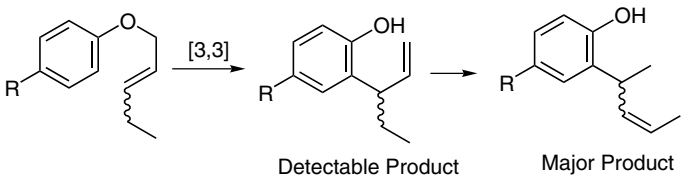
Abnormal Claisen Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

The first example of abnormal Claisen rearrangements was reported by Lauer and Filbert in 1936.[1] In contrast to the regular Claisen rearrangement ([3,3] σ migration),[2] the abnormal Claisen rearrangement[3] usually occurs for the allyl aromatic ethers. A similar reaction also occurs for the thermal rearrangement of cyclopropyl ketones to homoallylic ketones.[4] The abnormal Claisen rearrangement is believed to proceed via two consecutive processes, i.e., the normal *ortho* Claisen rearrangement of γ-alkylallyl aryl ether to an *o*-(α-alkylallyl) phenol and the isomerization of the resulting phenol. In general, this type of abnormal Claisen rearrangement does not occur smoothly, except when in the presence of Lewis acids $FeCl_3$, even though other Lewis acids (e.g., $HfCl_4$, $GaCl_3$, $ZrCl_4$) have limited ability to accelerate such reaction.[3a] It is reported that the abnormal Claisen rearrangement can be prevented by the application of 1,1,1,3,3,3-hexamethyldisilazane and *N*,*O*-bis(trimethylsilyl)acetamide.[5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Two kinds of mechanisms have been proposed for the abnormal Claisen rearrangement: the concerted process (Scheme 1)[6] and the stepwise process consisting of two consecutive steps (Scheme 2).[4] However, much experimental evidence is inconsistent with the stepwise mechanism.

N/A

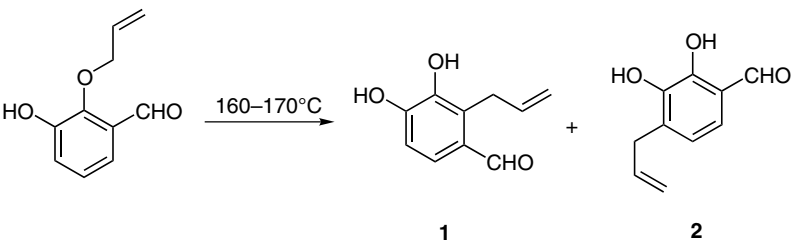
E. APPLICATIONS

This reaction has certain applications in organic synthesis.

F. RELATED REACTIONS

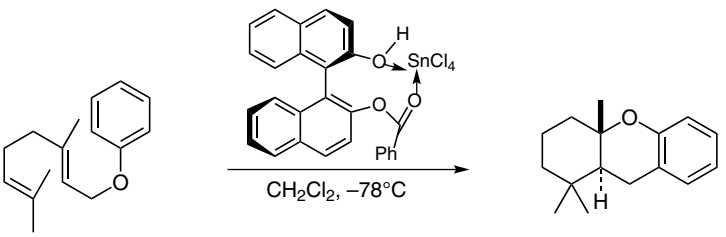
This reaction is related to the *Claisen Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

Caution! The reaction becomes vigorous and exothermic when heated above 200°C, especially on a large scale. To a 25-mL round-bottomed flask equipped with a magnetic stirring bar and an air condenser was added 5.06 g 3-hydroxy-2-(2-propenyloxy)benzaldehyde (28.43 mmol). The flask was gently heated to melt the solid and then placed in a Wood's metal bath at 165–170°C. After an induction period of a few minutes, the liquid in the flask darkened and evolved a gas. When the reaction was finished (detected by TLC) and cooled down, the mixture was triturated 10 times with boiling hexane. The dark, granular residue was dissolved in EtOAc and adsorbed on 10 silica. The mixture was separated by column chromatography using hexane/EtOAc/AcOH (65:35:1) as the eluent to give the major normal Claisen rearrangement product and the first abnormal Claisen rearrangement product, i.e., 2-allyl-3,4-dihydroxybenzaldehyde (**1**). The hexane extracts were evaporated and chromatographed on silica using hexane/EtOAc/AcOH (80:20:1) as eluent to give the second abnormal Claisen rearrangement product, i.e., 2,3-dihydroxy-4-allylbenzaldehyde (**2**) and other minor products.



Reference 3a.

General Procedure for the Preparation of Geranyl Phenyl Ether

To a stirred suspension of 176 mg sodium hydride (60% in oil, 4.4 mmol) in 20 mL THF at room temperature under argon atmosphere was added 0.376 g phenol (4.0 mmol) in portions followed by a catalytic amount of hydroquinone. The mixture was stirred for 0.5 h. HMPA (2 mL) and 0.74 mL geranyl chloride (4.0 mmol) were successively added. The whole mixture was stirred for 1 day. After decomposition of excess sodium hydride with 0.5 mL methanol, the mixture was poured onto ice water and extracted with ether. The combined organic layers were dried, concentrated, and purified by column chromatography on silica gel (hexane-dichloromethane as eluent).

General Procedure for the Enantioselective Cyclization of Geranyl Phenol Ether Promoted by the BINOL-$SnCl_4$ Complex

To a solution of BINOL (0.22 mmol) in 4 mL distilled CH_2Cl_2 was added 200 μL 1.0 M $SnCl_4$ in CH_2Cl_2 (0.2 mmol) at −78°C under argon atmosphere. After the mixture was stirred for several minutes at the same temperature, 0.230 g geranyl phenyl ether (0.1 mmol) was added dropwise at −78°C. After the resulting mixture was stirred for 3 days at −78°C, 16 μL pyridine (0.2 mmol) was added. Then the mixture was poured onto a saturated $NaHCO_3$ solution and extracted with ether. The combined organic layers were dried over anhydrous $MgSO_4$ and concentrated. The residue was purified by silica gel column chromatography using hexane/CH_2Cl_2 (4:1) as the eluent to give 98% of the rearrangement product as detected by GC.

Other references related to the abnormal Claisen rearrangement can be found in the literature.[8]

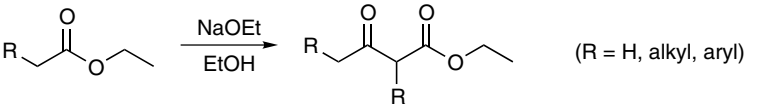
Acetoacetic Ester Condensation

(Claisen-Geuther Ester Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Geuther in 1863[1] and subsequently studied by Claisen.[2] It is a self-condensation of ester in the presence of alkali alkoxide in alcohol to form β-keto esters (e.g. ethyl acetoacetate from ethyl acetate) and is generally known as acetoacetic ester condensation.[3] This reaction was extensively explored by McElvain in 1930s.[4] In general, it is carried out under basic conditions (e.g., NaOEt) to generate β-keto-esters from aliphatic carboxylic acid esters.

B. GENERAL REACTION SCHEME

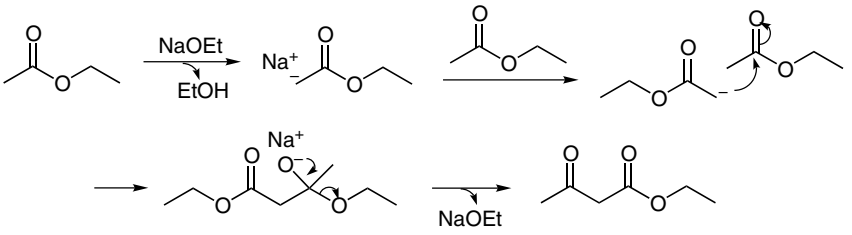


(R = H, alkyl, aryl)

C. PROPOSED MECHANISMS

The general mechanism for acetoacetic ester condensation shown here uses ethyl acetate as an example.[3f,4]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

Three esters (ethyl isovalerate, ethyl *t*-butylacetate, and ethyl isobutyrate) do not undergo this type of condensation under normal conditions with sodium ethoxide, presumably due to the steric hindrance. However, their condensation proceeds readily when mesitylmagnesium bromide is applied as the base.[5] In addition, the acetoacetic ester condensation has been improved to give high yields using some quaternary ammonium salts of long aliphatic chains as the phase transfer catalyst in benzene.[6]

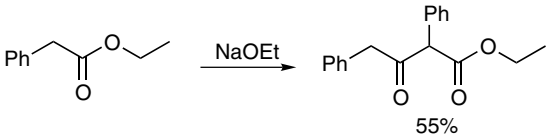
E. APPLICATIONS

This reaction is useful for the synthesis of a series of β-keto esters (both branched and unbranched). In addition, ethyl acetoacetate can be applied to the preparation of γ-diketones in reaction with epoxides followed by oxidation and decarboxylation.[7]

F. RELATED REACTIONS

This reaction is related to *Acetoacetic Ester Synthesis*.

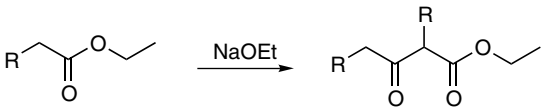
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a 500-mL flask equipped with a sealed stirrer and a reflux condenser were added fresh NaOEt (prepared from 4.6 g sodium) and 70.0 g ethyl phenylacetate (0.42 mol). The flask was heated with stirring in a steam bath at about 95°C for 6 h; however, the solid material (NaOEt) in the reaction mixture completely disappeared after a few minutes of heating. Then the flask was cooled to room temperature and treated carefully with 15 mL acetic acid in 100 mL water. At this point, a considerable amount of ethyl α,γ-diphenylacetoacetate precipitated. Ether (150 mL) was added to return this precipitate to solution, and the

separated aqueous layer was further extracted with 50 mL ether. The combined ether layers were washed sufficiently with saturated sodium bicarbonate solution. After the removal of ether, the residue was allowed to crystallize, and the resulting crystalline mass was again added to 20 mL alcohol and kept at 0°C. The precipitate was filtered off by suction and dried over a porous plate, and 28 g of material was obtained. The filtrate was then distilled from an oil bath to remove alcohol, and the unreacted ethyl phenylacetate was collected at 5 mmHg. The residue was dissolved in another 10 mL hot alcohol and cooled to 0°C. An additional 3 g ethyl α,γ-diphenylacetoacetate was recovered. The yield was 55% on the basis of sodium ethoxide used, or 78% based on the ethyl phenylacetate recovered. The product has an m.p. 75 – 77°C.



$R = C_nH_{2n+1}$, $n = 1, 2, \ldots 12$

Reference 3f.

To a 125 mL Claisen flask equipped with a 35-cm-long fractioning column were placed 0.1 mol corresponding ester and 0.05 mol NaOEt. The fractioning column was attached to a receiving flask (without cooling) that was in turn attached through a soda lime tower and a safety bottle to a manometer and a water pump. The flask was then heated carefully in an oil bath to a temperature and under a pressure that caused a moderate, but not too vigorous, evolution of alcohol vapor, as shown by the ebullition of the reaction mixture. The required temperature and pressure varied with the boiling point of the esters; the lower esters required lower reaction temperatures and higher pressures to prevent the loss of ester. Consequently, the time necessary for the completion of the reaction in these cases was increased. After the reaction had proceeded for some time, the temperatures and pressures could be raised and lowered, respectively, until the reaction mass ceased ebullition. The reaction product after cooling was treated with the calculated quantity of 30% acetic acid and shaken vigorously until the sodium salt had been completely decomposed. The β-keto ester was then extracted with 25 mL ether followed by the standard workup procedure. This procedure was quite satisfactory for all of the esters except ethyl α-pelargonylpelargonate and ethyl α-caprylcaprate, both of which suffered a small amount of pyrolysis to the corresponding ketone.

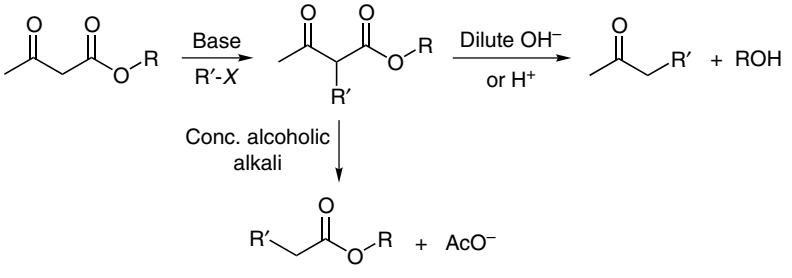
Acetoacetic Ester Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Simonsen in 1908;[1] unfortunately, it was not named after this inventor. It is the synthesis of α-substituted acetic acid esters or substituted acetones from acetoacetic ester by treatment of ethyl acetoacetate with a strong base, followed by alkylation and subsequent deacetylation or decarboxylation; it is known as acetoacetic ester synthesis.[2] Being adjacent to two electron-withdrawing groups (i.e., carbonyl and ester groups), the α-methylene protons in β-ketoesters (e.g., acetoacetic esters) are very acidic; the pKa of which could be as low as 10.[3] Therefore, the α-methylene proton is readily deprotonated, and the resulting α-carbanion can be alkylated or acylated. In addition, the acetoacetic esters can also be alkylated in acidic condition via the form of enol intermediate, although some unexpected products might form.[4] The new substituted β-ketoesters are then either treated with a concentrated base (normally strong base) to give substituted esters or are hydrolyzed under mild conditions (either acidic or basic) to give substituted acetones through decarboxylation.[5,6]

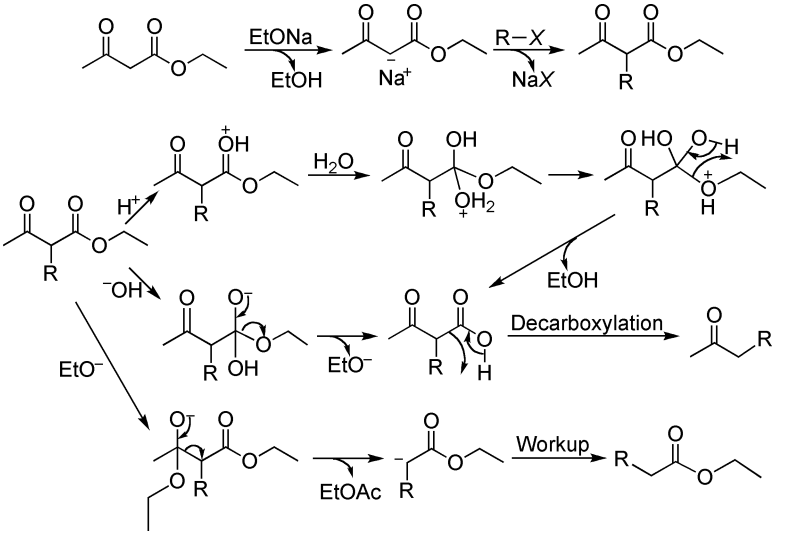
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is a general mechanism for acetoacetic ester synthesis from ethyl acetylacetate.

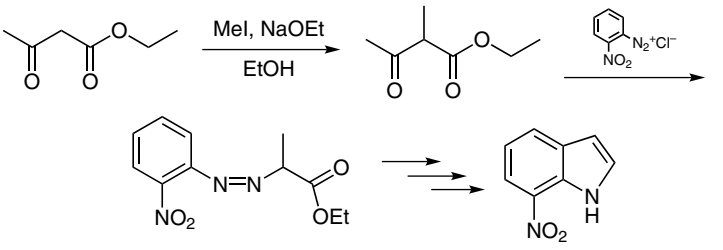


D. MODIFICATION

N/A

E. APPLICATIONS

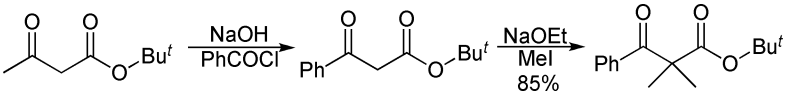
Besides the applications to synthesize ketones and esters, this reaction has been used to synthesize 7-nitro-indole by me in 1995, as shown in the following reaction route.



F. RELATED REACTIONS

This reaction is very closely related to *Acetoacetic Ester Condensation*; and mechanistically, the cleavage of β-ketoesters under strong base conditions is similar to the *Retro-Aldol Addition*.

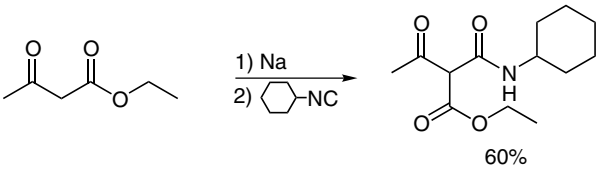
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a 500-mL three-necked flask equipped with a mechanical stirrer and two pressure-equalizing dropping funnels was added a mixture of 100 mL water and 50 mL hexane. The flask was placed in an ice bath. To the cooled mixture was added 40 mL *tert*-butyl acetoacetate and 13 mL of a solution of 66 g NaOH in 200 mL water. Through the two dropping funnels were added 40 mL freshly distilled benzoyl chloride and 54 mL of the NaOH solution over a period of 2 h with stirring. The solution was then warmed to 35°C for 30 min. The layers were separated in a separatory funnel, and the aqueous layer was collected and stirred with 16 g NH_4Cl for 15 h. After filtration to remove solids, 18 g NaCl was added to the filtrate to induce the separation of phases. The organic layer was collected, and the aqueous layer was extracted with ether. The extracts combined with the organic layer were dried by addition of benzene and azeotropic evaporation on rotary evaporator. The residue was distilled at 115–116°C (0.5 mmHg) to afford *t*-butyl α-benzoylacetate.

To the three-necked flask equipped with a dropping funnel was added NaOEt solution prepared from 1.1 g sodium in 15 mL absolute ethanol. When the solution was cooled to 5°C, 4.5 g of *tert*-butyl benzoylacetate was added under stirring. After a while, 10.0 g iodomethane, which had been cooled to −17°C was added. The reaction flask was stoppered, and after 16 h the reaction mixture was refluxed gently to ensure completion of the reaction. Sodium iodide precipitated during the course of the reaction. The solution was filtered, and ethanol was removed by rotary evaporation. The flask was cooled to 5°C, and the solution was neutralized with an NH_4Cl solution prepared from 2.7 g ammonium chloride in 20 mL water. The solution was extracted with ether (2 × 100 mL), and the ether extracts were combined. The aqueous layer then was acidified with 10 mL 1 M HCl and then extracted again with ether. The combined ether extracts were dried over anhydrous sodium thiosulfate, a procedure that also removes iodine. After filtration and evaporation, the residue was distilled at 85–90°C (0.2 mmHg) to give 85% of *tert*-butyl α,α-dimethyl-benzoylacetate.



Reference 8.

To a three-necked flask were added 300 mL anhydrous ether and 4.6 g sodium ribbons (0.2 mol), followed by 25.5 mL ethyl acetoacetate (0.2 mol) dropwise under well stirring. Then an additional 300 mL anhydrous ether was added, and the reaction mixture was refluxed for 4 h. Then 25.5 mL freshly distilled cyclohexyl isonitrile (0.2 mol) was added dropwise to the resulting viscous mixture. After being refluxed for 50 h, the reaction mixture

was diluted with 150 mL benzene and neutralized by adding an aqueous phosphate buffer solution while stirring vigorously. The benzene extracts were washed with 5% $NaHCO_3$ and water and dried over $MgSO_4$. Upon removal of solvent by evaporation, about 31.0 g *N*-cyclohexyl β-ethoxycarbonyl acetoacetamide was obtained, in a yield of 60%. The product was purified by crystallization in hexane, with on m.p. of 47.2–48°C.

Other references related to acetoacetic ester synthesis are cited in the literature.[9]

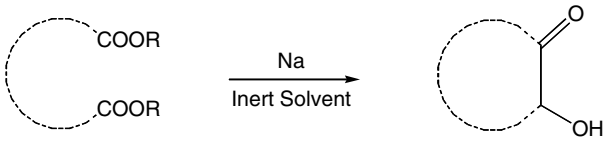
Acyloin Condensation
(Acyloin Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bouveault and Blanc in 1903,[1] and was further extended by Bouveault and Locquin.[2] It is the synthesis of symmetrical α-hydroxy ketones via the reductive condensation of esters in an inert solvent in the presence of sodium. Since symmetrical α-hydroxy ketones, the aliphatic analogs of benzoins, are generally known as acyloins, the formation of α-hydroxy ketones from esters is simply referred to as acyloin condensation.[3] In a few cases, it is also referred to as acyloin reaction.[4] For the individual acyloin, the name is derived by adding the suffix *oin* to the stem name of corresponding acid, e.g., acetoin prepared from acetate.[5] The most common method used to make acyloin is the reductive condensation of aliphatic esters with sodium in inert solvents, such as ether, xylene or even in liquid NH_3.[3aaa] The yield of this reaction can be greatly improved when trimethylchlorosilane presents.[4d] Intromolecular acyloin condensation from aliphatic diesters affords cyclic ketones of different ring sizes.

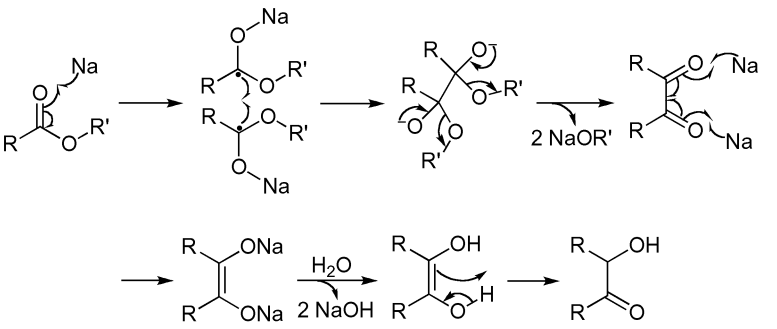
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Under the reductive condition, the ester group is reduced to hemiacetal radical by sodium, and the coupling of the radical pairs accompanied with the elimination of alkoxide affords the α-dicarbonyl intermediate, which is further reduced by two sodium atoms to ene-diolate. Upon hydrolysis, the ene-diol tautomerizes to acyloin product.[6] A general mechanism for acyloin condensation is displayed below.



D. MODIFICATION

This reaction has been modified to form bis(trimethylsilyloxy) alkenes.[4d] In addition, C_8K[7] and thiazolium salt,[8] such as 3-benzyl-5-(2-hydroxyethyl)-4-methylthiazolium chloride,[3c] have been applied for the acyloin condensation.

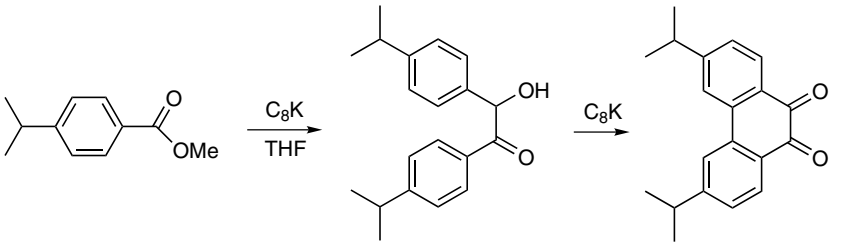
E. APPLICATIONS

This reaction has been used to synthesize cyclic ketones of intermediates to a large ring from diesters with long hydrocarbon chain between two ester groups.[9]

F. RELATED REACTIONS

This reaction is related to *Benzoin Condensation*, in which the benzoin is prepared from benzaldehyde.

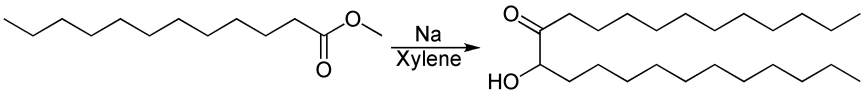
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

Preparation of C_8K. To a 100 mL argon-flushed and flame-dried three-necked round-bottomed flask, were added 2.4 g of graphite powder, and magnetic stir bar. The graphite powder was heated to 150°C under argon atmosphere while stirring. After 15 minutes, 1 g of clean potassium metal (25 mmol) was added in slices. The stirring at 150°C was continued until the bronze-colored C_8K was formed. The reagent was cooled to room temperature and kept under argon.

The generally procedure for acyloin condensation. To the above flask (protected under argon) was added 50 mL of dry THF, and the flask was kept at 25°C under argon atmosphere. Then a solution of 710 mg of methyl *p*-isopropylbenzoate (4 mmol) in 50 mL of solvent was dropped into the reaction mixture over 20 minutes under stirring. The reaction was monitored by TLC. After the ester was totally consumed, the mixture was stirred for 1 hour and then cooled to 0°C, and 10 mL of water was added to the solution (no violent reaction occurred at this moment). The reaction mixture was filtered through a fritted glass funnel, and the filter cake was washed with two 25-mL portions of ether. The combined filtrate was washed twice with 20 mL of water, the organic phase was dried over $MgSO_4$, and removed by evaporation. The crude product (400 mg) was then purified on a chromatographic preparative plate. Crystallization from methanol gave 175 mg of 3,6-diisopropylphenanthrenequinone, in yield of 30%, m.p. 155-157°C.



Reference 10.

To a 5-L three-necked flask (equipped with a high speed stirrer and protected by nitrogen or other inert gas) was added a mixture of 115 g of sodium (5 mol) and 3 L of xylene. The mixture was heated to 105°C, and the sodium melted. The stirrer was started and the sodium dispersed in a finely divided state in the xylene. From a separatory funnel, 535 g of methyl laurate (2.5 mol) was then added into the flask. The addition was at such a rate that the temperature did not rise above 110°C. The addition of the ester required about 1 hour. Stirring was continued for one-half hour after the ester had been added. Small portion of unchanged sodium were decomposed by the addition of an excess of methanol (1–2 mol). After cooling to about 80°C, 0.5 to 1 L of water was added cautiously until the alkali had

dissolved, and the layers were separated by decantation. After one or two more washings of the xylene layer with water, the remaining alkali was neutralized with a slight excess of mineral acid, and this excess acid was finally neutralized with sodium bicarbonate. The xylene was removed by steam distillation, and the residual oily layer was poured into a suitable vessel to solidify. The impure product contains 80–90% of the lauroin, which can be purified through crystallization from 95% ethanol, m.p. 62°C.

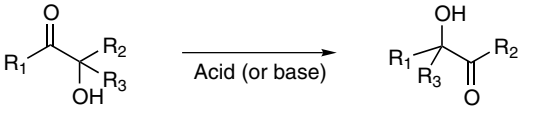
Acyloin Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

Acyloins are the general name of symmetrical α-hydroxy ketones, the aliphatic analogs of benzoins; and the individual name is derived by adding the suffix-*oin* to the stem name of the corresponding acid.[1] The acyloin rearrangement is the conversion of an α-hydroxycarbonyl compound into its structural isomer (also an α-hydroxylcarbonyl compound), which is accomplished by the interchange of the carbonyl group and migration of an alkyl group to the adjacent carbon atom.[2] While this rearrangement is usually promoted by acid[3] or base,[4] it also proceeds under pyrolytic conditions;[5] and the thermal acyloin rearrangement can be accelerated by high pressure.[6] The details of acyloin rearrangement are given in the literature.[7]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Both acid-(Scheme 1) and base-(Scheme 2) catalyzed reactions are displayed here.

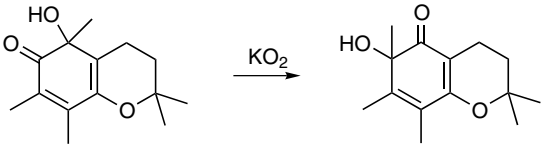
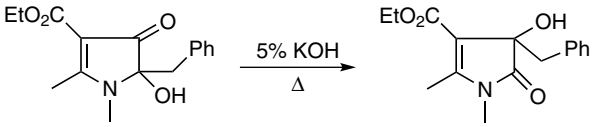
G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A solution of 236 mg 5-hydroxy-2,2,5,7,8-pentamethylchroman-6(5H)-one (1 mmol) in 20 mL dry THF was added to a stirred suspension of 70 mg potassium superoxide (KO_2, 1 mmol) in 50 mL dry THF at 0°C. The reaction mixture was stirred for 1 h at 0°C. The excess amount of KO_2 was decomposed by the addition of 10 mL water. The resulting mixture was extracted with diethyl ether. The combined organic layers were washed with brine, dried over anhydrous Na_2SO_4, and filtered. Upon removal of solvent under reduced pressure, the resulting solid residue was purified by silica gel column chromatography using a mixture of *n*-hexane and ethyl ether (1:l) as eluent to afford 224 mg 6-hydroxy-2,2,6,7,8-pentamethylchroman-5(6H)-one, in a yield of 95%.



Reference 9.

A mixture of 2.89 g 1,2-dimethyl-3-(ethoxycarbonyl)-5-benzyl-5-hydroxy-2-pyrrolin-4-one (10 mmol), 30 mL 5% aqueous potassium hydroxide (30 mL), and 30 mL chloroform was heated with stirring in a water bath at 65°C for 10 min. Then the mixture was allowed to stand at room temperature for 1 h. After filtration, the resulting solution was acidified with 6 *N* HCl. The precipitated hydroxypyrrolinone was extracted with $CHCl_3$ (2 × 40 mL). The combined organic layers were washed with water and dried over Na_2SO_4. Upon removal of the solvent under reduced pressure, the remaining white solid was recrystallized to give 1.74 g 1,2-dimethyl-3-(ethoxycarbonyl)-4-benzyl-4-hydroxy-2-pyrrolin-5-one, in a yield of 60%, m.p. 119°C.

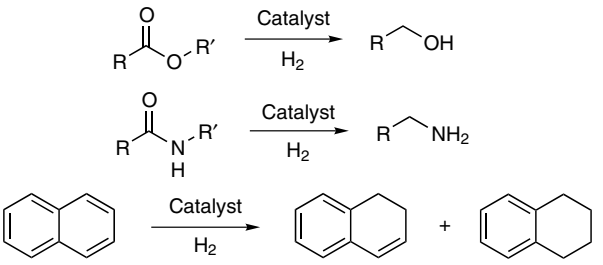
Adkins Catalyst

A. GENERAL DESCRIPTION OF THE REACTION

Adkins catalysts are kinds of metal complexes prepared from chromium, copper, nickel, platinum, etc. These catalysts were primarily developed by Homer Adkins and have been applied to many organic reactions, e.g., hydrogenation, dehydrogenation and decarboxylation. Hydrogenations include the hydrogenation of ester to alcohol,[1] hydrogenation of amide to amine,[2] and other hydrogenations.[3] Similarly, dehydrogenations include dehydrogenation of alcohol,[4] dehydrogenation of aromatic compounds,[5] and some other dehydrogenations.[6] The protocols for the preparation of these catalysts are also provided by Adkins.[7]

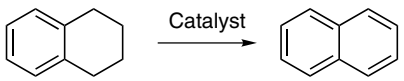
B. GENERAL REACTION SCHEME

Some representative reactions are illustrated here.



Hydrogenation

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

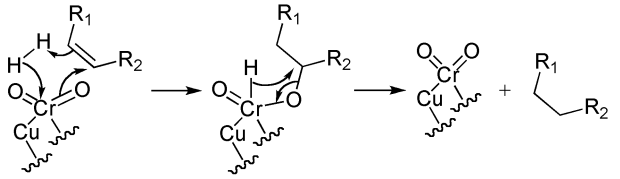


Dehydrogenation

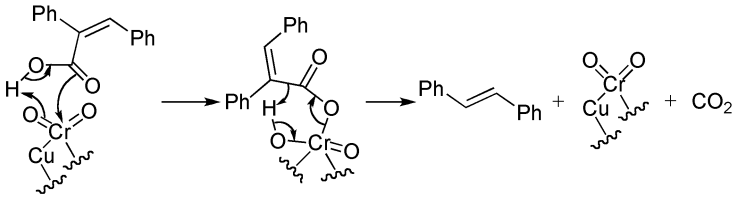
C. PROPOSED MECHANISMS

The mechanisms of a few representative reactions are illustrated: in the hydrogenation of alkene (Scheme 1), the decarboxylation of conjugated carboxylic acid (Scheme 2), and the dehydrogenation of diols (Scheme 3).

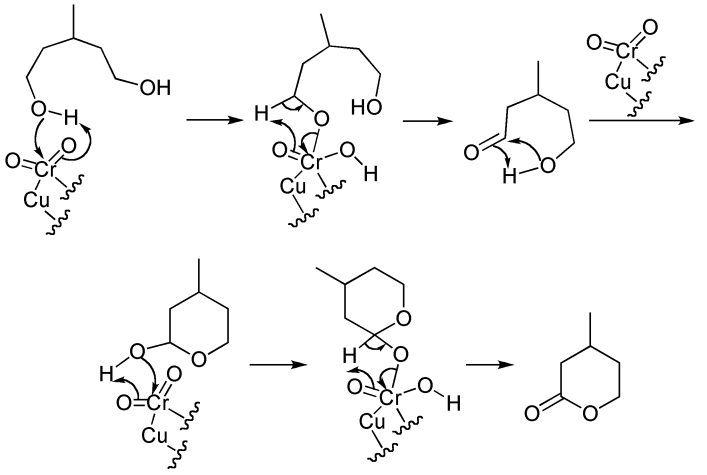
For hydrogenation, the Adkins catalyst will help the cleavage of a hydrogen-hydrogen bond so that the hydrogen can add to double bonds (Scheme 1).



SCHEME 1. *Hydrogenation of olefin over an Adkins catalyst.*



SCHEME 2. *Decarboxylation of α,β-unsaturated carboxylic acids.*



SCHEME 3. *Dehydrogenation of a diol.*

D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has broad applications in organic synthesis, especially on a large reaction scale.

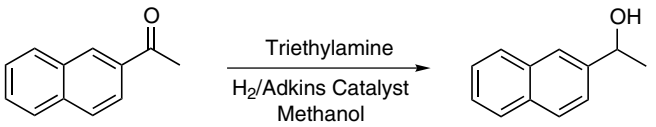
G. CITED EXPERIMENTAL EXAMPLES



Reference 3g.

The Preparation of Catalyst HJS 2

To a 900 mL of a solution (at 25°C) prepared from 178 g sodium dichromate dihydrate ($Na_2Cr_2O_7 \cdot 2H_2O$) and 225 mL 28% NH_4OH was poured 900 mL of a solution (at 80°C) containing 260 g copper nitrate trihydrate ($Cu(NO_3)_2 \cdot 3H_2O$) and 31 g $Ba(NO_3)_2$. The orange precipitate was collected on a filter, washed with 200 mL of water in two portions, pressed and sucked as dry as possible, dried at 75–80°C for 12 h and pulverized. This product was decomposed in a 1-L four-necked flask held in a Woods metal bath at 350°C. The flask was equipped with a wide air condenser, a funnel for introducing a solid, a thermometer, and a stainless-steel stirrer with a 1.25-cm-wide and 10-cm-long crescent blade. The material to be decomposed was added through the funnel during a period of 15 min with rapid stirring. The product was heated with stirring at a bath temperature of 350°C for 20 min after all of the material had been added. The product from the decomposition was leached by stirring for 30 min with 600 mL 10% acetic acid at room temperature. The powder was washed with water (6 × 100 mL), dried at 125°C for 12 h and pulverized. The catalyst so obtained was brownish black and amounted to 160–170 g. The cooper-chromium oxide catalyst was activated by shaking the catalyst, suspended in methanol, under approximately 4000 psi of hydrogen at 100°C for 5 min. The reaction vessel was then cooled to room temperature, and the compound to be hydrogenated was added.

The Hydrogenation of Methyl 2-Naphthyl Ketone

A mixture of 17 g methyl 2-naphthyl ketone and 10 g of the activated catalyst (described above) in 100 mL methanol was stirred under a hydrogen pressure of 4000 psi. Methyl-2-naphthylcarbinol was obtained, m.p. 74–75°C.

Other references related to the Adkins catalyst are cited in the literature.[8]

Ainley and King Synthesis
(Ainley-King-Sargent Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

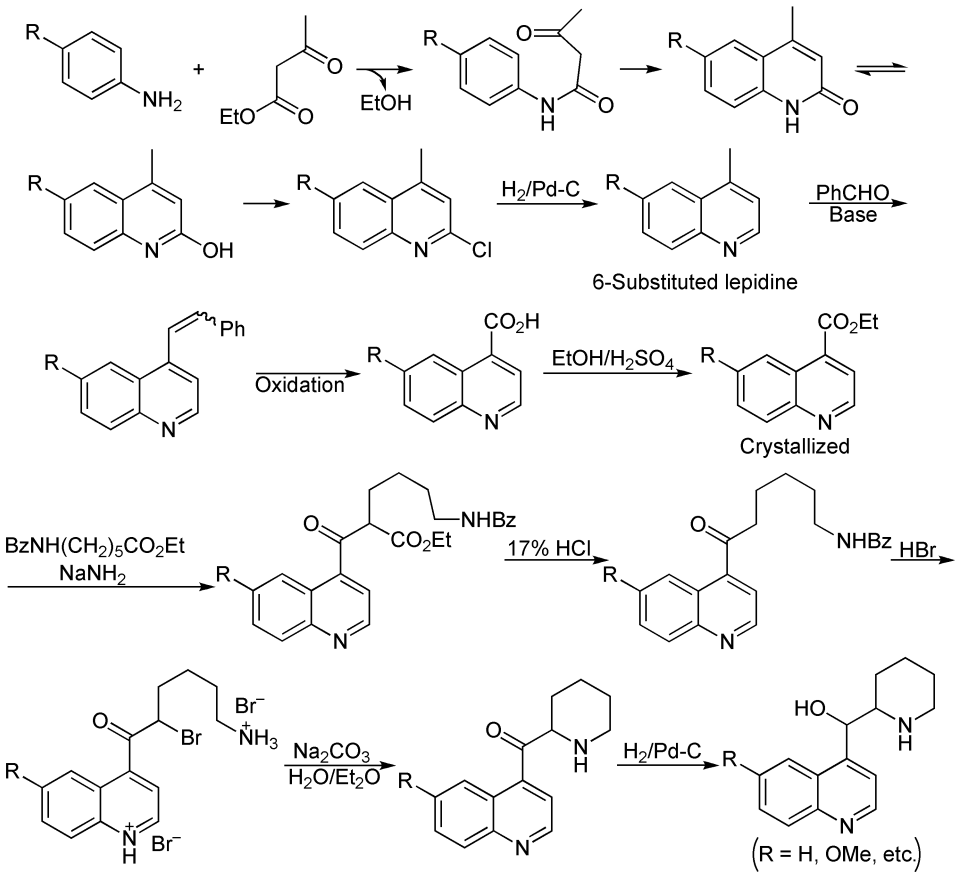
This reaction was reported first by Ruzicka et al. in 1924[1] and was extended by Ainley and King in 1935.[2] It is a multistep synthesis of α-piperidyl-4-quinolinemethanols[3] (or quinolyl-4-α-piperidylcarbinols[4]), involving the reaction of *(a)* amidation of *p*-anisidine by an acetoacetic ester, *(b)* electrophilic cyclization to give 2-hydroxy-lepidine, *(c)* replacement of the 2-hydroxyl group by a chlorine atom, *(d)* removal of chlorine by Pd/C catalyzed hydrogenation in AcOH, *(e)* condensation with benzaldehyde followed by oxidation to afford 4-quininic acid in 50% pyridine, *(f)* esterification of the 4-quininic acid, *(g)* Claisen-Geuther ester condensation[5] of ethyl quininate with ethyl ε-benzamidocaproate, *(h)* hydrolysis of the ester and β-decarboxylation, *(i)* α-bromination and cyclization, and *(j)* reduction of the carbonyl group to a secondary hydroxyl group via hydrogenation.[2,6] This reaction played an important role in the preparation of large quantities of quinine for antimalarial[3,4a,6,7] during the World War II and is generally known as the Ainley and King synthesis.[3,4a,6] Subsequently, this reaction has been modified by various researchers, especially by Sargent in 1946;[4] thus this synthesis is also referred to as the Ainley-King-Sargent synthesis.[8]

Compared to that of the Ruzicka protocol, the Claisen-Geuther ester condensation in this synthesis was optimized from 17% to 64% by replacement of sodium ethoxide with sodium or sodium amide. In addition, the cyclization to form the piperidinyl ring is carried out in a two-phase solvent system (H_2O and ether) using sodium carbonate as base.[2]

Among the subsequent modifications, it was found that, if the preparation of lepidine at the stage of dehalogenation is performed in warm alcoholic KOH in the presence of Raney nickel, the lepidine can be easily isolated; in addition, such dehalogenation can also be accomplished by zinc and acetic acid.[6] Moreover, the formation of quininic acid via oxidation in acetone was found to be superior to that in 50% pyridine due to the easy isolation of product.[5]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Details of this multistep reaction are not shown because each step is very simple and obvious in modern organic synthesis.

D. MODIFICATION

Although the general reaction route of the Ainley and King synthesis is generally followed, each step has been modified in same way to produce large quantities of quinine. Some of the modifications are the removal of chlorine by zinc and acetic acid to form lepidine and the formation of quininic acid in acetone during the oxidation.[6]

E. APPLICATIONS

This reaction provided the basic blueprint for the production of quinine in the 1940s, the product was widely used for the treatment of malaria.

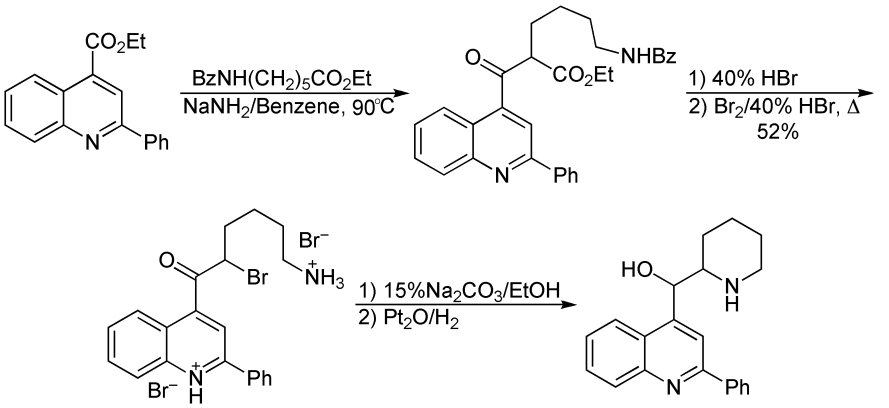
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

To a 5-L three-necked flask equipped with a Hirshberg stirrer and a condenser protected with a soda lime tube, were added 38.0 g powered sodium amide (1.65 mol), 360 g ethyl 2-phenylcinchoninate (1.30 mol), 345 g ethyl benzamidocaproate (1.31 mol), and 675 mL thiophene-free dry benzene. After the solution was stirred at 90°C for 22 h, the mixture was cooled in an ice water bath while a solution of 1.2 L concentrated HCl and 1 L water was added. The Hirshberg stirrer was then replaced with a stillhead, and the benzene steam distilled until the temperature of the vapor reached 108°C. After substituting a condenser for the stillhead, the remaining solution was refluxed for 40 h. The solution was then cooled and adjusted to pH 10–12 with 50% NaOH (920 mL). The ketone was extracted with 1.5 L $CHCl_3$ in portions and the combined organic layers were dried over Na_2SO_4. The chloroform solution of ketone was then extracted with 750 g 40% HBr, and chloroform was removed from the HBr layer by heating on a steam bath while stirring (30 min). The increase in weight of the solution was 304 g. (This part is not clearly stated, as the combined chloroform layers will be extracted with 48% HBr; it is not necessary to dry the chloroform solution with Na_2SO_4). Small amounts of ketone dihydrobromide can be isolated by cooling the solution; and recrystallization of the isolate solid in 96% ethanol is as yellow clusters of needles, with a m.p. of 225–227°C (dec.).

The solution of ketone dihydrobromide in 40% HBr was heated to 85°C and, under mechanical stirring, a solution of 138 g bromine in 275 mL 40% HBr was added over a period of 20 min, during which the temperature was maintained at 85–90°C. The product (ε-bromo-ε-(2-phenylcinchoninyl)-*N*-amylamine dihydrobromide) began to crystallize out before all the bromine was added. The mixture was heated to the boiling point and 250 mL 40% HBr was added, but the product did not dissolve. The reaction mixture was then chilled, and the precipitate was collected on a sintered glass funnel. It was washed by suspension in isopropanol to remove hydrobromic acid, then with acetone until the filtrate was colorless, and finally with ether. After drying in vacuo over NaOH, 334.5 g of a

light yellow powder was obtained, m.p. 210.5–212°C (dec.), and additional crop of 41 g of crystal was obtained after the mother liquors were concentrated to half volume. The total yield was 375 g (52%). (By acidifying the aqueous phase from the chloroform extraction of the ketone and washing the precipitate with ethanol to remove benzoic acid, 96 g of crude cinchophen was recovered.)

To a suspension of 140 g ε-bromo-ε-(2-phenylcinchoninyl)-*N*-amylamine dihydrobromide (0.25 mol) in 2.2 L absolute ethanol in a 4-L bottle was added 735 mL 15% (by weight) Na_2CO_3 solution. After displacing the air with nitrogen, the bottole was stoppered and shaken mechanically for 50 min. Then 3.0 g platinum oxide was added, and the bottle was filled with hydrogen. The reduction was performed at room temperature for 4 h, at which time the rate of hydrogen absorption had fallen from an initial 100 mL/min to 1 mL/min with the total uptake of 6.7 L. After removal of the catalyst and precipitated salts, ethanol was removed under reduced pressure. After decanting the aqueous phase, the residul oil was rinsed with water and dissolved in 1 L of absolute ethanol. The solution was filtered and 50 mL concentrated HCl was added. The precipitate was filtered, washed with acetone, and dried to give 71 g 2-phenyl-α-(2-piperidyl)-4-quinolinemethanol as a light pink powder, m.p. 226–228°C (dec.)

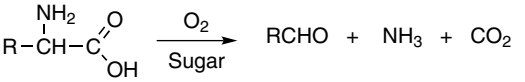
Akabori Amino Acid Reaction

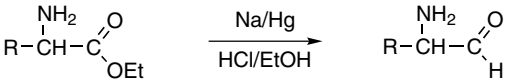
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Akabori in 1931.[1] It is the synthesis of an aldehyde, an α-amino aldehyde, or a primary amine from α-amino acid under different reaction conditions. In the presence of a reducing agent (usually a reducing sugar), an α-amino acid is oxidized to an aldehyde and ammonia by molecular oxygen (Scheme 1). For comparison, the α-amino acid ester is reduced by sodium amalgam in alcoholic solution in the presence of hydrochloric acid to give an α-amino aldehyde (Scheme 2). However, under pyrolytic condition, the α-amino acid is converted to primary amine in the presence of benzaldehyde (Scheme 3).

B. GENERAL REACTION SCHEME

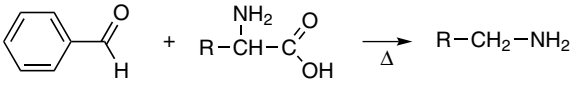


SCHEME 1. *Oxidation of α-amino acid to an aldehyde in the presence of a reducing sugar.*



SCHEME 2. *Formation of α-amino aldehydes via the reduction of α-amino acids or esters with sodium amalgam in the presence of ethanolic HCl.*

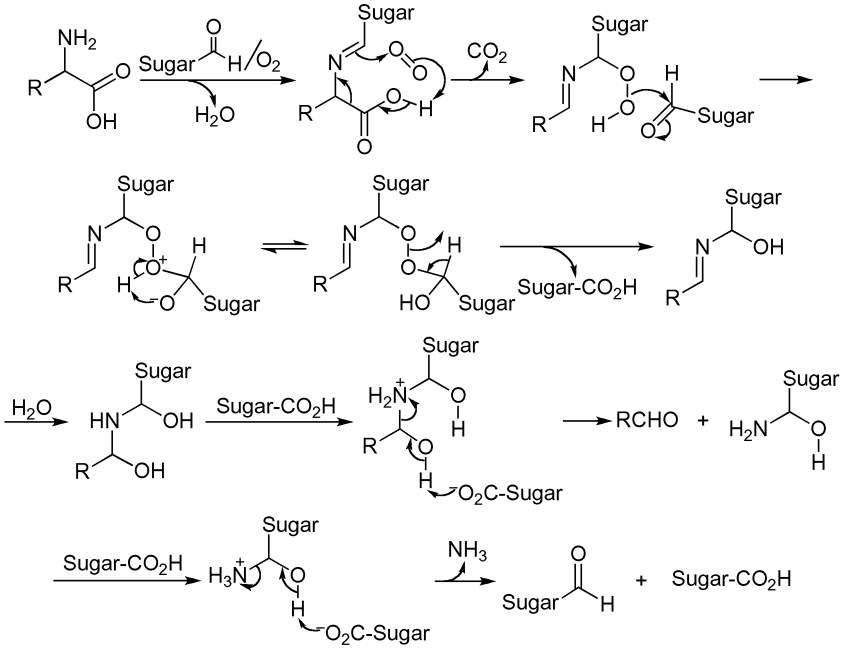
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



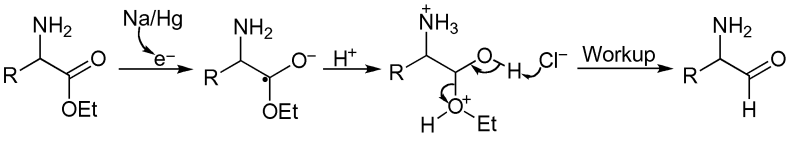
SCHEME 3. *Formation of a primary amine from the pyrolysis of an amino acid in the presence of an aromatic aldehyde (e.g., benzaldehyde).*

C. PROPOSED MECHANISMS

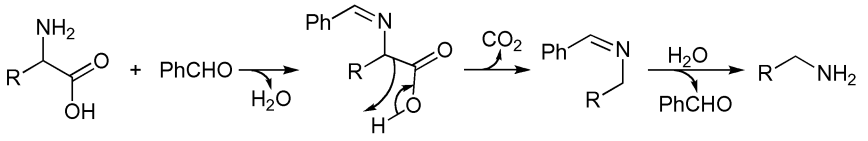
The mechanism for the conversion of α-amino acid to aldehyde in the presence of a reducing sugar (sugar was emphasized by the aldehyde group) is displayed in Scheme 4. The reduction of an α-amino acid or its ester derivatives to α-amino aldehyde by sodium amalgam in acidic alcohol is illustrated in Scheme 5, and the mechanism for the pyrolytic decarboxylation of an α-amino acid to a primary amine in the presence of an aromatic aldehyde is given in Scheme 6.



SCHEME 4. *Conversion of an α-amino acid into an aldehyde.*



SCHEME 5. *Reduction of an α-amino acid or its esters to α-amino aldehyde by a sodium amalgam.*



SCHEME 6. *Formation of primary amines via the pyrolysis of α-amino acids in the presence of an aromatic aldehyde.*

D. MODIFICATION

N/A

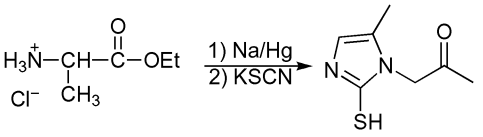
E. APPLICATIONS

This reaction has been used to synthesize dichlorophthalimido derivatives for the analysis of peptides, since the mass spectra of those derivatives are easily recognized due to the characteristic pattern of ions containing two chlorine atoms.[2] The simplicity of this technique is illustrated by the following general example, in which a few milligrams of a peptide is subjected to reaction with hydrazine dissolved in dimethlysulfoxide in a commercially available microwave oven for about 30 min. Samples are then removed from the solution in 5 min intervals, and the FAB MS of corresponding samples are recorded. In the case of oligopeptides, it is often possible to determine the entire sequence of amino acids via this application.

F. RELATED REACTIONS

N/A

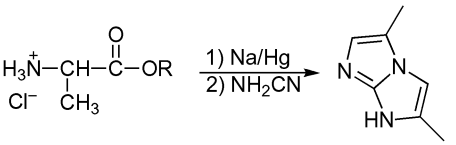
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

About 50 g of the hydrochloride salt of (DL)-α-alanine ethyl ester (0.56 mol) was subjected to reaction with 2 kg finely divided sodium amalgam (2.5%) at a pH between 2.0 and 4.5. The resultant mixture was then stirred for an additional 30 min. The solution was decanted from mercury and then filtered, and the pH of the filtrate was adjusted to 4.0 using a solution of sodium bicarbonate. Upon refluxing in the presence of 70 g potassium thiocyanate (0.72 mol), the solution acquired a dark brown color. After an additional 0.75-h reaction period, the solution was concentrated at atmospheric pressure until crystals began

to appear. The dark brown product was filtered off and subsequently recrystallized from water (charcoal was added to decolorize the solution), to give 16.5 g 1-acetyl-2-mercapto-5-methylglyoxaline as white blades, in a yield of 35%, m.p. 182–183°C.



Reference 4.

About 10 g of (DL)-α-alanine were first esterified with ethanol by standard methods. The resulting ester was then reduced with sodium amalgam using the reaction conditions described earlier. To the resultant 10 g solution of the aminoaldehyde, 10 g cyanamide in 60 mL 10% acetic acid aqueous solution was added, and the mixture was adjusted to pH 4.0–5.0 and then refluxed for 30 min. The cooled and filtered solution was then made alkaline by the addition of a solid sodium bicarbonate and extracted with ether to remove unused cyanamide and dicyandiamide. Sodium hydroxide was next added, and the solution was extracted with ether again. The ether solution was dried over Na_2SO_4 and evaporated. The residue was dissolved in a little anhydrous ether, and anhydrous hydrogen chloride was passed into the ether solution. The dark precipitated hydrochloride salt, in amount of 3.2 g, was recrystallized from ethanol to afford colorless prisms, m.p. 272°C (dec.).

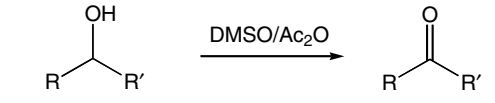
Albright-Goldman Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Albright and Goldman from the American Cyanamid Company in 1965.[1] It is a mild conversion of primary and secondary alcohols into corresponding aldehydes and ketones using the mixture of dimethyl sulfoxide and acetic anhydride as the oxidant. This reaction is particularly useful for the oxidation of the sterically hindered hydroxyl groups. In general, the oxidation is carried out by allowing a mixture of 1 mmol primary or secondary alcohol, 3 mL DMSO, and 2 mL (20 mmol excess) acetic anhydride to stand at room temperature for 18–24 h.[2]

B. GENERAL REACTION SCHEME

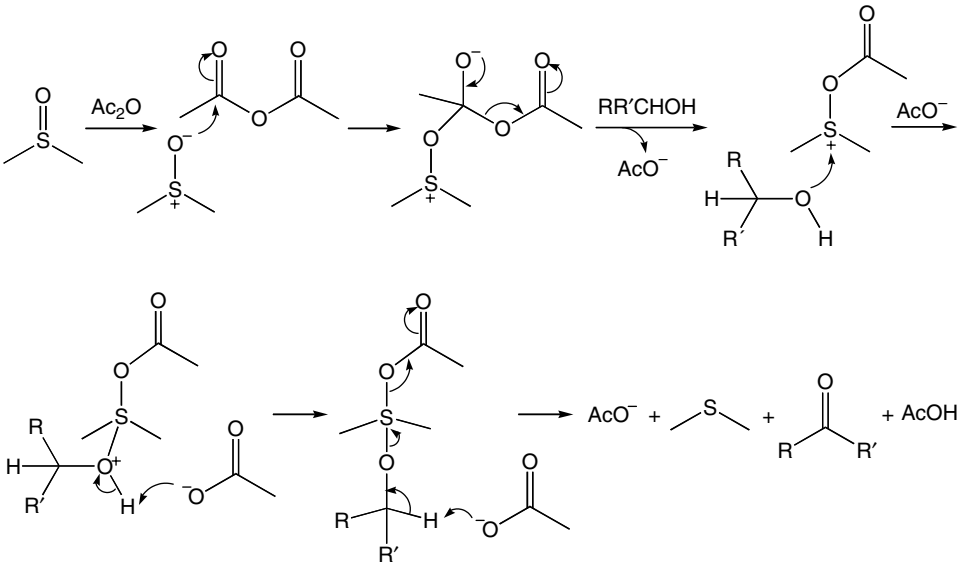


(R′ = H, alkyl or aryl)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is a simple illustration of this reaction.



D. MODIFICATION

This reaction has been modified using the mixture of DMSO and one of the following reagents: benzoic anhydride, polyphosphoric acid, and phosphorus pentoxide. However, it seems that the mixture of acetic anhydride and DMSO is still the best combination for this reaction.[3]

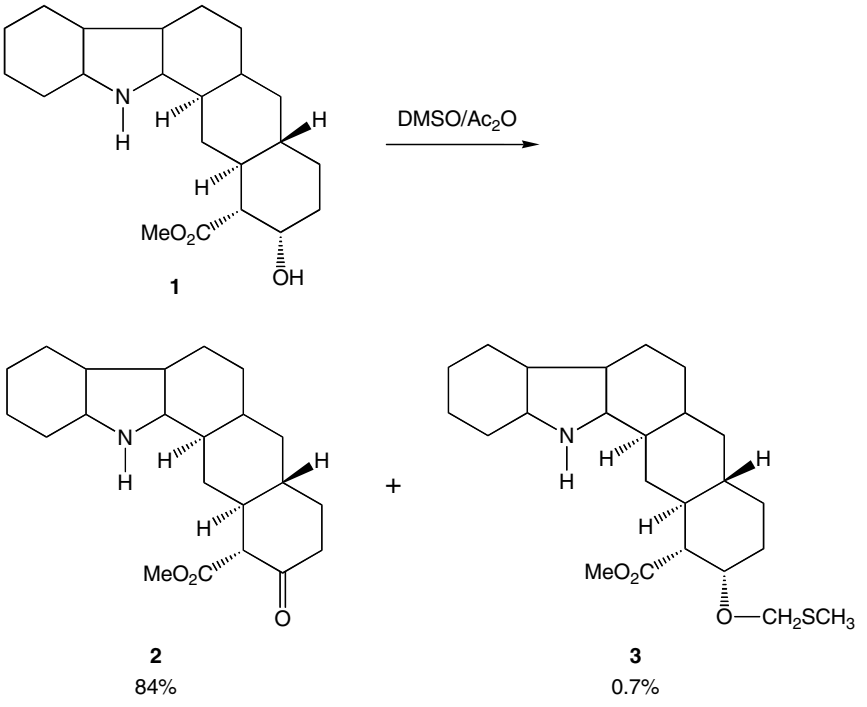
E. APPLICATIONS

This reaction has been used to convert primary and secondary alcohols into corresponding aldehydes and ketones, especially for the sterically hindered alcohols. This reaction has been commonly used in carbohydrate transformation. However, for the oxidation of phenols with DMSO/Ac_2O, the thiomethoxymethylation of the corresponding phenols occurs.[4]

F. RELATED REACTIONS

Other oxidation reactions using DMSO as an oxidant include the *Pfitzner-Moffatt Oxidation* (DMSO/dicyclohexylcarbodiimide), Swern oxidation (DMSO/oxalyl chloride or trifluoroacetic anhydride), Onodera oxidation (DMSO/phosphorus pentoxide), *Parikh-Doering Oxidation* (DMSO/pyridine-sulfur trioxide), *Corey-Kim Oxidation* (dimethyl sulfide/*N*-chlorosuccinimide), and Liu oxidation (DMSO/phenyl dichlorophosphate).

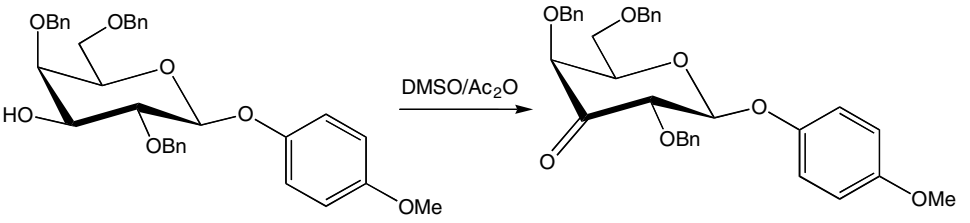
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

To a mixture of 886 g yohimbine (**1**) and 7.55 L dry dimethyl sulfoxide was added 5.05 L acetic anhydride. The mixture was stirred at room temperature for 18 h, then diluted with 16.8 L ethanol, stirred for 1 h, and mixed with 4.2 L water. Concentrated ammonium hydroxide (11 L) was added while maintaining the temperature at 15–30°C by cooling. The mixture was then diluted with 16.8 L water. Filtration gave a solid that was washed with water and dried to give 818 g (93%) of tan crystals, with a m.p. of 248–250°C (dec.). A slurry of this tan crystal was formed twice with 4 L ethanol, and 742 g methyl yohimban-17-one 16α-carboxylate **(2)** was obtained by filtration, in a yield of 84%, m.p. 253–254°C (dec.).

The filtrate from the first slurry with 4 L ethanol was concentrated to give a dark colored gum. The gum was dissolved in chloroform-acetone-ethanol (6:3:1) and filtered through synthetic magnesia silica gel. The filter cake was washed with acetone, and the combined filtrates were concentrated to give 40 g of dark gum. The gum (20 g) was chromatographed on a column of 300 g silica gel using chloroform-ethanol (99.3:0.7) as the eluting solvent and 250-mL cuts were collected. Evaporation of cuts 5–11 gave the product as a glass. The combined glass from two column purifications was crystallized from methanol to give 6.95 g (0.7%) methyl 17α-[(methylthio)methoxy]yohimban-l6α-carboxylate **(3)** as tan crystals, m.p. 195–198°C.



Reference 5.

To a mixture of 18 mL anhydrous DMSO and 15 mL acetic anhydride was added 2.93 g *p*-methoxyphenyl-2,4,6-tri-*O*-benzyl-β-D-galactopyranoside. The solution was stirred under nitrogen for 12 h at room temperature, then acetic anhydride was evaporated and the remaining solution was diluted with water and extracted with chloroform. The combined organic layers were washed with H_2O, dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by chromatography on silica gel using EtOAc/petroleum ether (1:3) as the eluent to give 2.45 g *p*-methoxyphenyl-2,4,6-tri-*O*-benzyl-β-D-xylo-hex-3-ulopyranoside as a light yellow solid, in a yield of 84%, m.p. 85–87°C; $\alpha_D^{23} = -52^\circ$ ($c = 1$, $CHCl_3$).

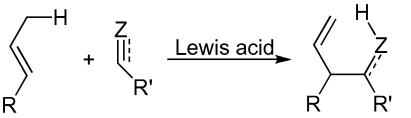
Alder Ene Reaction
(Conia Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Alder in 1943.[1] It is the reaction between an alkene of at least one allylic hydrogen (ene) and another unsaturated compound (i.e., enophile) to form a new olefinic compound with a new bond connecting the two unsaturated termini, and the allylic hydrogen is transferred to the enophile. Therefore, this reaction is generally known as the Alder ene reaction[2] and is occasionally referred to as ene cyclization,[3] ene functionalization,[4] or Alder ene synthesis.[5] This reaction has been extensively reviewed.[6]

B. GENERAL REACTION SCHEME



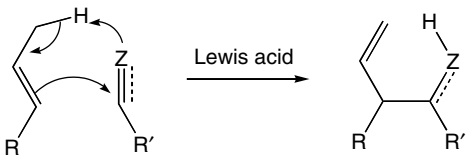
Z = C, N, O, S

(Lewis acid: $SnCl_4$, $BF_3{\bullet}Et_2O$, $Al(CH_3)_2Cl$, $CpRu(CH_3CN)_3PF_6$, etc.)

C. PROPOSED MECHANISMS

The mechanism of ene reaction is similar to that of *Diels-Alder Reaction*.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

Conia has developed an intramolecular version of Alder ene reaction of unsaturated ketones, where the carbonyl group functions as the ene component via the tautomerization and the olefinic moiety serves as the enophile.[7] This kind of Alder ene reaction is generally known as a Conia reaction.[8]

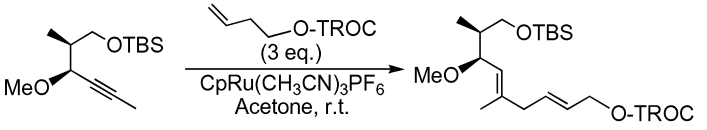
E. APPLICATIONS

This reaction has very wide applications in organic synthesis.

F. RELATED REACTIONS

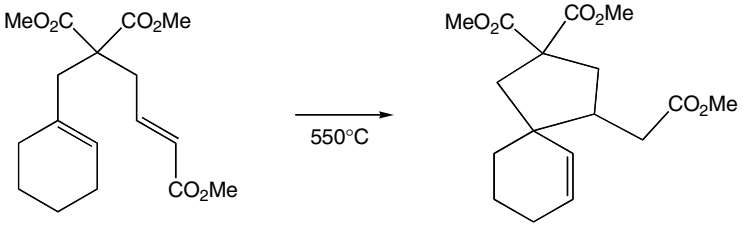
This reaction is related to *Pericyclic Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

The mixture of 900 mg 1-*O*-(tert-butyldimethylsilyl)-2-methyl-3-methoxy-hex-4-yn-1-ol (3.5 mmol) and 2.6 g 3-butenyloxycarbonyloxy-2,2,2-trichloroethane (10.5 mmol) in 7.0 mL acetone was treated with 76 mg $CpRu(CH_3CN)_3PF_6$ (0.18 mmol) for 20 min at room temperature. The reaction mixture was concentrated and purified by silica gel flash column chromatography using ether/petroleum ether (1:9 to 1:3) as the eluent to afford 1.49 g (2E,5E)(7S,8S)-9-(*tert*-butyldimethylsilyloxy)-7-methoxy-5,8-di-methylnona-2,5-dienoxycarbonyloxy-2,2,2-trichloroethyl, in a yield of 85%.



Reference 10.

Methyl 5,5-bis(methoxycarbonyl)-6-(l-cyclo-hexenyl)-2(E)-hexenoate (40 mg, 0.17 mmol) was distilled at 180°C (0.1 mmHg) into a horizontally mounted nonpacked quartz tube that was heated in an oven at 550°C at a 0.1 mmHg vacuum. The product was collected in a dry ice trap. Flash chromatography (3:1 hexane-ether) gave 32 mg of 2,2-bis(methoxycarbonyl)-4-[(methoxycarbonyl)-methyl]spiro[4.5]dec-6-ene, in a yield of 80%.

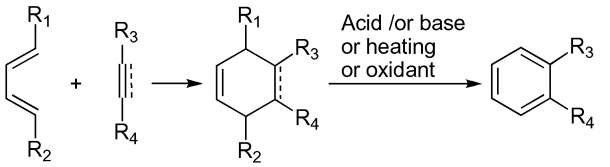
Alder-Rickert Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Alder and Rickert in 1936.[1] It is the extension of the *Diels-Alder Reaction* in which the Diels-Alder cycloadducts extrude the cleavable groups to give even more stable aromatic compounds[2] under thermal conditions or in the presence of either acid or base. Thus this reaction is generally known as the Alder-Rickert reaction.[3] In addition, the Diels-Alder cycloadducts can also be converted into aromatic compounds via rearrangement or oxidation.[4]

B. GENERAL REACTION SCHEME

Shown here is a typical Alder-Rickert reaction in which R_1 and R_2 are eliminated. Other groups are also possible to cleave.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

There are too many types of reactions to be generalized here; however, the formation of a stable aromatic ring will be the driving force for this reaction.

D. MODIFICATION

N/A

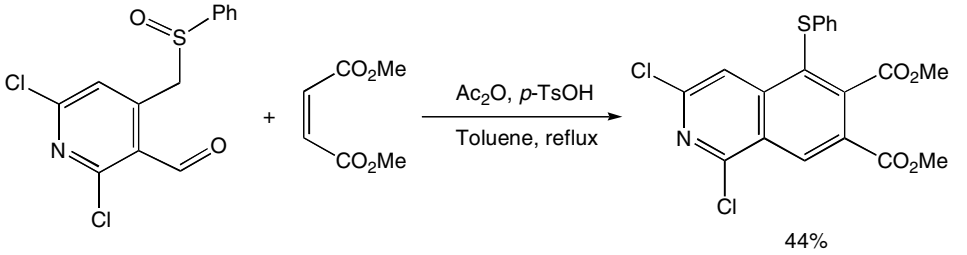
E. APPLICATIONS

This reaction has general applications in the formation of aromatic compounds.

F. RELATED REACTIONS

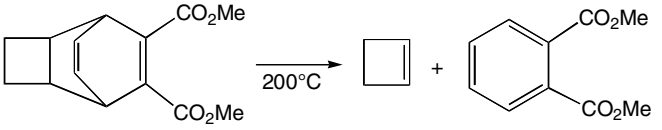
This reaction is related to *Diels-Alder Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



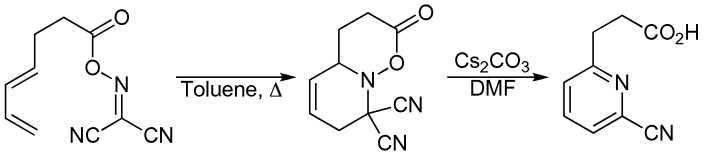
Reference 5.

To a flask equipped with a condenser were added 10 mL dry toluene, 3.0 mmol acetic anhydride, 0.15 mL dimethyl maleate (1.27 mmol), and a catalytic amount of *p*-toluenesulfonic acid. Under argon, 100 mg 2,6-dichloro-4-[(phenylsulfinyl)methyl]nicotinaldehyde (0.32 mmol) in toluene was added to above solution, dropwise over a period of 10 min. After the addition was complete, the yellow mixture was refluxed for an additional hour. The reddish yellow solution was cooled and washed with saturated aqueous $NaHCO_3$ solution. The organic layer was concentrated and purified by preparative layer chromatography to give dimethyl 1,3-dichloro-5-(phenylthio)isoquinoline-6,7-dicarboxylate, in a yield of 44% yield, m.p. 109–111°C.



Reference 6.

To a 5-mL flask with a capillary inlet attached to a source of dry nitrogen, was added 4.72 g of the Diels-Alder cycloadduct from cyclooctatriene and dimethyl acetylenedicarboxylate. The flask was connected to a 25-cm tube, which served as an air-cooled condenser, and which led to a trap cooled with liquid nitrogen. The system was evacuated at 100 mmHg, and the flask was heated in a bath at 200°C for 20 min. The flask was cooled, and nitrogen was admitted. The trap contained 0.97 g cyclobutene (95%), which was solid at the temperature of liquid nitrogen and liquefied when placed in a dry ice bath at −78°C. The residue from the pyrolysis of cycloadduct was shown to be dimethyl phthalate by comparing its infrared spectrum with the spectrum of an authentic sample and by saponification to phthalic acid, isolated by sublimation as phthalic anhydride.



Reference 7.

The solution of 205 mg 2-((*E*)-1-*oxo*-hepta-4,6-dienyloxyimino)malononitrile (1.01 mmol) in 200 mL dry toluene was stirred at reflux for 24 h. The solution was concentrated in vacuo to give a dark brown oil that was purified by flash column chromatography on silica gel eluting with hexanes/EtOAc (1:1) to give 139 mg 2-*oxo*-3,4,4a,7-tetrahydro-2H-pyridio[1,2-b]oxazine-8,8-dicarbonitrile as a thick brown oil, in a yield of 68%. The solution of 140 mg of the above cycloadduct (0.69 mmol) and 671 mg Cs_2CO_3 (2.06 mmol) in 5 mL dry DMF was stirred at room temperature for 18 h. The reaction mixture was diluted with 20 mL EtOAc and acidified to pH 2 with 10% aqueous HCl. The aqueous layer was extracted with 5 mL EtOAc three times. The combined organic layers were dried over Na_2SO_4 and concentrated in vacuo to give 87 mg 6-(2-carboxyethyl)pyridine-2-carbonitrile as a light tan solid, in a yield of 72%, m.p. 95–98.5°C.

Aldol Reaction and Aldol Condensation

A. GENERAL DESCRIPTION OF THE REACTION

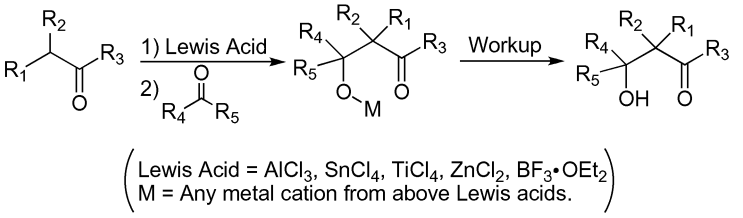
The aldol reaction[1] or aldol condensation,[2] first reported by Kane in 1838,[3] is one of the most important C-C bond formation reactions for aldehydes and ketones. Due to the electron-withdrawing characteristic of carbonyl groups in aldehydes and ketones, the α-methylene group is relatively acidic (with a pKa of 16–21[4]); therefore, aldehydes and ketones can isomerize into enolates or enols under basic or acidic conditions, respectively. The enolates or enols can further add to the carbonyl group in aldehydes or ketones,[5] giving β-hydroxyl carbonyl compounds known as aldols (aldehyde + alcohol). Enolates normally aggregate to form dimer, tetramer, or higher oliogmers and exist as monomer predominantly only in very dilute solutions.[6] In general, this reaction is complicated[7] because many possible reactions can occur at the same time. For example, the enolization of a ketone will give two possible enolates, which will add to the same molecule or another aldehyde or ketone (in a stepwise manner) to give aldols that differ in regioselectivity and stereoselectivity. In addition, the aldol products can undergo dehydration to form conjugated carbonyl molecules (α,β-unsaturated aldehydes or ketones, in this case; the whole process is also referred to as aldol condensation[8]), which might undergo the *Michael Addition* with the existing enolates. On the other hand, under the basic condition, the aldehydes can undergo disproportionation to give both carboxylic acid and alcohol (*Cannizzaro Disproportionation*) or to form the ester (*Tischenko Reaction*). Furthermore, the addition of an enolate to a carbonyl group could be complicated with either *O*-attack or *C*-attack.[6] If all of these possible reactions occur during the aldol reaction, then the aldol reaction will not be as useful. However, more selective methods have been developed to generate enolates

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

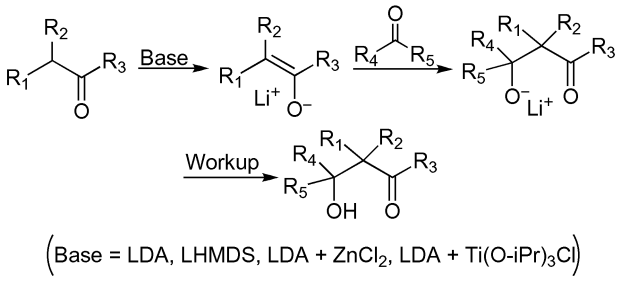
or enols, which selectively give the desired carbonyl molecules. Because this reaction is so important, it has been extensively reviewed in different aspects.[9]

B. GENERAL REACTION SCHEME

The aldol reaction or aldol condensation proceeds under either acidic (Scheme 1) or basic (Scheme 2) conditions.



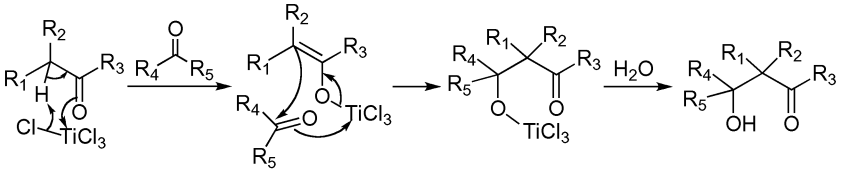
SCHEME 1. *Acid-catalyzed aldol reaction.*



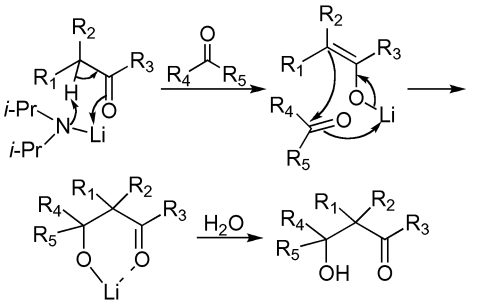
SCHEME 2. *Base-catalyzed aldol reaction.*

C. PROPOSED MECHANISMS

The mechanism is similar to that shown in Schemes 1 and 2 and illustrated in detail in Schemes 3 and 4.



SCHEME 3. *Mechanism of aldol reaction under acidic conditions.*



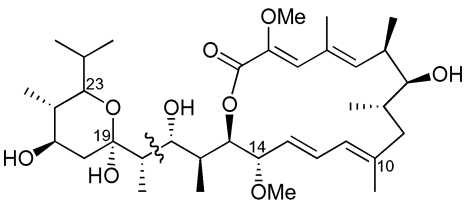
SCHEME 4. *Mechanism of aldol reaction under basic conditions.*

D. MODIFICATION

When aldehydes or ketones enolize to enols under acidic conditions, the enols are not as stable as aldehydes or ketones. However, the formed enols can be fixed or protected by a trimethylsilyl group to form trimethylsilyl vinyl ethers, which then undergo the aldol reaction. This modification is known as *Mukaiyama Aldol Reaction*.

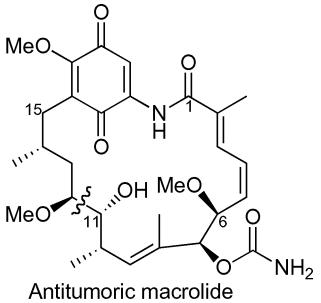
E. APPLICATIONS

Beside being used to form a variety of compounds (some of which are listed in the experimental section), the aldol reaction has been used to synthesize the following antibiotic macrolides, especially for the macrolide acutiphycin, which is primarily prepared by five steps of consecutive aldol reactions. Among the listed structures, the bonds arising from aldol reactions are labeled with many lines.



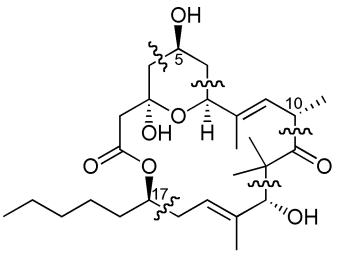
Macrolide antibiotic

(Ref. 10a).



Antitumoric macrolide

(Ref. 10b).



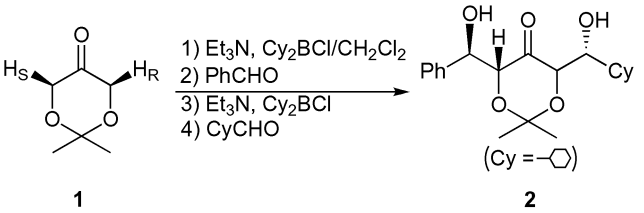
Synthesis of antineoplastic acutiphycin by consecutive aldol reactions

(Ref. 10c).

F. RELATED REACTIONS

Besides the aldol reaction to form β-hydroxyketone, *1,3-Dipolar Cycloaddition* can also form similar molecules. In addition to the *Mukaiyama Aldol Reaction*, the following are also similar or closely related to the aldol reaction: the *Claisen-Schmidt Condensation* (the aldol reaction between benzaldehyde and an aliphatic aldehyde or ketone in the presence of relatively strong bases to form an α,β-unsaturated aldehyde or ketone), the *Henry Reaction* (base-catalyzed addition of nitroalkane to aldehydes or ketones), the *Ivanov Reaction* (the addition of enediolates or aryl acetic acid to electrophiles, especially carbonyl compounds), the *Knoevenagel Reaction*[11] (the condensation of aldehydes or ketones with acidic methylene compounds in the presence of amine or ammonia), the *Reformatsky Reaction* (the condensation of aldehydes or ketones with organozinc derivatives of α-halo-esters), and the *Robinson Annulation Reaction* (the condensation of ketone cyclohexanone with methyl vinyl ketone or its equivalent to form bicyclic compounds).

G. CITED EXPERIMENTAL EXAMPLES

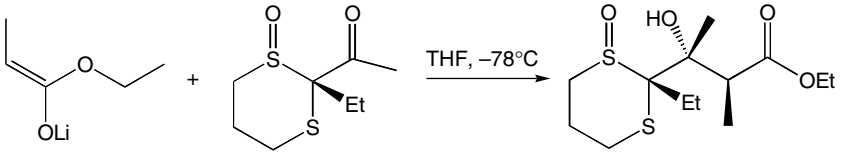


1 2

Reference 12 (a similar reaction condition is also found in Ref. 13).

To 10 mL CH_2Cl_2 was added 0.28 mL triethylamine (2.00 mmol), and the resulting solution was cooled to 0°C. To this solution, was added 2.0 mL 0.5 M dicyclohexylboron chloride in hexane (1.00 mmol), and the solution was stirred for 5 min. Then 0.13 g dioxanone (1.00 mmol) was added; and after being stirred for 15 min, 0.1 mL benzaldehyde (1.00 mmol) was added. After stirring for another 15 minutes, 0.28 mL of triethylamine (2.00 mmol) was added, followed by 2.0 mL of 0.5 M dicyclohexylboron chloride in hexane

(1.00 mmol). After another 15 minutes, 0.17 mL of cyclohexyl aldehyde (1.50 mmol) was added. After being stirred for an additional 15 min, the reaction mixture was quenched with 20 mL concentrated buffer (pH = 7). The resulting product was extracted with diethyl ether (3 × 50 mL). The combined extracts were washed with brine (2 × 10 mL) and dried over $MgSO_4$. Upon evaporation of the solvent, the residue was dissolved in 18 mL methanol and cooled to 0°C. To this solution were sequentially added 6 mL concentrated buffer (pH = 7) and 6 mL 30% H_2O_2. The solution was stirred at 0°C for 3 h and 150 mL Et_2O was then added; the separated organic layer was washed with saturated $NaHCO_3$ (2 × 15 mL) and 15 mL brine and was dried over $MgSO_4$. Upon removal of the solvent, four components were identified in the residual mixture as analyzed by ^1H NMR in a ratio of 83:9:6:2. The residue was isolated by DFC (9:1 hexane/CH_2Cl_2 followed by 9:1:2 hexane/CH_2Cl_2/AcOEt) to give 224 mg of the major product as a colorless liquid, in a yield of 64%.



Reference 14.

A solution of 4.5 mL 2.5 M n-BuLi in hexane (10.5 mmol) was slowly added to a cooled solution (−78°C) of 1.7 mL diisopropylamine (12.6 mmol) in 45 mL THF under a nitrogen atmosphere. After 30 min, a solution of 1.072 g ethyl propanoate (10.5 mmol) in 30 mL THF was slowly added. After being stirred for 30 min at the same temperature, a solution of 0.619 g 2-acetyl-2-ethyl-1,3-dithiane 1-oxide (3 mmol) in 20 mL THF was added dropwise via syringe, and the mixture was stirred for 5 min. Saturated aqueous NH_4Cl was added; and the aqueous layer was extracted with CH_2Cl_2 (3 × 50 mL). The combined organic phases were washed with brine and dried over $MgSO_4$. Upon removal of the solvent under reduced pressure, the residue was purified either by flash chromatography or by crystallization.

Other references related to the aldol reaction are cited in the literature.[15]

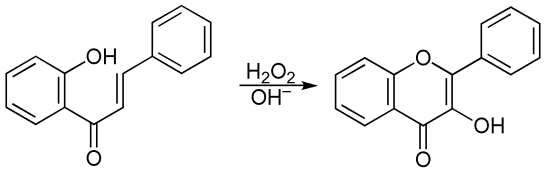
Algar-Flynn-Oyamada (AFO) Reaction

(Algar-Flynn-Oyamada Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Algar and Flynn[1] and concurrently by Oyamada[2] in 1934. It is the synthesis of flavones via oxidative cyclization of 2′-oxychalcones with hydrogen peroxide under alkaline conditions. Therefore, this reaction is generally known as the Algar-Flynn-Oyamada reaction.[3] In addition, this reaction has also been referred to as the Algar-Flynn oxidation,[4] Algar-Flynn-Oyamada oxidation,[5] Algar-Flynn-Oyamada (AFO) reaction,[6] Algar-Flynn-Oyamada condensation,[7] and AFO cyclization.[8] It has been found that a variety of 2-hydroxychalcones with methoxy groups in different positions in the two aromatic nuclei smoothly undergo the AFO oxidation.[9]

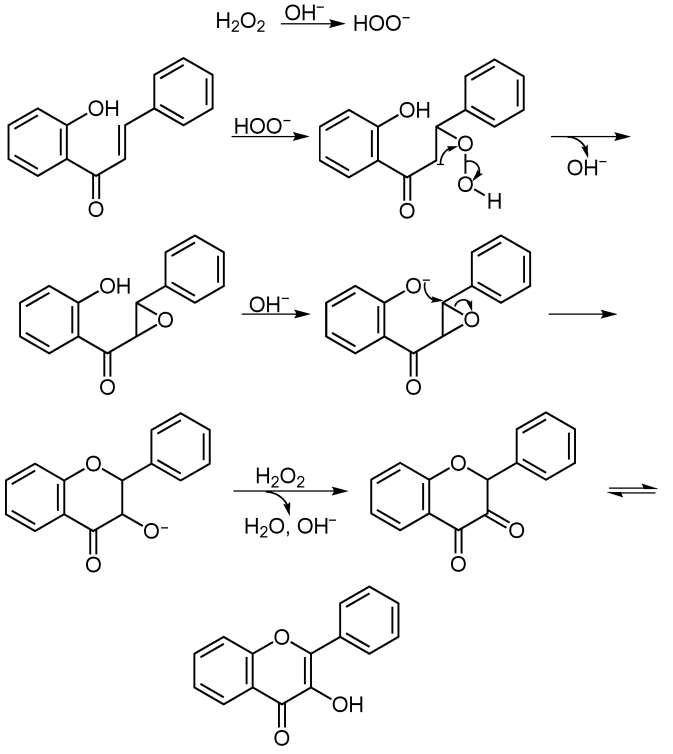
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism of this reaction is somewhat controversial. The initial formation of flavanone from 2′-hydroxychalcone and subsequent oxidation to flavonol has been postulated by Oyamada,[10] but the prior oxidation of 2′-hydroxychalcone into either an epoxide or a glycol followed by intramolecular cyclization to afford flavonol has been favored by Algar and Flynn.[1] However, because flavanones readily undergo ring-opening under alkaline conditions to the salts of the corresponding 2′-hydroxychalcones,[9] the mechanism proposed by Oyamada is difficult to validate.[11] In comparison, although a chalcone epoxide intermediate would lead to a flavone or a benzalcoumaranone,[1] no trace of a chalcone epoxide has ever been isolated.[3e] The α-attack is predominant for the intromolecular cyclization of the corresponding 2′-hydroxychalcone epoxide, yielding a diasteroisomeric mixture of aurone hydrates, which can be sustained for several days in an aqueous media at neutral pH.[8] Displayed here is one kind of reaction mechanism.



D. MODIFICATION

This reaction has been modified to convert 2′-hydroxychalcones into flavones via SeO_2 oxidation;[4] in addition, flavone has recently been prepared via a polystyrene-supported selenenyl bromide followed by H_2O_2 oxidation.[12]

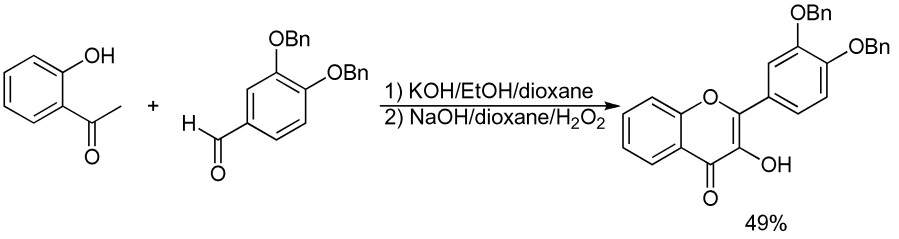
E. APPLICATIONS

This reaction is widely used for the preparation of flavones and flavonols.

F. RELATED REACTIONS

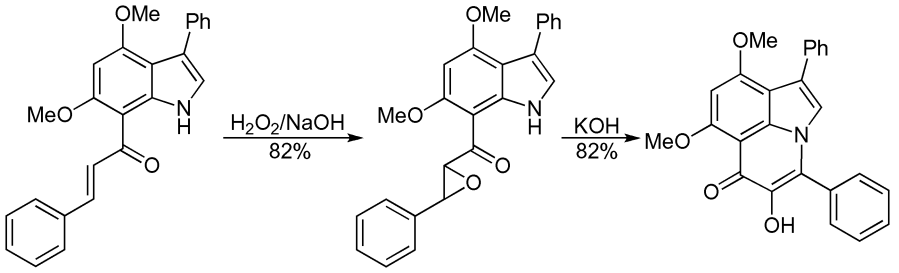
This reaction is related to the *Auwers Synthesis, Baker-Ollis Reaction*, *Kostanecki-Robinson Reaction* and *Allan-Robinson Annulation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3g.

A suspension of 10.0 g 3,4-dibenzyloxybenzaldehyde (31.4 mmol) and 4.28 g 2-hydroxyacetophenone (31.4 mmol) in 80 mL ethanol and 50 mL dioxane was cooled to 10°C, and 25 mL 40% w/v KOH solution was added dropwise. The reaction mixture was stirred for 66 h at room temperature. CH_2Cl_2 (400 mL) was added, and the organic layer was washed with H_2O (3 × 50 mL), dried over Na_2SO_4 and concentrated in vacuo. The oily residue was dissolved in 110 mL dioxane and 300 mL ethanol, and 100 mL of 5.4% (w/v) NaOH solution was added, followed by 11.4 mL of 35% H_2O_2 dropwise. The reaction mixture was stirred in an ice bath for 2 h and subsequently at room temperature overnight, resulting in a yellow suspension. After acidification with 100 mL 2 *M* HCl, the precipitate was filtered and washed with 500 mL H_2O. The crude product was recrystallized from ethanol to give 7.0 g 3′,4′-dibenzyloxy-3-hydroxyflavone as a light yellow solid, in a yield of 49%, m.p. 145.8–146.8°C.



Reference 3e.

To a solution of 0.69 g 1-(4,6-dimethoxy-3-phenylindol-7-yl)-3-phenyl-2-propen-1-one (1.8 mmol) in 30 mL aqueous THF was added 10 mL saturated NaOH; the mixture was stirred at room temperature for 5 min. To this mixture was added 15 mL 30% H_2O_2 dropwise, and the resulting mixture was stirred for 6–8 h. Water was added, and the resulting pale yellow precipitate was filtered, washed, and dried. After flash chromatography with dichloromethane and recrystallization (dichloromethane/petroleum ether), 0.59 g 1-(4,6-dimethoxy-3-phenylindol-7-yl)-3-phenyl-2,3-epoxypropan-1-one was obtained as a pale yellow powder, in a yield of 82%, m.p. 217–219°C. To a solution of 0.17 g 1-(4,6-dimethoxy-3-phenylindol-7-yl)-3-phenyl-2,3-epoxypropan-1-one (0.42 mmol) in 13 mL aqueous THF was added 3 mL saturated KOH solution and 0.3 g solid KOH (5.3 mmol). The reaction mixture was stirred at room temperature for 4 h. Water was added, and the resulting pale yellow precipitate was filtered, washed, dried, and flash column chromatographed (dichloromethane/methanol = 97:3). After recrystallization from dichloromethane/petroleum ether, 0.14 g 5-hydroxy-7,9-dimethoxy-1,4-diphenyl-6-oxo-6H-pyrrolo-[3,2,1-*ij*]quinoline was obtained, in a yield of 82%, m.p. 250°C.

Other references related to the Algar-Flynn-Oyamada reaction are cited in the literature.[13]

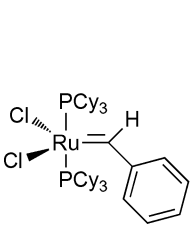
Alkene Metathesis
(Olefin Metathesis)

A. GENERAL DESCRIPTION OF THE REACTION

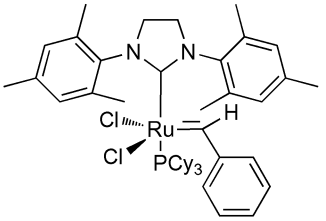
This reaction was first reported by Eleuterio in 1963[1] and concurrently by Bailey in 1964;[2] it was subsequently extended primarily by Grubbs et al.[3] It is the swap of olefinic substituents between two alkenes in the presence of a metallo-carbene complex. Therefore, it is generally known as the alkene metathesis[4] or olefin metathesis.[5] Occasionally, it is also referred to as the Grubbs metathesis,[6] Grubbs olefin metathesis,[7] and olefin disproportionation.[2] It is a synthetically powerful chemical transformation, enabling the synthesis of complicated molecular structures for the preparation of novel pharmaceuticals and is the basis of many important industrial processes. The catalyst used in this reaction is generally referred to as the Grubbs catalyst.[8] It is generally proposed that the alkene metathesis proceeds via insertion (or oxidative addition) followed by reductive elimination to afford the final product in the presence of only a catalytic amount of the Grubbs catalyst. During the development of alkene metathesis, different types of ruthenium-based metallo-carbene complexes were designed and are referred to as first-generation Grubbs catalysts, second-generation Grubbs catalysts, first-generation Hoveyda-Grubbs catalysts, and second-generation Hoveyda-Grubbs catalyst,[9] as shown. Many new ruthenium-based metallo-carbene complexes have recently been synthesized.[10]

According to the nature of alkene metathesis, this general reaction can be divided into different subgroups: cross-metathesis (CM),[11] ring-closing metathesis (RCM),[12] ring-opening metathesis polymerization (ROMP),[13] and acyclic diene metathesis polymerization (ADMET).[14] From an industrial perspective, a more cost-effective method for alkene metathesis is to generate the metallo-carbene *in situ*.[15] This reaction has been extensively reviewed.[16]

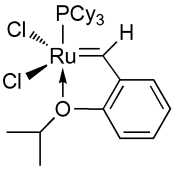
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



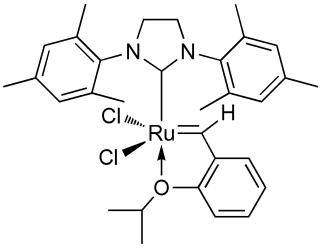
First-generation
Grubbs catalyst



Second-generation
Grubbs catalyst

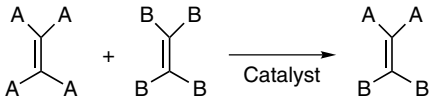


First-generation
Hoveyda-Grubbs catalyst



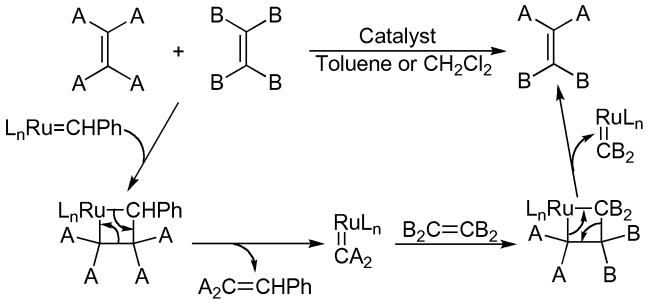
Second-generation
Hoveyda-Grubbs catalyst

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction generally involves insertion and subsequent reductive elimination.



D. MODIFICATION

This reaction has been modified to generate the catalyst *in situ*.[15]

E. APPLICATIONS

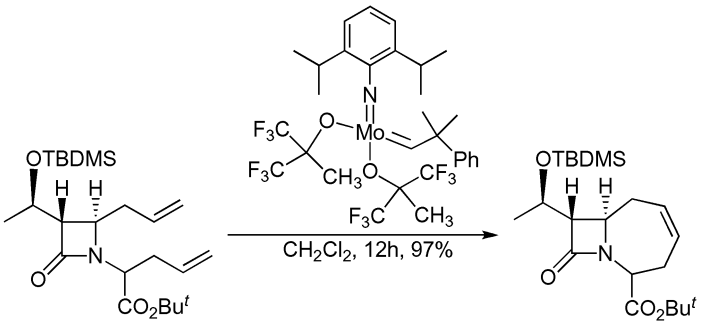
Besides its extensive application in industrial processes, e.g., ROMP and ADMET, the alkene metathesis has been applied to drug discovery and peptide synthesis. Examples include the synthesis of antifungal lactone (-)-gloeosporone,[17] the cross-metathesis of the amino acid homoallylglycine,[18] the introduction of carbon-carbon cross-linkages into

peptides,[19] and ring-closing olefin metathesis of non-natural α-amino acids.[20] Other applications are the synthesis of polymer bound olefins,[21] stereoselective preparation of cyclic 1-amino-1-carboxylic acids,[22] asymmetric synthesis of a potent inhibitor of HIV reverse transcriptase,[23] synthesis of the potential anticancer drugs epothilone A and B in solution and on solid support[24] (as well as the solution-phase combinatorial synthesis[25]), efficient synthesis of [2]-catenanes,[26] template-directed synthesis and polymerization of unsaturated crown ethers,[27] and synthesis of bridged oligocalix[4]arenes.[28] Moreover, this reaction has been applied to the general field of material sciences.[16]

F. RELATED REACTIONS

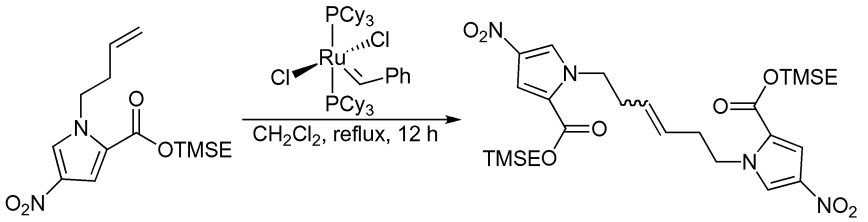
This reaction is related to *Tebbe Olefination*.[29]

G. CITED EXPERIMENTAL EXAMPLES



Reference 30.

The catalyst was added to a mixture of (2*R*)-*tert*-butyl 2-{(3*S*,4*R*)-3-[(1*R*)-(*tert*-butyldimethyl-silyloxy)ethyl]-2-oxo-4-(2-propenyl)-1-azetidinyl}-4-pentenoate and (2*S*)-*tert*-butyl 2-{(3*S*,4*R*)-3-[(1*R*)-(*tert*-butyldimethylsilyloxy)ethyl]-2-oxo-4-(2-propenyl)-1-azetidinyl}-4-pentenoate in CH_2Cl_2 (2 mL). The mixture was stirred for 12 h before destruction of the catalyst by exposure to air. The mixture was then evaporated, and the residue was chromatographed to afford a colorless oil as a mixture of the following-inseparable diastereoisomers: (2*R*,7*R*,8*S*)-*tert*-butyl-1-aza-8-[(1*R*)-(*tert*-butyldimethylsilyloxy)ethyl]-9-oxobicyclo[5.2.0]non-4-ene-2-carboxylate and (2*S*,7*R*,8*S*)-*tert*-butyl 1-aza-8-[(1*R*)-(*tert*-butyldimethyl-silyloxy)ethyl]-9-oxobicyclo[5.2.0]non-4-ene-2-carboxylate, in a yield of 97%, $R_f = 0.41$ (Et_2O:hexanes = 3:2).



Reference 31.

To 90 mL anhydrous CH_2Cl_2 was added 12.3 g 1,1,1-trimethylsilylethyl (4-nitro-1-but-3-enyl)-pyrrole-2-carboxylate (39.6 mmol); the resulting solution was purged with argon for 15 min. Then 0.760 g Grubbs catalyst (1.98 mmol, 2.5 mol %) was added to the solution, and the solution was refluxed while stirred under argon for 24 h. Another 0.76 g Grubbs catalyst was added, and the stirring/refluxing was continued for another 12 h until the reaction was complete as determined by TLC analysis. The solvent was removed in vacuo, and the residue was chromatographed on silica using hexane/EtOAc (5:1) as an eluent. Two isomers (*E* and Z) were collected in total amount of 8.71 g, in a yield of 74%.

Other references related to the Alkene metathesis are cited in the literature.[32]

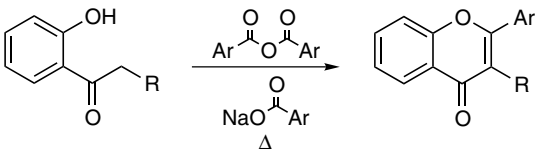
Allan-Robinson Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Allan and Robinson in 1924.[1] It is the synthesis of flavones or isoflavones derivatives by means of the condensation between *o*-hydroxyaryl ketones and an anhydride of aromatic acid in the presence of the sodium salt of corresponding acid in the anhydride. Thus this reaction is known as the Allan-Robinson condensation,[2] Allan-Robinson's flavone synthesis,[3] Allan-Robinson reaction,[4] and Allan-Robinson synthesis.[5]

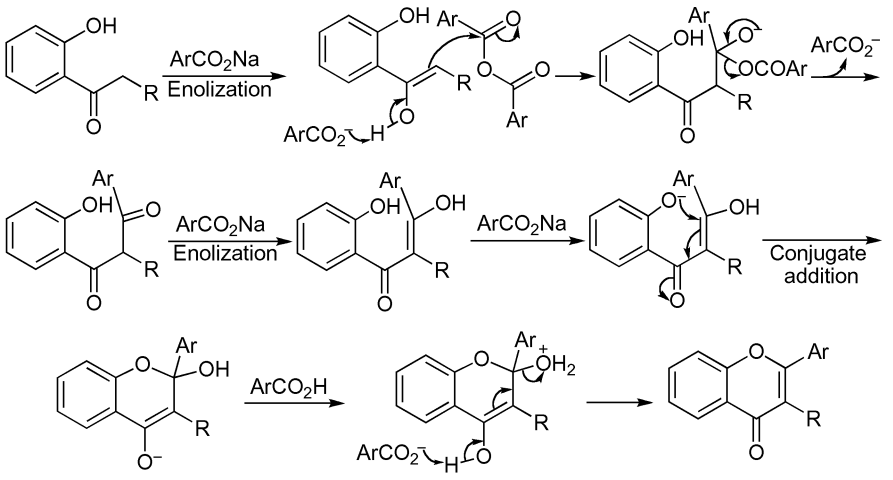
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general illustration of the reaction mechanism is provided here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

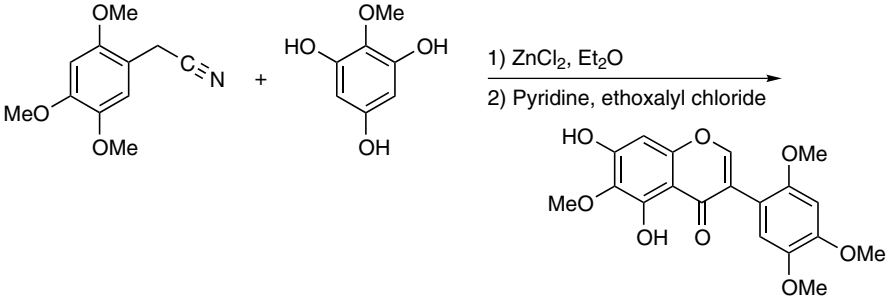
E. APPLICATIONS

This reaction has been used to synthesize the structurally disparate flavonoids and isoflavones.[6]

F. RELATED REACTIONS

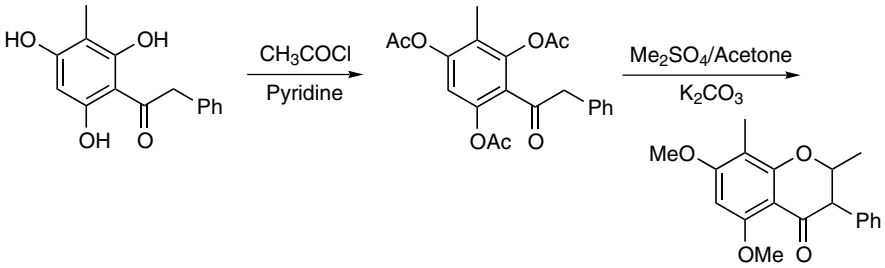
This reaction is closely related to the *Baker-Venkataraman Rearrangement* and *Kostanecki-Robinson Reaction*. Regarding the synthesis of flavone derivatives, the Allan-Robinson condensation is also related to the *Algar-Flyn-Oyamada (AFO) Reaction* and *Auwers Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a mixture of 4.2 g iretol, 6.0 g 2,4,5-trimethoxybenzyl cyanide and 5.0 g anhydrous zinc chloride in 150 mL anhydrous ether was bubbled with dried hydrogen chloride for 5 h at 0°C. After remaining at 0°C for 1 week, the ether solution was decanted from the oily layer of the ketimine hydrochloride-zinc chloride complex, which had separated. The oily layer was shaken with dry ether (2 × 250 mL) then heated under a nitrogen atmosphere on a steam bath with 400 mL water, which had been previously boiled with a stream of nitrogen bubbling through it. After cooling and standing, the product was collected and recrystallized from aqueous ethanol to afford 5.9 g of ketone as almost colorless rhombs, in a yield of 60%, m.p. 211–212°C. A part of the ketone (2.48 g) was dissolved in 50 mL dry pyridine, and 4.5 mL ethoxalyl chloride was added with shaking at 0°C. After remaining at 0°C for 3 days, it was poured into water and extracted with chloroform. The combined extracts were washed with dilute sulfuric acid and water, dried over $MgSO_4$, and evaporated to yield 3.18 g 2-carbethoxyisoflavone as an oil.



Reference 6d.

To a mixture of 1.0 g 2,4,6-trihydroxy-3-methyldeoxybenzoin and 20 mL pyridine was added 1.4 mL freshly distilled acetyl chloride at 0°C with stirring. After remaining for 24 h at 0°C, crushed ice was added and the solution was extracted several times with ether. The combined extracts were washed with ice cold hydrochloric acid, then with water, and then dried. Upon removal of ether via distillation, 1.4 g of a reddish brown semisolid mass was obtained.

About 0.2 g of this product (m.p. 224–225°C) was co-heated with 2 mL methyl sulfate and 5.0 g potassium carbonate in 150 mL dry acetone for 50 h. The product on repeated crystallization from methanol separated into 90 mg of colorless shining needles, m.p. 176–177°C. The second product, which separated from methanol as colorless needles (60 mg, m.p. 184–186°C), was characterized as the final product.

Other references related to the Allan-Robinson condensation are cited in the literature.[8]

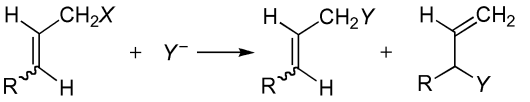
Allylic Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Claisen in 1912.[1] It is a migration of a carbon-carbon double bond within a three-carbon system (i.e., allylic), often occurring on the nucelophilic substitution of allylic systems in which the nucleophile adds to the carbon-carbon double bond along with the cleavage of the allylic leaving group. Thus this reaction is generally known as the allylic rearrangement,[2] and occasionally referred to as the allylic isomerization,[3] allylic transposition,[4]and allylic 1,3-rearrangement.[5] Because the allylic cation is relatively stable, the allylic rearrangement is often competed with regular S_N1 and S_N2 substitutions; therefore, the allylic rearrangement is also known as the S_N1' or S_N2' reaction. The allylic rearrangement can be promoted by light,[6] enzymes,[7] solvents,[8] acid,[6,9] (especially the Lewis acids such as $Eu(fod)_3$[10] PBr_3[11] and $NiCl_2$[12]) and transition metal catalysts (including tungsten,[13] rhodium,[14] cobalt[15] and palladium[16]). In addition, the allylic rearrangement also occurs under the conditions of electrophilic substitution.[17]

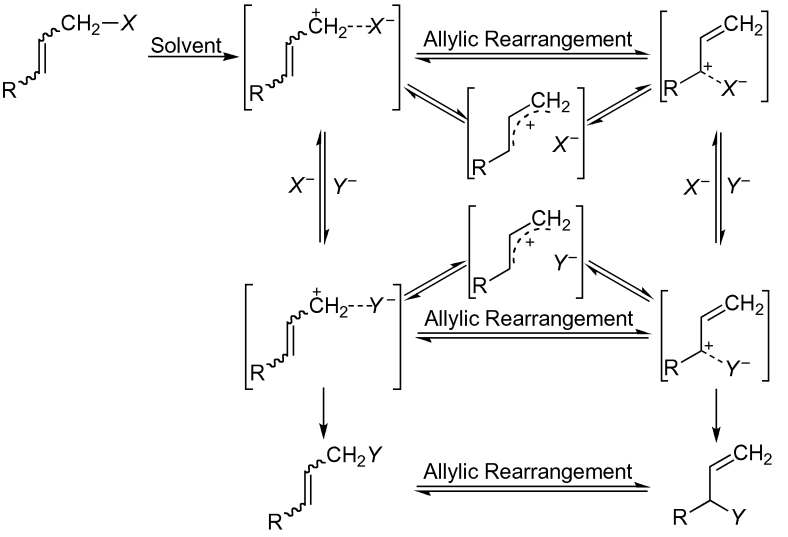
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction is proposed to occur through what is referred to as "super-conjugation" between α-methylene hydrogen and the π-double bond. The positive charge thus formed can be distributed to the double bond, especially under S_N1 conditions, forming a three-center two-electron system. On the other hand, the allylic cation can also isomerize to another resonance structure, via the distribution of the positive charge, resulting a relatively stable allylic cation. When a nucleophilic group attacks the allylic cation, it can bind to either one of the two positions as shown (a proposed mechanism).



D. MODIFICATION

This reaction has been extended to proceed via the promotion by means of enzymes, Lewis acids, transition metal complexes, and so on.

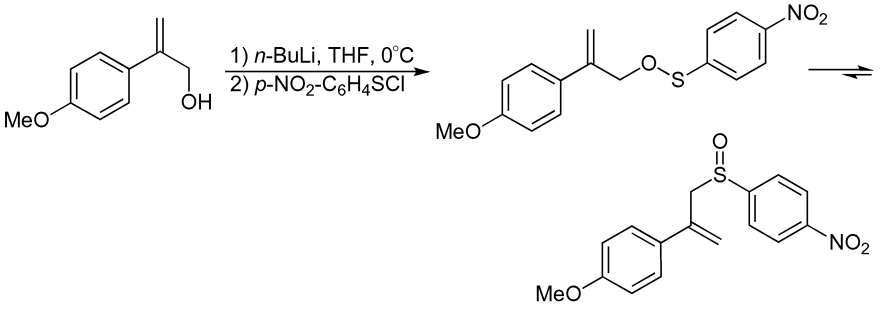
E. APPLICATIONS

The allylic rearrangement is so common in organic chemistry that it has been extensively used to synthesize a variety of organic molecules.

F. RELATED REACTIONS

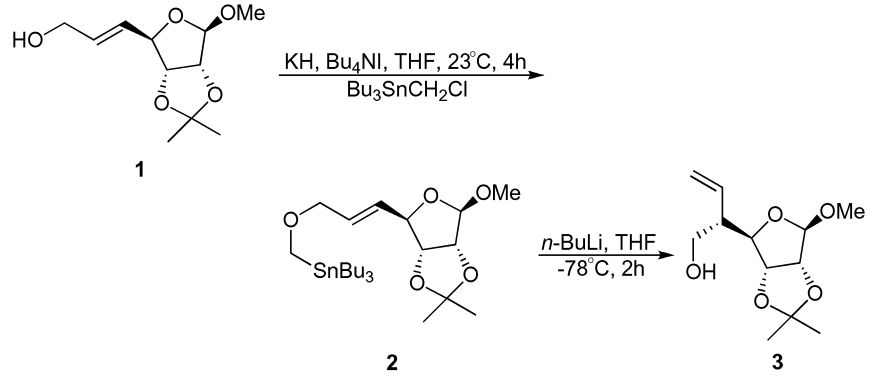
This reaction is similar to the *Chapman Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 18.

Under nitrogen atmosphere, 1.0 mL 2.0 M butyllithium in hexane (2.0 mmol) and 398 mg 4-nitrobenzenesulfenyl chloride (2.1 mmol) were added sequentially to a solution of 328 mg 2-(4-methoxyphenyl)-prop-2-en-1-ol (2.0 mmol) in anhydrous THF at 0°C. After being stirred for 30 min, the reaction mixture was diluted with EtOAc, washed with aqueous phosphate buffer (400 mM, pH 6.8) and brine, dried over $MgSO_4$, and concentrated in vacuo. The residue was purified by flash chromatography on silica gel with hexane/EtOAc (2:1) as an eluent to afford 2-(4-methoxyphenyl)prop-2-en-1-yl-4-nitrophenyl sulfoxide as a yellow solid, in a yield of 55%, m.p. 99.9–100.7°C, $R_f = 0.25$ (hexane/EtOAc = 2:1).



Reference 19.

To a suspension of 418 mg KH (10.4 mmol, prewashed with hexane) and 25 mg tetrabutylammonium iodide in 10 mL dry THF at 0°C was added dropwise a solution of 1.2 g (methyl (*E*)-5,6-dideoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hept-5-enofuranoside (**1**) (5.23 mmol) in 2 mL THF. The resulting red suspension was allowed to warm to 23°C, and the mixture was stirred for 1 h. The reaction was cooled to 0°C, and 2.1 g Bu_3SnCH_2I (6.8 mmol) in 2 mL THF was added dropwise over a period of 2 min. The mixture was stirred at 0–23°C for 4 h. Then the reaction was quenched with 10 mL saturated NH_4Cl solution. The layers were separated, and the aqueous layer was extracted with EtOAc. The combined organic layers were dried over anhydrous Na_2SO_4. Evaporation of the solvents provided the allyl stannylmethyl ether (**2**) as a colorless oil. This material was used for the next reaction without further purification. An analytical sample of structure **2** was obtained by flash chromatography over silica gel (5% EtOAc in hexane).

To a stirred solution of the formed crude stannyl ether **2** in 10 mL of THF at −78°C was added 3.2 mL 2.5 M *n*-BuLi in hexane (8 mmol) dropwise by a syringe pump over a period of 1 h. The resulting mixture was stirred for 2 h at −78°C. Then the reaction was quenched with saturated NH_4Cl solution, and the resulting mixture was warmed to 23°C. The layers were separated, and the aqueous layer was extracted with EtOAc (2 × 20 mL). The combined organic layers were dried over anhydrous Na_2SO_4. Upon evaporation of the solvents, the residue was chromatographed over silica gel using EtOAc/hexane (1:4) as an eluent to furnish 1.07 g of an inseparable mixture of methyl 5-(*S*)-deoxy-5-vinyl-2,3-*O*-isopropylidene-*β*-D-*ribo*-hexanofuranoside (**3**) and its epimer (4.4:1 by ^1H NMR) as a colorless oil, in a yield of 84%.

Other references related to allylic rearrangement are cited in the literature.[20]

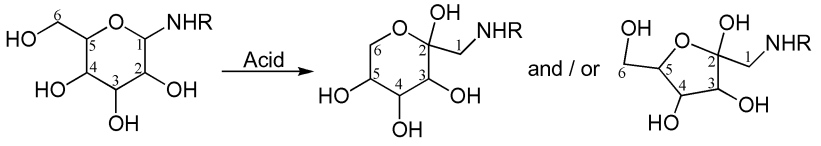
Amadori Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Amadori in 1925.[1] It is the transformation of *N*-glycosides of aldoses into *N*-glycosides of corresponding ketoses under acidic condition, or more generally the conversion of aldimines into ketoamines.[2] Thus this reaction is commonly known as the Amadori rearrangement.[3] This reaction often occurs in the formation of complex glycation end products[4] that have been potulated to play very important roles in biological processes. For example, in the *Maillard Reaction* pathway, the Amadori rearrangement appears to be involved in the manifestations of the pathological effects of diabetes, Alzheimer disease, and aging processes in general. Unfortunately, in its non-vivo applications, the Amadori rearrangement suffers from a variety of preparative shortcomings. This reaction is different from the so-called glycosylation in which the products are glycosides. This reaction has been extensively reviewed.[5]

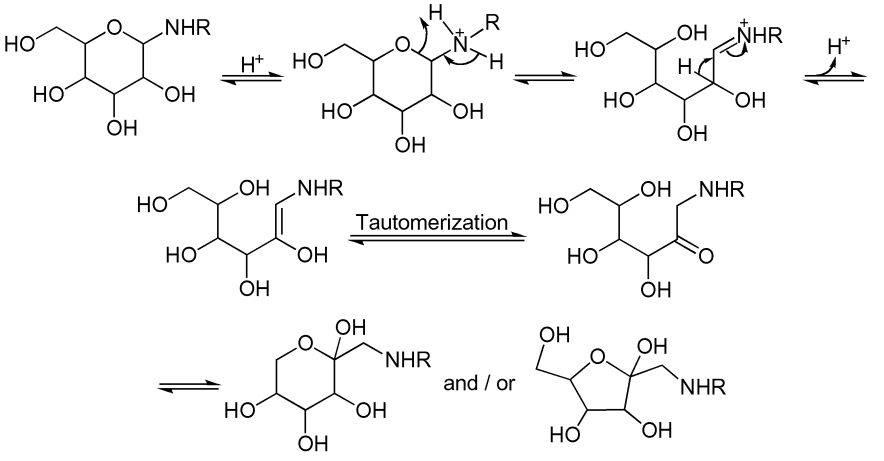
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A general illustration of the reaction detail is displayed here.



D. MODIFICATION

There is a Hodge and Rist modification of Amadori rearrangement, as shown in the first experimental protocol provided here.[6]

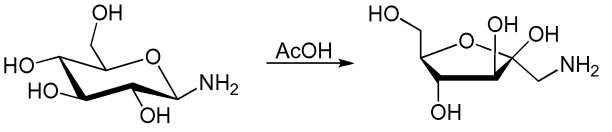
E. APPLICATIONS

This reaction has been extensively applied to the preparation of glycoproteins, via the reaction of the reducing sugars with the amino termini or the side chains of lysine and arginine residues in proteins. In addition, the Amadori rearrangement has been used for the synthesis of aminopolysaccharides.[7]

F. RELATED REACTIONS

This reaction is related to the *Lobry de Bruyn-van Ekenstein transformation* of aldoses involving the rearrangement of *N*-alkylamino-D-glucopyranosides into 1-alkylamino-1-deoxy-D-fructoses.[8]

G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

The Preparation of β-D-Glucopyranosylamine

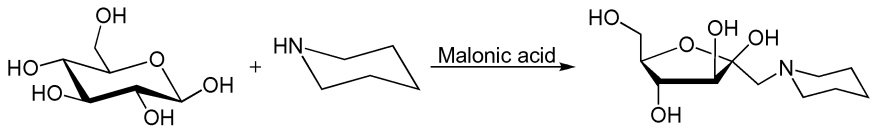
To 50 mL methanol, were added 20 g D-glucose and 0.5 g ammonium chloride, and the mixture was treated with ammonia gas at 0°C until the sugar dissolved. The solution was stored at 0°C until satisfactory crystallization had occurred. The first crystallization was slow and required storage of the solution for about a month. Subsequent recrystallizations with the aid of seed crystals were more rapid, but maximum yields required storage for a week or two. The crystals were separated, washed with methanol, and dried over sodium hydroxide in a vacuum desiccator. The crude product, 17 g, was dissolved in 17 mL water, and the solution was diluted with 170 mL methanol and sufficient ethanol to produce turbidity. After 48 h, the crystalline material was separated, washed with methanol, and stored over sodium hydroxide in an atmosphere of ammonia for 2 days.

Amadori Rearrangement of D-Glucopyranosylamine in Acetic Acid

To 10 mL glacial acetic acid was added 0.5 g β-D-glucopyranosylamine, and the solution was kept at 20°C. The optical rotation, $[\alpha]_D^{20}$, changed from a +18° to a value of −18° in 1 h and to a value of −65° after a period of 18 h. The solution had then become amber colored after this period. The acetic acid was removed by the repeated addition of toluene and evaporation in a rotary film evaporator apparatus. The residue, still containing a small amount of acetic acid, was redissolved in 10 mL water for hydrolysis to take place. After several hours, the solution was again concentrated; this treatment caused decomposition of any remaining D-glucosylamine. The residue was dissolved in 10 mL water and passed through a column containing 20 mL cation exchange resin (amberlite IR120-H, Rohm & Haas Co., Philadephia, Pa.); the resin was then washed with water, and the wash liquor was discarded. The basic materials held on the resin were eluted with 20 mL 1 *N*-hydrochloric acid. The eluent and wash liquor were combined, concentrated, and then adjusted to a volume of 0.1 mL. The specific rotation, $[\alpha]_D^{20}$ was −58°. Production of the stable basic substance having a levo-rotation (−58° in this case) indicates the presence of 1-amino-1-deoxy-D-fructose.

Hodge and Rist Modification of the Amadori Rearrangement

To 5 mL dimethylsulfoxide were added 0.2 g D-glucosylamine and 5 mL diethyl malonate. The mixture was heated for 90 min at 80°C and, after cooling back down to room temperature, was kept at room temperature overnight. The resultant brown solution was diluted with water and allowed to stand for several hours for effective hydrolysis of the remaining D-glycosylamines. The solution was then extracted several times with chloroform, and the aqueous portion was filtered through decolorizing carbon, concentrated using rotary film evaporation, and adjusted to a volume of 10 mL. The optical rotation, $[\alpha]_D^{20}$, was −43.5°, based on the weight of the original D-glucosylamine.



Reference 9.

The mixture of 90 g anhydrous D-glucose (0.50 mol) and 57 g piperidine (0.67 mol) was stirred mechanically at 60–75°C until a homogeneous amber sirup was obtained (~20 min). After the heating bath was removed, 18 g malonic acid (0.17 mol) was added slowly to the stirred sirup over a period of 10 min. The temperature rose to 80°C, and the color of the sirup deepened to a reddish hue. After stirring for 5 min longer, 70 mL ethanol was added; and the resulting solution was heated at 75°C for 30 min. After the addition of 70 mL acetone, seed crystals appeared; and after 1 h at 25°C, the first batch of D-glucose piperidine furanose was obtained (28 g), m.p. 123–125°C (dec.). Reheating the mother liquors at 95–100°C was required to produce further crystallization at 0°C without long waiting periods. A total of 37.0 g of crude product was obtained, in a yield of 30%. Recrystallization from 200 mL of hot ethanol and 200 mL acetone gave 33 g of pure product as colorless, glistening plates, in a yield of 27%, m.p. 126–127°C (dec.).

Other references related to the Amadori rearrangement are cited in the literature.[10]

Andrussow Process

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Andrussov (Andrussow) in 1927.[1] It is primarily an industrial process used to manufacture hydrogen cyanide from methane, ammonia, and oxygen over a catalyst of 90% Pt–10% Rh in the form of a pad of woven screens at 1050–1100°C and 2 atm.[2] Therefore, this reaction is known as Andrussow process.[3] In this process, the catalytic gauze is 3–5 mm thick, and when the high gas velocities are employed, the contact times achieved are of the order of a few milliseconds. The effluent stream contains about 8% HCN and a number of byproducts such as hydrogen, CO, and CO_2.[2b] It was reported that in 1978 the output of hydrogen cyanide exceeded 600 million pounds in the United States alone.[2b]

B. GENERAL REACTION SCHEME

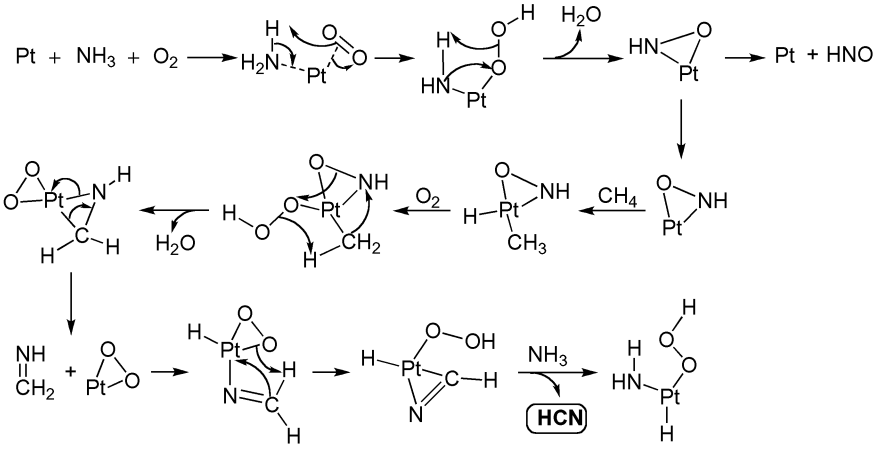
$$CH_4 + NH_3 + O_2 \xrightarrow{90\%\ Pt - 10\%\ Rh} HCN + H_2O$$

C. PROPOSED MECHANISMS

The mechanism for the oxidation of ammonia has been discussed by Zawadski;[4] however, at least three theories have been proposed for the Andrussow process.[5] Bodenstein and Krauss proposed the mechanism of the initial oxidation of ammonia with adsorbed oxygen to

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

form hydroxylamine,[6] while Zawadski believed that the imide (NH) was initially formed.[4] The third mechanism, proposed by Andrussov, is that the initial oxidation of ammonia with oxygen forms nitroxyl (HNO).[7] Later experimental evidence supported Andrussow's postulation.[5,8] Although 90% Pt–10% Rh rhudium is used as a catalyst, it is believed that platinum is the actually catalytic center. Therefore, the mechanism of this reaction is tentatively given here.



D. MODIFICATION

As rhodium is not the actual catalytic center and is very expensive, modifications have been done on both the catalyst and the starting materials. For example, one modification used α-Al_2O_3-supported platinum as a catalyst, and mixture of C_2H_6, NH_3, and oxygen as the reactants.[2a] In other modification, the combination of manganese oxide and bismuth oxide was tested as a catalyst.[5]

E. APPLICATIONS

This reaction is usually used to manufacture hydrogen cyanide.

F. RELATED REACTIONS

Homogenous oxidation of ammonia followed by hydration to form HNO_3 is called the Ostwald process.[9,10] On the other hand, the strongly endothermic process in which methane and ammonia react over platinum catalysts in the absence of air at 1150–1250°C is called the Degussa (or BMA) process,[11] which holds the advantages of higher HCN yield, higher NH_3 conversion per pass, and a fairly high purity of the byproduct hydrogen but has the disadvantage of needing external heating.

G. CITED EXPERIMENTAL EXAMPLES

$$CH_4 + NH_3 + O_2 \xrightarrow{68\%\ CuCl_2 - 32\%\ KCl} HCN + H_2O$$

Reference 5.

The fused salt (68% $CuCl_2$/32% KCl) reactor (which consisted of a 22-mm inside diameter glass tube, 15 in. in length) was heated externally. The preheated gaseous reactants were introduced near the bottom of the tube below the surface of the salt. Analysis of the products was made after steady state conditions were obtained.

Additional references about the Andrussow process are cited in the literature.[12]

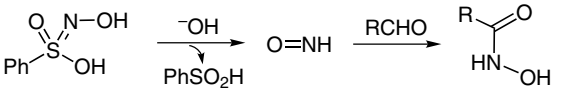
Angeli-Remini Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Angeli in 1896.[1] It is the preparation of hydroxamic acids from aldehyde and benzosulfohydroxamic acid. As an important class of reagents, hydroxamic acids have found a variety type of applications in inorganic, organic and pharmaceutical chemistry, including antibiotics,[2] inhibitors,[3] and strong metal ion-chelators,[4] etc. As of today, many other methods have been developed to prepare different hydroxamic acids.[5]

B. GENERAL REACTION SCHEME

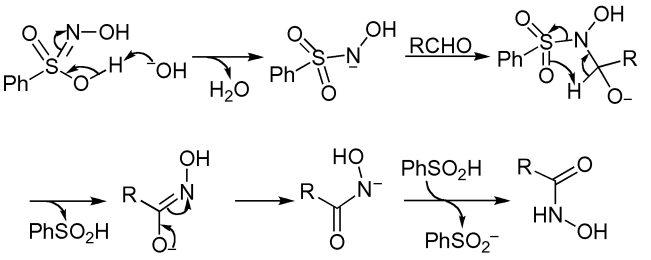
The original version of the Angeli-Remini reaction is displayed below.



C. PROPOSED MECHANISMS

The mechanism for the original Angeli-Remini reaction is proposed below.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

Different methods for the preparation of hydroxamic acids have been developed.[5]

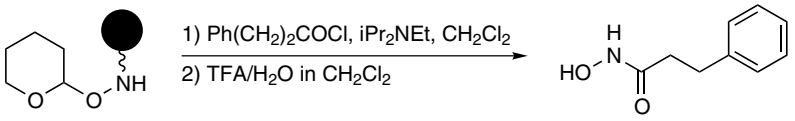
E. APPLICATIONS

This reaction is useful for the preparation of hydroxamic acids.

F. RELATED REACTIONS

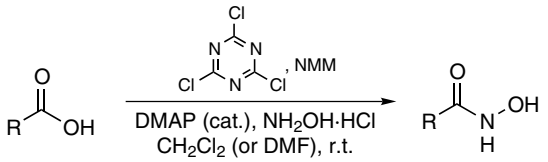
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

The mixture of 300 mg of alkoxyamine resin, 126 μL of diisopropylethylamine (0.72 mmol, 10 equiv.), and 53.4 μL of hydrocinnamoyl chloride (0.36 mmol, 5.0 equiv.) was shaken for 18 hours at room temperature under nitrogen. The resin was filtered and washed sequentially with MeOH (3×5 mL) and dichloromethane (2×5 mL). The resin was then treated with a solution of 2.5% TFA and 1% H_2O in 4 mL of dichloromethane, and the mixture was shaken for 1 hour. Resin was filtered and washed sequentially with MeOH (3×5 mL) and dichloromethane (2×5 mL), and then retreated with a solution of 50% TFA and 1% H_2O in 4 mL of dichloromethane under shaking for 1 hour. The resin was filtered, and the filtrate was concentrated in vacuo to give crude product which was purified by preparative TLC (5% MeOH in dichloromethane) to give 6.75 mg of hydroxamic acid, in yield of 88%.



Reference 7.

To a solution of 2.24 g of (*S*)-(*N*-benzyloxycarbonyl)proline (9.0 mmol), 1.0 g of *N*-methylmorpholine (NMM, 9.9 mmol), 0.01 g of DMAP (0.1 mmol) and 0.68 g of hydroxylamine hydrochloride (9.8 mmol) in 20 mL of dichloromethane, was added 0.5 g of cyanuric chloride (3.0 mmol) at 0 °C under stirring. The mixture was warmed to room temperature and stirred for 12 hours and then filtered on Celite. The organic phase was washed three times with 15 mL of 1 *N* HCl and then brine, dried over Na_2SO_4 and evaporated to give 2.3 g of (*S*)-(*N*-benzyloxycarbonyl)proline hydroxamate without further purification, in yield of 96%.

Other examples about the preparation and application of hydroxamic acids are cited in literature[8].

ANRORC Rearrangement
(Degenerate Ring Transformation of Heterocycles)

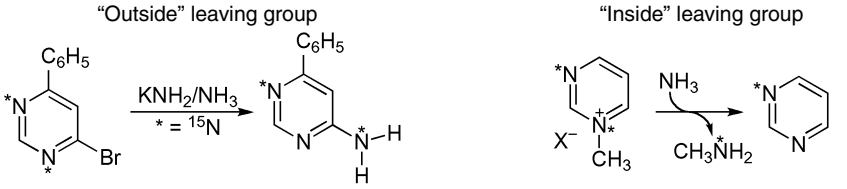
A. GENERAL DESCRIPTION OF THE REACTION

ANRORC rearrangement occurs in nucleophilic substitution of heterocyclic compounds, and stands for a whole process of the initial **A**ddition of a **N**ucleophile, followed by the **R**ing **O**pening and **R**ing **C**losure during the substitution. This transformation, known as S_N(ANRORC) reaction[1] or degenerate ring transformation,[2] is a very common transformation for heterocycles, and has been discovered for more than a century already. One example is the well-known *Dimroth Rearrangement*.[3] In ANRORC rearrangement, one (or more) of the ring atoms(s) will be replaced by one (or more) identical atom(s) present in the nucleophilic reagent that can be divided into two subgroups, including the reactions with the leaving group as a substituent on the heterocyclic ring ("outside" leaving group) and those with the leaving group as an integral part of the heterocyclic system ("inside" leaving group).[4]

B. GENERAL REACTION SCHEME

Listed below are two examples of such reaction with either an "outside" leaving group or "inside" leaving group.[5,6]

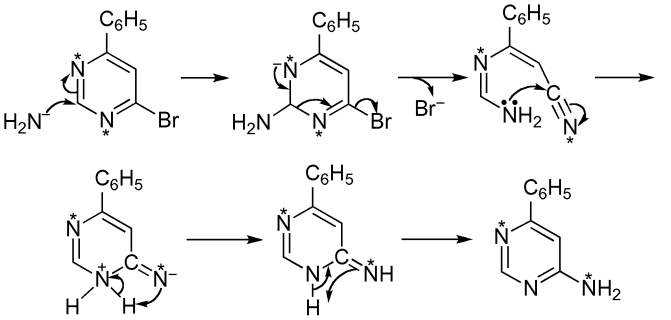
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



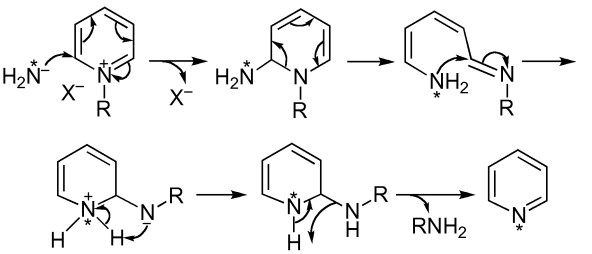
C. PROPOSED MECHANISMS

This reaction involves three consecutive steps: addition of nucleophile, ring opening and ring closure.

"Outside" leaving group



"Inside" leaving group



D. MODIFICATION

N/A

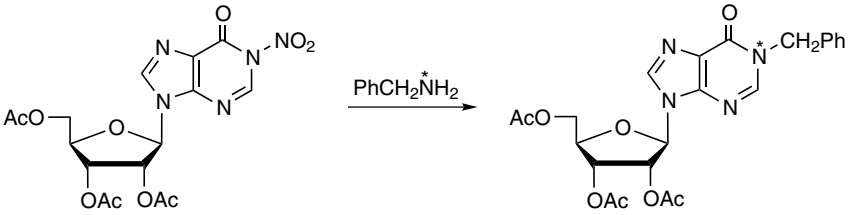
E. APPLICATIONS

This reaction has wide applications in heterocycle chemistry.

F. RELATED REACTIONS

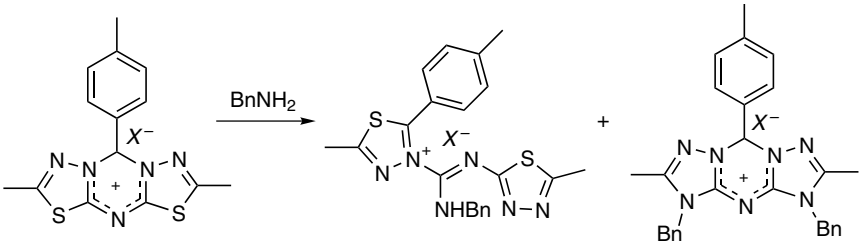
Dimroth Rearrangement is a special type of ANRORC rearrangement.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a small flask, were added 132 mg of nitroinosine (0.30 mmol) and 6.0 mL of CH_2Cl_2. After being cooled to -78°C, 64 mg of benzylamine (0.60 mmol) in 1.0 mL of CH_2Cl_2 was added. The resulting mixture was left overnight at -20°C. The mixture was then allowed to warm to room temperature and was stirred for 2 days (until no nitroinosine remained). After being treated with 46 μL of CF_3COOH (0.60mmol) for 35 hours, solvent was removed and the residue was purified by column chromatography to give final product.



Reference 8.

To a 250 mL of flask, were added 60.0 mL pyridine and 5.0 mmol of bis(1,3,4-thiadia-zolo)-1,3,5-triazinium halide. Triazinium halide will suspend in pyridine under stirring. To this suspension, 10 mmol of benzylamine was added and the mixture was stirred for 24 hours at room temperature. This procedure gave a clear solution with a slight red coloring, while the smell of hydrogen sulfide was observed. After the reaction, pyridine was removed via rotatory evaporation, the crude product was extracted with *tert*-butyl methyl ether and the solid residue was washed with water. After filtration and drying in vacuo, two main products were isolated by column chromatography on silica gel 60 (0.063 – 0.200 mm): *N*-benzyl-5-methyl-2-(4-methylphenyl)-*N*′-(5-methyl-1,3,4-thiadiazol-2-yl)-1,3,4-thiadiazole-3(2*H*)-carboximidamide (0.78 g, m.p. 161°C, in yield of 37%) and 3,5-dibenzyl-2,6-dimethyl-9-(4-methylphenyl)-3H,5H,9H-di[1,2,4]-triazolo[1,5-a:1′,5′-d][1,3,5]triazine-8-ium bromide (0.65 g, m.p. 238°C, in yield of 24%).

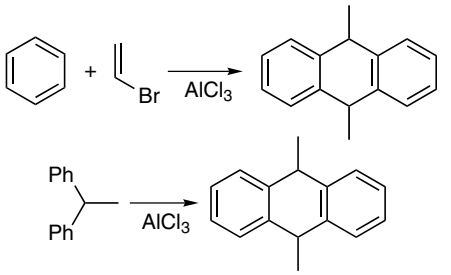
21

Anschütz Anthracene Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially studied by Anschütz between 1879 and 1886.[1] It is the synthesis of anthracene from vinyl bromide and benzene in the presence of aluminum chloride. In addition, methyl phenyl carbinol or 1,1-diphenyl ethane can also be converted into anthracene derivative in the presence of aluminum chloride.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The reaction mechanism is similar to that of *Friedel-Crafts Alkylation.*

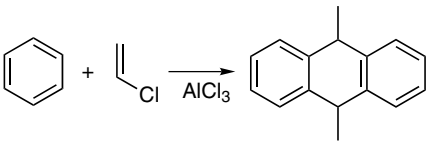
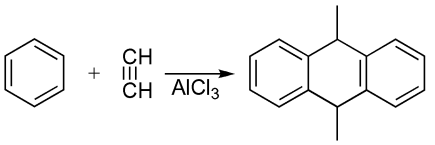
G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To a 1-L three-necked flask equipped with condenser, thermometer and gas inlet tube were added 300 mL thiophene-free benzene and 50 g $AlCl_3$. The solution was agitated using a stirrer at 1000–1400 rpm until the aluminum chloride was in a finely divided state. Then vinyl chloride gas was passed into the flask at such a rate that only a few bubbles of gas escaped from an alkali trap connected to the condenser. The reaction was kept at 0–5°C. No hydrogen chloride was evolved until an initial period of 15–20 min.

After 90 g vinyl chloride gas had been added, all of the hydrogen chloride apparently had been evolved. The reaction mixture was poured into ice and acidified with hydrochloric acid. After the heavy black layer had completely disappeared, the fluorescent brown top layer was separated, washed with water, and steam distilled. The distillate, consisting chiefly of unreacted benzene, was dried and fractionated. Besides benzene, some ethylbenzene was obtained in the fraction, boiling at 130–135°C. In no case was a styrene fraction (140–145°C) obtained. The residue from the steam distillation was a viscous, fluorescent greenish oil. Water was removed first at a pressure of 50 mmHg, after which unsymmetrical diphenylethane distilled at 130–140°C at 12 mmHg. The latter was a nearly colorless oil but possessed a strong violet fluorescence. On redistillation, most of the fraction boiled at 134–130°C (12 mmHg). Above 140°C the pressure was reduced to 0.5 mmHg, and traces of 9,10-dimethyldihydro-anthracene was sublimed at 180–200°C. The residue was poured into a beaker and solidified on cooling to a dark green resin having a reddish fluorescence when in solution. Occasionally, the residue from the steam distillation crystallized on standing. In this event, the solid was filtered and crystallized from alcohol. It was identified as 9,10-dimethyldihydro-anthracene and possessed the following characteristics: yellow platelets, melting at 179–181°C, and purplish fluorescence in solution.



Reference 3.

To a 1-L three-necked flask equipped with condenser, thermometer, and gas inlet tube were added 200 g benzene and 50 g $AlCl_3$. The acetylene, after being purified by passing through a solution of chromic acid, was washed and stored in gasometers from which it was led at a nearly constant rate (20 L/h) through a drying bottle to the three-necked flask. This flask was provided with an efficient return condenser through which the unabsorbed gas was discharged to a large bottle, where its volume was measured approximately. No gas escape if the pressure was 150 mmHg above atmospheric pressure. Provision was made for heating or cooling the reaction flask, and the mixture was shaken frequently during the course of the reaction. After passing 30–45 L acetylene through the reaction mixture, a reddish brown material was obtained that was hydrolyzed and distilled with steam to give two volatile fractions and a black tarry residue. The first fraction was unreacted benzene. A small portion of a material, b.p. 140–145°C, was also obtained. This gave evidence of the presence of styrene, which, however, was not present in sufficient quantity to be isolated. The second fraction, which came over slowly (in 4–6 h), when dried, boiled at 280–290°C and was identified as 1,1-diphenylethane, b.p. 286°C, by oxidation to benzophenone and the formation of benzophenone oxime, m.p. 140°C. The other fraction, which distilled above 360°C, solidified and, after several recrystallizations from alcohol, yielded long brown needles, m.p. 181°C. It was, therefore, identified as the 9,l0-dimethyl-anthracene hydride of Anschutz.

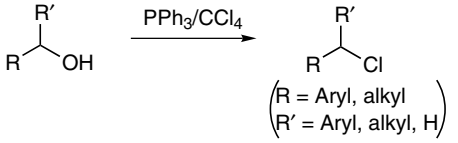
Appel Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported in 1966 by Lee et al.,[1] after the initial work of Horner et al. for the halogenation of alcohol using triarylphosphine dihalides in 1959.[2] In this reaction, primary and secondary alcohols are transformed into corresponding chlorides with a remarkable tendency of inversion of the configuration when the alcohols react with triphenylphosphine and carbon tetrachloride. This reaction has been extensively reviewed by Appel[3] and is generally known as the Appel reaction.[4] Likewise, the mixture of triphenylphosphine and carbon tetrachloride is referred to as the Appel reagent[5] and Appel agent.[6]

B. GENERAL REACTION SCHEME

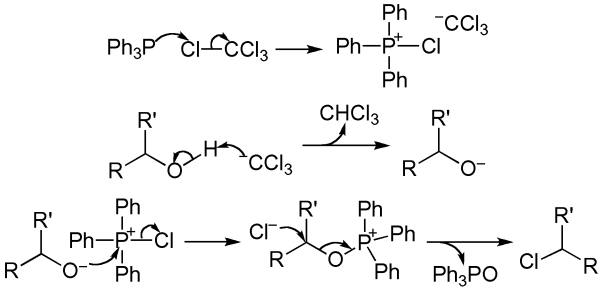


C. PROPOSED MECHANISMS

It is believed that this reaction involves the initial halophilic substitution between triphenylphosphine and carbon tetrachloride (i.e., triphenyl phosphine attacks the chlorine atom in carbon tetrachloride instead of the carbon atom in a traditional S_N2 substitution) and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

subsequent proton abstraction of alcohol from trichloromethyl anion, the attack of alkoxide on phosphonium chloride, and final S_N2 substitution from chloride, as shown. It is reported that chloride and four valent phosphine species form a tight ion pair that does not react with externally added nucleophiles (e.g., CN^-).[5]



D. MODIFICATION

The pair of both hexachloroacetone/triphenylphosphine[7] and dichloroselenurane/triphenylphosphine[4] are also applied to the chlorination of alcohol, and the first pair has been extensively studied in the chlorination of allyl alcohol.

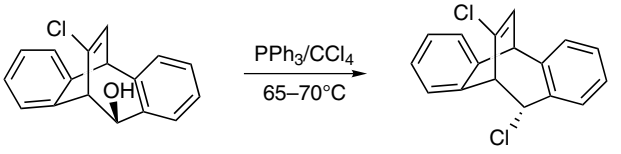
E. APPLICATIONS

This reaction has general applications for the preparation of alkyl chlorides.

F. RELATED REACTIONS

N/A

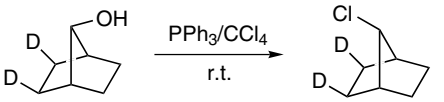
G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

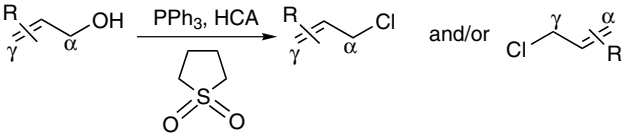
To a reaction flask, were added 1.08 g 6-chloro-2,3:8,9-dibenzobicyclo[3.2.2]nona-2,6,8-trien-*exo*-4-ol (4.0 mmol), 7.0 mL carbon tetrachloride, and 1.06 g triphenylphosphine (4.0 mmol). The solution was heated at 65–70°C for 36 h, and the reaction mixture was cooled and filtered. The yellow solution was chromatographed over a silica gel column with

hexane. The solution was evaporated, and solid was crystallized from 95% ethanol to give 0.80 g of a white crystalline solid, in a yield of 70%, m.p. 113°C.



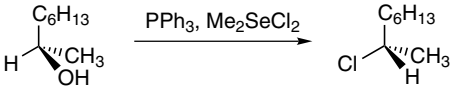
Reference 5.

A solution of 1.14 g *exo*,*exo*-2,31-dideuterio-*anti*-7-hydroxybicyclo[2.2.1] heptane (0.01 mol) and 2.88 g triphenylphosphine (0.011 mol) in 6 mL carbon tetrachloride was stirred in a closed flask for 24 h at room temperature. Solvent was distilled at $\leq$ 35°C (at 30 mmHg) in a dry atmosphere. The residue was heated slowly at 16 mmHg pressure to 175°C. The distillate, collected in a dry ice trap (1.15 g), was sublimed and eluted on a 1.5-g Florisil column first with pentane and then with methanol. Pentane was carefully distilled, and the residue obtained was sublimed at 55–70°C to give *exo*,*exo*-2,3-dideuterio-*syn*-7-chlorobicyclo[2.2.1] heptane, m.p. 43–45°C. (*Note*: After the solvent is removed, the residue can be directly purified via column chromatography.)



Reference 7a.

In a 100-mL, round-bottomed flask equipped with a magnetic stirrer were placed ~0.03 mol of the alcohol and (usually) a slight excess of Ph_3P in 10–15 mL of sulfolane. To the cooled (10°C), stirred solution was added hexachloroacetone (HCA) in ~10 mL sulfolane dropwise; after an initial temperature rise and formation of a precipitate, the temperature gradually dropped to ambient as the rest of the HCA solution was added. The reaction mixture was allowed to come to room temperature. Immediate flash distillation at 4–5 mmHg into a dry ice/acetone cooled receiver gave product. In most instances, the material was exclusively the allylic or saturated chloride.



Reference 4j.

The Preparation of Dimethyldichloroselenurane

To a stirred solution of 3.76 g dimethyl selenide (20 mmol) in 20 mL ethyl ether was added dropwise 2.70 g sulfuryl chloride (20 mmol) at 0°C. Stirring was continued for an additional 15 min. The crystals formed during the addition of sulfuryl chloride were filtered off, washed with anhydrous benzene, and dried under reduced pressure to give 5.82 g analytically pure dimethyldichloroselenurane, in a yield of 100%, m.p. 46–49°C.

General Procedure for Chlorination of Chiral Alcohols

In a 10-mL flask, 1.0 mmol alcohol and 1.0 mmol triphenylphosphine were dissolved in 3 mL of the appropriate solvent (benzene). To this solution was added 1.0 mmol dimethyldichloroselenurane in small portions over a few minutes. When the addition of the dimethyldichloroselenurane was completed, the solvent was removed under reduced pressure, and 10–15 mL of hexane was added to the residue. The precipitated triphenylphosphine oxide was filtered off. To remove the remaining traces, the hexane solution was passed through a short silica gel column. Removal of the solvent gave virtually pure chloride.

Other references using triphenylphosphine and carbon tetrachloride to produce chlorides are cited in literature.[9]

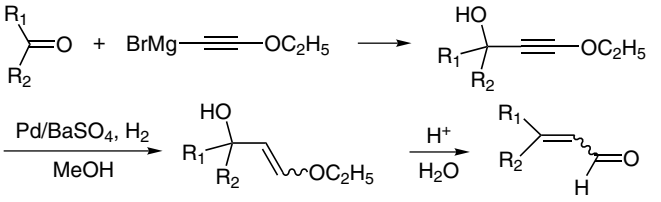
Arens-van Dorp Reaction
(Isler Modification)

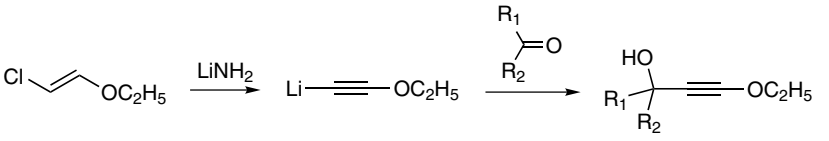
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Arens et al. in 1947.[1] It is the synthesis of α,β-unsaturated aldehyde from the reaction of ethoxyethynemagnesium bromide and ketone or aldehyde and is known as the Arens and van Dorp reaction.[2] Because the preparation of ethoxyacetylene is tedious, this reaction has been modified to generate lithium ethoxyacetylene by treatment of β-chlorovinyl ether with lithium amide, which then reacts with a ketone or aldehyde to form α,β-unsaturated aldehyde.[3] This new protocol is referred to as the Isler modification.

B. GENERAL REACTION SCHEME



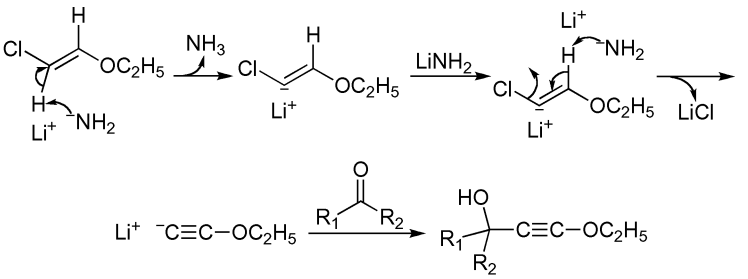
Isler modification



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism of the Arens-van Dorp reaction is clearly illustrated in the original reaction scheme; therefore, it is not necessary to repeat the mechanism here. The mechanism of the Isler modification is shown here.



D. MODIFICATION

In the presence of a chiral catalyst (BINOL), substituted acetylene and diethyl zinc can react with aldehyde to give chiral alkynyl alcohols of up to 99% e.e.[4]

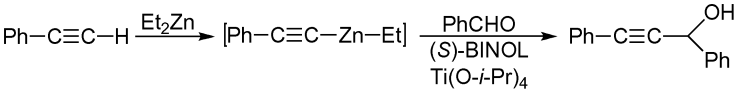
E. APPLICATIONS

N/A

F. RELATED REACTIONS

This reaction is related to the *Favorskii-Babayan Synthesis* and *Nef Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a 25-mL flask were added 1 mL toluene, 226 μL phenylacetylene (2.0 mmol), and 210 μL diethylzinc (2.0 mmol), and the mixture was refluxed for 1 h under nitrogen. After the solution was cooled to room temperature, 57.2 mg (*S*)-BINOL (>99% e.e., 0.2 mmol), 8 mL diethyl ether, and 150 μL $Ti(OiPr)_4$ (0.5 mmol) were added sequentially. The solution was stirred for 1 h more, and 0.5 mmol 4-methylbenzaldehyde was added. After 4 h, the reaction was quenched with saturated ammonium chloride. The resulting mixture was extracted with methylene chloride and concentrated under vacuum. Pure propargylic alcohol was obtained via short silica gel column chromatography, in a yield of 93% and 97% e.e.

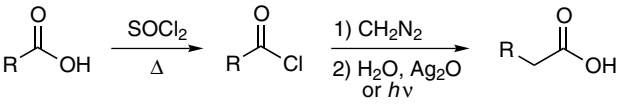
Arndt-Eistert Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Arndt and Eistert in 1935.[1] It is the extension of carboxylic acid by one CH_2 unit via the reaction of acyl chloride with diazomethane and is generally known as the Arndt-Eistert synthesis.[2] In addition, this reaction is also occasionally referred to as the Arndt-Eistert acid synthesis,[3] Arndt-Eistert homologation,[4] and Arndt-Eistert reaction.[5] This reaction has been extensively reviewed.[2x,6] Other reagents instead of diazomethane have been similarly applied to extend the length of the carboxylic acids.[7]

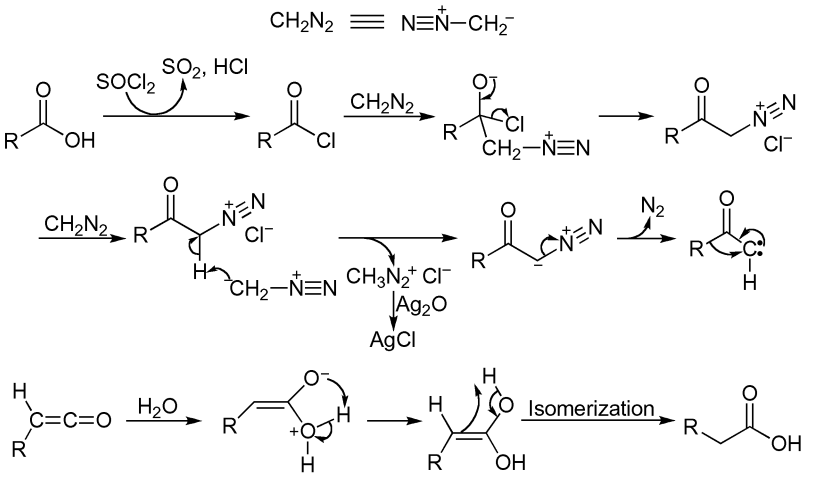
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism for the Arndt-Eistert synthesis is provided here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified using other reagents than diazomethane to elongate the carboxylic acid chain.[7]

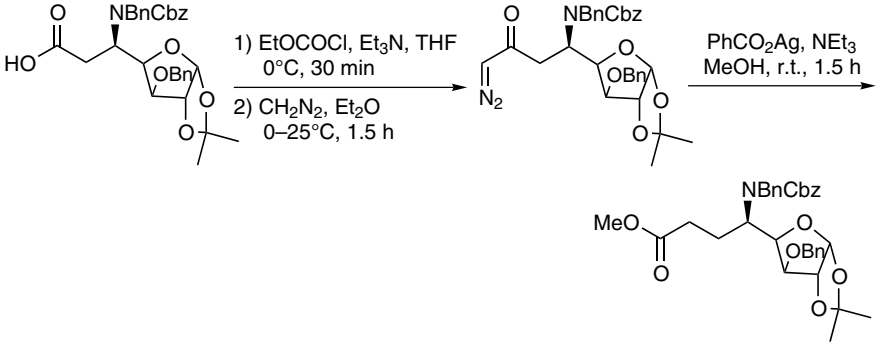
E. APPLICATIONS

This method has been used to synthesize unsaturated diazoketone[8] and amino acids.[9] Other early applications of such reactions to prepare carboxylic acids are cited in Ref. 10.

F. RELATED REACTIONS

This reaction is similar to the *Wolff Rearrangement* and *Nierenstein Reaction*.

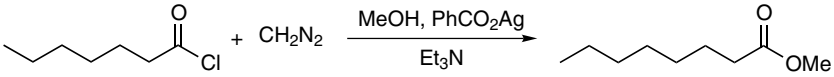
G. CITED EXPERIMENTAL EXAMPLES



Reference 11.

A solution of 0.80 g ethyl 3-*O*-benzyl-5-(*N*-benzyl-*N*-benzoxycarbonylamino)-5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*gluco*-hepto-furan-uronic acid (1.42 mmol) in 10 mL THF was cooled to 0°C under dry nitrogen, then 0.16 g triethylamine (1.57 mmol) and 0.17 mL ethylchloroformate (1.57 mmol) were added one after another. After 15 min, the suspension was allowed to warm to 25°C and filtered through celite. To the filtrate was added a freshly prepared solution of diazomethane in diethyl ether [(prepared from *N*-nitrosomethyl urea (1.02 g, 7.12 mmol) and 2 g KOH] dropwise over a period of 30 min. The mixture was stirred for 1.5 h, during which the reaction slowly come to room temperature. The solvent was evaporated under reduced pressure, and the residue was purified by column chromatography using petroleum ether/EtOAc (9:1) as an eluent to give 0.52 g 5,6,8-trideoxy-1,2-*O*-isopropylidene-3-*O*-benzyl-5-(*N*-benzyl-*N*-benzoxy carbonyl amino)-8-diazo-α-D-*gluco*-octo-1,4-furan-7-ulose as a thick liquid, in yield of 62%. R_f = 0.35 (*n*-hexane/EtOAc = 7:3); $[R]_D = -12.2^\circ$ (*c*4.0, $CHCl_3$).

To a solution of 0.5 g 5,6,8-trideoxy-1,2-*O*-isopropylidene-3-*O*-benzyl-5-(*N*-benzyl-*N*-benzoxy carbonyl amino)-8-diazo-α-D-*gluco*-octo-1,4-furan-7-ulose (0.85 mmol) in 12 mL anhydrous MeOH was added dropwise a solution of 0.06 g silver benzoate (0.27 mmol) in 1 mL triethylamine under dry nitrogen. The mixture was stirred at 25°C for 1.5 h. The solvent was evaporated, and the residue was purified by column chromatography using petroleum ether/EtOAc (95:5) to give 0.42 g methyl 3-*O*-benzyl-5-(*N*-benzyl-*N*-benzoxycarbonyl-amino)-5,6,7-trideoxy-1,2-*O*-isopropylidene-α-D-*gluco*-octo-1,4-furanuronate as a thick liquid, in a yield of 83%. R_f = 0.46 (*n*-hexane/EtOAc = 7:3); $[R]_D = -50.87^\circ$ (*c*3.0, $CHCl_3$).



Reference 25.

To a 1000-mL three-necked, round-bottomed flask equipped with a condenser, mechanical stirrer, and a dropping funnel were added 0.15 mol diazomethane in 150 mL dry ether, and the solution was cooled to −10°C. To this solution was added 8 g 7-octynoyl chloride (0.05 mol) in 50 mL dry ether. After stirring for 1 h, the solvent and excess of diazomethane were removed under reduced pressure at room temperature. The yellow oily residue did not solidify on cooling in attempted crystallization. It was, therefore, dissolved in 70 mL methanol and placed in a 500-mL three-necked, round-bottomed flask fitted with a mercury-sealed mechanical stirrer, a dropping-funnel, and a condenser connected to an azotometer. A solution of 1 g dry silver benzoate (prepared by mixing equivalent portions of silver nitrate and sodium benzoate) in 9 g triethylamine was then added dropwise over a period of 90 min. The reaction mixture turned black, and the evolution of nitrogen commenced immediately. A total of 93% of the theoretical amount of gas was collected. The reaction mixture was then refluxed for 5 min and filtered. Most of the alcohol was removed under a vacuum; the residue was dissolved in ether and washed successively with hydrochloric acid, sodium hydroxide, and water. After drying over magnesium sulfate, distillation yielded 13 g (80%) of product, b.p. 97–100°C at 8 mmHg.

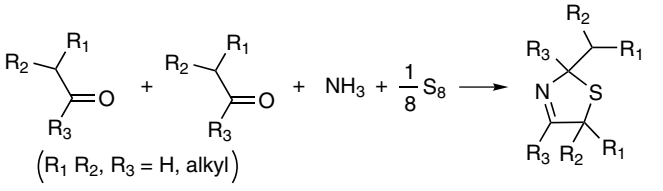
Asinger Reaction

(Asinger Multicomponent Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Friedrich Asinger in 1956.[1] It is a multicomponent reaction for preparing 3-thiazolines from ketones, ammonia, and sulfur[2] and is generally known as the Asinger reaction.[3] This reaction was subsequently extended to the synthesis of *m*-thiazines.[4] The Asinger reaction, together with other multicomponent reactions (MCRs)—such as the *Ugi Reaction*, *Biginelli Reaction*, *Passerini Reaction*, and *Hantzsch Dihydropyrimidine Synthesis*—have attracted more attention recently and have been commonly applied to the process of drug and agrochemicals discovery, because these reactions are highly atom economic and can efficiently produce a variety of molecular libraries of small molecular weight and structural diversity.[5] So far, more than 20 molecular scaffolds have been prepared from these MCRs.[5]

B. GENERAL REACTION SCHEME

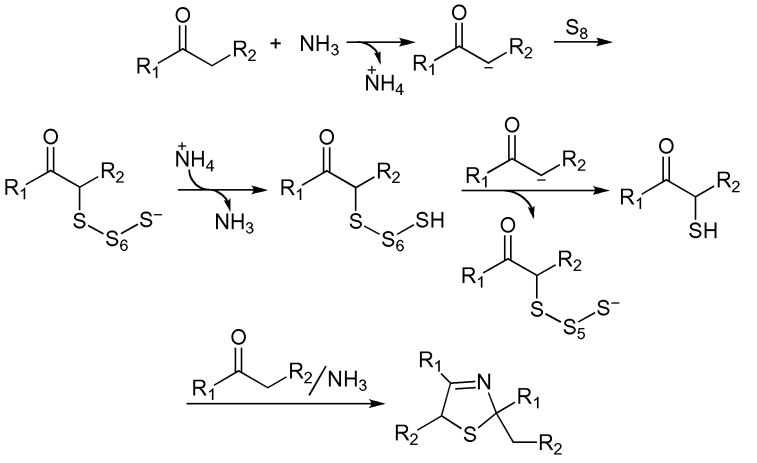


C. PROPOSED MECHANISMS

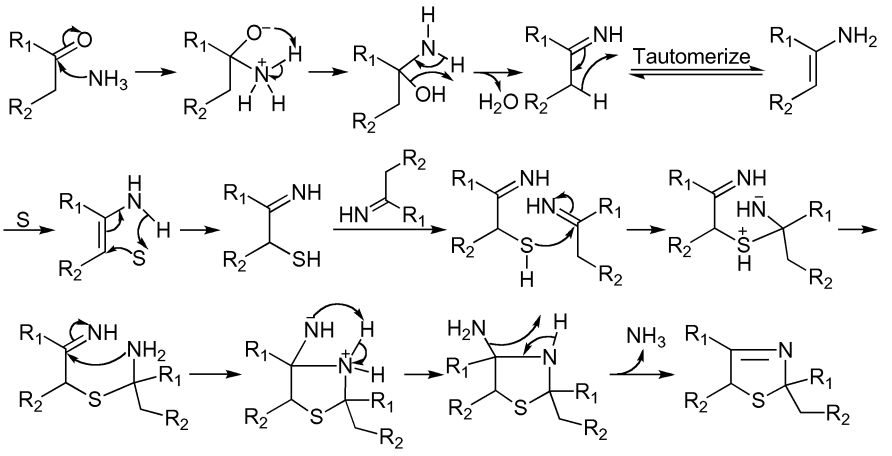
As proposed by Asinger, this reaction contains two steps. The first step is an α-thiolation catalyzed by amine to form α-surfhydryl ketone, and the second step is an α-aminoalkylation

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

of an SH acid and subsequent stabilization via ring closure with elimination of water (similar to the *Mannich Condensation*). The details are illustrated here.[6]



At least two weaknesses exist in this mechanism: (a) NH_3 is not strong enough to abstract an α-proton from ketone and (b) no detail is given about the formation of final 3-thiazolines. Therefore, an alternative mechanism is proposed here, as shown.



D. MODIFICATION

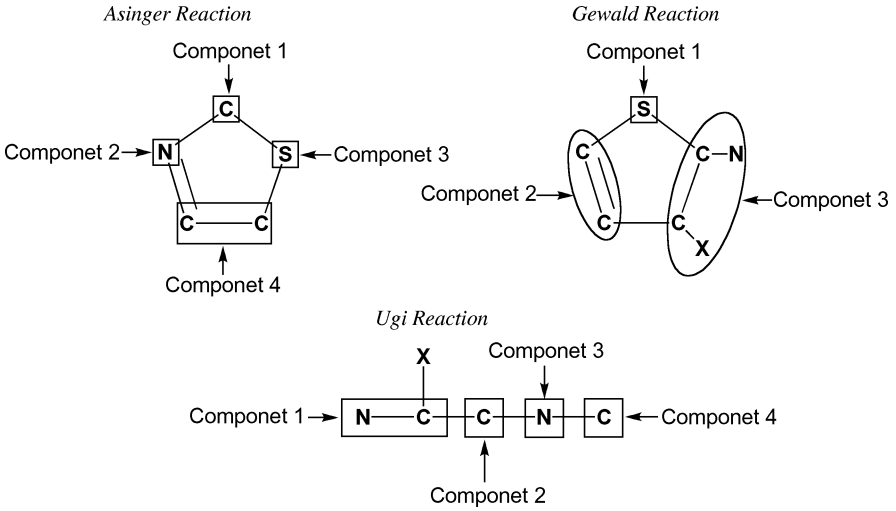
N/A

E. APPLICATIONS

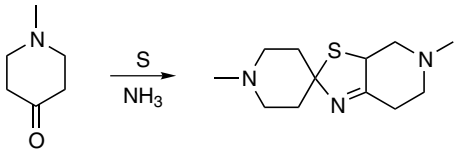
This reaction is useful in the preparation of 3-thiazoline derivatives.

F. RELATED REACTIONS

Being an MCR, the Asinger reaction shares similarities with other MCRs (e.g., Ugi, Gewald) in that more than one bond is formed in the final product. These reactions are shown here.[5]



G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a three-necked flask equipped with gas inlet and outlet were added a stir bar, 6.0 g sulfur, and 40.0 g 1-methyl-4-piperidone. The flask was cooled with ice, and under stirring ammonia gas was bubbled into the mixture. The temperature of the reaction was maintained between 40 and 50°C. The introduction of ammonia was continued until the last traces of sulfur disappeared (usually 2 h). The excess ammonia was removed by connecting the gas outlet to vacuum while stirring. The warm, viscous liquid was diluted with 200 mL 50% potassium carbonate solution, and the mixture was extracted with five 100-mL portions of ether. The ether solution was dried over potassium carbonate, filtered, and treated with hydrogen chloride. A yellow precipitate of 1,6′-dimethyl-2′,4′,5′,6′,7′,7a′-hexahydrospiro[piperidine-4,2′-thiazolo[5,4-c]-pyridine]dihydrochloride formed immediately, which was filtered, washed with ether, and dried under reduced pressue over $CaCl_2$ to afford 53.5 g of product, m.p. 200–205°C. An analytical sample was prepared by

recrystallization of this solid from a mixture of ethanol and isopropyl alcohol and melted at 240–241°C. The pure 1,6′-dimethyl- 2′,4′,5′,6′,7′,7a′-hexahydrospiro-[piperidine-4,2′-thiazolo[5,4-c]pyridine] was formed in quantitative yield from its dihydrochloride salt by neutralization with potassium carbonate solution. The base thus formed was purified by distillation under reduced pressure, and the fraction, b.p. 198–202°C at 16 mmHg was collected.

Other references related to the Asinger reaction are cited in the literature.[8]

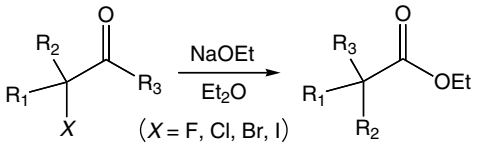
26

Aston-Greenburg Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

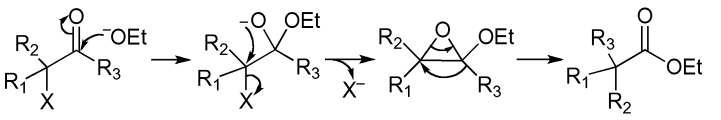
This reaction was first reported by Aston and Greenburg in 1940.[1] It is the transformation of α-haloketone into ester along with the migration of one of the alkyl (or aryl) moieties in this ketone to the α-position of another moiety when the α-haloketone is treated with alkali alkoxide (e.g., NaOEt, NaOMe). In many cases, this rearrangement is used to prepare the esters of tertiary α-carbon.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves the following steps: the addition of an alkoxyl group to the carbonyl group, the formation of epoxide, and the migration of the alkyl group, as illustrated below.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

N/A

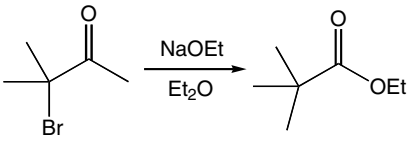
E. APPLICATIONS

N/A

F. RELATED REACTIONS

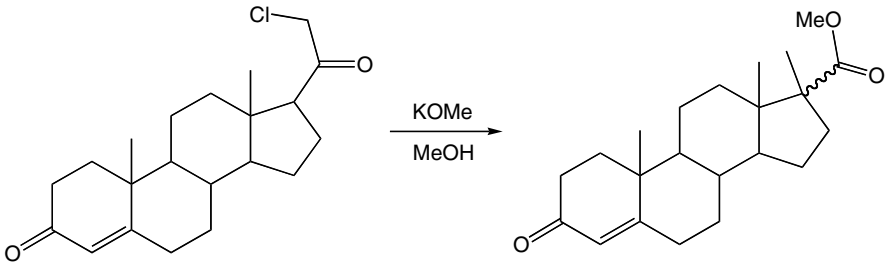
This reaction has a similar mechanism to the *Favorskii Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a flask equipped with condenser were added 500 mL ether, 29.2 mL absolute ethanol (0.5 mol), and 11.5 g sodium (0.5 mol). This mixture was refluxed for 48 h to ensure the completion of reaction and then cooled in ice. After that, 82.5 g 3-bromo-3-methyl-2-butanone (0.5 mol) was added over a period of 2 h. The solution was refluxed 3 h, then water was added to dissolve the precipitated sodium bromide. The organic layer was separated and fractionated via distillation, and 39.8 g ethyl trimethylacetate was obtained, in a yield of 61.3%, b.p.116°C at 725 mmHg, n_D^{20} 1.3912, d_4^{20} 0.856g/cm^3.



Reference 2.

To a flask equipped with condenser, were added 220 mL absolute methanol and 2.1 g potassium. After the potassium disappeared, 9.615 g chloroprogesterone was added to the solution in portions. The mixture was refluxed for 2 h with exclusion of moisture. After cooling, the solution was poured into water, and the product was extracted with ether. The organic layers were combined and washed until neutral, and 9.687 g oil was

obtained after removal of the solvent. This mixture was purified using 250 g aluminum oxide with petroleum ether-benzene (4:1 to 1:1) as an eluent. This fraction after drying and recrystallization from acetone-hexane gave 2.945 g methyl Δ^4-3-keto-17α-methyletienate, m.p. 173–173.5°C. Another fraction from the column using benzene and benzene-ether as an eluent yielded 378 mg methyl Δ^4-3-keto-17-isoetienate after removal of the solvent and recrystallization, m.p. 155.5–156°C. The rest of the mass was a mixture of the two products.

Other references related to the Aston-Greenburg rearrangement are cited in the literature.[3]

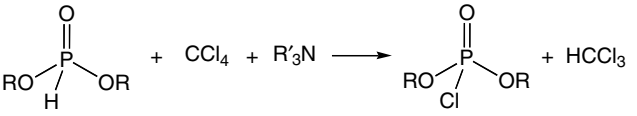
Atherton-Todd Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Atherton and Todd et al. in 1945.[1] It is a transformation of dialkylphosphite into dialkyl chlorophosphate in the presence of carbon tetrachloride and a base (usually tertiary amine, secondary amine, or primary amine). Therefore, it is generally known as the Atherton-Todd reaction.[2] In general, the formed dialkyl chlorophosphate is too reactive to be isolated, which further reacts with alcohol or amine to give phosphate or phosphoramidate. Only a few dialkyl chlorophosphates have been separated so far.[3]

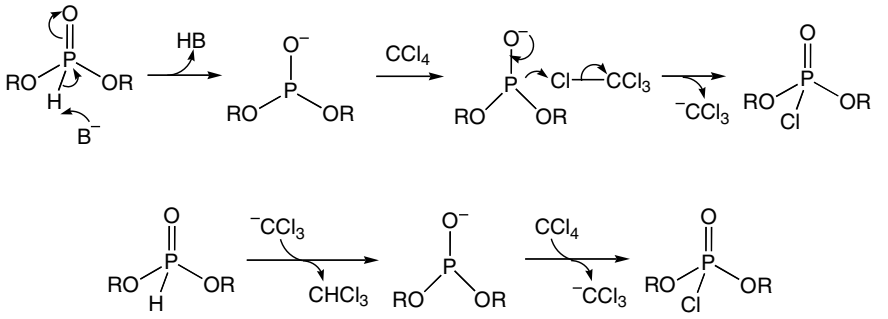
B. GENERAL REACTION SCHEME



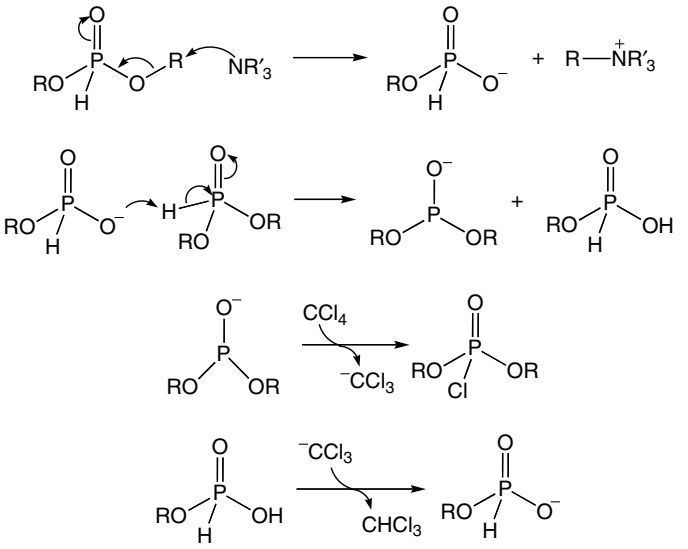
C. PROPOSED MECHANISMS

The commonly known mechanism for the Atherton-Todd reaction is based primarily on the early kinetic investigations.[4] It is believed that the initial step is the deportonation of the dialkyl phosphonate $(RO)_2P(O)H$ by a base to give a dialkyl phosphite anion that undergoes the halophilic substitution with CCl_4, as illustrated here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



However, it has been established that, in the initial step, amines as a base are actually alkylated and not protonated at the nitrogen by dialkyl phosphonates.[5] Therefore, an alternative mechanism is proposed in agreement with both experimental and computational results.[21]



D. MODIFICATION

It is reported that the original process can be improved effectively by employing an aqueous base and a phase-transfer catalyst.[6] After this modification, many mixed trialkyl phosphates, dialkylphosphorylated amines, hydrazines, and hydroxylamines can be easily prepared.

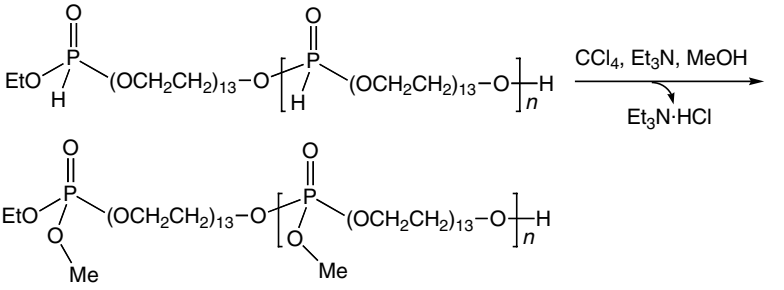
E. APPLICATIONS

This reaction has general applications in the preparation of trialkyl phosphates, dialkylphosphorylated amines hydrazines, and hydroxylamines.

F. RELATED REACTIONS

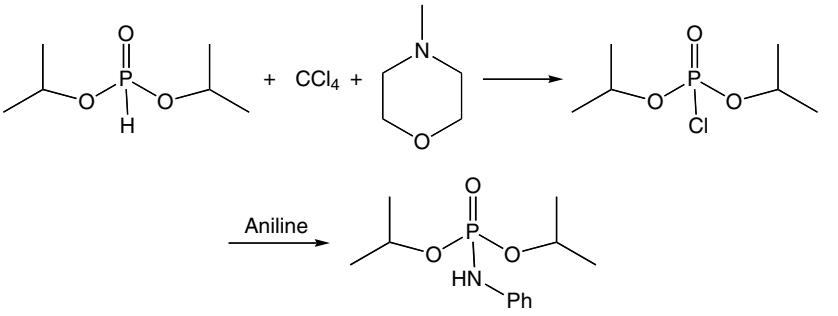
This reaction is related to the *Appel Chlorination*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a three-necked flask equipped with a magnetic stirrer, thermometer, reflux condenser, and a dropping funnel were added 9 mL dichloromethane, 22.5 mL carbon tetrachloride, 0.94 g triethylamine, and 0.72 mL methanol. Then 13.5 mL dichloromethane solution containing 2.3 g polymer (0.0036 mol of repeating units) was added dropwise at ambient temperature under continuous stirring. The reaction was allowed to proceed for 24 h. After filtration of the precipitated triethylamine hydrochloride, the filtrate was concentrated and the polymer product was precipitated by addition of diethyl ether. The product of poly(oxyethylene phosphate) was purified by dissolution in *N,N*-dimethylformamide (DMF) and reprecipitation in diethyl ether. The isolated product was dried at 30–40°C under reduced pressure (1 mmHg) to give 2.6 g of a polymer product, in a yield of 100%.



Reference 1.

To a 500 mL flask, were added 150 mL carbon tetrachloride and 83.0 g diisopropyl phosphite (0.5 mol). To this solution was added 50.5 g *N*-methylmorpholine (0.5 mol), no apparent reaction occurred until refluxing. After 3 h the solvent was removed in vaccum (distillate contained chloroform); the residue was stirred with 200 mL light petroleum; and

28.0 g of *N*-methylmorpholine hydrochloride (solid material) was obtained by filtration, washing with light petroleum, and drying. The ligroin solution was evaporated on a water bath, and the residue was distilled under reduced pressure. The main fraction (70.0 g) contained traces of solid and on filtration and redistillation afforded 58.0 g of colorless diisopropyl chlorophosphonate. When diisopropyl chlorophosphonate was treated with two equivalents of aniline, both aniline hydrochloride and diisopropylanilinophosphonate were obtained. The latter one has a m.p. of 121°C.

Auwers-Skita Rule
(Conformational Rule)

A. GENERAL DESCRIPTION OF THE REACTION

Auwers-Skita rule,[1] also called conformational rule, is an empirical rule related to the physical properties of geometrical isomers and their configurations. This rule was initially proposed by von Auwers,[2] and Skita[3] separately and was restated by Allinger.[4] This rule was extensively applied during the assignment of the structures of isomers before the NMR techniques were commonly available. This rule, applying to alicyclic epimers not differing in dipole moment, states that the isomer of smaller molecular volume and therefore higher physical constants (e.g., density, index of refraction, and boiling point) has the higher heat content (enthalpy),[4e,5] however, molecules of higher enthalpy have a lower melting point.[6] Between the pair of *cis*- and *trans*- isomers, *cis*-compounds are higher in specific gravity and refractive index but smaller in molecular refraction.[2,3] Between stereoisomers, the *trans*-form of a pair of stereoisomers has the lower density, boiling point, and refractive index.[7] This rule can even be used to assign the conformers, in which the conformer of higher enthalpy has a lower molecular volume.[8] In cyclic stereoisomers, when the substituents are bound to configurationally identical ring systems, the isomer with the higher density and the higher refractive index is that which has the higher heat content.[9] Usually, the (higher) boiling point and (lower) molar refraction can be related in a similar manner. In other words, isomers having the greater number of axial substituents within a series will have the higher boiling point and refractive index and the greater density.[10] Although this rule has been proved successful with a variety of disubstituted cyclohexanes,[11] it is recognized that such an empirical rule is of limited reliability, especially in complex systems, such as the configuration for isopinocampheol,[12] 3-methylcyclohexanol,[13] thiabicyclo[3.3.0]-octanes,[14] and other 1,3-disubstituted cyclohexenes.[15]

E. APPLICATIONS

This rule was extensively used to assign the structures between stereoisomers before the era of NMR.

F. RELATED REACTIONS

The van Arkel Rule (i.e., dipole rule) describes the relationship between physical properties and the dipole moment of geometrically isomeric olefins, i.e., the isomer of higher dipole moment has the higher boiling point, refractive index, and density.[4e,16]

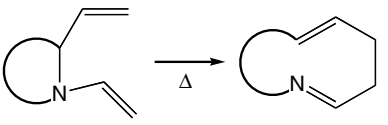
Aza-Claisen Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

Similar to normal *Claisen Rearrangement*, the *aza*-Claisen rearrangement[1] involves the cleavage of one bond and the formation of a new bond; however, in this reaction, one allyl carbon atom is displaced by a nitrogen atom and the carbon-nitrogen bond is the bond to break. In general, the nitrogen atom in *aza*-Claisen rearrangement is either in a heterocycle or a quaternary amine (ammonium salt), and the extension of heterocycle ring or cleavage of ammonium salt is probably the driving force for this reaction. Although one of the earliest examples of the *aza*-Claisen rearrangement—the reaction between *N*-methylpyrrole and dimethyl acetylenedicarboxylate (DMAD)—was reported by Alder in 1931,[2] this reaction is currently receiving renewed attention.[3–14]

B. GENERAL REACTION SCHEME

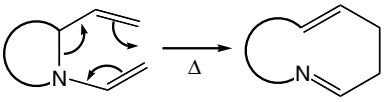
This reaction is represented by a general nitrogen-containing heterocycle, as illustrated here.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This rearrangement will be similar to a regular [3,3]-sigmatropic rearrangement.



D. MODIFICATION

N/A

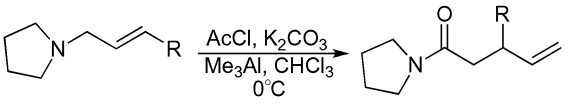
E. APPLICATIONS

This reaction has been used to prepare a variety types of nitrogen-containing compounds.[3−14]

F. RELATED REACTIONS

Conceptually, this rearrangement is related to the *Bellus-Claisen Rearrangement*, in terms of ring expansion.[8b,14g,14i] This reaction is also related to the regular *Claisen Rearrangement* and *Cope Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES

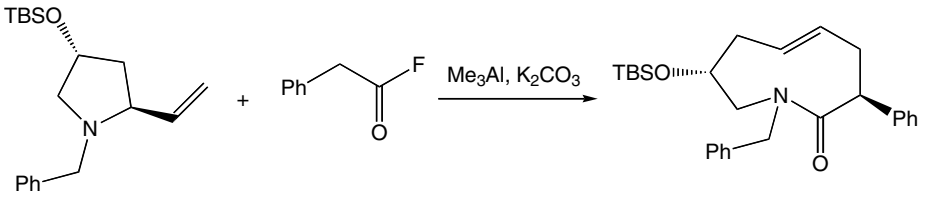


Reference 1ff.

Standard Procedure for the Zwitterionic *aza*-Claisen Rearrangement

To 35 mL dry $CHCl_3$ was added 1.6 g dry K_2CO_3 (11.6 mmol) under argon. The suspension was cooled to 0°C. *N*-allylpyrrolidine (5 mmol) and 6 mmol of acetyl chloride were added subsequently by means of a syringe. After about 30 min of stirring at 0°C, 0.25 mL 2 M Me_3Al in toluene (0.50 mmol) was added via syringe. The resulting mixture was also stirred at 0°C. After 24 h, a second volume of Me_3Al was injected. After 2–3 days, the reaction was stopped by quenching dropwise with saturated aqueous $NaHCO_3$ (5–10 mL) at 0°C until the Al_2O_3/K_2CO_3 precipitated. Then the organic layer was decanted, the solid residue was extracted with CH_2Cl_2 (5 × 20 mL), and the combined organic layers were dried over $MgSO_4$. The solvent was removed, and the crude mixture of diastereomeric amides and von Braun type products was purified by column chromatography. If necessary,

diastereomers were separated via HPLC or column chromatography on silica gel. If the crude product contained more than 10% of allylic amine (occurred in the majority of the experiments), the mixture was subjected to these reaction conditions for a second cycle.



Reference 4a.

To a small flask were added 70 mg dry K_2CO_3(0.5 mmol) and 15 mL CH_2Cl_2 under argon. The mixture was cooled to 0°C, then 320 mg of *N*-allylpyrrolidine (1 mmol) and 3–6 mmol of acid fluoride were added subsequently via a syringe. After about 15 min of stirring at 0°C, 0.75–1.5 mL Me_3Al in *n*-heptane (1.5–3 mmol) was added via syringe, and CH_4 evolved. The mixture was allowed to warm to room temperature, and the reaction was completed within hours (groups other than phenyl may take up to 2 days). In some cases, the addition of a second amount of acid fluoride and Me_3Al was necessary to achieve a complete conversion of the reactant. After the reaction, the mixture was diluted with Et_2O and filtrated through a short silica gel column to remove the polar impurities. The residual organic layer was washed with saturated $NaHCO_3$ solution and dried over $MgSO_4$. When solvent was removed below 20°C, (*p*S)*E*-3*S*,8*R*-1-benzyl-8-(*tert*-butyldimethylsilyloxy)-3-phenyl-2,3,4,7,8,9-hexahydro-1*H*-azonin-2-one was yielded. (*Note*: Heating to 40 – 60°C led to a fast epimerization to give the *p*R-lactams).

Other references related to the *aza*-Claisen rearrangement are cited in the literature.[15]

Baddeley Isomerization

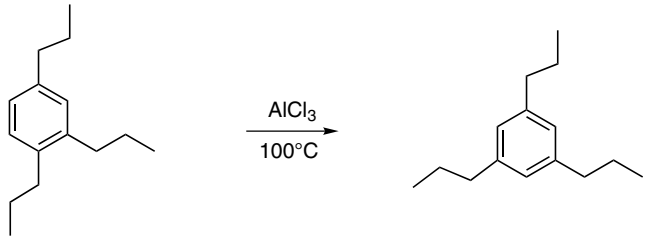
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Baddeley in 1930s.[1] It is the migration of alkyl groups in polyalkylbenzenes or polynuclear aromatic compounds in the presence of anhydrous aluminum chloride or the mixture of protonic acid and Lewis acid. In one of Baddeley's experiments, when 1,3,4-tri-*n*-propylbenzene was warmed with $AlCl_3$ at 100°C, the 1,3,5-tri-*n*-propyl was formed, along with the lower and higher alkylated benzenes.[1b] After extensive studies, it was found that the amount of α-isomer can be reduced by the addition to the reaction mixture of a variety of substances (e.g., nitrobenzene and excess acid chloride) that complex strongly with aluminum chloride.[2,3] Likewise, less α-isomer has been observed when this reaction is carried out in nitrobenzene. In addition, isomerization of hindered aromatic ketones occurs if the ketones are melted with an excess amount of aluminum chloride and sodium chloride.[4]

B. GENERAL REACTION SCHEME

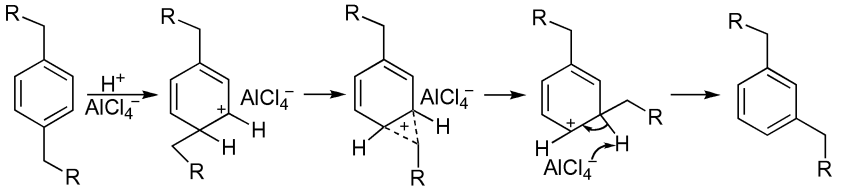
The reaction is simply illustrated by the isomerization of 1,2,4-tri-*n*-propylbenzene to 1,3,5-tri-*n*-propylbenzene in Baddeley's initial work.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



C. PROPOSED MECHANISMS

It is proposed that in the presence of a protonic acid and a Lewis acid, a direct [1,2] alkyl shift is involved in this isomerization, which is displayed here.[5]



However, in the absence of protonic acid, the Baddeley isomerization may involves the reaction of $AlCl_3$ with two aromatic molecules.[6]

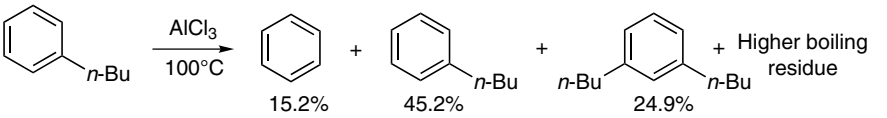
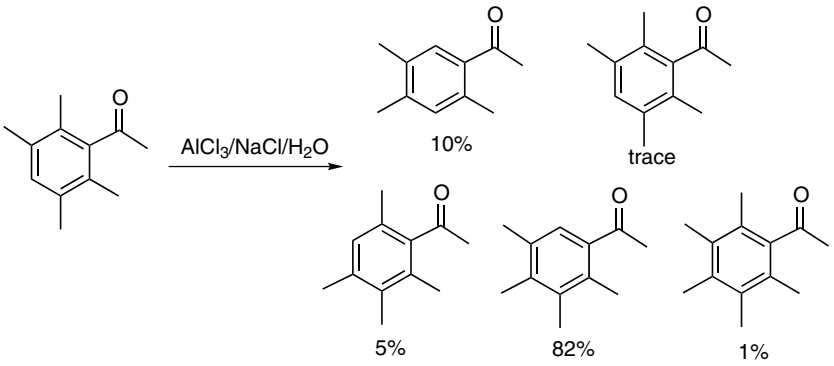
G. CITED EXPERIMENTAL EXAMPLES



Reference 6a.

To a flask equipped with a condenser were added 202.5 g *n*-butylbenzene and 40.0 g anhydrous aluminum chloride (sublimed). The mixture was stirred for 3 h at 100°C to form two layers, the lower being of relatively small volume and dark in color. After the reaction, the mixture was poured over cracked ice; and the organic layer was separated, washed with water, and dried over anhydrous calcium chloride. A total of 192.8 g hydrocarbon was recovered at this step. Careful fractionation of this hydrocarbon gave 15.2% benzene, 45.2% *n*-butylbenzene, b.p. 98.5–97.5°C at 50 mmHg (99.4 mol % *n*-butylbenzene and 0.6 mol % *s*-butylbenzene by mass spectrometer analysis), 27.7% dibutylbenzene, b.p. 160–162°C at 50 mmHg (at least 90 mol % *m*-di-*n*-butylbenzene), and 11.9% of a higher boiling residue.



Reference 7.

To a flask equipped with a refluxing condenser were added 7.5 g 2,3,5,6-tetramethylacetophenone (0.043 mol), 15 g anhydrous $AlCl_3$ (0.11 mol), 90 mg H_2O (0.005 mol), and 1 g NaCl (0.02 mol). The mixture was stirred at 100°C for 2 h. The reaction mixture was cooled, poured onto ice, and neutralized with saturated $NaHCO_3$ solution. The organic material was extracted with a total of 30 mL C_6H_6, washed with H_2O, saturated $NaHCO_3$ solution, and H_2O and dried over Na_2SO_4. Analysis of the mixture by GC (150 ft. MBMS column at 160°C, helium pressure 30 psi) showed the product distribution as 2,4,5-trimethylacetophenone (10%), 2,3,4,6-tetramethylacetophenone (starting material, trace), 2,3,4,6-tetramethylacetophenone (5%), 2,3,4,5-tetramethylacetophenone (82%), and pentamethylacetophenone (1%).

Other references related to the isomerization of polyalkyl aromatic compound in the presence of Lewis acids are cited in the literature.[8]

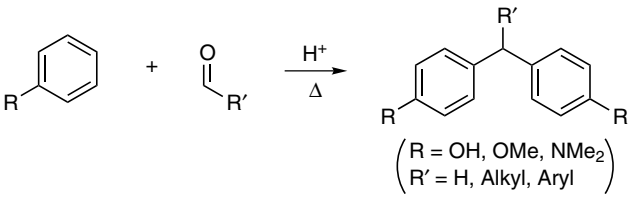
Baeyer Diarylmethane Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially studied by von Baeyer in 1872.[1] It is an acid-catalyzed condensation of aromatic compounds with formaldehyde or formaldehyde derivatives. In normal conditions, the reactive benzene derivatives such as phenols and arylamines are applied to condense with formaldehyde; however, a small number of less-reactive aromatics have also been used in this reaction, including benzene,[2a] toluene,[2b,c] benzyl chloride,[2b,c] biphenyl,[2b,c] iodobenzene,[2d] naphthalene,[2e] and mesitylene.[2f] Although no yields were given in the early studies, it is reasonable to obtain 70–80% yield for this type of reaction. Many other reactions have been developed to synthesize diarylmethanes, including Katritzky's benzotriazole method,[3] Kochi's dealkylative coupling,[4] Fukuzaw's 1,3-propandiol method,[5] and the reduction method.[6] In general, the condensation occurs at the *para*-position of substituted aromatics.

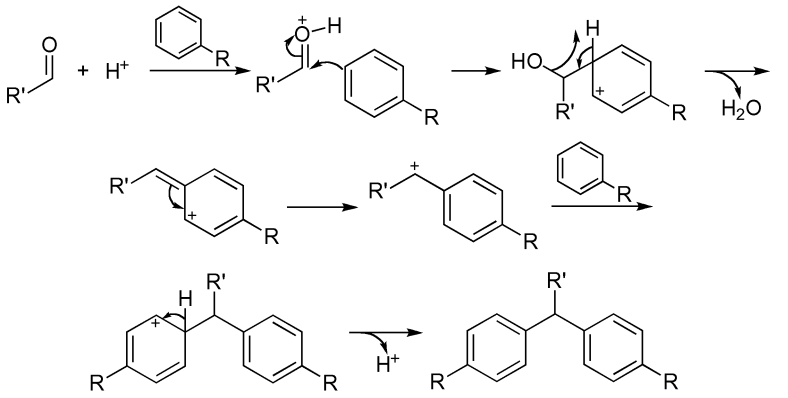
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is similar to that of the *Friedel-Crafts Alkylation*.



D. MODIFICATION

N/A

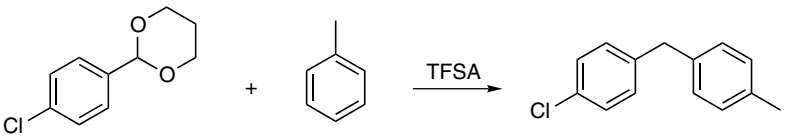
E. APPLICATIONS

This reaction can be applied to prepare diarylmethanes.

F. RELATED REACTIONS

This reaction is related to the *Baekeland-Lederer-Manasse Reaction*, which gives resinous product from the reaction between phenol and formaldehyde. In addition, this reaction is related to *Zinke Synthesis*.

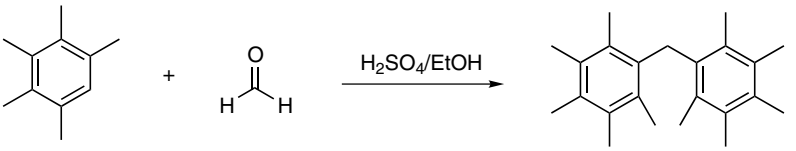
G. CITED EXPERIMENTAL EXAMPLES



Reference 5b.

To a solution of 199 mg 2-(4-chlorophenyl)-1,3-dioxane (1.0 mmol) in 5.0 mL toluene was added 8.0 mg TFSA (0.05 mmol) at room temperature while stirring. The mixture was refluxed for 17 h, then cooled down to room temperature and poured into aqueous $NaHCO_3$.

The organic layer was separated, and the aqueous phase was extracted with diethyl ether. The combined organic extracts were washed with brine and dried over $MgSO_4$. The product distribution was analyzed by GC/MS, using naphthalene as standard and comparing with an authentic sample. The *ortho*/*meta*/*para* ratio was found to be 27:7:56, in a yield of 81% on the basis of dioxane.



Reference 7.

To a 500-mL three-necked flask equipped with a reflux condenser, mechanical stirrer, and thermometer were added 0.67 mol pentamethyl benzene and 0.17 mol paraformaldehyde. The mixture was warmed to 75°C by a water bath. In a separate beaker was placed 170 mL 95% ethanol, and 68 mL 96% sulfuric acid was poured into at the side of the beaker ($EtOH/H_2SO_4$ = 2.5:1). This alcoholic solution was stirred and cooled to 5°C below the desired reaction temperature (75°C), and then poured into the flask. The heterogeneous mixture was stirred vigorously at 75°C for 1 h. When the solution was cooled down to room temperature, it was poured into 250 mL water, and 250–300 mL benzene was added to extract the product. The benzene extract was fractionated by distillation using a 10-in. Vigreux column to afford 86% of product, m.p. 220.6–221.2°C. Other polyalkylbenzenes react at different temperatures, and different solvents were used to extract the corresponding product. Yields were found between 50% and 86%.

Other references for making diarylmethanes can be found in the literature.[8]

Baeyer-Drewson Reaction
(Baeyer-Drewson Indigo Synthesis)

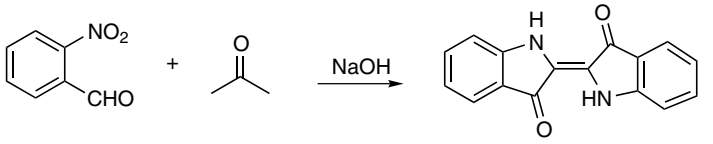
A. GENERAL DESCRIPTION OF THE REACTION

Indigo is one of the oldest and most important coloring agents obtained from the vegetable kingdom. von Baeyer initially developed a protocol to synthesize indigos in the 1880s and 1890s[1] via the condensation of 2-nitrobenzaldehyde with acetone in the presence of dilute NaOH or Na_2CO_3.[2] Therefore, this reaction is known as the Baeyer-Drewson reaction.[3] After the pioneering work of von Baeyer, many other methods have been developed to synthesize indigos, including the acidic hydrolysis of the dimethyl acetal of *o*-amino-phenylglyoxal,[4a] reduction of l-*o*-nitrophenyl-2-nitroethanol by the basic dithionite,[4b] acid or base treatment of 2-anilinoindoxyl,[4c] treatment of 2-oximinoindoxyl with sulfuric acid,[4d] reduction of *o*-nitrobenzoylacetic acid by base and glucose,[4e,f] and reduction of 2-chloroindolone.[4g,h] In addition, the *Heumann Indigo Process* was the industrial manufacturing process applied to making indigo in large quantitles.[5] The original indigo synthesis was developed for testing for *o*-nitrobenzaldehyde in alkaline acetone solution (not applicable to *o*-nitrobenzaldehydes with *meta*- or *para*-hydroxyl groups, otherwise, a second nitro group is needed to form 2,6-dinitroisovanillin.)[3,6] The Baeyer-Drewsen indigo synthesis in combination with the *Lieben Iodoform Reaction* has been developed to differentiate methylcarbinols from methyl ketones. As an example, a positive iodoform reaction and a negative indigo reaction indicate a methylcarbinol; a positive iodoform reaction and a positive indigo reaction indicate a methyl ketone; whereas a negative iodoform reaction can rule out both methylcarbonols and methyl ketones.[7]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

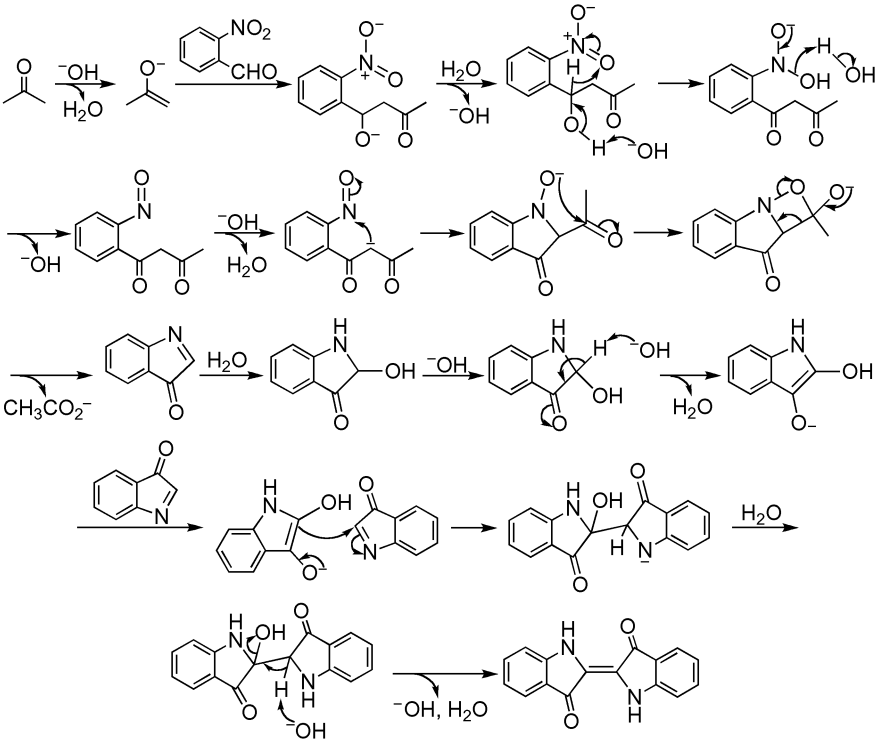
B. GENERAL REACTION SCHEME

Indigo should be the *trans*-isomer, preferentially stabilized by intramolecular hydrogen bonding available only in the *trans*-configuration.[8]



C. PROPOSED MECHANISMS

It is believed that this reaction occurs via the addition of an enolate, followed by the reduction of the nitro group and the final ring closure, as illustrated here.[7]



D. MODIFICATION

N/A

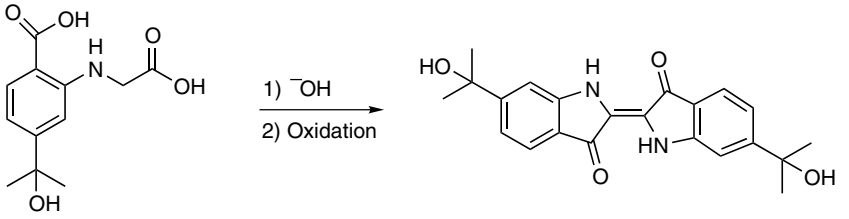
E. APPLICATIONS

This reaction is useful for the preparation of indigo derivatives; in addition, it can be applied for testing the presence of methyl ketones.

F. RELATED REACTIONS

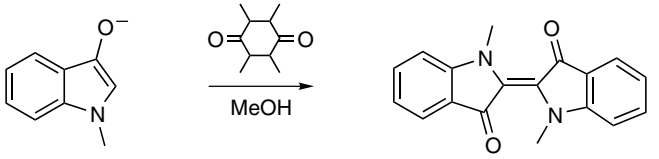
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A mixture of 10.1 g 2-amino-acetic-4-(α-hydroxyisopropyl)-benzoic acid (0.04 mol) and 50.5 g potassium hydroxide (0.90 mol) were fused in a nickel crucible to exclude air. The fusion was conducted initially at 180–200°C and was completed at 220–230°C within 15 min. Then the reddish yellow mass was cooled and dissolved in water. A current of air was led through the solution until a test portion no longer produced a bluish precipitate when air was drawn through. The oxidation product then formed was filtered off, washed successively with water and with very dilute hydrochloric acid, and finally dried to give 2.32 g of the shown product, in a yield of 31.0%. (*Note*: The name of the starting material has been changed from the original paper.)



Reference 10.

N,*N*′-dimethylindigo was prepared by the oxidation of 1 .05 mmol *N*-methylindoxyl acetate in 9 mL methanol by 2.2 mmol duroquinone under nitrogen and in the presence of 8.8 mmol sodium methoxide. After 15 min the mixture was acidified with hydrochloric acid and chromatographed on silica gel with chloroform to give 0.44 mmol pure *N*,*N*′-dimethylindigo, in a yield of 84%. Alternately, this *N*,*N*′-dimethylindigo can also be prepared according to the procedure of Ettinger and Friedlaender by oxidation of *N*-methylindoxyl in aqueous ammonia.[11] Recrystallization from heptanem under nitrogen

yielded 28% of needles, m.p. 180°C. No impurities were found by TLC or mass spectrometric (parent peak m/z 290).

Other references related to the Baeyer-Drewson reaction are cited in the literature.[12]

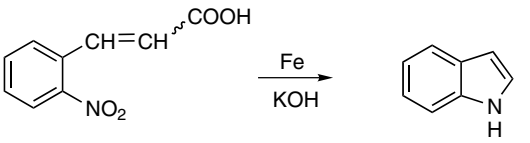
Baeyer Indole Synthesis

(Baeyer-Emmerling Indole Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Baeyer and Emmerling in 1869.[1] It is the synthesis of indole via the alkaline reduction of *o*-nitro-cinnamic acid by iron. Although the *Fischer Indole Synthesis* has been considered as the most versatile approach for the indole derivatives,[2] a few methods similar to Baeyer indole synthesis have also been developed so far.[3]

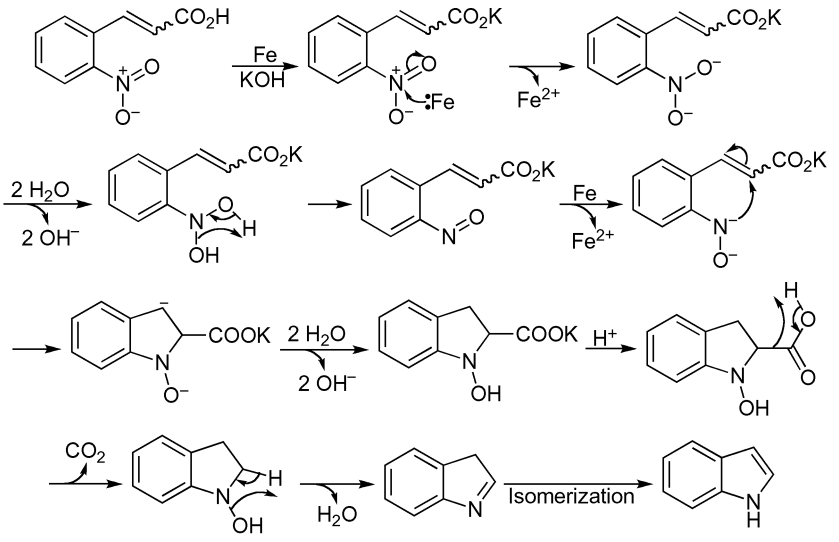
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed here is the mechanism of Baeyer indole synthesis.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

A few modifications have been developed, as described in detail in Cited Experimental Examples.[3]

E. APPLICATIONS

N/A

F. RELATED REACTIONS

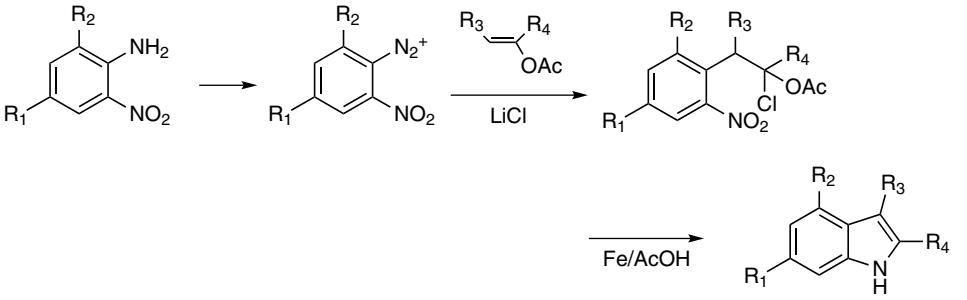
This reaction is related to the *Reissert Indole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES

Reference 3a.

The preparation of chromium-copper-on-charcoal catalyst has been reported elsewhere.[4] It is prepared by adding acid-washed charcoal to a strong hot solution of $Ca(NO_3)_2$, KNO_3, or KH_2PO_4. The amount of salt adsorbed was determined by filtering off the catalyst after a few minutes, evaporating the filtrate to dryness, and weighing the residue. (Interested readers should see Ref. 4 for details because chromium and copper salt were not mentioned here.)

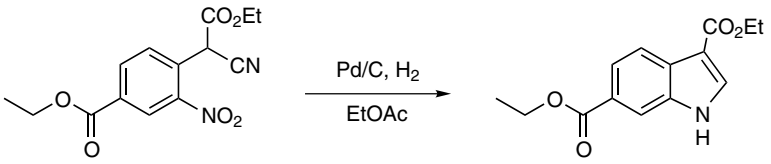
The apparatus was similar to the reported one;[5] however, in the runs above 625°C, a catalyst tube made from Corning 172 glass was used instead of the usual Pyrex. In the experiment, 10 mL of catalyst was used and preceded by about 10 mL of quartz chips, which served as a preheater for the incoming vapors. Before use, the catalyst was reduced *in situ* there with a slow stream of hydrogen for 30 min at 150–200°C, and then for 1 h at a few degrees above the actual reaction temperature. The *o*-ethyl aniline was passed through the reaction tube. The indole and skatole were isolated from the condensate by first extracting the unconverted aniline and aminostyrene with dilute hydrochloric acid and then steam distilling the residue to obtain the pure indole. The amount of indole present in the skatole was determined by repeated crystallization from water and alcohol.



Reference 3b.

2-Nitroaniline hydrochloride, prepared from heating a mixture of 1.38 g 2-nitroaniline (10.0 mmol) and 2.50 mL 12 M HCl (30.0 mmol) for several minutes, was cooled to −5°C in an ice salt bath. A cold solution of 725 mg sodium nitrite (10.5 mmol) in 3 mL water was added over 15 min with stirring, while the temperature of the reaction was held between −5° and 2°C. The mixture was stirred for an additional 15 min, and 30 mg urea (0.60 mmol) in 5.0 mL cold water was added. This cold solution was added over 10 min to a stirred mixture of 2.77 mL vinyl acetate (30.0 mmol) and 0.85 g LiCl (20.0 mmol) in 50 mL acetone-water mixture (v/v = 65:35) in a 100-mL two-necked flask fitted with a gas bubbler that was cooled to −5°C under an argon atmosphere. A cold solution of 0.26 g cupric chloride dihydrate (1.5 mmol) in 5 mL water was then added over 10 min, and the evolution of nitrogen commenced. The temperature of the reaction mixture was held between 3° and 10°C for 2 h and then warmed to room temperature over 2 h. After an additional 2 h, nitrogen evolution ceased, and the acetone was evaporated. The reaction mixture was poured into 50 mL water and extracted with dichloromethane (3 × 30 mL). The combined extracts were washed successively with water and brine and dried over anhydrous magnesium sulfate. Evaporation of the solvent and purification by flash column chromatography on 70 g silica gel using 35% dichloromethane in hexanes as an eluent gave 1.21 g l-acetoxy-l-chloro-2-(2-nitrophenyl)ethane as a light yellow oil, in a yield of 50%.

To a 250-mL one-necked flask fitted with a reflux condenser were added 1.22 g l-acetoxy-l-chloro-2-(2-nitrophenyl)ethane (5.00 mmol), 0.98 g 200 mesh iron powder (17.5 mmol), 2.10 g acetic acid (35.0 mmol), 0.68 g sodium acetate dihydrate (5.0 mmol), and 100 mL 80:20 (v/v) ethanol/water. The mixture was refluxed with stirring for 2 h under an atmosphere of argon. The reaction mixture was cooled, the ethanol was evaporated, and the residue was extracted with dichloromethane (3 × 30 mL). The combined extracts were washed successively with water and brine and dried over potassium carbonate. Evaporation of the solvent and purification by flash column chromatography on 50 g silica gel (50:50 dichloromethane-hexanes eluent) gave 0.53 g indole, in a yield of 90%.



Reference 3d.

A solution of 6.12 g ethyl 2-nitro-4-carbethoxyphenylcyanoacetate in 60 mL freshly distilled ethyl acetate was placed in a pressure bottle with 1 g 30% palladium-on-carbon. Hydrogenation was performed at a hydrogen pressure of 56 psi at 22°C. Approximately 3 mol of hydrogen per mole of starting material was absorbed during the first 15 min. The temperature was raised to 85–90°C, and another mole of hydrogen was absorbed during the next 2 h. The product, insoluble in ethyl acetate, was collected by filtration along with the catalyst. The product was dissolved in ethanol, filtered to remove the catalyst, and recrystallized twice from ethanol water. Finally, 4.70 g 3,6-dicarbethoxyindole was obtained, in a yield of 90%, m.p., 134–136°C.

Other references related to the Baeyer indole synthesis are cited in the literature.[6]

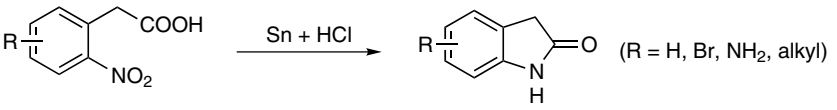
34

Baeyer Oxindole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by von Baeyer in 1878.[1] It is the synthesis of oxindole via the acidic reduction of *o*-nitrophenylacetic acid by tin and the subsequent cyclization of the resulting reduced intermediate. Besides such reaction conditions, other acidic reducing combinations can also be applied to the preparation of oxindole, including Zn + H_2SO_4, Zn + HOAc, and Fe + HOAc, $SnCl_2$ + NH_4Cl. Recently, other methods have been developed for preparing oxindoles.[2]

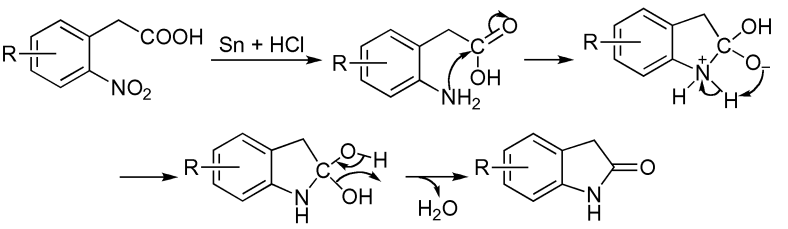
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed is the mechanism for the formation of oxindole.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

The reaction has been modified using a palladium catalyst as the coupling reagent, as shown in Cited Experimental Examples.

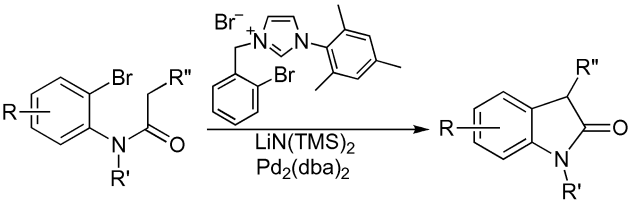
E. APPLICATIONS

This reaction has general usage for the preparation of oxindoles.

F. RELATED REACTIONS

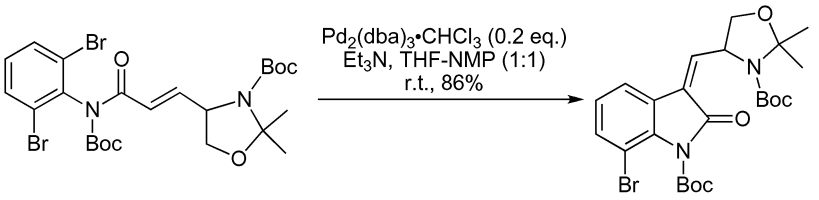
This reaction is related to the *Béchamp Reduction* and *Hinsberg Oxindole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

The reaction was carried out in THF using a certain amount of substrate, 1.5–3 mol % $Pd_2(dba)_2$, 3–6 mol % 1-mesitylimidazoium salt, and 1.5–2 eq. of $LiN(TMS)_2$. The reaction mixture was stirred at 68°C for 1–4 h and monitored by TLC. After the reaction, the solvent was evaporated, and the residue was directly purified by column chromatography. Normally, the isolated yield was in the range of 40–95%. (*Note*: This reference did not provide experimental details.)



Reference 2b.

To the mixed solvent of THF and NMP (1:1), were added certain amount of starting material, 0.2 eq. of $Pd_2(dba)_2{\cdot}CHCl_3$, and Et_3N. The mixture was stirred at room temperature and monitored by TLC. After the reaction, the solvent was evaporated, and the residue was purified on column chromatography. The yield was 86% with a Z:E selectivity of more than 95%. (Z:E > 20:1). The reaction temperature is crucial for the regioselectivity of this reaction, as an example, the Z:E ratio of the shown product was decreased to 3:1 when the reaction was conducted at 50°C. (*Note*: Experimental details were not given in this reference; interested readers should see Ref. 3).

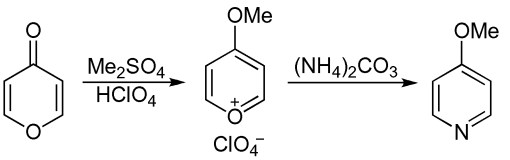
Baeyer Pyridine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

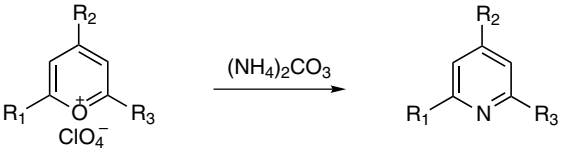
This reaction was first reported by von Baeyer in 1910.[1] It is the transformation of γ-pyrones or other pyrone derivatives into pyridines via pyronium salt intermediates, which subsequently react with an ammonium salt, such as ammonium carbonate. This reaction can be applied to the preparation of other types of heterocycles containing nitrogen. Besides this reaction, other methods have been developed to synthesize pyridines, which have been extensively reviewed by Bergstrom.[2] Other methods not included in Bergstrom's review include distillation of allylethylamine over heated lead oxide,[3a] passing a mixture of acetylene and hydrocyanic acid through a red-hot tube,[3b] heating pyrrole with sodium methylate and methylene iodide to 200°C,[3c] heating isoamyl nitrate with phosphorus pentoxide,[3d] and heating piperidine in acetic acid with silver acetate.[3e] These methods normally give low yields of pyridine derivatives.

B. GENERAL REACTION SCHEME



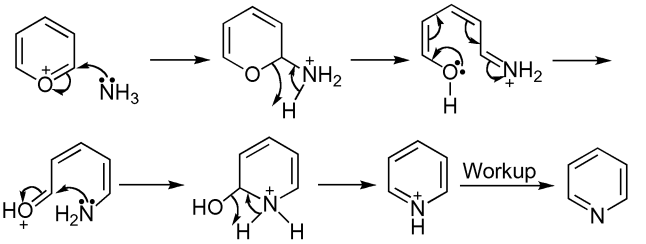
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

Starting from any pyronium salt:



C. PROPOSED MECHANISMS

It is believed that this reaction involves the following steps: the addition of amine, opening of the pyronium ring, closure of the ring, and elimination of water. This mechanism is similar to that of *ANRORC Rearrangement*.



D. MODIFICATION

N/A

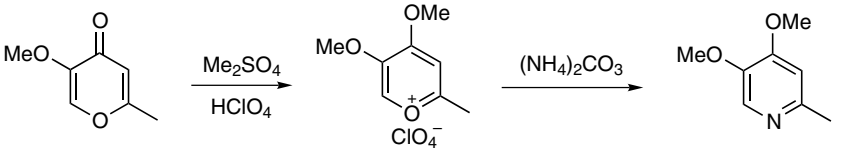
E. APPLICATIONS

This reaction has general application in the formation of pyridines.

F. RELATED REACTIONS

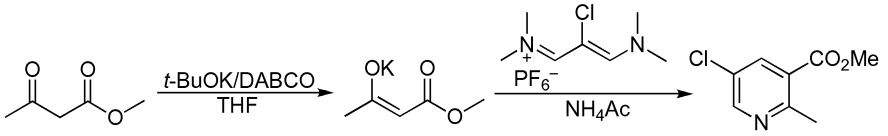
This reaction is related to the *Clauson-Kaas Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a flask equipped with a condenser were added 70 g 2-methyl-5-methoxy γ-pyrone (0.2 mol) and 31 g dimethyl sulfate (0.25 mol). The mixture was heated at 50°C for 2 h, and was then poured into 3 eq. of ice-cooled 20% $HClO_4$. After 2 h, the pyronium perchlorate salt was filtered and added to 175 mL 10% ammonium carbonate solution saturated with ammonium sulfate. After the reaction, the product was extracted with EtOAc. The product was obtained via evaporation of solvent and vacuum distillation, b.p. 75–80°C (1 mmHg). The product can also be converted to hydrochloride salt, m.p. 164°C.



Reference 5.

To a suspension of 2.9 g methyl acetoacetate (25 mmol) in 50 mL dry THF was added 16.4 mL 20 wt % *t*-BuOK in THF (26.3 mmol, 1.05 eq.) at 0°C. The slurry was warmed to room temperature and stirred for 45 min, then 1.0 eq. DABCO was added followed by 11.5 g vinamidinium hexafluorophosphate salt (37.5 mmol, 1.5 eq.) in one portion. The mixture was stirred for 45°C for 3 h, and 2 eq. ammonium acetate was added in one portion. The resulting dark solution was heated at reflux for 6 h and concentrated under reduced pressure. The yield was found to be 84%, m.p., 186–187°C. The residue was directly purified by chromatography on silica gel. Alternatively, the residue after evaporation of the THF can be extracted with EtOAc, and washed with water and saturated sodium chloride solution after the purification.

Other references related to Baeyer pyridine synthesis are cited in the literature.[6]

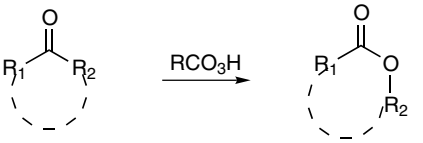
Baeyer-Villiger Oxidation

(Baeyer-Villiger Reaction, Baeyer-Villiger Rearrangement)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Baeyer and Villiger in 1899.[1] It is the oxidation of ketones or cyclic ketones into esters or lactones by peracids or hydrogen peroxide. This reaction is thus known as the Baeyer-Villiger oxidation,[2] Baeyer-Villiger reaction,[3] and Baeyer-Villiger rearrangement.[4] Typical peracids in this oxidation include peroxybenzoic acid, *m*-chloroperoxybenzoic acid (*m*CPBA), peroxyacetic acid, and trifluoroperoxyacetic acid. In this reaction, the more substituted group often migrates preferentially, and the migratory aptitudes of these groups are tertiary > secondary > cyclohexyl > benzyl > phenyl > primary > methyl. More importantly, both the stereochemistry and chirality of the migrating group are retained during the migration. This reaction has been extensively reviewed.[5]

B. GENERAL REACTION SCHEME

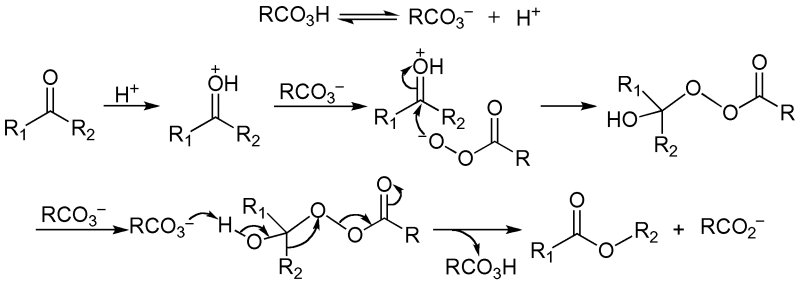


Dashed line, cyclic ketone.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A general mechanism is displayed here.



D. MODIFICATION

Because alkenes react readily with peroxyacids to form epoxides, the Baeyer-Villiger oxidation has been modified using bis[trimethylsilyl]peroxide[6a] or basic hydrogen peroxide.[6b] Recently, a modification of Baeyer-Villiger oxidation on cyclohexanone using tin-infused zeolite as catalyst and hydrogen peroxide as oxidation reagent has been developed.[6c,6d] This method can be extended to other ketones with high selectivity. It is said that this route is more environmentally friendly than the traditional manufacturing methods for caprolactone and other lactones. Moreover, as an environmentally friendly reagent, hydrogen peroxide has been widely applied for the Baeyer-Villiger oxidation under various conditions: (*a*) using $[(triphosPO)Pt]^{2+}$,[7a] montmorillonite-supported $SnCl_2$,[7b] Sn-palygorskite,[7c] organoselenium,[7d] selenoxides,[7e] aminomethyl polystyrene resin-supported tin complex,[7f] and water-tolerant Lewis acid in molecular sieves[7g] as catalysts; (*b*) using H_2O_2/nitrile as oxidant, such as H_2O_2/nitrile over $Mg(OH)_2$ or MgO,[7h] Mg/Al hydrotalcite,[7i] and H_2O_2/benzonitrile over hydrotalcite;[7j,7k] and *(c)* with tailoring Pt(II) chiral catalyst[7l] and Pt(II) catalyst[7m] or CH_3ReO_3/H_2O_2 in ionic liquids.[7n] In addition, other kinds of reagents have been applied as oxidant for the Baeyer-Villiger oxidation, including potassium peroxomonosulfate,[8a,8b] bis-cationic platinum (II) complex ($[[Pt(mu\text{-}OH)(Pom\text{-}Pom)]_2[BF_4]_2$ [Pom-Pom = $(OMe)_2PCH_2CH_2P(OMe)_2$]),[8c] and molecular oxygen/benzaldehyde.[8d] Furthermore, microbial[9a] and enzymatic[9b,9c] Baeyer-Villiger oxidation (e.g., monooxygenases,[9d–9h] cunninghamella echinulata NRRL 3655,[9i] and arabidopsis CYP85A2[9j]).

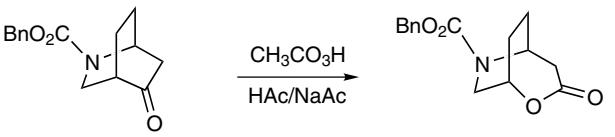
E. APPLICATIONS

This reaction has broad applications in organic synthesis for the preparation of esters and lactones.

F. RELATED REACTIONS

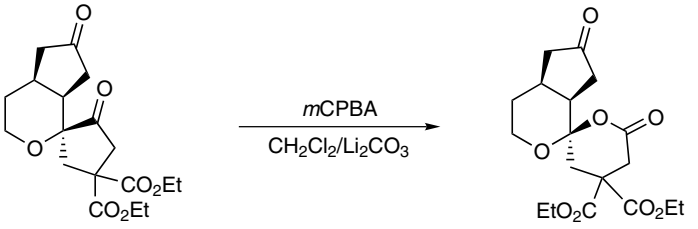
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a solution of 400 mg *N*-carbobenzyloxy-2-azabicyclo[2.2.2]octan-5-one (1.53 mmol) in 1 mL acetic acid containing 0.1 g sodium acetate was added 1 mL 28% peracetic acid. After the mixture was stirred in the dark for 24 h, 10 mL methylene chloride was added, and the solution was washed with saturated sodium sulfite (4 × 5 mL) followed by saturated sodium bicarbonate (2 × 5 mL). After removal of the solvent, the residue was purified by flash chromatography, and 338.0 mg 6-(benzyloxycarbonyl)-2-*oxa*-3-*oxo*-6-azabicyclo[3.2.2]-nonane was obtained, in a yield of 80%, b.p. 145–150°C (0.025 mmHg).



Reference 11.

To a solution of 0.045 mmol 4,4-dicarbethoxy-3,7β-dioxa-8,2-dioxobicyclo[4.3.0]-nonane-2-*spiro*-1′-cyclopentane in 1.0 mL dichloromethane were added a catalytic amount of Li_2CO_3 and 0.068 mmol *m*CPBA. The mixture was stirred for 5 h at room temperature and quenched by 0.5 mL 10% $Na_2S_2O_4$ solution. The product was extracted with chloroform (3 × 5 mL), and the combined organic layers were washed with 10% K_2CO_3 and brine and then dried over Na_2SO_4. Upon removal of solvent, the residue was purified by flash chromatography to afford 70–75% of 5,5′-dicarbethoxy-3,7β,2β-trioxa-8,3-dioxobicyclo[4.3.0]nonane-2-nonane-1-cyclohexane.

Other references related to the Baeyer-Villiger oxidation are cited in the literature.[12]

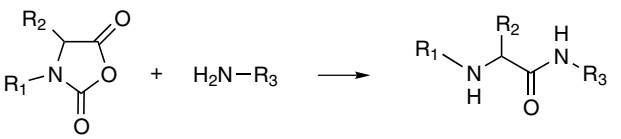
Bailey Peptide Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

Several methods have been developed to synthesize peptides, of which one is to use *N*-carboxyanhydrides (NCAs). The most successful application of the NCA method in peptide synthesis is the one developed by Bailey in 1949,[1] in which amino acids and peptide esters condense with NCAs at low temperatures in organic solvents.[2] This reaction is known as the Bailey peptide ester synthesis.[3] This method for peptide synthesis has the a great advantage of rapid acylation of an amino acid so that the reaction completes in a few minutes to a few hours to give a peptide in very high yield.[4] In addition, the reaction of NCAs with amino acids or peptides can be accomplished without protection of the functional group of the amino acids or the peptides. This method, therefore directly gives a free peptide from an amino acid. Although a by-product sometimes exists, *N*-substituted NCA has been developed so that the formed by-product can be easily removed from the conventional washing of the product with an acid or base.[5]

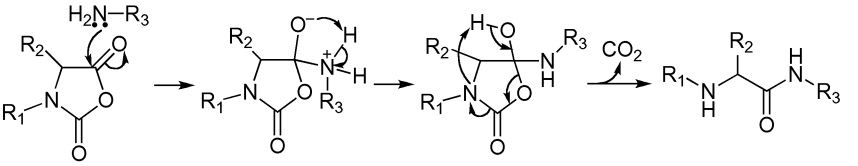
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is a simple illustration of this reaction.



D. MODIFICATION

N-substituted amino acid NCA has been applied to a similar reaction.[6b]

E. APPLICATIONS

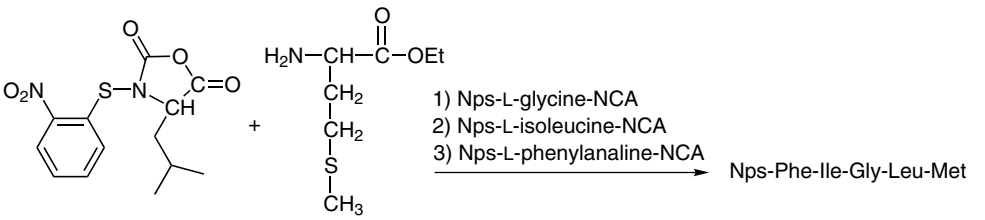
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a solution of 10.7 g L-methionine ethyl ester hydrochloride (0.05 mol) in 200 mL THF was added 7.0 mL triethylamine (0.05 mol). The resulting salt was filtered. To the solution, 17.0 g (0.055 mol) Nps-leucine NCA was added and stirred at room temperature for 2 h. Then the solvent was evaporated under reduced pressure at 35°C, the residual oil was dissolved in 200 mL ethyl acetate, and the solution was washed with 5% of citric acid, 5% of sodium bicarbonate, and water; and dried over Na_2SO_4. The solution was concentrated in vacuum at 40°C to give an oil, which was crystallized by adding *n*-hexane. Further purification can be done from recrystallization in ethyl acetate.

Then 13.3 g (0.03 mol) purified Nps-L-leucyl-L-methionine ethyl ester was dissolved in 150 mL methanol saturated with ammonia, and the solution was allowed to stand for 3 days. The solvent was evaporated to give a yellow solid, which was again dissolved in 150 mL methanol. The solution was concentrated, and diethyl ether was added to the residue. The resulting crystals of the Nps-dipeptide amide were obtained in 96% yield. The Nps-dipeptide amide was dissolved in 50 mL 1 N hydrochloric acid in methanol. After the solvent was evaporated, 300 mL diethyl ether was added. The resulting solid of the hydrochloride was isolated and washed with diethyl ether until the yellow color disappeared. The dipeptide amide hydrochloride (8.35 g, 0.028 mol) was dissolved in 150 mL tetrahydrofuran and treated with 4.2 mL (0.03 mol) triethylamine. After the crystals of the salt were removed by filtration, 7.6 g (0.03 mol) Nps-glycine NCA was added and allowed to react for 2 h at room temperature. The solvent was evaporated at 35°C. The residue was dissolved in 400 mL ethyl acetate, washed with 5% citric acid, 5% sodium bicarbonate, and water, and dried over sodium sulfate. The filtrate was concentrated to crystallize the Nps-tripeptide amide. The product was recrystallized from warm tetrahydrofuran. The Nps-protecting group of the tripeptide amide was removed by dissolving in 50 mL 1 N hydrochloric acid in methanol. Glycyl-L-leucyl-L-methionine amide hydrochloride was isolated by adding 400 mL diethyl ether, followed by filtration, and the filtrate was washed with diethyl ether. The tripeptide amide hydrochloride was dissolved in 200 mL tetrahydrofuran and treated with triethylamine, followed by 9.3 g (0.03 mol) Nps-L-isoleucine NCA. The isolation and purification of the product were done by the same procedure of Nps-tripeptide amide to give a pure Nps-tetrapeptide amide. The Nps group of 11.7 g (0.02 mol) Nps-L-isoleucylglycyl-L-leucyl-L-methionine amide was removed by action of hydrochloric acid. The tetrapeptide amide hydrochloride was treated in the presence of 3 mL (0.0214 mol) triethylamine with 7.8 g (0.022 mol) Nps-L-phenylalanine NCA in 300 mL tetrahydrofuran. The solvent was removed by evaporation, and the residue was diluted with 400 mL water to crystallize the Nps-pentapeptide amide. The product was collected by filtration and washed with 5% citric acid, 5% sodium bicarbonate, and water and then dried in vacuo over P_2O_5. The yield was 93%, m.p. 232–234°C.

Other references related to the Bailey peptide synthesis have been cited in the literature.[6]

Bakelite Process

(Baekeland-Manasse-Lederer Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

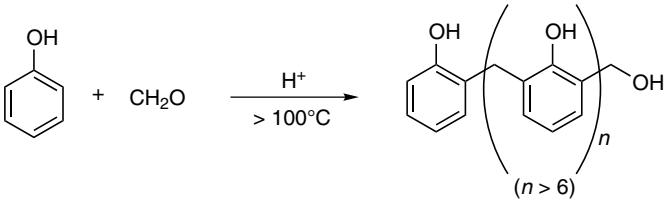
Orthohydroxy benzyl alcohol,[1] oxybenzylalcohol,[2] or simply phenol alcohol or saligenin[2,3] was first isolated by Piria in 1843.[1] It can be converted into resin (known as "saliretins"[4]) on heating. The reaction between phenol and aldehyde was first reported by von Baeyer in 1872,[5] who used an iron pressure cooker he invented, called a "bakelizer,"[2] and resulted in a sticky substance that he dismissively called "Schmiere". The actual reaction between formaldehyde and phenol was independently studied by Manasse[6] and Lederer in 1894,[7] after formaldehyde became a commercial product.

In Manasse's protocol, phenol was treated with an equivalent of strong alkali base in aqueous solution for several days until the odor of formaldehyde disappeared, whereas in Lederer's process, phenol was heated with weak base until the completion of the reaction.[1] Therefore, the reaction of phenol and formaldehyde under basic condition is referred to as the Manasse-Lederer reaction.[8] The resulting products, known as "shellac substitutes,"[2] are soluble in alcohol, acetone, and alkaline hydroxide and melt on heating and resolidify after cooling. In addition, the heating and melting can be repeated indefinitely.[3] It was Baekeland who in 1909 developed a process to make phenolic thermosetting resin from phenol and formaldehyde in an apparatus that provided external pressure[2] to balance the internal pressure.[2,3,9] Formaldehyde was heated with an excess of phenol and in the presence of an acid condensing agent to form fusible, soluble resins. This process consists of three phases. In the first phase, the product is referred to as initial condensation product, designated by Baekeland as Bakelite A, which at ordinary temperatures may be liquid, viscous, pasty, or

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

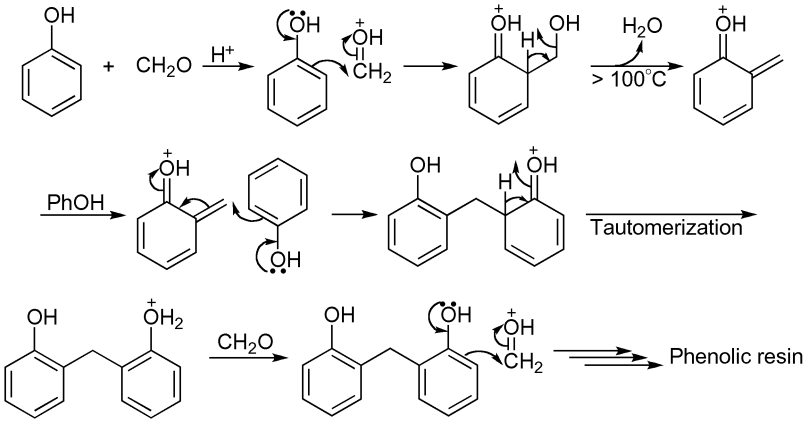
solid. Bakelite A is soluble in alcohol, acetone, phenol, and NaOH solution.[2] The product from the second phase—the so-called intermediate condensation product—is designated as Bakelite B, which is solid at all temperatures and insoluble in all solvents but may swell in acetone, phenol, or terpineol. It softens decidedly but does not melt and becomes elastic during heating and becomes again hard and brittle upon cooling. The product of the third phase is called the final condensation product, or Bakelite C, which is infusible, insoluble in all solvents, and indifferent to ordinary acids and alkaline solutions. Other properties of Bakelite C include poor conductivity of heat and electricity and excellent thermal stability. For example, Bakelite C can stand boiling with dilute H_2SO_4 and does not soften to any serious extent if heated (but chars without entering into fusion). It stands at temperatures as high as to 300°C.[2,9k] Therefore, the process to make Bakelite is referred to as the Bakelite process,[10] and Bakelite is the trademark of oxybenzylmethylen-glycolanhydride.[9k]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction should involve multiple condensation between formaldehyde and phenol, as shown here.



D. MODIFICATION

N/A

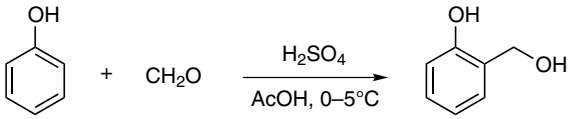
E. APPLICATIONS

This reaction has important applications in industry for making phenolic resins.

F. RELATED REACTIONS

This reaction is related to the *Rothemund Condensation* and *Zinke Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8f.

A substituted phenol (0.1 mol) was dissolved in 20 mL glacial acetic acid, and a cold solution of 20 g of conc. H_2SO_4 in 40 mL glacial acetic acid was then added. Over a period of 2.5 h, 4.2 mL 40% formaldehyde (0.055 mol) was added to the mixture at 0–5°C. The reaction mixture was stirred cold for an additional 3 h and was then stirred at room temperature for 24 h after the beginning of the reaction. The reaction mixture was poured into cold water, and the precipitate was filtered off and neutralized with sodium bicarbonate solution. The product was purified by crystallization.

Other references related to the Bakelite process are cited in the literature.[11]

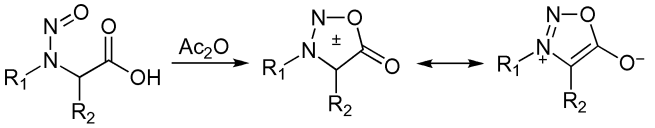
Baker-Ollis Sydnones Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

The sydnones, of both biological and structural importance, were first reported by Earl and Wackney in 1935[1] but were not studied intensively until 1946 and thereafter.[2] The structural importance of this type of compound is that no single valence structure can adequately explain the chemical and physical properties of sydnones, although many controversial structures have been proposed to solve this problem.[3] The most commonly used structure is the one proposed by Baker and Ollis in 1957.[4] From the structural point of view, sydnones represent only 1 of some 288 possible five-membered ring systems having similar electronic characteristics, of which relatively few have yet been prepared.[5] Generally, sydnones can be simply synthesized from *N*-nitroso derivatives of *N*-substituted α-amino acids with certain dehydrating agents, such as acetic anhydride.[6] The sydnones were reviewed by Stewart in 1964.[7]

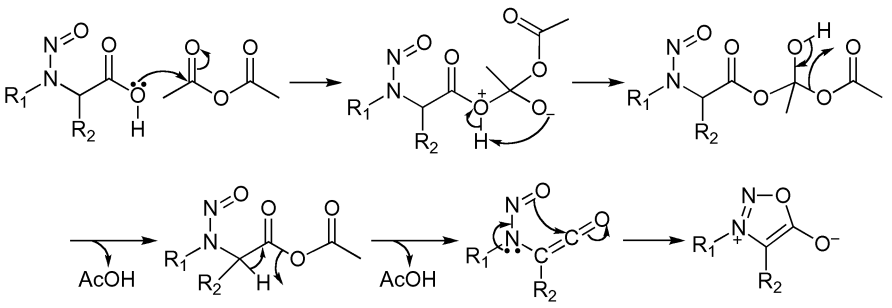
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The formation of sydnone is shown here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

Trifluoroacetic anhydride,[2h,6c] thionyl chloride,[2h] and carbonyl chloride[8] have been applied as dehydrating reagents. When trifluoroacetic anhydride is used, a reaction that usually takes a few days can be completed in seconds. In aqueous solution, *N*,*N*-diisopropylcarbodiimide[8] has been used in this reaction at room temperature.

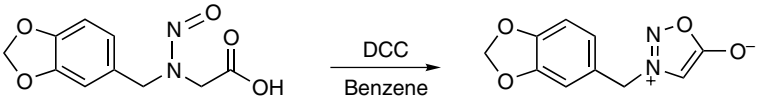
E. APPLICATIONS

N/A

F. RELATED REACTIONS

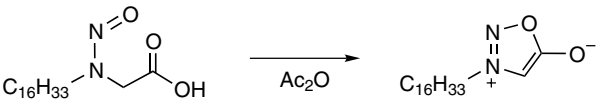
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a solution of 4 g *N*-nitroso-*N*-piperonylglycine in 150 mL dry benzene at 70°C was added a 50 mL dry benzene solution (also 70°C) containing enough *N*,*N*-dicyclohexylcarbodiimide (DCC), and *N*,*N*-dicyclohexylurea immediately precipitated. The mixture was stirred at 50–60°C for 2 h and filtered while hot. The filtrate was evaporated to dryness in *vacuo*, and the residue was recrystallized from 75 mL toluene; 2.7 g 3-piperonylsydnone (shiny needles) was obtained, in a yield of 72.4%, m.p. 158–159°C. A parallel run was also carried out using acetic anhydride as a cyclizing reagent, and a comparable yield was obtained.



Reference 10.

A mixture of 0.5 g nitroso acid and 10 mL acetic anhydride was kept at room temperature in the dark for 3–4 days, with gentle warming at intervals to maintain complete solution. The excess anhydride was decomposed with water, and the precipitated *N*-hexadecylsydnone was filtered off, washed, and recrystallized from aqueous ethanol to afford 0.33 g product as colorless needles, in a yield of 70%, m.p. 63.5–64.5°C.

Other references related to sydnones are cited in the literature.[11,12]

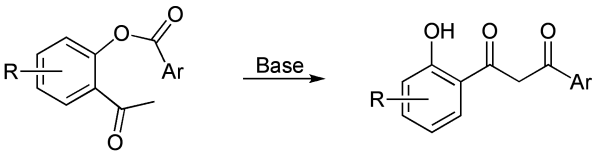
Baker-Venkataraman Rearrangement

(Baker-Venkataraman Transformation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first and concurrently reported by Baker[1] and Venkataraman[2] in 1933. It is the rearrangement of *o*-acyloxyketones into β-diketones under basic conditions and is generally known as the Baker-Venkataraman rearrangement[3] or Baker-Venkataraman transformation.[4] In addition, this reaction is also referred to as the Baker-Venkataraman reaction,[5] and Baker-Venkataraman synthesis.[6] Although this intramolecular acyl transfer reaction has become a major reaction in flavone chemistry,[7] the migration of acyl group has been confined to aromatic or heteroaromatic acyl group.[8] The resulting molecules can be applied to the synthesis of chromones and flavones and has been extensively reviewed.[9]

B. GENERAL REACTION SCHEME

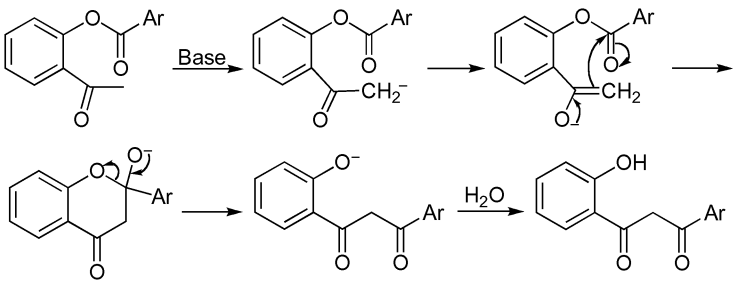


(R = alkyl, OH, alkoxyl)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Even though the mechanism of this reaction has been discussed elsewhere,[10] shown here is another illustration of this reaction.



D. MODIFICATION

N/A

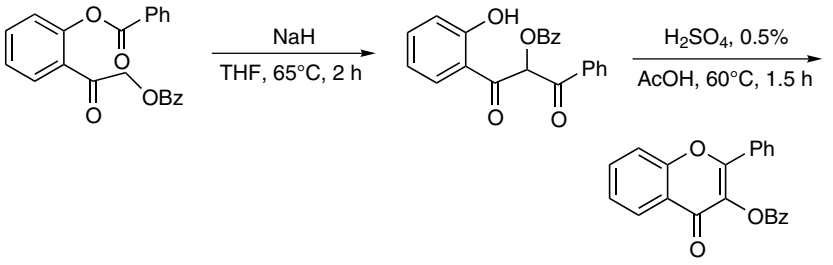
E. APPLICATIONS

This reaction has been applied to synthesize other types of molecules.[11]

F. RELATED REACTIONS

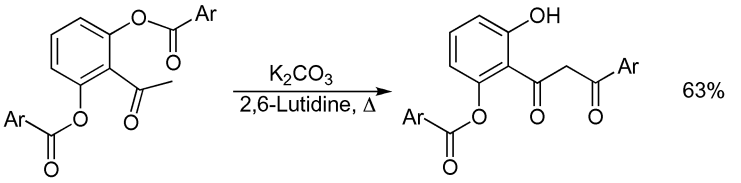
This reaction is related to the *Allan-Robinson Annulation* and *Kostanecki Acylation* in terms of the formation of flavones. In mechanism, this reaction is related to the *Fries Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 12.

To a suspension of 48.0 mg NaH (2.0 mmol) in 10 mL dry THF was added 250 mg 2,2′-dibenzoyloxyacetophenone (0.7 mmol) in 10 mL THF. The mixture was refluxed for 90 min, and then the cooled mixture was poured into a mixture of 120 g ice and 2 mL concentrated HCl. The precipitated crude β-diketone was washed with water and dried. This β-diketone was added to 10 mL acetic acid, and 0.25 mL conc. H_2SO_4 was added dropwise. The reaction mixture was heated at 60˚C for 90 minutes with stirring, and the solution was poured over 60 g ice. The precipitate was filtered, washed with water, and recrystallized from ethanol to yield 150 mg pure 2-phenyl-3-benzoyloxy-4-oxo-4H-1-benzopyran as colorless needles, in a yield of 63%.



Reference 13.

To a three-necked flask equipped with stirrer and condenser were added 10 g 2,6-bis(methoxybenzoxyl)-acetophenone, 12 g anhydrous potassium carbonate, and 100 mL 2,6-lutidine (or pyridine). The mixture was refluxed for 2 h. The resulting yellow precipitate and 2,6-lutidine (or pyridine) were dissolved in water and poured cautiously into an excess of ice cold 6 N HCl solution. The resulting pale yellow to bright orange precipitate was collected by filtration and dried. This product was not purified further and was subjected into cyclization to give flavone directly.

Other references related to the Baker-Venkataraman rearrangement are cited in the literature.[14]

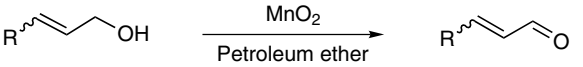
Ball-Goodwin-Morton Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

Manganese dioxide has been considered a specific reagent for oxidation of allyl alcohol to allyl aldehyde or ketones, and several different types of manganese dioxide have been used for this type of oxidation. The first type of these manganese dioxides was initially reported by Ball, Goodwin, and Morton in 1948.[1] In their original study, vitamin A alcohol was oxidized to vitamin A aldehyde using manganese dioxide suspended in petroleum ether. Other oxidations of alcohol using manganese dioxide include the oxidation of unsaturated steroidal alcohol,[2] polyene alcohol,[3] acetylenic alcohol,[4] ferrocene alcohol,[5] and benzyl alcohols.[6] It is interesting that manganese dioxide prepared by heating the corresponding carbonate or oxalate in air will oxidize benzyl alcohols dissolved in petroleum ether (or preferably in ethyl ether) to aldehyde in good yield but not the allylic alcohols.[1,2d,6] However, acid-washed manganese dioxide suspended in petroleum ether will oxidize allylic alcohols to corresponding aldehydes in good yield, but not for saturated alcohols.[6]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed is the oxidation mechanism; a similar mechanism has been proposed by Goldman for the oxidation of benzyl alcohols.[7]

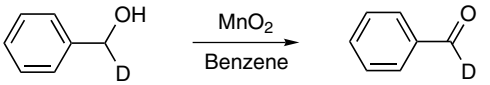
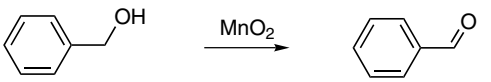
G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

The active manganese dioxide was prepared by azeotropic removal of water according to the reported procedure.[9] To 125 mL benzene were added 1 g deuterated benzyl alcohol (C_6H_5CHD-OH) and 10.5 g activated manganese dioxide under nitrogen (from 25 g wet manganese dioxide). The mixture was stirred for 1 h and then filtered through Celite, and benzene was removed carefully under reduced pressure. The product was analyzed directly after the purification by GLPC or distillation, the yield is 91.7%.



Reference 7a.

To a 500-mL flask were added 100 g activated manganese dioxide and ~ 300 mL solvent. The flask was immediately swirled and, if necessary, sealed and shaken vigorously to wet all of the MnO_2. Then 25 g of the alcohol to be oxidized was added, and the flask was stoppered and shaken in a shaking machine at a rate sufficient to keep the MnO_2 suspended for the time given, generally about 3 days. The solid then was separated from the solution

by suction filtration, using an inorganic filter aid when necessary (e.g., Celite), and the solid was washed with more solvent. The combined solution was concentrated to give the corresponding aldehydes.

Procedures for preparing different types of manganese dioxides have been reported.[7a,10] Other references related to this type of oxidation are cited in the literature.[11]

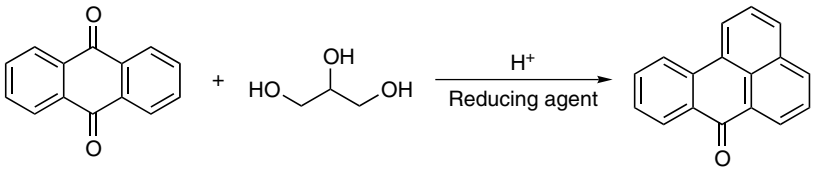
Bally-Scholl Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bally in 1905[1] and was investigated again by Bally and Scholl in 1911.[2] It is the synthesis of benzanthrone from the condensation of anthraquinone with acrolein in the presence of an acidic condensing agent, especially sulfuric acid. In addition, the formation of acrolein from glycerol and sulfuric acid was carefully studied by Scholl in 1936.[3] Therefore, this reaction is known as the Bally reaction,[4] Bally benzanthrone synthesis,[5] or Bally-Scholl reaction.[6] The yield of this reaction is usually 50–60%.[7] In industry, benzanthrone is produced from the reaction among anthraquinone, glycerol, and iron in concentrated H_2SO_4, where acrolein can be generated *in situ*, and 9,10-anthraquinone is reduced to anthracene-9(10H)-one.[8] Nevertheless, it has been applied to make different types of dye molecules.[9]

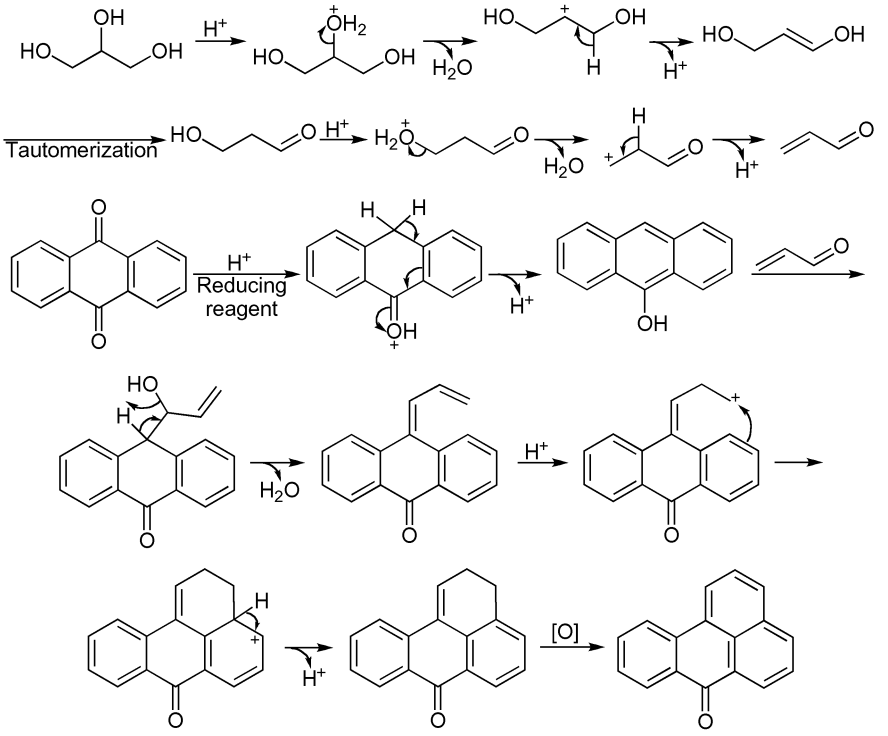
B. GENERAL REACTION SCHEME



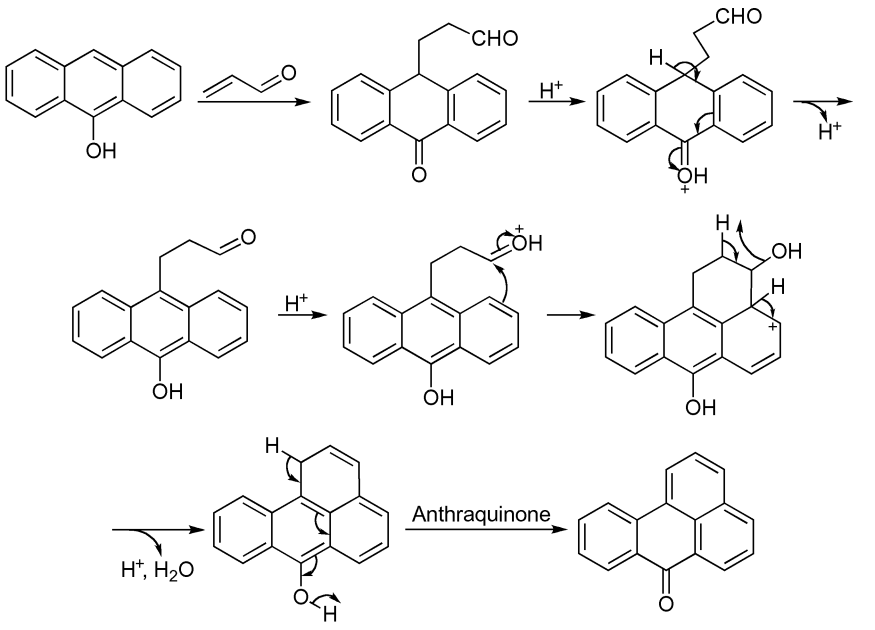
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is generally accepted[2,8,10] that this reaction involves the conversion of glycerol into acrolein and reduction of anthraquinone to anthrone, the latter undergoing the *Aldol Condensation* with acrolein.[2] After that, the consecutive dehydration, cyclization, and oxidation afford the final product of benzanthrone.[8] An illustration of the reaction mechanism is displayed here.



It may be possible that the anthrone undergoes the *Michael Reaction* with acrolein, and the cyclized product is then oxidized by anthraquinone and the latter is reduced to anthrone, as shown by the partial illustration of the mechanism. This route is consistent with the relatively low yield of 50–60%.[7]



D. MODIFICATION

This reaction has been modified to proceed from glycerol and anthraquinone in sulfuric acid in the presence of iron,[8] copper,[11] or a reducing agent of anthrone[12] or sodium hypophosphite.[13] Moreover, a reaction between hydroanthraquinone and acrolein in sulfuric acid to afford benzanthrone has also been developed.[14] Another modification is the reaction between anthraquinone-1-diazonium salt and α-methylacronitrile or α-methyl vinyl acetate in monovalent alcohol (e.g., MeOH, EtOH) in the presence of a catalytic amount of cuprous chloride.[15]

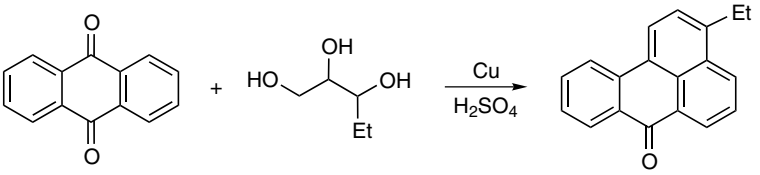
E. APPLICATIONS

This reaction has general application in preparation of benzanthrone.

F. RELATED REACTIONS

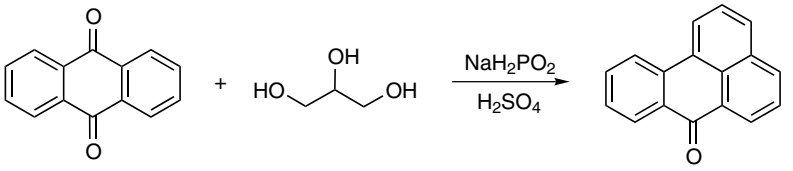
This reaction is related to the *Skraup Reaction* and *Scholl Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To 132 mL H_2SO_4 (2.4 mol) stirred at room temperature was slowly added 9.0 g anthraquinone (0.043 mol). When all of anthraquinone had dissolved, 5 mL water was added. The resulting mixture was maintained at 38–42°C while 6.0 g freshly precipitated copper (0.01 mol) was added over 90 min; after 3 h the copper had dissolved, and the mixture acquired a yellow-brown color with separation of some anthranol. A mixture of 14.4 g α-ethylglycerol (0.12 mol) and 14 mL water was added over 50 min while the temperature was raised to 80°C, and the whole solution was then maintained at 100°C for 2.5 h. The progress of the reaction was shown by the development of a red color; and considerable care was exercised in heating to avoid charring, which occurred quite readily. The whole mixture was cooled and poured into 500 mL boiling water, and the resulting mixture was boiled for a few minutes and kept overnight. The precipitate was collected, washed with water, and boiled with 150 mL 1% NaOH for 40 min to dissolve unchanged anthranol. The solution, which could not be filtered, was shaken several times with benzene, and the emulsion was centrifuged into two layers. The combined benzene extracts were boiled for 2 h with animal charcoal and then filtered. The solvent was removed principally by distillation and finally by evaporation in a vacuum at the ordinary temperature. The crystals that separated were pressed on a porous plate to remove an oily material and recrystallized from methanol, from which 0.5 g 1′-ethylmesobenzanthrone was separated in yellow needles, m.p. 106°C.



Reference 13.

Anthraquinone (208 g) was dissolved in 1000 g conc. H_2SO_4 at 80–110°C. Then a solution of 96 g sodium hypophosphite in 240 g glycerol was added in a manner such that a reaction temperature of 100°C could be maintained. The mixture was then heated to 120°C and kept at this temperature for 3 h. After that, the reaction mixture was poured into 3 L water, and the product that precipitated was filtered off. The solid was washed with hot water until the runnings were almost colorless, and the filter cake was then suspended in 1.5 L water and the suspension was rendered weakly alkaline and boiled up. After renewed filtration of the product, washing with hot water, and drying at 100°C, 200–225 g 92–97% pure benzanthrone was obtained, in the yield of 80–93%.

More procedures with experimental details for the preparation of benzanthrone can be found in the literature.[11,12,14,15] Other references related to the Bally-Scholl reaction are cited the literature.[16]

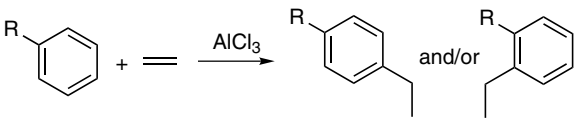
Balsohn Alkylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Balsohn in 1879,[1] just two years after Friedel and Crafts's acylation and alkylation with $AlCl_3$.[2] In its initial reaction, benzene was directly alkylated with ethylene in the presence of $AlCl_3$, and the prolonged reaction favored a higher yield of polyethylbenzenes, including pentaethylbenzene. Since then, many other acidic catalysts have been applied to similar reactions, and these catalysts include sulfuric acid,[3] phosphorus acid,[4] phosphorus pentoxide,[5] and boron trifluoride.[6] It should be pointed out that the Balsohn alkylation is not limited to ethylene itself but works for other alkenes[1,7] as well, and even for acetylene.[8] Other aromatics such as phenol also react in a similar fashion.[9] When higher alkenes react with aromatics, the less substituted end of the alkenes always reacts and attaches to the aromatic ring, whereas when acetylene is used, diphenylethane and 9,10-dimethyl-9,10-dihydroanthracene will form.[8] When sulfuric acid is used as catalyst, two other side reactions—polymerization and formation of ester—also compete with the actual alkylation.[3] Some of the reactions have been used on a large scale for industrial production.[10] In addition, the Balsohn alkylation follows the *para/ortho regio*-selectivity as shown in the *Friedel-Crafts Acylation* and *Friedel-Crafts Alkylation*.

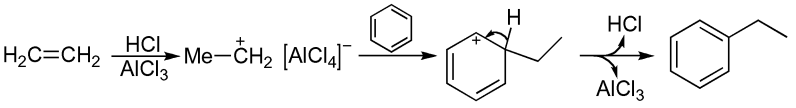
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Kinetic studies showed that this reaction is similar to that of ethylation of benzene with ethyl bromide when aluminum bromide presents; therefore, it is believed that this reaction occurs via the generation of carbocation as the first step,[11] as illustrated here.



D. MODIFICATION

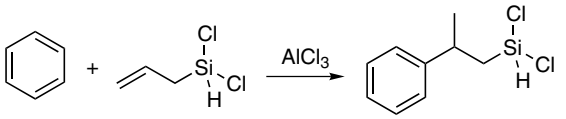
F. RELATED REACTIONS

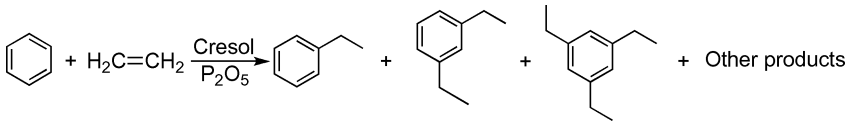
This reaction is related to the *Friedel-Crafts Alkylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 12.

To mixture of 13.9 g benzene (178 mmol) and 0.4 g anhydrous aluminum chloride (3 mmol) was added dropwise 5.0 g allyldichlorosilane (36 mmol) at room temperature. The mixture was stirred for 30 min, and 2.0 g sodium chloride (34 mmol) was added to the mixture, which then was warmed to 70°C and stirred for 1 h. After the salts were filtrated and the mixture was evaporated to remove benzene, the residue was subjected to vacuum distillation to give 5.7 g 3-phenyl-1,1-dichloro-1-silabutane (26 mmol), in a yield of 72%. (b.p., 64 – 67°C/0.6 mmHg). In addition, 0.6 g di-adducts was obtained.



Reference 13.

A mixture of 780 g benzene (10 mol), 50 g phosphorus pentoxide, 24 g lampblack and 10 g cresol were heated in an autoclave for 100 min at 250°C with agitation, while a approximate pressure of 27 atm was maintained by a periodic introduction of ethylene. The weight of the liquid in the autoclave was increased by 527.7 g, indicating that 18.86 mol ethylene had been absorbed. The reaction mixture was fractionated into five portions, corresponding to benzene (1.6%), monoethylbenzene, (23.1%), diethylbenzene isomers (42.3%), triethyl benzene isomers (24.4%), and higher ethylbenzene isomers (8.5%) by volume.

Other references related to the Balsohn reaction are cited in the literature.[14]

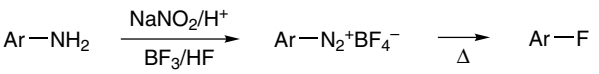
Balz-Schiemann Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Balz and Schiemann in 1927.[1] It is the most popular reaction to introduce a fluorine atom into aromatic rings through the thermal decomposition of diazonium tetrafluoroborate by diazotization of the corresponding aromatic amines. Therefore, this reaction is generally known as the Balz-Schiemann reaction[2] or Schiemann reaction[3] and is referred to as the Balz-Schiemann decomposition[4] as well. This reaction is especially important for synthesizing the specifically fluorinated aromatic compounds, of which the decomposition in the absence of solvent normally affords a fairly good yield of aromatic fluorides. The general procedure can be directly extended for preparing other aromatic halides. The Balz-Schiemann reaction has been extensively reviewed.[5]

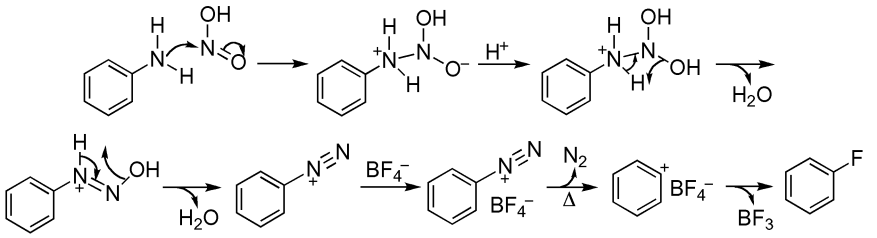
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the mechanism was studied by Swain et al.[6a] and Olah et al.,[6b] an illustrative detail of this reaction is proposed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been extensively modified for different conditions, using a large excess of HF,[7a] HPF_6 instead of HBF_4,[7b] $NaBF_4$ rather than HBF_4,[7c] microwave accelerated multiphase reaction,[7d] and photo-Balz-Schiemann reaction.[7e–7i] Other modifications of this reaction are cited in Refs.[7j–7t]

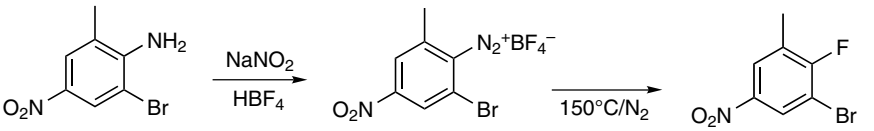
E. APPLICATIONS

This reaction has general application in the preparation of aromatic halides.

F. RELATED REACTIONS

The metal-catalyzed *Sandmeyer Reaction* is also widely used to prepare fluorinated aromatic compounds;[8] unfortunately, it is often accompanied by unwanted side reactions.

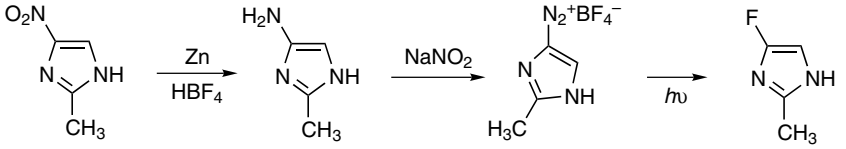
G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a 400-mL beaker were added 110 mL fluoroboric acid and 57.75 g 2-amino-3-bromo-5-nitrotoluene (0.25 mol). The beaker was placed in an ice bath, and the solution was efficiently stirred while adding a 35 mL of a cold solution of sodium nitrite (17 g, 0.25 mol) dropwise. When the addition was complete, the mixture was stirred for 15 min and filtered by suction on a sintered glass funnel. The solid diazonium salt was washed with fluoroboric acid, twice with ethanol, and several times with ether; 57.57 g diazonium fluoroborate was obtained, in a yield of 70%. This solid was subjected to thermal decomposition without further purification and was mixed with 150 g acid-washed sand. The mixture was placed in a three-necked flask, and a nitrogen supply was attached to allow a constant flow of

nitrogen through the apparatus during decomposition. The reaction was initiated by heating to 150°C for 10 min. The vigorous reaction was allowed to continue until the evolution of BF_3 gas had ceased. The nitrogen supply was removed, and the dark mass was cooled. The residue was dissolved in 600 mL dichloromethane, and the sand was filtered off. The solvent was removed, under reduced pressure, and the residue was purified by chromatography on alumina using dichloromethane as the eluent, and 20 g 2-fluoro-3-bromo-5-nitrotoluene was obtained, in a yield of 40%.



Reference 7e.

The solution of 5.08 g 2-methyl-4-nitroimidazole in 200 mL 42% tetrafluoroboric acid was cooled to -10°C; to this cooled solution was added 5.08 g zinc dust (78 mmol) in portions of ~ 0.1 g with rapid stirring. Each addition was made only after the prior portion had dissolved and the temperature had fallen to at least -5°C. The addition took about 1 h. Small aliquots were removed, diluted with water, and examined by UV. Total loss of the chromophore at 310 nm indicated the completion of reduction. Then a solution 2.04 g sodium nitrite (44 mmol) in 10 mL water was added dropwise. The resulting solution of the diazonium salt was diluted to 380 mL with cold 42% tetrafluoroboric acid and was irradiated under argon in a Pyrex immersion-well photoreactor using a 400-W high-pressure mercury lamp (Riko 400-HA). After 90 min, the diazonium chromophore at 280 nm had disappeared. The solution was cooled to -10°C with dry ice, neutralized slowly with 25% aqueous sodium hydroxide to pH 5–6, and extracted with EtOAc (5 × 200 mL). The combined extracts were dried over Na_2SO_4 and evaporated. The residual material was purified on 100 mL silica gel with EtOAc as an eluent to give 1.06 g 4-fluoro-2-methylimidazole, in a yield of 27%, m.p. 142–144°C.

Other references related to the Balz-Schiemann reaction are cited in the literature.[10]

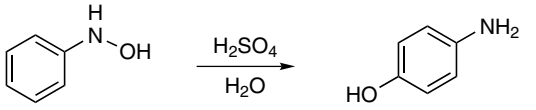
45

Bamberger Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bamberger in 1894.[1] It is an intermolecular rearrangement of *N*-phenylhydroxylamines in acidic aqueous solution to afford the corresponding 4-aminophenols, e.g., in aqueous sulfuric acid. Thus this reaction is generally known as the Bamberger rearrangement.[2] Occasionally, it is also termed the Bamberger reaction.[3] It is believed that in this rearrangement the hydroxyl group is introduced into the aromatic ring via a nucleophilic attack of a hydrosulfate ion on the anilenium ion, which is generated by the heterolytic N-O bond cleavage of *O*-protonated *N*-phenylhydroxylamine.[4] It has been found that alkoxy, halogen, phenoxy are incorporated into the aromatic ring when the rearrangement of *N*-phenylhydroxylamine is carried out in nucleophilic solvents, such as alcohols, hydrogen halides, and phenols.[5] There is much mechanistic evidence to favor the heterolytic N-O bond cleavage.[6] This rearrangement has been reviewed.[7]

B. GENERAL REACTION SCHEME

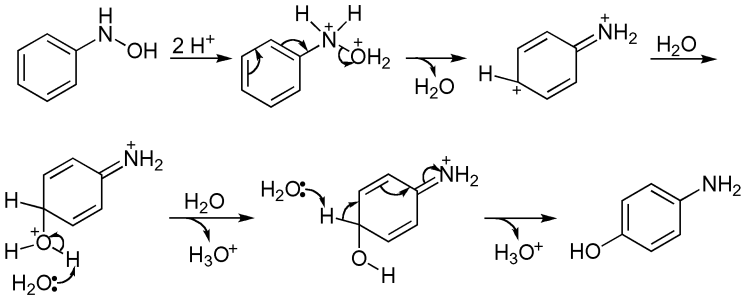


C. PROPOSED MECHANISMS

Under acidic conditions, phenylhydroxylamine is first protonated and subsequently transformed into anilenium by releasing a water molecule, during which the aromatic ring carries

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

a partial positive charge so that the nucleophilic attacking occurs at the *para* position (the amino group is an *ortho* and *para*-determining group). The mechanism of this rearrangement has been extensively studied in detail.[2g,4,6g,8]



D. MODIFICATION

This type of rearrangement has been extended to pyridines and isoquinolones.[9a] It is reported that the nitro group (NO_2) will migrate to the *ortho* position when it is connected to nitrogen atom of aniline.[9b–d] However, in the case of *O*-phenylhydroxylamine, the amino group will migrate to both the *ortho* and the *para* positions.[4] It has been found that when hydrogen is replaced by a sulfur atom in phenylhydroxylamine [i.e, PhN(OH)SR], the rearrangement rate will be 10^6 as fast as normal Bamberger rearrangement.[10]

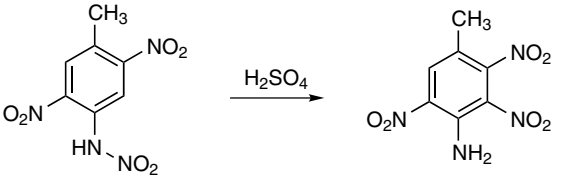
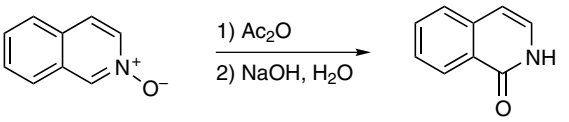
G. CITED EXPERIMENTAL EXAMPLES



Reference 9b.

To a flask were added 10 mL conc. H_2SO_4 and 0.5 g 4-amino-*N*,2,5-trinitrotoluene (2.06 mmol). The mixture was cooled at 0°C, stirred for 69 h, and then poured into 100 mL ice water. The resulting precipitate was filtered off and washed with water to give 0.44 g

4-amino-2,3,5-trinitrotoluene, in a yield of 88%, m.p., 145–151°C. Further recrystallization from hot ethanol gave pure 4-amino-2,3,5-trinitrotoluene, in 40% of recovery, m.p., 150–153°C.



Reference 9a.

In a typical experiment, 18.12 g isoquinoline-*N*-oxide was added to 150 mL acetic anhydride and refluxed gently for 5 h. The liquid soon turned dark red. The acetic anhydride was removed under an aspirator vacuum, and the residue was distilled. The volatile portion was collected in one fraction, which boiled at ~ 142°C (0.9 mmHg); however, an appreciable non-volatile portion remained. The solid distillate was heated on the steam bath with 4 g NaOH and 75 mL water for 40 min and then allowed to stand at room temperature overnight. A pale yellow solid was filtered off and washed with water to give 9.02 g isocarbostyril, in a yield of 53%, m.p., 208.0–209.5°C.

Other references related to the Bamberger rearrangement are cited in literature.[11]

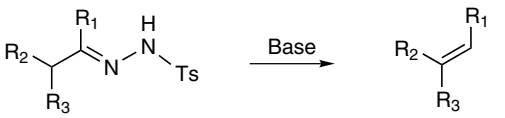
Bamford-Stevens Reaction
(Bamford-Stevens Olefination)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bamford and Stevens in 1952.[1] It is the transformation of ketones and aldehydes into alkenes through the base-promoted thermal or photolytic decomposition of *p*-toluenesulfonylhydrazones of the corresponding ketones or aldehydes.[2] Therefore, this reaction is generally known as the Bamford-Stevens reaction.[3] In addition, this reaction is also referred to as the Bamford-Stevens olefination.[4] The bases used in this reaction are strong bases, including NaOMe, LiH, NaH, $NaNH_2$, and BuLi. The alkenes formed are normally the thermodynamic product, i.e., the highly substituted alkenes. Depending on the reaction conditions (e.g., bases used, solvents), other types of products rather than alkenes can be prepared as well, including diazo compounds,[5] carbenes,[2e–h] cyclopropyl compounds,[2e–h,6] and alcohols.[7] This is because during the pyrolysis, *p*-toluenesulfonylhydrazone salts first lose *p*-toluenesulfinate anion to generate a diazo intermediate, and the diazo intermediate can change into different species, depending on the reaction conditions, such as solvents (protic vs. aprotic),[8] metal cations[9] and the type and concentration of alkali.[10]

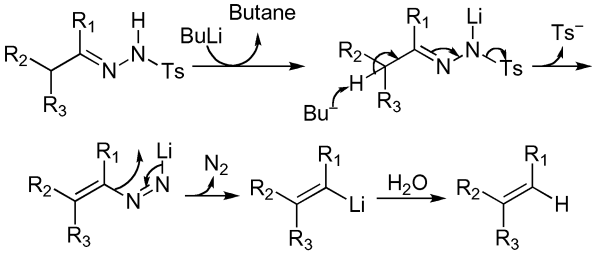
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is illustrated by the reaction with butyl lithium.



D. MODIFICATION

Hoffman has modified this reaction to generate diazo compounds *in situ*.[11]

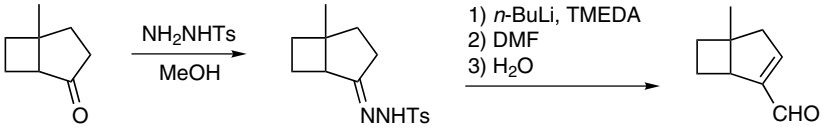
E. APPLICATIONS

This reaction has wide applications in the preparation of alkenes.

F. RELATED REACTIONS

This reaction is closely related to the *Shapiro Reaction* developed 15 years later.[12] The *Shapiro Reaction* is also the decomposition of *p*-toluenesulfonylhydrazones of ketones and aldehydes and is carried out under mild conditions to form less-substituted alkenes.

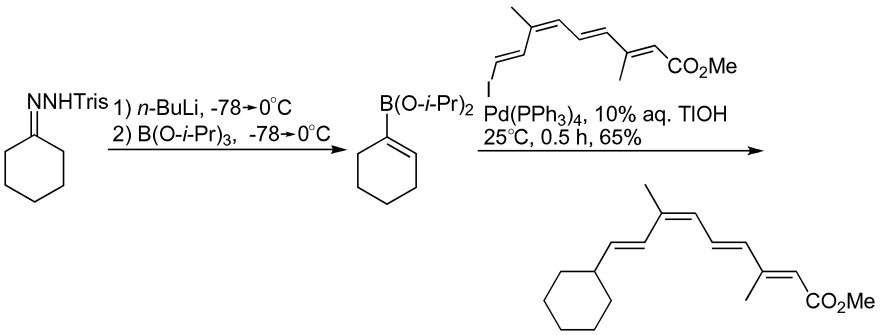
G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

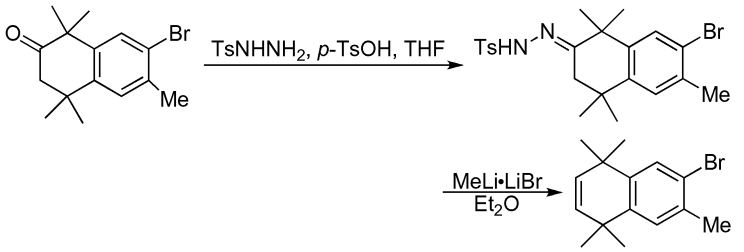
To a flask, were added 46 mL 60% aqueous MeOH and 3.53 g tosylhydrazine (18.9 mmol), and the mixture was heated to 60°C. Then 2.33 g (1*S*R,5*S*R)-methylbicyclo[3.2.0]heptan-2-one (18.8 mmol) was added dropwise to the solution. The reaction mixture was immediately stored at 5°C for 15 h. The resultant white crystals were filtered, washed with 60% aqueous MeOH, and air-dried for 10 min. A mixture of 4.91 g *E* and *Z* isomers of tosylhydrazone (*N*-1-[(1*S*R,5*S*R)-5-methylbicyclo[3.2.0]hep-2-yliden]-4-methyl-1-toluenesulfonoylhydrazone) was obtained as white crystals, in a yield of 89%, m.p. 174–176°C.

Caution: Nitrogen is produced in this reaction and allowance must be made for its escape. Do not use a sealed system. A suspension of 1.04 g of tosylhydrazone (3.59 mmol) in 15 mL TMEDA was cooled to −78°C, under a nitrogen atmosphere. Then 4.6 mL 2.3 M *n*-BuLi (10.58 mmol) was added dropwise to the frozen suspension, and the solution generated was kept at −78°C for 15 min and then allowed to warm to ambient temperature, whereupon it turned a dark red color. This solution was stirred for a further 5 h. When the solution was cooled to 0°C, 0.4 mL DMF (5.18 mmol) was added, and the solution was stirred at ambient temperature overnight. It was then poured into 60 mL 7.5% HCl (aq.) and extracted with CH_2Cl_2 (4 × 40 mL). The combined organic phases were washed with 40 mL sat. NaCl (aq.) and dried; solvent was removed in vacuum. The crude material was used directly in the next reaction. A small portion was purified by flash chromatography using CH_2Cl_2 as the eluent to give a pure sample for spectroscopic analysis.



Reference 14.

To a cold (−78°C) suspension of 0.14 g hydrazone (0.38 mmol) in 1.0 mL THF was added 0.37 mL 3.07 M *n*-BuLi (1.14 mmol), and the solution was stirred for 30 min. Nitrogen evolution was observed when the temperature was taken up to 0°C, before cooling to −78°C for the addition of 0.17 mL triisopropyl borate (0.75 mmol). The mixture was stirred for 1 h at 0°C and then warmed to room temperature. Then 0.035 g $Pd(PPh_3)_4$ (0.030 mmol) followed by iodide dissolved in 1.0 mL THF were added. After 10 min of stirring, a 2.6 mL of 10% aqueous solution of TlOH (1.16 mmol) was added, and the final mixture was stirred at 25°C for 30 min. It was then diluted with Et_2O and filtered through Celite. The filtrate was washed with a saturated $NaHCO_3$ solution three times, dried over Na_2SO_4, and evaporated. The crude residue was purified by column chromatography (SiO_2, 90:10 hexane/EtOAc) to afford 0.06 g ethyl (2*E*,4*E*,6*Z*,8*E*)-(cyclohex-1-en-1-yl)-3,7-dimethylnona-2,4,6,8-tetraenoate as a yellow solid, in a yield of 65%, m.p. 77.5°C (recrystallized from hexane/EtOAc).



Reference 15.

A suspension of 30.5 g 7-bromo-1,1,4,4,6-pentamethyl-1,3,4-trihydronaphtha-len-2-one (0.10 mol), 22.1 g *p*-toluene-sulfonylhydrazide (0.119 mol), and 4.92 g of *p*-toluenesulfonic acid monohydrate (25.9 mmol) in 611 mL MeOH was refluxed under nitrogen for 24 h. The resultant reaction slurry was cooled for 1 h in an ice bath, filtered, and rinsed with 150 mL cold MeOH to give 36.8 g [*aza*-(7-bromo-1,1,4,4,6-pentamethyl(2-1,3,4-trihydro-naphthylidene))methyl][(4-methylphenyl)-sulfonyl]-amine, in a yield of 77%.

A suspension of 20.0 g [*aza*-(7-bromo-1,1,4,4,6-pentamethyl(2-1,3,4-trihydro-naphthyl-idene))methyl][(4-methylphenyl)-sulfonyl]-amine (43.2 mmol) in 400 mL MTBE was treated with 86.3 mL of a 1.5 M solution of MeLi complexed with LiBr in Et_2O (0.13 mol) at room temperature under nitrogen. The reaction was stirred at room temperature for 1 h, cooled to 0°C, and quenched with 500 mL water. The reaction was extracted with 1 L MTBE. The organic layer was dried over $MgSO_4$, and the solvent was removed in vacuo to give 12.0 g -bromo-1,1,4,4,7-pentamethyl-1,4-dihydronaphtha-lene as a white solid, in a yield of 99%.

Other references related to the Bamford-Stevens reaction are cited in the literature.[16]

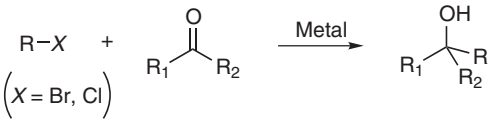
Barbier Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Barbier in 1898,[1] just 2 years earlier than the well-known but closely related *Grignard Reaction*.[2] In the *Grignard Reaction*, alkyl halides react first with magnesium to form Grignard reagents, which further attack the carbonyl groups to form carbon-carbon bonds; however, in the Barbier reaction,[3] both alkyl halides and carbonyl compounds are simultaneously mixed with magnesium turnings and form carbon-carbon bonds in one-step. In the latter case, a much smaller excess of the toxic halide can be used,[4] and similar results, including the R:S ratio, with respect to the *Grignard Reaction* can be obtained.[5] Therefore, the purification procedure is considerably simplified.[4,6] This reaction is known to be preferable for halides, like allyl and benzyl bromides,[7] and is believed to go through the single-electron transfer (SET) process.[8] Currently, many zero-valent metals have been successfully applied to similar reaction conditions, particularly lithium,[9] because it often results in exceptional yields.[10] Even metal halides instead of metal have been applied to this reaction.[11] One important advantage associated with the Barbier reaction over the *Grignard Reaction* is that this reaction tolerates water; and, in fact, many metals have been reported to be effective in mediating the aqueous Barbier reaction, including aluminum,[12a] antimony,[12b] bismuth,[12c,12d] cadmium,[12e] gallium,[12f] indium,[12g–12r] lead,[12s,12t] magnesium,[3b,5,12u] manganese,[12v,12w] samarium,[11d,12x–12ad] tin,[12ae–12jj] and zinc.[12kk–12yy] It has been reported that nonpolar solvents favor R-regioselection,[13a,13b] whereas polar solvents, such as DMSO, which is strongly coordinated[12x–12dd] with the tin of an allylic tin, lead to *γ-syn* selection.[13c] The versatility and mildness of this reaction[12ee–12jj] has been extensively reviewed.[14]

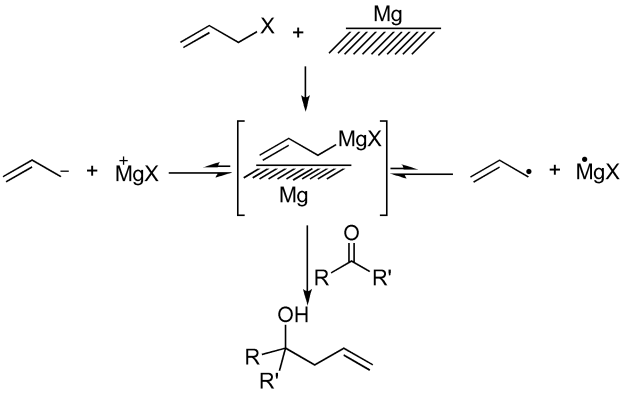
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism of both the Barbier reaction and the *Grignard Reaction* have been extensively studied.[15]It is believed that this reaction occurs at least partially via SET,[8] as illustrated here.[16]



D. MODIFICATION

Compared to the initial reaction conditions, the applications of other metals to this reaction can be considered modifications.

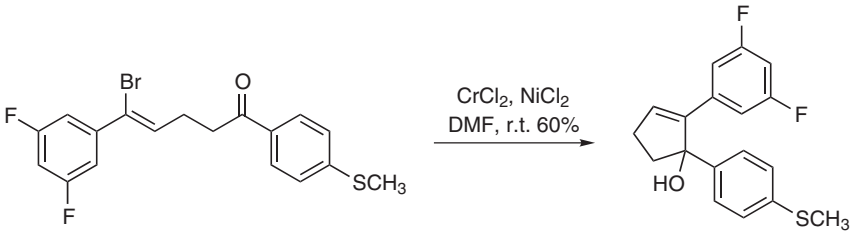
E. APPLICATIONS

This reaction has wide applications in organic synthesis.

F. RELATED REACTIONS

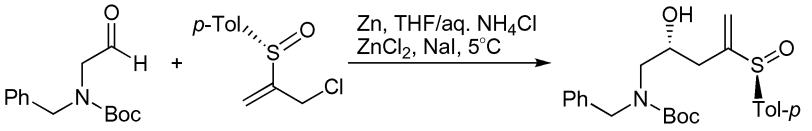
This reaction is closely related to the *Grignard Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



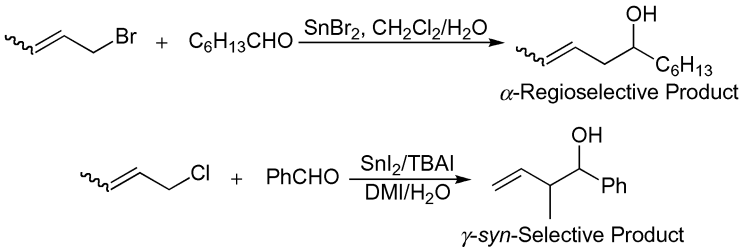
Reference 17.

To a flask in a dry box were added 154 mg chromium(II) chloride (1.25 mmol) and 65 mg nickel(II) chloride (0.5 mmol), and the flask was sealed under argon. To this flask was added a solution of 100 mg 5-bromo-5-(3,5-difluorophenyl)-1-(4-methylsulfanylphenyl)pent-4-en-1-one (0.25 mmol) in 2 mL DMF, and the solution was stirred for overnight at room temperature. The crude reaction mixture was then loaded directly to a silica gel column (3/1 petroleum ether/ethyl ether) to give 48 mg 2-(3,5-difluorophenyl)-1-(4-methylsulfanylphenyl)cyclopent-2-enol as a colorless oil, in a yield of 60%, as well as 12 mg of unreacted starting material (20%). This product was found to be unstable and needed to react in the next step very quickly to prevent decomposition. $R_f = 0.28$ (3/1 petroleum ether/ethyl ether).



Reference 7d.

To a solution of 320 mg (*S*)-allyl chloride (1.5 mmol) in 1 mL THF was added 670 mg NaI (4.5 mmol) under argon. After being stirred for 5 min at room temperature, a solution of the 1.5 mmol aldehyde in 0.5 mL THF was added, followed by the addition of 610 mg $ZnCl_2$ (4.4 mmol) in portions and 7.5 mL saturated aqueous NH_4Cl solution. The reaction mixture was then cooled in an ice water bath, and 150 mg Zn dust (2.3 mmol) was added in portion. After stirring at 0°C for 2 h, the reaction mixture was extracted with 10 mL CH_2Cl_2/Et_2O (1:2) and worked up in the usual way to obtain an oil, which was purified by flash chromatography to give the desired sulfinylamino alcohol, in a yield of 90%, as a 3:1 mixture of diastereomers.



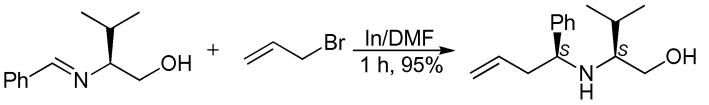
Reference 7f.

α-Regioselective Carbonyl Allylation by 1-Bromobut-2-ene with $SnBr_2$

A typical procedure is as follows: To a solution of 0.56 g $SnBr_2$ (2 mmol) and 0.27 g 1-bromobut-2-ene (2 mmol) in 6 mL mixed solvent of CH_2Cl_2-H_2O (1:1), was added 0.11 g heptanal (1 mmol) at ambient temperature under a nitrogen atmosphere. After being stirred for 24 h, the mixture was diluted with 120 mL of a mixed solvent (ether/dichloromethane = 2:1) and washed successively with 10 mL aqueous 10% HCl solution, 10 mL aqueous $NaHCO_3$ solution, 10 mL water, and 10 mL brine. The extracts were dried over anhydrous $MgSO_4$, and 0.082 g undec-2-en-5-ol (0.48 mmol) was obtained after evaporation of solvent and column chromatography (hexane/EtOAc = 7.1), in a yield of 48%.

γ−*Syn*-Selective Carbonyl Allylation by 1-Chlorobut-2-Ene with SnI_2 and TBAI

A typical procedure is as follows: To a solution of 0.74 g SnI_2 (2.0 mmol), 0.074 g TBAI (0.20 mmol), and 0.30 g NaI (2.0 mmol) in mixed solvent of 3 mL DMI and 0.1 mL H_2O, was added 0.19 mL 1-chlorobut-2-ene (2.0 mmol), followed by 0.10 mL benzaldehyde (1.0 mmol) at ambient temperature under a nitrogen atmosphere. After being stirred for 41 h, the mixture was diluted with 100 mL CH_2Cl_2 and was washed successively with 10 mL aqueous 10% HCl solution, 10 mL aqueous $NaHCO_3$ solution, 10 mL water, and 10 mL brine. The extracts were dried over anhydrous $MgSO_4$ and evaporated to give 0.13 g 2-methyl-1-phenylbut-3-en-1-ol as a colorless oil after column chromatography (hexane/EtOAc = 10:1), in a yield of 83%.



Reference 7e.

General Procedure for the Barbier-Type Allylation

A mixture of 1 mmol imine, 1.5 mmol indium and 1.5 mmol allyl bromide in 5 mL DMF was stirred for 1 h at room temperature under nitrogen. The reaction mixture was evaporated, and EtOAc and 1 N aqueous HCl were added to the resulting suspension and stirred for 30 min. Then 30% NaOH was added to neutralize the resulting solution, which was further stirred for 10 min. The mixture was extracted with EtOAc and washed with brine, dried over anhydrous potassium carbonate, and concentrated under reduced pressure. The mixture was purified by flash silica gel column chromatography with hexane/EtOAc (8:1) to give the product in 95% yield.

Other references related to the Barbier reaction are cited in the literature.[18,19]

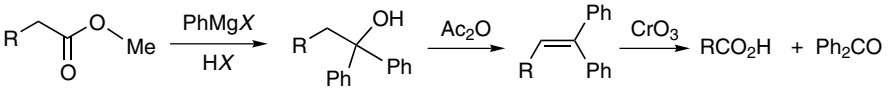
Barbier-Wieland Degradation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was reported independently by Wieland in 1912[1] and Barbier in 1913.[2] However, this reaction is generally known as the Barbier-Wieland degradation.[3] In this reaction, higher-order aliphatic acids (particularly in steroid side chains[3g,3j,4] and side chains of other cyclic compounds[5]) will degrade to the next lower homologs via the consecutive processes of (*a*) the formation of ester, (*b*) the reaction with phenylmagnesium bromide to form carbinol, (*c*) the dehydration to form diphenyl alkenes, and (*d*) the oxidation of alkenes by CrO_3 to give aliphatic acid. This method has been an important method for the elucidation of aliphatic acid structures, although it has failed in a few cases,[6] such as in cyclopropyl acetic acid[7] and lactone.[8] Currently, this method has been modified by using different oxidation reagents,[9] Grignard reagents,[10] and dehydration reagents.[11]

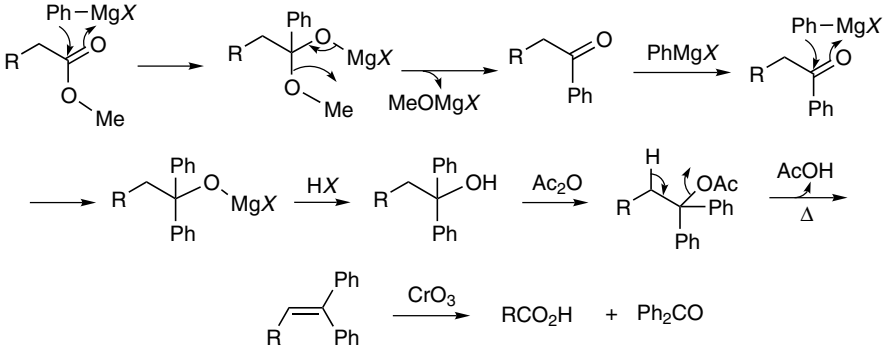
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction is believed to proceed via the process illustrated below.



D. MODIFICATION

The whole process has been modified using different oxidation reagents, such as the mixture of ruthenium tetroxide and sodium metaperiodate;[9] different Grignard reagents, such as methyl magnesium iodide[10] and different dehydration reagents, such as boric acid.[11] Other modifications are cited in Ref. 4b and Ref. 12.

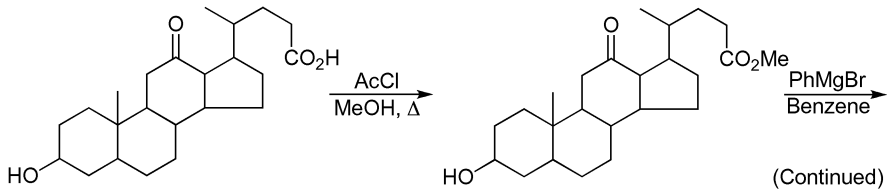
E. APPLICATIONS

This reaction was extensively applied to structural elucidations in the 1930s through the 1950s. Its recent synthetic applications are cited in Ref. 13.

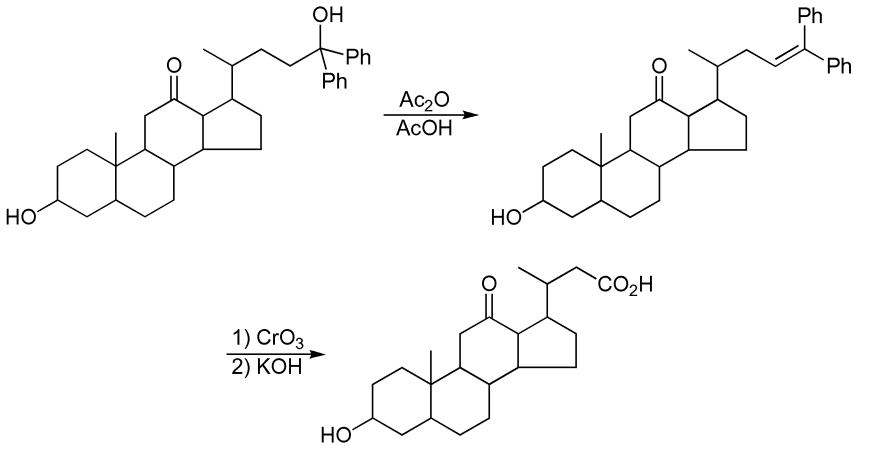
F. RELATED REACTIONS

This reaction is related to the *Miescher Degradation*.

G. CITED EXPERIMENTAL EXAMPLES



(Continued)



Reference 4g.

Preparation of Ester of Methyl 3-Hydroxy-12-Ketocholanate

To a solution of 5.95 g 3-hydroxy-12-ketocholanic acid in 50 mL methanol was added 2 mL acetyl chloride. The solution was refluxed for 15 min and then allowed to stand at room temperature for 3 h. The ester was obtained in crystalline form by carefully diluting the solution to 175 mL with water, in the amount of 5.10 g (99% yield), m.p., 110–112°C.

Preparation of Carbinol of 3-Hydroxy-12-Keto-Nor-Cholanyldiphenylcarbinol

A solution of phenylmagnesium bromide was prepared from 7.78 g magnesium (0.32 mol) and 37.5 mL bromobenzene in 150 mL dry ether. To this solution was added slowly with stirring a solution of 8.05 g methyl 3-hydroxy-12-ketocholanate (0.02 mol) in 150 mL dry benzene. The resulting solution was refluxed for 3.5 h and then decomposed by pouring it into a mixture of 500 mL ice and 50 mL conc. hydrochloric acid. The layers were separated, and the aqueous layer was extracted with ether. The combined ether extracts were washed with dilute hydrochloric acid, water, 5% sodium carbonate solution, and finally with water. The residue left after removing the solvent was steam distilled for 2 h, collected, and dried to give 13.27 g 3-hydroxy-12-keto-nor-cholanyldiphenylcarbinol.

Dehydration of Carbinol

A sample of 7.2 g of the crude 3-hydroxy-12-keto-nor-cholanyldiphenylcarbinol dissolved in 50 mL acetic acid and 25 mL acetic anhydride was refluxed for 2.5 h. The solvent was removed by vacuum distillation, and the gummy residue was dissolved in hot acetone. On standing in the cold room, 1.454 g 3-acetoxy-12-keto-bis-nor-cholanyldiphenylethylene was separated as crystals, in a yield of 24% (based on methyl 3-hydroxy-12-ketocholanate), m.p. 175–178°C

Oxidation of Alkene

To a suspension of 1 g 3-acetoxy-12-keto-bisnor-cholanyldiphenylethylene in 1 mL chloroform and 5 mL acetic acid was added slowly with stirring a solution of 0.63 g chromic acid in 0.5 mL water and 3 mL acetic acid. The temperature was kept at 3.5°C by slight cooling during the addition, which required ~30 min. After stirring for ~5 min more, the excess chromic acid was reduced by adding 2 mL methanol while cooling. The reaction mixture was concentrated in vacuum at room temperature until quite viscous. Water and ether were added, and the aqueous layer was repeatedly extracted with ether. The combined ether extracts were washed several times with dilute hydrochloric acid and then with water. The clear, colorless ether solution was extracted several times with 1% sodium hydroxide solution (total ~70 mL). The basic solution was concentrated to 30–35 mL and 2 g solid sodium hydroxide was added. After refluxing for 1.5 h, it was diluted with water and filtered into 20 mL 6N hydrochloric acid. The 3-hydroxy-12-keto-nor-cholanic acid that precipitated was separated and dried. It weighed 0.470 g and melted at 230–245°C. Crystallization from ethanol gave material melting at 248–250°C, which did not depress the melting point of an authentic sample.

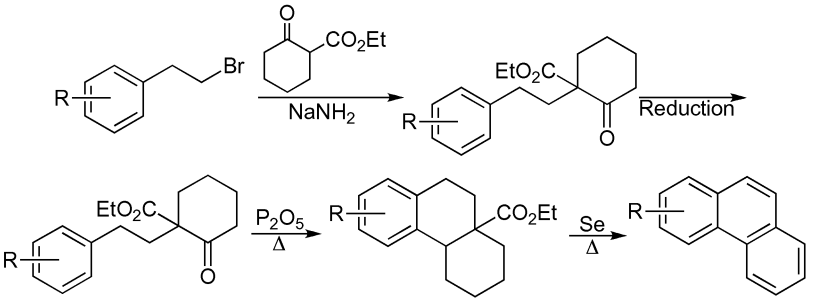
Bardhan Sengupta Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bardhan and Sengupta in 1932.[1] It is the synthesis of phenanthrene via the following consecutive processes: the alkylation of arylethyl halide with cyclohexanone under basic conditions, the reduction of the carbonyl group, cyclization to an aromatic ring in the presence of phosphorus pentoxide, and dehydrogenation to phenanthrene with selenium. Therefore, this reaction is known as the Bardhan-Sengupta synthesis.[2] Unfortunately, Bardhan and Sengupta's original claim of 1,4-dimethylphenanthrene prepared by this reaction has proven to be the 1,3-dimethylphenanthrene.[3] In this reaction, some side products, including the *spiro* compound, might form.[4] The synthesis of phenanthrene has been reviewed.[5]

B. GENERAL REACTION SCHEME

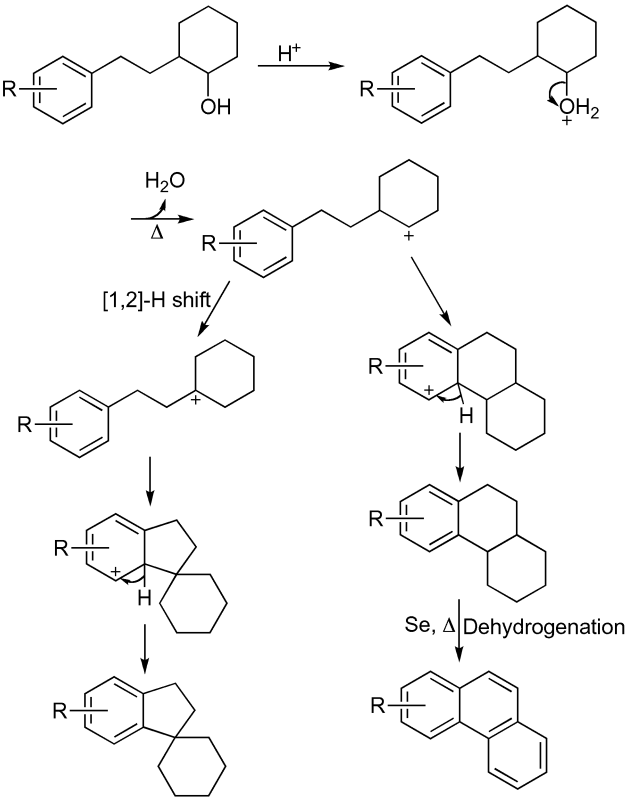
The whole reaction process is illustrated here.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Because the mechanism of this reaction has been studied[6] and is clearly shown in the reaction scheme, only a part of the mechanism is given here. The presence of an ester group in cyclohexanol will prevent the formation of *spiro* cyclics.



D. MODIFICATION

A few modifications have been carried out for this reaction.[6,7] The dehydrogenation of octahydrophenanthrene can also be carried out using sulfur.[8]

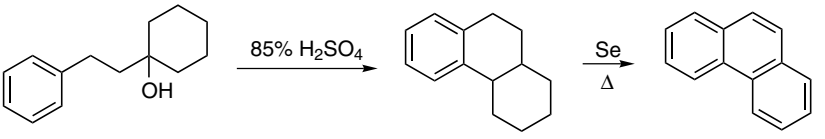
E. APPLICATIONS

This reaction is a general method for synthesizing different phenanthrenes and can be extended to other higher polynuclear aromatics.

F. RELATED REACTIONS

This reaction is related to the *Haworth Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

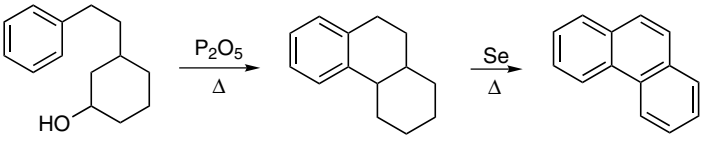
1-β-Phenylethylcyclohexanol was obtained from the *Grignard Reaction* between phenylethyl bromide and cyclohexanone, in a yield of 54%.

Dehydration of Carbinol

1-β-phenylethylcyclohexanol was added slowly with stirring to two volumes of 85% sulfuric acid cooled by ice pack (90% sulfuric acid is needed for the secondary alcohol). When all the alcohol had been added, the stirring was continued for 15–20 min at room temperature, and the mixture was then extracted with petroleum ether. The extract was agitated vigorously two or three times with cold 85% sulfuric acid, until the ether layer was a pale lemon yellow. The reaction mixture was washed with a 10% sodium carbonate followed by a 10% sodium sulfate solution, dried over anhydrous potassium carbonate, and fractioned under vacuum to give 90% yield of octahydrophenanthrene, b.p. 135–137°C at 10 mmHg.

Dehydrogenation of Octahydrophenanthrene by Selenium

The mixture of octahydrophenanthrene and 1.5–2 Eq. selenium in a flask equipped with a long Pyrex tube, which functioned as an air condenser, was heated in a potassium nitrate–sodium nitrate bath at 290–320°C for 14–15 h. The dehydrogenation product was extracted with benzene; the benzene extract was distilled at atmospheric pressure, and the residual was crystallized to give phenanthrene, m.p. 99.5°C.



Reference 6.

Dehydration of Carbinol

The procedure was precisely the same as used by Bardhan and Sengupta by which 5.5 g β-phenylethylcyclohexanol-3 was treated with 11.0 g phosphorus pentoxide, and the product upon distillation over sodium afford 4.1 g 1,2,3,4,4a,9,10,10a-octahydrophenanthrene, in a yield of 81.8%, b.p. 131°C at 5.0 mmHg.

Dehydrogenation of Octaphenanthrene

Octahydrophenanthrene (4.0 g) was heated with 4.0 g 10% palladized charcoal at 210–270°C for ~3 h in a slow steam of carbon dioxide. The mass was cooled and thoroughly extracted with ether. The solvent was removed, and 3.5 g crude phenanthrene was purified through its picrate, affording 3.0 g phenanthrene, m.p., 100°C.

Other refereces related to the Bardhan-Sengupta synthesis are cited in the literature.[9]

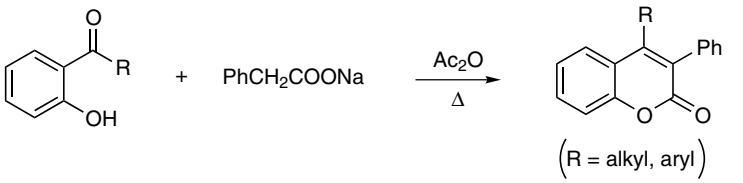
Bargellini Condensation
(Bargellini Coumarin Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bargellini in 1925.[1] It is the synthesis of coumarins from the reaction between *o*-oxyarylketones and sodium phenylacetates in the presence of acetic anhydride. This reaction is based on Bargellini's earlier work in which benzoylacetonitriles condense with polyhydric phenols, such as resorcinol, in the presence of concentrated sulfuric acid to give the corresponding coumarins.[2] Thus this reaction is known as the Bargellini condensation.[3] This reaction is inconvenient from the practical point of view and generally leads to poor yields,[4] so other methods have been developed for preparing coumarins.[5] The Bargellini condensation has been modified via the condensation of *o*-methoxybenzaldehydes with arylacetonitrile and demethylation with pyridine hydrochloride[6] and via 2,5-dimethoxycinnamic acid with boron tribromide.[7]

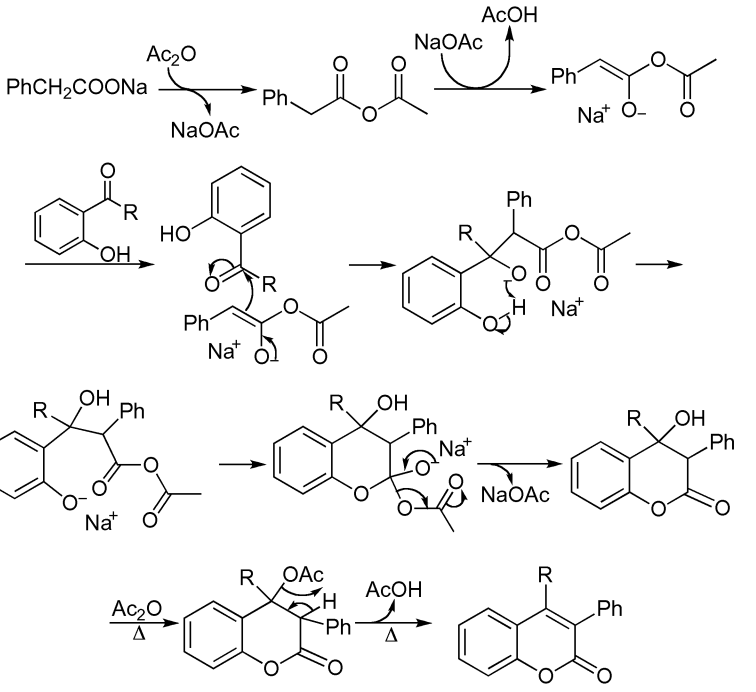
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

An exemplary mechanism is displayed below.



D. MODIFICATION

This reaction has been modified by the condensation of *o*-methoxybenzaldehydes with arylacetonitrile[6] or from the condensation of 2,5-dimethoxycinnamic acid with boron tribromide.[7]

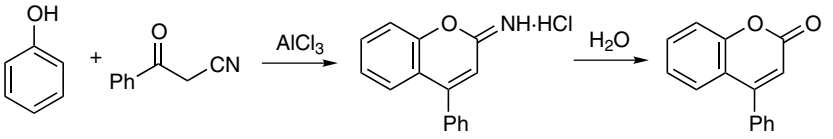
E. APPLICATIONS

This reaction has been applied to the synthesis of different coumarins.

F. RELATED REACTIONS

This reaction is related to the *Perkin Reaction* and *Pechmann Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



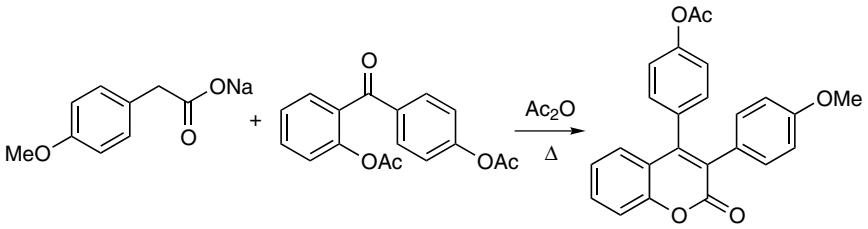
Reference 8.

General Procedure for the Acid-Catalyzed Reaction Between Phenol and Benzoylacetonitrile

To a stirred suspension of 0.1 mol anhydrous aluminum chloride in 15 mL isopropyl ether was added dropwise at 20–30°C a solution of 0.05 mol phenol and 0.05 mol benzoylacetonitrile in 60 mL isopropyl ether. The mixture, into which dry hydrogen chloride was continuously passed, was gradually heated at 50–60°C and kept for 5 h. The resulting mixture was chilled and poured over water containing crushed ice and concentrated hydrochloric acid. After it was stirred for 0.5 h, filtration and drying gave the crude intermediate shown. (Substitution of isopropyl ether for an inert solvent such as *sym*-tetrachloroethane afforded a lower yield of such intermediate.) The formation of such intermediate can also be carried out without any solvent but at a higher temperature (e.g., 70–80°C).

Conversion to Coumarin

The mixture of 0.6 g intermediate and 6 mL water was heated on a steam bath for 3 h. Upon cooling to room temperature, the solution was filtered to give 0.5 g coumarin, in a yield of 95%, m.p. 246–247°C. One recrystallization from the ethanol gave pure coumarin, m.p. 249–250°C.



Reference 4a.

A mixture of sodium *p*-methoxyphenylacetate (prepared from 5.56 g *p*-methoxyphenylacetic acid and 7.20 g 25% methanolic sodium methoxide) and 2,4′-diacetoxybenzophenone was refluxed in 50 mL acetic anhydride for 40 h. When the solution was cooled to room temperature, it was poured into water and stirred for 2 h. The aqueous phase was removed by decantation, and the organic gum was dissolved in methylene chloride. This solution was washed in turn with aqueous-saturated $NaHCO_3$, water, and brine and taken to dryness in vacuo. The residue was recrystallized once from methanol and twice from aqueous acetic acid to give 1.85 g 3-(*p*-methoxyphenyl)-4-(*p*-acetoxyphenyl)-coumarin.

Other references related to the Bargellini condensation are cited in the literature.[9]

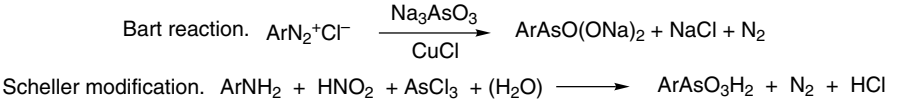
Bart Reaction
(Scheller Modification)

A. GENERAL DESCRIPTION OF THE REACTION

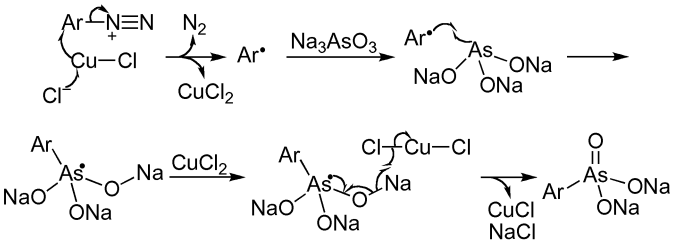
This reaction was first reported by Bart in 1910.[1] It is the synthesis of arylarsenic acids from aromatic diazonium compounds with alkali arsenites in the presence of cupric salts, powdered silver, or copper. Therefore, this reaction is generally known as the Bart reaction.[2] In addition, the reaction between aromatic diazonium and arsenious chloride in the presence of trace amounts of cuprous chloride is referred to as the Scheller modification.[3] Besides the Scheller modification, the Sakellarios modification is the reaction between sulfanilamide and phenyldisodium arenite.[4]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction proceeds via a radical mechanism, as proposed here.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

A few modifications have been developed for the Bart reaction, including the Scheller modification and the Sakellarios modification. The most useful and famous one is the Scheller modification.

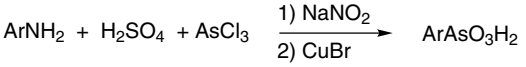
E. APPLICATIONS

This reaction can be applied for synthesizing aromatic arsenic acid, which has important applications in the pharmaceutical industry for isotopic labeling (^{76}As has a half-life of 26 h).[5] In addition, this reaction can be used to prepare arylstibonic acid,[6] and even other metals can be bounded to the aromatic ring in a similar fashion to form metallic aromatics, such as mercury,[7] tin,[8] lead,[9] and bismuth.[10]

F. RELATED REACTIONS

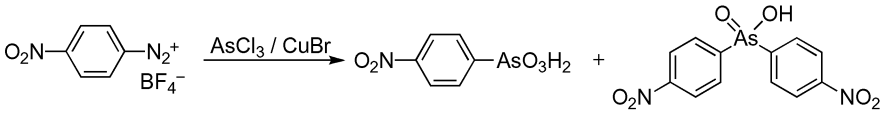
This reaction is related to the *Béchamp Reduction, Sandmeyer Reaction*, and *Rosenmund Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 11.

To a mixture of 0.1 mol aromatic amine, 10 g sulfuric acid, and 28 g arsenous chloride ($AsCl_3$) in 250 mL absolute alcohol cooled at 0°C was added an equivalent amount of saturated aqueous solution of sodium nitrite, using starch-iodide paper to protect the end point. Then, and not before, 1 g cuprous bromide was added to the mixture, and the resulting mixture was stirred vigorously. The solution was warmed to 60°C until no more nitrogen was evolved, then the reaction mixture was steam distillated to afford the corresponding arsonic acid, which can be further purified via recrystallization.



Reference 12.

To a two-necked flask equipped with a sealed stirrer and an outlet tube connected to a water trap were added 125 mL solvent and 0.1 mol *p*-nitrobenzenediazonium fluoroborate,

then 0.1 mol arsenic trichloride and 2 g catalyst (CuBr or CuCl) were added. In the majority of experiments, nitrogen was evolved immediately upon starting the stirring. After the evolution of nitrogen, the mixture was steam distilled to remove the organic solvent and volatile by-product. The residual liquid in the flask was condensed to 100 mL; on cooling, the precipitate was filtered and dissolved in sodium carbonate solution to remove the small amount of impurity. The filtrate was acidified to congo red with concentrated hydrochloric acid, and the mixture of *p*-nitrobenzenearsonic and *bis*-(*p*-nitropheny1)-arsinic acids was removed by filtration. The mixture was extracted with boiling water. The primary acid crystallized out of this solution and was purified by two recrystallizations from hot water. The water-insoluble portion, which consisted of crude secondary acid, was recrystallized from hot alcohol.

Other references related to the Bart reaction are cited in the literature.[13,14]

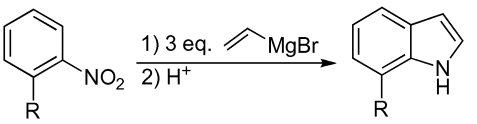
Bartoli Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Giuseppe Bartoli in 1989.[1] It is the treatment of an *ortho*-substituted nitroarenes with 3 eq. of vinylmagnesium bromide to afford 7-substituted indole,[2] and is generally known as the Bartoli indole synthesis.[3] Currently, this reaction has rapidly become the shortest and most flexible approach for indoles with 7-substituents.[2] In fact, this reaction is based on Bartoli's earlier work, in which he had extensively studied the reaction between nitroarenes and a lesser amount of Grignard reagents and found that aromatic nitroso compounds can be formed by using 2 eq. of vinylmagnesium bromide and nitroarenes.[4]

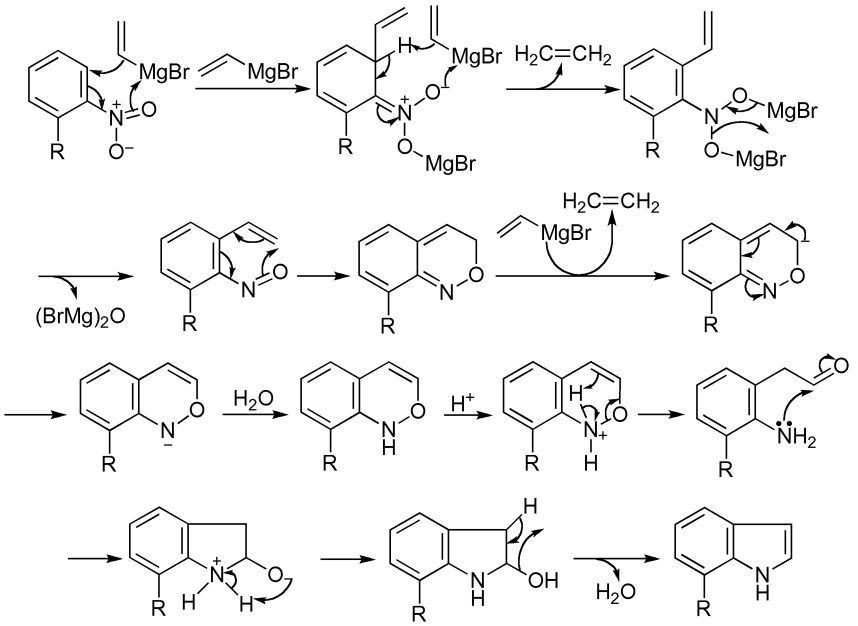
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism for Bartoli indole synthesis is proposed[5] as shown below, according to the fact that nitroso compounds may be generated from nitroarenes and 2 equivalents of Grignard reagents.[4]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

The reaction has been modified to take place on solid-state supporting material.[6]

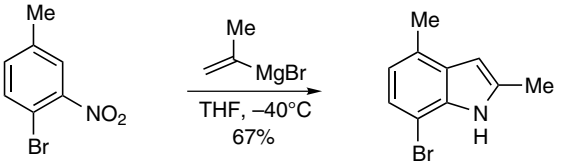
E. APPLICATIONS

Besides the general application in the preparation of 7-substituted indoles,[1,2] Bartoli indole synthesis has found other applications, including the synthesis of azaindoles[7] and optically pure 7-alkoxyltryptophan.[8]

F. RELATED REACTIONS

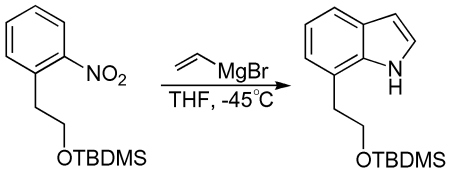
N/A

G. CITED EXPERIMENTAL EXAMPLES



Referece 2a.

To a two-necked flask equipped with a gas inlet (argon) and rubber septum was added 5.0 mmol 3-nitro-4-bromo-toluene. The flask was purged several times with argon before the addition of 35–40 mL dry THF and being cool to between -40° and -45°C. Then 15.0 mmol isopropenyl magnesium bromide (3 eq.) was added rapidly in one portion to the THF solution and stirred for a further 30–60 min (the exact length of time had no effect on the yield). Saturated ammonium chloride solution was added to the reaction mixture (at $\sim -40^\circ$C) before the mixture was allowed to warm to room temperature. The mixture was thoroughly extracted with diethyl ether (2×200 mL); the ether extracts were combined and thoroughly washed with a further 300 mL saturated ammonium chloride, 300 mL water, and 300 mL brine. They were dried over $MgSO_4$. Evaporation of the solvent and flash column chromatography (hexane/EtOAc = 9:1) afford 67% of 2,4-dimethyl-7-bromo-indole.



Reference 9.

The solution of 85.6 g *tert*-butyldimethyl[2-(2-nitrophenyl)ethoxy]silane (304 mmol) in 1000 mL THF was cooled to -65°C, and 913 mL 1.0 M solution of vinylmagnesium bromide in THF (913 mmol) was introduced while maintaining a temperature below -60°C. The reaction was stirred for 15 min at -45°C, then an additional 152 mL vinylmagnesium bromide (152 mmol) was added, and the reaction was stirred at -45°C for 30 min. The cold reaction solution was poured into 800 mL saturated NH_4Cl and extracted with EtOAc (500 mL, 200 mL, and 200 mL). The organic layers were combined, washed with 400 mL brine, and dried over $MgSO_4$. Upon removal of the solvent in vacuo, the residue was purified by silica gel chromatography using hexane/EtOAc (95:5) as the eluent to give 47.1 g 7-[2-(*tert*-butyldimethylsilanyloxy)ethyl]-1H-indole, in a yield of 56%.

Other references related to the Bartoli indole synthesis are cited in the literature.[10]

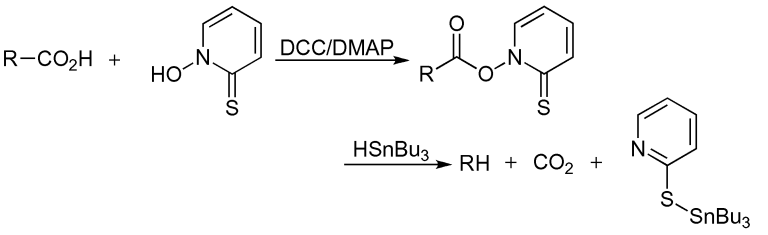
53

Barton Decarboxylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Barton in 1983.[1] It is a radical decarboxylation of organic acids to generate alkanes via a two-step process: the formation of thiohydroxamic acid esters of the corresponding organic acid[2] and the addition of a radical initiator and the radical transfer reagents of a good H-atom donor such as tri-*n*-butyltin hydride [$HSnBu_3$],[3] *t*-butylmercaptan [*t*-BuSH],[4] phenylselenol [PhSeH],[4] and tri(trimethylsilyl)silane [$(Me_3Si)_3SiH$].[5] Therefore, this reaction is generally known as the Barton decarboxylation,[6] or by the less common name Barton's radical decarboxylation.[7] However, THF cannot be applied as the H-atom donor,[8] besides the application of a radical initiator, the Barton decarboxylation can also be initiated by either photolysis[9] or sonication.[10] This important reaction has been extensively reviewed.[11]

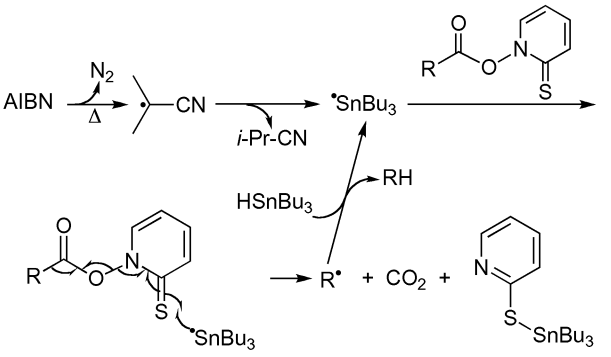
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

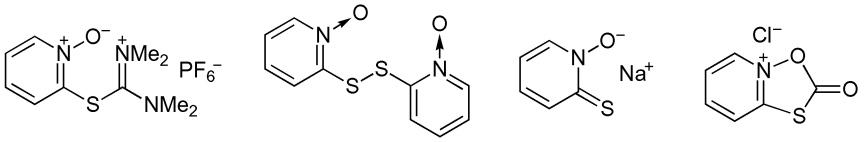
C. PROPOSED MECHANISMS

Displayed here is the mechanism for the Barton decarboxylation.



D. MODIFICATION

The formation of thiohydroxamic acid esters has been modified using different sources, including S-(1-oxido-2-pyridinyl)-1,1,3,3-tetramethylthiouronium hexafluorophosphate,[12a] 2,2-dithiopyridine-1,1-dioxide,[5] sodium salt of *N*-hydroxy-2-thiopyridine,[12b] and thiocarbonate.[12c] The structures of these thiohydroxamic acid sources are illustrated below. On the other hand, the decarboxylation has been modified using other good H-atom sources,[4,5] and via initiation from photolysis[9] and sonication.[10] When thiohydroxamic acid ester reacts with diphenyldiselenide, phenylselenide forms.[12c]



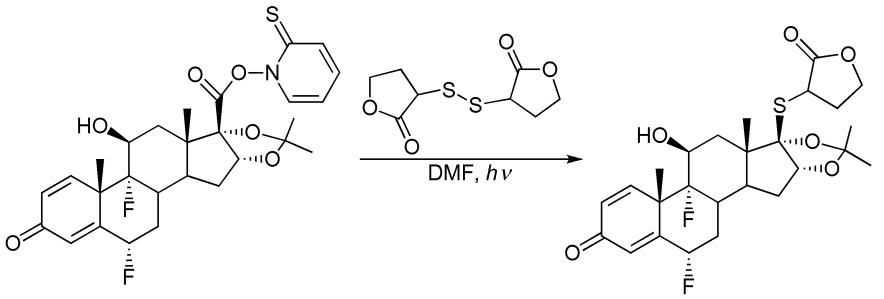
E. APPLICATIONS

This reaction is generally applied for removing the carboxylic group on organic compounds.

F. RELATED REACTIONS

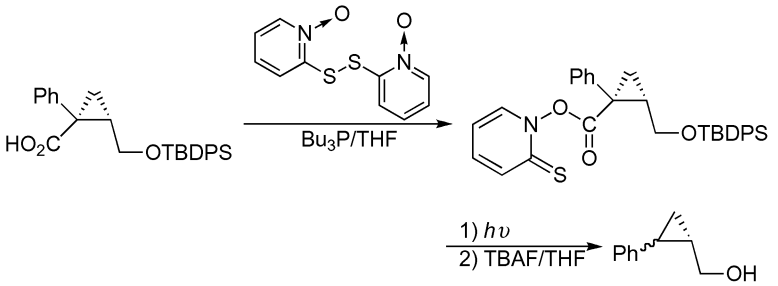
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

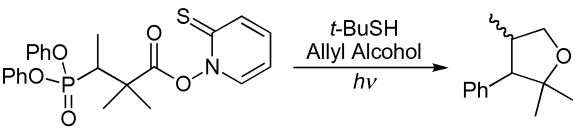
A solution of 2.50 g 2-thioxo-2H-pyridin-1-yl ester of 6α,9α-difluoro-11β-hydroxy-16α,17α-isopropylidenedioxy-3-oxoandrosta-1,4-diene-17β-carboxylic acid (4.57 mmol) in 15 mL dry DMF was added to a stirred suspension of 2.15 g butyrolactone disulfides (9.17 mmol) in 15 mL dry DMF under nitrogen at 0°C. The resulting mixture was then subjected to irradiation by two 200-W tungsten filament light bulbs for approximately 4 h. The reaction mixture was diluted with 650 mL EtOAc and washed with brine, water, 2 M HCl, water, saturated $NaHCO_3$, water and brine (200 mL each). The organic solution was dried, the solvent was removed under reduced pressure, and the residue was chromatographed on silica gel using $CHCl_3$/MeOH (50:1) as the eluent. The concentrated product was further purified by HPLC (60% MeCN-H_2O) to give 635 mg 6α,9α-difluoro-11β-hydroxy-16α,17α-isopropylidenedioxy-17β-(2-oxo-tetrahydrofuran-3-ylsulfanyl)androsta-1,4-dien-3-one as a white crystalline solid, in a yield of 27%.



Reference 5.

A mixture of 86.0 mg (1*S*,2*R*)-1-(*tert*-butyldiphenylsilyloxy)methyl)-2-carboxy-2-phenylcyclopropane (0.20 mmol), 61.0 mg 2,2-dithiopyridine-1,1-dioxide (0.24 mmol), 125 μL Bu_3P (0.50 mmol), and 1.0 mmol of a hydrogen donor (5 eq.) in 5 mL solvent (THF, benzene, or chlorobenzene) was stirred at room temperature under shading. After the disappearance of (1*S*,2*R*)-1-(*tert*-butyldiphenylsilyloxy)methyl-2-carboxy-2-phenylcyclopropane on TLC, the radical reaction was carried out by the addition of an initiator (Et_3B and Me_2Zn, 0.3 eq. or AIBN, 0.2 eq.) or irradiation with a high-pressure mercury lamp (300 W). The resulting reaction mixture was evaporated, and the residue was partitioned between EtOAc and H_2O. The organic layer was washed with brine, dried over Na_2SO_4, and evaporated. The residue was purified by column chromatography (silica gel,

hexane/*i*-Pr_2O, 100:1) to give the reductive decarboxylation products as an oil. A mixture of the oil and 400 μL TBAF (1.0 M in THF, 0.40 mmol) in 5 mL THF was stirred at room temperature for 12 h and then evaporated. The residue was partitioned between EtOAc and H_2O, and the organic layer was washed with brine, dried over Na_2SO_4, and evaporated. The residue was purified by column chromatography (silica gel, hexane/EtOAc, 9:1) to afford 1-phenyl-2-hydroxymethyl-propane as an oil.



Reference 14.

A solution of 0.107 g carboxylic acid, 2-thioxo-2H-pyridin-1-yl ester (0.2 mmol), and 45.3 μL *tert*-butylthiol (0.4 mmol) in 4.0 mL allyl alcohol in a Pyrex flask was photolyzed at room temperature with a 250-W Philips krypton lamp for 1 h. After removal of the volatiles under vacuum, ^1H and ^{31}P NMR spectra indicated a clean reaction and complete conversion of carboxylic acid, 2-thioxo-2H-pyridin-1-yl ester with essentially quantitative formation of diphenyl phosphate (^{31}P NMR δ -10.36 in $CDCl_3$). Purification by preparative TLC (hexane/EtOAc = 20:1) gave 32.0 mg *cis/trans*-2,2,4-trimethyl-3-phenyltetrahydrofuran as the major product, in a yield of 82%.

Other references related to the Barton decarboxylation are cited in the literature.[15]

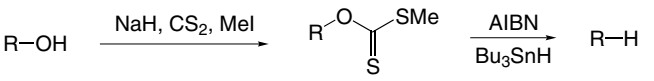
Barton Deoxygenation
(Barton-McCombie Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Barton and McCombie in 1975.[1] It is a two-step process for removing the hydroxyl group of an alcohol involving the initial acylation of such alcohol to the corresponding xanthate followed by a reductive cleavage of the resultant thiocarbonyl compound in the presence of a good H-atom donor/radical initiation system. Therefore, this reaction is generally known as the Barton deoxygenation[2] or the Barton-McCombie reaction.[3] The H-atom donor/radical initiation system used in this reaction includes tributyltin hydride/AIBN, tributyltin hydride/Et_3B,[4] diphenylsilane/peroxide (or Et_3B),[5] trialkylsilane/peroxide/thiol,[6] 5,10-dihydrosilanthrene/AIBN,[3c] tris(trimethylsilyl)silane/AIBN,[7] dibutylphosphine oxide/AIBN (or Et_3B),[8] phosphine-borane/AIBN,[9] H_3PO_2/Et_3N/AIBN,[10] and tetraphenyldisilane/AIBN.[11] As of today, this reaction has become the most effective and practical deoxygenation method of the hydroxyl group in organic compounds (especially carbohydrates, nucleosides, and nucleotides) and has found widespread application in synthetic organic chemistry. Due to some intrinsic problems with the Barton deoxygenation—toxic tin hydride and disposal problems—the original procedure has been modified via the preparation of different xanthates (with CH_3, SCH_3, Ph, OPh, or imidazolyl on xanthates)[12] and the application of different reduction systems.[3c,5–10] Other modifications include the application of a catalytic amount of tributyltin hydride rather than 1.5–3 equivalents of Bu_3SnH at the reduction step under normal conditions[13] and a single-step procedure that does not use the metal hydride reagent.[14] The reactivity of Barton deoxygenation is observed in the following order: primary alcohol > secondary alcohol > tertiary alcohol. This reaction has been extensively reviewed.[15]

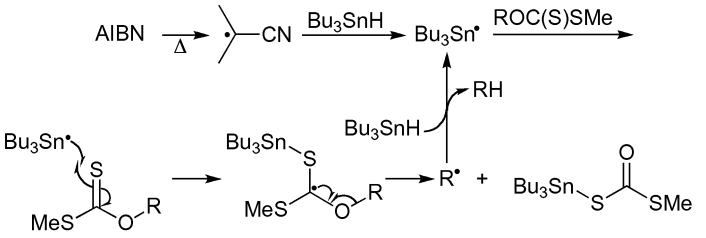
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction involves a rapid, reversible addition of the stannyl radical to the thiocarbonyl group followed by a slower fragmentation of the radical, with cleavage of the carbon oxygen bond.[3f,4b,4e,15]



D. MODIFICATION

The original procedure has been extensively modified, including the preparation of different xanthates, the application of different reduction systems, and the use of a catalytic amount of tributyltin hydride. Other modifications are collected in the literature[16] including the photolysis of a carbazole in the presence of $Mg(ClO_4)_2$[16a] or benzoates[16b] and the formation of alkyl halide using carbon tetrachloride or bromotrichloromethane as the solvent instead of the tin hydride.[16c]

E. APPLICATIONS

This reaction has found widespread application in organic synthesis, especially in the preparation of deoxy carbohydrates, deoxy nucleosides, and nucleotides. In addition, this reaction can also be applied for converting aldehydes/ketones to alkanes after the reduction of the carbonyl groups.[17] Unfortunately, this reaction has failed in a few circumstances.[18]

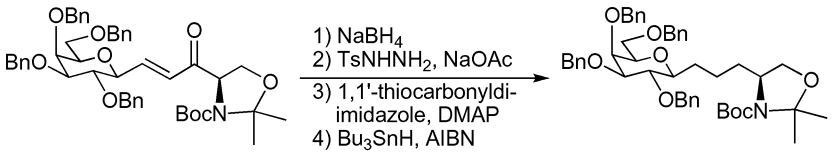
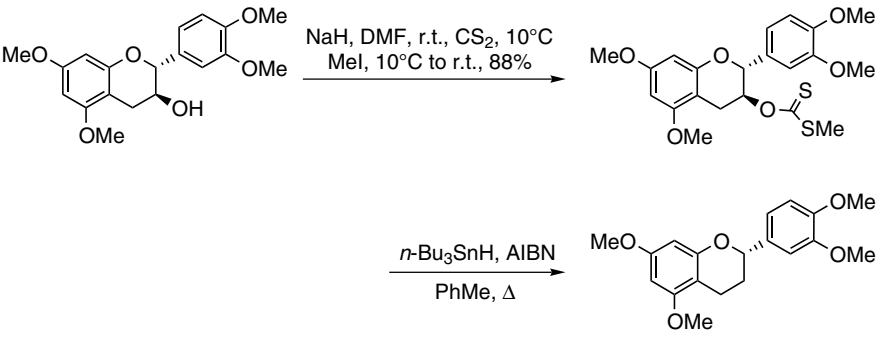
G. CITED EXPERIMENTAL EXAMPLES



Reference 19.

To a solution of 400 mg (E)-6,10-anhydro-7,8,9,11-tetra-*O*-benzyl-2,4,5-trideoxy-1,2-*N*,*O*-isopropylidene-2-(*tert*-butoxycarbonylamino)-D-*threo*-L-*galacto*-undec-4-en-3-ulose (0.51 mmol) in a mixed solvent of 1.5 mL MeOH and 1.5 mL Et_2O cooled at 0°C, was added 41 mg $NaBH_4$ (1.07 mmol) under stirring. The mixture was stirred at 0°C for 10 min and at room temperature for 10 min, then diluted with 1.0 mL acetone and partially concentrated. The residue was suspended in 100 mL CH_2Cl_2, washed with H_2O (2 × 10 mL), dried over $MgSO_4$, and concentrated. To the solution of crude allylic alcohol and 285 mg freshly recrystallized *p*-tolenesulfonylhydrazide (1.53 mmol) in 7 mL dimethoxyethane at 85°C was added 1.53 mL 1 M aqueous sodium acetate in six portions over 3 h. After an additional 2.5 h at 85°C, the mixture was diluted with 5 mL H_2O and extracted with CH_2Cl_2 (2 × 30 mL). The organic phase was dried over $MgSO_4$ and concentrated. The residue was eluted from a silica gel column with cyclohexane/EtOAc (from 9:1 to 4:1) to give 311 mg of a ~6:1 mixture of diastereomeric alcohol 3-hydroxy-6,10-anhydro-7,8,9,11-tetra-*O*-benzyl-2,4,5-trideoxy-1,2-*N*,*O*-isopropylidene-2-(*tert*-butoxycarbonylamino)-D-*lyxo*-D-*manno*- and -D-*altro*-undecitol (**1**, 3R/3*S* = ~1:1) and their C-5 transposed isomers 5-hydroxy-6,10-anhydro-7,8,9,11-tetra-*O*-benzyl-2,4,5-trideoxy-1,2-*N*,*O*-isopropylidene-2-(*tert*-butoxy-carbonylamino)-D-*lyxo*-D-*manno*- and -D-*altro*-undecitol (**2**, 5R/5*S* = ~1:1), in a yield of 78%. An analytical sample of 3-hydroxy-6,10-anhydro-7,8,9,11-tetra-*O*-benzyl-2,4,5-trideoxy-1,2-*N*,*O*-isopro-pylidene-2-(*tert*-butoxy-carbonylamino)-D-*lyxo*-D-*manno*- and -D-*altro*-undecitol was obtained by preparative TLC (2.5:1 cyclohexane/EtOAc).

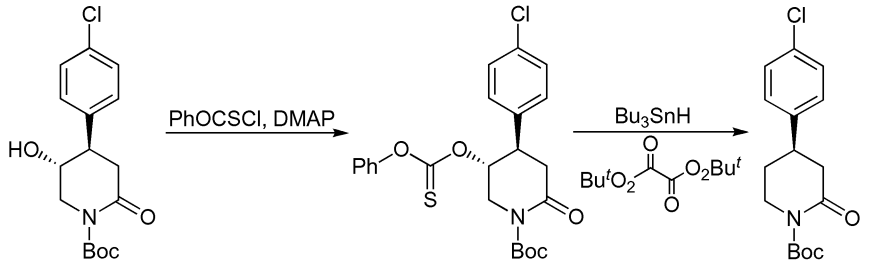
To the solution of 300 mg of a ~6:1 mixture of **1** and **2** (0.38 mmol) in 3 mL anhydrous THF at 70°C, were added 677 mg 1,1′-thiocarbonyldiimidazole (3.80 mmol) and 696 mg 4-*N*,*N*-(dimethylamino)pyridine (5.70 mmol) under stirring. After an additional 6 h at 70°C, the mixture was concentrated. The residue was eluted from a short silica gel column (1.5 × 8 cm, d × h) with 2.5:1 cyclohexane/EtOAc to give 285 mg of the corresponding thiocarbonylimidazolides (83%), which were slightly contaminated by uncharacterized by-products. To a solution of 285 mg thiocarbonylimidazolides (~ 0.32 mmol) in 3.0 mL anhydrous toluene at 85°C were added 0.86 mL Bu_3SnH (3.20 mmol) and 5.3 mg AIBN (0.032 mmol) under stirring. The solution was stirred at 85°C for an additional 2 h and then concentrated. The residue was eluted from a silica gel column (3.5 × 15 cm, d × h) with 10:1 cyclohexane/EtOAc to give 185 mg 6,10-anhydro-7,8,9,11-tetra-*O*-benzyl-2,4,5-trideoxy-1,2-6,10-anhydro-7,8,9,11-tetra-*O*-benzyl-2,3,4,5-tetradeoxy-1,2-*N*,*O*-isopropylidene-2-(*tert*-butoxycarbonyl-amino)-D-*threo*-L-*galacto*-undecitol as a syrup, in a yield of 63%.



Reference 20.

To a solution of 1.84 g 5,7,3′,4′-tetra-*O*-methylcatechin (5.31 mmol) in 5 mL DMF was added 0.25 g 60% NaH in oil (6.4 mmol) all at once. The mixture was stirred with a powerful magnetic stirrer at room temperature (mild exotherm) for 10 min while hydrogen evolved, and then it was immersed in a +10°C water bath; 0.48 mL of CS_2 (8.0 mmol) was added dropwise in 5 min, and stirred at +10°C for 10 min. To the resulting yellow to amber suspension was added 0.50 mL MeI (8.0 mmol) dropwise in 5 min. Halfway through the addition, the stirrer stopped, and the mildly exothermic addition was continued without cooling to reduce viscosity. The reaction mixture remained pasty and soon hardened; it was left at room temperature for 20 min and then dissolved in the mixed solvent of 40 mL H_2O and 60 mL toluene. The phases were separated, and the aqueous phase was extracted with 20 mL toluene. The combined organic phases were washed with 40 mL H_2O and concentrated, and the residue was chromatographed on SiO_2 first with CH_2Cl_2/hexane (1:1) to remove a forerun and then with CH_2Cl_2/EtOAc (19:1) to elute the product. Mixed fractions with a nonpolar contaminant were again subjected to column chromatography (SiO_2, EtOAc/CH_2Cl_2/hexane 1:7:12 for forerun, 1:19:0 for product), and all product-containing fractions were combined, evaporated, and dried in vacuo to yield 2.04 g 5,7,3′,4′-tetra-*O*-methyl-3-*O*-[[(methylthio)thiocarbonyl]-oxy]catechin as a yellowish solid, in a yield of 88%.

A stirred solution of 4.17 g intermediate 5,7,3′,4′-tetra-*O*-methyl-3-*O*-[[(methylthio)thiocarbonyl]-oxy]catechin (9.55 mmol) in 150 mL anhydrous toluene was heated to reflux under nitrogen and a solution of 10.3 mL *n*-Bu_3SnH (38.2 mmol) and 0.31 g AIBN (1.9 mmol) in 80 mL anhydrous toluene was added dropwise through the reflux condenser over a period of 4.25 h. Reflux was continued for 4 h. The cooled reaction mixture was directly chromatographed on SiO_2. A forerun was eluted using toluene, and then a mixture of (2*S*)-5,7,3′,4′-tetramethoxyflavan and a slightly more polar impurity was eluted using toluene/EtOAc (12:1). A late fraction containing mostly impurity was set aside for the isolation of the impurity; from the remaining mixture, (2*S*)-5,7,3′,4′-tetramethoxyflavan was isolated by further column chromatography on SiO_2 with EtOAc/$CHCl_3$/hexane (1:7:12). Evaporation and drying in vacuo yielded 2.52 g (2*S*)-5,7,3′,4′-tetramethoxyflavan as a colorless glass, in a yield of 80%.



Reference 21.

To a solution of 0.31 g (*R*)-1-(*tert*-butyloxycarbonyl)-4-(4-chlorophenyl)-5-hydroxyl-2-piperidone (0.93 mmol) and 0.20 g phenyl chlorothionoformate (1.14 mmol) in 15 mL CH_2Cl_2 was added a solution of 2.17 g 4-(dimethylamino)pyridine (DMAP) (17.8 mmol) in 15 mL CH_2Cl_2 under nitrogen and within a period of 15 min. After stirring for 18 h at 25°C, the reaction mixture was quenched with 1 M HCl, and then 40 mL CH_2Cl_2 was added. The organic phase was washed twice with 1 M HCl and subsequently with a saturated aqueous solution of $NaHCO_3$ and brine. The dried organic phase over Na_2SO_4 was evaporated, and the residue was subjected to column chromatography (light petroleum-EtOAc) to give 0.37 g phenyl thiocarbonate, in a yield of 85%, m.p. 153–154°C, $[R]_D^{20} = +31^\circ$ (c = 1.2, CH_2Cl_2).

To a solution of 0.35 g (4*R*,5*R*)-1-(*tert*-butyloxycarbonyl)-4-(4-chlorophenyl)-5-[*O*-(phenyloxythiocarbonyl) hydroxy]-2-piperidone (0.75 mmol) in 50 mL acetone were added 0.30 g tributyltin hydride (1.39 mmol) and subsequently 10 mg di-*tert*-butyl peroxyoxalate. The solution was left at 25°C for 18 h. The opalescent solution was evaporated, and the oily residue was subjected to column chromatography (light petroleum-EtOAc) to give 0.22 g (*R*)-1-(*tert*-butyloxycarbonyl)-4-(4-chlorophenyl)-2-piperidone, in a yield of 94%, m.p. 95.0–96.0°C, $[R]_D^{20} = +22^\circ$ (c = 2.1, CH_2Cl_2).

Other references related to the Barton deoxygenation (or the Barton-McCombie reaction) are cited in the literature.[22]

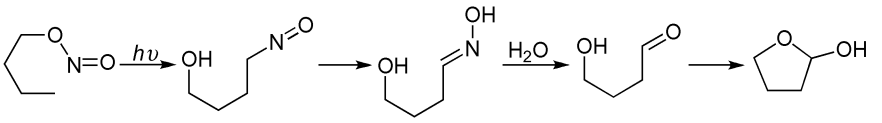
Barton Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was reported by Barton in 1960.[1] It is the transformation of a nitrite ester into a nitroso alcohol under photolytic conditions and involves the homolytic cleavage of a nitrogen-oxygen bond followed by an intramolecular δ-hydrogen abstraction with the resulting oxygen-centered radical.[2] Thus this reaction is known as the Barton reaction.[3] The formed nitroso compound can tautomerize to an oxime derivative that further hydrolyzes to aldehyde[1] or can be oxidized to nitrile.[4] This reaction is useful in the conversion of the angular methyl groups (Δ methyl groups) in steroids into carbonyl groups.[1,5]

B. GENERAL REACTION SCHEME

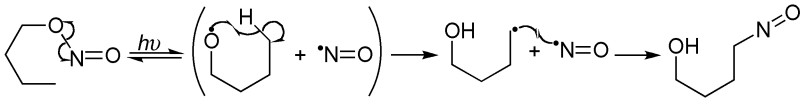


C. PROPOSED MECHANISMS

Although the mechanism of this reaction has been extensively studied,[4,6] it is believed that the homolytic cleavage of the nitrogen-oxygen bond is reversible, which initially

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

conforms to a geminate recombination.[4] However, in the subsequent stages, the partners are separated; therefore, the "solvent cage" effect is not shown in this reaction, as illustrated here in detail for the transformation of nitrite ester into nitroso compound.



D. MODIFICATION

N/A

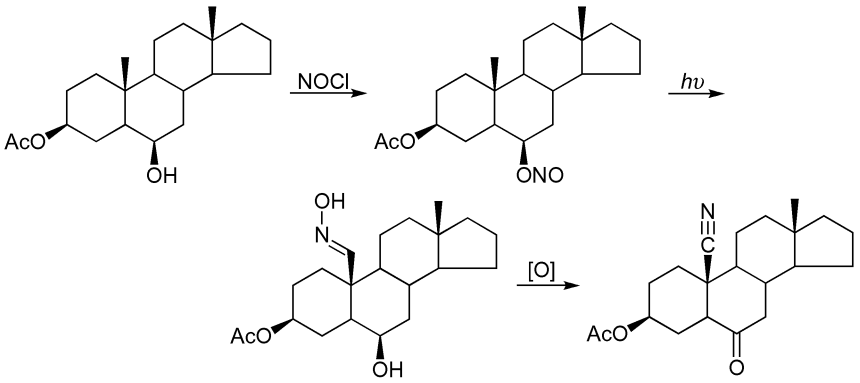
E. APPLICATIONS

This reaction has been applied for activating the methyl group that is three carbon atoms away from the hydroxyl group, especially for methyl groups occurring in steroids.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

A solution of 600 mg 3β-acetoxy-6β-hydroxyandrostane in 10 mL pyridine at 0°C was treated with an excess of nitrosyl chloride. The product was worked up as usual (extraction); after crystallization from methylene chloride-hexane, 500 mg 3β-acetoxyandrostan-6β-yl nitrite was obtained, m.p. 135–138°C.

A solution of 70 mg 3β-acetoxyandrostan-6β-yl nitrite in 2 mL toluene was photolyzed in a Pyrex test tube at 4°C using a 200-w Hanovia high-pressure mercury arc lamp. After 15 min the nitroso dimmer was filtered off and washed with toluene. The dimmer was refluxed in 5 mL isopropyl alcohol for 1 h. Evaporation of the solvent furnished a noncrystalline oxime. This oxime in 2 mL pyridine was treated with 200 mg chromium trioxide in 7 mL pyridine at room temperature overnight and worked up as usual. Crystallization from methylene chloride-methanol gave 25 mg 3β-acetoxy-19-nitriloandrostan-6-one, m.p. 230–236°C.

Reference 7.

A stream of NOCl, generated from 87.4 g $NaNO_2$ and 509 mL 35% HCl, was introduced to an ice cold solution of 298 g alcohol **1** (0.634 mol) in 3 L pyridine at −40°C over 30 min. The mixture was stirred at −40°C for 30 min and poured into 4.4 L ice water. The resulting precipitate was collected by filtration and washed with 2.5 L H_2O. The wet precipitate was dissolved in a mixture of 2.9 L CH_2Cl_2 and 52 mL pyridine, and the organic layer was separated and concentrated. The residue was triturated with 1.2 L hexane, and the white powder was filtered and washed with 0.5 L hexane to give 296 g nitrite ester **2**, in yield of 94%, m.p. 254–258°C (dec.), $R_f = 0.68$ (CH_2Cl_2/EtOAc = 8/1).

A solution of 20 g nitrite ester **2** in 1.2 L acetone containing a small amount of pyridine (0.16 mL) was irradiated with a high-pressure mercury lamp (400 W) through a Pyrex filter under nitrogen atmosphere for 1 h. A total of 14 batches of the photoreaction mixture were combined and concentrated, and 1.4 L 1,2-dichloroethane was added to the residue; the solution was refluxed for 1.5 h. The resulting slurry was collected by filtration and washed with dichloroethane to give 206 g oxime **3** as white crystals, in a yield of 74%. The filtrate was concentrated to 1.2 kg, and an additional 31 g oxime **3** was obtained (11%) as a crystalline powder. The total yield was 85%, m.p. 285–289°C (dec.), $R_f = 0.16$ (CH_2Cl_2/EtOAc = 8:1).

Other references related to the Barton reaction are collected in the literature.[8]

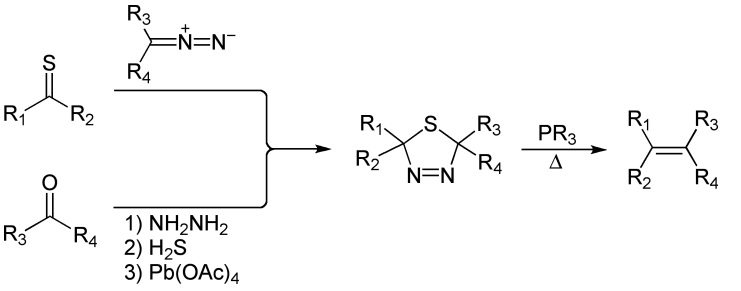
Barton-Kellogg Olefination

(Barton-Kellogg Olefin Synthesis; Barton-Kellogg Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Barton[1] and Kellogg[2] concurrently in 1970. It is the coupling of two ketones into alkenes, particularly applicable to the synthesis of moderately to highly hindered alkenes. Therefore, it is generally known as the Barton-Kellogg olefination,[3] Barton-Kellogg olefin synthesis,[4] or Barton-Kellogg reaction.[5] In this reaction, the steric constraints are gradually introduced via sequential processes involving a *1,3-Dipolar Cycloaddition* to form five-membered Δ^3-1,3,4-thiadiazoline, followed by the nitrogen elimination to three-membered episulfide, and finally the sulfur extrusion to afford the alkenes.[6] Although this reaction can be used for the synthesis of asymmetric alkenes from two different ketones, symmetric alkenes will always be formed as by-products.

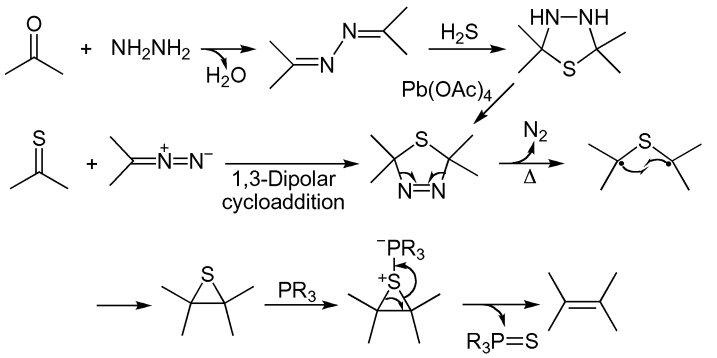
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is the olefination mechanism.



D. MODIFICATION

N/A

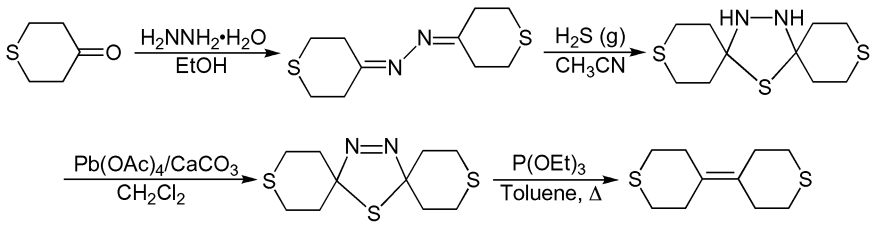
E. APPLICATIONS

This reaction has been applied for synthesizing alkenes, especially those overcrowded alkenes.[7]

F. RELATED REACTIONS

The *McMurry Reaction* is similar to the Barton-Kellogg reaction. However, the *McMurry Reaction* is unsuccessful for preparing some of the overcrowded alkenes, such as tetra-*tert*-butylethylene.[8]

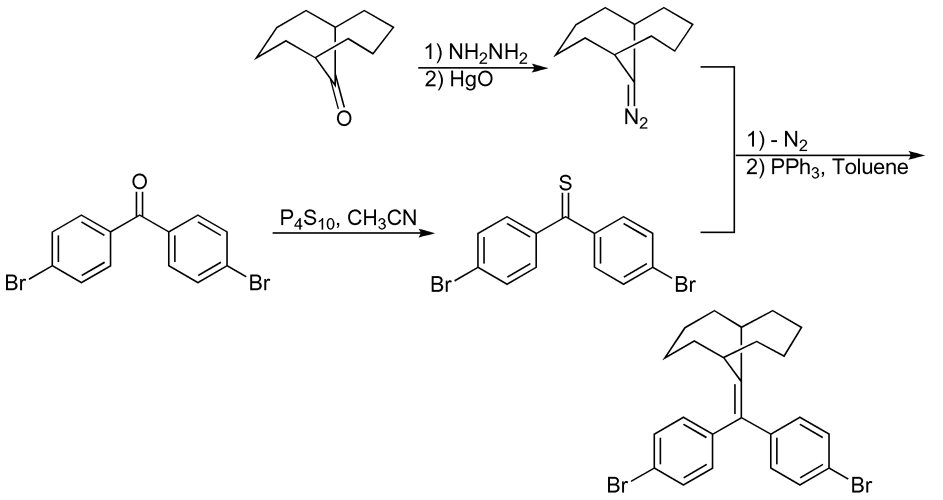
G. CITED EXPERIMENTAL EXAMPLES



Reference 7b.

A solution of 5.0 g tetrahydro-4*H*-thiopyran-4-one (43.0 mmol) in 125 mL ethanol at reflux temperature was added dropwise to mixed solution of 1.06 mL $H_2NNH_2 \cdot H_2O$ (>99%, 21.6 mmol) and 50 mL ethanol. The mixture was refluxed overnight. After cooling to room

temperature and the removal of solvent in vacuo, 4.90 g pure tetrahydro-4H-thiopyran-4-on azine was obtained, in a yield of 100%. The 4.90 g tetrahydro-4H-thiopyran-4-on azine was dissolved in 150 mL CH_3CN and stirred under H_2S (g) atmosphere for 5 days. After evaporation of the solvent, 5.54g pure 3,7,11-trithia-14,15-diazadispiro[5.1.5.2]pentadecane was obtained as a light yellow solid, in a yield of 98%. This compound (21.1 mmol) was oxidized with a mixture of 13.0 g $Pb(OAc)_4$ (29.3 mmol) and 13.0 g $CaCO_3$(0.13 mol) in 160 mL dry CH_2Cl_2. After work up, 5.87 g brown solid was obtained, which was recrystallized from hot EtOAc to yield 3.39 g pure 3,7,11-trithia-14,15-diazadispiro[5.1.5.2]pentadec-14-ene, in a yield of 62%. This solid (13.0 mmol) was mixed with 12.0 mL triethyl phosphite (70 mmol) and 200 mL toluene and refluxed for 24 h. After cooling to room temperature, the solvent was removed in vacuo, and the solid residue was triturated with 25 mL methanol. The solid was filtered off and subsequently, sublimed (80°C at 0.1 mmHg) to give 1.93 g of pure 4,4-bis(tetrahydro-4H-thiopyranylidene) in a yield of 74%, m.p., 144.1°C.



Reference 7c.

To a 25-mL flask were added 1.2 g bicyclo[4.4.1]-undecan-11-one (7.25 mmol), 10 g hydrazine monohydrate (200 mmol, 10 mL), and 1.0 g hydrazine sulfate (9 mmol). The mixture was refluxed for 4 days, and upon cooling a solid precipitated. The mixture was extracted with Et_2O, washed twice with H_2O, once with saturated brine, and dried over Na_2SO_4. Solvent removal gave a white solid, which was used directly for the next step in the reaction.

To a flask containing 2.0 g yellow HgO (9.23 mmol) was added a solution of 300 mg bicyclo[4.4.1]undecan-11-one hydrazone (1.67 mmol) in 30 mL Et_2O; then 2.0 g Na_2SO_4 (14.08 mmol) was added, followed by a few drops of a saturated ethanolic solution of NaOH. The resulting yellow suspension was stirred for 14 h, filtered, and evaporated to yield a crystalline orange solid. This solid was used for next step in the reaction without further purification.

To a suspended mixture of 2.0 g 4,4-dibromobenzophenone and 4.02 g P_4S_{10} (9.05 mmol) in 20 mL acetonitrile, was added 3.1 g $NaHCO_3$ (36 mmol). The mixture was stirred at 50°C for 12 h, during which time it became dark blue. After cooling, the mixture was transferred to a separatory funnel containing Et_2O and H_2O, and the resulting

blue organic layer was washed three times with saturated aqueous $NaHCO_3$, washed once with saturated brine, and then dried over Na_2SO_4. The solvents were removed to give a blue solid, which was recrystallized (argon was blown over the solution during boiling and cooling) from MeOH to give dark blue microcrystals of the product (the thioketone). This material was contaminated ($\sim$ 25% by ^{1}H NMR) with starting material; however, the subsequent reaction was unaffected by such contamination so that no additional purification was attempted.

To a 50-mL flask were added 1.14 g the thioketone (3.25 mmol) and 5 mL THF (deep blue). Then the orange solution of 580 mg diazoalkane (3.25 mmol) in 15 mL THF was added, causing gas evolution. The resulting blue solution was protected from light and refluxed for 12 h. After removal of THF, the residue was subjected to radial chromatography (SiO_2, petroleum ether) to give 1.06 g bis(4′,4″-bromophenyl)methylenebicyclo[4.4.1]-undecane episulfide as a colorless solid, in a yield of 66%.

This episulfide (1.06 g, 2.13 mmol) and 1.12 g triphenylphosphine (4.26 mmol) were dissolved in 15 mL toluene and refluxed for 2 nights. After cooling, the reaction mixture was filtered through SiO_2, and evaporated, and the residue was subjected to radial chromatography (SiO_2, petroleum ether) to afford 0.815 g bis(4′,4″-bromophenyl) methylenebicyclo[4.4.1]-undecane, as a colorless solid, in a yield of 87%.

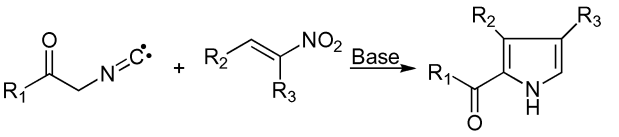
Barton-Zard Pyrrole Synthesis

(Barton-Zard Pyrrole Condensation; Barton-Zard Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Barton and Zard in 1985.[1] It is the synthesis of 2-substituted pyrroles (2-pyrrole-carboxylates or 2-sulfonyl pyrroles) via the basic condensation between alkyl isocyanoacetate (or tosylmethyl isocyanide) and α,β-unsaturated nitroalkenes (or β-nitroacetates). Therefore, this reaction is generally known as the Barton-Zard pyrrole synthesis,[2] Barton-Zard pyrrole condensation,[3] or the Barton-Zard reaction.[4] This reaction is convenient for the synthesis of pyrroles with various substituents at the β positions (R_2 and R_3) but is not applicable for the synthesis of pyrroles without a substituent at position 2. The yields of this reaction are generally high (80–90%), however, if R_2 is hydrogen, the yield is moderate. A nonionic strong base, such as DBU and guanidine, is generally used in this reaction. Currently, this method has been developed for preparing polypyrroles and porphyrins fused with various aromatic rings or bicyclic frameworks, starting from aromatic nitro compounds and ethyl isocyanoacetate.[5] The formed polypyrroles and porphyrins can be applied as functional dyes. The reaction has been reviewed.[6]

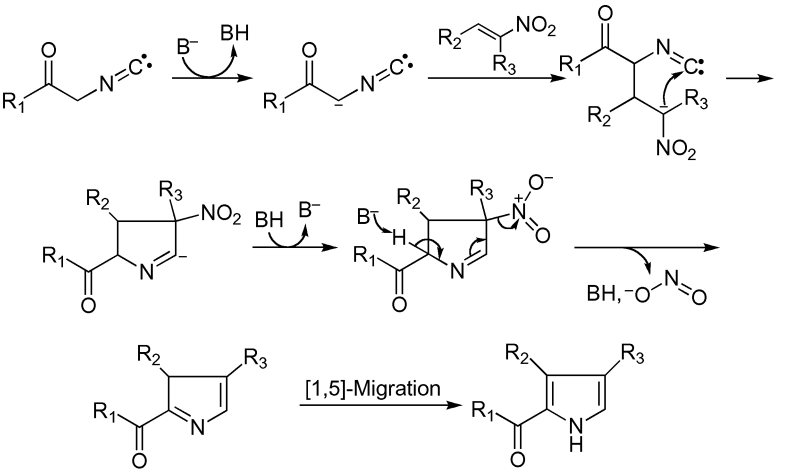
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The reaction mechanism is shown below.



D. MODIFICATION

A few modifications have been developed for this reaction.[7]

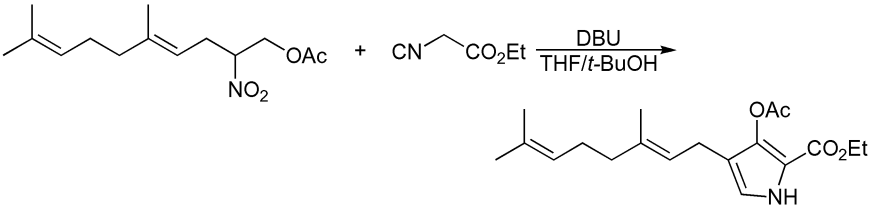
E. APPLICATIONS

This reaction has been applied for preparing polypyrroles and porphyrins.[5] Although the substituted isoindoles can also be prepared from substituted nitrobenzenes, the simple isoindole cannot be prepared in this manner because nitrobenzene does not react with ethyl isocyanoacetate.[8]

F. RELATED REACTIONS

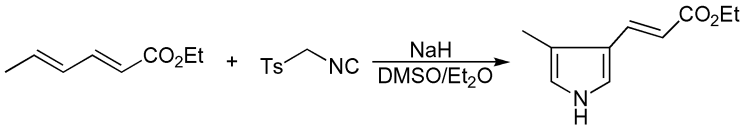
This reaction is similar to the *Leusen Pyrrole Condensation*,[9] based on the reaction of tosylmethyl isocyanide and electron-deficient alkenes (a toluenesulfinate anion is eliminated).[10] The most important advantage of this reaction is that α-free pyrroles can be obtained directly.

G. CITED EXPERIMENTAL EXAMPLES



Reference 11.

To a stirred solution of 3.04 g (*E*)-5,9-dimethyl-2-nitrodeca-4,8-dienyl acetate (11.29 mmol) in 28 mL of a mixed solvent of anhydrous THF/*t*-BuOH (1:1) were added 1.23 mL ethyl isocyanoacetae (11.29 mmol) and 3.38 mL DBU (22.58 mmol) dropwise while cooling at 0°C. After stirring for 26 h, 30 mL water and 30 mL EtOAc were added. The mixture was extracted with EtOAc (2 × 20 mL) and the combined organic layers were washed with water (2 × 20 mL) and 30 mL brine, dried over Na_2SO_4, and concentrated. The residue was purified by column chromatography on silica gel (EtOAc/hexane = 1:9) to give 2.36 g ethyl 4-(3,7-dimethylocta-2,6-dienyl)pyrrole-2-carboxylate as a yellow oil, in a yield of 18%.



Reference 10k.

A solution of 15 g tosylmethyl isocyanide (75 mmol) and 10.0 g ethyl sorbate (71.3 mmol) in 50 mL dry DMSO and 100 mL ether was added to an ice cold suspension of 3.6 g NaH (88.5 mmol, 59% dispersion in oil) in 100 mL ether. The mixture was stirred for 3 h at 20°C, poured into 50 mL saturated aqueous NH_4Cl solution, and extracted with ether (4 × 50 mL). The combined extracts were washed with saturated aqueous NH_4Cl solution, and dried over $MgSO_4$. Evaporation of the extract gave 13.0 g of crude ethyl 3-(4-methyl-3-pyrrolyl)acrylate. Crystallization from EtOH gave 10.6 g of pure product, in a yield of 80%; m.p. 88–89°C.

Other references related to the Barton-Zard pyrrole synthesis are cited in the literature.[12]

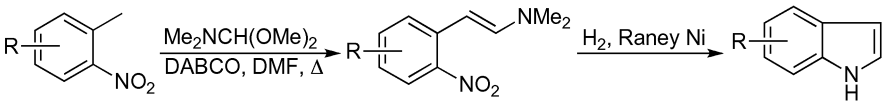
Batcho-Leimgruber Indole Synthesis

(Leimgruber-Batcho Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Batcho and Leimgruber in 1971.[1] It is a general, mild, two-step process for indole synthesis that consists of the condensation between substituted *o*-nitrotoluene and *N*,*N*-dimethylformamide dimethyl acetal to give an *o*-nitrophenylacetaldehyde enamine, and the subsequent reductive cyclization to furnish the indole. Therefore, this reaction is known as the Batcho-Leimgruber indole synthesis[2] or the Leimgruber-Batcho reaction.[3] The reagents used to reduce the nitro group can be Fe(II), hydrogen, dithionite,[4] and hydrazine hydrate-Raney Nickel,[5] etc.; and the reductive cyclization using the combination of hydrazine hydrate-Raney Nickel generally gives better yield than other reducing reagents reported.[6] This reaction is a particular useful method for synthesizing indoles with substituents at the benzene ring rather than at the heterocyclic pyrrole ring.

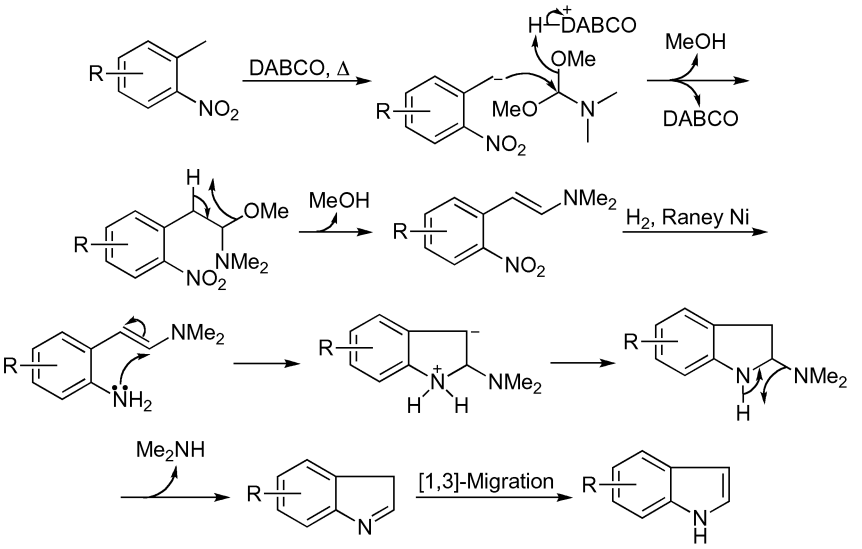
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The *ortho* electron-withdrawing nitro group enables the proton abstraction from the methyl group, forming an anion that attacks the electrophilic carbon of the dimethylformamide dimethyl acetal to form the enamine. Upon the reduction of nitro group, ring closure occurs and eliminates dimethylamine to afford indole. The mechanism is illustrated below.



D. MODIFICATION

The modification of this reaction includes the variation of the applied base, the reducing reagents, and the available acetals of dimethylformamide. Some of the modifications are collected in the literature.[7]

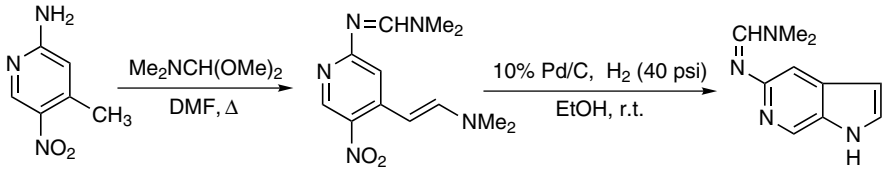
E. APPLICATIONS

This reaction has been applied for synthesizing indoles with substitutents in the benzene ring rather than the pyrrole moiety of the indole ring. In addition, this method has been adapted for synthesizing amides and esters via solid-support synthesis.[8]

F. RELATED REACTIONS

This reaction is closely related to the *Reissert Indole Synthesis*, which consists of a decarboxylation in the final step.[4]

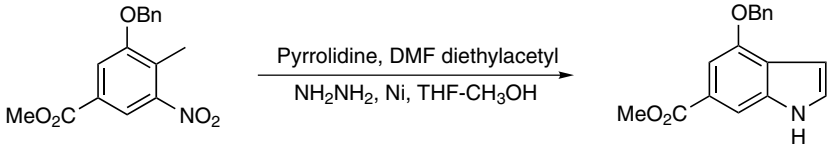
G. CITED EXPERIMENTAL EXAMPLES



Reference 7a.

To a solution of 10.0 g 2-amino-4-methyl-5-nitropyridine (65.3 mmol) in 90 mL DMF was added 87.0 mL *N*,*N*-dimethylformamide dimethyl acetal (653.0 mmol) in one portion. The deep red reaction mixture was heated at 110°C overnight and then cooled to room temperature and concentrated in vacuo to provide 17.7 g *N*,*N*-dimethyl-*N*-[4-(2-dimethylamino)vinyl)-5-nitropyridin-2-yl]formamidine as a red solid, in a yield of 100%. An analytical sample was purified by recrystallization from benzene, m.p. 149–151°C.

A mixture of 8.0 g *N*,*N*-dimethyl-*N*-[4-(2-dimethylamino)vinyl)-5-nitropyridin-2-yl]formamidine (30.4 mmol) and 2.0 g 10% palladium on carbon in 80 mL EtOH was hydrogenated at room temperature under 40 psi of hydrogen pressure for 24 h, and the mixture was filtered through Celite and concentrated in vacuo. The resulting dark brown foam was chromatographed (10–20% 2 M NH_3-MeOH/CH_2Cl_2) to provide 3.4 g *N*, *N*-dimethyl-*N*′-(1H-pyrrolo[2,3-c]pyridin-5-yl)formamidine, in a yield of 60%, m.p. 162–166°C.



Reference 9.

To a solution of 29.0 g methyl 3-(benzyloxy)-4-methyl-5-nitrobenzoate (0.0962 mol) in 60.0 mL DMF was added 12.0 mL freshly distilled pyrrolidine (0.144 mol) and 19.0 mL *N*, *N*-dimethylformamide dimethyl acetal (of 94% purity, 0.134 mol). The dark red colored reaction mixture was heated at 110°C for 3.5 h and concentrated on a rotary evaporator. Then 350 mL CH_3OH and 15 mL CH_2Cl_2 were added to the residue, and the solution was stored at 6°C for 12 h. The garnet colored precipitate was filtered and carefully washed with cold CH_3OH. Upon removal of the solvent under high vacuum, 23.24 g of a 10:1 mixture of pyrrolidino-styrene and *N*, *N*-dimethylamino-styrene was obtained, in a yield of 64%.

To a solution of 21.5 g of the nitrostyrenes in 300 mL of mixed solvent (THF/CH_3OH = 1:1) at room temperature was added 1 mL Raney nickel (50% slurry) at pH 9.0. Then 5 mL 55% hydrazine hydrate was added dropwise under stirring accompanied by vigorous evolution of gas. When the evolution of gas subsided (∼1.3 h), an additional 5 mL hydrazine hydrate was added, and the reaction mixture was warmed to 43°C. Over the next 3 h, two additional portions of hydrazine hydrate (4 mL, 1 mL) were added, and the reaction mixture was stirred until gas evolution ceased. The Raney nickel was filtered on a pad of Celite and washed with CH_2Cl_2. The filtrate was worked up. Flash chromatography of the residue

(EtOAc/hexanes = 3:7) afforded 14.06 g methyl 4-(benzyloxy)-1H-indole-6-carboxylate as a white solid, in a yield of 88%, m.p. 165.0–166.8°C.

Other references related to the Batcho-Leimgruber indole synthesis are cited in the literature.[10]

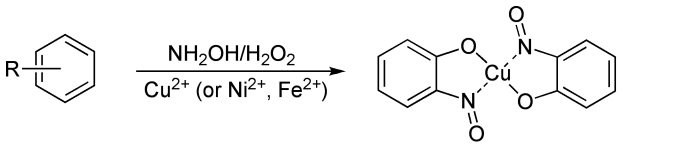
Baudisch Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Baudisch in 1939.[1] It is the synthesis of *o*-nitrosophenols from benzene (or its derivatives), hydroxylamine, and hydrogen peroxide in the presence of copper salts and is generally known as the Baudisch reaction.[2] In contrast to conventional nitrosation of phenol with HNO_2, which always leads to *p*-nitrosophenols, the Baudisch reaction proceeds via the simultaneous introduction of the nitroso and hydroxyl group into the adjacent position on the aromatic nucleus to form reddish violet copper salts.[3] Besides the copper salts, other metal salts (Ni^{2+}, Fe^{2+}, etc) can also be applied to this reaction.[4] The free *o*-nitrosophenols, due to the formation of intramolecular hydrogen bonding, is volatile[2e] and can be obtained via acidifying the complexes with HCl followed by extraction in petroleum ether.[5] It is known that the presence of copper salts is necessary to stabilize the nitrosyl radical to form stable complexes and to prevent the further oxidation of *o*-nitrosophenols to *o*-nitrophenols or the rearrangement to *p*-quinone monoximes.[6] If the reaction is applied to phenols instead of nonhydroxyl benzene derivatives, similar products are obtained with higher yields in a much shorter reaction period, because the higher solubility of phenols in water.[7] However, the Baudisch reaction is not applicable to aromatic aldehydes and primary amines because the aldehyde group will react with the nitrosyl radical or hydroxylamine directly to form hydroxamic acid or oxime (i.e., the *Angeli Remini Reaction*), and primary amine will react with the nitrosyl radical to form diazo compounds.[5] Some of the aromatic nitroso compounds have shown some antiviral activity, such as against HIV.[8]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

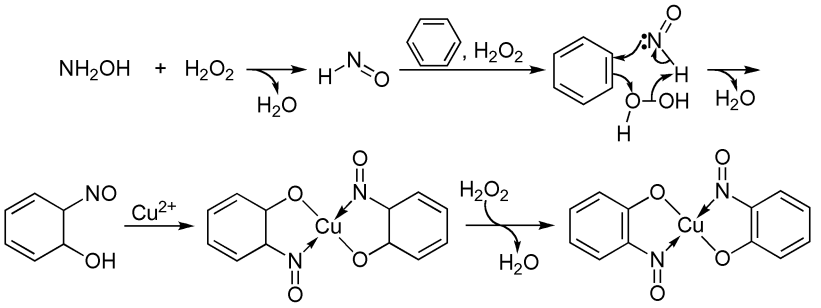
B. GENERAL REACTION SCHEME



(R = alkyl, phenyl, Cl, Br, NO_2, etc.)

C. PROPOSED MECHANISMS

Baudisch[9] and Cronheim[6a] postulated that some of the cupric ion which is reduced to cuprous ion, which forms the complex $[Cu(NO)]^-$ with nitrosyl radicals that were generated via the prior oxidation-reduction reactions among the various reagents. Then this complex attacks the aromatic ring, leading to nitrosation, followed by the hydroxylation adjacent to the position of nitrosation. However, this mechanism has been questioned.[2e] A tentative mechanism is thus proposed here.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has been used to prepare more than 50 *o*-nitrosophenols.

F. RELATED REACTIONS

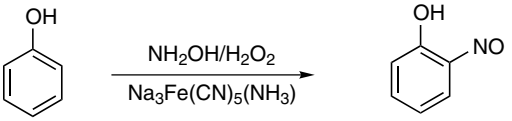
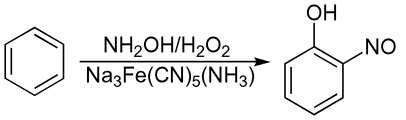
G. CITED EXPERIMENTAL EXAMPLES



Reference 2e.

A total of 4 mL 30% hydrogen peroxide was added to a solution of 1 g phenol, 4 g hydroxylamine hydrochloride, and 2 g sodium pentacyanoaminneferrate(II) in 200 mL water and 60 mL petroleum ether (b.p. 30–70°C). The mixture was stirred at room temperature for 1 h, the ether layer was separated, and the aqueous layer was extracted with petroleum ether repeatedly until the green color was scarcely found in the ether layer. The petroleum ether extracts of *o*-nitrosophenol were transferred to a flask, which was connected to an empty flask by means of a T-tube fitted with a glass stopcock. After air was pumped out through the stopcock, the empty flask was cooled with an ice-salt mixture, and the flask containing the extract was warmed with hot water. *o*-Nitrosophenol, which was volatilized with the petroleum ether, was condensed in the ice-cooled flask.



Reference 10.

Sodium pentacyano-ammine-ferroate (2 g) was dissolved in 100 mL water; then 25 mL benzene and 50 mL ligroin (a kind of petroleum ether) were added, and the mixture was cooled with ice water. Then 2 g hydroxylamine chloride was added (color changes from brown to grass green), followed by 4 mL Merck superoxol (color changes from grass green to deep brownish violet). After the mixture was shaken violently for 1 h, the color of the benzene-ligroin layer was deep green, due to the formation of large amounts of *o*-nitrosophenol. The green benzene-ligroin layer was separated, washed with ice water, and shaken with a dilute copper sulfate solution; a deep red, water-soluble *o*-nitrosophenol copper salt was formed while the benzene-ligroin became entirely colorless and was used for further extraction of the aqueous layer. After undergoing shaking for 1 or 2 h, the deep green benzene-ligroin was again separated and *o*-nitrosophenol was converted into the red copper salt. The copper salt solutions were combined and acidified in presence of petroleum ether with hydrochloric acid. The deep green petroleum ether was washed with ice water free from excess acid. The solution, kept away from light in the cold, lasts for weeks without any change.

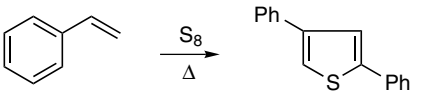
Baumann-Fromm Thiophene Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Baumann and Fromm in 1891.[1] It is the synthesis of 2,4-diarylthiophenes via the reaction between substituted styrenes and sulfur. Besides the major product of 2,4-diarylthiophene, some minor 2,5-diarylthiophenes are also found in this reaction.[2] Similarly, butadiynes can react with hydrogen sulfide to afford thiophenes.[3] However, at 600°C in the presence of a ferrous sulfide-alumina catalyst, styrene reacted with hydrogen sulfide to give 60% benzothiophene.[4] On the other hand, thiophenes can also be prepared via the reaction between ethylbenzene and sulfur,[5] acetophene and hydrogen sulfide,[6] or 1,4-diketones and phosphorus trisulfide (or phosphorus pentasulfide).[7] The preparation of 2,4-diarylthiophene has been reviewed.[8]

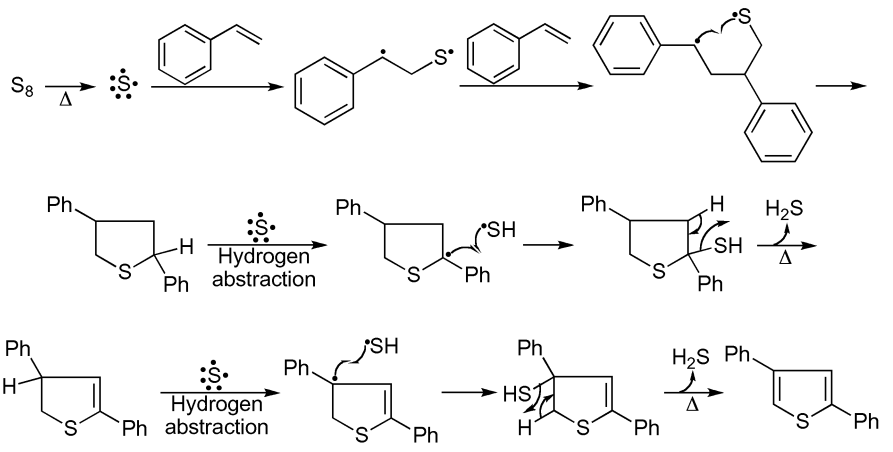
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction proceeds through a radical mechanism, similar to the vulcanization of rubber.[5] A tentative mechanism is illustrated here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified using different starting materials, such as ethylbenzene[5] and acetophenone.[6]

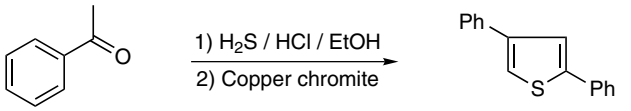
E. APPLICATIONS

This reaction has been used to prepare 2,4-diarylthiophene.

F. RELATED REACTIONS

This reaction is related to the *Bogert-Herrera Reaction*[8] and *Volhard-Erdmann Cyclization*.[9]

G. CITED EXPERIMENTAL EXAMPLES

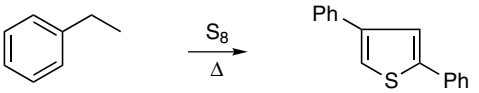


Reference 10.

Acetophenone (40 g) was dissolved in 300 mL absolute alcohol and cooled to 0°C in an ice salt bath. Dry hydrogen chloride was passed in for a few minutes until the rate of gas influx could be regulated, and then hydrogen sulfide was also passed in at a slow rate. Approximately 140 g dry hydrogen chloride (the amount calculated to saturate the alcohol) was passed into the solution over a period of 6 h during which time the reaction flask was kept in the ice-salt bath. When all the hydrogen chloride was used, the bath was

allowed to come to room temperature, while hydrogen sulfide was passed continuously into the flask for 8 h longer. About 3 h later, white crystals began to form in the flask, and a purple resin precipitated. After 14 h, the gas-inlet tubes were removed, and the flask was stored in the refrigerator overnight. The white crystals were stirred up and filtered from the mother liquor, leaving the purple resin of thioacetophenone in the flask. The crystals of "anhydroacetophenone disulfide" were washed once with alcohol and dried. The crude product melted from 106–109°C. The yield was 23.5 g, or 57% of the theoretical level. After two recrystallizations from acetone, the product was obtained in white hexagonal bars, m. p. 107–108°C (corrected).

"Anhydroacetophenone disulfide" (3 g) was dissolved in 35 mL dry xylene, and 10 g copper chromite powder was added, and the mixture was refluxed. No hydrogen sulfide was evolved during the course of 3 h. At the end of this time, the mixture was cooled and filtered. The residual catalyst was washed thoroughly with xylene, and the combined washings and filtrate were distilled under a water-pump vacuum to remove xylene. The brown residue solidified on cooling. It was dissolved in 80 mL boiling methanol and treated with norite. Upon cooling, white flaky crystals deposited. These were recrystallized from methanol and dried, and 1.5 g 2,4-diphenylthiophene was obtained, in a yield of 83%.



Reference 11.

Ethylbenzene (4.1 mol) and sulfur (6.2 mol) were placed in a 800 mL bomb, and heated to 340–350°C for 40 min, at which time a small leak in the bomb head developed and heating was stopped. Hydrogen sulfide at high pressures seemed to attack the brass threads of the valve very rapidly. After releasing 78 g hydrogen sulfide, the heating was continued for a second time until the leaking happened again. A total of 378 g liquid containing a small amount of solid was removed from the bomb. The solid was filtered off, and the liquid was distilled. The residue in the distilling flask, along with the solid filtered from the original reaction mixture, was extracted with hot alcohol; this solution on cooling deposited 86.5 g 2,4-diphenylthiophene as a light yellow crystalline substance, which on recrystallization had a melting point of 119.5–120.5°C.

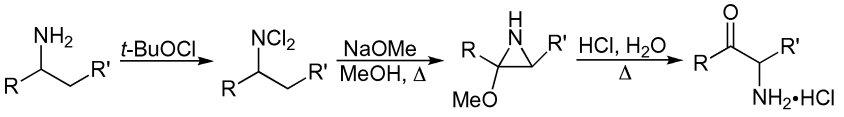
Baumgarten α-Amino Ketone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Baumgarten in 1954.[1] It is the synthesis of α-amino ketones from the rearrangement of *N*,*N*-dichloro-*sec*-alkylamines by means of the treatment of sodium methoxide.[2] *N*,*N*-Dichloro-*sec*-alkylamines were initially prepared via the chlorination of *sec*-alkylamine by chlorine.[1]

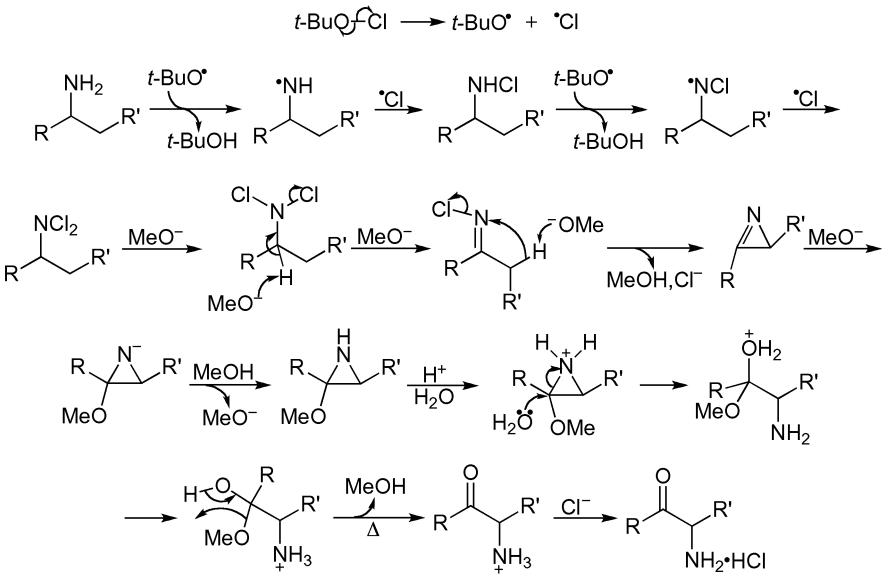
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that the reaction proceeds via *N*-chloro-imine intermediate, as illustrated here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

It has been modified for preparing α-amino ketones from the reaction between more generally available nitriles and a Gringard reagent.[2] In addition, this reaction has been applied to the synthesis of α-amino acids.[2b]

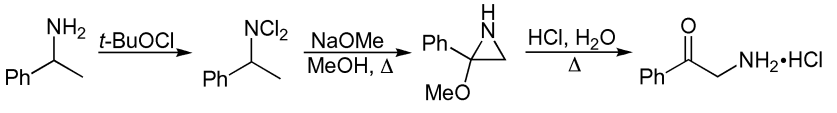
E. APPLICATIONS

It is a specific method to synthesize α-amino ketones and α-amino acids.

F. RELATED REACTIONS

N/A

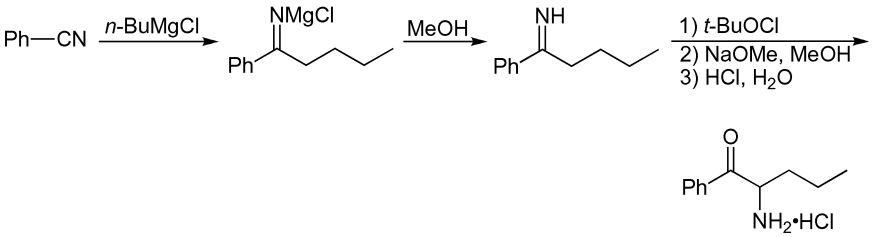
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

In a thoroughly dry 500-mL three-necked round-bottomed flask fitted with a mechanical stirrer, dropping funnel, and a Y-tube containing a calcium chloride drying tube and a thermometer were placed 24.2 g α-phenylethylamine (26 mL, 0.20 mol) and 50 mL dry

benzene. The solution was cooled in an ice-salt bath to 5°C, and a solution of 44.5 g (50 mL, 0.41 mol) of *tert*-butyl hypochlorite in 50 mL dry benzene was added at such a rate as to maintain the temperature below 10°C. After the addition of the *tert*-butyl hypochlorite solution was complete, the reaction mixture was stirred at room temperature for 1–4 h. The Y-tube was replaced by a reflux condenser fitted with a calcium chloride drying tube, and a freshly prepared solution of 13.8 g (0.60 mol) sodium in 140 mL anhydrous methanol was added to the benzene solution of *N*,*N*-dichloro-α-phenylethylamine at such a rate as to maintain gentle reflux. After the addition of the sodium methoxide was complete, the reaction mixture was refluxed until a negative test was obtained with acidified starch-iodide paper (45–70 min). The reaction mixture was cooled in an ice water bath, and the precipitated NaCl was removed by filtration through a Büchner funnel. The filter cake was washed with three 25-mL portions of dry benzene. The combined filtrates were added, slowly with shaking or stirring, to 150 mL 2 *N* HCl contained in a 1-L beaker. The layers were separated, and the benzene layer was extracted with three 50-mL portions of 2 *N*HCl. The combined acid extracts were washed twice with 50-mL portions of ether. The ether extracts were discarded. The pale amber to yellow aqueous solution was evaporated to dryness at a temperature not greater than 40°C. The residue was transferred to a 1-L round-bottomed flask fitted with a reflux condenser to which was added 400 mL isopropyl alcohol-hydrochloric acid solution. The mixture was refluxed for at least 30 min and was filtered hot through a Büchner funnel. The residual solid was returned to the flask and extracted in the same manner with a 150-mL portion of the isopropyl alcohol-hydrochloric acid solution. The solid residue NaCl was discarded. The two extracts were cooled separately in the refrigerator overnight and then filtered on a Büchner funnel. The nearly colorless crystals were washed on the filter with two 50-mL portions of dry ether. Each of the filtrates was diluted with an equal volume of dry ether (400 mL and 150 mL, respectively) and allowed to stand in the refrigerator overnight. From these diluted filtrates additional crops of crystals were collected. The combined yield of the three to four crops of phenacylamine hydrochloride was 18.9–24.8 g (55–72%), m.p. 185–186°C (dec.). Normally the product is sufficiently pure for use without further purification; however, the product may be recrystallized from an isopropyl alcohol-hydrochloric acid solution, using 100 mL of the solution for each 6 g of compound. The recovery is ~5.5 g per 6.0 g of crude product.



Reference 2a.

Only the procedure of making *n*-butyl phenyl ketimine is given, the rest of procedures are similar to the first example.

To a solution of 84 mL 3 M *n*-butylmagnesium chloride (0.25 mol) and 150 mL dry ether, was added a solution of 10.3 mL benzonitrile (0.1 mol) in 10 mL of dry ether dropwise at such a rate as to maintain a slight reflux. After the addition was complete, the gray solution containing a precipitate was refluxed for 10 h in an oil bath and cooled in an ice bath. To this

cooled solution, 60 mL dry methanol was added dropwise, during which the first portion was added slowly and cautiously because the reaction was quite vigorous. After the addition was complete, the reaction mixture containing a finely divided white precipitate was stirred at room temperature for 20 min. The mixture was then cooled in ice and filtered by suction through a 0.25-in. layer of Celite in a Büchner funnel. The filter cake was washed with three 25-mL portions of dry ether, which were added to the filtrate. The ether was evaporated, and to the remaining yellowish residue was added 80 mL dry benzene. Usually a small amount of precipitate either remained after evaporation or formed on addition of the benzene, and this was removed by filtering the mixture through a Büchner funnel into a tarred flask. The evaporator flask was washed with small portions of dry benzene for a total of 30 mL. After weighing the flask plus filtrate and washings, weighed samples of the solution were taken for analysis. The apparent yield of the *n*-butyl phenyl ketimine was 70–86%.

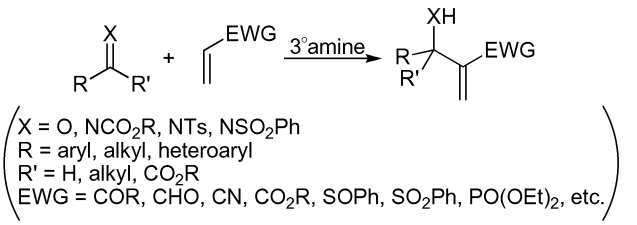
Baylis-Hillman Reaction
(Morita-Baylis-Hillman Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

Although the Baylis-Hillman reaction[1] has been primarily credited to Baylis and Hillman from Celanese Corporation, from their initial work patented in 1972,[2] the initial discovery of this reaction has roots back to 1968, when Morita et al. reported a tricyclohexylphosphine catalyzed reaction between an aldehyde and acrylic compounds.[3] Therefore, this reaction is also widely referred to as the Morita-Baylis-Hillman reaction.[4] The Baylis-Hillman reaction is essentially a three-component reaction involving the coupling of the α-position of activated alkenes with carbon electrophiles (i.e., aldehydes) under the influence of a catalyst/catalyst system, with the characteristics of atom efficiency and the formation of dense functionality. Likewise, the corresponding reaction between alkenes and imines under similar conditions is referred to as the aza-Baylis-Hillman reaction[5] or aza-Morita-Baylis-Hillman reaction.[6] In a few cases, this reaction is also cited as Morita reaction,[7] Morita-Baylis-Hillman alkylation,[8] and Morita-Baylis-Hillman cyclization.[9] In this reaction, the activated alkenes include acrylonitrile, acrolein, acrylates, and α,β-unsaturated ketones. The catalysts applied include tricyclohexylphosphine (the original Morita condition),[3] a variety of tertiary amines (1,4-diazabicyclo[2.2.2]octane (DABCO, the standard amine catalyst), 3-hydroxyquinuclidine (an optimal catalyst), DBU 3-quinuclidone, quinuclidine, and indolizine),[10] and chalcogenides.[4ij,11] Unfortunately, this reaction also has some drawbacks, such as the slow reaction rate (up to weeks in an extreme case),[12] being limited to electrophilic α,β-unsaturated carbonyl compounds; and almost exclusively occuring in the reactions involving β-unsubstituted α,β-unsaturated carbonyl compounds and cyclic enones.[13] Therefore, different measures have been taken to optimize this reaction, including the application of activated alkenes,[14] reactive electrophiles,[15] aqueous medium,[16] high pressure,[17] microwave irradiation,[18] and Lewis acids.[19] This reaction has been extensively reviewed.[10c,10g,20]

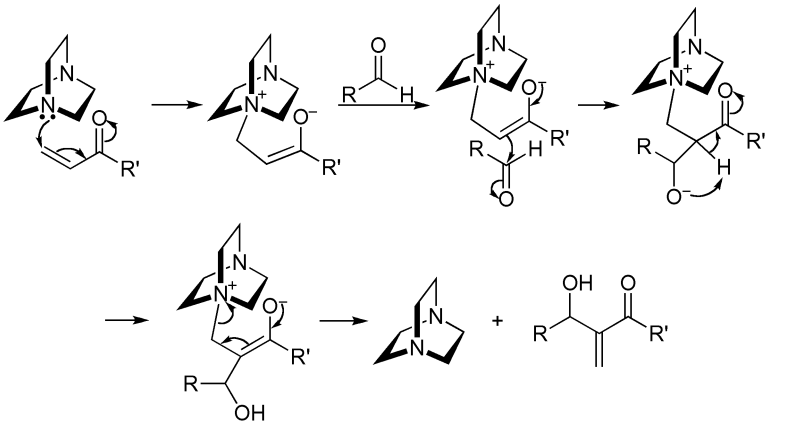
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The accepted mechanism is similar to the one originally proposed by Morita (as illustrated here) and is supported mainly by kinetic studies.[14c,21] However, none of the zwitterionic intermediates shown in the mechanism has been isolated to date.



D. MODIFICATION

This reaction has been extensively studied recently and modified in many aspects compared to the original reaction conditions, including the application of reactive alkenes, electrophiles, aqueous medium, high pressure and Lewis acid catalysts.

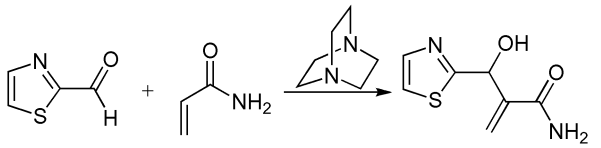
E. APPLICATIONS

Owing to its atom efficiency and the generation of dense functionality, this reaction has wide applications in producing of variety a molecules. Some of the Baylis-Hillman adducts have shown promising biological activities.[22]

F. RELATED REACTIONS

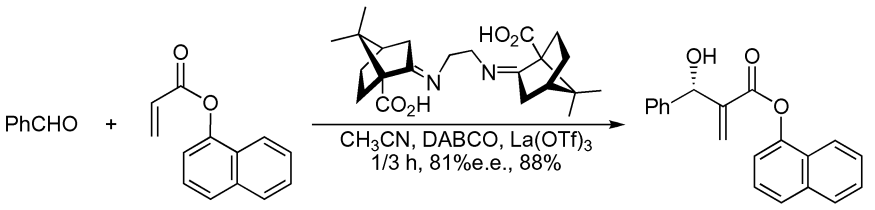
N/A

G. CITED EXPERIMENTAL EXAMPLES



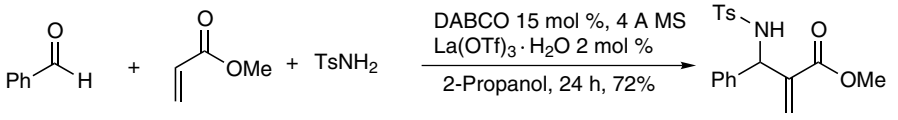
Reference 23.

A clear solution of 2.0 mmol aldehyde and 2.0 mmol acrylamide in 5 mL 1,4-dioxane was slowly charged with 5 mL deionized water under stirring. The homogeneous reaction mixture was stirred at ambient temperature in the presence of 1 Eq DABCO, and the reaction progress was monitored by TLC. Upon completion or as indicated, the reaction mixture was partitioned with 250 mL ethyl acetate and 20 mL brine. The aqueous layer was extracted with chloroform (3×60 mL). The combined organic layer was dried over anhydrous $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by flash column chromatography on silica gel, eluting with ethyl acetate and/or methanol to give the desired product, in a yield of 99%. (*Note*: Acrylamide was considered to be unreactive in the Baylis-Hillman reaction.[20b])



Reference 19a

To a solution of 12 mg chiral ligand (0.03 mmol) in 2.6 mL CH_3CN was added 9 mg $La(OTf)_3$ (0.015 mmol) at room temperature under a nitrogen atmosphere. After stirring for 10 min, 54 mg benzaldehyde (0.51 mmol), 0.10 g α-naphthyl acrylate (0.51 mmol), and 17 mg DABCO (0.15 mmol) were added sequentially. The resulting mixture was stirred for 20 min and the reaction was quenched with 5 mL H_2O. The mixture was extracted with 10 mL CH_2Cl_2, and the layers were separated. The organic layer was washed with 10 mL brine, dried over $MgSO_4$, and concentrated. The crude product was purified by silica gel using 8:1 hexane/EtOAc as an eluent to give 0.13 g alcohol as a white solid, in a yield of 88%. The enantiomeric ratios were determined as 81% e.e. by HPLC analyses using a chiral column.



Reference 24a.

In a dry flask were added 855 mg tosylamide (5 mmol), 84 mg DABCO (0.75 mmol), and 58.5 mg $La(OTf)_3 \cdot H_2O$ (0.1 mmol) together with 900 mg 4-Å molecular sieves. Then 2.5 mL *iso*-PrOH, 505 μL benzaldehyde (5 mmol), and 450 μL methyl acrylate (5 mmol) were added, and the reaction mixture was stirred for 48 h at ambient temperature. The mixture was filtered through a thin layer of Celite, which was rinsed three times with 10 mL *iso*-PrOH. The solvent was evaporated, and to the crude mixture were added 25 mL methanol and 10 mL 1 M sulfuric acid. The solution was stirred for 1 h, and then methanol was evaporated. The remaining acidic solution was diluted with water and extracted with dichloromethane (3×30 mL). The organic phase was then successively washed with saturated $NaHCO_3$, 1 M NaOH, water, and saturated NaCl solution and dried over Na_2SO_4. Evaporation of the solvent gave 1.38 g pure methyl α-methylene-β-[(*p*-toluenesulfonyl)-amino]-3-phenylpropionate as a white crystalline material, in a yield of 80%, m.p. 76–77°C.

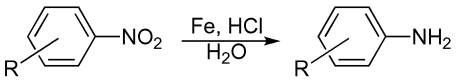
Béchamp Reduction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Béchamp in 1854.[1] It is the reduction of aromatic nitro compounds to the corresponding aromatic amines by iron, ferrous salts, or iron catalyst in aqueous acid. Thus this reaction is generally referred to as the Béchamp reduction.[2] Besides iron, zinc and tin are often used to reduce the aromatic nitro compounds in the presence of an acid;[3] however, the reduction of aromatic nitro compounds often stops at an intermediate stage, yielding hydroxylamines,[4] hydrazines,[5] azoarenes,[6] or azoxyarenes.[7] These intermediates definitely indicate some aspects of the mechanism. Although the main drawbacks of the Béchamp reduction include the slow reaction rate and costly steam distillation compared with the catalytic hydrogenation of aromatic nitro compounds, the Béchamp reduction usually shows higher selectivity to the desired product.[8] In addition, this reaction might give much better results if some neutral organic solvents were added to the aqueous reaction mixture, such as acetonitrile and propylene carbonate.[9] Recently, a highly chemoselective catalytic hydrogenation of nitrobenzenes using homogeneous iron complex catalysts has been reported.[10] The Béchamp reduction has been reviewed.[11]

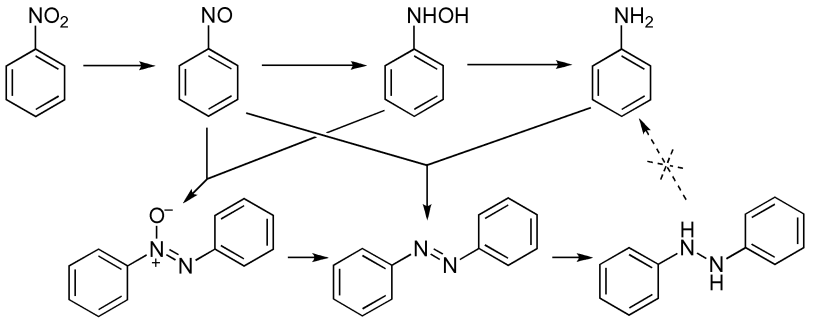
B. GENERAL REACTION SCHEME



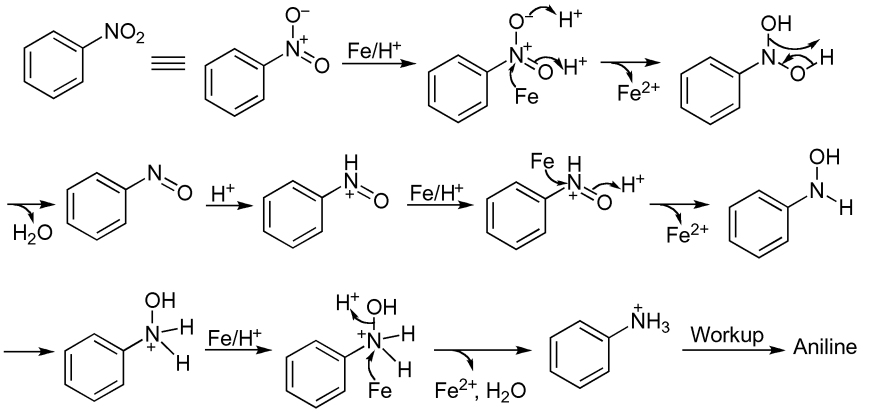
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is proposed that the nitro group is reduced via a multistep process, as shown below.[10,12]



A tentative mechanistic detail of the Béchamp reduction is also illustrated below.



D. MODIFICATION

N/A

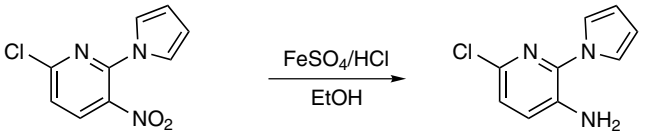
E. APPLICATIONS

This reaction is generally used to reduce aromatic nitro compounds into aromatic amines.

F. RELATED REACTIONS

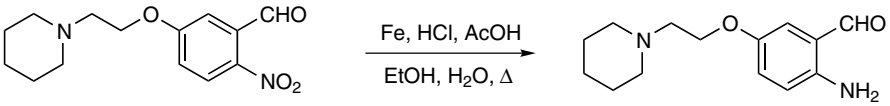
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To 300 mL EtOH was added 9.27 g 6-chloro-3-nitro-2-pyrrolopyridine (41 mmol), followed by 115.25 g $FeSO_4 \cdot 7H_2O$ (414 mmol), 0.5 mL 10 N HCl, and 5 mL water. The mixture was heated at 80°C for 90 min, while a 30% ammonia solution was added in little fractions to maintain a basic pH. After cooling, EtOH was evaporated under vacuum. The residue was poured in 100 mL water and extracted with Et_2O. After the usual treatment, the first amount of the product was obtained. The aqueous phase was alkalinized with ammonia solution and extracted with EtOAc. Finally, 4.59 g 3-amino-6-chloro-2-pyrrolopyridine was obtained as a beige powder, in a yield of 57%, m.p. 89°C (recrystallization from 80% Et_2O and 20% *n*-hexane).



Reference 14.

To mixture of 1.2 g iron (21.6 mmol), 0.25 mL 10 N HCl, 10 mL acetic acid, 10 mL ethanol and 5 mL water was added 1.0 g 2-nitro-5-(2-piperidin-1-ylethoxy)benzaldehyde (3.6 mmol). The mixture was refluxed for 15 min with stirring, and iron was removed by filtration. The product was worked up as usual.

Other references related to the Béchamp reaction are cited in the literature.[15]

Beckmann Rearrangement and Beckmann Fragmentation

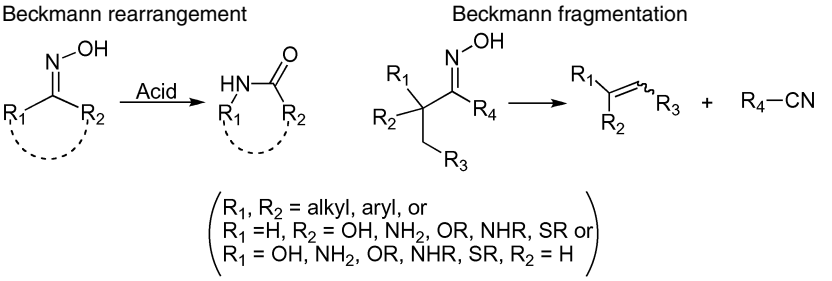
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Beckmann in 1886.[1] It is the rearrangement of an oxime to its corresponding amide in the presence of an acid and is generally known as the Beckmann rearrangement.[2] Oximes of cyclic ketones give lactams as the final products, resulting in the ring enlargements. An important example is the conversion of cyclohexanone oxime into ε-caprolactam, which is a basic component for the fabrication of nylon 6.[3] The oxime is formed by the reaction of a ketone with hydroxyamine. The Beckmann rearrangement of oxime derivatives proceeds stereospecifically, and the stereo-configuration of the migrating group is retained. The migrating substituent is the electrofuge that can better stabilize a partially positive charge.[4] This rearrangement has been applied to the construction of a variety of nitrogen-containing compounds, including amines (via imines),[5] amidines,[6] thioimidates,[7] imidoyl halides,[8] iminophosphonates,[9] and enaminones.[10] However, certain oximes, particularly those having a quarternary carbon *anti* to the hydroxyl, are likely to undergo the rearrangement to form nitriles instead of amides. This type of transformation is called the Beckmann fragmentation,[11,12] which was first reported by Werner and Piguet in 1904.[13] Because this kind of transformation is so different from the regular Beckmann rearrangement, it is sometimes called abnormal Beckmann rearrangement,[2y,4,11a,11f,14] secondary Beckmann rearrangement,[15] Beckmann fission,[16] etc. Besides those oximes having a quarternary carbon *anti* to the hydroxyl group, other oximes such as the bridged bicyclic ketoximes[17] and oximes with an electron-donating substituent at the α-carbon also undergo fragmentation rather than rearrangement under Beckmann rearrangement conditions. A variety of substituents, notably alkyl, aryl, hydroxy, alkoxy, amino, and thioalkoxy

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

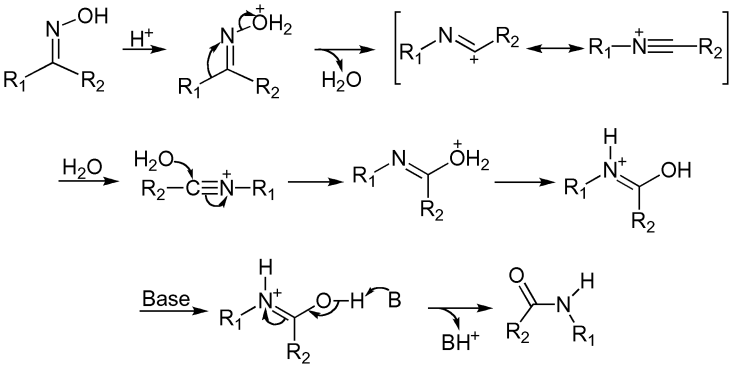
(thioether) can stabilize the intermediate carbonium ion and facilitate fragmentation.[2y,18] The Beckmann fragmentation has been applied to the modification of steroids and other organic syntheses.[19] Owing to their importance, both the Beckmann rearrangement and the Beckmann fragmentation have been extensively reviewed.[20] Currently, the Beckmann rearrangement has been carried out under mild conditions[21] and in supercritical water;[22] it has also been modified to be catalytic.[23]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is commonly assumed that the reaction involves an initial protonation at the oxygen atom of the oxime moiety, giving an oxonium cation, and is followed by the migration of an alkyl group plus the departure of a water molecule to give the nitrilium cation. The latter ion is, in turn, hydrolyzed in a basic solution to finally yield an amide.[24] The mechanism is illustrated below.



D. MODIFICATION

This reaction has been modified to be catalytic[23] and to occur under mild conditions,[21] in supercritical water,[22] and under photo-irradiation.[25]

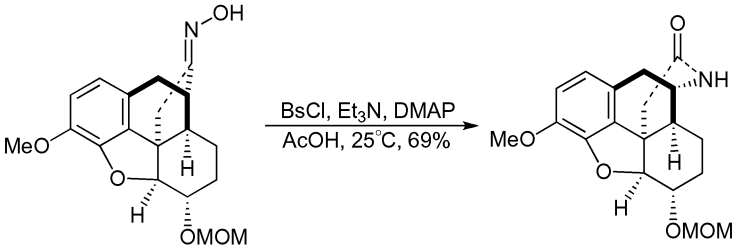
E. APPLICATIONS

This reaction has been used to synthesize different types of nitrogen-containing compounds.

F. RELATED REACTIONS

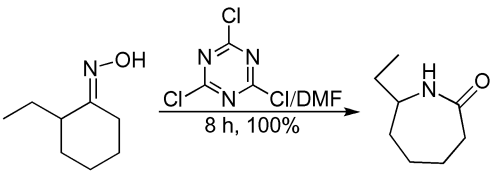
This reaction is related to the *Schmidt Reaction* and *Tiemann Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 26.

A solution of 25 mg (1*R*,4*S*,12*S*,13*S*,16*R*)-9-methoxy-13-(methoxymethoxy)-11-oxapentacyclo[8.6.1.$0^{1,12}$.$0^{4,16}$.$0^{6,17}$]-heptadeca-6(17),7,9-trienone oxime (0.072 mmol), 28 mg *p*-bromobenzenesulfonyl chloride (0.11 mmol), 16 μL Et_3N (0.12 mmol), and a catalytic amount of DMAP in 5 mL CH_2Cl_2 was stirred for 1 h at ambient temperature. The solvent was removed under reduced pressure, and the residue was taken up by 2 mL acetic acid. The resulting solution was stirred for 1 h and was neutralized with saturated aqueous $NaHCO_3$. The mixture was extracted with CH_2Cl_2, washed with saturated aqueous NaCl, dried over anhydrous Na_2SO_4, and concentrated under reduced pressure. Chromatography of the residue on silica gel column (6 g, EtOAc/MeOH, 12:1) gave 17 mg (1*R*,5*S*,13*S*,14*S*,17*S*)-10-methoxy-14-(methoxymethoxy)-12-oxa-4-azapentacyclo[9.6.1.$0^{1,13}$.$0^{5,17}$.$0^{7,18}$]-octadeca-7(18),8,10-trien-3-one as a colorless oil, in a yield of 69%. $[R]_D^{23}$ = +114.2 (c 1.47, $CHCl_3$).



Reference 21.

To 2 mL DMF was added 1.83 g 2,4,6-trichloro-[1,3,5]triazine (TCT, 10.0 mmol) at 25°C. After the formation of a white solid, the reaction was monitored by TLC until the complete disappearance of TCT, then 1.41 g ethylcyclohexanone oxime (10.0 mmol) in 15 mL DMF was added. After the addition, the mixture was stirred at room temperature and monitored by TLC until completion (~8 h). Then 20 mL water was added, and the product was extracted with organic solvent. The organic phase was washed with 15 mL of a

saturated solution of Na_2CO_3, followed by 1 N HCl and brine. The organic layer was dried over Na_2SO_4, and evaporation of the solvent gave 1.41 g 7-ethylazepan-2-one without other purifications, in a yield of 100%, m.p. 91°C.

Other references related to the Beckmann rearrangement and the Beckmann fragmentation are cited in the literature.[27]

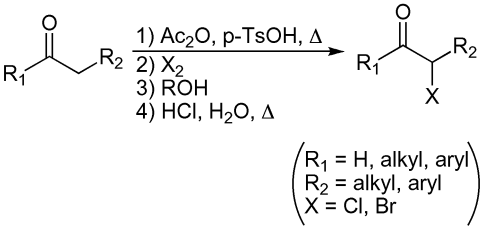
Bedoukian Halogenation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bedoukian in 1944.[1] It is a reaction for preparing α-brominated ketones or aldehydes via a sequential process, including the formation of enol acetate, the addition of bromine to enol acetate, and the acidic hydrolysis of the resulting intermediate addition.[2]

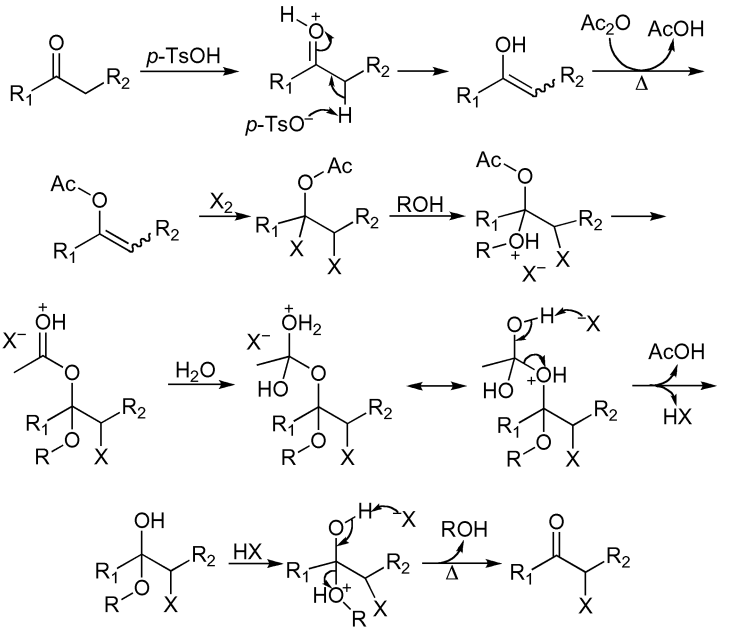
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed here is the general mechanism of the halogenation.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified for preparing α-halogenated ketones via enol tosylate,[3] enol ethers,[4] and enol silyl ether.[5]

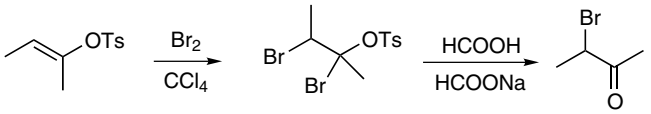
E. APPLICATIONS

This reaction provides an alternative method for preparing α-halogenated carbonyl compounds.

F. RELATED REACTIONS

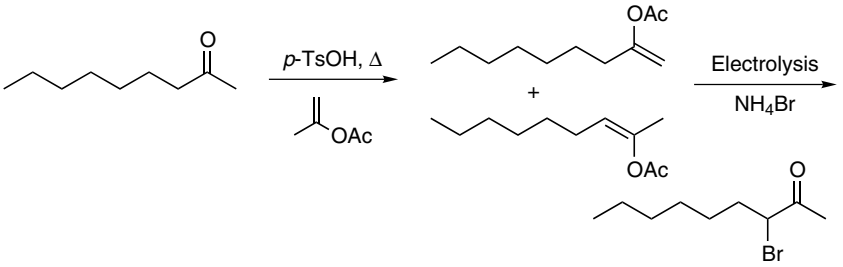
This reaction is related to the *Hell-Volhard-Zelinsky Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



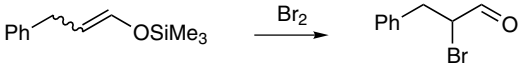
Reference 3.

To a solution of 0.5 mL CCl_4 containing 0.0358 g 2-buten-2-yl tosylate (0.01585 mmol) cooled in an ice bath was added 0.025 g bromine (0.1585 mmol); the mixture was kept cold until the completion of the addition. Evaporation of solvent gave the crude product. The flask containing erythro-2,3-dibromo-2-butyl tosylate was added the 0.125 M buffer of formic acid–sodium formate, and the reaction was monitored to completion. Then the solution was neutralized with $NaHCO_3$ and extracted with CCl_4. Removal of the solvent afforded 3-bromo-2-butanone. (*Note*: No complete experimental procedure was given in the original literature.)



Reference 2a.

A mixture of 1.02 g 2-octanone (7.92 mmol), 1.9 g isopropenyl acetate (19 mmol), and 50 mg *p*-TsOH was refluxed for 48 h. The mixture was worked up in the usual manner to give 1.32 g 1- and 2-octen-2-yl acetates, in a yield of 90%, b.p. 54–57°C (at 11 mmHg). To an electrolysis apparatus (an undivided cell equipped with two platinum electrodes (3 cm^2), a gas lead pipe, and a thermometer) were added 30 mg enol acetate, 19.7 mg NH_4Br (0.201 mmol), 6 mL acetonitrile, and 2 mL water. This solution was under a constant current of 6.7 mA/cm^2 at 3.0–5.0 V (anode voltage −0.75 V vs. Ag wire) at 20–25°C. After 2.3 F/mol of electricity was passed, the mixture was concentrated, and the residue was taken up in benzene:EtOAc (1:l). The usual workup gave 33.3 mg 3-bromo-2-octanone, in a yield of 95%. (*Note*: The corresponding chemical in the original literature was not relevant.)



Reference 5.

To a solution of 25 mL CCl_4 containing 6.2 g silyl enol ether was added slowly, over several hours, 1 equivalent of bromine in carbon tetrachloride. The rate of addition was maintained so that the solution was always colorless to pale orange. After the usual workup, 4.9 g 2-bromo-3-phenylpropanal was obtained as a colorless liquid, in a yield of 77%, b.p. 70–75°C (at 2 mmHg).

Other references for the preparation of α-halogenated carbonyl compounds are cited in the literature.[6]

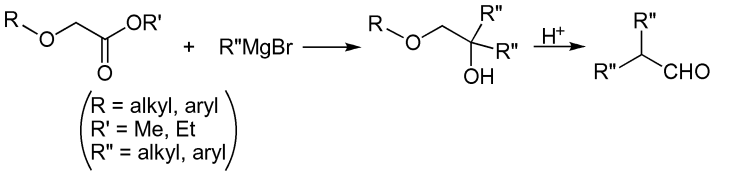
66

Béhal-Sommelet Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Béhal and Sommelet in 1904.[1] It is the transformation of methyl β-hydroxylalkyl ethers into aldehydes in the presence of acids, preferably oxalic acid. The methyl β-hydroxylalkyl ethers can be prepared via the *Grignard Reaction* between the Grignard reagents and esters of α-methoxy acetic acids.

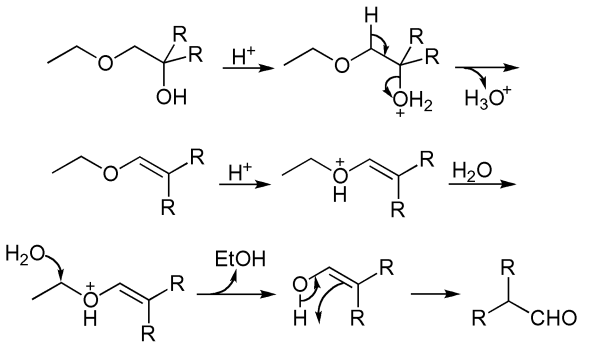
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction undergoes dehydration in the presence of an acid to form an intermediate of vinyl ether that breaks down to the aldehyde. Some insight about the mechanism can be found in the rearrangement of methylallyl alcohol into isobutyraldehyde.[2]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

The formation of methyl β-hydroxylalkyl ethers has been modified using Grignard reagents and esters of α-phenoxyacetic acids because this reaction is easier to handle. The formed phenyl β-hydroxyalkyl ethers are further converted into ethyl β-hydroxyalkyl ether by heating under pressure with alcoholic potassium hydroxide because the ethoxy compounds are more readily converted into the aldehydes.[3] In the presence of oxalic acid, the hydrocarbon chain of aldehydes can be extended while reacting with vinyl ether.[4] It has been found that the reaction between a Grignard reagent and ethoxymethyleneaniline also affords aldehyde.[5] In addition, vinyl ether can be converted into aldehyde when heated at 215°C over SiO_2.[6]

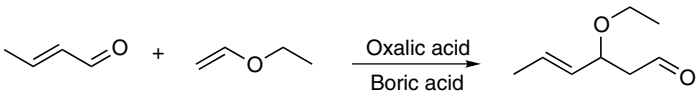
E. APPLICATIONS

It is a general method for preparing α-branched aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Serini Reaction*.

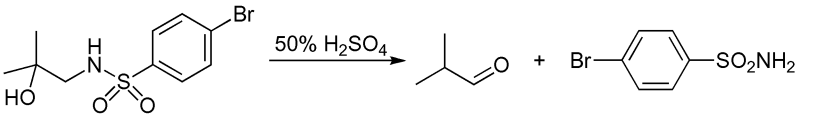
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a mixture of 630.0 g crotonaldehyde (9.0 mol) and 0.42 g boric acid–oxalic acid, was added 216.0 g vinyl ethyl ether (3.0 mol) over a period of 26 min while maintaining a reaction temperature of 40°C by periodic cooling. The red solution was stirred for an additional 15 min followed by neutralization of the catalyst with 5 g sodium carbonate in 200 mL water. Neutralization of the catalyst caused a color change from red to pale

yellow. The organic layer was distilled to provide 469 g wet crotonaldehyde and 195 g 3-ethoxy-4-hexenal, which distilled at 60–65°C (at 10 mmHg), in a yield of 46%.



Reference 7.

A total of 5 g l-*p*-bromobenzenesulfonamide-2-methyl-2-propanol was added to 60 mL 50% sulfuric acid, and the mixture was steam distilled until 100 mL distillate had been collected. To this distillate was added 4 g methone in 50 mL alcohol and a few drops of glacial acetic acid. The mixture was allowed to stand at room temperature for 8–9 days, after which the white crystals were removed by filtration and washed with aqueous alcohol to give 1.43 g methone derivative of isobutyraldehyde, m.p. 146–149°.

To the acid residue from the steam distillation was added an equal volume of water. The solid that separated was washed with water to afford 2.80 g *p*-bromobenzenesulfonamide, in a yield of 73%, m.p., 158–160°C.

Other references related to the synthesis of aldehydes are cited in the literature.[8]

Beirut Reaction

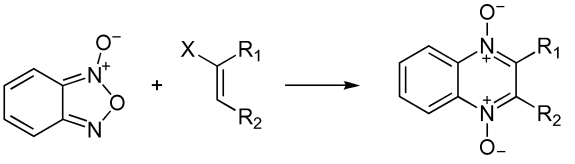
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Haddadin and Issodorides in 1965.[1] It is the preparation of quinoxaline-1,4-dioxides from the cycloaddition between benzofuroxan (i.e., benzofurazan *N*-oxide) and dienes, α,β-unsaturated ketones, enamines, or enolates. Unfortunately, this reaction is not named after the authors who discovered it; instead it is known as the Beirut reaction[2] after the city in which the inventors carried out is the initial work.[3] In most cases, ketones,[4] β-diketones,[5] β-ketoesters,[5b] β-ketonitrile,[2e] 1,3-dinitrile,[2d,2e,6] and β-ketoamides[7] all are suitable for this reaction, and the corresponding enolates can be easily prepared in the presence of a weak base such as triethylamine.[2a,2d,2e,5b] In addition, even phenolic enolates from phenol, resorcinol, hydroquinone, or benzoquinone undergo a similar dehydrative condensation with benzofuroxan under mild conditions (e.g., $NaOH/H_2O$, H_2O, $MeOH/RNH_2$, SiO_2/MeCN at room temperature), to give phenazine N,N'-dioxide derivatives.[3]

It should be pointed out that the Beirut reaction from unsymmetrically monosubstituted-benzofuroxanes affords two regio-isomers;[2e,5a] however, often only one regio-isomer is obtained after the workup and purification process,[2e] as shown in the reaction between 5-substituted benzofurxanes with benzoylacetonitrile, which gives only 7-substituted quinoxaline-1,4-dioxides.[8] Such high practical regioselectivity is probably due to the fact that the monosubstituents in benzofuroxanes do not have a directing effect on the formation of quinoxaline-1,4-dioxides.[5a] When aroylacetophenones are applied as the enolate precursors, the *ortho*-substituents have shown some directing effect, possibly owing to the steric hindrance, and the *para*-substituents do not have such effect.[5a] Besides the formation of quinoxaline N,N'-dioxides, the Beirut reaction can be used for quinoxaline mono-*N*-oxides as well.[2k]

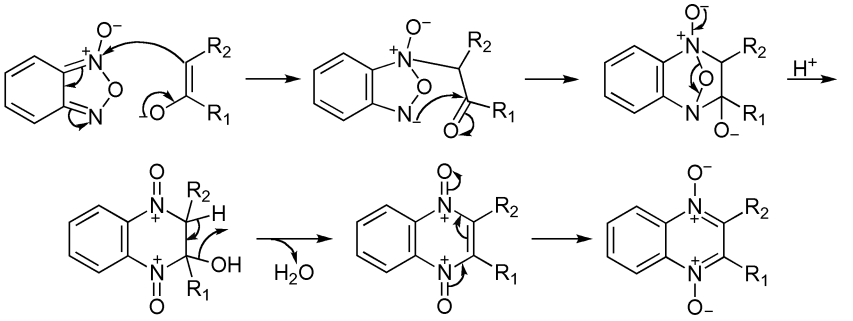
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction is assumed to involve the initial conjugate addition of enolate (or enamine) to the benzofuroxane ring, followed by the attack of nitrogen atom on the resumed carbonyl group,[3,5b] as shown below. In addition, the fused benzo moiety in benzofuroxane plays an important role, which provides the extra driving force for the Beirut reaction owing to the rearomatization of such a fused benzene ring. Furoxanes without a fused benzene ring are inactive in the Beirut reaction.[2f]



D. MODIFICATION

This reaction has been extended to use different phenolic enolates in the preparation of phenazine derivatives.[3]

E. APPLICATIONS

This reaction provides a general tool for phenazine derivatives via the reduction of quinoxaline-1,4-dioxides.[1] Such reduction can be achieved by catalytic hydrogenation (e.g., complex hydrides, H_2-Pd/C, or dissolving metals)[9] or other reducing reagents, such as sodium dithionite ($Na_2S_2O_4$),[5b,10] sodium hyposulfite ($Na_2S_2O_3$),[11] PCl_3.[7] In addition, under light illumination, quinoxaline-1,4-dioxides easily rearrange to benzimidazolone derivatives via an oxaziridine intermediate, as shown by the conversion of 2-benzoyl-3-phenylquinoxaline-1,4-dioxide to 1,3-dibenzoylbenzimidazolone.[12]

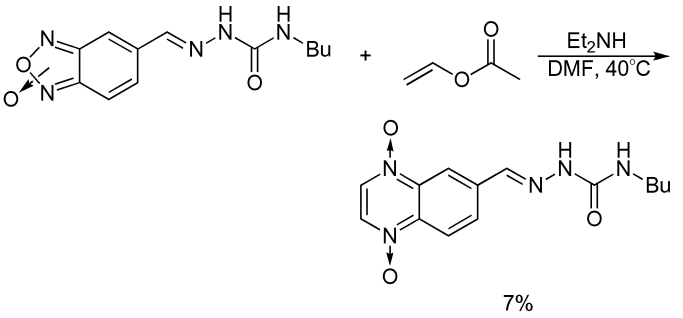
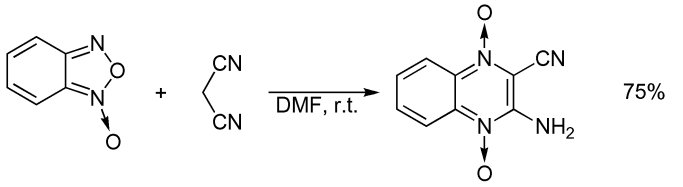
G. CITED EXPERIMENTAL EXAMPLES



Reference 2d.

To a solution of 0.2 g 4-butyl-1-[(benzo[1,2-*c*]1,2,5-oxadiazol-5(6)-yl-N_1-oxide) methylidene]semicarbazide (0.72 mmol) and 0.07 mL Et_2NH in 0.5 mL DMF, was added 0.13 mL vinyl acetate (1.44 mmol) over 10 min at 0°C. The reaction mixture was then stirred at 40°C for 24 h. An additional 1.3 mL vinyl acetate (14.4 mmol) and 1.0 mL Et_2NH were added, and the stirring was continued at 40°C for 48 h. After that, the solvent was removed in vacuo and the oily residue was co-evaporated with toluene (3 × 10 mL). The residue was purified by silica gel column chromatography using CH_2Cl_2 as the eluent to afford 7% 4-butyl-1-[(quinoxalin-6-yl-N_1,N_4-dioxide)methylidene] semicarbazide as colorless oil.



Reference 6.

To a solution of 1.36 g benzofuroxan (10 mmol) and 0.7 g malononitrile (10.6 mmol) in 4 mL DMF cooled at 0°C in an ice bath was added a solution of 0.2 mL Et_3N in 3.0 mL DMF. The resulting mixture was stirred below ambient temperature for 1.5 h, after that solution was filtered, the solid was washed with Et_2O to give 1.51 g 3-amino-2-quinoxalinecarbonitrile 1,4-dioxide, in a yield of 75%, m.p. 190°C (dioxane).

Other references related to the Beirut reaction are cited in the literature.[13]

Belluš-Claisen Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Malherbe and Belluš in 1978.[1] It is a variant of the *Claisen Rearrangement* involving the reaction of an allylic ether, thioether, or amine with a ketene to form a γ,δ-unsaturated ester, thioester, or amide, of which the double bond is in *trans* configuration. Thus this reaction is known as the Belluš-Claisen rearrangement,[2] Belluš-Claisen reaction,[3] or the Belluš reaction.[4] In addition, this reaction is also referred to as the acyl-Claisen rearrangement,[4,5] ketene-Claisen reaction,[3] and ketene Claisen rearrangement,[6] ignoring the contribution from Belluš. For the specific reaction of allylic amine, the corresponding rearrangement is also cited as the *Aza-Claisen Rearrangement*[7] and zwitterionic *Aza-Claisen Reaction*.[8]

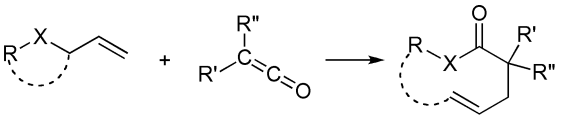
In the absence of heteroatom at the allylic position, alkenes usually undergo *[2+2] Cycloaddition* with ketenes to give cyclobutanones;[9] in contrast, in the case of allyl ether, thioether, or amine, the heteroatom (oxygen, nitrogen, sulfur, etc.) can chelate with ketene to form zwitterions, which undergo [3,3] sigmatropic rearrangement under the help of a base or a Lewis acid to afford γ,δ-unsaturated ester, thioester, and amide. In a special case, the Belluš-Claisen rearrangement of cyclic allyl ethers, thioethers, and amines can lead to the formation of ring-enlarged lactones, thiolactones, and lactams with *trans*-configurated double bonds by adding four carbon atoms to the rings.[2] It should be pointed out that when the heteroatom is oxygen or sulfur, the corresponding allyl ether or thioether reacts only with electrophilic ketenes, with a reactivity order of dichloroketene $\approx$ chloro(trichloroethyl)ketene $>>$ chloro(methyl)ketene $>$ chloroketene $\approx$ chloro(cyano)ketene.[2] In comparison, when the heteroatom is nitrogen, the allylic amines

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

can react with ketenes preformed,[10] or generated *in situ*[2] by zinc-induced dehalogenation of a 2-chloroacyl chloride,[11] photolysis of a chromium-carbene complex,[12] or dehydrohalogenation of an acyl halide[13] (with Et_3N[9e]). However, for this type of rearrangement, the presence of sane ring strain on the allylamines is necessary, otherwise a strong Lewis acid (e.g., Me_2AlCl) is required to promote the reaction.[12]

Even though the non-electrophilic ketenes are not feasible for the Belluš-Claisen rearrangement with oxygen and sulfur as heteroatoms, the reaction of halogenated ketenes provides an alternative route for those ketenes because the halogen atoms in the resulting esters and thioesters can be easily removed by various methods, such as the treatment with Zn/AcOH,[1] catalytic hydrogenation,[14] and radical dechlorination.[15] During the rearrangement, the original stereochemistry can be transferred into corresponding products.[12,16]

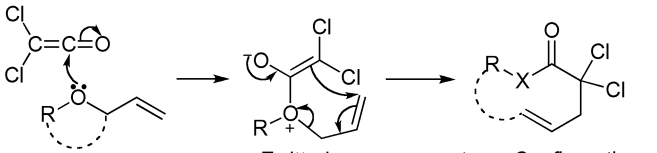
B. GENERAL REACTION SCHEME



R = alkyl, aryl, etc.
R' = alkyl, aryl, Cl, etc.
R" = alkyl, aryl, H, Cl, etc.
X = O, S, NR

C. PROPOSED MECHANISMS

Being a [3,3] sigmatropic rearrangement, this reaction is especially facilitated by the negative charge at the C_2 position,[17] the positive charge at the heteroatom, and the ring strain in the starting material, so that the Belluš-Claisen rearrangement often proceeds easily at room temperature.[2] Shown below is a representative mechanism between the reaction of an allylic ether and a dichloroketene.



Zwitterion *trans*-Configuration

D. MODIFICATION

Although this reaction is still at an early stage of development, a few modifications have been exploited. These modifications include the extension of the Belluš-Claisen rearrangement to ring strain molecules (such as 2-vinyloxetane,[3] 2-vinyloxirane,[13] and 2-vinylaziridines[13]) and to tertiary allyl amines,[3,12] the application of chiral Lewis acid derived from MgI_2 and bis(oxazolinyl)aryl ligands,[4] and the implementation of electron-rich ketene equivalents (e.g., alkoxyketenes, aminoketenes) by the photolysis of chromium carbene complexes.[12]

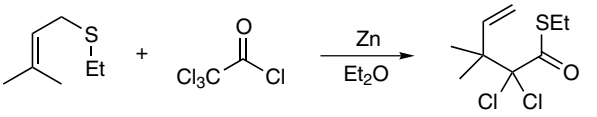
E. APPLICATIONS

This reaction has great potential in organic synthesis.

F. RELATED REACTIONS

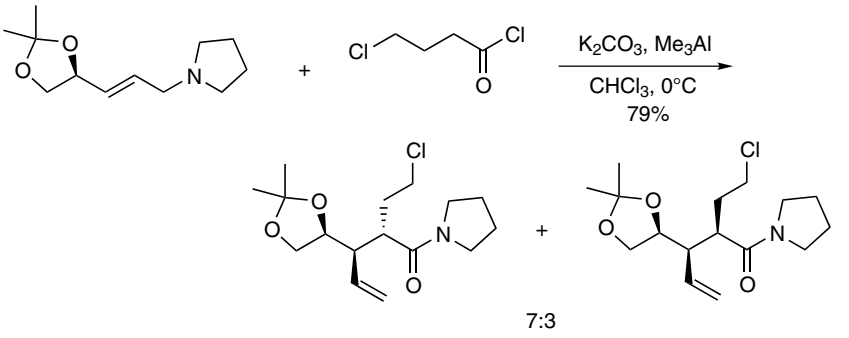
This reaction is closely related to the *Aza-Claisen Rearrangement*, *Claisen Rearrangement*, and *Abnormal Claisen Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

To a 750-mL flame-dried, five-necked flask equipped with a condenser, addition funnel, stirrer, thermometer, and nitrogen inlet were added 13.0 g ethyl 3-methyl-2-butenyl sulfide (0.10 mol), 7.2 g activated zinc (0.11 mol), and 200 mL anhydrous ether. Under stirring, a solution of 11.5 mL trichloroacetyl chloride (18.5 g, 0.105 mol) in 100 mL anhydrous ether was added to the suspension over a period of 4 h. After that, an additional 3.5 g activated zinc (0.05 mol) was added to the flask, and the mixture was stirred for an additional hour. Pentane (200 mL) was added to precipitate the zinc salts, and the solution was decanted from the residue. The residue was washed twice with ether-pentane (50 mL), and the combined solutions was washed successively with water, a cold solution of 10% $NaHCO_3$, and brine and then dried over $MgSO_4$. Upon removal of solvent under vacuum, 17.2 g of crude ethyl thioester of 2,2-dichloro-3,3-dimethyl-4-pentenoic acid was obtained which was further purified by vacuum distillation to give 9.1 g product, in a yield of 38% (should be >38%), b.p. 66°C 0.25 mmHg.



Reference 6a.

To a suspension of 3.2 g K_2CO_3 (23.2 mmol) in 60 mL dry $CHCl_3$ at 0°C under an argon atmosphere were added 2.35 g *N*-allylpyrrolidine (11.12 mmol) and 13 mmol ε-chlorobutanoyl chloride by means of a syringe. After being stirred at 0°C for 30 min,

a solution of 0.50 mL 2 M Me_3Al in toluene (1.02 mmol) was added via syringe. The mixture was stirred at 0°C, and after 24 h, a second volume of Me_3Al was injected. After 6 days, the reaction was quenched by addition of 5–10 mL saturated aqueous $NaHCO_3$ at 0°C dropwise until the Al_2O_3/K_2CO_3 precipitated. Then the organic layer was decanted, the solid residue was extracted with CH_2Cl_2 (5 × 20 mL), and the combined organic layers were dried over $MgSO_4$. Upon removal of solvent, the residue was purified by column chromatography using EtOAc/hexanes (1:1) to 2.77 g (2*S*,3*R*,4*S*)-2-(2-chloroethyl)-3-ethenyl-4,5-(isopropylidendioxy) pentanoic acid pyrrolidinamide (R_f = 0.17) and (2*R*,3*R*,4*S*)-2-(2-chloroethyl)-3-ethenyl-4,5-(isopropylidendioxy) pentanoic acid pyrrolidinamide (R_f = 0.22), in a yield of 79%. These diastereomeric amides (7:3) can be isolated by preparative HPLC (5% 2-propanol in hexanes) to afford 1.94 g of the major diasteromer, in a yield of 55%.

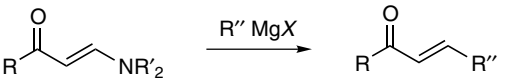
Bénary Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bénary in 1909.[1] It is the reaction between a Grignard reagent (or an organolithium reagent) and an enamino ketone or aldehyde to yield an α,β-unsaturated ketone or aldehyde.[2] Therefore, it is generally known as the Bénary reaction.[3] The Bénary reaction is a general reaction for preparing not only α,β-unsaturated ketones and aldehydes but also α,β-unsaturated esters with stereoselectivity.[3a] The reaction might occur via different mechanisms—for example, in the case of β-amino vinyl ketones, the reaction seems to proceed through a 1,4-addition-elimination,[3a,4] whereas β-aminopropenals seems to react with organomagnesium and organolithium reagents mainly via a 1,2-addition at the carbonyl group.[3a] For the Bénary reaction, it is found that higher yields can be obtained when the reactions are carried out in toluene with Grignard reagents.[5]

B. GENERAL REACTION SCHEME

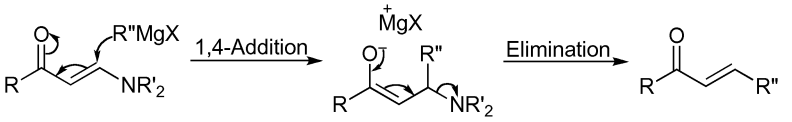


C. PROPOSED MECHANISMS

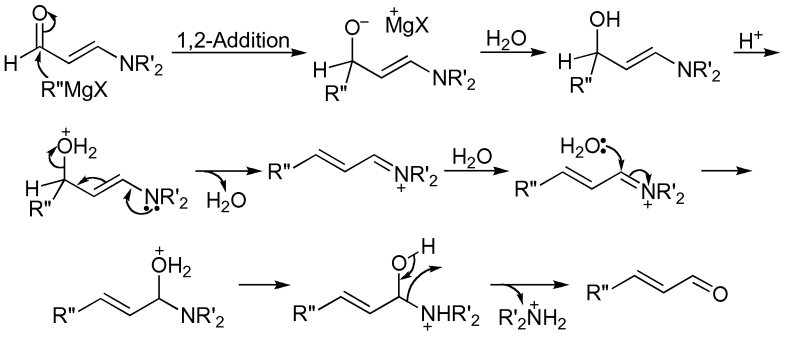
It is believed that the reaction occurs mainly via 1,4-addition followed by the elimination,[3,4] as shown below.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

1,4-Addition–elimination mechanism.



1,2-Addition mechanism.



D. MODIFICATION

This reaction has been modified via the conjugate addition (1,4-addition) and elimination of alkenyl-dialkylboranes with enones to prepare highly functionalized dienones.[6]

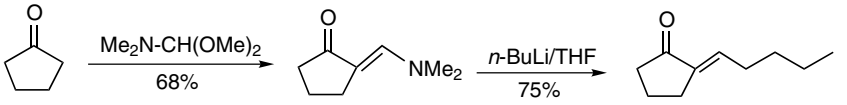
E. APPLICATIONS

This reaction has a general application in the preparation of α,β-unsaturated ketones, aldehydes, and esters.

F. RELATED REACTIONS

N/A

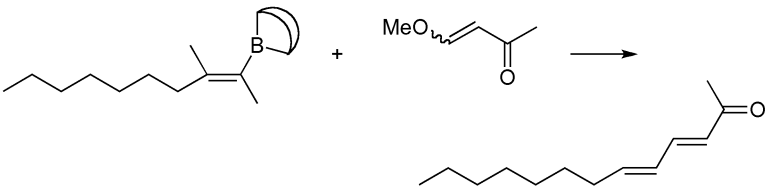
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

A mixture of 8.4 g cyclopentanone (0.1 mol) and 11.9 g *N*,*N*-dimethylformamide dimethyl acetal (0.1 mol) was refluxed under nitrogen at 110°C for 12 h. The resulting mixture was stripped of methanol and distilled in a Kugelrohr apparatus to afford 12.2 g 2-[(dimethylamino)methylene]-cyclopentanone as an amber oil, in a yield of 88%.

To 350 mL THF at −30°C under nitrogen was added 11.12 g 2-[(dimethylamino)methylene]-cyclopentanone and 57.2 mL 1.6 M *n*-butyllithium (1.1 eq.) dropwise over 30 min. The mixture was stirred to room temperature over 2 h. The excess *n*-butyllithium was destroyed with 5.0 mL water, and the solvent was removed in vacuo. The oily residue was treated with 100 mL water and extracted five times with 100-mL portions of ether. The ether was washed with water, dried over $MgSO_4$, and evaporated in vacuo (40°C, 10 mmHg) to afford 9.4 g 2-pentylidenecyclopentanone, in a yield of 75%, b.p., 100–102°C (8 mmHg).



Reference 6.

A dry nitrogen-flushed, 25-mL centrifuge tube equipped with a Teflon-coated magnetic stirring bar and capped with a rubber septum was charged with 2.46 g *B-trans*-l-nonen-l-yl-9-BBN (10 mmol), 0.34 g *n*-octane (3 mmol) as an internal standard, and 7.6 mL anhydrous diethyl ether. To the resulting solution was added 1.2 g 4-methoxy-3-buten-2-one (12 mmol). The reaction mixture was stirred for 24 h at 25°C and then quenched with 0.61 g ethanolamine (10 mmol). A precipitate of 9-BBN-ethanolamine adduct was formed almost immediately. After the resulting slurry was stirred for 1 h, the reaction mixture was centrifuged. Analysis of the supernatant by GC revealed that *trans*,*trans*-3,5-tridecadien-2-one was formed in 100% yield. The supernatant was decanted from the solid, and the volatiles were removed in vacuo. There remained 1.85 g *trans,trans*-tridecadien-2-one in a yield of 95%, with a purity > 95% by GC.

Benkeser Reduction

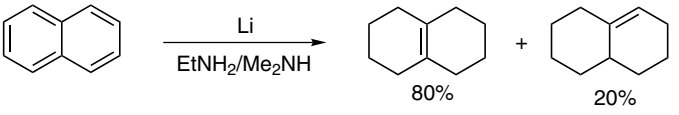
A. GENERAL DESCRIPTION OF THE REACTION

Although Dumanskii initially reported the reduction of simple aromatics to mono-olefins by lithium in liquid ammonia and calcium hexaamine $[Ca(NH_3)_6]^{2+}$ suspended in anhydrous ethyl ether in 1916,[1] these procedures were cumbersome and usually gave highly impure products;[2] thus the reduction of aromatic compounds using lithium or calcium was not developed until Benkeser's work in 1952.[3] The generaly known Benkeser reduction[4] is the reduction of aromatic and olefinic compounds with lithium or calcium to unsaturated olefins and fully reduced hydrocarbons in the presence of low molecular weight amines. In fact, Benkeser found that low molecular weight monoamines, particularly methylamine and ethylamine, were excellent media for reduction with lithium.[5] In neat monoamines, aromatic compounds are reduced to mono olefins,[5a,5d,5f] whereas in monoamine-alcohol solution, di-olefins are obtained.[5c] Although ethylenediamine, with the same nitrogen-carbon ratio as methylamine but with less volatility, has been applied as an alternative solvent for the Benkeser reduction,[6] the Benkeser reduction in ethylenediamine frequently results in overreduction of the substrate, giving a mixture of products. This drawback has been overcome by using 1 mole of ethylenediamine or *N*,*N*′-dimethylethylenediamine per gram-atom of lithium with or without the proton donor (alcohol).[7] So far, the lithium-reducing systems have been applied to the reduction of furan or benzofuran,[8] aryl halides,[9] carbazole,[10] epoxide,[11] carboxamide,[12] fluorene,[13] carboxylic acid,[14] quinoline, isoquinoline,[15] etc. Under certain conditions, the amination to hydrocarbon also occurs, besides the normal reduction.[16] Compared to the reduction of aromatics and olefins by lithium, the reduction by calcium in methylamine or ethylenediamine resembles the lithium-amine-reducing system and holds the advantage of donating two electrons per atom.[17] The calcium-reducing systems have also been applied extensively to the reduction of aromatic hydrocarbons,[2,18]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

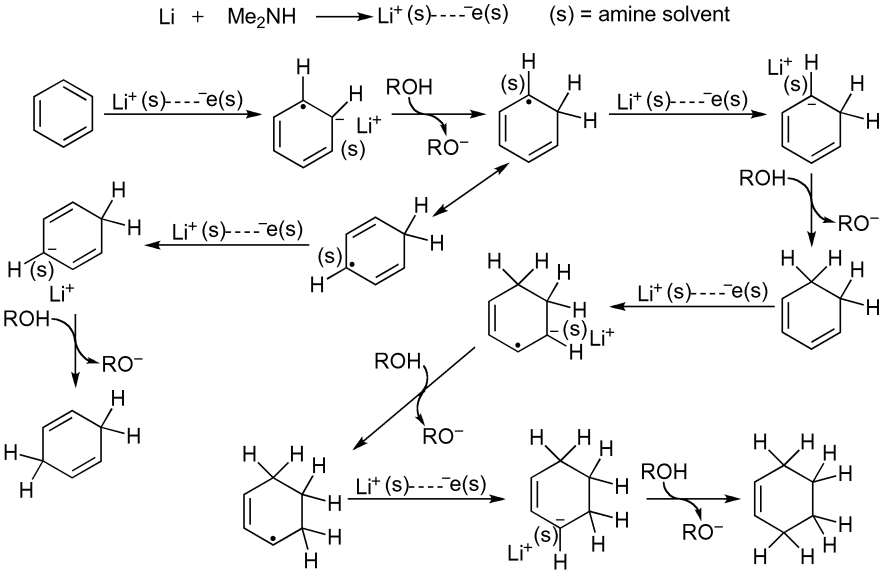
carbon-carbon double[2] and triple bonds,[19] benzyl ether,[19a] allylic ether,[11] epoxide,[11,19a] ester,[21] aliphatic nitrile,[22] dithiane,[21,23] thiophenyl, and sulfonyl groups.[19a] Similar reduction systems include the reduction by sodium in low molecular weight amine[24] and hexamethylphosphamide (HMPA) with alcohol.[25] In addition to these reducing systems, Benkeser also studied the electrochemical-reducing systems extensively,[26] which have also been extended by other research groups.[27]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction occurs via a radical mechanism, and the solvated electron is the real reducing reagent. Details of the Benkeser reduction are illustrated here, using benzene as an example.[28]



D. MODIFICATION

The reaction has been modified for reducing aromatics under electrochemical conditions.[26,27]

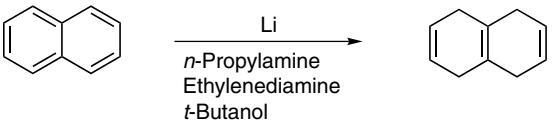
E. APPLICATIONS

This reaction has broad applications in the reduction of a variety of molecules.[2,8–15,18–25]

F. RELATED REACTIONS

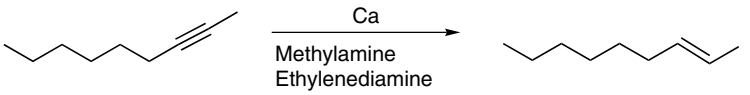
This reaction is closely related to the *Birch Reduction*, in which the alkali metals and alcohols are used in liquid ammonia. However, in laboratories, the Benkeser reduction is more commonly used because the solvent is safer and more convenient than liquid ammonia.[29]

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a cold solution (-6°C) of 12.8 g naphthalene (0.10 mol) in 100 mL *n*-propylamine, 30 g ethylenediamine (0.5 mol) and 44.4 g *t*-butanol (0.6 mol), was added 3.5 g lithium (0.5 mol) portionwise in small pieces. The solution was warmed to 20°C and maintained by the addition of lithium. After1.5 h, the reaction mixture was poured over 150 g ice and 100 mL water and then extracted with ether. The ether was washed with water, brine, and evaporated under reduced pressure to give 12.2 g of a colorless solid that was triturated with methanol, filtered, and dried to give crude product. Recrystallization from 50 mL methanol gave 9.8 g 1,4,5,8-tetrahydronaphthalene, in a yield of 74%, with a purity of 93% by GLPC.



Reference 19b.

Methylamine (75 mL) was distilled through a potassium hydroxide drying tube into a 500-mL three-necked, round-bottomed flask equipped with a mechanical stirrer, gas inlet tube, and a reflux condenser through which ethylene glycol was circulated (-25°C). All exits were protected with a U-tube of mercury. Then 50 mmol 2-nonyne, 2.51 g calcium shot (0.0625 mol), and 75 mL ethylenediamine freshly distilled from sodium were placed in the reaction flask. The mixture was then stirred for the indicated amount of time. If the reaction became too vigorous, it was controlled with a dry ice–acetone bath or by surrounding the flask with a small amount of dry ice. Prolonged cooling caused the reaction to stop (it resumed when allowed to warm up) and the ethylenediamine to solidify. A gray solid formed during the reaction, which often sparked when dry upon exposure to the atmosphere and reacted vigorously with water. The methylamine was allowed to evaporate by disconnecting the cooling liquid from the condenser. The flask was cooled to 0°C (ice water bath) and 200 mL diethyl ether was added. The mixture was hydrolyzed by the cautious, dropwise addition of 200 mL 2 M aqueous NH_4C1. A vigorous reaction accompanied this addition. The layers were separated, and the aqueous layer was extracted with two 75-mL portions of diethyl ether. The organic extracts were combined with the organic phase from the reaction mixture and washed with two 75-mL portions of water, two 75-mL portions of NH_4C1,

75 mL 5% $NaHCO_3$, and 75 mL brine and then dried over anhydrous Na_2SO_4. The solvent was removed by fractional distillation through a 4-in. vacuum-jacketed column. A short-path distillation of the remaining oil gave the product (*trans*-2-alkene) in a yield of 75–88%.

Other references related to reduction by either lithium or calcium are cited in the literature.[30]

Benzidine Rearrangement
(Semidine Rearrangement)

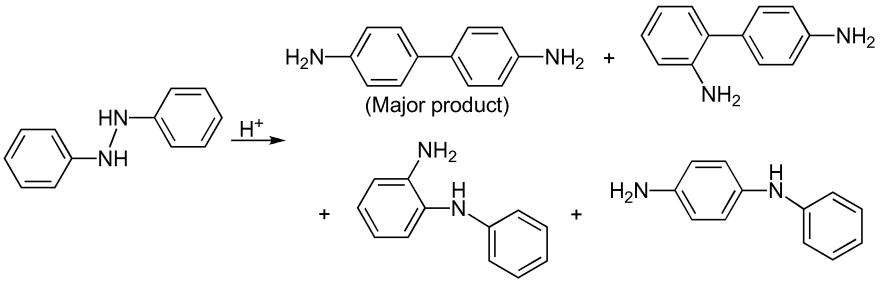
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hofmann in 1863.[1] It is an acid-catalyzed rearrangement of hydrazobenzenes (in general, the *N*,*N*′-diaryhydrazines) to 4,4′-diaminobiphenyls (benzidines) and is generally known as the benzidine rearrangement.[2] However, when hydrazobenzene contains a *para*-substituent, then the favored product is *p*-aminodiphenylamine, and such rearrangement is referred to as the semidine rearrangement.[3] In the benzidine rearrangement, besides the major product (4,4′-diaminobiaryls), other products may also be formed, including the 2,4′-diaminobiaryls, 2,2′-diaminobiaryls, and the *o*- and *p*-arylaminoanilines. The formation of different rearrangement products has led extensive studies on the reaction mechanisms, including the kinetic isotope effect,[2l−2n,2u,4] kinetic studies,[2a,2e,3i−3l,5] and other aspects of the mechanism (disproportionation,[6] salt formation,[7] intramolecular character,[8] effect of acid concentration,[9] effect of micelles,[2a,2c,10] Hückel molecular orbital calculation,[11] observation of dication intermediate,[3d,12] general acid catalysis,[13] photolytic rearrangement,[2a,2h,3h] etc.). The rearrangement to form benzidine is believed to occur via a [5,5]-sigmatropic shift in a concerted nature.[2k,2n,3c] Other mechanistic studies on benzidine rearrangement are available in Ref. 14.

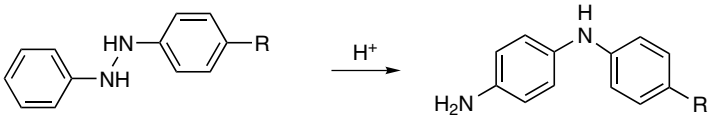
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

Hydrazobenzene without *para*-substituent.



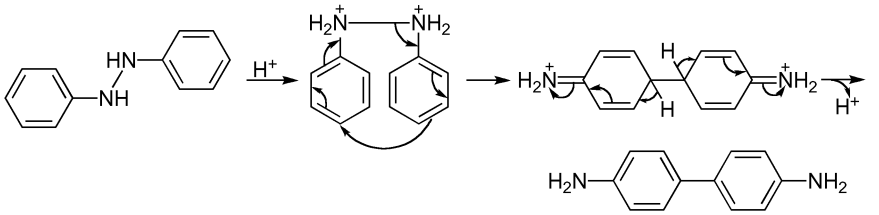
Hydrazobenzene with a *para*-substituent.



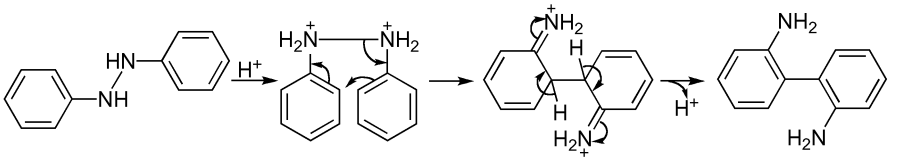
C. PROPOSED MECHANISMS

Based on extensive mechanism studies, it is believed that the rearrangement occurs via cationic intermediates, as illustrated here.

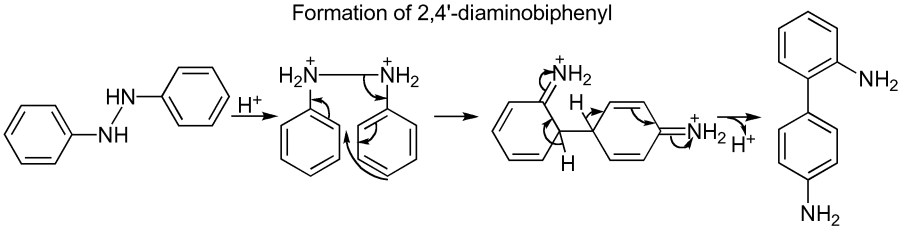
Formation of 4,4'-diaminobiphenyl



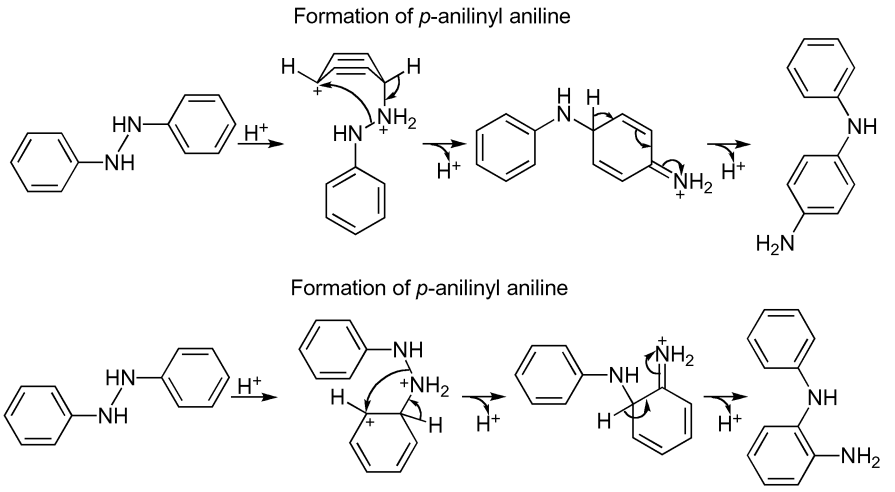
Formation of 2,2'-diaminobiphenyl



Formation of 2,4'-diaminobiphenyl



(Continued)



The last two pathways predominate in the rearrangements when a substituent exists at the *para*-position of one aryl group.[3c]

D. MODIFICATION

This rearrangement has been carried out using different acids as catalyst.

E. APPLICATIONS

This reaction has general application in the preparation of biphenyls with or without amino groups.

F. RELATED REACTIONS

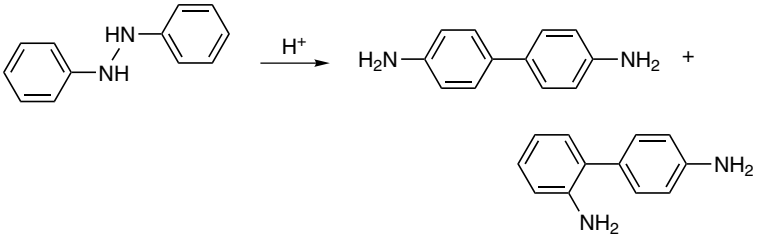
G. CITED EXPERIMENTAL EXAMPLES



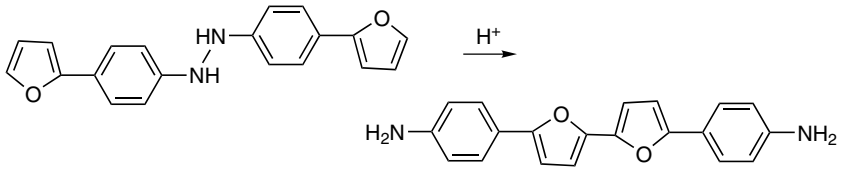
Reference 4.

Partial Conversion

Hydrazobenzene (2.2 g) was obtained by reduction of 2.4 g azobenzene in 150 mL acetone with 12 g zinc powder and 15 mL saturated NH_4Cl solution. After being dried for 12 h over $CaCl_2$ and under vacuum, 1.5 g hydrazobenzene (8.15 mmol) was dissolved in a mixture of 306 mL freshly distilled 95% EtOH and 102 mL water. Another solution was prepared from 10.5 g LiCl (248 mmol), 41 mL 2.0 N HCl and 61 mL water. Each solution was cooled to 0°C under argon. The two solutions were mixed under a flow of argon and kept at 0°C for 30 min, after which 50 mL saturated KOH solution was added quickly. Air was bubbled through the alkaline solution for 24 h to oxidize unused hydrazobenzene to azobenzene. The solution was evaporated to a smaller volume at room temperature. Approximately 10 mg azobenzene distilled in the evaporation. The mixture that remained was extracted with ether (4×100 mL). The ether solution was washed with 2 N HCl (3×100 mL) and water (2×50 mL). The ether solution was dried over $MgSO_4$ and evaporated in a rotary evaporator to give 1015 mg azobenzene (5.58 mmol, 68.5%). This was sublimed to give 989 mg azobenzene (5.38 mmol, 66%). The combined aqueous washings were made alkaline with saturated KOH solution and were extracted with ether (3×100 mL). Workup gave 379 mg residue. This was dissolved in 8 mL CH_2C1_2, and hexane was added slowly to the solution to precipitate 210 mg 4,4′-diaminobiphenyl, mp 125–126°C. After filtration, the solution was evaporated to give 126 mg residue. This was chromatographed on silica gel with cyclohexane/absolute EtOH (5:l) to give 11 mg unknowns (two or more), 47.6 mg (0.26 mmol, 3.2%) 2,4′-diaminobiphenyl as an oil, and 77.6 mg 4,4′-diaminobiphenyl, m.p. 125–126°C. The two portions of 4,4′-diaminobiphenyl were combined and crystallized from hot water to give 237 mg (1.29 mmol, 15.8%) 4,4′-diaminobiphenyl, m.p. 125–126°C.

Total Conversion

The procedure was as described but with a smaller amount of hydrazobenzene. The rearrangement mixture was kept in the refrigerator for 48 h and then made alkaline (the yields are 90–98%). Treatment with air was omitted.



Reference 2e.

A solution of 1.0 g bis[4-(2-furyl)phenyl]diazane (3.16 mmol) in 50 mL ethanol was cooled to 0°C under nitrogen. To this solution was added a solution of 3 mL conc. hydrochloric acid in 10 mL ethanol. The reaction mixture was allowed to stand in a refrigerator for 24 h, during which time the hydrochloride salt of benzidine rearrangement product was precipitated out from the solution and was almost free from impurities. The precipitate was filtered and neutralized with 1 N sodium bicarbonate solution. Further purification was

achieved by column chromatography using EtOAc/CH_2Cl_2 (1:1 v/v) as the eluting solvent to afford 0.75 g pure rearrangement product, in a yield of 75%, m.p. 203–205°C.

Other references related to the benzidine rearrangement and semidine rearrangement are cited in the literature.[15]

Benzilic Acid Rearrangement

(Benzil-Benzilic Acid Rearrangement)

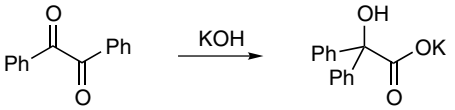
A. GENERAL DESCRIPTION OF THE REACTION

This rearrangement was first reported by von Liebig in 1838.[1] It is the conversion of benzil (α-diketone) into the salt of α-hydroxy acid by means of base treatment and is generally known as the benzilic acid rearrangement[2] or benzil-benzilic acid rearrangement.[3] It is one of the oldest and most widely studied carbon-carbon bond cleavage reactions[4] and is a specific hydroxide ion catalyzed rearrangement.[2mm,2bbb,2ccc,5] This rearrangement is normally carried out in the favored solvents of water and aqueous ethanol,[3d] and it can also be performed in other aqueous organic solvents, such as in aqueous dioxane[2mm,2bbb,2ccc,6] or even in solid state.[2f,7] The rearrangement may take up to 4 days at room temperature but completes within a few hours under refluxing.[3d] On the other hand, the counterion of the base also affects the reaction rate of the rearrangement when the reaction is carried out in aqueous organic solvents, whereas the metal cation effect is not important when the reaction occurs in water. For example, when 2,2′-dichlorobenzil was treated with base in 50% aqueous dioxane at 60.5°C, barium hydroxide caused the rearrangement to occur about 15 times faster than that with sodium hydroxide, whereas thallous hydroxide effected the reaction about 5 times faster than that with barium hydroxide;[6] in 67% aqueous dioxane at 49.5°C, only lithium hydroxide among the alkali hydroxides can increase the rate about

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

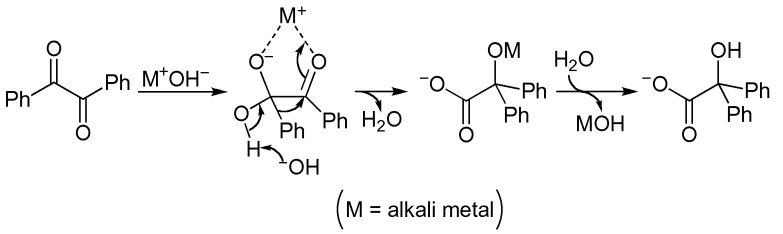
3 times of other alkali hydroxides.[2mm] For the rearrangement of unsymmetrically substituted benzils, rings containing electron-withdrawing substituents migrated preferentially to phenyl, while phenyl rearranges before the ring containing electron-donating substituents.[8] It is generally assumed that this rearrangement occurs via the preliminary reversible addition of hydroxide ion to benzil followed by an irreversible migration of a phenyl group and subsequent proton exchange.[2bbb] The coordination of metal cation also helps this rearrangement.[2mm]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is illustrated below for the reaction of simple benzil.



D. MODIFICATION

This reaction has recently been carried out under the irradiation of microwave which completed within 1 min.[3d]

E. APPLICATIONS

This reaction has general application for preparing benzilic acids and their esters which have important biological activities.[9] The formed benzilic acid can be used as reducing reagent to transform α,β-unsaturated ketones into saturated ketones.[2b] In addition, the benzilic acid rearrangement on cyclic α-diketones will lead to ring contracted products.[2j,2ii,2kk,2nn]

F. RELATED REACTIONS

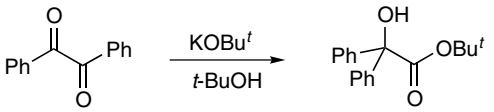
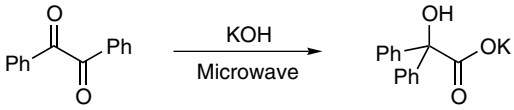
G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

A solution prepared from 2.5 g potassium in 100 mL *tert*-butyl alcohol (dried by distilling from sodium) in a flask protected from moisture was heated. With frequent flushing by nitrogen, 8.0 g benzil was added quickly with stirring. After being refluxed for 2 h, excess alcohol was removed by distillation, leaving a solid residue that was hydrolyzed with sodium bicarbonate solution and extracted with ether. Acidification of the aqueous layer gave 0.85 g benzilic acid (9.79%), m.p. 149–150°C after one recrystallization from water. The dried ether solution was concentrated to a residue that was crystallized once from carbon tetrachloride to afford 8.26 g crude *t*-butyl benzilate, in a yield of 76%, m.p. 53–55°C. Further recrystallization from carbon tetrachloride gave pure material, m.p. 60.0–60.2°C, which was soluble in ether and ethanol and insoluble in water.



Reference 3d.

The mixture of 0.56 g KOH (10 mmol) and 0.1 mL water was allowed to stand for 2 min. to dissolve the KOH, then 0.42 g powdered benzil (2 mmol) was added to the KOH solution, and the mixture was well ground with a pestle to form a milky material. Then 5 mL Celite was added, and the resulting mixture was ground again. The final mixture was irradiated in a domestic microwave oven (70% power) for 15s once and then three times for 10s. Diethyl ether (5 mL) was added to the mixture, which was stirred for a while and filtered. The mixture was acidified to pH 1.5 with 25 mL 3 M HCl and then extracted with 100 mL ethyl acetate. The organic phase was dried over $MgSO_4$ and concentrated to give 0.393 g benzilic acid as a white solid, in a yield of 86%, m.p. 146–148°C.

Other references related to the benzilic acid rearrangement are cited in the literature.[10]

Benzoin Condensation

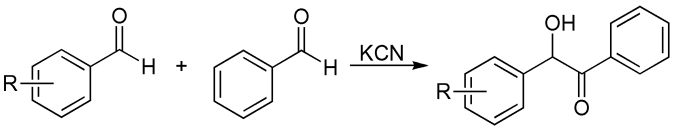
A. GENERAL DESCRIPTION OF THE REACTION

Benzoin condensation,[1] sometimes known as the benzoin reaction,[2] is the condensation between aromatic aldehydes to form α-hydroxyl ketones (i.e., benzoins) in the presence of a catalyst. It should be pointed out that benzoin itself is not produced from benzaldehyde by acid or base catalysis or under thermal or free-radical conditions; in fact, benzoin is generated from benzaldehye in the presence of a catalyst.[3] The first benzoin condensation catalyzed by cyanide ion was reported by Stange in 1824,[1oo,4] and has been extensively studied by others since.[5] The interest in benzoin condensation is probably due to the fact that benzoins can be converted into 1,2-diphenyl amino ketones or 1,2-diphenyl amino alcohols, which have shown some important biological functions, such as tumor-necrotizing activities.[6] Since 1943, It has been known that thiamin (vitamin B_1) and related thiazolium salts can catalyze the benzoin condensation in the presence of a mild base.[1w,1ii,1ss,7] Currently, other catalytic systems have been developed, including *N*, *N*′-disubstituted *o*-phenylenediamines,[8] thiazolium cyclophane,[1o] and enzymes.[9] The benzoin cndensation is normally carried out in aqueous solution, and the addition of salt (LiCl, KCl) can increase the reaction rate;[1u] however, the condensation can also be performed in organic solvent, such as anhydrous petroleum ether.[5e] In contrast to the salt effect in aqueous solution, the addition of salt (LiCl, $LiClO_4$) into organic solvents (ethylene glycol, formamide, and DMSO) results in the decreasing of reaction rate.[1u] However, a few aldehydes were found not to form benzoin under the benzoin condensation condition; instead ethylenediol and ethanediol were formed.[10] This condensation when catalyzed by cyanide ion, is assumed

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

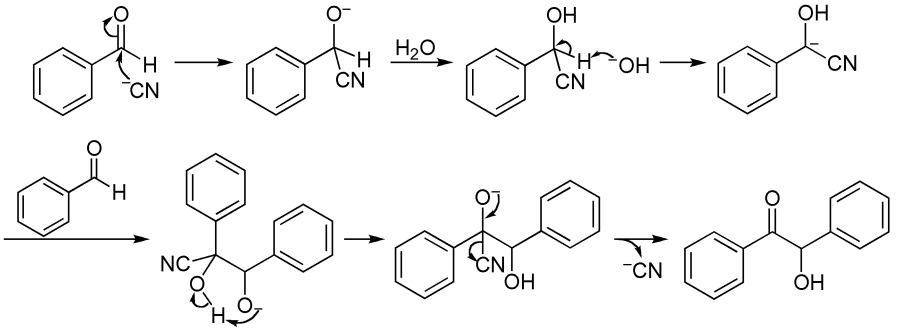
to occur via the addition of cyanide to an aldehyde group, deprotonation to form carbanion, and the addition of carbanion to a second aldehyde group to form benzoin.[1ee,5c,5j,7e,11] The mechanism is similar when catalyzed by thiazolium salt.[1n,1r,1w,1x,1dd,1gg,1ii,1jj,1ll,1pp,1rr]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism in the presence of cyanide is displayed here.



D. MODIFICATION

The original benzoin condensation catalyzed by cyanide ion has been modified to use thiamin and a related thiazolium salt,[7] diamine,[8] or enzyme[9] as a catalyst. In addition, the aldehyde group can be replaced by a bisulfite group[1ddd] or converted to silyl-ester[12] to undergo the benzoin condensation.[1ddd]

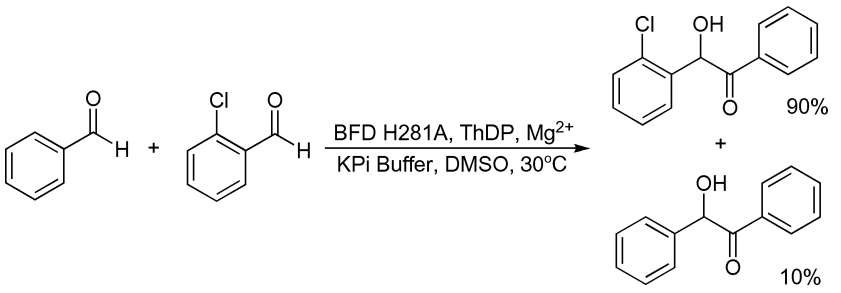
E. APPLICATIONS

This reaction is generally applied for preparing benzoins that can be oxidized to benzil,[1hhh] or converted to other diphenyl α-amino ketones or alcohols.

F. RELATED REACTIONS

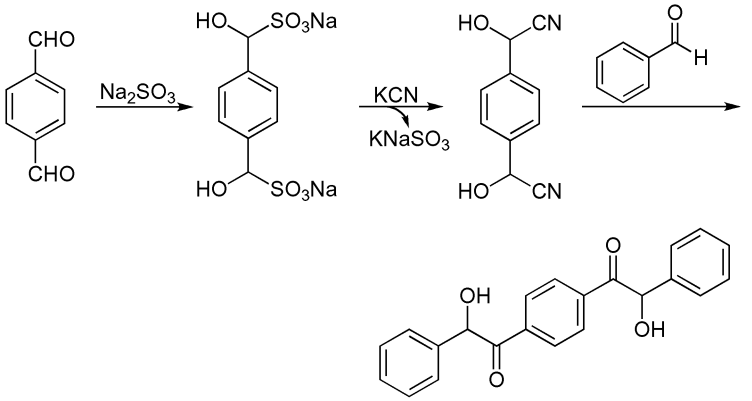
This reaction is related to the *Acyloin Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 1ooo.

2-Chlorobenzaldehyde (113 μL, 1.0 mmol) was dissolved in 10 mL DMSO and 40 mL KPi buffer (50 mM, pH 7.0, ThDP 0.5 mM, $MgCl_2$ 2.5 mM) to give a 20 mM solution. After the addition of 102 μL benzaldehyde (1.0 mmol, 20 mM), 516 units BFD H281A was added, and the reaction mixture was stirred at 30°C for 26 h. The aqueous phase was extracted with 20 mL dichloromethane, the organic phase was dried over Na_2SO_4, and the solvent was removed under reduced pressure. The crude product (160 mg, 65%) was purified by column chromatography (hexane/EtOAc = 9:1) on a deactivated silica gel to yield 80 mg (*R*)-2′-chlorobenzoin as colorless needles, in a yield of 33%, e.e.: > 99%, m.p. 70°C; $[\alpha]_D^{21} = -338.0(0.1, CHCl_3)$.



Reference 1ddd.

Terephthalaldehyde biscyanohydrin was prepared from 10.0 g sodium bisulfite adduct (0.0292 mol) and the stoichiometric amount of potassium cyanide. This aqueous solution (which contained the inorganic reaction by-products) was then added to 18.9 g stirred benzaldehyde (0.178 mol) at 68°C over a period of 10 min. Subsequently, the reaction mixture was stirred at 68–70°C for 2 h. After cooling, the semisolid mass was washed with water and the excess benzaldehyde was removed under reduced pressure at 88–100°C. The bisbenzoin, $C_6H_5CH(OH)C(O)C_6H_4C(O)CH(OH)C_6H_5$, was isolated in 46% yield by treatment of the semisolid mass with benzene followed by crystyallization from methanol, m.p. 230–233°C. The bisbenzoin can be oxidized to bisbenzil as well, as described next.

The residue (14.8 g) was dissolved in 140 mL 80% acetic acid and heated with stirring at 101–105°C together with 20.0 g ammonium nitrate (0.2498 mol) and 0.2 g cupric acetate. On cooling, 6.39 g of yellow crystals appeared, in a yield of 64%, m.p. 116–119°C. Crystallization from ethanol gave 5.74 g pure 1,4-bis(phenylglyoxyloyl)benzene in a yield of 57%, m.p. 123.5–124.2°C.

Other references related to the benzoin condensation are cited in the literature.[13]

Bergius Process

A. GENERAL DESCRIPTION OF THE REACTION

This process, first invented by Bergius in 1913,[1] is based on Bergius's earlier research under high pressure in Hanover in 1909, in which cellulose was initially converted into a coal-like substance followed by the hydroliquefaction of the coal itself.[2] The generally known Bergius process[3] is a simple process for converting brown coal completely into crude oil in the presence of certain catalysts. In this process, the brown coal, also known as lignite, is ground into a fine powder and placed into a high-pressure reactor where the coal powder reacts with hydrogen gas at high temperature (425–480°C) and high pressure (200–700 atm). The initial catalyst for brown coal was molybdenum oxide in low concentration, along with sulfuric acid to partially neutralize the calcium humates in the brown coal.[2] Subsequently, iron, molybdenum, and tin, were commonly used as liquefaction catalysts in large-scale plants in Germany and England before World War II. Although iron remains the catalyst metal of choice because of the cost and availability, the effectiveness of well-dispersed molybdenum at low concentrations has led to much research on precursors based on that metal and on possible recovery and recycling of the catalyst.[4] Different from the regular hydrogenation reaction (or process) with Platinum or Palladium as catalyst, sulfur added to the reaction systems of the Bergius process is not only nonpoisonous to the catalyst, but also beneficial for increasing the efficiency of the catalyst.[5] After the development of the catalysts, Bergius won a Nobel Prize in 1931 for his contribution to industrial science.[6] This liquefaction of coal has also been carried out in supercritical fluids, such as in *sc*H_2O. Under this condition, the liquid hydrocarbons were extracted from the coal into the *sc*H_2O,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

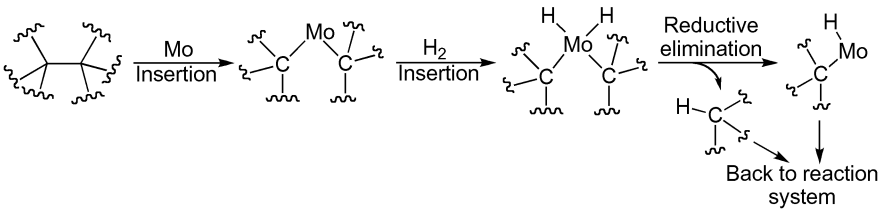
and the catalysts were recovered by precipitation induced by a pressure reduction. The advantages associated with such modification include the prevention of caking formation with coal, convenient separation of hydrocarbons from solvent, high efficiency by rendering the coal residue more porosity, and optimization of the yield up to 50 wt %.[7]

B. GENERAL REACTION SCHEME

$$C + H_2 \xrightarrow[\Delta,\ \text{high pressure}]{\text{Catalyst}} C_nH_{2n+2}$$

C. PROPOSED MECHANISMS

The hydroliquefaction of coal in the Bergius process is not a simple reaction or process; in fact, it involves a series of organometallic transformation, such as insertion, migration, and reductive elimination. Therefore, only a small part of the reaction scheme is displayed here to show a possible conversion.



D. MODIFICATION

This process has been modified using different metals as catalyst and has been carried out in supercritical fluids, such as $sc H_2O$.[6]

E. APPLICATIONS

This process has been used to produce hydrocarbons in the range of gasoline, diesel, and jet fuel from coal.

F. RELATED REACTIONS

The mechanism in Bergius process might be similar to the hydrogenation of alkenes using the *Adkins Catalyst*.

G. CITED EXPERIMENTAL EXAMPLES

$$C + H_2 \xrightarrow[420°C,\ 1500\ psi\ H_2]{MoS} C_nH_{2n+2}$$

Reference 8.

Experiments were run using 0.9%, 2.0%, 3.0%, and 5.0% sulfided molybdenum naphthenate (as the percent of molybdenum in the resid) to select a catalyst level. Standard conditions of 30 min at 420°C at a 3:1 tetralin/resid ratio, 3 wt % sulfided molybdenum naphthenate catalyst, and 1500 psi of hydrogen pressure were selected for determination of the relative reactivity to hydroconversion of the coal-derived vacuum resids. It was found that both catalyst concentration and hydrogen pressure have strong effect on the conversion of coal to hydrocarbon.

Other references related to the Bergius process are cited in the literature.[9]

Bergman Cyclization

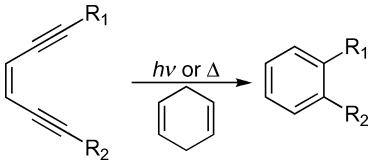
A. GENERAL DESCRIPTION OF THE REACTION

The generally known Bergman cyclization[1] (or cyclisation[2]), sometimes also referred to as the Bergman cycloaromatization,[3] Bergman reaction,[4] and Masamune-Bergman cyclization,[5] is the formation of aromatic compounds from (*Z*)-enediynes via a 1,4-biradical intermediate. Although this reaction can be traced back to 1940–1950s,[6] it is Bergman who first proposed and proved the existence of the 1,4-aryldiradical intermediate in the gas phase for the thermal rearrangement of substituted 3-hexene-1,5-diynes in 1972.[7] Unfortunately, this reaction was largely ignored until the discovery of the enediyne class of anticancer antibiotics in the 1980s, including calicheamicin,[8]esperamicin,[9] dynemicin,[10] and kedarcidin.[11] These enediyne antibiotics are among the most potent antibiotic antitumor agents ever investigated.[12] Their reactivity is believed to be the action of the enediyne moiety, which undergoes a Bergman cyclization to generate a reactive diradical that can abstract hydrogen atoms from the backbone of DNA, thus cleaving the DNA.[13] The Bergman cyclization is an endothermic reaction (8.5 $\pm$ 1.0 Kcal/mol),[14] and the formed 1,4-biradical is believed to be a reactive σ,σ-biradical[15] that abstracts hydrogen from the proton donor (usually 1,4-cyclohexadiene) to give an aromatic compound; this intermediate sometimes also abstracts a chlorine atom from CCl_4 to form substituted 1,4-dichlorobenzenes or reacts with dissolved oxygen to form quinone.[16] The significant electronic configurational mixing from a closed-shell structure to the open-shell character of 1,4-biradical in this cyclization has led extensive mechanistic studies, mainly through computation.[1i,1p,1q,1w,1aa–1dd,1ff,1pp,1qq,1vv,1zz,4,17] The factors that affect the Bergman cyclization include solvent,[1ss] molecular strain energy,[1vv,19] the distance

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

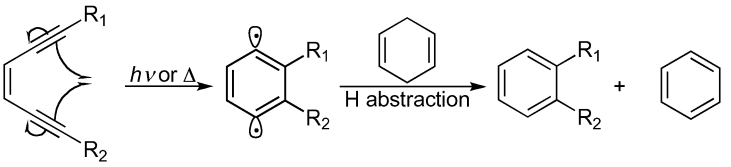
separating the acetylenic termini,[12] and electronic effect.[1gg,1uu,1xx,20] The Bergman cyclization can be carried out either thermally[1kk,1nn,13a,17c,21] or photochemically,[1b,1f,1u,1ff,21e,22] and the formed 1,4-biradical intermediate can either polymerize to give polymer[23] or initiate a radical polymerization process.[1r,24] When a carbon-carbon double bond (ethylene moiety) is replaced by a heteroatom (nitrogen), the corresponding cyclization is called aza-Bergman cyclization.[17f,25] Currently, this cyclization has been used to prepare macrocyclic compounds[26] and, more importantly, in photodynamic therapy[27] and biomedicine.[28]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is displayed below.



D. MODIFICATION

The original thermal cyclization has been modified to occur under photo irradiation.[1u,1ff,21e,22b–22e]

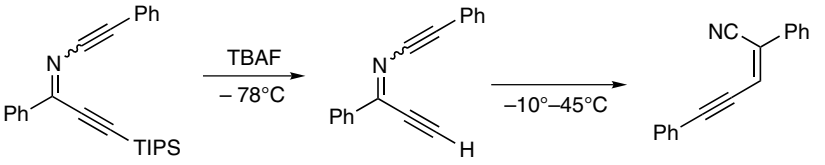
E. APPLICATIONS

This reaction can be applied to radical polymerization,[1r,23,24] the preparation of substituted quinones,[16] 1,4-dichlorobenzenes, macrocyclic compounds,[26] and heteroaromatic compounds (via aza-Bergman cyclization).[1f,25] However, the most important application of this reaction is in photodynamic therapy[27] and biomedicine.[28]

F. RELATED REACTIONS

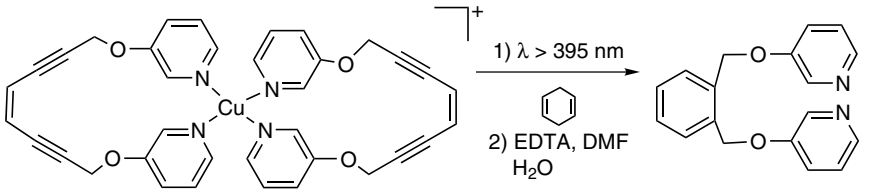
This reaction is related to the *Myers-Saito Cyclization* and *Schmittel Cyclization.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 29.

A solution of 68.0 mg 1,4-diphenyl-6-(triisopropylsilyl)-3-aza-3-ene-1,5-diyne (0.176 mmol) in 6.0 mL dry THF was cooled to –78°C and then a 1 M solution of TBAF (0.194 mmol) was added slowly. After being stirred at –78°C for 5–10 min the mixture was poured into 10 mL ice water and extracted by CH_2Cl_2 (2 × 15 mL). The dry organic solution was plugged through a small column before evaporation. The conversion of aza-enediyne to (*Z*)-2,5-diphenyl-pent-2-en-4-ynenitrile was followed by ^{1}H NMR and/or UV-vis spectroscopy. After the conversion was complete, the (*Z*)-2,5-diphenyl-pent-2-en-4-ynenitrile was purified by flash chromatography on silica gel (0–10% CH_2Cl_2 in hexanes) to afford 36.0 mg product as a yellow solid, in a yield of 89%, m.p. 79.3–80.7°C, R_f = 0.41 (50% CH_2Cl_2 in hexanes).



Reference 1u.

Under anaerobic condition, a Schlenk tube was charged with 20 mg $[Cu(bpod)_2]PF_6$ (0.03 mmol) dissolved in 20 mL dry, degassed (five freeze–pump–thaw cycles) CH_3CN. To this solution, either a 10-fold excess of degassed 1,4-cyclohexadiene or > 5000-fold excess of 2-propanol was added as a hydrogen-atom donor. In both cases, the final concentration of $[Cu(bpod)_2]PF_6$ in solution was 1 mM. These solutions were photolyzed with light of $\lambda \geq 395$ nm within a temperature-controlled bath (0–3°C) for 4 h (2-propanol) to 12 h (1,4-cyclohexadiene), depending on the concentration of the hydrogen-atom donor. Upon photolysis, the solutions change to a brown color, and a precipitate began to form within 1 h. To isolate the photoproduct, larger-scale photolysis was performed (∼275 mg) using the same ratios of hydrogen-atom donor. Upon completion of the photolysis, the solutions were concentrated, stirred with a 1:3 mixture of degassed ether/CH_3CN to precipitate the product, and filtered anaerobically. The solid was subsequently washed with ether and dried in vacuo to yield ∼135 mg (47%) of solid metal-containing photoproduct. The solid inorganic photoproduct (∼90 mg) was dissolved in 25 mL DMF. A 10-fold excess of aqueous Na_2EDTA solution was added to sequester the metal, and the mixture was allowed to be stirred gently at 0°C for 12 h. The precipitate was filtered and the uncomplexed organic material was extracted with dichloromethane. The organic layer was then washed with water, using a separatory funnel, and dried over anhydrous Na_2SO_4. The resulting brown oil was purified by flash chromatography (20% MeOH/CH_2Cl_2, R_f = 0.47) and had a

yield of 87% (based on 2 mol of ligand per mole of reacted complex) of the dark yellow Bergman-cyclized ligand.

Other references related to the Bergman cyclization are cited in the literature.[30]

Bergmann Degradation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bergmann in 1934.[1]It is a method of elucidating peptide sequences via carboxyl terminal (or C-terminal) peptide degradation,[2] involving the Curtis rearrangement of *N*-benzoylamino acids or *N*-benzoylpeptide hydrazides. The thermal rearrangement of the corresponding azides in the presence of benzyl alcohol yields the appropriate benzylurethanes. The removal of the *N*-benzyloxycarbonyl group is accomplished by catalytic hydrogenation in the presence of hydrochloric acid followed by boiling in water. This method removes the C-terminal amino acid residue as the next lower aldehyde in the homologous series and leaves the rest of the peptide in the form of its amide.[3] The acyl azide of C-terminal amino acid residue can be prepared in many ways, including the nitrosylation of *N*-formylaminoacyl hydrazide followed by nucleophilic displacement with sodium azide,[4] reaction with diphenylphosphoryl azide,[5] reaction between the mixed anhydride of amino acid and the TMS azide,[6] and other methods.[7]

B. GENERAL REACTION SCHEME

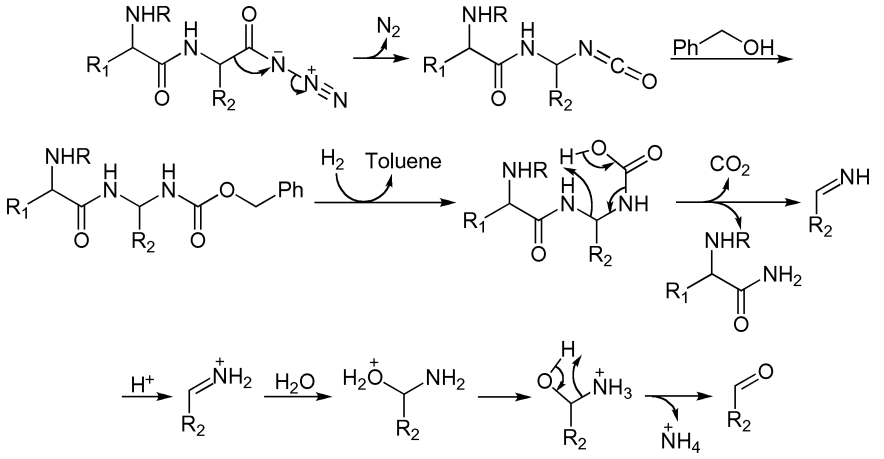
C. PROPOSED MECHANISMS

Displayed is the reaction mechanism, including the benzoylation, hydrogenation, and formation of aldehyde.



D. MODIFICATION

N/A

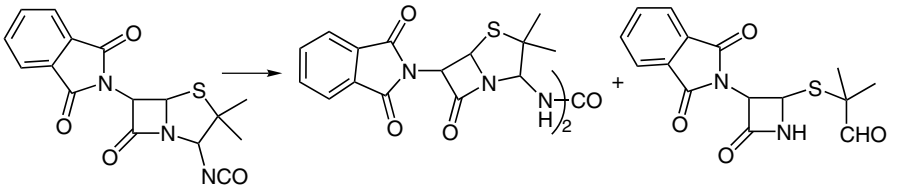
E. APPLICATIONS

This reaction has general application in protein and peptide sequencing. In addition, this method has been used to cleave the penicillin nucleus.[8]

F. RELATED REACTIONS

This reaction is related to *Curtius Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

To a stirred solution of 3.68 mL 1 N HCl in 300 mL 50% aqueous tetrahydrofuran at room temperature was added dropwise over 3.25 h a solution of 1.26 g 2,2-dimethyl-6-phthalimido-3-penamyl isocyanate (3.68 mmol) in 200 mL THF. The reaction mixture was stirred for an additional 0.5 h after the addition of the isocyanate was complete. The reaction mixture was then extracted with CH_2Cl_2 (3×200 mL), and the combined methylene chloride extracts were washed with two 150-mL portions of water, dried over anhydrous magnesium sulfate, filtered, and concentrated under reduced pressure to an oil. From this oil was obtained 0.02 g *N*,*N*′-bis(2,2-dimethyl-6-phthalimido-3-penamyI)urea mixture by fractional crystallization from an ethanol-petroleum ether (b.p. 30–60°C), which after recrystallization from acetone-petroleum ether, was purifed as a hygroscopic crystalline solid, m.p. 184–185.5°C. The filtrate after removal of the urea was concentrated to a viscous oil, which on crystallization from benzene-ligroin (b.p. 90–100°C) yielded in four crops of 1.0 g 3-phthalimido-4-(1′-formyl-1′-methylethylthio)-2-aze-tidinone, in a yield of 76%, m.p. 101–105°C. Two recrystallizations from benzene-ligroin gave an analytical sample, m.p. 110–119°C.

Bergmann-Stern Azlactone Synthesis

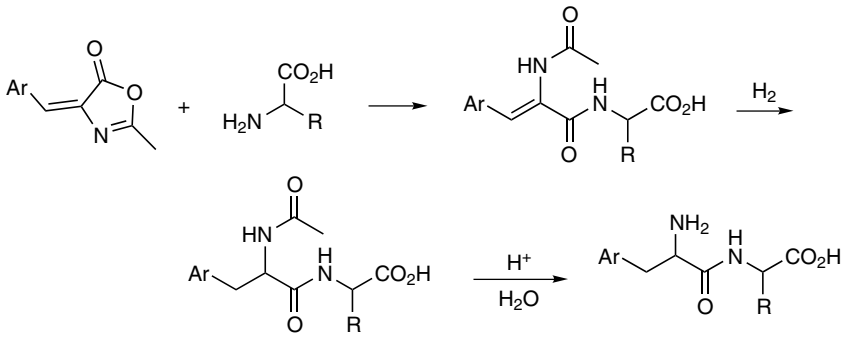
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bergmann and Stern and others in 1926.[1] It is the synthesis of peptides by aminolysis of azlactones from α-amino acids or corresponding esters and is generally known as the Bergmann-Stern azlactone synthesis.[2] This reaction involves the conversion of an acetylated amino acid and an aldehyde into an azlactone (also known as 5-oxazolone[3]) with an alkylidene side chain, the reaction of azlactone with the second amino acid to form an acylated unsaturated dipeptide along with the opening of the azlactone ring, the catalytic hydrogenation of the resulting *N*-acyl enamine, and final hydrolysis to give dipeptide. In fact, the first unsaturated azlactone was prepared by Plöchl, who condensed benzaldehyde with hippuric acid.[4] It was Erlenmeyer who coined the word of *azlactone* to describe the formed oxazolone and who initially showed the usefulness of these compounds in formation of α-keto acids and α-amino acids.[5] In comparison, the first saturated azlactone was reported by Mohr and Geis in 1908 by heating *N*-benzoyl-α-aminoisobutyric acid with acetic anhydride.[6] In most cases, the azlactone is racemic even though the starting material is optically active,[7]and the partly optically active azlactone racemizes more rapidly than it reacts with *p*-nitrophenol.[8] It was Bergmann who realized the racemization of *N*-acyl or benzoyl derivatives of α-amino acids in the presence of acetic anhydride, even in a catalytic amount, and who developed the method of synthesizing peptide.[9] This method has been greatly improved, and its scope has been extended by gently heating α-amino acid with trifluoroacetic anhydride to form 4-substituted-2-(trifluoromethyl)-6-oxazolone.[10] Overall,

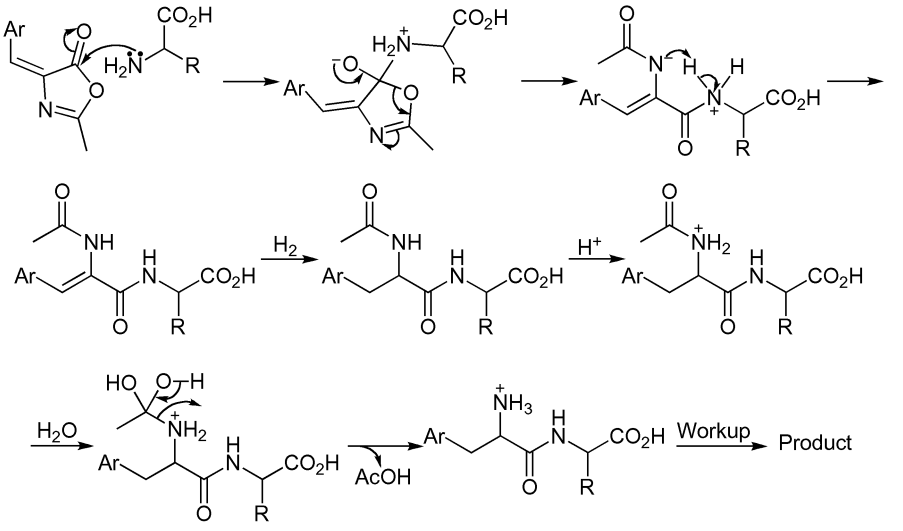
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

this reaction can be used to synthesize peptides containing tyrosine, arginine, histidine, glutamic acid, and other amino acids.[11] In addition, the formed azlactones can be converted into α-keto acids and α-amino acids.[5]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to heat amino acid with trifluoroacetic anhydride to form 4-substituted-2-(trifluoromethyl)-6-oxazolone,[10] which can react with the succeeding amino acid to form peptide. The azlactone with a saturated side chain can be prepared from α-keto acid and subjected to the peptide synthesis.[12]

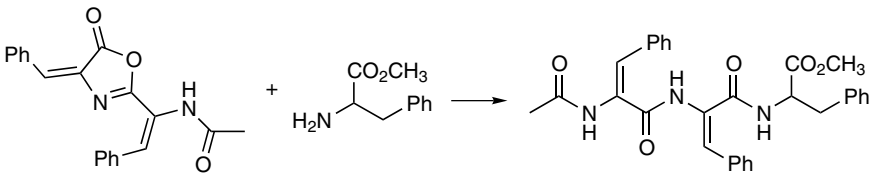
E. APPLICATIONS

This reaction has general application in the preparation of peptide. The azlactone itself can be converted into α-keto acid or α-amino acid.[5]

F. RELATED REACTIONS

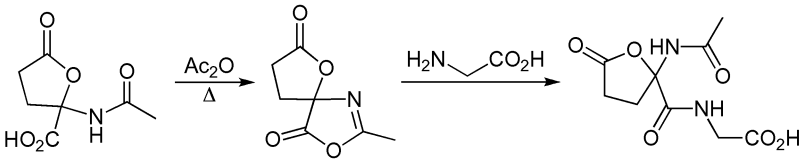
This reaction is related to the *Erlenmeyer-Plöchl Azlactone Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To a solution of 1.0 g azlactone (3.0 mmol) in 20 mL dry chloroform was added to a 5 mL $CHCl_3$ solution containing 0.64 g phenylalanine methyl ester hydrochloride (3.0 mmol) and 0.30 g NEt_3 (3.0 mmol). The reaction mixture was allowed to reflux for 8 h; then the solvent was removed under reduced pressure. The residue was washed with water and recrystallized from methanol-water and chloroform-petroleum ether to give methyl ester of Ac-(dehydro-Phe)$_2$-L-Phe, m.p. 188–189°C. (*Note*: No yield was given in the original reference.)



Reference 12.

A suspension of 3 g α-acetamino-α-hydroxyglutaric lactone in 60 mL acetic anhydride was heated on a boiling water-bath until all the material dissolved; 10–15 min was required,

during which time the solution became orange-yellow. After removal of the excess acetic anhydride in vacuo, the crude azlactone, a yellow viscous oil, was suspended in 30 mL acetone and treated immediately with a solution of 1.12 g glycine in 15 mL normal sodium hydroxide (1 N). The mixture, containing a trace of undissolved material, was shaken for 30 min, neutralized with 15 mL normal sulfuric acid (1 N), evaporated to dryness in vacuo, and extracted thoroughly with cold 95% alcohol. The alcoholic solution was evaporated to dryness; the residue was taken up in a small amount of water and decolorized with charcoal. The aqueous solution was then evaporated to dryness, and the residue was washed with cold alcohol. The 1.3 g of insoluble portion was recrystallized by suspension in hot alcohol with dropwise additions of water until solution took place. On cooling, 0.7 g of the lactone of α-acetamino-α-hydroxyglutarylglycine was separated from the solution.

Other references related to the Bergmann-Stern azlactone synthesis are cited in the literature.[14]

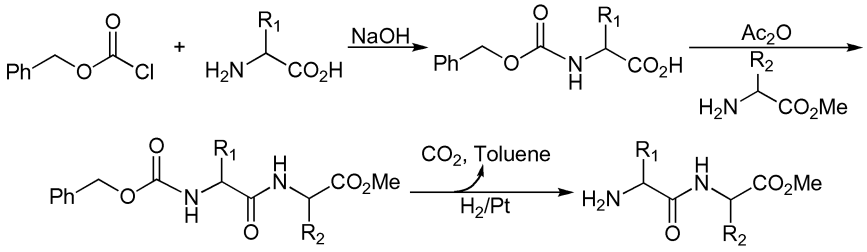
Bergmann-Zervas Peptide Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

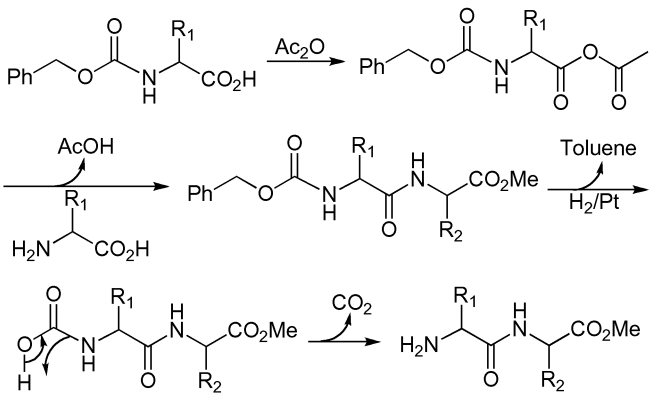
This reaction was first reported by Bergmann and Zervas in 1932.[1] It is a synthesis of peptide involving the process of conversion of the amino acid into its *N*-carbobenzoxy derivative, activation of the carboxyl group, formation of peptide with the second amino acid, and deprotection via hydrogenolysis.[2] However, the original procedure did not lend itself to the preparation of cysteine or cystine peptides, as the catalyst (Pd, Pt) was not active enough in the presence of a sulfur-containing molecule. Therefore, the reductive removal of the carbobenzoxy group was modified by treatment of the resulting peptide with metallic sodium in liquid ammonia.[3] Moreover, other deprotection methods have been developed, such as the acidic hydrolysis using phosphonium iodide,[4] and hydrogen iodide in acetic acid.[4] In addition, the carbobenzoxy group can also be cleaved using hydrogen bromide[2,5] or hydrogen chloride.[6] This method has become a standard method for protecting amino groups in peptide synthesis.[7]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

The removal of the carbobenzoxy group has been modified by reductive cleavage using sodium in liquid ammonia[3] or nonhydrolytic cleavage using acidic hydrolysis (HI, HBr or HCl).[2,4–6]

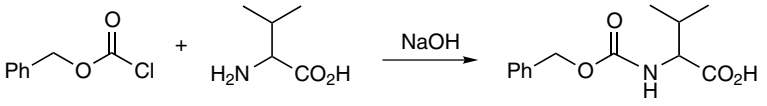
E. APPLICATIONS

This method has been extensively applied for peptide synthesis.[7]

F. RELATED REACTIONS

This reaction is related to the *Fischer Peptide Synthesis*.

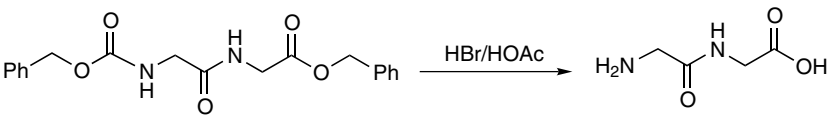
G. CITED EXPERIMENTAL EXAMPLES



Reference 7r.

DL-Valine (11.7 g, 0.10 mol) was dissolved in 25 mL 4 N sodium hydroxide. With cooling in an ice-bath, there were added simultaneously with stirring, over a period of 45 min, 25 mL 4 N sodium hydroxide and 23 mL carbobenzoxy chloride solution (from 200 g of 20% phosgene in toluene and 38 mL benzyl alcohol, allowed to react and then concentrate under reduced pressure to 80 g). The solution was acidified with hydrochloric acid, which

deposited an oil. The mass was crystallized by dissolving in dilute sodium hydroxide, reprecipitating with hydrochloric acid, and permitting it to stand overnight in the refrigerator to yield 21.0 g carbobenzoxy-DL-valine, in a yield of 84%, m.p. 75–77°C (uncor.). In later preparations, ether or ethyl acetate was used to extract the initial oil obtained upon acidification; the extracts were dried, and the solvent was removed by evaporation. The residue was crystallized by dissolving in benzene, precipitating with hexane, and seeding with material from the first preparation to yield 20.5 g carbobenzoxy-DL-valine, in a yield of 82%.



Reference 2.

Carbobenzoxyglycylglycine benzyl ester (5 g) was suspended in 25 mL glacial acetic acid, and a stream of dry hydrogen bromide was bubbled through the hot solution (60°C) for 1 h. During the reaction, the starting material dissolved, and after 15 minutes the dipeptide hydrobromide began to separate. Dry ether (100 mL) was then added, and the reaction flask was kept in the refrigerator for 4 h. The supernatant liquid was decanted, and the solid was washed with small portions of ether and dried in vacuo. To obtain the free peptide, the hydrobromide was dissolved in a minimum amount of water, excess pyridine was added, and the peptide was precipitated with absolute alcohol. It was filtered, washed with absolute alcohol and dry ether, and dried in vacuo over sulfuric acid for 48 h to afford glycylglycine, in a yield of 83%, m.p. 222°C (dec.).

Other references related to the Bergmann-Zervas peptide synthesis are cited in the literature.[8]

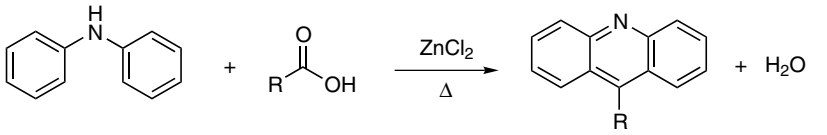
Bernthsen Reaction
(Bernthsen Acridine Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bernthsen in 1878.[1] It is one of the earliest methods for the synthesis of acridine by heating diphenylamine hydrochloride with benzonitrile. Therefore, this reaction is generally known as the Bernthsen reaction.[2] In the modified method, the mixture of diphenylamine, an aromatic or aliphatic carboxylic acid, and zinc chloride is heated at 200–270°C for 20 h.[3,4] Heating zinc chloride with *N*-acyldiphenylamine[5] or a mixture of diphenylamine and acyl chloride also affords acridines.[6]

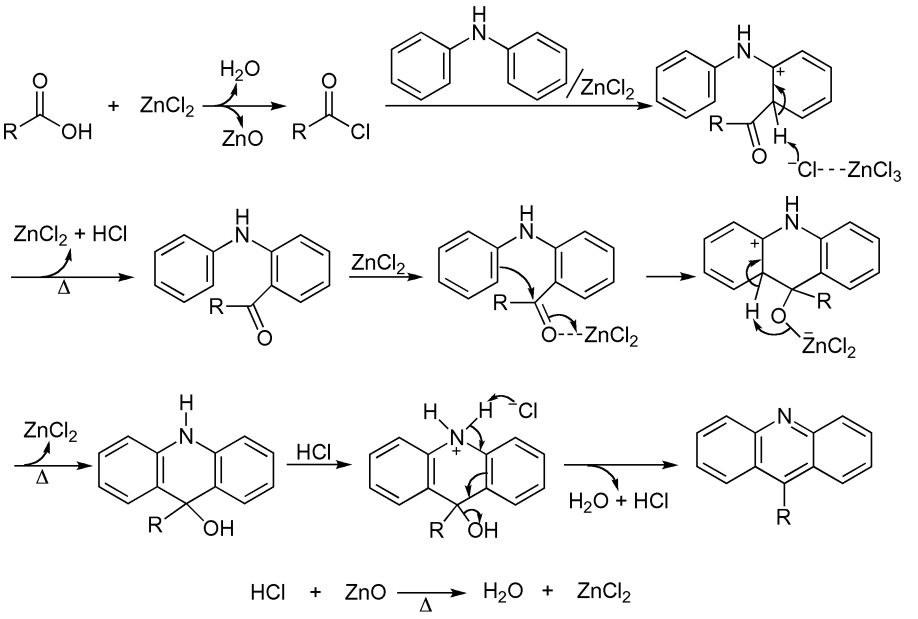
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is proposed for this reaction, as shown here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified to form the intermediate of 2-acyltriphenylamine from triphenylamine.[2d]

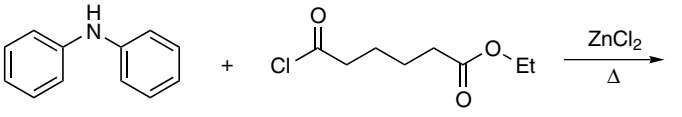
E. APPLICATIONS

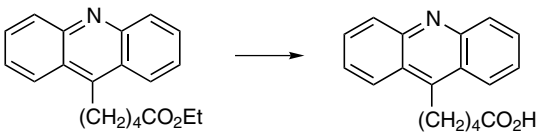
This reaction has generally been used to prepare substituted acridines, which can be converted into quinolines.[7]

F. RELATED REACTIONS

N/A

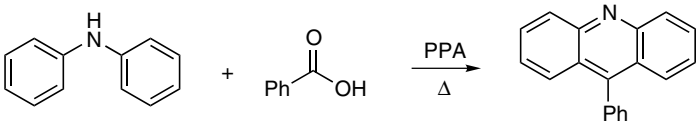
G. CITED EXPERIMENTAL EXAMPLES





Reference 6.

A mixture of equimolecular amounts of ethyl adipyl chloride and diphenylamine was heated with a small amount of anhydrous zinc chloride at temperatures ranging between 180°C and 220°C for 30 h. The dark brown liquid mixture was saponified by boiling with 8% ethanolic sodium hydroxide solution for 3 h. The solid sodium salt was dissolved in water, and unreacted diphenylamine was removed by ether extraction. The alkaline solution was acidified, extracted again to remove adipic acid, and then carefully neutralized to phenolphthalein. A brownish solid [6-(9-acridyl)valeric acid] precipitated, which was filtered and recrystallized from boiling pyridine. The yield was 12%. The compound dissolved to give a yellow solution in alkali and showed a green fluorescence in acids. It melted at 265–269°C (dec.) after some sintering.



Reference 2d.

A mixture of 0.06 mol diphenylamine, 0.03 mol benzoic acid, and 230–250 g polyphosphoric acid was heated with stirring at 195–205°C for 15 min. The reaction mixture was then poured onto ice and filtered or decanted. Examination of the infrared spectra of the gummy solid indicated that it contained mainly diphenylamine, a small amount of ketonic product, and possibly some 9-substituted acridine. Treatment of the solution with 25% sodium hydroxide solution caused the precipitation of a solid (while the solution was still acidic), which was apparently the phosphate salt of the 9-phenyl acridine. This product was washed with water and alcohol to give analytically pure material after drying in vacuo. The yield was 18%, m.p. 184–185°C.

Other references related to the Bernthsen reaction are cited in the literature.[8]

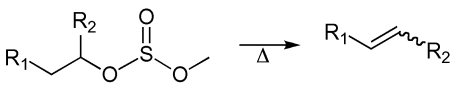
Berti Olefination

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Berti in 1954.[1] It is a reaction for preparing olefin via the pyrolysis of methyl sulfites of aliphatic or alicyclic alcohols. This reaction is similar to the *Chugaev Reaction* (the pyrolysis of xanthates of alcohols) but occurs via a *trans* pyrolytic elimination mechanism.[2] Different from the pyrolysis of other esters of alcohol (via the quasi six-membered ring transition sate[2]), the Berti olefination is evidenced to undergo a nonconcerted mechanism with the heterolysis of the carbon-oxygen bond, yielding ion pairs followed by direct proton loss or a 1,2-hydride shift and subsequent proton loss from the cationic species.[1,3,4] Important examples are the pyrolysis of *cis*-2-phenylcyclohexyl methyl sulfite to 1-phenylcyclohexene (78%) in preference to 3-phenylcyclohexene (22%)[1c] and the pyrolysis of 1,2-*cis*-cyclohexyl diol sulfite to cyclohexanone; the pyrolysis of 1,2-*trans*-cyclohexyl diol sulfite gives cyclopentaldehyde.[1b]

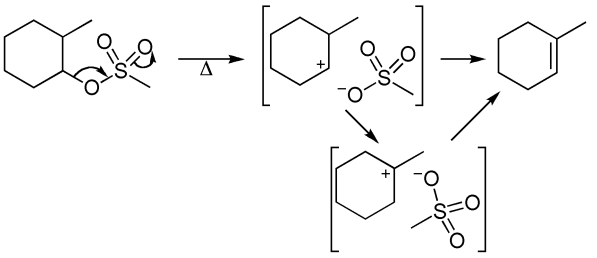
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction is evidenced to undergo a heterolytic cleavage of C–O bond to form olefins.[1,3,4]



D. MODIFICATION

N/A

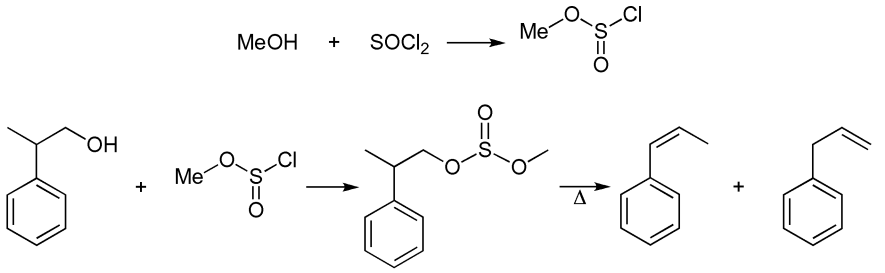
E. APPLICATIONS

This reaction has general applications for the preparation of olefins.

F. RELATED REACTIONS

This reaction is related to the *Chugaev Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 1c.

Methyl chlorosulfinate was prepared by the method of Carre and Libermann.[5] A 500-mL three-necked, round-bottomed flask, fitted with a mechanical stirrer, calcium chloride tube, and dropping funnel was used. To 260 g thionyl chloride, 64 g anhydrous methanol was added dropwise with stirring over 43 min. The reaction mixture was left 48 h at room temperature to allow for the reaction to complete. Then it was distilled under reduced pressure through a 50-cm Vigreux column; the fraction boiling between 35° and 36°C

(65 mmHg) was collected to give 199 g methyl chlorosulfinate, in a yield of 88%. The product can be stored for some time in the refrigerator, but it slowly undergoes decomposition.

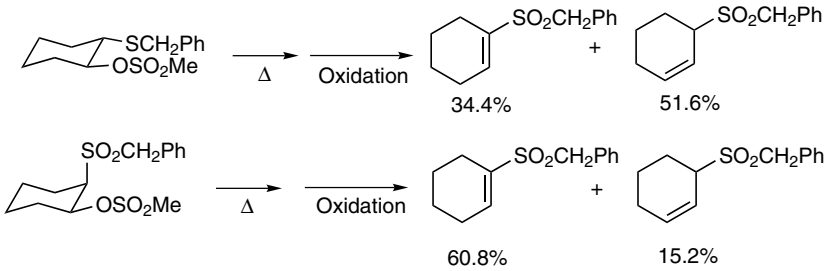
General Procedure for Preparation of Methyl Alkyl Sufites

Equimolar amounts of the alcohol and methyl chlorosulfinate were used. A slight excess (1.1–1.2 mol) of pyridine was employed. Dry ether was commonly used as the solvent, but dioxane and benzene gave equally good results. A solution of the alcohol and the pyridine was placed in a three-necked flask provided with a mercury-sealed stirrer and dropping funnel. Calcium chloride tubes surmounted the third neck and the top of the funnel. A solution of the chlorosulfinate was added slowly with stirring, controlling the temperature below 10°C. After the addition of the chlorosulfinate was completed, the stirring was continued for 30 min, then the precipitated pyridine hydrochloride was filtered off and the filtrate was washed with 0.1 N HC1, 5% sodium bicarbonate, and water. After drying over magnesium sulfate, the solvent was eliminated in vucuo.The residue may be purified by vacuum distillation or recrystallization. It also can be pyrolyzed without further purification.

Pyrolysis of Methyl α-Methyl-Phenethyl Sulfite

Method A The decomposition of this sulfite was found to start at 245°C. Methyl α-methylphenethyl sulfite (8 g) was heated at 285°C for 75 min. At the end of this time, 97% of the theoretical amount of sulfur dioxide had been absorbed in the sodium hydroxide solution. The distillate weighed 5 g, and 0.5 g tarry residue remained in the pyrolysis flask. The distillate was redistilled, and 4.15 g of the fraction boiling between 93° and 111°C (97 mmHg) was collected. This fraction was found to contain 2% dimethyl sulfite, 1% α-methylphenethyl alcohol, 53% propenylbenzene, and 43% allyl benzene.

Method B Through the column heated at 340–350°C, 21 g methyl α-methylphenethyl sulfite was dropped in about 1 h. After all the liquid had been passed through, the system was swept with nitrogen for 15 min, then the column was taken off and the receiver was stoppered and heated on a steam bath under a pressure of 5 mmHg to bring all volatile products into the dry ice trap. A residue of 4 g unchanged sulfite was left in the flask. The liquid that had collected in the dry ice trap was dissolved in ether and washed with water to eliminate sulfur dioxide and methanol. After the elimination of the ether, 9 g of liquid remained (96% based on unrecovered sulfite). The refractive index did not change after distillation from sodium.



Reference 2.

Pyrolysis of Methyl *cis*- and *trans*-2-*p*-Tolylthiocyclohexyl Sulfites.

These were pyrolyzed directly in a 25-mL distillation flask fitted with a 3-in. Vigreux head. The sulfite was heated to 200°C under nitrogen at atmospheric pressure for ~30 min. Vacuum (1 mmHg) was then applied, and the decomposition products were distilled slowly from the reaction mixture. The olefins were condensed in the air-cooled receiver, and the methanol and sulfur dioxide were allowed to pass into the dry ice trap. The yield of olefin was 86% from the *cis* isomer and 76% from the *trans* isomer. Analysis for the percentage of l-substituted and 3-substituted cyclohexene was made by oxidation to the sulfones, and the position of the absorption maximum in the ultraviolet spectra was determined. The oxidized product from the *cis* isomer had an absorption maximum at 229 mμ, corresponding to that of a mixture of 40% 1-*p*-tolylsulfonyl-1-cyclohexene and 60% 3-*p*-tolylsulfonyl-1-cyclohexene. The oxidized product from the *trans* isomer had its absorption maximum at 232 mμ, corresponding to 80% of the 1-substituted isomer.

Other references of the pyrolysis of esters (except for the *Chugaev Reaction*) to afford olefins are cited in literature.[6]

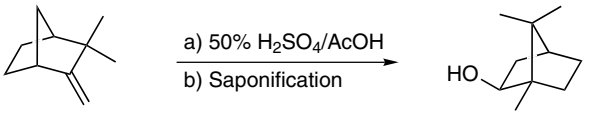
Bertram-Walbaum Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bertram and Walbaum in 1894.[1] It is a conversion of camphene into isoborneol by the treatment of camphene with 50% sulfuric acid[1] in acetic acid followed by saponification. Therefore, this reaction is generally known as the Bertram-Walbaum reaction[2] or Bertram-Walbaum method.[3] As a typical example, 20 g of camphene in 50 mL acetic acid was treated with 0.8 mL H_2SO_4 in 1.2 mL water at 50°–60°C for 3 h, then saponified and steam distilled to give 13.7 g crude isoborneol.[3] In addition, 98–100% formic acid[4] (with $BF_3{\cdot}Et_2O$[5]) is often applied as the reaction media for the Bertram-Walbaum reaction, instead of the combination of acetic acid and sulfuric acid; however, it is found that the application of acetic acid gives *exo*-norborneol in preference.[6] In this reaction, due to the nature of substituents, higher molecular weight by-products (e.g., dimers of olefins) might form in different amounts.[2b] For comparison, treatment of olefin in acetic acid containing 0.15 M acetamide and 0.1 M *p*-toluenesulfonic acid only allows the addition of acetic acid to olefins without any skeletal rearrangement.[7] It should be pointed out that the reversal reaction (i.e., from alcohol to olefin) under same conditions is also referred to as the Bertram-Walbaum reaction.[2a]

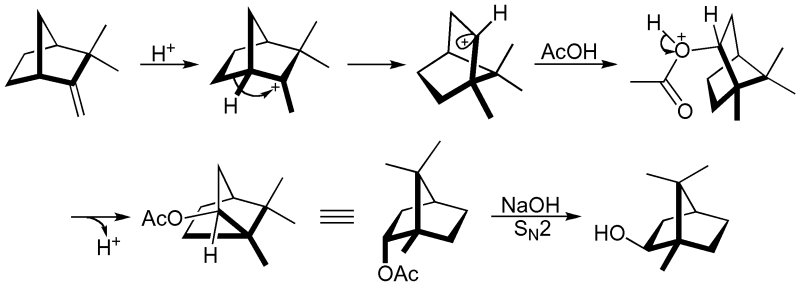
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that this reaction involves the protonation of *exo* double bond of camphene to generate a tertiary carbocation, followed by the carbon skeleton rearrangement to give a transient secondary carbocation, which is immediately trapped by acetic acid. Upon saponification via S_N2, the *endo* acetate is converted into *exo* alcohol as outlined in the mechanism shown here.



D. MODIFICATION

This reaction has been modified to undergo in concentrated formic acid.[4,5]

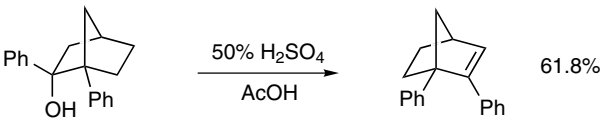
E. APPLICATIONS

This reaction has certain applications in terpene chemistry.

F. RELATED REACTIONS

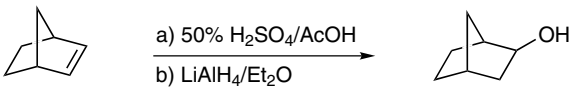
This reaction is related to the *Wagner-Meerwein Rearrangement, Demjanov Rearrangement, Tiffeneau-Demjanov Ring Expansion* and *Retropinacol Rearrangement* involving carbocation intermediates.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a solution of 1.65 g 1,2-diphenyl-2-*endo*-norbornanol (6.25 mmol) in 30 mL acetic acid was added 1 mL 50% H_2SO_4; the resulting solution was stirred on a steam bath regulated at 70 ± 2°C for 2 h. When the solution was poured into water, a white solid formed immediately, which was filtered with suction, washed with water and dried to give 0.95 g 1,2-diphenyl-norbornene, in a yield of 61.8 %, m.p. 95.4–98.0°C (after four recrystallizations from ethanol).



Reference 6.

To 25 mL glacial acetic acid was added 4.9 g norbornene and ~0.5 mL 50% H_2SO_4. The solution was refluxed for 1 h, which quickly turned dark gray. The reaction mixture was poured into 400 mL water and extracted twice with ether. The combined organic phase was left overnight over solid Na_2CO_3, and the ether solution was washed twice with aqueous Na_2CO_3 and then dried over $MgSO_4$. Charcoal was added, and the solution was filtered then refluxed overnight in ether with excess $LiAlH_4$ to afford the *exo*-norborneol.

Other references related to the Bertram-Walbaum reaction are cited in the literature.[8]

Betti Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Betti in 1900.[1] It is a special case of the *Mannich Reaction* involving the components of an ammonia, a 2-naphthol, and at least one benzaldehyde to give either a phenyl β-naphtholaminomethane or a *m*-naphthoxazine derivative. The latter upon acidic hydrolysis (e.g., HCl) decomposes to the hydrochloride salt of former molecule along with a benzaldehyde.[1,2] Thus this reaction is known as Betti's condensation[3] or the Betti reaction;[4] likewise, the corresponding β-naphtholmethylamines are generally referred to as Betti's amines[5] or Betti bases.[6]

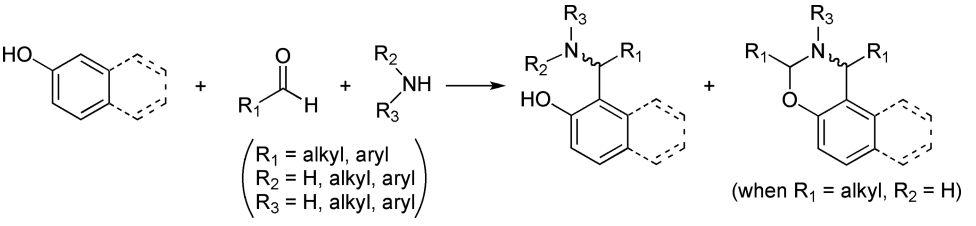
In this reaction, the course of condensation and the type of products formed depend on several factors, such as the nature of hydroxyaromatic compounds, amines, aldehydes, and the actual ratio of the components in the reaction system.[7] For examples, besides the initial ammonia, this reaction has been extended successfully to both primary amines[5] and secondary amines;[3]and among the secondary amines, the reaction particularly works for dimethylamine, diethylamine, and piperidine.[3] In addition, when one of the secondary amines exists in large excess or when dimethylamine or ammonia is removed from the reaction system via vaporization, good yields of pure products are often achievable.[6c] Besides the commonly used β-naphthol, many other hydroxyaromatic compounds are suitable for this reaction as well, such as phenols, and quinolinols.[3,4a] It is found that among kojic acid, 8-quinolinol, and 8-hydroxquinaldine, kojic acid is the most reactive compound for the Betti reaction, which reacts with benzylideneaniline in less than 1 day

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

at room temperature; 8-quinolinol needs weeks and 8-hydroxquinaldine takes months for the corresponding reactions.[4a] On the other hand, when a stoichiometric amount of naphthol, amine, and 2 equivalents of aldehyde are used, the resulting Betti base can further react with additional aromatic aldehyde to afford the corresponding Schiff base, whereas naphthoxazine is yielded in the case of aliphatic aldehyde.[7] In addition, even in the case of benzaldehydes, it is found that the stability of Betti bases from monochlorobenzaldehydes is smaller than simple benzaldehyde, and that the stability of Betti bases from those monochlorobenzaldehydes decrease in the order of *m*-Cl > *o*-Cl > *p*-Cl.[5] When nitrobenzaldehyde is applied, more than 90% of nitrohydrobenzamide can be obtained from β-naphthol and alcoholic ammonia.[5] Moreoever, it is reported that reaction in benzene is advantageous over that in alcohol solvent.[7] All the generated Betti bases can decompose to give β-naphthol and benzaldehyde, especially in alkaline solution.[5]

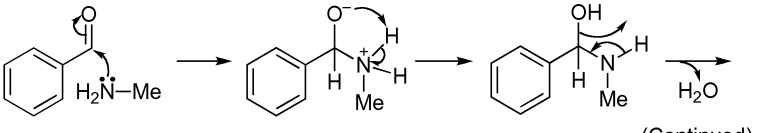
The importance of this reaction relies on the fact that the Betti bases can function as both excellent ligands and auxiliaries in asymmetric synthesis.[8] The racemic Betti amines can be separated into their optical antipodes.[5] In this respect, among the Betti bases from monochlorobenzaldehydes, only the *dextro* form of the *ortho* and *meta* chloro compounds could be resolved with satisfaction, while the *levo* antipodes are extremely difficult to obtain due to their higher solubilities.[5]

B. GENERAL REACTION SCHEME

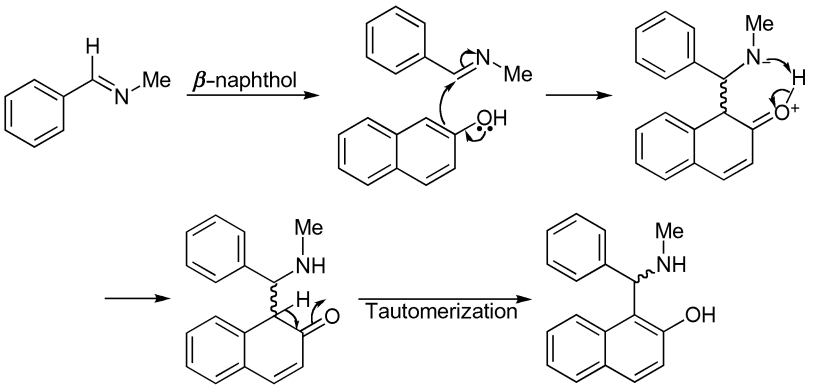


C. PROPOSED MECHANISMS

It is agreed that Betti reaction involves the initial reaction between aldehyde and amine, followed by the second condensation of naphthol (or phenol or other active methylenes),[3] as shown by the reaction among β-naphthol, benzaldehyde, and methylamine.



(Continued)



D. MODIFICATION

On the basis of Betti's initial work, the Betti reaction has been extended to both primary amines[5] and secondary amines.[3] The resulting Betti amines have been applied as ligands or chiral auxiliaries in asymmetric synthesis.[8] In addition, the Betti reaction has also been extended to the reaction among aldehydes, secondary amines, and compounds of active methylene moiety, such as dibenzyl ketones which can tautomerize to enols and mimic naphthol.[9] Moreover, the reaction of aromatic aldoximes and β-keto esters to afford isoxazolones should also be considered as an extension of the Betti reaction.[10]

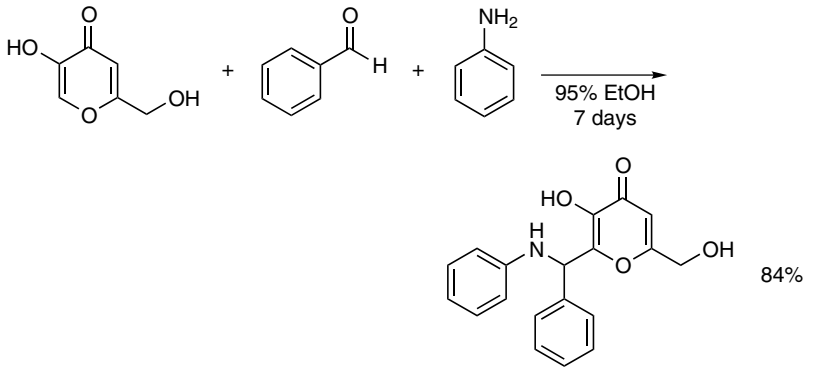
E. APPLICATIONS

This reaction should have wide applications for affording chiral ligands and auxiliaries for asymmetric synthesis.

F. RELATED REACTIONS

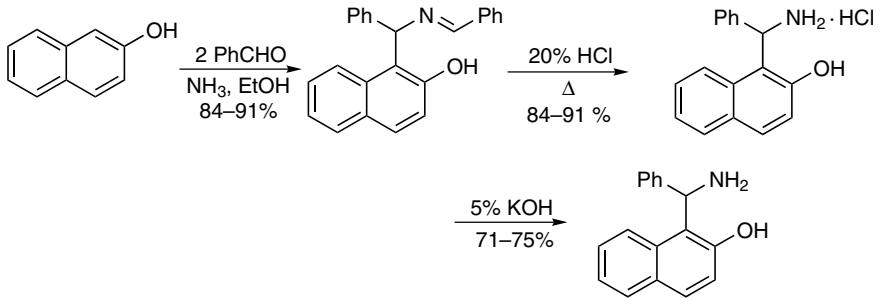
This reaction is closely related to the *Mannich Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To the solution of 5.31 g benzaldehyde (0.05 mol) and 4.66 g aniline (0.05 mol) in 50–100 mL 95% ethanol was added 7.11 g kojic acid. The mixture was stoppered and allowed to stand for 1 week, while the kojic acid derivatives precipitated within 1 day. The solid was filtered and washed, then purified by recrystallization from ethanol to afford 13.58 g of the Betti amine, in a yield of 84%, m.p. 176°C.



Reference 11.

To a cold solution of 144 g β-naphthol (1.0 mol) in 200 mL 95% ethanol in a 1-L round-bottomed flask were added first 212 g freshly distilled acid-free benzaldehyde (2.0 mol) and then ~200 mL 95% ethanol saturated with NH_3 at room temperature. The solution became red and warmed up spontaneously. The flask was stoppered and allowed to stand for 2 h. Then the stopper was removed, and the excess NH_3 was allowed to escape. After 12 h, the condensation product, which had separated as white needles, was filtered with suction and washed with 50 mL ethanol. The mother liquors on standing for 3 days deposited an additional quantity of the condensation product. The yield was 284–306 g (84–91% of the theoretical amount), m.p. 148 –150°C.

The condensation product thus obtained was introduced into a 5-L round-bottomed flask arranged for steam distillation, and treated with three to four times its volume of 20% HCl. The mixture was steam distilled to remove all the benzaldehyde formed by the hydrolysis (~2 h). Meanwhile, an abundant flocculent precipitate of light pink or white needles separated. The mixture in the flask was cooled thoroughly and filtered with suction. The yield was 240–260 g (84–91% of the theoretical amount), m.p. 190–220°C (dec.).

To obtain the amine, 200 g finely divided hydrochloride salt was placed in a 1500-mL beaker and stirred into a smooth paste with 300 mL water. To this was added 50 g crushed ice, and the mixture was cooled in an ice bath. Then 750–800 mL 5% KOH solution was added slowly under stirring until a nearly clear solution resulted. The cold solution was transferred to a separatory funnel and extracted eight to ten times with 300-mL portions of ether. The combined ether extract was dried overnight with 50 g anhydrous Na_2SO_4, filtered, and concentrated to ~300 mL. When the solution was cooled in an ice bath, the amine crystallized and was filtered with suction. The first crop of crystals weighed 112–115 g. Further concentration of the mother liquors to ~100 mL and cooling yield an additional 14–18 g of the product. The total yield was 127–131 g (73–75% of the theoretical amount), m.p. 124–125°C.

Other references related to the Betti reaction are cited in the literature. [12]

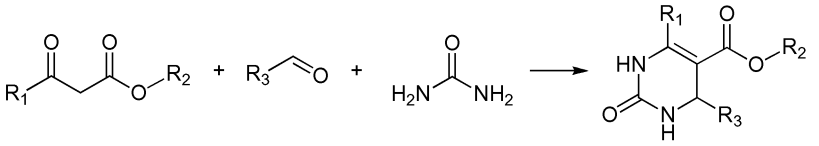
Biginelli Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although in most cases the Biginelli reaction is cited from 1893,[1] the initial reaction was actually reported by Biginelli in 1891.[2] The Biginelli reaction is an one-pot, three-component condensation of β-dicarbonyl compounds (e.g., β-keto esters) with aldehydes and urea (or thiourea) in the presence of a catalytic amount of acid to form dihydropyrimidine derivatives with normal yields of 20–50%.[3] Therefore, besides the general name of Biginelli reaction,[4] this reaction is also referred to as the Biginelli condensation,[5] Biginelli cyclocondensation,[6] Biginelli multicomponent condensation,[7] Biginelli synthesis,[8] and Biginelli dihydropyrimidine synthesis.[5l,9] In addition, dihydropyrimidine itself is called the Biginelli compound.[5l,10] This reaction has attracted extensive attention recently, though it was ignored for a quite long time. This is because dihydropyrimidine derivatives have shown important biological activities,[11] and the reaction itself involves three components at the same time, which is a perfect example of a multicomponent reaction (MCR), used in the combinational synthesis.[7,12] In terms of its versatility and importance, the Biginelli reaction has been extensively modified to give high yields of product. So far, different Lewis acids—including BF_3,[13] $BiCl_3$,[14] $CeCl_3$,[15] $FeCl_3$,[16] $InCl_3$,[15,17] $LaCl_3$,[18] $LiClO_4$,[19] $Mn(OAc)_3$,[20] and $Yb(OTf)_3$,[21] — and protic acids — such as HCl,[9c,16] H_2SO_4,[5l] and acetic acid[22] have been applied as catalysts. The solvents often used are CH_3CN,[23] CH_2Cl_2,[23] THF,[23] and dioxane[9e] etc. Other modifications include the application of microwaves,[24] running a catalyst-free[23] or solvent-free[3,25] reaction, and carrying out the reaction in a polyphosphate ester[26] or fluorous phase.[7] The Biginelli reaction can be enantioselective when catalyzed by $InCl_3$ or $CeCl_3$ in the presence of chiral ligands.[15]

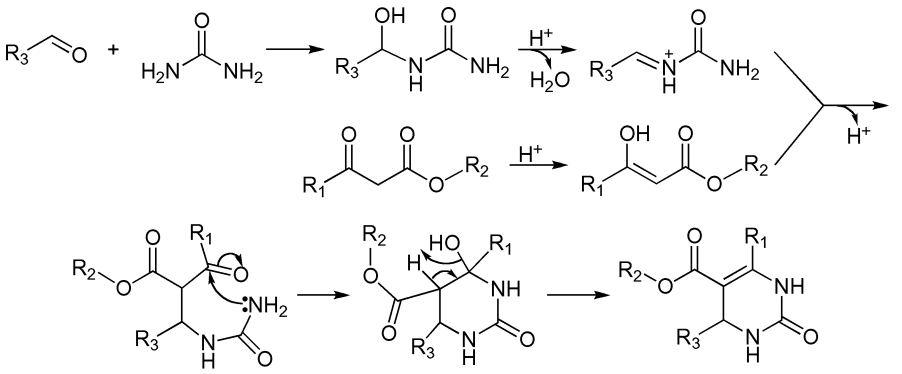
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It has been documented that the Biginelli reaction involves an aldehyde-urea condensation to form *N*-acyliminium ion as the key intermediate, followed by the addition of a π-nucleophile to the electron-deficient *N*-acyliminium ion and finally a ring closure,[9c,27] as illustrated below.



D. MODIFICATION

The original Biginelli procedure has been modified extensively to increase the overall yields, including the addition of Lewis acid catalyst,[13–21] application of polyphosphate ester[26] or fluorous solvent,[7] and introduction of microwaves[24] and even solvent-free[3,25] or catalyst-free[23] reaction conditions.

E. APPLICATIONS

This reaction has been successfully applied to the synthesis of complicated pentacyclic alkaloid ptilomycalin A,[5n,28] and other alkaloids, including crambine,[29] crambescidin,[30] and batzelladine.[5i,31]

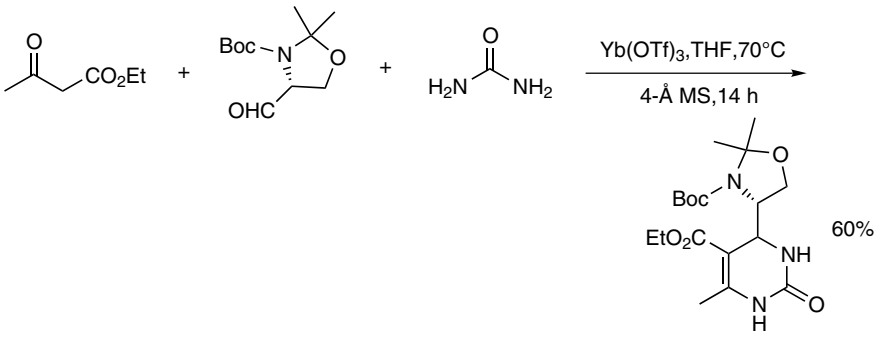
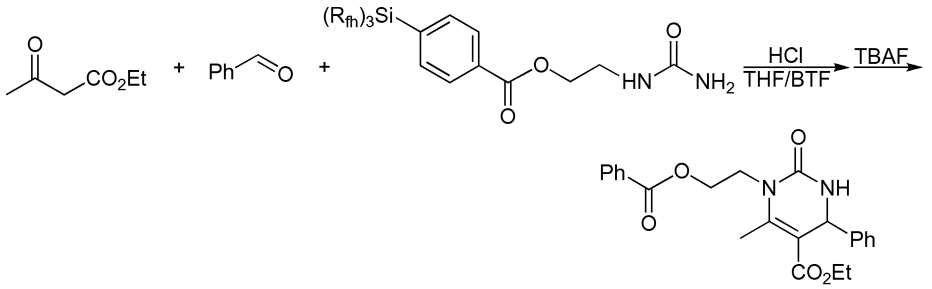
G. CITED EXPERIMENTAL EXAMPLES



Reference 21.

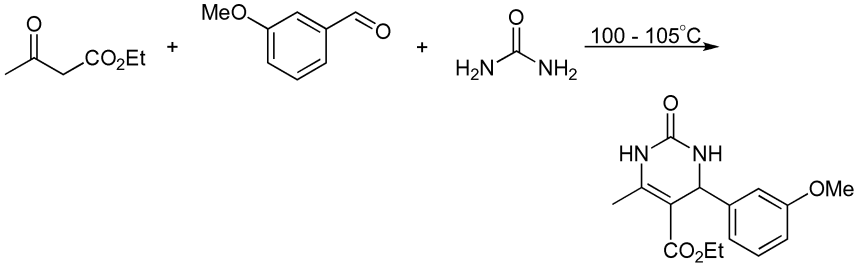
A screw-capped vial, containing a magnetic bar, was charged with 2.0 mmol Garner aldehyde, 255 μL ethyl acetoacetetate (2.0 mmol), 360.0 mg urea (6.0 mmol), 620 mg $Yb(OTf)_3$ (1.0 mmol), 200 mg powdered 4 Å molecular sieves, and 5 mL anhydrous THF. The mixture was stirred at 70°C for 14 h then cooled to room temperature, diluted with 100 mL EtOAc, filtered through a pad of Celite, and washed with H_2O (2 × 10 mL). The organic phase was dried over Na_2SO_4, concentrated, and eluted from a column of silica gel with cyclohexane-EtOAc (1:2, containing 0.3% Et_3N), to afford 460 mg diastereoisomers of (4*R*,4′S)- and (4*S*,4′S)-4-(3′-*tert*-butoxycarbonyl-2′,2′-dimethyl-oxazolidin-4′-yl)-6-methyl-2-oxo-1,2,3,4-tetra-hydropyrimidine-5-carboxylic acid ethyl esters (5:1 ratio), in a yield of 60%.



Reference 7.

A solution of 18 mg urea (9.6 μmol) in 0.75 mL THF/BTF (2:1) was treated at 25°C with 10 eq. ethyl acetoacetate, 10 eq. of benzaldehyde, and 1 μL HCl. After 3 days at 50°C, volatiles were removed in vacuo, and FC-84 and toluene (10 mL each) were added. The toluene phase was extracted with FC-84 (5 × 5 mL). The combined fluorous phases were filtered and concentrated. The resulting white solid was diluted with 0.5 mL THF/BTF (1:1) and treated dropwise with a 1 M tributylammonium fluoride (TBAF) solution in 10 μL THF (10 μmol). After the mixture was stirred for 0.5 h at 25°C, volatiles were removed in vacuo and FC-84 and toluene were added (10 mL each). The fluorous phase was extracted with toluene (3 × 5 mL). The combined toluene phases were extracted with saturated aqueous $NaHCO_3$ solution (3 × 10 mL) and brine (3 × 10 mL), dried over Na_2SO_4, filtered, and concentrated to afford 2.8 mg 1-(2-(benzoyloxy)ethyl)-6-methyl-

2-oxo-4-phenyl-1,2,3,4-tetrahydro-pyrimidine-5-carboxylic acid ethyl ester, in a yield of 71%, m.p. 129°C.



Reference 23.

Solvent-Free and Catalyst-Free Conditions

Small-Scale (Milligram Level) A mixture of 272 mg freshly distilled 3-methoxybenzaldehyde (2 mmol), 260 mg freshly distilled ethyl acetoacetate (2 mmol), and 180 mg urea (3 mmol) was heated at 100–105°C under stirring. After few minutes during the progress of reaction, the solid started to separate out; after completion (1 h, TLC) the resulting solid was crushed, washed with cold water, filtered, and dried under vacuum to give the crude product, which was reasonably pure (>95% purity by ^{1}H NMR). However, recrystallization from hot ethanol provided 476 mg analytically pure product, in a yield of 82%, m.p. 207–208°C.

Large-Scale (Kilogram Level) A mixture of 530 g benzaldehyde (5 mol), 650 g ethyl acetoacetate (5 mol), and 360 g urea (6 mol) placed in a 2-L round-bottomed flask was stirred by a mechanical stirrer at room temperature for 2 min for uniform mixing, and then the temperature was raised to 100–105°C. No exothermic reaction was observed during addition and mixing. Stirring was continued for another hour at that temperature. During the progress of reaction (approximately during the first 20 min, all the urea dissolved and solids started to appear), the reaction mixture became a thick slurry, with the solids deposited. At this stage, although no efficient stirring or agitation could be made, the reaction was not affected. After 1 h the reaction mixture was cooled in an ice water bath (0–5°C), and 200 mL water was added. The solid was carefully broken into pieces with a spatula and filtered. The yellow solid was then washed with 100 mL cold water followed by 50 mL cold rectified spirit to provide 1.025 kg colorless solid that was practically pure (79% yield), m.p. 201–202°C. A portion of it was recrystallized from hot ethanol to give analytically pure sample.

Other references related to the Biginelli reaction are cited in the literature.[32]

Birch Reduction
(Metal-Ammonia Reduction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Wooster in 1937,[1] and subsequently by Hückel et al in 1939,[2] for the reduction of aromatic compounds by sodium in liquid ammonia with water; however, no structural information was provided. It was Birch who extended Wooster's protocol in 1944[3] and since then had extensively explored the reduction of benzene and aromatic derivatives with alkali metal (i.e., Li, Na, K) in liquid ammonia in the presence of an alcohol (as the proton donor) to produce corresponding cyclohexa-1,4-diene derivatives.[4] Therefore, the reduction of aromatic compounds by alkali metal in liquid ammonia in the presence of alcohol is generally known as the Birch reduction[5,6] or metal-ammonia reduction.[7] In addition, this reaction is also referred to as the Birch reaction,[6ddd,8] and in one instance is cited as the Birch-Hückel reduction.[9]

Different from the transition metal (e.g., Pd, Pt, etc.) catalyzed hydrogenation, by which aromatic compounds can be converted into the fully hydrogenated molecules,[5aa] the Birch reduction uses the ammonia-solvated electrons arising from alkali metal as the reducing agent, which bears the extremely negative single-electron redox potential;[10] thus even the electron-enriched aromatic systems (i.e., carrying electron-donating groups) can be reduced accordingly. In addition, once the solvated electron adds to aromatic system, the radical anion is quenched by alcohol, so that cyclohexa-1,4-diene derivatives are often produced from benzene derivatives without further reduced species. It should be pointed out that the existing alkali metal also reacts with alcohol to generate hydrogen, in a reaction known as the hydrogen reaction, which competes with the reduction of aromatic compounds.[5aa] It is reported that both the rate[5aa] and yield[11] of the Birch reduction decreases in the order of Li > Na > K; as a result, the relatively slower reduction of sodium with aromatic compounds

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

(compared to lithium) may allow a simultaneous base-catalyzed isomerization from the isolated diene system to the more stable conjugated diene system, which in turn is further reduced to tetrahydro stage by the existing metal. In comparison, lithium has higher reducing power and does not tend to promote the isomerization of the isolated diene system.[6ww] Such difference between lithium and sodium presumably is the reason that Wooster et al did not exploit this reaction successfully. However, the combination of lithium-methylamine-alcohol can further reduce the aromatic system into tetrahydro derivatives.[6ggg] It should be pointed out that iron salts can strongly catalyze the sodium-based Birch reduction, but they have less effect on the lithium-based Birch reduction.[6hh] Although the Birch reduction and hydrogen reaction have a similar reaction order when the alkali metal concentration is around 0.01 M (or less), the hydrogen reaction decreases in an inverse order—that is, the reaction rate increases in the order of Li < Na < K.[5aa] Therefore, it is suggested that the reduction be carried out at the lowest possible temperature with methanol as the quenching agent to reduce the effect from the hydrogen reaction, because ethanol shows a faster rate than does butanol.[5aa,11d] Moreover, it is reported that both the Birch reduction and hydrogen reaction can be accelerated by the addition of an alkali cation common to the dissolved alkali metal (e.g., alkali bromide), whereas both reactions are disfavored by the addition of the complexing cryptands of the corresponding alkali cation, indicating that the formation of intermediate ion pairs or shifting pre-equilibria in which solvated electrons are involved. In addition, I propose that the added alkali cation might further stabilize the radical anion, causing a shift in the equilibrium to the end of product. Besides the commonly used alcohols, ethers and alkyl halides could be applied as anion quenchers,[9] and sometimes, a co-solvent such as THF[5x] is also added to the reaction system, presumably to alternate the solubility of aromatic compounds.

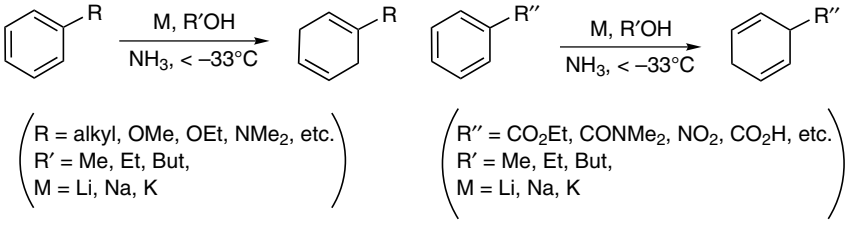
On the other hand, one of the advantages associated with the Birch reduction is its efficient steric control on the aromatic system—that is, the formed cyclohexa-1,4-diene system is the isomer with the maximum number of alkoxy and/or alkyl groups on the residual double bonds, known as the Birch rule.[5ccc,5mmm,12] In other words, the electron-withdrawing groups, (e.g., NO_2, COR, and CO_2H),[13] facilitate the formation of anion and subsequent reduction at the position on the aromatic ring bearing such group, leading to the formation of 1,4-dihydro derivatives via the addition of hydrogen *para* to the electron-withdrawing group;[14] whereas electron-donating groups (such as OMe, Me, NR_2, and $SiMe_3$) are deactivating substituents,[13] resulting in the generation of 2,5-dihydro derivatives by *meta* addition of hydrogen to the strongly deactivating group.[14] When both electron-withdrawing and electron-donating groups exist on the aromatic system, the former has a greater directing effect, whereas among the electron-donating groups, the ones with oxygen or nitrogen atoms outweigh the alkyl groups. Thus the empirical order for directing is as follows: carboxy > amino/alkoxyl > alkyl.[14] For the fused aromatic ring system, the ring with the most fusions to another aromatic ring is normally the one to undergo the Birch reduction;[14] however, the carbon skeleton for the fused aromatic system may rearrange during the Birch reduction. As an example, the reduction of biphenylene gives the expected 1,4,4a,8b-tetrahydrobiphenylene and the unexpected 4,5-benzobicyclo[4.2.0]octa-2,4-diene.[6ii] In the fused aromatic system, a ring with a hydroxyl group would be deactivated due to the formation of anion analogous to phenoxide.[14]

One of the most important applications of the Birch reduction is to convert aryl alkyl ethers into 1-alkoxycyclohexa-1,4-dienes which are then used as the starting materials in organic synthesis.[5x,13] Compared to the benzene series, the Birch reduction of naphthalenes may afford different products, depending on the position of the alkoxyl group.

For example, along with the loss of the methoxyl group, both 1-methoxy-2-naphthoic acid and 3-methoxy-2-naphthoic acid will be converted into 1,2,3,4-tetrahydro- or 1,2,3,4,5,8-hexahydro-2-naphthoic acid depending on the reaction conditions or proportion of reagents used, whereas 2-methoxy-1-naphthoic acid is mainly converted into 1,4,5,8-tetrahydro-2-methoxy-1-naphthoic acid without loss of the methoxyl group.[6s;6ii] Besides the reduction of aromatic systems, the Birch reaction has been found to reduce acetylenes stereospecifically to *trans*-olefins[15] and to hydrogenate graphite and carbon single-walled nanotubes (SWNTs).[16] However, the Birch reduction cannot reduce hexamethylbenzene and highly substituted benzene rings in [2*n*]-cyclophanes,[5oooo] probably due to the steric hindrance. In addition, the Birch reaction can also cleave the C-C bond in the presence of the aromatic system. For instance, the Birch reaction with lithium-ammonia can remove the tertiary cyano group,[17] whereas potassium sand in ether can cleave pentaphenyl ethane,[18] and sodium-potassium alloy is able to break 1,1,2,2-tetraphenylethane.[18] It is pointed out that the cleavage of 1,2-diarylethanes increases in the order of aryl = anthracene < naphthalene < benzene, with the alkali metal order of Li < Na < K, and the solvents in the order of NH_3 < THF < HMPA.[5ppp] It should be noted that the configuration is retained during the bond cleavage under Birch-like conditions.[14] Furthermore, the Birch reduction has often been used to generate hydroxyl groups by the removal of the benzyl-protecting group.[5i,20] It is interesting that in the absence of the harsh conditions of the Birch reduction, an enzyme-catalyzed reduction for the two-electron reduction of benzoyl-CoA to cyclohexa-1,5-diene-1-carbonyl-CoA has been observed, where a conjugated diene is formed instead of 1,4-diene in the Birch reduction.[10]

Nevertheless, the Birch reduction also has certain drawbacks, including the tedious experimental procedure, the use of strongly basic solutions, and sometimes the solubility problem of substrates.[5llll]

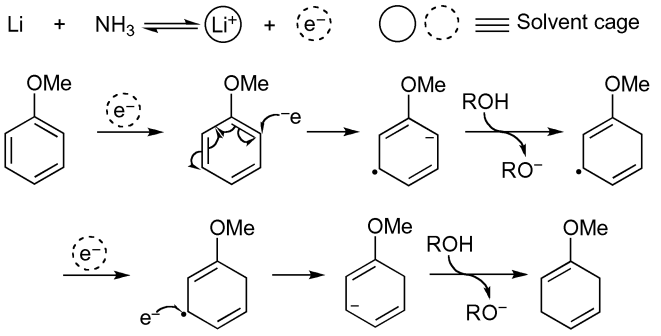
B. GENERAL REACTION SCHEME



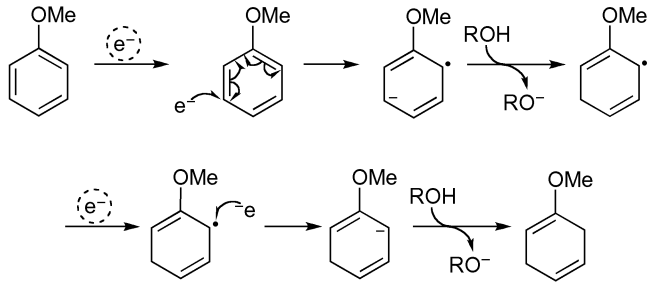
C. PROPOSED MECHANISMS

It is generally accepted that the metal ammonia solution (MAS) contains both the solvated electron and alkali cation, in which the solvated electron has extremely high single-electron redox potential[5aa] so that the solvated electron can even reduce electron-enriched aromatic systems. In this reduction, the solvated electron adds to the aromatic ring to generate a radical anion, which is protonated by an alcohol; then a second solvated electron adds to the ring to form a new radical anion, followed by alcohol

quenching to afford the unconjugated cyclohexa-1,4-diene.[5ccc,5mmm] The protonation of the radical anion by alcohol is the rate-limiting step.[5ccc,5mmm] However, there is disagreement about the electron density of the radical anion, for which Birch himself believed that the *meta* position of the radical anion formed from anisole had the highest electron density (Scheme 1),[21] whereas Zimmerman suggested the position *ortho* to the maximum number of substituents to be most electron rich, from the Hückel calculation (Scheme 2).[5ccc] Displayed here are Birch's mechanism and Zimmerman's explanation for the regioselectivity of the Birch reduction of anisole. The Birch reduction on a aromatic system with an electron-withdrawing group should have a similar reaction process but a different position for the solvated electron to attack.



SCHEME 1. *Birch's mechanism for the reduction of anisole.*



SCHEME 2. *Zimmerman's mechanism for the reduction of anisole.*

D. MODIFICATION

This reaction has been extensively modified. One of the important modifications is the quenching of radical anion by an alkylation agent to give an alkyl-substituted cyclohexa-1,4-diene derivative,[5xa,5nnnn,13,22] a condition known as the Birch reductive alkylation.[22b] On the other hand, a pyrrole nucleus bearing an extremely enriched electron density and

an acidic hydrogen atom normally does not undergo the Birch reduction;[5oo] however, the pyrrole nucleus has been successfully reduced to a dihydropyrrole derivative by replacing the acidic hydrogen atom with an *N*-*t*-butylcarboxyl (Boc) group.[5oo] In addition, an ammonia-free methodology has been developed by using a di-*tert*-butylbiphenyl radical anion (generated from di-*tert*-butylbiphenyl and lithium in THF) to provide electrons and bis(methoxyethyl)amine as an acid, so that a number of electrophiles, such as silyl halides, chloroformates, acid chlorides, and enolizable aldehydes, can be trapped by the radical anion.[5f] Furthermore, this reaction has been carried out via electrochemical reduction in an aqueous media,[5llll] using a concentrated aqueous solution of tetrabutylammonium hydroxide.[23] Moreover, calcium has been applied successfully for the ultrasound-promoted reduction of the aromatic compound;[24] likewise, a photo-reduction[6f] system has been developed to reduce aromatic compounds by irradiation of an acetonitrile/water (9:1) solution in the presence of $NaBH_4$ and *m*- or *p*-dicyanobenzene.[5wwww]

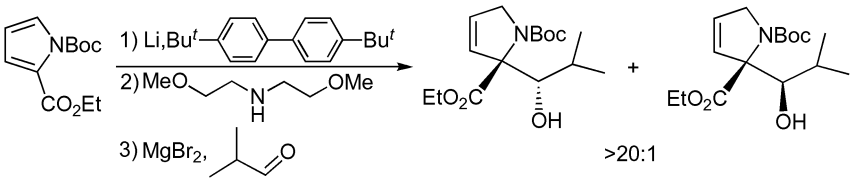
E. APPLICATIONS

This reaction has been widely used to convert the aryl alkyl ethers into 1-alkoxycyclohexa-1,4-diene derivatives. In addition, this reaction has been used to remove the benzyl group on oxygen, cleave the C-C bonds, and reduce acetylenes into *trans*-olefins stereospecifically.

F. RELATED REACTIONS

This reaction is closely related to the *Benkeser Reduction*.

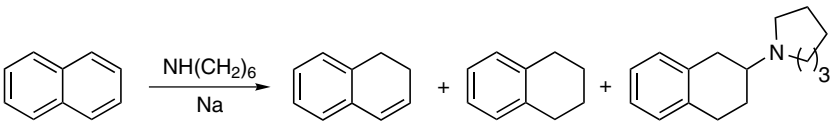
G. CITED EXPERIMENTAL EXAMPLES



Reference 5f.

A Schlenk tube containing 119 mg small strips of lithium ribbon (17.0 mmol), antibumping granules, and 4.5 g di-*tert*-butylbiphenyl (16.9 mmol) was evacuated and purged with argon several times. The mixture was ground with a magnetic stirrer until all the lithium became a dark powder. Freshly distilled THF (50 mL) was then added, and the mixture was cooled down to −78°C before a mixture of 1.1 g *N*-Boc ethyl 2-pyrrole carboxylate (4.4 mmol) and 0.8 mL bis-methoxyethylamine (5.3 mmol) in 25 mL freshly distilled THF was added dropwise to the turquoise solution. The mixture was then stirred at −78°C for a further 15 min after which 1.0 g freshly prepared $MgBr_2$ (5.4 mmol) in 20 mL THF was added, and the mixture was stirred for an additional 30 min. Distilled isobutyraldehyde

(0.7 mL, 7.0 mmol) was then added. After 30 min the reaction mixture was quenched with 10 mL saturated NH_4Cl aqueous solution. Stirring was continued at $-78^{\circ}C$ for a further 30 min and then the solution was warmed to ambient temperature. The reaction mixture was poured into a 50 mL 1 M HCl solution and extracted with Et_2O (3×60 mL). The combined organic layers were dried over Na_2SO_4, filtered, and evaporated under reduced pressure. The residue was purified by gradient column chromatography by eluting with neat petroleum ether to recover the di-*tert*-butylbiphenyl and then 5% acetone in petroleum ether to afford 1.07 g product as a colorless oil, in a yield of 74%.



Reference 6ddd.

To a 500-mL three-necked flask equipped with a stirrer, air condenser, and nitrogen inlet tube were added 6.4 g naphthalene (0.05 mol) and 4.6 g dispersed sodium (0.2 mol), followed by 100 mL hexamethylenimine. A red color developed within 20 min. The mixture was stirred at 25°C for 12 h, and the unreacted sodium, which had agglomerated, was removed. The remaining solution was cooled and treated cautiously with water until the reaction mixture became colorless, then acidified with 10% aqueous HCl. After the hydrocarbons had been removed by extraction with ether, the aqueous layer was basified with dilute NaOH, and surplus hexamethylenimine was removed by steam distillation. The steam distillation residue was extracted with ether. Drying over anhydrous Na_2SO_4 and distillation yielded 6.2 g 2-*N*-hexamethylenyl tetralin, in a yield of 55%.

Other references related to the Birch reduction are cited in the literature.[25]

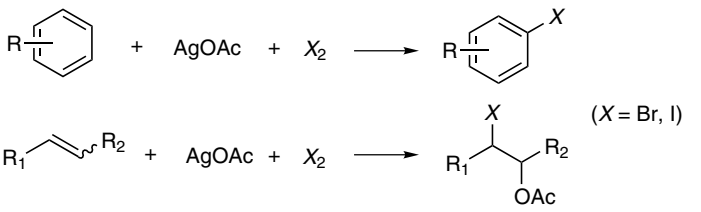
Birckenbach-Goubeau Halogenation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Birckenbach and Boubeau in 1932.[1] It is the halogenation of aromatic compounds with halide cations generated from halogen and silver perchlorate under anhydrous conditions. Especially when silver acetate is employed as the silver salt and acetic acid as the reaction medium, many aryl aliphatic acids can be halogenated.[2] In addition, the halogen cations can also be produced by mixing halogen with other metal halides (gold, copper, mercury, etc.), such as the iodination of cyclohexene in anhydrous ether with iodine and a slight excess of cuprous chloride to form *trans*-1-chloro-2-iodocyclohexane in an 80% yield.[3,4] However, when cyclohexene was treated with iodine and silver acetate at −80°C, 2-iodo-1-cyclohexanol acetate was produced.[4] Similarly, the mixture of bromine and silver acetate is an effective aromatic bromination agent and is an agent for converting alkenes to bromoacetates.[5]

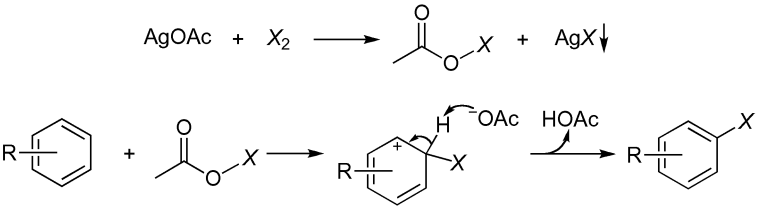
B. GENERAL REACTION SCHEME



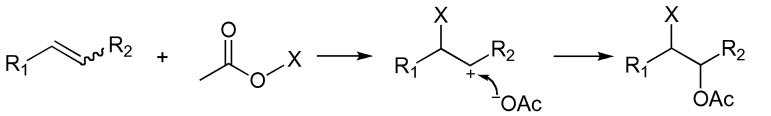
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that acetyl hyperbromite[5] or hyperiodite[6] is formed as an intermediate when bromine or iodine reacts with silver acetate, giving bromine or iodine cation. Positive iodine has been stabilized via coordination with pyridine.[7] Therefore, a tentative mechanism is illustrated here.



In the case of reaction with alkenes, it will be:



D. MODIFICATION

Besides the original silver salt, different metal salts have been used in this reaction, including the salts of mercury,[5,8] gold,[9] copper,[9,10] and even zinc.[5]

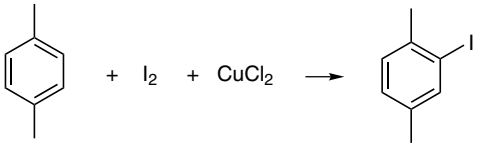
E. APPLICATIONS

This reaction can be used to prepare brominated or iodinated aromatic compounds or dihaloalkanes; the latter is produced from the mixture of metal halide and halogen with alkenes.[3,4]

F. RELATED REACTIONS

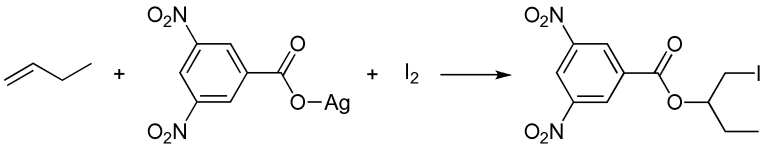
This reaction is related to the *Simonini Reaction* and *Hunsdiecker Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a 500-mL flask equipped with a Teflon paddle stirrer and a reflux condenser was placed 70 mL xylene, 13.0 g iodine (0.05 mol), and 13.3 g $CuCl_2$ (0.1 mol). The reaction was stirred at 140°C for 5 h. The reaction mixture was cooled and filtered, and the filtrate was washed with 100 mL 20% sodium thiosulfate solution to discharge any residual iodine. The filtrate was dried over magnesium sulfate, the solution was filtered, and the excess xylene was removed on a rotary evaporator at 60°C (13 mmHg) to give 22.8 g of crude product, which was distilled to afford 19.8 g iodoxylenes, in a yield of 85%, b.p. 65–72°C (0.2 mmHg).



Reference 11.

To a mixture of 75 mL dry chloroform and 9.5 g silver 3,5-dinitrobenzoate (0.03 mol) cooled in an ice-salt mixture a solution of 0.03 mol iodine dissolved in 20 mL dry chloroform was added over 10–15 min with shaking. 1-Butene was then passed into the solution for 15 min with continuous shaking. The solid silver iodide that precipitated was removed, and the filtrate was washed with six 25-mL portions of 5% sodium carbonate solution. The chloroform solution was then dried over Drierite, the chloroform was removed by distillation, and boiling petroleum ether was added to dissolve the ester. The solution was then cooled, and 1-iodo-2-butanol 3,5-dinitrobenzoates was removed and purified by recrystallization from petroleum ether, in a yield of 46%.

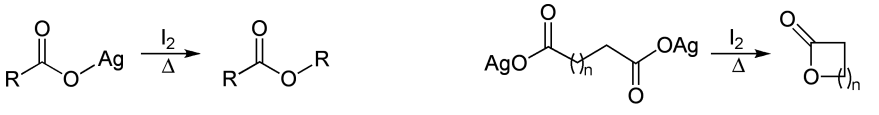
Birnbaum-Simonini Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction has initially been reported by Birnbaum[1] in 1869 and subsequently by Simonini[2] in 1892. It is the reaction for preparing esters by heating a mixture of silver salts of carboxylic acids and iodine and is generally known as the Birnbaum-Simonini reaction.[3] For comparison, the silver salts of dicarboxylic acids will form lactones when heated together with iodine.[4] Because of the cost and inconvenience of preparing and drying the silver salts, this reaction has been improved by heating the mixture of halogen with lead tetra-salts of carboxylic acids, giving comparable yields.[5] Such oxidative formation of esters from metal salts of carboxylic acids[1,2,3,5] has also been modified to the oxidation of carboxylic acids themselves,[6] and their corresponding peracids and peranhydrides.[7] However, in the presence of olefin, no ester is formed.[5]

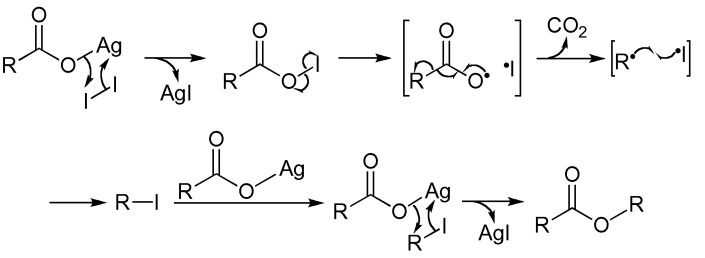
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that carboxyl hyperiodite is formed as an intermediate, which might decompose to give alkyl radical after decarboxylation, as illustrated here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified for preparing esters from a reaction between lead tetra-salts of carboxylic acids and iodine.[5] In this reaction, the mixture will be heated to $>100^{\circ}C$ to prevent caking or gelling of the reaction mixture; and *sym*-tetrachloroethane, *o*-dichlorobenzene, and mineral can be used as solvent. The yields depend markedly on the structure of the acid. For example, straight-chained aliphatic acids react quite satisfactorily, and the yields increase with the molecular weight of the acid. Unsaturated fatty acids give tars, and benzoic acid gives iodobenzene; fatty acids with one or two α-alkyl groups give diminished yields or no ester at all, respectively.

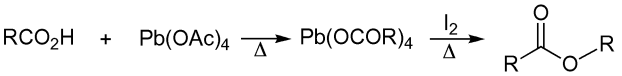
E. APPLICATIONS

This reaction can be used to prepare esters from carboxylic acids.

F. RELATED REACTIONS

This reaction is related to the *Birckenbach-Goubeau Halogenation* and *Hunsdiecker Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



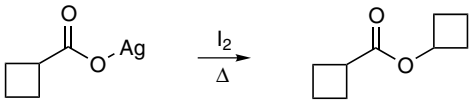
Reference 5.

Preparation of Lead Tetra-Salts

Lead tetraacetate (0.25 mol) and 1 mol of a carboxylic acid were heated together at 60–80°C, and the acetic acid was distilled at 10 mmHg pressure as it formed. The product was pure enough for further reactions without other treatment. When the lead tetra-salt melted > 80–100°C, a solvent, such as 1,1,2,2-tetrachloroethane, *o*-dichlorobenzene, or mineral oil, was used to prevent caking and local superheating of the product.

Generalized Preparation of Esters

A mixture of 0.25 mol of lead tetra-salt, 300 mL solvent, and 0.125 mol iodine was heated until gas evolution began and was maintained at 85–105°C until gas evolution ceased (~20 min). The temperature was then raised to 150–200°C (depending on the boing points of the solvent and alkyl iodide) for ~1 h. The workup of the reaction mixture depended on the relative boiling points of the solvent and the ester. For higher-boiling solvents, the ester was distilled from the reaction mixture, washed with dilute sodium carbonate solution, dried, and fractionated through a short column. For lower-boiling solvents, the solvent was distilled, the residue was triturated with 300 mL ether, filtered to remove lead salts. Then the ether solution was washed with sodium carbonate solution and sodium thiosulfate solution, dried, and fractionally distilled. For high-boiling esters, the product was not distilled but was recrystallized from a suitable solvent. Recovery of free carboxylic acids was accomplished by acidifying the sodium carbonate wash solutions with mineral acid and distilling or recrystallizing the nonaqueous phase that separated. For the case of lauric acid, the yield is 54%.



Reference 8.

Iodine (22 g) and 36.0 g silver cyclobutanecarboxylate (0.18 mol) were thoroughly ground with 1 g powdered, soft glass in a mortar. This mixture was rapidly transferred to a dry 2-L long-necked flask and warmed on the steam cone. At ~90°C, a vigorous reaction occurred, with the evolution of carbon dioxide and condensation of liquid on the walls of the flask. The reaction mixture was heated for an additional 30 min at 100°C. The liquid products were then lyophilized into a dry ice trap and taken up in ether. The ethereal solution was washed with 0.5 M sodium bisulfite solution and 1% sodium bicarbonate solution, water and dried over anhydrous magnesium sulfate. The ether was removed through a glass helix-packed column. The residue was fractionated through a microcolumn and yielded 1.1 g ester mixture, in yield of 8%, b.p. 92.5–93.5°C (20 mmHg).

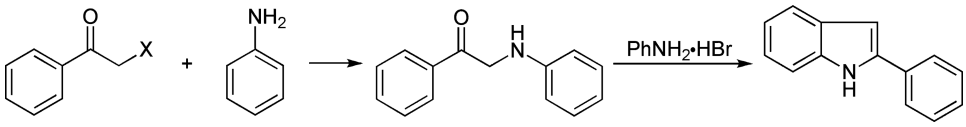
Bischler Reaction

(Möhlau-Bischler Indole Synthesis, Möhlau-Bischler Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Möhlau in 1881[1] and subsequently by Bischler in 1892.[2] It is the reaction for preparing 2-substituted indoles by heating α-haloketone, α-hydroxyketone, or α-anilinoketone with excess aniline via the cyclization of a 2-arylaminoketone intermediate. Therefore, this reaction is known as the Bischler reaction,[3] Mohlau-Bischler indole synthesis,[4] Mohlau-Bischler reaction,[5] or Mohlau-Bischler synthesis.[6] This reaction has been used for the preparation of a number of tetrahydrocarbazoles from anilines and 2-chlorocyclohexanones[7] and *N*-substituted indole-3-acetic acids and acetamides, which are useful for the preparation of tryptamines.[8] In addition, this reaction can be applied to the synthesis of benzofuran and benzothiophene.

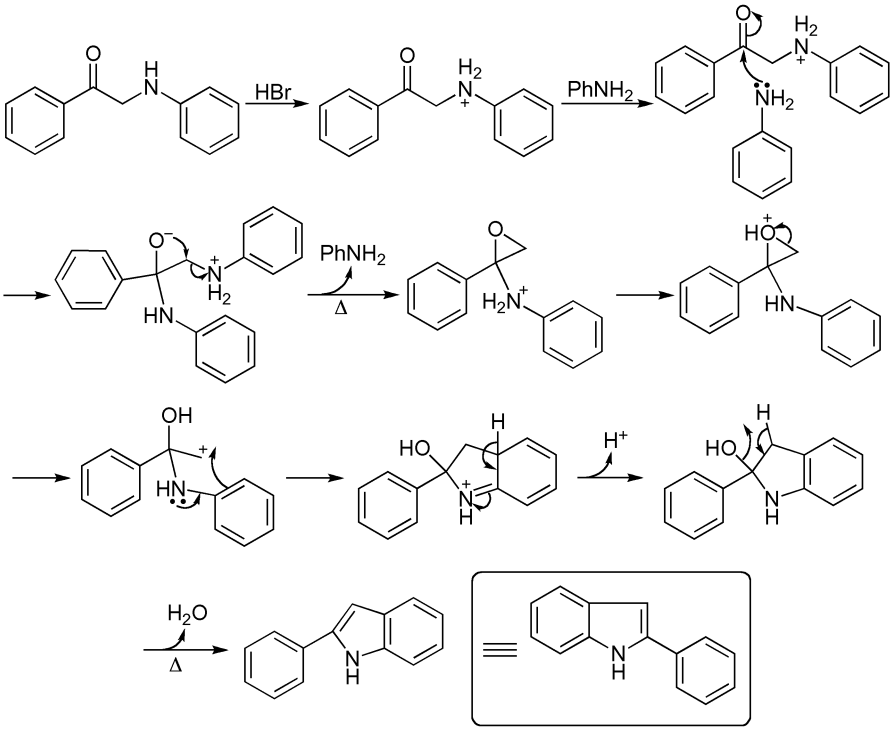
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that this reaction occurs via a carbocation intermediate, as illustrated below.[9]



D. MODIFICATION

This reaction has been modified to react with α-chlorocyclohexanone.[7]

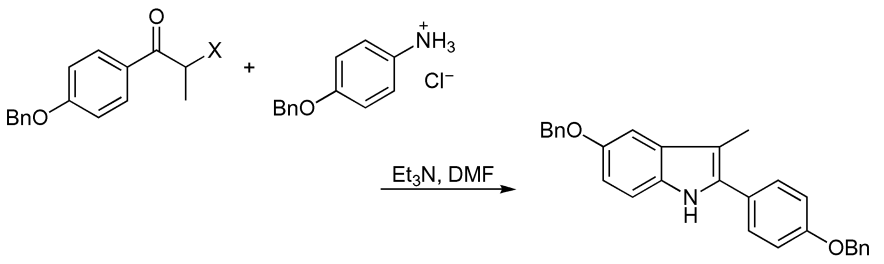
E. APPLICATIONS

This reaction is generally used to synthesize 2-substituted indoles; in addition, this reaction can also be used to prepare benzofuran, benzothiophene, and tetrahydrocarbazoles.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES

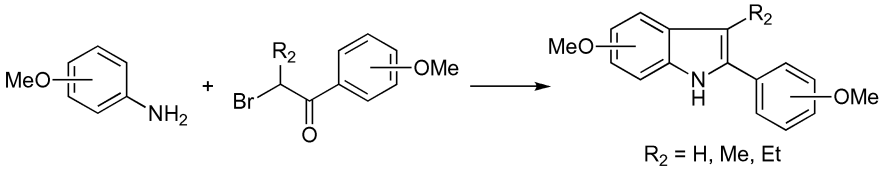


Reference 10.

To a flask were added 45.0 g 4-benzyloxyaniline hydrochloride (0.23 mol), 21.0 g 4′-benzyloxy-2-bromophenylpropiophenone (0.066 mol), and 50 mL DMF. The reaction was refluxed for 30 min and then cooled to room temperature and then partitioned between EtOAc and 1 N HCl. The EtOAc was washed with $NaHCO_3$ and brine, then dried over $MgSO_4$. The solution was concentrated, and the residue was taken up in CH_2Cl_2; hexanes were added to precipitate out 25.0 g of a crude solid. The solid was dissolved in CH_2Cl_2, evaporated onto silica gel, and chromatographed using CH_2Cl_2/hexane (1:5) to yield 9.2 g 2-phenyl-3-methyl-1H-indole as a tan solid, in a yield of 33%, m.p. 150–152°C.

Two-Step/One-Pot Procedure

Bromophenylpropiophenone (50 g, 0.16 mol) in 200 mL DMF was treated with 44.0 g aniline hydrochloride, and the reaction was purged with nitrogen for ∼10 min. Triethylamine (54.6 mL) was added, and the reaction was heated at 120°C for 2 h. TLC analysis (EtOAc/hexanes) showed the starting material had disappeared, forming a more polar spot. The reaction mixture was allowed to cool down, and an additional 48.0 g of the aniline hydrochloride was added. The reaction was heated to 150°C for 2 h. An additional 5.0 g of the aniline hydrochloride was added, and the reaction was heated at 150°C for an additional 30 min. The reaction mixture was allowed to cool to room temperature and then poured into ∼1.5 L water and extracted with 2 L EtOAc. The solids were dissolved with additional EtOAc as necessary. The EtOAc layer was washed with 1 L 1 N NaOH, 1 L water, and brine, then dried over $MgSO_4$ and filtered. The organic layers were concentrated down to yield a crude solid that was stirred with 500 mL of methanol and filtered. This solid was then stirred with 500 mL ethyl ether and filtered. The solid was stirred alternatively with methanol and ether until it was of whitish color and had a melting point of > 150°C. Reaction gave 36.0 g 2-phenyl-3-methyl-1H-indole, in a yield of 51%.



Reference 11.

General Procedure for Preparation of Methoxy-2-(Methoxypheny1)-1H-Indoles

A solution of 0.06 mol (2-bromoacy1)anisole was added slowly to a boiling mixture of 0.2 mol methoxyaniline and 35 mL *N*,*N*-dimethylaniline with stirring. After the addition, the mixture was kept at 170°C in a bath. After cooling, EtOAc was added and the mixture was extracted with 2 N HCl. The aqueous layer was extracted several times with EtOAc. After washing with 2 N HCl and water, the organic layer was dried over $MgSO_4$. The solvent was removed in vacuo and the resulting residue was chromatographed over SiO_2 with CH_2Cl_2 as the eluent. The product was recrystallized from EtOH, affording colorless crystals in a 10–50% yield.

Other references related to the Bischler reaction are cited in the literature.[12]

Bischler-Napieralski Isoquinoline Synthesis

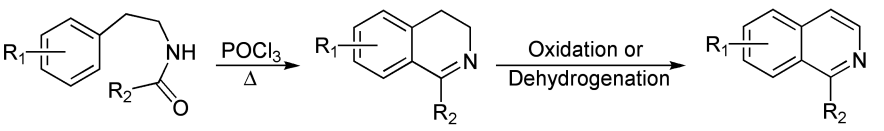
(Bischler-Napieralski Reaction; Bischler-Napieralski Cyclization)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bischler and Napieralski in 1893.[1] It is a two-step reaction via the cyclization of *N*-acyl phenylethylamines with dehydrating agents to form 1-alkyl or 1-aryl 3,4-dihydroisoquinolines, followed by dehydrogenation or oxidation to afford isoquinolines.[2] Thus this reaction is generally known as the Bischler-Napieralski isoquinoline synthesis,[3] Bischler-Napieralski reaction[4] or Bischler-Napieralski cyclization.[5] The dehydrating agents used include phosphoric acid,[6] sulfonic acid derivative,[6] phosphorus oxychloride ($POCl_3$),[6,7] phosphorus pentoxide,[8,9] zinc chloride,[9] aluminum chloride,[9] and ferric chloride[9]. This reaction has been successfully used to synthesize numerous naturally occurring alkaloids, that including laudanosine, laudanine, and papaverine; cotarnine[10] and hydrastinine; salsoline, pectenine, and corypallin; the anhalonium alkaloids;[9] and takatonine[7f] and petaline.[7e] This reaction is generally carried out in boiling toluene or xylene in the presence of the listed dehydrating agents,[9] but it can be carried out in low boiling point solvents such as acetonitrile[7c] or dichloromethane[7e,7f] as well. In addition, this reaction can be used to synthesize thiophene derivatives.[11]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

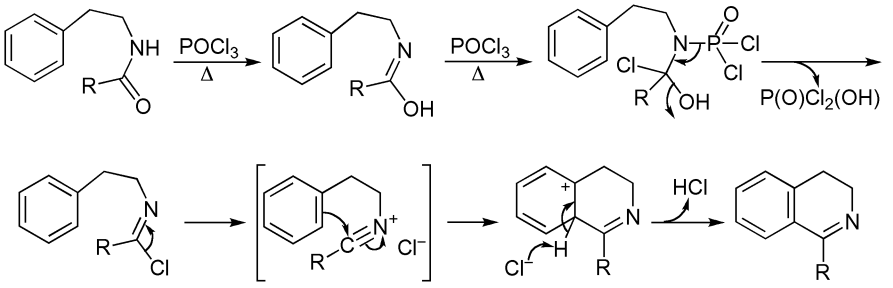
B. GENERAL REACTION SCHEME



(R_1 = alkyl, aryl, halogen, etc.
R_2 = alkyl, aryl)

C. PROPOSED MECHANISMS

It is believed that this reaction proceeds via initial formation of hydrochloric salts of imidoyl chloride when $POCl_3$, PCl_5, or $SOCl_2$ is used as a reagent, followed by the formation of imidoyl chloride by the loss of hydrogen chloride, which is in equilibrium with nitrilium salt.[12] Then the 3,4-dihydroisoquinoline is formed via the ring closure of nitrilium salt, as indicated in the direct formation of such dihydroisoquinoline via alkylation of nitrile with phenylethyl halide in the presence of a Lewis acid.[13] An exemplary mechanism of the Bischler-Napieralski reaction is illustrated here.



D. MODIFICATION

This reaction has been modified to occur in a solvent such as CH_3CN[7c] and CH_2Cl_2.[7e,7f] The synthesis of thiophene analogues of isoquinolines is another modification.[11]

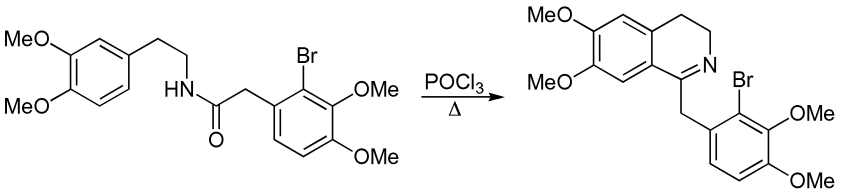
E. APPLICATIONS

This reaction has general applications in the preparation of alkaloids containing an isoquinoline skeleton.[7e,7f,9,10]

F. RELATED REACTIONS

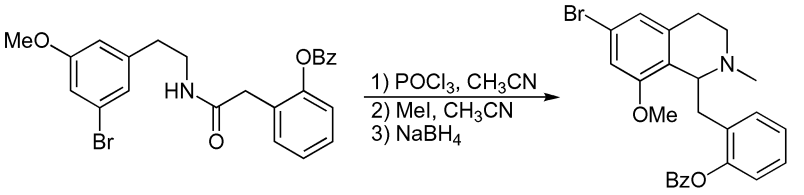
This reaction is related to the *Bradsher Pyridinium Salt Synthesis*, *Pictet-Gams Synthesis, Pictet-Spengler Reaction*, and *Skraup Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

A mixture of 7.013 g *N*-(3,4-dimethoxyphenethyl)-2-bromo-3,4-dimethoxyphenylacetamide (16 mmol), 12.240 g $POCl_3$ (80 mmol), and 100 mL dry toluene (100 mL) was refluxed under nitrogen for 3 h. The cooled mixture was poured into 100 mL ice water and stirred for 2 h. The organic layer was discarded. The water layer and precipitates were then basified with 200 mL 2 N NaOH and extracted with CH_2Cl_2 (50 mL × 3). The extracts were washed with 100 mL water, dried over Na_2SO_4, and evaporated to give 5.731 g 1-(2-bromo-3,4-dimethoxybenzyl)-6,7-dimethoxy-3,4-dihydroisoquinoline as a solid, in a yield of 85%, m.p. 120–124°C. Recrystallization from benzene-Et_2O gave an analytical sample, m.p. 123–125°C; R_f = 0.15 on silica gel TLC plate (5% MeOH in CH_2Cl_2).



Reference 15.

A solution of 300 mg *N*-(3-bromo-5-methoxyphenethyl)-2-benzyloxyphenylacetamide (0.66 mmol) in 5.5 mL dry acetonitrile was treated with 0.6 mL phosphoryl chloride and refluxed under nitrogen for 1 h; the solvent was evaporated off, and the excess of reagent was removed in vacuo. A solution of the residue in $CHCl_3$ was rapidly washed with 1 N NaOH and H_2O, dried, and evaporated under reduced pressure. The unstable 3,4-dihydrobenzylisoquinoline was refluxed with 1.05 mL MeI (17 mmol) in 4 mL acetonitrile under nitrogen for 3 h. Evaporation gave the crude alkylammonium iodide, which was reduced in 1.1 mL $CHCl_3$ and 6.6 mL CH_3OH by adding 200 mg $NaBH_4$ (5.3 mmol) in

portions and then stirring for 30 min at room temperature. The solvent was evaporated off, H_2O was added, and the mixture was extracted with $CHCl_3$. The organic phase was dried, and the residue was chromatographed on silica gel, eluting with ethyl acetate, to afford 75 mg 1-(2-benzyloxybenzyl)-6-bromo-8-methoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline, in a yield of 25%, $R_f = 0.26$ (EtOAc).

Black Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

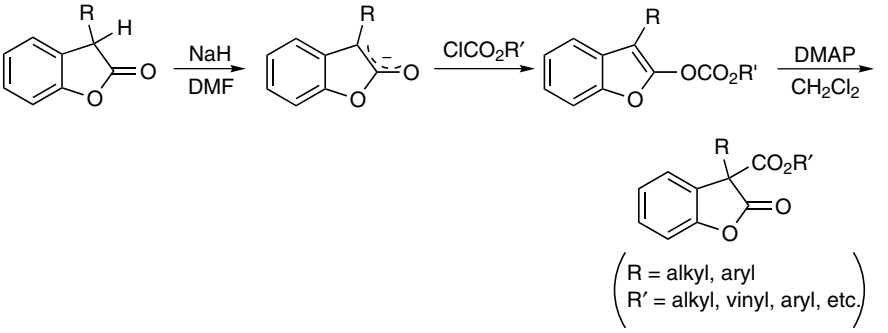
This reaction was first reported by Black in 1986.[1] It is a 4-*N*,*N*-dimethylamino-pyridine (DMAP) catalyzed [1,3] translocation of an ester group (e.g., formate) from an oxygen atom to the adjacent α-carbon atom of the carbonyl group for the carbonate esters of benzofuran enolates. Therefore, this reaction is generally known as the Black rearrangement.[2] Similar to the competition between *O*-alkylation and *C*-alkylation in the reaction of enolate with alkylating agents,[3] the *O*-acylation and *C*-acylation also complete with each other in the reactions of enolates with acylating reagents. Although it has been reported that under several circumstances, the *C*-acylations are favored—such as the application of acyl chlorides rather than anhydrides as acylating agents,[4] the inverse addition of enolate to acyl chlorides[5] at low temperature,[6] and using enolates of divalent countercations instead of alkali[7] — the *O*-acylation may still predominate for certain types of substrates. As an example, the acylation of benzofuran enolates under the above-mentioned conditions affords *O*-acylated products in preference, with maximal *C*-acylation up to 30%.[8] Especially for the enolate of the diaryl acetic acid esters, only *O*-acylated products were isolated.[9] The high preference for *O*-acylation probably lies in the high electron density located at the negative oxygen atom, resulting in the kinetically favored products.[8]

In the presence of a catalytic amount of DMAP, the enol carbonates of benzofuran derived from *O*-acylation with alkyl chloroformates rearrange to the corresponding carbon-acylated isomers within a short period of time (usually <2 min).[8] Such rearrangement is often accompanied by the appearance of a transient deep blue color. In addition, in the presence of DMAP, the acylation and Black rearrangement can be run in an "one-pot" fashion resulting almost exclusively in *C*-acylation products of high yields.[8] Different from

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

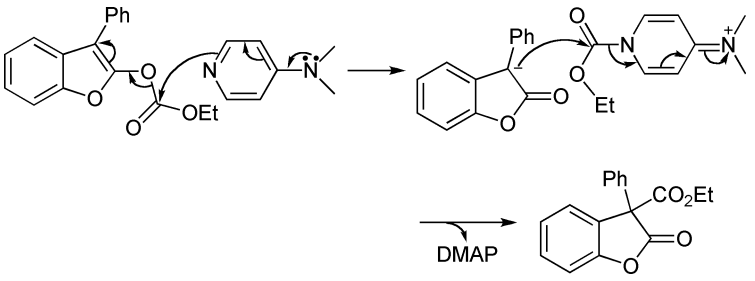
common acylations that take place under acidic conditions, the Black rearrangement can be applied in the basic conditions necessary for generating enolates.[8] Even though the solvent effect has been reported for this rearrangement, DMAP still retains its catalytic efficacy in a highly polar basic medium to maintain the regioselectivity.[8]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Due to the noticeable solvent effect of this rearrangement (e.g., slower rearrangement observed in DMF than in halogenated solvents), the rearrangement is assumed to involve polar donor-acceptor ion pairs.[8] Shown here is a representative mechanism for the carbonate ester of benzofuran.



D. MODIFICATION

This reaction has been extended to the translocation of the acyl group for indole derivatives.[10] In addition, a chiral planar DMAP derivative has been developed and applied for the enantioselective rearrangement of *O*-acylated azlactone[11] and the same catalyst recently has been used for an intermolecular reaction to form 1,3-diketones.[12] Moreover, 3-(2,2,2-triphenyl-1-acetoxyethyl)-4-(dimethylamino) pyridine (TADMAP) has been applied as a chiral nucleophilic catalyst to catalyze the carboxyl migration of oxazolyl, furanyl, and benzofuranyl enol carbonates with good to excellent levels of enantioselectivity. The rearrangement for oxazole derivatives are particularly efficient for giving chiral lactams and lactones.[2]

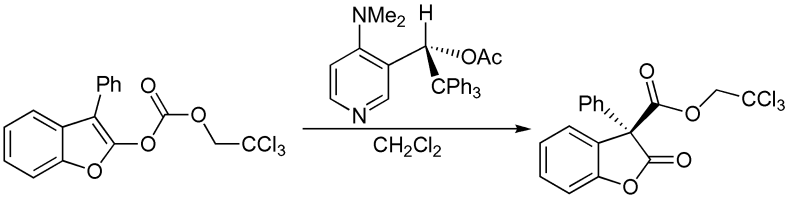
E. APPLICATIONS

This reaction has limited applications for the formation of quaternary chiral centers in benzofuran series.

F. RELATED REACTIONS

This reaction is related to the *Steglich Rearrangement* for benzofuran and indole derivatives.

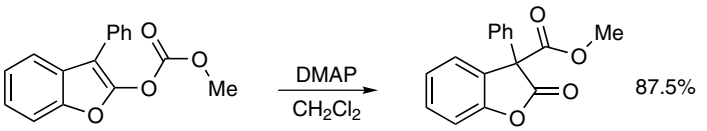
G. CITED EXPERIMENTAL EXAMPLES



92%, 86% *e.e.*

Reference 2.

After the solution of 38 mg 3-phenyl-benzofuran-2-yl 2′,2′,2′-trichloroethyl carbonate (0.10 mmol) and 8.7 mg (*R*)-3-(2,2,2-triphenyl-1-acetoxyethyl)-4-(dimethylamino) pyridine (TADMAP, 0.020 mmol) in 1 mL CH_2Cl_2 was prepared at $-78^{\circ}C$, the mixture was allowed to warm to $-40^{\circ}C$ and stirred at such temperature for 18 h. Then the solution was warmed to room temperature and concentrated under nitrogen stream. The residue was purified by flash chromatography (silica gel, 15 × 1.5 cm column) using EtOAc/hexanes (2:1) as the eluent. After elution with 200 mL EtOAc/hexanes (2:1), the column was further washed with 200 mL EtOAc. The first compound eluted within the first 80 mL and these fractions were evaporated to afford 35 mg of 2,3-dihydro-2-oxo-3-phenyl-3-benzofurancarboxylic acid 2′,2′,2′-trichloroethyl as a colorless oil, in a yield of 92% with 86% e.e., $R_f = 0.50$ (Et_2O/hexane = 1:1). Evaporation of further collected fractions from the column after 200 mL of solvent recovered 8.3 mg of the catalyst TADMAP, corresponding to 95% of catalyst recovery.



Reference 8.

To a 125-mL separatory funnel were charged 1 g carbonic acid, methyl 3-phenylbenzofur-2-yl ester and 20 mL CH_2Cl_2. The solution was effected by swirling. Then 40 mg DMAP was added, and the solution was briefly shaken. During the shaking, a deep blue/purple color developed immediately and disappeared after about 1 min. The solution was then washed successively with 5% HCl (3 × 20 mL) and 100 mL water, dried over $MgSO_4$; and con-

centrated. The residue was purified by bulb-to-bulb distillation (140–147°C, 0.05 mmHg) to afford 87.5% of 2,3-dihydro-2-oxo-3-phenyl-3-benzofurancarboxylic acid methyl ester as a clear, colorless oil that solidified after standing for several days to a white, crystalline solid, m.p. 68–70°C.

Other references related to the Black rearrangement are cited in the literature.[13]

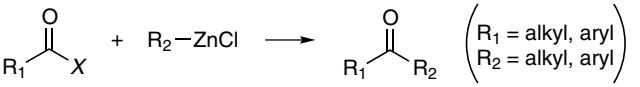
Blaise Ketone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Blaise in 1907.[1] It is the reaction between an organozinc halide and acyl halide to form ketone,[1,2] and is generally known as the Blaise ketone synthesis.[3]In this reaction, organozinc chloride can be prepared by the reaction between anhydrous zinc chloride and a Grignard reagent;[3b] the resulting organozinc chloride is referred to as the Blaise reagent;[4] which can be applied directly to the coupling with acyl halide without any isolation.[3b] The yield of expected ketones can be as high as 80%, presumably due to the lower reactivity between organozinc chloride and ketones than that between the ketone and corresponding Grignard reagents.[3b] As a result, even a hydroxyl group can be tolerated in this reaction without protection.[5] In addition, the coupling between organozinc chloride and β-hydroxy carbonyl chloride to form β-hydroxy ketones and further conversion into α,β-unsaturated ketones in boiling dilute sulfuric acid is known as the Blaise-Maire reaction.[3a,6]

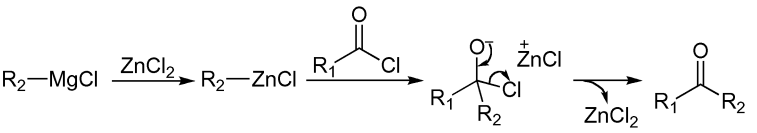
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is obvious that the Blaise ketone synthesis proceeds via the nucleophilic addition of an organozinc reagent to the carbonyl group followed by the releasing of chloride, as displayed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

The Blaise ketone synthesis has been extended to the synthesis of α,β-unsaturated ketones, known as the Blaise-Maire reaction.[3a,6] In addition, the organozinc chloride has been replaced by an organocadmium reagent for a better yield.[3b]

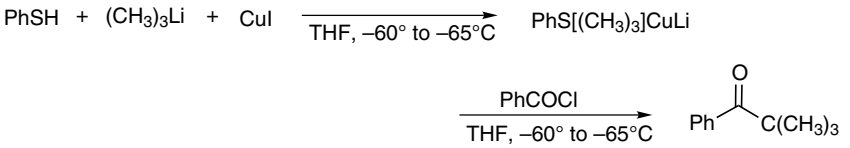
E. APPLICATIONS

This reaction has important applications in organic synthesis.

F. RELATED REACTIONS

This reaction is related to the *Grignard Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

A dry 200-mL round-bottomed flask was fitted with a magnetic stirring bar and a 100-mL pressure-equalizing dropping funnel, the top of which was connected to a nitrogen inlet. After the apparatus had been flushed with nitrogen, 50 mL 1.60 M *n*-butyllithium (0.080 mol) solution was placed in the flask and cooled with an ice bath. Under a nitrogen atmosphere, a solution of 8.81 g freshly distilled thiophenol (0.0801 mol) in 30 mL anhydrous THF was added dropwise to the cooled, stirred solution. An aliquot of the resulting solution was standardized by quenching in water, followed by titration with 0.10 N HCl to a green end point with a bromocresol indicator. The concentration of lithium thiophenoxide prepared in this manner was typically 1.0 M.

A dry 250-mL three-necked, round-bottomed flask was equipped with a sealed mechanical stirrer, a glass stopper, and a rubber septum through which were inserted hypodermic needles used to evacuate the flask and to admit nitrogen. After the apparatus had been flushed with nitrogen, 4.19 g purified copper(I) iodide (0.0220 mol) was added, and while warming with a flame, the apparatus was evacuated and then refilled with nitrogen. After

this procedure had been performed twice, the flask was allowed to cool, the stopper was replaced with a thermometer, and 45 mL anhydrous THF was added with a hypodermic syringe. With continuous stirring, 22 mL 1.0 M lithium thiophenoxide solution (0.022 mol) was added with a syringe to the slurry of copper(I) iodide. After 5 min, the resulting yellow solution was cooled, with continuous stirring, to −65°C with an acetone–dry ice cooling bath. Some copper(I) thiophenoxide usually separated from solution at ∼ −45°C. When the temperature of the mixture had reached ∼ −65°C, 13.6 mL 1.60 M *tert*-butyllithium (0.0218 mol) solution was added with a syringe to the stirred mixture at such a rate that the temperature of the mixture remained at −65° to −60°C. The resulting cloudy yellow-orange solution of the cuprate reagent was stirred at −65° to −60°C for 5 min.

With a syringe, a solution of 2.81 g freshly distilled benzoyl chloride (0.0200 mol) in 15 mL anhydrous THF was added dropwise, with stirring, to the cold solution (−65° to −60°C) of cuprate reagent. The resulting yellow-brown solution was stirred for 20 min (at −65° to −60°C) and quenched by the addition, with a syringe, of 5 mL anhydrous methanol. The red-orange reaction mixture was allowed to warm to room temperature and then poured into 100 mL aqueous saturated ammonium chloride. The copious precipitate of copper(I) thiophenoxide was separated by suction filtration and washed thoroughly with several 50-mL portions of diethyl ether. The combined filtrate was extracted with three 100-mL portions of ether. The combined ethereal solution was washed with two 50-mL portions of aqueous 1 N sodium hydroxide and with one 50-mL portion of aqueous 2% sodium thiosulfate. Each of the aqueous washes was extracted in turn with a fresh 50-mL portion of ether. The combined ethereal solution was dried with anhydrous $MgSO_4$, filtered, and concentrated by distillation through a short Vigreux column. The residual pale yellow liquid was distilled through a short column under reduced pressure, yielding 2.73–2.82 g of *tert*-butyl phenyl ketone as a colorless liquid, in a yield of 84–87%, b.p. 105–106°C (15 mmHg).

$$CH_3(CH_2)_{10}CH_2Br + Mg + ZnCl_2 \xrightarrow[\text{Benzene}]{ClC(O)(CH_2)_8CO_2Et} CH_3(CH_2)_{11}C(O)(CH_2)_8CO_2Et$$

Reference 8.

A Grignard reagent was prepared from 0.72 g magnesium and 7.5 g dodecyl bromide in 50 mL dry ether in a 500-mL flask fitted with the usual equipment and an inlet through which nitrogen was continuously passed. To the reagent was added 4.1 g freshly fused zinc chloride dissolved in 12 mL ether. After the mixture was refluxed for 30 min, 60 mL sodium-dried benzene was added to dissolve the white precipitate of dodecyl zinc chloride. With continuous stirring and refluxing, 6.0 g ω-carbethoxynonoyl chloride (prepared from ethyl hydrogen sebacate and thionyl chloride in 90% yield) dissolved in 50 mL dry benzene was slowly added. The reaction mixture was refluxed for another 2 h; decomposed with dilute HCl; and washed with dilute ammonium chloride solution, water, dilute sodium carbonate, and water. After removal of the solvent, the syrupy residue was saponified. The crystalline sodium salt was very insoluble in both cold water and cold benzene and was purified by thorough extraction with each. The filtered salt was digested with dilute HCl and the free acid crystallized from acetone-petroleum ether (b.p. 60–68°C) to give 5.3 g 10-ketodocosanoic acid as light, shiny crystals, in a yield of 62%. After one more crystallization, the melting point was 91.5°C.

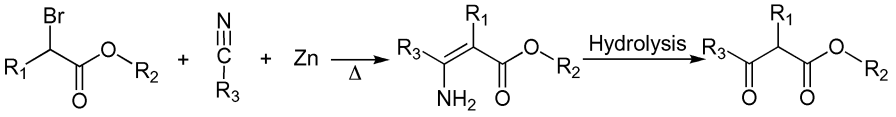
Blaise Reaction
(Blaise Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Blaise in 1901.[1] It is the reaction between a nitrile and zinc reagent from an α-bromoester (i.e., the Reformatsky reagent) to give an enamino ester or the further product of a β-keto ester upon acidic hydrolysis.[2] Therefore, it is generally known as the Blaise reaction.[3] Occasionally, it is also referred to as the Blaise condensation.[4] Although it is a one-step synthesis of higher aliphatic β-keto esters from a stable and accessible starting material, the easy introduction of functionalities and the straightforward nature of the conversion have been overshadowed by the problems of low yield, narrow scope, and competing side reactions.[5] It is found that the structure of bromoester strongly affects the efficiency of this reaction–for example, esters of bromoacetic acid give no isolable yield of β-keto esters, whereas esters of α-bromopropionic acid and α-bromoisobutyric acid give β-keto esters in yields varying from 30% to 60%.[5d] However, when a Reformatsky reagent reacts with an excess amount of cyanogens $(CN)_2$, 30–60% of nitrile will form, resulting in a valuable method for synthesizing α-cyano ester, which is not easily obtained in good yields by other direct syntheses.[6] The original reaction procedure has been modified to a convenient preparation of enamino ester and β-keto ester by refluxing aliphatic or aromatic nitriles with 3–5 equivalents of α-bromo esters in THF in the presence of activated zinc dust.[2] This modification has been applied to the total synthesis of the paralytic shellfish poisons, saxitoxin, and gonyautoxin.[2]

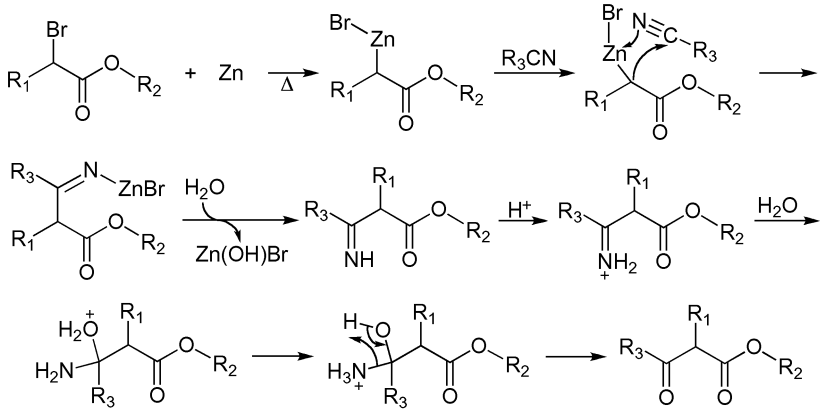
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction is believed to proceed by a mechanism analogous to that of the *Reformatsky Reaction*,[1] involving an initial condensation of the nitrile with the Reformatsky reagent; the intermediate is finally transformed into β-keto ester via acidic hydrolysis,[5d] as illustrated here.



D. MODIFICATION

This reaction has been modified via the generation of Reformatsky reagent *in situ* by refluxing the mixture of α-bromo esters and nitriles in the presence of activated zinc dust.[2] In addition, when a benzene solution of α-bromo esters are added slowly to a refluxing mixture of zinc and nitriles, a high yield of α,α-di and α-monosubstituted β-keto esters are obtained.[5c] On the other hand, the Blaise reaction has been improved by using a Zn-Ag couple under ultrasonic radiation. For example, the coupling by means of different forms of activated zinc instead of a zinc-silver couple or without the use of ultrasound does not occur or gives only poor yield.[3m] Moreover, it is reported that methanesulfonic acid can be used as an *in situ* activator of zinc to remove the induction period of the Blaise reaction.[3d] Furthermore, this reaction has been modified to afford β-amino esters via the reduction of the intermediate obtained by the hydrolysis of the reaction mixture with concentrated potassium carbonate.[2]

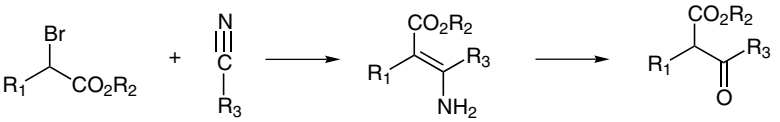
E. APPLICATIONS

This reaction can be generally applied to the preparation of enamino esters and β-keto esters, which can be asymmetrically reduced to yield chiral β-amino or hydroxyl esters and further hydrolyzed to β-amino or hydroxyl acids and cyclized to form β-lactams or lactones.[7] In addition, this reaction has been successfully used in the synthesis of the paralytic shellfish poisons, saxitoxin, and gonyautoxin.[2]

F. RELATED REACTIONS

This reaction is related to the *Reformatsky Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

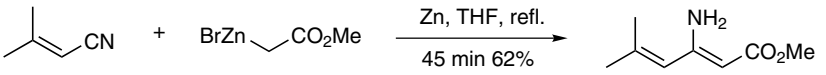
General Procedure for the Preparation of Enamino Esters

To a suspension of 327 mg activated zinc dust (5 eq.) in 3 mL refluxing anhydrous THF under nitrogen were added 4 drops α-bromo ester. After the appearance of the green color (this color is very evident with bromoacetates; when substituted bromo esters are used, however, the color may not appear), 1 mmol nitrile was added in one portion, and then 4 mmol α-bromo ester was injected by syringe pump over 45 min. The mixture was refluxed for an additional 10 min, diluted with 9 mL THF, and quenched with 1.3 mL 50% aqueous K_2CO_3. Rapid stirring for 30 min gave two cleanly separated layers. The upper organic layer was decanted, the residue was washed three times with THF, and the combined organic layers were dried with $MgSO_4$. Concentration and purification by PTLC (SiO_2 developed with 1:l hexanes/Et_2O, typically) gave the enamino ester product, contaminated with $< 25\%$ of its β-keto ester. Hydrolysis during purification could be minimized by avoiding contact of the enamino ester with dry silica gel. Column chromatography on solvent-wetted SiO_2 was an effective procedure for isolating pure enamino ester. Note that it was crucial to use the prescribed volumes of THF and K_2CO_3 solution. Otherwise, emulsions would form, and the clear, Zn^{2+}-free THF layer would not separate, making the workup tedious and decreasing the yield. For each mole of zinc salt produced, the cooled reaction mixture should be diluted to a total volume of 3 mL, and then 0.33 mL 50% aqueous K_2CO_3 should be added with vigorous stirring.

General Procedure for the Preparation of β-Keto Esters

The THF solution of crude enamino ester obtained as described earlier was subjected to acid hydrolysis as follows. The THF solution was treated with 1 mL 10% aqueous HCl at room temperature for 30 min, or a time sufficient for the UV-active enamino ester to be no

longer detectable by TLC. The mixture was concentrated, diluted with CH_2Cl_2, washed with saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and purified by PTLC (SiO_2 developed with 1:l hexanes:Et_2O, typically) to yield the pure β-keto ester.



Reference 7b.

A suspension of 20.0 g activated zinc powder (0.3 mol) in 185 mL dry tetrahydrofuran was stirred at reflux while a few drops of methyl bromoacetate were added. After stirring a few minutes, the suspension color turned to dark green. A total of 5 g 3,3-dimethylacrylonitrile (62 mmol) was added in one portion, followed by 23 mL methyl bromoacetate (250 mmol), which was added over 1 h. After completion of the addition, the red reaction mixture was cooled, diluted with 550 mL tetrahydrofuran and then with 110 mL aqueous 50% potassium carbonate solution, and was vigorously stirred for 30 min. The mixture was then filtered through a pad of celite, and the filtrate was concentred in vacuo. The residue was taken up with 500 mL dichloromethane, washed with brine, dried over Na_2SO_4, filtered, and concentrated in vacuo. The crude product was purified by chromatography (50% ether/pentane, $R_f = 0.7$) to give 5.95 g (2*Z*)-3-amino-5-methyl-2,4-hexadienoic acid methyl ester as a yellow oil, in a yield of 62%.

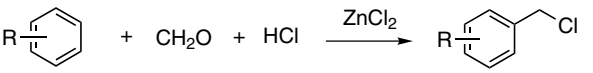
Blanc Chloromethylation
(Blanc Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Grassi-Cristaldi and Maselli in 1898[1] and subsequently extended by Blanc in 1923.[2] It is the reaction for introducing the chloromethyl group into aromatic rings when aromatic compounds are treated with formaldehyde and hydrogen chloride in the presence of zinc chloride. Therefore, this reaction is generally known as the Blanc chloromethylation.[3] Although aliphatic ketones could be chloromethylated in a similar manner, only those aromatic ketones carrying at least two alkyl groups could be chloromethylated in this reaction.[4] In fact, this reaction is a good indirect method for methylation of aromatic compounds if combined with subsequent reduction.[4,5] Chloromethylation of phenyl rings is important for the functionalization of resins, which provides an alternative to polymers employing functionalized monomer in the polymerization step.[6] Although the uncatalyzed chloromethylation of aromatic rings has been reported—such as chloromethylation using formaldehyde and HCl in acetic acid at 85°C[7] and using chloromethyl methyl ether in acetic acid at 100°C[8]—these results could not be repeated and are strongly questioned.[9] This reaction has been used to synthesize benzyl chloride, 6-chloromethyldehydroabietic acid,[10] hydrindene,[11] methylcholanthrene,[12] cyclophane,[13] Bakelite,[14] etc. This reaction has been reviewed.[15]

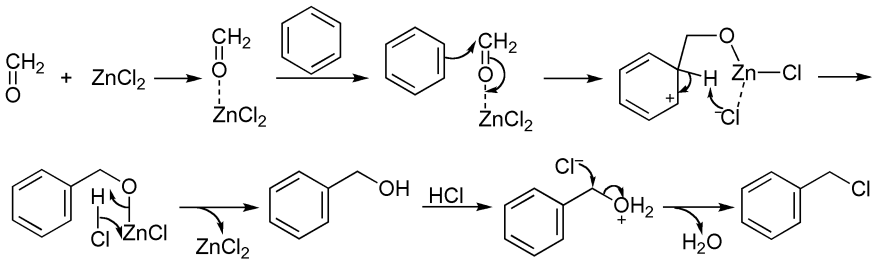
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that the formation of complex between formaldehyde and zinc chloride polarizes formaldehyde so that the electrophilic aromatic substitution can occur, as displayed here.



D. MODIFICATION

Although the original Blanc procedure using paraformaldehyde (sometimes called trioxymethylene) and fused and pulverized zinc chloride is followed in many preparations,[16] this reaction has been modified by using either 85% phosphoric acid as catalyst[17] or $ZnCl_2$ as catalyst but with $AlCl_3$[12] or $NiCl_2$[18] as cocatalyst. In addition, 40% formaldehyde has been used for this reaction instead of paraformaldehyde.[18] Bromomethylation of aromatic compounds could be considered another modification.[19]

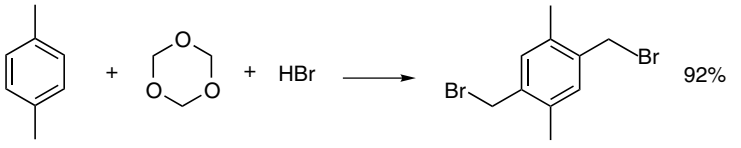
E. APPLICATIONS

This reaction is generally used to introduce the chloromethyl group into aromatic compounds.

F. RELATED REACTIONS

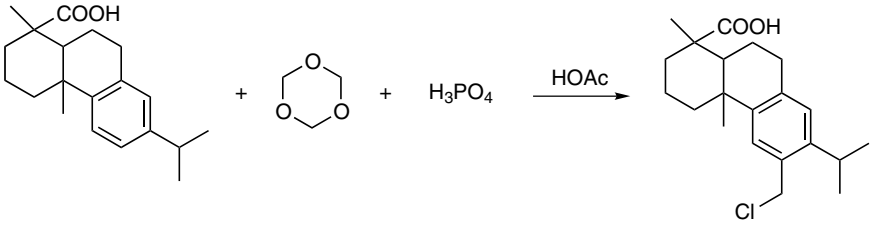
This reaction is related to the *Quelet Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



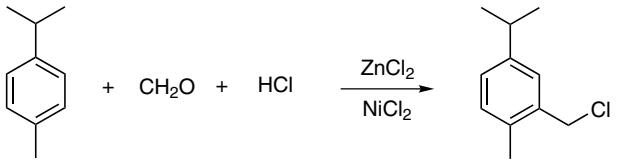
Reference 19.

To a solution of 95 mL 48% HBr (0.57 mol) in a 500-mL round-bottomed flask were added 7.65 g paraformaldehyde (0.25 mol) and 15.20 mL *p*-xylene (0.12 mol). After 28 h of refluxing, the mixture separated into two liquid phases and a white precipitate, which was filtered, yielding 34 g crude 1,4-dibromomethyl-*p*-xylene, in a yield of 97%. Recrystallization from CCl_4 gave 32 g of pure product as white needles, in a yield of 92%, m.p. 126–127°C.



Reference 17.

A solution of 25 g dehydroabietic acid, 3.3 g paraformaldehyde, and 5.2 mL 85% phosphoric acid in 50 mL glacial acetic acid was heated with vigorous stirring at 105–110°C for 11 h while treated with a stream of gaseous hydrogen chloride. The reaction mixture, which had separated into two layers, was diluted with water and extracted with ether. The ether extract was washed with water and dried over Drierite. Upon evaporation of the solvent, there was obtained a resinous, pale yellow residue, which was converted under reduced pressure to a froth that could be powdered and dried. The crude material (27.2 g) did not yield a crystalline product—that is, 6-chloromethyldehydroabietic acid.



Reference 18.

p-Cymene (50 g), 20 g anhydrous zinc chloride, 1 g nickel chloride, and 40 g 40% formaldehyde were stirred together at 60°C while hydrogen chloride was passed through. After 8 h, the reaction mixture was steam distilled. It was found that it was better to use the small quantities mentioned and to carry out many preparations rather than to use larger quantities. Forty-seven grams of colorless liquid was obtained by distillation at 123–124°C (20 mmHg), in a yield of 69%.

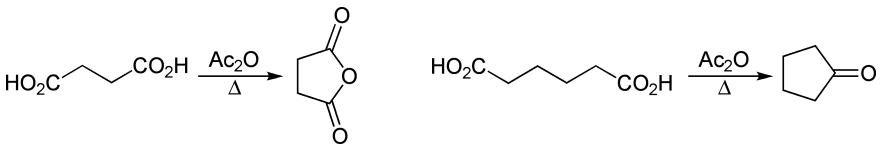
Blanc Rule

A. GENERAL DESCRIPTION OF THE REACTION

This rule was first generalized by Blanc in 1907,[1] although it was originally investigated by Lapworth in 1899[2] and subsequently by Perkin in 1904.[3] In 1907, Blanc reported[1] that glutaric acid on treatment with acetic anhydride formed an intramolecular anhydride, and when adipic and pimelic acids were subjected to the same treatment, cyclopentanone and cyclohexanone were generated correspondingly. Therefore, he summarized that when a dicarboxylic aliphatic acid was heated with acetic anhydride and distilled, the ketone of one less carbon atom would form, unless it was possible for a five- or six-membered cyclic anhydride to form. This generalization is called the Blanc rule.[4] It should be pointed out that the cyclizations can also be accomplished without the use of acetic anhydride by mere application of heat in a high vacuum.[5,6] This rule has been applied to a great number of substituted products of aliphatic dicarboxylic acids, especially in the constitutional analysis of the carbon skeleton of polycyclic systems, such as sterols and bile acids.[5,7,8] However, this rule has been found to be unsuccessful in a few cases,[9] and an alternative method has been developed to differentiate the cyclopentanones and cyclohexanones.[10] In this rule, the dicarboxylic aliphatic acids are normally heated $>200^{\circ}C$.[7]

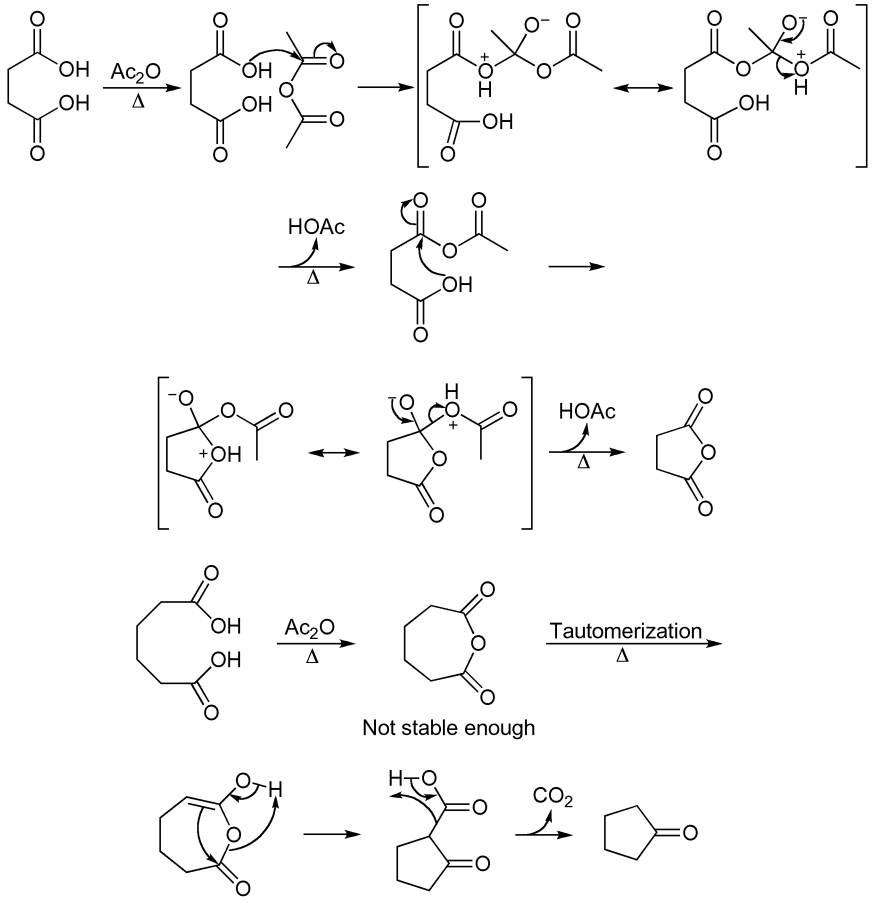
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is illustrated by showing the formation of succinic anhydride and cyclopentanone.



D. MODIFICATION

It has been modified by heating the dicarboxylic acid in the absence of acetic anhydride[6] and by using a mixture of acetic anhydride and potassium acetate.[7]

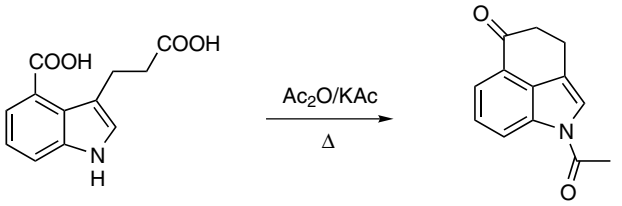
E. APPLICATIONS

This rule has been applied to characterize five-membered or six-membered ketone rings in steroid skeletons. In addition, this rule can also be used to prepare a variety of cycloketones.

F. RELATED REACTIONS

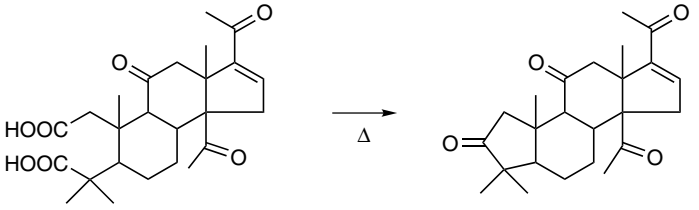
This rule is related to *Bredt's Rule*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

A solution of 143 mg β-(4-carboxy-3-indole)-propionic acid (0.6 mmol) and 15 mg potassium acetate (0.15 mmol) in 5 mL acetic anhydride was maintained at reflux temperature for 16 h. The acetic anhydride was distilled under reduced pressure. The residue was extracted with refluxing benzene. The solution was clarified by filtration and concentrated under diminished pressure. The remainder (125 mg) was recrystallized from a mixture of dichloromethane and ether to give 104 mg 1-acetyl-5-keto-1,3,4,5-tetrahydrobenz(ed) indole, m.p. 120–140°C. Further recrystallization from a mixture of dichloromethane and ether gave 90 mg pure product, in a yield of 71%, m.p. 147–152°C.



Reference 6

Dicarboxylic acid (2 g) was heated to 300°C for 2 h under a stream of nitrogen and at reduced pressure. Evolution of gas developed immediately. The residue was dissolved in benzene and chromatographed over 60 g alumina. The following fractions were collected: (a) benzene, 44 mg; (b) benzene-ether 3:1, 180 mg; (c) benzene-ether 1:1, 226 mg; (d) ether, 86 mg; and (e) chloroform, 340 mg. Fraction C crystallized, and further crystallizations from ether gave pure product, m.p. 195–197°C. No yield was given in original publication.

Other references related to the Blanc rule are cited in the literature.[11]

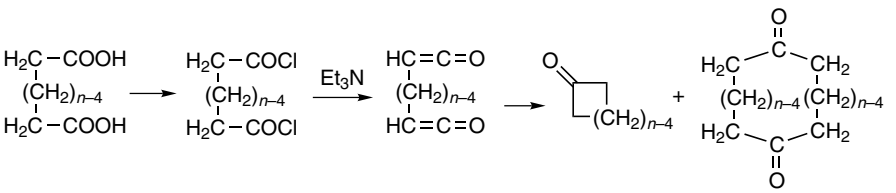
Blomquist Cyclic Ketone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Blomquist in 1947.[1] It is the reaction to form intermediate to macrocyclic ketones via the process of intramolecular condensation of aliphatic diketenes at diluted concentration followed by hydrolysis and decarboxylation of cyclic ketene derivatives.[2] The intermolecular condensation of diketenes will form even larger macrocyclic diketones,[3] which can be converted into simple macrocyclic diketones.[4] The ketene can be easily obtained by the treatment of acyl chloride of dicarboxylic acid with tertiary amines, of which triethylamine gives the best result.[3] Although some polyketene products also form in this process, they can be easily removed.[3] Other methods for preparing macrocyclic ketones include the Ziegler,[5] Hunsdiecker,[6] Ruzicka,[7] and Gliński[8] reactions.

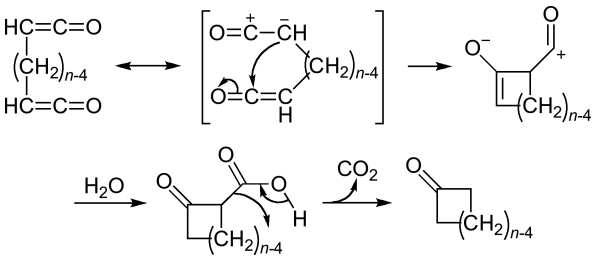
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is proposed as shown below.



D. MODIFICATION

N/A

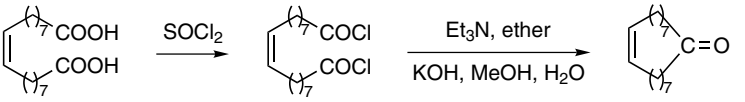
E. APPLICATIONS

This reaction has general application in the preparation of intermediate to macrocyclic ketones, such as muscone and civetone.[2]

F. RELATED REACTIONS

This reaction is related to the *Ruzicka Reaction.*

G. CITED EXPERIMENTAL EXAMPLES

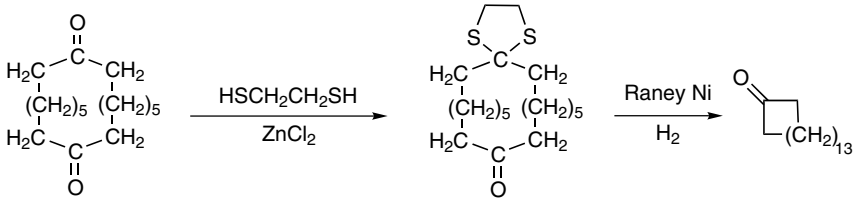


Reference 2.

A mixture of 1.8 g 9-octa-decene-1,18-dioic acid (5.8 mmol), 2 mL thionyl chloride (3.3 g, 28 mmol), and 5 mL absolute ether was warmed gently. Sulfur dioxide and hydrogen chloride distilled gradually. After 30 min, the temperature was raised to ~70°C, and the reaction was kept at this temperature for 1 h. Removal of excess thionyl chloride in vacuo at 50–60°C gave 2.03 g of the crude acid chloride, which still had an odor of thionyl chloride. A solution of the crude acid chloride in 200 mL absolute ether (Grignard dried) was added over a period of 15 h from a Hershberg dropping funnel down the condenser into a stirred, refluxing mixture of 500 mL absolute ether (Grignard dried) and 10 mL triethylamine. At the end of this time, the dropping funnel and condenser were rinsed with absolute ether, and

500 mL ether was removed by distillation of the combined ethereal solution. The remaining ethereal solution, triethylamine hydrochloride, and polymer were washed with 50-mL and 30-mL portions of 3 *N* HCl and finally with water until the washes were neutral to congo red. The ethereal solution was dried over anhydrous $MgSO_4$. The ether was distilled, and the residue weighed 1.72 g. To hydrolyze the ketene dimer, this material was dissolved in a solution of 2.0 g potassium hydroxide in 2.0 mL water and 30 mL methanol. The solution was kept at room temperature for 40 h and then was refluxed 1.5 h. The saponification mixture was cooled and diluted with water to ~200 mL; the neutral organic material was extracted repeatedly with ether. The combined ethereal solution was washed with water and dried over anhydrous $MgSO_4$. The ether was distilled, and 545 mg residue, crude civetone, was obtained. The material remaining in the aqueous layer was investigated sufficiently to ensure that no civetone was being lost as α-civetonecarboxylic acid.

The civetone was distilled at 0.2 mmHg pressure and a bath temperature of ~160°C. A nearly colorless distillate (476 mg) was obtained, in a yield of 33%.



Reference 4.

Conversion of 1,9-Cyclohexadecanedione to Its Ethylenedithioketal

After removing 50 mL benzene by distillation from a solution of 5.44 g 1,9-cyclohexadecanedione (0.0216 mol) in 200 mL of reagent-grade benzene, 2.03 g ethanedithiol (0.0216 mol), 20 g anhydrous Na_2SO_4, and 1.5 g freshly fused and powdered zinc chloride were added rapidly. The mixture, in a stoppered flask, was placed in the refrigerator overnight and allowed to stand 5 days at room temperature. The insoluble material was separated and thoroughly washed with benzene. The combined benzene filtrate and washings were evaporated to dryness and redissolved in hexane, leaving 1.0 g of insoluble material having a melting point of 204–210°C. This made up the crude bis-ethylenedithioketal. (An additional 1.1 g of this material—with a melting point of 206–210°C—was obtained by extracting the benzene-insoluble substances with water and chloroform and subsequently adding hexane to the chloroform extract.). Evaporation of the original hexane solution gave 4.66 g crude mono-ethylenedithioketal, which solidified in about 3 days. This crude product, containing unreacted diketone, was used for subsequent transformations without further purification.

Reductive Desulfurization of the 1,9-Cyclohexadecanedione Dithioketals

Crude 1,9-cyclohexadecandione dithioketal (4.66 g) was added to a suspension of 15 g Raney nickel in 200 mL ethanol, which had been previously refluxed for 1 h with 5 mL acetone. The mixture was refluxed for 3 h, cooled, and filtered. The filtered Raney nickel was allowed to stand under methanol. To the ethanolic filtrate was added a solution of 5 g semicarbazide hydrochloride and 10 g sodium acetate in 10 mL water. Although a white

precipitate formed immediately, the mixture was allowed to stand 24 h before filtration. The methanolic solution obtained after removal of the Raney nickel was treated similarly, and the resulting solid semicarbazone combined with that obtained earlier. The total semicarbazone precipitates were digested with 300-mL and 250-mL portions of boiling methanol. The insoluble material weighed 1.59 g and had a melting point of 221–227°C, corresponding to that of 1,9-cyclohexadecanedione disemicarbazone. An additional 0.29 g of impure disemicarbazone, (m.p. 186–191°C) separated when the methanolic filtrates stood at room temperature for 1 day. Concentration of the methanol solution gave three crystalline fractions of cyclohexadecanone semicarbazone: (a) 1.0 g with a melting point of 172–173°C, (b) 0.77 g with a melting point of 168–172°C, and (c) 1.25 g with a melting point of 170–175°C. The 3.02 g cyclohexadecanone semicarbazone corresponds to a 47% conversion from 1,9-cyclohexadecanedione. The yield, adjusted for recoverable diketone derivatives, was 90%.

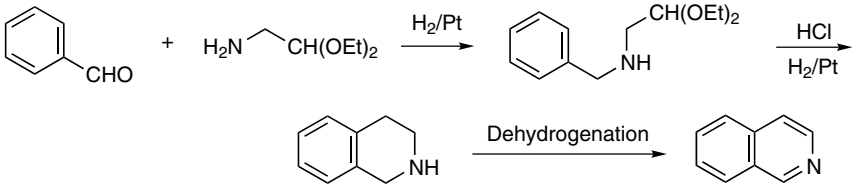
Bobbitt Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bobbitt in 1965.[1] It is the reaction to synthesize 1,2,3,4-tetrahydroisoquinoline by cyclo-condensation of substituted benzylaminoacetals in the presence of hydrochloric acid, and is generally known as the Bobbitt reaction.[2] This reaction is not only good for the preparation of 1-substituted isoquinolines, but 4- and *N*-substituted isoquinolines as well. Although the initial preparation of 1-alkylisoquinolines has been developed by Quelet and Vinot,[3] the involvement of boron trifluoride as a cyclizing reagent has made it generally unsuitable for the synthesis of oxygenated isoquinolines. The Bobbitt reaction has overcome the potential problems via the addition of aliphatic Grignard reagents to the Schiff bases, followed by the cyclization[4] and its modification.[5] In addition, the *N*-substituted 1,2,3,4-isoquinoline can be easily prepared via the reductive alkylation of benzylamine and cyclization[6] and other related methods;[7] and the 4-substitued 1,2,3,4-isoquinoline (4-OH-1,2,3,4-isoquinoline[8]) could be synthesized via the condensation of 1,2-dihydroisoquinolines with aldehyde.[1b]

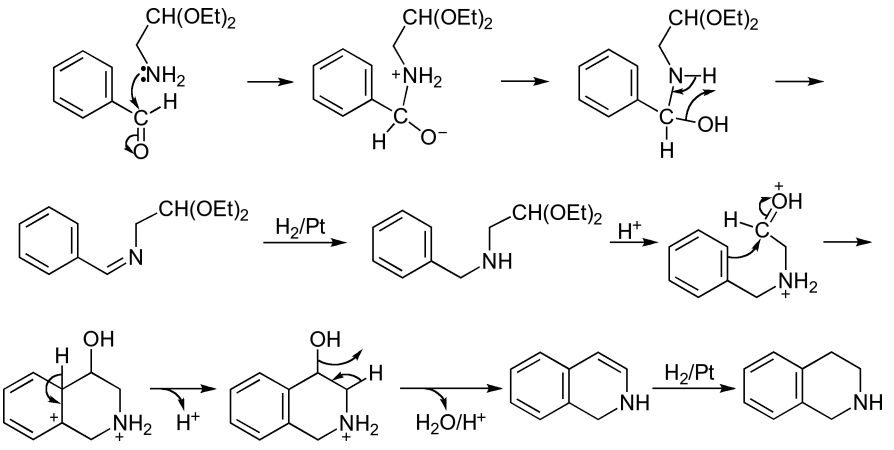
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is the illustration of reaction mechanism.



D. MODIFICATION

The 1-alkyl substituted isoquinolines have been modified via the reaction between imines and ethyl chloroformate followed by trimethyl phosphite to form carbamate phosphonate intermediates that cyclize into isoquinolines in the presence of Lewis acid.[5]

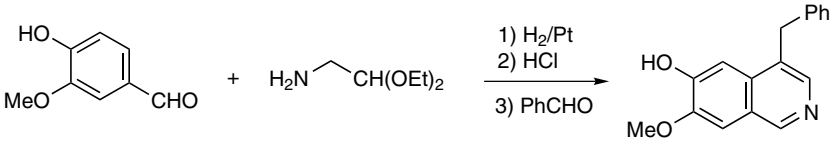
E. APPLICATIONS

This reaction has general application in synthesis of 1-, 4- and *N*-substituted 1,2,3,4-tetrahydroisoquinolines and 1-, and 4-substituted isoquinolines. In addition, this reaction has been applied to the synthesis of some alkaloids such as salsoline,[6] salsolidine,[6] carnegine,[6] and lophocerine.[9]

F. RELATED REACTIONS

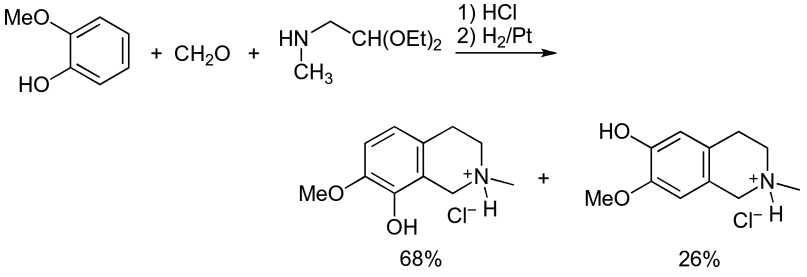
This reaction is related to the *Pomeranz-Fritsch Isoquinoline Synthesis.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 1b.

Vanillin (3.04 g, 0.02 mol), dissolved in a minimum amount of absolute ethanol, was combined with 2.66 g of aminoacetaldehyde diethylacetal (0.02 mol), and the mixture was diluted to 15 mL with absolute ethanol and hydrogenated at atmospheric pressure and room temperature over 200 mg of previously reduced platinum oxide. Hydrogen consumption stopped at about 90% completion after about 3 h. The catalyst was removed by filtration and the solvent was evaporated under vacuum. The residual oil was dissolved in 50 mL concentrated hydrochloric acid. The solution which had become hot was cooled and washed with three 30-mL portions of 3 : 2 ether-benzene to remove starting aldehyde. A two-fold excess of benzaldehyde (4.24 g, 0.04 mole) dissolved in 50 mL of ethanol was added to the acidic solution which was subsequently boiled for 30 min. The cooled solution was diluted with an equal volume of water and washed with three 50-mL portions of ether to remove the excess benzaldehyde. The solution was made basic with ammonium hydroxide to pH 8. The precipitate was removed by filtration and crystallized once from water-ethanol to give 3.33 g of 4-benzyl-6-hydroxy-7-methoxyisoquinoline, in a yield of 63%, m.p. 185–190°C. The analytical sample has m.p. at 192–193°C.



Reference 7a.

The mixture of 2.48 g guaiacol (0.02 mol), 3.0 g 40% aqueous formaldehyde (0.04 mol), and 3.6 g methylaminoacetaldehyde dimethyl acetal (0.03 mol) in 25 mL ethanol was stirred at room temperature for 24 h. The solvent was removed on a rotary evaporator and the resulting thick oil was dissolved in 50 mL cold 6 *N* HC1 and washed with ether. The acidic solution was stirred at room temperature for 15 h. The last traces of ether were removed on a rotary evaporator and the solution was hydrogenated over 4 g of 5% palladium on carbon at room temperature and atmospheric pressure until no more hydrogen was absorbed (about 0.02 mol). The catalyst was removed by filtration and the solution was concentrated on a rotary evaporator to a yellow syrup. The syrup was treated with 50 mL of hot ethanol and cooled. Crystals formed and were collected to yield 1.20 g of the crude hydrochloride of 2-methyl-6-hydroxyl-7-methoxy-1,2,3,4-tetrahydroisoquinoline, in a yield of 26%, m.p. 281–284°C. The mother liquor after the removal of 2-methyl-6-hydroxyl-7-methoxy-1,2,3,4-tetrahydroisoquinoline hydrochloride was concentrated and cooled to yield 3.12 g of crystalline crude hydrochloride of 2-methyl-7-methoxy-8-hydroxyl-1,2,3,4-tetrahydroisoquinoline, in a yield of 68%, m.p. 208–212°C.

Other references related to the Bobbitt reaction are cited in the literature.[10,11]

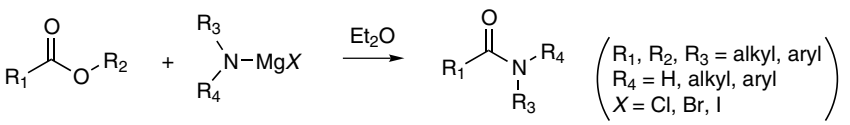
Bodroux Amide Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bodroux in 1904.[1] It is the preparation of substituted amide from the reaction between a simple aliphatic or aromatic ester and an aminomagnesium halide (1:2 ratio) obtained by treatment of a primary or secondary amine with a Grignard reagent at room temperature. However, the direct aminolysis of carboxylic esters with primary amines requires high temperatures and the use of an autoclave.[2] Besides the magnesium amides,[1,3] other metal amides have also been developed, including the alkali,[4] aluminum,[5] tin,[6] and titanium amides.[7] This reaction has been modified as the reaction between esters and lithium aluminum amide prepared from the $LiAlH_4$ and amine (1:5 ratio of $LiAlH_4$ to amine for the best result) at 25°C in Et_2O.[2] The process for preparing lithium aluminum amide is indicated by the formation of a precipitate and usually is completed within 15–30 min for unhindered amines; it takes much longer time for hindered amine (e.g., overnight for *t*-$BuNH_2$).[2] More recent modifications for preparing amide include the reaction between a carboxylate, amine, and Grignard reagent in a 1:1:1.5 molar ratio.[8]

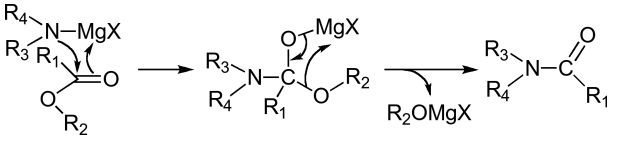
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is similar to the reaction between a Grignard reagent and ester, as illustrated here.



D. MODIFICATION

The original reaction procedure has been modified by using carboxylate, amine, and a Grignard reagent[8] and by using ester and lithium aluminum amides.[2]

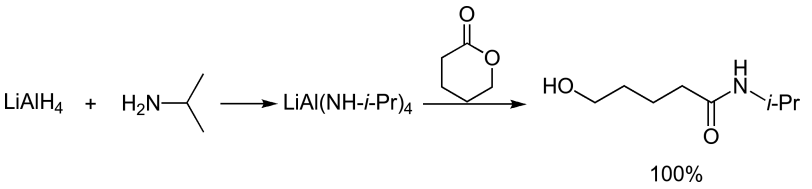
E. APPLICATIONS

This reaction is generally used to prepare substituted amides.

F. RELATED REACTIONS

This reaction is related to the *Willgerodt-Kindler Reaction*.

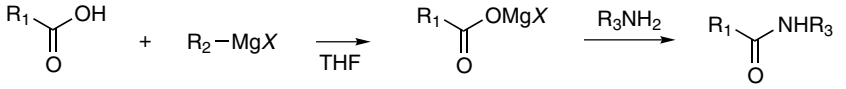
G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

A suspension of 1 g $LiAlH_4$ (26 mmol) in 20 mL anhydrous Et_2O or THF was refluxed for 90 min. After the mixture was cooled to 25°C, 130 mmol of isopropylamine was added dropwise with stirring. After the addition was finished, stirring was maintained at 25°C until the precipitation was complete (15–30 min). After the addition of another 15 mL anhydrous Et_2O or THF, a ready-to-use-suspension was obtained. Then 26 mmol δ-valerolactone was added dropwise to the Et_2O suspension, and the new mixture was stirred at 25°C overnight (until the precipitate disappeared). The reaction was then carefully quenched by the successive addition of 1 mL H_2O, 1 mL 10% NaOH, and 3 mL H_2O. Stirring was maintained until the new precipitate became white and powdered. After filtration, the precipitate was carefully rinsed with CH_2C1_2 (5×10 mL), and the combined organic phases were dried over $MgSO_4$

and concentrated in vacuo to give the crude *N*-(1-methylethyl)-5-hydroxypentanamide as a pale yellow viscous liquid that could be purified via column chromatography, in a yield of 100%.



Reference 8.

The general procedure for the synthesis of the amides from carboxymagnesium halides is as follows. To a solution of 2 mmol alkylmagnesium halide was added 10–15 mmol of carboxylic acid at 0°C under nitrogen. After the reaction mixture had been stirred at 70°C for 15 min, 5 mmol amine was added at 0°C. The reaction vessel was heated at 70°C for 30 min to 3 h. The mixture was quenched with 25 mL 10% hydrochloric acid at 0°C and extracted with dichloromethane (2 × 20 mL). The combined extracts were dried over $MgSO_4$, filtered, and concentrated. The residue was chromatographed on silica gel with ethyl acetate–light petroleum as the eluent. The reported yields were up to 65% if carried out in the noted conditions, and the tested amines include butylamine, diisopropylamine, morpholine, aniline, 1-phenylethylamine, and 1,2,3,4-tetrahydroisoquinoline. The best solvent for these conditions is THF, although Et_2O gives comparable yields. The mixture of THF and DMF (or THF/HMPA) does not afford any products. (*Note:* The procedure has been modified from the reported one for the purpose of easy follow-up.)

Bodroux-Chichibabin Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction had been initially reported by Gattermann and Maffezzoli[1] and concurrently by Chichibabin (or Tschitschibabin)[2] in 1903 and subsequently by Bodroux in 1904,[3] it was named after Bodroux and Chichibabin, as the Bodroux-Chichibabin reaction.[4] This reaction is the synthesis of aliphatic or aromatic aldehydes by treatment of ethyl orthoformate with corresponding Grignard reagents. In this reaction, after addition of the orthoformates to the ethereal solution of the Grignard reagent, and removal of solvent via distillation, the acetal will form and can be converted into aldehydes on treatment with acidic water. Other orthoformates can also be used for this reaction.[5] When ethyl orthoformate is applied in this reaction, the replacement of the first ethoxyl group is a slow reaction,[6] but the yields can be improved by refluxing the mixture of Grignard reagent and orthoformate.[6] It was found that in the reaction between the orthoformate (if prepared from 1,3-diol and alcohol) and the Grignard reagent, the acetals with axial 2-alkoxy groups react rapidly with a variety of Grignard reagents with high retention of configuration to give (very unstable) products with the axial 2-alkyl groups; in contrast, the diastereoisomers with equatorial 2-alkoxy groups appear to be unreactive and, under forcing conditions, give mixtures of several products.[7]

B. GENERAL REACTION SCHEME

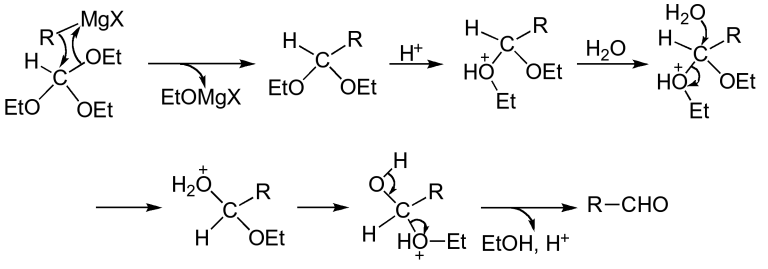
C. PROPOSED MECHANISMS

A general mechanism is displayed below.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has been generally applied to the synthesis of aldehydes.

F. RELATED REACTIONS

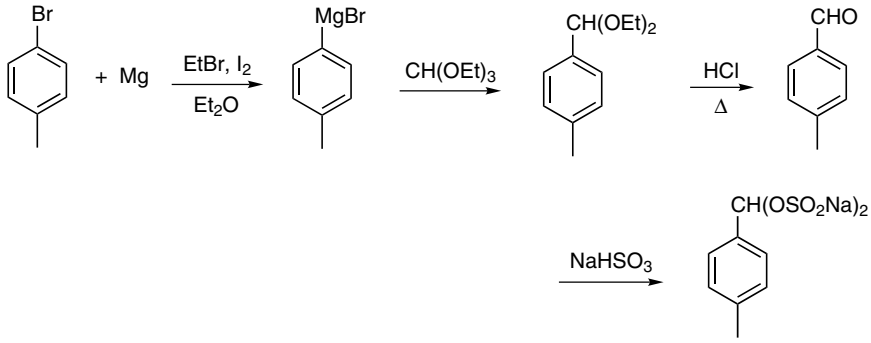
This reaction is related to the *Bouveault Reaction.*

G. CITED EXPERIMENTAL EXAMPLES

Reference 4c.

To a three-necked flask equipped with a dropping-funnel, mechanical stirrer, and condenser with openings protected by calcium chloride tubes was added fresh magnesium turnings. The flask was heated on a steam bath while a current of dry air was passed through. After the flask had cooled, 10 mL ether and a crystal of iodine were introduced. Then the alkyl halide (or aryl halide) in 10 mL ether was dropped onto the magnesium. After the reaction started, enough ether was added to the solution to bring the total amount of ether up to 4.5 moles per mole of alkyl halide. After the addition was complete, the mixture was refluxed and stirred for 15 min longer. Then, with stirring, the orthoformic ester, dissolved in an equal volume of ether, was added at the rate of about two drops per

second. No apparent reaction occurred. After the addition of the reagent was complete, the reaction mixture was refluxed and decomposed by the addition of ice and 5 N H_2SO_4 and refluxed for a few minutes to decompose the acetal. If the ether had been distilled off, the cooled mixture was extracted with ether three times (50 mL each time); otherwise, the ether layer was merely separated. The combined ethereal solutions were shaken vigorously with 50 mL saturated sodium bisulfite solution, and the filtrate was shaken with fresh bisulfite solution and again filtered. The combined solids were washed with 50 mL cold alcohol and then with 50 mL ether and spread in the air to dry. (*Note:* Readers should consult the original paper for details about this modified procedure.)



Reference 8.

The Grignard reagent was prepared by adding a solution of 20.8 g *p*-bromotoluene (0.122 mol) in 100 mL ether dropwise (45 min) to the suspension of 3.3 g magnesium powder (0.136 mol) in 20 mL ether under stirring. The reaction was started by the addition of 0.5 mL ethyl bromide and a crystal of iodine; after all the bromide was added, the solution was refluxed for 2 h. Ethyl orthoformate (22 g, 0.142 mol) in 30 mL ether was then rapidly added within 5 min and the reaction mixture was refluxed for 5 h. The ether was then distilled off on the steam bath; when practically all of it was removed, there was a sudden vigorous reaction. At this point, the flask was quickly immersed in an ice bath and allowed to remain there until all evidence of a reaction had disappeared. After standing overnight, 50 g ice and 125 mL cold 5 N HCl were added, the small residual amount of ether was evaporated, and the reaction mixture was refluxed for 30 min on the steam bath under an atmosphere of carbon dioxide. The aldehyde was then steam distilled in an atmosphere of carbon dioxide, and the distillate was extracted three times with ether (60 mL each time). The combined ether extracts were evaporated on the steam bath to remove solvent and propionic aldehyde (b.p., 50°C), and the residue of impure *p*-tolualdehyde was taken up in 20 mL ether. The ethereal solution was then vigorously shaken with a freshly prepared, saturated aqueous solution of sodium bisulfite, the solid was filtered off, and the filtrate was shaken again with fresh bisulfite solution and filtered. The combined solids were washed with ether and dried, and 20.3 g of solid was obtained, in a yield of 74.4%.

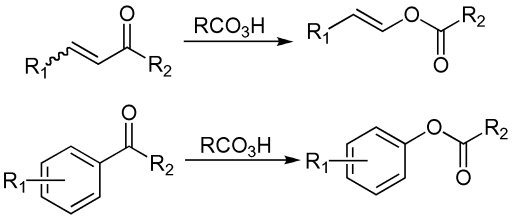
Böeseken Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Böeseken in 1929.[1] It is the reaction for transforming the α,β-unsaturated carbonyl compounds into enol esters[2] or aromatic carbonyl molecules (benzaldehys or phenyl ketones) into phenol esters[3] via oxygen insertion from the alkaline oxidation by peracids. The peracids used can be hydrogen peroxide,[4] peroxybenzoic acid,[5] peroxyacetic acid,[6] etc. This base-catalyzed oxidation of carbonyl compounds are different both in mechanism and in direction of cleavage from the acid-catalyzed oxidation (e.g., the *Baeyer-Villiger Oxidation*), indicating the migration of an alkyl or aryl group to an electron-deficient oxygen atom. The ease of cleavage and migratory aptitude of groups from ketone under alkaline peroxide oxidation is found in the order of primary alkyl > secondary alkyl > methyl and phenyl.[7] A faster and cleaner solid-state oxidation of hydroxylated benzaldehydes using urea-hydrogen peroxide as the oxidation reagent can be considered as the modification of this reaction.[3]

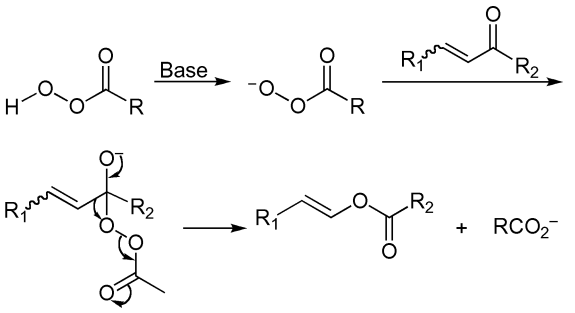
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism for the alkaline oxidation of α,β-unsaturated carbonyl compound by peracids is proposed as shown below.



D. MODIFICATION

This reaction has been modified by using urea-hydrogen peroxide as an oxidizing reagent.[3]

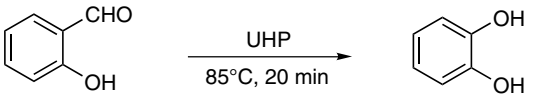
E. APPLICATIONS

This reaction can be used to prepare different phenols (e.g., via the oxidation of benzaldehydes or phenyl ketones), enol esters (from α,β-unsaturated carbonyl compounds) and aldehydes (from the further hydrolysis of corresponding enol esters).

F. RELATED REACTIONS

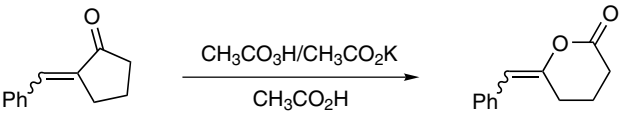
This reaction is related to the *Baeyer-Villiger Oxidation.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

Benzaldehyde (2 mmol) was added to 376 mg finely powdered urea–hydrogen peroxide adduct (UHP, 4 mmol) in a glass test tube, and the reaction mixture was placed in an oil bath at 85°C for 20 min. After completion of the reaction (monitored by TLC, hexane/EtOAc = 8:2), the reaction mixture was extracted into ethyl acetate, and the combined extracts were washed with water and dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure to afford the crude product, which was purified by chromatography to deliver pure product, in a yield of 85%.



Reference 8.

To a solution of 14.05 g benzylidenecyclopentanone (0.082 mol) in 70 mL glacial acetic acid saturated with potassium acetate was added 12 mL commercial peroxyacetic acid (containing 0.076 mol peracid) within 10 min under stirring. After 40 min, 93% of the peroxyacetic acid and 53% of the hydrogen peroxide content of the reagent had been consumed; after 70 min 95% of peroxyacetic acid and 68% of the hydrogen peroxide content had been consumed. Ether and water (100 mL each) were added to the reaction mixture. The aqueous layer was separated and extracted with ether (2×50 mL). The ethereal solutions were combined, washed consecutively with water (3×50 mL), sodium carbonate solution (2×25 mL), and again with water (2×50 mL). After filtration through $MgSO_4$ and concentration on the steam bath, a residue was obtained, which solidified on cooling. Recrystallization from isopropyl ether yielded 8.4 g 6-phenyl-5-hydroxyl-5-hexenoic acid δ-lactone (colorless flakes), m.p. 79–80°C. Somewhat less pure additional material (1.0 g) was isolated from the recrystallization mother liquors. The total yield obtained was 67% on the basis of peroxyacetic acid and 82% on the basis of the ketone used.

99

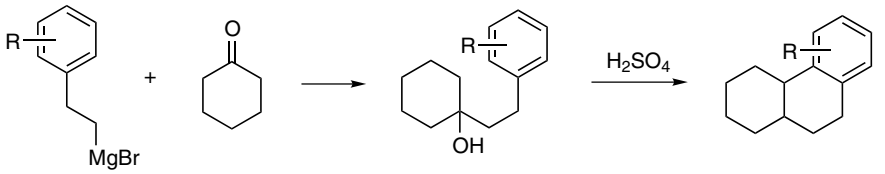
Bogert-Cook Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

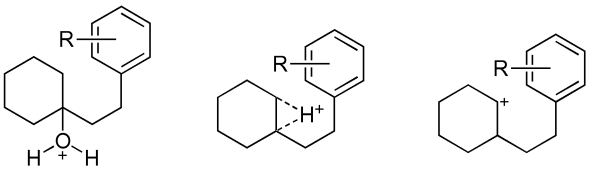
This reaction was first reported almost coincidently by Cook[1] in 1932 and Bogert[2] in 1933. It is a two-step process for preparing octahydrophenanthrene derivatives from a *Grignard Reaction* between β-phenylethylmagnesium bromide and cyclohexanones followed by cyclodehydration of the tertiary alcohol with concentrated sulfuric acid, accompanied by a small amount of spirane. In this reaction, when the intermediate carbinol is treated with a milder dehydrating agent (e.g., iodine, potassium hydrogen sulfate, 50% sulfuric acid), it is converted into the corresponding olefin,[2] which can also cyclize to octahydrophenanthrene derivatives.[3] These experimental results led to the early idea that the mechanism of this reaction involved the initial dehydration followed by the cyclization of the olefin produced,[4] which is now known to be erroneous.[5] It is believed that three possible intermediates can be formed, depending on the acidity and temperature of the reaction.[5b] On the other hand, when an alkyl or alkoxyl group is at the position *meta* to the side chain in the phenyl ring, cyclization can proceed to yield the 5- or the 7-substituted phenanthrene derivatives.[6] The yields of spirane formed vary, depending on the reactivity of the aromatic nucleus at the cyclization position.[5b] The particular stereoisomer formed by cyclization of the carbinol intermediate with an unreactive aromatic nucleus (*o*-chlorophenyl) is different from that obtained from the corresponding carbinol with a more reactive nucleus (phenyl).[5b]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

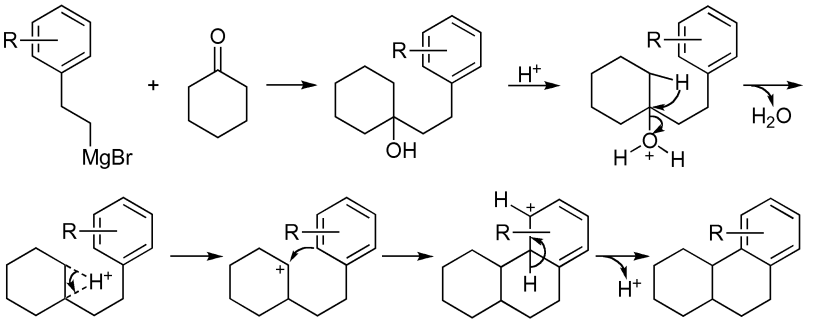
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



It is believed that three possible intermediates (**I**, **II**, and **III**) can be formed, depending on the acidity and temperature of the reaction.[5b] The bridged ion **II** is of appreciably lower energy than the free carbonium ion.[7] Under mild conditions, intermediate **I** predominates in the reaction, but only aryl groups with extremely reactive nuclear positions can cyclize; however, if the aromatic nucleus is moderately reactive, the cyclization occurs via the bridged ion **II**. If the aryl nucleus is unreactive, the cyclization takes place only after the higher energy carbonium ion (**III**) has formed to some extent. Nevertheless, an illustrative mechanism is shown for this reaction.



D. MODIFICATION

The cyclization of olefin has been modified using mercuric acetate and perchloric acid[8] or mercuric perchlorate in acetic acid.[9]

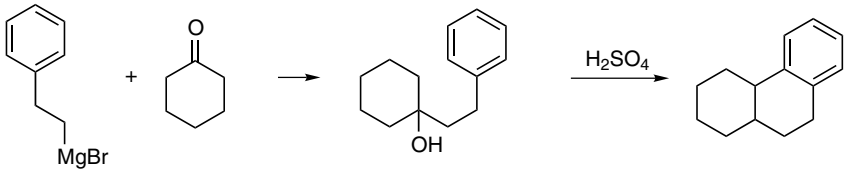
E. APPLICATIONS

This reaction has a general application in the preparation of polynuclear hydrocarbons containing a phenanthrene nucleus.

F. RELATED REACTIONS

This reaction is related to the *Bardhan Sengupta Synthesis*.

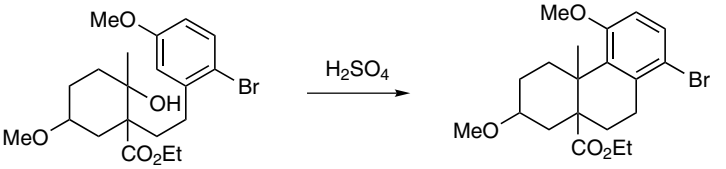
G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

The white needle-shaped 1-β-phenylethylcyclohexanol-1 was prepared from phenylethyl bromide and cyclohexanone, which was crystallized by making a saturated solution in warm petroleum ether and chilling it with an ice salt or solid carbon dioxide–alcohol mixture. The yield was 54%, m.p. 57°C, b.p. 145°C at 2–3 mmHg.

It is advised that 90% sulfuric acid be used for the secondary alcohols and 85% for the tertiary ones. The alcohol was added slowly with stirring to two volumes of the acid cooled by an ice pack. When all the alcohol had been added, the stirring was continued for 15–20 min at room temperature, and the mixture was then extracted with petroleum ether. The extract was agitated vigorously two or three times with cold 85% sulfuric acid, until the ether layer was a pale lemon yellow, then it was washed with a 10% sodium carbonate followed by a 10% sodium sulfate solution, dried over anhydrous potassium carbonate, and fractioned under diminished pressure to give *as*-octahydrophenanthrene, in a yield of 90%, b.p., 135–137°C (10 mmHg).



Reference 10.

The crude tertiary alcohol (5 g) was dissolved in 50 mL benzene and added to 107 g 90% sulfuric acid. The reaction mixture was stirred for 1 h at 0–2°C and then poured onto ice. After processing and evaporatively distilling at 150–155°C (0.15 mmHg), 1 g 2,5-dimethoxy-8-bromo-4a-methyl-10a-carbethoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene was obtained.

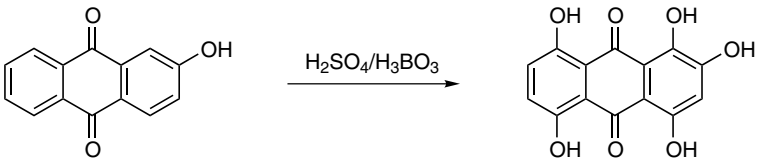
100

Bohn-Schmidt Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bohn in 1889[1] and subsequently by Schmidt in 1891.[2] It is the introduction of hydroxyl groups into anthraquinone molecules containing at least one hydroxyl group by the oxidizing action of fuming sulfuric acid (i.e., oleum).[3] Therefore, it is generally known as the Bohn-Schmidt reaction.[3,4] It is reported that if boric acid is added to the reaction mixture, then ordinary concentrated sulfuric acid can be used instead of the oleum, and boric acid can form esters with hydroxyanthraquinones to prevent the further oxidation.[5] In addition, selenium, selenium oxide, and mercury can be added as catalytic agents.[6]

B. GENERAL REACTION SCHEME

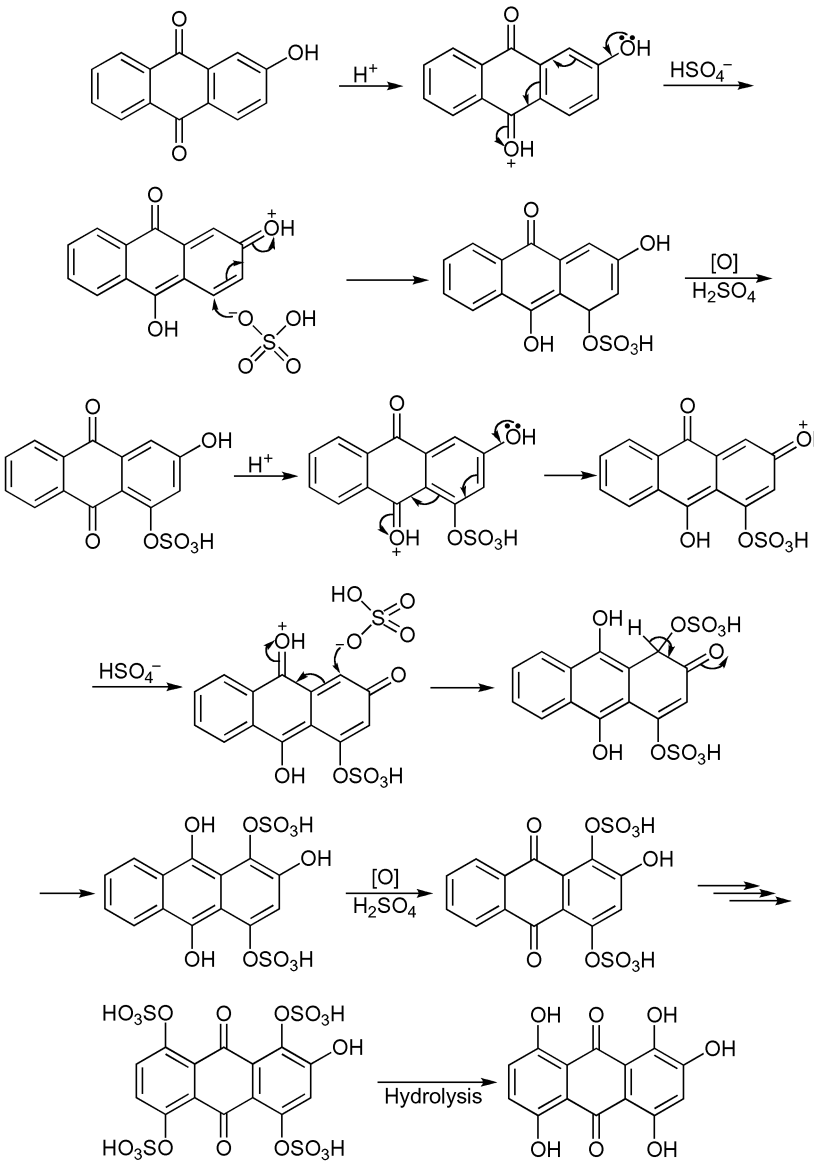


C. PROPOSED MECHANISMS

Because no illustrative mechanism is available, a tentative mechanism is proposed here for the reaction. It should be pointed out that oleum or even concentrated sulfuric acid has

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

the oxidation power, and hydroquinone or semihydroquinone can be oxidized into quinone by sulfuric acid.



D. MODIFICATION

This reaction has been modified to proceed in the presence of selenium or selenium oxide as catalyst.[6]

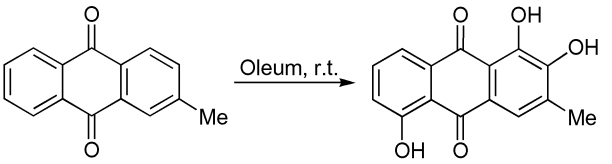
E. APPLICATIONS

This reaction has been applied to the technical preparation of important dyes such as Alizarin Green S, Alizarin Bordeaux, Alizarin Cyanine R, and Alizarin Cyanin Black.[3]

F. RELATED REACTIONS

This reaction is related to the *Boyland-Sims Oxidation* and *Elbs Persulfate Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

3-Methylalizarin (1 g) was treated with 6 mL 100% oleum at room temperature for 14–18 h. The reaction mixture was diluted with 50 mL concentrated H_2SO_4, and the resulting solution was poured onto 250 g crushed ice. The sulfuric ester that separated was filtered, and the wet cake was dissolved in 10% aqueous NaOH. The violet solution was acidified carefully with concentrated H_2SO_4, avoiding an excess of the acid. On boiling for 15 min, the precipitate was filtered and washed well. The dry precipitate (0.75 g) showed two spots on the oxalated silica gel plates using benzene as solvent. One spot corresponded to the starting material of 3-methylalizarin. The crude mixture was dissolved in DMF and then absorbed on column-grade silica gel. A dark violet band was eluted from the column upon elution with benzene. The eluate was concentrated to 1–2 mL, and to it was added 5 mL methanol. The compound crystallized in bright red microplates (80 mg) and was identified as 1,2,5-trihydroxy-3-methyl-anthraquinone, m.p. 220°C.

Other references related to the Bohn-Schmidt reaction are cited in the literature.[8]

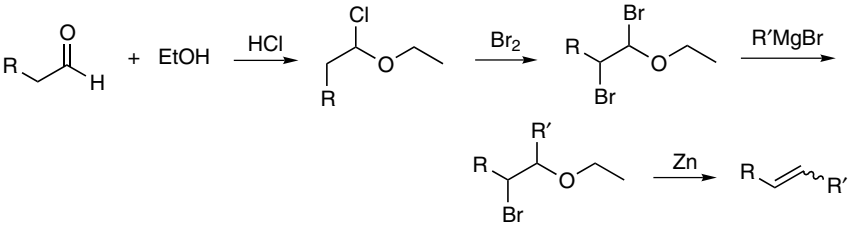
Boord Olefin Synthesis
(Boord Elimination)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Boord in 1930.[1] It is a general and flexible process for synthesizing different types of olefins with regio-specificity starting with the condensation of aldehydes with alcohol in the presence of hydrogen chloride gas, followed by the treatment with bromine to form α-bromo ether, and then further treatment with Grignard reagent, and zinc-induced reductive elimination of halogen and alkoxy groups. Therefore, this reaction is generally known as the Boord elimination,[2] or Boord olefin synthesis.[3] Unfortunately, the stereoselectivity of this reaction is poor, giving a mixture of *Z*- and *E*-olefins.[4,5] In zinc-induced reductive elimination, the larger the molecular weight of the alkoxy group, the slower the reaction rate. For example, the reactivity is found in the order of methoxy > ethoxy > butoxy > isobutoxy > 2-ethylhexoxy.[5]

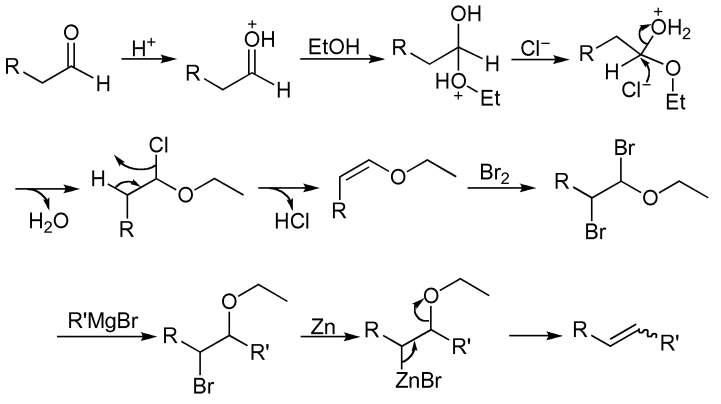
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although the mechanism is almost clearly shown in the reaction scheme, a tentative illustration is given here to show the reaction details.



D. MODIFICATION

When dibromides from alkyl vinyl ethers were condensed with Grignard reagents and the resulting β-bromoethers were treated with zinc, 53–84% of olefins could be yielded, which is 10–30% higher than the traditional procedure from aldehydes.[5]

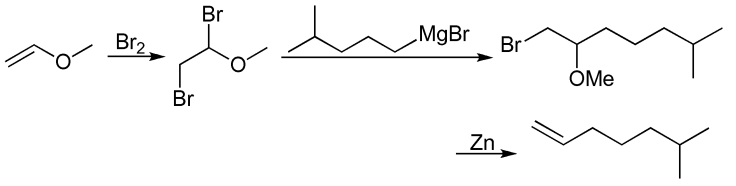
E. APPLICATIONS

This reaction has general application in preparation of different types of olefins.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

Bromination of *Alkyl Vinyl Ethers*

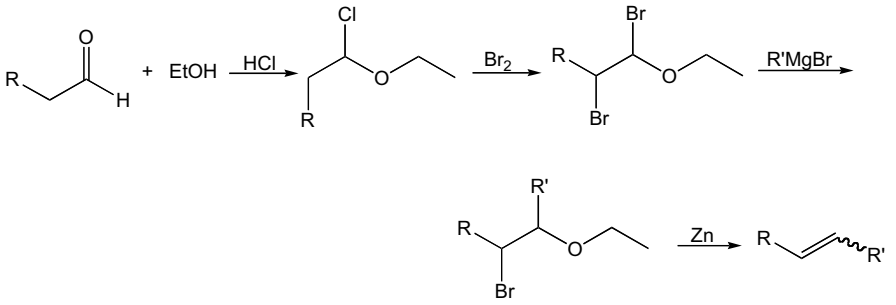
In a three-necked flask, suitably equipped and surrounded by a dry ice–acetone bath were placed 300–400 mL sodium-dried ethyl ether and 1 mol methyl vinyl ether. The theoretical amount of bromine was added, with stirring, at a rate of about 1 drop per second. The dibromides were not isolated from the ether solution, which were used as such in the *Grignard Reactions*.

Preparation of β-Bromoethers

The Grignard reagents from isoamyl chlorides (redistilled) were prepared in the manner described by Dreger.[6] The condensation was carried out in a conventional way, using a 20% excess of the Grignard reagent. After removal of the ethyl ether solvent by simple distillation, the β-bromoether was fractionated over solid sodium hydroxide at reduced pressure (column rated at about 10 theoretical plates at atmospheric pressure). The condensation with the dibromides was carried out in the customary way, the temperature of the reaction mixtures being maintained at 0–10°C. After distillation, 69% of 1-bromo-2-methoxy-5-methyl hexane was obtained, b.p. 98–99°C at 23 mmHg.

The Dealkoxybromination

The dealkoxybromination reaction was carried out as previously described.[1b] The olefin was purified only by washing with water and fractionation over metallic sodium at less than five-plate efficiency; yet the quality was obviously good. Finally, 84% of 5-methyl-1-hexene was obtained, b.p. 85.4–85.6°C.



Reference 1b.

Preparation of Alkyl-α-Chloroethyl Ether

The method[1a] has been generalized and extended to include the preparation of *n*-propyl- and *n*-butyl-α-chloroethyl ethers. It was found advisable for the purpose of synthesis to avoid distillation, the yield being diminished as much as 20–25% by a single fractionation. The upper ethereal layer was removed and dried over calcium chloride. For the α-chloroethyl ethers mentioned, the yield varies from 80 to 90% of crude or 60 to 69% of the distilled product.

Formation of Alkyl-α,β-Dibromoethyl Ethers (R-O-CHBr-CH_2Br)

The alkyl-α-chloroethyl ethers were brominated. The crude reaction product may be submitted directly to distillation under diminished pressure, but it was found advisable in this case to avoid distillation. The hydrogen chloride was removed under diminished pressure or by aspirating a slow current of air through the reaction mixture. The yields vary from 93 to 95% of crude or 88.5 to 91% of distilled product. For the case of *n*-butyl-α,β-dibromoethyl ether, the yield was 95.2%, b.p. 115°C at 36 mmHg.

Formation of Alkyl-β-Bromoethyl Ethers

A flask was surrounded by ice water, and the dibromoether—dissolved in an equal volume of anhydrous ether—was added through the dropping funnel at such a rate that the mixture remained cold. Mechanical stirring was used throughout the reaction which finished 15 min after the addition was completed. The reaction mixture was decomposed by pouring onto ice and acidifying with dilute hydrochloric acid. The ether layer was separated, dried over calcium chloride, and the ether was removed by distillation. The product was then transferred to a smaller flask, ~5% of its weight of solid sodium hydroxide was added, and it was then fractionated. α-Ethoxy-*n*-butyl bromide may be distilled at atmospheric pressure, but the higher members are best distilled under diminished pressure.

Synthesis of Olefins

For conversion into the olefin, the β-bromoether was dissolved in approximately 25 times its volume of 90% alcohol and placed in a three-necked flask under a spiral condenser. The flask was provided with a mechanical stirrer with a mercury seal. Zinc dust (2–3 eq.) was added, and the reaction mixture was digested at the boiling point for several hours. The lower bromoethers decomposed more slowly than those of higher molecular weight. β-ethoxy-*n*-amyl bromide yielded 60–65% of the crude pentene by treatment for 10 to 12 h, while β-ethoxyisoheptyl bromide gave a yield of 85–90% isoheptene in 5 h. The zinc dust tends to become coated with the basic salt produced. Mechanical stirring serves to obviate this difficulty in part, and there is some advantage in adding the zinc portion-wise. The separation of the olefin from the reaction mixture differed slightly, depending on its boiling point. In the case of α-pentene, the water in the spiral condenser was kept at 40°C so that the olefin volatilized from the reaction mixture continuously.

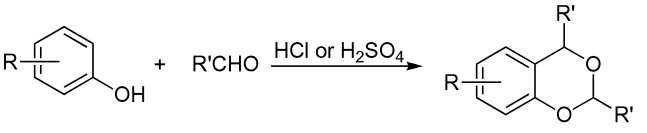
102

Borsche-Berkhout Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Borsche and Berkhout in 1904.[1] It is the reaction for preparing 1,3-benzodioxanes from phenols and aldehydes in the presence of acid, such as HCl and H_2SO_4. The formed 1,3-benzodioxanes can be oxidized into lactones[1,2] and converted into prodrugs of anti-inflammatory agents.[3] It is found that an electron-withdrawing group at position 8 will decrease the stability of such dioxane system toward alkali solution—for example, 6,8-dinitro-1,3-benzodioxane was easily cleaved in 1% of KOH solution to 2-hydroxy-3,5-dinitrobenzyl alcohol, whereas 6-nitro-1,3-benzodioxane was stable to boiling in 25% aqueous alkali or alcholic potassium ethoxide.[4]

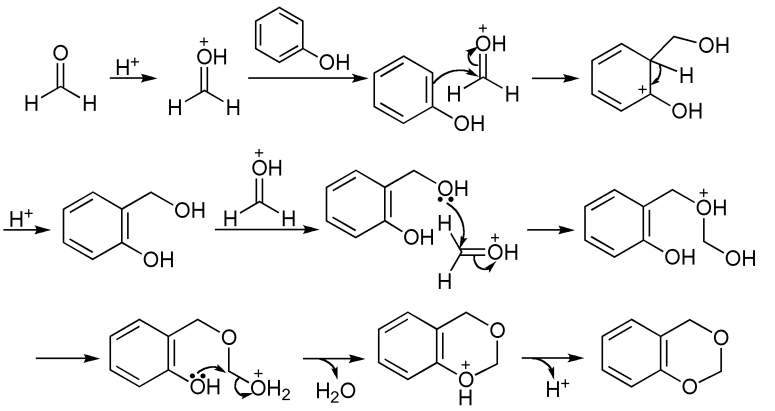
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because no information about the reaction details is available, a tentative mechanism for the reaction between phenol and formaldehyde is proposed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

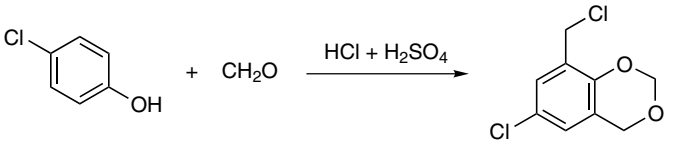
E. APPLICATIONS

This reaction can be generally applied to the synthesis of 1,3-benzodioxanes.

F. RELATED REACTIONS

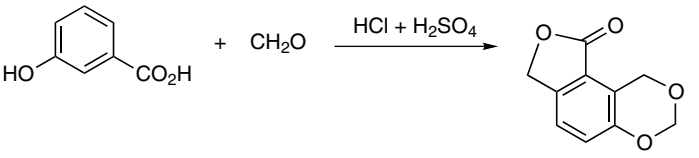
This reaction is related to *Bakelite Process*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a mixture of 500 mL concentrated hydrochloric acid and 15 mL concentrated sulfuric acid warmed to 40°C were added 20 g *p*-chlorophenol and 80 mL 40% formaldehyde. Hydrogen chloride was bubbled rapidly through the stirred mixture and kept at 40°C for 1.5 h, at which point the solution had clarified with the separation of some solid. Crude solid (30 g) was crystallized three times from methanol to give 18.5 g 6-chloro-8-chloromethyl-1,3-benzodioxane, m.p. 103°C.



Reference 5.

To 1 L 40% formaldehyde in a three-necked flask (equipped with a mercury-sealed stirrer, a thermometer, and a glass tube with an opening of ~1 mm in diameter leading to the bottom of the flask for introducing dry hydrogen chloride) was added 50 g *m*-hydroxybenzoic acid. In ~5 min the acid had dissolved, and then 1 L concentrate hydrochloric acid and 50 mL concentrated sulfuric acid were added with stirring; hydrogen chloride was passed rapidly through the entire solution heated to 60°C. A white solid began to form after ~1.5 h, but the reaction was continued for a total of 3 h, at which time considerable more solid had separated. After cooling overnight in a refrigerator, the crystals were filtered off and washed until free from formaldehyde. One crystallization from methanol gave 21.5 g 6-hydroxymethyl-1,3-benzodioxane-5-carboxylic acid lactone, m.p. 176°C.

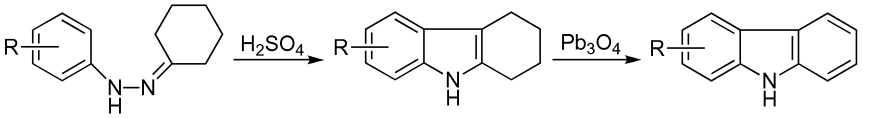
103

Borsche-Drechsel Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Drechsel[1] in 1888 and then by Borsche[2] in 1904. It is the reaction involving the cyclization of arylhydrazones of cyclohexanone to tetrahydrocarbazoles and the subsequent oxidation of tetrahydrocarbazoles into carbazoles. In this reaction, cyclohexanone phenylhydrazone is converted into tetrahydrocarbazole when heated with dilute sulfuric acid,[1,3] a process that is completely analogous to the *Fischer Indole Synthesis*. However, Borsche was the first to realize the full scope of this reaction, and had prepared many substituted tetrahydrocarbazoles.[4] Other acids can also be used in this reaction—for example, acetic acid has been found to give cleaner products.[5] Different oxidants have been applied for converting the tetrahydrocarbazoles into carbazoles, such as lead oxide,[4] mercury acetate,[5,6] palladium chloride,[7] and chloranil.[8] However, only chloranil was found to be a good reagent in this reaction. In addition, a mixture of cinnamic acid and palladium black is another excellent reagent for the preparation of carbazoles,[9] in which cinnamic acid was reduced to hydrocinnamic acid.

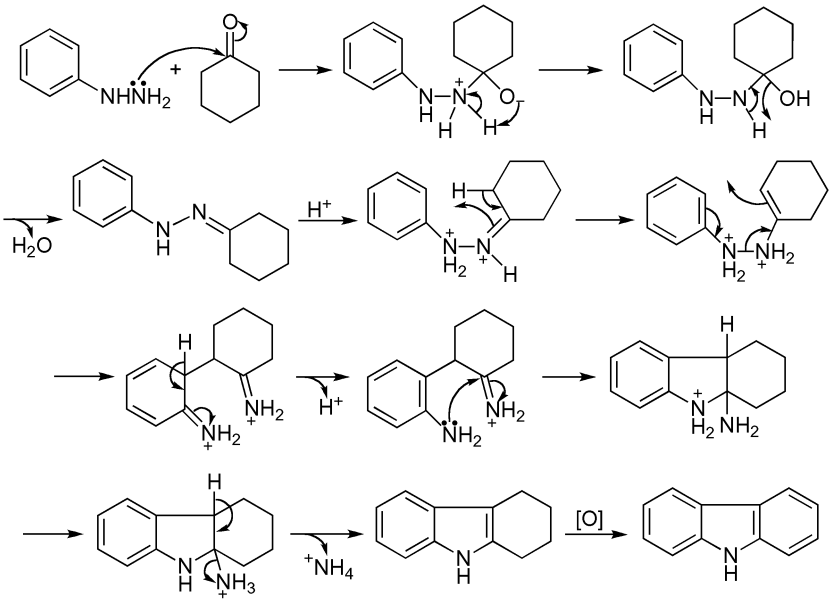
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is similar to the *Fischer Indole Synthesis* as outlined below.



D. MODIFICATION

The conversion of tetrahydrocarbazoles into carbazoles has been modified by using a mixture of cinnamic acid and palladium black.[9]

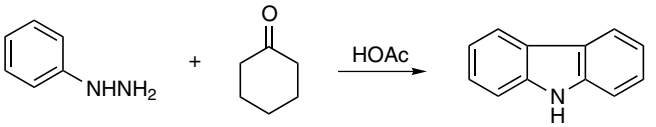
E. APPLICATIONS

This reaction has general application in the preparation of tetrahydrocarbazoles and carbazoles.

F. RELATED REACTIONS

This reaction is related to the *Bucherer Carbazole Synthesis, Fischer Indole Synthesis, Graebe-Ullmann Synthesis* and *Piloty-Robinson Pyrrole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

Phenylhydrazine (108 g, 1 mol) was added over 1 h to a stirred, refluxing solution of 98 g cyclohexanone (1 mol) in 360 g glacial acetic acid. After undergoing refluxing and stirring for an additional hour, the mixture was cooled to 5°C and filtered. The crude solid was washed with water, 75% methyl alcohol, and air dried to give 150 g 1,2,3,4-tetrahydrocarbazole, in a yield of 88%. Crystallization from methyl alcohol gave a first crop of 120 g and a second crop of 24 g. The reaction goes equally well if acetic acid is replaced by formic or propionic acid.

Other references related to the Borsche-Drechsel reaction are cited in the literature.[11]

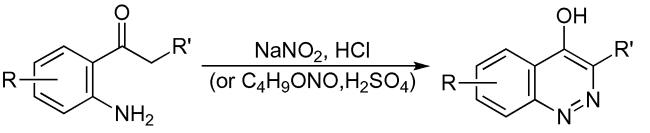
104

Borsche-Koelsch Cinnoline Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

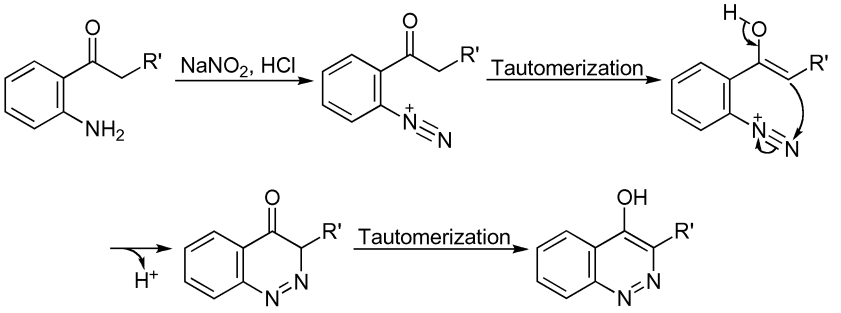
This reaction was initially reported by Borsche[1] in 1941 and Koelsch[2] in 1943. It is the reaction to form 4-hydroxycinnonlines[3] or 4-hydroxy-3-alkylcinnolines[4] via the diazotization of *ortho*-aminoarylketone followed by a slow step of cyclization.[5] In general, the aminoarylketone is diazotized in either aqueous solution or acetic acid solution, and the solution of the diazonium salt is allowed to stand in the dark at room temperature until it no longer gives a diazo coupling reaction with *p*-naphthol.[4] The time required for the completion of the cyclization under these conditions varies from a few days to 2–3 months. The reaction time appears to be a function of the basicity of the original amine. The yield of cinnoline obtained likewise depends on the character of the *o*-aminoarylketone used in its preparation. In general, the less basic the aminoarylketone, the shorter the time required for the cyclization and the greater the yield of corresponding cinnolines.[4] The substituted cinnolines are potential antimalarial drugs.[4]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

After the diazotization of *o*-aminoarylketone, 3-amino-cinnolines can be prepared in the presence of nitromethane;[6] on the other hand, the 4-alkyl-cinnolines can be synthesized similarly from *o*-amino-α-alkylstyrenes.[7]

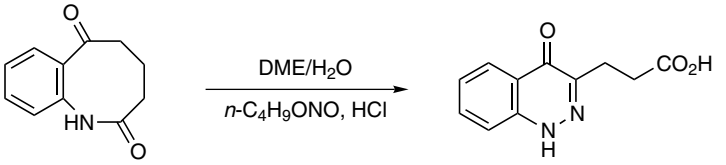
E. APPLICATIONS

This reaction is generally used to prepare 4-hydroxycinnolines.

F. RELATED REACTIONS

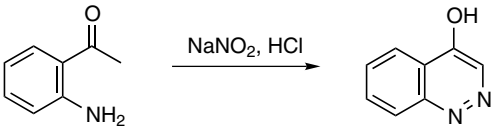
This reaction is related to the *Widman-Stoermer Synthesis* and *von Richter Cinnoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



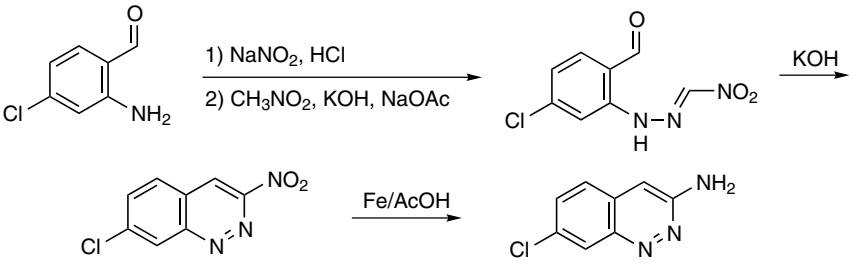
Reference 8.

To a suspension of 1 g of 4,5-dihydro-lH,3H-l-benzazocine-2,6-dione in 20 mL 1,2-dimethoxyethane and 0.1 mL water was added 0.84 g freshly prepared *n*-butyl nitrite. Hydrogen chloride gas was bubbled through the mixture at 25°C for 5 min; the resulting solution was stirred overnight at room temperature, after which time the intermediate diazonium chloride usually had separated. The solution or suspension was diluted with 10 mL water, the mixture was warmed for 5 min on a steam bath, and the resulting suspension was filtered. The solid residue was crystallized from aqueous ethanol to give 4-oxo-1,4-dihydro-cinnolin-3-ylpropionic acid, in a yield of 61%, m.p. 226–228°C.



Reference 4.

o-Aminoacetophenone (37.5 g, 0.278 mol) was dissolved in 120 mL water and 90 mL concentrated hydrochloric acid and diazotized between 0° and 7°C by the dropwise addition of 59 mL 5 N sodium nitrite solution. The solution was then treated with charcoal and filtered. A small amount of excess nitrous acid was removed from the filtrate by the addition of urea, and the solution was stored in the dark at room temperature until a diazonium reaction was no longer obtained with an alkaline solution of the anilide of 2-hydroxy-3-naphthoic acid (44 days). The reaction mixture consisted of a dark red solution in which was suspended some needle-like crystals and several globules of a red-brown oil. There was evidence of the evolution of a considerable amount of nitrogen. The solid material was removed by filtration. An additional crop of crystals was obtained by allowing the filtrate to stand for several hours at room temperature. After recrystallization from ethanol 17.4 g of product was obtained as slender white needles, in a yield of 42.9%, m.p. 236°C.



Reference 6a.

To a mixture of 7 g crude, moist 2-amino-4-chlorobenzaldehyde (~0.04 mol), 2.9 g sodium nitrite (0.042 mol) and 75 g crushed ice, made into a slurry in a Waring blender; a mixture of 9 mL concentrated hydrochloric (0.11 mol) acid and 50 g crushed ice was added in one portion. The mixture was blended for about 5 min until a clear solution was obtained. Small amounts of crushed ice were added periodically during the blending to keep the temperature low. The solution was filtered through a chilled funnel onto a small amount of crushed ice. Meanwhile a solution of 4.3 mL nitromethane (0.08 mol) in 5 mL ethanol was added slowly with stirring to a solution of 5.7 g potassium hydroxide (0.1 mol) in 3.5 L ice water. After the nitromethane had dissolved, 3.3 g sodium acetate (0.04 mol) was added to the solution. The diazonium solution was poured slowly into the solution of potassium *aci*-nitromethane. A yellow precipitate formed immediately. The mixture was allowed to stand for 20 min. The crude nitroformaldehyde 5-chloro-2-formylphenylhydrazone was collected by filtration and transferred to the Waring blender without further purification. A solution of 1.3 g potassium hydroxide in 50 mL water was added to the solid in the blender. A blood red color developed immediately. The mixture was blended until the red color faded into a chocolate brown (5–10 min). The mixture was poured into a beaker, allowed to stand for 2.5 h and filtered. The resultant brown solid was dried overnight in the vacuum desiccator. The crude material, 1.51 g, was recrystallized from acetone or, preferably, ethyl acetate,

giving 1.1 g (13%, based on 4-chloro-2-nitrobenzaldehyde) of 7-chloro-3-nitrocinnoline as pale yellow needles, m.p. 165.5–166°C

The reduction of 3.0 g 6-chloro-3-nitrocinnoline (0.014 mol) by iron in acetic acid gave 1.91 g of 3-amino-6-chlorocinnoline as bright yellow needles, in a yield of 74%, m.p. 215°C (dec.)

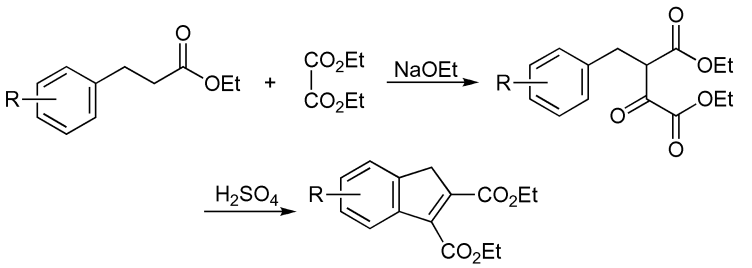
Bougault Reaction
(Bougault Cyclization)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bougault in 1915.[1] It is the reaction for preparing indene derivatives via the condensation of β-arylpropionic acid ester with diethyl oxalate followed by the cyclization of the resulting glyoxylate ester with sulfuric acid. Thus this reaction is known as the Bougault cyclization[2] or Bougault reaction.[3] In this reaction, phosphoric acid may be the reagent of choice for cyclization, particularly when sulfuric acid leads to hydrolytic cleavage, ester exchange, or extensive sulfonation.[2] This reaction has been extended to the synthesis of dihydronaphthalenes[2] and phenanthrene.[4]

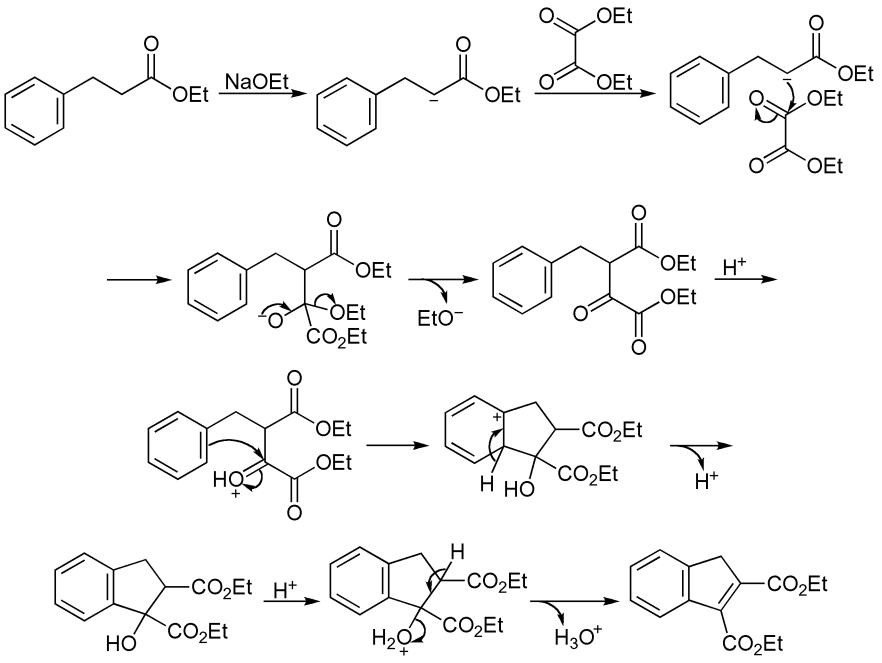
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is displayed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified by the application of phosphoric acid as a cyclization reagent.

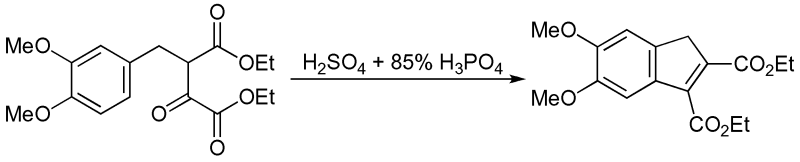
E. APPLICATIONS

This reaction can be applied to the synthesis of indene, dihydronaphthalene, and naphthalene derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

A keto-ester (3.4 g, 0.01 mol) was added slowly to a mixture of 15 mL concentrated sulfuric acid and 15 mL 85% phosphoric acid at 0–5°C. After standing at room temperature for 3 h, the mixture was poured onto chopped ice. The product separated slowly in crystalline form, which was removed, dried, and recrystallized from benzene-hexane to give 1.8 g diethyl 5,6-dimethoxyindene-2,3-dicarboxylate in a yield of 55%, m.p., 159–160°C. This was the only product obtained under varying cyclization conditions with sulfuric-phosphoric acids.

Reference 4.

Potassium ethoxide was prepared from 1.95 g potassium and 9.2 mL absolute ethanol in 150 mL anhydrous ether. To this mixture 14.6 g diethyl oxalate was added. After 15 min, a solution of 13.5 g ethyl (3′-methoxy-2-biphenylyl)-acetate in 50 mL dry ether was added, and the mixture was refluxed for 51 h. The reaction mixture was cooled and extracted with 5% sodium hydroxide solution. The aqueous layer was saturated with carbon dioxide, and the precipitated oil was taken up in ether. Evaporation of the ether solution afforded 10.6 g crude diethyl α-keto-α'-(3-methoxy-2-biphenylyl)-succinate, which was used in subsequent experiments without purification. From the alkali-insoluble fraction, 4.2 g ethyl (3′-methoxy-2-biphenylyl)-acetate was recovered.

Cyclization of 5.9 g α-keto-α'-(3-methoxy-2-biphenylyl)-succinate was effected by stirring it vigorously with 30 mL 80% sulfuric acid for 10 min on a steam bath. By dilution of the reaction mixture with 300 mL water, 5.4 g dark yellow solid was obtained. This solid dissolved in 400 mL benzene, leaving only a small quantity of a black residue. The benzene solution contained two isomeric compounds. The lower-melting isomer, which was more abundant, was slightly less soluble in benzene and crystallized in fairly pure form from the dilute solution. When the lower-melting compound no longer crystallized in pure form, the solvent was evaporated, and the residue was taken up in glacial acetic acid. The higher-melting compound crystallized from acetic acid in a fairly pure condition as a flocculent mass. When hard kernels of impure material began to form, the acetic acid was replaced by benzene. The alternation between solvents was continued unti1 there was no residue left on evaporation. After a total of 37 crystallizations, 2.36 g 3-methoxyphenanthrene-9,10-dicarboxylic acid anhydride was obtained as yellow needles, m.p. 221.5–222°C.

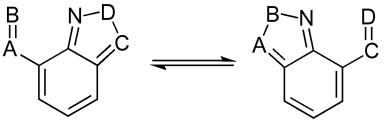
Boulton-Katritzky Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Boulton and Katritzky in 1962.[1] It is a type of monocyclic rearrangement of heterocycles[2] in the presence of either an acid[3] or a base[4] or under photoirradiation[5] and has been widely used in heterocyclic chemistry.[6] Therefore, this reaction is generally known as the Boulton-Katritzky rearrangement.[7] Occasionally, it is also referred to as the Boulton-Katritzky reaction.[8] This reaction has been reported to occur via a unimolecular one-step mechanism[7d] and suggested to be a [1,9]-sigmatropic rearrangement;[7n,9] but a recent computational study suggests a pseudo-pericyclic reaction.[4,7a] In addition, computational studies have shown that the pivotal nitrogen atom is not a mandatory prerequisite for this rearrangement,[4] although most of the reported rearrangements do involve nitrogen atoms, a rearrangement involving sulfur atoms is also known.[10] For example, the balance between substituted nitrobenzofuroxans depends on steric, electronic, conformational, and strain effects.[7i,11] The Boulton-Katritzky rearrangement has been extensively reviewed.[5,10b,12]

B. GENERAL REACTION SCHEME

This reaction is generally described as shown below.[13]

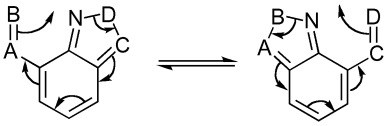


(A, C = N, N^+-O^-, N^+-$\bar{N}$-R, C-R
B, D = O, NR, S)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction has been suggested to be a [1,9]-sigmatropic rearrangement,[7n,9] but has been proved to be a pseudo-pericyclic reaction from computational studies,[4,7a,7c,13] as illustrated here.



D. MODIFICATION

Because this reaction is general in heterocyclic chemistry, many individual reactions can be treated as modifications of the original reaction—for example, the substitution of nitrogen by sulfur atom in the ring system.[10]

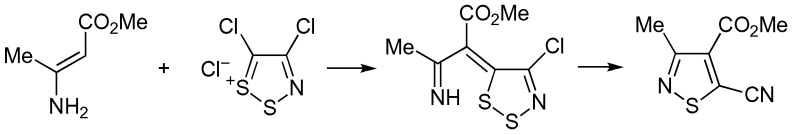
E. APPLICATIONS

This reaction has been widely used in heterocyclic chemistry for preparing certain types of nitrogeneous heterocycles, such as nitrobenzofuroxans, which have been used for the inhibition of nucleic acid and protein biosyntheses.[7c] Some interesting rearrangements are listed in experimental examples.

F. RELATED REACTIONS

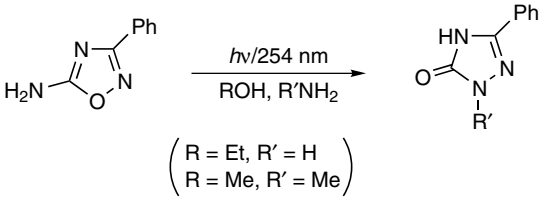
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 10a.

A mixture of 0.34 g methyl 3-aminocrotonate (3 mmol) and 0.63 g 4,5-dichloro-1,2,3-dithiazolium chloride (3 mmol) in 25 mL dichloromethane was stirred at room temperature for 1 h after which 0.49 mL pyridine (6 mmol) was added. The mixture was stirred for a further 30 min. The product was separated by flash chromatography on silica gel, eluting with dichloromethane/light petroleum (1:3) to give 0.43 g methyl 5-cyano-3-methylisothiazole-4-carboxylate, in a yield of 78%. Colorless crystals can form from dichloromethane–light petroleum, m.p. 55 – 56°C.



Reference 5.

To a solution of 0.5 g oxadiazole in 90 mL methanol was added 10 mL ethanolic methylamine (in a large excess). The solution was apportioned into two quartz tubes and then irradiated for 1.5 h. After removal of the solvent, the residue was chromatographed to give 10% of starting material and 60% of 1-methyl-3-phenyl-1,2,4-triazolin-5-one, m.p. 218–219°C. Similarly, irradiation of 0.5 g oxadizaole in the presence of 20 mL methanolic ammonia for 1.5 h, followed by the workup of the residue with minimum of methanol and filtration, afforded 0.25 g 3-phenyl-1,2,4-triazolin-5-one, m.p. 325–330°C. Chromatography of the mother liquor gave additional 0.05 g 3-phenyl-1,2,4-triazolin-5-one and 0.05 g starting material (10%); the total yield for this reaction was 60%.

Other references related to the Boulton-Katritzky rearrangement are collected in the literature.[14]

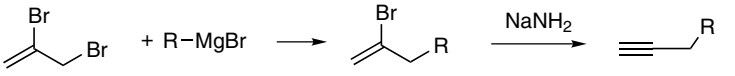
Bourgel Alkyne Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

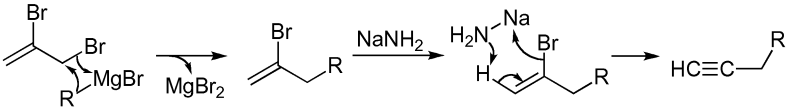
This reaction was first reported by Bourguel in 1925.[1] It is the synthesis of alkynes by the treatment of 2,3-dibromo-1-propene with a Grignard reagent to form a 3-substituted 2-bromo-1-propene, which further reacts with sodium amide. The yields are normally very high.[2] Another advantage of using sodium amide in the last step is that other internal alkynes can isomerize to terminal alkynes.[3]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism for the generation of alkyne is illustrated below.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

N/A

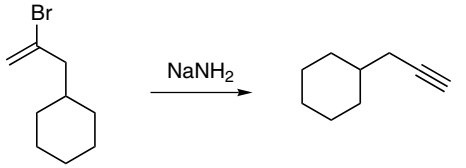
E. APPLICATIONS

This reaction has general application for the preparation of alkynes.

F. RELATED REACTIONS

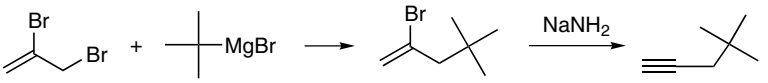
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

A mixture of 120 g sodium amide (3.1 mol) and 200 mL purified mineral oil was ground together in a mortar until the amide was finely pulverized. This suspension was transferred to a 2-L round-bottomed, three-necked flask fitted with a reflux condenser holding a calcium chloride tube, a 500-mL separatory funnel, and an efficient mechanical stirrer through a mercury seal. The mortar and pestle were rinsed with an additional 250 mL of the oil, which was then added to the reaction flask. The mixture was heated in an oil bath maintained at 160–165°C, the stirrer was started, and 203 g cyclohexylbromopropene (1.0 mol) was dropped over 1.5 h. Ammonia was evolved, and was allowed to pass through the condenser and collected in water. After all the cyclohexylbromopropene had been run in, heating was continued for ~2 h; the mixture was cooled, and 500 mL ether was added. This mixture was poured onto 1.5 kg cracked ice in a 5-L flask and then acidified with 280 mL concentrated HCl. The ether layer was separated, dried over calcium chloride, and transferred to a 1-L modified Claisen flask for distillation. The ether was distilled at ordinary pressure, and then the cyclohexylpropyne was distilled under diminished pressure. The product, which was boiled up to 115°C (at 20 mmHg), was collected and fractionated. The cyclohexylpropyne boils at 58–63°C (20 mmHg). The higher-boiling material was chiefly unchanged cyclohexylbromopropene, which could be used again in a subsequent run. The amount of cyclohexylpropyne was 80 g, in a theoretical yield of 66%. The pure compound boils at 61–63°C at 24 mmHg.



Reference 5.

Formation of 4,4-Dimethyl-2-Bromo-1-Pentene

In a 3-L three-necked flask fitted with a mechanical stirrer, a reflux condenser, and a dropping funnel were placed 200 g 2-bromo-allyl bromide (1.0 mol) and 200 mL anhydrous ether. The flask was placed in an ice bath, and through the dropping funnel was added an ether solution of 1.33 mol *tert*-butylmagnesium chloride, which had been prepared and titrated previously. The Grignard reagent was added at such a rate that the ether boiled gently. The addition required 30–45 min. After the addition was complete, the ice bath was removed, and the mixture was gently refluxed on a water bath for ~2 h to ensure completion of the reaction. The mixture was then cooled and the excess Grignard reagent was decomposed by slowly adding a solution of 35 mL concentrated HCl in 350 mL water through the dropping funnel. The ether layer was separated, washed with a saturated sodium bicarbonate, dried over calcium chloride, and distilled. After the ether was removed, the 4,4-dimethyl-2-bromo-1-pentene was collected at 135–138°C. The yields varied from 80 to 110 g (45–62% of the theoretical amount).

Preparation of 4,4-Dimethyl1-Pentyne

Sodium amide (62 g) was ground in a mortar with 104 mL purified high-boiling mineral oil until a fine suspension was obtained. This was transferred to a round-bottomed, three-necked flask fitted with a reflux condenser protected with a calcium chloride tube, a 500-mL dropping funnel, and an efficient mechanical stirrer. An additional 125 mL mineral oil was used in transferring the suspension from the mortar to the reaction flask. The mixture was heated in an oil bath at 160–165°C, the stirrer was started, and 92 g 4,4-dimethyl-2-bromo-1-pentene was added through the dropping funnel. Heating and stirring were continued for 2 h after the addition of the bromo compound was complete. The mixture was then cooled, diluted with 250 mL xylene, and poured onto ~700 g cracked ice to which had been added 140 mL concentrated HCl. The oil layer was separated, washed with a saturated sodium bicarbonate, dried over calcium chloride, and distilled in a modified Claisen flask. In the first fractionation, the material boiling between 50° and 100°C was saved. On redistillation, the product boiling at 73-75°C at ordinary pressures was collected. There was some loss in the preparation due to the heptyne passing off with the ammonia. By using ice water in the condenser and washing the ammonia that escaped with the xylene, the yield was increased to 45%.

Bouveault Aldehyde Synthesis

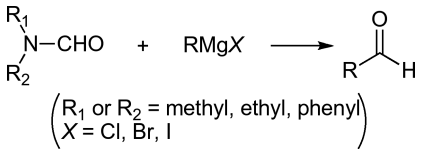
(Bouveault Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bouveault in 1896.[1] It is the reaction for synthesizing aldehydes by the treatment of *N*,*N*-disubstituted formamides with either Grignard reagent or organic lithium reagent in an ether solvent. Thus this reaction is referred to as the Bouveault aldehyde synthesis[2] or Bouveault reaction.[3] It should be pointed out that this reaction works only in certain cases because the reaction is complicated and sometimes produces tertiary amines as the chief products.[4] For example, when *N*,*N*-disubstituted formamide is treated with 3 eq. Grignard reagent, the tertiary amine is the major product; however, when methylformamide or ethylformamide is treated with an equal amount of Grignard reagent, the major product is an aldehyde. Especially when diphenylformamide is used, the only product found is an aldehyde, whereas diethylformamide and piperidylformamide will give more amine than aldehyde when treated with Grignard reagent.[2] It is found that the greater the R group in the Grignard reagent, the more aldehyde is yielded.[2] It is suggested that the workup is easier when a slight excess of Grignard reagent is used in this reaction.[5] This reaction has been improved by either running in a co-solvent of ether-HMPA[6] or irradiating with high-frequency ultrasound in THF or tetahydropyran.[7]

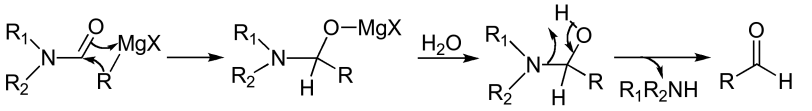
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple mechanism is displayed here.



D. MODIFICATION

This reaction has been modified by using co-solvent of ether-HMPA for a better yield.[6] In addition, when the reaction mixture is irradiated by a high-frequency ultrasound (50 kHz), the yield is increased more than 20% within a shorter reaction time.[7]

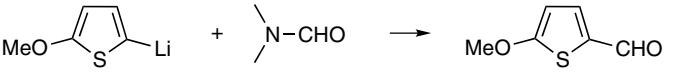
E. APPLICATIONS

This reaction has general application in the preparation of aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Bodroux-Chichibabin Reaction*.

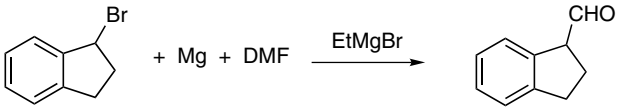
G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

A solution of methoxythienyllithium, prepared from 10 mL 2-methoxythiophene and phenyllithium in 125 mL ether, was added in a slow stream to an ice cold solution of 8 mL dimethylformamide (0.11 mol) in 75 mL ether with efficient stirring. The yellow suspension was left at room temperature overnight, then poured onto ice. The ether layer was washed with water, dried over Na_2SO_4, and evaporated. The residue was distilled to give 9.27 g of 5-methoxy-2-thienaldehyde, in a yield of 67%, b.p. 79–81°C at 0.9 mmHg. A colorless

needle was obtained when the compound was crystallized from ether-hexane at –20°C, m.p. 24–26°C.



Reference 8.

To a stirred solution of 5 mmol ethylmagnesiumbromide in 100mL anhydrous THF containing magnesium turnings was added 5-bromoindane dropwise. The exothermic reaction initiated spontaneously and the remaining 5-bromoindane was added, taking care to keep the reaction from boiling over. When the reaction had returned to room temperature, the flask was cooled to 0°C. A solution of DMF in 75mL anhydrous THF was added over 15 min, causing a mild temperature rise. The flask was removed from the ice bath and allowed to stir for a further 2 h. The color changed from purple-brown to a light pea green during this period. The reaction was then quenched by the addition of ~80 mL 3 M HCl. The biphasic mixture was added to 500 mL water, and the product was extracted with ether (2 × 50 mL). The extracts were combined and washed with 100 mL water, 100 mL sodium bicarbonate solution, and 50 mL brine. Removal of the solvent and distillation under vacuum gave 10.1 g 5-formyl indane as a clear, colorless oil, boiling at 132 – 137°C, in a yield of 69%.

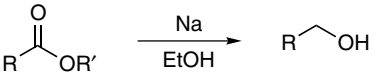
Bouveault-Blanc Reduction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bouveault and Blanc in 1903.[1] It is the reduction of esters into alcohols with sodium in ethanol, in which sodium serves as a single electron-reducing agent and ethanol is the proton donor. Therefore, this reaction is generally known as the Bouveault-Blanc reduction.[2] Occasionally, it is also referred to as the Bouveault-Blanc reaction.[3] Besides ethanol, other alcohols can be applied as proton donors. However, in the absence of proton donor, the reduction of esters with sodium leads to the formation of acyloins (i.e., *Acyloin Condensation*). It should be pointed out that the Bouveault-Blanc reduction under appropriate conditions also effects the ring reduction of aromatic compounds (e.g., *Birch Reduction*). Although this method was widely used in the reduction of esters before lithium aluminum hydride appeared, it also sometimes failed.[4] For example, the reduction of methyl ester of isonoragathic acid gave alcohol in poor yield;[5] the reduction of methyl linoleate by the alcoholic sodium afforded octadecadiene-9,10-ol-1 and octadecadiene-10,12-ol-1.[6] It was found that the reduction of α-benzylamino-β-methoxy ester gave the unexpected de-methoxy amino alcohol.[7] Nevertheless, the Bouveault-Blanc reduction is an inexpensive substitute for lithium aluminum hydride reductions of esters in industrial production and was the "only alternative prior to the development of the metal hydride"[8] as the reducing agent. It has been proved that this reduction occurs via a radical mechanism, in which esters are first reduced to ketyl radicals and further to alcohols.[9] As a result, the ketyl radical can cyclize to form cyclic or spirocyclic molecules if a double bond exists in the appropriate location of the ester.[9] Recently, a reduction of organometallic complex was found to resemble the reduction behavior of the Bouveault-Blanc reduction.[10]

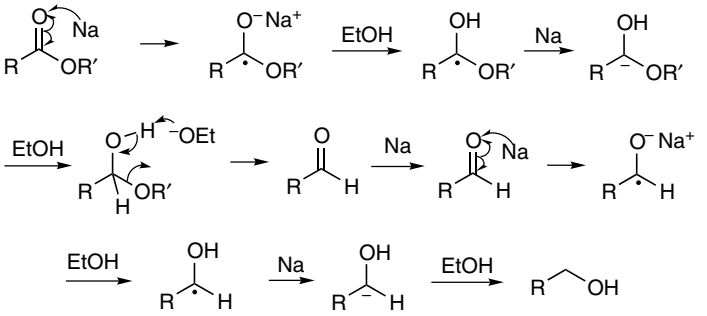
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A radical mechanism is proposed here.



D. MODIFICATION

The conversion of organometallic complex (η^2-formaldehyde complex: $Cp'_2Nb(Cl)(\eta^2\text{-}CH_2O)$) to the diamagnetic hydride complex ($Cp'_2Nb(H)(\eta^2\text{-}CH_2O)$) is an organometallic version of the Bouveault-Blanc reduction. This reaction provides access to reduction products that are not available with the use of hydridic reductants and requires the presence of alcohol to facilitate the second reduction event.[10]

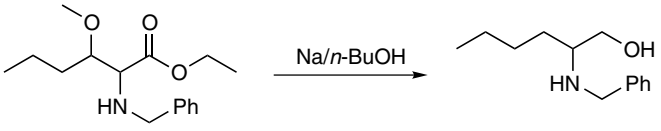
E. APPLICATIONS

This reaction can be generally used to reduce esters, aldehydes, and ketones to the corresponding alcohols. In addition, if a double bond exists on the appropriate location of the ester, a cyclic or spirocyclic alcohol will form.[9]

F. RELATED REACTIONS

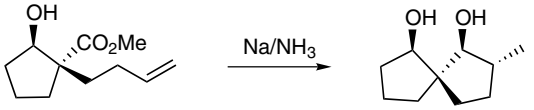
This reaction is related to the *Benkeser Reduction* and *Birch Reduction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

In a three-necked flask equipped with a mechanical stirrer and two reflux condensers was placed a solution of 55 g ethyl α-benzylamino-β-methoxy-*n*-caproate (0.197 mol) in 500 mL anhydrous *n*-butanol. The flask was placed in an oil bath maintained at 140°C. As soon as the contents of the flask had begun to boil, the burner was removed from under the bath and the temperature of the bath was permitted to fall to 115°C. At this point, 55 g sodium buck shot (2.4 mol) was added as rapidly as possible. The butanol was kept boiling vigorously until all of the sodium had dissolved, additional *n*-butanol was added at intervals to keep the sodium butoxide formed in solution. After all of the sodium metal had dissolved, the flask was cooled to 25°C, and 100 g ice was added. The solution was acidified with 6 *N* HCl. The solvents were then removed by distillation in vacuo. When an estimated 50 g sodium chloride had crystallized, the evaporation was interrupted, the sodium chloride was removed, and the distillation was continued until butanol no longer appeared in the distillate. The residue solidified on cooling to 25°C. The resultant paste was made strongly alkaline with 6 *N*NaOH and extracted with three 100-mL portions of ether. The combined ethereal extracts were washed with 25 mL water and dried over anhydrous magnesium sulfate. The solvent was removed, and the residue was distilled to give 25 g of a pale yellow oil, b.p. 130-133°C (0.1 mmHg). The distillate was caused to crystallize, and after two recrystallizations from acetone, the product was obtained as colorless needles, m.p. 46.5 – 47.5°C.



Reference 9.

To 150 mL liquid ammonia at –78°C, were added 0.3 g sodium in small pieces (12.0 mmol, 6.0 eq.). After 15 min, a solution of (±)-(1*RS*,2*SR*)-methyl 1-(but-3-enyl)-2-hydroxycyclopentane-1-carboxylate (2.0 mmol, 1.0 eq.) in 5 mL THF was added dropwise. The reaction mixture was warmed to -33°C and stirred in refluxing ammonia for 10 min. The excess of sodium was then destroyed by the addition of ammonium chloride, and the ammonia was evaporated under a stream of nitrogen (fume hood). Et_2O was added, and the reaction mixture was neutralized by a solution of 10% HCl. The residue was extracted with Et_2O. The organic layers were dried over $MgSO_4$ and filtered; the solvent was removed in vacuo. The crude oil was purified by crystallization in pentane, and 95% (±)-(1*SR*,2*RS*,5*SR*,6*RS*)-2-methyl-spiro[4.4]nonane-1,6-diol was obtained, m.p. 132 – 133°C, R_f = 0.10 (petroleum ether/EtOAc = 50:50).

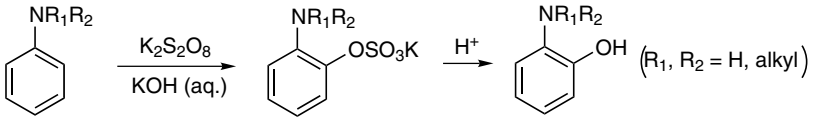
Boyland-Sims Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Boyland and Sims in 1953.[1] It is a two-step process involving the oxidation of aromatic amines by alkaline persulfate to give predominantly the *o*-amino aryl sulfates and subsequent conversion of *o*-amino aryl sulfates into *o*-hydroxy aryl amines through acid promoted hydrolysis. Therefore, this reaction is generally known as the Boyland-Sims oxidation.[2] Occasionally, it is also referred to as the Boyland-Sims peroxydisulfate oxidation.[3] In this reaction, primary, secondary, and tertiary aromatic amines all can be converted to the *o*-sulfate esters under this condition.[4] Even though the yields are generally 10–40%, the starting material is generally recoverable, even in the presence of an excess amount of persulfate.[2e] It is reported that a substantial amount of insoluble, brown amorphous materials appears in some of the oxidations.[1,4c,4d] Except for the oxidation of anthranilic acid,[5] the formation of *ortho* sulfate esters is exclusive for other aromatic amines;[2a,4] when both *ortho* positions of aromatic amines are blocked, the *para* substitution takes place.[1,4b–d] It is suggested that this reaction proceeds via a nucleophilic displacement on peroxide oxygen,[6] or an *ipso* attack followed by the rearrangement to *ortho* sulfate in the case of tertiary amines.[2d,7] The scope of this reaction has been extended to include indoles and aminopyrimidines,[8] and has been extensively reviewed.[9]

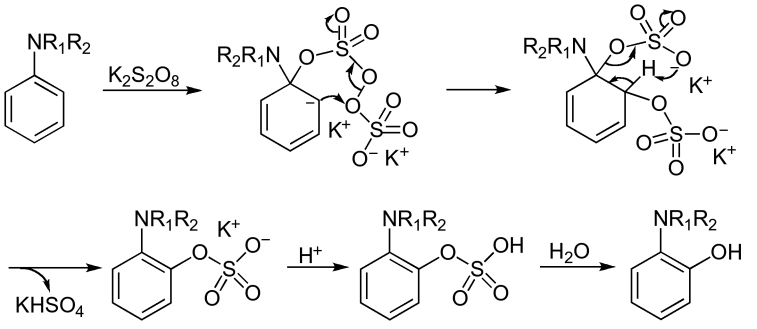
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is proposed that this reaction involves an *ipso* attack by peroxydisulfate followed by the cleavage of the peroxide bond to form the *ortho* sulfate ester, as illustrated below.[2d,7]



D. MODIFICATION

N/A

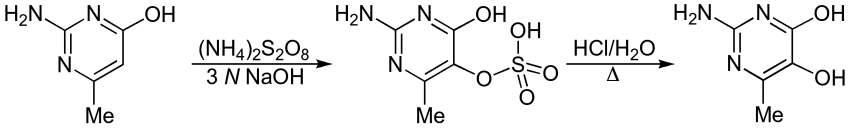
E. APPLICATIONS

This reaction has general application in the preparation of *o*-amino phenols.

F. RELATED REACTIONS

This reaction is related to the *Elbs Persulfate Oxidation*.

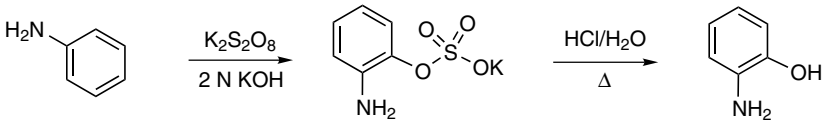
G. CITED EXPERIMENTAL EXAMPLES



Reference 8c.

To a stirred ice cold 3 N NaOH solution (220 mL) containing 12.5 g 2-amino-4-hydroxy-6-methylpyrimidine was added dropwise a solution of 34.2 g ammonium persulfate in 70 mL water over 1 h. After being stirred overnight, the solution was acidified with concentrated HCl, and 14.5 g 2-amino-4-hydroxy-6-methyl-5-pyrimidyl hydrogen sulfate was collected, m.p. 297°C (dec.). Recrystallization from water afforded the product as colorless prismatic needles, m.p. 311°C (dec.).

A solution of 76.0 g 2-amino-4-hydroxy-6-methyl-5-pyrimidyl hydrogen sulfate in 208 mL 5 N HCl was refluxed for 30 min, and then cooled. 2-Amino-4,5-dihydroxy-6-methylpyrimidine hydrochloride was collected and made into a slurry with sodium hydrogen carbonate solution and refiltered. The solid was purified by recrystallization from water to afford 30 g 2-amino-4,5-dihydroxy-6-methyl-5-pyrimidine as colorless prismatic needles, m.p. > 310°C.



Reference 1.

To a mixture of 5 g aniline, 500 mL water and 50 mL 2 N KOH solution at room temperature was added a saturated aqueous solution of 14.5 g potassium persulfate over 8 h with continuous stirring. The mixture was kept overnight, and the precipitate was collected, in an amount of 2.9 g. The filtrate was evaporated to 100 mL under reduced pressure, washed with ether (3 × 100 mL), and made acid to Congo red with 2 N H_2SO_4. The filtered solution was extracted with butanol (6 × 100 mL), and a slight excess of aqueous 2 N KOH was added to the combined organic phase. The butanol extract was evaporated to dryness under reduced pressure. The residue was extracted with hot 95% aqueous ethanol (4 × 100 mL), and the combined extracts were evaporated to 25 mL and kept at 0°C for some hours. *O*-Aminophenyl potassium sulfate (1.9 g, 15.5%) was obtained, separating from 90% ethanol containing a trace of aqueous KOH as a light brown plate.

A mixture of 500 mg *o*-aminophenyl potassium sulfate and 2 mL concentrated HCl was heated at 100°C for 30 min, and then partially neutralized with 2 N KOH to afford 245 mg of *o*-aminophenol as needles, in a yield of 90%, m.p. 173–174°C.

Other references related to the Boyland-Sims oxidation are cited in the literature.[10]

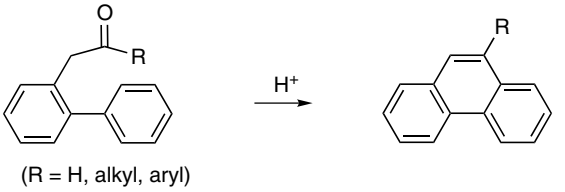
Bradsher Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

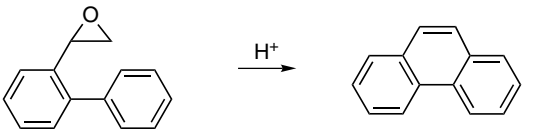
This reaction was first reported by Bradsher in 1939.[1] It is a reaction for synthesizing a variety of polycyclic aromatic compounds, especially the phenanthrene series, by acid catalyzed cyclization. This reaction is sometimes called the Bradsher reaction,[2] Bradsher cyclization,[3] Bradsher-type aromatic cyclodehydration,[4] and *Parham Cyclization*.[5] So far, different types of functional groups linking to an aromatic ring have been found to be applicable for the general purpose of acid-catalyzed cyclization, and these groups include the carbonyl group in ketone[6] or aldehyde,[7] aldehyde derivative (e.g., acetal),[8] nitrile,[9] amino alcohol,[10] carbinol,[11] nitrile (converted to carbonyl by a Grignard reagent),[12] haloether,[13] olefin,[14] olefin oxide,[15] and glycols.[16] On the other hand, this cyclization can also be triggered via photoirradiation,[17] or a strong base.[18] In the cyclization involving a carbonyl group, this reaction is thought to proceed through four steps: (a) protonation of the carbonyl oxygen, (b) attacking of the positive carbon atom (of carbonyl) to the *ortho* position of the aromatic ring, (c) elimination of a proton, and (d) transannular elimination of water.[6e,19] However, no enol form of carbonyl group is found to be involved in this reaction.[20] The general mechanism should involve the arenium ion as an intermediate and final dehydration. This reaction has shown to be of significant value with a wide range of applications.[21] The cyclization of ketones or aldehydes have been reviewed.[22]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

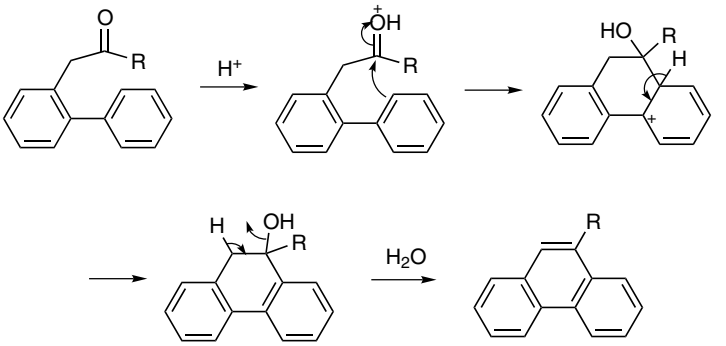


(R = H, alkyl, aryl)



C. PROPOSED MECHANISMS

A general mechanism is displayed below.



D. MODIFICATION

The initial reaction system has been extensively modified and adapted to different functional groups[1,6–16] and methods.[17]

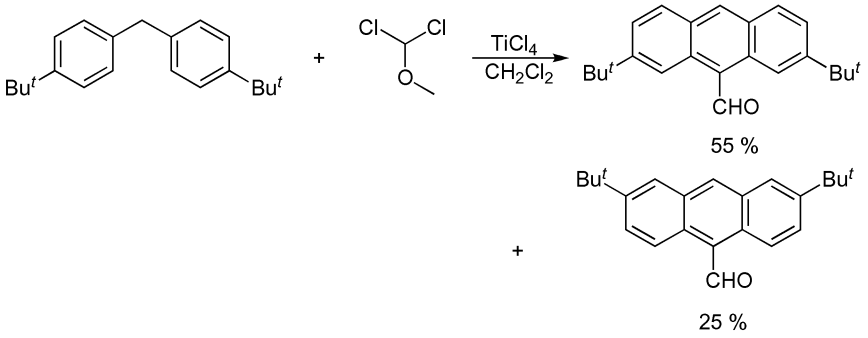
E. APPLICATIONS

This reaction has wide application in the preparation of a variety of polycyclic aromatic compounds[2a,20] and other molecules.[15]

F. RELATED REACTIONS

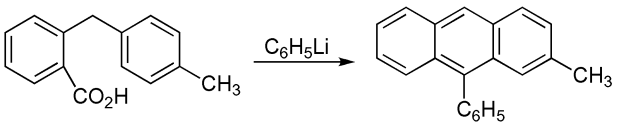
N/A

G. CITED EXPERIMENTAL EXAMPLES



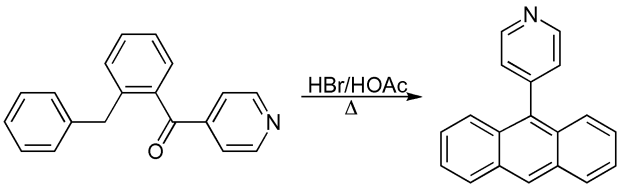
Reference 2a.

To a solution of 1.0 g 4,4′-di-*t*-butylphenylmethane (3.57 mmol) and 1.7 mL dichloromethyl methyl ether (19.2 mmol) in 50 mL CH_2Cl_2 was added a solution of 1.45 mL $TiCl_4$ (13.2 mmol) in 5 mL CH_2Cl_2 at 0°C. The reaction mixture was kept at room temperature for 1 h before the addition of 20 mL cold water; it was extracted with CH_2Cl_2 (30 mL × 3). The extract was washed with water (30 mL × 2), dried over Na_2SO_4, and concentrated. The residue was chromatographed over silica gel (Wako, C-300; 100 g) with hexane/benzene (1:1) as the eluent. The first fraction afforded a pale yellow solid, which was recrystallized from hexane to give 627 mg 2,7-di-*tert*-butyl-9-formylanthracene as pale yellow prisms, in a yield of 55%, m.p. 107–110°C. The second fraction afforded 285 mg 2,7-di-*tert*-butyl-10-formylanthracene as a pale yellow oil, in a yield of 25%.



Reference 18a.

To an ether solution of phenyllithium, a solution containing 5 g *o*-(4-methylbenzy1)benzoic acid in 150 mL dry ether was added gradually with stirring over a period of 30 min. The dark reaction mixture was stirred for 15 h at room temperature, and then ~ 200 mL ice water was added dropwise with cooling and stirring. The ether layer was separated, washed with water until neutral, and finally dried over sodium sulfate. The ether was removed on the steam bath, and the residue was dissolved in 50 mL dry benzene and chromatographed by passing it through a 2.5 × 35 cm column carefully packed with 125 g alumina (Merck and Co.). Benzene was used for the elution of the hydrocarbon fraction. Because no crystalline product was obtained, the chromatographic process was repeated, the benzene solution was concentrated, and the fluorescent residue was crystallized from ethanol to give 2.48 g 2-methyl-9-phenyl-phenanthracene as granular light yellow crystals, in a yield of 42%, m.p. 120°C.



Reference 3.

A mixture of 4.5 g 2-benzyl-phenyl 2-pyridyl ketone (0.017 mol), 25 mL 48% hydrobromic acid, and 50 mL glacial acetic acid was reflux for 52 h. The solution was neutralized with dilute NaOH, and the resultant precipitate was collected, washed with water, and dried; 3.9 g of 9-(2-pyridyl)anthracene was obtained, in a yield of 92%. The product was recrystallized from a mixture of ethanol and methanol to afford light yellow-green crystals, m.p. 163–165°C.

Other references related to the Bradsher cyclization are cited in the literature.[23]

112

Bradsher Cycloaddition

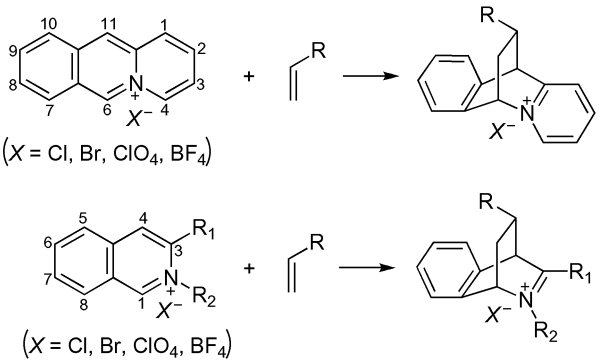
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bradsher in 1958[1] and was extensively explored by Bradsher and co-workers in the following two decades. It is the [4 + 2] cycloaddition of a common dienophile with cationic aromatic azadienes, such as acridizinium and isoquinolinium, to form a tricyclic system containing as many as four chiral centers and an iminium ion.[2] Therefore, this reaction is generally known as the Bradsher cycloaddition.[3] Furthermore, this reaction in some cases is referred to as the cationic polar cycloaddition[4] to distinguish cycloadditions employing cationic or anionic components from those employing dipolar or uncharged components.[5] Moreover, for compounds carrying a positive charge, such as acridizinium and isoquinolinium, the electron requirement of the diene-like part is different from that of traditional *Diels-Alder Cycloaddition*; therefore, the Bradsher cycloaddtion is also known as the inverse-electron-demand *Diels-Alder Reaction*,[2a,6] or simply the ionic *Diels-Alder Cycloaddition*.[7] This reaction has been proved to be exclusively regiospecific and often highly stereospecific.[8] The high stereospecificity and exclusive regiospecificity (*exo* addition) originate from the electrostatic interactions rather than from the secondary orbital interactions or steric effects.[8d,9] On the basis of a relatively large Hammett ρ-value (1.7) in the reaction between substituted acridizinium and styrene,[10] this reaction was initially proposed to occur via a two-step mechanism.[10,11] Lately it is thought to be via a weak charge-transfer complex existing along the reaction pathway,[8c,12] in a concerted but nonsynchronous manner,[8b] although the charge-transfer complex does not always play the role.[12b] It is reported that the substituent at position 9 of the acridizinium ring affects the reaction rate and that electron-withdrawing groups on acridizinium and electron-donating groups on styrene will accelerate the reaction.[13] Likewise, a nitro group at position 5 of the isoquinolinium salt will greatly enhance the reaction rate.[14] The dienophiles participating

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

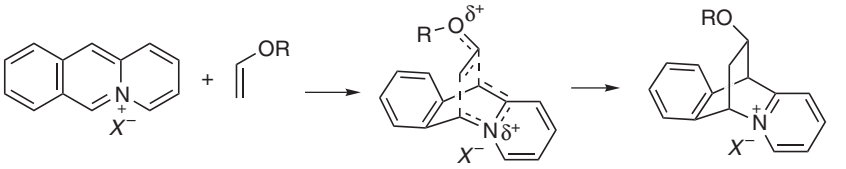
in this cycloaddition include alkenes, dienes, styrenes, benzynes, vinyl ethers, vinyl silyl ethers, enamines, ketene acetals, and ketene aminals.[6] This reaction has been modified for using 3-unsubstituted isoquinolines and has been used to synthesize 1-naphthaldehydes and 1-naphthylamines.[8a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction proceeds via a concerted but nonsynchronous cycloaddition with a weak charge-transfer complex along the reaction pathway.[12] Therefore, a tentative mechanism is outlined here.



D. MODIFICATION

This reaction has been modified to react with 3-unsubstituted isoquinolinium to form 1-naphthaldehydes and 1-naphthylamines.[8a]

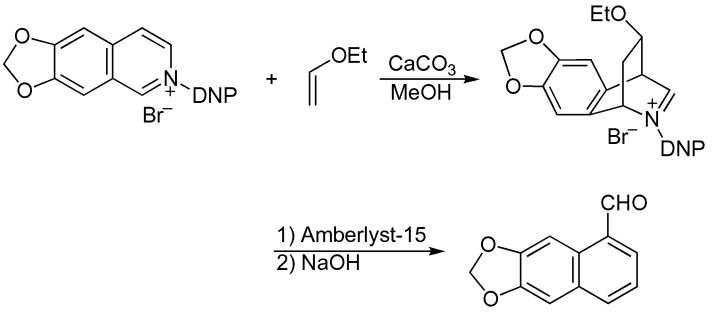
E. APPLICATIONS

This reaction is generally used for the preparation of tricyclic systems containing an iminium ion. In addition, this reaction has been used to synthesize the single diastereoisomer of *cis*-1,2-dideoxy-C-glucosides.[15] Other synthetic applications of this reaction, such as the preparation of angucycline antibiotics, have been published.[16]

F. RELATED REACTIONS

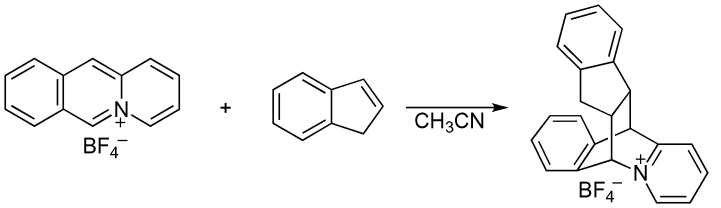
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 8a.

Cycloaddition and conversion to naphthaldehyde are best performed without purification of intermediates. To a stirred suspension of 0.503 g 2-(2,4-dinitrophenyl)-6,7-(methylenedioxy)isoquinolinium bromide (1.2 mmol) and 0.675 g powdered $CaCO_3$ in 4.0 mL MeOH was added 0.864 g ethyl vinyl ether (12 mmol). After 12 h, another portion of vinyl ether (12 mmol) was added, and stirring was continued for an additional 12 h [TLC (SiO_2): 15% MeOH/CH_2C1_2, $R_f \sim 0.78$]. The suspension was filtered over Celite, the filter cake was washed with CH_2C1_2, and the combined filtrate was evaporated. The crude adduct was stirred at 37°C with 300 mg Amberlyst-15 resin in 30 mL THF and 3 mL H_2O for 18 h. After filtration and evaporation, the residue was dissolved immediately in 5 mL THF and transferred to a solution of 0.4 g NaOH in 4 mL H_2O and 10 mL MeOH; it was then heated at reflux for 5 min. The resultant dark red solution was concentrated under reduced pressure, diluted with H_2O, extracted with EtOAc, and chromatographed (SiO_2, 1:l ether/hexanes) to give 230 mg 6,7-(methylenedioxy)naphthaldehyde, in a yield of 96%, m.p. 121°C after recrystallization from ether/hexane, $R_f \sim 0.50$ (SiO_2, ether/hexane = 2:1).



Reference 16.

A mixture of acridizinium tetrafluoroborate and a twofold excess of freshly distilled indene was refluxed for 6 h in acetonitrile with a small quantity of hydroquinone. The adduct was isolated by evaporation of the solvent under reduced pressure and trituration of the residue with ethyl acetate or anhydrous ethyl ether to remove any polymer that might have been formed. After the trituration, a 96% yield of adduct was obtained,

m.p., 172–178°C. Fractional crystallizations from ethanol afforded two compounds with melting points at 142–148°C and 194–195°C, respectively.

Other references related to the Bradsher cycloaddition are cited in the literature.[18]

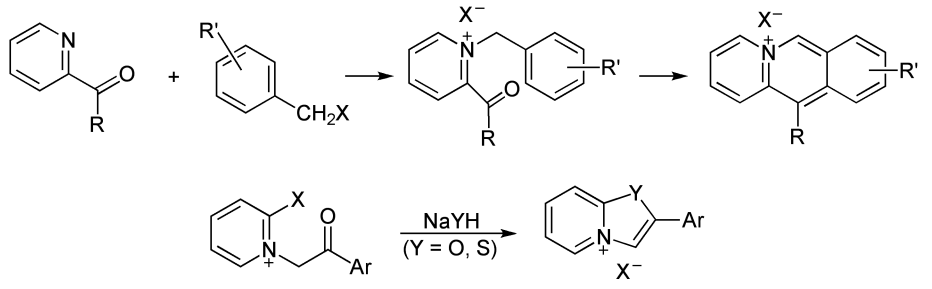
Bradsher Pyridinium Salt Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bradsher in 1955.[1] It is a reaction for synthesizing pyridinium ring-containing heterocycles, such as oxazole[3,2-a] pyridinium,[2] thiooxazole[3,2-a]pyridinium,[3] and acridizinium salt.[1] The resulting quaternary ammonium salts are important versatile intermediates for complex heterocyclic skeletons used in pharmaceutical and materials chemistry. For example, the acridizinium salts are widely used for the *Bradsher Cycloaddition*[4] and the oxazole[3,2-a] pyridinium can undergo ring opening from either the 5-membered ring when reacting with alkali, hydrosulfide, ammonia and primary amines, CH-acids, etc. or the 6-membered ring in reaction with secondary amines.[4] The formation of quinolizinium ion has been reviewed.[5]

B. GENERAL REACTION SCHEME

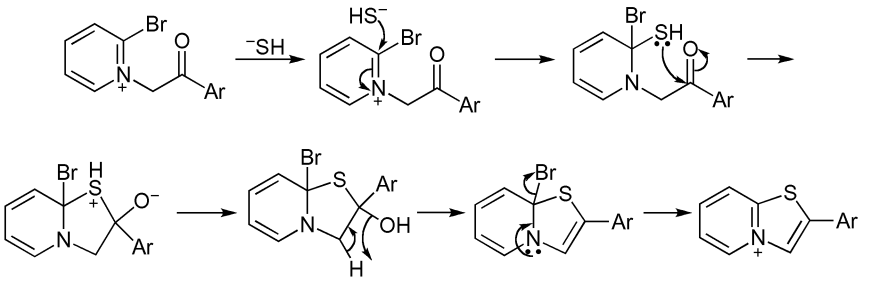


(R = H, alkyl, aryl, X = Cl, Br, I, etc.)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism for forming acridizinium salt is similar to the *Bradsher Cyclization* when a carbonyl group exists in the reaction system. However, the mechanism for forming oxazole[3,2-a] pyridinium is different from what is proposed here.



D. MODIFICATION

The preparation of quinolizinium salt from ketone has been extended to oxime,[6] nitrile,[7] and trimethylsilyl groups;[8] in addition, the quinolizinium salt has also been prepared directly from the reaction between pyridine and aryl halide under heating[9] or photoirradiation.[8,10] The preparation of thiooxazole[3,2-a]pyridinium has also been modified.[11]

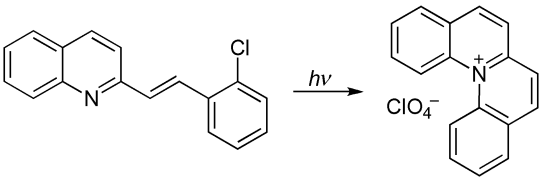
E. APPLICATIONS

The prepared quinolizinium salt or pyridinium salt can be generally used for *Bradsher Cycloaddition*. The formed oxazole[3,2-a]pyridinium or thio-analogues can be cleaved to afford different molecules from either 5-membered or 6-membered rings.[12]

F. RELATED REACTIONS

This reaction is related to the *Bradsher Cyclization*.

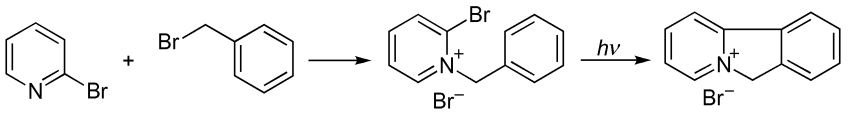
G. CITED EXPERIMENTAL EXAMPLES



Reference 10a.

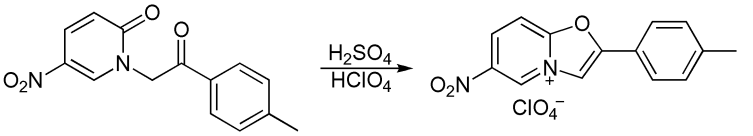
A solution containing 53 mg aryl chloride (0.2 mmol) in 1 L acetonitrile in a Pyrex reaction vessel was irradiated through an aqueous nickel sulfate filter with a 300-W high-pressure mercury lamp. The reaction mixture was magnetically stirred at room temperature,

and the progress of the photocyclization was monitored by UV spectroscopy. After the peak at 405 nm reached a maximum, the solvent was evaporated. The residue was dissolved in water and insoluble solids were filtered off. Saturated aqueous lithium perchlorate was added to the filtrate, and the resulting yellow solid was filtered off, washed with cold water, and recrystallized from ethanol to give 27 mg dibenzo[cf]quinolizinium perchlorate as yellow crystals, in a yield of 41%, m.p. 255–257°C.



Reference 10b.

A mixture of 7.9 g 2-bromopyridine (0.05 mol) and 8.3 g α-bromotoluene (0.05 mol) in 10 mL sulfolane were kept at 45°C for 4 days. The white solid that precipitated during this period was suspended in ether and collected. It was recrystallized from ethanol–ethyl acetate to afford 12.4 g *N*-benzyl-2-bromopyridinium bromide as colorless needles, m.p. 158–160°C. Then 2.0 g *N*-benzyl-2-bromopyridinium bromide in 430 mL water was irradiated with a water-cooled 450-W Hanovia UV source equipped with a Pyrex filter. The ultraviolet spectrum of the samples taken during the irradiation showed a shift from the absorption maximum of 278 nm for the starting material to two absorption maxima at 256 and 313 nm. The change was complete after 5 h. The dark green solution was then evaporated to small volume and treated with 0.5 g decolorizing charcoal. After filtering, the solution was evaporated to dryness; the residue was dissolved in a minimum quantity of ethanol and precipitated by careful addition of ethyl acetate to afford 0.8 g benz[a]indolizinium bromide as the hemihydrate, in a yield of 50%. The product had m.p. 207.5–209.5°C after one recrystalization from absolute ethanol. When 10% hydrobromic acid was used as the solvent in the irradiation, the use of decolorizing charcoal was unnecessary and 1.18 g product was isolated after an irradiation period of 8 h, in a yield of 75%.



Reference 11a.

N-Phenacyl-5-nitro-2-pyridone (10 mmol) was dissolved in 10 mL concentrated sulfuric acid, and the resulting solution was kept for 20–25 h. Then 2.5 mL 71% perchloric acid (25 mmol) was carefully added to the mixture; after being stirred for 10–15 min the solution was poured into 500 mL vigorously stirred diethyl ether. After being decanted the oily residue was mixed again with 500 mL fresh ether; this procedure was repeated until a pure white powder formed. The precipitate was filtered, washed with ether, and dried in vacuum over P_2O_5. The yield of 2-tolyl-6-nitrooxazo[3,2-a]pyridinium perchlorate was between 95% and 98%.

Other references related to the Bradsher pyridinium salt synthesis are cited in the literature.[13]

Brandi-Guarna Reaction
(Brandi Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Brandi *et al.*, probably as early as in 1986.[1] It is a group of reactions for forming tetrahydropyridone derivatives. It involves the initial *1,3-Dipolar Cycloaddition* of nitrones and alkylidenecyclopropanes to yield the mixtures of isoxazolidine regioisomers with spiro-fused cyclopropane rings located on the C-4 and C-5, respectively, and the thermolysis of the 1,3-dipolar cycloadducts via a unique homolytic cleavage of the weak nitrogen-oxygen bond accompanying by the subsequent opening of the adjacent cyclopropane ring and closure of the diradical to afford tetrahydropyridones; *N*-bridgehead bicyclic ketones are ultimately formed from the cyclic nitrones. Therefore, this reaction is generally known as the Brandi-Guarna reaction[2] or simply the Brandi reaction.[3] In addition, the analogous reactions involving the *1,3-Dipolar Cycloaddition* of alkylidenecyclopropanes and nitrile oxides followed by similar ring enlargement to form *aza*-heterocycles are also referred to as the Brandi reaction.[4]

It should be pointed out that the alkylidenecyclopropanes are not stable due to the *exo* double bond and strained cyclopropane ring. The *1,3-Dipolar Cycloaddition* of alkylidenecyclopropanes with nitrones was reported by Akmanova in 1982 (i.e., the reaction between *N*-(phenylaminooxoethylidene) aniline *N*-oxide and 2,2-dimethylmethylenecyclopropane),[5] although the *1,3-Dipolar Cycloaddition* has been known since the 1960s.

For the *1,3-Dipolar Cycloaddition* of nitrones with methylenecyclopropane, generally a mixture of 5-spirocyclopropane isoxazolidines, and 4-spirocyclopropane isoxazolidines forms;[6] however, due to the steric effect, the 5-regioisomer is usually favored, with the ratio of 5-regioisomer to 4-regioisomer ranging from 2:1 to greater than 20:1.[4] In addition, the *1,3-Dipolar Cycloaddition* often proceeds via an *anti-anti* transition state, with each regioisomer arising from an *anti-anti exo* or *anti-anti endo* approach;[4,7] under these circumstances, there is generally no control over *exo-endo* selectivity.[7] It is possible that the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

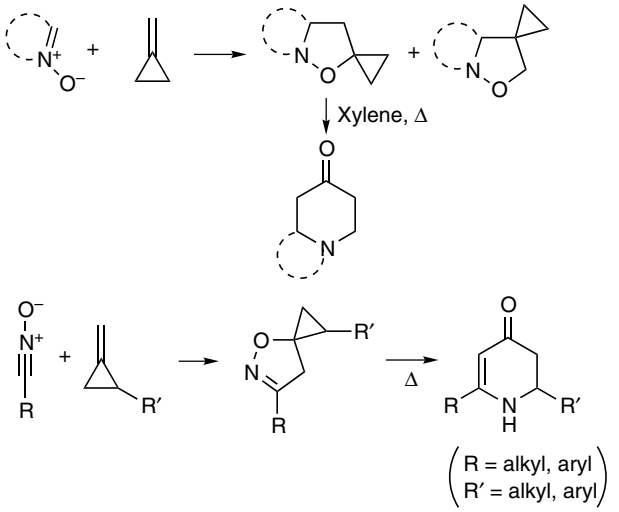
4-spirocyclopropane isoxazolidine regioisomers are formed from cycloreversion of primary cycloadducts and subsequent cycloaddition.[8]

Most of known isoxazolidines are quite stable at temperatures below 100°C and can be purified before thermolysis,[4] except for *N*-aryl-3-phenyl-4-(ethoxycarbonyl)-5-spirocyclopropane isoxazolidines, which quickly decompose at room temperature to give tetrahydropyridones.[9] In theory, flash vacuum thermolysis (FVT) is best for the Brandi reaction, due to the reduced possibility for intermolecular hydrogen exchange; in comparison, the thermal rearrangement in solution often leads to the formation of isomeric enaminones and lower selectivity between epimeric ketones.[7] For example, FVT on aryl-substituted dispiro-[2.0.3.3]oxazadecanes at 600°C exclusively gives azepan-4-ones.[10] However, the best practical conditions for the Brandi reaction is to reflux the cycloadducts in toluene.[7] In addition, it was found that the Brandi reaction may take alternative reaction routes in different solvents—for example, 1,2-tetrahydroisoquinoline fused 4-chloro-4-methoxycarbonyl-5-spirocyclopropane isoxazolidine thermolyzes in xylene at 150°C to afford 56% of α-ketolactam, whereas only 8% of α-ketolactam is obtained in DMSO at same temperature, along with 15% of benzoquinolizinone.[11] In addition, the effect of polar solvent has been observed in the formation of cyclobutane-annelated isoxazolidine when spirocyclopropane isoxazolidine is treated with the mild Lewis acid Al_2O_3 in CH_2Cl_2.[4]

On the other hand, in those spirocyclopropane isoxazolines with more than one cyclopropane ring, after the opening of the spirocyclopropane ring vicinal to the oxygen atom, the rest of the spirocyclopropane ring might also undergo ring enlargement,[12] although this type of reaction has not been extensively exploited yet.[4]

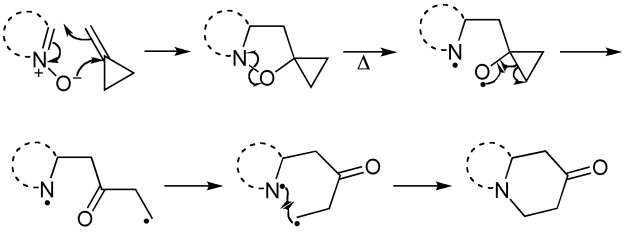
It should be pointed out that nitrile oxides are generally more reactive than corresponding nitrones, which are often prepared *in situ* due to the aptitude of self-dimerization for furoxans.[13] In addition, the cycloaddition of nitrile oxides with alkylidenecyclopropanes of either the electron-donating or the electron-withdrawing group shows a slightly lower regioselectivity than the corresponding nitrones but holds higher regioselectivity with small methylidenecyclopropane than the nitrones.[4]

B. GENERAL REACTION SCHEME

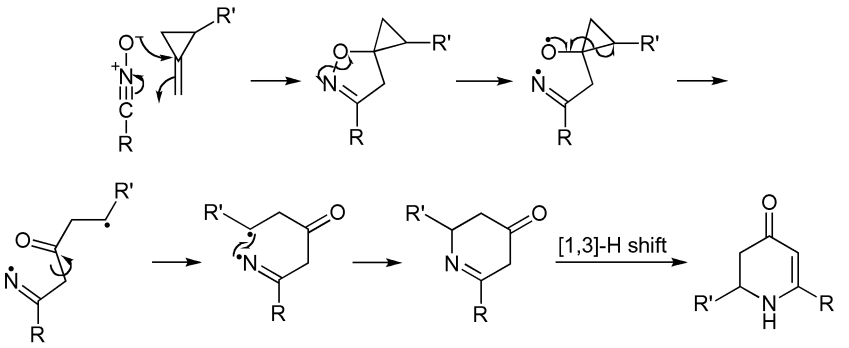


C. PROPOSED MECHANISMS

The reaction combines a *1,3-Dipolar Cycloaddition* and the thermolysis of cycloadducts, and the rearrangement of isoxazolidine intermediate proceeds via the initial cleavage of the weak nitrogen-oxygen bond, followed by the ring opening of the spirocyclopropane ring adjacent to oxygen atom and the final closure of the C,N-diradical.[14] Shown below are two simple mechanisms for the reaction with nitrone (Scheme 1) and with nitrile oxide (Scheme 2).



SCHEME 1. *Brandi-Guarna reaction from nitrones.*



SCHEME 2. *Brandi-Guarna reaction from nitrile oxides.*

D. MODIFICATION

The *1,3-Dipolar Cycloaddition* of nitrones has been extended to bicyclopropylidene, which could be combined with the subsequent thermolysis in a one-pot manner to afford spirocyclopropane-tetrahydropyridones efficiently due to the absence of the regioisomeric problem and higher boiling point (100°C) of bicyclopropylidene.[15] In addition, two intramolecular versions of the Brandi reaction have been developed, with the chain connecting either to nitrone functionality or to the cyclopropane ring.[4] Moreover, the thermolysis has been extended to proceed in the presence of a protic acid, resulting in a ring contraction along with the extrusion of ethylene to give β-lactams from isoxazolidines.[16]

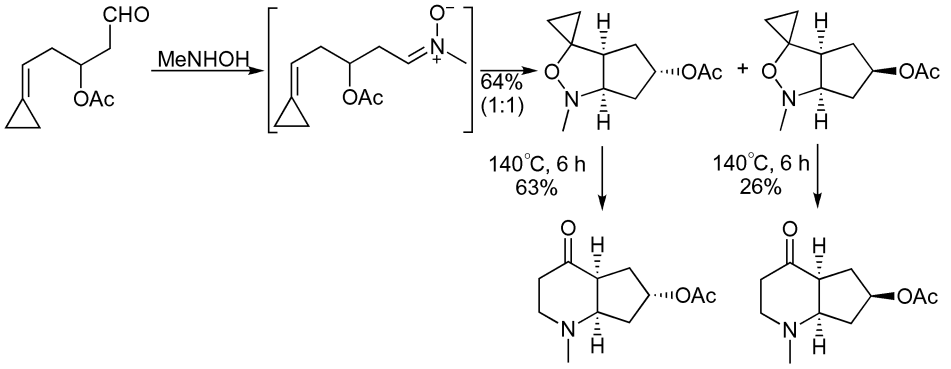
E. APPLICATIONS

This reaction has broad application in the preparation of heterocycles.

F. RELATED REACTIONS

N/A

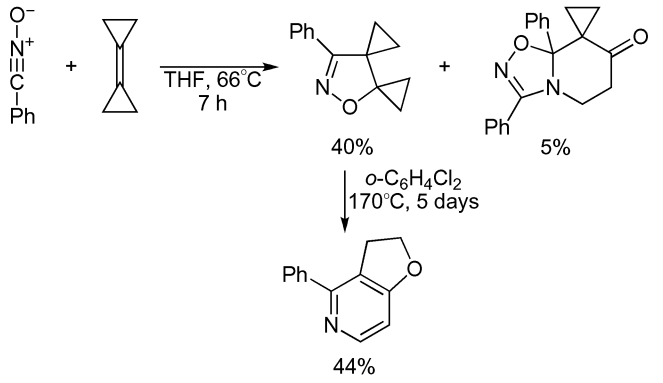
G. CITED EXPERIMENTAL EXAMPLES



Reference 16a.

To a solution of 850 mg 3-(acetyloxy)-5-cyclopropylidenepentanal (4.7 mmol) in 235 mL Et_2O, were added 468 mg *N*-methylhydroxylamine hydrochloride (5.6 mmol) and 453 μL pyridine (5.6 mmol) at room temperature. The resulting solution was stirred at room temperature overnight, and the salt was filtered through a short pad of Celite. Upon removal of the solvent, the residue was purified by silica gel column chromatography using pentane/Et_2O (1:3) as the eluent to afford 379 mg (3a*R*,5*R*,6a*S*)-1,3a,4,5,6,6a-hexahydro-1-methylspiro[3*H*-cyclopent[*c*]isoxazole-3,1-cyclopropan]-5-yl acetate (32%, $R_f = 0.25$) and 379 mg (3a*R*,5*S*,6a*S*)-1,3a,4,5,6,6a-hexahydro-1-methylspiro[3*H*-cyclopent[*c*]isoxazole-3,1-cyclopropan]-5-yl acetate (32%, $R_f = 0.14$).

A solution of 51 mg (3a*R*,5*R*,6a*S*)-1,3a,4,5,6,6a-hexahydro-1-methylspiro[3*H*-cyclopent[*c*]isoxazole-3,1-cyclopropan]-5-yl acetate (0.24 mmol) in 30 mL xylenes was refluxed for 6 h. After being cooled at room temperature, the solution was passed through a short pad of silica gel, eluting first with petroleum ether to remove the high-boiling solvent and then with MeOH to recover the product. After removal of MeOH, the residue was purified by silica gel chromatography using MeOH/Et_2O (1:9) as the eluent to afford 27 mg (4a*R*,6*R*,7a*S*)-6-(acetyloxy)-octahydro-1-methyl-4*H*-cyclopenta[*b*]pyridin-4-ones as a colorless oil (53%) and 5 mg (4a*R*,6*S*,7a*S*)-6-(acetyloxy)-octahydro-1-methyl-4*H*-cyclopenta[*b*]pyridin-4-ones as a colorless oil (10%).



Reference 15.

To a refluxing solution of 240 mg bicyclopropylidene (3.0 mmol) in 3 mL THF containing 277 mg $NaHCO_3$ (3.3 mmol) was added a solution of 513 mg benzohydroximoyl chloride (3.3 mmol) in 10 mL of THF dropwise over a period of 6 h, and the solution was stirred for an additional hour. After being cooled to room temperature, the salts were filtered off over Celite. Removal of the solvent in vacuo gave a crude mixture, which was purified by silica gel flash chromatography using petroleum ether/Et_2O (4:1) to afford 240 mg 9-phenyl-7-oxa-8-azadispiro[2.0.2.3]non-8-ene as a white solid, in a yield of 40%, m.p. 87–89°C (hexane), $R_f = 0.34$. In addition, 44 mg spiro[cyclopropane-1,8′-3,8a-diphenyl-7-oxo-5,6,8,8a-tetrahydro-7H-1,2,4-oxadiazolo[4,5-a]pyridine was also obtained as a pale yellow solid, in a yield of 5%, m.p. 84–86°C, $R_f = 0.39$.

A solution of 19.9 mg 9-phenyl-7-oxa-8-azadispiro[2.0.2.3]non-8-ene (0.1 mmol) in 1 mL *o*-dichlorobenzene in a sealed tube was heated at 170°C for 5 days. After being cooled to room temperature, the mixture was loaded to a short pad of silica gel and initially washed with petroleum ether to remove the *o*-dichlorobenzene followed by petroleum ether/Et_2O (3:8) to afford 8.7 mg 4-phenyl-2,3-dihydrofuro[3,2-c]pyridine as an oil, in a yield of 44%, $R_f = 0.33$.

Breckpot β-Lactam Synthesis

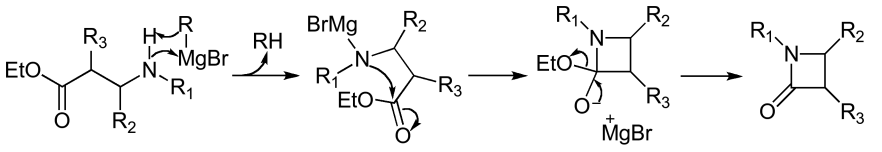
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Breckpot in 1923.[1] It is the synthesis of β-lactam via the cyclization of esters of β-amino acids with Grignard reagent and is known as the Breckpot β-lactam synthesis.[2] This reaction has been modified to form β-lactam by the treatment of β-amino acid with Mukaiyama's reagent,[3] or the β-amino ester with *N*-methyl pyridinium salt.[4]

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

A simple mechanism is displayed here.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

This reaction has been modified by using Mukaiyama's reagent[3] or *N*-methyl pyridinium salt[4] to convert the β-amino acids into β-lactams.

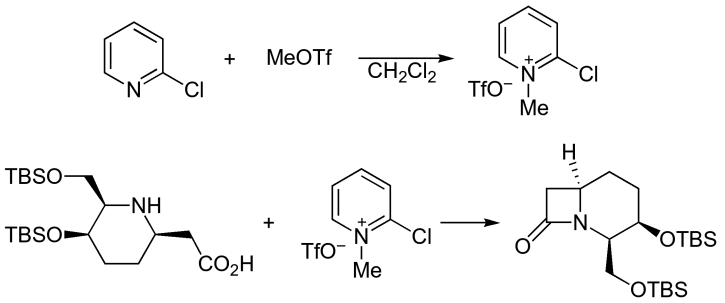
E. APPLICATIONS

This reaction has been used to synthesize β-lactams[5] such as azetidinone.

F. RELATED REACTIONS

Although there is no reaction directly related to the Breckpot β-actam synthesis, other methods of preparing β-lactams include the cycloaddition of imino compound with ketene,[6] the reaction between diazomethane and isocyanate,[7] and the use of bromomalonic ester and primary amine.[8]

G. CITED EXPERIMENTAL EXAMPLES



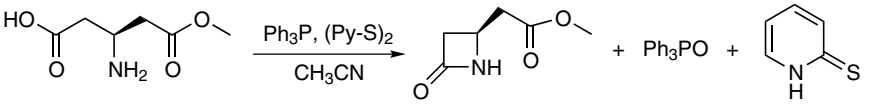
Reference 4.

Preparation of *N*-Methyl-2-Chloropyridinium Triflate

In a resealable tube was added 2.4 g 2-chloropyridine (2.0 mL, 21.1 mmol) and 3.5 mL CH_2Cl_2. The solution was degassed by three freeze–thaw cycles, and the tube was then purged with argon. The colorless solution was cooled to -78°C; and, with stirring, 3.48 g methyl trifluoromethanesulfonate (2.4 mL, 21.2 mmol) was added over 45 s, as a white precipitate began to form. The cooling bath was removed, the tube was closed under argon, and the cloudy mixture was stirred for 16 h. Then 20 mL toluene was added to the white mixture, and after stirring for additional 30 minutes, the precipitate slowly settled to the bottom of the tube, leaving a clear supernatant, which was removed via syringe. An additional 20 mL dry toluene was added to wash the precipitate, and the toluene was removed via syringe, with all operations being done under a stream of argon. The washed precipitate was dried under high vacuum for 48 h at room temperature to afford 5.5 g *N*-methyl-2-chloropyridinium triflate, in a yield of 94%, m.p. 162–164°C.

The Preparation of β-Lactam

To a solution of 1.08 g 2-chloro-1-methylpyridinium triflate (3.90 mmol) in 230 mL dry CH_3CN was added 1.48 g *N*,*N*-diisopropylethylamine (2.0 mL, 11.5 mmol). The colorless solution was heated at 65–70°C while a solution of 0.50 g amino acid (1.2 mmol) in 230 mL dry CH_3CN was slowly added via syringe pump over 4 h. After the addition was complete, the slightly yellow solution was heated at 65–70°C for 15 min more and then was stirred at room temperature for 12 h. The solution was diluted with 150 mL CH_2Cl_2 and concentrated to 5% of its original volume. An additional 200 mL CH_2Cl_2 was added, and the solution was concentrated to 10 mL and partitioned between 500 mL CH_2Cl_2 and 400 mL H_2O. The cloudy aqueous phase was extracted with CH_2Cl_2 (4 × 120 mL). The combined organic layer was washed with 100 mL brine, dried, and evaporated to a dark red oil, which was chromatographed on a 7 cm × 15 cm plug of SiO_2 using EtOAc/hexanes (1:3) as an eluent to give 433 mg (2*R*,3*R*,6*R*)-8-oxo-3-*tert*-butyldimethylsilyloxy-2-*tert*-butyldimethylsilyloxy-methyl-1-azabicyclo-[4.2.0]octane, in a yield of 90%, m.p. 58–59°C.



Reference 3.

At room temperature, to a 0.05 M acetonitrile solution of (S)-3-amino-4-(methoxycarbony1)butyric acid was added 1.2 eq. triphenylphosphine and 2-pyridine disulfide, respectively. Then the reaction mixture was heated to 55–60°C for 12 h with stirring, the homogeneity and a yellow color were seen at the end of the reaction. After removal of the solvent in vacuo, the product was separated from the triphenylphosphine oxide and thione by chromatography on silica gel using 1:l ethermethylene chloride for elution, and the fractions containing the desired β-lactam compound (TLC, $R_f = 0.20, CH_2Cl_2$-Et_2O, 1:1) were further purified by chromatography on silica gel, affording 84% (S)-4-[(methoxycarbony1)-methyl]-2-azetidinone, m.p. 67.5–68°C.

Bredt's Rule

A. GENERAL DESCRIPTION OF THE REACTION

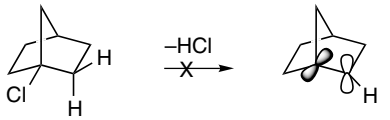
This phenomenon was first reported by Bredt in 1902[1] and was summarized as Bredt's rule in 1924.[2] Bredt's rule[3] is an empirical formulation[4] that may be stated in qualitative terms: a double bond cannot be placed with one terminus at the bridgehead of a bridged ring system,[5] such as in $[x.y.z]$ bicyclic system ($x \geq y \geq z$, $z \neq 0$), unless the rings are large enough to accommodate the double bond without excessive strain (e.g., $S = x + y + z \geq 9$; for a tricyclic system, $S \geq 11$).[6] When the ring is big enough, the so called anti-Bredt' rule[7] molecules can be synthesized and isolated where the double bonds exist at the bridgehead carbon.[8] Bredt's rule is useful mainly as an exclusion criterion during the assignment of structures and the interpretation of reactions of bridged ring compounds.[5] Due to the nature of Bredt's rule, many organic reactions readily operating under regular conditions do not occur easily,[5] such as the dehydrohalogenation of halides, dehydration of alcohols, decarboxylation of β-keto acid (with a bridgehead carboxyl group), enolization of ketones, formation of anhydride, enol lactonization of γ- and δ-keto acids, and formation and reaction of lactams. In a bicyclic system that holds CH bonds perpendicular to the π orbitals, Bredt's rule provides powerful kinetic stabilization.[9]

B. GENERAL REACTION SCHEME

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The excessive strain arising from the torsional forces on the double bond of the bicyclic system will twist the *p* orbital of doubly bonded carbon atoms away from the maximal overlap,[4] thus destabilizing the molecule, as illustrated below.



D. MODIFICATION

N/A

E. APPLICATIONS

Bredt's rule is used in the assignment of structures and interpretation of reactivity for bicyclic systems.

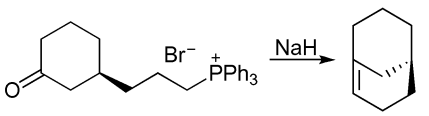
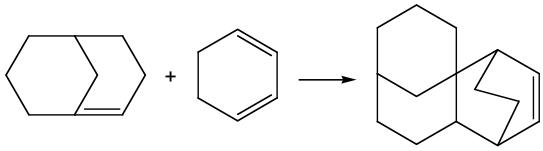
G. CITED EXPERIMENTAL EXAMPLES



Reference 8a.

Sodium hydride (1.05 g, 43.6 mmol), washed oil free with dry pentane, and 5.25 g (+)-3-(3-oxocyclohexyl)propyl-triphenylphosphonium bromide (10.9 mmol), were suspended in 40 mL dry tetraglyme containing 0.96 g 2-methyl-2-butanol under nitrogen. After the mixture was heated to 70°C for 30 min, the temperature was raised gradually to 120°C over 4 h, and the mixture was kept at this temperature for 20 min. Distillation in vacuo (120°C, 10 mmHg) removed low-boiling fractions, and the residue was vacuum distilled

(oil bath temperature 120–125°C, 5 mmHg) into a cold trap. The distillate was diluted with dry pentane, dried over anhydrous Na_2SO_4, and chromatographed on Florisil. Elution with dry pentane yielded 360 mg (-)-(S)-bicyclo[3.3.1]-1(2)-nonene as a colorless oil, in a yield of 27%.



Reference 10.

A solution of 122 mg bicyclo[3.3.1] non-1-ene (1.0 mmol) in 8 mL pentane was combined with a solution of 0.78 g 1,3-cyclohexadiene (9.72 mmol) at room temperature. After 48 h, analysis by TLC indicated 2% of the adduct had formed. The solution was sealed in a Carius tube and heated to 110°C for 42 h. After removal of the solvent, 150 mg of adduct was isolated by preparative TLC, in a yield of 74%.

Brook Rearrangement

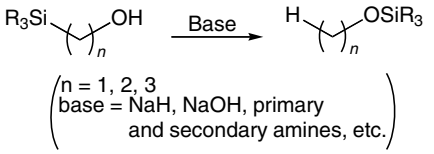
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Brook in 1958.[1] It is a base-catalyzed intramolecular migration of a silyl group from a carbon atom to an oxygen anion via a mechanism involving a hypervalent pentacoordinate silicon species[2] with retention of the configuration at the silicon atom and inversion of the configuration at the carbon atom.[3] Therefore, this transformation is generally known as the Brook rearrangement.[4] However, it falls into two types: the normal Brook rearrangement and the radical Brook rearrangement.[5] When a hydroxyl group presents in silanes, the driving forces for such rearrangement during the treatment with base is the stronger Si–O bond over C–Si bond. Although the most common rearrangement is the [1,2] rearrangement (in α-silyl alcohols), the migration of the silyl group to a longer distance has also been reported, such as the [1,3] (in β-silyl alcohols),[6] [1,4] (in γ-silyl alcohols),[7] and [1,5] Brook rearrangement.[4b] In addition, protiodesilylation of a β-hydroxyalkylsilane under basic conditions in the presence of a proton source is known as a homo-Brook rearrangement.[4h,4r,8] The substituents on carbon that can delocalize a negative charge, such as the vinyl and aryl groups, can accelerate the rearrangement.[2] On the other hand, this rearrangement is reversible in some cases and requires an excess amount of base. The reverse rearrangement is called the *anti*-Brook rearrangement,[3,9] reverse Brook rearrangement,[3,4p,9,10] Wright-West rearrangement,[11] Wittig rearrangement,[2] or *retro*-Brook rearrangement.[7b,7c,12,13] The driving force for the reverse Brook rearrangement presumably is the stronger stability of alkoxide over carbanion.[3] It is found that the Brook rearrangement can even be initiated using a neutral base such as carbene[14] or by the addition of anion to the carbonyl group in ketones or lactones.[15] In addition, the silyl group can migrate not only to the oxygen atom but also to the nitrogen atom; the migration in latter case is called the *aza*-Brook rearrangement.[16] A similar migration tendency is also

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

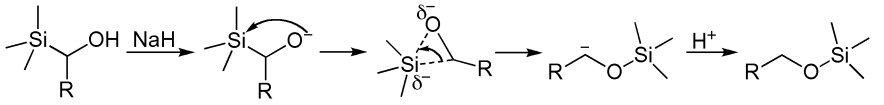
found in tin compounds, and the migration of stannyl group analogues to Brook rearrangement is called *stannyl*-Brook rearrangement,[12a,17] or the *stanna*-Brook rearrangement.[15a,18] Likewise, the similar rearrangement on sulfur-containing compounds is referred to as *thia*-Brook rearrangement.[19] This rearrangement has been applied to the preparation of a variety of building blocks[20] and complex natural products,[21] and has been extensively reviewed.[22]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is illustrated by a simple [1,2]-Brook rearrangement.



D. MODIFICATION

The *aza*-Brook,[16] *stanna*-Brook,[12a,15a,17,18] and *thia*-Brook[19] rearrangements should be considered as modifications of the regular Brook rearrangement.

E. APPLICATIONS

This reaction has been used to synthesize different building blocks[20] and even complex natural products.[21]

General Procedure for the Preparation of *N*-Boc-Oxazolidines

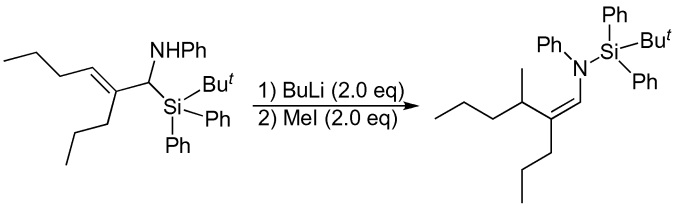
A mixture of *N*-Boc-protected amino acid (5 mmol), 195 mg paraformaldehyde (6.5 mmol), and 43 mg *p*-toluensulfonic acid (0.25 mmol) in 50 mL benzene was refluxed with the aid of a Dean-Stark trap, and heating was continued until no starting material was detected by TLC (1–3 h). The reaction mixture was cooled to room temperature, washed with 5% $KHCO_3$ (2 × 30 mL) and brine (30 mL), dried, and concentrated. The crude product was purified by column chromatography or by crystallization from suitable solvents. For (4*S*)-*N*-*tert*-butyloxycarbonyl-4-methyl-1,3-oxazolidin-5-one from *N*-Boc-analine, 825 mg was obtained by crystallization from CH_2Cl_2-hexane as white needles, in a yield of 82%, m.p. 66–67°C.

General Procedure for the Preparation of α-Amino Acids-Derived Dimers

Method A A 0°C solution of 220 μL diisopropylamine (1.6 mmol) in 5 mL THF was treated with 1.53 mmol *n*-BuLi and stirred for 15 min. Then 360 μL tributyltin hydride (1.35 mmol) was added and stirred for an additional 15 min. The solution of Bu_3SnLi thus prepared was cooled to −78°C and treated with 5 mL THF solution with oxazolidinone (0.9 mmol). The reaction mixture was stirred at −78°C for 3 h, quenched by addition of 2 mL phosphate buffer (pH = 7.0); and then partitioned between the phosphate buffer and EtOAc. The aqueous layer was extracted with 10 mL EtOAc, and the combined organic phase was washed with 15 mL brine, dried, filtered, and concentrated under reduced pressure to give a residue that was purified by column chromatography (SiO_2, EtOAc/Hexane = 1 : 3).

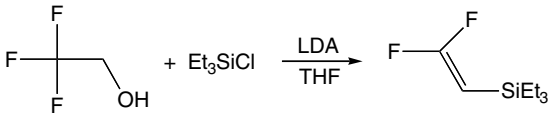
Method B A 0°C solution of 300 μL bis(tributyltin) (0.6 mmol) in 2 mL THF was treated with 0.6 mmol *n*-BuLi and stirred for 15 min. It was then cooled to −78°C, and treated via cannula with a solution of 0.4 mmol oxazolidinone in 4 mL THF. The resulting solution was stirred for 3.5 h. The rest of the procedure was similar to Method A. Using Method A, 115 mg di-*tert*-butyl (4*S*,4′*S*,5*S*,5′*S*) 5,5′-dihydroxy-4,4′-dimethyl-5,5′-bi-1,3-oxazolidine-3,3′-dicarboxylate was obtained from column chromatography (EtOAc/hexane = 1 : 8) as a white foam, in a yield of 63%.

To a stirred solution of 20.3 mg silyl amine (0.0446 mmol) in 1.7 mL THF was added 0.06 mL BuLi solution in hexane (1.59 M, 0.0954 mmol) at −78°C, and the



Reference 16d.

solution was stirred at the same temperature for 30 min. To this solution was added 0.2 mL HMPA and 0.008 mL methyl iodide (0.129 mmol) at −78°C, and the solution was stirred at the same temperature for 30 min. The solution was warmed to 0°C, and saturated NH_4Cl solution was added. The aqueous layer was extracted with ether. The organic layer was washed with brine, dried over Na_2SO_4, and concentrated. The residue was chromatographed (hexane/EtOAc = 30:1) to afford 20.9 mg *N*-*t*-butyldiphenylsilyl-*N*-((*Z*)-3-methyl-2-propyl-2-hexenyl)aniline as a colorless oil, in a yield of 100%.



Reference 23.

To a 500-mL three-necked, round-bottom flask with a septum cap (flame dried) under an inert atmosphere was added 50 mL THF, 5.0 g trifluoroethanol (50 mmol), 50 mmol triethylsilyl chloride, and 5.0 mL HMPA in a dry ice bath. To this mixture was added 175 mmol LDA in 100 mL THF (3.5 eq.), and the solution was stirred at 0°C for 3 h or at −20°C for overnight. Then the solution was injected into 500 mL H_2O in a 1000-mL flask at room temperature via syringe with slow stirring. After being stirred for 10 min, 100 mL 5 M HF solution was added, and the solution was vigorously stirred for 30 min at room temperature to allow the conversion of the silanol to the corresponding fluorosilane, then 50 mL pentane was added, and the organic phase was separated, washed with aqueous $NaHCO_3$, and dried over anhydrous $MgSO_4$. After removal of the drying agent, the solvent was evaporated under gentle vacuum. The residue was subjected to distillation, and 60% of difluoroacetyltriethylsilane was obtained.

Brown Hydroboration

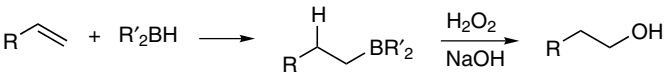
A. GENERAL DESCRIPTION OF THE REACTION

This reaction can be traced back to the doctoral dissertation of Brown at Chicago in 1939, when he first carried out a reaction of diborane with alkenes.[1] However, the real origin and extensive studies of hydroboration started in 1956 when Brown moved to Purdue.[2] It is the addition of boron hydrides to the less-substituted carbon atom of alkenes (*anti*-Markownikoff addition),[3] allenes, dienes, and alkynes to form organoboranes from the less hindered side in a *cis* fashion. The formed organoboranes can then be converted to a variety of compounds,[4] including acetylenes, acids,[5] alcohols,[6] aldehydes,[5] alkanes,[7] alkenes,[8] amines,[5] esters,[5] ketones[5] and nitriles. Therefore, this reaction is generally known as the Brown hydroboration.[9] When one or two hydrogen atoms in hydroborane are substituted by bulk groups, more valuable organoboranes are formed, which show dramatically improved regioselectivity and diastereoselectivity in hydroboration. These organoboranes are the volatile dimmer (B_2H_6), borabicyclo[3.3.1]nonane (9-BBN),[8,10] thexylborane ($ThxBH_2$),[11] thexyldialkylborane, thexylalkylchloroborane (ThBHCl),[12] disiamylborane (Sia_2BH), diisobutylene-2-borane ($DibBH_2$),[13] catecholborane (CBH),[14] pinacolborane (PBH),[15] *trans*-2,5-dimethylborolane,[16] dilongifolyborane (Lgf_2BH), LimBH,[17] diisopinocampheyl-borane (Ipc_2BH),[18] isopinocampheylboranes,[19] etc. As for the electron deficiency on the boron atom, boron hydride can form complex with Lewis bases (the borane carriers[20]) as well. The early studied boron hydride complexes are $BH_3{\cdot}THF$ and $BH_3{\cdot}Me_2S$, which can be added to alkenes rapidly and quantitatively to yield a wide variety of fully or partially substituted organoboranes.[21] The boron hydride complexes with Lewis bases fall into three categories: ether complex, thioether complex, and amine complex. The most common etheral hydroborate is $BH_3{\cdot}THF$;[21] the thioether hydroborates[20,22] include dimethyl

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

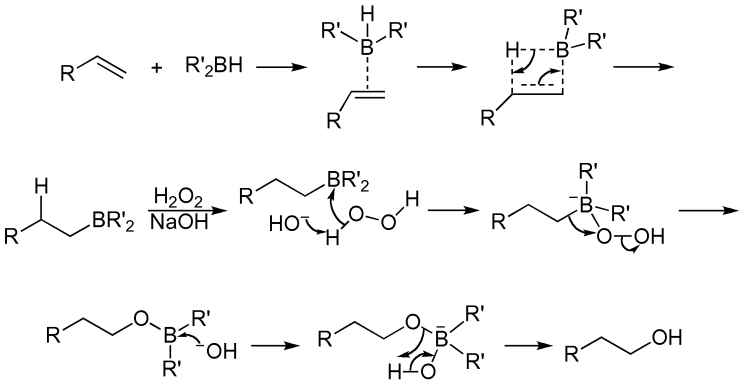
sulfide, 1,4-oxathiane, *tert*-butyl methyl sulfide, isoamyl methyl sulfide, ethyl isoamyl sulfide, *tert*-butyl isoamyl sulfide, diisoamyl sulfide, tetrahydrothiophene, tetrahydrothiopyran, thioanisole, 3-ethylthiotetrahydrofuran, bis(3-tetrahydrofuryl) sulfide, and bis(2-methoxyethyl) sulfide.[20] The amine hydroborates[23] include ethylenediamines[24] and tertiary amines,[25] (such as *N*,*N*-dialkyl-*tert*-alkylamines,[26] *tert*-butyldialkylamine,[27] *N*,*N*-dialkylanilines,[28] *N*-ethyl-*N*-isopropylaniline,[29] *N*,*N*-diisopropyl-*N*-isobutylamine,[30] and pyridine[31]). Different organoboranes might show different chemoselectivities. For example, the hydroborations of fluorinated terminal alkenes give 1- or 2-alcohol by using pinacolborane or catecholborane, respectively.[14] The new improvement in hydroboration is transition-metal promoted hydroboration,[32] which can alter the chemoselectivity and even the reaction mechanism. For instance, when the carbonyl group and alkene coexist in a molecule, catecholborane will add to the carbonyl group first, whereas in the presence of less than 1% of $Rh(PPh_3)_3Cl$, the hydroboration of alkene takes place preferentially.[33] As for the versatile applications of the Brown hydroboration, more than 500 research papers have been published in this area, and hydroboration itself has been extensively reviewed in the literature.[4,32,34]

B. GENERAL REACTION SCHEME

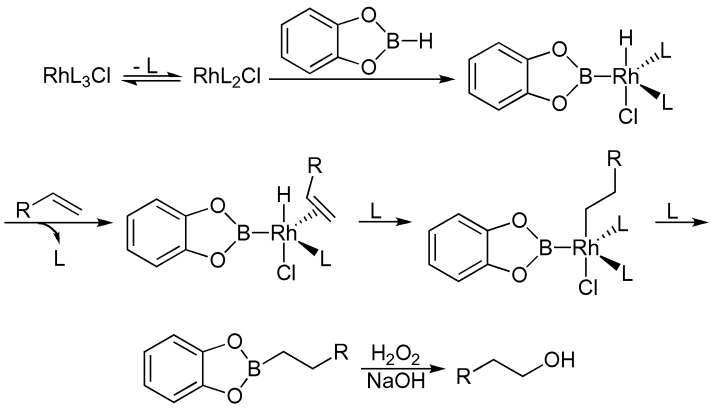


C. PROPOSED MECHANISMS

An exemplary mechanism of the regular hydroboration of alkenes is illustrated in Scheme 1. The mechanism for the transition-metal promoted hydroboration is shown in Scheme 2.[35]



SCHEME 1. *General mechanism of the hydroboration of olefin.*



SCHEME 2. *Mechanism of transition-metal promoted Brown hydroboration.*

D. MODIFICATION

The original hydroborane (B_2H_6) has been modified to different organoboranes for the enantioselective hydroboration, as shown in Figure 1.

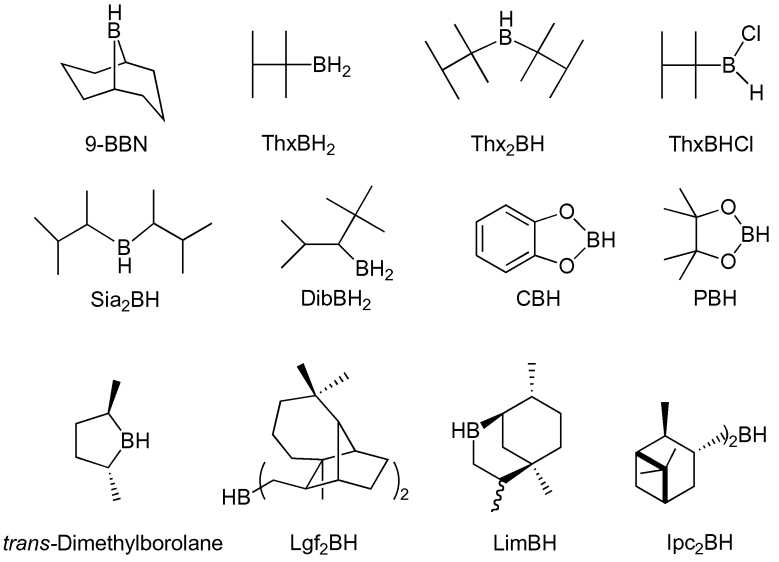


FIGURE 1. *Sterically hindered hydroboranes for enantioselective hydroboration.*

E. APPLICATIONS

The Brown hydroboration has wide applications in functional group transformations, as outlined in Figure 2.[36] The enantiopure boranes from α-pinene and their applications are given in Figure 3.[19]

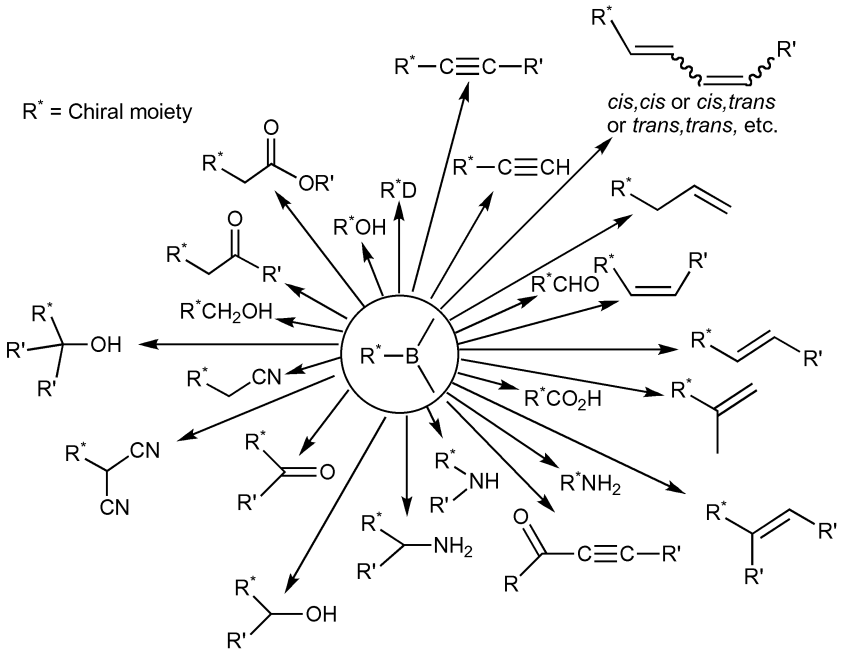

FIGURE 2. *Conversion of alkylborane into different functional groups.*

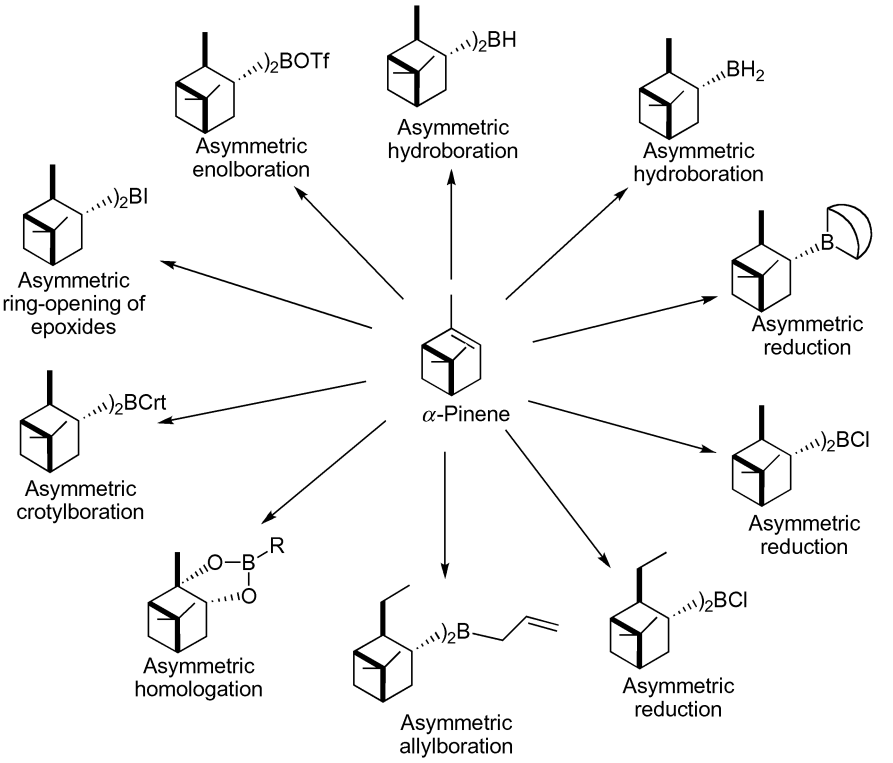

FIGURE 3. *Hydroboranes prepared from α-pinene.*

F. RELATED REACTIONS

This reaction is similar to the *Suzuki Coupling*.

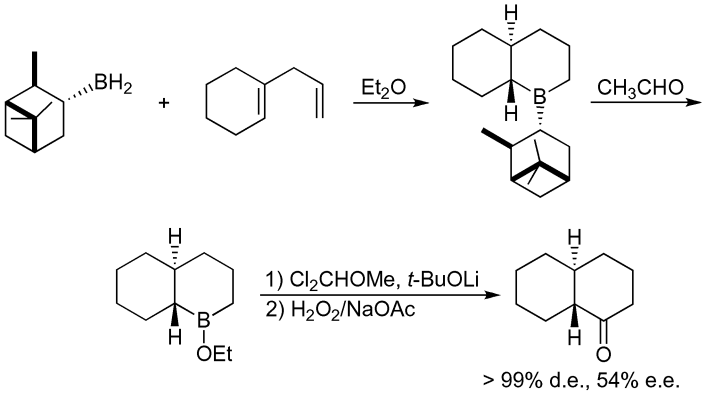
Hydroboration of Representative Olefins using Dioxane-BH_2Cl

Hydroboration of representative olefins—such as 1-octene, 1-decene, styrene, α-methylstyrene, 2-methyl-1-pentene, *cis*-4-methyl-2-pentene, 2-methyl-2-butene, α-pinene, cyclohexene, 3-carene, 1-phenyl-2-methyl-1-propene, 2,3-dimethyl-2-butene and 1,2-dimethylcyclopentene—with dioxane-BH_2Cl was carried out in dioxane and dichloromethane solvents. The procedure followed for all the olefins in both the solvents are same. The procedure followed for 1-decene in dichloromethane is representative.

An oven-dried 50-mL round-bottomed flask provided with a septum inlet and stirring bar was cooled to 0°C under nitrogen. The flask was charged with 5 mmol dioxane-BH_2Cl in 8.7 mL dichloromethane. To this was added 1.4 g 1-decene (10 mmol). The final solution is 0.5 M for BH_2Cl and 1.0 M for 1-decene. The contents were further stirred at room temperature. The course of reaction was followed by ^{11}B NMR and hydride analysis of residual active hydride. Both these studies showed the completion of the reaction after 15 min. The reaction mixture was treated with the slow addition of water followed by the addition of 7.0 mL 3.0 M sodium hydroxide (21 mmol), then 3.0 mL methanol was added followed by the slow addition of 6 mmol hydrogen peroxide. The contents were further stirred at room temperature for 3 h and at 40°C for 1 h to ensure complete oxidation. The organic compound was extracted into diethyl ether. Drying and evaporation of the solvent provided essentially pure 1-decanol in 98% by GC, and 1.48 g 1-decanol was obtained, in a yield of 95%.



Reference 6a

A solution of $IpcBH_2$ (20 mmol) in 28.5 mL Et_2O was cooled to $-10^\circ C$, and HCl in Et_2O (20 mmol) was added to it dropwise with stirring. After the addition was complete, the ^{11}B NMR spectrum indicated the formation of a major amount of $IpcBHCl{\cdot}Et_2O$. In another flask, 2.68 g 1-allyl-1-cyclohexene (22 mmol) was dissolved in 10 mL Et_2O and cooled to $0^\circ C$. To it, preformed $IpcBHCl{\cdot}Et_2O$ solution was added dropwise, and the mixture was allowed to stir at $0^\circ C$ for 1 h. When the ^{11}B NMR spectrum indicated major formation of R_2-BCl (δ 74), the reaction mixture was cooled to $-20^\circ C$ (ice water bath), and 5.0 mL 1.0 M LAH (5 mmol) in Et_2O was added dropwise with stirring. The stirred mixture was allowed to warm to $24^\circ C$ (12 h). The ^{11}B NMR indicated the formation of clean trialkylborane (δ 81). The mixture was cooled to $0^\circ C$; and 2.5 mL acetaldehyde was added and stirred for 1 h, when the ^{11}B NMR spectrum indicated the formation of borinate ester (δ 52). The volatiles were removed by applying reduced pressure (10 mmHg, 30 min), the borinate ester was dissolved in 20 mL Et_2O, and the solution was cooled to $0^\circ C$. To it 2.7 mL α,α-dichloromethyl methyl ether (30 mmol) was added, followed by the dropwise addition of lithium *tert*-butoxide in *n*-hexanes (40 mmol, generated from *tert*-butyl alcohol and *n*-butyllithium) with stirring. The mixture was stirred at $0^\circ C$ for 1 h and then at $24^\circ C$ for 4 h. Water (10 mL) was added, and then the mixture was washed with water to pH = 7. Solvent was removed and 20 mL THF was added followed by the addition of 8.0 mL 3.0 M NaOAc and 8.0 mL 30% H_2O_2; the mixture was stirred at $24^\circ C$ for 1 h and then at 40–$50^\circ C$ for 1 h. The mixture was diluted with 40 mL Et_2O and then washed with water (4×10 mL), 10 mL brine, and dried over $MgSO_4$. The solvent was removed, and the residue was distilled at 64–$66^\circ C$ (0.5 mmHg) to afford 2.42 g the desired ketone in a yield of 76%, m.p., $38^\circ C$.

Other references related to the Brown hydroboration are cited in the literature.[37] Note that more than 500 references to this procedure can be found.

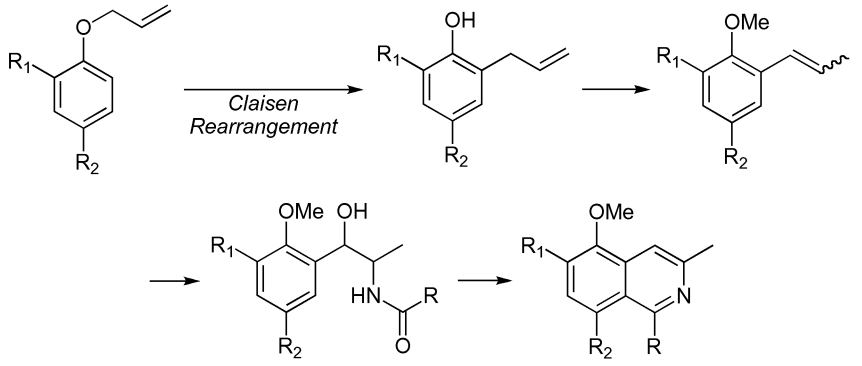
Bruckner Isoquinoline Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction may be traced back to 1935 when Bruckner reported the structure of 1,3-dimethyl-6,7-methylenedioxyisoquinoline.[1] The reaction is a unique method for synthesizing isoquinolines from allyl phenyl ether via the process of a *Claisen Rearrangement*, double-bond migration, amination, and cyclization.[2]

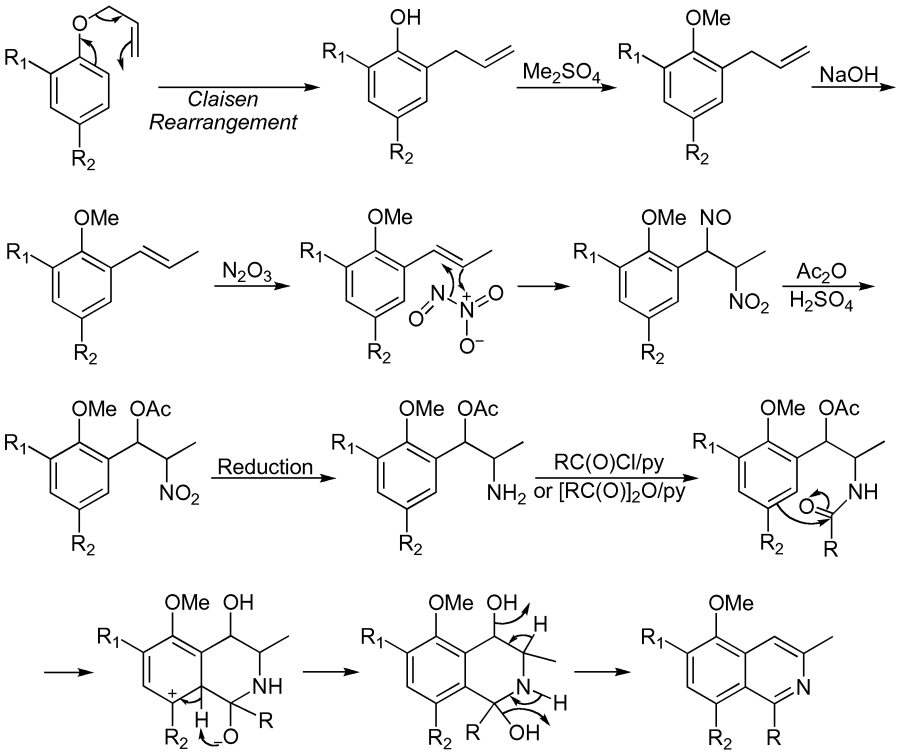
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is the reaction mechanism proposed by Govindachari and Pai.[2]



D. MODIFICATION

This reaction has been modified by using either phenyl oxazoline[3] or substituted benzaldehyde and nitroethane[4] as the starting materials for preparing isoquinoline.

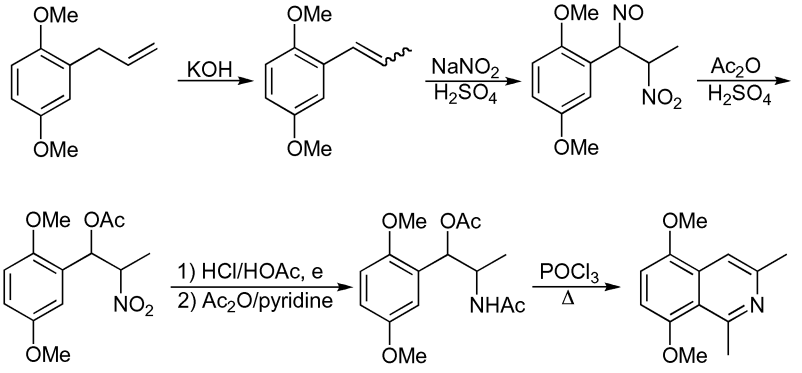
E. APPLICATIONS

This reaction can be used to synthesize the substituted isoquinolines.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

Preparation of 2,5-Dimethoxypropenylbenzene

2,5-Dimethoxyallylbenzene was treated with a solution of potassium hydroxide in ethylene glycol at 170–175°C for 3 h to give 85% 2,5-dimethoxypropenylbenzene, b.p. 126°C (13 mmHg).

Preparation of 2,5-Dimethoxypropenylbenzene Pseudonitrosite

A solution of 1 g freshly distilled 2,5-dimethoxypropenylbenzene in 10 mL ether was treated with a solution of 21 g sodium nitrite in 8 mL water. Then 10 mL 4 N H_2SO_4 was added dropwise over 20 min. The solution turned green and then yellow, and a white crystalline solid appeared. It was left in an ice chest overnight, and the precipitate was filtered, washed with ether, then water, and dried in air. A total of 20 such experiments run simultaneously yielded 18 g 2,5-dimethoxypropenylbezneen pseudonitrosite, m.p. 130°C (dec.).

Formation of α-(2,5-Dirnethoxyphenyl)-β-Nitropropanol Acetate

A suspension of 7 g finely powdered pseudonitrosite in 20 mL acetic anhydride was cooled in ice and treated gradually, with good stirring, with 2 mL acetic anhydride containing a drop of concentrated sulfuric acid. The pseudonitrosite dissolved with evolution of nitrous fumes. After 2 h, the solution was poured onto ice water, the acetic anhydride was decomposed, and the emulsion was extracted with ether. The ether extract was dried and the ether extract was removed, yielding 7 g of a colorless syrupy oil, which could not be induced to crystallize. Attempts at purification by distillation in vacuo led to extensive decomposition.

Preparation of α-(2,5-Dimethoxyphenyl)-β-Acetylaminopropanol

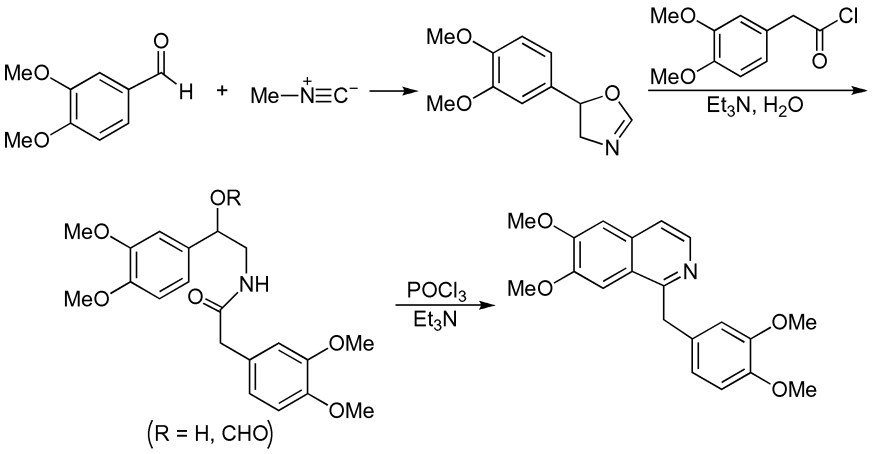
A solution of 7 g nitropropanol acetate in 100 mL alcohol, 50 mL glacial acetic acid, and 3 mL concentrated hydrochloric acid was reduced at a mercury cathode with the temperature kept below 60°C. At the end of the reduction, the solution was made neutral to Congo Red by the addition of sufficient sodium acetate and evaporated to dryness in vacuo at 50°C.

The residue was dissolved in 50 mL water and saturated with sodium bicarbonate. On standing in the ice chest overnight, the acetylamino compound separated. It was filtered, washed with a little water, and dried. Recrystallization from alcohol yielded 3.1 g α-(2,5-dimethoxyphenyl)-β-acetylaminopropanol, m.p. 156°C.

Acetylation of α-(2,5-dimethoxyphenyl)-β-acetylaminopropanol with acetic anhydride in pyridine at room temperature yielded α-(2,5-dimethoxyphenyl)-α-acetoxy-β-acetylaminopropane, melting at 98–100°C after recrystallization from benzene.

Formation of 1,3-Dimethyl-6,8-Dimethoxyisoquinoline

A solution of 1 g acetylamino compound in 10 mL dry toluene was treated with 3 mL phosphorus oxychloride and refluxed for 75 min, with exclusion of moisture. The solution was then poured into ice water, and the excess phosphorus oxychloride was decomposed by gentle warming on a water bath. A fluorescent orange-yellow solution was obtained, which was cooled strongly in ice and basified with sodium hydroxide solution. The isoquinoline was extracted with ether, and the ether extract was dried over potassium carbonate. Removal of the ether yielded 0.75 g of a thick oil, which was dissolved in dry benzene and passed through a column of 30 g alumina. On washing the column with benzene, a yellow zone moved rapidly into the filtrate. This fraction of the eluate on removal of benzene yielded 0.65 g of a pale yellow oil, which solidified on rubbing. Recrystallization from petroleum ether yielded pale yellow silky needles, melting at 70°C.



Reference 3.

n-BuLi (74.5 mmol) was added dropwise over 20 min to a -78°C solution of 75 mmol methyl isocyanidee in 200 mL anhydrous THF. After 40 min, 73.5 mmol veratraldehyde in 120 mL THF was slowly added to the yellow suspension of α-lithiomethyl isocyanide at such a rate that the temperature did not exceed −60°C. Stirring was continued for 30 min, then 2 mL MeOH was added, and the whole mixture was allowed to warm to room temperature. Extraction and crystallization in Et_2O yielded 13.0 g 5-(3,4-dimethoxyphenyl)-2-oxazoline in a yield of 85%, m.p. 49–50°C.

3,4-Dimethoxyphenyl acetyl chloride (414 mg, 1.93 mmol) in 18 mL dry CH_2Cl_2 was added dropwise to a solution of 400 mg 5-(3,4-dimethoxyphenyl)-2-oxazoline (1.93 mmol) in 20 mL dry CH_2Cl_2. After 30 min, 35 mg water (1 eq.) and 195 mg triethylamine (1 eq.) in

1.5 mL dry THF were added slowly. The hydrolysis products were extracted after 30 min, washed with brine, and evaporated. NMR analysis showed a 2.2:1 mixture of alcohol and ester that could be isolated via column chromatography. The ester melted at 166–167°C, and the alcohol melted at 126°C. The formate was hydrolyzed with $NaHCO_3$ in aqueous THF for 3 h.

$POCl_3$ (580 mg) was added dropwise to a refluxing solution of the above crude product of formate and alcohol in CH_3CN. After 1 h, the mixture was cooled, poured into ice water, washed with Et_2O, basified with 2 N NH_4OH, and extracted with EtOAc. Chromatography gave 371 mg papaverine, in a yield of 57% from oxazoline.

Other references related to the Bruckner isoquinoline synthesis are cited in the literature.[5]

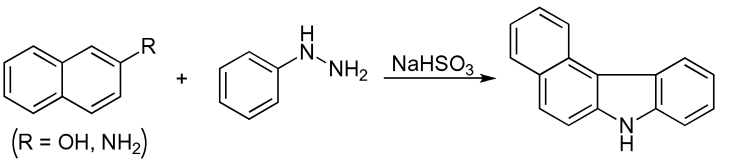
Bucherer Carbazole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bucherer in 1906.[1] It is the synthesis of carbazoles from aryl hydrazines, sodium bisulfite, and 1- or 2-naphthols (or 1- or 2-naphthylamines)[2] and is generally known as the Bucherer carbazole synthesis[3] or Bucherer reaction.[4] In addition, the reaction between 2-aminonaphthalene-1-sulfonic acid and phenylhydrazine also gives carbazole,[5] indicating that sulfonation of naphthylamine might be the early step in the reaction pathway. This reaction has been most commonly used hitherto for the preparation of dibenzocarboles.[6]

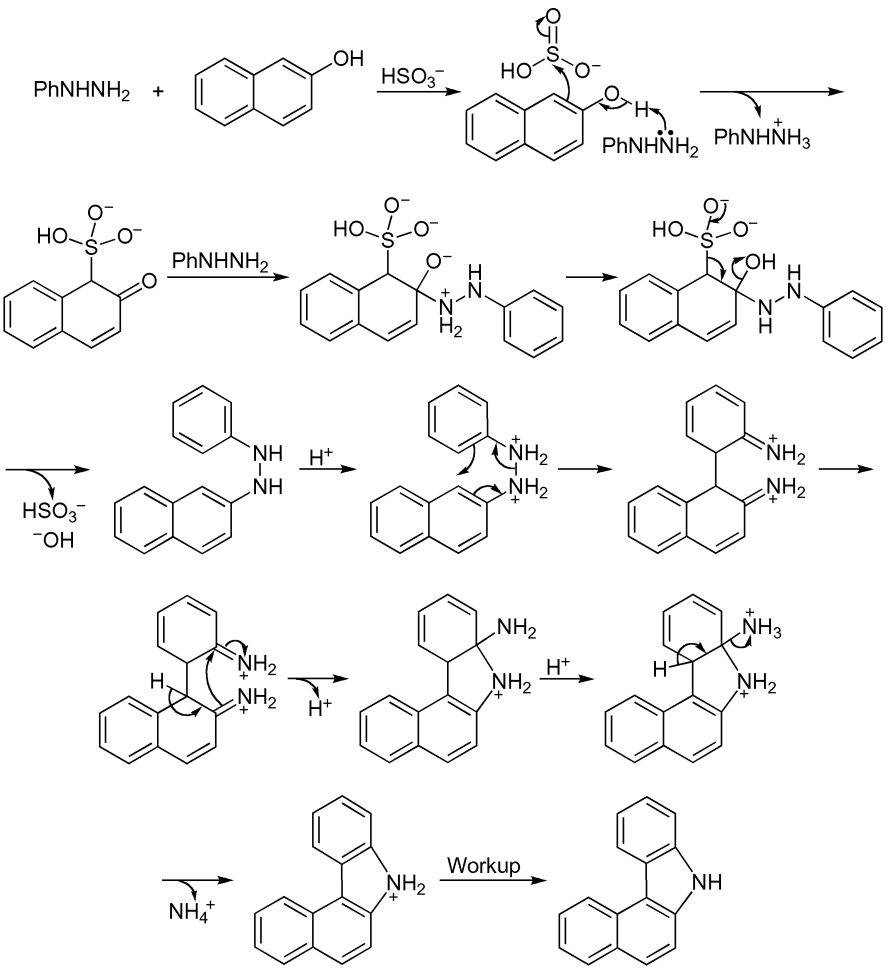
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is proposed for this reaction.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified by using aryl hydrazine and tetralone in the presence of HCl to form carbazole.[6]

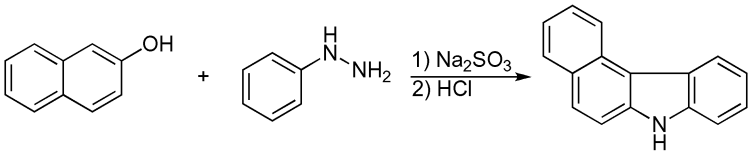
E. APPLICATIONS

This reaction is useful for the preparation of fused carbazole derivatives.

F. RELATED REACTIONS

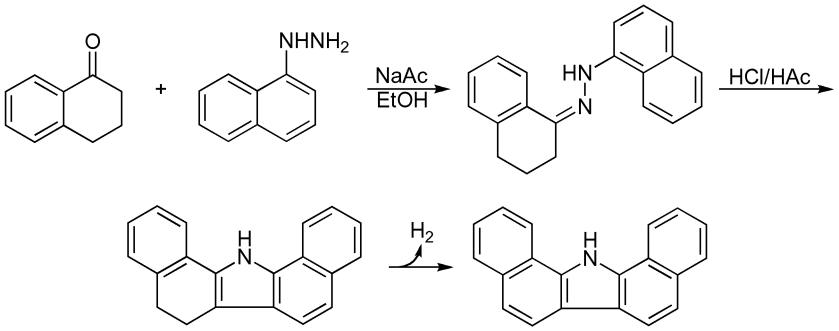
This reaction is related to the *Borsche-Drechsel Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

2-Naphthol (14.4 g, 0.10 mol) and 10.8 g phenylhydrazine (0.10 mol) were refluxed in 250 mL 36% sodium sulfite solution for 17 h. The reaction mixture was then treated with 200 mL concentrated hydrochloric acid under reflux for 2.5 h. The oily layer that separated was isolated by decanting the upper aqueous layer and was triturated with ether to give a red-brown solid. The solid was extracted with sodium hydroxide solution and filtered. The remaining yellow solid was dried and sublimed (100°C), and the sublimate was recrystallized from aqueous methanol to give 2.5 g 3,4-benzocarbazole as white needles (11.5 mmol), in a yield of 11.5%, m.p. 136–137°C.



Reference 6.

A mixture of 2.6 g α-tetralone, 4.0 g α-naphthylhydrazine hydrochloride, and 3.0 g sodium acetate was refluxed with 50 mL ethanol for 2 h. After cooling, an excess of water was added; the precipitate of the crude naphthylhydrazone was collected by suction, washed with water, and dissolved in 20 mL of the cyclization reagent (acetic acid and hydrogen chloride). After 5 min of heating on a water bath, the mixture was poured into water and the precipitate was washed thoroughly with water, dried, and crystallized from the mixture of benzene and ligroin to afford 2.5 g 3,4-dihydro-1,2,7,8-dibenzocarbazole, m.p., 178°C.

A mixture of 1.2 g 3,4-dihydro-1,2,7,8-dibenzocarbazole, 1.7 g chloranil, and 30 mL dry xylene was refluxed for 2 h. After cooling, the tetrachlorohydroquinone was filtered off by suction and washed with some xylene; the filtrate was shaken with a 10% aqueous solution of sodium hydroxide and then with water, and dried over calcium chloride. After the evaporation of xylene in a vacuum, the residue obtained was recrystallized twice from benzene, giving 1.0 g 1,2,7,8-dibenzocarbazole as pale yellowish needles, m.p. 212°C.

Bucherer Reaction

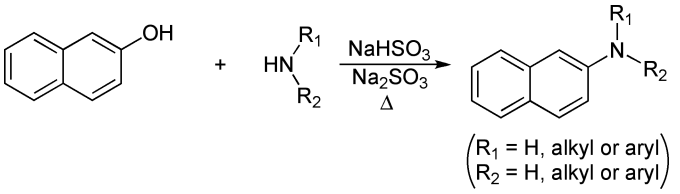
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bucherer in 1904.[1] It is a reaction for synthesizing β-naphthylamine from β-naphthol and aqueous ammonium sulfite or bisulfite via the formation of tetralone-sulfonic and tetralone-iminosulfonic acids and is generally known as the Bucherer reaction.[2] Although α-naphthylamine can also be prepared in a similar fashion, the corresponding reaction is much more difficult because of the steric interaction with *peri*-position.[3] It is know that the key step of this reaction is the ketonization of naphthol.[4] When 1,7-dihydroxynaphthalene is treated with a large excess of ammonia at 250°C, both aminonaphthol and diaminonaphthalene will form, but the major product is still the aminonaphthol;[5] however, the addition of sodium hydroxide into the solution will decrease the amount of diaminonaphthalene.[3] Only one hydroxyl group of binaphthol will be converted into an amino group to form NOBIN.[6] When primary or secondary amine is used in this reaction, *N*-substituted β-naphthylamine will form,[3,7] and α-amino acid can be readily linked to a naphthalene ring by the Bucherer reaction as well.[8] In contrast to this reaction, naphthol can also be converted into naphthylamine in a reaction with a complex of ammonia and Lewis acid, such as $CaCl_2$[9] or $ZnCl_2$.[10]

B. GENERAL REACTION SCHEME

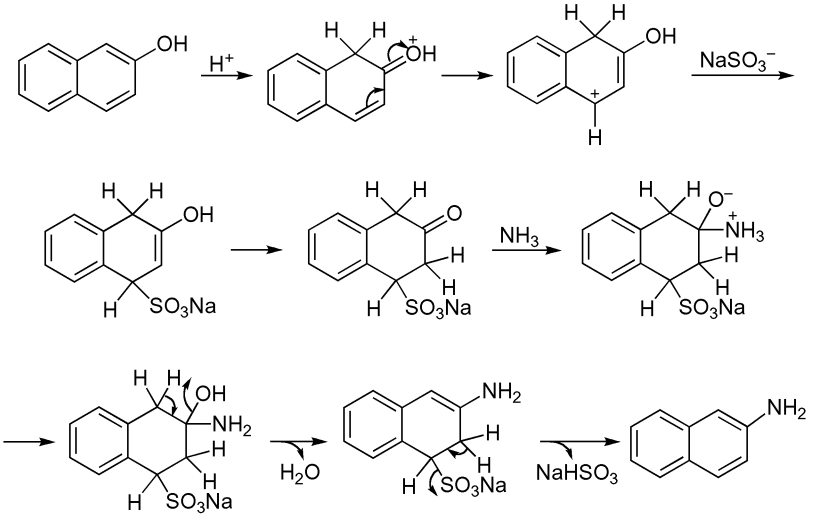
The general reaction is illustrated, including the reaction with ammonia and primary and secondary amines.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



C. PROPOSED MECHANISMS

Amination of β-naphthol with ammonia in the presence of sodium sulfite is shown below.



D. MODIFICATION

The amination of naphthalene using primary or secondary amines is one type of modification,[3,7] and the treatment of naphthol with a complex of Lewis acid and ammonia is another modification.[10] The latter was reported before the Bucherer reaction was published.

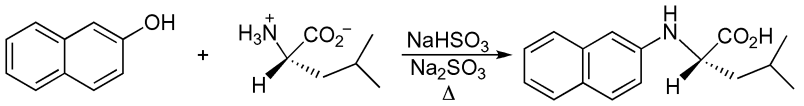
E. APPLICATIONS

This reaction is generally used to convert naphthols into naphthylamines.

F. RELATED REACTIONS

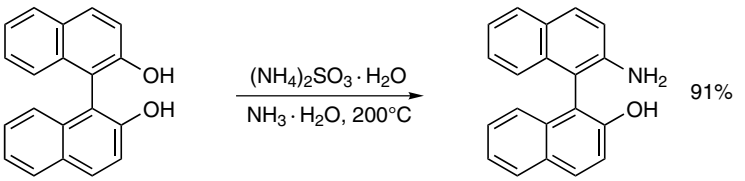
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A mixture of 10 g L-leucine (76 mmol), 11 g β-naphthol (76 mmol), and 9.6 g anhydrous Na_2SO_3 (76 mmol) was placed in a pressure vessel equipped with a magnetic stirring bar. Saturated $NaHSO_3$ solution (60 mL) was added; the bottle was sealed and heated slowly to 115°C while being stirred. After 1 day, two homogeneous layers formed. Heating and stirring were continued for 3 additional days. After being cooled, the bottle was emptied into a 1000-mL beaker and rinsed alternately with 5% $NaHCO_3$ and acetone. The combined washes and reaction mixture were diluted to 500 mL with water, the pH was adjusted to 8.5–9.0 with saturated Na_2CO_3 solution, and the mixture was washed twice with 60-mL portions of dichloromethane. The organic phase was back washed with two 60-mL portions of 5% $NaHCO_3$ solution, which were combined with the original aqueous phase. The 2-naphthol-containing organic phase may then be discarded or the unreacted 2-naphthol may be recovered. The aqueous phase was adjusted to pH 3 with 6 N hydrochloric acid (SO_2 and CO_2 were evolved). The resultant white precipitate was collected and washed with 50 mL ethyl acetate. The aqueous phase was extracted with two 50-mL portions of ethyl acetate and was then either discarded or evaporated to recover unreacted amino acid. The combined ethyl acetate extracts were dried over anhydrous $MgSO_4$, filtered, and evaporated to dryness. The remaining solids were recrystallized from 95% ethanol to afford 4.8 g of (S)-(-)-α-*N*-(2-naphthyl)leucine as white crystals in a yield of 25%, m.p. 173°C.



Reference 6.

To a 125-mL Teflon-lined autoclave was added 5.0 g 1,1′-bi-2-naphthol (17.5 mmol), 23.5 g $(NH_4)_2SO_3 \cdot H_2O$ (175 mmol), and 65 mL of concentrated aqueous ammonia. The mixture was stirred at 200°C in an oil bath for 5 days. It was then cooled down to ambient temperature and filtered. The resulting solid was washed with water followed by recrystallization from benzene to afford 4.5 g pure 2-amino-2′-hydroxy-1,1′-binaphthyl, in a yield of 91%.

Bucherer-Bergs Hydantoin Synthesis

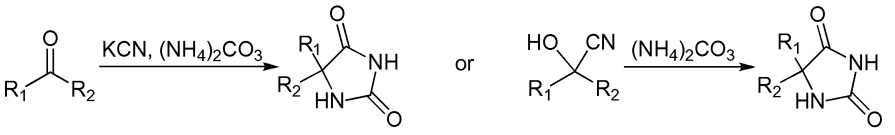
(Bucherer-Bergs Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first observed by Ciamician and Silber in 1905 who obtained 5,5-dimethylhydantoin from a mixture of acetone and hydrocyanic acid that had been exposed to sunlight for a period of 5–7 months.[1] Subsequently, Bergs reported the preparation of 5-substituted hydantoins from the corresponding aldehydes or ketones by treatment with potassium cyanide, ammonium carbonate, and carbon dioxide under several atmospheres of pressure at a temperature of 80°C for 4–6 h.[2] However, it was Bucherer who modified Bergs's procedure for synthesizing hydantoin from cyanohydrin and ammonium carbonate in an aqueous solution or benzene at temperatures below 60–70°C,[3] and studied the mechanism.[4] Therefore, this reaction is generally known as the Bucherer-Bergs reaction.[5] Occasionally, it is also referred to as the Bucherer-Bergs condition,[6] Bucherer-Bergs procedure,[7] Bucherer-Bergs method,[8] and Bucherer-Bergs hydantoin synthesis.[9] This reaction has been further modified by Henze.[10] So the Bucherer-Bergs hydantoin synthesis is the preparation of hydantoin from carbonyl compounds by treatment with 2 eq. potassium cyanide and 4 eq. ammonium carbonate[11] or from the corresponding cyanohydrin and ammonium carbonate. This reaction is one example of the multicomponent reactions (MCRs);[12] however, the carbonyl compounds—including formaldehyde, certain unsaturated aldehydes, certain hydroxy and nitroaryl aldehydes, bisdimethylaminoacetone, and pyruvic acid—are not suitable for this reaction.[11] The hydantoin itself not only demonstrates many biological activities, such as anticonvulsants,[13] antiarrhythmics,[14] antidiabetics,[15] serotonin, and fibrinogen receptor antagonists,[16] but is the starting material for preparing a variety of α-amino acids via hydrolysis.[14a,17]

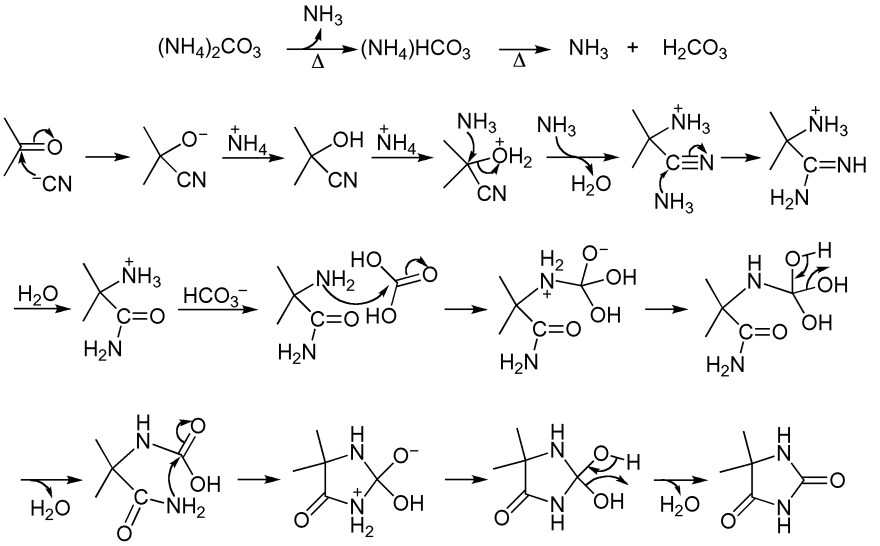
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Details of the reaction mechanism are tentatively shown below.



D. MODIFICATION

This reaction has been modified from acid-catalyzed cyclization of uredo acids;[18] from palladium catalyzed MCR among aldehydes, carbon monoxide, and ureas;[19] and from Ugi five-component condensation.[20] Alternatively, hydantoins can also be synthesized via other methods, such as the *1,3-Dipolar Cycloaddition* of 1-oxa-4-azabutadiene and aryl isocyanates[21] and the decomposition of barbituric acids in alcohol.[8]

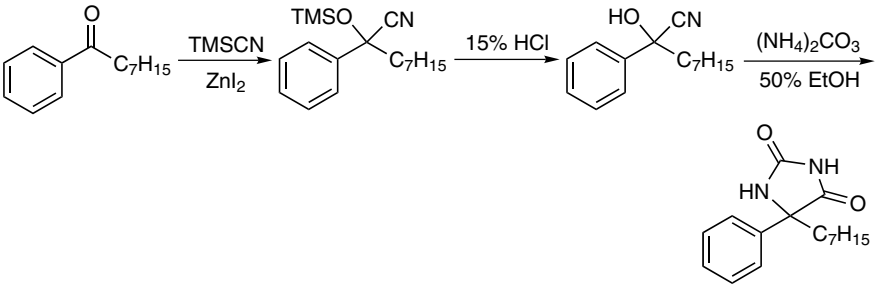
E. APPLICATIONS

This reaction is generally used for the synthesis of substituted hydantoins, which are further used to prepare different α-amino acids.

F. RELATED REACTIONS

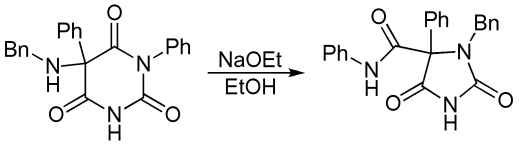
This reaction is related to the *Read Synthesis of Hydantoin* from amino acids and cyanate salts.[22]

G. CITED EXPERIMENTAL EXAMPLES



Reference 23.

A mixture of 1.5 g octanophenone (7.5 mmol), 0.70 g cyanotrimethylsilane (TMSCN) (7.5 mmol), and 5–10 mg ZnI_2 was stirred at room temperature under a nitrogen atmosphere. After 2 h, the TMS ether was hydrolyzed to the cyanohydrin by adding 10 mL ether and 10 mL 15% HCl; the resulting mixture was stirred vigorously for 1 h. The acidic layer was washed with ether (3 × 20 mL). The extracts were combined and evaporated to give 1.8 g cyanohydrin in a yield of 100%. This 1.8 g cyanohydrin (9.0 mmol) and 3.6 g $(NH_4)_2CO_3$ (3.6 mmol) were dissolved in 30 mL 50% ethanol while stirring under a nitrogen atmosphere. The mixture was heated slowly between 40° and 60°C for 12 h. The basic mixture was evaporated to half volume and cooled to room temperature. The precipitate was filtered and recrystallized from hot ethanol to give 0.5 g 5-heptyl-5-phenylhydantoin, in a yield of 21%, m.p. 124–126°C.



Reference 8.

To a solution of 0.18 g sodium (8 mmol) in 27 mL anhydrous ethanol was added 2 mmol 5-benzylamino-1,5-diphenylbarbituric acid. The mixture was refluxed for 3 h under an argon atmosphere. The solution was evaporated to dryness. The residue was taken up with a small amount of water, and insoluble material was removed by filtration. The filtrate was acidified with cold 1 N HCl. The precipitate was filtered off and dried under reduced pressure. If no crystallization was observed, the solution was extracted with ethyl acetate (4 × 5 mL), and the combined organic layers were dried over Na_2SO_4 and evaporated to dryness. The crude oil was dissolved in mixture of ethanol–diethyl ether and cyclohexane. After the solution was cooled for at least 5 days, pure crystals were separated by suction filtration and dried to give 85% 1-benzyl-5-phenyl-5-phenylcarbamoylhydantoin, m.p. 185–195°C.

Other references related to the Bucherer-Bergs hydantoin synthesis are cited in the literature.[24]

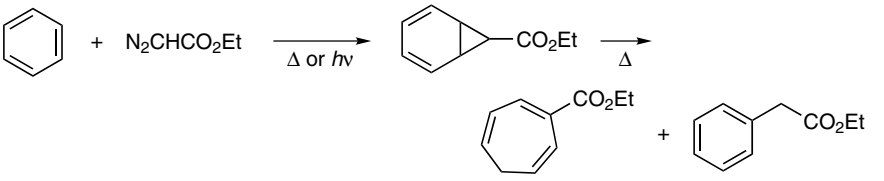
Büchner Ring Expansion
(Büchner Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Büchner et al. in 1885.[1] It is the synthesis of cycloheptatriene and phenylacetic acid derivatives through the rearrangement of norcaradiene carboxylates (i.e., the intermediate) generated from the reaction between aromatic compounds and carbene species, and this reaction is thus known as the Büchner reaction[2] or the Büchner ring expansion.[3] In this reaction, the carbene species can be generated from thermal or photolytical decomposition of diazoacetic acid esters. It is believed that an equilibrium exists between norcaradiene and cycloheptatriene derivatives in which the latter predominates in the equilibrium[4] according to the following experimental facts: (*a*) cycloheptatriene on hydrogenation gives cycloheptane,[5] whereas the addition of dienophiles usually gives products derived from norcaradiene[6] and (*b*) both the reaction of tropylium ion and cyanide ion followed by hydrolysis and the reaction of benzene and methyl diazoacetate followed by treatment with ammonia lead to the same substance.[4c] However, with two electron-withdrawing groups (e.g., CN) on the cyclopropyl ring, the 7,7-dicyano-norcaradiene is stable and can be isolated and subjected to other reactions.[7] Because the carbenes arising from the decomposition of diazo compounds are active, the normal Büchner ring expansion between these carbenes and aromatic compounds always afford a mixture of isomers.[8] However, when an rhodium complex [$Rh_2(OCOCF_3)_4$] is used, one major product will form with improved yield.[9] Other organometallic rhodium complexes might also be applicable for the Büchner ring expansion, such as the dirhodium tetraprolinate [Rh_2(S-DOSP)$_4$], which prefers the C-H insertion product,[10] and rhodium porphyrin complex, which shows competition between the addition and the C-H insertion.[11] Other organometallic complexes used in this reaction include copper complexes, such as Tp^{Br3}Cu(MeCN) and Tp^{Ms}Cu; the former gives predominately the addition products with monosubstituted benzenes, and the latter forms the α-C-H insertion product as the major product.[12]

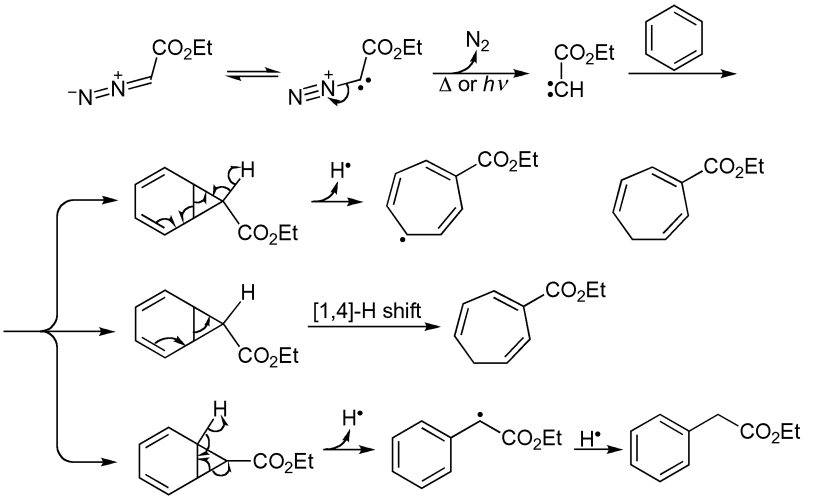
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is illustrated below.



D. MODIFICATION

This reaction has been modified for using organometallic carbene complexes to form either the addition or the C-H insertion products, depending on the catalyst used.[9–12]

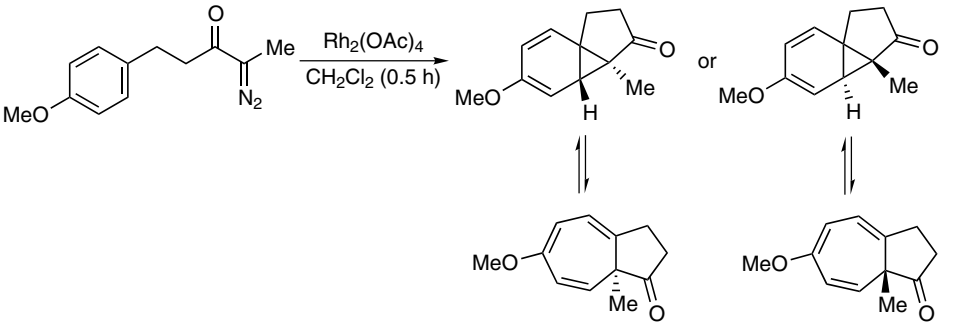
E. APPLICATIONS

Besides the general application in synthesis of cycloheptatrienes, different bicyclic products—for example, β-tetralones and azulenones—can be prepared via the intramolecular Büchner ring expansion.[12]

F. RELATED REACTIONS

This reaction is similar to the *Pfau-Plattner Azulene Synthesis*.

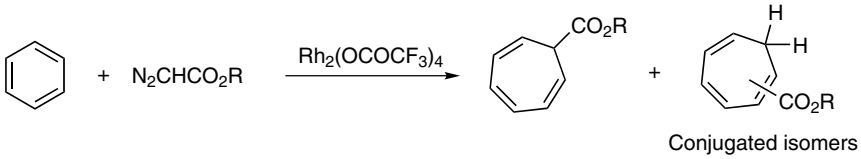
G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

3-(4′-Methoxyphenyl)propanoyl chloride (0.44 g, 2.22 mmol)—prepared from 0.46 g 3-(4′-methoxyphenyl)propanoic acid (0.46 g, 2.55 mmol) and 15 mL freshly distilled thionyl chloride and purified by bulb-to-bulb distillation at 110°C (0.3 mmHg)—in 10 mL ether was added dropwise over 20 min to an ethereal diazoethane solution—prepared from 7.15 g *N*-ethyl-*N*-nitrosourea (61.1 mmol) at −20°C while stirring under nitrogen. The solution was allowed to slowly return to room temperature while being stirred for 3 h. The ether and residual diazoethane were evaporated under reduced pressure at room temperature, using a rotary evaporator fitted with an acetic acid trap. Purification by chromatography, using ethyl acetate/hexane (5:95) as the eluant, gave 0.42 g 2-diazo-5-(4′-methoxyphenyl)pentan-3-one as a yellow oil, in a yield of 75%.

2-Diazo-5-(4′-methoxyphenyl)pentan-3-one (100 mg, 0.459 mmol) in 100 mL CH_2Cl_2 was added dropwise over 1 h to a refluxing solution of 0.5 mg rhodium(II) acetate in 100 mL CH_2Cl_2. The reaction was monitored by TLC and was complete once the diazoketone had been added. Evaporation of the solvent at reduced pressure gave the crude product as a yellow oil. A ^{1}H NMR spectrum was recorded to determine the efficiency of the cyclization (88%) (percent of azulenone compared to aromatic by-products). Purification by flash chromatography, with gradient ethyl acetate–hexane as the eluant, gave 70 mg 3,8a-dihydro-6-methoxy-8a-methylazulen-1(2H)-one as a colorless oil, in a yield of 80%. No resolution of signals for enantiomers was seen in a ^{1}H NMR chiral shift study using (+)-Eu(hfc)$_3$. It was difficult to obtain this azulenone completely free of aromatic impurities.



Reference 9.

A diazo ester (5 mmol) was added with an automatic syringe (Sage Model 352) to the aromatic substrate (0.1 mol) containing the catalyst (0.02 mmol) within ∼ 2 h while the mixture was stirred magnetically at room temperature. After the decomposition of diazo ester, the reaction mixture was analyzed by VPC using an internal standerd (dimethyl fumarate

or diethyl phthalate). In preparative experiments, the mixture was distilled under vacuum (10^{-2}– 10^{-3} mmHg) to give alkyl cyclohepta-2,4,6-triene-1-carboxylate at a relatively low temperature so as to minimize the isomerization. For the reaction with benzene, the total yield of cycloheptatriene derivatives was 100%.

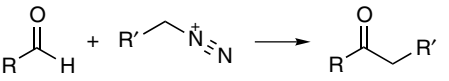
Büchner-Curtius-Schlotterbeck Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Büchner and Curtius in 1885[1] and subsequently by Schlotterbeck in 1907.[2] It is the reaction for forming ketones from aldehydes and aliphatic diazo compounds and is thus known as the Büchner-Curtius-Schlotterbeck reaction.[3] This reaction has been extended to synthesize β-keto esters from the condensation between diazo esters and aldehydes.[4] It should be pointed out that epoxides and aldehydes are also produced in this reaction, and the preparation of keto esters can also be performed in the presence of Lewis acids[5] or via a two-step process involving an *Aldol Reaction* of diazo ester and aldehyde followed by the oxidative elimination of nitrogen.[6]

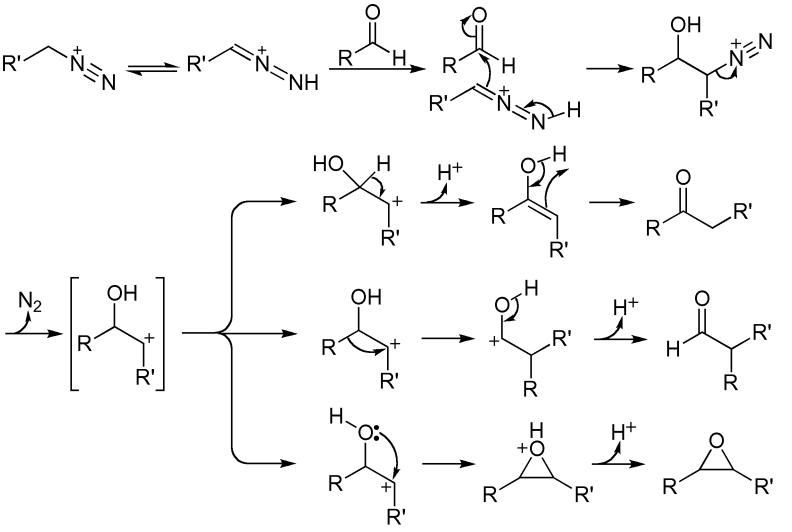
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is displayed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified to undergo in the presence of Lewis acids.[5]

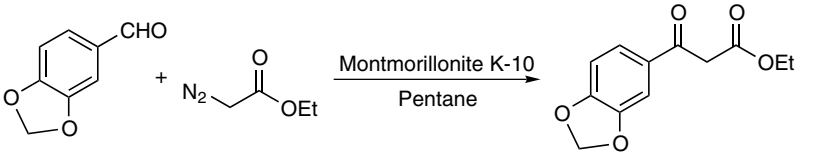
E. APPLICATIONS

This reaction has general application in the preparation of ketones and β-keto esters.[7]

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

A mixture of 5 mmol aldehyde, 7.5 mmol ethyl diazoacetate, and 100 mg montmorillonite K-10 in 10 mL pentane was stirred at room temperature for 6 h. After completion of the reaction (TLC), the catalyst was removed by filtration and washed with pentane (3 × 5 mL). The solvent was removed under reduced pressure to obtain the crude product, which was further purified by column chromatography on silica gel (ethyl acetate/light petroleum = 1:9) to give 69% β-keto ester, m.p. 41°C.

Other references related to the Büchner-Curtius-Schlotterbeck reaction are cited in the literature.[8]

Buchwald Indoline Synthesis

(Buchwald Indole-Indoline Ring Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Buchwald in 1991.[1] It is a regiospecific synthesis of 3,4-disubstituted indoline and indole derivatives that involves the generation of a zirconocene-stabilized benzyne complex from *N*-allyl *o*-haloaniline, which undergoes intramolecular olefin insertion to a tricyclic indoline zirconacycle and then reacts with electrophiles or oxidating agents to give indoline derivatives.[1] Refluxing with ammonium formate in MeOH in the presence of Pd/C, the 3,4-disubstituted indoline derivatives are converted into indole derivatives, respectively;[2] alternatively, the intermediate *exo*-methylene indoline derivative can be transformed into indole via ene reaction.[1] This reaction is therefore referred to as the Buchwald indoline synthesis,[3] or the Buchwald indole-indoline ring synthesis.[3]

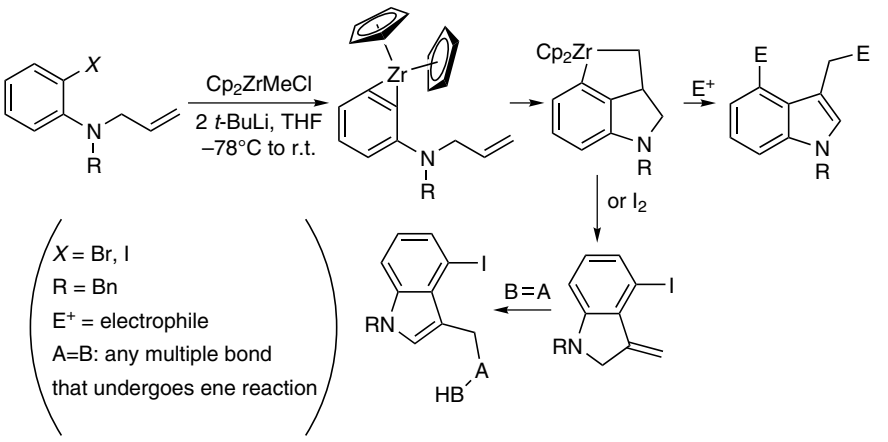
It should be pointed out that the 4-position of the indole ring systems is so electron deficient that the substituents are difficult to introduce at the 4-position by normal electrophilic substitution.[4] To circumvent this problem, two approaches have been developed: formation of the pyrrole ring using an annelation method onto an appropriately substituted aromatic precursor and direct introduction of the substituent into the 4-position of the existing indole framework.[4] Some known indole synthesis methods, including the *Batcho-Leimgruber Indole Synthesis*, *Bartoli Indole Synthesis, Fischer Indole Synthesis, Larock Indole Synthesis, Madelung Indole Synthesis*, and *Reissert Indole Synthesis*, belong to the annelation approaches, whereas only a few 4-substituted indole preparations are accomplished by the second approach, such as the application of chromium tricarbonyl complexs

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

of indoles,[5] thallation/palladation,[6] and lithiation.[7] However, the first approach requires properly substituted starting materials, which can be expensive or not readily available, and the second approach uses toxic chromium complex.[4] In comparison, the Buchwald indoline synthesis requires only a catalytic amount of zirconocene and has been successfully applied to the synthesis of a variety of molecules containing indole or indoline scaffolds, such as tryptamine,[2,8] serotonin,[4] tryptophan[4] analogs, and some natural products (including makaluvamine C,[2] damirones A and B,[2] dehydrobufotenine,[2] clavicipitic acid,[9] and pharmacophore of CC-1065[4,9]).

On the other hand, the Buchwald indoline synthesis also holds some weakness, such as employing the air and moisture-sensitive zirconocene ($Cp_2Zr(Me)Cl$), the availability of *N*-allyl-*o*-bromoaniline, and the limited scope for indoles with substituents at both the 3- and 4-positions.[9] By applying the later-developed *Buchwald-Hartwig Amination*, Buchwald himself extended the indoline synthesis to other kinds of indoline and indole derivatives from an aryl Grignard reagent, an olefin, a primary amine, and the air-stable titanocene Cp_2TiCl_2.[9] In this modification, the aryl Grignard reagent is converted into a titanocene-stabilized benzyne complex, which intermolecularly inserts with olefin and then couples with amine to give indoline derivatives. In addition, 2-(*o*-halo-phenyl)ethylamine can be directly converted into indoline via the *Buchwald-Hartwig Coupling*;[2] likewise, *o*-bromobenzylic bromide can react with benzylamine to afford indoline by the *Buchwald-Hartwig Coupling*.[9] Even secondary amides and carbamates can be intramolecularly mounted onto aromatic nucleus, giving a variety of benzo-heterocycles.[10]

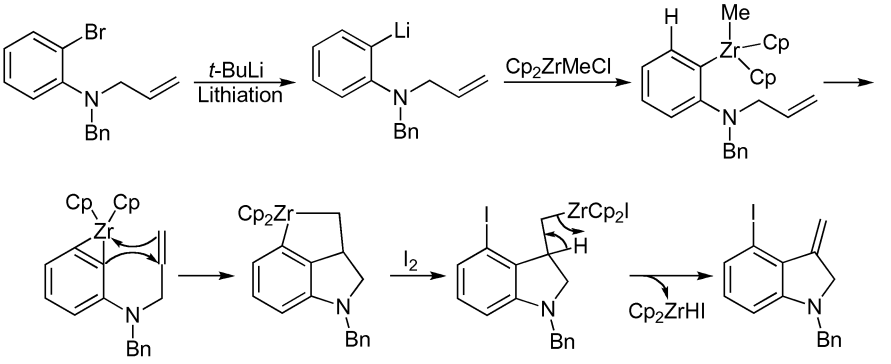
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

As described in the definition of Buchwald indoline synthesis, this reaction involves the formation of a zirconocene-stabilized benzyne complex that intramolecularly inserts to an *N*-allyl group to give a tricyclic indoline zirconacycle. In the presence of oxidating reagent or electrophiles, the indoline zirconacycle decomposes into indoline derivatives.[1]

Upon dehydrogenation, corresponding indole derivatives can be prepared. Displayed here is an illustration for the formation of *N*-benzyl-3-methylene-4-iodo-indoline.



D. MODIFICATION

The Buchwald indoline synthesis has been extended for preparing other kinds of indoline and indole derivatives not just 3,4-disubstituted indolines and indoles, starting from a readily available aromatic Grignard reagent, an olefin, a primary amine, and air-stable titanocene Cp_2TiCl_2.[9] In addition, the *Buchwald-Hartwig Coupling* has been used for the preparation of indoline and indole derivatives from readily available 2-(*o*-halo-phenyl)ethylamine[2] and 2-(*o*-halo-phenyl)ethylbromide and benzylamine.[9] Moreover, the *Buchwald-Hartwig Coupling* has also been used to modify the *Fischer Indole Synthesis* by coupling with aryl halide and hydrazone in the presence of methanesulfonic acid as the catalyst.[11]

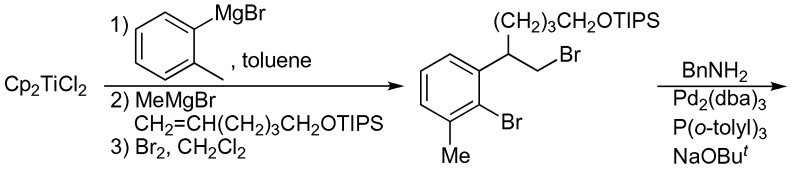
E. APPLICATIONS

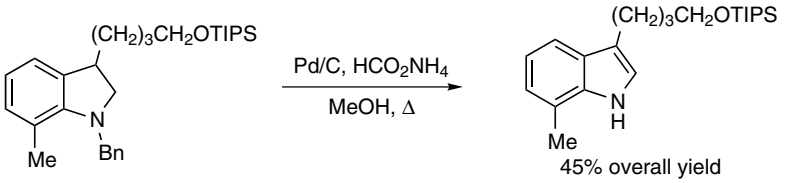
This reaction in combination with its modifications has broad application in the synthesis of polysubstituted indoline and indole derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



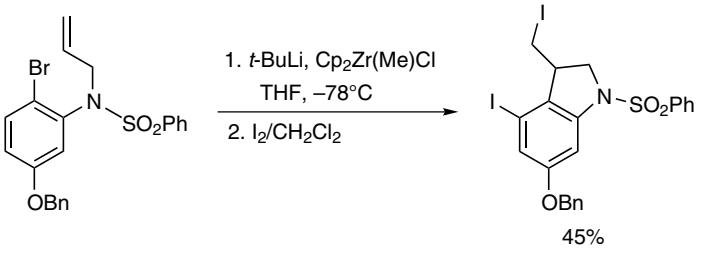


Reference 9.

To a solution of 0.08 M Cp_2TiCl_2 in toluene (2–4 mmol, 1.0 eq.) in a resealable Schlenk flask at room temperature was added 1.1 eq. of a THF solution of *o*-methylphenyl magnesium bromide under argon. After 1 h, 2.0 eq. of triisopropylsilyl hex-5-en-1-ol ether and a 1.0 eq. MeMgBr in Et_2O were added, then the flask was sealed and heated to 50°C for 4 h. After being cooled to room temperature, the solvent was removed in vacuo, and CH_2Cl_2 (12 mL/mmol Cp_2TiCl_2) was added. Then the solution was cooled to −78°C. A solution of 2.05 eq. Br_2 in CH_2Cl_2 at an appropriate concentration (6 mL/mmol Cp_2TiCl_2) at −78°C was added dropwise. The solution was warmed slowly to room temperature, then the solvent was removed in vacuo. *Caution:* Care should be used to ensure that the excess bromine has been destroyed. Hexane (30 mL/mmol Cp_2TiCl_2) was added; then the mixture was filtered through a pad of Celite, and the solvent was evaporated. The dibromide product was partially purified by flash chromatography, and a portion of the material (typically 25–50%) was used directly in the next step.

The appropriate amount of the above dibromide (1.0 eq.) was mixed with 4 mol % $Pd_2(dba)_3$, 16 mol % P(*o*-tolyl)$_3$, 4.0 eq. NaO-*t*-Bu, and 2.0 eq. benzylamine in toluene. The flask was sealed, then heated to 80°C for 16 h. Upon cooling to room temperature, the mixture was poured into a separatory funnel containing Et_2O and H_2O. The organic layer was washed with brine, dried over $MgSO_4$, and filtered and the solvent was evaporated. The indoline product was partially purified by flash chromatography, and a portion of the material (typically ∼50%) was used directly in the next step.

The indoline derivative (1.0 eq.) was treated with 10 mol % (by weight) Pd/C and 10.0 eq. ammonium formate in MeOH. The solution was refluxed for 1.5 h, then allowed to cool to room temperature and filtered through a short pad of Celite. The solvent was evaporated, and the residue was dissolved in CH_2Cl_2. The organic layer was washed with H_2O, brine, dried over Na_2SO_4, and filtered, and the solvent was evaporated. The residue was purified by flash chromatography using hexane/CH_2Cl_2 (4:1 then 2:1) to afford 80 mg 3-[4-(triisopropylsilyl)oxy]butyl-7-methylindole as a colorless oil, in an overall yield of 45% from Cp_2TiCl_2.



Reference 12.

To a flame-dried Schlenk flask with a stir bar was charged 50 mL THF, 2.39 g zirconocene(methyl)chloride (8.8 mmol), 4.04 g *N*-allyl-*N*-(benzenesulfonyl)-5-(benzyloxy)-2-bromophenylamine (8.8 mmol), and 17.6 mmol *tert*-butyllithium in hexane at −78°C. After stirring at this temperature for 15 min, the solution was allowed to warm to 23°C and stirred for an additional 2 h. The THF was then removed in vacuo, and the residue was dissolved in 50 mL CH_2Cl_2. To this solution was added a suspension of 5.20 g iodine (20.5 mmol) in 50 mL CH_2Cl_2 at 0°C, and the mixture was stirred at 0°C for 4 h. After removal of CH_2Cl_2 in vacuo, the residue was dissolved in 100 mL Et_2O and washed with saturated aqueous Na_2SO_3 (3 × 100 mL) and water (3 × 100 mL), dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by flash chromatography using EtOAc/petroleum ether (1:10) as the eluent to afford 2.3 g (3*RS*)-1-(benzenesulfonyl)-6-(benzyloxy)-4-iodo-3-(iodomethyl)-2,3-dihydro-1*H*-indole as a yellow solid, in a yield of 45%, m.p. 49°C (Et_2O).

Buchwald-Hartwig Amination

(Buchwald-Hartwig Reaction)

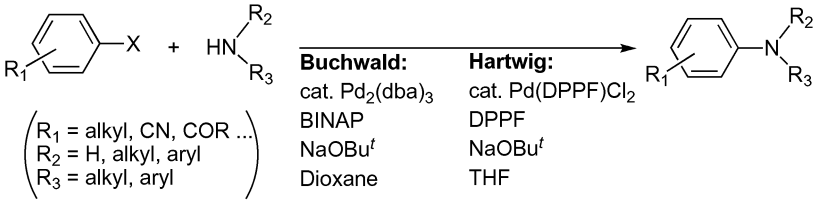
A. GENERAL DESCRIPTION OF THE REACTION

This reaction can be traced back to the original work of Migita in 1983,[1] and had been established gradually and concurrently from Buchwald[2] and Hartwig[3] since 1994. It is the transition metal (palladium) catalyzed cross-coupling between aryl halides or pseudohalides (triflates) and primary or secondary amines to form aromatic amines. Therefore, this reaction is generally known as the Buchwald-Hartwig amination.[4] In addition, this reaction has also been referred to as the Buchwald-Hartwig amidation,[5] Buchwald-Hartwig arylamination,[6] Buchwald-Hartwig C-N coupling,[7] Buchwald-Hartwig coupling,[8] Buchwald-Hartwig C-N cross coupling,[9] Buchwald-Hartwig reaction,[10] and in very rare cases as the Buchwald-Hartwig-Migita type coupling.[11] In this coupling reaction, the source of palladium is usually $Pd(OAc)_2$ or Pd_2dba_3 (tri(dibenzylideneacetone)dipalladium). While numerous ligands have been used to create the catalysts, it is found that when the strongly hindered phosphine ligands except for PPh_3[12] or very potent *N*-heterocyclic carbenes are applied as ligands, the coupling products are normally produced in high yields;[13] and among these ligands, the most common ones are DPPF(1,1′-bis-(diphenylphosphanyl)-ferrocene) and BINAP (2,2′-bis(diphenylphosphino)-1,1′-binaphthyl).[4u,4v,14] In this coupling, once the chelated palladium catalyst forms, the oxidative addition of the aryl halide occurs; then the amine joins the complex, and the halide anion is removed from the complex by base, and finally the catalytic species is generated again via the reductive elimination of the product. It is found that $Pd(PPh_3)_4$ can be applied to the intramolecular version of such coupling (cyclization), and aryl iodides in this case are superior to corresponding bromides.[12a] In contrast, when aryl iodide are used in the intermolecular coupling, high yields can be achieved for those

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

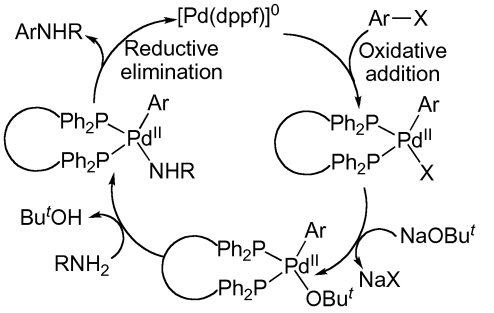
reactions between secondary amines in dioxane, whereas when primary amines are used, acceptable yields can be obtained for aryl iodides with an *ortho*-substituent.[15] However, when BINAP is used as ligand, it is not necessary to have an *ortho*-substituent adjacent to halide, and the loading amount of catalyst can be reduced.[14b] For comparison, DPPF is a good ligand for the coupling of electron-deficient aryl halide so that it is not necessary to use sterically encumbered phosphine as ligand. Under this condition, the reductive elimination over β-hydrogen is presumably due to the chelation and large bit angle of palladium, but not from steric effects.[16] On the other hand, it has been found that if $Pd(OAc)_2$ is used as a source of palladium, it must be premixed with BINAP before the addition of base, otherwise small number of catalyst can form, leading to a slow reaction in poor yield.[17] This reaction can be extended to synthesize aryl ethers by replacing primary or secondary amines with alcohols or phenols,[18] where palladium can be replaced by copper.[19] This reaction has found wide applications in the preparation of arylamines,[4r] nucleotide derivatives,[10h,20] tetracyclic systems,[10e] etc. Due to the versatility of this coupling, this relatively new reaction has already been reviewed many times.[4u,10e,11,12,14a,21,22]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The reaction mechanism is illustrated using DPPF as ligand as displayed below.[22,23]



D. MODIFICATION

This reaction has been modified to form aryl ethers from alcohols or phenols,[18] and to synthesize aryl amines using copper reagents.[19]

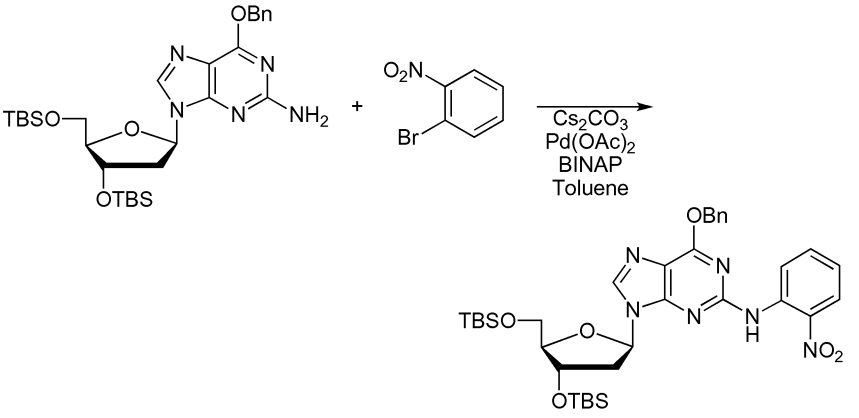
E. APPLICATIONS

This reaction has wide applications for the synthesis of aniline derivatives, indole alkaloids, pharmaceuticals, ligands, organic components and so on.[12a,14a,24]

F. RELATED REACTIONS

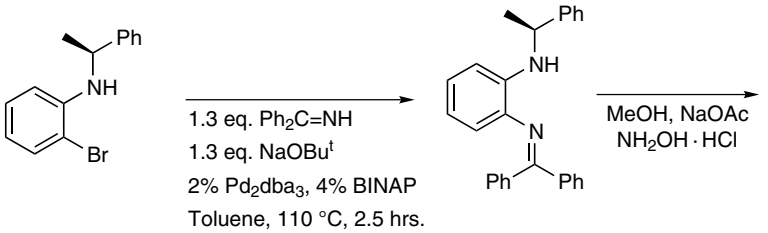
This reaction is related to many type of coupling reaction catalyzed by palladium complex, including the *Hiyama Coupling, Negishi Cross-Coupling, Sonogashira Coupling, Stille Coupling* and *Suzuki Coupling*.

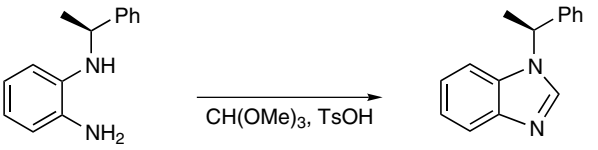
G. CITED EXPERIMENTAL EXAMPLES



Reference 10h.

An oven-dried reaction vial was charged with 0.100 g of nucleoside (0.171 mmol), 0.078 g of cesium carbonate (0.24 mmol, 1.4 equiv), 0.004 g of palladium acetate (0.017 mmol, 0.1 equiv), 0.016 g of BINAP (0.025 mmol, 0.15 equiv), 0.22 mmol of aryl bromide (1.3 equiv), and 1 mL of toluene. The vial was flushed with argon prior to sealing. The reaction mixture was stirred for 30 min at room temperature, heated at 80°C for 16 h, and then diluted with ethyl acetate. Centrifugation and concentration in a vacuum of the supernant liquid afforded a residue, which was purified by flash chromatography (silica gel, 10-30% ethyl acetate in hexane) to afford 0.116 g of N^2-(2-nitrophenyl)-O^6-benzyl-3′,5′-bis-*O*-(*tert*-butyldimethylsilyl)-2′-deoxyguanosine as a yellow amorphous solid, in yield of 96%.





Reference 4r.

An oven-dried pressure tube equipped with magnetic stir bar and rubber septum was cooled under argon. The pressure tube was charged with 70.9 mg Pd_2dba_3 (0.0774 mmol, 2.0 mol %), 96.4 mg *rac*-BINAP (0.155 mmol, 4.0 mol %), and 15.0 mL toluene. The rubber septum was replaced with a Teflon screw cap, and the mixture was heated at 110°C in an oil bath for 30 min. The solution was then allowed to cool to room temperature, and 844 μL benzophenone imine (5.03 mmol, 1.30 equiv), 1.07 g bromoaniline (3.87 mmol, 1.00 equiv), and 483.4 mg sodium *tert*-butoxide (5.03 mmol, 1.30 equiv) were added. The pressure tube was sealed and heated in an oil bath at 110°C with stirring for 2.5 h. The solution was then allowed to cool to room temperature, diluted with diethyl ether, filtered through a pad of Celite, and concentrated via rotatory evaporator to give a crude dark brown-black oil which was purified by flash chromatography (gradient elution with 10% CH_2Cl_2/hexane to 50% CH_2Cl_2/hexane) to provide 1.44 g *N*-[(*S*)-1-phenylethyl]-*N*′-(diphenylmethylene)-1,2-benzenediamine as a yellow oil, in a yield of 99%. R_f = 0.14 (50% CH_2Cl_2/hexane).

To a 50 mL round-bottomed flask equipped with a magnetic stir bar were added 504.0 mg of above benzenediamine (1.34 mmol, 1.0 equiv), 30 mL methanol, 263.3 mg sodium acetate (3.21 mmol, 2.4 equiv), and 167.5 mg hydroxylamine hydrochloride (2.41 mmol, 1.8 equiv). The resulting solution was then stirred at room temperature for 1 hour. The solution was partitioned between 0.1 M NaOH and CH_2Cl_2, and the organic layer was dried over Na_2SO_4, filtered, and concentrated via rotatory evaporator. The resulting oil was purified by flash chromatography (elution with 6:1 hexane/EtOAc, then 4:1 hexane/EtOAc) to yield 268.8 mg *N*-[(*S*)-1-phenylethyl]-1,2-benzenediamine as a colorless oil that turned light red upon standing in solution or neat, in a yield of 95%, R_f= 0.21 (30% hexane/ethyl acetate).

To a 15 mL round-bottom flask equipped with magnetic stir bar was added 194.8 mg *N*-[(*S*)-1-phenylethyl]-1,2-benzenediamine (0.92 mmol, 1.0 equiv), 10.0 mL triethylorthoformate, and 17.5 mg *p*-toluenesulfonic acid monohydrate (0.092 mmol, 0.10 equiv), and the resulting solution was stirred for 8 h. The solution was then diluted with ethyl acetate and washed with $NaHCO_3$. The aqueous layer was back-extracted with ethyl acetate, and the combined organic layers were dried over Na_2SO_4, filtered, and concentrated via rotatory evaporator to give a brown oil. Purification by flash chromatography (elution with 1% MeOH/CH_2Cl_2) provided 185 mg 1-[(*S*)-1-phenylethyl]-1*H*-benzimidazole as a white solid, in a yield of 91%, m.p. 151–152°C, R_f = 0.26 (5% methanol/CH_2Cl_2).

Other references related to the Buchwald-Hartwig amination are collected in the literature.[25]

Burton Trifluoromethylation

A. GENERAL DESCRIPTION OF THE REACTION

Although many methods have been available for the introduction of trifluoromethyl group into aromatic compounds, the Burton trifluoromethylation, first reported in 1985,[1] is probably one of the most feasible methods for incorporating the CF_3 group directly into the molecules via *in situ* generation and coupling of CF_3Cu with aryl halide. All other earlier methods[2] had some drawbacks, including the application of expensive reagents (e.g., CF_3I, $(CF_3)_2Hg$) or requiring high temperatures or reducing aryl halides.[3] In contrast, trifluoromethyl copper is generated in the Burton trifluoromethylation via *in situ* metathesis of (trifluoromethyl)cadmium [CF_3CdX + $(CF_3)_2Cd$] or (trifluoromethyl)zinc [CF_3ZnX + $(CF_3)_2Zn$]; in addition, trifluoromethyl copper can also be generated *in situ* from cheap difluorodihalomethanes (Freon) precursors with soluble copper (I) salts, such as CuCl, CuBr, CuI, and CuCN. The metathesis reaction of copper (I) salts with [CF_3CdX] occurs rapidly even at –30°C, although the exchange between [CF_3ZnX] and CuBr is slow. One recent development of trifluoromethylation starts from CF_3SiMe_3.[4] It has been found that CF_3Cu is a versatile CF_2 transfer reagent, involving a selective C-F bond scission to form a difluorocarbene copper complex, and insertion of the CF_2 unit to the C-F bond of CF_3Cu provides a method for longer chain $CF_3(CF_2)_nCF_2$-Cu (n = 0–14) compounds.[5]

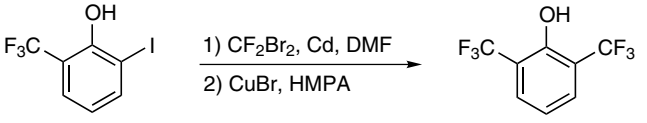
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A mixture of 21.0 g Cd powder (187 mmol) in 83 mL DMF was treated at 0°C with 11.5 mL CF_2Br_2 (125 mmol) at a rate that maintained the temperature below 40°C. The mixture was stirred at room temperature for an additional 30 min and was then diluted with 83 mL HMPA. The reaction mixture was cooled to 0°C, and to it was added 8.96 g CuBr (62.5 mmol), causing an exotherm to ~ 18°C. The mixture was then warmed to room temperature and stirred for 10 min. The resultant mixture of [CF_3Cu] was treated with 6.0 g 2-iodo-6-(trifluoromethyl)phenol (20.8 mmol) and then heated at 60°C for 90 min. The reaction mixture was cooled to room temperature and poured into a mixture of 3 N HCl and ether (200 mL each), and then the solids were removed from the mixture by filtration. The aqueous phase was extracted with ether, and the combined extract was washed with saturated NaCl and then dried over $MgSO_4$. The volatile was distilled from the crude product, which was then isolated by distillation to furnish 2.37g 2,6-bis(trifluoromethyl)phenol, in a yield of 47%, b.p. 70°C (30 mmHg).

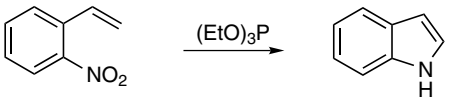
Cadogan-Sundberg Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction can be traced back to the initial work of Cadogan for the preparation of carbazole by the reductive cyclization of aromatic nitro compounds with triethyl phosphite.[1] This reaction was then extended by Sundberg to the formation of indoles by the treatment of *o*-nitrostyrene with triethyl phosphite[2] or the formation of indolines from the *o*-alkyl nitrobenzenes.[3] Thus the formation of indole from the reduction of *o*-nitrostyrenes is referred to as the Cadogan-Sundberg indole synthesis.[4]

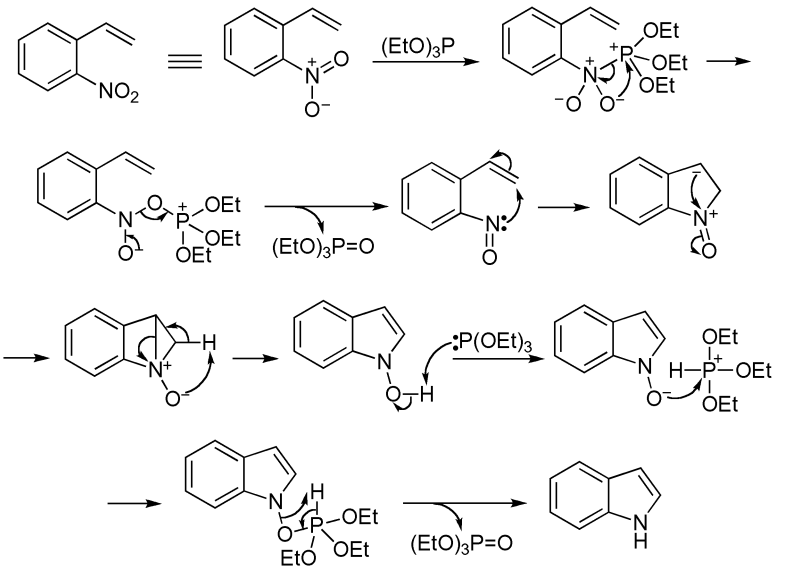
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The Cadogan-Sundberg indole synthesis involves the insertion of phosphorus atom to the N=O double bond of the nitro group followed by the cleavage of triethyl phosphate to give *N*-hydroxyl indole. Subsequently, the *N*-hydroxyl indole was reduced by a second triethyl phosphite to afford indole as shown here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

The reductive cyclization of *o*-nitrostryene (i.e., the Cadogan-Sundberg indole synthesis) has been improved by the transition metal catalyzation,[5] selenium-based reductive cyclization,[6] or hydrogen/Raney nickel reduced cyclization.[7]

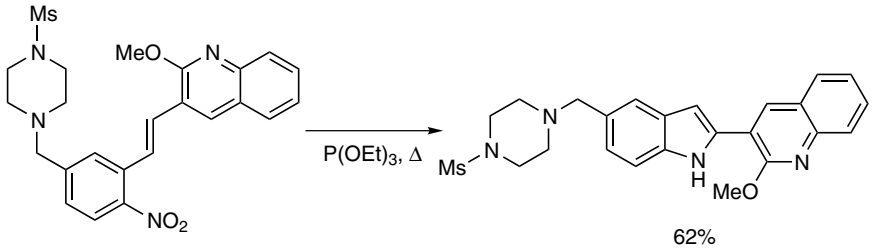
E. APPLICATIONS

This reaction is useful for the preparation of indole derivatives.

F. RELATED REACTIONS

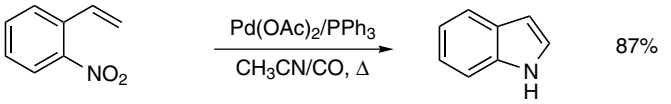
This reaction is related to the *Bartoli Indole Synthesis* from aromatic nitro compounds.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A solution 1.5 g *trans*-3-{2-[5-(4-methanesulfonylpiperazine-1-ylmethyl)-2-nitrophenyl]vinyl}-2-methoxyquinoline (3.10 mmol) in 15.5 mL $P(OEt)_3$ was heated to 155°C for 2 h and the solvent was removed under reduced pressure. The residue was purified by flash silica gel chromatography to give 908 mg 2-methoxy-3-[5-[[4-(methysulfonyl)-1-piperazinyl]methyl]-1*H*-indol-2-yl]quinoline as a light yellow solid, in a yield of 62%, m.p. 197–198°C.



Reference 5e.

To an oven-dried, threaded ACE glass pressure tube was added 298 mg 2-nitrostyrene (2.00 mmol), 26 mg palladium diacetate (0.12 mmol), 124 mg triphenylphosphine (0.48 mmol), and 4 mL CH_3CN. The tube was fitted with a pressure head, the solution was saturated with CO (4 cycles to 4 atm of CO), and the reaction mixture was heated to 70°C (oil bath temperature) under 4 atm of CO atmosphere until all starting material was consumed as judged by TLC ($\sim$ 15 h). The reaction mixture was diluted with 10 mL 10% aqueous HCl and extracted with Et_2O (3 $\times$ 10 mL). The combined organic phases were washed with 10 mL 10% HCl and dried over $MgSO_4$. Upon removal of the solvent, the residue was purified by chromatography using hexanes/EtOAc (9:1) to afford 203 mg indole as white crystals, in a yield of 87%.

Other references related to the Cadogan-Sundberg indole synthesis are cited in the literature.[9]

Caglioti Reaction

(Caglioti Reduction, Caglioti Alkene Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Caglioti in 1962.[1] It is a conversion of a carbonyl group in either ketones or aldehydes into a methylene group or an olefinic moiety with vicinal carbon by treatment of the corresponding *p*-tosylhydroazones of the ketones or aldehydes with a hydride base, such as diborane (B_2H_6), lithium hydride (LiH), sodium borohydride ($NaBH_4$), lithium aluminum hydride ($LiAlH_4$), sodium cyanoborohydride ($NaBH_3CN$), and catecholborane. This reaction is thus generally known as the Caglioti reaction.[2] Occasionally, it is also referred to as the Caglioti reduction[3] and Caglioti alkene synthesis.[4]

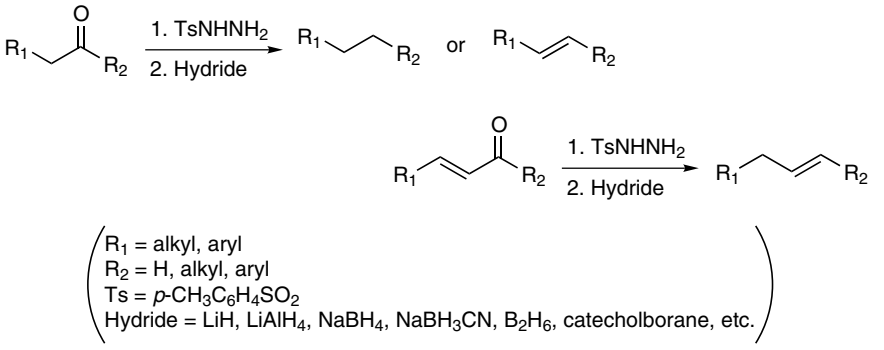
In terms of conversion of carbonyls into methylene groups, the Caglioti reaction is an alternative to the normal *Wolff-Kishner Reduction*, *Huang-Minlon Modification*, and *Clemmensen Reduction*, but it is more closely related to *Bamford-Stevens Reaction*. When diborane is applied as a hydride source, the Caglioti reaction is often carried out for the reduction of α,β-unsaturated ketones in the presence of acetic anhydride.[2d] However, such conditions have been used only a few times due to the formation of diverse product, such as dienes and vicinal diacetates. It was found that when diborane is generated *in situ* from $NaBH_4$ and $BF_3{\cdot}Et_2O$ in diglyme while moisture and air are rigorously expelled from the reaction system, high yields of alkenes can be achieved from α,β-unsaturated ketones.[2d] The higher reactivity of diborane in diglyme rather than in THF is probably due to the formation of a stable complex between diborane and THF.[2d] When $LiAlH_4$ is applied as the hydride source,[2b,2e,5] mixture of hydrocarbons are obtained for the reduction of tosyl-

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

hydrazones of α,β-unsaturated ketones.[5a] Although $LiAlH_4$ is a strong hydride donor, it still fails to reduce the tosylhydrazone of 2,2-dimethyl-3,4-dien-hexaldehyde that has been successfully reduced by *Wolff-Kishner Reduction* in DMSO at 100°C by using $KOBu^t$ as the base.[5c] It is interesting that $LiAlH_4$ can simultaneously remove the α-nitro group and reduce the carbonyl group so that the *p*-tosylhydrazones of α-nitroketones in THF can be directly converted into saturated hydrocarbons.[2b] When $NaBH_4$ is applied for the reduction of *p*-tosylhydrazones of ketones, the reactions are often refluxed in methanol or dioxane.[6] However, the reaction often suffers from the relatively low selectivity at the reaction temperature.[6b,6c] As examples, the reaction might be accompanied by the concomitant reduction of the acetoxy group,[7] ester group,[8] and aromatic nitro group.[9] Even though lithium hydride (LiH) has been used in a few cases,[10] the low solubility of LiH may result in a sluggish reaction mixture.[10b] It was found that such difficulty can be overcome by the addition of a small amount of diglyme.[10b] Compared with the above hydride bases, sodium cyanoborohydride ($NaBH_3CN$) is a mild and highly selective reagent for reducing the tosylhydrazones of aliphatic ketones and aldehydes.[5a] The reduction can be carried out under acidic condition, such as in a 1:1 mixture of DMF and sulfolane containing *p*-toluenesulfonic acid at 100–105°C.[6c] Similar to the failure of $LiAlH_4$ in reduction of 2,2-dimethyl-3,4-dien-hexaldehyde with a carbonyl group adjacent to a tertiary carbon, $NaBH_3CN$ also fails to convert a β-tetralone with *spiro*-piperidine at the α-position; however, such type of carbonyl group can be converted by the *Huang-Minlon Modification*.[11] When catecholborane is used as the hydride source,[2b,12] the reduction occurs in mild conditions, such as at neutral pH, room temperature, and in an aprotic solvent; in addition, the reduction of the tosylhydrazones of ketones and aldehydes is also tolerated for most of functional groups and gives only a single hydrocarbon product.[12a]

It should be pointed out that from the known results, regardless of which hydride source (e.g., diborane,[2d] $NaBH_3CN$,[5a] and catecholborane[12b]) is applied for the reduction of α,β-unsaturated carbonyl molecules, the new formed carbon-carbon double bond will migrate to the original carbonyl location.

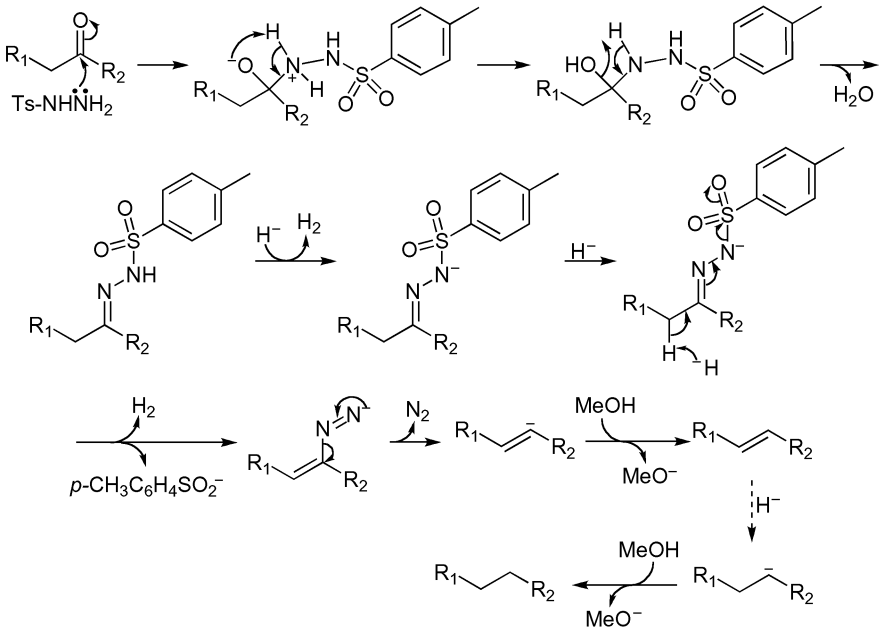
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It has been proposed that this reaction involves the initial reduction of tosylhydrazone to tosylhydrazine, followed by the elimination of *p*-toluenesulfinic acid and the decomposition

of the diimide intermediate to hydrocarbon.[6a,6c] However, because the sulfonamide proton is slightly acidic (pKa = 8.5),[5b] the initial reaction should remove such hydrogen atom. Upon the subsequent deprotonation of the α-proton and elimination of the *p*-toluenesulfinate, unsaturated diazo anion is formed, which decomposes to give an alkenyl anion. The abstraction of proton from solvent or any hydrogen source will give a neutral alkene. Furthermore, in the presence of an excess amount of hydride source, the addition of hydride to the olefinic double bond will afford a carbanion that can be simply quenched by solvent or a proton source. Provided here is an illustration of the reaction details.



D. MODIFICATION

The initial reaction condition has been extended to use catecholborane as the hydride source.[2b,12] In addition, optimal conditions when diborane is used as the hydride source have been developed using *in situ* generated diborane from $NaBH_4$ and $BF_3{\cdot}Et_2O$ in diglyme while rigorously removing moisture and air.[2d] Moreover, cyclic 1,3-diketones can be converted into cyclic 2-enones using a relatively weak base.[5b]

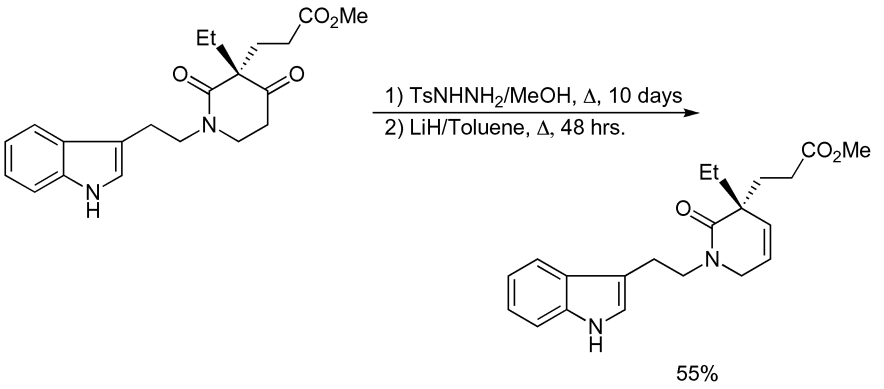
E. APPLICATIONS

Similar to the *Wolff-Kishner Reduction* and *Clemmensen Reduction*, this reaction is also useful for the conversion of carbonyl compounds into hydrocarbons and olefins.

F. RELATED REACTIONS

This reaction is closely related to the *Bamford-Stevens Reaction*.

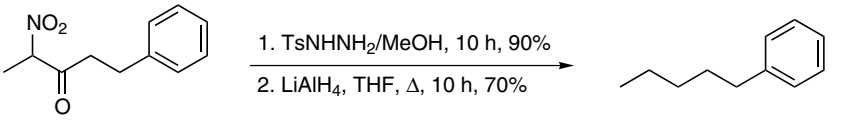
G. CITED EXPERIMENTAL EXAMPLES



Reference 10a.

A mixture of 2.0 g (*R*)-3-ethyl-1-[2-(1*H*-indol-3-yl)ethyl]-2,4-dioxo-3-piperidinepropanoic acid methyl ester (5.4 mmol) and 2.0 g (*p*-toluenesulfonyl)hydrazine (10.8 mmol) in 10 mL MeOH was refluxed for 2 days; then an additional 1.0 g (*p*-toluenesulfonyl)hydrazine (5.4 mmol) in 2.0 mL MeOH was added. The operation was repeated every 48 h over 10 days. The mixture was then concentrated under reduced pressure, and the residue was chromatographed on silica gel using hexane/EtOAc (1:1) to give 2.30 g pure (*R*)-3-ethyl-1-[2-(1*H*-indol-3-yl)ethyl]-2-oxo-4-[[(4-methylphenyl)sulfonyl]hydrazono]-3-piperidinepropanoic acid methyl ester as a yellow amorphous solid, in a yield of 80%.

To a suspension of 70 mg LiH (8.80 mmol) in 5 mL toluene was added 1.0 g above hydrazone (1.86 mmol). The mixture was refluxed for 48 h. After being cooled to 20°C, the above mixture was poured into crushed ice and extracted with CH_2Cl_2. The collected organic phases were washed with brine, dried, and concentrated in vacuo. Chromatography on silica gel using hexane/EtOAc (1:1) gave 362 mg (*R*)-3-ethyl-1-[2-(1*H*-indol-3-yl)ethyl]-2-oxo-1,2,3,6-tetrahydro-3-pyridinepropanoic acid methyl ester as a pale yellow oil, in a yield of 55%.



Reference 2b.

To a solution of 1.77 g 2-nitro-5-phenyl-3-pentanone (8.53 mmol) in 5 mL MeOH was added 10 mL MeOH solution of 1.65 g (*p*-tolylsulfony1)hydrazine (8.9 mmol); the mixture was stirred for 10 h, then water was added to precipitate 2-nitro-5-phenyl-3-pentanone (*p*-tolylsulfonyl)hydrazone, which was purified by recrystallization from MeOH/water, in a yield of 90%, m.p. 104–105°C.

To a solution of 0.3 g $LiAlH_4$ (7.92 mmol) in 30 mL dry THF at 0°C was added 0.99 g purified hydrazone (2.64 mmol) in 20 mL dry THF under a nitrogen atmosphere dropwise. The resulting mixture was stirred at 60°C for 10 h and cooled to room temperature. The

reaction mixture was treated with 20 mL cold water, acidified with 2 *N* HCl, and extracted with *n*-pentane (3 × 30 mL). The combined organic layers were dried over Na_2SO_4, filtered, and concentrated by distillation; the residue was purified by short silica gel chromatography using *n*-pentane as the eluent to give 70% of pentylbenzene, b.p. 115°C at 60 mmHg.

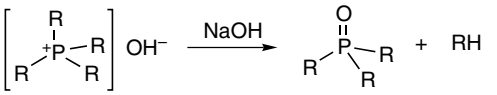
Cahours-Hofmann Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Cahours and Hofmann in 1857.[1] It is the degradation or decomposition of quaternary phosphonium hydroxides into hydrocarbons and trialkyl (or triaryl) phosphine oxides in the presence of bases such as NaOH. The trialkyl phosphine can be simply prepared by the interaction of phosphorus trichloride and zinc alkyls,[2] whereas the quaternary phosphonium hydroxides can be formed by the reaction between base and quaternary phosphonium halides, the latter come from the trialkyl (or triaryl) phosphine and alkyl halides. It is believed that this reaction involves the attack of hydroxide ion on a transient pentacovalent adduct arising from a phosphonium cation and a second hydroxide.[3] The decomposition or degradation of quaternary phosphonium hydroxide is in the following order, according to the alkyl or aryl groups attaching to the phosphorus atom: CH_2=CH-CH_2, $C_6H_5CH_2$ > C_6H_5 > CH_3 > $C_6H_5CH_2CH_2$ > C_2H_5 > C_3H_7. Similarly, tetrahydroxylmethyl phosphonium chloride decomposes in aqueous base to give trihydroxylmethyl phosphine oxide, hydrogen gas and formaldehyde.[4] In contrast to the formation of trialkyl phosphine oxide from this reaction, trialkyl phosphine sulfide can form directly from the reaction between trialkyl phosphine and sulfur.[5]

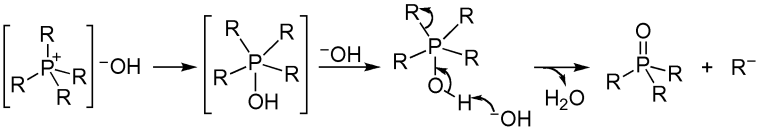
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that this reaction involves a transient pentacovalent phosphorus intermediate, as shown below.



D. MODIFICATION

The trialkyl phosphine oxide can be made from the oxidation of trialkyl phosphine by nitric acid.[4]

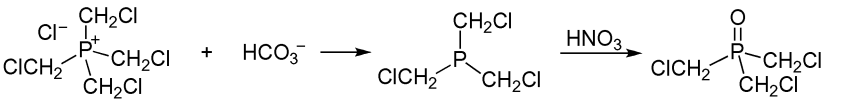
E. APPLICATIONS

This reaction can be used to synthesize different trialkyl- or triarylphosphine oxides.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



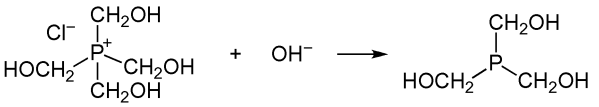
Reference 4.

Preparation of Tri-(Chloromethyl)phosphine

Tetra-(chloromethy1)-phosphonium chloride (5 g) in 20 mL water was treated with 8 g sodium bicarbonate. The solution became milky and gave a strong formaldehyde reaction with fusion reagent. The phosphine was shaken out with carbon bisulfide, dried over sodium sulfate, and distilled under diminished pressure; b.p. 100°C (7 mmHg). While heated at atmospheric pressure, tri-(chloromethyl)phosphine decomposes. It is a colorless, mobile liquid with a powerful, benumbing odor and with slight solubility in water.

Preparation of Tri-(Chloromethyl)phosphine Oxide

Tri-(chloromethyl)phosphine (0.75 g) was boiled for 1 h with 4 mL nitric acid. After evaporating on the water bath until the odor of nitric acid had disappeared, a syrup remained that crystallized on cooling to afford pure tri-(chloromethyl)phosphine oxide, m.p. 88–89°C, which is easily soluble in water and alcohol.



Reference 6.

Sodium hydroxide (1.6 g, 0.040 mol) in 25 mL water was added rapidly to 7.6 g tetra-(hydroxymethyl) phosphonium chloride (0.040 mol) in 50 mL water under nitrogen at room temperature in a closed system connected to a gas buret. No gas evolution was observed after stirring 20 h. The solvent was stripped at 50–60°C with water-pump vacuum, and 50 mL ethanol was added and the sodium chloride was filtered under nitrogen. Removal of ethanol in vacuum (45°C) gave 4.8 g tri-(hydroxymethyl) phosphine as clear viscous liquid, in a yield of 97%.

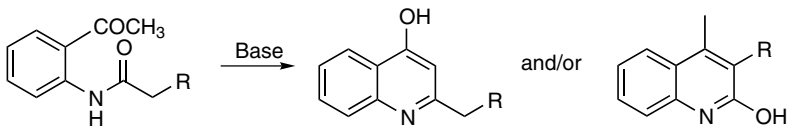
Camps Reaction
(Camps Quinoline Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially discovered by Guareschi in 1894 for the preparation of 2-hydroxy-3-cyano-4-methylquinoline by the condensation of *o*-aminoacetophenone with ethyl cyanoacetate,[1] which was subsequently extended by Camps.[2] It is a formation of hydroxyquinolines by means of the treatment of *N*-acyl *o*-acylanilines with a base in alcohol solution and is generally known as the Camps reaction.[3] Occasionally, it is also referred to as the Camps quinoline synthesis.[4] In this reaction, a variety of substituents can be introduced into position 3 and 4;[5] and *o*-amino derivatives of acetophenone, benzophenone, benzoylacetic ester, benzoylcarbinol, propiophenone,[6] etc. all undergo this reaction. When *o*-amino acetophenone reacts with esters of aliphatic acids, two isomers form simultaneously due to the subtle acidity difference between the methyl group (on acetyl group) and the methylene group (from acyl group on nitrogen). However, when an electron-withdrawing group, such as CN, $COCH_3$, COC_6H_5, CO_2Et, or C_6H_5, exists on the methylene group, only one product forms.[5]

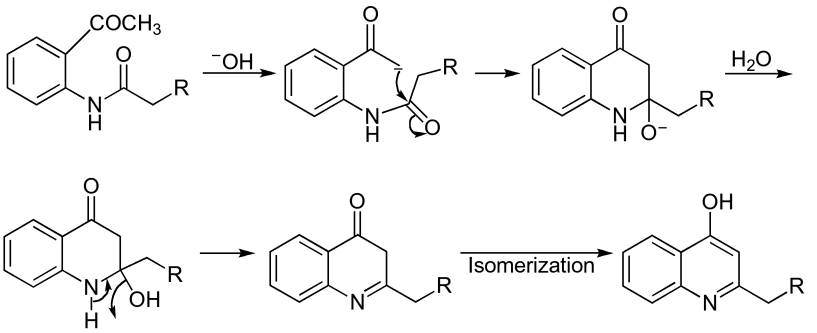
B. GENERAL REACTION SCHEME



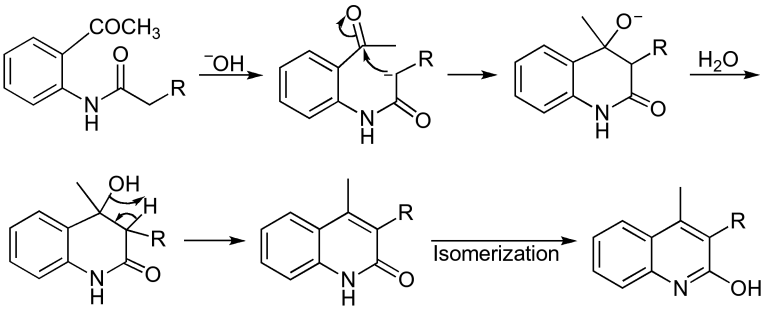
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is the formation of quinoline isomers arising from the deprotonation occurring at different positions (Schemes 1 and 2).



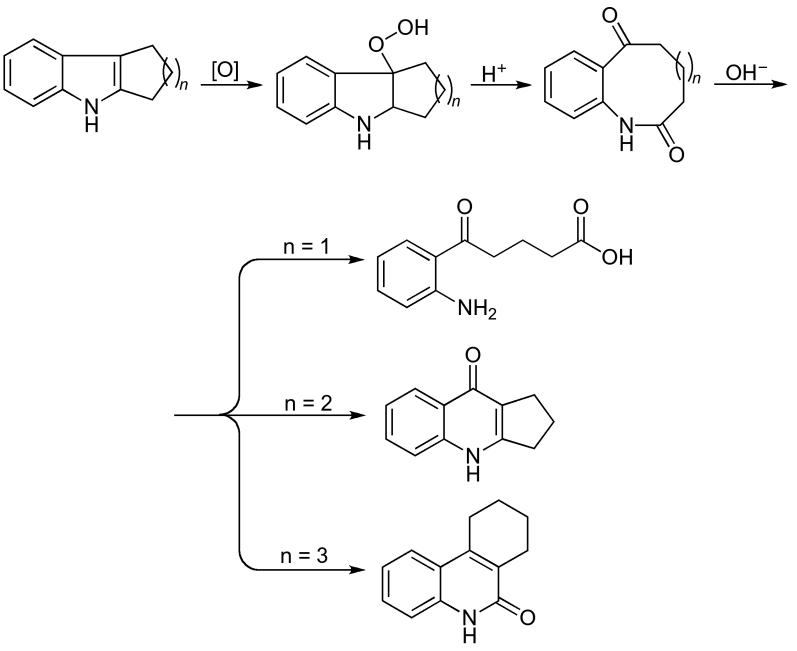
SCHEME 1. *Formation of 2-alkyl-4-hydroxyl quinoline.*



SCHEME 2. *Formation of 3,4-dialkyl-2-hydroxyl-quinoline.*

D. MODIFICATION

o-Amino phenylpropynic acid when treated with base also gives the corresponding substituted quinolines.[7] In addition, the Camps quinoline synthesis has been successfully adapted to fused indole systems. For example, 2,3-cyclopentenoindole, after converting to 1-*aza*-7,8-benzo-cyclooctane-2,6-dione via catalytic oxidation or autoxidation, gives 6-*o*-aminobenzoylbutyric acid when treated with base (or acid). The homologous lactam with base yields 2,3-cyclopenteno-4-quinolone, whereas the homologous 10-membered lactam undergoes an intramolecularly angular condensation to tetrahydrophenanthridone, as illustrated here.[3b]



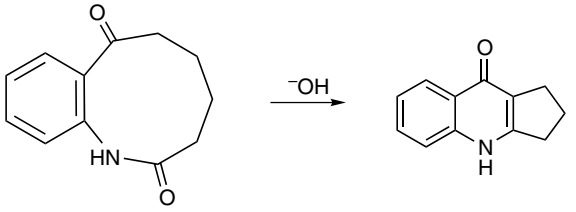
E. APPLICATIONS

This reaction is generally used to synthesize 3- and 4-substituted quinolines.

F. RELATED REACTIONS

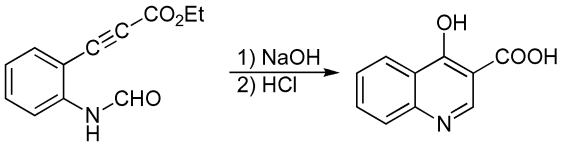
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

When 50 mg 1-*aza*-8,9-benzcyclononene-2,7-dione was dissolved in cold 2 N sodium hydroxide, a yellow solution was obtained that, after a few seconds, warmed up slightly and became colorless. On neutralization, 2,3-cyclopenteno-4-quinolone was obtained as a colorless crystalline, which melted at 298°C under decomposition and progressive charring. On recrystallization from a mixture of benzene and ethanol, the crystals decomposed at 325–327°C. This compound in alcoholic solution gave a red-brown ferric chloride test.



Reference 7.

In a 1-L three-necked flask equipped with a stirrer, a condenser, and a dropping funnel was placed a solution of 4.0 g ethyl *o*-formamidophenylpropiolate (0.018 mol) in 71 mL absolute ethanol. The stirred, light green solution was warmed in an oil bath at 70°C, and 494 mL water was added dropwise over a 30-min period. During the addition, the temperature of the heating bath was raised gradually so that as the last the water was being added the solution was refluxing. Sodium hydroxide (8.24 g, 0.21 mol) in 82 mL water was added to the stirred, boiling solution, which thereupon displayed a strong, greenish blue fluorescence. After being heated under reflux for 2 h, the solution, which had turned light green, was cooled in an ice bath and freed of a small amount of flocculent material by filtration. The filtrate was made acidic to Congo Red with 20% hydrochloric acid. After refrigeration of this mixture, the product was collected by filtration, washed with a small volume of cold water, and dried at 100°C for 1 h. The cream-colored material weighed 2.2 g and yielded 1.1 g 4-hydroxy-3-quinolinecarboxylic acid as white needles after recrystallization from 500 mL absolute ethanol, in a yield of 32%, m.p. 263.0–263.5°C (dec.). The ethanolic mother liquor was saved.

Cannizzaro Reaction

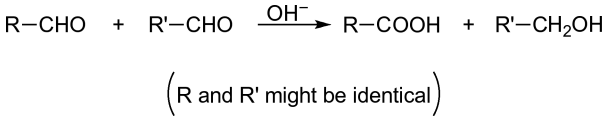
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Cannizzaro in 1853.[1] It is the disproportionation of an aldehyde to an equimolar mixture of primary alcohol and carboxylic salt (i.e., with optimal yield of 50%) when treated with concentrated NaOH or other strong bases that is restricted to aldehydes without α-hydrogens to undergo *Aldol Condensation*. Therefore, it is generally known as the Cannizzaro reaction.[2] The reaction is found to be first order in base and second order in aldehyde; whereas at higher base concentrations, it is second order in both base and aldehyde.[3] In addition, the hydride transfer involved in this reaction takes place directly between aldehydes without intervention of reaction medium. For example, when the reaction is run in D_2O, the recovered alcohol contained no α-deuterium, indicating that the hydrogen comes from another mole of aldehyde and not from the medium.[4] It is interesting that benzyl benzoate can be prepared from the Cannizzaro reaction of benzladehyde.[5] The reaction in which the oxidant aldehyde differs from the reductant aldehyde is referred to as the cross (or crossed) Cannizzaro reaction.[6] The crossed Cannizzaro reaction is quite useful for synthesizing a high yield of alcohol. For example, in reactions of formaldehyde with any other aldehydes, formaldehyde is oxidized to formic acid,[7] especially when the reaction is catalyzed with $Ba(OH)_2 \cdot 8H_2O$ at 100–110°C in an oil bath or under microwave irradiation; under these conditions, more than 80–90% of the alcohol can form without any solvent.[8] For the crossed Cannizzaro reaction, an aldehyde bearing an electron-withdrawing substituent undergoes the reaction at a much faster rate than an aldehyde with an electron-donating group appended. When different aromatic aldehydes (rather than formaldehyde) are used, the aldehyde with an electron-donating group will be reduced, and the aldehyde with the electron-withdrawing group will be oxidized. For example, the following studied aldehydes are arranged in order of diminishing susceptibility to oxidation: *m*-nitrobenzaldehyde,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

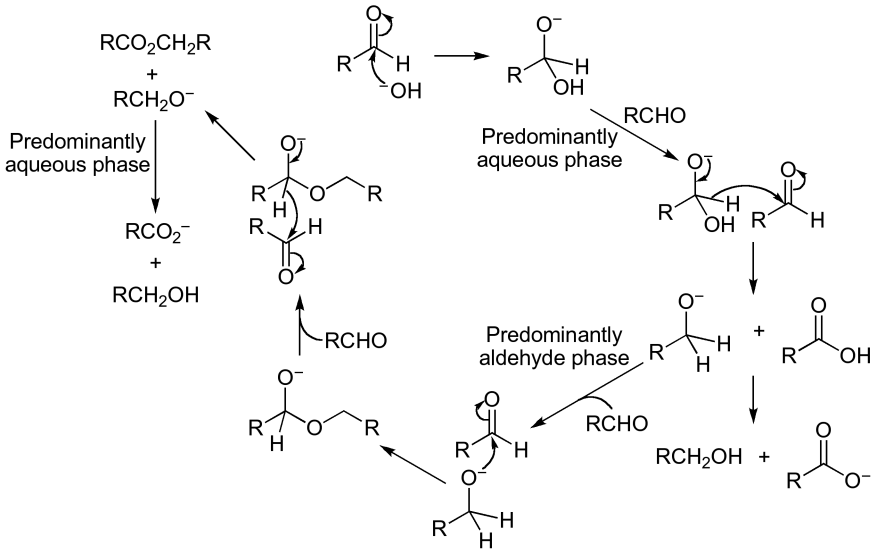
furfural, *p*-bromobenzaldehyde, benzaldehyde, and *p*-anisaldehyde.[9] This order correlates with the combined resonance and inductive influences of the substituent groups on the formyl group, contributing to the ease of (*a*) hydroxide ion attack and (*b*) hydride transfer. The reaction also takes place at high temperature and high pressure (HTHP, e.g., 250°C and 4 MPa) without any catalyst (base) to give more than 50% of methanol when formaldehyde is used.[10] In addition, the reaction also occurs on a solid surface (e.g., MgO[11] and TiO_2[12]) and in gas phase.[13]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because organic aldehyde and aqueous base are not miscible, this reaction is actually a heterogenous reaction.[14] An illustrative mechanism is outlined here.



D. MODIFICATION

This reaction has been modified to occur at HTHP[10] and in solvent-free conditions using $Ba(OH)_2 \cdot 8H_2O$ under microwave irradiation.[8]

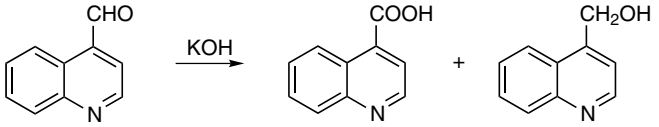
E. APPLICATIONS

This reaction has general application in the preparation of alcohols from aldehydes without α-hydrogens.

F. RELATED REACTIONS

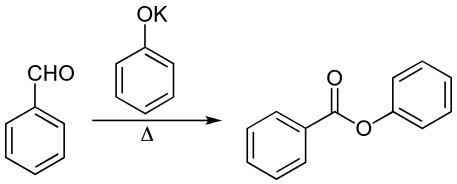
This reaction is related to the *Tishchenko Reaction*, *Meerwein-Ponndorf-Verlay Reduction*, and *Oppenauer Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 15.

A mixture of 0.01 mol cinchoninaldehyde and 0.01 mol potassium hydroxide was heated for 1–3 h on a steam bath; then the mixture was cooled and filtered to remove the insoluble by-product (which was purified by crystallization from aqueous pyridine and was proved to be hydrobenzoin from aldehyde). The aqueous alkaline filtrate was thoroughly extracted with ether to remove all the quinolyl-4-methanol formed. Finally, the aqueous solution left from the ether extraction was made neutral to Congo Red paper with hydrochloric acid and was chilled to precipitate, affording cinchoninic acid, which was crystallized from benzene as white crystals, m.p. 99–100°C.



Reference 14.

To a 50-mL flask was added 1.32 g anhydrous potassium phenolate (0.01 mol) and 50 g benzaldehyde (0.47 mol). The flask was sealed off and was then heated at 100°C for 18 h. The reaction mixture was filtered, and the filtrate was distilled in a Hickman still to remove residual salts. The distillate was redistilled through a Vigreaux distilling column at 10 mmHg to yield 15 g benzyl benzoate.

Other references related to the Cannizzaro reaction are collected in the literature.[16]

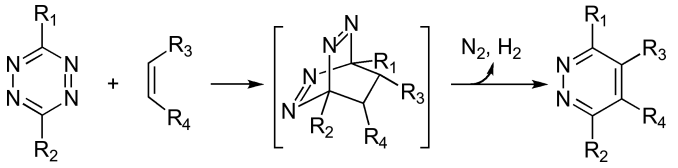
Carboni-Lindsey Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Carboni and Lindsey in 1959.[1] So far, more than 800 articles have been published on this topic,[2] including several reviews.[3] It is the reaction between tetrazines and a variety of unsaturated compounds, including dienes, acetylenes, and aliphatic and aromatic olefins, to yield 3,6-disubstituted pyridazines with the evolution of 1 equivalent of nitrogen,[1] and is generally known as the Carboni-Lindsey reaction.[2,4] This reaction apparently proceeds by the 1,4-addition of the -C–N-N–C- diene system of the tetrazine to an appropriate olefinic or acetylenic dienophile, followed by a rapid *retro-Diels-Alder Reaction*, leading to the final product accompanyed by the loss of nitrogen.[5] The Carboni-Lindsey reaction can be moderated by lowering the reaction temperature or by employing diluents such as ether or benzene.[1] Completion of the reaction is signaled by the disappearance of the characteristic red or violet-red tetrazine color and by the cessation of nitrogen evolution.[1] Because this reaction is dominated by a HOMO (dienophile)-LUMO (diene) interaction,[5a] the Carboni-Lindsey reaction takes place with a complementarily inverse electron demand of diene/dienophile substituent effects,[6] by which dienophiles containing electron-releasing substituents usually facilitate the reaction, and those with electron-attracting groups exhibit a retarding effect.[1]

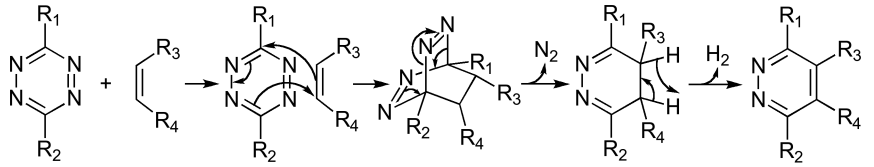
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Essentially, this reaction involves a *Diels-Alder Reaction* between tetrazine and a dienophile to form a bicyclic intermediate, which subsequently undergoes a *retro-Diels-Alder Reaction* accompanyed by the evolution of nitrogen to release the ring strain, as displayed below.[7]



D. MODIFICATION

The original reaction has been modified extensively using a variety of diene analogues to react with unsaturated compounds followed by the evolution of a volatile molecule, as reviewed in Ref. 3c.

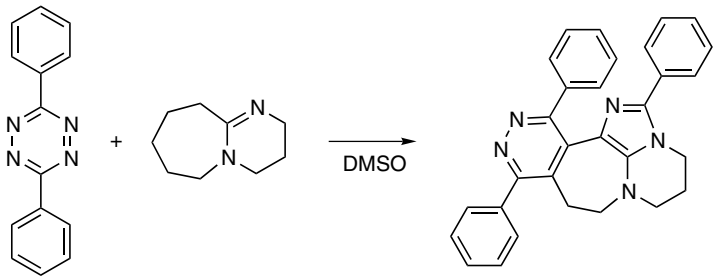
E. APPLICATIONS

This reaction has very broad application in the preparation of a variety of heterocycles.

F. RELATED REACTIONS

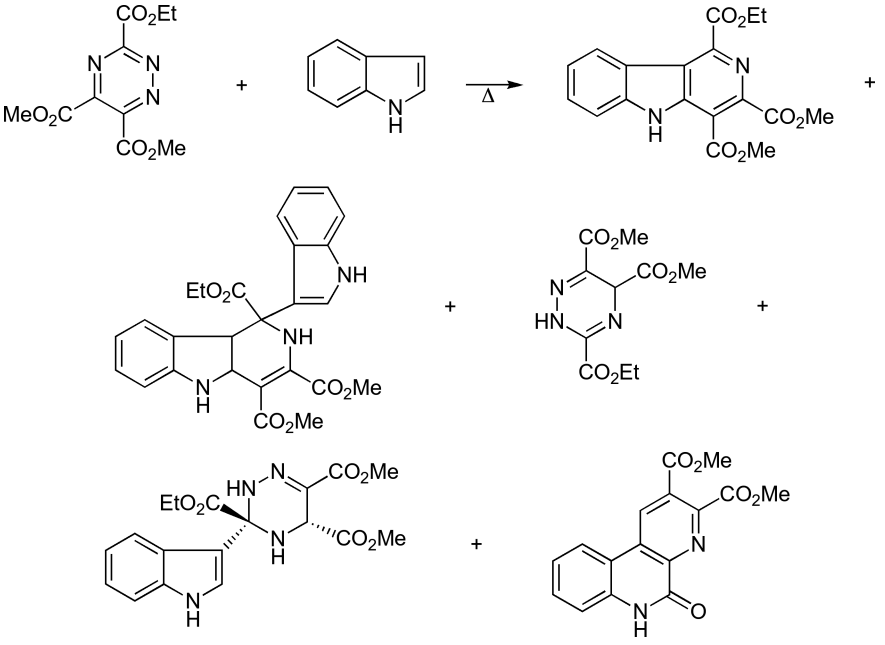
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

To a solution of 1.68 g diphenyltetrazine (7.18 mmol) in 15 mL dimethyl sulfoxide was added 0.219 g DBU (1.44 mmol). This mixture was then heated at reflux under nitrogen for 2 h. The solution was cooled to room temperature, and 20 mL dichloromethane was added followed by 15 mL H_2O. The aqueous layer was removed, and the organic layer was washed twice with H_2O. The white precipitate, if any, was filtered and washed with several small amounts of dichloromethane. The concentrated organic layer was submitted to flash chromatography on silica gel with EtOAc followed by EtOAc:MeOH (9:1) to afford 0.295 g 2,8,11-triphenyl-3*H*,4*H*,5*H*,6*H*,7*H*-imidazo[4,5,1-*ef*][1,3]-diazaperhydroino[1,2-*f*] pyridazino[4,5-*d*]azepine as a yellow solid, m.p., 245–248°C (dec.).



Reference 9.

Preparation of Triazine

Ethyl oxalamidrazonate (7.5 mmol) was suspended in 50 mL anhydrous ethanol under argon with gentle heating. This suspension was then added dropwise with stirring to a solution of the dione (1 eq. unless otherwise noted) in 50 mL anhydrous ethanol also under argon at room temperature. After completion of the addition, stirring was continued at room temperature for 16 h, and the mixture was subsequently refluxed for 1 h. The solvent was removed in vacuo, and the crude product was purified by flash chromatography on silica gel to give corresponding triazine.

General Procedure for the Reaction of Indole with 1,2,4-Triazines and 1,2-Diazines

Indole (50 mg, 0.43 mmol), triazine or diazine, and the anhydrous solvent in appropriate amounts were placed in a reaction vessel consisting of a Pyrex glass tube (5 mm i.d. $\times$ 150 mm) sealed at one end. The vessel was capped with a septum and purged with argon. A balloon filled with argon on a syringe needle was inserted through the septum to maintain an argon atmosphere without allowing pressure build up during the reaction. The vessel was then placed in a sand bath pre-equilibrated to the desired temperature. For a representative reaction of indole (1.2 eq.) and 3-carbethoxy-5,6-dicarbomethoxy-1,2,4-triazine at 80°C for 48 h under argon, the following products were obtained after flash chromatography on silica gel and final centrifugal TLC purification, which are listed in the order of elution. (*a*) 1-Carbethoxy-3,4-dicarbomethoxy-γ-carboline (CH_2Cl_2/EtOAc = 9:1, 33% yield), yellow solid, m.p., 144–145°C; (*b*) l-carbethoxy-3,4-di-carbomethoxy-1-(3-indolyl)-2H-γ-carboline, mixture of tautomers eluted with CH_2Cl_2/EtOAc (9:l), in a yield of 21%; (*c*) 3-carbethoxy-5,6-dicarbomethoxy-2,5-dihydro-l,2,4-triazine was eluted and purified with CH_2Cl_2/EtOAc (4:l) as colorless oil, in a yield of 19%; (*d*) 3-carbethoxy-5,6-dicarbomet hoxy-3-(3-indolyl)-2,3,4,5-tetrahydro-l,2,4-triazine was eluted and purified with CH_2C1_2/EtOAc (4:1) as a white solid, in a yield of 6%, m.p. 217–218°C; (*e*) dimethyl 5-oxobenzo[f][1,7]naphthyridine-2,3-dicarboxylate was eluted and purified with CH_2Cl_2/MeOH (19:l) as a white solid, in a yield of 20%, m.p. 234–235°C.

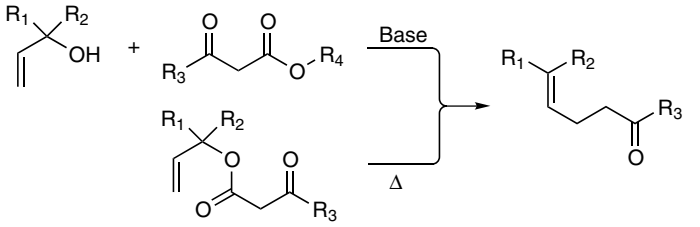
Carroll Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Carroll in 1940.[1] It is a well-established thermal rearrangement for preparing γ, δ-unsaturated ketones from allyl acetoacetates or base-catalyzed reactions between allyl alcohols and β-ketoesters. Therefore, it is generally known as the Carroll rearrangement.[2] This rearrangement in principle is a complement to the *Claisen Rearrangement*[3] and has not found widespread application in organic synthesis due to the harsh conditions[3,4] (temperatures of 130–220°C after *in situ* preparation of the β-ketoester) and lack of an efficient method for β-ketoesters.[3] However, when the formed β-ketoesters are treated with 2 eq. of base (e.g., LDA), the enolate form of the β-ketoesters can rearrange in much milder conditions.[3,5] It was found that the β-ketoesters from secondary or tertiary alcohols rearrange faster than those from primary alcohols.[4] On the other hand, the adsorption of the tertiary allylic acetoacetate on neutral alumina will also facilitate the Carroll rearrangement.[6] Recently, it was found that this rearrangement can be catalyzed by a ruthenium complex with high regioselectivity, but a lower regiospecificity compared to the uncatalyzed Carroll rearrangement.[7]

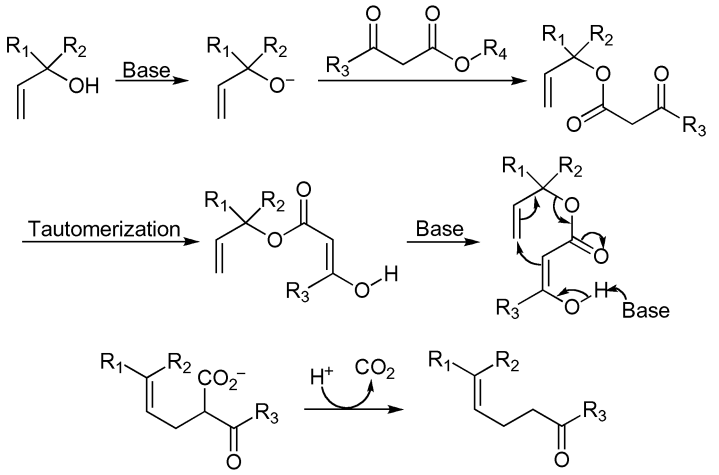
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The reaction mechanism is given here by showing the reaction between an allylic alcohol and a β-ketoester in the presence of a general base.



D. MODIFICATION

The rearrangement of allyl β-ketoesters absorbed on an alumina surface at 60°C is one of the modifications,[5] other modifications include a ruthenium complex catalyzed rearrangement.[6]

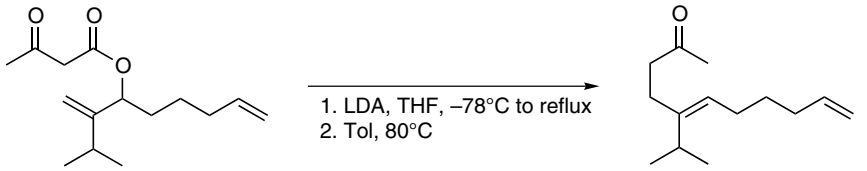
E. APPLICATIONS

This reaction has general application in the preparation of γ,δ-unsaturated ketones.

F. RELATED REACTIONS

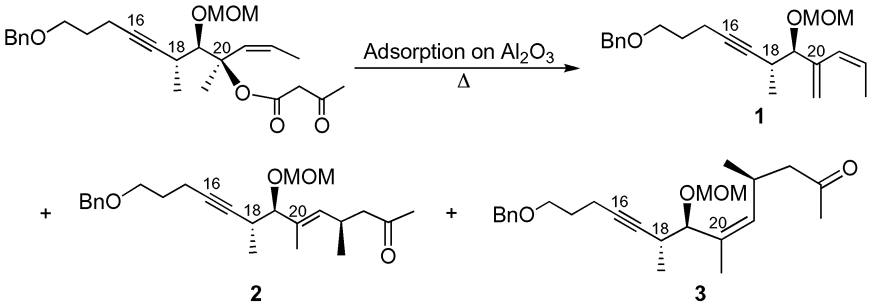
This reaction is related to the *Claisen Rearrangement*, *Ficini-Claisen Rearrangement*, and *Overman Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

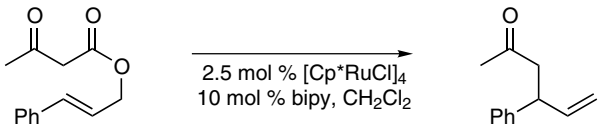
At 0°C, 21.14 mL *n*-BuLi (0.053 mol) was added to 53.0 mL THF containing 7.85 mL $(i\text{-Pr})_2NH$ (0.056 mol). The resulting solution was stirred for 30 min and then cooled to −78°C. Then 4.44 g 2-methyl-3-methylene-8-penten-4-yl acetoacetate (0.018 mol) in 20 mL THF was added dropwise to the LDA solution at −78°C. The reaction mixture was warmed to room temperature and stirred for 4 h followed by 1 h of refluxing, which was then cooled to room temperature, concentrated *without heating*, and taken up in water. The water layer was then washed with Et_2O. The Et_2O layer was further washed with 0.01 M NaOH. The combined aqueous layers were diluted with CH_2Cl_2. Then, 1 M HCl was added slowly to this H_2O/CH_2Cl_2 mixture with rapid stirring. Upon complete acidification, the two layers separated. The CH_2Cl_2 layer was separated, and the water layer was further extracted with CH_2Cl_2. The combined CH_2Cl_2 layers were washed with brine, dried over Na_2SO_4, and concentrated *without heating*. The residue was dissolved in 20 mL toluene and heated at 80°C for 1 h. The solution was concentrated and purified by flash chromatography on silica gel (80:1 hexanes/EtOAc) to give 2.25 g 5-(1-methylethyl)-5E,10-undecadien-2-one with a yield greater than 75%.



Reference 6.

To a solution of 552 mg (1*R*,2*R*,3*R*)-8-benzyloxy-2-methoxymethoxy-1,3-dimethyl-1-((*Z*)-prop-1-enyl)oct-4-ynyl 2-oxobutanoate in 30 mL CH_2Cl_2 was added 17 g neutral alumina. The solvent was evaporated under reduced pressure, and the resulting dry powder was stirred at 60°C. After 12 h, the solid reaction mixture was suspended in EtOAc, filtered through Celite, and thoroughly washed with EtOAc. The filtrate was evaporated under reduced pressure, and analysis of the GC-MS and ^1H NMR spectra of the crude material indicated the formation of compounds (6*R*,7*R*,9*Z*)-1-benzyloxy-7-methoxymethoxy-6-methyl-8-methyleneundec-9-en-4-yne (**1**), (4*R*,5*E*,7*R*,8*R*)-13-benzyloxy-7-methoxymethoxy-4,6,8-trimethyltridec-5-en-9yn-2-one (**2**), and (4*S*,5*Z*,7*R*,8*R*)-13-benzyloxy-7-methoxymethoxy-4,6,8-trimethyltridec-5-en-9-yn-2-one

(**3**) in a 4:92:4 ratio. The crude material was purified by flash chromatography (petroleum ether/EtOAc gradient, 90:10 to 80:20) to afford 37 mg (9%) of **1**, R_f = 0.76 (petroleum ether/EtOAc, 70:30); 305 mg (61%) of **2** as colorless oils, R_f = 0.56 (petroleum ether/EtOAc, 70:30); and 17 mg (3%) of **3**, R_f = 0.50 (petroleum ether/EtOAc, 70:30).



Reference 7b.

In a Schlenk tube under argon, $[Cp^*RuCl]_4$ (2.5 mol %) and bipyridine (10 mol %) were dissolved in 2 mL methylene chloride. The resulting deep purple solution was allowed to stir briefly before the addition of 1 mmol of allyl-β-ketoester in 3 mL methylene chloride via cannula. The reaction was allowed to stir under argon until the resulting dark burnt orange solution returned to purple ($\sim$1.5 h). Following solvent evaporation, the crude product was purified via flash chromatography (SiO_2, 15% Et_2O/hexane), providing the products in a 94% yield as a pale yellow oil with >95% purity.

Other references related to Carroll Rearrangement are cited in the literature.[9]

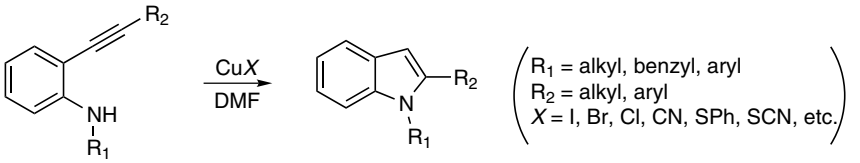
Castro Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Castro in 1966.[1] It is the synthesis of indoles by cuprous halide catalyzed intramolecular cyclization of *o*-ethynylanilines or the coupling between *o*-haloaniline and cuprous mono-substituted acetylide and is generally known as the Castro indole synthesis.[2] In this reaction, the *o*-ethynylanilines are readily available by either *Castro-Stephens Coupling* or *Sonogashira Coupling* from *o*-haloanilines and acetylene or mono-substituted acetylenes. This reaction is especially suitable for the preparation of 2-substituted indoles and can be applied as an alternative for *Fischer Indole Synthesis*.[1] During the coupling, the reactivity of *o*-haloanilines are found to be on the order of I > Br > Cl >> fluorine, while the catalytic efficiency of cuprous salts varies along with the counteranions and decreases in the sequence of Cl > Br > I > CN > SPh > SCN.[1] In addition, this reaction is distinctly affected by the solvent effect. For example, (*o*-amino)phenylacetylide, slightly soluble in DMF at room temperature, cyclizes intramolecularly in DMF to give indole exclusively; however, the same starting material, soluble in warm pyridine, affords only either uncyclized acetylene or tolane (i.e., diphenylacetylene) in pyridine.[1] In addition, *o*-aminotolane will not cyclize in the presence of CuI or cuprous phenylacetylide in pyridine, but undergoes the cyclization smoothly when treated with CuI in DMF.[1] Therefore, indoles can be synthesized in two steps: *Castro-Stephens Coupling* in pyridine and Castro indole synthesis in DMF.[1]

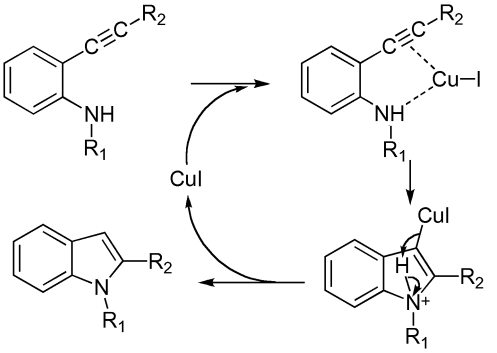
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because no mechanism about Castro indole synthesis is available, a tentative illustration about the reaction mechanism is provided below.



D. MODIFICATION

This reaction has been modified by the treatment of *N*-benzyl (2-trimethylsilylethynyl)aniline in DMF with CuI and $CaCO_3$ to give *N*-benzylindole with concurrent elimination of the trimethylsilyl group.[2c]

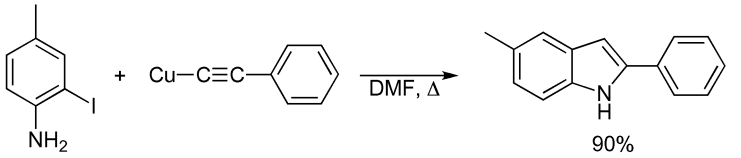
E. APPLICATIONS

This reaction has general applications in the preparation of indoles, especially the 2-substituted indoles.

F. RELATED REACTIONS

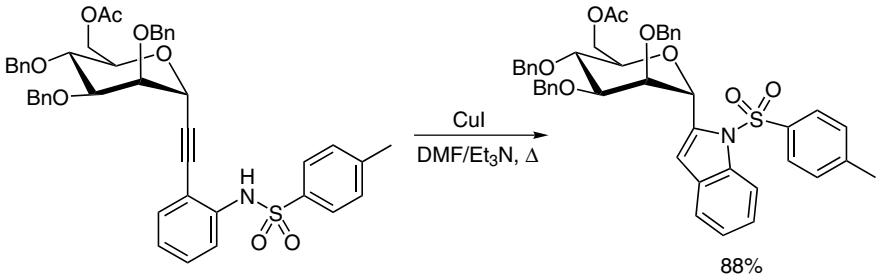
This reaction is related to the *Castro-Stephens Coupling*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a 200-mL, three-necked flask equipped with a nitrogen inlet, a reflux condenser connected to a mercury trap, and a magnetic stirring bar was added 1.86 g cuprous phenylacetylide (0.011 mol) and 80 mL dimethylformamide (DMF). The flask and contents were thoroughly flushed with nitrogen with stirring. Under nitrogen 2.56 g 2-iodo-4-methylaniline (0.011 mol) in 20 mL DMF was added. The resulting mixture was stirred at 120°C for 22 h. The dark reaction mixture was filtered, and the filtrate was concentrated to dryness in vacuo in a rotary evaporator. The resulting residue was taken up in chloroform, filtered, added to petroleum ether (b.p. 60–70°C), and concentrated. The residue was purified by recrystallization from chloroform-petroleum ether to yield 2.04 g 5-methyl-2-phenylindole, in a yield of 90%, m.p. 214–214.5°C.



Reference 2a.

To a solution of 3.71 g 1-(6-*O*-acetyl-2,3,4-tri-*O*-benzyl-α-D-mannopyranosyl)-2-*o*-(*p*-toluenesulfoamidyl)phenylethyne (4.99 mmol) in 60 mL Et_3N and 30 mL DMF was added 187 mg CuI (0.98 mmol). After stirring at 80°C for 30 min, water was added. The mixture was extracted three times with EtOAc. The combined organic layer was subsequently washed with aqueous NH_4Cl solution, water, and brine each for two times. Upon removal of the solvent, the residue was purified by silica gel column chromatography using ether/hexanes (1:2) to give 3.28 g 2-(6-*O*-acetyl-2,3,4-tri-*O*-benzyl-α-D-mannopyranosyl)-1-(*p*-toluenesulfonyl) indole, in a yield of 88%.

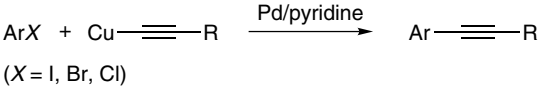
Castro-Stephens Coupling

(Stephens-Castro Coupling, Castro Coupling)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Castro and Stephens in 1963.[1] It is the preparation of arylacetylenes by the coupling of cuprous acetylides with aryl halides in boiling pyridines.[2] Therefore, this reaction is generally known as the Castro-Stephens coupling,[3] Stephens-Castro coupling,[4] or simply as the Castro coupling.[5] Currently, this coupling is one of the most commonly used methods for the synthesis of aryl acetylenes.[6] Moreover, under the Castro-Stephens coupling condition, acetylenes also couple with vinyl halides[7] or even allyl halides[8] and amines,[1] by which indoles are formed in the coupling with amines.[1,9] It is reported that the reactivity of vinyl halide in this coupling is in the order of I > Br > Cl,[10] and the reactivity order of aryl halides decreases in the sequence of I > Br > Cl >> F, while the efficacy of the cuprous species varied with the nature of the ligand in the sequence Cl> Br > I > CN > SPh > SCN. However, this coupling has also shown some limitations, including the poor coupling of terminal acetylenes with an electron-withdrawing group[11] and the coupling of acetylenes with an epoxide or quinone group.[12]

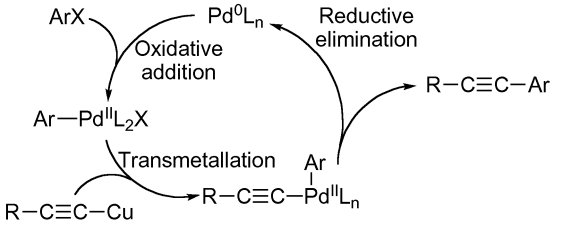
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A mechanism similar to other alkynylative couplings is illustrated here.[3]



D. MODIFICATION

This coupling has been modified to undergo in the presence of cuprous iodide and triethylamine;[13] in the presence of bis(triphenylphosphine) palladium(II) chloride, cuprous iodide, and triethylamine;[14] or under the conditions of catalytic CuI, Ph_3P, K_2CO_3, and DMF at 120°C.[15]

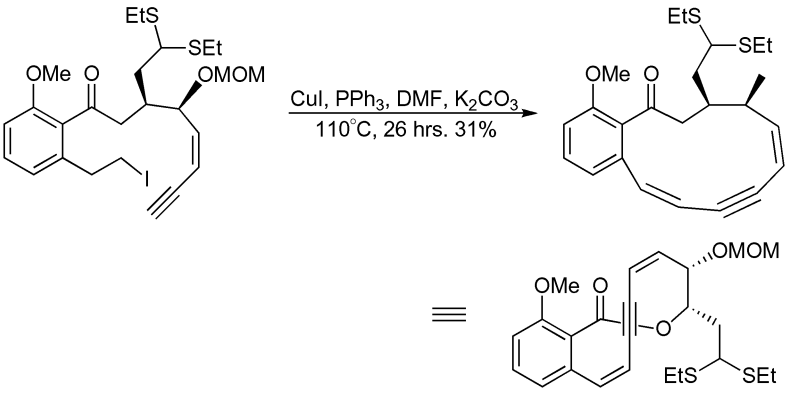
E. APPLICATIONS

This reaction has been widely used for the preparation of aryl acetylenes and vinyl acetylenes.

F. RELATED REACTIONS

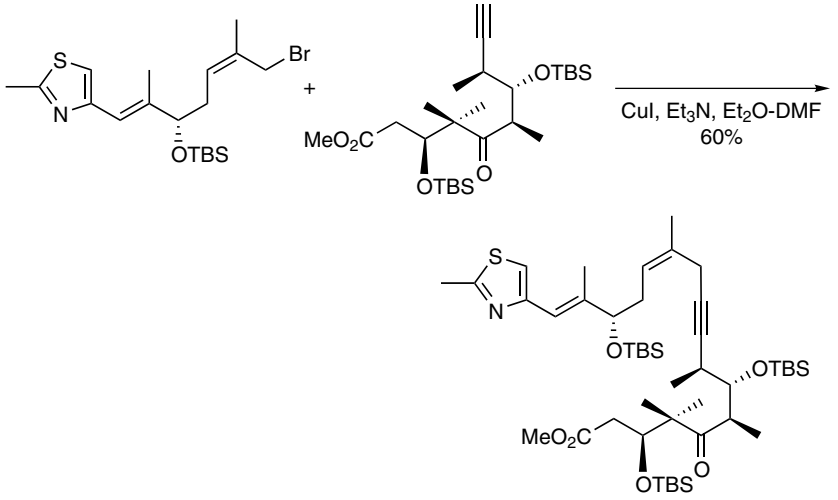
This reaction is closely related to the *Sonogashira Coupling*, which uses a catalytic amount of palladium and copper, whereas the Castro-Stephens coupling uses a stoichiometric amount of copper.[16]

G. CITED EXPERIMENTAL EXAMPLES



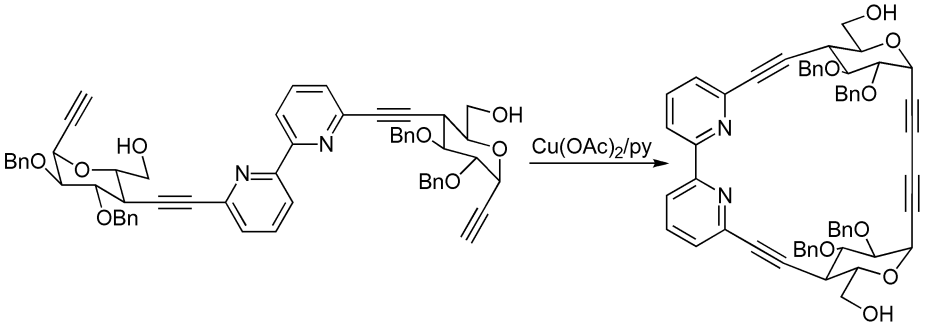
Reference 17.

A mixture of 54 mg (1*E*,3*Z*)-(1*S*,2*S*)-2-(2-iodovinyl)-6-methoxybenzoic acid 1-(2,2-bis-ethylsulfanylethyl)-2-methoxymethoxyhex-3-en-5-ynyl ester (91 μmol), 2 mg copper(I)-iodide (11 μmol), 6 mg triphenylphosphine (23 μmol), and 22 mg K_2CO_3 (159 μmol) in 20 mL dry DMF was heated at 110°C for 26 h. Extractive workup with ether and column chromatography (EtOAc/hexanes = 1:9) furnished 13 mg (1*Z*,9*Z*)-(7*S*,8*S*)-7-(2,2-bis-ethylsulfanylethyl)-4-methoxy-8-methoxymethoxy-8,9-dihydro-6-oxabenzocyclododeca-1,9-dien-11-ynone as a colorless oil, in a yield of 31%.



Reference 18.

To a stirred solution of acetylene (70.0 mg, 0.135 mmol) in 1.0 mL Et_2O and 0.4 mL DMF at room temperature were added 18.8 μL Et_3N (0.135 mmol) and 25.7 mg CuI (0.135 mmol). After the mixture became clear (~5 min), a solution of allyl bromide (29.1 mg, 0.068 mmol) in 1.0 mL Et_2O was added. The solution was stirred for 18 h, quenched with 5 mL saturated aqueous $Na_2S_2O_3$, and extracted with Et_2O (3 × 2 mL). The combined extracts were dried over $MgSO_4$ and concentrated in vacuo; the residue was purified by chromatography on silica gel, eluting with 50–60% CH_2Cl_2/hexane to give 35.6 mg of coupling compound as a colorless oil, in a yield of 60%.



Reference 19.

A degassed solution of 449 mg $Cu(OAc)_2$ (2.47 mmol) in 450 mL pyridine was treated at 50°C under nitrogen with a solution of 112 mg 3,3′-[(2,2′-bipyridine-6,6′-diyl)diethyne-2,1-diyl]-bis-[2,6-anhydro-4,5-di-*O*-benzyl-3-deoxy-D-glycero-D-gulo-oct-7-ynitol] (0.12 mmol) in 1 mL pyridine within 10 h, stirred for 20 h, and evaporated. The residue was dissolved in 20 mL CH_2Cl_2 and 7 mL saturated aqueous KCN solution and stirred for ~12 h. Extraction with CH_2Cl_2 and following double flash chromatography (CH_2Cl_2/MeOH, 49:1; and $CHCl_3$/AcOEt, 4:1) gave 66 mg 2,6:11,15-dianhydro-4,5,12,13-tetra-*O*-benzyl-3,14-C-[(2,2′-bipyridine-6,6′-diyl)diethyne-2,1-diyl]-3,7,8,9,10,14-hexadeoxy-D-erythro-l-ido-l-gulo-hexadeca-7,9-diynitol as a white solid, in a yield of 59%, $R_f = 0.26$ (EtOAc), m.p. 189–191°C (dec.).

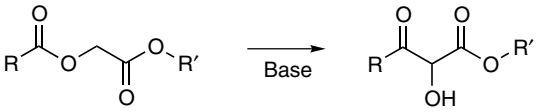
Chan Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Chan in 1984.[1] It is a base-induced rearrangement of α-acyloxy-acetates to α-hydroxy-β-keto-esters[2] and is thus known as the Chan rearrangement.[2,3] It should be pointed out that under similar conditions amino ketone can also be prepared.[4] The intermediate enediolate formed in the presence of an excess amount of base (usually LDA) can react with Me_3SiCl or Ac_2O to afford corresponding trimethylsilyl or acetyl derivatives.[1,2] This reaction is a convenient means for assembling an array of three contiguous oxygenated carbons[2] and has successfully been applied to the syntheses of some natural products, including the indole-bisoxazole fragment of diazonamide A,[4] (+)-aplasmomycin,[5] boromycin,[6] taxol,[7] and polyoxazole.[4]

B. GENERAL REACTION SCHEME

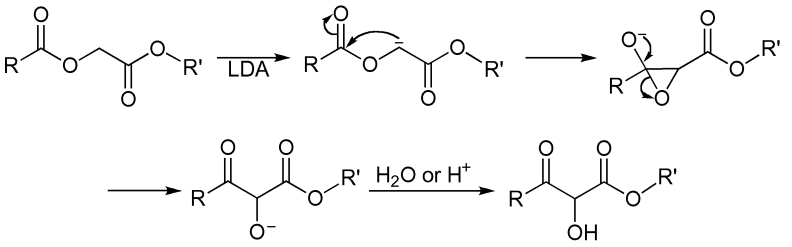


C. PROPOSED MECHANISMS

This reaction involves the deprotonation of α-(acyloxy) acetate, and the resulting carbanion adds to the carbonyl moiety of the α-acyloxy group to form an epoxide, which

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

subsequently undergoes fragmentation to give the α-hydroxy-β-keto ester,[1,2] as displayed here.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has a general application in the synthesis of compounds containing three contiguous oxygenated carbons[2] and has been successfully applied to the preparation of diazonamide A,[4] aplasmomycin,[5] boromycin,[6] taxol,[7] etc.

F. RELATED REACTIONS

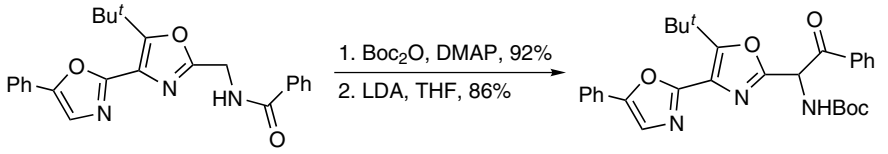
G. CITED EXPERIMENTAL EXAMPLES

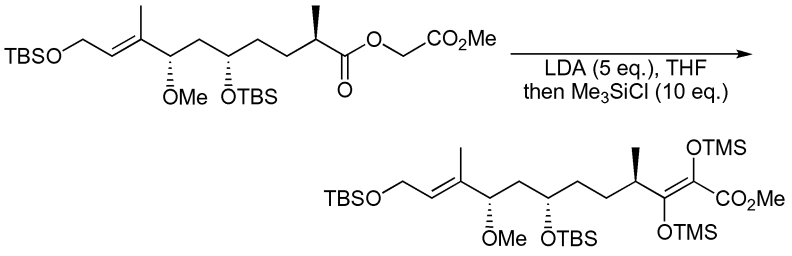


Reference 4.

A solution of 32 mg *N*-(5′-*tert*-butyl-5-phenyl-[2,4′]bioxazolyl-2′-ylmethyl)-benzamide (0.080 mmol) in 1 mL THF was treated with 10 mg DMAP (0.089 mmol) and 35 mg Boc_2O (0.16 mmol). The reaction mixture was stirred for 19 h, diluted with EtOAc, washed with 10% HCl, saturated $NaHCO_3$, and dried over $MgSO_4$. Upon filtration and concentration, the residue was purified by column chromatography on SiO_2 (EtOAc/hexanes, 1:19–1:9) to give 37 mg of the oily imide, in a yield of 92%. $R_f = 0.64$ (EtOAc/hexanes, 1:1).

A solution of 0.050 mL *i*-Pr_2NH (0.36 mmol) in 1 mL THF was treated with 0.2 mL 1.6 M BuLi in hexane (0.32 mmol) and cooled to –78°C. A solution of 35 mg above imide (0.070 mmol) in 1 mL THF was added, and the reaction mixture was stirred for above 30 min,

diluted with EtOAc, washed with 10% HCl, saturated $NaHCO_3$, and dried over Na_2SO_4. After filtration and evaporation, the residue was purified by column chromatography on SiO_2 (EtOAc/hexanes, 1:9–3:7) to give 30 mg of oily [1-(5′-*tert*-butyl-5-phenyl-[2,4′] bioxazolyl-2′-yl)-2-oxo-2-phenylethyl]-carbamic acid *tert*-butyl ester, in a yield of 86%. $R_f = 0.64$ (EtOAc/hexanes, 1:1).



Reference 2.

To a solution of LDA, prepared by the addition of 43 μL 1.6 M *n*-BuLi in hexane (0.072 mmol) to a solution of 9.4 μL diisopropylamine (0.072 mmol) in 0.2 mL THF at 0°C over 15 min was added a solution of 8 mg ester (0.014 mmol) in 0.15 mL THF. The mixture was stirred for 1 h and then cooled to –78°C; 13.5 μL TMSCl (0.11 mmol) was then added. After being stirred for 10 min, the solution was allowed to warm to 0°C and was stirred for an additional 15 min. The mixture was poured into hexane, and the resulting solution was washed with pH 7 phosphate buffer (3 × 5 mL). The extracts were combined, washed with brine, and dried over Na_2SO_4. Concentration gave 13 mg of crude product as a clear oil.

Chapman Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mumm and co-workers in 1915[1] and was extensively investigated by Chapman in 1920s and 1930s.[2] It is the thermal rearrangement of aryl imidates to *N*, *N*-diaryl amides, and is generally known as the Chapman rearrangement.[3] Occasionally, this reaction is also referred to as the Beckmann-Chapman rearrangement.[4] It was found that this rearrangement follows approximately a first-order kinetics[5] and proceeds readily with high yields in either polar or nonpolar solvents,[2e] but it is accelerated by polar solvents. In addition, this reaction can even take place in a solid state at one-fifteenth to one-fifth the rate of that estimated in solution.[4c] In fact, it is an intramolecular nucleophilic aromatic substitution that proceeds stereospecifically with migration of that aryl ring attached to oxygen, and the *ortho* substituents on the aryl ring connecting to oxygen atom have been shown to enhance the migration rate. This effect is known as steric acceleration due to the hindered rotation (SAHR) effect,[3l,3m] as the free rotation will restrict the formation of a four-membered ring in the transition state.[3l] Moreover, it is also found that a *para* electron-donating group also increases the migration rate, whereas a *para* electron-withdrawing group (Cl, NO_2, etc.) decreases the reaction rate.[4c] This rearrangement has been used for the preparation of substituted *N*-phenylanthranilic acids.[3r] It should be pointed out that if the migrating aryl moiety has an α-acidic hydrogen at the *ortho* position, then an "abnormal" Chapman Rearrangement also occurs.[3q]

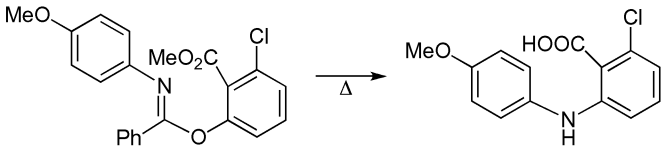
The Preparation of 2,6-di-*t*-Butylphenyl *N*-Phenylbenzimidate

Exactly 10.0 g 2,6-di-*t*-butylphenol (0.0486 mol) and 0.1 g triphenylmethane were dissolved in 150 mL tetrahydrofuran. While the solution was stirred under nitrogen, ~31 mL 1.6 *M* butyllithium in hexane was added, whereupon the red color of the triphenylmethyl carbanion just appeared. Then 10.47 g *N*-phenylbenzimidoyl chloride (0.0486 mol) in 75 mL tetrahydrofuran was added, and the system was stirred overnight at room temperature under nitrogen. After the reaction mixture was combined with 400 mL ethyl ether, it was extracted with water, dried with anhydrous magnesium sulfate, and freed of solvent on a rotary evaporator to give 19.35 g of a viscous red oil. Chromatography on 400 g alumina, using hexane as the elution solvent, afforded some 2,6-di-*t*-butylphenol and impure 2,6-disubstituted phenyl *N*-phenylbenzimidates. Two recrystallizations from methanol afforded 4.28 g imidate as colorless plates, in a yield of 23%, m.p. 127.5–128.5°C.

The Chapman Rearrangement

A 1.0 g 2,6-disubstituted phenyl *N*-phenylbenzimidate was sealed in a glass tube in air and heated at 305°C for 6 h. The resulting cooled mass was chromatographed to give *N*-(2,6-di-*t*-butylphenyl)benzanilide with a broad melting point of 129–133.5°C.



Reference 3r.

To a solution of NaOEt prepared from 0.11 g sodium (4.7 mmol) and 10 mL absolute ethanol, cooled in an ice bath, was added in rapid succession 0.88 g methyl 2-chloro-6-hydroxybenzoate (4.7 mmol) and a solution of 1.14 g *N*-4-methoxyphenylbenzimidyl chloride (4.7 mmol) in 30 mL dry ether. The reaction mixture was shaken vigorously, whereupon a precipitate of sodium chloride began to form. The mixture was allowed to stand at room temperature for 48 h, the solvent was evaporated, and the residue was diluted with water. The resulting oily solid was removed by extraction with ether, the ethereal solution was dried, and the ether was distilled. The crude imido ester was heated in a nitrogen atmosphere at 210–215°C for 70 min, then dissolved in 10.8 mL ethanol; the alcoholic solution was diluted with 5.4 mL water and 5.4 mL of a 1 *M* ethanolic sodium ethoxide. The solution was refluxed for 1.5 h, the alcohol was evaporated on a steam bath, and the aqueous solution was acidified with dilute HCl. The dark oil that formed was separated by decantation, and the crude benzoate of the substituted anthranilic acid was dissolved in 22 mL ethanol. A solution of 7.2 g sodium hydroxide in 7.2 mL water was added, and the mixture was refluxed for 1 h. The alcohol was evaporated, and the solution was then acidified. The brown solid was extracted *exhaustively* with boiling water to remove the benzoic acid, and the remaining brown solid was recrystallized from aqueous ethanol. The yellow needle-like crystals of *N*-(4′-methoxyphenyl)-6-chloroanthranilic acid, in a total amount of 0.36 g, was obtained, in a yield of 27.7%, m.p., 139.5–140.5°C (dec).

Other references related to the Chapman rearrangement are cited in the literature.[6]

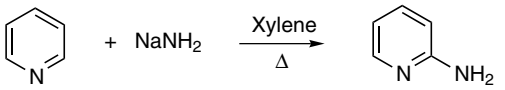
Chichibabin Amination

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Chichibabin in 1914.[1] It is the preparation of 2-aminopyridine from pyridine and sodium amide in boiling inert solvent (such as xylene, toluene, and benzene),[2] and is generally known as the Chichibabin amination[3] or Chichibabin reaction.[4] This reaction is a simple method of synthesizing 2-aminopyridine for which the traditional procedure for aromatic amines via nitration and subsequent reduction works poorly for pyridines. Strangely enough, it is found that the yield of 2-aminopyridine depends to a large extent on the condition of the sodium amide used in the synthesis.[5] For example, the purest sodium amide fails to react appreciably with pyridine, whereas less pure sodium amide (commercial product or standing in laboratory for some time) gives good yields. It is possible that the impurities in sodium amide may have the catalytic effect. In this reaction, if the amount of sodium amide is increased, then a second amino group might be introduced to the aromatic ring.[6] However, when both position 2 and 6 are blocked by substituents, the amino group will be introduced into position 4, though with a low yield. The source of amine in this reaction can be sodium amide ($NaNH_2$), potassium amide (KNH_2),[7] or even organic amide (KNHR).[8] In addition, if organic amine is connected to a pyridine ring, then cyclic amine will form under these conditions. Moreover, this reaction works not only for the pyridine series but also for other nitrogen-containing heterocycles, including purines,[7b] pyrazines,[9] naphthyridines,[10] triazine,[7] and pyrimidines.[7b] It is proposed that this reaction if carried out in liquid ammonia takes place at least partially via the S_N(ANRORC) mechanism.[7]

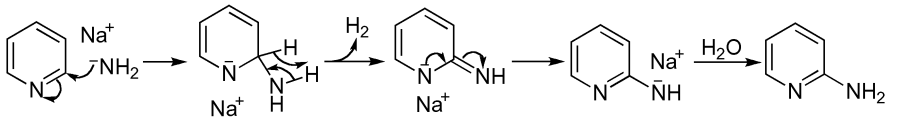
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

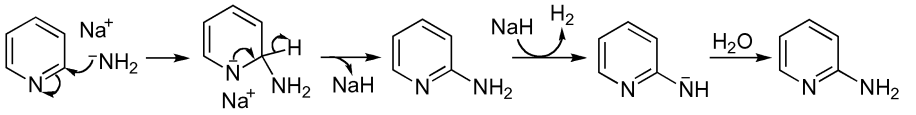


C. PROPOSED MECHANISMS

The reaction may involve the addition of an amide anion to the pyridine ring, followed by elimination of hydrogen and the formation of 2-aminopyridine upon hydrolysis (Scheme 1). More plausibly, the reaction may proceed via the addition of an amide anion to the pyridine ring, followed by the elimination of hydride, which then deprotonates at the amino group, as shown in Scheme 2.



Scheme 1.



Scheme 2.

D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has a general application in the preparation of nitrogen-containing aromatic amines, for which the traditional procedure via nitration followed by reduction works poorly or is not applicable.

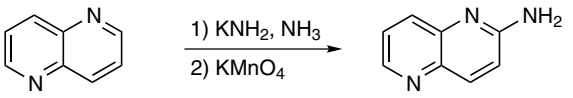
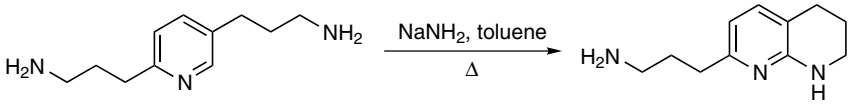
G. CITED EXPERIMENTAL EXAMPLES



Reference 3j.

To 15 mL liquid ammonia containing potassium amide, obtained by a reaction with 0.15 g potassium was added 0.20 g 1,5-naphthyridine. After the mixture was stirred for 10 min and 0.80 g $KMnO_4$ was added in small portions, the mixture was stirred for another 10 min. The potassium amide was then decomposed with $(NH_4)_2SO_4$. After evaporation of the ammonia, a concentrated aqueous solution of ammonia was added, and the mixture was continuously extracted with chloroform over 48 h. The residue obtained on evaporation of the chloroform was taken up in a minimum amount of methanol and developed by use of an Autoliner Desaga (model 121000) on a plate (20 × 40 cm) covered by a 2-mm layer of silica gel DFW and eluted with chloroform/ethanol (10:1) to give one band, which was extracted with methanol. Evaporation of methanol afforded 80 mg 2-amino-1,5-naphthyridine, in a yield of 36%, m.p., 203.5–205°C.



Reference 8.

To a solution of 233 g 3,3′-pyridine-2,5-diyldipropan-1-amine (1.21 mol) in 4 L toluene was added 255 g $NaNH_2$ (90 wt %, 5.88 mol); the mixture was heated to 90°C for 7 h. The reaction was monitored by HPLC and was considered complete when less than 1% of starting material was left. The mixture was cooled to 5°C, and 1 L 4.4 M NaCl was added at such a rate as to maintain the temperature at 10°C. When the addition was complete, the mixture was allowed to warm to 18–22°C and was stirred for 18 h. The layers were separated, and the aqueous phase was extracted with toluene. Water was added to the aqueous phase, and it was further extracted with toluene. The toluene extracts were combined to give 6.1 kg of solution. Evaporation of solvent afforded 207 g 3-(5,6,7,8-tetrahydro-1,8-naphthyridin-2-yl)propan-1-amine, in a yield of 90%.

Chichibabin Pyridine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Chichibabin in 1906.[1] It is the preparation of substituted pyridines by thermal cyclo-condensation of aldehydes and ammonia by passing aldehydes and ammonia over a contact catalyst such as alumina.[2] Therefore, this reaction is generally known as the Chichibabin pyridine synthesis[3] or Chichibabin synthesis.[4] In addition, this reaction is also referred to as the Chichibabin-Bayer reaction[5] or Chichibabin cyclotrimerization.[6] Besides aldehydes, ammonia gas also reacts with acetylene or acetonitrile over a heated contact catalyst to give pyridine derivatives;[3] in addition, the Chichibabin pyridine synthesis also takes place with aliphatic and aromatic ketones, α,β-unsaturated aldehyde, and keto acids. It is reported that when higher aliphatic aldehyde reacts with ammonia at high temperature, besides the expected pyridine product, the abnormal pyridine derivatives also form in which the higher aliphatic aldehyde breaks down in part to formaldehyde that cyclo-condenses with two molecules of the higher aldehyde and ammonia.[2e] Moreover, the yield of 3,5-diphenylpyridine from phenylacetaldehyde can be increased by a factor of about three by the addition of an equivalent amount of isobutyraldehyde, basic iron acetate, or methanolic formaldehyde.[7] It is proposed that this reaction proceeds through a series of *Aldol Condensations*, followed by a cyclization and dehydrogenation.[8] Currently, this reaction has been applied to the syntheses of pyridine and collidine derivatives.[9]

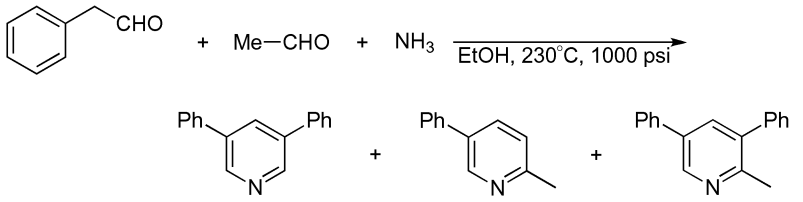
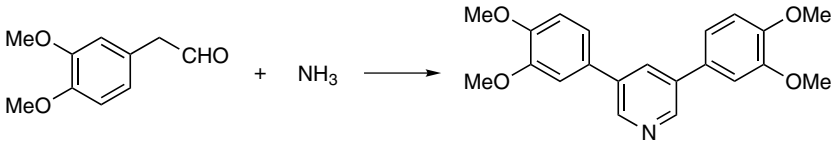
G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

Phenylacetaldehyde (120 g, 1 mol) and 0.5 mol of another aldehyde component were dissolved in 350 mL saturated solution of ammonia in absolute ethanol. The solution was sealed in a 1-L stainless-steel bomb and heated at 225–230°C for 6 h with constant rocking. The pressure was ~1000 psi. The bomb was then cooled and opened; the contents was transferred to a distilling flask. As much ethanol as possible was distilled on the steam bath at atmospheric pressure. The residue was subjected to a preliminary distillation in which everything boiling up to ~280°C (1 mmHg) was collected; except in the case of the acetaldehyde condensation, in which a preliminary distillation with superheated steam at 200°C was resorted to (omission of this preliminary treatment led to difficulties in the subsequent extraction step). The distillate was taken up in ether and extracted 15 times with 2 *N* HCl. The residual ether layer was discarded, and the aqueous layer plus a third layer—which invariably formed—were made basic with an excess of concentrated ammonium hydroxide. The bases liberated were extracted with ether and dried over potassium carbonate; the solution was then concentrated.

For the case of the condensation among phenylacetaldehyde, acetaldehyde, and ammonia, 60.5 g of crude basic reaction product on standing overnight deposited 15.0 g 3,5-di-phenylpyridine, which was collected after diluting the mixture with 50 mL ligroin (b.p. 60–71°C). The material melted at 136–138°C. The remaining material was distilled to give three arbitrary fractions. The first fraction (b.p. up to 174°C, at 13 mmHg), weighed 3.9 g and was proved to be 2-methyl-5-phenylpyridine. The second fraction (b.p. 174–230°C, 13 mmHg), weighed 27.65 g and was proved to be 2-methyl-3,5-diphenylpyridine, with an actual of boiling point 226–228°C at 13 mmHg. The third fraction (b.p. 230–250°C, 13 mmHg), weighed 4.33 g and was proved to be 2-methyl-3,5-diphenylpyridine.



Reference 7.

A solution of 45.5 g homoveratric aldehyde in 250 mL freshly prepared absolute alcohol was boiled under reflux for 1 h while a current of dry ammonia gas was bubbled through it. The solvent and excess ammonia were then distilled at reduced pressure, and the spongy, apparently amorphous residue was heated with 100 mL 1 *N* HCl in anhydrous ethanol (or methanol). The excess ethanol and hydrogen chloride were then distilled (at atmospheric pressure or in vacuo) and the residue was slurried with acetone. Most

of the tarry material dissolved and light-colored crystals of the hydrochloride of 3,5-diveratrylpyridine remained. They were collected, washed with acetone until nearly colorless, and dissolved in 350 mL boiling 95% ethanol. The addition of 100 mL concentrated aqueous ammonia and 100 mL water to this solution led to the precipitation of 3,5-diveratrylpyridine in the form of shiny leaflets. The suspension was chilled, and 5.66 g of the crystals was collected. Recrystallization gave 4.44 g 3,5-diveratrylpyridine, m.p. 170–173°C.

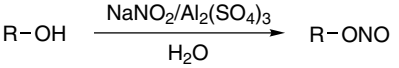
Chretien-Longi Reaction

A. GENERAL DESCRIPTION OF THE REACTION

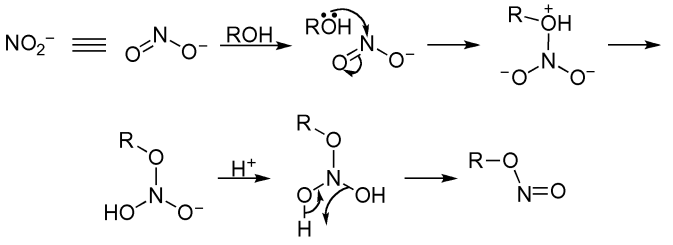
This reaction was first reported by Chretien and Longi in 1944.[1] It is a general preparation of nitrite ester by means of the treatment of alcohols with nitrous acid in aqueous acidic solution.[2] In the original protocol, alcohol was mixed with sodium nitrite followed by the addition of aluminum sulfate, which hydrolyzes to lower the pH.[1] This reaction has been modified to occur in acetic acid.[2]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is proposed here.



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

The original procedure has been modified to take place in aqueous acetic acid solution.

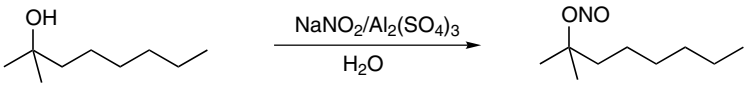
E. APPLICATIONS

This reaction is used for the preparation of nitrite esters.

F. RELATED REACTIONS

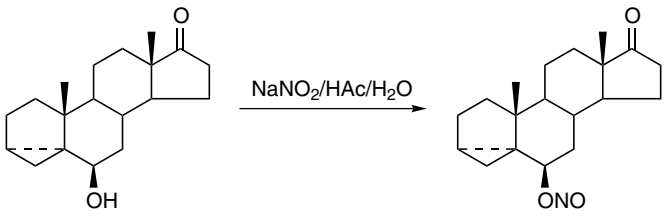
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

In a three-necked flask fitted with a stirrer and a dropping funnel were placed 43.2 g 2-methyl-2-octanol (0.3 mol) and 41.4 g sodium nitrite (0.6 mol) dissolved in a minimum amount of water. The mixture was cooled to 0°C and then, with continuous stirring, 71 g $Al_2(SO_4)_3 \cdot 18H_2O$ (0.12 mol) dissolved in sufficient water to give a 40% solution was added over a period of 1 h. After the addition was complete, the reaction mixture was stirred at ice temperatures for 2 h more and poured into a separatory funnel; the aqueous layer was removed, and the yellow organic layer was washed three times with water and dried over anhydrous sodium sulfate. Rectification gave 37.8 g 2-methyl-2-octyl nitrite, in a yield of 72%, b.p., 56°C (3 mmHg).



Reference 2.

6β-Hydroxy-3α,5α-cycloandrostan-l7-one (804 mg) was dissolved in 53 mL glacial acetic acid. A freshly prepared solution of 2.8 g sodium nitrite in 17.6 mL water was added, and the resulting solution was allowed to stand at room temperature for 15 min. The solution was then shaken with 200 mL ether and 500 mL water. The aqueous solution was separated and extracted with 200 mL ether. The ether solutions were combined and washed in series with three 100-mL portions of water, two 150-mL portions of 5% sodium

bicarbonate solution, and three 100-mL portions of water. The ether solutions were dried over anhydrous magnesium sulfate. The ether was evaporated, leaving 858 mg clear, orange viscous oil. This material was placed on a column of 80 g neutral activity III alumina in 10 mL ether solution. Elution with 1:23 ether/pentane solution yielded 503 mg of the nitrite ester of 6β-hydroxy-3α,5α-cycloandrostan-17-one as a pale green oil.

Chugaev Reaction

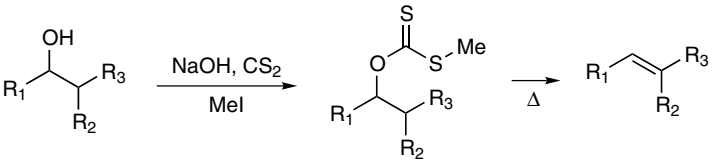
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Chugaev (Tschugaeff) in 1899.[1] It is the conversion of alcohols into olefins by the pyrolysis of the corresponding xanthate esters and is generally known as the Chugaev reaction;[2] in addition, this reaction is occasionally referred to as the Chugaev elimination,[3] Chugaev xanthate reaction[4] and Chugaev xanthic reaction.[5] This pyrolysis proceeds via an intramolecular *cis*-elimination without the rearrangement of the carbon skeleton, a phenomenon generally referred to as the Chugaev reaction rule.[6] This reaction is particularly useful for the conversion of secondary and tertiary alcohols into olefins[7] because the xanthate esters of primary alcohols have higher thermal stability and thus are relatively difficult to decompose during heating and can even be distilled in vacuo.[7] On the other hand, this reaction is reported to be first order in kinetics[8] via a concerted cyclic mechanism,[9] by which the eliminated groups are all in *cis*-configuration[8a,10] with only a few exceptions[2d,6,11] and the preference for hydrogen removal follows the order of $3^\circ > 2^\circ > 1^\circ$.[12] The unusual feature of this reaction is that no carbon skeleton rearrangements occur during pyrolysis, which are often encountered in the dehydration of certain alcohols by other methods.[10] However, the original procedure—in which the xanthate ester is prepared by reacting sodium or potassium (preferably the latter) with alcohol in an inert solvent (e.g., xylene) followed by the addition of carbon disulfide and then refluxing with methyl iodide or methyl sulfate (methyl ester affording the best yield)—is generally avoided because it is dangerous and inconvenient.[7] Therefore, it is modified to react alcohol with 1 eq. NaOH or KOH and CS_2 in a neutral solvent (e.g., Et_2O, CCl_4) to form xanthate in one step, followed by the reaction with methyl iodide. This modification is less hazardous and more practicable.[7] This reaction has been used for the preparation of a variety of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

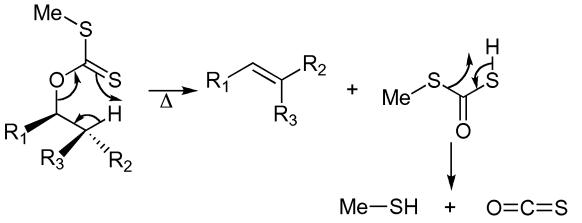
olefins, including benzylidene cyclohexane,[13] bornylene,[14] chlolesterylene,[14] guajene,[15] limonene,[14] menthene,[1] tetraphenylethylene,[13] and thujene.[14]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction takes place via an intramolecular cyclic concerted process, as outlined here.[8a,10–12]



D. MODIFICATION

This reaction has been modified to generate xanthates in one step via the reaction of alcohols with CS_2 and NaOH (or KOH).[7]

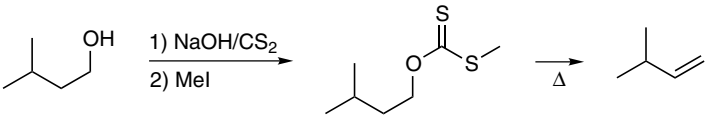
E. APPLICATIONS

This reaction has wide application in the synthesis of olefins.

F. RELATED REACTIONS

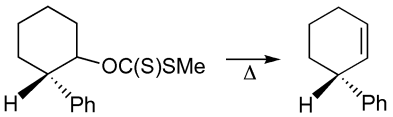
This reaction is related to the *Cope Elimination* and *Hofmann Elimination*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

In a 2-L flask were placed 40.5 g finely pulverized sodium hydroxide, 89 g isoamyl alcohol, 600 mL diethyl ether, and 50 mL carbon tetrachloride. The flask was attached to a trident fitted with a mechanical stirrer, a Pyrex reflux condenser, and a dropping funnel. The mixture was stirred for 0.5 h to dissolve part of the base and form a finely divided suspension of the remainder. Then 76 g carbon disulfide was added over 1 h, with the temperature below 30°C. After 3 h of stirring, 149 g methyl iodide was added dropwise, and the mixture was stirred and refluxed for 6 h. After filtering off the potassium iodide, the lower-boiling constituents were removed by distillation, and the residual xanthate was distilled at 10 mmHg through a 68 × 1.1-cm, indented, total-condensation column. The yellow distillate (b.p. l00–105°C) was further purified by one more distillation. Then the collected xanthate ester was heated in a 1-L flask under a partial reflux column for 7.5 h by a free flame, the distillate being condensed by a copper coil packed in an ice–salt mixture. The distillate was purified by three extractions with 40% potassium hydroxide solution and one treatment with 20 mL saturated mercuric chloride solution to remove the mercaptan; then it was dried over anhydrous sodium sulfate and distilled through the 68 × 1.1-cm column. The isopropylethylene collected boiled at 19–20°C (740 mmHg).



Reference 10.

To a 50-mL round-bottomed flask equipped with a Friedrich condenser was placed 5.0 g methyl *cis*-2-phenylcyclohexylxanthate. A gas bubbler was attached to the condenser so that the course of the decomposition could be followed. The flask was immersed in a Wood's metal bath, and the temperature was gradually increased. A slight decomposition began when the bath temperature reached 165°C. It was then raised to 210–215°C, maintained at that level for 40 min, and then it was increased to 235–240°C for 5 min. After cooling, the material in the flask was transferred to a 10-mL modified Claisen flask and distilled. 3-Phenyl-cyclohexene in two fractions, with a combined weight of 2.1 g (71%), came over at 70–71°C (2 mmHg).

Other references related to the Chugaev reaction are cited in the literature.[16]

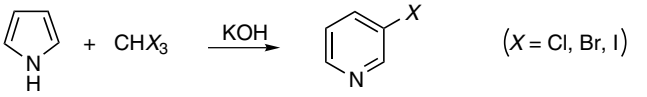
Ciamician-Dennstedt Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ciamician and Dennstedt in 1881.[1] It is a transformation of pyrrole into 3-halopyridine by heating the mixture of pyrrole and haloform or methylene halides in alkaline solution. Therefore, this reaction is known as the Ciamician-Dennstedt reaction.[2] It is known that haloform, when treated with a base,[3] such as NaOH, KOH, will afford dihalocarbene; in addition, methylene halides when treated with a strong base,[4] such as NaOEt and NaOMe, will also form dihalocarbene. The generated dihalocarbene then electrophilically adds to pyrrole to form an unstable dihalocyclopropane, which then rearranges to a 3-halopyridine.[5] In most cases, haloform is used rather than methylene halides, and the *Reimer-Tiemann Reaction* always competes with this reaction when the dihalocarbene inserts into aromatic ring and forms aldehyde via hydrolysis.[6] Therefore, the yield of the Ciamician-Dennstedt reaction is always low, in the reported range of 1–30%.[4a,6] Similar to pyrrole, indene will be transformed to naphthalene,[7] and indole will be converted to quinoline.[8] It is reported that a chloro, bromo, carbethoxy, or phenyl group on indene will inhibit the addition of dichlorocarbene to the indene ring, while the electron-donating groups (e.g., methyl, isopropyl, and ethoxy) have no effect on the yield compared with indene itself.[9] It is interesting that more than 30% of pyridine can be obtained via vapor phase reaction between pyrrole and haloform, without the added base.[8]

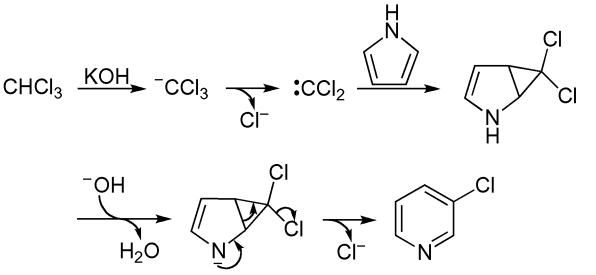
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The reaction involves the generation of dihalocarbene from haloform and a base, e.g., KOH, which then inserts into the pyrrole ring. The subsequent ring enlargement affords the pyridine derivative, as illustrated by the reaction of chloroform and pyrrole.



D. MODIFICATION

The Ciamician-Dennstedt reaction has been modified to take place in a vapor phase via passing the mixture of pyrrole and chloroform (1:5 ratio) into a glass tube at 550°C to give 33% of pyridine derivative.

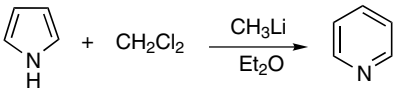
E. APPLICATIONS

This reaction can be used for the preparation of 3-halo pyridines, naphthalenes, and quinolines.

F. RELATED REACTIONS

N/A

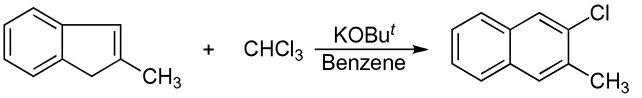
G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

A solution of methyllithium (0.4 mol) in 235 mL diethyl ether was added with vigorous stirring to a solution of 7.0 g pyrrole (0.104 mol) in methylene chloride. The addition was carried out under a protective atmosphere of nitrogen, and the temperature was maintained at 25°C. After the addition was complete (2 h), the reaction mixture was hydrolyzed with ice water, and the polymeric material was removed by filtration over cellulose powder. The solution was acidified and nonbasic material was extracted with ether. The aqueous layer was then made basic, saturated with potassium carbonate, and exhaustively extracted with ether. The combined ether extracts were dried with potassium carbonate and the solvent was distilled off over a Vigreux column. The residue was distilled over a micro Vigreux

column. Pyridine (2.60 g, 0.033 mol) was collected between 114° and 114.5°C, in a yield of 32%.



Reference 9.

A solution of 15.6 g 2-methylindene (0.12 mol) in 15 mL dry thiophene-free benzene was added to dry pulverized potassium *t*-butoxide (maintained under dry oxygen-free nitrogen) prepared from 2.0 g potassium (0.051 mol) and *t*-butyl alcohol. The orange slurry was stirred vigorously, and cooled in an ice bath, while 4.8 g freshly distilled chloroform (0.040 mol) was added over a period of ~15 min. A static nitrogen atmosphere was maintained during the addition, and the mixture was then allowed to stand at room temperature overnight. The entire mixture was steam distilled from water containing 0.08 mol sodium carbonate. An undetermined amount of nonvolatile red tar remained in the flask. The distillate was extracted with petroleum ether (b.p. 60–68°C), and the condenser was washed with the same solvent. The organic washes and extracts were dried, filtered, and the solvent was removed by distillation. Fractional distillation of the residue afforded 9.6 g unreacted 2-methylindene (0.0727 mol). The light green residue, m.p. 113–120°C, was recrystallized once from ethanol, and 2.61 g 2-methyl-3-chloro-naphthalene was obtained as refractive pale green platelets, in a yield of 37%, m.p. 122.5–123°C.

Other references related to the Ciamician-Dennstedt reaction are cited in the literature.[10]

Claisen Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ludwig Claisen in 1912.[1] It is initially defined as the thermal isomerization of an allyl vinyl ether or of its nitrogen- or sulfur-containing analogous derivatives to afford a bifunctionalized molecule in a $[\pi_{2a} + \sigma_{2s} + \pi_{2s}]$ process. In fact, the Claisen rearrangement[2] is a highly stereoselective [3,3]-sigmatropic rearrangement of allyl vinyl or allyl aryl ethers to yield γ,δ-unsaturated carbonyl compounds or *o*-allyl substituted phenols, respectively. This reaction can be chemoselective, regioselective, diastereoselective, and entantioselective and afford a variety of multifunctionalized molecules.[3] When allyl aryl ethers undergo this rearrangement, the resulting γ,δ-unsaturated carbonyl compound will transform into *o*-allyl phenols via re-aromatization; however, if the *ortho* position is blocked by other substituents rather than hydrogen, then the *Cope Rearrangement* occurs and the allyl group will migrate to the *para* position of the aromatic ring followed by enolization (*para* Claisen rearrangement).[3,4] In most cases, the reaction proceeds preferably via a chair-like transition state,[5] and chiral, enantiomerically enriched starting materials give products of highly optical purity. Occasionally, this reaction also takes a boat-like transition state.[6] So far, all the Claisen rearrangements, if not catalyzed, occur at a relatively high temperature, e.g., >100°C.[3,7] In addition, this rearrangement runs faster in a polar solvent,[8] and it is observed that the relative rate of the rearrangement for allyl vinyl ether decreases in the order of water > trifluoroacetic acid > methanol > ethanol > 2-propanol > acetonitrile > acetone ≈ benzene > cyclohexane.[9] Moreover, the microwave irradiation can also accelerate the reaction rate.[10] It is quite interesting that substituents on allyl vinyl ether play important roles on the reactivity of corresponding allyl vinyl ethers, and those substituent effects are summarized in Table 1.[3] It is clear that the introduction of those rate-enhancing groups will accelerate the respective rearrangement accordingly. As a result,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

the same reaction can take place at low temperature, and these modifications lead to more than 20 variations of the traditional Claisen rearrangement.[11] These modified Claisen rearrangements include the *Abnormal Claisen Rearrangement*,[12] acyl-Claisen rearrangement,[13] allene Claisen rearrangement,[14] allenoate-Claisen rearrangement,[11] aromatic amino-Claisen rearrangement,[15] *Aza-Claisen Rearrangement*,[16] *Carroll Rearrangement*,[17] chelate Claisen rearrangement,[18] C-O coupling-Claisen rearrangement,[19] 1,3-diaza-Claisen rearrangement,[20] diosphenol-Claisen rearrangement,[21] enzymatic Claisen rearrangement,[22] Eschenmoser-Claisen rearrangement,[23] Ficini-Claisen rearrangement,[24] Ireland-Claisen rearrangement,[25] Johnson-Claisen rearrangement[26] (also called Johnson ortho ester Claisen rearrangement[27]), Metalla-Claisen rearrangement,[28] photo-Claisen rearrangement,[29] propargyl Claisen rearrangement,[30] reductive Claisen rearrangement,[31] Reformatsky-Claisen rearrangement,[32] retro-Claisen rearrangement (or process),[33] ring-expansion Claisen rearrangement,[34] and thio-Claisen rearrangement.[6b,34] It should be noted here that *Aza-Claisen Rearrangement, Carroll Rearrangement*, Eschenmoser-Claisen rearrangement, Ireland-Claisen rearrangement and Johnson-Claisen rearrangement have gained much more attention than the others, though the other variations are gradually showing importance and versatility. The Ireland-Claisen rearrangement can set up two stereogenic centers with high levels of predictability through the judicious choice of solvent.[36] Among these variations, the *Abnormal Claisen Rearrangement*, *Aza-Claisen Rearrangement*, and *Carroll Rearrangement* have been described separately. Because of its versatility and importance, the Claisen rearrangement has been extensively reviewed.[3,37]

B. GENERAL REACTION SCHEME

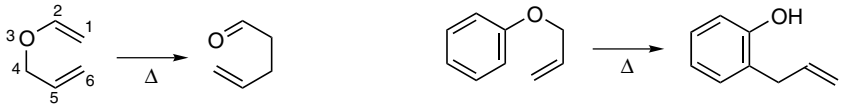

TABLE 1. The Position and Substituent Effect on Rearrangement Rate

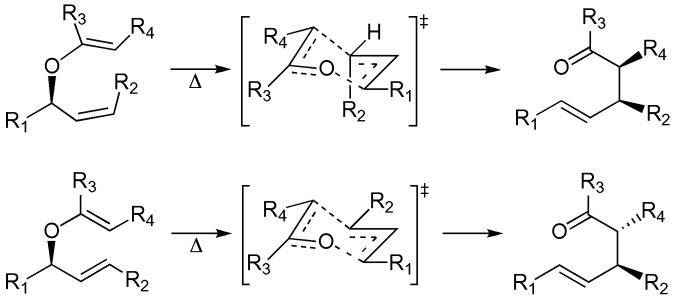
Accelerating Groups		Decelerating Groups	
Electron-Donating Position 1,2,4,6	Electron-Withdrawing Position 2,4,5	Electron-Donating Position 5	Electron-Withdrawing Position 1,6

C. PROPOSED MECHANISMS

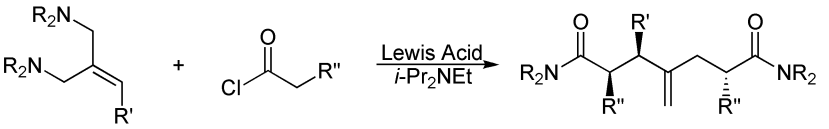
Most rearrangements take place via a chair-like concerted mechanism as outlined here.



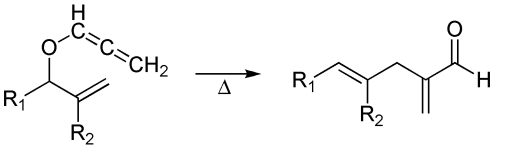
D. MODIFICATION

The most important modifications of the Claisen rearrangement are summarized here.

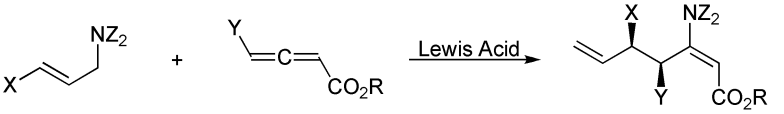
Acyl-Claisen rearrangement.



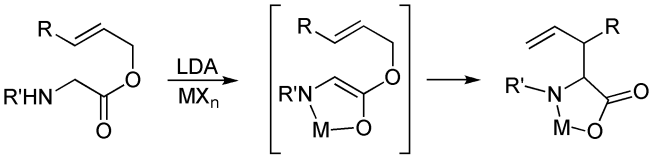
Allene Claisen rearrangement.



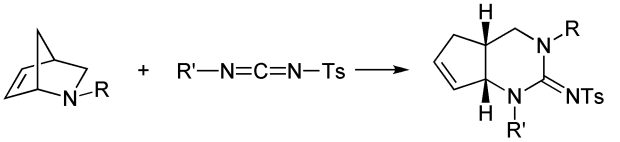
Allenoate-Claisen rearrangement.



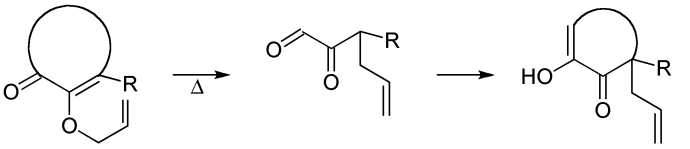
Chelate Claisen rearrangement.



1,3-Diaza-Claisen rearrangement.



Diosphenol-Claisen rearrangement.



Eschenmoser-Claisen rearrangement.

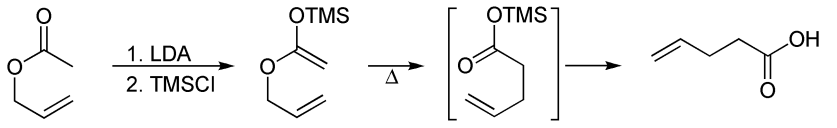
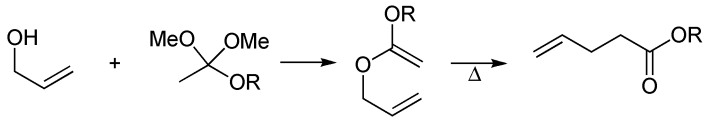
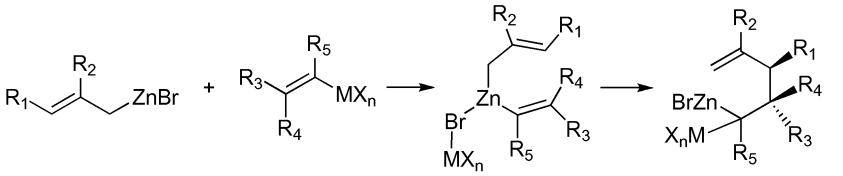
Ireland-Claisen rearrangement.



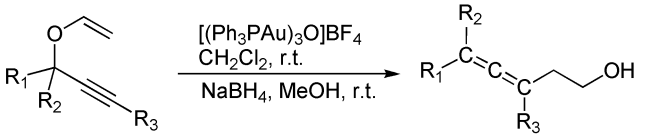
Johnson-Claisen rearrangement.



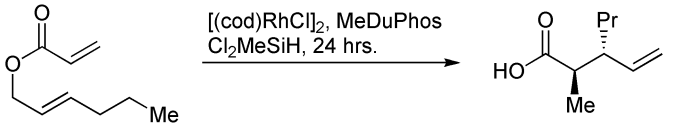
Metalla-Claisen rearrangement.



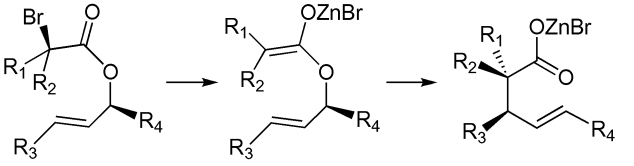
Propargyl Claisen rearrangement.



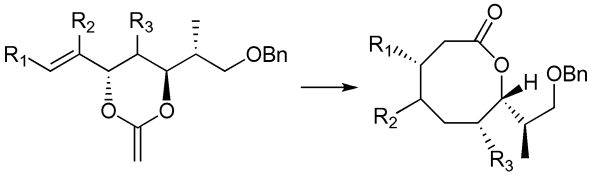
Reductive Claisen rearrangement.



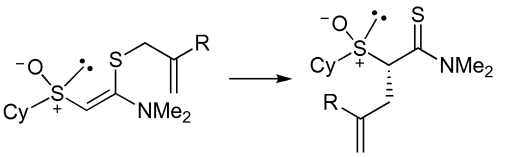
Reformatsky-Claisen rearrangement.



Ring-expansion Claisen rearrangement.



Thio-Claisen rearrangement.



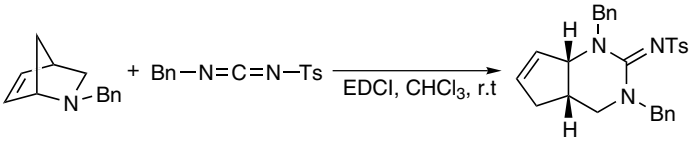
E. APPLICATIONS

This reaction, along with its various modifications have wide applications in organic synthesis, even in the formation of polymer.[38]

F. RELATED REACTIONS

This reaction is related to the *Cope Rearrangement* and *Overman Rearrangement*.

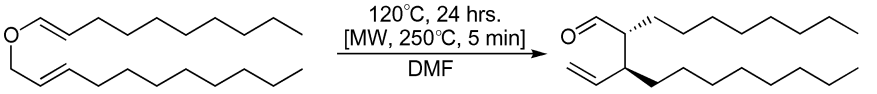
G. CITED EXPERIMENTAL EXAMPLES



Reference 20b.

2-Benzyl-2-*aza*-bicyclo[2.2.1]hept-5-ene (0.100 g, 0.538 mmol) and 0.094 mL DIEA (0.538 mmol) were added to a solution of 0.103 g EDCI (0.538 mmol) and 0.172 g *N*-tosyl-*N′*-benzyl thiourea (0.538 mmol) in 5 mL $CHCl_3$ at room temperature. The resulting solution was maintained at room temperature overnight. The reaction mixture was then poured into a mixture of 65 mL EtOAc and 65 mL 0.25M aqueous citric acid. The organic layer was washed with 65 mL 0.25M aqueous citric acid and 65 mL water (twice), dried over Na_2SO_4, and concentrated. Purification of the residue on silica gel, eluting with hexanes/EtOAc (2:3)

gave 0.170 g *N*-(1,3-dibenzyl-1,3,4,4a,5,7a-hexahydro-cyclopentapyrimidin-2-ylidene)-4-methylbenzene sulfonamide as a colorless oil, in a yield of 67%.



Reference 19.

Conventional Heating

A test tube was charged with 160 mg *E*-1-dec-1-enyl-*E*-undec-2-ene (519 μmol) and 500 μL DMF, evacuated, and backfilled with argon (flushing for 10 min). This was then sealed and heated at 120°C for 24 h. After cooling to room temperature, 20 mL Et_2O was added, and the solution was extracted with water (3 × 25 mL). The combined organic layers were dried over $MgSO_4$ and concentrated under reduced pressure. The product was obtained as a yellow oil without further purification (144 mg, 90% yield), dr = 94:6 (^{1}H NMR).

Microwave Heating

A microwave vial was charged with 76 mg *E*-1-dec-1-enyl-*E*−undec-2-ene (247 μmol) and 1 mL DMF. This was then sealed and heated at 250°C for 5 min in a microwave synthesizer. Et_2O was added (20 mL) and extracted with water (3 × 25 mL). The combined organic layers were dried over $MgSO_4$ and concentrated under reduced pressure. The product was obtained as a yellow oil without further purification (61 mg, 80% yield), dr = 91 : 9 (^{1}H NMR).

Other references related to the Claisen rearrangement are cited in the literature.[39]

Claisen-Schmidt Condensation

(Claisen-Schmidt Reaction)

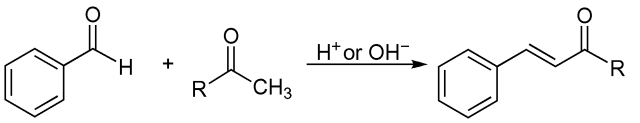
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Claisen[1] and Schmidt[2] concurrently in 1881. It is the condensation of an aromatic aldehyde with an aliphatic aldehyde or ketone in the presence of a base or an acid to form an α,β-unsaturated aldehyde or ketone[3] with high chemoselectivity.[4] Therefore, this reaction is generally known as the Claisen-Schmidt condensation[5] and is occasionally referred to as the Claisen-Schmidt reaction.[6] In this reaction, the asymmetric ketones react with the aromatic aldehyde through the less substituted position (a methyl group) under basic conditions or through the more substituted position under acidic catalysis.[3] However, this reaction is often contaminated with some minor side reactions, including *bis*-condensation, aliphatic aldehyde dimerization,[7] and *Cannizzaro Reaction* or *Tischenko Reaction* of aromatic aldehydes.[8] It was reported that the reaction between arylaldehydes and cycloalkanones afford predominantly α,α'-diarylidenecycloalkanones instead of α-arylidenecycloalkanones.[8] The orientation of the generated exocyclic bonds is exclusively *trans* with respect to the aryl ring and the carbonyl group of the cycloalkanone.[9] So far, the Claisen-Schmidt condensation has been applied to the preparation of chalcone,[10] flavanone,[10c] 1,3-diarylpropane derivatives, and a new family of macrocycles in a single step.[8,11] This condensation can be accelerated by microwave activation either in a polar solvent (e.g., H_2O) or without solvent, starting from aldehydes or by means of acetals.[3] The benefits of using microwave irradiation in this reaction include the concomitant enhancement of reaction yield and the reduction in reaction time.[12] On the other hand, magnesium oxide crystal has been applied as catalyst for this condensation, in which the catalyst can be reused for five times without loss of activity and selectivity; in

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

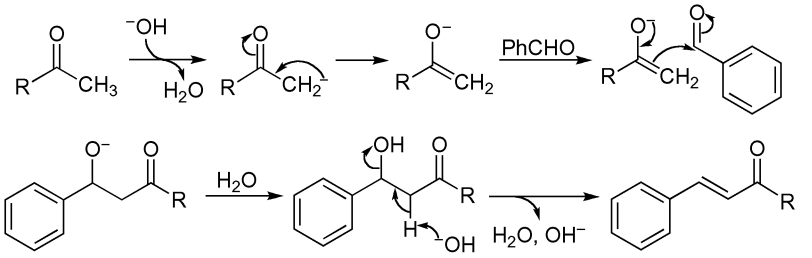
addition, it is observed that any of the reactants (benzaldehydes and acetopheones) with substituent groups in either of the two aromatic rings undergo the Claisen-Schmidt condensation at a slower rate than the unsubstituted reactants.[13] Recently, this condensation has been used to build a 644-member library of chalcones by parallel synthesis from substituted acetophenones and benzaldehydes.[10a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Essentially, the Claisen-Schmidt condensation involves an *Aldol Condensation*,[3,10a] as illustrated by the reaction under basic condition.



D. MODIFICATION

Microwave irradiation has been introduced to accelerate the Claisen-Schmidt condensation;[3,12] in addition, magnesium oxide crystal has been applied as catalyst for this condensation.[13]

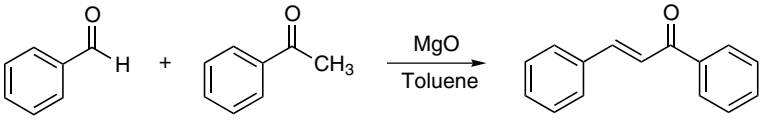
E. APPLICATIONS

This reaction has general application in the preparation of chalcones, flavanones, 1,3-diarypropanes, etc.

F. RELATED REACTIONS

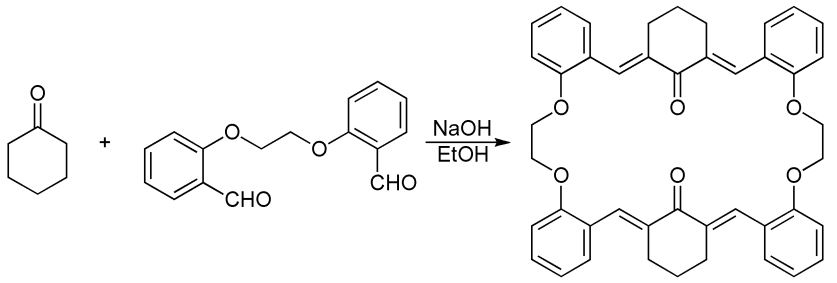
This reaction is related to the *Aldol Condensation.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

A mixture of 0.35 mL acetophenone (3 mmol), 0.254 mL benzaldehyde (2.5 mmol), and 0.175 g magnesium oxide crystal was introduced into a 50-mL round-bottomed flask containing 10 mL dry toluene, which was stirred under reflux for 12 h under nitrogen atmosphere (to avoid the oxidation of benzaldehyde to benzoic acid). After completion of the reaction (as monitored by TLC), the reaction mixture was centrifuged to separate the catalyst and washed several times with ether. The combined organic layers were dried over $MgSO_4$ and the solvent was removed under reduced pressure. After purification by flash chromatography on silica gel using 5% ethyl acetate in petroleum ether, the chalcone was obtained in 98% yield.



Reference 8.

To an 1.83 L 95% ethanolic solution containing 10.1 g 1,2-bis(2-formylphenoxy)ethane (37.4 mmol) and 5.53 g cyclohexanone (56.3 mmol) was added aqueous NaOH solution (22.5 g/45 mL, 563 mmol) in one portion. After being stirred at room temperature for 6 days, a bright yellow precipitate was filtered from the reaction. The precipitate was washed thoroughly with 1.0 M HCl and water and dried in an oven (90°C) to constant weight (10.3 g). A portion of the precipitate (920 mg) was washed with hot chloroform to afford 380 mg 9,10:18,19:24,25-tetrabenzo-5,8,20,23-tetraoxa-tricyclo[25.3.1.$1^{12,16}$]-dotriaconta-1,3,9,11,16,18,24,26 -octaene-31,32-dione as a bright yellow powder, in a yield of 34%, m.p.: solid turns brown at 292–293°C and melts sharply at 297–298°C.

Other references related to the Claisen-Schmidt condensation are cited in the literature.[14]

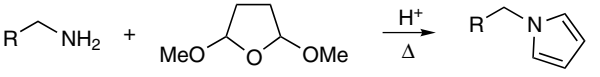
Clauson-Kaas Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Clauson-Kaas and Tyle in 1952.[1] It is a synthesis of pyrrole derivative from the condensation between a primary aliphatic or aromatic amine and 2,5-dimethoxy-tetrahydrofuran in the presence of an acid catalyst. Therefore, this reaction is generally known as the Clauson-Kaas reaction[2] or occasionally referred to as the Clauson-Kaas procedure.[3] The acid catalysts used in this reaction include acetic acid,[2d,3b,4] phosphorus pentoxide,[5] and 4-chloropyridinium hydrochloride.[6] This reaction opens a door to convert the primary amino group into a pyrrole group,[7] which has been used to prepare a variety of pyrrole derivatives containing different substituents,[8] especially for polycyclic structures containing pyrrole.[7] However, this reaction is not a good method for synthesizing pyrrole if the desired compound contains an acidic labile group—for example, in the presence of a imidazole group, this reaction either does not work[9] or give only poor yield.[2d] Alternatively, the pyrrole can be prepared from a primary amine and 1,4-dichloro-1,4-dimethoxybutane in the presence of an acid catalyst (e.g., Amberlyst A-21).[10]

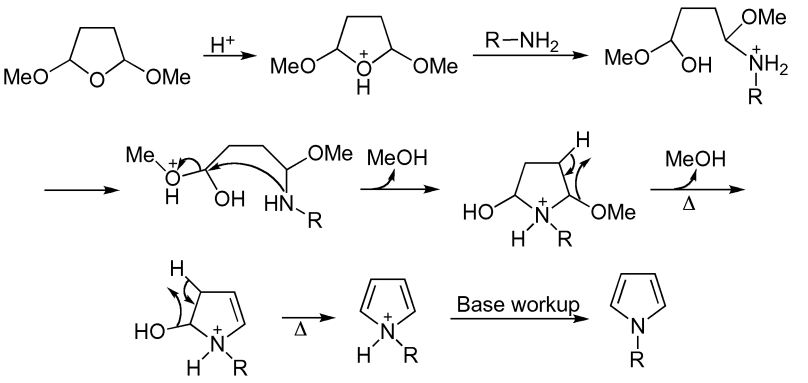
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple illustration of the reaction mechanism is provided here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified to start from 1,4-dichloro-1,4-dimethoxybutane and primary amine in the presence of an acid catalyst.[10]

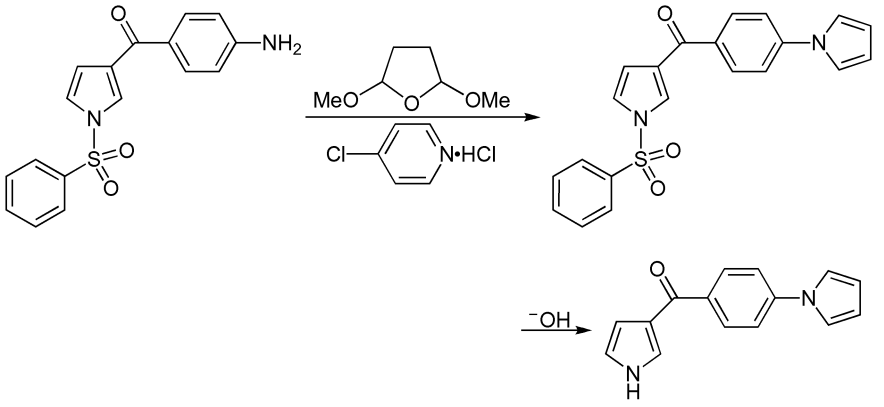
E. APPLICATIONS

This reaction has general application in the synthesis of pyrrole derivatives.

F. RELATED REACTIONS

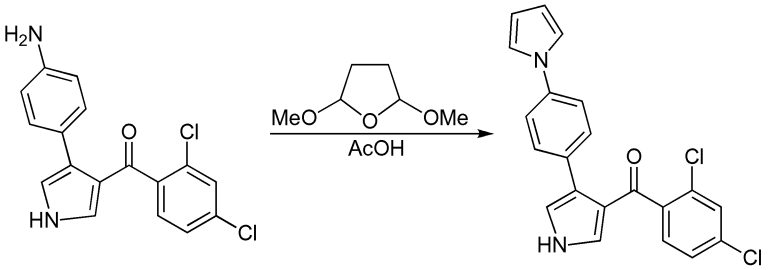
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

A mixture of 1.5 g crude 1-benzenesulfonyl-1*H*-pyrrol-3-yl-4-aminophenyl-methanone, 0.97 g 4-chloropyridine hydrochloride (6.47 mmol), and 0.88 g 2,5-dimethoxytetrahydrofuran (5.8 mmol) in 30 mL dioxane was refluxed for 3 h under a nitrogen atmosphere. The resulting solution was evaporated under reduced pressure, and the residue was dissolved in Et_2O, dried over Na_2SO_4, and evaporated under reduced pressure. The residue was dissolved in 50 mL dioxane; to this solution, 50 mL 5 *N* NaOH solution was added. The reaction mixture was vigorously stirred at room temperature for 24 h. The organic layer was collected, and the aqueous solution was thoroughly extracted with EtOAc (2 × 50 mL). The combined organic layer and extracts were washed with saturated NaCl solution, dried over Na_2SO_4, and evaporated under reduced pressure. The residue was flash chromatographed with EtOAc/petroleum ether (3:1) followed by recrystallization from toluene/petroleum ether to provide 0.26 g 1*H*-pyrrol-3-yl-4-pyrrol-1-ylphenyl-methanone, in a yield of 24%, m.p. 172–173°C.



Reference 11.

A solution of 1.0 g [4-(4-aminophenyl)-1*H*-pyrrol-3-yl]-(2,4-dichlorophenyl) methanone (3.0 mmol) and 410 mg 2,5-dimethoxytetrahydrofuran (3.1 mmol) in 20 mL acetic acid was refluxed for 30 min. After the mixture was cooled, the solvent was removed and the residue was chromatographed on aluminum oxide (EtOAc as the eluent) to give 810 mg pure (2,4-dichlorophenyl)-[4-[4-(1*H*-pyrrol-1-yl)phenyl]-1*H*pyrrol-3-yl]methanone, in a yield of 70%.

Other experimental details for the Clauson-Kaas reaction are available,[7,8,12] and additional references related to the Clauson-Kaas reaction are cited in the literature.[13]

Clay-Kinnear-Perren Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Clay in 1951[1] and was subsequently extended by Kinnear and Perren in 1952.[2] It is the synthesis of alkylphosphonic dichlorides from alkyl chlorides, phosphorous trichloride and aluminum chloride and is known as the Clay-Kinnear-Perren condensation,[3] Kinnear-Perren-Clay reaction,[4] or simply the Kinnear-Perren reaction.[5] The resulting alkylphosphonic dichlorides can be further hydrolyzed to alkylphosphonic acids or subjected to the conditions to make other phosphorus-containing derivatives. As pointed out by Clay, the order of mixing reagents, control of reaction temperature, anhydrous conditions of the reagents and apparatus, and the final molar ratio of water to ionic complex in hydrolysis all have important effects on this reaction.[1] For example, no reaction takes place if $AlCl_3$ was dissolved in alkyl chloride before the addition of PCl_3 and the molar ratio of H_2O to complex being hydrolyzed must be within the limits of 7:1 to 11:1. It was also found that complex formed from alkyl chloride, PCl_3 and $AlCl_3$ has high thermal stability with a melting point $\sim$370°C; the solution of such a complex in nitromethane conducts an electric current, indicating an ionic nature of the structure $[RPCl_3]^+[AlCl_4]^-$.[1] In addition, Kinnear and Perren reported[2,6] that when propyl or higher primary or secondary alkyl chlorides are used, only rearranged products are formed (similar to the *Friedel-Crafts Alkylation*[5g]); in a special case, the elimination of the methyl group from *tert*-amyl chloride also occurs.[2] The tendency of such rearrangement limits the utility of this reaction.[7] Similarly, the molar ratio is also important in the alcoholysis of such complexes.[8] However, no rearrangement was found for the complex from chloromethyltrimethylsilane,[9] even though chloromethyltrimethylsilane undergoes a *Wagner-Meerwein Rearrangement* to chlorodimethylethylsilane when treated with $AlCl_3$;[10] this reaction does not apply to chlorosilane either.[9]

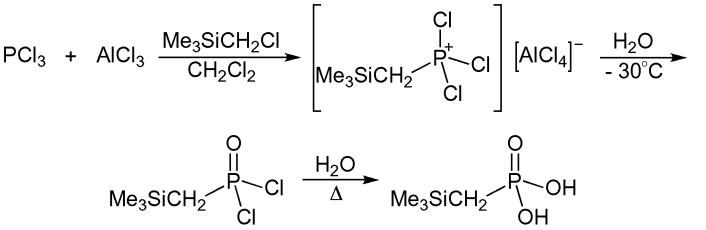
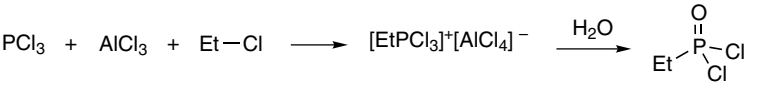
This reaction is related to the *Clayton-Jensen Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A mixture of 133.4 g anhydrous aluminum chloride (1.0 mol) and 137.4 g phosphorus trichloride (1.0 mol) in 300 mL methylene chloride was prepared under dry nitrogen. Chloromethyltrimethylsilane (122.7 g, 1.0 mol) was added dropwise with stirring over a 1-h period while the reaction temperature was maintained at 25–28°C by external cooling. The mixture was stirred for an additional hour at 25°C to give a clear solution of the complex salt. An equal volume of methylene chloride was added, and the solution was cooled to −30 in dry ice–acetone. Then 162 mL water was added dropwise with rapid stirring over a 1-h period. The temperature was kept below −20°C during hydrolysis of the complex to minimize the hydrolysis of the phosphonyl dichloride. Precipitated aluminum salt was removed on a filter and washed with methylene chloride. The filtrate was dried over calcium chloride at 0°C. After removal of the solvent, the crude product was distilled through an efficient column to give 64 g trimethylsilylmethylphosphonyl dichloride, b.p. 64°C (1.4 mmHg). Treatment of the distillation residue with boiling water gave 20 g of the corresponding phosphonic acid, m.p. 121°C from water.



Reference 1.

To a mixture of 13.3 g anhydrous $AlCl_3$ and 13.7 g PCl_3 was added 19.3 g ethyl chloride; the bottle was closed and placed in a shaking machine. (All reagents and the reaction bottle were cooled in a refrigerator at ∼ 4°C just before weighing and mixing). Up to the moment of closing the bottle, the temperature of the mixture had risen to 9°C. After 15 min of shaking, the temperature of the mixture had risen to 23°C. At this temperature, the solid $AlCl_3$ dissolved, accompanied by a sudden rise in temperature, which reached ∼35°C. The solution became pale yellow in color. After ∼12 min, the temperature dropped to 25°C, accompanied by the deposit of a white crystalline precipitate. The shaking of the mixture was continued for 1 h. The reaction bottle was then placed in a refrigerator at ∼4°C. After 24 h, the supernatant liquid was poured off, leaving 18 g dry crystalline material, m.p. 370°C (approximately). A solution of the complex in nitromethane was found to exhibit an electrical conductivity equivalent to that of a univalent salt in water.

This crystalline complex was dissolved in 200 mL methylene chloride, transferred to a three-necked 500-mL flask, cooled to 0°C, and hydrolyzed by adding dropwise (at the rate of 10 drops/min) 25.3 mL cold concentrated hydrochloric acid (4°C). The mixture was stirred for 2 h, beginning with the addition of the first drop of hydrochloric acid. The reaction flask was immersed in an ice water mixture which kept the temperature between 0° and 7°C throughout the hydrolysis. The cold mixture was filtered, and the filtrate was distilled to remove excess solvent, followed by vacuum distillation of the residue at 28 mmHg. The vacuum distillate yielded 7.6 g ethyl phosphonyl dichloride as a colorless liquid, b.p. 174.5°C.

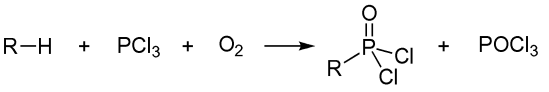
Clayton-Jensen Chlorophosphonation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially studied almost coincidently by three groups: Clayton and Jensen;[1] Soborovsky, Zinovyev, and Englin in the pre-Soviet Union;[2] and Graf in Germany.[3] However, Clayton and Jensen first reported this reaction in 1948,[1] although Graf might study this reaction first whereas had published his result last.[4] It is the direct chlorophosphonation of aliphatic hydrocarbons by treatment of the hydrocarbons with oxygen and phosphorus trichloride (benzene does not react[1]). Because this reaction is always contaminated by the oxidation of phosphorus trichloride to phosphorus oxychloride,[4] the yield of phosphonyl chloride is generally ~25% based on PCl_3 used.[1] Even though more than 16 catalysts have been tested for this reaction, no apparent catalytic effect of these substances has been clearly found;[5] in contrast, sulfuric acid,[1] iodine,[1] iron powder,[5] and boron trifluoride[5] actually inhibit this reaction. In addition, there is no appreciable influence of light on the yield.[1] In this reaction, the steric effect is obvious, for example, a 13% yield was obtained for the reaction of toluene, whereas a 2.3% yield was obtained from diphenylmethane, and no product at all was yielded from triphenylmethane.[6] In addition, this reaction works only for phosphorus trichloride, not for other phosphorus halides (PBr_3, PI_3, etc.).[1] It is interesting that, to an extent, a higher yield is obtained when more hydrocarbon is used—for example, the yield increases from 20.0% to 29.2% when the molar ratio of cyclohexane to PCl_3 increases from 0.5 to 2.0; however, a further increase in yield is not detectable when more cyclohexane is used.[5] It is reported that this reaction is not spontaneous when sufficient pure reagents are used; The apparently spontaneous nature of the reaction arises from the presence of trace amounts of an initiator in the hydrocarbon.[7] Accordingly, no effective change in yield was found when the reaction was carried out in a temperature range of -40° to 70°C.[5]

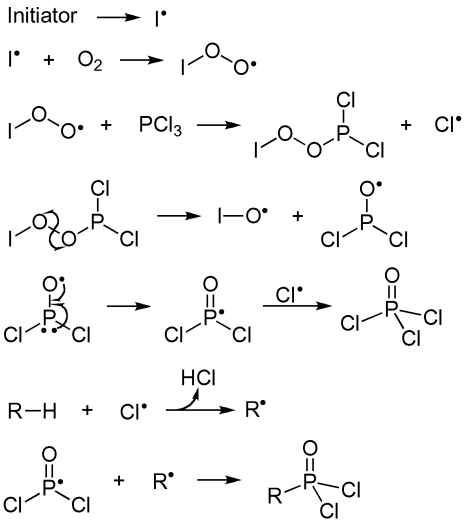
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although extensively studies have been carried out by Flurry[7] and Mayo,[4] a new mechanism is proposed here to satisfy most of the experimental results.



D. MODIFICATION

N/A

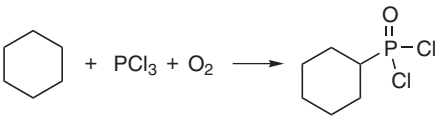
E. APPLICATIONS

This reaction has general application in the preparation of alkyl phosphonyl chlorides, which are the intermediates for alkyl phosphonic acid and corresponding esters.

F. RELATED REACTIONS

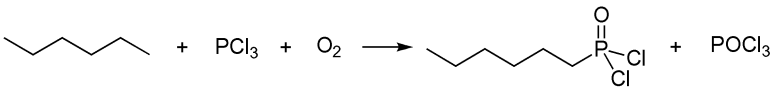
This reaction is related to the *Clay-Kinnear-Perren reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a flask equipped with an inlet tube, a thermometer and a cold finger condenser containing powdered dry ice was added 1 eq. cyclohexane and more than 4 eq. PCl_3. The flask was cooled by ice water bath; when the liquid temperature approached that of the bath (1–2°C), introduction of oxygen or air was begun. Reaction set in at once, as indicated by rapid rise in temperature. The rate was limited (in the absence of diluents and inhibitors) by the oxygen supply, usually so that the reaction temperature did not exceed 15°C. When the phosphorus trichloride was exhausted, or nearly so,the temperature of the reaction mixture quickly returned to 1–2°C. Stirring under oxygen was continued for 10–60 min more. The reaction mixture was then weighed and transferred to a Claisen distilling flask with a side arm like a Vigreux column and with thermometers to measure both liquid and vapor temperatures. The bulk of the cyclohexane and phosphorus oxychloride was distilled at atmospheric pressure up to a residue temperature of ~160°C. The residue was then transferred to a smaller flask, and removal of cyclohexane and phosphorus trichloride was continued up to a vapor temperature of 50°C at 20 mmHg pressure. Cyclohexylphosphonyl chloride, easily separated from other materials, was collected up to 135°C at 20 mmHg, or near 85°C at 0.3 mmHg. It was usually colorless, with a melting point in the range of 35–39°C (m.p. after recrystallization from petroleum ether, 39.5–40.5°C). The yield of cyclohexylphosphonyl chloride ($C_6H_{11}POCl_2$) and diphosphonyl chloride [$C_6H_{10}(POCl_2)_2$] was in the range of 70–90%.



Reference 1.

A total of 41 g 99% pure *n*-heptane (0.41 mol) was mixed with 224 g PCl_3 (1.64 mol) and bubbled, by means of a sintered glass plate, with oxygen at a slow rate for 5 h. The maximum temperature was kept below 60°C by means of a water bath. The light yellow liquid was distilled at 10 mmHg, phosphorus oxychloride boiling below 90°C was discarded, and the fraction boiling between 106° and 108°C was collected in a total amount of 28.1 g; in addition, ~16 g of residue was obtained. The narrow boiling fraction, which could not be made to crystallize, was analyzed for phosphorus and chlorine.

Other references related to the Clayton-Jensen chlorophosphonation are cited in the literature.[8]

Clemmensen Reduction

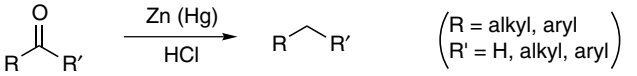
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Clemmensen of Park Davis Co in 1913.[1] It is the reduction of carbonyl groups (in aldehydes and ketones) to methylene groups with zinc amalgam and hydrochloric acid, and is generally known as the Clemmensen reduction.[2] In some cases, mercury salt (e.g., $HgCl_2$) is not necessary; and the reaction is carried out in acetic acid with zinc and HCl.[3] This reduction is a complementary method for the *Wolff-Kishner Reduction* and *Minlong Huang Reduction* of carbonyl groups with some obvious advantages, such as the adaptability to base labile and acid stable compounds without the rearrangement that the *Wolff-Kishner Reduction* often bears.[4] Although the Clemmensen reduction generally converts carbonyl group into methylene group, it is important to be aware of a few circumstances in which abnormal reactions occur: (*a*) the hydroxyl aromatics (isomer of cyclic vinyl ketone) are not reduced; (*b*) the α-keto acids or α-keto esters are partially reduced to only α-hydroxyl acids or esters, respectively;[5] (*c*) the reduction of 1,3-diketones always involves the rearrangement via pinacol-type intermediate;[6] (*d*) the reduction of 2,2-diphenyl-l,3-indandione gives 2,2-diphenylindan and 1,2-diphenylindene (the latter is the major product) and the rearrangement of the phenyl group occurs when the 2 position of indanone is disubstituted;[7] (*e*) the reduction of β-keto esters affords pure hydrocarbon, which apparently involves both alcoholysis and decarboxylation[8] (it is reported that such event does not occur in absolute alcohol with HCl present[9]); (*f*) the reduction of butyroin gives only 4-octanone, which strangely reduces the hydroxyl group and leaves the carbonyl group untouched;[10] (*g*) the reduction of benzophenone is not successful, giving a resinous product;[11] (*h*) the reduction of acetophenone in dilute hydrochloric acid gives styrene instead of ethylbenzene;[1] (*i*) the reduction of 2-unsubstituted isoflavone gives mixtures of isoflavenes;[12] (*j*) the reduction of atom-bridged bicyclic α-aminoketones

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

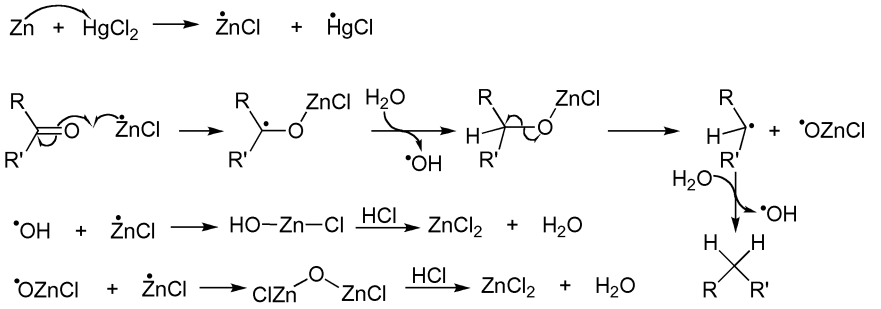
involves two competing reactions—the cleavage of the Cα-N bond and the conversion of CO to CH_2[13]—affording rearranged (ring-contraction) or ring-opening products;[14] (*k*) the reduction of cyclic thioketone affords ring-contraction product;[15] and (*l*) the reduction of ω-dimethylaminoacetophenone yields the cleavage product ethylbenzene.[16] It has been reported that alcohol is not the intermediate of the Clemmensen reduction, because under this condition, alcohol will not give hydrocarbon, except for allyl and benzyl alcohol, which change into chloride.[17] In contrast, it is believed that carbonium is involved in this reduction[3c,18] and reaction occurs at the zinc surface. For molecules that are not so soluble in these reaction conditions, such as keto acids, the addition of alcohol will improve the yield; however, the resulting acid might also be converted into ester. Under these conditions, the addition of toluene to the reaction solution will optimize the yield.[19]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that the alcohol is not the intermediate in this reduction; therefore, the mechanism outlined here is similar to that described by di Vona and Rosnati,[17] although another mechanistic illustration was given by Nakabayashi.[18] In this reduction, radical HgCl· will react similarly, so its reaction path is not given. The new radical ·OHgCl can be reduced to mercury by zinc, and mercury will again participate in the reaction cycle, as shown below.



D. MODIFICATION

The addition of water-miscible solvent, such as alcohol, acetic acid, or dioxane, will facilitate the reduction of keto acids. In addition, transformation of the acid into low melting point ester and the addition of a certain amount of toluene to retain the ester in a clear surface layer can simplify the reduction and optimize the yield.[19]

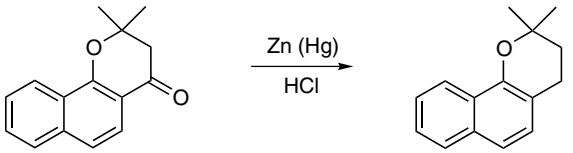
E. APPLICATIONS

This reaction has been widely used to convert a carbonyl group into a methylene group, with important applications in the preparation of polycyclic aromatics[20] and aromatics containing unbranched side hydrocarbon chains,[21] the latter is not attainable from the *Friedel-Crafts Alkylation*.

F. RELATED REACTIONS

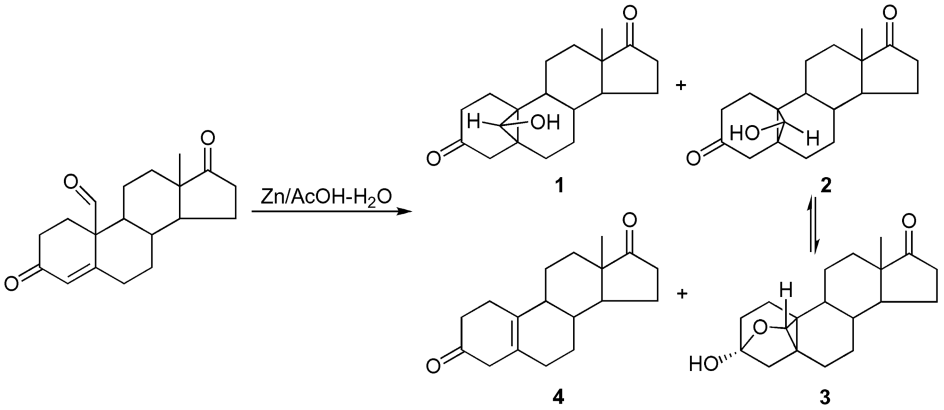
This reaction is a complementary reduction for the *Wolff-Kishner Reduction* and *Minlong Huang Reduction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 22.

To a mixture of 2.0 g zinc powder and 0.10 g $HgCl_2$ was added 20 mL water; the resulting slurry was shaken thoroughly for 5 min. To it was added 10 mL 18% HCl (1:1 mixture of H_2O and conc. HCl), and the mixture was again shaken vigorously when zinc amalgam was obtained. To this zinc amalgam was added 2.2 mmol γ-naphthopyrone and 25 mL HCl (4:1 mixture of conc. HCl and H_2O), and the contents were refluxed for 3 h. After completion of the reaction (monitored by TLC), the contents were extracted with diethyl ether. Workup of the organic layer provided a product that, on purification using column chromatography, yielded 80% of oily 3,4-dihydro-2,2-dimethylnaphthopyran.



Reference 3b.

To a solution of 8.0 g 19-formylandrost-4-ene-3,17-dione (26.5 mmol) in 160 mL 50% acetic acid was added 40.0 g zinc powder. The mixture was stirred for 1.5 h and was diluted with 500 mL CH_2Cl_2 and filtered. The filtrate was washed with water and aqueous $NaHCO_3$, dried, concentrated ($\sim$ 15 mL) and diluted with Et_2O to give 5.0 g (19*R*)-19-hydroxy-5β,19-cycloandrostane-3,17-dione (**1**), in a yield of 62.5%, m.p. 160–167°C, which on recrystallization from CH_2Cl_2–Et_2O gave an analytically pure sample, m.p. 169–179°C (dec.). A portion of the mother liquor (1 g) on flash column chromatography eluted with 80% Et_2O-LP gave 240 mg estra-5(10)-ene-3,17-dione (**4**) in a yield of 3.3%, m.p. 144–148°C, and 130 mg (19*R*)-19-hydroxy-5β,19-cycloandrostane-3,17-dione (**1**), m.p. 160–167°C, and 45 mg of a mixture of (19*S*)-19-hydroxy-5β,19-cycloandrostane-3,17-dione (**2**) and (19*S*)-3-hydroxy-3β,19-oxido-5β,19-cycloandrostan-17-one (**3**), in a yield of 0.56%, m.p. 160–165°C. The wide melting point range observed results from the thermal instability of the cyclopropanols.

Cohen Reductive Lithiation

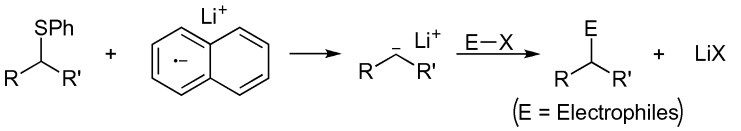
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was originally reported coincidently by Cohen[1] and Screttas[2] in 1978 but was extensively investigated by Cohen.[3] It is the formation of organic lithium compound by reductive lithiation of phenyl thioethers with aromatic radical anions, and the formed organic lithium compound can react with electrophiles to produce a variety of molecules. Currently, the aromatic radical anions used include lithium naphthalenide (LN),[4] lithium 1-(dimethylamino)-naphthalenide (LDMAN),[3s] lithium *p*,*p*′-di-*tert*-butylbiphenylide (LDBB)[3m] and lithium 2,6-di-*tert*-butylnaphthalenide (LDBN).[3b] Besides the phenyl-thioethers, the following molecules can also be reduced by the above aromatic radical anions: acetals,[5] allylic and benzylic ethers,[3m,6] amines,[7] carboxylic acids and esters,[8] epoxides,[3p,9] ketones,[10] nitriles,[11] organic halides,[12] selenides,[13] sulfates,[14] sulfides,[7] sulfones,[15] and tetrahydrofurans.[3m,16] In addition, the versatility of this method is also shown in the preparation of allylsilane,[17] 1,3-diol,[18] highly crowd amines (from α-amino nitriles),[19] butenyl alcohol (via sigmatropic [2,3] rearrangement),[4] and especially the five-membered carbocycles via the anionic cyclization with good stereoselectivity.[3a,4] Unfortunately, the aromatic radical anions involved in this reaction must be generated in tetrahydrofuran (THF), and no other solvent has been successful for the generation of such anions with lithium counterions, except for dimethyl ether (DME), which works for LDMAN.[3b] It was found that the reductive lithiuation of epoxides and oxetanes involves the transfer of an electron to an antibonding orbital (LUMO) of the corresponding heterocycle followed by a ring opening to an intermediate containing an oxyanion and a carbon radical. Two methodologies have been developed to stabilize both the LUMO and the

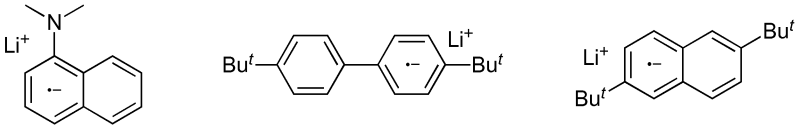
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

formed intermediates, the application of a Lewis acid (e.g., $BF_3{\cdot}Et_2O$) and the introduction of a vinyl group to the α-position of THF.[3m] It was reported that during the reductive lithiation of tetrahydrofurans and tetrahydropyrans, both the axial and the equatorial epimers predominantly give the axial lithio derivative.[3s]

B. GENERAL REACTION SCHEME



Other aromatic radical anions are also given here.



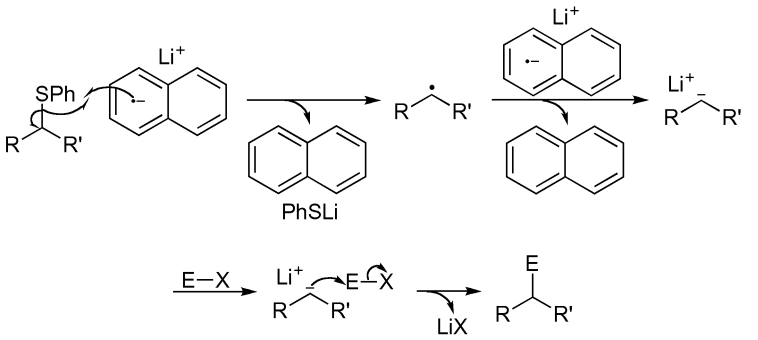
Lithium 1-(dimethylamino)-naphthalenide (LDMAN).

Lithium *p,p′*-di-*tert*-butylbiphenylide (LDBB).

Lithium 2,6-di-*tert*-butylnaphthalenide (LDBN).

C. PROPOSED MECHANISMS

This reaction involves single electron transfer process as displayed below.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has wide application in organic synthesis.

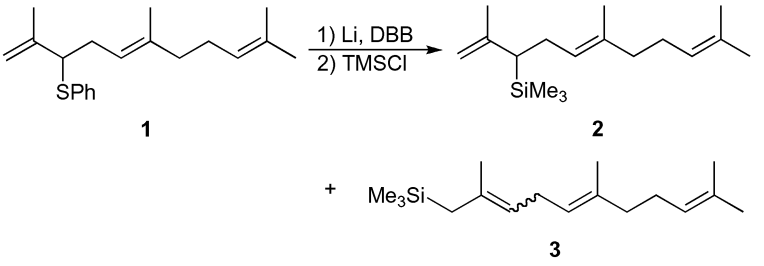
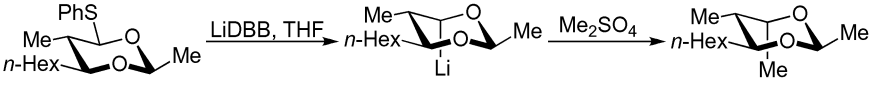
G. CITED EXPERIMENTAL EXAMPLES



Reference 17.

To a two-necked, round-bottom flask equipped with an argon inlet were added 1.4 mL THF and 18 mg DBB (0.07 mmol, 0.1 eq.). Small lithium pieces (233 mg, 33.5 mmol, 50 eq.) were prepared and quickly added to the solution of DBB while the flask was rapidly purged with argon. The mixture was sonicated for 5 min, then cooled to −78°C. A solution of 200 mg allylthioether **1** (0.67 mmol, 1 eq.) in 1 mL THF was added to the preformed solution of LiDBB under argon, and the mixture was stirred until the original dark green color reappeared; then 146 mg TMSCl (1.34 mmol, 2 eq.) was added. The reaction was maintained at −78°C for an additional 5 min, and the resulting solution was filtered to remove the excess of lithium. The mixture was extracted three times with Et_2O. The combined organic layers were washed with water and brine, dried over $MgSO_4$, and concentrated to dryness. Purification of the resulting yellow oily residue by chromatography (hexane) yielded 135 mg of a mixture of structures **2** and **3** in a 8:92 ratio as a colorless oil, in a total yield of 76%, R_f = 0.78 (hexane).



Reference 20.

A 0.2 M solution of LiDBB in dry THF was prepared according to the reported procedure.[3k] The phenylthioacetal (200 mg, 0.468 mmol) was dissolved in 4 mL dry THF, and to it was added a crystal of 1,10-phenanthroline. The solution was cooled under argon to −78°C, and then *n*-BuLi (2.0 M solution in hexanes) was added dropwise until a permanent red coloration just appeared (typically 50–100 mL was enough to quench any moisture in the reaction). The LiDBB solution (4.0 eq.) was added dropwise to the reaction mixture. Initially, an orange-red color appeared, and addition was continued until a permanent dark green color persisted. After 5 min, the green reaction mixture was treated with 492 mg Me_2SO_4 (370 mL, 3.90 mmol, 6.0 eq.), and then was stirred at −78°C for 1 h. The reaction

mixture was quenched with 10% NH_4OH/saturated NH_4Cl (1:1). The reaction mixture was extracted with CH_2Cl_2 (three times), and the combined organic layers were washed with brine, dried over anhydrous Na_2SO_4, and evaporated under reduced pressure. The crude product was purified by chromatography (SiO_2). Initially, 20% CH_2Cl_2/hexanes was used as the eluent to remove thiophenol and di-*tert*-butylbiphenyl, followed by 3% *tert*-butylmethyl ether/hexanes to afford 106 mg (2*R*,4*S*,5*R*,6*S*)-2,4,5-trimethyl-6-hexyl-1,3-dioxane (0.494 mmol) as a pale yellow oil, in a yield of 76.5%.

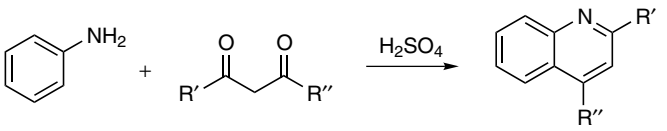
Combes Quinoline Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Combes in 1888.[1] It is the synthesis of quinolines by the condensation of primary aromatic amines with acetoacetone or other β-diketones followed by cyclization in the presence of sulfuric acid. This method provides a rapid access to the 2,4-substituted quinoline skeleton;[2] but, it suffers from low regioselectivity,[3] such as in the case of *meta*-substituted anilines with two different *ortho* positions for ring closure. It was found that polyphosphoric acid is a better catalyst than sulfuric acid for the cyclization,[4] and the factors that affect this reaction have been reviewed by Roberts and Turner.[5]

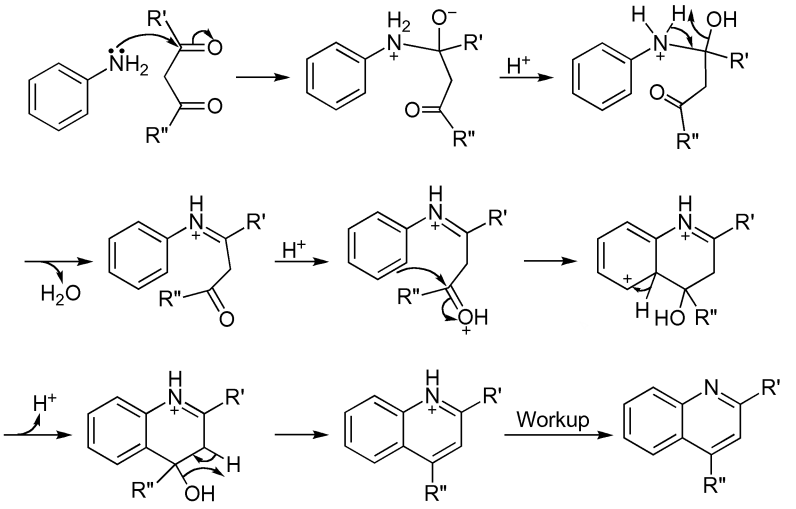
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves a condensation between aniline and β-diketone followed by an acid-catalyzed cyclization, as displayed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified to use polyphosphoric acid as the acidic catalyst to improve the overall yield.[4] In addition, Vilsmeier reagent can be applied to the cyclization step.[6]

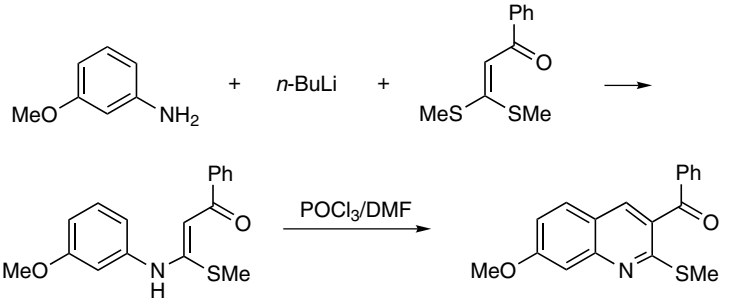
E. APPLICATIONS

This reaction has a general application in the preparation of quinoline derivatives, especially for those quinolines with substituents at position 2 and/or 5.

F. RELATED REACTIONS

This reaction is related to the *Camps Reaction, Conrad-Limpach Quinoline Synthesis, Doebner-Miller Reaction, Gould-Jacobs Quinoline Synthesis, Niementowski Reaction,* and *Skraup Reaction*.

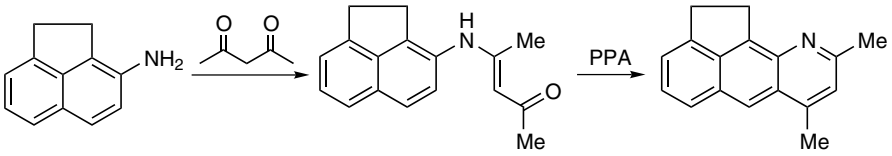
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

To a stirred solution of 10 mmol *m*-methoxyaniline in 50 mL dry THF was added 5.2 mL *n*-BuLi (12 mmol) under nitrogen atmosphere over a period of 10 min at −78°C. The reaction mixture was brought to room temperature and was further stirred for 45 min. A solution of 10 mmol α-oxoketene-*S*,*S*-acetal in 25 mL dry THF was added at 0°C, and the reaction mixture was further stirred at room temperature for 2 h. It was refluxed for 18–20 h to complete the reaction, then cooled, poured into 100 mL of saturated NH_4Cl solution, and extracted with $CHCl_3$ (2 × 50 mL). The combined extracts were washed with water (2 × 50 mL) and brine (50 mL), dried over Na_2SO_4, and evaporated to give crude 3-(3-methoxyanilino)-3-methylthio-1-phenylprop-2-en-1-one, which was purified by column chromatography over silica gel using hexanes/EtOAc as the eluent. A total of 2.45 g of product was obtained, in a yield of 82%. This compound can be further purified by recrystallization from $CHCl_3$/hexane to afford light yellow crystals, m.p. 75–76°C, $R_f = 0.59$ (9:1 hexanes/EtOAc).

A solution of 5 mmol α-oxoketene-*N*,*S*-acetal in 5 mL DMF (or DMA, $Cl_2CHCHCl_2$) was added dropwise at 0°C to a solution of Vilsmeier reagent prepared from 0.7 mL $POCl_3$ (7.5 mmol) and 7.5 mmol DMF or DMA at 0–5°C under nitrogen atmosphere. After further stirring for 5–6 h at room temperature, the reaction mixture was heated to 80–90°C for 3–4 h (monitored by TLC). It was then cooled, poured into 100 mL ice cold saturated $NaHCO_3$ solution, and extracted with chloroform (4 × 50 mL). The combined organic extracts were washed with water (3 × 50 mL) and 25 mL brine and dried over Na_2SO_4; the solvent was evaporated under reduced pressure to afford crude 3-benzoyl-7-methoxy-2-methylthioquinoline, which was purified by column chromatography over silica gel using hexanes/EtOAc as the eluent; 1.25 g quinoline was obtained, in a yield of 81%. This quinoline can be further purified by recrystallization from $CHCl_3$/hexane to afford a light yellow solid, m.p. 105–106°C, $R_f = 0.60$ (9:1 hexanes/EtOAc).



Reference 4.

3-Aminoacenaphthene (8.68 g, 51.3 mmol) and 13 mL 2,4-pentanedione (127 mmol) were mixed and heated for 16 h at 100°C. The mixture was cooled, and the product was recrystallized from benzene-hexanes to give 10.0 g 3-[(l-methyl-3-oxobut-l-enyl)amino]acenaphthene as light brown crystals (39.8 mmol), in a yield of 78%, m.p. 150–152°C.

The enamine (0.45 g, 1.79 mmol) was mixed in a Pyrex tube with 10 g polyphosphoric acid. The mixture was heated gradually to 160–170°C with stirring. After all of the solid had dissolved (∼ 2 h), the tube was cooled, water was added, and the reaction mixture was quenched with excess aqueous NaOH. The resulting mixture was extracted with 200 mL ether, and the extract was washed with water and dried over Na_2SO_4. Evaporation of the solvent gave 0.42 g pure yellow-orange 7,9-dimethyl-l0-azaaceanthrene, in a yield of 100%, m.p. 164–166°C.

Conrad-Limpach Quinoline Synthesis

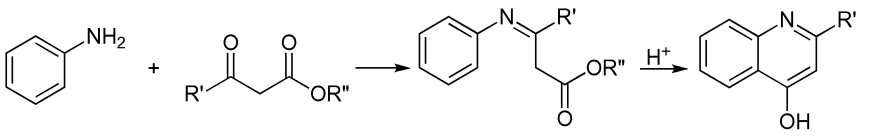
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Conrad and Limpach in 1887.[1] It is the synthesis of 4-quinolones, which often isomerize (or aromatize) to 4-hydroxyquinolines through the thermal condensation of primary aromatic amines with the carbonyl group of β-ketoesters followed by the cyclization of Schiff base intermediates (alkyl β-arylaminocrotonates). Therefore, it is known as the Conrad-Limpach quinoline synthesis[2] or Conrad-Limpach synthesis.[3] However, during the condensation of primary aromatic amines with β-ketoesters, the amino group might also react at the ester group of β-ketoesters to form β-ketoacetamide intermediates (isomerize to ketoacetanilides), which cyclize to 2-hydroxyquinolines; this type of conversion was initially discovered on Knorr in 1886.[4] Therefore, the Conrad-Limpach quinoline synthesis sometimes is also referred to as Conrad-Limpach-Knorr quinolone synthesis,[5] Conrad-Limpach-Knorr reaction,[6] and Knorr-Conrad-Limpach method.[7] Nevertheless, there are still some distinctive differences between these two reactions. For example, β-ketoesters are used in Conrad-Limpach quinoline synthesis, whereas ethyl acetoacetate is mostly used in the *Knorr Quinoline Synthesis*, in addition, higher temperature of condensation results in the Knorr product, whereas moderate or lower temperatures lead to the Conrad-Limpach product.[6] Furthermore, the presence of iodine or an acidic catalyst is often necessary for the Conrad-Limpach quinoline synthesis.[6] In this reaction, the condensed intermediates have seldom been isolated and characterized because, in most cases, these intermediates are viscous oils that are directly subjected to thermal cyclization.[8] During the cyclization, the protonated carbonyl group will function as an electrophile, whereas the aromatic ring acts as a nucleophile;[9] if an

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

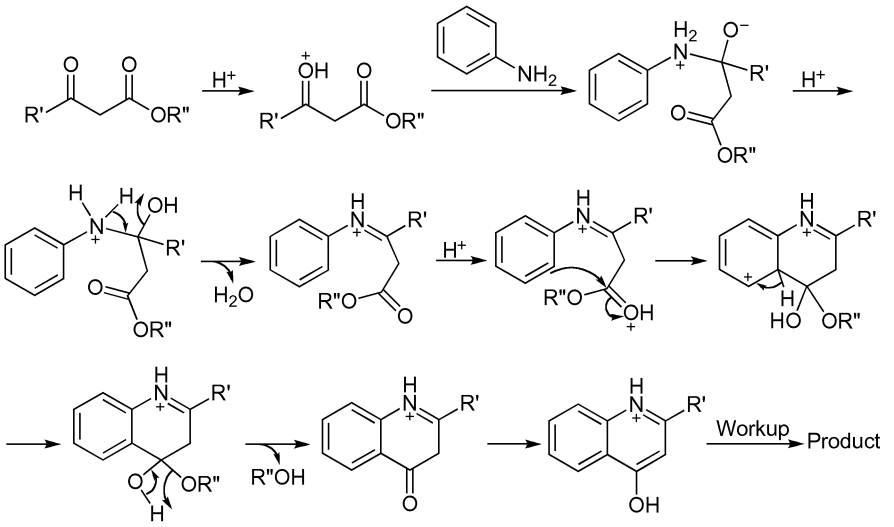
electron-withdrawing group exists on the aromatic ring, such as a nitro group, then the cyclization is difficult.[6,7,10] Similarly, as a poor nucleophile, 3-aminopyridine is difficult to react with β-ketoesters to form naphthyridine;[9] it is surprising, however, that 2,6-diaminopyridine reacts conveniently to afford naphthyridine even at room temperature,[11] this is likely attributed to the distribution of an electron cloud to the pyridyl ring from the two strong electron-donating amino groups.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a general illustration of the reaction.



D. MODIFICATION

This reaction has been modified for the use of acetoacetonitriles[12] and Meldrum's acid[13] instead of β-ketoesters to afford 4-hydroxyquinolines.

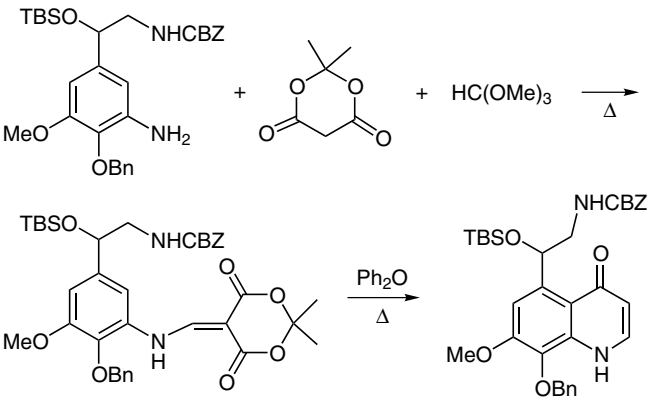
E. APPLICATIONS

This reaction is generally good for the synthesis of 4-hydroxyquinolines and 4-quinolones.

F. RELATED REACTIONS

This reaction is related to the *Camps Reaction, Combes Quinoline Synthesis, Doebner-Miller Reaction, Gould-Jacobs Quinoline Synthesis, Niementowski Reaction* and *Skraup Reaction*.

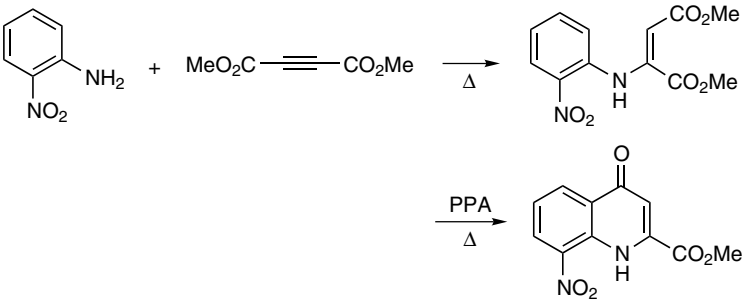
G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

Meldrum's acid (0.413 g, 2.87 mmol) was refluxed under nitrogen in 35 mL trimethyl orthoformate for 2 h. *O*-Benzyl *N*-2-(5-amino-4-benzyloxy-3-methoxyphenyl)-2-(*tert*-butyldimethylsilyloxy)ethyl carbamate (1.14 g, 2.39 mmol) dissolved in 15 mL trimethyl orthoformate, was added to the solution of Meldrum's acid, and the mixture was refluxed for 4 h. The solvent was removed in vacuo and the residue was subjected to flash chromatography (2:1 hexane/EtOAc) to give 1.00 g 5-[5-[2-(benzyloxycarbonylamino)-1-(*tert*-butyldimethylsilyloxy)ethyl]-2-benzyloxy-3-methoxyphenylaminomethylene]-2,2-dimethyl-1,3-dioxane-4,6-dione as a white solid, in a yield of 87%, m.p. 110–111°C after recrystallization from EtOAc/hexanes.

To a solution of 100 mL diphenyl ether was added 1.09 g 1,3-dioxane-4,6-dione (1.57 mmol). A stream of nitrogen was passed through the solution for 20 min and the flask was then lowered into a large silicone oil bath preheated to 240°C. The temperature of the bath dropped to 225°C and rose again to 240°C in 5–7 min. The solution was stirred in the bath for a total of 18 min, then removed and allowed to cool. The solvent was removed under vacuum (0.1 mmHg, 110°C). Flash chromatography (1:2 to 6:1 hexanes/EtOAc) gave 0.326 g *O*-benzyl *N*-2-(*tert*-butyldimethylsilyloxy)-2-[8-benzyloxy-7-methoxy-4(1*H*)-quinolinon-5-yl]ethyl carbamate as a tan solid, in a yield of 35%. An analytical sample, m.p. 63–65°C, was obtained by recrystallization from EtOAc/hexanes.



Reference 5.

An equal molar amount (0.02 mol) of *o*-nitroaniline and dimethyl acetylenedicarboxylate was mixed in 100 mL anhydrous methanol and refluxed for 24–48 h. The reaction mixture was cooled in ice, and the precipitated product was removed by filtration. Successive crystal crops were obtained by concentration in vacuo of the mother liquors to give 95% of a *Michael Addition* product, m.p. 130–131°C.

A paste, formed from intimately mixing 2–4 g Michael adduct with 20–30 g polyphosphoric acid, was heated with stirring at 140–180°C for 30 min. Considerable foaming resulted, and the mixture turned progressively darker. After cooling to 100°C, the viscous solution was poured into a mixture of chopped ice and water and scratched with a glass rod to induce crystallization. If allowed to stand at ice bath temperatures for 5–10 h before filtration, the filterability of the product was improved. The solid, removed by vacuum filtration, was air dried and recrystallized from methanol. The sample was purified by sublimation at 0.5 mmHg at 20°C under its melting point, the yield was 47%, m.p. 195°C.

Other references related to the Conrad-Limpach quinoline synthesis are cited in the literature.[14]

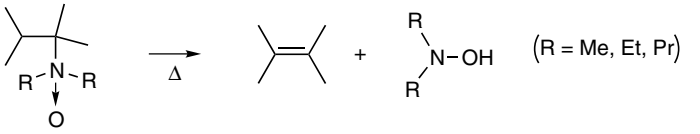
Cope Elimination
(Cope Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Wolffenstein in 1898.[1] It is the synthesis of olefins from thermal decomposition (i.e., pyrolysis) of *N*-oxides of tertiary amines. However, this reaction did not drawn much attention until 1949, when Cope extensively explored its scope and mechanism.[2] Therefore, this reaction is referred to as the Cope-Mamlock-Wolffenstein hydroxylamine elimination,[3] but is more generally known as the Cope elimination[4] or Cope reaction.[3,5] On the other hand, the reversal process of this reaction (e.g., the addition of hydroxylamine to double bond) is generally referred to as the reverse Cope elimination[6] or *retro*-Cope elimination.[7] This reaction is cleanly first order in substrate,[4o] and undergoes an intramolecular five-membered cyclic synchronous transition state,[4g] in which hydrogen and nitrogen are coplanar.[4p] An isotopic labeling study indicates that both the C-H and the C-N bond cleavage may be well advanced at the transition state, with considerable development of double-bond character.[4m] The pyrolysis of tertiary amine oxides occurs in the temperature range of 120–150°C without any solvent present;[4o] however, this pyrolysis can occur under extremely mild conditions and even at room temperature when dimethyl sulfoxide is used as a solvent.[4o] The order of the eliminating alkyl group after correction for the number of available β-hydrogen atoms is *p*-phenylethyl >> *t*-butyl > isobutyl ~ isopropyl ~ *n*-decyl > *n*-butyl > isoamyl > ethyl > *n*-propyl.[2g] Of particular preparative importance is that this reaction is free from side reactions compared to other eliminations,[4p] and it produces medium-size *trans* olefins during the elimination[2i,2j] (with same exceptions[4m]), especially for the highly strained bridge double bond.[4l] However, the pyrolysis of allyldialkylamine oxides and benzyldimethylamine oxide at temperatures of 80–165°C, result in the migration of the allyl and benzyl groups from the nitrogen to the oxygen atom, instead of an elimination.[9] This reaction has also been studied theoretically.[4g,10]

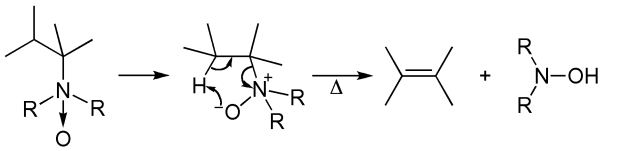
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves an intramolecular five-membered cyclic synchronous transition state, as displayed below.



D. MODIFICATION

This reaction has been modified to occur at extremely mild conditions in a solvent of DMSO.[4o] In addition, the *sila*-Cope elimination has recently been developed.[11]

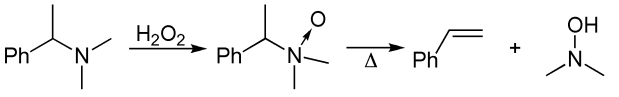
E. APPLICATIONS

This reaction has general application in the preparation of olefins.

F. RELATED REACTIONS

This reaction is related to the *Bamford-Stevens Reaction, Chugaev Reaction, Hofmann Elimination* and *Ramberg-Bäcklund Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



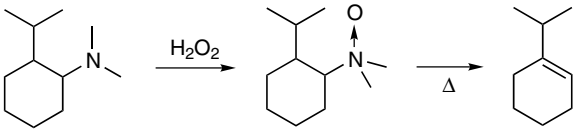
Reference 2k.

N,*N*-Dimethyl-(α-phenylethy1)-amine (11.0 g) was stirred with 18.3 g 35% aqueous hydrogen peroxide (150% excess) for 11 h at room temperature. The excess hydrogen peroxide was decomposed by stirring the mixture with 8 cm^2 of clean platinum foil until

the evolution of oxygen ceased. Most of the water was removed by distillation at 35 mmHg pressure and a bath temperature of 45–55°C; the distillate and material that condensed in a trap cooled with a mixture of dry ice and trichloroethylene in the vacuum line were saved. The residual syrup was diluted with 25 mL absolute ethanol and concentrated again under reduced pressure while nitrogen was admitted through a capillary ebulliator inlet. The process was repeated twice to remove as much water as possible. The amine oxide remained as a viscous syrup, which from its odor contained a small amount of styrene.

A 100-mL round-bottomed flask fitted with a capillary nitrogen inlet and containing the tertiary amine oxide was connected by a large-diameter tube to a condenser set for distillation, which led to two receivers in series cooled in a mixture of dry ice and trichloroethylene. The system was evacuated to 5 mmHg, and the flask was immersed in an oil bath at 85°C. The bath temperature was slowly raised to 115°C over 35 min, at which time almost all of the material had distilled. The bath temperature was raised to 150°C to complete the distillation; 0.35 g of a tarry residue remained. The distillate was combined with the distillate obtained in concentration of the amine oxide solution, pentane was added as a solvent, and the mixture was washed with dilute hydrochloric acid. The acid solution was extracted with pentane, and the pentane solutions were washed with water until neutral. The combined aqueous layers containing hydrochloric acid were concentrated under reduced pressure to a crystalline residue, which was dried by adding absolute alcohol, reconcentrating under reduced pressure, and placing in a vacuum desiccator over phosphorus pentoxide. The yield of *N*,*N*-dimethylhydroxylamine hydrochloride was 6.73 g (94%), m.p. 101–104°C (sealed capillary).

The pentane solution containing the neutral product was dried over magnesium sulfate and concentrated at atmospheric pressure, after the addition of a crystal of picric acid as a polymerization inhibitor. Distillation of the residue afforded 5.34 g styrene, in a yield of 70%, b.p. 82–83°C at 102 mmHg.



Reference 2d.

N,*N*-Dimethyl-D-neomenthylamine was oxidized, and the resulting amine oxide (5.85 g) was pyrolyzed in a round-bottomed flask equipped with a capillary nitrogen inlet and connected through a Vigreux column to two traps in series and cooled in a dry ice acetone mixture. The flask was heated to 90–130°C (7 mmHg) for 30 min and raised to 160°C. The contents of the traps were allowed to melt and then were combined and diluted with 40 mL pentane. The pentane solution was extracted with hydrochloric acid, which when treated with excess sodium hydroxide solution, gave 0.54 g *N*,*N*-dimethyl-D-neomenthylamine (9% recovered), b.p., 87–92°C (10 mmHg). After being washed and then evaporated, the pentane solution yielded 3.38 g menthene in a yield of 77%, b.p., 97–98°C (80 mmHg). (*Note*: The procedure was completely reorganized according to the described experiment.)

Cope Rearrangement

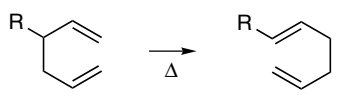
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Cope and Hardy in 1940.[1] It is the thermal isomerization of a 1,5-diene through the highly stereoselective [3,3] sigmatropic rearrangement leading to a more stable 1,5-diene and is generally known as the Cope rearrangement.[2] From 1940, the Cope rearrangement and its variants have been extensively explored, and the comparable variants include the *amino*-Cope rearrangement,[3] *aza*-Cope rearrangement[4] (or *aza*-Cope reaction[5]), *diaza*-Cope rearrangement,[6] *oxaza*-Cope rearrangement,[7] *oxonia*-Cope rearrangement,[8] *oxy*-Cope rearrangement[9] (or *oxa*-Cope rearrangement[10]), *sila*-Cope rearrangement[11] (or *silyoxy*[12] or *silylox*-Cope rearrangement[13]), and *thio*-Cope rearrangement.[14] On the one hand, the Cope rearrangement can be either thermally[15] or photochemically[16] activated; on the other hand, it also can be catalyzed by acid,[8e,17] antibody,[18] and enzyme[19] or mediated via an indium atom.[9o] For this popular rearrangement, a few mechanisms have been proposed; a stepwise mechanism[20] (or two-step mechanism[20b,21]), a mechanism with a diradical character[22] (via dissociation into a pair of resonance stabilized allyl radicals followed by ring closure[21]), and a concerted mechanism.[8e,23] Much experimental evidence favors the concerted mechanism, and it has been reported that the stepwise mechanism occurs only in cases with strong radical stabilizing substituents at C2 and C5, such as the reaction of 2,5-diphenyl-1,5-hexadiene;[21] and the mechanism with the diradical character is even less popular.[21] In the Cope rearrangement via the concerted mechanism, the chair-like transition state is favored,[24] and the transition state is not polarized; as a result, no apparent solvent effect has been observed when decane and anisole are used as solvents.[23b] It should be pointed out that besides the reaction in the

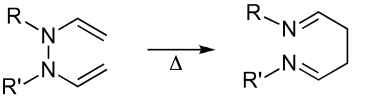
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

solution phase, the Cope rearrangement can also occur in a vapor phase.[16] Although most of the rearrangements involve the double allylic alternation, single *Allylic Rearrangement* has also been observed,[25] for which the term *oxy*-Cope rearrangement[9] has been proposed. Besides extensive experimental studies, comparable theoretical studies have been carried out.[21,22,26] It is important to note that when a hydroxyl group appears at position 3 of the 1,5-diene, the rearrangement rate is extremely accelerated, especially when such a molecule is treated with a strong base, such as potassium hydride (KH), the reaction rate can be 10^{10}–10^{17} faster than the normal Cope rearrangement.[27] This fast Cope rearrangement is known simply as the *oxy*-Cope rearrangement.[9,15,25] When two hydroxyl groups occur at positions 3 and 4, the rearrangement occurs at a temperature as low as –78°C.[28] The driving force for the neutral or anionic *oxy*-Cope rearrangement is to form an enol or enolate, which can irreversibly tautomerize to the corresponding carbonyl compound. It has been reported that the fast rate for the *oxy*-Cope rearrangement is due to the bond-weakening effect of the anionic alkoxy group on the adjacent C3-C4 bond;[29] as a result, the reaction runs faster when the alkoxy anion is more naked (modulated by the application of a larger counterion and crown ether).[30] In addition, when the unsaturation of 1,5-diene is extended (i.e., more double-bond conjugated to the 1,5-diene), the rearrangement is even faster.[9n] This reaction has been extensively reviewed.[31]

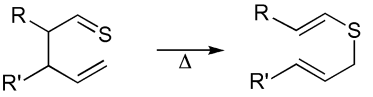
B. GENERAL REACTION SCHEME



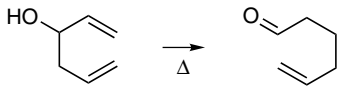
Cope rearrangement.



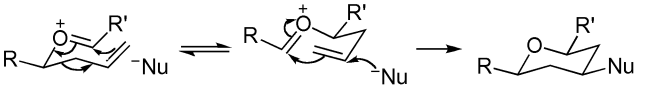
Diaza-Cope rearrangement.



Thia-Cope rearrangement.



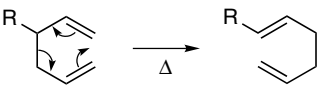
Oxy-Cope rearrangement.



Oxonia-Cope rearrangement.

C. PROPOSED MECHANISMS

In most cases, this reaction involves a concert mechanism, as simply displayed here.



D. MODIFICATION

This reaction is very popular and has been extensively studied and modified. The modifications include the different variants of the Cope rearrangements outlined earlier. In addition, this reaction has been modified to proceed by means of indium metal,[9o] acid,[8e,17] antibody,[18] and enzymes.[19]

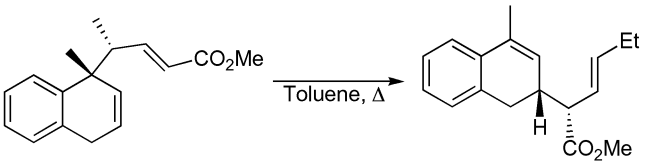
E. APPLICATIONS

This reaction has very broad applications in modern organic synthesis.

F. RELATED REACTIONS

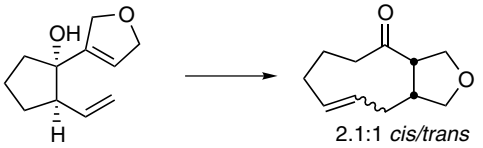
This reaction is related to the *Claisen Rearrangement* and its variants.

G. CITED EXPERIMENTAL EXAMPLES



Reference 32.

A solution of 74 mg (*R*, 2*E*)-methyl 4-((*S*)-1,4-dihydro-1-methylnaphthalen-1-yl)hex-2-enoate (98.4% e.e.) in 5 mL toluene was refluxed for 6 h. Toluene was evaporated, and the residue was purified by flash chromatography on silica gel (20:1 pentane/ether eluent) to provide 68 mg (*S*, 3*E*)-methyl 2-((*R*)-1,2-dihydro-4-methylnaphthalen-2-yl)hex-3-enoate as a colorless oil (98.0% e.e.), in a yield of 92%, R_f = 0.38 (10:1 pentane/ether).



Reference 9p.

To a solution of 80.0 mg 18-crown-6 in 5 mL THF was added 50 mg alcohol (0.277 mmol) by syringe. After being cooled to -40°C, 0.60 mL KHMDS solution in toluene (0.5 M, 0.30 mmol) was added dropwise, and the solution was stirred for 1 h. While still cold, the reaction mixture was poured into 30 mL 1 N HCl solution and extracted with EtOAc (2 × 30 mL). The combined organic extracts were dried over $MgSO_4$ and concentrated in vacuo. The remaining residue was purified by chromatography (4:1 hexanes/ether) to give 27.0 mg *cis*-cyclic ketone (0.150 mmol, 54% yield) as the less polar product and 13.0 mg *trans*-cyclic ketone (0.072 mmol, 26% yield) as the more polar product.

Other references related to the Cope rearrangement and *oxy*-Cope rearrangement are cited in the literature.[33]

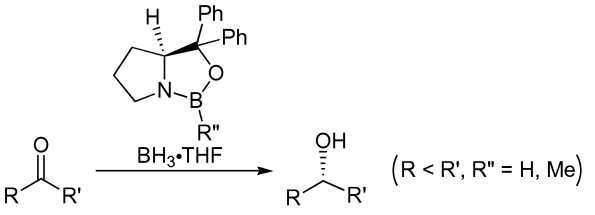
Corey-Bakshi-Shibata Reduction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Core, and co-workers in 1987.[1] It is a reduction of ketone by borane in the presence of a chiral oxazaborolidine catalyst, with excellent enantioselectivity, high chemical yield,[2] high turnover of the catalyst, and exceptional rate enhancement.[3] Therefore, this reaction is often known as the Corey-Bakshi-Shibata reduction,[4] or simply the CBS reduction.[5] Occasionally, this reaction is also referred to as the Corey-Bakshi-Shibata asymmetric reduction.[6] Likewise, the chiral oxazaborolidine, known as the Corey-Bakshi-Shibata catalyst[7] or the CBS catalyst,[2,7] is a small molecule with multifunctionality.[3] The endocyclic boron-methylated catalyst shows a superior air and moisture stability[5c,5d] that can be weighed in the open air.[3] It was proposed that this reduction undergoes a catalytic cycle in four principal steps: the coordination of the nitrogen atom of the Lewis base to borane, complexation of the ketone to the endocyclic boron (functioning as Lewis acid) via the Lewis acid–base interaction, hydride transfer from borane to the carbonyl carbon, and dissociation of the alkoxyborane moiety and regeneration of the catalyst.[5c] It is reported that up to two of the three hydrides of borane can be transferred for reduction.[8] On the one hand, this reaction has been extensively modified experimentally, including variations of the catalyst,[9] borane reagent,[10] order and rate of addition,[8c] solvent,[8c] and temperature.[8b] This reaction has also been investigated theoretically,[5c,11] especially from the work of Nevalainen.[12] This reaction has been reviewed several times.[13]

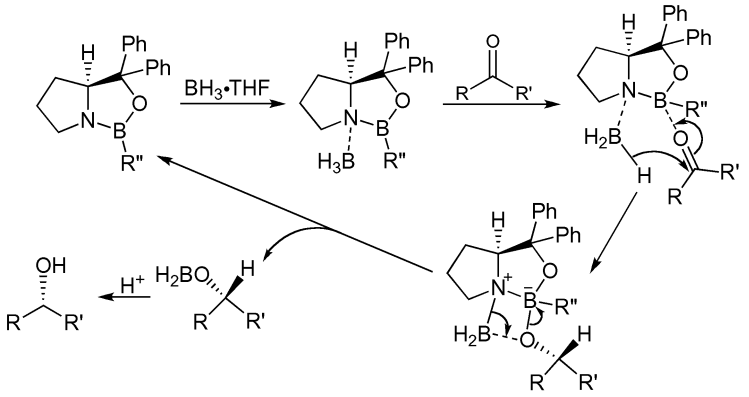
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The reaction involves the coordination of a nitrogen atom to borane, the carbonyl group to the endocyclic boron atom and subsequent hydride transfer and decomposition of the alkoxyborane intermediate to the chiral alcohol.



D. MODIFICATION

This reaction has been modified to have a methyl group attach to the endocyclic boron atom of the CBS catalyst.[3,5c,5d]

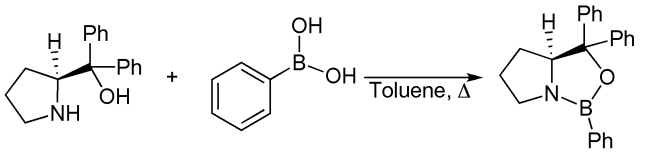
E. APPLICATIONS

This reaction has a general application in the stereospecific transformation of prochiral ketones into secondary alcohols.

F. RELATED REACTIONS

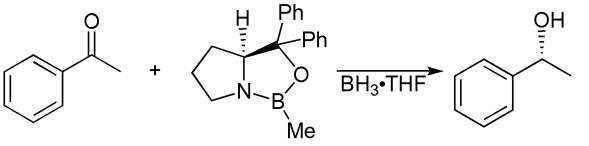
This reaction is related to the *Brown Hydroboration*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4e.

In a 100-mL dry Schlenk flask were added 2.0 mmol amino alcohol, 2.1 mmol phenylboronic acid, and 40 mL dry toluene. The suspension mixture was heated to reflux in an atmosphere of argon for 24 h with azeotropic removal of water, which was trapped by 10 g 4-Å molecular sieves placed in a pressure-equalizing dropping funnel between the flask and the condenser. The toluene was then removed in vacuo,and the residue was purified by Kugelrohr distillation (215–220°C, 0.5 mbar) to give 93% pure (*S*)-1,3,3-triphenylperhydropyrrolo[1,2-c][1,2,3]oxazaborole.



Reference 2.

To 20 mL of a 0.074 M solution of catalyst in THF at 0°C was added 1.77 mL 1 M BH_3·THF. This was followed quickly by the addition of 0.35 g acetophenone (2.94 mmol) in 0.5 mL THF. The solution was stirred for 30 min at room temperature, treated with 5 mL 0.5 M HCl, and stirred for an additional 10 min. The solution was extracted twice with Et_2O. The extracts were washed with brine, dried over Na_2SO_4, and concentrated. A GC analysis indicated a yield of 100% with 85.5% e.e.

Other references related to the Corey-Bakshi-Shibata reduction are cited in the literature.[14]

Corey-Chaykovsky Epoxidation

(Corey-Chaykovsky Reaction)

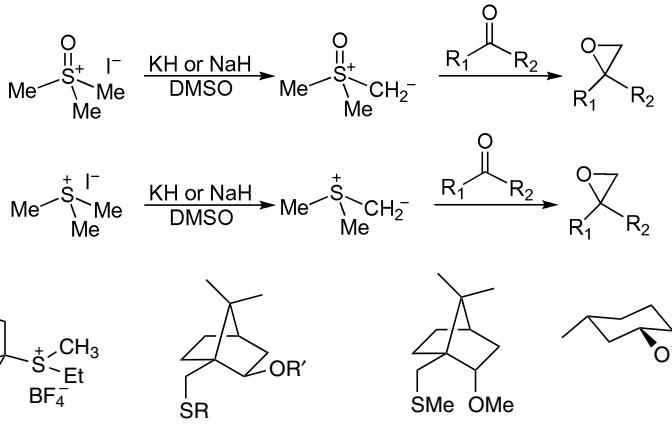
A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction was first reported by Johnson in 1958,[1] it was Corey and Chaykovsky who extensively explored its scope in the 1960s.[2] It is the preparation of monosubstituted or geminally disubstituted epoxides from aldehydes or ketones with either methylsulfonium or methyloxosulfonium ylides. Therefore, it is often known as the Corey-Chaykovsky reaction;[3] and occasionally, it is also referred to as Corey-Chaykovsky epoxide synthesis,[4] Corey-Chaykovsky epoxidation,[5] or Corey-Chaykovsky oxiranylation.[6] Likewise, methylsulfonium or methyloxosulfonium ylide is known as the Corey-Chaykovsky reagent.[7] Traditionally, trimethylsulfoxonium ylide ($Me_2S{=}CH_2$) is prepared from trimethyl sulfoxonium iodide with NaH in DMSO that is stable at 0°C in an inert atmosphere and condenses with carbonyl compounds at 0–25°C.[4] Trimethyloxosulfonium ylide ($Me_2S(O){=}CH_2$) reacts at temperature of 50°C.[4] In this reaction, the ylide behaves as a nucleophile at the initial stage, and epoxide is formed from a backside attack of an oxido anion on the β-carbon.[3d] It has been reported that pentacoordinate 1,2λ^4-oxathietanes are intermediates in the addition step of this reaction.[3d] A few mechanisms have been proposed for this epoxidation, including the concerted mechanism, *anti*-addition, and torsional rotation pathways;[3b] however, it has been reported that the concerted mechanism is not favorable, and the *trans* epoxides are formed via the *anti*-addition pathway.[3b] This reaction has been modified to start from a dry mixture of trimethylsulfonium salt with potassium *tert*-butoxide and NaH, which remain stable, and the ylide is generated upon

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

the addition of DMSO or a DMSO/THF solution of carbonyl compounds.[4] Similar to the *Wittig Reaction*, the Corey-Chaykovsky ylide leads to the formation of olefin,[8] as shown by the reaction with benzophenone at 75–100°C.[9] Furthermore, the ylide can add to alkene to form cyclopropane,[3c] imines to give aziridines,[10] etc. This reaction has been made catalytically in two phases.[11] It has been reported that if chiral sulfur ylides are used, optical active epoxides can be obtained from the achiral aldehydes and ketones.[12] So far, different chiral sulfur ylides have been designed as shown in reaction scheme.

B. GENERAL REACTION SCHEME



Trost[12a]

Furukawa[12b]

Solladié-Cavallo[12e–12j]

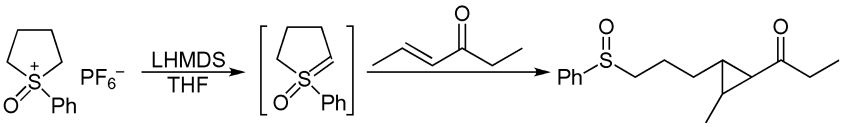
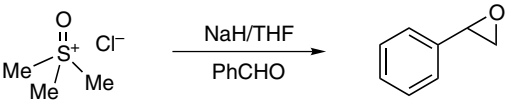
G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

To a solution of 0.10 g five-membered oxosulfonium salt (0.31 mmol) in 2 mL dry THF was added dropwise a solution of 0.32 mL 1 M lithium bis(trimethylsilyl)amide (0.32 mmol), and the mixture was stirred at room temperature for 10 min. A solution of 0.03 g 4-hexen-3-one (0.31 mmol) in 2 mL dry THF was then added dropwise to the mixture, and the resulting solution was stirred for 14 h. The mixture was quenched with water and extracted with CH_2Cl_2. The combined organic layers were washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel using EtOAc/$CHCl_3$ (1:1) as an eluent to give 98% of product as a colorless liquid.



Reference 2a.

The ylide was prepared by refluxing a mixture of 0.04 mol sodium hydride, 5.12 g (0.04 mol) trimethyloxosulfonium chloride, and 30 mL dry tetrahydrofuran under nitrogen until the evolution of hydrogen ceased (∼2 h). With the reaction mixture held at 55°C, a solution of 3.18 g (0.03 mol) benzaldehyde in 30 mL dry tetrahydrofuran was slowly added dropwise with stirring over a period of 1.5 h and the reaction mixture was then stirred at 55°C for an additional hour. The mixture was concentrated under reduced pressure (generated by a water aspirator) to a volume of ∼10 mL, then 50 mL water was added. The mixture was extracted with pentane (some resinous material remained in the aqueous phase). The combined pentane extracts were dried over anhydrous sodium sulfate and evaporated; the pale yellow residue was evaporatively distilled at 80°C (5.0 mmHg) to yield 2.0 g of colorless styrene oxide, in a yield of 55.6%.

Corey-Fuchs Reaction

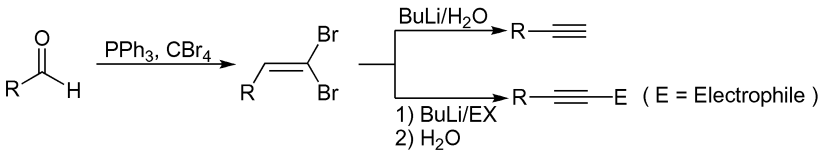
(Corey-Fuchs Dibromoolefination, Corey-Fuchs Homologation, Corey-Fuchs Olefination)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and Fuchs in 1972.[1] It is a two-step process to prepare a terminal alkyne with one-carbon homologation of an aldehyde or to prepare an alkyne derivative by the treatment of the alkynide intermediate with an electrophile before an aqueous workup. Therefore, it is generally known as the Corey-Fuchs reaction.[2] Occasionally, it is also referred to as the Corey-Fuchs dibromoolefination[3] and Corey-Fuchs homologation.[4] In this reaction, the first step is the reaction of an aldehyde with PPh_3 and carbon tetrahalide[1,5] or haloform[6] to form dihaloalkene, and the second step involves the treatment of dihaloalkene with a base (e.g., BuLi,[7] LDA,[5] or KO^tBu[6]) to generate a haloalkyne that undergoes metal-halogen exchange to give lithium alkynide. Aqueous workup of such lithium alkynide affords the corresponding terminal alkyne, whereas the treatment of this intermediate with an electrophile before workup generates alkyne derivatives.[8] Therefore, this reaction is also known as the Corey-Fuchs ethynylation.[9] In addition, because dihaloalkene is formed as a reaction intermediate that can be obtained before the treatment with a strong base, this reaction is also referred to as the Corey-Fuchs olefination.[10]

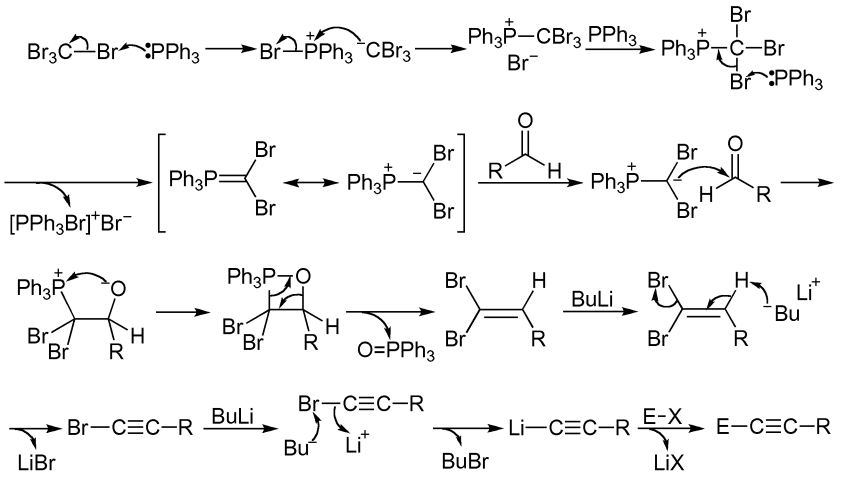
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Provided below is a simple illustration of the reaction mechanism.



D. MODIFICATION

Haloform has been applied to this reaction.[6] In addition, zinc dust has been added to the procedure to prepare dibromoalkene with an improved yield.[11]

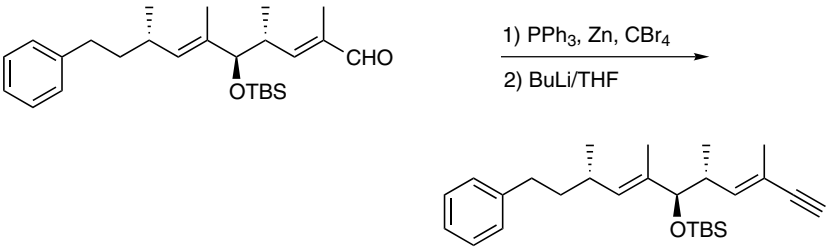
E. APPLICATIONS

This reaction has general application in the preparation of alkyne derivatives, especially for the terminal alkynes.

F. RELATED REACTIONS

This reaction is related to the *Wittig Reaction*.

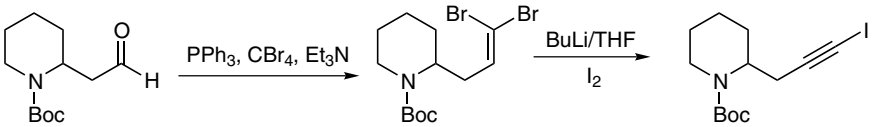
G. CITED EXPERIMENTAL EXAMPLES



Reference 11.

To a mixture of 1.45 g PPh_3 (5.51 mmol) and 0.36 g zinc dust (5.51 mmol) in 20 mL CH_2Cl_2 was added 1.83 g CBr_4 (5.51 mmol) at 0°C. The resultant yellow slurry was stirred at 0°C for 15 min and 23°C for 15 min. The solution of 1.14 g (2*E*,4*R*,5*R*,6*E*,8*S*)-2,4,6,8-tetramethyl-5-(*t*-butyldimethylsilyloxy)-10-phenyl-2,6-decadien-1-al (2.755 mmol) in 8 mL CH_2Cl_2 was then added via cannula. The resulting reaction mixture was stirred at 23°C for 6 h. Pentane (100 mL) was added, and the precipitates formed were filtered off through Celite. The solid residue was dissolved in 10 mL CH_2Cl_2, reprecipitated with 30 mL pentane, and filtered again. This process was repeated for a total of three times. The combined pentane filtrates were concentrated, and the resulting liquid was purified on silica gel (1% EtOAc/hexanes) to give 1.54 g (3*E*,5*R*,6*R*,7*E*,9*S*)-1,1-dibromo-3,5,7,9-tetramethyl-6-(*t*-butyldimethylsilyloxy)-11-phenyl-1,3,7-undecatriene as a colorless oil, in a yield of 98%.

To a stirring solution of 1.52 g (3*E*,5*R*,6*R*,7*E*,9*S*)-1,1-dibromo-3,5,7,9-tetramethyl-6-(*t*-butyldimethylsilyloxy)-11-phenyl-1,3,7-undecatriene (2.66 mmol) in 14 mL THF cooled to –78°C was added 2.23 mL 2.5 M *n*-BuLi in hexanes (5.59 mmol). The resulting yellow solution was stirred at −78°C for 15 min then warmed to 0°C and stirred at 0°C for 30 min. Saturated NH_4Cl solution was added. The mixture was diluted with ether and washed with brine until pH = 7. The combined organic layers were dried over $MgSO_4$ and concentrated. Flash chromatography (silica gel, 1% EtOAc/hexanes) gave 1.01 g (3*E*,5*R*,6*R*,7*E*,9*S*)-3,5,7,9-tetramethyl-6-(*t*-butyldimethylsilyloxy)-11-phenyl-3,7-undecadien-1-yne as a colorless oil, in a yield of 92%.



Reference 10d.

To a cold (−40°C) solution of 8.87 g PPh_3 (33.82 mmol, 6.4 eq.) in 140 mL dry CH_2Cl_2 was slowly added 5.61 g CBr_4 (16.91 mmol, 3.2 eq.) in 20 mL CH_2Cl_2 under nitrogen. After 15 min of stirring, 15.5 mL NEt_3 (0.111 mol, 12.51 eq.) was added, and the flask was cooled to −78°C. Then, 1.2 g 2-(2-oxoethyl)-1-piperidinecarboxylic acid *tert*-butyl ester (5.28 mmol, 1 eq.) in 20 mL CH_2Cl_2 was added. The temperature reached 0°C over 2 h and the reaction mixture was quenched with water followed by the addition of 10 mL

30% H_2O_2. After being stirred for 15 min at room temperature, the product was extracted with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$ and concentrated. The residue was purified by flash chromatography on silica gel (petroleum ether/EtOAc, 19:1) to furnish 1.77 g 2-(3,3-dibromo-2-propenyl)-1-piperidinecarboxylic acid *tert*-butyl ester as a white solide, in a yield of 87%, m.p. 135°C.

n-BuLi (5.55 mL, 12.49 mmol, 2 eq.) was added dropwise under nitrogen to 30 mL THF solution containing 2.39 g dibromide (6.25 mmol, 1 eq.) at −78°C. After being stirred for 1 h, the solution was warmed to 0°C, and 2.38 g iodine (9.37 mmol, 1.5 eq.) in 20 mL THF was added. After being stirred overnight at room temperature, the reaction mixture was quenched with a saturated $Na_2S_2O_3$ solution. The aqueous layer was extracted with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$ and concentrated to give 2.16 g 2-(3-iodo-2-propynyl)-1-piperidinecarboxylic acid *tert*-butyl ester as a slightly yellow solid, in a yield of 99%, m.p.139°C.

Corey-Gilman-Ganem Oxidation

(Corey-Ganem Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and co-workers in 1968.[1] It is an efficient synthesis of α,β-unsaturated esters by treatment of α,β-unsaturated aldehydes (or allyl alcohols) with manganese dioxide and potassium cyanide in a proper alcohol. This reaction is thus known as the Corey-Gilman-Ganem oxidation[2] in general or simply the Corey-Ganem oxidatin.[3]

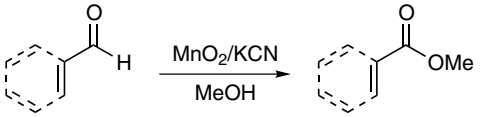
It should be pointed out that manganese dioxide is a mild oxidant that usually converts primary allylic alcohols into conjugated aldehydes without significant further oxidation to carboxylic acids.[4,5] However, in the presence of HCN and cyanide, the α,β-unsaturated aldehydes could be converted into cyanohydrins, which are susceptible to the oxidation of MnO_2 to acyl cyanides. In the presence of an alcohol, the α,β-unsaturated esters are obtained.[1] It should be emphasized that this reaction works only for α,β-unsaturated aldehydes and will not cause any *cis-trans* isomerization for the α,β-unsaturated double bond.[1] For example, benzaldehyde (> 95%), cinnamaldehyde (> 95%), furfural (> 95%), geranial (85–95%), and farnesal (> 95%) have all been transformed into the corresponding methyl esters.[1]

For comparison, silver oxide (Ag_2O) is usually applied to convert a saturated aldehyde into a carboxylic acid; when it is used for α,β-unsaturated aldehydes, it usually causes an undesired *cis-trans* isomerization for the α,β-unsaturated bond as well as other base-induced side reactions.[1] However, in the presence of potassium cyanide, the more powerful oxidant of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

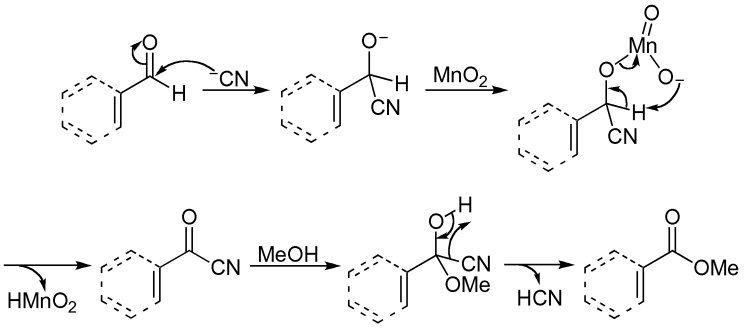
argentic oxide (AgO) oxidizes the α,β-unsaturated aldehydes only into the corresponding carboxylic acids. Therefore, either methyl ester (with active MnO_2) or carboxylic acid (with AgO) could be obtained as expected.[1] Unfortunately, this reaction fails to oxidize piperonal[2] and allyl alcohols with extended conjugation;[6] in addition, this reaction may have the potential problem of the conjugate addition from cyanide ion.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction involves the formation of cyanohydrins, which are then converted into the corresponding acyl cyanides; the acyl cyanides are subsequently transformed to either acids or esters in the presence of appropriate solvents, such as acetic acid or methanol.[1,6,7] A tentative illustration of the mechanism for the Corey-Gilman-Ganem oxidation is thus given here.



D. MODIFICATION

This reaction has been improved by the treatment of aldehydes with trimethylsilyl cyanide to give trimethylsilyl cyanohydrins, which are subsequently hydrolyzed to cyanohydrins under weakly acidic conditions and oxidized by MnO_2 to acyl cyanides. Such improvement works under the condition that the original reaction protocol fails.[6] In addition, MnO_2 has been implemented to a tandem oxidation process (TOP) recently because of its mild oxidation ability.[5a]

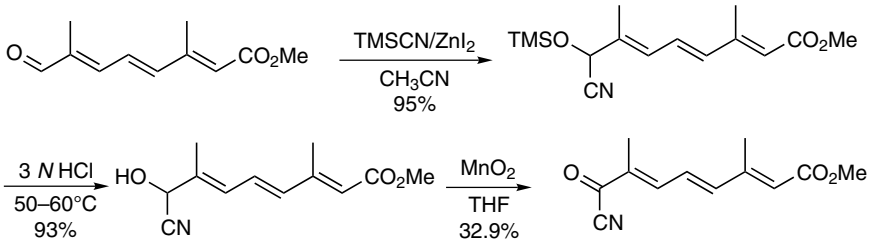
E. APPLICATIONS

This reaction has certain application in the preparation of α,β-unsaturated esters.

F. RELATED REACTIONS

This reaction is related to the *Ball-Goodwin-Morton Oxidation*.

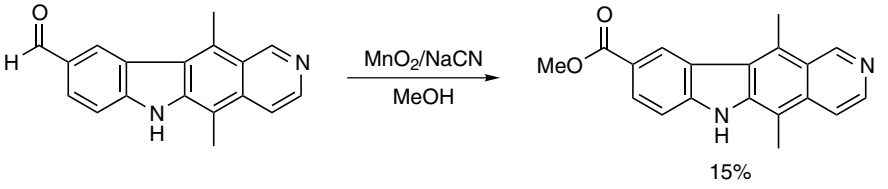
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

To a solution of 5.3 g methyl 7-formyl-3,7-dimethyl-2,4,6-octatrienoate (27.0 mmol) in 50 mL dry CH_3CN containing a few milligrams of ZnI_2 was added 3.65 mL trimethylsilyl cyanide (27.0 mmol), and the resulting solution was stirred under an atmosphere of nitrogen at room temperature for 2.5 h. The reaction mixture was then treated with charcoal, filtered through Celite, and concentrated to a syrup that was dried in vacuo to afford 7.6 g methyl 8-cyano-8-(trimethylsilyloxy)-3,7-dimethyl-2,4,6-octatrienoate, in a yield of 95%. After that, 6.0 g of this intermediate (20.4 mmol) was suspended in 80 mL 3 *N* HCl, and the mixture was stirred under a nitrogen atmosphere for 2 h at 50–60°C. After cooling, a pale yellow solid was collected by filtration, washed with water, and dried in vacuo to yield 4.2 g methyl 8-cyano-8-hydroxy-3,7-dimethyl-2,4,6-octatrienoate, in a yield of 93%.

To a solution of 2.3 g cyanohydrin (10.4 mmol) in 100 mL THF was added 7.5 g activated MnO_2; the mixture was stirred under a nitrogen atmosphere for 2.5 h at room temperature. The MnO_2 was then removed by filtration and washed with THF. The filtrate, including washings, was concentrated under reduced pressure to a syrup that crystallized to 2.2 g of a solid, which was taken up in CH_2Cl_2 and further purified by flash chromatography to give 750 mg methyl 7-(cyanocarbonyl)-3,7-dimethyl-2,4,6-octatrienoate, in a yield of 32.9% (isolated and pure), m.p. 91–92°C.



Reference 8.

A mixture of 40 mg 9-formylellipticine (0.144 mmol), 200 mg MnO_2 and 200 mg NaCN in 50 mL MeOH was stirred under refluxing for 96 h. The TLC on silica gel ($CHCl_3$/MeOH/NH_4OH, 90:9:1) showed the disappearance of the starting material at $R_f =$ 0.77 and the formation of a major spot at R_f = 0.81. The reaction mixture was cooled to

room temperature and filtered through Celite, and the remaining on Celite was washed with 20 mL MeOH. The combined filtrates were evaporated under reduced pressure to dryness, and the residue was stirred in 12 mL water, of which the pH was adjusted to 8 with the dropwise addition of acetic acid. This suspension was stored at 5°C for 18 h and filtered. The residue was washed well with water, air-dried, and flash chromatographed on silica gel using a gradient of 2–8% MeOH in $CHCl_3$. Appropriate fractions were pooled and evaporated to afford a residue that was dissolved in glacial acetic acid and filtered. This solution was evaporated to dryness under reduced pressure, and the residue was dissolved in hot EtOAc and left at 0°C for 72 h. The deposited solid was filtered and dried to afford 6 mg ellipticine-9-carboxylic acid methyl ester as a yellow solid, in a yield of 15%, m.p. 272–274°C (dec.), R_f = 0.24 (benzene/EtOH = 9:1). (*Note:* Be aware that the yield might vary owing to the loss of any small amount of material in such a small reaction scale.)

Corey-Kim Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and Kim in 1972.[1] It is the preparation of aldehydes and ketones from the oxidation of primary and secondary alcohols via their dimethylalkoxysulfonium salts. Therefore, this reaction is generally known as the Corey-Kim oxidation[2] or simply the Corey-Kim reaction.[3] This reaction is operationally simple, highly selective, and efficient.[1] On large reaction scale, the dimethylalkoxysulfonium salt of alcohols are formed with dimethylsulfide and chlorine;[1] whereas on a laboratory scale, the dimethylchlorosulfonium salt can be generated more conveniently from *N*-succinimide chloride (or *N*-chlorosuccinimide, NCS) and dimethylsulfide, by which the formation of hydrogen chloride is avoided.[1] The combination of *N*-succinimide chloride and dimethylsulfide is therefore called the Corey-Kim reagent[4] which offers a milder oxidation condition and cleaner products.[1] Upon treatment with the base, the dimethylchlorosulfonium salt cleaves intramolecularly to give aldehydes and ketones. The application of 6-morpholinohexan-1-thiol ether[2b] or dodecyl methyl sulfide[2d] as the substitute for dimethylsulfide results in an odorless oxidation condition. In addition, the Corey-Kim reagent provides a new methylation of an unsaturated bond from the nucleophilic addition of carbanion followed by the treatment with Raney nickle.[4a]

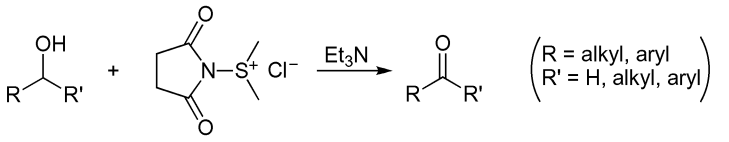
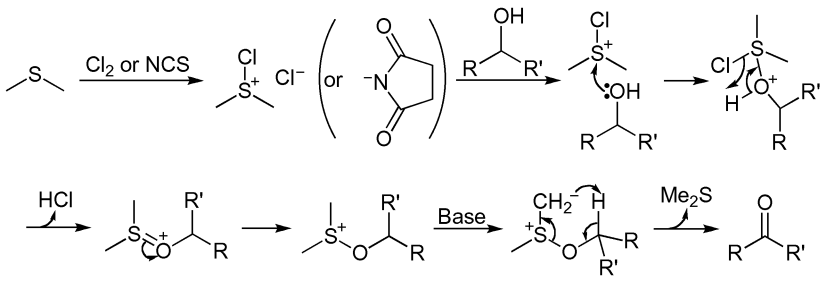
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a simple illustration of the reaction mechanism.



D. MODIFICATION

The nonvolatile thioethers have been substituted for the dimethyl sulfide to provide an odorless oxidation condition.[2b−2d]

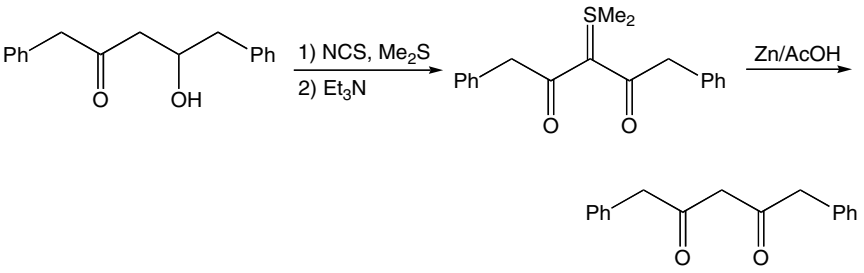
E. APPLICATIONS

This reaction has general applications in the conversion of primary and secondary alcohols into aldehydes and ketones, respectively.

F. RELATED REACTIONS

This reaction is related to the *Dess-Martin Oxidation, Swern Oxidation*, and *Pfitzner-Moffatt Oxidation*.

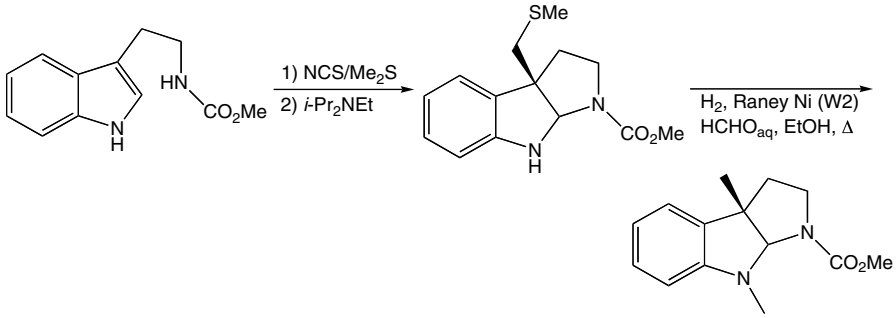
G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

To a stirred suspension of 20 mmol NCS in 60 mL anhydrous CH_2Cl_2 was added dropwise 40 mmol dimethyl sulfide at –70°C under argon, and stirring was continued for 1 h. Then a solution of 4.0 mmol 4-hydroxy-1,5-diphenyl-pentan-2-one in 6 mL CH_2Cl_2 was added; at the same temperature, the solution was stirred for 1 h. Triethylamine (60 mmol) was then added, and after 1 h the reaction mixture was treated with 20 mL saturated brine. This mixture was extracted with ether, and the organic layer was washed with saturated brine and evaporated. The residue was purified by column chromatography using 95:5 chloroform/acetone as an eluent to give 80% dimethylsulfonium 1-(phenylacetyl)-2-oxo-3-phenylpropylide as a pale yellow viscous oil.

To a stirred suspension of 1.5 mmol of the ylide and 30 mmol zinc powder in 25 mL CH_2Cl_2 was added 30 mmol acetic acid at 0°C, and stirring was continued at room temperature overnight. The mixture was filtered through Celite, and the filtrate was washed with saturated $NaHCO_3$ and water, eluted with CH_2Cl_2 through a short column of Florisil (100–200 mesh), and evaporated. The crude product was crystallized from methanol to give 88% 1,5-diphenyl-2,4-pentanedione, m.p. 64–65°C.



Reference 4a.

To a solution of *N*-chlorosuccinimide (133 mg, 1.0 mmol) in CH_2Cl_2 was added 75 mg dimethyl sulfide (1.2 mmol) at –78°C, and the mixture was stirred for 1 h. To this reaction mixture, was added a solution of 109 mg indole derivative (0.5 mmol) in CH_2Cl_2 and 155 mg diisipropylethylamine (1.2 mmol); the whole mixture was stirred for 2 h at –78°C. The mixture was treated with cooled brine and extracted with CH_2Cl_2. The combined organic layers were washed and dried over $MgSO_4$. After evaporation of the solvent,

a residue was purified by column chromatography on silica gel (EtOAc/*n*-hexane 1:5 to1:2) and afforded 139 mg 3a-methylthiomethyl-1-methoxycarbonyl-8-methyl-1,2,3,3a,8,8a-hexahydropyrrolo[2,3-*b*]indole in a yield of 92%, m.p. 86.5–87.5°C (white powder was recrystallized from Et_2O). (*Note:* The procedure for the second step is not provided in the original literature.)

Corey-Kwiatkowski Reaction

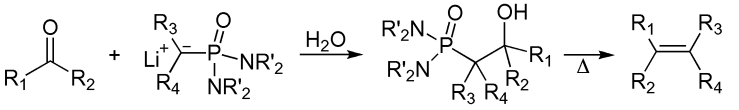
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Corey and Kwiatkowski in 1966.[1] It is the preparation of olefins from the reaction between aldehydes or ketones and lithium alkylphosphonamides followed by the decomposition of β-hydroxyphosphonamide intermediates in refluxing benzene or toluene.[1] Therefore, it is known as the Corey-Kwiatkowski reaction.[2] The direct addition product (i.e., the lithio derivative) is quite stable even at 0°C in THF under nitrogen.[1] The hydroxyphosphonamides from ketones generally decompose faster than those from aldehydes, and the ones with α-substituent(s) decompose even faster.[3] This method is good for a wide variety of olefins, including the mono-, di-, tri- and tetra-substituted olefins.[1,3] Compared to the *Wittig Reaction*, this method of olefination has following obvious advantages:[1] (*a*) the absence of triphenylphosphine oxide, which can complicate the isolation of olefin; (*b*) the possibility of purification at the stage of β-hydroxyphosphonamide; (*c*) relatively easy control of stereochemistry of the olefins (to form either *cis*- or *trans*-olefin); and (*d*) availability and potential low cost of the phosphonamides, which can be prepared from phosphonyl dichlorides and dimethylamine[3] or cyclic diamines[4] (phosphonyl dichloride can be synthesized by alkylation of phosphorus trichloride with alkyl chloride and $AlCl_3$).[3] In addition, the alkyl phosphonamides can be replaced by alkyl phosophonothiate where the formed β-hydroxyphosphonothiate can decompose at low temperature (e.g., room temperature), and silver salt can be applied as catalyst.[5] The lithio derivatives of both phosphonamides and phosphonothiates can be derivatized via alkylation with alkyl halides.[1,3,5] The reaction between lithium phosphonamide or phosphonate and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

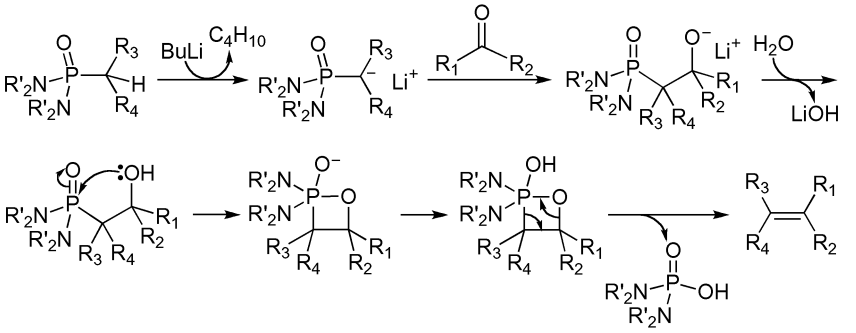
ester to give β-keto phosphonamide or phosphonate is called the Corey-Kwiatkowski condensation.[6]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a simple illustration of the reaction mechanism.



D. MODIFICATION

This reaction has been modified to start with cyclic phosphonamides via the reaction between phosphonyl dichloride with diamines.[4]

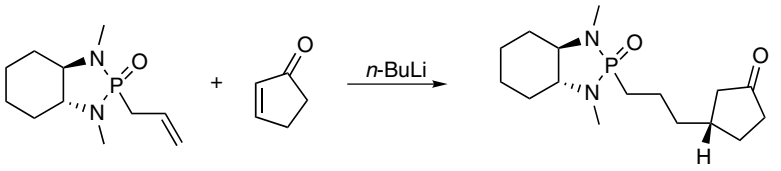
E. APPLICATIONS

This reaction has general application in the synthesis of multisubstituted olefins.

F. RELATED REACTIONS

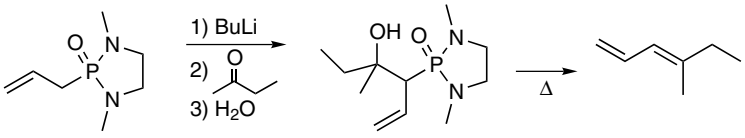
This reaction is related to the *Wittig Reaction* and *Emmons-Horner Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To a solution of 1 mmol allyl phosphonamide in 10 mL THF was added 1.2 mmol of *n*-BuLi (1.6 or 2.5 M solution in hexane) at −78°C under argon. A solution of 1.2 mmol α,β-unsaturated-cyclopentanone in 5 mL THF at −78°C was added immediately via cannula. The reaction mixture was stirred at −78°C for 30 min, slowly quenched with saturated aqueous NH_4Cl (or with MeI (10 eq.), with BnBr (5 eq.), and with allyl bromide (5 eq.)) to form further alkylated products and allowed to warm to ambient temperature. The mixture was diluted with 50 mL EtOAc and washed with 20 mL brine and 20 mL water. The organic layer was separated, dried over $MgSO_4$, and concentrated in vacuo. The resulting crude product was purified by column chromatography (EtOAc/MeOH) to give 88% of 1,4-addition product, with R:S ratio of 93:7.



Reference 4c.

To a stirred solution of 0.628 g cyclic allyl phosphonamide (3.61 mmol) in 10 mL tetrahydrofuran was added 2.4 mL 1.6 M *n*-butyllithium (3.84 mmol) at –78°C under argon. After 0.5 h, 0.285 g methyl ethyl ketone (4.18 mmol) was added. Water (0.2 mL) was added after an additional 10 min, and the solution was allowed to warm to room temperature, whereupon the reaction mixture was diluted with 100 mL methylene chloride and filtered through a glass wool plug. The solution was dried over sodium sulfate and filtered, and the solvent was evaporated under vacuum at room temperature to yield 0.816 g of a sticky yellow syrup containing some residual methylene chloride.

A suspension of 0.389 g of the sticky syrup (1.58 mmol, containing some methylene chloride) in 0.5 mL Nujol along with 0.4 g anhydrous calcium carbonate was degassed and then heated to 133°C for 2 h under vacuum, the volatile products were collected in a trap and held at –196°C. The trapped material was distilled into a tared flask to yield 0.175 g *cis*- and *trans*-mixture of 4-methyl 1,3-hexadienes, in a yield of 90% after correction of CH_2Cl_2.

Corey-Link Reaction

(Corey-Link Amino Acid Synthesis)

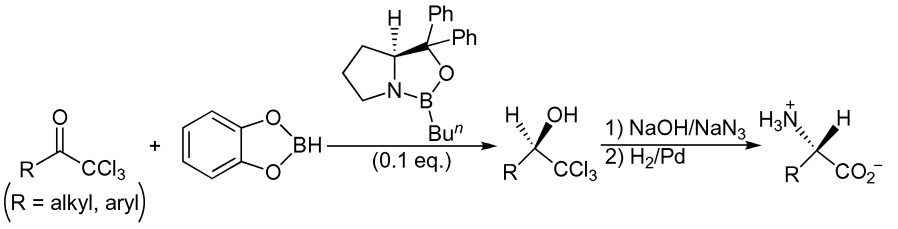
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and Link in 1992.[1] It is an enantioselective synthesis of α-amino acids by means of the asymmetric reduction of trichloromethyl ketones from catecholborane in the presence of either (*R*)- or (*S*)-oxazaborolidine, followed by the treatment of the resulting alcohols with base and sodium azide and subsequently the reductive conversion of the azido group into an amino group. Therefore, this reaction is generally known as the Corey-Link reaction.[2] Occasionally, it is also referred to as the Corey-Link amino acid synthesis,[2e,3] Corey-Link procedure,[2e] etc.

In this reaction, the trichloromethyl ketones can be prepared either from the nucleophilic addition of trichloromethide to aldehydes followed by oxidation or from acylation of carbon nucleophile by trichloroacetyl chloride.[1] It has been found that in the presence of catalytic amount of either (*R*)- or (*S*)-oxazaborolidine, the reduction of the corresponding trichloromethyl ketones by catecholborane usually gives high selectivity, e.g., with greater than 97:3 of enantioselectivity.[1] Upon treatment of 2 eq. sodium azide and 4 eq. NaOH in aqueous dimethyl glycol, the trichloromethyl carbinol is smoothly converted into α-azido acid with inversion of the configuration.[1] Then the α-azido acids can be reduced by palladium-catalyzed hydrogenation,[1] zinc in acetic acid,[4] or possibly by the *Staudinger Reaction* to give α-amino acids. Due to the nature of this reaction, the Corey-Link reaction is useful for the preparation of α-azido esters, α-azido acids, and α-amino acids with desired stereochemistry by the correctly chosen chiral catalyst.[1]

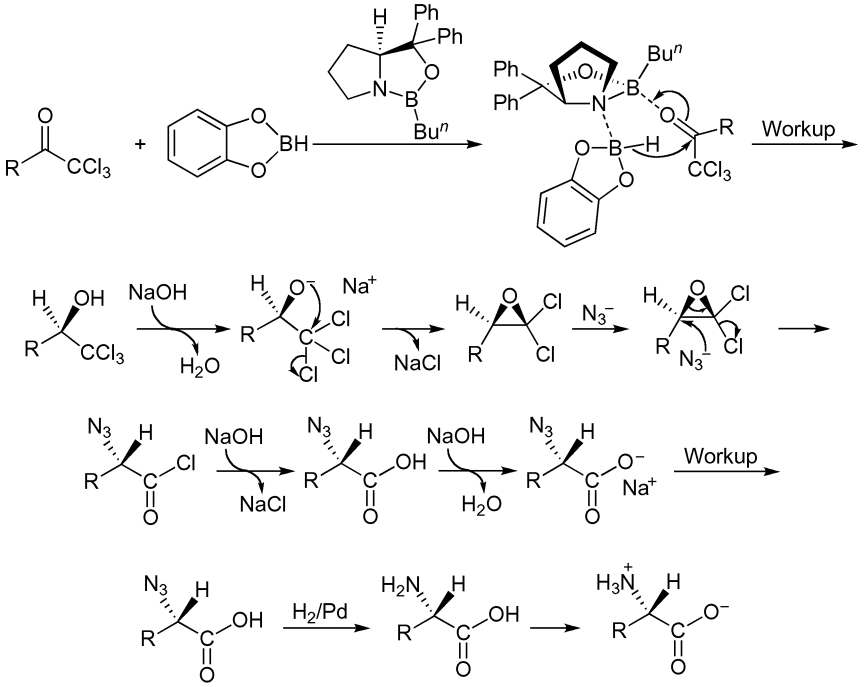
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The high enantioselectivity for the reduction of trichloromethyl ketones by catecholborane is due to the directive effect of (*R*)- or (*S*)-oxazaborolidine.[5] After deprotonation by base, the trichloromethyl carbinol forms alkoxide and attacks the adjacent trichloromethyl group intramolecularly to form *gem*-dichlorooxirane or *gem*-dichloroepoxide, which is highly reactive toward nucleophilic attack by azide anion and proceeds a S_N2 substitution with exclusive inversion of the configuration accompanied by concerted ring opening to give α-azido acid.[1] Finally, the resulting α-azido acid can be simply converted into α-amino acid. The detail of this reaction is displayed below.



D. MODIFICATION

This reaction has been modified by treatment of *gem*-trichloromethyl-substituted tertiary alcohols (generated from the nucleophilic addition of trichloromethide), e.g., $CHCl_3$ + LHMDS) by sodium azide and an organic base (e.g., DBU) in alcohol to form α-azido ester in a one-pot manner.[2,6] The resulting α-azido ester can then be selectively converted into α-azido alcohol with cold $NaBH_4$.[7]

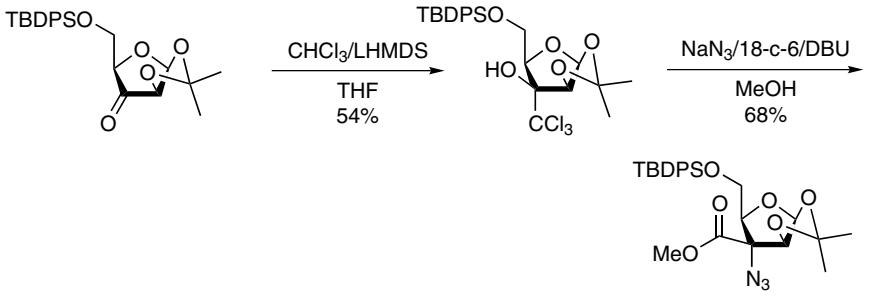
E. APPLICATIONS

This reaction has general applications in the preparation of α-amino acids of determined stereochemistry.

F. RELATED REACTIONS

This reaction is related to the *Corey-Bakshi-Shibata Reduction* and *Strecker Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2e.

To a solution of 15 mL anhydrous pyridine (187 mmol) in 150 mL anhydrous CH_2Cl_2 was added 9.4 g CrO_3 (94 mmol), and the mixture was stirred for 15 min. After the mixture was cooled to 0°C, a solution of 10.0 g 5-*O*-*tert*-butyldiphenylsilyl-1,2-*O*-isopropylidene-β-D-arabinofuranose (23.0 mmol) in 70 mL CH_2Cl_2 was added dropwise. Acetic anhydride (9.0 mL, 94 mmol) was added, and the mixture was stirred for 30 min. The whole mass was poured into a 500-mL 1:4 mixture of toluene and EtOAc. After being stirred for 20 min, the mixture was filtered through a layer of silica, and the silica gel was rinsed three times with EtOAc. The combined filtrate was evaporated under reduced pressure to give 8.70 g 5-*O*-*tert*-butyldiphenylsilyl-1,2-*O*-isopropylidene-β-D-arabinofuran-3-ulose as an oil, in a yield of 90%.

To a solution of 2.6 mL $CHCl_3$ (32 mmol) in 25 mL anhydrous THF was added 2.5 g 5-*O*-*tert*-butyldiphenylsilyl-1,2-*O*-isopropylidene-β-D-arabinofuran-3-ulose (5.9 mmol). After the solution was cooled to –78°C, 21.3 mL 1.0 M LiHMDS solution in THF (21.3 mmol)

was added slowly. The solution was stirred at –78°C for 3 h, and the reaction mixture was then poured into an ice cold saturated aqueous $NaHCO_3$ solution. The mixture was extracted with CH_2Cl_2, and the combined organic phases were dried over Na_2SO_4 and evaporated to dryness under reduced pressure. The residue was purified by silica gel chromatography using hexanes/EtOAc (9:1) as the eluent to afford 1.72 g 5-*O*-*tert*-butyldiphenylsilyl-3-*C*-trichloromethyl-1,2-*O*-isopropylidene-β-D-lyxofuranose as an oil, in a yield of 54%.

To 25 mL anhydrous MeOH was added 2.9 g tertiary alcohol (5.3 mmol), then 1.04 g NaN_3 (16.0 mmol) and 15.0 mg 18-crown-6 (0.057 mmol) were added. Then 4.0 mL DBU (26.7 mmo) was added dropwise, the resulting mixture was stirred at 50°C for 1 h and poured into 50 mL saturated aqueous NH_4Cl solution. The mixture was extracted with ether, the combined organic extracts were dried over Na_2SO_4 and evaporated to dryness under reduced pressure. The residue was purified by silica gel chromatography using hexanes/EtOAc (9:1) as the eluent to afford 1.83 g 3-*C*-azido-5-*O*-*tert*-butyldiphenylsilyl-1,2-*O*-isopropylidene-3-*C*-methoxycarbonyl-β-D-arabinofuranose as an oil, in a yield of 68%.

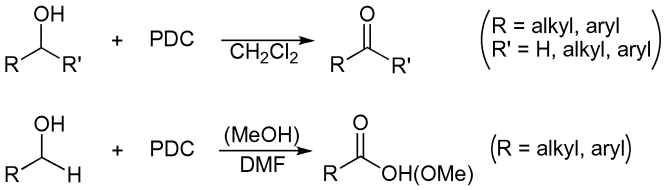
Corey-Schmidt Oxidation
(PDC Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and Schmidt in 1979.[1] It is the oxidation of an organic compound using pyridinium dichromate (PDC) and is simply known as the PDC oxidation.[2] PDC is a stable, bright orange solid prepared by dissolving CrO_3 in a minimal volume of water followed by precipitation after the addition of pyridine. PDC is less acidic than PCC but more acidic than the Collins reagent. In this reaction, primary alcohols can be oxidized to either aldehydes[3] or carboxylic acids[4] or even esters,[5] depending on the substrate and solvent. Normally, the suspension of PDC in dichloromethane oxidizes primary alcohols to the corresponding aldehydes,[3] whereas PDC in DMF oxidizes primary alcohols into either carboxylic acids[4] or methyl esters (in the presence of methanol for latter case[5]). Similarly, PDC can also oxidize the aldehyde group into a carboxylic group in a solvent of DMF.[6] The oxidation of alcohols to other esters are not successful. On the other hand, secondary alcohols can be oxidized to ketones too.[7] In addition, pyridinium dichromate can also oxidize the active methylene group (either allylic or benzylic) into a carbonyl group in the presence of *t*-butyl hydroperoxide,[8] whereas PDC alone will not affect the benzyl ethers of alcohols.[9] This oxidation has shown some advantages over other chromium-based oxidations (e.g., Jones, Fieser, CrO_3/AcOH, and pyridinium chlorochromate) in the oxidation of diols into diketones, and the rest of the chromium-based oxidations are reported to give lower yields accompanyed by other oxidized products when compared to the Corey-Schmidt oxidation.[7] It has been reported that when a methylamino group is present in the substrate alcohol, the oxidation using PDC does not succeed.[10] This oxidation has been reviewed.[11]

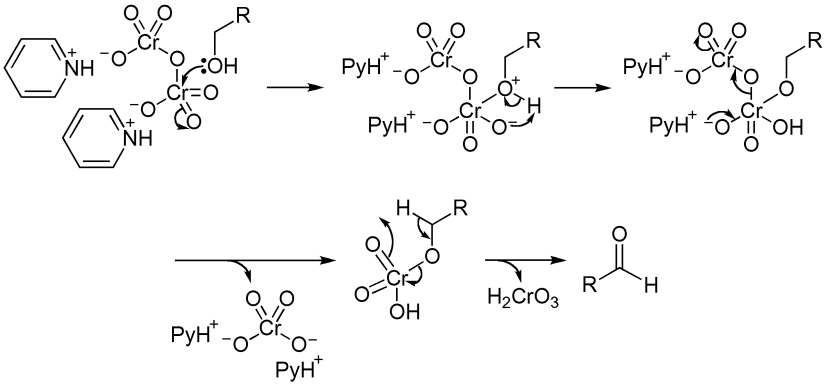
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

PDC was originally prepared by Corey and co-workers by adding 1 eq. pyridine to a solution of chromium (VI) trioxide and concentrated hydrochloric acid, which precipitated as pyridinium dichromate salt. In the PDC oxidation, the six-valent chromium atom is reduced to only four valents, as displayed here.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has wide application for the oxidation of alcohols.

F. RELATED REACTIONS

This reaction is related to the *Corey-Suggs Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES

Reference 12.

Pyridinium dichromate (15.64 g, 41.6 mmol) was suspended in a mixture of 320 mL dry CH_2Cl_2 and 11.8 mL acetic anhydride (124.8 mmol). A solution of 11.11 g 1-*O*-methyl-3,5-di-*O*-benzyl-α,β-D-ribofuranose-3,4,5,5′-$^2H_4$ (32.0 mmol) in dry CH_2Cl_2 was added to the suspension, and the reaction mixture was refluxed at ~80°C for 3 h. After the dilution with EtOAc, a precipitate was formed, and the solution was filtered through silica gel using EtOAc as the eluent. The solvents were evaporated, and the residue was co-evaporated with toluene to give 7.93 g 1-*O*-methyl-3,5-di-*O*-benzyl-α,β-D-ribofuranose-2-ulose-3,4,5,5′-$^2H_4$ as an oily product (23.0 mmol, 72%), which was taken to the next step without further purification.

Reference 4a.

(*R*)-2-Hydroxy-1-*tert*-butoxycarbonylaminoethylcarbamic acid benzyl ester (1.0 g, 3.22 mmol) was dissolved in 3.2 mL DMF. Solid PDC (3.64 g, 9.67 mmol) was then added, and the reaction mixture was stirred for 20 h at room temperature. The reaction mixture was then poured into 100 mL water, acidified to pH 3, and extracted with EtOAc (4 × 30 mL). The organic phase was washed with water. Upon the addition of saturated $NaHCO_3$ solution (3 × 30 mL), the product transferred to the aqueous phase, which was washed once with EtOAc and then acidified with solid $NaHSO_4$ to pH 3. The precipitated product was then extracted with EtOAc (3 × 30 mL), and the combined extracts were washed with water, dried over anhydrous $MgSO_4$, and evaporated to yield 596 mg (*R*)-benzyloxycarbonylamino-*tert*-butoxycarbonylaminoacetic acid, [(*R*)-Boc-(Cbz)-Agl-OH], in a yield of 59%, m.p. 149–150°C.

Corey-Suggs Oxidation
(PCC Oxidation)

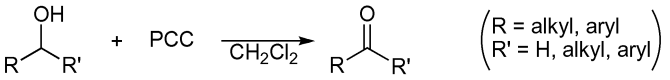
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and Suggs in 1975.[1] It is the oxidation of primary and secondary alcohols into carbonyl compounds using pyridinium chlorochromate (PCC) commonly in a solvent of dichloromethane. Therefore, this reaction is known as the Corey-Suggs oxidation[2] but more generally referred to as PCC oxidation.[3] Likewise, PCC is usually called the Corey-Suggs reagent.[2,3g] This reaction was originally reported as using 1:1.5 ratio of substrate to PCC for a complete oxidation; however, it was subsequently reported that the Corey-Suggs oxidation involves only two electrons, and a 1:1 ratio of substrate to PCC is enough for the complete conversion of alcohols into carbonyl compounds.[4] The Corey-Suggs oxidation has become a popular method in organic synthesis because of its commercial availability, efficiency, shelf-stability, and versatility.[2] Since PCC is very acidic, a tautomerization is always accompanied after the generation of the carbonyl group, leading to the isomerization of product.[5] However, it has been reported that a peroxide bond can sustain under such acidic oxidation conditions,[6] and cyclic acetal will be converted into lactone.[7] On the other hand, when different hydroxyl groups are present, the allylic or benzylic alcohol will be oxidized before the oxidation of the regular alcohol groups;[8] this preference of selectivity is enhanced when PCC is used in conjunction with dimethylamino pyridine (DMAP).[8c,8d] In addition, the oxidation from poly[vinylpyridinium] chlorochromate (PVPCC) is much faster than normal PCC.[9] Using PCC as oxidizing reagent, cyclic allyl alcohols can be transformed into α,β-unsaturated cycloketones,[8a,8b] in which the C=C double bond can sit at a different ring of the cyclic compound.[8a] However, the oxidation of a tertiary cyclic allyl alcohol leads to a rearrangement involving the migration of double bond.[10] The substitution of PCC with *n*-butylammonium chlorochromate (BACC) makes

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

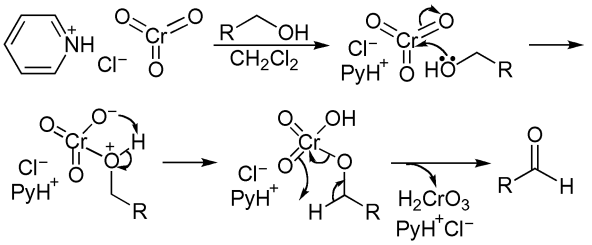
this oxidation homogeneous when 18-crown-6 is present.[11] The Corey-Suggs oxidation can also be improved using ultrasound agitation.[2] It has been reported that under the Corey-Suggs oxidation conditions, a substrate with a double bond of 5 carbons from the hydroxyl group might form cyclic ketone via tandem oxidation-cyclizationoxidation.[12]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A mechanism similar to the *Corey-Schmidt Oxidation* is displayed here.



D. MODIFICATION

This reaction has been widely modified, including the substitution of PCC with PVPCC[9] or BACC[11] and the absorbing of PCC with silica gel accompanied by ultrasound agitation.[2]

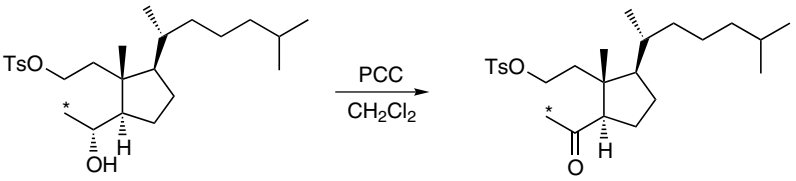
E. APPLICATIONS

Similar to the *Corey-Schmidt Oxidation*, the Corey-Suggs oxidation also has general application in the oxidation of alcohols.

F. RELATED REACTIONS

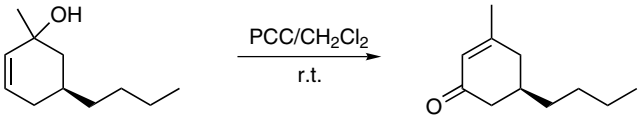
This reaction is related to the *Corey-Schmidt Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To a solution of 980 mg [9-^{13}C]-11-tosyloxy-9,11-seco-de-A,B-cholestan-8α-ol (2.23 mmol) in 30 mL CH_2Cl_2 was added 960 mg pyridinium chlorochromate (4.46 mmol) at room temperature. The dark brown mixture was stirred at room temperature for 15 h and was then directly loaded onto a short silica gel column and eluted with EtOAc/hexane (1:4.5). Further purification by HPLC (1:4 EtOAc/hexane) afforded 860 mg [9-^{13}C]-9,11-seco-11-tosyloxy-de-A,B-cholestan-8-one as a liquid, in a yield of 88%.



Reference 10.

To a solution of 205 mg PCC (pyridinium chlorochromate, 0.95 mmol) in 2 mL CH_2Cl_2 was added 80 mg (1*RS*,5*S*)-1-hydroxy-1-methyl-5-butyl-2-cyclohexene (0.48 mmol) in 0.2 mL CH_2Cl_2 dropwise. The resulting dark brown mixture was stirred at room temperature for 2 h, quenched with water, and extracted with Et_2O. Drying over $MgSO_4$, and concentration in vacuo gave an oil that was purified by flash chromatography (SiO_2, hexanes/Et_2O) to yield 66 mg (*R*)-3-methyl-5-butyl-2-cyclohexenone as a colorless oil, in a yield of 83% (97.9% e.e.).

Corey-Winter Olefination

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Corey and Winter in 1963.[1] It is the transformation of 1,2-diols into alkenes via the *cis*- (or *syn*-) elimination of cyclic thionocarbonate in the presence of trimethyl- or triethylphosphite. The intermediate cyclic thionocarbonate is prepared from the reaction of 1,2-diols with either thiophosgene[2] or thiocarbonyldiimidazole,[3] or by the treatment of 1,2-diols with *n*-BuLi followed by the addition of CS_2 and methyl iodide.[1] Therefore, this reaction is known as the Corey-Winter olefination,[2e,4] Corey-Winter olefination reaction,[5] Corey-Winter reaction,[2a,6] Corey-Winter alkene synthesis,[3a,7] Corey-Winter *cis*-deoxygenation,[8] and Corey olefin synthesis.[2h] A similar preparation of olefins was again reported by Corey and Hopkins in 1982,[9] and the reaction under this condition is referred to as Corey-Hopkins methodology[10] or Corey-Hopkins protocol.[2c] On the one hand, it is assumed that the Corey-Winter olefination proceeds via the attack of phosphite on sulfur, leading to an unstable carbene, which reacts with another phosphite to exclude carbon dioxide and produce the olefin.[1,7] On the other hand, the reaction has also been claimed to undergo a concerted, cyclo-elimination mechanism for the product-forming step.[7] This reaction has been proved to be a position-specific (i.e., regiospecific) and stereospecific reaction for synthesizing olefin,[1,2f] which is also good for the highly substituted[1] or highly strained olefins.[7] In addition, this reaction has been successfully applied to the preparation of sugar derivatives.[7]

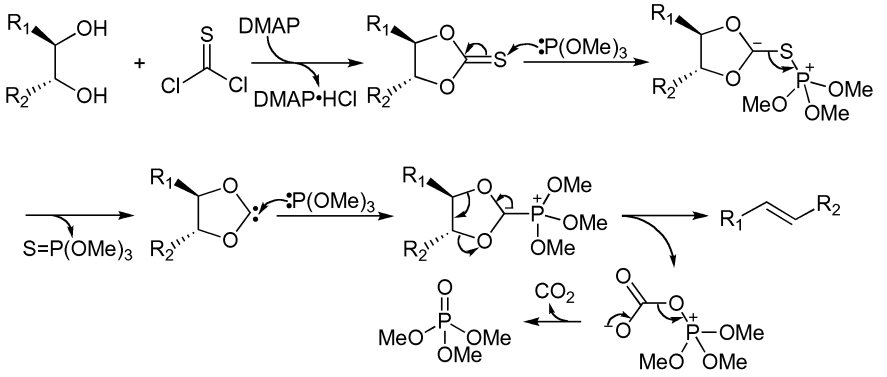
C. PROPOSED MECHANISMS

Provided here is a simple illustration of the reaction mechanism using thiophosgene and trimethyl phosphite.



D. MODIFICATION

N/A

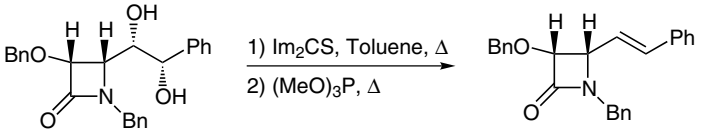
E. APPLICATIONS

This reaction has general application in the preparation of stereospecific olefins and even highly strained olefins.

F. RELATED REACTIONS

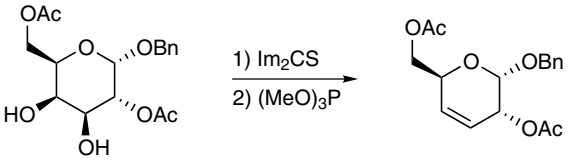
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

A mixture of 1 mmol diol, 0.24 g 1,1′-thiocarbonyldiimidazole (1.2 mmol), and 5 mL toluene was heated at 100°C until the starting diol disappeared as monitored by TLC (typically 16 h). The reaction mixture was then cooled to room temperature, diluted with CH_2Cl_2, and washed with 0.1 N HCl and a saturated solution of $NaHCO_3$. After drying over $MgSO_4$, the solvent was evaporated under reduced pressure to give the corresponding crude thiocarbonate. The obtained crude thiocarbonate was dissolved in 4 mL $P(OMe)_3$, and the resulting solution was kept at reflux until the intermediate thiocarbonate was consumed (typically 16 h). Then, the mixture was cooled to 40°C, and the solvent was removed under vaccum to give the alkene, which was purified by flash column chromatography (0.199 g, 54%), m.p. 75–78°C.



Reference 11.

To a solution of 1.71 g diol (4.83 mmol) in 28 mL dry acetonitrile was added under nitrogen 2.58 g 1,1′-thiocarbonyldiimidazole (14.5 mmol), and the solution was stirred at room temperature for 5 h. The reaction mixture was then poured into brine and extracted with $CHCl_3$. The organic extracts were dried over Na_2SO_4 and concentrated under reduced pressure. Dry column chromatography of the residue (hexanes/EtOAc, 75:25 → 35:65) gave 1.72 g benzyl 2,6-di-*O*-acetyl-3,4-*O*-thiocarbonyl-α-D-galactopyranoside (4.34 mmol, 90%) and 280 mg benzyl 2,6-di-*O*-acetyl-3,4-di-*O*-(1′*H*-imidazol-1′-ylthiocarbonyl)-α-D-galactopyranoside (0.488 mmol, 10%).

A solution of 1.63 g thiocarbonate (4.12 mmol) in 100 mL trimethyl phosphite was refluxed for 4.5 h. The reaction mixture was then concentrated under high vacuum (1 mmHg), and the residue was purified by dry column chromatography (hexanes/EtOAc, 85:15) to give 1.05 g benzyl 2,6-di-*O*-acetyl-3,4-dideoxy-α-D-*erythro*-hex-3-enopyranoside (3.28 mmol), in a yield of 80%.

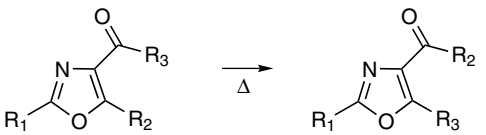
Cornforth Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Cornforth in 1949.[1] It is the thermal rearrangement of 4-carbonyl substituted oxazoles to their isomeric oxazoles[2] through a ring-opening process to form a zwitterionic dicarbonyl nitrile ylides followed by a ring closure (i.e., 1,5-dipolar cyclization[2a]). Therefore, this reaction is generally known as the Cornforth rearrangement.[2b,3] Although this rearrangement is a special type of heterocyclic ring transformation (HRT) which has been found for "almost all heterocycles of any ring size and any type, number or distribution of heteroatoms,"[4] it has been applied to the syntheses of 5-alkyl-,[2a] 5-amino-,[1,2b,3d] 5-aryl-,[2a] 5-(arylthio)-,[3d] and 5-halo-oxazoles.[2a] More importantly, this reaction provides a method for synthesizing the substituted amino acids.[5] Comparably, 1-acylaziridines can rearrange into 2-alkyloxazolines by thermal inducement or triggering by a strong acid or nucleophilic reagent.[6]

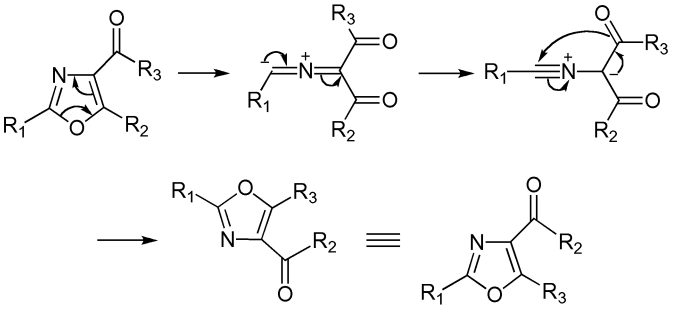
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction involves an intermediate of zwitterionic dicarbonyl nitrile ylides, which cyclizes to the oxazole isomer, as shown here.



D. MODIFICATION

N/A

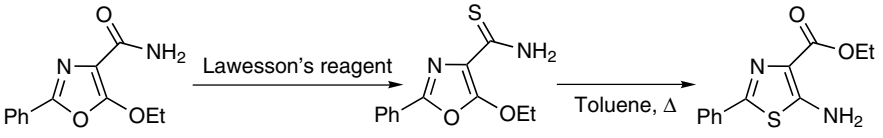
E. APPLICATIONS

This reaction can be used for the preparation of substituted oxazoles and amino acid and even imidazole[3d] and oxazolo[4,5-d]pyrimidin-7-one.[7]

F. RELATED REACTIONS

This reaction is related to the *ANRORC Rearrangement* and the *Boulton-Katritzky Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES

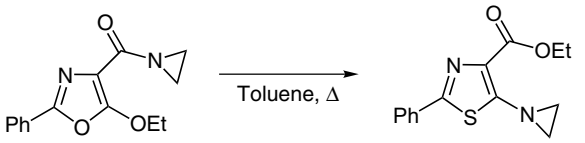


Reference 2a.

A mixture of 4.64 g 2-phenyl-4-(aminocarbonyl)-5-ethoxyoxazole (2.0 mmol) and 8.09 g 2,4-bis(methoxyphenyl)-l,3-dithia-2,4-diphosphetane 2,4-disulfide (*Lawesson's Reagent*) (2.0 mmol) in 50 mL tetrahydrofuran was refluxed for 2 h. The solvent was removed under reduced pressure. Flash chromatography of the residue on silica gel (hexane/EtOAc, 4:1) afforded 3.27 g 2-phenyl-4-(aminothiocarbonyl)-5-ethoxyoxazole as an oil that solidified

under vacuum, in a yield of 66%. Pure sample can be obtained via recrystallization from cyclohexane, m.p. 117–119°C.

A solution of 1.0 mmol 2-phenyl-4-(aminothiocarbonyl)-5-ethoxyoxazole in 50 mL toluene was refluxed for 17 h. The solvent was removed under reduced pressure, and the residue was recrystallized from cyclohexane to give 87% of 2-phenyl-4-(ethoxycarbonyl)-5-aminothiazole, m.p. 134–135°C.



Reference 3d.

A solution of 5 mmol 2-phenyl-5-ethoxyoxazole-4-carboxylic acid chloride in 20 mL benzene was added to a solution of 5 mmol aziridine and 0.5 g triethylamine (5 mmol) in 40 mL benzene at 0°C. The mixture was then stirred for 3 h at room temperature, filtered, washed with water, and dried over $MgSO_4$. Upon removal of benzene by evaporation, the resulting amides were recrystallized several times from petroleum ether (b.p. 60–70°C) to give 80% of 2-phenyl-5-ethoxyoxazole-4-carboxy-aziridine amide, m.p. 82–83°C.

This amide was refluxed in dry toluene for 17 h. The solvent was then removed and the residue was recrystallized from petroleum ether. More than 90% of pure ethyl 2-phenyl-5-aziridinoxazole-4-carboxylate was obtained, m.p. 118–119°C.

Other references related to the Cornforth rearrangement are cited in the literature. [8]

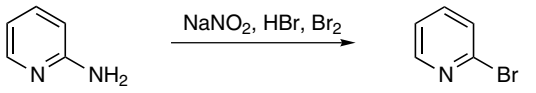
Craig 2-Bromo-Pyridine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

The preparation of 2-bromopyridine from 2-aminopyridine was first reported by Chichibabin and Ryasanjev in 1915,[1] however, the yield was low.[2] In 1934, Craig reported a modified method for preparing 2-bromo-pyridine in high yield from 2-amino-pyridine,[2] therefore, this reaction is called Craig 2-bromo-pyridine synthesis. In this reaction, a concentrated aqueous solution of sodium nitrite and 2-amino-pyridine was added to a concentrated hydrobromic acid saturated with bromine. It was found that 2 mole of bromine and at least 2.5 mol of sodium nitrite are necessary to obtain an optimal yield of 2-bromo-pyridine.[2] This method has been used to prepare 2-bromo-pyrimidines.[3]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because no mechanistic detail has been reported for this reaction in the literature, a tentative mechanism is proposed here according to the experimental fact that 2 mol of bromine and sodium nitrite are necessary for the best results.[2]

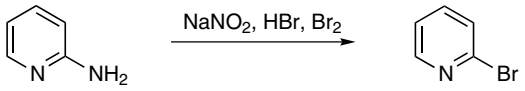
Reference 3.

To a suspension of 20.2 g 2-amino-4,5-diethoxypyrimidine (0.11 mol) in 55 mL 48% hydrobromic acid, 16.9 mL bromine (0.32 mol) was added at 0°C with stirring, over a period of 45 min. During this addition, the mixture became very thick but subsequently thinned out again. A solution of 19.4 g sodium nitrite (0.28 mol) in 28 mL water was added,

still at 0°C,over a 30-min period, and the stirring was continued for an additional 30 min. The resulting dark solution was cooled to −10°C, and 200 mL 20% solution of sodium hydroxide was added until a permanent basic reaction was produced. Filtration yielded 21.5 g 2-bromo-4,5-diethoxypyrimidine as a pale yellow solid, m.p. 49°C, in a yield of 79.0%.



Reference 4.

In a 5-L, three-necked flask fitted with a mechanical stirrer, a dropping funnel, and a thermometer for reading low temperatures was placed 790 mL 48% hydrobromic acid (7 mol). The flask and contents were cooled to 10–20°C in an ice salt bath, and 150 g 2-amino-pyridine (1.59 mol) was added over a period of ∼10 min. While the temperature was kept at 0°C or lower, 240 mL bromine (4.7 mol) was added dropwise. A solution of 275 g sodium nitrite (4 mol) in 400 mL water was added dropwise over a period of 2 h, the temperature being carefully maintained at 0°C or lower. After an additional 30 min of stirring, a solution of 600 g sodium hydroxide (15 mol) in 600 mL water was added at such a rate that the temperature did not rise above 20–25°C. The nearly colorless reaction mixture was extracted with four 250-mL portions of ether. The extract was dried for 1 h over 100 g solid KOH and was then distilled through a Vigreux column (15 cm in length). 2-Bromo-pyridine distils was collected at 74–75°C (13 mmHg), and 216–230 g product was obtained, in a yield of 86–92%.

Criegee Glycol Oxidation

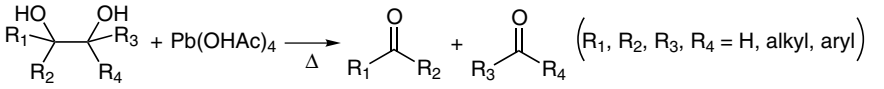
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Criegee in 1931.[1] It is an oxidation of 1,2-diols (or glycols) to aldehydes or ketones with lead tetraacetate [$Pb(OAc)_4$, LTA] via the cleavage of C-C bond between the hydroxyl-carrying carbon atoms. This oxidation takes place almost quantitatively at room temperature, and the oxidation rate depends greatly on the structure of glycol and corresponding solvent.[2] Originally, this reaction was reported to occur only in anhydrous organic solvent,[3] and much of the efforts are focused on the drying of the solvent;[2] however, this reaction was proved to be feasible in organic solvent with moisture or even in aqueous solution if the oxidation is faster than the hydrolysis of lead tetraacetate,[2,4] as shown in the oxidation of monosaccharides such as glucose and mannose.[2] In addition, lead tetraacetate can oxidize not only 1,2-diols but also α-amino alcohols,[5] α-hydroxyl carbonyl compounds,[6] and α-keto acids.[6b] In this oxidation, the configuration or even conformation of diol plays an important role, and it is found that the oxidation of *cis*-diol is faster than *trans*-diol, especially when *cis*-diol forms a five-membered ring structure. As a result, the amount of *cis*-diol on a five-membered ring can be titrated regardless the presence of *trans*-diol on a five membered ring, or *cis*-diol or *trans*-diol on a six-membered ring.[7] However, when *cis*-diol on pyranoside exists in the boat conformation, the oxidation of such diol with lead tetraacetate might proceed fast compared to the *cis*-diol in a five-membered ring. In addition, this reaction can also be carried out in solvents such as acetic acid, benzene, chloroform, nitrobenzene, and tetrachloroethane.[2] During the oxidation of sugars, it was found that glucose, glycerol, mannitol, and xylose are oxidized readily in aqueous solution, whereas sucrose cannot be oxidized under a similar condition.[4a] Interestingly, it was found that the oxidation of α-hydroxyl tertiary amine is different from a similar oxidation on α-hydroxyl primary or secondary amine, by which the oxidation of the former gives a secondary amine

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

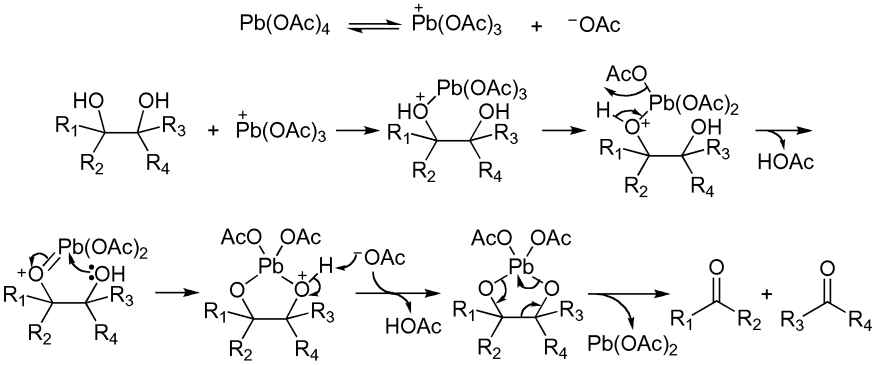
and aldehyde involving the cleavage of a C-N bond, whereas the latter involves the cleavage of a C-C bond.[5] The Criegee glycol oxidation is similar to the oxidation of diols using periodate in aqueous solution, i.e., the *Malaprade Reaction*; however, during the oxidation of 1,2,3-triols, the extensive periodate oxidation gives only aldehydes or ketones as well as formic acid.[8] The oxidation from excess lead tetraacetate gives aldehydes or ketones and carbon dioxide (from the middle hydroxyl group) as well.[4b] It was found that the decomposition of lead tetraacetate holds an ionic mechanism.[9] Other oxidations using lead tetraacetate include the oxidation of alcohols (to ketones),[9b] conjugated dienes (to esters of *cis*- or *trans*-glycol),[10] olefin (to glycol acetate or allylic acetate),[10a,11] cyclooctanol (to ether-containing tetrahydrofuran rings),[10a] thioether (to sulfone),[12] sugars,[4,12,13] and amines.[5]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

According to the fact that the decomposition of lead tetraacetate involves a cationic mechanism, the Griegee glycol oxidation mechanism is outlined tentatively.



D. MODIFICATION

N/A

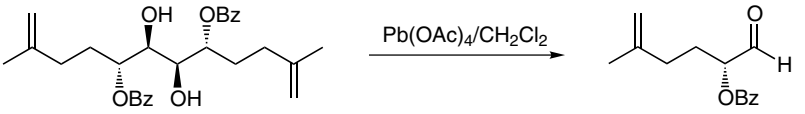
E. APPLICATIONS

This reaction has wide application in the analysis of carbohydrate structures and the cleavage of adjacent diols, α-keto alcohols, α-keto acids, and hydroxyamines. In addition, this oxidation also renders a method for preparing aldehydes and ketones.

F. RELATED REACTIONS

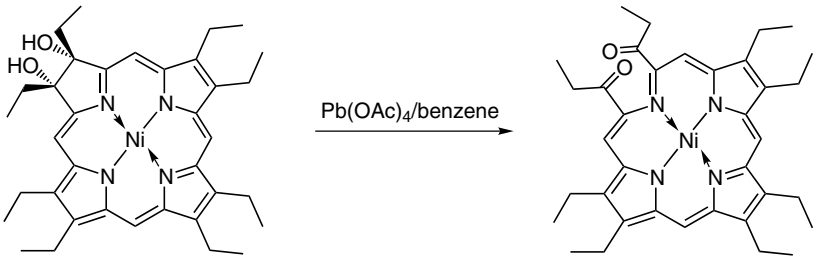
This reaction is related to the *Malaprade Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

A solution of 190 mg lead tetraacetate in 10 mL CH_2Cl_2 was cooled to $-20°C$ and 115 mg (5*R*,6*R*,7*R*,8*R*)-2,11-dimethyl-5,8-bis(benzoyloxy)-6,7-dihydroxydodeca-1,11-diene (0.50 mmol) was added. After stirring for 1 h at this temperature, the reaction mixture was warmed to room temperature and quenched with 0.5 mL ethylene glycol. The upper phase was separated, and the residue was washed with CH_2Cl_2. The combined organic solution was washed with water and brine, and dried over Na_2SO_4. The solvent was removed under reduced pressure, and the residue was then purified by flash column chromatography on silica gel (5% ethyl acetate in hexane) to give 105 mg (2*R*)-2-benzoyloxy-5-methylhex-5-enal, in a yield of 91%.



Reference 15.

Nickel(II) *cis*-diol (75 mg) dissolved in 8 mL anhydrous benzene was stirred with 54 mg freshly crystallized (from HOAc), dried (over KOH pellets in vacuo, dark) lead tetraacetate (in excess) for 15 min at room temperature. Ethylene glycol (0.5 mL) was added, and stirring was continued for 2 min. Chloroform (50 mL) was added, and the mixture was washed with water (2 × 25 mL) and the combined organic phases were dried over Na_2SO_4, filtered, and taken to dryness. The residue was chromatographed on silica gel 60 (12 cm × 3 cm) with chloroform. The leaf green fraction was collected, evaporated, and crystallized from dichloromethane-methanol to give 57 mg (2,3,7,8,12,13,17,18-octaethyl-2,3-dioxo-2,3-secochlorinato)-nickel(II) as small green needles, in a yield of 76%, m.p. 180–185°C, $R_f = 0.48$ ($CHCl_3$).

Other references related to the Criegee glycol oxidation are cited in the literature.[16]

Criegee Ozonolysis

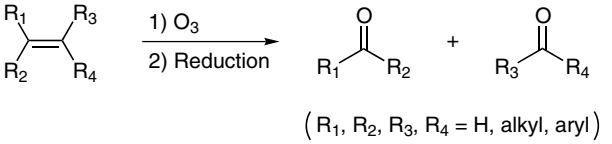
A. GENERAL DESCRIPTION OF THE REACTION

It was Schönbein who studied the ozonolysis first;[1] however, it was Criegee who initially investigated the mechanism of ozonolysis beginning in the 1950s.[2] Therefore, Criegee was considered the "father of modern ozone organic chemistry,"[1] and the reaction between olefins and ozone to form aldehydes, ketones, carboxylic acids, etc. is known as the Criegee ozonolysis[3] or Criegee reaction.[4] This reaction occurs in three steps: formation of primary ozonides, splitting of primary ozonides, and formation of secondary ozonides.[5] In this reaction, ozone as an electrophile,[6] adds to the C=C double bond of olefin via a concerted *1,3-Dipolar Cycloaddition*, a symmetry allowed ($4_s + 2_s$) cycloaddition,[5] to form vibrationally excited primary ozonide[7] (POZ, the 1,2,3-trioxolane,[8] or the so-called molozonide[1]) in a *syn*- or an *anti*-form,[5] which quickly splits to an excited carbonyl oxide (Criegee intermediate, CI[5,7–9]) and a carbonyl compound, which in turn couple stereospecifically into the secondary ozonide[5] (SOZ, the 1,2,4-trioxolane,[8,10] or the so-called true ozonide[1]) via retrocycloaddition. Then the secondary ozonide is reduced to aldehyde or ketone via a variety of reducing reagents, including Zn/AcOH, Me_2S, Ph_3P, Me_3P, and $(NC)_2C{=}C(CN)_2$. This reaction is usually carried out in a suitable solvent (AcOH, CCl_4, $CHCl_3$, hexane, EtOAc, CH_2Cl_2, etc.) at low temperature by passing a stream of dry ozonized oxygen (1–15% O_3) until the disappearance of the olefins. In addition, a unified concept[11] was proposed for this reaction, which differs from the Criegee mechanism in the prediction of the position of a labeled oxygen atom when the primary ozonide reacts with a labeled aldehyde in a crossover experiment.[12] It was found that the electron-donating groups accelerate the reaction, and the electron-withdrawing groups decrease the reaction rate.[6] This reaction is frequently

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

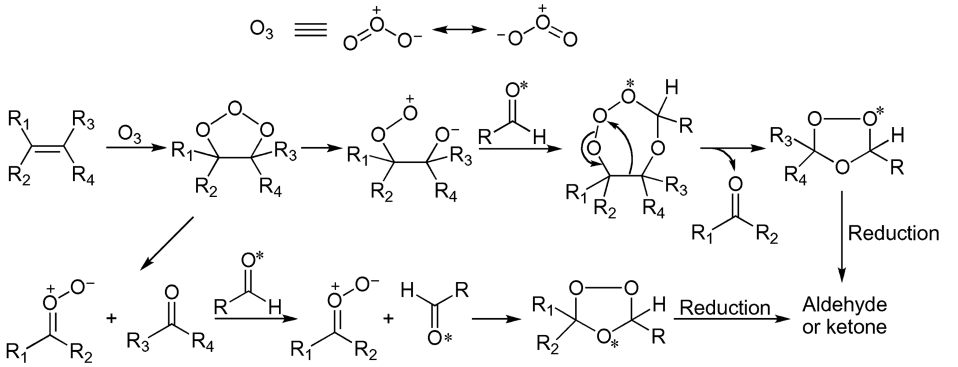
used for structure determination as well as synthetic purposes. Sometimes, ammonia and primary amines are added during the ozonolyses of olefins as the participating solvents, and "amozonolysis" is used for this reaction condition.[13] Tertiary amines are formed as reductive amination products in high yield when secondary amines are added to the solution of mono- or 1,1-disubstituted olefins during ozonolysis.[14] It has been reported that the ozonolysis of olefins is one of the major methods of forming aerosol.[15] On the other hand, this reaction has also been studied extensively in theory.[16]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A mechanism of the unified concept is demonstrated here.[12]



D. MODIFICATION

This reaction has been modified for synthesizing tertiary amines via reductive amination by the addition of secondary amines during the ozonolysis.[13]

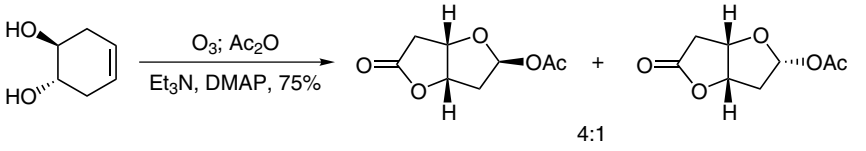
E. APPLICATIONS

This reaction has general application in the determination of the structure of molecules containing C=C double bonds as well as in the preparation of aldehydes and ketones.

F. RELATED REACTIONS

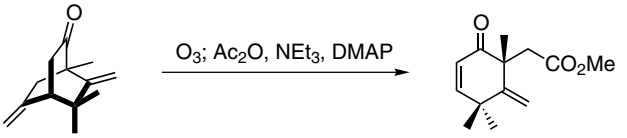
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

A solution of 0.44 g cyclohexenyl diol (3.8 mmol) in 190 mL EtOAc at −78°C was purged with ozone until the solution turned blue. The system was then purged with N_2 for approximately 10 min or until the blue color disappeared. To this solution were added slowly (∼30 min each) via syringe pump 2.36 g Ac_2O (23.2 mmol) and 3.8 g Et_3N (38.0 mmol), and stirring was continued at −78°C for 10 min before the addition of 0.2 g DMAP (1.8 mmol). The reaction mixture was allowed to warm to room temperature and stir overnight. It was then quenched with $NaHCO_3$ and extracted with EtOAc (3 × 100 mL). The combined organics were dried over Na_2SO_4, filtered, and concentrated. Flash column chromatography with Et_2O furnished 0.52 g lactone as crystalline solids, in a yield of 75% with a diastereomeric ratio of 4:1.



Reference 17.

Precooled dry ozone in oxygen gas was passed through a cold (−70°C) suspension of 200 mg (-)-(1*R*,4*S*)-1,5,5-trimethyl-6,8-bis(methylene)bicyclo-[2.2.2]octan-2-one (1.05 mmol) and 10 mg $NaHCO_3$ in 5 mL MeOH-CH_2Cl_2 (1:4) for 5 min. Excess ozone was flushed off with oxygen. The solvent was evaporated in vacuo, and the residue was dissolved in 2 mL dry benzene. To this mixture were added 1 mL acetic anhydride (10.5 mmol), 0.7 mL triethylamine (5.2 mmol), and a catalytic amount of DMAP; the resulting mixture was stirred at room temperature for 15 min and then refluxed for 6 h. The reaction mixture was diluted with water and extracted with ether. The ethereal extract was washed with 3 *N* aqueous HCl and water. Evaporation of the solvent and purification of the residue over a silica gel column using EtOAc/hexane (1:50) as the eluent furnished 80 mg unreacted starting material. Further elution of the column with EtOAc/hexane (1:20 to 1:10) as the eluent furnished 93 mg (+)-methyl (1*R*)-1,5,5-trimethyl-6-methylenecyclohex-3-en-2-one-1-acetate as an oil, in a yield of 67% based on the consumed starting material.

Criegee Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Criegee in 1944.[1] It is the rearrangement of peroxy ester into ketone, ester, or carbonate and alcohol via oxygen insertion or consecutive oxygen insertion. Therefore, it is generally known as the Criegee rearrangement.[2] The peroxy ester is primarily formed from the reaction between peracid and tertiary alcohol. In addition, the peroxy ester can also be prepared from the reaction between ketone and peracid (i.e., the *Baeyer-Villiger Oxidation*), and the additional product of peracid to ketone is often referred to as the Criegee intermediate.[2e,3] From this point of view, the *Baeyer-Villiger Oxidation* is a subset of the Criegee rearrangement.[2e] In this reaction, the often-used peracids include *p*-nitroperbenzoic acid[2f] and trifluoroperacetic acid[2c,2d,4] because they are strong enough and give good leaving groups. It is widely assumed that the migrating group rearranges from a position *anti*-periplanar to the dissociating oxygen-oxygen bond of the peroxy ester.[5] During the rearrangement, the electron-donating ability of the migrating group will facilitate such movement,[2i,6] whereas the electron-withdrawing or electron-deficient group will not migrate.[7] This reaction has been proven to occur via an ionic mechanism,[1] but the second step of migration is believed to be concerted.[3a] For this reaction, allylic hydroperoxides will yield cyclic or acyclic enol ethers,[2f] and the isopropenyl group can be easily removed.[8] The major differences between the Criegee rearrangement and the *Baeyer-Villiger Oxidation* include (*a*) a consecutive oxygen insertion occurs in former, but no oxygen insertion has been reported for ketones and aldehdyes;[5] and (*b*) the starting material is tertiary alcohols in the Criegee rearrangement, but ketones are used in the *Baeyer-Villiger Oxidation*.

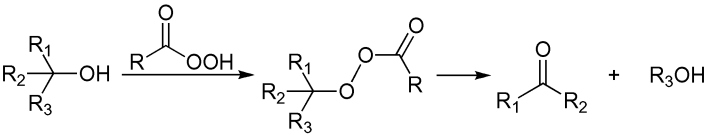
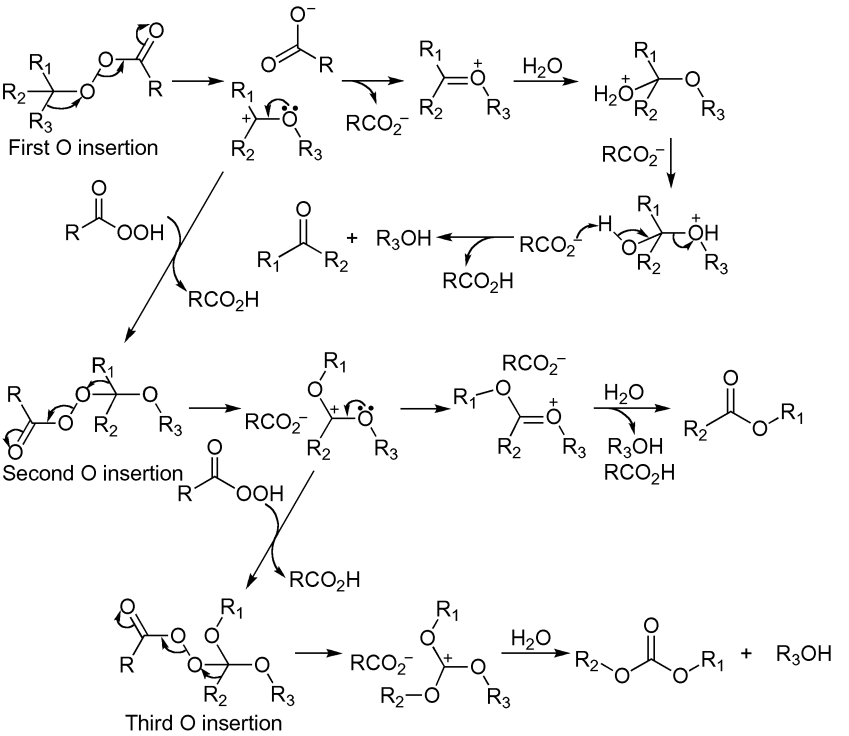
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the reaction mechanism, including the formation of ketone, ester, and orthoester via oxygen insertion.



D. MODIFICATION

N/A

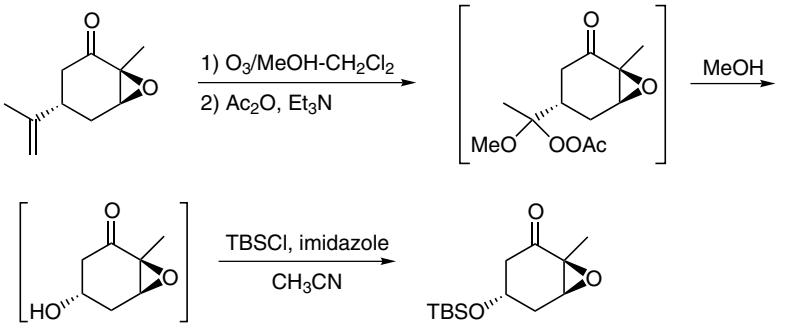
E. APPLICATIONS

This reaction is useful for the removal of the isopropenyl group and conversion of tertiary alcohols into ketones and aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Baeyer-Villiger Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES

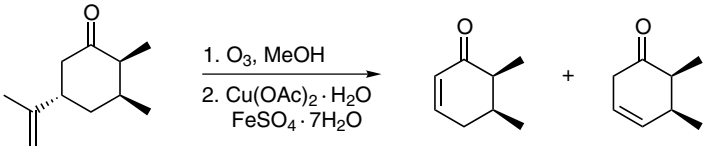


Reference 8a.

A solution of 20 g (1*S*,4*S*,6*S*)-1-methyl-4-(1-methylethenyl)-7-oxabicyclo-[4.1.0]-heptan-2-one (120 mmol) and 20 mL methanol (494 mmol) in 200 mL dichloromethane was cooled with a dry ice–acetone bath; the nitrogen inlet tube was replaced with a gas dispersion tube, and the gas outlet tube was connected to a trap through a wide 4-mm i.d. tube immersed in a 2 L 1 M KI solution. Then ozonized air (4 L/min) was continuously passed through the reaction mixture at $-68 \pm 3^{\circ}$C. The reaction turned pale blue after 65 min, indicating the completion of the reaction. Then excess ozone was removed by purging with nitrogen (4 L/min) for 30 min, and the mixture was allowed to warm to 14°C over 40 min to ensure complete conversion of the initially formed ozonide to the desired hydroperoxide. Then the mixture was cooled to -25°C, and 117 mL triethylamine (839 mmol) was added over 5 min while maintaining the temperature of the mixture below -25°C. Then 2.0 g DMAP (16.4 mmol) was added in one portion, followed by the slow addition of 79.6 mL acetic anhydride (843 mmol) over 10 min while maintaining the reaction temperature between -25° and -38°C. The mixture was allowed to warm to -8°C over 30 min and stirred at $-7 \pm 1^{\circ}$C for 1.5 h. TLC analysis indicated a complete reaction. The reaction was quenched by the slow addition of 33 mL methanol, while maintaining the temperature of the mixture below 10°C (over 7 min). After being stirred at 5°C for 5 min, the mixture was diluted with 220 mL hexane, washed consecutively with 10% aqueous citric acid (2×150 mL) and saturated aqueous $KHCO_3$ (2×80 mL), dried over Na_2SO_4, and concentrated to dryness at 30°C under reduced pressure to give 38.2 g crude (1*S*,4*S*, 6*S*)-4-(1-acetylhydroperoxy-1-methoxyethyl)-1-methyl-7-oxabicyclo[4.1.0]heptan-2-one as a yellow oil. This material was relatively unstable and was immediately used in the next step without further purification.

A mixture of the crude product (120 mmol in theory) and 2.0 g NaOAc (24.4 mmol) in 245 mL methanol was stirred at 37°C overnight. TLC analysis indicated a complete reaction. Then the mixture was concentrated to dryness at 39°C, and the residue (29 g) was dissolved in 40 mL acetonitrile. The resulting solution was concentrated to dryness at

35°C under reduced pressure, and additional 40 mL acetonitrile was added. The resulting solution was again concentrated to dryness at 35°C under reduced pressure, and then 35 mL acetonitrile and 29.5 g imidazole (433 mmol) were added. After the mixture was cooled with an ice water bath, *tert*-butylchlorodimethylsilane (32.6 g, 217 mmol) was added. The cold bath was removed, and the mixture was stirred at room temperature for 4 h. The reaction was quenched by the addition of 10 mL methanol. After the mixture was stirred for 5 min, 55 mL ice water was added, and the mixture was extracted with hexanes (2 × 50 mL). The combined organic extracts were washed with 50 mL 2:3 v/v mixture of methanol and water, dried over Na_2SO_4, and concentrated to dryness at 40°C under reduced pressure. Further drying of the residue at 46°C and 0.4 mmHg for 1 h gave 25.2 g crude (1*S*,4*S*,6*S*)-4-[[(1,1-dimethylethyl)dimethylsilyl]oxy]-1-methyl-7-oxabicyclo[4.1.0]heptan-2-one as a pale yellow oil, with a 81.7% yield on the basis of the initial starting material used.



Reference 8b.

Ozone was passed through a solution of 6.62 g (*S*,*S*,*S*)-2,3-dimethyl-5-(2-propen-2-yl)-cyclohexanone (39.8 mmol) in 100 mL dry methanol for 1.5 h while cooling between −10° and −40°C. The slightly blue solution was then purged with argon for 10 min, and 16.0 g $Cu(OAc)_2{\cdot}H_2O$ (80.0 mmol) was added while stirring at −20°C. After 15 min, 13.3 g $FeSO_4{\cdot}7H_2O$ (48.0 mmol) was added, and the mixture was warmed slowly to room temperature. After being stirred for 18 h, water was added and the mixture was washed five times with diethyl ether. The combined organic phases were washed with a saturated $NaHCO_3$ solution, brine and water, and dried over $MgSO_4$. After the removal of the solvent in vacuo, the crude product was purified by column chromatography (SiO_2, petroleum ether/*tert*-butyl methyl ether, 10:1), providing 2.11 g (*S*,*S*)-5,6-dimethyl-2-cyclohexenone (43% yield) and 0.62 g (*S*,*S*)-5,6-dimethyl-3-cyclohexenone (13% yield) as colorless liquids.

Crum-Brown-Gibson Substitution Rule

A. GENERAL DESCRIPTION OF THE REACTION

This is one of the many rules guiding the position of the incoming electrophile on an aromatic ring, primarily in the substituted benzene ring, in electrophilic aromatic substitution. The Crum-Brown-Gibson rule,[1] proposed by Crum-Brown and Gibson in 1892,[2] is the best known rule for the directive influence[3] for electrophilic aromatic substitution, although several investigators had proposed similar rules before Crum-Brown and Gibson, including Körner in 1874,[4] Hübner in 1875,[5] Nölting in 1876,[6] and Armstrong in 1887.[7] In addition, a few other investigators also proposed explanations for electrophilic aromatic substitution after 1892, including Flürscheim in 1902,[8] Vörlander in 1902,[9] Fry in 1911,[10] Stieglitz in 1922,[11] and Prins in 1925.[12] The rules from Körner, Hübner, and Nölting are also combined as the Hübner-Nölting-Körner rule.[13] The original Crum-Brown-Gibson rule stated that the substituent already present on the benzene ring is considered to be linked to hydrogen (i.e., the benzene ring can be replaced by a hydrogen atom), and if the corresponding compound can be directly oxidized, then the second incoming group will take up the position *meta* to the existing substituent; otherwise, the incoming group would enter the position either *para* or *ortho* to the existing substituent. For example, if the existing substituent is Cl, the corresponding compound is HCl, which cannot be oxidized directly to HClO, then, Cl is a *para*- and *ortho*-directing group.[13] It should be pointed out that the Crum-Brown-Gibson rule and the other rules listed earlier all are empirical generalizations of experimental results and do not provide information about the reaction mechanism.[14] In addition, most of the rules cover only the majority of experimental results with a few exceptions.[3]

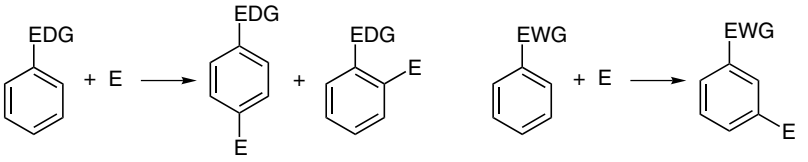
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

The advanced knowledge about the electrophilic aromatic substitution is generally summarized here. The existing substituent on the aromatic ring (e.g., benzene) has a twofold effect on such substitution: the effect on determining the location of incoming electrophilic group and the effect on the substitution reaction rate. Basically, this substitution is a two-step process: the addition of an electrophile to the C=C double bond on the aromatic ring and the elimination of a hydrogen atom from the attacking position. The existing substituent on the aromatic ring can be the electron-donating group or the electron-withdrawing group, which affect the reaction quite differently. If such an effect is not counted, (i.e., regardless of the electronic character of substituent), then *para*- or *ortho*-substitution is favored. This is because a carbocation intermediate is formed in the first step by the addition of an electrophile, and this carbocation intermediate can isomerize to three other resonance structures, as illustrated later. If the incoming electrophile attacks at either the *para*- or *ortho*-position, the resonance structures of the resulting carbocation intermediate include two secondary carbocations and one tertiary carbocation, and normally tertiary carbocation is much more stable than the secondary carbocation. In contrast, if the incoming electrophile enters at the position *meta* to the existing group, then the formed carbocation intermediate contains only three resonance structures of secondary carbocations, indicating the preferred position would be either the *para*- or *ortho*-position. Considering the steric hindrance from the existing substituent and incoming electrophile, the *para*-substitution is the most favored. However, compared to hydrogen, all the substituents on the aromatic ring can be divided into either electron-donating groups or electron-withdrawing groups. For the case of halogens and the electron-donating groups (either contributing a lone electron pair such as OR or NR_2 or donating a certain electron cloud via superconjugation such as alkyl), they can further stabilize all the formed carbocation intermediates, but stabilize the formed carbocation intermediates only when the incoming electrophile primarily enters at either the *ortho*- or the *para*-position of the existing substituent, and yield the *ortho*- and *para*-substituted products. This is because the electron-donating group is either directly linked to the formed carbocation or in conjugation with the carbocation. Therefore, these substituents are called *ortho*/*para* directors.[15] For comparison, if the existing group is an electron-withdrawing substituent excluding halogen (e.g., NO_2, CN), it will destabilize all the resonance structures of the carbocation intermediate but destabilize the carbocation intermediate formed primarily from *ortho*- or *para*-incoming electrophile, because the electron-withdrawing group is either directly connected to carbocation or in conjugation with carbocation. Therefore, only the carbocation intermediate from the *meta*-attacking electrophile can productively form the final *meta*-substituted product. Thus the electron-withdrawing groups are also called *meta* directors.[15]

Accordingly, the substituent favoring the *ortho*- or *para*-substitution (i.e., electron-donating group) is called the *ortho*/*para* director; in addition, because all these groups stabilize the formed carbocation intermediates and facilitate the substitution, these groups are also called activators. On the other hand, the electron-withdrawing group, which disfavors the formation of the carbocation intermediate, will slow down the reaction rate compared to benzene; thus the electron-withdrawing groups are also called deactivators.

The substituents on the polycyclic aromatic compounds, such as naphthalene, phenanthrene, fluoranthrene, and pyrene, are much more complicated; however, the substitution positions are still determined by the relative stabilities of the formed carbocation intermediates.[16]

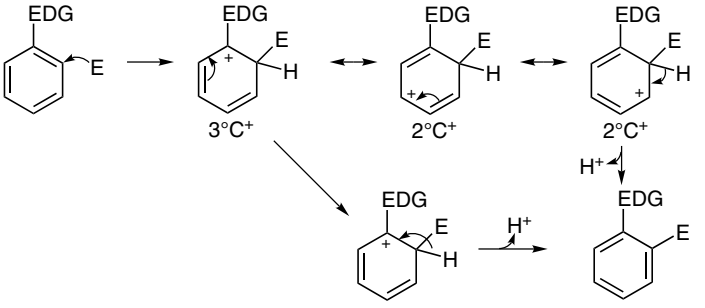
B. GENERAL REACTION SCHEME



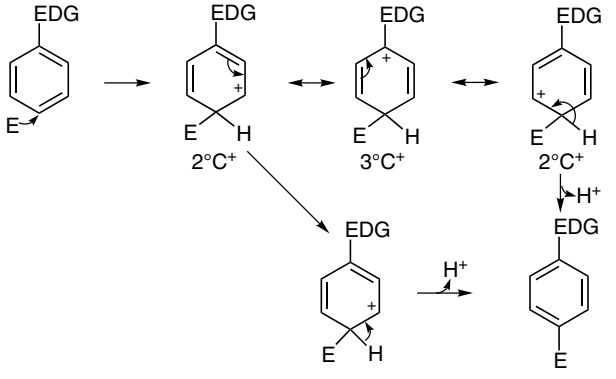
(*EDG*, electron-donating group; *E*, electrophile; *EWG*, electron-withdrawing group)

C. PROPOSED MECHANISMS

In the case of *ortho*-substitution.



In the case of *para*-substitution.



In the case of *meta*-substitution.

Curtius Rearrangement

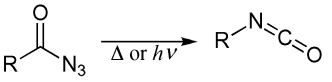
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Curtius in 1890.[1] It is the formation of isocyanate by thermal decomposition of acyl azides prepared from acyl halide and sodium azide and is generally known as the Curtius rearrangement.[2] Although this reaction is thought to proceed via a concerted mechanism[3] and form carbonyl nitrene intermediate,[3a,3b,3g,4] from which the R group migrates to the nitrogen atom to give isocyanate, some evidence supporting the stepwise mechanism has also been reported.[3a] Nevertheless, the Curtius rearrangement occurs with complete retention of configuration at the migrating carbon,[5] and the migration from the carbon to the nitrogen atom is an irreversible intramolecular reaction in first-order kinetics.[6] Because it is an intramolecular rearrangement, a solvent or salt effect is not evident.[6] The intermediate isocyanate can be isolated or subjected to subsequent reaction directly—for example, isocyanate reacts with water to form an unstable carbamic acid, which undergoes spontaneous decarboxylation to produce amine with one fewer carbon unit. This special reaction is referred to as the Curtius reaction.[7] In addition, the Curtius rearrangement is also known as the Curtius-type reaction,[7b] Curtius degradation,[8] Hofmann-Beckmann-Curtius-Lossen rearrangement,[9] and Curtius-type rearrangement.[10] On the one hand, the Curtius rearrangement has been used with great success for the preparation of non-commercially available isocyantes from a diverse assortment of carboxylic acids, including aliphatic,[11] aromatic,[12] heterocyclic,[13] unsaturated,[14] and chiral acids.[15] In addition, this rearrangement is good for the preparation of tetrazoles,[16] cyanamides,[16] oxazolidones,[17] amino alcohol,[18] furano carbamate,[7a] etc. On the other hand, the pyrolysis of acyl azides can also be carried out photolytically,[3b,3g,4,19] via a concerted mechanism.[3b] When acyl

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

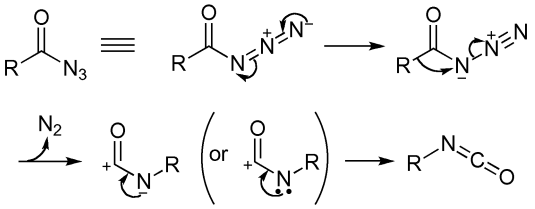
azide contains a halogen or hydroxyl group at the α-position, an aldehyde or ketone forms.[7c] It should be pointed out that benzenesulfonyl azide also undergoes a similar rearrangement and gives a sulfurylaniline intermediate.[10d] Recently, the Curtius rearrangement was carried out under microwave irradiation[20] and was modified using phase-transfer catalysis;[21] however, the most important modification of the Curtius rearrangement is to use the Shiori reagent[18]—that is, diphenylphosphoryl azide (DPPA).[22]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple mechanism involving a nitrene intermediate is displayed here.



D. MODIFICATION

This rearrangement has been modified to use the Shiori reagent as the azide source;[22] in addition, this reaction has been extended to proceed under photo [3b,3g,4,19] or microwave[20] irradiation.

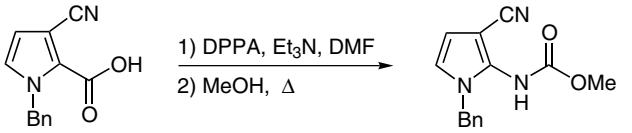
E. APPLICATIONS

The major applications of this rearrangement are the preparation of a variety of isocyanates and amines. In addition, this reaction is also valuable for the preparation of tetrazoles,[16] cyanamides,[16] oxazolidones,[17] amino alcohol,[18] and furano carbamate.[7a]

F. RELATED REACTIONS

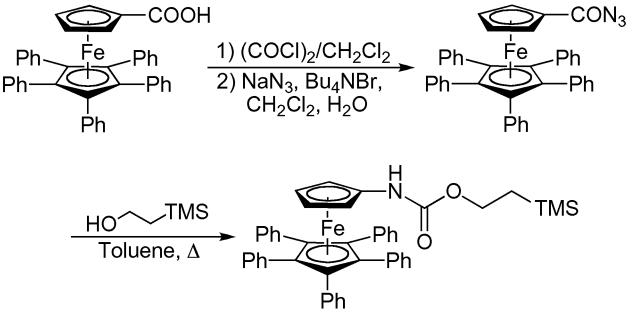
This reaction is related to the *Hofmann Degradation*, *Lossen Rearrangement*, and *Schmidt Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 22b.

To a solution of 7.04 g 1-benzyl-3-cyanopyrrole-2-carboxylic acid (31.12 mmol) in 75 mL *N,N*-dimethylformamide at 0°C was added 7.65 mL diphenylphosphoryl azide (DPPA, 9.72 g, 35.30 mmol, 1.1 eq.) and 4.75 mL triethylamine (3.42 g, 33.80 mmol, 1.1 eq.). The solution was allowed to stir at room temperature for 6 h. Methanol (7 mL) was added, and the reaction mixture was heated at 65°C for 8 h. The solvents were evaporated in vacuo, and the resulting residue was dissolved in 140 mL EtOAc. The solution was then extracted with 1 N aqueous HCl solution (3 × 80 mL), washed with saturated aqueous $NaHCO_3$ solution (3 × 80 mL), dried over anhydrous $MgSO_4$, and concentrated to dryness. The residue was recrystallized from ethanol to give 4.695 g 1-benzyl-2-methoxycarbonylamino-3-cyanopyrrole, in a yield of 59%, m.p. 140–142°C.



Reference 23.

1,2,3,4,5-Pentaphenylferrocene-1′-carboxylic acid (2.00 g, 3.3 mmol) was suspended in 20 mL CH_2Cl_2. Oxalyl chloride (0.84 g, 0.58mL, 6.6 mmol) was added followed by a drop of DMF. The mixture was stirred at room temperature for 3 h, after which the solvent and residual oxalyl chloride were removed in vacuo. The red solid thus obtained was taken up in 20 mL CH_2Cl_2. Tetrabutylammonium bromide (0.004 g, 0.01 mmol) was added, followed by a solution of 0.32 g NaN_3 (4.9 mmol) in 4 mL H_2O, and the mixture was stirred rapidly at room temperature for 18 h. An additional 50 mL water was added to the mixture, and the organic layer was separated. The aqueous layer was extracted with CH_2Cl_2 (2 × 20 mL), the combined organic layers were dried over $MgSO_4$ and filtered, and the solvent was removed in vacuo. Column chromatography (1:1 CH_2Cl_2/petroleum ether) gave 1.69 g 1,2,3,4,5-pentaphenyl-1′-acylazidoferrocene as a red solid, in a yield of 81%, m.p. 250°C (dec).

1,2,3,4,5-Pentaphenyl-1′-acylazideferrocene (1.48 g, 2.3 mmol) was dissolved in 15 mL toluene; the solution was heated to 105°C, and 0.67 mL of 2-(trimethylsilyl)ethanol (4.7 mmol) was added in a single portion. The red solution obtained was stirred at this temperature for 3 h, by which time the color had changed to dark orange. The mixture was cooled to room temperature, 50 mL 1 M NaOH was added, and the solution was stirred for

5 min. The organic layer was separated, and the aqueous layer was extracted with CH_2Cl_2 (2×20 mL). The combined organic layers were dried over $MgSO_4$ and filtered, and the solvent was removed in vacuo to give an orange solid. Chromatography (1:1 CH_2Cl_2/petroleum ether) gave 1.61 g 1,2,3,4,5-pentaphenylferrocene-1′-(2-trimethylsilyl)-ethyl carbamate as an orange solid, in a yield of 95%, m.p.132–134°C.

Other references related to the Curtius rearrangement are cited in the literature.[24]

[m+n(+. . .)] Cycloaddition

A. GENERAL DESCRIPTION OF THE REACTION

Modern organic synthesis with its increasing ecological concerns demands a highly efficient process to transform simple starting materials rapidly into complex building blocks, from which the desired products can be formed.[1] One of the best ways to address this challenge relies on the application of a cycloaddition reaction, in which two or more molecules can combine and form new ring structures, along with the formation of multiple bonds and multiple stereogenic centers in a single step.[2] In addition, cycloadditions are also considered the right choice when high regioselectivities, chemoselectivities and stereoselectivities are concerned.[3] Except for the famous *Diels-Alder Reaction*, *1,3-Dipolar Cycloaddition*, and *[2+2] Cycloaddition* (including a special case of *Paterno-Buchi Reaction*), which are described separately, many types of cycloadditions currently used in organic syntheses are summarized in this chapter of cycloaddition, including [2+1], [2+2+1], [2+2+2], [2+2+2+1], [3+2+1], [3+2+2], [3+2+2+2], [3+3], [4+1], [4+2+1], [4+2+2], [4+3], [4+4], [5+1], [5+1+2+1], [5+2], [5+2+1], [5+3], [5+4], [6+2], [6+3], [6+4], [6+6], and [8+2] cycloadditions. Each of these cycloadditions can be treated as an individual reaction like the other named reactions discussed in this book; therefore, for each type of cycloaddition I have provided one experimental example accompanied along with related references.

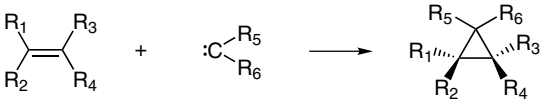
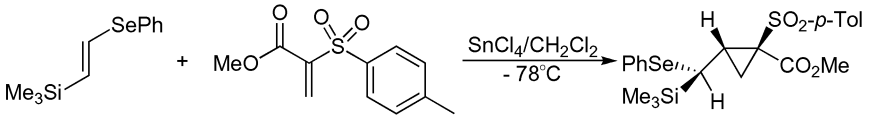
[2+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a solution of 250 mg 1-phenylseleno-2-trimethylsilylethene (1.0 mmol) in 2.4 mL dichloromethane was added 0.173 mL $SnCl_4$ (391 mg, 1.5 mmol) followed by 312 mg 2-*p*-toluenesulfonylacrylate (1.3 mmol) at −78°C. The mixture was stirred at −78°C for 3 h. The reaction mixture was quenched by 0.32 mL triethylamine (230 mg, 2.3 mmol) and then with saturated aqueous $NaHCO_3$. The mixture was extracted with dichloromethane, and the organic phase was washed with water, dried over Na_2SO_4, and evaporated in vacuo. The residue was purified by column chromatography over silica gel eluting with hexane/ether (2:1) to give 278 mg methyl *R*-1-(*p*-toluenesulfonyl)-*c*-2-[(phenylseleno)-(trimethylsilyl)methyl]-1-cyclopropanecarboxylate, in a yield of 56%. An analytically pure sample was recrystallized from hexanes/ether as colorless crystals, m.p. 117–119°C.

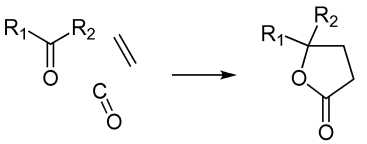
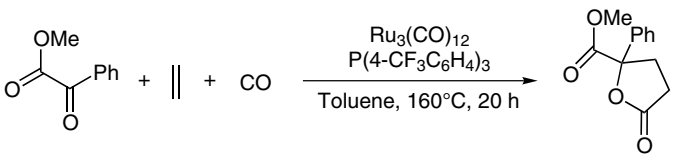
[2+2+1] Cycloaddition

A. GENERAL REACTION SCHEME

In this reaction, the π-bond of the ketone or aldehyde, the π-bond of the alkene, and the carbon atom of CO are integrated into compounds with a five-membered ring, such as γ-butyrolactones.[1]



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A 50-mL stainless autoclave were charged with 328 mg methyl benzoylformate (2 mmol), 70 mg P(4-$CF_3C_6H_4)_3$ (0.15 mmol), 6 mL toluene, and 32 mg $Ru_3(CO)_{12}$ (0.05 mmol). After the system was flushed with 10 atm ethylene three times, it was pressurized with ethylene to 3 atm and then with carbon monoxide to additional 5 atm. Then the autoclave was immersed in an oil bath at 160°C. After 20 h, it was removed from the oil bath and allowed to cool for ∼1 h. The gases were then released. The contents were transferred to a round-bottomed flask with toluene, and the volatiles were removed in vacuo. The residue was subjected to column chromatography on a silica gel (eluent, hexane/EtOAc, 5:1) to give 413 mg tetrahydro-5-oxo-2-phenyl-2-furancarboxylic acid methyl ester as a colorless solid, in a yield of 94%. Purification by bulb-to-bulb distillation afforded the analytically pure product, m.p. 54–56°C, $R_f = 0.34$ (hexane/EtOAc, 5:1).

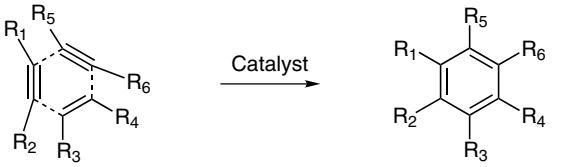
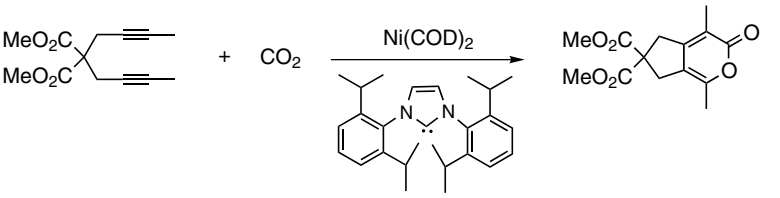
[2+2+2] Cycloaddition

A. GENERAL REACTION SCHEME

The [2+2+2] cycloaddition reaction of three unsaturated partners provides a powerful tool to form three carbon-carbon bonds in a single chemical transformation,[1] especially for the formation of polycyclic compounds via intramolecular cyclization with high regio-, chemo- and stereoselectivities.



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

An oven-dried two-neck round-bottomed flask equipped with a magnetic stir bar, septum, gas adapter, and balloon was evacuated and filled with CO_2. A solution of 200 mg 2,2-di-but-2-ynyl-malonic acid dimethyl ester (0.85 mmol) was added, and the flask was submerged into a 60°C oil bath. To the stirring solution, 3 mL toluene solution containing 12 mg $Ni(COD)_2$ (0.04 mmol) and 31 mg IPr (0.08 mmol) was added. The dark greenish black reaction mixture was then heated for 2 h (or until complete consumption of the starting material was observed as judged by GC), cooled to ambient temperature, concentrated, and purified by recrystallization in CH_2Cl_2 and hexanes to afford 228 mg 1,4-dimethyl-3-oxo-3,5-dihydro-7H-cyclopenta[c]pyran-6,6-dicarboxylic acid dimethyl ester as a white solid, in a yield of 96%.

Other references related to [2+2+2] cycloaddition are cited in the literature.[3,4]

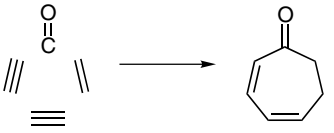
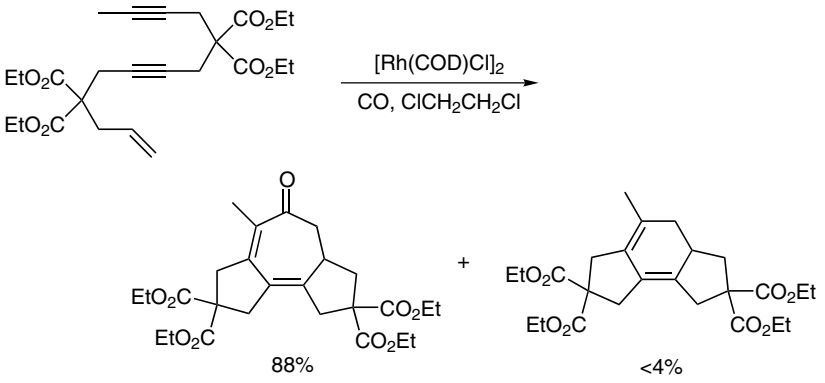
[2+2+2+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

4,4,9,9-Tetra(carbethoxy)tridec-1-ene-6,11-diyne (100 mg, 0.216 mmol) was introduced to a Schlenck tube, followed by 2.16 mL $Cl(CH_2)_2Cl$ under argon, and then CO was bubbled into the solution at room temperature. After 15 min 5.3 mg $[Rh(COD)Cl]_2$ (0.0108 mmol, 5 mol %) was added under CO, and the resulting mixture was stirred at room temperature for an additional 5 min. Then the reaction mixture was heated to 50ºC with stirring and kept for 16 h under CO (ambient pressure, bubbled into the solution). All volatiles were removed from the reaction mixture under reduced pressure, and the crude product was purified by flash chromatography on silica gel (EtOAc/hexanes, 1:9 to 3:7) affording 93 mg 6-methyl-2,2,8,8-tetra(carbethoxy)-5-oxo-1,3a,4,5,7,9-hexahydro-3H-cyclopenta[e]azulene as a light yellow oil, in a yield of 92.5% (88% isolated yield, R_f = 0.30, EtOAc/hexanes, 1:4), and <4 mg 5-methyl-2,2,7,7-tetra(carbethoxy)-1,3,3a,4,6,8-hexahydro-as-indacene as a colorless oil, in 5.5% yield (<4% isolated yield, R_f = 0.56, EtOAc/hexanes, 1:4).

No other references related to [2+2+2+1] cycloaddition are found in the available literature.

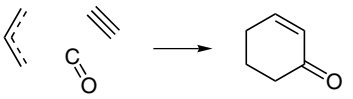
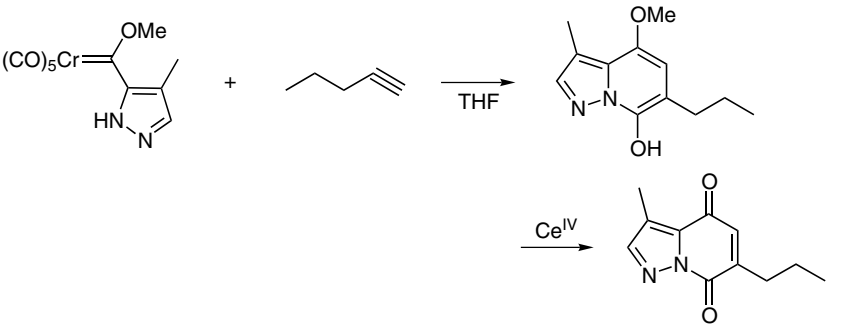
[3+2+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A 3.2 mL THF solution of 102 mg chromium complex (0.32 mmol) and 0.05 mL 1-pentyne (0.49 mmol) was deoxygenated by the freeze-thaw method (−196→25°C, three cycles) in a 25-mL pear-shaped flask that had the 14/20 joint replaced by an 8-mm threaded high-vacuum stopcock. The solution was then heated under argon at 45°C for 18 h and then diluted with 10 mL ether and oxidized by being poured into 5 mL 0.5 M aqueous cerric ammonium nitrate solution and being stirred at room temperature for 30 min. The organic layer was washed with water and brine and dried over $MgSO_4$. After the removal of solvents, the residue was flash chromatographed with an eluent mixture of CH_2C1_2/ether/hexanes (1:1:4) to provide 20 mg quinone as a pale yellow solid, in a yield of 31%, m.p. 129.5–130.5°C.

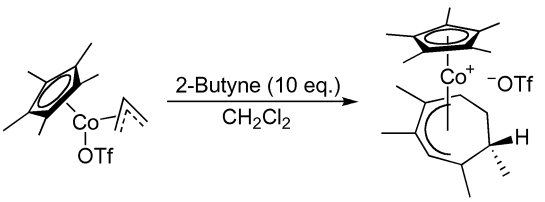
[3+2+2] Cycloaddition

A. GENERAL REACTION SCHEME

B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a drybox, was placed 315.5 mg $(C_5Me_5)Co(\eta^3\text{-}C_3H_5)(OTf)$ (0.820 mmol) in a flask equipped with a Kontes valve. This flask was removed to the Schlenk line, and 10 mL dichloromethane was added. On the high vacuum line, 0.44 g 2-butyne (8.2 mmol) was added by vacuum transfer. The solution was cooled to -78°C and then allowed to warm slowly to room temperature while being stirred overnight. The solvent was evaporated, the residue was washed with diethyl ether and then dissolved in dichloromethane and filtered through Celite. Evaporation gave 327.3 mg of a red, somewhat impure solid, in a yield of 81%. The material could be partially purified by being dissolved in a minimal amount of dichloromethane and added dropwise to an excess of rapidly stirring diethyl ether.

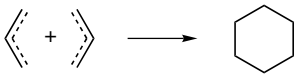
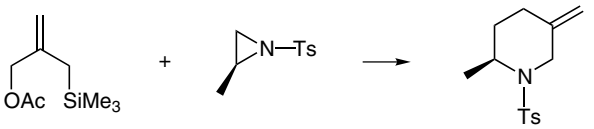
[3+3] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a suspension of 50 mg $Pd(OAc)_2$ (0.22 mmol, 1 eq.) in 1.6 mL THF was added 0.33 mg $P(O\text{-}i\text{-}Pr)_3$ (1.34 mmol, 6 eq.) and then 0.18 mL 2.5 M *n*-BuLi in hexanes (0.45 mmol, 2 eq.); the resultant yellow solution (0.14 M palladium catalyst) was stirred for 15 min before use.

A solution of 150 mg tosyl aziridine (0.71 mmol, 1.5 eq.) in 3 mL THF was treated with 0.34 mL freshly prepared 0.14 M palladium catalyst solution (0.05 mmol, 10 mol %) and 0.10 mL alkene (0.47 mmol, 1 eq.); the reaction mixture was refluxed for 16 h. Solvent was removed in vacuo and the residue was purified by flash chromatography to yield 102 mg (*S*)-2-methyl-5-methylene-1-(toluene-4-sulfonyl)-piperidine as a white solid, in a yield of 82%, m.p. 68–69°C.

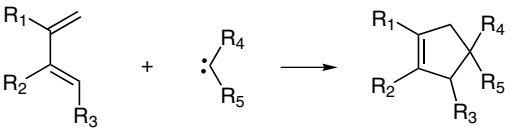
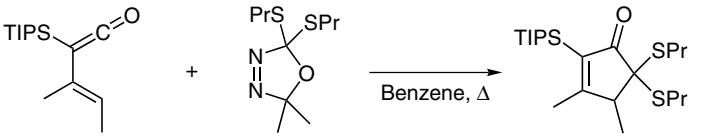
[4+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A benzene solution of 0.05 M vinylketene (1 eq.) and 2 eq. of bis(propylthio)carbene precursor was refluxed until the completion of the reaction (typically 1–2 h). The resulting solution was cooled down to room temperature and directly chromatographed on silica gel (hexane, then EtOAc/hexane) to give 96% of product as a colorless oil.

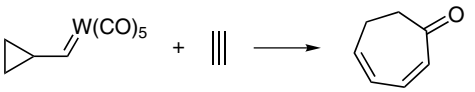
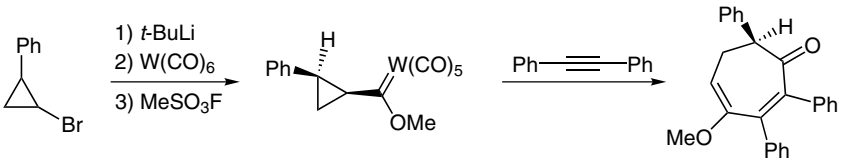
[4+2+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a solution of 1.10 g 1-bromo-2-phenyl cyclopropane (5.7 mmol) in 25 mL diethyl ether at –78°C under nitrogen was added via syringe 6.7 mL 1.7 M *t*-butyllithium (10.5 mmol) in pentane. The mixture was stirred for 30 min at –78°C, and then transferred via cannula to a suspension of 2.0 g tungsten hexacarbonyl (5.7 mmol) in 100 mL diethyl ether at 0°C. The mixture was warmed to room temperature, and then stirred for 1 h. The mixture was cooled to 0°C, and 1.4 mL methyl fluorosulfonate (17.7 mmol) was added, and the mixture was stirred at room temperature for 30 min. The reaction mixture was poured into saturated $NaHCO_3$ solution in a separatory funnel and then extracted with hexane. The hexane layer was washed three times with water and then brine, dried over $MgSO_4$, and concentrated. The residue was purified via column chromatography using pure hexane as the eluent to give two fractions. The first fraction (0.804 g, 29%) was identified as the *cis* isomer complex that is used in the highlighted reaction example. The second fraction (0.536 g, 20%) was the *trans* isomer.

To 20 mL refluxing xylene under nitrogen was added a solution of 0.1 g carbene complex (0.207 mmol), 0.060 g diphenylacetylene (0.330 mmol), and 0.090 g 1,2-(bis)-diphenylphosphinobenzene (0.20 mmol) in 30 mL xylene over a period of 6 h. Then the solution was refluxed for an additional 10 h. The mixture was cooled to 25°C, and the solvent was removed on a rotary evaporator. The residue was dissolved in 1:1 hexane/EtOAc and then filtered through celite. After the removal of the solvent on a rotary evaporator, final purification was achieved by flash chromatography using hexane/EtOAc (9:1 to 4:1) as the eluent, to give 0.040 g cycloheptadienone, in a yield of 53%.

No other references related to [4+2+1] cycloaddition are found in the available literature.

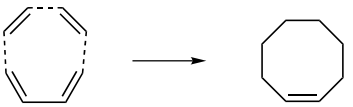
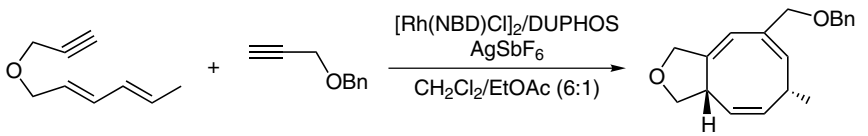
[4+2+2] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

Preparation of Catalyst

To a vial containing 75 mg $[Rh(NBD)Cl]_2$ (0.16 mmol) was added 2 mL THF. After being stirred for 15 min, this orange solution was quickly transferred via cannula to a vial with 2 mL THF solution containing 98 mg (S,S)-Me-DuPHOS (0.32 mmol). After being stirred for 15 min, this red solution was transferred via cannula to a vial containing a

solution of 56 mg $AgSbF_6$ (0.16 mmol) in 2 mL THF. After 15 min, this dark suspension was transferred to a tarred vial using a syringe fitted with a filter. The cherry red filtrate was concentrated in vacuo and kept under vacuum (< 1 mmHg) overnight to remove all solvent, and 211 mg of an orange-red solid was collected. This catalyst can be stored under nitrogen at 0°C for a short period of time.

Cycloaddition Procedure

To a clean, dry 15-mL Schlenk tube was added 30 mg catalyst in 2 mL CH_2Cl_2. Hydrogen was gently bubbled through the orange-red solution for 3 min causing it to become dark and cloudy. Then 0.5 mL EtOAc was added, followed by sparging with nitrogen for 3 min. The terminal alkyne (1.9 mmol) was added along with 0.5 mL CH_2Cl_2, and the reaction was stirred to ensure homogeneity. Finally, the dienyne (0.38 mmol) was added along with 0.5 mL CH_2Cl_2. The reaction was freeze-pump-thawed three times, back-filled with nitrogen, and stirred overnight in a 60°C oil bath. Flash chromatography with 5% or 10% EtOAc in hexanes yields 73% of the pure product.

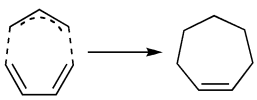
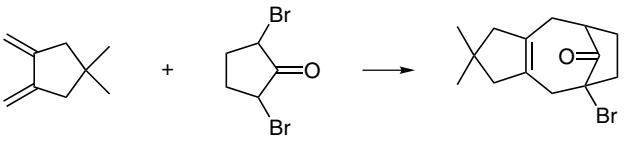
[4+3] Cycloaddition

A. GENERAL REACTION SCHEME

The cycloaddition between dienes and allylic cations provides a convenient method for forming complex seven-membered rings from simple starting materials.[1]



B. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To a 35 mL trifluoroethanol solution of 2.05 g dibromocyclopentanone (8.47 mmol, 1.2 eq.) was added under dry nitrogen a solution of 862 mg 1,1-dimethyl-3,4-dimethylene-cyclopentane (7.06 mmol, 1.0 eq.) in 35 mL toluene. The resulting solution was cooled down to –23°C via a dry ice-carbon tetrachloride bath while vigorously stirring. Then 2.57 g triethylamine (25.4 mmol, 3.6 eq.) was added dropwise. After 40 min, the reaction was quenched with water and allowed to warm to room temperature. The reaction mixture was diluted with ether, washed with water and brine, and dried over magnesium sulfate. Flash chromotagraphy, and drying under vacuum afforded 1.059g (3R, 6R)-6-bromo-10,10-dimethyltricyclo[6.3.1^{3,6}.0]-undec-1(8)-ene-12-one, in a yield of 53%.

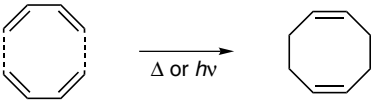
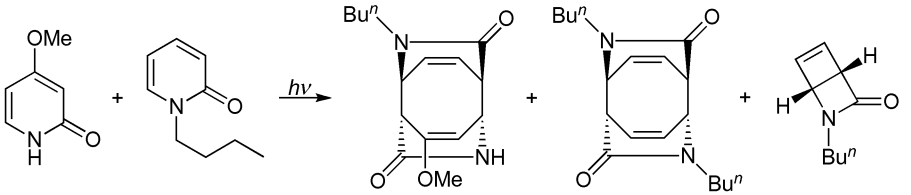
[4+4] Cycloaddition

A. GENERAL REACTION SCHEME

The [4 + 4] cycloadditions is a versatile method for the preparation of 1,5-cyclooctadiene, especially under photochemical reaction condition.[1]



B. CITED EXPERIMENTAL EXAMPLES



Reference 2.

A stream of dry nitrogen was passed through a solution of 454 mg 4-methoxy-2-pyridone (3.62 mmol) and 77 mg *N*-butyl-2-pyridone (0.51 mmol) in 8.3 mL methanol in a Pyrex test tube for several minutes, and the test tube was then sealed with a septum and fitted with a nitrogen balloon. This tube was taped to the side of a water-cooled quartz cooling jacket surrounding a 450-W medium-pressure mercury lamp inside of a Pyrex filter and irradiated for a total of 72 h. The methanol was removed in vacuo, and the residue was taken up in acetonitrile. On standing, 4-methoxy-2-pyridone crystallized from solution. The mother liquor was concentrated and chromatographed. A gradient of hexane and ethyl acetate (1:1 hexane/ethyl acetate to 100% ethyl acetate) led to the isolation of Dewar pyridone (2-butyl-2-azabicyclo[2.2.0]hex-5-en-3-one) in a 5% yield, $R_f = 0.70$ (3:2, hexane/EtOAc), 8% (1α,2β,5β,6α)-3,7-dibutyl-3,7-diazatricyclo[4.2.2.2^{2,5}]-dodeca-9,11-diene-4,8-dione, R_f = 0.17 (1:1, hexane/EtOAc), and 51% (1α,2β,5β,6α)-3-butyl-9-methoxy-3,7-diazatricyclo-[4.2.2.2^{2,5}]dodeca-9,11-diene-4,8-dione using isopropanol/acetonitrile (1:9) as the eluent, $R_f = 0.25$ (1:9, isopropanol/acetonitrile), m.p. 179°C.

Other references related to [4+4] cycloaddition are cited in the literature.[3]

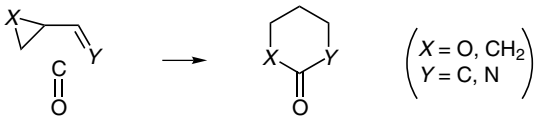
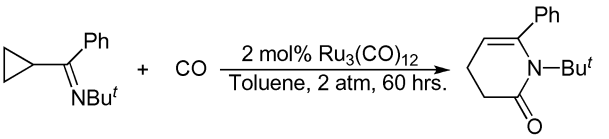
[5+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A 50-mL stainless autoclave was charged with 201 mg cyclopropyl phenyl *N*-(1,1-dimethylethyl) ketimine (1 mmol), 3 mL toluene, and 13 mg $Ru_3(CO)_{12}$ (0.02 mmol). The system was flushed with 10 atm of CO three times, after which it was pressurized to 2 atm

and immersed in an oil bath at 160°C. After 60 h the autoclave was removed from the oil bath and cooled for 1 h, followed by release of the CO. The contents were transferred to a round-bottomed flask with ether, and the volatiles were removed in vacuo. The residue was subjected to column chromatography on silica gel with an eluent of hexane/Et_2O (3:1) to give 175 mg 3,4-dihydro-1-(1,1-dimethylethyl)-6-phenyl-2(1*H*)-pyridinone as a white solid, in a yield of 76%.

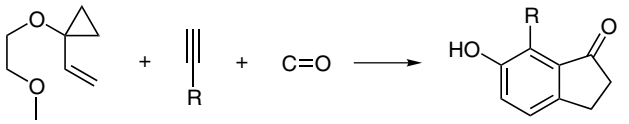
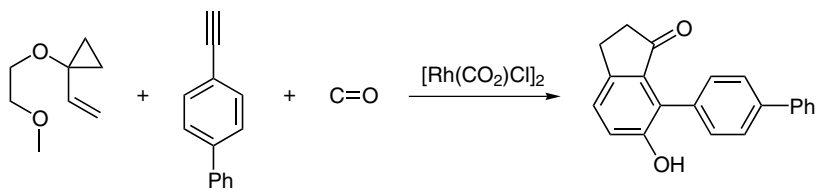
[5+1+2+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

In an oven-dried, borosilicate glass test tube, capped with a rubber septum and dried under a CO atmosphere from a balloon, was added 4 mg $[Rh(CO)_2Cl]_2$ (0.010 mmol) in

4.0 mL toluene. A 25-G needle outlet was added, and the atmosphere of the test tube was sparged with CO from the balloon for 15 min. During this time, 114 mg vinylcyclopropane (0.80 mmol) and 70 mg biphenylacetylene (0.40 mmol) were added sequentially. After sparging was completed, the reaction was heated in a 60°C, thermostat-controlled oil bath under a CO atmosphere (balloon). The reaction was monitored using TLC. After 30 h, the reaction was cooled to room temperature, and the crude reaction mixture was then purified directly by flash column chromatography (silica gel, dichloromethane) to afford 112 mg cycloadduct as an off-white solid, in a yield of 93%.

No other references related to [5+1+2+1] cycloaddition are found in the available literature.

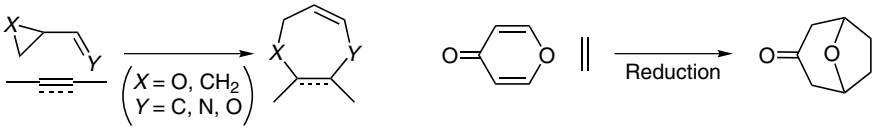
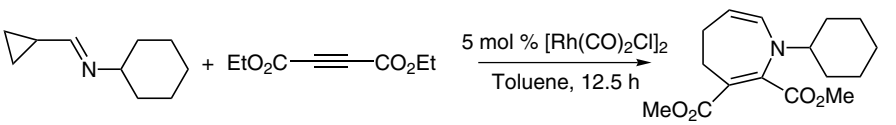
[5+2] Cycloaddition

A. GENERAL REACTION SCHEME



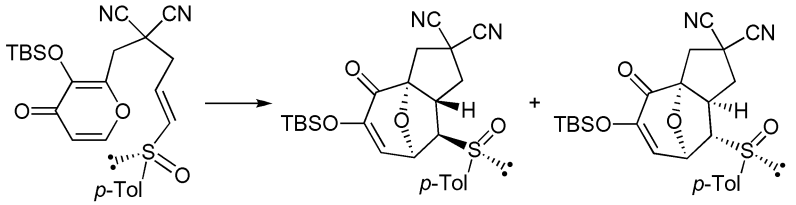
B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

An oven-dried, 50-mL reaction flask, under a positive pressure of dry nitrogen, was charged with 2.0 mmol cyclohexamine and 15 mL toluene. Hexadecane (100 μL) was added

as an internal standard to determine conversion and GC yields. Cyclopropyl formaldehyde (170 μL, 2.2 mmol) was then added, and the reaction quickly turned cloudy. A Dean-Stark trap with a 5-mL hold-up volume was attached to the reaction setup. The reaction was allowed to stir at room temperature for 1 h, and then heated to reflux for 1 h with azeotropic removal of the water. The reaction was then cooled to 60°C, and 38.9 mg $[Rh(CO)_2Cl]_2$ (0.1 mmol) was added. A 10 mL toluene solution containing 0.49 mL DMAD (3.99 mmol) was added by syringe pump over 12.5 h. The reaction was cooled to room temperature and filtered through a short pad of silica gel using Et_2O as the eluant and concentrated in vacuo. The residue was purified by flash column chromatography (Et_2O/petroleum ether as the eluant) to give 1-cyclohexyl-4,5-dihydro-1*H*-azepine-2,3-dicarboxylic acid dimethyl ester in 85% isolated yield.



Reference 2.

A 10 mL toluene solution of 100 mg 2-[(3-*t*-butyldimethylsilyloxy-4-oxo-4*H*-2-pyranyl)methyl]-2-[(2*E*,R_S)-3-*p*-tolylsulfinyl-2-propenyl]malononitrile (0.21 mmol) was refluxed for 10 h. The solvent was evaporated and the crude product was purified by flash chromatography (25–50%, EtOAc/hexanes) to afford a 91:9 ratio of diastereoisomers of (1*R*,5*S*,6*R*,7*R*,R_S)-9-*t*-butyldimethylsilyloxy-6-[*p*-tolylsulfinyl-10-oxo-11-oxatricyclo[5.3.1.$0^{1,5}$]undec-8-ene-3,3-dicarbonitrile (R_f = 0.54; hexane/EtOAc,1:1) and (1*S*,5*R*,6*S*,7*S*,R_S)-9-*t*-butyldimethylsilyloxy-6-[*p*-tolylsulfinyl-10-oxa-11-oxatricyclo-[5.3.1.$0^{1,5}$]undec-8-en-3,3-dicarbonitrile (R_f = 0.70; hexane/EtOAc, 1:1) as colorless oils, in a yield of 98%.

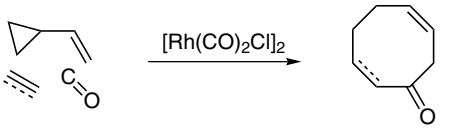
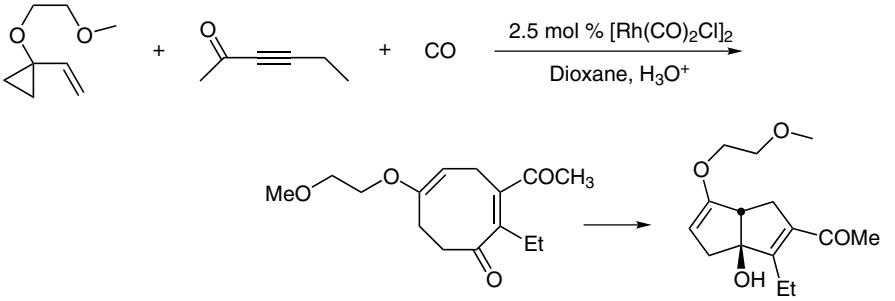
[5+2+1] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To an oven-dried, septum-capped test tube were added 0.025 mmol $[Rh(CO)_2Cl]_2$ and 2.0 mL 1,4-dioxane, followed by 1.0 mmol vinylcyclopropane via syringe. The reaction mixture was purged with a stream of CO from a balloon for 15 min. The alkyne (1.2 mmol) was added via syringe. The septum was pierced with a needle, and the test tube was placed in an autoclave, pressurized to 2 atm, and heated to 60°C in a thermostat-controlled oil bath (for 1 atm reactions, the test tube was heated directly in an oil bath under a balloon of CO). The reaction was monitored by TLC or GC, and upon completion the reaction was cooled to room temperature. Water (200 mL) and 1% HCl in ethanol (25 mL) were added, and the hydrolysis was monitored by TLC (24 h). After hydrolysis, the reaction was concentrated in vacuo. Purification by flash chromatography (silica gel; 1:1, EtOAc/pentane) afforded 97% 5-acetyl-4-ethyl-3α-hydroxy-3,3α,6,6α-tetrahydro-2*H*-pentalen-1-one.

No other references related to [5+2+1] cycloaddition are found in the literature.

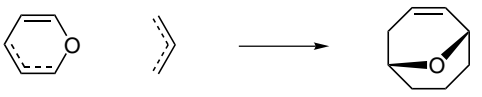
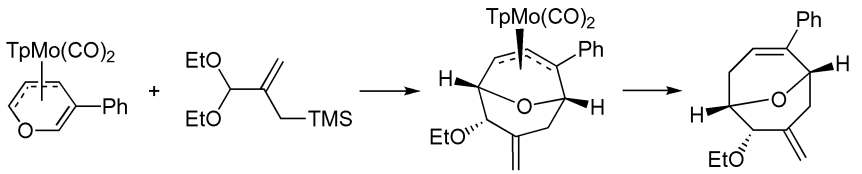
[5+3] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a solution of 180 mg molybdenum complex (0.34 mmol) and 298 mg allylic acetal (1.38 mmol) in 3.4 mL dry CH_2Cl_2 was added 17.0 mg $Sc(OTf)_3$ (0.034 mmol, 10 mol %) at –78°C under an argon atmosphere. The mixture was stirred at –78°C for 1 h. After the reaction was complete, the mixture was passed through a short pad of silica gel with 9:1 CH_2Cl_2/EtOAc. The filtrate was concentrated under vacuum and the residue was purified by flash chromatography using *n*-hexanes/CH_2Cl_2 as the eluent to afford 170.8 mg pure (+)-dicarbonyl[hydridotris(1-pyrazolyl)borato]{η-(2,3,4)-(1*S*,2*R*,5*S*,6*S*)-6-ethoxy-7-methylen-2-phenyl-9-oxabicyclo[3.3.1]non-3-en-2-yl}molybdenum in 98% e.e. as a red crystalline solid, in a yield of 80%. Recrystallization from *n*-hexanes/CH_2Cl_2 afforded 116 mg product in 99.5% e.e. with a 55% yield. $R_f = 0.25$ (*n*-hexanes/EtOAc, 7:1), m.p. > 200°C.

To a solution of 125 mg of the molybdenum complex (0.20 mmol) in 3.2 mL CH_2Cl_2 was added at room temperature 495 μL 37% aqueous HCl (6.0 mmol) dropwise over 2 min. The mixture was stirred at room temperature for 20 min and 30 mL EtOAc and 30 mL water were then added. The organic layer was washed with 30 mL saturated aqueous $NaHCO_3$, dried over Na_2SO_4, and evaporated. The residue was purified by flash chromatography (2:1, *n*-hexanes/CH_2Cl_2) to afford 41.4 mg (+)-(1*S*,5*S*,6*S*)-6-ethoxy-7-methylen-2-phenyl-9-oxabicyclo[3.3.1]non-2-ene, with 99.5% e.e. as a white solid, in a yield of 80%. $R_f = 0.08$ (2:1, *n*-hexane/CH_2Cl_2), m.p. 42–43°C.

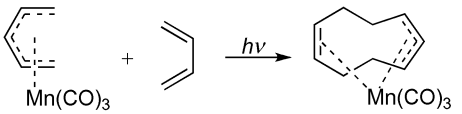
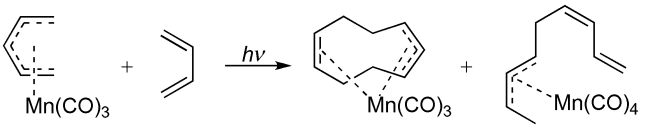
[5+4] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A mixture of 300 mg [$Mn(CO)_3(\eta^5\text{-}C_5H_7)$] (1.46 mmol) and ~5 mL 1,3-butadiene in *n*-hexane was irradiated by UV light at 235K. During the reaction, a large amount of pale brown decomposition product formed, which further turned into orange and finally faint yellow. After 1 h, the starting materials were completely consumed. Upon warming to room temperature, the reaction mixture was purified by HPLC using *n*-hexane as the eluent, and two fractions were obtained: tetracarbonyl-η^3-Z,E,Z-3,6,8-nonatrien-3-yl-mangan (60 mg, yellow oil, in a yield of 14%) and tricarbonyl-$\eta^{3:2}$-2,6-cyclononadien-1-yl-mangan (90 mg, yellow crystal, in a yield of 24%). (*Note:* this summary was translated from the original German article.)

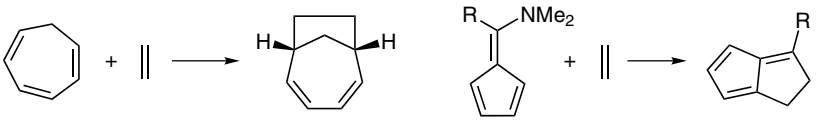
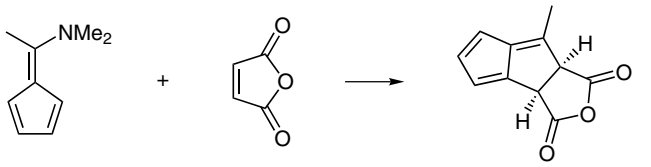
[6+2] Cycloaddition

A. GENERAL REACTION SCHEME

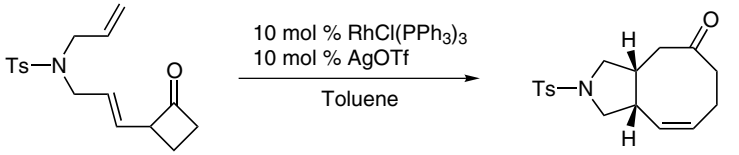


B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A benzene solution (10 mL) containing 270 mg 6-methyl-6-dimethylaminolfulvene (2 mmol) and 215 mg maleic anhydride (2.2 mmol) was stirred at 25ºC for 30 min. The solution was concentrated in vacuo to give a brown oil. The crude product was purified by flash column chromatography (silica gel) with 10% EtOAc/hexane to give 305 mg adduct, in a yield of 81%, $R_f = 0.35$ (15% EtOAc/hexane), m.p., 57–58ºC.



Reference 2.

To a base-washed, oven-dried Schlenk flask was added a solution of the substrate in toluene (0.014 M). Argon was bubbled through the solution for 10 min, followed by the addition of 10 mol % $RhCl(PPh_3)_3$ and 10 mol % AgOTf; then argon was bubbled again through the solution for 10 min. The mixture was stirred at 100ºC for 3 h. After being cooled to room temperature, the mixture was concentrated, and the residue was purified by flash column chromatography with silica to give 95% of the cycloaddition product. Other catalytic systems suitable for this cycloaddition include $[RhCl(CO)_2]_2$, $RhCl(CO)(PPh_3)_2$, $[RhCl(CO)_2]_2$ + n-Bu_3P, and $[RhCl(CO)_2]_2$ + PPh_3.

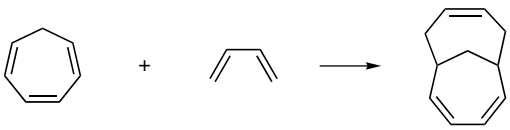
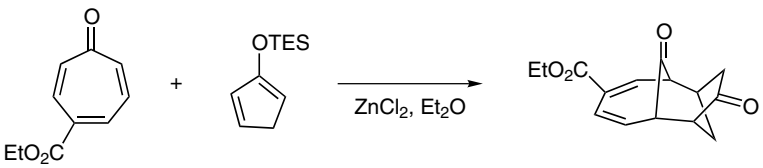
[6+4] Cycloaddition

A. GENERAL REACTION SCHEME



B. CITED EXPERIMENTAL EXAMPLES



Reference 1.

A solution of 71 mg 4-carboethoxy tropone (0.40 mmol, 1 eq.) in 3 mL dry ether was cannulated into a round-bottomed flask containing 6 mg freshly fused $ZnCl_2$ (0.04 mmol, 0.1 eq.). A solution of 235 mg 2-triethylsilyloxycyclopentadiene (1.20 mmol, 3 eq.) in 3 mL ether was then added to the reaction mixture via cannula. The reaction mixture was allowed to stir at room temperature for 5 min and then it was quenched by the addition of 5 mL 1M HCl solution and 5 mL THF. After being stirred overnight, the layers were separated, and the aqueous layer was then extracted with 5 mL EtOAc. The combined organic layers were washed with 5 mL saturated $NaHCO_3$ solution, dried over anhydrous magnesium sulfate, filtered, and concentrated in vacuo. The crude product was purified by flash chromatography using 40% EtOAc in hexanes to afford 91 mg 3,11-dioxo-tricyclo[4.4.1.$1^{2,5}$]dodeca-7,9-diene-8-carboxylic acid ethyl ester, in a yield of 88%.

[2+2] Cycloaddition

A. GENERAL DESCRIPTION OF THE REACTION

Any process involving the breakage of two π bonds and the formation of two σ bonds to form a four-membered ring structure in general should belong to [2+2] cycloaddition. Among the [2+2] cycloadditions, the reaction between a carbonyl compound and an alkene to form oxetane is known as the *Paterno-Büchi Reaction*, while the [2+2] cycloaddition of ketenes and imines to give 2-azetidinones (i.e., β-lactams) is referred to as the *Staudinger [2+2] Cycloaddition* and the [2+2] photocycloaddition between an enol of a 1,3-dicarbonyl compound (β-diketone, β-dialdehyde, or β-ketoaldehyde) and an olefin to form a cyclobutanol intermediate followed by a retro aldol condensation to 1,5-dicarbonyl compound is named the *de Mayo Reaction*. These reactions are discussed in their own chapters; therefore, this chapter will focus primarily on the formation of the four-membered ring of the carbon skeleton.

According to the Woodward-Hofmann rule, a concerted [2+2] cycloaddition of regular olefins at ground states is thermodynamically prohibited, whereas the olefins at excited states activated by UV irradiation is allowed.[1] Thus the normal cycloaddition of olefins under photochemical conditions are known as photochemical [2+2] cycloaddition,[2] [2+2] photocycloaddition,[3] and [2π+2π] photocycloaddition.[4] On the other hand, the reversion of [2+2] cycloaddition could also occur under UV irradiation, according to Woodward-Hofmann rule; and such a process is referred to as [2+2] photocycloreversion.[5] However, it should be pointed out that not all the [2+2] cycloadditions occur and under photochemical conditions, some unstable olefins—due to high electron deficiency or high ring strain (typically confined to ketenes, allenes, ketenimines and multifluorinated olefins)—can also

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

undergo the thermal [2+2] cycloadditions, with or without the help of Lewis acids or transition metal complexes via stepwise biradical or zwitterionic intermediates. In addition, most of reported [2+2] cycloadditions are intramolecular cycloadditions, due to a better defined regioselectivity, rate enhancement, and the ability to construct a polycyclic structure in one step.[6]

The first photochemical [2+2] cycloaddition was probably reported by Ciamician and Silber in 1908 for the synthesis of camphorcarvone,[7] which was confirmed by Büchi and Goldman in 1957.[8] Under photoirradiation, most of olefins undergo [2+2] cycloaddition. For example, norbornadiene (bicyclo[2.2.1]hepta-2,5-diene) with two ethylenic units fixed in space gives quadricyclane (tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane) as the dominant photoproduct;[9] acetylene[2c] or 1,2-dichloroethylene[10] reacts with chiral 2(5*H*)-furanones (α,β-unsaturated lactones) to afford cyclobutene-fused lactones. In addition, acetylene also cyclizes with benzothiophene photochemically to form naphthalothiophene[3a] with an intramolecular enone moiety.[11] While acenaphthylene undergoes dimerization on irradiation into two isomeric dimmers,[12] 1,1-diethoxyethylene cyclizes with chiral polyfunctional 2-cyclohexenones to give only identified head-to-tail regioisomers, which are controlled by the rate of 1,4-biradical formation.[13] In addition, the photochemical [2+2] cycloaddition even occurs for olefins with certain steric hindrance. For example, *trans*-2-cyclooctenone reacts with dimethoxyethylene in a stepwise manner to give [2+2] cycloadduct;[14] singlet exciplex of *trans*-stilbene reacts with olefins properly,[15] and the olefin tethered with benzene undergoes *ortho* [2+2] cycloaddition.[16] In addition, benzyne, *N*,*N*-diethylpropynylamine (ynamine),[17] and enynamine[18] cyclize with C_{60}; and even *m*-phenylenebis(arylmethanofullerene) undergoes photochemical [2+2] cycloaddition to form the dimerized fullerene structure.[19] The rare occurring steric hindrance in photochemical [2+2] cycloaddition is attributed to the large number of mechanisms by which excited-state energy can be dissipated.[20] However, in a few cases, the extreme steric hindrance does burden the photochemical [2+2] cycloaddition. For instance, although 1,2-diphenylcyclobutene reacts with 2,5-dimethyl-2,4-hexadiene and itself, it does not undergo reaction with tetramethylethylene; moreover, 1,2-diphenylcyclopentene and 1,2-diphenylcyclohexene are unreactive in photochemical [2+2] cycloaddition,[3] and the methyl groups in 1,2-diphenyl-3,3,4,4-tetramethylcyclobutene effectively inhibit the possible [2+2] reaction with tetrachloroethylene.[20] Another example is the intramolecular cyclization of bis(1-methylethenyl-cyclopentadienyl)zirconium complex to form the catalyst for *ansa*-metallocene polymerization. While the 1-cyclohexylethenyl series cyclizes in a quantitative yield of complex, the 1-phenylethenyl series affords only 5% of corresponding product.[21]

In addition, molecules with olefinic structure can undergo photochemical [2+2] cycloaddition even in solid states. For example, cinnamic acid stacking in head-to-tail and head-to-head conformations in α- and β-crystalline shapes proceed photochemical [2+2] cycloaddition to afford α- and β-truxinic acids respectively,[22] while 1,4-bis(β-pyridyl-2-vinyl)benzene on Au(111) in solution dimerizes when irradiated by longer wavelength UV light ($\lambda > 400$ nm) but polymerizes under a shorter UV light ($\lambda < 400$ nm).[23] Producing the necessary unpaired electrons, the [2+2] cycloaddition is attributed to the origin of the magnetism in polymerized-C_{60} materials.[24] Although the only conjugated triene or higher polyene reported to undergo photochemical [2+2] cycloaddition is all-*trans*-hexatriene-1,6-dicarboxylic acid,[25] the [2+2] cycloaddition and photocycloreversion are responsible for the healing of the polymer.[3b] Moreover, coumarin is reported to undergo a thermal [2+2] cycloaddition in crystalline inclusion complexes under high vacuum conditions.[26]

It should be pointed out that in singlet [2+2] photocycloaddition, the regioselectivity and stereoselectivity are determined by the pericyclic minimum and exciple (or excimer) minimum, and the energy barrier between these two minima. As a result, HOMO-HOMO and LUMO-LUMO interactions favor the head-to-head regiochemistry and *syn*- or *cis*- stereochemistry in an excimer.[27] In contrast, the Rydberg-like excited singlet state is responsible for the [2+2] photocycloreversion.[5] Moreover, for the intramolecular [2+2] cycloaddition of hexa-1,5-dienes, the cycloaddition generally follows the rule of five, i.e., forming a five-membered ring rather than a six-membered ring via the 1,5-closure[28] due to the kinetic preference,[3a] as shown in the cyclization of 2-acyl-1,5-hexadienes[29] and even in the case of *o*-bisvinylbenzene in which the two vinyl groups are isolated by *o*-phenylene.[30] However, due to steric hindrance, the rule of five is dissipated in a few cyclizations. For example, in the cyclization of 1,5-hexadien-3-ones and 1-acyl-1,5-hexadienes, the substitution at C(s) results in a shift from a 1,5-closure to a 1,6-cyclization; the greater the substituent, the larger extent for this shift.[29] In addition, the existence of a bulky group between the two isolated alkene moieties or an electron-withdrawing group (e.g., ester) at the terminal of alkene also causes a violation of the rule of five.[31] Moreover, the rule of five is not followed when the 1,5-hexadiene systems undergo electron-transfer-induced rearrangements via a bifunctional 1,4-cyclohexanediyl radical cation intermediate.[32] In all these circumstances, when six-membered structures are formed, the reaction is known as the straight mode.[29,31]

On the other hand, allenes are a type of molecule with unsaturated carbon skeletons, which can undergo [2+2] cycloadditions under thermal conditions or photochemical initiation, or by Lewis acids or transition metal complex promotion. The reported cycloaddition between allene and enone is an example of cycloaddition under photochemical conditions,[33] while the intramolecular *gem*-difluoroallene-alkyne cycloaddition in the presence of either a stiochiometric or a catalytic amount of molybdenum hexacarbonyl [$Mo(CO)_6$] is an example of [2+2] cycloaddtion promoted by a transition metal complex.[34] Another transition metal complex is the imidotitanium complex.[35] Even though allenes are an inherently strained species[6] and can undergo thermal [2+2] cycloadditions, the strictly thermal reactions generally incur the drawbacks of high reaction temperatures, affording a mixture of chemoisomeric, regioisomeric, and stereoisomeric products in moderate or low yields.[36] For example, difluoroallene reacts with dichlorodifluoroethlene at 135°C to give a mixture of two isomers, the ratio of which varies along with the reaction time and with an overall preference of *exo*-difluoromethylene moiety. The reaction of difluoroallene with methylacrylonitrile at 100°C gives 39% isolated products in favor of different isomers.[37] However, [2+2] cycloaddition of alkynyl allene under microwave irradiation affords bicyclomethylenecyclobutenes with complete regioselectivity.[38] In addition, the strained 4-ethenylidene-1,3-oxazolidin-2-ones have been found to undergo a facile [2+2] cycloaddition with either alkenes or alkynes to furnish methylenecyclobutane and methylenecyclobutene derivatives.[36] In these reactions of allenes, the geometry of olefins can be completely transferred to the cycloadducts, whereas the cycloaddition of internal allenes with axial chirality might afford diastereomeric mixture of products.[39]

Ketenes are another type of unsaturated molecules of high electron deficiency and structural strains; therefore, they are very reactive for the [2+2] cycloaddition. The most common [2+2] cycloaddition involving ketenes are *Staudinger [2+2] Cycloadditions* to form β-lactones, initially reported in 1911, and the dimerization of ketenes.[40] Besides the easy cycloaddition with imine, as shown in the *Staudinger [2+2] Cycloaddition*, ketenes can also react with aldehydes to afford β-lactones. It has been found that high diastereoselectivity can

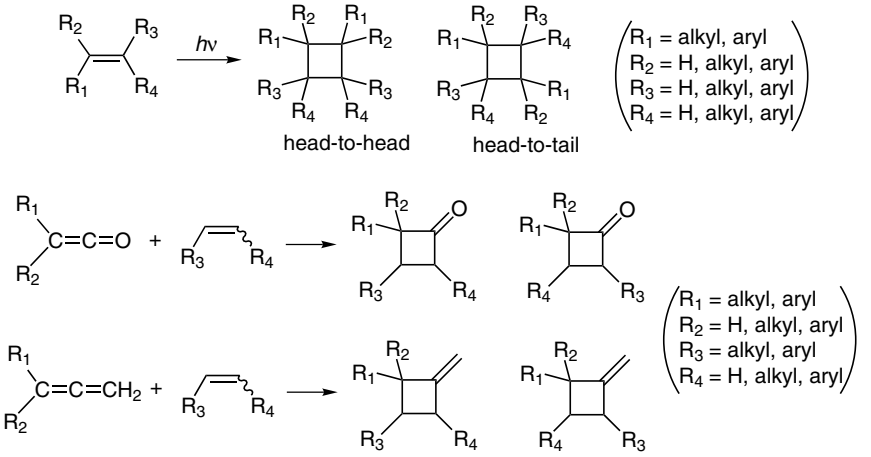
be reached for the reaction between trimethylsilkylketene and aldehydes when bulky, achiral Lewis acids are applied,[41] and the use of chiral Lewis acids leads to the optically active β-lactones.[42] For example, TADDOL-$TiCl_2$ catalyzed cycloaddition of trimethylsilylketene and aldehydes affords predominantly *cis* α-silylated β-lactones with moderate enantiomeric excesses,[43] and Cu(II)-bis(oxazoline) complexes mediate a highly enantioselective cycloaddition between (silyl)ketenes and chelating carbonyl compounds.[42a] Some other Lewis acids, including $BF_3{\cdot}OEt_2$[44] and a Me_3Al complex of axially chiral 1,1-binaphthalene-2,2-diol,[45] are also used for the cycloaddition of ketenes. In reactions with unactivated alkenes, the cycloaddition is often complicated by the dimerization of ketene itself; however, ketenes react with activated alkenes (e.g., vinyl ethers) more readily.[46] In this reaction, both C=O and C=C bond of ketene could be involved in the cycloaddition, although in preference with alkenes across the C=C bond;[46] therefore, the ketenes are often converted into the corresponding ketene silyl acetal,[47] ketene aminal[48] or ketene dimethyldithioacetal[49] to proceed the [2+2] cycloaddition. For example, the threefold [2+2] cycloaddition of benzyne and ketene silyl acetals gives polyoxygenated tricyclobutabenzenes,[47b] while squaric acid can be simply prepared from the [2+2] cycloaddition between tetraalkoxyethylenes and oxyketenes.[50] One of the most interesting [2+2] cycloadditions related to ketene is probably the recently reported one-pot process in which the nucelophilic catalyst serves up to four discrete roles: catalytic dehydrohalogenation of acid chlorides to form ketenes, catalytic dehydrohalogenation of α-chloroamines to form the corresponding imines, catalyst for the [2+2] cycloaddition to β-lactams, and reagent for the nucleophilic ring opening of β-lactams to afford β-substituted aspartic acids of high enantioselectivity and diastereoselectivity.[51] The cycloaddition of ketenes with alkenes can also be promoted by transition metal complexes, including the chromium[52] and titanium complexes.[51] Certainly, ketenes also react with allenes[53] and carbodiimides.[54] It is interesting that the intramolecular cycloaddition between the ketene and the alkene moiety with an aryl group also follows the rule of five.[55] In addition, such reactions have been measured to have a Hammett constant (F) of -1.39, a quantified indication of a modest charge development at the transition state that would be stabilized by an electron-donating group of styrene, and the cycloaddition is accelerated by the said electron-donating groups.[55]

As an substitute for ketenes, keteniminium cations can also react with imines to afford β-lactams.[56] It has been found that ketoketenes give better yields of cycloadducts than do ketene iminium salts, whereas aldoketene iminium salts prevail in corresponding aldoketenes in respective reactions.[57] In addition, ketenimines bearing an electron-withdrawing group (e.g., tosyl, cyano) on the nitrogen atom can react with imines to furnish azetidin-2-imines.[56]

Furthermore, for cyclic olefins, as the size of carbocyclic ring decreases, double bonds are more bent and twisted, thus the cyclic olefins show increased reactivity and can undergo the [2+2] cycloaddition thermally.[29] In parallel, the highly strained *anti*-Bredt rule olefins also readily undergo [2+2] cycloaddition. For example, 1-tricyclo[3.3.1.$1^{3,7}$]decene (adamantene) dimerizes to give both head-to-head and head-to-tail cycloadducts in a 1:2 ratio.[29] On the other hand, the thermal [2+2] cycloaddition also proceeds readily for the olefins of strong electron-withdrawing substituents, such as multifluorinated alkenes. For example, α,β,β-trifluorostyrenes bearing three fluorine atoms on the vinyl moiety readily dimerizes at temperatures ranging from 80° to 160°C via biradical intermediates.[58] On the basis of this reaction, a set of radical substituent constants has been established.[58b,58c] Likewise, 1,1-dichloro-2,2-difluoroethylene reacts with 1,3-dienes smoothly at 80°C.[59] In contrast, the Lewis acid can also promot the thermal cycloaddition of olefins, as indicated

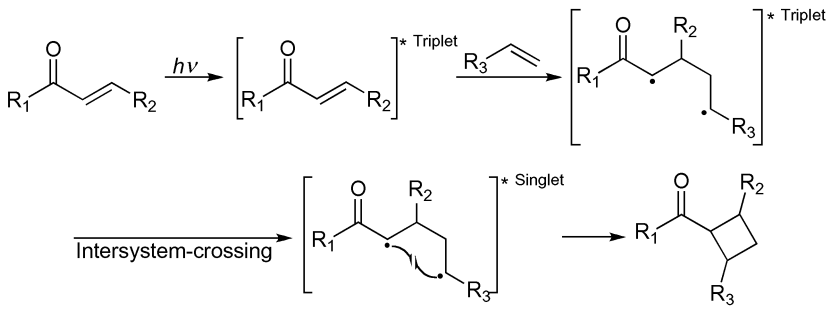
by the cyclodimerization of *trans*-anethole by $Fe(ClO_4)_3$[60] and the cycloaddition between 2-phenylselenyl propene and 3-buten-2-one by $EtAlCl_2$.[61]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The photochemical [2+2] cycloaddition between olefins generally proceeds through the excited state, while the reaction between alkenes and α,β-unsaturated carbonyl compounds involves the attack of an alkene to the triplet (π–π^*)-excited enone, forming an 1,4-biradical intermediate, which, after intersystem crossing to the singlet ground-state potential energy surface, cyclizes to cyclobutane derivatives.[2a] While the photosensitized dimerization of conjugated dienes proceeds via the attack of a triplet diene on an unactivated diene, forming a stable biradical intermediate that then cyclizes to cyclobutane derivatives,[59] the reaction between alkene and ketenes involves sequential nucleophilic additions via a zwitterionic intermediate or an antarafacial concerted process, depending on the nature of alkene.[55] The reaction between alkyl-substituted allenes and 1,1-dichloro-2,2-difluoroethene proceeds via a two-step, diradical intermediate process, as supported by the stereochemical characters and kinetic isotope effects.[55] A general illustration of [2+2] photocycloaddition between alkenes and α,β-unsaturated carbonyl compounds is provided below; the mechanisms for other types of cycloadditions outlined here can be found in corresponding references.



D. MODIFICATION

Because there are so many different types of [2+2] cycloadditions known to date, it is difficult to classify them.

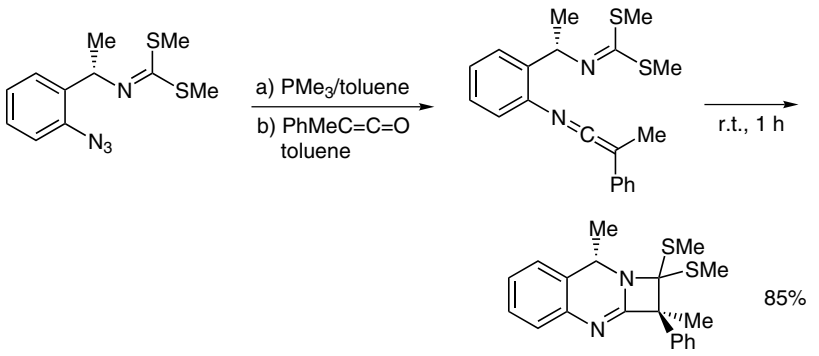
E. APPLICATIONS

This reaction has been extensively used in organic synthesis, as discussed above.

F. RELATED REACTIONS

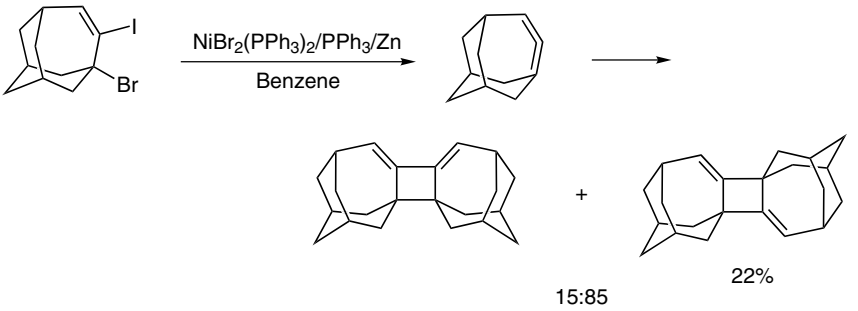
This reaction is related to the *Diels-Alder Reaction, de Mayo Reaction, Paterno-Büchi Reaction*, and *Staudinger [2+2] Cycloaddition*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 63.

To a solution of 0.8 g dimethyl *N*-[1-(2-azidophenyl)ethyl]dithiocarbonimidate (3 mmol) in 15 mL dry toluene, was added 3 mL 1 M trimethylphosphane in toluene (3 mmol), and the mixture was stirred at room temperature until the evolution of nitrogen ceased (15–30 min). Then, 0.40 g methyl phenyl ketene (3 mmol) was added, and the reaction mixture was stirred at room temperature until the ketenimine band $\sim$2000 cm^{-1} was not observed by IR spectroscopy (3–4 h). Upon removal of the solvent under reduced pressure, the residue was purified by silica gel column chromatography using hexanes/EtOAc (4:1 v/v) as the eluent to afford 0.90 g *trans*-2,8-dimethyl-1,1-bis(methylthio)-2-phenyl-1,2-dihydroazeto[2,1-*b*]quinazoline as colorless prisms (Et_2O), in a yield of 85%, m.p. 141–142°C.



Reference 29.

A suspension of 221 mg $NiBr_2(PPh_3)_2$ (0.30 mmol), 155 mg PPh_3 (0.59 mmol), and 155 mg activated zinc (2.4 mmol) in 1.8 mL dry benzene (1.8 mL) was heated to 50°C under argon atmosphere. After 15 min, the mixture became a dark red suspension. To this mixture was added dropwise a solution of 208 mg 3-bromo-4-iodo-4-homoadamantene (0.59 mmol) in 1.5 mL dry benzene at ambient temperature. The mixture was stirred for 1.3 h, and then filtered through neutral Al_2O_3 with benzene. Removal of the solvent afforded a 15:85 mixture of head-to-head and head-to-tail [2+2] cycloadducts as dark black crystals, whose recycling GPC separation and MPLC (SiO_2) and recrystallization from ethanol gave head-to-tail [2+2] cycloadduct as colorless crystals in a 22% yield, m.p. 264.0–264.5°C.

Other references related to [2+2] cycloaddition are cited in the literature.[64–67]

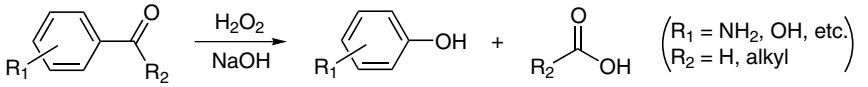
Dakin Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Dakin in 1909.[1] It is the preparation of phenols from aryl aldehydes or aryl ketones involving the oxidation of corresponding aromatic compounds by hydrogen peroxide in the presence of a base and subsequent hydrolysis of the aryl formate or alkylcarboxylate intermediates. Therefore, this reaction is generally known as the Dakin reaction.[2] It has been reported that the *para*- or *ortho*- substituents (such as OH, NH_2) on aryl aldehydes or aryl ketones will facilitate this reaction,[2l] especially for the ortho OH group, which accelerates the reaction via the formation of an intramolecular hydrogen bonding.[3]

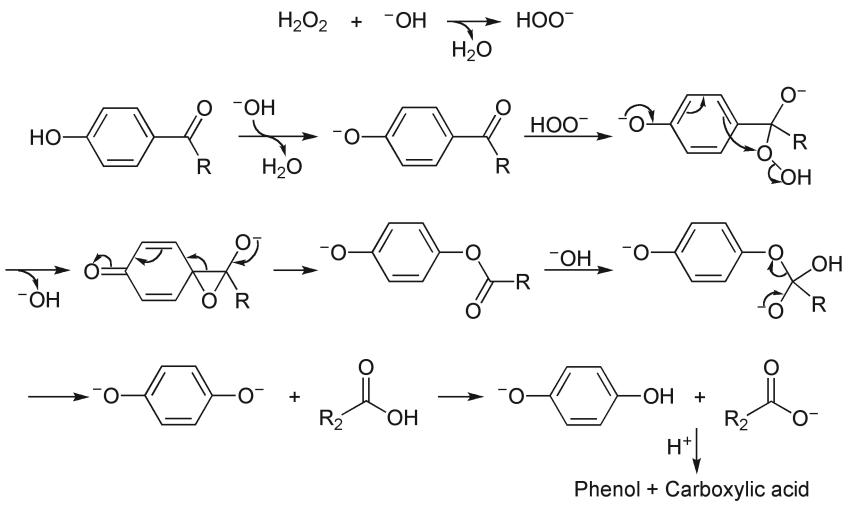
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Provided here is a tentative mechanism that reflects the effect of *para*- or *ortho*-OH to accelerate the reaction rate.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified by using sodium percarbonate[2e] and urea-hydrogen peroxide complex[2b] as the oxidant. In addition, this reaction has been efficiently carried out in liquid ionic solvent.[2a]

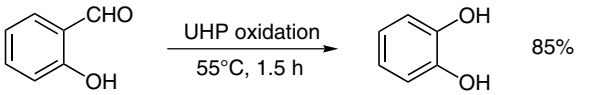
E. APPLICATIONS

This reaction has general applications in the synthesis of phenols from aryl aldehydes or aryl ketones.

F. RELATED REACTIONS

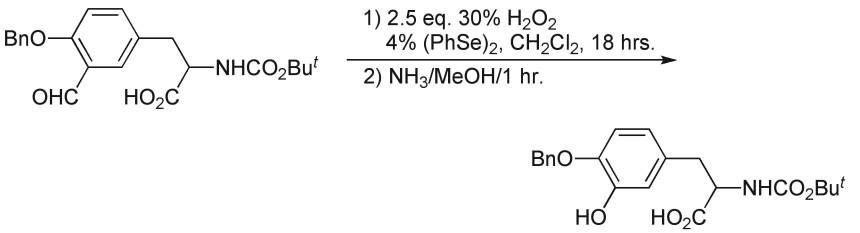
This reaction is related to the *Baeyer-Villiger Oxidation* and *Criegee Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a glass test tube containing 376 mg finely powdered urea-hydrogen peroxide (UHP) adduct (4 mmol) was added 2 mmol *o*-hydroxy-benzaldehyde, and the reaction mixture was placed in an oil bath at 55°C for 1.5 h. After completion of the reaction, as monitored by TLC (8:2 v/v, hexane/EtOAc), the reaction mixture was extracted into EtOAc, and the combined extracts were washed with water and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure to afford the crude product, which was purified by chromatography to give 85% catechol.



Reference 2c.

To a solution of 0.096 g 3-formyl-4-(benzyloxy)-*N*-Boc-L-tyrosine (0.24 mmol) in 3 mL dichloromethane were added 0.003 g diphenyl diselenide (0.01 mmol) and 0.062 mL 30% aqueous hydrogen peroxide (0.614 mmol). The reaction mixture was stirred at ambient temperature for 18 h. The mixture was then diluted with water and EtOAc, washed with brine, dried over $MgSO_4$, and concentrated on a rotary evaporator. The residue was dissolved in 3 mL methanol, and gaseous ammonia was bubbled through the solution for 20 min. The reaction mixture was then stirred at ambient temperature for 1 h. The mixture was then concentrated, and the residue was redissolved in water. The aqueous solution was acidified to pH 1 with 1 N HCl and back extracted with EtOAc. The organic extracts were washed with brine, dried over $MgSO_4$, and concentrated to give 0.073 g *N*-[(1,1-dimethylethoxy)carbonyl]-3-[3-hydroxy-4-(phenylmethoxy)phenyl]-L-alanine as a white foam, in a total yield of 78% for the two steps.

Other references related to the Dakin reaction are cited in the literature.[4]

Dakin-West Reaction

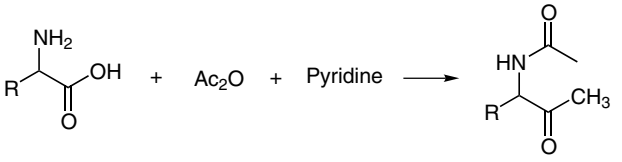
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Dakin and West in 1928.[1] It is the preparation of α-acetamido alkyl methyl ketones via the intermediate of azlactone by the treatment of α-amino acids with acetic anhydride in the presence of a base, such as pyridine. Therefore, this reaction is generally known as the Dakin-West reaction.[2] It was found that high temperature is usually necessary for this reaction when pyridine is used as solvent;[3] however, the addition of small amount of DMAP enables the reaction to occur at ambient temperatures with higher yield.[3,4] Many mechanisms have been proposed for this reaction, and the most probable one involves the acetylation of the amino group, followed by the cyclization to azlactone intermediate, which forms a stable carbanion when treated with a base; the acetylation of such carbanion leads to the formation of an azlactone of an α-acetamido-β-keto acid, which subsequently converts to α-acetamido alkyl methyl ketone upon decarboxylation.[5] It is such decarboxylation evolving 1 eq. CO_2 that makes this reaction difficult to control for scaling up during manufacturing.[6] Therefore, this reaction has been modified to use DMAP and triethylamine with additional acetic acid to provide water to promote the hydrolysis of azlactone; at the same time, alanine is added to control the CO_2 evolution.[6] Other studies of this reaction indicate that this reaction is generally applicable to acyclic alkyl and aryl acid anhydrides, including propionic, butyric, methoxyacetic, and benzoic anhydrides;[5b] however, only those α-amino acids and their derivatives that are able to form azlactones with an active α-hydrogen will undergo the Dakin-West reaction.[5b] Besides the use of anhydride in this reaction, benzoyl fluoride has also been found to react with α-amino acids in the presence of pyridine.[5b] It is interesting that treatment of *N*-acyl-*N*-alkyl α-amino

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

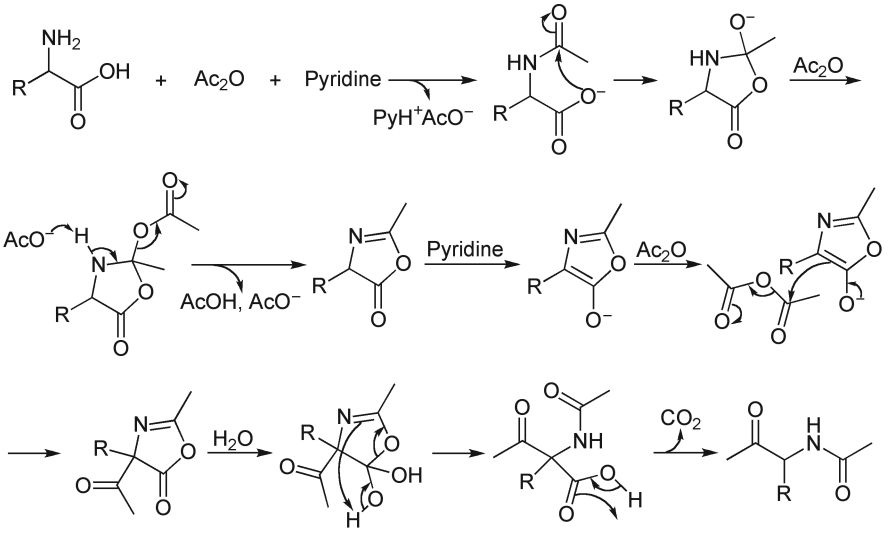
acids with trifluoroacetic anhydride under these reaction conditions leads to the formation of trifluoromethyl-substituted oxazole, acyloins, or morpholines, depending on the nature of substituents on the amino acid and/or the reaction conditions.[7]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves the acetylation of the amino group, formation of azlactone, deprotonation by a base, and additional acetylation and hydrolysis, as displayed here.



D. MODIFICATION

This reaction has been modified to use DMAP and triethylamine with additional acetic acid to control the evolution of carbon dioxide.[6]

E. APPLICATIONS

This reaction is generally used in the synthesis of α-amino ketones.

F. RELATED REACTIONS

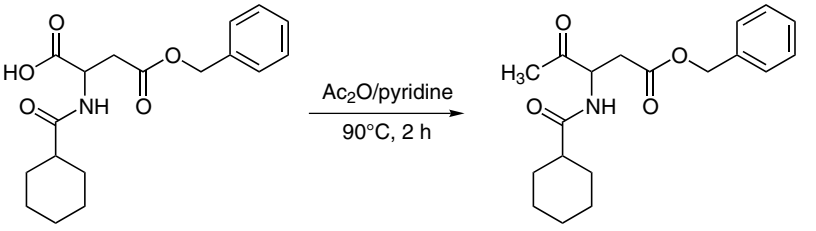
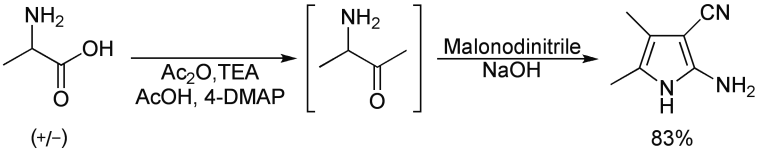
G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A mixture of 1.72 g 2-(cyclohexanecarbonylamino)-succinic acid 4-benzyl ester (5.16 mmol), 5 mL pyridine, and 3 mL acetic anhydride was heated at 90°C for 2 h. Excess acid anhydride and pyridine were removed under reduced pressure, and the residue was then diluted with 150 mL ether. The organic phase was then washed successively with 50 mL 1.0 *N* HCl and 50 mL water, then dried over solid sodium sulfate, decanted, and concentrated under reduced pressure to yield an oil. The residue was purified by column chromatography (EtOAc/hexanes) to provide 1.16 g 3-(cyclohexanecarbonyl-amino)-4-oxo-pentanoic acid benzyl ester as a pale yellow oil, in a yield of 68%.



Reference 6.

A mixture of 338.5 g acetic anhydride (3.3 mol), 45 g acetic acid (0.75 mol), 379.5 g triethylamine (3.75 mol), and 1.83 g 4-(dimethylamino)-pyridine (0.015 mol) in a reaction vessel was heated to 50°C. Then 135 g racemic alanine (1.5 mol) was added as a solid over 6 h thereby maintaining the reaction temperature at 45–55°C. After completion of the alanine addition, the reaction mixture was stirred at 50°C for an additional 8 h. Acetic anhydride, triethylamine, and acetic acid were distilled off by vacuum distillation (10–15 mbar), while gradually raising the jacket temperature to a maximum of 100°C. The residue (GC assay > 95% acylaminoketone intermediate) was cooled to room temperature and diluted with 815 mL water. Malonodinitrile (94.5 g, 1.425 mol) was added, and this mixture was slowly added to 500 g aqueous sodium hydroxide solution (30%). The speed of addition was adjusted so that the reaction temperature did not exceed 60°C. The resulting suspension was cooled to 0°C, filtered, washed with water, and dried in vacuum at 55°C to yield 168 g 2-amino-3-cyano-4,5-dimethylpyrrole, in a yield of 83% for the total of the two steps, m.p. (DSC) 172°C.

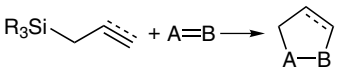
Danheiser Annulation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Danheiser and co-workers in 1981.[1] It is the synthesis of five-membered carbocycles[1,2] and heterocycles (including dihydrofurans,[3] pyrrolines,[3] isoxazoles,[4] azulenes,[5] and furans[6]) from organosilanes and electron-deficient compounds via a [3+2] annulation,[7] by which organosilanes serve as three-carbon components (such as allenylsilanes,[1] propargylsilanes,[7b] and allylsilanes)[7] and electron-deficient compounds (such as α,β-unsaturated compounds[7]). Thus this reaction is referred to as the Danheiser annulation.[8] It should be pointed out that this reaction can be promoted by strong Lewis acids such as $TiCl_4$.[9] In addition, when allylsilane and propargylsilanes are used as a three-carbon component source, a large trialkylsilyl group will facilitate this annulation and suppress the normal desilylation, leading to the formation of allenes.[7b] Moreover, allylstannanes are also found to undergo this reaction.[10]

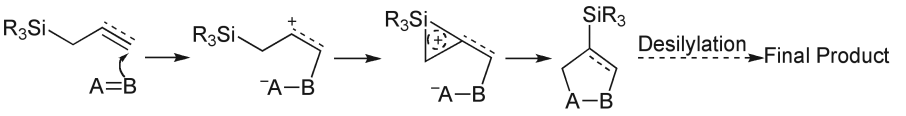
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A tentative mechanism is proposed below.



D. MODIFICATION

N/A

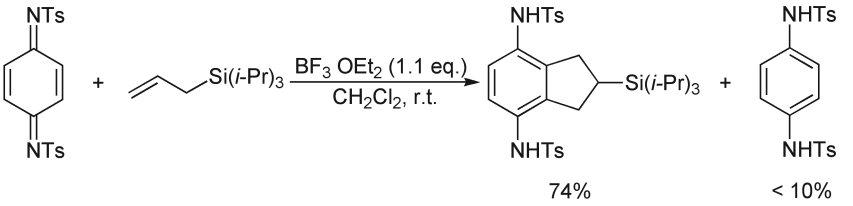
E. APPLICATIONS

This reaction has general application in the synthesis of five-membered carbocycles and heterocycles.

F. RELATED REACTIONS

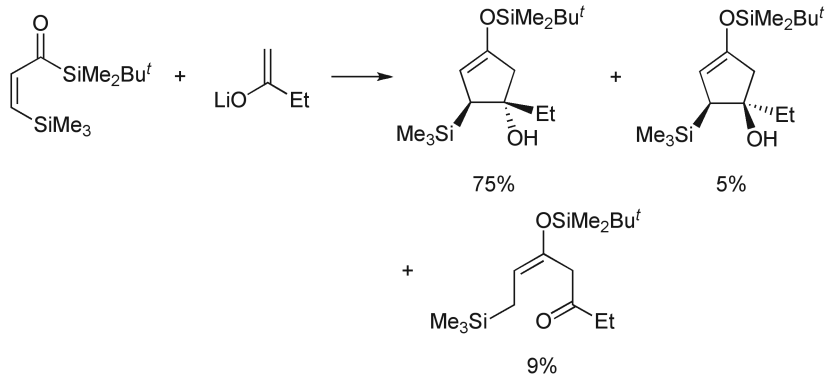
This reaction is related to *1,3-Dipolar Cycloaddition*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7a.

To a cold solution (at 0°C) of 8 mL dichloromethane containing 96 mg allyltriisopropylsilane (0.48 mmol) and 83 mg quinoneimide (0.20 mmol) was added 1.1 eq. $BF_3{\cdot}OEt_2$. The reaction was allowed to attain room temperature gradually and was stirred at that temperature for 72 h and then quenched by ice cold water. The mixture was extracted with CH_2Cl_2 (3×10 mL). The combined organic layer was washed with water, brine, and water (10 mL each) and dried over anhydrous Na_2SO_4. Upon removal of solvent, the residue was purified by column chromatography to give 74% of product, m.p., 238–239°C.



Reference 11.

To a cooled (–80°C) solution of LDA, prepared from 199 μL diisopropylamine (1.42 mmol) and 971 μL 1.44 M *n*-BuLi in hexane (1.40 mmol) in 1.4 mL THF was added dropwise a solution of 125 μL 2-butanone (1.4 mmol) in 1.4 mL THF. After being stirred at –80°C for 15 min, the solution was added dropwise via a cannula to 58 mL cooled (–80°C) THF solution containing 300 mg cis-α,β-unsaturated ketone (1.24 mmol). The reaction mixture was allowed to warm to 0°C over 30 min, and quenched by 81 μL AcOH (1.42 mmol) in 0.5 mL THF. The mixture was diluted with 30 mL saturated aqueous NH_4Cl and extracted with Et_2O (30 mL × 3). The combined organic phases were washed with 50 mL saturated brine, dried, and concentrated. The residual oil was subjected to column chromatography (silica gel, 40 g; elution with 12:1 hexane/Et_2O) to give 294 mg annulation product, in a yield of 75%, plus 109 mg of two other products as mixture that could be separated by MPLC (10 mM silica gel, elution with 40:1 haxane/Et_2O).

Other references related to the Danheiser annulation are cited in the literature.[12]

Darzens Condensation

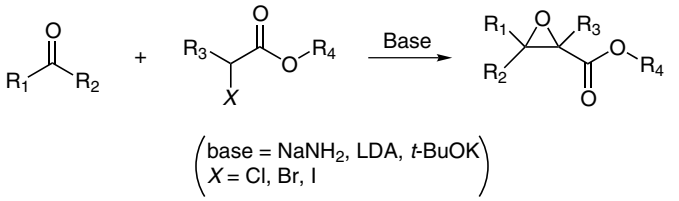
A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction was initially reported by Erlenmeyer in 1892,[1] it is often known as the Darzens condensation,[2] Darzens glycidic ester condensation[2ee,2ww,3] or Darzens reaction,[3c,3d,4] after Darzens's work in the 1900s.[5] Other names used for this condensation include Darzens-type condensation,[4f] Darzens synthesis,[6] and Darzens glycidic ester synthesis.[2yy,7] This reaction is the synthesis of glycidic esters from the condensation between aldehydes or ketones and esters of α-halo-carboxylic acids. Currently, besides the α-halogenated carboxylic esters, this type of condensation has been extended to α-halogenated nitriles,[8] sulfoxides,[9] sulfones,[10] sulfoximines,[11] carboxylic amides,[4f] etc. Therefore, a rather general definition of the Darzens condensation is accepted,[2aaa] including all the base-catalyzed condensations between carbonyl compounds and molecules carrying activated protons at the α-halogenated position, which results in the formation of an oxirane ring and the release of a halide ion. A special case is the reaction between carbonyl compounds and α-halogenated ketimine, which is also referred to as the *aza*-Darzens reaction.[4f] Normally, this reaction would be carried out in an anhydrous aprotic nonpolar solvent (e.g. benzene, ethyl ether) at low temperature,[3c] although ethanol and even aqueous dioxane have also been used as a solvent.[2aaa] Specifically, this reaction has been modified to occur in the solid-liquid two-phase system using a solid base and catalyst at temperatures higher than 100°C.[3c] The catalysts often used are crown ethers and quaternary salt, and their catalytic efficiences are found in the following order: 18-C-6 > DC-18-C-6 > DB-18-C-6 > $Bu_4P^+Br^-$ > $PhCH_2N^+Et_3Br^-$.[3c] This reaction has been proven to undergo a

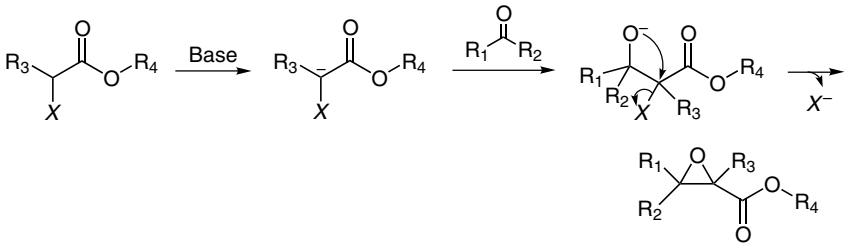
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

carbanion mechanism, instead of a carbenoid[3f] or divalent radical mechanism,[2zz] and normally produces more stable erythro diastereomers.[12]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur in solid-liquid two-phase systems in the presence of crown-ether or quaternary salt as the catalyst.[3c]

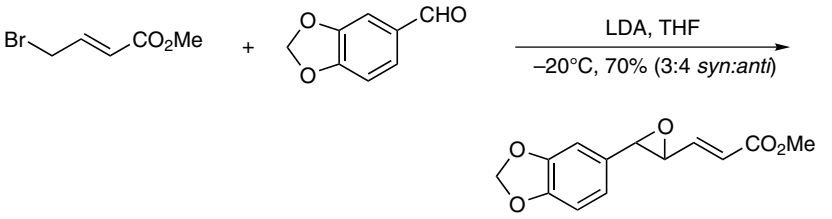
E. APPLICATIONS

This reaction has general applications in the synthesis of epoxide (or oxirane) and glycidic esters.

F. RELATED REACTIONS

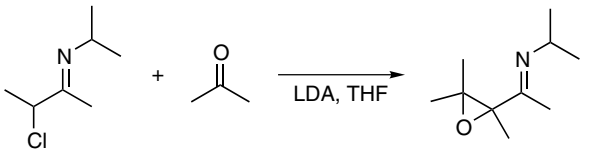
This reaction is related to the *Aldol Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 21.

An LDA (34 mmol) solution [generated by the addition of 23.4 mL of 1.6 M *n*-BuLi (37.4 mmol) to a solution of 4.75 mL diisopropylamine (34 mmol) in 40 mL THF at −20°C under nitrogen] was added dropwise to a stirred solution of 10.2 g piperonal (68 mmol) and 2 mL methyl 4-bromocrotonate (17 mmol) in 60 mL THF under nitrogen at −20°C. Typically, the transfer lasts 1 h for 20 mmol crotonate. The reaction was stirred for 2 h at −20°C and then quenched with 40 mL saturated aqueous NH_4Cl. The layers were separated, and the aqueous layer was extracted with ether (3 × 20 mL). The combined, organic layers were then washed with saturated aqueous $NaHSO_3$ (from 40 g $NaHSO_3$ solid), 20 mL saturated aqueous $NaHCO_3$, and brine (3 × 30 mL). They were then dried over $MgSO_4$ and concentrated. Purification by flash chromatography (ether/petroleum ether, 1 : 3) afforded 2.95 g methyl 4,5-epoxy-5-[3′,4′-methylenedioxypehnyl]pent-2-enoate as 43:57 of *syn* to *anti* mixture, in a yield of 70%.



Reference 4f.

To a solution of lithium diisopropylamide (LDA, 0.105–0.150 mol) at 0°C in 150 mL THF (prepared from 0.105–0.150 mol *n*-BuLi and 0.2 mol diisopropylamine) was added a solution of 0.1 mol α-chloro ketimine in 20 mL THF. The deprotonation was complete after 2 h at 0°C, then 0.1–0.2 mol acetone was added dropwise to the solution of 3-chloro-1-aza-allylic anion. After the addition, the reaction mixture was stirred for 10 h at room temperature. The reaction mixture was then poured into water and extracted with ether (3×100 mL). The combined extracts were dried over $MgSO_4$, and the solvent was removed under reduced pressure. The product was purified via vacuum distillation between 50°C and 60°C at 13 mmHg.
