space group with $a = 8.1214$ Å, 8.2975 Å, and 7.9071 Å, respectively, while Sr_2NaReO_6 was determined to be monoclinic $P2_1/n$ with $a = 5.6737$ Å, $b = 5.7988$ Å, $c = 8.0431$ Å, and $\beta = 90.02°$. The cubic structure consists of a rock salt lattice of corner-shared ReO_6 and MO_6 (M = Li, Na) octahedra that, in the monoclinic structure, are both tilted and rotated. A discrepancy exists between the symmetry of Sr_2LiReO_6 indicated by the single-crystal refinement of flux-grown crystals (cubic, *Fm*-3*m*) and the symmetry indicated by the powder diffraction data collected on polycrystalline samples prepared by the ceramic method (tetragonal, *I*4/*m*). It is possible that the cubic crystals are a kinetic product that forms in small quantities at low temperatures, while the powder represents the more stable polymorph that forms at higher reaction temperature. The structure is shown in Fig. 11.65.

Single-crystal structure analyses of double perovskite rhenates, Sr_2LiReO_6, Ba_2LiReO_6 and Ba_2NaReO_6 indicate cubic symmetry while that of Sr_2NaReO_6 shows monoclinic symmetry.

In addition a mixed Ba–Mg compound has been synthesized. The XRD patterns of the annealed samples of Ba_2MgReO_6 composition were completely indexed based on a primitive an F-centered cubic cell with $a = 8.0850$ Å. This indexation is only in slight disagreement with the cell parameters reported by Sleight et al. for barium-containing compound. The Ba_2MgReO_6 structure model was taken as from Woodward for the F-centered cubic cell and a BO_6 octahedra tilt system, where $a = b = c = 2\,a_{per}$, a°a°a° tilt system, corresponding to Glazer's notation.

The magnetic properties of Ba_2MgReO_6 were also studied. A similar unexpected behavior as in the case of the $Sr_7Re_4O_{19}$ oxide was observed. The temperature dependence of magnetization shows an anomalous course in the case of Ba-containing samples. The results of the zero-field cooled measurements drastically differed from the field cooled ones, and their observed values are negative until 19 K was reached at the field strength of 100 G for Ba_2MgReO_6. The Ba_2MgReO_6 compound demonstrates a temperature-independent curve of magnetization between 300 and 30 K. Despite this observation, hysteresis loops were observed for both the Ba and for the Sr-containing compound inclusive at 300 K.

Barium oxy-rhenate compounds are not available commercially and no CAS numbers have been issued.

11.5.6. Radium Rhenium Compounds

Although radium rhenate compounds could be synthesized similar to those exhibited by the Ba–Re–O system, it is unlikely that they ever will be due to the high radioactivity of ^{226}Ra and the high cost of rhenium.

12.1. ALKALINE EARTH—IRON INTERMETALLIC COMPOUNDS

Only Be^0 metal forms intermetallic compounds with the metal, Fe^0. The others do not form any compounds. The compounds, $Be_{0.2}Fe_{0.8} = BeFe_4$, $Be_{0.56}Fe_{1.44} = BeFe_{2.57}$, $Be_{12}Fe$, $Be_{17}Fe_2$, Be_5Fe and Be_2Fe are known. A phase diagram has not been published.

The compound, Be_5Fe has the structure form shown in Fig. 12.1.

The lattice direction (100), is shown but the (001) direction is identical. The cubic faces are face-centered with Fe atoms and there are five (5) internal rows of Be atoms. It is a cubic material with cell parameters of: $a = b = c = 4.1543$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 50.70 Å^3, $Z = 4$. Cell occupancy is shown in Table 12.1.

The compound, $Be_{12}Fe$ has a similar structure form, except that the Fe atoms form a body-centered cube (Fig. 12.2).

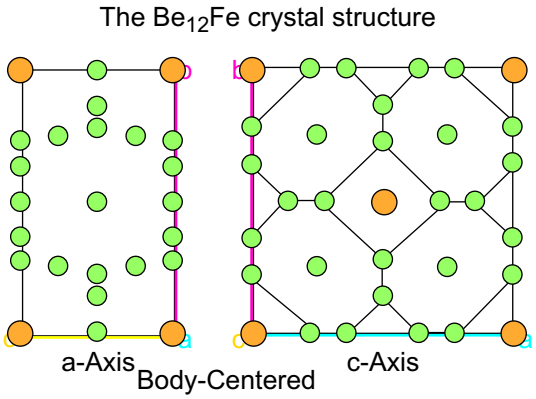

FIGURE 12.2

Both the *a*- and *c*-axes are shown [the (100) and (001) directions in the lattice]. There are three (3) internal arrangements of Be atoms within the unit cell, arranged in a distorted octahedron around a central Be atom. Cell parameters are: $a = 4.232$ Å, $b = c = 5.548$ Å, $\alpha = 81.636°$, $\beta = \gamma = 67.58°$, cell volume $= 111.31$ Å^3, $Z = 2$. Cell occupancy is shown in Table 12.2:

The compound, Be_2Fe has the structure form shown in Fig. 12.3.

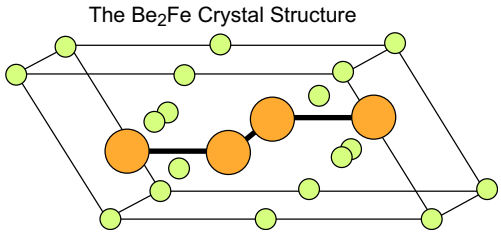

FIGURE 12.3

The lattice direction (100), is shown. The Fe atoms are arranged in a zigzag manner. It is a monoclinic material with cell parameters of: $a = b = 4.215$ Å, $c = 6.853$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 105.44$ Å^3, $Z = 4$. Cell occupancy is shown in Table 12.3.

The compound, $Be_{17}Fe_2$, has the structure form shown in Fig. 12.4.

The cell parameters are: $a = b = 4.137$ Å, $c = 10.72$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 158.89$ Å^3, $Z = 2$. Cell occupancy is shown in Table 12.4.

The compound, $Be_{0.56}Fe_{1.44}$ has the body-centered cubic structure where the Be atoms and Fe atoms are distributed randomly at the central position in the lattice (Fig. 12.5).

Cell parameters are: $a = b = c = 2.732$ Å, $\alpha = \beta = \gamma = 90°$. Cell volume = 20.53 Å^3, $Z = 1$. Cell occupancy is shown in Table 12.5.

The compound, $Be_{0.2}Fe_{0.8}$, has a similar body-centered cubic structure shown in Fig. 12.6.

Unit cell parameters are: $a = b = c = 2.4162$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 10.86 Å^3, $Z = 1$. Cell occupancy is shown in Table 12.6.

Mg, Ca, Sr and Ba do not form intermetallic compounds with Fe. None of these compounds are used in the Industry and they are not offered for sale commercially.

12.2. ALKALINE EARTH—OXY-IRON COMPOUNDS

A large number of compounds are known with iron. The number of compounds that have been synthesized varies from a few with MgO to many with BaO.

12.2.1. Beryllium Oxy-Iron Compounds

Beryllium oxide, BeO, does not form any compounds with the iron oxides.

12.2.2. Magnesium Oxy-Iron Compounds

The system, MgO–FeO, does not form any compounds as shown in the phase diagram presented as follows. Only solid mixtures of oxides appear. A eutectic was found at 1530 °C and 0.5 molar ratios of oxides. No compounds are known in this system (Fig. 12.7).

In the Fe^{3+}-containing system of MgO–Fe_2O_3, the ferrite, $MgFe_2O_4$, is in great demand. The ever expanding electronic industry's need of ferrites, both hard and soft, is evident from the estimated world ferrite production of 5,16,000 metric tons per year (MTPY) in 1990 to 15,00,000 MTPY in the year 2005. The ferrite grade iron oxide, a-Fe_2O_3, required for such production of ferrites in the year 2005 would be of about 10,50,000 MTPY.

The production of ferrites has been on the rise ever since the commercialization of these took place some 60 years ago. The magnesium ferrite, $MgFe_2O_4$, prepared from these synthetic iron oxides, showed a high resistivity of ~108 ohm/cm. All ferrites showed saturation magnetization, $4\pi M_s$, in the narrow range of 900–1200 G. The Curie temperature, T_C, of all these fell within a small range limit of 670 ± 30 K. All ferrites had low dielectric constants (e_c), 12–15, and low dielectric loss, tan δ, which decreased with the increase in frequency indicating a normal dielectric dispersion, as found in ferrites. The presence of an insignificant amount of polarizable Fe^{2+} ions can be attributed to their high resistances and low dielectric constants. Impurities inherent in the samples had no marked influence on the electrical properties of the ferrites prepared from the iron ore rejects, suggesting the possibility of formation of a ferrite of constant composition, $MgFe_2O_4$, of low magnetic and dielectric losses at lower temperatures of 1000 °C by ceramic technique.

Super-paramagnetism is a unique and important aspect of magnetism in nanoparticles. The super-paramagnetic properties of the spinel $MgFe_2O_4$ ferrite nanoparticles with a particle size from about 6 to 18 nm have been studied. The blocking temperature is a function of the particle size and increases with increasing particle size. The coercivity of $MgFe_2O_4$ nanoparticles is also a function of the particle size below the blocking temperature. When the temperature rises above the blocking temperature, the nanoparticles show non-hysteresis magnetization behaviors. With these interesting super-paramagnetic properties, $MgFe_2O_4$ nanoparticles have potentials for applications such as ferro-fluids, magneto-caloric refrigeration, and the contrast agents for magnetic resonance imaging. The structure has the form shown in Fig. 12.8.

The tetrahedral and octahedral cation sites are shown in gray and white, respectively, and the O atoms as small circles. A unit cell is outlined. **$MgFe_2O_4$ is one of the most important ferrites**. The oxides, MgO and Fe_2O_3 were heated together at 900 °C and quenched in

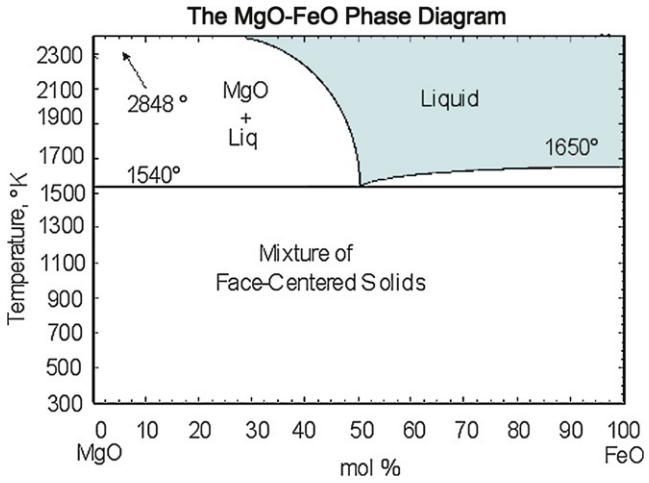

FIGURE 12.7

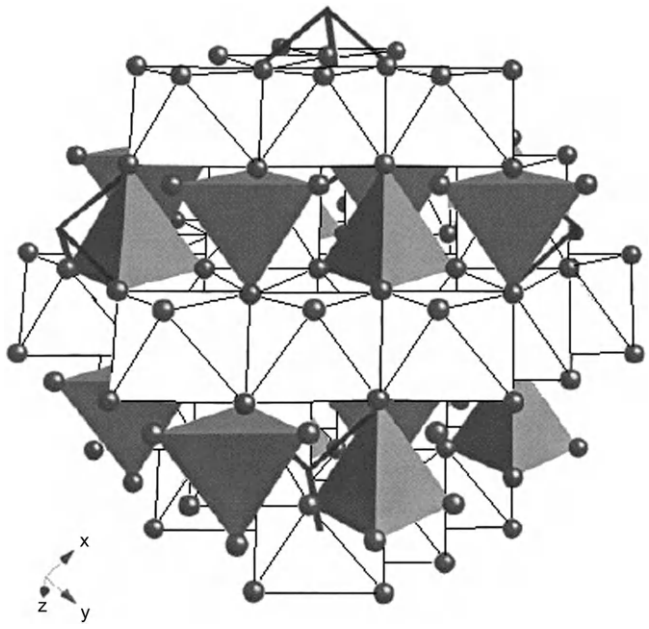

FIGURE 12.8

air. The structural behavior of magnesioferrite was determined from in situ synchrotron X-ray powder diffraction data (SXRD) [$\lambda = 0.92225$ Å] at room pressure and temperatures from 28 to 982 °C on heating and cooling. The "*a*" parameter of the unit cell increases linearly on heating, but deviates to give a discontinuity at 581 °C.

Above 581 °C and on cooling from 982 °C, the "*a*" parameter varies linearly. This parameter at 28 °C before heating [8.39704 Å] and after cooling to 47 °C [8.39514 Å] differs because the cation order, frozen in the structure, is not the same. Cation order, $x,\{^{iv}[Mg_{1-x}Fe_x]^{vi}[Mg_{x/2}Fe_{1-x/2}]_2O_4\}$, analyzed in terms of the inversion parameter, and the order parameter, $Q = 1 - (3/2)x$, show no change on heating until the temperature is high enough to cause exchange of Mg^{2+} and Fe^{3+} cations between the octahedral and tetrahedral sites. This activation barrier is overcome at 581 °C, where the sample achieves the maximum ordered state on heating [$x_{max} = 0.867$] and begins to move toward equilibrium. This relaxation is toward a more ordered configuration and is a kinetically controlled process. Above 581 °C, the cations become continuously disordered along the equilibrium pathway to the maximum temperature studied [$T_{max} = 982$ °C, $x = 0.769$] and reverse along the equilibrium pathway on cooling. At T_B, the maximum equilibrium order is frozen in, and maintained to room temperature, where $x_{max} = 0.895$.

The influence of Sn^{4+} and /or Mo^{6+} ions on the microstructure and humidity sensitivity of the Mg ferrite prepared by a self-combustion method was studied. The sintered compacts have a typical porous structure. The average grain size changes from 500 to 100 nm by partial substituting of Mg ions with Sn ions in $MgFe_2O_4$. The $Mg_{0.9}Sn_{0.1}Fe_2O_4$ porous ceramic exhibits the best humidity sensitivity among the specimens studied. Its electrical resistivity changed remarkably, by three orders of magnitude, when the relative humidity increased from 11 to 98%. Among the studied elements, this composition exhibits a short response time. However, the response time is not yet a satisfactory value. These preliminary results show that the promoting effects of Sn^{4+} ions on humidity sensitivity of Mg ferrite can be related with the changes in porosity and grain size (specific surface area). Further investigations are necessary to shorten the response time, without any decrease in humidity sensitivity, and to explain the role of Sn^{4+} substituent.

In another paper, epitaxial $MgFe_2O_4$ thin films were synthesized by oxide molecular beam epitaxy at 300 °C. Reflection high-energy electron diffraction and transmission electron microscopy (TEM) showed that the films were epitaxial with a (001) orientation. Magneto-optic Kerr effect and superconducting quantum interference device magnetization measurements revealed that films were ferrimagnetic with a saturation ellipticity of 0.005 °C, and saturation magnetization of 120 emu/cm^3. The ferrimagnetism was attributed to the formation of a partially inverted spinel structure with a cation distribution $[Mg^{2+}_{0.2}Fe^{3+}_{0.8}][Mg^{2+}_{0.8}Fe^{3+}_{1.2}]O_4$.

ptMagnesioferrite, $MgFe_2O_4$ was found to undergo a transformation to a high-pressure phase with the suggested $CaMn_2O_4$—structure at around 17 GPa. Thermodynamic calculations, however, postulate the breakdown of $MgFe_2O_4$ into its constituent oxides at high pressure and temperature prior to the formation to the high-pressure phase. This behavior was experimentally observed by use of DAC (Diamond Anvil Cell) technique where synthetic $MgFe_2O_4$ at 26 ± 4 GPa and laser heating between 1500 and 2000 K were employed. The high-pressure phase of $MgFe_2O_4$ was identified and the break down products MgO and Fe_2O_3 by Mössbauer spectroscopy, Raman spectroscopy and synchrotron X-ray diffraction (SXRD). The multiphase assemblage results suggest that inhomogeneous conditions prevailed during the laser annealing in the DAC experiments.

Two different reactions were suggested at high pressure and temperature:

$$T < 1800 \text{ K: } MgFe_2O_4 \Rightarrow Fe_2O_3 + MgO$$
$$T > 1800 \text{ K: } MgFe_2O_4 \Rightarrow \text{hp-}MgFe_2O_4.$$

Magnetic properties, such as Curie temperature (T_C), saturation magnetization (M_s), remanent magnetization (M_r), and coercivity (H_c) of nanoparticles of magnesium ferrites ($MgFe_2O_4$), were studied in a broad range of temperatures varying from room temperature to 800 K. The magnetization decreased with increasing temperature, approaching zero at ~750 K. The Curie temperature, determined by means of the inverse susceptibility versus temperature, was ~738 K. The saturation magnetization, coercivity, and remanence decreased with increasing temperature, being close to zero at temperatures near T_C. However, for temperatures 100 K above room temperature, these magnetic properties were still the same as those at room temperature. The coercivity temperature dependence could be expressed in terms of $T^{3/4}$, indicating that $MgFe_2O_4$ nanoparticles may form a system of random and noninteracting identical particles. The results were discussed in terms of interparticle interactions induced by the thermal fluctuations, cation distribution, and other imperfections that exert fields on Mg^{2+} ions that could increase with temperature.

In the Fe^{2+}- and Fe^{3+}-containing system of MgO–Fe_3O_4, no compounds are known.

In the Fe^{4+}-containing system of MgO–FeO_2, no compounds have been discovered.

In the Fe^{5+}-containing system of MgO–Fe_2O_5, no compounds have been discovered to date.

In the Fe^{6+}-containing system of MgO–FeO_3, a set of samples of Fe/MgO, in the concentration range between 1.5 and 9 wt% of Fe, was prepared by the impregnation method and then calcined at 1073 K. All of them were characterized by XRD and Raman and Mössbauer spectroscopy. The data obtained showed that the solids were made up of **$MgFeO_4$** nanoclusters and Fe^{3+} ions dispersed in the MgO matrix. The size of the clusters and the amounts of each phase were calculated using the XRD and Mössbauer data. No other data were available for this compound and no other Fe^{6+}-containing magnesium ferrates have been synthesized.

In the Fe^{7+}-containing system of MgO–Fe_2O_7, no compounds have been discovered. These compounds are expected to be unstable and to be highly oxidizing to organic compounds. Only alkali-based compounds are known.

$MgFe_2O_4$ is offered for sale commercially with the CAS number of 12068-86-9 by many manufacturers.

12.2.3. Calcium Oxy-Iron Compounds

Several types of compounds are known in the CaO–Fe_xO_y systems.

In the Fe^{2+}-containing system of CaO–FeO, $CaFeO_2$, a material exhibiting an unprecedented layered structure containing $3d^6$ iron atom in a high-spin distorted square-planar coordination, was reported. This phase, obtained through a low-temperature reduction procedure using calcium hydride, was characterized through powder neutron diffraction, synchrotron XRD, Mössbauer spectroscopy, XAS experiments as well as first-principles density functional theory (DFT) calculations. The XAS spectra near the Fe–K edge for the whole solid solution $(Sr_{1-x},Ca_x)FeO_2$ supported the fact that iron is in a square-planar coordination for $0 \leq x \leq 0.8$ but clearly suggests a change of coordination for $x = 1$. The structure reported has the form shown in Fig. 12.9.

This structure contains infinite FeO_2 layers in which the FeO_4 units distort from square planar toward tetrahedra and rotate along the *c*-axis in an unprecedented manner. This is in marked contrast to the well-studied and accepted concept that octahedral rotation in perovskite oxides occurs but the octahedral shape is kept almost regular. This phase exhibits high-spin configuration and G-type antiferromagnetic ordering as in $SrFeO_2$. However, the distortion of the FeO_2 layers leads to only a slight decrease of the Neel temperature with respect to $SrFeO_2$. First-principles DFT calculations have provided a clear rationalization of the structural and physical observations for $CaFeO_2$ and highlight how the nature of the cation influences the structural details of the $AeFeO_2$ family of compounds (Ae = Ca, Sr, Ba). Using the results of these calculations, the driving force for the distortion of the FeO_2 layers in $CaFeO_2$ was also discussed in several articles. The tetrahedral structure of $SrFeO_2$ (space group *P*4/*mmm*) consists of layers of corner-sharing FeO_4 squares with strontium atoms in between. The structure closely resembles the sheet-like lattice geometry of superconducting copper oxides. There is no known structural instability as a function of temperature in $SrFeO_2$ or the similar compound $CaFeO_2$.

In another study, based on DFT with the generalized gradient approximation plus on-site Coulomb repulsion method, a study of the electronic, magnetic, and optical properties in infinite-layer iron oxide $CaFeO_2$ and $BaFeO_2$ was made. $CaFeO_2$ possesses a *P*421/*m* tetragonal symmetry. The single downspin electron of the Fe^{2+} ion occupies a d_z^2 level instead of Jahn–Teller instability from the double degenerated d_{x-y}^{22} and d_z^2 levels predicted in crystal field theory. Magnetic structure shows great contrast between intralayer and interlayer exchange interactions. Linear dielectric function, on the other hand, exhibits obvious anisotropic behavior between in plane and out of plane responses. For the larger ionic size of Ba, $BaFeO_2$ is found to have a *P*4/*mmm* tetragonal symmetry, which is similar to $SrFeO_2$. Together with the previous calculations of $SrFeO_2$, it was found that the anisotropic behaviors in these two dimensional (2D) structures are robust and independent of A-site size.

In the phase diagram of this system, two compounds are shown (Fig. 12.10).

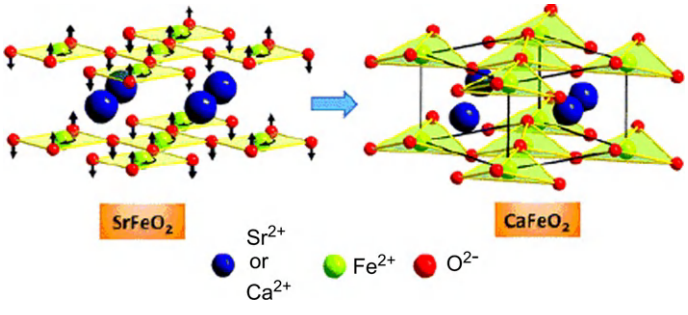

FIGURE 12.9

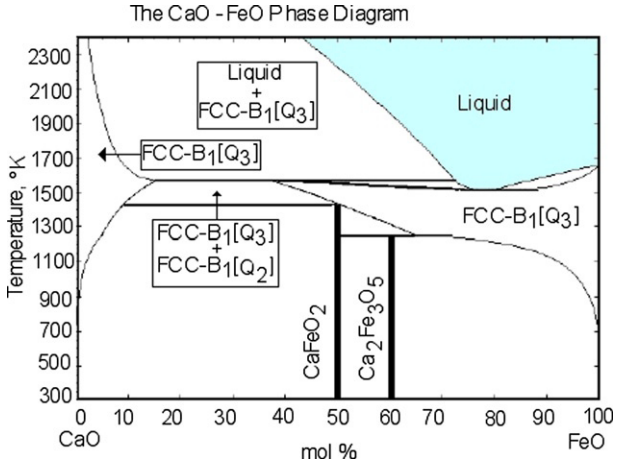

FIGURE 12.10

Little is known concerning the $2CaO \cdot 3FeO$ compound. Dicalcium ferrite, $Ca_2Fe_3O_5$, belongs to the $ABO_{3-\delta}$ perovskite family with $\delta = +0.5$. It presents ordered oxygen vacancies in the (101) directions of the cubic perovskite structure, leading to the orthorhombic distortion ($a_c\sqrt{2} \times 4a_c \times a_c\sqrt{2}$), and to a stacking sequence of planes of Fe^{3+} ions in octahedral and tetrahedral coordination. This compound is said to be antiferromagnetic with $T_n = 725$ K.

In the Fe^{3+}-containing system of $CaO–Fe_2O_3$, the compound, calcium ferrite, $CaFe_2O_4$ is known. It has the general structure shown in Fig. 12.11.

The phase diagram of the system, shown as follows, presents three compounds. These compounds represent the mol ratios (Fig. 12.12).

$2CaO–Fe_2O_3$
$CaO–Fe_2O_3$
$CaO–2Fe_2O_3$

All of these compounds melt incongruently.

The $CaFe_4O_7$ compound is stable only over a limited temperature range of 260 K. This compound decomposes according to:

$$CaFe_4O_7 + \text{heat}\ (T > 1593\ \text{K}) \Rightarrow \alpha\text{-}Fe_2O_3 + CaFe_2O_4$$

Investigations of the iron-rich part of the Ca–Fe–O phase diagram at 1200 °C, have verified the specification of the crystallographic and magnetic characteristics of three compounds, $CaFe_4O_7$, $Ca_4Fe_9O_{17}$ and $Ca_3Fe_{15}O_{25}$. ^{57}Fe Mössbauer spectroscopy studies were made on these compounds. $CaFe_4O_7$ and $Ca_4Fe_9O_{17}$ must be considered as antiferromagnetic, whereas $Ca_3Fe_{15}O_{25}$ is ferrimagnetic. Parallel crystallographic and magnetic analyses indicate that these ferrites can be classified in the hexagonal ferrite family with the magnetoplumbite structure.

The standard Gibbs energy change for the reactions $CaO + Fe_3O_3 \Rightarrow CaFe_2O_4$ and $2CaO + Fe_3O_3 \Rightarrow Ca_2Fe_2O_5$ has been determined from solid-state electromotive force (e.m.f.) measurements, using CaF_2 as solid electrolyte. The temperature dependence of the standard Gibbs energies of formation from the elements is represented by the equations:

$$\Delta G_f\,(CaFe_2O_4) = -1448.4 \times 10^3 + 128.0\,T + 27.95\,T\ln(T)$$
$$(1030 < T/\text{K} < 1280\ \text{K}$$

$$\Delta G_f\,(Ca_2Fe_2O_5) = -2049.9 \times 10^3 = 12.84\,T + 55.91\,T\ln(T)$$
$$(1140 < T/\text{K} < 1340\ \text{K}$$

By applying a "third law" analysis of the experimental data, the standard enthalpy of formation of $CaFe_2O_4$ from constituent oxides at 298 K was evaluated as:

$$\Delta H_{298}\,(CaFe_2O_4) = -17.5 \pm 0.4\ \text{kJ/mol}.$$

In another study, the compositions of the calcium alumino-silicato-ferrite phases in commercial iron-ore sinters, which are solid solutions based on the ferrites $CaFe_4O_7$, $CaFe_2O_4$, and $Ca_2Fe_2O_5$ of the $CaO–Fe_2O_3$ system, were studied. The sequence of the formation of the calcium alumino-silicato-ferrites and their compositions with Ca_2SiO_4 and Ca_3SiO_5 silicates in sinters were found to be analogous to the crystallization of the ferrite and silicate phases in the ternary $CaO–SiO_2–Fe_2O_3$ system. This allows the phase diagram of this system to be used for the explanation of the formation of the mineral binder compositions for ore grains during sintering of commercial superfluxed sinters.

The hemicalcic ferrite $CaFe_4O_7$ crystallizes in the monoclinic system, space group $C2$ with the parameters: $a = 10.409$ Å, $b = 6.005$ Å, $c = 31.640$ Å, $\beta = 96°30$. Its crystalline structure is related to that of the hexagonal ferrite types of compound. It is constructed by an

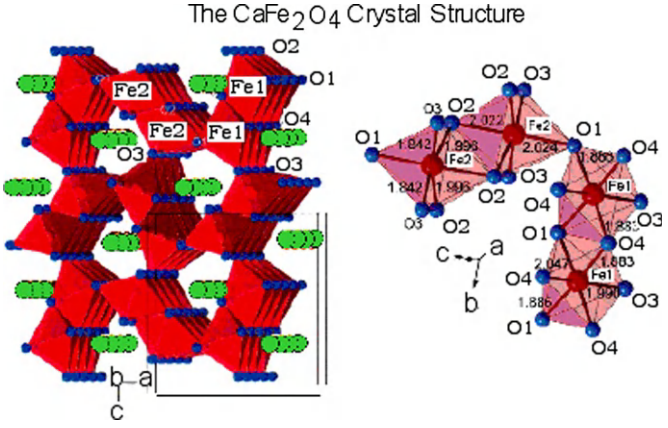

FIGURE 12.11

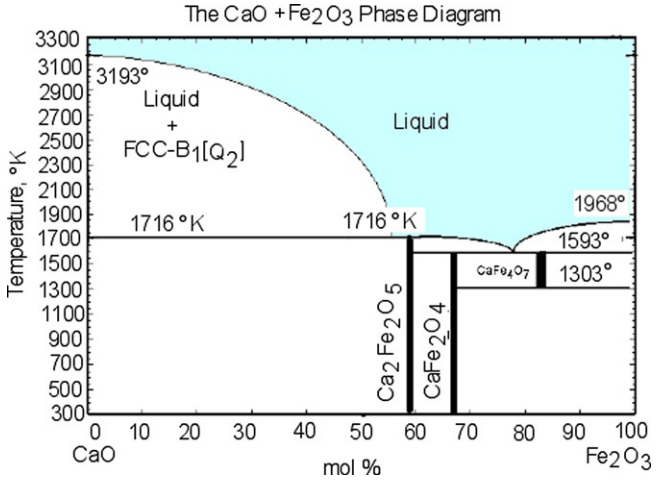

FIGURE 12.12

alternating stacking process along c_0 axis of two structural blocks with the following characteristics:

- A plane of trigonal-based FeO_5 bipyramids surrounded by two mixed Fe···Ca layers
- A triple layer of iron atoms, formed by a plane of mixed tetrahedral and octahedral polyhedra surrounded by two octahedral polyhedra. This type of ordering is also encountered in the spinel structure (mixed and "kagomé" system).

The total conductivity of $CaFe_2O_{4-\delta}$, studied in the oxygen partial pressure range from 10^{-17} to 0.5 atm. at 1023–1223 K, was predominantly *p*-type electronic under oxidizing conditions. The oxygen ion transference numbers determined by the steady-state oxygen permeation and Faraday efficiency measurements varied in the range of 0.2 to 7.2×10^{-4} at 1123–1273 K, increasing with temperature. No evidence of any significant cationic contribution to the conductivity was found. The Mössbauer spectroscopy, thermogravimetry, and XRD measurements showed that the orthorhombic lattice of calcium ferrite is essentially intolerant to the oxygen vacancy formation and to doping with lower valence cations, such as Co and Ni. The oxygen nonstoichiometry (δ) is almost negligible, 0.0046–0.0059 at 973–1223 K and $P(O_2) = 10^{-5}$ to 0.21 atm., and provides a substantial dimensional stability of $CaFe_2O_{4-\delta}$ ceramics. The average linear thermal expansion coefficients, calculated from the controlled atmosphere dilatometry and high-temperature XRD data, were $(9.6–13.9) \times 10^{-6}$/K in the oxygen pressure range from 10^{-8} to 0.21 atm. at 873–1373 K. Decreasing the $P(O_2)$ partial pressure resulted in a modest lattice contraction and in the "p to n" transition indicated by the conductivity and Seebeck coefficient variations. The phase decomposition of $CaFe_2O_{4-\delta}$ occurred at oxygen chemical potentials between the low-$P(O_2)$ stability limit of $CaFe_2O_{5-\delta}$ Brownmillerite and the hematite/magnetite boundary in binary Fe–O system.

An (hk0)-oriented *p*-type $CaFe_2O_4$ (E_g: 1.9 eV) photocathode was prepared, and hydrogen and oxygen gases were produced from a photocell short circuited by connecting the $CaFe_2O_{4-\delta}$ and *n*-type TiO_2 electrodes under illumination without applying an external voltage. The open-circuited voltage was 0.97 V and the short-circuit current was about 200 $\mu A/cm^2$, and the amount of evaluated hydrogen and oxygen gases after 2 days of reaction were about 70 and 4 μmol, respectively. The circuit employed is shown in Fig. 12.13.

The $CaFe_2O_4$ composition was studied, in order to analyze its physical and chemical behavior, in order to verify its stability under industrial conditions, when applied as pigments. The characterization was accomplished using thermal analysis, XRD, nitrogen adsorption, scanning electronic microscopy (SEM) and diffuse reflectance. It was observed that a succession of exothermic reactions occurred, due to the thermal decomposition of the organic material used, and that stability at 700 °C was reached.

The material became completely crystalline at 800 °C. Between 700 and 1100 °C, the color was stabilized, showing an absorption edge in the region of 650 to 750 nm, characteristic of the desired red color.

Single-crystal diffraction data collected for $CaFe_2O_4$ at high pressure reveal that, above 50 GPa, an isosymmetric phase transition (i.e. no change in symmetry) was marked by a volume decrease of 8.4%. X-ray emission spectroscopic data at ambient and high pressure confirmed that the nature of the phase transition was related to the Fe^{3+} high-spin/low-spin transition. The bulk modulus, K_0 , calculated with a Birch–Murnaghan EoS ($K' = 4$) was remarkably different [$K_0 = 159(2)$ GPa for $CaFe_2O_4$ "high-spin" and $K_0 = 235$ GPa for $CaFe_2O_4$ "low-spin"]. Crystal structure refinements revealed a decrease of 12% of the Fe^{3+} crystallographic site volume. The geometrical features of the low-spin Fe^{3+} crystallographic site at high pressure (bond lengths, volume) indicated a relevant decrease of Fe^{3+}–O bond lengths, and the results were in agreement with tabulated values for crystal radii of Fe^{3+} in high- and low-spin state. The reduced crystal size of Fe^{3+} in the low-spin state suggested that in lower Earth mantle assemblages, Fe^{3+} partitioning in crystallographic sites should be strongly affected by the iron spin state.

The 2:1 compound, $Ca_2Fe_2O_5$, has the crystal structure shown in Fig. 12.14.

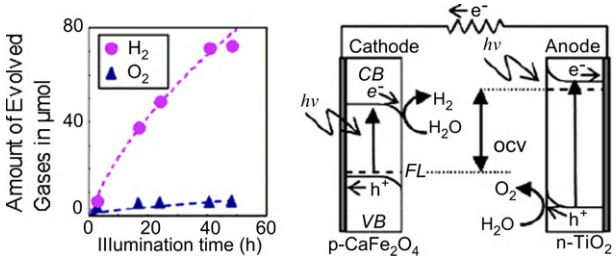

FIGURE 12.13

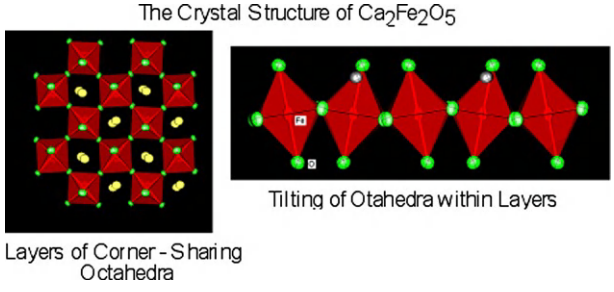

FIGURE 12.14

The transition metal compound, $Ca_2Fe_2O_5$ (CFO), which is an antiferromagnet with a Nëel temperature of 725 K, has been investigated extensively in light of an observed weak ferromagnetism phenomena. Two magnetic transitions at $T_1 \approx 140$ K and $T_2 \approx 60$ K were observed in the CFO crystal. Magnetic measurements indicated that $Ca_2Fe_2O_5$ is an antiferromagnet, with weak parasitic ferromagnetism. The lattice, with the space group *Pcmn*-D_{2h}^{16}, can be considered as an oxygen-deficient perovskite. The magnetic structure as determined from a neutron diffraction study was of G-type, and Fe^{3+} spins are directed approximately along *c*-axis. $Ca_2Fe_2O_5$ showed a first-order phase transition from space group *Pnma* to a modulated structure described by superspace group, *Imma* (00°)s00. The transition starts at 947 K during heating and the reverse transition in cooling conditions starts at 923 K, as determined from differential thermal analysis. In situ high-temperature single-crystal XRD experiments revealed a phase coexistence over a range of ca. 25 K. Data collected in this range showed a good fit to a combined model of the two simultaneously occurring phases, which was refined using the software Jana2006. In situ high-temperature TEM [selected area diffraction (SAED), dark field and high-resolution images] was utilized to prove the existence of *Pnma* and *Imma*(00°) s00 domains within the temperature range of the phase coexistence. Remaining planar defects were observed within the *Pnma* phase at temperatures below the phase transition. From the analysis of high-resolution electron micrographs, these defects were proven to be antiphase boundaries (APBs) with a displacement vector of $\mathbf{R} = 1/2$ [111].

In another paper, calcium ferrite was synthesized in air at 1573 K and thermoelectric properties (direct current electrical conductivity σ, Seebeck coefficient α, thermal conductivity, thermal expansion a_L) were measured from 373 to 1050 K in air. The Seebeck coefficient was positive over all temperatures, indicating conduction by holes, and electrical properties were continuous through the *Pnma* ⇒ *Imma* phase transition. Based on the thermopower and conductivity activation energies as well as estimated mobility, polaron hopping conduction was found to dominate charge transport. The low electrical conductivity, <1 S/cm, limits the power factor ($\alpha^2\sigma$), and thus the figure of merit for thermoelectric applications. The thermal conductivity values of ~2 W/m K and their similarity to Ruddlesden–Popper phases implies the potential of the alternating tetrahedral and octahedral layers to limit phonon propagation through Brownmillerite structures. Bulk linear coefficient of thermal expansion ($\sim 14 \times 10^{-6}$/K) was calculated from volume data based on high-temperature in situ XRPD, and showed the greatest expansion perpendicular to the alternating layers.

The oxygen-deficient perovskite, $Ca_2Fe_2O_5$, which is of the Brownmillerite-type of structure, exhibits a structural phase transition at ca. 970 K from space group *Pnma* ($a = 0.54$ nm, $b = 1.48$ nm, $c = 0.56$ nm) to a modulated structure with an aperiodic sequence of FeO_4 tetrahedral chains, described by the superspace group *Imma*(00)s00. In situ high-temperature TEM (transmission electron micrographs) were was used in order to prove the co-existence of both phases within a coexistence range of ca. 25 K. Polycrystalline material was pulverized, sonicated in ethanol and dispersed on a holey carbon film on a Cu grid. In-situ TEM was performed using a high-voltage atomic resolution microscope operated at 1250 kV (point resolution 0.12 nm) with a high-temperature heating stage and a drift-compensating device. The hypothesis of phase coexistence was proven by dark-field TEM (DF-TEM), selected-area electron diffraction and high-resolution imaging. At 1100 K, the entire grain under observation showed the modulated structure by the presence of satellite reflections in (h01) layer. The modulation wave vector of $\boldsymbol{q} = 0.58c^*$ determined from the diffraction pattern was in good agreement with results from XRD experiments. By carefully lowering the temperature, the two-phase regime was approached where reflections from the primitive lattice (which are not allowed in the HT phase) and satellite reflections show up simultaneously. The DF micrographs show the coexistence of the phases in real space. Domains of the high-temperature (HT) phase were identified by fringes caused by the modulation. The domains of the low-temperature phase (P_L) grow upon lowering the temperature. Within the P_L phase, residual defects are observed which were analyzed to be APBs. Such APBs are formed during the growth of the P phase when two P_L domains get in contact and are shifted by a displacement vector of $\mathbf{R} = 1/2$ [111] (this centering vector is lost during the HT ⇒ P_L transition). An APB can be modeled in a way such that the substructure of octahedral layers stays intact whereas the configuration of the tetrahedral layers changes across the boundary.

The perovskite-related oxide $Ca_2Fe_2O_5$ takes up additional oxygen under high pressure and elevated temperature. The Mössbauer spectra from a number of preparations establish the existence of new phases that are structurally related to the original lattice. The latter features an ordered arrangement of oxygen vacancies that form alternate layers of octahedral and tetrahedral Fe polyhedra. The introduction of oxygen to give $CaFeO_{2.60}$ initially increases the number of octahedral layers to give a sequence [ootot]. Some of the iron, in the double-octahedral layers, undergoes oxidation to the 5+ oxidation state (by a nominal charge-disproportionation of Fe^{4+} at low temperature). At least six distinct iron sites can be identified, and their coordination numbers

established. It is believed that the charge disproportionation (CD) is reversed with increasing temperature. Further uptake of oxygen to give $CaFeO_{2.69}$ produces some layers with five coordination. Mössbauer spectra revealed the existence of unusually complicated and subtle magnetic interactions, which include spin-reorientation effects. It was proposed that this transformation may be triggered by a change in oxidation state of some of the cations. Oxidation can extend to at least $CaFeO_{2.80}$ before any substantial intergrowth of $CaFeO_3$ becomes apparent. It was clear that a wide range of nonstoichiometry can be achieved by the intergrowth of layers of Fe in different coordination, and the extra oxygen is counterbalanced by the generation of Fe^{5+} cations in octahedral coordination. The CD appears to be established within 2D layers of corner-sharing octahedra.

$Ca_2Fe_2O_5$ powder samples, undoped and doped with Na^+, Mg^{2+}, Al^{3+}, Ti^{4+}, Ge^{4+}, were prepared with different synthesis routes to investigate the origin of the weak ferromagnetic component reported in literature for calcium ferrite single crystals. XRPD and EPR measurements have shown the presence of Fe_3O_4 magnetite as impurity phase in all the samples. This ferrimagnetic phase deeply influences the magnetic behavior with features very similar to those reported in literature for $Ca_2Fe_2O_5$, both powders and single crystals. Our results support the hypothesis that the weak ferromagnetic component observed in $Ca_2Fe_2O_5$ can be also due to the presence of magnetite impurity traces (Fe_3O_4) in the samples.

In the CaO–FeO–Fe_2O_3 system, the compound, $CaFe_3O_5$, is known. As in magnetite, Fe_3O_4, calcium ferrite $CaFe_3O_5$ is an oxide in which electron transfer occurs between the iron ions ($Fe^{3+}/Fe^{2+} = 2$). This intervalence exchange process has been studied by ^{57}Fe Mössbauer spectroscopy and by electrical conductivity measurements. In $CaFe_3O_5$, the Fe^{3+} and Fe^{2+} ions occupy different crystallographic sites and have a deformed octahedral coordination. Each $Fe^{2+}O_6$ octahedron shares an edge with two $Fe^{3+}O_6$ octahedra. In the antiferromagnetic region ($T_n = 282 \pm 2$ K), the Fe^{3+} and Fe^{2+} ions are well differentiated. Thermally-activated electron transfer was observed above T_n in the paramagnetic region and was well characterized by the Mössbauer spectra obtained. These were analyzed using the hypothesis of an electron jump limited to a trimer $Fe^{3+}\cdots Fe^{2+}\cdots Fe^{3+}$ which leads to a relaxation time of 180 ns at 298 K and 80 ns at 400 K. Within this temperature interval, the process follows the Arrhenius Law with an activation energy of 0.10 eV. Electrical conductivity measurements led to similar results with an activation energy of 0.09 ± 0.02 eV.

In another study, solid-state calcium ferrite formation reactions between different kinds of iron oxides and CaO under controlled $P(O_2)$ pressures at 1273 K have been investigated. The calcium ferrite formation rates were evaluated, using a thermogravimetric (TG) method. The phase identification and quantification of calcium ferrites in the experiment have been carried out by using XRD method (the Rietveld method). It was found that intermediate calcium ferrite phases of $CaFe_2O_4$ and $CaFe_3O_5$ are formed prior to the $Ca_2Fe_2O_5$ formation when Fe_2O_3 and Fe_3O_4 were used as a starting iron oxide, respectively. When starting from wüstite, intermediate calcium ferrite phases are not formed. The rates of $Ca_2Fe_2O_5$ formation are found to be different depending on the starting reactant iron oxide phases. The $Ca_2Fe_2O_5$ formation rate from wüstite is faster than that from Fe_3O_4, and that from Fe_3O_4 is faster than that from Fe_2O_3. It is also found that the $Ca_2Fe_2O_5$ formation rate starting from Fe_3O_4 decreases with $P(O_2)$, but that starting from wüstite is independent from $P(O_2)$.

In the Fe^{4+}-containing system of CaO–FeO_2, the compound, $CaFeO_3$, is known. Mössbauer spectroscopy of $CaFeO_3$ suggested a "charge disproportion" reaction of Fe^{4+} into Fe^{3+} and Fe^{5+} below 290 K. Crystal structure was investigated at 298 and 113 K (in a "charge disproportionate" state) by using a monochromated synchrotron radiation facility. The crystal structure was found to be similar to $GdFeO_3$ with *Pbnm* at 293 K. At 113 K, two kinds of nonequivalent Fe cations (which could be assigned to Fe^{3+} and Fe^{5+}) form a NaCl-type arrangement on the Fe sublattice; the space group is monoclinic $P2_1/n$ which is one of the subgroups of *Pbnm*. On the difference Fourier map, a residual peak was observed at the center of Fe···O bond; this suggests the strong covalent mixing between e_g(Fe) levels and 2p(O) ones. The Fe···O···Fe bond angle in $CaFeO_3$ was determined to be about 160°, which significantly differs from the 180° angle bonding of $SrFeO_3$. It indicated that the e_g bandwidth in $CaFeO_3$ is narrowed and that eventually the itinerant nature was suppressed. This accounted for the observation that the charge disproportion tends to occur in $CaFeO_3$ with decrease in temperature.

In another paper, stoichiometric $CaFeO_3$ was prepared and was characterized by crystallographic, magnetic and electrical measurements. A slight tetragonal distortion from the ideal cubic perovskite structure was found. The tetra-molecular unit cell has units of: $a = 5.325$ (3) Å and $c = 7.579$ (5) Å. The susceptibility showed a maximum at about 115 K and the temperature dependence of electrical resistivity changed from metallic to semiconductive in the vicinity of the magnetic transition temperature. These indicate a phase transition from the metallic-paramagnetic (the HT phase) to the semiconductive-antiferromagnetic phase. The Mössbauer spectra indicated that a charge-disproportionation (CD) $2Fe^{4+} \Rightarrow Fe^{3+} + Fe^{5+}$ associates with the transition. Using a diamond anvil cell, ^{57}Fe Mössbauer

spectroscopy has been carried out on the perovskite oxide $CaFeO_3$ under high pressures up to 65 GPa at various temperatures.

The critical temperature of the CD (CD reaction: $2Fe^{4+} \Rightarrow Fe^{3+} + Fe^{5+}$) and a magnetic ordering have been determined as a function of pressure. The CD occurs at an almost constant temperature of about 290 K in the pressure range of 0–17 GPa. At an increase of the pressure above 20 GPa, the CD reaction was suppressed and its critical temperature reduced to lower than 6 K. On the other hand, the magnetic ordering temperature of 125 K at an ambient pressure rises to 400 K at 34 GPawithout the occurrence of the CD. This suggests that the different charged particles control the charge and spin order separately in $CaFeO_3$.

In situ ^{57}Fe Mössbauer spectroscopy and XRD on $CaFeO_3$ ($Fe^4{:}t^3{}_2e^1$) under pressure have revealed a first-order high-spin ($S = 2$) to low-spin ($S = 1$) transition near 30 GPa. The spin and structure transition were an alternative manifestation of the electronic instabilities of the σ-bonding Fe–O– ($Fe^{4-} + Fe^{4+}$), $0 < \sigma < 1$, occurs at a $T_t \sim 290$ K. Such instabilities, found at the transition, localized to itinerant σ-band electrons, reflected a sensitivity to interactions with the lattice.

Single crystals of $CaFeO_3$ have been synthesized at high pressure of 4.5 GPa with a mixture of $KClO_4$, NaCl and $CaCl_2$ as flux and oxidizing agent. The temperature dependence of the resistivity showed a metal-insulating transition at 295 K, corresponding to the charge disproportionation. A screw-spin type antiferromagnetic transition was observed at 115 K. These results indicated that the crystals were free from oxygen defect. Energy-dispersive powder XRD study with synchrotron radiation at high pressure revealed that a moisture was necessary to crystal growth of $CaFeO_3$.

In addition, a compound, $CaFe_5O_7$, which is a mixture of Fe^{4+} and Fe^{3+} is known. This compound can be written as: $CaO{\cdot}3FeO_2{\cdot}2Fe_2O_3$. It has the unit cell parameters of: $a = 3.064$ Å, $b = 5.2199$ Å, $c = 17.822$ Å, $\alpha = \beta = 90°$, $\gamma = 107.07$ Å^3, cell volume = 272.46 Å^3.

It was found that $CaFe_5O_7$ does not disappear by decomposition to three solid phases at about 1050 °C, as suggested by previous phase diagrams. Instead it disappears by melting at about 1100 °C. On cooling, part of the liquid solidifies to a eutectic structure, Wustite + $Ca_2Fe_2O_5$. A revision of Turkdogan's oxygen potential–temperature diagram was proposed in order to account for the new information. No other information is available concerning this compound.

In the Fe^{5+}-containing system of $CaO–Fe_2O_5$, no compounds are known.

In the hexavalent iron, Fe^{6+}-containing system of $CaO–FeO_3$, the compound, $CaFeO_4$ is known. $CaFeO_4$ is commonly prepared directly from the reaction between an aqueous solution of the acetate or chloride of the metals and potassium ferrate:

$$K_2FeO_4(aq) + Ca(C_2H_3O_2)_2 \Rightarrow CaFeO_4(s) + 2KC_2H_3O_2(aq)$$

The results showed that the synthesized sample mainly consists of calcium ferrate (VI), and calcium ferrate (VI) hydrate that mainly exists as $CaFeO_4{\cdot}2H_2O$ with the highest obtained purity of 74.9%. Calcium ferrate is a strong oxidizer when acidified. It has the structure form shown in Fig. 12.15.

The structure is orthorhombic with space group *P-nam* and unit cell parameters of: $a = 9.230$ Å, $b = 10{,}706$ Å, $c = 3.024$ Å. The coordination of the oxygen atoms around Fe is that of a distorted octahedron. Around the

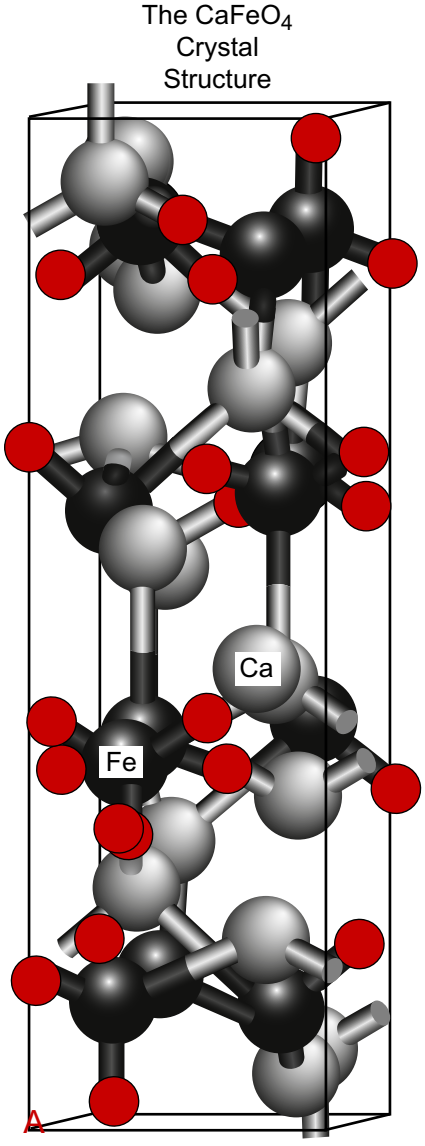

FIGURE 12.15

Ca atoms, there is a coordination of nine oxygen atoms in a configuration first noted for $CaTi_2O_4$, for which $CaFeO_4$ is isomorphous.

Calcium ferrate, $CaFeO_4$, is offered commercially for use as an antibacterial water treatment chemical. Calcium ferrite, $CaFe_2O_4$, is also offered for sale commercially with the CAS number of 12013-33-1.

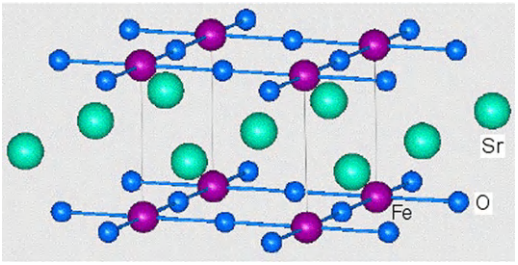

FIGURE 12.17

12.2.4. Strontium Oxy-Iron Compounds

SrO forms a number of ferrites and ferrates with iron oxides.

In the Fe^{2+}-containing system of SrO–Fe, the compound, $SrFeO_2$ is known. Its structure was presented above in the Ca section. One phase diagram presented for the system of SrO–FeO reveals no compounds formed, just a eutectic at 1630 K (Fig. 12.16).

However, $SrFeO_2$ exhibits some exotic magnetic and electronic properties. Neutron diffraction studies show the presence of antiferromagnetic ordering with a very high Nëel temperature ($T_N = 473$ K). The magnetic ordering temperature is very high in spite of the low-dimensional nature of the magnetic structure. Magnetic properties of $SrFeO_2$ have been examined by DFT band structure and total energy calculations. Ab-initio calculation of the zone center phonon modes has also been reported. It is of fundamental and practical importance to understand the stability of $SrFeO_2$ and $CaFeO_2$ as a function of temperature and pressure. Detailed lattice dynamical calculations to understand the phonon properties of these compounds have been carried out.

One view of this structure has the form shown in Fig. 12.17.

A first-principles study of $SrFeO_2$, an infinite-layer oxide with Fe atoms in a perfect square-planar coordination down to essentially 0 K was carried out. The results revealed this striking behavior relies on the double occupation of the $3d_z^2$ orbitals of high-spin Fe^{2+}. Such an electronic state results from the hybridization of iron's $3d_z^2$ and 4s orbitals, which enables a large reduction of the intra-atomic exchange splitting of the $3d_z^2$ electrons. The generality of the phenomenon was discussed.

The magnetic structure has the form shown in Fig. 12.18.

$SrFeO_2$ presents Fe^{2+} ions in a square-planar coordination, forming unprecedented infinite FeO_2 layers that remain undistorted down to at least 4.2 K. As a result of the tetragonal point symmetry at the Fe site, the z^2 orbital is fully symmetric and can hybridize with the formally-empty Fe-4s state. It has been concluded that $SrFeO_2$, an unusual high-spin Fe^{2+} layered phase, is free from structural instabilities and exhibits strong magnetic interactions. The hybridization of iron's $3d_z^2$ and 4s orbitals, which results in a large

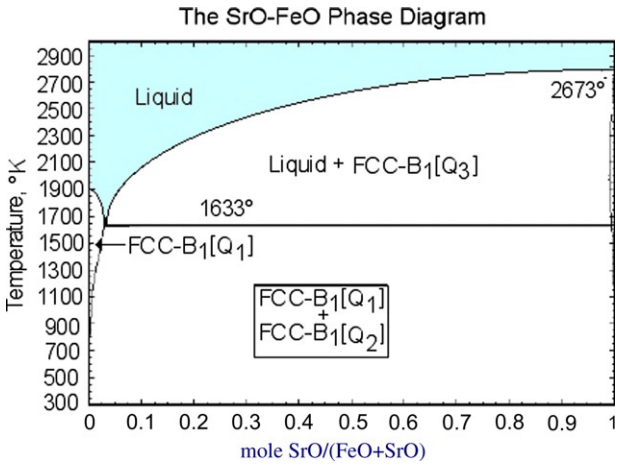

FIGURE 12.16

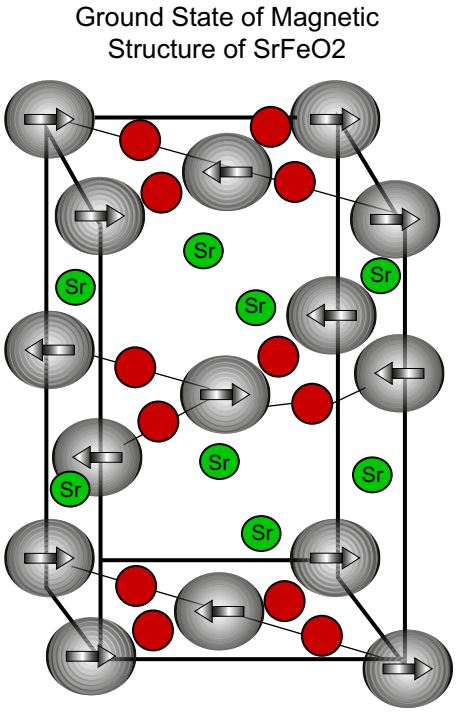

FIGURE 12.18

reduction of the intra-atomic exchange splitting associated to the z^2 electrons, is the key feature to understand the structural stability of the material.

Single-crystal thin films of $SrFeO_2$, which is an oxygen-deficient perovskite with "infinite layers" of $Fe^{2+}O_2$, were prepared by using CaH_2 for low-temperature reduction of epitaxial $SrFeO_{2.5}$ single-crystal films deposited on $KTaO_3$ substrates. This reduction process, removing oxygen ions from the perovskite structure framework and causing rearrangements of oxygen ions, topotactically transforms the Brownmillerite $SrFeO_{2.5}$ to the *c*-axis oriented $SrFeO_2$. The layered oxoferrate(II) $SrFeO_2$ (see scheme: Fe = red, Sr = yellow, O = gray) was synthesized by the reduction of the slightly oxygen-deficient perovskite $SrFeO_{3-x}$ at 400 K with CaH_2 in a form of topotactical reaction (Fig. 12.19).

The square-planar-coordinated iron(II) ions in $SrFeO_2$ exhibit a high-spin d^6 configuration with a doubly occupied d orbital. $SrFeO_2$ orders antiferromagnetically at an unusual high Nëel temperature of $T_N = 473$ K.

In the system, $SrFeO_{3-x}$, an example is the family of compounds, $SrFeO_x$ ($2.5 \leq x \leq 3$). The valency of the Fe ions can be changed by heating a sample in either an oxidizing or a reducing environment. As a result, the oxygen content can vary in between 2.5 and 3. For example, in $SrFeO_{2.875}$, some Fe ions can be assigned to the oxidation state +3 and others to +4. The oxygen vacancies order so that FeO_5 square pyramids are formed. These $SrFeO_x$ compounds are examples of defect perovskites. Their chemistry can be described according to the homologous series $A_nB_nO_{3n-1}$, $n = 2-\infty$.

The ordering of these vacancies is shown in Fig. 12.20. Fe ions are located in both square pyramids and in octahedra.

An infinite-layer structure artificial superlattice thin film, $[CaFeO_2]/[SrFeO_2]$, was prepared by low-temperature reduction of a Brownmillerite-structure artificial superlattice thin film $[CaFeO_{2.5}]/[SrFeO_{2.5}]$ grown on a $SrTiO_3(001)$ substrate. Both the $Ca_2Fe_2O_5$ and $Sr_2Fe_2O_5$ Brownmillerite structures changed to the infinite-layer structures and an unusual square-planar-coordination FeO_2 plane was stabilized in the infinite-layer superlattice. The low-temperature reduction technique is useful for making superlattices that cannot be made by simply depositing a film.

$Sr_3Fe_2O_5$ adopts the *Immm* space group (No. 71), $a = 3.5168$ Å, $b = 3.95405$ Å, $c = 20.91727$ Å, $Z = 2$. Sr(1) on 2*c* (0.5,0.5,0), Sr(2) on 4*i* (0,0,0.31242), Fe on 4*i* (0,0,0.09616(4)), O(1) on 2*a* (0,0,0), O(2) on 4*j* (0.5,0,0.59526), O(3) on 4*i* (0,0,0.19298), with 100% occupancy, $B_{iso}(Sr(1)) = 0.792$ Å^2, $B_{iso}(Sr(2)) = 0.486$ Å^2, $B_{iso}(Fe) = 0.3$ Å^2, $B_{iso}(O(1)) = 0.723$ Å^2, $B_{iso}(O(2)) = 0.791$ Å^2, $B_{iso}(O(3)) = 0.847$ Å^2, $R_p = 2.95\%$, $R_{wp} = 3.76\%$.

The oxidation behavior of $Sr_3Fe_2O_5$ in air has been described. The transformation to $Sr_3Fe_2O_{7-y}$ ($y \leq 1$) phase takes place dramatically above 250 °C. The oxygen content of the sample, using a TG method, was $y \sim 0.4$ as checked by its XRD pattern. It was noted that there is ambiguity in determining the oxygen content by TG because $Sr_3Fe_2O_5$ is highly air sensitive, in contrast to $SrFeO_2$. It was found that if the $Sr_3Fe_2O_5$ sample was exposed to air even for a short period of time for the setup of the TG experiment, a part of it was readily oxidized, absorbed water and was even decomposed (to yield, e.g. $Sr_3Fe_2(OH)_{12}$). Initial decrease in weight below 150 °C was due to the release of water. For this reason, a precise estimation of the oxygen content by TG could be not made. If no reaction of $Sr_3Fe_2O_5$ occurred during the setup, the observed weight gain would give the final composition: $Sr_3Fe_2O_{7-y}$ ($0.5 < y < 0.9$). This is somewhat smaller than the expected composition of $Sr_3Fe_2O_{6.6}$. It was concluded from the TG measurements that the oxygen content of the product is far less than 6 ($y = 1$) that had been thought as the lower limit. The oxygen content of $y = 0.5$ was evident from Neutron diffraction, synchrotron XRD, and Mössbauer spectroscopy measurements.

When the composition of $SrFeO_2$ was changed by the addition of FeO to form $SrFe_2O_3$, a new class of

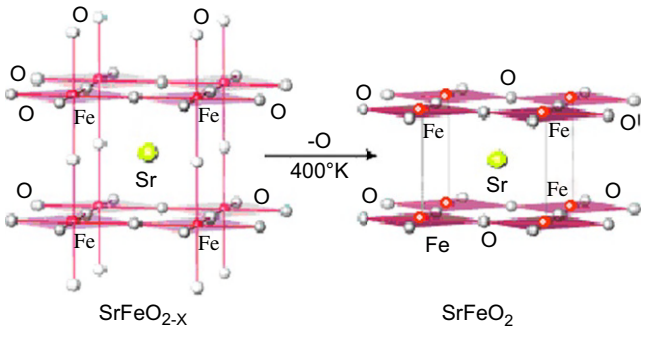

FIGURE 12.19

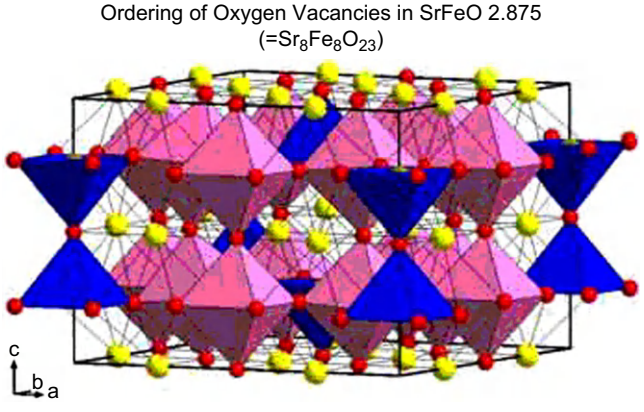

FIGURE 12.20

commercial magnets was born. The birth of this family of magnets was announced in 1952 (isotropic) and 1954 (anisotropic). Also known as Ceramic magnets, they are manufactured in two compositions: Strontium based ($SrFe_2O_3$) and Barium based ($BaFe_2O_3$). The process consists in milling the raw materials compound into single crystals approximating a single domain in size. Then the powder is wet or dry pressed in a dye under the influence of a magnetic field. After that, the pressed compacts are sintered in ovens at high temperatures. Their good coercive force results from the high crystal anisotropy of Barium and Strontium iron oxide. Nowadays, Ceramic magnets are the lowest cost magnetic material available. They are very hard and brittle and must be ground to obtain close mechanical tolerances.

Ferrite has a high resistance against corrosion, acids, salts, lubricants and gases. Ceramic, also known as Ferrite, magnets (general composition $BaFe_2O_3$ or $SrFe_2O_3$) have been commercialized since the 1950s and continue to be extensively used today due to their low cost. Ferrite magnets are stronger than AlNiCo and have much better corrosion resistance than Rare Earth MAGNETS. Ceramic Magnets offer the best value when comparing cost with other type of magnets. Ceramic (Ferrite) magnets are inexpensive, moderate in magnetic strength, and they are easily magnetized in a variety of formats. Ceramic magnets offer good corrosion resistance and generally do not require a coating or plating. Consideration should be given to the grade of alloy when exposing Ceramic magnets to temperature extremes. Ceramic (Ferrite) magnets have good resistance to external demagnetization fields because of its high-Intrinsic Coercive Force (Hci). This resistance and low cost make Ceramic magnets a popular choice for electromechanical applications.

In the Fe^{3+}-containing system of SrO–Fe_2O_3, the phase diagram has the form shown in Fig. 12.21.

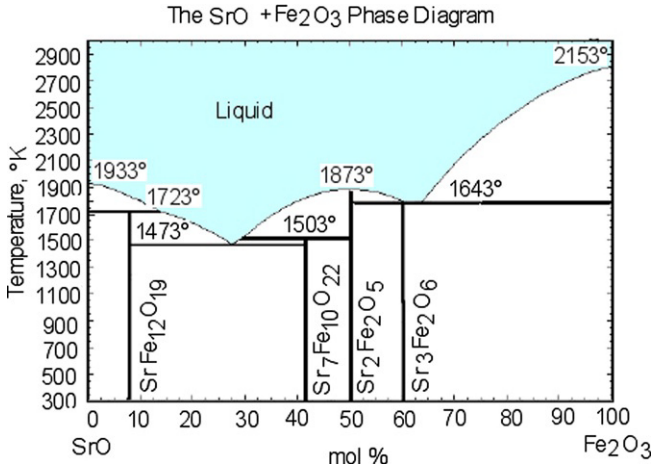

FIGURE 12.21

$Sr_2Fe_2O_{5+x}$ materials have been tested as thin film gas sensors since the reversible uptake of oxygen at elevated temperatures can readily occur.

This is accompanied by significant changes in the electrical conductivity that can be monitored as a sensor transduction signal in a sensing thin film device. Therefore, thermal stability of the sensing thin film system plays an important role in the sensitivity, rapid response and longer term signal reproducibility of the sensors. This arises because the ceramic-based gas sensors are operated at elevated temperature. As a result, the films may react with the underlying substrate changes at $Sr_2Fe_2O_{5+x}/Al_2O_3$ (sapphire and sintered alumina) interface were observed after a further annealing at 850 °C for 5 h. Additional layer appears in the interface indicating that interface reactions occurred.

The change in structure is shown in Fig. 12.22. Single crystals of strontium monoferrite, $SrFe_2O_4$, were obtained by growth from a melt at 1550 °C. The monoclinic crystals belong to space group $P112_1/n$ ($a = 8.1098$, $b = 9.1177$, $c = 10.8495$ Å, $\beta = 91.53°$, $V = 801.96$ Å^3, $Z = 2$, $D_{calc} = 4.36$ g/cm^3).

The structure was solved by direct methods using a single-crystal diffraction data set. The main structural features of $SrFe_2O_4$ are layers of FeO_4 tetrahedra perpendicular to the *a*-axis (Fig. 12.23).

The stacking of the layers parallel to [100] results in a three-dimensional (3D) framework containing tunnels, where the strontium cations are located. Individual

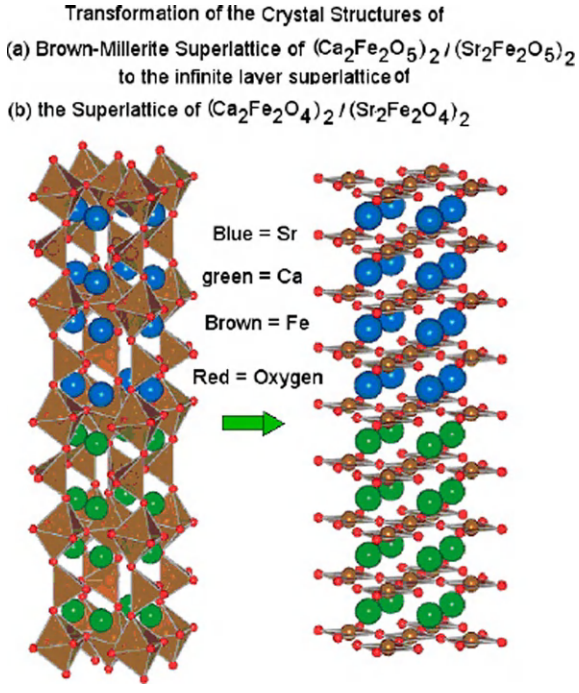

FIGURE 12.22

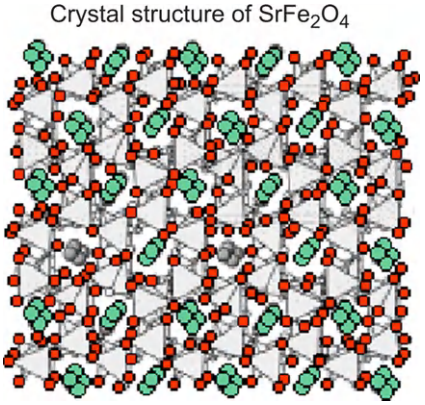

FIGURE 12.23

layers can be described as being built by the condensation of di-trigonally shaped, six-membered, tetrahedral rings. The sequence of up (U) and down (D) pointing apices within a single ring is UUUDDD. The structure belongs to the family of the zeolite ABW-type structures and is the first zeolite type compound with exclusively ferric iron occupying the tetrahedral positions of the framework.

The citrate–nitrate gel combustion route was used to prepare $SrFe_2O_4$(solid), $Sr_2Fe_2O_5$(solid) and $Sr_3Fe_2O_6$(solid) powders and the compounds were characterized by XRD analysis. Different solid-state electrochemical cells were used for the measurement of e.m.f. as a function of temperature from 970 to 1151 K. The standard molar Gibbs energies of formation of these ternary oxides were calculated as a function of temperature from the e.m.f. data and are represented as:

$$\Delta G_f\ (SrFe_2O_4(solid)\ T)/kJ/mol = -1494.8 + 0.3754\ (T/K)\ (970 \le T/K \le 1151)$$

$$\Delta G_f\ (Sr_2Fe_2O_5(solid)\ T)/kJ/mol = -2119.3 + 0.4461\ (T/K)\ (970 \le T/K \le 1151)$$

$$\Delta G_f\ (Sr_3Fe_2O_6(solid)\ T)/kJ/mol = -2719.8 + 0.4974\ (T/K)\ (969 \le T/K \le 1151)$$

Standard molar heat capacities of these ternary oxides were determined from 310 to 820 K using a heat flux type differential scanning calorimeter. Based on second law analysis and using the thermodynamic database–FactSage software, thermodynamic functions such as $\Delta_f H^\circ(298.15\ K)$, $S^\circ(298.15\ K)$ $S^\circ(T)$, $C_p^\circ(T)$, $H^\circ(T)$, $\{H^\circ(T) - H^\circ(298.15\ K)\}$, $G^\circ(T)$, produced the free energy functions, $\Delta_f H^\circ(T)$ and $\Delta_f G^\circ(T)$ for these ternary oxides. These were also recalculated from 298 to 1000 K.

Permanent ferrite magnets are made of **hard ferrites**, which have a high coercivity and high remanence after magnetization. These are composed of iron and Ba and Sr oxides. The high coercivity means the materials are very resistant to becoming demagnetized, an essential characteristic for a permanent magnet. They also conduct a magnetic flux well and have a high magnetic permeability. This enables these so-called *ceramic magnets* to store stronger magnetic fields than iron itself. They are cheap, and are widely used in household products. The maximum magnetic field B is about 0.35 T and the magnetic field strength H is about 30 to 160 kiloampere turns per meter (400–2000 oersteds). The density of ferrite magnets is about 5 g/cm^3. The most common hard ferrites are **Strontium ferrite**, $SrFe_{12}O_{19}$ ($SrO{\cdot}6Fe_2O_3$), a common material for permanent magnet applications. They are used in e.g. subwoofer magnets and as a medium for magnetic recording. The crystal and magnetic structure of strontium ferrite $Sr_4Fe_4O_{11}$ ($SrFeO_{2.75}$) has been investigated using neutron powder diffraction and magnetic susceptibility measurements over the temperature range 1.5–293 K and by Mössbauer spectroscopy at room temperature. $Sr_4Fe_4O_{11}$ is orthorhombic (symmetry group *Cmmm*) over the temperature range 1.5–293 K. Its crystal structure contains two iron sites occupied by trivalent and tetravalent iron. The trivalent magnetic moments order antiferromagnetically below $T_N = 232(4)$ K and the magnetic unit cell coincides with the chemical cell. The ordered moments are parallel to the *b*-axis and the tetravalent iron moments form a magnetically frustrated sublattice. The extrapolated value of the Fe^{3+} moment is 3.55(5) μbar at 0 K. The antiferromagnetic coupling occurs by the superexchange mechanism and is mediated by oxygen ions. There are no signs of long-range magnetic order in the tetravalent sublattice down to 1.5 K.

The crystal structure of the $Sr_2Fe_2O_5$ Brownmillerite compound has been investigated using electron diffraction and high-resolution electron microscopy (HREM). The S–$Sr_2Fe_2O_5$ structure demonstrates 2D order: the tetrahedral chains with two mirror-related configurations (L and R) are arranged within the tetrahedral layers according to the -L-R-L-R- sequence, and the layers themselves are displaced with respect to each other over 1/2[111] or 1/2[11†] vectors of the Brownmillerite unit cell, resulting in different ordered stacking variants. A unified superspace model is constructed for ordered stacking sequences in Brownmillerites based on the average Brownmillerite structure with $a = 5.5298$ Å, $b = 15.5875$ Å, $c = 5.6687$ Å, and $(3+1)$-dimensional superspace group: $I2/m(0\beta\gamma)0s$, $q = \beta b^* + \gamma c^*$, $0 \le \beta \le 1/2$, $0 \le \gamma \le 1$.

In another paper, the evolution of crystal and magnetic structures of $Sr_2Fe_2O_5$ with temperature was studied using neutron powder diffraction. The measurements were made in the temperature range from room temperature up to 1223.15 K and the patterns were analyzed using the Rietveld method. The oxide undergoes two-phase transitions: (i) from the antiferromagnetic to the paramagnetic state and (ii) from the orthorhombic to the cubic structure. The changes in structural parameters

with temperature were discussed and a new structural model was proposed for the cubic phase. The diffraction patterns were refined using *Ib'm'*2, *Ibm*2, and *Fm*3*c* symmetry groups in the antiferromagnetic, the paramagnetic and the cubic state, respectively, with $Z = 4$.

Atomistic simulations of the structures and defect energetics of the two mixed-conducting strontium ferrite materials, $Sr_2Fe_2O_5$ and $Sr_4Fe_6O_{13}$, have been reported. Oxygen Frenkel defects are found to be the predominant intrinsic defects in both materials, with the Frenkel energy in the intergrowth structure, $Sr_4Fe_6O_{13}$, being much less than that in $Sr_2Fe_2O_5$ or other known oxide ion conductors. Formation of electronic defects under oxidizing and reducing conditions is calculated to be more favorable in the $Sr_4Fe_6O_{13}$ intergrowth structure than in $Sr_2Fe_2O_5$. Comparison of solution energies for cobalt incorporation shows $Sr_4Fe_6O_{13}$ has a slight preference for Co^{2+} being located on lower coordination sites, whereas in $Sr_2Fe_2O_5$, Co^{2+} ions located on tetrahedral sites are most favorable. Binding energy calculations suggest the possible formation of Co^{2+}-vacancy clusters with increasing Co^{2+} concentration. The rapid oxide ion conductivity in $Sr_4Fe_{6-x}Co_xO_{13\pm\delta}$ membranes is thought to arise from a combination of factors: a low-oxygen Frenkel energy (to produce an intrinsic population of mobile interstitial oxide ions and vacancies), low-migration energy barriers, and ease of distortion of polyhedra. A comparison of the two structures is shown in Fig. 12.24.

The pressure dependence of the crystal structure of $Sr_2Fe_2O_5$ has been studied at room temperature by angle-dispersive synchrotron XRPD and ^{57}Fe Mössbauer spectroscopy using diamond anvil cell techniques. Between 11 and 14 GPa the low-pressure Brownmillerite-type structure with an equal number of octahedrally and tetrahedrally coordinated Fe^{3+} sites is transformed into a tetragonal perovskite-like structure. The Mössbauer spectra of the high-pressure phase reveal two subspectra with an intensity ratio of about 3:1. The Mössbauer parameters are consistent with two five-coordinated Fe^{3+} sites differing in the degree of structural distortion of the FeO_5 polyhedra. Laser annealing of the high-pressure phase at 15 GPa induces a transformation from the tetragonal perovskite into an orthorhombic phase that is isostructural with $Sr_2Mn_2O_5$. This structure consists of a network of corner-sharing FeO_5 square pyramids. The coordination number of the Sr^{2+} ions has increased from 8 in the Brownmillerite structure to 10 in the $Sr_2Mn_2O_5$-type phase.

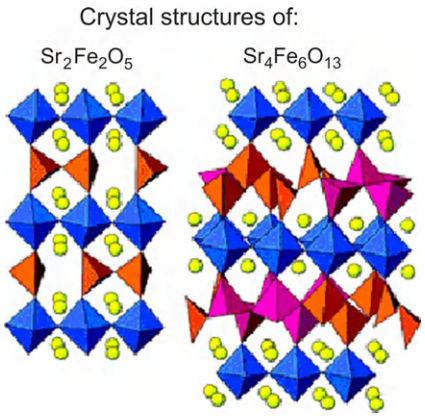

FIGURE 12.24

The electronic structure of strontium ferrite $Sr_3Fe_2O_6$ was calculated using the tight-binding linear muffin-tin orbital method in the local spin density approximation of DFT with Coulomb correlations correction (LSDA + U). The semiconducting character of the spectrum with charge transfer energy gap of 1.82 eV was obtained in reasonably good agreement with experimental data. The iron ions are found to be in the high-spin state. The calculated value of the local spin magnetic moment of Fe^{3+} ion is 3.94 μbar. This is not typical for trivalent iron ion in the high-spin state. It was shown that the strong hybridization between Fe^{3d} and O^{2p} orbitals favors the $d^6\underline{l}$ configuration of Fe^{3+} ion, where $\underline{l}$ is a hole in the oxygen p shell. The mechanism of oxygen transport in ferrite was discussed based on the total energy calculations of the different spatial configurations of oxygen vacancies.

The system $Sr_3Fe_2O_{6.00-6.90}$ forms a single phase of unusual structure, derived from that of perovskite by interleaving nonmagnetic layers of strontium-oxygen ions between pairs of perovskite layers composed of strontium–iron–oxygen ions. It exhibits a broad range of oxygen stoichiometry. As a consequence of this structure and the variable valence of the iron atom, a variety of magnetic interactions are possible. Between 1.4 and 300 K specimens of higher oxygen concentration are antiferromagnetic. The Nëel temperature (130 K for $Sr_3Fe_2O_{6.90}$) approaches 0 K at the composition $Sr_3Fe_2O_{6.50}$. Specimens in this range have positive paramagnetic Curie temperatures, indicative of a ferromagnetic type interaction. Specimens with oxygen content lower than $Sr_3Fe_2O_{6.50}$ exhibit strongly negative $Fe^{3+}\cdots O^{=}\cdots Fe^{3+}$ exchange. At the lower oxygen limit, $Sr_3Fe_2O_{6.00}$, strongly antiferromagnetic ordering appears stable to above room temperature.

The crystal and oxygen defect structure of the $n = 2$ Ruddlesden–Popper phase, $Sr_3Fe_2O_{6+\delta}$, has been studied by in situ high-temperature neutron powder diffraction in the temperature range $20 \leq T \leq 900$ °C in air. The analysis of the neutron diffraction data revealed the presence of structural oxygen vacancies on both the O(1) sites linking the octahedra along the *c*-axis and the O(3) sites in the FeO_2 planes of the perovskite layers. The oxygen vacancies on the O(3) site increase with temperature up to 0.25 per formula unit at $T = 900$ °C. This result supports the previously

proposed oxygen ion diffusion mechanism in $Sr_3Fe_2O_{6+\delta}$ that involves the migration of vacancies from an O(3) site to an adjacent O(1) site. The total linear expansion along the *c*-axis $a_c = 17.7 \times 10^{-6}/K$ mainly affects the perovskite block while the width of the rock salt layers remains stable with temperature. Oxygen defect phases such as $Sr_3Fe_2O_7$, $Sr_3Fe_2O_{6.5}$ and $Sr_3Fe_2O_6$ are antiferromagnetic compounds with semiconductor-like behaviors and thermally activated carriers.

In the Fe^{2+}–Fe^{3}-containing system of SrO–Fe_3O_4 (FeO–Fe_2O_3), the compound, $Sr_2Fe_3O_6$ is known. Different samples of the ferrite "$Sr_4Fe_6O_{13}$" = $(Sr_2Fe_3O_{6+\delta})_2$, synthesized in air, nitrogen, and argon, have been studied by HREM. It was shown that this oxide is oxygen deficient, i.e. $Sr_4Fe_6O_{13-\delta}$, and that its structure is modulated. The electron diffraction study showed that the modulation vector is $pa^* + qc^*$, with $p = (1 - \delta)/2$ varying in the range [0.4–0.5] and q close to one. It was shown that the component of the modulation vector along *c* induces complex modulated structures. It was also demonstrated that oxygen nonstoichiometry corresponds to the generation of the microphases, $[Sr_8Fe_{12}O_{26}]$, $[Sr_2Fe_3O_6]_n$, whose first integral member $n = 1$ (which corresponds to p = 0.4), was isolated for the first time by synthesis under argon. Structural models involving intergrowths of single perovskite $[Sr_2Fe_3O_6]\infty$ layers with complex $[Sr_2Fe_4O_{7-\delta}]\infty$ layers involving two kinds of pyramidal ribbons, FeO_5 trigonal bi-pyramids and FeO_5 distorted tetragonal pyramids, were used to explain the oxygen deficiency.

In the Fe^{4+}-containing system of SrO–FeO_2, reduction with CaH_2 of the double-layered perovskite $Sr_3Fe_2O_7$ yielded the novel two-legged $S = 2$ ladder compound $Sr_3Fe_2O_5$. Together, with the synthesis of $SrFeO_2$, this opens up new avenues for solid-state chemistry and physics of a series of *n*-legged ladders $Sr_{n+1}Fe_nO_{2n+1}$. The $SrFeO_x$ system with $2.5 \leq x \leq 3.0$ was prepared and examined by differential thermal analysis, thermogravimetry, powder XRD, and the ^{57}Fe Mössbauer effect. The following diagram illustrates the structural transformation from FeO_6 octahedra in $Sr_3Fe_2O_7$ to FeO_4 squares in $Sr_3Fe_2O_5$, which occurs via the intermediate $Sr_3Fe_2O_6$ (Sr-blue, O-red, Fe-yellow) (Fig. 12.25).

Four single phases with different structures exist in this system, the typical compositions of which are $SrFeO_3$, $SrFeO_{2.86}$, $SrFeO_{2.73}$, and $SrFeO_{2.50}$.

NB-the latter three compositions can be transposed into formulas with an even number of atoms- that is:

$$SrFeO_{2.50} = Sr_2Fe_2O_5$$
$$SrFEO_{2.73} = Sr_{11}Fe_{11}O_{30}$$

The compounds, $SrFeO_{2.86}$ and $SrFeO_{2.73}$, have tetragonal and orthorhombic structures, respectively. Their unit cells are related to the cubic perovskite cell for $SrFeO_3$ in the manner that $a_t \approx 2 \times 2^{1/2}\ a_c$, $c_t \approx 2a_c$ and $a_o \approx 2c_o \approx 2 \times 2^{1/2}\ a_c$, $b_o \approx 2a_c$, where the suffixes c, t, and o stand for the cubic, tetragonal, and orthorhombic structures, respectively. These single-phase compositions suggest the ideal series of $SrFeO_{3\text{-}1/n}$, where $n = \infty$, 8, 4, and 2 to give an oxygen ratio of $x = 3$, 2.875, 2.75, and 2.50, correspondingly. The vacancy ordered phase of $SrFeO_{2.86}$, $SrFeO_{2.73}$, and $SrFeO_{2.50}$ show first-order transitions to their cubic, disordered structures at 250, 320, and 830 °C, respectively. Formation of the cubic, disordered structure above a temperature depending on the composition is suggested for the whole composition range. The material $Sr_2FeO_{3-\delta}$ is thought to exist in four different oxygen phases within the range of $3 - \delta = 2.5$–3.32.

The cubic $SrFeO_3$ $(3 - \delta = 3)$, tetragonal $Sr_8Fe_8O_{23}$ $(3 - \delta = 2.875)$ and the orthorhombic phases, $Sr_4Fe_4O_{11}$ $(3 - \delta = 2.75)$, and $Sr_2Fe_2O_5$ $(3 - \delta = 2.5)$ have the general structure shown in Fig. 12.26.

Evidence from Mössbauer measurements have suggested that these are the only stable phases that exist in this range and stoichiometries other than these are an inhomogeneous mixture of the four phases.

The cubic phase $SrFeO_3$ has helical antiferromagnetic order at ~140 K and is highly conductive. It consists of well-ordered FeO_6 octahedra where the Fe ions have 4+ valence. By reducing the oxygen content, $Sr_8Fe_8O_{23}$ was obtained. This phase shows antiferromagnetic order at ~70 K and displays an order of magnitude increase in resistivity below this temperature.

The phase is made up of square pyramidal FeO_5 that forms dimers. These are adjacent to distorted FeO_6 and

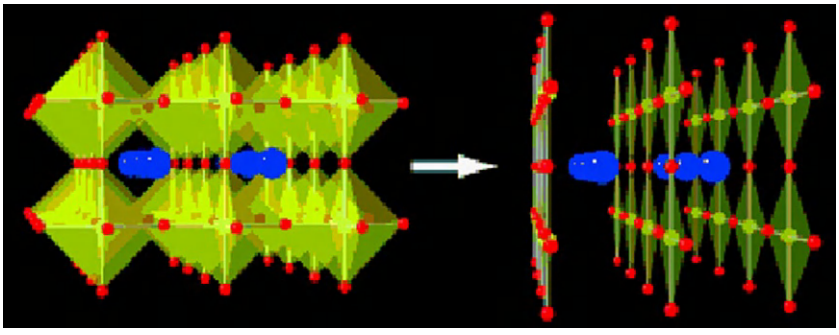

FIGURE 12.25

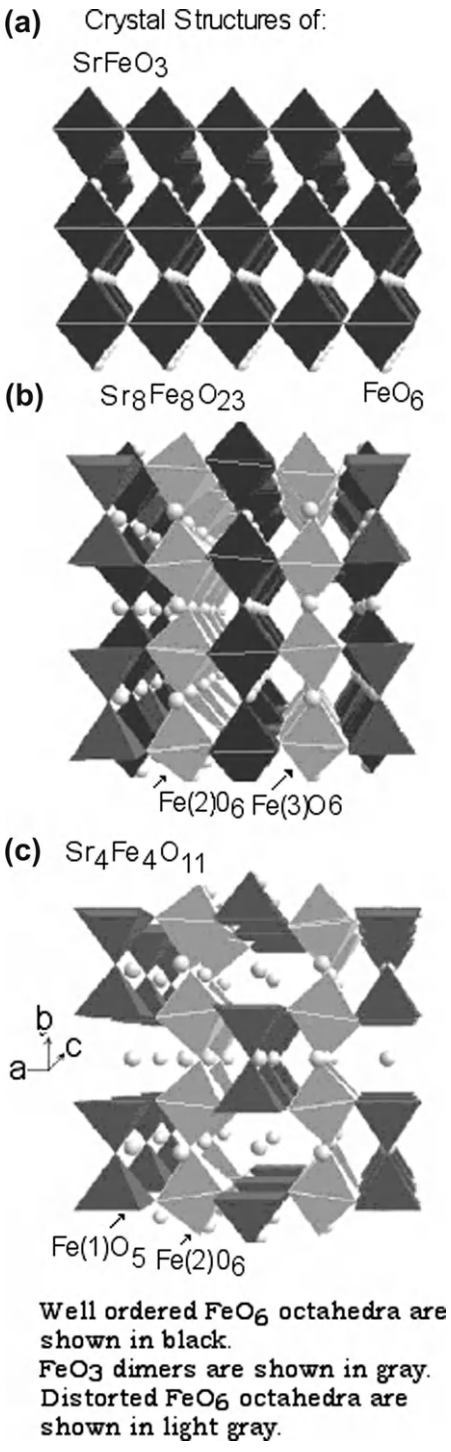

FIGURE 12.26

well-ordered FeO_6 octahedra. It has been argued that the Fe ions in the distorted FeO_6 octahedra have a valence of 3.5+ while the other Fe ions are both 4+. The increase in resistivity was said to be caused by charge ordering of the $Fe^{3.5+}$ ions to Fe^{3+} and Fe^{4+} reminiscent of the partial charge ordering Verwey transition in Fe_3O_4. Further reduction in oxygen content then leads to the $Sr_4Fe_4O_{11}$ phase, that is antiferromagnetic below ~230 K and shows semiconductor-like resistivity. It contains square pyramidal FeO_5 units that form dimers and distorted FeO_6 octahedra. The Fe ions are believed to have valences of 3+ and 4+, respectively.

The Fe^{4+} ions in the FeO_6 octahedra have antiferromagnetic order, while the Fe^{3+} ions are not believed to possess any long-range magnetic order. However, there is evidence that spin frustration in the Fe^{3+} moments can cause weak spin glass behavior below ~50 K. The $Sr_4Fe_4O_{11}$ phase also shows an exchange bias like effect below ~230 K, which is well above the temperature where the spin glass behavior is observed. The magnetic ordering temperature of the Fe^{4+} ions is around 230 K, suggesting they play a key role in the mechanism causing the exchange bias like effect. Finally, there is the oxygen deficient, $Sr_2Fe_2O_5$ phase. It has the Brownmillerite structure and is composed of FeO_4 tetrahedra and distorted FeO_6 octahedra, where the Fe ion is believed to have a valence of 3+.

Evidence has been presented for a novel phase of ideal composition $SrFeO_{2.75}$ in the system $SrFeO_{3-\delta}$ ($0.5 < \delta < 0$). Electron diffraction evidence suggested an orthorhombic or body-centered tetragonal symmetry with lattice parameters related to the cubic perovskite lattice parameter a_c by $a\ 2\sqrt{2}a_c$, $b\ \sqrt{2}a_c$, $c\ 2\sqrt{2}a_c$. A plausible model for the structure was presented which is related to that of $SrFeO_{2.5}$. Powder XRD photographs revealed only a simple cubic perovskite cell for $SrFeO_{2.75}$, presumably because the ordered domains giving rise to the superstructure observed in electron diffraction are small in extent. At other intermediate compositions, slow cooling gave mixtures of the novel phase and either $SrFeO_{2.5}$ or $SrFeO_3$. The two-phase regions narrow at high temperatures and TG studies at 1 atm. pressure of oxygen indicated a single phase between $SrFeO_{2.5}$ and $SrFeO_{2.75}$, stable between 500 and 950 °C.

The compound, Sr_2FeO_4, has the general form shown in Fig. 12.27.

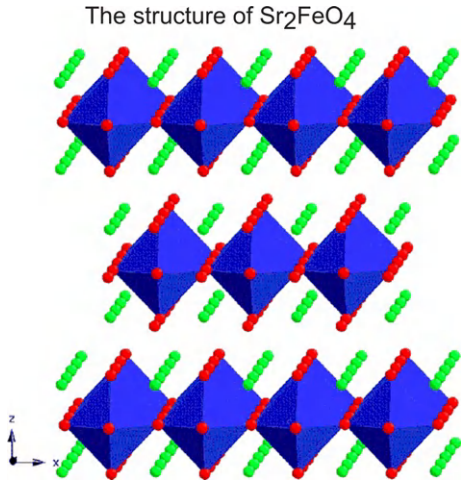

FIGURE 12.27

In order to make clear the phase relationships and non-stoichiometry of the $SrFeO_{2.5}$–$SrFeO_3$ system at elevated temperatures, measurements were made using high-temperature gravimetry and high-temperature powder XRD analysis under the controlled oxygen partial pressure of $1–10^{-5}$ atm. at temperatures above 400 °C. At 400–900 °C, the system was found to consist of the $SrFeO_{2.5+\delta}$ phase of the Brownmillerite-type structure with small oxygen excess-type nonstoichiometry and the $SrFeO_{3-\delta}$ phase of the cubic perovskite-type structure with large oxygen-deficient type nonstoichiometry. At temperatures above 900 °C, the Brownmillerite phase transformed to the perovskite type and the system was composed of only the cubic perovskite-type phase.

In the following diagram, structural changes of a reductive reaction are shown in Fig. 12.28.

In this diagram, reduction of Sr_2FeO_4 (left) to Sr_2FeO_3 (right) to obtain a one-leg spin ladder, i.e. a one-dimensional (1D) spin chain is shown in Fig. 12.28(a); a reductive reaction of $Sr_4Fe_3O_{10}$ (left) to $Sr_4Fe_3O_7$ (right) to obtain a three-leg spin ladder, i.e. a 3D spin chain, is shown in Fig. 12.28(b). These materials all contain iron in the tetravalent ⇒ divalent state, i.e. $Fe^{4+} \Rightarrow Fe^{2+}$. These Fe ions are believed to have valences corresponding to these values.

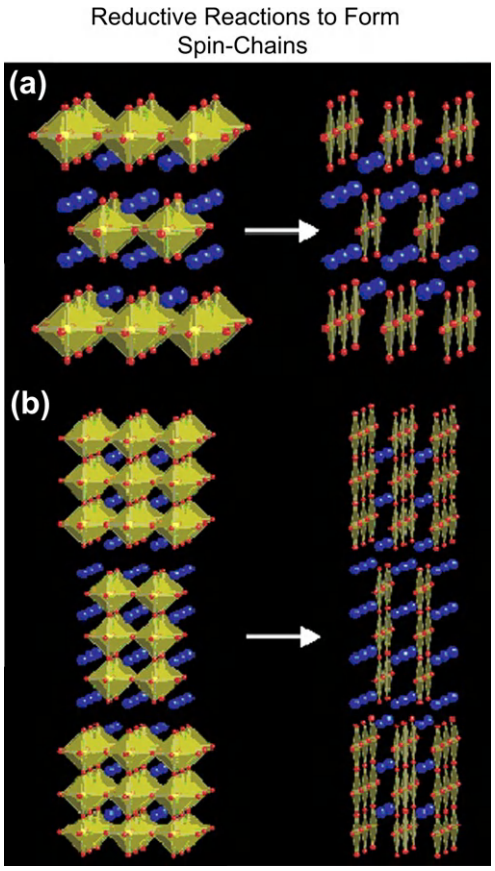

FIGURE 12.28

The solid-state reactions occurring in the system $SrCO_3$–Fe_2O_3 (composition Fe/X (iron cationic fraction) = 0.5–0.923) have been studied. At Fe/X = 0.5, $Sr_2Fe_2O_{5-\delta}$ (Brownmilletite) forms by annealing of the activated mixture at 850 °C under nitrogen while the non-stoichiometric perovskite ($SrFeO_{3-\delta}$) is the equilibrium product when annealing is performed under air.

At Fe/X = 0.66 a mixture of $SrFe_2O_4$ and $SrFe_2O_5$ is the final product no matter what is the annealing atmosphere. The enthalpies of reaction at these compositions have been determined. By increasing iron content (Fe/X = 0.8), the annealing at 850 °C of the activated mixture leads to $SrFe_2O_4$, $SrFe_2O_5$ and $SrFe_{12}O_{19}$ (indicated as the usual term for strontium hexaferrite).

Finally at Fe/X = 0.923, $SrFe_{12}O_{19}$ is produced from the mechanically activated mixture at temperatures lower (approximately 800 °C) than in the case of conventional solid-state route. In the case of the last two compositions, no reaction enthalpy could be determined as the process is too slow.

Strontium ferrate(IV), Sr_2FeO_4, crystallizes with a tetragonal unit cell, $I4/mmm$, $a = 3.8642(1)$, $c = 12.3968(2)$ Å, and $V = 185.1$ Å^3. The structure of this compound is of the K_2NiF_4 type as refined by Rietveld analysis of powder XRD data. This material contains iron(IV) in a very slightly distorted octahedral environment. The behavior of the high-pressure magnetic, structural, and transport properties of Sr_2FeO_4 (Fe^{4+}), an antiferromagnetic ($T_N = 60$ K) insulator, using diamond anvil cells up to $P = 30$ GPa. With the increasing pressure a significant increase in the conductance (σ) is observed and at $P_M = 19$ GPa the compound metallizes as concluded from the onset of a negative slope of $\delta(T)$. Magnetic studies performed with ^{57}Fe Mössbauer spectroscopy showed no evidence of a magnetic moment collapse at P_M and beyond, up to $P = 30$ GPa. No structural phase transition occurs up to 30 GPa. The coexistence of magnetic moments and metallic state in this oxide is clear evidence of an intra-ligand p–p gap as proposed by the XPS data analyses.

Sr_2FeO_4 and $Sr_3Fe_2O_7$ have been studied using low-temperature powder neutron diffraction, magnetometry and ^{57}Fe Mössbauer spectroscopy. Sr_2FeO_4 orders antiferromagnetically at 60 K while the Nëel temperature of $Sr_3Fe_2O_7$ is 110 K. At room temperature the Mössbauer spectrum of $Sr_3Fe_2O_7$ is interpreted in terms of a disproportionation, $Fe^{4+} \leftrightarrow Fe^{3+} + Fe^{5+}$, though neutron diffraction measurements show a single, crystallographic iron site. Neutron diffraction data collected below the Nëel temperatures from Sr_2FeO_4 (4 K) and $Sr_3Fe_2O_7$ (6 and 90 K) only show broad weak magnetic reflections indicative of antiferromagnetic ordering in two dimensions. Mössbauer data collected below T_N from Sr_2FeO_4 indicate the presence of at least four magnetically different Fe^{4+} sites. The pseudobinary system, SrO–Fe_2O_{3+x}, is

known in air to produce $Sr_{m+1}Fe_mO_{3m+1}$ ($m = 1, 2, 3, \infty$) Ruddelsden–Popper phases and the phases, $Sr_4Fe_6O_{14}$ and $SrFe_{12}O_{19}$. Sr_2FeO_4 ($m = 1$) decomposes in air at 930 °C to form SrO and $Sr_3Fe_2O_{7-\delta}$. The $Sr_4Fe_3O_{10-\delta}$ ($m = 3$) is stable in air up to 850 °C. Above this temperature, it disproportionates into $Sr_3Fe_2O_{7-\delta}$ ($m = 2$) and $SrFe_{3-\delta}$ ($m = \infty$). In an oxygen atmosphere, $Sr_3Fe_2O_{7-\delta}$, $SrFeO_{3-\delta}$, $Sr_4Fe_6O_{12-\delta}$ and $SrFe_{12}O_{19}$ are stable to 1520, 1600, 1245 and 1450 °C, respectively. $Sr_3Fe_2O_{7-\delta}$ is tetragonal, $SrFeO_{3-\delta}$ is tetramorphic: (a) cubic perovskite ($\delta = 0$), (b) tetragonal ($\delta = 0.16$–0.24), (c) orthorhombic ($\delta = 0.25$) and (d) Brownmillerite ($\delta = 0.5$). $Sr_4Fe_6O_{12-\delta}$ and $SrFe_{12}O_{19}$ are orthorhombic and hexagonal (magnetoplumbite), respectively.

In the Fe^{5+}-containing system of SrO–Fe_2O_5, no compounds are known. This valence state is not stable and decomposes readily:

$$2Fe^{5+} \Rightarrow Fe^{4+} + Fe^{6+}$$

In the Fe^{6+}-containing system of SrO–FeO_3, the compound of $SrFeO_4$ is known. Cathodes comprised of Fe(VI) salts, and capable of three-electron reduction, have been found to be useful for the formation of energetic super-iron batteries. This study presented a synthesis procedure for $SrFeO_4$ or strontium super-iron cathodic salts, and introduced mixed salts containing barium and strontium cations, $Sr_xBa_{(1-x)}FeO_4$. The XRD and first IR spectra of $SrFeO_4$ were presented, and compared to known spectra of K_2FeO_4 and $BaFeO_4$. The measured solubility of $SrFeO_4$ was found to be low in concentrated KOH electrolytes (0.001 mM in 13.5 M KOH), a factor of use in alkaline cathodic chemistry. AAA batteries were prepared and discharged with this new cathode, and exhibit high discharge energies, approaching, but slightly lower than those previously observed for barium super-iron alkaline batteries. The discharge energy further approaches the barium cell when the mixed cathode salt is employed, particularly for $x = 0.25$–0.5 in $Sr_xBa_{(1-x)}FeO_4$.

The synthesis and analysis of a range of Fe (VI) compounds has been presented. Fe(VI) compounds have also been variously referred to as ferrates or super-iron compounds. Fe(VI) salts with detailed syntheses in this paper include high-purity alkali earth Fe(VI) salts $BaFeO_4$, and $SrFeO_4$. Two conventional, as well as two improved Fe(VI) synthetic routes, were presented.

The conventional syntheses include solution phase oxidation (by hypochlorite) of Fe(III), and the synthesis of less soluble super-irons by dissolution of Fe_4^{2-}, and precipitation with alternate cations. These new routes include a solid synthesis route for Fe(VI) salts and the electrochemical synthesis (include in situ and ex situ synthesis) of Fe(VI) salts. Fe(VI) analytical methodologies summarized were FTIR, ICP, titrimetric, UV/VIS, XRD, Mössbauer and a range of electrochemical analyses. Fe(VI) compounds have been explored as energy storage cathode materials in both aqueous and non-aqueous phase in "super-iron" battery configurations, as well as novel oxidants for synthesis and water treatment purification. Preparation of reversible Fe(VI/III) thin film toward a rechargeable super-iron cathode was also presented. In addition, the preparation of unusual $KMnO_4$ and zirconia coatings on Fe(VI) salts, via organic solvent deposition, was summarized. These coatings can stabilize and activate Fe(VI) salts in contact with alkaline media.

$SrFe_{12}O_{19}$ is offered for sale commercially as a basis for manufacturing ceramic magnets.

12.2.5. Barium Oxy-Iron Compounds

Similar to the SrO system, barium forms a number of oxy-ferrites and oxy-ferrates. No Ba^0–Fe^0 compounds are known.

In the Fe^{2+}-containing system of BaO–FeO, several compounds are known. The compound, $BaFeO_2$ has been thoroughly studied. Based on the DFT with the generalized gradient approximation plus the on-site Coulomb repulsion method, the electronic, magnetic, and optical properties in infinite-layer iron oxide $BaFeO_2$ were elucidated. It was revealed that $BaFeO_2$ possesses a $P4/mmm$ tetragonal symmetry that is similar with $SrFeO_2$. The structure has the general form shown in Fig. 12.29.

Another view of this perovskite structure is shown in the following diagram. The J_{1-4} spin vectors within the lattice are also shown in Fig. 12.30.

It has been demonstrated that the single downspin electron of Fe^{2+} occupies the d^2 level instead of the double degenerate dx^2-y^2 and d^2 levels predicted from Jahn–Teller instability in crystal field theory. Magnetic structure shows great contrast between intralayer and interlayer exchange interactions. Linear dielectric function, on the other hand, exhibits obvious anisotropic behavior between in plane and out of plane responses.

If FeO is added to $BaFeO_2$, the compound, $BaFe_2O_3$ is obtained. This compound has found extensive usage in Industry as a solid-state ceramic magnet. The following

FIGURE 12.30

diagram presents some of the shapes that have been manufactured (Fig. 12.31).

Disc magnets can be pressed into any desired shape or size, then magnetized. They are readily available in various forms, are hard and brittle, but cannot be drilled or machined. They are stable and resistant to demagnetization, cost effective, corrosion resistant. Uses include: Electric motors, Audio speakers, Electronic equipment, Industrial automation systems, Conveyor belts, and Automotive sensors.

In the Fe^{3+}-containing system of $BaO–Fe_2O_3$, the phase diagram shows five (5) compounds. These are the 7:2, 2:1, 1:2, 2:3 and 1:6 compounds in the $BaO–Fe_2O_3$ system (Fig. 12.32).

FIGURE 12.31

Another phase diagram has been published purporting to show the most stable compounds in the $BaO–Fe_2O_3$ system. This is shown as follows for purposes of comparison in Fig. 12.33.

Little is known concerning the $Ba_7Fe_4O_{13}$ compound. Its structure has not been published at this date and no information is readily available.

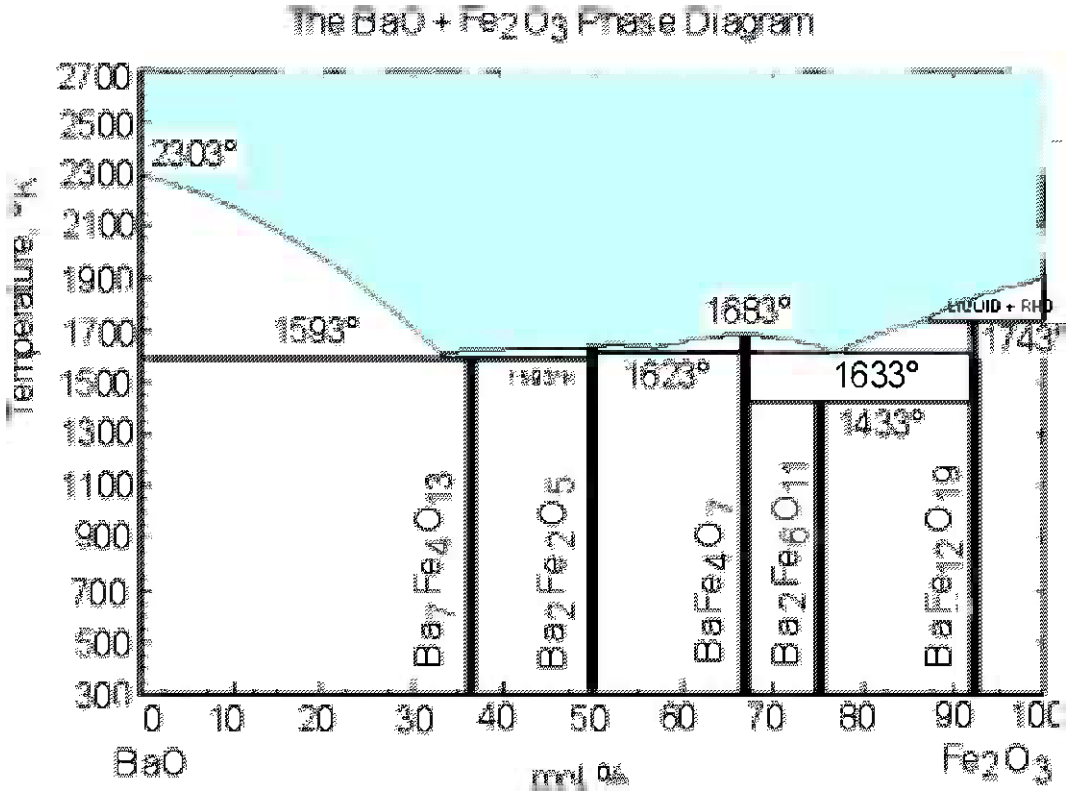

FIGURE 12.32

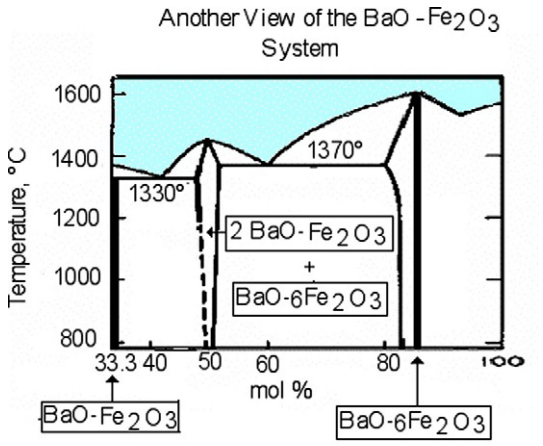

Fig 12-33

FIGURE 12.33

The compounds, $Ba_2Fe_2O_5$, $BaFe_4O_7$, and $BaFe_{12}O_{19}$ will be described below. The $BaO–6Fe_2O_3$ compound has the structure shown in Fig. 12.34.

This compound is also used as a powder for manufacturing ceramic magnets. It is pressed in the desired shape and then magnetized at about 230–330 °C. Upon cooling, the magnet is hard and retains its magnetic remanance. Other compounds that have been tried for this purpose include $BaFe_{15}O_{23}$ and $BaFe_{18}O_{27}$. The only difference between these compounds is the number of Ba^{2+} ions actually incorporated within the unit cell.

The literature concerning the $Ba_2Fe_6O_{11}$ compound is not extensive. $Ba_2Fe_6O_{11}$ has been synthesized in both powder and single-crystal form from the ternary composition 15 B_2O_3–37.5 Fe_2O_3–47.5 BaO (mole ratio). Although a metastable phase, it displays great stability and will not decompose even when subjected to temperatures as high as 1200 °C. When heated to the melting point, this compound recrystallized to $BaFe_{12}O_{19}$ and $BaFe_2O_4$, the equilibrium compounds. A Mössbauer experiment at 300 K revealed that a hyperfine spectrum is present leading to the conclusion that the compound is magnetically ordered. XRD data are given. It crystallizes in the orthorhombic space group *Pnnm*: $a = 23.024(10)$ Å, $b = 5.181(3)$ Å, $c = 8.900(4)$ Å, $Z = 4$. Fe^{3+} ions occur in both octahedral (Fe···O mean distance: 2.02 Å) and tetrahedral (Fe···O mean distance: 1.865 Å) coordination. Two types of Ba^{2+} ions are found, with six and seven neighboring oxygen atoms. The structure consists of sheets of edge-shared FeO_6 octahedra that are connected by means of corner-shared tetrahedra. $Ba_2Fe_6O_{11}$ is a complex antiferromagnet with a Nëel temperature $T_N = 488$ K.

Although it does not appear within the phase diagram, the 1:1 compound, $BaFe_2O_4$ is said to be tetramorphic. However, only two of these structures have been established. This compound undergoes polymorphic transitions at 800 and 1000 °C. The resulting phases are: γ-$BaFe_2O_4$ stable up to 800 °C with an orthorhombic phase, β-$BeFe_2O_4$, stable between 800 and 1000 °C, pseudo orthorhombic phase, crystal parameters of: $a = 5.463$ Å, $b = 9.461$ Å, $c = 8.710$ Å. α-$BaFe_2O_4$, stable above 1000 °C, and hexagonal with $a = 5.158$ Å, $c = 9.016$ Å, space group $P6_322$ with $Z = 2$. If β-$BaFe_2O_4$ is quenched, a metastable form, δ-$BaFe_2O_4$ is obtained with $a = 5.442$ Å, $b = 9.325$ Å and $c = 8.670$ Å, that is stable at room temperature. A comparison of two of these structures is shown in Fig. 12.35.

Numerous studies have been completed on the phase relations in the Ba–Fe–O ternary system. Three stable phases have been reported, $Ba_2Fe_2O_5$, $BaFe_2O_4$ and the hexagonal $BaFe_{12}O_{19}$. In spite of this, many apparently contradictory results have been found, with the hexagonal $BaFe_2O_4$ phase usually being reported as coexisting with $BaFe_{12}O_{19}$ and Fe_2O_3, along with other metastable phases. They are mutually insoluble in each other as solids, and both coexist up to 1000 °C. After this point, a third phase, the metastable hexagonal $BaFe_{12}O_{11}$, can also develop until the ternary mixture reaches its liquid point at 1175 °C. There it reverts to $BaFe_{12}O_{19}$ and α-$BaFe_2O_4$ on cooling. Fine-particle spinel ferrites, such as $BaFe_2O_4$, are useful for the low-temperature preparation of high-density ferrites and as suspension materials for ferromagnetic liquids.

Unit cell parameters of γ-$BaFe_2O_4$ are: $a = 5.387$ Å, $b = 8.458$ Å, $c = 10.4244$ Å, $\beta = 113.934°$, $\alpha = \beta = \gamma = 90°$, cell volume is 434.12 Å^3, $Z = 4$. Cell occupancy is shown in Table 12.7.

δ-$BaFe_2O_4$ has the unit cell parameters of: $a = 5.442$ Å, $b = 8.67$ Å, $c = 9.325$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, cell volume is: 439.37 Å^3, $Z = 2$. Cell occupancy was not given.

Unit cell parameters for γ-$BaFeO_4$ are: $a = 5.458$ Å, $b = 5.458$ Å, $c = 10.016$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 120°$, cell volume = 232.60 Å^3, $Z = 2$. Cell occupancy is shown in Table 12.8.

Unit cell parameters of δ-$BaFe_2O_4$ are: $a = 5.463$ nm, $b = 8.71$ nm, $c = 9.461$ nm, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, Cell volume = 450.18Å^3, $Z = 2$.

Barium ferrite $Ba_2Fe_2O_5$ has been studied using various techniques. XRD and TEM have shown the phase to crystallize with a monoclinic symmetry, the unit cell being a complex supercell of a cubic perovskite cell. The Mössbauer resonance spectrum exhibits five sextuplets that have been assigned to Fe^{3+} in O*h*, T*d*, and fivefold coordinated sites. Obviously, $Ba_2Fe_2O_5$ does not adopt the Brownmillerite structure of homologous calcium (or strontium) ferrite and the oxygen vacancy ordering is more complex. The compound, $Ba_2Fe_2O_5$ has a complicated structure shown in Fig. 12.36.

Barium ferrite $Ba_2Fe_2O_5$ is a complex perovskite-related structure. The crystal is monoclinic $P2_1/c$, with $a = 6.969$, $b = 11.724$, $c = 23.431$ Å, $\beta = 98.74°$. The composition of one unit cell is $Ba_{28}Fe_{28}O_{70}$. The structure was solved using a combination of HREM, crystallographic image processing (CIP) and electron diffraction. The structure can be described as a perovskite with 14 oxygen positions unoccupied with respect to the ABO_3 stoichiometry in the monoclinic unit cell. These positions can be identified from the potential map obtained by HREM and CIP. They form two linear groups.

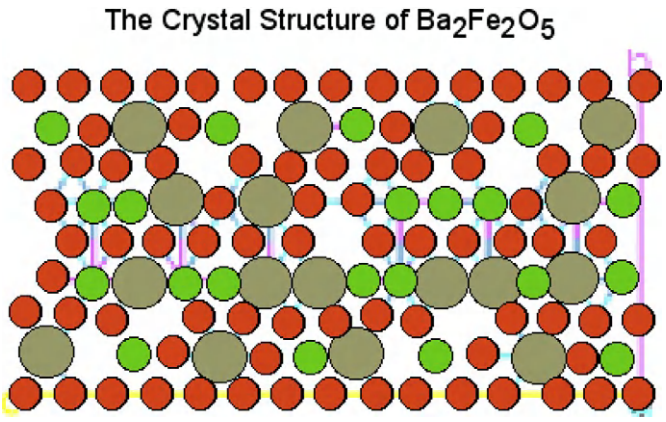

FIGURE 12.36

Seven of them lie on a line along [476]*m* (corresponding to [110]*c* of perovskite), while the seven other symmetry-related positions lie along [46]*m* (corresponding to [101]*c* of perovskite).

Cell occupancy is shown in Table 12.9.

The standard molar Gibbs energy of formation of $BaFe_{12}O_{19}$(solid), $BaFe_2O_4$(solid), $Ba_2Fe_2O_5$(solid), $Ba_3Fe_2O_6$(solid) and $Ba_5Fe_2O_8$(solid) have been determined using solid-state electrochemical technique employing CaF_2(solid) as an electrolyte. The reversible emf values have been measured in the temperature range from 970 to 1151 K. The oxygen chemical potential corresponding to three phase equilibria involving technologically important compound $BaFe_{12}O_{19}$(solid) has

been determined using solid-state electrochemical technique employing CSZ as an electrolyte from 1048 to 1221 K. The values of $\Delta_f G^0{}_m(T)$ for the above ternary oxides are given by:

$$\Delta_f G^0{}_m(BaFe_{12}O_{19}, (solid)/kJ/mol = -5431.3 + 1.5317 (T/K) \quad (970 \le T/K \le 1151)$$

$$\Delta_f G^0{}_m(BaFe_2O_4, (solid)/kJ/mol = -1461.4 + 0.3745 (T/K) \quad (970 \le T/K \le 1151)$$

$$\Delta_f G^0{}_m(Ba_2Fe_2O_5, (solid)/kJ/mol = -2038.3 + 0.4433 (T/K) \quad (970 \le T/K \le 1149)$$

$$\Delta_f G^0{}_m(Ba_3Fe_2O_6, (solid)/kJ/mol = -2700.1 + 0.6090 (T/K) \quad (969 \le T/K \le 1150)$$

$$\Delta_f G^0{}_m(Ba_5Fe_2O_8, (solid)/kJ/mol = -3984.1 + 0.9300 (T/K) \quad (973 \le T/K \le 1150)$$

The uncertainty estimates for $\Delta_f G^0{}_m$ includes the standard deviation in the e.m.f and the uncertainty of the data taken from the literature. An isothermal oxygen potential diagram for the system Ba–Fe–O was constructed at 1100 K based on the thermodynamic data obtained in this study.

In the FeO–Fe_2O_3-containing system of BaO–Fe_3O_4, no compounds are known.

In the Fe^{4+}-containing system of BaO–FeO_2, various barium orthoferrates over wide Fe^{4+} concentrations have been prepared and their magnetic properties were investigated. The hexagonal phase with large Fe^{4+} concentration is ferromagnetic above the anomaly point. With increasing Fe^{3+}, it tends to be antiferromagnetic. The cubic tetragonal phases are paramagnetic with positive paramagnetic Curie temperature. In these phases, the Fe^{4+}–Fe^4 interaction is ferromagnetic, but the Fe^{3+}–Fe^{4+} and Fe^{3+}–Fe^{3+} interactions are antiferromagnetic. Some of the Fe^{3+} and Fe^{4+} ions in these phases take low-spin states due to strong uniaxial crystalline fields caused by neighboring oxygen vacancies. The triclinic I phase appears to have a magnetic structure of a 1D antiferromagnet. The magnetic structures of the triclinic II and rhombohedral phases resemble that of the triclinic I.

The compound $BaFeO_{3-x}$ exists in many forms, depending on the oxygen deficiency: triclinic ($2.64 < \delta < 2.67$), rhombohedral ($2.62 < \delta < 2.64$), tetragonal ($2.75 < \delta < 2.81$) and hexagonal ($2.63 < \delta < 2.92$). Furthermore, the hexagonal phase is classified into 6H- and 12H-type $BaFeO_{3-}$ The hexagonal phase has a wide range in oxygen content ($BaFeO_{2.63–2.92}$). The other phases have the limited compositions and the distinct structures of perovskite: triclinic I, $BaFeO_{2.50}$; triclinic II, $BaFeO_{2.64–2.67}$; rhombohedral I and II, $BaFeO_{2.62–2.64}$; and tetragonal, $BaFeO_{2.75–2.81}$. The phases contain Fe^{4+} ions correlating with the oxygen content. The hexagonal phase shows a continuous change in oxygen content with temperature down to $BaFeO_{2.63}$. The perovskite-like phases, however, show characteristic transformations. The triclinic I phase oxidizes to the triclinic II form at 320–500 °C and to the hexagonal form at 720–915 °C in oxygen. These transformations are related to oxidation–reduction of iron ions ($Fe^{3+} \Leftrightarrow Fe^{4+}$) as the oxygen content is changed in the crystal structure.

The structure of the mixed valency $Ba_5Fe_5O_{14}$ ($BaFeO_{2.8}$), prepared using a molten KOH-$Ba(OH)_2$ flux, has been determined using single-crystal XRD. $Ba_5Fe_5O_{14}$ forms twinned crystals with the orthorhombic space group *Cmcm*, $a = 5.7615$, $b = 9.9792$ and $c = 24.347$ Å, $Z = 4$. The structure, which is closely related to the 10H $BaFeO_{2.65}$ perovskite, is composed of two oxygen-deficient BaO_2 layers and eight BaO_3 layers with a $(hchhc)_2$ stacking sequence, where h and c denote hexagonal or cubic layers. A displacement of barium and oxygen atoms in the BaO_2 layers from hexagonal special positions lowers the symmetry from hexagonal to orthorhombic. This combination of stacking and vacancies creates trimers of face-sharing FeO_6 octahedra pillared by dimers of corner-sharing FeO_4 tetrahedra. The Fe^{4+} atoms are located in the center of the trimer and in the tetrahedral sites. The magnetism of $Ba_5Fe_5O_{14}$, investigated using SQUID magnetometry, is characteristic of a strongly coupled antiferromagnet.

$BaFeO_{2.8-\delta}$ with a crystal structure different from any of those previously reported in the system $BaFeO_y$ ($2.54 \le y \le 43.0$) was prepared by a low-temperature method of synthesis, based on the oxidative thermal decomposition of $BaFe[(CN)_5NO_2]\cdot 3H_2O$. The structure was solved *ab* initio by a high-resolution synchrotron XRPD method. The compound crystallizes in space group *P63/mmc*, Z"10, unit cell parameters $a = 5.77944$, $c = 24.60871$ Å. The structure consists of 10H close packed $(hchch)_2$ stacking of BaO_n layers (eight BaO_3 layers and two oxygen-deficient BaO_2 layers). Additional oxygen deficiencies are randomly distributed on the h-BaO_3 layers. Six iron ions occupy octahedral sites sharing faces between them along the *c*-axis and four occupy tetrahedral sites (2 T′ and 2 T″) sharing faces with the octahedra and sharing corners between them. This new barium ferrate polytype is believed to be stabilized only at this low temperature (850 °C) and atmospheric oxygen pressure, since it has not been described for samples prepared with other methods of synthesis.

The structure of the mixed-valent $Ba_5Fe_5O_{14}$ ($BaFeO_{2.8}$), prepared using a molten KOH–$Ba(OH)_2$ flux, has been determined using single-crystal XRD. $Ba_5Fe_5O_{14}$ forms twinned crystals with the orthorhombic space group *Cmcm*, $a = 5.7615(8)$, $b = 9.9792(14)$ and $c = 24.347(3)$ Å, $Z = 4$. The structure, which is closely related to the 10H $BaFeO_{2.65}$ perovskite, is composed of two oxygen-deficient BaO_2 layers and eight BaO_3 layers with a $(hchhc)_2$ stacking sequence, where h and c denote hexagonal or

cubic layers. A displacement of barium and oxygen atoms in the BaO_2 layers from hexagonal special positions lowers the symmetry from hexagonal to orthorhombic. This combination of stacking and vacancies creates trimers of face-sharing FeO_6 octahedra pillared by dimers of corner-sharing FeO_4 tetrahedra. The Fe^{4+} atoms are located in the center of the trimer and in the tetrahedral sites. The magnetism of $Ba_5Fe_5O_{14}$, investigated using SQUID magnetometry, is characteristic of a strongly coupled antiferromagnet.

The compound, $BaFe_2O_5$, is a perovskite-based structure. Numerous investigations have shown that it contains the Fe^{4+} ion in a cubic structure. No lower valance states like Fe^{3+} or Fe^{2+} have been detected. It contains octahedral units of FeO_6 interspersed with Ba^{2+} ions. When a trivalent ion like Y^{3+} is added to this compound (or any other divalent cation like Ba^{2+}), it does so be the defect equation:

$$Y_{Ba}^{3+} + V_{Ba}^{-} \Leftrightarrow 2Ba_{Ba}^{2+}$$

The stoichiometry changes from octahedrons of FeO_6 to five-sided pentagons of FeO_5, is shown in the following diagram. Note that both Fe^{3+} and Fe^{2+} have appeared (Fig. 12.37).

Related compounds include $BaFe_2O_5$ and Ba_2FeO_4.

Crystals of Ba_2FeO_4 and Ba_3FeO_5, grown from a "self-sealing" KOH-$Ba(OH)_2$ flux, have been characterized by single-crystal XRD, Mössbauer spectroscopy, and magnetic measurements. Ba_2FeO_4 forms non-merohedral twinned crystals with the monoclinic space group $P21/n$, $a = 6.034$ Å, $b = 7.647$ Å, $c = 10.162$ Å, $\beta = 92.931°$, and $Z = 4$. Ba_3FeO_5 crystallizes in the orthorhombic space group *Pnma*, with $a = 10.301$ Å, $b = 8.151$ Å, $c = 7.611$ Å, and $Z = 4$. Although both compounds feature discrete FeO_4^{4-} tetrahedra, the anion found in Ba_2FeO_4 has shorter Fe–O bonds and is significantly distorted, relative to the Ba_3FeO_5 anion.

An iron valence of 4+ was confirmed by magnetic susceptibility measurements and by the low-temperature isomer shifts of −0.152 and −0.142 mm/s relative to α-iron for Ba_2FeO_4 and Ba_3FeO_5, respectively (Fig. 12.38).

The standard Gibbs Free Energy of the following compounds have been established as shown in Fig. 12.39.

In the Fe^{5+}-containing system of BaO–Fe_2O_5, no compounds are known.

In the Fe^{6+}-containing system of BaO–FeO_3, the ferrate, FeO_4^{2-}, ion is thermodynamically a stronger oxidant than the common oxidants MnO_4^- and CrO_4^{2-}. Thus, it has been used in various fields such as oxidation of organic substrates, water disinfection and degradation of organic synthetic pollutants. Super-iron batteries incorporating Fe(VI) cathodes salts with a higher capacity and energy advantage compared to the conventional alkaline batteries have also been recently introduced.

In one study, the thermal decomposition of solid samples of iron(VI) oxides, $K_2FeO_4 \cdot 0.088\ H_2O$ (**1**) and $BaFeO_4 \cdot 0.25H_2O$ (**2**) in inert atmosphere has been examined using simultaneous thermogravimetry and differential thermal analysis (TG/DTA), in combination with in situ analysis of the evolved gases by online coupled mass spectrometer (EGA–MS). The final decomposition products were characterized by ^{57}Fe Mössbauer spectroscopy. Water molecules were released first, followed by a distinct decomposition step with endothermic DTA peak of **1** and **2** at 273 and 248 °C, respectively, corresponding to the evolution of molecular oxygen as confirmed by EGA–MS. The released amounts of O_2 were determined as 0.42 and 0.52 mol pro formula of **1** and **2**, respectively. The decomposition product of K_2FeO_4 at 250 °C was

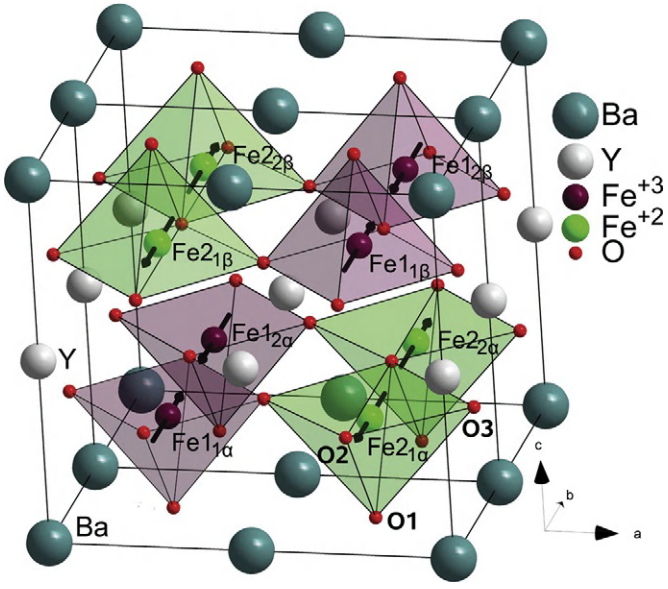

FIGURE 12.37

FIGURE 12.39

determined as Fe(III) species in the form of $KFeO_2$. Formation of an amorphous mixture of superoxide, peroxide, and oxide of potassium may be other products of the thermal conversion of iron(VI) oxide **1** to account for less than expected released oxygen. The TG and Mössbauer data suggest that barium iron perovskite with the intermediate valence state of iron (between III and IV) was the product of thermal decomposition of iron(VI) oxide **2**.

Nanocrystalline $BaFeO_4$ was prepared and purified by special measures. Magnetic susceptibility measurements confirmed the existence of Fe(VI). XRD studies indicated that it has an orthorhombic unit cell with space group *Pnma* and lattice parameters $a = 8.880$ Å, $b = 5.512$ Å, $c = 7.214$ Å. High-resolution transmission electron microscopy (HRTEM) and SAED characterization provided further proofs to the accuracy of XRD data.

Higher capacity batteries based on an unusual stabilized iron(VI) chemistry are presented. The storage capacities of alkaline and metal hydride batteries are largely cathode limited, and both use a potassium hydroxide electrolyte. The new batteries are compatible with the alkaline and metal hydride battery anodes but have higher cathode capacity and are based on available, benign materials. Iron(VI/III) cathodes can use low-solubility K_2FeO_4 and $BaFeO_4$ salts with respective capacities of 406 and 313 mA/h/g. Super-iron batteries have a 50% energy advantage compared to conventional alkaline batteries. A cell with an iron(VI) cathode and a metal hydride anode is significantly (75%) rechargeable.

Barium ferrite is available commercially as $BaFe_{12}O_{19}$ with the CAS number of 11138-11-7.

12.2.6. Radium Oxy-Iron Compounds

While radium ferrites or ferrates could undoubtedly be synthesized with properties similar to those of the Ba–Fe–O system, no data exists in the technical literature concerning such compounds. This is undoubtedly due to lack of interest in Industrial and Academic circles.

12.3. ALKALINE EARTH—RUTHENIUM COMPOUNDS

The number of known compounds in the Ae–Ru–O system is much less than the number of Fe compounds in the Ae–Fe–O system. The chemistry of ruthenium consists mostly of complex cations like $[Ru(NH_3)_6]^{3+}$, $[RuCl(NH_3)_5]^{3+}$ or $[Ru(NH_3)_5SH]^{2+}$. In general, Ru_xO_y derived compounds involve only a few of specific valence states of Ru. The alkaline earth ions precipitate soluble RuO_4^{2-} as black $MgRuO_4 \cdot H_2O$, black $CaRuO_4 \cdot H_2O$, red $SrRuO_4 \cdot H_2O$ and red $BaRuO_4 \cdot H_2O$. This was reported in 1893.

12.3.1. Beryllium Oxy-Ruthenium Compounds

Be does not form any oxy-ruthenium compounds in the system, Be–Ru–O. However, it does form intermetallic compounds of varying proportions of Be^0/Ru^0 metals. The phase diagram is shown in Fig. 12.40.

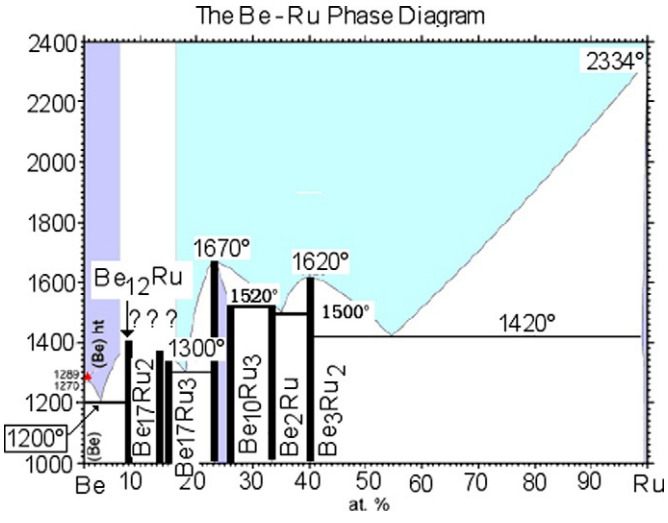

FIGURE 12.40

The Be_2Ru Crystal Structure

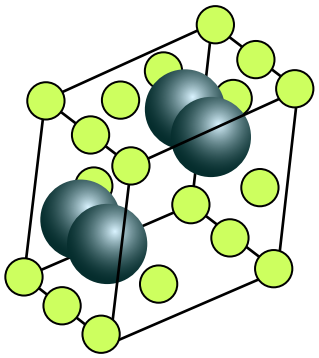

FIGURE 12.41

Six compounds are shown but only three (3) structures have been published. The compound, Be_3Ru_2 is cubic with cell parameters of: $a = b = c = 9.892$ Å, $\alpha = \beta = \gamma = 109.47°$, cell volume = 744.68 Å^3. The exact lattice structure has not been forthcoming.

The compound, Be_2Ru, has the structure shown in Fig. 12.41.

Cell parameters are: $a = b = 5.96$ Å, $c = 9.18$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 282.40 Å^3, $Z = 4$. Cell occupancy is shown in Table 12.10.

$Be_{17}Ru_3$ has the structure shown in Fig. 12.42.

Cell parameters are: $a = b = c = 9.5523$ Å, $\alpha = \beta = \gamma = 109.471°$, cell volume = 670.97 Å^3, $Z = 1$. Cell occupancy is shown in Table 12.11.

The $Be_{17}Ru_3$ Crystal Structure

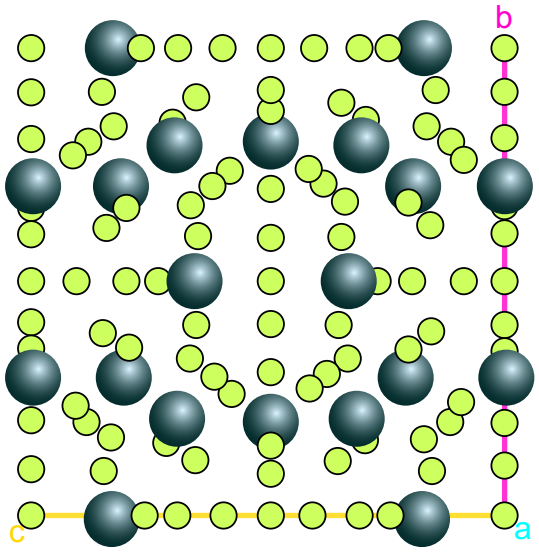

FIGURE 12.42

In contrast, the compound, $Be_{17}Ru_2$, has a structure that is completely different from that of $Be_{17}Ru_3$ (Fig. 12.43).

Cell parameters are: $a = b = 4.203$ Å, $c = 10.94$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 166.75 Å^3, $Z = 2$. Cell occupancy is shown in Table 12.12

No usage has arisen in the Industry and these compounds remain an Academic oddity.

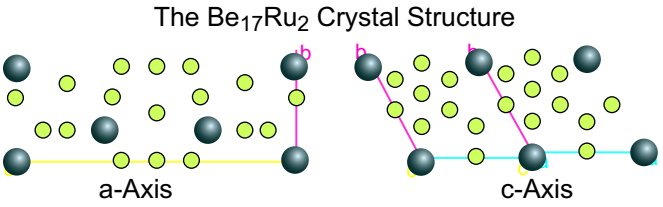

FIGURE 12.43

12.3.2. Magnesium Ruthenium Compounds

No intermetallic compounds in the system, Mg^0–Ru^0, are known.

MgO forms no compounds with the oxides of Ru_xO_y, where x or y can vary from 2 to 8. As a matter of fact, the only available reference is one that dated 1893 where a soluble RuO_4^{2-} compound was used to precipitate insoluble ortho-ruthenates:

$$Ae^{2+} + RuO_4^{2-} \Rightarrow AeRuO_4 \cdot H_2O$$

In the Ru^{2+}-, Ru^{3+}-, Ru^{4+}-, Ru^{5+}-, Ru^{6+}-, Ru^{7+}- or Ru^{8+}-containing systems of Mg–Ru–O (40 possible compounds), no details of synthesized compounds have been published.

Magnesium ruthenates are not offered commercially.

12.3.3. Calcium Ruthenium Compounds

No intermetallic compounds in the system, Ca^0–Ru^0, are known.

In the Ru^{2+}-containing system of CaO–RuO, a complex compound involving two uranyl carbonate **minerals**, "Liebigite", $Ca_2[UO_2(CO_3)_2]\cdot 10H_2O$, and "Andersonite", $CaNa_2[UO_2(CO_3)_2]\cdot 6H_2O$, was found to coexist as a trace, with the presumed formulation $Ca_2[RuO_2(CO_3)_2]\cdot 10H_2O$. No other data has been forthcoming.

In the Ru^{3+}-containing system of CaO–Ru_2O_3, no compounds have been reported.

In Ru^{4+}-containing system of CaO–RuO_2, the compound, $CaRuO_3$ is known. The magnetic ground state of the perovskite structure $CaRuO_3$ has been unexplained for decades. It has been shown that paramagnetic $CaRuO_3$ can be made ferromagnetic by very small amounts of partial substitution of Ru by Ti. Magnetic hysteresis loops were observed at 5 K for as little as 2% Ti substitution. Ti is nonmagnetic and isovalent with Ru, indicating that the primary effect of the substitution of Ti for Ru is the disruption of the magnetic ground state of $CaRuO_3$ through disorder. The data suggested that $CaRuO_3$ is poised at a critical point between ferromagnetic and paramagnetic ground states. The magnetic ground state of $CaRuO_3$ (Ru^{4+}, $4d_4$: t_{2g}^4, e_g^0 with $S = 1$) is controversial. Recent publications indicate that paramagnetic behavior (or exchange enhanced paramagnetism) down to 30 mK, is also supported by the single line shape of a ^{99}Ru Mössbauer spectrum measured at 4.1 K. The high- and low-temperature resistivity results indicate that $CaRuO_3$ is a non-Fermi liquid metal.

Magnetic studies of ceramic and single-crystal $CaRuO_3$ samples have demonstrated that irreversibility appears in the zero-field-cooled and field-cooled curves only when measured at low-applied magnetic fields. A small hysteresis loop opens at low temperatures, and the remanent magnetization decreases with temperature and disappears at 90 and 71 K for the ceramic and crystal samples, respectively. The easy axis for the magnetization is in the [001] direction. Mössbauer studies of 1% ^{57}Fe doped in $CaRuO_3$ show a magnetic sextet at 4.1 K that disappears at 90 K. ^{57}Fe ions experience an exchange field from their magnetic Ru^{4+} neighbors and also become magnetically ordered. $CaRuO_3$ has a perovskite-like structure.

In another paper, it was proposed that $CaRuO_3$ is not paramagnetic, but rather shows the characteristics of short-range magnetic interactions, possibly spin glass behavior, or alternatively, the data are consistent with an itinerant electron picture of ferromagnetism. Neutron diffraction experiments at 10 K showed that no additional magnetic neutron scattering peaks exist, indicating that $CaRuO_3$ is not a canted antiferromagnet. It

has been well established that the isostructural $SrRuO_3$ is a ferromagnet (FM) with a Curie temperature $T_C = 165$ K. The stark contrast between $SrRuO_3$ and $CaRuO_3$ was unexpected because the closed shells-like character of Sr and Ca do not contribute to the density of states at the Fermi surface and therefore should not be the origin for the different magnetic ground states of these two compounds. Since a common structural feature of the two compounds is that they are composed of an array of corner-shared RuO_6 octahedra, it was assumed that the degree of tilting and rotation of these octahedra within their ideal cubic perovskite structure governs the observed differences in the magnetic ground states. A narrow itinerant 4d band is formed through hybridization of Ru-t_{2g} and O-2p orbitals. The 4d bandwidth thus formed sensitively depends on the degree of hybridization. $CaRuO_3$ is believed to have a narrow itinerant 4d-band width (narrower than for $SrRuO_3$), which is too narrow for long-range magnetic ordering, but not so narrow as to cause $CaRuO_3$ to be nonmetallic. It means that $CaRuO_3$ is on the verge of magnetic ordering and readily evolves into an ordered phase. On the other hand, no long-range magnetism has been observed in the isostructural orthorhombic $LaRuO_3$ down to 4.2 K. The Ru^{3+} ($4d^5$, t_{2g}^5, e_g^0) ions are assumed to be in the low-spin state with ($S = 0.5$). In that sense, $LaRuO_3$ differs from both $CaRuO_3$ and $SrRuO_3$ compounds.

A high-pressure dense phase of $CaRuO_3$ was recently created by high-pressure and high-temperature experiments where it was successfully quenched to room temperature. The crystal structure at ambient conditions was identified to be of the post-perovskite type, which is entirely different from the perovskite structure of the regularly synthesized $CaRuO_3$. A quasi 1D magnetism was discovered in the post-perovskite $CaRuO_3$ (Ru^{4+}: $4d^4$, *Cmcm*), which is iso-compositional with the perovskite $CaRuO_3$ (*Pbnm*). An antiferromagnetic spin chain function with $-J/kB = 350$ K well reproduces the experimental curve of the magnetic susceptibility vs temperature, suggesting long-range antiferromagnetic correlations. The anisotropic magnetism is probably owed to the d_{yz}-2pπ-d_{zx} and d_{zx}-2pπ-dyz superexchange bonds along the *a*-axis. The Sommerfeld coefficient of the specific heat is small, 0.16 mJ/mol/K^2, indicating that the magnetism reflects the localized nature of the 4d electrons. This was the first observation of an integer ($S = 1$) spin chain antiferromagnetism in the 4d electron system.

The shift in structure is shown in Fig. 12.44.

This shows a sketch of the crystal structures of (a) the perovskite and (b) the post-perovskite $CaRuO_3$. The figures used the same drawing scale. The post-perovskite phase is 1.7 % denser in volume than the perovskite phase. Single crystals of $CaRuO_3$ (**1**) and $SrRuO_3$ (**2**) have been

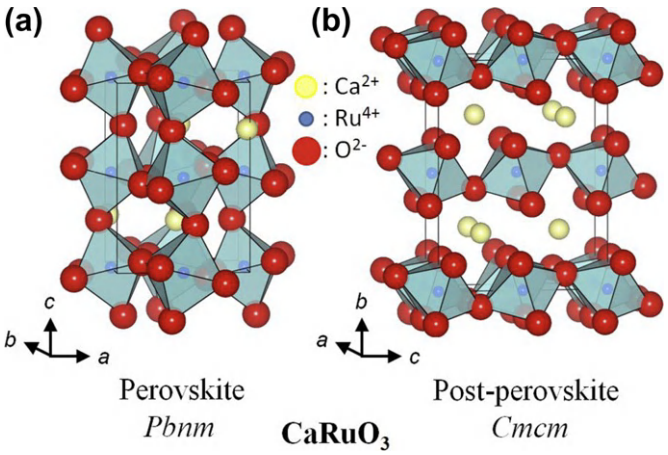

FIGURE 12.44

synthesized by a flux method and their structures have been determined by means of single-crystal XRD techniques. The crystallographic data are (**1**): formula weight fw = 189.15, orthorhombic, space group *Pnma* (No. 62), $a = 5.524$, $b = 7.649$, $c = 5.354$ Å, $V = 226.2$ Å^3, $Z = 4$, $Dx = 5.554$ g/cm^3, $\mu = 81.97$/cm, final $R = 0.031$ for 297 observed reflections. (**2**): formula weight = 236.69, cubic, space group *Pm* (No. 200), $a = b = c$ =3.910 Å, $V = 59.8$ Å^3, $Z = 1$, $Dx = 6.572$ g/cm^3, $\mu = 275.28$/cm, final $R = 0.032$ for 33 observed reflections.

$CaRuO_3$ is a non-Fermi liquid metal near a magnetic instability, as characterized by the following properties: (1) the heat capacity C (T,B) ~ T log T is readily enhanced in low applied fields, and exhibits a Schottky peak at 2.3 K that exhibits field dependence when T is reduced; (2) the magnetic susceptibility diverges as T^{σ} at low temperatures with $1/2 < \delta < 1$, depending on the applied field; and (3) the electrical resistivity exhibits a $T^{3/2}$ dependence over the range . No Shubnikov–de Haas oscillations are discerned at 1.7 K < T < 24 K for applied fields up to 45 T. These properties, which sharply contrast those of the itinerant FM $SrRuO_3$, indicate $CaRuO_3$ is a rare example of a stoichiometric oxide compound that exhibits non-Fermi liquid behavior near a quantum critical point.

The standard Gibbs energy of formation of $CaRuO_3$(s) has been determined using a solid-state galvanic cell with CaF_2(s) as the solid electrolyte referred to as the fluoride cell. The fluoride cell is represented by:

$$-\mathrm{Pt/O_2(gas)}, \{\mathrm{CaO(solid)} + \mathrm{CaF_2(solid)}\}//\mathrm{CaF_2}// \{\mathrm{CaF_2(solid)} + \mathrm{RuO_2(solid)} + \mathrm{CaRuO_3(solid)}\}, \mathrm{O_2(gas)/Pt(+)}$$

The standard Gibbs energy of formation of $CaRuO_3$(s) obtained by the fluoride cell can be represented by:

$$\Delta_f G^\circ(\mathrm{CaRuO_3(solid)})/\mathrm{kJ/mol} = -984.1 + 0.2841 \cdot (T/\mathrm{K}) \quad (815 < T/\mathrm{K} < 1053)$$

The slope and intercept of the above equation correspond to the enthalpy and entropy of formation, respectively, of $CaRuO_3$(solid), from its elements at an average experimental temperature $T_{av} = 934$ K. Using the Neumann–Kopp rule, the heat capacity of $CaRuO_3$(solid) was estimated. The standard enthalpy of formation of the compound at 298.15 K was then calculated by using estimated heat capacity data and the e.m.f. data obtained from fluoride cell and was found to be −995.0 kJ/mol.

The effects of Ru-site metal dopants on the low-temperature magnetization of $CaRuO_3$ have been reported. Dopants of two types were tested: those with closed d shells in their expected oxidation state (Al^{3+}, Zn^{2+}, Ti^{4+}, V^{5+} and Pt^{2+}), and those with unpaired d electrons (Mn^{4+}, Fe^{3+}, Co^{2+}, Ni^{2+} and Cu^{2+}) in their expected oxidation state. The results were consistent with the recent proposal that $CaRuO_3$ is not a classical antiferromagnet, but rather is poised at a critical point between ferromagnetic and paramagnetic ground states. Additions of Ti, Fe, Mn and Ni result in ferromagnetic behavior.

The compounds, $(Ca_{0.5},Mg_{0.5})RuO_3$ and $(Ca_{0.5},Sr_{0.5})RuO_3$, having the $CaTiO_3$ perovskite structure (point group = *oP*20, space group = *Pm*-3*m*) have also been synthesized.

It was discovered that Sr_2RuO_4 has superconductivity at a modest temperature of about 1.0 K. This compound is a perovskite ruthenium oxide and a representative of the Ruddlesden–Popper family, $(Sr,Ca)_{n+1}Ru_nO_{3n+1}$ with $n = 1$. These materials exhibit a rich variety of magnetic phases. There is a strong resemblance in the structure to the cuprate compounds, the role of the RuO_2 plane is analogous to the role of the CuO_2 plane in the cuprates. The mechanism of superconductivity in Sr_2RuO_4 has been widely studied. It was suggested that Sr_2RuO_4 is a possible candidate of a *p*-wave superconductor. The assumption is that the triplet pairing is induced by ferromagnetic fluctuations. Since $SrRuO_3$ is a strong FM, ferromagnetic fluctuations should be present in $Sr_2RuO_{4.2}$. Calculations indicate that Sr_2RuO_4 is a FM.

A summary of the electronic band structure is shown in Fig. 12.45.

The electronic band structure receives its basic character from the 4d-t_{2g} orbitals of the Ru ion: {d_{yz}, d_{zx}, d_{xy}} which disperse dominantly in each RuO_2-plane via the π-hybridization with the O-2p-orbitals. It is easy to see that the d_{yz}- and d_{zx}-orbitals have a very anisotropic dispersion yielding two-quasi 1D bands, that hybridize to form a one electron-like (β-band) and one hole-like (α-band) Fermi surface.

The doping of Ca for Sr introduces a gradual rotation of the RuO_6 octahedra around the *z*-axis and yields a modification in the band structure, which the analysis of the emerging magnetic properties in region III is

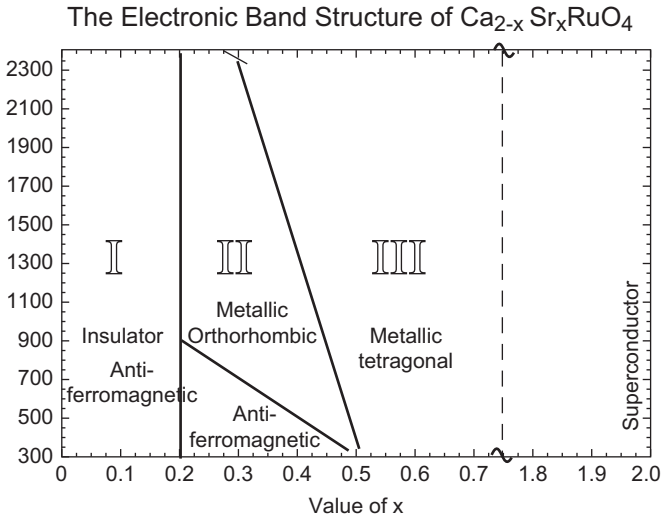

FIGURE 12.45

based on. The region III is metallic, paramagnetic and has tetragonal crystal symmetry. The region II is metallic, at low temperature with presumably antiferromagnetic correlation and has orthorhombic symmetry. In both regions the susceptibility over a certain range of temperature is Curie like with a spin $S = 1/2$. The region I is a Mott insulator with antiferromagnetic long-range order of a spin $S = 1$.

The growth of single crystals of the layered perovskite Ca_2RuO_4 by a floating-zone method was accomplished in another paper. It was confirmed that stoichiometric Ca_2RuO_4 is a Mott insulator. Canted antiferromagnetic (CAF) ordering occurs below 113 K. The development of a short-range CAF order below 150 K was also observed. The origin of the temperature-induced Mott transition in Ca_2RuO_4 was studied. The local density approximation + dynamical mean-field theory was used as a method. The following was shown:

(1) The Mott transition is driven by the change in structure from long to short *c*-axis layered perovskite (L-Pbca to S-Pbca); it occurs together with orbital order, which follows, rather than produces, the structural transition.

(2) In the metallic L-Pbca phase the orbital polarization is ~0.

(3) In the insulating S-Pbca phase the lower energy orbital, ~xy, is full.

(4) The spin-flip and pair-hopping Coulomb terms reduce the effective masses in the metallic phase. These results indicate that a similar scenario applies to $Ca_{2-x}Sr_xRuO_4$ ($x < 0.2$). In the metallic $x < 0.5$ structures, electrons are progressively transferred to the xz/yz bands with increasing *x*. However no orbital-selective Mott transitions were found down to ~30 K.

Application of very modest pressures to pure Ca_2RuO_4 transforms it from an antiferromagnetic Mott insulator to a quasi 2D metal with a ferromagnetic ground state. The smallness of the moment compared with the saturated moment of the localized Ru^{4+} ion reflects the itinerant character of the magnetism.

The structure of Ca_2RuO_4 has been reported. It is a layered perovskite having the localized structure shown in Fig. 12.46.

This structure is made up of RuO_2 layers built up of corner-sharing RuO_6 octahedra. The structure combines a rotation around the *c*-axis with a tilt around the *b*-axis. It is characterized by a long *c*-axis (L-Pbca) at $T_s = 360$ K and by a short one (s-Pbca) below T_s.

This layered perovskite undergoes a paramagnetic metal to paramagnetic insulator transition at $T_M = 360$ K. A similar insulator-to-metal transition also happens when a modest (~0.5 GPa) pressure is applied to this compound. This nature of these transitions is still under question. While it is clear that a Mott-type mechanism makes the 2/3-filled t_{2g} bands insulating, two differing scenarios, with different orbital occupations, have been suggested ($n = n_{xy} + n_{xz} + n_{yz}$) and ($p = -(n_{xy} + n_{xz})/2$). In the first, only the xy-band becomes metallic, i.e. the transition is orbital-selective where n and p jump from (2,2) and 1 in the insulator to (1,3) and $-1/2$ in the metal. In the second, there is a single Mott transition, assisted by the crystal-field splitting, $\Delta = e_{xz/yz} - e_{xy} > 0$, similar to the case of $3d^1$ perovskites. The spin-hop and pair-hopping Coulomb terms reduce the effective masses in the metallic phase. To date, the issue remains open.

Data concerning $Ca_3Ru_2O_7$ has been reported. The laminar perovskite $Ca_3Ru_2O_7$ naturally forms ferromagnetic double layers of alternating moment directions, as in the spin-valve superlattices. The mechanism of huge magnetoresistive effect in the material has been controversial due to a lack of clear understanding of various magnetic phases and phase transitions. In this neutron diffraction study in a magnetic field, we identify four different magnetic phases in $Ca_3Ru_2O_7$ and determine all first-order and second-order phase transitions between them. The spin-valve mechanism then readily explains the dominant magnetoresistive effect in $Ca_3Ru_2O_7$.

Huge magnetoresistive effect has also been observed recently in the double-layered perovskite $Ca_3Ru_2O_7$, which orders antiferromagnetically at $T_N = 56$ K and is isostructural to the manganites. Its behavior at low temperatures is similar to that in the manganites when a magnetic field is applied perpendicular to the easy axis of magnetization. A smaller magnetoresistive effect occurs in a first-order metamagnetic transition when the magnetic field is applied along the easy axis. The spin-valve mechanism has been proposed in both experimental and theoretical studies. However, the situation is complicated by a first-order metal-insulator transition (MIT) at $T_{MIT} \approx 46$ K. In particular, the spin-valve explanation runs into severe difficulty with the recent experimental conclusion that the fully spin-polarized phase is the least favorable for electronic conduction. Thus, alternative mechanisms such as orbital order have been proposed. The field-induced "ferromagnetic" phase (which should be called the paramagnetic phase) as well as the antiferromagnetic phases of $Ca_3Ru_2O_7$, has been deduced from bulk measurements. They form the foundation in current understanding of the novel magnetoresistive phenomena in $Ca_3Ru_2O_7$.

In the following diagram, the crystal structure has the form shown in Fig. 12.47.

$Ca_3Ru_2O_7$ shows perovskite-like structures, with double layers of RuO_6 octahedra that corner share with each other to form planes with Ca–O layers intervening within and between the double-layer planes. The Ca–O layer helps stabilize the perovskite structure without contributing to the total spin of this system. Since no oxygen ions within the intervening Ca–O layer are shared by the Ru ions of the adjacent layers, the exchange

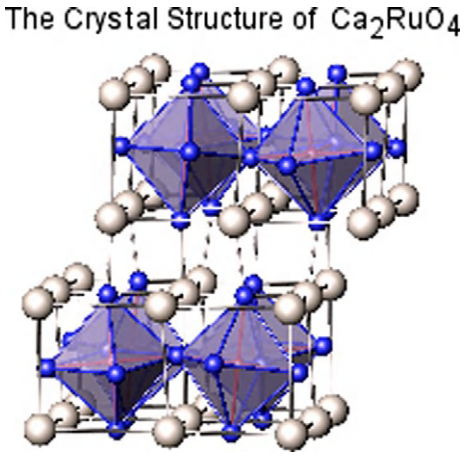

FIGURE 12.46

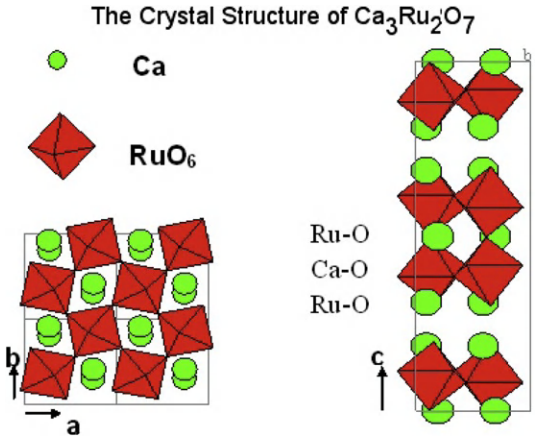

FIGURE 12.47

interactions and conductivity perpendicular to the RuO planes are expected to be weaker compared with those within the RuO planes. Compared with the ionic size of Sr^{2+} (Sr = 1.18 Å) the ionic size of Ca^{2+}(Ca = 1.00 Å) is smaller, resulting in an orthorhombic distortion with $a = 5.3720$ Å, $b = 5.55305$ Å, and $c = 19.572$ Å. This corresponds to a space group of either $A2_1ma$ (with a being the short axis) or $Cmc2_1$ (with a being the long axis).

The distortion exhibits itself as a rotation (around the c-axis) and a tilting (away form the c-axis) of the RuO_6 octahedra as clearly illustrated in the above figure. The tilting projects primarily along the ac plane, giving rise to an orthorhombic structure with anisotropic a- and b-lattice parameters. It is estimated that the Ru–O–Ru bond angles, which reflect the distortion effect, differ considerably from 180°. Within the ab plane, the Ru–O–Ru bond angles alternate between 149.87° and 150.47°, whereas for the Ru ions in the double layers the Ru–O–Ru bond angle is 152.13°. The tilting and rotation of RuO_6 octahedral is so severe that even the individual octahedra are contorted. Within the octahedra, the O–Ru–O bond angle is distorted away from 180°: around 177° for O–Ru–O bond angles along the c-axis, between 179.42° and 179.53° for O–Ru–O bond angles perpendicular to the c-axis. Compared with the Ru–O bond (~1.9910 Å) sandwiched between the RuO_6 planes, the other Ru–O bonds are longer (~1.9914 Å).

The polarized Raman spectra of the layered ruthenate, $Ca_3Ru_2O_7$, has been measured between 5 and 300 K in several exact scattering configurations. All observed Raman lines were assigned to definite phonon modes of A_1 or A_2 symmetry on the basis of their polarization properties and by comparison to the results of lattice dynamical calculations for the orthorhombic $A2_1ma$ structure. It was established that the Fano-shaped A_2 mode, which exhibits a strong anomaly near the metal–nonmetal transition at $T_M = 48$ K, involved mainly in-plane breathing-type oxygen vibrations. Other A_2 modes also exhibit detectable anomalies near T_M.

The magnetic and interplane transport properties of $Ca_3Ru_2O_7$ at high magnetic fields and low temperatures. $Ca_3Ru_2O_7$ with a bilayered orthorhombic structure was determined to be a Mott-like system with a narrow charge gap of 0.1 eV. Of the host of unusual physical phenomena revealed in this study, a few are particularly intriguing:

(1) a collapse of the c-axis lattice parameter at a metal–nonmetal transition, T_{MI} (=48 K), and a rapid increase of T_{MI} with low uniaxial pressure applied along the c-axis;
(2) quantum oscillations in the gapped, nonmetallic state for 20 mK $< T <$ 6.5 K;
(3) tunneling colossal magnetoresistance, which yields a precipitate drop in resistivity by as much as three orders of magnitude;
(4) different in-plane anisotropies of the colossal magnetoresistance and magnetization. All results appear to indicate a highly anisotropic ground state and a critical role of coupling between lattice and magnetism. The implication of these phenomena was discussed.

Only the interoxide phases, Ca_2RuO_4, $Ca_3Ru_2O_7$, and $CaRuO_3$, are present in the pseudo-binary system CaO–RuO_2. The standard Gibbs energies of formation (ΔG_f^0) of the three calcium ruthenates from their component oxides have been measured in the temperature range 925–1350 K using solid-state cells with yttria-stabilized zirconia as the electrolyte and $Ru + RuO_2$ as the reference electrode. The standard Gibbs energies of formation ΔG_f^0 of the compounds can be represented by:

$$Ca_2RuO_4: \Delta G_f^0/\mathrm{J/mol} = -38{,}340 - 6.611\,T$$
$$Ca_3Ru_2O_7: \Delta G_f^0/\mathrm{J/mol} = -75{,}910 - 11.26\,T$$
$$CaRuO_3: \Delta G_f^0/\mathrm{J/mol} = -35{,}480 - 3.844\,T$$

The data for Ca_2RuO_4 correspond to the stoichiometric composition, which has an orthorhombic structure, space group $Pbca$, with short c-axis ("S" form). The structural features of the ternary oxides responsible for their mild entropy stabilization are discussed. A 3D oxygen potential diagram for the system Ca–Ru–O is developed as a function of composition and temperature from the results obtained. Using the Neumann–Kopp rule to estimate the heat capacity of the ternary oxides relative to their constituent binary oxides, the standard enthalpies of formation of the three calcium ruthenates from the elements and their standard entropies at 298.15 K are evaluated.

The 2D ruthenate family $Ca_{2-x}Sr_xRuO_4$ presents a rich phase diagram, evolving as x is varied from the Fermi liquid triplet superconductor Sr_2RuO_4 to the antiferromagnetic (Mott) insulator Ca_2RuO_4. The origin and indeed the nature of some of the phases remain the subject of controversy. Further interest has been added by surface studies, which indicate that (contrary to intuition) the Mott state is less stable on the surface than in the bulk. Bulk $Ca_{1.9}Sr_{0.1}RuO_4$ exhibits a metal to insulator transition as the temperature is decreased below 150 K, whereas surface sensitive probes place the transition at $\approx$125 K. This unexpected result challenges the conventional notion that correlation effects are stronger at surface, and requires explanation.

In the Ru^{5+}-containing system of CaO–Ru_2O_5, the compound, $Ca_2Ru_2O_7$ has been studied. Single crystals of the ruthenate, $Ca_2Ru_2O_7$, were obtained. An XRD study on a single crystal revealed that this material crystallizes in a pyrochlore structure with a lattice parameter, $a = 10.197$ Å. The magnetic susceptibility above 30 K is the summation of a Curie–Weiss contribution

and a constant term independent of temperature. The effective moment per Ru atom is only 0.36 Bohr magnetons, one order of magnitude smaller than that expected from a localized spin model with $S = 3/2$ for Ru^{5+}. Below 23 K, the localized spins freeze in a spin glass state. The resistivity at room temperature is 2×10^{-3} Ohm-cm, comparable to that in metallic, highly correlated oxides. Spin glass properties of the ruthenate, $CaRu_2O_7$, were studied by precise magnetization measurements. The effective moment per Ru atom is only 0.25 μbar, which is one decade smaller than that expected from a localized spin model with $S = 3/2$ for Ru^{5+}. In spite of the small moment, a spin glass transition occurs at $Tg = 25.0$ K, and the nonlinear susceptibility $X_{nl}(\sim X^2)$ diverges negatively at Tg. The value of the critical exponent δ can be estimated as $\delta = 3.7$ from the magnetic field dependence of X_{nl} at Tg, which is comparable to those of other pyrochlore spin glasses and the canonical spin glasses.

The magnetism of a series of ruthenium pyrochlore oxides $A_2Ru_2O_7$ (A = Hg, Cd, Ca), whose electronic properties within a localized ion picture are characterized by non-degenerate t_{2g} orbitals (Ru^{5+}, $4d^3$) and thereby subject to geometrical frustration, has been investigated by a muon spin rotation/relaxation (muSR) technique. The A cation (mostly divalent) was varied to examine the effect of covalency (Hg > Cd > Ca) on their electronic property. In a sample with A = Hg that exhibits a clear metal-insulator (MI) transition below 100 K (which is associated with a weak structural transition), a nearly commensurate magnetic order is observed to develop in accordance with the MI transition. Meanwhile, in the case of A = Cd where the MI transition is suppressed to the level of small anomaly in the resistivity, the local field distribution probed by muon indicates emergence of a certain magnetic inhomogeneity below <30 K. Moreover, in $Ca_2Ru_2O_7$ that remains metallic, it was determined that a highly inhomogeneous local magnetism below >>25 K that comes from randomly oriented Ru moments and thus described as a "frozen spin liquid" state. The systematic trend of increasing randomness and itinerant character with decreasing covalency suggests close relationship between these two characters. As a reference for the effect of orbital degeneracy and associated Jahn–Teller instability, the examination of a tetravalent ruthenium pyrochlore, $Tl_2Ru_2O_7$ (Ru^{4+}, $4d^4$) was conducted, where the result of muSR indicates a nonmagnetic ground state that is consistent with the formation of the Haldane chains suggested by neutron diffraction experiments.

In the Ru^{6+}-containing system of CaO–RuO_3, the compound, $CaRuO_4$ has been studied. It has the structure shown in Fig. 12.48.

For the Mott insulator $CaRuO_4$, it has been observed that the orbital population dramatically changes with temperature. Together, with the finding that a substantial

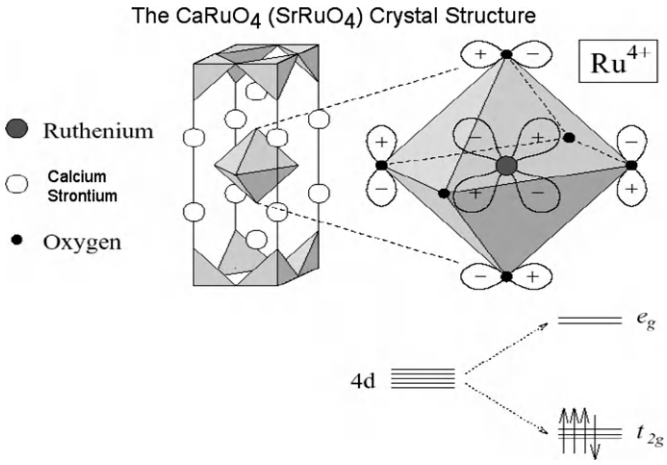

FIGURE 12.48

orbital angular momentum is present in the Ru 4d band, it has been argued that the cooperation between the strong spin-orbit coupling and the small distortion of the RuO_6 octahedra causes the interesting changeover of the spin and orbital anisotropy as a function of temperature. However, the published data concerning this compound are sparse and its properties have not been thoroughly established. $CaRuO_4$ is one of the layered Ruddlesden–Popper series of calcium ruthenates in which $n = 1$. The Sr series is shown below. The Ca series is identical in nature.

In the Ru^{7+}-containing system of CaO–Ru_2O_7, no compounds are known.

In the Ru^{8+}-containing system of CaO–RuO_4, no compounds are known.

Both of these ruthenium oxides are highly oxidizing, unstable, and liable to explode spontaneously. Perhaps this is the reason why no Ru^{7+} and Ru^{8+} compounds are known.

Calcium ruthenates are not available commercially.

12.3.4. Strontium Ruthenium Compounds

No intermetallic compounds in the system, Sr^0–Ru^0, are known.

In the Ru^{2+} series containing of SrO–RuO, the $SrRu_3O_4$ has been studied. It has been reported that this compound is a triplet odd-parity (p- or f-wave) superconductor. However, to date, no further research papers have appeared.

Perovskite ruthenium oxides of the Ruddlesden–Popper type, $(Sr/Ca)_{n+1}Ru_nO_{3n+1}$, have attracted significant attention due, in part, to the recent discovery of superconductivity in $Sr_2Ru_4O_4$. In addition, these materials exhibit a rich variety of magnetic phases, and bear strong structural resemblance to the cuprate superconductors, with RuO_2 planes taking the place of the

CuO_2 planes. Since the discovery of high-temperature superconductivity in layered cuprates, understanding of Mott-Hubbard MIT in a quasi 2D system has been a subject of significant interest. While Sr_2RuO_4 is a good metal and is believed to be well described within a framework of Fermi liquid theory, Ca_2RuO_4 is an insulator. It was suggested that the MIT in $(Sr,Ca)_2RuO_4$ is of the Mott-Hubbard type resulting from lattice distortions caused by the smaller size of the Ca^{2+} ion compared to the Sr^{2+} ion. In this scenario, the lattice distortions lead to a reduction of an electronic orbital overlap, similar to that observed in 3D $RNiO_3$, thus reducing W. A similar effect is expected for $(Sr/Ca)_3Ru_2O_7$, although the structural distortions and the corresponding bandwidth reduction may be smaller in this more rigid two-plane structure. Thus Sr/Ca substitution in layered $(Sr/Ca)_{n+1}Ru_nO_{3n+1}$ $(n = 1,2)$ provides a way for a continuous "tuning" of Mott-Hubbard parameter, U_yW, making it an ideal system for an experimental study of a transition from normal metal to Mott insulator at a constant carrier doping in a quasi 2D system.

In the Ru^{3+}-containing system of $SrO–Ru_2O_3$, the compound, $SrRu_2O_4$ has been found to be superconducting. However, only one paper is known in which it is compared to MgB_2 as a superconductor. The superconducting phase diagram for a 2D, three-band tight-binding model of $SrRu_2O_4$ using the fluctuation exchange approximation (FLEX) method was calculated. Electron interactions were modeled by a local-atom interaction with intraband, interband and exchange terms and an atomically local spin–orbit interaction is included as well. These results suggested that FLEX produces a singlet-pairing state with dx^2/y^2 orbital symmetry, a result that is not in agreement with many experimental results. However, it was determined that the values for the interaction strengths that are required to generate $T_C \sim 1.5$ K lead to normal-state quasi particle line widths that are in reasonable agreement with experimental results. At early stages, $SrRu_2O_4$ was believed to be close to a ferromagnetic instability. Ferromagnetic quantum critical spin fluctuations were believed to be responsible for triplet superconductivity, and even for stabilizing the particular chiral p-wave state. It was later discovered that $SrRu_2O_4$ is actually closer to a material possessing an antiferromagnetic spin-density wave instability (which makes stabilization of a p-wave state rather puzzling). However, it is generally accepted that critical fluctuations are very important for superconductivity in this compound.

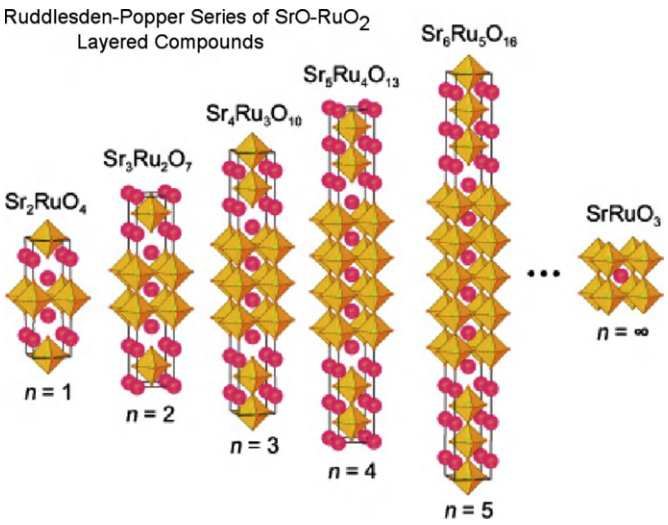

FIGURE 12.49

In the Ru^{3+} system of $SrO–Ru_2O_3$, the only compound mentioned in the literature is $Sr_3Ru_3O_7$. This compound undergoes ferromagnetic transitions below about 105 K and has revealed the existence of a well-defined, magnetically tuned quantum critical point. Only one paper has been published to date.

In the Ru^{4+}-containing system of $SrO–RuO_2$, a number of compounds are known. A Ruddlesden–Popper series $Sr_{n+1}Ru_nO_{3n+1}$ of layered perovskite ruthenate compounds shows that, with increasing number of consecutive RuO_2 layers, there appears to be an empirical trend toward ferromagnetism. This is shown in Fig. 12.49.

The magnetic properties of these compounds are summarized in Table 12.13.

The layered perovskite Sr_2RuO_4 first received widespread attention due to the discovery of superconductivity by Maeno and coworkers in 1994. Since then, a decade of intensive research has established the unconventional nature of that superconductivity, although a host of questions remain open concerning its microscopic origin. In parallel with work on the superconducting state, considerable experimental effort has been expended on understanding the metallic state from which the superconductivity condenses. Sr_2RuO_4 has a critical temperature of $T_c = 1.5$ K (in the clean limit)

TABLE 12.13

N	1	2	3	∞
Compound	Sr_2RuO_4	$Sr_3Ru_2O_7$	$Sr_4Ru_3O_{10}$	$SrRuO_3$
Magnetic properties	Paramagnetic	Metamagnetic transition (98)	Ferromagnetic $T_c = 148$ K	Ferromagnetic $T_c = 165$ K

and originally attracted interest because it possesses a layered perovskite structure like the high Tc cuprates and is therefore one of the very few perovskite oxide superconductors containing no copper. Further studies then indicated that the properties of Sr_2RuO_4 itself deviate strongly from the BCS "standard model" of s-wave superconductivity. There is now good evidence that Sr_2RuO_4:

(1) Shows spin triplet pairing,
(2) Exhibits time-reversal symmetry breaking of the orbital part of the pair wave function,
(3) Possesses line nodes in the gap function.

Sr_2RuO_4 is a layered superconductor with a $T_c \approx 0.95$ K. The electrical resistivity is strongly anisotropic and has an unusual T dependence: $ab \approx T^2$ for $T <$ K and $ab \approx T$ for $T > 100$ K; the ratio c/ab is about 850 around 4 K and 220 around 290 K. The de Haas–van Alphen effect (dHvA) and Shubnikov —de Haas (SdH) experiments show the presence of three anisotropic "Fermi surfaces". Experiments on Sr_2RuO_4 and related oxides indicate that this conductor is close to a spin 1 Mott insulating state. A model has been presented for the insulating and conducting states of these compounds and a mechanism for the MIT. It was claimed that there are two bands of non-Fermi liquids (which are close to half-filled) and an almost full band. The residual Hund's coupling in this (primarily 4d) band was argued to cause triplet correlations among the low-energy spinon excitations of the two bands of non-Fermi liquids below about 100 K. Based on this, it was clear that the experimentally observed superconducting state was likely to be a triplet p-wave type. This prediction has since been verified.

The physics of transition metal oxides is, in a first approximation, mainly the physics of the d-electron shell. If we take strontium and oxygen to have the usual nominal valences Sr^{2+} and O^{2-}, the ruthenium ion Ru^{4+} in Sr_2RuO_4 is left in a $4d^4$ electronic configuration. In the octahedral crystal field environment of the layered perovskite structure of Sr_2RuO_4, the energetically low-lying d levels are the three orbitals—nominally referred to as d_{xy}, d_{xz}, and d_{yz}—that belong to the t_{2g} representation of the octahedral group (see following figure). These orbits can thus accommodate six ($\Downarrow\Uparrow$) paired electrons and are partially filled in the $4d^4$ configuration of Sr_2RuO_4.

In the conventional theories of spin-fluctuation mechanism for superconductivity, the ferromagnetic spin fluctuation leads to triplet pairing, while the antiferromagnetic one causes singlet pairing. However, recently a mechanism leading to spin triplet superconductivity due to antiferromagnetic spin fluctuation has been proposed for Sr_2RuO_4. It was found that the anisotropy in spin fluctuation and the nesting property of the Fermi surface play crucial roles for the Cooper pairing. In the

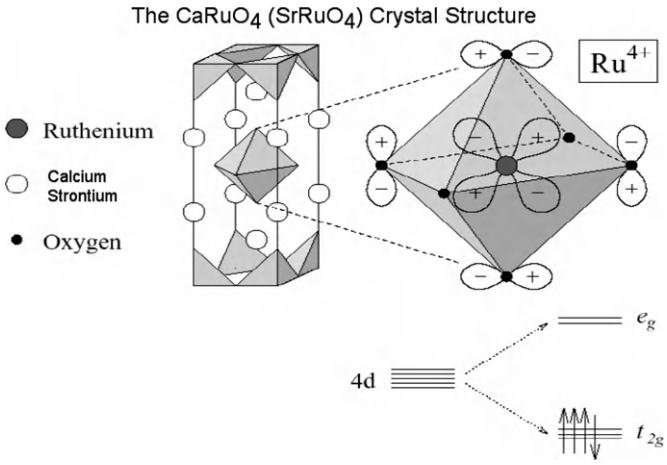

FIGURE 12.50

previous studies, however, the spin anisotropy was assumed phenomenologically. Further study of the origin of the anisotropy, using the more realistic three-band Hubbard model with spin orbit coupling and interband interactions, has been made. Its structure has the form shown in Fig. 12.50.

In this model, an anisotropy is naturally obtained, which becomes large enough, depending on the parameters, to support the superconducting mechanism for triplet pairing. It was found that the Hund coupling between the orbitals plays an important role. In general, metallic behavior is fairly rare among the transition metal oxides, and, more often than not, the d electrons remain localized, frequently forming a magnetic insulating state. This is mainly due to the large on-site (Hubbard) repulsion and the small interatomic overlap, both arising from the small orbital radius of the d electrons, particularly in the 3d series. There are exceptions, though, and Sr_2RuO_4 is one of several ruthenium oxide systems where the d electrons are itinerant. From the simplest point of view, the Fermi surface is then formed in a tight-binding fashion from the d_{xy}, d_{xz}, and d_{yz} atomic orbitals on the ruthenium sites. There is also some antibonding admixture of the oxygen p orbitals that, unlike the situation in most other oxide metals, has significant weight at the Fermi energy level. The layered structure of Sr_2RuO_4 prevents strong overlap of the orbitals along the c-axis, hence the electronic structure is, to a first approximation, 2D.

Density functional calculations have been used to investigate the spin structure of quantum fluctuations (QF), low-lying excitations and their relationship to superconductivity in Sr_2RuO_4. It has been demonstrated how the presence of the Fermi surface nesting in this highly 2D system leads in theory to establishment of antiferromagnetic spin density superstructure in the ground state and therefore in QF. These calculations confirmed the ground state spin structure that

develops in Sr_2RuO_4 upon partial Ti substitution (as found in experiment), even at concentrations typical for additives. The Ti disrupts the Ru–O–Ru chains, leading to an increase in the local density of states, and thereby favors moment formation on the neighboring Ru sites. Supercell calculations and frozen spin wave calculations have shown a marginal antiferromagnetic instability at the Fermi surface-nesting vector. At this wave vector, the magnetocrystalline anisotropy was found to be very small. The spin structure of QF and low-energy excitations are discussed in relation to these results. The nesting leads to the following effects:

(1) development of the spin structure in QFs and related low-lying excitations as a result of enhancement of the intersite exchange,
(2) effect of *lasing* on QFs, which implies selecting and amplifying waves out of the wave packet with nesting vector **qN** only.

The crystalline strontium ruthenate can be viewed as a superconducting liquid crystal, since the triplet nature of superconductivity makes it close to symmetry-broken phases of ^{3}He liquid, whereas the spin and orbital moments are ordered on the scale of spin–spin correlation length.

The oxide superconductor Sr_2RuO_4 has emerged as an archetypal strongly correlated electron system. Quantum oscillation measurements have revealed a Fermi surface consisting of three slightly warped cylinders populated by quasi particles with masses ranging from 3.4 to 14.6 times the bare electron mass. There is strong evidence that Sr_2RuO_4 is a spin triplet superconductor, and the simplicity of the Fermi surface combined with detailed knowledge of the quasi particle properties from quantum oscillation and orbital-specific NMR measurements means that Sr_2RuO_4 may be a key system for understanding unconventional superconductivity. A comparison of Sr_2RuO_4 with 3D nearly ferromagnetic 3d metals has suggested that quasi 2D spin fluctuations may be responsible for the fact that Sr_2RuO_4 is the first nearly ferromagnetic metal to show superconductivity.

In the ternary Sr–Rh–O system, several compounds have already been reported:

$Sr_{0.75}Rh_4O_8$ ($SrRu_{16}O_{32}$)
$SrRh_2O_4$
$Sr_6Rh_5O_{15}$
Sr_2RhO_4
Sr_4RhO_6
$(Sr_{0.5}Ca_{0.5})RuO_3$

The latter compound is dimorphic and has either the structure of $GdFeO_3$ (PG = o*P*20, SG = *Pnma*) or the $CaTiO_3$ structure (PG = *cP*5, SG = *Pm-3m*).

The above compounds were synthesized by rather conventional methods, and appear well characterized. Recently, two new members were added to the rhodate system, which were prepared by a high-pressure method; the perovskite $SrRhO_3$ and the bilayered $Sr_3Rh_2O_7$. At the end of the high-pressure studies, it was clear that the three compounds form a novel perovskite family as expressed by the general formula $Sr_{n+1}Rh_nO_{3n+1}$ (n = 1, 2, and infinity), indicating that this must be a Ruddlesden–Popper series.

$Sr_3Ru_2O_7$ is the bilayered member of the perovskite Strontium Ruthenate series and is the sister compound to the well-known spin triplet superconductor $Sr_2RuO_{4.9}$. It is a Fermi liquid at low temperatures with a large electronic specific heat, σ, of 110 mJ/Ru mol K^2 indicating strong electronic correlations. Its large Wilson ratio of 10 and structural similarity to the tri-layered, ferromagnetic $Sr_4Ru_3O_{10}$ have lead to the generally accepted view that this material is an exchange-enhanced paramagnet on the verge of ferromagnetism. High-pressure and high-temperature heating (6 GPa and 1500 °C) brought about successful preparation of a polycrystalline sample of the expected member at $n = 3$ of $Sr_{n+1}Rh_nO_{3n+1}$. Neutron diffraction studies revealed the orthorhombic crystal structure (*Pbam*) at room temperature and 3.4 K. Local structure distortions rotationally tilt the RhO_6 octahedra ~12° in the perovskite-based blocks along the *c*-axis, and approximately a 20% disorder was found in sequence of the alternating rotational tilt. The sample was also investigated by measurements of specific heat, thermo power, magnetic susceptibility, and electrical resistivity. The data clearly revealed enhanced paramagnetism and electrically conducting character, which reflected the nature of the correlated $4d_5$ electrons of Rh^{4+}. However, no clear signs of magnetic and electrical transitions were observed above 2 K and below 70 kOe, providing a remarkable contrast to the rich electronic phenomena for the significantly relevant ruthenate, $Sr_4Ru_3O_{10}$. Its structure is shown in Fig. 12.51.

This is a structural view of $Sr_4Rh_3O_{10}$. The fine lines signify the orthorhombic unit cell. Cooperative rotations along the *c*-axis of the RhO_6 octahedra are indicated by circular arrows in the diagram. There is approximately a 20 % stacking error, such as A''(B'') at A'(B') blocks, was indicated by the neutron diffraction study. The tilting of each RhO_6 octahedron was ~12° along the *c*-axis. Two-step metamagnetic transitions are additionally observed at 5.8 T and at 6.3 T, which coincide with a range of broad maximum in the magnetoresistance. At low temperatures, these two metamagnetic features each further split in two. Such a behavior of multiple transitions is qualitatively different from the first order transition at 5.1 T and indicate the complexity of such metamagnetic transitions.

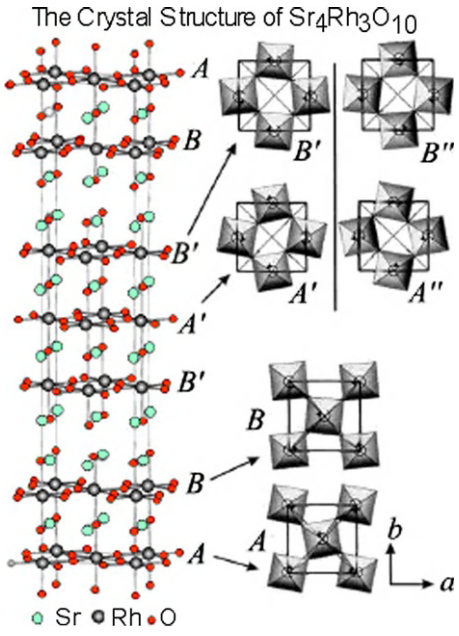

FIGURE 12.51

A novel material was produced by special processing of crystals of Sr_2RuO_4 (which is known to be a triplet superconductor with T_c values ~ 1.0–1.5 K). This material was claimed to be superconductive (zero DC resistance and expulsion of magnetic flux) at temperatures exceeding 200 K, that is at least 20 K higher than the copper-bearing compounds known as "high-temperature" superconductors. The special processing includes laser ablation and deposition of a silver coating and laser micromachining; Ag doping and enhanced oxygen are observed in the resultant surface layer. The transition, whether measured resistively or by magnetic field expulsion, is broad and not abrupt. When the transition was registered by resistive methods, the critical temperature is markedly reduced when the measuring current is increased. The resistance disappeared by about 190 K. The highest value of Tc registered by magneto-optical visualization is about 220 K and even higher values (up to 250 K) were indicated from the SQUID magnetometer measurements.

Laser ablation is one of the non-traditional methods of materials processing that may substantially alter the physical properties of samples. In addition to removing atoms from the surface, it may leave behind a recrystallized surface layer of altered composition and properties. The superconducting layer thickness is estimated to be 4–5 μm. The deeper layers (total thickness of the samples is 25 μm) have also been affected, and demonstrate pronounced ferromagnetism at temperatures as high as room temperature. This is itself also interesting since Sr–Ru–O systems never before demonstrated ferromagnetism at temperatures higher than 150 K.

However, other workers have not been able to reproduce these results and $Sr_2RuO_{6+\delta}$ is not regarded as a superconductor but retains its ferromagnetism. Time will tell if this compound, $Sr_2RuO_{6+\delta}$ ($\delta < 1.0$) proves to be a replacement for the high-temperature cuprate compounds currently under usage in the Industry.

In the Ru^{5+}-containing system of SrO–Ru_2O_5, the $Sr_2Ru_2O_7$ compound has been synthesized. $Sr_3Ru_2O_7$ is the $n = 2$ member of the Ruddlesden–Popper series of layered perovskites $Sr_{n+1}Ru_nO_{3n+1}$ octahedral ruthenium oxide. The four electrons in the ruthenium 4d t_{2g} orbitals hybridize with the oxygen 2p to create metallic bands that are narrow but still sufficiently broad to avoid insulating transitions. Thus, $Sr_3Ru_2O_7$ has a Ru–O bilayer per formula unit and the Ru effective spin has mainly a Heisenberg character. The (*H*,*T*) "crossover" phase diagram is rather similar to that derived for $CeRu_2Si_{21}$ whose properties are dominated by layers of octahedral ruthenium oxide . The four electrons in the ruthenium 4d t_{2g} orbitals hybridize with the oxygen 2p to create metallic bands that are narrow but still sufficiently broad to avoid insulating transitions.

Thus, $Sr_3Ru_2O_7$ has a Ru–O bilayer per formula unit and the Ru effective spin has mainly a Heisenberg character. The (*H*,*T*) "crossover" phase diagram is rather similar to that derived for $CeRu_2Si_2$. There is a rapid super-linear rise in magnetization in a field of 5.5 T for magnetic fields applied in the *ab*-plane. The metamagnetism is broadened as the temperature is raised. Metamagnetism is seen for all temperatures below 10 K, centered on a field of approximately 5.5 T. In metallic systems such as $Sr_3Ru_2O_7$, the change in magnetization is due to a rapid change from a paramagnetic state at low fields to a more highly polarized state at high fields via a crossover or a phase transition. However, some of the basic physics is same in both cases. The observation of itinerant metamagnetism demonstrates the existence of strong ferromagnetic coupling in the system. Thus, experimental results of the metamagnetism in $Sr_2Ru_2O_7$ give strong evidence for a new type of quantum critical behavior, namely a quantum critical end point. This study showed that this behavior can be caused by band structure effects, e.g. by the vicinity of a Van Hove singularity. The phase diagram for the multi-layer ruthenates, developed as a function of magnetic field and band filling, showed the presence of a quantum critical end point that terminates a first-order phase boundary. At the end point, the Fermi level of the majority spin band is precisely located at the Van Hove singularity. Thus, this system is rather susceptible to disorder effects. The possible appearance of Condon-domain like structures in a metamagnetic system was investigated. Condon-domains are the result of the coexistence of two magnetic phases at a first-order phase transition and may influence the motion of carriers via domain-wall scattering.

The magnetization curves are in good qualitative agreement with the observed behavior in $Sr_4Ru_3O_{10}$ for magnetic fields parallel to the *ab*-plane(2). Furthermore, the data are consistent with the experimental findings in $Sr_3Ru_2O_7$, where smooth metamagnetism has been observed at fields that are two to three times larger than the critical field in $Sr_4Ru_3O_{10}$. In the following figure, the resistivity (ρ_{res}) versus magnetic field of $Sr_3Ru_2O_7$ for three samples (of increasing purity) is shown in Fig. 12.52.

The top trace shows the unusual T^3 dependence previously reported for $\rho_{res} = 2.8\ \Omega/cm$. The temperature dependence of ρ_{res} at the MMT (magnetic moment temperature) changes to a negative gradient at low temperatures, with a minimum that increases systematically with temperature, as the sample gets purer. The susceptibility (χ) and resistivity (ρ_{res}) versus magnetic field across the metamagnetic field is shown in the following diagram (Fig. 12.53). The measurements were made at $T = 20$ mK on different crystals, both having $\rho_{res} = 0.5\ \Omega/cm$. The ac excitation field was 0.32 G at a frequency of 83.4 Hz. The temperature of each curve is between 0.06 and 0.1 K and the magnetic field is perpendicular to the RuO_2 planes. As the sample purity increases, the same basic peak remains as the dominant feature, but more structure develops. One observes a pronounced dip at 7.5 T, and the central peak is seen to have very steep sides at 7.8 and 8.1 T. The system's properties appear to be governed by the presence of a metamagnetic QCP (Quantum critical point = magnetically ordered phase).

The magnetic spectrum of $Sr_4Ru_2O_9$, in which the spectral feature from the RuO_6 units is shifted by 1 eV to lower energy upon increasing the Ru valence from Ru(IV) to Ru(V), results in a better separation of the RuO_6^- related state from the SrO band. This shift to lower energy that occurs in a manner fully analogous to the behavior observed in the spectra of 3d-TM oxides due to the increase of covalence with increasing valence.

Thus, the e_g-related peak in $Sr_4Ru_2O_9$ is individually identifiable in the energy range 530.5–532.5 eV. It is evident that the lower energy t_{2g}-related peak at 528.5 eV is narrower than the broad higher energy e_g- related peak as already observed in the Ru $L_{2;3}$ XAS spectrum discussed earlier. This is a direct result of the stronger covalent dp σ-like mixing between the O-2p and Ru-4d(e_g) orbitals. Ru(V) with the $t_{2g}^3e_g$ configuration has been known to possess a high-spin state ($S = 3/2$).

In the Ru^{6+}-containing system of SrO–RuO_3, the compound, $SrRuO_4$, has been described. The rapid suppression of the superconducting temperature, T_c, was the first indication that $SrRuO_4$ is a p-wave superconductor. The spin triplet Cooper pairs satisfy the Spin-Statistics Theorem by having odd orbital angular momentum and comply with the SST by virtue of being odd in time or frequency. The possibility of spin triplet, p-wave pairing in $SrRuO_4$ ($T_c = 1.4$ K) has generated considerable interest. $SrRuO_4$ is a perovskite with strong anisotropy and strong ferromagnetic fluctuations. The latter are expected to favor triplet pairing; measurements show a Knight shift that remains constant down to $T/T_c << 1$, as expected for a spin triplet state for the field orientation used. Bonalde et al. measured the penetration depth down to 40 mK using a tunnel diode oscillator. Several samples were measured. At the lowest temperatures, the superfluid density varied quadratic ally with temperature, suggesting the presence of nodes. However, other experiments in $SrRuO_4$ point to a state with a finite energy gap. One widely considered candidate was the axial state $d(k) = \Delta_0 z(k_x + ik_y)$ where z is perpendicular to the basal plane. The authors ruled out "gapless" behavior from impurities that can give a T^2-dependence even to a superconductor with an energy gap. They concluded that the quadratic dependence may arise from nonlocality. The issue is not settled and several other triplet pairing states have also been investigated for this material. At this point in time, the only known p-wave superconductor is $SrRuO_4$

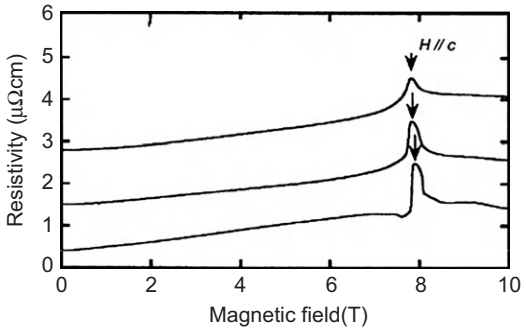

FIGURE 12.52

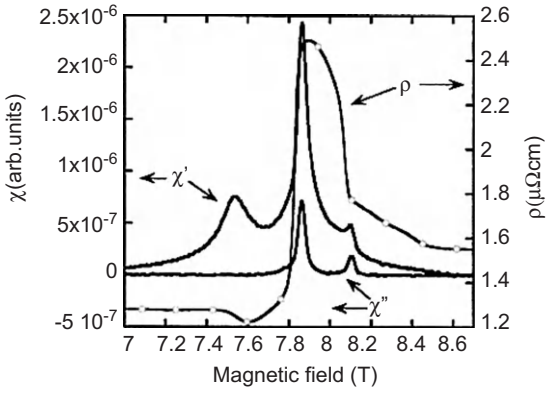

FIGURE 12.53

which with a T_{max} of about 1.5 K for the undoped compound. The known d-wave superconductors include the heavy fermion systems and the cuprates. Both p- and d-wave superconductors exhibit points of zero gap magnitude called nodes. The main difference between the p-wave and d-wave order parameters is the relative phases exhibited by the different lobes of the order parameter.

In the Ru^{7+}-containing system of SrO–Ru_2O, only two papers mention the compounds, $Sr_2Ru_2O_9$ and $Sr_3Ru_2O_{10}$. Little data has been forthcoming concerning these compounds that are described as "itinerant metamagnets", meaning that their degree of magnetism can be easily disrupted by the formation of oxygen vacancies and/or other lattice imperfections.

In the Ru^{8+}-containing system of SrO–RuO_4, no compounds are known.

Strontium ruthenate is available commercially as Sr_2RuO_4.

12.3.5. Barium Ruthenium Compounds

No intermetallic compounds in the system, Ba^0–Ru^0, are known.

In the Ru^{2+}-containing system of BaO–RuO, no compounds are known.

In the Ru^{3+}-containing system of BaO–Ru_2O_3, no compounds are known.

In the Ru^{4+}-containing system of BaO–RuO_2, several compounds are known. $BaRuO_3$ exists in two polytypes (4H and 9R) based on different stacking sequences of close-packed BaO_3 layers. Raman measurements on ceramic samples of both structures and on a 9R single crystal have been performed. The symmetries of most of the 9R modes have been determined from polarization-resolved measurements on the single crystal. A factor group analysis predicts nine Raman modes in the 9R and eight in the 4H structure.

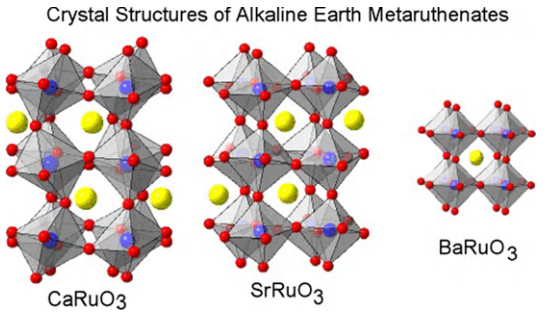

FIGURE 12.55

The $BaRuO_3$ compound falls into the class of hexagonal stacked polytypes known for CrO_6, MnO_6 and FeO_6 compounds (Fig. 12.54).

The cubic perovskite $BaRuO_3$ has been synthesized under 18 GPa at 1000 °C. Rietveld refinement indicates that this compound has a stretched Ru–O bond. The cubic perovskite $BaRuO_3$ remains metallic to 4 K and exhibits a ferromagnetic transition at $T_c = 60$ K, which is significantly lower than the $T_c \approx 160$ K for $SrRuO_3$. The availability of cubic perovskite $BaRuO_3$ not only makes it possible to map out the evolution of magnetism in the whole series of $AeRuO_3$ (Ae = Ca, Sr, Ba) as a function of the ionic size of the A-site r_A, but also completes the known polytypes of $BaRuO_3$.

The crystallography of $ARuO_3$ is shown in the above diagram. This diagram shows a comparison of the structures for these three compounds (Fig. 12.55). (a) Schematic drawing of the three perovskites $CaRuO_3$, $SrRuO_3$, and $BaRuO_3$ where red balls stand for O, gray for RuO_6, and yellow balls for alkaline earths Ca, Sr, and Ba.

In the following diagram, the magnetic spectrum of $Sr_4Ru_2O_9$, in which the spectral feature from the RuO_6 units is shifted by 1 eV to lower energy upon increasing the Ru valence from Ru(IV) to Ru(V), results in a better separation of the RuO_6^- related state from the SrO band (Fig. 12.56).

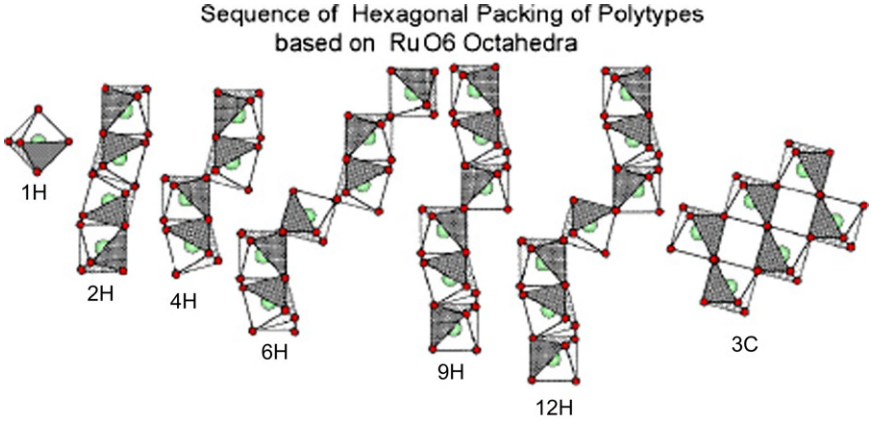

FIGURE 12.54

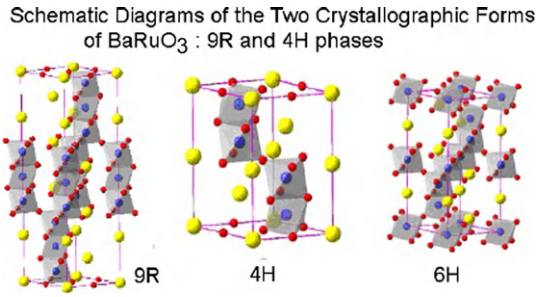

FIGURE 12.56

This shift to lower energy occurs in a manner fully analogous to the behavior observed in the spectra of 3d-TM oxides due to the increase of covalence with increasing valence.

It has been determined that if the 9R form is heated under pressure, it transforms into the other configurations at specific pressures, as shown in Fig. 12.57.

Extension of the plot of T_c versus r_A in perovskites $ARuO_3$ (A = Ca, Sr, Ba) shows that T_c does not increase as the cubic structure is approached, but has a maximum for orthorhombic $SrRuO_3$. Suppressing T_c by Ca and Ba doping in $SrRuO_3$ is distinguished by sharply different magnetic susceptibilities σ(T) of the paramagnetic phase. This distinction has been interpreted in the context of a Griffiths' phase on the (Ca Sr)RuO_3 side and bandwidth broadening on the (Sr,Ba)RuO_3 side.

The phase diagram of the magnetic transition temperatures versus the tabulated average A-site ionic radius r_A for $Sr_{1-y}Ba_yRuO_3$ and $Sr_{1-x}Ca_xRuO_3$ is shown in Fig. 12.58.

Three members in the phase diagram $CaRuO_3$, $SrRuO_3$, and $BaRuO_3$, in which the A-site size variance is 0, are distinguished by the solid symbols. The shaded area in the phase diagram represents the phase having the characteristic x^{-1}(T) of the Griffiths' phase. Letters inside the diagram stand for the crystal structure as determined by XRD at room temperature, O for orthorhombic, T for tetragonal, and C for cubic. The inset shows the temperature dependence of inverse magnetic susceptibility of $Sr_{1-x}Ca_xRuO_3$ measured with a magnetic field $H = 1$ T and of $Sr_{1-y}Ba_yRuO_3$ measured with a magnetic field $H = 0.5$ T in this work.

In another paper, single crystals of $BaRuO_3$ were grown using a $BaCl_2$ flux at ambient pressure. Most of the crystals had the nine-layer rhombohedral structure (9R), a form considered to be the stable form of $BaRuO_3$ at ambient pressure. However, some $BaRuO_3$ crystals in this preparation had the four-layer hexagonal (4H) structure that had been considered as a phase produced only at high pressure (15–30 kbar). The crystal structure of 4H $BaRuO_3$ was refined for the first time. Single-crystal XRD data gave a space group of $P6_3/mmc$ (No. 194), $a = 5.729$ Å, $c = 9.500$ Å, $Z = 4$, a final conventional R(based on F_0) of 2.01%, and a_wR2 (based on F^2_0) of 4.07%. The structure of 4H $BaRuO_3$ may be described as perovskite related with a four-layer stacking of BaO_3 layers in the sequence **hchc**. This led to pairs of face-sharing RuO_6 octahedra that are connected to other octahedra by corner sharing. The Ru–Ru distance in the Ru_2O_9 dimer of 4H $BaRuO_3$

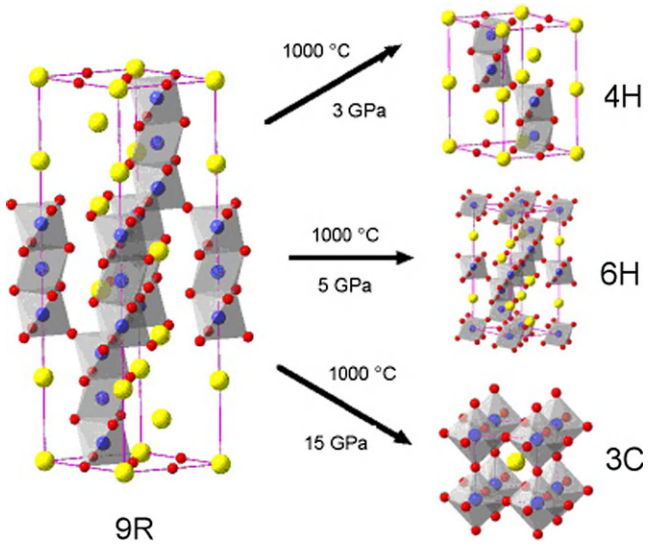

FIGURE 12.57

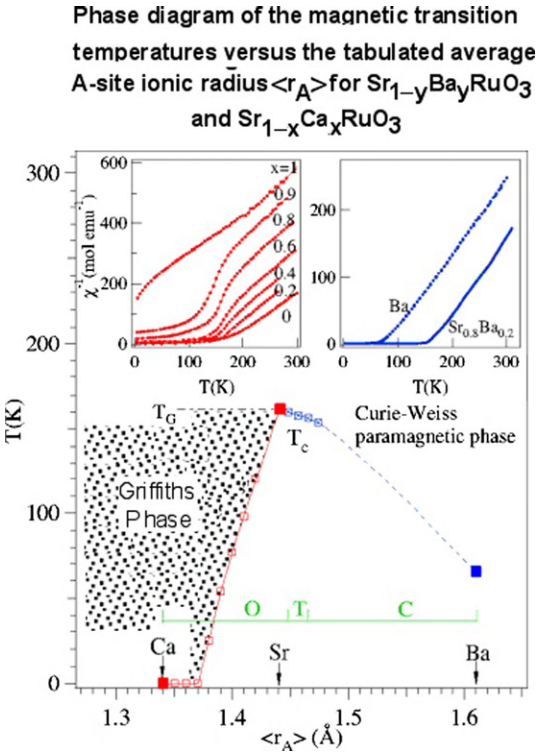

FIGURE 12.58

is 2.537 Å, which indicates the presence of a metal–metal bond.

The single-phase 6H $BaRuO_3$ with the hexagonal $BaTiO_3$ structure was synthesized at 5 GPa and 1000 °C. Rietveld refinement of the powder X-ray data for the 6H phase resulted in the lattice parameters to be $a = 5.7127$ Å and $c = 14.0499$ Å; the average Ru–O distance and direct Ru–Ru distance in the Ru_2O_9 dioctahedron being 1.992 and 2.5658 Å, respectively. The electrical resistivity of the 6H $BaRuO_3$ follows a relationship of σ versus $T^{3/2}$ below 60.0 K, a signature deviation from the Fermi liquid behavior. Both magnetic susceptibility and specific heat data indicate that the 6H $BaRuO_3$ is an exchange-enhanced Pauli paramagnet due to the electron correlation effect with large Wilson ratio R_W and Stoner enhancement factor. The comprehensive evolution of transport and magnetic properties from 9R across 4H to 6H $BaRuO_3$ was discussed.

The results of magnetic susceptibility and electrical resistivity measurements, made on single crystals of the nine-layer and four-layer crystallographic forms of $BaRuO_3$, have been reported. The two forms differ in the relative amounts of corner and face sharing of RuO_6 octahedra. They display qualitatively different properties below approximately 100 K: the four-layer form shows a metallic resistivity down to low temperatures, while the nine-layer shows a crossover to a more resistive state. No local moment magnetism is observed in either phase below 400 K, which is of particular interest in the context of previously observed magnetic and superconducting phases in the Sr–Ru–O system. Resistive measurements to temperatures below 0.1 K reveal no occurrence of superconductivity in either form. Temperature-dependent reflectivity spectra of non-perovskite nine-layer $BaRuO_3$ single crystal and four-layer $BaRuO_3$ epitaxial film was measured. In optical conductivity spectra obtained through Kramers–Kronig transformation, it was observed that both materials show pseudogap formations in their metallic states. A clear development of pseudogap as well as a coherent component as a function of temperature is evidently distinguished from other pseudogap systems, such as high T_c cuprates and heavy electron systems. We suggested that these interesting features should be related to the structural characteristics of the layered structures with face sharing of RuO_6 octahedra, which might induce 1D instability. High electrical conductive $BaRuO_3$ thin films with (110) perovskite orientation have been successfully fabricated on Si(100) substrates by pulsed ArF excimer laser deposition and post-annealing. The resistivity of the films at room temperature is in the range of 10^{-2} to 10^{-3} Ω/cm.

The observation of a modulated structure and a ferromagnetic insulating state in a high-quality single crystal of a nine-layer $BaRuO_3$ was reported. Using X-ray scattering, the modulated satellites were observed to double the unit cell along the *c*-axis at low temperature. The ferromagnetic insulating state is confirmed by magnetic and resistivity measurements. Analyzing the peak profiles from the modulation and host structure respectively, showed a lattice distortion at $T \approx 55$ K. These findings elucidate the intimate relationship between ferromagnetism and lattice distortion in a nine-layer $BaRuO_3$.

The compound, Ba_2RuO_4, has been grown as an epitaxial $Ba_2RuO_{4-\delta}$ film with the K_2NiF_4 structure by pulsed laser deposition on (100) $SrTiO_3$ substrates. XRD and cross-sectional TEM results indicate that the films are *c*-axis oriented, single-domain, and contain relatively few stacking faults and intergrowths. Electrical measurements indicate metallic conductivity to low temperatures, but no evidence of superconductivity. It is significant that films with the composition $BaRuO_3$ could not be prepared.

The study of the solid-state reactions in air or oxygen of the ternary system Ba–Ru–O shows the existence of the new compounds $Ba_4Ru_3O_{10}$ and $Ba_5Ru_3O_{12}$. The crystal symmetry of $Ba_4Ru_3O_{10}$ is monoclinic ($P2_1/a$) with the unit cell constants $a = 5.776(1)$ Å, $b = 13.076(1)$ Å, $c = 7.234(2)$ Å and $\beta = 113.53(3)°$. $Ba_4Ru_3O_{10}$ is isostructural with $Ba_4Ir_3O_{10}$ and the structure consists of trinuclear groups $[Ru_3O_{12}]$ of face-sharing octahedra 2D connected via terminal corners to form $[Ru_3O_{10}]$ zigzag layers. The magnetic properties confirm the oxidation state (Ru^{4+}) of ruthenium. $Ba_5Ru_3O_{12}$ is isostructural with $Ba_5(Ir_{1.5}Ru_{1.5})O_{12}$ with the cell parameters $a = 10.862(1)$ Å, $b = 5.893(1)$ Å and $c = 19.790(2)$ Å ($Pnma$). The crystal structure was refined on the basis of a single crystal in which part of the ruthenium was replaced by platinum. The structure consists of isolated $[Ru_3O_{12}]$ trimeric groups separated by barium atoms. Valence bond calculation confirms that the electronic charges are localized, and the magnetic behavior is interpreted in terms of antiferromagnetic isolated trimeric units.

The compound $Ba_5Nb_2O_9(O_2)$ has been synthesized by solid-state reactions. The crystal structure has been refined from X-ray powder data. $Ba_5Nb_2O_9(O_2)$ is isostructural with $Ba_5Ru_2O_9(O_2)$ with the cell parameters $a = 6.045$ Å, $c = 18.316$ Å ($P6_3/mmc$). Perpendicular to the *c*-axis, the structure is built up by the periodic stacking of three close packed $[BaO_3]$ layers separated by a layer of composition $[Ba_2O_2]$ containing $(O_2)^{2-}$ peroxide ions. The compound $Ba_5Ru_2O_{10}$ has been obtained by thermal decomposition of $Ba_5Ru_2O_9(O_2)$. The structure has been refined from X-ray powder data. The structure is similar to $Ba_5Ru_2O_9(O_2)$ but now the composition of the layer is $[Ba_2O]$. The magnetic properties of $Ba_5Ru_2O_9(O_2)$ and $Ba_5Ru_2O_{10}$ have been interpreted in terms of isolated dimers and confirm the structural results. All these phases belong to a new family of compounds formulated as $[A_2(O_2)][A_nB_{n-1}O_{3n}]$ where *n* represents the number of $[AO_3]$ successive

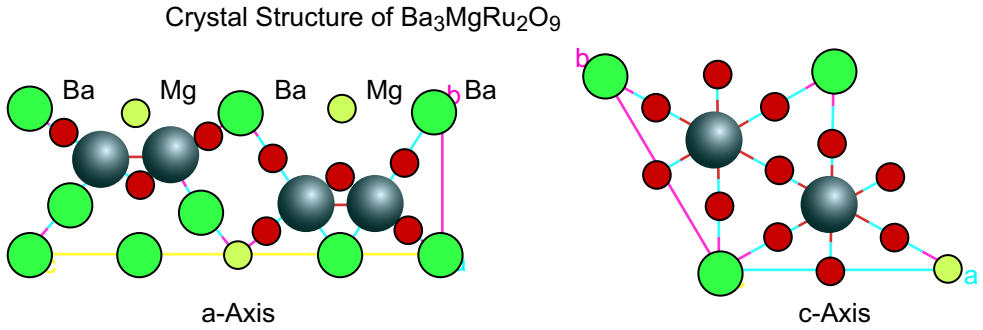

FIGURE 12.59

layers in the hexagonal perovskite slabs. This series can be extended to ternary barium sulfides.

In the Ru^{5+}-containing system of $BaO–Ru_2O_5$, only one compound is known. The compound, $Ba_3MgRu_2O_9$, has the structure shown in Fig. 12.59.

Cell parameters are: $a = b = 5.762$ Å, $c = 14.155$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, $Z = 2$.

Cell volume = 409.99 $Å^3$. Cell occupancy is shown in Table 12.14.

In the Ru^{6+}-containing system of $BaO–RuO_3$, the compound, $BaRuO_4$ has been synthesized. However, it cannot be formed by solid-state methods since it contains a peroxy-ruthenate grouping, RuO_4^{2-} that is potentially explosive. Because RuO_4 will readily decompose explosively at slightly elevated temperatures, it cannot be synthesized directly, nor is it commercially available through major chemical vendors. However, if K_2RuO_4 in solution is contacted by $BaCl_2$, a barium peroxy-ruthenate hydrate is precipitated:

$$BaCl_2(aq) + K_2RuO_4(aq) \Rightarrow BaRuO_4 \cdot H_2O(solid)$$

The structure of the so-called barium ruthenate monohydrate is more likely $BaRuO_3 \cdot (OH)_2$. This is a hexagonal compound with $a = 5.787$ Å, $c = 8.491$ Å, $Z = 2$, space group = $P6_2/mmc$. In the subcell, partial occupancy can be explained by steric considerations. Refinement of the structure results in a rhombohedral call with $a_0 = a\sqrt{3} = 10.23$ Å, $c_0 = 3c = 25.471$ Å, $Z = 18$, space group = $R3c$. The dihydroxy-trioxo-ruthenate(VI) ions have a trigonal-bipyramid configuration with three-short Ru–O bonds (1.755 Å) and two longer Ru–OH bonds (2.02 Å). They form six layers of $RuO_3(OH)_2^{2-}$ ions, stacked perpendicularly to the c-axis and separated by Ba^{2+} ions. Stacking defects in the succession of layers has led to statistical hexagonal symmetry.

A solution of barium chloride precipitates K_2RuO_4 to form red precipitate $BaRuO_4 \cdot H_2O$. No anhydrides like Ru_2O_7 and Ru_2O_3 are known, but RuO_3 can be formed. No acid like $HRuO_4$ that would form the salts is known, because, when these salts are decomposed with acid, then an unstable RuO_4 and lower oxides result. The latter are the basic oxides and form salts with acids.

In the Ru^{7+}-containing system of $BaO–Ru_2O_7$, no compounds are known.

In the Ru^{8+}-containing system of $BaO–RuO_4$, no compounds are known.

No barium ruthenates compounds are available commercially.

12.3.6. Radium Ruthenium Compounds

No intermetallic compounds in the system, Ra^0–Ru^0, are known. Although radium probably forms the same type of compounds with ruthenium oxides, there have been no mention of such in the scientific literature (to date).

12.4. ALKALINE EARTH—OSMIUM COMPOUNDS

Osmium has the following valence states: +1, −1, −2 in solution media and 2+, 3+, 4+, 5+, 6+, 7+, and 8+ in solid media. However, the number of compounds actually synthesized is small compared to the other elements in this 8d series.

Thus, not all of the oxide compounds are stable enough to form compounds with the alkaline earths. The most common oxidation states are +2, +3, +4, and +8. The +8 oxidation state is notable for being the highest attained by any chemical element. Osmium tetraoxide, OsO_4, is a very toxic compound, formed when powdered osmium is exposed to air, and is a very volatile, water-soluble, pale yellow, crystalline solid with a strong smell. In basic solution, it forms red osmates $OsO_4(OH)_2^{2-}$. OsO_2, osmium dioxide, is black, non-volatile, and much less reactive and toxic. Only two osmium oxide compounds have major applications: osmium tetroxide—for staining tissue in electron microscopy and the non-volatile osmates for organic oxidation reactions.

12.4.1. Beryllium Osmium Compounds

In the $BeO–Os_xO_{2x+1}$ system, no compounds are formed as the valence of Os is varied from +2 to +8.

It does, however form intermetallic compounds of the nature, $Be^0–Os^0$. Three compounds are known: $Be_{12}Os$, $Be_{17}Os_2$ and $Be_{17}Os_3$. The latter two compounds have structures identical to the Be^0Ru^0 series of compounds. These structures are compared in Fig. 12.60.

The cell parameters for $Be_{17}Os_2$ are: $a = b = 4.224$ Å, $c = 10.95$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 139.20$ Å^3, $Z = 6$. Cell occupancy is shown in Table 12.15.

$Be_{17}Os_3$ has the cell parameters of: $a = b = c = 9.8225$ Å, $\alpha = \beta = \gamma = 109.471$ Å, cell volume $= 729.54$ Å^3, $Z = 12$, but an exact structure has not been published. Cell occupancy is shown in Table 12.16.

$Be_{12}Os$ has the following cell parameters but an exact structure has not been published: $a = 8.4803$ Å, $b = 10.628$ Å, $c = 11.305$ Å, $\alpha = 96.546°$, $\beta = \gamma = 90°$, cell volume $= 1012.26$ Å^3, $Z = 6$.

These compounds remain as research oddities and no commercial usage has evolved.

12.4.2. Magnesium Osmium Compounds

Magnesium does not form any intermetallic compounds with osmium metal.

In the system of $MgO–Os_xO_y$, where $x = 1$ or 2 and y varies from 2 to 8, very few compounds are known.

In the Os^{3+}-containing system of $MgO–Os_2O_3$, the compound, $MgOs_2O_4$ has been studied. The 3s

band of Mg is lower in energy than the other alkaline earths, and appears around the Fermi level, which makes $MgOs_2O_4$ always metallic in conductivity. No data concerning structure are available and no other compounds have been described in this system.

In the Os^{6+}-containing system of $MgO–OsO_3$, the compound, $MgOsO_4$, is too unstable to be isolated. However, this compound is formed momentarily by the addition of K_2OsO_4 in solution upon the surface of MgO particles. It then causes the dihydroxylation of various organic olefins with excellent yields. A typical reaction is shown in Fig. 12.61.

New bifunctional catalysts composed of OsO_4^{2-} and WO_4^{2-} designed and prepared by a counter-ionic stabilization technique involving the reactions of K_2OsO_4–Na_2WO_4 with nanocrystalline MgO are well characterized. This bifunctional catalyst, NAP-Mg-OsW, performs tandem Heck asymmetric dihydroxylation and asymmetric dihydroxylation-*N*-oxidation reactions, in the presence of the chiral ligand 1,4-bis(9-*o*-dihydroquinidinyl)phthalazine [$(DHQD)_2PHAL$] in a single pot. It is quite impressive to note that H_2O_2 is used as a terminal oxidant to provide *N*-methylmorpholine *N*-oxide (NMO) in situ by the oxidation of *N*-methylmorpholine (NMM) in the asymmetric dihydroxylation-*N*-oxidation catalyzed by NAP-Mg-OsW. No other compounds are known in this system.

In the Os^{4+}-, Os^{5+}-, Os^{7+}-, and Os^{8+}-containing systems, no compounds are known.

Magnesium osmates are not available commercially and no CAS numbers have been issued.

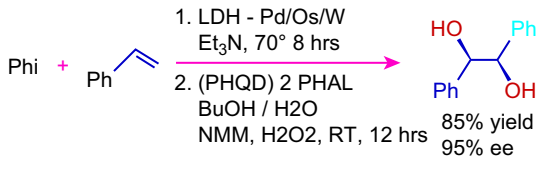

FIGURE 12.61

12.4.3. Calcium Osmium Compounds

Calcium does not form any intermetallic compounds with osmium metal.

In the system of $CaO–Os_xO_y$, where $x = 1$ or 2 and y varies from 2 to 8, no compounds involving the Os^{2+}, Os^{7+} and Os^{8+} ions are known.

In the Os^{3+}-containing system of $CaO–Os_2O_3$, the compound, $CaOs_2O_4$ has been studied from a theoretical standpoint. It is metastable and has not yet been isolated. It is expected to have a spinel structure shown in Fig. 12.62.

Theoretically, determined structure parameters of spinel osmates are shown in Table 12.17. Angle denotes the Os–O–Os bond angle; OsO and Os–Os denote the nearest neighbor Os–O bond length, and Os–Os bond length, respectively.

For comparison, the same parameters for the pyrochlore and iridate, $Y_2Ir_2O_7$, are also listed. It is apparent that the A-site element has a considerable effect on the Os–O bond angle and its length. $CaOs_2O_4$: Its reciprocal lattice (Brillouin Zones) band structure from nonmagnetic LDA + SO calculation was found to be metallic. The energy bands around the Fermi level appear as $J_{eff} = 1/2$ states similar to the ones found in Sr_2IrO_4, and also in $Y_2Ir_2O_7$, where a metal rather than the interesting topological insulator scenario of was obtained due to a 2-4-2 sequence of degeneracy at the ⌜ point.

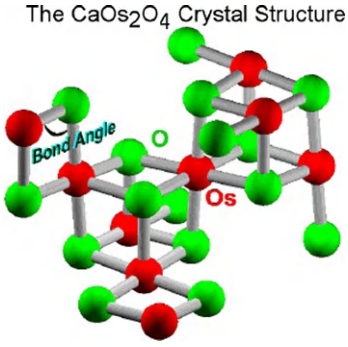

FIGURE 12.62

TABLE 12.17

	Angle	Os–Os	Os–O
$CaOs_2O_4$	98.50 Å	3.07 Å	2.04 Å
$SrOs_2O_4$	94.50 Å	3.12 Å	2.05 Å
$BaOs_2O_4$	103.10 Å	3.28 Å	2.11 Å
$Y_2Ir_2O_4$	129.70 Å	3.60 Å	1.99 Å

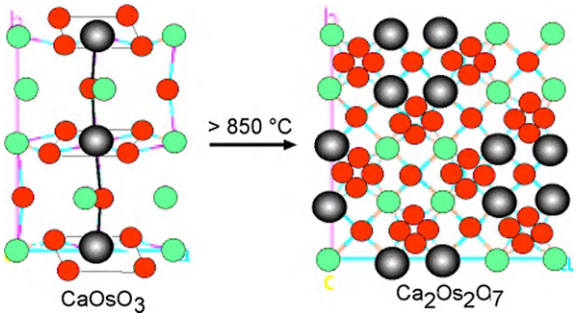

FIGURE 12.63

To date, these compounds have not been isolated in a stable form at room temperature.

In the Os^{4+}-containing system of CaO–OsO_2, the compound, $CaOsO_3$, has been studied. The thermal decomposition of $CaOsO_3$ by differential thermal analyses, thermogravimetry and XRPD has been studied. In nitrogen $CaOsO_3$ decomposes at 880 ± 10 °C into CaO, osmium metal and oxygen due to the reaction $CaOsO_3 \Rightarrow CaO + Os + O_2$. In static air, the decomposition occurs in three stages:

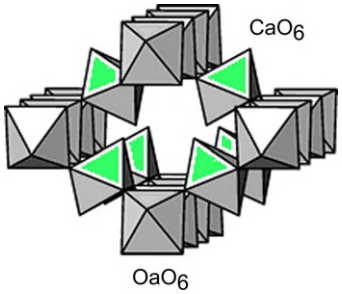

FIGURE 12.64

$$2CaOsO_3(solid) + 0.5O_2(gas) \Rightarrow Ca_2Os_2O_7(solid) \quad [850–808\ °C]$$

$$Ca_2Os_2O_7 \Rightarrow Ca_2Os_2O_{6.5} + 0.25O_2 \quad [850–1000\ °C]$$

$$Ca_2Os_2O_{6.5} \Rightarrow CaO + OsO_4 + 0.25O_2 \quad [>1005\ °C]$$

The first intermediate $Ca_2Os_2O_7$ is isostructural with orthorhombic $Ca_2Nb_2O_7$ and its cell parameters are: $a_0 = 3.745$ Å, $b_0 = 25.1$ Å, $c_0 = 5.492$ Å, $Z = 4$, space group *Cmcm* or *Cmc*2. $Ca_2Os_2O_7$ exhibits metallic conductivity and its electrical resistivity is 4.6×10^{-2} ohm/cm at 296 K. Note that a change in oxidation potential has occurred with $CaOsO_3$(IV) ⇒ $Da_2Os_2O_7$ (V) (Fig. 12.63).

The arrangement of the OsO_6 and CaO_6 octahedra in $Ca_2Os_2O_7$ may perhaps be better seen in Fig. 12.64.

Cell parameters of $CaOsO_3$ are: $a = b = 5.808$ Å, $c = 7.898$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 263.12 Å^3, $Z = 4$. Cell occupancy is shown in Table 12.18.

Cell parameters for $Ca_2Os_2O_7$ are: $a = b = c = 7.2408$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 268.44 Å^3, $Z = 2$, Cell occupancy is shown in Table 12.19.

$Ca_2Os_2O_7$ adopts a stoichiometric, orthorhombic weberite structure but the distortion of the OsO_6

octahedra and eightfold Ca–O coordinations decrease with increasing temperature indicating that this material lies close to the weberite/pyrochlore phase boundary. No other compounds are known in this system.

In the Os^{5+}-containing system of $CaO–Os_2O_5$, the $Ca_2Os_2O_7$ compound has been described as a decomposition product of $CaOsO_3$. Its structure was presented above. No other compounds have been synthesized in this system to date.

In the Os^{6+}-containing system of $CaO–OsO_3$, the compound, Ca_3OsO_6, has been studied. Single crystals of Ca_3OsO_6 can be obtained from stoichiometric amounts of CaO_2 and Os, Pt capsule, 6 GPa, 1500 °C, 1 h, LiCl, and KCl in a mass ratio of 1:5:2 (Pt crucible, 750 °C, 12 h). The compound is orthorhombic: $a = 14.859$, $b = 7.550$, $c = 5.487$ Å, $Z = 8$. Refinement was achieved in space group $Pna2_1$ by means of conventional least squares and Fourier techniques using intensity data corrected for absorption effects. The final R value is 0.047. Like ferroelectric compounds $BaMF_4$ (M = Zn, Co,…), the structure consists of two octahedra thick slabs with a distorted perovskite structure; theses slabs are linked by Ca^{2+} ions; but, in contrast to these compounds, the corner-sharing OsO_6 octahedra form zigzag chains along the b-axis and the Ca atoms are no longer situated in a mirror plane of this derivative . An attempt to prepare Ca_4OsO_6 by the reaction of four moles of **CaO_2 to OsO_3 met with failure**.

No calcium osmate compounds are offered for sale commercially.

12.4.4. Strontium Osmium Compounds

Strontium does not form any intermetallic compounds with osmium metal.

In the system of $SrO–Os_xO_y$, where $x = 1$ or 2 and y varies from 2 to 8, no compounds involving the Os^{2+}, Os^{7+} systems are known.

In the Os^{3+}-containing system of $SrO–Os_2O_3$, $SrOs_2O_4$ has the same structure as its calcium homologue. Neither of these compounds have been obtained in a pure state at room temperature since they tend to decompose in air to SrO, OsO_4 and oxygen. $SrOs_2O_4$ is metastable and has not yet been isolated. It is expected to have a spinel structure with electrical characteristics of a metal. No other compounds are known in this system.

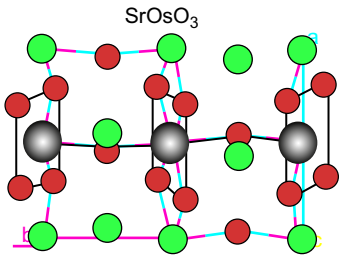

FIGURE 12.65

In the Os^{4+}-containing system of $SrO–OsO_2$, the compound, $SrOsO_3$ has been studied. It has the same structure as the Ca homologue shown in Fig. 12.65.

Cell parameters are: $a = 5.32$ Å, $b = 5.58$ Å, $c = 7.92$ Å. $\alpha = \beta = \gamma = 90°$, cell volume = 234.52 Å^3, $Z = 2$. Cell occupancy is shown in Table 12.20.

Like its calcium homologue, it decomposes to form $Sr_2Os_2O_7$ where a change in valency occurs. The decomposition of orthorhombic $Sr_2Os_2O_7$ depends strongly on the partial pressure of air above the samples investigated. A defect structure can be formed. If the pressure is low, the defect pyrochlore $Sr_2Os_2O_{6.4}$ is obtained. It has the same structure as the pyro-osmate, $Sr_2Os_2O_7$. The thermal decomposition of $SrOsO_3$ in a dynamic airflow has been studied using differential thermal analysis, thermogravimetry and XRPD. It decomposes to the pyro-osmate above 800 °C. After decomposition of the pyro-osmate above 920 °C, a new phase was discovered, which has the formula $SrOsO_4$, a scheelite structure and tetragonal unit cell parameters $a_0 = 5.422$ Å, $c_0 = 11.92$ Å, $Z = 4$, space group $I4_1/a$, and a pycnometric density of 6.46 g/cm^3. Above 1030 °C, $SrOsO_4$ decomposes into SrO, osmium tetroxide and osmium metal.

No other compounds have been found in this system.

In the Os^{5+}-containing system of $SrO–Os_2O_5$, the thermal decomposition of $Sr_2Os_2O_7$ by DTA, thermogravimetry and XRPD has been studied. Orthorhombic

TABLE 12.20

4	Os1	Os	4	a	−1	0	0	0	1.0

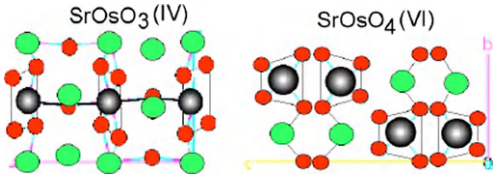

FIGURE 12.66

$Sr_2Os_2O_7$ evolves oxygen slowly above 845 °C transforming into the intermediate orthorhombic $Sr_2Os_2O_{7-x}$ up to $x \leq 0.16$. At $x = 0.16$–0.20 a new cubic phase begins to form. The cubic phase $Ca_2Os_2O_{7-y}$ has a pyrochlore structure type and its homogeneity region is spread to $y \leq 0.60$. Above 1010 °C the pyrochlore, $Sr_2Os_2O_{7-y}$, decomposes completely into SrO, osmium metal, osmium tetroxide and oxygen.

A body-centered cubic structure related to the cubic $KSbO_3$ structure has been found for phases with compositions close to $BaOs_2O_6$, $SrOs_2O_6$, and $SrRe_2O_6$. A primitive cubic structure also related to the cubic $KSbO_3$ structure has been found for phases with compositions close to $NaOsO_3$, $BiPtO_{3.5}$, and $BiOsO_{3.5}$. The ternary oxides $Cd_2Ir_2O_7$, $Ca_2Ir_2O_7$, and $Ca_{1.7}Os_2O_7$ have been prepared with the cubic pyrochlore structure. All iridium phases contain Ir^{5+} and are the first oxide examples of iridium in an oxidation state higher than 4. The osmate compositions contain osmium in a +5 state, i.e. Os^{5+}.

In the Os^{6+}-containing system of SrO–OsO_3, the compound $SrOsO_4$ has the structure shown in Fig. 12.66.

A comparison of the two valence states is shown. The OsO_6 octahedra are connected in the former and isolated in the latter. Cell parameters of $SrOsO_4$ are: $a = b = 5.422$ Å, $c = 7.0867$ Å, $\alpha = \beta = 112.492°$, $\gamma = 90°$, cell volume = 175.21 Å^3, $Z = 4$. Cell occupancy is shown in Table 12.21.

Single crystals of the compound $Sr_3(OsO_4(OH)_2)_2 \cdot H_2O$ were prepared in closed steel tubes under high pressure and investigated by single-crystal X-ray determination. It crystallizes with triclinic symmetry, space group C_1^i–$P1$, $a = 5.7877$ Å, $b = 10.407$ Å, $c = 10.485$ Å, $\alpha = 10.82°$. $\beta = \gamma = 104.30°$, $Z = 2$. $OsO_4(OH)_2$ octahedra are occupied by osmium in the oxidation states Os^{6+} and Os^{8+} in a disordered manner. The crystal chemistry was shown and the statistical distribution of the different valence states of osmium was discussed with respect to calculations of the Coulomb term of lattice energy.

In the Os^{8+}-containing system of SrO–OsO_4, the compound, $SrOsO_5$ has been synthesized. The crystal chemistry of oxides of Osmium shows it to form different oxidation states and generally as anions in the anionic part of the solids. This clear decision in favor of the anionic part of crystal structures is caused with the combination of osmium with large cations like Alkaline Earth– and Rare Earth–metals. Despite different valence states of osmium, the oxygen surrounding is to a great extent octahedral. Besides isolated OsO_6 octahedra, edge shared $^1{}_\infty[Os_2O_{10}]$-double (showing Os–Os interchanges), $^1{}_\infty[Os_2O_{10}]$-chains and 2- or 3D networks oxo-osmates reveal the structures of perovskites, pyrochlores and stacking variants of perovskites. $SrOsO_5$ is a representative for Osmium in an unusual coordination by oxygen. At least two osmium metal clusters are present and the formulation is: $Sr_2[Os_2O_{10}]$.

The crystal structure of a strontium osmate(VIII) compound, $Sr[OsO_5(H_2O)] \cdot 3H_2O$, has been described but details are lacking concerning its preparation. It is likely that this compound was produced in solution by the use of $K_2[OsO_4(OH)_2]$ or $Na_2[OsO_4(OH)_2] \cdot 2H_2O$. Vibrational spectra show the $[OsO_4(OH)_2]^2$-ions to have *cis*-octahedral structures. In addition, the first mixed-valence compound involving an alkaline earth metal tetra-oxodihydroxo-osmate(VI,VIII), $Sr_3(OsO_4(OH)_2)_2 \cdot H_2O$, has been reported.

There are no strontium osmates offered for sale commercially and no CAS numbers have been issued.

12.4.5. Barium Osmium Compounds

Barium does not form any intermetallic compounds with osmium metal.

In the system of BaO–Os_xO_y, where $x = 1$ or 2 and y varies from 2 to 8, no compounds involving the Os^{2+}, Os^{5+}, Os^{7+} or Os^{8+} ions have been synthesized.

In the Os^{3+}-containing system of BaO–Os_2O_3, the compound, $BaOs_2O_4$, has not been isolated. The presumed spinel structure was described above for

TABLE 12.21

2	Sr1	Sr	4	b	–4..	0	1/4	5/8	1.0
3	Os1	Os	4	a	–4..	0	1/4	1/8	1.0

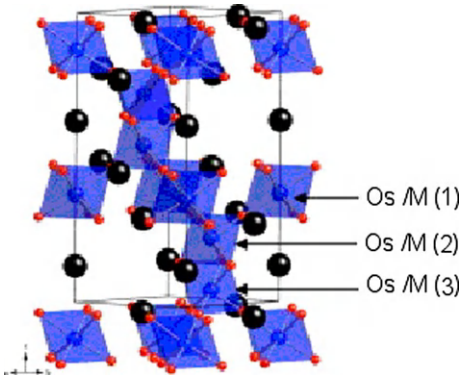

FIGURE 12.67

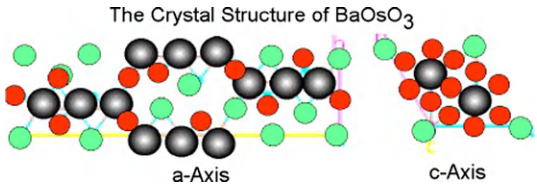

FIGURE 12.68

the Ca and Sr homologs. The bond angles for $BaOs_2O_4$ were presented above. The major difference between the Ba homologue and the others is that the LDA + SO calculation with $U = 0$ gives that at the Γ point the eight $J_{eff} = 1/2$ states have degeneracy 4–2–2 and not 2–4–2 as found in the Ca and Sr cases. These differences significantly affect its band structure. The value of U will induce magnetism, but axion insulator or Dirac metal state for BaOs2O4 is not found for any reasonable U.

Two complex oxide compounds, containing Os^{3+}, have been studied. Two complex oxides of osmium, $Ba_2Fe_{0.92}Os_{1.08}O_6$ and $Ba_2Co_{0.77}Os_{1.23}O_6$, have been prepared as single crystals from molten potassium hydroxide. Both oxides crystallize in the hexagonal space group $P6_3mc$ with $a = 5.7403(1)$ Å and $c = 14.0771(6)$ Å and $a = 5.7745(2)$ Å and $c = 14.0946(7)$ Å for $Ba_2Fe_{0.92}Os_{1.08}O_6$ and $Ba_2Co_{0.77}Os_{1.23}O_6$, respectively. The structure of these compounds is related to the 6H $BaTiO_3$ structure but exhibit mixed occupancy of both metals on the three crystallographically independent metal sites.

The relevant structure is shown in Fig. 12.67. The black spheres represent Ba^{2+} while M(1), M(2) and M(3) represent the MO_6 octahedra where M is $Fe_{0.92}Os_{1.08}O_6$ or $Co_{0.77}Os_{1.23}O_6$.

In the Os^{4+}-containing system of $BaO–OsO_2$, the structure of the compound, $BaOsO_3$ has been determined. It differs from that of the homologues, $CaOsO_3$ and $SrOsO_3$ (Fig. 12.68).

Cell parameters are: $a = b = 6.221$ Å, $c = 8.166$ Å, $\alpha = \beta = 67.69°$, $\gamma = 60°$, cell volume = 244.35 Å^3, $Z = 6$. Cell occupancy is shown in Table 12.22.

Whereas the Ca and Sr homologues decompose to form the $Ae_2Os_2O_7$ type of structure with a change from Os^{4+} to Os^{5+}, the compound, $Ba_2Os_2O_7$ is unknown. One paper states that $BaOsO_3$ decomposes at 835 °C in air and is complete by 890 °C to form $BaOsO_4$. The latter then decomposes at 1060 °C to form BaO and OsO_4.

The crystal structure and magnetic properties of a barium osmate $Ba_{11}Os_4O_{24}$ were investigated. This compound crystallizes in a cation-deficient double perovskite-related structure (space group $I4_1/a$; $Z = 4$), which is isostructural with the strontium rhenate, $Sr_{11}Re_4O_{24}$. This compound shows semiconductive behavior with thermal activation. A weak ferromagnetic transition has been found at 7.5 K through its magnetic susceptibility measurements. At 6.8 K, a λ–type specific heat anomaly has been observed.

No other Os^{4+}-containing compounds are known.

In the Os^{6+}-containing system of $BaO–OsO_3$, the compound, $BaOsO_4$ is known. It is an intermediate product in the decomposition of $BaOsO_3$ in air and has the structure shown in Fig. 12.69.

The compound, Ba_3OsO_6 containing Os(VI) has been thoroughly documented. There is ample evidence in chemical literature that the compound Ba_3OsO_6 is stable up to at least 1300 K.

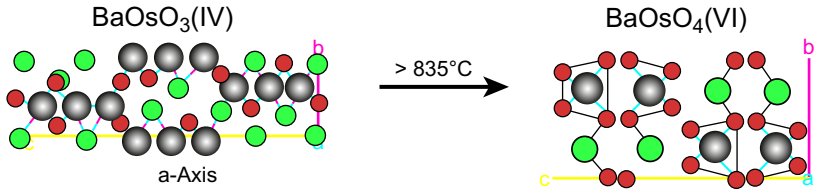

FIGURE 12.69

No other barium osmate compounds are known to date. None of these compounds are available commercially.

12.4.6. Radium Osmium Compounds

Radium does not form any intermetallic compounds with osmium metal. While radium undoubtedly will form Os compounds very similar to those of the Ba system, there is no record of anyone having tried to synthesize such compounds. The lack of interest in the Industry and Academia is probably the major factor for this situation.

13.1. ALKALINE EARTH COBALT COMPOUNDS

13.1.1. Beryllium Cobalt Compounds

Beryllium, in the system Be–Co–O, does not form any cobaltate type of compounds.

However, it does form a series of intermetallic compound with Co metal. The phase diagram shows four compounds (Fig. 13.1).

However, two of the compounds shown are high-temperature phases only and are not stable at room temperature. The compound, BeCo, has a body-centered structure shown in Fig. 13.2.

Cell parameters are: $a = b = c = 2.625$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 18.09 Å^3, $Z = 1$. Point group = cP2, space group = Pm-3m. Cell occupancy is shown in Table 13.1.

The structure of the compound, Be_9Co, has not been published. It has the cell parameters of: $a = b = c = 6.5936$ Å, $\alpha = \beta = \gamma = 109.471°$, cell volume = 220.67 Å^3.

The compound, Be_5Co has the structure shown in Fig. 13.3.

The Co^0 atoms occupy face-centered positions. Cell parameters are: $a = b = c = 4.138$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 50.10 Å^3. $Z = 4$, point group = cF24, space group = F-43m. Cell occupancy is shown in Table 13.2.

The structure of the compound, Be_3Co, has not been published. It has the cell parameters of: $a = b = 8.3783$ Å, $c = 13.7652$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 836.81 Å^3, $Z = 4$.

The exact structure of the compound, $Be_{21}Co_5$, has not been published. It has the cell parameters of: $a = b = c = 10.781$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 886.06 Å^3, $Z = 4$.

The structure of the compound, $Be_{17}Co_2$, is shown in Fig. 13.4.

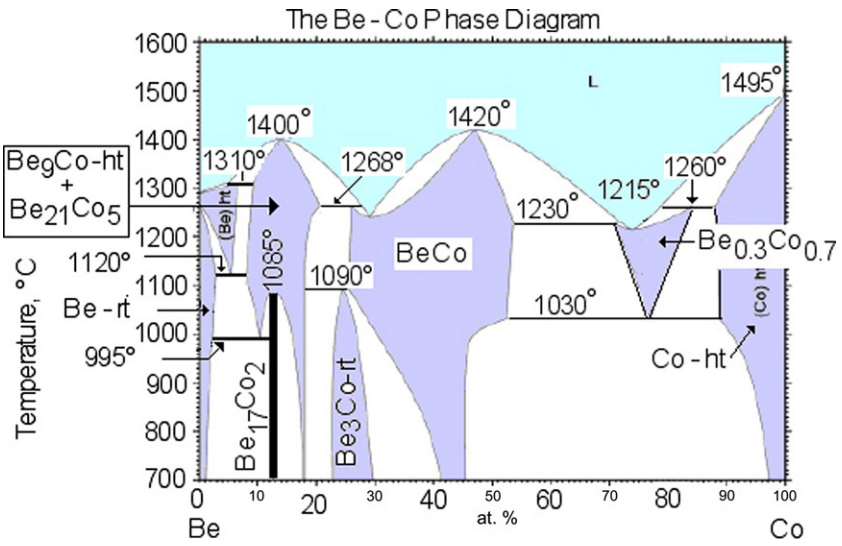

FIGURE 13.1

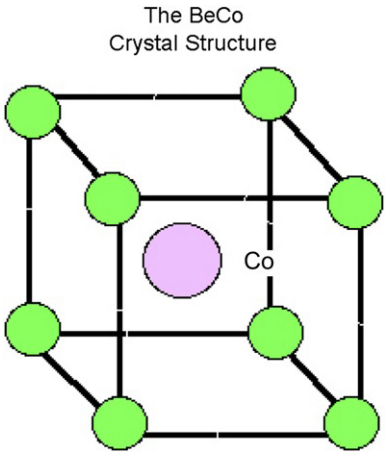

FIGURE 13.2

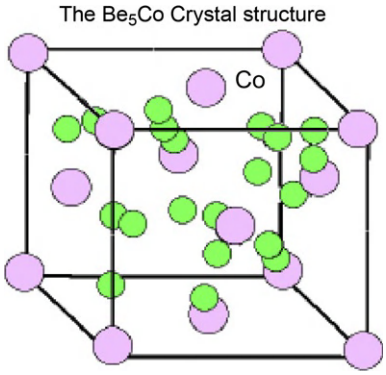

FIGURE 13.3

Cell parameters are: $a = b = 4.115$ Å, $c = 10.9818$ Å^3, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 161.34 Å^3, $Z = 1$, point group = hP19, space group = P-6m2. Cell occupancy is shown in Table 13.3.

$Be_{12}Co$ is body centered with Co atoms and has the structure shown in Fig. 13.5.

The Co atoms occupy a body-centered cube and there are three internal layers of Be atoms, making this structure be made of five layers of Be^0–Co^0 atoms. The cell parameters are: $a = 4.249$ Å, $b = c = 5.5408$ Å, $\alpha = 81.546°$, $\beta = \gamma = 67.454°$, cell volume = 111.47 Å^3, $Z = 2$. Point group = tl26, space group = $I4/mmm$. Cell occupancy is shown in Table 13.4.

Be_2Co has the structure where the body-centered cubic lattice is randomly occupied by Be^0 or Co^0 in the ratio of 2:1 (Fig. 13.6).

Cell parameters are; $a = b = c = 2.2361$ Å, $\alpha = \beta = \gamma = 109.47°$, cell volume = 8.61 Å^3, $Z = 2$, point group = cI2, space group = Im-3m. Site occupancy is shown in Table 13.5.

13.1.2. Magnesium Cobalt Compounds

Magnesium metal does not form any intermetallic compounds with Co metal.

In the Co^{2+}-containing system of MgO–CoO, the compound $MgCoO_2$ is known. It has the structure shown in Fig. 13.7.

Other than its structure, no other references are available concerning its physical and chemical properties. Cell parameters are: $a = b = c = 2.9963$ Å, $\alpha = \beta = \gamma = 60^\circ$, cell volume $= 19.02$ Å^3, $Z = 4$, point group = cF48, space group = *Fm*-3*m*.

The compound, $MgCo_3O_4$, has been mentioned in at least one paper regarding its catalytic activity regarding the decomposition of methane, CH_4. The process of catalytic methane oxidation is very important in Industry as it is directly applicable to the purification of exhaust gases from a large spectrum of industries, vehicles, catalytic heat generators, etc. Unfortunately, this compound was not very active in this capacity, in comparison to other Pt compounds.

In the Co^{3+}-containing system of MgO–Co_2O_3, the compound, $MgCo_2O_4$, has the structure shown in Fig. 13.8.

In one paper, an investigation of the synthesis and electrical properties of the spinel, $MgCo_2O_4$, was made because it was being considered as a candidate of the cathode materials of magnesium ion batteries in the

future. Samples were synthesized using two types of techniques: (1) solid-state reaction and (2) a wet process. The crystal structures of the samples were analyzed by X-ray diffraction (XRD), and their electrical conductivities were obtained through the DC resistance and AC impedance measurements. By solid-state reaction, a sample of a single $MgCo_2O_4$ phase was not obtained. The sample synthesized at 800 °C for 24 h, after milling together of Co_3O_4 and MgO powder, was comprised of dual phases of spinel-type and rock salt-type structures. Samples synthesized at temperatures higher than 880 °C showed a single rock salt-type phase without electrical conductance. The $MgCo_2O_4$ sample showed *p*-type semiconducting behavior similar to the spinel type of Co_3O_4, but its electrical conductivity at room temperature was shown to exceed that of Co_3O_4. In contrast, a sample consisting of a single spinel-type phase was successfully synthesized by wet process, which exhibited an electrical conductivity of the order 102 S/cm, being much higher than those of the samples

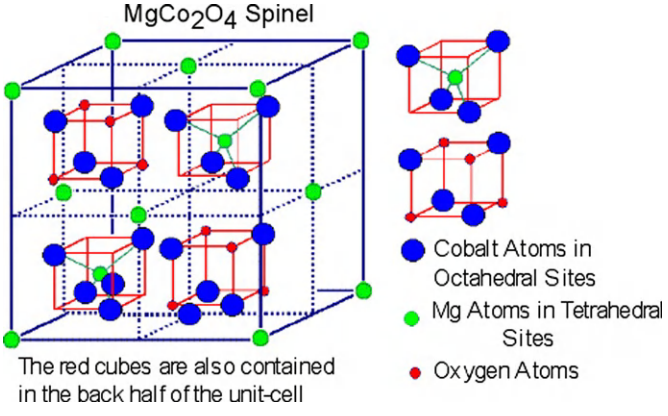

FIGURE 13.8

synthesized by solid-state reaction. Thus, it was concluded that the substitution of Co^{2+} in Co_3O_4 with Mg^{2+} was found to enhance the electrical conductivity of the spinel-type phase.

In another work, the compounds, $FeCo_2O_4$ and $MgCo_2O_4$, were synthesized by the urea combustion and oxalate decomposition method, respectively. Powder XRD, high-resolution transmission electron microscopy (HRTEM), selected area electron diffraction (SAED) and X-ray photoelectron spectroscopy (XPS) have been used to characterize the phases. Scanning electron microscopy (SEM) showed the distinct features in the morphology, submicron size of $FeCo_2O_4$ and needle-shaped particles of $MgCo_2O_4$. Galvanostatic cycling was carried out in the voltage range 0.005–3.0 V vs Li at a current of 60 mA/gm (~0.08 C) up to 50 cycles. The observed first-cycle charge capacities are, $FeCo_2O_4$: 827 mA/h/gm (corresponding to theoretical 7.3 mol of Li per mole of $FeCo_2O_4$) and $MgCo_2O_4$: 736 mA/h/gm (5.7 Li). At the end of 50 cycles, $FeCo_2O_4$ retained ~90% of its first-charge capacity, and a coulombic efficiency of ~99% is noted between 20 and 50 cycles. $MgCo_2O_4$ showed extensive capacity fading and retained only 0.9 mol of cyclable Li in the range 28–50 cycles. These results show that Fe is a better counter ion than Mg. The average charge and discharge voltages are ~2.0 V and ~1.2 V, respectively, for both the compounds. Cyclic voltamperograms, up to 12 cycles on $FeCo_2O_4$, complemented the galvanostatic cycling results. Impedance studies were carried out on $FeCo_2O_4$ at various voltages during the first cycle and after 10 cycles, and the data were interpreted.

$MgCo_2O_4$ spinel catalysts were prepared via the solution combustion synthesis (SCS) and coprecipitation (CP) methods. The produced powder catalysts were characterized by XRD, BET, FESEM, TPD, and XPS. The performance of these catalysts toward the decomposition of N_2O to N_2 and O_2 was evaluated in a temperature programmed reaction apparatus in the absence of and in the presence of oxygen ($W/F = 0.03$ g s/cm^3). The catalyst prepared by the CP method has been found to provide the best activity; the half conversion temperature (T_{50}) of nitrous oxide was 380 and 415 °C in the absence and in the presence of oxygen, respectively. The $MgCo_2O_4$ spinel catalysts were directly deposited, by in situ SCS and CP, over ceramic honeycomb monoliths and tested in a lab-scale test rig. Again, in this case, a prevalent activity of the catalytic monolith prepared by CP was observed. The higher activity of the catalyst prepared by CP could be correlated with its higher surface area and its higher capacity of enriching the surface with the more reactive supra-facial, weakly chemisorbed, oxygen species.

Magnesium ion batteries (MIBs) with a Mg metal-negative electrode are expected to combine high energy density and high electromotive force, owing to the divalent ion careers and its low redox potential. However, it has been reported to date that the cell voltage of MIBs is not high enough (1.5 V), being far below that of lithium ion batteries (LIBs) (4–5 V). In this work, the authors have investigated the potentiality of Mg–Co–O and Mg–Ni–O complex oxides as the positive electrode for MIBs, which are composed of these positive electrodes and a Mg-negative electrode in acetonitrile with $Mg(ClO_4)_2$ salt as an electrolyte. These MIBs exhibited a relatively high open circuit voltage (OCV) and can light a blue diode after charge. However, as the combination of the acetonitrile electrolyte and metal Mg can yield a passivation on the surface of the Mg electrode, these materials were also checked for use in a well-established Li ion battery system. Results confirmed that the charged battery can show a high OCV. In order to attain such a high cell voltage, it would be significant to exploit the unstabilized ion after charge in the host complex oxide. This was not accomplished.

A novel route of low-temperature preparation of Mg, Ni and Zn cobaltite spinel catalysts has been investigated. Cobalt oxalate, co-precipitated with the oxalate of magnesium, nickel or zinc, respectively, in a 2:1 ratio, has been used as starting material. Cobaltite synthesis proceeds during thermal treatment of coprecipitated oxalates in air. It was established that coprecipitated oxalates are solid solutions and the oxidation of Co^{2+} to Co^{3+} during thermal treatment begins at lower temperatures than that of the dissociation onset of the anhydrous product, thus facilitating the synthesis of cobaltites. A preparation procedure that allows avoiding local overheating of the material due to the strongly exothermal processes of oxalate dissociation was developed. The application of this procedure permits the formation of spinel phases of $MgCo_2O_4$, $NiCo_2O_4$ and $ZnCo_2O_4$ with specific surface areas of 63, 94 and 81 m^2/g, respectively, at 250 °C. No other compounds are known in this system.

No other compounds are known in:

(1) the Co^{2+}–Co^{3+}-containing system of MgO–Co_3O_4,
(2) the Co^{4+}-containing system of MgO–CoO_2,
(3) the Co^{5+}-containing system of MgO–Co_2O_5 or
(4) the Co^{6+}-containing system of MgO–CoO_3.

Magnesium cobaltite or cobaltate compounds are not offered commercially and no CAS numbers have been issued.

13.1.3. Calcium Cobalt Compounds

Calcium metal does not form any intermetallic compounds with cobalt metal.

In the Co^{2+}-containing system of CaO–CoO, the compound, $CaCoO_2$ is not stable at room temperature. The existence of gaseous cobaltates of alkaline earth metals has been established by high-temperature mass spectrometry. Gaseous molecules: $CaCoO_2$, $SrCoO_2$ and $BaCoO_2$ were found for the first time. On the basis of the measured constants of the equilibrium of gas-phase reactions the standard enthalpies of formation: -149 ± 19 kJ/mol, -149 ± 20 kJ/mol and -250 ± 16 kJ/mol; standard atomization enthalpies were: 1251 ± 22 kJ/mol, 1233 ± 23 kJ/mol and 1353 ± 20 kJ/mol for $CaCoO_2$, $SrCoO_2$ and $BaCoO_2$, respectively.

The compound, Ca_2CoO_3 (II), has been found to be a slab-layered rock salt type of compound. It is not stable at room temperature but has been found to exist in the CaO–Co_3O_4 series of compounds. Consequently, it has been established as a thin-layer structure on silicon matrices. Thin films of the *p*-type thermoelectric misfit-layered oxide, $[Ca_2CoO_3]_{0.62}[CoO_2]$, were prepared for the first time by means of the atomic layer deposition technique using $Ca(thd)_2$, $Co(thd)_2$, and O_3 as precursors. As deposited films were amorphous; however, with heat treatment in an O_2 gas flow, well-crystallized highly *c*-axis-oriented $[Ca_2CoO_3]_{0.62}[CoO_2]$ films were obtained. The oxygen content of the O_2-annealed film was further controlled through a reductive N_2 annealing. Because the degree of reduction was dependent on the annealing temperature, the choice of N_2-annealing temperature provided a tool for precise tuning of the oxygen content (Fig. 13.9).

With decreasing oxygen content, the lattice parameter (*c*) and the Seebeck coefficient (*S*) were found to increase. The room-temperature S values were 113 and 128 μV/K for the oxygen-richest sample and the most reduced sample, respectively.

Large and high-quality single-crystal flakes of the $[Ca_2CoO_3]_{0.62}[CoO_2]$ compound can also be obtained if the crystals are grown from Co_3O_4 and $CaCO_3$ reagents with chloride flux. Typical single-crystal flake size is about $5 \times 5 \times 0.02$ mm^3. Obtained crystal flakes were consolidated by the spark plasma sintering (SPS) technique at 1100 K for 1 h. Grain alignment was checked by XRD and also was confirmed by SEM observations on the fractured surface. At 1000 K, electrical conductivity of the textured ceramics is about 270 S/cm, twice as high as that of powder sample sintered by the SPS procedure. The Z_T value of the textured sample reaches 0.4 at 1000 K, being 50% improvement relative to the powder-sintered sample, although the thermal conductivity increases simultaneously. The constructed commensurate supercell has the following parameters: $a' = 3 \cdot a = 14.5$ Å, $b' \approx 8 \cdot b_1 \approx 5 \cdot b_2 = 28.2$ Å, $c' = 10.8$ Å and $\beta = 94.3°$.

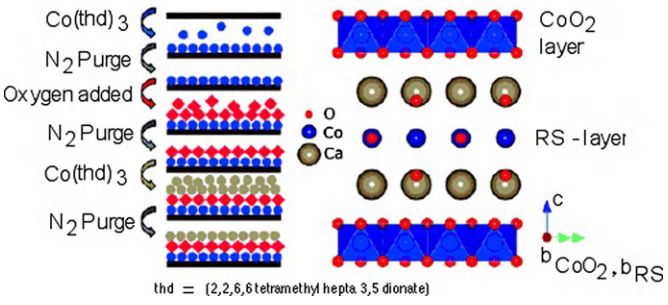

FIGURE 13.9

Electronic transportation and thermodynamic properties of misfit-layered polycrystalline $[Ca_2CoO_3]_{0.62}[CoO_2]$ were measured in order to clarify the nature of metal–semiconductor transition (MST) at $T_{MS} \approx 400$ K. Above this, a simultaneous decrease of resistivity and increase of thermopower with temperature give rise to a great enhancement of thermoelectric power factor up to 1000 K. A first-order phase transition characteristic around T_{MS} was revealed by anomalies of resistivity, differential scanning calorimetry, and thermal expansion. The first-order characteristic of the MST can be rationalized by using the virial theorem via an itinerant to localized electron transition in the narrow eT band within the $[CoO_2]$ plane. Above T_{MS}, the reduction of the retained delocalized states within the matrix of localized states, and the enhancement of charge carrier effective mass with increasing temperature, has been hypothesized to account for the considerable enhancement of the observed thermopower.

Another paper has examined the temperature transition of $[Ca_2CoO_3]_{0.62}[CoO_2]$ in detail. The formation mechanism of thermoelectric $[Ca_2CoO_3]_{0.62}[CoO_2]$ (CCO) on β-$Co(OH)_2$ templates with maintained orientations was investigated by identifying the intermediate phases and specifying the relationship between their crystallographic orientations. β-$Co(OH)_2$ templates were mixed with the complementary reactant $CaCo_3$ and a compact was prepared by tape casting, with the developed (001) plane of the templates aligned along the casting plane. High-temperature XRD of the compact revealed that β-$Co(OH)_2$ decomposed into Co_3O_4 by 873 K, and Co_3O_4 reacted with CaO to form CCO by 1193 K via the formation of the newly detected intermediate phase β-Na_xCoO_2-type Ca_xCoO_2 at 913–973 K. Pole figure measurements and SEM and TEM observations revealed that the relationship between the crystallographic planes was (001) β-$Co(OH)_2$ parallel to the {111} plane of Co_3O_4 that is parallel to the (001) plane of (001) CCO. The crystal structures of the four materials possess the common CoO layer (or similar), which is composed of edge-sharing CoO_6 octahedra, parallel to the planes. The cross-sectional HRTEM analysis of an incompletely reacted specimen showed

transient lattice images from Ca_xCoO_2 into CCO, in which every other CoO_2 layer of Ca_xCoO_2 was preserved. Thus, it was demonstrated that a textured CCO ceramic is produced through a series of in situ topotactic conversion reactions with a preserved CoO_2 layer as its template.

The cobaltite, $Ca_3Co_4O_{9+\delta}$ has shown a large thermoelectric effect and is considered to be a good candidate for use as a thermoelectric material. The composition of $Ca_3Co_4O_{9+\delta}$ is better expressed as $[Ca_2CoO_3][CoO_2]_{b1/b2}$ with the misfit-layered structure featuring different periodicities along the *b*-axis, with b1 referring to the *b*-axis length of the NaCl-type $[Ca_2CoO_3]$ sublattice and b2 referring to the *b*-axis length of the $[CoO_2]$ sublattice. The crystal structure of $Ca_3Co_4O_{9+\delta}$ can be viewed as being of two subsystems, i.e. the distorted NaCl-type Ca_2CoO_3 sublattice and the CdI_2-type $[CoO_2]$ sublattice, alternately stacked along the *c*-axis. In this paper, measurements of the electrical resistivity and Seebeck coefficient for a series of misfit-layered oxides, $Ca_3Co_yO_{9+\delta}$ (where $y = 4$–6), prepared by solid-state reaction, were reported. Structural parameters are refined with the superspace group X2/m(0b0)s0 using powder XRD data. With partial substitution of Si^{4+} for Co^{3+}, the resistivity decreases, while the thermopower increases simultaneously. These results indicate that partial substitution of Si^{4+} improves the thermoelectric characteristics of $Ca_3Co_4O_{9+\delta}$.

The compound, Ca_3CoO_4, has also been reported. It was prepared by reacting Ca metal with Co(2-methoxyethoxide) in 2-methoxyethanol. The resulting clear solution was carefully hydrolyzed with water to obtain a sol. The sol was dried and pyrolyzed at 400 °C to obtain a moisture sensitive powder that showed diffraction peaks due to $CaCO_3$ perhaps due to reaction with atmospheric CO_2. Further sintering at 800 °C furnished crystalline Ca_3CoO_4. However, no further description of this compound has appeared in the current literature.

In the Co^{3+}-containing system of CaO–Co_2O_3, the crystal structure and transport properties of the quasi one-dimensional (1D) cobalt oxide $CaCo_2O_4$ was studied. The $CaCo_2O_4$ phase crystallizes in calcium-ferrite type structure shown in Fig. 13.10.

The structure of $CaCo_2O_4$ belongs to an orthorhombic system (space group: *Pnma*) with lattice parameters, $a = 8.789$ Å, $b = 2.9006$ Å and $c = 10.282$ Å. A Curie–Weiss-like behavior in magnetic susceptibility was seen with the nearly trivalent cobalt low-spin state (Co^{3+}, 3d t_{2g}^6, $S = 0$). A semiconductor-like temperature dependence of resistivity ($p = 3 \times 10^{-1}\ \Omega$ cm at 380 K) with dominant hopping conduction at low temperature, metallic-temperature-dependent large thermoelectric power (Seebeck coefficient: $S = +147\ \mu V/K$ at 380 K), and Schottky-type specific heat with a small

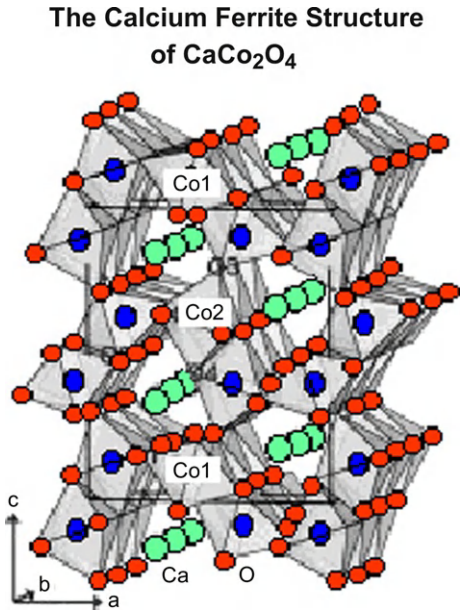

FIGURE 13.10

Sommerfeld constant ($\gamma = 4.48$ mJ/Co mol K^2), were also observed. These results suggested that the compound possesses a metallic electronic state with a small density of states at the Fermi level. The doped holes are localized at low temperatures due to disorder in the crystal. The carriers probably originate from slight off-stoichiometry of the phase. It was also found that *S* tends to increase even more beyond 380 K. The large *S* is possibly attributed to residual spin entropy and orbital degeneracy coupled with charges by strong electron correlation in the cobalt oxides.

Electrospinning is a well-established method for synthesizing micro-dimensional and 1D fibers from a large variety of precursor solutions. Initially, research focused on the production of polymer nanofibers. However, in recent years, a large variety of oxide ceramics have been produced through electrospinning of sol–gel systems. In one study, polycrystalline calcium cobaltite ($Ca_3Co_4O_9$) fibers of diameter 30–100 nm were electrospun from sol–gels based on a novel combination of polyvinyl alcohol, cobalt acetate and calcium acetate precursors. XRD data have showed that, at calcination temperatures of between 250 and 500 °C, metastable CoO and $CaCO_3$ exist as transition phases and that subsequent heating at 650 °C converted these phases to calcium cobaltite. Thermal analysis has confirmed this staged calcination mechanism and also revealed the effect of oxygen starvation on the final structures. Microscopic analysis confirmed the highly crystalline nature of the oxide fibers, and the presence of highly faceted grains, around 20–40 nm in thickness. These are the primary building blocks in these fibers.

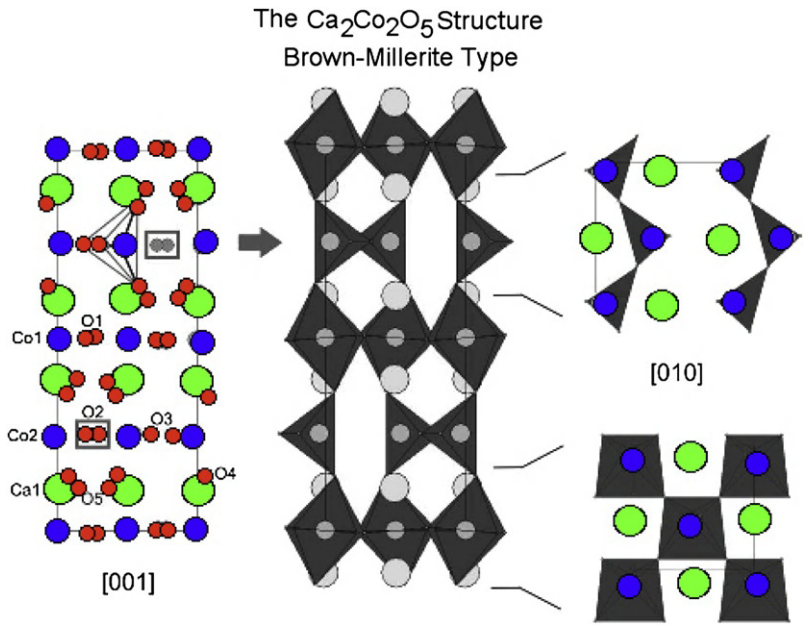

FIGURE 13.11

Furthermore, the material will only exist in fibrous form if calcination is a staged process, rather than a single, high-temperature process. Bulk calcium cobalt oxide is regarded as a competitive thermoelectric material due to its structural complexities associated with a layered structure. Microscopic analysis has shown that this layered structure is preserved when the electrospun nanostructured form is preserved. The measured thermopower in these nanostructures is at least 30% higher than that reported from bulk material at 300 K.

The Co^{3+}-containing compound, $Ca_2Co_2O_5$, has the Brownmillerite type of structure, as shown in Fig. 13.11.

A well-crystallized epitaxial $Ca_2Co_2O_5$ thin film was deposited on a $NdGaO_3$ substrate by the pulsed laser deposition technique. Its average Brownmillerite structure (space group: *Ibm*2 with $a \approx a_p\ 2$, $b \approx 4a_p$ and $c \approx a_p\ 2$) has been determined by direct methods using precession electron diffraction data recorded on a cross-sectional sample.

This compound can also be synthesized by a CP (chemical precipitation) method plus SPS (spark plasma sintering) using cobalt and calcium nitrates as starting materials and sodium hydroxide as a precipitant. Single-phase $Ca_2Co_2O_5$ ceramics can be obtained by SPS at 800 °C for 5 min using the precursor powders calcined at 700–850 °C for 2 h. It is critical to obtain stochiometric precursor by controlling the final pH 13.2 during the CP process. The SPS process is effective in obtaining single-phase $Ca_2Co_2O_5$ ceramics. The thermoelectric properties of the prepared sample were investigated from 100 to 700 °C. At 700 °C, the electrical resistivity, Seebeck coefficient, thermal conductivity and figure of merit of the sample were 9.30×10^{55} Ω/m, 178 μV/K, 1.55 W/mK and 0.21, respectively.

Textured Bi-substituted $Ca_2Co_2O_5$ ceramics have been prepared using a CP method combined with SPS. The Bi substitution is effective in increasing the grain orientation of the $Ca_2Co_2O_5$-based ceramics (from 0.46 to 0.85). Electrical conductivity increases obviously with partial substitution of Bi^{3+} for Ca^{2+} (from 113.9 to 142.4 S/cm at 973 K). The $Ca_{1.92}Bi_{0.08}Co_2O_5$ sample exhibits higher power factor (4.4×10^{-4} W m^{-1} K^{-2}) than that of pure $Ca_2Co_2O_5$ (3.2×10^{-4} W m^{-1} K^{-2}) at 973 K, indicating that the $Ca_2Co_2O_5$ system is another promising *p*-type material for high-temperature thermoelectric applications.

The electrochemical performance of mixed oxides, $Ca_2Fe_2O_5$ and $Ca_2Co_2O_5$ for use in Li-ion batteries was studied in lithium-batteries with Li as the counter electrode. The compounds were prepared and characterized by XRD and SEM. $Ca_2Fe_2O_5$ showed a reversible capacity of 226 mAh/g at the 14th cycle and retained 183 mAh/g at the end of 50 cycles at 60 mA/g in the voltage window 0.005–2.5 V. A reversible capacity in the range, 365–380 mAh/g, which is stable up to 50 charge–discharge cycles is exhibited by $Ca_2Co_2O_5$ in the voltage window, 0.005–3.0 V and at 60 mA/g. This corresponds to recyclable moles of Li of 3.9 ± 0.1 (theoretical: 4.0). Significant improvement in the cycling performance and attainable reversible capacity were noted for $Ca_2Co_2O_5$ on cycling to an upper cutoff voltage of 3.0 V as compared to 2.5 V. Coulombic efficiency for

both compounds is >98%. Electrochemical impedance spectroscopy data clearly indicate the reversible formation/decomposition of polymeric surface film on the electrode surface of $Ca_2Co_2O_5$ in the voltage window, 0.005–3.0 V. Cyclic voltammetry results compliment the galvanostatic cycling data.

When a molten salt method was used to synthesize $Ca_2Co_2O_5$ powder, using Co_3O_4 and $CaCO_3$ as raw materials and $CaCO_3$–$CaCl_2$ as a eutectic salt, the resultant was a ceramic exhibiting the highest thermoelectric behavior ever recorded. The formation process of $Ca_2Co_2O_5$, via molten salt mechanisms, was further investigated by powder XRD and SEM techniques. The results showed that sheet-like particles can be obtained at 963 K. The electrical conductivity and the Seebeck coefficient of the specimen were measured from 323 to 963 K. The measured properties increased with increasing temperature and the highest value of power factor (2.0×10^{-4} W/m/K^2) was obtained at 963 K. This indicates that molten salt synthesis is a promising method to prepare high temperature, high thermoelectric performance materials.

The Co^{3+}-containing compound, $Ca_3Co_2O_6$ is also known. A polycrystalline sample of $Ca_3Co_2O_6$ was prepared by solid-state reaction of $CaCO_3$ and Co_3O_4 at 1243 K in air. The electrical resistivity (γ) of $Ca_3Co_2O_6$ exhibited semiconducting behavior and ranged from 1.6×10^2 to 1.3×10^{-1} Ω/cm at temperatures from 400 to 1170 K. The Seebeck coefficient (S) showed a positive value, and decreased from 660 to 140 μV/K with increasing temperature from 350 to 1170 K. The power factor (S^2/p) tended to increase with increasing temperature, and the maximum value was 1.6×10^{-5} W/(m/K^2) at 1150 K. It has the structure shown in Fig. 13.12.

This diagram shows (a) the $Ca_3Co_2O_6$ hexagonal cell, octahedral Co(I) and trigonal Co(II) sites are shown in light and dark blue, respectively; (b) proposed magnetic exchange pattern between the Co(II) sites; (c)a sketch showing one possible arrangement of the normalized Co(II) magnetic moments in the incommensurate magnetic ground state (μ\\c-axis, shown vertical).

$Ca_3Co_2O_6$ is a very interesting system, characterized by low-dimensional magnetism and topological frustration. The diagram shows the crystallographic structure of the compound is made up of chains of face-sharing polyhedra running along the c-axis, arranged in the ab-plane on a triangular lattice. Due to local symmetry, one half of the Co ions have a magnetic moment (Co(II), μ ~ 5.1 μbar), subject to (antiferro-)ferromagnetic (inter-)intrachain interactions. In this sketch, magnetic sites are located at the center of dark blue polyhedra, representing oxygen cages with trigonal prismatic (TP) coordination. This novel 1D cobaltate, $Ca_3Co_2O_6$, is not a ferromagnetic (FM) half metal but a Mott insulator. Both the octahedral and the trigonal Co ions are formally trivalent, with the octahedral being in the low-spin and the trigonal in the high-spin state. The inclusion of the spin-orbit coupling leads to the occupation of the minority-spin d^2 orbital for the unusually coordinated trigonal Co, producing a giant orbital moment (1.57 μbar). It also results in an anomalously large magneto-crystalline anisotropy (of order 70 meV), elucidating why the magnetism is highly Ising like. The crystal structure of $Ca_3Co_2O_6$ (space group = $R3c$) shown above is highly anisotropic. Along the c-axis, there are chains of alternating CoO_6 TPs and CoO_6 octahedra with a Co–Co spacing of 2.59 Å. In the ab-plane, the CoO_6 chains are arranged in a triangular lattice with a Co–Co separation of 5.24 Å, double that found along the chains. Both the cobalt ions are trivalent with alternate high-spin ($S = 2$) and low-spin ($S = 0$) states

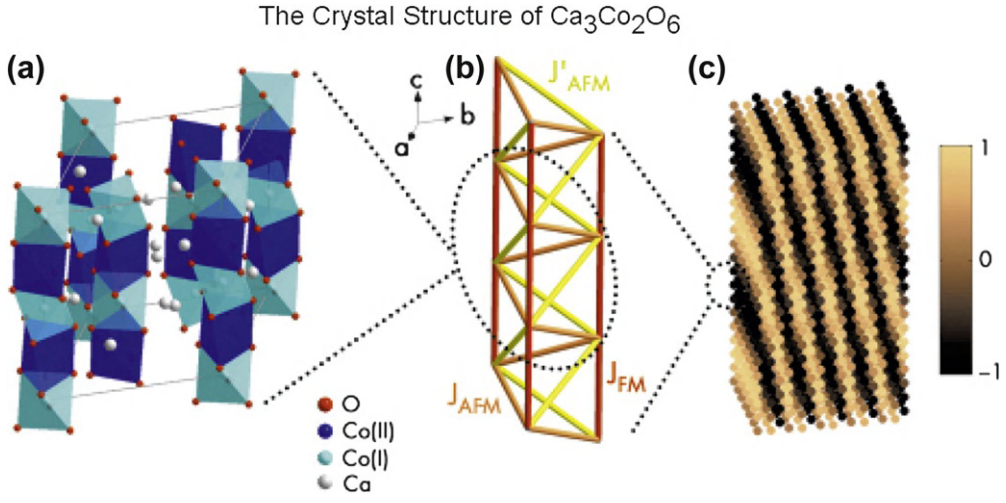

FIGURE 13.12

corresponding to the CoO_6 TPs and the octahedra, respectively. The intrachain coupling is FM while the interchain coupling is antiferromagnetic (AFM). At low temperatures (~8 K), a series of equally spaced steps emerge in the magnetization when a magnetic field is applied along the *c*-axis. Magnetization steps have been observed at 0 T, 1.2 T, 2.4 T, 3.6 T, with possible steps at the higher fields of 4.8 T and 6 T. When the temperature is increased to an intermediate value (~10 K), only the 3.6 T step remains. The hysteresis in the magnetization as a function of magnetic field is then greatly reduced. At these temperatures, the magnetization is saturated above 3.6 T with a value of $M_{Sat} = 5.1$ μbar/f.u, indicating complete FM ordering. Below 3.6 T, the value of the magnetization is $M_{sat}/3$. This latter value is ascribed to two-thirds of the chains having spin up and one-third having spin down.

$Ca_3Co_2O_6$ has been the focus of considerable experimental and theoretical attention due to its peculiar magnetic properties for several years. Below the Neel temperature ($T_N \sim 25$ K), 3D long-range magnetic order is established. At low temperature, an unexpected evolution of the magnetic order parameter versus both temperature and magnetic field has been observed. In particular, diffracted intensities corresponding to antiferromagnetic (AFM) reflections decrease on cooling below 17 K, while the bulk magnetization increases in a series of equally spaced steps versus the magnetic field, instead of smoothly approaching its saturation value. Depending on external conditions, the relaxation of the magnetization toward its equilibrium state can also be dramatically modified. Magnetic ordering occurs below 24 ± 2 K. Above 80 K, the Curie–Weiss law is followed and an effective magnetic moment of 5.7 ± 0.2 μbar was found. $Ca_3Co_2O_6$ is ferrimagnetic at low temperatures, with FM ordering dominating within the Co···O chains. In high magnetic fields, above around 2.7 MA/m, a field-induced transition from ferrimagnetic to FM structure occurs, implying turning of the spins in one of the chains.

In another paper, the magnetic coupling between quasi 1D FM chains in $Ca_3Co_2O_6$ oxide was studied using magnetic measurements under hydrostatic pressures (*P*) up to 12 kbar. It was found that the low-temperature ferrimagnetic phase, resulting from the AFM coupling of FM chains, was stabilized under pressure. Both the critical field for the spin-flip transition of the linear chains (H_{SF}) and the temperature T^* where the long-range ferrimagnetic ordering sets in rise under pressure with the following rates: $dH_{SF}/dP \approx 135$–155 Oe/kbar and $dT^*/dP \approx 0.073$ K/kbar, respectively. It was shown that these variations can be accurately described in terms of the interchain bond-length compression.

In the $Ca_3Co_2O_6$ compound, it has been found that it is an ising magnetic system on a triangular lattice. This compound is isostructural to $Sr_4PtO_{6.9}$, a structure related to the hexagonal perovskites (PVs). The "-A-B-A-B-" hexagonal stacking of the $[AO_3]$ layers yields the 2H hexagonal PV of the $A_3B_3O_9$ formula. This stacking mode creates octahedral crystallographic sites that are occupied by B cations, leading to the oxygen stoichiometric 2H-$BaCoO_3$ compound. By considering an A_3O_9 unit obtained by tripling the $[AO_3]$ layer and also by the removal of three oxygen anions, an A_3O_6 layer can also be built. So, in addition to the octahedral site created by the stacking of A_3O_9 units, the stacking of the A_3O_6 units generates a TP site occupied by a A′ cation. Finally, by mixing of the $[A_3O_9]$ and $[A_3A'O_6]$ blocks, a large family of oxides with general formula $A_{3n+3}mA'nB_{3m+n}O_{9m+6n}$ can be described. There, the ratio between the $[A_3A'O_6]$ and $[A_3O_9]$ blocks is given by $n/m \cdot 10$. For these compounds, the unit cell $a \approx 10$ Å corresponds to $\sim a_h\sqrt{3}$, where a_h is the hexagonal *a* parameter. Along the *c*–*b*-axis, the structures can be described as chains of face-shared octahedra and TPs, occupied by the B and A_h cations, respectively. This is consistent with the needlelike aspect of the crystals.

In the Co^{2+}–Co^{3+}-containing system, i.e. CaO–Co_3O_4, three misfit layer compounds with the same chemical formula $Ca_3Co_{4-x}O_{9-\partial}$ have been isolated. They exhibit either a monoclinic or an orthorhombic symmetry. These crystals are constituted of two interpenetrating Co sublattices showing incommensurate periods along the *b*-axis. The structure of the three crystals can be described as an alternate stacking along [001] of distorted rock salt-type slabs $[Ca_2CoO_3]$ and of $[CoO_2]$ layers displaying a distorted CdI_2-type structure. Relating to the symmetry and the different observed *c* periods, different sequences are found for the $[CoO_2]$ layers running along [001] within the three crystals. Two of them were determined by single XRD using the four-dimensional (4D) superspace formalism. A significant displacement modulation is implied, acting mainly on Ca and O atoms involved in the intersystem bonding scheme. This modulation leads to a noticeable distortion of the CoO_6 octahedra of the $[CoO_2]$ layers. Strong interactions, via Ca–O bonds, are evidenced between the two sublattices. A systematic positional disorder is observed inside the [CoO] layer.

Single crystals of $(Ca_2CoO_3)_{0.7}CoO_2$ with a $Ca_3Co_4O_9$ structure were grown using a modified strontium chloride flux technique, and their electrical and thermal properties were determined. Growth conditions were established for obtaining plate-like single crystals of a relatively large size ($5 \times 10 \times 0.05 \times$ mm^3). At 973 K, thermoelectric power *S* and electrical resistivity ρ of the specimens are ≈ 240 μV/K and $\approx 2.3 \times 10^{-5}$ Ωm, respectively, and their thermal conductivity κ is nearly 3 Wm^1/K, as determined by mathematical extrapolation. The figure of merit $Z_T = S^2T/\rho\kappa$ derived there

was ≈0.87 at 973 K. The relatively low κ is likely the result of a misfit structure between the CoO_2 layer and the Ca_2CoO_3 slab.

The compound, $Ca_2Co_3O_6$, has been mentioned in regard to its magnetic properties relative to $Ca_3Co_2O_6$. This dicalcium compound also has a low-temperature ferrimagnetic phase, resulting from the AFM coupling of FM chains, by stabilization under pressure. Both, the critical field for the spin-flip transition of the linear chains (H_{SF}), and the temperature T^* where the long-range ferrimagnetic ordering sets in rise under pressure, were determined. The compound $Ca_2Co_3O_6$ is a quasi 1D magnetic system made up of spins aligned in chains. Due to the weak AFM interaction between FM chains, it exhibits a 3D transition at low temperatures. This compound adopts a spinel-like structure.

In the Co^{4+}-containing system of CaO–CoO_2, the preparation of $CaCoO_3$ via solid-state methods has not been successful, under ambient or high-pressure conditions. However, the defect material, $SrCoO_{3-\geq}$ is a FM oxide with the cubic PV crystal structure, which can be prepared under high oxygen pressure.

The energy gap of any given PV is usually less than 3.0 eV. Many show good photocatalytic activity in the visible light region and can be used as a photocatalytic agent. In one paper, a PV-type oxide $CaCoO_3$, stable in solution, was prepared by citric complexometry. Photocatalytic degradation experiments, using the $CaCoO_3$ to dispose of a water-soluble dye, were carried out. The conditions of photocatalytic degradation such as photocatalytic time, amount of photocatalyst, the illumination intensity, pH value and additional oxidant (H_2O_2) on photocatalysis were also studied in the research. The results showed that $CaCoO_3$ has a significant photocatalysis-decolorizing effect on the acid red dye. When the concentration of the catalyst is 4 gm/l, the reaction time was 180 min, pH value was 2, the illumination intensity was 60 W, with the dosage of 10% H_2O_2 at 50 ml/l. The degradation ratio of the acid red dye was 97.2%.

No other compounds are known in this system.

In the Co^{5+}-containing system of CaO–Co_2O_5, the compound, $CaCo_2O_6$, has been studied briefly. Hopping conductivity in 1D $CaCo_2O_6$ single crystals (published 2002), with a chain-like structure, has been found to be lower than other similar compounds but no further work has been undertaken.

In the Co^{6+}-containing system of CaO–CoO_3, the results of three-dimensional (3D) numerical simulation of the magnetic structure and magnetization curves of $Ca_3Co_2O_6$ have been presented. The structures of the low-temperature and high-temperature phases differ significantly: the false frustrated low-temperature phase is transformed into a partially disordered AFM honeycomb structure. Two additional magnetization steps at low temperatures are formed at the expense of the domain structure and the ferrimagnetic phase. All fundamental hypotheses used in terms of the 2D model have found their confirmation during the 3D simulation.

No other compounds have been documented.

Calcium cobaltate or cobaltite compounds are not offered for sale commercially nor is a CAS number available.

13.1.4. Strontium Cobalt Compounds

Strontium does not form any intermetallic compounds with Co metal.

In the Co^{2+}-containing system of SrO–CoO, the compound, $SrCoO_2$ is not very stable at room temperature. The existence of gaseous cobaltates of alkaline earth metals has been established by high-temperature mass spectrometry. Gaseous molecules: $CaCoO_2$, $SrCoO_2$ and $BaCoO_2$ have been found for the first time. On the basis of the measured constants of the equilibrium of gas-phase reactions the standard enthalpies of formation: (-149 ± 19) $kJ \cdot mol^{-1}$, (-149 ± 20) kJ/mol and (-250 ± 16) kJ/mol; standard atomization enthalpies obtained were: (1251 ± 22) kJ/mol, (1233 ± 23) kJ/mol and (1353 ± 20) kJ/mol for $CaCoO_2$, $SrCoO_2$ and $BaCoO_2$, respectively.

A study of the Sr···Co···O system concerning Sr_2CoO_3 has allowed the isolation of a new layered cobaltite $[Sr_2CoO_3][CoO_2]_{1.8}$. It was noted that the Co^{3+} ion is present. The structural analysis by transmission electron microscopy shows a composite structure consisting in two substructures related to triple rock salt-type layers and single CdI_2-type layer, respectively. The structure of this compound is similar to that of the well-known misfit cobaltite $[Ca_2CoO_3][CoO_2]_{1.62}$, also called "$Ca_3Co_4O_9$". The latter is intensively studied for thermoelectric power application to convert waste heat energy into electricity at temperature well above 300 K. A large thermoelectric power is also found for this new cobaltite $[Sr_2CoO_3][CoO_2]_{1.8}$, which exhibits a Seebeck coefficient such as $S_{300\ K} \approx 110\ \mu V/K$. This value, lower than that of $[Ca_2CoO_3][CoO_2]_{1.62}$ ($S_{300\ K} \approx 125\ \mu V/K$), shows that the misfit character, quantified by the ratio $b_1/b_2 = 1.8$ and 1.62 for the "Sr-" and "Ca-" based misfit cobaltites, respectively, is directly connected to the thermoelectric properties in these materials.

The stoichiometric compound, Sr_2CoO_3, is not very stable but the alternative strontium-defect compound has been observed. The incommensurate modulated crystal structure of the hexagonal cobalt oxide $Sr_{1.261}CoO_3$ has been studied using a 4D superspace profile analysis of neutron powder diffraction (NPD) data. $Sr_{1.261}CoO_3$ is a composite crystal that consists of $[CoO_3]$ and [2Sr] subsystems. The $[CoO_3]$ subsystem

forms 1D chains that run parallel to the *c*-axis and consist of face-sharing CoO_6 polyhedra with octahedral (O_h) and TP coordinations. The structure analysis reveals that the [CoO_3] chains contain 73.9% O_h and 26.1% TP sites, and that the TP sites have longer Co–O bonds than the O_h sites: $d_{av} = 2.039$ Å (TP) and 1.895 Å (O_h). The averaged Co bond valences are $Co^{3.56+}$ in the O_h sites and $Co^{2.45+}$ in the TP sites, suggesting that a considerable amount of Co^{3+} ions are mixed with Co^{4+}ions in the O_h sites and with Co^{2+} ions in the TP sites. The observed magnetic susceptibility can be well explained assuming that the compound has the Co mixed valence state with the spin configurations of $S = 0$ low-spin state for $Co^{3+}(d^6)$, $S = 1/2$ low-spin state for $Co^{4+}(d^5)$ and $S = 3/2$ high-spin state for $Co^{2+}(d^4s^2)$. The Weiss temperature, approximately 0.8 K, implies that $Sr_{1.261}CoO_3$ naturally assumes a Curie paramagnetic state, probably owing to the obstruction of the intrachain magnetic interaction by the nonmagnetic Co^{3+} ions. These results suggest that the nonmagnetic Co^{3+} ions play an essential role in the magnetism of $Sr_{2-\delta}CoO_3$ systems.

No other compounds are known in this system.

In the Co^{3+}-containing system of SrO–Co_2O_3, the geometric and electronic properties of $SrCoO_{2.5}$ ($Sr_2Co_2O_5$) have been studied using the local-spin density approximation together with the Hubbard method. The geometric optimization shows that the energy of a unit supercell for $SrCoO_{2.5}$ with the space group *Pnma* is at least 1.37 eV lower than the others, so we infer that the *Pnma* structure is the ground state of $SrCoO_{2.5}$ at low temperature. The electronic band structure calculations demonstrate that the paramagnetic ordering $SrCoO_{2.5}$ at high temperature has the character of an indirect band gap semiconductor, while the AFM ordering $SrCoO_{2.5}$ at low temperature has the character of a conductor. The magnetism calculation shows that the magnetic moment of Co is 2.96 μbar, comparable with the experimental measurement at the liquid nitrogen temperature, i.e. 3.30 ± 0.5 μbar.

This compound ($Sr_2Co_2O_5$) has the Brownmillerite-type of structure as determined by NPD measurements at temperatures ranging from 10 to 623 K, across the Néel temperature ($T_N = 537$ K) of this AFM oxide. The study was complemented with differential scanning calorimeter (DSC), DC susceptibility and magnetization measurements. Although the refinement of the crystal structure from NPD data was possible in the orthorhombic *Pnma* and *Ima*2 space groups, the support of ab initio band structure calculations has allowed the selection, without ambiguity, of the *Ima*2 space group as the ground state for $SrCoO_{2.5}$ Brownmillerite structure. In *Ima*2 the crystallographic structure of $SrCoO_{2.5}$ can be described as layers of corner-sharing CoO_6(1) octahedra alternating along the *a*-axis, with layers of vertex-sharing CoO_4(2) tetrahedra, and conforming chains running along the [0,0,1] direction. The magnetic structure below $T_N = 537$ K was determined to be *G*-type with the magnetic moments directed along the *c*-axis. This magnetic arrangement is stable from T_N down to 10 K. At $T = 10$ K, the magnetic moment values for Co1 and Co2 atoms are 3.12(13) μbar and 2.88(14) μbar, respectively, compatible with a $Co^{2+}L①$ state, where L① stands for a ligand hole. The magnetic susceptibility curves show, below 200 K, a divergence of zero-field cooling and field cooling curves, displaying broad maxima which are interpreted as due to the presence of FM clusters embedded into an AFM matrix. This inhomogeneity is inherent to the synthesis process, where, by quenching microcrystalline samples of the $SrCoO_{3-x}$ composition from high temperature, cubic, FM PVs have been identified by diffraction methods.

The electrochemical oxidation of the antiferromagnetically ordered $SrCoO_{2.5}$, with Brownmillerite-type structure, to the cubic ferromagnet $SrCoO_3$, with PV structure, has been investigated in situ by NPD as well as by XAFS spectroscopy, in specially designed electrochemical cells as a function of the charge transfer. One mechanism proffered is shown in Fig. 13.13.

For fuel cells, the operating temperatures are usually about 1000 °C. Under such extreme conditions the mechanical and thermal stability of electrodes are significantly limited. One of the very few exceptions is the $SrCoO_{2.5}$ system, which can be electrochemically oxidized via a reversible topotactic redox reaction, in an aqueous alkaline electrolyte at room temperature, yielding $SrCoO_{3.0}$ as the final reaction product. The reaction can formally be described by:

$$SrCoO_{2.5} + xO^{2-} \Rightarrow SrCoO_{2.5+x} + 2xe^- \quad (0 < x < 0.5)$$

The Co is purely Co^{3+} for the starting compound whereas Co^{4+} is achieved for the final reaction product. From NPD experiments, two intermediate phases, $SrCoO_{2.75}$ and $SrCoO_{2.82}$, have been characterized. Superstructure reflections have been observed for the $SrCoO_{2.82}$ phase only. To investigate the true symmetry of the intermediate phase, an electrochemically prepared sample of $SrCoO_{2.82}$ has been measured ex

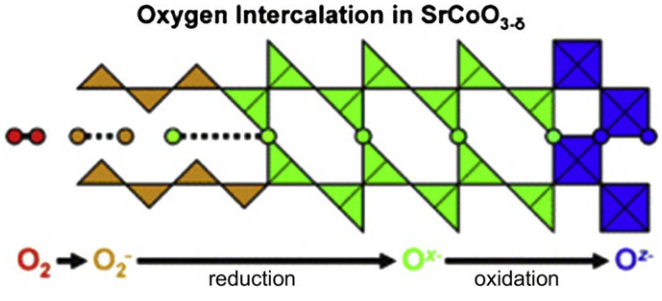

FIGURE 13.13

situ on the high-resolution powder diffractometer at beam line **BM01B**. It was found that reflections, indexed in the averaged cubic PV cell as (h00) or (hh0), are clearly separated into two distinct diffraction peaks, whereas (hhh) reflections were unique, where the profiles of (111), (200), (220) reflections are reported and compared with that of the cubic $SrCoO_3$ PV. This combined NPD and X-ray powder diffraction (XRPD) study represents the first observation of 3D oxygen ordering during an oxygen intercalation reaction. The $SrCoO_{2.82}$ phase can be described as being in a tetragonal unit cell, related to the PV cell by $a = b = 2a\sqrt{2}$ and $c = 2a$. The structure of this intermediate phase confirms the strongly topotactic character of the oxygen intercalation reaction. Overall, the first part of the reaction covers the continuous formation from $SrCoO_{2.5}$ to $SrCoO_{2.7}$ while the second starts from $SrCoO_{2.8}$ to give the fully oxidized $SrCoO_3$ phase. Around $SrCoO_{2.75\pm0.05}$, a plateau is observed leading to the assumption that around this charge transfer a "stand-by" of the Co oxidation takes place.

Temperature-dependent XRD and NPD have been exploited, in complement with DTA–TGA, conductivity and thermal expansion measurements, to revisit the structural evolution of $SrCoO_{2.5}$ Brownmillerite-like phases from room temperature to 1200 °C (Fig. 13.14).

Three different polymorphs have been identified: the orthorhombic "O" Brownmillerite phase between room temperature and 653 °C, the hexagonal "H" phase between 653 and 920 °C, and the cubic PV "C" above 920 °C, which is transformed again, by cooling, into the "H" phase at 774 °C. The metastable "O" Brownmillerite phase can only be obtained by quenching in liquid N_2 from 1000 °C. The refinement of the crystal and magnetic structures of $SrCoO_{2.5}$ from NPD data collected "in situ" as a function of temperature in an air atmosphere led to define structural details of the very distinct coordination polyhedra present in the different polymorphs, which have been correlated with the transport properties. The conductivity shows little dependence up to 250 °C, and it abruptly increases above this temperature, which is concomitant with a contraction of the Co_2–O_3 bonds of the tetrahedral CoO_4 units of the "O" Brownmillerite structure at 350 °C, suggesting the presence of an insulator-to-metal transition in this structural polymorph. The dramatic reduction of conductivity above 500 °C is connected with the transformation to the "H" polymorph, with a complete oxygen sublattice and a face-sharing octahedral framework with a poor 1D electronic conduction. Further heating above 900 °C boosts again the conductivity when the sample is entering the cubic PV region, characterized by a 3D vertex-sharing network of CoO_6 octahedra. The total conductivity displays a maximum value of 150 S/cm at 900 °C and it increases during the cooling run, thus displaying a characteristic metallic

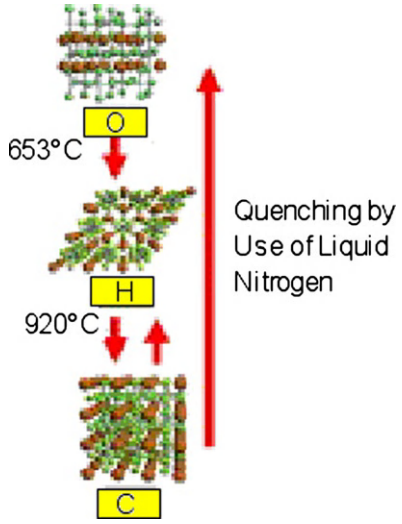

FIGURE 13.14

behavior for the "C" phase. This polymorph presents conductivity values substantially above the required 100 S/cm in solid oxide fuel cells (SOFCs), suggesting that it is a good candidate for cathode materials in energy conversion devices.

In another study, three very distinct polymorphs of overall stoichiometry $SrCoO_{2.5}$ were identified in the temperature range 25–1200 °C, starting from the "O" Brownmillerite phase previously obtained by quenching in liquid N_2 from 1000 °C. A metal–insulator transition was detected in the "O" phase, correlated to subtle structural changes. A drop of conductivity associated to the "H" hexagonal polymorph was followed by a huge increase of σ when entering the cubic "C" phase. These transformations can be seen in Fig. 13.14.

The phase separation and inhomogeneities induced by oxygen non-stoichiometry in $SrCoO_{2.5+x}$ have been examined more thoroughly. In previous work, it has been shown that as oxygen is driven into the $SrCoO_{2.5}$ electrochemically, the material structurally separates into two different phases: one is AFM $SrCoO_{2.5}$, and the other is FM $SrCoO_{2.75}$.

A recent (2010) paper shows that two distinct FM phases appear for $SrCoO_{2.88}$ and $SrCoO_3$, with $T_c = 220$ and 280 K, respectively. These changes may perhaps be better seen in Fig. 13.15.

The phase diagram of $SrCoO_{2.5+x}$ suggests that the four magnetic line phases are the only stable ground states in the system. While AFM $SrCoO_{2.5}$ is orthorhombic, the three FM phases are pseudo-cubic and, unlike the magnetic properties, do not show the coexistence of different structures. The existence of the distinct $T_c = 220$ K and $T_c = 260$ K magnetic phases with no structural differentiation indicates the presence of magnetic phase separation.

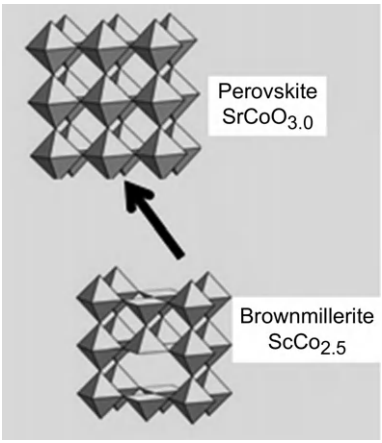

FIGURE 13.15

A dense phase of a post-layered PV $Sr_3Co_2O_6$ was created by a high-pressure and high-temperature synthetic route and quenched to ambient conditions. The structure of $Sr_3Co_2O_6$ was determined by synchrotron XRPD. $Sr_3Co_2O_6$ crystallizes in the K_4CdCl_6-type structure (an infinite chain-type structure), which is 6% denser than the known, iso-compositional layered PV $Sr_3CoO_{7-\delta}$ (δ~1). The K_4CdCl_6 type of $Sr_3Co_2O_6$ shows complex magnetic behavior reflecting the spin-chain nature as well as the analogue oxides $Ca_3Co_2O_6$ and Ca_3CoRhO_6, whose microscopic magnetic origin is still highly debated. Its structure has the form shown in Fig. 13.16.

Under normal preparation conditions, this compound exhibits oxide defects. The structural and magnetic phase diagrams of the bilayer Ruddlesden–Popper phase, $Sr_3Co_2O_x$, was extended beyond previously reported limits of $x \approx 6.1$ to $x = 6.60$. The room temperature crystal structure for the $x = 6.60$ material is orthorhombic with oxygen vacancies located in the apical position that links the two nominally CoO_2 layers

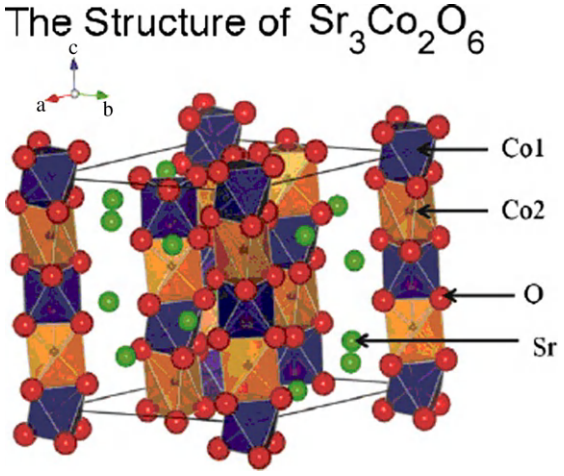

FIGURE 13.16

in the PV block. An antiferromagnetic ground state is converted to FM by moderate magnetic fields and high-temperature magnetic susceptibility data indicate short-range FM order. The oxygen defect structure of $Sr_3Co_2O_x$ in the range $5.64 < x < 5.80$ was also studied. Oxygen vacancies are present in both the in-plane sites, as well as the linking apical site. Critically, this linking site is displaced significantly along z ① from its ideal position, creating a particularly short Co–O bond. Using a combination of NPD data and crystal-chemical considerations, we provide a model of the local Co ion environments. Additionally, low-temperature NPD and magnetization data show that the magnetic ground state of these oxygen-deficient materials is a complex antiferromagnet, with considerable sensitivity to precise oxygen content.

Two low-dimensional cobaltite series in the Sr–Ca–Co–O system have been investigated for their solid solution limit, structure, and compatibility phase relationships (850 °C in air). Thermoelectric properties have been measured for selected members of these solid solutions. In $(Ca,Sr)_3Co_4O_9$, which has a misfit layered structure, Sr was found to substitute in the Ca site to a limit of $(Ca_{0.8}Sr_{0.2})_3Co_4O_9$. Compounds in the homologous series consist of 1D parallel $Co_2O_6^{6-}$ chains that are built from successive alternating face-sharing CoO_6 TPs and "n" units of CoO_6 octahedra along the hexagonal c-axis. In the $Ca_{n+2}Co_nCo'O_{3n+3}$ series, only the $n = 1$ phase ($Ca_3Co_2O_6$) could be prepared under the present synthesis conditions. Sr substitutes in the Ca site of $Ca_3Co_2O_6$ to a limit of $(Ca_{0.9}Sr_{0.1})_3Co_2O_6$. In the $Sr_{n+2}Ca_nCoO_{3n+3}$ series, Ca substitutes in the Sr site of the $n = 2$, 3, and 4 members to a limit of $(Sr_{0.7}Ca_{0.3})_4Co_3O_9$, $(Sr_{0.67}Ca_{0.33})_5Co_4O_{12}$, and $(Sr_{0.725}Ca_{0.275})_6Co_5O_{15}$, respectively. While the members of the $Ca_{n+2}Co_nCo'O_{3n+3}$ and $Sr_{n+2}Ca_nCoO_{3n+3}$ series have reasonably high Seebeck coefficients and relatively low thermal conductivity, the electrical conductivity is not capable of achieving high Z_T values.

No compounds are known in the Co^{2+}–Co^{3+}-containing system of SrO–Co_3O_4.

In the Co^{4+}-containing system of SrO–CoO_2, the compound, $SrCoO_3$ has received some attention. The magnetic ground state of cobalt PV $SrCoO_3$ is under much debate at present due to its complex magnetic properties. To shed further light on this issue, various magnetic structures of enlarged double cells have been examined. The calculation was carried out self-consistently within the unrestricted Hartree–Fock approximation and the real-space recursion method. The results showed that the magnetic ground state mainly depends on the competition between the crystal field strength Dq and Hund's coupling j. For a fixed value of j, it can be either the intermediate-spin state ($t^4_{2g}e^1_g$), the low-spin state coupled with the intermediate-spin state ferromagnetically ($t^5_{2g}e^0_g$-$t^4_{2g}e^1_g$-FM), or the low-spin state ($t^5_{2g}e^0_g$) as Dq

increases. However, the intermediate-spin state is the most probable candidate for the magnetic ground state in view of the experimental photoemission spectra and magnetic moment.

The electrical resistivity of the FM defect structure, $SrCoO_{3-\delta}$ ($0 < \delta < 0.5$) was measured in the temperature range from 77 to 300 K. All samples were good conductors and showed metallic behavior. The magnetic transition was independent of the electrical conductivity in $SrCoO_{3-\delta}$. The logarithm-specific electrical resistivities (log p) at 80 K and 300 K monotonously decreased with increasing the oxygen deficiency. This result was explained by considering the itinerant electron model.

$SrCoO_{3-\delta}$ is a material with multiple phase structures. The influence of Sc^{3+} doping in the B-site of $SrCoO_{3-\delta}$ on its lattice structure/phase stability, electrical conductivity, and cathode performance for intermediate-temperature SOFCs (IT-SOFCs) was investigated by XRD, four-probe DC conductivity and impedance spectroscopy measurements, respectively. The introduction of large size Sc^{3+} (0.745 Å) cation together with the sol–gel synthesis technique, led to a substantial stabilization of the cubic phase of $SrCoO_{3-\delta}$, even at a Sc^{3+} doping amount as low as 5 mol%. Such stabilization resulted in a sharp increase in the electrical conductivity of the material, which was found to be p-type in nature. A maximum electrical conductivity and favorable cubic phase stability of the material were reached at the Sc^{3+} doping concentration of 5–10 mol%. A further increase of Sc^{3+} doping, however, lowered the electrical conductivity due to the blocking effect of Sc^{3+} for the electron conduction. An area-specific resistance as low as 0.25 Ωcm^2 was reached at 600 °C for $SrSc_{0.1}Co_{0.9}O_{3-\delta}$ as a cathode material in IT-SOFCs, based on $Sm_{0.15}Ce_{0.85}O_{1.925}$ as the electrolyte.

Atomic resolution Z-contrast imaging and electron energy-loss spectroscopy (EELS) methods were used to study the defect structure of oxygen-deficient strontium cobaltite ($SrCoO_{3-\delta}$) after repeated oxidation/reduction cycles at elevated temperatures. Ordered microdomains were found in the reduced sample. Z-contrast imaging showed ordering in alternate CoO_2 planes, characteristic for a Brownmillerite-type vacancy ordered structure. EELS showed that the average valence state of cobalt had decreased after testing. In the tested sample, cobalt was found in +3 and +2 valence states, respectively. In addition, cobalt oxide precipitates were found at grain boundaries and in triple pockets in this sample, indicating a cobalt deficiency of the grains.

$SrCoO_{3-\delta}$ forms a PV structure with oxygen vacancies and is FM for $\delta < 0.25$. A study of polycrystalline samples has been made by controlling the oxidation state, using electrochemistry methods. Under these conditions, it was found that, magnetically, the system segregates into separate, stable phases that correspond to $SrCoO_{2.75}$ ($T_C = 165$ K), $SrCoO_{2.875}$ ($T_C = 220$ K), and $SrCoO_3$ ($T_C = 280$ K), with two-phase behavior for intermediate oxygen concentrations.

A large-size single crystal of stoichiometric $SrCoO_{3.00}$ was prepared with a two-step method combining the floating zone technique and subsequent high-oxygen pressure treatment. $SrCoO_3$ crystallizes in a cubic PV structure with space group Pm-3m, and displays an itinerant FM behavior with the Curie temperature of 305 K. The easy magnetization axis is found to be along the [111] direction, and the saturation moment is 2.5 μbar/f.u. in accord with the picture of the intermediate-spin state. The resistivity at low temperatures (T) is proportional to $T2$, indicative of the possible effect of orbital fluctuation in the intermediate spin FM metallic state. Unusual anisotropic magnetoresistance is also observed and its possible origin was discussed.

The Ruddlesden–Popper homologous series of compounds, $Sr_{n+1}Co_nO_{3n+1}$ ($n = 1$, 2, 3, 4, and ∞), were successfully synthesized by a high-pressure and high-temperature technique. Structure refinement revealed that these compounds crystallize in tetragonal structures, while the compound, $n = \infty$, is cubic. These compounds are FM with the Curie temperature decreasing from 255 K for $n = 1$ to about 200 K for $n = 2$ to 4 and down to 175 K for $SrCoO_3$. Co^{4+} ions were present as intermediate spin states for $n = 1$–4, but the low-spin state (coupled electrons) was present in $SrCoO_3$. Negative magnetoresistance was observed for Sr_2CoO_4 and found to be larger than that for $SrCoO_3$ (Fig. 13.17).

In a homologous compound, $Sr_6Co_5O_{15}$ [$=Sr_6(Co^{3+}{}_2,Co^{4+}{}_3)O_{15}$], the crystal structure of the defect compound, $Sr_6Co_5O_{14.3}$ has been analyzed by XRD of a c-axis elongated prismatic single crystal grown by a flux method. $Sr_6Co_5O_{14.3}$ is an oxygen-deficient phase of $Sr_6Co_5O_{15}$ that contains 1D columns of Co–O octahedra and triangular prisms. Oxygen defects are preferentially introduced in an O site shared by the

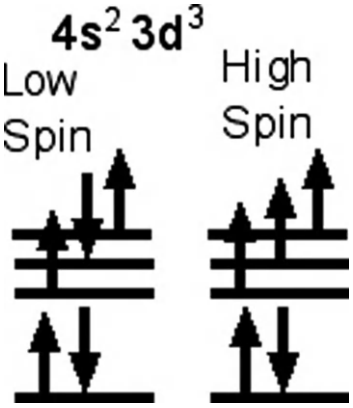

FIGURE 13.17

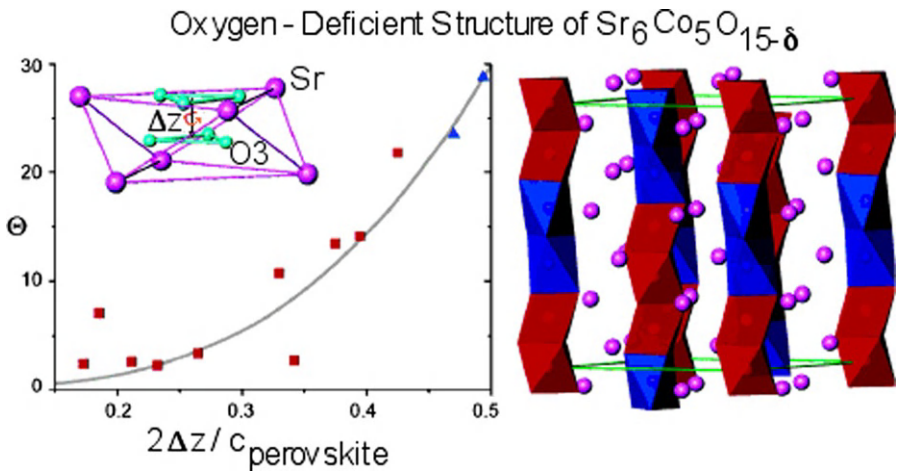

FIGURE 13.18

Co–O triangular prism and octahedron in the structure of $Sr_6Co_5O_{15}$. The average structure of $Sr_6Co_5O_{14.3}$ can be improved by splitting the oxygen defect site with the rhombohedral space group $R3$ ($a = 9.4334$ Å and $c = 12.5156$ Å).

Polycrystalline samples of $Sr_6Co_5O_{15}$ ($m = 1$, $n = 1$) and $Ca_3Co_2O_6$ ($m = 1$, $n = 0$), which are the members of homologous series $(A_3Co_2O_6)m(A'_3Co_3O_9)n$ (A, A′ = Ca, Sr, Ba), were prepared by solid-state reaction in air. The theoretical density ratios of obtained pellets, 89% for $Sr_6Co_5O_{15}$ and 95% for $Ca_3Co_2O_6$, sintered by the SPS method, increased compared to those of $Sr_6Co_5O_{15}$ (60%) and $Ca_3Co_2O_6$ (67%) prepared by solid-state reaction, respectively. Electrical resistivity (ρ) of $Sr_6Co_5O_{15}$ and $Ca_3Co_2O_6$ exhibited semiconducting behavior in the range of 300–1120 K. The temperature dependence of electrical resistivity for $Sr_6Co_5O_{15}$ showed a hysteresis-like behavior. The electrical resistivity of $Sr_6Co_5O_{15}$ (6.1×10^{22} to 4.6 Ω cm) and $Ca_3Co_2O_6$ (4.1×10^{-2} to 1.2×10^{3} Ω cm), sintered by the SPS method, was lower than those of $Sr_6Co_5O_{15}$ (1.3×10^{1} to 8.0 Ω cm) and $Ca_3Co_2O_6$ (1.5×10^{-1} to 4.5×10^{3} Ω cm) when prepared by solid-state reaction. Seebeck coefficients (S) of $Sr_6Co_5O_{15}$ and $Ca_3Co_2O_6$ were positive and were more than 100 μV/K in the range of 300–1120 K. Both compounds showed different temperature dependencies, respectively. The power factor (S^2/p) tended to increase with increasing temperature; the maximum values of the power factor were 1.4×10^{-5} W/(m K^2) for $Sr_6Co_5O_{15}$ and 1.6×10^{-5} W/(m K^2) for $Ca_3Co_2O_6$ prepared by solid-state reaction, and 3.0×10^{-5} W/(m K^2) for $Sr_6Co_5O_{15}$ and 5.2×10^{-5} W/(m K^2) for $Ca_3Co_2O_6$ sintered by the SPS method.

Two selected members of the homologous Ruddlesden–Popper series, $Sr_{n+1}Co_nO_{3n+1}$, were studied because of their potential applications as thermoelectric materials. Both the $n = 3$ member, $(Sr_{0.8}Ca_{0.2})_5Co_4O_{12}$, and the $n = 4$ member, $Sr_6Co_5O_{15}$, have distorted hexagonal PV-related structures that possess 1D cobalt oxide chains separated by alkaline earth cations. The linear chains consist of one unit of CoO_6 TP alternating with n units of CoO_6 octahedra. Crystal structures and reference powder XRD patterns of $(Sr_{0.8}Ca_{0.2})_5Co_4O_{11}$ [$P3c1$, $a =$ 9.4196(2) Å, $c = 19.9857(6)$ Å, $V = 825.83$ Å^3, and $Dx = 5.358$ g/cm^3] and $Sr_6Co_5O_{15}$ [$R32$, $a = 9.497\,64(12)$ Å, $c = 12.3956(2)$ Å, $V = 968.34$ Å^3, and $Dx = 5.455$ g/cm^3] were reported.

The structure has the form shown in Fig. 13.18. Large single crystals of oxygen-deficient $Sr_6Co_5O_{15-\delta}$ compounds, i.e. $Sr_6Co_5O_{14.70}$ and $Sr_6Co_{4.9}Ni_{0.1}O_{14.36}$, were obtained by using K_2CO_3 flux in the presence of additives of transition metal oxides.

The single-crystal structure determination showed that the structures of $Sr_6Co_5O_{14.70}$ and $Sr_6Co_{4.9}Ni_{0.1}O_{14.36}$ crystallize in the space group R and can be described as 1D face-sharing CoO_3 polyhedral chains and Sr cation chains. Unlike the other known 2H-PV-related oxides in which the polyhedral chains consist of octahedra (O_h) and TP, the structure of $Sr_6Co_5O_{14.70}$ and $Sr_6Co_{4.9}Ni_{0.1}O_{14.36}$ contains Oh and intermediate polyhedra (IP). This can be attributed to a general structure formula $A_6A'_2B_3O_\delta$, which is closely related to the known $A_6A'B_4O_{15}$ phases by shifting of a B atom and the O_3 triangle along the c-axis. Further study of the O_3 triangle revealed that this oxygen position splits into two independent positions, corresponding to polyhedral geometry of IP and TP, respectively. Therefore, the polyhedral chain in the structure should be more precisely described as a random composite of the $4O_h + TP$ and $3O_h + 2IP$. This model was used to interpret the magnetic properties, although not quantitatively. A 4D structure analysis was also conducted for both $Sr_6Co_5O_{14.70}$ and $Sr_6Co_{4.9}Ni_{0.1}O_{14.36}$ with a commensurate modulated structure in a 4D superspace group, $R_3m(00y)0s$, $\gamma = p/k = 3/5$. By considering the same 4D superspace group, $Rm(00y)0s$, but different

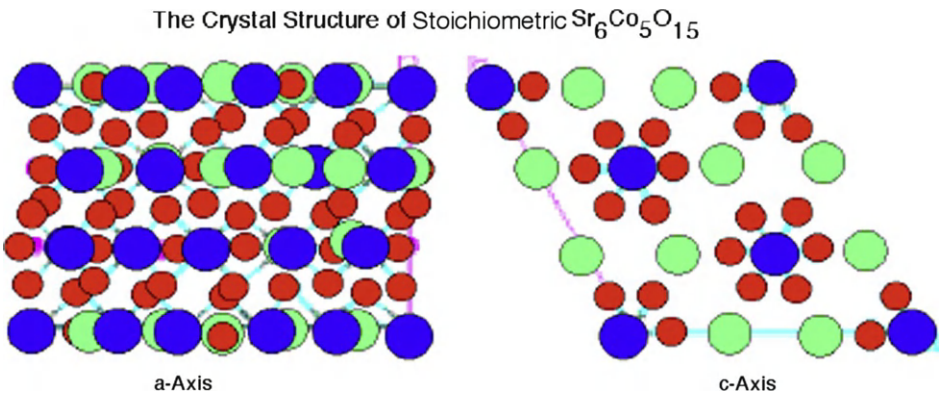

FIGURE 13.19

t-phases, one can understand the structure relationship between $Sr_6Co_5O_{14.70}$ and $Sr_6Rh_5O_{15}$.

The latter has the form shown in Fig. 13.19.

Cell parameters are: $a = b = c = 6.9282$ Å, $\alpha = \beta = \gamma = 86.859°$, cell volume $= 331.11$ Å^3, $Z = 3$. Cell occupancy is shown in Table 13.6.

A single-crystalline film of Sr_2CoO_4 with square-lattice CoO_2 sheets (K_2NiF_4-type structure) was synthesized, and its electronic properties were characterized. The compound exhibited both FM and metallic behaviors, with a fairly high Curie temperature T_C of ~250 K, in contrast to the superconductivity recently found in a triangular-lattice CoO_2-sheet compound. The film's large magnetoresistance with current perpendicular to the CoO_2 plane showed field-hysteretic behavior analogous to tunneling magnetoresistance. The electronic structure of Sr_2CoO_4 was also investigated to characterize the quasi 2D FM metal state in terms of optical spectroscopy and first principles calculation.

Two reports have confirmed that the compound, Sr_2CoO_4 (formal oxidation state Co^{4+}), showed a high Curie temperature (~250 K), but they described different magnetic moments of 1.8 and 1 μbar per Co. Using both commonly used functionalisms in the correlated band approach (designated as LDA + U) as well as the local-spin density approximation (LSDA), the combined effects of correlation and hybridization of the cobalt atom with O $2p$ states were calculated and analyzed. Sr_2CoO_2 is already FM within LSDA ($M = 1.95$ μbar). Increasing U from zero, the two LDA + U schemes affect the moment oppositely out to a critical value $U_c = 2.5$ eV. At this point they transform discontinuously from different states to the same large U state. Fixing U at Uc, spin moment calculations showed a similar behavior out to a minimum at 1 μbar (a half metallic state), beyond which the fully localized limit scheme jumps to a state with energy minimum very near 2 μbar (very close to the LSDA moment). Although the energy minima occur very near to integer values of the moment per cobalt atom (1 μbar, 2 μbar), the strong 3d-2p mixing and resulting 3d orbital occupations seem to preclude any meaningful $S = 1/2$ or $S = 1$ assignment to the Co ion.

The electronic and magnetic properties of Sr_2CoO_4 compound were further studied using ab initio electronic structure calculations. Two kinds of FM solutions: (i)

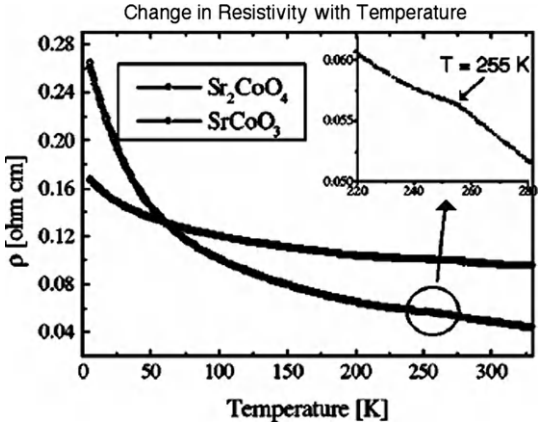

FIGURE 13.20

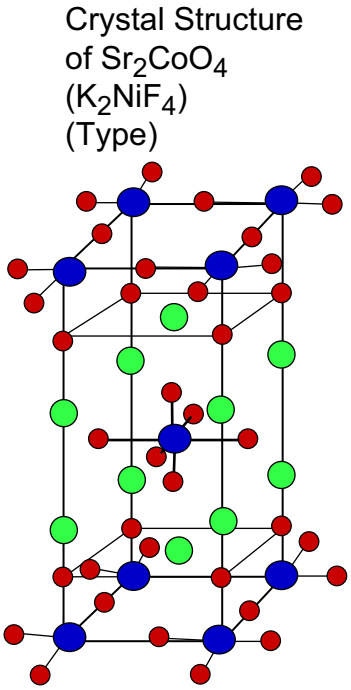

FIGURE 13.21

half-metallic and (ii) metallic were found. The half-metallic solution is a ground state of the system and the metallic one is a metastable state. The strong hybridization between Co-3d and O-2p orbitals decides the electronic and magnetic properties of the compound. The total magnetic moment per formula unit is found to be ~3 μbar ($S = 3/2$). These calculations gave the magneto-crystalline anisotropy energy of ~2.7 meV, which provides a good description of experimentally observed large magnetocrystalline anisotropy. The Heisenberg exchange parameters up to fourth nearest neighbors were also calculated. The mean-field theory gives $T_C = 887$ K. The possible physical implications of the FM half-metallic ground state are also discussed.

Sr_2CoO_4 is not very stable in air at room temperature. However, it was found that by Y doping, the pure Sr_2CoO_4 phase could be obtained. The refined structure of the Y-doped Sr_2CoO_4 was found to be of the K_2NiF_4 type with space group $I4/mmm$. Refinement results indicated that for $x = 0.5$ in $Sr_{2-x}Y_xCoO_4$, the in-plane Co–O (1) bond length 1.876 Å is a bit shorter compared to that for $y = 0$ 1.898 Å, while the Co–O (2) bond distance along the c-axis is longer 2.030 Å compared to $x = 0$ 1.994 Å. This indicated that the Y^{3+} doping caused the Co–O bonds to contract within the ab plane and to elongate along the c-axis, yielding more distortion of the CoO_6 octahedron compared with the undoped Sr_2CoO_4. The resistivity of these two compounds is compared in Fig. 13.20.

Sr_2CoO_4 has a lower room temperature resistivity [0.04 Ω cm] than that of $SrCoO_3$ [0.09 Ω cm]. However, the resistivity of both samples showed a very gradual increase with decreasing of temperature and never tended to reach infinity at low temperature. This result indicates that the resistance of both compounds is dominated by carrier scattering at grain boundaries as is widely seen for polycrystalline samples.

The structure of Sr_2CoO_4 has the form shown in Fig. 13.21.

In addition, the reduced Ruddlesden–Popper phases, $Sr_3Co_2O_{5+\delta}$ with $\delta = 0.91$, 0.64 and 0.38, have been prepared in a nitrogen atmosphere. The crystal structures were determined by powder neutron diffraction. Oxygen vacancies are found both in 0(3) and 0(4) sites but the majority are along one crystallographic axis in the CoO_2 plane, inducing an orthorhombic distortion of the normally tetragonal $n = 2$ Ruddlesden–Popper structure. Superstructures due to oxygen ordering are observed by electron microscopy. The magnetic measurements reveal complex behavior with some FM interactions present for $Sr_3Co_2O_{5.91}$ and $Sr_3Co_2O_{5.64}$.

In the Co^{5+}-containing system of $SrO–Co_2O_5$, no compounds are known to date.

In the Co^{6+}-containing system of $SrO–CoO_3$, the structure of the $SrCrO_4$ compound was determined, crystallizing in the monoclinic space group $P21/n$ (no. 14), with lattice parameters $a = 6.73$ Å, $b = 7.33$ Å, $c = 7.07$ Å, $b = 104°$ and $Z = 4$. The structure is similar to the structure of $SrSeO_4$, as given in the literature.

Strontium cobaltites or cobaltates are not offered for sale commercially and no CAS numbers have been assigned to date.

13.1.5. Barium Cobalt Compounds

Barium metal does not form any intermetallic compounds with cobalt metal.

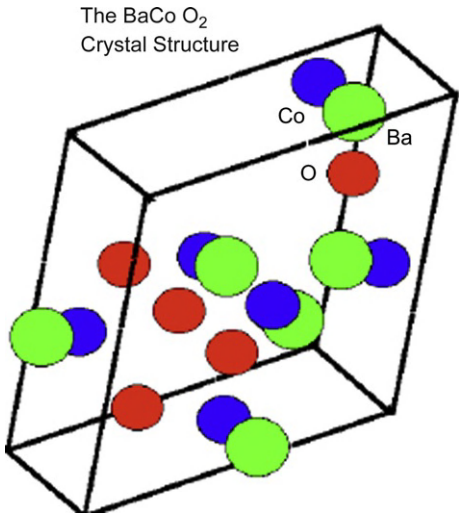

FIGURE 13.22

In the Co^{2+}-containing system of BaO–CoO, the compound, $BaCoO_2$, has been found not to be very stable in air at room temperature. The existence of gaseous cobaltates of alkaline earth metals has been established by high-temperature mass spectrometry. Gaseous molecules, $CaCoO_2$, $SrCoO_2$ and $BaCoO_2$, have been found for the first time. On the basis of the measured constants of the equilibrium of gas-phase reactions the standard enthalpies of formation: (-149 ± 19) kJ/mol, (-149 ± 20) kJ/mol and (-250 ± 16) kJ/mol; standard atomization enthalpies were: (1251 ± 22) kJ/mol, (1233 ± 23) kJ/mol and (1353 ± 20) kJ/mol for $CaCoO_2$, $SrCoO_2$ and $BaCoO_2$, respectively.

By a combination of high pressure and high temperature, high-temperature XRD has allowed the determination of the structure of **stoichiometric** $BaCoO_3$ shown in Fig. 13.22.

Cell parameters are: $a = b = 5.852$ Å, $c = 6.723$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 199.46$ Å^3, $Z = 3$. Cell occupation is shown in Table 13.7.

Only one or two references list this compound and no other compounds like $BaCo_2O_4$ or Ba_2CoO_3 are known.

In the Co^{3+}-containing system of BaO–Co_2O_3, the compound, $BaCoO_3$, is not known. However, a carbonato type of compound has been established. The crystal and magnetic structure of $Ba_5Co_5O_{14}$ $\{Ba_5[2Co^{3+}, 3Co^{4+}]_5O_{14}\}$ has been determined by means of X-ray and neutron diffraction. This oxide has trigonal symmetry (space group $P\text{-}3m1$) and lattice parameters $a = 5.6453$ Å and $c = 11.9223$ Å. The main structural feature is the presence of blocks of composition Co_3O_{12}, folded along the c-axis, built up by units of three sharing-faces octahedra connected through their terminal corners to two CoO_4 tetrahedra, which define layers parallel to the basal plane (001). The material shows FM behavior with $T_C \approx 47$ K. As determined from neutron diffraction data, the magnetic moments are aligned parallel lying on the (101) plane (and equivalent), making an angle of 63° with the c-axis. The Curie temperature (T_C) strongly increases with the hydrostatic pressure (1.1 K/GPa) until 6 GPa, and it decreases for higher pressures. From the electronic point of view, $Ba_5Co_5O_{14}$ is a low-dimensional system with an Anderson localization state of the charge carriers. This structure is related to the 2H-ABO_3 by means of the expression $a = a_{2H}(3)^{1/2}$ and $c = 2c_{2H}$. It can be described from the ordered intergrowth of two blocks, $[Ba_2Co_2O_6]^{\delta-}$ and $[Ba(CO_3)_{0.60}]^{\delta+}$, alternating along the a-axis. The first block corresponds to two 2H-like rods and the second one can be related to the $BaCO_3$ aragonite-type structure.

The thermoelectric properties of $Ba_3Co_2O_6(CO_3)_{0.7}$ have been investigated using prismatic single crystals elongated along the c-axis. $Ba_3Co_2O_6(CO_3)_{0.7}$ has a pseudo 1D structure similar to that of 2H PV-type $BaCoO_3$ and contains CoO_6 octahedral columns running parallel to the c-axis. The prismatic crystals are grown by a flux method using a K_2CO_3–$BaCl_2$ flux. The electrical conductivity (σ) along the columns (c-axis) exhibits a metallic behavior (670–320 S/cm in the temperature range of 300–1100 K), whereas the temperature dependence of the electrical conductivity perpendicular to the c-axis is semiconducting. The Seebeck coefficient (S) along the columns is positive and greater than 100 μV/K over the measured temperature range (116–128 μV/K). $Ba_3Co_2O_6(CO_3)_{0.7}$ shows power factors (σS^2) of 5.5×10^{-4}–9.0×10^{-4} W/μm/K^2 above room temperature, relatively high values for an oxide material.

The systematic search of new intermediate phases between 2H-$BaCoO_3$ and $Ba_3Co_2O_6$ structures has shown, for the first time, the existence of polymorphism in mono-dimensional phases of the homologous series $(A_3B_2O_6)$-$(A_3B_3O_9)$. A new $Ba_8Co_7O_{21}$ phase, different

TABLE 13.7

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	O1	O	6	c	1	0.420	0.302	0.2067	1.0
2	Ba1	Ba	3	b	.2.	0.347	0	5/6	1.0
3	Co1	Co	3	a	.2.	0.418	0	1/3	1.0

from the trigonal phase previously reported, has been synthesized. The new material is orthorhombic (space group $Fd2d$) with unit cell parameters $a_o = 1.14$, $b_o = 1.98$, and $c_o = 1.75$ nm. Both orthorhombic and trigonal phases are built up of isolated rows of polyhedra parallel to the c-axis formed by one TP and six octahedra-sharing faces, but with a different spatial arrangement between the chains. The orthorhombic structure can be derived from a hcp stacking of Ba_8O_{24} and $Ba_8Co_2O_{18}$ layers.

The $BaCo_4O_7$ compound provides a novel topology for studying geometric frustration, in which face-sharing tetrahedra of magnetic ions link to form trigonal bipyramids on a Kagomé lattice. Mean-field models of the generic magnetic phase diagram of $BaCo_4O_7$ determined show a variety of magnetic states as a function of two exchange parameters: J_{ab} and J_c, where J_{ab} links Co ions in the Kagom'e planes and J_c links Co ions from the Kagomé plane to the interleaving triangular layer. It has been found that the addition of Y^{3+}–Ca^{2+} to this compound greatly improves the thermoelectric properties of the composite.

$\{Y_{0.5}/Ca_{0.5}\}BaCo_4O_7$ contains Kagomë layers of Co ions, whose spins are strongly coupled according to a Curie–Weiss temperature of −2200 K. At low temperatures, $T = 1.2$ K, a diffuse neutron scattering study with polarization analysis revealed that characteristic spin correlations close to a predicted 2D coplanar ground state with staggered chirality was present. The absence of 3D long-range AF order proved negligible coupling between the Kagomé layers. The scattering intensities are consistent with high-spin $S = 3/2$ states of Co^{2+} in the Kagomé layers and low-spin $S = 0$ states for Co^{3+} ions at interlayer sites.

The average crystal structure of $Y_{0.5}Ca_{0.5}BaCo_4O_7$ is shown in Fig. 13.23. Thicker lines between the Co_2 atoms highlight the Kagomé layers. All Co atoms are tetrahedrally coordinated by oxygen, as shown in the polyhedral representation (left), emphasizing the threefold

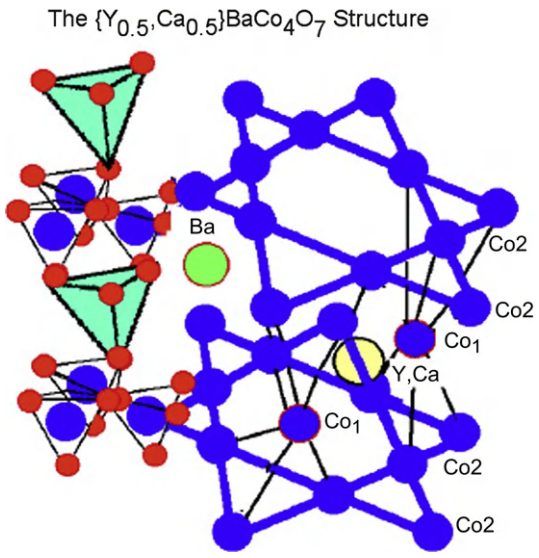

FIGURE 13.23

symmetry axes, going through Co_1(blue), which allow trimerization of Co_2 in the Kagomé substructure.

The above description involves an average of the two compounds, (Ba,Y)Co_4O_7 and (Ba,{Y,Ca})Co_4O_7. A novel mixed valent cobaltite, $CaBaCo_4O_7$, has been synthesized. Its structure, closely related to the $LnBaCo_4O_7$ oxides of the "114" series, differs from the latter by a large orthorhombic distortion, involving a buckling of the CoO_4 tetrahedra of the Kagomé layers. Importantly, this new phase is ferrimagnetic with a $T_C = 70$ K and a very large coercive field of 2 T at 5 K, in contrast to $LnBaCo_4O_7$ oxides, which exhibit magnetic frustration. Neutron diffraction studies have been carried out in the temperature (T) range between 10 and 130 K on a single crystal of $YBaCo_4O_7$, which has the stacking of Kagomé and triangular lattices of CoO_4 tetrahedra along the c-axis. This structure has the form shown in Fig. 13.24.

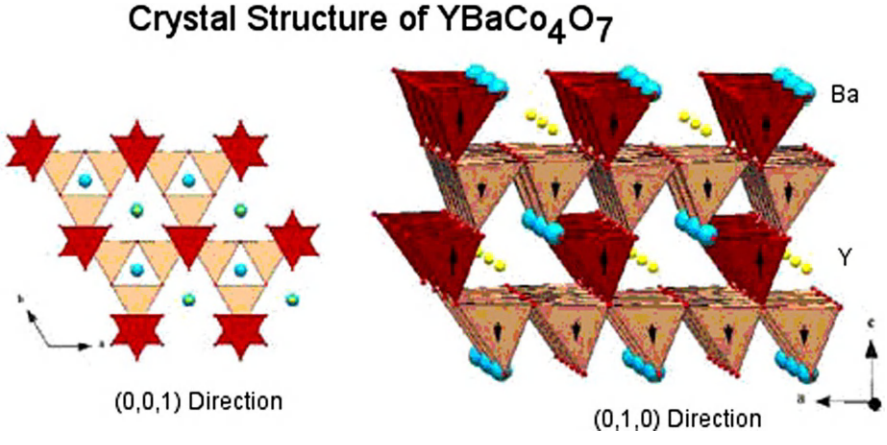

FIGURE 13.24

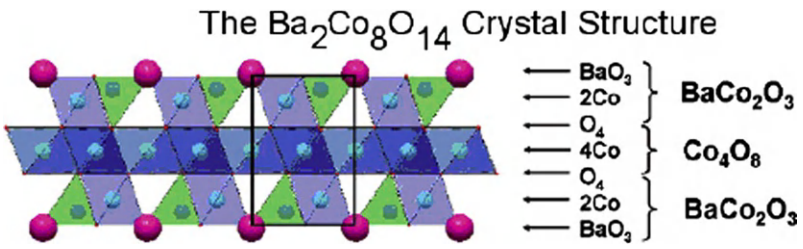

FIGURE 13.25

Structural transitions have been found at two temperatures $T_{c1} \sim 70$ K and $T_{c2} \sim 105$ K. With decreasing T, magnetic order appears along with the transition at T_{c2}, but it does not grow to an ideal long-range order even at the lowest T studied (~10 K). Two groups of magnetic diffuse reflections, which originate from the Co moments of the Kagomé and triangular lattices, are observed separately in the reciprocal space. With further decreasing T, the growth rates of the intensities of these two are enhanced by another transition at T_{c1}. These magnetic behaviors seem to be related to the release of the geometrical frustration. At 10 K, the patterns of the magnetic short-range order have been determined for both sites of the Kagomé and triangular lattices. Extraordinary oxygen ordering and mobility have been found in an oxygen-nonstoichiometric mixed-valence cobalt oxide, $YBaCo_4O_{8.5}$. The excess oxygen atoms appear to be incorporated in an orderly way into the $YBaCo_4O_7$ parent lattice with different configurations as the oxygen content varies. Intense electron beam irradiation was used to observe recurrent oxygen migration in the lattice, causing reversible structural modulation transitions. The oxygen migration can be attributed mainly to the electron beam heating effect.

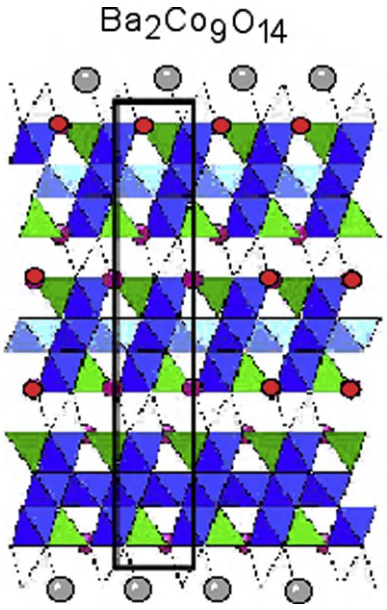

FIGURE 13.26

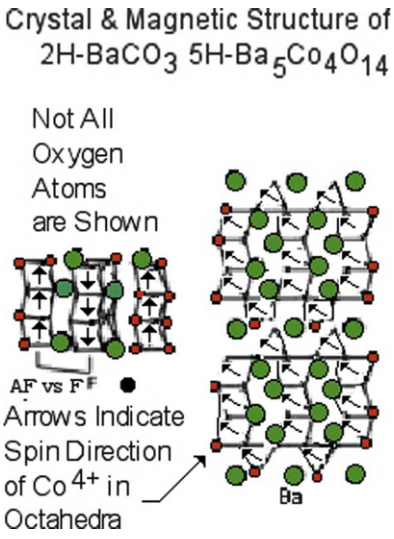

FIGURE 13.27

A complex compound, $Ba_2Co_8O_{14}$ is also known. It has the structure shown in Fig. 13.25.

In the Co^{2+}–Co^{3+}-containing system of BaO–Co_3O_4, the compound $Ba_2Co_9O_{14}$ is known. It has the structure shown in Fig. 13.26.

The formula is perhaps better written: $Ba_2(Co^{3+})_4(Co^{4+})_3O_{14}$. Very little information concerning this compound is available in the literature.

In the Co^{4+}-containing system of BaO–CoO_2, the compound, $BaCoO_3$ has been studied. The stoichiometric compound has a hexagonal-2H pseudo-PV structure with space group $P63/mmc$, and lattice parameters $a = 5.645$ Å and $c = 4.752$ Å. This structure has the form shown in Fig. 13.27.

A series of defect structures are known. In the following diagram, three projections are shown (Fig. 13.28).

The three projections are:

(a) The (ab, cb) projection of the 2H-$BaCoO_3$ structures showing the chains made of face-shared CoO_6 octahedra separated by the Ba^{2+} cations (circles).

(b) Corresponding ($\vec{a}$ $\vec{b}$) projection reveals the triangular lattice of the CoO_6 chains.

(c) Perspective view of the $Ca_3Co_2O_6$ structure showing the chains of face-shared CoO_6 TPs and octahedra.

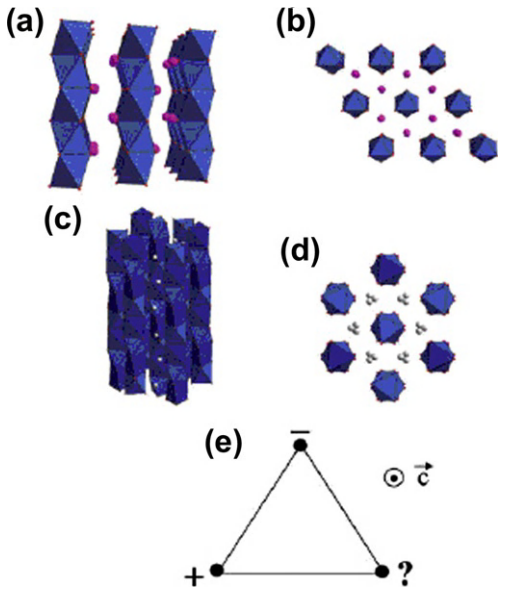

FIGURE 13.28

The circles are for the Ca^{2+} cations separating these chains

(d) The corresponding $(\vec{a}\ \vec{b})$ projection is also shown together with the projection of the chain magnetization (e) to illustrate the magnetic frustration.

The two first members for these cobaltites are 2H-$BaCoO_3$ [(m) 1, n, 0]; (a and b in the Figure) and $Ca_3Co_2O_6$ [(*m*) 0, *n*, 1]; (c and d in the Figure). In the latter, the chains set on a triangular lattice are made of 1:1 alternation of a CoO_6 octahedron (oct) and a TP; these chains are separated by Ca^{2+} cations.

The cubic (c) or hexagonal (h) stacking of $[AO_{3-\delta}]$ layers allows us to describe the so-called hexagonal PVs illustrated for the $BaCoO_{3-\delta}$ phases by the 2H (see above Figure) and 12H terms in Fig. 13.29.

This figure shows the (ab,cb) projection of the 12H-$BaCoO_3$ structure (a) and the corresponding (ab,bb′) projection (b). The (*a*,*b*) plane projection of the former illustrates the triangular array of chains (*P*63/*mmc* space group) made of the face-shared CoO_6 octahedra separated by the Ba^{2+} cations. It must be recalled that this compound is the $(m = 1,\ n = 0)$ term of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ series with A = Ba and B = Co. In contrast to the 1D structure of the 2H structure (*a*, *b*), the (*a*, *b*) projection of the 12H structure demonstrates that the units of four face-shared octahedra, reminiscent of the 2H chains, are bridged together by new types of CoO_x polyhedra resulting from the "$O_{2.6}$" oxygen deficiency.

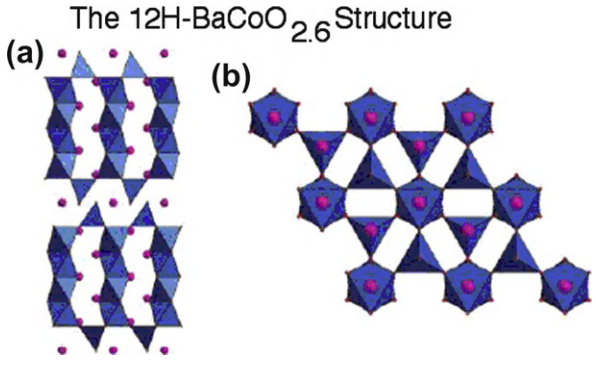

FIGURE 13.29

The magnetic structure of the AFM hexagonal PV $BaCoO_3$ was investigated by neutron diffraction using a powder sample in the temperature range between 60 and 1.5 K. It was found that AF diffraction peaks clearly appear below the Néel temperature ($T_N = 15$ K), which are indexed with the propagation vector k = (1)/(3),(1)/(3),0), indicating that the AF super unit cell is three times larger than the crystallographic unit cell. Data from a parallel muon-spin rotation/relaxation (σ^+SR) measurement allowed the final selection of a unique AF spin structure from several possible spin arrangements compatible with the neutron diffraction pattern. The proposed AF structure is modulated along the (110) direction and described by $m_l = m_0\cos(2\pi kl)$, where m_l is the moment at the Co^{4+} site l and $m_0 = (0,0,0.53\ \mu bar)$ at 1.5 K

Ordering of ionic vacancies in the $BaCoO_{2.94}$ hexagonal-related PV has been studied. An electron diffraction and high-resolution electron microscopy study shows that oxygen vacancies in $BaCoO_{2.94}$ lead to a threefold superstructure along the $(110)_{2H}$ direction, the …hhh… hexagonal sequence characteristic of the 2H type being maintained. According to compositional and structural data, the most probable structural model should be formed by three AO_3-layers intergrowing with one $AO_{2.67}$-layer along the *c*-axis. In such oxygen-deficient layers, one of each six oxygen atoms in every oxygen row is removed, leading to the observed superstructure.

The systematic search of new intermediate phases between 2H-$BaCoO_3$ and $Ba_3Co_2O_6$ structures has shown, for the first time, the existence of polymorphism in monodimensional phases of the homologous series $(A_3B_2O_6)$-$(A_3B_3O_9)$. A new $Ba_8Co_7O_{21}$ phase, different from the trigonal phase previously reported, has been synthesized. The new material is orthorhombic (space group *Fd*2*d*) with unit cell parameters $a_o = 1.14$, $b_o = 1.98$, and $c_o = 1.75$ nm. Both orthorhombic and trigonal phases are built up of isolated rows of polyhedra parallel to the *c*-axis formed by one TP and six octahedra-sharing faces, but with a different spatial arrangement between the chains. The orthorhombic structure can be derived from the hcp stacking of Ba_8O_{24} and $Ba_8Co_2O_{18}$ layers.

The crystal structure of $Ba_3Co_2O_6(CO_3)_{0.60}$ has been determined by means of X-ray, neutron and electron diffraction, and high-resolution electron microscopy. This compound has a hexagonal symmetry (space group P) and lattice parameters $a = 9.683$ and $c = 9.5180$ Å related to the 2H-ABO_3 by means of the expression $a = a\sqrt{H^3}_{1/2}$ and $c = \sqrt{c-2}\sqrt{H}$. It can be described from the ordered intergrowth of two blocks, $[Ba_2Co_2O_6]-$ and $[Ba(CO_3)_{0.60}]+$, alternating along the a-axis. The first block corresponds to two 2H-like rods and the second one can be related to the $BaCO_3$ aragonite-type structure. Neutron diffraction data elucidate the relative orientation of carbonate groups along c-axis in the aragonite-like blocks.

The thermoelectric properties of the modified carbonate-barium cobaltite, $Ba_3Co_2O_6(CO_3)_{0.7}$, have been investigated using prismatic single crystals elongated along the c-axis. $Ba_3Co_2O_6(CO_3)_{0.7}$ has a pseudo 1D structure similar to that of 2H PV-type $BaCoO_3$ and contains CoO_6 octahedral columns running parallel to the c-axis. The prismatic crystals are grown by a flux method using a K_2CO_3–$BaCl_2$ flux. The electrical conductivity (σ) along the columns (c-axis) exhibits a metallic behavior (670–320 S/cm in the temperature range of 300–1100 K), whereas the temperature dependence of the electrical conductivity perpendicular to the c-axis is semiconducting. The Seebeck coefficient (S) along the columns is positive and greater than 100 μV/K over the measured temperature range (116–128 μV/K). $Ba_3Co_2O_6(CO_3)_{0.7}$ shows power factors (σS^2) of 5.5×10^{-4}–9.0×10^{-4} W/μm/K^2 above room temperature, relatively high values for an oxide material.

Single-crystal Ba_2CoO_4 was grown using the floating zone technique. Single-crystal refinement of XRD data indicates that Ba_2CoO_4 has a monoclinic structure with $a = 5.9176$ Å, $b = 7.6192$ Å, $c = 10.3790$ Å, and $\beta = 91.734°$ at room temperature. Magnetic susceptibility, specific heat, and thermal conductivity show anomalies at $T_N = 25$ K, due to AFM ordering. However, the magnitude of the Néel temperature T_N is significantly lower than the Curie–Weiss temperature ($|\Theta| \approx 110$ K), suggesting either reduced-dimensional magnetic interactions and/or the existence of magnetic frustration. The latter may be induced by disorder evident from the variable-range hopping behavior in the electrical resistivity, nonzero T term in the specific heat, and T^2 dependence in the thermal conductivity at low temperatures. A crystal chemical study based on the cation arrays allows the establishment of a new relationship between Ba_2CoO_4 and 2H$\cdots$$BaCoO_3$. Moreover, the Ba subarray seems to be related to the structure of elemental Ba. The structure is shown in Fig. 13.30.

Large single crystals of Ba_2CoO_4 were synthesized. Single crystals were also obtained for Sr doped $Ba_{2-x}Sr_xCoO_4$. Powder and single-crystal XRD results indicate that pure Ba_2CoO_4 has a monoclinic structure at room temperature. With Sr doping, the lattice structure changes to orthorhombic when $x \geq 0.5$ and to tetragonal when $x = 2.0$. In addition, Ba_2CoO_4 and Sr_2CoO_4, have completely different basic building blocks in the structure. One contains the CoO_4 tetrahedron and the latter the CoO_6 octahedron, respectively.

Electronic and magnetic properties were characterized and discussed. The magnetic susceptibility, specific heat and thermal conductivity show that Ba_2CoO_4 has an AFM ground state with an AF ordering temperature $T_N = 25$ K. However, the magnitude of the Neel temperature T_N is significantly lower than the Curie–Weiss temperature ($|\Theta| = 110$ K), suggesting either reduced-dimensional magnetic interactions and/or the existence of magnetic frustration. The AF interaction persists in all the samples with different doping concentrations. The Neel temperature does not vary much in the monoclinic structure regime but decreases when the system enters orthorhombic.

Magnetically, Ba_2CoO_4 has an AF insulating ground state while Sr_2CoO_4 has a FM metallic ground state. Neutron powder refinement results indicate a magnetic structure with the spin mostly aligned along the a-axis. The result from a muon-spin rotation/relaxation (mu + SR) experiment agrees with our refinement. It confirms the AF order in the ab-plane. The spin dynamics and its anisotropy in the AF phase were also studied. The results from inelastic neutron scattering show that spin waves have a clear dispersion along a-axis but not along c-axis, indicating spin anisotropy. This work finds the strong spin-lattice coupling in this novel complex material. However, if Sr^{2+} is substituted in the structure, a radical change is obtained (Fig. 13.31).

The effect of the oxygen content on the magnetic and transport properties of the FM $Eu_{0.9}Ca_{0.1}BaCo_2O_{5.5+\delta}$ has been investigated. Unlike the increase in T_C with calcium content, paradoxically the T_C value decreases as the oxygen content increases, as observed in the undoped phase. Assuming that the Goodenough-Kanamori rules apply to this very complex magnetic system, these experiments suggest that the Co^{3+} disproportionation into Co^{4+} and Co^{2+}, plays an important role in the appearance of ferromagnetism. The magnetic phase separation scenario of FM domains embedded in an AFM matrix plays an important role in the ferromagnetism of the calcium doped "112" cobaltites. All the samples covering a wide range of oxygen content, exhibit p-type conductivity.

In the Co^{5+}-containing system of BaO–Co_2O_5, the compound, $BaCo_2O_6$, remains unknown.

In the Co^{6+}-containing system of BaO–CoO_3, no compounds are known.

Barium cobaltite or coabaltate compounds are not offered for sale commercially.

13.1.6. Radium Cobalt Compounds

Although radium undoubtedly forms the same type of compounds as barium, no reports of such syntheses have reached the literature. This is due to the lack of interest in Industry, coupled with the corresponding one in Academia.

13.2. ALKALINE EARTH RHODIUM COMPOUNDS

Rhodium has the known stable oxides that include Rh_2O_3, RhO_2 and $RhO_2 \cdot xH_2O$. Only Be^0 forms intermetallic compounds with rhodium metal.

13.2.1. Beryllium Rhodium Compounds

The system, Be^0–Rh^0, forms two compounds. There are also two established compounds in the BeO–Rh_xO_y system.

BeRh forms the CsCl type of structure where the Rh^0 atom is in a body-centered lattice. This structure has the form shown in Fig. 13.32.

Cell parameters are: $a = b = c = 2.739$ Å, $\alpha = \beta = \gamma = 90°$, cell volume: 20.55 Å^3, $Z = 2$, cell occupancy is shown in Table 13.8.

$Be_{15.34}Rh_{2.36}$ has the structure shown in Fig. 13.33.

Cell parameters are: $a = b = 4.193$ Å, $c = 10.881$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 165.42 Å^3, $Z = 1$. Cell occupancy is shown in Table 13.9.

FIGURE 13.31

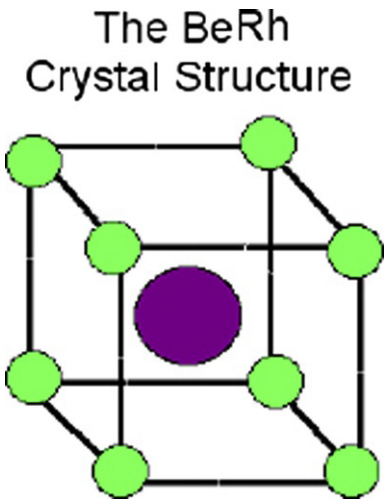

FIGURE 13.32

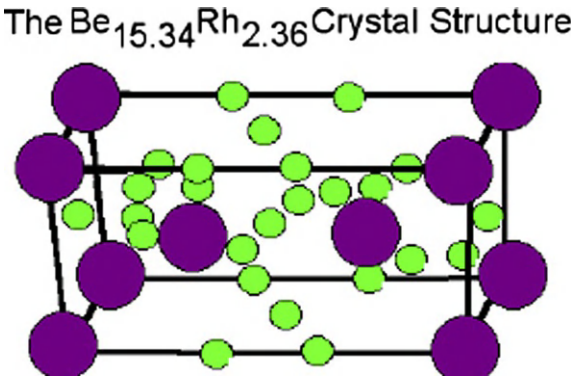

FIGURE 13.33

No other compounds are known in this system.

In the $BeO–Rh_2O_3$ system, beryllium forms only one compound, $BeRh_2O_4$, but it is dimorphic. One form has the $BeAl_2O_4$ structure shown in Fig. 13.34.

Cell parameters are: $a = b = c = 5.9284$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 147.23$ Å^3, $Z = 9$. Cell occupancy is shown in Table 13.10.

The other form of $BeRh_2O_4$ is shown in Fig. 13.35.

Cell parameters are: $a = b = c = 5.9256$ Å, $\alpha = \beta = 119.982$ Å, $\gamma = 90°$, cell volume $= 147.38$ Å^3, $Z = 6$. Cell occupancy is shown in Table 13.11.

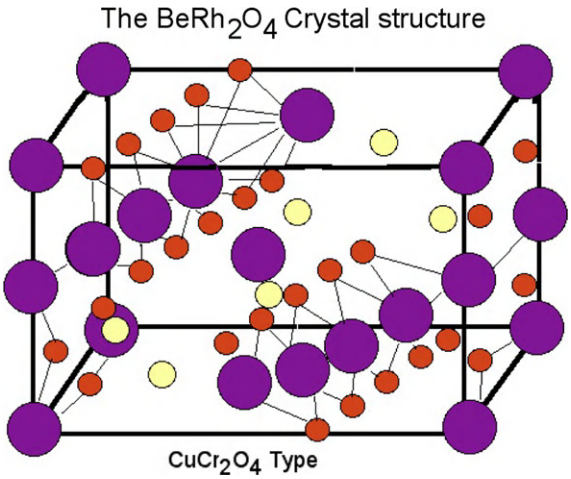

FIGURE 13.35

Little information is available in the literature concerning these compounds. It has been stated the $BeRh_2O_4$ is expected to be semiconducting in its electrical properties (because it contains Rh^{3+}-$4d^5$ electrons) but no specific measurements have been published.

No other compounds are known. Beryllium rhodite or rhodate compounds are not available commercially nor has a CAS number ever been assigned.

13.2.2. Magnesium Rhodium Compounds

Magnesium does not form any intermetallic compounds with rhodium metal.

No compounds are known:

(1) In the Rh^{2+}-containing system of MgO–RhO
(2) In the Rh^{2+}–Rh^{3+}-containing system of MgO–Rh_3O_4,
(3) In the Rh^{4+}-containing system of MgO–RhO_2,
(4) In the Rh^{5+}-containing system of MgO–Rh_2O_5,
(5) In the Rh^{6+}-containing system of MgO–RhO_3.

In the Rh^{3+}-containing system of MgO–Rh_2O_3, only one compound, $MgRh_2O_4$, has been reported. The structure has the form shown in Fig. 13.36.

Cell parameters are: $a = b = c = 6.004$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 153.04$ Å^3, $Z = 8$.

Cell occupancy is shown in Table 13.12.

A precise decomposition curve for stoichiometric $MgRh_2O_4$ was determined experimentally to evaluate its thermodynamic properties. The standard state enthalpy and entropy at 298 K for decomposition to Rh, MgO and O are 88.8 ± 1.9 kcal/mol and 59.8 ± 1.4 cal/mol/K, respectively. A third law entropy for $MgRh_2O_4$ was estimated for 298 K as 35.2 ± 1.5 cal/mol/K. Solid solutions between $MgRh_2O_4$ and $MgAl_2O_4$ were prepared that exhibited positive deviations from Vegard's law. Preliminary data on decomposition of the solid solution are consistent with positive deviations

from ideality becoming negative as $MgAl_2O_4$ is approached.

The Gibbs free energy of formation and heat capacity of α-Rh_2O_3 and $MgRh_2O_4$, the MgO···Rh···O phase diagram, and constraints on the stability of $Mg_2Rh^{4+}O_4$ have been studied. The oxygen potentials of the reactions were measured using electrochemical cells of the type Pt, metal + oxide|CSZ|YDT (air), Pt. Relative to a reference pressure of 1 bar, the following was determined:

$$\mu_{O_2(\beta\text{-}Rh_2O_3)}\ (\pm 63\ \text{J/mol}) = -278{,}500 + 283.8T - 11.69T\ \ln T\ (860\ \text{K} < T < 1355\ \text{K})$$

and:

$$\mu_{O_2(MgRh_2O_4)}\ (\pm 63\ \text{J/mol}) = 297314 + 369.405T - 23.3338T\ \ln T\ (940\ \text{K} < T < 1495\ \text{K})$$

The constant pressure heat capacities of α-Rh_2O_3 and $MgRh_2O_4$ were measured with a DSC operated in step heating mode between 360 and I065 K. Best fits to the data (in J/mol/K with an uncertainty of ±2 J/mol/K) gave:

$$C_p(\beta\text{-}Rh_2O_3) = 123.6 + 0.0141T - 208.8T^{-0.5} - 2{,}312{,}000/T^2$$

and:

$$C_p(MgRh_2O_4) = 174.0 + 0.014T - 4297000/T^2$$

A third law analysis showed satisfactory internal consistency of the Gibbs free energy of formation and heat capacity data of β-Rh_2O_3, but with a much lower value for $S_{298.15,\ \beta\text{-}Rh2O3}$ (71.5 ± 1.5 J/mol/K compared with those made earlier (1989)). This is attributed to the new C_p(β-Rh_2O_3) data that are significantly different from the original measurements of Wöhler and Jochum (1933) and the adjusted values of 1989.

Spinels prepared in the MgO···Rh···O system are solid solutions between $MgRh_2^{3+}O_4$ and $Mg_2Rh^{4+}O_4$ and the interpretation of the data for $\mu_{O_2(MgRh_2O_4)}$ requires an understanding of phase relationships in the MgO···Rh···O system. From an isothermal projection of oxygen potentials onto the Mg···Rh binary at 1373 K, the mole fraction $MgRh_2^{3+}O_4$ in spinel ($X_{MgRh_2O_4}$) in equilibrium with MgO and Rh at 1373 K was estimated to be about 0.92. (i.e. $X_{Mg_2RhO_4} \approx 0.08$). This provides a calibration point for determining the temperature dependence of $a^{spinel}_{MgRh_2O_4}$ in $MgRh_2^{3+}O_4$-$Mg_2Rh^{4+}O_4$ solid solutions, (where "a" is a lattice parameter). A third law analysis showed that, once corrected for $a^{spinel}_{MgRh_2O_4}$, the data for $\mu_{O_2(MgRh_2O_4)}$ and $C_p(MgRh_2O_4)$ become fully consistent. The calculated value for $S_{298.15,\beta\text{-}Rh_2O_4}$ is 105.75 ± 2 J/mol · K. This is in reasonable agreement with the assumption of additive oxide entropies $S_{298.15,\ MgRh_2O_4} \approx 98.4$ J/mol/K, using the value of $S_{298.15,\ \beta\text{-}Rh_2O_3}$. It was concluded that the data for β-Rh_2O_3 and $MgRh_2^{3+}O_4$ are internally consistent.

From the third law analysis, it is also possible to determine the activity of $Mg_2Rh^{4+}O_4$, in $MgRh_2^{3+}O_4$-$Mg_2Rh^{4+}O_4$ solid solutions ($a^{spinel}_{MgRh_2O_4}$) as a function of temperature. The data for $a^{spinel}_{MgRh_2O_4}$ may be combined with the e.m.f. measurements for the spinel + MgO + Rh assemblage to evaluate the Gibbs free energy of formation of $Mg_2Rh^{4+}O_4$:

$$\Delta_f G^{O}{}_{Mg_2RhO_4,T}\ (\pm 6000\ \text{J/mol}) = -100076.3 + 100.0T\ (1008 < T < 1495\ \text{K})$$

It was perceived that $Mg_2Rh^{4+}O_4$ is an important component in rhodate spinels at high temperatures, thus extending the stability field of spinel in the MgO–Rh–O system.

It has been reported that if a thin layer of Rh metal is deposited upon a fresh layer of MgO, the composite is superior to any other catalyst for the conversion of methane to synthesis gas or "syn-gas". This is a mixture of CO and H_2, and is a very important petrochemical feedstock. At high temperature, $MgRh_2O_4$, is formed on the surface that is very stable and acts as a source

TABLE 13.12

of oxygen and electrons, the oxygen atoms being replaced from the MgO substrate.

$$CH_4 + H_2O \Leftrightarrow CO + 3H_2$$
$$\Delta H^0 = +206\ \text{kJ/mol}$$

No other compounds are known. Magnesium rhodites or rhodates are not available commercially and no CAS numbers have been issued.

13.2.3. Calcium Rhodium Compounds

Ca^0 and Rh^0 do not form any intermetallic compounds.

No compounds are known in the systems:

(1) in the Rh^{2+}-containing system of CaO–RhO,
(2) in the Rh^{2+}–Rh^{3+}-containing system of CaO–Rh_3O_4,
(3) in the Rh^{5+}-containing system of CaO–Rh_2O_5,
(4) in the Rh^{6+}-containing system of CaO–RhO_3.

In the Rh^{3+}-containing system of CaO–Rh_2O_3, $CaRh_2O_4$, an insulator, forms a full range solid solution with the metallic conductor, $Na_2Rh_2O_4$. This compound, prepared by solid-state reaction of the oxides, is not very stable at room temperature. It has the structure shown in Fig. 13.37.

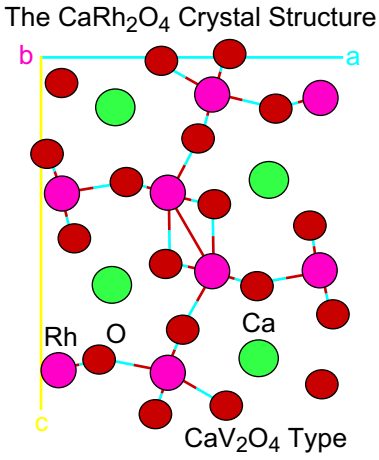

FIGURE 13.37

Cell parameters are: $a = 3.085$ Å, $b = 9.167$ Å, $c = 10.745$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 303.87 Å^3, $Z = 4$. Cell occupancy is shown in Table 13.13.

The Gibbs free energy of formation of $CaRh_2O_4$(solid) has been determined using two techniques viz., quadrupole mass spectrometer coupled to a Knudsen cell and solid-state cell incorporating CaF_2(solid) as the solid electrolyte. In the former method, equilibrium O_2(gas) pressures were measured over the phase field Rh(solid) + Rh_2O_3(solid), in the temperature range 793.7–909.1 K and over the three-phase mixture $CaRh_2O_4$(solid) + Rh(solid) + CaO(solid) was measured from 862.1 to 1022.7 K.

The Gibbs free energy of formation of Rh_2O_3 (solid) from elements in their standard state has been given in the literature as:

$$\Delta_f G^0\ (Rh_2O_3\ (\text{solid}))\ (\text{kJ/mol} \pm 2.0) = -363.2 + 0.241T\ (\text{K}).$$

The Gibbs free energy of formation of $CaRh_2O_4$(solid) from elements in their standard state was given by:

$$\Delta_f G^0\ (CaRh_2O_4\ (\text{solid}))\ (\text{kJ/mol} \pm 2.0) = -1030.5 + 0.3437T\ (\text{K}).$$

In the electrochemical technique, the cell configuration employed was:

$$(-)Pt/O_2\ (\text{gas}).\ \{CaO(\text{solid}) + CaF_2(\text{solid})\}//CaF_2//\{CaRh_2O_4\ (\text{solid}) + Rh_2O_3(\text{solid}) + CaF_2(\text{solid})\},\ O_2(\text{gas})/Pt(+).$$

The e.m.f. values were measured in the temperature range 879.7–1000 K can be represented by the following expression:

$$E_V\ (\pm 7.63 \times 10^{-4}) = 0.3928 - 2.374 \times 10^{-4}T\ (\text{K})$$

From the measured e.m.f. of the cell and requisite $\Delta_f G^0$ values from the literature, $\Delta_f G^0$ ($CaRh_2O_4$ (solid)) from elements in their standard state has been calculated and can be represented by:

$$\Delta_f G^0\ (CaRh_2O_4\ (\text{solid}))\ (\text{kJ/mol} \pm 2.0) = -1079 + 0.390T\ (\text{K})$$

The two values complement each other. The uncertainty estimates for $\Delta_f G^0$ include the standard deviation

TABLE 13.13

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy

in the e.m.f. and uncertainty in the data taken from the literature. The slope and intercept of the above equation gives the entropy and enthalpy of formation of the compound at the average experimental temperature $T_{av} = 940$ K.

In the Rh^{4+}-containing system of CaO–RhO_2, the compound, $CaRhO_3$ has been synthesized. High-pressure phase transitions of $CaRhO_3$ PV (perovskite phase) were examined at pressures of 6–27 GPa and temperatures of 1000–1930 °C, using a multi-anvil apparatus. The results indicate that $CaRhO_3$ PV successively transforms to two new high-pressure phases with increasing pressure. Rietveld analysis of powder XRD data indicated that, in the two new phases, the phase stable at higher pressure possesses the $CaIrO_3$-type post-perovskite (PPV) structure (space group *Cmcm*) with lattice parameters: $a = 3.1013$ Å, $b = 9.8555$ Å, $c = 7.2643$ Å, $V_M = 33.43$ cm^3/mol. The Rietveld analysis also indicated that $CaRhO_3$ PV has the $GdFeO_3$-type structure (space group *Pnma*) with lattice parameters: $a = 5.5631$ Å, $b = 7.6308$ Å, $c = 5.3267$ Å, $V_M = 34.04$ cm^3/mol. The third phase stable in the intermediate P, T conditions between PV and PPV have monoclinic symmetry with the cell parameters: $a = 12.490$ Å, $b = 3.1233$ Å, $c = 8.8630$ Å, $\beta = 103.96°$, $V_M = 33.66(1)$ cm^3/mol ($Z = 6$). Molar volume changes from PV to the intermediate phase and from the intermediate phase to PPV are −1.1 and −0.7%, respectively. The equilibrium phase relations determined indicate that the boundary slopes are large positive values: 29 ± 2 MPa/K for the PV–intermediate phase transition and 62 ± 6 MPa/K for the intermediate phase–PPV transition. The structural features of the $CaRhO_3$ intermediate phase suggest that the phase has edge-sharing RhO_6 octahedra and may have an intermediate structure between PV and PPV.

In another study, high-pressure phase transitions of $CaRhO_3$ PV were examined at pressures of 6–27 GPa and temperatures of 1000–1930 °C, using a multi-anvil apparatus. The results indicated that $CaRhO_3$ PV successively transforms to two new high-pressure phases with increasing pressure. Rietveld analysis of powder XRD data indicated that, in the two new phases, the phase stable at higher pressure possesses the $CaIrO_3$-type PPV structure (space group *Cmcm*) with lattice parameters: $a = 3.1013(1)$ Å, $b = 9.8555(2)$ Å, $c = 7.2643(1)$ Å, $V_M = 33.43(1)$ cm^3/mol. The Rietveld analysis also indicated that $CaRhO_3$ PV has the $GdFeO_3$-type structure (space group *Pnma*) with lattice parameters: $a = 5.5631(1)$ Å, $b = 7.6308(1)$ Å, $c = 5.3267(1)$ Å, $V_M = 34.04(1)$ cm^3/mol. The third phase stable in the intermediate P, T conditions between PV and PPV has monoclinic symmetry with the cell parameters: $a = 12.490(3)$ Å, $b = 3.1233(3)$ Å, $c = 8.8630(7)$ Å, $\beta = 103.96(1)°$, $V_M = 33.66(1)$ cm^3/mol ($Z = 6$). Molar volume changes from PV to the intermediate phase and from the intermediate phase to PPV are −1.1 and −0.7%, respectively. The equilibrium phase relations determined indicate that the boundary slopes are large positive values: 29 ± 2 MPa/K for the PV–intermediate phase transition and 62 ± 6 MPa/K for the intermediate phase–PPV transition. The structural features of the $CaRhO_3$ intermediate phase suggest that the phase has edge-sharing RhO_6 octahedra and may have an intermediate structure between PV and PPV.

In another paper, the discovery of the PV to PPV transition in $MgSiO_3$ in a laser-heated anvil apparatus, has led to wide attention being focused on the PPV phase of $MgSiO_3$. This relates to the fact that the PPV phase is likely to play a key role in Earth's lowermost mantle, and because the PV to PPV transition can explain many features of the "D" seismic discontinuity. The PPV phase of $MgSiO_3$ cannot be quenched to ambient pressure/temperature conditions so that further studies must be conducted using analogue compounds of $MgSiO_3$ PPV, like $CaRhO_3$, that are quenchable to ambient pressure/temperature conditions. However, it can only be obtained at high pressure/temperature conditions using a multi-anvil apparatus. Further studies on this material revealed structural phase transitions at high P–T along with a metal–insulator transition caused by hole doping. In the case of $CaIrO_3$, the PPV phase of $CaIrO_3$ synthesized at 2 GPa, 1373 K transforms into a PV phase at 2 GPa, 1673 K. In other words, the PV phase can be synthesized at temperatures higher than those needed for synthesizing the PPV phase. This is also the case for $CaRhO_3$ (6 GPa, 1873 K) and $CaRuO_3$ (23 GPa, 1343 K). Within density functional theory, the equations of state for PV and PPV forms of $CaRhO_3$ have been obtained with equilibrium values of volume in agreement with experiment. Energy magnitudes point to a stabilization of PPV versus PV. This is interpreted by use of analyses of the charge density and the chemical bonding plots, showing that the Rh–0 interactions within two oxygen sublattices are selectively differentiated and reinforced for one of the two oxygen sublattices within the PPV variety with respect to the PV variety that has only one. Investigation of the magnetic properties shows no magnetic order and a metallic character for PV while ferromagnetism occurs in PPV with a tendency to insulating behavior. This long-range order is favored by direct $t_{2g} \leftrightarrow t_{2g}$ interactions through edge-sharing octahedra in PPV $CaRhO_3$, stronger than indirect $t_{2g} \cdot P_\pi \cdot t_{2g}$ ones in the PV variety. The structure is shown in Fig. 13.38.

$CaRuO_3$ PPV undergoes an AFM transition at ~270 K while the PV shows no magnetic transition above 1.0 K. The factor, 1/X, of $CaRuO_3$ PPV is about three times as large as that of the PV at 300 K. The differences in magnetic properties between the PV and PPV of $CaRuO_3$ indicate that the effect of antiferromagnetic interaction on magnetic susceptibility in the PPV is larger than that in the PV. Considering the origins of magnetic properties

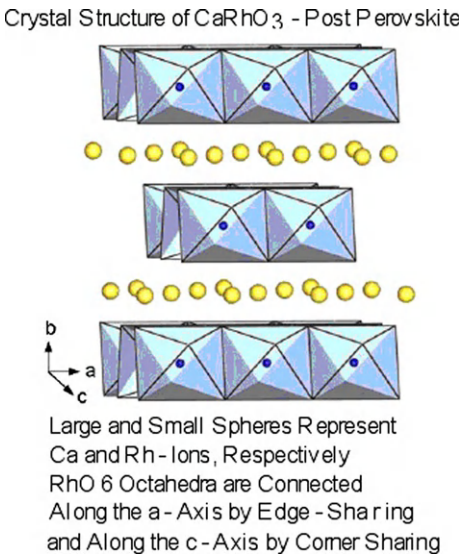

FIGURE 13.38

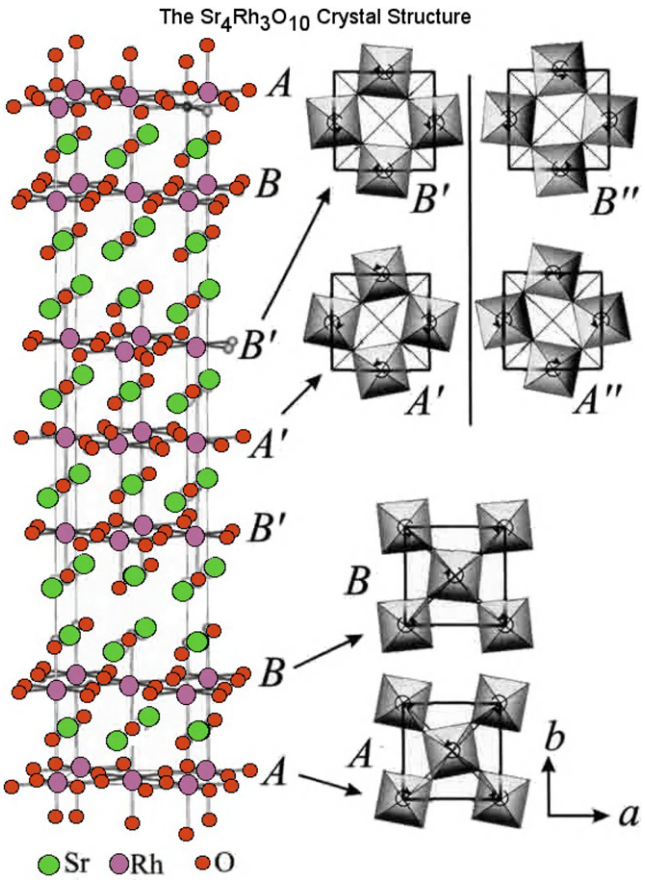

FIGURE 13.39

of those compounds, the difference of effect of antiferromagnetic interaction between the PV and the PPV can be comprehended. It was thought that magnetism of $CaRuO_3$ PV originates mainly from an interaction with itinerant electrons and superexchange interaction for Ru–O–Ru linkages. It was suggested that the difference in magnetic interaction between the PV and the PPV may be caused by the inhibition of itinerant magnetism with decreasing d-band width caused by reduction of the Ru–O–Ru bond angle of corner-sharing octahedra in PPV (139.0°), which is smaller than in PV (151.2°), and by change from a 3D to a quasi 2D Ru–O network.

Calcium rhodate compounds are not offered for sale commercially nor have any CAS numbers been issued.

13.2.4. Strontium Rhodium Compounds

In the ternary Sr–Rh–O system, several compounds have been reported: $Sr_{0.75}Rh_4O_8$, $SrRh_2O_4$, $Sr_6Rh_5O_{15}$, Sr_2RhO_4, and Sr_4RhO_6, which were synthesized by solid-state conventional methods. Recently, two new members were added to the rhodates system, which were prepared by a high-pressure method; the PV $SrRhO_3$ and the bilayered $Sr_3Rh_2O_7$. At the end of the high-pressure studies, it was clear that these compounds form a novel PV family as expressed by the general formula $Sr_{n+1}Rh_nO_{3n+1}$ ($n = 1$, 2, and infinity), indicating this must be a Ruddlesden–Popper series. It was also stressed that all the members were magnetically and electrically active because the oxygen-coordinated rhodium ions were formally tetravalent and had an unpaired electron per each (t^5_{2g}-e^0_g) configuration. Since all compounds in $Sr_{n+1}Rh_nO_{3n+1}$ formally form a spin-1/2 system, an appearance of quantum critical characters could be highly expected in the vicinity of the $Sr_{n+1}Rh_nO_{3n+1}$ composition or at physically extreme conditions. In fact, past studies on the $n = \infty$ compound suggested a substantial influence from quantum critical fluctuations.

A neutron diffraction study produced details of the structure of $Sr_4Rh_3O_{10}$ as shown in Fig. 13.39.

Because the significantly relevant systems, $Sr_3Rh_2O_7$ and $SrRhO_3$, share a common structure model with each corresponding ruthenate, the structurally intermediate $Sr_4Rh_3O_{10}$ was expected to share the tri-layered structure model with the ruthenate, $Sr_4Ru_3O_{10}$. High-pressure and high-temperature heating (6 GPa and 1500 °C) brought about successful preparation of a polycrystalline sample of the expected member at $n = 3$ of $Sr_{n+1}Rh_nO_{3n+1}$. Neutron diffraction studies showed the same orthorhombic crystal structure (*Pbam*) at room temperature and 3.4 K. Local structure distortions rotationally tilt the RhO_6 octahedra ~12° in the PV-based blocks along the *c*-axis, and approximately a 20% disorder was found in sequence of the alternating rotational tilt. The result clearly supported the *Pbam* model for the structure of $Sr_4Rh_3O_{10}$ as well as $Sr_3Rh_2O_7$. These compounds were also investigated by measurements of specific heat, thermopower, magnetic susceptibility, and

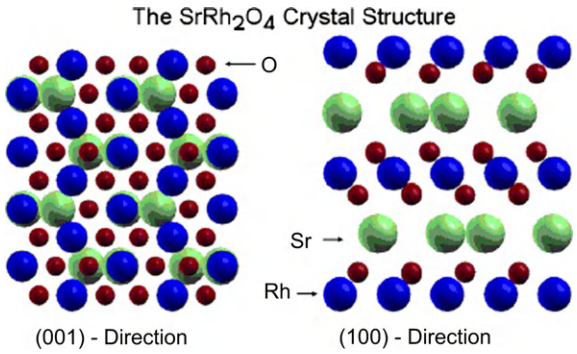

FIGURE 13.40

electrical resistivity. The data clearly revealed enhanced paramagnetism and electrically conducting character, which reflected nature of the correlated 4d5-electrons of Rh^{4+}. However, no clear signs of magnetic and electrical transitions were observed above 2 K and below 70 kOe, providing a remarkable contrast to the rich electronic phenomena for the significantly relevant ruthenate, $Sr_4Ru_3O_{10}$.

No compounds have been found in the Rh^{2+}-containing system of SrO–RhO.

In the Rh^{3+}-containing system of $SrO–Rh_2O_3$, the compound, $SrRh_2O_4$ has the structure shown in Fig. 13.40.

$SrRh_2O_4$ exists as RhO_2 sheets, isostructural to the CoO_2 sheets of Na_xCoO_2, and stacked in the same way. Similar to the Na ions in Na_xCoO_2, the Sr ions are distributed over the two TP (trigonal prismatic) sites in between the layers. The hexagonal crystal structure consists of hexagonal Rh sheets, coordinated above and below (along the *c*-axis) with hexagonal O sheets to produce an octahedral coordination of the Rh. These RhO_2 blocks are stacked in alternating fashion. That is, considering the stacking -O-Rh-O-O-Rh-O., one has a stacking pattern of .ABC·CBA. This yields two different types of TP sites between the one over the Rh ions (B) and the other over the O in the layer on the opposite side of the Rh sheet.

Density functional calculations have been used to obtain the electronic structure of β-$SrRh_2O_4$ in comparison with spinel $ZnRh_2O_4$. Both materials are band insulators, with substantial crystal field-induced band gaps, reflecting a strong transition metal–O hybridization. However, due to the bonding topology in these materials, the valence bands are very narrow. This leads to high thermoelectric powers within standard Boltzmann transport theory, and indicates that they can be the basis of good thermoelectric materials, provided that they can be doped into metallic states with reasonable carrier mobility. In the case of β-$SrRh_2O_4$, scattering due to Sr disorder is important. In addition, again in β-$SrRh_2O_4$, the band gap may be large enough to be of interest for photo-electrochemical H_2 production.

β-$SrRh_2O_4$ was prepared as a black powder by solid-state reaction of $SrCO_3$ with Rh metal in air. The compound crystallizes in the space group $P63c$, $Z = 1$, with $a = 3.0626$ Å and $c = 11.3996$ Å. The structure consists of $Cd1_2$-type layers of edge-sharing RhO_6 octahedra with an AABB oxygen layer sequence. Strontium is found in partial occupation of both available interlayer sites, in TP coordination.

Transport and thermal properties were examined for the layered rhodium oxide β-$Sr_{1-x}Rh_2O_4$. The parent compound $SrRh_2O_4$ is a band insulator. Transport and thermal properties were examined for the layered rhodium oxide β-$Sr_{1-x}Rh_2O_4$. The introduction of Sr^{2+} deficiencies results in an insulator–metal transition around $x \leq 0.2$. The metallic phase for $x > 0.2$ is a strongly correlated Fermi liquid with an enhanced quasi particle mass. The enhanced thermoelectric power of $S = 150\ \mu V/K$ at 1000 K in this metallic phase suggested that $Sr_{1-x}Rh_2O_4$ has great potential as a thermoelectric material.

α-$SrRh_2O_4$ has a triangular planar lattice of d^3 Cr^{3+} made from edge-sharing RhO_6 octahedra; the plane shows a very small orthorhombic distortion from hexagonal symmetry. With a Weiss temperature of ~596 K and a 3D magnetic ordering temperature of 43 K, the magnetic system is quasi 2D and frustrated. NPD shows that the ordered state is an incommensurate helical magnet, with an in-plane propagation vector of k = (0, 0.3217, 0). Temperature-dependent synchrotron powder diffraction characterization of the structure shows an increase in the inter-plane spacing on cooling below 100 K and an inflection in the cell parameters at the magnetic ordering temperature. These anomalies indicate the presence of a moderate degree of magneto-structural coupling. This material has a layered structure with triangular sheets of formula RhO_2 separated by Sr^{2+} in TP co-ordination. No other compounds are known in this system.

Results were presented concerning XRD, electrical resistivity, thermal stability and magnetic susceptibility data of the four phases found in the Rh_2O_3–SrO system within the compositional interval of 0–70 mol% SrO. Only Sr_2RhO_4 was already described in the literature; $Sr_3Rh_2O_{6.5}$, $SrRh_2O_4$ and $SrRh_3O_{5.5}$ are completely new. The first two crystallize in a hexagonal system with the unit cell parameters corresponding to: $a = 9.602$ Å, $c = 8.222$ Å and $a = 3.054$ Å, $c = 11.39$ Å, respectively, while $SrRh_3O_{5.5}$ is monoclinic with $a = 14.554$ Å, $b = 12.193$ Å, $c = 7.903$ Å and $\beta = 98.53°$. It has been found that, in these phases, resistivity strongly depends on oxygen content and whether Rh ions exhibit variable oxidation states. All the Rh_2O_3–SrO binaries represent interesting objects for more detailed studies of the nature of several magnetic anomalies exhibited by them.

Single crystals of $Sr_6Rh_5O_{15}$ were grown from a molten potassium carbonate flux. The structure was solved by both the traditional 3D crystallographic approach and the 4D superspace group approach using JANA2000. Both methods produced an equivalent structure determination, thereby confirming the 4D superspace group approach as an effective structure solution method for 3D commensurate composite structures. $Sr_6Rh_5O_{15}$ corresponds to the $n=1$, $m=1$ member of the $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$ family of 2H hexagonal PV-related oxides. This compound is characterized by pseudo 1D polyhedral chains of four face-sharing RhO_6 octahedra followed by one RhO_6 TP. These chains in turn are separated by Sr_∞ chains. Magnetic measurements were carried out on oriented single crystals, and a very large magnetic anisotropy in the magnetic susceptibility was observed. The crystal structure has the form shown in Fig. 13.41.

In this diagram, the structure of $Sr_6Rh_5O_{15}$ consists of chains of four face-sharing RhO_6 octahedra followed by one RhO_6 TP. They are labelled: light gray, RhO_6 octahedra; dark gray, RhO_6 TPs; green spheres, Sr atoms. The compound contains more than one valence of rhodium, namely:

$$Sr_6(2Rh^{3+}, 3Rh^{4+})_5O_{15}$$

In the Rh^{2+}–Rh^{3+}-containing system of SrO–Rh_3O_4, the stoichiometric compound, $SrRh_3O_5$, is not known. No other compounds have been synthesized.

In the Rh^{4+}-containing system of SrO–RhO_2, single crystals of layered PV $Sr_2RhO_{4-\delta}$ ($\delta=0.0$ and 0.1) were successfully grown by the floating zone method. Stoichiometric single crystals ($Sr_2RhO_{4.0}$) were obtained by O_2-annealing the as-grown crystals ($Sr_2RhO_{3.9}$). $Sr_2RhO_{4.0}$ and $Sr_2RhO_{3.9}$ show quasi 2D Fermi liquid behavior at low temperatures, whereas there are large differences in the anisotropy of electrical resistivity $\rho_c(3\text{ K})/\rho_{ab}(3\text{ K})$ and Wilson ratio R_w between $Sr_2RhO_{4.0}$ and $Sr_2RhO_{3.9}$:

$$\rho_c(3\text{ K})/\rho_{ab}(3\text{ K}) = 2400 \text{ for } Sr_2RhO_{4.0};\ R_w = 3.8$$
$$\rho_c(3\text{ K})/\rho_{ab}(3\text{ K}) = 19{,}000 \text{ for } Sr_2RhO_{3.9};R_w = 6.4$$

The differences experienced in the temperature dependence of the in-plane electrical resistivity ($T<15$ K), magnetic susceptibility ($T<300$ K) and specific heat ($T<10$ K) of $Sr_2RhO_{4.0}$ and $Sr_2RhO_{3.9}$ are mainly derived from those differences between the density of states and band structure near the corresponding Fermi level. It was stated that the changes in these physical properties, which are accompanied by oxygen defects in the $Sr_2RhO_{4-\delta}$ system, can be explained by the rigid band model. Moreover, these results also suggest that t_{2g} band filling can be controlled by adjusting the oxygen defect content δ in the $Sr_2RhO_{4-\delta}$ system. Although many similarities are observed in this study between the physical properties of $Sr_2RhO_{4.0}$ and $SrRu_2O_4$, $Sr_2RhO_{4.0}$ does not exhibit superconductivity down to 36 mK.

The bilayered rhodium oxide, $Sr_3Rh_2O_7$, was synthesized by high-pressure and high-temperature heating techniques. The single-phase polycrystalline sample of $Sr_3Rh_2O_7$ was characterized by measurements of magnetic susceptibility, electrical resistivity, specific heat, and thermopower. The structural characteristics were investigated by powder neutron diffraction technique. The rhodium oxide $Sr_3Rh_2O_7$ [*Bbcb*, $a=5.4744$ Å, $b=5.4716$ Å, $c=20.875$ Å] is isostructural to the meta-magnetic metal, $Sr_3Ru_2O_7$, with five 4d electrons per Rh (which is electronically equivalent to the hypothetical bilayered ruthenium oxide, where one electron per Ru is doped into the Ru-327 unit). The present data showed that the rhodium oxide $Sr_3Rh_2O_7$ is metallic with enhanced paramagnetism, similar to $Sr_3Ru_2O_7$. However, neither manifest contributions from spin fluctuations nor were any traces of a meta-magnetic transition found within the studied range from 2 K to 390 K below 70 kOe.

Study of the structural changes occurring during the reduction process of the $Sr_2RhO_{4+\delta}$ (214), i.e. the 2:1:4 atom-ratios, (n = 1 term of the Ruddlesden-Popper series), shows that for $\delta<0.02$ values, this material dissociates into the Sr_4RhO_6 (416) mono-dimensional phase, $\alpha=\infty$, $\beta=0$ compound of the $(A_3B_2O_6)_\alpha\cdot(A_3B_3O_9)_\beta$ family, and Rh metal. During the first stage, this process occurs by the formation of an intergrowth between the (214) and (416) materials which can be only detected by high-resolution electron microscopy and is easily interpreted on the basis of the structural relationship established between them. Further reduction allows the segregation of both phases as separated entities, which coexist with Rh metal. The dissociation

The Crystal Structure of $Sr_6Rh_5O_{15}$

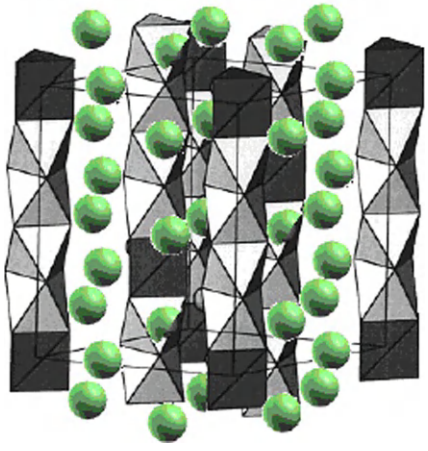

FIGURE 13.41

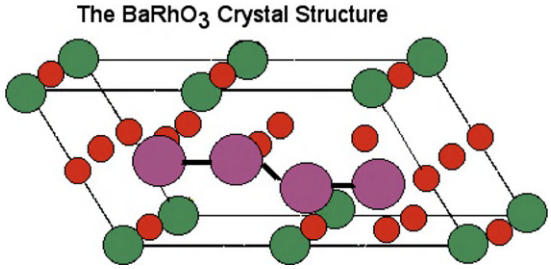

FIGURE 13.42

process is reversible and, under oxidizing conditions, a layered material with anionic composition $\delta = 0.06$ is always obtained. This behavior seems to be a general way of accommodating the compositional changes in layered A_2BO_4 phases where the B-cation is always in an octahedral environment. The structural mechanism of this transformation is proposed, and the structural relationship between these two low-dimensional oxides is established. When heated, transition from the layered Sr_2RhO_4 to the mono-dimensional Sr_4RhO_6 phase occurs:

$$2Sr_2RhO_4 + \text{heat} \Rightarrow Sr_4RhO_6 + RhO_2$$

In the Rh^{5+}-containing system of $SrO–Rh_2O_5$, no compounds are known.

In the Rh^{6+}-containing system of $SrO–RhO_3$, no compounds have been discovered.

Strontium rhodate or rhodite compounds are not available for sale commercially.

13.2.5. Barium Rhodium Compounds

A number of barium rhodate compositions have been reported in the literature.

In the Rh^{2+}-containing system of BaO–RhO, no compounds have been synthesized.

In the Rh^{2+}–Rh^{3+}-containing system of $BaO–Rh_3O_4$, no mention of any of the possible compounds such as $BaRh_3O_5$ or $Ba_2Rh_3O_6$ can be found in the technical literature.

In the Rh^{3+}-containing system of $BaO–Rh_2O_3$, the compound, $BaRh_2O_4$, is expected to have a similar crystal structure as that of $SrRh_2O_4$. However, such a determination has not appeared in the literature at this time. No other compounds have been synthesized in this system.

In the Rh^{4+}-containing system of $BaO–RhO_2$, the compound, $BaRhO_3$ has a crystal structure form shown in Fig. 13.42.

Barium rhodium oxide, $BaRhO_3$, was prepared at 1175 °C and 60–65 kbar by the reaction of BaO_2 and RhO_2. A hexagonal black platelet obtained in the reaction product was found to possess a four-layer stacking sequence in space group $P6_3/mmc$ having hexagonal unit cell parameters $a = 5.744(1)$ and $c = 9.642(1)$ Å. The structure was determined from 707 independent reflections of which 224 were considered observed. Averaging equivalent reflections yielded 132 unique observed reflections. Refinement of the structure by least-squares methods gave a conventional R value of 4.4%. The structure consists of a four-layer stacking sequence of close-packed BaO_3 layers containing tetravalent rhodium in all the octahedral oxygen interstices. The compound was found to be isostructural with previously reported $BaMO_3$ phases. This is the first single-crystal refinement of the 4H polytype using a four-circle X-ray diffractometer.

Cell parameters are: $a = b = 5.772$ Å, $c = 9.641$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 278.14 Å^3, $Z = 4$.

Cell occupancy is shown in Table 13.14.

Three different phases in the Ba–Rh–O system were prepared under high-pressure/high-temperature conditions. The black crystalline products were studied by XRD techniques and the space groups for several phases were obtained. The first phase, the 4H polytype $BaRhO_3$, was reported in the literature, but in addition two new phases were isolated and their structures determined. The second high-pressure Ba–Rh–O product, previously reported to be an 18R polytype, was observed to be isostructural with $BaIrO_3$. This phase was found to be non-stoichiometric with a deficiency in rhodium in octahedral sites, and a stoichiometry of $BaRh_{0.92}O_3$. The space group is $C2/m$ and the unit cell parameters are $a = 10.005$, $b = 5.764(1)$, $c = 14.937$ Å, $\beta = 102.99°$ and $Z = 12$. The third phase isolated in this study was observed to possess a Hollandite-type structure with space group $I2/m$, where the RhO_6 octahedra share

TABLE 13.14

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy

2	O2	O	6	g	.2/m.	1/2	0	0	1.0
3	Rh1	Rh	4	f	3m.	1/3	2/3	0.11	1.0
4	Ba1	Ba	2	d	-6m2	1/3	2/3	3/4	1.0
5	Ba2	Ba	2	a	-3m.	0	0	0	1.0

edges and vertices. Its unit cell parameters are $a = 9.435$, $b = 3.1041$, $c = 10.399$ Å, $\beta = 94.45°$ and $Z = 1$. Refinement of the structure generated the composition $Ba_{1.72}Rh_8O_{16}$.

The $\alpha = 3$, $\beta = 6$ term of the series $(A_3B_2O_6)_\alpha \cdot (A_3B_3O_9)_\beta$ has been synthesized in polycrystalline form. The structural characterization by powder XRD, electron diffraction and high-resolution electron microscopy indicates that this material is isostructural with $Ba_9Co_8O_{24}$. In the structure, seven face-sharing octahedra alternate with a TP defining chains running parallel to the *c*-axis of a rhombohedral unit cell (*Rc*), with parameters $a = 1.00766(4)$ nm and $c = 4.1571(2)$ nm. The structural refinement shows the presence of a small percentage of Rh vacancies leading to the composition $Ba_9Rh_{7.92}O_{24}$. Pauli paramagnetic behavior is observed.

The structure, 2H-$BaRhO_3$ has not yet been synthesized. Single crystals of two new barium rhodates were grown from a molten potassium carbonate flux. These rhodates, $Ba_{11}Rh_{10}O_{30}$ and $Ba_{32}Rh_{29}O_{87}$, are structurally related to the 2H-hexagonal PV structure and are characterized by pseudo 1D chains of alternating face-sharing TPs and octahedra. The structures of $Ba_{11}Rh_{10}O_{30}$ and $Ba_{32}Rh_{29}O_{87}$ were solved using the 4D superspace group approach in January 2000. $Ba_{11}Rh_{10}O_{30}$, with a repeat of nine RhO_6 octahedra followed by one RhO_6 TP, contains the longest chain sequence of face-sharing octahedra known for this 2H-PV-related family of oxides. A structural analysis of these two compounds revealed clear trends in metal–metal distances and octahedral heights not previously identified for this family of oxides. The application of these trends toward the structure of the all-octahedra-containing end member of the structural series, the hypothetical 2H-$BaRhO_3$, enabled a prediction of its rhodium–rhodium distance, octahedral height, and lattice parameters.

A plot of the interatomic distances between Rh–Rh atoms and the number of Rh atoms in the chain are shown in Fig. 13.43.

No other compounds are known in this system.

In the Rh^{5+}-containing system of BaO–Rh_2O_5, no compounds have appeared in the literature.

In the Rh^{6+}-containing system of BaO–RhO_3, the synthesis and microstructural characterization, by means of selected-area electron diffraction and high-resolution electron microscopy, of $Ba_7Rh_6O_{18}$ was reported. This material, isostructural to $Ba_7Co_6O_{18}$, is formed by rows of one TP and five face-sharing octahedra running parallel to the *c*-axis of a trigonal unit cell, with parameters $a = 10.04(5)$ and $c = 31.65(7)$ Å. The substitution of Sr by Ba is accommodated by means of twin formation due to a rearrangement of the rows of polyhedra. This compound belongs to the 1D oxide of the homologous series $(A_3Rh_2O_6)_\alpha$–$(A_3Rh_3O_9)_\beta$.

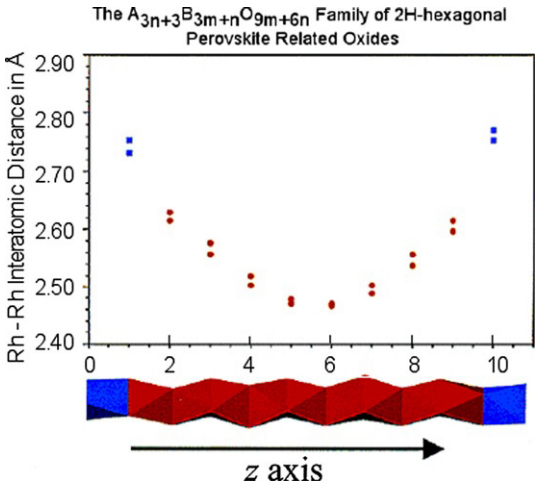

FIGURE 13.43

Barium rhodate or rhodite compounds are not offered for sale commercially and no CAS numbers have been issued.

13.2.6. Radium Rhodium Compounds

Although radium probably forms similar types of compounds as those of barium rhodates, no mention of such is available in the current literature. This is undoubtedly due to the lack of interest in both Academia and Industry. The radioactivity of ^{126}Ra and the high cost of rhodium metal ($1975.00/oz—July 2011) are probably the major factors in this lack of interest.

13.3. ALKALINE EARTH IRIDIUM COMPOUNDS

Iridium has the electron configuration [Xe] $4f^{14}$ $5d^7$ 6 and the valence states of −3, −1, 0, 1, 2, **3**, **4**, 5, 6. The first four states are found only in solution. It is the +3 and +4 states that are the more important. IrO_2, a brown powder, is the only well-characterized oxide of iridium. Ir_2O_3, has been described as a blue-black powder that is oxidized to IrO_2 by HNO_3. Iridium also forms iridates such as K_2IrO_3 and $KIrO_3$ with oxidation states +4 and +5, but no similar compounds have been found with the alkaline earths.

13.3.1. Beryllium Iridium Compounds

The system, Be^0–Ir^0, has been stated to form at least three intermetallic compounds, Be_4Ir, $Be_{44}Ir_7$ and $Be_{13}Ir_3$. However, only one compound, $Be_{17}Ir_2$ has had its structure published. It has the form shown in Fig. 13.44.

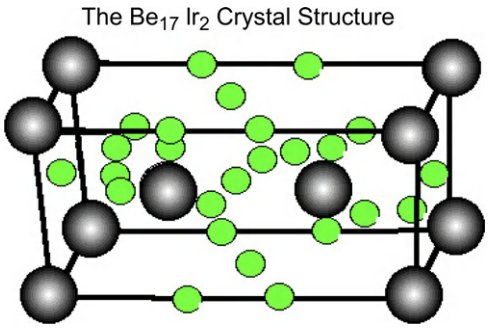

FIGURE 13.44

Cell parameters for $Mg_{17}Ir_2$ are: $a = b = 4.193$ Å, $c = 10.892$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 165.34$ Å^3, $Z = 6$. Cell occupancy is shown in Table 13.15.

It is somewhat puzzling that $Be_{17}Ir_2$ does not appear in a published phase diagram. Yet, the structures of the compounds, $Be_{44}Ir_7$, $Be_{13}Ir_3$ and Be_3Ir have not appeared in the open literature. By comparing the published data for the Mg–Ir system, it becomes obvious that the Be–Ir system was misinterpreted and that these three compounds do not exist.

Beryllium oxide(s) does not form any compounds with the iridium oxides.

13.3.2. Magnesium Iridium Compounds

Magnesium metal forms a series of intermetallic compounds with Ir^0 metal, as shown in the partial phase diagram of Fig. 13.45.

The compound, Mg_3Ir, has the structure shown in Fig. 13.46.

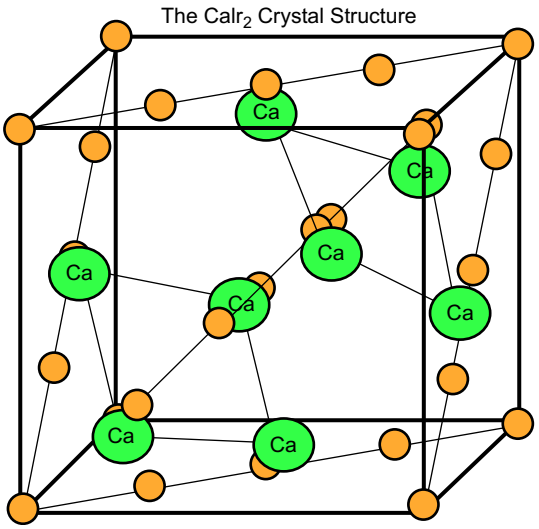

FIGURE 13.48

In the system of MgO–Ir_xO_y, no compounds have been documented. Even the known oxides of Ir_2O_3 and IrO_2 have not been observed to form stable compounds with MgO.

None of these compounds are available commercially.

13.3.3. Calcium Iridium Compounds

In the Ca–Ir system, only one structure has been reported (Fig. 13.48).

Cell parameters are: $a = b = c = 5.3351$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 107.38 Å^3, cell occupancy is shown in Table 13.18.

No compounds have been reported in the Ir^{2+}-containing system of CaO–IrO, in the Ir^{3+}-containing system of CaO–Ir_2O_3 or in the Ir^{2+}–Ir^{3+}-containing system of CaO–Ir_3O_4.

In the Ir^{4+}-containing system of CaO–IrO_2, the types of compounds formed in the system depends upon the oxygen partial pressure available during the solid-state reaction. The diagram presented as Fig. 13.49 shows this phenomenon.

The diagram shows the minimum partial pressure required during reaction of CaO with Ir metal at 1300 K. This is a constant factor for each of the three compounds (the horizontal lines). Excess Ir metal is present at all times until the pressure is reached where IrO_2 is produced directly. The vertical lines represent a separation of bi-compositional areas of compounds

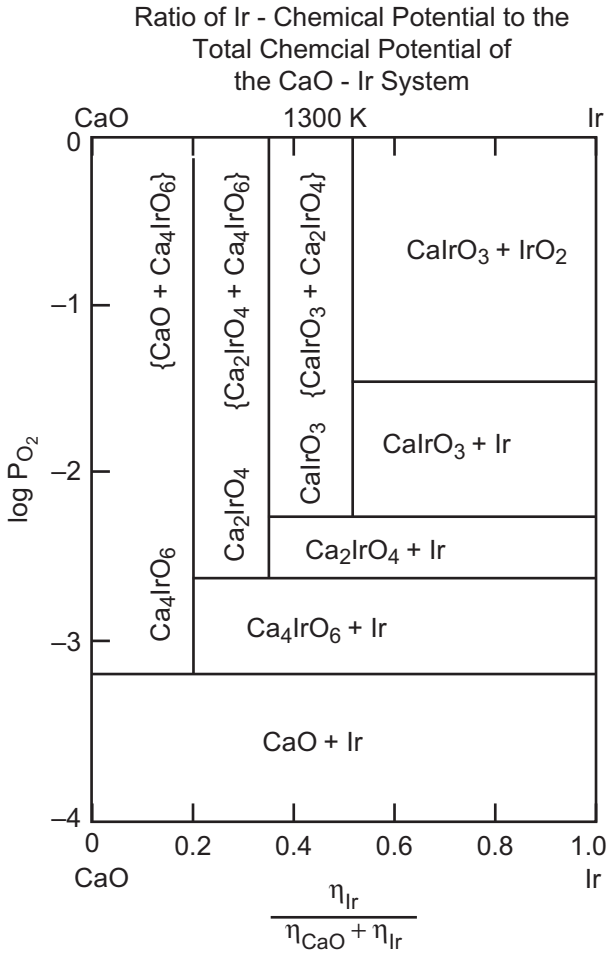

FIGURE 13.49

produced as a function of the ratio of the chemical potential of Ir in terms of the chemical potential of both components. The standard Gibbs energies of formation of the compounds, obtained from the e.m.f. of the cells, can be represented by the equations:

$$IrO_2 \quad \Delta G^0_f/\mathrm{J/mol} = -239{,}230 + 172.19T$$

$$CaIrO_3 \quad \Delta G^0_{f(ox)}/\mathrm{J/mol} = 460 + 1.13T$$

$$Ca_2IrO_4 \quad \Delta G^0_{f(ox)}/\mathrm{J/mol} = -31{,}145 + 0.81T$$

$$Ca_4IrO_6 \quad \Delta G^0_{f(ox)}/\mathrm{J/mol} = -37{,}400 + 2.01T$$

where $\Delta G^0_{f(ox)}$ represents the standard Gibbs energy of formation of the ternary compound from its component binary oxides CaO and IrO_2. Based on the thermodynamic information, this chemical potential diagram for the system Ca–Ir–O was developed. The standard Gibbs

TABLE 13.18

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	Ir	Ir	16	c	.-3m	0	0	0	1.0
2	Ca	Ca	8	b	-43m	3/8	3/8	3/8	1.0

energies of formation of IrO_2, $CaIrO_3$, Ca_2IrO4 and Ca_2IrO_6 were measured in the temperature range 940–1350 K using solid-state cells with $Y_2O_3{\cdot}ZrO_2$ as the electrolyte and pure oxygen gas at a pressure of 0.1 MPa as the reference electrode. For the design of appropriate working electrodes, phase relations in the ternary system Ca–Ir–O were investigated at 1300 K. The only stable oxide detected along the binary Ir–O line was IrO_2. Three ternary oxides, $CaIrO_3$, Ca_2IrO_4, and Ca_4IrO_6, compositions of which fall on the joined $CaO–IrO_2$, were found to be stable. Each of the oxides coexisted with pure metal Ir. Therefore, five working electrodes were prepared, consisting of mixtures of:

$$\mathrm{Ir} + \mathrm{IrO_2},$$
$$\mathrm{Ir} + \mathrm{IrO_2} + \mathrm{CaIrO_3},$$
$$\mathrm{Ir} + \mathrm{CaIrO_3} + \mathrm{Ca_2IrO_4},$$
$$\mathrm{Ir} + \mathrm{Ca_2IrO_4} + \mathrm{Ca_4IrO_6},$$
$$\text{and } \mathrm{Ir} + \mathrm{Ca_4IrO_6} + \mathrm{CaO}.$$

These mixtures unambiguously define unique oxygen chemical potentials under isothermal and isobaric conditions.

When three condensed phases coexist at equilibrium in a ternary system such as Ca–Ir–O, the system is bivariant. At a fixed temperature and total pressure, three condensed phases coexist only at a unique partial pressure of oxygen (as shown above). Therefore, horizontal lines on the diagram represent three-phase equilibria. On reducing the oxygen partial pressure at 1200 K, IrO_2 dissociates first followed by the ternary oxides in the order of decreasing cationic fraction of Ir. The stability domain of each stoichiometric phase is defined by a plane, because the sum of the chemical potentials of the different components weighted by the appropriate stoichiometric coefficients is equal to the Gibbs energy of formation of the phase. Lines, defined by the intersection of the corresponding planes, represent two-phase fields. Points of intersection of three planes identify three-phase equilibria.

The compound, $CaIrO_3$ has the form shown in Fig. 13.50. The structure of the Ca_4IrO_6 has not been elucidated. $CaIrO_3$ dissociates to Ir and Ca_2IrO_4 at 1408 K.

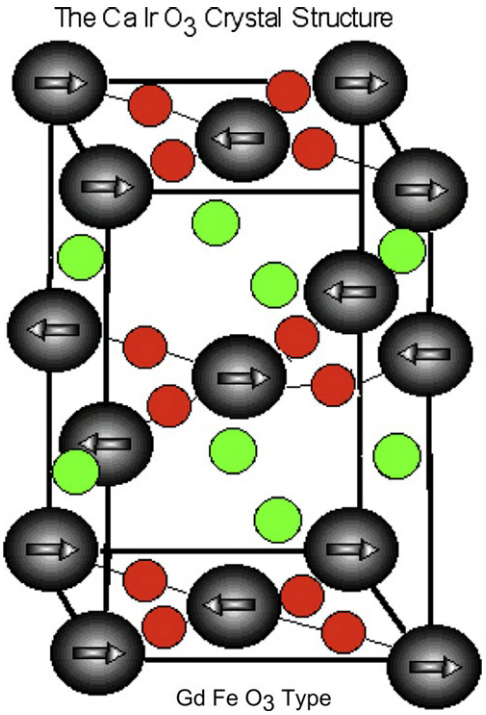

FIGURE 13.50

Cell parameters are: $a = 5.346$ Å, $b = 5.587$ Å, $c = 7.677$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 229.30$ Å^3, $Z = 10$. Cell occupancy is shown in Table 13.19.

In another paper, the structure of $CaIrO_3$ (*Cmcm*) was refined at high pressure and at low temperature using time-of-flight NPD data. Evidence supporting deviation from space group *Cmcm* to $Cmc2_1$ has been determined to be inconclusive. As the $CaIrO_3$ (*Cmcm*) unit-cell volume changes, refinements indicated deformation of cation-centered coordination polyhedra, rather than tilting. Structure models demonstrated that Ca^{2+}-centered polyhedra are an order of magnitude more compressible than Ir^{4+}-centered octahedra. Bond valence sums show significant chemical strain (over-bonding) of calcium and oxygen at ambient conditions. Implications for structure change in $CaIrO_3$ PPV were discussed and a method for predicting the Clapeyron slope between PV and PPV phases was proposed based on

extrapolation of the volume ratio between cation-centered polyhedra.

Further work has included the preparation of single crystals of $CaIrO_3$ via a flux growth method. Crystal structure parameters, including the anisotropic displacement parameters, were determined based on a single-crystal XRD experiment. The unit-cell dimensions are $a = 3.147$, $b = 9.866$, and $c = 7.302$ Å. The structure was found to be a 3D dense structure with small vacant spaces. The $CaIrO_3$ structure can be described as a pseudo 1D oxide and was compared with Ca_4IrO_6 structure. The IrO_6 octahedra are significantly distorted, in contrast to other octahedral Ir^{4+} compounds. The O–O distances for faces and edges shared between polyhedra are shorter than other non-shared edge distances. These effects were explained by Pauling's rules and occurred to decrease the repulsion between the cations. Thermal vibrations of Ca and Ir atoms were found to be significantly anisotropic. Thermal vibrations of Ca and Ir atoms in this structure are restricted in orientation toward the shared face, shared edges, and shortest cation–cation directions. The single-crystal experiment shows that $CaIrO_3$ crystals grow fastest along the *a*-axis and that they assume a prism or needle shape. Strongly preferred orientation of such prism-shaped $CaIrO_3$-type PPV $MgSiO_3$ crystals may develop under the shear flow in the Earth's mantle.

Several calcium iridium oxides were prepared by solid-state reactions and by a hydroxide precipitation technique. These phases were characterized by XRPD data, electrical and magnetic properties. The calcium-rich phase, Ca_4IrO_6, was an insulator exhibiting Curie–Weiss behavior above 77 K with a Weiss constant of −47 K and a magnetic moment of 1.76 μbar.

In contrast, Ca_2IrO_4 is a semiconductor and the temperature-dependent susceptibility above 77 K was analyzed in terms of 1D linear chains of octahedrally coordinated Ir^{4+} ions. Its structure has the form shown in Fig. 13.51.

Single crystals of tetracalcium iridium hexa-oxide, Ca_4IrO_6, tricalcium magnesium iridium hexa-oxide, Ca_3MgIrO_6, and tricalcium zinc iridium hexa-oxide, Ca_3ZnIrO_6, were prepared via high-temperature flux growth and structurally characterized by single-crystal XRD. The three compounds are isostructural and adopt the K_4CdCl_6 structure type, comprised of chains of alternating face-shared $[CaO_6]$, $[MgO_6]$ or $[ZnO_6]$ TPs and $[IrO_6]$ octahedra, surrounded by columns of Ca^{2+} ions. Two $CaIrO_3$ phases were also isolated, but only the orthorhombic PV modification was sufficiently pure for magnetic studies. This compound was Pauli paramagnetic with metallic conductivity.

The pressure–volume–temperature (P–V–T) relation of $CaIrO_3$ and the PPV variety was measured at pressures and temperatures up to 8.6 GPa and 1273 K, respectively, with energy-dispersive synchrotron XRD using a DIA-type, cubic-anvil apparatus. Unit-cell dimensions were derived from the Le Bail full profile refinement technique, and the results were fitted using the third-order Birch–Murnaghan equation of state. The derived bulk modulus K_{T0} at ambient pressure and temperature is 168.3 ± 7.1 GPa with a pressure derivative $K_{0T0} = 5.4 \pm 0.7$. All of the high-temperature data, combined with previous experimental data, are fitted using the high-temperature Birch–Murnaghan equation of state, the thermal pressure approach, and the Mie-Grüneisen-Debye formalism.

The refined thermoelastic parameters for CaIrO3 ppv are:

Temperature derivative of bulk modulus

$$<\text{eth}>oK_T = oT_P = -0.038 \pm 0.011 \text{ GPa/K},$$
$$aK_T = 0.0039 \pm 0.0001 \text{ GPa/K}$$
$$\partial K_T/\partial T_V = -0.012 \pm 0.002 \text{ GPa/K}$$
$$\partial P/\partial T_{2V} = 1.9 \pm 0.3 \times 10^{-6} \text{ GPa}_2/\text{K}^2$$

Using the Mie-Grüneisen-Debye formalism, the Grüneisen parameter $c_0 = 0.92 \pm 0.01$ and its volume dependence $q = 3.4 \pm 0.6$ were obtained. The systematic variation of bulk moduli for several oxide PPVs can be described approximately by the relationship $K_{T0} = 5406.0/\text{V(molar)} + 5.9$ GPa.

A structural, thermodynamic, and transport study of the newly synthesized $Sr_5Rh_4O_{12}$, $Ca_5Ir_3O_{12}$, and Ca_4IrO_6 single crystals was conducted. These quasi 1D insulators consist of a triangular lattice of spin chains running along the *c*-axis, and are commonly characterized by a partial AFM order, a small entropy removal associated with the phase transitions, and a sizable low-temperature specific heat linearly proportional to temperature. $Sr_5Rh_4O_{12}$ is antiferromagnetically ordered below 23 K with strong evidence for an Ising character. Isothermal magnetization of $Sr_5Rh_4O_{12}$ exhibits two-step like transitions leading to a ferrimagnetic state at 2.4 T and a FM state at 4.8 T, respectively. $Ca_5Ir_3O_{12}$ and Ca_4IrO_6 are also

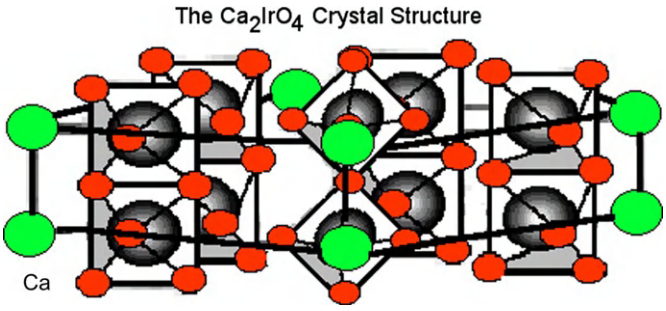

FIGURE 13.51

antiferromagnetically ordered below 7.8 and 12 K, respectively, and show an unusually large ratio of the Curie–Weiss temperature to the Néel temperature. In particular, $Ca_5Ir_3O_{12}$, which includes both Ir^{4+} and Ir^{5+} ions, reveals that only $S = 1/2$ spins of the Ir^{4+} ions are involved in the magnetic ordering, whereas $S = 1$ spins of the Ir^{5+} ions remain disordered. All results suggest the presence of a geometrical frustration that causes incomplete long-range AFM order in these quasi 1D compounds.

In the Ir^{5+}-containing system of CaO–Ir_2O_5, the ternary oxides $Ca_2Ir_2O_7$, $Cd_2Ir_2O_7$, and $Ca_{1.7}Os_2O_7$ have been prepared. They possess the cubic pyrochlore structure. All of these iridium phases contain Ir^{5+} and are the first oxide examples of iridium in an oxidation state higher than 4. A body-centered cubic structure related to the cubic $KSbO_3$ structure has been found for phases with compositions close to $BaOs_2O_6$, $SrOs_2O_6$, and $SrRe_2O_6$. The osmate compositions contain osmium in a +5 state, i.e. Os^{5+}. A primitive cubic structure also related to the cubic $KSbO_3$ structure has been found for phases with compositions close to $NaOsO_3$, $BiPtO_{3.5}$, and $BiOsO_{3.5}$.

No compounds have been documented in the Ir^{6+}-containing system of CaO–IrO_3.

Calcium–iridium compounds are not offered for sale commercially.

13.3.4. Strontium–Iridium Compounds

In the Sr–Ir system, only one compound, $SrIr_2$, has been reported. It has an identical crystal structure to $CaIr_2$ except for the cell parameters: $a = b = c = 7.7351$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 114.13 Å^3, cell occupancy is shown in Table 13.20.

A number of compositions of several phases in the Sr–Ir–O system have been reported within the past 30 years, and the single-crystal structures of three of these were determined. The formulation for one of these phases, namely the body-centered cubic, has been assigned different ratios of strontium, iridium and oxygen by various workers, which has led to some confusion as to its exact chemical composition. To clarify this situation, a study of the composition of the different Sr–Ir–O phases was carried out by electron microprobe analysis using a Kevex quantum energy dispersive detector, which is readily capable of detecting the K_α X-ray emission from oxygen along with that from heavier elements. Reference standards of pure IrO_2, SiO_2 (quartz), fused $SrCl_2$ and $SrCO_3$ were used for calibration of Ir, O, Cl and Sr contents, respectively. In addition, the Sr to Ir ratio was determined by using known standards such as the well-characterized monoclinic and orthorhombic (high-pressure) forms of $SrIrO_3$, and Sr_2IrO_{4-}. The analysis of the body-centered cubic Sr···Ir···O phase indicates a chemical formula of $Sr_{0.79}IrO_{2.8}Cl_{0.07}$. The trace of chlorine may be necessary to stabilize this structural form of the compound. The standard Gibbs energies of formation of $SrIrO_3$, Sr_2IrO_4 and Sr_4IrO_6 have been determined in the temperature range from 975 to 1400 K using solid-state cells with (Y_2O_3) ZrO_2 as the electrolyte and pure oxygen gas at a pressure of 0.1 MPa as the reference electrode. For the design of appropriate working electrodes, phase relations in the ternary system Sr–Ir–O were investigated at 1350 K. The only stable oxide detected along the binary Ir–O was IrO_2. Three ternary oxides, $SrIrO_3$, Sr_2IrO_4 and Sr_4IrO_6, compositions of which fall on the join SrO–IrO_2, were found to be stable. Each of the oxides coexisted with pure metal Ir. Therefore, three working electrodes were prepared consisting of mixtures of $Ir + SrO + Sr_4IrO_6$, $Ir + Sr_4IrO_6 + Sr_2IrO_4$, and $Ir + Sr_2IrO_4 + SrIrO_3$. These mixtures unambiguously define unique oxygen chemical potentials under isothermal and isobaric conditions. Used for the measurements was a novel apparatus, in which a buffer electrode was introduced between reference and working electrodes to absorb the electrochemical flux of oxygen through the solid electrolyte. The buffer electrode prevented polarization of the measuring electrode and ensured accurate data. The standard Gibbs energies of formation of the compounds, obtained from the e.m.f. of the cells, can be represented by the following equations:

$$SrIrO_3: \Delta G^{o}_{f\,(ox)}/\mathrm{J/mol} = -58{,}860 - 1.23T\ (\pm 650)$$

$$Sr_2IrO_4: \Delta G^{o}_{f\,(ox)}/\mathrm{J\ mol^{-1}} = -82{,}315 - 2.86T$$

$$Sr_4IrO_6: \Delta G^{o}_{f\,(ox)}/\mathrm{J\ mol^{-1}} = -84{,}690 - 6.78T$$

where $\Delta G^{o}_{f(ox)}$ represents the standard Gibbs energy of formation of the ternary compound from its component binary oxides SrO and IrO_2. Based on the thermodynamic information, chemical potential diagrams for the system Sr–Ir–O were developed.

No compounds have been reported in the Ir^{2+}-containing system of SrO–IrO, in the Ir^{3+}-containing system of SrO–Ir_2O_3, or in the Ir^{2+}–Ir^{3+}-containing system of SrO–Ir_3O_4.

TABLE 13.20

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	Ir	Ir	16	c	.-3m	0	0	0	1.0
2	Sr	Sr	8	b	-43m	3/8	3/8	3/8	1.0

In the Ir^{4+}-containing system of $SrO–IrO_2$, $SrIrO_3$ has been found to be a non-Fermi liquid metal near a FM instability, as characterized by the following properties:

(1) small ordered moment but no evidence for long-range order down to 1.7 K;
(2) strongly enhanced magnetic susceptibility that diverges as $T^{-\gamma}$ at low temperatures with $1/2 < \gamma < 1$, depending on the applied field;
(3) heat capacity $C(T,H) \sim -T \log T$ that is readily amplified by low applied fields;
(4) a strikingly large Wilson ratio at $T < 4$ K; and
(5) a $T^{3/2}$ dependence of electrical resistivity over the range $1.7 < T < 120$ K.

A phase diagram based on such data implied that $SrIrO_3$ is a rare example of a stoichiometric oxide compound that exhibits non-Fermi liquid behavior near a quantum critical point ($T = 0$ and $\mu_0 H = 0.23$ T). However, the phase diagram was never published in the open literature.

Single crystals with the composition $Sr_5Ir_3O_{11}$ were found to grow in the system $SrO–IrO_2$. A single-crystal structure determination [tetragonal, space group $I4/mmm$, with $a = 3.890(1)$ and $c = 16.890$ Å, and $R = 0.050$] revealed alternate stacking of single and double IrO_6 PV layers interleaved with SrO layers along the c-axis. Although the refined metal–oxygen distances were quite reasonable, the thermal parameters of one "heavy" atom (iridium) and one "light" atom (oxygen) were non-positive definite. Careful examination of Weissenberg and transmission electron microscopy photographs showed that the single crystals actually contained random distributions of single and double IrO_6 PV layers arising from the intergrowth of Sr_2IrO_24 and $Sr_3Ir_2O_7$ phases.

Single crystals of $Sr_3Ir_2O_7$ were grown for the first time by the $SrCl_2$ flux method using SrO_2 and IrO_2 in a sealed Pt tube under ambient pressure. The compound crystallizes in a tetragonal unit cell [$a = 3.896$ and $c = 10.585$ Å] with space group $I4/mmm$ (No. 139) and $Z = 2$. The crystal structure was solved by means of single-crystal XRD and refined to $R = 0.014$. The structural refinement showed that the IrO_6 octahedra are rotated about the c-axis by about 12°, similar to the rotational distortion recently found in Sr_2IrO_4. However, unlike in Sr_2IrO_4, the IrO_6 rotations in $Sr_3Ir_2O_7$ are not correlated, hence no superlattice reflections appear.

The electronic structures of the 5d Ruddlesden–Popper series $Sr_{n+1}Ir_nO_{3n+1}$ ($n = 1$, 2, and ∞) were studied using optical spectroscopy and first-principles calculations. These included Sr_2IrO_4, $Sr_3Ir_2O_7$ and $SrIrO_3$. As 5d orbitals are spatially more extended than 3d or 4d orbitals, it has been widely accepted that correlation effects are minimal in 5d compounds. However, we observed a bandwidth-controlled transition from a Mott insulator to a metal as we increased n. In addition, the artificially synthesized PV $SrIrO_3$ showed a very large mass enhancement of about 6, indicating that it was in a correlated metallic state. Sr_2IrO_4 should be occupied by five t_{2g} electrons. The large SO coupling can split the degenerate t_{2g} orbitals into $J_{\text{eff},1/2}$ and $J_{\text{eff},3/2}$ bands. The $J_{\text{eff},1/2}$ bands can be very narrow due to a decreased hopping integral caused by the isotropic orbital and mixed spin characters. Bulk $SrIrO_3$ has a hexagonal crystal structure at room temperature and atmospheric pressure. It transforms to the PV structure only at a higher pressure and temperature. The structure of the atmospheric pressure form of $SrIrO_3$ has been shown to be a monoclinic distortion of the hexagonal $BaTiO_3$ structure ($a = 5.604$ Å, $b = 9.618$ Å, $c = 14.172$ Å, $\beta = 93.26°$). The cell dimensions have been studied to 1000 °C and the coefficients of thermal expansion given. The structure transforms at 40 kbar and 1000 °C to an orthorhombic PV ($a = 562$ Å, $b = 5.583$ Å, $c = 7.892$ Å) with a 3% decrease in volume. This high-pressure phase only retransforms slowly at atmospheric pressure and 1200 °C and exhibits metallic conductivity and Pauli paramagnetism.

Schematic band diagrams of 5d $Sr_{n+1}Ir_nO_{3n+1}$ compounds, which are well described by the effective total angular moment J_{eff} states due to strong spin-orbit coupling are shown as follows: (a) Mott insulator, Sr_2IrO_4, (b) barely insulator, $Sr_3Ir_2O_7$, and (c) correlated metal, $SrIrO_3$. E_F represents the Fermi level and the arrow indicates the direction for the bandwidth W increase.

Sr_2IrO_4 has the symmetry of space group $I\,4_1/acd$ and lattice parameters $a = 5.4994$ and $c = 25.7841$ Å. The unit cells of the two compounds are related to one another by the transformation matrix (1, −1, 0/1, 1, 0/0, 0, 2). The main difference between the two structures is that the MO_6 octahedra (M = Ru, Ir) have a regular, undistorted configuration in the ruthenium compound, while they are tilted by about 11° around the c-axis of the unit cell in the iridium compound. The oxygen atoms of the IrO_2 layers were found to be disordered over two sets of positions x, x, 1/4 with $x = 1/4 \pm \delta$. This means that the IrO_6 octahedra assume two configurations and, on a local level, their relative orientation does not obey the symmetry requirements of space group $I4_1/acd$ in all cases. The MO_6 octahedra are elongated along the c-axis, and this distortion is more pronounced in Sr_2RuO_4 than in Sr_2IrO_4. The coordination of the strontium atoms is ninefold in both compounds. Because of the tilting of the IrO_6 octahedra, however, the coordination polyhedra are different in the two cases. No phase transitions have been observed down to 10 K in either compound.

The magnetic structuring of Sr_2IrO_4 is shown in Fig. 13.52.

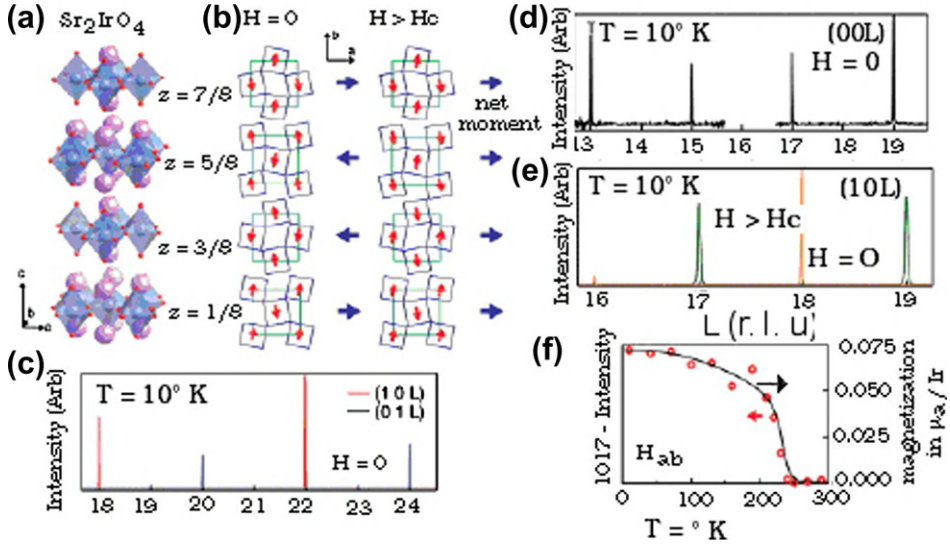

FIGURE 13.52

The following describes these factors:

Magnetic ordering pattern of Sr_2IrO_4: (**a**) Layered crystal structure of Sr_2IrO_4, consisting of a tetragonal unit cell (space group $I4_1/acd$) with lattice parameters $a \approx 5.5$ Å and $c \approx 26$ Å. The blue, red, and purple circles represent Ir, O, and Sr atoms, respectively. (**b**) Canted AFM ordering pattern of $J_{\text{eff}} = 1/2$ moments (arrows) within IrO_2 planes and their stacking pattern along the *c*-axis in zero field and in the weakly FM state, determined from the X-ray data shown in (C) to (E). (**c** and **d**) L-scan profile of magnetic XRD ($\lambda = 1.1$ Å) along the (1 0 L) and (0 1 L) direction (C) and the (0 0 L) direction (D) at 10 K in zero field. The huge fundamental Bragg peak at (0 0 16) and its background were removed in (D), r.l.u., reciprocal lattice unit. (**e**) L-scan of magnetic XRD ($\lambda = 1.1$ Å) along the (1 0 L) direction at 10 K in zero field and in the in-plane magnetic field of ≈ 0.3 T parallel to the plane. (**f**) The temperature dependence of the intensity of the magnetic (1 0 19) peak (red circles) in the in-plane magnetic field $H \approx 0.3$ T. The temperature-dependent magnetization in the in-plane field of 0.5 T is shown by the solid line.

An extremely damage-robust $SrRuO_3/IrO_2$ top electrode (TE) FeRAM, prepared with a Cu BEOL process, was demonstrated for the first time as a promising device for 130 nm CMOS embedded memory. The ferroelectric capacitor with a $SrRuO_3/IrO_2$ TE showed no degradation during the Cu metallization (used to suppress the oxygen and lead vacancies at theTE interface). Switching charge (Qsw) of 40 $\mu C/cm^2$ was achieved for $0.45 \times 0.45\ \mu m^2$ TE size capacitor. The opposite state polarization margin of 90% was retained against imprint at 70 h and 150 °C bake. This high-reliable capacitor, with a large Q_{sw} and a small bit line capacitance of "chain" structure, increased the signal window drastically. A signal window of 730 mV at 1.8 V operation voltage after a three-level Cu metallization was achieved. This technology makes possible future 130 nm embedded FeRAM and other devices beyond.

No compounds have been discovered in the Ir^{5+}-containing system of $SrO–Ir_2O_5$, or in the Ir^{6+}-containing system of $SrO–IrO_3$.

Strontium iridate compounds are not offered for sale commercially, nor have any CAS numbers been issued.

13.3.5. Barium Iridium Compounds

Barium metal does not form any intermetallic compounds with iridium.

No compounds have been discovered in the Ir^{2+}-containing system of BaO–IrO, in the Ir^{3+}-containing system of $BaO–Ir_2O_3$, in the Ir^{2+}–Ir^{3+}-containing system of $BaO–Ir_3O_4$, in the Ir^{5+}-containing system of $BaO–Ir_2O_5$, or in the Ir^{6+}-containing system of $BaO–IrO_3$.

In the Ir^{4+}-containing system of $BaO–IrO_2$, the high-pressure and high-temperature sequence of the Ruddlesden–Popper type of $BaIrO_3$ layered compounds have been studied. The structures have the general form shown in Fig. 13.53.

The high-pressure sequence of the PV polytypes of $BaIrO_3$ has been investigated in the pressure range up to 10 GPa. At ambient pressure, the so-called "9R" polytype has been prepared by solid-state reaction and slow cooling in air to yield an almost fully oxygen-stoichiometric $BaIrO_{2.96}$ composition. The crystal structure has been refined from XRD data in the monoclinic $C2/m$ space group with $a = 10.0046$ Å, $b = 5.75362$ Å, $c = 15.1839$ Å, $\beta = 103.27°$; it contains trimers of face-sharing octahedra

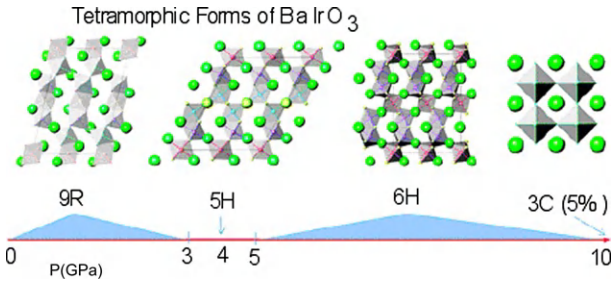

FIGURE 13.53

(or Ir_3O_{12} trioctahedra) that are linked by their vertices to form columns parallel to the *c*-axis with a stacking of layers of corner-sharing (c) and face-sharing (h) IrO_6 octahedra along the sequence hhchhc. This structure is stable up to 3 GPa. At 4 GPa a new 5H polytype of $BaIrO_3$ has been stabilized as a pure phase. The crystal structure has been solved by ab initio procedures from powder XRD data. It is monoclinic with $a = 9.9511$ Å, $b = 5.7503$ Å, $c = 13.71003$ Å, $\beta = 118.404°$, and it was refined in the $C2/m$ space group from NPD data collected at room temperature. This polytype can be described as a stacking of IrO_6 octahedra along the sequence hchcc. The structure contains chains of double dimer units of face-sharing octahedra; the twin dimers are connected to single layers of vertex-sharing octahedra, forming infinite chains along *c*. This is a unique stacking that, with this repetition length, has never been described before among the hexagonal polytypes of ABO_3 PVs. The 5H polytype is stable in a narrow pressure range. At 5 GPa, the 6H structure is formed and is stable up to 10 GPa. The 6H-$BaIrO_3$ polytype is monoclinic, space group $C2/c$, with $a = 5.7483$ Å, $b = 9.9390$ Å, $c = 14.3582$ Å, $\beta = 91.319°$. The structure consists of dimers of face-sharing octahedra separated by single corner-sharing octahedra, showing the sequence hcchcc along the *c*-axis. At 10 GPa the cubic 3C perovskite structure could be identified as a minority phase, with $a = 4.0611$ Å, defined in the *Pmm* space group. The uncertain stability of the 5H polytype, as well as the novel pressure sequence displayed by $BaIrO_3$ (that is distinct from the classical sequence 9R-4H-6H-3C exhibited by many transition metal oxides, for instance $BaRuO_3$) is a result of the commanding stability of the "9R" ambient pressure structure, which is reinforced by a strong Ir–Ir bond across the octahedral faces. The Ir–Ir Coulombic repulsion across shared faces destabilizes the 4H polytype relative to the 6H phase to allow stabilization of the hybrid 5H polytype in a narrow pressure range.

In another study, the 6M-$BaIrO_3$ with the distorted hexagonal $BaTiO_3$ structure was synthesized by high-pressure sintering. Through Rietveld refinement of the powder XRD data, the lattice parameters $a = 5.7459$ Å, $b = 9.9289$ Å, $c = 14.3433$ Å, and $\beta = 91.340°$ were obtained (Fig. 13.54).

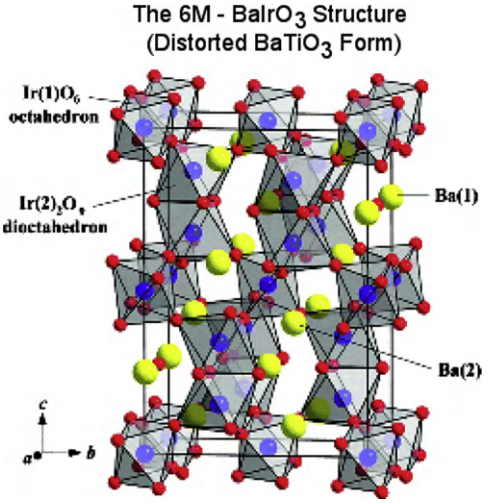

FIGURE 13.54

In the Ir_2O_9 dioctahedron, the average Ir–O distance and direct Ir–Ir distance were equal to 2.067 and 2.719 Å, respectively. The temperature dependence of electrical resistivity shows that the 6M-$BaIrO_3$ is a new metallic iridate. It is an abnormal metal, being deviated from the Fermi liquid behavior, following a linear relationship of μ versus T below 20 K. Both magnetic susceptibility and specific heat data indicate that it is an exchange-enhanced Pauli paramagnet, because of the electron–electron correlation effect.

The crystal structure of 6M-$BaIrO_3$ is monoclinic (space group $C2/m$), and contains zigzag chains of the Ir_3O_{12} trimer with the face-shared IrO_6 octahedra along the *c*-axis. Each trimer is linked to form a corner-shared network along the *c*-axis, and a 2D network perpendicular to the *c*-axis as well. $BaIrO_3$ single crystals exhibit a giant nonlinear conduction as a function of pulsed external current, and shows a negative derivative resistance from 2 to 6 A/cm^2 at 4.2 K. This structure belongs to a new class of collective excitation in solids that are associated with the giant nonlinear conduction.

At ambient pressure, $BaIrO_3$ crystallizes in the distorted 9R-$BaRuO_3$ structure, with the space group $C2/m$, due to a large tolerant factor (about 1.051) as calculated from the ion radii in Shannon Table. $BaIrO_3$ is a weak ferromagnet, with the Curie temperature T_C about 183 K. It is the first known ferromagnet that contains a 5d transition metal cation in a ternary oxide, which originates from spin polarization of Ir cations rather than spin canting. The polycrystalline sample of $BaIrO_3$ is a semiconductor. The obvious kink in the T curve corresponds to the Curie temperature T_C. Below T_C, the electrical resistivity increases more rapidly with the decreasing temperature. For the single crystal,

the temperature dependence of resistivity in the *ab*-plane is similar with that of the polycrystalline $BaIrO_3$, but the electrical resistivity at low temperature is much smaller than the corresponding value of polycrystal at the same temperature. However, along the *c*-axis, that is the high conductivity axis.

$BaIrO_3$ transforms to a more insulating phase below T_C, and then transforms to metallic and insulating states at 80 K and 26 K, respectively, which is different from the *p*-*T* curve of polycrystal. Polycrystalline single-phase samples of $BaIrO_{2.73}$ and $BaIrO_{2.96}$ have been successfully prepared. Superconducting quantum interference device data indicate the magnetic susceptibility of both samples is low and only weakly temperature dependent in the range $180\,K < T < 296\,K$, demonstrating the presence of delocalized electrons. The materials exhibit high electrical conductivity that is dependent on the oxygen stoichiometry. In addition, magnetic susceptibility data for both compositions show that a transition to a ferromagnetically ordered state occurs at 180 K. It is proposed that this ferromagnetism arises from a difference in the relative populations of the α and β spin bands and not from localized electrons.

The 5d-electron-based $BaIrO_3$ is a nonmetallic weak ferromagnet with a Curie temperature at $T_C = 175\,K$. Its largely extended orbitals generate strong electron–lattice coupling, and magnetism and electronic structure are thus critically linked to the lattice degree of freedom. Here we report results of our transport and magnetic study on slightly Sr-doped $BaIrO_3$. It is found that dilute Sr doping drastically suppresses T_C, and instantaneously leads to a nonmetal–metal transition at high temperatures. All results highlight the instability of the ground state and the subtle relation between magnetic ordering and electron mobility. It is clear that $BaIrO_3$ along with very few other systems represents a class of materials where the magnetic and transport properties can effectively be tuned by slight alterations in lattice parameters.

$BaIrO_3$ shares a number of unique features with other iridates such as the layered Sr_2IrO_4 and $Sr_3Ir_2O_7$. They are all characteristically insulating with unusual temperature dependence of resistivity and negative differential resistivity or non-ohmic behavior. These iridates are all weakly FM with high-magnetic ordering temperatures ($T_C = 240\,K$ and 285 K for Sr_2IrO_4 and $Sr_3Ir_2O_7$, respectively) and yet only a fraction of the expected ordered moment ($\mu_S = 0.14\,\mu bar/Ir$ and $0.04\,\mu bar/Ir$ for Sr_2IrO_4 and $Sr_3Ir_2O_7$, respectively). In addition, all these materials often show a simultaneous transition in magnetization and resistivity, but none displays sensitivity of T_C to high magnetic fields and detectable magnetoresistance near and below T_C except at very low temperatures. It is striking that all their counterparts to the ruthenates ($BaRuO_3$, Sr_2RuO_4, and $Sr_3Ru_2O_7$) are metallic or even superconducting and that all these ruthenates are less structurally distorted. Clearly, the lattice degree of freedom plays a critical role in determining the ground state in these systems with extended electron orbitals.

The 5M $BaIrO_3$ variation, which is intervenient in the 9M and 6M forms, was synthesized under high pressure and high temperature, and the physical properties were obtained. The measurement of low-temperature electrical resistivity shows that the 5M-$BaIrO_3$ is a Fermi liquid metal, because of the linear relationship of p versus T^2 at low temperature. The relationships of magnetic susceptibility versus temperature indicate that the 5M $BaIrO_3$ staked variety is a weak ferromagnet, with the Curie temperature T_C about 54.3 K. By calculation of the low-temperature specific heat data, using the Wilson ratio R_W of 1.67 and Stoner enhancement factor *S* of 2.8, a modest electron-electron correlation effect in the 5M-$BaIrO_3$ arrangement was seen.

No barium iridates are offered for sale commercially nor have any CAS numbers been issued.

13.3.6. Radium Iridium Compounds

Although it is likely that radium forms the same type of compounds with iridium oxides, no description of any type of iridate compounds has appeared in the technical literature. The most likely stable compound is expected to be $RaIrO_3$. The lack of interest from Industry and Academia probably stems from the high cost of Ir metal and the radioactivity of ^{226}Ra.

14.1. ALKALINE EARTH NICKEL COMPOUNDS

In general, only the Nickel oxides, NiO and Ni_2O_3, form compounds with the alkaline earths. The NiO_2 compound does not appear in most systems.

In the Ae–Ni–O system, the electronic structure of various nickel oxides with nickel valence varying from 1+ to 3+ was investigated with the aim to find similarities and differences to the isoelectronic cuprates. Only if the Ni ions are forced into a planar coordination with the O ions, can a $S = 1/2$ magnetic insulator be realized with the difficult Ni^{1+} oxidation state and possibly doped with low-spin ($S = 0$) Ni^{2+} holes directly analogous to the superconducting cuprates? The more common Ni^{3+} oxidation state cannot be used to make a parent magnetic insulator as it forms rather as localized ($S = 1$) Ni^{2+} embedded in a sea of itinerant O holes. Strong coupling of these holes to the localized spins via 2p-3d hybridization leads to a heavy fermion system with a large Kondo temperature, which was confirmed experimentally for $LaNiO_3$. In both nickelates and cuprates the antibonding e_g shell of the 3d complex is partly occupied with three electrons in Ni^{1+} and Cu^{2+}, two electrons in Ni^{2+} and Cu^{3+}, and one electron in Ni^{3+} and Cu^{4+} (if it exists). The results for a planar coordinated Ni^{3+} oxidation state show that even in this case the Jahn–Teller paradigm does not work and the Fermi energy enters the nonbonding O 2p orbital, a configuration which is not a Jahn–Teller split 3d ion. It was concluded that nickelates cannot be used in a manner directly analogous to the superconducting cuprates. Of the various nickelate compounds possible, it is the perovskite structures that are the most stable (Fig. 14.1(A)).

14.1.1. Beryllium Nickel Compounds

Beryllium metal forms a series of intermetallic compounds with Ni^0 metal. The phase diagram is shown in Fig. 14.1(B).

FIGURE 14.1

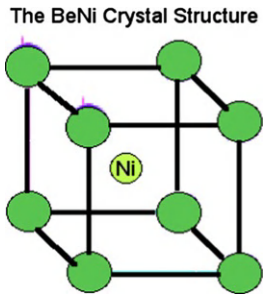

FIGURE 14.2

The compound, BeNi, has the structure form where the Ni atom in the body-centered position of a cubic lattice (Fig. 14.2).

Cell parameters of BeNi are: $a = b = c = 2.604$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 17.66$ Å^3, $Z = 1$. Cell occupancy is shown in Table 14.1.

The compound, Be_7Ni, is known but its structure has not yet been finalized. Cell parameters of the cubic lattice are: $a = b = c = 6.6026$ Å, $\alpha = \beta = \gamma = 109.471°$, cell volume $= 221.58$ Å^3, $Z = 2$. It is a high-temperature form.

The compound, $Be_{21}Ni_7$ is also known with the cell parameters of: $a = b = c = 10.8018$ Å^3, $\alpha = \beta = \gamma = 60$, cell volume $= 891.20$ Å^3, $Z = 2$. Its structure has not been finalized. It also is a high-temperature form.

The compound, $BeNi_3$, has also been discovered with cell parameters of: $a = 2.578$ Å, $b = 3.647$ Å, $c = 3.914$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 36.80$ Å^3, $Z = 1$. Its exact structure is not available. No other intermetallic compounds are known.

In the beryllium oxy-nickelate systems, i.e. Be–Ni–O, no compounds are known. This includes possible combinations of BeO such as: BeO–NiO, BeO–Ni_2O_3, BeO–Ni_3O_4, BeO–NiO_2, and BeO–Ni_2O_5.

Beryllium nickelate compounds are not offered for sale commercially and no CAS numbers have been assigned to date.

14.1.2. Magnesium Nickel Compounds

Magnesium metal forms a few intermetallic compounds with Ni metal. The phase diagram is shown in Fig. 14.3.

The compound Mg_2Ni is known. It has the structure shown as follows. The cell parameters of Mg_2Ni are:

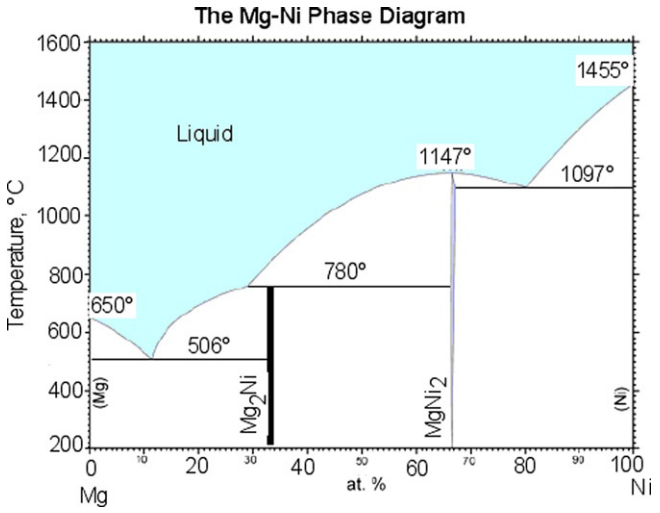

FIGURE 14.3

$a = b = 5.2117$ Å, $c = 13.2538$ Å. $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 311.77$ Å^3, $Z = 6$ (Fig. 14.4).

Cell occupancy is shown in Table 14.2.

The compound, Mg_2Ni is also known. Its structure has the form shown as follows in Fig. 14.5.

Cell parameters are: $a = b = 4.825$ Å, $c = 15.294$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 318.35$ Å^3, $Z = 8$. Cell occupancy is shown in Table 14.3.

No other intermetallic compounds are known.

MgO forms a limited number of oxy-nickelate compounds. In the Ni^{2+}-containing system of MgO–NiO, the compound, $MgNiO_2$, has been mentioned in a number of papers. If a bed of nano-sized Ni metal particles is deposited upon a layer of MgO, the composite catalyzes certain organic compounds like CH_4 (or other aliphatics) to form a synthesis gas. When the catalyst bed is heated to a high temperature, the formation of $MgNiO_2$ has been observed. It is not stable at room temperature but its structure has been determined as: $MgNiO_2$ (cubic system, spatial group $Fm3m$, parameter $a = 4.1922$ Å). Its symmetry and unit cell parameter are essentially the same as for those of MgO.

The compound, $MgNi_2O_3$, has been synthesized by an oxalate method in which oxalic acid is added in excess to a solution of the chlorides of the two metals. The thermal decomposition processes taking place in the solid-state mixture of $NiC_2O_4 \cdot 2H_2O$–$MgC_2O_4 \cdot 2H_2O$

(2:1 mole ratio) have been investigated in air using thermogravimetry or differential-thermogravimetry (TG-DTG), differential scanning calorimeter (DSC) and XRD techniques. The decomposition proceeded through a four well-defined steps while TG curves closely corresponded to the theoretical mass loss. The result of XRD showed that well-crystallized $MgNi_2O_3$ formed in the sample calcined at 600 °C for 2 h. The activation energies for the decompositions of NiC_2O_4 and MgC_2O_4 were calculated through the Ozawa and

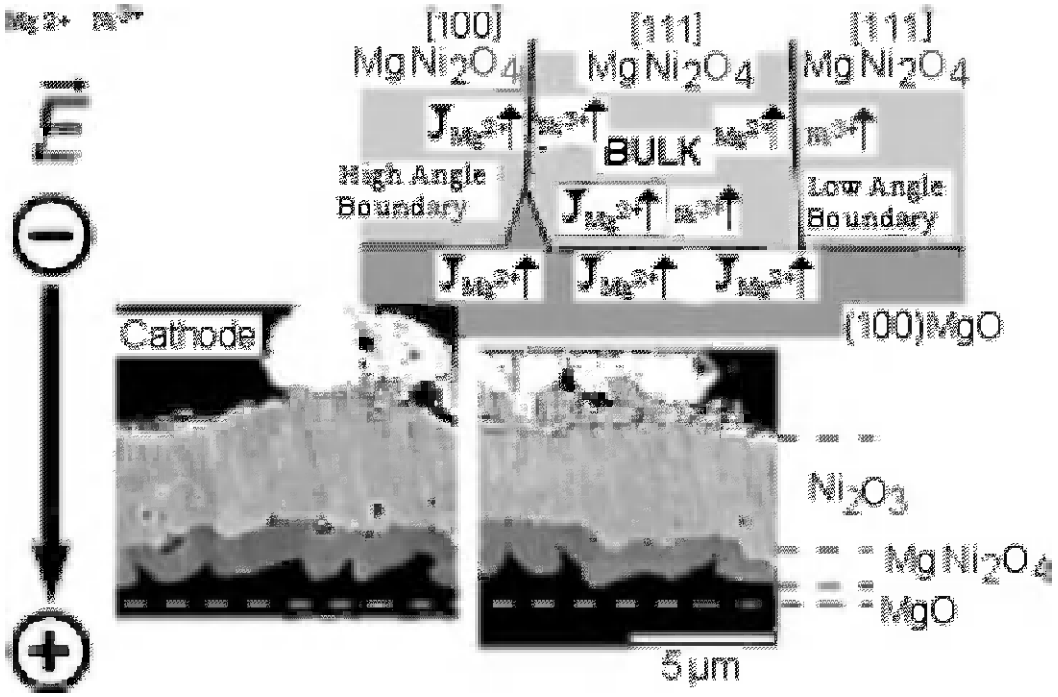

FIGURE 14.6

Kissinger–Akahira–Sunose (KAS) methods, and the possible conversion functions have been estimated through the comparative method. No further data concerning this compound are available and the crystal structure remains unknown.

In the Ni^{3+}-containing system of $MgO–Ni_2O_3$, the compound, $MgNi_2O_4$, has been synthesized. Under working conditions, certain ceramic materials like $MgNi_2O_4$ are often exposed to high electrical fields in addition to high temperatures. For this reason, the investigation of the reaction kinetics and the morphological evolution of the moving interfaces of a spinel-forming solid-state reaction under the influence of an external electric field was conducted. A model, based on linear transport theory and defect thermodynamics was used to analyze the results. This is shown in Fig. 14.6.

Compared to a reference reaction without external electric field, the reaction rate was found to be strongly enhanced by an external field and the morphology of the product layer was significantly changed. Systematic kinetic studies confirmed a linear law with a constant growth rate for the electric field-driven spinel formation. The role of grain boundaries as fast diffusion paths was highly accentuated. A relationship between large angle grain boundaries in the product phase and the local reaction kinetics was pointed out. An analysis of the reaction rate indicates an unusually high transference for the trivalent ions compared to the divalent ions in the grain boundaries of the spinel phase.

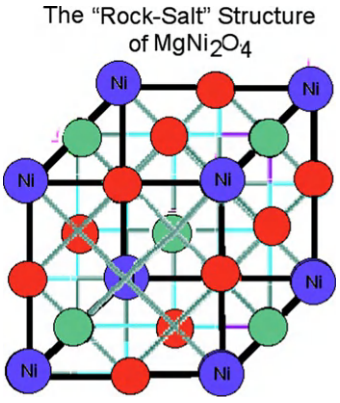

FIGURE 14.7

$MgNi_2O_4$ forms the rock salt structure as shown in the following diagram, with $a = 6.235$ Å (Fig. 14.7).

No compounds are known in the $Ni^{2+}–Ni^{3+}$-containing system of $MgO–Ni_3O_4$, in the Ni^{4+}-containing system of $MgO–NiO_2$, or in the Ni^{5+}-containing system of $MgO–Ni_2O_5$.

Magnesium nickelate compounds are not offered commercially and no CAS numbers have been issued to date.

14.1.3. Calcium Nickel Compounds

Calcium metal forms a series of intermetallic compounds with nickel metal.

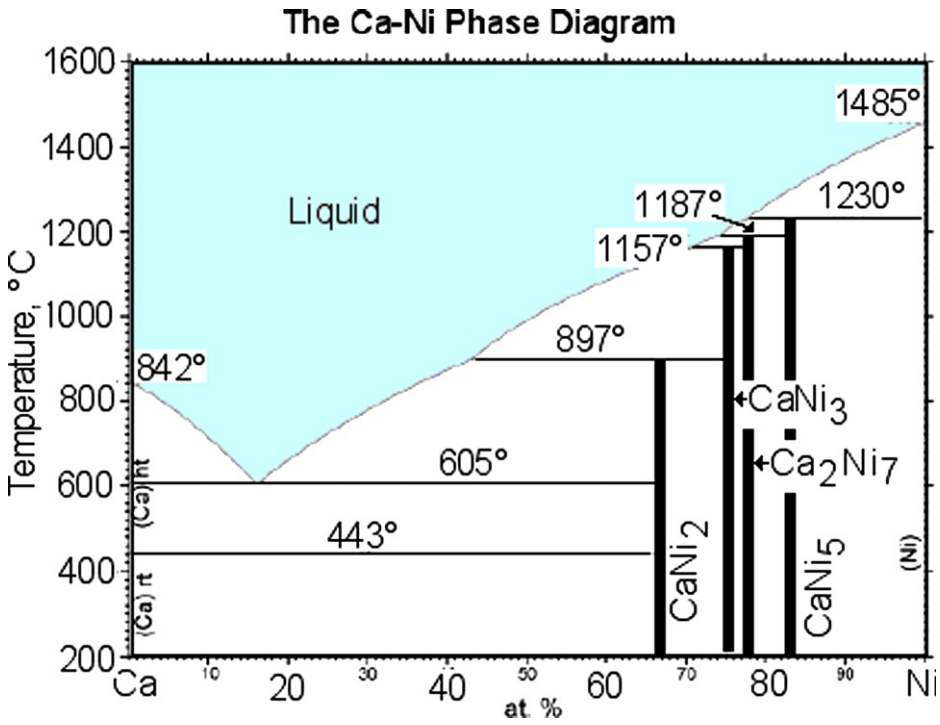

FIGURE 14.8

FIGURE 14.9

The phase diagram is shown in Fig. 14.8:

The compound, Ca_2Ni_7, has the structure shown in Fig. 14.9.

Cell parameters are: $a = b = 5.009$ Å, $c = 12.363$ Å, $\alpha = \beta = 78.31°$, $\gamma = 60°$, cell volume $= 261.18$ Å^3, $Z = 6$. Cell occupancy is shown in Table 14.4.

$CaNi_2$ has the structure shown in Fig. 14.10.

Cell parameters are: $a = b = c = 5.1272$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 95.31$ Å^3, $Z = 6$. Cell occupancy is shown in Table 14.5.

The compound, $CaNi_3$, has the structure shown in Fig. 14.11.

Cell parameters are: $a = b = 5.032$ Å, $c = 8.5797$ Å, $\alpha = \beta = 72.954°$, $\gamma = 60°$, cell volume $= 176.90$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.6.

The compound, $CaNi_5$, has the structure shown in Fig. 14.12.

Cell parameters are: $a = 3.948$ Å, $b = c = 4.962$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 84.11$ Å^3, $Z = 1$. Cell occupancy is shown in Table 14.7.

No other compounds are known. Calcium nickelides are not used in the Industry and little interest in their

diffraction and electron microscopy analysis, and measurement of their electrical conductivity, Seebeck coefficient and thermal conductivity were carried out to determine the relative thermoelectric properties of this oxide semiconductor. $CaNi_2$ is inferior to other known thermoelectric materials.

A patent dated 2008 described a process for producing hydrogen comprising reacting at least one hydrocarbon and steam in the presence of a complex metal oxide and a steam-hydrocarbon reforming catalyst in a production step under reaction conditions sufficient to form hydrogen and a spent complex metal oxide. This was entitled: "Use of Mixtures of Calcium Oxide, CaO, and Nickel Oxide, Using NiO with Pt/ZrO".

> "Two mixtures of CaO/NiO with different metal ratios, 1:1, CaO:NiO (nominally "CaNiO2") and 2:1 CaO:NiO (nominally "Ca_2NiO_3") were prepared. Solutions of 0.50 molar (M) $Ca(NO_3)_2$ and 0.50 M $Ni(NO_3)_2$ (0.25 M for Ca_2NiO_3) were co-precipitated with a 1.0 M $NaHCO_3$ solution. The precursors were heated at 750 °C for 10 hours (12 hours for "Ca_2NiO_3") under oxygen flow. The mixtures were shown by powder x-ray diffraction to be physical mixtures of the oxides, not ternary complex metal oxides. A steam-methane reforming reaction was carried out using this 1:1 CaO:NiO mixture and 1% Pt/ZrO_2. The rates of production of hydrogen, carbon dioxide, carbon monoxide, and methane versus time on stream were given. The reaction process can be subdivided into several regions. The temperature profile of the reaction exhibited multiple exothermic and endothermic peaks. Between 10 and 30 minutes after initiation, a region of substantial production of H_2 with little production of carbon monoxide or carbon dioxide by-products was observed.
>
> The regeneration reaction of the spent nominally "$CaNiO_2$" was carried out at 700 °C under 20% oxygen/argon. The carbon dioxide production rate and the temperature changes with time on stream were recorded. In accordance with previous results, an initial exothermic reaction was observed, believed to be due to the oxidation of nickel metal to nickel oxide. This reaction yielded 41.8 kcal per/mole of nickel. This exothermic event, however, only resulted in a relatively small increase in the rate of carbon dioxide production, which quickly reverted back to the initial rate. Consequently, even after more than 8 hours of heating, there was still a substantial rate of CO_2 production ($\approx$0.035 mmol/min.), thus the said "$CaNiO_2$" was still not completely regenerated, demonstrating that this is not a practical oxide mixture for the preparation of hydrogen by the present process.
>
> Similarly, the nominally "Ca_2NiO_3" composition, a physical mixture of 2 parts calcium oxide, CaO, to one part nickel oxide, NiO, and therefore also not a ternary oxide, was also not completely regenerated by heating at 700 °C for 8 hours".

In the Ni^{3+}-containing system of $CaO–Ni_2O_3$, no compounds have been reported.

The Ni^{2+}–Ni^{3+}-containing system of $CaO–Ni_3O_4$ remains unknown.

In the Ni^{4+}-containing system of $CaO–NiO_2$, the compound, $CaNiO_3$ has been studied. Perovskite oxides (ABO_3) are generally stable and exhibit high photocatalytic activity. A series of perovskite oxides was synthesized by means of blend deposition using the nitrate of A and B as the raw materials, and using ammonia or sodium carbonate to cause precipitation. The result of activity evaluation indicates that the effect of A is low while that of B is outstanding. The activity of $CaNiO_3$ is one of the highest among those photocatalysts studied. The test result of XRD and TEM shows that the purity of $CaNiO_3$ is comparatively high and the particle shape is approximately round with a diameter in the range of 150–200 nm. The photocatalytic activity of $CaNiO_3$ and TiO_2 was compared, and showed that the activity of the two photocatalysts is equal under UV irradiation. Under sunlight, the $CaNiO_3$ activity is higher than that of TiO_2, so that that the rate of degradation of acid-red-B is 63% and 47%, respectively. In addition, the compound oxides of $CaFe_xNi_{1-x}O_3$ ($x = 0.1$–0.9) have been synthesized. Among them, the activity of $CaFe_{0.3}Ni_{0.7}O_3$ is one of the highest and under sunlight, the degradation of acid-red-B can reach 91%. Addition of Co and Ag to the $CaFe_{0.3}Ni_{0.7}O_3$ composition showed that Co produces a compound that is much lower in activity, while the activity of $CaFe_{0.3}Ni_{0.7}O_3$ was increased by the addition of Ag so that the rate of degradation of acid-red-B is 96%.

The kinetics of degradation of acid-red-B under UV was studied over $CaNiO_3$ catalyst. The reaction order was defined to be 1.4. The pre-exponential factor of the reaction was $k_o = 1.01 \times 10^7$ mol-0.4 $L_{0.4}$ min^{-1}, and the activation energy was $E_a = 35.5$ kJ/mol. The mechanism of degradation of acid-red-B was analyzed by IR and UV–VIS spectral analysis. According to these results, the double bond of nitrogen in acid-red-B degradation disappeared firstly, then the naphthalene ring was broken and finally the benzene ring was cracked. The photocatalysis is improved by adding H_2O_2 into the solution, and the activity is raised with the increase of the amount of H_2O_2. Increasing the acidity of the solution also aids in the decomposition of acid-red-B.

In another paper, a novel microwave heating method for preparation of $CaNiO_3$ as a photocatalyst material was described. The optimum preparation conditions are that the microwave power is 560 W, the microwave heating time is 30 min, the calcination temperature is 700 °C and the calcination time was 5 h. The compound was measured by X-ray diffraction. In visible light and under the conditions of simulated fuel wastewater, the photocatalytic properties of the catalyst material were studied using acid-red-B. The results show that the photocatalytic material prepared by that microwave heating has a high photocatalytic performance of degradation, and the degeneration rate of the dye may reach 98%.

No compounds in the Ni^{5+}-containing system of $CaO–Ni_2O_5$ have been documented.

Calcium–nickel compounds are not offered commercially nor are calcium nickelates. No CAS numbers have been issued.

14.1.4. Strontium Nickel Compounds

Strontium metal forms just one compound with nickel metal as shown in the following phase diagram in Fig. 14.13.

The structure of the compound, SrNi, has not been published. The structure was said to be orthorhombic with cell parameters of: $a = b = 3.332$ Å, $c = 7.009$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume = 67.39 Å^3, $Z = 4$.

No other intermetallic compounds are known.

The constitution of the SrO–NiO system was studied experimentally for the first time. Samples were prepared either from $SrCO_3$ and NiO or from $Sr(NO_3)_2$ and $Ni(NO_3)_2 \cdot 6H_2O$ and characterized by high-temperature X-ray powder diffraction, scanning electron microscopy, thermogravimetric and differential thermal analyses. In the SrO–NiO quasi-binary system an eutectic reaction: liquid (SrO + NiO) was found to occur at 1396 ± 5 °C, while the homogeneity range of terminal solid solutions is negligible. Thermodynamic calculations using the regular solution model for the liquid and rock salt-type phases were employed to predict liquidus and solidus curves. Three ternary compounds, $SrNiO_{2.5}$, $Sr_5Ni_4O_{11}$, and $Sr_9Ni_7O_{21}$ were observed in the samples prepared from nitrate solutions, but only $Sr_9Ni_7O_{21}$ was proved to be thermodynamically stable in air up to 1030 ± 6 °C. When heating in air, $SrNiO_{2.5}$ and $Sr_5Ni_4O_{11}$ were found to transform irreversibly into a mixture of $Sr_9Ni_7O_{21}$ and NiO. Isothermal section of the SrO–NiO–O subsystem, which represents phase equilibria at 950–1030 °C as well as an isobaric section of the Sr–Ni–O system in air were constructed (Fig. 14.14).

In the Ni^{2+}-containing system of SrO–NiO, single crystals of $SrNiO_2$ were prepared by high temperature and oxygen pressure. It is isotypic with $SrCuO_2$ (space group D—$Cmcm$, $a = 3.581$, $b = 16.362$, $c = 3{,}915$ Å). The relationship between $SrNiO_2$ and K_2NiF_4 type was discussed. This compound is not stable at room temperature.

The compound, Sr_2NiO_3, is much more stable in air at room temperature. Sr_2NiO_3 compounds with one-dimensional (1D) Ni–O chains have been successfully synthesized in the form of single-crystalline thin films using a combinatorial approach. The crystal structure was examined using X-ray diffraction and high-resolution TEM (see Fig. 14.15). Polarized absorption spectroscopy and third-harmonic generation

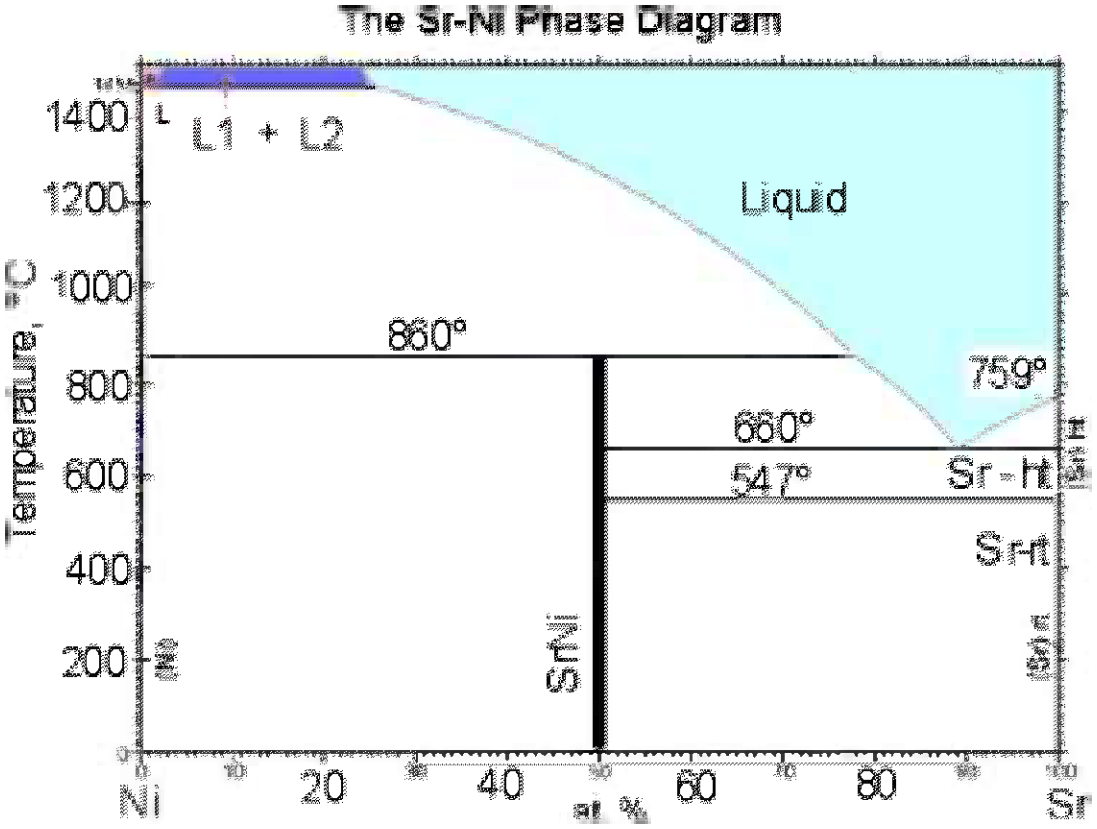

FIGURE 14.13

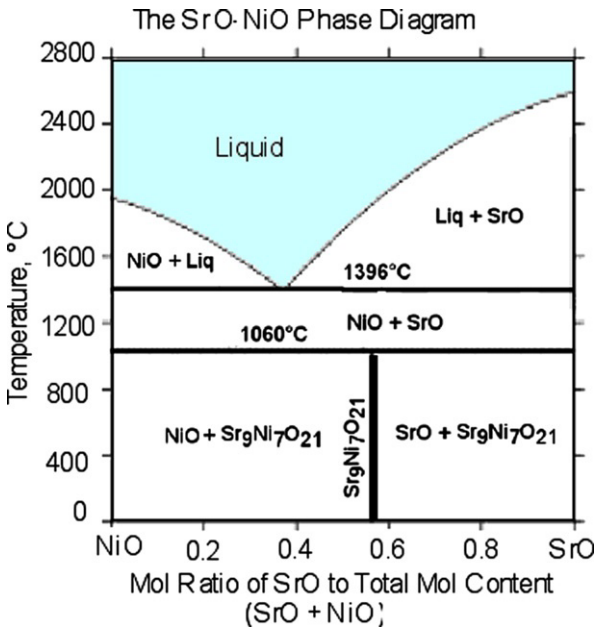

FIGURE 14.14

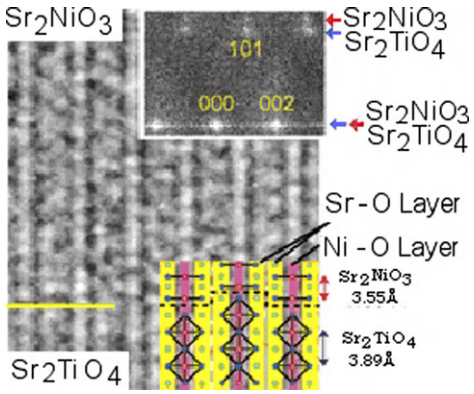

FIGURE 14.15

spectroscopy revealed a 1D electronic structure and sizable nonlinear optical susceptibility, respectively, for Sr_2NiO_3.

In the Ni^{3+}-containing system of SrO–Ni_2O_3, the compound, $SrNi_2O_4$ remains unknown. However, the trivalent Ni^{3+} ion has been observed to exist with Ni^{4+} in various compounds.

No compounds involving the Ni^{2+}–Ni^{3+} ions have been discovered in the system SrO–Ni_3O_4.

In the Ni^{4+}-containing system of SrO–NiO_2, the compound, $SrNiO_3$ is not stable at room temperature. The constitution of the Sr–Ni–O system was studied experimentally for the first time. Samples were prepared either from $SrCO_3$ and NiO or from $Sr(NO_3)_2$ and $Ni(NO_3)_2 \cdot 6H_2O$ and characterized by high-temperature X-ray powder diffraction, scanning electron microscopy, thermogravimetric and differential thermal analyses. In the SrO–NiO quasi-binary system, an eutectic reaction: liquid SrO + NiO was found to occur at 1396 ± 5 °C, while the homogeneity range of terminal solid solutions is negligible. Thermodynamic calculations using the regular solution model for the liquid and rock salt-type phases were employed to predict liquidus and solidus curves. Three ternary compounds, $SrNiO_{2.5}$, $Sr_5Ni_4O_{11}$, and $Sr_9Ni_7O_{21}$ were observed in the samples prepared from nitrate solutions, but only $Sr_9Ni_7O_{21}$ was proved to be thermodynamically stable in air up to 1030 ± 6 °C. When heated in air, $SrNiO_{2.5}$ and $Sr_5Ni_4O_{11}$ were found to transform irreversibly into a mixture of $Sr_9Ni_7O_{21}$ and NiO:

$$36\ SrNiO_{2.5} + O_2 \Rightarrow 4\ Sr_9Ni_7O_{21} + 8\ NiO$$

$$18\ Sr_5Ni_4O_{11} + 3\ O_2 \Rightarrow 10\ Sr_9Ni_7O_{21} + 2\ NiO$$

Isothermal section of the SrO–NiO–O subsystem, which represents phase equilibria at 950–1030 °C as well as an isobaric section of the Sr–Ni–O system in air were constructed.

However, the actual stoichiometry of $Sr_5Ni_4O_{11}$ remains questionable. A crystal structure investigation of the so-called $Sr_5Ni_4O_{11}$ from single-crystal X-ray data has shown that the composition of this oxide is in fact close to $Sr_4Ni_3O_9$. The structure has been solved in the trigonal *P*321 space group. The final refinement gave an *R* factor of 0.045 for 512 independent reflections. The structure contains NiO_3 chains with two NiO_6 octahedra and one NiO_6 trigonal prism alternating and sharing faces. The chains run along the threefold axis and are connected by Sr ions. The Ni–O distances seem to indicate a possible repartition of Ni^{4+} in the octahedral sites and Ni^{2+} in the trigonal prisms.

In another study, two crystal phases of strontium–nickel oxides, $SrNiO_3$ and compounds with composition near $Sr_2Ni_2O_5$, containing tetra- and trivalent nickel ions, respectively, have been synthesized in an oxidizing atmosphere. $SrNiO_3$, synthesized under high pressures of oxygen above 50 atm., has a hexagonal unit cell with $a = 5{\cdot}355 \pm 0{\cdot}001$, $c = 4{\cdot}860 \pm 0{\cdot}001$ Å and is isostructural with $BaNiO_3$ with a perovskite-like structure. The phase with composition near $Sr_2Ni_2O_5$ with hexagonal unit cell has been synthesized above 600 °C and at 1 atm. of wet oxygen gas. The existence of water has a remarkable effect to form both the compounds of $SrNiO_3$ and $Sr_2Ni_2O_5$. The former compound is not stable and decomposes slowly:

$$4\ SrNiO_3 \Rightarrow 2\ Sr_2Ni_2O_5 + O_2$$

The so-called 1D oxides, showing chains of two-times face-shared octahedra and/or trigonal prisms, found in $Sr_3Yb_{0.89}NiO_6$; Sr_3PbNiO_6; $Sr_{12}Ni_{7.5}O_{27}$; $Sr_4Ni_3O_9$; $BaNi_{0.83}O_{2.5}$ and $NaSr_{12}Ni_7O_{23}$ have been thoroughly examined. Large chains of the type, filled by Ni^{3+} and Ni^{4+}, are found in $Sr_9Ni_{6.64}O_{21}$.

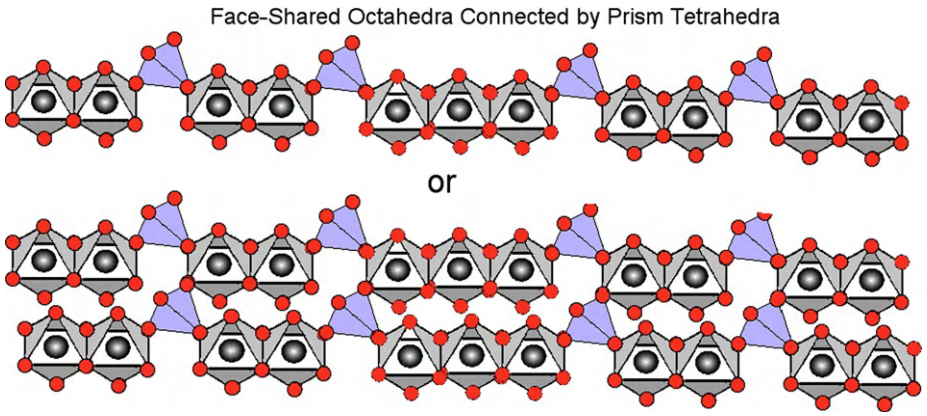

FIGURE 14.16

Crystals of the phase $Sr_9Ni_{6.64}O_{21}$ have been grown. This compound is the $n=2$ member of the $A_{3n+3}A_nB_{n+3}O_{6(n=9)}$ series. The composition and the crystal structure have been established from X-ray single-crystal diffraction data. The structure contains face-shared chains of NiO_6 polyhedra parallel to the *c*-axis and is related to the hexagonal 2H polytype perovskite. $Sr_9Ni_{6.64}O_{21}$ crystallizes in the space group *Rc* (No. 167) with $a=9.467$ Å, $c=35.87$ Å, $V=2784$ Å^3, and $Z=6$ (Fig. 14.16).

Single crystals of $Sr_{12}Ni_{7.5}O_{27}$ were prepared in closed silver tubes using a KO_2 flux. X-ray investigations show trigonal symmetry, space group D_3^2-*P*321, $a=9.474$ Å, $c=7.802$ Å, $Z=1$. It belongs to the modified perovskites, characterized by face-shared Ni_2O_9 double octahedra and under-occupied trigonal NiO_6 prisms. The oxidation state of the nickel ions can be verified by calculations of the Coulomb terms of the lattice energy.

No other strontium nickelates have appeared in the current technical literature. They are not available commercially and no CAS numbers have been assigned to date.

14.1.5. Barium Nickel Compounds

Barium metal does not form any intermetallic compounds with nickel metal as shown in Fig. 14.17.

In the BaO–In_xO_y system, only a few compounds are known.

In the Ni^{2+}-containing system of BaO–NiO, $BaNiO_2$, which is one of the stable phases in the Ba–Ni–O system, is an insulator consisting of zigzag chains of Ni^{2+} ions. Susceptibility measurements have been accomplished by several groups wherein it was reported that $BaNiO_2$ is diamagnetic. This means that Ni^{2+} is in a low-spin state with $S=0$, a state sometimes achieved with ions in square planar d^8 systems. On the other hand, the moment estimated from the Curie constant is fairly large, indicating that Ni^{2+} is in a high-spin state with $S=1$. Using extensive neutron scattering on single crystals of $BaNiO_2$, it was shown that this structure exhibits paramagnetism with full Ni^{2+} moment at each site at room temperature. Since the magnetic-scattering intensity decreases with decreasing temperature, magnetic susceptibility, heat capacity and muon spin relaxation (μSR) measurements were carried out to show that $BaNiO_2$ is, in fact, in a nonmagnetic state at low temperatures. This compound has the form shown in Fig. 14.18.

Cell parameters are: $a=4.732$ Å, $b=c=5.4192$ Å, $\alpha=116.159°$, $\beta=\gamma=90°$, cell volume $=124.67$ Å^3, $Z=4$. Cell occupancy is shown in Table 14.8.

A better view of the relationship of the Ni^{2+} ions and the Ba^{2+} ions is shown in Fig. 14.19.

In this same system, the compound, Ba_3NiO_4, has the structure shown in Fig. 14.20.

The structure of Ba_3NiO_4 involves a co-planar arrangement of O atoms around Ni atoms.

Cell parameters are: $a=b=c=7.1268$ Å, $\alpha=\beta=\gamma=66.836°$. Cell volume $=293.52$ Å^3, $Z=6$. Cell occupancy is shown in Table 14.9.

A recent review describes features of the crystal chemistry of oxo-nickelates containing large cations like alkali-, alkaline earth and rare earth metals. Starting with alkali oxo-nickelates, K_2NiO_2 is the only known oxo-nickelate showing O–Ni–O dumbbells with nickel in the oxidation state Ni^{2+}. The trigonal planar coordination (found within silver-oxo-compounds) is restricted to Ba_3NiO_4 and $K_9Ni_2O_7$. Square planar polygons (NiO_4) are found in $Nd_4Ni_3O_8$; Na_2NiO_2; Ki_2NiO_2; $BaNiO_2$ and $SrNiO_2$ for example. A special quality in the crystal chemistry of connected square planar NiO_4 polygons is the formation of Ni_6O_{12} rings in $Ba_2NaNi_3O_6$. All the other oxo-nickelates exhibit octahedral or trigonal prismatic coordination of nickel by oxygen. Always of interest are the so-called 1D oxides, showing chains of two times face-shared octahedra and/or trigonal prisms, found in $Sr_{12}Ni_{7.5}O_{27}$; $Sr_4Ni_3O_9$ or $BaNi_{0.83}O_{2.5}$. Many of the oxidation states of nickel are published with non-integral valence states like

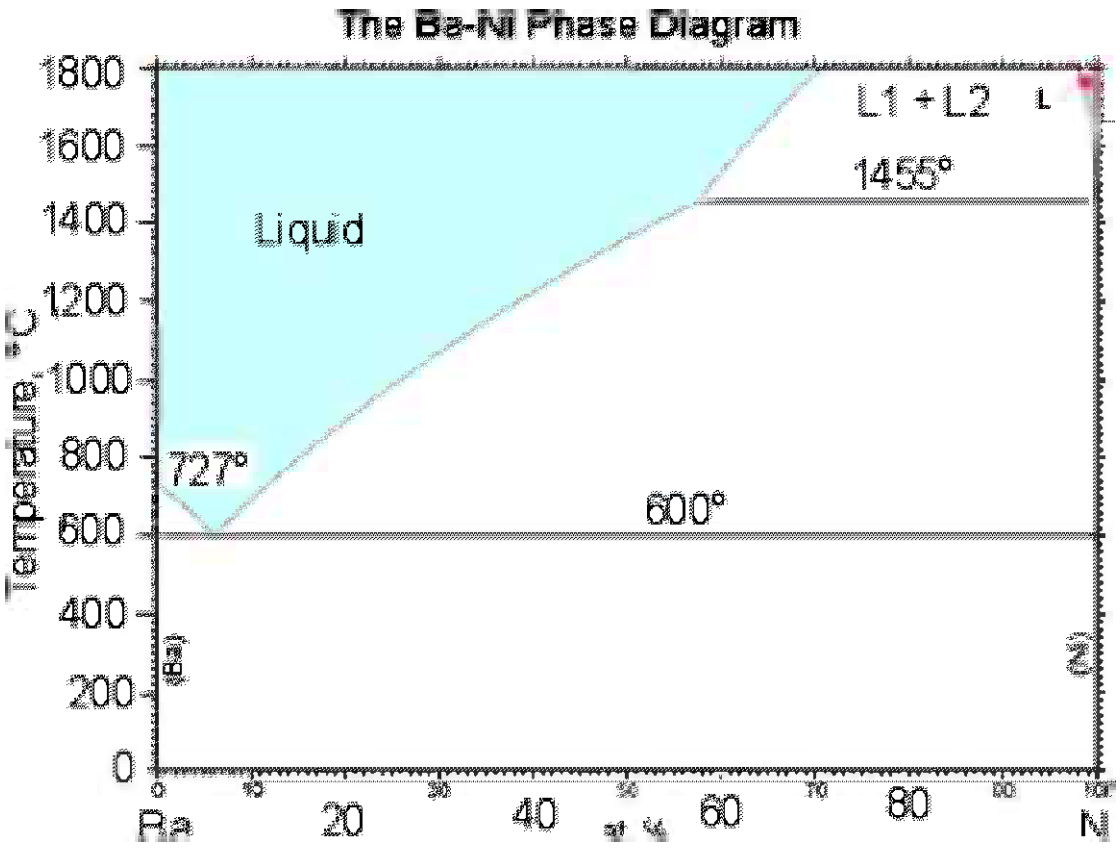

FIGURE 14.17

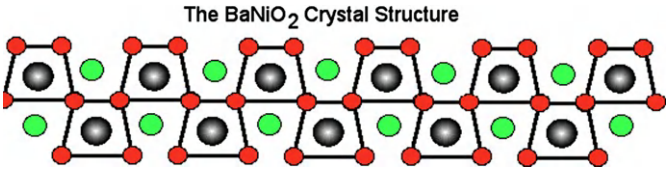

FIGURE 14.18

$Ni^{2.667+}$, $Ni^{2.5+}$, $Ni^{2.292+}$, $Ni^{3.614}$. Using calculations of the Coulomb terms of lattice energy most of the mixed valences could be split up in integral numbers protecting the electro neutrality between metal ions and oxygen, i.e. $Ni^{2.5+} = Ni^{2+} + Ni^{3+}$ and $Ni^{2.667} = Ni^{2+} + 2Ni^{3+}$.

Single crystals of $BaNi_{0.83}O_{2.5}$ were grown from mixtures of $BaCO_3$ and NiO using KOH as a flux. The composition and the crystal structure have been established from X-ray single-crystal diffraction data. $BaNi_{0.83}O_{2.5}$ is stoichiometric and crystallizes in a trigonal structure, space group *R*32, with hexagonal unit cell parameters (Å) $a = 9.8890(4)$ $c = 12.867(4)$, volume 1089.7(3) $Å^3$, and $Z = 18$. $BaNi_{0.83}O_{2.5}$ contains two kinds of Ba atoms both coordinated with 10 oxygen atoms, and three different Ni atoms octahedrally coordinated to oxygen at distances which approximately correspond to Ni_{2+} and to low-spin Ni_{3+} and Ni_{4+}. NiO_6 octahedra share opposite faces giving rise to chains parallel to the *c*-axis, in which some Ni–Ni distances are shorter than in Ni metal. This structure, which is compared with that of $BaNiO_3$, can be considered like a close packing of Ba and oxygen atoms in which almost one-quarter of the octahedral sites are occupied by nickels. $BaNi_{0.83}O_{2.5}$ is an electrical insulator. The results of magnetic measurements from room temperature to 5 K are given.

Crystals of $NaBa_2Ni^{2+}{}_2Ni^{3+}O_6$ were prepared by either electro synthesis in molten NaOH or controlled cooling in a NaOH flux. They crystallize in an F-centered orthorhombic unit cell, space group *Fmmm*, and are formed from the stacking along the c-axis of compact $[NaNi_3O_6]^{4-}$ blocks that are separated by Barium cations. It appears that, due to a perfect coincidence between the (a, a, c) unit cell constants and the related primitive hexagonal lattice (a, a, c, $\gamma = 120°$), a recurrent twinning mechanism, characterized by a threefold axis from one block to the subsequent one, occurred in the crystals studied. Thus, the coexistence of three independent domains yielded a misleading C-centered orthorhombic false symmetry. After the stacking fault detection from electron diffraction and HREM pictures was realized, a special attention was given to the X-ray data refinement process. This led to the establishment and concept of the existence of three independent domains and to good reliability factors. The composition plane located at the barium layers level was also investigated. It was shown that the barium environment at the twin interface adopts a symmetrical oxygen coordination in agreement with the full coherence of domains boundaries observed in HREM pictures. Therefore, valence bond calculations indicate a D1–D1 interface that is more stable than that of D1–D2 and D1–D3, and confirms the large size of superimposed monodomains. The compounds progressively decompose from 300 °C, forming a mixture of NiO, $BaCO_3$, and $BaNiO_3$. The magnetic susceptibility measured for $NaBa_2Ni_3O_6$ follows a Curie–Weiss law that involves high-spin Ni^{2+} and Ni^{3+} cations. The spin blocks are shown in Fig. 14.21.

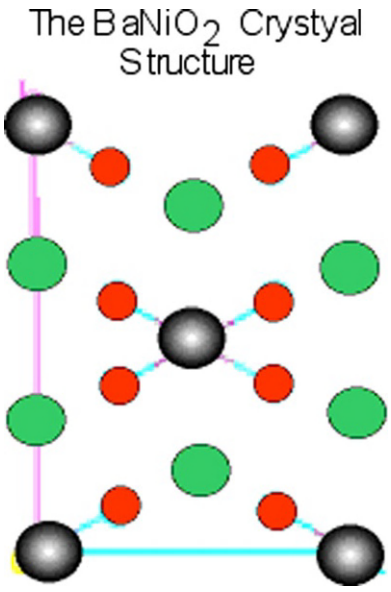

FIGURE 14.19

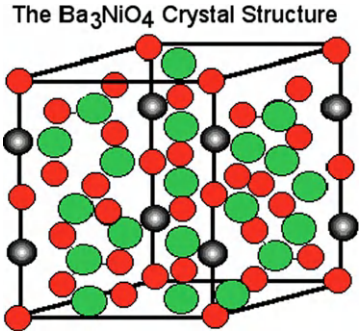

FIGURE 14.20

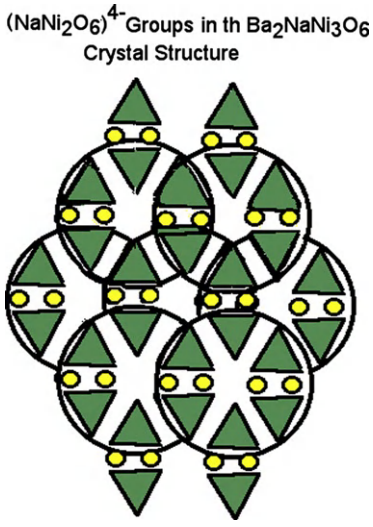

FIGURE 14.21

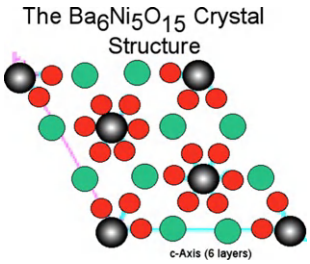

FIGURE 14.22

In the Ni^{2+}–Ni^{4+}-containing system of $BaO–Ni_3O_5$, the compound, $Ba_6Ni_5O_{15}$ has been synthesized. It has the structure shown in Fig. 14.22.

These layers are shown in the *c*-axis direction. If this layer turned 90° in the *b*-direction and then stacked 6-high, the complete structure is revealed. The *a*- and *b*-faces consist of: atoms in a six-layer configuration.

Cell parameters are: $a = b = c = 7.1409$ Å, $\alpha = \beta = \gamma = 87.643°$, cell volume $= 263.23$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.10.

In the Ni^{3+}-containing system of $BaO–Ni_2O_3$, the compound, $BaNi_2O_4$ remains unknown. No other Ni^{3+}-containing compounds have been synthesized.

In the Ni^{4+}-containing system of $BaO–NiO_2$, the crystal structure of $BaNiO_3$ has been determined using a single crystal. The space group is $P6_3/mmc$ and lattice constants are: $a = 5.629$ Å, $c = 4.811$ Å with $Z = 2$. This structure is characteristic with linear chains of Ni atoms having a Ni–Ni distance of 2.405 Å wherein the NiO_6 octahedron is trigonally distorted.

In another study, $BaNiO_3$ and intermediates with compositions ranging between $Ba_3Ni_3O_8$ $\{Ba_3(Ni^{2+}+2Ni^{4+})O_8\}$ and $Ba_2Ni_2O_5$ $\{Ba_2(2Ni^{3+})O_5\}$ were prepared. $BaNiO_3$ is black, stable in alkali, and has a structure made up of layers identical with the (111) planes of a perovskite but stacked in a close-packed hexagonal fashion. When fired at 730 °C in an atmosphere of 730 mm of oxygen, the structure changes due to loss of oxygen to form one of the series, $Ba_3Ni_3O_8$ or $Ba_2Ni_2O_5$ wherein the oxygen content is a function of the temperature between 730–1200 °C, at which a sharp melting point occurs. These latter materials are black but their crystal structures have not yet seen determined.

Single crystals of $BaNiO_3$ have been synthesized in molten KOH. The enthalpies of formation from the component oxides at 25 °C of $BaNiO_2$, $BaNiO_{2.63}$, and $BaNiO_3$ have been measured using high-temperature reaction calorimetry. As the value of x increases in $BaNiO_{2+x}$, the enthalpy of formation becomes more exothermic. From the enthalpy of formation data, an enthalpy of oxidation of -196 ± 20 kJ/(mole O_2) was obtained. This value is very similar to the values of -202 and -220 kJ/(mole O_2) obtained for $YBa_2Cu_3O_{7-y}$ and $La_{2-x}Ba_xCuO_{4-y}$, respectively, that are related to the high-temperature superconductor compositions. Energetic and structural data were discussed in terms of a model in which the holes have significant oxygen character.

The effect of hole doping into the divalent nickel oxide Y_2BaNiO_5, which provides a good example of 1D electronic structure in the presence of strong d–d interactions, has been examined by means of several techniques including X-ray absorption and electron energy-loss spectroscopy at oxygen K-edges (O_K-edges). The crystal structure of this compound shows 1D chains of vertex-sharing NiO_6 octahedra running along the *z*-axis. Hole doping into this material is realized by substituting Ca^{2+} or Sr^{2+} ions for the Y^{3+} ions. It was suggested that the doped holes have antibonding Ni $3d(3z^2\text{-}r^2)$–$O^{2p}(z)$ character.

The effect of Ba substitution in $LnNiO_3$ (Ln = Pr, Sm, Eu) perovskites on the structural and catalytic properties was studied by means of textural measurements, X-ray and neutron powder diffraction (XRD, NPD), thermogravimetric analysis, temperature-programmed reduction and catalytic activity in CO oxidation to CO_2 were employed. All the samples were prepared using

TABLE 14.10

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	O1	O	18	f	1	0.152	0.1617	0.317	1.0
2	O3	O	18	f	1	0.152	0.0099	0.123	1.0
3	O2	O	9	e	.2	0.138	0	1/2	1.0
4	Ba1	Ba	9	e	.2	0.672	0	1/2	1.0

soft-chemistry procedures, decomposing citrate precursors at 1073 K, and subsequently oxygenating them at 1273 K under a very high oxygen pressure (200 bar). This treatment, necessary for the stabilization of Ni^{3+}–Ni^{4+} mixed valences, resulted in very low specific areas (1–2 m^2/g). The X-ray diffraction profiles indicated pure perovskite phases with orthorhombic distortion, which increased in the order Pr < Sm <Eu. The Rietveld refinement of NPD data for a selected $Pr_{0.95}Ba_{0.05}NiO_3$ sample showed a significant reduction in the Ni–O distances with respect to the undoped compound, concomitant with the hole doping of the d-bands of the solid. Temperature-programmed reduction profiles revealed that the reduction of Ni^{3+} occurs through two consecutive reduction steps ($Ni^{3+/4+} \Rightarrow Ni^{2+} \Rightarrow Ni^0$). Both unsubstituted and Ba-substituted samples were tested in CO oxidation and it was found that the intrinsic activity is enhanced with Ba substitution particularly for the $Pr_{0.95}Ba_{0.05}NiO_3$ sample. This higher activity in CO oxidation appears to be related to the relative ease of oxygen removal from the hole-doped perovskites and to the presence of oxygen vacancies.

In the Ni^{5+}-containing system of $BaO–Ni_2O_5$, no compounds are known.

Barium nickelates are not offered for sale commercially and no CAS numbers have been issued to date.

14.1.6. Radium Nickel Compounds

Although radium probably forms the same compounds as its barium homologue, there is no evidence that such compounds have ever been synthesized. This is undoubtedly due to lack of interest in both Industry and Academia.

14.2. ALKALINE EARTH PALLADIUM COMPOUNDS

Pd forms very few compounds with the alkaline earths. Palladium primarily exists in the 0, +2, +4 oxidation states; the +4 oxidation state is comparatively rare. The +5 or +6 state has not been observed. The known oxides include PdO, PdO_2 and Pd_3O_4.

14.2.1. Beryllium Palladium Compounds

Beryllium forms a number of compounds with Pd metal, as shown in the following phase diagram in Fig. 14.23.

Seven compounds are shown but only the high Be-containing compounds, i.e. =Be > 50 atom%, have had their structures determined. Be_2Pd_3, $BePd_2$, and $BePd_3$ all melt incongruently and Be_3Pd_4 is a

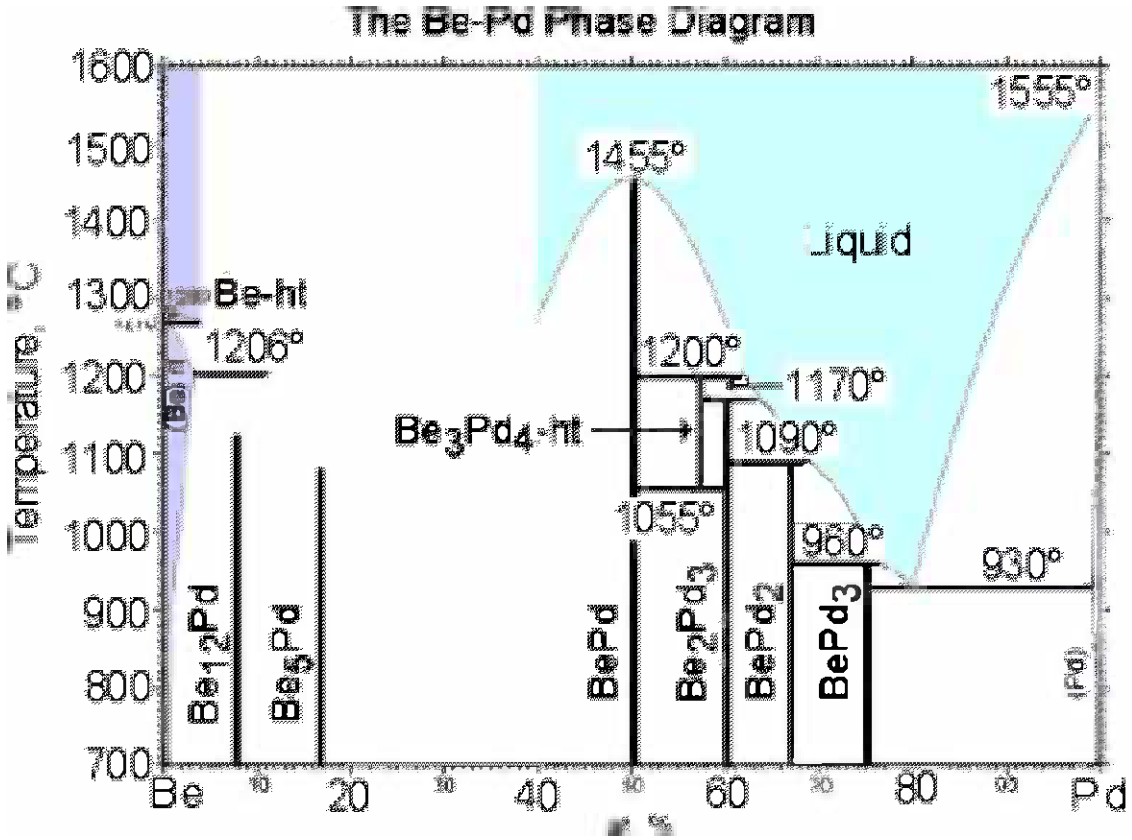

FIGURE 14.23

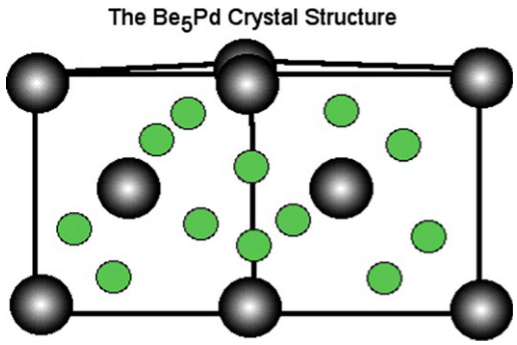

FIGURE 14.24

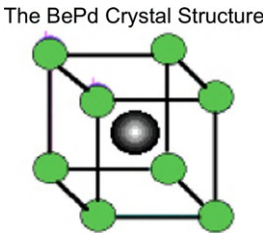

FIGURE 14.25

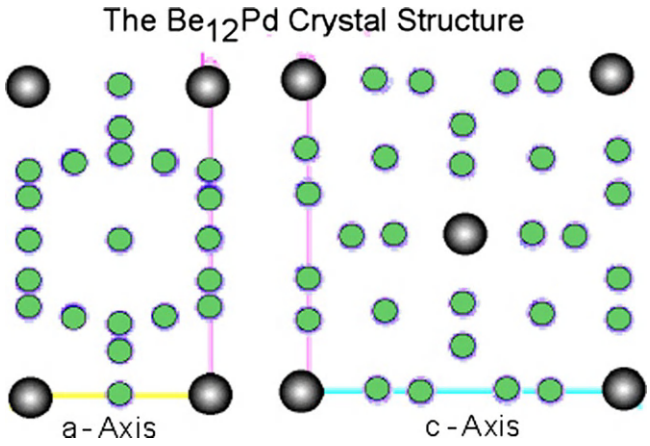

FIGURE 14.26

high-temperature compound, stable only between 1055–1200 °C.

Be_5Pd has the structure shown in Fig. 14.24.

It is cubic with cell constants of: $a = b = c = 4.2299$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 53.52 Å^3, $Z = 3$. Cell occupancy is shown in Table 14.11.

BePd has the structure shown in Fig. 14.25.

Cell parameters are: $a = b = c = 2.813$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 22.26 Å^3, $Z = 1$. Cell occupancy is shown in Table 14.12.

$Be_{12}Pd$ has the structure shown in Fig. 14.26.

The cell is body-centered in regard to the Pd atoms. Cell parameters are: $a = 4.251$ Å, $b = c = 5.5634$ Å, $\alpha = 81.607°$, $\beta = \gamma = 67.539°$, cell volume = 112.37 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.13.

BeO does not form any compounds with PdO or PdO_2. A search of the literature revealed no stable compounds.

No beryllium palladates have been reported. They are not offered for sale commercially and no CAS numbers have been issued to date. Perhaps this is due to the lack of interest in Industry and Academia.

14.2.2. Magnesium Palladium Compounds

Mg metal forms a series of intermetallic compounds with Pd metal as shown in the following phase diagram shown as follows. Two of the compounds melt congruently. The other four melt incongruently. Mg_5Pd_2 is dimorphic, as is MgPd. Not all of the crystal structures have been shown. Of the six compounds

shown here, the structures of the Mg_4Pd and $Mg_{0.9}Pd_{11}$ compounds have not been described in the literature (Fig. 14.27).

$Mg_{85}Pd_{14}$ may better be described as: $Mg_{83}(Mg_{0.51}Pd_{0.49})_4Pd_{12}$. It has the structure shown in Fig. 14.28.

Cell parameters are: $a = b = c = 14.2185$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 2032.58$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.14.

Mg_3Pd is dimorphic. The two crystal structures are shown in Fig. 14.29.

Na_3As type

$a = b = 4.613$ Å, $c = 8.412$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 154.99$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.15.

Cu type

$a = b = c = 2.7719$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 15.06$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.16.

The compound, Mg_5Pd_2, has the structure shown in Fig. 14.30.

Cell parameters are: $a = 8.161$ Å, $b = c = 8.644$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$. Cell volume $= 528.02$ Å^3, $Z = 2$. Cell occupancy is shown in Table 14.17.

The compound, Mg_2Pd, is not shown in the phase diagram but has the structure shown in Fig. 14.31.

Cell parameters are: $a = b = c = 8.5192$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 437.20$ Å^3, $Z = 32$. Cell occupancy is shown in Table 14.18.

The compound MgPd is dimorphic with the structures shown in Fig. 14.32.

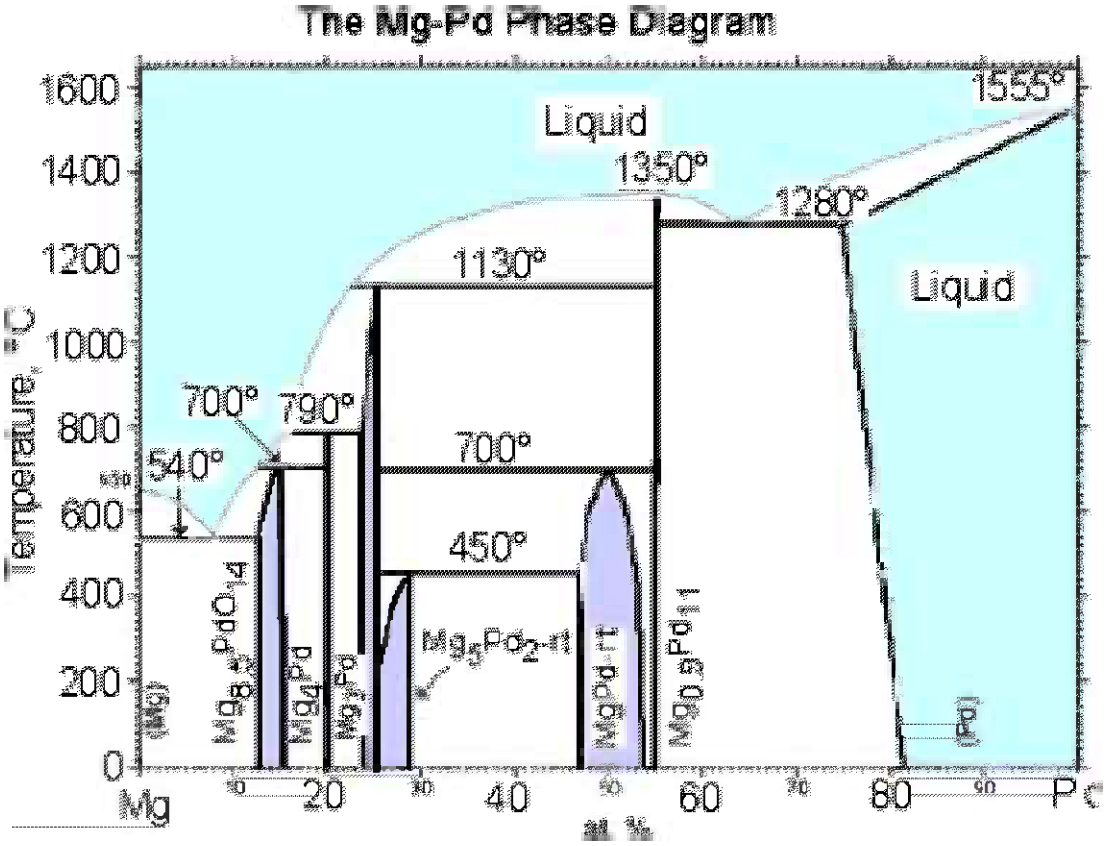

FIGURE 14.27

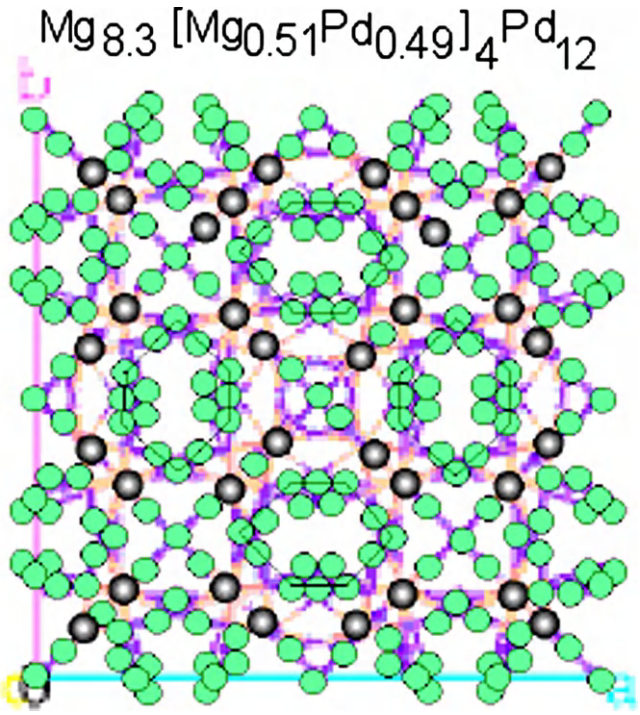

FIGURE 14.28

The two structures are essentially the same except for the *a*-parameter in the CuTi type.

CsCl type

$a = b = c = 3.122$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 30.37 Å^3, $Z = 1$. Cell occupancy is shown in Table 14.19.

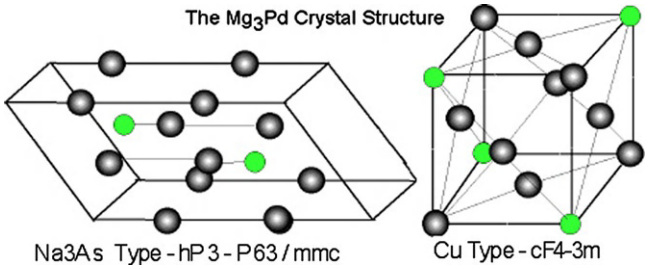

FIGURE 14.29

CuTi type

$a = 3.422$ Å, $b = c = 3.033$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 31.40 Å^3, $Z = 1$. Cell occupancy is shown in Table 14.20.

No other intermetallic compounds are known.

In the Mg–Pd–O system, only a few compounds are known. No compounds involving: the Pd^{2+}-containing system of MgO–PdO, the Pd^{3+}-containing system of MgO–Pd_2O_3, the Pd^{5+}-containing system of MgO–Pd_2O_5 and the Pd^{2+}–Pd^{3+}-containing system of MgO–Pd_3O_4 have been reported.

In the Pd^{4+}-containing system of MgO–PdO_2, a spinel phase has been synthesized ($a_0 = 8.501$ Å) whose stoichiometry is believed to be Mg_2PdO_4. This is the only reference to be found concerning the Mg–Pd–O system.

Magnesium palladium compounds are not offered for sale commercially and no CAS numbers are known.

14.2.3. Calcium Palladium Compounds

Ca^0 metal forms a series of compounds with Pd^0 metal as shown in the following phase diagram in Fig. 14.33.

Six compounds are shown but only CaPd and $CaPd_2$ melt congruently. Incongruently melting compounds include: Ca_9Pd, Ca_3Pd, Ca_5Pd, and Ca_3Pd_2. The compound, CaPd has the CsCl structure shown in Fig. 14.34.

Cell parameters are: $a = b = c = 3.518$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 43.54$ Å^3, $Z = 1$. Cell occupancy is shown in Table 14.21.

The compound, Ca_5Pd_2, has the form shown in Fig. 14.35.

Cell parameters are: $a = 6.708$ Å, $b = 7.704$ Å, $c = 8.996$ Å, $\alpha = 96.77°$, $\beta = 111.89°$, $\gamma = 90°$. Cell volume = 427.87 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.22.

The compound, Ca_3Pd, has the form shown in Fig. 14.36.

Cell parameters are: $a = 6.691$ Å, $b = 7.699$ Å, $c = 9.937$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 5.11.89 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.23.

The compound, Ca_3Pd_2, has the form shown in Fig. 14.37.

Cell parameters are: $a = b = c = 7.642$ Å, $\alpha = \beta = \gamma = 71.608°$, cell volume = 389.83 Å^3, $Z = 9$. Cell occupancy is shown in Table 14.24.

The compound, $CaPd_2$, has the form shown in Fig. 14.38.

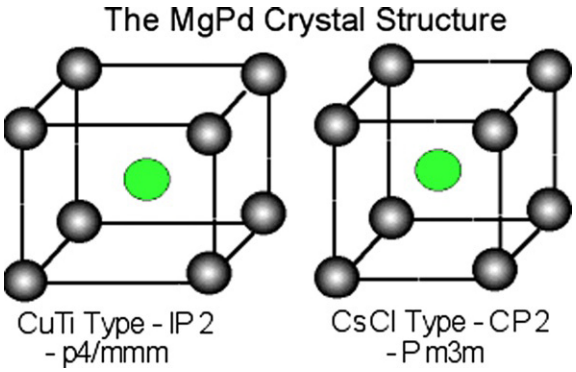

FIGURE 14.32

Cell parameters are: $a = b = c = 5.4108$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 112.01 Å^3, $Z = 8$. Cell occupancy is shown in Table 14.25.

The compound, $CaPd_5$, has the form shown in Fig. 14.39.

Cell parameters are: $a = 4.224$ Å, $b = c = 5.147$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 96.91 Å^3, $Z = 1$. Cell occupancy is shown in Table 14.26.

Although the compound, Ca_9Pd is shown in the phase diagram, its structure remains unknown. No other intermetallic compounds have been discovered.

In the Pd^{2+}-containing system of CaO–PdO, three novel black compounds of the $MePd_3O_4$ type have been synthesized. All three have the cubic $Na_xPt_3O_4$ structure with unit cell constants $a_0 = 5.826$ Å for $SrPd_3O_4$, $a_0 = 5.747$ Å for $CaPd_3O_4$, and $a_0 = 5.742$ Å for $CdPd_3O_4$.

The electronic energy band structure for cubic palladium oxides $CaPd_3O_4$ in the $NaPt_3O_4$ structure has been calculated by the full-potential linear augmented-plane-wave method within the local-density approximation. $CaPd_3O_4$ is almost semiconducting, but has a very small number of carriers. It was proposed that this compound would be a good candidate as an excitonic insulator, similar to CaB_6. Furthermore, the bands near the Fermi level have 1D character. The metal-insulator transition in $Ca_{1-x}Li_xPd_3O_4$ has been studied through charge transport measurements. The resistivity, the Seebeck coefficient, and the Hall coefficient have been consistently explained in terms of a simple one-band

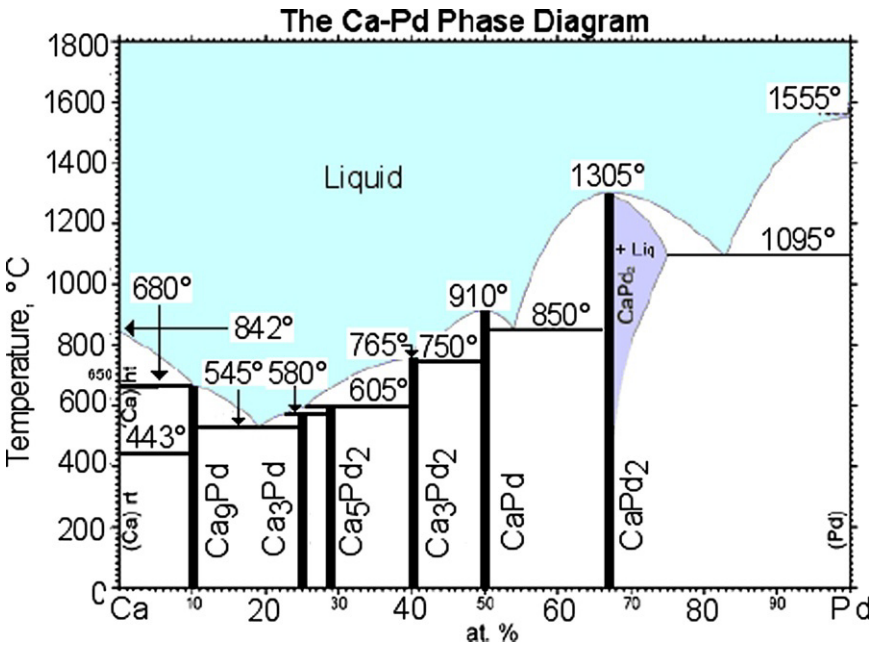

FIGURE 14.33

picture, where a hole with a moderately enhanced mass is itinerant three dimensionally. Contrary to the theoretical prediction presented in the literature [Phys. Rev. B 62, 13 426 (2000)], $CaPd_3O_4$ is unlikely to be an excitonic insulator, and holds a finite carrier concentration down to 4.2 K. Thus, the metal-insulator transition in this system is basically driven by localization effects.

Single crystals of the ternary palladates, $SrPd_3O_4$ and $CaPd_3O_4$, have been grown out of a potassium hydroxide flux. Small cubic crystals can be readily isolated from the soluble flux matrix and characterized by SEM and single-crystal X-ray diffraction. Both $SrPd_3O_4$ and $CaPd_3O_4$ crystallize with the $NaPt_3O_4$ structure and feature square planar coordination of palladium

atoms. $SrPd_3O_4$ and $CaPd_3O_4$ crystallize in space group $Pm3$(no. 223) with $a = 5.8120$ Å, $V = 196.33$ Å^3, $Z = 2$, and $a = 5.7356$ Å, $V = 188.68$ Å^3, $Z = 2$, respectively. It has the structure shown in Fig. 14.40.

A systematic study of the crystal structures of oxopalladates has shown that a change in scale occurs wherein an arrangement of planar PdO_4 polygons link to other isolated PdO_4 units to form $^1_\infty[PdO_3]$- and $^1_\infty[PdO_2]$-chains, square $^1_\infty[Pd_4O_8]$-tubes, and in-plane $^1_\infty[PdO_2]$-nets up to two- and three-dimensional networks. Remarkable is the formation of isolated Pd_6O_{12} rings and cage compounds ($Tl^+Pd_{12}O_{24}$ macropolyhedron) created by the perpendicular crossing of three $Pd_4(gap)_4O_{16}$ rings. PdO_4 polygons in combination with lone pair (LP) active elements produce PdO_4LP_2 octahedra. Pd^{4+} in octahedral coordination corresponds to the expectation but Pd^{4+} inside tetrahedral units and Pd^{2+} inside octahedral units and trigonal prismatic oxygen surrounding Pd^{4+} belong to the abnormal coordination. Mixed valence Pd^{2+} or Pd^{5+} and Pd^{3+} are rarities in palladium chemistry. The metal-rich compounds show a tendency to create clusters.

No compounds are known in the Pd^{3+}-containing system of $CaO–Pd_2O_3$, in the mixed valence of the $Pd^{2+}–Pd^{3+}$-containing system of $CaO–Pd_3O_4$, in the Pd^{4+}-containing system of $CaO–PdO_2$, or in the Pd^{5+}-containing system of $CaO–Pd_2O_5$.

Calcium palladates are not offered for sale commercially and no CAS numbers have been issued.

14.2.4. Strontium Palladium Compounds

Strontium metal forms three intermetallic compounds with Pd. However, the phase diagram has not yet published. The known compounds are: SrPd, $SrPd_3$ and $SrPd_5$.

SrPd has the structure shown in Fig. 14.41.

It consists of Pd–Sr dumb bells tied together into an orthorhombic structure.

Cell parameters are: $a = 4.192$ Å, $b = 4.524$ Å, $c = 6.031$ Å, $\alpha = \gamma = 90°$, $\beta = 110.33°$, cell volume = 107.10 Å^3, $Z = 2$. Cell occupancy is shown in Table 14.27.

TABLE 14.27

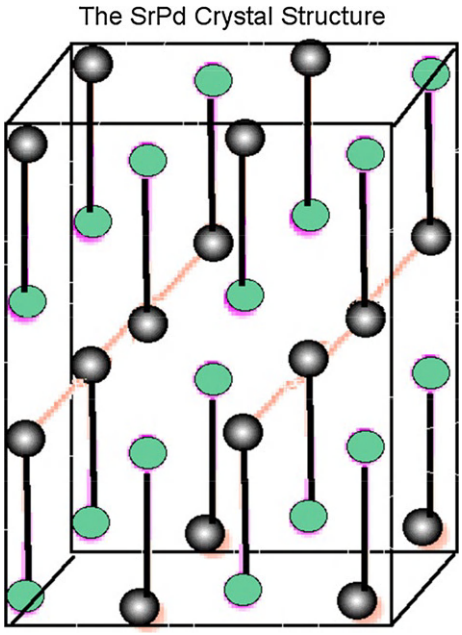

FIGURE 14.41

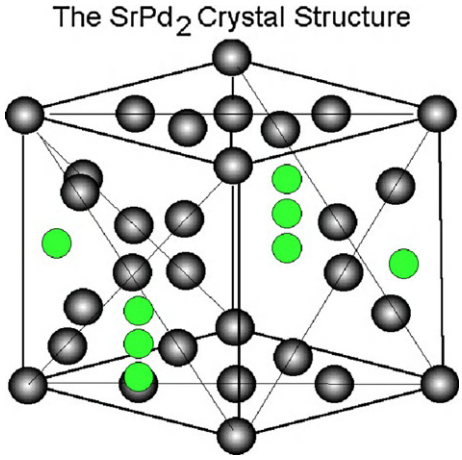

FIGURE 14.42

$SrPd_2$ has the structure shown in Fig. 14.42.

Cell parameters are: $a = b = c = 5.5338$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 119.83$ Å^3, $Z = 6$. Cell occupancy is shown in Table 14.28.

$SrPd_5$ has the structure shown in Fig. 14.43.

Cell parameters are: $a = 4.392$ Å, $b = c = 5.383$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 110.22$ Å, $Z = 2$. Cell occupancy is shown in Table 14.29.

No other intermetallic compounds are known.

In the Pd^{2+}-containing system of SrO–PdO, Sr_2PdO_3 is body-centered orthorhombic with $a_0 = 3.970$ Å, $b_0 = 3.544$ Å, and $c_0 = 12.84$ Å; the structure proposed for this compound is closely related to the K_2NiF_4 structure.

Three novel black compounds of the $MePd_3O_4$ type have been synthesized. All three have the cubic $Na_xPt_3O_4$ structure with unit cell constants $a_0 = 5.826$ Å for $SrPd_3O_4$, $a_0 = 5.747$ Å for $CaPd_3O_4$, and $a_0 = 5.742$ Å for $CdPd_3O_4$.

A hitherto unknown black $SrPd_3O_4$ [cubic, $a = 5.826$ Å, $NaPt_3O_4$ type] and brown Sr_2PdO_3 [according to X-ray powder patterns orthorhombic, D_{2h}^{25}; $a = 3.977$, $b = 3.530$, $c = 12.82$ Å] were prepared. Single crystals of the ternary palladate $SrPd_3O_4$ were grown out of a potassium hydroxide flux. These small cubic crystals can be readily isolated from the soluble flux matrix and were characterized by SEM and single-crystal X-ray diffraction. $SrPd_3O_4$ features square planar coordination of the palladium atoms. The structure has the form shown in Fig. 14.44.

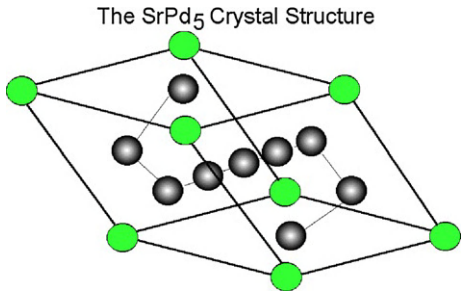

FIGURE 14.43

2	Pd	Pd	6	c	-4m.2	1/4	0	1/2	1.0
3	Sr	Sr	2	a	m-3.	0	0	0	1.0

Cell parameters are: $a = b = c = 5.825$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 197.65 Å^3, $Z = 2$. Cell occupancy is shown in Table 14.30.

Sr_2PdO_4 has the structure shown in Fig. 14.45.

Call parameters are: $a = 3.652$ Å, $b = 3.972$ Å, $c = 6.949$ Å, $\alpha = 106.61°$, $\beta = 104.76°$, $\gamma = 0°$, cell volume = 0.27 Å^3, $Z = 2$. Cell occupancy is shown in Table 14.31.

The relationship between the two structures is illustrated in Fig. 14.46.

No compounds have been discovered in the Pd^{3+}-containing system of SrO–Pd_2O_3, in the Pd^{2+}–Pd^{3+}-containing system of SrO–Pd_3O_4, or in the Pd^{5+}-containing system of SrO–Pd_2O_5.

In the Pd^{4+}-containing system of SrO–PdO_2, $SrPdO_3$ was prepared by the citrate method. XRD, SEM and TGA characterizations were carried out. The catalytic activity toward hydrogen evolution reaction was investigated, the activation energy, and reaction order and reaction mechanism have been determined using Tafel polarization and impedance techniques. The modified surface showed up to 100 times more efficiency toward electrocatalytic production of hydrogen. Adsorption of hydrogen on the catalyst was the rate-determining step and the reaction order at the surface of the catalyst is 0.86. The molar magnetic susceptibility was measured using Faraday's method and antiferromagnetic character was observed. However, no details of the structure were given and no other confirmation has appeared in the literature.

Strontium palladates are not available commercially for sale nor have any CAS numbers been issued to date.

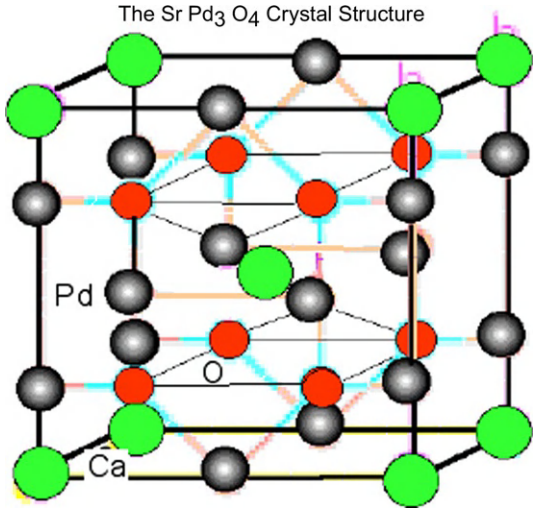

FIGURE 14.44

14.2.5. Barium Palladium Compounds

Barium metal forms a few intermetallic compounds with Pd metal. The phase diagram is incomplete but is shown in Fig. 14.47.

The structure of the compound, BaPd, differs from that of the Ca and Sr homologs (Fig. 14.48).

It consists of two chair forms of (Ba-Pd)$_3$ with the following cell parameters: $a = 4.352$ Å, $b = 4.683$ Å, $c = 6.283$ Å, $\alpha = \gamma = 90°$, $\beta = 110.25°$, cell volume = 120.01 Å^3, $Z = 6$. Cell occupancy is shown in Table 14.32.

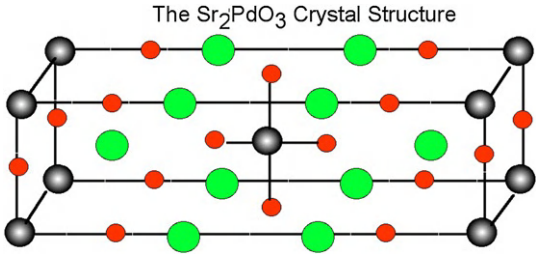

FIGURE 14.45

TABLE 14.31

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy

2	Sr1	Sr	4	i	mm2	0	0	0.3521	1.0
3	O2	O	2	d	mmm	1/2	0	1/2	1.0
4	Pd1	Pd	2	a	mmm	0	0	0	1.0

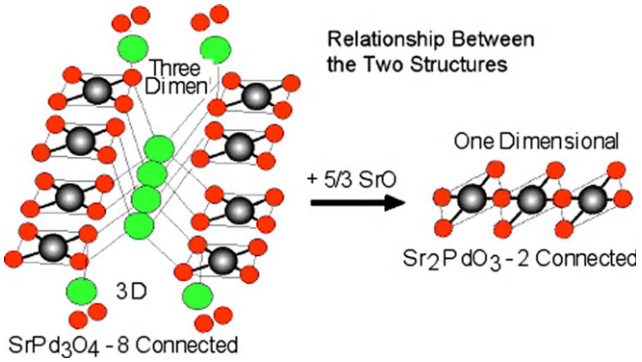

FIGURE 14.46

The compound, $BaPd_2$, has the structure shown in Fig. 14.49.

Cell parameters are: $a = b = c = 5.634$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 126.42 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.33.

The compound, $BaPd_5$, has the structure shown in Fig. 14.50.

Cell parameters are: $a = 4.332$ Å, $b = c = 5.541$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 115.09 Å^3, $Z = 2$. Cell occupancy is shown in Table 14.34.

In the Pd^{2+}-containing system of BaO–PdO, the compound, Ba_2PdO_3, has received some attention in the literature. Ba_2PdO_3 is isostructural with Sr_2CuO_3. Its structure has the form shown in Fig. 14.51.

The structural arrangement involves PdO_4 square planes as a 1D chain. The cell parameters are: $a = 3.8362$, $b = 4.080$, $c = 13.335$ Å.

The compounds, $BaPdO_2$ and $BaPd_3O_4$, are unknown in this system, contrary to the CaO–PdO and SrO–PdO systems.

No compounds are known in the Pd^{3+}-containing system of BaO–Pd_2O_3, in the Pd^{2+}–Pd^{3+}-containing system of BaO–Pd_3O_4, in the Pd^{4+}-containing system of BaO–PdO_2, or in the Pd^{5+}-containing system of BaO–Pd_2O_5. It is likely that the lack of formation in these systems is due to the large radius of the Ba^{2+} ion.

Barium palladate compounds are not available commercially nor have any CAS numbers been assigned at this date.

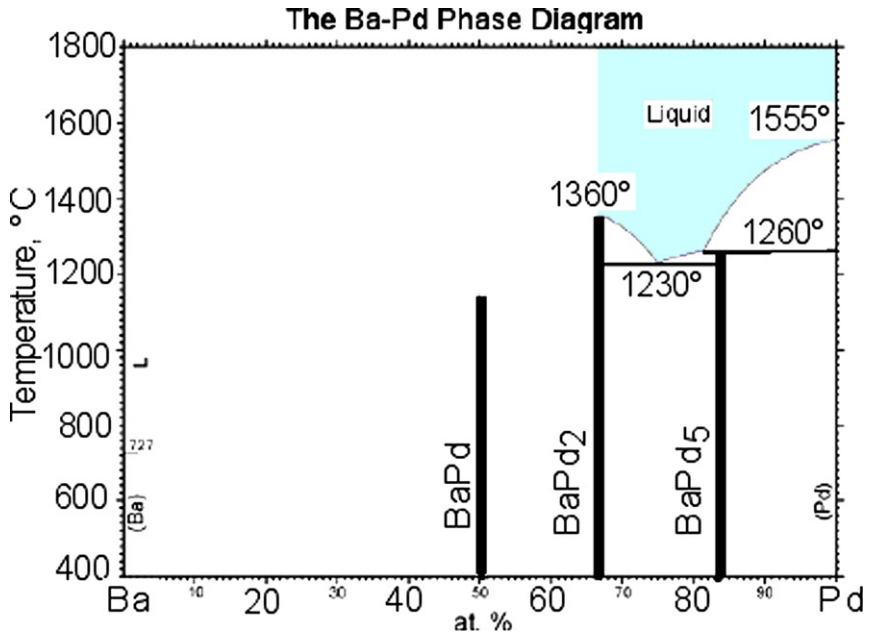

FIGURE 14.47

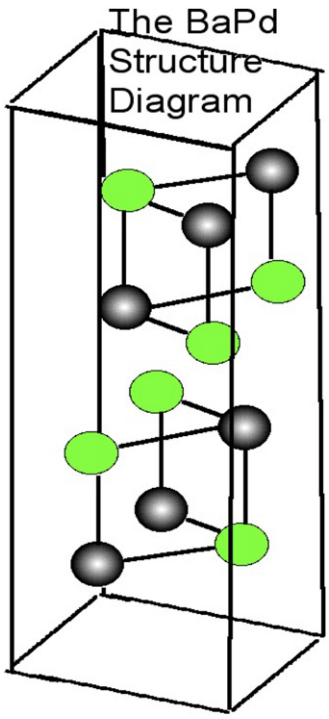

FIGURE 14.48

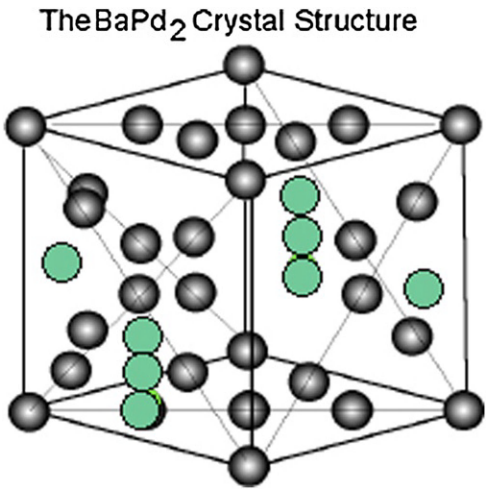

FIGURE 14.49

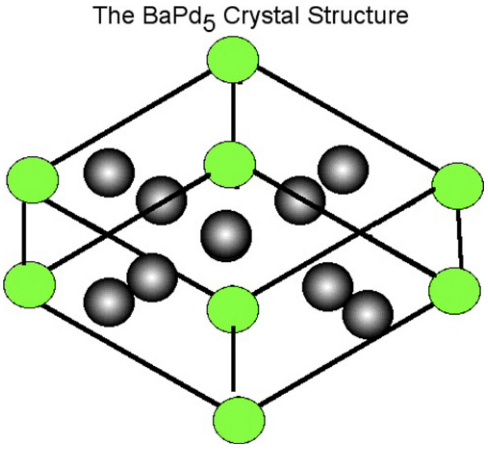

FIGURE 14.50

14.2.6. Radium Palladium Compounds

Because barium forms only one or two compounds with palladium oxides, it is likely that radium does not form any compounds in the systems of $RaO–Pd_xO_y$. However, there is no record of any attempts to form such compounds, due to the high cost and high radioactivity of the $^{226}Ra^{2+}$ ion.

14.3. ALKALINE EARTH PLATINUM COMPOUNDS

Platinum has two major oxidation states, Pt^{2+} and Pt^{4+} which form the oxides, PtO_2 and the less common PtO. These can react to form:

$$2\,PtO + PtO_2 \Rightarrow Pt_3O_4$$

where Pt is in the +4 valence state.

A study has been made concerning the coordination of Pt^{2+} and Pt^{4+} by oxygen wherein the crystal structures of oxo-platinates were systemized. Pt^{2+} exclusively shows,

3	Ba	Ba	1	a	6/mmm	0	0	0	1.0

in solids, a square and planar coordination well known and typical for Cu^{2+}, Pd^{2+} and Ni^{2+} as well. Often mixed valences (Pt^{2+}/Pt^{4+}) are observed in a square planar oxygen surrounding. Some exceptionally rare coordination is the dumbbell like O–Pt^{2+}–O. The crystal chemistry of Pt^{4+} resembles the countless metal ions showing octahedral coordination by oxygen. Despite different compositions the compounds $BaLn_2PtO_5$, $Ba_3Cu_2Ln_2PtO_{10}$, $Ba_5Ln_8Zn_4O_{21}$, $Ba_{13}Ln_8Zn_4Pt_4O_{37}$ and $Ba_{17}Ln_{16}Zn_8Pt_4O_{57}$ show amazing relationships of polyhedra connections. Additionally was shown that $Ba_4Sm_4Zn_3PtO_{15}$ is isotypic to $Ba_6Nd_2Al_4O_{15}$ and $Ba_4NaCu_{0.5}Pt_{1.5}O_8$ to $Ba_{15}Pt_6O_{27}$. Oxo-platinates containing lone pair active elements show one-side open polyhedra. The positions of the free (s^2) electrons were then calculated using the Coulomb terms of lattice energy. The large size of the Pt ion precludes the formation of stable compounds containing the smaller alkaline earth cations like $Be^{2+}$and Mg^{2+} and possibly Ca^{2+}, if they exist at all.

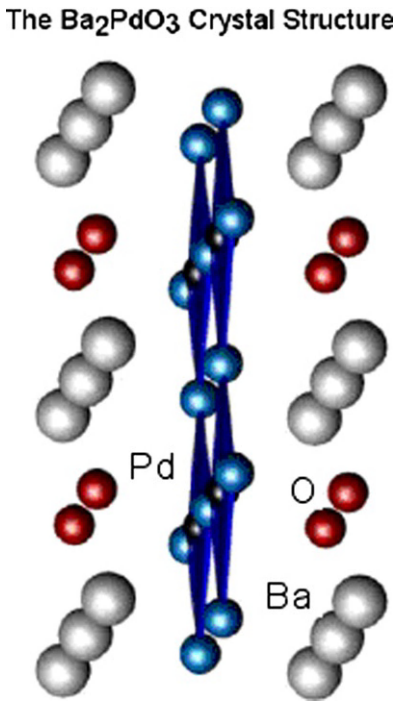

FIGURE 14.51

14.3.1. Beryllium Platinum Compounds

Beryllium forms a few intermetallic compounds with platinum as shown in the phase diagramin Fig. 14.52.

Not all of these compounds have been fully described and only Be_5Pt and $Be_{12}Pt$ have their structure identified. BePt is said to melt congruently but the other melting points have not been clarified.

Be_5Pt has the structure shown in Fig. 14.53.

Cell parameters are: $a = b = c = 4.2271$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 53.41$ Å^3, $Z = 4$. Cell occupancy of Be_5Pt is shown in Table 14.35.

$Be_{12}Pt$ has the structure shown in Fig. 14.54.

Cell parameters are: $a = 4.252$ Å, $b = c = 5.5414$ Å, $\alpha = 81.536°$, $\beta = \gamma = 67.44°$, cell volume $= 111.35$ Å^3, $Z = 2$. Cell occupancy is shown in Table 14.36.

The structures of $BePt_{15}$, BePt, and Be_2Pt_5 remain unknown.

In the system, Be–Pt–O, no platinite or platinate compounds are known.

These compounds remain an Academic oddity and no Industry usages have resulted.

14.3.2. Magnesium Platinum Compounds

Magnesium forms a few intermetallic compounds with platinum. However, the phase diagram is the only one in the alkaline earth series that has not been published. At least four compounds are known. Mg_3Pt has the form shown in Fig. 14.55.

Cell parameters are: $a = b = 7.9103$ Å, $c = 8.3223$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 450.98$ Å^3, $Z = 6$. Cell occupancy is shown in Table 14.37.

MgPt has the unit cell form shown in Fig. 14.56.

Cell parameters are: $a = b = c = 4.863$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 115.00$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.38.

The compound, $MgPt_3$, is dimorphic and has the structures shown in Fig. 14.57.

$SrPb_3$ type

$a = 3.722$ Å, $b = c = 3.884$ Å, $\alpha = \beta = \gamma = 90°$, $Z = 1$. Cell volume $= 56.00$ Å^3. Cell occupancy is shown in Table 14.39.

$AuCu_3$ type

Cell parameters are: $a = b = c = 3.906$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 59.59$ Å^3, $Z = 2$. Cell occupancy is shown in Table 14.40.

The compound, $MgPt_7$, has the crystal structure shown in Fig. 14.58.

Unit cell parameters are: $a = b = c = 5.5324$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 119.74$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.41.

No other intermetallic compounds have been discovered.

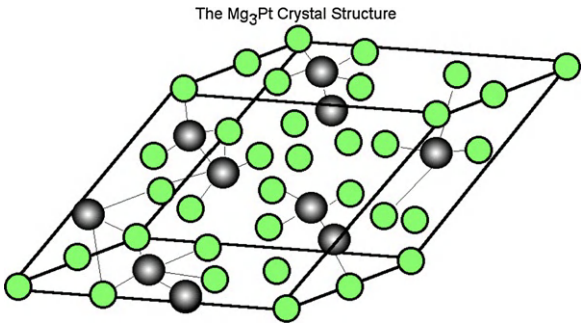

FIGURE 14.55

In the system, Mg–Pt–O, only the +2 and +4 states of Pt form stable compounds. In the Pt^{2+}-containing system of MgO–PtO, the compound, $MgPt_3O_4$, has the structure shown in Fig. 14.59.

Cell parameters are: $a = b = c = 5.642$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 179.11$ Å^3, $Z = 2$. Cell occupancy is shown in Table 14.42.

Other than its structure, little has been published concerning this compound.

In the Pt^{4+}-containing system of $MgO–PtO_2$, the Mg_2PtO_4 compound has been synthesized. Mg_2PtO_4 and Zn_2PtO_4 can be synthesized at 850–900 °C and oxygen pressures of 150–200 atm. Both oxides are inverse spinels with unit cell constants of $a_0 = 8.521$ Å and $a_0 = 8.549$ Å for Mg_2PtO_4 and Zn_2PtO_4, respectively.

The compound, $MgPtO_3$, is not stable and has only been characterized as an inverse spinel when layered Pt metal is used as a catalyst at 600 °C on a base of $MgAl_2O_4$ to dehydrogenate certain alkanes like n-butane.

No other Pt compounds are known in the MgO–PtO or $MgO–PtO_2$ systems. No magnesium platinate compounds are offered for sale commercially and no CAS numbers have been issued to date.

14.3.3. Calcium Platinum Compounds

Ca metal forms a series of intermetallic compounds with Pt metal as shown in the following phase diagram in Fig. 14.60.

The phase diagram is incomplete and pertinent data like melting points are missing for three of the compounds. At least six compounds are known.

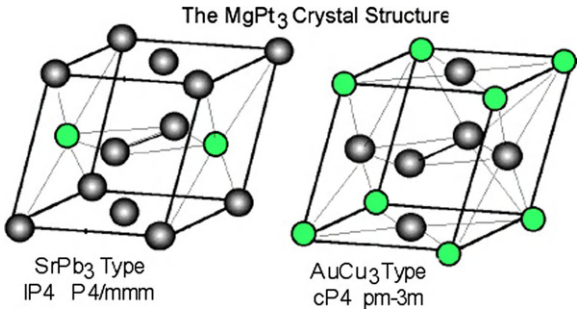

FIGURE 14.57

The Ca_3Pt_2 compound has the structure form shown in Fig. 14.61.

Cell parameters for Ca_3Pt_2 are: $a = b = c = 7.5524$ Å, $\alpha = \beta = \gamma = 71.126°$, cell volume = 374.06 Å^3, $Z = 9$.

Cell occupancy is shown in Table 14.43.

The compound, Ca_5Pt_2, has the crystal form shown in Fig. 14.62.

Cell parameters are: $a = 6.627$ Å, $b = 7.662$ Å, $c = 8.7302$ Å, $\alpha = 96.91°$, $\beta = 112.31°$, $\gamma = 90°$, cell volume = 406.64 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.44.

The compound, Ca_5Pt_3, has the crystal form shown in Fig. 14.63.

Cell parameters are: $a = 5.753$ Å, $b = c = 8.6675$ Å, $\alpha = 83.677°$, $\beta = \gamma = 70.628°$, cell volume $= 384.60$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.45.

The compound, $CaPt_2$, has the crystal form shown in Fig. 14.64.

Cell parameters are: $a = b = c = 5.3945$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 111.06$ Å^3, $Z = 8$. Cell occupancy is shown in Table 14.46.

The compound, $CaPt_5$, has the crystal form shown in Fig. 14.65.

Cell parameters are: $a = 4.368$ Å, $b = c = 5.322$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 107.14$ Å $\pm 3 \pm$, $Z = 1$. Cell occupancy is shown in Table 14.47.

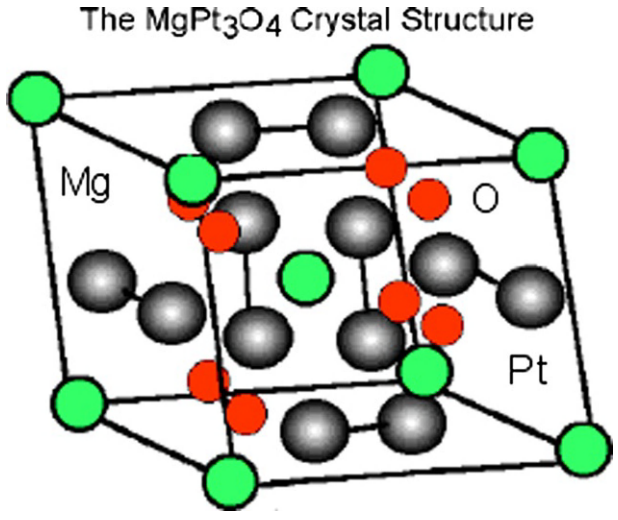

FIGURE 14.59

The compound, Ca_2Pt_7, is known but its structure has not been documented. The thermodynamic properties of this compound include:

Enthalpy of formation: $\Delta H_f = -7.19$ kJ/mol;

Entropy of formation: $S_f = -6.2$ J/K/mol.

No other intermetallic compounds have been discovered.

In the Ca–Pt–O system, a few compounds are known. In the Pt^{2+}-containing system of MgO–PtO, the compound, $CaPt_3O_4$ has been synthesized. It has the structure shown in Fig. 14.66.

Cell parameters are: $a = b = c = 5.743$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 189.42$ Å^3, $Z = 2$. Cell occupancy is shown in Table 14.48.

In the Pt^{3+}-containing system of CaO–Pt_2O_3, the compound, $CaPt_2O_4$ has been studied. It has a structure that is a two-dimensional analog of the platinum-bronze structure. It crystallizes in the D^3_{4h}-$P4_2/mmc$ space group of the tetragonal system with two formula groups per unit cell and dimensions of $a = 5.7786$ Å and $c = 5.5987$ Å. The structure is unique in that non-intersecting chains of Pt occur in the x and z directions. One and three dimensions are known and $CaPt_2O_4$ forms the missing link. The unusual formation of Pt^{3+} oxidation state was explained by the metallic bonding between the Pt ions.

A study was made of tight-binding electronic band structures by calculation for the three representative types of ternary platinum oxides with columnar PtO_4 chains, $NaPt_3O_4$, $CaPt_2O_4$, and $CdPt_3O_6$. Despite the dimerization in its columnar PtO_4 chains, $CaPt_2O_4$ is metallic because the upper half of the z^2 band overlaps with the other d-block bands. The dimerization of the columnar PtO_4 chains does not represent a charge density wave instability but is probably caused by the

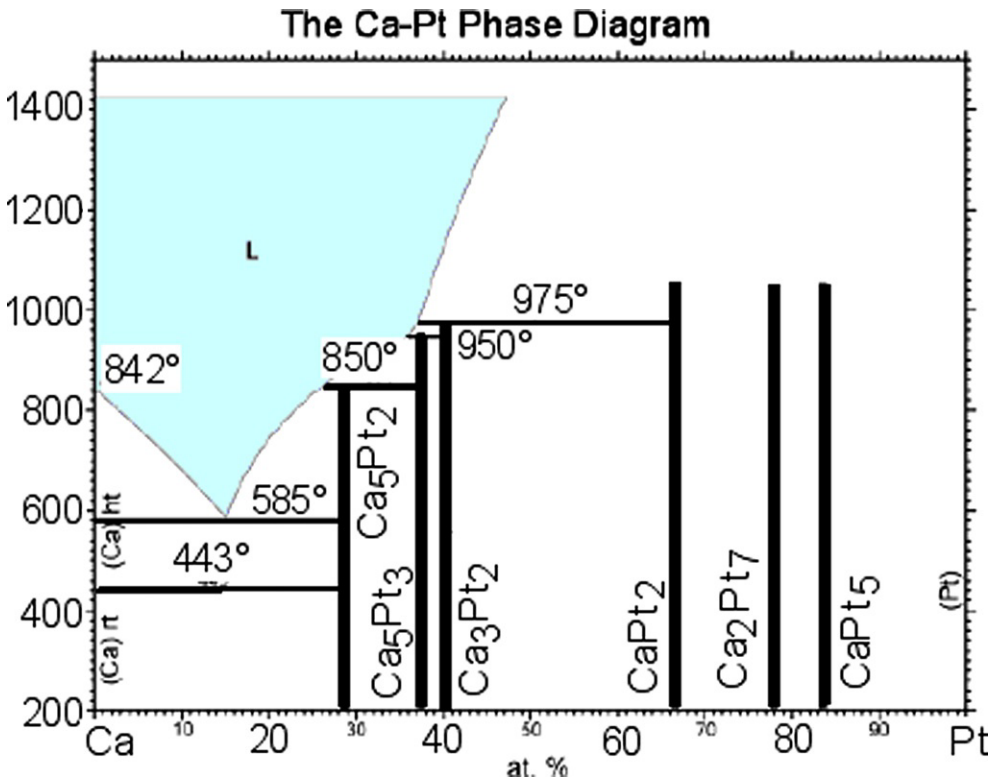

FIGURE 14.60

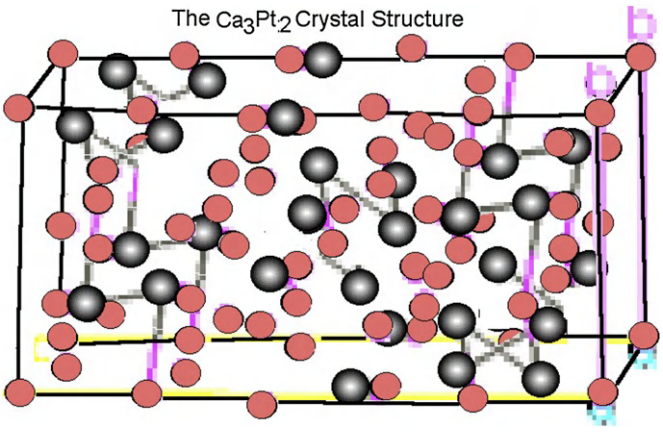

FIGURE 14.61

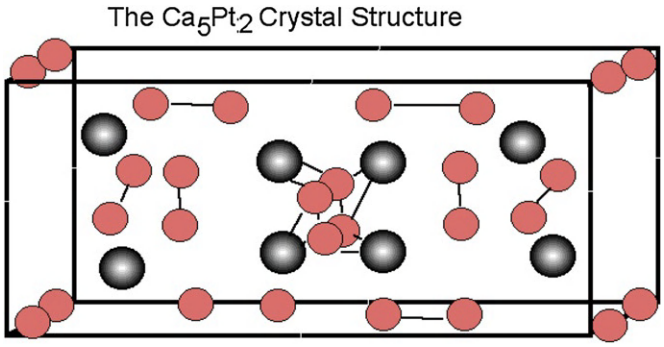

FIGURE 14.62

alternation of filled and unfilled square-prism sites along each chain.

In the Pt^{4+}-containing system of $MgO–PtO_2$, the compound, $CaPtO_3$, has been studied. ABX_3 post-perovskites (or strongly metastable phases at room pressure) are of importance as analogs of post-perovskite $MgSiO_3$, a deep-earth phase stable only at very high pressure. Commonly, $CaIrO_3$ has been used for this purpose, but it has been suggested that $CaPtO_3$ might provide a better analog. The isothermal in compressibility of orthorhombic post-perovskite-structured $CaPtO_3$ to 40 GPa was measured at ambient temperature, by X-ray powder diffraction using synchrotron radiation. A third-order Birch–Murnaghan equation of state fitted to the experimental data yields $V_0 = 228.10$ Å^3, $K_0 = 168.2$ GPa and $K_{-0} = 4.51$. Similar fits to the cube of each axis of the unit-cell shows that the *b*-axis is the most compressible ($b_0 = 9.9191$ Å, $K_0 = 123.3$ GPa, $K_{-0} = 2.37$); the *a*-axis ($a_0 = 3.12777$ Å, $K_0 = 195.7$ GPa, $K_{-0} = 6.63$) and *c*-axis ($c_0 = 7.3551$ Å, $K_0 = 192$ GPa, $K_{-0} = 12.2$) are both more inflexible and have almost identical incompressibility when the material is close to ambient pressure, but the *c*-axis

shows greater stiffening on compression. Comparison of these axial incompressibility with those of $CaIrO_3$ shows that $CaPtO_3$ is slightly less anisotropic under compression (possibly because of the absence of Jahn–Teller distortion), suggesting that $CaPtO_3$ may be a somewhat better analog of $MgSiO_3$. Our sample also contained minor amounts of a cubic four phase, for which the third-order Birch–Murnaghan equation-of-state parameters were found to be: $V_0 = 186.00$ Å^3, $K_0 = 213$ GPa and $K_{-0} = 4.9$.

The structure of one Pt^{4+}-containing compound is known. The Ca_4PtO_6 compound, containing Pt^{4+}, has the structure shown in Fig. 14.67.

Cell parameters are: $a = b = c = 6.5322$ Å, $\alpha = \beta = \gamma = 90.274$ Å, cell volume $= 278.72$ Å^3, $Z = 6$.

Cell occupancy is shown in Table 14.49.

Ca_2PtO_4 is also known. The derivation of the energy-volume equations of state EOS for Ca_2PtO_4 as a Ca_2IrO_4 type, and in K_2NiF_4 type (knf) structures, has led to an energy destabilization at a larger volume for the latter. This led to the proposal that the former is a post-K_2NiF_4—pknf—occurring compound at high pressures having a reduced

dimensionality, 2D-knf ⇒ 1D-pknf and a rearrangement of the PtO_6 octahedra from corner sharing in knf to edge sharing in pknf. Bader charge analysis indicated an increased covalence of Pt–O bond with such a transformation. The lowered dimensionality is also illustrated from the density of states (Fig. 14.68).

This diagram illustrates the facts:

- Transformations of 3D perovskite (pv) to 2D post-perovskite (ppv-ABO_3) with pressure *P* are known.
- That, in parallel, the K_2NiF_4 type (knf) is a potential low *P* form of Ca_2IrO_4 type (pknf).
- Pressure transformation of 2D corner-sharing octahedra (knf) to 1D edge-sharing octahedra (pknf) occurs.
- Augmentation based on DFT computations of equation of state, charge density, DOS for the Ca_2PtO_4 case was confirmed.

A novel A-site ordered perovskite $CaCu_3Pt_4O_{12}$ was synthesized under high pressure and high temperature of 12 GPa and 1250 °C. $CaCu_3Pt_4O_{12}$ is the first perovskite in which the B site is fully occupied by Pt^{4+}. The crystal structure refinement based on the synchrotron powder X-ray diffraction data shows that $CaCu_3Pt_4O_{12}$ crystallizes in the space group *Im* (cubic) with a lattice constant of $a = 7.48946$ Å. The magnetic susceptibility data show the antiferromagnetic transition at $T_N = 40$ K, which is attributed to the magnetic ordering

of Cu^{2+} spins with $S = 1/2$. It has the structure shown in Fig. 14.69.

No other calcium platinate compounds are known. There are no calcium platinates offered for sale commercially.

14.3.4. Strontium Platinum Compounds

Platinum metal forms a small number of intermetallic compounds with strontium metal, as shown in the following phase diagram in Fig. 14.70.

The compound, $SrPt_5$ has the structure shown in Fig. 14.71.

Cell parameters are: $a = 4.364$ Å, $b = c = 5.397$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 110.08$ Å^3, $Z = 1$. Cell occupancy is shown in Table 14.50.

$SrPt_2$ has the crystal form shown in Fig. 14.72.

Cell parameters are: $a = b = c = 5.499$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 117.59$ Å^3, $Z = 8$. Cell occupancy is shown in Table 14.51.

Although Sr_9Pt is listed as a compound in the phase diagram, its crystal structure has not been finalized. The only data available are the cell parameters of: $a = b = c = 4.307$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 56.59$ Å^3, $Z = 2$.

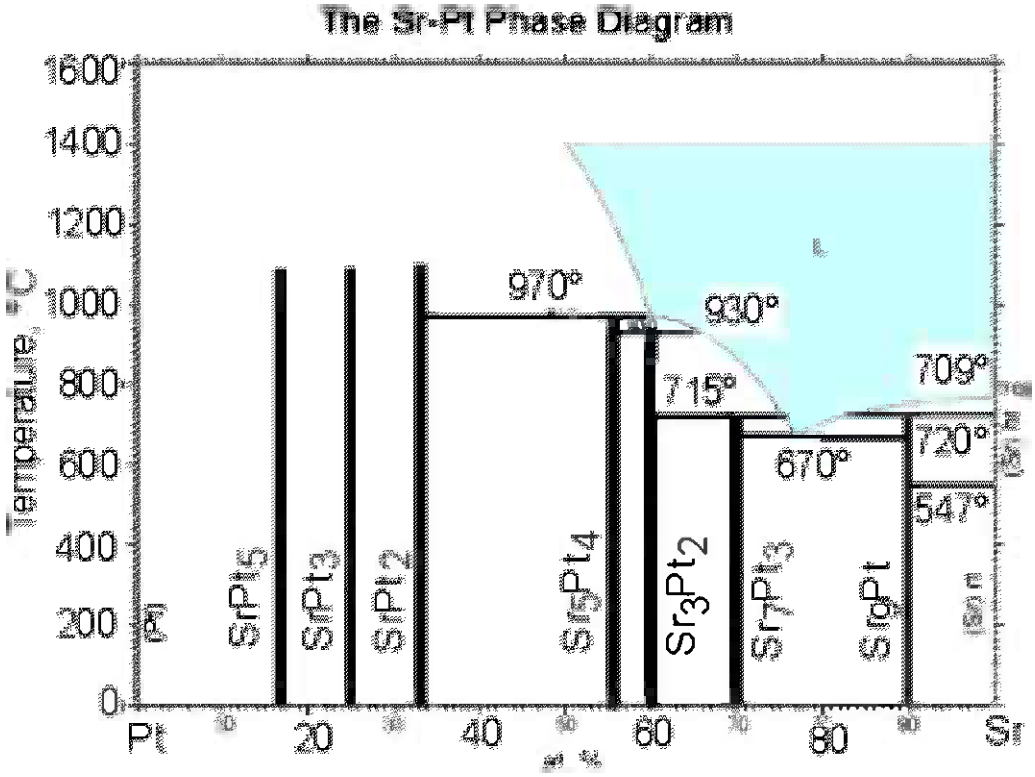

FIGURE 14.70

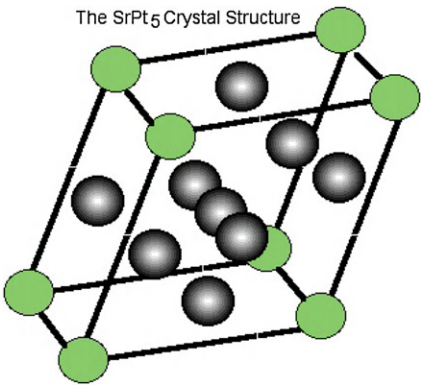

FIGURE 14.71

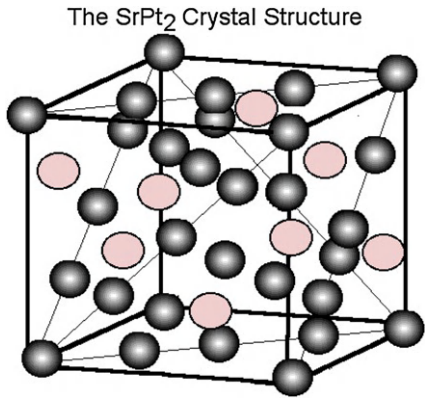

FIGURE 14.72

The compound, Sr_7Pt_3, has the crystal structure shown in Fig. 14.73.

Cell parameters are: $a = 7.134$ Å, $b = 7.929$ Å, $c = 24.326$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 1359.45 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.52.

The compound, Sr_5Pt_4, has the form shown in Fig. 14.74.

Cell parameters are: $a = 7.879$ Å, $b = 8.147$ Å, $c = 15.606$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 1001.75 Å^3, $Z = 4$. Cell occupancy is shown in Table 14.53.

The compound, Sr_3Pt_2, has the crystal form shown in Fig. 14.75.

Cell parameters are: $a = b = c = 8.007$ Å, $\alpha = \beta = \gamma = 71.33°$, cell volume = 447.01 Å^3, $Z = 9$. Cell occupancy is shown in Table 14.54.

In the Pt^{2+}-containing system of SrO–PtO, the structure of $SrPtO_2$ has been determined (Fig. 14.76).

Pt forms a square planar structure of PtO_4 units surrounded by layers of four Sr ions, arranged in a cubic lattice.

The structures and electronic properties of a number of real and hypothetical ABX2 compounds sharing (or evolving from) a single $P4/mmm$ structural type were

TABLE 14.50

examined. These include the known $CaCuO_2$ and $SrPtO_2$ phases. A number of variations of this *P*4/*mmm* ABX_2 framework, some obvious, some exotic, all with a chemical motivation, were investigated. Careful attention was given to the d-orbital splitting patterns and magnetic states (ferromagnetic or antiferromagnetic) of these compounds, as well as their stability gaged by phonon dispersions and energetics. $SrPtO_2$, and $LaPtO_2$ have antiferromagnetically coupled ground states.

No other data are available concerning the other possible compounds in this Pt^{2+}-containing system.

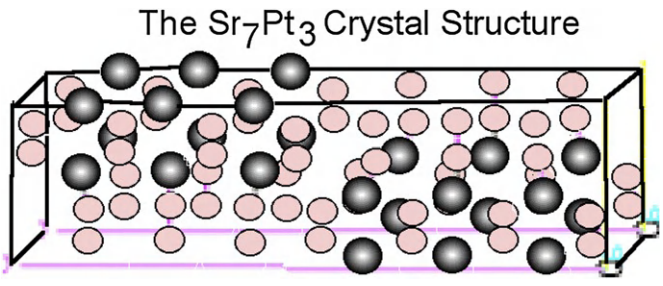

FIGURE 14.73

In the Pt^{4+}-containing system of SrO–PtO_2, the compound, Sr_4PtO_6 has been studied. It has the structure shown in Fig. 14.77.

Cell parameters are: $a = b = c = 6.881$ Å, $\alpha = \beta = \gamma = 90.093°$, cell volume $= 325.89$ Å^3, $Z = 6$. Cell occupancy is shown in Table 14.55.

Another view of the structure is shown in Fig. 14.78.

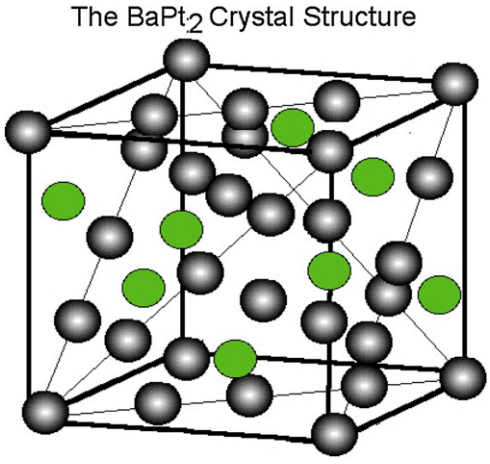

FIGURE 14.80

Here, only two of the PtO_6 octahedra show the Pt atom. The crystals are trigonal with space group *R*3*c*; the triply primitive hexagonal cell dimensions are $a = 9.74$, $c = 11.90$ Å. The platinum ions are octahedrally coordinated with oxygen and are linked in the *c*-direction through strontium ions surrounded by trigonal prisms of oxygen atoms. These strings of coordination polyhedra are connected laterally by strontium atoms in eightfold coordination with oxygen. This structure is of the same type as that reported for K_4CdC_{16}. The isolation of one PtO_6 group from the next is postulated as a reason for the ease of hydrolysis of the compound. Sr_4IrO_6 and Sr_4RhO_6 have the same structure.

No other compounds in the systems, SrO–PtO or $SrO–PtO_2$ have been reported.

Strontium platinate or platinite compounds are available for sale commercially.

14.3.5. Barium Platinum Compounds

Barium metal forms a few intermetallic compounds with Pl metal. The phase diagram is incomplete but lists two compounds, as shown in Fig. 14.79.

The compound, $BaPt_2$, has the structure shown in Fig. 14.80.

Cell parameters are: $a = b = c = 5.6144$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 125.14$ Å^3, $Z = 8$. Cell occupancy is shown in Table 14.56.

A better view of $BaPt_2$ is shown in Fig. 14.81.

No other data are available in the literature.

The compound, $BaPt_5$, has the structure shown in Fig. 14.82.

Cell parameters are: $a = 4.337$ Å, $b = c = 5.505$ Å, $\alpha = 120°$, $\beta = \gamma = 90\underline{0}$, cell volume $= 113.82$ Å^3, $Z = 1$. Cell occupancy is shown in Table 14.57.

No other intermetallic compounds are known. There have been no descriptions of the physical properties of these compounds and they are not offered for sale commercially. No CAS numbers have been issued to date.

In the Pt^{2+}-containing system of BaO–PtO, if $BaCO_3$ is heated with Pt metal in an oxidizing atmosphere, the compound, $BaPtO_2$ is formed:

$$BaCO_3 + Pt + O_2 + \text{heat (600–800 °C)} \Rightarrow BaPtO_2$$

$$5\ BaPtO_2 + \text{heat (>800 °C)} \Rightarrow 5\ BaPtO_{2.38} + O_2$$

However, heating this compound above 800 °C in an oxidizing atmosphere causes oxidation of Pt^{2+} to Pt^{4+} with formation of a defect structure lacking oxygen atoms. Above 1200 °C, this structure looses further oxygen to form compounds of indeterminate compositions. $BaPtO_2$ has the structure shown in Fig. 14.83.

Nonetheless, other than structure, little is known concerning this compound.

The compound, $BaPt_3O_4$, is known. It has the structure shown in Fig. 14.84.

Cell parameters are: $a = b = c = 5.715$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 186.66 Å^3, $Z = 1$. Cell occupancy is shown in Table 14.58.

Little data concerning its physical or electrical properties have been published for this compound. The technical literature is devoid of any mention of other BaO–PtO compounds.

In the Pt^4-containing system of $BaO–PtO_2$, the compound, Ba_4PtO_6, is known. It has the structure shown in Fig. 14.85.

Cell parameters are: $a = b = c = 7.241$ Å, $\alpha = \beta = \gamma = 89.66°$, cell volume $= 379.69$ Å^3, $Z = 6$. Cell occupancy is shown in Table 14.59.

The compound, $Ba_{15}Pt_6O_{27}$, has the structure shown in Fig. 14.86.

Cell parameters are: $a = 8.638$ Å, $b = c = 10.108$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 764.32$ Å^3, $Z = 4$. Cell occupancy is shown in Table 14.60.

$BaPtO_3$ was prepared by the reaction of $BaO_2 + PtO_2$ at high O_2 pressures and by the thermal decomposition of $BaPt(OH)_6$ at 500–700 °C in O_2 at 1 atm. The powder pattern can be indexed based on a hexagonal cell with $a = 5.64$, $c = 27.44$ Å, corresponding to a 12-layer perovskite structure. The oxygen content of $BaPtO_{3-x}$ materials was determined by firing the samples in H_2 to form $Ba(OH)_2 + Pt$ and calculating x from the weight loss.

The compound, Ba_2PtO_4 is also known but data concerning this compound is sparse. It has the following cell parameters: Ba_2PtO_4. Orthorhombique $a = 17.62$ Å, $b = 10.17$ Å, $c = 8.85$ Å. A related compound, Ba_4PtO_6 is hexagonal, $a = 10.064$ Å, $c = 12.663$ Å.

Other compounds in the Pt^{4+} system of $BaO–PtO_2$ include $Ba_4Pt_3O_9$. It is monoclinic with $a = 17.46$ Å, $b = 10.08$ Å and $c = 8.55$ Å. This compound has the formal arrangement of $Ba_4(Pt^{4+}{}_{1-y}–Ba^{2+}{}_y)O_9$ where $y < 1.0$.

$$3\ Ba_4Pt_3O_9 \Rightarrow Ba_{12}Pt_9O_{27}$$

This composition has a hexagonal structure with $a = 5.83$ Å $\approx a_{hex}\sqrt{3}$ and $c = 4.31$ Å $\approx c_{hex}\sqrt{2}$. A variety of perovskite-type mixed oxides corresponding to the solid solution $Ba_{12-x}[Ba_xPt_{3-x}]Pt_6O_{27}$ (where 0 is less than or equal to x less than or equal to 3) was studied by X-ray photoelectron spectroscopy (XPS). Pt was found to be in two valence states, Pt^{2+} and Pt^{4+} and the quantity of Pt^{2+} decreases when x increases. The intrinsic activity, for catalytic CO oxidation, was found to be dependent on x. At low temperature (below 170 °C), the highest activity is obtained for $Ba^{12}Pt_9O_{27}$ ($x = 0$) and the activity decreased with increasing x. The apparent activation energies increased, from 80 to 110 kJ/mol, when x increased; for a sample of metallic platinum catalyst studied in the same conditions, a value of 120 kJ/mol was found. The partial reaction order/O-2 (in the range of 0.64–0.90) increased with x while the partial order/CO (in the range of −0.34 to −0.70) decreased when x increased. Moreover, for the oxide containing only Pt^{4+} ($Ba_{15}Pt_6O_{27}$) the reaction orders were similar to those determined for the metallic platinum. Hence, there is undoubtedly a correlation between the Pt^{2+}/Pt^{4+} ratio in these oxides and the catalytic activity for CO oxidation. This can be explained by assuming that CO chemisorption on Pt^{2+} is weaker than on Pt^{4+}, which implies a less inhibitor effect of CO at low temperature.

A single-crystal study of $Ba_3Pt_2O_7$ showed that the structure tolerates a variable composition which can be written $Ba_3Pt_{2+x}O_{7+2x}$. The crystal studied had a hexagonal cell of dimensions $a = 10.108 \pm 0.006$ Å and

$c = 8.638 \pm 0.009$ Å, and a probable space group $P62c$, $Z = 4$. The density determined by water displacement was 7.99 g/cm^3; the theoretical density for $Ba_3Pt_2O_7$ is 7.94 g/cm^3. The structure was determined from the set of 401 observed independent reflections obtained from 5189 reflections measured by the automated counter methods. Refinement on F was carried to a conventional R of 8.0%. The structure has barium–oxygen layers with an essentially four-layer stacking sequence of the double hexagonal (ABAB) type. Platinum is found mainly in face-sharing octahedra, but is also distributed over some sites in which the coordination is nearly square planar and other sites in which the coordination is trigonal prismatic with three Pt–O bond lengths of 2.00 Å and three long Pt–O distances of 2.65 Å. The platinum with planar coordination is 0.08 Å from the plane of the four oxygen atoms.

No other barium–platinum compounds are known. Data concerning the electrical properties of these compounds is almost non-existent. They are not offered for sale commercially and no CAS numbers have been assigned to any of these compounds.

14.3.6. Radium Platinum Compounds

Although Ra^{2+} most likely forms the same type of compounds as Ba^{2+}, there is no record of any effort to study such compounds. No such compounds have been reported and the likelihood of anyone doing so is nil. In view of the high cost of both Pt and Ra metals, and the radioactivity of ^{226}Ra, a description of the properties of radium platinates or platinites will never be published.

15.1. ALKALINE EARTH COPPER COMPOUNDS

Copper forms both oxidic and intermetallic compounds with the alkaline earths. These compounds have been thoroughly studied after the copper-based high-temperature superconducting compounds like $HgBa_2Ca_2Cu_3O_{8+\delta}$ were announced in 1997. There now exist a large number of papers and books relating to these types of compounds. No description of these superconducting compounds will be given here.

15.1.1. Beryllium Copper Compounds

Only two intermetallic compounds of Be–Cu have been discovered as shown in the following phase diagram. The third compound shown is a high-temperature form not stable at room temperature (Fig. 15.1).

A Be/Cu alloy compound structure has been used as a plasma-facing material for the International Thermonuclear Experimental Reactor (ITER). Bonding of Be to Cu alloy was completed by diffusion bonding or brazing. Methods such as scanning electron microscope (SEM), energy dispersive spectrum (EDS), X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) analysis were employed to inves tigate the interface structure of joint, fracture mechanism and phases of shear fracture surface were also studied. Be to Cu alloys were formed using Ti as interlayer interface under the bonding 'temperature 850 °C. The formational free energy of the possible intermetallic compounds was calculated by the Castep module of Material Studio, according to "flux-energy principal" to confirm the formation of interface reaction. The atomic population and overlap population of intermetallic compounds were analyzed. The formational energy of vacancy and diffusion migratory energy of Be, Cu, α-Ti and β-Ti were calculated by "Castep", and the atomic population of simple vacancy attachment of atoms to Be, Cu, α-Ti, or β-Ti were analyzed. Intermetallic Ti compounds were the main stable type formed. It was found that $TiBe_2$-αTi, Ti_2Cu, Ti_3Cu_4, Ti_2Cu_3 and $TiCu_4$ layered structures were formed

http://dx.doi.org/10.1016/B978-0-444-59550-8.00015-6

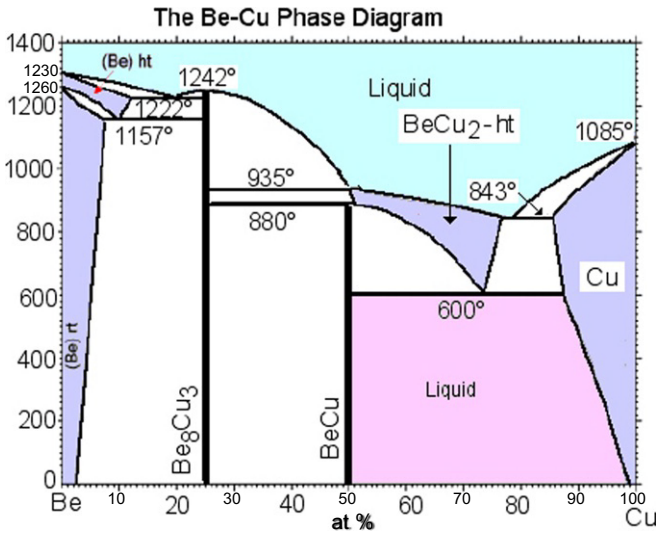

FIGURE 15.1

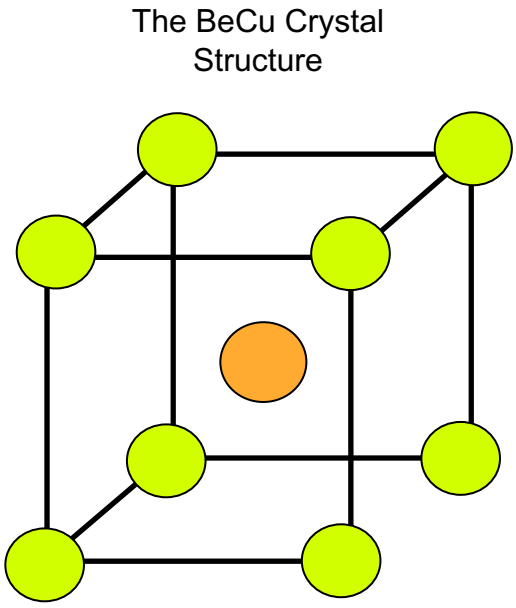

FIGURE 15.2

on the joint interface (there was a segregated Ti_2Cu phase present as well). The shear strength of joints was found to be lower. The fracture was determined to be cleavage–intergranular cracking. The XRD analysis showed that the joints ruptured around the interface between Ti_2Cu layer and Ti_3Cu_4 layers. The use of Ti as an interface has come under question.

Of the known compounds, BeCu has the structural form shown in Fig. 15.2.

In this diagram, Cu is in the body-centered position. Cell parameters are: $a = b = c = 2.702$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 19.73$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.1.

At the vacuum ultraviolet (VUV) free electron laser in Hamburg (FLASH), an infrared (IR) beamline is being built to allow novel pump and probe experiments combining coherent IR pulses with the free electron laser radiation in the VUV spectral range. It provides useful IR radiation generated as a "dedicated" undulator over the wavelength range from 200 μm to 10 μm and possibly even shorter. Another important application of the beamline is electron diagnostics of the longitudinal charge distribution of the electron bunches. One of the most important tasks of the front ends in undulator beamlines is to handle the very intensive photon beam. In treating for such a high heat load, a grazing geometry technique, wherein inclining an irradiated surface to the photon beam to reduce the heat flux level, is very commonly used. In addition to this traditional method, advanced material such as "Glidcop" (copper alloy strengthened by adding alumina) for copper was applied to masks, absorbers and xy-slits in Spring-8 because of its structurally toughness against the thermal stress. From the results of analyses and various evaluation tests, the following conclusions were attained:

(1) The static strength of the brazed joint between low-Z material and a cooling body made of copper, or beryllium/copper (Be/Cu), is about eight times as large as a graphite/copper (G/Cu) joint.
(2) Concerning the vacuum properties, beryllium is much superior to graphite.

$BeCu_2$ has the crystal structure shown in Fig. 15.3.

Cell parameters are: $a = b = c = 4.3364$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 53.38$ Å^3, $Z = 8$. Cell occupancy is shown in Table 15.2.

The compound, Be_8Cu_2, has the structure shown in Fig. 15.4.

This compound involves the site occupancy shown at the top (orange) of the diagram where each site is randomly occupied. Cell parameters are: $a = 2.557$ Å, $b = c = 4.179$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 38.67$ Å^3, $Z = 2$. Cell occupancy is shown in Table 15.3.

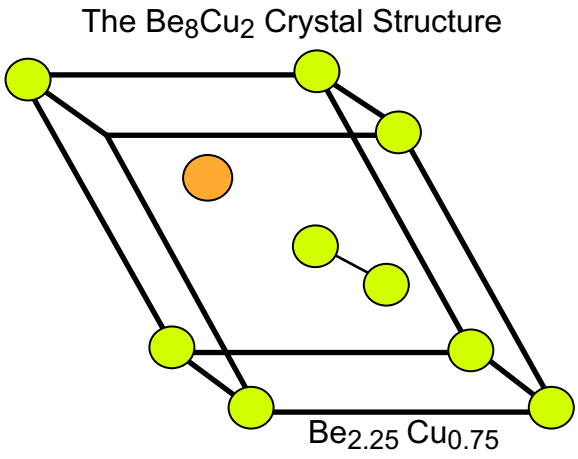

FIGURE 15.4

In contrast, fracture in room temperature tensile bars of Cu–Be occurred in the Be_2Cu–BeCu reaction zone layer at the copper–beryllium interface. This bond exhibited high-fracture strength values (322, 331 MPa). The fracture was a mixed mode consisting of dimple rupture and trans-granular cleavage. A continuous layer of intermetallics is formed between the copper and beryllium at the diffusion bonding temperature (450 °C). These phase(s), although exhibiting high strength, also exhibited poor ductility and fracture toughness.

The compound, BeCu2, has the structure shown in Fig. 15.5.

Cell parameters are: $a = b = c = 2.4162$ Å, $\alpha = \beta = \gamma = 109.47°$, cell volume = 10.86 Å^3, $Z = 2$. Cell occupancy is shown in Table 15.4.

No other intermetallic compounds are known.

BeO does not form any compounds with the copper oxides. No compounds have been described in the current literature. Be–Cu alloys are available commercially but no BeO–CuO_x compounds are offered for sale.

15.1.2. Magnesium Copper Compounds

Magnesium forms two intermetallic compounds with Cu as shown in the above phase diagram, as shown in Fig. 15.6.

No other compounds are known. The cell parameters of Mg_2Cu and $MgCu_2$ are not available.

$MgCu_2$ has the structure shown in Fig. 15.7.

This is a typical Laves phase, called the C15 type structure, that belongs to cubic system. Space group is *Fd*3*m*.

A simple comparison of the $MgCu_2$ structure can be made (Fig. 15.8).

It should be clear that this structure is a combination of the two phases.

Magnesium metal is known to easily form hydrides. The addition of copper improves that function. In contrast to Mg_2Cu, the compounds $MgNi_2$ and $MgCu_2$ do not form hydrides under conventional hydrogenation conditions. It is assumed that the hydrogenation does not occur because the enthalpy of formation of the hydride phase is large and positive. Using Miedema's rule, a calculation of the enthalpy of formation of substituted alloys based on these two copper compounds was made. For certain alloy mixtues, the enthalpy of

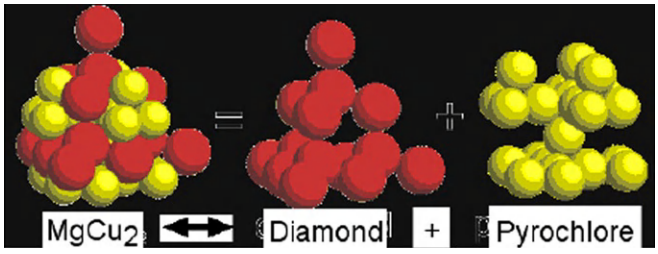

FIGURE 15.8

formation is believed to be 10–20 kJ/mol lower. Synthesized alloys were made with the above calculation as a guide. However no hydride was formed under the conditions used, 4.0 MPa at 573 K. The size of the interstitial holes compared to the hydrogen atomic size was used to explain these results.

The deformation behavior of $MgCu_2$ Laves phase intermetallic compound was studied by compression experiments. $MgCu_2$ was plastically deformed at a temperature above 673 K, where the strain rate was low. The large temperature and strain rate dependences of the stress and small activation volumes obtained over the temperature range 673–873 K suggested that the deformation was rate controlled by the Peierls mechanism. The compounds with stoichiometric composition showed the usual large strain hardening over the temperature range 673–973 K. However, when the compounds included the Cu-rich or Mg-rich composition within the limit of Laves phases, they showed

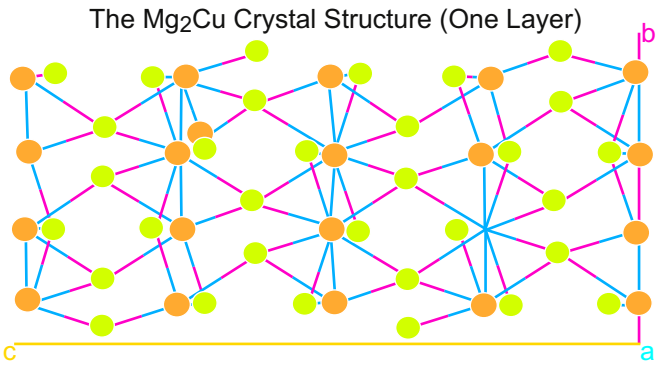

FIGURE 15.9

a mild yield drop (though the type of yield drop varied with composition and the test temperature). The compounds rapidly cooled from the melts showed a gum elastic deformation, which was considered to be due to the stress-induced transformation, at the condition of very low stress and room temperature.

The charge density distribution of the intermetallic compound $MgCu_2$ was obtained by the maximum entropy method (MEM) from the synchrotron powder diffraction data. In the MEM charge density map, the overlap of electron densities was clearly observed between the neighboring Cu atoms. This showed that there is a rather strong covalent bond between Cu–Cu atoms. It was also found that the Cu–Cu bonding occurs along the very well-known Kagomé net, which characterizes the Laves phase structure. At least, in the case of $MgCu_2$, the Kagomé network is the real electronic network in reality, rather than a geometrical concept to represent structural characteristics of Laves phase compounds.

The compound, Mg_2Cu, has the structure shown in Fig. 15.9.

The three-dimensional (3D) structure consists of two layers within a tetragonal cell with no atoms on the corners of the lattice.

Cell parameters are: $a = b = 5.235$ Å, $c = 9.536$ Å, $\alpha = \beta = 98.01°$, $\gamma = 119.49°$, cell volume $= 218.60$ Å^3, $Z = 8$. Cell occupancy is shown in Table 15.5.

Mg_2Cu spontaneously undergoes hydrolysis in water at room temperature, and reacts with water to form $Mg(OH)_2$, Cu and hydrogen. Cu nanoparticles were formed as well as Cu_2O. The hydrolysis behavior of Mg_2Cu was compared to that previously found for Mg_2Ni. The Cu nanoparticles prepared by hydrolysis of Mg_2Cu were spherical in shape with a mean size of about 10 nm.

A mechanical alloying (MA) process was used to synthesize the nanocrystalline Mg_2Cu and the nanocomposite Mg_2Cu/Pd hydrogen storage materials. The structure of these materials has been examined by XRD and SEM. Thermodynamic and electrochemical properties have also been investigated. The MA for 18 h led directly to the formation of the orthorhombic-type structure with a crystallite sizes of about 30 nm. The results show that the maximum absorption capacity reaches 2.25 wt% for nanocrystalline Mg_2Cu alloy. This is lower than in the polycrystalline Mg_2Cu alloy (2.6 wt%) because of a significant amount of strain, chemical disorder and defects introduced into the material during the MA process. On the other hand, mechanically coated Mg_2Cu alloy with palladium has effectively reduced the degradation rate of the studied electrode material. Nano-structured Mg_2Cu shows excellent hydrogen storage properties because nano-structured materials have more surface area and more defects, which means more nucleation sites with hydrogen, and smaller particles, which means shorter diffusion distance for hydrogen in the alloy particles.

The dehydrogenation kinetics of air exposed samples of MgH_2/Mg_2Cu and $MgH_2/MgCu_2$ have been studied with in situ time resolved X-ray powder diffraction. The X-ray setup enabled the recording of full diffraction patterns within 150 s, thereby allowing the study of structural changes combined with simultaneous extraction of kinetic parameters. Phase fractions as a function of time and temperature were derived from series of consecutive diffraction patterns by numerical integration of selected diffraction peaks. The apparent activation energy for the dehydrogenation of the MgH_2/Mg_2Cu, and $MgH_2/MgCu_2$ sample was found to be 108 kJ/mol and 160 kJ/mol, respectively. Furthermore, substantially improved dehydrogenation kinetics of MgH_2 and resistance toward oxidation of Mg due to the presence of $Mg_2Cu/MgCu_2$ are discussed in relation to previous work. In the hydrogenation process for the super-laminates at 573 K, Mg_2Cu is formed through interdiffusion between Mg and Cu metals. Then the Mg_2Cu decomposes into MgH_2 and $MgCu_2$. In the

TABLE 15.5

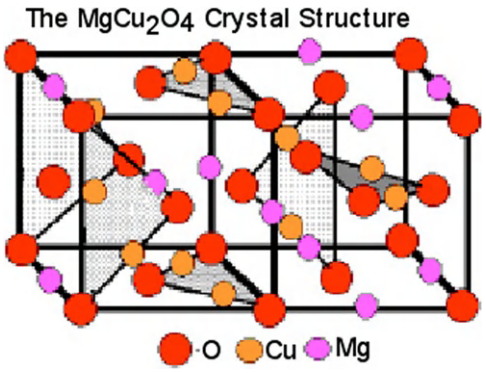

FIGURE 15.10

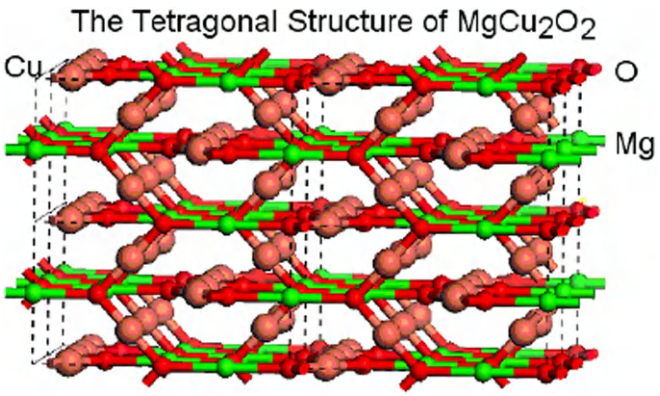

FIGURE 15.11

dehydrogenation process at 573 K, the MgH_2 compound releases hydrogen and returns to metallic Mg. The Mg then reacts with $MgCu_2$, and Mg_2Cu is formed again. Throughout the sequence, Mg_2Cu phase absorbs and desorbs hydrogen reversibly at 473 K.

No other intermetallic compounds are known. Mg–Cu alloys are not available commercially, and no CAS numbers have been issued to date.

In the Cu^+-containing system of MgO–Cu_2O, the compound, $MgCu_2O_2$, is one of the family of compounds that exhibit p-type conductivity and are transparent conductive oxides (TCO) like indium tin oxide. TCOs are used in:

(1) Transparent electrodes in flat panel displays (ITO)
(2) Organic light-emitting diodes
(3) Solar cells
(4) Touch screen panels
(5) Transparent electronic windows
(6) Electrochromic windows
(7) Electromagnetic shielding

$MgCu_2O_2$ has the form shown in Fig. 15.10.

Another view of the $MgCu_2O_2$ lattice is shown in Fig. 15.11.

The lattice constants of the family of MCu_2O_2 are given in Table 15.6

The stability of these oxides has been calculated and rated according to their decomposition into constituent oxides, i.e.

$$\Delta E = E(MCu_2O_2) - [E(Cu_2O) + E(MO)]$$

where $E(MCu_2O_2)$ is the total energy of the bulk alloy and $E(Cu_2O)$ and $E(MO)$ is the total energy of bulk Cu_2O and the bulk alkaline earth oxide in the rock salt structure. The results determined were shown in Table 15.7.

Of these, $MgCu_2O_2$ and $CaCu_2O_2$ are unstable while $SrCu_2O_2$ and $BaCu_2O_2$ are stable. Cation coordination and M–O distances impact on stability:

Mg: 4 coordinate in these compounds
Ba: 6 coordinate in these compounds

In the Cu^{2+}-containing system of MgO–CuO, no data concerning the $MgCuO_2$ compound are available. However, the compound, $MgCu_2O_3$, has received some attention in the literature.

This compound has a ladder-like structure, as shown in Fig. 15.12.

A thermodynamic evaluation of the ternary Mg–Cu–O system has been made and a set of parameters consistently describing the system has been determined. Güggenite is the only ternary solid phase within the system and its stoichiometry is close to $MgCu_2O_3$.

The MgO phase can dissolve a considerable amount of CuO. This can be described by a simple model in which Mg^{2+} substitution by Cu^{2+} occurs. Phase diagrams were given for the MgO–CuO_x system at 0.21 and 1 bar oxygen partial pressures as well as a potential diagram. An isothermal section at 1423 K is also presented. Available experimental data are rather limited and most of them are well described by the calculation. There are still uncertainties concerning the

CuO solubility in MgO and on the Cu^{1+}/Cu^{2+} ratio present in MgO. For this reason, it is not presented here.

The electrical conductivity of $MgCu_2O_3$ was measured on single crystals in the temperature range $180 < T < 300$ K. The compound is a thermally activated semiconductor with a band gap of 0.94 eV and a resistivity of $2.8 \times 10^4\ \Omega$ at 21 °C. Neutron diffraction experiments on powder samples revealed an AFM phase transition at $T_N = 94.5$ K, while the magnetic susceptibility measured in the temperature range $12 < T < 292$ K is atypical for an AFM. The magnetic structure was derived from the neutron experiments. The magnetic moment per Cu^{2+} ion is 0.33 μbar and thus is anomalously small.

In another paper, the magnetic properties of undoped and Li-doped $MgCu_2O_3$ single crystals were studied by magnetic susceptibility and neutron diffraction measurements. The pure compound was found to be a semiconductor with an AFM ground state ($T_N = 95$ K). Above T_N, short-range magnetic correlations within the Cu–O chains of the $MgCu_2O_3$ structure give rise to a predominantly one-dimensional (1D) magnetic behavior. This was revealed by the quantitative interpretation of the susceptibility measurements. Below T_N, the 3D magnetic structure, derived from neutron diffraction experiments, can be described by an essentially, collinear model. A small spin canting, however, exists, because adjacent CuO_6 octahedra are strongly tilted with respect to each other. The magnetic structure can be represented by two independent magnetic sublattices, which, in the mean-field approximation, are not coupled. The topology is similar to the one producing an infinitely degenerate state in AFM face-centered cubic (fcc) lattices. Doping experiments with Li clearly demonstrated the importance of spin fluctuations and fluctuations of the local exchange fields for lifting the degeneracy in such a system. A remarkably small amount of Li (about 2 mol% Li) is sufficient to disturb the magnetic lattice in such a way that the almost collinear spin arrangement changes into an arrangement where the spins of one sublattice are strongly canted with respect to the spins of the other sublattice.

This structure ($MgCu_2O_3$), which is homologous to $BaCu_2O_3$ and $SrCu_2O_3$, can be viewed as stacked buckled Cu_2O_3 planes of the prototypical planar TLL $SrCu_2O_3$ system. These compounds show, in addition to the common AFM-period doubling along the chain (*b*-axis), different magnetic structures in *c*- and *a*-directions. These include ferromagnetic (FM) ordering in *c*-direction and on the kinked PL-rungs for A1/4Mg, and AFM ordering for A1/4Ca. Along the *a*-axis, AFM period doubling and/or an incommensurate spiral-type wave near 3/7 commensurability, respectively, have been observed.

By comparing $SrCu_2O_3$ having straight rungs to the strongly "kinked" rungs in $MgCu_2O_3$ (with decreased buckling (Cu–O–Cu bond) at angle H), it has been determined that there is a transition from a super-exchange dominated AFM to a FM rung (a strengthening crosspiece in the structure of a chair) exchange model. This is governed by Hund's rule coupling at the intermediate O of the ring center that approaches $\Theta = 90°$. It also depends upon the crystalline field strength that caused splitting of on-site energies for differently oriented O-2p orbitals if it is small. Comparing the observed magnetic structures one concludes that this transition occurs at a critical H_c in between those of A1/4Ca and A1/4Mg. Near H_c, the ring exchange J_r is expected to be small.

In another paper, it was claimed that:

> "In the system $Mg_{1-x}Cu_{2+x}O_3$, the phase with $x = 0$, i.e. the compound $MgCu_2O_3$, does not exist. Neutron powder measurements and single-crystal X-ray studies clearly show that the Mg lattice site is partially occupied by Cu^{2+} ions with typical values of $x = 0.1$. This substitutional disorder, best denoted by the formula $(Mg_{1-x}Cu_x)Cu_2O_3$, is surprising, since the coordination polyhedron of the Mg site is a compressed oxygen octahedron, while the Jahn–Teller ion Cu^{2+} usually prefers a tetragonally elongated oxygen octahedron, as it exists on the regular Cu site of the lattice. The local environment of the Cu^{2+} ions on the Mg site was also checked by electron paramagnetic resonance (EPR) measurements".

No other compounds in the MgO–Cu_xO_y system are known. No magnesium cuprate compounds are offered for sale commercially and no CAS numbers have been issued to date.

15.1.3. Calcium Copper Compounds

Ca metal forms at least three intermetallic compounds with copper metal as shown in Fig. 15.13.

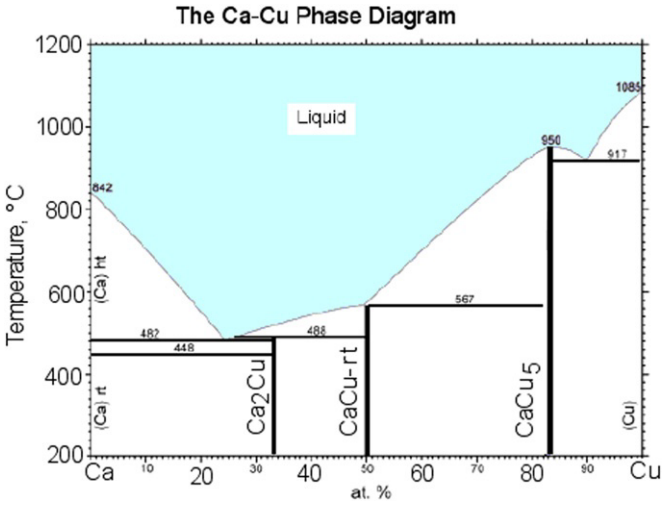

FIGURE 15.13

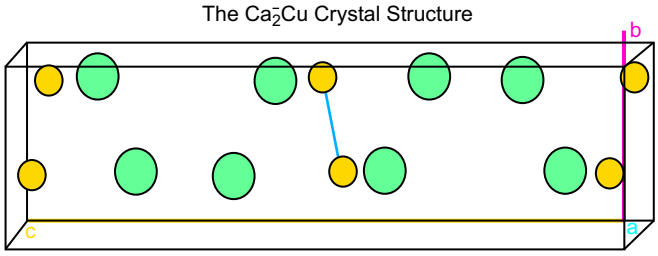

FIGURE 15.14

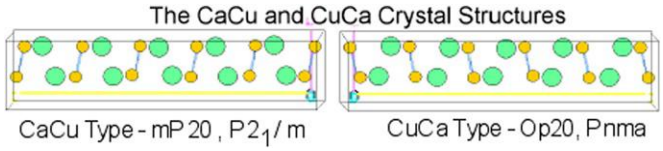

FIGURE 15.15

The compound, Ca_2Cu, has the structural form shown in Fig. 15.14.

Cell parameters are: $a = 4.161$ Å, $b = 6.126$ Å, $c = 14.532$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 370.37$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.8.

X-ray structural analysis shows that Ca_2Cu is orthorhombic, *Pnma*, $a = 6.126$, $b = 4.161$, $c = 14.532$ Å, $Z = 4$, $D = 2.58$ mg/m^3, (Mo K_α) $= 8.4$/mm. The structure comprises stacked Cu-centered trigonal prisms of Ca atoms that share two rectangular faces. This allows the formation of infinite zigzag chains of Cu atoms.

CaCu is dimorphic with the structures shown above in Fig. 15.15.

CaCu type $a = 4.271$ Å, $b = 5.882$ Å, $c = 19.473$ Å, $\alpha = 94.3°$, $\beta = \gamma = 90°$, cell volume $= 487.58$ Å^3, $Z = 10$. Cell occupancy is shown in Table 15.9.

CuCa type $a = 4.271$ Å, $b = 5.894$ Å, $c = 38.822$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 976.72$ Å^3, $Z = 10$. Cell occupancy is shown in Table 15.10.

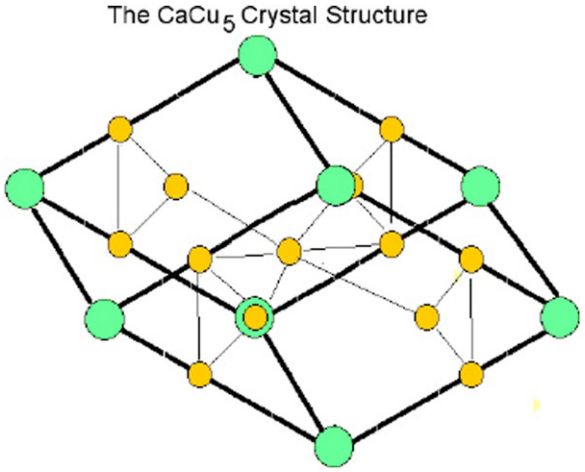

FIGURE 15.16

X-ray photoelectron and ultraviolet photoemission measurements have been made on $Ca_{10}Cu_{90}$ alloys. The core-level XPS spectra of Ca show strong satellites that are discussed in terms of the core-hole screening effects. It was suggested that these spectra are due to the mixing of d^0-, d^1-, and d^2-configurations of calcium in the final state and that band-like effects are important. In the case of the X-ray photoemission valence band only small differences have been observed between the alloy and the noble metal, whereas for ultraviolet photoemission valence bands the corresponding changes are more pronounced. The energy shifts of the X-ray photoemission valence bands are attributed to the enhancement of the p partial density of states just below the Fermi level in the case of the alloy. In addition, linear muffin-tin-orbital band calculations have been performed for the $CaCu_5$ compound by using a super-lattice with and without the Ca 2p core hole. When the core hole is created, the weight of the Ca 3d local partial density of states is increased at the Fermi level, whereas the Cu 3d band remains almost unchanged. The compound, $CaCu_5$, has the form shown in Fig. 15.16.

Cell parameters are: $a = 4.047$ Å, $b = c = 5.074$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$. Cell volume $= 90.83$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.11.

Another view of the $CaCu_4$ structure is given in Fig. 15.17.

This structure is adopted by a number of other intermetallic compounds. An example is:

Single crystals of dysprosium heptanickel tritin were synthesized from the constituent elements by arc melting. Two of the five Ni atoms are at general sites and all other atoms are at sites with either twofold or m symmetry. The structure contains '$DyNi_5Sn$' and '$DyNi_2Sn_2$' fragments and represents a new member of the $CaCu_5$ series of intermetallics.

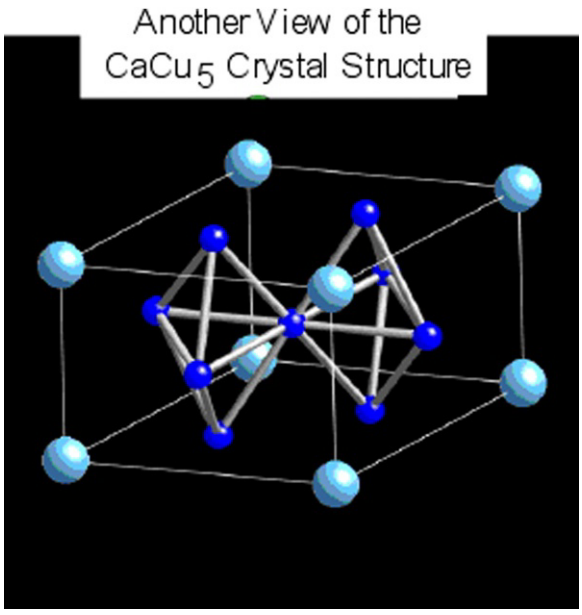

FIGURE 15.17

No other Ca–Cu intermetallic compounds are known. They are not offered for sale commercially and no CAS numbers have been assigned to date.

The system, Ca–Cu–O, forms several stable cuprate compounds with CaO.

In the Cu^{+}-containing system of CaO–Cu_2O, the compound, $CaCu_2O_2$, is known and was discussed in the Mg–Cu–O section presented above. Its structure was given as shown where the larger orange-red balls are Cu^{+}, the smaller red balls are oxygen and the green balls are Ca^{2+} (Fig. 15.18).

Oxides with the structure MCu_2O_2 (M = Ca, Ba, Mg and Sr) are promising materials for the development of new p-type transparent conducting oxide thin films. By using as precursors calcium and copper tetramethyl-heptanedionate dissolved in meta-xylene, mixed calcium copper films have been grown in the temperature range from 450 °C to 550 °C.

At these temperatures, deposited films exhibited a high-mirror reflection effect, good adherence and were reasonably uniform with the cationic composition of the films being easily controlled by adjusting the copper calcium ratio in the precursor solution. In $CaCu_2O_2$, copper is in the Cu^{1+} oxidation state and depending on the oxygen partial pressure used, the films either consisted of $CaCu_2O_3$ or a mixture of CaO, CuO and Cu_2O. Optimization of annealing conditions increased the presence of Cu^{1+} in the film. Films had a maximum transmittance of 50% in the visible range and were highly resistive. Appropriate annealing conditions reduced the resistivity of the films. It has been determined that $CaCu_2O_2$ is not stable in air and moisture and decomposes while $SrCu_2O_2$ is stable. The latter forms a transparent conductive layer on several substrates and remains stable. The conductivity is p-type and is due to Cu^{+} vacancies in the lattice.

In the Cu^{2+}-containing system of CaO–CuO, contrary to $SrCu_2O_3$, the pseudo-ladder two-leg compound $CaCu_2O_3$ does not show a significant spin gap behavior as expected for typical two-leg ladder systems. $CaCu_2O_3$ single crystals (size about 2–3 mm^3) were cut from a boule, grown in an IR furnace by the traveling solvent floating zone method. The crystals were found to be phase pure as confirmed by X-ray diffraction, energy dispersive X-ray (EDX) and thermogravimetric analysis. However, the EDX results indicate a deficiency of Ca, with a balancing excess in Cu, corresponding to a non-stoichiometric composition $Ca_{1-y}Cu_{2+y}O_{3-\delta}$. The lattice constants determined as $a = 9.944$ Å, $b = 4.078$ Å and $c = 3.461$ Å agree well with published values. Note, that $MgCu_2O_3$, referred to above, has the same lattice structure. Magnetic measurements on single crystals have been performed in a SQUID magnetometer for temperatures from 5 K up to 120 K in magnetic fields (m0Hp7T) applied along the different crystallographic axes. The magnetic susceptibility has been determined from magnetization measurements at 1 T. The structure has the form shown in Fig. 15.19.

Experimental and theoretical studies of the unoccupied electronic structure of $CaCu_2O_3$ single crystals

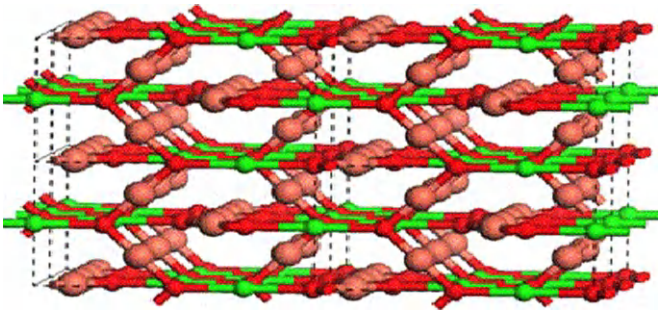

FIGURE 15.18

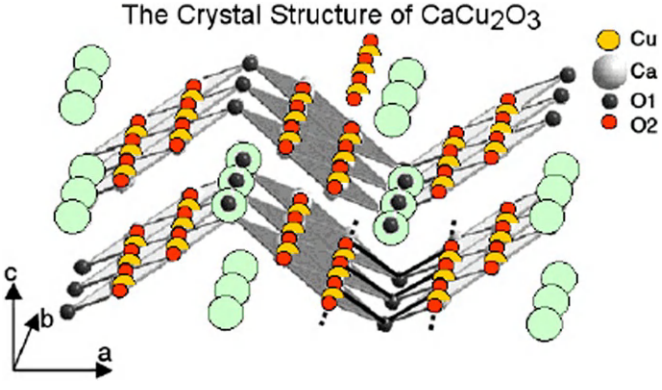

FIGURE 15.19

have been performed using polarization-dependent X-ray absorption spectroscopy and band structure calculations. The measured hole distribution shows an unusual large number of holes in electron orbitals parallel to the interlayer direction which is in agreement with the theoretical analysis. A corresponding strong interlayer exchange was found to be responsible for the missing spin gap which is generic for other two-leg ladder cuprates. It has been shown that strong anisotropy in the electronic spectrum suppresses superconducting temperature in comparison with conventional copper oxide superconductors with square lattices.

Magnetization measurements on single crystals show $CaCu_2O_3$ to be a 3D AFM ($T_N = 27$ K), showing relatively strong magnetic anisotropy and metamagnetic transitions. The 3D behavior is due to exchange between the ladders as deduced from electronic structure calculations within the local density approximation.

In the compounds $MgCu_2O_3$ and $CaCu_2O_3$ the Cu and O atoms are connected topologically in the same way as in the fascinating spin ladder compound $SrCu_2O_3$. In contrast to the latter, the Cu–O–Cu bonding angle corresponding to the "rungs" is significantly less than 180° in $MgCu_2O_3$ and $CaCu_2O_3$. As a consequence, the magnetic susceptibility is quite different compared with that of $SrCu_2O_3$. Single-phase samples of $CaCu_2O_3$ revealed a deficiency of Ca, a balancing excess in Cu, and an oxygen deficiency corresponding to $Ca_{1-x}Cu_{2+x}O_{3-\delta}$. The excess Cu atoms, which are located near the Ca sites, are in the $3d^{10}$ state. The deficiency of oxygen causes a Curie term in the magnetic susceptibility due to the interruption of Cu–O–Cu bonds. From the overall behavior of the susceptibility an antiferromagnetic ordering at a Néel temperature of about 27 K was concluded.

Magnetization and high-field electron spin resonance (ESR) response of the $S = 1/2$ Heisenberg pseudo-ladder magnet $CaCu_2O_3$ is dominated at low temperatures by a few percent of 'extra' Cu spin states arising due to the structural disorder. These 'extra' spins interact with the bulk spins and jointly order in an antiferromagnetical structure at $T_N = 27$ K. At $T \leq T_N$, ESR data reveal a small magnon anisotropy gap of the order of $\sigma \leq 1.0$ MeV. Substitution of 15% of nonmagnetic Zn for Cu reduces the concentration of 'extra' spins and results in the suppression of the magnetic order and closing of the magnon gap. These results support the scenario with a significant role of the 'extra' spins for stabilization of the magnetic order in this frustrated quantum magnet.

In another paper, experimental results for the thermal conductivity kappa (κ) of the pseudo-two-leg ladder material $CaCu_2O_3$ have been presented. The strong buckling of the ladder rungs renders this material a good approximation to $S = 1/2$ Heisenberg chain. Despite a strong suppression of the thermal conductivity of this material (K) in all crystal directions due to inherent disorder, a dominant magnetic contribution (mag) of K-mag along the chain direction was found. K-mag is linear in temperature, resembling the low-temperature limit of the thermal Dried weight Dth of the $S = 1/2$ Heisenberg chain. The comparison of K-mag and Dth yields a magnetic mean-free path of l.0 mag approximately 22 ± 5 Å, in good agreement with magnetic measurements.

The resistivity $\rho(T)$ of the spin-ladder compound $CaCu_2O_3$ measured along the Cu–O–Cu leg (j||b) exhibits a strongly activated character. It increases from ~10^4 to ~10^9 Ωm if T decreases from 350 to 100 K. The charge transfer above $T \approx 200$ K is governed by a quasi-1D nearest-neighbor hopping (NNH) conductivity mechanism characterized by the law $\rho(T) = \exp(E_a/kT)$. Below 200 K, a novel quasi-1D variable-range hopping (VRH) conductivity law $\rho(T) = \exp[(T_0/T)^{3/4}]$ is observed. The NNH activation energy, Ea, and the VRH characteristic temperature, T0, exhibit high sensitivity to the cation (Ca,Cu) content, decreasing by 2.3–2.5 times and by 3.0–3.2 times, respectively, when the composition of Ca is changed from 0.854 to a range of 0.786–0.798 and the composition of Cu from 2.039 to a range of 2.159–2.163. The behavior of E_a and T_0 can be attributed to a corresponding variation of the concentration of intrinsic defects associated with Cu vacancies. On the other hand, no direct dependence of E_a and T_0 to the excess oxygen concentration is observed. A detailed analysis of $K(T)$ demonstrates that conventional d-dimensional models of the hopping conductivity, based on the electron localization in disordered systems, cannot interpret the experimental data at any $d = 1$, 2 or 3, since this leads to the mismatch of the characteristic energies and/or unphysical values of the characteristic length scales. The observed VRH conductivity law on the low-temperature interval, $\ln \rho \sim T^{3/4}$, contradicts the models above, too. Instead, it was found that this law can be substantiated and the correct matching of the energy and length scales can be found within a model of Fogler et al (2004) by treating $CaCu_2O_3$ as a 3D array of quasi-1D electron crystals.

The packing structure of 3 unit cells (a°—3b°—c°) for Ca_2CuO_3 (a) and the model cluster $Ca_{18}Cu_8O_{28}$ (b) used in the *ab initio* calculation of vibrational states are shown in Fig. 15.20.

The enthalpies of reactions between alkaline earth cuprates M_2CuO_3 (M = Ca, Sr) and hydrochloric acid were measured in a hermetic swinging calorimeter at 298.15 K. The M_2CuO_3 samples were prepared by solid-phase synthesis from calcium or strontium carbonate and copper oxide and characterized by X-ray powder diffraction, EDX and wet analysis. The

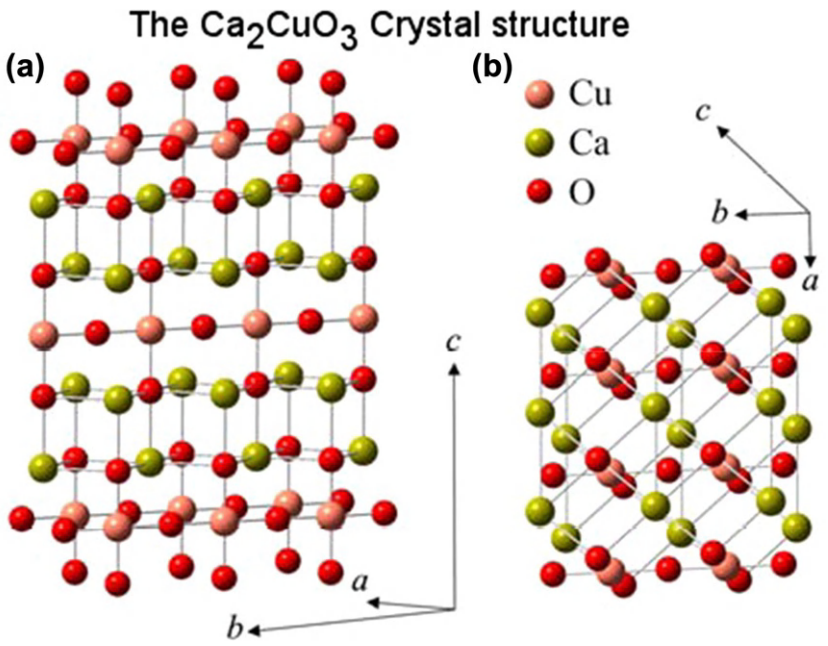

FIGURE 15.20

standard enthalpies of formation obtained for the cuprates, -1431 ± 4 kJ/mol for Ca_2CuO_3 and -1374 ± 3 kJ/mol for Sr_2CuO_3, were discussed and compared with previous experimental and assessed values.

The results were presented using a combined periodic and cluster model approach to the electronic structure and magnetic interactions in the spin chain compounds Ca_2CuO_3 and Sr_2CuO_3. An extended t-J model was presented that includes in-chain and interchain hopping and magnetic interaction processes with parameters extracted from ab initio calculations. For both compounds, the in-chain magnetic interaction was found to be around -240 meV, larger than in any of the other cuprates reported in the literature. The interchain magnetic coupling is found to be weakly antiferromagnetic, i.e. -1 meV. The effective in-chain hopping parameters are estimated to be -650 meV for both compounds, whereas the value of the interchain hopping parameter is 30 meV for Sr_2CuO_3 and 40 meV for Ca_2CuO_3, in line with the larger interchain distance in the former compound. These effective parameters were shown to be consistent with expressions recently suggested for the Néel temperature and the magnetic moments, and with relations that emerge from the t-J model Hamiltonian. Next, the physical nature of the band gap was investigated. Periodic calculations indicated that an interpretation in terms of a charge-transfer insulator is the most appropriate one, in contrast to the suggestion of a covalent correlated insulator recently reported in the literature.

The enthalpies of reactions between alkaline earth cuprates, M_2CuO_3 (M = Ca, Sr), and hydrochloric acid were measured in a hermetic swinging calorimeter at 298.15 K. The M_2CuO_3 samples were prepared by solid-phase synthesis from calcium or strontium carbonate and copper oxide and characterized by X-ray powder diffraction, EDX and wet analysis. The standard enthalpies of formation obtained for the cuprates, ~1431 ± 4 kJ/mol for Ca_2CuO_3 and ~1374 ± 3 kJ/mol for Sr_2CuO_3, were discussed and compared with previous experimental and assessed values.

In situ high-pressure energy dispersive X-ray diffraction measurements on polycrystalline powder of Ca_2CuO_3 with a Cu–O chain structure have been performed in a diamond-anvil cell (DAC) instrument using synchrotron radiation. The resistance versus pressure and capacitance versus pressure relationships up to 20 GPa have been studied simultaneously using the DAC technique at room temperature. The results showed that the structure of Ca_2CuO_3 is stable under pressures up to 34 GPa. According to the Birch–Murnaghan equation of state, assuming $B_0' = 4$, the bulk modulus $B_0 = 165.4 \pm 1.8$ GPa has been obtained. It was found that the resistance decreases continuously with increasing pressure up to 20 GPa. However, a sharp drop in the pressure range of 1.8–6.0 GPa was observed. Meanwhile the capacitance increased all along with the pressure and displayed a steep jump at the same pressure range in which the resistance rapidly changed. This metallization phenomenon may be ascribed to an electronic structure transition induced by the pressure.

The CaO–CuO system has been investigated at high oxygen pressure. Only two ternary compounds, $Ca_{0.83}CuO_2$ and $Ca_{14}Cu_{24}O_{41}$, were found to be stable at

$p(O_2) = 500$ bar. $Ca_{14}Cu_{24}O_{41}$ has been synthesized as a bulk phase for the first time. The formation of this phase occurred only in a very narrow range of temperature and oxygen pressure. Resistivity measurements at high pressure from 3 to 8.5 GPa show a superconducting transition in the whole range of pressures. Magnetic properties of this compound at ambient pressure have been also studied. A study of structural and electrical properties under high pressure and low temperature for $S = 1/2$ Heisenberg two-leg ladder compound $Sr_{0.4}Ca_{13.6}Cu_{24}O_{41+\delta}$ was made. It showed a superconducting transition above 3 GPa with a maximum T_c of 13 K. The $Sr_{0.4}Ca_{13.6}Cu_{24}O_{41+\delta}$ phase survives at least up to 9 GPa and down to 7 K without decomposition or phase transition, indicating that it was responsible for the observed superconductivity. The most important role of high pressure for realizing superconductivity was the fact that enhancement of the interaction between the Cu_2O_3 ladder and the 1D CuO_2 chain which accelerates redistribution of holes via locally formed Cu_{ladder}–O_{chain} hybrid orbitals occurs. Electrical property of the normal state is affected by the carrier density, dimensionality, random potential, and spin scattering which are related to structural modification under high pressure.

In another paper, the low-temperature crystal structure of a 1D chain-ladder composite material $Sr_{0.4}Ca_{13.6}Cu_{24+y}O_{41+z}$ was determined by the Rietveld analysis of neutron diffraction data using a super-space group approach. The hole distribution between the chain and ladder planes was estimated by the bond valence sum (BVS) calculation based on Cu–O interatomic distances. The minimum of the distance between ladder-copper and chain-oxygen atoms [Cu(1)–O(3)] was revealed to expand with lowering temperature. The BVS calculation indicated that such a structural change corresponds to a redistribution of holes from the ladder to the chain and that almost all of the holes are localized in the chain below or near the Néel temperature. By assuming reasonable magnetic interactions between hole-unoccupied Cu sites on the chain plane, we propose a possible magnetic structure model taking into account the distribution of holes and observed magnetic neutron Bragg reflections. The results suggest the presence of spin dimers, spin trimers, and "lone" spins in the chain, of which the latter two have effective magnetic moments. These moments may be an origin of staggered antiferromagnetic spin modulation onto the spin liquid state.

In the Cu^{3+}-containing system of MgO–Cu_2O_3, the compound, $Ca_3Cu_2O_6$, has been studied. The double doped unit cell of $La_{2-\delta}Ca_{1+\delta}Cu_2O_{6+\delta}$ (LCCO-52) consists of two chemical formulas, $La_2CaCu_2O_7$ and $Ca_3Cu_2O_6$ which are responsible for the occurrence of superconductivity with $n = 2$ superconducting CuO_2 planes per chemical formula. The distance x between double doped unit cells projected into a CuO_2 plane

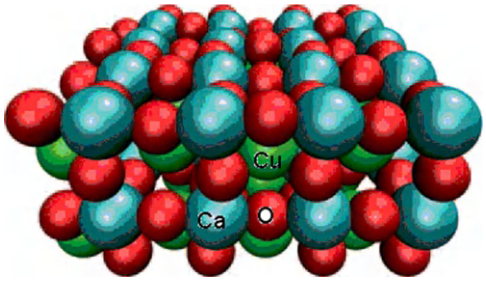

FIGURE 15.21

matches the experimental transition temperature, T_c, quite well. The ternary compound La_2CuO_4 is the parent material for several high-temperature superconductors (HTSC) by doping with an alkaline earth or alkali metal (Ba, Sr, Ca, Na, K, …) and/or introduction of oxygen deficiency or interstitial oxygen excess within the crystal.

In the Cu^{2+}–Cu^{3+}-containing system of MgO–Cu_3O_4, the compound, $CaCu_3O_5$, is mentioned in a patent (1993) but no corroboration has appeared in the literature. The compound, $Ca_2Cu_3O_6$, is also mentioned in the literature concerning the superconductor, $Ba_2Ca_{n-1}+xCu_{n+y}O_z$. It is described as shown in the following:

$Ca_2Cu_3O_6$—Active block

$Ba_2(Ca_{x/2}Ca_{y/2}H_vC_1)_2O_{3+}\delta$—Transformed charge reservoir

---

$Ba_2Ca_2Cu_3(Ca_{x/2}Ca_{y/2}H_vC_1)_2O_{10+\delta}$

In the Cu^{4+}-containing system of MgO–CuO_2, the compound, $CaCuO_3$, is a perovskite with the general structure shown in Fig. 15.21.

Its stability, measured in terms of Gibbs energy of formation, is $\Delta G_f = -6.00$ eV at 298 K for the reaction:

$$CaO + CuO + 1/2O_2 \Rightarrow CaCuO_3$$

$CaCuO_3$ is not mentioned in the open literature except in regard to an additive for preparing high-temperature superconducting compounds, La–Sr–Ca–Cu–O, Ba–Y–Ca–Cu–O, Bi–Sr–Ca–Cu–O, Nd–Ce–Ca–Cu–O, Tl–Ba–Ca–Cu–O, Ba–K–Ca–Bi–O, and Ba–Rb–Ca–Bi–O. Other possible compounds like Ca_2CuO_4 and $CaCu_2O_5$ are only mentioned in the same sense.

The same may be said for compounds in the Cu^{5+}-containing system of MgO–Cu_2O_5.

Calcium cuprate compounds are not offered for sale commercially and no CAS numbers have been issued to date.

15.1.4. Strontium Copper Compounds

Strontium forms two intermetallic compounds with copper metal as shown in the following phase diagram in Fig. 15.22.

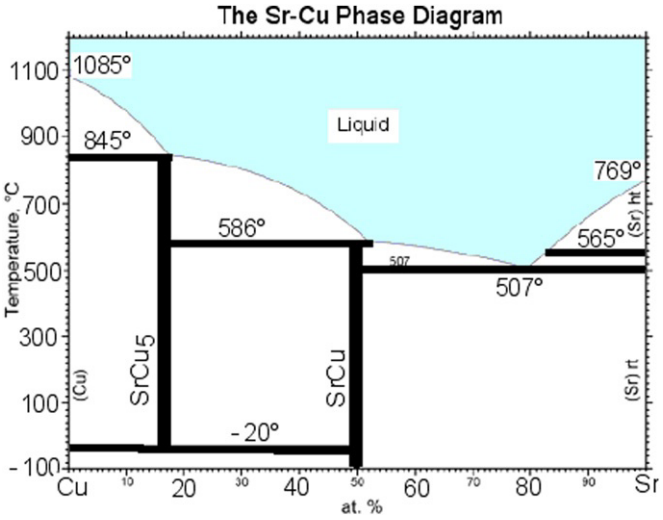

FIGURE 15.22

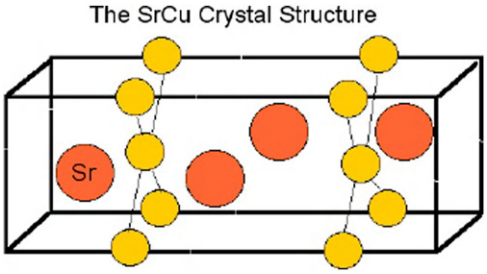

FIGURE 15.23

SrCu has the structure form shown in Fig. 15.23.

Cell parameters for SrCu are: $a = b = 4.341$ Å, $c = 15.384$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 251.00$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.12.

The compound, $SrCu_5$, has the crystal form shown in Fig. 15.24.

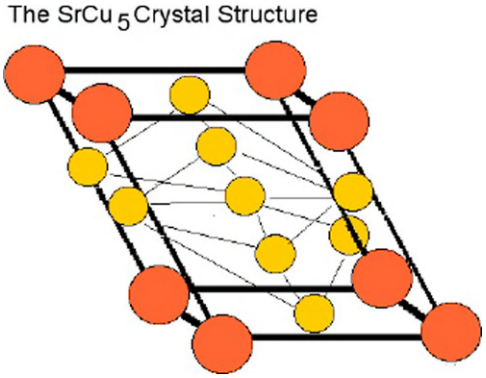

FIGURE 15.24

Cell parameters are: $a = 4.057$ Å, $b = c = 5.2635$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 97.10$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.13.

No other intermetallic Sr–Cu compounds are known. There have been no studies of the physical or electrical properties of these compounds in the recent literature. They are not available commercially and no CAS numbers have been issued to date.

No phase diagrams are available for the Sr–Cu–O system.

In the Cu^+-containing system of $SrO–Cu_2O$, the compound, $SrCu_2O_2$ is known. It is a wide band gap p-type conductive oxide. $SrCu_2O_2$ thin films were prepared on SiO_2 glass substrates by pulsed laser deposition. The film deposited in O_2 atmosphere of 7×10^{-4} Pa at 573 K showed high optical transmission in visible and near-infrared regions. Potassium was doped at the Sr site for substitutional doping. The optical band gap of the K-doped film was estimated to be ~3.3 eV. The DC electrical conductivity of the K-doped film at 300 K was 4.8×10^{-2} S/cm and the activation energy was 0.10 eV. A positive sign of Seebeck and Hall coefficients demonstrated the p-type conduction of the film. Hole

concentration and mobility at 300 K were $6.1 \times 10^{17}/cm^3$ and 0.46 $cm^2/V/s$, respectively.

Preparation of p-type transparent conducting Ca-doped $SrCu_2O_2$ thin films deposited on a quartz glass substrate has been carried out by a pulsed laser deposition technique. X-ray diffraction patterns illustrate that Ca-doped $SrCu_2O_2$ thin films with oriented growth have been obtained at a deposition temperature as low as 350 °C. The film deposition at 350 °C has a conductivity of 8.2×10^{-2} S/cm, carrier concentration of $1.33 \times 10^{17}/cm^3$, hole mobility of 3.82 $cm^2/V/s$ and a band gap of 3.2 eV at room temperature (300 K). A transparent p–n hetero-junction diode was fabricated using *p*-type $SrCu_2O_2$:Ca and *n*-type ZnO:Al thin films on an ITO-coated glass substrate. The junction exhibits nonlinear and rectifying I–V characteristics.

A near-UV emitting diode was fabricated by successive hetero-epitaxial growth of In_2O_3:Sn(ITO), *n*-electrode, *n*-ZnO, and *p*-$SrCu_2O_2$ (SCO) on an extremely flat surface of yttria-stabilized ZrO_2 single crystalline substrate using a pulsed-laser deposition technique. Upon current injection at room temperature, the resulting diode emitted near-UV light with a peak at 382 nm. The threshold voltage for emission was 3 V, which is in agreement with the energy difference between the ZnO donor level and the SCO acceptor level. The epitaxial relationship between SCO and ZnO depends on the deposition temperature of SCO on ZnO. The inhomogeneity of the SCO crystal was improved by raising the deposition temperature from 350 °C to 600 °C. The threshold current for near-UV emission from the diode fabricated by deposition of the SCO film at 600 °C was reduced to 1/5 of that at 350 °C. One reason why this hetero-epitaxial growth occurs for oxides with large lattice misfit is explained in terms of the high ionicity of chemical bonds in oxides.

Photoemission spectra of K-doped $SrCu_2O_2$ excited with vacuum ultraviolet synchrotron radiation have been measured over a range of photon energies between 36 eV and 164 eV. Intensity changes in the spectra with changing photon energy showed that the states at the top of the valence band are of dominant Cu 3d atomic character, although there is evidence for significant hybridization between O-2p and Cu-3d states. The experimental results were compared with partial densities of states derived from calculations using a hybrid exchange approximation to density functional theory.

In another study, transparent oxide p–n hetero-junction diodes based on $SrCu_2O_2$ (SCO) were fabricated by RF-magnetron sputtering. A Zn-terminated polar plane (Zn-face), an O-terminated polar plane (O-face), and a non-polar plane (A-face) of highly oriented polycrystalline ZnO plates were used as substrates to clarify what effect the surface polarity of ZnO has upon the p–n heterojunction characteristics. Highly transparent and very electrically conductive SCO films were obtained by the application of low RF power ($\hat{E} < 0.5$ W/cm^2) under high deposition pressures (8–10 Pa). Although none of the as-prepared p-$SrCu_2O_2$/n-ZnO hetero-junctions showed a very good rectifying I–V characteristics, the junction between SCO and the O-terminated ZnO polar surface exhibited clear rectifying I–V characteristics after post-deposition annealing at 923 K in Ar gas. The origin of the variation in the I–V characteristics that depended on the crystal axis orientation of the ZnO substrates was assumed to be due to the surface polarity of the ZnO surface. It would appear that not only the gas-sensing characteristics but also the diode properties depend on the crystal axis orientations of the ZnO layer. A transparent p-n junction based on zinc oxide (ZnO) was suggested to have the good gas-sensing properties.

Liquid precursors for $SrCu_2O_2$ were made by dissolving copper formate and strontium acetate in water. Bulk single-phase powdered $SrCu_2O_2$ was synthesized through the spray deposition of liquid precursors at 180 °C followed by a 4 h anneal at 775 °C and 2.0×10^{-5} Torr vacuum. Additionally, $CaCO_3$ was successfully added to the precursor solution and subsequently incorporated after annealing. This was a critical demonstration of the ability to perform cation substitutions by this approach. Employing the liquid precursor for thin films resulted in mixed phase $SrCu_2O_2$ and Cu_2O due to Sr loss during annealing. The liquid precursor was also successfully inkjet printed. The deposition-temperature phase diagram presented was shown in Fig. 15.25.

The structure of $SrCu_2O_2$ is based on planar zigzag chains running in orthogonal [100] and [010] directions, shown in Fig. 15.26.

The tetragonal structure of $SrCu_2O_2$ belongs to the space group $I\,41/amd$ with a unit cell containing two formula units and defined by the lattice constants

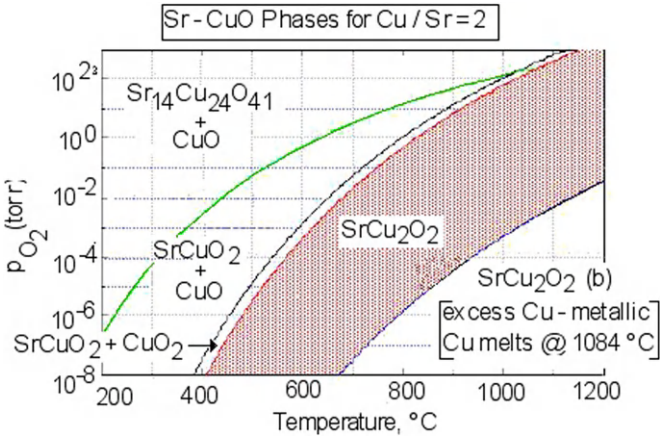

FIGURE 15.25

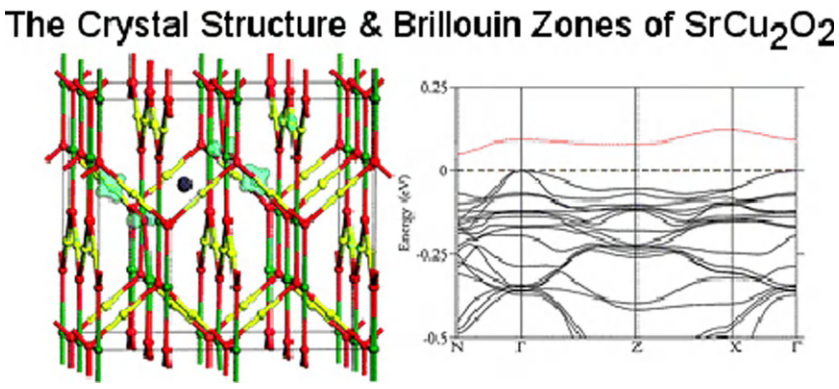

FIGURE 15.26

$a = 5.469$ Å and $c = 9.826$ Å. In the simplest ionic model description $SrCu_2O_2$ is a d_{10} Cu(I) oxide with an upper valence band of filled Cu-3d states that sits above a band of filled O-2p states. The conduction band is derived from empty Cu-4s states.

Within the linear O–Cu–O units the Cu-$3d_{2z}$ orbitals have r-like symmetry, the $3d_{xz}$ and $3d_{yz}$ p-like symmetry and the $3d_{xy}$ and $3d_{x2!y2}$ d-like symmetry. Thus O-2p orbitals can mix with Cu-$3d_{2z}$ via strong r overlap and with $3d_{xz}$ and $3d_{yz}$ via weaker p interactions. However $3d_{xy}$ and $3d_{x2!y2}$ must remain localized on Cu as there are no orbitals on oxygen having the correct d symmetry for covalent mixing. Provided that the oxygen stoichiometry is unchanged, introduction of singly charged K^+ onto Sr^{2+} sites must be accompanied formally by oxidation of a corresponding number of the Cu^+ ions present in the lattice to Cu^{2+}. Of course this introduces holes into the previously full Cu-3d bands. An issue of particular importance is the extent to which the Cu-3d and O-2p states mix, especially at the top of the valence band: it has been suggested that delocalization of hole states off copper and onto oxygen by O-2p/Cu-3d-hybridization at the top of the valence band is a prerequisite for good hole mobility.

A closer view of the structure is shown in Fig. 15.27.

The transparency of $SrCu_2O_2$ to light can be explained by the calculation of dipole transition matrix elements. The calculated effective masses for the conduction band states are found to be larger than those for the valence states for $SrCu_2O_2$, opposite to the trend in conventional semiconductors and *n*-type transparent conductive oxides.

It was predicted that adding a small amount of Ca (~16%) into $SrCu_2O_2$ would increase the band gap and reduce the hole effective mass of $SrCu_2O_2$, therefore increasing the transparency and conductivity.

The electronic structure of $SrCu_2O_2$, a wide gap (~3.3 eV) *p*-type oxide semiconductor, was examined by photoelectron and optical spectroscopy. The spectroscopy results were compared with the energy band structure calculated by the local density approximation method to clarify the origins of *p*-type conductivity in this material. Despite the significant difference in band gap energy, the basic electronic structure around the band gap region was found to be quite similar to that of Cu_2O. Thus, the 3d-4sp orbital of Cu^+ ion is hybridized with the 2p orbital of ligand O^{2-} ions due to the covalence of Cu–O bonds, to form states near the valence band maximum; the conduction band minimum is predominantly composed of the hybridized orbital of Cu-4sp and O-2p, forming the direct band gap at Γ point of the Brillouin zone. A sharp absorption band observed near the fundamental absorption edge is likely attributable to an exciton. Although the corresponding exciton emission was not observed near the absorption edge,

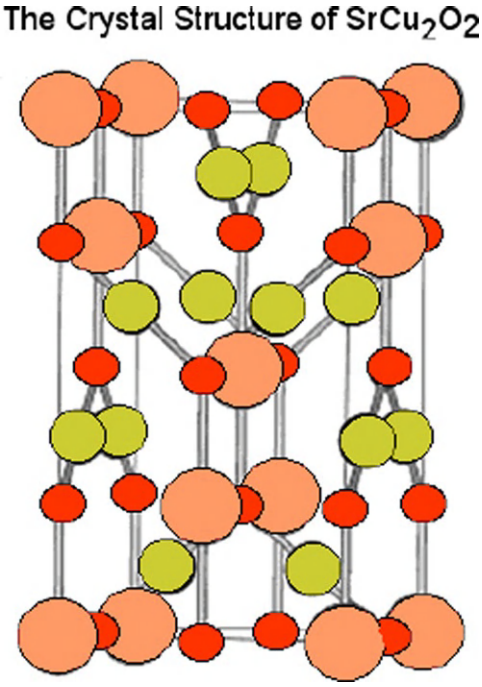

FIGURE 15.27

a blue-green emission band (stokes shift of ~1.0 eV) was observed at −2.47 eV. The emission is presumably attributable to intraatomic transitions of Cu^{+}, partially allowed by p-orbital mixing into s- and d-orbitals.

In another paper, *p*-type $SrCu_2O_2$ (SCO) films were deposited by pulsed laser deposition, from SCO target, on glass and *n*-type Si substrates. SCO films were deposited at two different substrate temperatures, namely 300 °C and 500 °C, while the oxygen pressure was kept constant at 5×10^{-2} Pa and their properties were investigated. Films deposited at 300 °C were single-phase $SrCu_2O_2$, whereas deviation from stoichiometry was observed for films deposited on Si at 500 °C. Both SCO films were *p*-type materials and their resistivity increased with the increase of the substrate temperature (from 142 Ω cm to 10 kΩ cm). Their transparency reached 70% even for films with thickness of 800 nm. SCO films deposited on *n*-type Si showed rectifying behavior and the p-SCO/n-Si hetero-structure formed from low-temperature deposited SCO (300 °C) exhibited better *p*/*n* junction properties than that formed at the substrate temperature of 500 °C. Improvements which can be implemented for enhancing the output performance of the hetero-junction were addressed.

A modulated structure analysis of the mutually incommensurate composite crystal, $(Sr_2Cu_2O_3)_{0.70}CuO_2$ with two-legged spin ladder, has been performed on the basis of a (3+1)-dimensional superspace group approach. It has been found that the symmetry of $(Sr_2Cu_2O_3)_{0.70}CuO_2$ should be described by a centrosymmetric super-space group. In the modulated composite structure of $(Sr_2Cu_2O_3)_{0.70}CuO_2$, displacement modulation of O atoms in the CuO_2 chain was found to be fairly large and played an important role. Structural interaction between the CuO_2 chain and the Cu_2O_3 ladder has been extensively investigated. The crystal structure of the quasi 1D cuprate $Ca_{0.83}CuO_2$, also known as $Ca_4Cu_5O_{10}$, $(Sr_2Cu_2O_3)_{0.70}CuO_2$, ($Sr_{14}Cu_{24}O_{41}$) etc., was determined using a superspace group approach. The compound consists of two interpenetrating subsystems of CuO_2 chains and Ca atoms. Structural parameters were refined with a superspace group of $F2/m(1+\alpha 0)\,\gamma 0s$ using powder X-ray and neutron diffraction data. Lattice parameters were refined to be $a_1 = 2.8043$ Å, $b = 6.3179$ Å, $c_1 = 10.5744$ Å, and $\beta_1 = 90.10°$ for the [CuO_2] subsystem and $a_2 = 3.3652$ Å, $b = 6.3179$ Å, $c_2 = 10.5893$ Å, and $\beta_2 = 93.04(1)°$ for the [Ca] subsystem. The Ca atoms suitably sit in the center of the modulated O_6 octahedra (Fig. 15.28).

A remarkable displacement modulation of the O and Ca atom sites was observed parallel to the *b*-axis and the *c*-axis, respectively. On the other hand, the Cu atom sites deviated mainly in the *a* direction to yield a periodic fluctuation between the nearest Cu–Cu distances.

In another paper, the temperature dependence of atomic modulation in the incommensurate composite crystal structure of $(Sr_2Cu_2O_3)_{0.70}CuO_2$, "$Sr_{14}Cu_{24}O_{41}$" with two-legged Cu_2O_3 ladder and edge-shared CuO_2 chain has been investigated by single-crystal X-ray diffraction method using centrosymmetric (3 + 1)-dimensional superspace group. The displacement modulations of all constituent atoms at 150 K have been compared with those obtained at room temperature. The hole distribution between the Cu_2O_3 ladder plane and the 1D CuO_2 chain has been considered on the basis of: the changes of lattice constants of incommensurate basic structure, the role of the atomic modulation and the interatomic distances between Cu atom in the Cu_2O_3 and O atom in the CuO_2. It was indicated that the small amount of holes doped in the Cu_2O_3 ladder have been back-transferred to the CuO_2 chain and that almost all of the holes in $(Sr_2Cu_2O_3)_{0.70}CuO_2$ are localized in the CuO_2 at low temperature.

Single crystals of $[Sr_2Cu_2O_3][CuO_2]x$ ($x = 1.436$) were obtained by a slow cooling method using KCl as a flux. KCl acted as a good intermediate for the growth of this compound. This compound takes a composite crystal structure. The first subsystem is [$Sr_2Cu_2O_3$] and second subsystem is [CuO_2]. Both subsystems have an

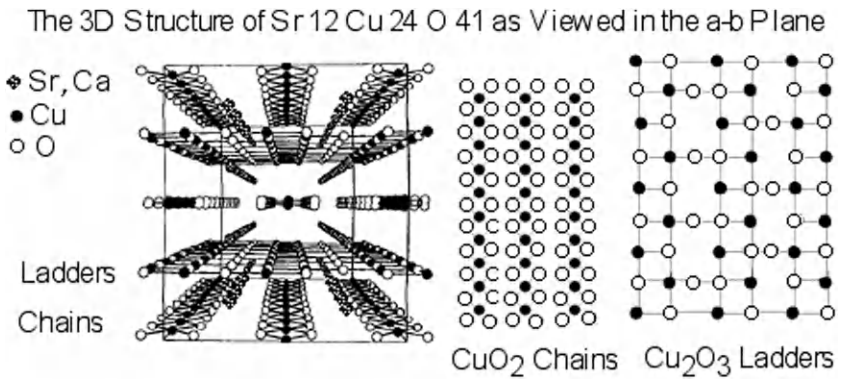

FIGURE 15.28

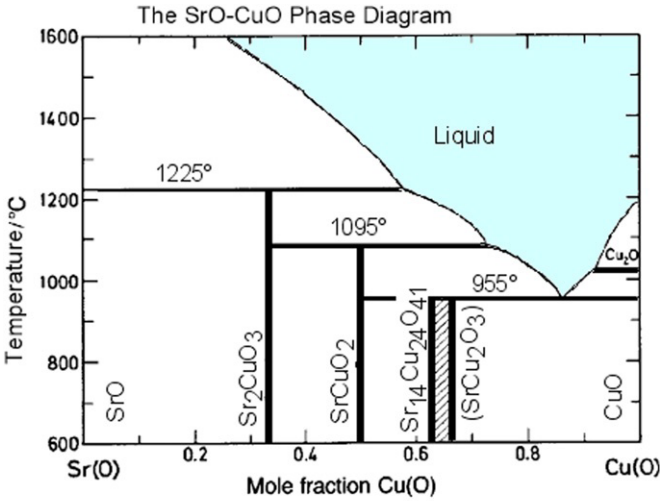
orthorhombic structure with superspace group $M_{TST}^{Az,ma}$: $M_{TST}^{Az,ma}$. The compound has mutually incommensurate periods along the *c*-axis. The lattice parameters are $a = 11.457$ Å, $b = 13.409$Å, $c_1 = 3.935$ Å and $c_2 = 2.740$ Å. Characteristic features of this compound are found in chains and sheets composed of Cu and oxygen atoms. On the basis of the structural studies of the samples grown by floating zone and flux methods, it was concluded that the phase $(M_2Cu_2O_3)(Cu_{1+}O_{2+})$, described as the $m/n = 1/1$ member, with Cu-deficient Cu–O ribbons in the series $(M_2Cu_2O_3)m(CuO_2)n$ can be treated as an individual structural type intermediate between $SrCu_2O_3$ and incommensurate-type phases $(M_2Cu_2O_3)m(CuO_2)n$ with *m* and *n*. The deficiency of the Cu sites in CuO ribbons is a particular crystal chemistry feature of this structural type, in addition to the geometrical feature ($m = n$). The structural type of the 'Cu-deficient ladder' can transform into the incommensurate-type phases $(M_2Cu_2O_3)m(CuO_2)n$ ($m/n = 5/7, 7/10, 9/13$, etc.) in the presence of free $[CuO_4]^{6-}$ radicals in the melt. A realization of the $(M_2Cu_2O_3)m(CuO_2)n$ phase with a particular m/n value is caused by the type of M cation was concluded. On the basis of recent data, the role of trivalent ions in the chemical composition of the $(M_2Cu_2O_3)m(CuO_2)n$-type compounds was also analyzed. The occurrence of the superconductivity in $(Sr,Ca)CuO_2$ samples was discussed by analogy with cuprates of the infinite-layer structure type.

$Sr_{14-x}Ca_xCu_{24}O_{41}$ crystals at high Ca concentrations are superconducting under pressure and hole pairing was proposed to be a robust feature of doped ladders. The measured dielectric response in the microwave region, the low-energy Raman data, the nonlinear transport properties along with soft X-ray scattering allowed the conclusion that the ground state in $Sr_{14-x}Ca_xCu_{24}O_{41}$ for a wide range of Ca concentrations ($x \leq 12$) is characterized by charge density wave correlations. This state seems to be driven not by phonons but by Coulomb forces and many body effects. The similarity in the finite frequency Raman response as opposed to the very different behavior of the DC resistivity between undoped and doped ladders was highlighted in this discussion. It was found that at high Ca concentrations, although the resistivity shows a crossover between insulating and linear in temperature metallic regime, the carrier relaxation is characterized by the same large activation energy ($\approx$2000 K) which determines the Arrhenius behavior of the CDW compound $Sr_{14}Cu_{24}O_{41}$.

In the Cu^{2+}-containing system of SrO–CuO, the phase diagram shows four compounds in Fig. 15.29.

It has been shown that tetragonal $SrCuO_{2-\delta}$ is superconducting at liquid N_2 conditions. Formation regions of orthorhombic and tetragonal $SrCuO_2$-type compounds in the $Sr_{1-x}Ca_xCuO_2$ system were studied at 1000 °C under both ambient and high pressure



An *x*–*t* diagram for the Sr(O)–Cu(O) system in air

FIGURE 15.29

conditions. Under ambient pressure, single-phase samples of the orthorhombic phase solid solution were formed in the region between $x = 0.0$ and 0.45, mixed-phase samples containing the orthorhombic phase in the region between $x = 0.5$ and 0.65, and the tetragonal phase at $x = 0.9$. The tetragonal phase solid solution was obtained under 2–5 GPa in the compositional region between $x = 0.2$ and 0.8. The tetragonal phase was stabilized under pressure higher than 4 GPa for the samples with $x = 0.0$–0.1. No tetragonal phase was obtained in the samples of Ca content $x = 1.0$. The compound, $SrCuO_2$, has been found to have the structure shown in Fig. 15.30.

The tetragonal phase with $x = 0.9$ obtained under ambient pressure decomposed at above 4 GPa to a mixed phase. The minimum lattice constants for the *a*-axis in both orthorhombic and tetragonal phase were determined to be 0.386 nm. Solid solution limit for both tetragonal and orthorhombic phases was explained by the concept of minimum Cu···O distance (=1.93 Å) to stabilize $[CuO_4]$ coordination. Single crystals of the orthorhombic $SrCuO_2$ were grown by a traveling solvent floating zone (TSFZ) method. It was found that a suitable chemical composition of the traveling solvent for the TSFZ growth was Sr:Cu = 3:7 in molar ratio. Lattice constants of the grown crystal were $a_0 = 3.92$, $b_0 = 16.35$ and $c_0 = 3.57$ Å and the chemical composition was Sr:Cu = 1.00:0.98 in molar ratio. The grown crystal was compressed at 1000 °C and 6 GPa for 1 h.

The orthorhombic crystal was transformed to polycrystalline tetragonal $SrCuO_2$ with $a_0 = 3.93$ and $c_0 = 3.43$ Å by the high-pressure treatment. Preferable orientation of crystalline axis was found in the obtained polycrystalline sample of the tetragonal $SrCuO_2$. The axial relationship between the single crystalline

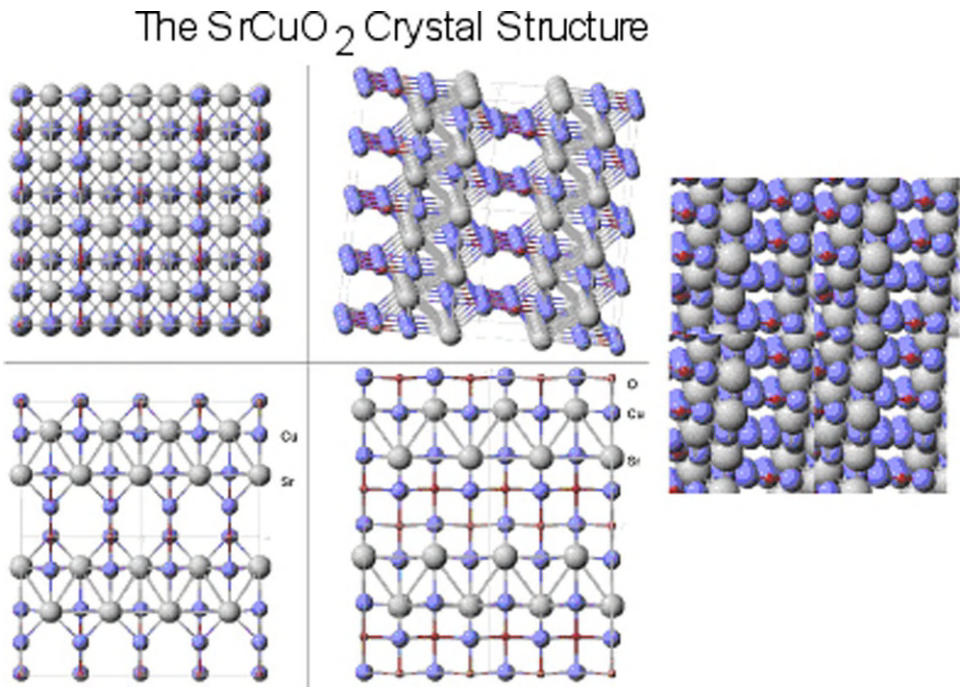


FIGURE 15.30

precursor of the orthorhombic $SrCuO_2$ and the obtained tetragonal $SrCuO_2$ was discussed from the viewpoint of the orientation of the [CuO_4] square planar coordination. A pressure-induced splitting of the Cu–O chains was found in $SrCuO_2$ subjected to pressures >7 GPa compared to room temperature. The high-pressure phase is a superstructure of the infinite-layered tetragonal superconducting phase of $SrCuO_2$ and is not stable under ambient conditions. The Cu–O chains buckle with further increasing pressure, and a new high-density polymorph of $SrCuO_2$ is formed at 34.2 GPa.

Processes of $SrCuO_2$ and Sr_2CuO_3 ceramics decomposition induced by contact with water and carbon dioxide were studied by EPR. The dominant signals in the spectra were found to originate from $Sr_2Cu(OH)_6$ (for Sr_2CuO_3) and $SrCu(OH)_4 \cdot H_2O$ (for $SrCuO_2$) compounds. The thermally induced conversion of $SrCu(OH) \cdot 4H_2O$ into $Sr_2Cu(OH)_6$ was analyzed, and its product CuO was found to exist in a nanocrystalline form. The presence of CO_2, reacting with $Sr(OH)_2$, was shown to modify the decomposition process, leading to the appearance of $SrCu(OH)_4 \cdot H2O$, some hydroxycarbonates and $Cu(OH)_2$ on the surface of ceramics were studied. At temperatures higher than 300 °C CuO reacts back with $Sr(OH)_2$. For the samples in contact with atmospheric moisture, this compound, deposited on a surface of $SrCuO_2$, decomposes to $Sr_2Cu(OH)_6$. The presence of the AFM compounds, $Cu(OH)_2$, CuO, and $Cu_2[(OH)_2CO_3]$, in the samples can influence the results of magnetic measurements of the studied ceramics. The unit cell parameters found for these compounds were shown in Table 15.14.

A comparison of the two crystal structures is shown in Fig. 15.31.

If Sr_2CuO_3 is heated to 1000 °C, it decomposes to form $SrCuO_2$:

$$Sr_2CuO_3 + \text{heat} \Rightarrow SrCuO_2 + SrO$$

The stability of the infinite layer $SrCuO_2$ upon heating in air was investigated by a high temperature X-ray diffraction method. The infinite layer $SrCuO_2$ first reacted gradually with CO_2 in air to form $SrCO_3$ when the temperature was above 300 °C. When the temperature was over 400 °C, the infinite layer $SrCuO_2$ transformed into orthorhombic $SrCuO_2$. The lattice

TABLE 15.14

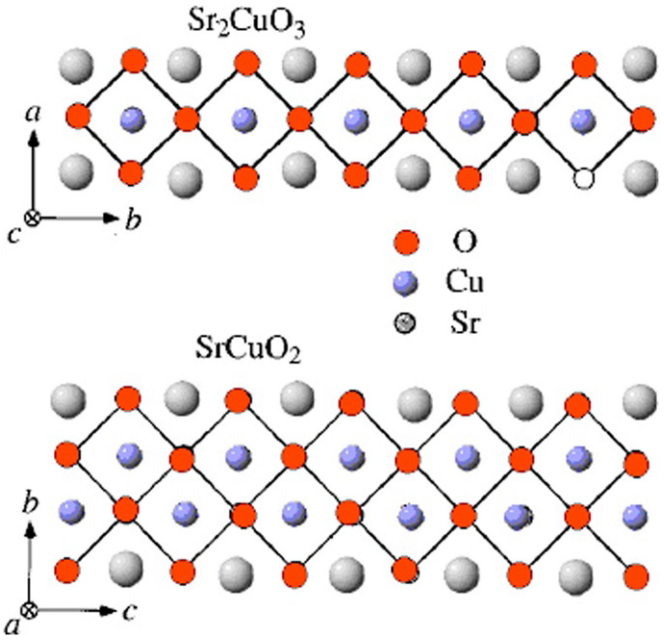

FIGURE 15.31

parameters a and c of the infinite layer $SrCuO_2$ showed different thermal expansion coefficients, i.e. $d\alpha/dT = 3.392 \times 10^{-5}$ Å/°C and $dc/dT = 5.80 \times 10^{-5}$ Å/°C. High-purity samples of the chain cuprate $SrCuO_2$ were investigated and a huge magnetic heat conductivity K_{mag} was observed. An extremely large spinon mean-free path of more than a micrometer demonstrates that K_{mag} is only limited by extrinsic scattering processes which is a clear signature of ballistic transport in the underlying spin model. The standard enthalpy of formation obtained for the cuprate, Sr_2CuO_3 was −1374 kJ/mol.

The crystal structure of the quasi 1D cuprate Sr_2CuO_3 has been studied under high pressure using neutron powder diffraction methods. Full structure refinements were undertaken, using the Rietveld method, with data acquired between room pressure and 0.55(1) GPa at room temperature. The compressibility of Sr_2CuO_3 is anisotropic, a consequence of the ordered nature of the anion vacancies in this material. The effect of high pressure and chemical substitution on the crystal structure of the $Sr_{2-x}Ca_xCuO_3$ system was discussed and it was suggested that the substitution of Sr^{2+} by Ca^{2+} may constitute a "chemical pressure" effect in this solid solution. The availability of accurate bond length compressibility data for Sr_2CuO_3 may now allow an appraisal of the effect of applied pressure on the remarkable electronic properties of this material, through appropriate band structure calculations. Sr_2CuO_3 behaves almost perfectly like a 1D AFM with an exchange coupling of $J = 1700^{+150}_{-100}$ K. For Sr_2CuO_3, $J_a = -119$ meV for the intrachain coupling and $J_b = -0.28$ meV for the interchain coupling was obtained. The experimental Neel temperatures were found to be proportional to the ratio J_b/J_a to a high accuracy. This indicates that the isolated chain is an antiferromagnet with vanishing T_N.

A single-phase $Sr_2CuO_{3+\delta}$ superconductor of $T_c = 75$ K with the K_2NiF_4 structure under high pressure was formed under high pressure to form partially occupied "apical oxygen" sites which also acts as the dopant. Oxygen atoms only partially occupy the apical sites next to the CuO_2 planes and act as hole dopants. After post-annealing the as prepared sample from 150 to 300 °C, the superconducting transition temperature (T_c) could be systematically enhanced up to 95 K. Transmission electron microscopy (TEM) measurements on the $Sr_2CuO_{3+\delta}$ superconductors revealed a series of modulated structure phenomena resulting from dopant ordering. The distribution geometry of dopant such as the partially occupied apical oxygen here can be an additional route to reach further higher T_c.

The copper K-edge EXAFS recorded from the compound Sr_2CuO_3 was best fitted to a first-shell coordination of four oxygen atoms at 1.95 Å. In contrast, the best fit to the data recorded from the oxygen-rich compound $Sr_2CuO_{3.9}$ was to a first shell of two oxygen atoms at 1.75 Å and a second shell of three oxygen atoms at 1.90 Å. These results may be associated with the incommensurate ordering in $Sr_2CuO_{3.9}$ of the anionic sublattice, a fact suggested by powder neutron diffraction as well. The short Cu···O bond distance is also consistent with the high nominal oxidation state of copper, ca + 3.8 in $Sr_2CuO_{3.9}$.

The synthetic conditions of the "$Sr_2CuO_{3+\delta}$" phase (214) in the Sr–Cu–O system were investigated using high-pressure techniques at 5 GPa and 1400 °C. Sr_2CuO_3 powder was used as starting materials, and $KClO_3$ as oxidizer. The effect of the initial amount of $KClO_3$ on the structure and the physical properties was investigated. Two crystallographic domains of the tetragonal fundamental structure: $a \approx 3.76$ Å, $c \approx 12.54$ Å, and $a \approx 3.79$ Å, $c \approx 12.46$ Å, respectively were observed. TEM investigations of the latter have shown evidence of modulations along the [110] direction which leads to a new superlattice with a periodicity of $5a/\sqrt{2} \times 5a/\sqrt{2} \times c$. Moreover, two new phases appeared in this system; one is monoclinic and related to the infinite layer structure with $a = 8.430$ Å, $b = 11.100$ Å, $c = 3.641$ Å, $\beta = 83.2°$, the other suggested a change of the space group from body centered (I) to primary (P). The electrical properties and magnetic behavior observed for these materials were discussed in relation with the synthesis conditions and observed phases. Bulk superconductivity up to 80 K has been obtained.

In another paper, a *single-phase* superconductor $Sr_2CuO_{3+\delta}$ with nominal $\delta = 0.4$ (detected from XRD

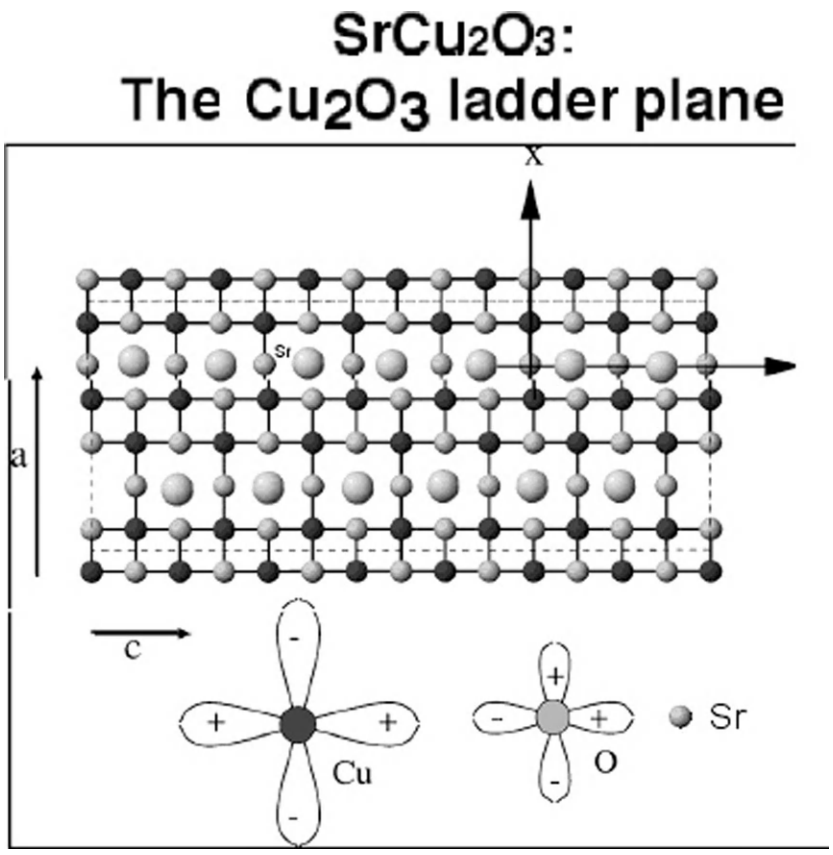

FIGURE 15.32

data) ($T_c = 75$ K) has been synthesized using a high-pressure technique. The structure and microstructure of this material have been carefully studied by means of transmission electron diffraction (ED), high-resolution transmission electron microscopy (HRTEM), electron energy-loss spectroscopy (EELS) and energy dispersive analysis of X-ray (EDX) techniques. Interestingly enough, ED and HRTEM investigations reveal that almost all grains of the tetragonal form $Sr_2CuO_{3+\delta}$ exhibit modulated features. This result strongly suggests that the superconductivity at 75 K in the material is associated with the modulated phases. Two types of modulated phases having different primitive cells but equal in volume are found in the sample. One is the face-centered orthorhombic modulated phase with a space group *Fmmm* and lattice constants of $5\sqrt{2}a_p \times 5\sqrt{2}a_p \times c_p$. The other is the base-centered monoclinic modulated phase with a space group $C2/m$ and unit cell parameters of $a_m = 5\sqrt{2}a_p \times c_p$, $b_m = c_p$, and $\beta = 101.3°$. The relative ratio of the former to the latter phase contents is about 4:1. Oxygen K absorption edges from EELS measurements suggest that the two modulated phases have the same hole intensity. Defects such as twin boundaries, small-angle asymmetrical tilt boundaries and dislocations are frequently observed in the C_2/m monoclinic modulated phase. The compound, $SrCu_2O_3$, has the ladder-like structure shown in Fig. 15.32

A 3D structure is shown in Fig. 15.33.

The temperature-dependent magnetic excitation of the 1D spin-ladder compound $SrCu_2O_3$ was investigated by use of Raman spectra. At low temperatures a two-magnon peak is identified at 3160 ± 10/cm and its temperature dependence analyzed in terms of a thermal expansion model. It was found that the two-magnon peak position must include a cyclic ring exchange of $J_{cycl}/J_{perp} = 0.09$–0.25 with a coupling constant along

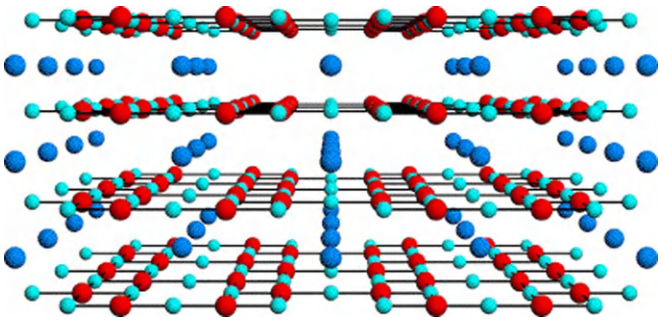

FIGURE 15.33

the rungs of J_{perp} of approximately 1215/cm (1750 K) in order to be consistent with other experiments and theoretical results.

The two-leg ladder $SrCu_2O_3$ belongs to the homologous series $Sr_{n-1}Cu_nO_{2n-1}$ and was first synthesized in 1991. Due to the massive reaction of the sample material with the crucible (Au or Pt), only short reaction times up to 30 min has been used typically. An improved composite crucible with a single-crystalline MgO inset in a sealed Pt capsule was used to demonstrate its capability for single-crystal growth of $SrCu_2O_3$. Experiments with a typical duration of 15 h were conducted at pressures between 3 and 6 GPa at temperatures between 950 and 1500 °C. Slow cooling of the melt effected directed growth of the first $SrCu_2O_3$ millimeter-sized single crystals.

In the Cu^{3+}-containing system of SrO–Cu_2O_3, the compound, $Sr_2Cu_2O_5$, has been studied. These quantum spin ladder materials have attracted much recent interest. The materials consist of ladders made of AFM chains of $S = 1/2$ spins coupled by interchain AFM bonds. Examples of two-leg ladder materials are $SrCu_2O_3$ and $LaCuO_{2.5}$; an example of a three-leg ladder material is $Sr_2Cu_2O_5$. Superconductivity has apparently been discovered in the ladder material $Sr_{0.4}Ca_{13.6}Cu_{24}O_{41}$ under pressure with $T_c = 12$ K at 3 GPa. Part of the interest in quantum-spin ladder materials stems from the fact that they are simple model systems for theories of superconductivity based on magnetic pairing mechanisms.

In the Cu^{2+}–Cu^{3+}-containing system of SrO–Cu_3O_4, the compound, $SrCu_3O_5$, has received some attention in the literature because it fits into the "spin-ladder" class of materials. Only ladders with an even number of legs exhibit a spin gap (i.e. a finite energy scale for triplet excitations) as seen from different characteristic behaviors of the spin susceptibility observed in $SrCu_2O_3$ and $SrCu_3O_5$, typical two-leg and three-leg compounds, respectively.

Other than a comparison to $SrCu_2O_3$, no other data are available for this compound.

In the Cu^{4+}-containing system of SrO–CuO_2, the compound, $SrCuO_3$, has not been described. However, the Sr_2CuO_4 compound has been found to be superconducting. Sr_2CuO_3 (orthorhombic, *Immm*) is converted at about 400 °C under oxygen at 160 bar to $Sr_2CuO_{3.9}$ [tetragonal, $I4/mmm$; $a = 3.7907(7)$, $c = 12.417(2)$ Å], which is structurally related to La_2CuO_4. Although the formal Cu oxidation state in this material appeared to be higher than any previously reported for Cu in an oxide environment (around +3.8), powder neutron diffraction data provided no evidence for O_2^{2-} or O_2^- ions, but are consistent with a highly defective structure containing Sr, Cu, and O vacancies. The cation vacancies are in a 2:1 ratio to maintain the stoichiometry, and the O vacancies are confined to the CuO_2 layers. Additional peaks in the neutron diffraction profile were indicative of an ordering process to give an extended, possibly incommensurate, structure. Cu K-edge EXAFS suggested that the resulting local Cu coordination contains two very short Cu···O bonds (1.755 Å).

The best fit to the data recorded from X-ray analysis to the oxygen loss in the compound, $Sr_2CuO_{3.9}$, is to a first shell of two oxygen atoms at 1.75 Å and a second shell of three oxygen atoms at 1.90 Å. The result may be associated with the incommensurate ordering in $Sr_2CuO_{3.9}$ of the anionic sublattice which had been suggested by powder neutron diffraction. The short Cu···O bond distance was also consistent with the high-nominal oxidation state of copper, ca + 3.8 in $Sr_2CuO_{3.9}$. The superconductivity found in $Sr_2CuO_{4-\delta}$ showed that new physics has occurred in a highly studied region of the cuprate phase diagram. Moreover, evidence was adduced that 30% of the oxygen sites in the CuO_2 layers are vacant, a conclusion which is at odds with the universally made assumption that superconductivity originates in stoichiometric CuO_2 layers. A metastable superconductor with non-stoichiometric CuO_2 layers exists in an unexplored overdoped region of the phase diagram of cuprate superconductors. The enhanced T_c of 95 K found in $Sr_2CuO_{4-\delta}$ for $\delta \approx 0.6$ corresponds to an average copper valence of ~2.8+. New mechanisms are needed to account for the enhanced superconductivity. Two possibilities were suggested. One involves a band of paired electrons formed by the overlap of negative-U oxygen vacancies. The second involves pairing in the CuO_2 layer that is enhanced either by an optimal inhomogeneous distribution of oxygen sites or by a distribution of vacancy-rich/vacancy-poor regions.

The synthesis of new superconducting $Sr_2CuO_{4-\delta}$ thin films ($T_c^{onset} \sim 75$ K) using a molecular beam epitaxial (MBE) method has been reported. This superconductor has a tetragonal structure with an in-plane lattice constant $a_0 = 3.79$ Å and a *c*-axis lattice constant $c_0 = 13.55$ Å. This *c*-axis lattice constant is significantly larger than previously reported for this system. Strong oxidation using ozone gas at a low temperature of around 350\^circC is essential to the realization of phase conversion from the orthorhombic insulating phase (Sr_2CuO_3) to the tetragonal superconducting phase ($Sr_2CuO_{4-\delta}$).

In the Cu^{5+}-containing system of SrO–Cu_2O_5, the compound, $SrCu_2O_6$, is unknown and no other compounds like $Sr_2Cu_2O_7$ or $SrCu_4O_{11}$ have been found.

Strontium–copper compounds are not offered for sale commercially and no CAS numbers have been issued to date.

15.1.5. Barium Copper Compounds

Barium forms but two intermetallic compounds with Cu metal as shown in Fig. 15.34.

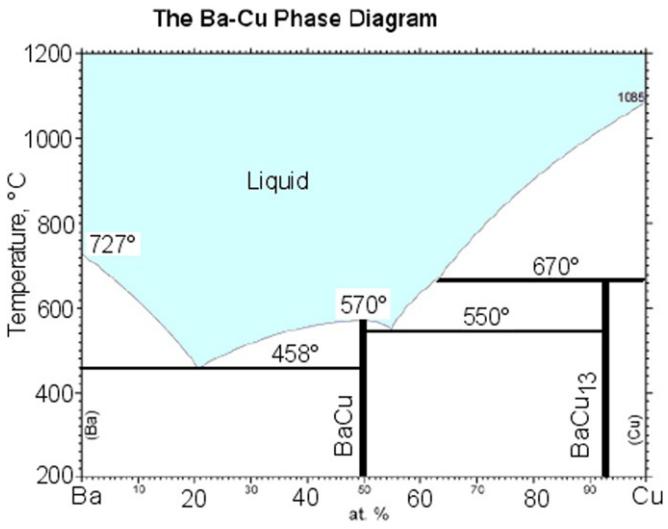

FIGURE 15.34

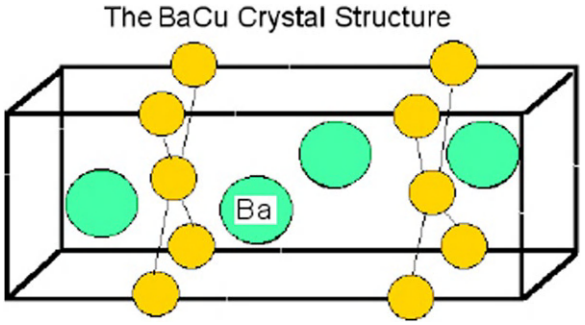

FIGURE 15.35

BaCu has the structure shown in Fig. 15.35.

Cell parameters are: $a = b = 4.496$ Å, $c = 16.232$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 284.12$ Å^3, $Z = 4$.

Cell occupancy is shown in Table 15.15.

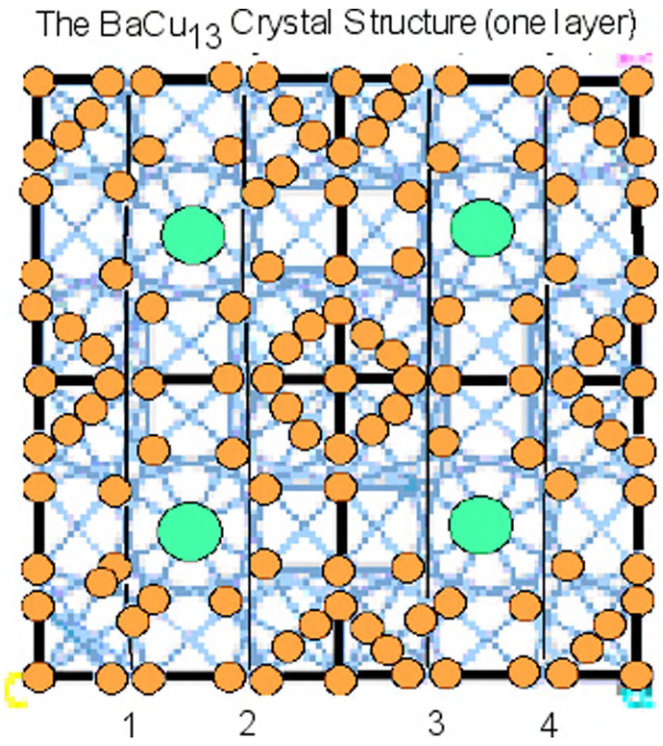

FIGURE 15.36

The compound, $BaCu_{13}$, has the crystal structure form shown in Fig. 15.36.

Only one layer is shown. In the 3D structure, there are two of these layers, separated by the layers of Cu atoms labeled 1 and 2 and 3 and 4.

Cell parameters are: $a = b = c = 8.3113$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 405.97$ Å^3, $Z = 8$. Cell occupancy is shown in Table 15.16.

The thermodynamic constants for these compounds (from Johnson et al., 2005) are shown in Fig. 15.37.

FIGURE 15.37

No other intermetallic compounds are known in this system. Ba–Cu intermetallic compounds are not offered for sale commercially.

In the Cu^{+}-containing system of BaO–Cu_2O, the compound $BaCu_2O_2$, has been studied because of its relationship to the high-temperature superconducting compound, $YBa_2Cu_3O_{6+x}$. The quaternary phase relations near $YBa_2Cu_3O_{6+x}$ have been investigated using a solid-state ionic technique. Three invariant reactions were discovered. At 850 °C, $YBa_2Cu_3O_{6+x}$ with excess Cu_2O reacts to form Y_2BaCuO_5 and $BaCu_2O_2$ at 1×10^{-3} atm. oxygen pressure, while pure $YBa_2Cu_3O_{6+x}$ decomposes to Y_2BaCuO_5, $BaCu_2O_2$, and $YBa_3Cu_2O_{6.5\pm x}$ at 4×10^{-4} atm. oxygen. These results show that the phase relations near $YBa_2Cu_3O_{6+x}$ change markedly with oxygen pressure.

Although $SrCu_2O_2$ is stable, transparent to light and is a superconductor when oxygen vacancies are formed in the $SrCu_2\ O_{2-\delta}$ composition, Brillouin zone measurements have shown that the Γ-gap of $BaCu_2O_2$ is smaller so that the light transmission properties are much lower than any of the other alkaline earth copper (cuprite) compounds. It has been determined that the cuprite, $BaCu_2O_2$, containing monovalent copper is the only phase stable at reduced partial pressure of oxygen and(or) at high temperatures. $BaCu_2O_2$ (tetragonal with cell parameters of: $a = 5.722$, $c = 10.064$ Å, space group $I41/amd$, $Z = 4$) was identified by X-ray powder diffraction and has the structure shown in Fig. 15.38.

The interaction between components in the system $(BaO)_x$–$(CuO,Cu_2O)_{1-x}$ was investigated experimentally using differential thermal, thermal gravimetric, and X-ray diffraction analyses at temperatures up to 950 °C. It was found that at least three ternary compounds, $Ba_2Cu_3O_5$, $BaCuO_2$, and $BaCu_2O_2$, are formed in the system. $Ba_2Cu_3O_5$ is formed at relatively low temperatures (375–630 °C); $BaCuO_2$ is formed at higher temperatures but is unstable in the presence of excess copper oxide.

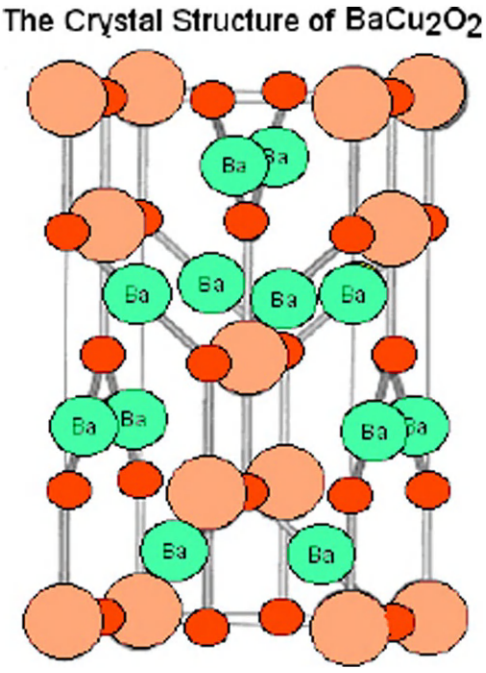

FIGURE 15.38

The compound $BaCu_2O_2$ is a result of $BaCuO_2$ disproportioning in the presence of excess copper oxide at temperatures above 900 °C, i.e.

$$2\ BaCuO_2 + 2\ CuO + \text{heat} \Rightarrow 2\ BaCu_2O_2 + O_2$$

A series of emf measurements were carried out on the electrodes, defined as:

$$BaCuO_2 \| BaCu_2O_2 \| Cu_2O$$

$$Ba_2CuO_3 \| BaCuO_2 \| BaCu_2O_2$$

These were measured over the ranges 1003–1132 K and 1175–1235 K in air. From the results, the Gibbs free

energy of formation of $BaCu_2O_2$ and Ba_2CuO_3 was determined to be:

$$\Delta G^0_{fox}\ (BaCu_2O_2)\ (kJ/mol) = -25.09 + 0.01548\ T\ (K)$$

$$\Delta G^0_{fox}\ (BaCu_2O_3)\ (kJ/mol) = +5.79\ -\ 0.07492\ T\ (K)$$

In contrast, data from another paper gave a differing result when flowing Ar with a partial O_2 pressure of 1.27 Pa was used. A solid-state galvanic cell:

$$Pt,\ Ar\ +\ O_2,\ Cu_2O\ +\ BaCu_2O_2\ +\ BaF_2||BaF_2||BaF_2\ +\ BaO,\ O_2\ +\ Ar,\ Pt$$

was measured as a function of temperature in the range 970–1170 K. Single-crystal BaF_2 was used as the solid electrolyte. The partial pressure of oxygen in the argon gas flowing over the electrodes was 1.27 Pa. The reversible e.m.f. of the cell can be expressed by $E = 224 - 0.016\ T\ (\pm 1.8)$ mV. The Gibbs free energy of formation of barium cuprite from component oxides according to the reaction is:

$$BaO(s)\ +\ Cu_2O(s) \Rightarrow BaCu_2O_2(s)$$

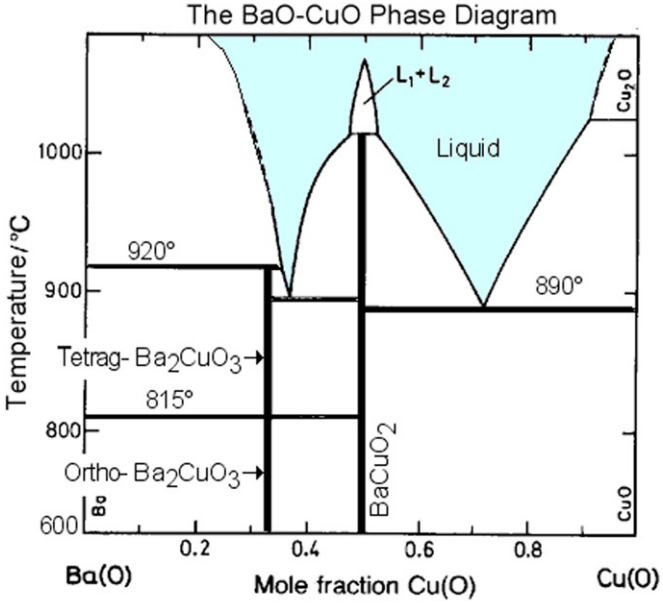
$$\Delta G^0_f\ =\ -43\ 230 + 3.09\ T(\pm 350) J/mol$$

The composition of melt from the crystallization and liquidus regions of the BaO–CuO_x phase diagram was studied within the range 50.0–80.0 mol% CuO at $p(O_2) = 21$ kPa. At 900–1050 °C, melt in the range of the compositions studied was structured and consisted of oxides having cubic structure of $BaCuO_2$; (Ba/Cu = 0.80–0.96), tetragonal structure of $BaCu_2O_2$; (Ba/Cu = 0.50–0.62), and monoclinic structure of CuO. The off-stoichiometry of $BaCu_2O_2$ manifested itself in electron diffraction (ED) patterns taken in a TEM as diffuse scattering streaks extending in the [100] and [010] directions. These data have been explained by considering the existence of clusters having a suggested composition of $Ba_2Cu_3O_{3.5+x}$ that were produced by a $BaCu_2O_{2+x}$ disproportionation, integrated into the $BaCu_2O_2$ structure. Thermal effects observed in the liquidus region, which are accompanied with a change in oxygen content, were also associated with the cluster structure of the melt and its evolution in response to varying temperature.

The Gibbs energy changes for the syntheses of the interceramic compounds of $BaCuO_2$ and $BaCu_2O_2$ were investigated as a basic study in the Y–Ba–Cu–O system that includes the superconductor, $YBa_2Cu_3O_{6.5+x}$. For the compound $BaCuO_2$, thermogravimetry analysis with CO_2–O_2–N_2 gas mixtures was employed, and equilibrium temperatures were determined at which CO_2 partial pressures in the gas mixtures were equilibrated with mixed powder of $BaCuO_2$, CuO, and $BaCO_3$. The Gibbs energy change for the reaction of $BaCO_3 + CuO = BaCuO_2 + CO_2$ was determined from the relation between CO_2 partial pressure and equilibrium temperature, taking into consideration the effect of CO_2 dissolution in $BaCuO_2$. For the study on $BaCu_2O_2$, electromotive force (e.m.f.) measurement using yttria-stabilized zirconia solid electrolyte was conducted. A technique using two cells was applied to the e.m.f. measurement for minimizing the effect of dispersion of oxygen from samples, and the Gibbs energy change for the reaction of $BaCuO_2 + CuO = BaCu_2O_2 + 1/2O_2$ was decided from the measured O_2 partial pressure.

In the Cu^{2+}-containing system of BaO–CuO, the phase diagram shows two compounds. The compound $BaCuO_2$ has received some attention in Academia. In particular, if excess oxygen atoms are added to the overall molecule, $BaCuO_{2+\delta}$, a complex magnetic structure results, as shown in Fig. 15.39.

To clarify the combined magnetic behavior of $BaCuO_{2+x}$, which contains, in the body-centered cubic (bcc) unit cell, two $Cu_{18}O_{24}$ spherical clusters, eight Cu_6O_{12} ring clusters, and six CuO_4 lone units, measurements of magnetization, Cu nuclear magnetic resonance (NMR) near 6 T, and pure quadrupole resonance (PQR) in zero field were made on samples with well-defined oxygen contents $x = 0$ and 0.14. Quantitative analysis of Curie–Weiss-like susceptibility data for $BaCuO_{2.00}$ indicated that Cu spins within the Cu_6 clusters go into a ferromagnetically (FM) ordered ground state with a maximum spin $S_r = 3$ below ~100 K, and those within the Cu_{18} clusters into an FM-like ground state below



An *x*–*t* diagram for the Ba(O)–Cu(O) system in an Ar–O_2 mixture with p_{O_2} = 21 kPa.

FIGURE 15.39

~20 K with net spin $S_s \sim 5$ that is less than the maximum possible spin $S_s = 9$. For $BaCuO_{2.14}$ the Cu spins within the Cu_6 clusters go into an FM ordered ground state at a lower temperature of ~30 K, and these clusters exhibit no signature of long-range magnetic ordering down to 2 K. The NMR spectra for $BaCuO_{2.00}$ observed below ~12 K have a trapezoidal structure that is known to be a characteristic of long-range magnetic ordering, and is consistent with the AFM ordering of the Cu_6 clusters below $T_N = 15$ K (as predicted previously). On the other hand, the spectrum for $BaCuO_{2.14}$ observed in a temperature range between 1.2 and ~50 K had an electric quadrupole-split powder pattern structure. This provides microscopic evidence that there is no long-range magnetic ordering in $BaCuO_{2.14}$. The addition of 0.14 mol of oxygen atoms resulted in a large suppression of some magnetic entities. However, some anomalies in the NMR and PQR data for $BaCuO_{2.14}$ near ~10 K, which could be associated with short-range ordering of the paramagnetic Cu_{18} clusters, were found.

Phase equilibrium experiments using quantitative energy dispersive X-ray spectrometric analysis (EDS) of a $BaCuO_2$ single crystal grown from a Ba–Cu–O melt were completed. Results showed this phase to be relatively copper rich with a nominal composition of $Ba_{0.94}Cu_{1.06}O_{2+\delta}$. The structure is a "two-ladder" type of compound shown in Fig. 15.40.

The $BaCuO_2$ compound can be deposited as an infinite layer phase, even if the real structure is present in many percents of copper vacancies, $V_{\overline{Cu}}$, in the CuO_2 planes. In addition, it was found that, in the $(BaCuO_2)_2$ layers of the investigated superconducting superlattices, the Cu/Ba ratio obtained by the simulations is less than one. However, in this latter case, the copper vacancies are localized only in the CuO_2 planes between barium atoms. Non-stoichiometric compounds with an excess of oxygen are compatible with the experimental data, indicating the $Ba_2Cu_{2-x}O_{4-y}$ layers as the "reservoir charge blocks" in the superconducting superlattices.

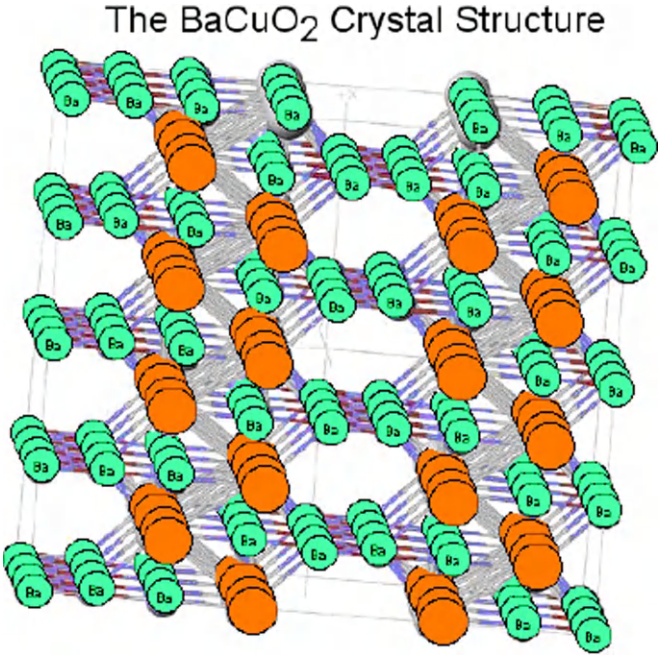


FIGURE 15.40

The interaction between components in the system $(BaO)_x$–$(CuO,Cu_2O)_{1-x}$ was investigated experimentally using differential thermal, thermal gravimetric, and X-ray diffraction analyses at temperatures up to 950 °C. It was found that at least three ternary compounds, $Ba_2Cu_3O_5$, $BaCuO_2$, and $BaCu_2O_2$, are formed in the system. $Ba_2Cu_3O_5$ is formed at relatively low temperatures (375–630 °C); $BaCuO_2$ is formed at higher temperatures but is unstable in the presence of excess copper oxide. This compound has been found to convert to the Ba_2CuO_4 form spontaneously at room temperature if allowed to sit in air:

$$2\,BaCuO_2 \Rightarrow Ba_2CuO_3 + CuO$$

In other words, the stable form of Cu^{2+} in these compounds is Ba_2CuO_3. $BaCuO_2$ melts congruently at 1020 °C. Neutron diffraction experiments have been performed in order to study the magnetic ordering of $BaCuO_{2+\delta}$. In these measurements, unpolarized neutrons and polarized neutrons with full polarization analysis have been utilized. From these measurements, it has been determined that $BaCuO_{2+\delta}$ orders antiferromagnetically below $T_N = 15.0 \pm 0.5$ K with a magnetic propagating vector $\mathbf{k} = [1,1,1]$. This structure is commonly referred to as a $[\pi\pi\pi]$ or a G-structure. The Cu atoms in the Cu_6 ring clusters, located at the (1/4,1/4,1/4) positions, order ferromagnetically within these clusters while the clusters themselves order antiferromagnetically. The ordered magnetic moment of each of these Cu atoms is 0.89 ± 0.05 μbar at $T = 4.2$ K. No evidence of long-range magnetic ordering of the Cu atoms in the Cu_{18} clusters, located at the (0,0,0) and (1/2,1/2,1/2) positions, was found down to a temperature $T = 2.5$ K.

The specific heats of samples of $BaCuO_2$ and $BaCuO_{2+\delta}$, were measured for the temperature range $0.35 \leq T \leq 30$ K in magnetic fields to 7 T. Magnetization and/or neutron diffraction measurements had been made earlier. $BaCuO_{2+\delta}$ has a complex structure with 90 formula units in a bcc unit cell; 6 Cu are "lone spins," 48 are in 8-Cu_6O_{12} "ring clusters," and 36 are in $2Cu_{18}O_{24}$ "sphere clusters". The ring and sphere clusters have ferromagnetically ordered ground states with spins $S = 3$ and 9, respectively. AFM ordering of the ring clusters occurs with a Néel temperature $T_N(0) \sim 15$ K. The specific heat of $BaCuO_2$ shows a cooperative

ordering anomaly associated with the AFM ordering of the ring clusters. Schottky-like anomalies, having maxima at ~5 and ~0.7 K, are identified with the ordering of the sphere clusters and the lone spins, respectively. Only Schottky-like anomalies are observed for the specific heat of $BaCuO_{2+\delta}$. It was suggested that the increase in the Cu oxidation state, due to the addition of 0.14 mol of O, increases Cu–O covalent bonding (spin compensation) and/or produces nonmagnetic Cu^{3+}, which in addition to the known increase in the Cu–O bond lengths, disrupts the superexchange paths that lead to the AFM ordering of the ring clusters in $BaCuO_2$. For $BaCuO_2$ the magnetic entropy was 90% of that predicted for the ordering of the three Cu structures. On the other hand, the magnetic entropy for $BaCuO_{2+\delta}$ was only 65% of that predicted, which suggests a relative large suppression of some magnetic entities due to the addition of 0.14 mol of O. Although $BaCuO_{2+\delta}$ is an insulator, the specific heat has a T-proportional component that is magnetic field dependent and is presumably associated with the magnetic degrees of freedom.

Pulsed laser deposition was used to synthesize artificially layered high-temperature superconductors. Thin-film compounds were formed when the constraint of epitaxy was used to stabilize $SrCuO_2$–$BaCuO_2$ superlattices in the infinite layer structure. Using this approach, two new structural families, $Ba_2Sr_{n-1}Cu_{n+1}O_{2n+2+\delta}$ and $Ba_4Sr_{n-1}Cu_{n+3}O_{2n+6+\delta}$ have been synthesized; these families are superconductors at temperatures as high as 70 K.

In another paper, $(BaCuO_2)_2/(CaCuO_2)n$ superconducting superlattices were grown by pulsed laser deposition for n ranging from 1 to 6. The critical temperature was found to depend strongly on the growth conditions. A maximum Tc value of about 80 K (zero resistance temperature) was found for superlattices grown at high oxygen pressure ($PO_2 \sim 0.8$ mbar) and relatively high temperature ($Tg = 600$ °C). The dependence of Tc on the number n of $CaCuO_2$ layers (for superlattices grown exactly in the same conditions) was investigated. Tc versus n showed the expected behavior with a maximum Tc value of 80 K for $n = 2$–3. However, such values are somewhat lower than that expected for a cuprate structure containing 3–4 CuO_2 planes and having an optimum carrier concentration. Two possible explanations for this effect were envisaged. The first one deals with the chemistry of the "charge reservoir" block, the second one with the special role of interelectron interaction in these highly disordered artificial structures. Finally, it was shown that, taking into account the degree of disorder, a shift of Tc of about 20 K relative to the *bulk* value Tc_0, consistent with the microscopic parameters of these materials, can be foreseen.

Magnetic and electrical transport properties of artificially layered $[(BaCuO_2)_2/(CaCuO_2)_2]N$ superlattices grown by pulsed laser deposition have been investigated. It has been found that these superlattices have a metallic normal-state resistivity with a transition temperature of about 74 K. The concentration of holes, from Hall measurements, is as high as 0.55 carriers per unit cell. From magnetization measurements, a critical current density of about 6×10^5 A/cm^2 was estimated at 10 K. Magnetoresistivity and magnetization decay allowed the measurement of the activation energy for the so-called "fluxons" motion. The observed value is not far from that of $YBa_2Cu_3O_{7-x}$, especially at low temperatures. All these features show that the layer by layer pulsed laser deposition was a viable technique for the synthesis of these new artificially layered high-temperature superconducting materials having interesting electrical and magnetic properties.

The complex ternary system Ba–Cu–O was re-visited using a 0.1 MPa oxygen pressure. It was established that, for such pressure, the $BaO_2 \Rightarrow BaO + 1/2O_2$ reaction has an important role in order to reach the equilibrium state. In this case, the pathway for the phase formation was then described by ternary sections such as BaO_2–BaO–CuO. The temperatures and the reactions that form the three compounds observed in this system have been determined. $Ba_2CuO_{3.04}$ decomposes by a peritectic-like reaction at 1033 °C and shows a structural transition from orthorhombic to tetragonal crystal form at 825 °C; $BaCuO_2$ is a congruent melting compound at 1035 °C and $Ba_2Cu_3O_{5.5}$ undergoes a peritectoid decomposition into $BaCuO_2$ and CuO at 893 °C. The stability of the $BaCuO_x$ ($x \geq 2$) phase was mapped over a wide range of temperature (300–1100 °C) and oxygen pressure (10^{-5}–10^3 bar). At ambient pressure and temperature, $BaCuO_x$ is found to be in a metastable state. Long annealing at 450 °C tends to decompose this phase into $Ba_2Cu_3O_5$ and BaO_2. Having obtained the phase stability domain in the $[T,p(O)_2]$ plane the authors were able to prepare single-phase samples of $BaCuO_x$ with different oxygen contents suitable for precise intrinsic thermodynamical measurements. They showed that the behavior of the low-temperature specific heat ($1.1 \leq T \leq 32$ K) and its dependence on the magnetic field ($0 \leq B \leq 14$ T) may be understood by taking into account a many-level magnetic system directly related to the Cu_6O_{12} and $Cu_{18}O_{24}$ structural blocks of $BaCuO_x$. Depending on the oxygen concentration, competition between AFM ordering and the many-level system was observed. With increasing oxygen content, the Néel temperature decreased whereas amplitude of the many-level system increased. The zero-field AF transition belongs to the 3D isotropic Heisenberg universality class.

The compound, $BaCu_3O_4$, has been observed to form as a "satellite-type" secondary phase when the

superconducting compound, $YBa_2Cu_3O_{7-\delta}$, is heated to >1400 °C. Superconducting single crystals of $YBa_2Cu_3O_{7-\delta}$ displaying a secondary phase pattern superimposed on the orthorhombic bulk phase pattern have been investigated by X-ray diffraction. The crystal structure of the satellite phase material has been solved and shown to correspond to a new alkaline earth oxocuprate (II) $BaCu_3O_4$. It has orthorhombic symmetry. The space group is D^{19}_{2h}-*Cmmm* with $a = 10.986$ Å, $b = 5.503$ Å, $c = 3.923$ Å and $Z = 2$. All the oxygen atoms of the structure are involved in a 2D network of copper–oxygen square planar coordination polyhedra having edge linkage. Short distances d(Cu–Cu) = 2.752 Å are found along infinite 1D copper chains. Structural similarities with $YBa_2Cu_3O_{7-\delta}$ may explain the frequent occurrence of $BaCu_3O_4$ within the host phase, and consequently its possible role as a weak link between superconducting regions. Metastable $BaCu_3O_4$ has been synthesized by MOCVD (metal-organic chemical vapor deposition) techniques on perovskite substrates. Strain effects lead to an epitaxial island growth of micrometer-sized crystallites with two orientations relative to the substrate surface. They were used for a polarized single-crystal analysis by micro-Raman spectrometry. The results can be used to detect $BaCu_3O_4$ as an impurity phase in $YBa_2Cu_3O_{7-\delta}$ thin films with a mole fraction level of less than 1%, a sensitivity which exceeds that of XRD by at least one order of magnitude.

The structure of $BaCu_3O_4$ phase occurring as particles on the surface of (001) $RBa_2Cu_3O_7$ epitaxial films prepared by MOCVD has been investigated using quantitative electron diffraction and HREM. The orthorhombic unit cell is $a = 10.97$ Å, $b = 5.54$ Å, $c = 3.94$ Å with space group *Cmmm*, the values being in agreement with an XRD study. The structure consists of alternating Cu_3O_4 and Ba layers along the *c*-axis. The compound can be stabilized due to the formation of low-energy coherent boundaries with $RBa_2Cu_3O_7$ and/or perovskite substrates.

The compound, Ba_2CuO_3, is said to be dimorphic, forming a orthorhombic crystal structure below 810 °C and a tetragonal form above that temperature, the last being apparently unstable above ~920 °C. This compound is unstable in moisture and CO_2 and so has not been studied intensively. Ba_2CuO_3 was fabricated by solid-state reactions of CuO (99+% purity) or $Cu(NO_3)_2 \times 2.5H_2O$ (98% purity) and $Ba(NO_3)_2$ (99+% purity). The mixtures were calcined in porcelain crucibles in air for 24 h at 920 °C, for Ba_2CuO_3. The oxide $Ba_2CuO_{3+\delta}$ was synthesized and a maximum oxygen content of 3.5 was found corresponding to an orthorhombic structure. The departure from stoichiometry was measured at various temperatures and the experimental results were interpreted in terms of two domains of oxygen vacancies. This system was characterized by the presence of two fundamental mixed crystal fields: the first ($0 \le x \le 0.5$) formed by solids with tetragonal symmetry, deriving from $Ba_2CuO_{3+\delta}$; the second ($0.7 \le x \le 2$) formed by solids with orthorhombic symmetry and structurally related to Sr_2CuO_3 characterized by a preferential presence of oxygen vacancies along b_o. The oxide $Ba_2CuO_{3+\delta}$, where $\delta = 0.3$ has the structure shown in Fig. 15.41.

In contrast, the reaction of BaO + CuO, in flowing argon ($PO_2 = 10^{-6}$ atm.), resulted in two compounds corresponding to the formulas, $Ba_2CuO_{3-\delta}$ and $Ba_3CuO_{4-\delta}$. The cell parameters and structural type were defined. In presence of pure oxygen or CO_2 free air, these formulas were observed.

The latter composition can exist with two modifications characterized by a different distribution of oxygen vacancies. One structure is shown in Fig. 15.42. The structure of this compound has the orthorhombic space group *Cmmm* and the lattice parameters $a = 10.94(2)$ Å, $b = 5.47(1)$ Å, $c = 3.91(1)$ Å

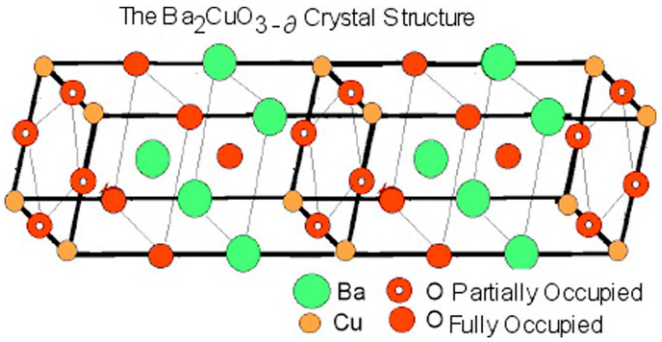

FIGURE 15.41

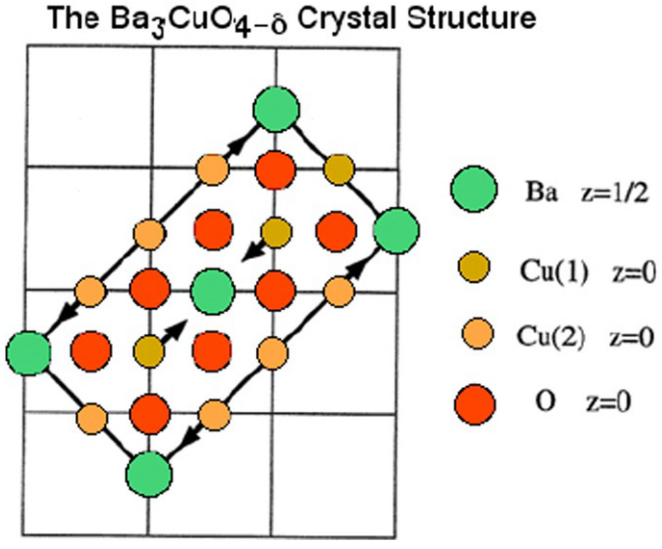

FIGURE 15.42

and is characterized by a stacking of Cu_3O_4 layers connected by barium atoms.

The flat copper–oxygen layers contain ordered vacancies on the copper sites with two vacancies per unit cell. The Cu atoms are displaced by 0.028 Å toward the vacancies as shown by the arrows.

In the Cu^{2+}–Cu^{3+}-containing system of BaO–Cu_3O_4, the compound, $BaCu_3O_5$, is unknown. However, the $Ba_2Cu_3O_6$ compound has been mentioned in the literature. The superconductors, $Ba_4CaCu_3O_{8+\delta}$ and $Ba_6CaCu_3O_{10-\delta}$, have been synthesized and the stability of these two ternary compounds has been investigated by means of X-ray diffraction, differential thermal analysis and thermogravimetry analysis. These phases are metastable at low temperature in atmospheric oxygen, i.e. $p(O_2) = 1$ bar. The DTA/TGA curves indicate an equilibrium recovery between 300 °C and 400 °C corresponding to the decomposition into BaO_2, CaO and $Ba_2Cu_3O_6$ (where Cu is actually in the $\{2Cu^{3+}\text{-}Cu^{2+}\}$ state) while in the superconductor formulation, Cu is in the Cu^{4+} state, i.e. $\{2Cu^{4+}\text{-}Cu^{2+}\}$.

In another publication, spontaneous crystallization from a solution in a melt at a pressure of $(0.8–1) \times 10^{-3}$ Pa was used to obtain single crystals of a novel non-perovskite-like superconducting phase $Ba_2Cu_3O_{6-\delta}$, (space group = *Pccm*, $a = 13.065$, $b = 20.654$, and $c = 11.431$ Å). The superconducting properties of the crystals were investigated by the modulated microwave absorption. The superconducting transition temperatures were 5 (sample No. 1), 7 and 13 K (sample No. 2). The superconductivity in the $Ba_2Cu_3O_{6-\delta}$ crystals is attributed to the presence of CuO_2 chains of edge-sharing copper–oxygen squares. Non-perovskite-like $Ba_2Cu_3O_{6-\delta}$ crystals are a new class of 1D superconductors. It has been observed that, in these compounds, each compound has a unique sequence of layers in the *c*-axis direction:

- **superconducting layers**: $[CuO_2^-]$ and $[-O_2Cu]$
- **insulating layers**: $[Y^{3+}]$ or $[-Ca^{2+}]$
- **hole-donating layers**: [Cu–O_b] or [Bi–O]

Cuprate superconductors have a σ_h horizontal reflection plane ⊥ to the *c*-axis direction at the center of the unit cell. Other reflection planes are at the top and bottom of the unit cell. All atoms (except those in the σ_h plane) thus appear twice in the unit cell.

No further work is available concerning these compounds.

In the Cu^{4+}-containing system of BaO–CuO_2, it has been observed that a Cu analog of $BaTiO_3$, $BaCuO_3$, does not exist because the Cu^{4+} ion does not exist in oxides.

However, complex compounds are formed when the system is formed with the combination of chloride (Cl^-) units in the structure. In crystallography, a structure is often described in terms of geometrical arrangements. The term "low dimensionality" means that building blocks form less than 3D arrangements, typically chains or columns (1D) or layers (2D). New compounds having low-dimensional arrangements of transition metal building blocks have been prepared. The presence of alkaline earth polyhedra induced the formation of low-dimensional transition metal sublattices, as AE frameworks have themselves been seen to make low-dimensional arrangements. If the transition metal (Co_{II}, Ni_{II} or Cu_{II}) sites in a compound form a simple arrangement such as a linear chain, that compound may harbor interesting physical properties e.g. magnetic frustration, high-temperature superconductivity, or anisotropic conductivity. This is illustrated in Fig. 15.43.

A schematic model of "zero to three dimensions" for understanding the connection between crystal structures of varying dimensionalities using the example of carbon is shown here. The C_{60} carbon cage, known as Buckminster-Fullerene, is a closed system, forming a 0D arrangement. Such cages are sometimes found to hold guests inside, such as smaller molecules or metals, but here it is simply described as a model of minimum dimension. Carbon nanotubes are shown as a 1D example. The strong σ/π-bonds between carbon atoms in graphite form sheets, shown as an example of a 2D arrangement; in between the layers there are weak π–π interactions leading to electronic conductivity. The diamond, the hardest material known, is tetrahedrally sp^3-bonded forming a 3D network.

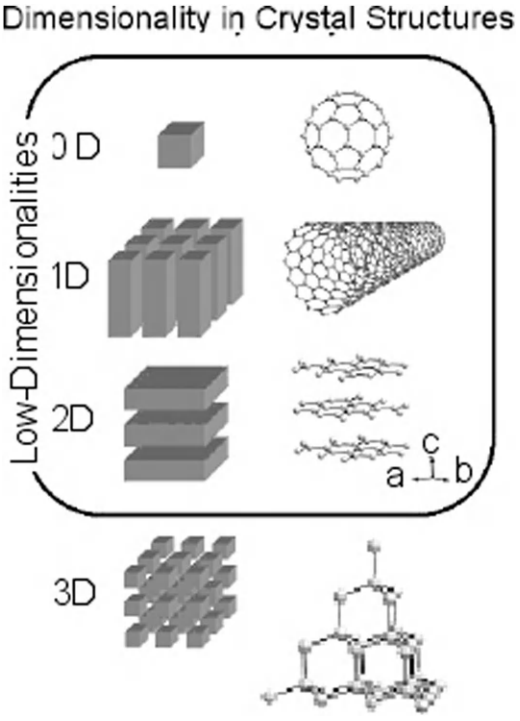

FIGURE 15.43

The addition of halogen ions to the simple $Ba_xCu_yO_z$ compounds shown above (where x, y, z varies from 1 to 8) forms very complex compounds where x, y, and z can vary from 1 to 128.

Ba atoms form a 1D column in the $Ba_9Cu_7O_{15}C_{l2}$ structure (Kipka and Mueller-Buschbaum, 1976) with a rather interesting combination of units, as shown in Fig. 15.44.

One of the units is a Ba_3O_{15} polyhedra ring (a) formed by connecting three BaO_6 irregular polyhedra. Each Ba–Ba distance in the triangular arrangement is 4.26 Å. Another Ba unit forms a $[BaO_4]_3[CuO_2]_3$ ring (b) with three BaO_6 hexagons and three CuO_4 squares connected by edge sharing. Those two distinctive Ba units are connected in the sequence ABAB… to form a 1D column along the [001] direction that has encloses of enough volume to hold Cl atoms inside. Because of this Ba column arrangement, magnetic interactions between Cu cations are limited to occur within Cu_6O_{12} rings. The Cu building blocks are separated. (c) The two Ba arrangements connect in the sequence ABAB… to form a 1D column along the [001] direction. (d) Each CuO_4 square (blue) is a fragment of a Cu_6O_{12} ring.

As an example of a 2D arrangement, a bilayered Ba coordination with a combination of oxygen and halide anions can be seen in the $Ba_2Cu_3O_4X_2$ (X═Cl and Br) structure. A central Ba atom bonds to eight neighboring atoms: four O and four X atoms at the distances 2.74 and 3.14 Å, respectively, to form a square antiprismatic $[BaO_4C_{l4}]$ polyhedron. The $[BaO_4C_{l4}]$ polyhedra are connected through the halides to form a $[BaO_2X]_n$ bilayer in the (110) plane (Fig. 15.45).

In this diagram, the following may be discerned: (a) Ba atomic arrangement in the $Ba_2Cu_3O_4X_2$ (X═Cl and Br) structure is shown. Each Ba atom takes a coordination with four O and four X atoms to form a $[BaO_4X_4]$ polyhedron. (b) View of the $[BaO_2X]_n$ zigzag layer along the [010] direction. (c) The $[BaO_2X]^n$ zigzag layer formed in the (001) plane.

The chain structure of this compound can be more easily seen in Fig. 15.46.

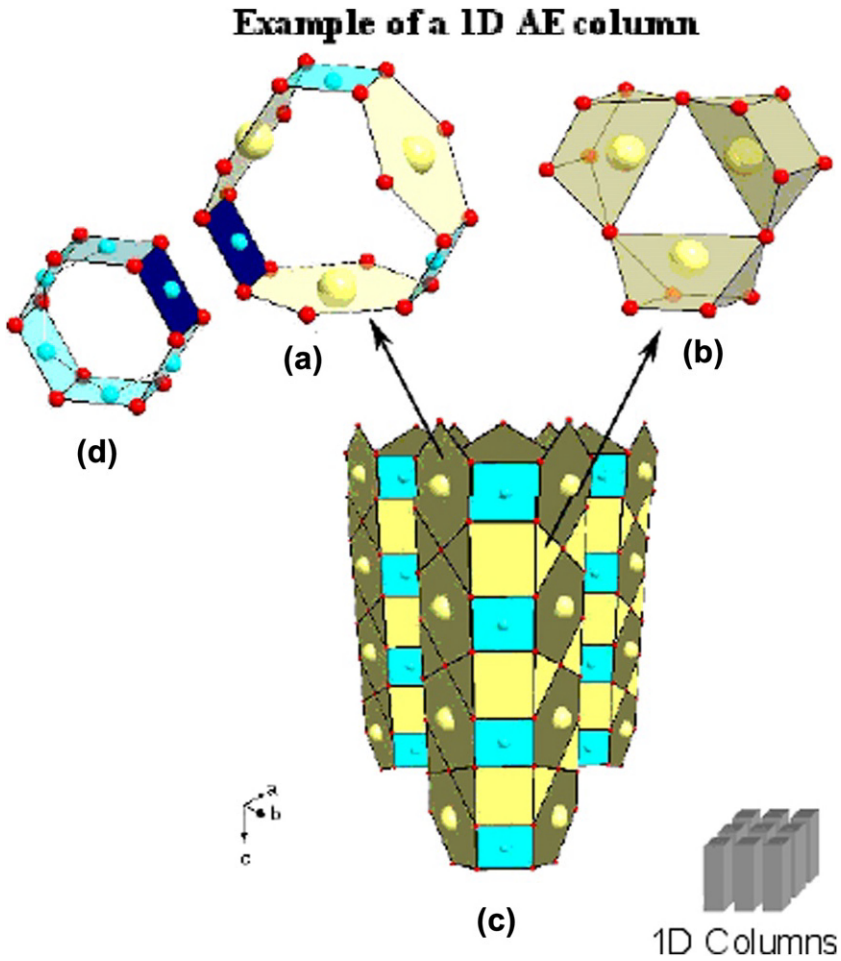

FIGURE 15.44

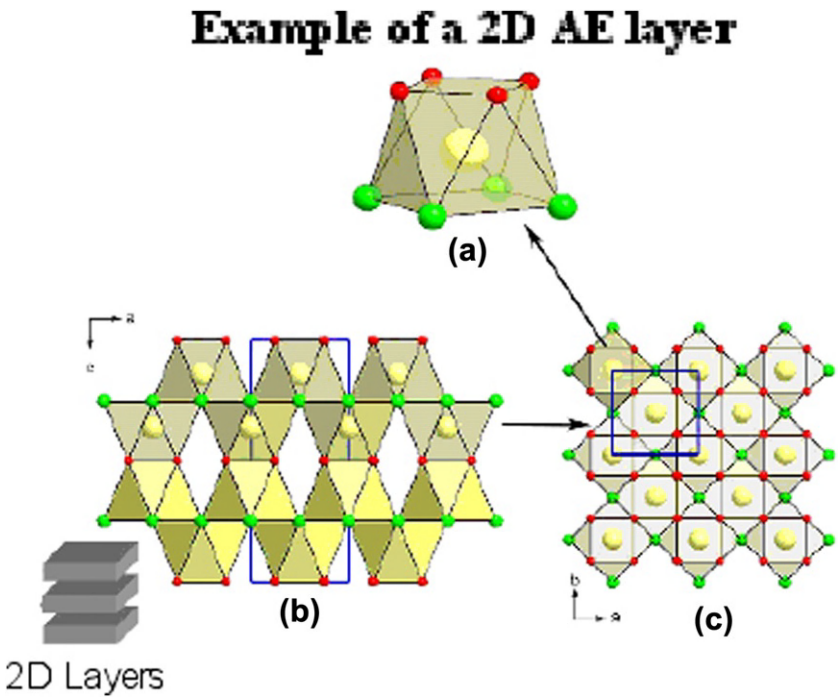

FIGURE 15.45

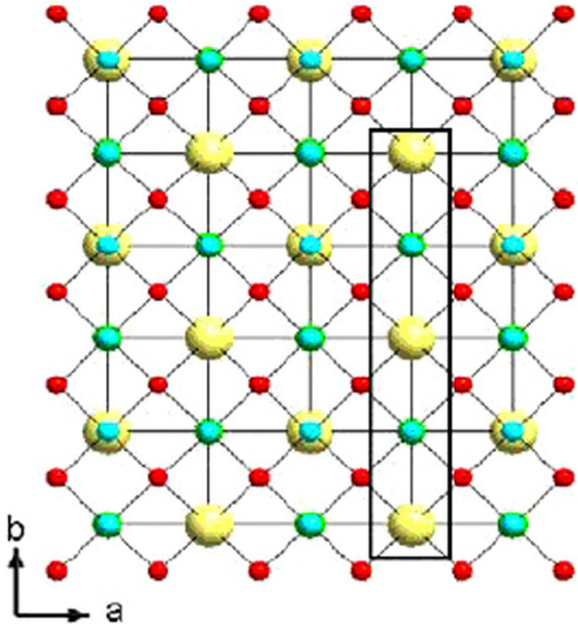

FIGURE 15.46

Here is shown: (a) The [BaCuOCl] layer in the compound $Ba_2Cu_3O_4Cl_2$. Ba atoms (yellow), Cu atoms (light blue), O atoms (red), Cl atoms (light green). The common $[BaCuO_4]_n$ chain arrangement is indicated with a black box.

Examples of alkaline earth 3D networks are mainly found in compounds with Sr or Ba atoms. A Ba cage in the $Ba_{44}Cu_{45}O_{87}Cl_4$ compound (Kipka & Mueller-Buschbaum, 1977) is formed by edge sharing of two hexagonal faces and 24 triangles. The Ba atoms are separated by the distances of 3.9–4.3 Å. This Ba_{20} cage is connected to the six nearest neighboring cages by face sharing to form a 3D cage network. There is a Cu_6O_{12} ring as a guest inside of each Ba_{20} cage, making this structure a vivid example of AE polyhedra blocking interactions between transition metals as shown in Fig. 15.47.

This figure shows Ba_{20} cages in the $Ba_{44}Cu_{45}O_8Cl_{47}$ structure: (a) Each Ba_{20} cage (light yellow) connects to six neighboring Ba_{20} cages by face sharing to form the 3D network arrangement. (b) Each Ba_{20} cage holds a Cu_6O_{12} ring. The same metal arrangement occurs in the $Ba_{41}Cu_{44}O_{84}Cl_2$ and $Ba_{88}Cu_{88}O_{175}Br_2$ structures. (c) The Cu_6O_{12} ring.

Barium cuprite or cuprate compounds are not offered for sale commercially and no CAS numbers have been assigned to date.

15.1.6. Radium Copper Compounds

Although Ra^{2+} undoubtedly forms the same type of compounds as Ba^{2+} with copper oxides, there have been no reports of the synthesis of such compounds. This is undoubtedly due to the high cost of RaO or Ra metal and the lack of interest in Industry and Academia for such compounds.

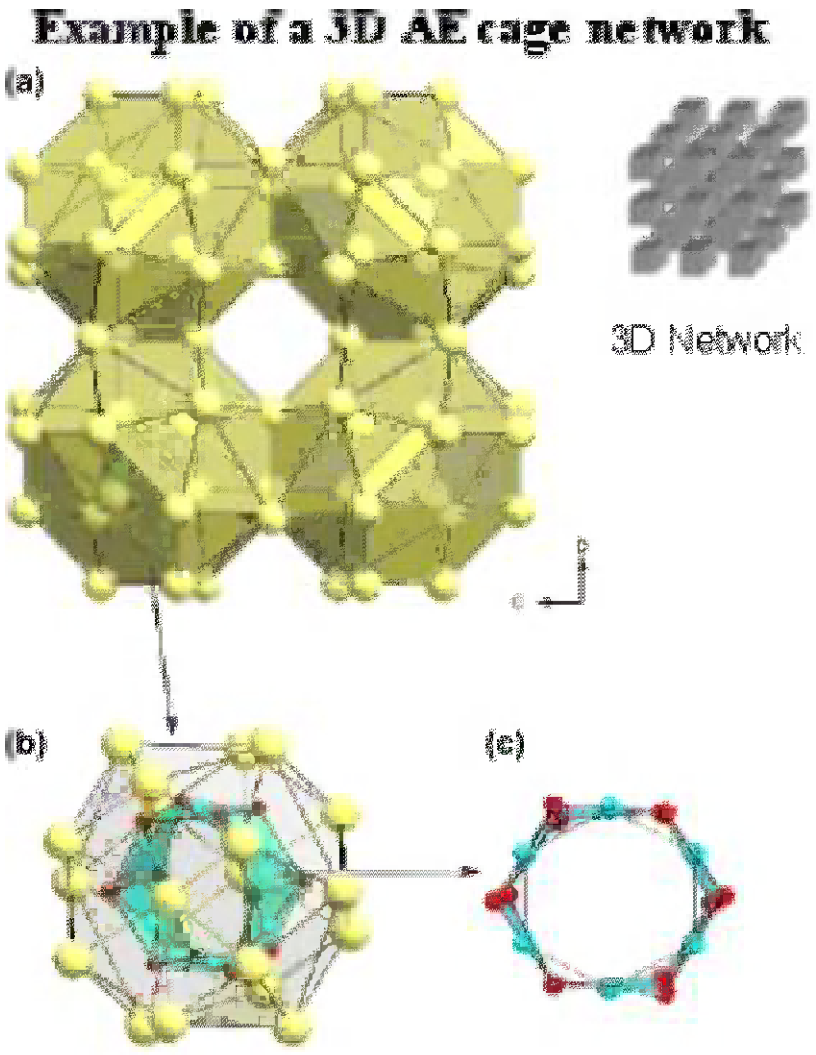

FIGURE 15.47

15.2. ALKALINE EARTH—SILVER COMPOUNDS

Silver has the valence states of: +1, +2, and sometimes +3. The major oxide is Ag^{+} as Ag_2O. It is a fine black or dark brown powder. Silver(I,III) oxide is used as part of the manufacture of silver oxide–zinc alkaline batteries. It has an empirical formula AgO, which might suggest that silver is in the +2 valence state. However, AgO is diamagnetic and X-ray diffraction studies have shown that silver atoms have two different coordination environments, one having two collinear oxide neighbors and the other four coplanar oxide neighbors. AgO is therefore best formulated as $Ag^{I}Ag^{III}O_2$ or $Ag_2O{\cdot}Ag_2O_3$. It is also known as silver peroxide, although it does not have peroxide (O_2^{2-}) anions.

15.2.1. Beryllium Silver Compounds

The metal, Be, forms just one compound with Ag metal as shown in Fig. 15.48.

Be_2Ag has the structure shown in Fig. 15.49.

Cell parameters are: $a = b = c = 4.4456$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 62.13$ Å^3, $Z = 8$. Cell occupancy is shown in Table 15.14.

Although it is not shown in the phase diagram, the compound, $Be_{12}Ag$ has the structure shown in Fig. 15.50.

Cell parameters are: $a = 4.246$ Å, $b = c = 5.5709$ Å, $\alpha = 81.55°$, $\beta = \gamma = 67.599°$, cell volume $= 112.64$ Å^3, $Z = 2$. Cell occupancy is shown in Table 15.15.

No other intermetallic compounds are known.

In the system Be–Ag–O, no known compounds have been documented.

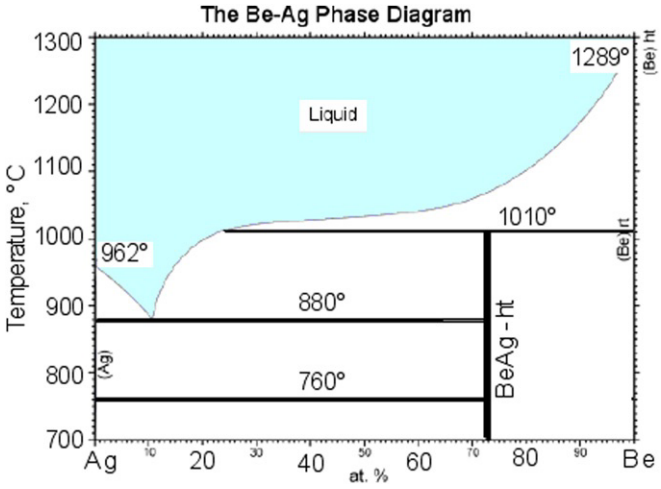

FIGURE 15.48

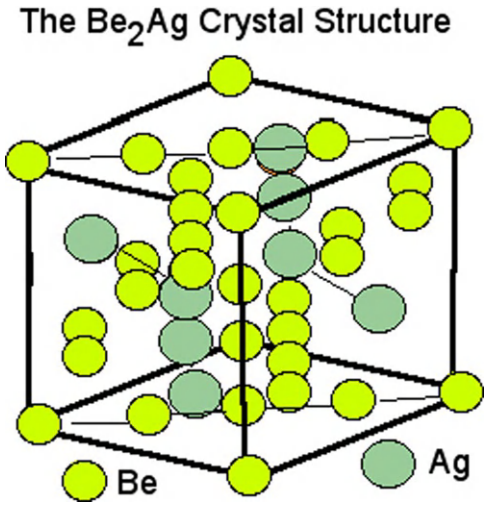

FIGURE 15.49

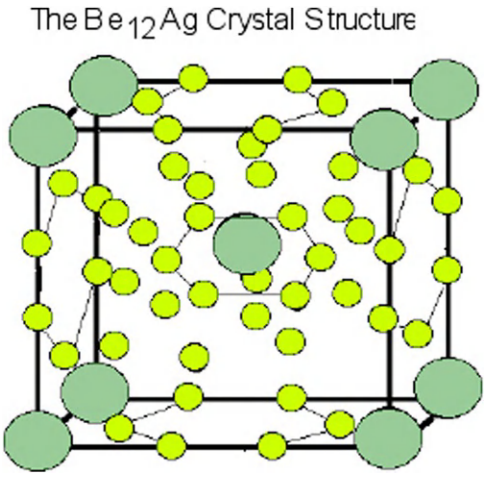

FIGURE 15.50

15.2.2. Magnesium Silver Compounds

Mg metal forms a series of intermetallic compounds with Ag metal as shown in Fig. 15.51.

The structure of the $MgAg_3$ compound is shown in Fig. 15.52.

Cell parameters are: $a = b = c = 4.1111$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 69.48$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.16.

MgAg has the structure shown in Fig. 15.53

Cell parameters are: $a = b = c = 3.3138$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 36.39$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.17.

The compound, $Mg_{54}Ag_{17}$, does not have a published structural arrangement of the atoms in the unit cell. The cell parameters are: $a = b = c = 12.4723$ Å, $\alpha = 107.57°$, $\beta = \gamma = 110.38°$, cell volume $= 1492.43$ Å^3, $Z = 2$.

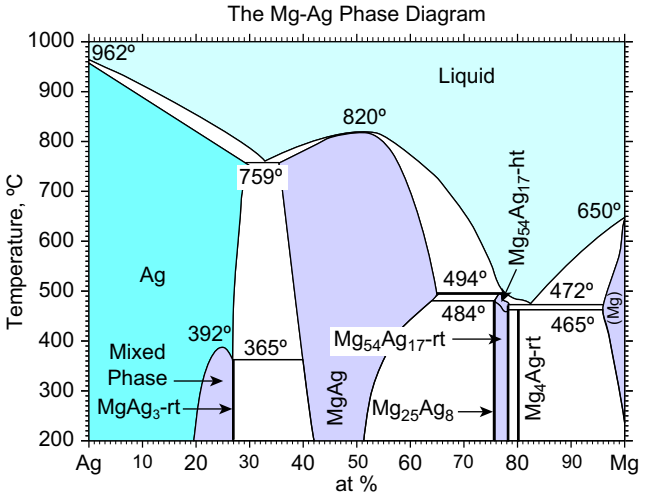

FIGURE 15.51

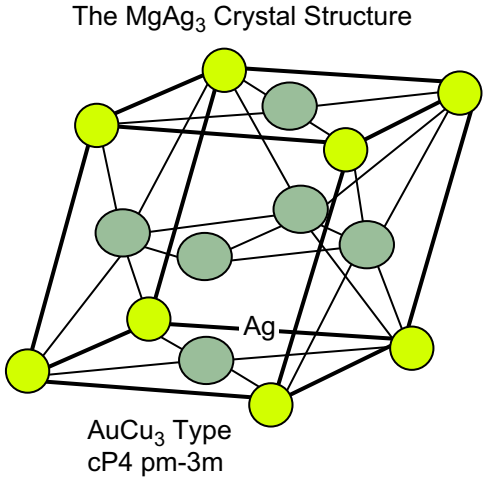

FIGURE 15.52

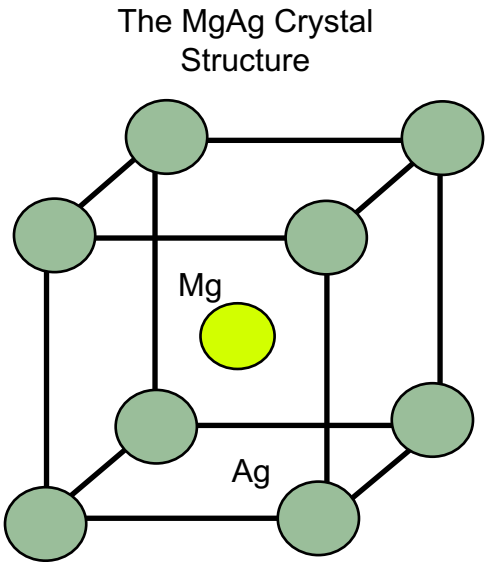

FIGURE 15.53

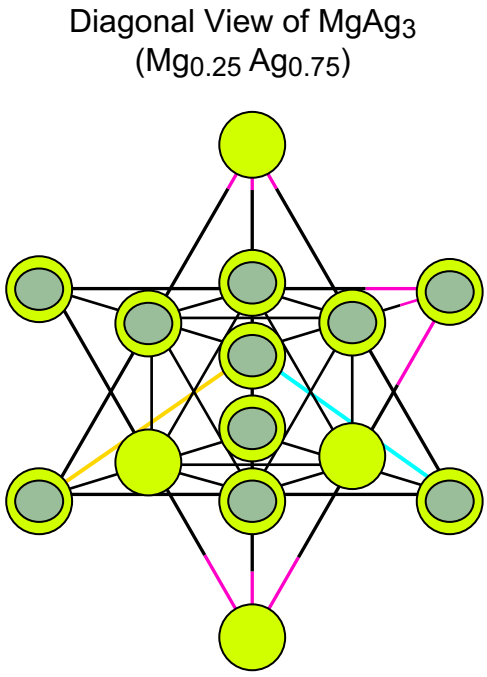

FIGURE 15.54

The hydrolysis behavior of some Mg-rich compounds (Mg_2Cu, $Mg_{54}Ag_{17}$ and Mg_3Au) at room temperature has been systematically investigated. Cu, Ag and Au nanoparticles have successfully been prepared by the hydrolysis of these compounds. The Cu, Ag, and Au nanoparticles obtained by the hydrolysis method are close to spherical in shape with a particle size below 20 nm. A continuous skeleton of magnesium atoms could be the channel for the dissolution of Mg atoms in these Mg-rich compounds, which is helpful in the hydrolysis of these Mg-rich compounds. The hydrolysis of the Mg-rich compounds provides a new and relatively simple method for the production of transition metal nanoparticles.

The compound, $Mg_{25}Ag_8$, does not have a published structural arrangement of the atoms in the unit cell. The cell parameters are: $a = b = c = 12.461$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 1368.05 Å^3, $Z = 64$. No other information is available.

The compound, Mg_4Ag, was obtained by melting the elements in a sealed Ta-ampoule and heating at 472 °C. Mg_4Ag is formed from $Mg_{54}Ag_{17}$ and δ-Mg. It is hexagonal with space group of $P63/m$ with $a = 12.485$ Å and $c = 14.412$ Å in a unique structure type. It is a hitherto unknown I_3-cluster phase with building blocks of three vertex-connected icosahedra as the fundamental structural units, joined via a small number of connection types: 1.9 icosahedra, 1.3 tri-capped trigonal prisms and 0.4 Frank-Kasper Z15 polyhedra per unit cell.

There are compounds such as $Mg_{0.996}Ag_{0.004}$ and Mg_1Ag_3 cited but no structural data are available. These two compounds appear to be based upon a Mg metal site in the lattice which is randomly sited by Ag atoms to provide the correct ratio of Mg/Ag atoms in the structure shown in Fig. 15.54.

In another paper, MgB_2 with T_c of 37 K could be fabricated through the diffusion reaction between Mg_4Ag and amorphous B at relatively low temperatures above 550 °C. The melting point of Mg_4Ag is 472 °C, much lower than that of pure Mg (650 °C). Therefore the reaction between Mg_4Ag and B is a liquid–solid diffusion reaction. The fabrication of MgB_2 wires through a powder-in-tube method and an in situ reaction process by using Mg_4Ag powder and amorphous B powder as the starting materials was accomplished. The J_c–B properties of the wires depended on not only the size of starting powder but also the reaction temperature. No other intermetallic compounds are known. One of these materials is available commercially and no CAS numbers have been issued to date.

In the Ag–O-containing system of $Mg_xAg_yO_z$, where x, y or z can vary from 1 to 8, no compounds have been studied or published in the current or past literature. Magnesium does not form any type of oxygen-dominated compounds with Ag. Such compounds, if they exist, have not been offered commercially for sale nor has any interest been shown in the technical literature to date.

15.2.3. Calcium Silver Compounds

Calcium forms several intermetallic compounds with silver. In one seminal paper, the Ca–Ag binary system has been assessed with CALPHAD approach based on experiment information about phase diagram and thermodynamic properties. The excess Gibbs energies of the solution phases including liquid, bcc and fcc were formulated with Redlich–Kister polynomial functions. The intermetallic compounds Ca_2Ag_9, Ca_2Ag_7, $CaAg_2$, CaAg, Ca_5Ag_3 and Ca_3Ag were treated as stoichiometric phases. Self-consistent thermodynamic parameters have been obtained and the calculated results agree well with literature data (Table 15.18).

The phase diagram presented was shown in Fig. 15.55.

$CaAg_2$ has the structure shown in Fig. 15.56.

Cell parameters are: $a = 4.683$ Å, $b = c = 5.934$ Å, $\alpha = 75.42°$, $\beta = \gamma = 66.78°$, cell volume $= 138.28$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.19.

The $CaAg_2$–$CaZn_2$–$CaAl_2$ pseudo ternary system has been studied by micrographic and X-ray diffraction analyses of 37 alloys, melted and annealed at 973 K or 873 K in tantalum crucibles. Single-crystal and powder X-ray data show a distribution of the phases among four structure types: $MgAg_2$, $MgCu_2$, $MgNi_2$ (the Laves phases) and $CeCu_2$ (for the first time reported as KHg_2). A good separation of the structural domains was obtained by means of a 2D map based on the size and electronic factors. The different volume effects, shown by the $CeCu_2$-type phases compared to those of the Laves phases, were accounted for on the basis of the hard-sphere space-filling model.

CaAg has the structure shown in Fig. 15.57.

Cell parameters are: $a = 4.058$ Å, $b = 4.654$ Å, $c = 6.077$ Å, $\alpha = 90°$, $\beta = 109.50°$, $\gamma = 90°$, cell volume $= 108.19$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.20.

The compound, Ca_5Ag_3, has the structure shown in Fig. 15.58.

Cell parameters are: $a = b = 8.039$ Å, $c = 9.415$ Å, $\alpha = \beta = 115.27°$, $\gamma = 90°$, cell volume $= 485.05$ Å^3, $Z = 4$.

Cell occupancy is shown in Table 15.21.

The compound, Ca_2Ag_7, has the structure shown in Fig. 15.59.

Only one layer is shown. The actual 3D structure consists of three of the layers in which the Ag atoms are arranged in a cage-like structure three dimensionally. Cell parameters are: $a = b = 5.486$ Å, $c = 14.078$ Å, $\alpha = \beta = 90°$, $\gamma = 119.52°$, cell volume $= 368.65$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.22.

In one paper, a theoretical method based on electronic packing frustration (EPF) for DFT-calibrated μ2-Hückel calculations in probing these structural pressure (SP)

effects was used. Applying this method to the Ca_2Ag_7 structure, a variant of the $CaCu_5$ type with defect planes, revealed its formation is EPF driven. The defect planes resolve severe SPs surrounding the Ca atoms in a hypothetical $CaCu_5$-type $CaAg_5$ phase.

The compound, Ca_3Ag_8, is not included in the phase diagram presented above. It has the structure shown in Fig. 15.60.

Only one layer of this cage-like structure is seen. The 3D structure exhibits a cage of Ag atoms around 4-Ca atoms, arranged in a flat structure in the center of the unit cell. Cell parameters are: $a = b = c = 8.496$ Å, $\alpha = \beta = \gamma = 109.47°$, cell volume $= 472.04$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.23.

This cage structure is better seen in Fig. 15.61.

A Z-14 structure is exhibited for the Ca_3Ag_8 structure. Such structures may be regarded as arrangements of

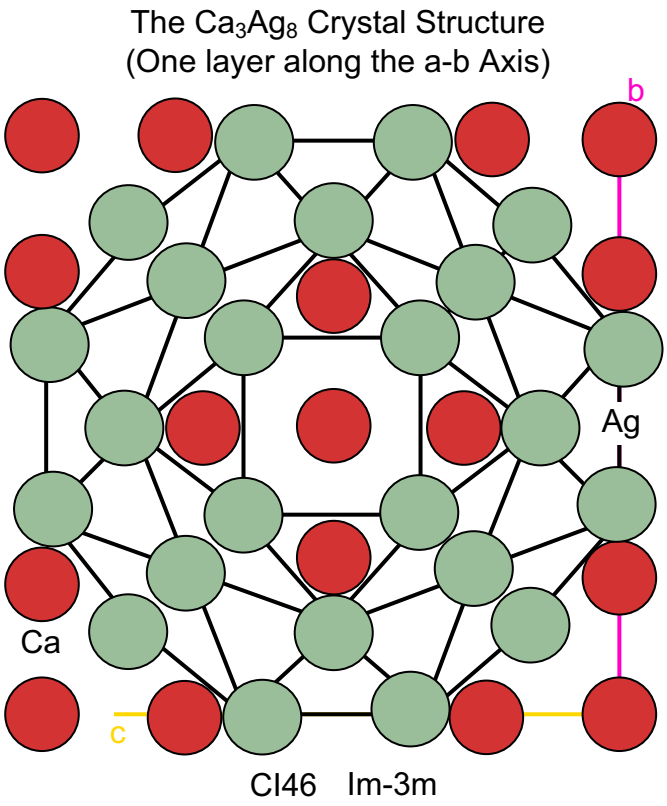

FIGURE 15.60

nested polyhedral units, isolated or linked, centered at sites of high symmetry. Ca_3Ag_8 is a centered unit of 27 atoms having a cubo-octahedron as the outermost polyhedron.

The compounds, Ca_2Ag_9 and Ca_3Ag, are shown in the phase diagram but little concerning their physical,

structural or electrical properties has appeared in the scientific literature. Both are known to exhibit Frank-Kasper type of structural arrangements with Ca_3Ag having 26 of Z-15 type of units, while Ca_2Ag_9 has 36 of $Z = 16$ units in their unit cell structures. No other papers have documented these compounds.

No other intermetallic compounds are known and no calcium–silver compounds are offered for sale commercially. No CAS numbers have been issued to date.

In the Ag^+-containing system of CaO–Ag_2O, no compounds are known. In the systems, CaO–AgO, CaO–Ag_2O_3 and CaO–AgO_2, no compounds have been discovered. It may be concluded that calcium and silver do not form any oxygen-dominated compounds. No such compounds are offered for sale commercially and no CAS numbers have been issued to date.

15.2.4. Strontium Silver Compounds

Strontium metal forms several intermetallic compounds with silver metal as shown in Fig. 15.62.

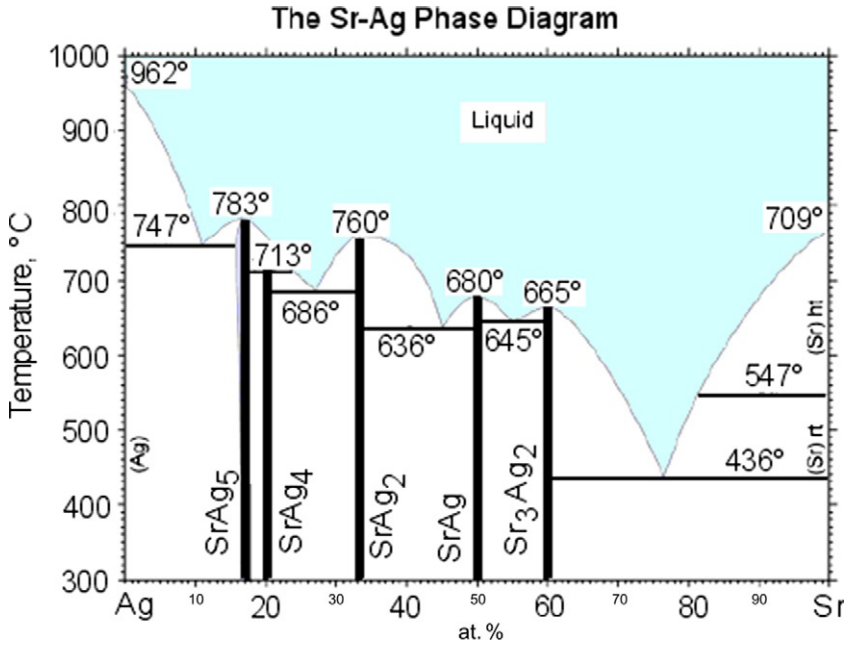

FIGURE 15.62

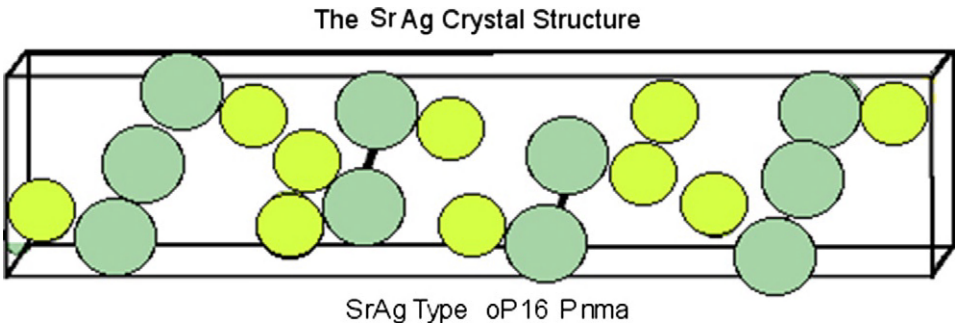

FIGURE 15.63

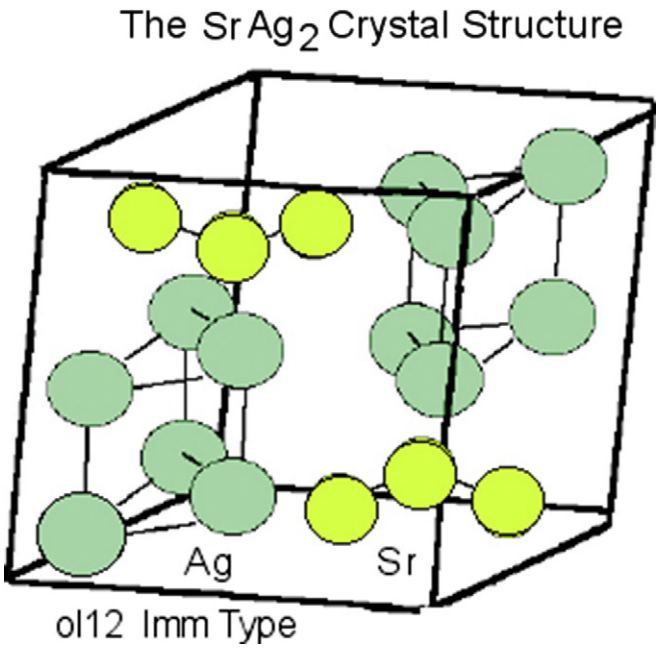

FIGURE 15.64

SrAg (CAS = 11091-79-5) has the structure shown in Fig. 15.63.

Cell parameters are: $a = 4.788$ Å, $b = 6.385$ Å, $c = 16.558$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 506.20 Å^3, $Z = 8$. Cell occupancy for SrAg is shown in Table 15.24.

The structure of SrAg is a variant of the CrB–FeB type of trigonal-prismatic coordination around the Ag metal and differs from CaAg and BaAg only in the arrangement and sequence of the prisms along the a-axis.

The compound, $SrAg_2$, has the structure shown in Fig. 15.64.

It is identical to that of Ca_2Ag. Cell parameters are: $a = 4.817$ Å, $b = c = 6.115$ Å, $\alpha = 77.788°$, $\beta = \gamma = 66.911°$, cell volume = 153.56 Å^3, $Z = 8$. Cell occupancy is shown in Table 15.25.

No data concerning the $SrAg_2$ compound are available in the current scientific literature.

$SrAg_5$ (CAS-12250-17-8) has the structure shown in Fig. 15.65.

Cell parameters are: $a = 4.631$ Å, $b = c = 5.644$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 127.66 Å^3, $Z = 1$. Cell occupancy is shown in Table 15.26.

Contrary to expectation, the isotypic phases $SrAg_5$ and $SrPd_5$ ($CaCu_5$-type) do not form a continuous mixed

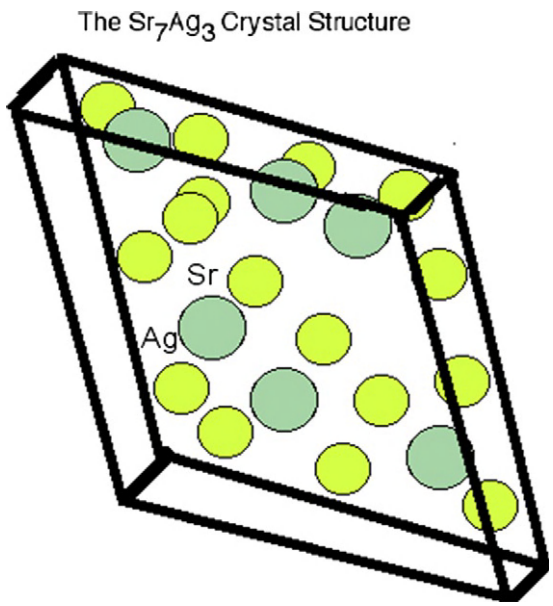

FIGURE 15.66

crystal series. In the range 40% $SrPd_5$ and 90% $SrPd_5$ the mixed crystals have a different structure, which is however closely related to the $CaCu_5$ structure. The diamagnetism of $SrAg_5$ ($\sim 10.9 \times 10^{-6}$ $cm^3/g/atom$) increases linearly on replacing Ag by Pd, attaining a limiting value of $\sim 10.9 \times 10^{-6}$ $cm^3/g/atom$ at 38% $SrPd_5$. In these alloys, palladium is incorporated in a nonvalent state with a completely filled 4d band.

The compound, Sg_7Ag_3, has the structure shown in Fig. 15.66.

Cell parameters are: $a = 7.277$ Å, $b = c = 11.383$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 816.15 $Å^3$, $Z = 2$.

Cell occupancy is shown in Table 15.27.

The compound, Sr_3Ag_2, has the structural form shown in Fig. 15.67.

Cell parameters are: $a = b = c = 8.4594$ Å, $\alpha = \beta = \gamma = 72.145°$, cell volume = 533.014 $Å^3$, $Z = 9$. Cell occupancy is shown in Table 15.28.

Crystal structure of the phases, strontium-silver (Sr_3Ag_2 CAS number 93509-33-2), calcium-gold (Ca_5Au_3), strontium-gold (Sr_7Au_3), and strontium-silver (Sr_7Ag) was investigated. Sr_3Ag_2 is rhombohedral (Er_3Ni_2-type), space group $R3$, with $a = 9.962$ and $c = 18.935$ Å. Ca_5Au_3 is tetragonal (Cr_5B_3 type), space group $I4/mcm$, with $a = 7.867$ and $c = 14.39$ Å. Sr_7Au_3 is hexagonal (Th_7Fe_3 type), space group $P63/mmc$, with $a = 11.07$ and

4	Sr(1)	Sr	3	a	-3.	0	0	0	1.0

$c = 7.161$ Å. Sr_7Ag_3 has Th_7Fe_3-type structure with $a = 11.38$ and $c = 7.277$ Å.

No other intermetallic compounds are known. Several of these intermetallic compounds are offered for sale commercially and the CAS numbers have been noted above.

In the SrO–Ag_2O and SrO–AgO systems, no compounds like $SrAg_2O_2$ or $SrAgO_2$ have been documented in the current literature. It may be concluded that strontium and silver do not form any oxygen-dominated compounds.

No such compounds are offered for sale commercially and no CAS numbers, involving Sr–Ag–O compounds have been issued to date.

15.2.5. Barium Silver Compounds

Barium metal forms three compounds with Ag metal, as shown in Fig. 15.68.

The Ba···Ag system was studied by thermal analysis, metallography and X-ray diffraction. Four intermediate phases were identified: $BaAg_5$ and $BaAg_2$ which melt congruently at 715 and 770 °C, respectively, and BaAg and Ba_3Ag_2 which form peritectically at 560 and 360 °C, respectively. Three eutectics were formed: between silver and $BaAg_5$ at 700 °C and 86.0 atom% Ag, between $BaAg_5$ and $BaAg_2$ at 655 °C and 76.5 atom % Ag and between Ba_3Ag_2 and barium at 340 °C and 22.0 atom% Ag.

The crystal structures of $BaAg_5$ ($CaCu_5$-type), $BaAg_2$ ($CeCu_2$-type) and BaAg (FeB-type) were confirmed. The phase Ba_3Ag_2 was found to be isotypic with Er_3Ni_2. The $BaAg_5$ phase showed a homogeneity range, the maximum width extending from $BaAg_{4.5}$ to $BaAg_7$ in the high-temperature region. The mechanism of formation for the silver-rich phases of the solid solution was studied by diffractometric investigation of a single crystal of the composition $BaAg_{6.74}$.

$BaAg_5$ has the structural form shown in Fig. 15.69.

Cell parameters are: $a = 4.612$ Å, $b = c = 5.802$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 134.50$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.29.

The selective oxidation of $BaAg_5$ has been examined at 650–680 °C in flowing 3%H_2/Ar ($PO_2 \leq 1.1 \times 10^{-19}$ atm.). Under these conditions, a continuous external barium oxide scale formed. Depletion of Ba from the underlying $BaAg_5$ led to the formation of a continuous

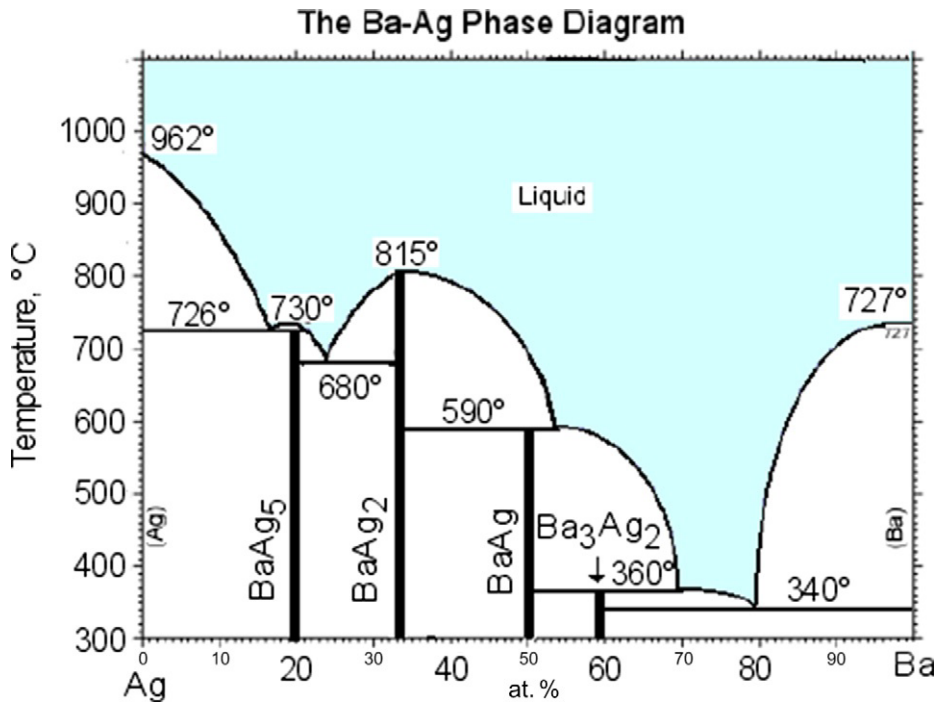

FIGURE 15.68

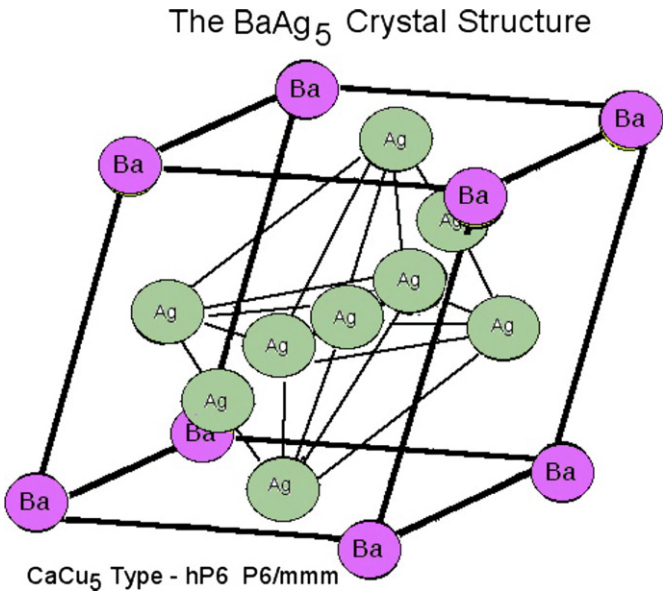

FIGURE 15.69

Ag layer between the oxide scale and the $BaAg_5$. Ba was only detected along grain boundaries in the continuous Ag layer, which was consistent with the negligible solubility reported for Ba in bulk Ag. The local thickness of the continuous Ag layer was inversely correlated to the local Ag grain size. Subsequent experiments with Ag-clad $BaAg_5$ revealed that surface oxide formation commenced at exposed Ag grain boundaries. $BaAg_5$ specimens clad with fine grained Ag foil exhibited more extensive oxide formation in a given time than specimens clad with coarse grained Ag foil. These observations confirmed that outward Ba migration through the continuous Ag layer occurred preferentially along Ag grain boundaries. This work demonstrates that an intermetallic compound may undergo external oxidation even when a continuous metallic (or intermetallic) layer, that possesses a low solubility for the oxidizable element, forms under the oxide scale.

The compound, $BaAg_2$, has the structural form shown in Fig. 15.70.

Cell parameters are: $a = 4.952$ Å, $b = c = 6.3405$ Å, $\alpha = 78.91°$, $\beta = \gamma = 67.014°$, cell volume $= 1368.53$ Å^3, $Z = 4$.

3	Ba	Ba	1	a	6/mmm	0	0	0	1.0

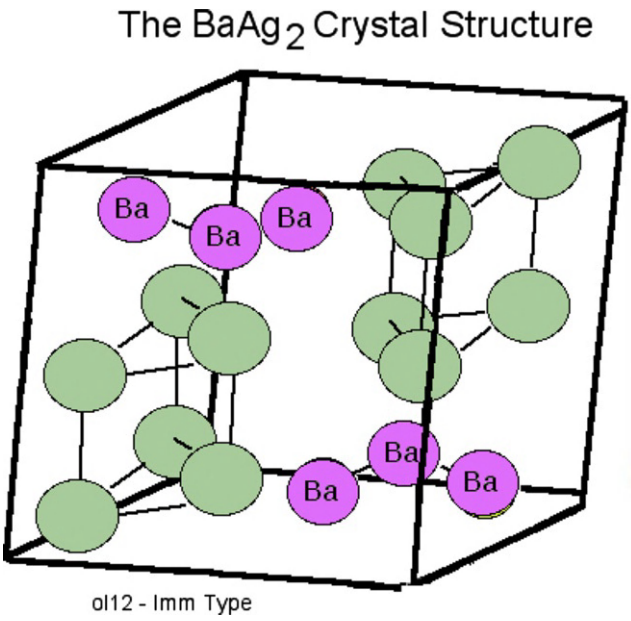

FIGURE 15.70

Cell occupancy is shown in Table 15.30.

Ba_3Ag_2 has the structure shown in Fig. 15.71.

Cell parameters are: $a = b = c = 8.802$ Å, $\alpha = \beta = \gamma = 72.30°$, cell volume $= 601.87$ Å^3, $Z = 9$. Cell occupancy is shown in Table 15.31.

The above two compounds have not been thoroughly researched in the literature and little data concerning their physical and chemical properties can be found in the current literature.

The compound, BaAg has the structural form shown in Fig. 15.72.

Cell parameters are: $a = 4.982$ Å, $b = c = 8.657$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 286.85$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.32.

No other intermetallic compounds are known. None of these intermetallic compounds are offered for sale commercially and no CAS numbers have been issued to date.

The system, $Ba_xAg_yO_z$, where x, y or z can vary from 1 to 8, does not form any barium argentite or argentate compounds. No references were found describing any compositions within this system.

15.2.6. Radium Silver Compounds

Although radium undoubtedly forms the same type of compounds as barium, there are no papers or references describing such work on intermetallics or oxygen-dominated compounds. This is due to lack of interest in Industry and Academia concerning such compounds and the high cost of Ra metal or RaO.

15.3. ALKALINE EARTH GOLD COMPOUNDS

Gold has the valence states of: −1, 0, +1, + 2, +3, +4 and +5 but Au(I) and Au(III) dominate its chemistry. Au(I), referred to as the aurous ion, is the most common oxidation state. Very few, if any, oxygen-dominated compounds form with the alkaline earths but a few intermetallic compounds are known.

15.3.1. Beryllium Gold Compounds

Be metal forms six compounds with gold metal as shown in Fig. 15.73.

Two of these compounds are not stable at room temperature. In addition, only one of these compounds, BeAu, has structural data available, and its diagram is shown in Fig. 15.74.

Cell parameters are: $a = b = c = 4.668$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 101.72 Å^3, $Z = 4$. Cell occupancy is shown in Table 15.33.

No further data are available concerning this compound.

A compound not shown in the phase diagram, Be_5Au, is stated to have the structure shown in Fig. 15.75.

The structure is cubic with Au atoms at face-centered positions in the unit cell.

Cell parameters are: $a = b = c = 4.313$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 56.75 Å^3, $Z = 4$. Cell occupancy is shown in Table 15.34.

A compound, $Be_{12}Au$, is also not listed in the phase diagram but has the structure shown in Fig. 15.76.

Cell parameters are: $a = 4.252$ Å, $b = c = 5.5453$ Å, $\alpha = 81.55°$, $\beta = \gamma = 67.46°$, cell volume = 111.53 Å^3, $Z = 2$. Cell occupancy is shown in Table 15.35.

No structural data are available for the following compounds:

$BeAu_3$
$BeAu_2$
Be_3Au
Be_4Au
Be_3Au_4

The only work concerning these compounds was contained in the paper that illustrated the phase diagram. No further endeavors have appeared in the open literature and these are the only known Be–Au compounds known to date.

In the BeO–Au_xO_y system, where x or y can be 1, 2 or 3, no compounds are known. BeO does not form any stable oxy-aurite compounds and no papers concerning such compounds exist in the current literature.

15.3.2. Magnesium Gold Compounds

Magnesium metal forms a number of intermetallic compounds with gold. The phase diagram has the form shown in Fig. 15.77. The diagram is incomplete in that the melting points of some of the compounds were not given.

A number of compounds are shown but data regarding these compounds are sparse.

The compound, $MgAu_{16}$, has the structure shown in Fig. 15.78.

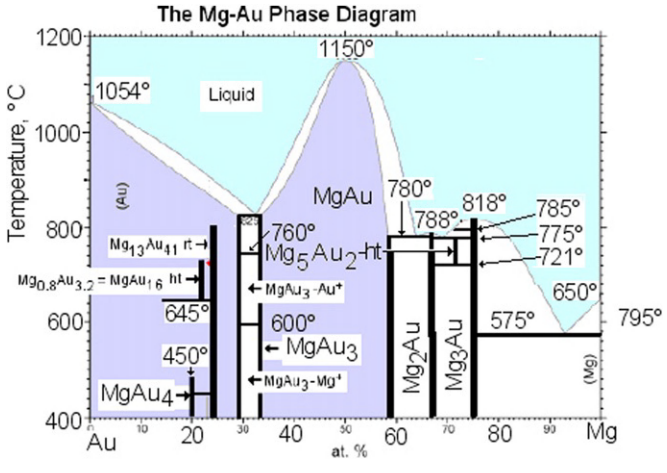

FIGURE 15.77

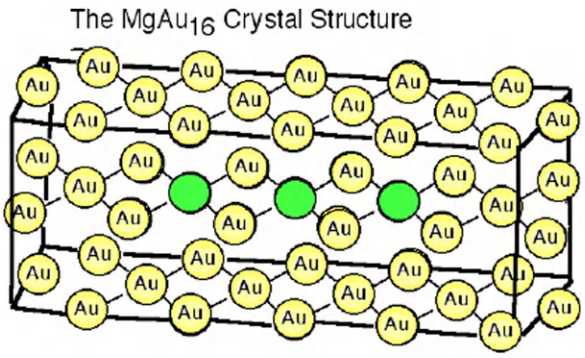

FIGURE 15.78

Although the Mg atoms are shown at specific sites in the unit cell, they actually are scattered randomly throughout the structure.

Cell parameters are: $a = b = 4.073$ Å, $c = 8.644$ Å, $\alpha = \beta = 103.63°$, $\gamma = 90°$, cell volume = 135.20 Å^3, $Z = 4$, cell occupancy is shown in Table 15.36.

The compound, $Mg_{13}Au_{41}$, has the structural form shown in Fig. 15.79.

Cell parameters are: $a = 9.441$ Å, $b = c = 14.927$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 1,821.77 Å^3, $Z = 2$. Cell occupancy is shown in Table 15.37.

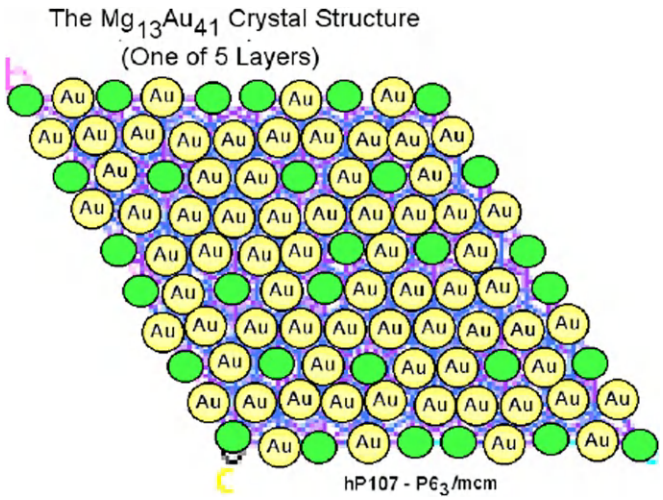

FIGURE 15.79

The compound, Mg_2Au, has the unit-cell structure shown in Fig. 15.80.

Cell parameters are: $a = 8.253$ Å, $b = 13.561$ Å, $c = 18.328$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 2,051.25 Å^3, $Z = 2$. Cell occupancy is shown in Table 15.38.

The compound, Mg_3Au, has the structure shown in Fig. 15.81.

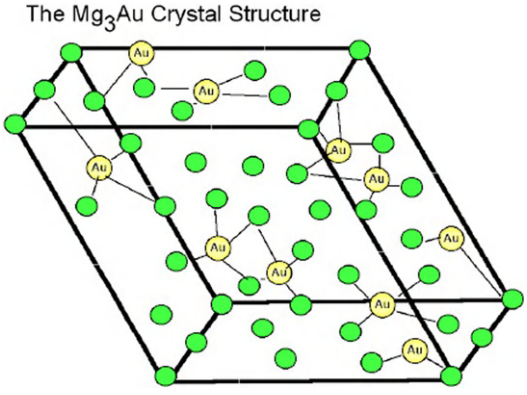

FIGURE 15.81

Cell parameters are: $a = b = c = 8.0594$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 477.02$ Å^3, $Z = 6$. Cell occupancy is shown in Table 15.39.

The MgAu compound has the structural form shown in Fig. 15.82.

Cell parameters are: $a = b = c = 3.272$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 34.97$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.40.

The compound, $MgAu_3$, has the structure shown in Fig. 15.83. Only the top and side layers are shown. The full structure consists of a 5 by 5 matrix of these layers.

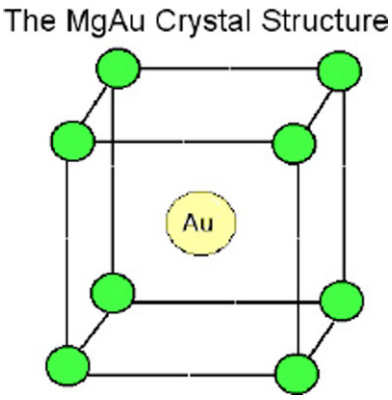

FIGURE 15.82

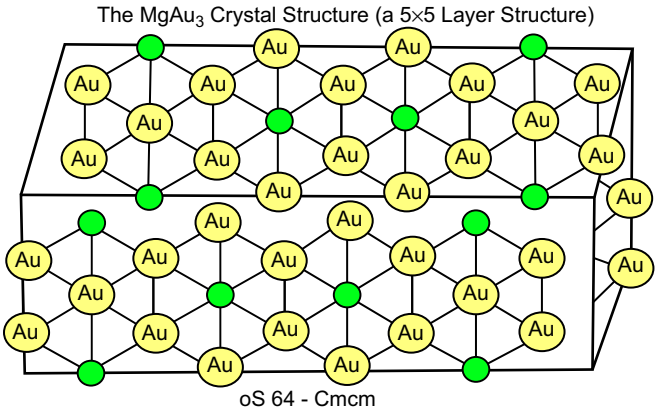

FIGURE 15.83

Cell parameters are: $a = 5.747$ Å, $b = 9.437$ Å, $c = 10.381$ Å, cell volume $= 540.99$ Å^3, $Z = 16$. Cell occupancy is shown in Table 15.41.

Another form of $MgAu_3$ is shown in Fig. 15.84.

These two compounds are probably the $MgAu_3$–Au^+ and $MgAu_3$–Mg^+, respectively, as shown in the phase diagram.

Cell parameters are: $a = 5.742$ Å, $b = 10.322$ Å, $c = 23.592$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 1342.55 Å^3, Z = 40. Cell occupancy is shown in Table 15.42.

Although $MgAu_4$ and Mg_2Au_5 are shown in the phase diagram, there are no data concerning their properties or structure in the current technical literature. No other Mg–Au intermetallic compounds are known. Mg_2Au is offered for sale commercially with a CAS number of 12399-98-2.

In the MgO–Au_xO_y system, where x or y can be 1, 2 or 3, no compounds have been discovered or documented in the current literature. No compounds are known. MgO does not form any stable oxy-aurite compounds and no papers concerning such compounds exist in the current literature.

15.3.3. Calcium Gold Compounds

Calcium forms several intermetallic compounds with gold. In one seminal paper, the Ca–Au binary system has been assessed with a CALPHAD approach based on experiment information about phase diagram and thermodynamic properties. The excess Gibbs energies of the solution phases including liquid, bcc and fcc were formulated with Redlich–Kister polynomial functions. The intermetallic compounds $CaAu_5$, $CaAu_3$, $CaAu_2$, CaAu, Ca_4Au_3, Ca_5Au_3 and Ca_2Au were treated as stoichiometric phases. Self-consistent thermodynamic parameters were obtained and the

calculated results agreed well with literature data (Table 15.43).

The phase diagram presented is shown in Fig. 15.85.

A total of 13 compounds have been documented. At least nine structures of these intermetallic compounds have been published while the structures of Ca_2Au, Ca_5Au, Ca_3Au and Ca_4Au_5 have not been solved. Very little literature exists to date concerning these compounds.

Eight appear in the phase diagram while five (Ca_5Au_2, Ca_5Au_3, Ca_5Au_4, Ca_2Au_3 and $CaAu_3$) do not. A total of four appear in both the phase diagram and structural data published in the current literature.

TABLE 15.43

Compound	ΔH_f (kJ/mol)	ΔS (J/mol)	ΔG_f (kJ/mol)	Temp (K)
$CaAu_5$	-41	-4.0	-37.0	900
$CaAu_3$	-66.0	-13.0	-54.0	900
$CaAu_2$	-87.1	-23.3	-68.2	900

Ca_5Ag_3	—	—	-87.6	900
Ca_4Au_3	—	—	-87.7	900
Ca_2Au	—	—	-86.5	900

The compound, Ca_2Au, has received some attention in the literature. The local meta-GGA exchange correlation density functional (TPSS) with a relativistic effective core potential was employed to systematically investigate the geometric structures, stabilities, and electronic properties of bimetallic Ca_2Au_n ($n = 1$–9) and pure gold Au_n ($n \leq 11$) clusters. The optimized geometries show that the most stable isomers for Ca_2Au_n clusters have 3D structure when $n \geq 2$, and that one Au atom capping the Ca_2Au_{n-1} structure for different-sized Ca_2Au_n ($n = 1$–9) clusters is the dominant growth pattern. The average atomic binding energies and second-order difference in energies show that the Ca_2Au_4 isomer is the most stable among the Ca_2Au_n clusters. The same pronounced even–odd alternations are found in the HOMO–LUMO gaps, VIPs, and hardnesses. The polarizabilities of the Ca_2Au_n clusters show an obvious local minimum at $n = 4$. Moreover, the inverse corrections to the polarizabilities versus the ionization potential and hardness were found for the gold clusters.

Ca_5Au_3 is tetragonal (Cr_5B_3 type), space group $I4/mcm$, with $a = 7.867$ and $c = 14.39$ Å.

Ca_3Au has the structure shown in Fig. 15.86.

Cell parameters are: $a = 6.784$ Å, $b = 7.795$ Å, $c = 10.004$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 528.50$ Å^3, $Z = 4$. Cell occupation is shown in Table 15.44.

The compound, CaAu, has the structural form shown in Fig. 15.87.

Cell parameters are: $a = 3.961$ Å, $b = 4.576$ Å, $c = 5.881$ Å, $\alpha = \gamma = 90°$, $\beta = 109.68°$, cell volume $= 100.37$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.45.

The compound, $CaAu_2$, has the structure shown in Fig. 15.88.

3	Au	Au	4	c	.m.	0.3786	1/4	0.4483	1.0

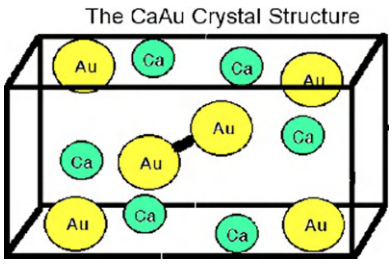

FIGURE 15.87

Cell parameters are: $a = 4.611$ Å, $b = c = 5.841$ Å, $\alpha = 74.45°$, $\beta = \gamma = 66.75°$, cell volume $= 131.63°$, $Z = 2$. Cell occupancy is shown in Table 15.46.

Brittle single crystals of $CaAu_2$ and $SrAu_2$ were synthesized by the reaction of alkaline earth metals and gold powder at 750 °C. The structures were determined from X-ray single-crystal diffractometer data:

$CaAu_2$: *Imma*, $Z = 4$, $a = 4.611(1)$ Å, $b = 7.067(2)$ Å, $c = 8.079(2)$ Å, $R/Rw(w = 1) = 0.069/0.071$ for 248 structure factors with F_o^2 $3(F_o^2)$ and 11 variables.

$SrAu_2$: *Imma*, $Z = 4$, $a = 4.732(2)$ Å, $b = 7.484(2)$ Å, $c = 8.165(3)$ Å, $R/Rw(w = 1) = 0.032/0.038$ for 542 structure factors with F_o^2 $3(F_o^2)$ and 12 variables.

Both compounds crystallize with the KHg_2 ($CeCu_2$) structure type. The structures consist of 3D gold frameworks with a trigonal pyramidal $3 + 1$ coordination for each gold atom. Calcium and strontium occupy channel-like cavities within the gold partial structures.

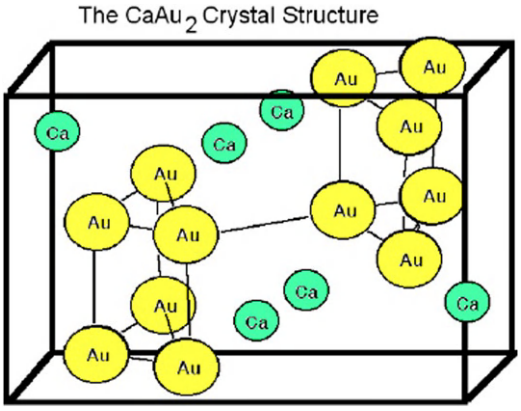

FIGURE 15.88

In contrast, the compound, Ca_3Au_4, has the structure shown in Fig. 15.89.

Cell parameters are: $a = 5.9084$ Å, $b = c = 8.1709$ Å, $\alpha = 114.38°$, $\beta = \gamma = 103.85°$, cell volume $= 321.77$ Å^3, $Z = 6$. Cell occupancy is shown in Table 15.47.

A new intermetallic in the Ca–Au phase field has been synthesized, using an unusual high-pressure route, with the stoichiometry Ca_3Au_4. The structure of the intermetallic compound was investigated using powder X-ray and powder neutron diffraction techniques. Ca_3Au_4 adopts the Pu_3Pd_4 structure type, which crystallizes in the rhombohedral space group R containing 42 atoms in a hexagonal unit cell.

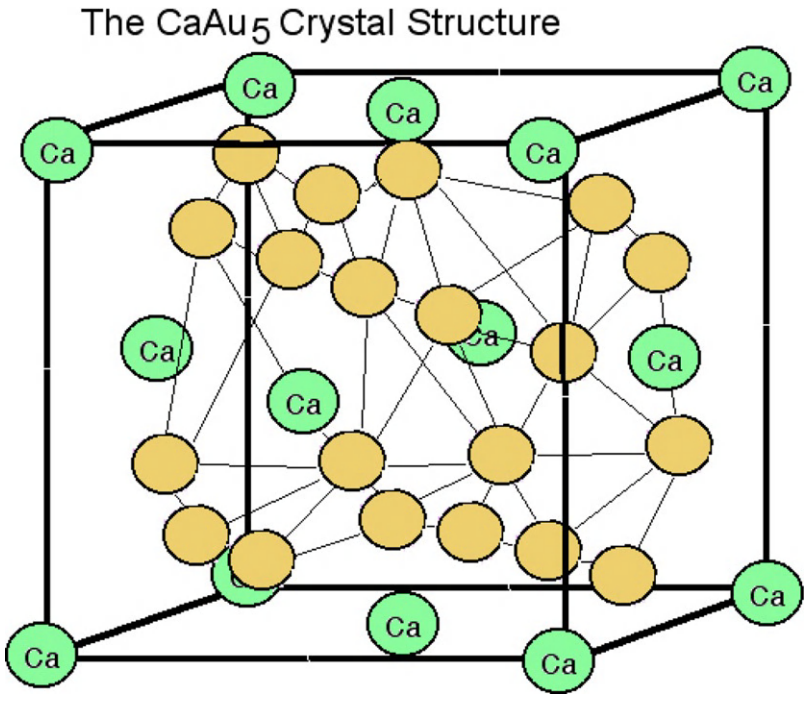

FIGURE 15.90

The following phases appear in the phase diagram but their structures have not been determined:

Ca_2Au, Ca_4Au, Ca_5Au, and Ca_4Au_5

In contrast, the opposite occurs in that following phases do not appear in the phase diagram, but their structures have appeared in the technical literature:

$CaAu_5$, Ca_5Au_2, Ca_5Au_3, Ca_5Au_4 and Ca_7Au_2

$CaAu_5$ has the structure shown in Fig. 15.90.

Cell parameters are: $a = b = c = 5.478$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 116.24$ Å^3, $Z = 6$. Cell occupancy is shown in Table 15.48.

The compound, Ca_5Au_2, has the structural form shown in Fig. 15.91.

Cell parameters are: $a = 6.809$ Å, $b = 7.746$ Å, $c = 9.090$ Å, $\alpha = 96.73°$, $\beta = 111.99$ Å, $\gamma = 90°$, cell volume $= 440.98$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.49.

3	Ca(1)	Ca	8	f	1	0.408	0.1094	0.0791	1.0
4	Ca(3)	Ca	4	e	2	0	0.0783	1/4	1.0

The compound, Ca_5Au_3, has the structure shown in Fig. 15.92.

Cell parameters are: $a = b = 7.867$ Å, $c = 9.095$ Å, $\alpha = \beta = 115.63°$, $\gamma = 90°$, cell volume = 445.30 Å^3, $Z = 4$. Cell occupancy is shown in Table 15.50.

Ca_5Au_3 is tetragonal (Cr_5B_3 type), space group *I*4/*mcm*, with $a = 7.867$ and $c = 14.39$ Å. First principles density functional calculations were carried out to probe the oxidation states of the transition metal and alkaline earth elements in the Cr_5B_3-type compounds which has a general formula AE_5T_3 consisting of T_2 dimers and isolated T atoms. Typical compositions are: Ca_5Au_3, Ca_5Ag_3, Ca_5Hg_3, Sr_5Cd_3, and Ca_5Zn_3. The electronic structures of all these AE_5T_3 compounds are best described as $[(AE^{2+})_5(T–T)^{4–}(T^{2–})]+4e^-$. In the covalent bonding of the AE^{2+} ions with the transition metal anions T^{2-}, the $(n–1)$d orbitals of AE^{2+} contribute more than the *n*s and *n*p orbitals of AE^{2+}.

The compound, Ca_5Au_4, has the structure shown in Fig. 15.93.

Cell parameters are: $a = 7.727$ Å, $b = 8.019$ Å, $c = 8.028$ Å, $\alpha = \gamma = 90°$, $\beta = 109.16°$. Cell volume = 469.88 Å^2, $Z = 2$. Cell occupancy is shown in Table 15.51.

Another view of this structure is shown in Fig. 15.94.

Coordination polyhedron around the M–M dimers in the Ca_5Au_4 structure can be seen in Fig. 15.95.

The dark blue spheres form a trigonal biprism, and the light blue spheres cap its four rectangular faces. The coordination polyhedra surrounding a M_2 dimer are Au_2Ca_{12} in Ca_5Au_4. In the crystal structure of Ca_5Au_4 planar $CaAu(1)_2$ layers, which are isostructural with the $YbAg_2$ layers of Yb_3Ag_2, alternate with $Ca_4Au(2)_2$ slabs. The Au atoms are also present as Au_2 dimers with short interatomic distance, i.e. Au(1)-Au(1)) = 285 pm and Au(2)-Au(2)) = 296 pm.

The chemical bonding of the M_2 dimers (M = Ag, Au, Hg) present in Yb_3Ag_2, Ca_5Au_4 and Ca_3Hg_2 was examined on the basis of first principles electronic band structure calculations. In these compounds, the 6s- and 5d-block bands of M are completely filled while the frontier levels of M are given by partially filled 6p-block bands such that the transition metal atoms M are best described as anions with electron configuration (5d) 10(6s)2(6p)1. Thus, the M_2 dimers (M = Ag, Au, Hg) of Yb_3Ag_2, Ca_5Au_4 and Ca_3Hg_2 are present as $[Ag–Ag]_4$, $[Au\text{-}Au]_4$, and $[Hg\text{-}Hg]_2$ Zintl anions, respectively. It is these compounds in which the M_2 dimers have a single bond formed by the p–p_4 interaction between the 5p and 6p orbitals of M atoms. The anions of late transition metal elements are different from those of late main group elements in their tendency for covalent bond formation.

Two novel intermetallic compounds have been synthesized and structurally studied by single-crystal diffractometer data: Ca_7Au_3 (*oP*80, space group *Pbca*, $a = 20.742$, $b = 18.036$, $c = 6.665$ Å, $Z = 8$, $R = 0.051$) and Ca_5Au_4 (*mP*18, space group $P21/c$, $a = 8.028$, $b = 8.019$, $c = 7.727$ Å, $\beta = 109.16°$, $Z = 2$, $R = 0.104$). Both atomic arrangements, which represent new structural types, are based on Au-centered Ca trigonal prisms and are geometrically related to the Th_7Fe_3 and Pu_5Rh_4 structures.

The compound, Ca_7Cu_3, has the structure shown in Fig. 15.96. Only one layer is shown. The 3D structure has two layers in the tetragonal structure.

The cell parameters are: $a = 6.665$ Å, $b = 18.036$ Å, $c = 20.742$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 2493.39 $Å^3$, $Z = 8$. Cell occupancy is shown in Table 15.52.

No other intermetallic compounds have been documented. Several intermetallic compounds like Ca_2Au (CAS = 90992-80-2) are offered for sale commercially.

In the Au^+- or Au^{2+}-containing systems of CaO–Au_2O or CaO–AuO, no compounds are known.

The compound, $CaAu_2O_4$, in the Au^{3+}-containing system of CaO–Au_2O_3, has been reported. The compound was prepared as yellowish-green powder from a 1:1 molar CaO–Au_2O_3 mixture of oxides when heated at high pressure and temperature (>70 MPa and 845 °C). Single crystals of $CaAu_2O_4$ crystallize in

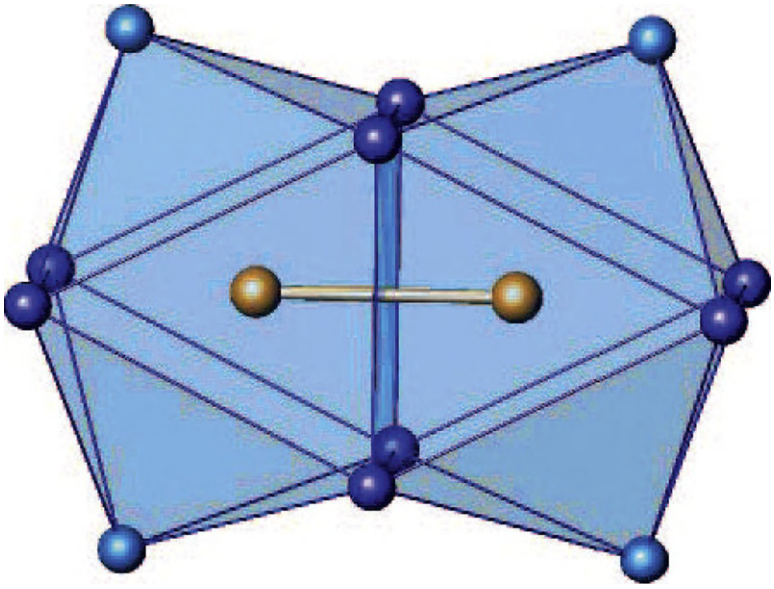

FIGURE 15.95

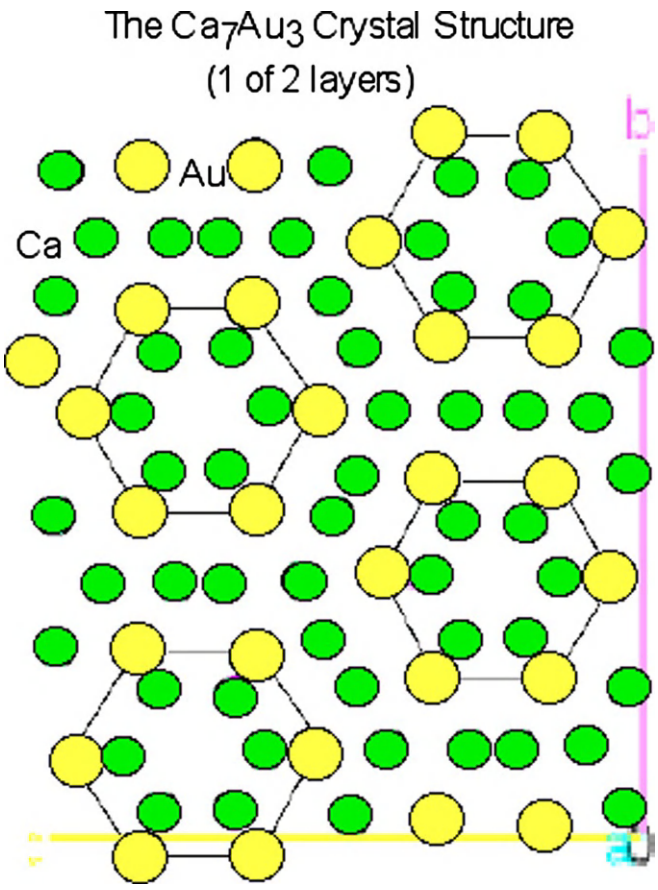

FIGURE 15.96

the tetragonal space group $I41/a$ with $Z = 4$. To date, only two studies have been made of this compound (1995 and 2010).

No other compounds are known in the CaO–Au_xO_y system, where x or y can be 1, 2 or 3. No compounds, such as oxygen-dominated calcium aurite or aurate, are offered commercially and no CAS numbers have been issued to date.

15.3.4. Strontium Gold Compounds

Strontium metal forms several compounds with gold, as shown in Fig. 15.97.

Six compounds are shown. Of these, five have had their structure elucidated and a sixth, Sr_2Au_3, is not shown in the phase diagram but has had its structure established. One compound in the phase diagram, $SrAu_9$, remains to have its structural characteristics documented.

The crystal structure of the phases, strontium–silver (Sr_3Ag_2), calcium–gold (Ca_5Au_3), strontium–gold (Sr_7Au_3), and strontium–silver (Sr_7Ag_3) has been determined. Sr_3Ag_2 is rhombohedral (Er_3Ni_2 type), space group $R3$, with a 9.962 and c 18. 93509-33-2 is the CAS registry number. Sr_7Au_3 is hexagonal (Th_7Fe_3 type), space group $P63mc$, with $a = 11.07$ and $c = 7.161$ Å. Sr_3Ag_2 is rhombohedral (Er_3Ni_2 type), space group $R3$, with a 9.962 and c 18. 93509-33-2 is the CAS registry number of Sr_3Ag_2.

$SrAu_5$ has the structure shown in Fig. 15.98.

Cell parameters are: $a = 4.615$ Å, $b = c = 5.627$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 126.55$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.53.

$SrAu_2$ has the structure shown in Fig. 15.99.

Cell parameters are: $a = 4.732$ Å, $b = c = 6.022$ Å, $\alpha = 76.83°$, $\beta = \gamma = 66.87°$, cell volume $= 144.58$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.54.

Brittle single crystals of $SrAu_2$ were synthesized by the reaction of alkaline earth metals and gold powder at 750 °C. The structure was determined from X-ray single-crystal diffractometer data. $SrAu_2$: *Imma*, $Z = 4$, $a = 4.732(2)$ Å, $b = 7.484(2)$ Å, $c = 8.165(3)$ Å, $R/Rw(w = 1) = 0.032/0.038$ for 542 structure factors with

F_o^2 $3\sigma(F_o^2)$ and 12 variables. This compound crystallizes with the KHg_2 ($CeCu_2$) structure type. The structure consists of 3D gold frameworks with a trigonal pyramidal (3 + 1) coordination for each gold atom. Strontium occupies channel-like cavities within the gold partial structures.

SrAu has the structure shown in Fig. 15.100.

Cell parameters are: $a = 4.697$ Å, $b = 6.192$ Å, $c = 4.013$ Å, $\alpha = 94.21°$, $\beta = \gamma = 90°$, cell volume = 1163.98 Å^3, $Z = 20$. Cell occupancy is shown in Table 15.55.

Sr_3Au_2 has the structure shown in Fig. 15.101.

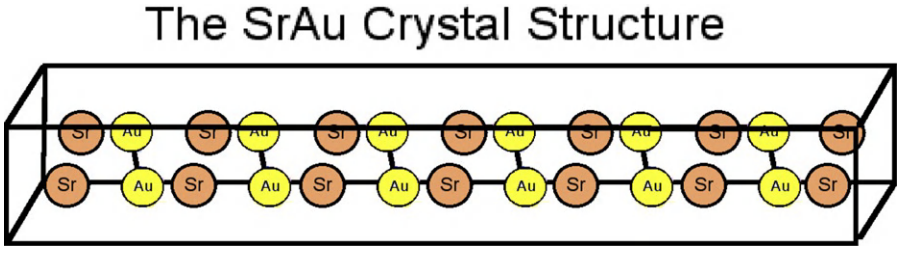

FIGURE 15.100

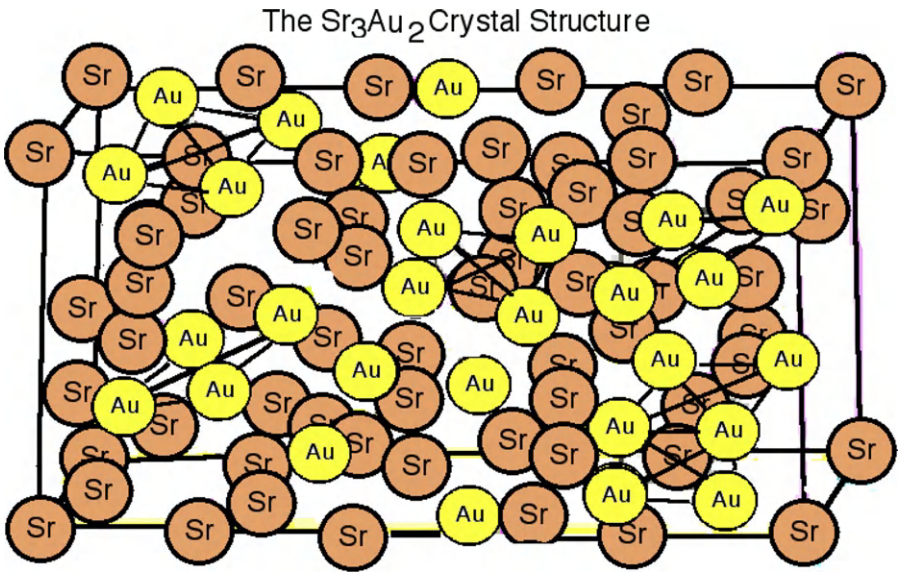

FIGURE 15.101

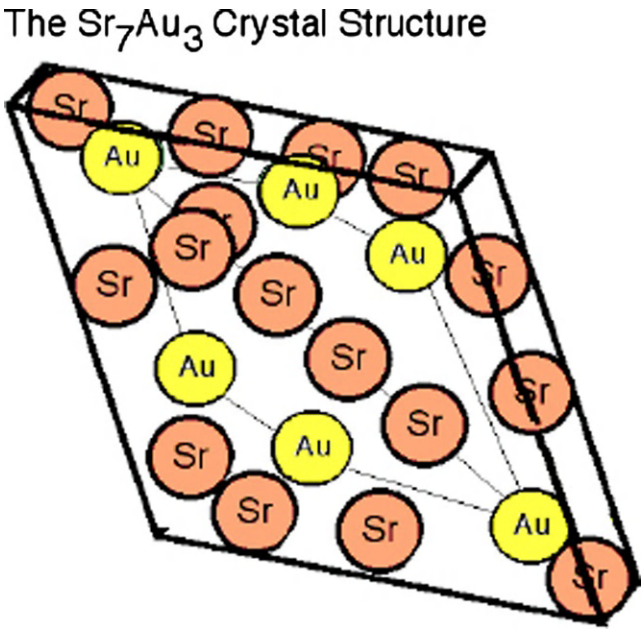

FIGURE 15.102

Cell parameters are: $a = b = c = 8.2583$ Å, $\alpha = \beta = \gamma = 71.11°$, cell volume $= 488.85$ Å^3, $Z = 9$. Cell occupancy is shown in Table 15.56.

The compound. Sr_7Au_3, has the structure shown in Fig. 15.102.

Cell parameters are: $a = 7.161$ Å, $b = c = 11.072$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 759.98$ Å^3, $Z = 5$. Cell occupancy is shown in Table 15.57.

No other intermetallic compounds have been discovered or documented.

In the Au^+- or Au^{2+}-containing systems of SrO–Au_2O or SrO–AuO, no compounds have been documented in the literature. The Au^{3+}-containing system of SrO–Au_2O_3 has been studied.

Two aurates, $BaAu_2O_4$ and $SrAu_2O_4$, have been prepared as polycrystalline greenish-brown powders from alkaline earth peroxides and elemental Au by applying an elevated oxygen pressure (gold tubes, $T = 873$–923 K, $p(O_2) = 333$ MPa, 3d). Single crystals of $BaAu_2O_4$ were obtained by adding a 3% aqueous hydrogen peroxide solution and decreasing the temperature to 823 K, with otherwise similar conditions. X-ray single-crystal structure determination on $BaAu_2O_4$ led

to the tetragonal space group $I41/a$ (No. 88) with four formula units per unit cell, which has the dimensions $a = 6.4297$ Å and $c = 10.251$ Å. The crystal structure was determined and refined to a final R value of 1.88% using 240 unique reflections. The crystal structure of the isotypic $SrAu_2O_4$ was refined by full profile analysis of powder X-ray diffraction data ($a = 6.1830$ Å, $c = 10.1704$ Å, $I41/a$, $Z = 4$, $R_I = 5.88\%$, and $R_{Pr} = 8.93\%$). Both aurates(III) are isostructural with $LaPd_2O_4$ and contain square planar AuO_4 units which are stacked along [100] and [001] planes and connected to a 3D framework by common corners. The alkaline earth ions are coordinated by eight oxygen atoms to form slightly distorted dodecahedra. The aurates(III) are diamagnetic and decompose under normal atmosphere at temperatures above 773 K.

The hitherto unknown compound, $Sr_5Au_2O_8$, was prepared by the reaction of an Sr/Au alloy with $Sr(OH)_2$ in closed silver tubes. The crystal structure was determined by means of an X-ray single-crystal investigation. $Sr_5Au_2O_8$ forms orthorhombic crystals: space group D_2^7-$F222$; $a = 11.7449$ Å; $b = 11.7407$ Å; $c = 6.5155$ Å; $Z = 4$. The O^{2-} ions are coordinated in a quadratic planar arrangement around Au^{3+} and as a distorted cube around Sr^{2+}.

No other compounds are known in the $SrO–Au_xO_y$ system, where x or y can be 1, 2 or 3. No compounds, such as oxygen-dominated strontium aurite or aurate, are offered commercially and no CAS numbers have been issued to date.

15.3.5. Barium Gold Compounds

Ba metal forms at least four compounds with gold metal. The phase diagram illustrates the nature of these phases (Fig. 15.103).

$BaAu_5$ has the structure shown in Fig. 15.104.

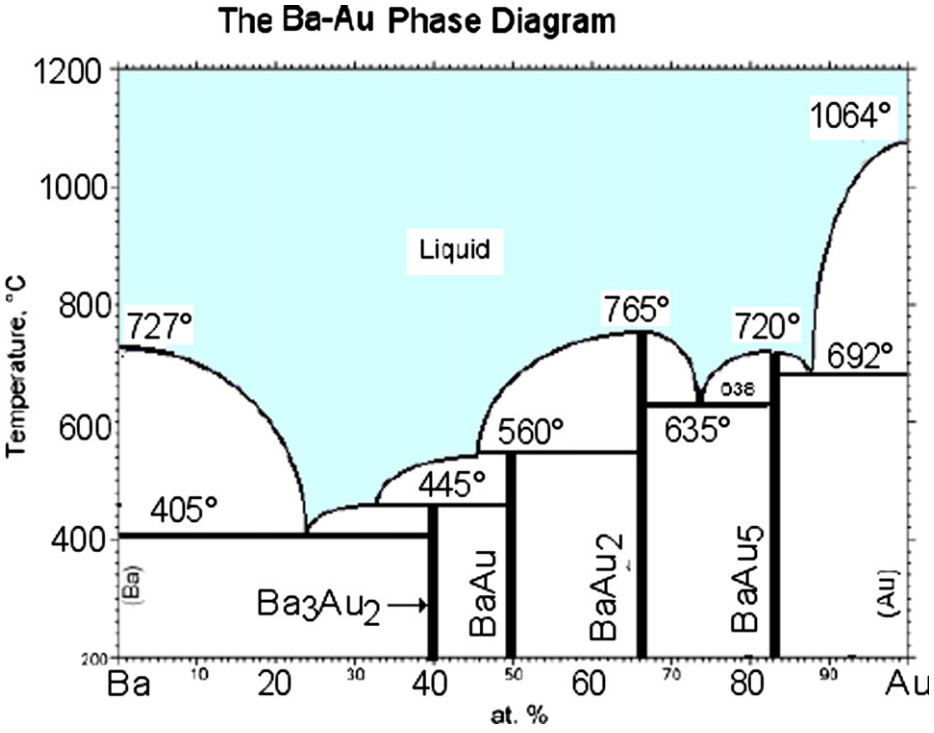

FIGURE 15.103

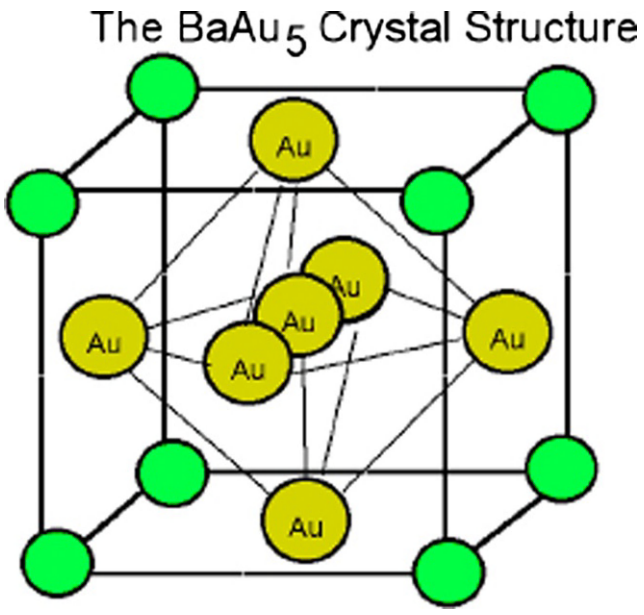

FIGURE 15.104

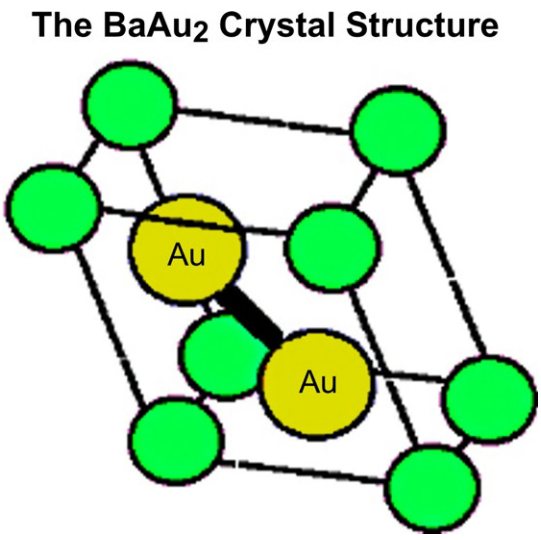

FIGURE 15.105

Cell parameters are: $a = 4.542$ Å, $b = c = 5.693$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 127.35$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.58.

The compound, $BaAu_2$, has the structural form shown in Fig. 15.105.

Cell parameters are: $a = 4.119$ Å, $b = c = 4.804$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 82.32$ Å^3, $Z = 1$. Cell occupancy is shown in Table 15.59.

BaAu has the structure shown in Fig. 15.106.

Cell parameters are: $a = 4.925$ Å, $b = 6.392$, $c = 8.338$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 262.32$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.60.

Four of these hitherto unknown Ba–Au phases, $BaAu_5$, BaAu, $BaAu_2$ and Ba_3Au_2 are isotypic with the corresponding silver compounds. Ba_3Au_2 has the structural form shown in Fig. 15.107.

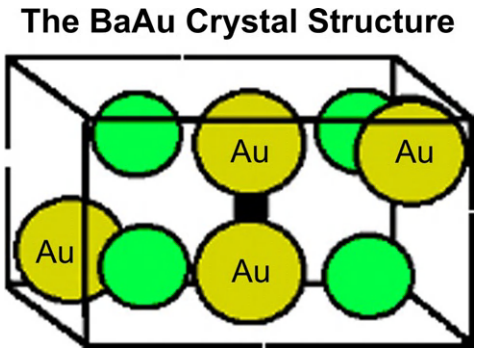

FIGURE 15.106

Cell parameters are: $a = b = c = 8.6056$ Å, $\alpha = \beta = \gamma = 71.052°$, cell volume $= 552.71$ Å^3, $Z = 8$. Cell occupancy is shown in Table 15.61.

The hitherto unknown compound Ba_4AgAuO_6 was prepared by oxidizing Ba/Au/Ag alloy with BaO_2/$Ba(OH)_2$ mixture in closed Ag tubes. X-ray single-crystal investigation led to orthorhombic symmetry space group *D-Cmcm*; $a = 13.275$, $b = 5.782$, $c = 11.396$ Å, $Z = 4$. Ba_4AgAuO_6 shows distorted pentagonal bipyramidal polyhedra around Ba^{2+} and square planar AuO_4 polygones. Ag^+ shows an unusual $2 + 2$ coordination by O^{2-}.

Another barium aurate compound, $Ba_9Au_2O_{12}$, has been discovered. It has the structure shown in Fig. 15.108.

Only one layer is shown. There are three intermediate layers in the *b*-direction having the same arrangement of atoms. $Ba_9Au_2O_{12}$ was prepared by oxidizing Ba–Au alloy with BaO_2 in sealed gold tubes. X-ray single-crystal investigation indicated orthorhombic symmetry, space group D_{2h}^{16}-*Pnam*, with Au^{3+} coordinated with square planar polygons of O^{2-}. There are five different Ba–O polyhedra.

Cell parameters are: $a = 7.133$ Å, $b = 14.093$ Å, $c = 17.165$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 1725.52$ Å^3, $Z = 4$. Cell occupancy is shown in Table 15.62.

No other Ba–Au–O compounds are known. None of the above compounds are offered for sale commercially and no CAS numbers have been issued to date.

15.3.6. Radium Gold Compounds

Although Ra metal or radium oxide probably forms the same type of compounds with Au_2O or Au_2O_3 as Ba^0 or BaO, there is no record in the literature of anyone having done so.

16.1. ALKALINE EARTH ZINC COMPOUNDS

Zn forms a few intermetallic (IM) compounds with the alkaline earths. There are also a few "zincate" compounds known.

16.1.1. Beryllium Zinc Compounds

Be does not form any IM compounds with Zn metal as shown in Fig. 16.1.

In the Be–Zn–O system, no "zincate" compounds have been documented to date.

16.1.2. Magnesium Zinc Compounds

Mg forms a series of IM compounds with Zn metal as shown in Fig. 16.2.

Five compounds are shown, but only $MgZn_2$ melts congruently. The others melt incongruently at relatively low temperatures.

Phase layer growth and interdiffusion in the binary Mg–Zn system was investigated utilizing solid-to-solid diffusion couples annealed at 295, 315 and 325 °C for 21, 7 and 5 days, respectively. The diffusion microstructure was examined by scanning electron microscopy and concentration profiles were determined using X-ray energy dispersive spectroscopy and electron microprobe analysis. The Mg solid solution, Mg_2Zn_{11}, $MgZn_2$ and Mg_2Zn_3 in all three couples were observed in addition to the high temperature, $Mg_{51}Zn_{20}$ phase at 325 °C. The $MgZn_2$ phase was observed to grow the thickest layer, followed by the Mg_2Zn_3 and the Mg_2Zn_{11} phases. Activation energies for the parabolic growth were calculated to be 105 kJ/mol and 207 kJ/mol for the Mg_2Zn_3 and $MgZn_2$, respectively. Relevant interdiffusion coefficients were calculated for the phases present by analyses of concentration profiles.

In the Mg–Zn binary system, as the composition goes from magnesium- to zinc-side, there are stoichiometric compounds of $Mg_{48}Zn_{52}$, Mg_2Zn_3, $MgZn_2$ and

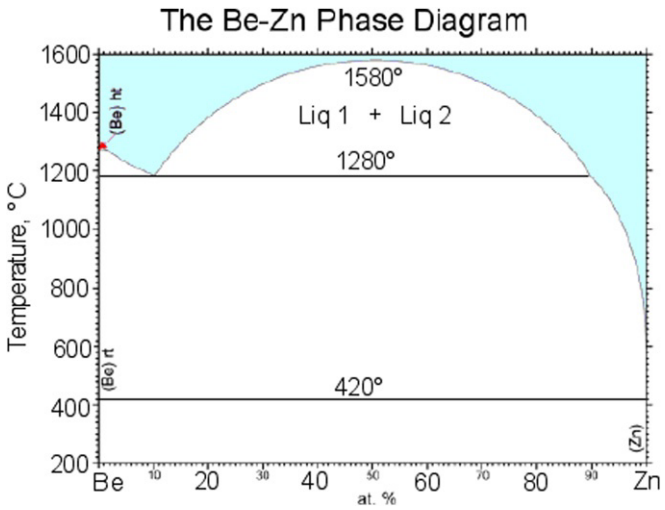

FIGURE 16.1

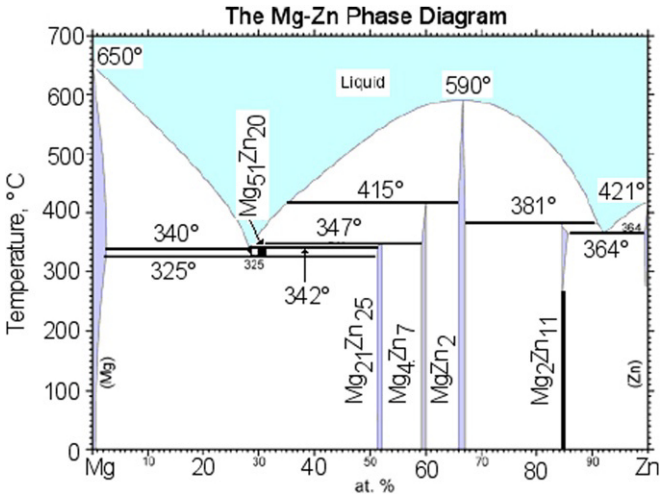

FIGURE 16.2

Mg_2Zn_{11}. Their valence bands are composed of Mg electrons spread over the crystal as if they are nearly free electrons in pure magnesium and localized Zn-3d electrons. The electronic states for the IM compounds, $Mg_{48}Zn_{52}$, Mg_2Zn_3, $MgZn_2$ and Mg_2Zn_{11} in the Mg–Zn binary system were investigated by measuring the coefficients, **g**, of the electronic contribution to the heat capacities and calculating the densities of states (DOS) in the vicinities of the Fermi levels (EF) by the DV-Xa molecular orbital method. The g value of Mg_2Zn_{11} was found to be nearly equal to that of pure Zn while the g value of $Mg_{48}Zn_{52}$ and Mg_2Zn_3 was similar to that of pure Mg. The g value of $MgZn_2$ was comparable to the simple compositional average of the g values of pure Mg and Zn. Such g values probably result from the localization or de-localization of valence electrons, consistent with the DOS theoretically

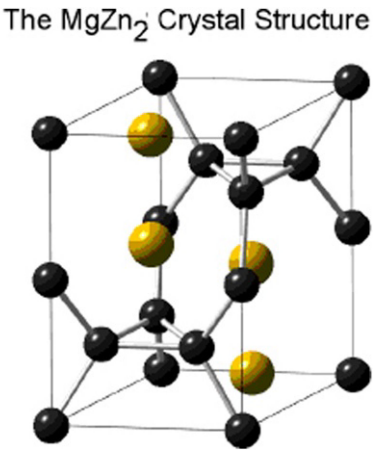

FIGURE 16.3

calculated by the DV-Xa molecular orbital method. The combined use of the measured g and the calculated DOS are expected to provide an important method to clarify electronic states of substances as thermal spectroscopy.

$MgZn_2$ has the structural form shown in Fig. 16.3.

Cell parameters are: $a = b = 5.2234$ Å, $c = 8.5562$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 202.17$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.1.

A considerable amount of work has been accomplished concerning the C16 type of Laves-phase $MgZn_2$ compound because of its formation when steel, corrosion-proofed by zinc plating, is exposed to seawater. In addition, interest in the Laves phases has grown recently due to their promising behavior as solid-state hydrogen storage materials. They also have interesting magnetic and electrical properties. The Laves phase structures ($MgCu_2$, $MgZn_2$ and $MgNi_2$ types) are adopted by a large number of binary IM compounds of composition AB_2. These phases belong to the class of tetrahedral close-packed alloys. Two of the structural features of the Laves phases which have aroused interest are, firstly the dependence of the structure adopted (especially the choice between the cubic $MgCu_2$ and hexagonal $MgZn_2$ types) on the number of valence electrons of the constituent metal atoms and, secondly the structural distortions observed in a number of the hexagonal $MgZn_2$ type phases. By performing extended Hückel band calculations on model, AB_2 compounds with both the cubic and hexagonal structures and on the B sub-nets alone, structure electron count and deformation electron count correlations can be derived. These correlations depend on the highly peaked nature of the DOS of the Laves phases, primarily due to the B network.

The $MgCu_2$ type structure (*Strukturbericht* symbol C15) is face-centered cubic, belonging to the space group $Fd3m$ (O_h^7) with eight formula units per non-primitive

TABLE 16.1

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	x	y	z	Occupancy
1	Zn2	Zn	6	h	mm2	0.1697	0.3394	1/4	1.0
2	Mg	Mg	4	f	3m.	1/3	2/3	0.563	1.0
3	Zn1	Zn	2	a	-3m.	0	0	0	1.0

cubic unit cell. The *A*-sublattice of the $MgCu_2$ structure defines a cubic diamond net, while the *B*-sublattice can be described in terms of B_4 tetrahedra sharing all of their vertices in such a way that each pair of fused tetrahedra adopts a staggered conformation.

The $MgZn_2$ type structure (*Strukturbericht* symbol C14) is hexagonal, belonging to the space group *P*63/*mmc* (D^4_{6h}) with four formula units per unit cell. The *A*-sublattice of the $MgZn_2$ structure defines a hexagonal diamond net. The *B*-sublattice is composed of B_4 tetrahedra, though their arrangement is distinct to that in $MgCu_2$. The tetrahedra alternately share vertices and faces along the *c*-axis, thereby forming chains of epically fused trigonal bipyramids. These chains are linked together by vertex sharing in the *ab* plane.

The $MgNi_2$ type structure (*Strukturbericht* symbol C36) also belongs to the hexagonal space group *P*63/*mmc* (D^4_{6h}), though it possesses eight formula units per unit cell. The $MgNi_2$ structure is a composite of the $MgCu_2$ and $MgZn_2$ structures.

The $MgZn_2$ crystal was found to have hexagonal axes with $a = 5.15$ and $c = 8.48$ Å. The unit cell contains four molecules. Crystals of the compound were formed by melting together the calculated amounts of magnesium and zinc under a molten mixture of sodium and potassium chlorides to prevent oxidation. The melt was then allowed to cool slowly in the electric furnace, about 4 h being taken to cool from 10° above to 10° below the melting point of the compound, 595 °C. The least distance between two magnesium atoms is 3.16 Å, between two zinc atoms, 2.52 Å, and between a magnesium and a zinc atom, 3.02 Å. The values computed from the atomic radii of magnesium and zinc determined from the crystal structure are respectively 3.22 Å, 2.67 Å, and 2.95 Å.

The single-crystalline elastic constants of the Laves phase $Mg(Cu,Zn)_2$ have been determined by the ultrasonic pulse-echo technique over the temperature range 4.2–298 K and over the composition range 10–51 mol% $MgZn_2$. The compositional dependence of the elastic contents indicates that a changing electron concentration causes initial contact and then a subsequent overlap of a Brillouin zone boundary by the Fermi surface. This contact occurs near 20 mol% $MgZn_2$ and correlates with previous measurements of magnetic susceptibilities and of specific heats. Debye temperatures at 0 K were also determined from the experimental values of the elastic constants.

The C14 Laves-phase $MgZn_2$ was investigated from 30 to 36 atom% Mg. This allowed measurement of chemical disorder that was monitored over a limited concentration range so that the influence on electron properties could be investigated. These studies included thermodynamic calculations of atomic configurations of Mg and Zn at off-stoichiometric compositions, electronic transport measurements, and electronic band structure calculations of $MgZn_2$. The disorder introduced by alloying was found to be substitutional for all C14 alloys, and to have a markedly stronger effect on resistivity and magnetoresistance, $\Delta p(B)/p(0)$, on the Mg-rich side due to strain introduced when Mg substitutes for Zn. $p(T)$ and Hall constant were characteristic for weakly disordered binary alloys. $\Delta p/p$ of $MgZn_2$ was large, reached 6 at 4.2 K and 8 T, and decreased strongly at off-stoichiometric compositions. The results were discussed in view of the band structure results and in terms of relations between atomic order and electronic properties. Several properties were found to resemble pure Zn. An empirical correlation over more than six orders of magnitude in $\Delta p/p$ was found for Zn and Zn-based alloys.

If the compound, $MgZn_2$, is subjected to high temperature and pressure, this Laves phase transforms by diffusion-controlled reaction at the $MgZn_2$ surface of the nanoparticles according to: $8\ MgZn_2 \Rightarrow 2\ Mg_4Zn_7 + O_2$. Isothermal aging of plastically deformed Mg–Zn alloys resulted in precipitation along the {1012} twin boundaries. The bulky precipitates so formed had structures similar to those recently reported for the rod-like β_1 precipitates, but allowed a more detailed study by high-resolution TEM due to their larger size. The core of the precipitates often had the structure of the monoclinic Mg_4Zn_7 phase, and had the orientation, $[0001]_{Mg}//[010]$; $\{1010\}_{Mg}//(201)$, with either the matrix or the twin. On this Mg_4Zn_7 phase, the hexagonal $MgZn_2$ phase grew in two directions, both with $[010]_{Mg4Zn7}//[1120]_{MgZn2}$ orientations. One of these orientations formed a known orientation relationship, $[0001]_{Mg}//[1120]_{MgZn2}$ or $\{1120\}_{Mg}//(0001)_{MgZn2}$ with the matrix. The part of the precipitate with the $MgZn_2$ structure was usually in direct contact with the twin boundary. Both the Mg_4Zn_7 and $MgZn_2$ phases have layered structures that can be described as similar building blocks of

icosahedrally coordinated atoms. The atomic positions of zinc atoms comprise the vertices of these icosahedra and form "thick" rhombic tiles. The orientations of these rhombuses remain unchanged across the interfaces between the two phases. Near the interface with $MgZn_2$, transition structures formed in the Mg_4Zn_7 phase with the Zn:Mg atom ratio between those of the Mg_4Zn_7 and $MgZn_2$ phases. In these transition structures, the unit cell of the Mg_4Zn_7 phase is extended along [100] or [001] by half a unit cell length by continuation of the rhombic tiling.

The compound, $Mg_{51}Zn_{20}$, has the structure shown in Fig. 16.4.

Both the *a*-*c* plane and the *a*-*b* planes of the three dimensional (3D) structure are shown. The black lines show how the structure is divided into parts, with layers of Mg atoms and layers of Zn atoms.

Cell parameters are: $a = b = c = 12.2971$ Å, $\alpha = \beta = 107.828°$, $\gamma = 11046°$, cell volume $= 1430.57$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.2.

The structure of the pseudo-cubic $Mg_{51}Zn_{20}$ phase, which is related to icosahedral quasicrystals, was interpreted as a modulated crystal. It essentially comprises distorted close-packed layers with ordered atomic vacancies. The basic reciprocal lattice vectors point to the vertices of a distorted icosahedron. The crystal structure of $Mg_{51}Zn_{20}$, a phase designated conventionally as "Mg_7Zn_3" has been determined by the single-crystal X-ray diffraction (XRD) method. It was solved by the examination of a Patterson synthesis, and refined by the ordinary Fourier and least squares method; the *R* value obtained was 4.8% for 1167 observed reflections. The crystal is orthorhombic, space group *Immm*, with $a = 14.083$, $b = 14.486$, $c = 14.025$ Å, and $Z = 2$. There are 18 independent atomic sites, Zn1–Zn6, Mg1–Mg10, A, and B, and the last two sites are statistically occupied by Zn and Mg atoms with the occupancies; 0.46-Zn7 + 0.52-Mg11 and 0.24-Zn8 + 0.74-Mg12, for A and B, respectively. The structure of the crystal is described as an arrangement of icosahedral coordination polyhedra, to which all the atomic sites but Zn3 site belong. In this arrangement, the Zn atoms other than the Zn3 and Zn8(B) center the icosahedral coordination polyhedra with coordination number 12. The Zn3, Zn8 atoms, and all the Mg atoms except Mg11(A) are located at the centers of various coordination polyhedra with the coordination numbers from 11 to 15. The distances between neighboring atoms are 2.71–3.07, 2.82–3.65, and 2.60–3.20 Å for Zn–Zn, Mg–Mg, and Zn–Mg, respectively.

The hydrogen absorption capacity of the $Mg_{51}Zn_{20}$ IM compound was investigated. The equilibrium pressures at 300, 330 and 380 °C were found to be 3.6, 8.05 and 31.0 atm., respectively. The highest hydrogen content in $Mg_{51}Zn_{20}$ corresponds to the nominal composition $Mg_{51}Zn_{20}H_{95}$ (3.62 wt% hydrogen). Evidence of MgH_2 formation in the hydrided material was found.

The atomic structure of amorphous $Mg_{70}Zn_{30}$ alloy and the structural change in the crystallization process under isothermal annealing were studied by EXAFS and XRD. The results of both measurements show that atoms begin to take short-range and long-range order of $Mg_{51}Zn_{20}$ crystal during the crystallization process under isothermal annealing.

The compound, Mg_2Zn_{11}, has the structure shown in Fig. 16.5.

Cell parameters are: $a = b = c = 8.5521$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 625.37$ Å^3 $Z = 8$.

Cell occupancy is shown in Table 16.3.

Mg_2Zn_{11} can be seen as an intermediate step in structural complexity between the simple Laves-phase $MgZn_2$ on one side, and the complex 1/1 approximation and quasicrystals Zn(Mg)Al and Zn(Mg)Sc on the other. The structure can be described as a cubic packing of a triacontahedron whose center is partially occupied by a Zn atom. This partially occupied site turned out to play a major role in understanding the lattice dynamics. Data from inelastic neutron scattering demonstrated a Van Hove singularity in the vibrational spectrum of Mg_2Zn_{11} for energy as low as 4.5 meV, which is a unique feature for a nearly close-packed metallic alloy. This

corresponds to a gap opening at the Brillouin zone boundary and an interaction between a low-lying optical branch and an acoustic one, as could be deduced from the dispersion relation measured by inelastic X-ray scattering. Second, the measured phonon DOS exhibits many maxima, indicating strong mode interactions across the whole energy range. The origin of the low-energy modes in Mg_2Zn_{11} and other features of the vibrational spectra were studied carefully, using both ab initio and empirical potential calculations. A detailed analysis of vibrational eigenmodes was presented, linking features in the vibrational spectrum to atomic motions within the structural building blocks.

The Gibbs–Thomson coefficient and solid–liquid interfacial energy of the solid Mg_2Zn_{11} phase in equilibrium with Zn–Mg eutectic liquid have been determined to be $(3.3 \pm 0.2) \times 10^{-8}$ Km and $(20.8 \pm 2.1) \times 10^{-3}$ J/m^2 from the equilibrated grain boundary groove shapes with a numerical model. The grain boundary energy of the solid Mg_2Zn_{11} phase has been calculated to be $(40.9 \pm 4.5) \times 10^{-3}$ J/m^2 by considering a force balance at the grain boundary grooves. The thermal conductivity ratio of the eutectic Zn–Mg liquid phase to the solid Mg_2Zn_{11} phase has also been found to be 0.81.

The Mg_4Zn_7 compound has the structure shown in Fig. 16.6.

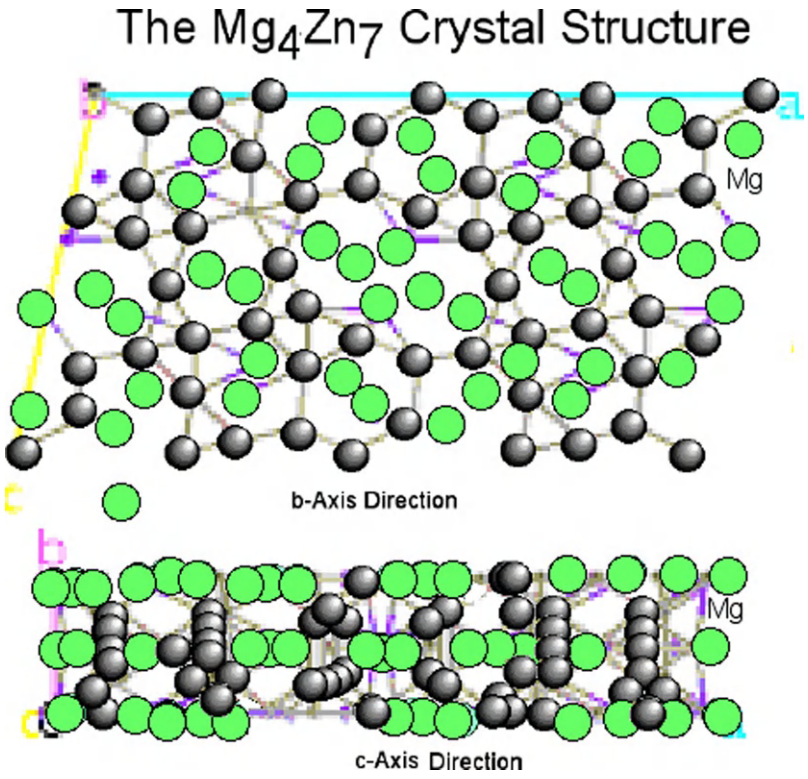

FIGURE 16.6

As shown in the *c*-axis slice of the 3D structure, there are three layers of Mg atoms holding the Zn atoms together. The *b*-axis part of the 3D structure shows the relationship of the Zn atoms to the Mg atoms in the structure.

Cell parameters are: $a = 5.242$ Å, $b = 13.242$ Å, $c = 14.284$ Å, $\alpha = 102.25°$, $\beta = 90°$, $\gamma = 101.41°$, cell volume $= 948.23$ Å^3, $Z = 10$. Cell occupancy is shown in Table 16.4.

The Frank-Kasper family, characterized by tetrahedral close packing, includes the compound, Mg_4Zn_7. Constraints of close packing dictate that only special atomic environments with triangulated coordination shells occur, namely $Z = \{12,14,15,16\}$ with 12–16 nearest neighbors surrounding the central atom. Icosahedral quasicrystal Frank-Kasper phases are represented by prototype $Al_6Mg_{11}Zn_{11}$ (cI162) while the Mg_4Zn_7 (mC110) phase is an approximant of a decagonal quasicrystal. The Laves phase of $MgZn_2$ (hP12) may be viewed as a common approximation for both quasicrystal Frank–Kasper families. The quasicrystal Frank-Kasper structures are pseudo-binary, in that large atoms (e.g. Mg) center highly coordinated polyhedra ($Z = 14$, 15 or 16) while smaller atoms (e.g. Al or Zn) have icosahedral $Z = 12$ coordination. In both icosahedral and decagonal structures about 60% of the atoms are of the smaller $Z = 12$ coordinated type.

The structure of the compound, Mg_2Zn_3, has been examined. However, the finalized structure is not yet documented. This compound was not included in the phase diagram. Cell parameters are: $a = 5.31$ Å, $b = 11.65$ Å, $c = 14.45$ Å, $\alpha = 81.9°$, $\beta = 84°$, $\gamma = 84.0°$, cell volume $= 875$ Å^3, Z is not given.

The compound, $Mg_{21}Zn_{25}$, is included in the phase diagram, but its structure has not been elucidated.

No other Mg–Zn IM compounds have been discovered to date.

In the Mg–Zn–O system, few compounds have been discovered. For example, the instability of such compounds does not allow the direct preparation of any compounds from the oxides themselves. However, the use of organic complexes has allowed the formation of a semiconducting composition, $Mg_xZn_{1-x}O$. The synthesis and characterization of the first hetero-bimetallic methylzinc–magnesium alkoxide clusters $[Me_6MgZn_6(OR)_8]$ [R = Et (**1-a**), *n*-Pro (**1-b**), *n*Bu (**1-c**)] with a bis-cubane-shaped $MgZn_6O_8$ core has been described. The thermal degradation of 1-a to c and mixtures of 1-a and the homo-metallic MeZn–alkoxide cubane [{MeZnOtBu}$_4$] in dry synthetic air led to wide-band gap semiconducting $Mg_xZn_{1-x}O$ nanoparticles at temperatures below 500 °C. The final materials were characterized by different analytical techniques such as PXRD, REM, TEM, EDX, and IR spectroscopy. The morphology of the as-prepared magnesium-containing ZnO samples is influenced by the different organo groups (alkoxo) in the precursors. EDX mapping showed that magnesium is uniformly distributed in the ZnO matrix. The incorporation of magnesium led to a distortion of the ZnO lattice with an increased *a*-axis and decreased *c*-axis parameters. Room temperature photoluminescence (PL) spectra reveal that the near-band edge emission of Mg^{2+}-doped ZnO is shifted to higher energies relative to that of pure ZnO. Combinations of ZnO with MgO form wurtzite solid solutions for Mg concentrations up to 30%, resulting in an increase in optical band gap to 3.9 eV. At Mg concentrations above 45%, rock salt $Mg_{1-x}Zn_xO$ solid solutions are stabilized for deposited thin films, and can be tailored in band gap in the deep-ultraviolet range between 4.8 eV for x 0.55 up to 7.8 eV for MgO. ZnO is polymorphic and it is known to exist in two cubic structures. Stabilization of a rock salt ZnO phase can be achieved by the application of external pressure.

No other compounds have been documented in the literature. No magnesium zincate compositions are offered for sale commercially and no CAS numbers have been issued to date.

16.1.3. Calcium Zinc Compounds

Calcium forms a number of IM compounds with Zn metal. The phase diagram is shown in Fig. 16.7.

The Ca–Zn system displays eight intermediate compounds, with pronounced maxima in the liquidus at Zn-rich concentrations. The available experimental phase diagram data have been reviewed by Itkin and Alcock. Their reported diagram is based mainly on the DTA measurements of Messing et al., but with

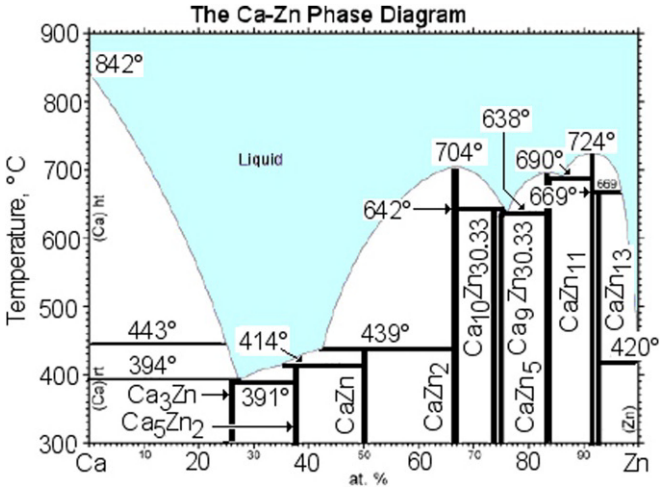

FIGURE 16.7

modification of the compounds, Ca_7Zn_4 and Ca_7Zn_{20} to Ca_5Zn_3 and $CaZn_3$ based on later crystallographic information. Very limited amounts of experimental data have been found in the literature for the Ca–Zn system. Because of the high vapor pressure of the Ca–Zn alloys above 50 atom% Zn, Messing et al. used vapor effusion measurement for compound identification. They reported eight intermediate stoichiometric compounds: Ca_3Zn, Ca_7Zn_4, CaZn, 2, Ca_7Zn_{20}, $CaZn_5$, $CaZn_{11}$ and $CaZn_{13}$. Apart from $CaZn_2$, $CaZn_5$ and $CaZn_{11}$, all compounds undergo peritectic decomposition. Later on, the compounds Ca_7Zn_4 and Ca_7Zn_{20} were replaced with the formulas, Ca_5Zn_3 and $CaZn_3$, respectively, based on the more accurate crystallographic investigations of Bruzzone et al. and Fornasini and Merlo. Thermodynamic data were determined (Table 16.5).

TABLE 16.5

High-pressure forms of IM compounds with the composition $CaZn_2$, $SrZn_2$, $SrAl_2$, and $BaAl_2$ were synthesized from $CeCu_2$-type precursors ($CaZn_2$, $SrZn_2$, $SrAl_2$) and $Ba_{21}Al_{40}$ by multi-anvil techniques and investigated by X-ray powder diffraction ($SrAl_2$ and $BaAl_2$), X-ray single-crystal diffraction ($CaZn_2$), and electron microscopy ($SrZn_2$). Their structures correspond to that of Laves phases. Whereas the dialuminides crystallize in the cubic $MgCu_2$ (C15) Laves structure, the dizincides adopt the hexagonal $MgZn_2$ (C14) structure. This trend is in agreement with the structural relationship displayed by sp bonded Laves phase systems at ambient conditions.

$CaZn_2$ has the structure shown in Fig. 16.8.

Cell parameters are: $a = 4.5911$ Å, $b = c = 5.7813$ Å, $\alpha = 78.773°$, $\beta = \gamma = 66.606°$, cell volume $= 129.17$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.6.

$CeCu_2$-type polar IMs can be transformed to Laves phases upon simultaneous application of pressure and temperature. The observed structures are controlled by the valence electron concentration, as shown in Fig. 16.9. This trend is in agreement with the structural relationship displayed by sp bonded Laves phase systems at ambient conditions.

$CaZn_{13}$ has the structure shown in Fig. 16.10.

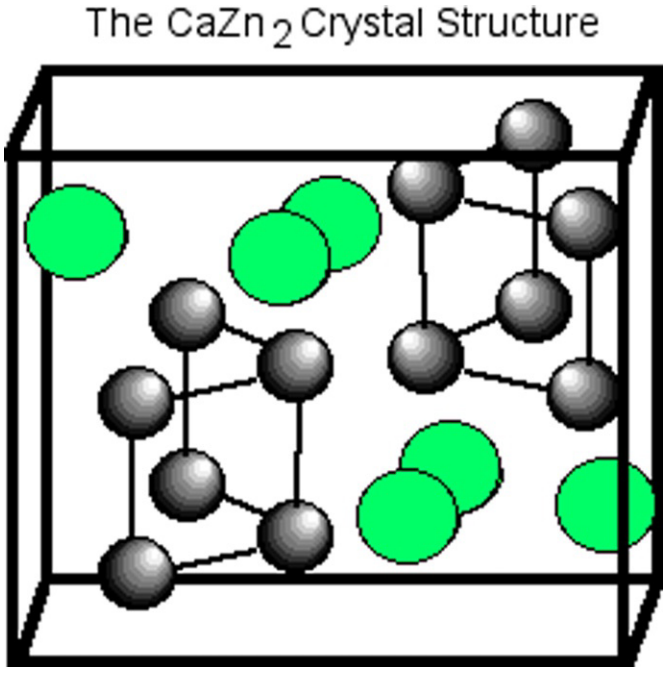

FIGURE 16.8

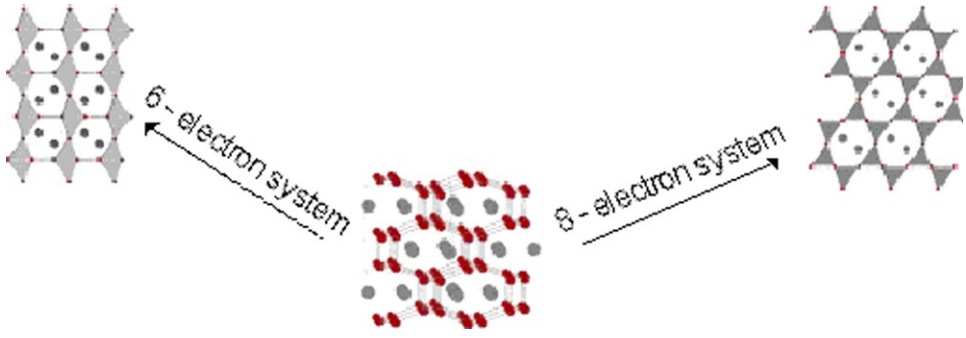

FIGURE 16.9

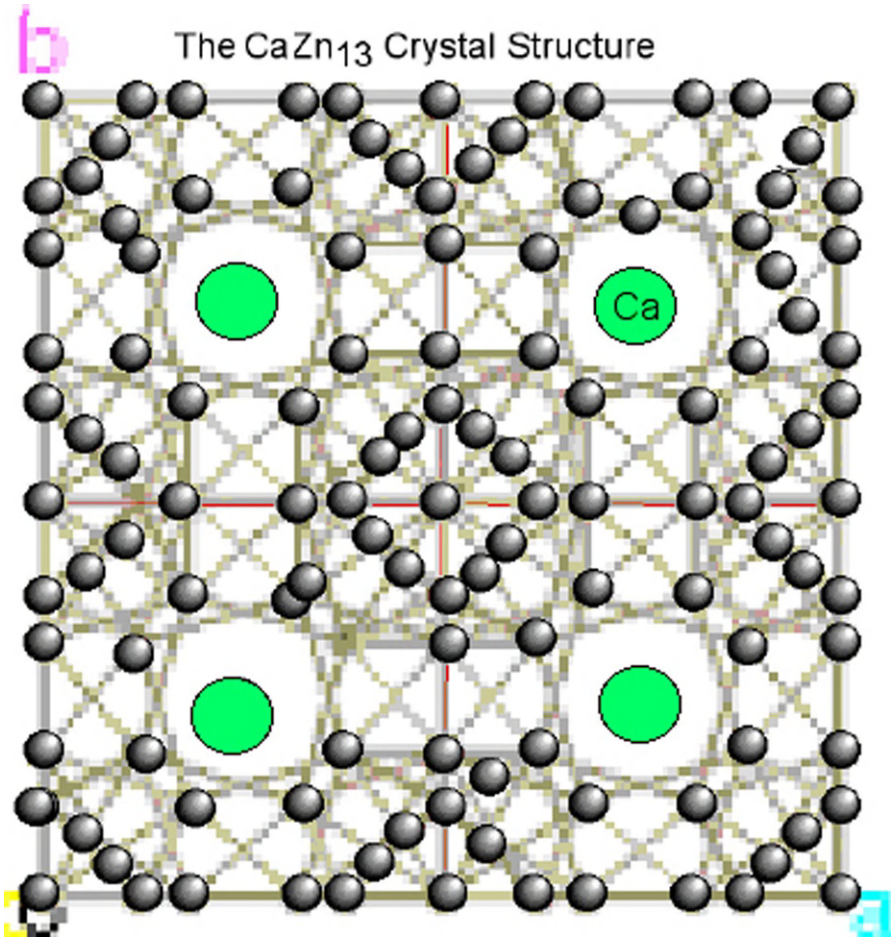

FIGURE 16.10

The Ca atoms lie within channels in the structure, one Ca atom per unit cell. A total of four units are shown here in this *a*-*c* plane. In the *b*-direction, there are layers of Zn atoms between the channels so that this diagram represents eight unit cells in a 3D structure. Cell parameters are: $a = b = c = 8.65641$ Å, $\alpha = \beta = \gamma = 60°$, cell volume = 458.67 Å^3, $Z = 8$. Cell occupancy is shown in Table 16.7.

The compound, $CaZn_5$, has the crystal structure shown in Fig. 16.11.

Cell parameters are: $a = 4.242$ Å, $b = c = 5.370$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 105.98 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.8.

$CaZn_5$ is supplied commercially with the CAS number: 12258-72-9. The eutectic 7.3:2.7 molar ratio mixture of calcium and zinc metal melts at 394 °C and was explored as a solvent for the growth of new IM phases for potential use as hydrogen storage materials. The reaction of nickel in this molten mixture produces two new phases—the $CaCu_5$-related structure $CaNi_2Zn_3$ ($P6/mmm$, $a = 8.9814$ Å, $c = 4.0665$ Å) and a new cubic structure (Fd–$3m$, $a = 21.5051(4)$ Å). The structure determined was shown in Fig. 16.12.

In this diagram, the features include:

(a) The $CaNi_2Zn_3$ structure type; the $CaCu_5$ substructure is indicated by a dashed unit cell.
(b) The coordination environments of the two calcium sites in this structure.

In contrast, the cubic structure is much more complicated and is shown in Fig. 16.13 and Table 16.9.

TABLE 16.8

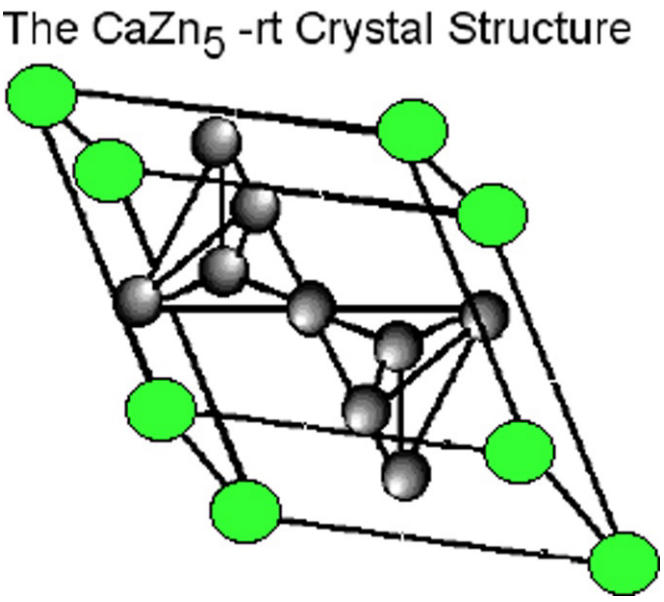

FIGURE 16.11

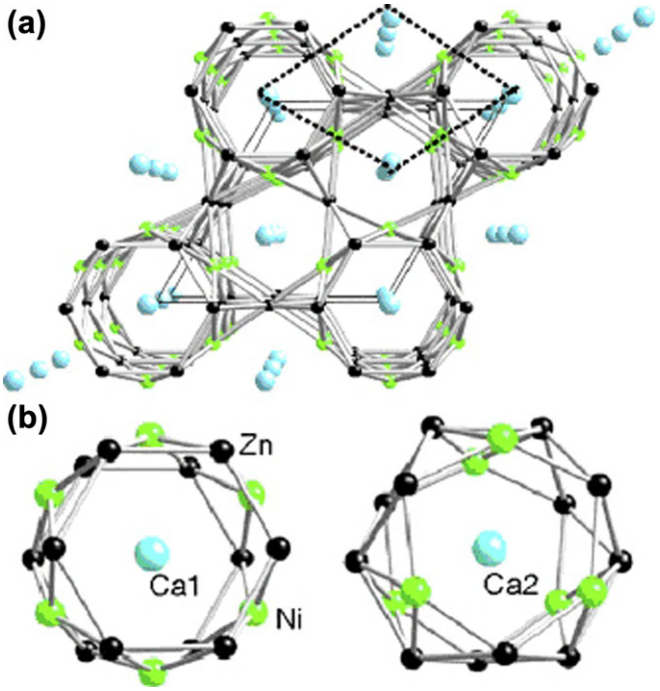

FIGURE 16.12

The zinc-rich compounds in the binary systems with the heavier alkaline earth elements, $CaZn_{11}$ and $CaZn_5$, have been synthesized from melts of the elements. Their crystal structures have been refined based on modern single-crystal X-ray data. $CaZn_5$ (hexagonal, space group $P6/mmm$, $a = 5.3899$, $c = 4.2456$ Å, $Z = 1$, $R1 = 0.0144$) crystallizes with the $CaCu_5$ structure type and exhibits a small but distinct phase width $Ca_{1-x}Zn_{5+2x}$ up to a composition of $Ca_{0.87}Zn_{5.26}$ ($a = 5.3338$, $c = 4.3004$ Å, $R1 = 0.0170$) achieved through a gradual substitution of Ca by Zn_2 dumbbells. The high-temperature form of $SrZn_5$, which was prepared by quenching of melted samples, also adopts the ideal $CaCu_5$ structure type ($a = 5.54.1$, $c = 4.28.2$ Å, $R1 = 0.0314$).

The room temperature modification of $SrZn_5$ (orthorhombic, space group $Pnma$, $a = 13.133$, $b = 5.299$, $c = 6.697$ Å, $Z = 4$, $R1 = 0.0349$) forms a singular structure, whereas the Ba compound of corresponding composition (orthorhombic, space group $Cmcm$, $a = 10.783$, $b = 8.398$, $c = 5.320$ Å, $Z = 4$, $R1 = 0.0281$) crystallizes with a third, also rather uncommon structure. For the compound $CaZn_{11}$ ($BaCd_{11}$ structure type; tetragonal, space group $I41/amd$, $a = 10.6811$, $c = 6.8281$ Å, $Z = 4$, $R1 = 0.0299$) the originally proposed structure type was confirmed and also refined using single-crystal data. The chemical bonding in all these compounds was analyzed using FP-LAPW band structure methods. Together with geometrical criteria and observed valence electron numbers of isotypic compounds, the results were used to compare and discuss the stability of the different structures of the IM phases in the systems AZn_5 and AM_{11} (M = Zn, Cd, Hg).

$CaZn_{11}$ has the structure shown in Fig. 16.14.

Cell parameters are: $a = 6.832$ Å, $b = c = 8.304$ Å, $\alpha = 8.026°$, $\beta = \gamma = 65.31°$, cell volume = 390.98 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.10.

Little is known concerning this compound.

The Ca_3Zn compound has the crystal structure shown in Fig. 16.15.

Cell parameters are: $a = 4.152$ Å, $b = 6.496$ Å, $c = 10.186$ Å, $\alpha = 107.38°$, $\beta = \gamma = 90°$, cell volume = 280.22 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.11.

Ca_3Zn was found to crystallize with the Re_3B type of structure (space group, $Cmcm$ and $Z = 4$). The structure was refined with anisotropic temperature factors using single-crystal diffractometer data to an R value of 0.022. Single-crystal examination showed that CaZn crystallizes with the CrB type of structure (space group, $Cmcm$ and $Z = 4$).

TABLE 16.9

The $Ca_{21}Ni_2Zn_{36}$ structure type

(d) This view highlights the hexakaidecahedron of calcium sites, encapsulating the triangles of Zn3 atoms and the Ca4 site in comparison to the contents of the Mg26 hexakaidecahedron of $Mg_{35}Cu_{24}Ga_{53}$

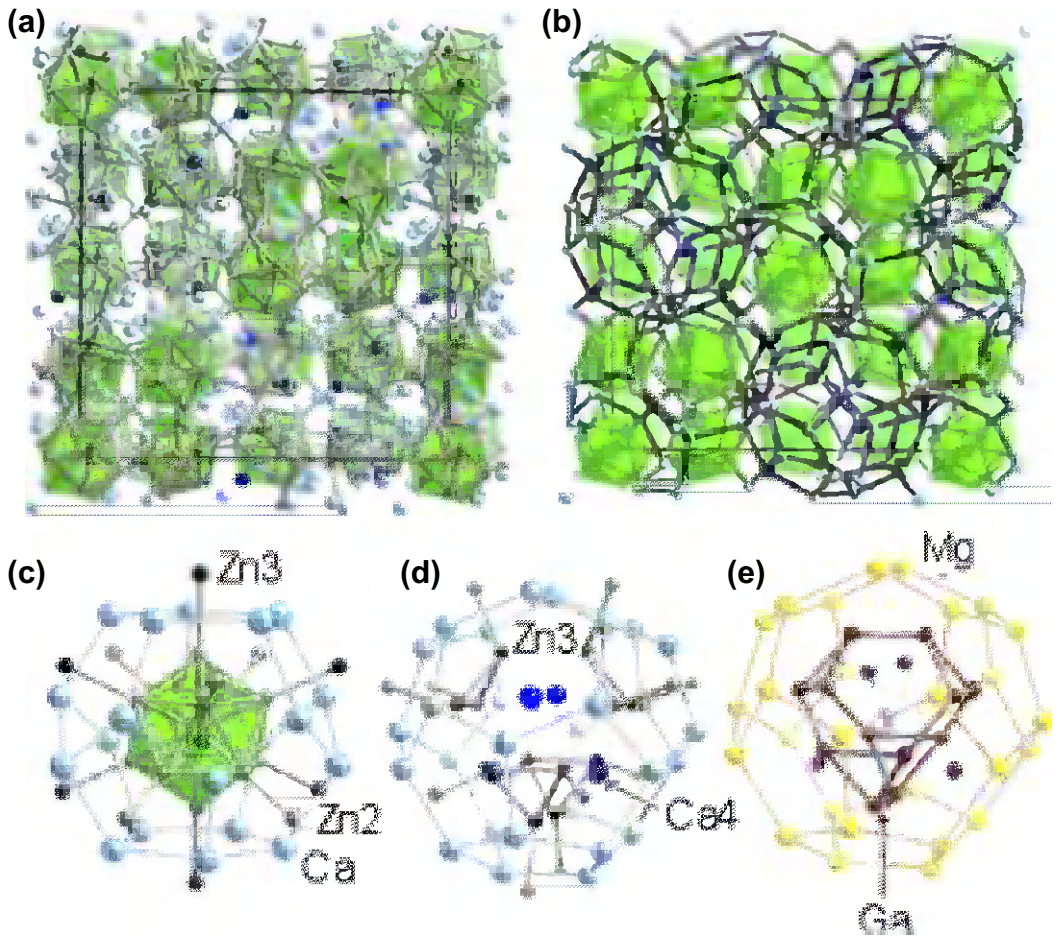

FIGURE 16.13

The compound, Ca_5Zn_3, has the structural form shown in Fig. 16.16.

Cell parameters are: $a = b = 7.962$ Å, $c = 9.539$ Å, $\alpha = \beta = 114.67°$, $\gamma = 90°$, cell volume = 488.12 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.12.

Ca_5Zn_3 has been synthesized from stoichiometric amounts of the pure elements. It crystallizes with the Cr_5B_3 type of structure: space group $I4/mcm$, $a = 7.963$ Å, $c = 15.407$ Å, $c/a = 1.93$, $Z = 4$, $R = 4.05\%$ (all F_o), 3.93%. Around one central calcium atom, distorted rhombic dodecahedra occur that contain all the remaining calcium atoms and all zinc atoms. They build up a 3D infinite network. In the tetragonal *ab*-plane, the rhombic dodecahedra are interconnected as well via common faces as via Zn–Zn dumbbells (Zn–Zn 263 pm), along [001] they share common zinc atoms. This compound is supplied commercially with the CAS number of 67907-40-8.

Density functional calculations were carried out to probe the oxidation states of the transition metal and alkaline earth elements in the Cr_5B_3-type compounds. AE_5T_3 consisting of T_2 dimers and isolated T atoms (i.e. Ca_5Au_3, Ca_5Ag_3, Ca_5Hg_3, Sr_5Cd_3, and Ca_5Zn_3) were studied. The electronic structures of all these AE_5T_3 compounds are best described as $[(AE^{2+})_5(T–T)^{4-}(T^{2-})] + 4e^-$. In the covalent bonding of the AE^{2+} ions with the transition metal anions T^{2-}, the (n–1)

d orbitals of AE^{2+} contribute more than the ns and np orbitals of AE^{2+}.

The compound, $Ca_{3.33}Zn_{10.11} = Ca_{10}Zn_{30.33}$, has the structural characteristics shown in Fig. 16.17.

Cell parameters are: $a = 7.327$ Å, $b = c = 9.168$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 533.34$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.13.

No data are available for this compound other than the structural data shown above. It has not merited further study of its physical or electronic properties.

CaZn has the structure shown in Fig. 16.18.

Cell parameters are: $a = 4.202$ Å, $b = 4.442$ Å, $c = 6.174$ Å, $\alpha = 90°$, $\beta = 109.90°$. $\gamma = 90°$, cell volume $= 108.34$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.14.

Single-crystal examination showed that CaZn crystallizes with the CrB type of structure (space group, *Cmcm*, and $Z = 4$).

Nine diffusion couples and 32 key samples were prepared to map the phase diagram of the Ca–Mg–Zn system. Phase relations and solubility limits were determined for binary and ternary compounds using scanning electron microscopy, electron probe microanalysis and XRD. The crystal structure of the ternary

compounds was studied by XRD and electron backscatter diffraction. Four ternary IM compounds were identified in this system: $Ca_3Mg_xZn_{15-x}$ ($4.6 \leq x \leq 12$ at 335 °C, IM1), $Ca_{14.5}Mg_{15.8}Zn_{69.7}$ (IM2), $Ca_2Mg_5Zn_{13}$ (IM3) and $Ca1_{.5}Mg_{55.3}Zn_{43.2}$ (IM4). Three binary compounds were found to have extended solid solubility into ternary systems: $CaZn_{11}$, $CaZn_{13}$ and Mg_2Ca form substitutional solid solutions where Mg substitutes for Zn atoms in the first two compounds, and Zn substitutes for both Ca and Mg atoms in Mg_2Ca. The isothermal section of the Ca–Mg–Zn phase diagram at 335 °C was constructed based on the obtained experimental results. The morphologies of the diffusion couples in the Ca–Mg–Zn phase diagram at 335 °C were studied.

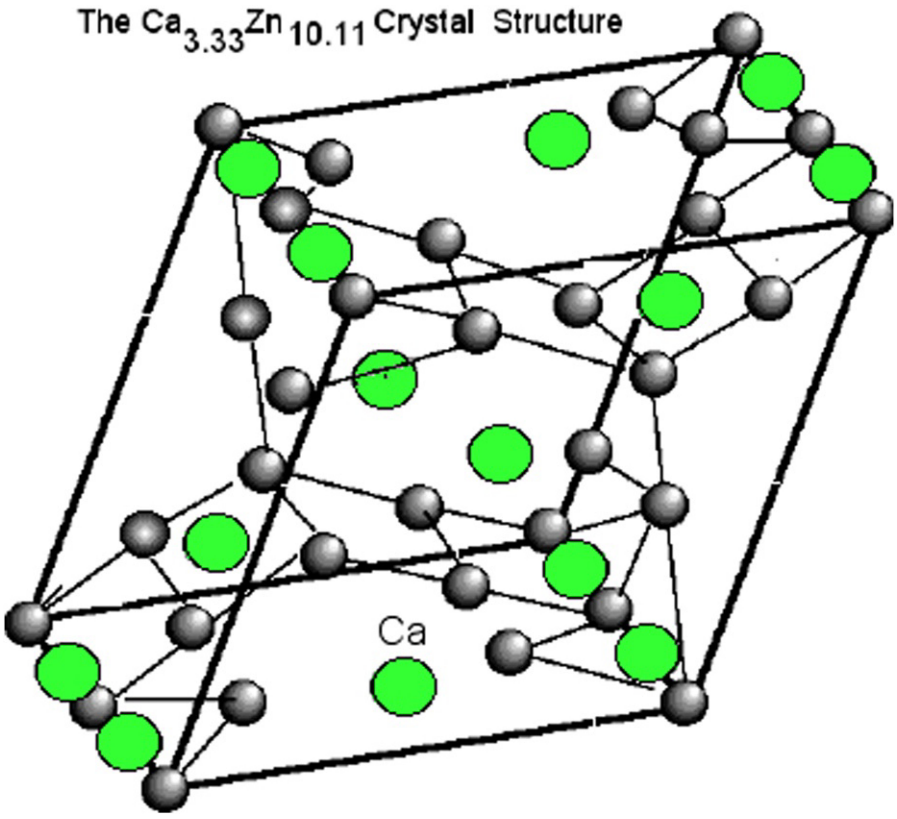

FIGURE 16.17

3	Ca(1)	Ca	4	c	4/m..	0	0	0	1.0
4	Zn(1)	Zn	4	a	422	0	0	1/4	1.0

Depending on the terminal compositions of the diffusion couples, the two-phase regions in the diffusion zone have either a tooth-like morphology or contain a matrix phase with isolated and/or dendritic precipitates. The ternary diagram has the form shown in Fig. 16.19.

In the Ca–Zn–O system, few "zincate" compounds are known. One compound, calcium hexahydroxodizincate dihydrate, $CaZn_2(OH)_6 \cdot 2H_2O$ (CZO), is well known in the literature as an active material for secondary Zn electrodes employed in batteries. In principle, this material is able to promote a better charge/discharge reversibility as well as solve the problems of shape change and dendrite formation in the Zn electrodes. It has the structure shown in Fig. 16.20.

The crystalline CZO structure is characterized by the presence of Ca atoms bonded to six oxygen atoms, resulting in $[CaO_6]$ clusters with octahedral coordination. On the other hand, the Zn atoms are coordinated to four oxygens in a tetrahedral configuration, i.e. forming $[ZrO_4]$ clusters. The H_2O molecules are bonded by hydrogen bridges to the hydroxyl groups [OH] for the charge balance of the lattice. Lozenge-like CZO microparticles were obtained by MH processing at 130 °C for 1 and 2 h, respectively. XRD patterns and Rietveld refinement confirmed that the pure CZO phase with monoclinic structure was obtained when the MH conditions were performed at 130 °C for 2 h. UV-Vis absorption spectra showed an increase in the E_{gap} values with the processing time. This phenomenon was mainly attributed to a reduction of intermediary energy levels associated to the ZnO (secondary phase) within the band gap. The origin of the orange PL emission of this material was attributed to the existence of singly ionized oxygen vacancies and/or distortions on the $[ZnO_4]$ clusters into the lattice. FEG-SEM micrographs indicated that the processing time is a key factor in the formation and growth processes of CZO microparticles.

Synthesis of $CaZn_2O_2$ was accomplished via a method involving a solution combustion method. The procured calcium nitrate, zinc nitrate, and acetamide (fuel) were used for the synthesis of nanoparticles (1:1 nitrates). They were dissolved in a small quantity of distilled water in a silica crucible, introduced into the muffle furnace, which was preheated to 500 °C. The solution undergoes dehydration and catches fire by spreading throughout the mass, finally yielding calcium zincate. Calcium zincate nanoparticle is formed by the complete combustion of the calcium nitrate and zinc nitrate with acetamide as fuel.

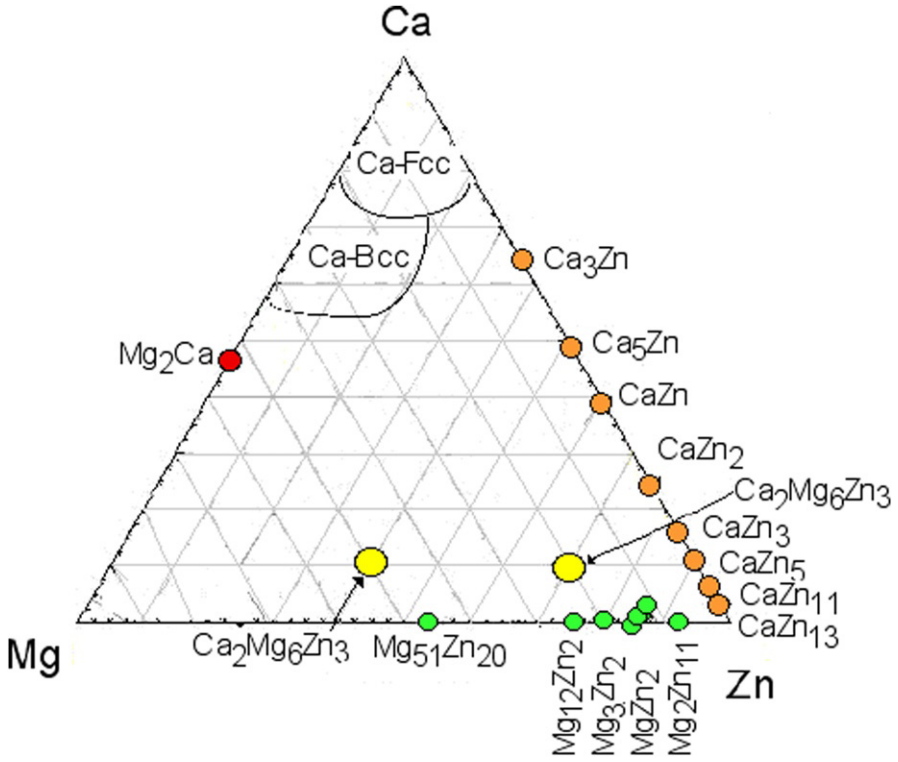

FIGURE 16.19

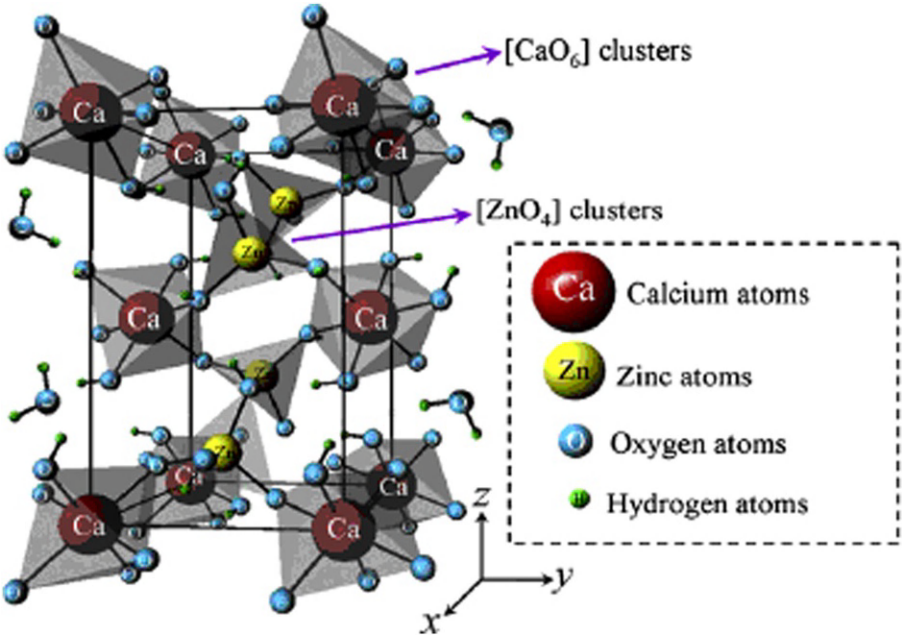

FIGURE 16.20

$$11Ca(NO_3)_2 + 11Zn(NO_3)_2 + 20CH_3CONH_2 \Rightarrow 11CaZnO_2 + 40\,CO_2 + 50H_2O + 32N_2$$

Calcium zincate nanoparticles ($CaZnO_2$) of average crystallite size 43.59 nm were used as a photocatalyst in presence of sunlight against Coralline Dark Red 2B ago dye (30 mg/l). Adsorption studies were carried out at different pH, and photocatalyst dosages. The calcium zincate nanoparticle was found to be an efficient low-cost photocatalyst which degraded Coralline Dark Red 2B dye in presence of sunlight in a relatively short period of time. Best results were obtained when the solution pH was >9.0.

Ca zincate ($CaZn_2(OH)_6 \cdot 2H_2O$) was found to play an important role in the geochemical behavior of Zn in cementation systems. One paper described the determination of a solubility product for Ca zincate and its range of application. Calcium zincate was synthesized and characterized by XRD. Samples were then equilibrated at 25 °C and an ionic strength of 0.1 M in a pH range between 11.4 and 12.7. A solubility product, $\log K_{s0} = 43.9$, was determined for infinite dilution using the Davies equation for the following reaction. The solubility product can be used to successfully interpret the results of experiments in which Zn is equilibrated with C-S-H(I) at pH values between 11.7 and 12.78 at 25 °C and an ionic strength of 0.1 M. However, the solubility product is not able to model both the Zn and Ca concentration at a given pH value because dissolution is incongruent.

Pure, crystalline, fine particulate calcium zincate was prepared. Its chemical composition, $Ca(OH)_2 \cdot 2Zn(OH)_2 \cdot 2H_2O$ was established by chemical analysis, weight loss in thermo gravimetric analysis, and by X-ray powder diffraction pattern. Its solubility in different KOH solutions at 298 K was determined. The solubility data were used to determine the activities of ZnO and H_2O with respect to pure solid ZnO and liquid water, respectively, in calcium zincate. They were also used to determine the vapor pressure of water over calcium zincate and other thermodynamics properties of this system. The equilibrium constant of the reaction $Ca(OH)_2 \cdot 2Zn(OH)_2 \cdot 2H_2O(S) = Ca(OH)_2(s) + 2ZnO(s) + 4H_2O(l)$ was found to be 0.049 ± 0.015. The standard free energy of formation of calcium zincate was found to be -1785 ± 150 cal/mol at 298 K. The standard heat of formation was found to be −665 cal/mol, and the standard entropy of formation was found to be 3.35 cal/°mol.

No other calcium zincate compounds are known.

16.1.4. Strontium Zinc Compounds

Sr metal forms four compounds with Zn metal as shown in Fig. 16.21.

The Sr–Zn system displays the four stoichiometric compounds SrZn, $SrZn_2$, $SrZn_5$, and $SrZn_{13}$. The accepted phase diagram is due mainly to Bruzzone and Merlo who used DTA, metallographic and X-ray methods to determine the phase boundaries. Additional

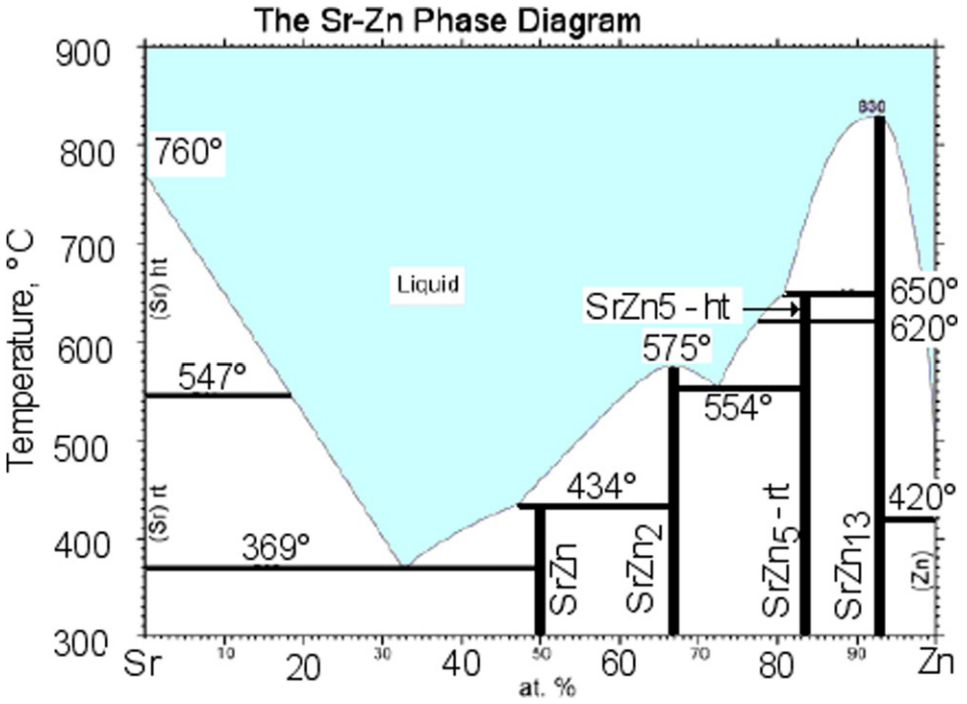

FIGURE 16.21

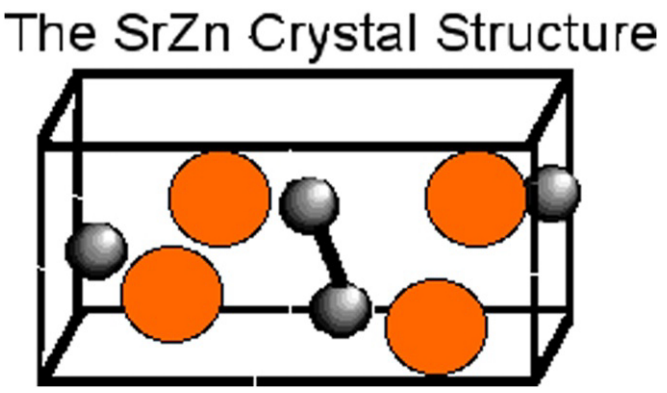

FIGURE 16.22

measurements of the solubility of Sr in liquid Zn have been made by Shunk, using a metallographic method, and by Volkovich et al. using an e.m.f. technique in the range from 0.1 to 4 atom% Sr. Thermodynamic data are shown in Table 16.15.

The compound, SrZn, has the structure shown in Fig. 16.22.

Cell parameters are: $a = 4.607$ Å, $b = 6.417$ Å, $c = 8.714$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 257.91$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.16.

SrZn has the space group, *Pnma*, and crystallizes with the FeB-type structure. The atomic parameters of SrZn were refined using single-crystal diffractometer data. Equi-atomic compounds of calcium, strontium, barium, europium and ytterbium, which crystallize with structures based on the trigonal prismatic coordination of the partner atom, were examined in terms of the shape of the trigonal prism.

The compound, $SrZn_2$ has the structural conformation shown in Fig. 16.23.

Cell parameters are: $a = 4.777$ Å, $b = c = 6.0283$ Å, $\alpha = 80.449°$, $\beta = \gamma = 66.658°$, cell volume $= 146.34$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.17.

High-pressure forms of IM compounds with the composition $CaZn_2$, $SrZn_2$, $SrAl_2$, and $BaAl_2$ were synthesized from $CeCu_2$-type precursors by multi-anvil techniques and investigated by X-ray powder diffraction ($SrAl_2$ and $BaAl_2$), X-ray single-crystal diffraction ($CaZn_2$), and electron microscopy ($SrZn_2$). Their structures correspond to that of Laves phases. Whereas the dialuminides crystallize in the cubic

$MgCu_2$ (C15) structure, the dizincides adopt the hexagonal $MgZn_2$ (C14) structure. This trend is in agreement with the structural relationship displayed by sp bonded Laves phase systems at ambient conditions. $CeCu_2$-type polar IMs can be transformed to Laves phases upon simultaneous application of pressure and temperature. The observed structures are controlled by the valence electron concentration.

If $SrZn_2$ is heated in air, it decomposes. Oxidative decomposition of $SrZn_2$ ($CeCu_2$ type) into SrH_2 and $SrZn_{13}$ ($NaZn_{13}$ type) upon hydrogenation was demonstrated. X-ray powder patterns (Cu-Kα) of the product mixture were shown for synthesis temperatures of 100, 150, and 300 °C (reaction time 24 h, pressure 50 bar).

The compound, $SrZn_5$ has the structure shown in Fig. 16.24.

Cell parameters are: $a = 5.312$ Å, $b = 6.707$, $c = 13.147$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 468.44$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.18(A).

The $SrZn_5$ compound stable at room temperature, has the structure shown in Fig. 16.25.

Cell parameters are: $a = 4.283$ Å, $b = c = 5.549$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 114.21$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.18(B).

The $SrZn_5$ phase undergoes a structural transformation at 620 °C. The high-temperature form of $SrZn_5$, which was prepared by quenching of melted samples, adopts the ideal $CaCu_5$ structure type ($a = 5.541$ Å,

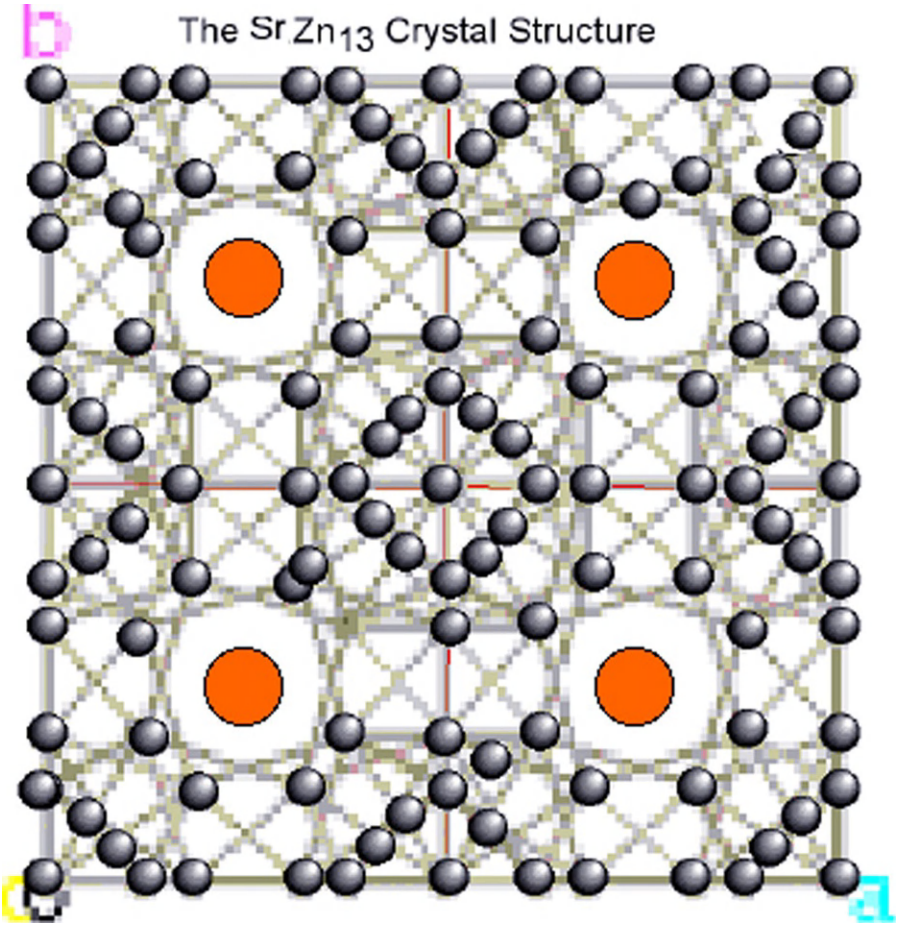

FIGURE 16.26

$c = 4.282$ Å, $R1 = 0.0314$). The room temperature modification of $SrZn_5$ (orthorhombic, space group *Pnma*, $a = 13.133$ Å, $b = 5.2991$ Å, $c = 6.6972$ Å, $Z = 4$, $R1 = 0.0349$) forms a singular structure, whereas the Ba compound of corresponding composition (orthorhombic, space group *Cmcm*, $a = 10.783$, $b = 8.398$, $c = 5.320$ Å, $Z = 4$, $R1 = 0.0281$) crystallizes with a third, also rather uncommon structure.

The compound, $SrZn_{13}$ has the structure shown in Fig. 16.26.

The Sr atoms lie within channels in the structure, one Sr atom per unit cell. A total of four units are shown here in this *ac*-plane. In the *b*-direction, there are layers of Zn atoms between the channels so that this diagram represents eight-unit cell in a 3D structure.

Cell parameters are: $a = b = c = 8.65641$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 458.67$ Å^3, $Z = 8$. Cell occupancy is shown in Table 16.19.

Single crystals of strontium undecazinc, $SrZn_{11}$, were obtained when decomposing $SrZn_2$ under conditions of high pressure and high temperature. This novel binary Sr–Zn compound crystallizes in the space group *I*4/*amd* ($BaCd_{11}$ structure type) with one Sr position ($\bar{4}$m2) and three Zn sites ($\bar{4}$m2,·2/m·1). The structure is described in terms of all-face-capped Zn(8) tetrahedra as the central building unit, defined by the Zn atoms on .2/m. and 1. These building units are condensed into chains by the central tetrahedra-sharing edges, and the chains are interconnected by shared capping atoms. The resulting 3D framework of Zn atoms yields channels that are occupied

TABLE 16.19

by Sr and Zn atoms on the high-symmetry $\bar{4}$m2 positions. For the compound, $CaZn_{11}$, crystal parameters were: (tetragonal, space group $I41/amd$, $a = 10.6811$, $c = 6.8281$ Å, $Z = 4$, $R1 = 0.0299$). The originally proposed structure type was confirmed and also refined by using single-crystal data.

The ternary system, Sr–Mg–Zn, has also been studied and has the form shown in Fig. 16.27.

No other Sr–Zn IM compounds are known.

In the Sr–Zn–O system, few "zincate" compounds are known. In the system, SrO–Zn_2O, no compounds have been reported. In the SrO–ZnO system, two novel blue-emitting phosphors have been synthesized. Two new blue-emitting phosphors, $SrZnO_2$:Pb^{2+} and Ce^{3+} were synthesized using an adipic acid or sucrose-template sol–gel route, respectively. The resulting phosphor particles were fine, nanocrystalline and pure. The optimum activator concentrations were found to be 1 mol% Pb^{2+} and 12 mol% Ce^{3+}. Two excitation bands centered at 283 and 317 nm, plus a weak shoulder at 275 nm, were observed for Pb^{2+}-doped samples. However, only one broad excitation band with a maximum at 294 nm was observed for Ce^{3+}-doped samples fired at 1000 °C for 2 h. The emission spectra of $SrZnO_2$:Pb^{2+} showed a very broad band extending from 374 to 615 nm with a maximum at ~455 nm which was ascribed to the $^3P_1 \Rightarrow {}^1S_0$ transition on the Pb^{2+} ions allowed by the strong spin-orbit coupling. Similarly, $SrZnO_2$:Ce^{3+} showed a broad emission band extending from 374 to 609 nm and centered at 467 nm. This broad emission was attributed to the $5d^1 \Rightarrow 4f^1$ transition of Ce^{3+} ions. The lower level $^2F_{5/2}$ of the $4f^1$ is populated but the level $^2F_{7/2}$ is almost empty at room temperature where all measurements were taken.

In another paper, the $SrZnO_2$:Sm^{3+} phosphor has been synthesized by a gel-combusting method and characterized using X-ray powder diffraction, TEM, TG as well as excitation, and emission spectroscopy. The luminescence properties of this phosphor have been studied. It crystallizes in an orthorhombic structure with *Pnma* space group and unit cell with the lattice parameters: $a = 5.830$ Å, $b = 3.340$ Å and $c = 11.348$ Å. These materials can be efficiently excited in the UV to visible region (350–420 nm, main peaks 413 and 380 nm), making them attractive as conversion phosphors for LED applications. A red emission at 600–730 nm (main peaks 607 and 655 nm) is observed for

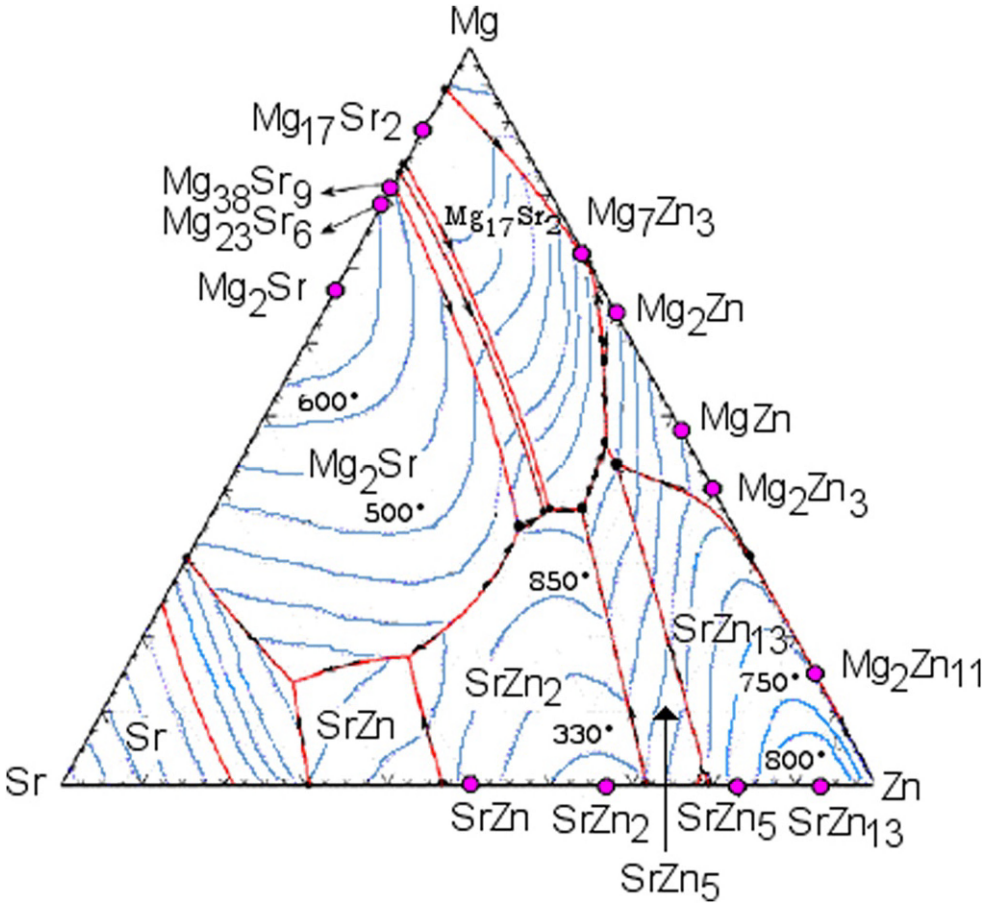

FIGURE 16.27

$SrZnO_2:Sm^{3+}$ which is a promising conversion phosphor for white-light LEDs.

The crystal structure of $SrZnO_2$ has been determined by 3D Patterson- and Fourier syntheses. The space group is $D^{16}{}_{2h}$-*Pmnb*. The orthorhombic unit cell ($a = 3.35$, $b = 5.84$, $c = 11.37$ Å) contains four formula units; $d_x = 5.52$, $d_{pyc} = 5.49$ g/cm^3. With the last refinement, R and R_1 fall to 0.064 and 0.069, respectively (CuKα). The [ZnO_2]-arrangement is a previously unknown two-dimensional (2D) one. It can be derived from the cristobalite arrangement. Sr is situated between the waved layers. In $SrZnO_2$, the ZnO_4 tetrahedra share edges with each other and form waved layers. The Sr atoms are located at the cavity between the layers.

Colorless crystals of $SrZn(OH)_4 \cdot H_2O$ have been obtained by electrochemical oxidation of Zn in a zinc/iron pair in an aqueous ammonia solution saturated with strontium hydroxide. The X-ray crystal structure determination was successful including all hydrogen positions: P1, $Z = 2$, $a = 6.244(1)$ Å, $b = 6.3000$ Å, $c = 7.701$ Å, $\alpha = 90.59(1)°$, $\beta = 112.56(2)°$, $\gamma = 108.66(2)°$, $N(F \geq 3\sigma F) = 1967$, $N(\text{Var.}) = 84$, $R/R_w = 0.020/0.024$. In $SrZn(OH)_4 \cdot H_2O$, Zn^{2+} is tetrahedrally coordinated by four OH^- ions while Sr^{2+} has $6OH^-$ and one H_2O as neighbors. The polyhedra around Sr^{2+} are connected to chains which are linked three dimensionally by isolated tetrahedra [$Zn(OH)_4$]. Hydrogen bonds between H_2O as donor and OH^- were characterized by Raman spectroscopy.

No other SrO–ZnO compounds have been documented to date. Strontium zincate compounds are not offered for sale commercially and no CAS numbers have been issued.

16.1.5. Barium Zinc Compounds

Only a few IM compounds are known in the Ba^0–Zn^0 system as shown in Fig. 16.28.

The Ba–Zn system was investigated by differential thermal, metallographic and X-ray analysis. Among the five intermediate phases identified, the Ba_2Zn, BaZn and $BaZn_{13}$ compounds melt congruently at 360, 340 and 885 °C, respectively. $BaZn_2$ and $BaZn_5$ form peritectics at 380 and 635 °C, respectively. Three eutectics are formed: between Ba and Ba_2Zn at 345 °C (25.0 atom% Zn); between Ba_2Zn and BaZn at 330 °C (46.0 atom% Zn); between BaZn and $BaZn_2$ at 325 °C (53.5 atom% Zn). The crystal structures of BaZn (CsCl type), $BaZn_5$ ($BaZn_5$ type) and $BaZn_{13}$ ($NaZn_{13}$ type) were confirmed. Ba_2Zn, isotypic with Ba_2Cd and Ba_2Hg, belongs to the $MoSi_2$ type. The atomic parameters of $BaZn_2$, which crystallizes in the $CeCu_2$-type structure, have been refined using single-crystal diffractometer data.

The compound, BaZn, has the structural form shown in Fig. 16.29.

Cell parameters are: $a = b = c = 4.093$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 68.57 Å^3, $Z = 1$. Cell occupancy is shown in Table 16.20.

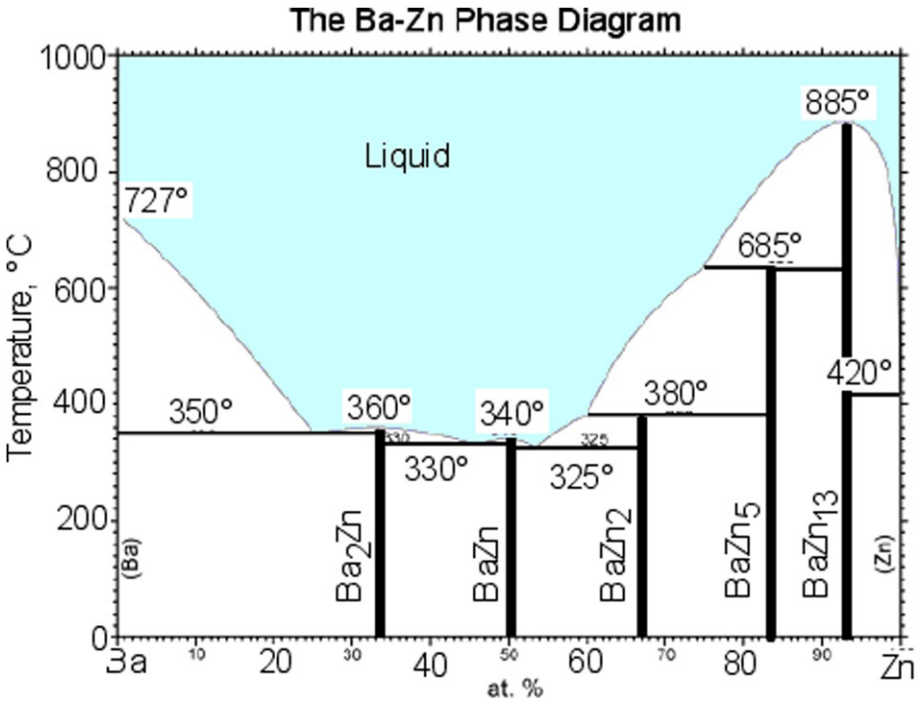

FIGURE 16.28

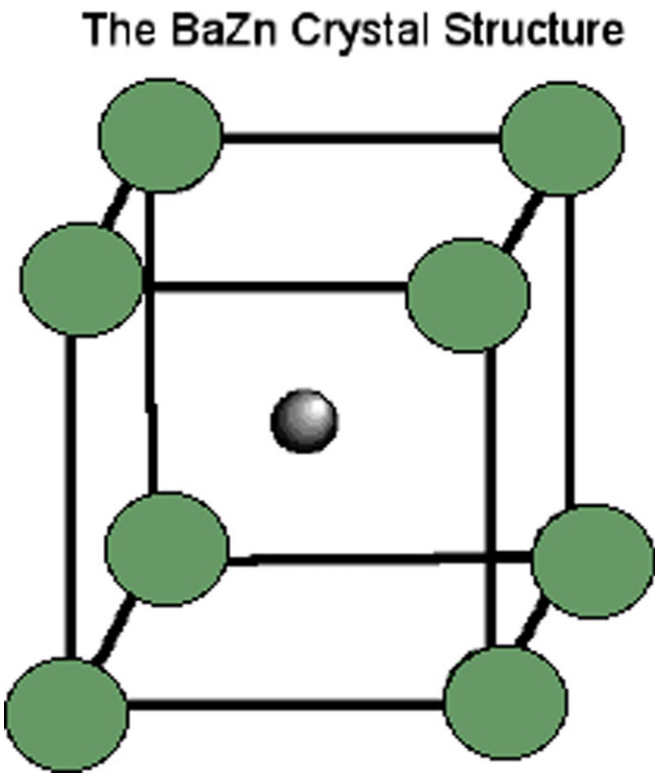

FIGURE 16.29

Very little data concerning this compound are available except for those involving structure.

The compound, Ba_2Zn has the structural form shown in Fig. 16.30.

Cell parameters are: $a = b = 4.175$ Å, $c = 8.0415$ Å, $\alpha = \beta = 105.05°$. $\gamma = 90°$, cell volume $= 130.38$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.21.

There is no mention of this compound in the technical literature. Structural data are the only references to be found.

The compound, $BaZn_2$, has the structure shown in Fig. 16.31.

Cell parameters are: $a = 5.009$ Å, $b = c = 6.1564$ Å, $\alpha = 78.616°$, $\beta = \gamma = 61.995°$, cell volume $= 158.31$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.22.

The literature is devoid of any mention of the physical or electrical properties of this material.

The compound, $BaZn_5$, has the structural form shown in Fig. 16.32.

Cell parameters are: $a = 5.318$ Å, $b = c = 6.8489$ Å, $\alpha = 103.92°$, $\beta = \gamma = 90°$, cell volume $= 242.13$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.23.

No data concerning the physical or electrical properties of this compound are available in the current technical literature.

$BaZn_{13}$ has the structural form shown in Fig. 16.33.

The Ba atoms lie within channels in the structure, one Ba atom per unit cell. A total of four units are shown here in this *ac*-plane. In the *b*-direction, there are layers of Zn atoms between the channels so that this diagram represents eight-unit cell in a 3D structure.

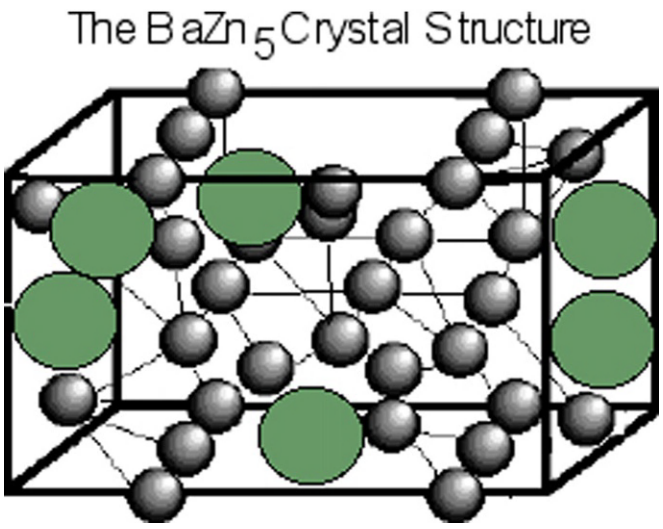

FIGURE 16.32

Cell parameters are: $a = b = c = 8.7391$ Å, $\alpha = \beta = \gamma = 60°$, cell volume $= 471.94$ Å^3, $Z = 8$. Cell occupancy is shown in Table 16.24.

No other IM compounds are known and no barium zincide compounds are offered for sale commercially.

In the Ba–Zn–O system, the magnetic properties of Y–Ba–Zn–O samples in which Y_2O_3, $BaCO_3$ and ZnO powders were mixed at atomic ratios of Y:Ba:Zn = 1:2:3 were explored. Abnormal magnetic behavior has been seen on the M-H and M-T curves. At liquid nitrogen temperature, the samples expelled the permanent magnets but no levitation was observed unlike in type II superconducting samples. The M-H curves were quite dependent on the field direction ($H//ab$ and $H \perp ab$-plane). At low-field regime, ferromagnetism was clearly seen but diamagnetism appeared at fields higher than 1.0 T. Some traces of Meissner-like expulsion up to 500 Oe were also seen.

In the system BaO–ZnO, the crystal structure of $BaZnO_2$ has been determined by Patterson- and Fourier syntheses along the [1,0,0] dimension. The space group is $P3_12$–D_3^4. The hexagonal unit cell ($a = 5.886$ Å, $c = 6.734$ Å, $c/a = 114$) contains three formula units: $d_{calc} = 5.82$, $d_{pyk} = 5.78$ g/cm^3. The last refinement gave $R = 0.075$; $R' = 0.113$ (MoKα-radiation). The ZnO_2 arrangement is very similar to that of low quartz; Ba is situated in interstitial holes. In this sense, $BaZnO_2$ is a stuffed derivative of low quartz.

Single crystals of Ba_2ZnO_3 were prepared by solid-state reaction. It crystallizes monoclinic: space group $C_{2h}^{6=}$, $C12/c1$; $a = 5.833$; $b = 11.376$; $c = 12.585$ Å; $\beta = 93.63°$; $Z = 8$. The crystal structure was characterized by $^{\infty}{}_1[ZnO_3]$ chains along the [100] direction. They are connected by Ba^{2+} in sevenfold oxygen coordination. Ba_2ZnO_3 is an example of *zweier* single chain

TABLE 16.24

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy

compounds i.e. containing a repeat unit of two tetrahedra. These chains run parallel to [100]. The Ba^{2+}, cation lies on two crystallographic-independent sites, both seven coordinate. A(1) is in distorted pentagonal bipyramidal coordination and A(2) shows monocapped trigonal prismatic coordination.

Photoluminescent properties of novel red-emitting Mn^{2+}-activated MZnOS (M = Mg, Ca, Ba, OS = oxysulfide) phosphors were investigated (Fig. 16.34).

Mn^{2+}-activated MgZnOS phosphors show a single symmetric narrow red emission band in the wavelength range of 550 to 700 nm due to the $^4T_1(^4G) \Rightarrow {}^6A_1(^6S)$ transition of Mn^{2+}. Peak centers are at about 614 nm for M = Ca and 634 nm for M = Ba, regardless of the excitation wavelength and Mn^{2+}-doping concentration.

A comparison was made between the luminescence properties of Mn^{2+} in the Ca versus Ba compound. A similarity between them is that both Mn^{2+}-activated CaZnOS and BaZnOS can be efficiently excited under host lattice excitation in the wavelength range of 250 to 350 nm due to efficient energy transfer between the host lattice (MZnOS) and activator (Mn^{2+}). An unexpected difference is that Mn^{2+}-activated CaZnOS can also be efficiently excited under the excitation of Mn^{2+} itself (d–d transitions) in the wavelength range of 350 to 500 nm. This difference is ascribed to different crystal structures, different coordination

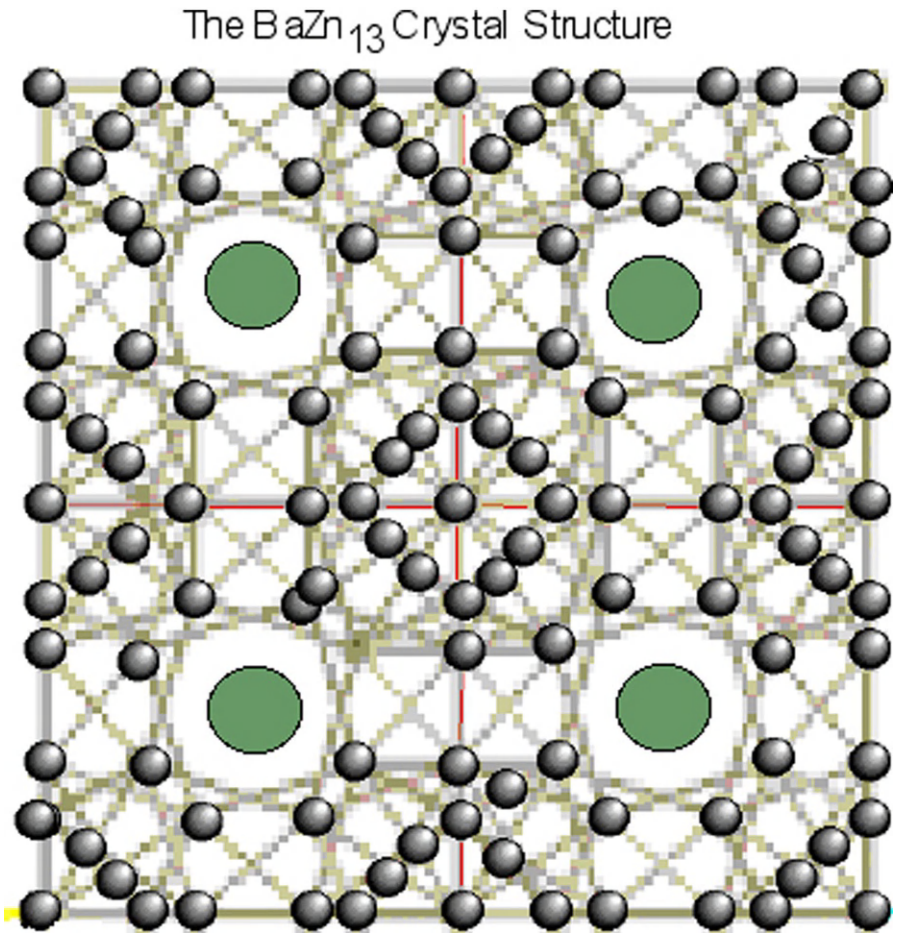

FIGURE 16.33

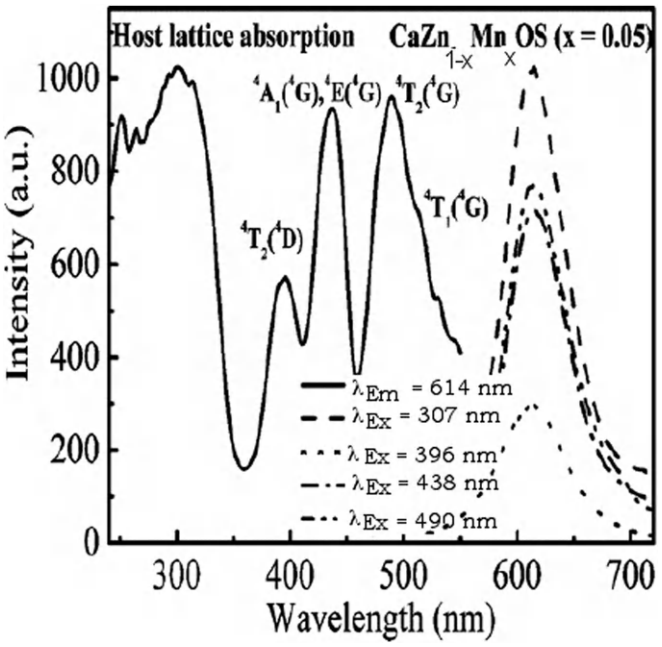

FIGURE 16.34

environments, and point symmetries for Mn^{2+} in these two compounds. The potential applications of these phosphors are pointed out. Among them, Mn^{2+}-activated CaZnOS shows great potential for application as an alternative red-emitting LED conversion phosphor due to its high absorption and strong excitation bands in the wavelength range of 350 to 500 nm.

The wide-band gap oxy-sulfide semiconductor BaZnOS adopts a high-symmetry modification of the $SrZnO_2$ structure type and contains layers of vertex-linked ZnO_2S_2 tetrahedra, which represent a novel coordination environment for zinc in the solid state. BaZnOS: orthorhombic, space group *Cmcm*; $a = 3.9619$ Å, $b = 12.8541$ Å, $c = 6.1175$ Å, $Z = 4$. Diffuse-reflectance spectroscopy measurements reveal a direct band gap of 3.9 eV, consistent with the white color and the results of band structure calculations. The band gap is larger than those observed in ZnO and ZnS, consistent with the more ionic nature of BaZnOS. Attempts to dope this compound electronically have so far not proved possible.

Crystallization from supersaturated sodium hydroxozincate solutions by adding solutions of alkali earth metal hydroxides yields crystals of $Sr_2Zn(OH)_6$ and $Ba_2Zn(OH)_6$. The X-ray structure determination on these crystals was successful including all hydrogen positions:

$Sr_2Zn(OH)_6$: $P2_1/n$, $Z = 2$, $a = 5.794$ Å, $b = 6.160$ Å, $c = 8.141$ Å, $\beta = 91.23°$, $N(F^2{}_0{}^\circ - 2\sigma F^0) = 1127$, $N(\text{Var.}) = 53$, $R_1/wR_2 = 0.047/0.081$,

$Ba_2Zn(OH)_6$: $P2_1/n$, $Z = 2$, $a = 6.043$ Å, $\beta = 6.336$ Å, $c = 8.451$ Å, $\beta = 91.23°$, $N(F^2{}_0{}^\circ - 2\sigma F^0) = 1669$, $N(\text{Var.}) = 54$, $R_1/wR_2 = 0.029/0.067$.

$Sr_2Zn(OH)_6$ and $Ba_2Zn(OH)_6$ crystallize isotypically in a distorted Li_2O type of structure. Sr^{2+} and Ba^{2+} form a cubic primitive arrangement of distorted octahedra of OH^- around Zn^{2+} ions, filling therein alternating cubic gaps in an ordered way.

No other barium zincate materials are known. They are not offered for sale commercially and no CAS numbers have been issued to date.

16.1.6. Radium Zinc Compounds

Although Ra metal or radium oxide probably forms the same type of compounds with Zn or ZnO as Ba^0 or BaO, there is no record in the literature of anyone having done so.

16.2. ALKALINE EARTH CADMIUM COMPOUNDS

Cd metal forms a number of IM compounds with the alkaline earths. Only a few "cadmates" are known.

16.2.1. Beryllium Cadmium Compounds

Be metal does not form any IM compounds with Cd metal.

The systems, BeO–Cd_2O, BeO–CdO and BeO–Cd_2O_3, have not been documented in the past or current technical literature.

16.2.2. Magnesium Cadmium Compounds

Mg metal forms three IM compounds with Cd metal as shown in Fig. 16.35.

These compounds are eutectic over a wide range of temperatures and compositions. Two are dimorphic and exhibit room- and high-temperature modifications of their structure. The compound, Mg–Cd, has the structure shown in Fig. 16.36.

Cell parameters of MgCd are: $a = 3.2217$ Å, $b = 5.0051$ Å, $c = 5.2712$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 84.98$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.25.

Little is known concerning this compound other than its structural data.

The compound, Mg_3Cd, has the structure shown in Fig. 16.37.

Cell parameters are: $a = 5.083$ Å, $b = c = 6.314$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 175.17$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.26.

In contrast, the $MgCd_3$ compound has the structure shown in Fig. 16.38.

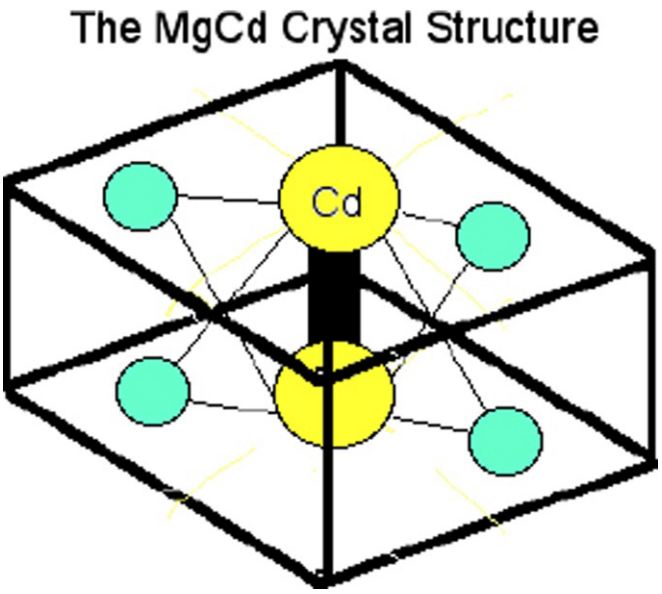

FIGURE 16.38

Cell parameters are: $a = 5.0452$ Å, $b = c = 6.2335$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 169.77$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.27.

The Mg–Cd system has a close-packed hexagonal (c.p.h.) lattice and possesses ordered structures for concentrations corresponding to Mg_3Cd, MgCd and $MgCd_3$. In general, the c.p.h. lattice can be divided into four large hexagonal sublattices (lattice constants of them now become $a' = 2a$ and $c = c$). For ordered MgCd, two of these sublattices are occupied by Mg while the other two by Cd; and for the ordered Mg_3Cd three sublattices are occupied by Mg and the remaining one is occupied by Cd, for the ordered $MgCd_3$ the relation is just the reverse. The order–disorder transformation of these alloys has been measured through temperature dependencies of several physical properties, such as specific heat (C_p), expansion coefficient (β) and electrical resistivity (ρ). For the Mg_3Cd alloy C_p vs temperature curve showed anomalous behavior similar to β-brass, while the presence of latent heats has been confirmed for MgCd and $MgCd_3$ alloys. For Mg_3Cd and MgCd alloys, β vs temperature curves indicated a close parallelism to their C_p vs temperature curves. On the other hand, for $MgCd_3$ alloy, a noteworthy contraction was associated with its disordering, causing the coefficient of thermal expansion to tend toward negative infinity at the Curie point. The ρ vs temperature curves for these alloys have characteristic from of the order–disorder transformation. During the annealing of the previously quenched Mg_3Cd and MgCd alloys, their hardness decreases with time. It is interesting to note that these highly ordered superlattices possess hardness smaller than the random alloys of the same compositions.

In another paper, using XRD studies of the structural state of type Mg_3Cd alloys during the ordering stage accompanied by an increase in their electrical resistivity Ω, the authors analyzed the problem of the admissibility of previously postulated interpretations of the anomalous variation in Ω in the initial stages of ordering of certain investigated alloys. It was tentatively concluded that this anomalous variation may be associated with the non-monotonic character of the dependence of Ω on the degree of order. The kinetics of order–disorder processes in alloys of type Mg_3Cd and $MgCd_3$ in the single-phase and two-phase regions were both investigated by measuring the electrical resistance of the material directly at the temperatures at which tests are carried out. It was shown that in a $MgCd_3$-type alloy the processes involved in an order–disorder transition proceed much more slowly in the two-phase region than in the single-phase region. The Mg_3Cd alloy, on the other hand, exhibited no such delay effects. This difference in the behavior of these alloys investigated was said to be due to lattice distortions, accompanying transitions in the two-phase region, which are greater for $MgCd_3$ than for Mg_3Cd.

Antiphase boundaries (APBs) and stacking faults affect the deformation behavior of many IMs. In an ordered c.p.h. structure of $D0_{19}$ type (e.g. Mg_3Cd, Ti_3Al-based alloys), stable planar faults of two types are possible on the basal plane. These are APBs and complex stacking faults (CSFs), which are a combination of an APB and a stacking fault. The latter can be either of shear or of climb type. If the bounding partial dislocations of a CSF lie in its plane, then it is designated as a shear CSF, otherwise it is called a climb CSF. A mathematical formulation of the theory of diffraction from a $D0_{19}$ structure having a shear or climb type of CSF has been carried out. The diffraction effects owing to the presence of these CSFs have been found. Integrated intensities and widths of the reflections are affected. These have been evaluated in terms of the probability of the occurrence of these faults.

The resolution of lattice fringes in ordered and partially ordered Cu_3Au has been calculated using the dynamical theory of electron diffraction, taking into consideration

TABLE 16.27

No.	Site notation	Atom	Multiplicity	Wyckoff	Site symmetry	*x*	*y*	*z*	Occupancy
1	Cd1	Cd	6	h	mm2	0.16667	0.33333	1/4	1.0
2	Mg1	Mg	2	d	-6m2	1/3	2/3	3/4	1.0

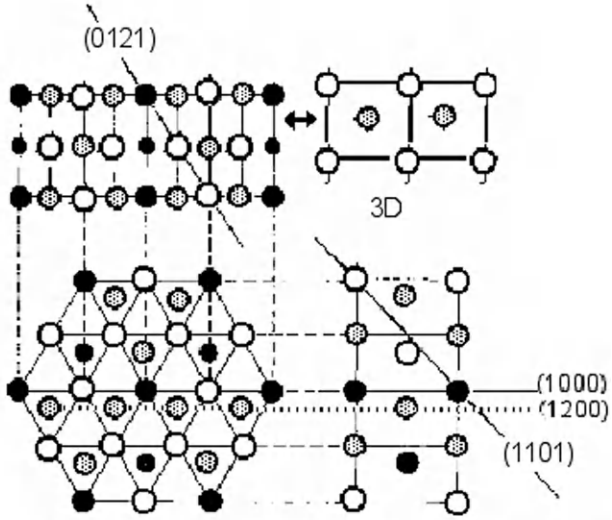
the effects of such variables as foil thickness and orientation, objective lens defocus, degree of order and, for partially ordered alloys, the position of small ordered domains in the foil. The experimental observations were found to be in excellent agreement with these calculations. Lattice defects in ordered Cu_3Au have been studied using this technique. Thus, the domain wall thickness at the translational antiphase domain boundaries was shown to be one or two atomic diameters and the antiphase boundary separating the pair of fundamental lattice dislocations, which constituted a super-dislocation, was revealed. A clear distinction exists between the lattice image contrast of predominantly ordered and disordered regions and this has been utilized to study partial long-range order and short-range order. Short-range order in this system is characterized by a dispersion of small highly ordered domains, ~15 Å diameter, in a predominantly disordered matrix.

The later stages of DO_{19} ordering in Mg_3Cd have been investigated by direct lattice imaging. The DO_{19} structure involves a hexagonal abab … stacking, similar to the LI_2 cubic structure with abcabc … stacking.

Unit cell high steps (5.3 Å) have been clearly resolved in the following interfaces:

- the order–disorder interface,
- translational antiphase boundaries,
- rotational domain boundaries.

These observations are thought to indicate a ledge mechanism for ordering and domain growth. Lattice imaging and corresponding optical diffraction have also been used for phase identification and determination of unit cell dimensions (Fig. 16.39).



Atomic Configurations of the DO13 Structure, as Viewed from the three Pricipal Axes. Open corcles refer to the Mg-atoms while the black or dotted circles refer to the two Types of Cd-atoms

FIGURE 16.39

In addition, the characteristic domain structure of the DO_{19} phase was been studied in detail, and the unusual multiple domain junctions were explained in terms of the orthorhombic lattice distortion upon transformation. Considerably more information has been discovered by lattice imaging than is possible by conventional electron microscopy. A model for the twinned structure of Mg_3Cd from its ordered, hexagonal state was derived from the classical twin indices for (1012) twinning. Use of these indices transforms the ordered hexagonal Mg_3Cd structure into an ordered orthorhombic structure having identical atom positions as the hexagonal structure, but with a different sequence of magnesium and cadmium occupancy. This different sequence gives rise to additional X-ray super lattice lines.

No other IM compounds are known for this system.

In the Mg–Cd–O system, no known compounds, similar to those in the Mg–Zn–O system have been documented in the available technical literature.

Magnesium cadmates are not available commercially for sale and no CAS numbers have been issued to date.

16.2.3. Calcium Cadmium Compounds

Ca metal forms several IM compounds with Cd metal as shown in Fig. 16.40.

The compound, CaCd has the structural form shown in Fig. 16.41.

Cell parameters are: $a = b = c = 3.8378$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 56.53$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.28.

Other than structural data, little is available concerning the physical or electrical properties of this material in the past or current literature.

The compound,$CaCd_2$, has the structure shown in Fig. 16.42.

Cell parameters are: $a = 4.9242$ Å, $b = c = 6.1772$ Å, $\alpha = 75.32°$, $\beta = \gamma = 66.51°$, cell volume $= 157.03$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.29.

This is the high-temperature form. The low-temperature form is shown in Fig. 16.43.

Cell parameters are: $a = 9.6542$ Å, $b = c = 5.9964$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, cell volume $= 157.03$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.30.

$CaCd_2$ forms the KHg_2 structure at elevated temperatures (orthorhombic, space group $= Imma$) and the $MgZn_2$-type Laves phase at ambient conditions (hexagonal, space group $P63/mmc$, $Z = 4$).

The compound, $CaCd_6$ has the unique structure shown in Fig. 16.44.

Cell parameters are: $a = b = c = 13.5793$ Å, $\alpha = \beta = \gamma = 109.47°$, cell volume $= 1927.58$ Å^3, $Z = 24$. Cell occupancy is shown in Table 16.31.

The $CaCd_6$ structure, also known as the 1/1 cubic approximant, is the pure A-cell, tiling A.cI2. The precise

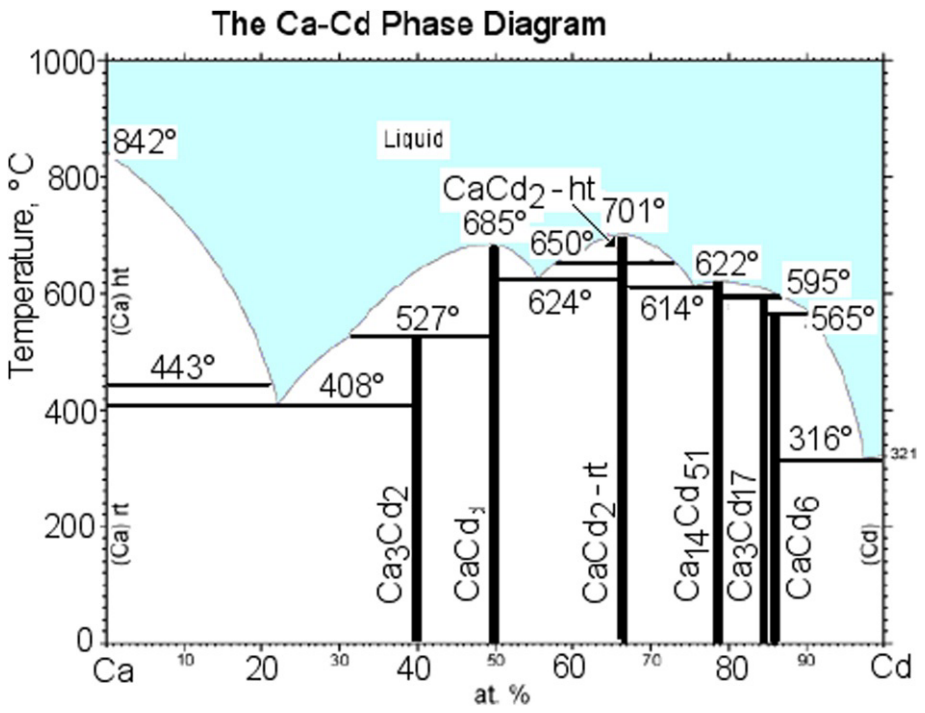


FIGURE 16.40

structure remains controversial since the Pearson type has been given variously as cI160, cI176, cI184 and cI232 as a result of uncertainty regarding the proper orientations of the Cd_4 cluster-center tetrahedra. In fact, there appears to be a low temperature order–disorder phase transition (around $T = 100$ K) in which these tetrahedra lock into specific relative orientations.

Thermodynamically stable binary icosahedral quasicrystals occur in the alloy system, Ca_7Cd_5. In each case, the phase diagram of the binary alloy contains a 1/1 cubic approximant of structure type Cd_6Ca at a close by composition. This Cd_6Ca structure can be represented in a conventional simple cubic unit cell with a lattice parameter of $a = 15.7$ Å. However, the Pearson (point group) symbol for Cd_6Ca is cI176 indicating that it is cubic, body-centered, with 176 atomic positions

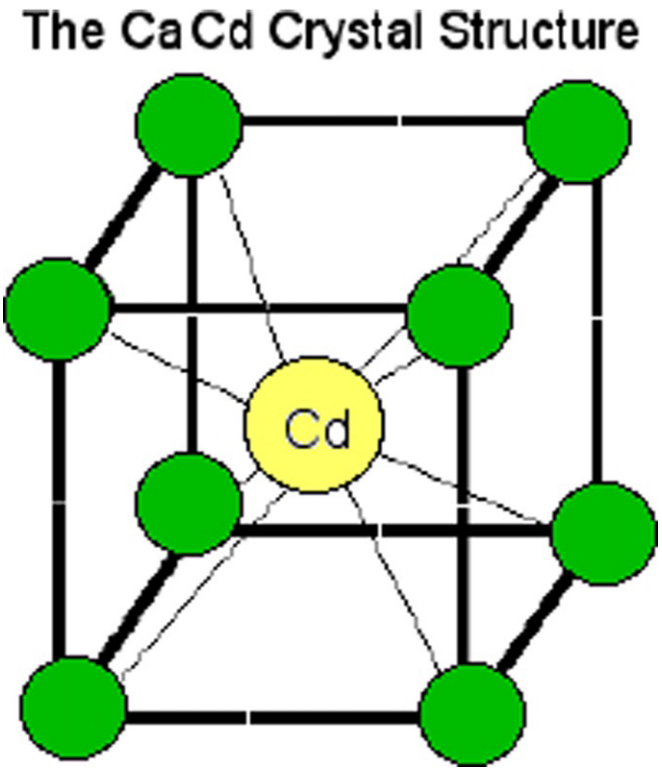

FIGURE 16.41

3	Cd2	Cd	2	a	-3m.	0	0	0	1.0

per simple cubic unit cell. Since 176 is not a multiple of the basic 7-atom stoichiometric unit (6 Cd and 1 Ca), there must be a partial occupancy. In fact, the unit cell contains 144 Cd atoms, 24 Ca atoms and 8 vacancies. This is shown in Fig. 16.45.

The structure Ca_2Cd_7-hP68 is based on trigonal prisms, whose triangular faces are Y-faces, but their rectangular faces are not Z-faces, so this structure is not a CCT, and should not be considered a proper approximant. The clusters based at trigonal prism vertices are imperfect basic clusters, and instead of being centered by Cd_4 tetrahedra, they are centered by Cd_3 triangles.

The compound, $Ca_{14}Cd_{51}$, has the structural form shown in Fig. 16.46.

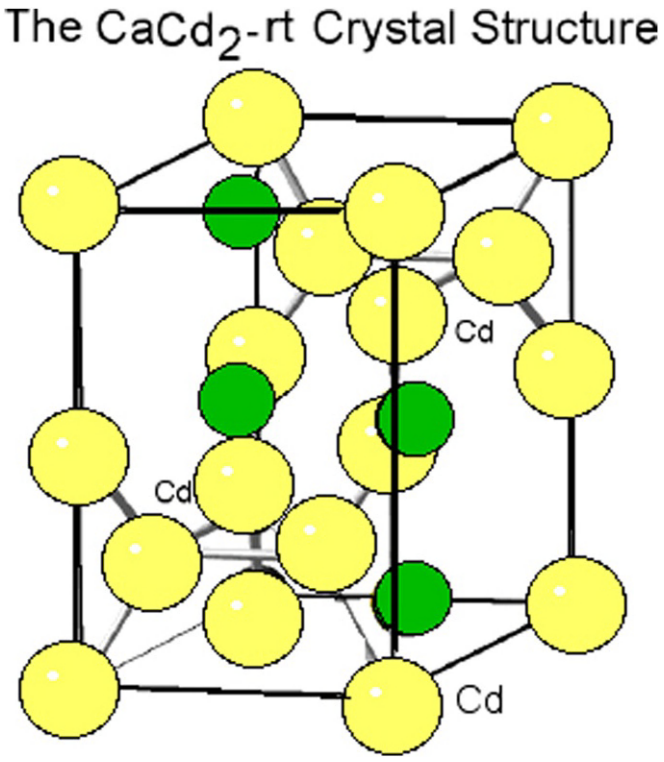

FIGURE 16.43

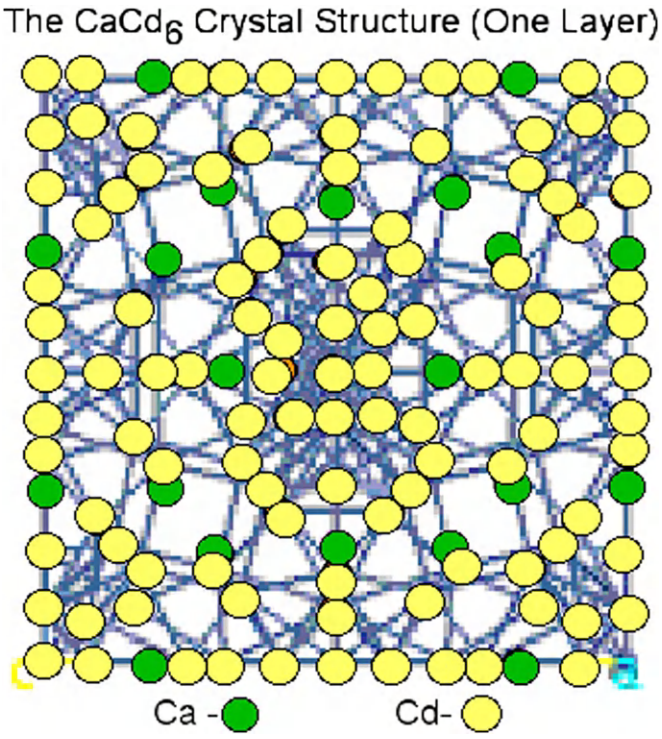

FIGURE 16.44

The Basic Icosahedral Clusters of the CaCd6 - Type of Compound. They Consist of Three Concentric Shells (labelled as b & d). The Internal cluster is in a Tetrahedron (a) while the Ca - atoms involve (c) involve a Hexagonal Pattern.

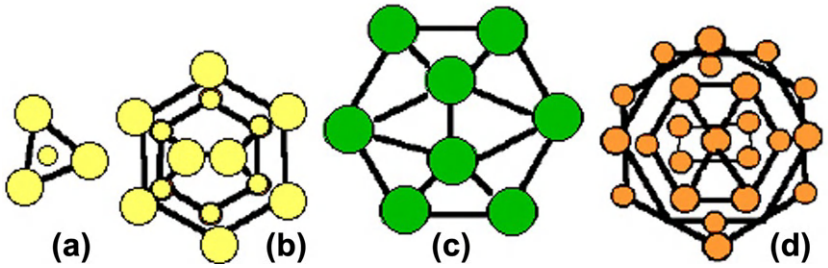

FIGURE 16.45

Cell parameters are: $a = 9.787$ Å, $b = c = 13.465$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 1536.71$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.32.

Only one *a*-*b* face is shown. The 3D model consists of two layers, separated by a layer of Cd atoms.

Thermodynamically stable binary icosahedral quasicrystals occur in the alloy systems, Cd_5Yb_7 and Cd_5Ca_7. Since their discovery, numerous attempts have been made to model their structure. Efforts that rely on "atomic surfaces" and higher dimensional space suffer problems since certain atomic positions appear to be displaced far from any simply represented position. Atomic surface representations also average over disorder phenomena in a manner that probably hides important details of the structure. One approach is to assume that the fundamental building motif of the structure is the large $Ca_{12}Cd_{54}$ atom cluster, as is observed in a 1/1" approximation. This phase, that is stable over a range of Cd-rich systems, is an alternative approach to model the quasicrystal structure to specify how the clusters arrange to fill space quasiperiodically, and to fill some empty regions with "glue" atoms. This approach is modeled in Fig. 16.47.

The compound, Ca_3Cd_2 has the conformational form shown in Fig. 16.48.

Cell parameters are: $a = 8.0236$, $b = c = 8.8642$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 630.14$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.33.

This compound is offered for sale commercially with the CAS number of 37191-29-0.

The closest cubic approximation to the $MCd_{5.7}$ (M = Ca, Yb) quasicrystals known so far, namely $Ca_{13}Cd_{76}$, was obtained by high-temperature reaction of the elements. It exhibits a new type of structure for IM compounds with an unprecedented arrangement of triacontahedral clusters (see following structure), which could prove useful in modeling the structures of the $MCd_{5.7}$ quasicrystals (Fig. 16.49).

No other IM compounds are known. At least one, Ca_3Cd_2, is offered for sale commercially.

In the Ca–Cd–O system, no compounds have been documented in the past or present technical literature. No description of such compounds (if they exist) has been published.

16.2.4. Strontium Cadmium Compounds

Strontium, metal forms a series of compounds with Cd metal as shown in Fig. 16.50. Six compounds are shown. The structures of all six compounds have been published.

The compound, SrCd, has the conformational form shown in Fig. 16.51.

Cell parameters are: $a = b = c = 4.0251$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 65.21$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.34.

Other than for structural data, no other description of this compound is available in the past or present technical literature.

$SrCd_2$ has the structural form shown in Fig. 16.52.

Cell parameters are: $a = 5.1643$ Å, $b = c = 6.5566$ Å, $\alpha = 79.42°$, $\beta = \gamma = 68.81°$, cell volume $= 84.98$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.35.

Other than structural data, this compound has not been subjected to any precise studies of its physical or electrical properties.

The $SrCd_6$ compound has the conformational structure shown in Fig. 16.53.

Only one layer is shown. The 3D structure consists of two layers, one at the (100) interface of the *ac*-directions and the other at (010) of the *ac*-interface layer.

Cell parameters are: $a = b = c = 13.8912$ Å, $\alpha = \beta = \gamma = 109.47°$, cell volume $= 2{,}063.39$ Å^3, $Z = 24$. Cell occupancy is shown in Table 16.36.

TABLE 16.32

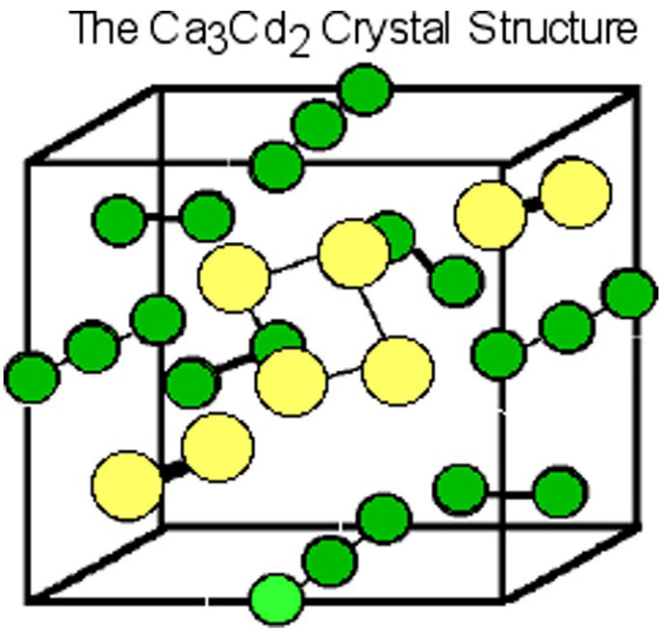

FIGURE 16.48

The basic building block of the $SrCd_6$ phase is shown in Fig. 16.54.

In Fig. 16.54(a) the cluster unit is built up of 12 MCd_{16} polyhedra and eight Cd_8 cubes. In Fig. 16.54(b), we see the alternative representation of the basic building block. The defect triacontahedron is entirely composed of Cd atoms; the pentagonal pyramids seen in the image belong to the 12 underlying MCd_{16} polyhedra. The bright triangular faces indicating missing corner atoms are in fact the planes that bisect the Cd_8 cubes seen in Fig. 16.54(a).

The coordination of Cd atoms around the different *Sr atoms* in the $SrCd_6$ phases can be described with one single polyhedron, the $SrCd_{16}$ polyhedron. It is a monocapped, double, pentagonal antiprism with nearly perfect fivefold symmetry. Twelve of these polyhedra are arranged to form the cluster unit that serves as the basic building block in the MCd_6 and $M_{13}Cd_{76}$ phases. This arrangement of MCd_{16} polyhedra automatically generate cube-shaped interstices (Cd_8 cubes!) that share square faces with the adjacent MCd_{16} polyhedra. Each cluster unit is associated with eight surrounding Cd_8 cubes (Fig. 16.55).

The Cd_{20} pentagonal dodecahedron is seen in Fig. 16.55(a)—the Cd_4 tetrahedron residing inside has been omitted in the image. The Cd_{30} icosidodecahedron is seen in Fig. 16.55(b), where the 12 pentagons in the polyhedron correspond to the intermediate pentagonal planes of the surrounding $SrCd_{16}$ polyhedra. Each of these pentagons has a Sr metal atom situated at their geometrical centers (seen as the large sphere in the magnified $SrCd_{16}$ polyhedron to the left in the figure), but these atoms have been omitted in the image. The defect rhombic triacontahedron is seen in Fig. 16.55(c)—the tips of the $12SrCd_{16}$ polyhedra are seen as pentagonal pyramids.

The $SrCd_{11}$ compound has the structure shown in Fig. 16.56.

Cell parameters are: $a = 7.673$ Å, $b = c = 9.299$ Å, $\alpha = 80.21°\beta = \gamma = 65.94°$, cell volume $= 550.40$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.37.

The unit cell is a body-centered tetragonal and the space group is $I4/amd$. The positions of the atoms show that Sr has 22 Cd atom neighbors while Cd atoms have 12–14 nearest neighbors.

The compound, $Sr_{13}Cd_{58}$, has a structure related to $Ca_{14}Cd_{51}$ and $Ca_{12}Cd_{54}$. These compounds have icosahedral conformations as shown in Fig. 16.57.

The overall structure of $Sr_{13}Cd_{58}$ has the form shown in Fig. 16.58.

Cell parameters are: $a = 15.912$ Å, $b = c = 16.058$ Å, $\alpha = 120,°\beta = \gamma = 90°$, cell volume $= 3{,}557.33$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.38.

The compound, Sr_5Cd_3, has the structure shown in Fig. 16.59.

Cell parameters are: $a = b = c = 8.7172$ Å, $c = 10.3388$ Å, $\alpha = \beta = 114.93°$, $\gamma = 90°$, cell volume $= 630.71$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.39.

Both the incongruently melting compounds, Ca_5Hg_3 and Sr_5Cd_3, have been synthesized from stoichiometric amounts of the pure elements. They crystallize with the Cr_5B_3 type of structure: space group $I4/mcm$, $Z = 4$. The most remarkable fragments are dumbbells X_2, which have interatomic distances only slightly longer than the sum of Pauling's covalent radii: Hg–Hg (Cd–Cd) = 306 (298) pm. The structure can be constructed by rhombic dodecahedra as the only

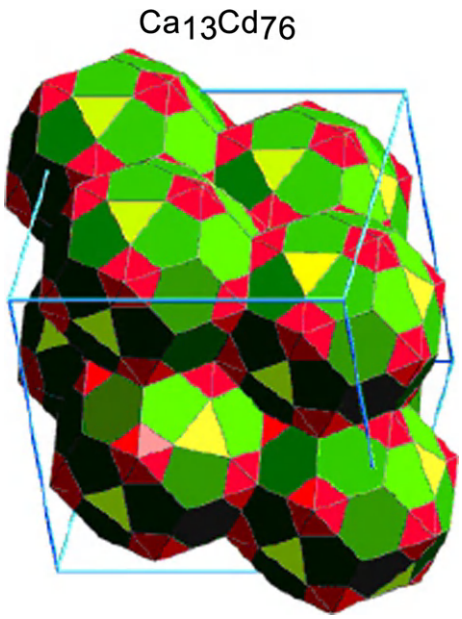

FIGURE 16.49

constituent moieties. These rhombic dodecahedra are built up by eight Ca (Sr) atoms and six Cd atoms and are furthermore centered by an additional Sr atom. Along [001] the rhombic dodecahedra share common vertices, but along [110] they are interconnected via common triangular faces. This kind of face sharing is responsible for the short distances obtained between the polyhedra, which leads to the occurrence of the dumbbells mentioned above.

In the Sr–Cd–O system, no cadmate compounds have been documented. The scientific literature is devoid of any mention of such materials. No strontium cadmate compounds have been offered for sale commercially and no CAS numbers have been issued to date.

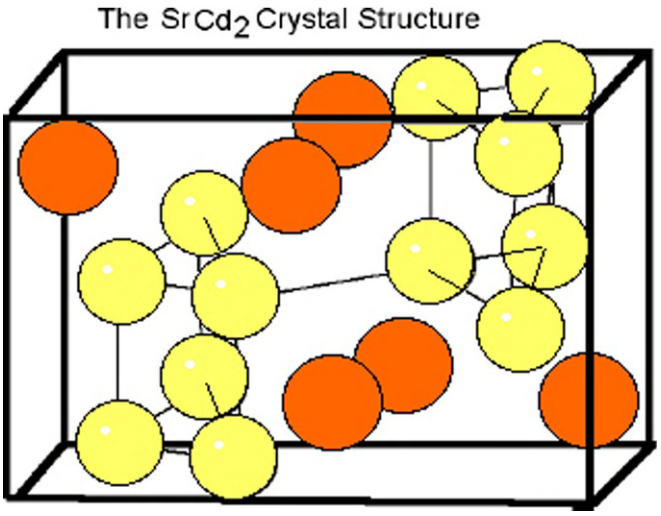

FIGURE 16.52

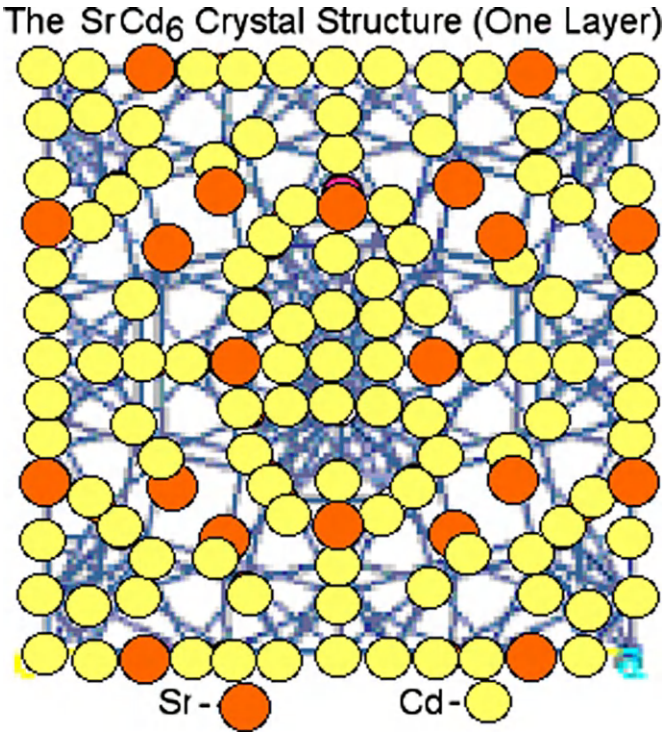

FIGURE 16.53

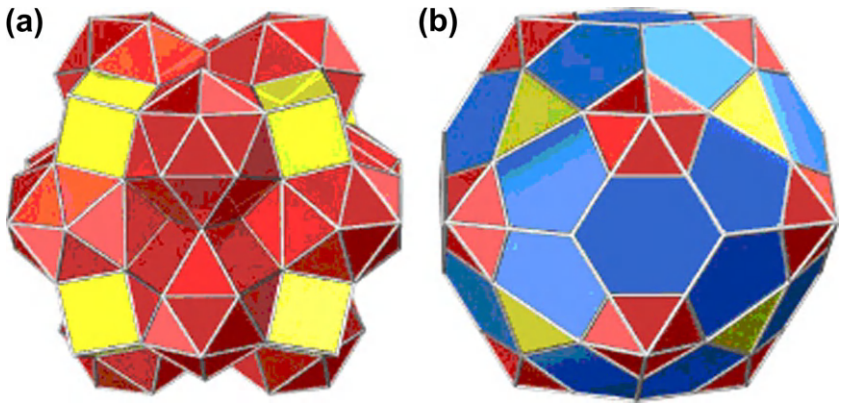

FIGURE 16.54

16.2.5. Barium Cadmium Compounds

Barium forms several IM compounds with cadmium metal as shown in Fig. 16.60.

Five Compounds are shown. All melt congruently except for Ba_2Cd which melts incongruently at 409 °C.

The compound, BaCd has the structure shown in Fig. 16.61.

Cell parameters of BaCd are: $a = b = c = 4.2131$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 74.78 Å^3, $Z = 1$. Cell occupancy is shown in Table 16.40.

BaCd has hexagonal symmetry with space group = $P6_3/mmc$, $Z = 4$ and is formed by a sequence along the (001) planes of slabs of trigonal prisms in which Bs is centered by Cd atoms and stacked in a close-fitting manner.It is a layered compound.

No further mention of this compound is available in the past or current literature except for those papers dealing with structure.

$BaCd_2$ has the structure shown in Fig. 16.62.

Cell parameters are: $a = 5.1643$ Å, $b = c = 6.5566$ Å, $\alpha = 79.42°$, $\beta = \gamma = 68.81°$, cell volume = 84.98 Å^3, $Z = 2$. Cell occupancy is shown in Table 16.41.

No mention of the physical or electrical properties of this compound is available in the past or current technical literature. It has not been characterized except for its structural characteristics.

In contrast, the Ba_2Cd compound has the structure shown in Fig. 16.63.

Cell parameters are: $a = 4.2722$ Å, $b = c = 8.1783$ Å, $\alpha = \beta = 105.14°$, $\gamma = 90°$, cell volume = 138.70 Å^3, $Z = 1$. Cell occupancy is shown in Table 16.42.

This compound is offered for sale commercially with the CAS number of 37190-20-8. No other description of the physical or electronic behavior of this compound has been documented in the past or current technical literature.

It has not found usage in Industry or interest by the Academic community.

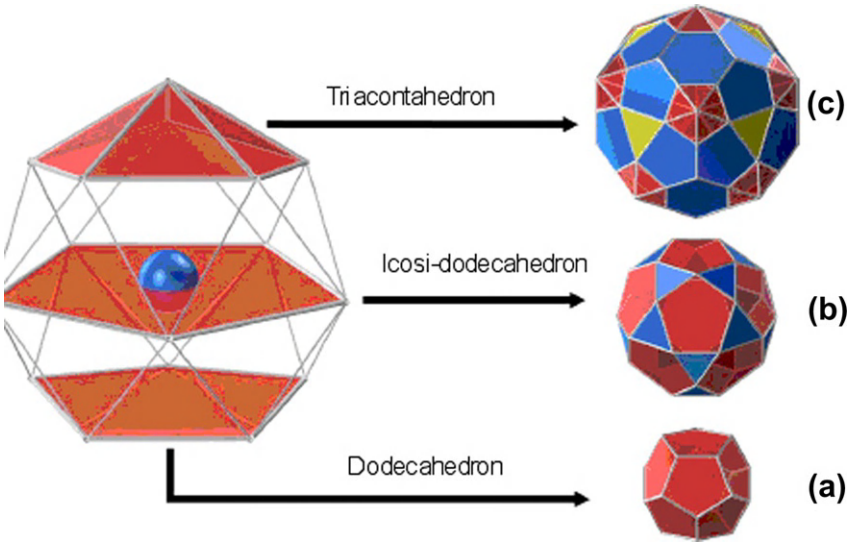

FIGURE 16.55

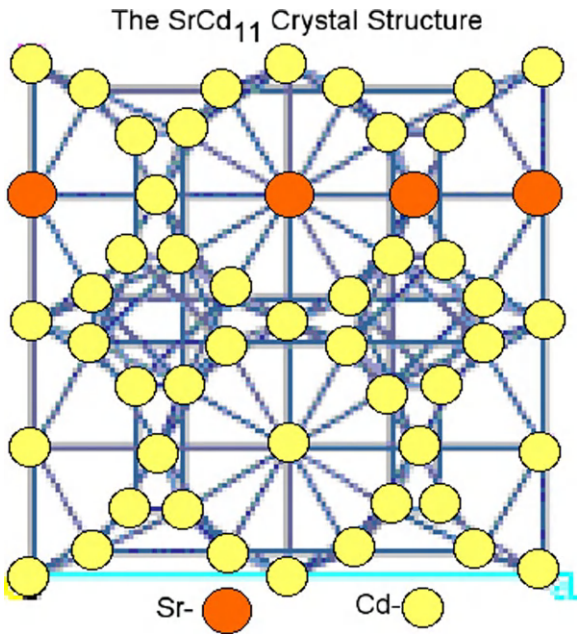

FIGURE 16.56

The compound, $BaCd_{11}$, has the conformational character shown in Fig. 16.64.

Cell parameters are: $a = 7.7455$ Å, $b = c = 9.3519$ Å, $\alpha = 80.14°$, $\beta = \gamma = 65.56°$, cell volume $= 561.00$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.43.

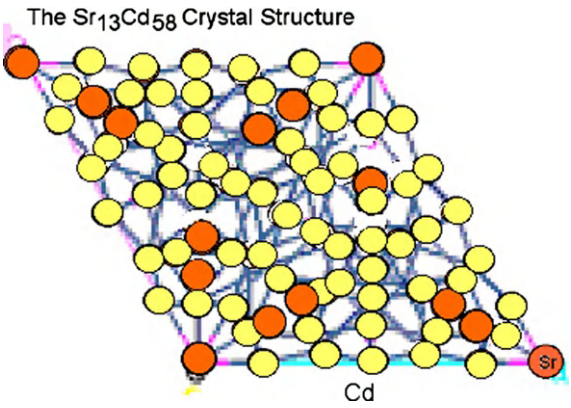

FIGURE 16.58

The $BaCd_{11}$ compound crystallizes in the space group $I41/amd$ with one Ba position (m2) and three Cd sites (m2, .2/m., 1). The structure is described in terms of all-face-capped Cd_8 tetrahedra as the central building unit, defined by the Cd atoms on .2/m. and 1 sites. The building units are condensed into chains by the central tetrahedra-sharing edges, and the chains are interconnected by shared capping atoms. The resulting 3D framework of Cd atoms yields channels that are occupied by Ba and Cd atoms on the high-symmetry $\bar{4}$m2 positions.

The compound, Ba_7Cd_{31}, has the structure shown in Fig. 16.65.

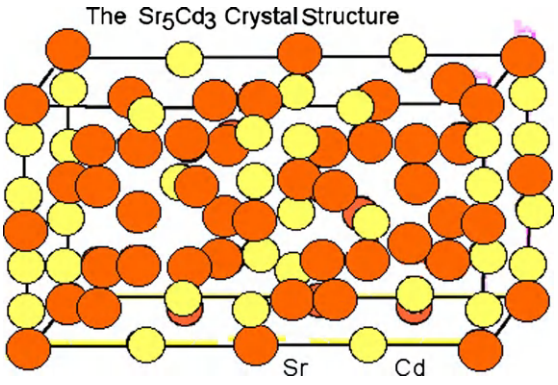

FIGURE 16.59

Cell parameters are: $a = 10.234$ Å, $b = c = 10.744$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 1018.92$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.44.

No other description of the physical or electronic behavior of this compound has been documented in the past or current technical literature. It has not found usage in Industry or interest by the Academic community.

Two Zintl compounds $Ba_2Cd_2As_3$ and $Ba_2Cd_2Sb_3$ have been synthesized and structurally characterized. They crystallize in a novel monoclinic structure type with the space group $C2/m$ (no. 12), featuring poly-anionic layers made of $CdPn_4$ tetrahedra (Pn = As, Sb) and homo-atomic Pn–Pn bonds. The topological relationships between the structure of $Ba_2Cd_2Sb_3$ and those of $BaCd_2Sb_2$ ($CaAl_2Si_2$ type) and $Ba_3Cd_2Sb_4$ (own type) were discussed as well. Based on electronic structures calculations, carried out by the density functional method, and resistivity measurements, pure $Ba_2Cd_2As_3$ was shown to be a small-gap semiconductor and pure $Ba_2Cd_2Sb_3$ to be a poor metal. The structures of these compounds are amenable to doping on both the cation and pnicogen sites, and make them promising materials for thermoelectric applications. A Zintl structure is shown in Fig. 16.66.

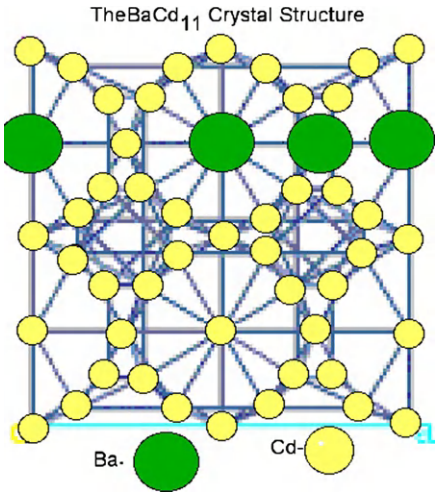

FIGURE 16.64

This compound has shown a high degree of thermoelectric power conversion, but only at very low temperatures, as shown in Fig. 16.67.

No other IM compounds of Ba–Cd metals are known.

In the system, Ba–Cd–O, the crystal structure of $BaCdO_2$ has been determined. The orthohombic unit cell [$a = 3.660$; $b = 6.168$; $c = 11.950$ Å; space group *Pmnb—D*] contains four formula units; $d_x = 6.94$, $d_{pyc} = 6.86$ g/cm^3. With the last refinement, R and R' fall to 0.058 and 0.075, respectively ($\sin\theta/\lambda \leq 0.950$). The total arrangement is related to that of ($SrZnO_2^2$). Here, the Cd atom is surrounded by 5 (4 + 1) O-neighbors [trigonal bipyramidal] while each Zn atom has a tetrahedral arrangement of four O neighbors.

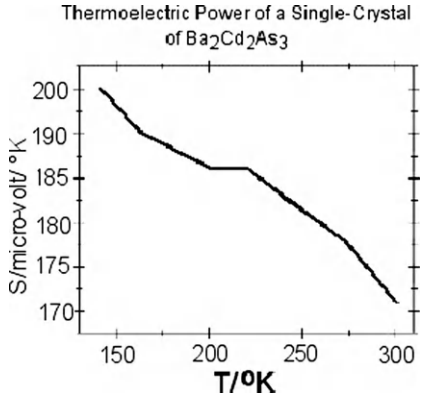

FIGURE 16.67

Therefore, the 2D $[ZnO_2]$-arrangement is replaced by a 3D one. Ba is situated at specific holes in the lattice, being surrounded by seven O atoms.

No other barium cadmate compounds have been documented in the past or present technical literature.

16.2.6. Radium Cadmium Compounds

Although Ra^0 and RaO undoubtedly form the same type of compounds with Cd^0 or CdO, there is no record of anyone having done so in the past or current literature. This is probably due to lack of interest by both Academia and Industry but more likely due to the high cost of either of these components.

16.3. THE ALKALINE EARTH MERCURY COMPOUNDS

Mercury forms several IM compounds with the alkaline earths. However, only a few oxide-based compounds are known.

16.3.1. Beryllium Mercury Compounds

Beryllium does not form any IM compounds with mercury. Nor does it form any compounds in the $BeO–Hg_xO_y$ system, where x and y can vary from 1 to 3.

16.3.2. Magnesium Mercury Compounds

Magnesium metal forms six different IM compounds with Hg metal. This is shown in Fig. 16.68.

The structures of five of these compounds are known and include the 1;1, 1:2, 2:1, 3:1 and 5:3 compounds. Of the six (6) compounds shown in the diagram, two melt congruently. The others melt incongruently. The structure of the compound, Mg_5Hg_2, remains unknown.

The formation enthalpies per mole of the compounds MgHg(solid) and CaHg(solid) have been determined as -28.2 ± 0.8 and -56.8 ± 4.6 kJ/mol, respectively. This was accomplished by studying the vaporization of compounds of the Mg–Hg and Ca–Hg systems, with a novel Knudsen cell–mass spectrometer system. Comparative values of −30 [MgHg(solid)] and −59 kJ/mol [CaHg(solid)] were predicted, using the

volume contraction model, as well as the values of −34.6 [MgHg(solid)] and −1.6 kJ/mol [CaHg(solid)] for the Pauling model of ionic bond, and using the electronegativities of Gordy and Thomas. The enthalpies of formation were compared with those of IM compounds having predominantly ionic bonds. The enthalpies of formation per mole of an atom of the compounds such as BaHg(solid) and SrHg(solid) were predicted as −61.6 and −77.9 kJ/mol, by applying the same Pauling model of ionic bond to the electronegativities of Gordy and Thomas.

The MgHg compound has the form shown in Fig. 16.69.

Cell parameters are: $a = 10.234$ Å, $b = c = 10.744$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 1018.92 Å^3, $Z = 1$.

Cell occupancy is shown in Table 16.45.

The de Haas–van Alphen effect has been observed in the quadrivalent β-brass compound MgHg. Five frequency groups have been measured in the {110} and {100} planes along with some effective masses at high symmetry points. All five groups observed are well explained by Skriver's relativistic LMTO band calculation. A football-shaped piece predicted in the third band has the size and shape of an observed closed section which was inverted with tetragonal harmonics. The remaining orbits arise from the multi-connected second band surface, a surface formed by connecting pockets at Γ and R with arms along <111> of the Brillouin surface of the crystal structure.

The compound, Mg_2Hg, has the structure shown in Fig. 16.70.

Cell parameters are: $a = 4.618$ Å, $b = 6.224$ $c = 8.843$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 252.77 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.46.

The compound, $MgHg_2$, has the conformational form shown in Fig. 16.71.

Cell parameters are: $a = b = 3.933$ Å, $c = 5.159$ Å, $\alpha = \beta = 111.79°$, $\gamma = 90°$, cell volume = 64.40 Å^3, $Z = 2$. Cell occupancy is shown in Table 16.47.

The compound, Mg_3Hg, has the structural form shown in Fig. 16.72.

Cell parameters are: $a = b = 4.858$ Å, $c = 8.639$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 1,018.92 Å^3, $Z = 1$. Cell occupancy is shown in Table 16.48.

The compound, Mg_5Hg_3, has the structure shown in Fig. 16.73.

Cell parameters are: $a = 5.919$ Å, $b = c = 8.243$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 348.30 Å^3, $Z = 2$. Cell occupancy is shown in Table 16.49.

Evaporation of the compounds Mg_5Hg_3(solid), Mg_2Hg(solid), Mg_5Hg_2(solid), and Mg_3Hg(solid) was studied using a Knudsen cell–mass spectrometer system. They evaporate according to the equations:

$$2Mg_5Hg_3(\text{solid}) \Rightarrow Hg(\text{gas}) + 5Mg_2Hg(\text{solid}), \quad (1)$$

$$5Mg_5Hg(\text{solid}) \Rightarrow Hg(\text{gas}) + 2Mg_5Hg_2(\text{solid}), \quad (2)$$

$$3Mg_5Hg_2(\text{solid}) \Rightarrow Hg(\text{gas}) + 5Mg_3Hg(\text{solid}), \text{ and} \quad (3)$$

$$Mg_3Hg(\text{solid}) \Rightarrow Hg(\text{gas}) + 3MgHg(\text{solid}) \quad (4)$$

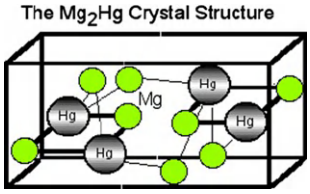

FIGURE 16.70

The Hg partial pressures of (Eqns 1 and 4) are:

$$\log(p\text{Pa}) = (4973.1 \pm 60.3)\text{K}/T + (9.886 \pm 0.12)\ (440 - 540\ \text{K}),$$

$$\log(p\text{Pa}) = (6605.6 \pm 69.1)\text{K}/T + (10.91 \pm 0.11)\ (499 - 7110\ \text{K}),$$

$$\log(p\text{Pa}) = (7118.3 \pm 116.5)\text{K}/T + (10.91 \pm 0.19)\ (548 - 9890\ \text{K}), \text{and}$$

$$\log(p\text{Pa}) = (7502.3 \pm 58.8)\text{K}/T + (11.29 \pm 0.10)\ (525 - 695\ \text{K})$$

The enthalpy changes of reactions (Eqns 1 and 4) were determined using the second and third Law method.

Formation enthalpies in kJ/mol at 298 K were obtained as:

-60.5 ± 4.3 ($MgHg_2$),
-56.4 ± 1.7 (MgHg),
-217.1 ± 7.3 (Mg_5Hg_3),
-79.8 ± 2.8 (Mg_2Hg),
-166.0 ± 6.8 (Mg_5Hg_2),
-84.2 ± 4.0 (Mg_3Hg).

for the compounds given in parentheses.

The superconducting transition temperatures of several of these Hg–Mg metallic compounds have been determined. The critical temperature decreases monotonically with increasing Mg content, and shows no apparent crystal structure dependence. An attempt was made to extrapolate to the transition temperature of pure Mg. This procedure yielded an estimate (rather uncertain) of between 1.0 and 10.0×10^{-3} K for the T_c of pure Mg. The transition temperatures of Hg_2Mg, HgMg, Hg_3Mg_5, $HgMg_2$ and $HgMg_3$ fall in the range 4·0–0.16 K. The critical temperatures of a few compounds of Hg with Ba and Ca have also been measured above 1.25 K.

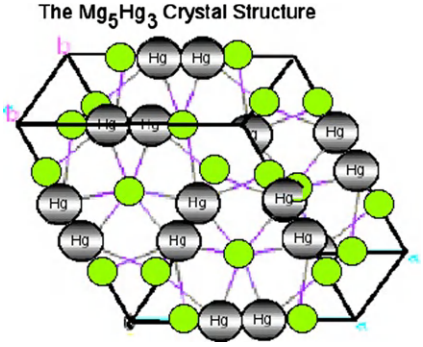

FIGURE 16.73

Magnesium–mercury amalgams are supplied commercially with the CAS numbers of Mg_5Hg_3(solid) [12055-41-3], Mg_2Hg(solid) [12055-30-0], Mg_5Hg_2(solid) [55200-37-8].

In the system, MgO–Hg_xO_y, where x and y can vary from 1 to 3, no compounds have been documented in the past or present literature.

16.3.3. Calcium Mercury Compounds

Calcium metal forms a number of IM compounds with Hg metal as shown in Fig. 16.74.

Nine (9) compounds are shown in the diagram, two of which melt congruently. The others melt peritectically or incongruently. The structures of eight compounds have been documented in the current literature. The structure of Ca_3Hg_2 has not been documented.

The CaHg compound has the structure shown in Fig. 16.75

Cell parameters are: $a = 10.234$ Å, $b = c = 10.744$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 1018.92$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.50(A).

The formation enthalpies per mole of an atom of the compound CaHg(solid) was determined as -56.8 ± 4.6 kJ/mol, by studying the vaporization of compounds of the Ca–Hg system with a novel Knudsen cell–mass spectrometer system. A value of -59 kJ/mol [CaHg(solid)] was predicted using the volume contraction model, and the Pauling model of ionic bonds combined with the electronegativities of Gordy and

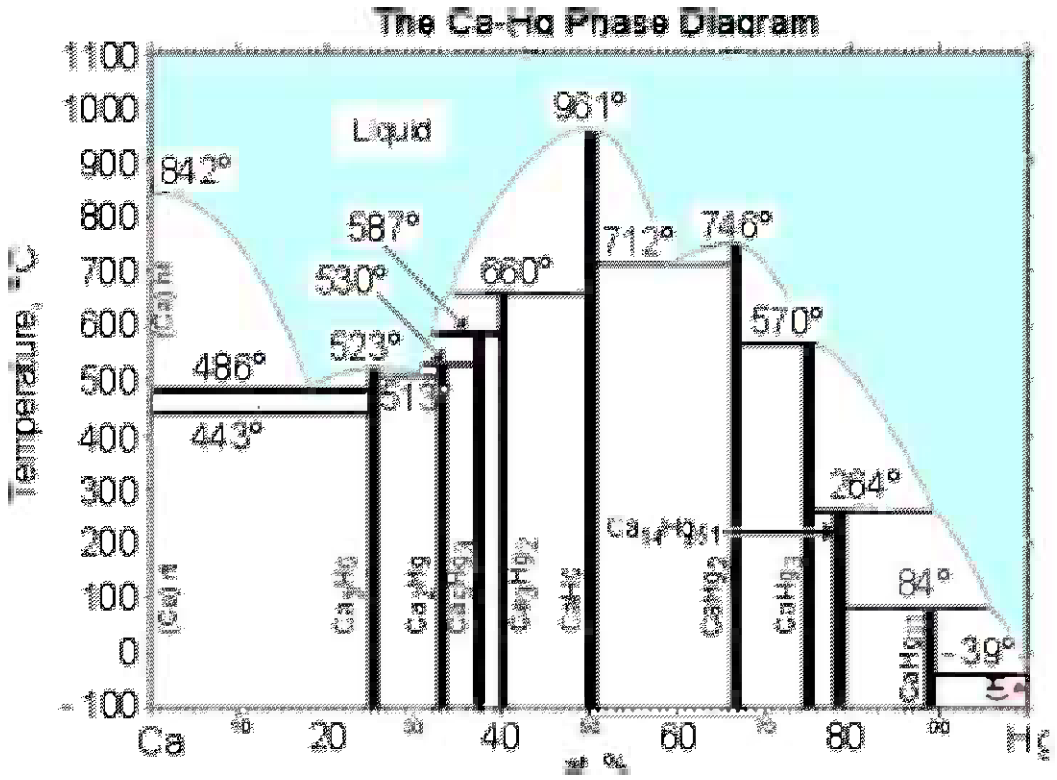

FIGURE 16.74

Thomas. The enthalpy of formation was compared with those of IM compounds with predominantly ionic bond. The enthalpies of formation per mole of an atom of the compounds BaHg(solid) and SrHg(solid) were predicted as −61.6 and −77.9 kJ/mol, by applying the Pauling model of ionic bond with the electronegativities of Gordy and Thomas.

The compound, $CaHg_2$, has the structural form shown in Fig. 16.76.

Cell parameters are: $a = 3.5712$ Å, $b = c = 4.8943$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 74.07$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.50(B).

Vapor pressure measurements in the system Ca–Hg (0–50 atom% Ca) at temperatures between 250 and 500 °C confirmed the existence of the phases $CaHg_5$, $CaHg_3$, $CaHg_2$, and CaHg. No other phases exist in the examined range. $CaHg_3$ crystallizes with a stoichiometric composition without any range of homogeneity, but $CaHg_5$ and $CaHg_2$ have small (0.2 and 0.8 atom%, respectively) homogeneity ranges. The examinations confirm the peritectic decomposition of $CaHg_5$ (263 °C) and the stability of $CaHg_3$, $CaHg_2$ and CaHg up to

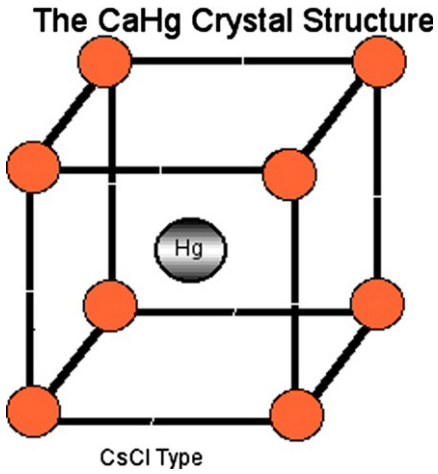

FIGURE 16.75

temperatures above 500 °C. The heats of reaction of the Hg-rich Ca–Hg-compounds formed from CaHg and Hg, as calculated from vapor pressure measurements are relatively small. Further experiments proved that

Hg is not soluble in Ca at least at a temperature of 450 °C.

The compound, Ca_2Hg has the structure shown in Fig. 16.77.

Cell parameters are: $a = 4.892$ Å, $b = 7.863$ Å, $c = 9.874$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 74.07$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.51.

The physical or electronic properties of this material have not been documented in the past or present literature. The only related data have been that of its structure determination. Ca_2Hg is offered commercially with a CAS number of 39461-28-4.

The compound, Ca_3Hg, has the structure shown in Fig. 16.78.

Cell parameters are: $a = 6.8282$, $b = 8.1513$, $c = 10.152$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 565.29$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.52.

The chemical bonding of the Hg_2 dimers present in Ca_5Au_4 and Ca_3Hg_2 was examined based on first principles electronic band structure calculations. In these compounds, the 6s- and 5d-block bands of Hg are completely filled while the frontier levels of Hg are given by partially filled 6p-block bands such that the transition metal atoms Hg are best described as anions with electron configuration $(5d)^{10}(6s)^2(6p)^1$. Thus, the Hg_2 dimers in Ca_5Au_4 and Ca_3Hg_2 are present as $[Au\text{-}Au]^{4-}$, and $[Hg\text{-}Hg]^{2-}$ Zintl anions, respectively. In these compounds, the Hg_2 dimers have a single bond formed by the p_σ–p_σ interaction between the 5p and 6p orbitals of Hg atoms. The anions of late transition metal elements are different from those of late main group elements in their tendency for covalent bond formation.

This compound is supplied commercially with the CAS number of 39461-28-4.

The compound, $CaHg_3$, has the structure shown in Fig. 16.79.

Cell parameters are: $a = 5.024$ Å, $b = c = 6.635$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 191.39$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.53.

This compound is supplied commercially with the CAS number of 12049-40-0.

The compound, Ca_5Hg_3, has the structure shown in Fig. 16.80.

Cell parameters are: $a = 9.3573$ Å, $b = c = 8.1892$ Å, $\alpha = 90°$, $\beta = \gamma = 115.95°$, cell volume = 492.92 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.54.

Both the incongruently melting compounds, Ca_5Hg_3 and Sr_5Cd_3, have been synthesized from stoichiometric amounts of the pure elements. They crystallize with the Cr_5B_3 type of structure: space group $I4/mcm$, $Z = 4$; Ca_5Hg_3 (Sr_5Cd_3): $a = 8.189$ (8.717) Å, $c = 14.701$ (16.601) pm, $c/a = 1.80$ (1.90), $R = 2.33\%$ (2.97%). The most remarkable fragments are dumbbells X_2, which have interatomic distances only slightly longer than the sum of *Pauling's* covalent radii: Hg–Hg (Cd–Cd) = 306 (298) pm. The structure can be visually viewed as rhombic dodecahedra as the only constituent moieties. These rhombic dodecahedra are built up by eight Ca (Sr) atoms and six Hg (Cd) atoms and are furthermore centered by an additional Ca (Sr) atom. Along [001] the rhombic dodecahedra share common vertices, but along [110] they are interconnected via common triangular faces. This kind of face sharing is responsible for the short distances obtained between the polyhedra, which leads to the occurrence of the dumbbells mentioned above.

The compound, $CaHg_{11}$, has the structure shown in Fig. 16.81.

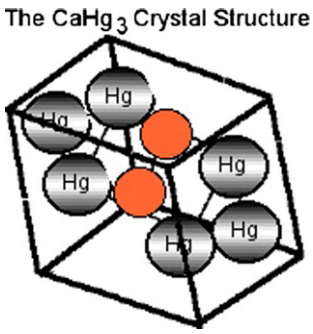

FIGURE 16.79

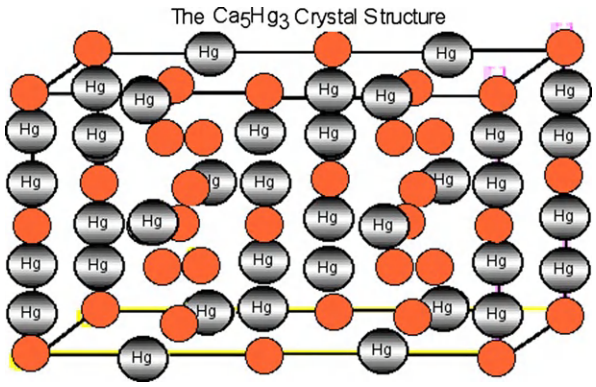

FIGURE 16.80

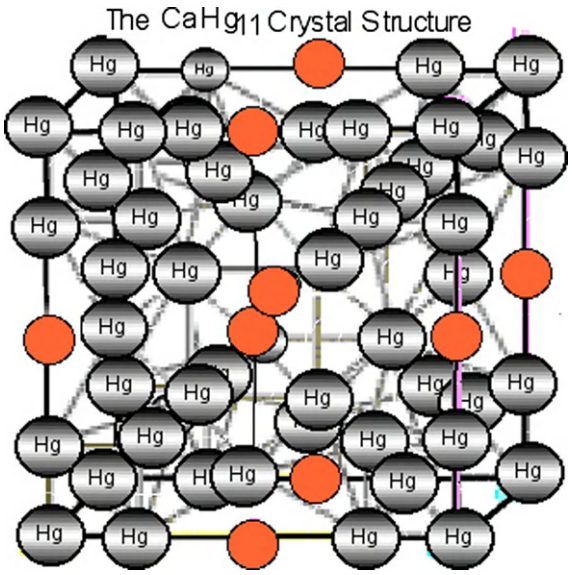

FIGURE 16.81

Cell parameters are: $a = b = c = 9.635$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 884.74$ Å^3, $Z = 3$. Cell occupancy is shown in Table 16.55.

This compound has not been the subject of any scientific investigation and the only data relating to it involve structural constants.

The compound, $Ca_{14}Hg_{51}$, has the structure shown in Fig. 16.82.

Cell parameters are: $a = 9.6332$ Å, $b = c = 13.442$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 1506.92$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.56.

This compound has similar structural properties to those of the Ca–Cd system (Fig. 16.83).

It also forms compact icosahedral structures as shown in Fig. 16.83.

The compound, Ca_3Hg_2, has the structure shown in Fig. 16.84.

Cell parameters are: $a = 4.1974$ Å, $b = c = 9.4762$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 301.52$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.57.

The coordination polyhedron around the Hg–Hg dimers in Ca_3Hg_2 is shown in Fig. 16.85.

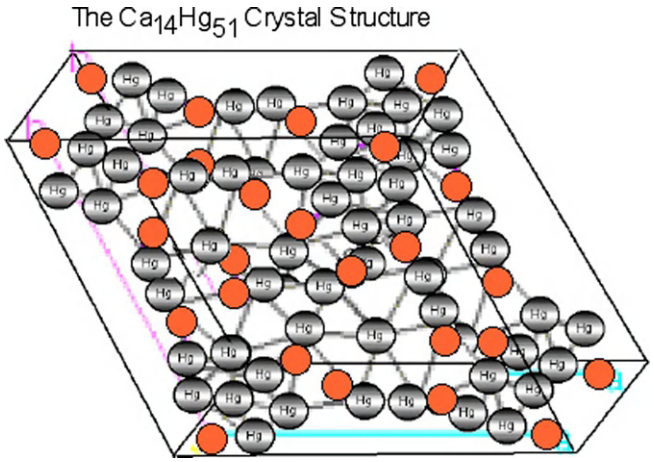

FIGURE 16.82

The dark blue spheres form a trigonal biprism, and the light blue spheres cap its four rectangular faces.

A number of calcium mercuride compounds are offered for sale commercially, as noted above.

In the CaO–HgO system, the only known compound is $CaHgO_2$ that has the structure shown in Fig. 16.86.

Cell parameters are: $a = 6.5391$ Å, $b = c = 3.6482$ Å, $\alpha = \beta = 74.02°$, $\gamma = 60°$, cell volume $= 69.59$ Å^3, $Z = 2$. Cell occupancy is shown in Table 16.58.

No other calcium mercurate compounds are known. No calcium mercurate compounds are offered for sale commercially and no CAS numbers have been issued.

16.3.4. Strontium Mercury Compounds

Strontium metal forms a number of IM compounds with Hg metal as shown in Fig. 16.87.

Nine (9) compounds are known, two of which melt congruently. The others melt incongruently. The structures of all nine compounds have been documented in the current literature.

The strontium–mercury system has been investigated using thermal, micrographic and X-ray methods. Two compounds melt congruently: SrHg (850 °C) and

Cell parameters are: $a = b = c = 3.9552$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 61.86 Å^3, $Z = 1$. Cell occupancy is shown in Table 16.59.

Other than structural data, this compound has not been the subject of an intensive survey of its physical or electronic properties.

The compound, $SrHg_2$, has the structure shown in Fig. 16.89.

Cell parameters are: $a = 4.9852$ Å, $b = c = 6.2864$ Å, $\alpha = 178.16°$, $\beta = \gamma = 66.64°$, cell volume = 165.24 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.60.

Other than structural data, this compound has not been studied intensively and an intensive survey of its physical or electronic properties remains to be accomplished.

The compound, Sr_3Hg, has the structure shown in Fig. 16.90.

Cell parameters are: $a = 7.4053$ Å, $b = 8.5232$, $c = 11.0824$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 699.29 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.61.

In contrast, the compound, $SrHg_3$, has the structure shown in Fig. 16.91.

Cell parameters are: $a = 6.1063$ Å, $b = c = 6.9064$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 210.89 Å^3, $Z = 2$. Cell occupancy is shown in Table 16.62.

Little data concerning this compound are available concerning its physical or electronic properties. A few papers, studying the structural characteristics, have been published

The compound, Sr_3Hg_2, has the structure shown in Fig. 16.92.

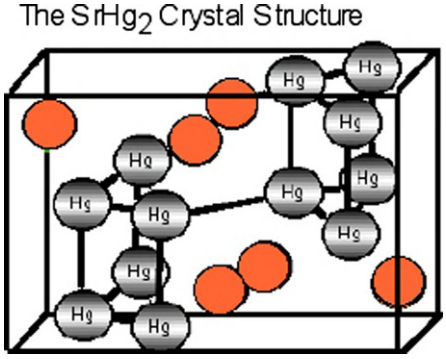

FIGURE 16.89

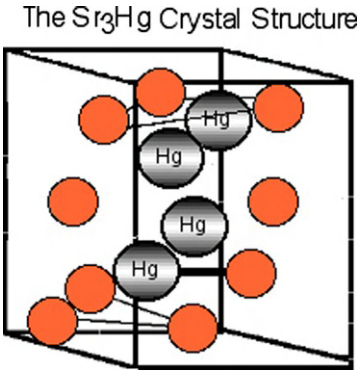

FIGURE 16.90

Cell parameters are: $a = 45.531$ Å, $b = c = 8.8833$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 359.29 Å^3, $Z = 4$. Cell occupancy is shown in Table 16.63.

Mixtures of strontium and mercury in molar ratios of 7:3 have been annealed for 20 days at 520 °C. From the pure product, Sr_3Hg_2 single crystals have been obtained. Sr_3Hg_2 crystallizes in the U_3Si_2 type of structure (space group $P4/mbm$); the cell constants are $a = 8.883$ (2) and $c = 4.553(1)$ Å. All of the Hg atoms are involved in Hg_2 dumbbells with Hg–Hg distances of 3.41 Å.

The compound, $SrHg_{11}$, has the structure shown in Fig. 16.93.

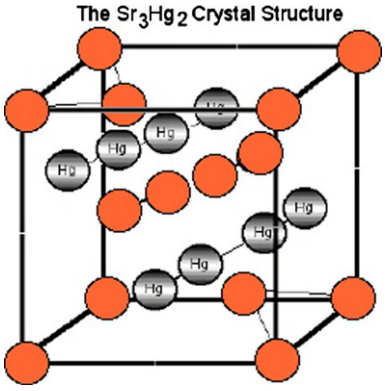

FIGURE 16.92

Cell parameters are: $a = b = c = 9.5102$ Å, $\alpha = \beta = \gamma = 90°$, cell volume = 860.14 Å^3, $Z = 3$. Cell occupancy is shown in Table 16.64.

The silvery metallic air-sensitive $SrHg_{11}$ compound can be prepared as a homogeneous, microcrystalline sample starting directly from stoichiometric mixtures of the elements. It decomposes peritectically and represents the mercury richest thermodynamically stable phases in the binary diagram. It crystallizes isotypically in space group $Pm3m$ ($Z = 3$) with the lattice constants: $SrHg_{11}$: $a = 9.510$ Å (powder), $BaHg_{11}$: 95871(1) pm (powder). Based on a systematical symmetry analysis one can show the relationship between the MHg_{11} structure type, β-Hg and a cubic close packing of spheres.

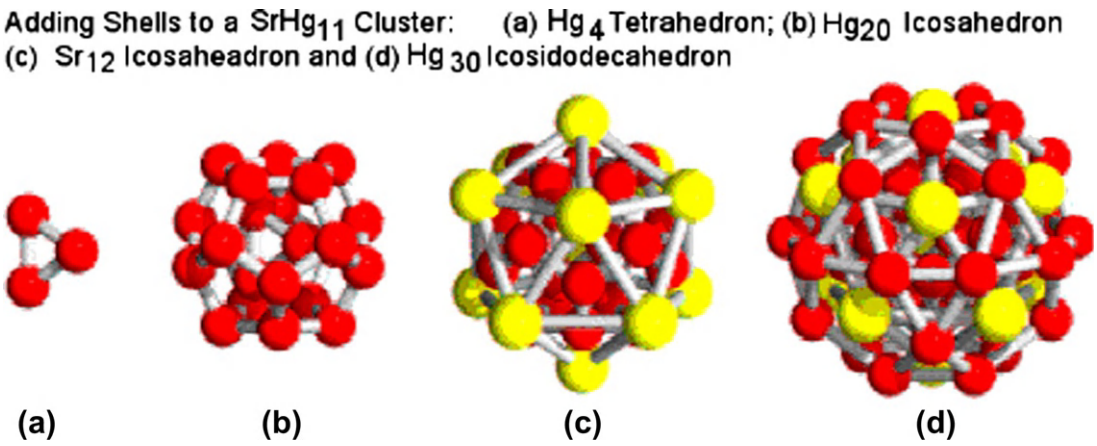

FIGURE 16.94

Furthermore the description of the structure can be based on a 3D arrangement of four capped tetragonal hexagon prisms $SrHg_{20}$, the latter ones being typical for the first coordination sphere of the Hg atoms ($C_N = 20$). Together, with additional, formally isolated Sr atoms these polyhedra constitute the topology of the Cu_3Au structure type. An alternative description emphasizes polyhedra based on three shells around a centering Hg atom in the sense Hg at Hg_{12} at Hg_{32} at Sr_{12}. These endohedral polyhedra, which serve as complex building units, constitute the 3D structure by formal condensation.

Finally, the structure can be regarded as built-up from centered cubo-octahedra $HgHg_{12}$, square planar and cube-shaped Hg_4 and Hg_8 units (Fig. 16.94).

The compound, $Sr_{14}Hg_{51}$, has the structure shown in Fig. 16.95.

This compound is related to the compounds, $Ca_{14}Hg_{51}$ and $Ca_{14}Cd_{51}$. It also forms compact icosahedral structures as shown above.

Cell parameters are: $a = 9.884$ Å, $b = c = 13.783$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 1,624.75 Å^3, $Z = 1$. Cell occupancy is shown in Table 16.65.

The compound, $Sr_{13}Hg_{58}$, has a structure related to $Ca_{13}Cd_{76}$. This structure is also shown in Fig. 16.96.

Cell parameters are: $a = b = c = 15.9424$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume = 3474.47 Å^3, $Z = 2$. Cell occupancy is shown in Table 16.66.

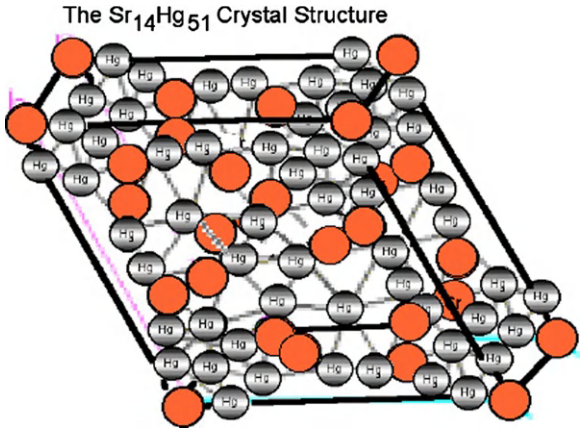

FIGURE 16.95

The compound, $SrHg_8$, does not appear in the phase diagram. However, the mercury-rich IM compound $SrHg_8$ has been prepared by reaction of the elements at 200 °C. Single-crystal XRD analysis revealed that it adopts a new structure type (Pearson symbol *oP*72, space group = *Pnma*, $a = 13.328$ Å, $b = 4.9128$ Å, $c = 26.446$ Å) (Fig. 16.97).

The Sr atoms are centered within two types of 18-vertex Hg polyhedra formed by augmenting pentagonal prisms with octagonal waists. The condensation of these Sr at Hg_{18} clusters is associated with the formation of a complex

anionic Hg–Hg bonding network, as supported by electronic structure calculations which reveal strong mixing of Hg 6s and 6p states in highly delocalized bands superimposed with a narrower 5d band below the Fermi level.

No other IM compounds are known. A few Sr–Hg compounds are available for sale commercially, as noted above.

Little work has been reported on simple inorganic compounds containing Sr and Hg in combination. $SrHg_2O_2Cl_2$ has been prepared as reddish brown powder by the solid-state reaction of strontium peroxide

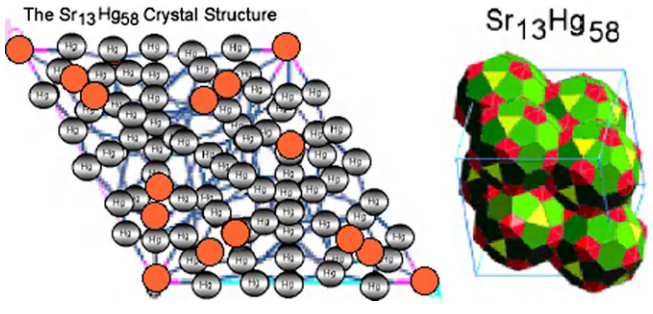

FIGURE 16.96

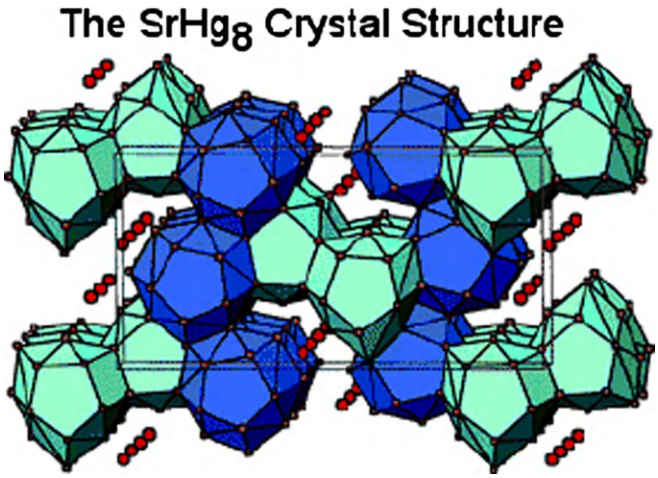

FIGURE 16.97

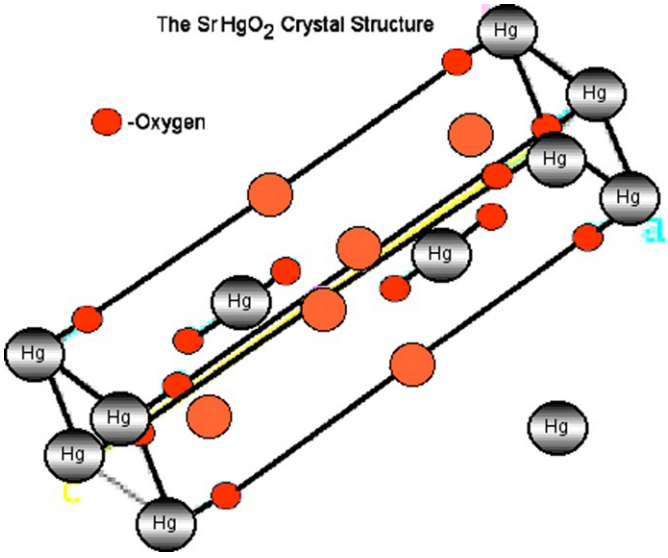

FIGURE 16.98

SrO_2 with calomel, Hg_2Cl_2. The crystal structure of the new phase $SrHg_2O_2Cl_2$ includes an unusual T-shaped HgO_3 grouping as part of infinite $[Hg_2O_2]$-infinity sheets. In the structure of $SrHg_2O_2Cl_2$ ($P\ 21/n$, $a = 9.9432$, $b = 7.0226$, $c = 8.2877$ Å, $= 102.441$, $V = 565.44$ Å^3, $Z = 4$). One can isolate a cationic r-octahedron grouping, SrO_8.

The only known oxy-mercury compound known is $SrHgO_2$ that has the structure shown in Fig. 16.98.

No other compounds are known in the SrO–HgO system.

16.3.5. Barium Mercury Compounds

Barium metal forms a number of IM compounds with Hg metal as shown in Fig. 16.99.

At least eight compounds are shown but only five of these have been studied in regard to their structure. The structure of the compounds, $BaHg_6$, $BaHg_{13}$ and $BaHg_4$ remains unknown at this point in time.

The compound, BaHg, has the structure shown in Fig. 16.100.

Cell parameters are: $a = b = c = 4.1313$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 70.50$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.67.

Other than structural data, this compound has not been the subject of an intensive survey of its physical or electronic properties.

The compound, $BaHg_2$, has the structure shown in Fig. 16.101.

Cell parameters are: $a = 5.1444$, $b = c = 6.4731$, $\alpha = 77.15°$, $\beta = \gamma = 66.59°$, cell volume $= 180.97$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.68.

In contrast, the compound, Ba_2Hg, has the structure shown in Fig. 16.102.

Cell parameters are: $a = 15.192$ Å, $b = c = 4.202$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 267.95$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.69.

The above two compounds have not been studied intensively and little has been established concerning their physical or electronic properties.

The compound, Ba_7Hg_{31}, has the structure shown in Fig. 16.103.

Cell parameters are: $a = b = 10.778$ Å, $c = 10.189$ Å, $\alpha = 120°$, $\beta = \gamma = 90°$, cell volume $= 1025.03$ Å^3, $Z = 1$. Cell occupancy is shown in Table 16.70.

This compound has not been studied intensively and little has been established concerning its physical or electronic properties.

The compound, $BaHg_{11}$, has the structure shown in Fig. 16.104.

Cell parameters are: $a = b = c = 9.5875$ Å, $\alpha = \beta = \gamma = 90°$, cell volume $= 881.28$ Å^3, $Z = 4$. Cell occupancy is shown in Table 16.71.

This silver-metallic air-sensitive compound can be prepared as a homogeneous, microcrystalline sample starting directly from stoichiometric mixtures of the elements. It decomposes peritectically and represents one of the mercury richest thermodynamically stable phases in the binary diagram. It crystallizes isotypically in space group $Pm3m$ ($Z = 3$) with the lattice constants: $BaHg_{11}$: 9.5871 Å (powder). Based on a systematical symmetry analysis, one can show the relationship between the $BaHg_{11}$ structure type, β-Hg and a cubic close packing of spheres, respectively. Furthermore the description of the structure can be based on a 3D arrangement of four capped tetragonal hexagon prisms $BaHg_{20}$, the latter ones being typical for the first coordination sphere of the Ba-atoms

($C_N = 20$). Together with additional, formally isolated Hg atoms, these polyhedra constitute the topology of the Cu_3Au structure type. An alternative description emphasizes polyhedra based on three shells around a centering Hg atom in the sense Hg at Hg_{12} at Hg_{32} at Ba_{12}. These endohedral polyhedra, which serve as complex building units, constitute the 3D structure by formal condensation. Finally, the structure can be regarded as built-up from centered cubo-octahedra $HgHg_{12}$, square planar and cube-shaped Hg_4 and Hg_8 units. These icosahedra are shown in Fig. 16.105.

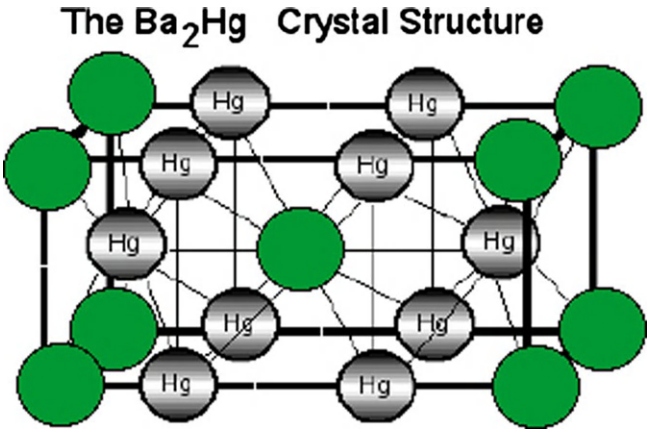

FIGURE 16.102

The compounds, $BaHg_6$, $BaHg_{13}$ and $BaHg_4$ are shown in the phase diagram but their structures have not been elucidated or documented.

No other IM compounds are known. No Ba–Hg compounds are offered for sale commercially and no CAS numbers have been issued to date.

Very few oxymercurate compounds are known. The $BaHg_2O_2$ compound has the structure shown in Fig. 16.106.

$BaHgO_2$ was prepared for the first time by an oxygen-high pressure technique. X-ray investigations of single crystals indicate a hexagonal symmetry, space group D_6^6–$P6_322$ (No. 182); $a = 6.904$ Å; $Z = 6$. Hg^{2+} is coordinated by two oxygen ions and Ba^{2+} by six oxygen

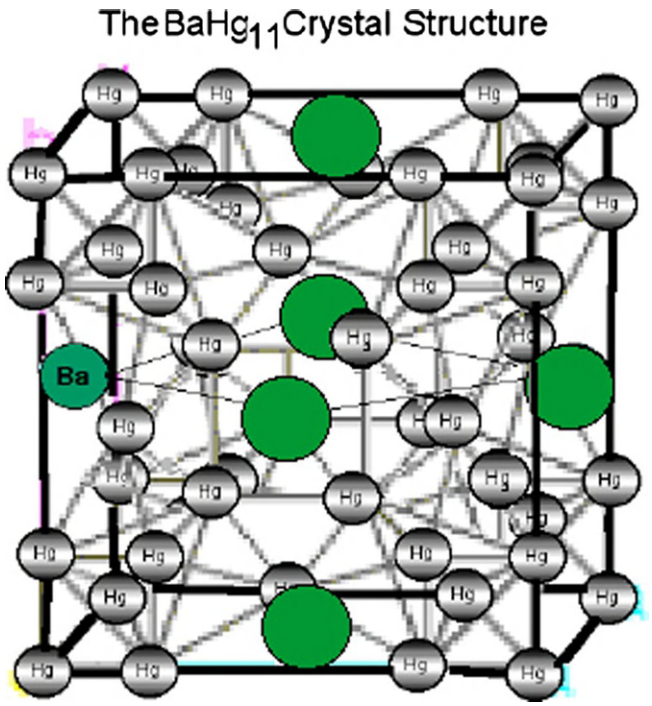

FIGURE 16.104

ions. 2D layers of trigonal BaO_6 prisms are connected by O–Hg–O dumbbells along [001].

During an investigation of the BaO–HgO system, a new polymorph of $BaHgO_2$ was obtained with a rhombic configuration. This phase was characterized by X-ray powder diffraction, scanning electron microscopy, and EDS analysis. Similar to the $SrHgO_2$ and $CaHgO_2$ counterparts, it crystallizes with the 3R delafossite structure with cell parameters $a = 4.097$, $c = 19.348$ Å, space group $R3/m$, and $Z = 3$. It is also shown that the distortion from the 3R delafossite structure, reported for $SrHgO_2$, might be the effect of a merohedral twinning due to stacking faults.

Recent results in the field of oxomercurate(II) chemistry have been reviewed. The methods of preparation and the crystal chemistry of oxomercurates were also discussed. Although only one compound has been documented in the Ba–Hg–O system, a number of oxomercurates (M_2HgO_4), alkaline earth oxomercurates ($MHgO_4$, $CdHgO_4$), rare earth oxomercurates, ternary oxomercurates ($BaAg_2Hg_2O_4$ and $Ba_3Pt_4HgO_{11}$) and the compounds $Ba_2Hg_2Pd_7O_{14}$,

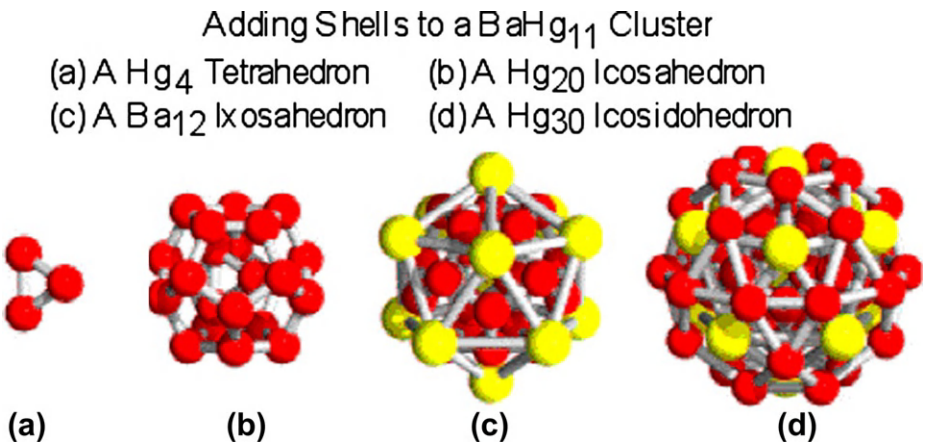

FIGURE 16.105

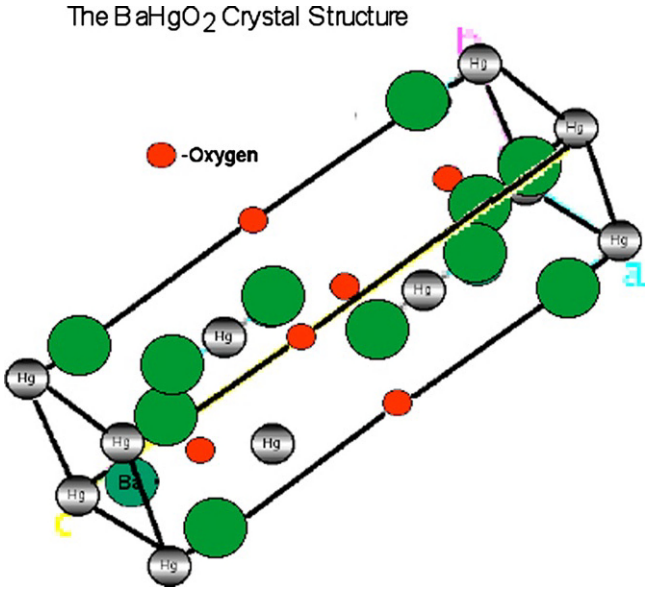

FIGURE 16.106

$HgCr_6$, $Hg_2Nb_2O_7$ and HgV_2O_6 were analyzed. The change in crystal chemical behavior from oxomercurates to mercury-oxometallates was also discussed in this paper.

A novel method of thermogravimetry under controlled mercury and oxygen partial pressures was developed, which allowed the attainment of precise thermodynamic data for the equilibrium:

$$MHgO_2(solid) \Leftrightarrow MO(solid) + Hg(gas) + 1/2O_2(gas) \quad (M = Ca, Sr, \text{ and } Ba)$$

Temperature dependencies of equilibrium constants K_p are described by the equations:

$$\text{Log } K_p(CaHgO_2) = -(9424 + /-540)/T + (10.28 + /-0.57), (888 - 1013\ K)$$

$$\text{Log } K_p(SrHgO_2) = -(10197 + /-890)/T + (10.10 + /-0.83), (1043 - 1118\ K)$$

$$\text{Log } K_p(BaHgO_2) = -(10474 + /-730)/T + (9.94 + /-0.64), (1098 - 1163\ K)$$

Thermal stability of mercurates increases in the order $CaHgO_2 < SrHgO_2 < BaHgO_2$.

16.3.6. Radium Mercury Compounds

While radium undoubtedly forms the same type of compounds as barium, there is no record of anyone having done so. This is probably due to the high cost of radium metal or the oxide, RaO.

General References

The published literature concerning the known alkaline earth compounds is extremely diverse and lengthy. It encompasses a multitude of technical books, journals and scientific chronicles, stretching back at least 100–150 years. In perusing these references, the author has determined that most of the pertinent and reliable data concerning a given alkaline earth compound was published after about the 1930s, a date that marked the beginning of the "Electronic Age," of which we, the public, are experiencing today. Yet, a considerable amount of research and published data, prior to the 1930s, exists concerning such compounds. The best sources for this data are:

1. "Treatise on Inorganic Chemistry" by H. Remy, Vols. I & II, Elsevier Pub. Co. (1936).
2. "The Chemical Elements and Their Compounds" by N.V. Sidgwick, Vol. I & II, Oxford Clarendon Press (1930).
3. "Dana's Manual of Mineralogy" by C.S. Hurlbut—18th Ed., J. Wiley & Sons (1953)
4. "Reference Book of Inorganic Chemistry" by W. M. Latimer & J. H. Hildebrand, The Macmillan Co. (1940)

These volumes cover most of the INORGANIC compounds known at the date of publication including some of the alkaline earth compounds (which are a fraction of all of the inorganic and organo-inorganic materials covered in these references). That is, the number and amount of data pertaining to alkaline earth compounds are a small fraction of the total content. A number of tables, diagrams and figures are included in these references and are, in some cases, the source for some of the figures and tables included in this volume.

Since no reference book exists devoted solely to alkaline earth compounds, the author began to peruse the scientific literature to that end. This book is designed to document all of the alkaline earth compounds known to date in the scientific literature. It is a reference book intended to bring together, in an organized fashion, information difficult to find, or dispersed in many published journals and books. Many of these references are obscure and not easily discovered except by persistent searching. For example, it is easy to find papers and publications relating to $BaGeO_3$, a compound related to $BaSiO_3$. As many as 1490 papers are associated with various aspects of this compound. Yet it is β-$BaGeO_3$, not α-$BaGeO_3$, that has the $BaSiO_3$ crystal structure. The author has sorted through these papers in order to describe, accurately, the known properties of α- and β-$BaGeO_3$.

As such, the previously published subject matter has been the source of information presented here. The author has assembled results and conclusions, published by various researchers in the open literature, regarding a particular compound. He then used his personal knowledge and experience to discuss a variety of viewpoints and judgments reached by diverse authors concerning the physical and chemical properties for each compound presented within this volume. The reader then has a starting point concerning whether a particular compound is known to exist and what properties it may exhibit.

Although there are many other resources for inorganic compounds like the Wiley Encyclopedia, Scifinder, Scopus/Scirus, the Gmelin Handbooks, PubMed, Springer/Link, the NIMS Materials database and the Web of Science, they cover a vast multitude of compounds and are, in some cases, difficult or costly to access. In contrast, the present book is limited to alkaline earth compounds. This is the major worth of this book—a place to determine what alkaline earth compounds are known to exist. The author did not use these sources of information but lists these sources of information for use by the reader:

SciFinder®
A Division of the American Chemical Society

- References from more than 10,000 currently published journals and patents from more than 63 patent authorities
- Important scientific discoveries from the present to the mid-1800s
- The latest scientific breakthroughs almost as soon as they are published with references added

daily and some patent information as recent as 2 days ago
- The world's largest collection of organic and inorganic substance information

What is Scirus—A Scientific Web-based search Engine
– Filters out nonscientific Web pages
– Searches Web Journals
– Searches 300 Million Web Sites
– Searches Digital Archives
– Searches for pdfs and papers

SCOPUS

Scopus, officially named **SciVerse Scopus**, is a bibliographic database containing abstracts and citations from academic journal articles. It covers nearly 18,000 titles from over 5000 international publishers, including coverage of 16,500 peer-reviewed journals in the scientific, technical, medical, and social sciences (including arts and humanities). It is owned by Elsevier and is available online by subscription. Searches in Scopus incorporate searches of scientific web pages through Scirus, another Elsevier product, as well as patent databases.

THE GMELIN HANDBOOK

The eight edition of the *Gmelin Handbook of Inorganic and Organometallic Chemistry* is said to be the most extensive printed compilation of information and data on metallic chemical elements and their compounds and alloys. It was compiled by the Gmelin Institute, part of the Max Planck Institute, and published in over 400 volumes between 1924 and 1998 by Springer-Verlag. All information in the handbook was derived from the primary journal and patent literature of chemistry, physics, and metallurgy, and then critically appraised and organized by chemical element and species. Gmelin is typically used to locate factual information on specific compounds:

History and Occurrence
Formation and Preparation (Bildung und Darstellung)
Physical properties (crystallographic, optical, spectral, electrical, magnetic, mechanical, thermodynamic)
Chemical properties and reactions, electrochemical behavior, etc.
Uses, toxicology, miscellany

MATERIALS DATABASE "MATNAVI"

National Institute for Materials Science, 1-2-1 Sengen, Tsukuba, Ibaraki, 305-0047 JAPAN

The NIMS materials database (MatNavi) gathers useful numerical data from a variety of material databases and academic documents made public. Various MatNavi database sections are composed of the: Polymer Database, Inorganic Material Database, Computational Electronic Structure Database, Metallic Material Database, Diffusion Characteristics Database, and the Superconducting Material records found in the open literature. Structures and phase diagrams may be accessed in these databases if known.

PubMed comprises more than 21 million citations for biomedical literature from MEDLINE, life science journals, and online books. Citations may include links to full-text content from PubMed Central and publisher web sites. PubMed was first released in January 1996.

Springer/Link is an integrated full-text database for journals, books, protocols, e-References, and book series published by Springer. SpringerLink currently offers 2436 fully peer-reviewed journals and 40,153 books online. General and detailed information about their journals, books, software and other products is available in the corporate website.

THOMSON REUTERS

Web of Science ® provides researchers, administrators, faculty, and students with quick, powerful access to the world's leading citation databases. Authoritative, multidisciplinary content covers over 12,000 of the highest impact journals worldwide, including Open Access journals and over 150,000 conference proceedings. You will find current and retrospective coverage in the sciences, social sciences, arts, and humanities, with coverage to 1900.

These sites on the Internet are presented for those Readers who wish to use them to determine the origin of the papers and publications discussed in this book. The author did not use them but consulted directly publications from various journals and published books.

The present volume is modeled upon that of the Gmelin Handbook.

However, the reader will soon discover that references to the scientific literature, including tables, drawings and figures, are not given within the book. There is a good reason for this. Early in the writing of the manuscript, the author assembled known data and results published as papers and books in the open literature. He then described succinctly was known about a particular alkaline earth compound and added references. Since his description was based upon the compilation and personal assessment of what several authors had published in the past, just one compound required 6–8 citations. Many compounds required 8–12 references and sometimes even more. Therefore, the decision was made not to include citations because the reference pages would consume a large part of the book. If the reader wishes to ascertain which authors discovered the properties of a particular compound, a good starting point is the above bibliographic database references available on the Internet.

Concerning figures, the author has drawn all of these, starting with figures published within various articles and books. In many cases, more than one author(s) published essentially the same result, each a refinement of the previous one. The author then formed the figure (such as a crystal structure) according to the latest results known to date. For example, the author redrew many phase diagrams that were not complete and added known data to complete the diagram. Because most of the figures had several contributors, no citations have been included since they, like the information presented for each compound, would consume a considerable space within the manuscript.

Most of the tables are compilations of previously published data derived from books and journals or from the **NIMS Materials database (MatNavi)**. For example, some tables present unit-cell occupancies for a specific crystal structure. These were derived from the literature but have many authors. No specific citations are presented for these tables as well.

Some of the journals and books that were consulted during the creation of this manuscript include the following:

1. Journal of Applied Crystallography—published by International Union of Crystallography, 2 Abbey Square, Chester CH1 2HU, England

Barium chromium compounds, 813–819
Barium cobalt compounds, 978–983
Barium copper compounds, 1070–1079
Barium di-aluminate, 564
Barium dialuminide, 534–536, 534f, 535f, 535t, 536f
Barium diborate, *See* Barium metaborate
Barium digallide, 582, 582f
Barium digermanide, 423, 424f, 425f, 425t
Barium dihydrogen orthoarsenate, 307
Barium di-molybdate, 839, 839f, 841, 841f
Barium di-niobate, 759, 759f
Barium distannide, 442–443, 443f
Barium di-tantalate, 790–791, 791f
Barium di-thallide, 629–630, 629f, 630f, 630t
Barium dithionate, 168–169
Barium dithionite, 168
Barium fluorapatite, 263
Barium fluoride, 60–62, 62f, 62t, 63t, 64t
Barium gallates, 596–598
Barium gallides, 580f, 581–584, 581f, 581t, 582t
Barium germanates, 410–412, 410f, 411f, 412f
Barium germanides, 423–428, 423f, 424t
Barium gold compounds, 1109–1113
Barium hafnate compounds, 698–700, 698f, 698t, 699f, 699t
Barium hafnide compounds, 698
Barium hexa-aluminate, 564–565, 565f
Barium hexagallate, 598
Barium hydride, 30
Barium hydroxide, 123–124, 123t, 124f
Barium hydroxyapatite, 262–263
Barium hyperoxides, 132, 132f
Barium hypobromite, 89, 89f
Barium hypochlorite, 76
Barium hypophosphate, 282
Barium hypophosphite, 237, 237f
Barium indates, 618–621, 618f
Barium indides, 610–612, 610f, 611f, 611t
Barium iodate, 99
Barium iodide, 66–68, 67f, 67t, 68f, 68t, 69t
Barium iodoapatite, 264
Barium iridium compounds, 1002–1004
Barium manganese compounds, 891–895
Barium mercury compounds, 1170–1174
Barium metaborate, 511–512, 511f
Barium metaniobate, 752, 754f, 755, 755f
Barium metaphosphate, 279–280, 279f, 280t
Barium molybdates, 835–841
Barium monogallate, 596–597, 596f, 597f
Barium monogermanide, 423–428, 425f, 426f, 426t, 427f, 427t, 428f
Barium monohydrogen orthoarsenate, 308
Barium monoindate, 619, 619f
Barium monomolybdate, 838–839
Barium monostannide, 442, 443f
Barium nickelates, 1019
Barium nickel compounds, 1015–1019
Barium niobate, 760
Barium niobium compounds, 752–760
Barium nitrate, 221–223, 222f, 222t
Barium nitride, 209–210, 210t
Barium nitrite, 213–215, 213t, 214f
Barium orthoborate, 512–513, 513f
Barium orthophosphates, 259–262
Barium osmium compounds, 958–960
Barium oxide, 113–115, 114t
Barium oxy-iron compounds, 930–937
Barium palladium compounds, 1029–1030
Barium pentastannide, 443, 444f
Barium perborate, 514–515, 514f
Barium perbromate, 95–96, 95f
Barium perchlorate, 86, 87t
Barium periodate, 103–104, 103f
Barium peroxide, 129–130, 129f
Barium peroxodisulfate, 172
Barium peroxy-monosulfate, 171, 171f
Barium peroxyphosphate, 285–286
Barium phosphide, 233–234, 233f, 234f
Barium phosphite, 240–241, 241f
Barium platinum compounds, 1044–1048
Barium plumbates, 476–480, 477f, 479f
Barium plumbides, 469–472, 469f, 470f
Barium polyphosphates, 279–280, 279f, 280t
Barium pyroarsenate, 308
Barium pyroarsenite, 296
Barium pyroborate, 513–514, 514f
Barium pyrophosphate, 271, 271f
Barium pyrosulfate, 162
Barium rhenium compounds, 907–909
Barium rhodium compounds, 993–994
Barium ruthenate monohydrate, 953
Barium ruthenium compounds, 950–953
Barium–scandium system, 641–643, 641f, 642f, 642t
Barium selenate, 184
Barium selenide, 177, 177t, 178f
Barium selenite, 180–181
Barium silicates, 400–403, 400f, 401f, 402f
Barium silicide, 381–386, 382f, 382t, 383t, 384f, 384t, 385f, 386f, 386t, 387f
Barium silver compounds, 1089–1091
Barium stannates, 454–458, 454f, 455f
Barium stannides, 441–446, 442f

Barium sulfate, 156–158, 157f, 157t
Barium sulfide, 141–142, 141f
Barium sulfite, 149
Barium tantalum compounds, 785–794
Barium technetium compounds, 898–899
Barium tellurate, 196–197
Barium telluride, 188–190
Barium tellurite, 193–194
Barium tetraaluminide, 530–534, 533f, 534f
Barium tetraborate, 515–516, 515f, 516f
Barium tetra-indide, 611, 611f, 612t
Barium tetra-molybdate, 839
Barium tetrathionate, 169, 169f, 169t
Barium thallates, 633–635, 633f, 634f, 634t
Barium thallides, 629–631, 629f, 629t
Barium thionates, 168–169
Barium thiosulfate, 160
Barium titanates, 669–672, 670f, 670t, 671f, 672f
Barium titanides, 669
Barium tri-molybdate, 839
Barium tri-niobate, 759
Barium triplumbide, 471–472, 472f
Barium tristannide, 443, 443f, 443t, 444f
Barium tungstates, 858–867
Barium tungstite, 867
Barium vanadium compounds, 722–728
Barium–yttrium compounds, 650–651, 651t, 652f
Barium zinc compounds, 1136–1140
Barium zirconates, 684–686, 684f, 685f, 685t, 686f, 687t
Barium zirconides, 684
Baryte, 38
BaTiO3 type calcium hafnate compounds, 692–693, 692f, 692t
BaTiO3 type strontium hafnate compounds, 695, 696t
Baylis–Hillman reaction, 48
Bémont, G., 21–22
