
D. MODIFICATION

N/A

E. APPLICATIONS

This process was used for the production of butadiene for synthetic rubber by both the former Soviet Union and Germany during World War II.

F. RELATED REACTIONS

This reaction is closely related to the *Ostromislensky Reaction*.

G. CITED EXPERIMENTAL EXAMPLES

Because this is an industrial production process, no preparative experimental procedure is provided here.

Other references related to this reaction are cited in the literature.[9]

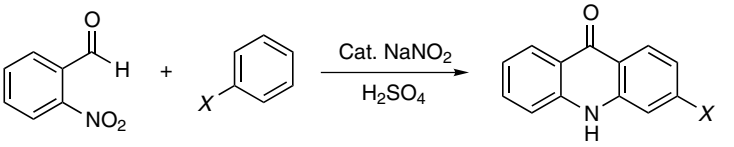
Lehmstedt-Tanasescu Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although acridone was not first synthesized by Lehmstedt,[1] it was Lehmstedt who extensively explored the methods for the preparation of acridones, including the reaction between anthranilic acid and chloro-nitrobenzene,[2] desulfurization of thioacridone by copper,[3] and treatment of *ortho*-nitro benzaldehyde with chloro-nitrobenzene and sulfuric acid.[4] Among these methods, the one between *o*-nitrobenzaldehyde and halobenzene is known as the Lehmstedt-Tanasescu method[5] or Lehmstedt-Tanasescu reaction.[5,6] In addition, this preparation of acridone is also referred to as the Tanasescu synthesis.[7]

B. GENERAL REACTION SCHEME

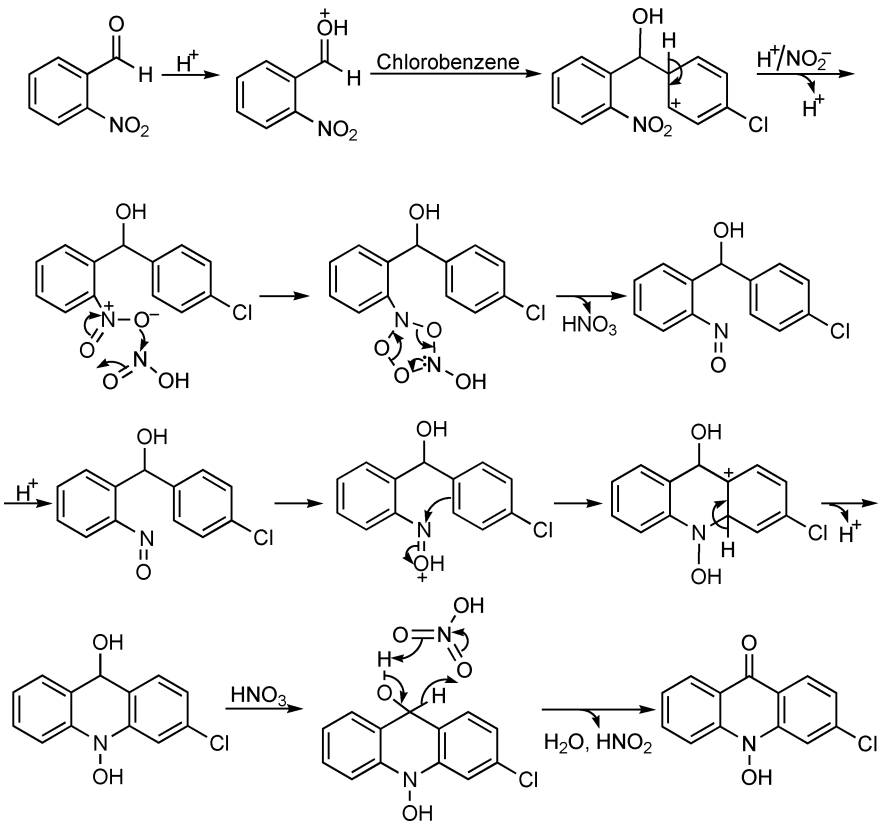


C. PROPOSED MECHANISMS

As limited mechanistic information is available, only a tentative mechanism is proposed here, although it may not correctly explain the experimental results. In this mechanism, sodium nitrite is converted into nitrous acid under acidic conditions, which reduces the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

nitro group to a nitroso group, and the nitrous acid itself is oxidized to nitric acid. The nitric acid then oxidizes the alcohol into a ketone. A part of this mechanism is outlined here.



D. MODIFICATION

This method has been extended to the reaction between anthranilic acid and chlorobenzene.[2]

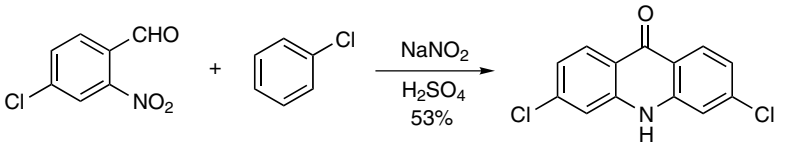
E. APPLICATIONS

This reaction has limited application in the preparation of acridone derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

A mixture of 18.5 g crude 2-nitro-4-chlorobenzaldehyde (0.1 mol) prepared from the oxidation of 2-nitro-4-chloro-toluene by concentrated sulfuric acid in acetic anhydride, 78.8 g chlorobenzene (0.7 mol), 37.5 mL conc. H_2SO_4, and 0.35 g $NaNO_2$ was treated for 6 days by alternating 9 h of shaking and 15 h of standing. At the end of each 2-day period (except the last) 10 mL conc. H_2SO_4 containing 0.1 g $NaNO_2$ was added to the reaction mixture. The mixture was poured into 500 mL water and steam distilled until no further aldehyde solidified in the condenser. The residue from the steam distillation was filtered and digested twice with benzene, leaving 14 g 3,9-dichloroacridone as a dark yellow solid, in a yield of 53%, m.p. $> 315^{\circ}$C.

Other references related to the Lehmstedt-Tanasescu reaction and acridone synthesis are cited in the literature.[8]

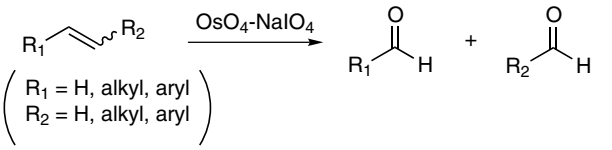
Lemieux-Johnson Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Lemieux and Johnson in 1956.[1] It is a conversion of an olefin into two individual aldehydes by means of an oxidative cleavage of a carbon-carbon double bond with osmium tetraoxide-sodium periodate. Therefore, it is known as the Lemieux-Johnson oxidative cleavage,[2] Lemieux-Johnson reaction,[3] or simply Lemieux-Johnson oxidation.[4] In addition, the combination of osmium tetraoxide and sodium periodate is referred to as Lemieux-Johnson reagent.[5] It should be pointed out that a lactol may be obtained directly from the oxidation of the olefin with a hydroxyl group near the olefinic bond.[4a]

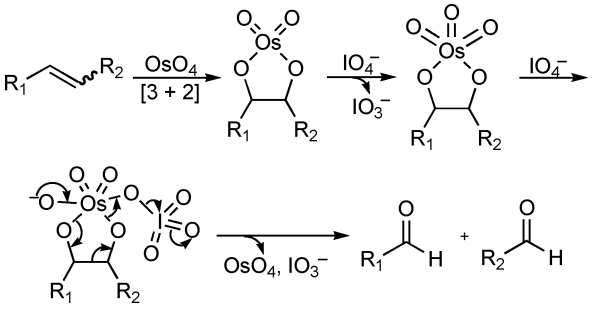
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Without added sodium periodate, olefins are converted only into *cis*-diols by OsO_4 upon workup, therefore, it is plausible that sodium periodate further oxidizes osmium species and triggers the cleavage of carbon-carbon bond, as shown here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been improved by addition of 2,6-lutidine to suppress the side reactions and increase the yields of aldehydes.[6] In addition, this oxidation has been modified by using osmium tetraoxide and oxone as oxidants, which directly convert 1,2-disubstituted olefins into two individual carboxylic acids.[3] On the basis of this modification, osmium tetraoxide has been made to be a three-dimensional networked nanomaterial that, in combination with oxone, forms a superior heterogeneous catalyst, which even oxidizes alkynes into carboxylic acids.[7]

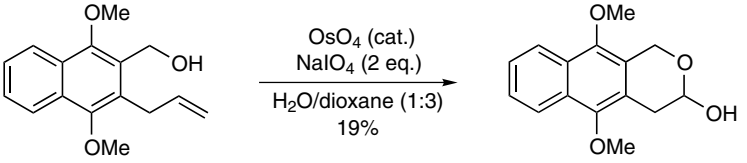
E. APPLICATIONS

This reaction is very useful for the conversion of olefins into aldehydes.

F. RELATED REACTIONS

N/A

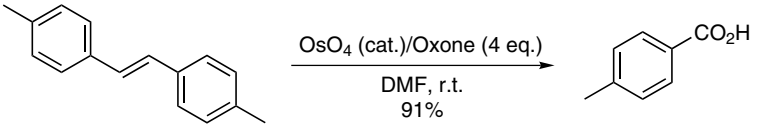
G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To a solution of 100 mg 2-allyl-3-hydroxymethyl-1,4-dimethoxynaphthalene (0.4 mmol) in 5 mL water and 15 mL dioxane was first added a catalytic amount of osmium tetroxide (10 mg), and then 170 mg sodium periodate (0.8 mmol) was added portionwise over a period of 1 h. The suspension formed was stirred for 3 days, poured into water, extracted with ether, washed with brine, dried over $MgSO_4$, and evaporated at reduced pressure. Flash

chromatography on silica gel with 40% EtOAc in hexane gave 20 mg 3,4-dihydro-5,10-dimethoxy-1*H*-naphtho[2,3-*c*]pyran-3-ol, in a yield of 19%.



Reference 3.

To a 0.2 M DMF solution of 4,4′-dimethyl *trans*-stilbene was added 0.01 eq. of OsO_4 (2.5% in *t*-BuOH) under stirring; 5 min later, 4 eq. Oxone was added in one portion, and the solution was stirred at room temperature until the solution became colorless. This usually marked the completion of the reaction which was verified by TLC. Na_2SO_3 (6 eq. w/w) was added to reduce the remaining oxidant, and the solution was stirred for an additional hour. EtOAc was added to extract the products and 1 N HCl was used to dissolve the salts. The organic extract was washed with 1 N HCl (3 ×) and brine and dried over Na_2SO_4; the solvent was removed under reduced pressure to obtain the crude product, which was purified by silica gel column chromatography to give 91% *p*-toluic acid.

Other references related to the Lemieux-Johnson oxidation are cited in the literature.[8]

Leuckart Reaction

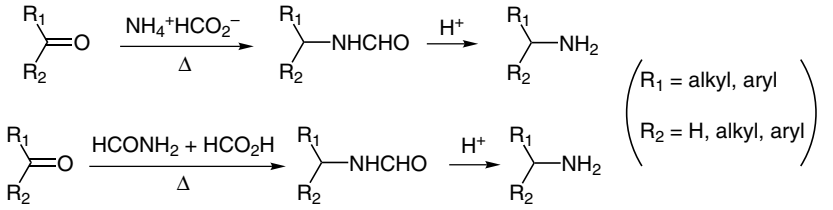
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Leuckart in 1885.[1] It is the reductive amination of carbonyl compounds (i.e., aldehydes and ketones) with ammonium formate or the combination of formic acid and formamides to give primary, secondary, or tertiary amines. Therefore, it is generally known as the Leuckart reaction.[2,3] Occasionally, it is also referred to as the Leuckart reductive amination,[2b] Leuckart alkylation,[4] Leuckart synthesis,[5] or Leuckart reduction.[6] This reaction occurs between a carbonyl compound and formamide, or ammonium formate, or a combination of formic acid and formamide,[3m,3o,3p] from which the primary and secondary amines are obtained as the formyl derivatives; tertiary amines are produced as the formates.[3m] Although it has been reported that higher yields might be obtained if formamide rather than ammonium formate is used in this reaction,[5d] more evidence has indicated that ammonium formate is the actual reactant.[3q] For example, benzophenone condenses with ammonium formate only in diethylene glycol solution at 120–130°C and does not react with formamide.[3q] In this reaction, formic acid and formates function as reducing reagents or hydride donors,[2hh,3c,7] so that tertiary amine can be prepared either from the reaction between aldehyde and a formamide (or a monoalkylformamide) or from the reaction between an aldehyde (or a ketone) and a dialkylformamide.[3o] Interestingly, it has been found that ammonium formate, ammonium sulfate, and magnesium chloride can catalyze the condensation between carbonyl compounds and dialkylformamides to form tertiary amines.[3o,3q] Even though the Leuckart reaction is not a moisture-sensitive reaction,[3b] it has been proved that if water is removed from the reaction, the yields of the corresponding amines will be increased for any reagents other than formamide, in the following order: formamide < ammonium formate ~ combination of formamide and ammonium formate < combination of formamide and formic acid.[3m] However, if water is not removed,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

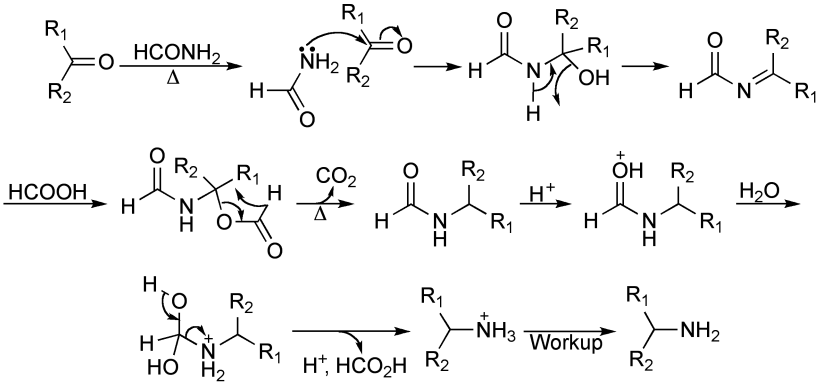
then the combination of formamide and ammonium formate give the best yields at low temperature.[3m] When the reaction is carried out at a temperature $<100^{\circ}C$, it has been found that the higher the reaction temperature, the higher the yield of tertiary amines and the lower the yield of secondary amines. Likewise, at a lower reaction temperature, the reaction with a higher concentration of formic acid gives higher yield of secondary amines. However, the concentration effect of formic acid at a high reaction temperature is not as effective as that at low temperature.[3m]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism of this reaction has already been studied.[2tt,3m] Therefore, the mechanism is illustrated by the formation of a primary amine from a ketone and the combination of formamide and formic acid, as shown below.



D. MODIFICATION

This reaction has been modified to occur in the presence of an excess amount of formic acid by Wallach,[8] thus the reaction under such conditions is known as Leuckart-Wallach alkylation[9] or Leuckart-Wallach reaction.[10] In addition, this reaction has been modified

to produce primary amines in high yield using ammonium formate ($NH_4^+HCO_2^-$) as a reducing agent and Cp*Rh(III) as a catalyst at relative low reaction temperatures.[10a]

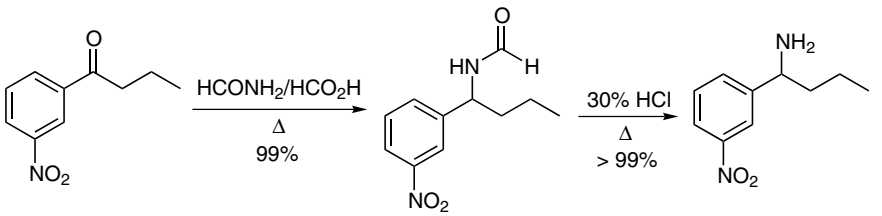
E. APPLICATIONS

This reaction has wide application in the preparation of primary, secondary, and tertiary amines.

F. RELATED REACTIONS

This reaction is related to the *Eschweiler-Clarke Methylation.*

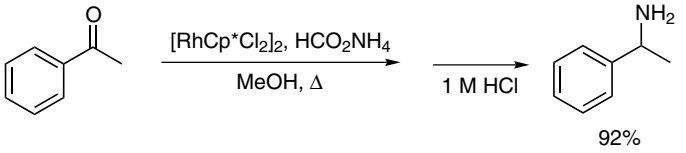
G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

A mixture of 25.0 g 1-(3-nitrophenyl)-1-butanone (129 mmol), 77 mL formamide, and 35 mL formic acid was refluxed until the reaction was complete (followed by ^1H NMR spectroscopy). After cooling to ambient temperature, 200 mL water was added, and the mixture was extracted with Et_2O (3×100 mL). The combined organic layers were washed with brine, dried over Na_2SO_4, and concentrated to furnish 28.7 g (±)-1-butyl-1-(3-nitrophenyl)formamide as a red oil, in a yield of 99%.

A mixture of the formamide and 100 mL 30% HCl was refluxed for overnight. After cooling to ambient temperature, 200 mL water was added. The reaction mixture was carefully adjusted to pH 10 with 33% aqueous NaOH and extracted with Et_2O (3×100 mL). The combined organic layers were washed with brine, dried over Na_2SO_4, and concentrated to furnish >99% (±)-1-butyl-1-(3-nitrophenyl)amine as a red oil.



Reference 9a.

To a 1000-mL Schlenk tube containing 257 mg $[RhCp^*Cl_2]_2$ (0.416 μmol) and 26.2 g $HCOONH_4$ (416 mmol) was added 9.71 mL acetophenone (83.2 mmol) and 83.2 mL MeOH. The reddish brown mixture was frozen, and the whole system was evacuated. The

system was closed and then stirred at 70°C for 7 h. After the resulting dark green solution was cooled to room temperature, 160 mL 1 M HCl was added, and the mixture was washed with CH_2Cl_2 (2×20 mL) to remove the neutral compounds. After the addition of 15 mL cold 12 M NaOH solution to the aqueous layer, the mixture was extracted with CH_2Cl_2 (6×50 mL). The combined organic layers were dried over anhydrous Na_2SO_4. Filtration and evaporation under reduced pressure gave 9.3 g α-amino ethylbenzene, in a yield of 92% with $> 99\%$ purity as determined by ^{1}H NMR and GC analyses. Further distillation at 83°C (44 mmHg) afforded 8.6 g α-amino ethylbenzene, in a yield of 85%.

Leuckart Thiophenol Synthesis

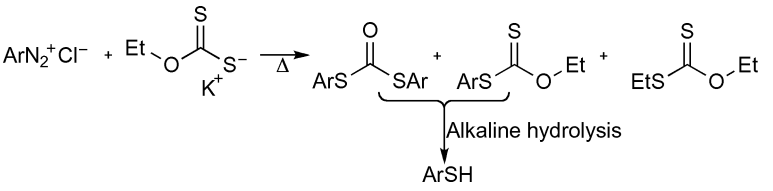
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Leuckart in 1890.[1] It is the synthesis of thiophenol involving the reaction between a diazonium salt and potassium ethylxanthate to form diazonium ethylxanthate, which decomposes upon heating to both diarylthiocarbonate and aryl xanthate that then afford thiophenol upon alkaline hydrolysis. Therefore, this reaction is simply known as the Leuckart thiophenol synthesis[2] or Leuckart synthesis.[2,3] It has been found that aryl xanthate, diarylthiocarbonate, and ethyl ethylxanthate all are produced in this reaction, and the yield of diarylthiocarbonate is slightly higher than that of ethyl ethylxanthate.[2] It is clear that aryl xanthate is not the intermediate in the formation of diarylthiocarbonate. Even though the decomposition of diazonium salt may produce a free radical, the formation of diarylthiocarbonate presumably involves a heterolytic mechanism, since the yield of diarylthiocarbonate is lower in methanol than that in water. Further evidence for the heterolytic mechanism is the detection of phenol arising from aryl carbonium and the absence of biaryl in reaction mixture. Although the presence of a large group at the *ortho*-position of diazonium salt can increase the yield of diarylthiocarbonate and the ratio of diarylthiocarbonate over aryl xanthate, there is no significant electronic effect from the substituent at the *para*-position, because diazonium salt with either a methoxy or a nitro group at the *para*-position gives similar yields of diarylthiocarbonate, and the orientation of substituents in both diarylthiocarbonate and aryl xanthates is the same as those in the initial diazonium salt. In comparison, the replacement of ethyl group by isopropyl or benzyl group in potassium ethylxanthate does not significantly affect the yield of diarylthiocarbonate. It has been found that the best yield of diarylthiocarbonate can be obtained when a 1:1 ratio

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

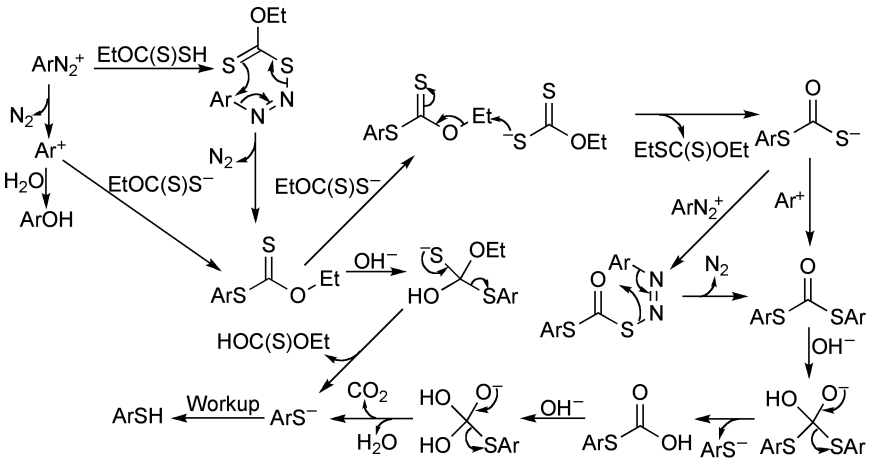
of diazonium salt and potassium ethyl xanthate are used, and the increase of acidity definitely lowers the yield of diarylthiocarbonate.[2] It is believed that the ethyl xanthate anion exists in the mesomeric form, which attacks the diazonium salt followed by loss of ethanol, giving the intermediate of $ArSC(O)S^-$ that then attacks the second diazonium ion to form diarylthiocarbonate.[4]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Even though a fragmental mechanism has been provided in the literature, a new mechanism is proposed here considering all the experimental results, including the rationalization on the 1:1 ratio between diazonium salt and potassium ethyl xanthate, and the pathway to form diarylthiocarbonate.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction provides a general method to prepare thiophenols.

F. RELATED REACTIONS

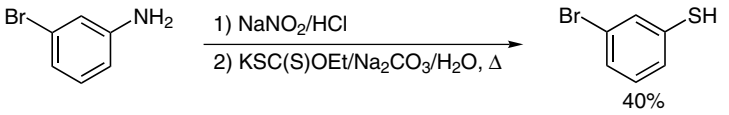
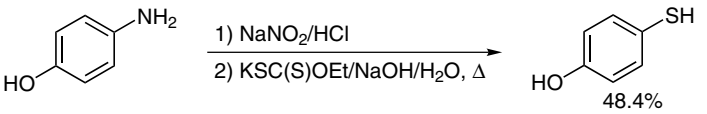
G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

m-Bromoaniline (43 g, 0.25 mol) was diazotized at 5°C with 49 mL conc. HCl and 17.2 g $NaNO_2$ (0.25 mol) in 110 mL water. The solution of the diazonium salt was added over a 1.5-h period to a solution of 40 g potassium ethyl xanthate (0.25 mol) and 33.0 g Na_2CO_3 (0.3 mol) in 250 mL water at 70°C. The mixture was maintained at this temperature for an additional hour, the resulting oil was separated, the aqueous phase was extracted twice with ether, and the ether layers were combined with the oil. The ether was removed on a steam bath in a stream of nitrogen, and the residual oil was added to a solution of 40 g NaOH in 250 mL MeOH and 40 mL water. The mixture was refluxed for 2 h under nitrogen, diluted with 4 L water, and acidified with hydrochloric acid. The resulting oil was separated, the aqueous phase was washed with methylene chloride, and the latter was combined with the oil and dried over anhydrous Na_2SO_4. Distillation at 100–104°C (10 mmHg) yielded 19.1 g *m*-bromothiopheno1, in a yield of 40%. The *m*-bromothiophenol was redistilled at 123–124°C (40 mmHg) for further purification.



Reference 6.

p-Aminophenol (110 g, 1.0 mol) was mixed with excess of 10% HCl (2.25 mol). The solution was cooled <15°C and diazotized by the gradual addition of 70 g $NaNO_2$ (1.0 mol) while the temperature was maintained between 1.5° and 20°C by means of ice. The diazo solution was then run slowly beneath the surface of a hot solution of 224 g potassium ethyl xanthate (1.4 mol) in 650 g water, and the reaction mixture was stirred vigorously and kept at 70 –75°C to ensure complete decomposition of the intermediate diazo combination. When all the diazo solution was in, the temperature was raised to 90°C and maintained for 30 min. The xanthate ester was then decomposed by adding 160 g solid NaOH (4 mol) and refluxing for several hours, the mixture was then strongly acidified with an excess of 50% H_2SO_4 and further refluxed in the presence of zinc and benzene to reduce any disulfide that may have been formed. The crude thiohydroquinone was separated as an oil, washed with dilute hydrochloric acid and water, and distilled in vacuo to afford 61.0 g thiohydroquinone as a clear colorless liquid, in a yield of 48.4%, b.p. 133–137°C at 11.0 mmHg.

Levinstein Process

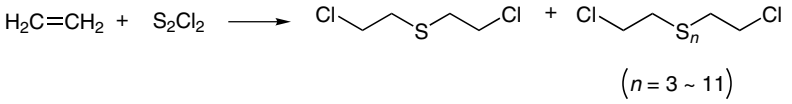
A. GENERAL DESCRIPTION OF THE REACTION

This reaction presumably was first reported by Levinstein. It is the preparation of bis(2-chloroethyl)sulfide by bubbling dry ethylene gas through sulfur monochloride at 35°C and distilling the remaining material.[1] This reaction is generally known as the Levinstein process[2] and is occasionally referred to as the Levinstein reaction.[3] The product produced from this process normally contains up to 70% of bis(2-chloroethyl)sulfide, and another 30% of bis(2-chloroethyl)polysulfides,[2h,2i] ranging from trisulfide to nonasulfide,[2h] depending on the conditions under which the reaction was carried out, including the temperature, degree of agitation, the rate of addition of ethylene, and the nature of sulfur monochloride used.[2i] The product of bis(2-chloroethyl)sulfide is often known as mustard gas.[1,2e,2g,2h,3,4] In addition, it is also called Levinstein mustard gas,[5] which has been applied as vesicant agent on the battlefield.[2a] As a result, this compound also gained other names, such as "H," the compound made from the Levinstein process;[2c,6] "HD," the distilled or nearly pure mustard,[2b,6] containing about 5% of impurity[2b] (e.g., 2-chloroethyl 2-chlorovinyl sulfide[2g]); "sulfur mustard," also called "LOST" or "S-LOST" after the two German chemists (Lommell and Steinkopf) who suggested its use as a chemical weapon;[7] "yellow cross" for its identifying mark during World War I;[6,7] "yperite," for the site of its first use;[6,7] and "HT," for the 60:40 mixture of HD and bis(2-chloroethylthio)ethyl ether.[2b] Interestingly, it has been found that ethylene does not react with pure sulfenyl chloride, but this reaction proceeds extremely fast in carbon tetrachloride, probably due to the low solubility of ethylene in sulfenyl chloride.[1] The formation of polysulfide is due to the disproportionation of sulfur monochloride to sulfur dichloride and trisulfurdichloride; the latter then reacts with ethylene

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

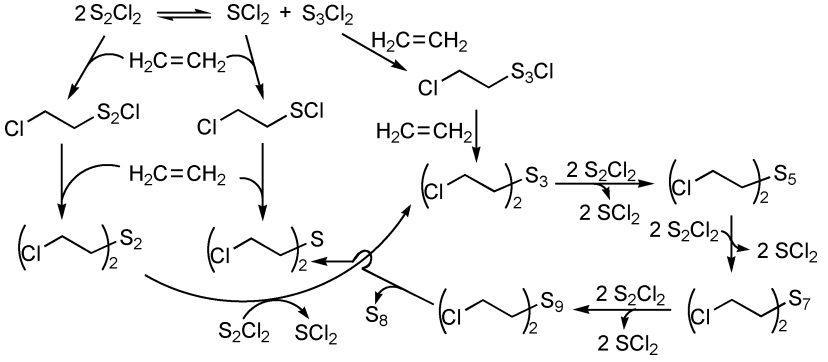
to form bis(2-chloroethyl)trisulfide and higher-order sulfides.[1] At higher reaction temperatures (e.g., 60°C), the yield of mustard gas is increased up to 80%, and sulfur deposits immediately; at lower temperatures (e.g., 20°C), the yield of mustard gas is lowered to 61%, and sulfur appears in the mustard gas in a few weeks.[2i]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown below is the mechanism for the interchanges between sulfides.



D. MODIFICATION

The production of mustard gas has been improved by the chlorination of thiodiglycol, which does not precipitate solid after distillation.[8]

E. APPLICATIONS

The reaction has been used for the production of the mustard gas for military usage.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES

Because this reaction is primarily for the industrial production of mustard gas, no laboratory preparation is provided here.

Other references related to the Levinstein process are cited in the literature.[9]

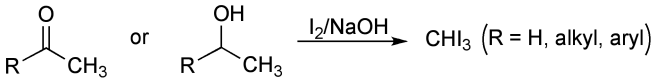
Lieben Iodoform Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Lieben in 1870.[1] It is an alkaline degradation of compounds with acetyl or methylcarbinol groups by means of iodine treatment to form volatile iodoform. This reaction has been widely used to test the presence of acetyl or methylcarbinol groups and is known as the Lieben reaction,[2] Lieben iodoform reaction,[2d,3] iodoform test of Lieben,[4] or Lieben test.[5] It is believed that the positive test of methylcarbinol group is because of the oxidation of such groups by hypoiodite generated *in situ* from the alkaline disproportionation of iodine.[2d] Similarly, other compounds that can generate the acetyl group under the test conditions also give a positive result,[2a] such as the retro *Aldol Reaction* of α,β-unsaturated compounds.[6] In addition, compounds with groups capable of exerting excessively high steric hindrance have also been reported to be positive toward the Lieben test.[2d] Unfortunately, some ketones, such as α-chloroacetophenone, acetomesitylene, propiophenone,[5b] pinacolone, and similar compounds involving steric hindrance[7] result in a negative test. While the original procedure involves the treatment of compounds with iodine and excess of base[5b] and can detect compounds at concentrations as low as 1 part in 2000,[1] it often gives ambiguous results because of the anesthetic action of the iodoform on the olfactory nerve.[8]

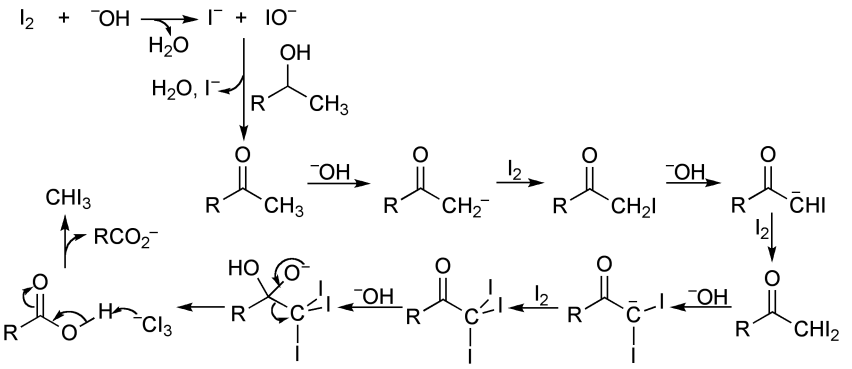
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A mechanism including the disproportionation of iodine, oxidation of methylcarbinol into acetyl group, and the final formation of iodoform is illustrated below.



D. MODIFICATION

Because of the importance of this reaction for structural identification in the early days, it has been modified to occur in dioxane with a slight excess of iodine-potassium iodide solution at 60°C to test water-insoluble compounds.[4a] In addition, this test has been improved from being an older test to a color test by the addition of pyridine, quinoline, or their homologs to the alkali hypochlorite or hypobromite solution, by which a carmine red or pink color develops immediately if an acetyl or methylcarbinol group exists.[8] Further improvement has been done to differentiate between the acetyl and the methylcarbinol groups by the addition of *ortho*-nitrobenzaldehyde in the alkaline solution, by which methyl ketone can undergo the *Baeyer-Drewson Indigo Synthesis*, whereas compounds with methylcarbinol groups won't. Under these conditions, the negative Lieben test indicates the absence of acetyl and methylcarbinol groups, whereas a positive Lieben test but negative indigo reaction shows the presence of methylcarbinol group, and both positive tests from Lieben iodoform reaction and the indigo reaction implies the presence of methyl ketones.[2d]

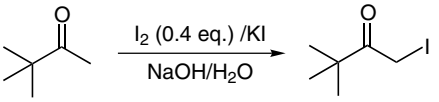
E. APPLICATIONS

This reaction had wide application in the structural elucidation of organic compounds before the modern spectroscopy. In addition, this reaction has been used to prepare α-monoiodo and α-diiodoketones by using a less than theoretical amount of iodine.[9]

F. RELATED REACTIONS

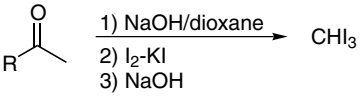
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A mixture of 80 g pinacolone and 800 mL 5% NaOH solution was cooled in an ice and salt mixture, and 80 g iodine, dissolved in aqueous potassium iodide, was added through a rapidly revolving hollow stirrer. The addition was complete in 2 h. The solution was immediately shaken with ether, and the resulting ether solution was washed with water. The solution was dried over Na_2SO_4, and the ether was removed. The strongly lachrymatory liquid thus obtained was distilled at 92–98°C (20 mmHg) to afforded 6 mL α-iodopinacolone as a liquid, which was shaken with mercury to remove the iodine color and redistilled twice at 48–49°C (2 mmHg). (No yield was given for the original experiment.)



Reference 2d.

About 100 mg of the compound being tested was dissolved in 5 mL dioxane in a 150 × 16 mm test tube, followed by the addition of 1 mL 10% NaOH. The iodine reagent was added dropwise with shaking until a slight excess of iodine caused a definite dark color that did not disappear on standing. The test tube was then placed in a water bath maintained at 60°C, and the dropwise addition of the iodine reagent was continued until the definite dark color persisted as before; but the warming at 60°C should not last $>$ 2 min. The excess of iodine was removed with a few drops of 10% NaOH solution, and the test tube was filled with cold water, allowed to stand for 15 min, and filtered. The characteristic odor of iodoform was readily distinguishable. As a confirmation, the crystals collected on the filter paper were dried at 100°C for 1 h and identified by their melting point. (Iodoform melts at 114–121°C).

Liebeskind-Srögl Cross-Coupling

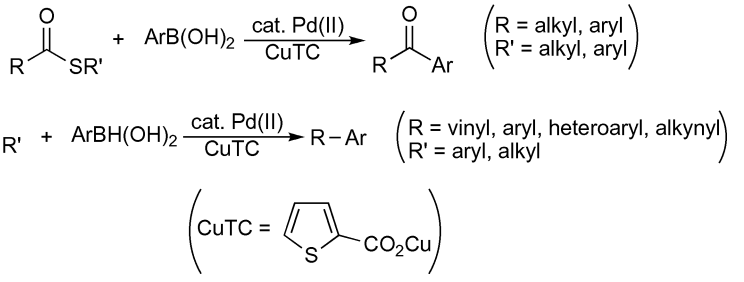
A. GENERAL DESCRIPTION OF THE REACTION

This reaction can be traced back to 1996 when Liebeskind used copper (I) 2-thiophenecarboxylate as a mediator for the coupling between alkyl tributyltin and alkyl halides.[1] This reaction had been extensively investigated by Liebeskind, in collaboration with Srögl,[2] and became a very useful palladium-catalyzed coupling reaction between an aryl boronic acid and a general sulfur containing molecules to form a variety of compounds, including ketones, thioethers, alkynes, and biaryls. Therefore, it is known as the Liebeskind-Srögl coupling,[3] Liebeskind-Srögl cross coupling,[2f,2g,4] or Liebeskind-Srögl thiol ester-boronic acid cross-coupling.[5] It should be pointed out that this reaction occurs under very mild, nonbasic conditions. For the coupling between aryl boronic acid and 4-halo-*n*-butylthiol esters, the presence of a catalytic amount of sodium iodide is crucial to facilitate the alkylation-activated coupling to form phenyl ketones. Among the tested palladium catalysts, *trans*-di(μ-acetato)-bis[*o*-(di-*o*-tolylphosphino)-benzyl]dipalladium(II) is the most efficient catalyst for this coupling.[2d] Other types of thioesters can also couple with aryl boronic acid to form ketones in the presence of a stoichiometric amount of copper(I) thiophene-2-carboxylate (CuTC) and a catalytic amount of palladium catalyst,[4b] where Cu(I) carboxylate activates both the carbon-sulfur bond for oxidative addition of palladium and the transmetalation by coordinative delivery of the carboxylate to the boron atom.[2e,2h] Under these conditions, sodium iodide is not necessary. In contrast to the *Suzuki Coupling*, aryl boronic acid can also couple with aryl or alkenyl iodide under nonbasic conditions in the presence of a palladium catalyst and Cu(I) carboxylate, so that the base-labile groups can tolerate this coupling condition.[2d] In addition, the coupling between the protected methyl thiopseudourea and phenyl boronic acid catalyzed by palladium in the presence of copper (I) thiophenecarboxylate provides a method for benzamidine derivatives.[2g] However, it has

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

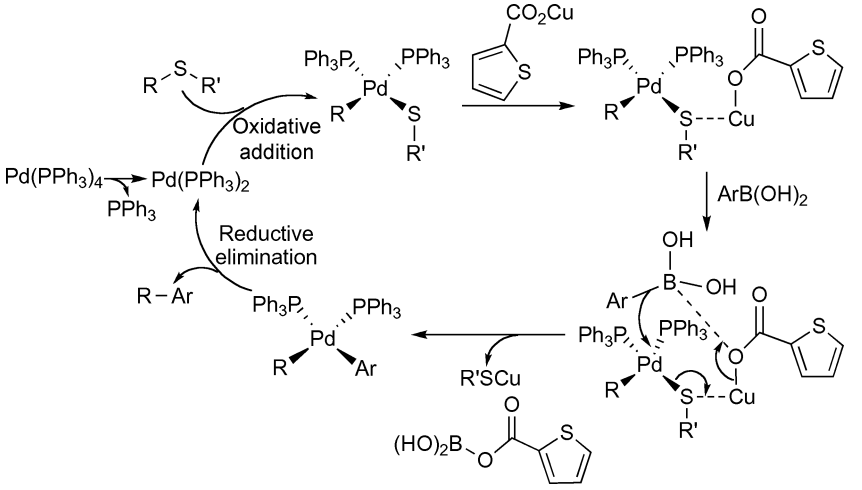
been found that the solvent is very crucial for the coupling between heteroaryl vinyl ether and aryl boronic acid, by which amide-based solvents, including DMF, DMA, and DMI (1,3-dimethyl-2-imidazolidinone), are the best solvents, and $Pd(PPh_3)_4$ is the best palladium catalyst.[4a] In addition, the π-electron-deficient heteroaryl thioether can also couple either with aryl boronic acid under similar conditions (palladium catalyst and Cu(I) carboxylate)[2f] or with aryl, alkenylstannanes in the presence of a catalytic amount of palladium catalyst and more than a stoichiometric amount of Cu(I) carboxylate—For example, CuTc or copper(I) 3-methylsalicylate (CuMeSal)[6] or copper(I) bromide dimethylsulfide complex.[7] Even thiourea can similarly couple with aryl boronic acid with the help of microwave irradiation.[3] For the preparation of alkynes from the coupling between alkynyl thioether and aryl boronic acid, it has been found that the reagent (e.g., CuCl, CuBr, CuI) and base (K_2CO_3, NaOAc) in the *Sonogashira Coupling* are not very effective. For this special case, dioxane and THF are found to be the best solvents, and any palladium catalyst and readily available copper (I) carboxylate are good for this coupling.[2e] The thioethers used for this coupling can easily be prepared from the coupling between aryl boronic acid and alkyl, heteroaryl, and alkyl *N*-thioimide in the presence of catalytic copper (I) carboxylate.[8]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism for the coupling between thioether and aryl boronic acid is illustrated below, using $Pd(PPh_3)_4$ as the catalyst, in the presence of a stoichiometric amount of copper (I) 2-thiophenecarboxylate as the transmetalation agent.



D. MODIFICATION

This reaction has been modified to occur efficiently under microwave irradiation.[3] Besides copper (I) 2-thiophenecarboxylate, Cu(I)-3-methylsalicylate (CuMeSal)[6,8,9] and copper diphenylphosphinate[10] have also been developed as mediators.

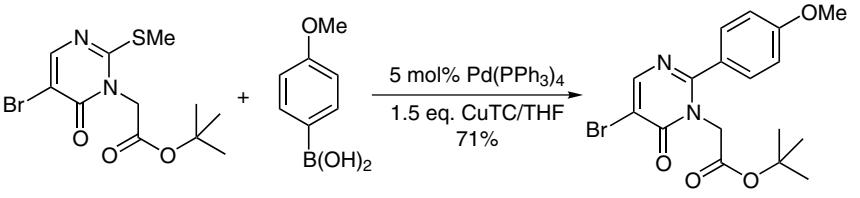
E. APPLICATIONS

This reaction, like other coupling methods has wide application in organic synthesis.

F. RELATED REACTIONS

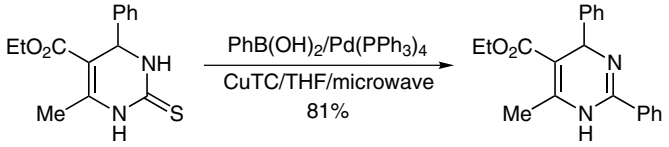
This reaction is related to the *Suzuki Coupling* and *Sonogashira Coupling*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2h.

A mixture of 415 mg 4-methoxyphenylboronic acid (2.73 mmol), 446 mg CuTC (2.34 mmol), 523 mg *tert*-butyl [5-bromo-2-(methylthio)-6-oxopyrimidin-1(6H)-yl]acetate (1.56 mmol), and 5 mol % $Pd(PPh_3)_4$ was placed in a flask. After three vacuum/argon cycles, 15 mL dry and degassed THF was added. The reaction was stirred for 12–18 h at 50–60°C and monitored by LC/MS. When the reaction was complete, the mixture was cooled to ambient temperature, EtOAc was added, and the mixture was filtered through a medium frit sintered glass funnel. The filtrate was washed with 1 N $NaHSO_4$, saturated $NaHCO_3$, and brine. The organic layer was dried over $MgSO_4$, filtered, and concentrated to a viscous solid. The residue was purified by flash chromatography (CH_2Cl_2/MeOH, 200:1) to afford 439 mg *tert*-butyl [5-bromo-2-(4-methoxyphenyl)-6-oxopyrimidin-1(6H)-yl]acetate as a pale yellow solid, in a yield of 71%.



Reference 3.

A microwave process vial was charged with a stir bar. To this vessel were added DHPM (69.1 mg, 0.25 mmol), 45.7 mg $PhB(OH)_2$ (0.375 mmol), 142.9 mg Cu(I) thiophene-2-carboxylate (CuTC) (0.75 mmol), and 8.7 mg $Pd(PPh_3)_4$ (3.0 mol %). The reaction vessel was flushed with argon and sealed. Through the septum was added 5 mL anhydrous THF, and the reaction vessel was irradiated at 100°C for 25 min. After cooling, the mixture was transferred to a round-bottomed flask and was adsorbed on silica gel. The residue was purified by flash chromatography on silica gel (hexanes/EtOAc, 3:1) to yield 81% dihydropyrimidine as a semisolid.

Lindlar Hydrogenation
(Lindlar Reduction)

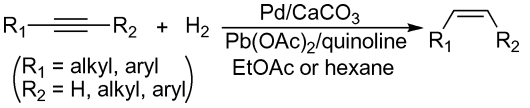
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported in 1947[1] and optimized by Lindlar in 1952.[2] It is a stereoselective reduction of alkynes to *cis*-alkenes by hydrogen in the presence of palladium that is impregnated onto calcium carbonate and then deactivated by lead acetate and quinoline. Therefore, this reaction is often known as the Lindlar reduction[3] or Lindlar hydrogenation,[3a–3c,3e] and the palladium on calcium carbonate poisoned with lead acetate and quinoline is referred to as the Lindlar catalyst.[1,3d,4] The Lindlar catalyst exists as a slurry mixture resulting in a heterogeneous hydrogenation.[1,4a] It has been found that palladium coated on $BaSO_4$ is superior to $CaCO_3$, presumably because of the stability of the solid support toward acid.[5] This catalyst is prepared by reduction of $PdCl_2$ with $CaCO_3$ slurry followed by the addition of lead acetate and 0.05–1 eq. quinoline.[4d] It has been found that the addition of quinoline lowers the reduction rate[6] but efficiently enhances the selectivity by inhibiting alkene surface interaction.[7] Although the addition of lead acetate has been suggested to block the most active catalyst sites and prevent overreduction of alkenes to alkanes,[1] it has been found that lead acetate does not block certain active sites but rather acts to modify the surface structure of the catalyst, such as the formation of the Pd_3Pb alloy particle.[1,4d] Such modifications on the catalyst surface also increase the selectivity.[4d] It is believed that the stereoselective reduction of alkynes to only *cis*-alkenes is because one face of the triple bond is shielded by the Lindlar catalyst so that hydrogen is restricted to approach the triple bond from the other side. In this reduction, the solvent also plays an important role. It has been reported that the *cis*/*trans* ratio was dramatically enhanced from 10:1 to 25:1 by changing the solvent from MeOH to hexane/EtOAc (1:1), and the *cis*/*trans* ratio was further increased to 86:1 by the addition of quinoline in hexane/EtOAc (1:1).[3d]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

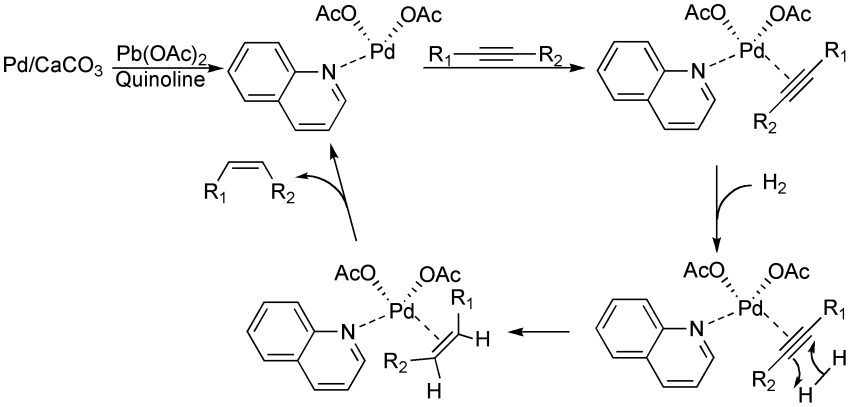
Even though the palladium in the Lindlar catalyst is known to be reduced to zero valence, it has been found that the palladium in Lindlar catalyst is still electron-deficient with a bond energy ~2.1 eV higher than that of Pd(0).[4a] Because of such an electron deficiency, alkynes are more strongly absorbed onto the catalyst, and once they are reduced to alkenes, the alkenes are released from the catalyst without overreduction to alkanes because of the relatively weaker interaction between catalyst and alkenes. However, an unprotected amino group sitting near the alkyne group will accelerate the overreduction of alkenes and reduce the selectivity,[4b] simply because of the strong electron-donating ability. In this case, the addition of 1 eq. of ethylenediamine in the reaction mixture will reduce the overreduction to a minimal level.[4b]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A possible mechanism for the hydrogenation is illustrated here, where acetate and quinoline all coordinate with palladium.



D. MODIFICATION

This reaction has been modified by the addition of $MnCl_2$ to enhance the selectivity during hydrogenation.[8] In addition, it has been found that palladium on Al_2O_3 is superior to the Lindlar catalyst operating under same conditions (e.g., temperature, hydrogen pressure, and Pd/substrate ratio).[4a]

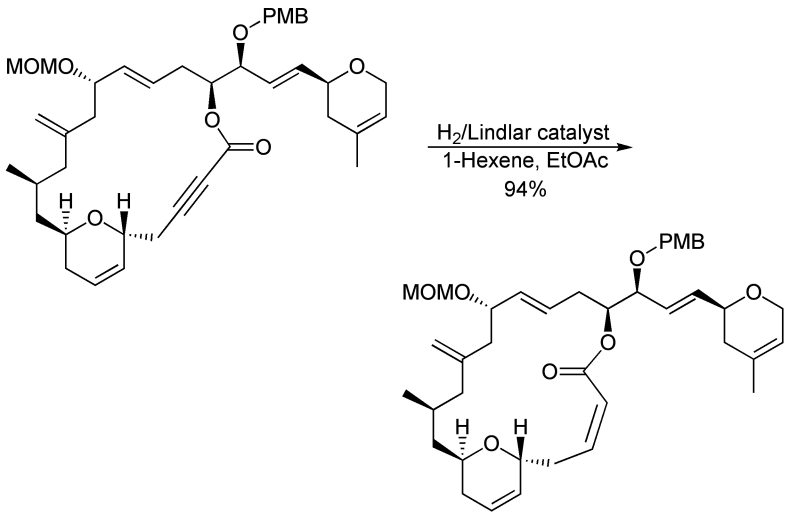
E. APPLICATIONS

This reaction has broad application in natural product synthesis.

F. RELATED REACTIONS

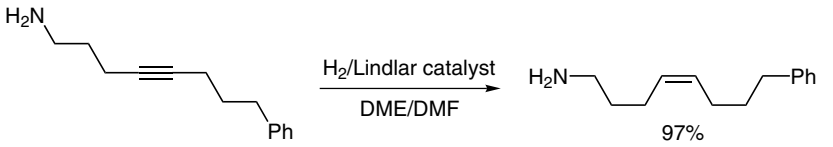
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a solution of 8.5 mg lactone (0.013 mmol) in 1 mL 1-hexene and 1 mL EtOAc was added 2 mg Lindlar catalyst. The resulting suspension was vigorously stirred under a hydrogen balloon for 1.5 h. The mixture was filtered through a pad of Celite and washed with EtOAc. Concentration of the filtrate gave a residue, that was purified by silica gel chromatography (20% EtOAc/hexane) to afford 8.0 mg *cis*-macrolactone, in a yield of 94%.



Reference 4b.

To a solution of 2.5 g alkyne (12.4 mmol) in 25 mL DMF was added 1.0 mL ethylenediamine (15 mmol) followed by 100 mg Lindlar catalyst. The reaction flask was evacuated, purged with hydrogen five times, and then stirred under a hydrogen atmosphere for 4 h. The reaction mixture was filtered over Celite and washed with 25 mL isopropyl acetate. The resulting solution was washed with 37 mL 2 wt % NH_4Cl and water (2×25 mL). The organic solution was concentrated to yield 2.45 g *cis*-aminoalkene as an oil, contaminated with 2.5% *trans*-aminoalkene and 0.5% aminoalkane in a yield of 97%.

Other references related to the Lindlar hydrogenation are cited in the literature.[10]

Lobry de Bruyn-Alberda van Ekenstein Transformation

(Lobry de Bruyn-van Ekenstein Transformation)

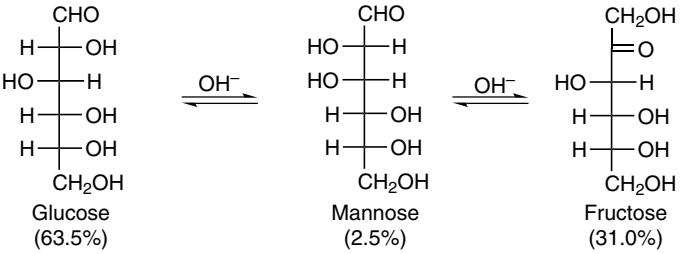
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Lobry de Bruyn in 1895,[1] and explored extensively by Lobry de Bruyn and Alberda van Ekenstein.[2] It is the reciprocal interconversion of carbohydrates into their isomers in an alkaline solution through the enediolic intermediate. The name of reaction given here is probably the only one time the full name of the people who discovered such reaction. It is known as the Lobry de Bruyn-Alberda van Ekenstein rearrangement,[3] Lobry de Bruyn-Alberda van Ekenstein transformation,[3f,4] Lobry de Bruyn-Albreda van Ekenstein C-2 epimerization,[5] or Lobry de Bruyn-van Ekenstein transformation.[6]

It is a very general glycochemical reaction[3b] catalyzed by hydroxide, regardless of the counterions, and depends only on the base concentration and temperature.[7] For example, the treatment of glucose by either KOH, NaOH, NH_4OH, $Mg(OH)_2$, Na_2CO_3, or K_2CO_3 will end up with the same equilibrium between glucose, mannose, and fructose.[7] Likewise, galactose can form an equilibrium with tagatose and talose.[8] It is found that such interconversion catalyzed by a base is essentially similar to the group transfer reaction of glucose-6-phosphate catalyzed by isomerase.[3b,9] It is interesting that sorbose does not occur in such a transformation;[10] and under treatment of lead hydroxide, glucose yields only mannose, and fructose gives neither of its corresponding aldose isomers (i.e., glucose and mannose).[7] In addition, it has been found that carbohydrates may degrade under basic conditions to lower analogs via retro-aldol condensation.[4c,8]

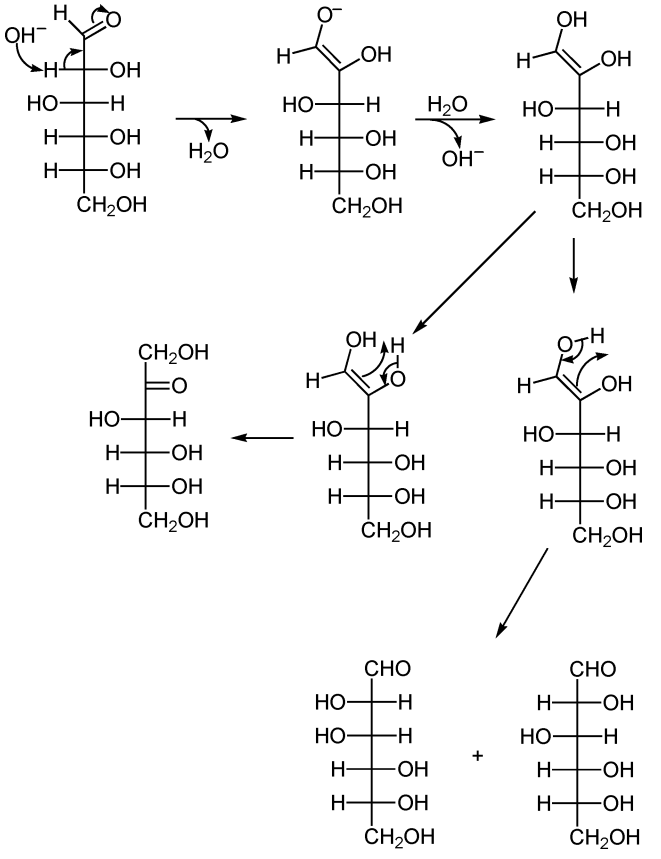
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

An interchange from glucose to mannose and fructose is illustrated here; a similar conversion from fructose or mannose to glucose can be depicted likewise.



D. MODIFICATION

N/A

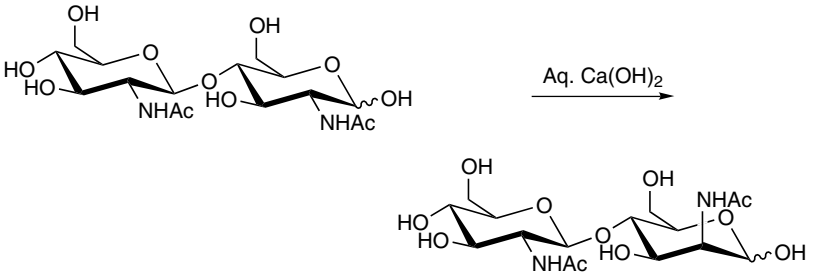
E. APPLICATIONS

This reaction can be used to prepare carbohydrate isomers on the basis of available carbohydrate molecules.

F. RELATED REACTIONS

This reaction is related to the *Aldol Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



23% conversion; starting material was then degraded by β-*N*-acetylhexosaminidase, and the mixture was separated by gel filtration column with 18% yield

Reference 5.

N,*N*′-Diacetylchitobiose (500 mg, 1.18 mmol) was dissolved in 25 mL saturated lime solution and left overnight at laboratory temperature. Dowex 50WX2 in H^+ form was used for the neutralization and the removal of Ca^{2+} ions. The mixture was evaporated and dissolved in 25 mL 50 mM citrate-phosphate buffer (pH 5.3) and the *β*-*N*-acetylhexosaminidase from *Aspergillus oryzae* (20 U) was added. The mixture was incubated at 37°C (typically 2 h) until all *N*,*N*′-diacetylchitobiose had disappeared (TLC). The enzyme was then deactivated by 5 min boiling, and the mixture was evaporated to 1–2 mL. The sample was loaded onto a Bio Gel P2 column (2.6 × 80 cm, flow rate 12 mL/h, void volume 190 mL) and eluted with H_2O to afforded 18% 4-*O*-(2-acetamido-2-deoxy-*β*-D-glucopyranosyl)-2-acetamido-2-deoxy-D-mannopyranose.

Lombardo Methylenation
(Lombardo Olefination, Lombardo Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

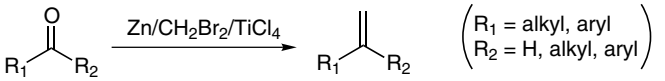
This reaction was first reported by Lombardo in 1982.[1] It is a modification of the *Takai-Nozaki Methylenation*[2] (also known as the *Nozaki-Hayashe Methylenation*[3]) to convert ketones/aldehydes into alkenes using the "low temperature aged" carbenoid reagent generated from zinc, dibromomethane, and $TiCl_4$. Therefore, this reaction is known as the Lombardo methylenation,[2,4] Lombardo olefination[5] or Lombardo reaction;[2,6] and the combination of $Zn/CH_2Br_2/TiCl_4$ is known as the Lombardo reagent[4a,4e,5b,6a,7] or Lombardo's reagent.[8] However, because this reaction is closely related to the condition reported by Takai, Oshima and co-workers in 1978,[9] this reaction is also referred to as the Lombardo-Oshima methylenation,[7b,10] Lombardo-Takai olefination[11] or Takai/Oshima-Lombardo methylenation;[12] and the Lombardo reagent is also referred to as the Lombardo-Oshima reagent.[10]

The Lombardo reagent is usually prepared by addition of $TiCl_4$ to a precooled suspension of zinc dust in a solution of dibromomethane in dry THF at very low temperature (e.g., $-40^\circ C$), and aged for 2 days at $4^\circ C$ before the methylenation.[4a] Different from the *Wittig Reaction*, the Lombardo methylenation is highly selective and occurs under nonbasic conditions.[13] This reaction is especially valuable for the methylenation of keto ester, for which the *Wittig Reaction* fails,[14] and for the olefination of β,γ-unsaturated enones without enolization.[15] Thus the Lombardo methylenation is an alternative olefination method when *Wittig Reaction* or *Tebbe Olefination* is not applicable.[3,10,11b,13,16] However, it also

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

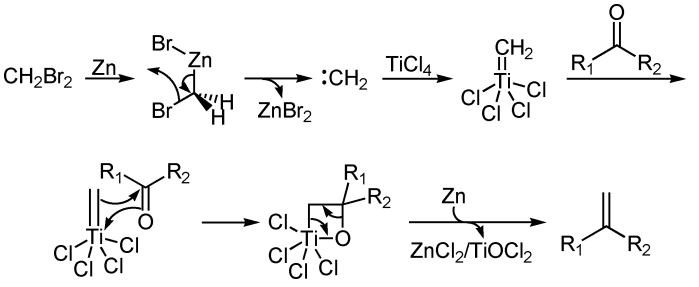
has some disadvantages, such as the lengthy preparation of the reagent,[6a] the heterogenous nature of the reaction condition,[6a] the need for a large excess of reagent,[11] and the low yield in conversion of ketene into allene.[6a] An excess amount of reagent makes the workup and isolation very difficult.[11]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is plausible that the Lombardo methylenation proceeds via an analogous pathway of *Tebbe Olefination*, as illustrated below.



D. MODIFICATION

N/A

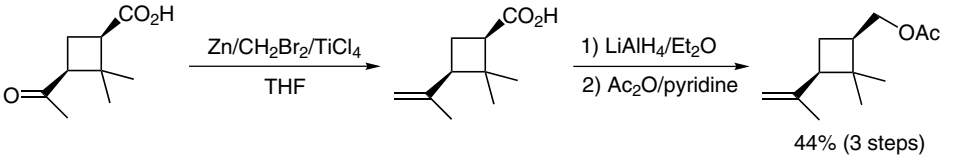
E. APPLICATIONS

This reaction has been widely used for the methylenation of carbonyl functionality.

F. RELATED REACTIONS

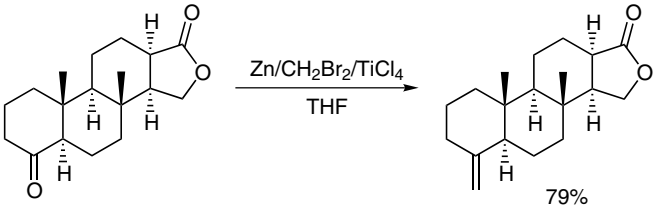
This reaction is related to the *Takai Olefination* and *Tebbe Olefination*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 17.

To a suspension of 24.9 g activated zinc (381 mmol, 10.9 eq.) in 150 mL anhydrous THF with 10 mL dibromomethane (142.5 mmol, 4.1 eq.) cooled at −45°C, was added 12.0 mL $TiCl_4$ (109 mmol, 3.1 eq.) dropwise. When the formation of yellow smoke had subsided, the mixture was warmed to 0°C and maintained with good stirring for 2 days. Anhydrous CH_2Cl_2 (40 mL) was added, followed by the dropwise addition of 5.97 g (+)-(1*R*)-*cis*-2,2-dimethyl-3-acetyl-cyclobutanecarboxylic acid (35.1 mmol) in 35 mL CH_2Cl_2. The mixture was stirred for 30 min and then at room temperature for 3 h. To this reaction mixture was then added 100 mL hexane and 1.5 *N* HCl (slow initially, total 140 mL). The mixture was stirred for 30 min and then separated. The aqueous layer was extracted with hexane twice, and the combined extracts were dried over Na_2SO_4, filtered, and evaporated to afford (+)-(1*R*)-*cis*-2,2-dimethyl-3-isopropenyl-cyclobutanecarboxylic acid. The acid was immediately taken up by Et_2O and reduced with $LiAlH_4$ to prevent epimerization and finally transformed into corresponding acetic acid ester: (+)-(1*R*)-*cis*-2,2-dimethyl-3-isopropenyl-cyclobutane-methyl acetate, in a total of 44% yield, b.p. 83–86°C.



Reference 7a.

A 10 mL 1.0 M solution of $TiCl_4$ in CH_2Cl_2 (10 mmol) was added dropwise over 10 min to a vigorously stirred suspension of 2.87 g activated zinc dust (44.0 mmol) and dibromethane (1.01 mL, 2.43 g, 14.0 mmol) in 25 mL THF at −40°C. The mixture was warmed to 0°C, and then stirred in a cold room at 0°C for 18 h. A portion (0.5 mL) of this Lombardo reagent was added dropwise over 5 min to a solution of 10 mg (5b,13a)- and (5a,13a)-8-methyl-18-nor-16-oxaandrostan-4,17-dione (0.0344 mmol) in 1 mL CH_2Cl_2 at 0°C, and the reaction was then stirred at 0°C for 30 min. The mixture was poured into 15 mL saturated aqueous $NaHCO_3$ and then extracted with 20 mL Et_2O. The separated organic phase was washed with 20 mL water, and both separated aqueous layers were then

extracted with 20 mL Et_2O. The combined organic extracts were dried over $MgSO_4$ and then evaporated in vacuo. Chromatography of the residue on silica gel using EtOAc/light petroleum (b.p. 40–60°C) (3:17) as the eluent gave 7.8 mg (5a,13a)-8-methyl-4-methylene-18-nor-16-oxaandrostan-17-one as white needles, m.p. 130–135°C, in a yield of 79%.

Lossen Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

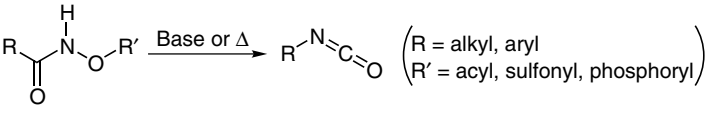
This reaction was first reported by Lossen in 1872.[1] It is a thermal or alkaline conversion of hydroxamic acid into an isocyanate via the intermediacy of its *O*-acyl, sulfonyl, or phosphoryl derivative. In the presence of water, amine, or alcohol, the isocyanate is converted into amine, urea or urethane, respectively. Therefore, this reaction is generally known as the Lossen rearrangement.[2,3] Occasionally, it is also referred to as the Lossen reaction,[4] Lossen degradation,[5] or Lossen transformation.[6]

Initially, this reaction was thought to occur via a similar mechanism of *Curtius Rearrangement* or *Hofmann Rearrangement*[7] by means of the formation of an univalent nitrogen intermediate (known as nitrene), from which the alkyl group migrates from the carbon to the nitrogen atom to form isocyanate.[7] However, such idea of the reaction mechanism is challenged on the basis of the modern valence theory, thus a few mechanisms are proposed to rationalize the Lossen rearrangement,[2k,2n,3bb,4c,4f] including the one proposed by Jones and Hurd.[8] In addition, the recently accepted mechanism[2k,2n,3bb,4c,4f] involves the deprotonation of N-H from a base, followed by the concurrent migration of an alkyl group and release of a carboxylate (or sulfonate or phosphonate) if the hydroxamic acid is activated by an acyl group (or correspondingly by a sulfonyl or phosphoryl group[2n]). It has been found that the rearrangement rate is directly proportional to the acidity of the leaving group or the conjugate acid of the leaving group if the leaving group is an anion;[2h] in addition, in the case of *O*-benzoyl phenylhydroxamic acid, the electron-donating group on the phenyl and electron-withdrawing group on the benzoyl moiety will facilitate the rearrangement, especially when these substituents are in the *meta*- or *para*-positions.[4c] It has been

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

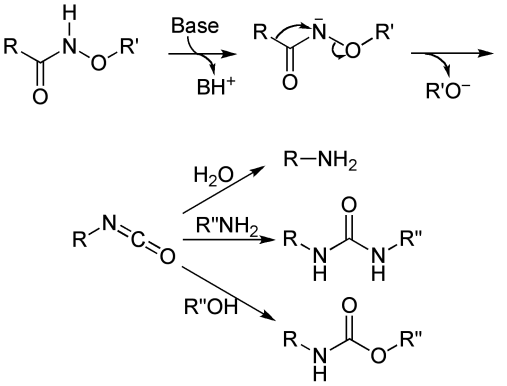
found that the stereochemistry of the migrating group is retained after the migration.[2l,3bb] Unfortunately, because of the intrinsic self-condensation reaction between the hydroxamic acid and the isocyanate, and the general unavailability of hydroxamic acid,[2b] this reaction had not been widely used in organic synthesis until recent modifications.[2f] In fact, the desired hydroxamic acid can easily be prepared from the reaction between hydroxamine and acyl halide, ester, or anhydride.[3bb] The Lossen rearrangement has been modified by the addition of a water-soluble carbodiimide,[2j] application of lithium aluminum hydride as base and reducing reagent,[2m] or protection of hydroxamic acid with a *t*-butylcarboxyl group[2b] as well as carrying out the reaction in the presence of formamide[2f] and using an enzyme to catalyze the reaction.[2e,3x]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple mechanism is depicted here for this rearrangement, including the formation of isocyanate derivatives.



D. MODIFICATION

This reaction has been modified to occur under different conditions, such as the addition of carbodiimide, and formamide, as described in Section A.

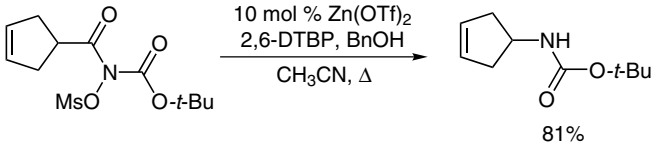
E. APPLICATIONS

This reaction has general application in the preparation of amine, urea, and urethane derivatives.

F. RELATED REACTIONS

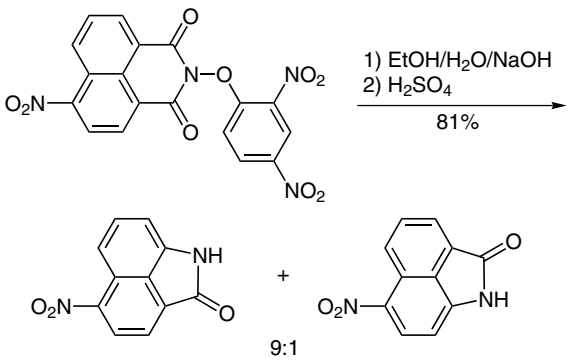
This reaction is related to the *Curtius Rearrangement* and *Hofmann Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a solution of 610 mg *N*-(*t*-butyloxycarbonyl)-*N*-(methanesulfonyloxy)cyclopent-3-enylcarboxamide (2.0 mmol) in 10 mL CH_3CN were added 238 mg benzyl alcohol (2.2 mmol), 382 mg 2,6-di-*t*-butylpyridine (2.0 mmol), and 72 mg zinc triflate (0.2 mmol). The mixture was heated with stirring at 85°C for 16 h and then cooled to room temperature. It was then diluted with 50 mL EtOAc, washed with water, 1 M H_3PO_4, and brine (50 mL each). The combined aqueous layers were back extracted with ethyl acetate (2 × 50 mL); the combined organic layers were dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was flash chromatographed (4:1, hexanes/EtOAc) to afford 352 mg *N*-(benzyloxycarbonyl)cyclopent-3-enylamine as a colorless solid, in a yield of 81%, m.p. 50–52°C.



Reference 9.

To a 22-L, of clean, three-necked flask were added 4.650 L deionized water and 10.75 L absolute ethanol. To this solution was added 236 g NaOH (5.9 mol, 4.04 eq.). The resultant solution was cooled to 10°C, and 620 g *N*-(2,4-dinitrophenoxy)-4-nitronaphthalimide (1.46 mol, 1.0 eq.) was added. The mixture was stirred for 44 h at ambient temperature until the completion was detected by TLC ($CHCl_3$/MeOH, 95:5). The pH was adjusted to 3 with 175 mL conc. H_2SO_4, and the mixture was cooled to < 10°C and filtered. The wet filter cake was reslurried in 3 L deionized water, and the pH was adjusted to 7–8 by the addition of saturated aqueous $NaHCO_3$ solution. The mixture was filtered, washed with water and 95% ethanol, and dried under vacuum to yield 254 g 5-nitrobenz[*cd*]indol-2(1*H*)-one, in a yield of 81%. ^{1}HNMR analysis of the product showed that the product was contaminated with ~10% of the regioisomer 6-nitrobenz[*cd*]indol-2(1*H*)-one.

Other references related to the Lossen rearrangement are cited in the literature.[10]

Luche Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Luche in 1985.[1] It is the modification of the initial aqueous allylation of carbonyl compounds (in 1983) via the intermediacy of tin in the presence of a catalytic amount of hydrobromic acid (HBr),[2] to the zinc mediated allylation of carbonyl compounds using ultrasonic irradiation in saturated aqueous NH_4Cl/THF solution.[1] Thus the new reaction condition is referred to as the Luche reaction.[3] In parallel, Li[4] and Chan[5] extended the Barbier-Grignard-type reaction to successfully proceed in aqueous media and contributed to the new area called "green chemistry."[6]

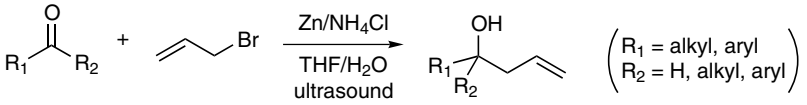
As a weak acid, ammonium chloride is often added to the reaction media to activate the metal surface[1a] so that the yield can be dramatically enhanced.[7] However, it is intriguing that under acidic conditions, zinc reduces proton to hydrogen; in addition, the expected allylzinc intermediate reacts violently with water,[3b] but these strong trends do not burden the process of the Luche reaction. When 1,3-dichloropropene, preferably 3-iodo-1-chloropropene is used in this reaction, 1,3-butadienes are obtained; however, when this reaction is interrupted by base treatment after the initial allylation to carbonyl group, vinyloxiranes are obtained as final products.[8] It has been found that when both ketone and aldehyde groups exist, aldehyde reacts in preference;[1b] likewise, aromatic aldehyde prevails in this reaction in the presence of an aliphatic aldehyde.[4c] For the reaction between aldehyde and bromopropenyl methylcarbonate to give the rearranged allyl methylcarbonate, it has been found that a mixture of diastereomers are obtained, and the ratio of *syn*/*anti* depends on the nature of the aldehyde. For example, *syn* adducts are preferentially formed from the conjugated aldehydes whereas the *anti* adducts prevail when nonconjugated aldehydes are used.[9] Moreover, as Luche pointed out, in the presence of a catalytic amount of nickel acetylacetone [$Ni(acac)_2$], allylzinc bromide undergoes conjugate addition with α,β-unsaturated

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

carbonyl compounds.[1c] However, the corresponding branched allylzinc chloride (e.g., 2-methyl allylzinc chloride) adds only to the carbonyl group of α,β-unsaturated compounds, even in the presence of nickel and a variety of ligands,[10] presumably due to the steric hindrance of the side chain. In addition, when a zinc-copper couple is used, alkyl halide reacts with α,β-unsaturated carbonyl compounds and nitriles via a conjugate addition under the conditions of the Luche reaction.[11,12] It is interesting that the allylation of carbonyl compounds with allyl bromide with terminal substituents undergoes γ-allylation rather than α-allylation, affording carbon skeleton rearranged products.[6a]

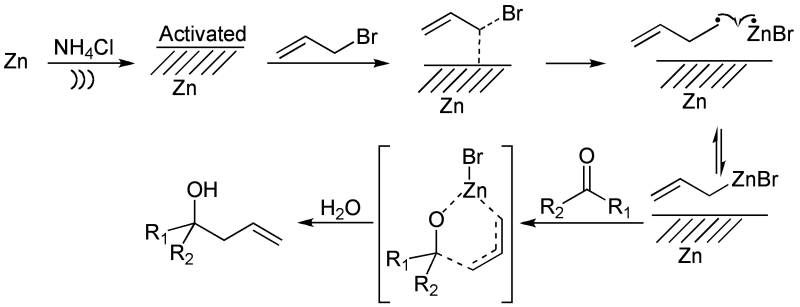
Besides zinc, some other metals have also been applied to facilitate the aqueous allylation of carbonyl compounds. It has been found that the combination of manganese and copper, even only a catalytic amount of copper in any oxidation state [e.g., Cu(0), Cu(I), or Cu(II)], is a highly regioselective mediator for the allylation of aromatic aldehydes in the presence of aliphatic aldehdyes, and this reaction is highly effective when combined with a catalytic amount of acetic acid or in aqueous NH_4Cl. The high regioselectivity is attributed to the difference in reductive potentials of the two types of aldehydes.[13] On the other hand, the metal indium—due to its lower first ionization potential than that of zinc, tin, and even magnesium and its insensitivity to boiling water or alkali—has been found to be the ideal mediator for the allylation of carbonyl compounds in aqueous solution. For example, the indium mediated allylation proceeds smoothly at room temperature without any other promoters; in addition, only a catalytic amount is needed in combination with zinc.[7]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the details of the mechanism are still under debate,[1a,14] the Luche reaction probably proceeds via radical mechanism,[3b,5a,15] similar to that of Barbier-Grignard-type reaction occurring in aqueous solution,[4d] as outlined here.



D. MODIFICATION

This reaction has been modified to proceed in aqueous solution using reverse-phase silica gel to substitute the co-solvent THF so that the slurry of zinc, C-18 silica gel, allyl bromide, and aldehyde are stirred in a saturated aqueous NH_4Cl solution at room temperature in an open vessel, affording comparable yields of products.[3b] In addition, when the combination of zinc and indium trichloride are used as the mediator, much cheaper allyl chloride is an effective allylation agent.[16] Moreover, other types of aqueous allylation protocols have been developed, including the application of gold,[4b] manganese,[4c,5b] magnesium,[4d] tin,[17] and indium.[18] Especially for the case of indium, acetylene can directly add to aldehyde in the presence of an indium salt;[6c] it is worth pointing out that the indium mediated reaction between the aldehydes and a propargyl bromide with a terminal aliphatic or aromatic substituent gives the allenylation products exclusively.[4e]

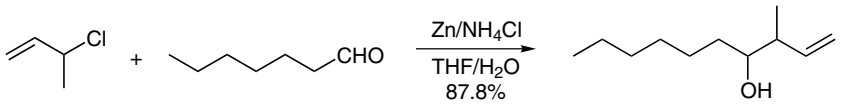
E. APPLICATIONS

This reaction has important application in modern organic synthesis, especially with respect to increasing environmental concerns.

F. RELATED REACTIONS

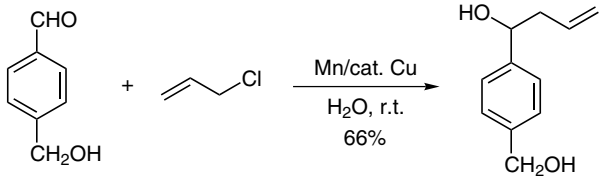
This reaction is related to the *Barbier Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

To a solution of 2.27 g heptaldehyde (19.9 mmol) in 20 mL saturated aqueous NH_4Cl and 4 mL THF, was added 1.56 g zinc (24 mmol) and 2.36 mL crotyl chloride (24 mmol). The reaction mixture exposed to the air was stirred overnight at room temperature, and the suspension (containing zinc salts) was then extracted with Et_2O, and the ether layer was dried over $MgSO_4$. Upon evaporation of Et_2O, the residue was quickly passed through a silica gel pad to afford 2.97 g 3-methyl-1-decen-4-ol as a 1:1 mixture of *erythro* to *threo* products, in a yield of 87.8%, $R_f = 0.5$ (EtOAc/hexane, 1:9).



Reference 5b.

To a 25-mL flask were added 136 mg 4-(hydroxylmethyl)benzaldehyde (1 mmol), allyl chloride (230 mg, 3 mmol), 165 mg manganese (3 mmol), 6.4 mg copper (0.1 mmol), and 2 mL water. The flask was stoppered and stirred vigorously at room temperature for 8 h followed by quenching with 1 *N* HCl and extracted with Et_2O. The combined ethereal solution was washed with brine, dried over anhydrous $MgSO_4$, and concentrated in vacuo. The crude product was purified by flash column chromatography using hexanes/EtOAc (2:1) as the eluent to give 117 mg 1-(4-(hydroxymethyl) phenyl)-3-buten-1-ol, in a yield of 66%.

Other references related to the Luche reaction are cited in the literature.[19]

Luche Reduction

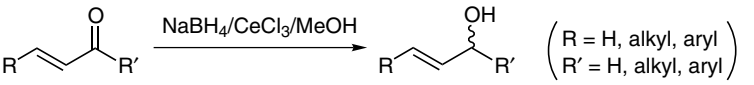
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Luche in 1978.[1] It is a reduction of carbonyl group into an alcohol using the combination of sodium borohydride ($NaBH_4$) and cerium chloride ($CeCl_3$) in methanol as the reducing reagent. Therefore, it is generally known as the Luche reduction,[2,3] and the combination of $NaBH_4$ and $CeCl_3$ is referred to as the Luche reagent.[4] This reaction occurs under very mild conditions, and can tolerate a variety of functional groups within the same substrates, including the azido (N_3),[5] peroxide (-OO-),[5] ester,[6] α-halocarbonyl,[5,7] cyano,[5] epoxide,[8] lactone,[6a,9] cyclopropanyl,[4e] vinyl ester,[5] *t*-butoxycarbamido,[5] phenoxycarbamido,[10] acetal,[2j] ketal,[6c,11] and carbonate[12]. More importantly, this reduction always gives 1,2-addition[3i,5,13] products if the carbonyl group is conjugated to an alkenyl,[2g,2i,2j,4,6,8–10,11a,12,14] aryl,[2d] or alkynyl[2a,5,15] group. In addition, this reduction also demonstrates chemoselectivity between ketone and aldehyde groups, and often the ketone is reduced in the presence of an aldehyde group;[5] if both conjugated aldehyde and isolated aldehyde group exist in the same substrate, then the conjugated aldehyde group is often reduced. This is because $CeCl_3$ functions as a Lewis acid that catalyzes the acetalization of the aldehyde group with methanol, and the isolated aldehyde group forms the acetal first and will remain during the reduction.[5] Similarly, the isolated ketone will not be reduced if a conjugated aldehyde or ketone group coexist. In addition, this reduction also provides a certain level of stereoselectivity and diastereoselectivity.[2a] Generally speaking, the selectivity at lower temperatures would be higher than that of the reduction conducted at higher temperatures;[2d] for the reduction of cyclohexanone series, the Luche reduction affords cyclohexanol with the hydroxyl group at the equatorial position via the axial attack.[2g,2j,5] Besides cerium chloride, other lanthallides are also suitable for such reduction,[16] and it has been found that the stereoselectivity is in a bell-shape

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

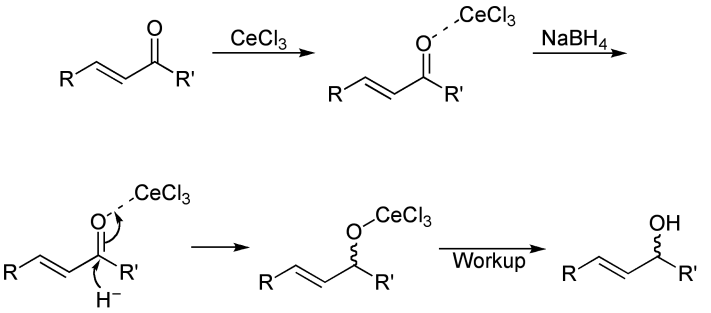
correlation with the size of lanthallides, in the order of $TbCl_3 > EuCl_3 \sim HoCl_3 > CeCl_3 \sim ErCl_3 > LaCl_3$.[2e]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that the coordination between cerium and the oxygen atom of the carbonyl group further polarizes the carbonyl group so that the 1,2-reduction is favored, as displayed below.



D. MODIFICATION

The combination of $LiAlH_4$ and $CeCl_3$ has been used for similar reduction conditions but with less 1,2-reduction selectivity.[5]

E. APPLICATIONS

This reaction has very broad application in organic synthesis.

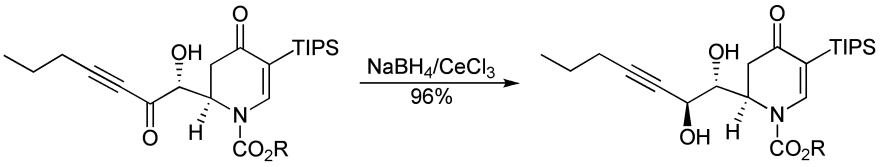
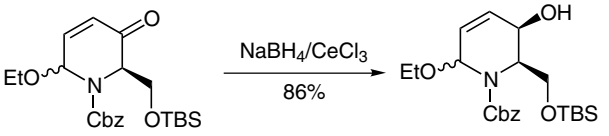
G. CITED EXPERIMENTAL EXAMPLES



R = *trans*-2-(α-cumyl)-cyclohexyl

Reference 2a.

To a solution of 100 mg (2*R*)-2-((1*R*)-hydroxy-1-hept-3-yn-2-one)-1-[((1*S*,2*R*)-2-(1-methyl-1-phenylethyl) cyclohexyoxy) carbonyl]-5-(triisopropylsilyl)-2,3-dihydro-4-pyridone (0.161 mmol) in 7 mL methanol was added 66 mg cerium(III) chloride heptahydrate ($CeCl_3 \cdot 7H_2O$, 0.177 mmol) in one portion. After being stirred for 10 min, the mixture was cooled to -50°C, and 9 mg sodium borohydride (0.241 mmol) was added. The reaction mixture was stirred for an additional 10 min, quenched with 10 mL water, and extracted with CH_2Cl_2 (3 $\times$ 10 mL). The combined extracts were dried over $MgSO_4$ and concentrated under reduced pressure. The residue was purified by radial PLC (silica gel, 30% EtOAc/hexanes) to give 96 mg (2*R*)-2-((1*R*,2*S*)-dihydroxy-hept-3-yne)-1-[((1*S*,2*R*)-2-(1-methyl-1-phenylethyl)-cyclohexyloxy)carbonyl]-5-(triisopropylsilyl)-2,3-dihydro-4-pyridone as a colorless oil, in a yield of 96%.



Reference 2b.

A 100-mL flask was charged with 555 mg (2*R*)-2-(*tert*-butyldimethylsilyloxymethyl)-6-ethoxy-3-oxo-3,6-dihydro-2*H*-pyridine-1-carboxylic acid benzyl ester (1.32 mmol), a magnetic stir bar and 6 mL CH_2Cl_2. The mixture was cooled to -78°C in a dry ice–acetone bath under a nitrogen atmosphere. To this solution was added a 10 mL 0.4 M $CeCl_3$ solution in methanol. After additional stirring and continued cooling, 75 mg $NaBH_4$ (1.98 mmol, 1.5 eq.) was added. The reaction was stirred at -78°C until only alcohol was visible by TLC ($\sim$2 h). The reaction mixture was diluted with 15 mL ether and quenched at -78°C by the addition of 4 mL 1 M $NaHSO_4$. This mixture was stirred for 20 min and separated. The aqueous layer was extracted with ether (4 $\times$ 10 mL), and the combined organic layers were washed with brine and dried over Na_2SO_4, filtered, and concentrated under reduced pressure. Flash chromatography provided 477 mg (2*R*,3*R*)-2-(*tert*-butyldimethylsilyloxymethyl-6-ethoxy-3-hydroxy-3,6-dihydro-2*H*-pyridine-1-carboxylic acid benzyl ester as a colorless oil, in a yield of 86%, $R_f = 0.36$ (EtOAc /hexanes, 1:4).

MacDonald-Fischer Degradation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by MacDonald and Fischer in 1952.[1] It is the degradation of hexoses into pentoses involving the steps of formation of dithioacetal, oxidation to unsaturated disulfone by means of perphthalic acid, hydrazine treatment, and benzaldehyde splitting of the corresponding hydrazone. Therefore, the whole process is known as the MacDonald-Fischer degradation.[2] In addition, when the unsaturated disulfone is dissolved in aqueous ammonia or methanol saturated with ammonia, 2-deoxy-2-amino sugar is resolved.[1] This reaction in combination with mass spectroscopy was used to study the structure and stereochemistry of carbohydrates.[2c,2d,3]

B. GENERAL REACTION SCHEME

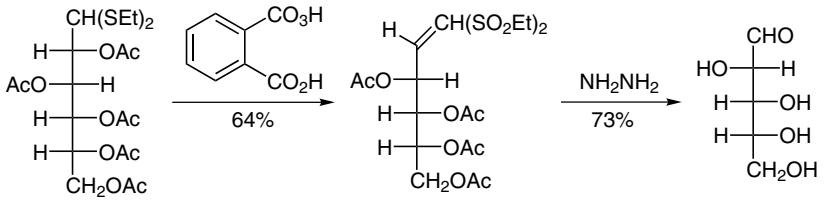
G. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To an ice cold solution of 20.0 g D-glucose diethyl mercaptal pentaacetate in 200 mL dry ether was added 35.21 g monoperphthalic acid in ether (4.8 eq.). The solution was cooled in ice for 1 h and then allowed to stand at room temperature for an additional 16 h. The ether was removed under reduced pressure, and the residue was extracted with $CHCl_3$ (4×75 mL). The chloroform was washed with saturated aqueous $NaHCO_3$ and then with water and was dried over Na_2SO_4. Then $CHCl_3$ was removed under reduced pressure to give 19.9 g D-arabo-3,4,5,6-tetraacetoxy-1,1-bis-(ethanesulfonyl)-hexene-1 as a crystalline material, m.p., 134–146°C. Two recrystallizations from diisobutyl ketone followed by one from isopropyl alcohol and one from methyl ethyl ketone by addition of petroleum ether (b.p. 35–60°C), gave 12.9 g pure product with a constant melting point of 160–162°C, in a yield of 64%.

D-arabo-3,4,5,6-tetraacetoxy-1,1-bis-(ethanesulfony1)-hexene-1(5g) was added to 100 mL methanol; to this was added 4.5 mL 85% hydrazine hydrate in water. The material dissolved rapidly and, after 4 h at room temperature, the solvent was removed at reduced pressure, then 50 mL water was added, and the mixture was extracted with $CHCl_3$ (4×20 mL). To the aqueous layer was added 35 mL benzaldehyde, 0.5 g benzoic acid, and 40 mL ethanol. The mixture was refluxed for 3 h. After cooling, the mixture was extracted with $CHCl_3$ (3×20 mL) and then 20 mL ether. The mixture was washed with 400 mL water, and concentrated to 10 mL. Charcoal was added, and water was removed from the filtered solution in a vacuum oven at 40°C. Then 5 mL hot methanol was added; after 24 h at 4°C, the crystalline residue was washed twice with cold methanol and dried in vacuum over $CaCl_2$ to give 1.10 g D-arabinose, in a yield of 73%.

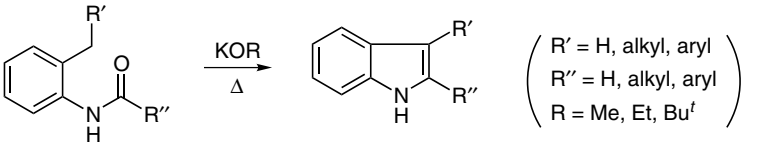
Madelung Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Madelung in 1912.[1] It is a synthesis of indole derivatives by means of the treatment of *ortho*-alkyl *N*-acylaniline with a strong base (e.g., potassium alkoxide) at high temperature (e.g., 300–400°C). Therefore, this reaction is known as the Madelung indole synthesis,[2] Madelung synthesis,[2b,2c,3] Madelung cyclization,[4] or Madelung reaction.[2b,5] It has been improved by using sodium amide or lithium amide as a base to substitute for potassium alkoxide,[5c] so that the reaction can occur at a relatively lower temperature. In addition, it has been reported that when butyl lithium is used as base, the reaction can take place at room temperature.[3a,6] In addition, *ortho*-alkyl *N*-benzoyl anilines react at relatively lower temperatures.[7] However, this method is difficult for the preparation of nitro- or halogen-substituted indoles.[8]

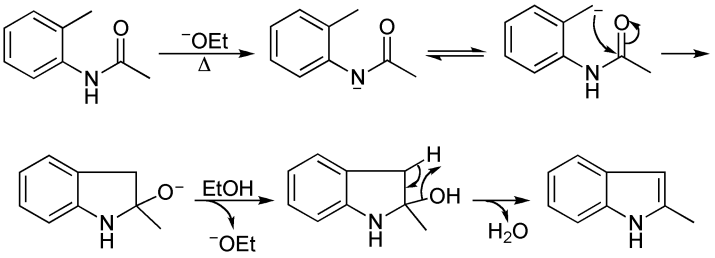
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that the removal of a benzylic proton to form a benzylic anion is the important step in this reaction. As potassium alkoxide or sodium alkoxide is not strong enough to deprotonate benzylic proton, thus a very high temperature is required for this reaction to proceed. However, if sodium amide, a even stronger base, is used, the reaction can occur at a relatively lower temperature; similarly, if amino group of aniline is protected by benzoyl group, a stronger electron-withdrawing group, then the acidity of benzylic proton is enhanced, thus a lower temperature is good enough for the Madelung indole synthesis. An illustrative mechanism is shown below.



D. MODIFICATION

This reaction has been modified by using lithium amide[5c] or butyl lithium[3a,6] as base so that the reaction can take place at milder conditions.

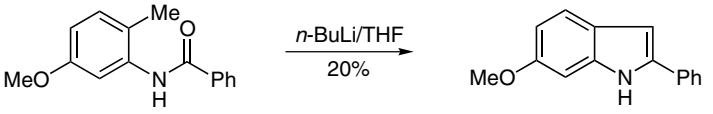
E. APPLICATIONS

This reaction is useful for the preparation of unsubstituted indole and indoles with substitutents at 2-position.

F. RELATED REACTIONS

N/A

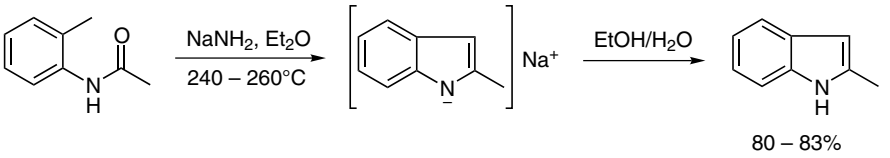
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To an ice-cooled solution of 2.41 g *N*-(2-methyl-5-methoxyphenyl) benzamide (10 mmol) in 20 mL dry THF was added 13.75 mL 1.6 M *n*-butyllithium in hexane (22 mmol) dropwise under a nitrogen atmosphere. This mixture was stirred at room temperature for

20 h, then cooled to 0°C and treated dropwise with 11 mL 2 N HCl. The organic layer was separated, and the aqueous layer was extracted with ether (3 × 20 mL). The combined organic layers were washed with brine, dried over Na_2SO_4, and concentrated in vacuo to obtain a black residue, which was then purified by flash chromatography (silica gel, toluene as the eluent) and crystallization from toluene to give 0.45 g 6-methoxy-2-phenylindole as a white solid, in a yield of 20%, m.p. 177–178°C.



Reference 9.

To a 1-L flask was added a mixture of 64 g finely pulverized $NaNH_2$, 100 g acetyl-*o*-toluidine, and ~50 mL dry ether. Then the flask was swept out with dry nitrogen, followed by a slow current of dry nitrogen passing through the mixture. The flask was heated in a metal bath to 240–260°C over a 30-min period and was maintained at this temperature for 10 min. A vigorous evolution of gas occurred, the cessation of which indicated the completion of this reaction. The metal bath was removed to allow the flask to cool, then 50 mL 95% ethanol and 250 mL warm water (~50°) were added successively. The decomposition of the sodium derivative of 2-methylindole and of any excess $NaNH_2$ were completed by warming the mixture gently with a Bunsen burner. The cooled reaction mixture was extracted with ether (2 × 200 mL), and the combined ether extracts were filtered, and concentrated to ~125 mL. The solution was then transferred to a 250-mL Claisen flask and distilled at 119–126°C (3–4 mmHg) as a water-white liquid, which rapidly solidified in the receiver to a white crystalline mass and weighed 70–72 g, in a yield of 80–83%, m.p., 56–57°C. This product could be further purified by dissolving it in 100 mL methanol, adding 30 mL water, and allowing the solution to stand in the ice chest for 5 h.

Other references related to the Madelung indole synthesis are cited in the literature.[10]

Maillard Reaction

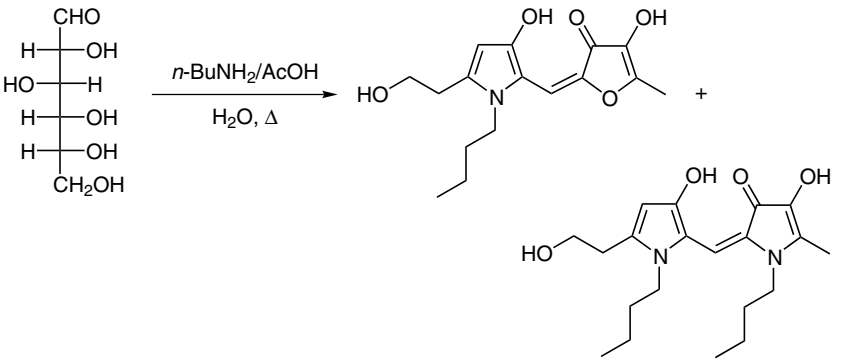
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ling and Malting in 1908 who studied the color formation in beer from sugars and amino groups.[1] Because the color is generally brown-like, this reaction is sometimes called nonenzymatic browning reaction.[2] However, it was Maillard who reported the coloring reaction between reducing sugars and amino groups in 1912[3] and initially realized the significance of this reaction in plant pathology, geology, and medicine; therefore, this reaction is generally known as the Maillard reaction.[4,5] In fact, this reaction is probably the most complicated organic reaction that involves any reaction between a reducing sugar and molecules with a free amino group (e.g., amino acids, peptides, and proteins). Depending on the source of reducing sugars and amino compounds, the products formed show different colors and flavors.[2b] Nonetheless, the end products are nitrogenous heterocyclic molecules with different substituents on nitrogen that give the brown-like colors.[4b] Generally speaking, this reaction involves three stages: the nucleophilic addition of an amino group to the aldehyde group of reducing sugar leads to glycosylamine, which then undergoes the *Amadori Rearrangement* to yield ketosyl compounds irreversibly and give different products via various reaction pathways, such as enolization, *Aldol Condensation*, dehydration, fragmentation of amino acid, and polymerization.[2a,6] The overall outcome of this reaction is the browning, fluorescence (by advanced glycation end products, AGEs[2a]), and cross-linking of protein.[4e] The products of the Maillard reaction are generally known as the Maillard reaction products (MRPs)[4a] or melanoidins.[4f] Among these products, some are reported to have antimutagenic[7] and antioxidant[8] activity, whereas other products are undesired, such as those in milk powder. It has been found that the activity of water, pH, reaction duration, and temperature all affect the extent of this reaction.[4d] Further information about this reaction can be located in the relevant books.[9]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

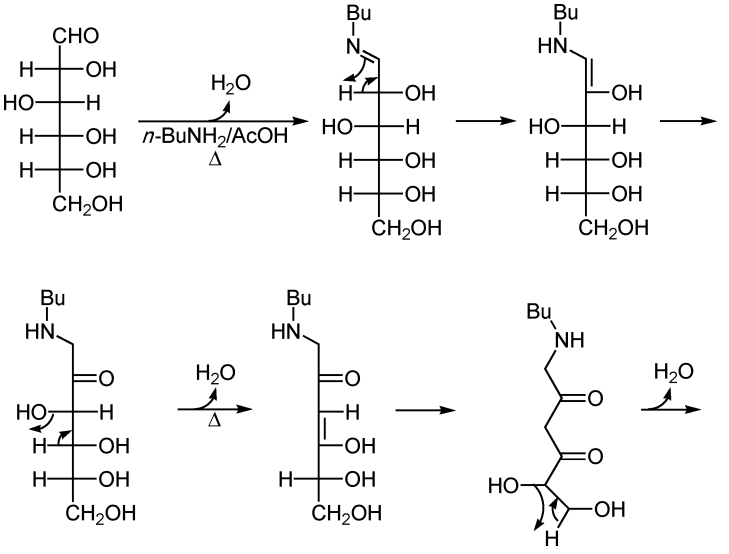
B. GENERAL REACTION SCHEME

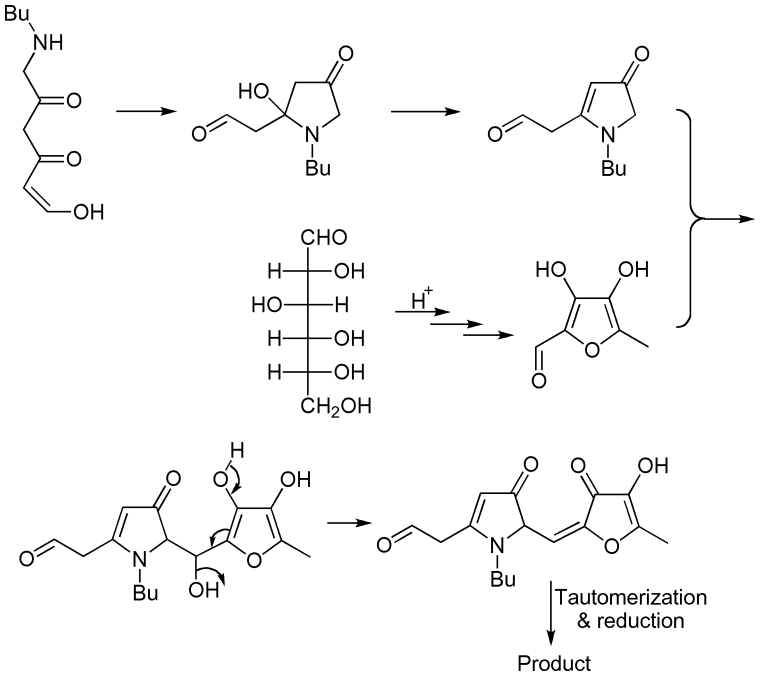
Shown below is a specific reaction between D-glucose and *n*-butylamine.[4b,4c]



C. PROPOSED MECHANISMS

It is assumed that the isolated products are correct as shown in the reaction scheme, and a tentative mechanism (partially) is outlined here to indicate the possible route for the formation of such product.[4c]





D. MODIFICATION

N/A

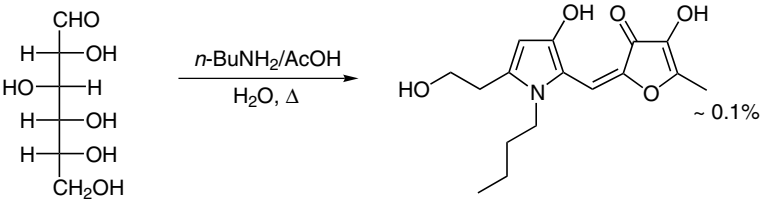
E. APPLICATIONS

This reaction has important application in sitology.

F. RELATED REACTIONS

This reaction is related to the *Amadori Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4c.

A mixture of 36.0 g D-glucose (0.2 mol), 30 mL *n*-butylamine (0.3 mol), and 21.0 mL acetic acid (0.35 mol) in 150 mL water was refluxed for 30 min. After it was cooled, the solution was extracted with 250 mL EtOAc. The organic layer was washed with 150 mL water and concentrated under reduced pressure. The mixture was separated by column chromatography on silica gel (20 cm × 5.5 cm (i.d.), EtOAc/MeOH, 100:3). A dark brown fraction (Fraction A, 30 mL) was followed by a light yellow fraction (Fraction B, 20 mL) and an intense yellow-orange fraction (Fraction C, 50 mL) in front of a light yellow fraction and a broad brown zone. Fraction C was further separated by thin-layer chromatography, using acetone/$CHCl_3$ (5:4) as the eluent. An intense yellow zone of $R_f = 0.65$ was extracted with acetonitrile/methanol (6:1) and concentrated under reduced pressure to afford 4-hydroxy-5-methyl-2-(*N*-butyl-3-hydroxy-5-(2-hydroxyethyl) pyrrolyl-2-methylidene)-2*H*-furan-3-one as a yellow-orange oil, in a very poor yield (0.1%).

Because this reaction has been studied extensively, it is impossible to collect all the references here; additional citations can be found in the literature.[10]

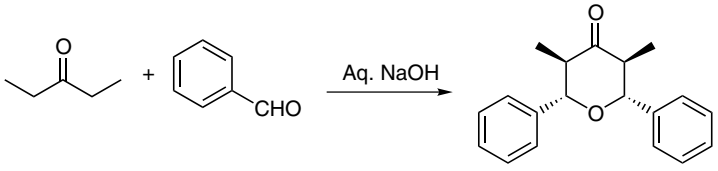
Maitland-Japp Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Japp and Maitland in 1904.[1] It is a one-pot three-component condensation to form multisubstituted tetrahydropyran-4-ones involving a ketone and 2 equivalent of aldehydes. According to the tradition of naming a reaction, such condensation should be known as the Japp-Maitland reaction, but it is generally referred to as the Maitland-Japp reaction.[2] When this reaction was carried out in a basic medium, a mixture of stereoisomers were obtained in low yields,[3] as shown in the original preparation of 2,6-diphenylmethyltetrahydro-4-pyranones from benzaldehyde and 2-butanone by Japp and Maitland.[1] Such reaction was not known for many years due to its long reaction time (e.g., > 7 days), use of excess aqueous reagents, low yield, and lack of generality.[2b] In contrast, when the reaction is promoted by a Lewis acid, the enantioenriched aldol products can be transformed into enantioenriched tetrahydropyran-4-ones without the loss of enantiomeric integrity.[2c] In fact, enantiomerically pure 2,6-*cis*-disubstituted tetrahydropyran-4-ones can be obtained in high yields.[2c]

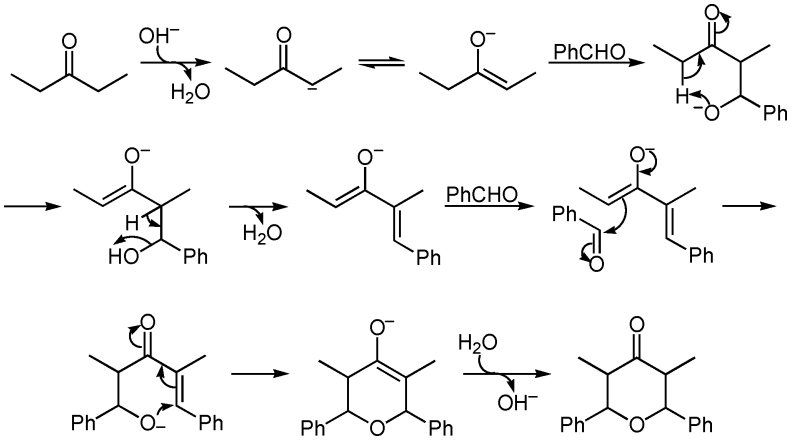
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction consists of an *Aldol Condensation*, a *Knoevenagel Condensation*, and a *Michael Reaction*.[2c] In addition, it may involve an olefinic intermediate, as evidenced in the condensation between a triethylcarbinol and a benzaldehyde to give 2,6-diphenyl-3,5-dimethyl-4-ethyl-4-tetrahydropyranol.[4] An illustration of the reaction route is provided here.



D. MODIFICATION

This reaction has been extended to use the dienolates of β-ketoesters,[2a,2c,2d] in which two different substituents can be mounted to the 2- and 6-positions of tetrahydropyran-4-ones due to the marked difference in the reactivity of the two enolate carbons by reacting with different aldehydes.[2d]

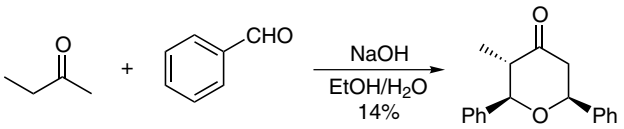
E. APPLICATIONS

N/A

F. RELATED REACTIONS

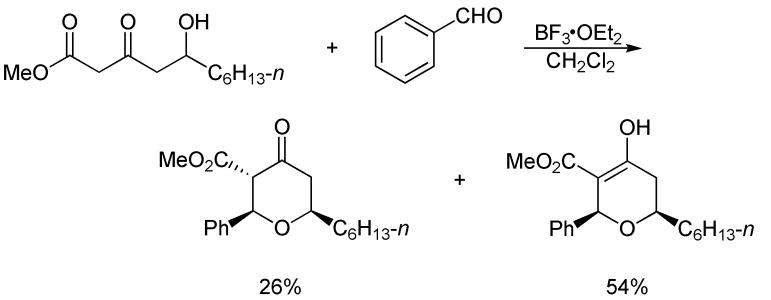
This reaction is related to the *Aldol Condensation* and *Michael Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A mixture of 223 g benzaldehyde (2.1 mol), 72 g 2-butanone (1 mol), 575 g 66% ethanol (12.5 mol), 1080 g water (60 mol), and 80 mL 10% NaOH (2 mol) was vigorously stirred for 8 days. The thick yellow oily layer was washed with water and taken up in ether, and the ethereal solution was dried over Na_2SO_4. Evaporation of the solvent gave a residue that was fractionated under reduced pressure (2–3 mmHg). The final fraction (b.p. 186–192°C) solidified upon standing, which was purified by crystallization in methanol to give 38 g *r-2*,*cis*-6-diphenyl-*trans*-3-methyltetrahydro-4-pyranone as shining crystals, in a yield of 14%, m.p. 82–83°C.



Reference 2d.

To a stirred solution of 53 mg 3-keto-5-hydroxyl undecanoic acid methyl ester (0.23 mmol), 29.7 mg benzaldehyde (0.28 mmol) in 2 mL CH_2Cl_2 was added 44 μL boron trifluoride etherate (0.35 mmol). The yellowish reaction mixture was stirred at room temperature for 90 min and then diluted with 30 mL ethyl acetate. This solution was washed with saturated aqueous $Na_2S_2O_3$ ($\times$ 3), brine ($\times$ 1) and dried over anhydrous $MgSO_4$. Upon removal of solvent, the residue was purified by flash column chromatography using petroleum ether/EtOAc (20:1) as the eluent to afford 80% pyran derivative in a 1:2 ratio, as shown.

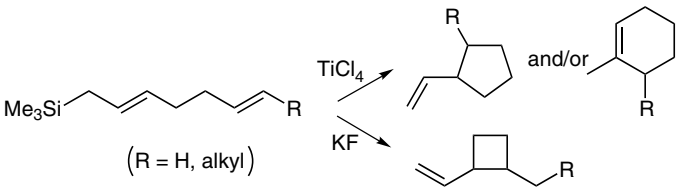
Majetich Annulation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Majetich in 1985.[1] It is a Lewis acid or fluoride promoted intramolecular cyclization of allylsilanes with their intrinsic olefinic group. Thus it is generally called the Majetich annulation. The special case of a 7-trialkylsilyl-1,5-diene system forming vinyl cyclobutanes when promoted by fluoride is known as the Majetich cyclobutane annulation or Majetich reaction, whereas cyclopentanes or cyclohexanes may form if a Lewis acid is used to promote the reaction.[2] This is because the fluoride ion confers an *anti*-orientation of the silyl alkene through kinetic control, and the Lewis acid prefers the synclinal orientation.[3] This reaction is especially useful for the preparation of bicyclic ring systems, such as 5-5, 6-5, 5-7, and 6-7 ring systems, via the intramolecular addition of allylsilanes to cycloalkenones.[4] It has been found that the formation of cyclohexane in a bicyclic ring system promoted by the Lewis acid is not sensitive to the size of the existing cycloalkenone, and the regioselectivity is not affected by the silicon ligand either. This particular reaction prefers an excess amount of Lewis acid and may lead to silyl dienol ethers if no acidic hydrolysis or incomplete hydrolysis is applied during the workup process.[3] Comparably, when a corresponding annulation is promoted by fluoride, it is better to carry out the reaction in DMF in the presence of three equivalent of HMPA, rather than the conventional solvent of THF.[3]

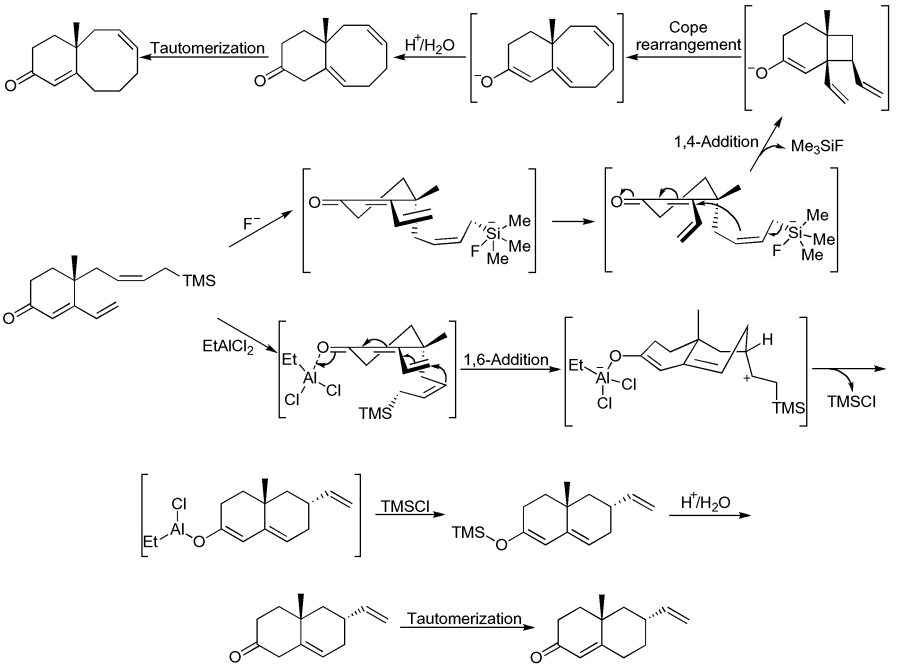
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A mechanism modified from Majetich is illustrated below to demonstrate the formation of a 6-membered ring and a 6-membered ring in a bicyclic system when promoted by a Lewis acid and fluoride, respectively.



D. MODIFICATION

N/A

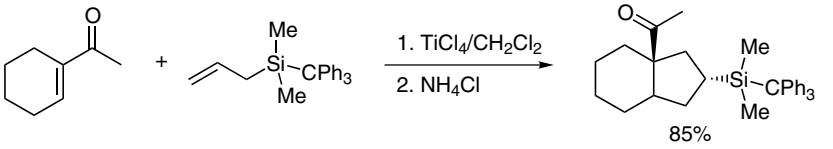
E. APPLICATIONS

This reaction has general application in the preparation of bicyclic systems.

F. RELATED REACTIONS

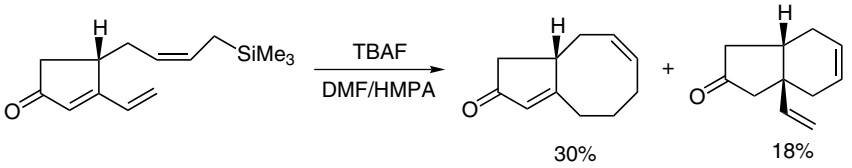
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To 3 mL CH_2Cl_2 solution containing 37.2 mg 1-acetyl cyclohexene (0.3 mmol) at –78°C was added 0.36 mL 1.0 M $TiCl_4$ in CH_2Cl_2 dropwise via syringe. After the mixture was vigorously stirred for 5 min, 0.12 g allyltrityldimethylsilane (0.36 mmol) was added dropwise as a solution in CH_2Cl_2. The reaction temperature was slowly allowed to reach 0°C over 4 h. The reaction was monitored by TLC (1:4, EtOAc/hexanes) and quenched by the addition of saturated aqueous NH_4Cl, resulting in a colorless mixture. The layers were separated, and the aqueous layer was extracted with CH_2Cl_2. The organic layers were combined, dried over Na_2SO_4, filtered, and concentrated. The residue was purified via flash chromatography (9:1, hexanes/EtOAc) to afford 0.11 g *trans*-1-acetyl-8-(dimethyltritylsilyl)bicyclo[4.3.0]-nonane as a colorless solid, in a yield of 85%, m.p. 152–153°C.



Reference 3.

A reaction vessel containing 4-Å molecular sieves was flame dried under vacuum for 5 min and placed under nitrogen. A DMF solution (3 mL) containing 35 mg anhydrous TBAF (0.13 mmol) was added to the flask and stirred for 20 min, followed by the addition of HMPA (0.54 mL, 3.0 mmol). A solution of 150 mg (*Z*)-4-[4-(trimethylsilyl)-2-butenyl]-3-vinyl-2-cyclopenten-1-one (0.64 mmol) in 2.0 mL DMF was added dropwise via syringe pump at room temperature over a 2-h period. The resulting mixture was stirred for an additional 12 h. Standard ethereal workup afforded 112 mg crude oily residue. Purification on silica gel (hexane/EtOAc, 10:1) provided 18 mg *cis*-3a,4,7,7a-tetrahydro-3a-ethenyl-2-indanone, in a yield of 18%, $R_f = 0.72$ (hexane/EtOAc, 1:1). Further elution provided 32 mg 1,2,4,5,9,9a-hexahydro-6H-cyclopentacycloocten-2-one, in a yield of 30%, $R_f = 0.50$ (hexane/EtOAc, 1:1).

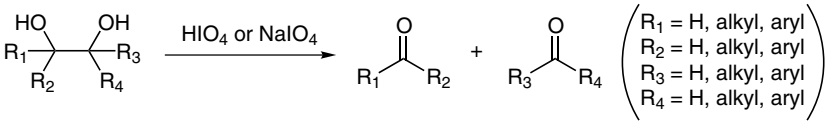
Malaprade Reaction
(Malaprade Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

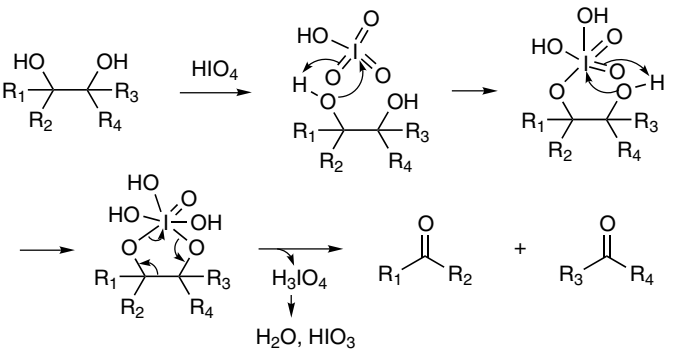
This reaction was first reported by Malaprade in 1928.[1] It is an oxidation of adjacent diols with periodic acid or its salt in aqueous solution. Thus it is generally known as the Malaprade reaction.[2,3] Occasionally, it is also referred to as the Malaprade oxidation.[4] In this oxidation, solvents such as methanol, ethanol, and acetic acid, can be added to the reaction solution to increase the solubility of organic substrates. Similar to the *Criegee Glycol Oxidation*, this reaction is also assumed to involve an acidic cyclic ester intermediate that decomposes to yield aldehyde and/or ketone.[5] This reaction has been extended to the cleavage of α-hydroxy carbonyl compounds, 1,2-dicarbonyl compounds, α-amino alcohols, α-amino acids,[6] and polyhydroxy alcohols.[7] In these oxidations, the hydroxyl group is oxidized to an aldehyde or a ketone group, the carbonyl group is oxidized to a carboxyl group, and the amino group is converted into an aldehyde group and ammonia (or a substituted amine in the case of a secondary amine). In the case of an adjacent polyhydroxyl alcohol, the reaction occurs at the terminal hydroxyl group, and middle hydroxyl groups are converted into formic acid.[7a] It has been found that this reaction proceeds faster under acidic conditions than that in neutral or basic solutions.[8] This reaction has been successfully used for the degradation of carbohydrates and in structural analysis.[2h,9]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

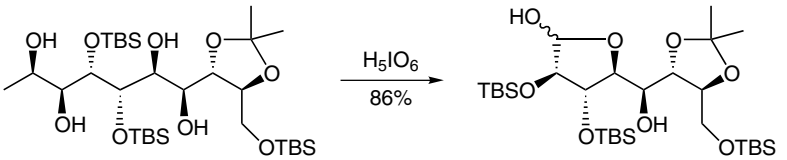
E. APPLICATIONS

This reaction has general application in the oxidation of vicinal diols, amino alcohols, and similar structures.

F. RELATED REACTIONS

This reaction is related to the *Criegee Glycol Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a solution of 500 mg (2*R*,3*S*,4*S*,5*R*,6*R*,7*R*,8*R*,9*S*)-4,5,10-tris[(*tert*-butyldimethylsilyl)oxy]-8,9-*O*-(l-methylethylidene)-2,3,6,7-decanetetrol (0.75 mmol) in 15 mL THF at 0°C was added 188 mg periodic acid (0.82 mmol). After being stirred at 0°C for

1 h, the reaction mixture was diluted with 50 mL Et_2O; washed with saturated $NaHCO_3$ (10 mL), H_2O (10 mL), and brine (10 mL); and dried over Na_2SO_4. Flash chromatography on silica gel (4:l, hexanes/Et_2O) afforded 400 mg lactol as a colorless oil, in a yield of 86%.

Malonic Ester Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

It is a general reaction using dialkyl malonates, mostly diethyl malonate, as starting material, and is commonly known as malonic ester synthesis.[1] In general, being activated by two electron-withdrawing ester groups, the α-methylene protons of dialkyl malonates are relatively acidic with a pKa $\sim$13 and can be readily deprotonated by sodium ethoxide to form the corresponding carbanions, which then participate in the reactions that other carbanions usually undergo, such as the nucleophilic substitutions and nucleophilic additions. For the nucleophilic substitution, mostly via the S_N2 mechanism, alkyl halides,[1j,2] sulfates,[2b] carbonates,[3] and mesylates[1b] are all suitable alkylating reagents. It has been found that the alkylation rate is related to the acidity of α-proton,[4] and in the presence of an excess amount of malonic acid ester, the yield of monosubstitution is improved.[2a] On the other hand, when the substitution on the secondary mesylate proceeds under almost neutral conditions, it results in a complete inversion of stereochemistry.[1a] In addition, malonic acid ester can function as an acid to facilitate the inversion of chirality without the occurrence of substitution.[5] Meanwhile, the fast alkylation of preformed enolate from alkyl malonic acid ester can afford the vinyl malonic acid ester.[6] During the alkylation of malonic acid ester, the reversible cleavage of formed alkyl malonic acid ester or dialkyl malonic acid ester gives a simple alkyl ester;[3b,3c] furthermore, the cleavage of the dialkyl malonic acid ester is faster than that of monosubstituted or unsubstituted malonic acid ester.[3c] For the reaction between sodium malonic acid ester and 2-bromo-2-nitropropane or 2-chloro-2-nitropropane, only the reaction with 2-chloro-2-nitropropane undergoes the expected substitution, whereas sodium 2-nitropropane and ethyl bromomalonate are generated from the reaction with 2-bromo-2-nitropropane.[7] These alkylated malonic acid esters are used to synthesize barbiturates[8] with urea or α-amino acid ester or α-amino acid and

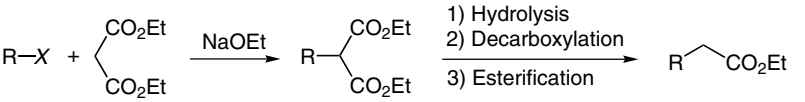
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

alkyl nitrite.[9] It is interesting that the allyl group can be applied as the protecting group of α-proton, which can be removed by $Ti(OPr)_4$; therefore, monosubstituted malonic acid ester can be easily obtained from allylic malonic acid ester.[10]

On the other hand, the sodium malonic acid ester enolate also undergoes nucleophilic addition reaction. For example, the addition to epoxide in the presence of $AlCl_3$ results in the formation of γ-hydroxy carboxylate[11] and γ-butyrolactone;[12] the addition of enolate to α-carbonyl acetylene yields 2-pyrone ester,[13] of which the alkyl group is from the solvent, regardless of the starting malonic acid ester.[13a] Similarly, the addition of sodium malonic acid ester enolate to imino acetylene gives 2-pyridones.[14] The addition of acyl halide leads to the formation of β-ketoester.[15] In the presence of $Mn(OAc)_3$, malonic acid ester adds to cyclopropylidene involving a free radical.[16] In a special case, the malonic acid ester enolate can undergo either nucleophilic substitution or nucleophilic addition when it reacts with α-chloro-aldehyde, depending on the aprotic solvent (e.g., THF) or protic solvent (e.g., H_2O).[17] The malonic ester synthesis has been modified for traceless synthesis on solid support.[18] After the desired reaction, one of the ester groups can be removed via hydrolysis, decarboxylation, and reesterification; however, the ester group can also be removed through pyrolysis at temperatures $\sim 470^{\circ}C$.[19]

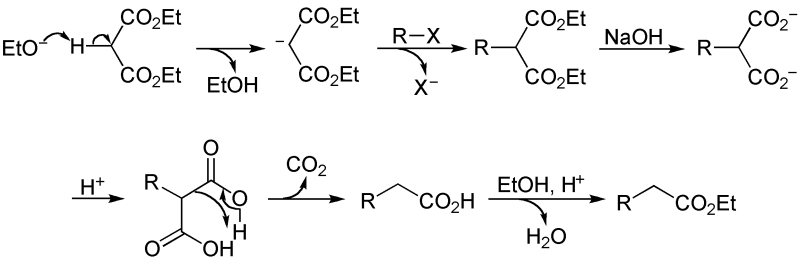
In general, malonic acid ester can be prepared from (*a*) α-chloroacetic acid and NaCN,[8] (*b*) carboxylation of aliphatic acid enolate then esterification with diazomethane,[20] and (*c*) aliphatic acid enolate with diethyl carbonate.[3c]

B. GENERAL REACTION SCHEME



(R–*X* = halide, tosylate, mesylate, carbonate)

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified for traceless synthesis via solid support.[18]

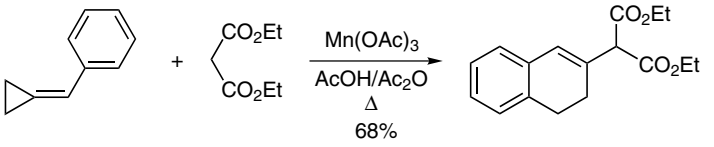
E. APPLICATIONS

This reaction has very general application in organic synthesis.

F. RELATED REACTIONS

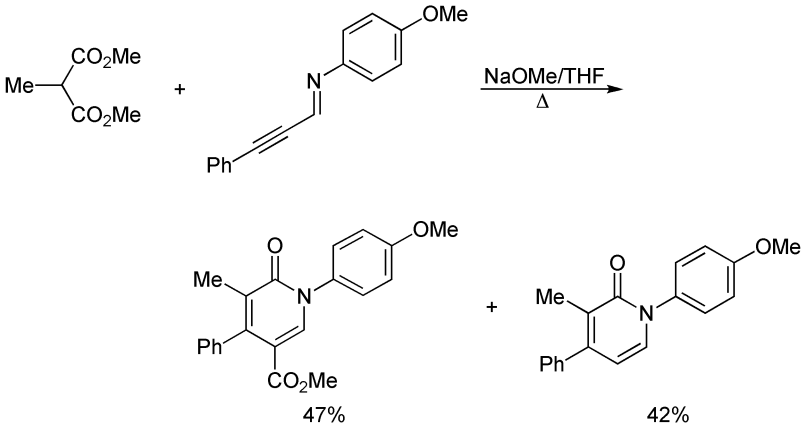
This reaction is related to *Acetoacetic Ester Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 16.

The mixture of 130 mg benzylidenecyclopropane (1.0 mmol), 530 mg $Mn(OAc)_3 \cdot 2H_2O$ (2.0 mmol), and 160 mg diethyl malonate (1.0 mmol) in 5 mL $AcOH/Ac_2O$ (9:1) was stirred at 65°C under a nitrogen atmosphere for 10 h. The mixture was diluted with 40 mL brine and extracted three times with EtOAc. The organic phases were combined, dried over $MgSO_4$, and concentrated. The residue was purified via silica gel chromatography (*n*-hexane/ EtOAc, 10:1) to afford 196 mg 2-(3,4-dihydro-naphthalen-2-yl)-malonic acid diethyl ester as a oil, in a yield of 68%.



Reference 14.

To a THF solution of 0.4 mmol sodium methoxide was added 0.5 mmol dimethyl methylmalonate in 2 mL THF at room temperature, followed by 2 mL THF solution containing 0.2 mmol alkynyl imine. The mixture was refluxed for 7 h and then cooled to room temperature. Brine (10 mL) was added to quench the reaction, and the mixture was extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were dried over Na_2SO_4 and concentrated. The residue was purified by preparative TLC to give 47% 2-pyridone and 42% decarboxylated 2-pyridone, respectively.

Other references related to the malonic ester synthesis are cited in the literature.[21]

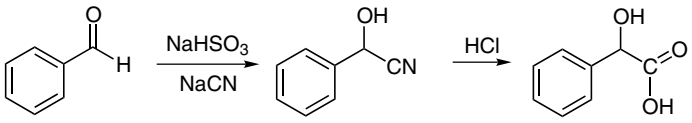
Mandelic Acid Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

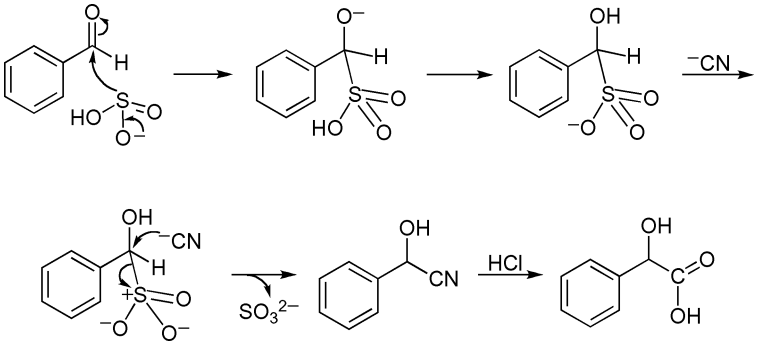
Mandelic acid is α-hydroxyl phenyl acetic acid. Mandelic acid and its derivatives are very useful in medicinal chemistry;[1] some of them have been used in pharmaceutical applications.[2] A few methods have been developed to synthesize mandelic acid and even optically pure mandelic acid. Shown here is the general method for the preparation of mandelic acid from benzaldehyde and sodium cyanide.

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

Because NaCN is extremely poisonous, other methods have been developed to prepare mandelic acid and its derivatives, as shown in Section G.

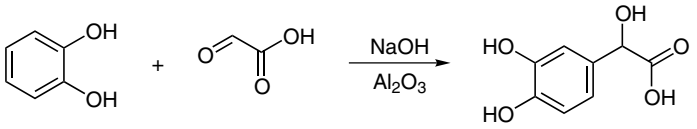
E. APPLICATIONS

Mandelic acid and its derivatives have found wide application in the pharmaceutical industry.[3]

F. RELATED REACTIONS

N/A

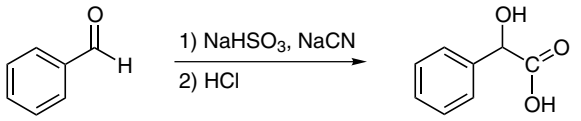
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

Catechol (5.00 g, 45.41 mmol) was dissolved in aqueous NaOH prepared from 3.21 g NaOH (80.3 mmol) and 55.0 mL water; then 2.04 g Al_2O_3 (20 mmol) was added. After 5 min, 50% aqueous solution containing 7.10 g glyoxylic acid (48.0 mmol) was added to the reaction mixture, and the resulting mixture was heated at 60°C for 24 h under vigorous stirring. The reaction mixture was then allowed to precipitate for 10 min and Al_2O_3 was removed by filtration. The filter cake was washed with 20 mL 1 M NaOH. The combined

aqueous solution was acidified to pH 3-4 with 6.0 mL 37% HCl and extracted with ethyl acetate to recover the unreacted catechol (1.2 g). The aqueous solution was further acidified to pH 1 by 2 mL concentrated HCl and extracted with ethyl acetate to isolate 5.1 g mandelic acid derivative (28.08 mmol) with 77.5% conversion, and 90.5% selectivity.



Reference 5.

In a 4-L wide-mouthed glass jar fitted with a mechanical stirrer was placed a solution of 150 g sodium cyanide (3 mol) in 500 mL water and 318 g benzaldehyde (3 mol). The stirrer was started, and 850 mL saturated sodium bisulfite solution was added to the mixture, slowly at first and then in a thin stream. The time of addition was 10–15 min. During the addition of the first half of the solution, 900 g cracked ice was added to the reaction mixture, a handful at a time. The layer of mandelonitrile, which appeared during the addition of the sulfite solution was separated from the water in a separatory funnel. The water was extracted once with ∼150 mL benzene, the benzene was evaporated, and the residual mandelonitrile was added to the main portion.

The crude nitrile (∼ 290 mL) was placed at once in a 25-cm evaporating dish, and conc. HCl (425 mL) was added. The hydrolysis was allowed to proceed in the cold for ∼12 h, after which the mixture was heated on a steam bath to remove the water and excess hydrochloric acid. After being heated for 5–6 h, the mixture was cooled and the ammonium chloride and mandelic acid mixture that separated was filtered. The filtrate was then evaporated to dryness. This residue was added to the solid material obtained earlier. The product was deeply colored and had to be dried in the air and light for at least 24 h. The total yield of the crude mandelic acid–ammonium chloride mixture was 370–390 g, depending on the amount of moisture. The mixture of ammonium chloride and mandelic acid was ground in a mortar, transferred to a 2-L flask, and washed twice with 750-mL portions of cold benzene. The insoluble portion was transferred to a suction funnel and sucked dry.

The mandelic acid was separated from the ammonium chloride by extraction with hot benzene. This was best done by dividing the solid mixture into 10 approximately equal parts. One of these portions was placed in a flask with 1 L boiling benzene. After a few minutes, the hot benzene solution was decanted through a suction funnel. The filtrate was cooled in an ice bath, and the mandelic acid that crystallized was filtered with suction. The benzene was returned to the extraction flask containing the residue from the first extraction, and a new portion of the ammonium chloride–mandelic acid mixture was added and extracted as before. The process was repeated until the mandelic acid was completely removed from the ammonium chloride. The amount of pure white mandelic acid, melting at 118°C, was 229–235 g, with a corresponding 50–52% yield.

Other references related to the mandelic acid synthesis are cited in the literature.[6]

Mannich Reaction

(Mannich Condensation, Mannich Aminomethylation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mannich and Kroesche in 1912.[1] It is a multicomponent condensation between an amine (1°, 2° amine or ammonia), an enolizable carbonyl compound (donor),[2] and a nonenolizable carbonyl compound (acceptor) to form a β-amino carbonyl compound[3] (ketone or ester[4]), with the concomitant formation of both carbon-carbon and carbon-nitrogen bonds, known as the Mannich base.[2,4,5] Thus this reaction is generally known as the Mannich reaction,[6,7] or Mannich condensation.[8] For the special case of condensation in which the nonenolizable carbonyl compound is formaldehyde, a methylamino group is introduced onto the enolizable carbonyl compound. This special condensation is commonly referred to as the Mannich aminomethylation.[6e,9,10] In addition, the Mannich reaction has been extended to different variants, such as the aza-Mannich reaction,[11] halo-Mannich reaction,[12] azido-Mannich reaction process,[2] (or azido ketone Mannich reaction),[13] vinylogous Mannich reaction,[14,15] nitro-Mannich reaction,[16] borono-Mannich reaction,[17] and List-Barbas-Mannich reaction.[6c,18] The aza-Mannich reaction is the condensation between imines,[11b] the halo-Mannich reaction is the one accompanied by the formation of a haloalkyl group,[12b] and the azido-Mannich reaction generates an imine *in situ* from the degradation of an azido group in the presence of triflic acid.[19] Similarly, the vinylogous Mannich reaction is the condensation between imine and conjugated enolate to form 6-amino-α,β-unsaturated carbonyl compound,[15] the nitro-Mannich reaction is the condensation between imine and nitro-alkane,[16g–16j,16o] and the List-Barbas-Mannich reaction is the proline-catalyzed stereoselective Mannich reaction.[6c] The Mannich reaction

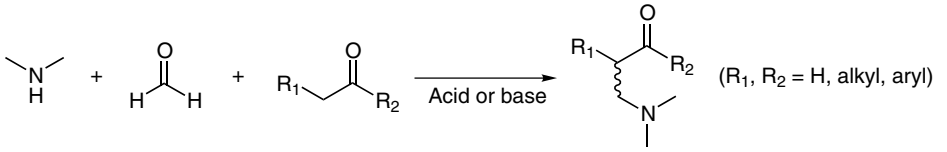
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

can also be divided into direct and indirect Mannich reactions: aldehyde (as acceptor), unmodified ketone (as donor), and amines are used directly in the direct Mannich reaction;[20] in the indirect Mannich reaction, either the ketone is converted into a preformed enolate or its equivalent (such as enolate, enol ether, or enamine), or the acceptor carbonyl compound is transformed into an imine intermediate.[21] In addition, besides the enolate equivalent undergoing the Mannich reaction, the electron-rich phenols also undergo the Mannich reaction with an imine component,[6b,6e,22] whereas an electron-deficient phenol such as 2,6-dinitrophenol fails for this reaction.[6e]

The Mannich reaction is one of the most popular reactions in modern organic synthesis because it generally occurs under very simple conditions and gives desired compounds in high yields with two potential chiral centers.[6e] Consequently, it has been extensively modified beside the variants already noted, including the coupling of (*a*) aldimines, such as the reaction between aldimine and silyl enol ether[4] or silicon enolate,[23] aldimine and fluorovinyl ether,[24] chiral aldimines and silyloxydienes,[25] and fluorinated aldimines with aliphatic aldehydes;[26] (*b*) iminium ions, such as the reaction between cyclic iminium ions and enol derivatives (enol silane, vinyloxytrimethylsilane),[27] and cyclic *N*-alkoxycarbonyl pyrrolinium ion and 2-trimethylsilyloxyfuran;[15b] (*c*) hydrozones, such as the coupling between chiral *N*-acylhydrazones and silyl enolates,[28] hydrazones with ketene silyl acetal,[29] and hydrazone ester and silicon enolates;[30] (*d*) imino esters, such as the reaction between α-imino ester and aldehydes,[3a] *N*-PMP-protected α-imino glyoxylate and α,α-disubstituted aldehyde,[31] α-imino ester and a glycinated Schiff base,[32] and *N*-acylimino ester and silyl enol ethers or vinyl ethers.[33] Furthermore, the Mannich reaction also occurs between the coupling of acetate enolate equivalent and α-amido sulfones or PMP-imines,[34] glyoxylate imines and ketene acetals,[35] alkynyl imine and silylketene acetals,[36] and phosphonylimine and hydroxyketones.[37] Moreover, the direct Mannich reaction has also been modified to occur between aldehydes, ketones, and carbamtes;[3b] between aldehydes, secondary amines, and methoxytris-(pentafluorophenyl)silane (i.e., $MeOSi(C_6F_5)_3$).[38]

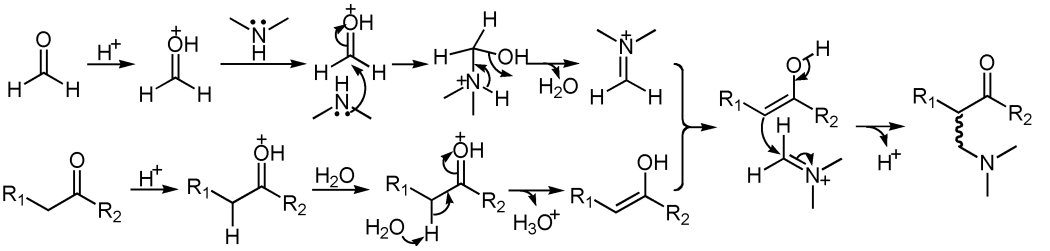
It is interesting that the condensation between electron-rich phenol, amine, and a chiral α-*N*,*N*-dibenzylamino aldehyde has been reported to be temperature sensitive, with high *syn* selectivity at high reaction temperatures while high *anti* selectivity is observed at low reaction temperatures.[22a] Similar to the *Aldol Condensation*, the Mannich reaction can be promoted or catalyzed by either acid or base. Furthermore, different protic acids or Lewis acid alone or in combination with a different chiral ligand or auxiliary group is used to enhance the stereoselectivity of the Mannich reaction, such as proline,[20,26,31,39] (*S*)-amino sulfonamide,[3a] BINOL phosphate,[40] *N*-spiro chiral quaternary ammonium bromide,[32] and dodecylbenzenesulfonic acid[41] as well as Lewis acids, such as $Cu(OAc)_2$,[9b] $CuClO_4$,[33,42] $Cu(OTf)_2$-chiral diamine complexes,[16i,16j,42,43] ZnX_2,[44] $ZnCl_2$,[28] $Zn(OTf)_2 \cdot H_2O$,[25] ZnF_2 with diamine complex,[30] Et_2Zn with (*S*, *S*)-linked BINOL,[45] dinuclear zinc catalyst,[46] chiral zirconium catalyst[4] (e.g., Zr(O-*t*-Bu)$_4$, (*S*)-6,6-BINOL[23]), $Bi(OTf)_3 \cdot 4H_2O$,[47] $Sc(OTf)_3$,[29] $InCl_3$ in MeOH,[48] $Y[N(SiMe_3)_2]_3$/TMS linked BINOL,[37] $AuCl_3$-PPh_3,[3b] $RuCl_2(PPh_3)_3$,[49] and AgOAc with ligand.[36,50] On the other hand, chiral basic molecules such as pyrrolidines with substituents at the 2- and 4-positions (or 3- and 5-positions) are also good catalysts for the Mannich reaction.[51] Finally, the Mannich reaction has also been modified to occur under various conditions, such as microwave irradiation,[6a] phase-transfer reaction,[32,52] in ionic liquid,[49] in aqueous solution without organic co-solvent,[30] $VO(acac)_2$ catalyzed reaction via the generation of iminium ions *in situ* from amine oxides,[22c] and immobilization of chiral ligand onto silica surface.[2d] This reaction is very useful in organic synthesis.

B. GENERAL REACTION SCHEME

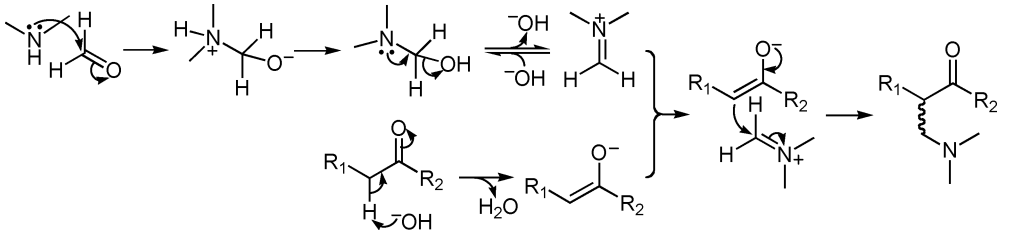


C. PROPOSED MECHANISMS

The mechanism of Mannich reaction under both acidic (Scheme 1) and basic (Scheme 2) conditions are outlined, using formaldehyde, dimethylamine, and a general ketone as example.



SCHEME 1. *Mannich reaction under acidic conditions.*



SCHEME 2. *Mannich reaction under basic conditions.*

D. MODIFICATION

This reaction has been extensively modified as described in Section A.

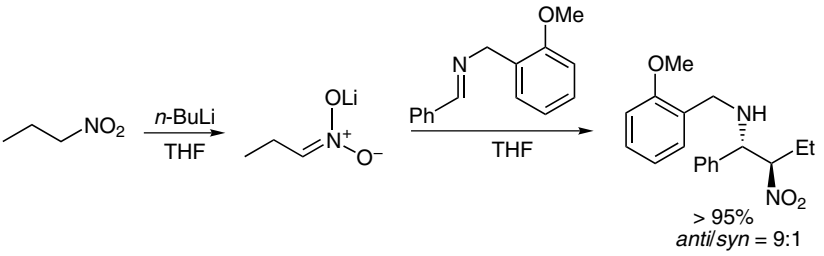
E. APPLICATIONS

This reaction has very broad application in organic synthesis, especially for the preparation of stereoselective compounds under catalytic conditions.

F. RELATED REACTIONS

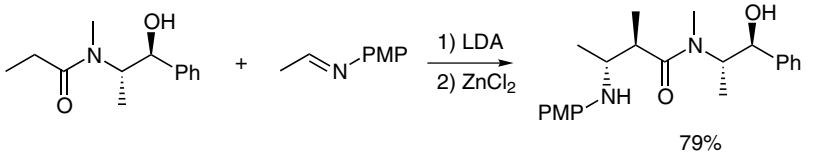
This reaction is related to the *Betti Reaction* and *Robinson-Schöpf Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 16h.

A solution of 0.56 mL 2.5 M *n*-butyllithium in hexanes (1.40 mmol) was added to 20 mL THF solution containing 0.13 mL 1-nitropropane (1.40 mmol) over 10 min at −78°C under nitrogen. The mixture was stirred for 10 min. A solution of 10 mL THF containing 1.0 mmol *N*-(*o*-methoxy)benzyl benzaldimine was then added, and the mixture was stirred at −78°C for 10 min. Then 0.14 mL AcOH (2.4 mmol) was added, and the mixture was stirred for an additional 20 min before being allowed to warm to 25°C over 30 min. Saturated aqueous $NaHCO_3$ (10 mL) and 20 mL Et_2O were then added, and the organic phase was separated, washed with 10 mL saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and evaporated to yield crude β-nitroamine, in a yield of 95% with a *syn/anti* ratio of 1:9.



Reference 53.

At −78°C, a solution of 1 mmol propionamide in 10 mL THF was slowly added to 20 mL THF containing 2 mmol LDA. After being stirred for 1 h at this temperature, the mixture was allowed to reach room temperature and was stirred for another 15 min. The reaction was then cooled to −78°C, and a solution of 2 mmol $ZnCl_2$ in 10 mL THF was added. The reaction was stirred for 1 h at −78°C and then allowed to warm to 0°C, at which time a solution of 4 mmol imine was slowly added. The mixture was stirred until TLC analysis indicated full conversion, and water (2 mmol) was then added. The resulting ZnO precipitate was filtered off and washed with CH_2Cl_2, and 40 mL saturated aqueous Na_2CO_3 was added to the filtrate. The crude reaction mixture was extracted with CH_2Cl_2. The combined organic fractions were collected, dried over Na_2SO_4, filtered, and concentrated. The residue was purified by flash column chromatography (hexanes/EtOAc, 2:8) to afford 79% (2*R*,3*R*,1′*S*,2′*S*)-(+)-3-(4-methoxyphenylamino)-*N*,2-dimethyl-*N*-(2′-phenyl-2′-hydroxy-1′-methylethyl)butanamide, m.p. 86–89°C (Et_2O).

Other references related to the Mannich reaction are cited in the literature.[54]

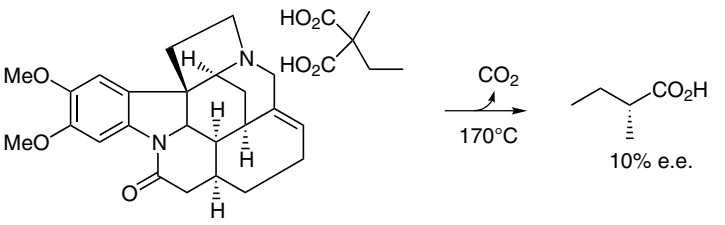
Marckwald Asymmetric Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Marckwald in 1904.[1] It is the synthesis of chiral L-valeric acid (α-methyl propanoic acid) from the pyrolysis of brucine salt of racemic α-methyl-α-ethylmalonic acid.[1,2] Therefore, it is generally known as the Marckwald asymmetric synthesis.[3] Occasionally, it is also referred to as the Marckwald method.[4] In this reaction, the brucine salts of racemic α-methyl-α-ethylmalonic acid essentially exist as a pair of diastereomers that are separated by fractional crystallization; the one with lower solubility is isolated. Upon pyrolysis of such crystalline salt at 170°C, the corresponding brucine salt of L-valeric acid forms upon decarboxylation, resulting in a 10% e.e.[2c] In addition, Marckwald defined the asymmetric synthesis as reactions that produce optically active molecules from symmetrically constituted compounds with the use of optically active materials and exclusion of any analytical processes, such as resolution.[5] However, this work was challenged as not being a true asymmetric synthesis because the procedure was similar to that of Pasteur.[3d] In fact, the fractional crystallization of the diastereomers is a resolution process. This process is used as base for many other preparations of chiral molecules, such as tartaric acid;[6] and under its influence, the kinetic resolution and true asymmetric synthesis have been developed in modern organic synthesis.[7] The asymmetric synthesis has been redefined by Morrison and Mosher as the reaction by which an achiral unit of the substrate is converted into a chiral unit in such a manner that the two resulting stereoisomers are produced in unequal amounts.[8]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

For achiral molecules that, when coupling with a chiral molecule (mostly alkaloids, such as brucine, cinchonidine, and sparteine), form a pair of diastereomers with different physical properties that can be separated by the methods of fractional crystallization, column chromatography, etc., resulting in the enantiomeric resolution. No actual mechanism is necessary for this reaction.

D. MODIFICATION

The original asymmetric synthesis has been extensively improved in modern organic synthesis, such as in the *Sharpless Epoxidation*, asymmetric hydrogenation, and enzymatic hydrolysis.

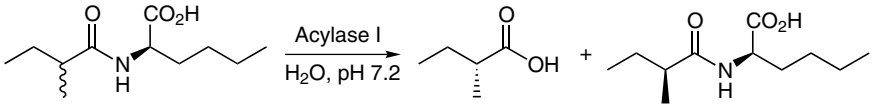
E. APPLICATIONS

The original procedure has some application in the preparation of chiral molecules.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A solution of 54 g DL-α-methylbutyryl-L-norleucine (0.25 mol) was treated with lithium hydroxide to pH 7.2 and then diluted to a volume of 10 L. After the addition of 1.5 g acylase I powder, the mixture was incubated at 37°C. After 40% completion of the hydrolysis, as determined by the manometric ninhydrin-CO_2 method on aliquots withdrawn periodically over a period of ~14 h, the pH of solution was adjusted to 5 by 2 *N* HCl. After the addition of Norit A, the digest was filtered to remove the major portion of the protein. After the readjustment of the pH to 8.5, the solution was concentrated in vacuo to a volume of ~500 mL, then acidified to pH 1.7 by concentrated HCl, and extracted twice with ether. The organic layers were combined and dried over anhydrous sodium sulfate. Removal of the solvent left a thick oily residue, which was a mixture of the free α-methylbutyric acid and residual α-methylbutyryl-L-norleucine. These were separated by dissolving the residue in a small amount of dry ether and adding a large excess of petroleum ether. The free acid remained in solution, whereas the acylated amino acid was separated as a white, oily mass. The residue was again dissolved in ether and again precipitated with excess petroleum ether. Both supernatant solutions were combined, and the solvent was removed by a stream of air. The residual oil was twice fractionated by distillation at 10 mmHg to yield 4.3 g of the final product, b.p. 69°C; α_D at 25°C was + 11.25° for a 2-d.cm tube. Using a d_{25} value of 0.94, the calculated $[\alpha]_{25}^{D} = +6.0°$.

The residual α-methylbutyryl-L-norleucine that had been precipitated from ether solution by excess petroleum ether was refluxed with 200 mL 2 *N* HCl for 2.5 h. After cooling to 25°C, the solution was extracted with ether as above, and the residual oil was subjected to fractional distillation at 10 mmHg. The clear liquid boiled at 69–69.5°C, and after the second distillation amounted to 6.2 g. The α_D at 28°C was −5.5° for a 2-d.cm tube, and using a d_{25} value of 0.94, the calculated $[\alpha]_{25}^{D}$ was –3.0°. The original α-methylbutyryl-L-norleucine when treated in the same fashion, did not yield any optical activity.

Other references related to the Marckwald asymmetric synthesis are cited in the literature.[10]

Markownikoff Rule and Anti-Markownikoff Rule

(Markovnikov Rule and Anti-Markovnikov Rule)

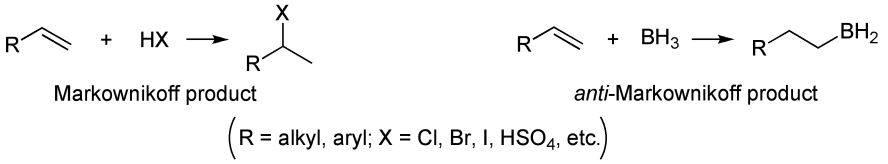
A. GENERAL DESCRIPTION OF THE REACTION

The Markownikoff rule[1] or Markovnikov rule[2] was first formulated by Markownikoff in 1870,[3] and specifies the orientation of the electrophilic addition of hydrogen halides to asymmetrical alkenes or alkynes in which hydrogen itself attaches to the least-substituted carbon atom in a double bond (or triple bond). This rule has been extended to the heterolytic addition of a polar molecule to an alkene or alkyne, of which the more electronegative atom (or group) of the polar molecule attaches to the carbon with more substituents. However, in the presence of peroxide, the order of addition for hydrogen bromide to alkene is reversed.[4] Furthermore, during the hydroboration of alkene or alkyne, hydrogen also attaches to the carbon atom with more substituents.[5] Such a reverse addition order to alkene or alkyne is known as the *anti*-Markownikoff rule[1d,1f,6] (or *anti*-Markovnikov rule[2b,7]) or *contra*-Markownikoff rule.[8] Likewise, the addition reaction that follows the Markownikoff rule is referred to as the Markownikoff addition[6f,9] or Markovnikov addition,[10] and the addition reaction against the Markownikoff rule is called *anti*-Markownikoff addition.[6f] In general, Markownikoff rule is followed when an electron-withdrawing or partially positive group exists on the double bond, in spite of steric hindrance.[6f] For example, the hydroboration of 1,1,1-trifluoropropene yields 74% secondary alcohol;[11] similarly, 87–92% of Markownikoff addition products were observed for 1-(trimethylsilyl)cyclopentene and 1-(trimethylsilyl)cyclohexene under kinetic conditions.[12] Similarly, dimethylchlorosilylethylene, methyldichlorosilylethylene, trichloromethylsilylethylene,[13] and vinyl halide[14]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

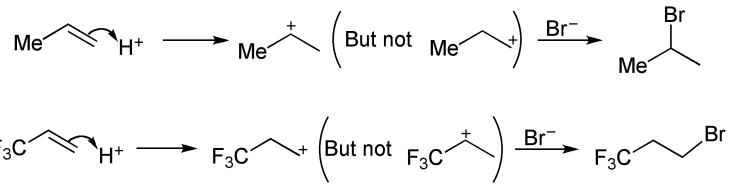
all give the Markownikoff products in addition reactions. Moreover, the ozonolysis of 1,2-dibenzoylpropene is found to follow the Markownikoff rule as well.[15] It is interesting that the acid-promoted cleavage of the cyclopropane ring also follows a modified version of the Markownikoff rule in that the ring opens between the carbons with the most and least alkyl substituents.[16] On the other hand, the hydroboration of an alkene with an alkyl group (or electron-donating group) often yields the *anti*-Markownikoff product.[5] For example, the hydroboration of alkylethylenes give 93–94% terminal alcohol, while 1,1-dialkylethylene and trialkylethylene yield 98–99% terminal alcohols.[6f] Even the addition of alkyl nitrite to styrenes in the presence of a cobalt complex and tetrahydroborate ion exclusively gives the *anti*-Markownikoff product.[6c] It is interesting that the addition of alkyl dichlorocarbamates to vinylsilanes always gives [2-chloro-2-(trialkylsilyl)ethyl]carbamates as the *anti*-Markownikoff product, either through an ionic or a radical mechanism.[6e]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

For the addition of hydrogen halide to asymmetrical alkenes, the proton first adds to the least-substituted carbon atom of the double bond, so that a more stable carbocation can form as an intermediate, then the halide attacks the carbocation to give the Markownikoff product. However, if a strong electron-withdrawing group exists on a carbon atom of the double bond, then the attachment of the proton to such a carbon atom will result in a relatively stable carbocation intermediate, and *anti*-Markownikoff product may predominate in such addition, as shown here by the addition of hydrobromide to propene and 1,1,1-trifluoropropene.



D. MODIFICATION

The acid-promoted cleavage of the cyclopropane ring similarly follows the Markownikoff rule.

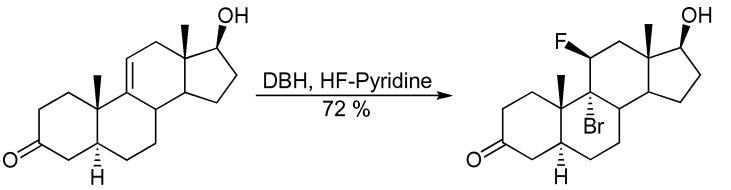
E. APPLICATIONS

This rule is normally used to rationalize the addition products.

F. RELATED REACTIONS

N/A

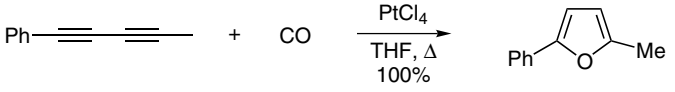
G. CITED EXPERIMENTAL EXAMPLES



Anti-Markownikoff product

Reference 6b.

1,3-Dibromo-5,5-dimethylhydantoin (DBH) (114 mg, 0.4 mmol) was placed in a polyethy1ene vial, followed by a few milliliters of CH_2Cl_2. A substantial amount of DBH was not soluble until 62 μL HF-pyridine (2.17 mmol) was added. Then 208 mg 17β-hydroxy-9(11)-androsten-3-one (0.72 mmol) was added, and the solution was stirred at room temperature for 1.5 h. Product was isolated in CH_2Cl_2 and then purified by column chromatography (benzene/EtOAc, 4:1) to afford 202 mg 9α-bromo-11β-fluoro-17β-hydroxyandrostan-3-one as a white solid, m.p. 138–140°C.



Reference 17.

A solution of 50.5 mg $PtCl_4$ (0.15 mmol) in 2.0 mL THF containing 5% H_2O was placed in a mini autoclave equipped with a magnetic bar and was stirred for 20 min at 100°C under 200 psi CO. To this green solution was added 1.05 g 1-phenyl-1,4-pentadiyne (7.5 mmol). The CO pressure was reduced to 20 psi, and stirring was continued at 80°C for 3 h. Then the reaction mixture was dried over $MgSO_4$, evaporated, and chromatographed on silica gel (hexan/ether) to afford 100% 1-phenyl-4-methyl furan. (*Note:* 2.0 mL THF in original procedure might not be enough to dissolve 1.05 g of the alkyne.)

Other references related to the Markownikoff rule and *anti*-Markownikoff rule are cited in literature. [18]

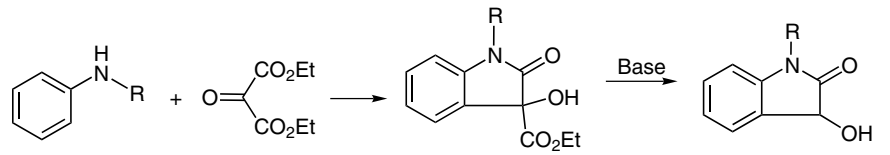
Martinet Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Martinet in 1913.[1] It is a synthesis of dioxindole derivatives by alkali treatment of the condensation products from substituted anilines and ethyl or methyl ester of oxomalonic acid in the absence of oxygen.[2] Thus it is known as the Martinet reaction.[3] In the presence of oxygen, the dioxindoles are further oxidized into isatins.[2] This reaction has been extended to the preparation of α- and β-naphthisatins.[4]

B. GENERAL REACTION SCHEME

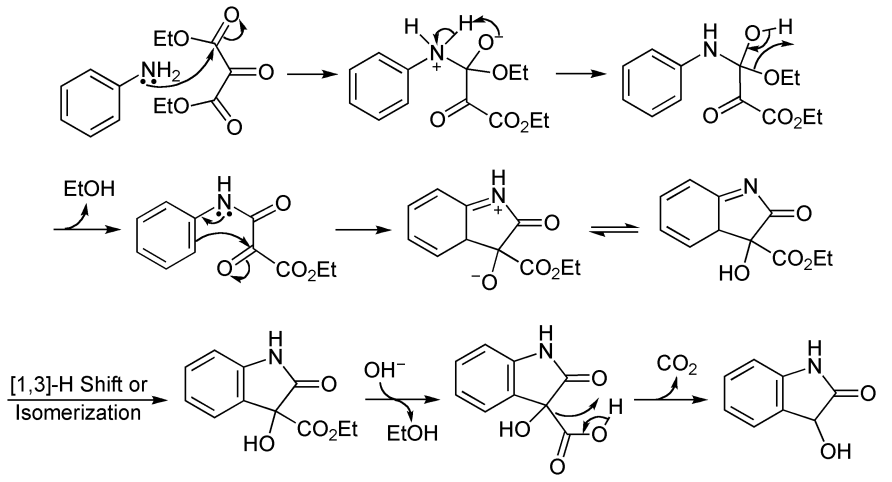


(R = H, alkyl, aryl)

C. PROPOSED MECHANISMS

A detailed mechanism is illustrated here for the reaction between aniline and ethyl oxomalonate.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

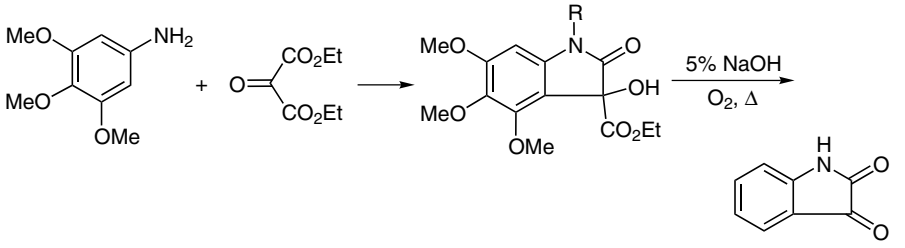
E. APPLICATIONS

This reaction is useful for the preparation of oxindole derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A solution of 1.8 g 3,4,5-trimethoxyaniline in 10 mL glacial acetic acid was treated with 1.9 g ethyl oxomalonate (dihydrate). The resulting olive green solution was heated on the steam bath for 10 min and then kept for 2 h at room temperature. Diluting the solution with 125 mL water and then adding solid ammonium carbonate to give a final pH of 8 caused the precipitation of 2.7 g 4,5,6-trimethoxy-3-hydroxy-3-carbethoxyoxindole as a light tan

solid, in a yield of 86.8%. Recrystallization from a mixture of ether-benzene-petroleum ether afforded pure product as colorless prisms, m.p. 189–190 °C. A solution of 450 mg above oxindole in 5.0 mL 5% NaOH solution was heated on a water bath, and a stream of air was passed through the solution for 10 min. The resulting light yellow solution was brought to pH 4 by the dropwise addition of 95% formic acid. The orange microcrystalline solid separated was collected and washed with water. Recrystallization from ethanol-water afforded 100 mg orange platelets, m.p. 194–195 °C(dec).

Martin's Sulfurane

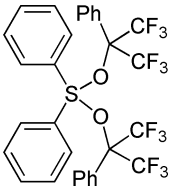
A. GENERAL DESCRIPTION OF THE REACTION

Martin's sulfurane[1] was first reported by Martin in 1971.[2] It is a ketal analog[3] of diarylsulfoxide with 2-phenyl-2-hexafluoropropanol prepared either from the treatment of diarylsulfide with one equivalent of 2-phenyl-hexafluoro-2-propyl hypochlorite followed by one equivalent potassium alkoxide of 2-phenyl-hexafluoro-2-propanol,[4] or from the treatment of diarylsulfide with two equivalents potassium alkoxide of 2-phenyl-hexafluoro-2-propanol with one equivalent of chlorine at -78°C.[2b,4] The second procedure is especially useful for the preparation of symmetrical sulfurane in high yield.[4] During the preparation, moisture must be avoided at all stages because of the high sensitivity toward moisture.[2b] As a result, the Martin's sulfurane is a very powerful dehydration reagent and can be applied to efficiently dehydrate alcohols under very mild conditions.[5] In general, dehydration of tertiary alcohols takes place via an E1 mechanism,[5b,5c] whereas dehydration of secondary alcohols occurs by a mechanism with considerable E2 character with a strong preference for the formation of *trans*-olefin[5b,5c] (>95% selectivity).[6] However, dehydration of primary alcohols without active β-hydrogen often results in asymmetrical ethers.[5b,5c] In addition, the Martin's sulfurane can also dehydrate the diols, by which epoxide can be prepared from *trans*-1,2-diol[5a,7] and oxetane and tetrahydrofuran can be formed from the treatment of 1,3-diol[5a] and 1,4-diol,[5a] respectively. In contrast, the dehydration of 1,4-hydroquinone from Martin's sulfurane results in 1,4-quinone.[3] More importantly, the dehydration by Martin's sulfurane can complete in seconds[5c] at a very low temperature (e.g., -50°C),[5c] which often provides advantages over other dehydrating reagents. For example, both sulfuric acid and phosphorus pentoxide fail to yield any olefin from tricyclopropylcarbinol, whereas 32% olefin is produced from the dehydration by the Martin's sulfurane.[5c] However, it should be pointed out that the Martin's sulfurane, together with the Burgess

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

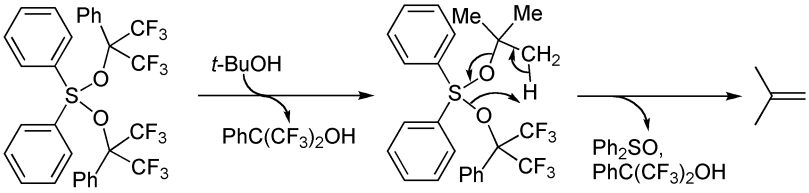
reagent and DAST, fails to dehydrate a tertiaryl alcohol to form an *exo*-double bond.[8] It is interesting that the spirosulfuranes, also developed by Martin, have been found much less reactive than the acyclic sulfuranes.[9] Other sulfuranes, such as tetraoxysulfurane,[10] 5-bis [α,α-bis(trifluoromethyl)-benzenemethanolato]-10-phenylphenothiazine, 5-bis-[α,α-bis(trifluoromethyl)benzenemethanolato]-10-phenoxathiin, and 5-bis[α,α-bis(trifluoromethyl)-benz-enemethanolato]thianthrene,[11] have also been developed for the dehydration of alcohols.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the dehydration of tertiary alcohol shows strong E1 elimination character, an alternative mechanism for the dehydration of *t*-BuOH is presented here.



D. MODIFICATION

Other sulfurane derivatives have been developed for the hydration of alcohols.[10,11]

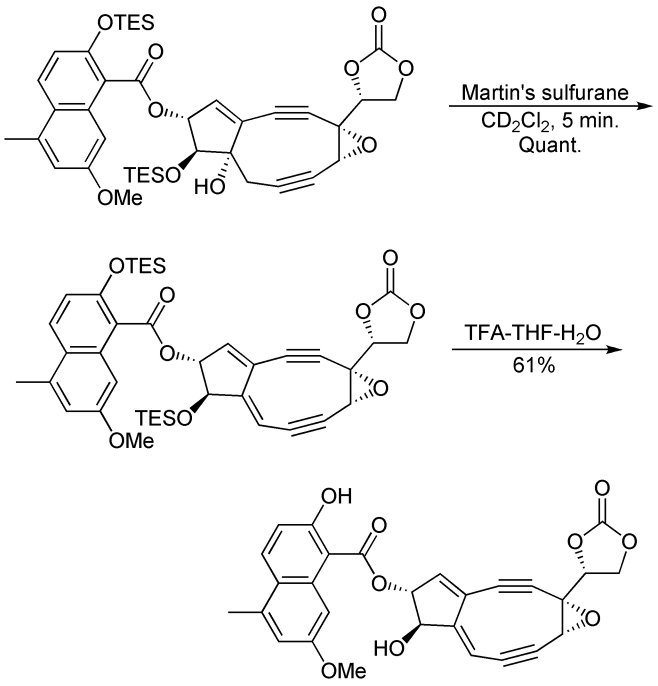
E. APPLICATIONS

This reagent is very useful for the dehydration of alcohols and the formation of olefins and cyclic ethers (e.g., epoxides, oxetanes, and THF).

F. RELATED REACTIONS

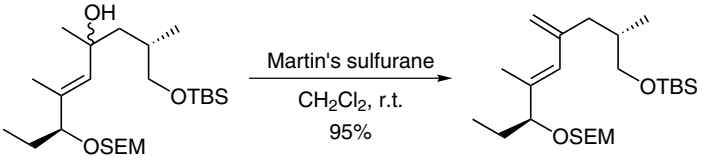
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 12.

To an 1.2 mL CH_2Cl_2 solution containing 3.9 mg alcohol (0.0052 mmol) was added 23.0 mg Martin's sulfurane dehydrating reagent (0.0340 mmol). The mixture was stirred for 10 min at room temperature and concentrated to 0.1 mL. A solution of trifluoroacetic acid/THF/water (1:10:5) was added, and the mixture was stirred for 35 min at 0°C. Et_2O (10 mL); 5 mL saturated $NaHCO_3$ was added, and the resulting mixture was stirred for 1 h at 0°C. The aqueous phase was extracted with Et_2O-EtOAc, and the combined organic layer was dried over anhydrous $MgSO_4$. After filtration, the solution was concentrated to 0.3 mL and exposed to flash column chromatography (silica gel, hexane/EtOAc). The fractions containing aglycon were pooled, concentrated to 0.2 mL, and then subjected to HPLC (Mightysil Si 60, 250–10 [5 μm], flow rate 4 mL/min, hexane/EtOAc as the eluent). The fractions, including pure aglycon (retention time 10 min 15 s), were concentrated to 0.2 mL, diluted with 3 mL MeOH, and then concentrated to 0.2 mL. This process was repeated, and the concentrate was taken up by 5 mL MeOH. In the end, 2.3 mg aglycon was obtained (0.0032 mmol), with a total yield of 61% for the two steps.



Reference 6b.

To a solution of 20 g alcohol (43.5 mmol) in 400 mL CH_2Cl_2 at room temperature was added Martin's sulfurane reagent until the completion of the reaction as monitored by TLC

analysis. The mixture was then concentrated in vacuo and chromatographed to give 18.26 g diene (95% yield) and its isomer (95:5). A small amount was further purified by PTLC to give an analytically pure sample.

Other references related to the Martin's sulfurane are cited in the literature.[13]

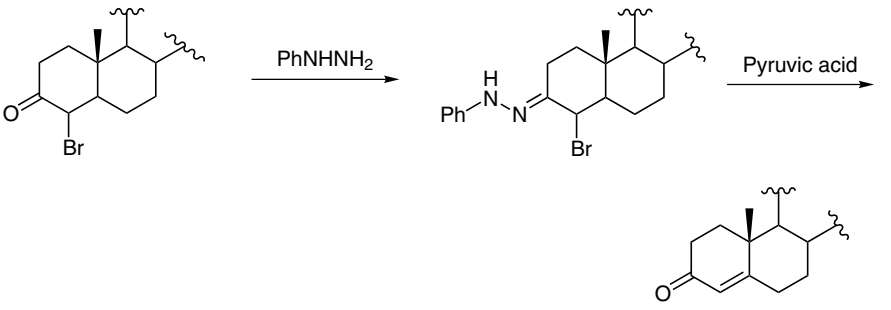
Mattox-Kendall Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mattox and Kendall in 1948.[1] It is a synthesis of α,β-unsaturated ketones by means of dehydrobromination of phenylhydrazone of a semicarbazone derivative of the corresponding α-bromoketone. Therefore, it is often known as the Mattox-Kendall reaction.[2] Occasionally, it is also referred to as the Kendall synthesis[3] or Mattox-Kendall dehydrobromination.[4] Although this reaction is primarily used for the transformation of steroids—such as the conversion of 2-bromo-3-ketoallo-steroids,[2b] 4-bromo-3-ketosteroid,[2b] 2,2-dibromo-3-ketoallosteroids,[2b] and 6-bromo-3-ketosteroids[2b]—into corresponding conjugated ketones, it is also applicable for other cyclic α-bromo ketones[5] or alicyclic ketones.[5] The dehydrobromination of intermediate hydrazone can be achieved using either pyruvate,[6] or pyruvic acid.[7] However, it has been reported that the rigorous purification of α-bromo ketone is essential for a high yield of corresponding conjugated ketone.[6] On the other hand, even though the α-bromo ketones can also be dehydrobrominated directly by a base such as collidine,[8] such dehydrobromination does not give conjugated enone under these conditions. It should be pointed out that the Mattox-Kendall reaction does not work for 2-bromo-1-tetralone and 2-bromo-1-keto-1,2,3,4-tetrahydrophenanthrene,[5] from which the bromo is replaced by a methoxy group upon boiling with methanol. In addition, this reaction does not work for methyl 4β-bromo-3-ketocholanate.[9]

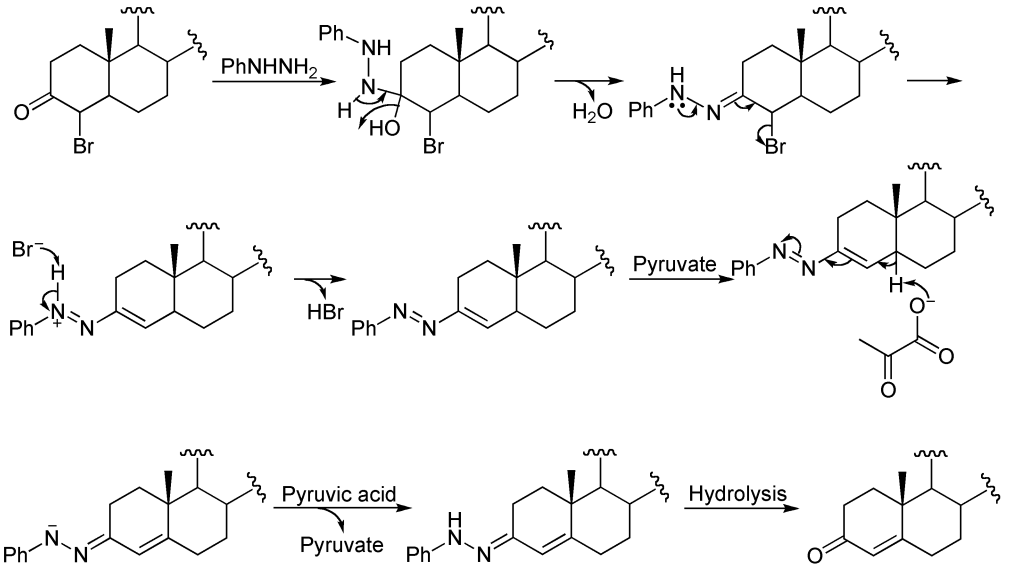
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is illustrated here using pyruvate as a base.



D. MODIFICATION

This reaction has been extended to directly eliminate hydrogen bromide by using collidine as a base.

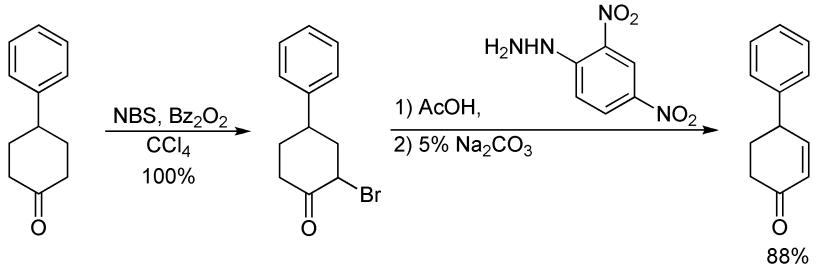
E. APPLICATIONS

This reaction is very useful in the preparation of conjugated enones, especially in steroids.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A mixture of 30 g 4-phenylcyclohexanone, 27.3 g *N*-bromosuccinimide, 0.05 g benzoyl peroxide, and 150 mL carbon tetrachloride was cautiously heated on a water bath. When the exothermic reaction had subsided, the mixture was refluxed for 20 min, cooled, filtered, and concentrated in vacuo. The remaining solution was deposited on ice and gave 48 g 2-bromo-4-phenylcyclohexanone in a quantitative yield that was recrystallized from cyclohexane and melted at 104–105°C.

To a hot solution of 1.0 g 2-bromo-4-phenylcyclohexanone in 30 mL acetic acid was added 0.52 g 2,4-dinitrophenylhydrazine, and the mixture was refluxed for 2 min. The corresponding dinitrophenyl hydrazone precipitated initially dissolved, and no crystals appeared upon cooling. The mixture was therefore diluted with $CHCl_3$, and the solution was washed with 5% Na_2CO_3 solution and water, dried over Na_2SO_4, and concentrated. The dark solid that remained was recrystallized from butanol. In addition to some amorphous insoluble material, 1.0 g brown-red crystals was obtained, in a yield of 88%, m.p., 122°C

Alternatively, a solution of 1.0 g *anti*-2,4-dinitrophenyl hydrazone in 30 mL acetic acid was refluxed for 2 min in an atmosphere of nitrogen. Water was added, and the precipitate formed was recrystallized from butanol to give 0.6 g 4-phenylcyclohex-2-en-1-one, in a yield of 83%, m.p., 122°C.

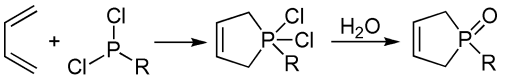
McCormack Cycloaddition
(McCormack Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by McCormack in 1953.[1] It is a synthesis of phospholene oxides involving the cycloaddition of dihalophosphines with 1,3-dienes and subsequent hydrolysis. Therefore, it is generally known as the McCormack reaction[2] or McCormack cycloaddition.[2f,2i,3] Occasionally, this reaction is also referred to as the McCormack synthesis.[4] The resulting products are called the McCormack adducts[3k] or McCormack cycloadducts.[3b,5] In general, this reaction is performed neatly[2a] without any solvent added. In addition, this reaction is often sluggish[2e,2g] and takes days or weeks to complete for less reactive dienes.[2e,2g,2h,3h] In contrast, the cycloaddition of phosphenium ion with 1,3-diene is much faster,[2e,2h,3a] taking as little as 15 min[2g] because of the highly electrophilic nature of phosphenium;[2h] the actual reaction time is depends on steric and electronic factors.[2e] It is interesting that even though 1,3-cycloheptadiene reacts with methyldichlorophosphine to give the corresponding adduct, 1,3-cyclohexadiene fails to undergo such cycloaddition.[2f,3b] This reaction has been modified to react with ethylene chlorophosphite (2-chloroethyl dichlorophosphite) to produce chlorophosphine oxide[2a] and react with phosphorus tribromide to form bromophosphine.[2b] Besides the general preparation of phospholene oxides, this reaction has been used to prepare bicyclic phospholene oxides, including hexahydrophosphindole 1-oxide,[3e] hexahydrophosphindole,[3b] and 7-phenyldinaphtho[2,1-b:1,2-d]phosphole.[2c] In addition, the corresponding phospholene sulfides can be prepared by addition of hydrogen sulfide to the McCormack cycloadducts.[3k] Similar to the *Diesl-Alder Cycloaddition*, the McCormack cycloaddition is also reversible,[2f] and has been applied to the preparation of dioxyphosphoranes,[6] for example.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

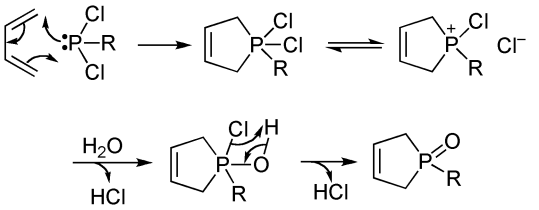
B. GENERAL REACTION SCHEME



(R = alkyl, alkoxyl, aryl, halogen)

C. PROPOSED MECHANISMS

It is believed that the lone-pair electrons of phosphorus in dihalophosphine is involved in the cycloaddition, as demonstrated below.



D. MODIFICATION

This reaction has been modified to react with 2-chloroethyl dichlorophosphite and phosphorus tribromide.

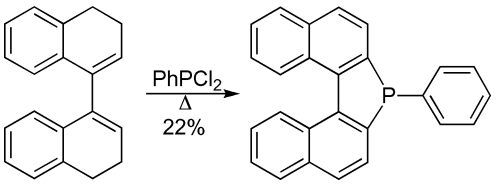
E. APPLICATIONS

This reaction has very general application in the preparation of phospholene oxides.

F. RELATED REACTIONS

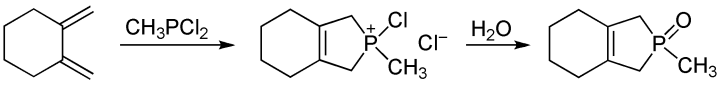
This reaction is related to the *Diels-Alder Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

A mixture of 1.11 mL $PhPCl_2$ (8.17 mmol) and 0.4 g bis-dialin (1.54 mmol) was refluxed at 220°C for 3 h under nitrogen. After cooling to room temperature, the solution was poured carefully into 20 mL 15% KOH aqueous solution. The resulting yellow solid was filtered off, washed with 10 mL 15% KOH aqueous solution, and dissolved in CH_2C1_2. The organic phase was washed with water and dried over Na_2SO_4. The solvent was removed by rotary evaporation, and the crude product was purified by flash chromatography (n-hexane/CH_2Cl_2, 8:1) and recrystallized from CH_2Cl_2/petroleum ether to afford 22% 7-phenyldinaphtho[2,l-b:l′, 2′-d] phosphole, m.p. 157–8°C.



82%

Reference 3c.

Methylphosphorous dichloride (37.4 g, 0.32 mol) was added to a mixture of 29.3 g 1,2-dimethylenecyclohexane (0.27 mol), 400 mg copper stearate, and 100 mL hexane in a wide-mouthed brown bottle with a Teflon-lined cap. The bottle was loosely capped until the initial exothermic reaction had subsided. As the solid cycloadduct formed, additional solvent was added (three 25-mL portions) to keep the adduct covered. The bottle was tightly sealed and allowed to stand for 13 days. The solid cycloadduct was filtered off, washed with petroleum ether (35–60°C, 3 × 50 mL), and added cautiously to 150 mL ice-cold, saturated $NaHCO_3$ solution. The resulting solution was extracted continuously with chloroform for 48 h. The chloroform extract was dried, filtered, and concentrated to give a brown solid residue. Distillation at 106–107°C (0.03 mmHg) gave 37.6 g phospholene oxide as a colorless oil, in a yield of 82%, which quickly solidified to a white, hygroscopic solid.

Other references related to the McCormack cycloaddition are cited in the literature.[7]

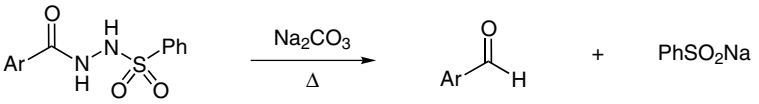
McFadyen-Stevens Reaction

A. GENERAL DESCRIPTION OF THE REACTION

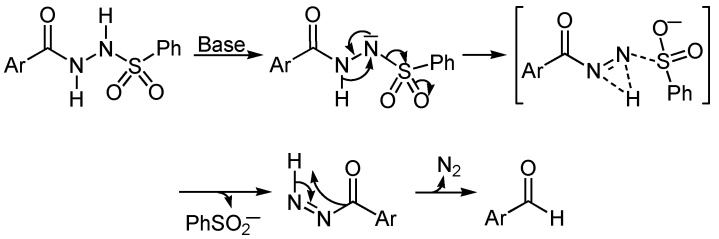
This reaction was first reported by McFadyen and Stevens in 1936.[1] It is a synthesis of aromatic or heterocyclic aldehydes from base-catalyzed thermal decomposition of acylbenzenesulfonylhydrazides in ethylene glycol. Therefore, it is generally known as the McFadyen-Stevens reaction.[2] Occasionally, it is also referred to as the McFadyen-Stevens reduction,[2g] McFadyen-Stevens synthesis,[3] or McFadyen-Stevens aldehyde synthesis.[2i,4] The general procedure of this reaction is to add 5 equivalents of solid sodium carbonate to the solution of acylbenzenesulfonylhydrazides in ethylene glycol at 160°C for a short time (1.25 min) then rapidly cooled it to obtain 70% of the corresponding aldehydes.[2i] However, the optimal condition for this reaction is to pyrolyze the acylbenzenesulfonylhydrazides in an aprotic solvent in the presence of an equivalent of base and solid powder;[2e] the aprotic solvent can be DMSO, DMF, or dimethylacetamide (DMA),[2e] and solids include "charcoal, copper, zinc, diatomaceous earth (Super Cel), glass wool (Pyrex), powdered soft glass, sodium carbonate, barium carbonate and barium hydroxide."[2i] It has been found that this decomposition is accelerated by electron-donating groups and retarded by electron-withdrawing substituents with a slop of -1.38 (ρ) for the Hammett plot.[2e] It is plausible that the decomposition of acylbenzenesulfonylhydrazide of aliphatic carboxylic acids to aldehydes holds similar mechanistic characters, in which the failure to yield corresponding aldehydes is attributed to the successive reaction of aliphatic aldehydes under basic conditions,[2e] whereas the aldehydes without α-protons, such as pivalaldehyde[2g] and apocamphane-1-carboxaldehyde,[2g] or cyclopropanecarboxaldehyde, due to the "unsaturation" properties of the cyclopropane ring,[5] can be obtained accordingly.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur with only one equivalent of base in the presence of a solid powder.

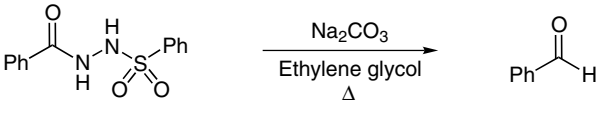
E. APPLICATIONS

This reaction has general application in the conversion of carboxylic acid into corresponding aldehydes.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



73%

Reference 2i.

To a stirred hot mixture of 0.5 g *N*-benzenesulfonylbenzhydrazide, 0.2 g powdered soft glass (finer than 30 mesh), and 5 mL ethylene glycol in a test tube was added anhydrous

sodium carbonate. The mixture was stirred at 160°C with a wad of glass wool. At the end of the reaction period, the test tube was quickly transferred from the heating bath to an ice bath. The reaction mixture was then washed through a sintered glass filter with methanol into a 0.05 M solution of 2,4-dinitrophenylhydrazine in 0.5% of methanolic hydrochloric acid. After several hours, the precipitate was washed with 5–10 mL acidic methanol and dried to a constant weight. The yield of this reaction was 73%.

McLafferty Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported from mass spectroscopy of butyric acid by Happ and Stewart in 1952,[1] but it was McLafferty who initially worked out the cyclic transition state and indicated the importance of such fragmentation pattern for the ionized organic molecules in mass spectroscopy beginning in 1956.[2] Thus this reaction is generally known as the McLafferty rearrangement[3,4] and is occasionally referred to as the McLafferty reaction[3j,5] as well. This reaction is generally defined as the rearrangement of monounsaturated molecular ion or radical ion with the cleavage of α,β-bond of the unsaturated system along with the concomitant transfer of a γ-hydrogen via a six-membered transition state by the formation of a pair of unsaturated fragments, regardless of which fragment holds the charge. This reaction, though without practical value in synthetic organic chemistry, is one of the most common fragmentations and studied most extensively in the field of mass spectroscopy.

It has been found that, during the fragmentation, the structural, steric, and electronic factors determine the actual fragmentation paths.[3j] Taking carbonyl compounds as an example, the critical activation barrier is in the range of 0.2–0.8 eV,[3c] corresponding to 4.61–18.45 Kcal/mol in energy. It has been found that the attachment of an electron-withdrawing group to a carbonyl group and an electron-donating group to the carbon with γ-hydrogen will enhance the McLafferty rearrangement.[3m] On the other hand, the ionization potential of enol is generally lower than that of olefin; thus the enolic ion and olefin are formed through the fragmentation; unless the charged olefin is more stable, in this case the neutral enol and charged olefin will be the fragmentation products, as shown by the fragmentation of aliphatic aldehydes.[3j] The latter case is known as the reverse McLafferty rearrangement,[6] complementary McLafferty rearrangement[3m] or McLafferty rearrangement with charged olefinic product.[3j] The special rearrangement of alkyl formate for the formation of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

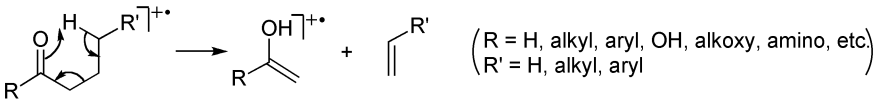
$HC(OH)_2^+$ (m/z = 47) ion is called the [R-2H] loss reaction or McLafferty + 1 rearrangement.[3g] In addition, as γ-hydrogen migrates through the overlapping of the orbitals of hydrogen and the oxygen of the carbonyl group, it is anticipated that the distance between the migrating γ-hydrogen and the oxygen, as well as the angle τ between the plane of carbonyl group and the γ-hydrogen, will be as small as possible.[3j] It is hypothesized that if the distance between γ-hydrogen and oxygen were >1.8Å, then no McLafferty rearrangement would be expected.[3j] In addition, the angle τ can be in the range of 0–90°, and it has been reported that when the angle is ~ 45°, the activation energy is ~ 76 Kcal/mol.[7] No McLafferty rearrangement is reported with a τ value > 50°.[3k] However, in the case of 12-keto steroids possessing a C-17 side chain with a C-20 hydrogen atom (e.g., 12-ketopregnanes, 12-ketoergostanes, and 12-ketocholanates), there is a very strong peak exhibited at m/z = 233 through the McLafferty rearrangement, though the distance between hydrogen and oxygen is predicted to be 3Å.[3m] Such a rearrangement is believed to occur after the cleavage of a ring. It should be pointed out that other functional groups, such as deuterium,[3j] phenyl,[8] trimethylsilyl[3n] and trimethylstannyl,[9] can also migrate. In general, hydrogen has a higher migrating tendency over deuterium, with an isotopic effect in the range of 0.5–1.0 for ketones, esters, and aromatic and heterocyclic substrates;[3j] secondary hydrogen is easier to migrate than the primary hydrogen.[3k]

In contrast to the migration of hydrogen, which has an analogous photochemical reaction (i.e., *Norrish Type II Reaction*[3j,10]), the migration of the trimethylsilyl group does not have a similar analogue in corresponding photochemistry.[3n] Different from the migration of hydrogen, almost all molecular ions of aldehydes, ketones, thioketones, carboxylic acids, and acetates that contain a δ-silyl group can undergo a silyl group migration through a seven-membered transition state, with a higher migration ability for a small silyl group in acyclic carbonyl compounds than that for a larger silyl group in cyclic carbonyl compounds.[3d] However, if the molecule contains a site or group of lower ionization potential than carbonyl,[3j] as in the case of amino ester,[10] amino ketone,[11] ω-amino ester,[12] isopropyl pyruvate,[13] and α-hydroxy ketones,[14] no McLafferty rearrangement is observed, because those groups will be first ionized.

Mechanistically, the McLafferty rearrangement can be either concerted with "simultaneous hydrogen transfer and β-cleavage," or stepwise with the "initial hydrogen transfer being followed by β-cleavage,"[3j] More and more experimental evidence supports the stepwise mechanism rather than the concerted one,[3e,3g,3h] although they cannot be differentiated from theoretical studies.[15] Furthermore, the infrared multiple photon (IRMP) activated dissociation of the butyrophenone molecular cation shows the involvement of a distonic ion as the intermediate, which provides solid support for the stepwise mechanism.[3h]

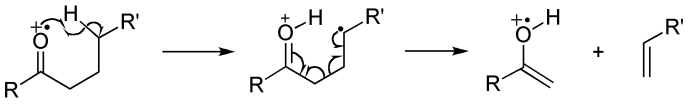
Besides the carbonyl compounds, organic molecules with other types of multiple bonds also undergo similar rearrangements, such as hydrazones, oximes, and semicarbazones.[3j] Even the molecules of epoxides without a double bond, undergo the MaLafferty rearrangement but in two distinct pathways: "inside" and "outside."[16]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown here is a stepwise mechanism for the McLafferty rearrangement of a carbonyl compound, including a hydrogen transfer to oxygen and the subsequent β-cleavage of the α,β-bond. In this mechanism, n-bonding carbonyl group is the highest occupied molecular orbital (HOMO) in carbonyl compounds, so that it is often excited, losing one electron to form a radical cation, which undergoes the β-cleavage to afford the two fragments.



D. MODIFICATION

N/A

E. APPLICATIONS

This rearrangement has very wide application in structural elucidation using mass spectroscopy as the tool.

F. RELATED REACTIONS

McMurry Coupling
(McMurry Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

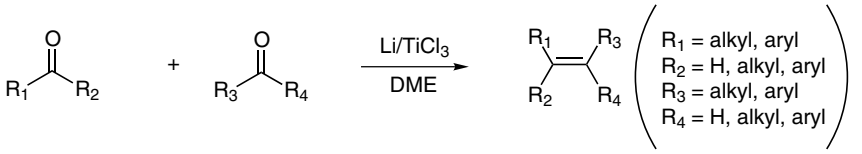
Although the initial study on the reductive coupling of carbonyl compounds to olefins by a low-valent titanium reagent had been conducted concurrently by Tyrlik ($TiCl_4$-Mg)[1] and Mukaiyama ($TiCl_4$-Zn)[2] by 1973, it was McMurry who pioneered in the application of using low-valent titanium as a reducing reagent for a variety of functional groups (e.g., nitro, oxime)[3] and extensively studied the scope of the coupling of carbonyl compounds begining in 1974, using $LiAlH_4$, $LiBH_4$, LiH, CaH_2, etc. in combination with $TiCl_3$ or $TiCl_4$.[4] Therefore, this reaction is generally known as the McMurry coupling,[5,6] or McMurry reaction.[5e,5f,7,8] Occasionally, it is also referred to as the McMurry condensation,[7e] McMurry cross-coupling,[5a,5t,8b,9] McMurry reductive coupling,[5f,10] McMurry pinacol coupling,[7c,11] McMurry synthesis,[7d] McMurry olefination,[12] or McMurry olefin synthesis.[13] The combination of $TiCl_3$ and Zn/Cu couple in DME[7h] or $TiCl_3$-Li in DME[14] is known as the McMurry reagent, which is usually in colloidal status.[14] It has been reported that the active reducing species in the McMurry coupling is Ti^{n+} ($0<n<3$) rather than Ti(0),[7g] as supported by a similar reactivity of TiO_2 single crystal after sputtering off the terminal oxygen by Ar^+ bombardment.[15]

In general, this reaction gives *trans*-olefins in preference,[5o,5t,7h,14] but sometimes contaminated with pinacol.[14] However, the formation of the predominant *cis*-stilbene from acetophenone under the McMurry coupling condition is because of the π-π preassociation.[5t] In addition, the *cis*-olefins are formed in the case of intramolecular cyclization to form macrocycles, such as zearalenone[5k] and helicene.[5p] On the other hand, this reaction primarily works for the coupling of aromatic carbonyl compounds,[3,14] and generally requires high temperatures and prolonged time for deoxygenation.[7f,14] The inability to effectively couple aliphatic carbonyl compounds into olefins is probably due to the strong alkyl-oxygen bond in the intermediate pinacolates.[14] In mechanistic terms, the McMurry coupling has

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

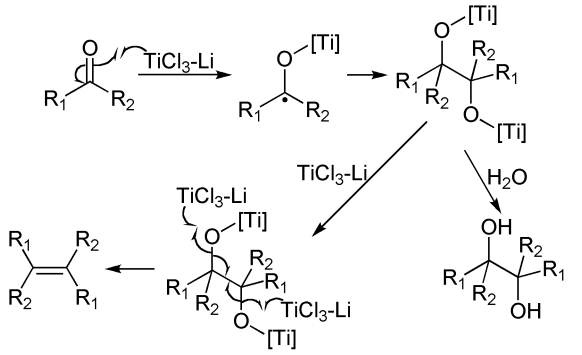
been proposed to involve the metallocarbenoid species to account for the formation of alkanes/olefins through direct deoxygenation of the carbonyl compounds.[8j,8l] However, the widely accepted mechanism consists of two defined steps: the pinacol reaction and the deoxygenation of pinacol to form olefin.[5s,5t,7b,7e,14] In this reaction, the reducing species donates an electron to the carbonyl compound to generate a radical anion, which dimerizes to form a pinacol product; the coupling of pinacol with low-valent titanium followed by deoxygenation results in the olefins. Because of the versatility of this reaction in the formation of olefins, especially in macrocycles, the McMurry coupling has been extensively modified to enhance the chemoselectivity and diastereoselectivity and shorten the reaction time. Some of the modifications are (*a*) the pretreatment of commercial titanium powder with chlorosilanes for the coupling of carbonyl compounds in THF, DME, EtOAc, or pyridine but not MeCN;[7g] (*b*) the addition of 10 equivalents of pyridine with respect to $TiCl_3$ to the THF-solvated low-valent titanium reagent;[5s] (*c*) the addition of a substoichiometric amount of iodine to a low-valent titanium reagent ($TiCl_3$-Li-THF);[7f] and (*d*) refluxing a mixture of a substoichiometric amount (0.25 eq.) of arenes (e.g., naphthalene), $TiCl_3$, and Li (or Mg) in THF or DME.[14] In addition, in the presence of a ligand (e.g., catechol), the McMurry coupling can be used to prepare pinacols with diastereoselectivity.[7c]

B. GENERAL REACTION SCHEME

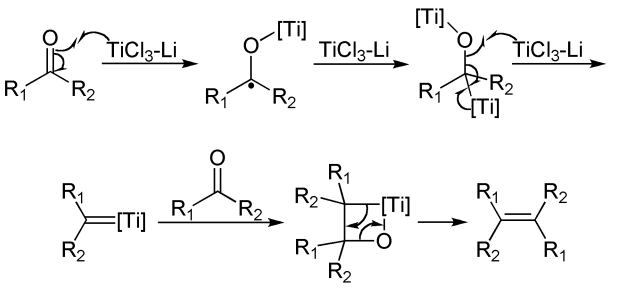


C. PROPOSED MECHANISMS

Two mechanisms involving the intermediate of either pinacol or metallocarbenoid are outlined in Scheme 1 and Scheme 2.



SCHEME 1. *McMurry coupling involving a pinacol intermediate.*



SCHEME 2. *McMurry coupling involving a metallocarbenoid intermediate.*

D. MODIFICATION

This reaction has been modified by the addition of pyridine[5s] or a substoichiometric amount of iodine[7f] or arenes[14] to the reaction solution and by treatment of the titanium powder with chlorosilane.[7g]

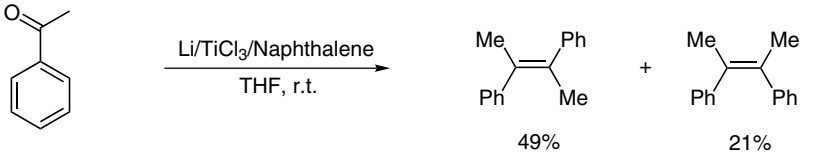
E. APPLICATIONS

This reaction has wide application in the preparation of olefins.

F. RELATED REACTIONS

This reaction is related to the *Barton-Kellogg Reaction.*

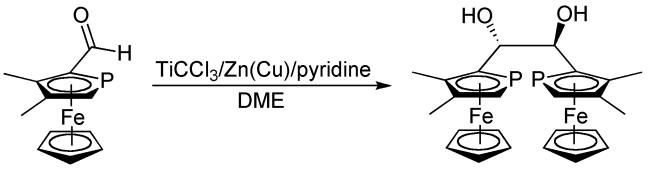
G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

To a stirred suspension of 0.23 g lithium (33 mmol) in 20 mL dry THF under argon was successively added 1.55 g $TiCl_3$ (10 mmol) in 20 mL THF and 0.32 g naphthalene (2.5 mmol) at room temperature. After the mixture was refluxed for 3 h, a thick dense homogeneous black mass of activated Ti species was obtained and was cooled to ambient temperature. To this solution was added 0.3 g acetophenone (2.5 mmol) in 5 mL THF under stirring. After the mixture was stirred at room temperature for 3 h, acetophenone disappeared as shown by TLC. Then the reaction mixture was diluted with hexane and quenched with

aqueous saturated NH_4Cl solution. The supernatant was passed through a bed of Celite. The eluent was removed by evaporation, and the naphthalene in the residue was separated by vacuum sublimation (50°C/10 mmHg). The remainder was subjected to preparative TLC (EtOAc/hexane, 5:95) to afford 70% 2,3-dimethylstilbene with an *E*/*Z* ratio of 7:3.



Reference 7e.

To a mixture of 1.09 g [$TiCl_3 \cdot DME_{1.5}$] (3.8 mmol), 1.076 g Zn(Cu) (15.1 mmol), and 0.31 mL pyridine (3.8 mmol) in 15 mL dry DME at 0°C was added 261.3 mg (*Rp*)-formylphosphaferrocene (1.05 mmol). The mixture was stirred at 0°C for 1 h and quenched by the addition of 10 mL saturated aqueous K_2CO_3. The mixture was filtered, and the solid residue was washed once with EtOAc. The organic layer was separated, and the aqueous phase was extracted once with EtOAc. The combined organic phases were dried over Na_2SO_4, filtered, and evaporated to dryness, giving an orange powder, which was further purified by chromatography on alumina with CH_2Cl_2/MeOH (100:1) to afford 67% *threo*-pinacol as an orange powder.

Other references related to the McMurry coupling are cited in the literature.[16]

Meerwein Arylation
(Meerwein Reaction)

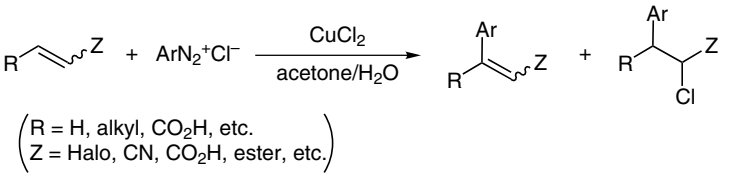
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meerwein et al. in 1939.[1] It is a copper salt-initiated reaction between an aryl diazonium salt and an alkene (or an alkyne, arene) that is activated by an electron-withdrawing group. Therefore, it is generally known as the Meerwein arylation[2,3] or Meerwein reaction.[2b,2f,2h,2j,4] The final products are the mixtures resulting from aryl addition and substitution.[2j] It is known that this reaction involves a single-electron transfer[2a] reductive cleavage of aryl diazonium salt by CuCl to form an aryl radical, which normally adds to the β-position of the activated alkenes to form a more stable radical.[2i,4bb] Subsequently, the new formed radical couples with a halide to form the addition product, or undergoes proton abstraction to give the substituted product. It is interesting that for the reaction between *p*-chlorobenzenediazonium chloride and maleic or fumaric acid, the resulting mixture of substituted fumaric acid and maleic acid are in an approximately ratio of 2:1, indicating the intermediate from aryl radical attack is unable to retain its configuration.[2j] It should be pointed out that a few factors strongly influence this reaction, such as the substrate, solvent, temperature, pH, and catalyst. On the one hand, the alkenes are generally activated by either the electron-withdrawing groups (e.g., halogens) or by conjugation with unsaturated functional groups (e.g., aryl, vinyl, cyano, and carbonyl groups).[2g] On the other hand, the aryl diazonium salt with an electron-donating group, especially at the *ortho*-position, often depresses the yield of the Meerwein reaction.[2g] Among the suitable solvents, acetone is the best followed by acetonitrile.[4dd] These unsaturated solvents may be involved in some fundamental way in this reaction.[4dd] To produce a high yield of product, this reaction is often carried out at a very low temperature[2e] in a buffer with pH regulated between 2 and 4.[4dd] At low pH, the competition from that *Sandmeyer Reaction* of the aryl diazonium salt becomes important, whereas at high pH, various side reactions start to take place to form resinous products.[4dd] Although zinc, cadmium, and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

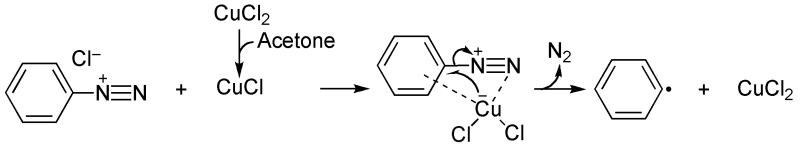
mercuric salts as well as copper powder have shown certain levels of catalytic activity, cupric chloride is the most effective catalyst.[3f] However, with increasing cupric salt concentration, the corresponding yield of the reaction decreases.[4bb] Overall, this reaction is best carried out in 65:35 acetone/water (v/v) at 0–25°C in the presence of 1–2 mol % $CuCl_2$, 2 eq. of LiCl, and an excess amount of alkene at pH ~ 2 under an oxygen-free atmosphere; CaO rather than NaOAc is added in some cases to neutralize the generated HCl.[2e] This reaction so far has been used to react with vinyl ferrocene,[2d] fluorinated olefins,[2g] benzene,[4cc] nitrobenzene[4cc] and chlorobenzene.[4cc] In addition, the reaction with vinyl sulfones forms α-halo-β-arylsulfones;[2i] likewise, the reaction with anthracene yields 9-aryl and 9,10-diaryl anthracenes;[2h] and the reaction with vinyl acetate or vinyl bromide forms 6- and 4-substituted indoles,[2e] respectively. Furthermore, this reaction has been modified to generate the aryldiazonium salt from arylamine and alkylnitrite.[2f] The ionic analogue of Meerwein arylation has been conducted photochemically by irradiation of aryl halide or diazonium salt with alkene present.[2a,2b]

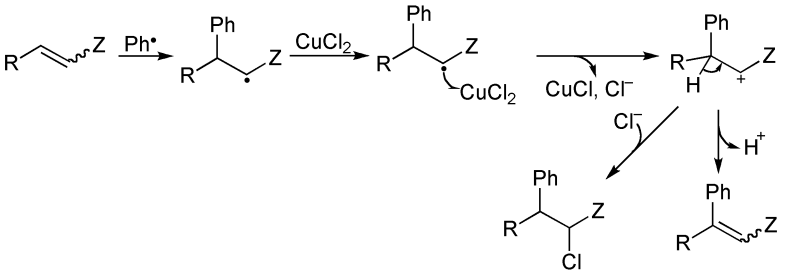
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is known that cupric chloride can be reduced by acetone to cuprous chloride,[2h] thus a novel mechanism is proposed here by which cuprous chloride can form a coordination complex in which the cuprous atom not only receives two pairs of electrons from nitrogen and chloride but also donates an electron pair to an electron-deficient aromatic ring, attaching to a strong electron-withdrawing diazo group. Single-electron transfer from a cuprous atom to an aromatic ring, and concomitant evolving nitrogen generates the aryl radical; at the same time, cuprous chloride is oxidized to cupric chloride again. The addition of an aryl radical to an electron-deficient alkene produces a new radical, which is then oxidized by cupric chloride to form carbocation and cuprous chloride. The coupling of a carbocation with chloride results in the addition product, whereas the β-elimination of a proton from carbocation yields the aryl-substituted product. The details of the mechanism are outlined here.





D. MODIFICATION

This reaction has been modified by using alkyl nitrite to produce the aryldiazonium salt.[2f] In addition, an ionic analogue of Meerwein arylation has been developed in which an aryl cation is generated photochemically.[2a,2b]

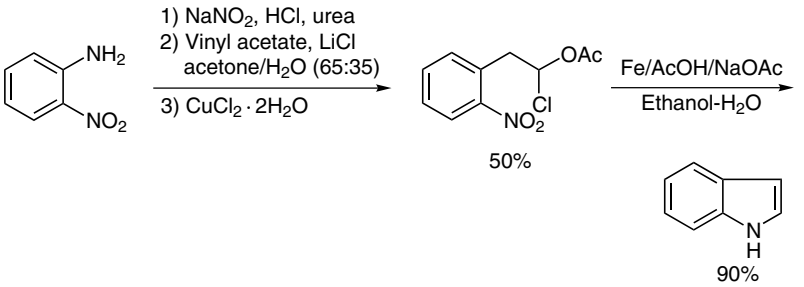
E. APPLICATIONS

This reaction has general application in the preparation of substituted styrene derivatives and aryl derivatives, especially for substituted indoles that are difficult to make by the traditional *Fischer Indole Synthesis*.[2e]

F. RELATED REACTIONS

This reaction is related to the *Sandmeyer Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2e.

2-Nitroaniline hydrochloride, prepared by heating a mixture of 1.38 g 2-nitroaniline (10.0 mol) and 2.50 mL conc. HCl (12 M, 30.0 mmol) for several minutes, was cooled to −5°C in an ice-salt bath, and a 3-mL cold aqueous solution of 725 mg $NaNO_2$ (10.5 mmol) was added over 15 min under stirring, while the temperature of the mixture was held between −5° and 2°C. The mixture was stirred for an additional 15 min, and 30 mg urea (0.60 mmol) in 5 mL cold water was added. This cold solution was added over 10 min to a stirred mixture

of 2.77 mL vinyl acetate (30.0 mmol) and 0.85 g LiCl (20.0 mmol) in 50 mL 65:35 (v/v) acetone/water in a 100-mL two-necked flask fitted with a gas bubbler that was cooled to −5°C under an atmosphere of argon. A cold solution of 0.26 g $CuCl_2 \cdot 2H_2O$ (1.5 mmol) in 5 mL water was then added over 10 min, and the evolution of nitrogen commenced. The temperature of the reaction mixture was held between 3° and 10°C for 2 h and then warmed to room temperature over 2 h. After an additional 2 h, nitrogen evolution had ceased, and acetone was evaporated. The reaction mixture was poured into 50 mL water and extracted with dichloromethane (3 × 30 mL). The combined extracts were washed successively with water and brine and dried over anhydrous magnesium sulfate. Evaporation of the solvent and purification by flash column chromatography in 70 g silica gel (35% dichloromethane in hexanes) gave 1.21 g 1-acetoxy-1-chloro-2-(2-nitrophenyl)ethane as a light yellow oil, in a yield of 50%.

In a 250-mL one-necked flask, fitted with a reflux condenser, were placed 1.21 g l-acetoxy-l-chloro-2-(2-nitrophenyl)ethane (5.00 mmol), 0.98 g 200 mesh iron powder (17.5 mmol), 2.10 g acetic acid (35.0 mmol), 0.68 g sodium acetate dihydrate (5.0 mmol), and 100 mL 80:20 (v/v) ethanol/water. The mixture was refluxed for 2 h under an atmosphere of argon. The reaction mixture was cooled, the ethanol was evaporated, and the residue was extracted with dichloromethane (3 × 30 mL). The combined extracts were washed successively with water and brine and dried over potassium carbonate. Evaporation of the solvent and purification by flash column chromatography on 50 g silica gel (dichloromethane /hexanes, 50:50) gave 0.53 g indole, in a yield of 90%, m.p. 52–53°C.

Other references related to the Meerwein arylation are cited in the literature.[5]

Meerwein-Ponndorf-Verley Reduction

(Meerwein-Ponndorf-Verley Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported concurrently by Meerwein and Schmidt[1] and Verley[2] in 1925, and by Ponndorf[3] in 1926, respectively. It is an aluminum alkoxide-catalyzed reduction of carbonyl compounds (ketones and aldehydes) to corresponding alcohols using another alcohol (e.g., isopropanol) as the reducing agent or hydride source. Therefore, it is generally known as the Meerwein-Ponndorf-Verley reduction (MPV)[4,5] or Meerwein-Ponndorf-Verley reaction.[6] Occasionally, it is also referred to as the Meerwein-Ponndorf reduction,[7] Meerwein-Ponndorf reaction,[8] or Meerwein-Schmidt-Ponndorf-Verley reaction.[9] About 12 years later, Oppenauer reported the reversion of this reaction in which alcohols were reversely oxidized into carbonyl compounds.[10] Since then, the interchanges between carbonyl compounds and alcohols in the presence of aluminum alkoxide are generally called the Meerwein-Ponndorf-Oppenauer-Verley reduction[11] or Meerwein-Ponndorf-Verley-Oppenauer reaction.[4e,4k,6e,11,12]

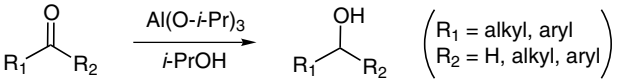
The formation of equilibrium between carbonyl compounds and alcohols is general for this reaction, except for the reduction of trifluoromethyl phenyl ketone.[13] The Meerwein-Ponndorf-Verley reduction has advantages of chemoselectivity, mild reaction conditions, operational simplicity, low cost, and scalability.[4a,14] In addition, this reaction does not affect other double bonds or triple bonds as well as other enolizable carbonyl compounds (e.g., β-keto ester, β-diketone). The catalysts suitable for this reaction include aluminum alkoxide and some transition-metal alkoxides (e.g., zirconium,[4g,4h,15] iron,[15a]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

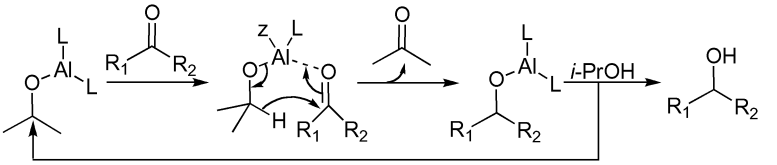
titanium,[4d] and lanthanide[4f]), which are used as homogenous catalysts; in addition, Al-, Ti- and Sn-β zeolites[4d] are also found to be efficient catalysts for this reduction. It is known that this reaction involves the following steps: (*a*) coordination of a carbonyl compound to the metal atom of the alkoxide catalyst, typically Al(*O*-*i*-Pr)$_3$, to increase the positive character of the carbonyl group;[16] (*b*) internal hydride transfer from an alkoxide ligand to the carbonyl group coordinating to the metal atom through a six-membered transition state,[6e,9,11,15a,16,17] to generate a new alkoxide ligand and carbonyl compound; and (*c*) dissociation of the new carbonyl compound and alcoholysis of the mixed metal alkoxide to release the alcohol and regenerate the catalyst.[15a] The increased positive character of the carbonyl compound during coordination is supported by the Hammett ρ constant of 1.296 for the equilibrium between substituted benzophenones and the secondary alcohol,[4l] and the internal hydride transfer is evidenced by the fact that such transfer takes place in the absence of any alcohol.[6m] The alcoholysis is found to be the rate-determining step.[18] The advantage of using Al(*O*-*i*-Pr)$_3$ as a catalyst is that acetone formed can easily be removed by heating to shift the equilibrium toward the alcohol,[18] although the removal of acetone is not necessary for most reactions.[19] It has been reported that when an acid in half equivalent amount of aluminum was added, the reduction rate was remarkably enhanced, especially when CF_3CO_2H was added.[4k] It is interesting that the reduction of carbonyl compounds by lithium alkoxide involves a radical intermediate.[4j]

Because the reaction often forms equilibrium, it has been modified to enhance the yields of reduction by using freshly prepared nonaggregated aluminum alkoxide[9] or by a slow addition of carbonyl compounds into the aluminum alkoxide solution.[19] In addition, this reaction has been modified to reduce carbonyl compounds enantioselectively by application of a chiral diol as auxiliary (e.g., 1,2:5,6-di-*O*-isopropylidene-D-mannitol,[4g,20] enantiopure 2,2′-dihydroxy-1,1′-binaphthyl[9]) or a chiral samarium catalyst.[4i,21] Moreover, the tandem Michael addition–MPV reduction and subsequent desulfurization can convert α,β-unsaturated ketones into saturated secondary alcohols or allyl alcohols in high enantioselectivity (e.g., 95% e.e.).[22] It is interesting that the reduction of α-amino aromatic ketone by catalytic Al(*O*-*i*-Pr)$_3$ resulted in an alcohol with high *anti* selectivity through the chelation of nitrogen to aluminum, whereas a similar reduction of an α-hydroxy ketone produced the alcohol with high *syn* selectivity.[4a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been extensively modified by the application of different catalysts or the addition of a chiral ligand as described in Section A.

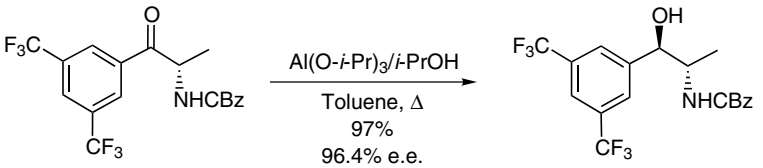
E. APPLICATIONS

This reaction has wide application in the reduction of carbonyl compounds.

F. RELATED REACTIONS

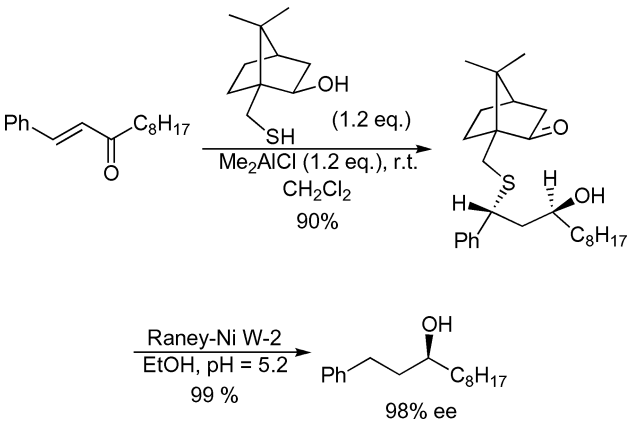
This reaction is closely related to the *Oppenauer Oxidation* as well as *Cannizzaro Reaction* and *Tishchenko Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

A mixture of 267 mg (S)-α'-*N*-carboxylbenylamino-ethyl-3,5-ditrifluoromethyl-phenylketone (0.637 mmol, 1 eq.), 26 mg Al(*O*-*i*-Pr)$_3$ (0.2 eq.), and 0.536 mL *i*-PrOH (11 eq.) in 0.8 mL toluene (1.3 mL/mmol) was heated at 50°C under nitrogen for 15 h. The reaction was cooled and quenched with 4 mL 1 N HCl and 4 mL EtOAc. The organic layer was washed with 4 mL water and concentrated. The crude product was further purified by a hexane tituration to give 260 mg (1*R*,2*S*)-1-(3′,5′-bistrifluoromethylphenyl)-2-benzyloxycarbonylamino-1-propanol as a white solid, in a yield of 97% with > 99% enantiomeric excess (ChiralPak AD-H (4.6 × 150 mm) column, 0.1:10:90 of TFA/*i*-PrOH/heptane, 1.5 mL/min at 30°C; retention times for desired 1*R*,2*S* enantiomers: 2.6 min and for undesired: 4.7 min, m.p., 141–142°C.



Reference 5p.

To a 20 mL dichloromethane solution of 100 mg (-)-10-mercaptoisoborneol (0.54 mmol) was added 0.57 mL 0.94 M dimethylaluminum chloride (0.55 mmol) dropwise at room temperature. After the mixture was stirred for 1 h, a 5 mL dichloromethane solution of 2-*trans*-nanoyl styrene (0.45 mmol) was added dropwise, and the mixture was stirred for 12 h at room temperature. The reaction mixture was quenched with a saturated NH_4Cl solution, and the aqueous layer was extracted with CH_2Cl_2 (3×50 mL). The combined organic layer was washed with brine, dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by column chromatography (hexane/EtOAc, 10:1 to 7:1) to afford (3S)-1-[(1S,4R)-2-oxobornane-10-sulfenyl]-1-phenyl-3-undecanol as a colorless oil, in a yield of 90%. To the ethanol solution of the compound was added 2 mL Raney Ni W-2 suspension in ethanol, and the mixture was stirred for 40 min at room temperature. The mixture was filtered with Celite and concentrated in vacuo. A preparative TLC afforded 99% of alcohol with 98% e.e.

Other references related to the Meerwein-Ponndorf-Verley reduction are cited in the literature. [23]

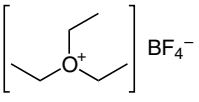
(Meerwein's Reagent)

A. GENERAL DESCRIPTION OF THE REACTION

This salt was first reported by Meerwein et al. in 1937.[1] Generally speaking, any combination of a trialkyloxonium[2] with a strong Lewis acid could be called Meerwein's salt,[3] such as triethyloxonium hexachloroantimonate (V) ($Et_3O^+SbCl_6^-$),[4] and triethyloxonium hexafluorophosphate ($Et_3O^+PF_6^-$).[5] However, Meerwein's salt, or known as Meerwein's reagent,[6] specifically means triethyloxonium tetrafluoroborate ($Et_3O^+BF_4^-$),[3a,6e,7] which can easily be prepared from diethyl ether, BF_3, and epichlorohydrin.[8] This reagent has been widely used as an alkylating agent for heteroatom nucleophiles, such as amides, lactams[9] (for *O*-alkylation to form amide acetals[7f,9b]), amines (for *N*-alkylation until quaternization),[7e] α-pyridones (for both *N*- and *O*-alkylation),[10] thiocarbonyl compounds (for *S*-alkylation),[7b] etc. In the presence of a superacid,[2] especially the magic acid ($FSO_3H + SbF_5$),[11] Meerwein's salt can even react with a carbon nucleophile, such as benzene and toluene. It should be pointed out that triethyloxonium hexachloroantimonate has been identified as the only Meerwein's salt used to prepare crystalline aromatic radical cations from any aromatic compounds with an oxidation potential <1.5 V.[4]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

No mechanism is needed for this reagent.

D. MODIFICATION

Other combinations of trialkyloxonium and Lewis acid are added to this group of salts, including triethyloxonium hexachloroantimonate ($Et_3O^+SbCl_6^-$)[4] and triethyloxonium hexafluorophosphate ($Et_3O^+PF_6^-$).[5]

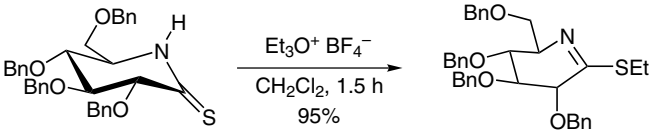
E. APPLICATIONS

This reagent has been widely used as an alkylating agent.

F. RELATED REACTIONS

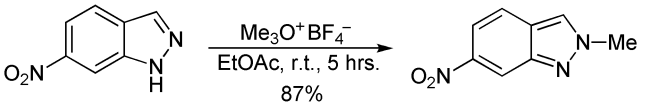
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7b.

To a solution of 300 mg gluconothiolactam (0.54 mmol) in 13 mL dry CH_2Cl_2 at 0°C was added 112 mg triethyloxonium tetrafluoroborate (0.59 mmol). The mixture was stirred at 0°C for 1.5 h, then the solvent was removed under vacuum to afford 298 mg ethyl 2,3,4,6-tetra-*O*-benzyl-D-gluconoiminothioether, in a yield of 95%.



Reference 12.

To a stirred mixture of 163 mg 6-nitro-1*H*indazole (1 mmol) and 3 mL EtOAc was added 192 mg trimethyloxonium tetrafluoroborate (1.3 mmol). The mixture was stirred at room temperature for 5 h under nitrogen and then diluted with 20 mL EtOAc and washed with 20 mL saturated $NaHCO_3$ solution. The organic layer was separated, and the aqueous layer was extracted with EtOAc (20 mL × 2). The combined organic layers were dried over anhydrous $MgSO_4$, filtered, and evaporated. The residue was purified by column

chromatography (1:1, EtOAc/hexane) to afford 154 mg 2-methyl-6-nitro-2*H*-indazole as a yellow solid, in a yield of 87%, mp 158–160°C (EtOAc).

Other references related to the Meerwein's salt are cited in the literature.[13]

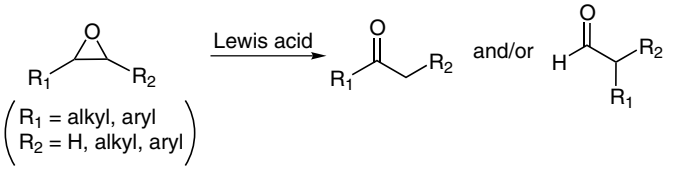
Meinwald Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meinwald in 1963.[1] It is a Lewis acid-promoted conversion of epoxide to carbonyl compounds (ketones or aldehydes).[2] Therefore, it is generally known as the Meinwald rearrangement.[2,3] The Lewis acids used for this reaction include $BF_3{\cdot}Et_2O$,[4] $ZnBr_2$,[3b] $MgBr_2$,[4] $InCl_3$,[5] and methylaluminium bis(4-bromo-2, 6-di-*tert*-butylphenoxide).[6] In addition, protic acid is also found to be suitable for this rearrangement.[3b] It should be pointed out that this reaction is generally carried out under anhydrous conditions in the presence of a stoichiometric or an excess amount of Lewis acid with protection by an inert atmosphere.[2] The nature of the products is determined by the migratory aptitude of the substituents attached to the epoxide moiety, the solvent and Lewis acid used. Recently, this reaction was carried out using a catalytic amount of Lewis acid.[2,7]

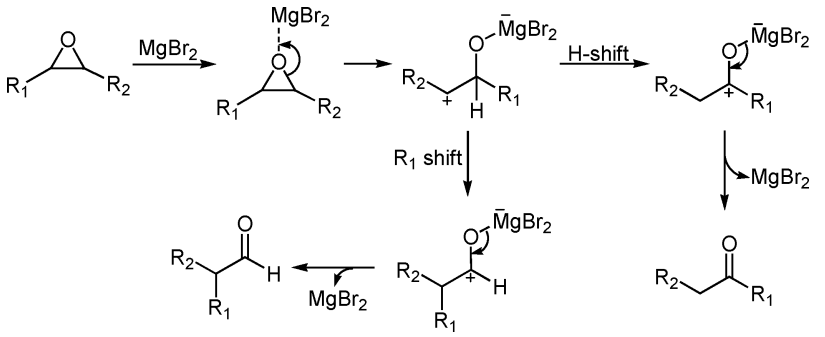
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Demonstrated below is the reaction mechanism using the Lewis acid $MgBr_2$.



D. MODIFICATION

This reaction has been modified to take place in the presence of a catalytic amount of Lewis acid.[2,7]

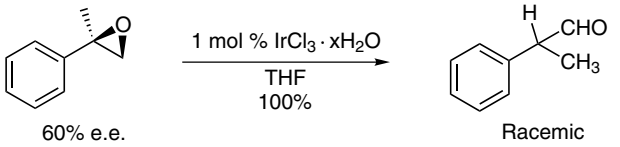
E. APPLICATIONS

This reaction has general application in the conversion of epoxides into aldehydes and ketones.

F. RELATED REACTIONS

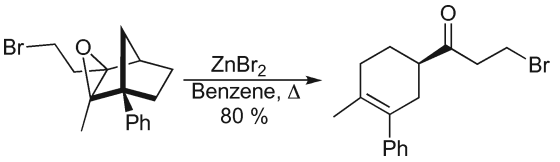
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To 1 mL THF solution containing 1 mg $IrCl_3 \cdot xH_2O$ (3.35×10^{-3} mmol) was added 45 mg (*R*)-α-methylstyrene oxide (0.335 mmol). The reaction mixture was stirred at 50°C and monitored by GC. After about 2 h, the reaction completed, and the solvent was removed to afford 100% racemic α-methylphenylacetaldehyde.



Reference 3b.

To a solution of 35 mg epoxide (0.11 mmol) in 3 mL benzene was added 117 mg anhydrous zinc bromide (0.52 mmol), and the mixture was stirred at 70 °C for ∼10 min. After cooling to room temperature, the mixture was diluted with ether, washed with water and brine, and dried over $MgSO_4$. Upon removal of the solvent, the residue was purified by column chromatography to afford 27 mg ketone as a colorless oil, in a yield of 80%.

Other references related to Meinwald rearrangement are cited in the literature.[8]

Meisenheimer Complexes
(Anionic σ Complexes)

A. GENERAL DESCRIPTION OF THE REACTION

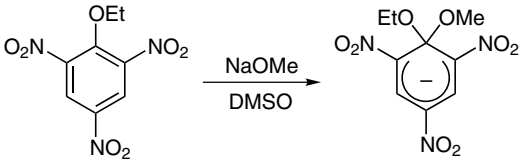
Although this type of structure was first reported by Jackson et al. in 1900 for the reaction between picryl ether and potassium alkoxide,[1] it was Meisenheimer who actually isolated and characterized the structure of such molecule for the first time in 1902.[2] Since then, the stable or transient anionic σ complexes[3] formed from electron-deficient aromatic compounds and a variety of organic and inorganic bases[4] are generally called the Meisenheimer complexes.[5] Occasionally, this type of molecule is also referred to as the Meisenheimer adducts,[6] Meisenheimer compounds,[7] Meisenheimer σ-adducts,[8] Meisenheimer σ complexes,[9] Jackson-Meisenheimer adducts,[10] or Jackson-Meisenheimer complexes.[5z,11]

The Meisenheimer complexes are the intermediates of most nucleophilic aromatic substitution (S_NAr) reactions,[5c,5z,12] which consist of two-step mechanisms:[5z,13] the formation of Meisenheimer complexes and the expelling of a leaving group to resume the aromaticity of the products. It is known that the aprotic solvent,[5z,14] especially DMSO, is best for the formation of such σ complexes,[15] and the addition of a nucleophile to the aromatic ring is the rate-limiting step.[13a,15] In general, only aromatic compounds that contain at least one strong electron-withdrawing group can form Meisenheimer complexes,[16] and the activating groups can be nitro,[5i,17] cyano,[18] carbonyl,[19] sulfonyl,[19] fluoroalkyl,[19] and many different heterocycles (including oxadiazole,[19,20] triazole,[19] and benzazole[19]). These activating groups have two obvious features during the formation of the Meisenheimer complexes: to reduce the electron density on the aromatic ring and to stabilize the formed complexes after the addition of the nucleophiles.[19] The nucleophiles involved in the formation of the Meisenheimer complexes can be categorized as *H*-, *C*-, *O*-, *N*- and *S*-nucleophiles, which attack the electron-deficient aromatics through the corresponding atoms. Among the Meisenheimer complexes studied so far, almost half the complexes are generated

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

through the attack of *O*-nuclephiles, primarily the alkoxide nucleophiles,[5z] except for a few cases of aryloxide nucleophiles.[12c] The *C*-nucleophiles known include the carbanions generated from nitromethanes[21] and carbonyl compounds (ketones and aldehydes) with α-hydrogen;[12b] the *N*-nucleophiles are primary and secondary amines[5c,22] and anilines.[23] Specifically, hydride-Meisenheimer complexes from *H*-nucleophiles are generated from enzymatic reduction and are important intermediates for the biodegradation of high explosives (e.g., TNT).[17a,17c,17e] In addition, some bidentate nucleophiles, such as enolate and phenoxide, can add to the aromatic ring through either an *O*- or a *C*-attack,[12b,14a] and pyrrolide and indolide anions can function as either *C*- or *N*-nucleophiles.[14a] It is interesting that anion generated from solvent DMSO (dimsyl dianion) is a tridentate, attacking the aromatic ring through the *O*-, *S*-, and *C*- atom.[14a] On the other hand, even though it has been predicted that the *O*-attack is preferred over *C*-attack for the enolate nucleophiles,[24] most of the Meisenheimer complexes from enolates are actually the *C*-attack ones. This is because that the *O*-attack is a kinetic controlled process whereas *C*-attack of enolate is under thermodynamical control.[12b] The formation of σ complexes from the *C*-attack of enolate, known as the *Janovsky Reaction*, has been widely applied in pharmaceutical tests.[12b] Besides the benzene derivatives, other substituted aromatics such as naphthalenes[5y,13b] and phenanthrenes[25] can also form corresponding Meisenheimer complexes. Kinetically, the nucleophile would preferentially add to the *meta*-position of the leaving group; in contrast, for the case of 2,4,6-trinitrofluorobenzene, the dominant Meisenheimer complex is the one formed by addition at position 1. This regioselectivity is referred to as K3T1 ("kinetic preference for reaction at the 3-position but thermodynamic preference for formation of the C-1 adduct").[12a] The formation of the Meisenheimer complexes has been used in the Sanger protein sequence[5c] as well as in many other synthetic applications.[17d,19,20,25] The formation of the Meisenheimer complexes has been modified using a micellar catalyst[13a] or an electrochemical reduction via a charge-transfer complex between trinitrofluorenone and electron-donating molecules (e.g., pyrrole, indole, and carbazole).[5i]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

N/A

D. MODIFICATION

The formation of the Meisenheimer complexes has been modified to take place under electrochemical reduction conditions through a charge-transfer complex between electron-deficient aromatics and electron-donative heterocycles.[5i]

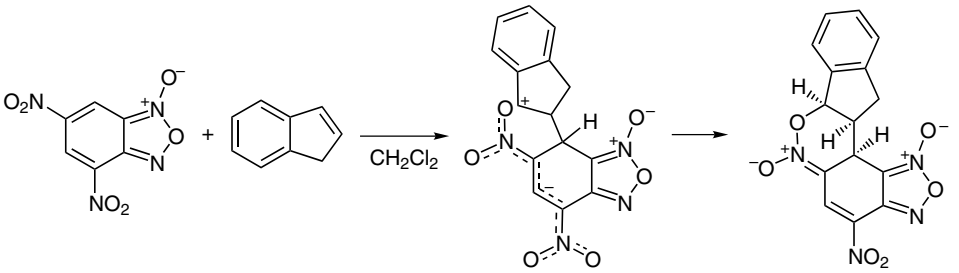
E. APPLICATIONS

The Meisenheimer complexes have been widely observed in nucleophilic aromatic substitution reactions.

F. RELATED REACTIONS

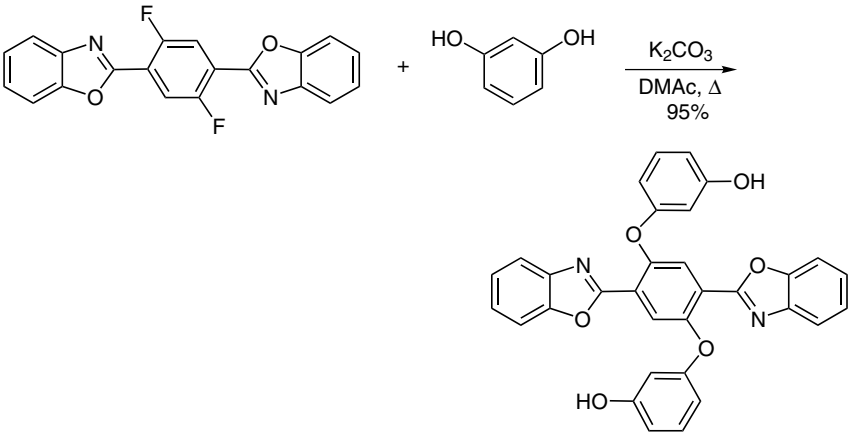
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 26.

To a stirred solution of 128 mg indene in 2 mL CH_2Cl_2 was added 226 mg 4,6-dinitrobenzofuroxan (1 mmol) at room temperature. The solution turned orange, and some precipitate was formed after 2 h. After 24 h at room temperature, the resulting yellow crystals were filtered, washed with diethyl ether, and dried over P_2O_5 under vacuum to afford the oxazine *N*-oxide, m.p. 165°C (dec.)



Reference 19.

To a three-necked reaction flask equipped with a nitrogen inlet and Dean-Stark trap fitted with a condenser and a nitrogen outlet, were added 0.576 g K_2CO_3 (4.17 mmol) and 0.410 g *m*-cresol (3.79 mmol) in a mixture of 8 mL DMAc and 12 mL toluene under stirring. The mixture was heated to 150°C to remove moisture via an azeotrope with toluene. After 4–6 h, the mixture was dehydrated and cooled to $\sim$ 60°C, then 0.6 g 1,4-bis(2-benzoxazolyl)-2,5-difluorobenzene (1.72 mmol) in 8 mL DMAc was added and stirred at 155°C for 20 h. The mixture was poured into 250 mL water containing 1% AcOH, and the yellow precipitate was filtered, washed, and dried at 80°C under vacuum for 24 h. The crude product was purified by flash column chromatography (CH_2Cl_2) to afford 95% 1,4-bis(2-benzoxazolyl)-2,5-bis(3-methylphenoxy)benzene as a light yellow crystalline, m.p., 274°C (DSC).

Other references related to the Meisenheimer complexes are cited in the literature.[27]

Meisenheimer Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meisenheimer in 1919.[1] It is a thermal transformation of tertiary aliphatic amine oxides (tertiary *N*-oxides) into substituted *N*-alkoxylamines[2] or *N*-hydroxylamines,[3] and is generally known as the Meisenheimer rearrangement.[2–4] Occasionally, it is also referred to as the Meisenheimer *N*-oxide rearrangement,[5] Meisenheimer reaction,[6] or Meisenheimer transformation.[7] In addition, depending on the location of the migrating group attached, this reaction is specifically called [1,2]-Meisenheimer rearrangement,[8] or [2,3]-Meisenheimer rearrangement[9] (or [2,3]-sigmatropic Meisenheimer rearrangement[10]). It is known that this reaction occurs through a radical mechanism involving a homolytic cleavage of a nitrogen-carbon bond and the migration of an alkyl group to form the *N*-alkoxylamine.[3c,4i,4pp] The migrating entity should be capable of stabilizing the generated radical, although a case of unlikely migration of a tertiary group has been reported (i.e., 3-homoadamantyl[3c]). However, this reaction does not apply to aromatic *N*-oxides.[2] It has been found that the aryl allyl *N*-oxides undergo a [2,3]-sigmatropic rearrangement through a cyclic transition state.[4m] In contrast, the rearrangement of *N*-propargylmorpholine *N*-oxide depends on the nature of the solvent, although such rearrangement is reported to take place through a similar cyclic transition state.[3a] For example, in aprotic solvents, *N*-propargylmorpholine *N*-oxide undergoes a regular Meisenheimer rearrangement; whereas in protic solvents (e.g., C_1-C_4 alcohols), the rate of Meisenheimer rearrangement is reduced, and the protonation results in the formation of an enaminoaldehyde.[3a] This reaction has been used to differentiate the *N*-oxides from isomerically hydroxylated metabolites through mass spectroscopy and to determine the position of *N*-oxides.[2] In addition, this reaction has been used for both the degradation of polyamines,[4d]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

and the living radical polymerization to produce a polymer with a narrow molecular weight distribution.[4i]

B. GENERAL REACTION SCHEME

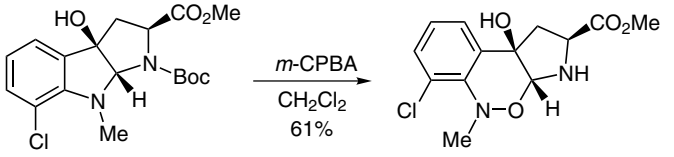
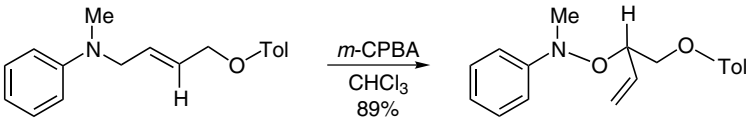
G. CITED EXPERIMENTAL EXAMPLES



Reference 4e.

To a solution of 100 mg methyl (2*S*,3a*R*,8a*S*)-7-chloro-3a-hydroxy-8-methyl-3,3a,8,8a-tetrahydro-2*H*-pyrrolo[2,3-*b*]indole-1,2-dicarboxylate (0.35 mmol) in 2 mL CH_2Cl_2 was added 61 mg *m*-CPBA (0.33 mmol, 1.0 eq.) in 1 mL CH_2Cl_2 dropwise under stirring at 0°C. After 30 min, an additional 61 mg *m*-CPBA (0.35 mmol, 1.0 eq.) in 1 mL CH_2Cl_2 was added dropwise, and stirring was continued at 0°C for a further 30 min. The solution was diluted with 5 mL CH_2Cl_2, washed with 10% aqueous Na_2CO_3, dried over Na_2SO_4, and rotary evaporated. HCl in EtOAc (1 M, 5 mL) was added with stirring to the residue. After 1 h, the solution was concentrated under reduced pressure, and saturated aqueous $NaHCO_3$ was added to adjust the pH to 8. The mixture was extracted with CH_2Cl_2 (2×10 mL), and the organic layer was dried over Na_2SO_4. Rotary evaporation and chromatography (hexanes/EtOAc, 1:1) gave 64 mg methyl (2*S*,3a*R*,9b*R*)-6-chloro-9b-hydroxy-5-methyl-1,2,3,3a,5,9b-hexahydro-4-oxa-3,5-diazacyclopenta[*a*]naphthalene-2-carboxylate as a yellow oil, in a yield of 61%, $R_f = 0.13$ (hexanes/EtOAc, 1:1).



Reference 4m.

To a well-stirred solution of 10 mmol tertiary amine in 50 mL $CHCl_3$, was added 3.44 g *m*-CPBA (10 mmol, 50%) in 50 mL $CHCl_3$ at 0–5°C over a period of 20 min. The reaction mixture was stirred for additional 10 h. The reaction mixture was washed with an aqueous solution of K_2CO_3 and dried over Na_2SO_4. The solvent was removed, and the residue was purified by column chromatography over silica gel with petroleum ether to afford 89% *O*-[2-(2-methylbut-3-enyl)]-*N*-methyl-*N*-phenylhydroxylamine as a viscous liquid.

Other references related to the Meisenheimer rearrangement are cited in the literature.[11]

Menke Nitration

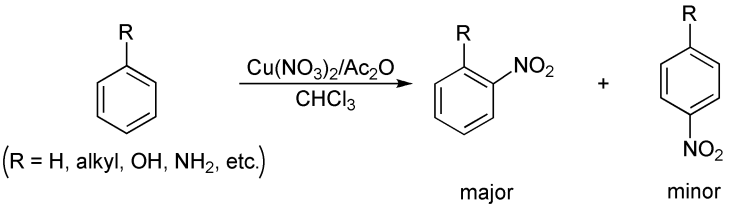
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Menke in 1925.[1] It is a nitration of aromatic compounds with cupric nitrate and acetic anhydride. Therefore, it is known as the Menke nitration.[2] This reaction is generally suitable for the aromatics with an electron-donating substituent (activating group), such as amino, hydroxyl, and gives the highest ratio of *ortho*-product.[3] For example, the nitration of phenol with cupric nitrate in acetic acid yields only *othro*-nitrophenol, whereas picric acid is produced in acetic anhydride;[4] likewise, the nitration of aniline gives only *ortho*-nitroaniline.[4] Under the Menke condition, it has been found that the nitrate salts of iron,[4,5] manganese,[4] cobalt,[4,5] nickel,[4,5] copper,[4,5] mercury,[4] lithium,[4] aluminum,[5] cerium,[5] and uranium[5] are all effective for the nitration of aromatics. Among these inorganic nitrates, cupric nitrate is the most effective reagent.[4] It is believed that under these conditions, diacetyl *ortho*-nitric acid and acetyl nitrate might be generated, which are efficient nitrating agents;[4–6] in addition, the excess of humidity would be scavenged by acetic anhydride.[7] Although chloroform is the mostly used solvent, other solvents, such as hexane, cyclohexane, nitromethane, acetonitrile, methylene chloride, and nitrobenzene are also suitable for this reaction.[6] It should be pointed out that the nitration rate is faster in the solvent with a higher dielectric constant than that of a lower dielectric constant.[6] The original protocol has been improved to use acidic monmorillonite clay supported cupric nitrate, known as "claycop" as the nitrating agent in acetic anhydride, so that toluene can be quantitatively converted into nitrotoluene isomers.[8] It is interesting that the application of a clay (e.g., H-ZSM-5 zeolite) impregnated with cupric nitrate or ferric nitrate—containing large number of active sites in the interior regions of the channels—produces > 90% of *para*-nitro isomer during nitration of toluene.[9] In addition, by the use of excess amounts of such claycop (e.g., 48-fold) and small amounts of fuming nitric acid, polynitrated aromatics

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

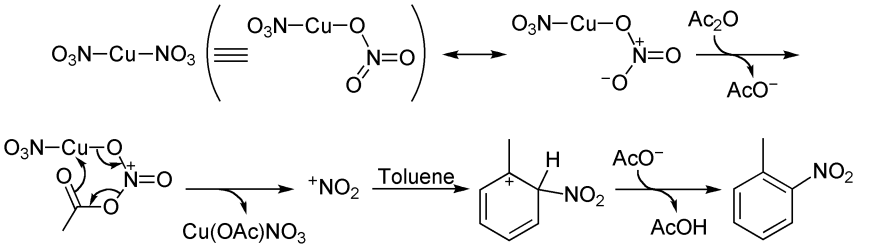
will be yielded. Under these conditions, not only the aromatics with an activating group will be nitrated but also those aromatics with deactivating groups, such as chlorobenzene and benzaldehyde, can be nitrated.[9] This reaction has been further extended to occur in trifluoroacetic anhydride to enhance the nitration yields.[6]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although it has been reported that diacetyl *ortho*-nitric acid and acetyl nitrate might be the nitrating agents, it is proposed here that the reaction of cupric nitrate and acetic anhydride yields the nitronium ion as the real nitration agent, which adds preferably at the *ortho*-position of the aromatic, resulting in the *ortho*-nitrated product, as shown by the example of toluene. This is because the newly generated carbocation is a tertiary carbocation, which is closest to the electron-donating group.



D. MODIFICATION

The acidic monmorillonite clay-supported cupric nitrate has been applied to improve the yield;[8] in addition, the application of cupric nitrate impregnated on H-ZSM-5 zeolite with a large number of internal active regions has altered the regioselectivity of nitration.[9] Further modifications have adapted the combination of cupric nitrate and trifluoroacetic anhydride as the nitrating agent.[6]

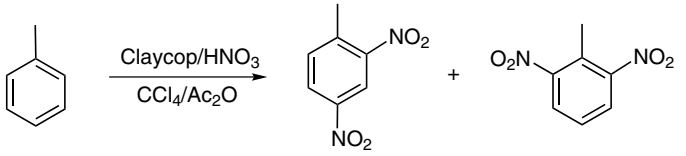
E. APPLICATIONS

This reaction has general application in the preparation of nitroaromatics with high *ortho*-selectivity.

F. RELATED REACTIONS

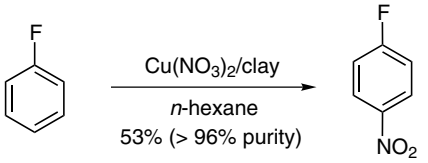
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a suspension of 4.8 g claycop in 30 mL CCl_4 and 15 mL acetic anhydride was added 1.07 mL toluene (10 mmol). The mixture was stirred vigorously at room temperature and followed by GLC. The reaction mixture was then cooled in an ice bath, and 7.5 mL fuming nitric acid was added dropwise. After the addition, the reaction mixture was kept at room temperature with vigorous stirring until completion (∼4 h) and then filtered. The filter cake was washed with CCl_4, and the combined organic portions were washed with water and dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by column chromatography to afford 95% dinitrotoluene with a 86:13 ratio of 2,4-dinitrotoluene to 2,6-dinitrotoluene.



Reference 10.

In a 1-L pear-shaped evaporating flask, were added 26 g cupric nitrate trihydrate and 400 mL acetone, and the mixture was vigorously stirred for ∼5 min. K10 clay (30 g) was then added, and stirring was continued for another 5 min. Then acetone was removed by rotary evaporation on a water bath at 50°C. After a dry solid crust adhered to the walls of the flask was flaked off with a spatula, and the rotary drying under vacuum was resumed for 30 min at the same temperature. This yielded the clay-supported cupric nitrate as a blue free-flowing powder.

To a solution of 0.96 g fluorobenzene (10 mmol) in 50 mL *n*-hexane was added 5 g clay-supported cupric nitrate and 9.4 mL acetic anhydride (100 mmol). The mixture was stirred vigorously at room temperature for 48 h, and then filtered under reduced pressure. The filter cake was washed with *n*-hexane, and the organic solvent was combined, dried, and evaporated. The residue was purified by silica gel column chromatography (cyclohexane/EtOAc, 9:1) to afford 53% nitrofluorobenzene, with 25:1 of *ortho*/*para* selectivity.

Menschutkin Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Menschutkin in 1890.[1] It is a synthesis of a quaternary ammonium salt from a tertiary amine and an alkylating agent and is generally known as the Menschutkin reaction.[2,3] Occasionally, it is also called the Menschutkin alkylation.[4] Essentially, this reaction is a type of nucleophilic substitution and can occur via either an S_N1 or an S_N2 mechanism, thus it is widely used as a model reaction to study the substituent and solvent effects on the reaction mechanism.[2a,2f,2g,2i] For example, the reactions of benzylic systems with pyridine and *N*,*N*-dimethylanilines have been found to take place through an S_N2 mechanism with looser cationic transition states when the benzylic systems bear electron-donating groups, whereas an S_N1 mechanism is dominant for a comparable reaction of benzylic systems carrying electron-withdrawing groups. However, such reactions between benzylic systems and aromatic tertiary amines actually undergo independent S_N1 and S_N2 simultaneously.[5] For comparison, the reaction between pyridine derivatives and chloromethyl alkyl ethers or sulfides proceeds the S_N1 mechanism.[2b] On the other hand, the reaction rate is very sensitive to the polarity of the solvent, which varies by orders of magnitude among the solvents with different dielectric constants.[2a] In general, the reaction is fast in the solvents of high dielectric constants.[2k] In addition, it has been found that the "catalytic effect of small amount of 'active' co-solvents dissolved in 'inert' solvent is much larger than" predicted on the basis of purely dielectric constants.[2g] This reaction is highly endothermic, with free energy change in the range of 103–105 Kcal/mol.[6]

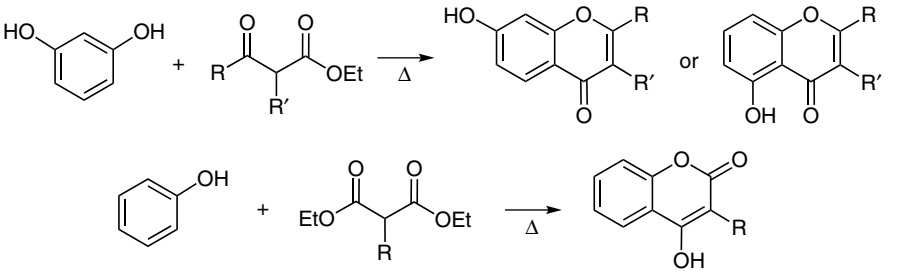
Mentzer Pyrone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mentzer et al. in 1946.[1] It is a synthesis of pyrone or flavone derivatives from the reaction between phenols and β-ketoesters[2] or malonates.[3] This reaction is normally carried out by cooking the mixture at high temperature for a long period.[2]

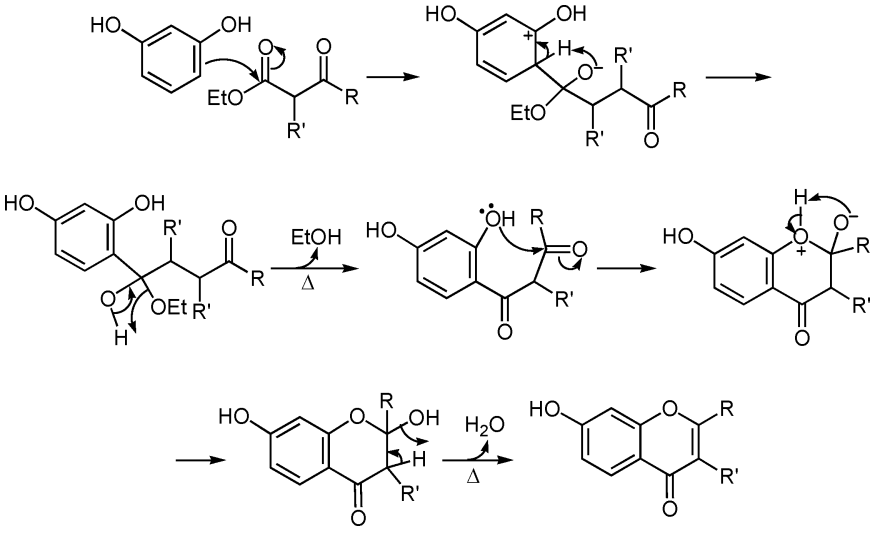
B. GENERAL REACTION SCHEME



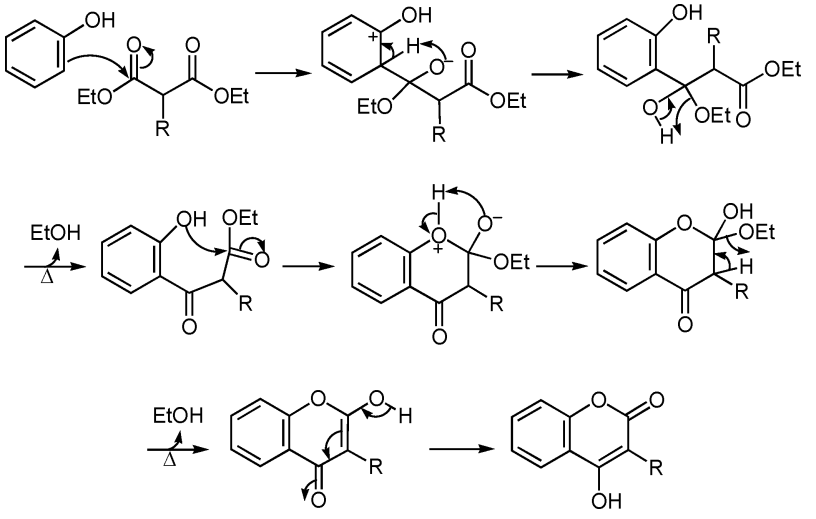
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism for the reaction between a phenol and a β-ketoester is demonstrated in Scheme 1, and the reaction between a phenol and a dialkyl malonate is outlined in Scheme 2.



SCHEME 1. *Reaction mechanism between phenol and β-ketoester.*



SCHEME 2. *Reaction mechanism between phenol and dialkyl malonate.*

D. MODIFICATION

This reaction has been modified to occur under microwave irradiation.[2]

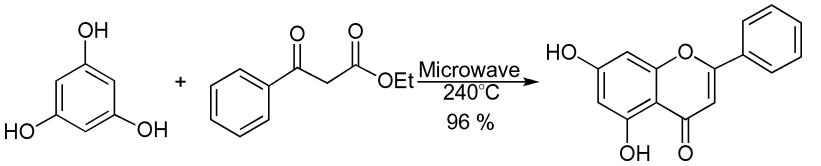
E. APPLICATIONS

This reaction can be used to prepare pyrone and flavone derivatives.

F. RELATED REACTIONS

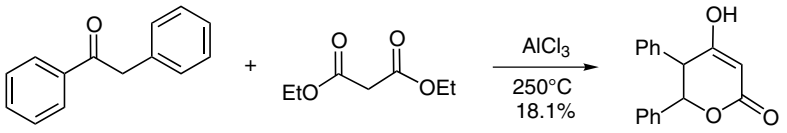
This reaction is related to the *Pechman Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

A mixture of 384 mg ethyl benzoyl acetate (2 mmol) and 126 mg phloroglucinol (1 mmol) was irradiated with microwaves (ETHOS D, Millestone, at 80% of a total output of 1000 W or with the temperature control set to 240°C) for 3 min. The crude was dissolved in 20 mL 10% aqueous NaOH solution and washed with Et_2O (2 × 20 mL). Then the aqueous layer was acidified with conc. HCl. The precipitate was filtered, washed with water, and vacuum dried to give 243 mg chrysin, in a yield of 96%, m.p., 288–290°C (dichloromethane-methanol).



Reference 3.

A mixture of 8.0 g diethyl malonate and 9.8 g deoxybenzoin in the presence of 500 mg anhydrous aluminum chloride was heated at 250°C for 1 h. The cold reaction mixture was poured onto water, and NaOH was added. The aqueous solution was washed with ether, and the aqueous layer was acidified with HCl. The aqueous acid solution was extracted with ether, and the organic layers were combined, dried over Na_2SO_4, and concentrated to afford 2.4 g 4-hydroxy-5,6-diphenyl-2-pyrone as an oil that solidified upon standing, in a yield of 18.1%. The solid was triturated with ether to remove soluble impurities and recrystallized from methanol to give a white solid, m.p. 187–188°C.

Other references related to the Mentzer pyrone synthesis are cited in the literature.[4]

Merrifield Solid-Phase Peptide Synthesis

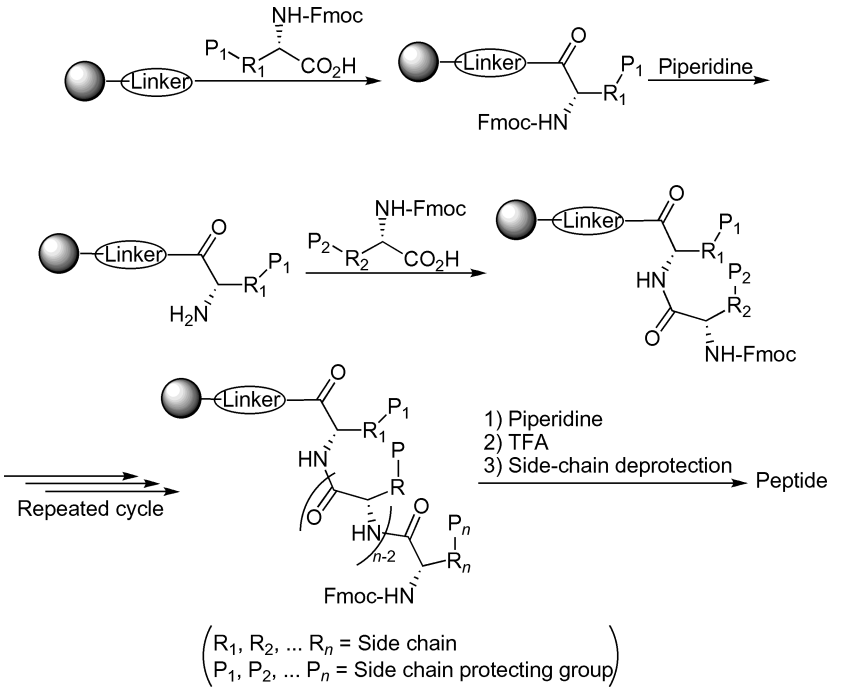
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Merrifield in 1963.[1] It is a synthesis of peptides and small proteins in which the resinous polymer supported amino acid and succeeding peptide repeatedly reacts with *N*-protected amino acids followed by deprotection until the desired peptide or protein is assembled. Therefore, it is generally referred to as the Merrifield solid-phase peptide synthesis[2] (or SPPS[3]), and the polymeric resin—that is, 1% divinylbenzene cross-linked polystyrene resin—is known as the Merrified resin.[4] This reaction, essentially because of the macroscopical insolubility of the resin in the chosen solvent,[2d] has made peptide synthesis economical, simple, and rapid, which can be automatically carried out due to its repetitive, stepwise nature.[2d] The initial protocol using *N*-benzyloxycarbonyl-protected amino acid has been improved and developed into two complementary methods. In the first method,[3] the *N*-*t*-butyloxycarbonyl (Boc) protected amino acid is attached to the solid phase via a linker moiety, the Boc group is then cleaved by trifluoroacetic acid, and the resin is neutralized by a tertiary amine; subsequently, the second *N*-Boc amino acid is added and linked to the resin in the presence of an activator. After the reaction completes, the resin containing the peptide is washed thoroughly with solvent to remove the unreacted material, and Boc is removed again in a similar manner to start a new coupling cycle until the desired sequence of peptide (or small protein) is reached, and the peptide (or small protein) is cleaved off from the resin by HF. By the same time, other protecting groups on the side chains of amino acids are also removed. The second protocol uses 9-fluorenylmethyloxycarbonyl (Fmoc) as the amino protecting group, which can be easily cleaved by piperidine in DMF or *N*-methylpyrrolidone. After the peptide synthesis, the small protein or peptide is released from the solid linker by the use of trifluoroacetic acid. However, it has been found that the ongoing peptide chain may stop growing or lead to a low

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

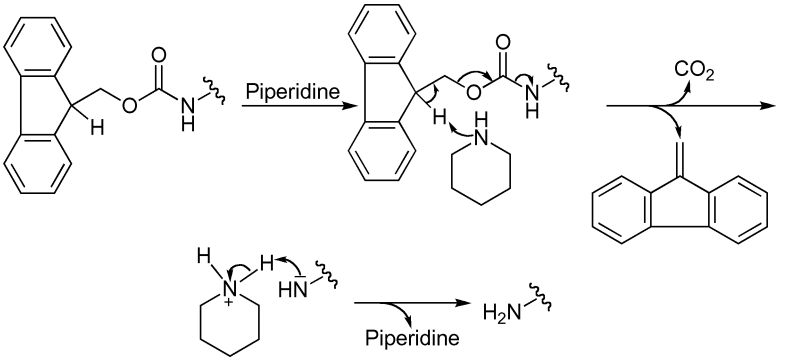
yield of peptide,[2i] due to the association of the peptide chain, the swelling problem of the resin, etc.;[2d] in this case, the application of a mixed solvent of CH_2Cl_2 and DMF apparently enhances the result.[2i] This method has been extended to oligonucleotide synthesis.[5]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The deprotection of Fmoc group by piperidine is displayed here.



D. MODIFICATION

This reaction has been modified extensively by application of different linkers, side chain protecting groups, and different solvent systems.

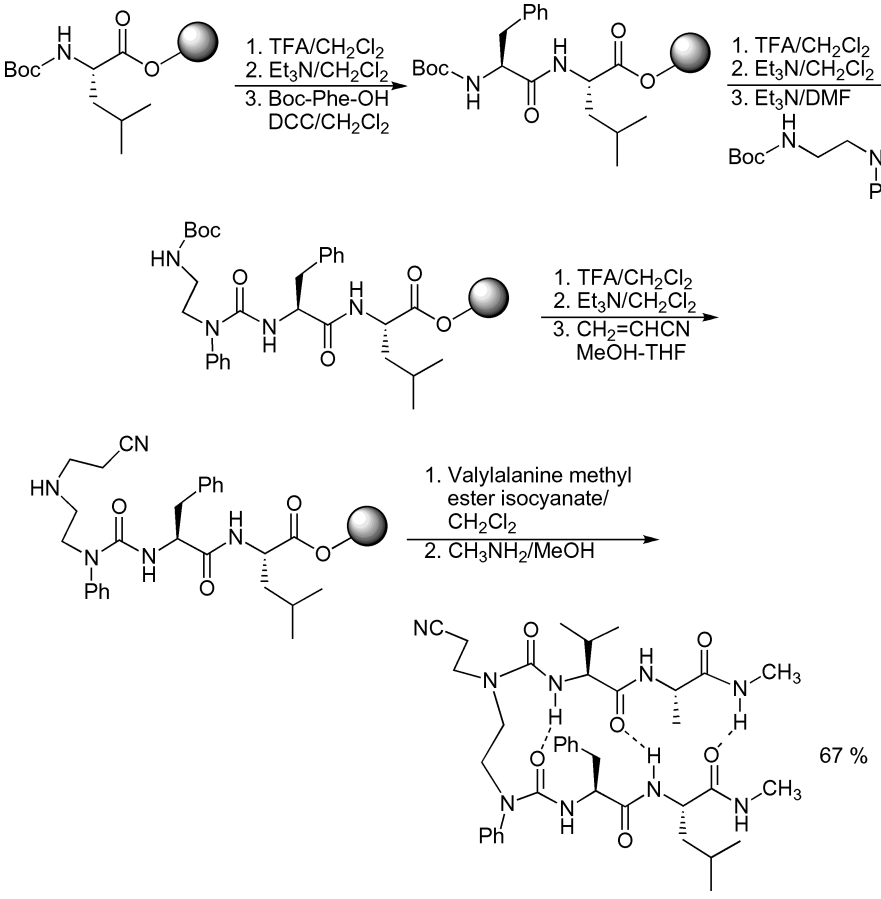
E. APPLICATIONS

This reaction has been widely used for the synthesis of peptides and small proteins.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

A 50-mL solid-phase reaction vessel was charged with 1.50 g Boc-leucine Merrified resin (0.80 mmol/g, 1.20 mmol). The resin was washed with CH_2Cl_2 (6 × 20 mL) and 20 mL of CH_2Cl_2/TFA/indole solution and was then shaken with 20 mL CH_2Cl_2/TFA/indole solution for 30 min. The solution was drained, and the resin was washed with CH_2Cl_2 (6 × 20 mL), CH_2Cl_2/Et_3N (10:1, v/v) (2 × 20 mL) and CH_2Cl_2 (6 × 20 mL). The resin was shaken with 796 mg *N*-Boc-Phe-OH (3.00 mmol), 3.0 mL 1.0 M DCC in CH_2Cl_2 (3.0 mmol), and 15 mL CH_2Cl_2 for 2 h. The resulting white suspension was filtered, and the residue was washed with 20 mL CH_2Cl_2 and EtOH (3 × 20 mL) to afford white beads.

These white resin beads were washed with CH_2Cl_2 (6 × 20 mL) and 20 mL of CH_2Cl_2/TFA/indole solution, and then shaken with 20 mL CH_2Cl_2/TFA/indole for 30 min. The solution was drained, the resin was washed with CH_2Cl_2 (6 × 20 mL) and CH_2Cl_2/Et_3N (10:1, v/v) (2 × 20 mL), CH_2Cl_2 (6 × 20 mL), and EtOH (3 × 20 mL). The resin was dried in vacuo and transferred to a 25-mL, round-bottomed flask, and gently stirred with 20 mL DMF, 1.20 mL Et_3N (8.61 mmol), and 1.08 g carbamoyl chloride at 50°C for 2 h. The suspension was transferred back to the 50-mL solid-phase reaction vessel and filtered, and the resin was washed with 20 mL DMF and CH_2Cl_2 (3 × 20 mL) to give pale tan beads.

The pale tan resin was washed with CH_2Cl_2 (3 × 20 mL) and 20 mL CH_2Cl_2/TFA/indole solution, and then shaken with 20 mL CH_2Cl_2/TFA/indole solution for 30 min. The solution was drained, and the resin was washed with CH_2Cl_2 (6 × 20 mL), CH_2Cl_2/Et_3N (10:1, v/v) (2 × 20 mL), and CH_2Cl_2 (6 × 20 mL). The resin was washed with THF (3 × 20 mL) and shaken with a solution of THF/MeOH/acrynitrile (15 mL, 5 mL, 5 mL) for 12 h. The solution was drained, and the resin was washed with CH_2Cl_2 (3 × 20 mL) to yield a new pale tan resin, which was shaken with 20 mL CH_2Cl_2 and 488 mg valylalanine methyl ester isocyanate (1.4 mmol) for 3.5 h. The solution was drained, and the resin was washed with CH_2Cl_2 (3 × 20 mL), and shaken with 20 mL 10 M methylamine in MeOH for 17 h. The solution was collected, the resin was washed with MeOH (2 × 20 mL), and the combined methylamine solution and MeOH washes were concentrated by rotary evaporation. The methylamine treatment and MeOH washing of the resin were repeated, and the combined residue from both treatments were concentrated by rotary evaporation to afford 769 mg of a white solid. Silica gel column chromatography (MeOH-$CHCl_3$) followed by radial-thin layer chromatography (*i*-PrOH-$CHCl_3$, 1:20) afforded 587 mg artificial β-sheet as a white foam, in a total yield of 67%.

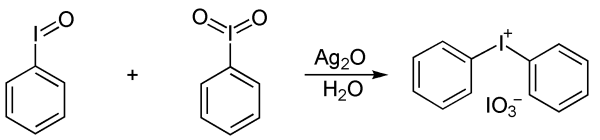
Meyer-Hartmann Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hartmann and Meyer in 1894.[1] It is the formation of diaryliodonium salt from the reaction between iodosobenzene (PhIO) and iodoxybenzene ($PhIO_2$) in the presence of silver (I) oxide, known as the Meyer-Hartmann reaction.[2] It has been reported that the mixture of an equal amount of iodosobenzene and iodoxybenzene is converted into diphenyliodonium hydroxide in the presence of alkali,[3] and the resulting diaryliodonium salt shows the chemical properties of ammonium hydroxide, thus termed a diaryliodonium salt.[4] In addition, iodoxybenzene itself could be converted to diphenyliodonium hydroxide under similar conditions.[5] Therefore, it is believed that silver (I) oxide, when mixed with water or moisture, hydrates and causes basicity. What is more, this reaction even takes place in the presence of a catalytic amount of silver (I) oxide.[6] It is the iodine atom in iodosobenzene that enters into the diphenyliodonium ion, whereas the iodine atom in iodoxybenzene is oxidized to iodate.[2] Although this reaction is time-consuming,[7] it is still the major method for preparing diaryliodonium salt, from which other iodonium salts can be prepared.[8] The diaryliodonium salt has wide application in industry. For example, it is commonly used for lithography and as a polymerization initiator.[9] A similar reaction for preparing *p*-iodophenyl phenyliodonium bisulfate has also been developed by Meyer and Hartman through the treatment of iodosobenzene with concentrated sulfuric acid.[10]

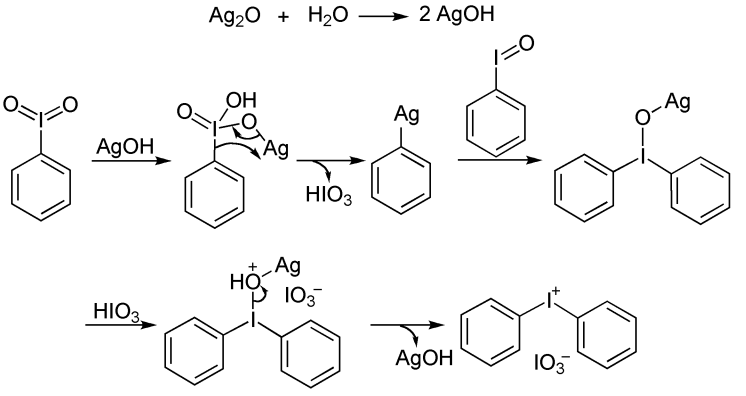
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is proposed here, which explains that only a catalytic amount of silver (I) oxide is required. Between iodosobenzene and iodoxybenzene, the latter has a higher tendency for silver hydroxide to attack because of its higher valent iodine atom. Upon cleavage of hydrogen iodate, phenyl silver forms, which then adds to iodosobenzene. Successive protonation from hydrogen iodate facilitates the formation of diphenyliodonium iodate and the cleavage of silver hydroxide, which enters another catalytic cycle. The slow reaction rate might arise from the gradual hydration of Ag_2O and the slow addition of silver hydroxide to iodoxybenzene.



D. MODIFICATION

This reaction has been modified by the replacement of Ag_2O with sodium hydroxide.[3]

E. APPLICATIONS

This reaction can be applied to the preparation of diaryliodonium salts.

Reference 11.

3-Iodoanisole (20 g, 85.5 mmol) was chlorinated in a chilled chloroform-ether mixture. Chilling with dry ice was necessary to precipitate the dichloride, which was air dried and weighed 15.7 g (51.6 mmol, 60%), m.p. 62–64°C. It was then hydrolyzed with 13 g Na_2CO_3 and 35 mL 5 *N* NaOH, washed with water and acetone, and dried at 50°C under vacuum to afford 7.3 g 3-methoxyiodosobenzene (29.2 mmol, 52%). This compound was shaken in an amber jar for 40 h with 7 g iodoxybenzene, 1 L water and Ag_2O freshly precipitated from 15 g $AgNO_3$. After filtration and clarification of the resultant solution, addition of a KI solution yielded 5 g 3-methoxydiphenyliodonium iodide (11.4 mmol), in a yield of 39%, m.p. 176–177°C (Fisher-Johns apparatus, inserted at 100°C).

Meyers Aldehyde Synthesis

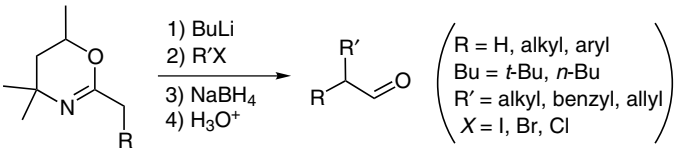
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meyers in 1969.[1] It is a 4,4,6-trimethyl-5,6-dihydro-1,3-oxazines-based aldehyde synthesis involving the steps of deprotonation, alkylation, reduction, and hydrolytic cleavage of the 1,3-oxazine ring. Therefore, it is known as the Meyers aldehyde synthesis.[2] During this process, the 5,6-dihydro-1,3-oxazines can be readily prepared from the condensation of 2-methyl-2,4-pentanediol and nitrile in concentrated sulfuric acid at 0°C.[3] The resulting 5,6-dihydro-1,3-oxazine is deprotonated by a lithium reagent, and then alkylated with an alkyl halide. The alkylated product is subsequently reduced by sodium borohydride or deuterium borohydride to tetrahydro-1,3-oxazine, which is then hydrolyzed in dilute oxalic acid solution.[4] It has been found that *t*-butyl lithium is the best suitable reagent for the purpose of deprotonation, followed by *n*-butyl lithium and phenyl lithium; other bases such as Grignard reagent, alkoxide, hydride, and dimethylsulfinyl reagent all fail for deprotonation.[3b] On the other hand, alkyl bromides and iodides are all good alkylating reagents, whereas alkyl tosylates do not work in this reaction.[3b] It has been reported that a considerable quantity of amino alcohol is also produced during the reduction from sodium borohydride,[3b] and such side reactions can be suppressed by reduction under basic conditions (pH = 9) instead of acidic conditions (pH = 5).[3b] However, as shown in Section C, an equivalent of amino alcohol will be naturally generated from the acidic hydrolysis of the tetrahydro-1,3-oxazine. The aldehydes produced in this reaction can be obtained by steam distillation from oxalic acid solution[1,3b,4a] if they are volatile enough, leaving the side product (e.g., amino alcohol) in the solution; otherwise they can be extracted after refluxing the oxalic acid solution for 1–2 h.[3b] This reaction can be used to prepare α,β-unsaturated aldehyde if the lithiated carbanion is allowed to react with a carbonyl compound, especially with β,β-disubstituted acroleins;[4a] silimarly, cycloalkyl

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

aldehyde[4b] and γ-hydroxy or γ-oxo aldehyde[5] can also be produced from this reaction by reacting lithiated carbanion with α,ω-dihaloalkane and epoxides, respectively. In addition, this reaction can also be used for the synthesis of ketones[6] by treatment of an excess amount of lithium reagent or from 2-alkenylozaxine using Grignard reagent followed by lithium reagent, etc.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown here is the mechanism of the Meyers aldehyde synthesis, including the formation of 5,6-dihydro-1,3-oxazine.

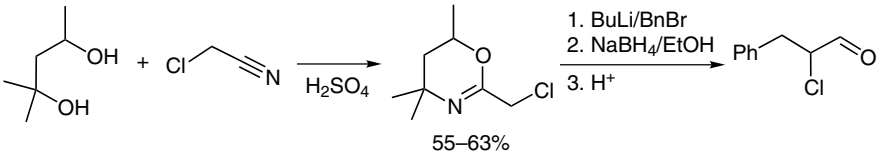
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a 500-mL flask equipped with a thermometer, a stirrer, and a 125-mL addition funnel was added 100 mL concentrated sulfuric acid. The acid was cooled to 0–5°C in an ice-acetone bath, and 41.6 g of chloroacetonitrile (0.55 mol) was added at such a rate that the temperature was maintained at 0–5°C. After the addition of the nitrile was completed, 59.0 g 2-methyl-2,4-pentanediol (0.4 mol) was added at such a rate that the same temperature was maintained. The mixture was stirred for an additional 1 h and then poured onto 400 g crushed ice. The aqueous solution was washed with CH_2Cl_2 (4 × 50 mL), and the CH_2Cl_2 extracts were discarded. The cold aqueous acidic solution was carefully poured into a beaker cooled at 0°C, containing 400 g $NaHCO_3$ and 300 mL Et_2O. Upon becoming neutral, a red-yellow oil appeared, which was taken up in the ether layer. The aqueous layer was extracted with Et_2O (4 × 200 mL) (water was added as needed), and the combined ether extracts were dried over anhydrous K_2CO_3. The ether was removed by rotary evaporation, and the residue was distilled through a 20-cm fractioning column to give 47–57 g 2-chloromethyl-4,4,6-trimethyl-5,6-dihydro-l,3-oxazine as a colorless liquid, in a yield of 55–63%, b.p. 41°C at 1.0 mmHg.

To 40 mL THF at –78°C under nitrogen was added 11 mmol *t*-butyllithium in pentane, followed by 1.76 g 2-chloromethyl-4,4,6-trimethyl-5,6-dihydro-1,3-oxazine (10 mmol) in 10 mL THF. The mixture was stirred for 30 min, and 10 mmol benzyl bromide was added via syringe. The mixture was allowed to stir for 2 h, and quenched at –30°C with cold 1 N HCl, then washed with pentane. The pentane extracts were discarded. The aqueous acid solution was neutralized with $NaHCO_3$, extracted with ether, and concentrated. Vacuum distillation of the residue at 0.15 mmHg afforded 72% of 2-(1-chloro-2-phenylethyl)-4,4,6-trimethyl-5,6-dihydro-1,3-oxazine, b.p. 98°C (0.15 mmHg), which solidified from pentane,

m.p., 65–66.5°C. This oxazine was dissolved in 10 mL 95% ethanol to which 0.5 mL 40% NaOH was added. To this solution was added more than one equivalent of $NaBH_4$ dissolved in a minimum amount of water, and the mixture was stirred for 1 h at 25°C. Excess amounts of sodium borohydride were destroyed at –45°C with 3 N HCl to avoid halogen removal. The alcohol was removed by rotary evaporation, and the residue was diluted with saturated salt solution. Ether extraction was followed by washing the ethereal extracts with brine, and drying over Na_2SO_4. Concentration afforded the tetrahydro-1,3-oxazine. This tetrahydro-1,3-oxazine was hydrolyzed in diluted oxalic acid solution, and steam distillation afforded 2-chloro-3-phenylpropanal, b.p. 112°C at 13 mmHg.

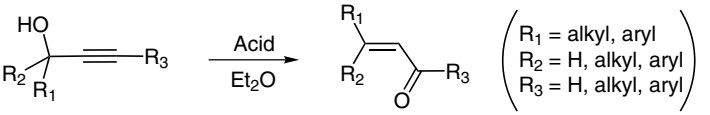
Meyer-Schuster Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meyer and Schuster in 1922.[1] It is an acid-catalyzed transformation of secondary or tertiary α-acetylenic alcohols into α,β-unsaturated carbonyl compounds, and is generally known as the Meyer-Schuster rearrangement[2] or Meyer-Schuster reaction.[2h,3] When the acetylenic group is terminal, the resulting product is an aldehyde.[2n] This reaction can be carried out either in acidic nonaqueous media or in highly acidic aqueous solutions;[3b] the former conditions include the application of ether saturated with dry HCl,[2m,2n] acetic anhydride,[2m,2n] acetyl chloride,[2m,2n] vanadium (V) salt,[4] or polyphosphoric acid trimethylsilyl ester;[2e] the latter conditions use the mixture of acetic acid and concentrated sulfuric acid.[2m,2n] The reaction involves three consecutive steps as follows: protonation of hydroxy group, 1,3-shift of the protonated hydroxy group, and enol/keto tautomerization.[2h,3b] Alternatively, this reaction may take place through an allenic carbonium ion intermediate, from which the nucleophilic attack by water ends up with α,β-unsaturated carbonyl compound.[2p,5] Thus electron-donating solvent can electrostatically solvate the intermediate cation and facilitate this reaction.[2h,2m,3b] Because intermediate alkynyl cation cannot expel a proton from an adjacent carbon atom,[2n] tertiary α-acetylenic alcohols exclusively undergo the Meyer-Schuster rearrangement.[2m]

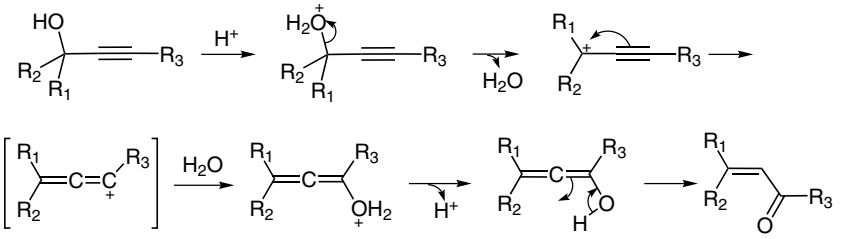
B. GENERAL REACTION SCHEME



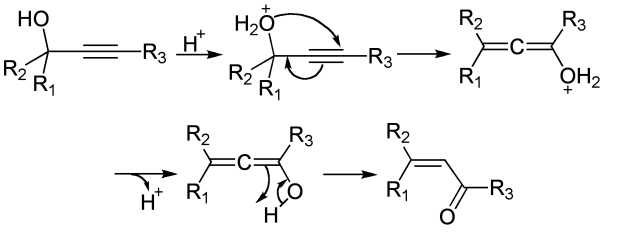
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction may proceed via an allenic cation intermediate generated by acidic dehydration, as shown in Scheme 1, or through a 1,3-shift of the protonated hydroxy group as shown in Scheme 2.



SCHEME 1. *Meyer-Schuster rearrangement involving an allenic cation intermediate.*



SCHEME 2. *Meyer-Schuster rearrangement involving a 1,3-shift of protonated hydroxyl group.*

D. MODIFICATION

This reaction has been adapted to primary acetylenic alcohol by treatment of the mixture of propargyl acetate and water with mercury(II) trifluoromethanesulfonate [mercuric triflate, $Hg(Tf)_2$] to give vinyl ketones under very mild conditions.[6] In addition, this reaction has been carried out at high temperatures without the addition of an acid catalyst.[7]

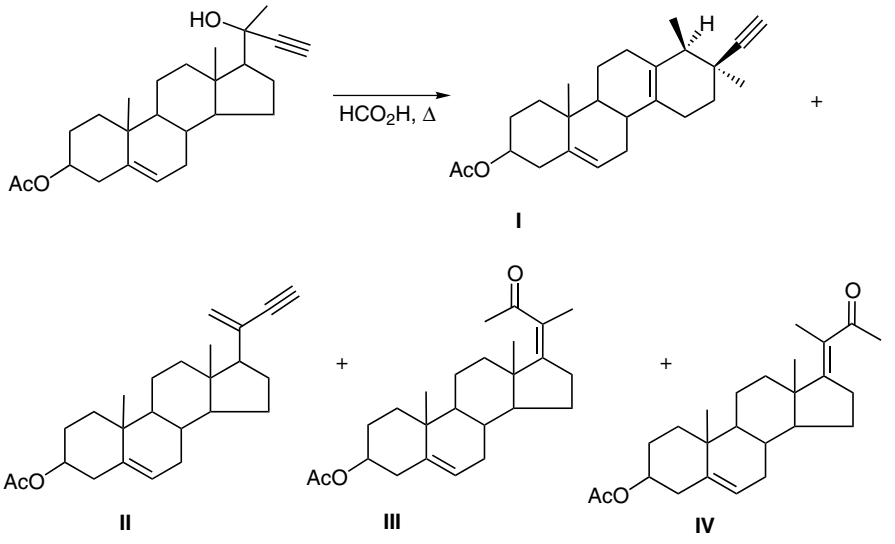
E. APPLICATIONS

This reaction is useful for the preparation of α,β-unsaturated carbonyl compounds.

F. RELATED REACTIONS

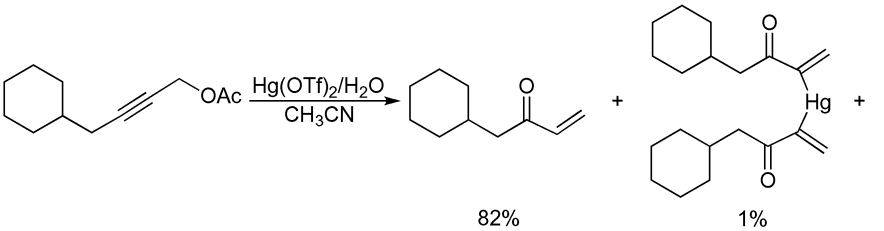
This reaction is related to the *Rupe Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES

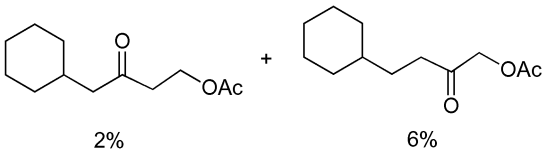


Reference 5.

A mixture of 5 g 20α-ethynylpregn-5-ene-3β,20β-diol 3-acetate and 25 mL 97% formic acid was heated with stirring on a steam bath for 3–4 min. When everything went into solution and a deep violet color developed, the solution was then poured over ice and extracted with CH_2Cl_2, washed with 2 N Na_2CO_3 and water, and dried over Na_2SO_4. After the solvent was evaporated, a brown residue was obtained, which solidified on standing. Four spots were identified by TLC. The residue was dissolved in 10 mL benzene and diluted with 10 mL hexane. The solution was then put on a column of 200 g alumina prepared in hexane, and the material was chromatographically separated into various fractions. The first fraction, in a total amount of 1 g, was eluted from the column with a 1:1 mixture of benzene and hexane, m.p., 141–142°C (methanol) (**I**). The second fraction was solely eluted with benzene that weighed 300 mg and contained two compounds, which were further separated by column chromatography using 30 g alumina to give 200 mg compound **I** and 50 mg **II**, m.p., 125–127°C (methanol). The third fraction in an amount of 1.1 g was eluted from the column with 2–5% ether in benzene and was identified as **III**, m.p. 176–178°C (methanol). The fourth fraction in an amount of 650 mg was eluted from the column with 4–10% EtOAc in benzene as oil, which was further purified by column chromatography using 50 g alumina, to afford 100 mg **III** and 450 mg compound **IV**, m.p., 119–121°C (methanol).



(Continued)



Reference 6.

To a stirred solution of 194 mg 4-cyclohexylbut-2-ynyl acetate (1.0 mmol) and 27 mg water (1.5 mmol, 1.5 eq.) in 9.5 mL acetonitrile was added 0.5 mL 0.1 M $Hg(OTf)_2$ (5 mol%) in acetonitrile at room temperature under argon. The mixture was allowed to stir at the same temperature for 4 h. After the addition of aqueous $NaHCO_3$, the organic material was extracted with ether. Dried and concentrated material was subjected to a column chromatography on silica gel using pentane and ether as eluents to give 128 mg 1-cyclohexylbut-3-en-2-one (82%) and a mixture of bis(4-cyclohexyl-3-oxobut-1-en-2-yl) mercury (1%), 4-cyclohexyl-3-oxobutyl acetate (2%), and 4-cyclohexyl-2-oxobutyl acetate (6%). (All yields are based on NMR measurements.)

Michael Addition

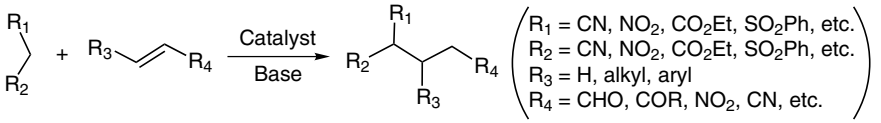
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Michael in 1887.[1] It is generally defined as the 1,4-addition (or conjugated addition) of a nucleophile to an electron-deficient alkene or alkyne. Thus this reaction is generally referred to as the Michael addition[2,3] or Michael reaction.[4,5] The nucleophiles are generally called the Michael donors,[6] while the electron-deficient alkenes or alkynes are known as the Michael acceptors,[5d,7] and the addition products are named the Michael adducts.[5h,8] Generally speaking, the more electron-rich the nucleophile is and the more electron-deficient the acceptor is, the easier the Michael addition occurs. Thus some Michael additions can proceed in neutral media[9] and even at room temperature without any catalyst.[10] Because both nucleophile and Michael acceptor become a part of the Michael adduct, this reaction is one of the most atom-efficient reactions[5e] and has been widely explored in many aspects. A part of the known nucleophiles include compounds containing heteroatoms of lone-pair electrons, such as primary and secondary amines,[7b] thiols,[7e,8c,11] and fullerenol;[12] neutral carbon-nucleophiles such as indoles,[5e,13] (*tert*-butyldimethylsiloxy) pyrrole,[5h] silyl ketene acetals, and enolsilanes;[14] carbon-nucleophiles with α-active protons, such as malonates,[5b,5c,5f,5g] β-ketoesters,[7d] silyl nitronates,[15] and nitroalkanes;[16] and anionic carbon-nucleophiles, such as enolates,[6,9,17] chiral Fischer aminocarbene complexes,[18] α-lithiated vinylic sulfoxide,[19] and enantio-enriched allenyltitaniums;[20] lithium eneselenolates generated from selenoamides;[21] and acylperoxy radicals.[22] Accordingly, the Michael addition involving noncarbon nucleophiles is generally referred to as hetero-Michael addition,[7e,11e,23] such as the *aza*-Michael addition,[24] *oxo*-Michael addition,[25] and *phospha*-Michael addition.[26] Specifically, the Lewis acid-promoted addition of silyl ketene acetals or enolsilanes to α,β-unsaturated carbonyl compounds to generate 1,5-dicarbonyl compounds is referred to as the *Mukaiyama-Michael Addition*.[14]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

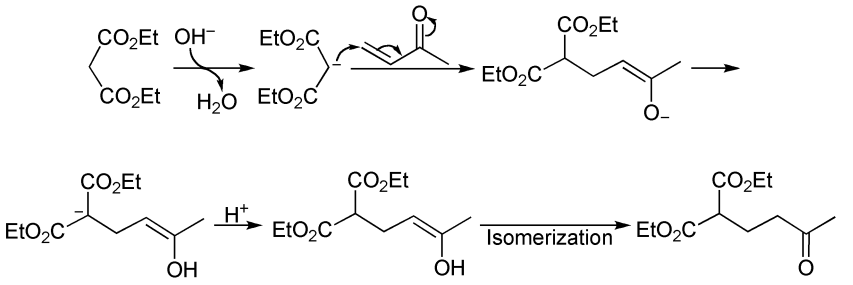
On the other hand, the initial Michael acceptors, such as α,β-unsaturated carbonyl compounds[7b] (e.g., acrylates[17,24b,27] and ethyl vinyl ketone[28]), have been extended to a variety of electron-deficient alkenes or alkynes, such as 2-*oxo*-3-butynoate,[7b] 2-*oxo*-3-pentynoate,[7b] cyclic enones[5c,5f] (e.g., cyclohexenone[5g]), chalcone,[5b,11b] acrynitrile,[29] alkylidene malonates,[13b,20] α,β-unsaturated imides,[30] nitroalkenes,[5c,31] nitrostyrene,[5c] α-methylene lactones,[5h] 1,4-benzoquinones,[5h] 3-alkylidene-3*H*-indole 1-oxide,[11d] 3-(*E*-enoyl)-4-phenyl-1,3-oxazolidin-2-ones,[7f,32] and α,β-unsaturated iodonium salt.[33] Although α,β-unsaturated aldehydes often give 1,2-addition products,[15] they also undergo regular Michael addition under certain conditions, such as in the reaction with 2-alkoxypropenals.[15,34] Furthermore, the carbon nucleophiles with α-active proton are often treated with base before the Michael addition. The bases used for this reaction range from strong bases such as butyl lithium to weak bases such as piperidine, quaternary ammonium hydroxide, and tertiary amines.[35] However, the Michael addition sometimes still requires a prolonged reaction time,[5f] thus different catalysts have been used or developed to facilitate the reaction or to enhance the diastereoselectivity and enantioselectivity of the Michael adducts. Some such catalysts are the organometallic complexes: chiral (salen)-aluminum complex,[30] Ru[(*S*, *S*)-Msdpen](η^6-hexamethylbenzene)((*S*, *S*)-MsDPEN) = (1*S*,2*S*)-*N*-(methanesulfonyl)-1,2-diphenylethylenedi-amine),[5c] *N*-spiro C_2-symmetric chiral quaternary ammonium bifluoride,[15] chiral Ni(II) complex of the Schiff base of glycine with (S)-*o*-[*N*-(*N*-benzylprolyl)amino]benzophenone,[36] $Cu(SbF_6)_2$-AdamBox,[9] $Cu(OTf)_2$-trisoxazoline,[13b,37] copper(II) bis-(5-*tert*-butylsalicylaldehydate),[9] $Yb(OTf)_3$-TMEDA,[38] and late transition metal complexes of BINOL-derived salens;[5g] Lewis acids such as $BF_3{\cdot}OEt_2$,[5h] $Cu(ClO_4)_2{\cdot}6H_2O$,[13b] $Hf(OTf)_4$,[5i] $InBr_3$,[13a] and $CeCl_3{\cdot}7H_2O$-NaI;[5e] chiral amines such as DBU,[16c] (*S*)-2-[bis(3,5-dimethylphenyl)methyl]pyrrolidine,[39] C_2-symmetric (2*S*,5*S*)-2,5-diphenylpyrrolidine,[39] (-)-quinine,[25] and proline;[31b] polymer catalysts such as antibody 38C2[40] and polymer-anchored chiral catalysts;[41] and solid base catalysts such as MgO[42] and Mg-Al-O-*t*-Bu hydrotalcite.[43] Furthermore, the solvent-free Michael addition has been established by application of $CeCl_3{\cdot}7H_2O$-NaI as catalyst[5e] or microwave irradiation of reactants on $BiCl_3$ or CdI_2,[44] $EuCl_3$,[45] $CeCl_3{\cdot}5H_2O$,[46] and alumina surfaces.[47] It is interesting that the thermal treatment or microwave irradiation of 1,5-ketodiesters or 1,5-diketones in DMSO in the presence of Na*X* (*X* = Cl, Br, I) results in the *retro*-Michael addition.[8a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown here is the mechanism of reaction between ethyl malonate and vinyl methyl ketone using NaOH as a base.



D. MODIFICATION

This reaction has been extensively modified by application of different bases and catalysts to enhance the diastereoselectivities and enantioselectivities.

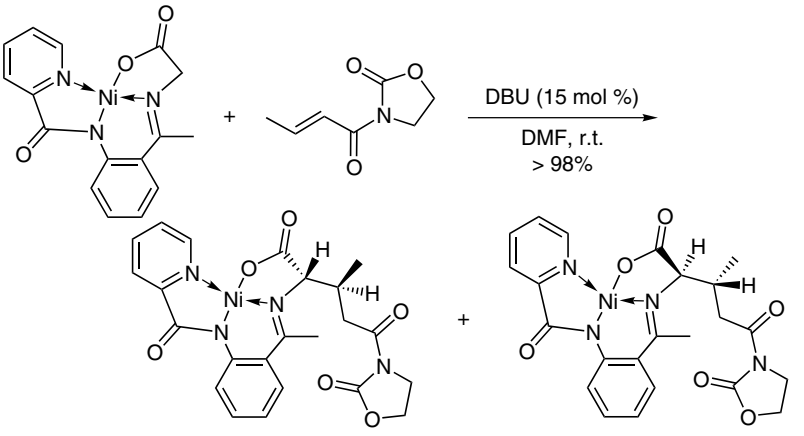
E. APPLICATIONS

This reaction has wide application in organic synthesis and is probably one of the most known organic reactions.

F. RELATED REACTIONS

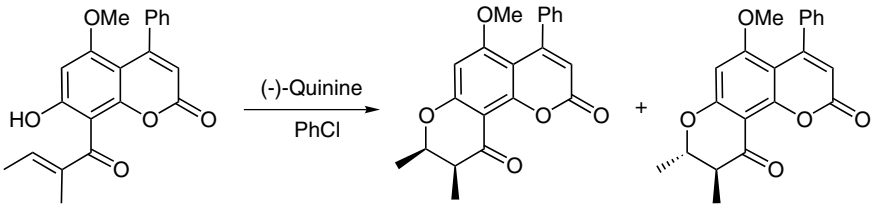
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7c.

To a suspension of 0.5 mmol Ni(II) complex of Schiff base arising from glycine and (*S*)-*o*-[*N*-(*N*-benzylprolyl)amino]-benzophenone in 2.0 mL DMF was added 0.525 mmol 3-(*trans*-3′-methylpropenoyl)oxazolidin-2-one; the mixture was stirred at ambient temperature for 10 min. Then 10 μL DBU (0.07 mmol) was added, and the reaction was monitored by TLC. After the reaction completed ($\sim$ 15 min), the mixture was poured into 80 mL icy 5% aqueous acetic acid and stirred with a glass bar to initiate crystallization of the product. The crystalline product was filtered off, thoroughly washed with water, and dried in vacuo to afford $>$ 98% of the addition products. The diastereomeric isomers were isolated by silica gel column chromatography (acetone/chloroform, 1/4), in a ratio of 2.4 to 1.



Reference 17.

A suspension of 0.140 g 7-hydroxy-5-methoxy-4-phenyl-8-tigloylcoumarin (0.40 mmol) in 2.5 mL chlorobenzene in the presence of 0.013 g (-)-quinine (0.041 mmol) was stirred at 4°C for 33 h under argon. After evaporation of solvent, 5 mL water was added. The aqueous mixture was extracted with $CHCl_3$ (3 $\times$ 20 mL). The organic solution was successively washed with 20 mL 10% HCl, 20 mL water, 20 mL brine and dried over $MgSO_4$. Upon evaporation of solvent, the residue was purified by silica gel column chromatography (benzene/EtOAc, 10:1) to afford 0.032 g (8*S*,9*S*)-8,9-dihydro-8,9-dimethyl-5-methoxy-4-phenyl-2*H*,10*H*−benzo[1,2-*b*;5,6-*b*′]dipyran-2,10-dione (23%, m.p. 193–194°C) and 0.098 g (8*R*,9*S*)-8,9-dihydro-8,9-dimethyl-5-methoxy-4-phenyl-2*H*,10*H*-benzo[1,2-*b*;5,6-*b*′]dipyran-2,10-dione as colorless prisms, in a yield of 70%, m.p., 219–221°C.

Other references related to the Michael addition are cited in the literature.[48]

Michaelis-Arbuzov Rearrangement

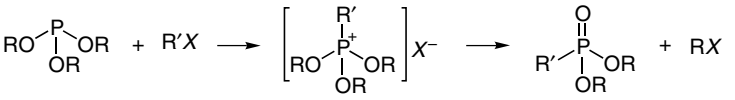
(Arbuzov Rearrangement, Arbuzov Reaction, Arbuzov Transformation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially discovered by Michaelis in 1898[1] and explored in great detail by Arbuzov and several subsequent investigators.[2] It is one of the most versatile routes to form alkyl phosphonates containing one phosphorus-carbon bond from the reaction of an ester of trivalent phosphorus (i.e., trialkyl phosphite) and alkyl halides. Therefore, this reaction is generally known as the Michaelis-Arbuzov rearrangement,[3] Arbuzov rearrangement,[4] or Arbuzov reaction.[5] Occasionally, it is also referred to as the Arbuzov dealkylation[6] or Arbuzov transformation.[7] Besides the rearrangement of phosphites, a similar reaction is also observed for dialkyl sulfite,[8] sulfenate ester,[9] alkoxysulfanes,[10] and other thio-derivatives,[11] and such an analogous rearrangement is referred to as the thio-Arbuzov reaction.[5s,9,10] It has been found that the Michaelis-Arbuzov rearrangement can be promoted by metal-centered radicals,[4f] anode oxidation,[4g] or photo irradiation, and the Arbuzov reaction occurring under photochemical illumination is generally called the photo-Arbuzov rearrangement.[4a,4e,12] In addition, this reaction can also be catalyzed by ruthenium.[4k] This reaction has been used in the synthesis of phosphonates, phosphinic acid esters, and phosphine oxides.

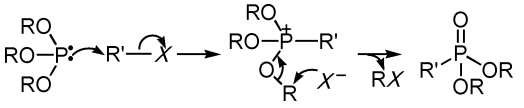
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

At least three mechanisms have been proposed for this reaction. The first one, originally postulated by Arbuzov,[2d] consists of an alkylation reaction that yields an alkoxyphosphonium ion and a nucleophilic substitution from the conjugate nucleophile (X^-), as shown here. The second mechanism, suggested initially by Rumpf,[13] is an autocatalyzed process, in which the species that attacks the alkoxyphosphonium ion is the ester of trivalent phosphorus (i.e., phosphite) rather than the conjugate nucleophile X^-. Although the majority of experimental results support the first type mechanism, the autocatalyzed mechanism is clearly favored in a few experiments, in which an ester of trivalent phosphorus reacts with dimethyl sulfate or methyl triflate rather than alkyl halides.[14] In addition, a radical mechanism was also proposed in 1982.[15] According to the first two mechanisms, if R′ = R as shown in Section B, only a catalytic amount of R′*X* is needed for the transformation of trialkyl phosphite into phosphonate. In addition, it has been found that haloalkyl phosphites can undergo an internal rearrangement upon heating.[16]



D. MODIFICATION

This reaction has been extensively modified. Besides the ruthenium-catalyzed, metal-centered radical or photo-Arbuzov rearrangements as described earlier, alkyl halides have been replaced by metal halides (e.g., $NiCl_2$),[17] trimethylsilyl chloride (TMSCl),[18] and organometallics.[19]

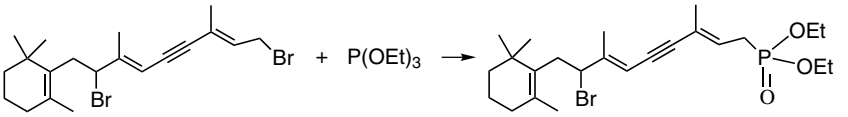
E. APPLICATIONS

The Arbuzov rearrangement has been widely used for the synthesis of a variety of phosphorus related compounds, including phosphonates,[20] phosphinates,[21] tertiary phosphine oxides,[22] phosphonyl, and phosphonyl halides.[23] Some of these products can be used for the *Wittig Reactions*, such as in the synthesis of carotene.[24]

F. RELATED REACTIONS

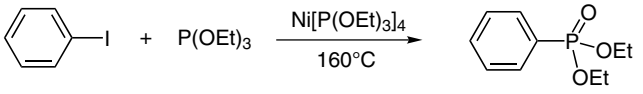
The reaction between alkyl halides and the anion of diethyl phosphonate, made by the ionization of the P-H bond by a very strong base, such as BuLi, to form a new carbon-phosphorus bond is known as the Michaelis-Becker reaction.

G. CITED EXPERIMENTAL EXAMPLES



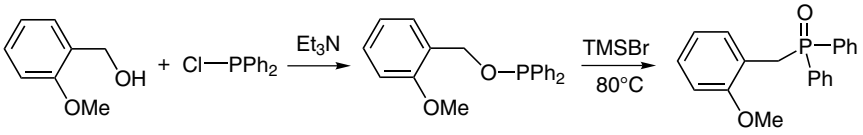
Reference 24.

To a distillation flask were added 107 g 1,8-dibromo-3,7-dimethyl-9-(2,6,6-trimethyl-l-cyclohexen-l-yl)-2,6-nonadien-4-yne, 100 mL toluene, and 83 g triethyl phosphite. The resulting mixture was heated at 145°C for 4 h. Upon removal of the solvent, the residue was distilled through a centrifugal molecular still to give 80.9 g 3,7-dimethyl-9-(2,5,6-trimethyl-l-cyclohexen-1-yl)-2,6,8-nonatrien-4-yn-1-ylphosphonic acid diethyl ester, in a yield of 70%, m.p. 28°C.



Reference 17.

To a flask equipped with a dropping funnel and refluxing condenser were added 10 g iodobenzene and 10 mg nickel tetra(triethyl phosphite). When the solution was heated to 160°C, 9.37 g triethyl phosphite (56.4 mmol) was added in small portions (∼ 5 drops). The solution became deep red upon each addition of phosphite. The color rapidly faded to yellow, ethyl iodide was distilled into a cold trap, and an exotherm was observed. When the reaction was completed (monitored by GLC), 9.88 g diethyl phenylphosphonate was obtained via distillation at 0.1 mmHg, b.p. 94–101°C, in a yield of 94%.



Reference 18.

In a nitrogen-flushed reaction vessel was added a solution of 100 μL chloro diphenyl phosphinite (0.56 mmol) in 5 mL dry THF, followed by 100 μL triethyl amine (0.8 mmol) and 81 μL 2-methoxybenzyl alcohol (0.6 mmol) successively. After overnight stirring at room temperature, triethyl ammonium salts were filtered off under nitrogen (glove box), and

rinsed with dry Et_2O. Solvents and remaining starting material were removed under vacuum. The crude reaction mixture was transferred to a flame-dried, nitrogen-flushed pressure-resistant reaction vessel, and 7 μL TMSBr was added. The reaction vessel was then made airtight with a Teflon stopper, and after being stirred for 2 h at 80°C, the crude reaction mixture was submitted to silica gel column chromatography (acetone/dichloromethane, 1:9), to afford 139 mg 2-methoxybenzyl diphenylphosphine oxide, in a yield of 77%.

Other references to the Arbuzov rearrangement are cited in the literature.[26]

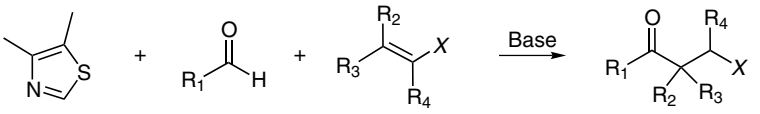
Michael-Stetter Reaction
(Stetter Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Stetter et al. in 1973.[1] It is a thiazolium-catalyzed nucleophilic conjugate addition of an aldehyde to an electron-deficient alkene to form a 1,4-bifunctional compound and is generally known as the Stetter reaction.[2,3] Occasionally, it is also referred to as the Stetter condensation.[4] Furthermore, since this reaction is analogous to the well-known *Michael Addition*, it is also called the Michael-Stetter reaction.[5] Besides thiazolium, imidazole and triazolium can also catalyze this reaction in a same way.[2b,2f,5c,5d] In this reaction, it is suggested that the addition of a catalyst to aldehyde changes the carbonyl group into an acyl anion equivalent,[2c] which then adds to an α,β-unsaturated compound (ketone, ester, nitrile, etc.) to form the 1,4-dicarbonyl compound.[5d] In addition, this reaction generally offers high enantioselectivity and diastereoselectivity,[2c] especially in the presence of a chiral triazolium salt;[2b,2c,2e] moreover, the intramolecular reaction is capable of forming tertiary ether, thioether, and quaternary stereocenters with very high enantioselectivity.[2e] However, the catalytic activity of thiazolium, as well as triazolium salt, is generally low for the Michael-Stetter reaction. Because the addition of acyl anion equivalent to α,β-unsaturated compound produces a relatively stable adduct,[2f] thiazolium or triazolium salt would not cleave from the adduct efficiently and resume another catalytic cycle.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

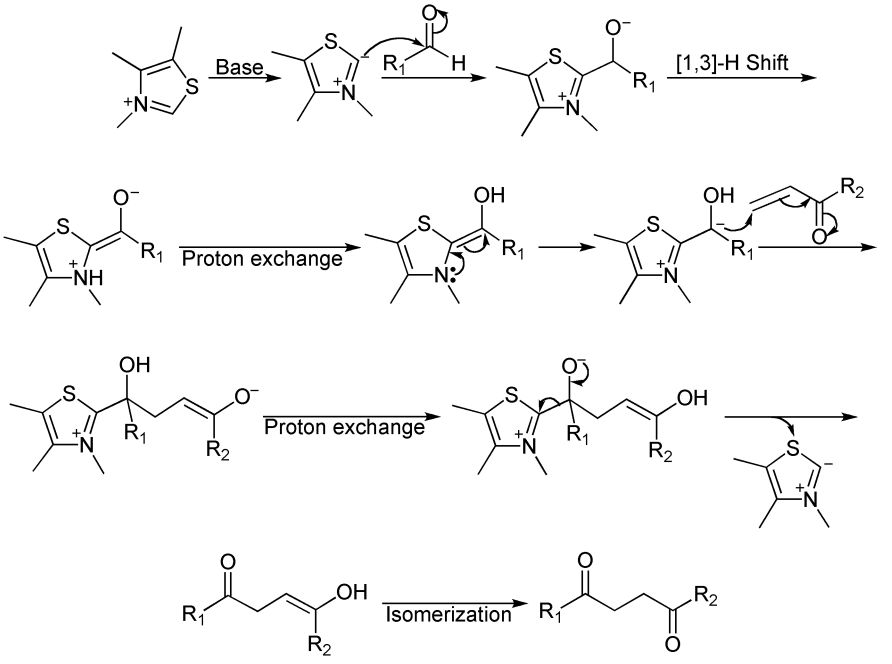
B. GENERAL REACTION SCHEME



(R_1 = H, alkyl, aryl
R_2 = H, alkyl
R_3 = H, alkyl, aryl
R_4 = H, alkyl, aryl
X = COR, CO_2R, CN, NO_2, SO_2R, etc.)

C. PROPOSED MECHANISMS

As the mechanism of this reaction is not very clear, a tentative mechanism between an aldehyde and an α,β-unsaturated ketone catalyzed by a thiazolium salt is displayed here.



D. MODIFICATION

N/A

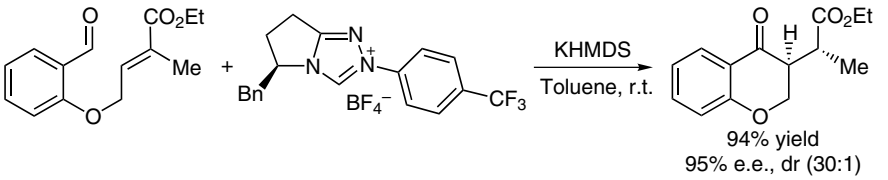
E. APPLICATIONS

This reaction has general application in the preparation of 1,4-bifunctional molecules starting from aldehydes.

F. RELATED REACTIONS

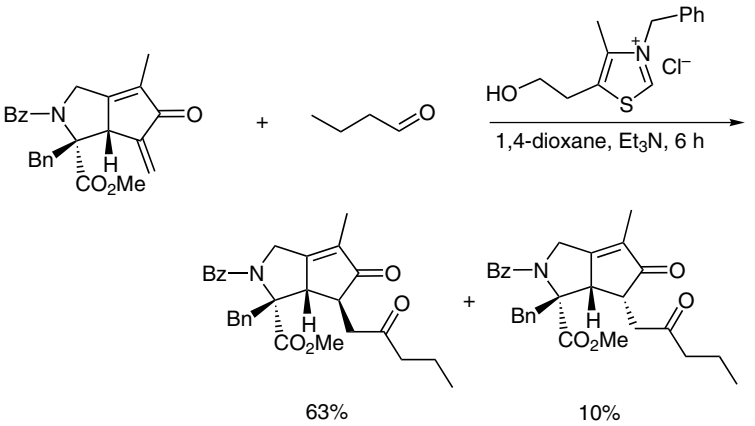
This reaction is related to the *Michael Addition*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

To a flame-dried, round-bottomed flask was added 13.0 mg triazolium salt (0.031 mmol) and 2 mL toluene. To this solution was added 61 μL 0.5 M KHMDS solution (0.031 mmol) via syringe, and the solution was stirred at ambient temperature for 5 min. Toluene and HMDS were removed in vacuo by placement under high vacuum for 1 h. Then 3 mL toluene was added, followed by a solution of 38.0 mg substrate in 2 mL toluene, and the resulting solution was allowed to stir at ambient temperature for 24 h. The reaction was quenched with 2 mL 15% AcOH/toluene and concentrated. The residue was purified by flash column chromatography using mixture of hexane and EtOAc (6:1) as the eluent to afford 35.7 mg (2*R*,3′*S*)-(4-oxo-chroman-3-yl)-propionic acid ethyl ester as a white solid, in a yield of 94%. The product was tested to be pure enough with 95% e.e. and 30:1 dr, $R_f = 0.7$ (hexane/EtOAc, 1:1).



Reference 6.

To a solution of 163 mg 1-benzyl-2-benzoyl-4-methyl-5-oxo-6-methylene-1,2,3,5,6,6a-hexahydrocyclopenta[c]pyrrole-1-carboxylic acid methyl ester (0.403 mmol) in 2 mL 1,4-dioxane were added 42 μL Et_3N (0.30 mmol), 184 μL butyraldehyde (2.03 mmol), and 22 mg 3-benzyl-5-(2-hydroxyethyl)-4-methylthiazolium chloride (0.080 mmol). The reaction vessel was sealed with a rubber septum and heated to 70°C for 6 h. The reaction mixture was then poured into 50 mL water, and the aqueous layer was extracted with Et_2O (3 $\times$ 25 mL). The combined organic layers were washed with 20 mL brine, dried over $MgSO_4$, and concentrated under vacuum. After the addition of 5 mL hexanes to the residue, a white precipitate formed. The precipitate was collected by decantation and purified by flash chromatography (hexanes/EtOAc, 9:1 to 2:1, v/v) to afford 121 mg of the major diastereomer of 2-benzoyl-1-benzyl-4-methyl-5-oxo-6-(2-oxopentyl)-1,2,3,5,6,6a-hexahydrocyclopenta[*c*]pyrrole-1-carboxylic acid methyl ester (63% yield) and 19 mg of the minor diastereomer (10% yield).

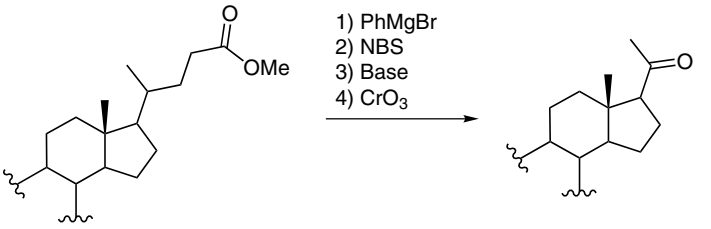
Miescher Degradation
(Meystre-Miescher Degradation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meystre and Miescher et al. in 1944.[1] It is a multistep cleavage of the side chain of steroid, such as bile acid methyl ester, to the stage of methyl ketone by sequential reactions with the phenyl Grignard reagent, dehydration of resulting tertiary alcohol to alkene, α-bromination by *N*-succinimide bromide, dehydrobromination of allyl bromide to form a conjugated diene, and oxidation of the diene by chromium trioxide. Thus it is known as the Miescher degradation[2] or Meystre-Miescher degradation.[3]

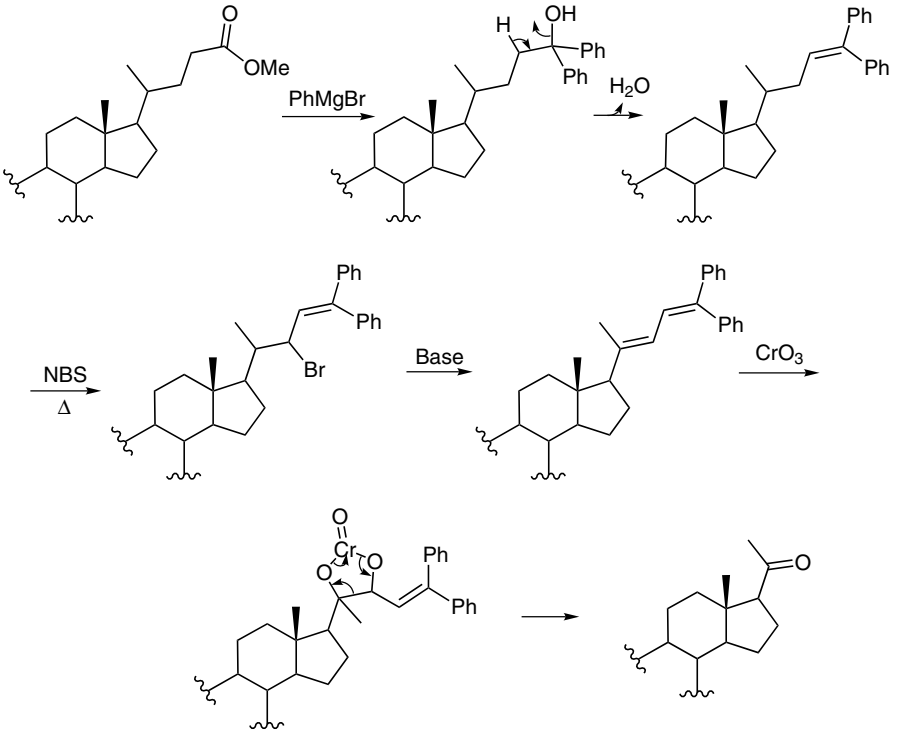
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction is a multistep process, and the reaction scheme displayed here illustrates the mechanism.



D. MODIFICATION

N/A

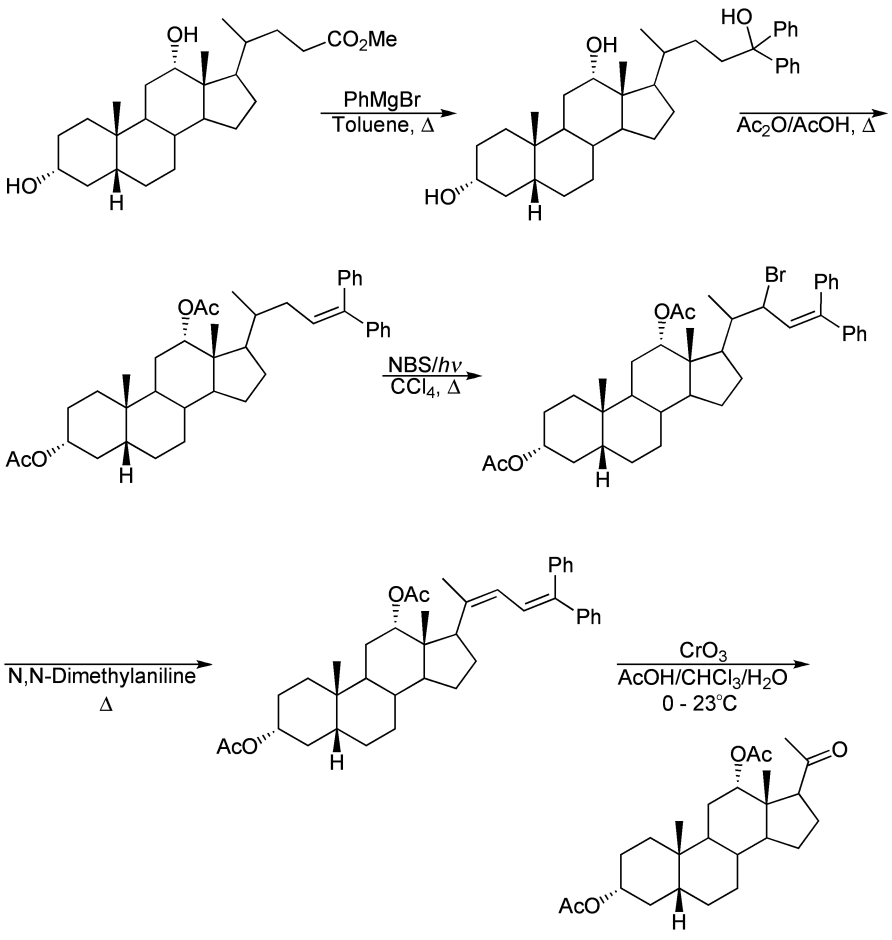
E. APPLICATIONS

This reaction has limited application in organic synthesis but is used primarily in steroid chemistry.

F. RELATED REACTIONS

This reaction is related to the *Barbier-Wieland Degradation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

Preparation of 3α,6β-Dihydroxy-*nor*-cholanyldiphenylcarbinol

A solution of 1 Kg methyl hyodesoxycholate in 12 L hot toluene was added to 7 L dry ether containing 39 mol PhMgBr. The ether was distilled off during the addition, and the reaction mixture was refluxed overnight. The mixture was worked up in the usual way to afford 1035 g crude 3α,6β-dihydroxy-*nor*-cholanyldiphenylcarbino1, m.p. 203–205°C (recrystallized twice from benzene).

Formation of 3α,6β-Dihydroxy-*bis*-*nor*-cholanyldiphenylethylene

3α,6β-Dihydroxy-*nor*-cholanyldiphenylcarbino1 (5 g) in a mixture of 100 mL acetic acid and 5 mL acetic anhydride was refluxed for 4 h. The solution was concentrated and poured into cold water. The suspended solid was coagulated by warming and dissolved in 300 mL methanol. NaOH (12 g) in 20 mL water was added, and the solution was

refluxed for 1 h, filtered, and diluted with water to afford 4.7 g 3α,6β-dihydroxy-*bis-nor*-cholanyldiphenylethylene as solid, m.p. 181–183°C. Recrystallization from 80% methanol gave needles, m.p., 184–186°C. (*Note*: The deacetylation is not necessary in this preparation, so that the next step of acetylation can be skipped.)

Preparation of 3α,6β-Diacetoxy-*bis-nor*-cholanyldiphenylethylene

A solution of 68.7 g 3α,6β-dihydroxy-*bis-nor*-cholanyldiphenyl-ethylene in 360 mL acetic acid and 36 mL acetic anhydride was refluxed for 3.5 h, cooled, filtered, and concentrated in vacuo. Petroleum ether (b.p. 100°C) was added and distilled off under reduced pressure to remove the last traces of acetic anhydride. The residue was crystallized from CCl_4 from which it separated with 31% of solvent which could be removed only by fusion; weight 82.5 g, m.p. 80–92°C. A sample of the glass remaining after drying in vacuo at 100°C was crystallized first from acetone and then from methanol to afford white crystals, m.p. 121.5–124°C.

Formation of 3α,6β-Diacetoxy-pregnan-20-one

To a solution of 54.2 g 3α,6β-diacetoxy-*bis-nor*-cholanyldiphenylethylene in 800 mL CCl_4 was added 17.8 g NBS. The flask was illuminated with a 150-W reflector floodlight and heated to reflux for 15 min. After cooling, the succinimide and excess *N*-bromosuccinimide were removed by filtration. To this solution was added 81 mL dimethylaniline; the solvent (CCl_4) was distilled off, and the residue was heated at reflux temperature for 10 min. After cooling, 300 mL 10% HCl was added and the mixture was shaken with ether and benzene. The ether-benzene layer was separated, washed with water, and dried over Na_2SO_4. The solvent was removed, and the residue was reacetylated by refluxing for 2 h with acetic acid (100 mL) and 25 mL acetic anhydride. After removing the solvent in vacuo, 62 g crude 1-(3,6-diacetoxy-*etio*-cholanyl)-1-methyl-4,4-diphenyl-1,3-butadiene was obtained. This crude butadiene was mixed with 125 mL acetic acid, 125 mL $CHCl_3$, and 25 mL H_2O and maintained at the temperature between 0° and 23°C. Then the solution of 40 g CrO_3 in 130 mL H_2O and 640 mL acetic acid was added while maintaining at the same temperature. After the oxidation, the excess CrO_3 was destroyed with SO_2, and the solvent was removed in vacuo. The residue was shaken with water and extracted with a mixture of $CHCl_3$ and ether, which was washed with 5% $NaHCO_3$ solution, water, dried over Na_2SO_4. Removal of the solvent left 57 g residue, which was subjected to a ketone separation with Girard's reagent P. The ketone-containing fraction weighed 14 g and was crystallized from methanol containing a little water, giving 3α,6β-diacetoxy-pregnan-20-one, m.p. 120–122°C. Further column chromatography on alumina afforded a fraction that after crystallization from petroleum ether (b.p. 69°C) and then from methanol melted at 131–133°C.

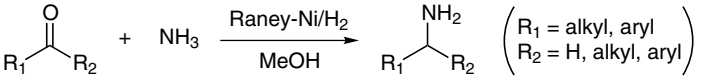
Mignonac Reaction

A. GENERAL DESCRIPTION OF THE REACTION

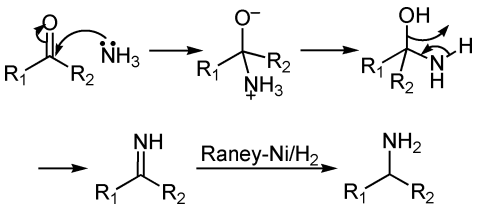
This reaction was first reported by Mignonac in 1921.[1] It is a direct synthesis of primary amines from catalytic hydrogenation of aldehydes or ketones over nickel in liquid ammonia or in alcohol saturated with ammonia and is known as the Mignonac reaction.[2] In addition, this reaction can also be applied to the hydrogenation of an oxime for the preparation of corresponding amine.[3] It has been found that the yield of amines can be enhanced if the intermediates from aldehydes or ketones with ammonia are isolated and the subsequent hydrogenation is carried out in an organic solvent.[3] In addition, this reaction has been improved by reduction of aldehydes or ketones over Raney nickel with a hydrogen pressure of 20–150 atms at temperatures ranging from 40° to 150°C.[4] However, this modification often requires high-pressure equipment.[5] An additional modification of this reaction is to carry out the reduction of aldehydes or ketones over platinum oxide in the presence of an excess amount of ammonium chloride in methanol that is saturated with ammonia, so that the newly generated primary amine is protonated immediately from ammonium chloride and can not further attack the rest of carbonyl compound.[5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified by the addition of an excess amount of ammonium chloride in alcohol during the catalytic hydrogenation.

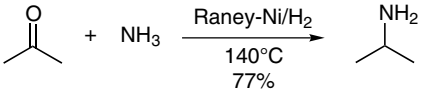
E. APPLICATIONS

This reaction has general application in the conversion of aldehydes or ketones into primary amines.

F. RELATED REACTIONS

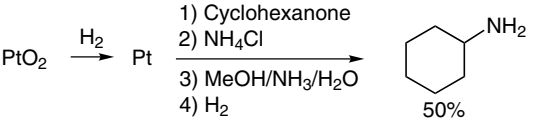
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A mixture of 696 g acetone (12.0 mol) and 204 g ammonia (12 mol) was hydrogenated in a stirred autoclave over 50 g Raney nickel at 140°C and 740 psi of hydrogen. After the reaction completed, the mixture was distilled to afford 545 g isopropylamine, in a yield of 77%, b.p. 31.5–32.5°C.



Reference 5.

In a 300-mL reduction bottle were added 10 mL distilled water and 0.2 g platinum oxide, and platinum oxide was reduced to platinum by shaking in an atmosphere of hydrogen for ~ 10 min. Then 29.4 g cyclohexanone (0.3 mol), 20.0 g NH_4Cl (0.37 mol), 225 mL absolute MeOH saturated with ammonia, and 25 mL aqueous ammonia were added to the reduction bottle. The mixture was reduced by shaking with hydrogen at 1–3 atms. Hydrogenation was continued until a constant pressure reading indicated the completion of the reduction. The shaker was then stopped, the bottle was vented, and the catalyst was allowed to settle. The platinum was removed by filtering the mixture through a Hirsch funnel into a 1-L round-bottomed flask, and any salt that collected on the filter was rinsed down with water. The flask and contents were then removed to a hood and refluxed under a condenser for 1 h to remove the excess ammonia. The solution was cooled, acidified to congo red paper with concentrated hydrochloric acid, and evaporated to about half of its volume under vacuum. Then 200 mL water was added, and the solution was washed with benzene (3×25 mL). The benzene extracts were discarded. The aqueous solution was then made strongly basic with 50% NaOH, the two layers formed were separated, and the water layer was extracted three or four times with ether. The ether extracts and the oily layer were then combined, washed with water, and dried over KOH. The cyclohexylamine was purified by distillation through a 13-cm. column packed with glass helices, in a yield of 50%.

Other references related to the Mignonac reaction are cited in the literature.[7]

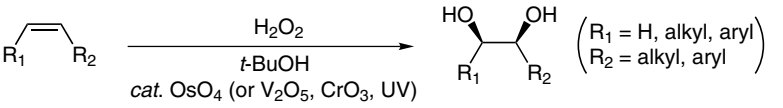
Milas Hydroxylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Milas and Sussman in 1936.[1] It is a transformation of olefins into *cis*-diols by the oxidation with anhydrous hydrogen peroxide (H_2O_2) in *tert*-butyl or *tert*-amyl alcohol in the presence of a catalytic amount of osmium tetroxide (OsO_4). Therefore, this reaction is known as the Milas hydroxylation, and hydrogen peroxide is referred to as the Milas reagent.[2] In the absence of OsO_4, the hydroxylation of olefin by H_2O_2 is not likely to occur.[1] However, OsO_4 is not the only reagent to trigger this hydroxylation, other transition metal oxides such as vanadium pentoxide and chromium trioxide are also effective under similar conditions,[3] even ultraviolet light can initiate the hydroxylation.[4] It has been found that this reaction exclusively affords the *cis*-diols;[3,5] although in some cases, it further converts the diols into other products due to overoxidation. For example, the hydroxylation of cyclohexene results in a large quantity of adipic acid,[3] while the oxidation of stilbene gives benzaldehyde quantitatively.[4] It has been found that solvents have a very important role in this reaction. For instance, the hydroxylation of alkene in the presence of OsO_4 in diethyl ether gives aldehyde predominantly.[6] It is interesting that the hydroxylation of conjugate dienes, as in the case of cyclopentadiene, affords *cis*-1,4-diols.[7] This reaction has been extended by Sharpless using *tert*-buyl peroxide as the oxidation agent under basic conditions to suppress the by-products,[2] such as the application of tetraethylammonium hydroxide as the base in *t*-BuOH or tetraethylammonium acetate as the base in acetone.[8]

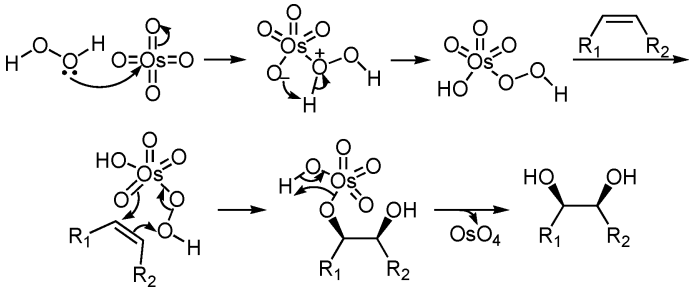
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although a mechanism has been proposed for this reaction,[9] it does not correctly present the real reaction path. Thus a tentative mechanism is outlined here. In the current mechanism, the peroxide bond in H_2O_2 is weakened through the bonding with osmium tetroxide, functioning as a strong electron-withdrawing group, so that the peroxide can easily add to the C=C double bond through a six-membered transition state, resulting in *cis*-diol. In addition, osmium tetroxide leaves the catalytic cycle upon the formation of *cis*-diol. There would be no reduction of osmium tetroxide by olefin to the Os(VI) complex, which is then oxidized by H_2O_2 to OsO_4.



D. MODIFICATION

This reaction has been modified by Sharpless to take place under basic conditions using *tert*-butyl peroxide as a hydroxylation agent.[2,8]

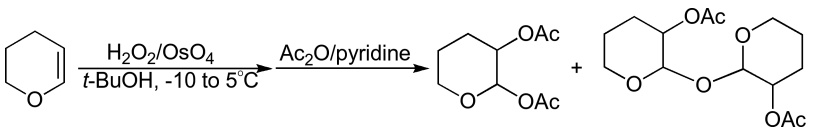
E. APPLICATIONS

This reaction is very useful for the preparation of *cis*-diols from olefins.

F. RELATED REACTIONS

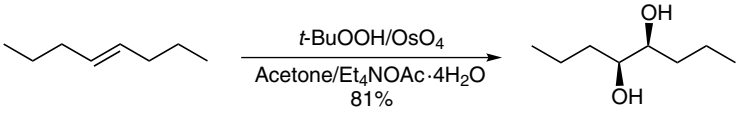
This reaction is related to the *Sharpless Dihydroxylation* and *Prévost Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a 2-L three-necked flask was added 196 g 3,4-dihydro-2H-pyran (2.3 mol) and 5 mL osmium tetroxide catalyst prepared from 0.5 g OsO_4 in 100 mL *t*-BuOH. While the flask was cooled to −10° to 5°C, 1320 mL 6% hydrogen peroxide in *t*-BuOH was added dropwise under stirring over a period of 4 h. An additional 3 mL catalyst solution was added after 2 hours and after all of the peroxide solution had been added. The reaction is highly exothermic, and care must be exercised not to add the peroxide at too fast a rate. The solution was allowed to stand overnight. The solvent was removed under reduced pressure at a bath temperature of 60°C or below. The residue (255 g) was acetylated by dissolving it in 600 mL pyridine and adding 750 mL acetic anhydride at 10°C. The solution was allowed to warm to room temperature and stand overnight. After destruction of the unused acetic anhydride by addition of excess 75% EtOH, the solvent was removed at reduced pressure. The residue (335 g) was allowed to stand overnight, whereupon some crystallization was noted, leading to 53 g 2-acetyl-3,4-dideoxyaldopentosyl 2-acetyl-3,4-dideoxyaldopentoside, which was collected on a filter. The solid was recrystallized from MeOH, m.p. 132–133°C. The filtrate, after separation of the disaccharide, was distilled at 1 mmHg to afford 135 g crude 2,3-diacetoxytetrahydropyran, b.p. 96–115°C. Redistillation of this material gave 115 g 2,3-diacetoxytetrahedropyran collected at 108–120°C and 2–5 mmHg.



Reference 8.

A 1-L Erlenmeyer flask equipped with magnetic stirrer was charged with 200 mL acetone, 11.2 g (*E*)-4-octene (100 mmol), 6.5 g $Et_4NOAc{\cdot}4H_2O$(25 mmol), and 18 mL (∼162 mmol) 90+% *tert*-butyl hydroperoxide. The mixture was stirred at room temperature until the Et_4NOAc had dissolved. The resulting solution was cooled in an ice bath and 10 mL (i.e., 50 mg or 0.2 mmol of OsO_4) of the catalyst solution containing OsO_4 in *tert*-butyl alcohol was added in one portion. The solution immediately became brownish purple. After 1 h, the ice bath was removed and the reaction mixture was allowed to warm to room temperature, stoppered loosely, and stirred overnight. Ether (400 mL) was added, and the resulting mixture was cooled by stirring in an ice bath. Then 50 mL of freshly prepared 10% $NaHSO_3$ solution was added in one portion. The ice bath was removed, and stirring was continued for 1 h, at which point the organic layer had become almost colorless. Solid NaCl was added until the aqueous layer was saturated, and stirring of the two-phase mixture was continued for several minutes. The organic layer was separated and washed with 50 mL brine. The combined aqueous layers were extracted with ether (2 × 100 mL). The combined organic layers were dried over Na_2SO_4 and when concentrated afforded an oil that,

upon distillation, gave 11.8 g *threo*-4,5-dihydroxyoctane, in a yield of 81%, b.p. 87–90°C (3 mmHg).

Mislow-Evans Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mislow et al. in 1968,[1] and was subsequently developed by Evans into a valuable method for the synthesis of allylic alcohols.[2] It is a base-promoted [2,3]-sigmatropic rearrangement of allyl sulfoxide into relatively unstable allyl sulfenate, which then decomposes into the corresponding allylic alcohol in the presence of a thiophilic reagent. Therefore, this reaction is generally known as the Mislow-Evans rearrangement.[3] Occasionally, this reaction is also referred to as the Mislow-Evans reaction,[3j] Mislow-Evans-Braverman rearrangement[4] or Mislow-Evans sulfenate-sulfoxide rearrangement.[5] This reaction is highly stereoselective[3g,3k,3l] and always gives *trans*-allylic alcohol predominately if a bulky substituent presents on the allyl sulfoxide. Whereas allyl sulfoxide without a bulky group yields the thermodynamically controlled mixture of allylic alcohols.[3m] On the other hand, this reaction is also sensitive to solvation.[3j] For example, the rearrangement rate of allyl *p*-tolyl sulfoxide is reduced by factors of 29 or 332 at 67°C in ethanol and 2,2,3,3-tetrafluoro-1-propanol, respectively, if compared with the reaction in methylcyclohexane.[1] This is rationalized by the further stabilization of allyl sulfoxide by solvation from a polar solvent, which increases the activation energy for the transformation of allyl sulfoxide to sulfenate, a less polar structure than sulfoxide.[3j]

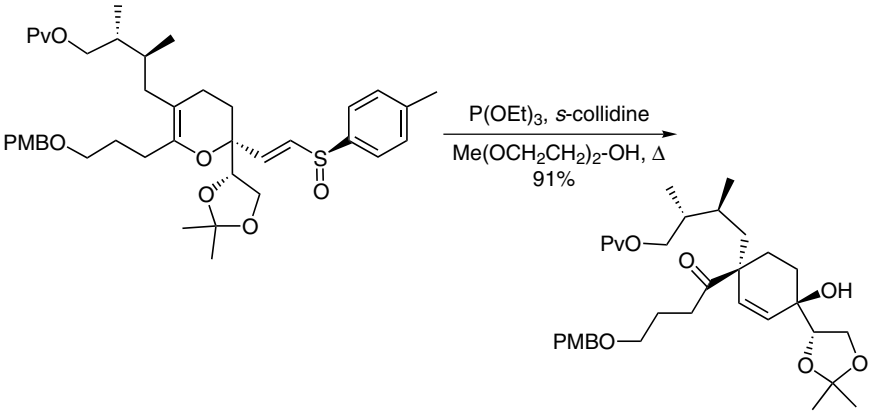
G. CITED EXPERIMENTAL EXAMPLES



Reference 3e.

A solution of 0.154 g vinylic sulfoxide (0.217 mmol), 0.18 mL triethyl phosphite (1.05 mmol), and 0.14 mL *s*-collidine (1.05 mmol) in 2.7 mL $MeOCH_2CH_2OCH_2CH_2OH$ was heated at 150°C for 15 h in a sealed vial under argon. After cooling, the reaction mixture was diluted with EtOAc and washed with saturated aqueous NH_4Cl and then water three times. The combined aqueous layers were extracted with EtOAc. The combined organic layers were washed with brine, dried with anhydrous Na_2SO_4, and concentrated. The residue was purified by silica gel column chromatography (EtOAc/hexanes, 2:3) to yield 0.117 g allyl alcohol after drying in high vacuum at 50°C to remove the residual *s*-collidine, in a yield of 92%. (*Note*: The whole process involves a [3,3]-Claisen rearrangement and subsequent Mislow-Evans rearrangement.)

Other references related to the Mislow-Evans rearrangement are cited in the literature.[6]

Mitsunobu Reaction

(Mitsunobu Coupling, Mitsunobu Esterification)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mitsunobu in 1967.[1] It is the alkylation of compounds with active protons by using primary or secondary alcohols as the alkylating agents in combination with triphenylphosphine and diethyl azodicarboxylate (DEAD) or diisopropyl azodicarboxylate (DIAD), to form molecules like esters, ethers, thioethers, and amines. Therefore, this reaction is generally known as the Mitsunobu reaction[2] or Mitsunobu coupling.[3] In addition, the specific reaction for forming esters by means of DEAD (or DIAD) and PPh_3 is generally referred to as the Mitsunobu esterification.[4] Occasionally, the Mitsunobu reaction is also called the Mitsunobu transformation (for the conversion of alcohol into amines)[5] or Mitsunobu cyclization (for the formation of cyclic compounds).[6] Because of its intrinsic features of stereospecificity,[7] as well as its occurrence in neutral media and at room temperature[8] without a prerequisite activation of alcohol,[8b] this reaction has been extensively studied and used to synthesize a variety of compounds since 1970.

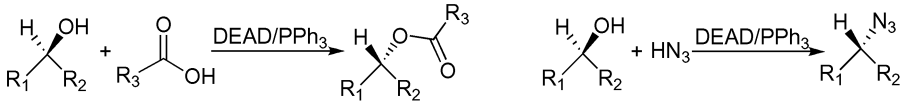
It is known that this reaction begins with the formation of a relatively stable betaine,[4b,4f,9] called the Morrison-Brunn-Huisgen intermediate,[9a,9c,10] through the irreversible Michael-type nucleophilic addition of triphenylphosphine on the N=N double bond of DEAD.[4f,9b,9d] Then the betaine intermediate abstracts a hydrogen atom from the nucleophile carrying an active proton,[9a] and alkoxy phosphonium salt[4i,4j,9a,9d,11] or alkoxyphosphorane[4i,4j,7c,9d,11c,12] forms, which then undergoes a normal S_N2 displacement from nucleophile to give the corresponding product. It has been found that both

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

alkoxy phosphonium salt and alkoxy phosphorane should be involved as the intermediates in this reaction,[4i,4j] depending on the order of the addition and the pKa of the nucleophile. In addition, the position of equilibrium between these intermediates depends on the pKa of the nucleophile and the polarity of the solvent.[4j] For example, only alkoxy phosphonium salt is observed when strong acid with low pKa, such as trifluoroacetic acid, is used as a nucleophile,[4j] and dioxytriphenylphosphorane can be detected only when the nucleophilic acid is added last.[4k,11c] In addition, this reaction is also evidenced to undergo through a radical mechanism,[4f,13] because a nitrogen radical has been detected when triphenylphosphine and an alkyl azodicarboxylate are mixed.[4f] Although this reaction takes place smoothly in neutral media at room temperature, due to the strong affinity of triphenylphsophine for oxygen and DEAD for hydrogen, the nucleophiles employed must be acidic enough—generally with a pKa of less than 11,[14] preferably < 10[8b]—to protonate the betaine intermediate, which prevents the formation of other side products. The compounds of carboxylic acid,[4b,4c,4e,4f,4i] phenol,[3c,3g,15] phosphate,[16] phosphonic acid,[16] and *N*-hydroxyimide[11b] are suitable oxygen nucleophiles; and phthalimide[9d,17] and hydrogen azide[11b] are suitable nitrogen nucleophiles. Other nucleophiles include hydrogen halide[11b] and activated carbon acid.[18]

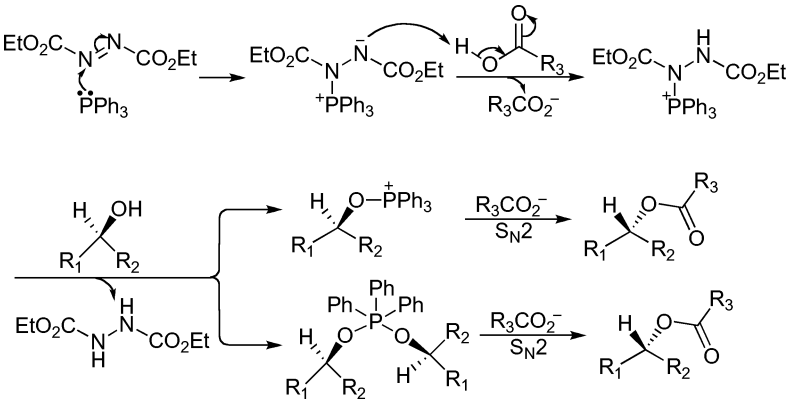
When secondary alcohols are used as alkylating agents, the stereochemistry is generally inverted via the *Walden Inversion*, because of the nature of S_N2 displacement.[3f,7b,7c,9a,11d,14,15] However, examples with partial retention of stereochemistry have also been reported.[15] Especially for the intramolecular version of the Mitsunobu reaction for the hindered alcohols, the products are formed with an exclusive retention of configuration.[11a] The overall result of this reaction is the alkylation of nucleophiles by alcohols, the simultaneous oxidation of triphenylphosphine to an oxide, and reduction of DEAD to hydrazinedicarboxylate. Thus triphenylphosphine oxide and dialkyl hydrazinedicarboxylate cannot be avoided in this reaction, which often prevents the desired products from being isolated. Therefore, this reaction has been extensively modified to ease the separation and purification of products. These modifications include the fixation of either triphenylphosphine[17] or dialkyl azodicarboxylate[19] to polymers, thus the resulting side products can be removed by simple filtration. In addition, phosphines with a basic moiety, such as 2-pyridyl[4l] and 4-dimethylaminophenyl,[20] are also used to improve the reaction, and the corresponding phosphine oxide can easily be washed away by acid. Furthermore, the nucleophile is also anchored to a fluorous reagent, to purify the product by extraction.[2r,8a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism containing the formation of phosphonium salt and phosphorane intermediates are displayed here.



D. MODIFICATION

This reaction has been extensively modified, including the fixation of phosphine and dialkyl azodicarboxylate onto a polymer or fluorous reagent and the introduction of a basic moiety to a phenylphosphine.[2r] In addition, bis(2-(1-adamantyl)ethyl) azodicarboxylate (BadEAD),[10] bis(1-adamantylmethyl) azodicarboxylate (BadMAD),[10] bis(5-norbornen-2-ylmethyl) azodicarboxylate (DNAD),[17] di-*tert*-butyl azodicarboxylate (DBAD),[21] fluorous azodicarboxylate (FDEAD),[22] *N*,*N*,*N*′,*N*′-tetramethylazodicarboxamide (TMAD),[23] and 1,1′-(azodicarbonyl)dipiperidine (ADDP),[23] have also been developed for the Mitsunobu reaction.

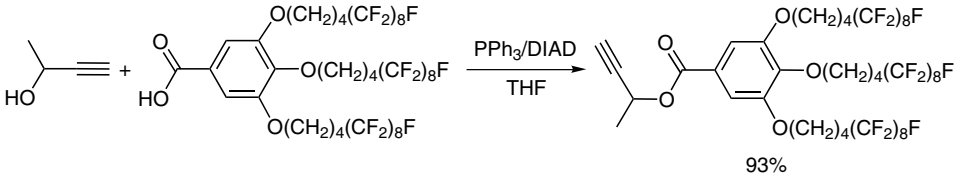
E. APPLICATIONS

This reaction has very wide application in organic synthesis, including the preparation of esters, ethers, thioethers, amines, and azides.

F. RELATED REACTIONS

This reaction is related to the *Appel Reaction, Staudinger Reaction*, and *Michaelis-Arbuzov Rearrangement*.

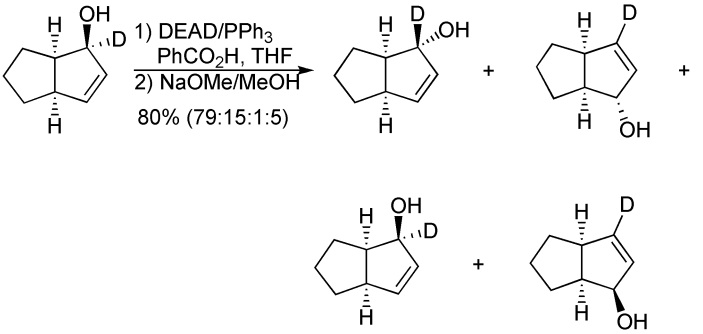
G. CITED EXPERIMENTAL EXAMPLES



93%

Reference 8a.

To a round-bottomed flask was added 0.478 g 3,4,5-tris(5,5,6,6,7,7,8,8,9,9,10,10,11,11,12,12,12-heptadecafluorododecan-1-yloxy)benzoic acid (0.30 mmol), 10 mL THF, and 0.211 g triphenylphosphine (0.804 mmol). The mixture was stirred under a nitrogen atmosphere at room temperature. Then 0.30 mL 10% 3-butyn-2-ol (v/v) in THF (0.38 mmol) was added to the reaction mixture, followed by 0.15 mL DIAD (0.76 mmol). The reaction mixture was stirred for 40 h. The solvent was evaporated by rotary evaporation, and the residue was recrystallized from $CHCl_3$/MeOH (1:1). A white solid was isolated by filtration and dried over P_2O_5 under an oil pump vacuum to afford 0.458 g ester, in a yield of 93%.



Reference 9d.

To a 2 mL THF solution of 0.120 g *endo*-2-deuterio-2-hydroxy-1R,5R-bicyclo[3.3.0]oct-3-ene (0.96 mmol) at 0°C, were added 0.30 g triphenylphosphine (1.14 mmol, 1.2 eq.), 0.20 gram DEAD (1.15 mmol, 1.2 eq.), and 0.14 g benzoic acid (1.14 mmol, 1.2 eq.). The resultant solution was stirred for 1 h at this temperature, and then the solvent was removed under reduced pressure, followed by the addition of 10 mL hexane/EtOAc (2:1). The solution was filtered, the solvent was removed under reduced pressure, and the crude product was purified by silica gel chromatography (petroleum ether). The purified benzoate mixture was then hydrolyzed by addition of 5 mL 5% NaOMe/methanol, and the resulting mixture was stirred for 3 h. The solvent was removed under reduced pressure, and the crude mixture was dissolved in 10 mL ether, washed once with 5 mL water and 5 mL brine, dried over Na_2SO_4, filtered, and concentrated to provide 80% of alcohols, with 79% of inversion.

Other references related to the Mitsunobu reaction are cited in the literature.[24]

Moffatt-Swern Oxidation

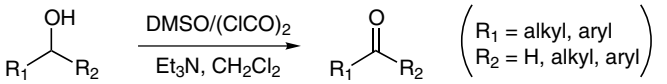
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Moffatt in 1965[1] and subsequently modified by Swern in 1978,[2] who introduced oxalyl chloride and triethylamine to the reaction system. It is the oxidation of primary and secondary alcohols to carbonyl compounds (aldehydes and ketones) from dimethyl sulfoxide (DMSO) in combination with oxalyl chloride and triethylamine under anhydrous conditions. Therefore, it is generally known as the Moffatt-Swern oxidation[3] or simply the Swern oxidation.[4] Occasionally, it is also referred to as the Swern-Moffatt oxidation,[3o] or Moffatt oxidation.[5] The combination of oxalyl chloride, DMSO, and triethylamine is called the Swern-Moffatt reagent[6] or Moffatt reagent.[7] It is known that this reaction involves the formation of an ylide through an alkoxydimethylsulfonium ion; if it is impossible to form the ylide, then there would be no such oxidation.[8] Compared to chromium-based oxidation reagents, such as PCC[9] and PDC,[10] the Swern-Moffatt reagent is less toxic. In addition, this reaction is also superior[11] to the PCC and *Dess-Martin Periodinane Oxidation* in some cases. On the other hand, this reaction does not cleave the adjacent di-carbonyl functionality. For example, the Moffatt-Swern oxidation converts terminal 1,2-diol into α-hydroxy aldehyde but not into an α-keto aldehyde,[3o] whereas the modification using the combination of DMSO/EDC/Cl_2CHCO_2H can transform α-hydroxyamide to α-ketoamide.[4b] Because this reaction is very mild and selective, it has been widely used in organic synthesis, even for the preparation of some very unstable aldehydes, which are subjected to subsequent transformation directly.[12] For ketones that are sensitive to triethylamine, they can be prepared by substituting triethylamine with the Hunig's base.[6] However, this reaction also has some flaws. For example, it must be carried out under anhydrous conditions because of oxalyl chloride; the reaction temperature is often very low to avoid the *Pummerer Rearrangement*.[13] In addition, this reaction may

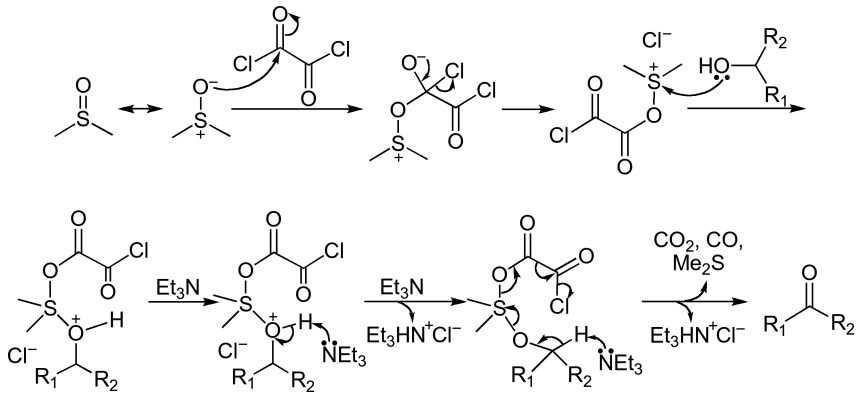
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

leave trace impurities that cannot be detected by spectroscopy or combustion analysis but could affect some subsequent reactions, such as palladium catalyzed reactions.[14] Moreover, this reaction may cause the racemization of chiral molecules.[3m]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to use the combination of DMSO/EDC/Cl_2CHCO_2H to oxidize α-hydroxyamide to α-ketoamide;[4b] in addition, Hunig's base has been substituted for triethylamine for the preparation of ketones, which are sensitive to triethylamine.[6]

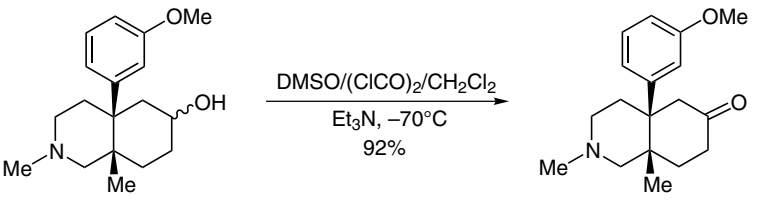
E. APPLICATIONS

This reaction has wide application in the preparation of ketones and aldehydes.

F. RELATED REACTIONS

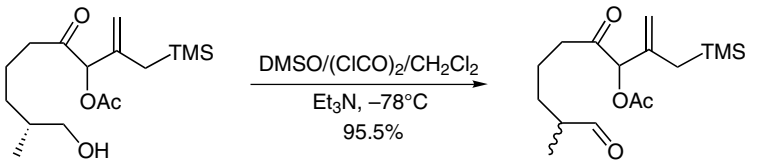
This reaction is related to the *Corey-Kim Oxidation* and *Pfitzner-Moffatt Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

Into a dry flask containing 3.45 mL oxalyl chloride in 15 mL CH_2Cl_2 (6.9 mmol, 2.0 M) cooled to −70°C was added 0.83 mL DMSO (11.7 mmol) in 10 mL CH_2Cl_2 over 10 min. The solution was stirred for an additional 10 min at −70°C, and 1.54 g *N*-methyl-4a-(3-methoxyphenyl)-8a-methyloctahydroisoquinoline-6-ol (5.32 mmol) in CH_2Cl_2 was added over 30 min. After an additional 30 min at −70°C, 1.11 mL Et_3N (7.98 mmol) was added, and the solution was warmed to room temperature, washed with 100 mL saturated aqueous $NaHCO_3$, dried over Na_2SO_4, concentrated, and purified via flash chromatography (4% MeOH-$CHCl_3$) to afford 1.40 g *N*-Methyl-4a-(3-methoxyphenyl)-8a-methyl-6-oxooctahydroisoquinoline, in a yield of 92%.



Reference 3m.

To a solution of 0.894 g oxalyl chloride (0.05 mmol) in 25 mL dichloromethane was added a solution of 1.0 g DMSO (12.8 mmol) in 4.0 mL dichloromethane at −78°C. A solution of 2.02 g (+)-3-acetoxy-9-hydroxy-8(*R*)-methyl-2-((trimethylsilyl)methyl)-non-1-en-4-one (6.41 mmol) in 6.0 mL dichloromethane was added, the solution was stirred for 20 min, and then 2.41 g triethylamine (17.1 mmol) was added. The cloudy white mixture was allowed to warm to −20°C, whereupon the mixture was poured into a vigorously stirred mixture of water (80 mL), ether (40 mL), and hexanes (40 mL). The organic layer was extracted with 40 mL ether. The organic layers were washed with aqueous 10% sodium bisulfate (2 × 40 mL) and brine (40 mL), dried over magnesium sulfate, filtered, and concentrated under reduced pressure to afford 1.91 g racemic 3-acetoxy-8-methyl-9-oxo-2-((trimethylsilyl)methyl)non-1-en-4-one as a light yellow oil, in a yield of 95.5%. (*Note*: The racemization might arise from the enolization after the formation of aldehyde under basic conditions.)

Other references related to the Moffatt-Swern oxidation are cited in the literature.[15]

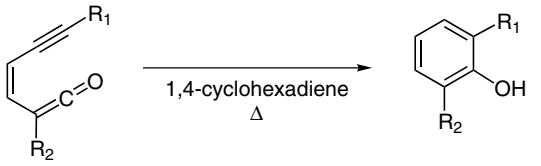
Moore Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

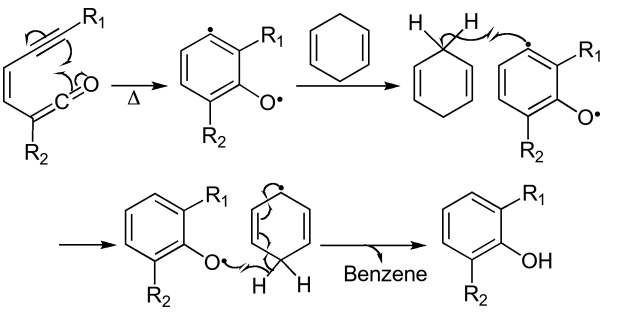
This reaction was first reported by Moore in 1985.[1] It is a synthesis of phenol (or quinone) derivatives by means of the thermal cyclization of enyne-ketenes between C_2 and C_7 via an aryl/phenoxy biradical intermediate. Therefore, it is generally known as the Moore cyclization.[2] Occasionally, it is directly referred to as the Moore reaction.[2d,3] It has been found that the biradical intermediate sometimes also shows the character of zwitterions.[2b,2d,2j] Although the cyclization between C_2 and C_7 is strongly favored in kinetics and thermodynamics,[2d] the formation of a five-membered fulvene biradical via C_2-C_6 cyclization is also known, especially for the enyne-ketenes with a phenyl or other radical-stabilizing group at the alkynyl terminus.[1,ba,2d,4] For example, the thermal decomposition of 4-phenylacetylenyl-2,3-dimethoxy-4-(trimethylsiloxy)-cyclobutenone in *p*-xylene at 135°C affords 52% cyclopenten-1,3-dione derivative but only 13% quinone.[1] The formation of a biradical intermediate via C_2-C_7 cyclization has been evidenced in the formation of spiroepoxide through the *exo* addition of an aryl radical to the proximal alkyne moiety and subsequent proton abstraction from an adjacent methoxy group by the resulting vinyl radical[5]and the partial cleavage of DNA during the decomposition of cyclobutenone.[6]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been extended to the cyclization of ketenimine.[7]

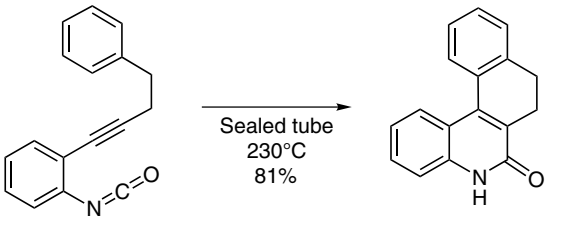
E. APPLICATIONS

This reaction has special application in formation of phenol and related derivatives.

F. RELATED REACTIONS

This reaction is related to the *Bergmann Cyclization* and *Myers-Saito Cyclization.*

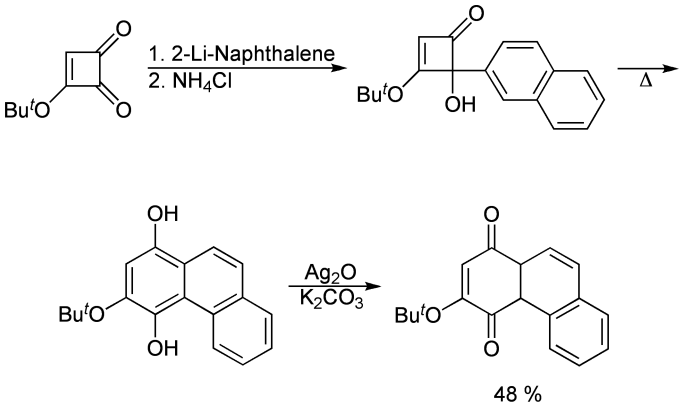
G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

A solution of 0.186 g enyne-isocyanate (0.75 mmol) in 10 mL 1,2-dichlorobenzene was refluxed for 14 days. The solvent was removed in vacuo, and the residue was purified by column chromatography to afford 0.050 g 7,8-dihydrobenzo[*k*]phenanthridin-6(5*H*)-one as brown crystals, in a yield of 27%. Similarly, a solution of 0.100 g same enyne-isocyanate

(0.40 mmol) in 2 mL 1,2-dichlorobenzene in a sealed glass tube was heated at 230°C for 24 h to afford 0.081 g 7,8-dihydrobenzo[*k*]phenanthrid in-6(5*H*)-one, in a yield of 81%, m.p. 245–246°C.



Reference 7.

To a solution of 180 μL 2-bromonaphthalene (1.3 mmol) in 8 mL dry THF cooled to −78°C under argon was added 0.74 mL 1.6 M *n*-BuLi in hexane (1.2 mmol). The solution was stirred for 30 min, the anion was added via cannula to a −78°C solution of 170 mg 3-*tert*-butoxy-3-cyclobutene-l,2-dione (1.1 mmol) in 30 mL dry THF. After being stirred for another 30 min, the reaction mixture was poured into 20 mL 1% NH_4Cl solution. The aqueous layer was extracted with EtOAc (2 × 30 mL). The organic layers were combined, washed with brine, dried over $MgSO_4$, filtered, and evaporated. The resulting alcohol was purified by flash column chromatography on silica gel (2:l, hexane/EtOAc) to give a white powder, which was used without characterization. The alcohol was dissolved in 80 mL dry *p*-xylene and refluxed under argon for 25 min. Upon cooling to room temperature, 550 mg Ag_2O (2.4 mmol) and 330 mg K_2CO_3 (2.4 mmol) were added, and the suspension was stirred at room temperature for 1.75 h. The reaction mixture was then filtered through Celite and evaporated to a bright yellow oil. The oil was purified by flash column chromatography on silica gel (10:1, hexane/EtOAc) to give 140 mg 2-*tert*-butoxy-l,4-phenanthrenedione as a bright yellow powder, in a yield of 48%.

Other references related to the Moore cyclization are cited in the literature.[8]

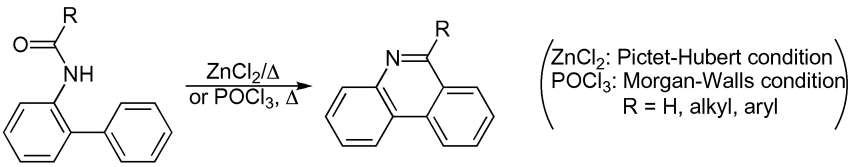
Morgan-Walls Cyclization

(Pictet-Hubert Phenanthridine Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pictet and Hubert in 1896[1] and subsequently modified by Morgan and Walls.[2] It is the synthesis of phenanthridine derivatives by means of the treatment of *N*-acyl *ortho*-aminobiphenyls with $ZnCl_2$ at high temperature[1] or with $POCl_3$.[2] Therefore, it is known as the Pictet-Hubert phenanthridine synthesis.[3] Due to the intrinsic disadvantages of the original protocol, including the long reaction time and low yield,[4] the modification by Morgan and Walls using $POCl_3$ as the dehydrating agent is often used to prepare phenanthridine, even though such modification was unsuccessful for the transformation of *ortho*-formamidobiphenyl itself to the parent phenanthridine scaffold.[4] This modification is referred to as the Morgan-Walls cyclization[5] or Morgan-Walls reaction.[4,6] Under these reaction conditions, it is best to use a high-boiling solvent, such as nitrobenzene.[7] In addition, HBF_4 has been found to be able to catalyze such a cyclization.[6a]

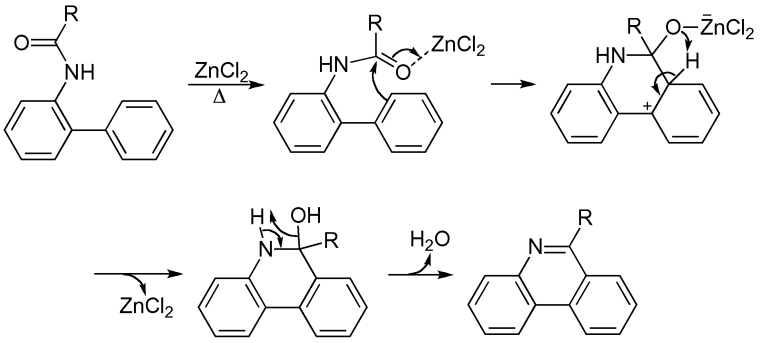
B. GENERAL REACTION SCHEME



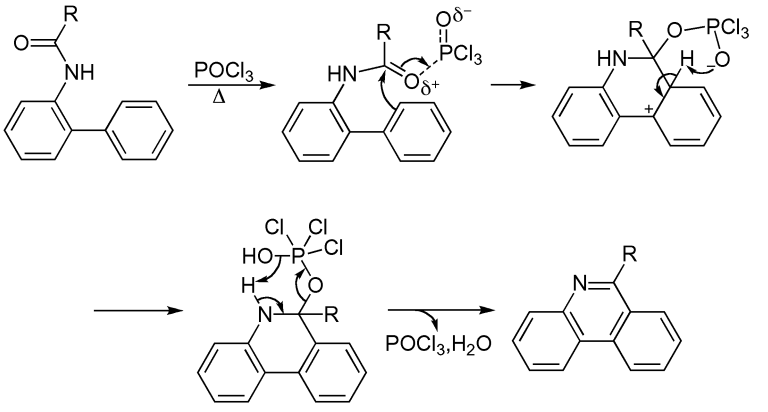
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The reaction mechanism under the initial Pictet-Hubert condition is displayed in Scheme 1 and the modified Morgan-Wall condition is outlined in Scheme 2. It is believed that the complexation of Lewis acid (e.g., $ZnCl_2$) with oxygen polarizes the carbonyl group, which facilitates the electrophilic substitution as shown below.



SCHEME 1. *Mechanism under Pictet-Hubert condition.*



SCHEME 2. *Mechanism under Morgan-Walls condition.*

D. MODIFICATION

The phenanthridine can be obtained from the reduction and dehydration of phenanthridone, which is easily prepared from the cyclization of *o*-biphenyl isocyanante with $AlCl_3$. In addition, the coupling between nitrile and biphenyl carbocation generated from *ortho*-diazonium biphenyl salt is also a good method for phenanthridine (i.e., the *Ritter Reaction*)[8].

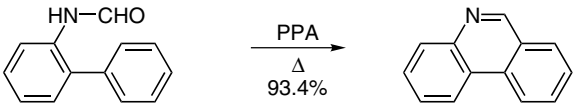
E. APPLICATIONS

This reaction is useful for the preparation of phenanthridine derivatives, especially for 6-substituted phenanthridines.[5b]

F. RELATED REACTIONS

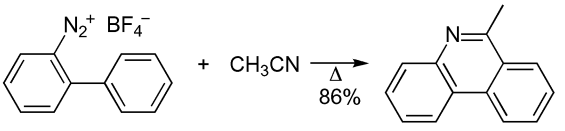
This reaction is related to the *Bischler-Napieralski Isoquinoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A mixture of 20 mL polyphosphoric acid and 2.0 g 2-formamidobiphenyl in a 100-mL round-bottomed flask was heated at 140–160°C for 1 h with constant stirring. The viscous reaction mixture was then poured into 200 mL cold water. The resulting milky solution was basified to pH 10 with a strong NaOH solution and allowed to stand several hours at room temperature. The light pink solid was filtered, washed extensively with water, and dried to give 1.70 g phenanthridine, in a yield of 93.4%, m.p. 104.5–106°C. The product can be further purified by recrystallization from ligroin to colorless needles, m.p. 106–107°C.



Reference 6a.

A solution of 1.07 g 2-biphenyldiazonium tetrafluoroborate in 25 mL anhydrous CH_3CN was refluxed for 12 h under conditions without moisture. Nitrogen evolution was complete in a few minutes. After cooling, the unreacted CH_3CN was evaporated, and the solid residue was treated with 15 mL $CHCl_3$ and 5% aqueous NaOH. The organic layer was extracted with 8% H_3PO_4 (3×15 mL). The combined extracts were washed with $CHCl_3$, neutralized with NaOH, and then extracted with $CHCl_3$. The combined $CHCl_3$ was dried over Na_2SO_4, and 0.66 g 6-methylphenanthridine was obtained after the evaporation of $CHCl_3$, in a yield of 86%, m.p. 84°C. GLPC analysis indicated that this product was contaminated by 4.5% 2-fluorobiphenyl.

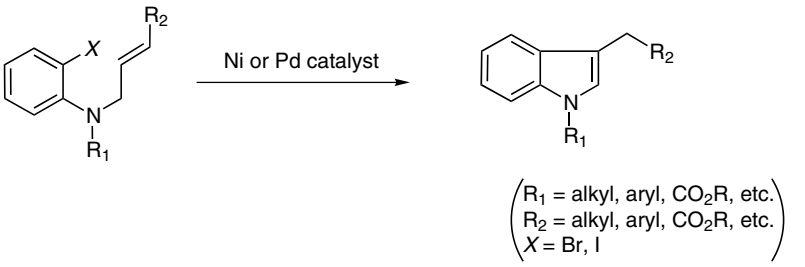
443

Mori-Ban Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mori and Ban in 1976.[1] It is a synthesis of indole derivatives by an intramolecular *Heck Reaction* of *o*-halo-*N*-allylanilines catalyzed by a low-valent metal complex and is known as the Mori-Ban indole synthesis.[2] In this reaction, the low-valent metal can be nickel[1] or palladium,[3] but the *ortho* halogen must be bromine or iodine.[4] Often the *o*-iodo-*N*-allylaniline is more reactive than corresponding *o*-bromo substrate.[5] In addition, it has been found that the catalyst can be deactivated under the reaction conditions, thus a periodic provision of fresh catalyst normally gives higher overall yields than that using the same total amount of catalyst at once.[5]

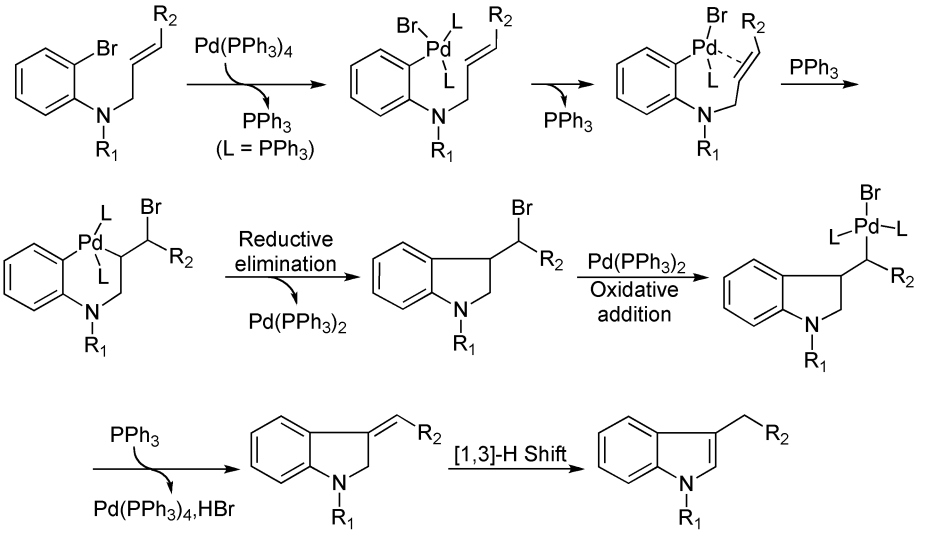
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A general mechanism for this reaction is displayed below, using *o*-bromo-*N*-allylaniline as the substrate and $Pd(PPh_3)_4$ as a catalyst.



D. MODIFICATION

This reaction has been modified by using a zirconocene complex as a catalyst;[6] in addition, a solid-phase supported substrate has been used in this reaction.[7]

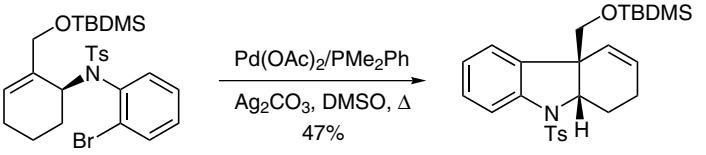
E. APPLICATIONS

This reaction has general application for the synthesis of indole and indoline derivatives.

F. RELATED REACTIONS

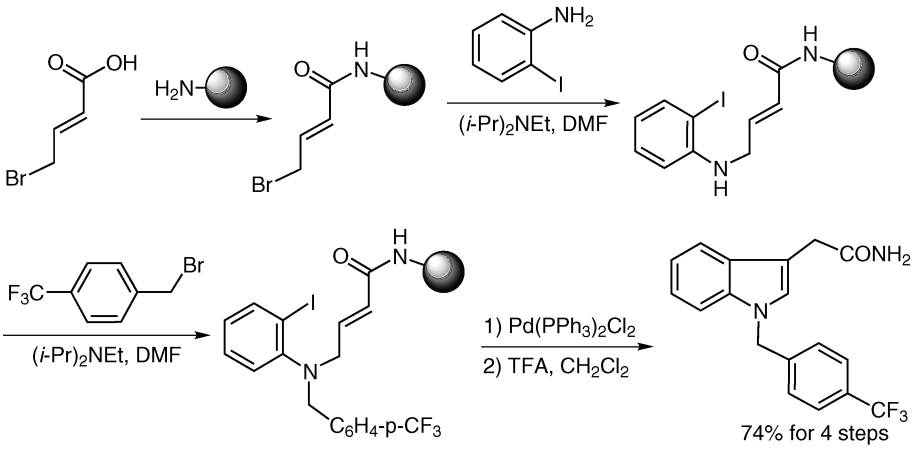
This reaction is related to the *Larock Indole Synthesis.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A solution of 763 mg (*S*)-*N*-(2-bromophenyl)-*N*-(2-[(2-*tert*-butyldimethylsilanyloxymethyl-2-cyclohexenyl)-4-methyl-benzenesulfonamide (1.39 mmol), 15.6 mg $Pd(OAc)_2$ (69.3 μmol), 20.0 μL Me_2PPh (139 μmol), and 382 mg Ag_2CO_3 (1.39 mmol) in 14 mL DMSO was heated at 120°C for 24 h. After cooling to room temperature, the mixture was filtered through the pad of Celite. Then EtOAc was added, and the organic layer was washed with brine, dried over Na_2SO_4, and concentrated. The residue was purified by silica gel column chromatography using hexane/CH_2Cl_2 (1:1) as the eluent to afford 306.9 mg (4a*S*,9a*S*)-4a-(*tert*-butyldimethylsilanyloxymethyl)-9-(4-methylbenzenesulfonyl)-2,4a,9,9a-tetrahydro-1*H*-carbazole as a white solid, in a yield of 47%.



Reference 7.

Rink amid resin (7.5 g, 0.48 mmol/g, 3.6 mmol) was deprotected with 100 mL 20% piperidine in DMF at room temperature for 1.5 h and then filtered and washed with DMF, MeOH, and CH_2Cl_2. The deprotected resin was suspended in 36 mL DMF and treated with 2.73 g DIC (21.6 mmol), followed by 3.56 g γ-bromocrotonic acid (21.6 mmol). The mixture was stirred at room temperature for 30 min and then filtered and washed with CH_2Cl_2 and DMF. The resulting resin was retreated with 36 mL DMF, 2.73 g DIC, and 3.56 g γ-bromocrotonic acid at room temperature for 30 min; it was then washed with DMF, MeOH, CH_2Cl_2, and Et_2O. It was dried in vacuo to give 7.41 g resin with a loading level of 0.32 mmol/g, which was determined by cleaving an aliquot with 30% TFA in CH_2Cl_2 at room temperature for 80 min. Then 1.2 g of this resin (0.38 mmol) was suspended in 10 mL DMF and treated with 387 mg *N*,*N*-diisopropylethylamine (3.0 mmol), followed by 420 mg 2-iodoaniline (1.9 mmol). The reaction mixture was stirred at 80°C for 18 h and then filtered and washed with CH_2Cl_2, MeOH, and CH_2Cl_2. It was dried in vacuo to give 1.25 g *o*-iodo-*N*-allylanlinide. A mixture of 230 mg of this *o*-iodo-anilide (0.070 mmol), 90 mg *N*,*N*-diisopropylethylamine (0.70 mmol), and 167 mg α'-bromo-α,α,α-trifluoro-*p*-xylene (0.70 mmol) in 2.5 mL DMF was stirred at 80°C for 22 h and then filtered, washed sequentially with MeOH and CH_2Cl_2, and dried in vacuo to give *o*-iodo-*N*-benzyl-allylanilide. The resulting resin was then suspended in 4 mL DMF-H_2O mixture (9:1) and treated with 29 mg tetrabutylammonium chloride (0.11 mmol), 21 mg triethylamine (0.21 mmol), and 4.9 mg bis-(triphenylphosphine)palladium(II) chloride (0.007 mmol). The suspension was stirred at 80°C for 8 h, at which time TLC indicated that the reaction was complete. The dark brown

reaction mixture was filtered; washed sequentially with CH_2Cl_2, MeOH, and CH_2Cl_2; and then dried in vacuo. The resulting resin was cleaved with 8 mL 30% TFA in CH_2Cl_2 at room temperature for 1.5 h. The crude cleaved product obtained was dissolved in 25 mL EtOAc, washed with 5 mL water to remove contaminated Et_3N-TFA salt, and then washed with 5 mL brine, dried over anhydrous Na_2SO_4, and concentrated in vacuo. The resulting product showed 85% purity by reversed-phase HPLC (2 mL/min, 7:3 H_2O/CH_3CN (0.2% TFA), linear gradient to 5:95 in 30 min; $R_f = 18.5$ min). After purification by preparative TLC using EtOAc/MeOH (95:5), 17.2 mg 2-[1-[4-(trifluoromethyl) benzyl]-1*H*-indol-3-yl]acetamide was obtained as a colorless solid, in a total yield of 74% for four steps.

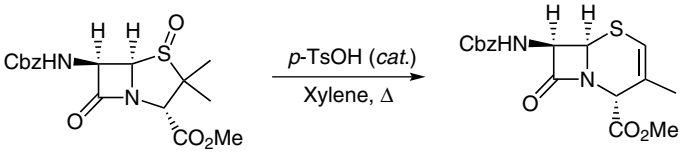
Morin Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Morin et al. in 1963.[1] It is an acid-promoted stereospecific transformation of penicillin sulfoxides into corresponding desacetoxycephalosporins[2] and is generally known as the Morin rearrangement[2,3] or Morin reaction.[4] Occasionally, this reaction is also referred to as the Morin process.[5] This reaction involves the following steps: (*a*) activation of sulfoxide by an acid, (*b*) generation of azetidinone sulfenic acid[2] via stereospecifically sigmatropic opening of the thiazolidine ring without concomitant rupture of the β-lactam[6] by abstracting a proton from the C-2 methyl group *cis* to the sulfoxide S-O bond,[2] (*c*) protonation of sulfenic acid, and (*d*) cyclization of protonated sulfenic acid with the adjacent π-bond and the final deprotonation.[5] This rearrangement is found to be general for penicillin[4a] and hetacillin sulfoxides.[4a] Further evidence for the protonation of sulfenic acid that cyclizes to adjacent π-bond has been demonstrated by the capture of putative cationic intermediate by carbon nucleophiles, such as indole, furan, and anisole.[3b] This reaction has clearly indicated the existence of a thermal equilibrium between the sulfoxide and the sulfenic acid.[7] In addition, it provides the first direct chemical correlation between the penicillins and cephalosporins and a practical preparation of important antibiotics containing deacetoxycephalosporin moiety.[8]

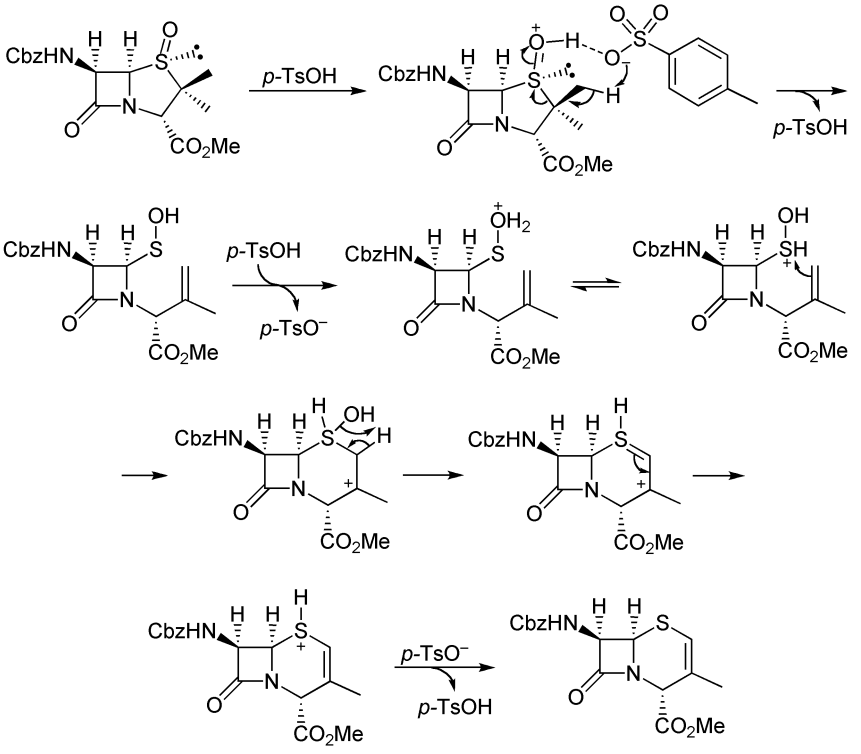
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although it is assumed that the reaction involves the activation of sulfoxide by an acid, formation of sulfenic acid, and cyclization with adjacent π-bond,[2] no detailed mechanism has been provided in literature. A tentative mechanism in full details is displayed here.



D. MODIFICATION

N/A

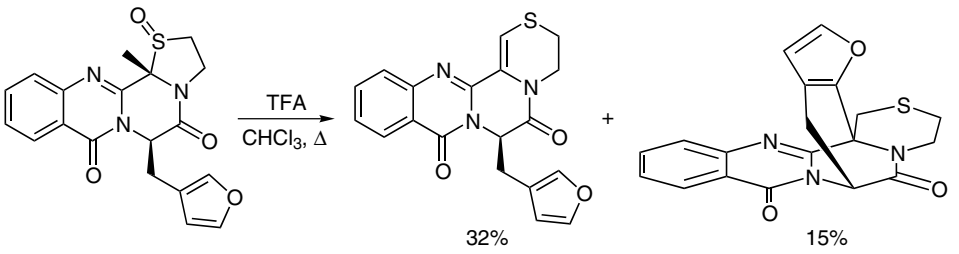
E. APPLICATIONS

This reaction has important application in the preparation of antibiotics containing deacetoxy-cephalosporin moiety.

F. RELATED REACTIONS

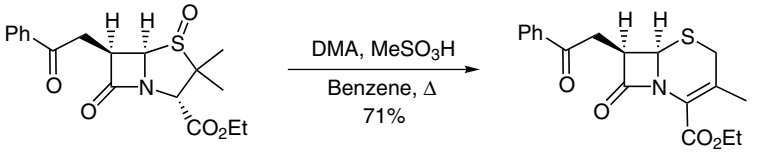
This reaction is related to the *Pummerer Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

To a 250-mL round-bottomed flask fitted with a reflux condenser and magnetic stirrer were added 680 mg sulfoxide (1.8 mmol), 90 mL $CHCl_3$, and 10 mL trifluoroacetic acid (130 mmol). The resulting rose-colored solution was refluxed for 18 h. The reaction mixture was then transferred to a separation funnel and washed successively with two 125-mL portions of 1 M Na_2CO_3 and 75 mL water. The aqueous washes were back extracted with $CHCl_3$, and the organic extracts were combined, dried over $MgSO_4$, filtered, and evaporated to give an amorphous solid residue. The residue was chromatographed using MPLC over silica gel (hexanes/EtOAc, 4:3) to afford a white foam. Then the foam was fractionally recrystallized from EtOAc/hexanes to afford 210 mg high pure thioether, in a yield of 32%, m.p. 189–192°C (EtOAc/hexanes). The mother liquor was concentrated to give a solid residue, which was recrystallized from EtOAc/hexanes to give 100 mg furan fused thioether, in a yield of 15%, m.p. 249–251°C (EtOAc/hexanes).



Reference 9.

A solution of 963 mg β,β,β-trichloroethyl 6β-(phenylcarbothio)penicillanate 1-oxide (α and β isomers, 1.98 mmol), 32 mL dry benzene, 24 mL *N*,*N*-dimethylacetamide, and 3 drops methanesulfonic acid were refluxed for 19 h under a Dean-Stark trap, protected from moisture with a drying tube (temperature of external heating bath was maintained between 110° and 120°C). Removal of the solvent by distillation under reduced pressure (temperature of bath ~ 50°C, 2–3 mmHg) and silica gel chromatography of the dark brown residue using CH_2Cl_2 as an eluent gave 659 mg β,β,β-trichloroethyl 7β-(phenylcarbothio)-deacetoxycephalosporanate as a white solid, in a yield of 71%. Recrystallization from CH_2Cl_2/petroleum ether gave an analytically pure sample as thin, white needles, m.p. 175.5–176.0°C.

Other references related to the Morin rearrangement are cited in literature.[10]

Mosher's Acid

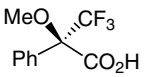
A. GENERAL DESCRIPTION OF THE REACTION

This compound was first applied by Mosher et al. as early as 1968 to determine the enantiomeric excess (% e.e.) of chiral molecules.[1] It is α-methoxy-α-(trifluoromethyl)phenylacetic acid (MTPA), made from the reaction between α,α,α-trifluoroacetophenone and sodium cyanide in DME followed by alkylation with Me_2SO_4 and subsequent hydrolysis.[2] This molecule has a boiling point of 105–110°C at 1 mmHg,[3] and 90–93°C at 0.3 mmHg,[2a] and has been widely used in the determination of enantiomeric excess of chiral molecules. Therefore, MTPA is referred to as the Mosher's acid,[2a,4] its derivative (i.e., acyl chloride) for the preparation of ester or amide from primary or secondary alcohol or amine is known as Mosher's reagent,[5] and the corresponding ester is called the Mosher ester.[4c,6] Unlike the preparation of mandelate or *O*-methylmandelate derivatives,[7] the racemization is impossible during the derivatization of Mosher's acid[2b,8] because no α-proton exists in this acid.[5b] In addition, both ^{1}H NMR[9] and ^{19}F NMR[10] can be used to determine the % e.e. value of enantiomeric compounds, although it has been reported that ^{1}H NMR is superior to ^{19}F NMR.[5b] It has been found that the % e.e. obtained from this method is very consistent with the result determined from chiral HPLC (e.g., $< 1\%$ error).[4c] In addition, this acid can also be used to determine the diastereomeric excess (% d.e.).[6i] More importantly, not only can MTPA be used to determine the absolute configuration (R or S) of alcohol by comparing the NMR signals of natural and synthetic alcohols,[11] but it has also been successfully used for the determination of stereochemistry of alcohols when there is no available basis for comparison.[6h,12] It has been found that while the chemical shift of one group attached to the carbinyl location in (R)-(+)-MTPA ester moves upfield, the chemical shift of the other group exclusively goes downfield; the reverse movement of chemical shifts are observed for the same carbinol in (S)-(-)-MTPA ester.[8a] As demonstrated in Section C,

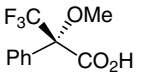
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

1A and 1B are the diastereomeric esters prepared from (R)-(+)-MTPA and (S)-(-)-MTPA, in which the (R)-(+)-MTPA ester always shows an upfield signal for the group L_2 and a downfield signal for the group L_3, compared to the alternate diastereomer—that is the (S)-(-)-MTPA ester.[8a] This is because the electron-withdrawing α-trifluoromethyl group, more or less, eclipses the carbonyl group in the ester, and one of the group (L_2 or L_3) will yield different time-weighted average preferential shieldings from the π-cloud of the α-phenyl group, resulting in a different chemical shift movement, even though the carbinyl proton is still located in the same relative position in each diastereomer.[8a] As shown in Section C in the case of (R)-(+)-MTPA ester, L_2 is juxtaposed with the phenyl group, which will be deshielded from such phenyl group and move upfield; similarly, in the case of (S)-(-)-MTPA ester, L_3 is juxtaposed with phenyl group and will go upfield too.[8a] To determine the absolute configuration of a given alcohol, both (R)-(+)-MTPA and (S)-(-)-MTPA esters are prepared, and different NMR spectra are measured, including ^{1}H NMR, COSY, and TOCSY, to assign the chemical shifts for every proton; the critical chemical shifts of protons on the groups attached to the carbinyl location are then used to calculate the difference of the chemical shift, and the absolute configuration of that chiral center is determined according to the layouts shown by 1A and 1B.[7,8a] For some alcohols, of which the chemical shift changes very small, the corresponding (R)- and (S)-2-naphthylmethoxyacetic acid (2-NMA) esters are employed to determine the configuration, due to their improved long-range anisotropic effects.[12b]

B. GENERAL REACTION SCHEME



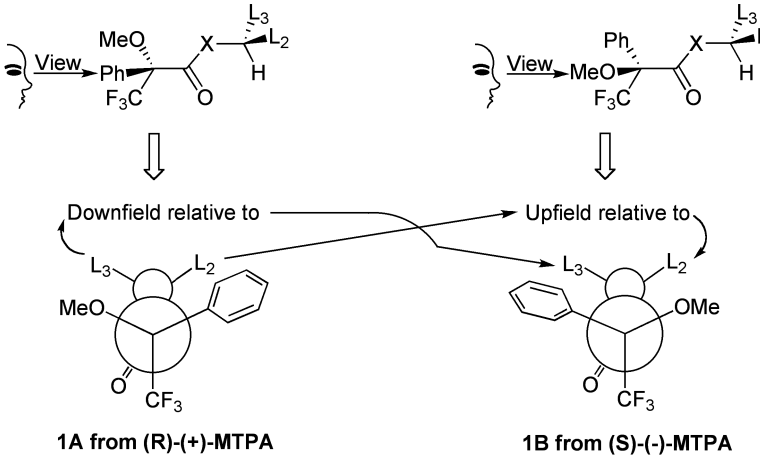
(R)-(+)-MTPA



(S)-(-)-MTPA

C. PROPOSED MECHANISMS

The correlation between the movement of chemical shift and the shielding/deshielding of the carbinyl group from the phenyl group of Mosher's acid is demonstrated here.



1A from (R)-(+)-MTPA **1B from (S)-(-)-MTPA**

D. MODIFICATION

Several analogues of Mosher's acid have been developed for determining the stereochemistry.[12b,13] In addition, a modified Mosher's method has been used to determined the absolute configuration of some natural products.[14] Moreover, the preparation of MTPA has been improved to one-pot synthesis by the addition of trimethylsilyl trichloroacetate to α,α,α-trifluoroacetophenone and subsequent hydrolysis.[2a]

E. APPLICATIONS

This compound has wide application in determination of enantiomeric excess and the absolute configuration of chiral compounds.

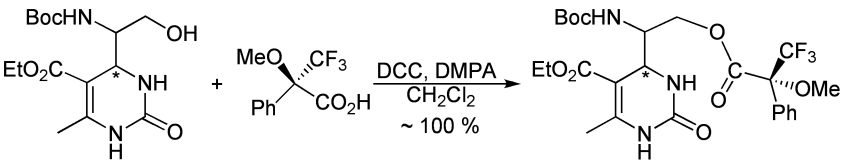
G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a stirred solution of 0.1 mmol (4*R*,1′*S*)- and (4*S*,1′*S*)-4-(1′-*tert*-butoxycarbonylamino-2′-hydroxyethyl)-6-methyl-2-oxo-1,2,3,4-tetrahydropyrimidine-5-carboxylic acid ethyl ester in 1 mL anhydrous CH_2Cl_2 were added 29 mg (R)-α-methoxy-α-(trifluoromethyl)phenylacetic acid (0.12 mmol), 25 mg 1,3-dicyclohexylcarbodiimide (0.12 mmol), and a catalytic amount of 4-*N*,*N*-(dimethylamino)pyridine. The mixture was stirred for an additional 12 h at room temperature, then concentrated. The residue was taken into EtOAc, washed with saturated aqueous $NaHCO_3$ and brine, dried over Na_2SO_4, and concentrated. The residue was purified by preparative TLC, affording the corresponding Mosher ester in almost quantitative yield.

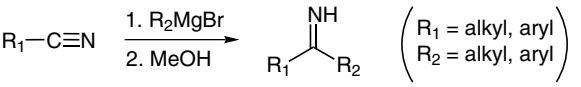
Moureau-Mignonac Ketimine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Blaise in 1901,[1] and subsequently explored by Moureau and Mignonac extensively since 1913.[2] It is a direct synthesis of ketimine involving the reaction between a nitrile and a Grignard reagent and careful hydrolysis at low temperature with hydrogen chloride and finally with ammonia. Therefore, it is known as the Moureau-Mignonac ketimine synthesis. It is found that the ratio of Grignard reagent to nitrile from 4.85 to 2 has almost no effect on the yield of ketimine.[3] Although many of the resulting ketimines can be hydrolyzed to ketones[4] or reduced to amines,[5] some of the synthesized ketimines are fairly stable toward hydrolysis, such as 2,2,6-trimethylcyclohexyl phenyl ketimine,[6] *t*-butyl-*o*-tolyl ketimine,[7] and isopropyl 1-methyl-3-isopropylcyclopentyl ketimine.[3] The latter ketimine in particular can survive refluxing with 6 N HCl for a period of 2 days.[3] In addition, it has been found that the hydrolysis of ketimine depends on the ketimine-enamine tautomerization (and/or resonance) and the steric hindrance.[8] For the monosubstituted aryl ketimine, the hydrolysis rate is in the order of *meta* > *ortho* > *para*.[8] The reaction has been improved to decompose the nitrile-Grignard complex in a toluene solution with anhydrous ammonia.[9] In addition, this reaction has also been improved by using a copper (I) salt to catalyze the addition of a Grignard reagent to nitrile[5] and by the decomposition of nitrile-Grignard complex in anhydrous methanol.[7]

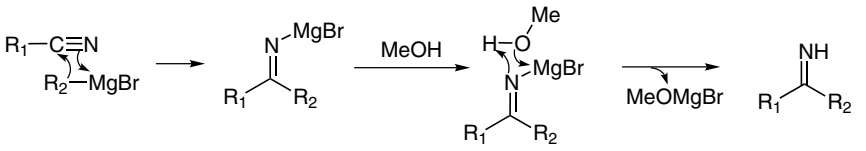
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the reaction mechanism to hydrolyze the nitrile-Grignard complex in anhydrous methanol.



D. MODIFICATION

This reaction has been modified to use copper (I) salt to accelerate the reaction[5] and anhydrous methanol to hydrolyze the nitrile-Gringard complex.[7]

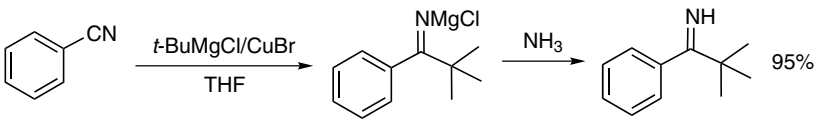
E. APPLICATIONS

This reaction is one of the best reactions for the preparation of ketimines.

F. RELATED REACTIONS

This reaction is related to the *Grignard Reaction*.

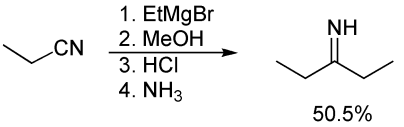
G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To a mixture of 2.0 g benzonitrile (19.4 mmol), 10.7 mL 2 M *tert*-butylmagnesium chloride in THF (21.4 mmol) and 40 mL THF, was added 50 mg CuBr (0.34 mmol), and the mixture was refluxed under nitrogen for 14 h. After cooling to 0–5°C (ice water bath), the nitrogen inlet tube attached to the condenser was replaced by a soda lime trap

and 10 mL anhydrous ammonia was condensed into the vessel. After allowing the mixture to warm to ambient temperature, it was filtered through Celite and the filtrate was concentrated at water-aspirator pressure on a rotary evaporator to afford 3.52 g α-(1,1-dimethylethyl)-benzenemethanimine as a colorless oil, which was further purified through Kugelrohr distillation to collect 2.97 g product, in a yield of 95%, b.p. 80–84°C at 0.6 mmHg.



Reference 7.

To the anhydrous diethyl ether solution containing 0.5 mol ethylmagnesium bromide was added 16 g propionitrile (0.285 mol) dropwise, and the mixture was refluxed for 4 h. After cooling to room temperature, the stirred complex was decomposed by the dropwise addition of 3 mol anhydrous methanol. Reaction was vigorous, and completion of the decomposition gave a white slurry, crystalline solid that could be easily filtered, although at the intermediate stage the mixture was sometimes gummy. Immediately following the decomposition, the slurry was filtered, and the filtrate was treated with hydrogen chloride. Then the diethyl ketimine hydrochloride (m.p. 104°C) was isolated by filtration, and the diethyl ketimine was regenerated with anhydrous ammonia and purified by distillation, in a yield of 50.5%, b.p. 86.5°C at 730 mmHg.

Other references related to the Moureau-Mignonac ketimine synthesis are cited in the literature.[10]

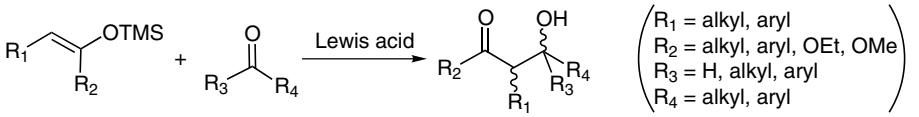
Mukaiyama Aldol Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mukaiyama et al. in 1974.[1] It is a Lewis acid-catalyzed nucleophilic addition of silyl enol ether to carbonyl compounds and is one of the most important carbon-carbon bond-forming reactions in current organic synthesis.[2] Therefore, this reaction is generally known as the Mukaiyama aldol reaction.[3,4] In addition, it is also referred to as the Mukaiyama reaction,[5] Mukaiyama aldol coupling,[6] or Mukaiyama aldolization.[7] It has been reported that the configuration of the silyl ether will determine the relative stereochemistry of the concomitantly forming vicinal stereocenters, while the inherent chirality of the carbonyl compounds primarily will determine the carbonyl facial selectivity.[6a] The stereoselectivity can be enhanced by the application of a chiral catalyst[3d,5b] or by the unbalanced one face shielding from a remote substituent.[3f] Some of the Lewis acid catalysts used in this reaction are $BF_3{\cdot}Et_2O$,[3a] $InCl_3$,[3f] $TiCl_4$,[5n] $Cu(OTf)_2$,[5b] and chiral (acyloxy) borane.[3d] This reaction has been extended to several different types of nucleophiles, including the Danishefsky's diene,[3g] ketene silyl acetals,[3d] imines,[8] and vinylogous silyl enol ether.[5b]

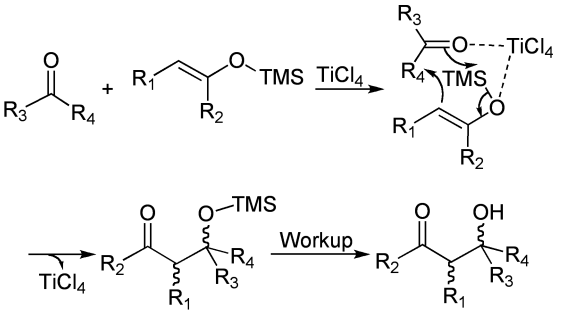
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is a general Mukaiyama aldol reaction catalyzed by Lewis acid $TiCl_4$.



D. MODIFICATION

This reaction has been extended to use different Lewis acids as the catalysts and the application of a variety of nucleophiles.

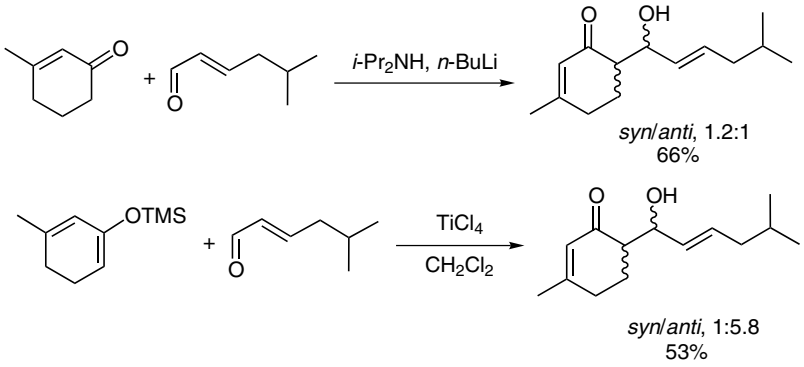
E. APPLICATIONS

This reaction has very broad application in organic synthesis.

F. RELATED REACTIONS

This reaction is related to the *Aldol Reaction* and *Mukaiyama-Michael Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 3d.

To a cooled (0°C) and stirred solution of 2.8 mL *i*-Pr_2NH (20 mmol) in 20 mL THF was added 11.5 mL 1.54 M *n*-BuLi in hexane under argon. After being stirred at 0°C for 30 min, the solution was cooled to −78°C, and 2.10 mL 3-methyl-2-cyclohexenone (18.1 mmol) was added. The mixture was stirred at −78°C for 30 min and then warmed to −18°C; a solution of 2.03 g 5-methyl-2-en-hexaldehyde (18.1 mmol) in 20 mL THF was added. After being stirred at −18°C for 15 min, the mixture was quenched with 3 mL saturated aqueous NH_4Cl, diluted with 200 mL EtOAc, and washed with saturated aqueous NH_4Cl (3 × 200 mL). The organic layer was dried and concentrated in vacuo. The residue was purified by silica gel column chromatography (EtOAc/hexane, 1:8) to provide 2.64 g rel-(6*R*)-6-[(1*S*,2*E*)-1-hydroxy-5-methyl-2-hexenyl]-3-methyl-2-cyclohexen-1-one and rel-(6*R*)-6-[(1*R*,2*E*)-1-hydroxy-5-methyl-2-hexenyl]-3-methyl-2-cyclohexen-1-one as an inseparable mixture (1.2:1), in a yield of 66%, $R_f = 0.35$ (EtOAc/hexane, 1:3).

For comparison, a solution of 666 mg (2*R*,3*R*)-2-*O*-(2,6-diisopropoxybenzoyl)tartaric acid (1.80 mmol), 382 mg *o*-phenoxyphenylboronic acid (1.79 mmol), and 3-methyl-2-cyclohexenone in 24 mL propionitrile was stirred for 30 min under argon to prepare 1-methyl-3-trimethylsiloxyl-cyclohex-1,3-diene. A solution of 1.0 g 5-methyl-2-en-hexaldehyde (8.92 mmol) and 2.46 g 1-methyl-3-trimethylsiloxyl-cyclohex-1,3-diene (13.4 mmol) in CH_2Cl_2 was cooled to −78°C, and a catalytic amount of $TiCl_4$ was added and stirred at the same temperature for 2.5 h; the mixture was quenched with 10 mL 0.2 M HCl, warmed to room temperature, and stirred for an additional 1 h. The resulting mixture was diluted with 100 mL EtOAc and washed with H_2O (3 × 50 mL). The organic layer was dried and concentrated in vacuo. The residue was purified by silica gel column chromatography (EtOAc/hexane, 1:5) to provide 2.61 g crude mixture (10:1) of the above product as a pale yellow oil, which was contaminated with *o*-phenoxyphenylboronic acid but used in the next step without further purification.

Other references related to the Mukaiyama aldol reaction are cited in the literature.[9]

Mukaiyama-Michael Reaction

(Mukaiyama-Michael Addition, Mukaiyama-Michael Conjugate Addition)

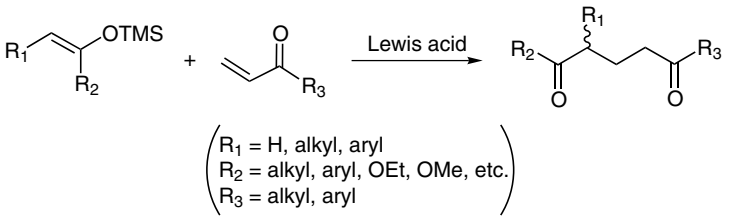
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Mukaiyama et al. in 1974.[1] It is a Lewis acid-catalyzed Michael conjugate addition of silyl enol ether to α,β-unsaturated compounds. Therefore, it is generally referred to as the Mukaiyama-Michael reaction.[2,3] Because this reaction is essentially a conjugate addition, it is also known as the Mukaiyama-Michael addition[2a,4] or Mukaiyama-Michael conjugate addition.[5] This reaction is a mechanistic complement for the base-catalyzed Michael addition,[2j,2l] and often occurs at much milder conditions and affords superior regioselectivity.[2g] Besides silyl enol ether, silyl ketene acetals are also suitable nucleophiles in this reaction.[2d,2i,2j,2k,4c] For the hindered ketene silyl acetals, the Lewis acid actually mediates the electron transfer from the nucleophiles to α,β-unsaturated carbonyl molecules.[2j,2k] On the other hand, the α,β-unsaturated compounds, such as 3-crotonoyl-2-oxazolidinone,[6] alkylidene malonates,[2f,7] and α-acyl-α,β-unsaturated phosphonates[2i] are often applied as the Michael acceptors. It has been found that the enantioselectivity is very sensitive to the reactant structures[2g]—for example, α-acyl-α,β-unsaturated phosphonates especially prefers the unique *syn*- vs *anti*-diastereoselectivity in this reaction.[2i] In addition,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

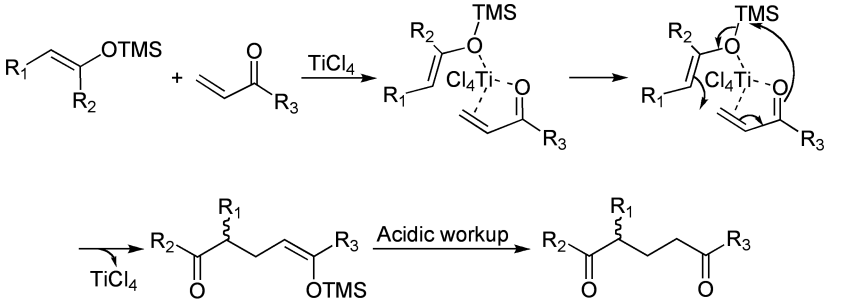
the stereochemistry is improved in the presence of a chiral Lewis acid, such as [Cu(*S*, *S*)-*t*-Bu-box](SbF$_6$)$_2$,[7,8] titanium-BINOL complex (*R*)-L50,[9] C_2-symmetric bis(oxazoline)-Cu(II) complexes,[2g,7] and oxazaborolidinone.[2b,4b] Moreover, the recently developed chiral imidazolidinone is also an effective catalyst for this reaction.[2a,3d]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that the coordination of α,β-unsaturated carbonyl compounds to Lewis acid facilitates this reaction, as illustrated by the tentative mechanism given here.



D. MODIFICATION

This reaction has been extensively modified by application of different types of chiral Lewis acid catalysts.

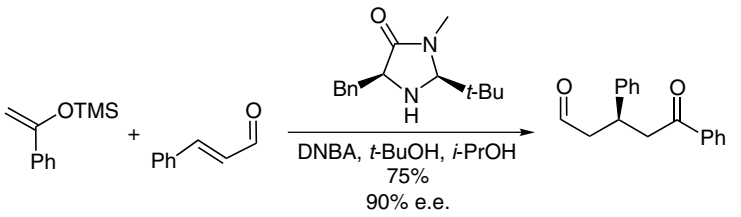
E. APPLICATIONS

This reaction has very wide application in organic synthesis.

F. RELATED REACTIONS

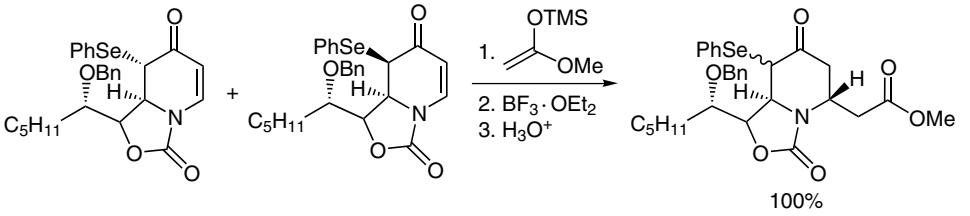
This reaction is related to the *Michael Addition* and *Mukaiyama Aldol Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

A mixture of 1 mmol *trans*-cinnamaldehyde, 0.3 mmol chiral 1-*N*-methyl-3-benzyl-5-*t*-butyl-imidazolidinone, and 0.3 mmol 2,4-dinitrobenzenesulfonic acid (DNBA) in 0.5 mL *t*-BuOH and *i*-PrOH (v/v, 5:1) was stirred at room temperature for 10 min. Then 5 mmol 1-(trimethylsilylox)ethylene was added, and the mixture was stirred for 4 h at room temperature. The solution was concentrated in vacuo. The resulting residue was then purified by silica gel chromatography to afford 75% (R)-5-oxo-3,5-diphenyl-pentanal, with 90% e.e.



Reference 2c.

To a solution of 70 mg (1*R*,1′*S*,8*S*,9*R*)-1′-((1-phenylmethoxy)hexane)-1,2,8-tetrahydro-8-phenylselenyl-2-oxaindolizine-3,7-dione (0.140 mmol) and 103 mg 1-methoxy-1-trimethylsiloxyethene (0.704 mmol) in 15 mL CH_2Cl_2 at −78°C was added dropwise 22 mg boron trifluoride etherate (0.154 mmol). The reaction mixture was allowed to stir at −78°C for 30 min and then quenched with saturated aqueous $NaHCO_3$. The organic layer was separated and concentrated under reduced pressure. The crude residue was redissolved in 7 mL THF, and then 1 mL H_2O followed by 2 drops 5% HCl were added. After 1 h, the reaction mixture was diluted with water and extracted with EtOAc. The combined organic extracts were dried over $MgSO_4$ and concentrated under reduced pressure. The residue was purified by silica gel radial PLC (20% EtOAc/hexanes) to give 79 mg (1*R*,1′*S*,5*R*,8*S*,9*S*)-1-((1′-phenylmethoxy)hexane)-8-phenylselenyl-1,2,5,6,6a,8-hexahydro-2-oxaindolizine-3,5-dione acetic acid methyl ester as a clear oil, which was an inseparable mixture of diastereomers.

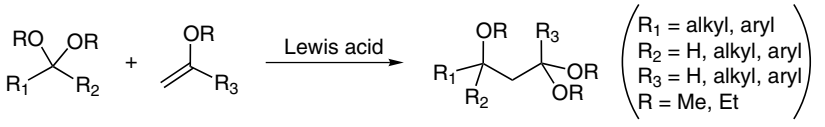
Müller-Cunradi-Pieroh Process

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Müller-Cunradi and Pieroh in 1939.[1] It is a Lewis acid-catalyzed reaction between acetal and enol ether to form 3-alkoxy acetals via carbocationic intermediate, and is known as the Müller-Cunradi-Pieroh process.[2] The resulting 3-alkoxyacetals can be easily converted into 3-alkoxy aldehyde by treatment of formic acid/sodium formate.[2] However, this reaction often gives a mixture of products resulting from the further reaction between 3-alkoxyacetal and enol ether.[3] It is believed that the formation of 1:1 adduct (i.e., 3-alkoxyacetal) depends on the relative reactivity of the initial acetal and 3-alkoxyacetal,[3] and only when the former reacts much faster than 3-alkoxyacetal with enol ether would this reaction be a practical method for organic synthesis. It has been found that if the acetal is much more labile toward acid-promoted hydrolysis than 3-alkoxyacetal, then 3-alkoxyacetal can be feasibly obtained by this method.[3] The reaction rate for acetals toward enol ether are found in the following order: saturated acetals < aromatic acetals = ortho esters < α,β-unsaturated acetals.[4]

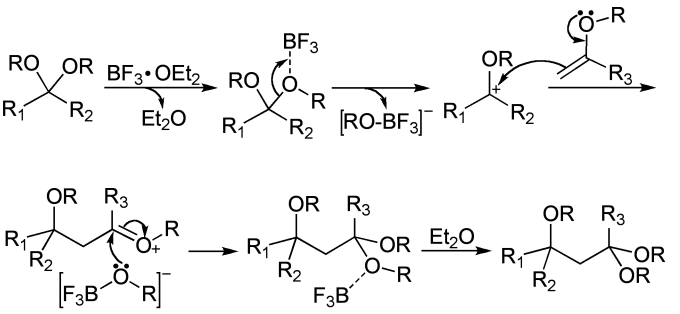
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Because no mechanistic details are available for this reaction, a tentative mechanism is provided here.



D. MODIFICATION

N/A

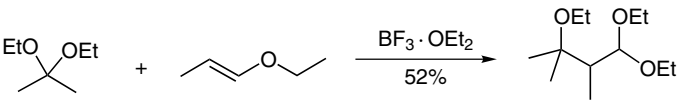
E. APPLICATIONS

This reaction is useful for the preparation of β-alkoxyl acetals, aldehydes and ketones.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To a stirred mixture of 233 g 2,2-diethoxypropane (1.77 mol, 3 eq.) and 1.2 mL boron trifluoride-etherate (9.5 mmol, 0.016 eq.) cooled at -10°C was added 51.5 g ethyl propenyl ether (0.6 mol, 1 eq.) slowly under nitrogen ($\sim$30 min). The resulting mixture was stirred at 0°C for 3 h and then at room temperature for 2 h. Powdered K_2CO_3 was then added with stirring until the solution turned orange. The reaction mixture was filtered through sintered glass and distilled over K_2CO_3. Unreacted 2,2-diethoxypropane was collected first (91 g, 0.69 mol) followed by 67.7 g 1,1,3-triethoxy-2,3-dimethylbutane, in a yield of 52%, b.p. 110–115°C at 110 mmHg.

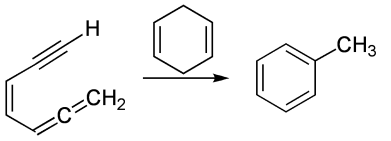
Myers-Saito Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Myers et al.[1] and Saito et al.[2] concurrently in 1989. It is a thermal intramolecular cyclization of eneyne-allene via a σ,π-biradical intermediate generated by the bonding between C_2 and C_7. Therefore, it is generally known as the Myers-Saito cyclization[3]. In addition, this reaction is also sometimes referred to as the Myers-Saito reaction[3h,3m,4] or Myers-Saito enyne-allene cycloaromatization reaction.[5] Compared to the *Bergman Cyclization*, this reaction takes place smoothly even below room temperature,[6] benefiting from a cyclic electron delocalization.[7] Similarly, the partially conjugated σ,π-biradical is less reactive than the σ,σ-biradical in the *Bergman Cyclization*.[8] This reaction has been reported to be an exothermic reaction,[3i,3m,7,8] and its enthalpy is estimated to be -13.5 Kcal/mol[9] (or -9.7 Kcal/mol[3i]), its corresponding activation energy is $\sim 23.3 \pm 0.5$ Kcal/mol[9] at 25°C. Besides the thermal initiation, this reaction can also be triggered by light,[10] acid,[11] or base;[12] however, the reaction rate is sensitive to the substituents on alkyne and allene moieties.[6] For example, when the hydrogen at the alkyne terminus is replaced by an aryl or a sterically bulky group (e.g., *t*-Bu, $SiMe_3$), the easily occurring C_2-C_7 cyclization is switched to the *Schmittel Cyclization* by formation of a bond between C_2-C_6.[3m] This reaction is very useful for building up polycyclic aromatic ring systems and developing potential anticancer drugs,[3m] such as neocarzinostatin.[9,13]

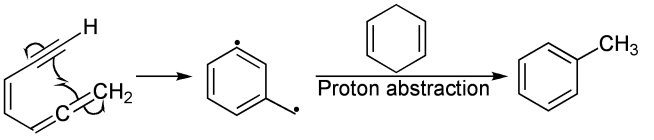
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism of this reaction is illustrated here by the simplest enyne-allene via the formation of a biradical intermediate.



D. MODIFICATION

This reaction has been extended to azaenyne-allene cyclization, the so-called *aza*-Myers-Saito cyclization.[14]

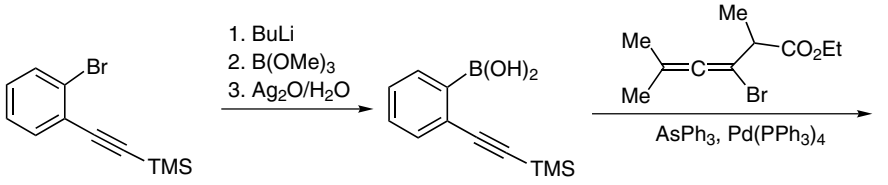
E. APPLICATIONS

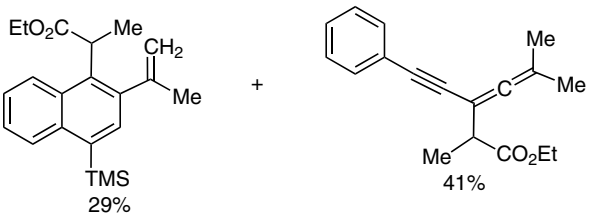
This reaction is very useful in the preparation of polycyclic aromatic ring systems.

F. RELATED REACTIONS

This reaction is related to the *Bergman Cyclization* and *Schmittel Cyclization*.

G. CITED EXPERIMENTAL EXAMPLES





Reference 5.

To a stirred solution of 1.01 g (2-bromophenylethynyl)trimethylsilane (4 mmol) in 20 mL dry THF was added 3.25 mL 1.6 M *n*-BuLi in hexane (5.2 mmol) at −95°C. After the mixture was stirred for 10 min, 0.54 g trimethylborate (5.2 mmol) was added. The solution was allowed to warm to −5°C, and 3.71 g Ag_2O in 16 mL water, 0.23 g tetrakis(triphenylphosphine)-palladium (0.2 mmol), 0.49 g triphenylarsine (1.6 mmol), and 0.99 g bromoallene (4 mmol) were added successively. The reaction was stirred at 25°C for 24 h. Ag_2O was removed by filtration, and the crude product was diluted in 40 mL Et_2O. The organic layer was washed with 50 mL distilled water, 50 mL saturated $NaHCO_3$, and 50 mL brine and dried over $MgSO_4$. After filtration, the solvent was removed under reduced pressure, and the residue was purified by column chromatography with hexane/Et_2O (10:1) to afford 0.39 g naphthalene (29%) and 0.44 g yne-allene (41%) as pale yellow oils.

Other references related to the Myers-Saito cyclization are cited in the literature [15].

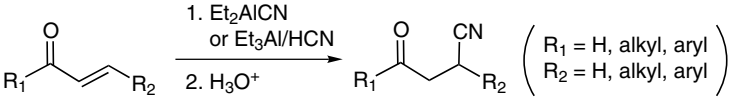
Nagata Reaction

A. GENERAL DESCRIPTION OF THE REACTION

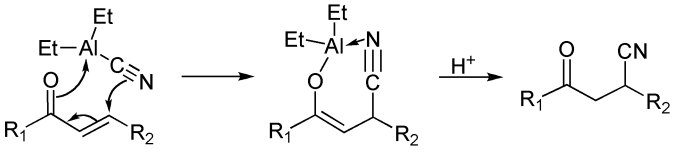
This reaction was first reported by Nagata et al. in 1962.[1] It is a conjugate hydrocyanation of an α,β-unsaturated carbonyl compound from diethylaluminum cyanide[2] or the combination of hydrogen cyanide and diethylaluminum chloride[3] (or triethylaluminum[4]) in an inert solvent. Therefore, it is generally known as the Nagata reaction.[2d,5] The solvents that are suitable for such reaction include ether, THF, and benzene.[4] Although the enol intermediate in a conjugate addition can be trapped when α,β-unsaturated ketones are treated with trimethylsilyl cyanide and dimethylaluminum chloride,[6] it is not always the case. For example, the enols resulting from the addition of diethylaluminum cyanide to some of the steroids could not be trapped through the formation of silyl enol ether or enol acetate; however, they could be trapped by further reaction with bromine.[2d] Furthermore, for the addition of Et_2AlCN to α,β-unsaturated silyl oxonium, both 1,2- and 1,4-adduct are obtained in CH_2Cl_2, whereas only 1,4-conjugate addition product is obtainable in THF.[7] It has been found that diethylaluminum cyanide will not add to the simple 3-substituted cyclohex-2-enone[2c] and α-sulfinyl quinone,[8] probably because of steric hindrance. This reaction has been extended to the hydrocyanation of an isolated carbonyl group of β-keto sulfoxide by the addition of Et_2AlCN to β-keto sulfoxide,[8] and the hydrocyanation of epoxide functionality by cleavage of the epoxide ring of an α-carbonyl epoxide.[5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

Other hydrocyanation reagents, such as KCN/Et_2AlCN/18-crown-6,[9] TMSCN,[8] and acetone cyanohydrin in combination with a catalytic amount of $Cp_2Sm(THF)_2$[4] have been used as the complements to Et_2AlCN.

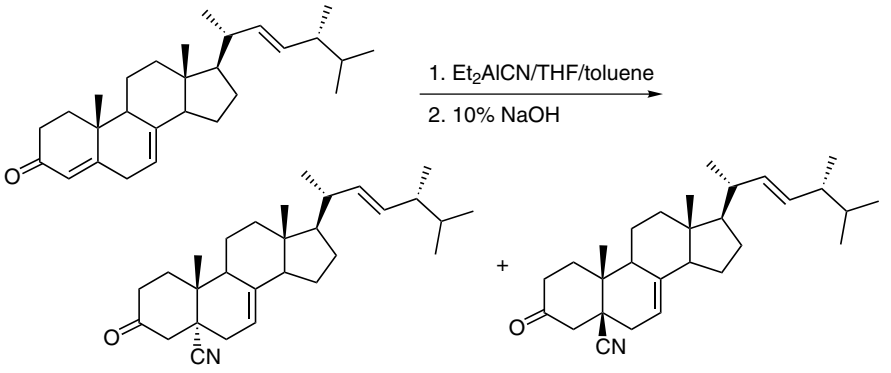
E. APPLICATIONS

This reaction is very useful for the introduction of a cyano group into the organic compounds.

F. RELATED REACTIONS

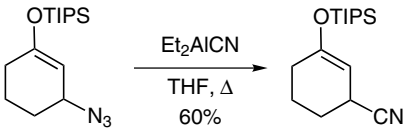
This reaction is related to the *Michael Addition.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a solution of 1.5 g 4,7,22(*E*)-ergostatrien-3-one (3.8 mmol) in 300 mL anhydrous THF was added 11.4 mL 1.0 M Et_2AlCN in toluene (11.4 mmol), and the solution turned dark red. After being stirried for 3.5 h, the mixture was washed with an ice-cold 10% NaOH solution (2 × 40 mL). (*Caution*! When the reaction is performed on a large scale, add the aqueous components dropwise to avoid a violent exotherm.) The aqueous layer was exhaustively extracted with CH_2Cl_2, the combined organic layers were dried with anhydrous $MgSO_4$ and filtered, and the solvent was evaporated in vacuo. The residue was purified by flash chromatography using an eluent of hexane/EtOAc (from 8:1 to 0:1) to afford 1.3 g 5α-cyano-7,22(*E*)-ergostadien-3-one (82%) and 0.2 g 5β-cyano-7,22(*E*)-ergostadien-3-one(13%). The α-isomer was recrystallized from EtOH to give white plates, m.p., 280–282°C, $R_f = 0.30$ (hexane/EtOAc, 3:1), and the β isomer was isolated as a white solid, m.p., 120–123°C, $R_f = 0.15$ (hexane/EtOAc, 3:1).



Reference 7.

To a 4-mL THF solution containing 74 mg triisopropylsilyl 3-azido-cyclohexenyl ether (0.25 mmol, 1.0 eq.) was added 500 μL 1.0 M Et_2AlCN in toluene. The mixture was refluxed for 60 h and then cooled to 25°C. Saturated aqueous $NaHCO_3$ (20 mL) and 40 mL Et_2O were added, and the mixture was filtered through Celite. The phases were separated. The extracts were washed with brine (2 × 10 mL), dried over $MgSO_4$, and evaporated in vacuo. The residue was purified by silica gel flash chromatography using an eluent of hexane/EtOAc (4:1) to afford 42 mg 3-cyano-1-triisopropylsilyloxy-cyclohexan-1-ene as a colorless oil, in a yield of 60%.

Other references related to the Nagata reaction are cited in the literature.[10]

Nazarov Cyclization
(Nazarov Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Nazarov et al. in 1942.[1] It is an acid-promoted cationic pericyclic reaction that transforms a divinyl ketone into 2-cyclopentenone. Therefore, it is generally known as the Nazarov cyclization,[2] or Nazarov reaction.[2bb,3] In general, this reaction requires 1 eq. of strong Brønsted acid or Lewis acid[2q,4] and undergoes a 4-π electrocyclic, conrotatory cyclization[2q,2u,2v,3m,3n,5] via a 3-oxy-pentadienylic cation.[2q,5] Although this reaction gives a thermodynamically favored cyclopentenone with more substituents,[2tt,6] the classical reaction protocol generally lacks control over the position of the endocyclic double bond (Scheme 1).[6,7] It has been found that the presence of an electron-donating group such as alkoxy on a vinyl group,[8] or the presence of a bridge-headed proton on the endocyclic intermediate[2w] facilitates the protic acid-promoted cyclization. Besides the conventional Lewis acid catalysts, such as $BF_3{\cdot}Et_2O$,[2q,4,9] $SnCl_4$,[2q,4] $TiCl_4$,[2q,4,9] and $AlCl_3$,[2q,4] more complicated Lewis acids have also been used for this reaction, such as TMSOTf,[3s,7a] $Cu(OTf)_2$,[2q,3s,4] $PdCl_2(MeCN)_2$,[10] Sc(pybox)$(OTf)_3$,[2u] Cu(pybox)$(OTf)_2$,[2v] dicationic Ir(III) complex [IrMe(CO)(dppe)-(DIB)]$(BARF)_2$ (where dppe = bis(diphenylphosphino)ethane, DIB = *o*-diiodobenzene, and BARF = [B(3,5-$C_6H_3(CF_3)_2)_4$]),[2q] and montmorillonite clay K10.[11] In addition, $MeSO_3H$ was found to be a superior protic acid for the Nazarov reaction.[3s]

It should be pointed out that this reaction has been carried out photochemically[2v] (i.e., the photo-Nazarov cyclization[2x,2y,12]), or under near-critical water conditions.[3m] More importantly, it has been improved to occur in a controllable fashion, through a *directed* Nazarov cyclization or an *interrupted* Nazarov reaction.[2zz,3h,3k,3u,3v] It is worth noting that two practically directed Nazarov cyclizations have been developed, one by Denmark by using the β-cation stabilizing effect and electrofuge of silicon (Scheme 2),[2oo,2tt,6,13] and the other from Ichikawa by application of a β-cation destabilizing effect and the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

α-electron-donating effect of fluorine[2ii,7] to control the regiochemistry (Scheme 3). Analogous to silicon, tin is also used to direct the Nazarov cyclization.[14] The interrupted Nazarov reaction has been developed by West et al. to extend the reaction of the cationic endocyclic intermediate with carbon nucleophiles.[3l,9,15] Furthermore, this reaction has been extended to imino-Nazarov cyclization of vinyl allenyl imine.[12,16]

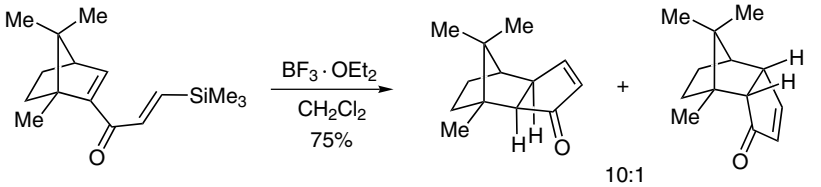
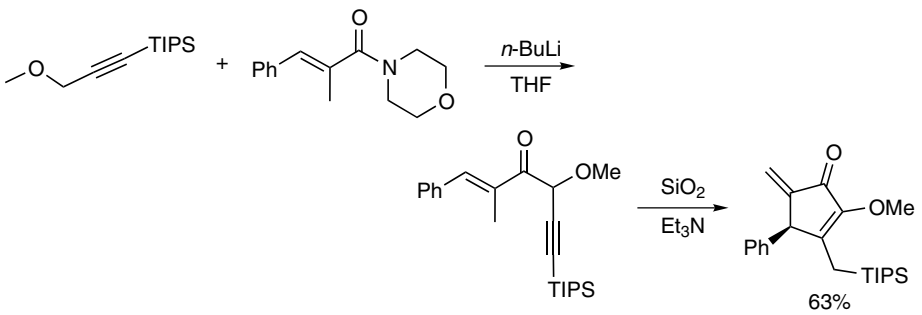
G. CITED EXPERIMENTAL EXAMPLES



Reference 3l.

A solution of 50 mg dienone (0.19 mmol) in 19 mL CH_2Cl_2 was cooled to $-78^{\circ}C$, and 94 μL $BF_3{\cdot}OEt_2$ (0.76 mmol) was added. After 10 min, the reaction was allowed to warm to $0^{\circ}C$ and was stirred for 8 h. Water (10 mL) was added, and the phases were separated. The aqueous layer was washed with Et_2O (2 $\times$ 15 mL), and the organic layers were combined, dried over $MgSO_4$, filtered, and concentrated to give a colorless oil. Silica gel radial chromatography (2 mm rotor; 9:1, hexanes/EtOAc) furnished 25 mg mixed cyclopentenone in a ratio of 10:1, in a yield of 75%. Careful chromatography of this mixture produced pure *exo*-diastereomer as a colorless oil, $R_f = 0.37$ (hexane/EtOAc, 9:1), and *endo*-diastereomer, $R_f = 0.34$ (hexane/EtOAc, 9:1).



Reference 3k.

To a solution of 147 mg 3-methoxy-1-triisopropylsilyl propyne (0.65 mmol) in 3 mL THF at −78°C was added 0.25 mL 2.5 M *n*-BuLi in hexanes (0.63 mmol). After 30 min, a solution of 125 mg enamide (0.54 mmol) in 1 mL THF was added dropwise via cannula. The reaction was stirred at −78°C for 1 h, quenched with 1 M HCl, and diluted with ether. The aqueous phase was extracted with Et_2O three times, and the combined organic extracts were washed with brine, dried over $MgSO_4$, and concentrated under reduced pressure. Removal of a trace solvent was done under high vacuum for 1 h. The crude product was transferred to a 4-dram vial charged with two glass beads. To a separate 4-dram vial containing 540 mg activated silica gel (9.0 mmol) was added 90 μL triethylamine (0.65 mmol). The mixture was stirred for 10 min and then transferred to the vial that contained the crude enone. The reaction was stirred at room temperature for 3 h. Direct purification of the reaction mixture by silica gel flash column chromatography with 5% EtOAc in hexanes gave cyclopentenone (126 mg) as a colorless oil, in a yield of 63%, $R_f = 0.33$ (5% EtOAc in hexanes).

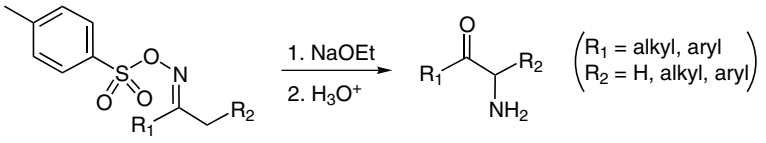
Neber Rearrangement
(Neber Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Neber et al. in 1926.[1] It is the transformation of a ketoxime *O*-arylsulfonate into an α-amino ketone involving the deprotonation of an α-methylene hydrogen by a base and the subsequent acidic hydrolysis of the resulting azirine intermediate. Therefore, this reaction is generally known as the Neber rearrangement[2] or Neber reaction.[2u,3] Different from the *Beckmann Rearrangement*,[4] in which the configuration of oxime controls the reaction direction, the Neber rearrangement does not hold such stereospecificity.[2u,2x] In addition, the amino group is generally introduced to the α-position with a higher acidic hydrogen in ketoxime *O*-arylsulfonate.[2u,2x] This rearrangement is generally carried out in ethanol by treatment of the ketoxime tosylate with sodium ethoxide, followed by the acidic hydrolysis.[2c] For cyclic ketones, the amino group is generally introduced at the equatorial positions at the α-carbon.[5] For 2,4-dinitrophenylacetone, even a weak base, like pyridine, is enough to trigger the rearrangement, as demonstrated in the isolation of the resulting azirine-pyridine hydrochloride complex.[6] It is interesting that the aldoxime tosylate usually results in the formation of corresponding nitrile or isonitrile under similar conditions.[2x,7] It should be pointed out that the starting material is usually prepared by the treatment of oxime with *p*-toluenesulfonyl chloride in pyridine.[2u]

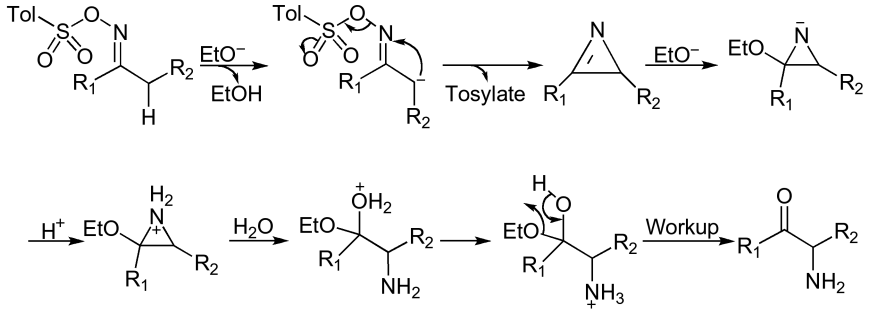
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although it has been proposed that this reaction is initiated by an alkoxide addition to C=N double bond followed by the loss of tosyloxy group to form a nitrene intermediate, which inserts to the α-carbon to form an alkoxy ethylenimine,[2u] more experimental evidence indicates that the Neber rearrangement involves an initial base-induced elimination of the more acidic α-proton accompanied by the loss of the tosyloxy group to give azirine ring.[2c,2x]



D. MODIFICATION

This reaction has been modified by using a liquid-liquid phase transfer catalyst.[2c]

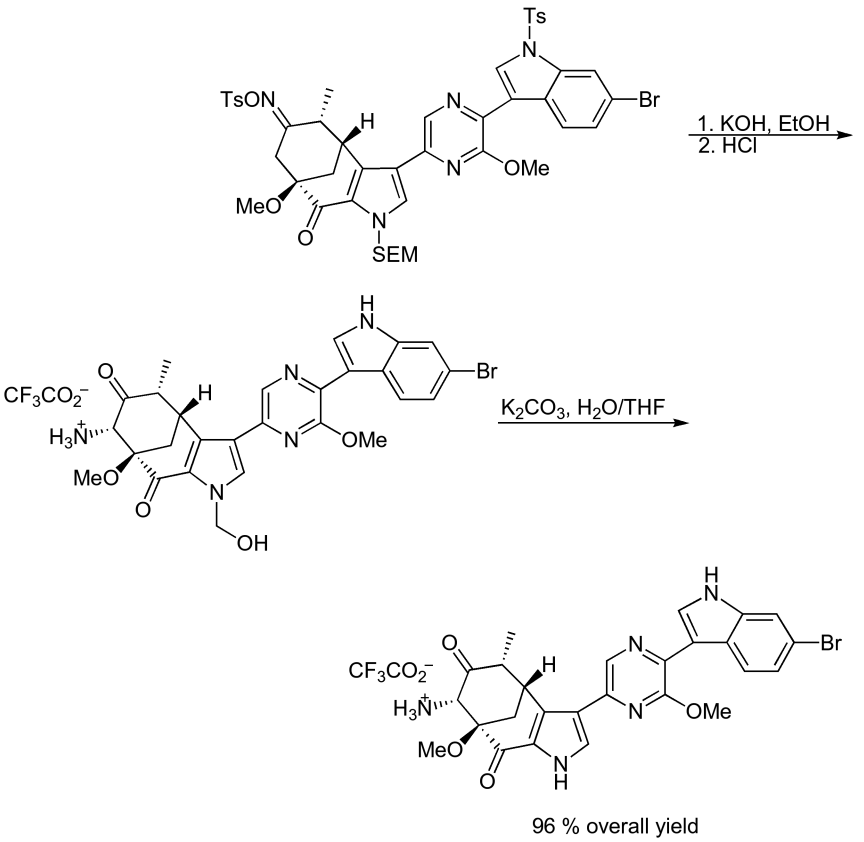
E. APPLICATIONS

This reaction has general application in the preparation of α-amino ketones.

F. RELATED REACTIONS

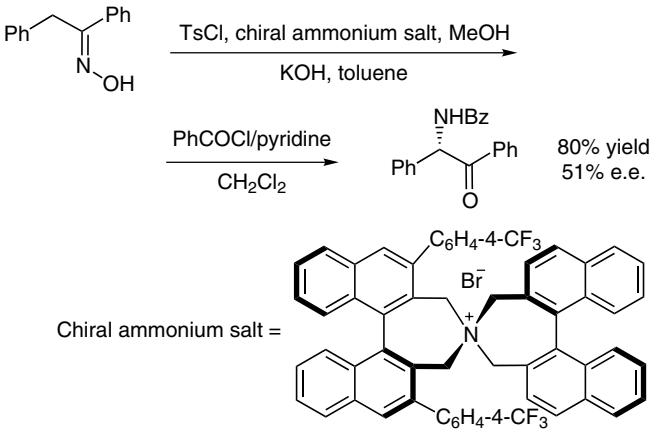
This reaction is related to the *Beckmann Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a stirred solution of 23.3 mg tosyl oxime (0.0236 mmol) in 3.5 mL EtOH at 0°C was added 450 μL 50% aqueous KOH dropwise over 1 min. The reaction mixture was stirred at 0°C for 3 h; then 5 mL 6 N aqueous HCl was added. The reaction mixture was heated to 60°C for 10 h, cooled to 23°C, and purified by loading to a reversed-phase Sep-Pak column with water containing 0.1% TFA (w/v) and by washing with 15% acetonitrile in water containing 0.1% TFA (w/v) to remove salts and then in 70% acetonitrile in water containing 0.1% TFA (w/v) to collect the crude product. The solvents were removed under reduced pressure to afford the hemiaminal intermediate, which was immediately mixed with 60 mg K_2CO_3 (0.434 mmol) in 2 mL THF; 200 μL H_2O was added at 23°C. The reaction mixture was stirred for 10 min and purified by a similar procedure for the hemiaminal intermediate to afford the crude product. After the solvents were removed under reduced pressure, the crude material was further purified by reversed-phased HPLC. Concentration under reduced pressure provided 15.0 mg amino ketone as an orange/red oil, in a yield of 96%.



Reference 2c.

cis-Benzyl phenyl ketoxime (63 mg, 0.3 mmol), 69 mg *p*-toluenesulfonyl chloride (0.36 mmol), 14 mg chiral quaternary ammonium salt (0.015 mmol, 5 mol %), and 123 μL MeOH (3 mmol, 10 eq.) were dissolved in 3 mL toluene. Then 1 mL 50% aqueous KOH was added to the mixture dropwise at 0°C. This mixture was stirred vigorously at 0°C for 48 hours. The resulting mixture was diluted with cooled water, and the organic layer was separated. The aqueous layer was extracted with ether. The combined organic layers were dried over $MgSO_4$. Upon removal of solvent, the residue was dissolved in 3 mL CH_2Cl_2. Pyridine (485 μL, 6 mmol) and 174 μL benzoyl chloride (1.5 mmol) were added sequentially, and the mixture was stirred at room temperature. After several hours, ~6 mL 6 N HCl was added, and the biphasic mixture was stirred vigorously for 3 h. The mixture was extracted with ether and dried over Na_2SO_4. After removal of the solvent, the residue was purified by silica gel column chromatography (ether/CH_2Cl_2/hexane, 1:30:20) to afford 76 mg α-benzamidylbenzyl phenyl ketone, in a yield of 80% and 51% e.e.

Other references related to the Neber rearrangement are cited in the literature.[8]

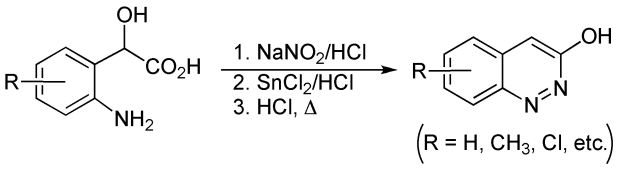
Neber-Bössel Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first described in 1929 by Bössel,[1] who was a student of Neber. This reaction was subsequently extended by Neber and co-workers.[2] It is the transformation of an *o*-amino mandelic acid into a 3-hydroxy-cinnoline involving the diazotization of the *o*-amino mandelic acid, reduction by stannous chloride, and subsequent acidic cyclization. Therefore, this reaction is generally known as the Neber-Bössel synthesis.[3]

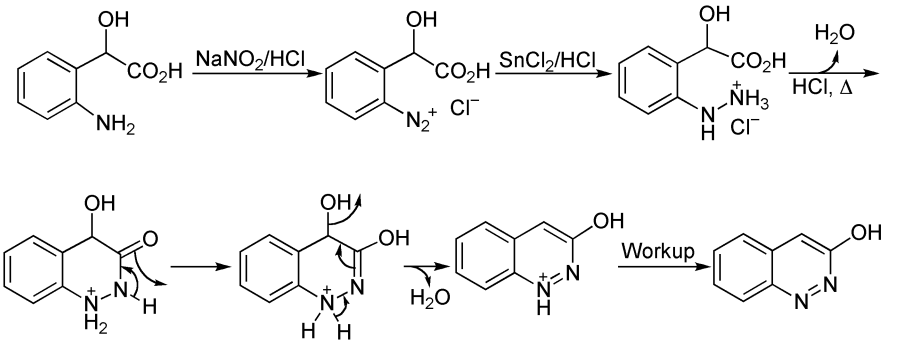
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is shown here for the formation of 3-hydroxycinnoline.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified by treatment of isatin with Grignard reagent to form α-substituted *o*-amino mandelic acid, from which 4-substituted 3-hydroxycinnoline can be prepared.[3b]

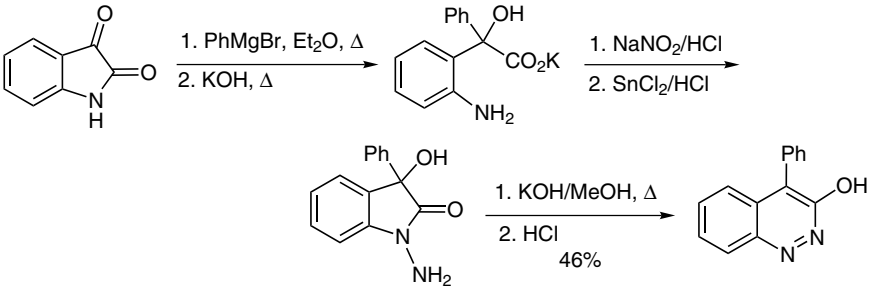
E. APPLICATIONS

This reaction provides a general synthesis of cinnoline derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

To the flask equipped with a dropping funnel and a Soxhlet extracter (modified for constant return of the extract) and protected by a drying tube was added 5.0 g magnesium turnings and 50 mL dry ether, followed by a crystal of iodine and a few drops of a

solution of 32.0 g bromobenzene in 50 mL dry ether. When the reaction started, the remainder of the bromobenzene was added at such a rate so as to maintain the moderate reflux (30–45 min). When all of the bromobenzene had been added, the ether solution was refluxed for an additional 15 min, then 300 mL dry benzene was introduced through the dropping funnel, and the Soxhlet thimble was charged with 10.0 g isatin. The benzene solution was refluxed for 24 h. To the mixture was added 100 g 10% H_2SO_4, and the mixture was steam distilled to remove the biphenyl; 1.5–2 L of distillate was collected. After the residue in the still pot had been cooled to 10–15°C in the ice bath, the solid formed was collected and digested with 200 g 10% NaOH. After the basic solution had been treated with charcoal and filtered, the pH of the solution was adjusted to 2 by 6 N H_2SO_4. The solid formed was collected and washed liberally with water to remove the Na_2SO_4 which separated with the product. The 3-phenyldioxindole remaining was recrystallized from 75 mL 50% EtOH or 50% acetic acid to give 8.5 g nearly colorless needles, m.p. 209–211°C.

A mixture of 10.0 g 3-phenyldioxindole (0.044 mol) and 100 g 5% KOH (0.088 mol) solution was refluxed for 3–4 h. After the solution had been cooled, 3.1 g $NaNO_2$ (0.044 mol) was added, and the resulting solution was added dropwise with stirring to 90 mL cold conc. HCl. A solution of diazotized α-phenylmandelic acid was added to a precooled (0–5°C), vigorously stirred solution of 28.8 g $SnCl_2 \cdot 2H_2O$ in 80 mL conc. HCl. A pale yellow solid, thought to be a tin salt, began to separate well before the addition of the diazonium solution was complete. The final mixture was stored overnight in the refrigerator, during which time the solid coagulated. The resultant solid was collected and washed thoroughly with water. After drying, the crude product weighed 8.1 g, m.p., 153–220°C. Recrystallization from benzene gave 3.8 g 1-amino-3-phenyldioxindole, m.p. 168.5–169.5°C.

A mixture of 1.0 g 1-amino-3-phenyldioxindole (4.2 mmol), 8.42 mL 1.984 N KOH solution and 10 mL MeOH was refluxed for 2 h. The hot solution was neutralized by the dropwise addition of 8.46 mL 1.974 N HCl, which effected the immediate separation of the canary yellow product along with some of the starting material. After the mixture had been cooled, the solid was collected, washed thoroughly with water, and recrystallized from 150 mL 95% EtOH, giving 0.42 g 4-phenyl-3-cinnolinol as yellow blades, m.p., 294–302°C (dec.)

No further references related to the Neber-Bössel synthesis are found in the literature.

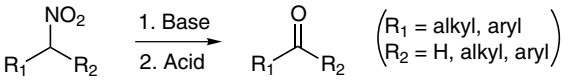
Nef Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Konovalov in 1893[1] and subsequently by Nef in 1894.[2] It is the transformation of a primary or secondary nitroalkane into the corresponding carbonyl compound (i.e, an aldehyde or a ketone)[3] by means of deprotonation of the nitroalkane to an *aci*-nitro compound followed by hydrolysis with a strong acid. Therefore, this reaction is generally known as the Nef reaction.[4] Occasionally, it is also referred to as the Nef transformation[5] or Nef conversion.[6] It should be pointed out that the primary nitroalkanes can also be converted into carboxylic acids under similar conditions,[4j,4ee] depending on the proton donating capability of the acid.[4ee] For example, 4-nitrobenzyl nitronate when treated with 4 *N* H_2SO_4 gives 93% of 4-nitrophenyl nitromethane, whereas it forms 86% 4-nitrobenzhydroxamic acid in 31 *N* H_2SO_4 (i.e., 85% H_2SO_4).[4ee] Moreover, it has been found that the yield of a ketone is generally low if the alkaline solution of a nitroalkane is added to the acid or exposed to an excess amount of acid.[4oo] However, this does not mean that the Nef reaction will occur only at low proton concentration.[4x] Furthermore, if there exists a considerable resonance stabilization in nitroalkane,[4ee,4rr] such as the conjugation with an olefinic moiety,[4uu] or a steric hindrance,[4rr] the Nef reaction will proceed with difficulty or not at all. It is very easy to monitor the reaction because of its characteristic transitory blue color.[4tt]

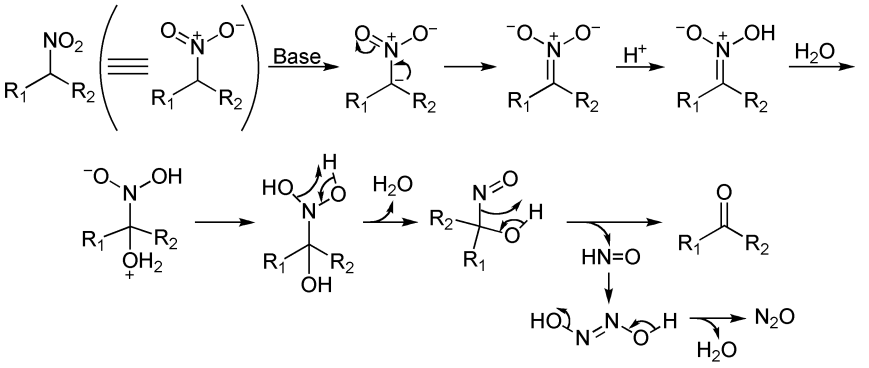
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A revised scheme based on a reported mechanism[4nn] is shown here.



D. MODIFICATION

Being anionic carbonyl synthons, the nitroalkanes have been explored extensively for their conversion into the corresponding carbonyl compounds. For example, the embedment of a nitroalkane onto an activated basic silica gel[4x] or the blockage of the C-protonation of nitronate with a protonated concave pyridine.[4m] The reaction under the latter condition is called the soft Nef reaction.[4m] In addition, the introduction of a γ-trimethylsilyl group is proved to smooth the Nef reaction.[4n] Moreover, when a primary nitroalkane is treated with nitrite/acetic acid, a carboxylic acid is resolved.[7] Furthermore, the oxidative Nef reaction has successfully converted the nitro cyclohexadienes into the substituted phenols via a nucleophilic addition.[4c,4g,4j]

E. APPLICATIONS

This reaction has general application in the synthesis of aldehydes and ketones, especially for 1,4-diketones[8] and dihydrofurans.[9] The 1,4-diketones can be prepared by the combination of a Michael reaction between a nitroalkane and an α,β-unsaturated ketone followed by a Nef reaction, whereas dihydrofurans can be synthesized by the Nef reaction followed by cyclohydration.

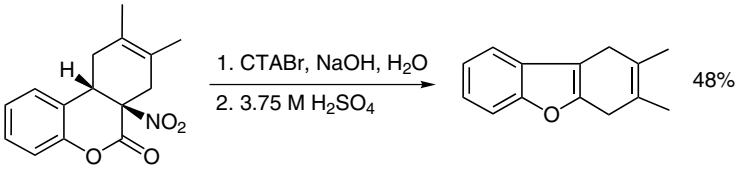
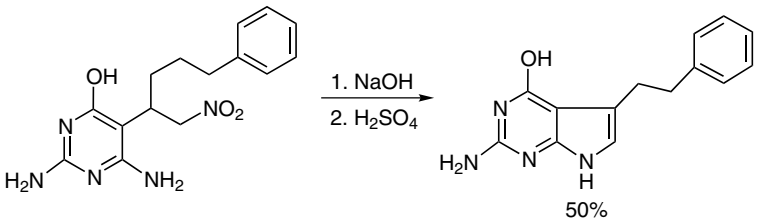
G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a 50-mL flask were added 0.147 g cetyltrimethylammonium bromide (CTABr, 0.4 mmol), 3.6 g NaOH (90 mmol), and 30 mL water; the resulting solution was warmed to 50°C. Then 0.546 g rel(6a*R*,10a*S*)-8,9-dimethyl-6a-nitro-6a,7,10,10a-tetrahydro-6*H*-benzo[*c*]chromen-6-one (2.0 mmol) was added rapidly, and the alkaline solution was stirred for 1 h. The final orange mixture was cooled to 0°C and added dropwise to a 100-mL flask at 0°C containing 15 mL 3.75 M H_2SO_4 solution. The heterogeneous mixture was left under stirring at this temperature for 5 min and then warmed to room temperature for 1 h. The mixture was transferred into a 250-mL separatory funnel, saturated with NaCl, and extracted with ethyl acetate. The combined organic layers were dried over Na_2SO_4 and evaporated under reduced pressure. The gummy solid obtained was purified by column chromatography to give 0.190 g 2,3-dimethyl-1,4-dihydrodibenzo[*b*,*d*]furan as a white solid, in a yield of 48%, m.p., 91–93°C (petroleum ether).



Reference 4d.

To an aqueous solution of 0.34 g NaOH (8.5 mmol) in 5 mL water was added 0.148 g 2,6-diamino-5-(1-nitromethyl)-3-phenylpropyl)-3*H*-pyrimidin-4-one (1.58 mmol) at room temperature. The mixture was stirred for 2 h and then was slowly added to a cold aqueous solution prepared from 1.37 g 98% H_2SO_4 (14 mmol) and 5 mL water. The resulting mixture was stirred at 0°C for 1 h and at room temperature for an additional hour. The color of the mixture changed to gray. Concentrated NH_4OH was added at 0°C to adjust the pH to 7. The precipitated solid was collected and purified by silica gel column chromatography (EtOAc/MeOH, 9:1) to give 0.2 g 2-amino-5-phenethyl-3,7-dihydropyrrolo[2,3-*d*]pyrimidin-4-one as a light yellow solid, in a yield of 50%.

Negishi Cross-Coupling

(Negishi Coupling, Negishi Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

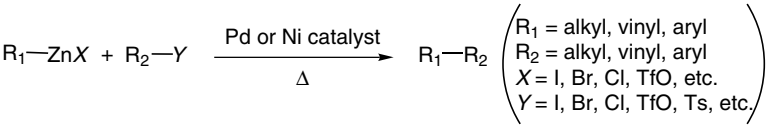
This reaction was first reported by Negishi et al. in 1977.[1] It is a palladium or nickel-catalyzed coupling between an aryl or alkenylzinc, zirconium or aluminum reagent[2] and an alkenyl or aryl halide or triflate; specifically, it is an organozinc reagent-mediated coupling with an alkenyl or aryl halides/triflates. Therefore, it is generally known as the Negishi cross-coupling,[2,3] Negishi coupling,[3m,3y,3z,3aa,3ll,4] or Negishi reaction.[3p,3dd,3nn,4x,4z,4ee,5] In addition, the zirconium based coupling is known as the zirconium-Negishi reaction.[6]

The Negishi cross-coupling can tolerate a variety of functional groups that include olefin,[3dd] ether,[3aa,3dd] nitrile,[3aa,3dd] ester,[3dd] nitro,[3aa] and amino[3aa] groups. The aryl zinc reagents can be prepared from aryl bromides (or iodides) by insertion of an activated Rieke zinc,[3y,7] or prepared through transmetallation by treatment of an *ortho*-aryl halide with lithium base (e.g., LDA) followed by $ZnBr_2$ or $ZnCl_2$.[3jj] Generally speaking, if the desired alkenyl zinc reagent are readily accessible via hydrometallation or carbometallation, the aryl electrophile (e.g., halide/triflate) can be added to the organozinc reagent as one-pot synthesis.[2] However, the common alkenyl electrophiles, such as vinyl bromide, vinylidene bromide, and especially the alkenyl triflates or phosphates prepared from corresponding carbonyl compounds, prefer the coupling with arylzinc reagents.[2] This reaction is commonly catalyzed by a transition metal of palladium or nickel with triaryl or trialkyl phosphines as ligands, such as $PdCl_2(dppf)_2$,[3al] $Pd[P(t\text{-}Bu)_3]_2$,[3aa,3nn,4bb,4cc] ($Pd_2(dba)_3/PCy_3$/NMI),[3dd] 4% $Ni(cod)_2$/8% *s*-Bu-Pybox,[3p,4x] or $Pd_2(dba)_3$/P(2-furyl)$_3$.[4cc] It has been found that the ligand has a substantial impact on the course of the Negishi cross-coupling.[3dd] For example, the decrease of the ratio of phosphine to palladium lowers the yield of the desired compound,[3dd] whereas the application of an electron-enriched ligand such as

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

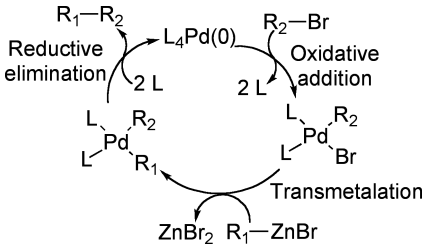
$P(t\text{-Bu})_3$[3aa,3nn,4bb,4cc] or especially dicyclohexyl *o*-(2,6-diisopropylphenyl)phenyl phosphine allows the coupling of two bulkyl aryl moieties,[3aa] with a load of palladium of $< 0.01\%$. In addition, Pd-*N*-heterocyclic carbene (NHC) catalyst facilitates the coupling at room temperature,[3o,3p] whereas the normal Negishi cross-coupling requires high temperature and long reaction time.[3y]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general modified mechanism is shown here, based on References 3z and 5a.



D. MODIFICATION

This reaction has been modified for various conditions, such as the application of microwave irradiation[3b,3y] and the application of phosphine-containing polymer prepared from the ruthenium-catalyzed ring-opening metathesis polymerization of the norbornene.[3t,5h] Most importantly, this reaction has been extended to the coupling of primary or secondary alkyl halides with aryl, vinyl, and even alkyl halide (or tosylate).[3l,3o,3p,3y,3dd,3nn,4v,4x,6]

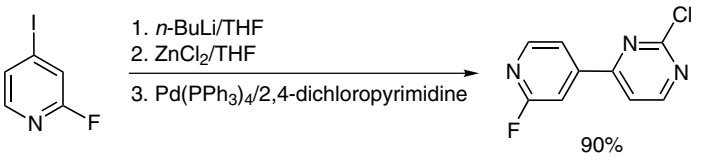
E. APPLICATIONS

This reaction has very general application in the formation of C-C bonds, including biaryls, aryl alkenes, alkanes, and even ketones.[8]

F. RELATED REACTIONS

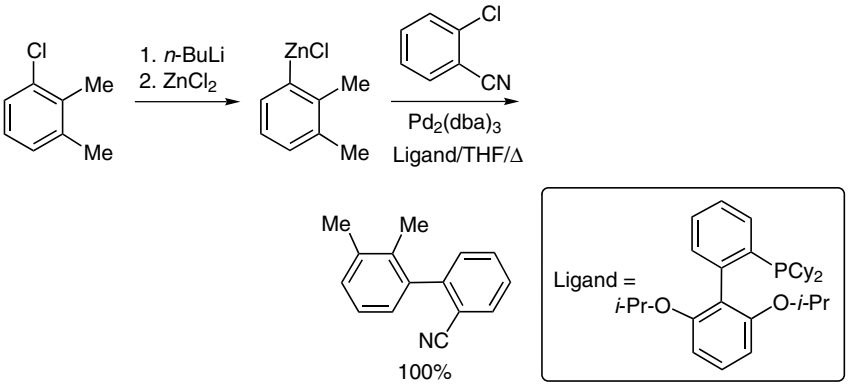
This reaction is related to the *Heck Reaction*, *Stille Coupling*, and *Suzuki Coupling*, etc.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3q.

4-Iodo-2-fluoropyridine (15.52 g, 69.60 mmol, 1 eq.) was dissolved in 150 mL dry THF and cooled to −70°C. Then *n*-BuLi (73.08 mmol, 1.05 eq.) was added, and the reaction mixture was stirred at −70°C for 20 min. Subsequently, 10.44 g dry $ZnCl_2$ (76.61 mmol, 1.1 eq.) was added as a solution in 60 mL dry THF while kept at temperature < −60°C. The reaction mixture was then warmed to room temperature, and 0.40 g $Pd(PPh_3)_4$ (0.35 mmol, 0.005 eq.) and 7.26 g 2,4-dichloropyrimidine (48.73 mmol, 0.75 eq.) in 100 mL dry THF were added. The reaction mixture was refluxed until complete conversion. Then the reaction mixture was poured onto a 10% aqueous EDTA solution, basified with saturated aqueous Na_2CO_3 solution, and extracted with CH_2Cl_2. Upon removal of the solvent, the residue was purified by flash column chromatography using petroleum ether/EtOAc (10:1) as the eluent to afford 9.17 g 2-chloro-4-(2-fluoropyridin-4-yl)pyrimidine as beige crystals, in a yield of 90%, m.p. 157–159°C.



Reference 3aa.

An oven-dried resealable Schlenk tube containing a magnetic stir bar was capped with a rubber septum and then evacuated and backfilled with argon (this sequence was repeated for three times). The Schlenk tube was charged with 0.75 mmol 2,3-dimethylphenyl chloride (1.5 eq.) and 1.0 mL dry THF. The resulting solution was cooled to −78°C; then 0.825 mmol *n*-butyllithium (1.65 eq.) in THF was added dropwise via syringe through the septum, and the resulting solution was stirred at −78°C for 1 h. $ZnCl_2$ (0.9 mmol, 1.8 eq.) was added in one solid portion by removal of the septum. After 30 min at −78°C, the Schlenk tube was removed from the cooling bath, and the resulting solution was stirred at room temperature for 1 h. Then 2.3 mg $Pd_2(dba)_3$ (0.5 mol %), 4.7 mg dicyclohexyl (2,6-diisopropylphenyl)phenyl phosphine (2.0 mol %), and 0.5 mmol 2-chlorobenzonitrile (1.0 eq.) were added with the

aid of 0.5 mL THF, which was used to rinse the walls of the tube. The septum was replaced with a Teflon screw cap, and the Schlenk tube was sealed. The reaction mixture was placed in a preheated oil bath at 70°C and magnetically stirred until the aryl halide had been completely consumed as judged by GC analysis. The reaction mixture was then cooled to room temperature, diluted with 1 mL water, and extracted with diethyl ether (4 × 10 mL). The combined organic phases were dried over Na_2SO_4 and concentrated under reduced pressure. The crude material obtained was purified by flash chromatography on silica gel to afford 100% 2,3-dimethyl-2′-cyano-biphenyl.

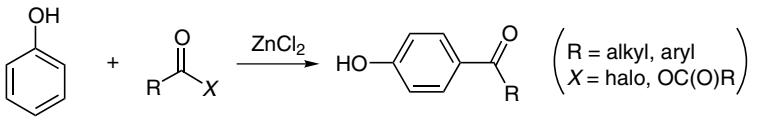
Nencki Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Nencki et al. in 1881.[1] It is the preparation of an acyl phenol derivative by zinc chloride-activated acylation between a phenol and an acyl chloride, anhydride, or even a carboxylic acid. Therefore, this reaction is generally known as the Nencki reaction.[2] The Nencki reaction generally takes place with at least one equivalent of zinc chloride;[3] however, it does not involve the formation of a complex between zinc chloride and acyl chloride or anhydride in a manner similar to that of aluminum chloride.[3] It has been found that the regioselectivity in preference of *para*-acylation decreases when the size of the acylating reagent increases.[4]

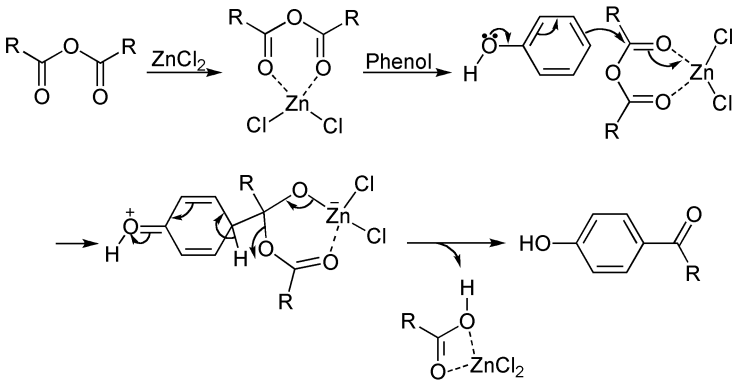
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A new mechanism is proposed here to illustrate the Nencki reaction from acyl anhydride, with the preference of *para*-acylation and the requirement of at least one equivalent of $ZnCl_2$.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified by using a catalytic amount of $ZnCl_2$ for the acylation of heterocycles.[3]

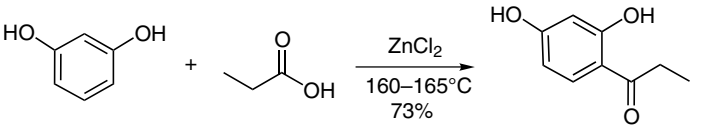
E. APPLICATIONS

This reaction is useful for the preparation of acyl phenol derivatives.

F. RELATED REACTIONS

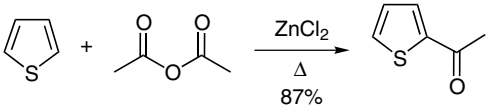
This reaction is related to the *Friedel-Crafts Acylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To a hot mixture of 80 g propionic acid and 80 g fused $ZnCl_2$ was added 50 g resorcinol. The mixture was refluxed to an intense bubbling of the solution, which occurred between 160 and 165°C. The solution was then allowed to cool slowly; it was then poured into a water and ice mixture and acidified with HCl. The dark brown oil solidified on standing, which was crystallized from alcohol by decolorizing from charcoal to afford 73% 4-propanoyl resorcinol.



Reference 3.

To a mixture of 168 g thiophene (2 mol) and 107 g 95% Ac_2O (1 mol) was added 4.0 g anhydrous $ZnCl_2$ (0.03 mol) pulverized under thiophene. The reaction mixture was maintained at a reflux temperature of 94–103°C over a period of 4 h, and then cooled to 50°C. Water (200 mL) was added. The material was thoroughly washed with water and finally neutralized with Na_2CO_3 solution. Water and unreacted thiophene were removed by distillation from a Vigreux-modified Claisen flask. The residue was vacuum distillated to afford 109 g 2-acetylthiophene, in a yield of 87%, b.p. 77–78°C at 4 mmHg.

Other references related to the Nencki reaction are cited in the literature.[6]

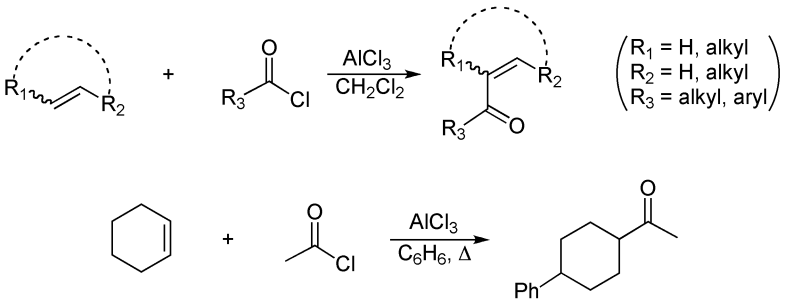
Nenitzescu Synthesis
(Darzens-Nenitzescu Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Nenitzescu in 1931.[1] It is the formation of an α,β-unsaturated ketone directly by aluminum chloride-promoted acylation of alkenes with acyl halides. Therefore, it is generally known as the Nenitzescu synthesis.[2] Occasionally, it is also referred to as the Nenitzescu acylation,[2d] or Nenitzescu reductive acylation (or Darzens-Nenitzescu reaction).[3] Under such reaction conditions, Nenitzescu prepared 2-butenyl methyl ketone from acetyl chloride and 1-butene,[4] and dimethylacetylcyclohexene from acetyl chloride and cyclooctene.[5] However, in the presence of benzene or hexane, the saturated ketones are often resolved, as supported by the preparation of 4-phenyl cyclohexyl methyl ketone from the reaction of cyclohexene and acetyl chloride in benzene[6] and the synthesis of 3- or 4-methylcyclohexyl methyl ketone by refluxing the mixture of cycloheptene and acetyl chloride in cyclohexane or isopentane.[5b,7] The formation of the saturated ketones is probably caused by the intermolecular hydrogen transfer from the solvent.[8] In addition, owing to its intrinsic strain, cyclopropyl group reacts in a manner similar to an olefinic functionality so that it can be readily acylated too.[9] It should be pointed out that under various reaction conditions, the Nenitzescu synthesis is often complicated with the formation of β-halo ketones, β,γ-enones, or β-acyloxy ketones.[8,10] This complication can be overcome by an aluminum chloride-promoted acylation with vinyl mercuric chloride, resulting in a high purity of stereochemistry.[11]

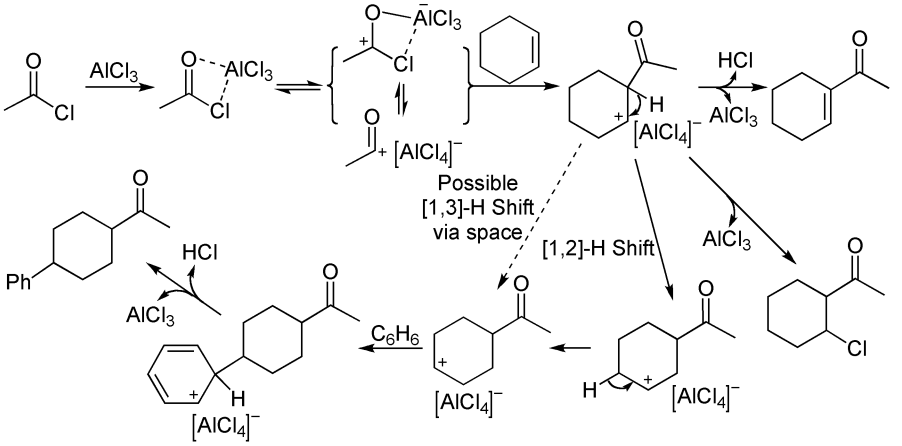
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the mechanism for the formation of acetylcyclohexane is known,[3] an alternative mechanism is proposed here for the acylation of cyclohexene with acetyl chloride. In this reaction, after the acyl cation is added to double bond, the elimination of the α-proton gives an α,β-unsaturated ketone, whereas the attack of chloride produces a β-chloroketone. Because acetyl is an electron-withdrawing group, it is plausible that the positive charge migrates to form a more stable carbocation, which electrophilically alkylates with benzene.



D. MODIFICATION

The formation of α,β-unsaturated ketones has been modified by the acylation of vinyl mercuric chloride.[11] In addition, this reaction has been extended to the acylation of alkynes,[10] and a zinc chloride-promoted acylation of olefins.[12]

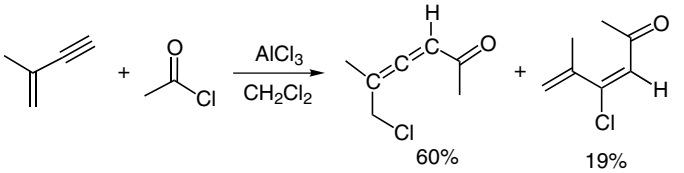
E. APPLICATIONS

This reaction has general application in the preparation of α,β-unsaturated ketones.

F. RELATED REACTIONS

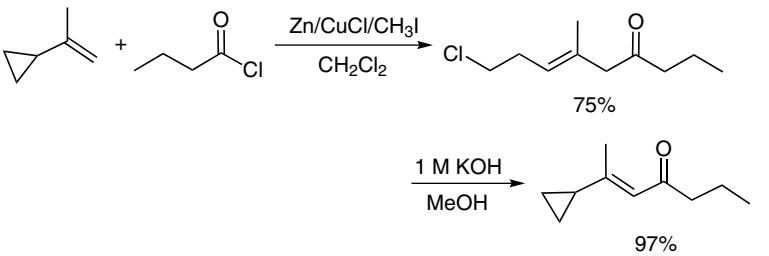
This reaction is related to the *Friedel-Crafts Acylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

A mixture of 3.33 g $AlCl_3$ (25 mmol), 1.96 mL acetyl chloride (27.5 mmol, 1.1 eq.), and 45 mL anhydrous CH_2Cl_2 was stirred until dissolution. The resulting solution was stirred for 3 min at 20 mmHg and then cooled to −90°C; 2.86 mL 2-methyl-1-buten-3-yne (30 mmol, 1.2 eq.) in 30 mL anhydrous CH_2Cl_2 was slowly added over 2 h. The solution was allowed to warm to −60°C, the mixture was stirred until the completion of reaction as monitored by TLC, and then it was transferred to a vigorously stirred mixture of crushed ice and Et_2O. The organic layer was quickly stirred with a saturated solution of $NaHCO_3$ and dried using $MgSO_4$ and stored in a refrigerator. After filtration and concentration in vacuo at room temperature, the crude product was quickly flash chromatographed on silica gel, eluting with a gradient of pentane-ether to afford 60% 5-methyl-6-chloro-3,4-hexadien-2-one, and 19% 5-methyl-4-chloro-3,5-hexadien-2-one, which were stored in refrigerator.



Reference 12.

A mixture of 6.54 g zinc dust (0.10 mol) and 0.99 g cuprous chloride (0.01 mol) in 30 mL CH_2Cl_2 was refluxed with stirring under nitrogen for 30 min. After the mixture was cooled to room temperature, 7.1 g iodomethane (0.05 mol) was added, and the mixture was then refluxed for an additional hour. Into the solution of the freshly prepared active zinc compounds was added 4.11 g 2-cyclopropyl-propene (0.05 mol) in 10 mL CH_2Cl_2 at 0–5°C under nitrogen with stirring. After a short period, 10 mL CH_2Cl_2 solution containing 1.07 g butyryl chloride (0.010 mol) was added dropwise into the stirred mixture over 15 min at 15–20°C with external cooling. An exothermic reaction took place, and the mixture

gradually turned red-brown. The reaction mixture was stirred at room temperature for 2 h and then was refluxed for another 2 h. After that, 30 mL10% H_2SO_4 was carefully added into the mixture under cooling with an ice water bath. The reaction mixture was filtered with suction and extracted with ether (3 × 50 mL). The combined ethereal solution was washed with saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and concentrated to give a mixture of products, which was purified to give 75% 9-chloro-6-methyl-6-en-4-nanone. This product upon treatment with 1 M KOH in methanol gave 97% 1-cyclopropyl-2-en-hept-4-one.

Other references related to the Nenitzescu synthesis are cited in the literature.[13]

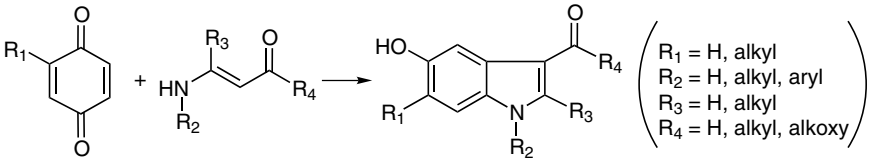
Nenitzescu Indole Synthesis

(Nenitzescu Reaction, Nenitzescu Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Nenitzescu in 1929.[1] It is the synthesis of a 5-hydroxyindole derivative involving the condensation between a 1,4-benzoquinone and a β-amino-α,β-unsaturated compound and subsequent cyclization. Therefore, this reaction is generally known as the Nenitzescu indole synthesis,[2] Nenitzescu reaction,[2e,2g,2i,2j,3] or Nenitzescu synthesis.[2g,2j,4] Occasionally, it is also referred to as the Nenitzescu cyclization,[5] Nenitzescu condensation,[2g,2l] or Nenitzescu process.[6] It should be pointed out that the synthesized indole derivatives by this reaction are restricted to those with an electron-withdrawing group at position 3, such as an ester or a carbonyl group.[6] In addition, the completion of this reaction requires an appropriate oxidizing agent to convert the initial adduct into the indole derivative.[2g,2j] From monosubstituted quinone, 4-, 6- and 7-substituted 5-hydroxyindole derivatives all are possible products, but 6-substituted isomer is the one normally obtained.[2k]

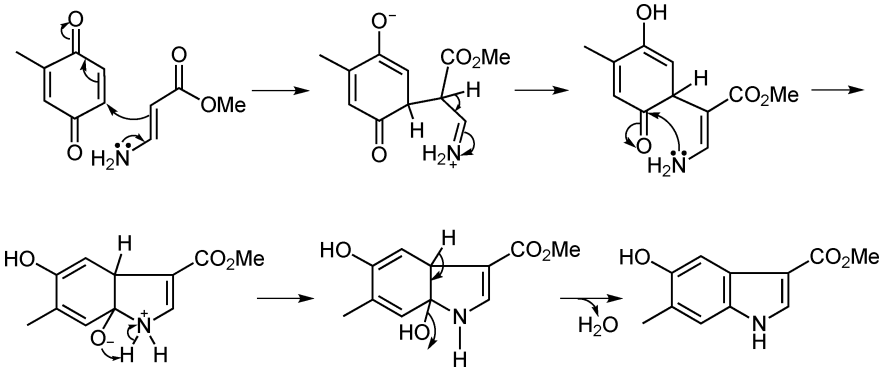
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Two kinds of mechanisms are possible for the Nenitzescu indole synthesis, depending on the order of carbon-carbon bond and carbon-nitrogen bond formation.[2g,2l,2m,3u,3v] However, the one involving the initial carbon-carbon condensation is more plausible as illustrated here for the reaction between 2-methyl 1,4-benzoquinone and β-amino methyl crotonate.[2g]



D. MODIFICATION

This reaction has been modified by using quinone mono-ketals to control the regioselectivity.[2e] In addition, an *aza*-Nenitzescu reaction involving the condensation between quinones and hydrazones has been developed for the synthesis of indazole derivatives.[7]

E. APPLICATIONS

This reaction is particularly useful for the preparation of 5-hydroxyindole derivatives.

F. RELATED REACTIONS

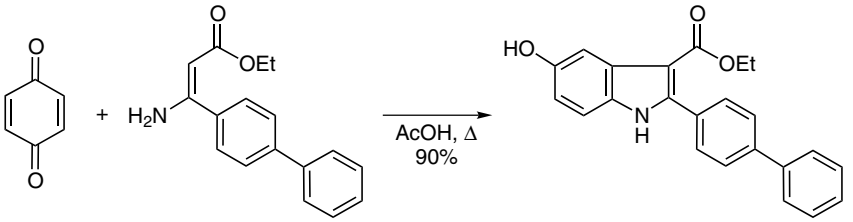
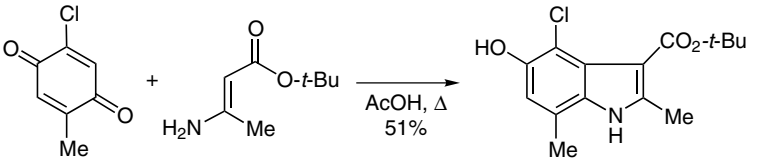
G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

1,4-Benzoquinone (1.71 g, 15.8 mmol) and 3.5 g ethyl 3-amino-3-(4-biphenylyl)-propenoate (9.8 mmol) in 50 mL acetic acid were refluxed for 1 h. After cooling, the crude product was precipitated out with light petroleum ether and filtered off, which was purified by column chromatography (EtOAc) and recrystallization (EtOAc) to yield 4.21 g ethyl 2-(4-biphenylyl)-5-hydroxyindole-3-carboxylate as a colorless solid, in a yield of 90%, m.p., 260–262°C.



Reference 2i.

To a hot solution of 3.12 g 5-chloro-2-methyl-l,4-*p*-benzoquinone (19.9 mmol) in 15 mL acetic acid, was added 3.14 g *t*-butyl-3-aminocrotonate (20 mmol). After 30 min without the application of heat, the solution was cooled, and the resulting pink precipitate was filtered and washed with chilled acetic acid to give 2.99 g *t*-butyl 4-chloro-5-hydroxy-2,7-dimethylindole-3-carboxylate, in a yield of 51%, m.p. 178–180°C (dec.)

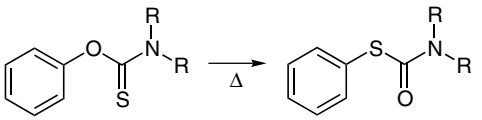
Newman-Kwart Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially and concurrently reported by Newman[1] and Kwart[2] in 1966. It is a thermal transformation of *N*,*N*-dialkyl *O*-arylthiocarbamate into *N*,*N*-dialkyl *S*-arylcarbamate. Therefore, it is generally known as the Newman-Kwart rearrangement.[3] Occasionally, it is also referred to as the Newman-Kwart reaction,[3g,4] Newman-Kwart synthesis,[5] or Miyazaki-Newman-Kwart rearrangement.[6] It has been found that the *ortho*-substituent in the migrating aromatic ring may enhance the rearrangement rate, the effect known as the steric acceleration due to hindered rotation (SAHR).[3m] In addition, for the rearrangement of *O*-binaphthol thiocarbamate into dithiol derivative, the stereochemistry is retained.[7]

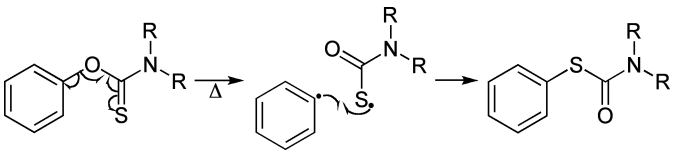
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Similar to the *Barton Decarboxylation* and *Barton Deoxygenation*, it is assumed that this reaction also involves a free radical mechanism, as proposed below.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

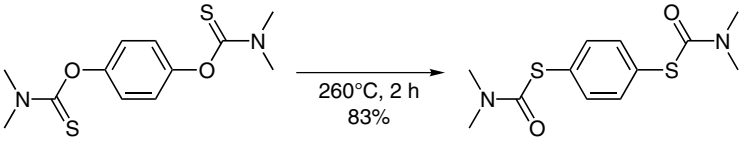
E. APPLICATIONS

This reaction has been used to prepare thio-analogs of binaphthol[7] and 1,4-dithiophenol[3g] derivatives.

F. RELATED REACTIONS

This reaction is related to the *Schönberg Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3g.

The bis-(*N*,*N*′-dimethylthiocarbamate) (10.0 g, 0.035 mol) was heated in the bulk at 260°C under nitrogen for 2 h. After cooling, the remaining material was crystallized from chloroform/methanol and further recrystallized from methyl ethyl ketone to afford 8.3 g bis-(*N*,*N*′-dimethyl-*S*-carbamate), in a yield of 83%, m.p. 201–203°C.

Other references related to the Newman-Kwart rearrangement are cited in the literature.[8]

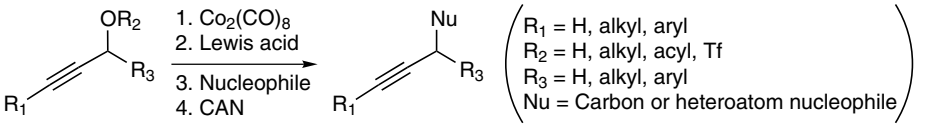
Nicholas Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Nicholas et al. in 1971.[1] It is a nucleophilic substitution on a propargylic alcohol, ether or ester by a carbon or heteroatom nucleophile involving the generation of a carbocation by a strong Lewis acid, stabilization of the propargylic cation via the formation of hexacarbonyldicobalt alkyne complex, and final liberation of alkyne moiety by oxidation with cerium ammonium nitrate or *N*-methylmorpholine *N*-oxide.[2] Therefore, this reaction is generally known as the Nicholas reaction.[2,3] Occasionally, it is also referred to as the Nicholas cyclization,[3i,3l,3x] or Nicholas propargylic substitution.[4] In this reaction, the propargylic cation can be generated by the treatment of a propargylic alcohol[3e,3i–3l,3p,3cc,3qq,5] ether,[3e,3j,3p,3q,3cc,3qq] or ester[3j,3q,3aa] (including acetate[3m,3q]) from a strong Lewis acid, such as $BF_3{\cdot}OEt_2$,[3e] $TiCl_4$,[3e] or $GeCl_4$.[3e] Among these Lewis acids, $BF_3{\cdot}OEt_2$ is the most commonly used acid for the Nicholas reaction.[3e] While some milder Lewis acids such as $MgBr_2$, LiCl, LiBr, and $ZnBr_2$, are not strong enough for this reaction,[3e] the mild acid of Montmorillonite K-10 is found to be an effective promoter.[6] In addition, the nucleophile can be either a carbon-nucleophile (such as an enolate,[3cc,5] arene,[3q] or a heterocycle[3m]) or a hetero-atom nucleophile (e.g., an alcohol,[3l,3aa] epoxide,[3i] or a carboxylic acid).[3f] Beacuse the cobalt-mediated cyclization is reversible,[3l] there exists an equilibrium at the propargylic center through a fluxional cationic intermediate; thus the original stereochemistry of the substrate is usually lost upon treatment by a Lewis acid.[3bb] It should be pointed out that the application of an Evans's oxazoline enolate in coupling with a propargylic cation to generate high stereoselectivity (i.e., in favor of the *syn*-adduct) is specifically referred to as the Nicholas-Schreiber reaction.[3cc]

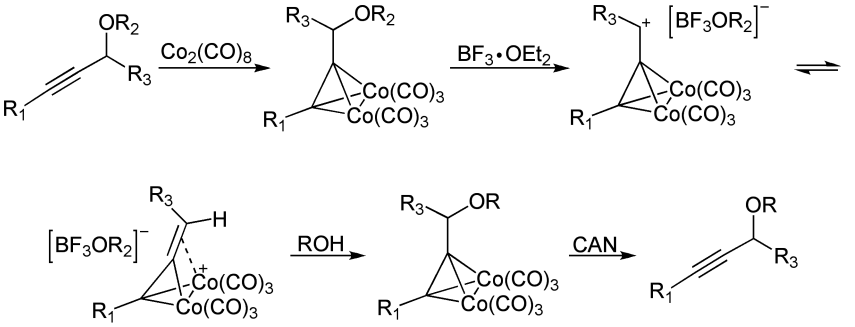
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is illustrated below to demonstrate the stabilization of propargylic cation from the cobalt complex, in which a general alcohol is used as a representative nucleophile.



D. MODIFICATION

Some of the modifications for the Nicholas reaction include the fixation of a propargylic substrate onto a solid phase,[3e] application of montmorillonite K-10 as acid to generate the propargylic cation,[6] complexation of alkyne with a ruthenium complex,[3d] and application of tetrabutylammonium fluoride for decomplexation.[3aq]

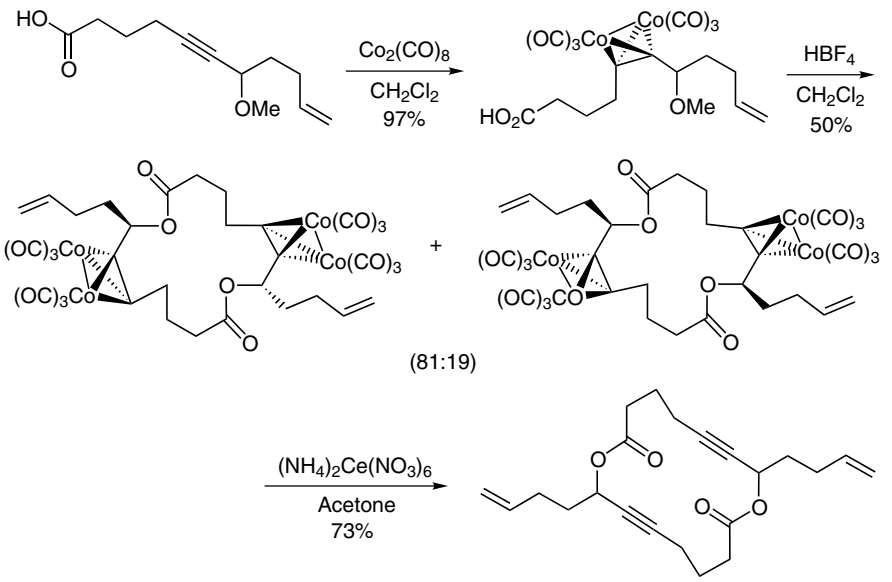
E. APPLICATIONS

This reaction is especially useful for the formation of cyclic ethers,[3i,3l,3aa] and macrocycles.[3m,3q,5]

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3f.

A flame-dried, round-bottomed flask equipped with a septum and gas inlet needle was charged with 253 mg 7-methoxyundec-10-en-5-ynoic acid (1.20 mmol) and placed under a nitrogen atmosphere. Then 2.5 mL CH_2Cl_2 was added followed by 494 mg $Co_2(CO)_8$ (1.44 mmol, 1.2 eq.) to yield a dark red/black solution that was stirred at room temperature for 30 min. A second portion of $Co_2(CO)_8$ (165 mg, 0.481 mmol, 0.4 eq.) was added and the reaction was allowed to stir at room temperature for an additional 30 min. The reaction mixture was added directly to a 60-g silica gel column eluting with 10–35% ether in petroleum ether to afford 577 mg 7-methoxyundec-10-en-5-ynoic acid hexacarbonyl dicobalt complex as a thick red oil, in a yield of 97%.

A flame-dried, round-bottomed flask equipped with a septum and gas inlet adapter was charged with 577 mg cobalt complex (1.16 mmol) and placed under a nitrogen atmosphere. CH_2Cl_2 was added, and the resulting dark red/black solution was cooled at 0°C. Then 0.16 mL 54% HBF_4 in ether (1.16 mmol) was added, and the reaction mixture was stirred at 0°C for 1 h. The reaction was quenched while still cold by the addition of 15 mL saturated $NaHCO_3$. The aqueous layer was removed, and the organic phase was dried over $MgSO_4$ and added to a sintered glass funnel packed with silica gel. Rinsing with 400 mL CH_2Cl_2 furnished 269 mg 8,16-dibut-3-enyl-1,9-dioxacyclohexadeca-6,14-diyne-2,10-dione hexacarbonyl dicobalt complex as a bright red/orange solid, in a yield of 50%, m.p. 124–125°C (dec).

A round-bottomed flask was charged with 53 mg 8,16-dibut-3-enyl-1,9-dioxacyclohexadeca-6,14-diyne-2,10-dione hexacarbonyl dicobalt complex (0.0534 mmol) and 12 mL acetone to yield a red suspension. The reaction flask was cooled at 0°C, and 472 mg cerium ammonium nitrate (CAN) (0.86 mmol) was added in eight portions (59 mg/portion) over 5 min. The cooling bath was removed, and the reaction was allowed to stir at room

temperature for 4 h. The resulting yellow-orange suspension was concentrated to yield a yellow solid that was transferred to a flask containing CH_2Cl_2 and water. The organic layer was separated, dried over $MgSO_4$, and concentrated to yield 21 mg yellow oil that was deposited on 40 mg silica gel and added to a 2-g silica gel column eluting with 5% ether in petroleum ether to afford 14 mg 8,16-dibut-3-enyl-1,9-dioxacyclohexadeca-6,14-diyne-2,10-dione as a white film, in a yield of 73%.

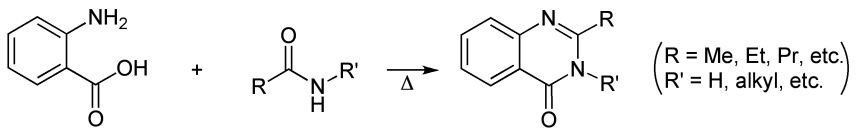
Niementowski Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Niementowski in 1895.[1] It is the thermal transformation of an anthranilic acid into 4-keto-3,4-dihydroquinazoline by the condensation with an amide. Therefore, it is generally referred to as the Niementowski reaction.[2] Occasionally, this reaction is also referred to as the von Niementowski synthesis,[2l,3] Niementowski condensation,[4] or Niementowski 4-oxoquinazoline synthesis.[5] Although the formation of 4-keto-3,4-dihydroquinazoline, also known as benzoylene urea,[6] appears to involve a simultaneous condensation between the amino group of anthranilic acid and the carbonyl group of an amide and the condensation between the carboxyl group of anthranilic acid and the amido group of the amide,[7] it actually proceeds via the formation of an intermediate of the anthranilate salt, which can be isolated as a crystal when the reaction mixture is dissolved in an alcohol.[2l] In addition, this reaction usually requires a high temperature and long reaction time; and a high yield is expected when a formamide or acetamide reacts with an anthranilic acid, whereas the yield decreases when a higher order of amide is used in this reaction.[2l,7,8] This general trend is caused by the thermal decarboxylation of the anthranilic acid.[2l]

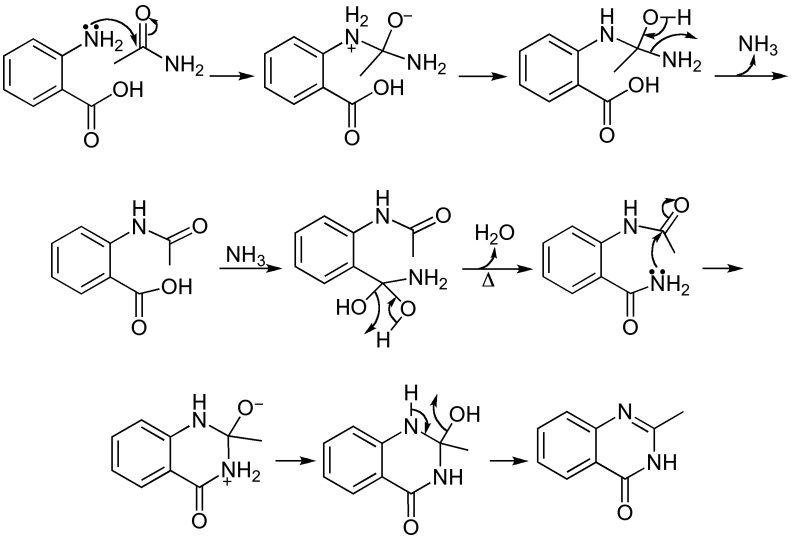
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A detailed mechanism for the reaction between anthranilic acid and acetamide is illustrated here, according to the proposed reaction path.[9]



D. MODIFICATION

This reaction has been extended to occur between an anthranilic acid and a thiobenzamide.[10] In addition, different anthranilic acid derivatives—including *o*-acylaminobenzamides,[2l] ammonium *o*-acylaminobenzoates,[2l] *o*-acetaminobenzonitrile,[2l] acetanthranil[2l] and anthranilic ester[2l]—have been used successfully in this reaction. Moreover, efficient reaction conditions have been established under microwave irradiation.[2a,2b,2d,2g,3a,4b]

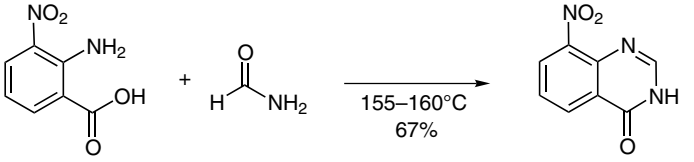
E. APPLICATIONS

This reaction is generally used for the preparation of quinazoline derivatives.

F. RELATED REACTIONS

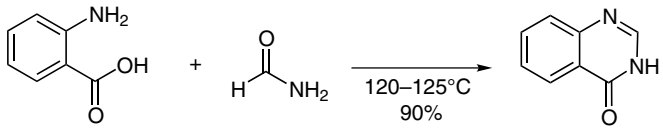
This reaction is related to the *Friedländer Condensation* and *Pfitzinger Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2k.

3-Nitroanthranilic acid (60 g) and 120 g freshly distilled formamide were heated in an open beaker in an oil bath at an inside temperature of 155–160°C for 6 h. The dark residue, after cooling, was pulverized and washed with 5% $NaHCO_3$ solution, then with water, and dried to afford 42 g crude 8-nitroquinazolone-4, in a yield of 67%, m.p. 240–248°C. The crude product was then recrystallized from nitrobenzene (100 mL per 15 g product) with a liberal use of charcoal for decolorization. The crystal was washed with ether to remove residual nitrobenzene, and pale yellow needles were obtained, which melted at 250–251°C.



Reference 10.

Anthranilic acid (137.1 g, 1.0 mol) was heated with 75.6 g formamide (1.68 mol) at 120–125°C for 4 h. The product was filtered and recrystallized from ethanol to afford 131.5 g 4-quinazolone, in a yield of 90%, m.p., 215.5–216.5°C.

Other references related to the Niementowski reaction are cited in the literature.[11]

Nierenstein Reaction

A. GENERAL DESCRIPTION OF THE REACTION

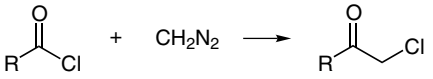
This reaction was first reported by Staudinger in 1914,[1] subsequently by Clibbens and Nierenstein in 1915,[2] and extensively studied by Nierenstein.[3] It is the synthesis of α-chloromethyl ketone by treatment of an aliphatic or aromatic acyl chloride with diazomethane. Therefore, it is generally known as the Nierenstein reaction.[4] Occasionally, it is also referred to as the Clibbens-Nierenstein reaction[5] or Nierenstein chloromethylation.[6]

Besides α-chloromethyl ketones, this reaction can be used to make other reactive halides carrying different elements (e.g., mercury)[7] and even molecules containing a halogen sensitive group, such as Si-H link.[8] It should be pointed out that α-chloromethyl ketone is not the only product from the reaction between an acyl chloride and a diazomethane; in fact, the direct product from such reaction is a diazoketone. For example, benzoyl chloride when reacting with diazomethane is quickly and completely transformed into diazoacetophenone, accompanied by the evolution of nitrogen.[9] The *in situ* generated diazoketones then decompose and produce a variety of products. For example, diazoketones lose nitrogen when decomposed catalytically; if no protic reagent is present, the resulting product is an ethylenic compound coupled from two diazoketone molecules;[10] when acyl chloride is added to more than two equivalents of diazomethane, the diazoketone can be obtained, purified, and further converted into corresponding acid, ester, amide or substituted amide.[11] However, when α-chloromethyl ketone is the desired product, the reversed process should be used so that the total amount of diazomethane is restricted to the minimum needed, in a way that an excess amount of diazomethane is quickly added into the acyl chloride solution.[9,11] Unfortunately, this reaction works poorly for preparing α-bromomethyl ketone, probably because the bromine atom is less mobile.[12] Under certain conditions, the dihalogenated dioxanes are also produced,[4a] as shown in the reaction between benzoyl bromide and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

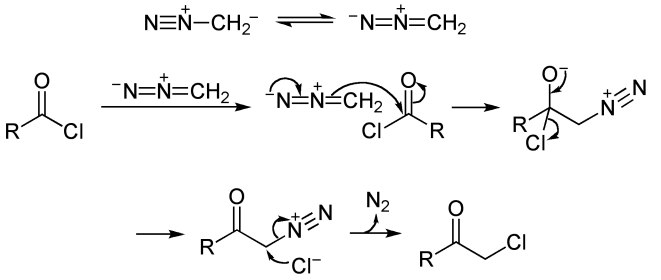
diazomethane, in which 62% 2,5-dibromo-2,5-diphenyl-1,4-dioxane is obtained, whereas only 28% ω-bromoacetophenone is yielded.[3a] Similarly, when the mobility of chlorine atom is reduced, the yield of the corresponding α-chloromethyl ketone decreases too. Examples are the reactions between diazomethane and phenylacetyl chloride, diphenylacetyl chloride, or triphenylacetyl chloride, by which the former two acetyl chlorides give 87% and 82% of the corresponding α-chloro-γ-phenyl-acetone, and α-chloro-γ,γ-diphenyl-acetone, respectively, and the latter yields 92% dioxane derivative.[3a] This reaction has been extended to a one-pot preparation of terminal olefins.[6]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a simple illustration of the reaction mechanism.



D. MODIFICATION

N/A

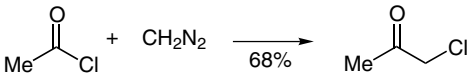
E. APPLICATIONS

This reaction has a general application in the preparation of α-chloromethyl ketones; in addition, the α-chloromethyl ketones can be converted into terminal olefins by treatment with a Grignard reagent, and these two steps can be combined into a one-pot process.[4a]

F. RELATED REACTIONS

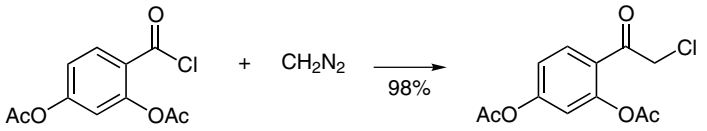
This reaction is related to the *Arndt-Eistert Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



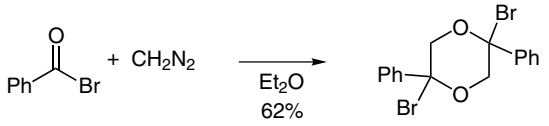
Reference 13.

To a 1-L three-necked flask containing 0.5 mol diazomethane and ~500 mL dried ether was added 0.25 mol acetyl chloride slowly from a dropping funnel with constant stirring of the solution, which was maintained at a temperature not greater than 5°C. The reaction mixture was allowed to stand for 2 h after the addition of the acetyl chloride and was then saturated with dry hydrogen chloride over a period of 2 h. The bulk of the ether was removed by distillation, and the residual solution was fractionated through a small column. The fraction boiling at 118–119°C at 736 mmHg was collected and weighed 15.8 g, in a yield of 68%.



Reference 3b.

An ether solution of 6 g diacetyl-β-resorcoyl chloride was treated with an excess of diazomethane. The solid left on evaporating crystallizes from dry benzene in prismatic needles, in a yield of 98%, m.p. 73°C.



Reference 3a.

Benzoyl bromide dissolved in anhydrous ether (dried over the Grignard reagent) was allowed to react with an excess amount of diazomethane. After evaporation of the solvent, the solid left was pulverized, mixed with dry sand (purified by washing with HCl) and extracted in a Soxhlet apparatus with ligroin (b.p. 50–60°C) and then with benzene (dried over sodium). The first extraction, which dissolved only bromoacetophenone, was concluded when no solid was left on evaporation of a little of the overflowing liquid. The benzene, which was dried in the same manner, dissolved 2,5-dibromo-2,5-diphenyl-1,4-dioxane, which was crystallized as long needles from benzene, in a yield of 62%, m.p. 159°C.

Other references related to the Nierenstein reaction are cited in the literature.[14]

Norrish Type I Reaction

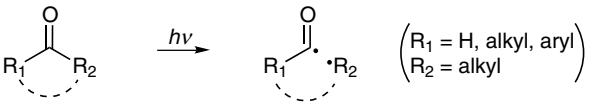
(Norrish Type I Process, Norrish Type I Cleavage)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Norrish in 1932.[1] It is a light-initiated carbon-carbon bond cleavage between the α-carbon and the carbonyl of a ketone or an aldehyde to form an alkyl and an acyl radical pairs, from which a variety of products can be formed, including alkane,[2] alkene,[2] cyclic acetal,[3] decarbonyl compound,[3] and oxetane.[4] In order to differentiate this reaction from other common photoreactions of ketones and aldehydes, it is generally known as the Norrish type I reaction.[4,5] In addition, it is also referred to as the Norrish type I process,[2,6] Norrish type I α-cleavage,[5c,7] Norrish type I photocleavage,[8] Norrish type I cleavage,[2,6a,9] and Norrish type I photochemical reaction.[8a] This reaction is initiated by a n-π^* excitation,[5b,6b,10] from the ground state (S_0) to its first excited singlet state (S_1),[5b] followed by an α-cleavage to form an acyl and an alkyl radical pairs. Alternatively, the first excited singlet may convert itself into the first excited triplet state through an intersystem crossing, which then undergoes the α-cleavage.[5a,6b] The α-cleavage taking place from the triplet excited state is sometimes called the *reluctant* Norrish type I reaction.[9h] This reaction is influenced by both the structure of the substrate and the reaction conditions, as evidenced in the different product distributions between the reactions in the gas phase and in the solution phase.[2] Even the product distribution in the solution phase is different from that when cyclodextrin is present, which often results in a cage effect.[5m,10] Similarly, the product distribution also differs from that occurring in the solid state,[9c,10] or in zeolite.[2,5m,9a,11] It has been found that aliphatic cyclic imides[5r] and small cyclic ketones up to cycloheptanone[5m] undergo only the Norrish type I reaction, from both singlet and triplet excited states;[5m] whereas acetophenone and benzophenone do not undergo the Norrish type I reaction, so that they are often used as the Norrish type I photosensitizers.[12]

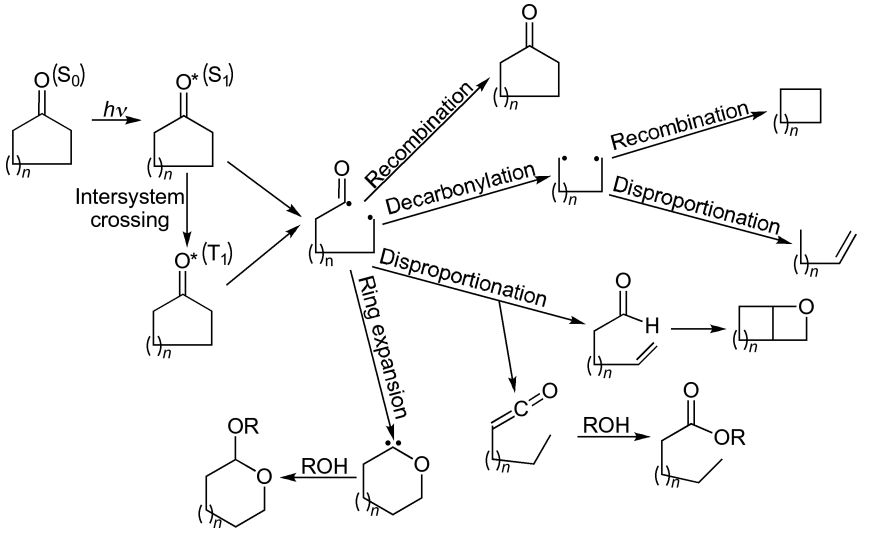
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism for the Norrish type I reaction is displayed below, including all the possible products.



D. MODIFICATION

This reaction has been carried out in the presence of zeolite[2,5m,9a,11] and cyclodextrin[5m,10] and in the solid state.[9i,10]

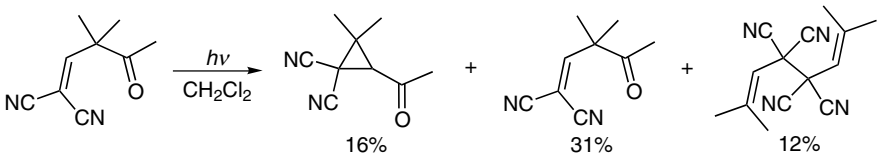
E. APPLICATIONS

This reaction provides a convenient source of hydrocarbon radicals.[13] In addition, it has been used extensively in organic synthesis and photochemistry.

F. RELATED REACTIONS

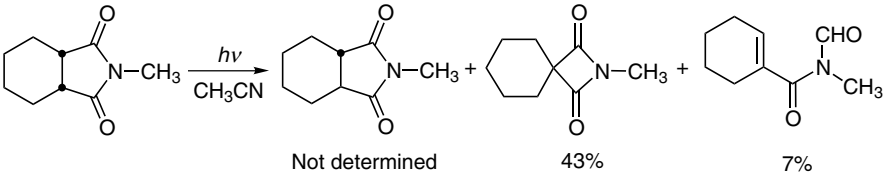
This reaction is related to the *Norrish Type II Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

To a quartz immersion well apparatus were added 128 mg 3,3-dimethyl-5,5-dicyano-pent-4-en-2-one (0.79 mmol) and 270 mL CH_2Cl_2. The solution was purged with argon for 1 h, then the apparatus together with a Pyrex filter was irradiated with six 9-W low-pressure mercury arc lamps with a maximum emission at 254 nm for 12 h. After completion of the irradiation, the solvent was removed under reduced pressure. The residue was separated by silica gel column chromatography using hexane/EtOAc (95:5) as the eluent to afford 22 mg 2,7-dimethyl-4,4,5,5-tetracyano-2,6-octadiene as a colorless oil (12% yield), 39 mg starting material (31% recovery) and 20 mg cyclopropylketone as a colorless oil, in a yield of 16%. Further elution with EtOAc afforded 29 mg highly polar material.



Reference 15.

A solution of 500 mg *N*-methylcyclohexane-*cis*-1,2-dicarboxyimide in 25 mL CH_3CN was purged with nitrogen and irradiated for 7 h. After removal of the solvent, the residue was separated by column chromatography to afford 298 mg of a mixture of starting material and *N*-methylcyclohexane-*trans*-1,2-dicarboxyimide, 88 mg *N*-methylcyclohexane-1,1-dicarboxyimide (43%, colorless crystal, m.p. 96–97°C), and 14 mg *N*-formyl-*N*-methyl-1-cyclohexene-1-carboxamide (7%).

Norrish Type II Reaction

(Norrish Type II Process, Norrish Type II Photoreaction, Yang Cyclization)

A. GENERAL DESCRIPTION OF THE REACTION

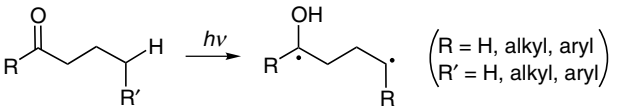
This reaction was first reported by Norrish in 1934.[1] It is a light initiated intramolecular abstraction of a δ-hydrogen of an excited ketone or aldehyde to generate a 1,4-biradical, from which different products can form, including alkene, enol, and cyclobutanol. Therefore, this reaction is generally known as the Norrish type II reaction,[2] Norrish type II process,[2z,3] or Norrish type II photoreaction.[4] Occasionally, this reaction is also referred to as the Norrish type II photochemical reaction,[2d,2h] Norrish type II cleavage,[5] Norrish type II photolysis,[6] Norrish type II photoelimination,[7] Norrish type II rearrangement,[8] or Norrish type II photofragmentation.[2f,9] *Type II* is used to differentiate this reaction from another type of photoreaction that ketone and aldehyde undergo, the *Norrish Type I Reaction.* In addition, because Yang at the University of Chicago extensively extended this reaction,[10] the Norrish type II reaction is also called the Yang reaction,[11] Yang cyclization,[2d,12] Norrish/Yang type II reaction,[13] Norrish-Yang type II reaction,[2h,14] or Norrish-Yang photocyclisation.[14a]

This reaction is influenced by both environmental and structural factors.[2h,2r,14b] For example, the solvent polarity affects the lifetime of the 1,4-biradical in a solution-phase reaction,[6a] although the solvent dynamics barely affects the intersystem crossing rate.[15] In addition, the behavior of a triplet ketone and 1,4-biradical is controlled by the interior size and shape when a ketone is encapsulated inside the zeolites.[2r] In addition, it is known that both the excited singlet (S_1) and triplet (T_1) state of a dialkyl ketone can undergo such reaction,[16] whereas an aryl alkyl thioketone proceeds from the excited triplet

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

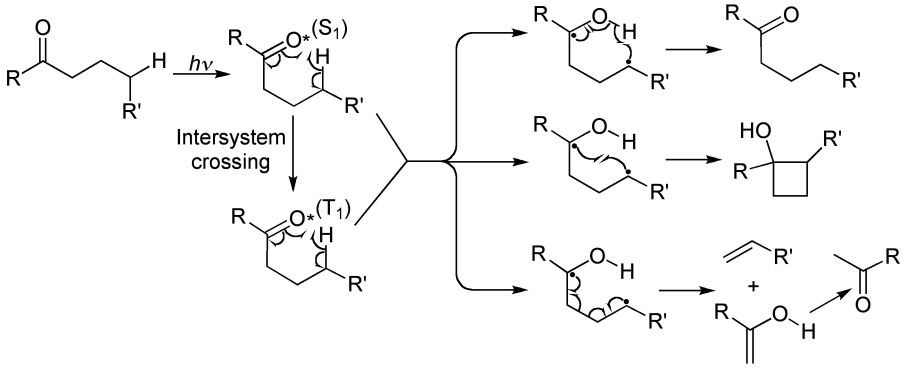
state (T_1),[16a] and the reaction of an ester primarily involves the excited triplet (T_1).[2n] For aliphatic or benzylic hydrogen abstraction, ketones with a lowest π-π^* triplet state are much less reactive than those with the lowest n-π^* triplet state.[17] The lifetime of the triplet is generally on the order of 10–100 ns,[14b,15] because of the small spin-orbit coupling.[15] For an aryl ketone, a skew 1,4-biradical is generated initially from the excited triplet state, which isomerizes to either a *cis*-biradical or a *trans*-biradical; after the intersystem crossing, the singlet *trans*-biradical leads to the fragmentation product, whereas the *cis*-biradical cyclizes to cyclobutanol.[14b] For special ketones like α-allylbutyrophenone and γ-cyclopropylbutyrophenone, the light-generated 1,4-biradicals undergo both rearrangement and a normal Norrish type II reaction.[4f] It is interesting that the light-initiated δ-hydrogen abstraction can also take place on an allylic alcohol from which the alcoholic hydrogen is abstracted from the olefinic moiety to yield an aldehyde, a process also known as the inverse Norrish type II rearrangement.[8a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism for the generation of a 1,4-biradical and all possible products arising from such 1,4-biradical are displayed here.



D. MODIFICATION

This reaction has been extended by Yang to the condition known as Yang cyclization.

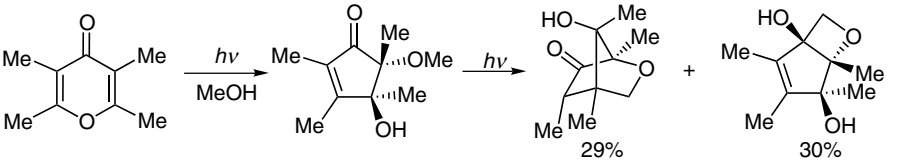
E. APPLICATIONS

This reaction has wide application in organic synthesis, especially for the generation of free radicals.[2z]

F. RELATED REACTIONS

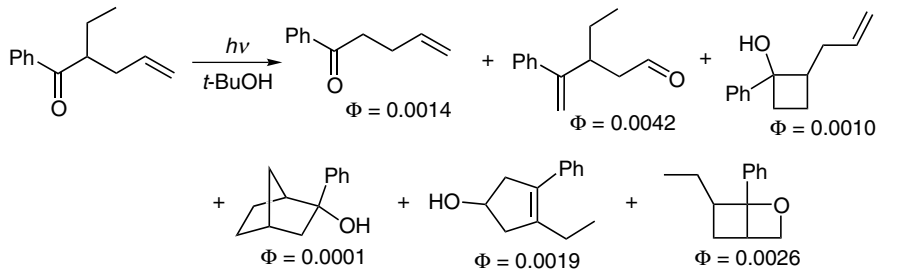
This reaction is related to the *Norrish Type I Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 18.

To a polished quartz tube were added 100 mL MeOH and 100 mg 2,3,5,6-tetramethylpyran-4-one (0.67 mmol), and the solution was deoxygenated for 15 min with a slow stream of dry nitrogen. Then the tube was placed at ~10 cm from the outside of the lamp's water jacket and irradiated until consumption of the pyran-4-one as detected by TLC. Upon removal of solvent under reduced pressure, the residue was purified via silica gel flash column chromatography with CH_2Cl_2/Et_2O/hexane (2:1:1) as the eluent to give 36 mg tetrahydrofuran-like derivative as a colorless oil, $R_f = 0.30$ (CH_2Cl_2/Et_2O/hexane, 2:1:1), in a yield of 29%. Further eluting the column with hexane/EtOAc (1:19) afforded 37 mg diol as a white waxy solid, in a yield of 30%, $R_f = 0.33$ (EtOAc), m.p., 153–156°C (dec).



Reference 4f.

A solution of 16.0 g α-allylbutyrophenone in 180 mL *tert*-butyl alcohol was irradiated under nitrogen in an immersion well with a Pyrex-filtered 450-W Hanovia mercury arc until < 10% of the starting ketone remained. GC analysis showed six products, but none of products was identified as 3-methyl-l-benzoylcyclopentane. After stripping of the solvent, the residue was chromatographed on neutral alumina with cyclohexane/$CHCl_3$ (1:1) as the eluent to afford five components, of which the first three were further purified by GC through a column packed with 15% QF-1 and 3% Carbowax. These compounds were 1-phenyl-3-penten-1-one, 4-phenyl-3-ethyl-4-pentenal, 1-phenyl-2-allylcyclobutanol, 2-phenylbicyclo[2.2.1]heptanol-2, and 3-phenyl-4-ethyl-3-cyclopentenol.

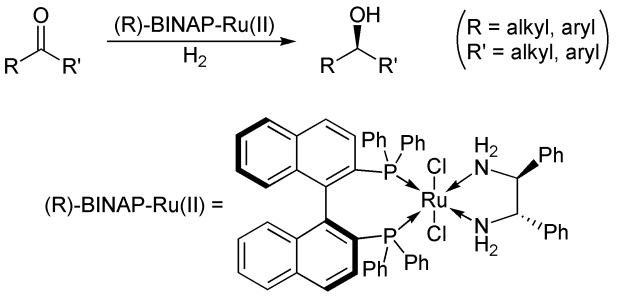
Noyori Hydrogenation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Ikariya[1a] and Noyori[1b] concurrently in 1985. It is a ruthenium or rhodium complex-catalyzed reduction of the carbonyl or alkenyl group by hydrogen with high efficiency and excellent enantioselectivity. Therefore, it is generally known as the Noyori hydrogenation[2] or Noyori reduction.[3] Occasionally, it is also referred to as the Noyori transfer hydrogenation[3i,4] or Noyori hydrogen transfer reaction.[3f] The ruthenium complex of [$RuCl_2$\{(R)-BINAP\}\{(R,R)-DPEN\}], where BINAP = 2,2-bis(diphenylphosphino)-1,1-binaphthyl and DPEN = 1,2-diphenylethylene-diamine,[5] is known as the Noyori catalyst[2d,6] or Noyori/Ikariya catalyst.[7] This catalyst is generally prepared in isopropanol by mixing $RuCl_2$ with an excess amount of strong base, such as $KOBu^t$, under hydrogen atmosphere to neutralize the HCl that is formed during the catalyst activation.[8] In this reaction, hydrogen is activated by binding to the ruthenium atom and subsequent attacking from a Brønsted base, such as alkoxide.[6b] During the reduction of ketone, the amino group is crucial to the activity of the catalyst,[8] of which the NH-proton interacts with the oxygen atom of ketone and a hydride bound to ruthenium is transferred to carbon atom of the carbonyl group through a six-membered transition state.[6b] It has been reported that the enantioselectivity arises from the specific recognition of the *re* or *si* face of the carbonyl group,[2d] and the combination of HCO_2H/Et_3N or $HCO_2Na/n\text{-}Bu_4NBr$ in H_2O/CH_2Cl_2 can be used as the hydrogen source.[7a] However, this reaction is not suitable for the compounds with functionalities that could be reduced during the high-pressure hydrogenation.[2d]

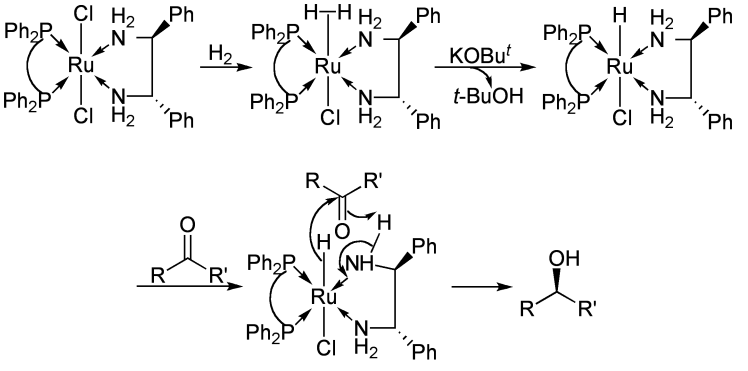
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A part of the mechanism for the catalyzed hydrogenation is shown below.



D. MODIFICATION

This reaction has been modified to use a self-supported catalyst.[5]

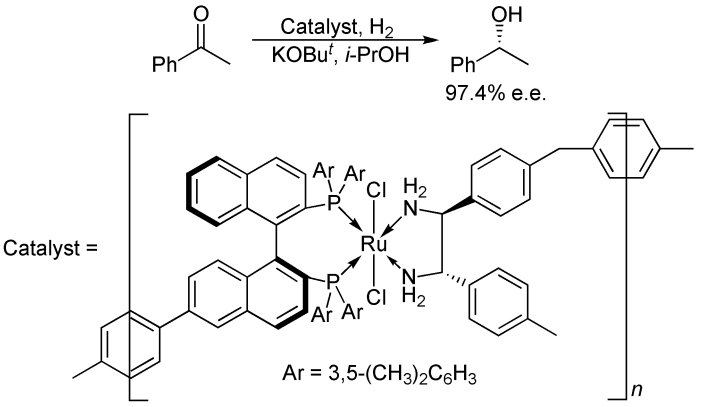
E. APPLICATIONS

This reaction is very useful for the enantiomeric hydrogenation of ketones and olefins.

F. RELATED REACTIONS

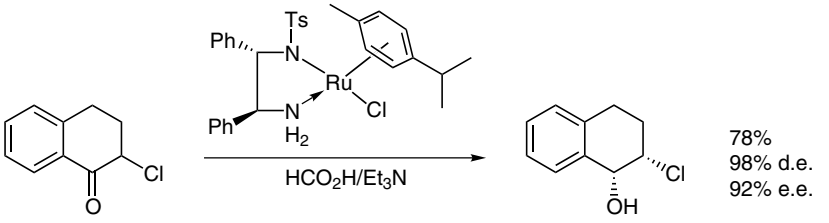
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To a test tube were added 4.6 mg ruthenium complex (3.0 μmol), 6.8 mg KO-*t*-Bu (60 μmol), 0.36 g acetophenone (3.0 mmol), and 2 mL anhydrous isopropanol under argon. Then the test tube was placed in a stainless-steel autoclave, purged with hydrogen six times, and then sealed. The autoclave was charged with hydrogen (40 atm), and the mixture was stirred at room temperature for 20 h. The remaining hydrogen was release, and the catalyst was recovered by filtration through a cannula under nitrogen. The alcohol was tested with 97.4% e.e.



Reference 7a.

To a solution of 10 μmol catalyst (*S*,*S*)-[RuCl(TsDPEN)(*p*-cymene)] in HCO_2H/Et_3N was added 2 mmol 2-chlorotetralone; the mixture was stirred at room temperature until completion of hydrogenation (5 days). The reaction mixture was then diluted with 20 mL CH_2Cl_2 and washed with a saturated solution of $NaHCO_3$ (2 $\times$ 15 mL). The organic layer was dried and concentrated, and the residue was purified by flash chromatography to afford 78% (1*R*,2*S*)-1-hydroxy-2-chloro-tetralin, with 98% d.e. and 92% e.e.

Other references related to the Noyori hydrogenation are cited in the literature.[9]

Nozaki-Hiyama-Kishi Reaction

(Nozaki-Hiyama-Kishi Coupling)

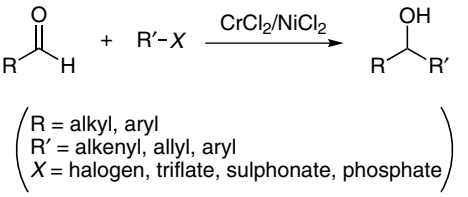
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hiyama and Nozak in 1977[1] and extended by Kishi in 1986.[2] It is a chromium-promoted coupling between a halide and a carbonyl compound. Therefore, it is often known as the Nozaki-Hiyama-Kishi reaction,[3] Nozaki-Hiyama-Kishi coupling,[3n,4] or Nozaki-Hiyama reaction.[3q,5] Occasionally, this reaction is also referred to as the Hiyama-Nozaki reaction,[6] Kishi-Nozaki reaction,[7] or Nozaki-Hiyama-Kishi Ni(II)/Cr(II) coupling.[4f] In addition, an intramolecular version of this reaction to afford a cyclic product is generally called the Nozaki-Hiyama-Kishi cyclization,[3f,3j,3k,8] and the special version of the Nozaki-Hiyama-Kishi reaction involving an allylic nucleophile is termed the Nozak-Hiyama allylation.[5d,9] Overall, this reaction has special features of high aldehyde chemoselectivity,[3t,3u] occurrence under mild conditions[6,10] and the compatibility with a wide range of nucleophiles, such as allyl, propargyl, aryl, and alkenyl halides, alkenyl triflates, allyl sulphonates and phosphates.[3n,3t,3u] However, this reaction does have some weaknesses, such as the high toxicity of chromium (II),[3m,3t,3u] the need of an excess amount of chromium (2 to 16 equivalents),[3t,3u] and the lack of facial selectivity.[3t,4g] It has been suggested that the nucleophile first reacts with Cr^{2+} via an oxidative insertion, the resulting complex then adds to the carbonyl group, and the nickel salt catalyzes the formation of C-Cr bond.[3t] It has been reported that when a bromofluoroalkene is applied as the nucleophile, only (*E*)-bromofluoroalkene couples with the aldehyde, giving moderate to good yields;[10] whereas for the coupling between an aryl bromide and an aromatic aldehyde, the aldehyde with an electron-donating group proceeds ordinarily, but the one with an electron-withdrawing group gives a predominant product of pinacol.[3m] When γ-monosubstituted

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

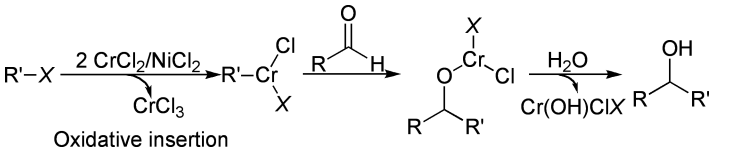
allylhalides are used as the nucleophiles, the corresponding homoallyl alcohols form with an excellent *anti* selectivity, regardless of the original configuration of the allyl halides.[3u] Usually, alkenyl halides or triflates completely retain their double-bond geometry during this coupling.[3u] In addition, this coupling reaction can also occur catalytically with only 7–15% of Cr^{2+} present, which is constantly recycled by the nontoxic manganese powder in the presence of trimethylchlorosilane.[3t,3u] Other catalytic conditions include the regeneration of Cr^{2+} by aluminum[11] or via an electrochemical reduction.[12] Recent development has made this reaction proceed with the control of enantioselectivity in the presence of some chiral ligands, such as salen,[5d] tridentate bis(oxazolinyl)carbazole,[5d] and DIANANE (*endo,endo*-2,5-diaminonorborane).[13]

B. GENERAL REACTION SCHEME

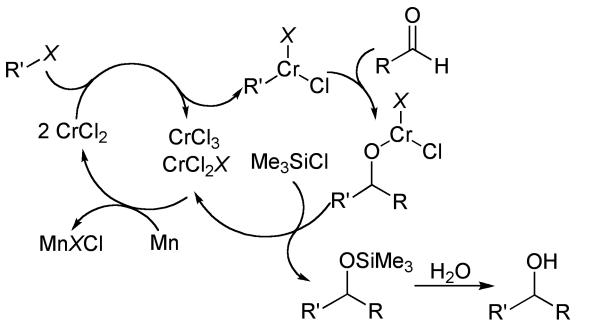


C. PROPOSED MECHANISMS

Although it has been reported that this reaction involves a radical intermediate,[9e] nonradical mechanisms are proposed here, including a stoichiometric Nozaki-Hiyama-Kishi reaction in Scheme 1, and a catalytic version of such reaction in the presence of manganese and trimethylchlorosilane in Scheme 2.



SCHEME 1. *Mechanism of regular Nozaki-Hiyama-Kishi reaction.*



SCHEME 2. *Mechanism of Nozaki-Hiyama-Kishi reaction with manganese and TMSCl present.*

D. MODIFICATION

This reaction has been modified to proceed catalytically,[3t,3u,11,12] by reducing Cr^{3+} back to Cr^{2+}. In addition, it is also made enantioselectively with a chiral ligand present.[5d,13]

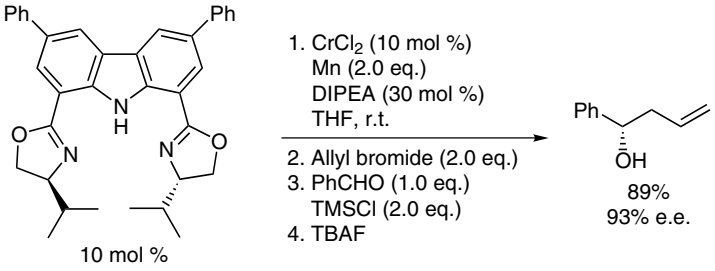
E. APPLICATIONS

This reaction has wide application in organic synthesis, especially for the synthesis of natural products.

F. RELATED REACTIONS

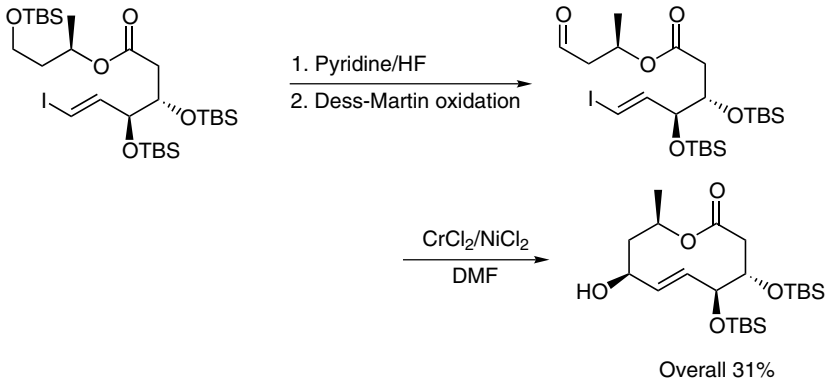
This reaction is related to the *Negishi Cross-Coupling*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5d.

A mixture of 27.1 mg 1,8-bis[4-(*S*)-isopropyloxazolin-2-yl]-3,6-diphenyl carbazole (0.05 mmol), 6.3 mg $CrCl_2$ (0.051 mmol), and 53.8 mg maganese (0.979 mmol) was azeotroped three times with toluene, dried under high vacuum, and suspended in 2 mL THF. The color of the suspension immediately turned to brown. To the stirred suspension was added 0.026 mL DIEPA (0.15 mmol), and after 5 min to the resulting mixture was added 0.086 mL allylbromide (0.99 mmol). After the mixture was stirred for another 30 min, the color turned to greenish brown. To this stirred mixture was added 0.05 mL benzaldehyde (0.49 mmol), and 0.125 mL TMSCl (0.985 mmol) successively at 0°C. After 12 h the color of the reaction mixture turned to reddish brown. The reaction was quenched with 1 mL saturated $NaHCO_3$ aqueous solution, filtered through Celite, and evaporated under vacuum. The crude product was dissolved in 2 mL THF, and the stirred mixture was treated with 1 mL 1 M TBAF solution. The reaction was quenched with 2 mL saturated NH_4Cl solution, extracted with Et_2O (10 mL $\times$ 4), dried over Na_2SO_4, and evaporated. The residue was purified by flash chromatography (hexane/EtOAc, 10:1) to afford 64.7 mg (*S*)-1-phenyl-3-butene-1-ol, in a yield of 89% with 93% e.e.



Reference 3j.

This preparation started from 0.0503 g (*R*)-3-(*tert*-butyldimethylsilyloxy)-1-methylpropyl (3*S*,4*S*,5*E*)-3,4-bis-(*tert*-butyldimethylsilyloxy)-6-iodo-5-hexenoate (0.073 mmol), which was deprotected and oxidized to aldehyde using the Dess-Martin periodinane. To a suspension of 0.130 g $CrCl_2$ (1.06 mmol) containing 0.5 mol % $NiCl_2$ in 12 mL degassed DMF was added via cannula the above aldehyde in 2.6 mL degassed DMF (predried with 2 × 0.5 mL benzene). The reaction mixture was stirred overnight at room temperature, and the solvent was distilled off under vacuum (0.1 mmHg). The residue was dissolved in 10 mL saturated NH_4Cl and extracted with Et_2O (4 × 10 mL) and EtOAc (2 × 10 mL). The organic layer was washed with brine (40 mL) and dried over $MgSO_4$. The crude product was purified by flash chromatography (EtOAc/hexane, 10:90, v/v) to yield 10 mg (*4S,5S,8S,10R*)-8-hydroxy-4,5-bis-(*tert*-butyldimethylsilyloxy)-10-methyl-3,4,5,8,9,10-hexahydro-2H-2-oxecinone, in an overall yield of 31% for three steps.

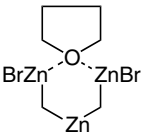
Nysted Reagent
(Nysted Methylenation)

A. GENERAL DESCRIPTION OF THE REACTION

This reagent was first reported by Nysted in 1975.[1] It is the cyclo-dibromo-di-*m*-methylene-(*m*-tetrahydrofuran)-trizinc[2] prepared by treatment of dibromomethane with activated zinc-lead couple[3] or hydrogen chloride-activated zinc dust[3b] in THF and is generally known as the Nysted reagent.[2–4] This reagent, in combination with $TiCl_4$ in THF or CH_2Cl_2, is very useful for converting a carbonyl group,[2b,2c,4c,4e] especially the sterically hindered oxo group, into a methylene group,[2b] and such transformation is known as the Nysted methylenation[5] or Nysted olefination.[2a] In some cases, this reagent is superior to the *Tebbe Reagent* in conversion of a carbonyl group into a methylene group.[6] In addition, during the workup process the protecting group such as MOM acetal can be removed simultaneously.[2b]

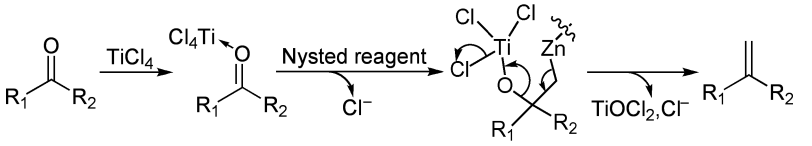
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A part of the mechanism for the olefination of a carbonyl compound is illustrated here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

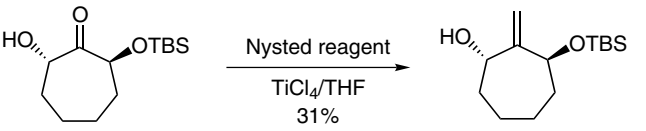
E. APPLICATIONS

This reagent is very useful for the conversion of the carbonyl groups into methylene groups.

F. RELATED REACTIONS

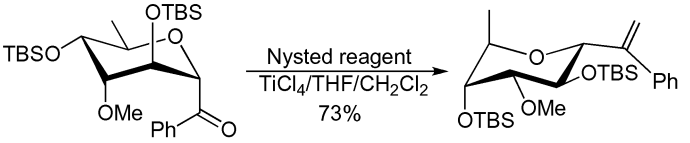
This reagent is related to the *Tebbe Reagent*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4d.

To a flame-dried flask equipped with a stirring bar and a nitrogen-filled balloon was added a 20% suspension of the Nysted reagent (4.23 g in THF, 1.9 mmol) and 3.5 mL THF. The suspension was cooled to 0°C, and 0.21 mL neat titanium tetrachloride (1.9 mmol) was introduced dropwise followed by 0.32 g *trans*-2-(*tert*-butyldimethylsilylox)-7-hydroxy-cycloheptanone (1.24 mmol) in 2.4 mL THF. The mixture was stirred at room temperature for 24 h, quenched with 100 mL 10% HCl, and transferred to a separatory funnel. The product was extracted with ether (3 × 100 mL), and the combined organic phases were dried and concentrated. The residue was purified via silica gel column chromatography using hexane/EtOAc (10:1) as the eluent to afford 74 mg *trans*-2-(*tert*-butyldimethylsilyloxy)-7-hydroxymethylenecycloheptane as a colorless oil, in a yield of 31%.



Reference 4f.

To a slurry of Nysted reagent (20 wt % suspension in THF, 320 mg, 0.7 mmol) and 74 mg 2,6-anhydro-1-phenyl-1-keto-3,5-bis-*O*-*tert*-butyldimethylsilyl-4-*O*-methyl-7-deoxy-α-D-altro-heptitol (0.15 mmol) in 2 mL dry THF at -78°C under nitrogen was added 0.6 mL 1 M $TiCl_4$ in CH_2Cl_2 dropwise. The mixture turned yellow and was warmed to room temperature and stirred overnight ($\sim$14 h). The resulting dark slurry was then cooled in an ice bath, and 0.5 mL Et_3N was added, followed by silica gel. The mixture was warmed to room temperature and was filtered through a plug of silica gel using EtOAc as a wash. The filtrate was concentrated, and the residue was isolated by silica gel column chromatography using petroleum ether/EtOAc (1:19) as eluent to afford 54 mg 3,7-anhydro-1,2,8-trideoxy-2-phenyl-4,6-bis-*O*-*tert*-butyldimethylsilyl-5-*O*-methyl-α-D-altro-oct-1-enitol as an oil, in a yield of 73%.

Other references related to the Nysted reagent are cited in the literature.[7]

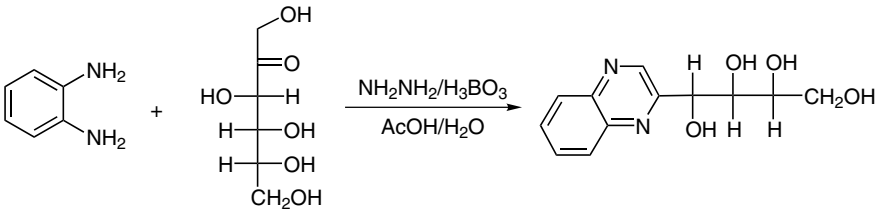
Ohle Quinoxaline Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first studied by Griess and Harrow in 1887,[1] then reported by Hinsberg in 1893,[2] and extensively explored by Ohle since 1934.[3] It is the preparation of 2-tetrahydroxybutyl-quinoxaline from the condensation between a monosaccharide and *o*-phenylenediamine.[4] Unfortunately, the yields are generally low, such as in the range of 15–30%.[5] The most feasible protocol is the one developed by Ohle by reacting monosaccharide, such as fructose, with hydrazine, *o*-phenylenediamine, and boric acid in a dilute acetic acid with bubbling of oxygen into the solution.[6] In addition, the hydrazone/osazone of the sugar is also used to react with *o*-phenylenediamine to give a moderate yield of the quinoxaline derivative.[5,7] Although atmospheric oxygen is the hydrogen acceptor, hydrazine is believed to be a better acceptor because a higher yield of quinoxaline is obtained in the presence of hydrazine.[8] Thus it is assumed that quinoxaline is formed from the reaction between *o*-phenylenediamine and the osazone of the monosaccharide, arising from hydrazine and the monosaccharide in the presence of oxygen. It has been found that the use of other oxidation reagents, such as hydrogen peroxide, benzoyl peroxide, hydroxylamine, methylhydrazine, phenylhydrazine, and semicarbazide provides no obvious advantages over Ohle's protocol.[9] It should be pointed out that hydroxylamine, methylhydrazine, phenylhydrazine, and semicarbazide may not function as the oxidation reagents under these conditions. The generated tetrahydroxybutyl quinoxaline can be converted into flavazole derivatives when refluxed with an excess amount of hydrazine or phenylhydrazine.[3c,3e] In addition, the side chain of quinoxaline can be modified or removed by oxidation.[6a]

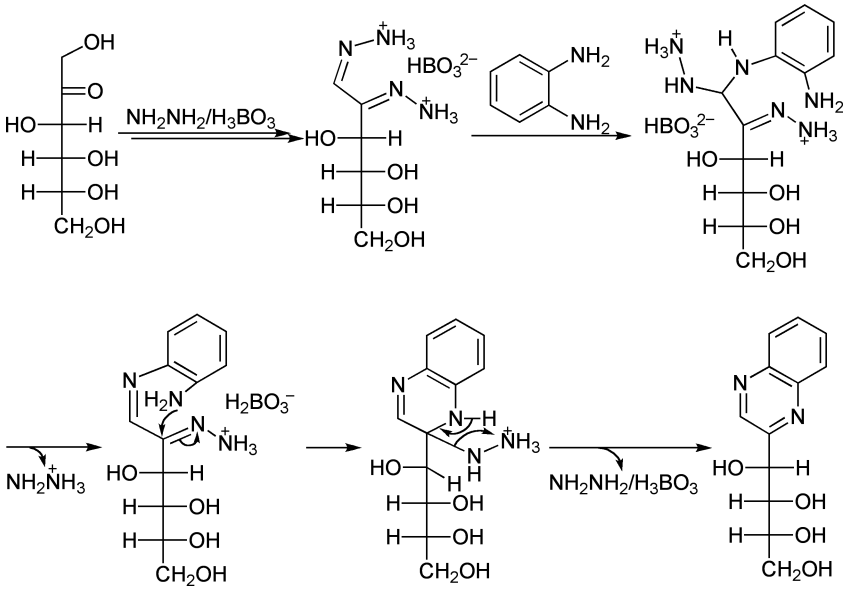
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism for the formation of hydrazone or osazone of carbohydrate with hydrazine or phenylhydrazine was described in detail for the *Fischer Phenylhydrazone and Osazone Synthesis*, so only a part of the mechanism for the preparation of quinoxaline derivative is illustrated here. The presence of boric acid and acetic acid may help the formation of hydrazone.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction is useful for the formation of quinoxaline derivatives.

F. RELATED REACTIONS

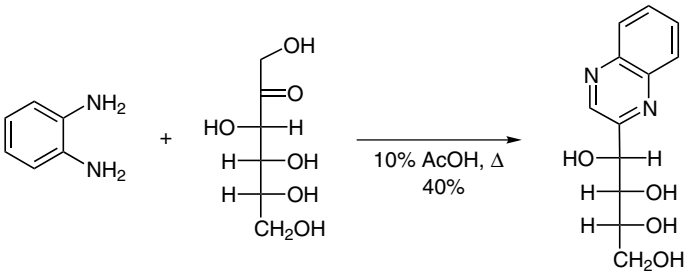
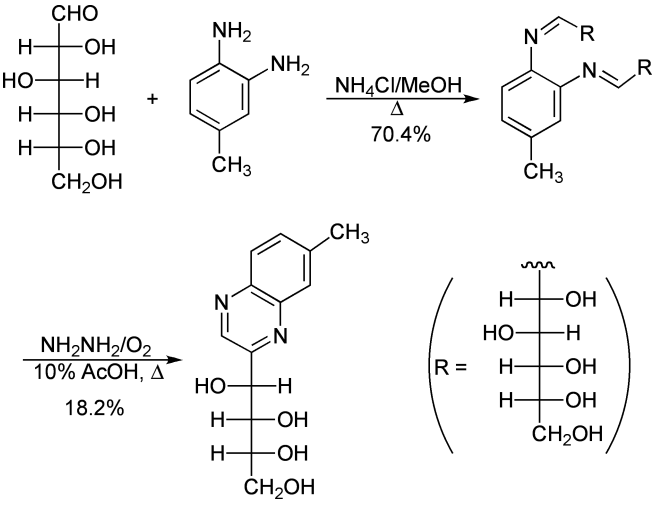
G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

1,2-Phenylenediamine (450 g, 4.16 mol) was placed in a 5-L, three-necked, round-bottomed flask equipped with a mechanical stirrer and thermocouple. Aqueous acetic acid (2.0 L, 10% solution) was added to the reactor, and the mixture was stirred for 30 min. Then 750 g D-fructose (4.16 mol) was added portionwise over 20 min. The mixture was heated at 80°C under stirring for 18 h. The reaction mixture was cooled to 10°C for 5 h. The solids were filtered through shark skin filter paper using a Büchner funnel. The solids were washed with water (2 × 500 mL). A rubber dam was placed over the funnel, and the funnel was kept under vacuum for 3 h. The light brown solids were placed in a vacuum oven for 18 h at an oven temperature of 60°C at 1 mmHg to afford 400 g 2-tetrahydroxybutyl-quinoxaline, in a yield of 40%, m.p., 181–184°C.



Reference 8.

A mixture of 36 g D-glucose, 12 g 3,4-diaminotoluene, 0.2 g NH_4Cl, and 800 mL MeOH were refluxed for 30 min. After cooling, the crystalline product was promptly separated by filtration to yield 33.8 g *N*,*N*-di-D-glucosyl-3,4-diaminotoluene, in a yield of 70.4%. This compound was further purified by recrystallization from a large volume of aqueous methanol, m.p., 142–143°C.

The mixture of 4.5 g of *N*,*N*-di-D-glucosyl-3,4-diaminotoluene and 50 mL 10% acetic acid was refluxed for 30 min. Under an ordinary atmosphere, no separable amount of the crystalline product was obtained, but under vigorous passing of oxygen through the solution, 0.35 g 2-D-*arabino*-tetrahydroxybutyl-6-methylquinoxaline was obtained after cooling, in a yield of 7.8%. However, when an equal molar amount of hydrazine was added to the reaction system under ordinary atmosphere, 0.82 g of the quinoxaline derivative was obtained, in a yield of 18.2%, m.p. 177–178°C.

Other references related to the Ohle quinoxaline synthesis are cited in the literature.[10]

Oppenauer Oxidation

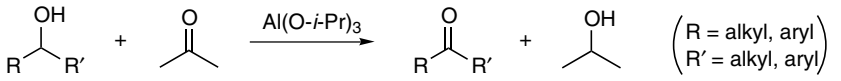
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Oppenauer in 1937.[1] It is the Lewis acid, primarily aluminum tri-isopropanoxide (i.e., Al(O-*i*-Pr)$_3$), catalyzed oxidation of secondary alcohols into ketones using another ketone or an aldehyde as the oxidant, which in turn is reduced to the corresponding alcohol. Therefore, it is generally known as the Oppenauer oxidation.[2] Because it is the reverse reaction of the *Meerwein-Ponndorf-Verley Reduction*, the interchange between alcohols and ketones in the presence of an aluminum catalyst is referred to as the MPVO reaction.[2h] Compared to other oxidation methods for alcohols, the Oppenauer oxidation is much more benign for the environment[2k] and is tolerated by many other functional groups, including carbon-carbon double and triple bonds, amino groups, aldehyde groups, halogens, and sulfur-containing groups.[2u] In addition, this reaction shows high selectivity[2k] and does not produce carboxylic acid from the overoxidation of a primary alcohol. Thus it is a very common method for the preparation of ketones.[2k] However, the Oppenauer oxidation also has problems in the oxidation of primary alcohols[2k,2u,3] and α-amino alcohols.[2aa,2dd,2ff] The unsuccessful oxidation of primary alcohol probably arises from the further *Aldol Condensation* between aldehyde and ketone, deactivation of the moisture-sensitive catalyst (i.e., deactivation of aluminum alkoxide by water),[2k] and the accompanying *Tishchenko Reaction*.[2m] As a result, an aldehyde such as benzaldehyde is often used as an oxidant in the Oppenauer oxidation.[2j,2m] The failure for oxidation of α-amino alcohol is probably due to the formation of a stable cyclic complex between α-amino alcohol and aluminum alkoxide,[2dd] which does not undergo further reaction. Therefore, some α-amino ketones have been used as oxidants for the Oppenauer oxidation too,[4] such as 1-methyl-4-piperidone.[5] The application of aluminum *t*-butoxide as catalyst is sufficient for the oxidation of an α-amino alcohol to an α-amino ketone at

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

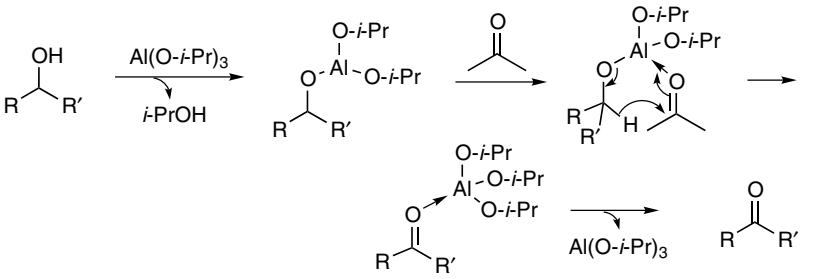
high temperature.[2aa] In addition, cyclohexanone can also be used as oxidant because of its high oxidation potential.[2cc–2ff,4] The Oppenauer oxidation has been extensively modified by the application of different transition metal compounds as catalysts to substitute for aluminum alkoxide, including chromium(III) alkoxide,[2m] magnesium alkoxide,[2a,2c] zirconium alkoxide,[2v] seven-membered oxazirconacycle,[2i] lanthanoid triisopropoxide,[2x] samarium(II) iodide,[2y] Cp*Ir(III) complex,[3,6] $RuCl_2(PPh_3)_3^3$, and heterobimetallic Ir(I)-Ru(II) catalyst.[3] Among these modifications, the Cp*Ir(III) complex can catalyze the oxidation of primary alcohol to aldehyde using 2-butanone as the oxidant,[2k] and the introduction of *N*-heterocyclic carbene ligand can effectively enhance the turnover number for the oxidation of secondary alcohols.[6]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that the alcohol displaces one of the alcoholic components of aluminum alkoxide to form a new aluminum alkoxide, which then forms a complex with oxidative ketone. The hydrogen transfer occurs through a six-membered transition state to give a new ketone and aluminum alkoxide. The mechanistic details are shown here.



D. MODIFICATION

This reaction has been extensively modified by the use of different transition metal compounds as catalysts, as described in section A.

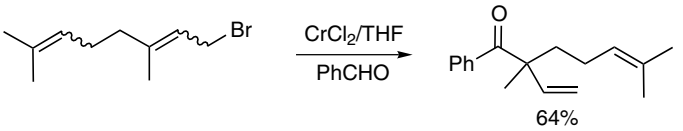
E. APPLICATIONS

This reaction is very useful in the preparation of ketones.

F. RELATED REACTIONS

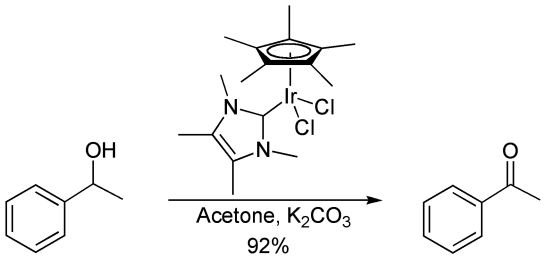
This reaction is closely related to the *Meerwein-Ponndorf-Verley Reduction* and is also related to the *Cannizzaro Reaction* and *Tishchenko Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2m.

To a flask was added 200 mg chromium(II) chloride (1.63 mmol, 2.5 eq.); then 2.5 mL THF was added under vigorous stirring. After a few minutes, 229 mg benzaldehyde (2.16 mmol, 3.0 eq.) and 156.3 mg 3,7-dimethyl-1-bromo-oct-2,6-diene (0.72 mmol, 1.0 eq.) were added. The resulting mixture was stirred for 3 h at 55°C, and the reaction was quenched with brine. The aqueous layer was extracted three times with diethyl ether, and the combined organic fractions were washed twice with brine, dried over $MgSO_4$, and concentrated in vacuo. The residue was purified by silica gel column chromatography using diethyl ether as the eluent, to afford 64% 2,6-dimethyl-1-phenyl-2-vinyl-hept-5-en-1-one as a colorless oil, in a yield of 64%, R_f = 0.64 (hexane/EtOAc, 98:2).



Reference 6a.

To a flask were added 20 μmol Cp*Ir(IMeMe)Cl_2 catalyst, 20 μmol K_2CO_3, and 8.0 mL acetone. To another flask were added 20.0 mmol 1-phenylethanol and 8.0 mL acetone. Then the alcohol solution was transferred to the solution containing the iridium catalyst and base, and the resulting mixture was stirred at 40°C for 4 h. After removal of the solvent, the product was analyzed with GC, indicating a 95% conversion of 1-phenylethanol to acetophenone with a yield of 92%, and a turnover number of 920 for such a catalyst.

Other references related to the Oppenauer oxidation are cited in the literature.[7]

471

Orton Rearrangement

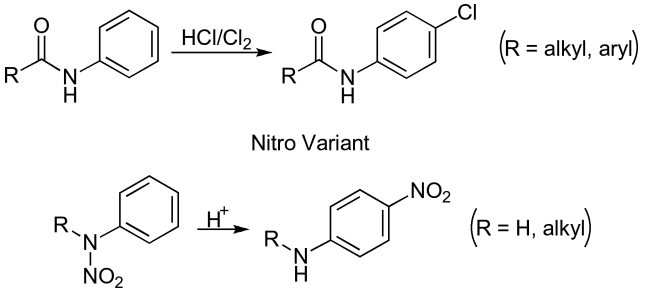
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Bender in 1886,[1] subsequently by Armstrong in 1890,[2] and was extensively explored by Orton et al. beginning in 1899.[3] It is the rearrangement of an *N*-chloro acyl anilide into an *N*-acyl *p*-chloroanilide in the presence of an acid such as HCl. Therefore, it is generally known as the Orton rearrangement.[4] This reaction is assumed to proceed via a multistep processes, including the liberation of chlorine and subsequent electrophilic substitution,[4i,5] as suggested by Orton.[3a] The former step is reversible, whereas the electrophilic substitution is irreversible.[4i,5] Although hypochlorous acid has been proposed as the intermediate during the chlorination at the aromatic ring[3e] because the Orton rearrangement occurs readily in a chlorinating solution in which HClO is the major species,[4b] this mechanism was abandoned by Orton.[3p] It is known that the Orton rearrangement is promoted simultaneously by proton (i.e., H^+) and chloride.[5b] The rearrangement of acetyl *N*-chloroanilide in acetic acid containing NaCl and sodium acetate buffer is a first-order reaction, and the reaction rate is accelerated by the addition of acetanilide or *N*-acetonaphthalide, with a maximal rate limit.[5c] It has been found that both solvent composition[5a] and substrate influence this rearrangement.[4i] For example, in acetic acid, no hydrogen chloride is detected,[5a] and no chlorination products are formed by the treatment of tertiary acyl anilides such as *N*-methyl benzanilide and *N*-phenyl benzanilide.[6] In addition, the Orton rearrangement can be triggered by a Lewis acid, such as $AgBF_4$,[7] as well as by light,[8] such as irradiation from a mercury-vapor lamp even in solid state.[9] Furthermore, the chlorination of acyl anilide from chlorine can proceed by two paths: the normal Orton rearrangement via *N*-chlorination or the direct chlorination of the aromatic ring, which may take place independently and simultaneously.[4i]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

Similar to the migration of chlorine, the nitro group has also been found to rearrange in a similar fashion when *N*-nitro-anilides are treated with a strong acid.[10] During these rearrangements, when the *para* position of the aniline moiety is occupied by an electron-donating group (such as Me, F, Cl, Br, Ph, and PhO), the *ortho*-nitroanilides are formed. In one case, the *para*-bromo group is found to be replaced by a nitro group. However, when the *para*-position is occupied by an electron-withdrawing group, such as a nitro, cyano, or sulfonyl group, then the rearrangement is relatively suppressed.[10c] It has been found that both the rearrangement yield and the *ortho*/*para* ratio of isomers increase when the solvent viscosity is increased.[10a] It is interesting that in the presence of HNO_3, H_2SO_4, HCl, or $HClO_4$, *N*-nitro-2,4-dichloroaniline is converted into 2-nitro-4,6-dichloroaniline,[11] whereas 2,4-dichlorobenzenediazonium bromide is obtained quantitatively in the presence of HBr.[12]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although a mechanism involving the formation of chlorine and subsequent electrophilic substitution has been proposed, it is possible that the N-Cl bond in the protonated *N*-chloro acyl anilide cleaves homolytically to form a chloro radical and an anilide radical, and the chloro radical adds to the *para*-position of the aniline moiety to form a conjugated iminium cation, followed by the elimination of the *para*-proton to give the rearranged product (Scheme 1). Alternatively, it is possible that after the protonation of *N*-chloro acyl anilide, chloride undergoes a halophilic substitution to form chlorine, then chlorine undergoes the electrophilic substitution (Scheme 2).

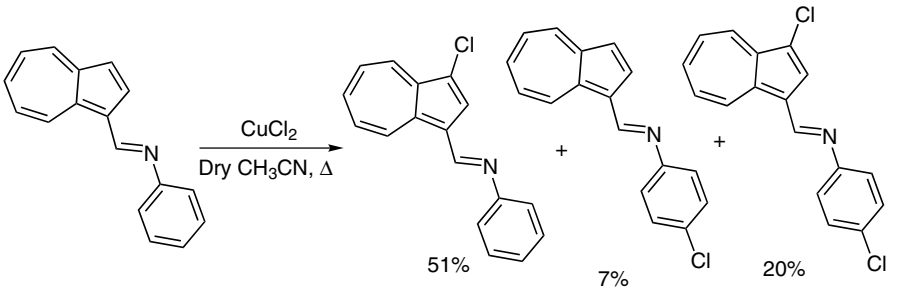
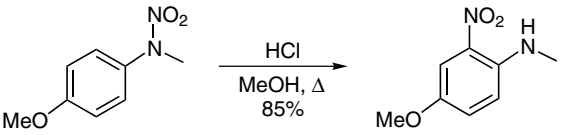
G. CITED EXPERIMENTAL EXAMPLES



Reference 4e.

Anhydrous copper chloride (0.121 g, 0.9 mmol) was dissolved in 10 mL boiling MeCN (distilled on CaH_2), and a yellow solution was obtained. Then 0.3 mmol *N*-(azulen-1-ylmethylene)aniline was added, and the color of the solution turned to red. The solution was vigorously refluxed for 5 h, then MeCN was evaporated to ~5 mL. After cooling to room temperature, 50 mL benzene and 50 mL saturated $NaHCO_3$ solution were

added, and the color of the organic layer turned to green. The organic layer was washed with water and dried over Na_2SO_4. The solvent was evaporated in vacuo to give 51% *N*-(3-chloroazulen-1-ylmethylene)aniline, 7% *N*-(azulen-1-ylmethylene)-4-chloroaniline, and 20% *N*-(3-chloroazulen-1-ylmethylene)-4-chloroaniline.



Reference 10c.

A mixture of 1.0 g *p*-methoxy-*N*-nitro-*N*-methylaniline, 50 mL methanol, and 50 mL conc. HCl was refluxed for 2 h and then allowed to stand for 20 h at 25°C. The solution was cooled to 0°C, and the solid product was collected by suction filtration. The solid was purified by neutral alumina column chromatography using benzene as the eluent to afford 85% 2-nitro-4-methoxyl-*N*-methylaniline, m.p. 98–99°C.

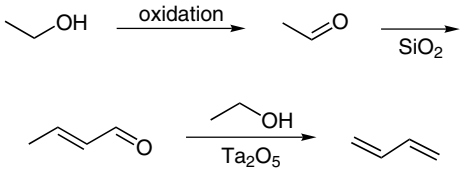
Ostromislensky Process

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ostromislensky in 1915.[1] It is a two-step process for the manufacturing of 1,3-butadiene from ethanol, involving the dehydrogenation of ethanol to acetaldehyde and the deoxygenation of crotonaldehyde. Therefore, it is known as the Ostromislensky process[2] or Ostromislensky reaction.[2] The crucial step in this process is the conversion of acetaldehyde into crotonaldehyde.[2] For the industrial production of 1,3-butadiene, a mixture of ~69 wt % of ethanol, 24 wt % of acetaldehyde, and 7 wt % of water is passed over a tanta catalyst (Ta_2O_5) supported on silica gel (2% Ta_2O_5/98% SiO_2) at 350°C.[3] This process provided > 60% of the emergency need of 1,3-butadiene for rubber during World War II in the United States.[4] It is known that silica gel is critical for the condensation of acetaldehyde, while Ta_2O_5 catalyzes the deoxygenation of crotonaldehyde in the presence of ethanol.[3] Alternatively, Zirconia can be used as catalyst for this reaction.[2]

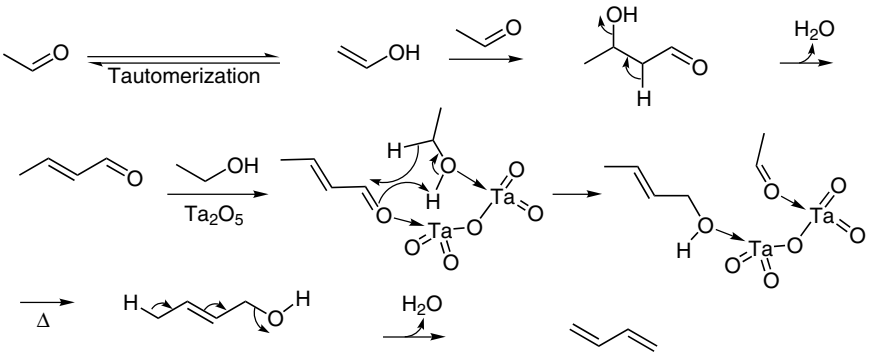
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Only a part of the mechanism for this industrial process is given here.



D. MODIFICATION

N/A

E. APPLICATIONS

This process has very important industrial application in the production of 1,3-butadiene for rubber.

F. RELATED REACTIONS

This reaction is related to the *Lebedev Process*.

G. CITED EXPERIMENTAL EXAMPLES

Because this is an industrial process for the production of 1,3-butadiene and no experiment at the laboratorial scale is available, no experimental protocol is provided for this reaction.

Other references related to the Ostromislensky process are cited in the literature.[5]

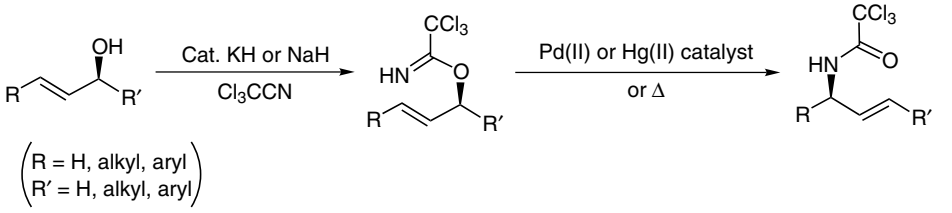
Overman Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Overman in 1974.[1] It is a thermal or Hg(II) or Pd(II) promoted rearrangement of an allyl trichloroacetimidate into an allyl trichloroacetamide. Therefore, it is generally known as the Overman rearrangement.[2] Occasionally, it is also referred to as the *aza-oxa*-Cope rearrangement[2c] or the Overman imidate rearrangement.[3] In this reaction, allyl trichloroacetimidate, readily available by the treatment of allyl alcohol with trichloroacetonitrile in the presence of a catalytic amount of potassium hydride,[3] undergoes a [3,3]-sigmatropic rearrangement with an excellent regiochemical[2c] and geometrical control[2c] as well as the complete retention of stereochemistry.[2d] The resulting allylic trichloroacetamides can be hydrolyzed or degraded into a wide variety of nitrogen-containing products, including amino sugars, nucleosides, peptides, amino acids, and many nitrogen heterocycles.[2b] The Overman rearrangement is generally carried out in a dry and nonnucleophilic solvent to minimize the hydrolysis of allyl trichloroacetimidate.[2b] It has been found that the substitution of potassium hydride with a catalytic amount of DBU (20 mol %) improves the yield from a substrate with an aromatic group at the terminal carbon of the allylic moiety.[2n,3] This reaction is especially useful for the preparation of the sterically hindered allylic amines that are difficult to obtain from conventional methods.[4] However, when the allylic double bond is a part of α,β-unsaturated carbonyl system or is attached with a strong electron-withdrawing group, such as dienyl ester, the Overman rearrangement is unsuccessful.[5] In addition, this rearrangement is problematic for the unsaturated pyranose substrates with axial hydroxy groups at the 1 and 4 positions.[6]

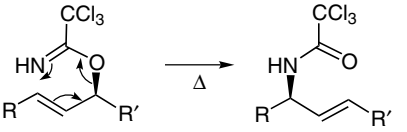
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction is believed to undergo a [3,3]-sigmatropic rearrangement, as shown below for the thermal rearrangement.



D. MODIFICATION

This reaction has been modified by using a chiral Pd(II) catalyst to yield allylic trichloroacetamides with good enantioselectivity.[7] In addition, a [3,3]-sigmatropic rearrangement of alloxy iminodiaza-phospholidines has been implemented recently for the preparation of different nitrogen-containing molecules.[2c]

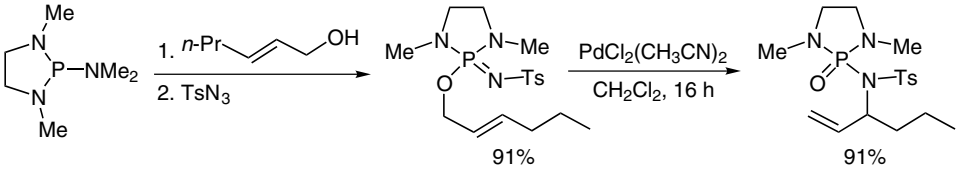
E. APPLICATIONS

This reaction has wide application in organic synthesis for the preparation of a wide variety of nitrogen-containing compounds.

F. RELATED REACTIONS

This reaction is related to the *Cope Rearrangement, Claisen Rearrangement*, etc.

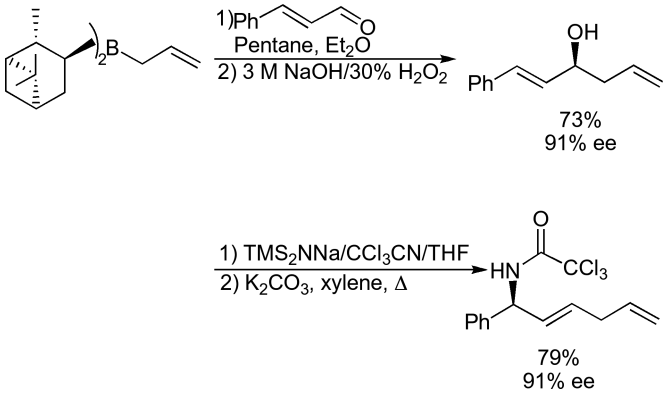
G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

To a flame-dried round-bottomed flask containing 0.6 mmol diazophospholidinyl dimethylamine in 6 mL benzene, was added 0.6 mmol hex-2-en-1-ol under nitrogen. The mixture was stirred for 6 h under a dynamic atmosphere of nitrogen and then checked for completion by ^{31}P NMR. Tosyl azide (0.6 mmol) was then slowly added to the stirring solution, resulting in rapid effervescence. After the complete addition of tosyl azide, the solution was stirred for 15 min and concentrated in vacuo to yield a crude syrup. The crude syrup was then dissolved in a minimum amount of CH_2Cl_2 and purified by flash column chromatography (EtOAc/hexanes, 1.5:1 + 5% NEt_3) to afford 91% (*E*)-*N*-(2-hex-2-enyloxy-1,3-dimethyl-2λ^5-[1,3,2]diazaphospholidin-2-ylidene)-4-methylbenzene-sulfonamide as a clear oil, $R_f = 0.38$ (EtOAc/hexanes, 2:1).

To a flame-dried round-bottomed flask under nitrogen, was added 8 mg bis(acetonitrile)dichloropalladium(II) (5 mol %) and 0.67 mmol iminodiazophospholidine in 5 mL CH_2Cl_2; the resulting solution was stirred for 16 h under a dynamic atmosphere of nitrogen and then checked for completion by ^{31}P NMR. The solution was then concentrated in vacuo. The residue was dissolved in a minimum amount CH_2Cl_2 and purified by flash column chromatography (EtOAc/hexanes, 2:1) to afford 91% *N*-(1,3-dimethyl-2-oxo-2λ^5-[1,3,2]diazaphospholidin-2-yl)-4-methyl-*N*-(1-vinyl-butyl)-benzenesulfonamide as a clear oil, $R_f = 0.36$ (EtOAc/hexanes, 2:1).



Reference 2d.

To a cooled solution of 6 mmol α-pinene-allyl borane in 6 mL pentane mixed with 3 mL Et_2O at $-100°$C was added a precooled solution of 0.7 g (2*E*)-3-phenylbut-2-enal in 6 mL Et_2O at $-78°$C. The mixture was stirred for 3 h, and then warmed to $-78°$C. To this solution was added 1.6 mL 3 M NaOH (slowly) and 1.3 mL 30% H_2O_2, and the solution was stirred for 14 h under positive nitrogen pressure while it slowly warmed to room temperature. The reaction mixture was then extracted with Et_2O (3 $\times$ 20 mL); the combined organic layers were washed with brine and dried over $MgSO_4$. Upon removal of the solvent, the residue was purified by silica gel flash column chromatography (hexanes/EtOAc, 200:1) to furnish 0.66 g (4*S*,5*E*)-6-phenylhepta-1,5-dien-4-ol, in a yield 73% with 91% e.e.

To a precooled solution of 0.5 g (4*S*,5*E*)-6-phenylhepta-1,5-dien-4-ol (2.7 mmol) in 13 mL THF at $-42°$C, was added 0.27 mL 1 M sodium bis(trimethylsilyl)amide in THF (0.27 mmol); the solution was stirred for 0.5 h, then 0.3 mL trichloroacetonitrile (2.9 mmol) was added. The reaction mixture was then allowed to warm to room temperature, and the solvent was removed under reduced pressure. The residue was diluted with 6 mL xylenes,

and 0.4 g K_2CO_3 (2.9 mmol) was added; the mixture was refluxed for 10 h (150°C). The mixture was then filtered through Celite, concentrated under reduced pressure, and purified by silica gel flash column chromatography (hexanes/EtOAc, 99:1) to afford 0.76 g 2,2,2-trichloro-*N*-[(1*S*,2*E*)-1-methyl-1-phenylhexa-2,5-dienyl]acetamide as an oily substance, in a yield of 79% with 91% e.e.

Other references related to the Overman rearrangement are cited in the literature.[8]

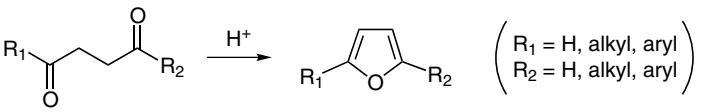
Paal-Knorr Furan Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

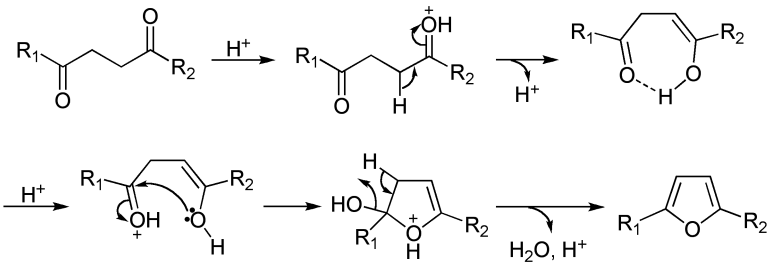
This reaction was first reported by Paal and Knorr in 1885.[1] It is an acid-catalyzed transformation of 1,4-dicarbonyl compounds into furan derivatives and is generally known as the Paal-Knorr reaction[2] or Paal-Knorr synthesis.[2b,3] The acidic catalysts reported in the literature include P_2O_5 (in ethanol),[4] *p*-TsOH or $ZnCl_2$ (in Ac_2O)[5] and polyphosphoric acid.[6] It has been found that the *meso*-diastereomers with substituents between two carbonyl groups cyclize faster when the substituents are electron-donating methyl groups, whereas the *dl*-isomers cyclize faster with bulky substituents.[2b] This reaction is believed to involve the protonation of the carbonyl group that tautomerizes to enol, which attacks the second protonated carbonyl group.[2b,3a] Although it is an important reaction for the preparation of furan derivatives, it is not widely applied in organic synthesis because of the generally low availability of suitable 1,4-dicarbonyl compounds.[2b,3a]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified by the cyclization of 2-ene-1,4-diones or 2-yne-1,4-diones under microwave irradiation in PEG-200 in the presence of formic acid and palladium on carbon.[3a]

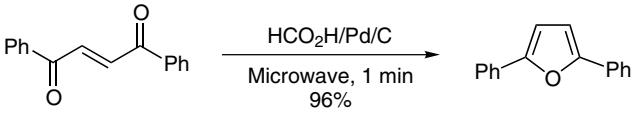
E. APPLICATIONS

This reaction is generally applicable for the preparation of furan derivatives.

F. RELATED REACTIONS

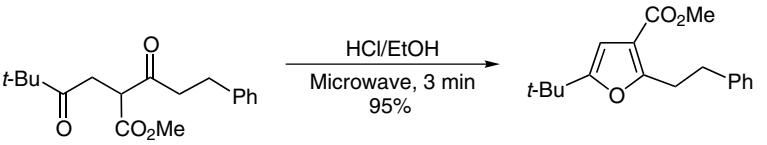
This reaction is related to the *Paal-Knorr Pyrrole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a 25-mL conical flask, were added 118 mg 1,4-diphenyl enedione (0.5 mmol), 1 mL formic acid, 2 mg 5% palladium on carbon, and 2 mL PEG-200. The reaction mixture was irradiated in the microwave oven at 400 W for 1 min, then cooled to room temperature, loaded on a filter silica gel column (100–200 mesh; 1 cm $\times$ 9 cm) using 1 mL CH_2Cl_2, and eluted with a hexane/CH_2Cl_2 solution to afford 105 mg 2,5-diphenylfuran as a white solid, in a yield of 96%, m.p. 86–88°C (recrystallized from CH_2Cl_2/hexanes, 2:98), $R_f = 0.68$ (hexanes/CH_2Cl_2, 1:1).



Reference 2a.

To a 50-mL round-bottomed flask equipped with a stir bar and a refluxing condenser were added 0.5 g 2,2-dimethyl-4-(methoxycarbo)-8-phenyl-oct-3,6-dione (1.64 mmol), 2 mL EtOH, and 0.1 mL 37% HCl. The flask was inserted into the cavity of a Discovery microwave system apparatus (from CEM) and heated at 150 W for 4 min with an internal temperature of 100°C. The mixture was diluted with EtOAc and washed several times with a saturated solution of $NaHCO_3$. The organic layer was dried over anhydrous Na_2SO_4 and concentrated. The residue was purified by flash column chromatography, eluting with hexane/EtOAc (8:1, $R_f = 0.75$) to afford 0.49 g methyl 5-*tert*-butyl-2-(2-phenyethyl)furane-3-carboxylate, in a yield of 95%.

Other references related to the Paal-Knorr furan synthesis are cited in the literature.[7]

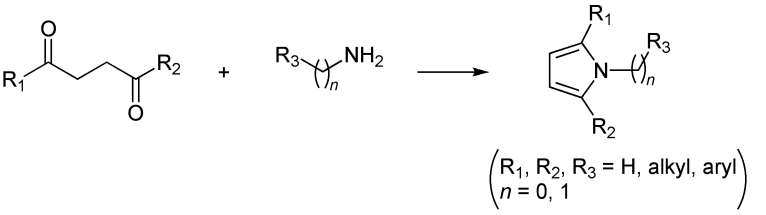
Paal-Knorr Pyrrole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported concurrently by Paal[1] and Knorr[2] in 1884. It is the acid-catalyzed formation of pyrrole derivatives from 1,4-dicarbonyl compounds and ammonia or primary amines. Therefore, it is generally known as the Paal-Knorr pyrrole synthesis,[3] Paal-Knorr synthesis,[4] Paal-Knorr reaction,[4b,4e–4h,5] or Paal-Knorr condensation.[4e–4g,6] Occasionally, it is also referred to as the Paal-Knorr cyclization,[5d,5e] Paal-Knorr cyclocondensation,[7] Paal-Knorr 1H-pyrrole synthesis,[3g] or Paal-Knorr pyrrole reaction.[7] This reaction provides a general route for pyrrole derivatives from a variety of 1,4-dicarbonyl compounds and primary amines,[4g,8] which can be catalyzed by either a Brønsted acid or Lewis acid, by which the latter is especially useful for molecules with acid-sensitive/epimerizable functionalities. In this reaction, the 1,4-dicarbonyl compounds provide the four carbons of the pyrrole ring through double condensation with the amines that contribute the nitrogen to the ring. However, the primary amines with an alkyl substituent at the α-position do not undergo this reaction. For example, no pyrrole was observed from the reaction of cyclohexyl amine.[4b] The mechanistic study demonstrates that *dl*-diastereomers of 3,4-dimethyl or 3,4-diethyl-2,5-hexanediones are 1.3–57.0 times faster than their corresponding *meso*-diastereomers to form pyrroles in aprotic solvents or aqueous solutions near neutrality, indicating a rate-limiting step in the hemiaminal cyclization.[4g] This reaction has been catalyzed by iodine,[5c] Fe^{3+}- montmorillonite,[3b] montmorillonite KSF-clay,[5c] and bulky Lewis acids such as titanium (IV) tetra-isopropoxide.[4e] Recently, this reaction was improved to finish in seconds under microwave radiation.[5b,5e,9]

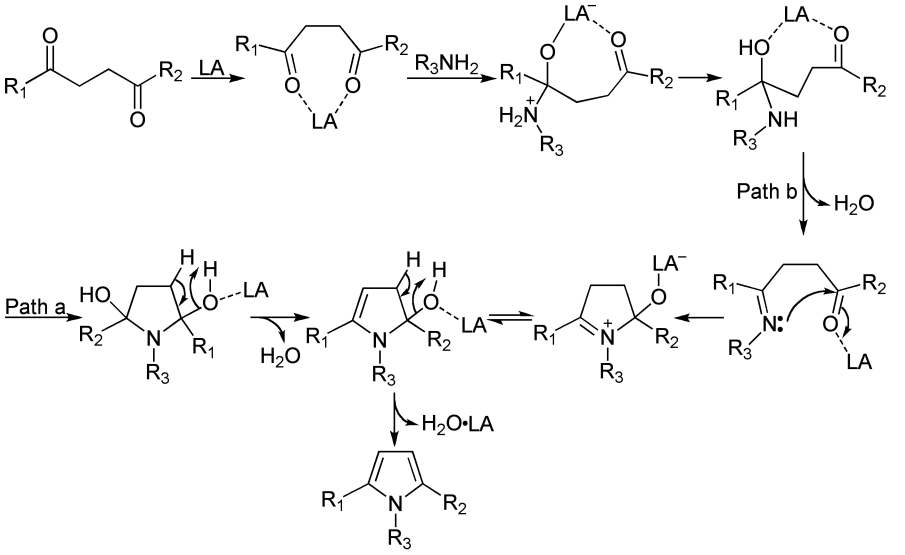
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is modified from that of Amarnath et al.[4g] under the catalysis of a general Lewis acid (LA), as illustrated here.



D. MODIFICATION

This reaction has been modified to proceed under solvent-free conditions[3e] and microwave irradiation.[5b,5e,9] In addition, this reaction has been catalyzed by various Lewis acids.

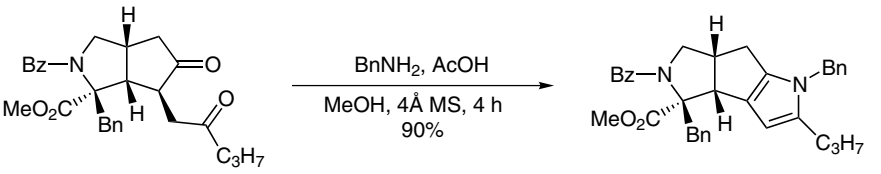
E. APPLICATIONS

This reaction has a general application in the synthesis of pyrrole derivatives.

F. RELATED REACTIONS

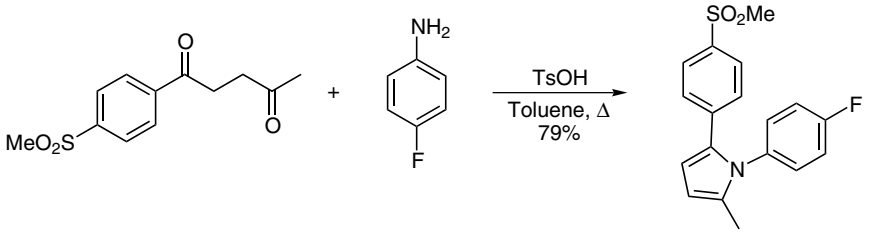
This reaction is related to the *Hantzsch Pyrrole Synthesis* and *Knorr Pyrrole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

To a solution of 10 mg 1,4-dione (0.021 mmol) in 0.5 mL methanol were added 23 μL benzylamine (0.21 mmol), 12 μL acetic acid (0.21 mmol), and 30 mg 4Å molecular sieves activated by flame drying under vacuum. The reaction mixture was stirred at 70°C for 1–4 h. Upon completion, the reaction mixture was diluted with 50 mL EtOAc and washed with 1 M HCl (2 × 20 mL). The organic layer was then dried over $MgSO_4$, and the solvents were removed in vacuo. The crude material was purified by flash chromatography (gradient elution; hexanes/EtOAc, 19:1–3:1, v/v) to afford 10 mg 5-benzoyl-1,4-dibenzyl-2-propyl-3b,4,5,6,6a,7-hexahydro-1*H*-1,5-diaza-cyclopenta[*a*]pentalene-4-carboxylic acid methyl ester, in a yield of 90%.



Reference 5f.

A mixture of 580 mg 1-[4-(methylsulfonyl)phenyl]pentane-1,4-dione (2.28 mmol), 0.24 mL 4-fluoroaniline (2.5 mmol), and 30 mg *p*-toluenesulfonic acid in 50 mL toluene was refluxed for 20 h using a Dean-Stark apparatus. The reaction mixture was cooled, filtered, and concentrated. The crude mixture (820 mg) was chromatographed (silica gel, hexane/EtOAc, 7:3) to give 595 mg pure 1-(4-fluorophenyl)-2-methyl-5-[4-(methylsulfonyl)-phenyl]-1*H*-pyrrole as a white solid, in a yield of 79%, m.p. (DSC) 157°C.

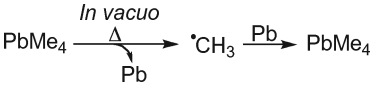
Paneth Technique

A. GENERAL DESCRIPTION OF THE REACTION

It was first reported by Paneth et al. in 1929.[1] It is a preparation of alkyl or aryl radicals, primarily methyl radical by thermal decomposition of organolead compounds under a vacuum system and is generally referred to as the Paneth technique.[2] In this process, tetramethyl lead is decomposed at 1–2 mmHg of pressure in a glass tube heated either by a mobile Bensen burner or by an electric furnace. The generated methyl radical is carried by hydrogen gas at a speed of 16 m/s down the tube to eliminate the deposited lead mirror by formation of tetramethyl lead again.[2a] Under these conditions, no diffusion against the flow of methyl radical occurs.[2a] Through the thermal decomposition, the methyl radical is clearly generated from tetramethyl lead, as evidenced by the disappearance of deposited lead mirror as far as 40 cm from the heated zone by reacting with the continual flowing of the methyl radical; even the space between the heated zone and deposited lead mirror is cooled by water.[2a,3] It has been found that tetraethyl lead reacts in the same fashion, whereas other higher order alkyl lead compounds give a mixture of radicals upon thermal decomposition.[4] Besides lead, other metals have been found to react with methyl radicals too, including arsenic,[5] antimony,[5] zinc,[5] cadmium,[5] and tellurium.[6]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This is a simple decomposition of an organolead compound; therefore, it is not necessary to provide a mechanism for this obvious reaction.

D. MODIFICATION

N/A

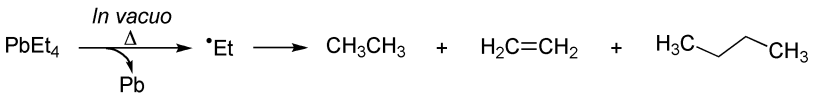
E. APPLICATIONS

This technique provides a convenient method for the production of radicals. In addition, this fast flowing technique is also useful for studying many unstable species in vacuo.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

A 50-mL round-bottomed flask equipped with a 50-cm long refluxing condenser was flushed with nitrogen and filled with 5 mL tetraethyl lead. Then the tetraethyl lead was pumped out, and the flask was filled with nitrogen several times to eliminate oxygen from the system. The flask was then fitted with a delivery tube extending under water into a 2-L bottle, which served to collect the gases. The flask was heated gently with a luminous Bunsen flame so that tetraethyl lead was kept just at the boiling point with no visible refluxing. The heating must be done very carefully to avoid the explosion. After the decomposition completed, a deposit of finely divided lead was left in the flask. This deposit was easily removed with nitric acid; no evidence of carbon was detected. It was apparent that most of the ethyl radicals reacted to form ethane and ethylene, with only a small amount of butane. Details of a fast-flowing decomposition of tetraethyl lead were also provided in the reference.[7]

Other references related to the Paneth technique are cited in the literature.[8]

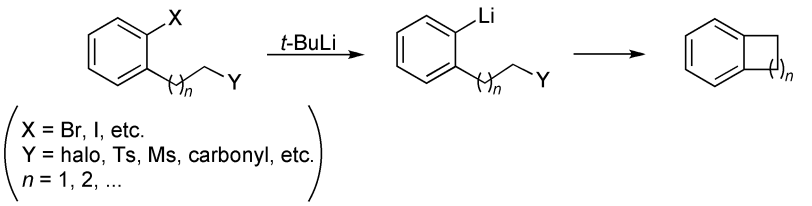
Parham Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially developed by Parham in 1975[1] and extended primarily by Bradsher after Parham's death in 1976.[2] It is the synthesis of aryl or heteroaryl ring fused carbocylces or heterocycles through the intramolecular reaction between a side chain electrophile and an aryl or heteroaryllithium generated from lithium-halogen exchange.[3] Therefore, this reaction is generally known as the Parham cyclization.[3a,3b,4] Occasionally, it is also referred to as the Parham reaction.[4j,4l,5] This reaction is very useful for the synthesis of alkaloids.[4a,4b,4l]

B. GENERAL REACTION SCHEME

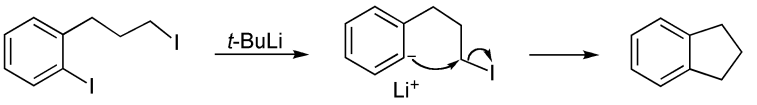


C. PROPOSED MECHANISMS

This is a very general reaction between aryl or heteroaryllithium and intramolecular electrophiles, and cannot be represented by a simple reaction. Thus a specific reaction is

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

given here to demonstrate the mechanism. When the electrophile is a carbonyl group, a cyclic carbinol will form; a carboxylic group will result in the formation of a cyclic ketone.



D. MODIFICATION

This reaction has many variants because of the number of different intramolecular electrophiles.

E. APPLICATIONS

This reaction is very useful for the preparation of aryl or heteroaryl fused carbocycles or heterocycles, especially for alkaloids.

F. RELATED REACTIONS

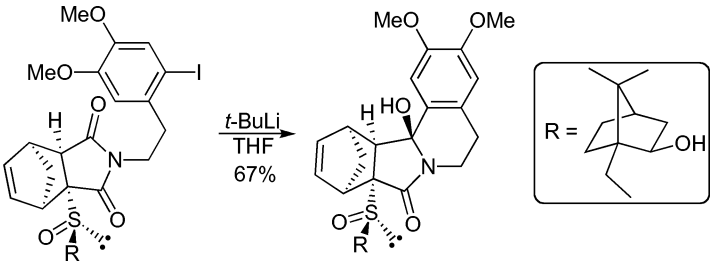
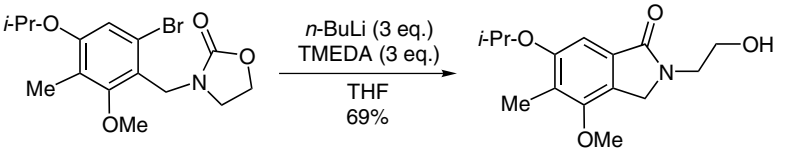
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a solution of 121 mg iodo imide (0.18 mmol) in 15 mL dry THF was added 0.63 mL 1.17 M *t*-BuLi in pentane (0.74 mmol) at −78°C. The resulting mixture was stirred at this temperature for 5 h, quenched by 5 mL saturated NH_4Cl, and allowed to warm to room temperature. The organic layer was separated, and the aqueous phase was extracted with Et_2O (2 × 5 mL) and CH_2Cl_2 (3 × 10 mL). The combined organic extracts were dried over Na_2SO_4 and concentrated in vacuo. The residue was crystallized from Et_2O to afford 66 mg (8a*R*,9*S*,12*R*,12a*S*,12b*S*)-(+)-8a-[(1*S*,2*R*,4*R*,S*R*)-(2-hydroxy-7,7-dimethylbicyclo[2.2.1]-heptan-1-yl)methylsulfinyl]-12b-hydroxy-2,3-dimethoxy-5,6,

8a,9,12,12ahexahydro-9,12-methaneisoindolin[2,3-*a*]isoquinolin-8-one, in a yield of 67%, m.p. 198–200°C.



Reference 4a.

A mixture of 2.0 mL 2.0 M *n*-BuLi in pentane (4 mmol) and 465 mg TMEDA (4 mmol) in 5 mL dry THF was carefully degassed by three freeze–thaw cycles and stirred at −78°C under dry deoxygenated argon. Then 0.47 g 3-(6-bromo-4-isopropoxy-2-methoxy-3-methylbenzyl)oxazolidin-2-one (1.31 mmol) in 15 mL degassed THF was added dropwise through a cannula. The mixture was stirred for 30 min at −78°C, quenched with 5 mL saturated NH_4Cl solution, and diluted with 30 mL water. The resulting mixture was extracted with CH_2Cl_2 (2 × 30 mL). The combined organic layers were dried over Na_2SO_4 and evaporated in vacuo. The solid residue was purified by flash column chromatography on silica gel using acetone/hexanes (80:20) as the eluent to afford 0.23 g 2-(2-hydroxyethyl)-6-isopropoxy-4-methoxy-5-methyl-2,3-dihydro-1*H*-isoindol-1-one, in a yield of 69%, m.p., 113–114°C (white crystals from hexane/toluene).

Other references related to the Parham cyclization are cited in the literature.[6]

Parikh-Doering Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Parikh and Doering in 1967.[1] It is to oxidize primary and secondary alcohols into aldehydes and ketones at room temperature using sulfur trioxide-pyridine complex in combination with dimethylsulfoxide and triethylamine. Therefore, this reaction is called the Parikh-Doering oxidation. In addition, this reaction is also known as the Parikh-Doering protocol[2] or Doering oxidation.[3] The attractive features of this oxidation include the fast reaction rate (usually completed within minutes),[1] convenient working conditions (room temperature instead of cryogenic reaction temperature),[1,4] functional group tolerance, negligible side products (methyl thiomethyl ether derivative of alcohol),[1] easy-to-handle reagents,[4] and flexibility to charge with more reagent if necessary.[4] The functional group tolerance is clearly demonstrated by the fact that double bond,[2,5] epoxide,[6] acetals,[3] etc. are not affected, even under the conditions for oxidizing alcohol in tosylate salt.[4] The Parikh-Doering oxidation is especially feasible for the oxidation of alcohols mounted onto polymer[7] and in the preparation of α,β-unsaturated carbonyl compounds,[1,5] by which the former situation has often been recognized as problematic under other conditions.[7] The oxidation has been proven to be superior to TPAP/NMO oxidation[3] but not as good as the *Moffatt-Swern Oxidation* and *Corey-Suggs Oxidation* for the oxidation of long-chain alcohols.[8] In addition, this reaction is not good for the highly strained alcohols.[9]

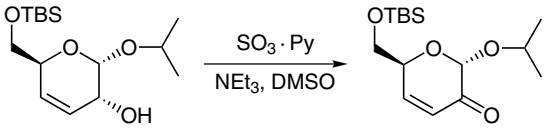
Reference 10.

To a solution of 10.2 g 1-*tert*-butyldiphenylsilyloxy-*cis*-2-butene-4-ol (31.2 mmol), 18.0 mL Et_3N (129 mmol), and 20 mL DMSO in 200 mL CH_2Cl_2 at 0°C, was added 9.75 g SO_3-pyridine complex (61.3 mmol). The reaction was warmed to room temperature, stirred for 2 h then poured onto 200 mL water and extracted with 200 mL Et_2O (three times). The combined organic layers were washed with 100 mL saturated aqueous NH_4Cl, 50 mL 10% aq. $CuSO_4$, 100 mL water (three times), and 100 mL brine; they were dried over Na_2SO_4. Concentration in vacuo gave an orange oil. ^1H NMR analysis of the unpurified mixture showed a 2:1 mixture of the isomeric *cis*- and *trans*-aldehydes. The orange oil was allowed to stand at room temperature under high vacuum (<1 mmHg) for 24 h, whereupon complete isomerization to the *trans*-aldehyde was observed by TLC. The oil was then subjected to silica gel chromatography (20:1; hexanes/EtOAc) to give 6.35 g (2*E*)-4-(2,2-dimethyl-1,1-diphenyl-1-silaprop-oxy)but-2-enal as a colorless solid, in a yield of 63%, $R_f = 0.35$ (4:1, hexanes/ EtOAc).



Reference 5a.

To a mixture of 80.68 g allyl alcohol (266.7 mmol) and 223 mL Et_3N (1.60 mol) in 700 mL DMSO was added dropwise a solution of 127 g SO_3·Py (798 mmol) in 500 mL DMSO over 10 min at room temperature. After being stirred at that temperature for 40 min, the reaction mixture was diluted with Et_2O, and the resulting solution was poured into an ice-cold saturated NH_4Cl solution. The mixture was extracted with Et_2O (three times). The combined organic layers were washed with saturated NH_4Cl solution (twice) and brine (twice), and dried over anhydrous Na_2SO_4. The solution was concentrated under reduced pressure, and the residue was purified by column chromatography (silica gel 1.0 kg, ether/hexane, 1:60–1:10) to give 74.41 g enone as a colorless oil, in a yield of 93%.

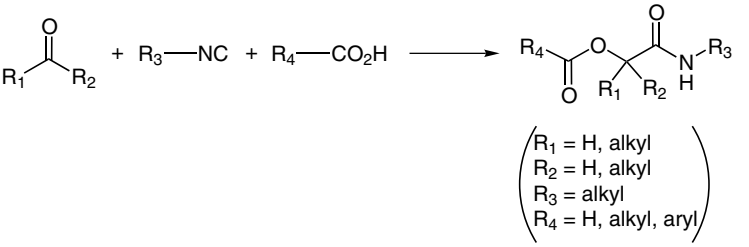
Passerini Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Passerini in 1921.[1] It is an atom-economical three-component condensation among isonitrile (i.e., isocyanide), carboxylic acid, and aldehyde (or ketone) to form α-acyloxy amide through acyl rearrangement and tautomerization. Therefore, it is generally known as the Passerini reaction.[2,3] Occasionally, this reaction is also referred to as the Passerini multicomponent condensation,[2i,2p,4] Passerini multicomponent reaction,[5] Passerini 3CC condensation,[2i] Passerini condensation,[2o,4,6] Passerini three-component condensation,[2p,3i,3s,7] and Passerini three-component coupling.[2d,8] Kinetically, this reaction is on the third order—that is, the first order in each of the reactants.[2u] Owing to its multicomponent nature and atom efficiency, the Passerini reaction has been used extensively in combinatorial chemistry.[2o,9] However, it still has a few drawbacks. For instance, aryl ketone and aryl isonitriles are not suitable for this reaction;[2t] in addition, the reaction is often sluggish[2d,2m] and results in low yields, unless either highly acidic carboxylic acid or electrophilic carbonyl compounds are used.[2d] This reaction has been modified to occur in aqueous solution with obvious advantages of a high reaction rate and easy separation.[2b] In addition, Lewis base,[2a] such as pyridine-trifluoroacetic acid[2q,2s] has been used to promote this reaction. On the other hand, Lewis acid has also been used to promote the Passerini reaction, such as $TiCl_4$,[2r,10] and $Zn(OTf)_2$/TMSCl.[2m] In particular, the use of a catalytic amount of tridentate indan(pybox) Cu(II) Lewis acid complex has shown the potential for asymmetric synthesis.[2d] Similarly, 1,2,3,4-tetra-*O*-acetyl-α-D-galacturonic acid has been used as an asymmetric inducer.[2e]

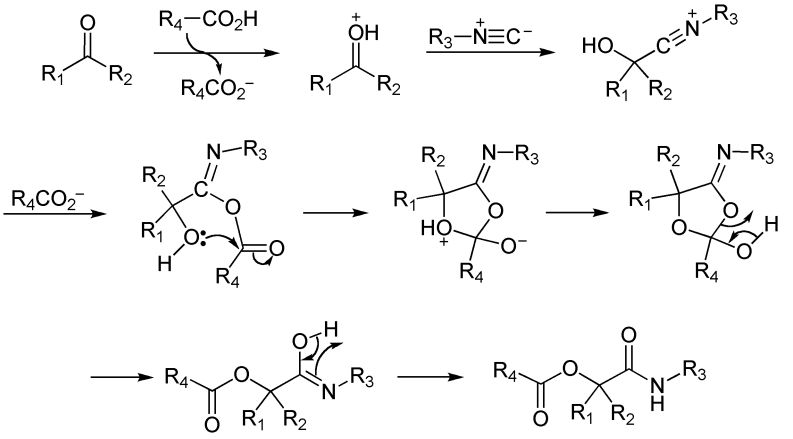
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Initially, Passerini proposed that the reaction involved an addition of carboxylic acid to carbonyl compound, giving acyloxy hemiacetal, which then reacted with isonitrile to form the final product.[1] However, current views about this reaction favor the following consecutive processes: the protonation of the carbonyl compound from carboxylic acid, followed by the attack of isonitrile to give a nitrilium ion, the nucleophilic addition of carboxylate, acyl group transfer, and the final amide tautomerization. A general mechanism for this reaction is shown here.[2a,2b]



D. MODIFICATION

This reaction has been modified to occur in aqueous solution[2b,3f] and ionic liquid (e.g., [bmim]BF_4).[3i] In addition, different Lewis acids have been used to promote this reaction.

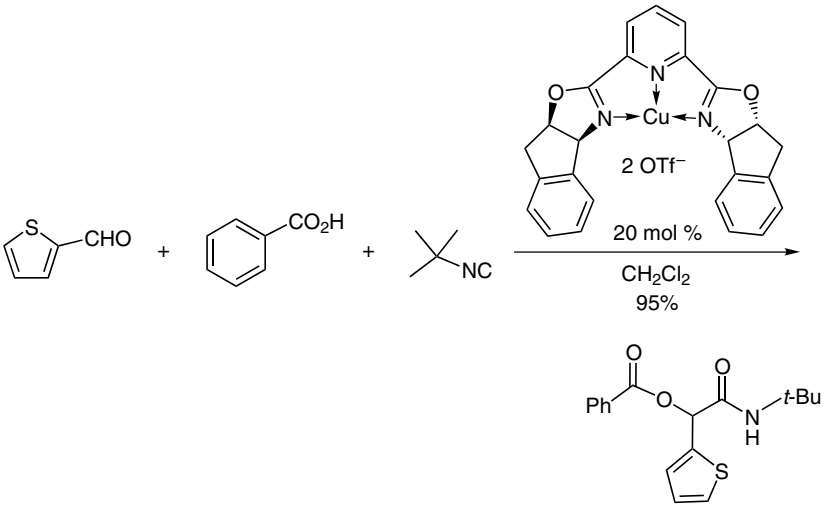
E. APPLICATIONS

This reaction has wide applications in combinatorial synthesis.

F. RELATED REACTIONS

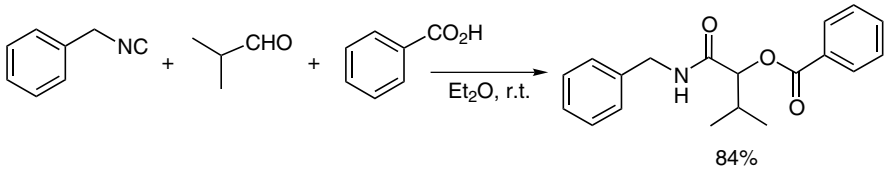
This reaction is related to the *Ugi Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2d.

To a 25-mL round-bottomed flask equipped with a stir bar and dried under argon with flame was added 7.0 mL CH_2Cl_2, 20 mol % $Cu(OTf)_2$, and 20 mol % indane (pybox) ligand. The mixture was stirred at 38°C until the components were completely dissolved. Then 2-thiophenecarboxyl (64 mg, 77 μL, 0.57 mmol, 1.05 eq.) was added, and the solution was cooled to 0°C and allowed to stand for 30 min, at which time 400 mg molecular sieves (AW-300) were added. In a separate flame-dried round-bottomed flask under argon were added 69 mg benzoic acid (0.57 mmol, 1.05 eq.) and 45 mg *t*-butyl isonitrile (61 μL, 0.54 mmol, 1.0 eq.), 3.0 mL CH_2Cl_2, and 100 mg AW-300 molecular sieves. This mixture was shaken for 30 min and then was drawn into a gas syringe and delivered to the first solution via a syringe pump over 4 h. The reaction was stirred for 24 h, during which time TLC analysis was conducted with EtOAc/hexanes (1:1) as the eluent. After the reaction completed, 2.0 mL saturated NaOCl solution was added, and the mixture was allowed to stir for an additional hour; solvent was removed under reduced pressure. The residue was purified by silica gel column chromatography with hexane/EtOAc (9:1–1:3) to afford 162 mg *t*-butylcarbamoyl(thiophen-2-yl)methyl benzoate as a white solid, in a yield of 95%, $R_f = 0.45$ (hexane/EtOAc, 2:1).



Reference 2h.

To a 10-mL Et_2O solution containing 610 mg benzoic acid (5 mmol) were added 360 mg isobutyric aldehyde (5 mmol) and 586 mg benzyl isocyanide (5 mmol). The resulting mixture was stirred overnight at room temperature. The crystallized product was filtered off, washed with cold Et_2O, and dried under high vacuum to give 1.30 g 1-benzylcarbamoyl-2-methyl propyl benzoate as a solid, in a yield of 84%.

Other references related to the Passerini reaction are cited in the literature.[11]

Paterno-Büchi Reaction

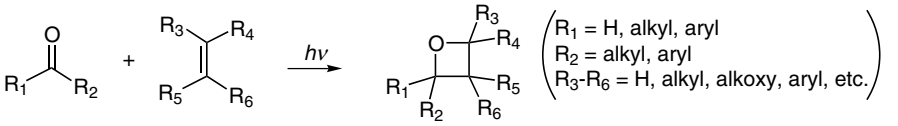
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Paterno and Chieffi in 1909,[1] and subsequently extended by Büchi et al. in 1954.[2] It is a photo-induced [2 + 2] cycloaddition of carbonyl compounds with olefins or other unsaturated substrates to form four-membered cyclic ethers, known as oxetanes,[3] with high regio- and stereoselectivity.[3b,4] Therefore, this reaction is generally known as the Paterno-Büchi reaction.[3,4a,4b,4e,5,6] Occasionally, this reaction is also referred to as the Paterno-Büchi cycloaddition,[7] Paterno-Büchi photocycloaddition,[4b,4c,8] or Paterno-Büchi coupling.[4c,9] All three types of ketones (i.e., dialkyl, diaryl, and aryl alkyl ketones) and aldehydes undergo the Paterno-Büchi reaction, even though some of these carbonyl compounds may undergo other types of photoreactions, including Norrish type I and type II reactions.[10] As a result, the Paterno-Büchi reaction is often sluggish.[4d] However, in the presence of an electron-enriched alkene, such as an enol ether or a polyalkylalkene, the Paterno-Büchi reaction dominates.[4e] In addition, the Paterno-Büchi reaction also competes with the radical polymerization of alkenes.[4d] In this reaction, the carbonyl compound is irradiated to either a singlet[4a,5j,5l,7c] or triplet[4a,4b,5d,5e,5j–5l,7l] excited state; then the electronically excited carbonyl group attacks the alkene at ground state, although such cycloaddition often takes place through a triplet carbonyl group.[5l] When the Paterno-Büchi reaction occurs through a triplet carbonyl, as in the case of the reaction with electron-rich alkenes (e.g., enol ethers), it is nonconcerted,[5j] and a biradical intermediate forms via an electrophilic attack from an n-π^* triplet carbonyl to form a C-O bond,[5l] which then cyclizes to oxetane with a low-energy barrier.[5j] In comparison, the singlet Paterno-Büchi reaction proceeds through conical intersections, via a nonconcerted C-O attack and a concerted C-C attack pathway.[5j] In addition, if electron transfer is exothermic, it is very possible that the Paterno-Büchi reaction occurs through the electron-transfer

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

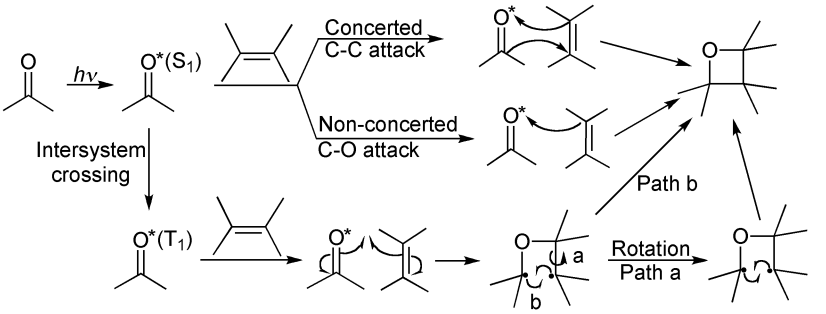
pathway.[4b] Moreover, other reaction intermediates are also found for the Paterno-Büchi reaction, such as exciplexes[11] and ion-radical pairs.[12] On the other hand, the regioselectivity of major oxetane from asymmetric olefins follows the *Markovnikov Rule* through the formation of the most stable biradical intermediates.[51] However, the stereoselectivity is controlled by the nature of reaction pair. It has been found that the spin-orbit coupling-controlled intersystem crossing determines the stereochemical outcome.[3b] In addition, temperature[3a,5d,13] and hydrogen bonding[4a] also affect the stereoselectivity. If the intersystem crossing at low temperature is much faster than bond rotation of biradical, then the resulting oxetane reflects the initial stereochemistry of the corresponding biradical.[13] In contrast, if the biradical is relatively stable, then the stereochemistry does not depend on the geometry of olefin.[13] Paterno-Büchi reaction is important not only because of its wide application in organic synthesis but also because of its major mutation processes for DNA through two adjacent pyrimidine bases.[5c] The cycloreversion of oxetane by photoelectron transfer (i.e., retro Paterno-Büchi reaction) is the tool for enzyme-catalyzed DNA repair.[14]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism of the Paterno-Büchi reaction through either a singlet or triplet excitation state of the carbonyl compound is illustrated below, regardless of stereochemistry.



D. MODIFICATION

N/A

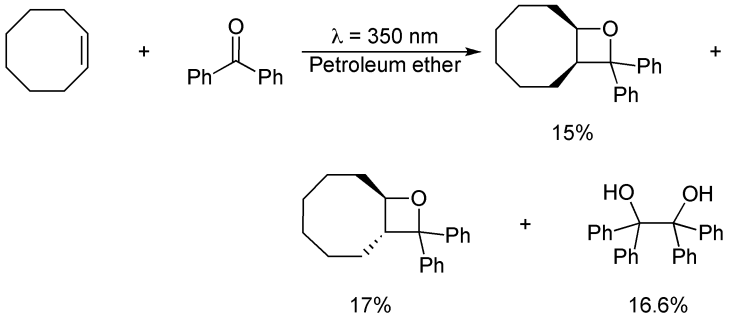
E. APPLICATIONS

This reaction has a wide application in organic synthesis.

F. RELATED REACTIONS

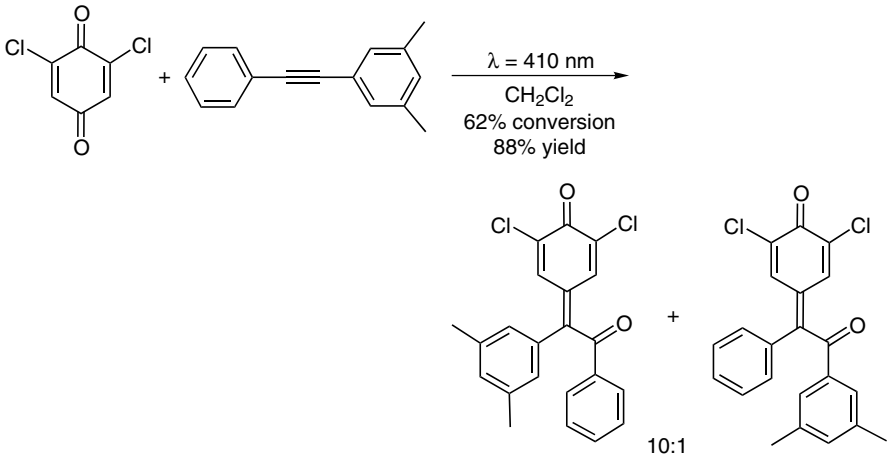
This reaction is related to regular [2 + 2] *Photoreaction* and *de Mayo Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 5d.

Under a nitrogen atmosphere, a solution of 2.11 g benzophenone (11.6 mmol) and 3.83 g *cis*-cyclooctene (34.8 mmol) in 300 mL petroleum ether at 5°C was irradiated in a Rayonet photoreactor at 350 nm for 24 h. A white precipitate (350 mg) was formed during the irradiation, which was collected by filtration and identified as 1,1,2,2-tetraphenylethanediol (benzpinacol) by ^{1}H- and ^{13}C-NMR spectroscopy. Distillation of the solvent and most of the residual olefin at 50°C (10 mbar) afforded 3.66 g yellow oil, which contained both diastereomeric oxetanes (*cis/trans* ≈ 40:60 by ^{13}C NMR spectroscopy). The crude product mixture (1.83 g) was purified by silica gel column chromatography with Et_2O/petroleum ether (1:10) as the eluent to afford 256 mg *cis*-10,10-diphenyl-9-oxabicyclo[6.2.0]decane as a colorless oil, in a yield of 15%. In addition, 285 mg *trans*-10,10-diphenyl-9-oxabicyclo[6.2.0]decane was obtained as a colorless oil, in a yield of 17%. Further purification of each diastereomers was carried out by bulb-to-bulb distillation (Kugelrohr) at 100°C (0.03 mmHg).



Reference 3d.

To a quartz cuvette fitted with a Teflon stopcock was added 53 mg 2,6-dichlorobenzoquinone and 63 mg phenyl *m*-xylyl acetylene in CH_2Cl_2 in a 0.1 M solution of each substance under argon. The cuvette was then placed in a clear Dewar flask filled with water at 25°C and irradiated with focused light from a medium-pressure mercury lamp (500 W) passed through an aqueous IR filter and an ESCO 410 nm filter. This ensured that the quinone itself was excited and not the diarylacetylene. After 22 h, the solvent was evaporated, and the residue was subjected to flash chromatography. 1-(3,5-Dimethylphenyl)-1-benzoyl-1-methylene-3,5-dichlorocyclohexa-2,5-dien-4-one was obtained as the major product, which was further recrystallized from acetonitrile, m.p., 191–192°C. The minor product was identified only by GC/MS. The total yield of quinone methide was 88% based on 62% of conversion.

Other references related to the Paterno-Büchi reaction are cited in the literature.[15]

Pauson-Khand Reaction

(Pauson-Khand Cyclization, Pauson-Khand Cycloaddition)

A. GENERAL DESCRIPTION OF THE REACTION

The reaction was first reported by Khand and Pauson et al. in 1973.[1] It is the dicobalt octacarbonyl [$Co_2(CO)_8$] mediated or promoted one-step synthesis of α,β-unsaturated cyclopentenone from the [2+2+1] cycloaddition of alkyne, alkene and carbon monoxide, through an intermediate of alkynedicobalt hexacarbonyl complex. Therefore, this reaction is generally known as the Pauson-Khand reaction,[2] Pauson-Khand cyclization,[2u,2z,3] or Pauson-Khand cycloaddition.[4] Occasionally, this reaction is also referred to as the Pauson-Khand annulation,[5] Pauson-Khand multicomponent cycloaddition,[6] Pauson-Khand carbonylative cocyclization,[7] Pauson-Khand bicyclization,[8] Khand annulation,[9] Khand cycloaddition,[9] Khand cyclization[9a] (cyclisation[10]), or Khand reaction.[11] Among these names, the Pauson-Khand reaction is the one used most often.

It is accepted that this reaction involves the formation of the alkynedicobalt hexacarbonyl complex from an alkyne and $Co_2(CO)_8$ by the evolving of two CO ligands,[12] followed by the alkene coordination at one of the two enantiotopic Co atoms with concomitant CO insertion,[13] and final reductive elimination of the metal to an α,β-unsaturated cyclopentenone.[2z] In the traditional protocol, the reaction mixture is heated in toluene at 110°C, or tertiary amine *N*-oxides are added to promote the reaction at ambient temperature.[2v] For the purpose of stereochemical control, many Pauson-Khand reactions are designed as intramolecular reactions[2cc,3f,3n,3p,5b,6,14] or using cyclic alkenes, such as norbornene.[12b,15] It has been found that the reactivity of cyclic alkenes is in the order of cyclohexene < cyclopentene < norbornene.[15a] For the intermolecular Pauson-Khand reaction, alkene is positioned adjacent to the less bulky acetylenic substituent during coordination because of steric hindrance, and a subsequent C–C bond forms between an alkenic

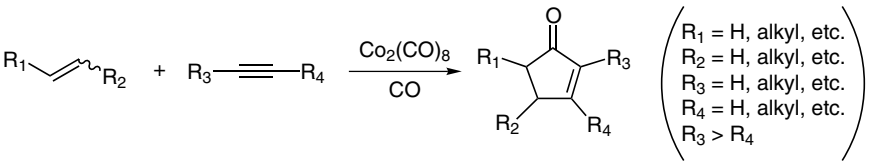
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

carbon and the closer acetylenic carbon, so that the larger group on alkyne is often found at the α-position of the resulting cyclopentenone.[13] Although the Pauson-Khand reaction is one of the most powerful reactions for forming very complicated structures with stereochemical control, it still has some drawbacks, such as the application of a stoichiometric amount of $Co_2(CO)_8$,[12a,16] high pressure of CO,[17] troublesome purification protocols,[2v] and low yields that depend on alkynes and alkenes.[2v] Therefore, the original protocol of the Pauson-Khand reaction has been extensively modified by the use of different catalysts or reaction conditions.

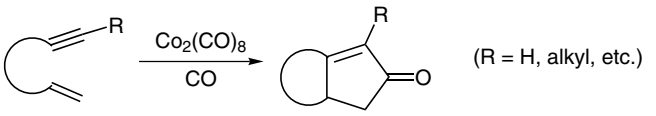
It has been found that besides $Co_2(CO)_8$, many other transition metal complexes are effective for promoting this reaction. For example, some of cobalt-based catalysts are $Co_2(CO)_8$, $Co_2(CO)_8$ in combination with $P(OPh_3)_3$,[18] $Co_2(CO)_8$/tetramethylthiourea (TMTU),[19] (ind)Co(COD),[20] $Co(acac)_2$ (with $NaBH_4$),[21] $Co_4(CO)_{12}$,[22] $Co_3(CO)_9(\mu^3\text{-CH})$,[23] $CoBr_2$/Zn/CO,[24] P,S-cobalt complexes,[25] and *N*-heterocyclic carbene dicobalt complex.[26] Titanium-based catalysts include $Cp_2Ti(PMe_3)_2$,[27] Cp_2TiCl_2/*n*-BuLi,[27] and (*S*,*S*)(EBTHI)Ti(CO)$_2$.[3m,3q] Some of the ruthenium-based catalysts are $Ru_3(CO)_{12}$,[14k,28] $[RuCl_2(CO)_3]_2$,[14k] Cp*RuCl(cod),[14k] and Ru(cod)(cot).[14k] Rhodium-based catalysts are $[RhCl(CO)_2]_2$,[29] *trans*-$[RhCl(CO)(dppp)]_2$[14j] and $[Rh(COD)Cl]_2$,[30] cobalt-rhodium heterobimetallic nanoparticle,[2f] and rhodium bisbenzodioxanPhos complex.[3c] Iridium-based catalysts are (S)-tolBINAP-Ir complex[31] and $[Ir(COD)Cl]_2$,[31] and molybdenum-based catalysts include $Mo(CO)_6$,[2q,14i,32] heterobimetallic (Mo-Co) complexes,[15c] and $Mo(CO)_3(DMF)_3$.[33] Among the molybdenum-based catalysts, $Mo(CO)_3(DMF)_3$ works even in the absence of any promoter. In addition, nickel and palladium are also effective for the Pauson-Khand reaction, such as $Ni(COD)_2$/ligand[27] and $PdCl_2$/TMTU.[34]

The Pauson-Khand reaction has also been carried out under different conditions, such as the use of chiral ligands, including PuPHOS,[2r,2ac,25] CamPHOS,[2r] and camphorsultam;[12b] the use of aldehydes as the carbon monoxide source;[17,30,35] the use of solid-supported cobalt catalyst to enhance purification, such as the dry-state adsorption;[2z] the use of colloidal cobalt nanoparticle;[36] and the use of metallic cobalt supported on mesoporous silica prepared by decomposing $Co_2(CO)_8$ on mesoporous silica supports (SBA-15 and MCM-41) in the refluxing toluene solution.[14h,36b] Other modifications include different promoting methods, such as photo-irradiation,[3d,16b] microwave irradiation,[2v] molecular sieves,[6,37] TEMPO,[38] *N*-oxides,[39] and supercritical fluids.[40] Furthermore, the cycloaddition between allene and carbon monoxide under similar conditions is known as the allenic Pauson-Khand reaction,[2q,14f,27,41] and the reaction among alkyne, carbodiimide, and CO is referred to as the *aza*-Pauson-Khand reaction.[42]

B. GENERAL REACTION SCHEME



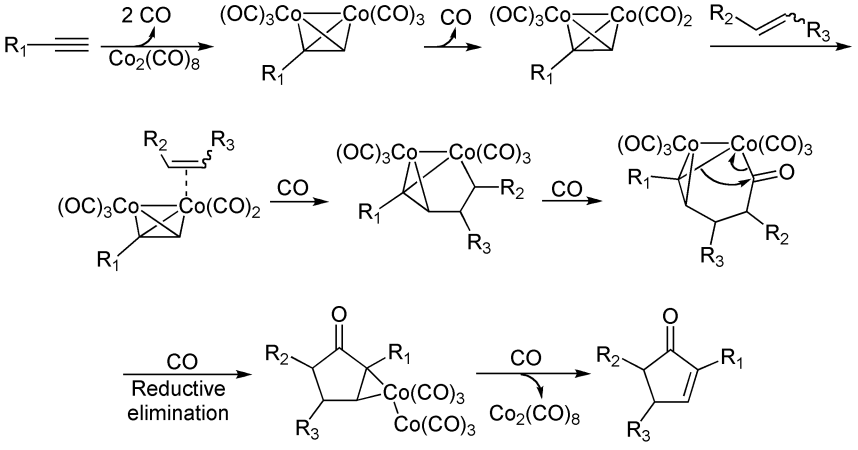
Intermolecular Pauson-Khand reaction



Intramolecular Pauson-Khand reaction

C. PROPOSED MECHANISMS

Displayed here is a general mechanism for the Pauson-Khand reaction, according to several studies.[12c,13,43]



D. MODIFICATION

This reaction has been extensively modified as described in Section A.

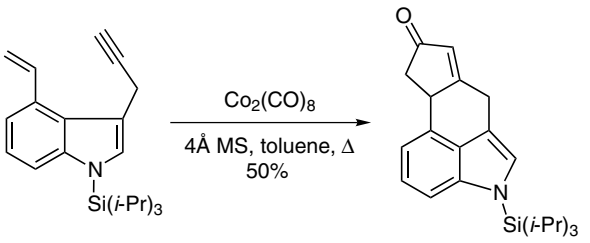
E. APPLICATIONS

This reaction has wide application in organic synthesis.

F. RELATED REACTIONS

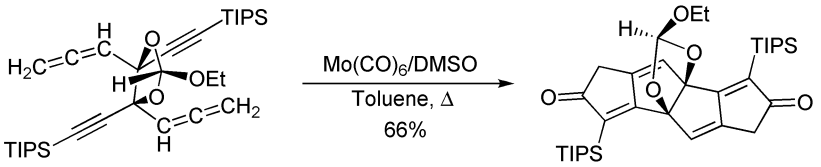
This reaction is related to the *Nicholas Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 44.

To a round-bottomed flask were added 0.33 g *N*-triisopropylsilyl-3-propargyl-4-vinyl indole (1.0 mmol), 2.64 g powered 4Å molecular sieves, and 20 mL dry toluene under argon at room temperature, followed by 0.41 g $Co_2(CO)_8$ (1.2 mmol). The resulting mixture was stirred for 2 h until total complexation of the enyne by TLC. Then the solution was refluxed for 18 h. After filtration and solvent evaporation, the residue was purified by flash chromatography (hexane/EtOAc, 4:1) to afford 0.18 g 4-triisopropylsilyl-4,6,6a,7-tetrahydroindeno[6,5,4-*cd*]-indol-8-one as a pale yellow oil, in a yield of 50%.



Reference 2q.

A mixture of 6.3 g $Mo(CO)_6$ (24 mmol) and 120 mL toluene was heated to 50°C for 2 hours to form a saturated solution. After that, a solution of 1.35 g *ortho*-ester (2.43 mmol) and 2.01 g DMSO (26 mmol) in 20 mL dry toluene was added. The resulting mixture was heated at 53–55°C for 36 h and then was filtered to remove the solids. The precipitate was washed with hexanes (2 × 20 mL). The combined organic layers were concentrated under reduced pressure, and the residue was purified by gradient silica gel column chromatography using hexanes/EtOAc (100:0–95:5) as the eluent, to afford 0.96 g tetraene, in a yield of 66%. This tetraene can be further purified by crystallization from hexanes.

Other references related to the Pauson-Khand reaction are cited in the literature.[45]

Payne Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

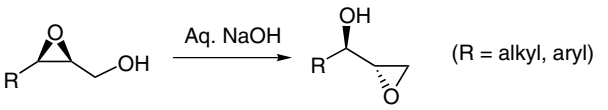
This reaction was first reported by Kohler et al. in 1931,[1] and its mechanism was proposed as early as 1957 by Angyal and Gilham.[2] It is a base-promoted stereospecific migration of 2,3-epoxy alcohols into isomeric epoxy alcohols with an inversion of configuration at the C-2 carbon of the original epoxide ring as of an S_N2 substitution[3] and was initially known as a β-oxanol rearrangement.[4] However, after Payne's extensive study on this reaction in 1962,[5] it is now generally referred to as the Payne rearrangement[6] or epoxide migration.[2,5,6g,7] Occasionally, this reaction is also called the Payne reaction.[8]

It should be pointed out that this rearrangement is reversible,[6g] and the equilibrium favors the more substituted epoxide isomer. It is a powerful method for the introduction of a different functionality when the migration of epoxide is followed by a ring opening from the nucleophilic attack of another nucleophile.[6g] In this reaction, solvent plays an important role. For example, the epoxy alcohol when treated with sodium hydride in THF would not yield the expected product from rearrangement, but gives the expected product when treated with NaOH in aqueous solution.[9] The delay of Payne rearrangement in THF has made THF a good medium for direct attacking of epoxide with an ylide generated *in situ*.[6d] On the other hand, it is known that the direction of such reversible rearrangement of epoxy alcohol is controlled by kinetics, not by thermodynamics,[10] and the application of a chiral epoxide migration catalyst results in the catalytic kinetic resolution of epoxy alcohols.[11] The rearrangement between 2,3-epoxy amine and aziridine alcohol under similar conditions is generally known as the *aza*-Payne rearrangement;[3,7a,8,12] and the migration between 2,3-epoxy thiol and thiirane alcohol is referred to as the *thia*-Payne rearrangement.[6g] However, different from the normal Payne rearrangement, the *aza*-Payne and *thia*-Payne rearrangements have the potential to form different products; thus the formation of aziridine and thiirane alcohols is referred to as

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

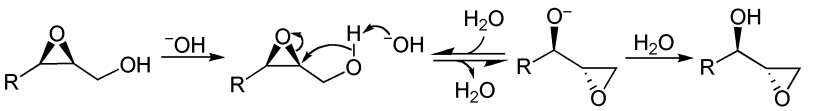
the *forward aza-* and *thia*-Payne rearrangements, respectively; whereas the rearrangement from aziridine alcohol or thiirane alcohol to the corresponding epoxy amine or thiol is known as the *reverse aza-* or *thia*-Payne rearrangement.[6g] The forward *aza-* and *thia*-Payne rearrangements are favored by complexation with Lewis acid, such as BF_3,[13] $AlMe_3$,[14] and TMSOTf.[15] It should be pointed out that the *aza*-Payne rearrangement followed by a ring opening has been used for the preparation of hydroxyethylamine dipeptide isostere (HDI) structures.[16]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is possible that a semiconcerted mechanism is involved in this rearrangement in aqueous solution, whereas in THF, a contact ion pair is probably the real reactive species, which does not attack the epoxide ring. A tentative mechanism is proposed here.



D. MODIFICATION

The *aza-* and *thia*-Payne rearrangement should be considered an extension of the normal Payne rearrangement.

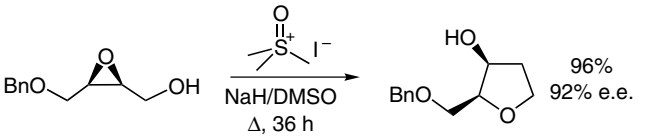
E. APPLICATIONS

This reaction has wide application in organic synthesis, especially in conjunction with the subsequent ring opening of a newly formed epoxide ring with other nucleophiles.

F. RELATED REACTIONS

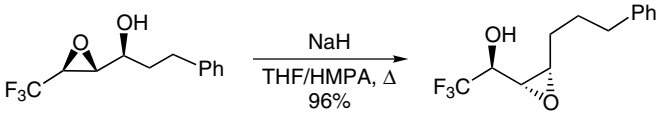
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 6d.

To a flame-dried flask was added NaH (prepared by sodium metal-dried pentane wash from 4.0 g 60% NaH in mineral oil (100 mmol, 10 eq.)) and 100 mL CaH_2-dried DMSO through a syringe. Trimethylsulfoxonium iodide (22.0 g, 100 mmol, 10.0 eq.) was then added in small portions over 20–30 min. After the addition of the trimethylsulfoxonium iodide was complete, the reaction was stirred for an additional 30 min until the bubbling of the milk white suspension ceased. The epoxy alcohol (1.94 g, 10 mmol, 1.0 eq.) dissolved in a small amount of dry DMSO was added dropwise, and the reaction was covered with aluminum foil and heated to 80–85°C for 36 h. The dark brown mixture was cooled and diluted with two times the volume of water and 1 mL saturated NH_4Cl. The mixture was extracted several times with EtOAc; the combined organic layers were washed with brine and dried over Na_2SO_4. After removal of the solvent under reduced pressure, the residue was column chromatographed using a hexane/EtOAc gradient to give 2-benzyloxymethylenyl-3-hydroxy-tetrahydrofuran as a thick oil, in a yield of 96% with 92% e.e.



Reference 6e.

To a stirring solution of 0.048 g sodium hydride (1.20 mmol, 60% in paraffin liquid) and 0.86 mL hexamethylphosphoric triamide (HMPA, 4.94 mmol) in 5 mL THF at 0°C was added 0.246 g (*E*)-*syn*-4,5-epoxy-6,6,6-trifluoro-1-phenyl-3-hexanol (1.00 mmol). After being stirred for 3 h at room temperature, the reaction mixture was quenched with 1 mL 3 *N*HCl and extracted with EtOAc three times. The combined organic layers were dried over $MgSO_4$. Upon evaporation of the solvent, the residue was purified by silica gel column chromatography to afford 0.237 g (*Z*)-*anti*-3,4-epoxy-1,1,1-trifluoro-6-phenyl-2-hexanol, in a yield of 96%.

Other references related to the Payne rearrangement are cited in the literature.[17]

Pearlman's Catalyst

A. GENERAL DESCRIPTION OF THE REACTION

Palladium hydroxide on carbon was first reported by Pearlman in 1967[1] and is now referred to as the Pearlman's catalyst in general.[2] It can be purchased from Aldrich in 20 wt %, which may contain water up to 50%.[3] It is a very active catalyst for the hydrogenation of carbon-carbon double bonds,[4] *hetero*-multiple bonds such as azide,[2g] and debenzylation.[2o] In particular, this reagent is good for hydrogenolysis of benzyl-nitrogen bonds under conditions in which other palladium-on-carbon catalysts fail[3]—for example, the removal of carbamate[2k] and benzylcarbamate functional groups.[2m] In addition, the Pearlman's catalyst has been used for the oxidation of Si-H bonds[2c] and the removal of the mesylate group on a phenyl ring.[2h] Most importantly, the Pearlman's catalyst is effective for the direct arylation of aryl iodides and bromides, with a high arylation-to-hydrodehalogenation ratio (> 30:1), both intermolecularly and intramolecularly;[2a] in addition, this arylation can tolerate an electron-withdrawing group on the aromatic ring and is also effective for high sterically hindered substrates.[2a]

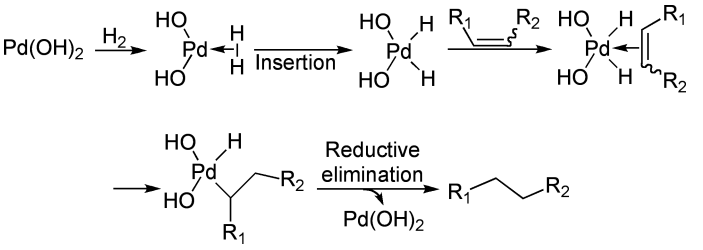
B. GENERAL REACTION SCHEME

$$Pd(OH)_2/C$$

C. PROPOSED MECHANISMS

Displayed below is the mechanism for the catalytic hydrogenation of a carbon-carbon double bond.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This catalyst has been extended to the arylation of aryl iodides and bromides.[2a]

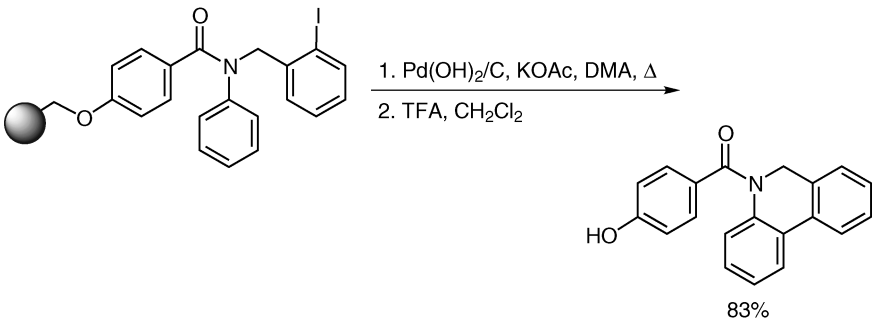
E. APPLICATIONS

This catalyst has wide application in hydrogenation and debenzylation as well as in arylation.

F. RELATED REACTIONS

N/A

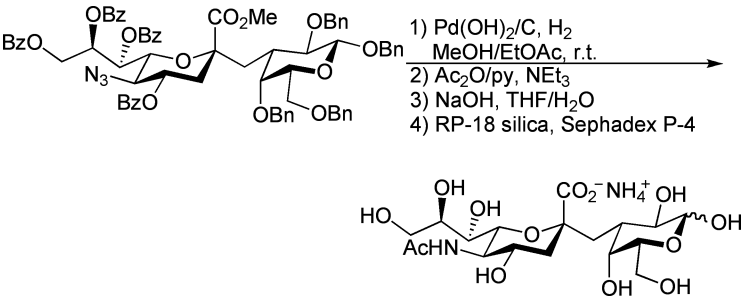
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To a 2- mL screw-cap vial equipped with a magnetic stir bar, were added 2 eq. potassium acetate, 0.1 eq. $Pd(OH)_2/C$, and 1 eq. *N*-phenyl-*N*-(*o*-iodo)benzyl 4-hydroxy-benzoamide loaded on Wang resin and 0.2 mL DMA under nitrogen atmosphere. The reaction mixture was then heated overnight at 145°C under stirring. After the reaction was judged complete by TLC analysis, the heat source was removed, and the reaction mixture was allowed to cool. The crude mixture was then treated with trifluoroacetic acid in THF to cleave the product off the Wang resin. The solution was evaporated, and the residue was

purified via silica gel column chromatography using EtOAc/hexanes as the eluent to afford 83% *N*-(4-hydroxybenzoyl)-(6H)-phenanthridine, m.p., 142–144°C.



Reference 2g.

A mixture of 10 mg benzyl 2,4,6-tri-*O*-benzyl-3-deoxy-3-*C*-[{methyl-(2,6-anhydro-5-azido-4,7,8,9-*tetra*-*O*-benzoyl-3,5-dideoxy-D-*erythro*-D-*manno*-non-2-yl)onate}-methyl]-*β*-D-*galacto*-hexopyranoside (32 μmol) and 18 mg $Pd(OH)_2$/C in 6 mL mixed solvent of MeOH and EtOAc (4:1) was kept under an atmosphere of hydrogen for 24 h. Then, the mixture was filtered through Celite and concentrated; the residue was taken up in a 1:1 mixture of pyridine and Ac_2O. After being stirred for 24 h at room temperature, the mixture was concentrated in vacuo and co-evaporated several times with toluene. Purification of the residue by flash chromatography (toluene/acetone, 6:1) afforded 3.8 mg amino sugar (3.65 μmol), in a yield of 45%. This amino sugar was dissolved in 10 mL THF-H_2O mixture (1:1), and 2 mL 0.1 M NaOH was added. After being stirred for 14 h at room temperature, the reaction mixture was lyophilized and passed through a RP-18 silica gel column (H_2O/EtOH, 9:1) and further purified by gel filtration on a Sephadex P-4 column eluting with a 0.3% NH_4HCO_3 buffer solution (flow rate: 0.7 mL/min, $t_R = 28$ min). After removal of the buffer solution, the residue was lyophilized from water to give 0.9 mg 3-deoxy-3-*C*-[{ammonium-(5-acetamido-2,6-anhydro-3,5-dideoxy-D-*erythro*-L-*manno*-non-2-yl)onate}-methyl]-D-*galacto*-hexopyranose as a white amorphous solid.

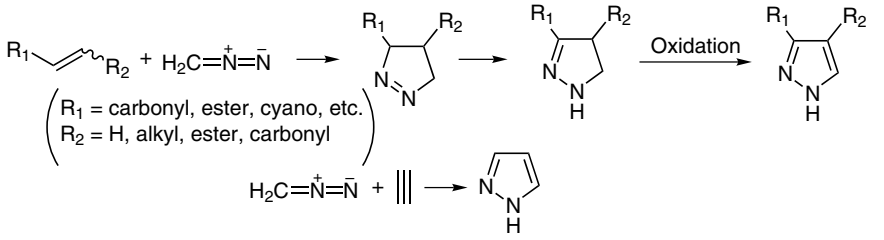
Pechmann Pyrazole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first developed by Pechmann in 1895.[1] It is the preparation of pyrazole derivatives involving a *1,3-Dipolar Cycloaddition* between a diazomethane (or other diazonium salt) and a molecule with carbon-carbon double bonds to pyrazoline and subsequent oxidation. It has been found that a carbonyl, ester, or cyano group that conjugates to the olefinic double bond, facilitates the formation of pyrazoline; whereas a phenyl group decreases the reactivity,[2] as shown in the cycloadditions of diazomethane with *p*-quinones,[3] 1,4-naphthoquinonedibenzenesulfonimide,[4] methyl crotonate,[5] and citraconic acid.[6] Upon the mixing of diazomethane with α,β-unsaturated esters or acid, a Δ^1-pyrazoline in which the nitrogen atom is always linked to the α-carbon of the carbonyl group is formed, which rearranges in the presence of hydrochloric acid to give Δ^2-pyrazoline containing a carbon-nitrogen double bond in conjugation with the carbonyl group.[7] Upon oxidation, (e.g., with bromine,) pyrazole derivatives are yielded,[5,6] although the dehydrogenation some times occurs without an oxidant present.[8] In addition, a direct preparation of pyrazole from *1,3-Dipolar Cycloaddition* between diazomethane and acetylene was also developed by Pechmann.[9]

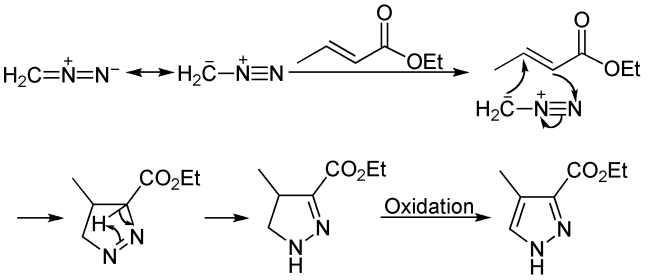
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the mechanism for the reaction between diazomethane and ethyl 2-butenate.



D. MODIFICATION

N/A

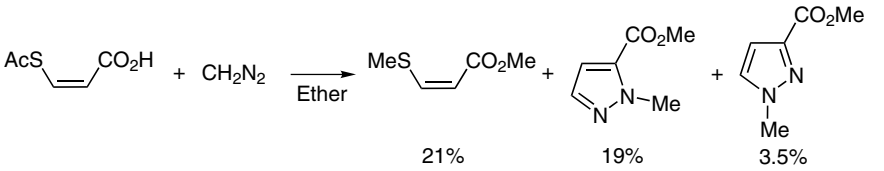
E. APPLICATIONS

This reaction has a general application in the preparation of pyrazole derivatives as well as cyclopropane derivatives upon decomposition of pyrazolines.

F. RELATED REACTIONS

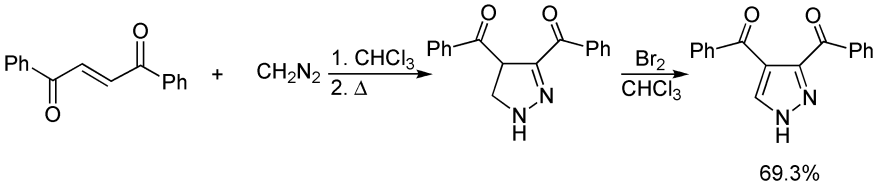
This reaction is related to 1,3-*Dipolar Cycloaddition*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To an undistilled diazomethane in ether, decanted from KOH pellets was added 1.0 g methyl *cis*-3-thioacetyl-acrylate (6.3 eq.). The temperature was maintained at −5 to 0°C for ∼8 h and then allowed to warm to room temperature. After standing for 3.5 days, the ether was removed under reduced pressure. The residue was chromatographed on silica gel with chloroform to afford 208.4 mg methyl *cis*-3-methylthio-acrylate (21%, b.p., 43–45°C at 0.5 mmHg), 185.6 mg 1-methyl-5-carbomethoxypyrazole (19%, b.p., 49–51°C at 0.5 mmHg), and 34 mg 1-methyl-3-carbomethoxypyrazole (3.5%, b.p. 126–127°C, 1.4 mmHg).



Reference 7.

The solution of diazomethane (2.7 g, 0.065 mol, prepared from 10.3 g nitrosomethylurea in 100 mL ether) was cooled to −10°C and poured into a cold (−10°C) solution of 15.7 g *trans*-dibenzoylethylene (0.065 mol) in 100 mL $CHCl_3$. The reaction was so fast that the product precipitated within 5 min. The mixture was allowed to stand at −10°C for 30 min, and then the solid was removed and dried in a vacuum desiccator to afford 18.0 g Δ^1-3,4-dibenzoylpyrazoline, in a yield of 99.6%, m.p. 108°C. This product was heated for 20 min in an oil bath at 115–120°C and then crystallized twice from 75% aqueous EtOH to afford Δ^2-3,4-dibenzoylpyrazoline, m.p., 129–129.5°C. To 50 mL $CHCl_3$ solution containing 8.34 g Δ^2-3,4-dibenzoylpyrazoline (0.03 mol) at 0°C was added a solution of 4.8 g bromine (0.03 mol) in 15 mL $CHCl_3$ at such a rate that the temperature did not exceed 12°C. An orange precipitate formed during the reaction. After the addition was complete, the solvent was evaporated at room temperature in a current of dry air. Much hydrogen bromide evolved, and the color of the solid changed to yellow. The residue was washed with water, then dissolved in 60 mL EtOH, filtered, and set aside for crystallization; 5.77 g 3,4-dibenzoylpyrazole was obtained after two recrystallizations from MeOH, in a yield of 69.3%, m.p. 169°C.

Other references related to the Pechmann pyrazole synthesis are cited in the literature.[11]

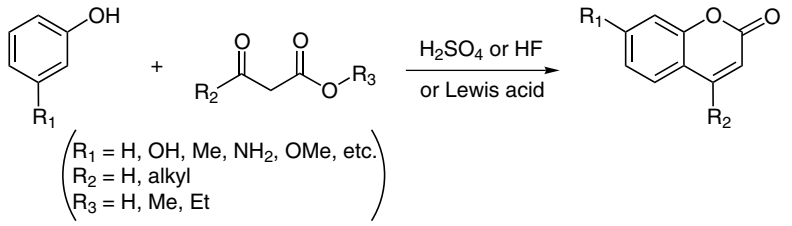
(Pechmann Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pechmann and Duisberg in 1883.[1] It is an acid-promoted synthesis of coumarin derivatives from the condensation of phenols and β-ketoesters or β-keto carboxylic acids and is generally known as the Pechmann reaction[2,3] or Pechmann condensation.[2l,4,5] Occasionally, this reaction is also referred to as the Pechmann coumarin synthesis,[2h,6] Pechmann cyclization,[4b,4c,7] Pechmann coumarin condensation,[2m,8] Pechmann cyclocondensation,[9] or the Pechmann synthesis.[2n,10] This reaction, under acidic conditions, involves an esterification or transesterification, followed by a cyclization and dehydration. It has been found that the outcome of this reaction depends on the nature of phenols, β-keto esters, and condensation reagents.[2e,2p] For example, only phenols with electron-donating groups at the *meta*-position of the hydroxy group readily undergo the Pechman condensation,[2p] whereas phenols with electron-withdrawing groups at the *meta*-positions[2p] or with electron-donating groups at other positions[2f] fail for this reaction. On the other hand, the α-substituents and γ-substituents[2p] on β-keto esters retard this reaction. Although this reaction is often carried out with concentrated H_2SO_4[2i] or 70% H_2SO_4,[2g] other acids, including Lewis acids, are also effective in promoting this reaction, such as $POCl_3$,[2p,4a] P_2O_5,[3n] HF,[2k] sulfamic acid,[3h] TFA,[11] triflic acid,[2b] polyphosphoric acid,[3kk,3rr] $KHSO_4$,[5e] dipyridine copper chloride,[5c] $ZnCl_2$,[2f,2g,2p,3l] AgOTf,[3a] $AlCl_3$,[2p,3tt] molecular iodine,[3a] VCl_3,[3b] $BF_3{\cdot}2H_2O$,[3c] BF_3,[3ss] $BiCl_3$,[5d] $ZrCl_4$,[3g] $SiCl_4$,[3nn] and $Yb(OTf)_3^{3j}$. However, the application of the common condensation reagent of P_2O_5 often results in the formation of chromone derivatives.[2p]

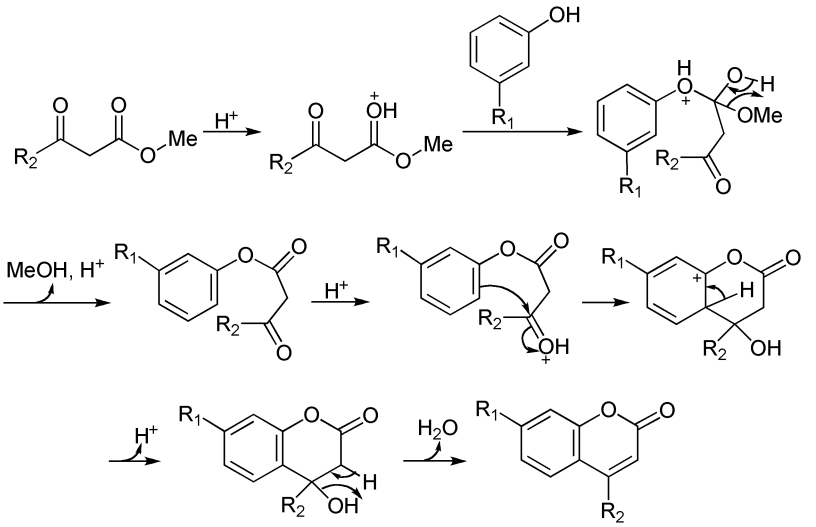
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a general mechanism for the Pechmann reaction between a phenol with a *meta*-electron-donating group and methyl β-keto ester under acidic conditions.



D. MODIFICATION

This reaction has been extensively modified to occur under various conditions, via the promotion by different acidic catalysts, including Lewis, acids, as described in Section A. In addition, cation exchange resin,[3h,3j,3o] Amberlyst ion-exchange resin,[3d] Nafion-H[5m] and Nafion resin/silica nanocomposites,[3k] Montmorillonite clay[3t,5j] and graphite/montmorillonite K10[3q] have been used as the condensation reagents. Moreover, this reaction has been generally accelerated by the use of microwave[3l,3n,3q,3s,5h,6a,10a,12] or ultrasound irradiation;[5d] in addition, this reaction can also be accelerated if carried out in neutral ionic liquid[5f] or acidic ionic liquid (e.g., non-chloroaluminate[3e] or Lewis acidic chloroalminate ionic liquid[5i]).

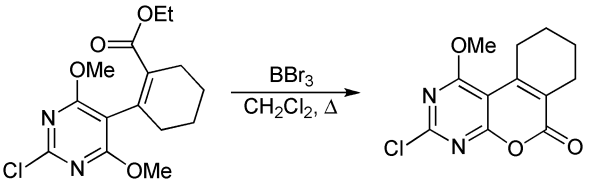
E. APPLICATIONS

This reaction has general application in the preparation of coumarin derivatives.

F. RELATED REACTIONS

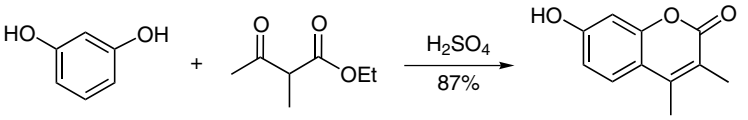
This reaction is related to the *Mentzer Pyrone Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To a flask were added 60 mL CH_2Cl_2, 2.7 g 2-(2-chloro-4,6-dimethoxy-pyrimidin-5-yl)-cyclohex-1-enecarboxylic acid ethyl ester (8.3 mmol), and 41 mL 1.0 M BBr_3 solution in CH_2Cl_2. The mixture was refluxed for 16 h and then cooled to 0°C; 20 mL MeOH was added. The reaction mixture was mixed with water and finally extracted with CH_2Cl_2. Upon evaporation of solvent, the residue was suspended in hexane then filtrated and washed with hexane to give, after drying ,1.57 g 2-chloro-4-methoxy-5,6,7,8-tetrahydro-10-oxa-1,3-diaza-phenanthren-9-one, in a yield of 71%, m.p., 184–186°C.



Reference 2c.

To a 1:1.5 molar ratio mixture of resorcinol (starting with 8 mmol) and ethyl 2-methylacetoacetate at 0°C was added an excess amount of 98% H_2SO_4 over 1 h. Then the mixture was stirred at room temperature until the reaction was complete as monitored by TLC ($\sim$ 16 h). The mixture was poured into ice water and allowed to stand overnight. The precipitated solid was filtered, washed with water until neutral, and dried in vacuo to afford 87% 3,4-dimethyl-7-hydroxycoumarin, which formed colorless crystals from EtOH, m.p., 220°C dec.

Other references related to the Pechmann reaction are cited in the literature.[13]

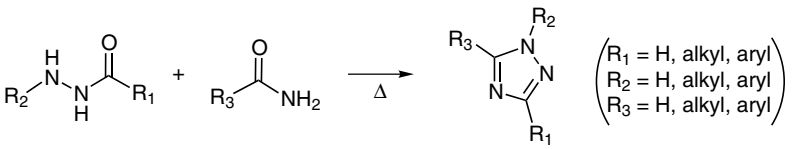
Pellizzari Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pellizzari in 1894.[1] It is the preparation of 1,2,4-triazole derivatives by baking the mixture of amide and acyl hydrazide. Therefore, it is generally known as the Pellizzari reaction.[2] This reaction is usually carried out at temperatures $> 250^{\circ}C$,[2b] but very reactive substrates can proceed at relatively lower temperatures, such as the coupling between diphenylformamidine and formhydrazide at $150^{\circ}C$.[3] This reaction is very useful for the preparation of monosubstituted-, disubstituted-, and 1,3,5-trisubstituted-1,2,4-1*H*-triazoles.[2b] However, at such a high temperature, transamination may occur between amide and acyl hydrazide, especially for the aliphatic acid hydrazides,[4] resulting in a mixture of triazoles and a lower yield of the expected triazole. It has been found that co-heating the mixture of formamide and hydrazine hydrochloride with two equivalents of pulverized KOH can improve the yield of 1,2,4-triazole to almost 17%.[5]

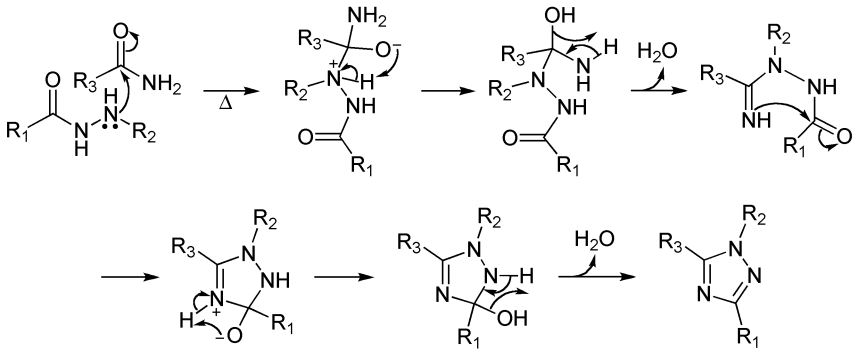
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A general mechanism is outlined below for the Pellizzari reaction.



D. MODIFICATION

N/A

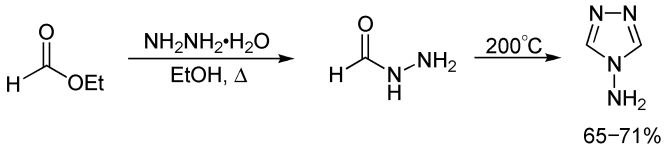
E. APPLICATIONS

This reaction can be used to prepare monosubstituted-, disubstituted-, and trisubstituted 1,2,4-1*H*-triazoles.

F. RELATED REACTIONS

This reaction is related to the *Einhorn-Brunner Reaction*.

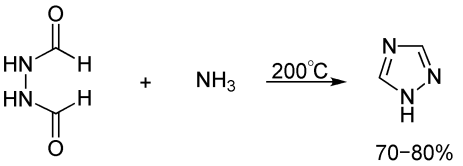
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

To a 1-L round-bottomed flask equipped with an efficient water condenser were added 148 g ethyl formate (2 mol) and 150 mL 95% EtOH. Then 120 g 85% hydrazine hydrate was added cautiously under stirring within 10 min. After the reaction had subsided, the solution was refluxed on a steam bath for 18 h. Then the bulk of the water and EtOH was removed by evaporation under reduced pressure until the volume in the flask was ~150 mL. The

resulting syrup (i.e., the crude formhydrazide), was heated under atmospheric pressure for 3 h, during which time the temperature of the bath was raised from 150° to 200°C. After cooling to ~100°C, the oil was taken up in 50 mL 95% EtOH, and 5 g Norite was added. The filtered solution was then diluted with 75 mL ether and placed in an ice box to cool. The crystalline product was filtered, washed with 50 mL 1:2 EtOH-ether and dried to give 55–60 g aminotriazole, in a yield of 65–71%, m.p., 77–78°C. Further purification can be undertaken by recrystallization from 95% EtOH by 2 mL EtOH per gram of aminotriazole followed by 2.5 mL ether, giving a melting point of 81–82°C.



Reference 7.

A mixture of 95 g *N*,*N*′-diformylhydrazine (1.08 mol) and 500 mL liquid NH_3 was heated in a steel pressure vessel at 200°C for 24 h. After removal of the ammonia, the residue was extracted with hot EtOAc. The extract was evaporated and the residue was distilled under reduced pressure to afford 70–80% 1,2,4-trazole, b.p. 124°C at 5 mmHg. A sample was recrystallized from EtOAc, m.p., 120°C.

Other references related to the Pellizzari reaction are cited in the literature.[8]

Perkin Reaction

(Perkin Condensation, Perkin Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Perkin in 1868.[1] It is the direct preparation of cinnamic acid derivatives from the thermal condensation between aromatic aldehydes and aliphatic carboxylic acid anhydrides or carboxylic derivatives (e.g., amide[2]) in the presence of a basic compound functioning as a catalyst. Therefore, this reaction is generally known as the Perkin reaction,[3,4] Perkin condensation,[2,3j,5] or Perkin synthesis.[5g,6] Occasionally, this reaction is also referred to as the Perkin cinnamic acid synthesis[4j,4o,4q] or Perkin coumarin synthesis.[7] Under the normal conditions, benzaldehyde is condensed with acid anhydride and the alkali salt of the same acid as the catalyst. However, it has been reported that the salt of the fatty acid as a base is not specific,[2] and the carbonates, acetates, phosphates, sulfites, and sulfides of sodium or potassium are all effective for this reaction.[2] In addition, even a strong organic base such as tertiary amine[3j,5d,6f,8] and pyridine[3b,9] are good catalysts for the Perkin reaction. It has been found that the Perkin reaction depends on the basicity of the catalyst, the activation of anhydride, and the nature of aromatic aldehyde. For example, the alkali acetate catalyzed Perkin reaction between *o*-chlorobenzaldehyde and acetic anhydride at 180°C for 8 h gives the following yields: Li^+, 58%; Na^+, 71%; K^+, 78%; Rb^+, 82%, showing the effect of basicity and concentration of the acetate.[8a] In addition, the electron-withdrawing groups on benzaldehydes have been found to facilitate the Perkin reaction, with a ρ value of $+2.25$ in the Hammet equation.[8a] Furthermore, other higher-order aliphatic acid anhydrides, such as butyric anhydride, normally give lower yields of α-alkyl cinnamic acids.[3b] It has been proposed that this reaction involves the enolization of anhydride and

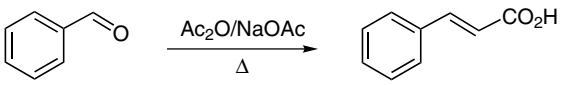
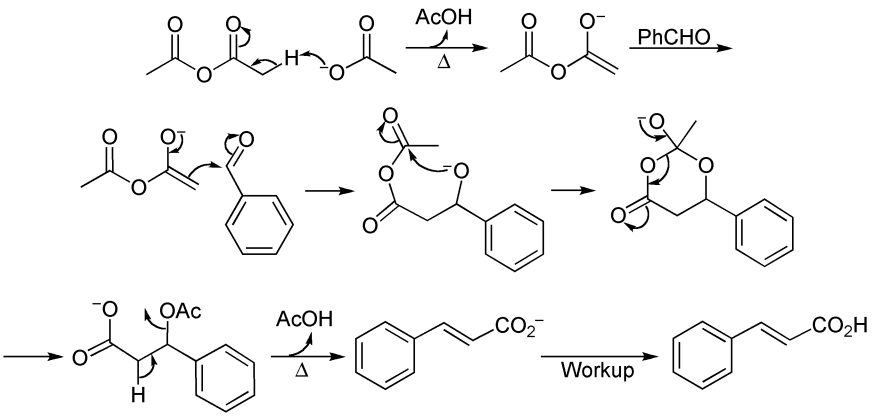
Aldol Condensation with an aromatic aldehyde, followed by the dehydration of aldol product to give the derivative of cinnamic acid.[2,6f,6g]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the mechanism for the sodium acetate catalyzed reaction between benzaldehyde and acetic anhydride.



D. MODIFICATION

The most important modification of the Perkin reaction was developed by Oglialoro using the sodium salt of acetic acid (e.g., phenylacetic acid,[3f,5i] phenoxyacetic acid[5l]) in condensation with acetic anhydride and an aldehyde (e.g., benzaldehyde,[3f,5i,5l,10] paraldehyde[11]). This type of reaction is referred to as the Perkin-Oglialoro reaction,[12] Perkin-Oglialoro condensation,[10,13] or Oglialoro modification.[3d,3g,5i] Other modifications include the use of different bases as the catalysts, (e.g., $NaB(OMe)_4$-LiCl,[3a] CaH_2,[3i] CsOAc,[3b] and CsF[3b]), the use of microwave irradiation and cesium acetate or fluoride in combination with a small amount of pyridine as catalyst[3b] and the continuous distillation of acetic acid to enhance the conversion rate.[8b]

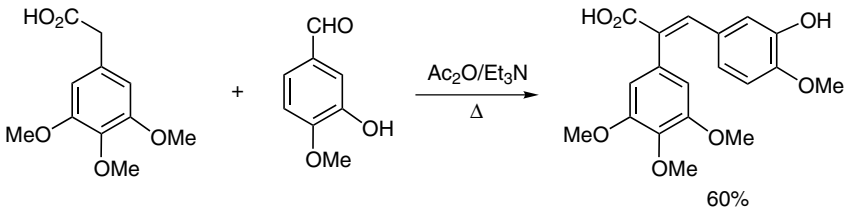
E. APPLICATIONS

This reaction is very useful for the preparation of cinnamic acid derivatives.

F. RELATED REACTIONS

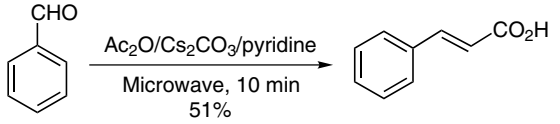
This reaction is related to the *Claisen Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5d.

A mixture of 0.67 g 3-hydroxy-4-methoxybenzaldehyde (4.4 mmol), 2.0 g 3,4,5-trimethoxyphenylacetic acid (8.84 mmol), 4 mL acetic anhydride, and 2 mL triethylamine was refluxed for 3 h. After acidification with 6 mL conc. HCl, the resulting solid was filtered off and recrystallized from ethanol to give 950 mg *E*-2-(3′,4′,5′-trimethoxyphenyl)-3-(3′-hydroxy-4′-methoxyphenyl)prop-2-enoic acid as fine yellow needles, in a yield of 60%, m.p., 237–239°C.



Reference 3b.

A mixture of 0.05 mol freshly distilled benzaldehyde, 0.1 mol acetic anhydride, and 0.05 mol Cs_2CO_3 with a small amount of pyridine was heated in a 800-W microwave oven for 10 min. The reaction mixture was then poured into 100 mL 5 % $NaHCO_3$, and the unreacted aldehyde was extracted with Et_2O (3 × 50 mL). The aqueous layer was filtered, and the clear filtrate was heated to boil and acidified to pH 2 by the addition of HCl. The crystalline product was filtered, washed with cold water, and dried to give 51% cinnamic acid, m.p. 133–134°C.

Other references related to the Perkin reaction are cited in the literature.[14]

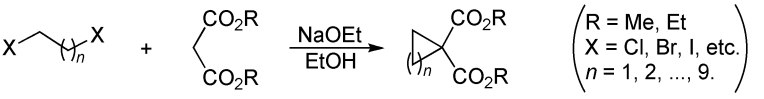
Perkin Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Perkin in 1883.[1] It is the nucleophilic alkylation between malonic ester and α,ω-alkyl dihalide to form cyclic aliphatic 1,1-diester or acid and is known as the Perkin reaction[2] or Perkin synthesis.[2] Although it was once referred to as the Perkin condensation,[3] this name should not be used for this type of reaction. Using this protocol, Perkin successfully prepared cyclopropane-,[4] cyclobutane-,[5] cyclopentane-,[6] cyclohexane-,[7] and cycloheptane-1,1-dicarboxylic acids.[8] However, this reaction is often complicated by the side reaction that forms $\alpha,\alpha,\omega,\omega$-tetracarboxylic ester from the S_N2 reaction between malonic ester and α,ω-alkyl dihalide,[9] this side reaction can be depressed if alcoholic sodium malonic ester is added slowly to the α,ω-alkyl dihalide with vigorous stirring.[9b] It is interesting that the K_2CO_3 promoted a reaction between dimethyl 1,3-acetonedicarboxylate and *trans*-1,4-dibromobutene yields vinyldihydrofuran.[10]

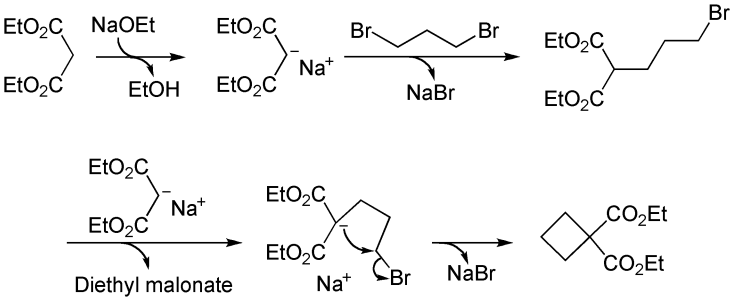
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is a representative reaction between diethyl malonate and 1,3-dibromopropane in absolute EtOH, using NaOEt as the base.



D. MODIFICATION

This reaction has been modified by the addition of alcoholic sodium malonic ester to a solution of α,ω-alkyl dihalide to depress the side reaction.[9b]

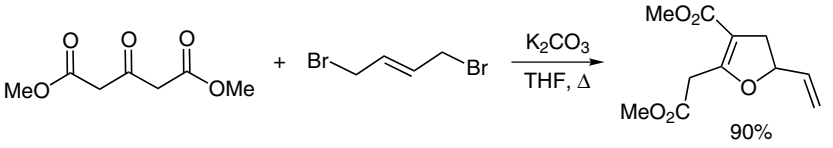
E. APPLICATIONS

This reaction is one of the major organic reactions for the preparation of alicyclic compounds.

F. RELATED REACTIONS

This reaction is related to *Malonic Ester Synthesis*.

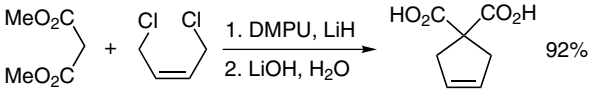
G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a 1 mmol solution of dimethyl acetonedicarboxylate in 15 mL dry THF was added 2.5 mmol powdered K_2CO_3. The mixture was stirred under nitrogen for 15 min at room temperature. Then 1 mmol *trans*-1,4-dibromo-2-butene in 10 mL dry THF was added through a syringe, and the resulting reaction mixture was refluxed until the completion of

reaction as monitored by TLC. After cooling to room temperature, the solution was filtered through a short pad of Celite, and the solution was evaporated under reduced pressure. The residue was purified by rapid flash chromatography to afford 90% 4,5-dihydro-2-methoxycarbonylmethyl-3-methylcarboxylate-5-vinylfuran, $R_f = 0.59$ (Et_2O/pentane, 7:3).



Reference 11.

To a 1-L two-necked, round-bottomed flask equipped with a magnetic stirring bar were added 33.0 g dimethyl malonate (0.25 mol), 50 mL dry *N*,*N*-dimethylpropyleneurea (DMPU), and 450 mL dry THF under a current of nitrogen. The mixture was cooled in an ice bath, and 5.0 g LiH powder (0.629 mol) was added in one portion under stirring. The nitrogen flow was discontinued, and the flask was sealed with a rubber septa connecting to a Nujor-filled bubbler by syringe needle. After 15 min, the ice bath was removed and stirring was continued until hydrogen evolution ceased, whereupon 28.4 mL *cis*-1,4-dichloro-2-butene (0.269 mol) was added rapidly by syringe. The mixture was heated at 40–45°C for 24 h and then cooled to 20°C; 50 mL water was added dropwise followed by 31.5 g solid $LiOH{\cdot}H_2O$ (0.750 mol). After the mixture was stirred at 20°C for another 24 h, an additional 350 mL water was added under stirring, and the whole mixture was extracted by EtOAc (5 × 500 mL); each washing was back washed with 30 mL brine. The combined aqueous phase was then acidified with 160 mL 6 N HCl and extracted with EtOAc (3 × 500 mL). The combined organic layers were washed with 3 N HCl (3 × 100 mL) and brine (2 × 50 mL), and dried over Na_2SO_4. Upon removal of the solvent by rotary evaporation and traces of solvent under high vacuum (1 h at 0.1 mmHg), 35.8 g 3-cyclopentene-1,1-dicarboxylic acid was obtained as an off-white solid, in a yield of 92%, m.p. 163–165°C.

Other references related to the Perkin synthesis are cited in the literature.[12]

Perkow Reaction

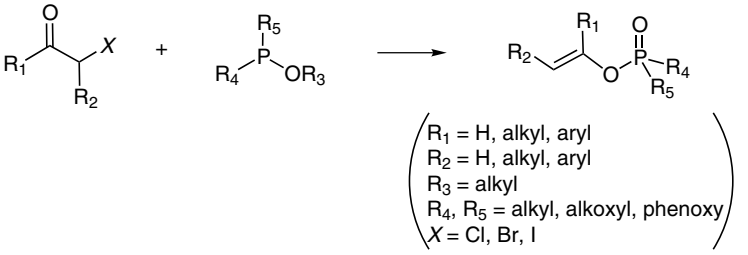
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Perkow in 1952.[1] It is the preparation of vinyl (or enol) phosphates from α-halo carbonyl compounds and trivalent phosphorus reagents and is generally known as the Perkow reaction.[2,3] In addition, this reaction is referred to as the Perkow synthesis,[4] Perkow rearrangement,[5] anomalous Arbuzov reaction,[6] Perkow-Arbuzov reaction,[7] or vinyl ester reaction.[8] Generally speaking, α-halo aldehydes are more reactive than α-halo ketones; whereas α-halo esters are the least reactive species for the Perkow reaction, and α-halo amides do not react at all.[2k] On the other hand, the α-halo carbonyl compounds also show a general reactivity scale of I > Br > Cl.[2k] The more α-halo atoms in the carbonyl compound, the faster the reaction occurs.[2k] For example, chloral and bromal undergo the Perkow reaction most readily, and such a vigorous reaction is usually controlled by either lowering the reaction temperature or carrying it out in an inert solvent;[1,4b,9] the normal Perkow reaction is carried out at 100–150°C.[2k] The trivalent phosphorus reagent should contain at least one alkoxy group, whose alkyl group is capable of evolving as a carbonium ion, and should not have a hydrogen or hydroxy group attaching to a phosphorus atom.[2k] Thus trialkyl phosphites, dialkyl ethylphosphonites, dialkyl phenylphosphonites, and methyl diphenylphosphinite are all possible reagents for this reaction;[2d] but trialkylphosphines, triaryl phosphates, and phosphorotriamidites do not undergo the Perkow reaction.[2k] For trialkyl phosphites with different alkyl groups, the smallest alkyl group is usually eliminated in this reaction; similarly, for phosphites containing one or two phenoxy groups, the alkyl group is always removed as alkyl halide.[2k] Both the electronic character of phosphorus[2b,2c] and the steric effects[2d,2h] are prominent in the Perkow reaction, as indicated by the predominant *trans*-configuration in vinyl phosphates,[2i] resulting from the initial attack of trialkyl phosphite from the less hindered side of halogen

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

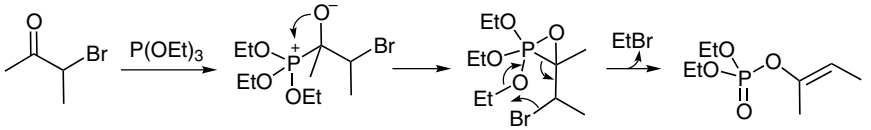
in eclipsed or gauched form of the α-halo ketones. α-Bromoketone gives more *trans*-vinyl phosphate isomer than does chloroketone.[2h] The reaction rate of triisopropyl phosphite is slower than that of triethyl phosphite in the Perkow reaction.[2h] However, this reaction is often complicated by the *Michaelis-Arbuzov Rearrangement*, by which phosphonate is formed instead of phosphate.[2k] It is known that the course of the reaction depends on the nature and position of halogen on the carbonyl compounds as well as the reaction temperature.[2k] In general, more Perkow products are produced from α-iodo ketones, even at low temperature, whereas more Michaelis-Arbuzov products are generated from α-chloroketone at high temperature.[2k] In addition, α-halo ketones with a halogen atom at the primary carbon prefer Michaelis-Arbuzov products, whereas ketones with a halogen atom at the secondary carbon yields more Perkow products. Moreover, the ketones containing more than one α-halogen atom, give exclusively or almost exclusively Perkow products.[2k]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

For this reaction, a variety of mechanisms have been proposed, in favor of the initial attack of the phosphorus atom on the α-halogen,[2f,10] the carbonyl oxygen,[11] the α-carbon bound to the halogen,[9,12] or the carbonyl carbon.[2b,2c,2h,8b,13] However, more and more experimental evidence supports the initial attack of phosphite on the carbonyl group as the rate-limiting step,[2h] followed by the rearrangement of the phosphorus moiety to oxygen to form the enol phosphonium halide.[2f,2h] Evidence in favor of halogen attack includes the formation of only *cis*-vinyl phosphates from α,α-dibromoketones and α-bromo-α-phenyl ketones.[2f] A representative mechanism is outlined here between 2-bromo-2-butanone and triethylphosphite.



D. MODIFICATION

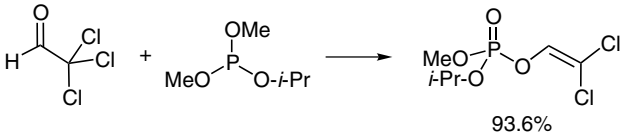
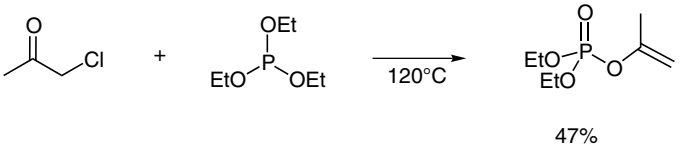
G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

To a solution of 76 g freshly distilled chloral (0.517 mol) in 75 mL CH_2Cl_2, was added dropwise 87 g dimethyl isopropyl phosphite (0.573 mol) within 1.5 h to maintain the moderate reflux. After the addition was completed, the refluxing was extended for an additional 30 min, then both solvent and excess phosphite were removed through rotary evaporation at 60°C (25 mmHg) to give 129 g of a colorless liquid. GLPC analysis showed that this liquid contained 93% 2,2-dichlorovinyl isopropyl methyl phosphate, in a yield of 93.6%. The liquid was distilled, and 109 g product was collected at 79°C (0.04 mmHg) as four fractions, which contained 10%, 6%, 4%, and 4% of dimethyl isopropyl phosphite, respectively, according to GPLC analysis. Then fraction 4 (containing only 4% of phosphite) was further chromatographed on a deactivated silica gel, eluting with 2% ether in CH_2Cl_2 to afford 5.76 g pure phosphate.



Reference 2e.

To 0.20 mol triethyl phosphite heated to 120°C was added 0.20 mol chloroacetone in small portions. After completion of the addition, the mixture was stirred at 120°C for 1 h, then the temperature was raised to 170°C for an additional hour, whereupon 47% of diethyl 2-propenyl phosphate was distilled, b.p. 64°C at 0.9 mmHg.

Other references related to the Perkow reaction are cited in the literature.[15]

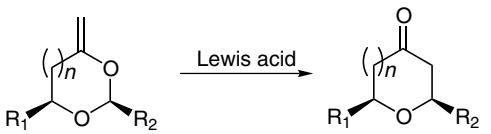
Petasis-Ferrier Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Petasis in 1995.[1] It is a Lewis acid promoted or induced conversion of enol acetals (e.g., 4-alkylidenyl-1,3-dioxanes[2]) into tetrahydropyranones.[3] Because this reaction is very similar to the *Ferrier Rearrangement*, it is normally called the Petasis-Ferrier rearrangement.[2–4] The Lewis acids that can promote this rearrangement include $BF_3{\cdot}Et_2O$, $ZnCl_2$, $TiCl_2(O\text{-}i\text{-}Pr)_2$, $MeAlCl_2$, and Me_2AlCl.[4h] It has been proposed that this reaction occurs via fragmentation, followed by *endo*-cyclization onto an oxocarbenium.[5] This reaction can tolerate a variety of functional groups, including silyl ether,[4h] and can directly produce *cis*-2,6-disubstituted tetrahydropyranone when Me_2AlCl is used as the Lewis acid, without the *Meerwein-Ponndorf-Verley Reduction* per Petasi's original procedure.[2,4h] This reaction has also been extended to the preparation of compounds containing medium-size rings.[4d]

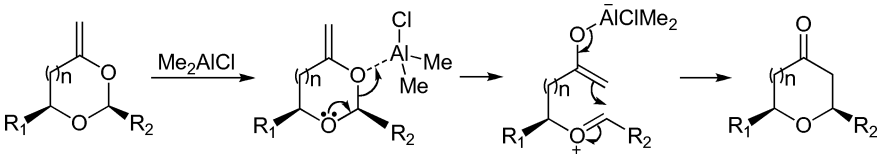
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A modified version of the mechanism described by O'Neil et al.[4d] is illustrated here.



D. MODIFICATION

The original procedure has been modified to use Me_2AlCl as the promoter,[2,4h] and the alkylidenyl in 1,3-dioxane has been extended to a *spiro*-cyclopropanyl group.[4d]

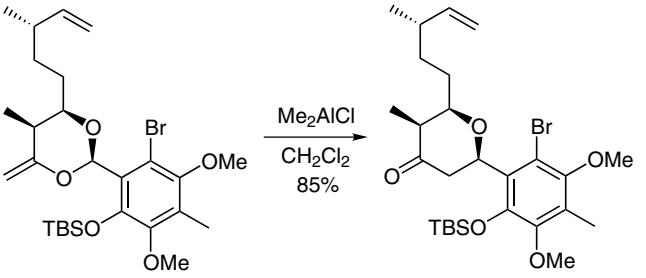
E. APPLICATIONS

This reaction is generally useful for the preparation of tetrahydropyrans, tetrahydropyranones, and medium cyclic compounds.

F. RELATED REACTIONS

This reaction is related to the *Ferrier-II Rearrangement*.

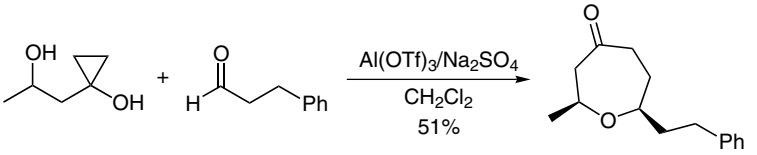
G. CITED EXPERIMENTAL EXAMPLES



Reference 4c.

To a solution of 1.6 g enol-acetal (2.9 mmol) in 36 mL dichloromethane was added 3.6 mL 1 M Me_2AlCl (3.6 mmol) in dichloromethane at $-78^{\circ}C$. The reaction mixture was stirred for 10 min then quenched at $-78^{\circ}C$ with 1.5 mL Et_3N, followed by 20 mL saturated aqueous $NaHCO_3$. The reaction mixture was then diluted with 100 mL dichloromethane, allowed to warm to 0–5°C, and acidified with 1 N HCl to pH 2. The aqueous phase was

extracted with dichloromethane (3 × 100 mL), and the combined organic extracts were dried over Na_2SO_4, and then concentrated in vacuo. Flash chromatography purification with 5% EtOAc in hexanes as the eluent afforded 1.4 g pyranone as a colorless oil, in a yield of 85%.



Reference 4d.

To a −10°C suspension of 1.5 mL CH_2Cl_2 and 430 mg Na_2SO_4 (3.02 mmol) was added 102 μL 3-phenylpropionaldehyde (0.772 mmol) under argon, followed by 73 mg $Al(OTf)_3$ (0.154 mmol). In a separate flask, a solution of 89.7 mg diol (0.772 mmol) in CH_2Cl_2 (1 mL) was prepared and added to the reaction flask via cannula. The resultant solution was stirred for 2 h, then a solution of 772 μL 1.0 M $TiCl_4$ in CH_2Cl_2 (0.772 mmol) was added. The resultant solution was stirred for 0.5 h. The reaction was then diluted with 10 mL CH_2Cl_2 and quenched with 10 mL saturated aqueous $NaHCO_3$. The aqueous layer was extracted with CH_2Cl_2 (3 × 10 mL). The combined organic layers were washed with brine, dried over Na_2SO_4, vacuum filtered, and concentrated in vacuo. Flash chromatography (EtOAc/hexanes,15:85) provided 91.8 mg keto-oxepane as a pale yellow oil, in a yield of 51%.

Peterson Olefination

A. GENERAL DESCRIPTION OF THE REACTION

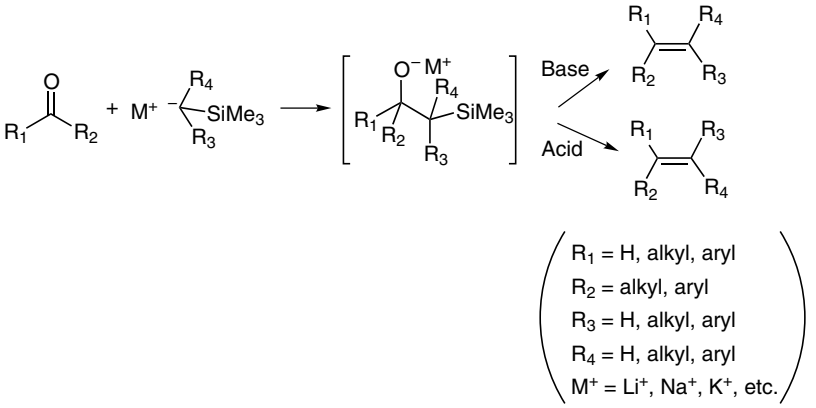
This reaction was first reported by Peterson in 1968.[1] It is a two-step synthesis of olefin involving the addition of an α-silyl carbanion to a carbonyl compound to form β-silyl alcohol (or β-hydroxy silane) and the elimination of silol. Therefore, this reaction is generally known as the Peterson olefination.[2,3] In addition, this reaction is also referred to as the Peterson reaction[2k,4] and Peterson elimination.[2f,5] Occasionally, the Peterson olefination is also called the Peterson alkenation[6] or Peterson alkenylation.[7]

As a complementary olefination method of *Wittig Reaction*, the Peterson olefination has the following advantages: a higher reactivity of α-silyl carbanions than the corresponding phosphorus reagents toward both ketones and aldehydes,[2k,8] a better *Z*-selectivity than the corresponding stabilized phosphorous components,[8] and a simpler workup and purification procedure without phosphorus side products.[2k] However, the low availability of certain α-silyl carbanions has limited its general use in organic synthesis,[2d,4h] especially for methylene derivatives,[4h] which may be obtained via the application of trimethylsilylmethyl magnesium chloride[2j] or [bis(trimethylsilyl)methyl]-lithium.[2x] Generally, the β-silyl alcohol generated from an α-silyl carbanion with an electron-withdrawing group undergoes elimination instantaneously to give the olefin as an *E*/*Z* mixture but in favor of *E* olefin,[2x] whereas the β-silyl alcohol arising from α-silyl carbanion with an electron-donating group could be isolated and converted into the corresponding olefin with controllable stereochemistry.[2x] Treatment of the isolated β-silyl alcohol with acid results in an *anti*-elimination, whereas the treatment of the same substrate with base leads to a *syn*-elimination.[5b,9] In this reaction, the α-silyl carbanions can be generated from direct lithiation of silane with a strong lithium base,[10] from lithium halogen exchange,[11] or from the addition of a carbanion to vinylsilane,[12] etc. On the other hand, besides the addition of α-silyl

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

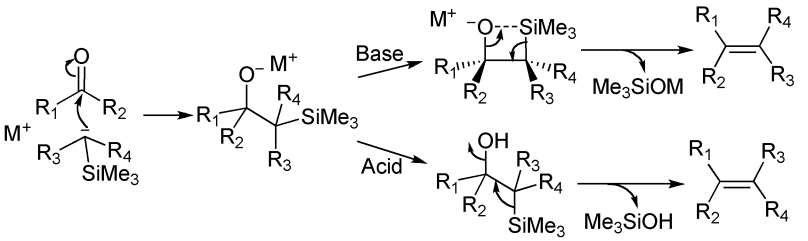
carbanion to carbonyl compounds, other methods are suitable for the generation of α-silyl alcohols, such as the addition of carbanion to α-silyl ketone[9b] or α-silyl epoxide.[9a] Acids such as H_2SO_4,[13] CF_3COOH,[2d] HF·Pyr,[2j] and $SOCl_2$[2m] are effective reagents for the elimination step. In addition, it has been found that fluoride (e.g., CsF)[2s,4u,7] and zinc bromide can be used as catalysts for this reaction.[2s]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is outlined below for the Peterson olefination.



D. MODIFICATION

This reaction has been modified by the use of an α-silyl selenoacetamide to generate *E*-olefins in preference[2g] and the use of an α-silyl thioether[2i] and *N*-cyclohexyl-(2-triethylsilylpropylidene)imine[2d] as α-silyl carbanion precursors. In addition, a germanium-Peterson reaction[4l] and a tin-Peterson reaction[4n] have been developed. Furthermore, an asymmetric version of the Peterson olefination has been developed by the use of an external chiral tridentate amino diether as a chiral ligand.[2k]

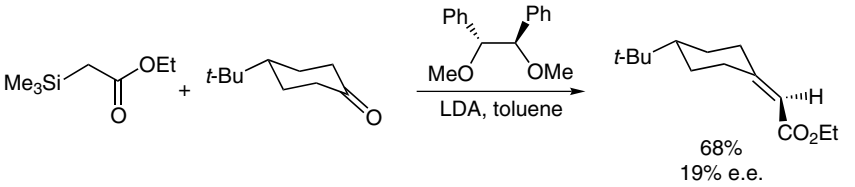
E. APPLICATIONS

This reaction has general application in the preparation of olefins.

F. RELATED REACTIONS

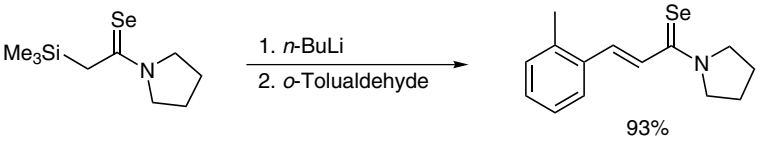
This reaction is related to the *Wittig Reaction* and *Tebbe Olefination*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2k.

A solution of 1.5 mmol ethyl trimethylsilanylacetate and 2.0 mmol chiral pinacol methyl ether in 6.0 mL toluene was added to a solution of LDA (1.6 mmol) in 5.0 mL toluene at −78°C. The mixture was stirred at −20°C for 1 h and cooled to −78°C again. Then a solution of 1.0 mmol 4-*tert*-butyl-cyclohexanone in 4 mL toluene was added dropwise over a period of 3 min, and the resulting mixture was stirred at room temperature for 5 h. Upon removal of the solvent, the residue was purified by silica gel column chromatography to afford 68% of (*S*)-(+)-ethyl (4-*tert*-butylcyclohexylidene)acetate as a colorless oil, with 19% e.e.



Reference 2g.

To 2.5 mL THF solution containing 0.26 g α-trimethylsilyl selenoacetamide (1.05 mmol) was added 0.625 mL 1.6 M *n*-BuLi (1.0 mmol) at 0°C; the mixture was stirred for 15 min. Then 0.12 mL *o*-tolualdehyde (1.0 mmol) was added; the reaction mixture instantly changed to reddish orange. After being stirred at room temperature for an additional hour, the reaction mixture was poured onto water and extracted with CH_2Cl_2. The organic layer was dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by silica gel column chromatography using hexane/dichloromethane as an eluent to give 0.258 g (*E*)-1-(3-(2-methylphenyl)-1-selenoxo-2-propenyl)pyrrolidine as a reddish orange solid, in a yield of 93%, m.p. 137–140°C.

Other references related to the Peterson olefination are cited in the literature.[14]

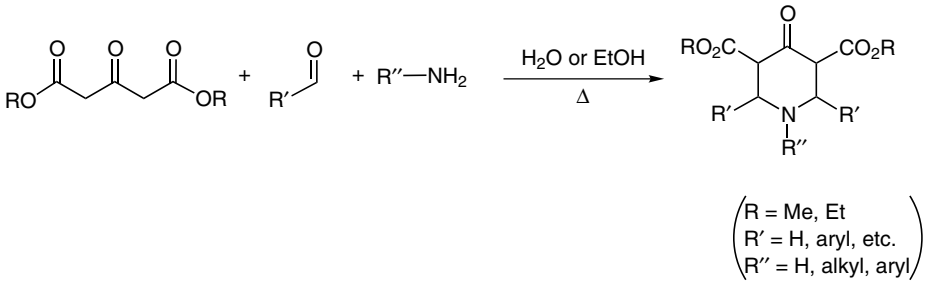
Petrenko-Kritschenko Piperidone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Petrenko-Kritschenko in 1906.[1] It is the preparation of piperidone via a double *Mannich Reaction* from acetonedicarboxylic ester, two equivalents of aldehyde, and ammonia (or a primary amine), and is known as the Petrenko-Kritschenko piperidone synthesis.[2] In this reaction, the mixture of reaction components is usually refluxed in an aqueous or alcoholic solution, and the resulting product is difficult to purify.[3] It has been found that the addition of acid to the reaction medium is useful for this reaction.[2]

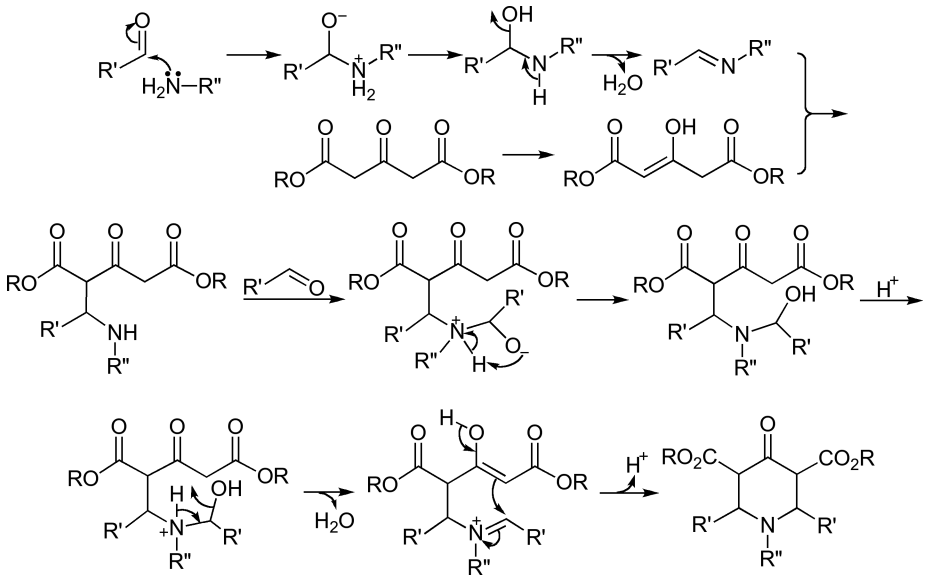
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is the detailed mechanism in the presence of an acid.



D. MODIFICATION

This reaction has been modified by the use of ammonia acetate in acetic acid as the reaction medium and source of ammonia.[2]

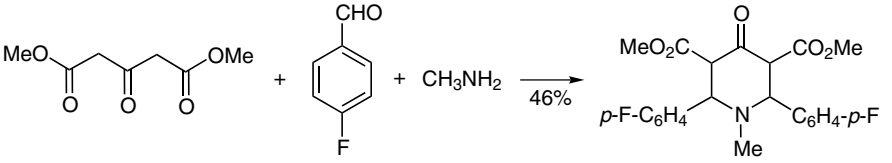
E. APPLICATIONS

This reaction is useful for the preparation of piperidone derivatives.

F. RELATED REACTIONS

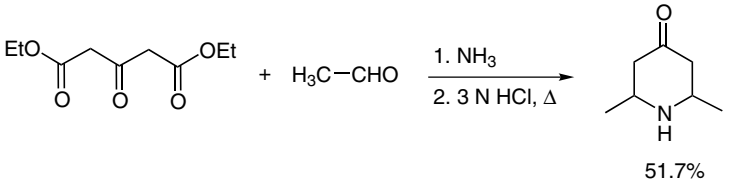
This reaction is related to the *Hantzsch Dihydropyridine Synthesis, Chichibabin Pyridine Synthesis*, and *Mannich Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

Exactly 0.04 mol *p*-fluorobenzaldehyde and 1.5 mL 40% aqueous solution of methylamine were dissolved in 20 mL methanol, and the mixture was cooled to 0°C. Over a course of ~1 h, 0.02 mol dimethyl oxoglutarate was added dropwise to the mixture under stirring at 0°C. The solution was allowed to stand overnight at 5°C. The resulting precipitate was filtered and washed by ether to give 3.84 g dimethyl 2,6-di-(4-fluorophenyl)-*N*-methyl-4-piperidone-3,5-dicarboxylate, in a yield of 46%, m.p. 128–130°C. When no precipitate formed, the solvent was removed in vacuo at 40–50°C, and the remaining residue was dissolved in ethanol or treated with Et_2O to obtain the crystal.



Reference 5.

Into a mixture of 101 g diethyl acetonedicarboxylate and 44 g acetaldehyde maintained at -25 ± 5°C was bubbled ammonia until tests showed that the liquid was saturated. The solution was stored at 0°C for 20 h, by which time it was a white sludge. To this mixture was added 250 mL 3 *N*HCl, and the solution was heated on a steam bath. Carbon dioxide soon began to evolve and continued to evolve even after 24 h yet very slowly. The solution was evaporated almost to dryness, and 25 mL water was added to the tan heavy precipitate and evaporated again. To the residue was added a solution of 100 g Na_2CO_3 in 480 mL H_2O and 200 mL $CHCl_3$; the layers were shaken and separated. The aqueous layer was extracted with CH_2Cl_2 (6×200 mL) until ethereal picric acid showed no yellow color. The organic layers were dried over $MgSO_4$ and distilled to give 32.9 g 2,6-dimethyl-piperidone as colorless liquid, in a yield of 51.7%, b.p. 99–105°C (25 mmHg).

Other references related to the Petrenko-Kritschenko piperidone synthesis are cited in the literature.[6]

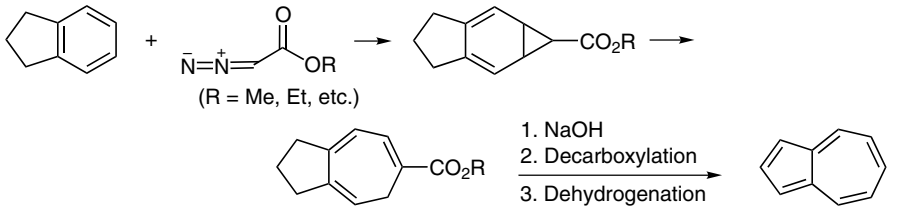
Pfau-Plattner Azulene Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

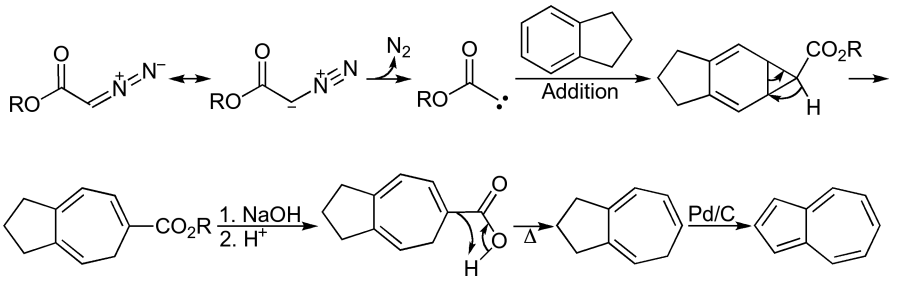
This reaction was first reported by Pfau and Plattner in 1939[1] after their earlier preparation of azulene from cyclopentenocycloheptanone[2] by the application of the ring expansion protocol discovered by Buchner in 1885.[3] It is a multistep preparation of azulene involving decomposition of diazoacetic ester, addition of the resulting carbene to indane, rearrangement of cycloheptatriene, hydrolysis of ester, decarboxylation, and dehydrogenation. Azulene is an isomeric structure of naphthalene[3b] with an intense blue or blue-violet color.[4] The dehydrogenation can be carried out by heating cycloheptatriene with sulfur, selenium, or palladium-charcoal,[4b] and the resulting azulene can be purified by the formation of a complex with trinitrobenzene[5] or use of column chromatography and partition procedures.[3b] This reaction has been improved by the direct addition of carbene to indane followed by dehydrogenation with a much higher yield.[6] In addition, this reaction has been modified by the intramolecular carbene addition of 4-phenyl 1-diazo-2-butanone followed by dehydrogenation.[7]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified by the direct addition of carbene, generated from diazomethane, to indane[6] and intramolecular carbene addition to the phenyl ring from 4-phenyl-1-diazo-2-butanone,[7] followed by dehydrogenation.

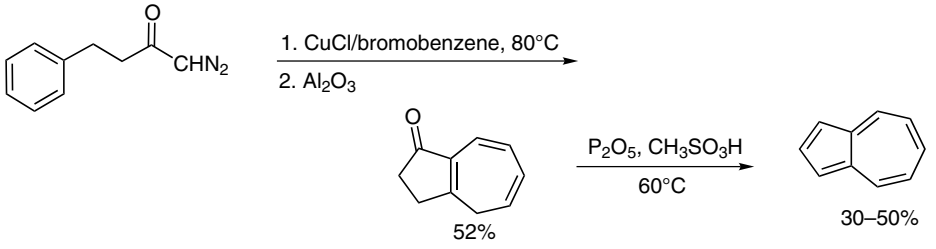
E. APPLICATIONS

This reaction has a limited use in organic synthesis, specifically for the azulene derivatives.

F. RELATED REACTIONS

This reaction is related to the *Büchner Ring Expansion*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To an oven-dried, 5-L three-necked flask equipped with a mechanical stirrer, a constant addition funnel, and a reflux condenser were added 3 L freshly distilled bromobenzene over CaH_2 and 0.8 g fresh anhydrous CuCl under nitrogen. At 80°C, 1 L dry bromobenzene containing 20.4 g 4-phenyl-1-diazo-2-butanone was added to the vigorously stirred suspension

dropwise for a period of 7 h. Heating and stirring were continued for an additional 1 h, then the pale yellow reaction mixture was cooled and filtered through 30 g alumina to remove CuCl and isomerize the unconjugated trienone to the more stable isomer. The alumina was washed with 500 mL EtOAc, and the combined organic filtrates were concentrated at 40°C (20–0.5 mmHg) to a brown oil. Chromatography on 200 g silica gel using EtOAc/petroleum ether (15:85) as the eluant gave 8.9 g 3,4-dihydro-1(2H)-azulenone as a light brown oil, in a yield of 52%.

To a homogeneous mixture of 5 g P_2O_5 (35 mmol) and 34 mL freshly distilled methanesulfonic acid at 60°C under nitrogen was added 0.48 g 3,4-dihydro-1(2H)-azulenone (3.3 mmol) dropwise under stirring within 7 min. The solution rapidly darkened to orange-brown. Progress of the reaction was followed by removing one-drop aliquots and quenching them in H_2O/hexane. The UV spectra of the hexane layer showed a gradual decrease at 226 nm and an increase at 274 nm. After ~6 h, the absorption at 226 nm was no longer discernible, and the reaction mixture was poured into 500 mL ice-cold water and extracted twice with pentane. The dark blue pentane layers were combined, washed with water until neutral, followed by brine, dried over $MgSO_4$, and concentrated under reduced pressure. The oily blue residue was purified by preparative layer chromatography on silica gel by using pentane as the eluent to give 130–210 mg azulene as beautiful dark blue crystals, in a yield of 30–50%, m.p. 98–98.5°C.

More experimental procedures are available in the literature.[6a,8] Other references related to the Pfau-Plattner azulene synthesis are cited in the literature.[9]

Pfitzinger Reaction

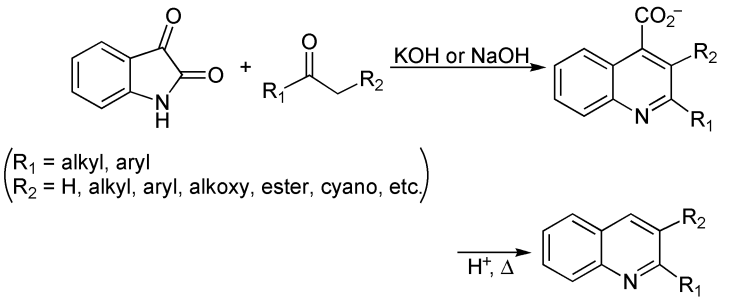
(Pfitzinger Quinoline Synthesis, Pfitzinger Synthesis, Pfitzinger Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pfitzinger in 1886.[1] It is a base-promoted condensation between an enolizable carbonyl compound and isatinate originating from isatin to form 2- or 2,3-disubstituted quinoline or cinchoninic acid derivative. Therefore, this reaction is generally known as the Pfitzinger reaction,[2,3] Pfitzinger condensation,[2r,2t,2u,2v,2y,4] or Pfitzinger synthesis.[2u,2y,5] Occasionally, it is also referred to as the Pfitzinger quinoline synthesis.[6] The isatins being used for this reaction include 5-sulfamoylisatin,[2b,2f] 5-methylisatin,[2x,7] methyl isatin-4-carboxylate,[5a] 5-bromoisatin,[2r] isatin,[2b,2h,2q,2x,2bb,5c,7] and isatic acid.[2t,2z] The enolizable carbonyl compounds suitable for this reaction include acetone,[2b,8] methyl aryl ketones[2b] (e.g., acetophenone,[9] *p*-fluoroacetophenone[2h]), methyl heteroaryl ketones,[2b] cyclohexanone,[2b] cyclopentanone (for *p*-quinindane),[2l,4c] cyclooctanone,[2r] cyclopentadecanone,[2r] malonates,[2b] keto ester[2c] (e.g., acetoacetic acid esters[2b]), keto ethers[2aa,2bb] (or alkoxy ketones,[2aa,2bb] such as ethoxyacetone,[2bb] ethoxymethyl ethyl ketone,[2bb] toloxypropanones,[7] and thiophenoxyacetone[2x]), anhydride,[6a] chalcones,[3d] 2-undecanone,[2o] phloroglucinol,[2m] 2-acetylphenothiazine,[10] and lactam acetal.[11] From these carbonyl compounds, the unsymmetrical methyl ketones often result in the formation of 2-alkyl quinolines.[2u] However, for alkyl aryl ketones, such as $ArC(O)(CH_2)_nCH_3$, only ketones with $n < 3$ can undergo this reaction, due to the steric hindrance;[2v] similarly, ketones with a general form of $ArC(O)CH_2Ar'$ don't undergo this reaction if Ar′ carries a large *ortho*-substituent, even when Ar′ carries two small methyl groups.[4d]

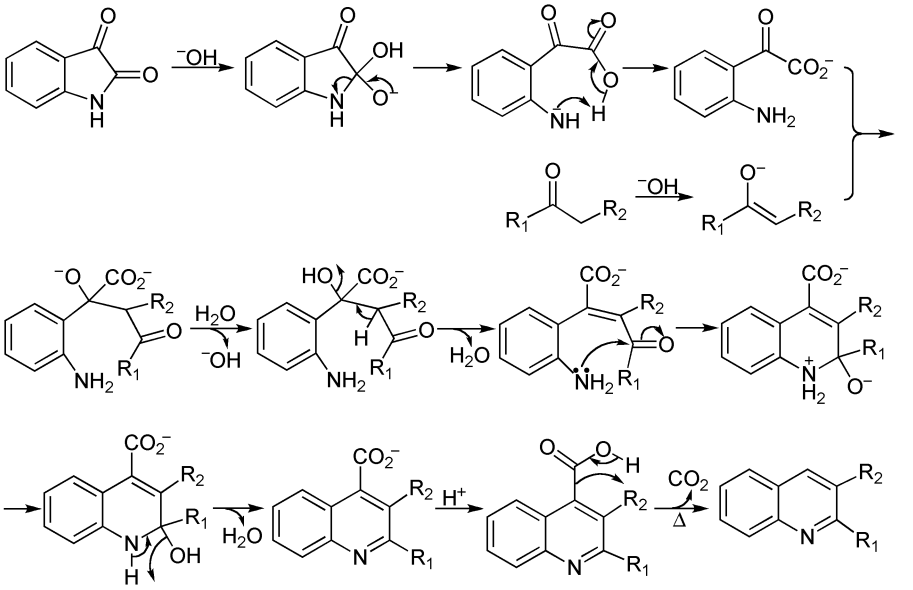
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a general mechanism for this reaction.



D. MODIFICATION

This reaction has been modified to occur under acidic conditions[4b,12] and microwave irradiation.[2e]

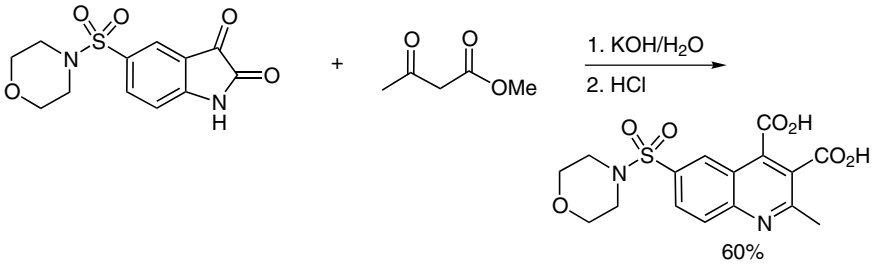
E. APPLICATIONS

This reaction has a broad application in the preparation of quinoline derivatives.

F. RELATED REACTIONS

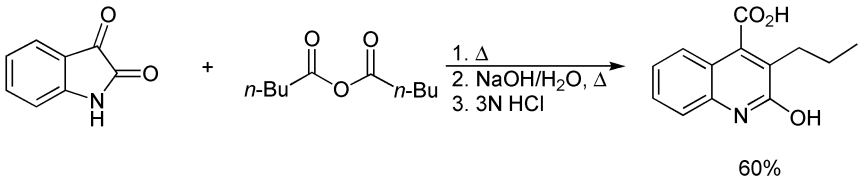
This reaction is related to the *Friedländer Condensation* and *Niementowski Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

To a suspension of 13.33 g 5-(morpholin-4-ylsulfonyl)-1*H*-indole-2,3-dione (45 mmol) in 100 mL H_2O, was added 20 g KOH under a nitrogen atmosphere. Then 14.62 g methyl acetoacetate (126 mmoL) was added, and the reaction mixture was stirred for 12 h. The mixture was cooled to 0°C, then 40 mL conc. HCl was slowly added. The resulting precipitate was filtered off, washed with water, and dried in vacuo at 70°C to give 60% 2-methyl-6-(morpholine-4-sulfonyl)-3,4-quinolinedicarboxylic acid.



Reference 6.

A mixture of 10 g isatin (68 mmol) and 18 mL valeric anhydride was heated under refluxing for 3 h. The resulting solution was then allowed to cool to room temperature, and the solid formed was collected by filtration, washed with small amounts of Et_2O, dried, and suspended in 30 mL H_2O. Sodium hydroxide pellets (4.3 g, 110 mmol) were added, and the resulting mixture was refluxed for 3 h, cooled, and acidified with 3 *N* HCl. The precipitate was collected by filtration, washed with cold water, and then dried under reduced pressure to constant weight, to afford 8.0 g 2-hydroxy-3-propyl-4-quinolinecarboxylic acid as a white solid, in a yield of 60%, m.p. 266–268°C.

Other references related to the Pfitzinger reaction are cited in the literature.[13]

Pfitzner-Moffatt Oxidation

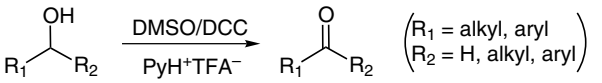
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pfitzner and Moffatt in 1963.[1] It is the oxidation of primary and secondary alcohols to the corresponding aldehydes and ketones under mild and almost neutral conditions by the combination of dimethyl sulfoxide (DMSO) and dicyclohexylcarbodiimide (DCC) in the presence of a proton source, such as phosphoric acid or pyridinium trifluoroacetate. This method was initially known as the Pfitzner-Moffatt technique,[2] and is now referred in general to as the Pfitzner-Moffatt oxidation.[3] Occasionally, it is called the Moffatt oxidation,[4] and the combination of DMSO and DCC is known as the Pfitzner-Moffatt reagent.[5] This reaction is applicable to primary and secondary hydroxyl groups in a variety of compounds, including alkaloids, steroids, and carbohydrates, in which other functional groups such as olefin, amine, tosylate, and tertiary hydroxyl groups are not affected.[2] However, this reaction also has some drawbacks. For example, the equatorial OHs in steroids are readily oxidized, whereas some axial OHs are inert to the Pfitzner-Moffatt reagent.[6] In addition, the oxidation of nucleotides with free 3′-hydroxyl groups such as thymidine 5′-phosphate and free 3′-hydroxyl containing nucleosides in the presence of anhydrous phosphoric acid, leads to the cleavage of the *N*-glycosidic bond and the release of the nitrogenous bases.[7] In this reaction, the amount of DMSO can be 10–100% of solvent, in combination with another inert molecule, such as benzene, as the co-solvent.[2] Strong mineral acids such as H_2SO_4, HCl, and $HClO_4$ are not good activators for DMSO.[2] It has been proposed that this reaction involves the activation of DMSO by DCC through an acid-catalyzed process, followed by an alcohol attack to form dimethylalkoxysulfonium salt and *N*,*N*′-dicyclohexylurea, and the formation of carbonyl compounds via proton transfers

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

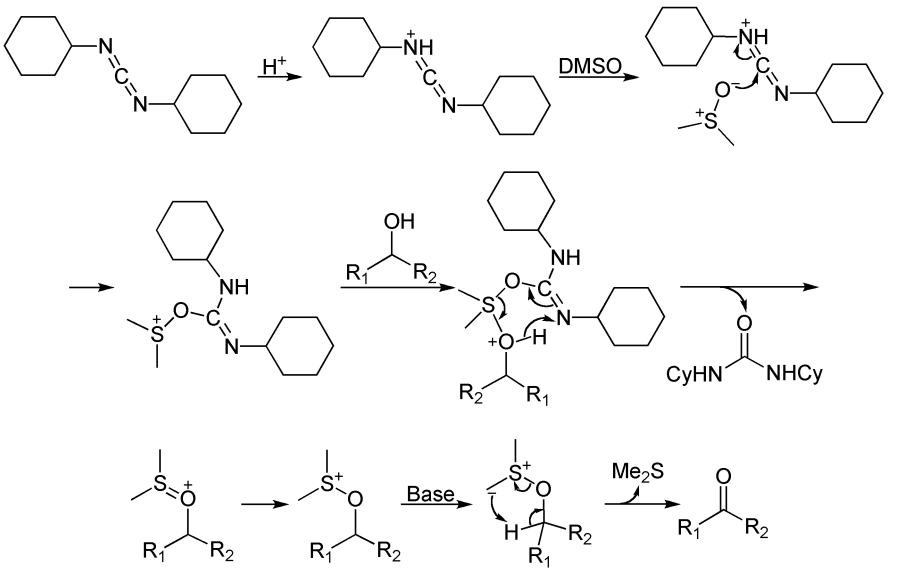
and the evolution of dimethylsulfide.[2,8] Sometimes, this reaction also yields by-products of $R_2CHO\text{-}CH_2SCH_3$ arising from the rearrangement.[2]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the mechanism for Pfitzner-Moffatt oxidation in the presence of both an acid and base.



D. MODIFICATION

N/A

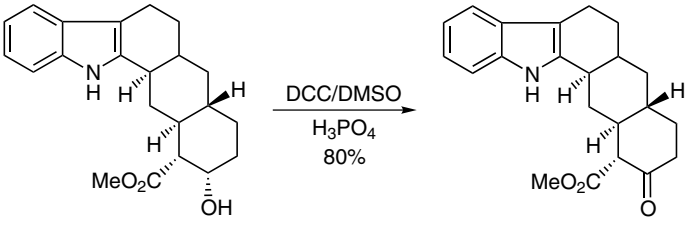
E. APPLICATIONS

This reaction has general application in the oxidation of primary and secondary alcohols to corresponding aldehydes and ketones.

F. RELATED REACTIONS

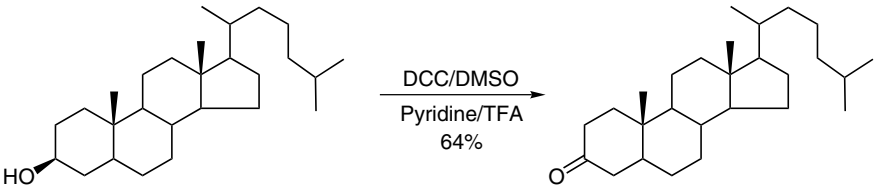
This reaction is related to the *Albright-Goldman Oxidation, Kornblum Oxidation*, and *Parikh-Doering Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a solution of 28.32 g yohimbine (0.080 mol) and 49.04 g DCC (0.24 mol) in dry DMSO (120 mL) was added 12.0 g crystalline orthophosphoric acid (0.12 mol). The mixture was allowed to stand for 17 h at room temperature and was diluted with CH_2Cl_2. The solid was filtered, and the product remained in the filter cake as a phosphate salt and was extracted from the *N*,*N*′-dicyclohexylurea with hot acetic acid water (1:2). Basification of the chilled extract with concentrated NH_4OH, filtration, and trituration of the solid with alcohol afforded 80% yohimbinone, m.p. 250–254°C (dec.).



Reference 10.

A mixture of 1.16 g cholestan-3β-ol (2.99 mmol), 1.85 g DCC (8.98 mmol), 0.24 mL pyridine (3 mmol), 5 mL DMSO (74 mmol), and 0.12 mL trifluoroacetic acid (1.5 mmol) was stirred for 5 h at room temperature. The addition of dry EtOAc to the reaction solution resulted in the precipitation of *N*,*N*′-dicyclohexylurea, which was filtered, washed with dry benzene. The filtrate was washed with water, dried, and concentrated in vacuo. The residue was chromatographed on Woelm neutral alumina to give 32% of cholestan-3β-ol and 64% of cholestan-3-one.

Other references related to the Pfitzner-Moffatt oxidation are cited in the literature.[11]

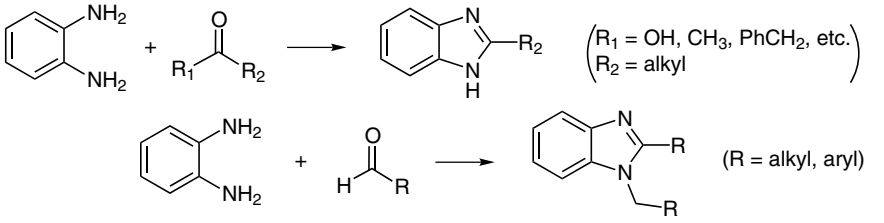
Phillips-Ladenburg Benzimidazole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

Although the first benzimidazole was prepared by Hobrecker in 1872,[1] it was Ladenburg who extensively explored the preparation of benzimidazole derivatives by the condensation between *ortho*-amino aniline and carbonyl compounds (aldehydes and ketones) in 1875.[2] Subsequently, Phillips further extended Ladenburg's preparation to the condensation between *ortho*-amino aniline and acetic acid[2a] to produce different kinds of carboxylic acids in the presence of dilute mineral acid.[3] Therefore, the preparation of benzimidazole from *ortho*-amino aniline is referred to as the Ladenburg method,[4] Phillips method,[4c] Phillips modification,[5] or the Phillips-Ladenburg reaction.[6] It has been proposed that the condensation between *ortho*-amino aniline and carbonyl compounds involves the formation of a Schiff base intermediate,[4b] whereas the condensation between *ortho*-amino aniline and acid proceeds via the *N*,*N*′-diacyl and monoacyl intermediate.[7] This condensation generally works for aliphatic acids[5] and is feasible for aromatic acids if the condensations are carried out above 180°C in sealed reaction vessels.[8]

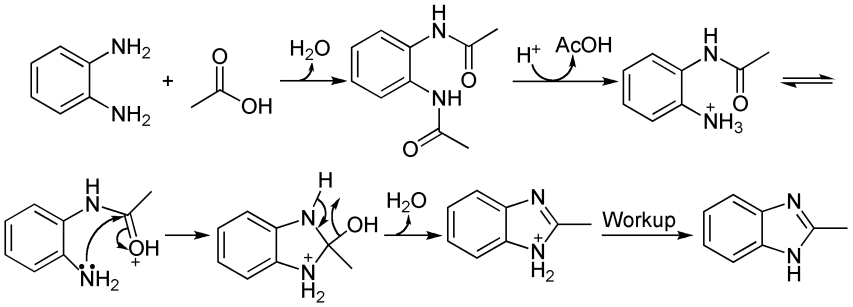
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism for the conditions of the Phillips modification—that is the condensation between *ortho*-amino aniline and carboxylic acid—is exemplified by the reaction with acetic acid in the presence of mineral acid.



D. MODIFICATION

This reaction has been modified for preparing oxazole, thiazole, and perimidine derivatives from the condensation of the corresponding *o*-aminophenol, *o*-aminobenzenethiol, and 1,8-naphthalenediamine with ketones.[9]

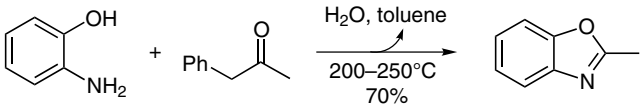
E. APPLICATIONS

This reaction is very useful in the preparation of benzimidazole derivatives.

F. RELATED REACTIONS

N/A

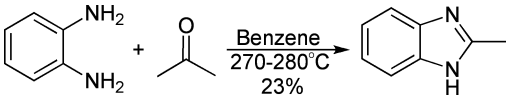
G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A mixture of 11 g *o*-aminophenol (0.1 mol) and 27 g benzyl methyl ketone (0.2 mol) was heated in a flask equipped with an inside thermometer and a condenser set downward for distillation for 6 h. The heating was maintained so that a temperature of $\approx 200^{\circ}$C was rapidly approached in the first hour and slowly raised to 250°C at the end of 6 h. The slightly yellow distillate (10 g) collected in the ice-cooled receiver consisted of two layers. The lower layer

(1–2 g) was found to be water, which had formed in the course of the reaction. The entire distillate was then taken up in 25 mL ether and dried over anhydrous Na_2SO_4. The filtered ether solution was fractioned, and the fraction boiling at 110–111°C (3 g) was identified as toluene by oxidation to benzoic acid with potassium permanganate. The dark brown viscous residue in the reaction flask was further distilled under reduced pressure, and the fraction coming over at 135–145 °C at 114 mmHg (10 g) was crude 2-methylbenzoxazole in 70% yield.



Reference 4b.

A mixture of 5.4 g fresh *o*-phenylenediamine recrystallized from heptane and water, 29.0 g acetone, and 20 mL dry benzene was heated. The initial gas evolution temperature was 260°C, and heating was carried out at 270–280°C for 2 h, during which time ~ 600 mL gas was evolved. Upon removal of volatile substances, successive recrystallizations from water of the heated residue gave 1.5 g 2-methylbenzimidazole as white leaflets, in a yield of 23%, m.p. 174.5–175.5°C.

Other references related to the Phillips-Ladenburg benzimidazole synthesis are cited in the literature. [10]

Photo-Fries Rearrangement
(Photo-Fries Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

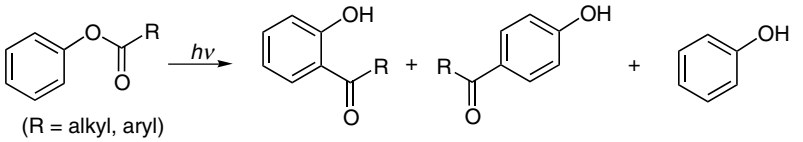
This reaction was first reported by Anderson and Reese in 1960.[1,2] It is the photo-initiated intramolecular[3] rearrangement of phenyl or aryl esters to isomeric acyl phenols or other acyl hydroxyl aromatics via acyl and phenoxy or aryloxy radical pairs. Because it is similar to the Lewis acid-promoted *Fries Rearrangement* discovered by Fries in 1908,[4] the photo-initiated rearrangement of phenyl or aryl esters is generally known as the photo-Fries rearrangement[5,6] or photo-Fries reaction.[5c,5h,7] This reaction is usually carried out in an aprotic solvent,[3a] proceeding directly from the lowest excited singlet state of ester[2,5a,5c] with quantum yields in the range of 0.1–0.3,[5a] and often competes with the de-excitation of the excited singlet state of the resulting phenol, which normally absorbs 10–100 times stronger than its precursor.[2b] This reaction is affected by electronic nature of substrate as well as the reaction environment. Although no apparent isotopic effect has been observed within an experimental error of 2%,[7k] the electron-deficiency of the carboxyl carbon and electron-enrichment of the *ortho*-position of the phenol ring facilitate the homolytic cleavage of C-O bond to form both phenoxy and acyl radicals.[8] For example, phenol *para*-cyano benozate rearranges faster than phenol *para-t*-butylbenzoate.[8] The photo-generated phenoxy and acyl radicals might combine together to form the precursor again or might form *ortho*- or *para*-acyl phenol before these radicals escape from the solvent cage to yield phenol. Thus the *ortho*- or *para*-acyl phenol is known as the *cage product*.[5d,5i] Compared with the normal Fries rearrangement catalyzed by Lewis acid, which gives predominantly *para*-acyl phenol product,[9] the photo-Fries rearrangement produces *ortho*-acyl phenol as the major product,[5f] even though it is known that both the *ortho*- and the *para*- positions of phenol are electron rich[10] because "formation of *para*-acyl phenol requires a greater extent of rotation of radical" than that in *ortho*-product. This regioselectivity is even enhanced when the photo-Fries rearrangement is carried out within a restricted environment, such as in the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

presence of zeolite. For example, less than 10% of *para*-products are formed from both phenyl acetate and phenyl benzoate within Li- and Na*X*, and *Y* zeolites, whereas no *para*-products are produced in K*X* and K*Y* zeolites.[7h] Similarly, only substituted 2-naphthols are observed from 1-naphthyl acetate and 1-naphthyl benzoate in *X* and *Y* zeolites.[5e] Occasionally, the migration of an acyl group to the *meta*-position is also noted.[7p,11] It should be pointed out that certain antibodies are capable of catalyzing the photo-Fries rearrangement.[5c]

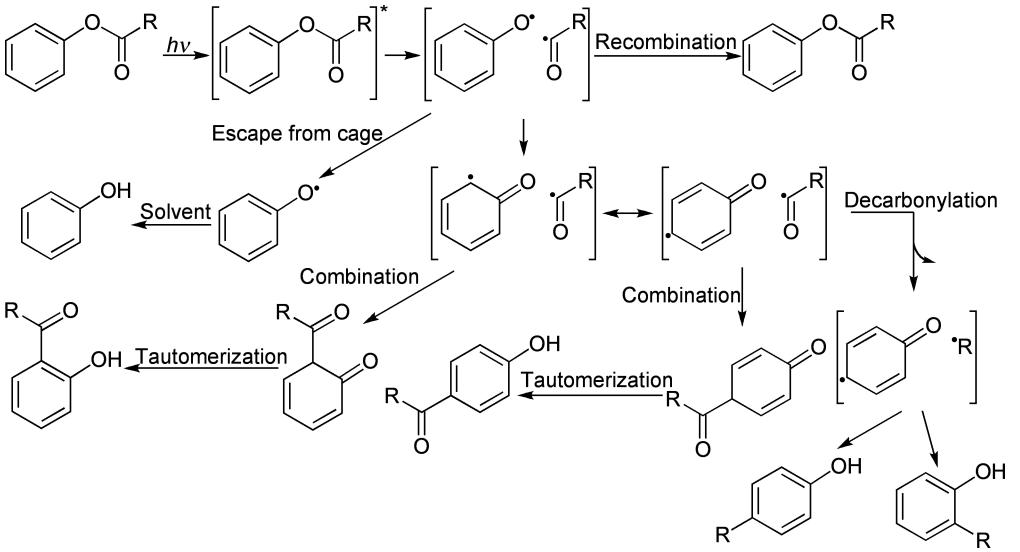
Besides phenyl and aryl esters, other kinds of compounds can also undergo the homolytic cleavage from photo-irradiation, such as amide,[6vv,6uuu] diphenyl ether,[2b,5c] phenyl benzyl ether,[2b] aryl sulfonate,[6zz,12] acetanilide,[6oo,12b,13] sulfonanilide,[6hh,14] *N*-arylsulfonamides,[6h] phenylsulfamates,[15] benzenesulfonanilide,[6hh] *N*-sulfonylcarbazoles,[6ll] aryl *N*-chloroacetylanthranilates,[6x] *N*-phenyl-urethane,[6oo] and phenyl cinnamate.[6sss,6eeee,7m,16] In the case of unsymmetrical phenyl ether, the actual homolytic cleavage pathway (i.e., via aryloxy-phenyl or aryl-phenoxy cleavage), depends on the substituents and correlates with the Hammett σ constants.[5c] The special case of rearrangement for acyl anilide is known as the photoanilide rearrangement.[17] Although the photo-Fries rearrangement is known to occur via the first excited singlet, the rearrangement of phenylsulfamates and cinnamates occur via the upper triplet excitation states.[15,18]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism is displayed here including the processes of radical recombination, decarbonylation, and rearrangement.



D. MODIFICATION

This reaction has been modified extensively to proceed under different conditions. For example, it has been performed in liquid crystalline matrixes,[6gg] in zeolite,[7f] in supercritical CO_2,[5g] on a silica gel surface,[6ggg] or in the presence of cyclodextrin.[3a,6o,6v,6z,6hh,6mm,6oo,7b,19] In addition, this reaction has been catalyzed by photoacid.[6ff] Moreover, this reaction has been extended to various substrates other than the regular phenyl (or aryl) esters as described earlier.

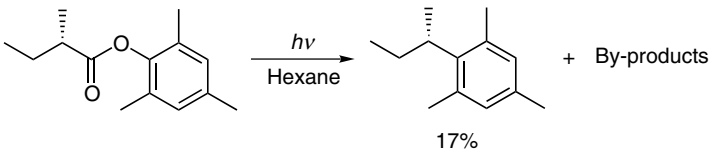
E. APPLICATIONS

This reaction may not be very useful in the actual organic synthesis because of its different by-products.

F. RELATED REACTIONS

This reaction is related to the *Fries Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5a.

To 150 mL hexane was added 124 mg 2,4,6-trimethylphenyl (*S*)-(-)-2-methylbutyrate (0.56 mmol). The solution was placed in a doughnut-shaped quartz flask that was irradiated from a low-pressure mercury lamp at 25°C for 12 h while argon was bubbled through. Upon removal of solvent, the residue was chromatographed on a silica-gel column with hexane/ether (10:1) as the eluent to afford 17 mg (*S*)-(+)-2-methylpropyl-2,4,6-trimethylbenzene (17% isolated yield and 26% conversion), 43 mg starting material (35% recovery), and 25 mg unidentified products.

Other references related to the photo-Fries rearrangement are cited in the literature.[20]

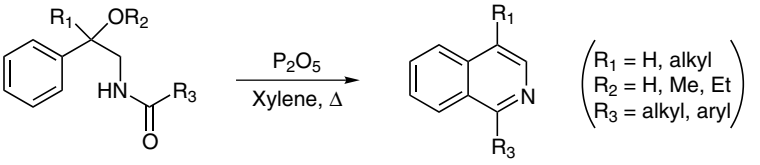
Pictet-Gams Synthesis
(Pictet-Gams Cyclization)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pictet and Gams in 1910.[1] It is the transformation of *N*-acyl 2-hydroxy (or alkoxy) phenylethylamine into isoquinoline derivatives by the treatment with a dehydration agent such as P_2O_5 in toluene or xylene.[2] This reaction is a modification of the *Bischler-Napieralski Isoquinoline Synthesis*,[3] and is generally known as the Pictet-Gams reaction,[3f,4] Pictet-Gams synthesis,[2,4a–4e,5] or Pictet-Gams isoquinoline synthesis.[4d,4e,6] Occasionally, it is also referred to as the Pictet-Gams cyclization,[5,7] or Pictet-Gams ring closure reaction.[8]

This reaction is a stepwise reaction[3f] involving the loss of the first water (or alcohol) molecule to form the styrylamide intermediate,[2,3f,9] followed by a ring closure and loss of the second water molecule. Although this reaction overcomes the further dehydrogenation in the *Bischler-Napieralski Isoquinoline Synthesis*,[3b] it is trammeled by the availability of its starting material,[5] and the occasional formation of oxazoline by-products,[2,3f,5,9a] as in the case of *N*-acyl 2-trifluoromethyl-2-hydroxy-phenylethylamine.[7] It is recommended that the treatment of carbinol by an alkaline-dehydrating agent, such as the Grignard reagent, would reduce the amount of oxazolines formed.[9b]

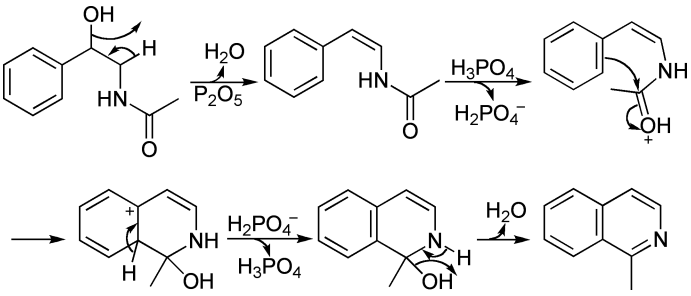
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A representative mechanism is displayed here for *N*-acetyl 2-hydroxy phenylethylamine.



D. MODIFICATION

$POCl_3$ has been applied as the dehydration reagent.[3b,5]

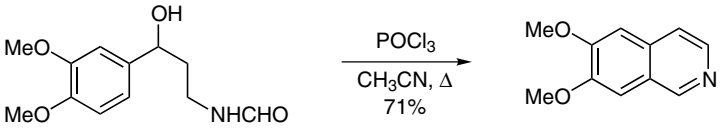
E. APPLICATIONS

This reaction is useful for the preparation of isoquinoline derivatives.

F. RELATED REACTIONS

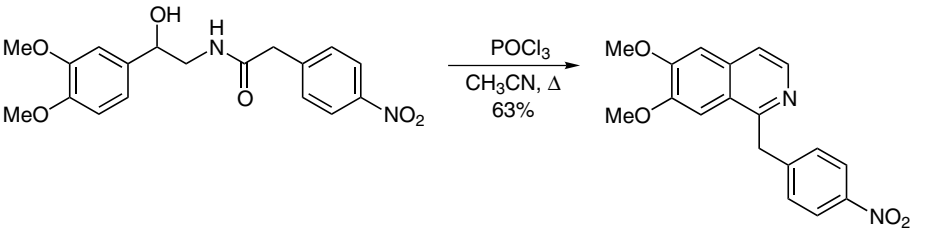
This reaction is related to the *Bischler-Napieralski Isoquinoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To a refluxing solution of 1.0 g *N*-[2-hydroxy-2-(3,4-dimethoxyphenyl)ethyl]formamide in 40 mL CH_3CN was added 2 mL $POCl_3$ mixed with 5 mL CH_3CN dropwise. After 1 hour, the mixture was cooled, the solvent was evaporated, and the residue was transferred to a separation funnel by ice water and washed with ether. The aqueous layer was basified with conc. NH_4OH and extracted with CH_2Cl_2. Upon removal of solvent, the residue was chromatographed to afford 0.628 g 6,7-dimethoxyisoquinoline, in a yield of 71%, m.p. 89–90°C.



Reference 3b.

A mixture of 0.12 mol *N*-[2-hydroxy-2-(3,4-dimethoxyphenyl)ethyl]-4-nitrobenzeneacetamide and 27.5 g $POCl_3$ (0.18 mol) in 500 mL CH_3CN was refluxed for 30 min. After the mixture was cooled, the solvent was removed under reduced pressure. The residue was dissolved in 400 mL 4 N HCl and washed with $CHCl_3$ (2×200 mL); the aqueous layer was basified with 50% NaOH and extracted with $CHCl_3$ (2×100 mL). The combined $CHCl_3$ extracts were dried over $MgSO_4$. Upon removal of solvent, the residue was purified by silica gel column chromatography ($CHCl_3$/MeOH/NH_4OH, 94:5:1). The collected fraction was dried and recrystallized from $CHCl_3/Et_2O$ to afford 63% 6,7-dimethoxy-1-(4-nitrobenzyl)isoquinoline, m.p. 195–196°C.

Other references related to the Pictet-Gams synthesis are cited in the literature.[10]

Pictet-Spengler Reaction

(Pictet-Spengler Cyclization, Pictet-Spengler Condensation)

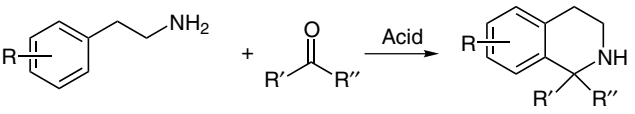
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pictet and Spengler in 1911.[1] It is the synthesis of tetrahydroisoquinoline or tetrahydro-β-carboline derivatives by the condensation of an arylethylamine and a carbonyl compound, primarily an aldehyde. Therefore, this reaction is generally known as the Pictet-Spengler reaction.[2,3] In addition, this reaction is also referred to as the Pictet-Spengler cyclization,[2a,2c,2g,3rr,4] Pictet-Spengler condensation,[3cc,5] or the Pictet-Spengler synthesis.[2c,3ss,6] Occasionally, it is called the Pictet-Spengler heterocyclization.[3ab] It is known that this reaction involves the formation of an imine from aldehyde and arylethylamine, which under acidic conditions electrophilically attacks the aromatic ring via the iminium intermediate to give tetrahydroisoquinolines.[2a] A comparable reaction from ketones may involve the formation of an enamine intermediate. Arylethylamine, such as phenylethylamine, phenylalanine, and tyrosine are all feasible amines,[2a] whereas certain aldehydes and ketones are not suitable candidates for this reaction, including acetone[2g] and some benzaldehydes with an *ortho*- electron-donating group.[4w] This reaction is best carried out under acidic conditions,[2a] although examples under basic conditions are also known.[7] The extension of this reaction by the formation of an *N*-acyliminium intermediate from the acylation of imine with acyl halide is now known as the *N*-acyliminium Pictet-Spengler reaction,[2a,3u,3y,3kk,8] *N*-acyliminium Pictet-Spengler condensation,[8e] or acyl Pictet-Spengler reaction,[3v,3hh] and has been adapted to solid-support condition promoted by a Lewis acid.[2a] Likewise, the cyclization of 2-aryl ethanol under similar reaction conditions gives [3,4]-benzo-dihydropyran derivatives and is referred to as the *oxa*-Pictet-Spengler reaction,[3p,3gg,3uu] or *oxa*-Pictet-Spengler cyclization.[4e,4m,4n]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

It has been found that in aqueous solution HCl and trifluoroacetic acid are superior to CH_3COOH, HCOOH, CSA, and TCA.[8c] Current studies of this reaction focus on the diastereoselective and enantioselective synthesis of tetrahydroisoquinolines via chirality transfer from the auxiliary group of either the arylethylamine or the carbonyl component,[2c,3sss,3uuu,9] or the application of chiral Lewis acid.[3oo,10]

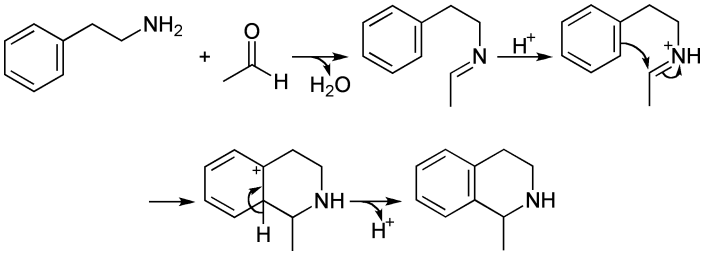
B. GENERAL REACTION SCHEME



R = electron-donating substituent
R′ = alkyl, aryl with electron-withdrawing group
R″ = H (preferred), alkyl

C. PROPOSED MECHANISMS

The mechanism is exemplified by the reaction between phenylethylamine and acetaldehyde in the presence of an acid.



D. MODIFICATION

This reaction has been extensively modified to different variants, such as the solid-support reaction,[3ll,3aaaa] *N*-acyliminium Pictet-Spengler reaction,[2a,3u,3v,3y,3hh,3kk,8] *oxa*-Pictet-Spengler reaction,[3p,3gg,3uu,4e,4m,4n] and stereoselective version of Pictet-Spengler reaction,[2c,3sss,3ooo,3uuu,9,10] In addition, the *N*-sulfonyl[3o] or sulfinyl[3xx] Pictet-Spengler reaction, and the keteniminium Pictet-Spengler cyclization[4o] and vinylogous Pictet-Spengler cyclization[2g] have also been reported. Moreover, this reaction has been promoted by microwave[3bb,3dd] or catalyzed by protic acid,[6c] superacid,[4q] or Lewis acid,[3ooo] such as $AuCl_3$/AgOTf,[8a] $Yb(OTf)_3$-TMSCl,[3ww] and zeolite.[3ff]

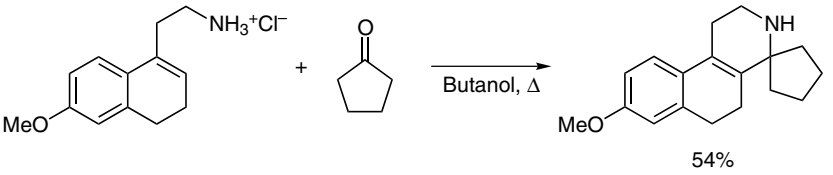
E. APPLICATIONS

This reaction has a wide and important application in alkaloid synthesis.[2g,5l]

F. RELATED REACTIONS

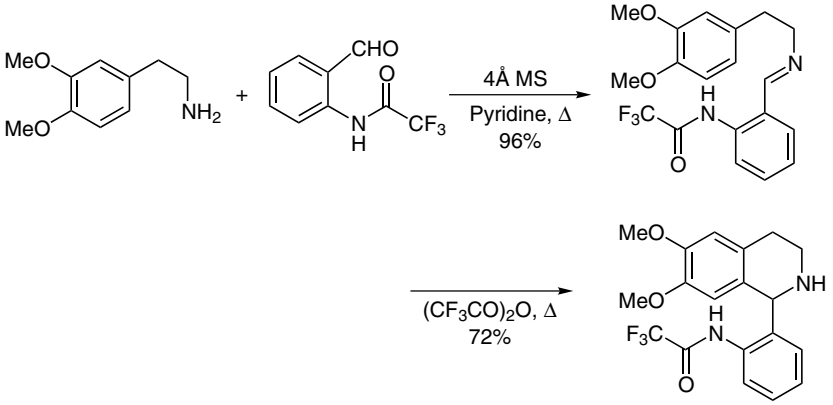
This reaction is related to the *Bischler-Napieralski Isoquinoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2g.

To 3 mL butanol were added 100 mg 2-(6-methoxy-3,4-dihydronaphthalen-1-yl)-ethylamine hydrochloride (0.45 mmol) and 53 mg cyclopentanone (0.63 mmol). The solution was then refluxed for 72 h, extracted with EtOAc, and washed with aqueous $NaHCO_3$. Upon removal of the solvent, the residue was purified by column chromatography to afford 60.4 mg 4-spirocyclopenta-8-methoxy-1,2,3,4,5,6-hexahydrobenzo[*f*]isoquinoline as a white solid, in a yield of 54%, $R_f = 0.19$ (MeOH/$CHCl_3$, 1:4).



Reference 4w.

A mixture of 2.17 g 2-(trifluoroacetylamino)benzaldehyde (10.0 mmol), 1.81 g homoveratrylamine (10.0 mmol), 1.0 g 4Å molecular sieves, and 15 mL pyridine was refluxed for 36 h. After filtration, the filtrate was concentrated under reduced pressure, and the resulting residue was purified on silica gel column using EtOAc/hexanes (2:3) as the eluent to afford 3.65 g *N*-[2-(3,4-dimethoxyphenyl)ethyl]-2-(trifluoroacetylamino)benzylidenimine as a yellow solid, in a yield of 96%. Recrystallization from EtOH afforded 3.0 g yellow needles, in a yield of 78%, m.p. 116.5°C. Then 1.0 g of the solid (2.63 mmol) was mixed with 3.0 mL trifluoroacetic anhydride (21.4 mmol), and the resulting mixture was heated at 80°C for 24 h. After removal of the volatiles in vacuo, the residue was purified by flash

chromatography using EtOAc/hexanes (1:2) as the eluent to give 900 mg 6,7-dimethoxy-2-(trifluoroacetyl)-1-[2-(trifluoroacetylamino)phenyl]-1,2,3,4-tetrahydroisoquinoline as a yellow solid, in a yield of 72%, m.p. 74.5°C.

Other references related to the Pictet-Spengler reaction are cited in literature.[11]

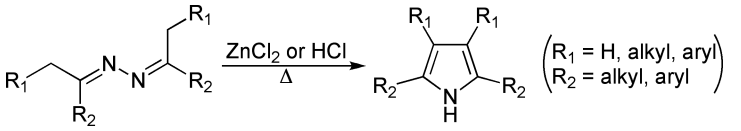
Piloty-Robinson Pyrrole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Piloty in 1910.[1] It is the thermal transformation of enolizable ketazines into pyrrole derivatives in the presence of a catalytic amount of Lewis acid (e.g., $ZnCl_2$) or Brønsted acid (e.g., HCl)[2] and is known as the Piloty pyrrole synthesis,[2,3] Piloty reaction,[3,4] Piloty cyclization,[4b] or Piloty synthesis.[4b,5] In 1918, Robinson extensively studied this reaction again, especially for the mechanism,[6] since then the Piloty pyrrole synthesis has also been referred to as the Piloty-Robinson pyrrole synthesis[7] or simply the Piloty-Robinson synthesis[7b,8] or Piloty-Robinson reaction.[8a] It should be pointed out that for the thermal transformation of aliphatic ketazines, a competitive route also occurs to give pyrazoline as a by-product.[6,9]

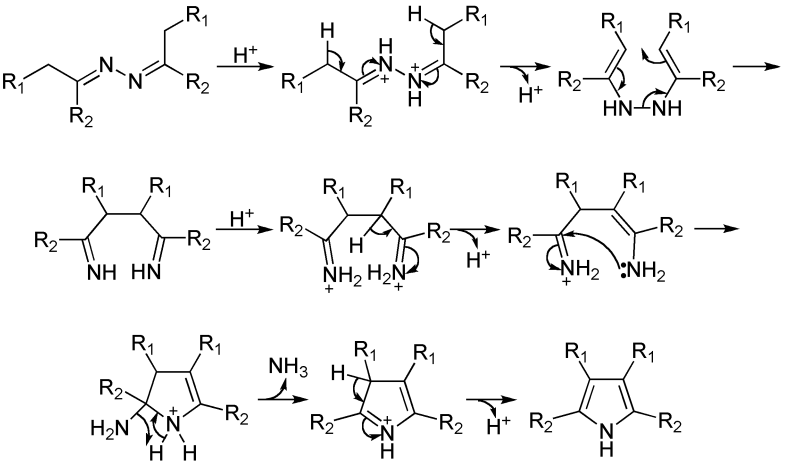
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It has been proposed that this reaction involves a series of processes, including the tautomerization of ketazine into bisvinylhydrazine, [3,3] rearrangement, ring formation, and the subsequent elimination of ammonia, as shown below.[7b,8c,9]



D. MODIFICATION

This reaction has been modified to occur under solid-supported condition[5a] or under microwave irradiation.[8a] In addition, the base-promoted transformation from ketazine into pyrrole has also been established by the treatment of alkyl aryl ketazine with two equivalents of strong base, such as LDA.[2] However, such reaction can lead to the formation of pyrrole, tetrahydropyridazine, or pyrazole, depending on the nature of ketazine. In general, the ketazine dianions with an electron-donating group at their carbon termini form pyrroles, whereas ketazine dianions without a substituent at the terminal carbon or with an electron-withdrawing group at the terminal carbon yield tetrahydropyridazines and pyrazoles.[2]

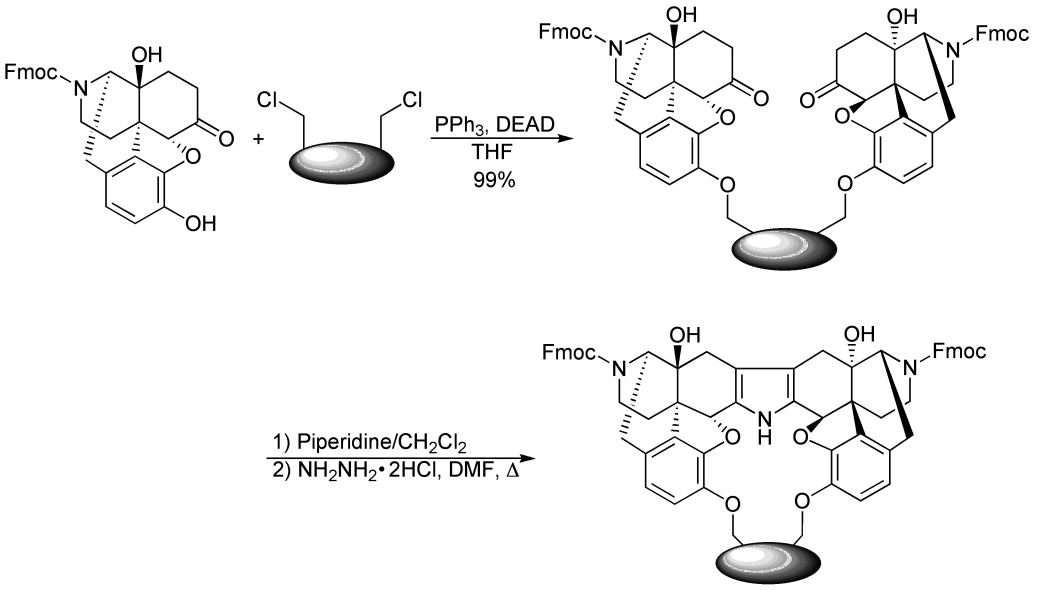
E. APPLICATIONS

This reaction is generally useful for the preparation of pyrrole derivatives.

F. RELATED REACTIONS

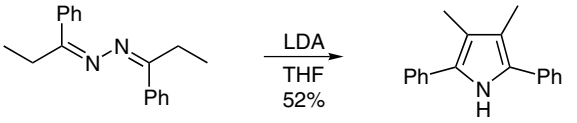
This reaction is related to the *Fischer Indole Synthesis, Hantzsch Pyrrole Synthesis, Knorr Pyrrole Synthesis* and *Paal-Knorr Pyrrole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5a.

To a mixture of 4.58 g morphinan (9.0 mmol), 3.0 g Wang resin (0.52 mmol/g, 1.56 mmol), and 1.33 g PPh_3 (5.1 mmol) in 30 mL anhydrous THF was added 2.04 mL 40% toluene solution of diethylazodicarboxylate (DEAD, 4.5 mmol) dropwise for 15 min at room temperature. The mixture was shaken at the same temperature for 16 h then the reaction solvent was removed by filtration. The remaining resin was washed three times, each with 30 mL DMF, MeOH, THF, and CH_2Cl_2, respectively, and dried in vacuo to afford 4.41 g resin, in a yield of 99%. This resin was then suspended in 35.2 mL CH_2Cl_2, and 8.8 mL piperidine was added dropwise at room temperature. The mixture was shaken at this temperature for 16 h and the solvent was removed by filtration. The remaining resin was washed three times, each with 40 mL DMF, MeOH, THF, and CH_2Cl_2, respectively, and dried in vacuo to afford 4.26 g of a new resin. This resin was again suspended in 42 mL DMF, and 865 mg hydrazine dihydrochloride (8.4 mmol) was added directly at room temperature. The mixture was heated at 50°C for 24 h and then allowed to cool to room temperature. The solvent was removed by filtration. The resulting resin was washed three times, each with 40 mL DMF, MeOH, THF, and CH_2Cl_2, respectively, and dried in vacuo to afford 4.04 g the resin bound pyrrole derivative.



Reference 2.

Under argon, a solution of 3.3 mmol diisopropylamine in 10 mL dry THF was treated with 3.3 mmol *n*-BuLi (15% hexane solution) at 0°C. After 10 min, 1.5 mmol propiophenone azine in 5 mL THF was added to the LDA solution at room temperature. Immediately, the yellow color of the starting ketazine turned to deep reddish brown and gradually to deep green within a few minutes. After being stirred for 24 h at room temperature, the reaction mixture was quenched with degassed water and extracted with ether. After drying over Na_2SO_4 and evaporation of the solvent, 52% 3,4-dimethyl-2,5-diphenylpyrrole was isolated through silica gel column chromatography using benzene as an eluent, m.p. 138–139°C.

Pinacol Coupling Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Fittig in 1859.[1] It is a synthesis of vicinal diols from carbonyl compounds via reductive coupling. Because vicinal diol (or 1,2-diol) is generally known as pinacol, the reductive coupling of carbonyl compounds to give vicinal diols is known simply as the pinacol coupling[2] or pinacol coupling reaction.[2a,2j,2m,2s,2u,2w,3,4] Specifically, the coupling between two different carbonyl groups is referred to as pinacol cross-coupling[5] or cross-pinacol coupling,[6] whereas the dimerization of a carbonyl group itself to give a symmetrically substituted 1,2-diol is called homo-pinacol coupling.[6] It is known that this reaction involves the initial single electron transfer (SET) from a low-valent metal to the carbonyl group to form a ketal radical, which then couples to form pinacol.[2q,2r,3e,7] Therefore, the molecules, which can be reduced to radicals or radical anions, undergo similar radical coupling reaction. Some of these molecules are aldehydes,[2h,2l,2u,3c,8] ketones,[2l,2r,3k,5b,9] α-ketoamides,[2j] α,β-unsaturated amides,[3f] alkyl dinitrone,[2c] benzaldimines (i.e., Schiff bases),[10] ferrocenylideneamine,[6] and aldehyde complexes.[2s]

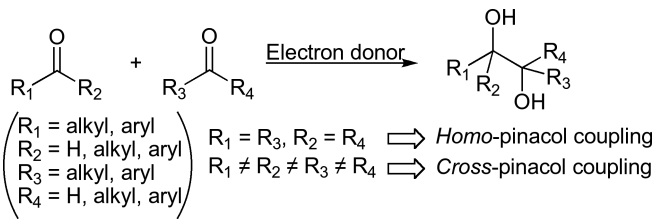
On the other hand, the large number of low-valent metals and their salts or complexes that can function as single-electron donors all are able to promote this reaction, thus different reaction systems have been established. These electron donors fall into different categories: single metals, metal salts, metallic redox pairs, metal cation complexes, hydrides, multi-component systems, and others. Among these electron donors, single low-valent metals that have been applied for the pinacol coupling include Al,[2l] Ce,[2q] Fe,[2q] In,[2l] Mg[2l] (or Rieke Mg[11]), Mn,[2l] Nb,[2t] Sn,[2t] U,[2g] Al,[12] and In;[2l] in addition, Mg[2l] and Mn[2l] have even been used for the aqueous pinacol coupling reactions, such as the Mg mediated pinacol coupling in 0.1 M NH_4Cl solution[2m] under ultrasound irradiation.[8] The metal salts that are suitable for this reaction are Ce(O-*t*-Bu)$_3$,[2h] SmI_2,[2j,3f] Sm(OTf)$_3$,[3a] $TiCl_3$,[2k,2l,2m] and $TiCl_4$/EtCN.[3e]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

It is interesting that SmI_2 can promote the coupling of α,β-unsaturated amides to give 1,6-diamides,[3f] whereas $TiCl_4$/EtCN initiates the coupling of α,β-unsaturated aldehyde selectively to give *dl*-diol;[3e] $Sm(OTf)_3$ produces (*R*,*R*)-diol.[3a] The metallic redox pairs include Al-Hg,[2a] Mg-Hg/$TiCl_4$,[9] Et_2AlI/Sm,[2l] SmI_2/Mg,[2r] $SmCl_3$/Sm,[2d] $SmCl_3$/Mg,[2d] $TiCl_3(DME)_{1.5}$/Zn-Cu,[13] VCl_3/Al,[2a] and $ZnCl_2$/Zn.[2l] Among these metallic redox pairs, $SmCl_3$/Mg,[2d] $SmCl_3$/Sm,[2d] VCl_3/Al[2a] and $ZnCl_2$/Zn[2l] have also been used to promote the pinacol coupling in aqueous solution. It has been suggested that for the system of SmI_2/Mg, the concentration of metals should be higher than that of ketone to lower the possibility of side reactions, such as *Benzoin Condensation* and *Tishchenko Reaction*.[2r] The metal cation complexes that are feasible for pinacol coupling are the complexes of chromium (II),[2l] titanium (e.g., $[Cp_2TiCl]_2$,[2k,2l,2t,14] Cp_2TiPh,[2f] Ti(III)-salen,[3d] and titanium-Schiff base complexes[2g,2l]), vanadium (e.g., $[V_2Cl_3(THF)_6]_2[Zn_2Cl_6]$,[2w,3j,5a,15] $Cp_2VCl_2/Me_3SiCl/Zn$,[3h,3i] and Cp_2VCl_2/$PhMe_2SiCl$/Al/imidazole[10]), and zirconium (e.g., anionic zirconaoxirane[5b]). Among these metal cation complexes, $[Cp_2TiCl]_2$ can be used for both anhydrous and deoxygenated aqueous solutions,[2k] which gives very high diastereoselectivity. Similarly, Cp_2TiPh shows a high *threo*-selectivity,[2f] and $[V_2Cl_3(THF)_6]_2[Zn_2Cl_6]$ selectively induces the formation of *syn,syn*-diols.[15] As for the hydrides that have been used for the pinacol coupling, Bu_3SnH,[2m,2n,2u] Ph_3SnH,[2q] Bu_3GeH,[2q] and $(TMS)_3SiH$[2q] have all been proven to be good electron carriers. Besides the systems mentioned for the pinacol coupling, there are many complicated systems that consist of at least three components, such as TBOxCr(III)Cl/Mn/Et_3SiCl,[3c] Mg/TMSCl/HMPA,[2r] SmI_2/HMPA/*t*-BuOH,[2j] Sm/I_2/Ti(O-*i*-Pr)$_4$,[2l] SmI_2/Mg/TMSCl/HMPA,[2b] Ti(III)/Zn/TMSCl,[2l] and tricarbonyl(benzaldehyde)chromium/SmI_2[2s]. It should be pointed out that the multicomponent system of tricarbonyl(benzaldehyde)chromium/SmI_2 gives only high *threo*-selectivity, whereas Sm/I_2/Ti(O-*i*-Pr)$_4$ mediated pinacol coupling must be carried out in anhydrous alcohol.[2l] Other reaction conditions use Al/KOH in dry MeOH,[2l] SmI_2/TMSCl,[2l] and $TiCl_4$/tetrabutylammonium iodide (or $MePh_3PI$ or $MeEt_3NI$);[16] the last system works only for aromatic aldehydes affording high *dl*-selectivity.

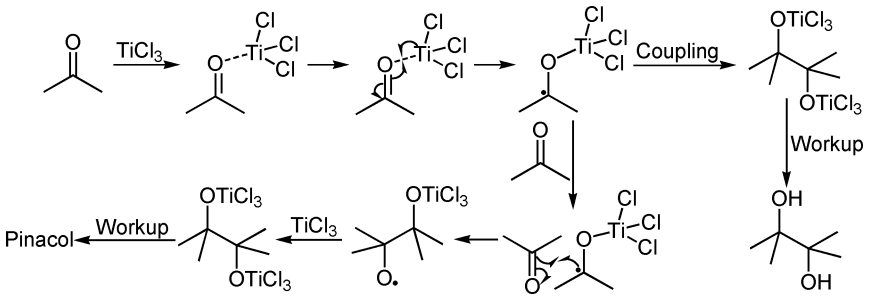
It should be pointed out that the homogeneous reaction conditions often give higher diastereoselectivies than the heterogeneous ones;[3g] in addition, trialkylchlorosilanes appearing in a few of these reaction systems are believed to cleave the metal-oxygen bond to recycle the catalysts,[17] by which triethylsilylchloride may offer better stereoselectivity than trimethylsilylchloride.[3c] On the other hand, certain pinacol couplings are reversible because of the newly formed carbon-carbon bonds are unusually weak, such as those in tetraarylpinacol.[3k] In addition, some ketones because of the steric hindrance will not undergo the pinacol coupling, such as 2,2,6,6-tetramethylcyclohexanone.[3k]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

An illustrative mechanism is displayed here for the coupling of acetone in the presence of $TiCl_3$, in which the carbonyl oxygen may coordinate to $TiCl_3$ and a single electron transfer occurs to give a ketal radical. The ketal radicals may couple together to give a pinacol dianion or attack a second carbonyl group to give alkoxy radical that is then reduced by $TiCl_3$ to a pinacol dianion. Final workup yields the pinacol.



D. MODIFICATION

This reaction has been extensively modified by the use of different single electron transfer systems as described in Section A, in either anhydrous or aqueous solution.

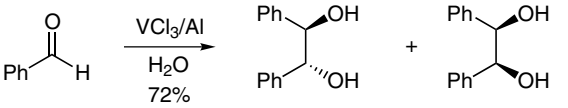
E. APPLICATIONS

This reaction has general application in the preparation of vicinal diols.

F. RELATED REACTIONS

This reaction is related to the *McMurry Coupling*.

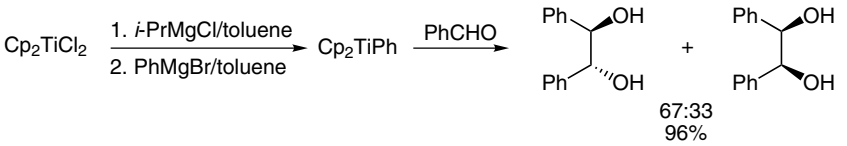
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

A suspension of 81 mg activated aluminum powder (3 mmol) and 52 mg VCl_3 (0.33 mmol) in 1–2 mL water was stirred for ~5 min at room temperature. Then 0.106 gram of benzaldehyde (1 mmol) was added to the mixture, which was stirred vigorously for

3 days. The reaction was quenched with 1 N HCl, and extracted with ether (3 × 30 mL). The combined organic layers were washed with brine, dried over Na_2SO_4, and filtered. The filtrate was concentrated under reduced pressure, and the residue was purified by silica gel column chromatography using hexanes/EtOAc (3:1) as the eluent to afford 72% pinacol product with a *dl*/*meso* ratio of 56:44.



Reference 2f.

To a suspension of 747 mg Cp_2TiCl_2 (3.0 mmol) in 10 mL dry degassed toluene was added a solution of freshly prepared *i*-PrMgCl from 259 mg *i*-PrCl (3.3 mmol) and 160 mg Mg (6.6 mmol) in 5 mL dry degassed ether under an argon atmosphere at room temperature. The reaction mixture was stirred for 30 min. To the resultant green solution was added a solution of freshly prepared PhMgBr from 471 mg phenyl bromide (3.0 mmol) and 146 mg magnesium (6.0 mmol) in 5 mL dry degassed ether at room temperature; the reaction mixture was stirred for further 30 min. To this dark green Cp_2TiPh solution, 212 mg benzaldehyde (2 mmol) was added at room temperature, and the reaction mixture was stirred for 1 h. The reaction was quenched by 10 mL 1 N HCl, and the mixture was stirred for 30 min. The organic layer was separated and washed with 20 mL brine. The aqueous layer was extracted with EtOAc (20 mL × 3). The combined organic layers were dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by silica gel flash column chromatography using hexanes/EtOAc (2:1) as the eluent to give 206 mg hydrobenzoin as white solids, in a yield of 96%.

Other references related to pinacol coupling reaction are cited in the literature.[18]

Pinacol Rearrangement

(Pinacol-Pinacolone Rearrangement)

A. GENERAL DESCRIPTION OF THE REACTION

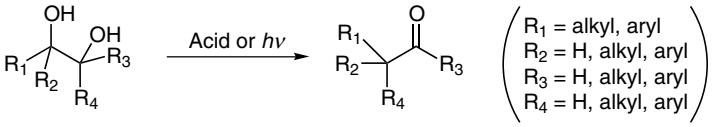
This reaction was first reported by Fittig in 1860.[1] It is an acid-promoted 1,2-rearrangement of vicinal diols to corresponding aldehydes or ketones. Because the vicinal diols are commonly called the pinaocls, this transformation is generally known as the pinacol rearrangement[2,3] or pinacol-pinacolone rearrangement.[2e,2g,4,5] Although this reaction is often carried out in H_2SO_4,[2m,2o,2r,2s,2v,2z,2aa,2bb,4c,6] many other acidic conditions have also been successfully used for this reaction, including the application of Brønsted and Lewis acids. Examples of Brønsted acids are HCO_2H,[2v] $HClO_4$,[2p,7] AcOH with a catalytic amount of H_2SO_4,[2x] AcOH with iodine,[8] and silica gel impregnated with H_3PO_4;[6d] representative Lewis acids include BF_3 in acetic acid,[2cc] $ZnCl_2$ in acetic anhydride,[2cc] $MgBr_2$,[9] and $AlCl_3$ in the absence of solvent.[2b] Some of these conditions produce higher yields than the corresponding rearrangements performed in H_2SO_4. For example, when pinacol is passed over a silica gel impregnated with H_3PO_4, it is converted into pinacolone in 94% yield, whereas the same reaction in H_2SO_4 yields only 65–72% product.[6d] It is agreed that this reaction is a stepwise rearrangement involving the formation of a carbocation intermediate by the dehydration of the protonated diol,[2e,2g,2k,2m,4b,10] the rate-limiting step,[2k] and the skeletal rearrangement by the migration of a neighboring substituent to the carbocation site.[10] However, both the computational[2g] study and the experimental results for the reaction in gas-phase or aprotic solvents[6b,11] indicate that a concerted mechanism dominates over the stepwise mechanism, because the dehydration of protonated diols is facilitated through the stabilization of resulting carbocation, and the activation energy for the 1,2-rearrangement of the stabilized carbocation is higher than a concerted pinacol rearrangement.[2g]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

On the other hand, to make this rearrangement a practical tool for organic synthesis, it is very important to know which hydroxyl group will be dehydrated and which group will migrate in both symmetric and asymmetric pinacols. The regioselectivity for this rearrangement is determined by the formation of the primarily formed carbocations,[10] the acid used,[2z,2ac,12] and the migratory aptitudes of the substituents on the vicinal diols.[2e] It is possible that in an asymmetric pinacol, the decrease of the basicity of one hydroxyl group caused by its neighboring substituents might facilitate the protonation on the other hydroxyl group.[2m] In addition, it has been reported that for certain pinacol rearrangements, the treatment by Brønsted and Lewis acids leads to different pinacolones.[2z,2ac,12] The migratory aptitudes of substituents on diols are generally determined by their electron density and steric hindrance. The groups with high electron density are easier to migrate than are the groups with electron deficiency, because such migration groups will rearrange to the new-formed carbocation.[12,13] Thus cyclopropyl,[2g] vinyl,[2g] 2-thienyl,[13] 2,5-dimethyl-3-thienyl,[2y] and 2-furyl[13] groups are all good migratory groups, whereas 2- and 3-pyridyl groups have smaller migratory aptitudes than a phenyl group.[2y] In addition, a good migratory group might not move in the pinacol rearrangement unless it can reach the adjacent carbon atom by a single movement from the opposite face of the leaving hydroxyl group,[2f] involving the so-called *Walden Inversion*.[2ee,2gg] Thus the electron-donating group, such as methoxy, enhances the migratory aptitude of the phenyl group at the *para*-position but depresses the aptitude when it sits at the *ortho*-position.[2x,4h] Similarly, the migratory aptitude of groups may be reversed between symmetric and asymmetric pinacols.[2o,4g] In addition, it has been established that the migration is stereospecific, with retention of the configuration of the migrating group.[2d,6a,14] It should be pointed out that both solvent[2bb] and temperature[2p] will affect the outcome of the pinacol rearrangemet. For example, the pinacol rearrangement can occur regularly in primary or secondary alcohols but not in tertiary alcohols because tertiary alcohols will be protonated and hydrated as well.[2x,2bb]

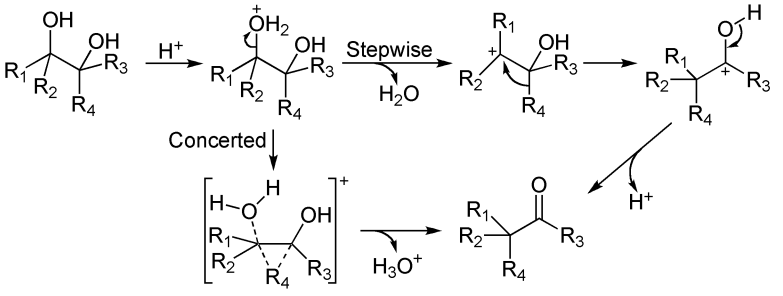
Beside pinacols, some other molecules can undertake a similar reaction through the formation of a carbocation and migration of a group to the carbocation, such as α-halohydrins,[2dd] α-hydroxy epoxides,[12,15] and aziridines.[15a] The rearrangement of aziridines under similar conditions is known as the *aza*-pinacol rearrangement,[15a] whereas α-hydroxy epoxides undergo semi-pinacol rearrangements to give aldols.[15b] Moreover, a similar rearrangement involving a double bond is referred to as the vinylogous pinacol rearrangement.[16] Furthermore, the pinacol rearrangement, promoted by photo-irradiation,[2j,10,17] thermolysis,[16] or in supercritical CO_2[18] can also occur in the absence of an acid; the photo-irradiation activated pinacol rearrangement is generally called photochemical pinacol rearrangement.[2j,10,17]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple pinacol rearrangement promoted by a protic acid is displayed here, including both stepwise and concerted pathways, though the stepwise route is the primary pathway.



D. MODIFICATION

This reaction has been extensively modified by the application of different initiation systems, including a variety of Brønsted and Lewis acids, photochemical irradiation, and supercritical CO_2. In addition, this rearrangement has been successfully extended to α-halohydrin, aziridines, and α-hydroxy epoxides, as noted in Section A.

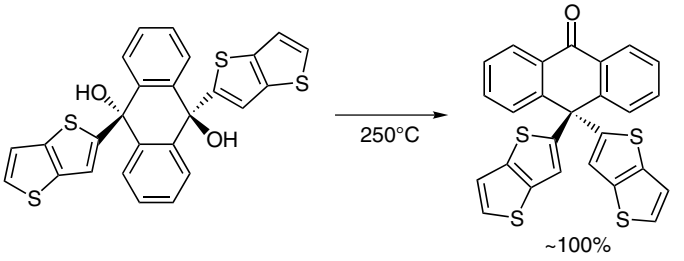
E. APPLICATIONS

This reaction has very broad application in organic synthesis.

F. RELATED REACTIONS

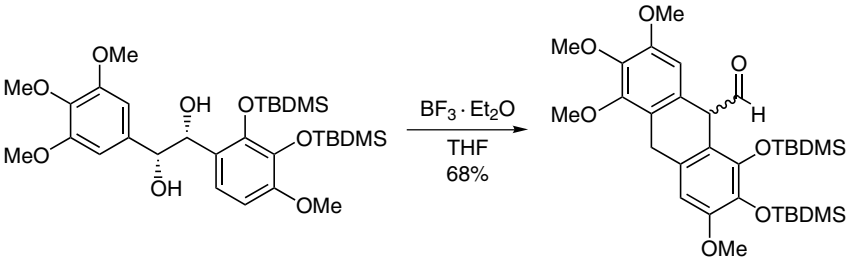
This reaction is related to the *Nametkin Rearrangement, Retropinacol Rearrangement*, *Tiffeneau Reaction*, and *Wagner-Meerwein Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 16.

Trans-9,10-bis(thieno[3,2-*b*]thienyl)-9,10-dihydroxy-9,10-dihydroanthracene (3.1 g, 6.3 mmol) was heated to 250°C on a hot plate equipped with a thermometer under a stereomicroscope to yield 2.92 g 10,10-bis(thieno[3,2-*b*]thienyl)-9,10-dihydroanthracene-9-one (6.2 mmol) in almost quantitative yield. An analytically pure sample was obtained by recrystallization from CH_2Cl_2/hexane, m.p. > 330°C.



Reference 2d.

$BF_3{\cdot}Et_2O$ (0.82 mL, 6.7 mmol, 2 eq.) was added dropwise to a stirred solution of 2.1 g (1*R*,1*R*)-1-[2′,3′-di[(*tert*-butyldimethylsilyl)oxy]-4′-methoxyphenyl]-2-(3,4,5-trimethoxyphenyl) ethane-1,2-diol (3.3 mmol) in 20 mL anhydrous THF under argon at room temperature. After 1 h, saturated aqueous $NaHCO_3$ was added to the mixture before extraction with EtOAc (4 × 15 mL) and drying of the combined organics. Evaporation of the solvent in vacuo afforded a light brown oil, which was subjected to flash column chromatography using hexanes/EtOAc (15:1) as the eluent to afford 1.3 g (±)-2-(2′,3′-di[(*tert*-butyldimethylsilyl)oxy]-4′-methoxyphenyl)-2-(3,4,5-trimethoxyphenyl)acetaldehyde as a clear oil that crystallized from MeOH as a colorless solid, in a yield of 68%.

Other references related to the pinacol rearrangement are cited in the literature.[19]

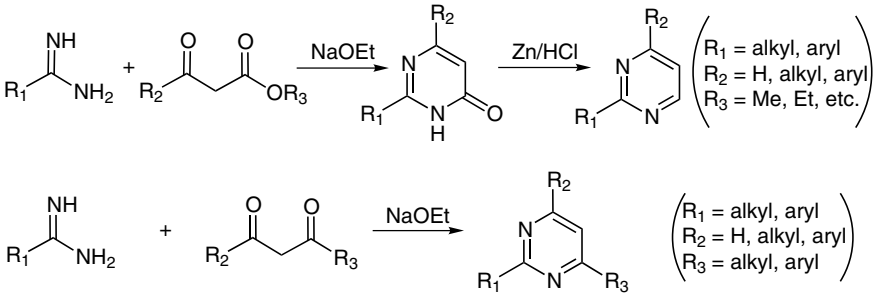
Pinner Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pinner in 1884.[1] It is a strong base-promoted condensation between a non-*N*-substituted amidine and a β-keto ester[2] or β-diketone[2b,3] to form a type of nitrogenous heterocycle known as pyrimidine, suggested initially by Pinner.[4] Thus it is referred to as the Pinner condensation[2a,5] or Pinner synthesis.[6] However, the preparation of pyrimidine hydrocarbon depends on the successful reduction of the carbonyl group at the 6-position and dehydration,[4] which in some cases is extremely difficult with reducing reagents such as zinc in either NaOH or HCl solution,[2d] although zinc reduction is the most commonly used method.[4] It has been found that using an excess amount of sodium ethylate at high temperature can result in pyrimidine in higher yield,[6] even though extending the reaction time has no obvious effect on the yield.[7]

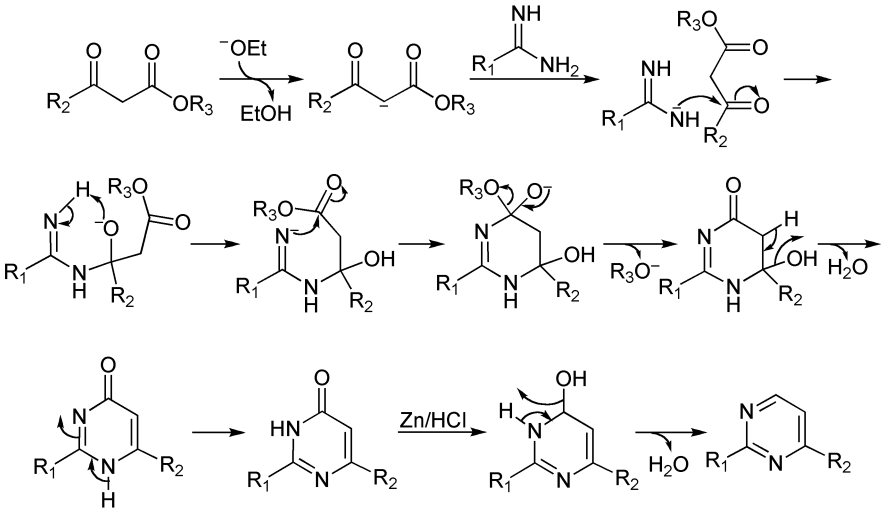
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Only the mechanism of the reaction between amidine and β-keto ester is provided here because the reaction between amidine and β-diketone undergoes a similar reaction pathway.



D. MODIFICATION

This reaction has been extended to the condensation between amidine and β-cyano ester,[8] amidine and β-hydroxyacetylene,[9] amidine and malonate,[10] *N*-vinyl amidine and acetal,[11] and a three-component reaction of amidine with aldehyde and acetylene.[12]

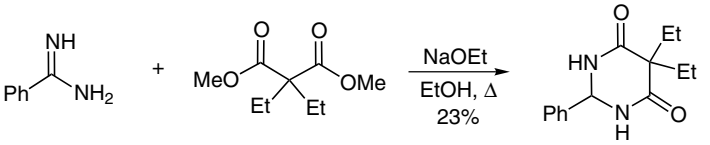
E. APPLICATIONS

This reaction is one of the most common methods for the preparation of pyrimidine derivatives.

F. RELATED REACTIONS

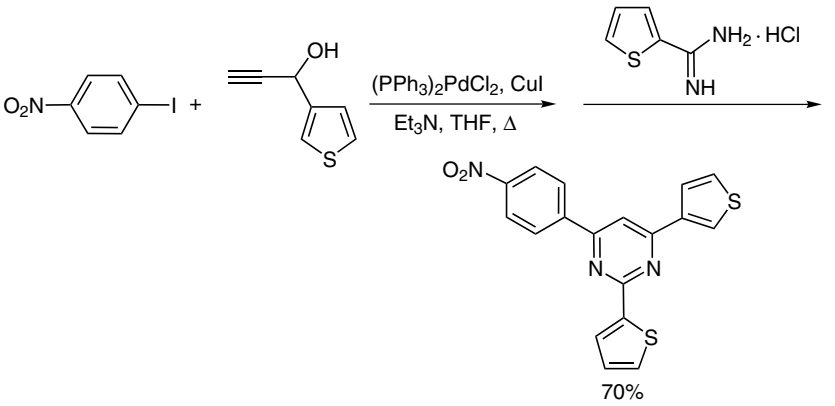
This reaction is related to the *Pinner Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a 75 mL solution of NaOEt in absolute ethanol prepared by addition of 4.5 g sodium in absolute ethanol were added 9.0 g benzamidine hydrochloride and 10 g carefully purified methyl α,α-diethylmalonate. The mixture was heated for 5 h at 70°C. The alcohol was partially removed by a current of dry air, and the residue was acidified with a slight excess of conc. HCl. After removal of the precipitated NaCl, the solution was further concentrated on the steam bath. The addition of water caused 5,5-diethyl-2-phenyl-4,6-diketo-tetrahydro-pyrimidine to separate in white needles, in an amount of 3.0 g. The product was further purified by recrystallization from dilute acetic acid.



Reference 9.

To a magnetically stirred solution of 0.25 g 4-iodo nitrobenzene (1.0 mmol), 22 mg $Pd(PPh_3)_2Cl_2$ (0.02 mmol), and 2 mg CuI (0.01 mmol) in a degassed mixture of 10 mL THF and 5 mL triethylamine under nitrogen was added a solution of 145 mg 1-(3-thienyl)-propyn-1-ol (1.05 mmol) in 10 mL THF dropwise at room temperature over a period of 30 min. The mixture was refluxed for 16 h and was allowed to cool to room temperature. Then 165 mg 2-thienyl amidinium chloride (1.0 mmol) was added, and the reaction mixture was refluxed again for 48 h. After cooling, the solvents were removed in vacuo, and the residue was dissolved in CH_2Cl_2 and filtered through a short pad of silica gel. The solvents were evaporated in vacuo, and the residue was recrystallized from CH_2Cl_2/pentane to give 255 mg analytically pure 2-(2-thienyl)-4-(3-thienyl)-6-(4-nitrophenyl) pyrimidine as a beige powder, in a yield of 70%.

Other references related to the Pinner condensation are cited in the literature.[13]

Pinner Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction was first reported by Beckurts and Otto in 1876,[1] the extensive studies on this reaction appeared in Pinner's work in 1877.[2] It is the transformation of nitriles into imidines or their salts by the treatment of nitriles with an excess of strong acid and one equivalent of alcohol followed by an excess of ammonia or amines. Therefore, it is generally known as the Pinner synthesis,[3a−3c] or Pinner reaction.[3d−3g] This reaction is generally carried out at 0°C[3c,4] with anhydrous ethanol and an excess amount of hydrochloric acid in a dry solvent, such as $CHCl_3$,[5] nitrobenzene,[5] dioxane,[6] benzene,[3b,5,7] or ether,[7b,8] affording five types of imidines, depending on the applied nitrogenous components. According to the substitution and distribution patterns of groups on nitrogen, imidines can be divided into unsubstituted (**I**), monosubstituted (**II**), symmetrically disubstituted (**III**), asymmetrically disubstituted (**IV**), and trisubstituted imidines (**V**), as shown in Figure 1.[9] The extremely reactive trichloroacetonitrile can react with alcohol in the absence of acid.[10] Besides ethanol and methanol, other alcohols are suitable for this reaction, including propanol,[11] isopropanol,[12] butanol,[11] isobutanol,[2a] octanol,[13] decanol,[13] benzyl alcohol,[14] phenol,[15] and thiophenol.[11,16] In addition, almost all the aromatic and aliphatic nitriles can undergo this reaction,[9] with only a few exceptions, such as the acyl cyanides (e.g., acetyl and benzoyl cyanides),[9] certain *ortho*-substituted aromatic nitirles (e.g., *o*-tolunitrile, 2-nitro-4-methylbenzonitrile, 2-amino-4-methylbenzonitrile, α-naphthonitrile),[9] and 9,9′-bifluoryl-1,1′-dinitrile.[17] It should be emphasized that this reaction must be carried out under anhydrous conditions, because imidine is not stable enough in the presence of moisture and can decompose to a nitrile or ester.[9] Especially, in the presence of a hydrogen ion, the formation of ester is accelerated.[9] In addition, in the presence of an excess amount of alcohol, the *ortho* ester may be generated from the imido ester intermediate.[3c]

B. GENERAL REACTION SCHEME

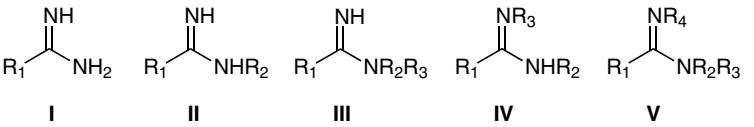

FIGURE 1. *Five types of imidines.*

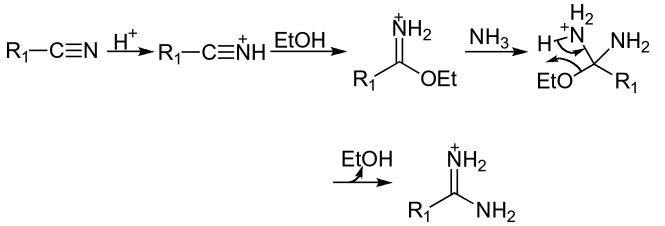
C. PROPOSED MECHANISMS

A general mechanism is illustrated here for the reaction of nitrile with ethanol and ammonia.



D. MODIFICATION

N/A

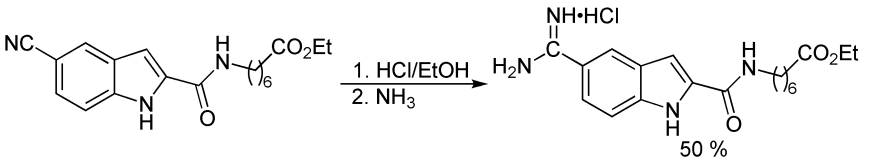
E. APPLICATIONS

This reaction is still the general method for the preparation of imidines. In addition, the thioimidate salts from thioglycolic acid has been used to the characterization of nitriles.[18]

F. RELATED REACTIONS

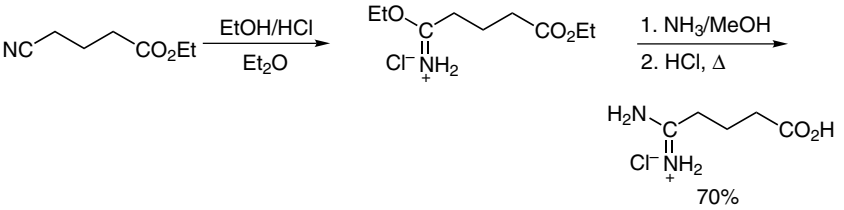
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 19.

A solution of 1.50 g heptanoic acid 7-[[(5-cyano-1*H*-indol-2-yl)carbonyl]-amino] ethyl ester (4.18 mmol) in 250 mL EtOH was treated with a stream of HCl gas for 30 min. The reaction vessel was sealed, and the solution was stirred for 48 h until ^{1}H NMR indicated the completion of conversion to the imino ether. The reaction was concentrated in vacuo, reconstituted in EtOH, and evaporated in vacuo again. The residue was taken up in 250 mL EtOH, and the mixture was treated with a stream of NH_3 gas for 30 min. The vessel was sealed, and the contents were stirred for 24 h for the consumption of imino ether. The reaction mixture was concentrated in vacuo to afford 820 mg of the corresponding amidino ester hydrochloride as a white solid, in a yield of 50%.



Reference 8a.

A solution of 9.84 g ethyl 4-cyanobutyrate (69.3 mmol) and 8.5 mL absolute ethanol (145 mmol) in 100 mL dry ether was cooled in an ice bath before gently saturating with HCl gas. The solution was then allowed to come to room temperature before capping the flask tightly and stirring at room temperature for 18 h. The solution was concentrated in vacuo to a viscous oil that rapidly solidified on standing. To the residue was added 40 mL 2.0 M ammonia in methanol (80 mmol) with ice bath cooling. The mixture was stirred vigorously for 5 min before the ice bath was removed. Stirring was continued for 1 h. The solvent was evaporated in vacuo, leaving a yellow oil and a solid. Then 100 mL absolute ethanol was added, and the mixture was stirred until all of the oil had dissolved. The mixture was chilled overnight at -20°C and filtered. Concentration of the filtrate in vacuo left an oil that still contained some solid. The mixture was then taken up in 100 mL $CHCl_3$ and filtered again. Concentration of the filtrate left $\sim$ 15 g crude amidine ester as a viscous yellow oil, which was dissolved in 150 mL conc. HCl and stirred at 95°C (bath temperature) for 1 h. The solution was concentrated in vacuo (aspirator first, then 0.5 mmHg), leaving 10.8 g pale yellow crystalline solid, of which 9.84 g solid was purified by recrystallization from 130 mL absolute ethanol and 0.5 mL pyridine to give 7.34 g 5-amino-5-iminopentanoic acid as white flakes, in a yield of 70%, m.p., 175–176°C.

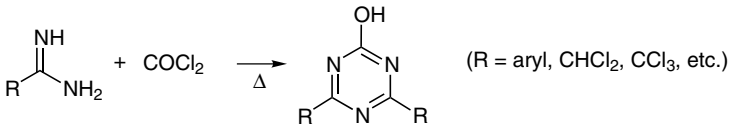
Pinner S-Triazine Synthesis
(Pinner Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pinner in 1890.[1] It is the synthesis of 2-hydroxy-4,6-diaryl-*sym*-triazines (or *sym*-triazines) from the condensation of aryl amidines and phosgene via the intermediate of bisimidylurea[2] and is known as the Pinner synthesis.[2,3] It has been found that a large amount of bisimidylurea intermediate can be isolated when the reaction is carried out in an ice-salt cooled bath, whereas the yield of *sym*-triazine is enhanced when the reaction temperature is increased.[2] However, this reaction might not be suitable for aliphatic amidines, including propionamidine,[1] caproamidine[1] and acetamidine,[2] except for the alkylamidines with strong electron-withdrawing groups, such as α,α,α-trichloroacetamidine, which trimerizes to form *sym*-triazine at room temperature.[4] Alternatively, other types of *sym*-triazines can be prepared from the thermal trimerization of amidine, such as by heating benzamidine to 115°C,[5] or treating simple *sym*-triazine with amidine.[6] It should be pointed out that Pinner also reported an alternative method for the preparation of *sym*-triazine from the direct trimerization of benzonitrile with fuming sulfuric acid as early as 1878.[7]

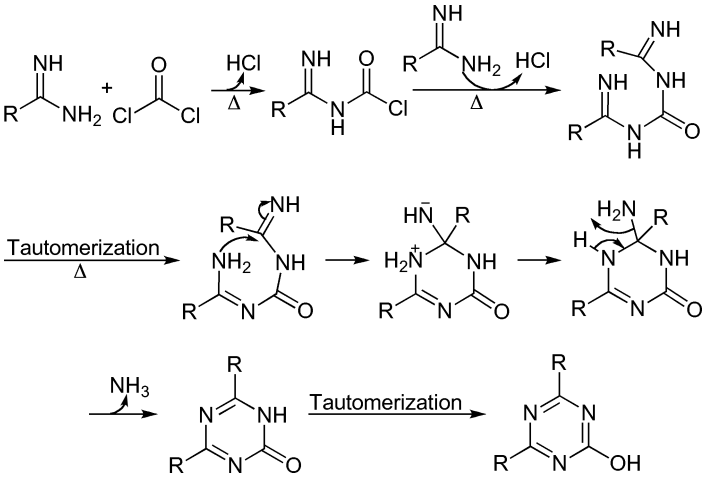
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is a tentative mechanism for this reaction.



D. MODIFICATION

This reaction has been extended to the trimerization of imidates,[8] and the reaction between amidine salt and imidate.[9] In addition, the reaction between amidrazone and α,β-dicarbonyl compounds has been used for the preparation of *as*-triazines or 1,2,4-triazines.[10]

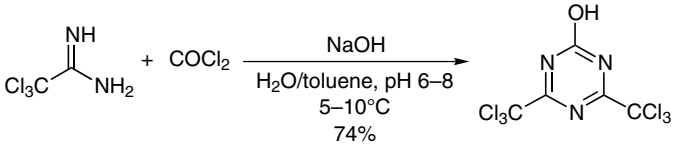
E. APPLICATIONS

This reaction is useful for the preparation of *sym*-triazines.

F. RELATED REACTIONS

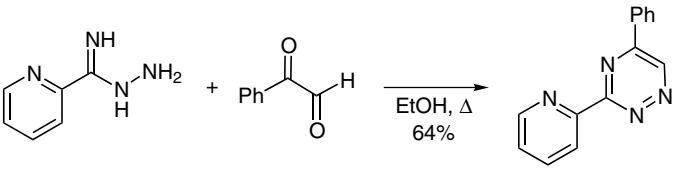
This reaction is related to the *Pinner Reaction* and *Pinner Condensation.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To 400 mL H_2O at 25°C was added 54.0 g trichloroacetamidine (0.33 mol) under stirring. The amidine dissolved completely upon the addition of approximately one quarter of a solution of 20 g NaOH in 50 mL H_2O. The solution was cooled to and maintained at 5–10°C throughout the course of the reaction. A solution of 25 g $COCl_2$ (0.25 mol) in 120 mL toluene was added dropwise with efficient stirring until the pH reached 6. By alternate addition of phosgene and more of the NaOH solution, the pH was maintained at 8–9. Finally, the pH was brought to 6, and the solid was filtered by suction and dried in vacuo over P_2O_5 to afford 41.0 g 6-hydroxy-2,4-bis-(trichloromethyl)-*s*-triazine, in a yield of 74%, m.p. 218–224°C. A small amount of product was further purified by first dissolving it in EtOH and subsequently adding cold water, m.p. 222–224°C.



Reference 10a.

An ethanolic solution of 1.52 g phenylglyoxal (10 mmol) was depolymerized by refluxing for 4 h and then cooled in acetone and dry ice. To this solution was added 1.36 g 2-pyridylamidrazone (10 mmol), and the mixture was refluxed for 2 h. The cooled solution was diluted with water, and the resultant precipitate was filtered to give 1.5 g 5-phenyl-3-(2-pyridyl)-*as*-triazine, in a yield of 64%, m.p. 142.5–145°C.

Other references related to the Pinner *s*-triazine synthesis are cited in literature.[11]

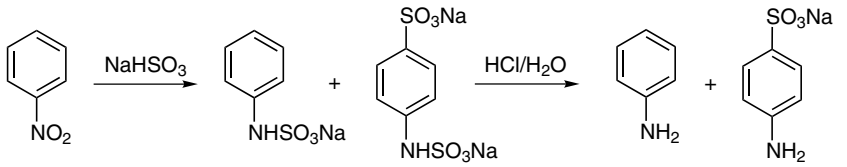
Piria Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Piria in 1851.[1] It is a two-step preparation of aromatic amines and amino sulfonic acids by the reduction of aromatic nitro compounds with bisulfite followed by hydrolysis in mineral acid.[2] Therefore, this reaction is generally known as the Piria reaction.[2,3] It has been proposed that the nitro group is initially reduced to a nitroso group, and aromatic ring sulfonation occurs at or beyond the stage of the nitroso formation,[2a] with the sulfonic group at either the *ortho*- or the *para*-position toward the nitro group.[2a] However, in the case of 4-nitrophenol, the sulfonic group enters the *meta*-position of the nitro group, possibly through 1,4-addition of $NaHSO_3$ to the -N=C-C=C- system present in the quinone-oxime form of the intermediate.[2a] In addition, the aromatic nitroso intermediate is further reduced to sulfaminic acid salt (e.g., $RNHSO_3Na$),[3h] as supported by the isolation of such molecule during reduction without successive acidic hydrolysis or by independent hydrolysis of sulfaminic acid into amine and sulfuric acid.[3h] In addition, it has been found that sodium sulfite reduces the nitro compound faster than sodium bisulfite, and the partially neutralized $NaHSO_3$ is even more effective in this reaction.[2b] Furthermore, it has been found that the reduction is faster when it is carried out in a dilute solution, indicating an ionic reduction.[2b] For the case of α-nitronaphthalene, amino-naphthalene disulfonic acid was isolated in a yield of 66%; the other two products normally found in a regular Piria reaction are obtained in a yield of only 32%.[2b]

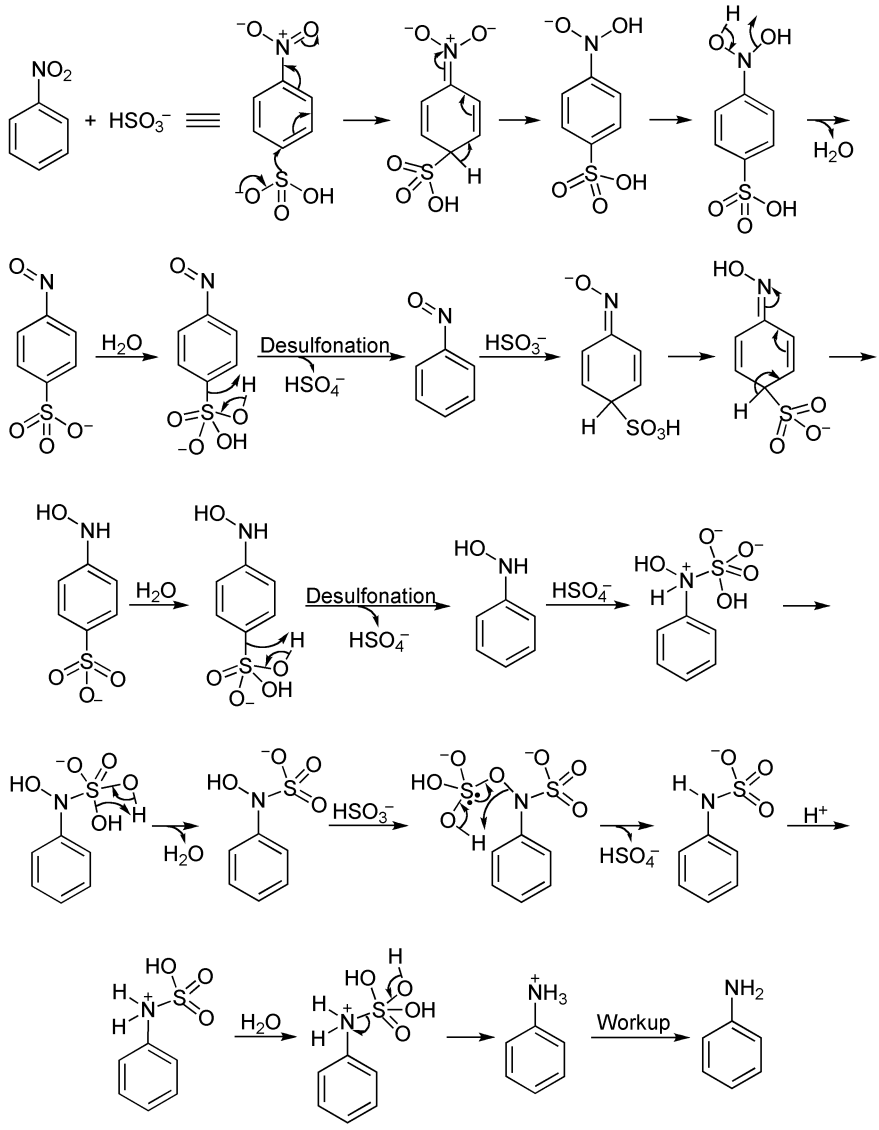
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although some mechanistic studies have been published about this reaction, a general route for the formation of an aromatic amine or aromatic aminosulfonic acid has been proposed.[3f] However, mechanistic details are not available from the literature. Displayed here is a tentative mechanism for the production of aniline from nitrobenzene. The formation of 2- and 4-aminobenzenesulfonic acid should proceed along a similar pathway.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has general application in the preparation of aromatic amines.

F. RELATED REACTIONS

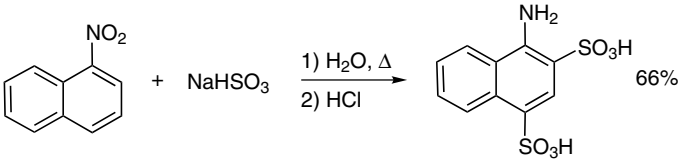
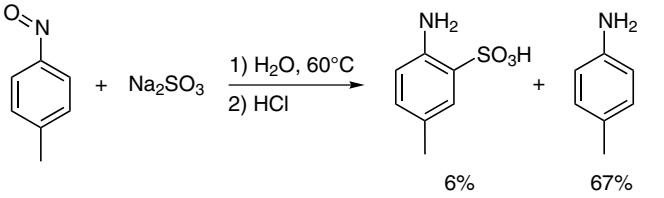
G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

A mixture of 35.0 g α-nitronaphthalene (0.2 mol), 200 mL 5.2 *N* $NaHSO_3$ (75% excess), and 250 mL H_2O was heated under a return condenser until the mixture was completely homogeneous. The contents of the flask were evaporated to 300 mL and treated with 50 mL 12 *N* HCl to give a heavy white precipitate, which was filtered from the cooled solution. This mixture was warmed with 300 mL water, which dissolved the salts present, leaving the naphthionic acid (solubility of 0.024 g in 100 mL water); 13.5 g aminosulfonic acid was thus obtained, in a yield of 29%. The combined filtrates were saturated with NaCl, and the precipitate produced was filtered off. It was nearly free from inorganic salts. When dry, it weighed 31 g, which, on the basis of a monosodium salt of a naphthylamine disulfonic acid is equivalent to a yield of 66%.



Reference 2a.

To 200 mL aqueous solution of 16.6 g Na_2SO_3 at 60°C was added 4.0 g *p*-nitrosotoluene. The mixture was shaken until the green color had disappeared (~5 min). Then 15 mL conc. HCl was added, and the solution was evaporated to 50 mL. On cooling, a solid formed that was filtered off, triturated with water, refiltered, dried, and weighed as 0.45 g, which is equivalent to a 6% yield of *p*-toluidine sulfonic acid. The filtrates were made alkaline with NaOH and extracted with ether. The extracts were combined and dried, and the ether was evaporated to afford 2.4 g *p*-toluidine, in a yield of 67%.

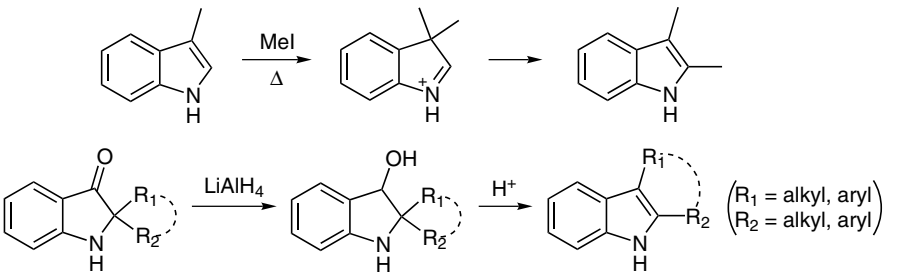
Plancher Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

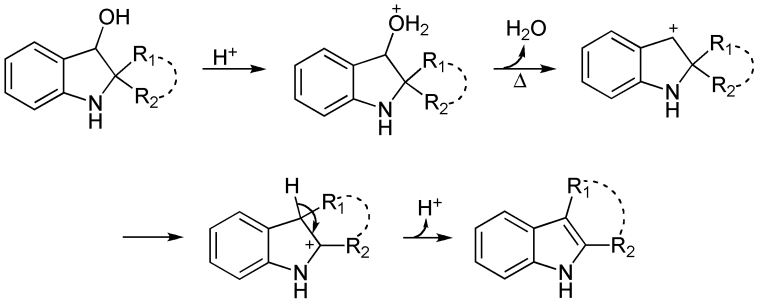
This reaction was first reported by Plancher in 1896.[1] It is the migration of an alkyl or aryl group from position 2 to position 3 of indolenines, or vice versa,[2] to form compounds originating from a more stable carbocation intermediate. Therefore, this reaction is generally known as the Plancher rearrangement.[2,3] The overall rearrangement is controlled not only by the migratory aptitude of the migrating group but also by the thermodynamic stability of the rearranged product.[2] However, such rearrangement normally does not occur at room temperature.[2b]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

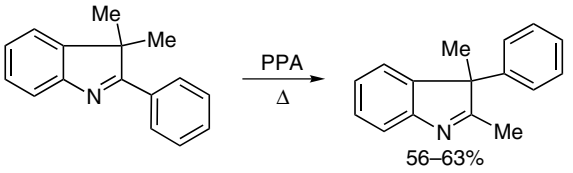
E. APPLICATIONS

This reaction has a limited application in the preparation of indole derivatives.

F. RELATED REACTIONS

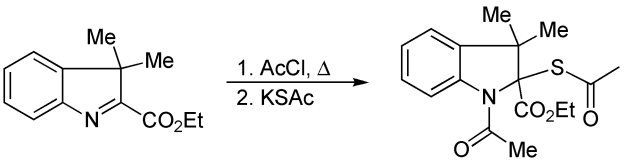
This reaction is related to the *Wagner-Meerwein Rearrangement.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 3h.

To 25 g stirred polyphosphoric acid was poured slowly 8.15 g 3,3-dimethyl-2-phenyl-3H-indole. The mixture was stirred until a uniform consistency was attained, and no attempt was made to moderate the exothermic reaction that took place. After the initial reaction subsided, the flask was placed in a hot air bath, and the bath temperature was raised to 150°C. The reaction mixture was heated at this temperature for 3–5 h, and without being cooled the reaction mixture was poured into 250 mL cold water. The solution was neutralized with solid K_2CO_3, and the tar-like material that separated was taken up in ether. The ether solution was washed with water, dried over anhydrous potassium carbonate, and concentrated by distillation. All volatile solvents were removed from the residue by heating under reduced pressure, and 89–90% 3H-indoles were obtained. The composition analysis indicated 70% 2,3-dimethyl-3-phenyl-3H-indole and 30% starting material.



Reference 3d.

A solution of 434 mg ethyl 3,3-dimethyl-3H-2-indolecarboxylate (2 mmol) in 4 mL freshly distilled acetyl chloride was kept at 40°C for 15 h, during which time the reaction was monitored by TLC (4% EtOH in benzene). After the addition of 5 mL benzene, solvent and excess reagent were removed under vacuum, and exclusion of moisture gave a light brown oil, of which TLC indicated two spots with R_f values smaller than the starting material. To this light brown oil was added an alcoholic solution of 570 mg potassium thioacetate (5 mmol) after which KCl separated. Stirring was continued for 2 h; the alcohol was removed and the residue was extracted with ether. The ether layer was washed with 5% $NaHCO_3$ and water until neutral and dried over Na_2SO_4. Upon removal of solvent, 545 mg of a yellow oil was obtained, which was purified by silica gel column chromatography (4% EtOH in benzene) to afford ethyl 1-acetyl-2-thioacetyl-3,3-dimethylindoline-2-carboxylate and its isomer, besides the recovery of 30 mg starting material.

Other references related to the Plancher rearrangement are cited in the literature.[4]

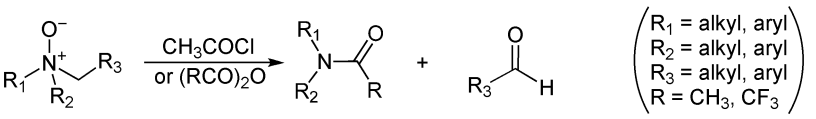
Polonovski Reaction
(Polonovski-Potier Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Polonovski in 1927.[1] It is the transformation of a tertiary amine oxide into a *N*,*N*-disubstituted acetamide and an aldehyde by treatment of the tertiary amine oxide with acetic anhydride or acetyl chloride. Therefore, this reaction is generally known as the Polonovski reaction.[2] Because the resulting acetylated tertiary amine oxide can undergo different reaction pathways, including the elimination of an α-hydrogen and the cleavage of one alkyl group (e.g., methyl) on the nitrogen atom to form different iminium intermediates,[2oo] this reaction is also referred to as the Polonovski transformation,[3] Polonovski demethylation,[4] Polonovski rearrangement,[5] or Polonovski elimination.[3] In addition, the replacement of acetic anhydride or acetyl chloride by trifluoroacetic anhydride, as introduced by Potier in 1968,[6] has made the Polonovski reaction a very useful transformation in alkaloid chemistry, because the Polonovski reaction under the modified condition can stop at the iminium stage, which can be trapped by the addition of cyanide to form an amino nitrile.[7] Therefore, this modification is generally known as the Polonovski-Potier reaction.[7a,7b,8] Occasionally, this reaction is also referred to as the Potier modification,[9] Potier-Polonovski rearrangement,[10] and Potier-Polonovski fragmentation.[11] It has been found that the elimination occurs via an E2 type mechanism,[7h] by which one of the carbon-nitrogen bonds to be broken must be both activated toward the cleavage by an adjacent electron-donating group and oriented *anti*-periplanar to the N-O bond.[2g] However, *cis*-elimination has also been observed for nupharidine-type alkaloids.[3] It has been reported that a similar transformation can also be promoted by an enzyme such as iron cytochrome P-450.[12]

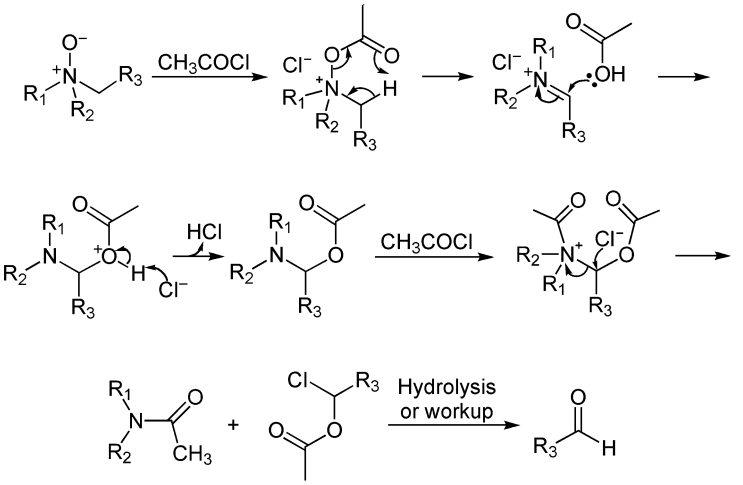
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

As mechanistic information is not available in detail, a tentative mechanism is proposed below by the treatment of acetyl chloride.



D. MODIFICATION

This reaction has been modified by the replacement of acetic anhydride or acetyl chloride with trifluoroacetic anhydride to obtain an iminium intermediate,[2ao,6] followed by the addition of cyanide to give amino nitriles.[7]

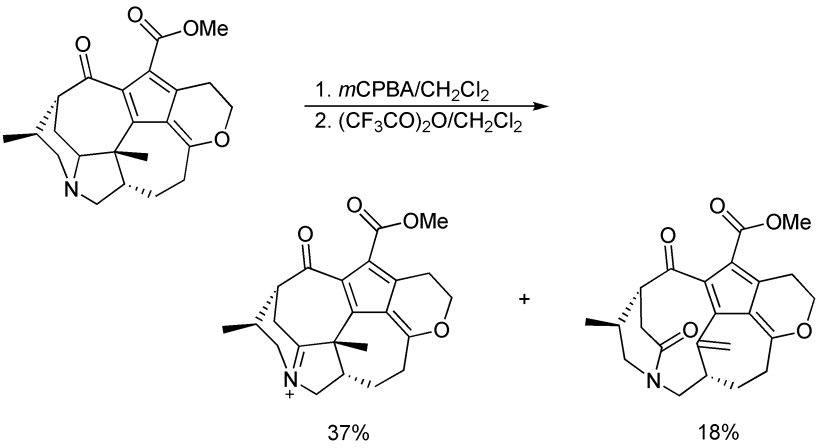
E. APPLICATIONS

This reaction has wide application in the transformation of alkaloids.

F. RELATED REACTIONS

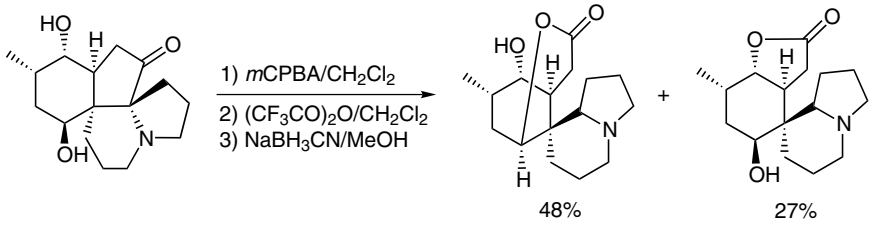
This reaction is related to *Hofmann Elimination*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2f.

m-Chloroperbenzoic acid (6 mg, 0.035 mmol) in 0.1 mL CH_2Cl_2 was added to a stirred solution of 10 mg daphnicyclidin D (0.026 mmol) in 0.1 mL CH_2Cl_2 at 0°C, and the mixture was stirred for 1 h. After the reaction mixture was concentrated, 10 μL trifluoroacetic anhydride (0.072 mmol) was added to the stirred solution of the residue in 0.2 mL dry CH_2Cl_2 under nitrogen at −20°C for 1 h. After the solvent was evaporated, the residue was subjected to C_{18} HPLC (25% CH_3CN in MeOH with 0.1% TFA) to afford 3.7 mg daphnicyclidins E and 1.8 mg daphnicyclidins J, respectively.



Reference 2g.

m-Chloroperbenzoic acid (8 mg, 0.047 mmol) in 0.1 mL CH_2Cl_2 was added at 0°C to a stirred solution of 10 mg serratinine (0.036 mmol) in 0.1 mL CH_2Cl_2. After 1 h, the reaction mixture was concentrated, and then 0.02 mL trifluoroacetic anhydride (0.14 mmol) was added to a stirred solution of the residue in 0.2 mL dry CH_2Cl_2 under nitrogen at −20°C. After 1 h, excess solvent and trifluoroacetic anhydride were immediately distilled off in vacuo at 0°C. The residue was dissolved in 0.1 mL MeOH, and an excess amount of $NaBH_3CN$ was added at 0°C. After 15 min the reaction mixture was poured into 10 mL H_2O and extracted with $CHCl_3$. Upon removal of solvent, the residue was purified on C_{18} HPLC (15% CH_3CN in MeOH with 0.1% TFA) to afford 4.8 mg Serratezomine A (48%) and 2.7 mg of its isomer (27%).

Other references related to the Polonovski reaction are cited in the literature.[13]

Pomeranz-Fritsch Reaction

(Pomeranz-Fritsch Synthesis, Pomeranz-Fritsch Isoquinoline Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

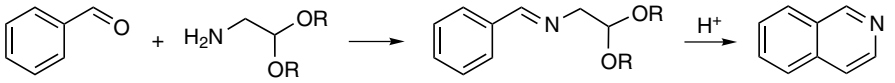
This reaction was first and concurrently reported by Pomeranz[1] and Fritsch[2] in 1893. It is the synthesis of isoquinolines via an acid-promoted electrophilic cyclization of benzalaminoacetals prepared from aromatic aldehydes and aminoacetals. Therefore, this reaction is known as the Pomeranz-Fritsch cyclization,[3] Pomeranz-Fritsch isoquinoline synthesis,[3,4] Pomeranz-Fritsch reaction,[4a,5,6] Pomeranz-Fritsch ring closure,[7] Pomeranz-Fritsch ring synthesis,[8] or Pomeranz-Fritsch synthesis.[3a,4a,9]

This reaction can directly give isoquinoline derivatives[10] and is generally favored by electron-donating substituents on the benzalaminoacetal;[4a,10] in addition, the cyclization normally occurs at the *para*-position of the electron-donating group, even though both *para*- and *ortho*-positions are available.[4a] In the presence of an electron-withdrawing group such as a nitro group, oxazoles instead of isoquinolines are formed.[5h] In this reaction, the feasible acid promoters include hydrochloric acid,[11] the combination of hydrochloric acid and acetic acid,[4a] methanesulfonic acid,[4a] orthophosphoric acid,[3b] perchloric acid,[12] polyphosphoric acid,[3b,5k,6a] sulfuric acid,[13] the combination of sulfuric acid and phosphorus pentoxide,[5h,7b] triflic acid,[4a] trifluoroacetic acids,[4a] and BF_3 in trifluoroacetic anhydride.[6c] However, as the traditional Pomeranz-Fritsch reaction gives low yields of isoquinolines,[4a] probably because of the steric and electronic effect[10] and the partial deactivation of the phenyl ring by the formation of a protonated imino group,[4a] this reaction has been extensively modified, such as the Bobbitt modification,[3a,4b,9e,14] Fischer modification,[9e,9f]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

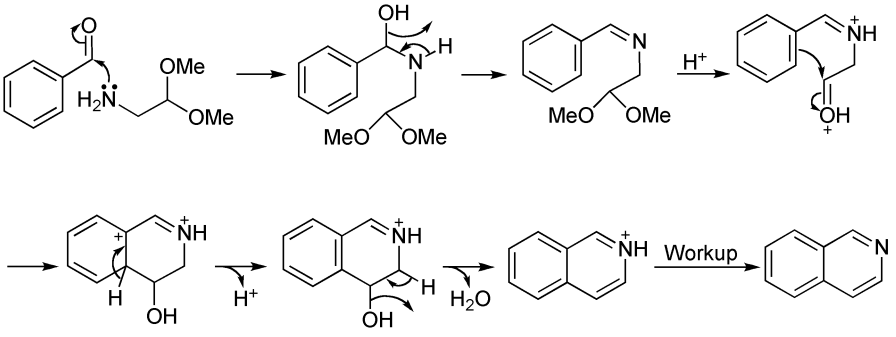
Jackson modification[4a,4c] and Schlittler-Müller modification.[4e,7c] The Fischer modification involves the treatment of benzalaminoacetal with fuming sulfuric acid,[9e] whereas Bobbitt modification produces tetrahydroisoquinoline derivative through the hydrogenation of an imine intermediate *in situ* to an aminoacetal, which in turn is converted into product by the acid-promoted cyclization and hydrogenation.[3a] This modification for tetrahydroisoquinoline is also known as the Pomeranz-Fritsch-Bobbitt cyclization.[3a] The Schlittler-Müller modification involves the preparation of benzalaminoacetal from benzyl amines and glyoxal semiacetal.[4e,7c] In addition, this reaction has been extended to prepare other types of aromatic heterocycles, such as thieno[2,3-c] and thieno[3,2-c]pyridines by intromolecular cyclization to thiophene ring.[5k]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Illustrated below is the mechanism of the reaction between benzaldehyde and dimethyl α-amino acetaldehyde.



D. MODIFICATION

This reaction has been modified to different variants, such as the Bobbitt modification, Fischer modification, and the Schlittler-Müller modification. In addition, different acids have been used as the promoters for this reaction.

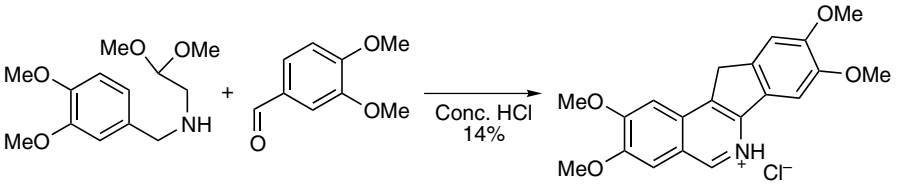
E. APPLICATIONS

This reaction has general application in the preparation of isoquinoline derivatives.

F. RELATED REACTIONS

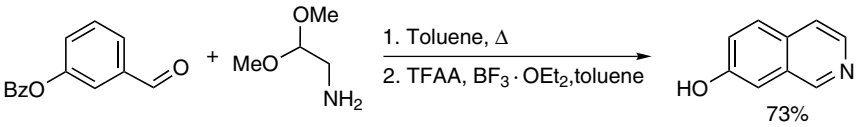
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

A mixture of 2.93 g (3,4-dimethoxybenzyl)-(2,2-dimethoxyethyl)amine (11.5 mmol), 4.11 g veratraldehyde (24.7 mmol) and conc. HCl was stirred at 100°C for 3 h. The reaction mixture was cooled and washed with ether (50 mL × 3), then basified with NH_4OH. The mixture was extracted with $CHCl_3$ (4 × 50 mL), the combined organic layers were washed with 100 mL H_2O, dried over Na_2SO_4, and concentrated. The residue was dissolved in 200 mL $CHCl_3$, the resulting solution was filtered, and 40 mL 2 M HCl in ether was added to the filtrate. The precipitate that formed was recrystallyzed from 300 mL MeOH to provide 0.594 g 2,3,8,9-tetramethoxy-11*H*-indeno[1,2-*c*]isoquinoline hydrochloride as a bright yellow hygroscopic solid, in a yield of 14%, m.p. 254–255°C.



Reference 15.

To a solution of 106 g 3-(benzyloxy)benzaldehyde (0.5 mol) in 1100 mL toluene was added 79 g aminoacetaldehyde dimethyl acetal (0.75 mol). The mixture was refluxed for 6 h using a Dean-Stark trap. After the mixture was cooled to 5°C, 212 mL trifluoracetic acid anhydride (1.5 mol) and 185 mL $BF_3{\cdot}Et_2O$ (1.5 mol) were added under nitrogen in succession at such a rate that the internal temperature was kept below 10°C. After 5 days of stirring at room temperature, the precipitated material was separated by filtration, washed with diethyl ether several times, and dissolved in 750 mL H_2O. The pH was adjusted to 9 by adding concentrated aqueous ammonia, and the precipitated product was separated by filtration, followed by washing with Et_2O and drying in vacuo to afford 53.2 g isoquinolin-7-ol as light yellow solid, in a yield of 73%, m.p, 228–230°C.

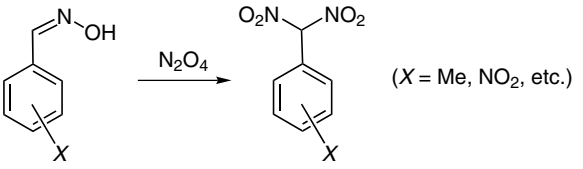
Ponzio Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction was first reported by Scholl in 1888[1] and extended by Born in 1896,[2] it was Ponzio who initially extended this reaction to aromatic compounds in 1897.[3] It is the transformation of ketoximes into *gem*-dinitro compounds via a pseudonitrole intermediate by means of oxidation with dinitrogen tetraoxide[4] and is generally known as the Ponzio reaction.[4,5] Besides the formation of *gem*-dinitro compounds, some other byproducts are also formed during this oxidation. For example, the oxidation of benzaldoxime yields 16% benzaldoxime peroxide, 16% diphenylglyoxime peroxide, 12% benzaldehyde, and 50% dinitrophenylmethane.[6] This reaction particularly works for aromatic oximes, such as *p*-tolylaldoxime, and anisaldoxime.[7] It should be pointed out that *meta*-nitro dinitrophenylmethane from *meta*-nitro benzaldehyde oxime is a more powerful explosive than TNT.[8] According to Ponzio, the oximes of benzaldehyde, hydroxymethyl phenyl ketone, and methyl phenyl 1,2-diketone all give the corresponding dinitromethanes accordingly, whereas the ketoximes of benzoylformic acid, acetophenone and benzophenone give negative results.[7] However, the oximes of a few aliphatic ketones can also be converted into corresponding *gem*-dinitro compounds, such as the oximes of acetone,[1] ethyl methyl ketone,[1] diethyl ketone,[1] methyl propyl ketone,[2] methyl isopropyl ketone,[2] and di-*n*-propyl ketone.[2] It has been reported that the oxidation of glyoximes such as dimethyl, methyl, and phenyl glyoximes yields glyoxime peroxides as the predominant products,[7] while the oxidation of mono-oxime of 1,2-diketone by dinitrogen tetraoxide leads to the formation of 1,2-diketone as well as carboxylic acid and *gem*-dinitro compounds from the carbon-carbon bond cleavage.[7,9]

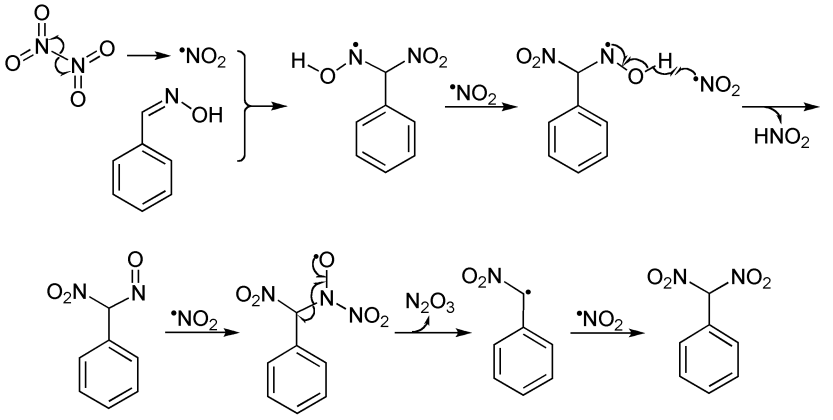
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because mechanistic information for this reaction is not available, a tentative mechanism is proposed here. It is assumed that dinitrogen tetraoxide may decompose homolytically to give a nitrogen dioxide radical, which adds to the carbon-nitrogen double bond to introduce the first nitro group.



D. MODIFICATION

N/A

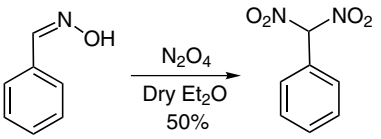
E. APPLICATIONS

This reaction is useful for the preparation of α,α-dinitrotoluene derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To 200 mL boiling anhydrous ether containing 5.0 g benzaldoxime (0.042 mol) was added 2.1 g dinitrogen tetraoxide (0.022 mol) in 10 mL anhydrous ether dropwise with stirring at a rate that maintained a gentle reflux (∼3 min). Stirring was continued for an additional 3 min, then 50 g ice was added. The ether layer was separated, washed once with water, and extracted with ice-cold 4% NH_4OH solution until the extracts were no longer colored. The red alkaline solution was washed with 100 mL ether, placed in a beaker, and covered with 50 mL ether. Upon careful neutralization at 0°C with aqueous oxalic acid, the red color disappeared. The aqueous solution then was extracted with 50 mL ether; the combined ether extracts were washed once with ice-cold water and dried for 10 min with anhydrous $MgSO_4$. Ether was removed in vacuo, to afford 3.5 g phenylnitrolic acid as pale yellow needles, in a yield of 50%, m.p. 56–57°C (dec.). The product was stable at −20°C for several weeks, but decomposed within a few hours at room temperature.

Other references related to the Ponzio reaction are cited in the literature.[11]

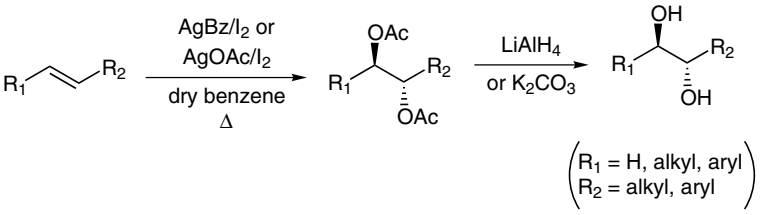
511

Prévost Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Prévost in 1933.[1] It is the one-pot transformation of alkenes into *trans* 1,2-diols through the joint oxidation with silver(I) carboxylate and iodine in an anhydrous solvent followed by the reduction or hydrolysis of 1,2-dicarboxylate intermediates.[2] Therefore, this reaction is generally known as the Prévost reaction.[2c,3] Occasionally, it is also referred to as the Prévost *trans*-dihydroxylation.[4] In addition, because this reaction is the complement of the *Woodward cis-Hydroxylation*,[5] for the conversion of the alkenes into vicinal diols, the Prévost reaction is also called the Woodward-Prévost reaction[2a,2c,5] or Prévost-Woodward reaction.[3a,6] In this reaction, silver(I) carboxylate can be silver(I) acetate[2a,3a] or silver(I) benzoate.[3a,3b,4] It has been reported that this reaction may involve the formation of an α-halocarboxylate, which can be easily transformed into the corresponding *trans*-1,2-dicarboxylate[2a] through a (cyclic) dioxolanyl cation intermediate in the presence of metal carboxylate[2c] from stereoselective nucleophilic displacement of the α-halo group.[2a] However, this reaction also has some drawbacks, such as poor facial selectivity of *epi*-iodination in cyclic substrates,[7] low reactivity of some haloacetates due to steric hindrance,[6c] rearrangement during the oxidation,[3i,6a] and low yields.[8]

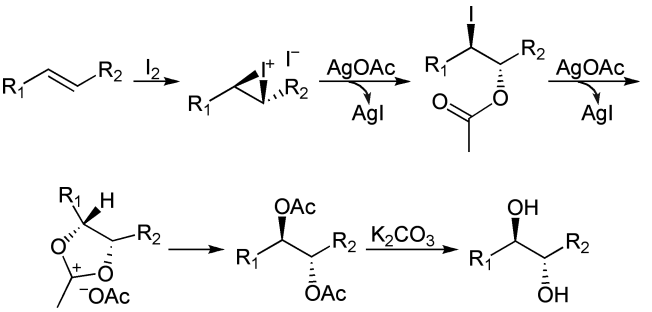
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Because detailed mechanistic information is not available, a tentative mechanism is proposed here. It is assumed that iodine first adds to the double bond to form an iodonium cation in a process similar to the bromination of alkene, then nucleophilic attack from acetate leads to the formation of the *trans*-α-iodoacetate. In the presence of silver acetate, α-iodo leaves to give a dioxoanyl carbocation, which is attacked by the second acetate anion to give *trans*-1,2-diacetate. Upon hydrolysis or $LiAlH_4$ reduction, diacetate is transformed into *trans*-1,2-diol. The displayed mechanism is similar to the one proposed by Sudalai.[3a]



D. MODIFICATION

This reaction has been modified by the use of Hg(II),[9] Cu(II),[6a,10] Th(I),[11] and Pb(IV)[12] salts in the related reactions. In addition, $Bi(OAc)_3$ is also used for this reaction because of its low toxicity, reasonable cost, and tolerance to moisture.[2c] Furthermore, similar reaction has been catalyzed by LiBr in the presence of either $NaIO_4$ or $PhI(OAc)_2$.[3a]

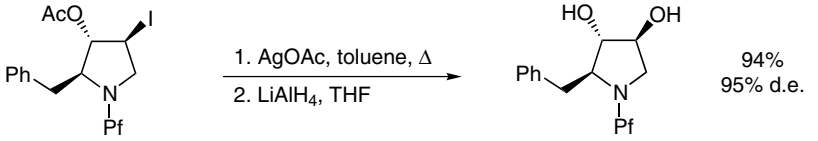
E. APPLICATIONS

This reaction is very useful for the conversion of alkenes into adjacent *trans*-diols.

F. RELATED REACTIONS

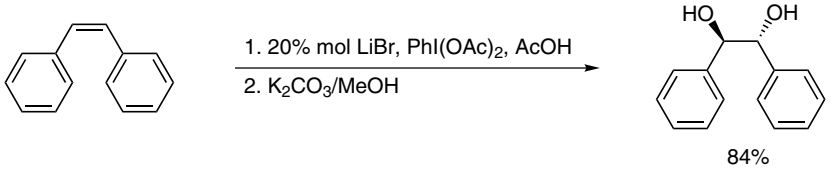
This reaction is related to the *Woodward cis-Hydroxylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

A mixture of 0.4 mmol 2-benzyl-3-acetyl-4-iodo-*N*-(9-phenylfluoren-9-yl) pyrrolidine and 0.133 g AgOAc (0.8 mmol) was refluxed in 4 mL anhydrous toluene for 3 h. Then the reaction mixture was filtered, and toluene was evaporated. The residue was reduced by 0.030 g $LiAlH_4$ (0.8 mmol) in 4 mL THF at 0°C. The mixture was filtered, and THF was removed in vacuo. The residue was purified by column chromatography using hexanes/EtOAc as the eluent to afford 94% (2*S*, 3*S*, 4*S*)-2-benzyl-3,4-dihydroxy-*N*-(9-phenylfluoren-9-yl) pyrrolidine with 95% d.e.



Reference 3a.

To a 25-mL round-bottomed flask were added 3 mmol *cis*-stilbene, 0.6 mmol LiBr, 3 mmol $PhI(OA(c)_2$, and 5 mL acetic acid. The mixture was heated at 95°C for 18 h then cooled to room temperature and extracted with EtOAc (3 × 30 mL). The combined organic layers were washed with saturated sodium thiosulfate solution, water, aqueous $NaHCO_3$, and dried over Na_2SO_4. Upon removal of solvent, 4.5 mmol K_2CO_3 and 20 mL MeOH were added to the flask containing the residue, and the mixture was stirred at room temperature for 24 h. When MeOH was removed by rotatory evaporation, the residue was taken up by EtOAc (3 × 30 mL). The combined organic phases were washed with water and brine and dried over Na_2SO_4. Upon removal of solvent, the residue was purified by column chromatography using petroleum ether/EtOAc (7:3) as the eluent to afford 84% of *trans*-diol.

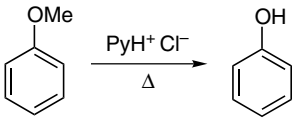
Prey Ether Cleavage

A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction was first reported by Klemenc in 1916,[1] it was Prey who modified the original protocol in 1941 and made it a simple and convenient method to cleave the aliphatic-aromatic ethers by heating the mixture of appropriate ether and pyridine hydrochloride.[2] Therefore, this transformation is called the Prey ether cleavage herein. To date, this reaction has been used to remove the methyl groups in anisole,[2a] phenetole,[3] *o*-methoxphenol,[3] *o*-dimethoxybenzene,[3] anisaldehyde,[3] methoxy-illudinine,[4] and 3,5-dichloro-2-methoxy-6-methylacetophenone.[5] In addition, by removal of a methyl group, a series of phenol derivatives have been prepared, such as *p*-pentadecylphenol,[6] desoxymorphine,[7] and β-dihydrothebainol.[8] It should be pointed out that phenyl ethyl ether can also be cleaved by this reaction but at a relatively lower speed.[3] It has been found that a few percent of pyridine hydrochloride is adequate for this reaction if dry hydrogen chloride is passed into the reaction system,[3] although dry hydrogen chloride itself does not cleave the listed ethers under similar conditions.[2b]

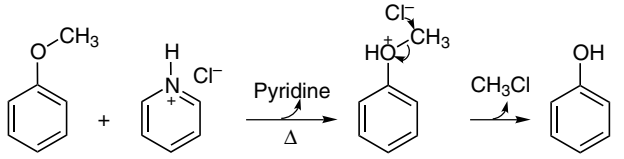
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that methyl aromatic ether is protonated from the thermally stable pyridine hydrochloride to form an oxonium ion, which undergoes nucleophilic substitution with chloride to evolve methyl chloride and yield phenol derivatives, as exemplified here by the reaction of anisole.



D. MODIFICATION

This reaction has been modified by passing dry hydrogen chloride into the reaction system with a small amount of pyridinium chloride present.

E. APPLICATIONS

This reaction has been used to cleave methyl aromatic ethers and phenoxy esters.[9] In addition, this reaction has been successfully used for determining methoxyl groups to an accuracy of 1% by conversion of pyridine hydrochloride into *N*-methylpyridinium chloride.[2c]

F. RELATED REACTIONS

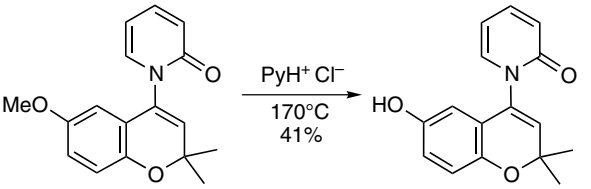
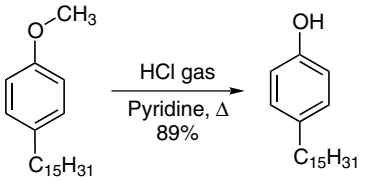
G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

A mixture of 5.67 g 4-(1,2-dihydro-2-oxo-1-pyridyl)-6-methoxy-2,2-dimethyl-2*H*-1-benzopyran (20 mmol) and 6.93 g pyridine hydrochloride (60 mmol) was heated to melt at 170°C for 2 h. The hot solution was poured into 150 mL 2% H_2SO_4, and the product was extracted with CH_2Cl_2. The organic layer was dried over $MgSO_4$ and evaporated. The

residue was purified by crystallization from MeOH to afford 2.21 g 4-(1,2-dihydro-2-oxo-1-pyridyl)-6-hydroxy-2,2-dimethyl-2*H*-1-benzopyran, in a yield of 41%.



Reference 6.

A solution of 8.92 g *p*-pentadecylanisole (0.028 mol) in 50 mL dry pyridine was refluxed, and a strong steam of HCl gas was passed into the stirred mixture. Refluxing ceased after minutes, and the mixture was heated again for 4.5 h then allowed to cool. Water (50 mL) and 100 mL Et_2O were added to the flask, and the phases were separated. The aqueous layer was extracted with Et_2O (2 × 100 mL), and the combined ether layers were washed with H_2O, dried over $MgSO_4$, and evaporated under reduced pressure to give an off-white solid, which was recrystallized from hexane to give 7.7 g *p*-pentadecylphenol, in a yield of 89%, m.p. 71.4–73°C.

Other references related to the Prey ether cleavage are cited in the literature.[11]

Prilezhaev Reaction

(Prilezhaev Epoxidation, Prileschajew Epoxidation, Prilezhaev Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Prilezhaev (also known as Prileschajew) in 1909.[1,2] It is the convenient transformation of alkenes with isolated olefinic double bond into epoxides[2b,2e] (i.e., oxirane[3]) or glycols[4] by means of oxidation with organic peracid in a neutral[4b] organic medium. Therefore, this reaction is generally known as the Prilezhaev reaction.[5] In addition, it is also referred to as the Prileschajew reaction,[6] Prilezhaev epoxidation[5a,7] or Prilezhaev oxidation;[8] while the organic peracid is known as the Prileschajew reagent.[9] This reaction can be carried out in many common organic solvents such as acetone, chloroform, diethyl ether, and dioxane,[3] using perbenzoic acid (also known as benzoyl hydrogen peroxide[10] or benzoylhydroperoxide[4b]) as the oxidant. This reaction is especially useful for the epoxidation of nonvolatile, water-insoluble olefins.[3] Although this reaction usually gives good to quantitative yields,[3,10] the actual yields and reaction time depend on both the peracid used and the number and nature of groups attaching to the olefinic double bond. For example, furoic peracid has been found to be more reactive than perbenzoic acid and camphoric acid peracid, whereas phthalic acid peracid is almost inactive for this reaction.[11] In addition, the introduction of an electron-withdrawing group to a phenyl ring increases the electrophilicity and reactivity of perbenzoic acid, thus the application of *m*-chloro-perbenzoic acid (*m*CPBA, or 3-chloroperbenzoic acid) in epoxidation of olefins is specifically known as *m*CPBA epoxidation.[12] In addition, the Prilezhaev epoxidation is tolerable for many functional groups, including aromatic ring, ester, and ether,[5c] and has shown excellent face selectivity for certain kinds of olefins. Such face selectivity may

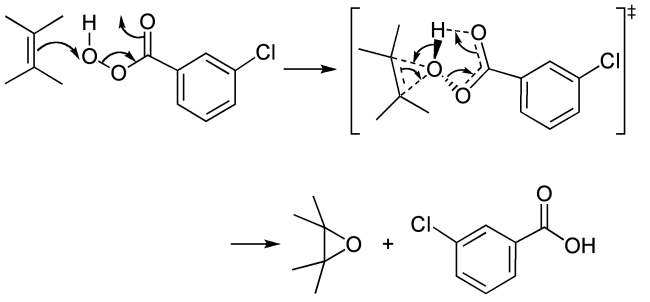
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

arise from steric hindrance, hydrogen bonding, and aromatic π-π stacking.[12d] The steric hindrance is clearly shown in the epoxidation of sterically hindered alkenes (e.g., steroidal olefins).[13] The effect of hydrogen bonding on face selectivity is observable during the epoxidation of cyclic alkenones[14] and olefins with hydrogen-bonding acceptors (e.g., allyl alcohols,[15] allylamides,[16] allyl carbamates,[17] allyl ethers,[18] α-diones,[19] and unsaturated carboxylic acids[20]). The face selectivity arising from hydrogen bonding is especially shown in the epoxidation of 3-hydroxycyclohexene to *syn*-epoxide, whereas the epoxidation of 3-methoxycyclohexene gives predominantly *anti*-product.[21] Such high diastereoselectivity is attributed to the hydroxy-group directivity.[2b,22]

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

Many mechanisms have been proposed for this reaction, such as the epoxidation via initial attack of a hydroxyl cation,[23] *1,3-Dipolar Cycloaddition* of a hydroxycarbonyl oxide to an olefinic double bond,[24] and the commonly accepted planar "butterfly" transition state,[2a,2b,24a,25] by which the π HOMO orbital of the olefin approaches the terminal oxygen of perbenzoic acid and interacts with the σ^* LUMO of the O-O bond at 180°.[25c] The planar butterfly transition state is further extended by Sharpless to a *spiro*-transition state,[26] which has been consolidated by many other investigators.[2c,25b,27] An illustrative mechanism from *m*CPBA epoxidation is provided here.



D. MODIFICATION

The reaction has been modified to avoid the application of perbenzoic acid by treating the solutions of olefins with air or oxygen in the presence of benzaldehyde so that perbenzoic

acid is generated *in situ* and consumed as it is formed.[28] In addition, such epoxidation has been catalyzed by organometallic complex such as Mn(salen).[5a]

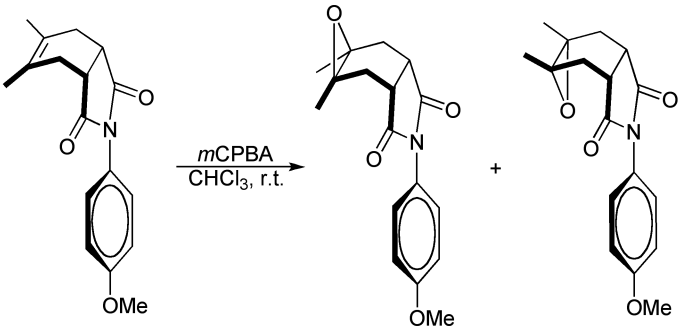
E. APPLICATIONS

This reaction has a very broad application in organic synthesis.

F. RELATED REACTIONS

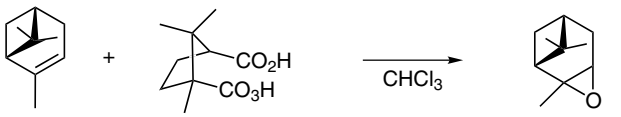
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 12d.

To a 100-mL round-bottomed flask equipped with a dropping funnel capped with a $CaCl_2$ drying tube were added 0.392 mmol 2-(4-methoxyphenyl)-5,6-dimethyl-3a,4,7,7a-tetrahydroisoindole-1,3-dione and 10 mL $CHCl_3$. Then 0.588 mmol *m*CPBA in 5 mL $CHCl_3$ was added to the flask dropwise via the dropping funnel over 20 min. The solution was stirred at room temperature for 3 h, washed successively with 100 mL 20% aq. $NaHSO_3$, 100 mL saturated aq. $NaHCO_3$, and 50 mL H_2O and dried over anhydrous $MgSO_4$. Upon the removal of solvent, the residue was separated by silica gel column chromatography with hexanes/EtOAc (1:1) as the eluent to afford 29% 9-(4-methoxyphenyl)-3,5-dimethyl-4-oxa-9-azatricyclo-[5.3.0.$0^{3,5}$]decane-8,10-dione (colorless crystals, m.p. 144–145°C) and 40% of its isomer (colorless crystals, m.p. 179–181°C).



Reference 11.

A total of 5 g d-pinene was mixed with a large excess of camphoric acid peracid in $CHCl_3$, and the mixture was allowed to stand at 0°C for 3 days. It was then shaken with a 10% NaOH to remove the unused peracid and camphoric acid and was finally washed with H_2O and dried over anhydrous Na_2SO_4 for 24 h. Upon removal of $CHCl_3$, the remaining liquid was purified by fractional distillation, b.p. 102–103°C at 50 mmHg.

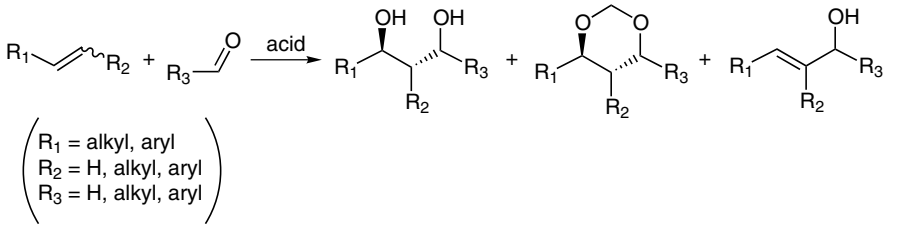
Prins Reaction
(Prins Cyclization)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kriewitz in 1899[1] and studied extensively by Prins since 1917.[2] It is an acid-catalyzed condensation between aldehydes and olefins to form a variety of compounds such as 1,3-dioxanes, 1,3-diols, allyl alcohols, or 1,3-diesters, depending on the nature of alkenes and the reaction conditions. Therefore, this reaction is generally known as the Prins reaction[3] or Prins cyclization.[4] In addition, this reaction is also referred to as aldol-Prins reaction[4aa] or Prins-pinacol reaction.[4y,5] This reaction can be carried out in an aqueous or an anhydrous medium,[3ee] and the aldehydes can be aliphatic, aromatic, α,β-unsaturated aldehydes or even cyclic acetals.[4aa] The acid can be either a Brønsted acid or a Lewis acid, by which the commonly used Brønsted acid is 10–65% sulfuric acid,[3u,3y,3cc,3gg] and the Lewis acid can be $AlCl_3$,[3gg] $ZnCl_2$,[3gg] BF_3,[6] $InCl_3$,[7] etc. In this reaction, the commonly used aldehyde is formaldehyde.[3m,3n,3r,3s,3u,3v,3y,3bb,3dd–3gg] It has been found that in aqueous solution with sulfuric acid as the catalyst, both 1,3-dioxanes and 1,3-diols can be obtained from olefins;[8] in addition, 1,3-dienes may be formed from the reaction between formaldehyde and trisubstituted olefins because of the dehydration.[9] When an excess amount of formaldehyde is used—for example, more than 10-fold—1,3-dioxane is predominantly formed.[3r] However, in the presence of an anhydrous organic acid and when sulfuric acid is used as the catalyst, diesters of 1,3-glycols are produced.[3gg] For the reaction between styrene and formaldehyde, telomer may be formed at a low ratio of formaldehyde over styrene.[3u] On the other hand, the Prins reaction has been found to be highly stereoselective with *trans*-addition for both alicyclic and acylic olefins,[3t,3v,3bb,3dd] especially the *anti*/*syn* ratio of formed diols increases when the size of aldehydes increase.[3m] It should be pointed out that if the formed carbonium ion is highly stabilized, the Prins reaction may be controlled by thermodynamics.[3v]

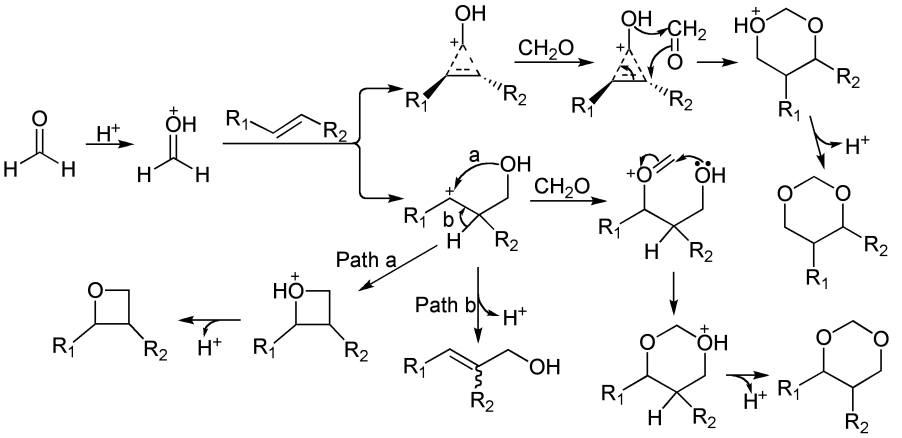
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is proposed that this reaction involves an acid-activated formaldehyde intermediate[3ee] (i.e., in the form of hydroxymethyl carbonium ion[3ff]) that electrophilically attacks the olefinic double bond to form an oxetane oxonium ion[3v,3z,10] or a three-member bridged carbocation,[3t] which upon solvolysis yields 1,3-glycol or 1,3-dioxane. An illustrative mechanism is given here.



D. MODIFICATION

This reaction has been extended to the reaction between aldehydes and alkenyl complexes of boranes, silanes, and stannes to give allylic alcohols,[3m] where the reaction with alkenyl complexes of silanes is known as the silyl-Prins reaction.[7] In addition, several Lewis acids-mediated or -promoted Prins reactions have recently been developed, including the application of TMSI,[4w] hafnium (IV) bis(perfluorooctanesulfonyl)amides (in fluorous biphase system),[3d] iron (III) species,[4m] and 2,6-di-*tert*-butylphenoxy(difluoro)borane.[3j]

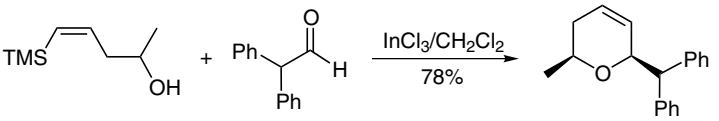
E. APPLICATIONS

This reaction has had wide application in organic synthesis, especially in the 1930s to 1940s for the production of dienes in large quantities for synthetic rubber manufacturing.

F. RELATED REACTIONS

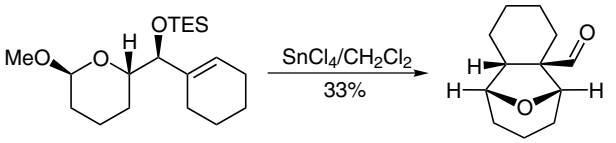
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a solution of 20 mL CH_2Cl_2 containing 0.39 g diphenylacetaldehyde (2 mmol) was added 0.44 g $InCl_3$ (2 mmol) under an atmosphere of nitrogen, and the resulting solution was stirred for 1 h. After this time, 0.32 g (*Z*)-5-trimethylsilylpent-4-en-2-ol (2 mmol) was added, and the reaction mixture was stirred at room temperature for an additional 16 h. The reaction mixture was then quenched with 10 mL distilled water, and the water layer was extracted with CH_2Cl_2. The combined organic extracts were dried with $MgSO_4$. Upon removal of solvent, the residue was purified by column chromatography using hexane/Et_2O (10:1) as the eluent to afford 0.41 g (±)-*cis*-2-benzhydryl-6-methyl-5,6-dihydro-2H-pyran as a colorless solid, in a yield of 78%, R_f = 0.43 (petroleum ether/Et_2O = 10 : 1), m.p. 75–77°C (from petroleum ether).



Reference 4y.

Tin (IV) chloride ($SnCl_4$, 42 μL, 0.23 mmol) was added dropwise to a solution of 0.16 g *rel*-(2*R*,6*R*)-[(6-methoxytetrahydropyran-2-yl)cyclohex-1-enyl]-*rel-(R)*-methoxytriethylsilane (0.46 mmol) in 9.5 mL CH_2Cl_2 at 0°C. After maintaining the reaction at 0°C for 30 min, the reaction mixture was poured into 5 mL saturated aqueous $NaHCO_3$, and the aqueous phase was extracted with CH_2Cl_2 (3 × 5 mL). The combined organic layers were washed with 10 mL brine, dried over Na_2SO_4, filtered, and concentrated. The residue was purified by silica gel column chromatography using hexanes/EtOAc (49:1) to afford 30 mg 12-oxatricyclo[6.3.1.$0^{2,7}$]dodecane aldehyde as a clear pale yellow oil, in a yield of 33%.

Other references related to the Prins reaction are cited in the literature.[11]

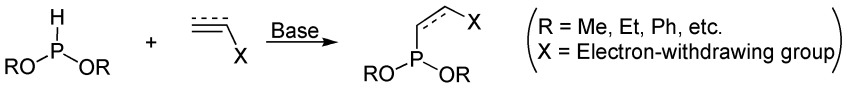
Pudovik Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pudovik in 1950.[1] It is a base-promoted nucleophilic addition[2] of organophosphorus anion to alkenes or alkynes[3] and is generally known as the Pudovik reaction.[4,5] Occasionally, it is also referred to as the Pudovik addition.[4b] In addition, since Abramov discovered a similar addition reaction of phosphorus compounds to carbonyl compounds at the same time,[6] the addition of organophosphorus compounds to activated unsaturated systems (e.g., alkenes,[2,3] alkynes,[2,3] ketones,[4h,7] aldehydes,[4h,7] and imines[1b,1d,8]) is generally called the Pudovik-Abramov reaction.[7a] This type of reaction has been reported to occur via an ionic or radical mechanisms.[3] The outcome of this reaction depends on the structure of unsaturated substrates, the phosphorus reagents, and the experimental conditions.[3] For example, in the addition of dialkylphosphite to aldehyde, the labile proton on the phosphorus atom (P-H) can be easily removed by a catalytic amount of di-*n*-butylamine,[4c] whereas solid-supported base such as Al_2O_3/KOH has been used for deprotonation of a series of secondary phosphines and phosphites.[4e]

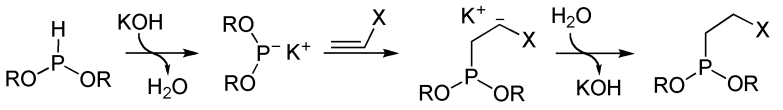
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Illustrated here is the reaction mechanism between dialkylphosphite and an activated alkene in the presence of KOH.



D. MODIFICATION

This reaction has been extended to the addition of organophosphorus compounds on imines.[1b,1d,8]

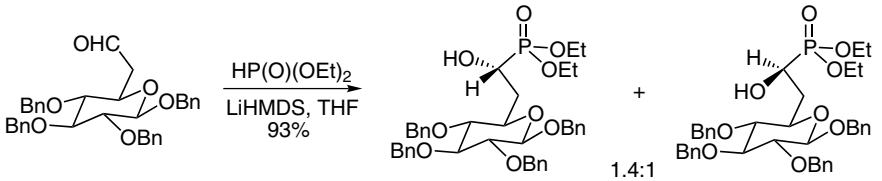
E. APPLICATIONS

This reaction has very broad application in the preparation of an array of organophosphorus compounds.

F. RELATED REACTIONS

This reaction is related to the *Atherton-Todd Reaction* and *Kabachnik-Fields Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 4g.

To a solution of 0.16 mL diethyl phosphite (1.23 mmol) in 0.7 mL THF at −78°C was added 1.23 mL 1 M LiHMDS solution in THF (1.23 mmol). The resulting solution was stirred for 5 min at −78°C, followed by the addition, via cannula, of a solution of 618 mg benzyl 6-deoxy-6-formyl-2,3,4-tri-*O*-benzyl-β-D-glucopyranoside (1.12 mmol) in 5 mL THF at −78°C. After 10 min, the reaction was quenched with aqueous NH_4Cl and Et_2O. The aqueous layer was further extracted with Et_2O. The combined organics were dried over $MgSO_4$, filtered, and evaporated. Upon removal of solvent, 650 mg benzyl 6-deoxy-6-[diethylphosphono(1′-hydroxy)-methyl]-2,3,4-tri-*O*-benzyl-β-D-glucopyranoside was obtained as a mixture of diastereomers (1.4:1 ratio), which are

separable by silica gel flash column chromatography using hexanes/EtOAc (1:1) as the eluent. On a smaller scale of starting material, the same procedure gave 108 mg diastereomeric mixture, in a yield of 93%, the major diastereomer (first eluting) has melting point of 122–123°C.

To a solution of 0.51 g (*R*)-(+)-2-phenylglycinol (3.72 mmol) in 10 mL dry toluene containing 0.5 g 3Å molecular sieves was added 0.38 mL benzaldehyde (3.74 mmol), and the resulting solution was stirred at room temperature for 2 h until an aliquot showed completion by the presence of the imino proton at δ 8.51. The reaction was filtered through Celite, and 0.31 mL dimethyl thiophosphite (3.69 mmol) was added. The reaction mixture was stirred at 0°C for 12 h, concentrated to an oil and subjected to column chromatography using hexanes/Et_2O as the eluent. A major diastereomer of *O*,*O*-dimethyl (*RS*)-{[(1*R*)-2-hydroxy-1-phenylethyl]amino}(phenyl)methyl-phosphonothioate, in the amount of 0.578 g was obtained, in a yield of 44.2%, and 0.14 g minor diastereomer (10.7%) and 0.27 g diasteromeric mixture (20.6%) were obtained as well.

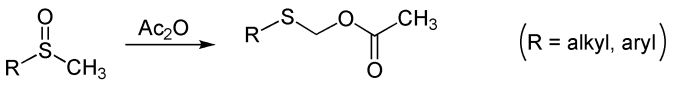
Pummerer Rearrangement
(Pummerer Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Pummerer in 1909.[1] It is an acid (e.g., HCl) or an anhydride (e.g., Ac_2O or TFAA) promoted transformation of sulfoxide bearing an α-proton to α-substituted sulfide through a sulfenium (or thionium) intermediate;[2] more generally, it is the reduction of sulfonium sulfur with concomitant oxidation or substitution at the α-carbon of sulfonium.[3] Therefore, this reaction is generally known as the Pummerer rearrangement[4,5] or Pummerer reaction.[2a,3,4a,4k,4o,4s,4t,6] Occasionally, the Pummerer cyclization is used to stand for the formation of heterocycles via the addition of an intramolecular nucleophile to the sulfenium intermediate.[4h,6o,6p,7] Besides HCl and acyclic anhydrides, some other Brønsted acids or Lewis acids are also used to activate this reaction, such as *p*-toluenesulfonic acid,[4y] ZnI_2,[4h] TMSOTf,[4m,6o] DAST(diethylaminosulfur trifluoride),[8]and Me_3SiX.[9] In addition, the Pummerer rearrangement can also occur under thermal conditions without promoters,[4u,4y] although it may be suppressed by the application of zeolite.[10] In this reaction, the formed sulfenium (or sulfonium) intermediate is very electrophilic, which can even react with some weak nucleophiles such as xylene and anisole.[4y]

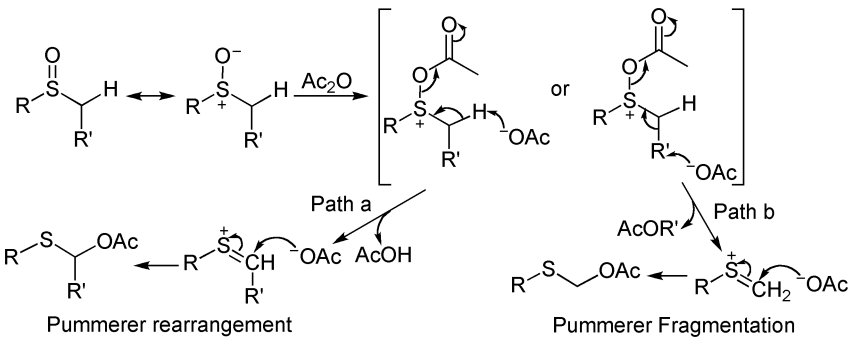
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Many mechanisms have been proposed for this reaction, that include: (*a*) the rearrangement via a carbonium intermediate involving either a concerted cyclic elimination of acetic acid, elimination of HOAc with an external base or elimination to form a sulfonium ylide, (*b*) internal transfer of the acetoxy group through either cyclic rearrangement, 1,2-shift of ylide, homolytic dissociation and recombination, or nucleophilic displacement of ylide.[3] Nevertheless, all these mechanisms involve the intermediate of a sulfur-stabilized carbonium ion, and if there isn't a conjugate electron-withdrawing group (e.g., carbonyl group) at the β-position of sulfoxide group,[11] the acetoxyl group always migrates to the least substituted α-carbon of sulfoxide.[3] Overall, the general accepted mechanism involves the activation of the sulfoxide through the conversion of the sulfoxide oxygen into a good leaving group either by acylation or protonation, followed by the formation of a sulfenium (thionium) ion,[2b,4h] a rate- and product-determining step,[3] and subsequent nucleophilic addition from different nuclophiles. It should be pointed out that after the activation of the sulfoxide oxygen atom, the migration of hydrogen to form a sulfenium ion affords the normal Pummerer rearrangement product, whereas the cleavage of α-alkyl group to generate a new sulfenium ion leads to the formation of new sulfide, and this process is known as the Pummerer fragmentation.[5b] An illustrative mechanism is provided here.



D. MODIFICATION

Because of its versatility, this reaction has been extended to different variants. For example, the thermal conversion of linear α-silyl sulfoxides into siloxymethyl sulfide for the preparation of carbonyl compounds,[12] vinyl sulfides,[4j] etc. is now known as sila-Pummerer rearrangement;[4e,5a,7e,12,13] in addition, the base treatment of α-chlorosulfoxide in the presence of trimethylsilyl chloride to form thioester is known as the silicon Pummerer rearrangement.[4x] Likewise, the reaction of vinylic sulfoxides[4e,9] or *o*-alkylphenyl sulfoxides[5c] via an electrophilic thionium ion from γ-proton loss is known as the vinylogous Pummerer reaction. Moreover, if a nucleophile adds to the vinylic bond, then this variant is also known as additive Pummerer reaction;[4j,6i,14] whereas the treatment of sulfoxide with DAST[8] or n-$Bu_4NH_2F_3$[5s] to produce α-fluorosulfide is referred to as the fluoro-Pummerer rearrangement, and the rearrangement involving the cleavage of an α-stannyl or an allylic stannyl group is called the tin-Pummerer rearrangement[5m] or

vinylogous tin-Pummerer rearrangement,[4e] respectively. The comparable rearrangement of selenium compounds is known as seleno Pummerer reaction or additive seleno Pummerer rearrangement.[4j]

On the other hand, sulfoxides bearing an α-proton may undergo a similar reaction to form thioether when they are treated with a Grignard reagent,[15] and α-thiomethyl ester might eliminate α-proton to form thionium for nucleophilic addition when it is treated with phenyliodine(III) bis-trifluoroacetate.[16]

E. APPLICATIONS

This reaction has very broad application in organic synthesis, such as the formation of an aldehyde by hydrolysis of α-acyloxysulfide,[17] the generation of vinyl sulfide by elimination of α-acyloxy group,[18] and the synthesis of glyoxal from β-ketosulfoxide.[4z] In addition, the formed vinyl sulfide has been used as an intermediate for many other reactions, such as *Diels-Alder Cycloaddition*[4s] and *Michael Addition*.[4j]

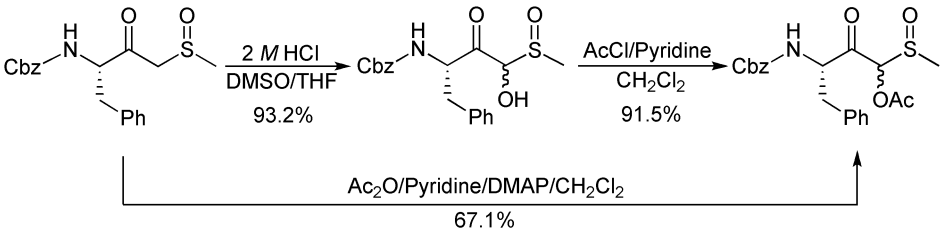
G. CITED EXPERIMENTAL EXAMPLES

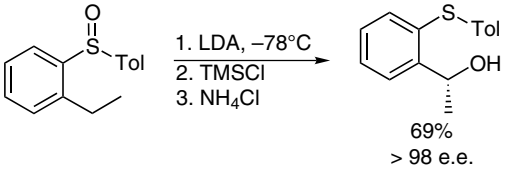


Reference 11.

(3*S*)-3-(*N*-Benzyloxycarbonyl)amino-1-methylsulfinyl-2-oxo-4-phenylbutane (166.2 mg, 0.462 mmol) was added to a mixture of 4.6 mL CH_2Cl_2, 0.5 mL pyridine, and 0.5 mL acetic anhydride, followed by 3 mg 4-dimethylamino pyridine. The resulting mixture was stirred at ambient temperature for 17.5 h, then 10 mL 1 M HCl and 15 mL EtOAc were added. The organic layer was separated and washed with 10 mL saturated $NaHCO_3$ aqueous solution and 10 mL brine, dried over Na_2SO_4 and concentrated under reduced pressure. The resulting residue was purified through preparative silica gel thin-layer chromatography to afford 124.5 mg (3*S*)-1-acetoxy-3-(*N*-benzyloxy-carbonyl)amino-1-methylthio-2-oxo-4-phenylbutane as a colorless solid, in a yield of 67.1%.

Alternatively, 708.6 mg (3*S*)-3-(*N*-benzyloxycarbonyl)amino-1-methylsulfinyl-2-oxo-4-phenylbutane (1.97 mmol) was dissolved in a mixture of 15 mL DMSO and 6 mL THF. Then 7.5 mL 2 M HCl was added. After the mixture was stirred for 18 h at ambient temperature, it was cooled in an ice bath and neutralized with 15 mL saturated $NaHCO_3$

aqueous solution (15 mL). Water (50 mL) and 50 mL EtOAc were added to the mixture. After the organic layer was separated, the resulting aqueous layer was extracted with EtOAc (2 × 25 mL). The combined organic layers were washed with 50 mL water and 30 milliliter brine, dried over anhydrous Na_2SO_4, and concentrated under reduced pressure. The resulting residue was crystallized in *n*-hexane/EtOAc to give 659.7 mg crude (3*S*)-3-(*N*-benzyloxycarbonyl)amino-1-hydroxy-1-methylthio-2-oxo-4-phenylbutane as a colorless crystal, in yield of 93.2%. This intermediate was then acetylated in CH_2Cl_2 with pyridine and acetyl chloride to afford 91.5% (3*S*)-1-acetoxy-3-(*N*-benzyloxycarbonyl)amino-1-methylthio-2-oxo-4-phenylbutane.



Reference 9.

To 3.0 mL THF solution containing 0.89 mmol *i*-Pr_2NH was added 0.6 mmol 2.3 M *n*-BuLi in hexane at 0°C. After being stirred for 30 min, the mixture was cooled to −78°C. Then a solution of 0.5 mmol (*S*)-1-ethyl-2-(*p*-tolylsulfinyl)benzene in 2 mL THF was added. After the mixture was stirred for 1 h, 1.5 mmol freshly distilled TMSCl was added at −78°C. When the reaction was completed (< 1 min), the mixture was hydrolyzed with a mixture of 1 mL saturated NH_4Cl and 1 mL CH_3CN at −78°C, then the solution was warmed to room temperature for overnight. The mixture was extracted with Et_2O (3 × 10 mL), washed twice with 10 mL saturated NH_4Cl, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was purified by flash silica gel column chromatography using hexane/EtOAc (2:1) as the eluent to afford 69% (1*R*)-1-2-(*p*-tolylsulfanyl)phenylethan-1-ol as a colorless oil, with 98% e.e.

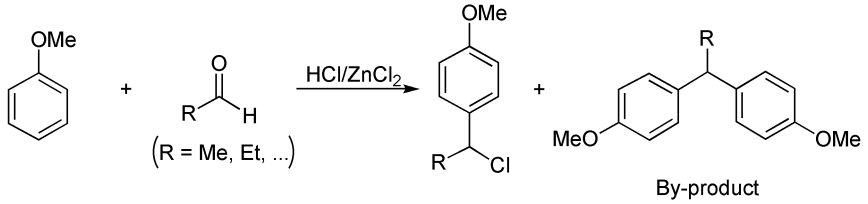
Quelet Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Quelet in 1932,[1] a natural extension of the *Blanc Chloromethylation*. It is the preparation of *para*-α-chloroalkyl aromatic derivatives by passing dry hydrochloric acid through the solution of a phenolic ether and an aliphatic aldehyde in the presence or absence of a Lewis acid reagent (e.g., $ZnCl_2$), and is known as the Quelet reaction[2] or the Blanc-Quelet reaction.[3] Although this reaction often occurs at the *para*-position of phenolic ether, it also takes place at the *ortho*-position if the *para*-position is blocked. Compared to the *Blanc Chloromethylation*, the Quelet reaction is much more sensitive to the substituent on the phenolic ether and is more limited in scope.[4] For example, a single halogen atom on the aromatic ring may cause the deactivation, such as the chloroethylation of *o*-, *m*- and *p*-chloroanisole, *m*- and *p*-bromoanisole from acetaaldehyde.[4] In addition, this reaction is also contaminated by further alkylation of the aromatic nucleus from the α-chloroalkyl aromatic to give bis-aryl-alkane.[4,5]

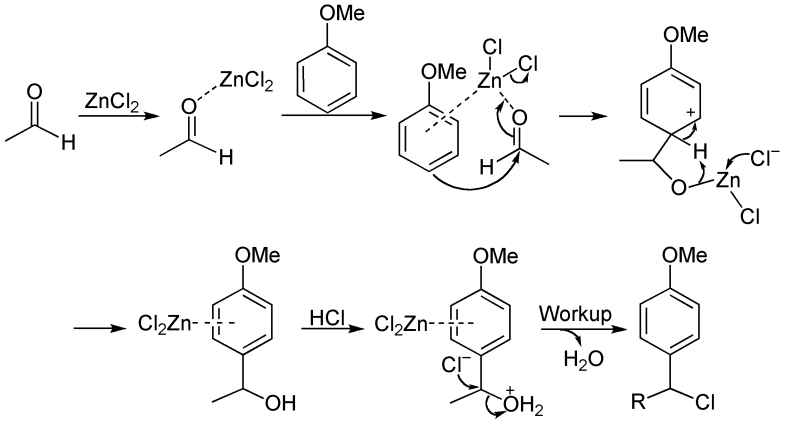
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is an illustration of the reaction mechanism between anisole and acetaldehyde in the presence of $ZnCl_2$.



D. MODIFICATION

N/A

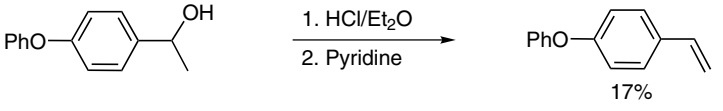
E. APPLICATIONS

This reaction has been used for the preparation of different styrene derivatives.[4,5a]

F. RELATED REACTIONS

This reaction is closely related to the *Blanc Chloromethylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a 1-L, three-necked, round-bottomed flask equipped with a condenser and gas absorption trap, a stirrer and an inlet tube were added 300 mL Et_2O and 50 g a mixture of 1-(4-phenoxyphenyl)-ethanol and its ether prepared from the Quelet chloroalkylation (the inlet tube should be under the surface of the solution). Then dry gaseous hydrogen chloride was passed into the stirred solution for 4 h, and heat was evolved at first. The mixture

became dark brown as the reaction proceeded. Most of the ether was then removed by distillation, and 175 mL pyridine was added. The resulting mixture was heated at 115°C for 6 h, after which the mixture was poured into 750 g ice and 250 mL conc. HCl. This mixture was extracted with $CHCl_3$ (200 mL, then 2 × 100 mL), and the combined organic layers were washed with water (3 × 100 mL) and dried over $MgSO_4$. Upon removal of solvent, the residue was fractionally distilled through a 6-in., Fenske-type column to give 8.2 g 4-phenoxystyrene, in a yield of 17%, b.p. 111–113°C.

Other references related to the Quelet reaction are cited in the literature.[6]

Radziszewski Reaction

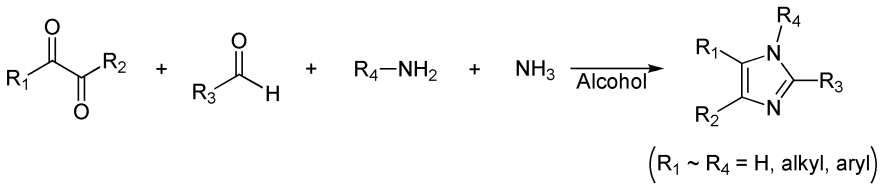
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Debus in 1858,[1] fully developed by Radziszewski beginning in 1882,[2] and further modified by Weidenhagen in 1935.[3] It is the synthesis of an imidazole derivative by the condensation of an α-dicarbonyl compound (e.g., glyoxal), an aldehyde and two equivalents of dry ammonia in alcohol. Therefore, this reaction is generally known as the Radziszewski reaction.[4] Occasionally, it is also called the Radziszewski synthesis,[5] *Weidenhagen Synthesis*,[5] or Debus-Radziszewski imidazole synthesis.[6] As a result, imidazole is also referred to as glyoxaline because of this reaction.[7] Other names that have been designated for imidazoles include iminazole[7] and 1,3-diazole,[7] which have been rarely used in recent literature; whereas the term *imidazole* was originally chosen as the name for such molecules by Hantzsch[8] and was given official recognition.[9]

In this reaction, a variety of α-dicarbonyl compounds—including glyoxal,[4b] pyruvaldehyde,[5b] porphyrin-2,3-diones,[10] and benzil[2a]—have been successfully used to the synthesis of corresponding imidazole derivatives. It is interesting that the replacement of one equivalent ammonia with a primary amine results in the formation of 1-substituted imidazoles.[11] Although this reaction in general gives poor yields of imidazoles[5b,12] and suffers from some side reactions (e.g., the reverse *Aldol Condensation* and oxazole formation)[12a] the condensation of benzil with benzaldehyde and ammonia in alcohol gives nearly a quantitative yield of 2,3,5-triphenylimidazole (lophine).[2a,13] This reaction is useful for the preparation of imidazoles with a substituent at position 2 from adjacent di-carbonyl compounds.[5a] In fact, this reaction is the only reaction of industrial importance for the production of imidazole derivatives.

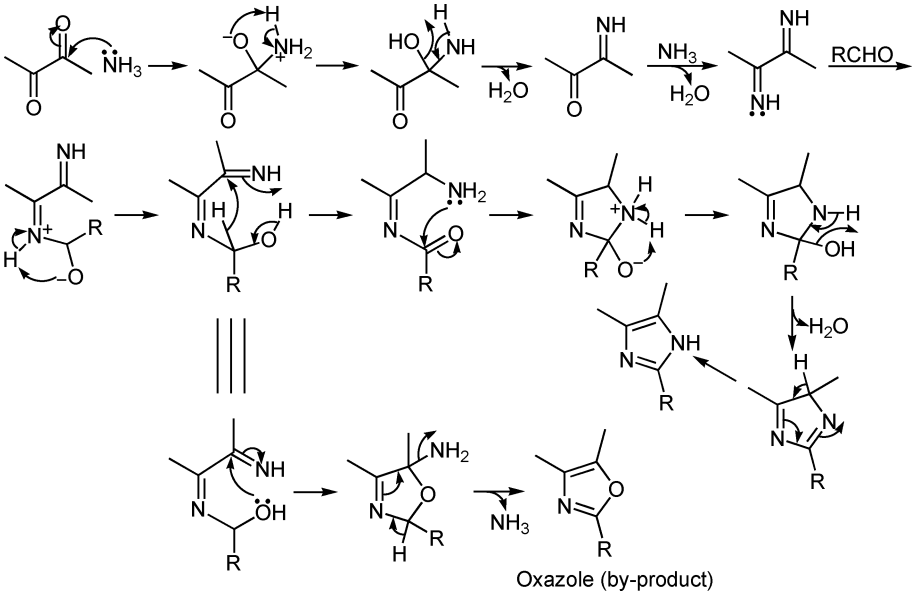
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although there is no general mechanism for this reaction in the cited literature, it is plausible that ammonia (or primary amine) reacts with an α-dicarbonyl compound to form α-diimine, which then condenses with an aldehyde, as displayed here. In the meantime, it is also possible to form an oxazole by-product from this multicomponent condensation.



D. MODIFICATION

This reaction has been extended by Weidenhagen through the condensation of α-acetoacetone, cupric acetate, and aqueous ammonia to afford imidazoles in yields up to 60%.[3,14] This method is thus known as the Weidenhagen modification[4b,15] or *Weidenhagen Synthesis*.[5a] In addition, the Radziszewski reaction has been further modified to proceed in acetic acid by the use of ammonium acetate or ammonium carbonate as the source of ammonia to give imidazoles of markedly improved yields,[16] and this protocol has been recently carried out under microwave irradiation.[12a] Furthermore, it has been reported that the reaction of an amidine with an α-halo ketone also readily yields imidazoles.[12b]

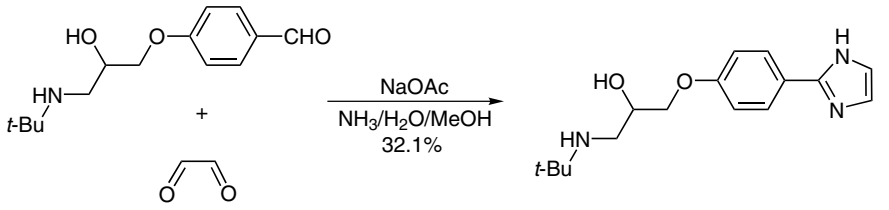
E. APPLICATIONS

This reaction is very useful for the preparation of imidazole derivatives.

F. RELATED REACTIONS

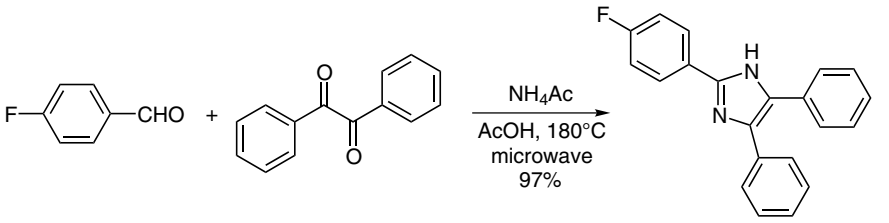
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

A mixture of 10 g 4-[3-(*tert*-butylamino)-2-hydroxypropoxy]-benzaldehyde (0.04 mol), 31 g 40% glyoxal (0.22 mol), 26 g $NaOAc{\cdot}3H_2O$ (0.19 mol), 100 mL concentrated ammonium hydroxide (NH_4OH), and 250 mL MeOH was stirred overnight at room temperature. After removal of MeOH under reduced pressure, the aqueous layer was treated with 100 mL saturated Na_2CO_3 solution and extracted with $CHCl_3$ (3×200 mL). The combined organic layers were dried, filtered, and concentrated. The residue was chromatographed on silica gel using 30% MeOH-$CHCl_3$ as the eluent, and 3.7 g 2-[4-[3-(*tert*-butylamino)-2-hydroxypropoxy]-phenyl]imidazole was obtained after final crystallization from CH_3CN, in a yield of 32.1%.



Reference 12a.

To a 2-mL Smithsynthesizer™ reaction vial containing a magnetic stir bar were added 1.0 mL acetic acid, 42 mg benzil (0.2 mmol), 25 mg 4-fluorobenzaldehyde (0.2 mmol), and 154 mg ammonium acetate (2.0 mmol). The reaction vessel was heated in the Smithsynthesizer reactor cavity for 5 min at 180°C, after which the vessel was rapidly cooled to 40°C by the unit. The reaction mixture was added dropwise to a concentrated NH_4OH solution cooled to 0°C and immediately formed a white precipitate, which was collected by filtration and washed with H_2O. The solid was dried in a vacuum oven for 18 h at 50°C to

afford 61 mg 2-(4-fluorophenyl)-4,5-diphenylimidazole as a bright white solid, in a yield of 97%.

Other references related to the Radziszewski reaction are cited in the literature.[17]

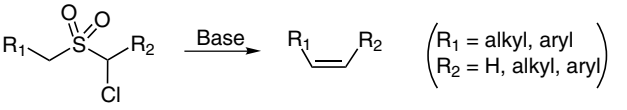
Ramberg-Bäcklund Reaction
(Ramberg-Bäcklund rearrangement)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ramberg and Bäcklund in 1940.[1] It is a base-promoted transformation of α-halosulfones into olefins with extrusion of SO_2 via an episulfone intermediate and is generally known as the Ramberg-Bäcklund reaction[2,3] or Ramberg-Bäcklund rearrangement.[2a,2c,2e,2f,2k,4] In addition, this reaction is occasionally referred to as the Ramberg-Bäcklund elimination,[2f] Ramberg-Bäcklund olefination,[5] Ramberg-Bäcklund synthesis,[5c] or Ramberg-Bäcklund olefin synthesis.[6] This reaction is applicable for nearly all α-halosulfones having at least one α'-hydrogen and occurs at very mild conditions. For example, it requires only a dilute base and moderate temperatures (room temperature to 100°C)[4e] and usually gives the *cis*-elimination product.[2i,4d] It is assumed that this reaction involves the deprotonation of α'-hydrogen to generate a sulfonyl carbanion, which undergoes an intramolecular nucleophilic displacement of α-halogen (a S_N2 reaction) to form an episulfone intermediate that is converted directly to a corresponding olefin.[4m] This mechanism is supported by the deuterium exchange experiment[7] as well as the actual isolation of 2,3-diphenylvinylenesulfone.[8] It has been reported that the α-halosulfones in general are very prone to 1,3-elimination to form episulfone when exposed to a base, regardless of the number of α-halogens;[4l] in addition, the formed episulfones being sufficiently stable may undergo a base-promoted process to evolve SO_2.[2p] However, the base treatment of trichloromethyl sulfones leads to the formation of sulfonic acid.[4l] More information about this reaction is provided in a few reviews.[3d,9]

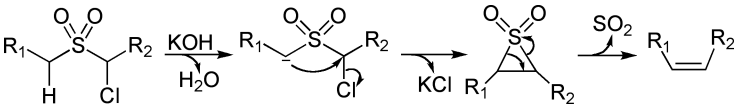
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is a general mechanism for the reaction between an α-chlorosulfone and KOH.



D. MODIFICATION

This reaction has been modified by the *in situ* chlorination of sulfone using CCl_4 as a chlorination reagent.[2d] In addition, the sulfones have been mixed with powdered KOH and Al_2O_3 to improve the extrusion of SO_2.[2o] The reaction is also extended to a solid-phase supported condition (e.g., resin).[2a]

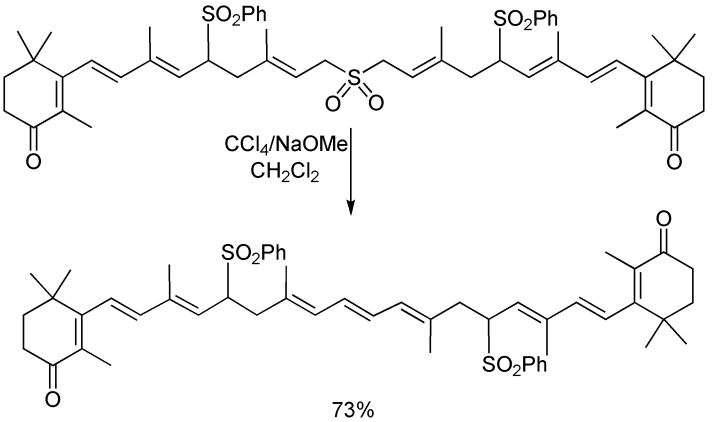
E. APPLICATIONS

This reaction has very broad application in organic synthesis, especially for the preparation of natural products[2i,10] and C-glycosides.[2k,2l,11]

F. RELATED REACTIONS

Mechanistically, this reaction is similar to the *Favorskii Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES

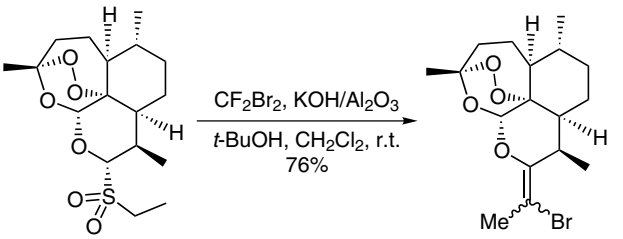


73%

Reference 2d.

To a stirred solution of 350 mg bis(5-benzenesulfonyl-3,7-dimethyl-9-(3-oxo-2,6,6-trimethyl-1-cyclohexenyl)-2,6,8-nonatrienyl) sulfone (0.38 mmol) in 10 mL CH_2Cl_2 was added 5 mL CCl_4 and 0.17 g NaOMe (3.14 mmol). The mixture was stirred at room temperature for 4.5 h, then 5 mL H_2O was added. The reaction mixture was extracted with CH_2Cl_2, washed with a saturated aqueous $NaHCO_3$ solution and H_2O, dried over anhydrous Na_2SO_4,

filtered, and concentrated under reduced pressure. The residue was purified by silica gel flash column chromatography to afford 236 mg 1,18-bis(3-oxo-2,6,6-trimethyl-1-cyclohexenyl)-5,14-dibenzenesulfonyl-3,7,12,16-tetramethyl-1,3,7,9,11,15,17-eicosaheptaene, in a yield of 73%.



Reference 4a.

10*R*-Ethanesulfonyldihydroartemisinin (220 mg, 0.61 mmol) was added to a stirred suspension of 3.80 g alumina-supported potassium hydroxide (KOH/Al_2O_3) in 45 mL CH_2Cl_2 and 9 mL *tert*-butyl alcohol at 5°C under nitrogen atmosphere. Then 0.73 mL dibromodifluoromethane (7.7 mmol) was added dropwise through a syringe for 5 min with additional stirring for 1 h at room temperature. After the reaction was complete, the excess solid reagent (KOH/Al_2O_3) was removed by suction filtration through a pad of Celite. The filter residue was washed thoroughly with CH_2Cl_2, and the combined filtrates were concentrated under reduced pressure. The residue was purified by silica gel column chromatography to give 76% 10-(1-bromoethylidene)-deoxoartemisinin. *E*-10-(1-bromoethylidene)-deoxoartemisinin, white crystals, m.p., 104–105°C; *Z*-10-(1-bromoethylidene)-deoxoartemisinin, white crystals, m.p., 120–121°C.

520

Raney Nickel

A. GENERAL DESCRIPTION OF THE REACTION

This reagent was first reported by Raney in 1925.[1] It is a porous nickel suspension primarily prepared from alkali soaking of 50% nickel-aluminum alloy[2] but can also be prepared by acid soaking (e.g., HCl). According to the temperature and alkali concentration,[3] different types of Raney nickel can be prepared, such as W-2,[4] W-6,[2a,3] and T-1.[3] It has been found that Raney nickels retain about one half to one hydrogen per atom of nickel, with the hydrogen attached in a metastable state.[5] This catalyst has surface area of 50–120 m^2/g, with 20% of that being metal and 80% non metal, with an average pore diameter of 84 Å, and with a high resistance to sintering.[6] It has been found that the activity of this catalyst is proportional to its hydrogen content, and the surface area decreases linearly with loss of hydrogen until ~70% of hydrogen is removed.[5] In addition, the activity of Raney nickel decreases along with the storing time.[7]

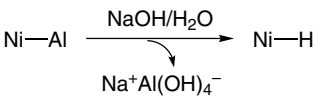
Generally speaking, Raney nickel has many applications in organic synthesis, such as reduction, oxidation, *N*-alkylation, desulfurization, dehydration and cleavage of chemical bonds. When employing a gaseous hydrogen source, many functional groups can be reduced, and even toluene can be hydrogenated.[8] However, without gaseous hydrogen, carbon-carbon double bonds, carbonyls, nitro groups, hydrazo, and azoxy groups are reduced.[9] In addition, other reagents have also been used as reducing reagents or hydrogen donors in the presence of Raney nickel, such as hydrazinium monoformate for the reduction of nitrile and nitro moieties,[10] hydrazine hydrate with an excess of alcohol for selective reduction of nitro groups in the presence of carbonyls,[11] and isopropanol for the reduction of aromatic rings (benzene) to cyclohexane and for the dehalogenation of halogenated aromatics.[12] Alternatively, the combination of Raney nickel and platinum has been used for the reduction of nitriles to primary amines,[13] and the combination of $Ti(O\text{-}i\text{-}Pr)_4$ and Raney nickel can

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

transform aliphatic ketones into enantiomeric amines through reductive amination in the presence of (*R*)- or (*S*)-α-methylbenzylamine.[14]

Other general applications of Raney nickel include desulfurization[15] and deselenization. It has been found that the desulfurization of sulfides[16] and sulfoxides[17] occurs through a radical process with complete racemization of chirality at the carbon atom adjacent to the sulfur atom, whereas the desulfurization of sulfones affords 90% retention of optical activity with apparent inversion of configuration at the carbon atom adjacent to sulfur.[18] However, the combination of Raney nickel and sodium hypophosphite leads to the retention of stereochemistry during desulfurization of optically active secondary alcohol.[19] It should be pointed out that the carbon-carbon bond may be cleaved under the condition of desulfurization, as shown in the hydrogenolysis of ethylenedithiol and its ether.[20] In deselenization, diselenides and phenyl selenobenzoate are transformed into selenides by Raney nickel.[21] Furthermore, Raney nickel has been used for the oxidation of secondary alcohols into ketones in refluxing benzene without hydrogen acceptor added,[22] and converting 1,4-diol into lactone.[23] On the other hand, alcohols can be used as alkylating agents in the presence of a Raney nickel catalyst, such as the alkylation of butylamine, *N*,*N*-dibutylamine with ethanol and propanol,[24] and the alkylation of piperazine.[25] In addition to these applications, Raney nickel has been widely used for the cleavage of chemical bonds; which include (*a*) the carbon-carbon bond during desulfurization (e.g., the cleavage of ethylenedithiol and its ether);[20] (*b*) *N*-*N* bond in conversion of carboxylic acid hydrazides into amides and ammonia;[26] (*c*) *O*-*O* bond in conversion of ozonide into aldehyde and ketone;[27] (*d*) *C*-*O* bond in decarboxylation of alkyl formates to alcohols and potential ketones,[28] and *C*-*O* bond during dehydration of alcohols, such as benzyl alcohol to toluene,[9] glycerol to 1,2-propanediol,[29] 2-propanolpyridine to 2-ethylpyridine and 2-methyl-6-ethylpyridine,[30] mandelamide to racemic phenylacetamide,[31] and tertiary alcohol to alkanes;[32] and (*e*) *N*-*B* bond in decomposition of borane-amine complex (except for Et_3N and pyridine) in the presence of methanol.[33] Interestingly, it has been found that the activity of Raney nickel can be enhanced by addition of cobalt,[34] amyl chloride,[35] platinum chloride ($PtCl_4$),[36] or platinum chloride in combination with Et_3N.[37] However, Raney nickel can also be poisoned by sulfur compounds[38] and HCl and organic halides.[35] It has been found that organic chlorides and bromides are moderately toxic to Raney nickel, and iodides are highly toxic. In addition, propyl chloride and halides with more than one halogen atom on the same carbon are also highly toxic.[35]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The aluminum in nickel-aluminum alloy would be soaked out and displaced by hydrogen, thus no further mechanism is needed.

D. MODIFICATION

Raney nickel has been prepared from nickel-magnesium alloy.[4] In addition, Raney cobalt in ethanol or dioxane shows a reactivity similar to Raney nickel.[39]

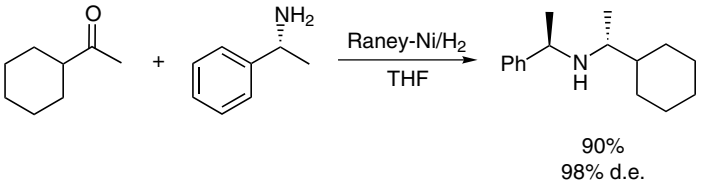
E. APPLICATIONS

This catalyst has very broad applications in organic synthesis.

F. RELATED REACTIONS

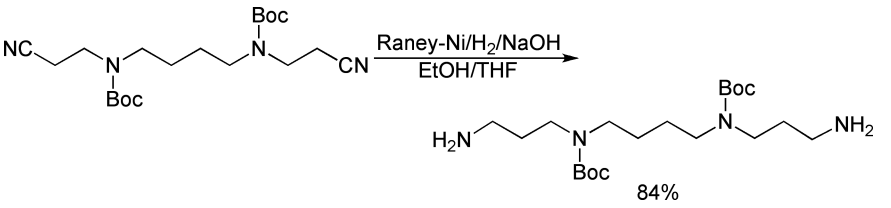
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

In an anhydrous solvent (any one from THF, MTBE, DME, hexane, toluene, CH_2Cl_2, 1,2-dichloroethane, EtOAc, and EtOH) were added 2.50 mmol methyl cyclohexyl ketone, 3.12 mmol titanium tetraisopropoxide, and 2.62–2.75 mmol (*R*)-α-methylbenzylamine. The solution was stirred at room temperature for 30 min. Raney-Ni (70–100 wt %) triturated with EtOH (twice) and the reaction solvent (twice) was added to the reaction solution, and the reaction vessel was pressurized to 120 psi (8.3 bar) with hydrogen. When the reaction completed, the mixture was stirred with 10 mL 1.0 M NaOH for 1 h. The heterogeneous mixture was then filtered through a bed of Celite and washed with EtOAc. The filtrate was evaporated to remove the low boiling organics, and the remaining aqueous solution was then extracted with CH_2Cl_2 (3 × 15 mL). The combined organic extracts were dried over Na_2SO_4, filtered, and then concentrated. The residue was purified by flash column chromatography to afford 90% (1*R*)-*N*-((*R*)-1-cyclohexylethyl)-1-phenylethanamine in 98% d.e.



Reference 13.

N_1,N_4-Di(*tert*-butyloxycarbonyl)-N_1,N_4-di(2′-cyano-ethyl)-1,4-butanediamine (1.70 g, 4.31 mmol) was dissolved in a mixture of 80 mL absolute ethanol and 20 mL THF. Raney-nickel (2.1 g, 17.8 mmol) as a 50% suspension in water was added together with 10 mL 2 N NaOH, and the reaction mixture was shaken under 45 psi hydrogen pressure at room temperature for 8 h. After the catalyst was filtered off and the solvents were removed in vacuo, a mixture of 100 mL water and 30 mL CH_2Cl_2 was added, and the organic phase was separated. The aqueous phase was further extracted with CH_2Cl_2 (3 × 30 mL), the combined organic layers were dried with Na_2SO_4. Upon removal of solvent in vacuo, 1.45 g N_1,N_4-di(*tert*-butyloxycarbonyl)-N_1,N_4-di(3-aminopropyl)-1,4-butanediamine was obtained as a yellow, highly viscous oil, in a yield of 84%. This product could be further purified by silica gel column chromatography using Et_3N/MeOH (1:10) as the eluent, R_f = 0.36 (35% aq. NH_3/MeOH, 1:10).

Other references related to Raney nickel are cited in the literature.[40]

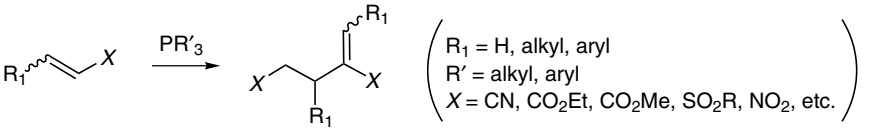
Rauhut-Currier Reaction
(Rauhut-Currier Dimerization)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rauhut and Currier in 1963.[1] It is a phosphine-catalyzed dimerization of electron-deficient alkenes[2] and is generally known as the Rauhut-Currier reaction[2,3] or Rauhut-Currier dimerization.[2a] Although this reaction is reported to have relatively low selectivity and low yield,[4] the dimerization of methyl acrylate at temperatures between 50° and 110°C always gives head-to-tail dimer,[5] and the intramolecular dimerization of unsymmetrical bis(enones) with sufficient steric or electronic bias gives single products.[2b] In addition, the reaction between ethyl acrylate and acrynitrile in *t*-butanol at 100°C in the presence of tributylphosphine gives 48% of only one type cross-condensation product as well as the self-dimerization products.[5a] The reaction of acrynitrile is very fast under the Rauhut-Currier reaction conditions at refluxing temperatures, which leads to the vigorous polymerization of acrynitrile.[5b] However, the dimer and trimer of acrynitrile can still be obtained if such reaction were carried out in acetonitrile by addition of an extra proton donor such as water or *t*-butanol, and separation of tributylphosphine before isolation of the product.[5b]

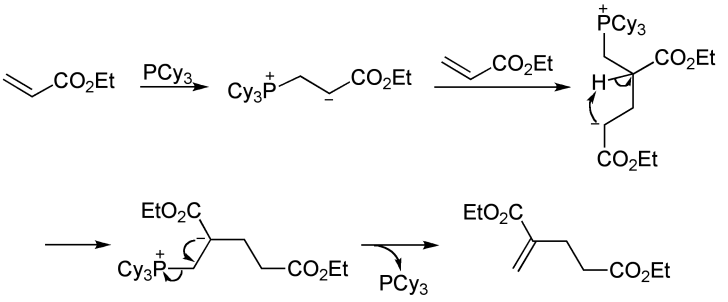
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is proposed that this reaction involves a reversible conjugate addition of phosphine to electron-deficient alkenes, followed by a *Michael Addition* of the resulting carbanion to the second alkene, and subsequent proton migration and elimination of phosphine,[2a] as illustrated here by the tricyclohexylphosphine catalyzed reaction of ethyl acrylate.



D. MODIFICATION

This reaction has been modified by the use of proazaphosphatranes[3] and tricyclohexylphsophine in combination with CS_2[6] as catalysts. In addition, the organometallic complexes of phosphine such as $Cp^*Ru(PCy_3)H_3$,[7] have been used as catalysts as well. It has been found that the activity of this type catalyst varies along with the phosphine ligands in the order of $P(OR)_3 < PAr_3 < PR_3$, with an optimal ratio of 1.5:1 for ligand to Ru.[8] Moreover, this reaction has been extended to the addition of activated alkenes to aldehydes, and it has been found that intramolecular addition of *cis*-alkene to aldehyde is faster than that of *trans*-alkene.[3]

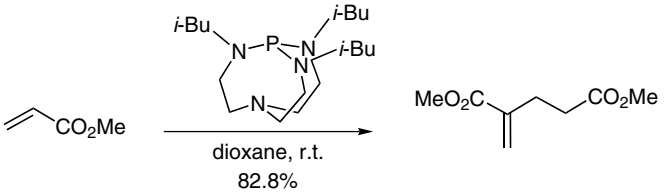
E. APPLICATIONS

This reaction should have general application in organic synthesis but has not yet been extensively explored.

F. RELATED REACTIONS

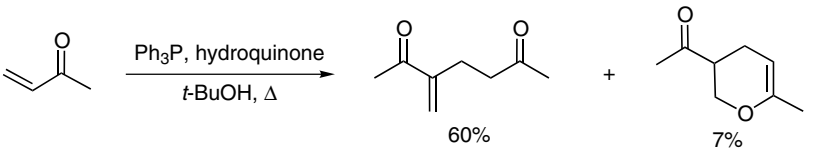
This reaction is very closely related to the *Baylis-Hillman Reaction*, and is also related to *Stetter Reaction* and *Benzoin Condensation* in mechanism.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a solution of 431 mg methyl acrylate (5 mmol) in 2 mL dioxane was added 0.5 mmol tri-isobutyl proazaphosphatranes in the same solvent by syringe. The mixture was stirred at room temperature for 3 h, then the solvent was removed under vacuum. The residue was purified by column chromatography using EtOAc/hexanes (1:4) as eluent to afford 82.8% 2-methylene-pentanedioic acid dimethyl ester.



Reference 5a.

To a 350-mL glass-lined reactor were added 20 g methyl vinyl ketone (285 mmol), 0.2 g hydroquinone, 1.85 g Ph_3P (7.1 mmol), and 100 g *t*-butanol under nitrogen. Then the reaction was sealed under nitrogen and heated at 118°C for 8 h. *t*-Butanol and unreacted methyl vinyl ketone were removed by vacuum distillation, and the residue was distilled through a small Vigreux column to afford 8.6 g fraction with a boiling point in the range of 55–75°C at 1.2 mmHg, along with 4.5 g residue. Gas-liquid chromatography analysis on the DC-710 column at 180–200°C showed the presence of 7.2 g 3-methylene-2,6-heptanedione (60% yield), 0.8 g 5-acetyl-5,6-dihydro-2-methylpyran (7% yield), and 0.4 g of an unknown compound. The expected 3-methylene-2,6-heptanedione was isolated by further fractional distillation through a 2-ft spinning-band column at 91–92°C (5 mmHg), with m.p. 5–7°C. Recrystallization of earlier distillation residue from ethanol yielded 1.4 gram triphenylphosphine, with a recovery of 75%. (*Note:* The original paper claimed 0.8 g 6-acetyl-5,6-dihydro-2-methylpyran, but is corrected here.)

Reed Reaction

(Reed Process, Reed Sulfochlorination)

A. GENERAL DESCRIPTION OF THE REACTION

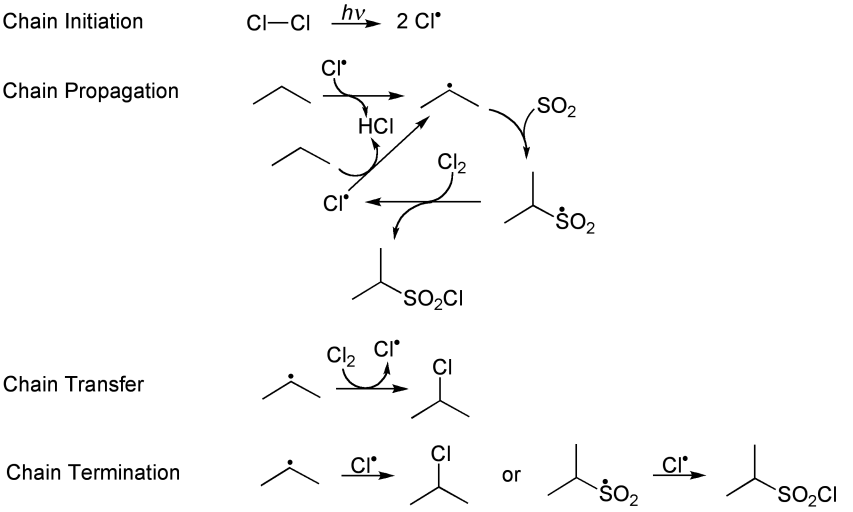
This reaction was first reported by Reed in 1936.[1] It is a photochemical transformation of hydrocarbon into aliphatic sulfonyl chlorides in the presence of sulfuryl chloride or sulfur dioxide and chlorine under actinic light illumination[2] and is known as the Reed reaction[2,3] or Reed process.[2b] This reaction is a primary industrial process for production of aliphatic sulfonyl chlorides with long hydrocarbon chains, which have wide applications in synthetic detergents[3a] and wetting agents.[2b,3b] This reaction is assumed to occur via a free-radical mechanism,[3a,4] and usually gives the mixtures of both sulfochlorination and chlorination products, including monosulfonyl chlorides, chloroalkyl monosulfonyl chlorides, polysulfonyl chlorides, chloroalkyl polysulfonyl chlorides, and alkyl chlorides and alkyl polychlorides.[2b] It has been found that under certain carefully controlled conditions, monosulfonyl chlorides can be produced predominantly[5] because the ratio of chlorination to sulfochlorination decreases along with the increase in the ratio of SO_2/Cl_2 supplied and both light intensity and frequency; in addition, lower reaction temperatures and smaller bubble size are also favorable for the production of sulfonyl chlorides with high purity.[2a] Although this reaction has been extensively used for the preparation of sulfonyl chlorides of long hydrocarbon chains, the corresponding sulfonyl chlorides from propane,[6] butane,[7] and isobutene[8] have also been successfully prepared from this reaction.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

It is believed that chlorine cleaves homolytically under UV light to generate the initial chlorine radical, which abstracts a proton from the hydrocarbon to form an alkyl radical that combines with sulfur dioxide, as illustrated here by the representative chain reactions of propane. It should be pointed out that proton abstraction by the chlorine radical occurs predominantly at tertiary or secondary carbons rather than at the primary carbons (i.e., terminal CH_3).



D. MODIFICATION

This reaction has been modified by the use of gamma-ray illumination; gamma-rays hold much higher energy than UV light. In this modification, the cleavage of a carbon-hydrogen bond is assumed to be the initiation step, which is rate-limiting step under the dose rate (intensity of gamma-ray) below 40 rad/min. However, the reaction rate depends on the supply of SO_2 and Cl_2 when the intensity is 400 rad/min.[2a] In addition, this reaction has been modified to initiate from free-radical initiators such as peroxides[9] and tetraethyl-lead.[2a]

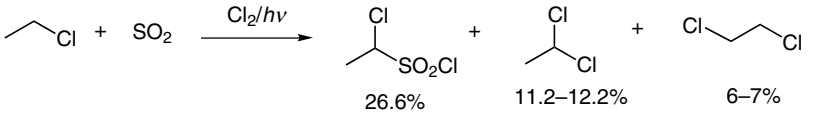
E. APPLICATIONS

This reaction has wide industrial application in the production of synthetic detergents[3a] and wetting agents[2b,3b] as well as for the modification of polyethylene.[3a]

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a round-bottomed flask equipped with a gas inlet tube and a dry ice cooled condenser, was added 1.0 mol ethyl chloride and 2.34 mol sulfur dioxide. Then 1.31 mol chlorine was slowly passed into the ethyl chloride and sulfur dioxide mixture through the gas inlet within 3.5 h while illuminated by one or two Westinghouse RS 275-watt sunlamps at a distance of about 6 in. The reaction mixture was first separated by atmosphere pressure distillation from a water bath, and the low-boiling fraction was added to 20% NaOH solution frozen at −70°C and warmed slowly to 0°C to remove HCl, SO_2, and SO_2Cl_2. Then the aqueous solution was neutralized with HCl, and the dichloroethanes were separated by steam distillation to give 6–7% 1,2-dichloroethane (b.p. 83°C) and 11.2–12.2% 1,1-dichloroethane (b.p. 57°C). The residue from initial distillation was further subjected to vacuum distillation to give 26.6% 2-chloroethanesulfonyl chloride as a water white lachrymatory liquid, b.p. 84°C at 12 mmHg. (*Note:* The author has no idea about the status of 20% NaOH solution frozen at −70°C, i.e., whether it is a solid, semi-solid or a solution).

523

Reformatsky Reaction

(Reformatskii Reaction, Reformatsky Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

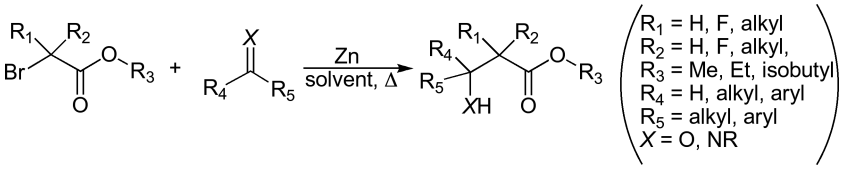
This reaction was first reported by Reformatsky (also spelled as Reformatskii) in 1887.[1] It is a zinc-mediated formation of β-hydroxy esters from the condensation between α-bromoester and an aldehyde or ketone, or more generally the reaction between an activated alkyl halide with a carbonyl compound in the presence of zinc to form a hydroxy compound.[2] Therefore, this reaction is generally known as the Reformatsky reaction,[3,4] or Reformatskii reaction.[5,6] Occasionally, it is also referred to as the Reformatsky (Reformatskii) condensation,[3f,3n,7] or Reformatsky addition.[8] The inserted complex between zinc and α-bromoester is generally referred to as the Reformatsky reagent.[9] Since its discovery, this reaction has been extensively explored because of its high functional group tolerance.[9c] However, the traditional Reformatsky protocol is also known to have several drawbacks, including a problem in its initiation and regulation because of the heterogeneity;[9f] the requirement for fresh preparation of zinc reagent;[9c,10] low reproducibility and access only to the thermodynamic products;[11] low yields because of the enolization of the Reformtasky reagent and many associated side reactions under the reaction condition, including the self-condensation of carbonyl compounds and α-bromoester;[12] elimination of α-bromoester;[12] and *retro*-Reformatsky fragmentation.[13] According to what now known, the use of an excess amount of zinc and α-bromoester can improve the yields,[3l] and the resulting addition products are better decomposed by use of dry hydrogen chloride[14] or 50% H_2SO_4.[15] Suitable solvents include 1,4-dioxane,[7c] THF,[12] Et_2O,[16] and benzene;[3j,12,14,17] but generally, benzene, especially the mixed solvent of benzene (e.g., benzene-ether), is the solvent of choice.[18] In addition, the small variation in the alcoholic moiety of α-bromoester remarkably

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

affects the reactivity of the α-bromoester.[19] For example, the methyl and ethyl α-bromoesters react regularly, whereas isopropyl, *t*-butyl and neopentyl esters are inert. It is interesting that the isobutyl ester reacts comparably with ethyl ester, which would be a choice when ethyl ester is involved in many side reactions.[19]

So far, this reaction has been used for the addition of Reformatsky reagent to aldehydes, ketones, thienyl aldehyde,[2,3g] isatins[3p] to prepare hydroxy compounds; to anils for β-amino esters;[20] to aroyl chloride[21] and 3-acyloxazolidin-2-ones[22] for β-keto esters; and to phenyl esters to form β-keto esters when neither the phenyl ester nor the α-bromoester bears α-hydrogen.[3m] In addition, many variants of α-bromoesters have been developed or used successfully for this reaction, such as α-bromolactone,[23] γ-bromocrotonate,[3g,3j,5l] bromofluoroacetate,[3f,24] iododifluoroacetate,[25] α-chloroesters,[9f,17b] α-methylene-β-bromoester,[9d] *N*,*N*-dialkyl-α-haloamides,[3k] and α,α-disubstituted α-bromoester[26] (e.g., methyl or ethyl α-bromoisobutyrate[3a,3b,3m,21,27]). Among these variants, iododifluoroacetate leads to the formation of α,α-difluoro-β-hydroxyester,[25] while bromofluoroacetate yields α-fluoro-β-hydroxyester in comparable yield with simple α-bromoester, though it does so more sluggishly.[3f] However, α,α-disubstituted α-bromoesters would produce the tetrasubstituted β-lactones rather than regular β-hydroxy esters when they react with ketones in DMF.[26] It is interesting that for the case of ethyl α-bromoisobutyrate, though β-lactones are formed predominantly under different conditions—such as using zinc or indium powder or at a sacrificial zinc or indium anode—the normal β-hydroxy esters will form at a sacrificial zinc anode if a catalytic amount of $NiBr_2$ is added.[27a] Similarly, the reaction of α-methylene-β-bromoester reacting with cyclic ketone will give spiro-α-methylene-γ-lactone.[9d] In contrast, the reaction of γ-halocrotonate, the so-called vinylogous Reformatsky reaction,[3j,28] is substrate- and solvent-dependent. For example, the reaction between methyl γ-bromocrotonate with cyclohexanone, 4-methylcyclohexanone, β-tetralone, and 3,4,5-trimethoxybenzaldehyde in boiling benzene yields normal vinylogous Reformatsky products,[3j] i.e., products resulting from γ-addition, whereas the same reaction in boiling ether yields α-substituted vinylacetate, probably because of charge migration in the organic zinc reagent.[3g] Likewise, the reaction between methyl γ-bromocrotonate with 2-methyl cyclohexanone and α-tetralone produces the vinylogous product through the γ-position addition.[3j] This reaction has been extensively reviewed.[29]

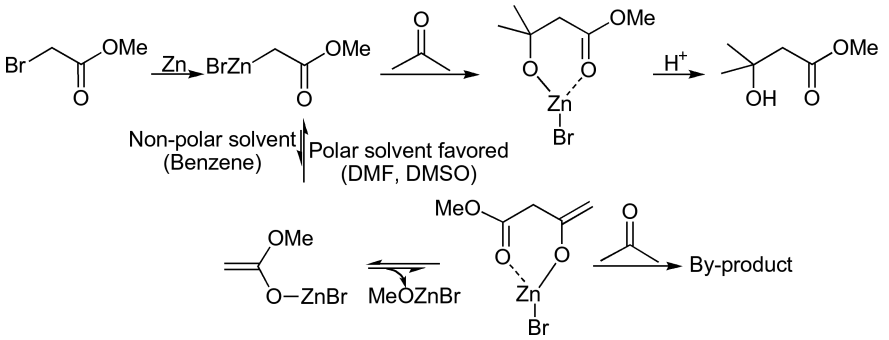
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Mechanistically, the insertion complex between zinc and α-bromoester generated *in situ* exists at least in two forms, such as the *C*-metalated and *O*-metalated species,[9g] and the

C-metalated species is normally referred to as the Reformatsky reagent.[9e,9f] These two species may further aggregate to form dimer by elimination of alkoxyzinc bromide,[9i] though the *C*-metalated species is the active one in this reaction. This assertion is supported first by the partial recovery of ketone during the complete consumption of zinc when an equivalent zinc and ketone are used;[3o] and second, by the titration experiment on ethyl α-bromoisobutyrate, in which 70% active reagent and 30% dimeric substance were identified.[9i] According to these experimental results, an illustrative mechanism is proposed here using acetone and methyl α-bromoacetate as an example.



D. MODIFICATION

This reaction has been extensively modified, and these modifications in general can be grouped into five categories: (a) different forms of active zinc, (b) other metallic reagents rather than zinc, (c) combination of zinc and other chemicals, (d) different catalysts, and (e) different reaction environment. So far, because of slow initiation of zinc in the traditional Reformatsky reaction, several types of activated zincs have been used, such as acid-washed zinc,[15] sand-paper polished zinc foil,[14] finely divided metallic zinc reduced from zinc halide by alkali metal (K),[30] granular zinc in a continuous flow system,[12] sacrificial zinc anode,[9f] Et_2Zn,[9b,9c] Zn/Ag,[31] and Zn/Cu.[17b,32] In addition, other metals or their salts have been successfully used for the substitution of the zinc reagent, including cadmium,[18,33] germanium (reduced from GeX_4 or GeX_2 by K),[34] lithium,[35] magnesium,[36] $CrCl_2$,[11] and SmI_2.[37] The combinations of zinc and other chemicals include Zn/Et_3Al,[38] $Zn/CeCl_3$,[24] $Zn/B(OMe)_3$ (in THF),[17a,39] Zn/TMSCl (5–10 mol %),[16] and $Et_2Zn/RhCl(PPh_3)_3$.[10b] In addition, $NiBr_2$(bipy),[9f] $Co(PPh_3)_4$,[40] Cp_2TiX,[8] and ate-type tin complexes of $Li^+[Bu_2SnI_3]^-$/HMPA[41] have been used to mediate this reaction. Finally, this reaction has been carried out under nontraditional conditions, such as in concentrated aqueous solution without co-solvent,[42] in an agate mortar and pestle without solvent,[43] on supported solid phase,[44] in ionic liquid,[45] and by sonic[39] or high intensity ultrasound acceleration.[46] In addition, different ligands, such as cinchona alkaloids[47] and (-)-*N*,*N*-dimethylaminoisoborneol ((-)-DAIB),[9a] have been used to enhance the enantioselectivity.

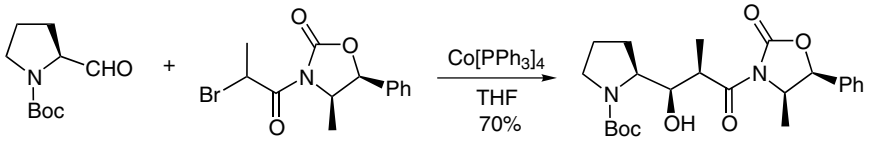
E. APPLICATIONS

This reaction has very broad applications in organic synthesis.

F. RELATED REACTIONS

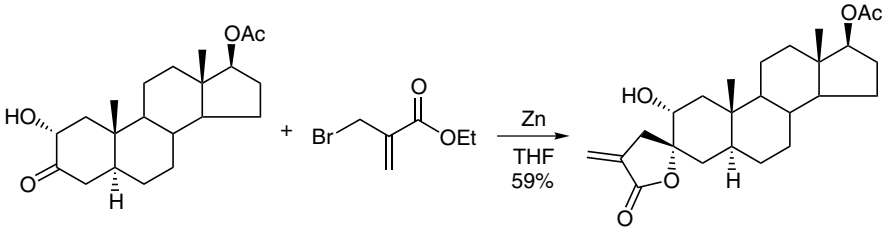
This reaction is related to the *Aldol Condensation*, *Blaise Condensation*, and *Luche Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 40.

To a solution of 0.31 g 3-(2-bromopropionyl)-4*R*-methyl-5*S*-phenyloxazolidin-2-one (1 mmol) in 5 mL anhydrous THF cooled to 0°C, was added 1 mmol $Co[PPh_3]_4$ solution dropwise over 30 min. Then 0.20 g *N*-Boc-L-prolinal (1 mmol) was added to the dark brown solution. After being stirred for 2 h, the reaction mixture was poured into cold 0.1 *N* HCl and extracted with EtOAc. Upon removal of solvent under reduced pressure, the residue was purified by flash column chromatography using hexane/EtOAc (4:1) as the eluent to afford 0.30 g (4*R*,5*S*,2′*R*,3′*R*,2″*S*)-3-[3′-(*N*-*tert*-butoxycarbonyl-2″-pyrrolidinyl)-3′-hydroxy-2′-methylpropanoyl)-4-methyl-5-phenyl-2-oxazolidinone as a colorless foam, in a yield of 70%.



Reference 9d.

To a solution of 1 mmol of *keto* steroid in 8 mL anhydrous THF under argon was added 1.2 mmol freshly activated zinc dust, and the mixture was stirred at 37°C for 15 min. Then 1.2 mmol ethyl 2-(bromomethyl)acrylate in 4 mL anhydrous THF was added, and the reaction was monitored intermittently by TLC. After being stirred at 37°C for 15 h, the reaction mixture was cooled to room temperature, and 2 mL 10% (w/v) HCl was added. After being kept at room temperature for 0.5 h, the solution was filtered and extracted with EtOAc, washed with water and brine, and dried over anhydrous Na_2SO_4. Upon removal of solvent, the residue was purified by column chromatography to afford 59% spiro-α-methylene-γ-butyrolactone, m.p. 256°C.

Other references related to the Reformatsky reaction are cited in the literature.[48]

Regitz Diazo Transfer

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Regitz in 1967.[1] It is a base-promoted transfer of a diazo group from an azide to an active methyl or methylene moiety of a substrate with one or more electron-withdrawing groups. Therefore, it is known as the Regitz diazo transfer.[2] The azides developed for this reaction include the most commonly used toluenesulfonyl azide (tosyl azide, TsN_3),[1,2b,3] and others such as *p*-acetamidobenzenesulfonyl azide,[4] 2,4,6-triisopropylbenzenesulfonyl azide (trisyl azide),[3a,5] 4-nitrobenzenesulfonyl azide (PNBSA),[6] methanesulfonyl azide (mesyl azide),[7] *p*-carboxybenzenesulfonyl azide,[8] trifluoromethanesulfonyl azide,[9] 2-azido-3-ethylbenzenethiazolium tetrafluoroborate,[10] 1-ethyl-2-azidopyridinium tetrafluoroborate,[10] (azidochloromethylene)-dimethylammonium chloride,[11] naphthalene-2-sulfonyl azide,[12] *p*-(*n*-dodecyl)benzenesulfonyl azide,[12] diphenyl phosphorazindaze,[13] *p*-nitrophenyl azide,[14] and polystyrene benzenesulfonyl azide.[15] The active methyl or methylene group adjacent to a single electron-withdrawing group is often activated by acylation before the diazotization, followed by deacylation.[6,16] It is worth noting that this reaction has some intrinsic drawbacks such as the azo coupling of the diazo compound with the starting material,[15] the unpredictable transfer of the azido group,[3a] and the difficulty in separation of the excess reagent and *p*-toluenesulfonamide.[7] For example, trisyl azide is superior to TsN_3 during the diazotization of cyclic ketone but predominantly transfers an azido group to the acyclic imide and ester enolate.[17]

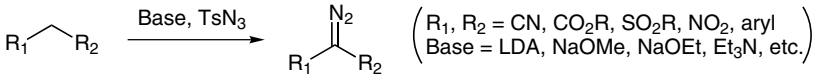
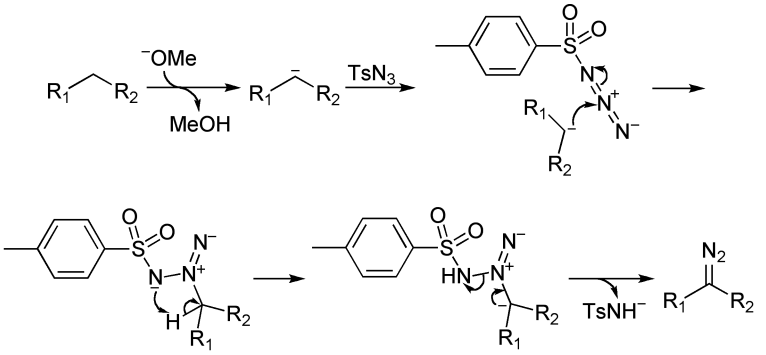
B. GENERAL REACTION SCHEME

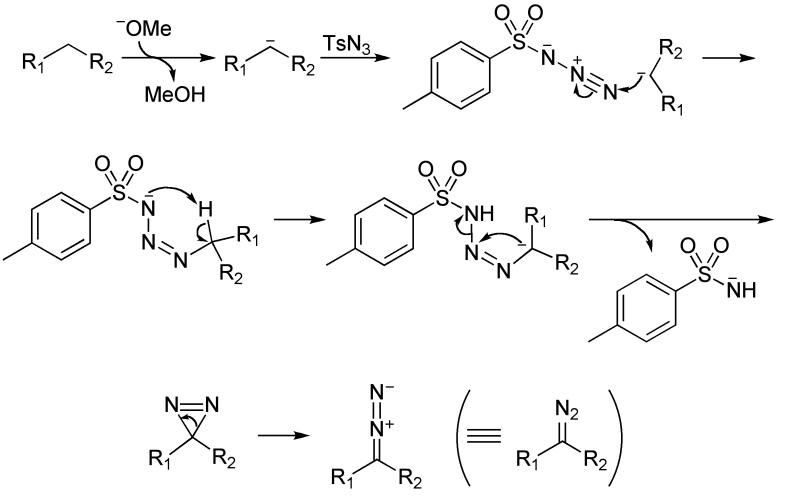


C. PROPOSED MECHANISMS

Two tentative mechanisms are proposed here for the reaction of TsN_3, where the attack of the generated carbanion at the middle nitrogen of TsN_3 is displayed in Scheme 1, and the attack of the carbanion at the terminal nitrogen of TsN_3 is shown in Scheme 2.



SCHEME 1. *Carbanion attack at the middle nitrogen.*



SCHEME 2. *Carbanion attack at the terminal nitrogen.*

D. MODIFICATION

This reaction has been extensively modified using different diazo sources.

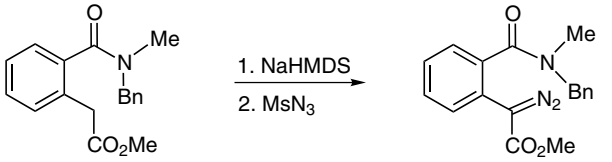
E. APPLICATIONS

This reaction has general applications in organic synthesis, especially for the *1,3-Dipolar Cycloaddition* of diazo compounds.

F. RELATED REACTIONS

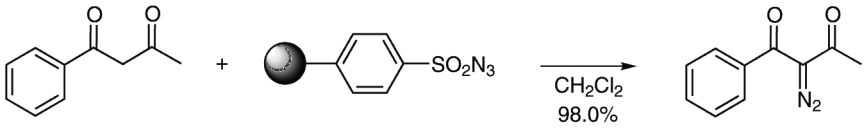
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 18.

To a stirred solution of 0.5 g methyl 2-benzylmethylcarbamoyl phenylacetate (1.6 mmol) in 15 mL THF at −78°C, was added 1.9 mL 1.0 M sodium bis(trimethylsilyl)amide in THF dropwise over a 20 min period. The mixture was stirred at −78°C for 1 h, and 0.2 mL mesyl azide in 1 mL THF was added in one portion. The resulting solution was stirred at −78°C for 2 h, warmed to room temperature, and stirred for an additional 2 h. The mixture was quenched with 30 mL phosphate buffer (pH = 7.0) and extracted with CH_2Cl_2. The combined organic layers were washed with brine, dried over Na_2SO_4, and filtered. Upon removal of solvent, the residue was purified by flash chromatography to afford 0.3 g methyl [2-(benzylmethylcarbamoyl)-phenyl]diazoacetate as a pale yellow oil, in a yield of 63%.



Reference 15.

To a 5.0-mL disposable polypropylene/polyethylene syringe was added 500 mg polystyrene benzenesulfonyl azide (0.75 mmol) that was swollen with CH_2Cl_2. A mixture of 81.0 mg 1-benzoylacetone (0.5 mmol) and 0.21 mL Et_3N (1.5 mmol) in 2.0 mL CH_2Cl_2 was drawn into the syringe. Then the syringe was fixed on a LabQuake shaker and rotated at room temperature. The reaction was monitored by TLC (1:1, Et_2O/heptane). After 4 h, the supernatant was collected, and the resin was washed with CH_2Cl_2 (3 × 5 mL). The washes were combined with the supernatant and concentrated to give a pale yellow solid, which was purified by short silica gel column chromatography using heptane/Et_2O as the eluent to afford 92.0 mg 2-diazo-1-phenyl-butane-1,3-dione, in a yield of 98%, m.p. 60–61°C.

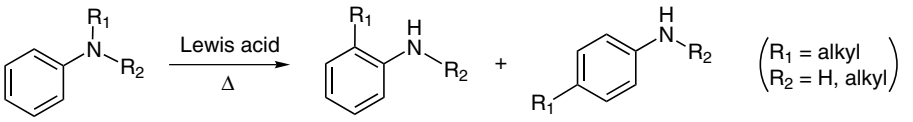
Reilly-Rickinbottom Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Reilly and Hickinbottom in 1920.[1] It is a Lewis acid-promoted thermal rearrangement of an *N*-alkyl aniline into an aryl-substituted aniline through the migration of an alkyl group from the nitrogen atom to the aromatic nucleus and is known as the Reilly-Hickinbottom rearrangement.[2] This reaction has been shown to be intermolecular, not intramolecular.[2b] It is the natural extension of the *Hofmann-Martius Rearrangement*,[2c] and usually yields predominantly *para*-alkylated aromatic amine derivatives without formation of alkyl halides.[2c] In addition, it often gives a higher yield of alkylated product when $ZnCl_2$ is used as catalyst.[2c] The only known exception is the $CoCl_2$-catalyzed rearrangement of *N*-benzylaniline, which gives an appreciable amount of the *ortho* isomer.[3] Sometimes, the multi-alkylated products are also formed in this rearrangement.[4]

B. GENERAL REACTION SCHEME

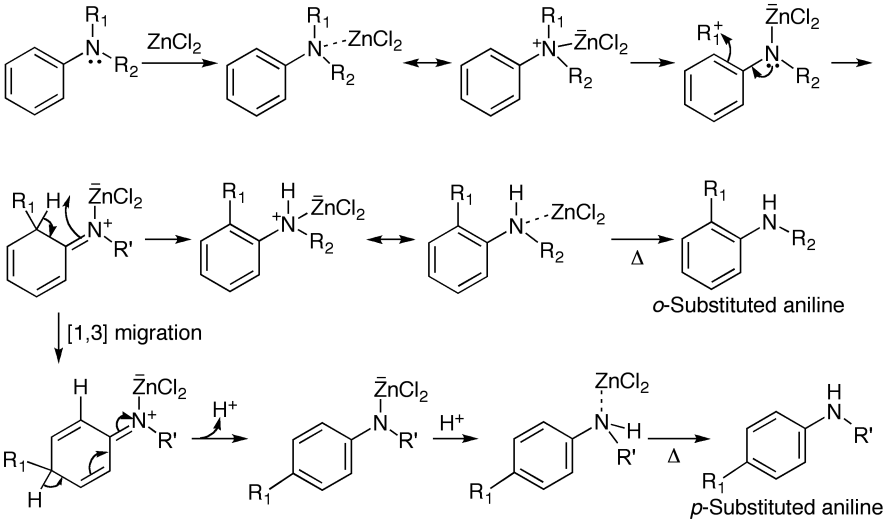


C. PROPOSED MECHANISMS

A mechanism catalyzed by $ZnCl_2$ involving a carbocation is outlined here. It is possible that the *p*-alkylated aromatic amines are at least partially generated from further migration

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

of the alkyl group of *o*-alkylated aromatic amines in the presence of a Lewis acid, resulting in both higher yield and higher ratio of *p*- to *o*-alkylated aromatic amines.



D. MODIFICATION

N/A

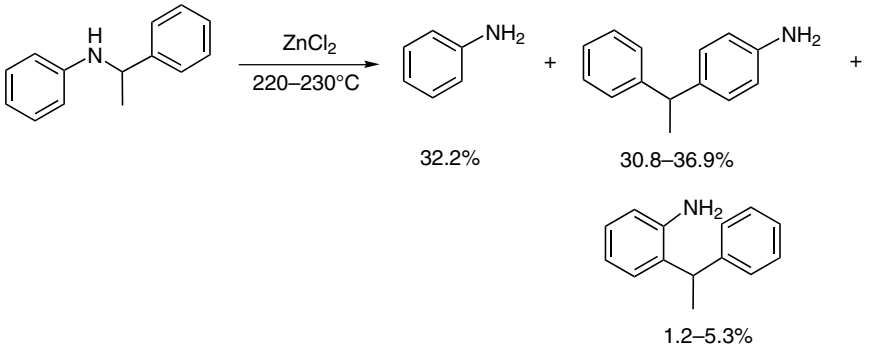
E. APPLICATIONS

This reaction has general application in the preparation of alkyl substituted aryl amines.

F. RELATED REACTIONS

This reaction is related to the *Hofmann-Martius Rearrangement.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

A mixture of 19.7 g *N*-α-phenylethyl aniline (0.1 mol) and 13.6 g anhydrous $ZnCl_2$ (0.1 mol) was heated in a sealed Pyrex tube at 220–230°C for 6 h. The cooled contents of the tube were digested on the steam bath with 100 mL 10% NaOH, and the resulting mixture was extracted with Et_2O (3 × 100 mL). Then the combined Et_2O layer was extracted with 6 *N* HCl (4 × 100 mL), and the combined aqueous solution was neutralized with 5% NaOH. After that, the aqueous solution was extracted with benzene, dried over K_2CO_3, concentrated, and distilled to afford 3.6 g aniline, 6.8 g (41%) of a mixture of *p*-α-phenylethyl aniline (in a ratio of 75–90%) and *o*-α-phenylethyl aniline (in a ratio of 3–13%), and 2.0 g of a higher boiling product. The acid-insoluble fraction gave 2.0 g polymer.

Reimer-Tiemann Reaction
(Reimer-Tiemann Formylation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Reimer[1] and subsequently extended by Reimer and Tieman in 1876.[2] It is the transformation of a formyl group onto the *ortho*- or *para*-position of an activating group in an electron-rich aromatic compound by warming with chloroform and aqueous alkali; therefore, it is generally known as the Reimer-Tiemann reaction.[3,4] Occasionally, this reaction is also referred to as the Reimer-Tiemann formylation,[5] Reimer-Tiemann aldehyde synthesis,[5g,6] or Reimer-Tiemann process.[7] In this reaction, the electron-rich aromatic compounds include phenols, naphthols,[4k] pyrroles,[8] indoles,[9] quinoxalines,[4i] thiazoles,[4i] tropolone,[10] and even pyrimidines with at least one hydroxy and two methyl groups.[4h] However, this reaction generally gives low yields of aromatic aldehydes[4b,5d,11] along with the recovery of starting material[4b,11] and some by-products, such as orthoformic ester,[12] hydroxy acids[13] and triphenylmethane resin.[11,15] Although the use of an excess amount of base and chloroform can reduce the amount of phenol recovered, the amount of triphenylmethane resin is increased too.[11] Other drawbacks of this reaction are associated with the biphasic nature of the reaction system, such as the inefficiency of mass transfer between the layers.[5a,5d] In addition, the presence of an alcohol may alter the nature of the biphasic system, but in most cases the addition of alcohol resulted in even lower yields.[15] It has been found that this reaction generally favors the *ortho*-formylated product because of the electrostatic effect,[4j] however, the *ortho*/*para* ratio varies along with the solvent,[16] substituents on the aromatic substrate,[4g] the haloform,[14] and alkali base[15b,17] used. For example, the methyl group increases the rate of *ortho*-formylation in *p*-cresol and decreases the *para*-formylation because of steric effect, whereas the formyl group decreases the *ortho*-formylation on *p*-hydroxybenzaldehyde.[4g] The larger the size of the cation in the alkali base, the more *para*-formylated product produced;[4i] likewise, the higher the concentration of phenoxide, the more *o*-substituted product formed.[4j] This is because the phenoxide and

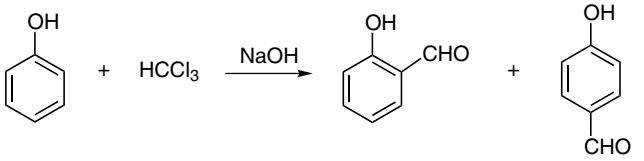
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

alkali cation form contacted ion pairs in high concentration, favoring the *o*-substitution. In a dilute solution, or with large cation size, such as Cs^+ or K^+, more loose ion pairs form.

It should be pointed out that certain five-, six- and seven-membered ring systems also undergo the ring expansion reaction, such as the formation of 3-chloropyridine from pyrrole (*Ciamician-Dennstedt Reaction*),[8a,18] chloroquinolines from indole,[9a,9d,19] and chloronaphthalenes and chloroazulenes from indenes.[20] On the other hand, the *ortho*- or *para*-substituted phenols, naphthols, and tetralols also produce 2,2- or 4,4-disubstituted cyclohexadienones, along with the normal Reimer-Tiemann products;[4i] in some cases, cyclohexadienones are the only products under Reimer-Tiemann reaction conditions, as exemplified by the formation of 1-methyl-1-dichloromethyl-2-keto-1,2-dihydronaphthalene from 1-methyl-2-naphthol, 1-allyl-1-dichloromethyl-2-keto-1,2-dihydronaphthalene from 1-allyl-2-naphthol, and 1-(3-chloro-2-butenyl)-1-dichloromethyl-2-keto-1,2-dihydronaphthalene from 1-(3-chloro-2-butenyl)-2-naphthol, respectively.[4k]

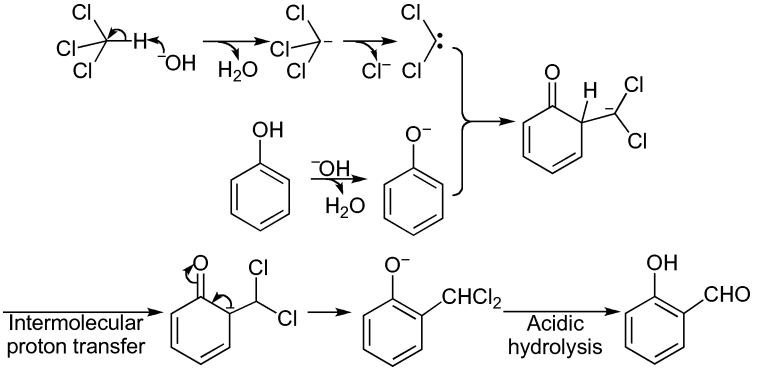
Nevertheless, compared to other formylation reactions, such as the *Duff Formylation, Gattermann Aldehyde Synthesis*, and *Gattermann-Koch Formylation*, the Reimer-Tiemann reaction is the only one that occurs under basic conditions, and in certain cases, it is the only feasible method for the direct formylation,[4i] e.g., the formylation of oestrogens.[5d]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is well known that under basic conditions, phenol is converted into phenoxide and chloroform is transformed into dichlorocarbene, a highly electron-deficient species, thus the Reimer-Tiemann reaction involves the electrophilic attack of dichlorocarbene on phenoxide, followed by intermolecular proton transfer, as indicated by the deuterium and tritium isotope labeling experiment.[21] An illustrative mechanism is thus provided for the formation of salicylaldehyde.



D. MODIFICATION

This reaction has been improved by use of a slightly "hydrated solid-liquid medium."[4b] In addition, photochemical Reimer-Tiemann reactions[3g,3i,3dd,3ff,22] have been developed that may involve an irreversible charge transfer.[22]

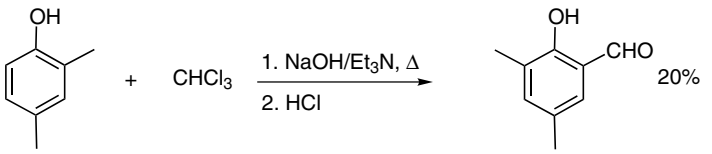
E. APPLICATIONS

This reaction has general application in the formylation of electron-rich aromatic compounds.

F. RELATED REACTIONS

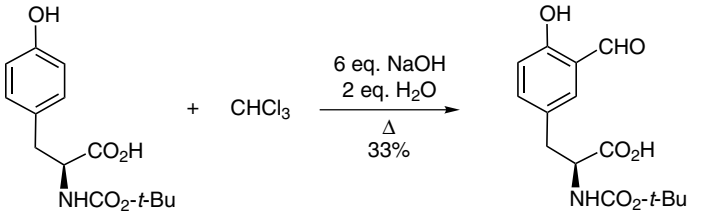
This reaction is related to the *Ciamician-Dennstedt Reaction*, *Duff Reaction*, *Gatterman Aldehyde Synthesis*, and *Gattermann-Koch Formylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4c.

A mixture of 83 mL 2,4-dimethylphenol and 4.2 mL triethylamine in 350 mL chloroform was added dropwise to 800 mL 50% NaOH in water at 75°C with vigorous stirring under refluxing. Then the reaction mixture was acidified with 110 mL concentrated HCl. After the addition of sufficient water to dissolve the salt, the dark oil layer was collected, and the product was extracted with CH_2Cl_2. After evaporation of the solvent, the product was purified by steam distillation, silica gel chromatography, and bisulfite reaction to give ~20% 2-hydroxy-3,5-dimethylbenzaldehyde. (*Note:* Vigorous stirring under reflux should stand for the refluxing of chloroform).



Reference 4b.

To a suspension of 2.0 g *N*-Boc-L-tyrosine (7.12 mmol) and 0.256 mL water in 30 mL $CHCl_3$ was added 1.71 g powdered NaOH (42.72 mmol). After the mixture was refluxed for 4 h, an additional 0.42 g NaOH (10.68 mmol) was added over 1.5 h. The reaction was then diluted with water and EtOAc, and the aqueous layer was acidified to pH 1 with 1 *N* HCl and back extracted with EtOAc. The combined organic layers were washed with brine, dried over $MgSO_4$, and concentrated. Flash column chromatography using $CHCl_3$/MeOH (12:1) with 1% acetic acid as the eluent afforded 0.72 g *N*-[(1,1-dimethylethoxy)-carbonyl]-3-(3-formyl-4-hydroxyphenyl)-L-alanine (33%) and 0.62 g *N*-Boc-L-tyrosine (31% recovery).

Other references related to the Reimer-Tiemann reaction are cited in the literature.[23]

Reissert Compound
(Reissert Reaction)

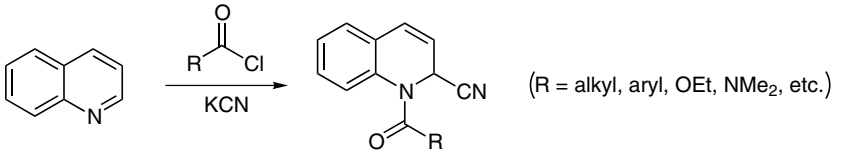
A. GENERAL DESCRIPTION OF THE REACTION

The compound 1-benzoyl-2-cyano-1,2-dihydroquinoline was first reported by Reissert in 1905 from the reaction between quinoline, benzoyl chloride, and aqueous potassium cyanide.[1] Subsequently, Grosheintz and Fischer extended this reaction to prepare acyl cyanodihydroquinoline from aliphatic acyl chloride with hydrogen cyanide and two equivalents of quinoline in dry benzene.[2] Later on, other types of heterocycles—such as isoquinoline,[3] benzimidazole,[4] 1,6-naphthyridines,[5] phenanthridine,[6] pyrimidine,[7] indazole,[8] purine,[9] quinazoline,[10] quinoxaline,[11] phthalazine,[12] pyridazine,[13] phenanthroline,[14] pyrazine,[15] oxazole,[16] and especially, pyridines[17]—were found to give compounds with structures similar to Reissert's dihydroquinoline. Thus all of these compounds, prepared similarly, are generally referred to as Reissert compounds,[18,19] and the method to prepare these types of compounds is known as the Reissert reaction[20] or Reissert-type reaction.[20d,20e] Among them, 2-cyano-1-benzoyldihydroquinoline is known as quinoline Reissert compound,[21] and 1-cyano-2-benzoyldihydroisoquinoline prepared from isoquinoline is known as isoquinoline Reissert compound,[18e,22] the corresponding 1,2,3,4-tetrahydro derivatives are referred to as dihydro-Reissert compounds.[22] Besides the regular benzoyl and acetyl[23] Reissert compounds, molecules with benzoyl substituted by sulfonyl,[24] alkoxycarbonyl,[25] carbamoyl,[26] and phosphate[27] have also been prepared. However, the preparation from aroyl and cinnamoyl chloride is unsuccessful in benzonitrile, ether, dioxane, acetone, or chloroform.[28] Reissert compounds can be easily converted into their conjugated bases through deprotonation, a process that has been widely used in organic synthesis. Generally speaking, because of the unsaturation of dihydroquinoline or dihydroisoquinoline moieties, Reissert compounds can undergo many reactions that normal alkenes undergo, such as polymerization[18c] and cyclopropanation.[29] More importantly, Reissert compounds can undergo a few reactions of particular interest. For example, upon acidic hydrolysis,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

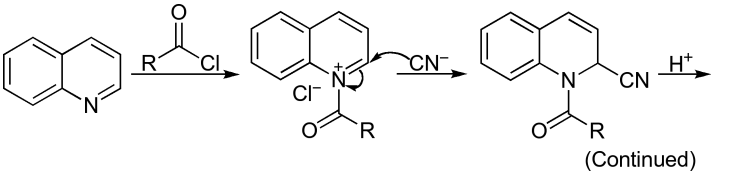
Reissert compounds decompose to aldehyde (from the acyl moiety) and quinaldic acid;[2,30] while when treated with PCl_5 in chloroform, Reissert compounds decompose to 2-cyano quinoline and benzoyl chloride.[31] In addition, Reissert compounds rearrange to *C*-acyl quinolines or isoquinolines when heated in strong base.[22] Similarly, the conjugate base of a Reissert compound can undergo alkylation with alkylating reagents, and the alkylated Reissert compound decomposes to alkyl-substituted quinolines or isoquinolines when treated with base.[21] In addition, these conjugate bases also condense with aldehydes to form secondary alcohols or their esters, of which the acyl groups migrate from nitrogen to oxygen in alkaline solution.[22] Furthermore, the condensation of Reissert compounds with Grignard reagents results in the formation of carbinols, which rearrange to 2-acyl quinolines when treated with NaH.[32] Moreover, cyclic urethanes can be prepared from the conjugate bases of alkoxycarbonyl Reissert compounds with aromatic aldehydes.[22,33] It should be emphasized that among these reactions, the one that decomposes to aldehyde under acidic conditions provides a route to convert acyl chloride into aldehyde.[2,30]

B. GENERAL REACTION SCHEME

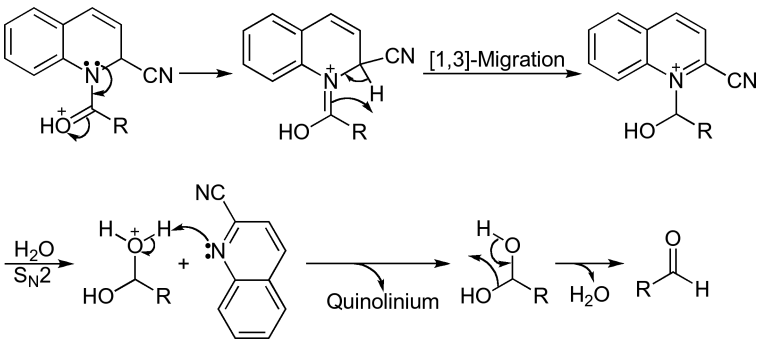


C. PROPOSED MECHANISMS

Although it has been proposed that the formation of Reissert compounds involves the addition of hydrogen cyanide to the carbon-nitrogen double bond followed by the acylation of the resultant secondary amine,[33] the actual reaction may involve the acylation before the addition.[20d] Because quinoline, isoquinoline and pyridine are basic, they can form salt with acyl chloride to further polarize the carbon-nitrogen double and facilitate the addition of cyanide, although pyridine and quinoline are inert toward the addition of cyanide without activation. On the other hand, the decomposition of the Reissert compounds to aldehyde under acidic conditions is believed to involve the protonation of the amido oxygen to form a conjugate acid and the cleavage of 2-proton and dissociation to aldehyde and quinaldonitrile;[30c] or it may involve protonation and cleavage to form a transient acyl anion, which abstracts a proton to form aldehyde.[30d,34] Displayed here is the formation of a Reissert compound and its acidic conversion into aldehyde.



(Continued)



D. MODIFICATION

Generally, the use of other heterocycles[3–17] besides quinoline would be considered modifications of the original Reissert protocol. This reaction has been extended to convert an acyl chloride into an aldehyde through a one-pot process by adding the acyl chloride to a solution of quinoline and hydrocyanic acid, and subsequent steam distillation of the entire mixture with sulfuric acid.[2] In addition, the formation of the Reissert compound has been modified to occur enantioselectively using TMSCN as the nucleophilic species in the presence of a Lewis acid–Lewis base bifunctional catalyst.[20d,35] Moreover, tri-*n*-butyltin cyanide[19s] and acetone cyanohydrin[20k] are also used for the preparation of the Reissert compounds.

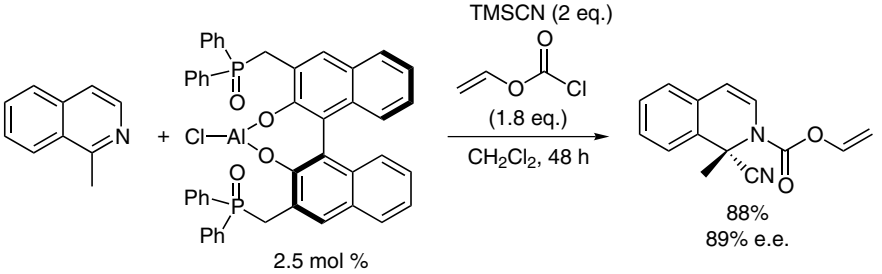
E. APPLICATIONS

Reissert compounds have very wide application in organic synthesis.

F. RELATED REACTIONS

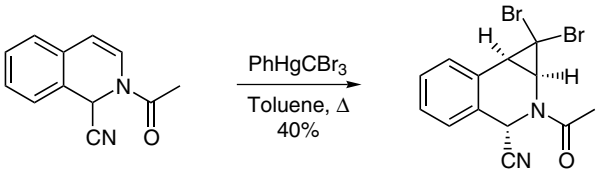
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 35b.

To a solution of 0.015 mmol aluminum catalyst with (*R*)-6,6′-dibromo-3,3′-bis (diphenylphosphinoylmethyl)-2,2′-dihydroxy-1,1′-binaphthyl as ligand in CH_2Cl_2 was added 0.6 mmol 1-methyl-isoquinoline in 2.25 mL CH_2Cl_2, followed by 160 μL TMSCN (1.2 mmol) and 91.8 μL vinyl chloroformate (1.08 mmol) at −60°C. After 48 h, the reaction was quenched by 5% NH_3 aqueous solution, and extracted with EtOAc. Upon removal of solvent under reduced pressure, the reside was purified by column chromatography using hexane/EtOAc as the eluent to afford 91% (+)-1-cyano-1-methyl-1,2-dihydroisoquinoline-2-carboxylic acid vinyl ester as a colorless oil, with 84% e.e. as determined by chiral HPLC analysis.



Reference 29.

A mixture of 2.64 g phenyltribromomethyl mercury (5 mmol) and 0.99 g 1-cyano-2-acetyl-1,2-dihydroisoquinoline (5 mmol, prepared from KCN and acetyl chloride) in 50 mL toluene was heated at 80°C for 2.5 h. The precipitated phenylmercuric chloride was removed by filtration, and the solvent was removed in vacuo. The residue was crystallized from ether-hexane to yield 745 mg 2-acetyl-1,1-dibromo-1a,2,3,7b-tetrahydro-1H-cycloprop[c]-isoquinaldonitrile, in a yield of 40%, m.p., 174–175°C.

Other references related to the Reissert compounds are cited in the literature.[36]

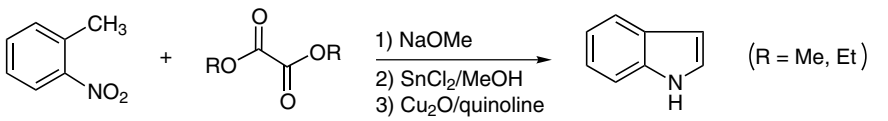
Reissert Indole Synthesis
(Reissert Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Reissert in 1896.[1] It is a multistep synthesis of indole derivatives from *ortho*-nitrotoluene involving the basic condensation of *o*-nitrotoluene with oxalic ester to *o*-nitrophenylpyruvic ester, reduction of the nitro group to an amino group, cyclization to indole-2-carboxylic acid and final decarboxylation. Therefore, it is generally known as the Reissert indole synthesis.[2] In addition, it is also referred to as the Reissert condensation[2h,2m] or Reissert synthesis.[3] In this reaction, *o*-nitrotoluene can be deprotonated with sodium ethoxide or potassium ethoxide, in which potassium ethoxide offers better results than sodium ethoxide.[4] The resulting *o*-nitrophenylpyruvic ester can be reduced by zinc in acetic acid, stannous chloride in MeOH,[5] or alkaline ferrous hydroxide,[6] or it can be hydrogenated by Pd/C in EtOH or PtO_2 in either EtOH or acetic acid.[2e] It has been found that the hydrogenation of 2-nitrophenylpyruvate ester with 5% Pd/C in EtOH is the best reduction condition for Reissert indole synthesis, although it is accompanied with up to 10% of 1,2,3,4-tetrahydro-2-quinolone as byproduct.[2e] If two *ortho*-nitro groups exist in phenylpyruvate ester, then the nitro group with the least steric hindrance undergoes reduction and cyclization before the reduction of the other one.[5] The 2-carboxyl group in the resulting indole derivative can be removed by heating with copper chromite in quinoline.[6]

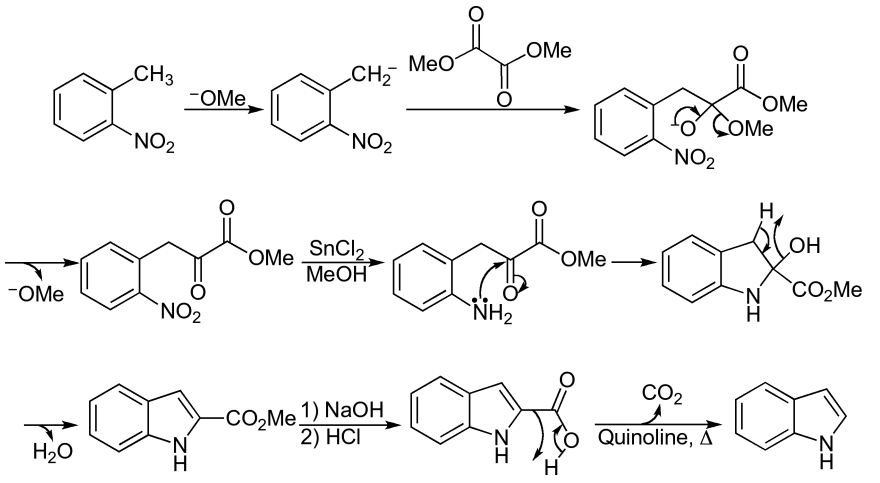
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed below is the reaction route for the Reissert indole synthesis from *o*-nitrotoluene and dimethyl oxalate, where the hydrolysis of methyl indole-2-carboxylate could be omitted, depending on the reaction conditions.



D. MODIFICATION

This reaction has been modified by reduction of *o*-nitrophenylpyruvic ester with stannous chloride dihydrate in DME at ambient temperature followed by the addition of aqueous titanium trichloride to improve both the purity and yield.[2d]

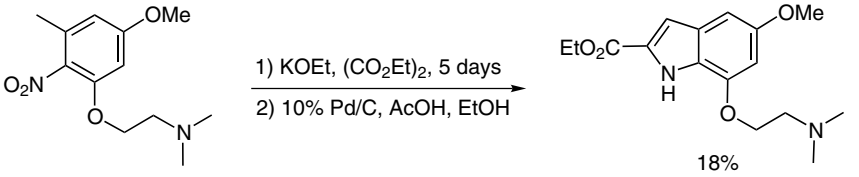
E. APPLICATIONS

This reaction has general application in the preparation of indole derivatives, and in some aspects, this reaction is even more useful than *Fischer Indole Synthesis*.[2m]

F. RELATED REACTIONS

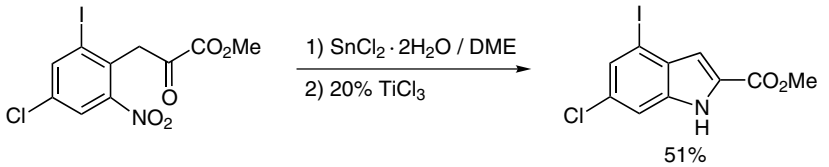
This reaction is related to the *Batcho-Leimgruber Indole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

Powdered potassium, prepared from 0.308 g potassium (7.87 mmol) in 6 mL xylene heated at 100°C and stirred rapidly while cooling, was washed with anhydrous Et_2O and covered with 10 mL Et_2O. Then 1.3 mL absolute EtOH (22.0 mmol) was added, and the mixture was stirred and refluxed until the potassium dissolved (~ 3 h). The cooled mixture was treated with 1.07 mL diethyl oxalate (7.87 mmol) and then with a solution of 2.0 g 2-(5-methoxy-3-methyl-2-nitrophenyloxy)-*N,N*-dimethylethanamine (7.87 mmol) in 5 mL dry Et_2O. After 115 h, the dark red precipitate was removed by filtration and washed with Et_2O. The red solid (1.189 g) was dissolved in 45 mL absolute EtOH, acidified with 0.78 mL acetic acid, and hydrogenated over 0.44 g 10% Pd/C at 1 atm of hydrogen for 8 h. The mixture was filtered through Celite, concentrated, diluted with 100 mL 0.2 M aqueous Na_2CO_3, and extracted with EtOAc. The combined extracts were washed with water and brine, dried over Na_2SO_4, evaporated, and purified by flash chromatography using 2% Et_3N in EtOAc as the eluent to give 0.44 g ethyl 7-[2-(dimethylamino)ethoxy]-5-methoxy-1*H*-indole-2-carboxylate as an oil, in a yield of 18%. (*Note*: 1.3 mL absolute EtOH was labeled 2.2 mmol in the original procedure but was corrected here.)



Reference 2d.

To a solution of 1.16 kg $SnCl_2{\cdot}2H_2O$ (5.15 mol) in 1.65 L dimethoxyethane at room temperature was added 880 g crude methyl (2-iodo-4-chloro-6-nitrophenyl)pyruvate, while the temperature was maintained < 30°C. After the mixture was stirred for an additional hour at room temperature, 20% aqueous $TiCl_3$ solution prepared from 2.65 kg $TiCl_3$ (3.43 mol) was then added dropwise to the mixture under cooling with an ice bath to keep the temperature < 10°C. The resulting mixture was stirred at 0–10°C for an additional hour, and 5.6 L 6 *N* HCl and 9.6 L 2:1 EtOAc/toluene mixture were added. The organic layer was separated, washed with 5.6 L 1 *N* HCl, and concentrated to give 632 g crude product. This product was suspended in 6.3 L acetonitrile, which dissolved after refluxing for 30 min, and the solution was allowed to cool to room temperature. The precipitate was filtered, washed with ice-cooled CH_3CN (2 × 600 mL), and dried in vacuo to give 295 g methyl 4-iodo-6-chloroindole-2-carboxylate as a white solid, in a yield of 51% with 93 wt % purity, m.p. 216–218°C.

Other references related to the Reissert indole synthesis are cited in the literature.[7]

Reppe Alkyne Cyclotrimerization

A. GENERAL DESCRIPTION OF THE REACTION

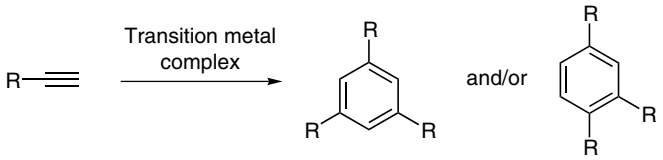
Although the thermal trimerization of acetylene to benzene was first reported by Berthelot in 1866 at temperatures $> 400^{\circ}C$,[1] it was Reppe who initially reported in 1949 the Ni(II) complex catalyzed [2 + 2 + 2] cyclotrimerization of alkynes,[2] a highly convergent and atom-economic approach to benzene derivatives.[3] This reaction is generally known as the alkyne cyclotrimerization.[3,4] Occasionally, it is also referred to as the alkyne trimerization.[5] When acetylene is used as the alkyne source, the corresponding reaction is more specifically called the metal-catalyzed acetylene trimerization[6] or acetylene cyclotrimerization.[3,7] This symmetry-allowed reaction is a highly exothermic transformation because three π-bonds are converted into three carbon-carbon σ-bonds in a one-step process,[6a] liberating as much as 142 Kcal/mol of energy.[8] However, in the absence of catalyst, this transformation encounters an unbelievably high activation energy, in the range of 60–80 Kcal/mol,[9] thus the pure trimerization of alkyne is almost useless for organic synthesis. By means of catalysis from a transition metal complex, the cyclotrimerization of alkynes is remarkably easy and is tolerable for a wide variety of functional groups, such as vinyl, aryl, ether, hydroxyl, ester, carboxyl, amino and silyl.[6b] In addition, the conjugated alkynes are found to be more reactive than the unconjugated ones.[10] Among the transition metals, the complexes from group VIII elements such as Co, Rh, Ni and Pd have the highest activities,[4j] and cobalt complexes are almost always the first choice (e.g., CpCo(L)CO, L = CO, PR_3, olefin).[10] Although Ni complexes are less reactive than their cobalt analogs, as indicated by the fruitless reaction between diyne-Ni complex and most disubstituted alkynes,[11] the nickel complex is

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

the only one successfully used in asymmetric reactions.[11,12] It has been found that Pd is the most active element among Ni, Pd, and Pt;[7j] and while the Rh-related Grubbs catalyst is almost as effective as cobalt catalyst, the corresponding reaction takes place via a completely different mechanism.[10] In addition, this reaction has been successfully catalyzed by other metal complexes such as Copper complex,[13] Iridium complex,[4f] tantalum-η^2-alkyne complexes,[4g] titanium complexes,[4h,4s] chromium (VI) complex,[4ab] dirhodaborane,[4l] Grubbs catalyst or Wilkinson's catalyst,[4p] as well as metal cluster[14] (e.g., $Os_3(\mu\text{-}SbPh_2)(\mu\text{-}H)(\mu^3,\eta^2\text{-}C_6H_4)(CO)_9$[4n]) and metal porphyrin complexes.[15] Moreover, enamine-directed[4q] and microwave promoted non-metal catalyzed alkyne cyclotrimerization[4c] have also been developed.

It is worth noting that when this reaction involves three different asymmetric alkynes, the regioselectivity is unpredictable, generating as many as 38 different isomers.[7e] For example, monosubstituted alkynes form 1,2,4- and 1,3,5-trialkylbenzenes, with the ratio varying along with the reaction conditions, including the kinetic vs. thermodynamic control and the electronic and spatial requirements of the catalyst.[6b] Recent developments have improved the regioselectivity by use of a partial or total intramolecular version[10] of cyclotrimerization using a silyl[16] or borate tether.[4i] Also of special interest, the cyclotrimerization through titanium metalation, known as metalative Reppe reaction,[7e,17] converts three different asymmetric alkynes into single aromatic compounds.[17]

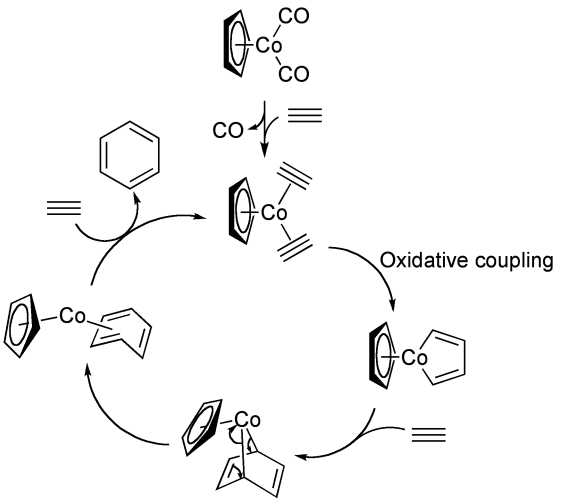
B. GENERAL REACTION SCHEME



(R = H, OH, NH_2, CO_2R', CO_2H, OR′, vinyl, aryl, alkyl, SR'_3, etc.)

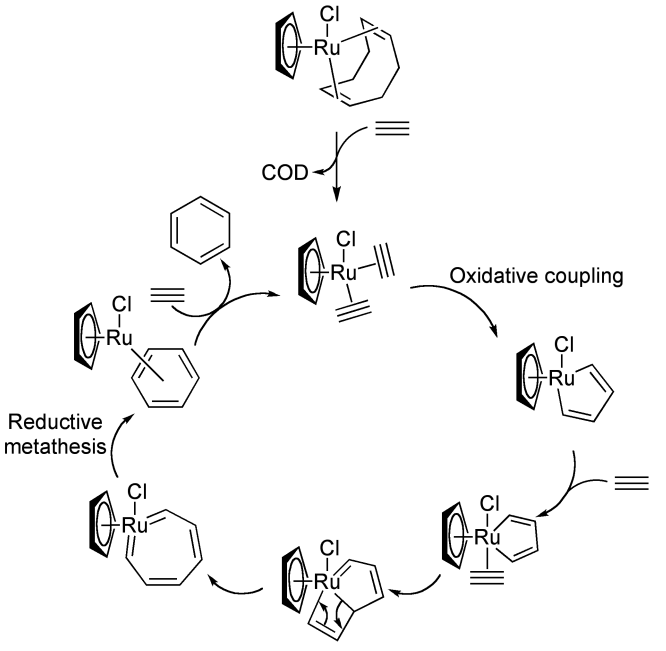
C. PROPOSED MECHANISMS

Although it is known that transition metal complexes can form three-membered metallocycles with alkenes and alkynes,[18] the cobalt-catalyzed reaction (using $CpCo(CO)_2$, for example) involves the formation of a cobalt-dialkyne complex, which transforms into metallocyclopentadiene through oxidative coupling,[6,18] and the insertion or addition of the third alkyne on metallocyclopentadiene leads to the metallocycle, which produces a benzene derivative by reductive elimination of the metal complex.[10] However, a theoretical study shows that this reaction may involve the direct addition of cobalt cyclopentadiene with the third alkyne in a fashion of *Diels-Alder Cycloaddition* to form the cyclopentadiene-cobalt-η^4-cyclohexatriene intermediate, which decomposes to yield the benzene derivative, instead of via reductive elimination.[6a] Thus a revised mechanism is displayed in Scheme 1. Alternatively, the metallocyclopentadiene may dimerize to give a cyclooctatetraene intermediate that decomposes into a benzene derivative and an alkyne, which is also an energetically feasible process.[7j,19]



SCHEME 1. *Mechanism of cobalt complex–catalyzed alkyne cyclotrimerization.*

In contrast, the cyclotrimerization catalyzed by the Grubbs catalyst involves consecutive intramolecular ring metathesis through carbene complexes[10] or formation of a ruthenabicyclo[3.2.0]heptatriene intermediate[3] similar to that formed in the cobalt complex-catalyzed reaction. This mechanism is illustrated in Scheme 2 using acetylene as the alkyne source and CpRuCl[COD] as catalyst.



SCHEME 2. *Mechanism of ruthenium complex–catalyzed alkyne cyclotrimerization.*

D. MODIFICATION

This reaction has been successfully extended to the reaction between alkynes and nitriles[3,6b,10,20] (which function as "heteroalkynes"), especially the electron-deficient nitriles,[4j] for preparing heterocycles, such as pyridines, by which the cobalt complex is the only choice of the catalyst.[10] In addition, the reaction has been extended to other reaction partners, such as olefins,[21] isocyanate (to form pyridone),[3] isothiocyanate (to form thiopyranimines),[3] and carbon disulfide (to give dithiopyrone).[3] Furthermore, the metalative Reppe reaction[7e,17] and the reaction using Grubbs catalyst[3,10] or the addition of Lewis acid (e.g., aluminum phenoxide)[22] have been developed to give cycloadducts regioselectively. It is worth mentioning that several non-metallic complexes catalyzed cyclotrimerizations of alkynes have also been developed: the diethylamine-catalyzed reaction of aroylethyne to 1,3,5-triaroyl benzene,[23] the disilane (Si_2Cl_6)-catalyzed cyclotrimerization of alkyne involving a free-radical mechanism[4w] and enamine-directed[4q] and microwave-promoted alkyne cyclotrimerization.[4c]

E. APPLICATIONS

This reaction has very wide applications in organic synthesis.

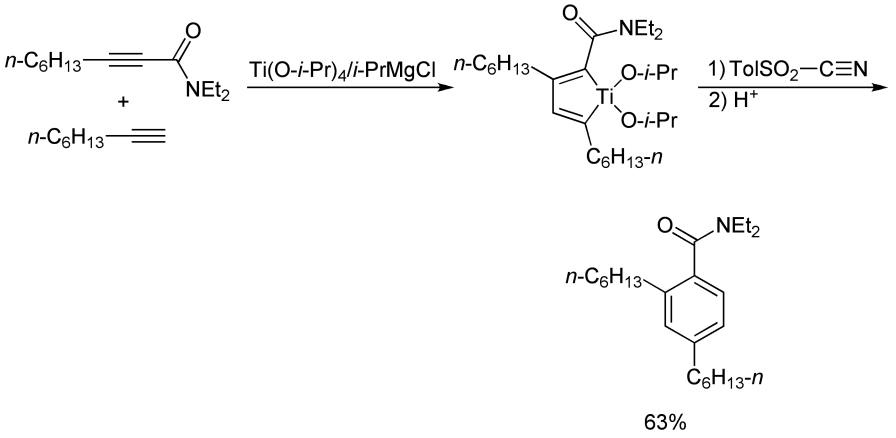
To 1 mL degassed dry 1,2-dichloroethane containing 9.5 mg Cp*RuCl(cod) (0.025 mmol), 105.1 mg 1-hexynyl-boronate (0.50 mmol) and 104.3 mg 1-hexyne (2.0 mmol) was added 30.8 mg propargyl alcohol (0.55 mmol) in 3 mL degassed dry 1,2-dichloroethane over 15 min at room temperature under an argon atmosphere. The resulting mixture was stirred at room temperature under an argon atmosphere for 5 h,

and then the solvent was removed under reduced pressure. To the residue were added 13.0 mg $Pd_2(dba)_3{\cdot}CHCl_3$ (0.0125 mmol), 15.9 mg PCy_3 (0.055 mmol), 184.5 mg *p*-iodoacetophenone (0.75 mmol), 3.5 mL toluene, and 1.5 mL 2 M K_2CO_3 solution. The reaction mixture was degassed at –78°C under reduced pressure and refilled with argon. After heating at 70°C for 3 h, the resultant solution was extracted with EtOAc (3 mL × 3), and the combined organic layers were dried over $MgSO_4$. Upon removal of solvent under reduced pressure, the residue was purified by silica gel flash column chromatography using hexane/EtOAc (6:1) as the eluent to afford 123.4 mg biphenyl as a pale yellow oil, in a yield of 73%, $R_f = 0.2$ (hexane/EtOAc, 3:1).



Reference 20.

To a stirred solution of 30 mg *N,N*-diethyl-2-nonynamide (0.143 mmol) and 0.053 mL $Ti(O\text{-}i\text{-}Pr)_4$ (0.179 mmol) in 2 mL Et_2O was added 0.295 mL 1.36 M *i*-PrMgCl in Et_2O (0.401 mmol) at −78°C under argon to give a yellow homogeneous solution. The solution was warmed to −50°C over 30 min, during which time its color turned red. After the solution was stirred at −50°C for an additional 5 h, 0.017 mL 1-octyne (0.115 mmol) was introduced at −50°C, and the solution was stirred for another 3 h. Then 31 mg pulverized *p*-toluenesulfonylnitrile (0.172 mmol) was added, and the reaction mixture was stirred for 3 h at −50°C. The reaction was terminated by the addition of 0.05 mL water and quickly warmed up to room temperature. The resulting heterogeneous mixture was dried over anhydrous Na_2SO_4 and filtered through a short pad of Celite. The filtrate was concentrated in vacuo to give a crude oil, which was purified by silica gel column chromatography to afford 25 mg *N,N*-diethyl-3,5-dihexyl-2-picolinamide as a colorless oil, in a yield of 63%.

Reppe Carbonylation

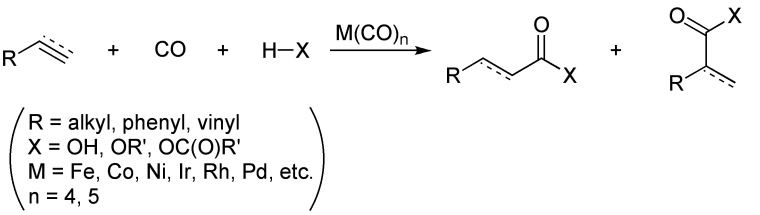
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Reppe in 1953.[1] It is a three-component reaction to transform unsaturated hydrocarbons (e.g., alkene, alkyne, conjugated dienes, styrene, etc.) and carbon monoxide (CO) into a variety of saturated or unsaturated acids, esters, or anhydrides using a CO complex of group VIII transition metals as a catalyst with water, alcohol, or acid as a nucleophile, respectively.[2] This reaction, as a part of the Reppe chemistry,[3] is generally known as the Reppe carbonylation[2,4] or the Reppe process.[5] Occasionally, it is also referred to as the Reppe reaction.[6] However, when water is applied as the nucleophile, the corresponding Reppe carbonylation is also referred to as hydrocarboxylation;[2] when alcohol is chosen as a nucleophile for the production of ester, the reaction is known as hydroesterification, hydroalkoxycarbonylation or hydrocarbalkoxylation.[2] In this reaction, although carbon monoxide complexes of all group VIII transition metals are active catalysts, the cobalt and palladium complexes are the most active ones.[2] In addition, this reaction is very versatile and tolerable for a wide variety of functional groups.[2] Theoretical calculations have indicated that this reaction is a thermodynamically favored and kinetically easy process.[4b] For the carbonylation of alkenes, it has been found that the reaction rate generally follows the order of aliphatic alcohols $\approx$ acids $>$ water $>$ phenols,[7] whereas among the alcoholic nucleophiles, the reactivity order is primary $>$ secondary $>$ tertiary alcohols,[7,8] although aliphatic alcohols with a carbon chain length between one and six have no apparent effect on the reaction rate.[7,9] However, in the presence of hydrogen, the effect of steric bulkiness vanishes.[10] For the carbonylation of alkynes, it has been found that water increases the reaction rate and especially the rate for the formation of linear acids.[2]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

In alkaline solution of an iron-carbon monoxide complex, the alkenes are converted into aldehydes and finally alcohols of one more carbon atom.[6a] Under these conditions, the iron complex of carbon monoxide was found to be binuclear,[11] whereas the mononuclear complex is labile at temperatures above 140°C.[12] In addition, it has been found that aldehyde is an initial product that is reduced to alcohol in the second stage of the reaction, and the nature of the base plays an important role in controlling the reaction path, either to produce aldehyde (e.g., KOH) or alcohol (e.g., alkyl amines).[6a] The formation of aldehyde is known as Reppe hydroformylation or the Reppe reaction.[6a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

For the Reppe carbonylation, it is proposed that the reaction involves the initial oxidative addition of a nucleophile to the transition metal complex, followed by the complexation of an unsaturated hydrocarbon to the metal and insertion into a metal-H bond. Subsequently, migration of hydrocarbon species to CO followed by a reductive elimination afford the corresponding product.[4a] Scheme 1 illustrates the formation of ester from acetylene, CO, and methanol in the presence of a catalytic amount of $Pd[CO]_4$. In addition, a mechanism analogous to that of *Hydroformylation*[13] is proposed and displayed in Scheme 2 for the Reppe formylation.

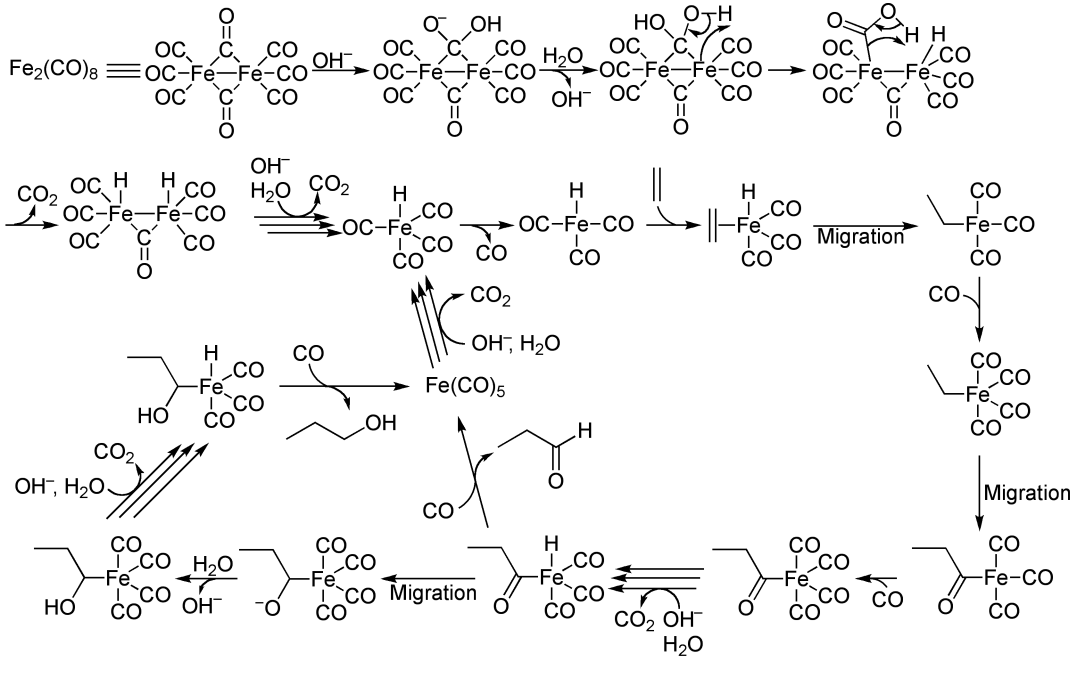


SCHEME 2. *Formation of alcohol and aldehyde from ethylene and CO in the presence of* $Fe_2(CO)_8$.

D. MODIFICATION

N/A

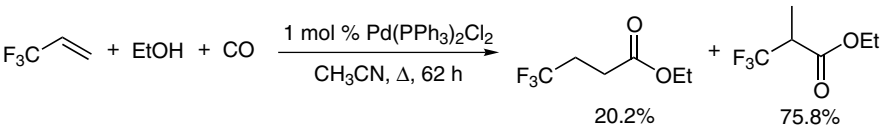
E. APPLICATIONS

This reaction has important application in industrial manipulation.[3b]

F. RELATED REACTIONS

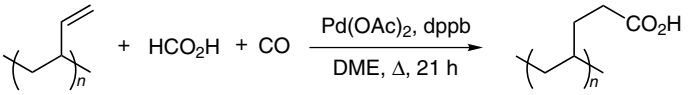
This reaction is related to the *Hydroformylation.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To a 50-mL stainless-steel autoclave fitted with a magnetic stirring bar were added 0.1 mmol $Pd(PPh_3)_2Cl_2$, 3 mL degassed ethanol, and 10 mL degassed acetonitrile. The autoclave was cooled with dry ice/acetone and evacuated, then 0.96 g gaseous trifluoropropene (10 mmol) was introduced and the autoclave was pressurized with CO up to 110 atm (at room temperature). The autoclave was heated to 100°C under stirring for 62 h. After that, the autoclave was rapidly cooled with ice water, and CO was carefully purged out to afford 75.8% ethyl 2-methyl-3,3,3-trifluoropropionate and 20.2% ethyl γ,γ,γ-trifluorobutyrate.



Reference 14.

To a 45-mL autoclave equipped with a glass liner containing a stirring bar were added 4 mL DME, 4.5 mg palladium acetate (0.02 mmol), and 17 mg dppb (0.04 mmol). To this mixture was added a solution of 270 mg 1,2-polybutadiene in 1 mL DME (equivalent to 5 mmol of vinyl groups) and then 460 mg formic acid (10 mmol). The autoclave was purged with CO and pressurized to 100 psi, and heated at 150°C for 21 h. Then the autoclave was cooled to room temperature, CO was vented, and the reaction mixture was filtered and evaporated to near dryness. Ether (30 mL) was used to rinse all the mass out of autoclave, and the polymer product precipitated instantly. After extracting with 30 mL 2 M NaOH, the ether layer was dried over $MgSO_4$ and evaporated to give a solid residue that did not contain any traces of starting polymer. The aqueous solution was acidified by 30 mL 6 M HCl,

and the precipitated polyacid was collected by filtration and dried in vacuo. A small amount of polyacid adhering to the glass wall was further recovered by small amount of acetone.

Other references related to the Reppe carbonylation are cited in the literature.[15]

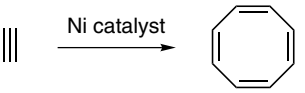
Reppe Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Reppe in 1948.[1] It is a nickel complex-catalyzed [2+ 2+ 2+ 2] cyclotetramerization of acetylene to cyclooctatetraene (COT), and is generally known as the Reppe cyclization.[2] Occasionally, it is also referred to as the Reppe reaction,[3] Reppe synthesis,[4] or Reppe cyclooctatetraene synthesis.[5] The nickel catalysts used for this reaction include $Ni(acac)_2$,[6] $Ni_2(COT)_2$,[7] 1,2-diaza diene nickel complex ($Ni(dad)_2$)[8] and even vapor-deposited nickel.[9] This reaction is the showcase of efficiency for organometallic complex-catalyzed reactions. For example, cyclooctatetraene was synthesized from pseudopelletierine by a 13-step manipulation in 1901 in very low yield,[10] whereas up to 90% yield of cyclooctatetraene can be obtained by pressurizing acetylene into a warm suspension of $Ni(CN)_2$ and CaC_2 in THF,[1a,11] or $NiBr_2/CaC_2$.[6a] In addition, it is known that the turnover number can be as high as up to 10^6 in neat propargylic alcohol, regardless of the catalyst.[12] Although it has been reported that nickel catalyst does not work for disubstituted alkynes,[13] in a few cases, disubstituted alkynes form octa-substituted cyclooctatetraenes, as evidenced in the reaction of 1-methyl-2-phenyl-acetylene on nickel prepared by vapor deposition[9] and cobalt complex-catalyzed cyclization of acetylenedicarboxylic acid ester.[14] In general, this reaction does not hold regioselectivity,[13c] and 1,2,4,7-tetrasubstituted cyclooctatetraene and 1,2,4,6- and 1,3,5,7-tetrasubstituted cyclooctatetraenes are often produced from monosubstituted acetylenes.[13c] Other types of substituted cyclooctatetraenes can be produced by application of monosubstituted or disubstituted acetylene with 3 equivalents of acetylene.[15] Often, this reaction is accompanied with side reactions yielding benzene derivatives.[15d,16]

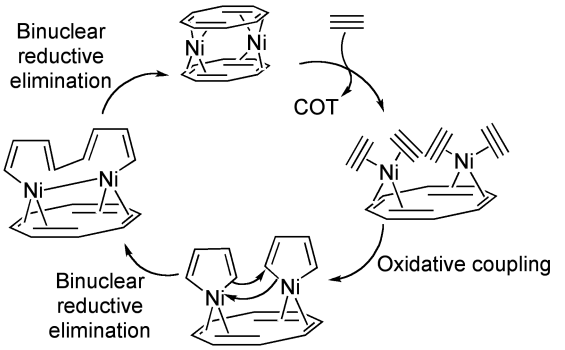
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction is believed to involve a number of complex processes,[17] by which four alkynes coordinate to a metal center to undergo either a stepwise coupling or a concerted "zipper-type" cyclization.[2d,13c] However, the $Ni_2(COT)_2$-catalyzed reaction involves the formation of a bis(cyclopentadienylnickel) complex,[7] a homobimetallic center,[2c] as supported by the actual determination of the structure from X-ray crystallography;[7] by the fast initiation of the reaction without an induction period when used directly for alkynes compared to other types of catalysts,[18] and by kinetic studies and labeling experiments.[2d,3,5] An illustrative mechanism catalyzed by $Ni_2(COT)_2$ is given here.



D. MODIFICATION

This reaction has been modified by use of the sterically hindered 1,2-diaza diene nickel complex, $Ni(dad)_2$ as catalyst to improve the regioselectivity. Under these conditions, primary propargylic alcohol is converted to 1,3,5,7-tetrasubstittued COT,[8] whereas secondary propargylic alcohol and propargylic esters are transformed into 1,3,6,8-tetrasubstituted COTs,[19] and propargylic ether is converted into 1,4,5,8-tetrasubstituted COT.[20] In addition, the ruthenium catalyst $[(Ph_3P)_3Ru(CO)H_2]$ has also been used successfully to convert diphenylbutadiyne into cyclooctatetraene.[21] It should be mentioned that a combination of Lewis acid and base (e.g., $AlBr_3$ and Et_3N) has also been developed to transform terminal acetylenes into 1,3,5,7- and 1,2,5,6-tetrasubstituted *syn*-tricyclo[4.2.0.$0^{2,5}$]octadienes which rearrange into 1,3,5,7- and 1,2,5,6-tetrasubstituted cyclooctatetraene through thermal or photochemical ring opening.[6b]

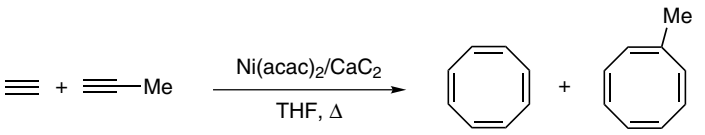
E. APPLICATIONS

This reaction has general application in the preparation of cyclooctatetraene derivatives.

F. RELATED REACTIONS

This reaction is closely related to the *Reppe Alkyne Cyclotrimerization*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 15d.

To a 1-L stainless-steel autoclave cooled with dry ice and trichloroethylene were added 10 g nickel acetylacetonate, 20 g powdered calcium carbide, and 30 g propyne dissolved in 250 mL THF also cooled with dry ice and trichloroethylene. The system was sealed, and the air was evacuated and replaced by acetylene to a pressure of 150–300 psi. The mixture was stirred and heated at 70–90°C for 7–12 hours while the acetylene was maintained at same pressure by represurizing acetylene at frequent intervals. After that, the mixture was steam distilled until 2 L of distillate was collected to separate volatile material (e.g., THF, benzene, substituted benzene, and cyclooctatetraene) from a water-insoluble residue (largely cuprene from polymerization of alkyne). The water-insoluble portion of the residue was separated by filtration, and extracted in a Soxhlet apparatus for 24 h with benzene containing a small amount of hydroquinone as a polymerization inhibitor. The benzene extract was concentrated and distilled, and the crude distillate was combined with the residue obtained by fractionation of the organic portion of the steam distillate (after the benzene, and cyclooctatetraene present had been removed as low-boiling fractions). This process yielded 40 g cyclooctatetraene and 14.1 g methylcyclooctatetraene (16%). Methylcyclooctatetraene was further purified by conversion into the crystalline silver nitrate complex and regeneration by shaking with a 100% excess of concentrated NH_4OH, extraction with pentane and redistillation, b.p. 84.5°C at 67 mmHg.

Reppe Vinylation
(Reppe Synthesis)

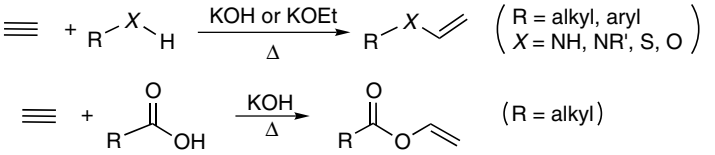
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Reppe in 1931.[1] It is a strong-base catalyzed addition of acetylene to form a variety of vinylic compounds and is known as the Reppe vinylation or Reppe synthesis.[2] In this reaction, vinyl ethers, vinyl sulfides, vinyl phenyl ethers, vinyl esters, and vinyl amines have been prepared by the addition of acetylene with alcohols, thiols or disulfides, phenols, carboxylic acids, and amines, respectively, at temperatures from 160° to 200°C and acetylene pressure from 100 to 300 psi.[3] It is known that acetylene is an explosive substance; however, acetylene can be handled safely under these reaction conditions by either diluting acetylene with inert material (e.g., N_2,[2,3] CO_2[3]), by using special apparatus, in which the amount of free space in the reaction system is minimized by packing material (e.g., steel or porcelain Raschig ring), or by using bunches of small reaction tubes.[3] The option of dilution with inert nitrogen is good for an autoclave operation, whereas the condition with minimized free space is good for continuous operation, especially with solid contact catalyst.[3] For the preparation of vinyl ethers from alcohols, the best catalysts are KOH and potassium alkoxide,[3] and the reactivity is in the order of primary alcohols > secondary alcohols > tertiary alcohols,[3,4] where the carbon chain in primary alcohols can be from C_1 to C_{18}, and the short-chain alcohols are best carried out in continuous fashion.[3] In addition, polyhydroxyl alcohols, such as ethylene glycol, glycerol, sorbitol,[3] pentaerythritol,[5] and sugar derivatives (e.g., mannitol[6]) can also be vinylated under these conditions to produce divinyl, trivinyl, or multivinyl ethers or cyclic acetals.[3] However, there is the potential that the potassium alkoxide catalyst may gradually diminish because of the transformation of the fatty acids into corresponding potassium carboxylates and hydrogen at such high temperature.[3] For the reaction between amines and acetylene, zinc or cadmium acetates are used as catalyst; however, alkylidenimines are formed instead of vinyl amines from primary aliphatic amines.[7] In addition, the β- or γ-hydroxy primary

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

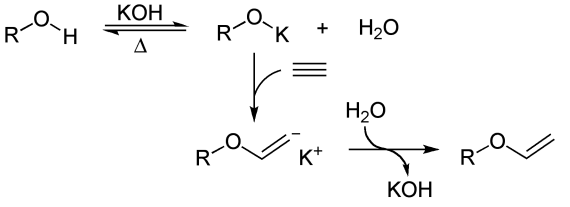
or secondary amines are converted into 2-methyloxazolidines or 2-methyltetrahydro-1,3-oxazines in reaction with acetylene with or without catalyst present, and nitrogen is the atom involved in the addition rather than oxygen.[8] For example, *N*-phenylethanolamine is converted into *N*-phenyloxazolidine with acetylene when zinc or cadmium acetate is used as catalyst.[9] Other less basic nitrogen-containing compounds, such as carbazoles, cyclic amides, pyrrolidones,[3] and *N*-monoalkyl sulfonamides,[10] have been vinylated under similar conditions with acetylene, even though *N*-monoaryl sulfonamide, *p*-toluenesulfonanilide, butanesulfonamide, and unsubstituted sulfonamides failed for this reaction.[10] Similarly, fatty acids such as lauric acid, stearic acid, and oleic acid have been successfully converted into corresponding vinyl esters;[11] and many phenols, especially monoalkylated phenols can be vinylated at 160°C using zinc naphthenate as catalyst.[3]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that a strong base such as KOH or potassium alkoxide will deprotonate the active hydrogen from the reactants, such as alcohols, thiols, amines, carboxylic acids, and phenols, to generate the nucleophiles that add to acetylene, as illustrated by the formation of vinyl ether from alcohol and acetylene. This can qualitatively explain the reactivity order among primary, secondary, and tertiary alcohols, without considering the steric hindrance. It is known that tertiary alcohol is less acidic than secondary and primary alcohol, therefore, less potassium *t*-butoxide will be formed than primary potassium alkoxide from KOH.[4]



D. MODIFICATION

The preparation of vinyl sulfides (or thioethers) has been extended by X-ray[12] or UV[13] irradiated addition of thiols to acetylene, and $Pd(OAc)_2$ or $Pd(PPh_3)_4$[14] catalyzed addition of thiol or disulfide to alkynes. In addition, alkyl halides (e.g., ethyl bromide, *n*-butyl bromide, *sec*-butyl bromide, benzyl chloride, etc.) have been successfully converted into corresponding vinyl sulfide through a one-pot process addition of acetylene mediated by thiourea.[15]

Furthermore, $[Pd(Triphos)](CF_3SO_3)_2$ has been used as an effective catalyst for the addition of amine to alkyne,[16] and the vinyl carbamate derivatives can be prepared in one step from acetylene, CO_2, and one of the following amines: dialkylamine, morpholine, piperidine, and pyrrolidine, using $RuCl_3 \cdot 3H_2O$ or $[RuCl_2(norbornadiene)]_n$ as the catalyst.[17] In addition, the preparation of vinyl phenyl ethers has been modified using tributyl(vinyl)tin[18] or 2,4,6-trivinylcyclotriboroxane-pyridine complex[19] as the vinyl source.

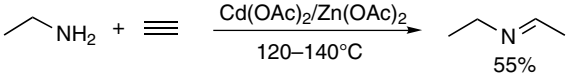
E. APPLICATIONS

This reaction has very important industrial applications for the production of vinylic monomers for polymerization.

F. RELATED REACTIONS

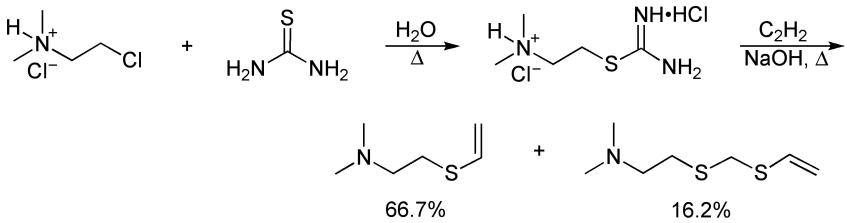
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

An autoclave containing a catalyst prepared from 2.5 g cadmium acetate dihydrate and 2.5 g zinc acetate dihydrate was evacuated, chilled in dry ice acetone and charged with 188.5 g ethylamine (4.18 mol) and acetylene to a pressure of 200 psi. The sealed autoclave was then heated at 120°C for 17 h and at 140°C for 12 h. More acetylene was added after cooling at 20°C before a final heating period of 6 h at 140°C. The maximum pressure was recorded as 785 psi. When the autoclave was cooled down to room temperature, the gases were vented slowly through traps at dry ice temperature. Than 50 g of a colorless liquid, assumed to be mostly ethylamine, was trapped. The minimum amount of acetylene absorbed was calculated to be 78 g (3 mol). The product was distilled in a 24-in. column of 23 mm diameter, which was packed with Podbielniak, stainless steel. Approximately 100 g ethylamine was recovered, and 77 g *N*-ethylethylidenimine was obtained, in a yield of 55% based on the ethylamine consumed, b.p. 38–47°C.



Reference 15a.

A solution of 477 g dimethylaminoethyl isothiouronium chloride hydrochloride was prepared by refluxing 144 g dimethylaminoethyl chloride hydrochloride (1 mol) and 83 g thiourea (1.1 mol) in 250 mL water for 6 h. Then 415 mL of this solution was charged to a 1-L autoclave with 160 mL 50% aqueous NaOH (3 mol). The autoclave was rushed with acetylene and heated to 120°C in 16 min and maintained at 120–132°C for 1 h at a maximum acetylene pressure of 480 psi. The total acetylene absorption was 1.73 mol. The reactor was cooled to room temperature, and the products were removed under nitrogen pressure. The crude products (744 g) were in two layers. The upper oil layer (173 g) was separated and flash distilled to give 145 g distillate (including 15 g water) and 25 g dry salt-like residue. The dry distillate (123 g) was fractionated through a 12 in. Vigreux column to give 85 g dimethylaminoethyl vinyl sulfide (66.7 %) and 15 g dimethylaminoethylthioethyl vinyl sulfide (16.2%).

Retro-Diels-Alder Reaction

(*Retro*-Diels-Alder Cleavage, *Retro*-Diels-Alder Fragmentation)

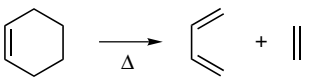
A. GENERAL DESCRIPTION OF THE REACTION

The first useful *retro*-Diels-Alder reaction was reported by Diels and Thiele as early as 1938.[1] It is a thermally allowed [$_{\pi}4_{s}+_{\pi}2_{s}$] cycloreversion[2] of an organic compound with a double bond in a six-membered ring, leading to the formation of a diene and a dienophile, i.e., the reversed process of the *Diels-Alder Cycloaddition*. Thus this reaction is generally known as the *retro*-Diels-Alder fragmentation,[3] or *retro*-Diels-Alder reaction.[2,3a,3y,5] Occasionally, it is also referred to as the *retro*-Diels-Alder cleavage.[6] Even though the *Diels-Alder Cycloaddition* is thermodynamically reversible, the *Diels-Alder Cycloaddition* products (i.e., the Diels-Alder cycloadducts) are fairly stable, and the *retro*-Diels-Alder reaction does not occur regularly, as demonstrated by the ample examples of the resistance of norbornenes and norbornadienes toward thermolysis.[4x] This is because two stronger σ-bonds must break for the formation of two π-bonds. However, as the unimolecular *retro*-Diels-Alder reaction is dominated by enthalpy of activation with small contribution from entropy of activation,[2,7] most *retro*-Diels-Alder reactions take place at very high temperature,[4i] if the resulting dienes and dienophiles are more stable.[4t] This is demonstrated by the thermal cracking of dicyclopentadiene at 180°C, a usual process for producing fresh cyclopentadiene in the laboratory. For the thermal *retro*-Diels-Alder reaction, it is possible to observe the lengthening of two breaking C–C σ bonds at the ground state,[8] and the ring strain may further weaken the breaking σ bonds. For example, the two breakable σ bonds in bicyclo[2.2.2]octene are found to be about 0.009 Å longer than corresponding σ bonds in bicyclo[2.2.2]octane; whereas the two σ bonds in bicyclo[2.2.1]heptene are ~0.02 Å longer than those of the saturated analogue.[9] Besides the normal thermolysis of Diels-Alder cycloadducts, a few conditions have also been reported to facilitate

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

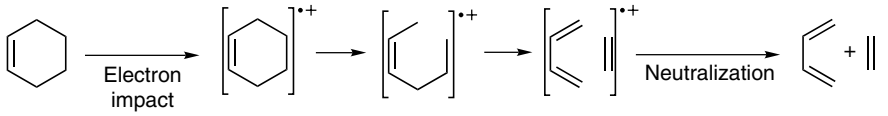
the *retro*-Diels-Alder reaction, such as the use of a catalytic antibody[4b,10] (e.g., antibody 9D9[11]), photo-initiation[4s,4u] (either by powerful irradiation or low power with longer illumination time[12]), electron impact,[3y,3aa] laser induction in the presence of SiF_4,[4w] flash vacuum pyrolysis,[4k,13] and the combination of Lewis acid and diene scavenger (e.g., $MeAlCl_2$ + maleic anhydride).[14] Among these conditions, the laser-induced *retro*-Diels-Alder reactions of norbornadiene, cyclohexene, 4-vinylcyclohexene, and 2,3-dihydropyran take place at ambient temperature;[4w] the antibody-catalyzed *retro*-Diels-Alder reaction to give nitroxyl and anthracene is found to be independent of a buffer, co-solvent effect, as well as pH when pH is regulated between 4 and 10;[4b] and electron impact-induced fragmentation is popularly used for structure determination in mass spectroscopy which may proceed through a stepwise or concerted process.[3aa] In addition, some special structural components may facilitate the *retro*-Diels-Alder reaction too, such as the anionic oxygen in *endo*-bicyclo[2.2.1]hepta-5-en-2-ol generated by treatment with phenyl magnesium bromide,[6d] the carbanion intermediate as in 7-phenylnorbornenyl,[4x] cycloadduct of 5-cyanocyclopentadiene,[4t] the trimethylsilyl group[4o] and the siloxy group,[4m] where the acceleration of the *retro*-Diels-Alder reaction from the carbanion intermediate is attributed to the "formation of resonance stabilized and weakly basic anions" from more strongly anionic cycloadducts,[4t] and the effect of the siloxy group can be seen even three bonds away from the reaction center.[4m] It should be mentioned that the thermal *retro*-Diels-Alder reaction of anthracene cycloadducts is accelerated by electron-donating groups[4m,4n] in the order of NH_2 > OH > OPh > OMe > Me > H,[4n] whereas it is less affected by electron-withdrawing groups and steric effects.[4m,4n] It is interesting that the reaction of anthracenedione is observed to be faster in aqueous solution than that in organic solvent and can be accelerated by addition of glucose and retarded by addition of organic solvent to the aqueous solution.[4h]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Mechanistically, the *retro*-Diels-Alder reaction is comparable to the *Diels-Alder Reaction*[4h] in that it may take place through a concerted or a stepwise path. Because this reaction is dominated by the enthalpy of activation rather than the entropy of activation, it is generally accelerated by the electron-withdrawing groups on the resulting dienophiles and the electron-donating groups on the forming dienes.[4h] The theoretical computation on the *retro*-Diels-Alder reaction of norbornene has indicated that the concerted mechanism is favored over the diradical in a stepwise route by 12.4 Kcal/mol,[4d] but the reaction of cyclohexene to form ethylene and butadiene does occur through an asymmetric stepwise mechanism from MINDO/3 calculation[4v] as well as by electron impact fragmentation study.[3aa] Under the conditions of high-energy photo-irradiation, the excited π^* singlet may be rapidly converted to diradicals directly.[3a] An illustrative mechanism is provided here for the reaction of cyclohexene to ethylene and butadiene under the electron impact condition.



D. MODIFICATION

This reaction has been extensively modified by the use of different reaction conditions as described in earlier sections.

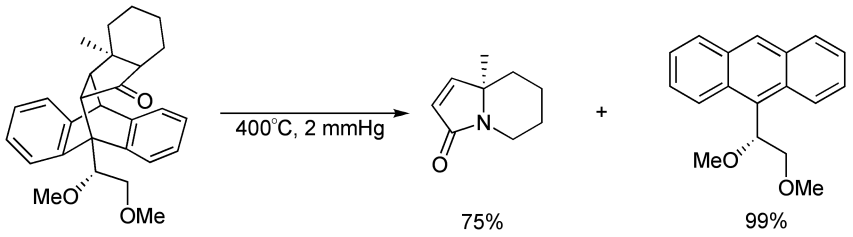
E. APPLICATIONS

This reaction has very wide application in organic synthesis, such as the formation of quinones,[4o] benzoquinones,[4h] heterocycles (e.g., oxazoles,[15] imidazoles,[15] pyridazine,[4c] pyrrole,[4c] furan[4c]) and olefins with stereospecificity[4z,14,16] as well as the protection of double bonds.[4r]

F. RELATED REACTIONS

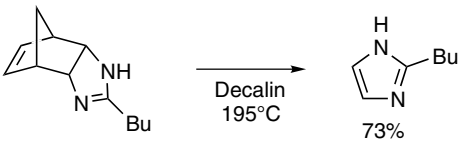
This reaction is closely related to the *Diels-Alder Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

The starting material (20.8 mg, 0.049 mmol) was placed in a small porcelain crucible, which was then inserted into one end of a fused silica tube with ball joints sealed by a glass cap held on by a clamp. The tube was then placed in a tube furnace with the other end connected to a high vacuum through a trap at -78°C. The tube was heated to 400°C for 4 min under high vacuum (< 2 mmHg). The cycloreversion products condensed on the glass tube as soon as they exited the tube furnace and were not detected in the traps. After cooling, the products were collected from the tube by washing with $CHCl_3$. After removal of solvent, the residue was purified by flash chromatography with EtOAc to afford 5.6 mg (+)-(*R*)–6,7,8,8a–tetrahydro–8a-methyl-5*H*-indolizin-3-one as a colorless oil (75% yield, $R_f = 0.13$, hexane/EtOAc, 1:1) and 13.9 mg (-)-(*R*)-9-(1,2-dimethoxyethyl)anthracene, in 99% recovery.



Reference 15.

(3aα,4a,7a,7aα)-2-Butyl-3a,4,7,7a-tetrahydro-4,7-methano-1H-benzimidazole (210 mg, 1.11 mmol) in 5 mL decalin was heated at 195°C for 2 h. The cooled reaction mixture was then applied to a silica gel column chromatography using 10% MeOH in $CHCl_3$ as the eluent to afford 100 mg 2-butylimidazole as an off-white solid, in a yield of 73%. The sample was further purified by vacuum sublimation at 70°C at 0.15 mmHg to give a white solid, m.p. 53–54°C.

Other references related to *retro*-Diels-Alder reaction are cited in the literature.[17]

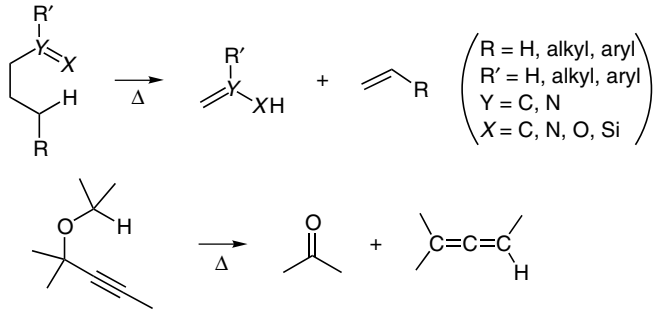
Retro-Ene Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was probably reported initially by Perkins and Cruz in 1927 during the preparation of undecylenic acid from ricinoleic acid, the major component of castor oil.[1] It is an intramolecular thermolysis of organic compounds with an unsaturated functional group involving the transfer of a γ-hydrogen to the unsaturated center via a six-membered transition state to yield both ene and enophile.[2] This reaction is thus generally known as the *retro*-ene reaction.[3,4] In addition, it is also referred to as *retro*-ene fragmentation,[2b,5] *retro*-ene decomposition[6] or *retro*-ene elimination.[7] Theoretically, this reaction belongs to a group of reactions known as pericyclic reactions,[8] but involves a [1,5]-H sigmatropic migration.[4a] In this reaction, the unsaturated functional groups include alkenyl,[9] alkynyl,[4c] allenyl,[4d,10] cyclopropyl,[11] carbonyl,[12] diazo,[13] and iminyl,[2a] occurring in the molecules of olefins, 1,6-dienes,[9] allyltrimethylsilanes,[14] acetylenic ethers,[4g,15] allylic and propargylic diazenes,[16] allylic sulfinic acid,[17] β-hydroxyethyl pyrazine,[4h] cyclic α-hydroxynitrosamines,[18] metastable immonium salts,[2a] allenic esters, allenic amides,[4d] etc. In most cases, this reaction involves a concerted mechanism,[2,4g,9,15,17,19] and gives a product with the stereochemical integrity preserved.[15] While olefins prefer an envelope-like transition state geometry,[20] only the *retro*-ene reaction through a planar transition state geometry is feasible for acetylene.[20b,21] Consequently, the *retro*-ene reaction does not take place among cyclic alkenes smaller than a seven-membered ring[22] or fused rings, of which one or more atoms involved in the reaction are part of the fused ring, except for a cyclopropyl ring.[12a,23] For the case of immonium salt, the alkyl group at γ-carbon facilitates the *retro*-ene reaction by distributing a substantial fraction of positive charge at the transition state.[2a] In addition, olefins with an acetylene group at β-position will undergo a competing *Cope Rearrangement* rather than the *retro*-ene reaction.[20b]

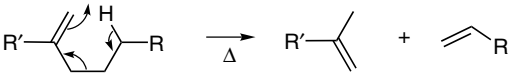
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is known that this reaction involves a concerted six-member transition state, as illustrated below.



D. MODIFICATION

This reaction has been extended to a variety of compounds with unsaturated functional groups, as described in Section A.

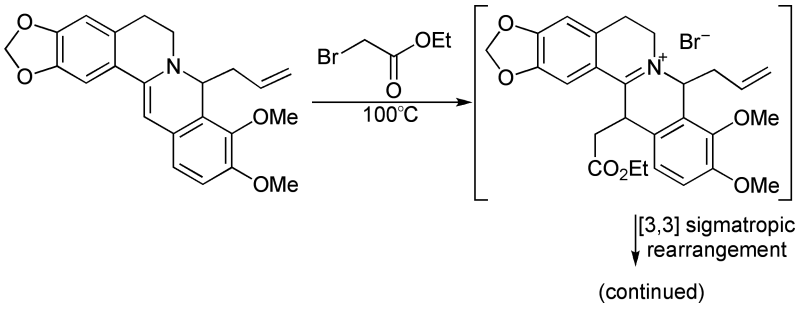
E. APPLICATIONS

This reaction has broad applications in organic synthesis.

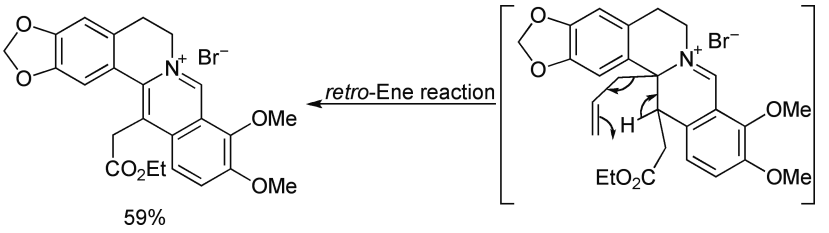
F. RELATED REACTIONS

This reaction is related to the *Alder Ene Reaction.*

G. CITED EXPERIMENTAL EXAMPLES

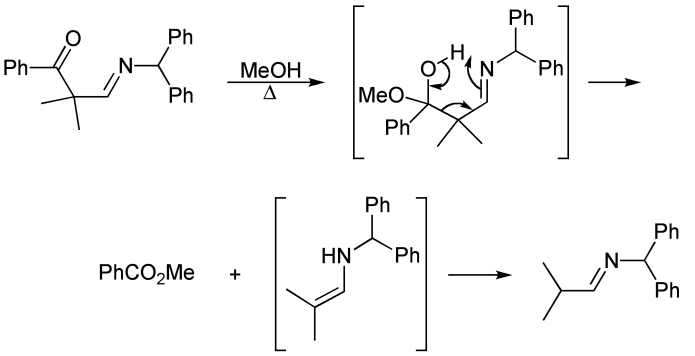


(continued)



Reference 24.

To a flask containing 50.5 mg 8-allyldihydroberberine (0.13 mmol) at 0°C was added 2 mL dry ethyl bromoacetate (18.03 mmol) during stirring under a nitrogen atmosphere. The solution was then heated to 100°C for 2.5 h to give a suspension. Then dry toluene was added, the mixture was filtered, and the filtrate was evaporated to afford 57.3 mg 13-(2-ethoxy-2-oxoethyl)-9,10-dimethoxy-5,6-dihydrobenzo[g]-1,3-benzodioxolo[5,6-a]quinolizinium bromide as an orange-yellow solid, which was further purified by recrystallization from dichloromethane containing 1% MeOH, and diethyl ether to give 39.3 mg pure product, as yellow needles, in a yield of 59%, m.p., 202–204°C.



Reference 4i.

A solution of 1.0 g *N*-(diphenylmethyl)-4-aza-2,2-dimethyl-l-phenyl-3-butenone (3 mmol) in 60 mL MeOH was refluxed for 8 h. The solvent was evaporated, and the residual oil was distilled under reduced pressure at 100°C (80 mmHg) to remove methyl benzoate, and the residue was purified to give *N*-(diphenylmethyl)-2-methylpropanimine. No yield was given in this experiment.

Other references related to the *retro*-ene reaction are cited in the literature.[25]

Retropinacol Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Zelinsky and Zelikow in 1901.[1] It is the conversion of alcohols with a tertiary β-carbon into olefin along with the migration of an alkyl group from the tertiary β-carbon in the presence of an acid. Therefore, this reaction is generally known as the retropinacol rearrangement.[2] It is known that alcohol is protonated to form an oxonium in the presence of an acid, which dehydrates to give the carbonium ion; the generated carbonium ion does not rearrange by itself, whereas the migration is facilitated by the base (conjugate base) attack at the β-position.[2q] Thus the extent of the rearrangement is determined by the strength of the base and the accessibility of the β-position to the base, so that shielding the β-carbon by either a bulky group or an electron-rich group can prevent the retropinacol rearrangement.[2q] Strictly speaking, the retropinacol rearrangement is the reverse of normal *Pinacol Rearrangement*, as demonstrated from the reaction between pinacolone and liquid sulfur trioxide to yield cyclic sulfate.[3]

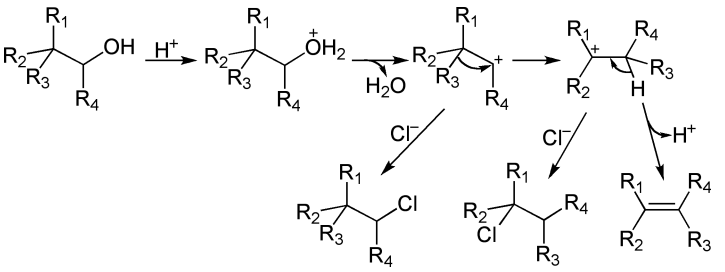
B. GENERAL REACTION SCHEME

(R_1, R_2, R_3, R_4 = alkyl
R_1 or R_2 could migrate also)

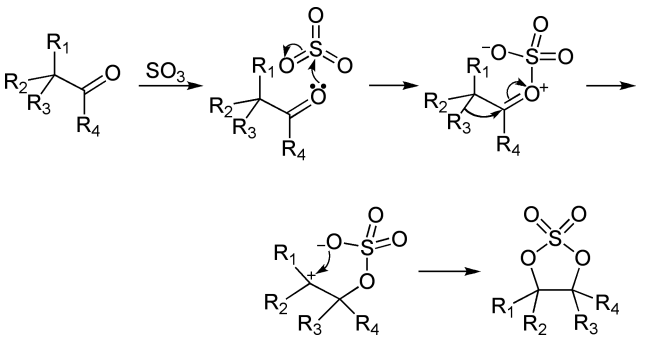
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The rearrangement of alcohol with a tertiary β-carbon in the presence of an acid is illustrated in Scheme 1, along with its competing reactions to form corresponding alkyl chlorides. In addition, the mechanism for the formation of a cyclic sulfate from pinacolone and liquid sulfur trioxide is provided in Scheme 2.



SCHEME 1. *Mechanism of retropinacol rearrangement.*



SCHEME 2. *Reaction between sulfur trioxide and pinacolone to form a cyclic sulfate.*

D. MODIFICATION

A base triggered retropinacol rearrangement has been developed, by the use of 2-chloro-1,1,2-trifluoroethyldiethylamine.[2k]

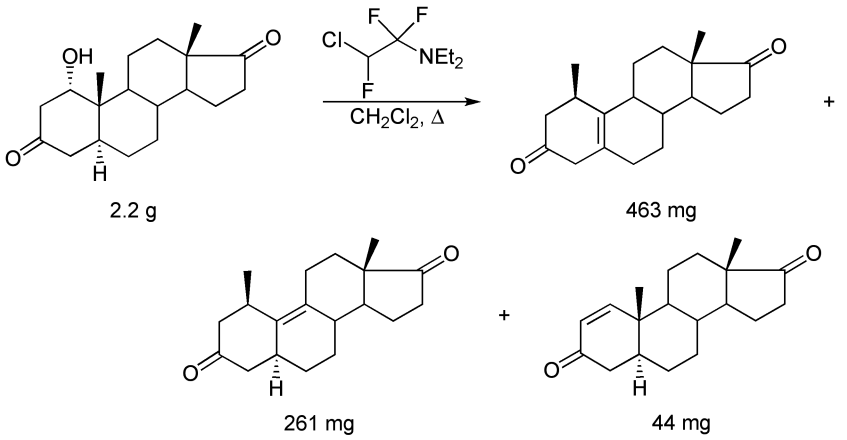
E. APPLICATIONS

This reaction has certain applications in organic synthesis.

F. RELATED REACTIONS

This reaction is related to the *Pinacol Rearrangement* and *Wagner-Meerwein Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2k.

A mixture of 2.2 g 1α-hydroxy-5α-androstane-3,17-dione and 2.2 mL 2-chloro-1,1,2-trifluoroethyldiethylamine in 25 mL CH_2Cl_2 was refluxed for 15 min, after which time the TLC indicated the completion of the reaction. This solution was washed with water, aqueous $NaHCO_3$ and water again, then dried over Na_2SO_4 and evaporated under vacuum to an oil. The residue was chromatographed on 200 g silica gel using EtOAc/benzene (1:19) as the eluent to afford 463 mg 1β-methylestr-5(10)-ene-3,17-dione, m.p. 136°C. This product was further purified by recrystallization from benzene/hexane to yield 257 mg pure 1β-methylestr-5(10)-ene-3,17-dione, m.p. 139–140°C. From the benzene mother liquors from which crude 1α-hydroxy-5α-androstane-3,17-dione was crystallized, 261 mg 1β-methylestr-9-ene-3,17-dione was recovered. Continued elution of the column (from which the two compounds and their mixture were obtained) with 5% EtOAc in benzene afforded 44 mg impure 10β-methylestr-1(2)-ene-3,17-dione, m.p. 99–107°C.

Other references relatd to the retropinacol rearrangement are cited in the literature.[4]

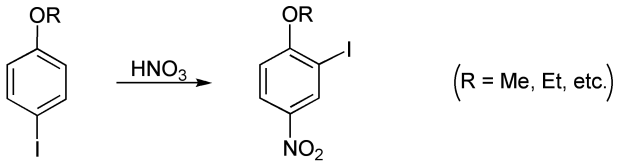
Reverdin Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Reverdin in 1896.[1] It is the preparation of 2-iodo-4-nitro-anisole from the nitration of 4-iodo-anisole, involving the migration of iodine from the 4-position to the 2-position during the nitration and is generally known as the Reverdin rearrangement.[2] Occasionally, it is also referred to as the Reverdin reaction.[3] It should be pointed out that bromine can migrate in a fashion similar to iodine and only a catalytic amount of nitro source is needed if a nitro group already exists on the aromatic ring.[3]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction is assumed to take place via an initial *ipso* attack of nitro at the iodo position and the subsequent liberation of iodine,[4] which then halogenates at the intermediate to form 2-iodo-4-nitro-anisole and 2,4-diiodoanisole, the latter is then slowly nitrosodeiodinated.[2b]

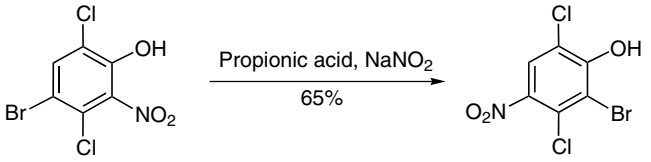
E. APPLICATIONS

This reaction has certain applications in organic synthesis.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A 20-mL scintillation vial equipped with a magnetic stir bar was charged with 1.33 g 4-bromo-3,6-dichloro-2-nitrophenol (4.64 mmol), 10 mL propionic acid, and 0.022 g sodium nitrite (0.32 mmol) and capped. The hazy red-orange solution was stirred at room temperature for 2 h and then poured into 10 mL brine. The mixture was extracted with ethyl ether (2 × 10 mL), and the combined ether layers were dried over anhydrous Na_2SO_4. Upon evaporation of solvent, 1.27 g of an orange solid was obtained, which was recrystallized three times from cyclohexane to afford 0.86 g 2-bromo-3,6-dichloro-4-nitrophenol, in a yield of 65%, m.p., 129–130°C (dec.).

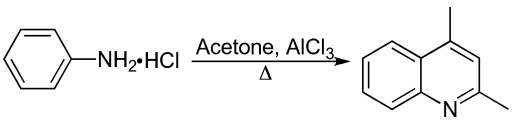
Riehm Quinoline Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Engler and Riehm in 1885.[1] It is a synthesis of 2,4-dimethylquinoline from the thermal condensation of aniline hydrochloride and acetone[2] or mesityl oxide along with the evolution of water and methane,[3] and is known as the Riehm quinoline synthesis.[4] This reaction can occur under the conditions with or without any condensation reagents[2] and may evolve other hydrocarbons as well.[2,3b]

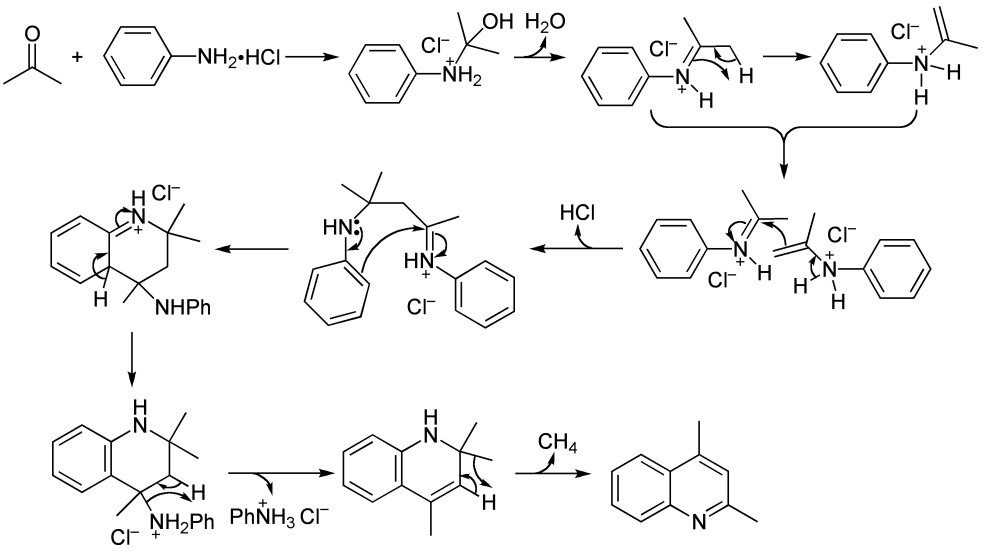
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction is assumed to involve the formation of ketylidene or alkylidene anils,[5] which dimerizes and cyclizes to give 1,2-dihydroquinoline.[3a,4] This intermediate then aromatizes by evolving the methyl or other hydrocarbon moiety in the presence of an acidic or a basic catalyst.[4] An illustrative mechanism is given here for the reaction between acetone and aniline hydrochloride.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction was modified by addition of iodine to the mixture of aniline and ketone to initiate the reaction.[4]

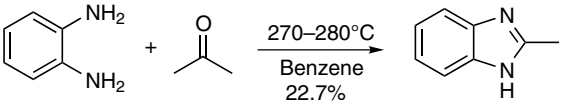
E. APPLICATIONS

This reaction is useful for the preparations of 2,4-disubstituted quinolines.

F. RELATED REACTIONS

This reaction is related to *Doebner Reaction* and *Doebner-von Miller Quinoline Synthesis*.

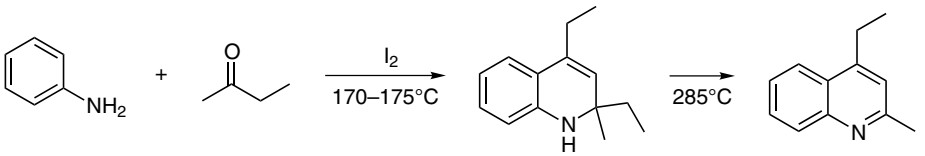
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

A 100-mL flask was equippd with a Claisen adapter that was sealed with a graduated tube for measuring the amount of water from azeotropic distillation. In addition, the center arm of the adapter was closed with a stopper, and the side arm was connected with a refluxing condenser, of which the top led to a solid dry ice trap and then to a 1500-mL eudiometer. The capillary tube with stopcock at the top of the eudiometer was sealed for the removal of

gas sample. To the 100-mL flask of this reaction system, were added 5.4 g freshly prepared *o*-phenylenediamine (recrystallized from heptane then water), 29.0 g freshly distilled acetone, and 20 mL dry benzene; the flask was heated with a heating mantle packed with glass wool for 2 h at 270–280°C. Gas evolution initially occurred at 260°C. After the reaction, the volatile solvent was removed by evaporation, and the residue was purified by crystallization from water to afford 1.5 g 2-methylbenzimidazole as white leaflets, in a yield of 22.7%, m.p. 174.0–175.5°C.



Reference 4.

2-Butanone (835 g) was passed into the reaction mixture of 279 g aniline and 9.0 g iodine maintained at 170–175°C. After the reaction, the residual 2-butanone and aniline was separated by preliminary distillation, and the residue was fractionated on a 4-ft. glass helix column, and the fraction that boiled at 170–174°C at 28 mmHg was collected to afford 95 g 2,4-diethyl-2-methyl-1,2-dihydroquinoline. Then the hydrochloride salt of dihydroquinoline was heated at 285°C for 5 min, and the residue was fractionated again to give 2-methyl-4-ethylquinoline.

Rieke Metal

A. GENERAL DESCRIPTION OF THE REACTION

This reagent was initially prepared by Rieke and Hudnall in 1972.[1] It is a general method of preparing superfine (e.g., nanometer size[2]) and highly active[3] and dispersed[4] metal particles of low valence from the heterogeneous reduction of corresponding anhydrous metal salts[5] by highly reductive metal (e.g., K, Na, Li)[6,7] or hydride (e.g., $NaBEt_3H$, $LiBEt_3H$)[2] in ethereal (e.g., THF,[3,8] DME,[3] glyme[9]) or hydrocarbon solvent (e.g., toluene[2]), in the presence of an electron-carrier such as naphthalene.[9a] The resultant low-valent metal (LVT)[10] is known as Rieke metal,[11] for example, Rieke Mg,[8] Rieke Zn,[12] and Rieke Ni.[11] So far, low-valent Cr, Mo, W, Mg, Mn, Ni, Zn, etc. have been prepared by this method. It has been found that the choice of solvent affects the outcome of this reduction, as indicated by the formation of metal colloid of Cr, Mo, and W in high yield from the reduction of $CrCl_3$, $MoCl_3$ and $MoCl_4$ with $NaBEt_3H$ in toluene at room temperature, whereas metal carbides (M_2C) are obtained from the reduction by $NaBEt_3H$ or $LiBEt_3H$ in THF of the same metal salts.[2] However, this preparation method for Rieke metal has a few limitations, such as the chemical incompatibility with certain functional groups (e.g., NO_2, CN, etc.),[9a] long reaction time,[11] necessary removal of a large amount of naphthalene before or after the reaction induced by these active metals,[11] and the intrinsic tendency toward deactivation and the need for further activation.[10]

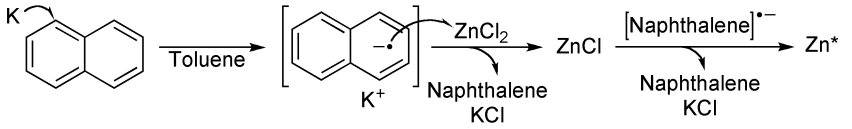
B. GENERAL REACTION SCHEME

$$MX_n \xrightarrow[\text{Ether or toluene}]{\text{K, Naphthalene}} M^* \quad \begin{pmatrix} M = \text{Cr, Mg, Mn, Mo, Ni, W, Zn, etc.} \\ X = \text{Cl} \\ n = 1, 2, 3, \text{etc.} \end{pmatrix}$$

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The highly active low valent metal is assumed to form via an electron-transfer reaction mediated by naphthalene[9] or biphenylene,[5] as illustrated below for the reduction of zinc chloride by potassium in toluene.



D. MODIFICATION

This preparation has been modified by electronic reduction in DMF solution containing 0.3 M $Bu_4N^+BF_4^-$ as electrolyte in an undivided cell with a platinum cathode and the anode prepared from the expected metal as cation source.[11]

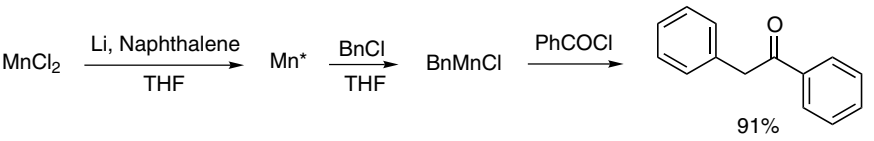
E. APPLICATIONS

Rieke metal has broad application in organic synthesis that requires an active metal of low valence, such as the *McMurry Coupling* (Cr) and the *Reformatsky Reaction* (Zn).

F. RELATED REACTIONS

N/A

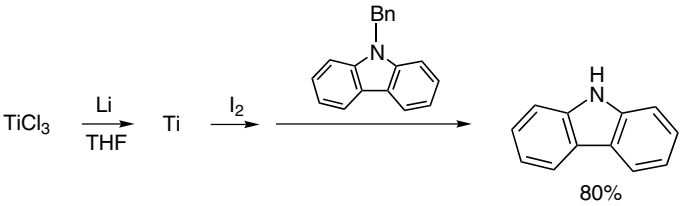
G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To a mixture of 0.139 g lithium (20 mmol), 0.256 g naphthalene (2 mmol), and 3.087 g manganese iodide (10 mmol) was added 15 mL freshly distilled THF via syringe at room temperature. The resulting mixture was then stirred at room temperature for 30 min to give a black slurry. To this highly active manganese slurry being stirred at room temperature was then added 1.13 g benzyl chloride (9 mmol) via syringe, and the resulting mixture was stirred at room temperature for 20 min. The reaction was monitored by gas chromatography. After the completion of the oxidative addition, the mixture was cooled to 0°C, and 1,2-dibromoethane was added to the mixture at the same temperature to scavenge the excess amount of active manganese for 5 min. The resulting mixture was transferred via cannula to the benzoyl chloride solution in THF at room temperature. After being stirred for 30 min, the

mixture was quenched with 3 M HCl solution and extracted with diethyl ether. The combined organic layers were washed with $NaHCO_3$, $Na_2S_2O_3$, and brine, dried over anhydrous $MgSO_4$, and concentrated. The residue was purified by flash column chromatography using EtOAc/hexanes as the eluent to afford 1.786 g benzyl phenyl ketone as a white solid, in a yield of 91%, m.p. 55–56°C.



Reference 10.

To a mixture of 1.55 g $TiCl_3$ (10 mmol) and 0.231 g Li (33 mmol) was added 50 mL dry THF, the resulting mixture was refluxed for 3 h under argon. After cooling, 0.635 g crystalline iodine (2.5 mmol) was added in portion and the mixture was stirred for 5 min. On addition of iodine, the black suspension of low valent titanium gradually turned brown. To this activated LVT-I_2 reagent, was added 0.643 g *N*-benzyl carbazole (2.5 mmol) in 5 mL THF. The resulting solution was then stirred at room temperature for 16 h, then diluted with hexane and passed through a short pad of Celite. Upon removal of THF, the residue was mixed with an EtOAc/hexanes (20:80) mixture, washed with brine, and dried over Na_2SO_4. After evaporation, the residue was purified by preparative TLC (SiO_2, hexane) to afford 0.335 g carbazole, in a yield of 80%.

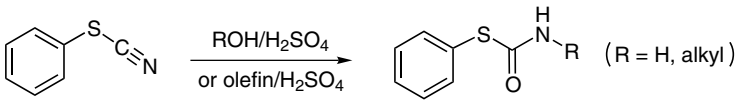
Riemenschneider Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Riemschneider in 1949.[1] It is an acidic transformation of alkyl or aryl thiocyanates into thiocarbamates and is known as the Riemschneider reaction.[2] In this reaction, when thiocyanates are treated with concentrated sulfuric acid, the corresponding thiocarbamates are obtained.[3] In parallel, when thiocyanates are treated with concentrated sulfuric acid in the presence of alcohol or olefin, the corresponding *N*-substituted carbamates are yielded.[4] The alcohols or olefins that are stable in the presence of sulfuric acid, including isopropyl alcohol, *sec*-butyl alcohol, *t*-butyl alcohol, cyclohexanol, isobutylene, and camphene all are suitable for this reaction, whereas low-order alcohols such as methanol and ethanol do not react with thiocyanate to give the corresponding *N*-substituted thiocarbamates.[4] In addition, the benzyl thiocyante[4] and some *ortho*-substituted phenyl thiocyanates cannot be transformed into the corresponding thiocarbamates under these conditions because they are sensitive to sulfuric acid.[3,4] Some unsuitable thiocyanates are *o*-carboxyl, *o*-methoxy, *o*-nitrophenyl thiocyanates,[3] and *o*-methyl-4-amino phenyl thiocyanate.[4]

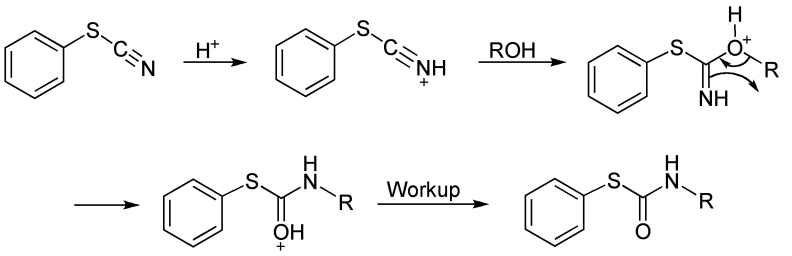
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Illustrated below is the mechanism for the reaction between phenyl thiocyanate and a general alcohol.



D. MODIFICATION

N/A

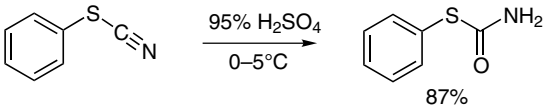
E. APPLICATIONS

This reaction has general application in organic synthesis as well as in analytical chemistry.

F. RELATED REACTIONS

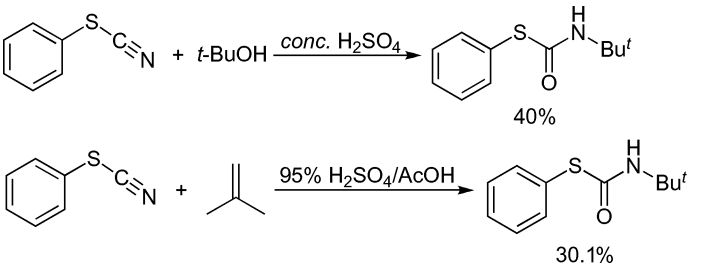
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A benzene solution of 2 g phenyl thiocyanate was treated slowly under shaking and ice cooling with 10 mL 95% H_2SO_4. The mixture was kept at 0–5°C for 15 h and then poured on ice. The precipitate was collected, washed with water, and dried in air. The phenylthiocarbamate was a needle crystal, m.p. 98°C; the yield was 87%.



Reference 4.

From *t*-Butyl Alcohol

To a mixture of concentrated sulfuric acid and 1.85 g *t*-butyl alcohol (25 mmol), was added 3.4 g phenyl thiocyanate (25 mmol) dropwise under stirring. After all the phenyl thiocyanate was added to the solution, the stirring was continued for 5 h with cooling on an ice bath. Then the reaction mixture was stirred into 250 mL ice water to yield yellow crystals, which were further purified by recrystallization several times from hexane following treatment with activated charcoal, m.p. 115°C. The yield was 40%.

From Isobutylene

To a mixture of 30 mL glacial acetic acid and 5 mL 95% sulfuric acid, was added 7.0 g phenyl thiocyanate (51 mmol) dropwise. At the same time, a slow stream of isobutylene was passed through the reaction mixture at a temperature of 10°C; within 40 min, the reaction mixture absorbed 6.0 g isobutylene (107 mmol). After being maintained at 10°C for 24 h, the contents of the reaction vessel were poured into 250 mL ice water, and extracted with ether. The combined ethereal solution was dried and evaporated. The residue was fractionated to give 5.5 g phenyl thiocyanate (71–73°C at 1.5 mmHg), the residue remained after the distillation was recrystallized from hexane to afford 0.7 g *N*-*t*-butyl phenylcarbamate, in a yield of 30.1% based on 21.4% conversion.

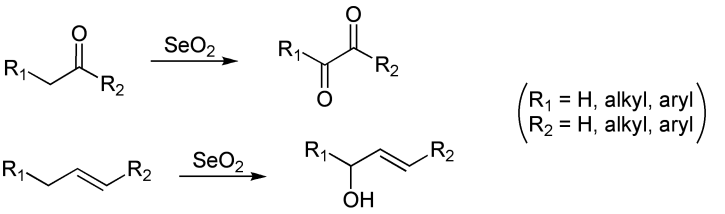
Riley Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Riley in 1930.[1] It is the oxidation of a methyl or methylene group activated by an adjacent double bond, carbonyl, aromatic, etc. into a carbonyl or alkoxyl group using selenium dioxide as the mild oxidant. Therefore, it is generally known as the Riley oxidation.[2] In this reaction, the methylene group is activated by a carbonyl group, and converted into an adjacent carbonyl group again;[3] whereas a hydroxy group is often introduced onto the allylic methylene group,[4] and the position of the double bond often remains untouched under the condition of allylic oxidation.[4c] In addition, the methylene group in an allylic moiety can be trapped at the alcohol stage by carrying out the reaction in acetic anhydride or acetic acid.[5] At low temperature, saturated hydrocarbons, alcohols, ethers, acids, esters, and most halides will not be oxidized by SeO_2;[5b] but at high temperature, even the double bond can be oxidized, as indicated by the high yield of glyoxal (80%) from ethylene,[6] and 19% of methylglyoxal from propylene at 220–240°C.[6c] The recovered selenium can be oxidized and used again.[5b] This reaction can also be carried out at room temperature under sunlight or UV.[5b]

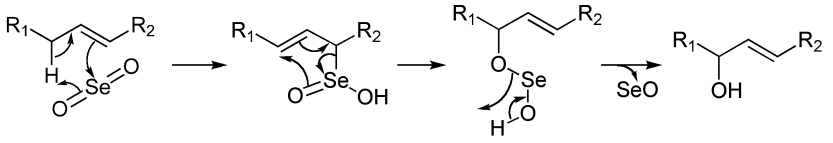
B. GENERAL REACTION SCHEME



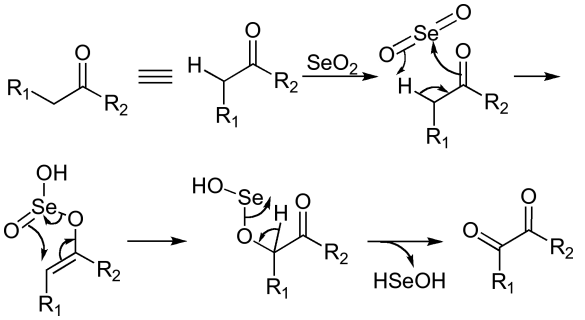
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The allylic oxidation is assumed to occur through an initial ene reaction followed by a [2,3]-sigmatropic rearrangement,[4b,4f] as illustrated in Scheme 1. Although not many mechanistic studies are available for the oxidation of a ketone or aldehyde to an adjacent dicarbonyl compound, it is plausible that such oxidation by SeO_2 undergoes a similar reaction pathway, as shown in the tentative mechanism outlined in Scheme 2.



SCHEME 1. *Mechanism of allyl alcohol formation by SeO_2 oxidation.*



SCHEME 2. *Tentative mechanism for the oxidation of ketone (or aldehyde) from SeO_2.*

D. MODIFICATION

N/A

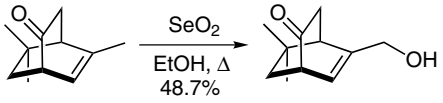
E. APPLICATIONS

This reaction has wide application in organic synthesis, especially for the preparation of allyl alcohol with retention of stereochemistry,[4d,4f,4g] and 1,2-diketones.[3]

F. RELATED REACTIONS

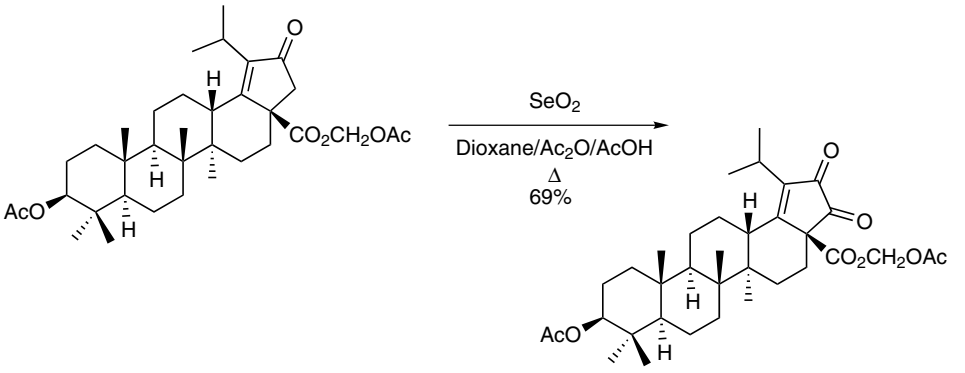
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A 2-mL magnetically stirred 95% ethanol solution containing 348 mg 2,7,7-trimethylbicyclo[2.2.2]oct-2-en-5-one (2.12 mmol) was treated dropwise with 2 mL 95% ethanol solution containing 250 mg SeO_2 (2.26 mmol). The reaction mixture was stirred and refluxed for 48 h, then diluted with ether and washed with brine. The ethereal phase was dried and concentrated to leave a residue that was purified by silica gel chromatography using 5% ether in petroleum ether as an eluent to afford 186 mg 2-hydroxymethyl-7,7-dimethylbicyclo[2.2.2]-oct-2-en-5-one as a colorless liquid (48.7%), and 52 mg of starting material (15% recovery).



Reference 3b.

A mixture of 5 mL dioxane solution containing 250 mg acetoxymethyl 3β-acetoxy-21-oxolup-18-en-28-oate (0.43 mmol), 200 mg SeO_2 (1.8 mmol), 2.5 mL AcOH, and 0.25 mL Ac_2O was refluxed until the oxidation was completed as monitored by TLC (PhMe/Et_2O, 10:1). After cooling, precipitated selenium was removed by filtration, and the filtrate was poured slowly into an excess of vigorously stirred water. The red-orange precipitate was filtered under reduced pressure, washed carefully with H_2O, and air dried. The crude product was dissolved in $CHCl_3$, and the solution was filtered through a column of alumina. The column was eluted with $CHCl_3$, and the filtrate was evaporated under reduced pressure. The residue was crystallized from butanone to afford 176 mg acetoxymethyl 3β-acetoxy-21,22-dioxolup-18-ene-28-oate as pale-orange needles, in a yield of 69%, m.p. 227–228°C.

Ritter Reaction

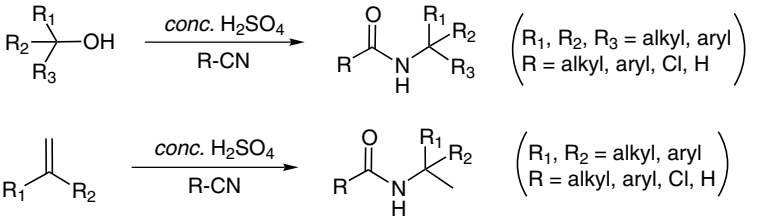
A. GENERAL DESCRIPTION OF THE REACTION

This reaction can be traced back as early as in 1922, when Kohler et al. investigated the reaction between methyl cyanoacetate and benzal-acetophenone or benzal-*p*-chloro-acetophenone in the presence of hydrogen chloride or hydrogen bromide to form lactams.[1] Subsequently, Bus reported the reaction of *N*-hydroxymethyl phthalimide with nitriles in the presence of sulfuric acid.[2] It was Ritter who extensively studied and extended the reaction of nitriles;[3] therefore, a strong acid-promoted amidation of alcohol or olefin with nitrile is generally known as the Ritter reaction.[4,5] Under strong acidic conditions, both alcohol and olefin are protonated to generate a carbocation with an empty *p*-orbital that can be filled by the lone pair electrons on the nitrogen atom of nitriles to form the nitrilium ion, which is converted to an amide upon hydrolysis.[4g,4n,4q,4w] Besides alcohols and olefins, some other types of molecules can also undergo this reaction under similar conditions by formation of carbocations such as trioxane,[4s] *N*-tosylazetidine,[6] aziridine,[4c] oxirane,[5uu] and epoxide.[4b,5e] It has been found that the outcome of this reaction depends on the reactivity of nitriles and the stability of carbocations,[4r] thus the reactions from tertiary alcohols normally give much higher yields than those from primary and secondary alcohols.[4r] In addition, temperature may affect the reaction, as demonstrated from the reaction between nitrile and chalcone, which takes place at temperatures $> 55^{\circ}C$ even when sulfuric acid is replaced by the much milder phosphoric acid and diluted with acetic acid; whereas the same reaction occurs more slowly below $55^{\circ}C$.[4z] Furthermore, it has been found that stereochemistry is completely retained in this reaction when a bromo group is present at the neighboring position, through the bromo bridge intermediate, as indicated from the exclusive formation of *threo*-2-acetamido-3-bromobutane and *threo*-2-benzamido-3-bromobutane from *threo*-3-bromo-2-butanol with acetonitrile and benzonitrile, respectively.[4u] However, given the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

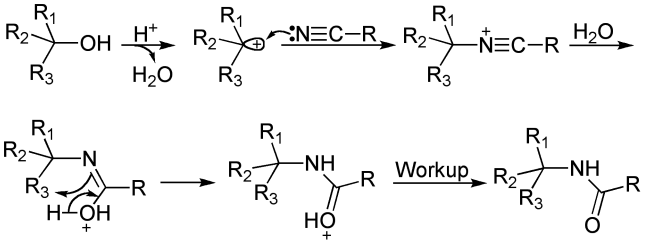
nature of this reaction, the Ritter reaction is also in competition with other side reactions involving carbocations, such as the ring-enlargement of cyclic carbocations[4w] and the rearrangement of carbocations.[4t]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves the initial formation of a carbocation from olefin or alcohol when treated with a strong acid such as sulfuric acid that is subsequently attacked by the lone pair electrons of the nitrogen atom of a nitrile to give a nitrilium ion, which, on addition of water during workup, hydrolyzes to form an amide,[4g,4n,4q,4w] as illustrated below using a general tertiary alcohol as an example.



D. MODIFICATION

The original reaction protocol has been extensively modified, including the activation of a primary alcohol with trifluoromethanesulfonic anhydride,[7] stabilization of primary carbocations with transition-metal complex (e.g., $Co(CO)_3$),[4r] replacement of sulfuric acid by Pd^{2+},[4p] liquid hydrogen fluoride,[4v] P_2O_5/SiO_2,[5b] bismuth salt (III),[5d,5e] heteropolyacids,[5g,5h] or a Lewis acid-assisted Brønsted acid, which is prepared from a 1:2 molar mixture of $B(OH)_3$ and 4,5,6,7-tetrachlorocatechol.[4a] In addition, the Ritter reaction has been extended to the reaction of nitrile with either aldose[5a] or ketose.[5ee] Further modifications include the sulfur mediated Ritter reaction;[5z] the application of acetic acid as co-solvent;[4o] and the reactions between olefin and cyanogen chloride,[8] haloolefin and nitrile,[9] camphene and hydrogen cyanide,[10] and especially metal cation and nitriles.[11]

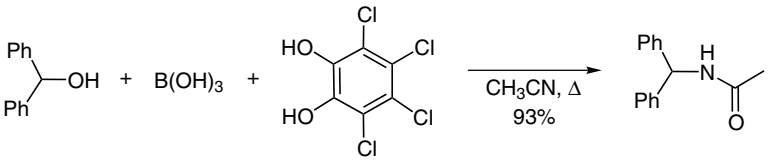
E. APPLICATIONS

This reaction has very wide applications in organic synthesis, not only for the general preparation of amides[5a] but also for a variety of monocyclic and fused heterocyclic compounds,[4m] bridged heterocycles,[4m] and polyamides.[4s,4x]

F. RELATED REACTIONS

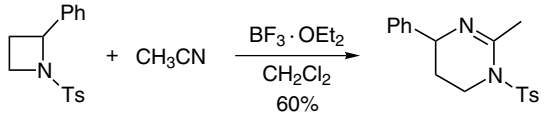
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

A dry, 10-mL round-bottomed flask equipped with a Teflon-coated magnetic stirring bar and a reflux condenser was charged with 6.2 mg $B(OH)_3$ (0.10 mmol), 50 mg tetrachlorocatechol (0.20 mmol), and 368 mg diphenylmethanol (2.0 mmol) in 5 mL acetonitrile. The mixture was refluxed for 11 h and then cooled to ambient temperature and mixed with saturated aqueous $NaHCO_3$. The product was extracted with EtOAc, and the combined organic layers were dried over $MgSO_4$ and concentrated. The residue was purified by silica gel column chromatography to afford 93% *N*-α,α-diphenylmethyl acetamide, m.p. 151°C.



Reference 6.

To a 10-mL round-bottomed flask were added 211 mg 2-phenyl-*N*-tosyl azetidine (1 mmol) and 3 mL anhydrous CH_2Cl_2 under argon at room temperature, followed by 1 mmol acetonitrile and a slow addition of 0.2 mmol freshly distilled $BF_3{\cdot}Et_2O$. After 2 h, 2 mL saturated aqueous $NaHCO_3$ solution was added. The organic layer was separated, and the aqueous layer was extracted with dichloromethane (2×5 mL). The combined organic layers were washed with water, brine, and dried over anhydrous Na_2SO_4 and concentrated. The residue was purified by column chromatography using 30% EtOAc in petroleum ether as the eluent to afford 60% 2-methyl-4-phenyl-1-(toluene-4-sulphonyl)-1,4,5,6-tetrahydropyrimidine as a colorless paste, $R_f = 0.42$ (EtOAc/petroleum ether, 2:3).

Other references related to the Ritter reaction are cited in the literature.[12]

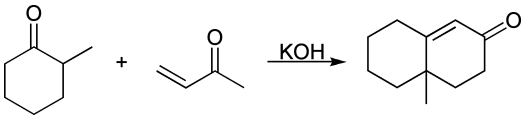
Robinson Annulation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rapson and Robinson in 1935.[1] It is the synthesis of α,β-unsaturated cyclohexanone resulting from the attachment of four carbon units to a ketone's carbonyl and α-carbon atom, respectively.[2] This reaction involves the following steps: the generation of an enolate from the ketone, *Michael Addition* of the enolate to the α,β-unsaturated ketone, *Aldol Condensation*, and dehydration. Therefore, this reaction is generally known as the Robinson annulation,[2–4] or Robinson annelation.[5] Occasionally, it is also referred to as the Robinson cyclization[6] or Robinson transposition reaction.[7] In addition, the corresponding reaction involving a nitrogen atom is similarly called the *aza*-Robinson annulation.[8] This reaction has been widely used in organic synthesis,[3,4] especially in the preparation of steroids.[2,5g,9]

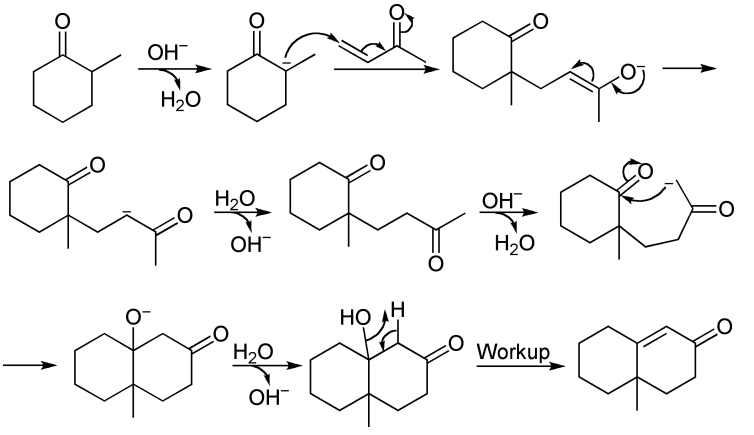
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is the mechanism of the Robinson annulation between cyclohexanone and vinyl methyl ketone in the presence of KOH.



D. MODIFICATION

This reaction has been extended to the *Michael Addition* on α,β-unsaturated nitrile by temporarily chelating the Grignard reagent to γ-hydroxy unsaturated nitrile.[3d] An alternative route involving a free-radical β-alkylation of nonactivated carbon atoms and subsequent anionic cyclization has been developed as a complementary route of the Robinson annulation.[3g] In addition, this reaction has been modified to occur under antibody catalysis[4r] or with the combination of a lithium enolate with aluminum tris(2,6-diphenylphenoxide).[4s] Further modifications include the Robinson annulation in supercritical CO_2,[5a] the reaction promoted by K_2CO_3 under ultrasound,[4c] and the solid-supported reaction under microwave irradiation.[4h]

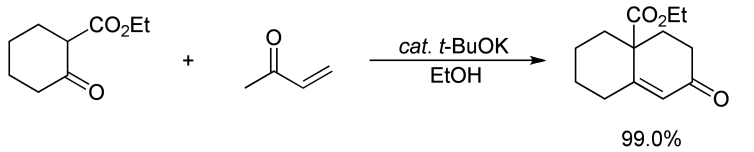
E. APPLICATIONS

This reaction has wide application in organic synthesis.

F. RELATED REACTIONS

This reaction is related to the *Aldol Condensation, Michael Addition*, and *Wichterle Reaction*.

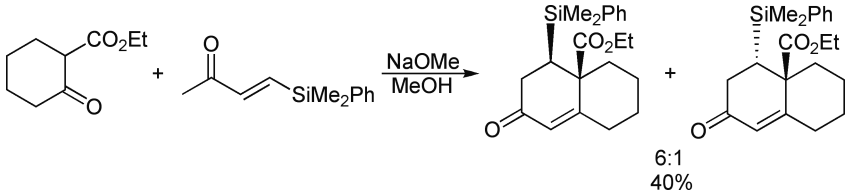
G. CITED EXPERIMENTAL EXAMPLES



99.0%

Reference 3c.

Potassium *t*-butoxide (296 mg, 2.65 mmol) was dissolved in 25 mL ethanol at 0°C under argon and stirred for 20 min. Then 8 mL ethyl 2-oxocyclohexanecarboxylate (50 mmol) was added slowly at the same temperature. After 15 min at 0°C, 4.15 mL methyl vinyl ketone (50 mmol) was added over 5 h via syringe pump. Then the resulting deep orange solution was refluxed for 6 h. The reaction mixture was cooled to ambient temperature. After being stirred for 18 h, the mixture was poured into a separatory funnel containing 30 mL saturated NH_4Cl and extracted with Et_2O (3 × 200 mL). The combined organic layers were dried over $MgSO_4$ and concentrated to give 11.0 g crude product as an orange oil, in a yield of 99.0%.



Reference 3b.

Sodium metal was dissolved in 4 mL methanol at ambient temperature. After complete dissolution, 2.1 mL ethyl 2-oxocyclohexanecarboxylate (14.7 mmol) was added slowly via syringe. After 15 min, 1.63 g β-phenyldimethylsilylvinyl methyl ketone (7.99 mmol) dissolved in 0.5 mL MeOH was added over 7 h via syringe pump. At the end of addition, the deep orange solution was stirred at ambient temperature for 18 h. Then the mixture was refluxed in a preheated bath at 80–85°C for 24 h before being cooled to ambient temperature. The reaction mixture was then poured into a separatory funnel containing 50 mL saturated NH_4Cl, and extracted with Et_2O. The combined organic layers were washed with brine and dried over $MgSO_4$. The solvent was removed under vacuum to give a crude orange oil, which was purified by flash column chromatography using hexanes/EtOAc (5:1) as the eluent to afford 1.03 g (±)-(4*R*,4a*R*) methyl 4-(dimethylphenylsilyl)-2-oxo-2,3,4,4a,5,6,7,8-octahydronaphthalene-4a-carboxylate and (±)-(4*S*,4a*R*) methyl 4-(dimethylphenylsilyl)-2-oxo-2,3,4,4a,5,6,7,8-octahydronaphthalene-4a-carboxylate as a 6:1 mixture of diastereomers, in a yield of 40%. These diastereomeric mixtures were further separated by a second column chromatography using hexane/EtOAc (8:1) to yield each diastereomer with analytical purity.

Robinson-Gabriel Oxazole Synthesis

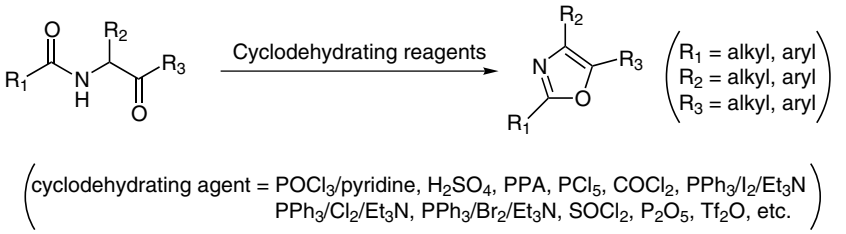
(Robinson-Gabriel Cyclodehydration, Robinson-Gabriel Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Gabriel in 1907[1] and subsequently by Robinson in 1909.[2] It is the synthesis of 2,5- and 2,4,5-substituted oxazole derivatives by the intramolecular condensation and dehydration of *N*-acyl α-aminoketones in the presence of a dehydration reagent such as PCl_5 or sulfuric acid. This reaction is thus known as the Robinson-Gabriel cyclization,[3] Robinson-Gabriel cyclodehydration,[4] Robinson-Gabriel dehydration,[4d,4e] Robinson-Gabriel oxazole synthesis,[4g,5] Robinson-Gabriel reaction,[4g,4h,6] or Robinson-Gabriel synthesis.[4a,5d,6b,7] Other cyclodehydrating reagents include the Burgess reagent ([(methoxycarbonyl-sulfamoyl) triethylammoniumhydroxide inner salt], i.e., $Et_3N^+SO_2N^-CO_2Me$),[4b,4f,8] phosphorus oxychloride ($POCl_3$),[4a,6b,7e] polyphosphoric acid (PPA),[5d,6b] phosgene ($COCl_2$),[6b] hexachloroethane/triphenylphosphine,[4b] triphenylphosphine/iodine/triethylamine,[3c,4c,6b,9] $SOCl_2$,[5a] trifluoroacetic anhydride,[4a,6b] triflic anhydride,[4a] P_2O_5,[7d] and anhydrous hydrogen fluoride.[6b] However, polyphosphoric acid is found to be superior to most of the above dehydrating reagents.[5d] As the nature of this reaction requires the application of harsh conditions, this reaction is not applicable to molecules with acid-labile functional groups.[5a]

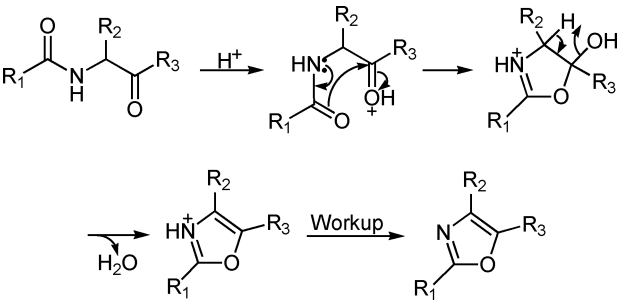
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction, through the isotopic labeling experiment,[5d,7g] is proved to involve the protonation of the ketone carbonyl, followed by nucleophilic attack by the amido oxygen to form dihydrooxazolol, which dehydrates to form oxazole,[4a] as illustrated below by an example using sulfuric acid as the dehydrating reagents.



D. MODIFICATION

The initial protocol has been extensively modified by the application of different dehydrating reagents as listed earlier, in which $POCl_3$/pyridine is a recently added reagent,[4b,4e–4g] and the application of $PPh_3/Cl_2/Et_3N$,[10] $PPh_3/Br_2/Et_3N$,[8] or Burgess reagent[8] has allowed the synthesis of oxazole derivatives in solid phase under milder conditions. Alternatively, the oxazoles and bis-oxazoles can be prepared from side chain oxidation of α-hydroxy amides followed by cyclodehydration with $PPh_3/I_2/Et_3N$,[3c] or cyclization of activated α-hydroxy amides to oxazolines followed by dehydrogenation,[4j] or the one-pot condensation between α-amino ketone and triethyl orthoester.[7f]

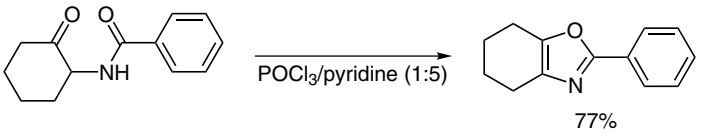
E. APPLICATIONS

This reaction has general application in the syntheses of 2,5-disubstituted and 2,4,5-trisubstituted oxazole derivatives, especially for the syntheses of 2,5-diaryloxazoles.[5d]

F. RELATED REACTIONS

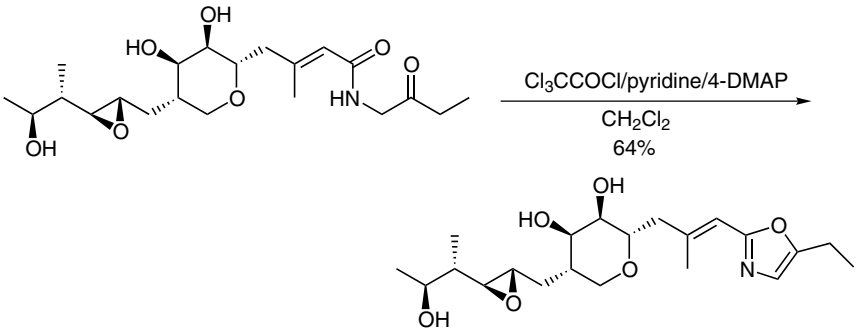
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4g.

To 2.5 mL dry pyridine solution containing 217 mg *N*-benzoyl-2-amino cyclohexanone (1.0 mmol) at 25°C was added 0.5 mL $POCl_3$. The resultant solution was then stirred for 3 hours. Upon completion, the reaction mixture was diluted with 10 mL EtOAc, transferred into 25 mL saturated aqueous $NaHCO_3$ cooled at 0°C, and extracted with EtOAc (3 × 15 mL). The combined organic layers were then washed with 25 mL water and brine each, dried over $MgSO_4$, and concentrated. The residue was purified by flash column chromatography to afford 77% 2-phenyl-5,5,6,6,7,7,8,8-tetrahydrobenzooxazole as a white solid, $R_f = 0.64$ (EtOAc/hexanes, 1:1).



Reference 7c.

To an ice bath-cooled 23 mL CH_2Cl_2 solution containing 960 mg *N*-(2-oxobutyl)-monamide (2.32 mmol), 46.4 mmol pyridine (20 eq.), and a few crystals of 4-(dimethylamino)-pyridine was added 20.9 mmol trichloroacetyl chloride (9 eq.). After being stirred for 30 min, the solution was washed with saturated aqueous $NaHCO_3$ solution, and then evaporated under reduced pressure. The residue was dissolved in 12 mL methanol, and the solution was cooled to 0°C before the addition of 7 mmol K_2CO_3 (3 eq.). After 15 min at 0°C, brine and EtOAc were added, and the organic layer was separated. The aqueous layer was further extracted with EtOAc, and the combined extracts were washed with brine, dried over $MgSO_4$, and then evaporated under reduced pressure. The residue was chromatographed on silica using 0–10% methanol in CH_2Cl_2 as the eluent to give 5-ethyl-2-(1-normon-2-yl)oxazole (589 mg), in a yield of 64%.

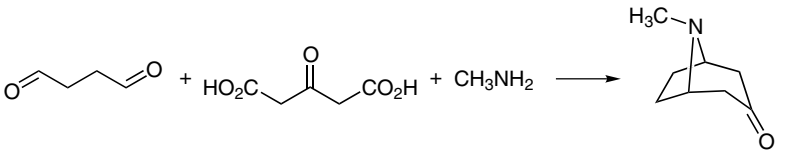
Robinson-Schöpf Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Robinson in 1917[1] and subsequently improved by Schöpf in 1935.[2] It is an ingenious one-pot multicomponent synthesis of tropinone from succindialdehyde, acetonedicarboxylic acid and methylamine in aqueous solution involving a double *Mannich Reaction*.[3] This reaction is thus known as the Robinson tropinone synthesis,[4] Robinson synthesis,[3a,4a,5] Robinson-Schöpf reaction,[3c,6] Robinson-Schöpf condensation,[7] or Robinson condensation.[4c] It has been reported that the Robinson tropinone synthesis can take place without any racemization at the stereogenic center adjacent to the aldehyde group, as demonstrated by the formation of *L-allo*-teloidinone from *D*-tartaraldehyde, and *D-allo*-teloidinone from *L*-tartaraldehyde respectively.[4a]

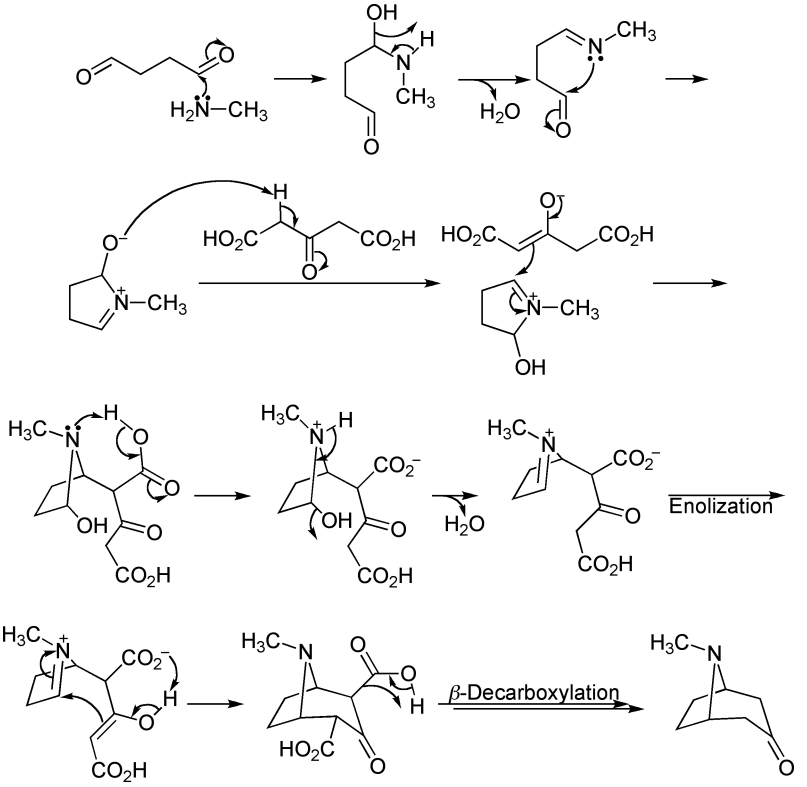
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The condensation of *cis*-cyclopentane-1,3-dialdehyde with high stereospecificity indicates that the reaction involves a stepwise process in which the cyclization step is affected by the nonbonded interactions.[3c] An illustrative mechanism is provided below for the reaction among succindialdehyde, acetonedicarboxylic acid, and methylamine.



D. MODIFICATION

This reaction has been extended to *cis*-cyclopentane-1,3-dialdehyde, methylamine, and acetonedicarboxylic acid to give a tricyclic amino ketone with high stereospecificity, of which the *N*-methyl group is primarily in the axial configuration with respect to the piperidone ring, and nitrogen and carbon bridges are *anti* to each other.[3c] Further modification can be found in the reaction using dialdehyde dioxime or 2,5-dimethoxytetrahydrofuran[3a] or *bis*-dimethyl acetal[7b] as the precursor of unstable dialdehyde.

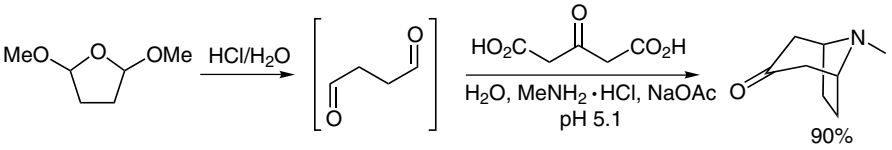
E. APPLICATIONS

This reaction has been used to the preparation of several alkaloids including cocaine, and atropine.[8]

F. RELATED REACTIONS

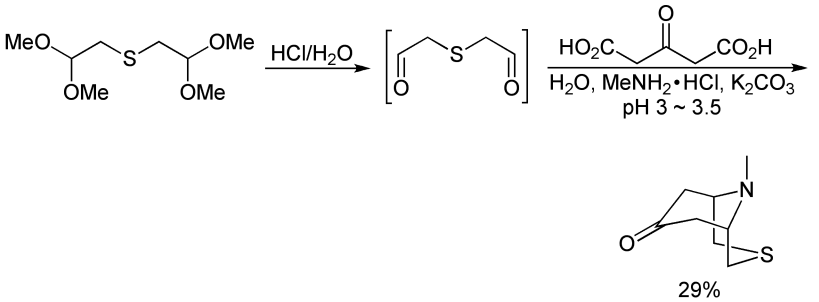
This reaction is related to the *Petrenko-Kritschenko Piperidone Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a 50 mL aqueous solution of 20.4 g 2,5-dimethoxytetrahydrofuran (0.154 mol) was added 2 mL conc. HCl (25 mmol), and the mixture was heated at 70–75°C for 30 min and then cooled to ambient temperature. A 500-mL, four-necked flask equipped with a thermometer, pH probe, mechanical stirrer, and nitrogen inlet was charged with 150 mL water, 50.0 g NaOAc (0.61 mol), 15 mL 40% $MeNH_2$ aqueous solution (0.17 mol), 14.2 mL conc. HCl (0.18 mol), and 24.8 g acetonedicarboxylic acid (0.17 mol). The solution (pH 5.1) was cooled to 10°C, and the dialdehyde solution was added to this flask over 10 min (final pH at end of addition was 5.1). The mixture was warmed to 40°C over 10 min, stirred at 40°C for 50 min, and then cooled to 20°C. Then the solution was alkalinized with 12.5 mL 50% NaOH solution to pH 10, and 40 g NaCl was added. After the NaCl was completely dissolved, the aqueous solution was extracted with CH_2Cl_2 (3 × 85 mL). The combined CH_2Cl_2 layers were concentrated to give 18.7 g tropinone as an off-white solid, in a yield of 90%, m.p. 40–42°C.



Reference 7b.

Thiodiacetaldehyde bis(dimethylaceta1) (265 g, 1.26 mol) was hydrolyzed in 700 mL hot water containing 12 mL conc. HCl. After completion of hydrolysis, the solution was cooled to 25°C, and 94 g methylamine hydrochloride (1.39 mol) and 220 g acetonedicarboxylic acid (1.51 mol) were added. The mixture was stirred, and solid K_2CO_3 was added slowly until the pH of the solution was 3.0. The clear solution was allowed to stand at room temperature in the dark, and the pH was held between 3.0 and 3.5 by the addition of hydrochloric acid after 2 h and after 7 h. After 24 h, the dark brown solution was acidified to pH 2 with

6 *N* HCl and extracted with four portions of ether. The aqueous solution was then made strongly alkaline, saturated with K_2CO_3, and extracted with 17 portions of CH_2Cl_2. The combined extracts were dried over Na_2SO_4, concentrated to 200 mL, and thoroughly mixed with alumina (20 mesh) to give, after the evaporation of the solvent, a brown powder that was placed in a Soxhlet thimble and extracted with ether. From the ether extracts, a dark crystalline solid was obtained, which on sublimation in vacuo afforded 62 g 9-methyl-3-thiagranatanin-7-one, in a yield of 29%, m.p. 124–128°C. The product could be further purified via recrystallization from benzene-ligroin, m.p. 126–128°C. No improvement in yield was seen in smaller scale experiments carried out in buffered solution at pH 3, in dilute solution, or in solution containing an excess amount of acetonedicarboxylic acid.

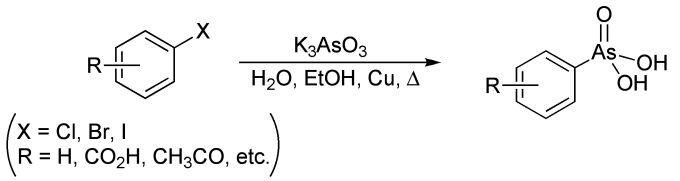
Rosenmund Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rosenmund in 1921.[1] It is the synthesis of an arylarsonic acid by refluxing the mixture of an aryl halide and aqueous tripotassium arsenite in the presence of alkali, alcohol, and copper powder,[2] and is known as the Rosenmund reaction[3] or Rosenmund synthesis.[4]

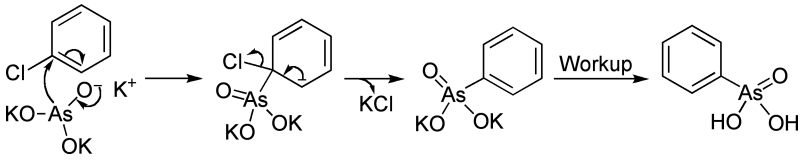
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

As no mechanistic information is available, it is assumed that this reaction follows a nucleophilic substitution pattern, as illustrated below.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction was extended by Albert and Schulenberg for the preparation of *p*-acetophenone-arsonic acid.[5]

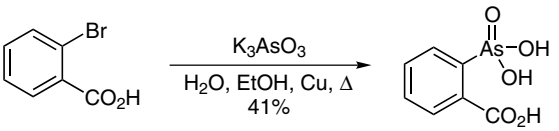
E. APPLICATIONS

This reaction is useful for the preparation of arylarsonic acid.

F. RELATED REACTIONS

This reaction is related to the *Bart Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

Under stirring, a mixture of 20 g *o*-bromobenzoic acid (0.1 mol), 63 mL 10% KOH solution, 20 mL EtOH, 40 mL 50% K_3AsO_3 solution, and a little freshly reduced copper was refluxed at 90–95°C for 12 h. The reaction mixture was filtered while hot to remove the copper; the filtrate was acidified with 20 mL conc. HCl and was evaporated to dryness on a steam cone. The residue was extracted with absolute methanol, and the methanol extract was evaporated to dryness. The residue was washed with ether to remove salicylic acid and unreacted *o*-bromobenzoic acid. The ether washed residue was recrystallized twice from hot water after decolorization with bone black to afford 10.1 g *o*-carboxyphenylarsonic acid, in a yield of 41%.

Rosenmund Reduction

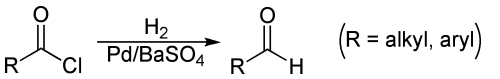
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rosenmund in 1918.[1] It is the transformation of an acyl chloride into corresponding aldehyde by the hydrogenation in a toluene solution over barium sulfate-supported palladium. Therefore, it is generally known as the Rosenmund reduction.[2] Occasionally, it is also referred to as the Rosenmund-Zetzsche reduction,[3] Rosenmund hydrogenation,[4] or Rosenmund hydrogenolysis.[5] This reaction is normally carried out by bubbling hydrogen gas through a rigorously dry solvent with 5–10% palladium catalyst in suspension, and the yield of aldehyde critically depends on the resistance of the aldehyde toward further reduction.[2u,6] Thus a variety of molecules are added as catalyst "poisons," "modifiers," or "regulators."[2d,6] These molecules include sodium acetate,[7] nitrogenous bases, such as quinoline with sulfur,[2v] *N*,*N*-dimethylaniline,[8] ethyldiisopropylamine,[9] 2,6-dimethylpyridine,[10] and sulfur-containing molecules, such as thiourea,[4a] thiophene,[4a] and dibenzothiophene,[4a] though the regulator is not always necessary for the reduction.[6,11] The presence of poisons or regulators is believed to block sites with the most catalytic activity and prevent undesired reactions;[2d] however, recent studies indicate that these poisonous molecules do not actually block the active sites but alter the surface of the catalyst,[2d,6] such as the formation of thin palladium particles.[6] During the Rosenmund reduction, it has been found that the reducible groups such as nitro and chloro in aromatic compounds are reduced;[2u] in addition, aliphatic aldehydes can be obtained in high yield (e.g., 80–90%) when aliphatic acyl chlorides are reduced in anhydrous acetone or EtOAc over palladium hydroxide-$BaSO_4$ in the presence of dimethylaniline.[2u] Reduction of unsaturated acyl chlorides in some cases result in the overreduction of double bonds and the extensive rearrangement of the double bond as well,[2aa] although in many cases the corresponding unsaturated aldehydes are obtained.[12] However, because palladium

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

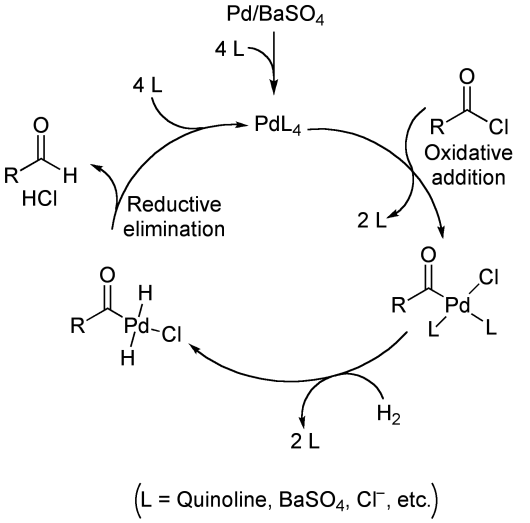
catalyst is labile under these reaction conditions and the particle size and surface structure change quickly,[6] the Rosenmund reduction is an unreliable and irreproducible method for organic synthesis,[6] and it is often in competition with other side reactions. For example, alcohols are often the by-products of the Rosenmund reduction.[2u] In addition, hydrocarbons with one less carbon atom formed by removal of an entire –COCl group are also obtained from the Rosenmund reduction;[2u] especially during the reduction of aromatic acyl chloride, as demonstrated by the formation of tetraphenylethane from diphenylacetyl chloride.[2w] Furthermore, some acyl chlorides do not undergo the Rosenmund reduction. For example, the reduction of trichloroacetyl chloride affords 50–60% of dichloroacetyl chloride instead of the expected chloral,[2t] the reduction of succinyl chloride leads to the formation of butyrolactone, and the reduction of adipyl chloride yields the corresponding aldehyde and cyclopentanecarboxylic acid as well.[13] Because of its intrinsic problems of reproducibility, the Rosenmund reduction has been widely replaced by the more reliable *Brown Hydroboration*,[2d] using lithium tributoxyborohydride as the reducing reagent.[2r]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because the reduction mechanism is not as clear as that of *Lindlar Hydrogenation*,[2q] a tentative mechanism in the presence of quinoline containing sulfur is provided below.



D. MODIFICATION

This reaction has been modified by employing THF as solvent at 0°C for the production of aliphatic aldehydes.[10] In addition, $Ru(PCy_3)_2(H)Cl_2$ has been used as a catalyst for the Rosenmund reduction.[2b]

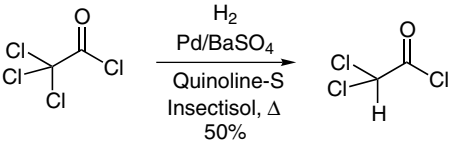
E. APPLICATIONS

This reaction had wide application in the preparation of aldehydes before the development of better methods in modern organic synthesis.

F. RELATED REACTIONS

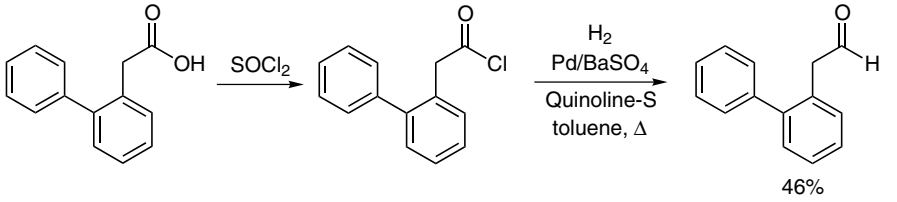
This reaction is related to the *Lindlar Hydrogenation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2t.

The mixture of 40 g trichloroacetyl chloride (0.22 mol), 4.0 g 2% $Pd/BaSO_4$ catalyst, 0.4 mL quinoline-S regulator, and 190 mL freshly refined petroleum fraction (i.e., Insectisol, refluxed over sodium and distilled fraction, b.p.190–220°C) was heated to 140°C. Hydrogen was passed through the stirred mixture at such a rate that a millimole of HCl per minute was collected in the aqueous exit gas scrubber. After 0.22 mol HCl had been titrated ($\sim$ 5 h), the mixture was cooled, filtered, and distilled. The fraction at 104–106°C (729 mmHg) was collected to afford 15.5 g dichloroacetyl chloride, in a yield of 50%.



Reference 2s.

The 2-biphenylylacetyl chloride was prepared by refluxing 25.5 g 2-biphenylylacetic acid with 18 mL thionyl chloride. An excess amount of thionyl chloride was removed under vacuum (water pump) at the temperature of a steam bath, and last traces of thionyl chloride were entrained by means of dry toluene. Then 0.5 g quinoline-sulfur regulator and 5.0 g $Pd/BaSO_4$ catalyst were added. Hydrogen was passed through the stirred solution until no more HCl evolved, then the catalyst was filtered off, and the filtrate was diluted with 100 mL ether. The resulting solution was stirred with a saturated aqueous Na_2SO_3 solution for 24 h. The addition product was collected, washed with ether, and decomposed by stirring with 250 mL 10% Na_2CO_3 solution for 3 h. The aldehyde was extracted with CH_2Cl_2, dried over $MgSO_4$, and concentrated. The residue was distilled to afford 10.9 g 2-biphenylylacetaldehyde as a colorless oil, in a yield of 46%, b.p. 130–133°C at 2 mmHg.

Other references related to the Rosenmund reduction are cited in the literature.[14]

Rosenmund-von Braun Reaction

(Rosenmund-von Braun Nitrile Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

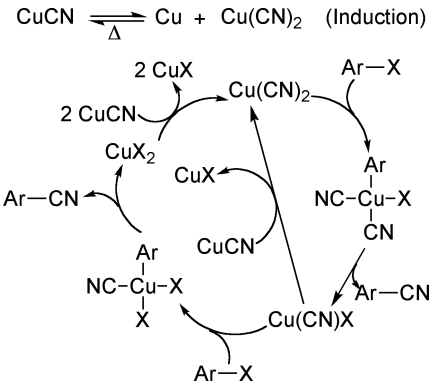
This reaction was first reported by Rosenmund et al. in 1919[1] and subsequently modified by von Braun et al. in 1931.[2] It is the synthesis of an aryl nitrile from an aryl halide and cuprous cyanide in a high boiling solvent. Therefore, it is generally known as the Rosenmund-von Braun reaction[3] or Rosenmund-von Braun cyanation.[3c,4] Occasionally, it is also referred to as the Rosenmund-von Braun aromatic nitrile synthesis,[3x] Rosenmund-von Braun cyanodehalogenation,[3c] Rosenmund-von Braun nitrile synthesis,[5] or Rosenmund-von Braun synthesis.[3x,6] This is a biphasic reaction in temperatures ranging from 150°C to 280°C,[3d,5a] using high boiling point solvents such as nitrobenzene,[3e] NMP[3c,7] and DMF.[3c] In addition, this reaction is an auto-catalyzed reaction,[5] as demonstrated by the reaction between *p*-bromotoluene and CuCN, which at 250°C completes only 15% within the first 60 min, while 60% more product is formed in the subsequent 30 min of reaction.[5a] Moreover, the presence of a small amount of nitrile effectively reduces the induction period.[3x] Some nitrogenous bases such as tertiary amine[8] and pyridine[5a]also promote this reaction. It has been found that $CuSO_4$ has a catalytic effect for this reaction, whereas hydroquinone retards the formation of aromatic nitrile, indicating that this reaction involves the divalent copper ion.[3x,5a] However, this reaction also has a few associated problems: the requirement for extreme reaction conditions (150–280°C);[3d] a harsh work-up process by heating with HCl and $FeCl_3$;[3c] a stoichiometric amount of cuprous cyanide which leads to the formation of equivalent amount of copper halide which may complicate the product separation and cause the problem of waste disposal as well.[3d]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

Although it has been reported that divalent copper is involved in this reaction, and a mechanism has been proposed to rationalize the reaction,[3x,5a] it is doubtful that the reaction involves the free aryl cation, Cu^{+} and Cu^{2+} ions. Thus an alternative mechanism is proposed below.



D. MODIFICATION

This reaction was modified by the replacement of CuCN with cheaper NaCN in the presence of palladium[9] or nickel catalyst,[10] as exemplified by the 5% $Pd(PPh_3)_4$/10% CuI catalyzed reaction[11] and the $Ni(CN)_2$ or $NaCN/NiBr_2$ based reaction under microwave irradiation[3f] for aryl bromide.[3b,3e] The latter condition is also used for the cyanation of aryl chloride with NaCN and $NiBr_2$.[3e] In addition, this reaction has also been extended to the preparation of some α,β-unsaturated nitriles.[3x] Further modifications include the copper-catalyzed domino halogen exchange-cyanation[3d] and the application of ionic liquid as reaction media.[3e,3h]

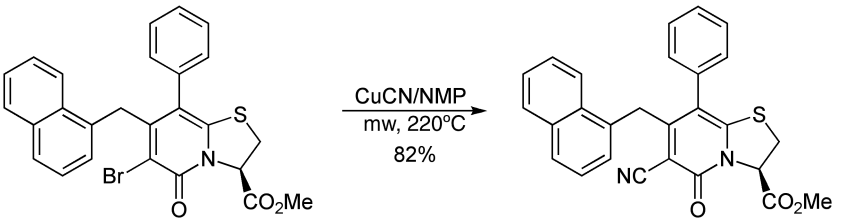
E. APPLICATIONS

This reaction has general application in the preparation of aromatic nitriles.

F. RELATED REACTIONS

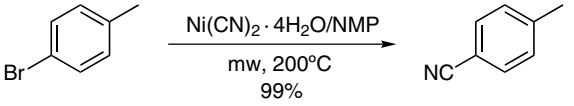
This reaction is related to the *Sandmeyer Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

At room temperature, 120 mg CuCN (1.3 mmol) was added to a stirred solution of 150 mg (3*R*)-6-bromo-7-naphthalen-1-ylmethyl-5-oxo-8-phenyl-2,3-dihydro-5*H*-thiazolo[3,2-α]pyridine-3-carboxylic acid methyl ester (0.30 mmol) in 1.0 mL NMP. The mixture was heated at 220°C for 20 min under microwave irradiation, and the solvent was then removed by lyophilization from deionized water. The residue was thoroughly extracted with CH_2Cl_2, dried, and concentrated. Silica gel column chromatography using heptane/EtOAc (1:1) as the eluent afforded 110 mg (3*R*)-6-cyano-7-naphthalen-1-ylmethyl-5-oxo-8-phenyl-2,3-dihydro-5*H*-thiazolo[3,2-α]pyridine-3-carboxylic acid methyl ester as a white foam, in a yield of 82%.



Reference 3e.

In a 10-mL glass tube were placed 0.171 g 4-bromotoluene (1.0 mmol), 110 mg $Ni(CN)_2{\cdot}4H_2O$ (0.6 mmol), 1.0 mL NMP, and a magnetic stir bar. The vessel was sealed with a septum and placed into the microwave cavity, and irradiated at 200°C for 10 min. After allowing the mixture to cool to room temperature, the reaction mixture was transferred to a separating funnel, and the tube was washed with water and then with ether. All washings were added to the separating funnel then another 20 mL water and Et_2O each were added, and the organic layer was separated. The aqueous layer was further extracted with Et_2O, and the combined organic layers were washed with water (3×40 mL) to remove remaining NMP. The organic layer was dried over $MgSO_4$ and concentrated to afford 99% of 4-methyl benzonitrile.

Rothemund Reaction
(Rothemund Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rothemund in 1935.[1] It is a one-pot synthesis of porphine or isoporphine by the thermal condensation of aldehydes with pyrroles and is generally known as the Rothemund condensation,[2] Rothemund synthesis,[2e,2g,3] or Rothemund reaction.[2e,4] Occasionally, it is also referred to as the Rothemund-Lindsey reaction.[4b,5] Nowadays, this reaction has become the mainstay for the synthesis of porphyrins,[4g] especially for 5,10,15,20-,[2g] (or $\alpha,\beta,\gamma,\delta$-)[6] tetrasubstituted hindered *meso*-porphyrins. Initial studies have indicated that the condensation between pyrrole and aldehyde can occur under various conditions, such as in gaseous acetaldehyde (or formaldehyde) when reacted with pure acetaldehyde or formaldehyde, in methanol at room temperature or at refluxing temperature, or in methanol at 85–90°C in a sealed tube.[1] It has also been found that the same reaction in a sealed tube at 150–155°C yields different products,[6b] and the addition of pyridine,[1] $CaCO_3/MgO$,[1] or $PbCrO_4$[1] results in higher yields of porphyrins. Thus many current preparations of porphyrin derivatives have been carried out in heterocyclic base, such as 2,4,6-collidine.[2g] Furthermore, the addition of a metal ion species, such as Cu(I)[7] and Co(II)[8] can increase the yield of expected porphyrins, as demonstrated by the duplication of the yield of porphyrin by use of zinc acetate.[9] Such enhancement of the yield is attributed to the acidifying effect of the added metal ion rather than to the template effect.[4i] Furthermore, it is known that the reaction involving an electron-deficient aldehyde normally leads to a higher yield of porphyrin than the electron-rich one,[2b] and the substituent on aldehyde will control the course of this reaction,[2b] in which a number of porphyrin analogues might form, such as chlorin,[4k] sapphyrin,[4c] isosmaragdyrin,[10] ozaphyrin,[11] hexaphyrin,[12] and corrole.[2e] It is the complication of this reaction by formation of other analogues and the difficulty in isolation of porphyrin out of these contaminants that results in the low yield of porphyrin.[2b] Among those porphyrin analogues, there might be "inverted"[2c,4g] or

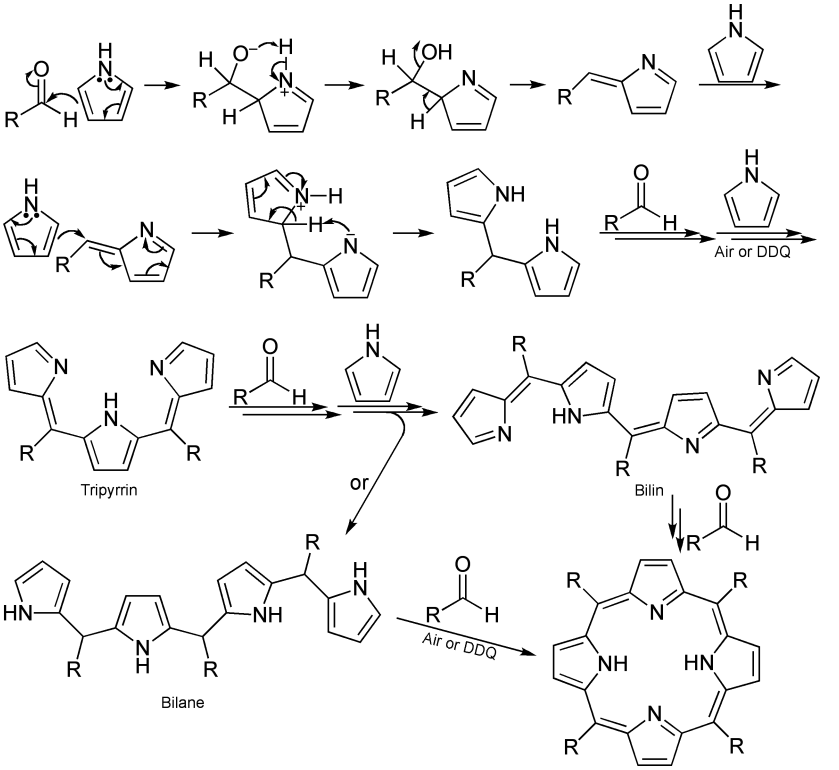
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

"*N*-confused"[4a,4c,4e,4f] (or mutant,[4d] carba[4d]) porphyrin, of which the position of nitrogen and carbon atoms are interchanged in one of the pyrrole rings.

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

This one-pot synthesis of porphyrin may involve a series of condensation and dehydration steps[4k] to form bipyrrin, tripyrrin, and bilane or bilin. The bilane or bilin then condenses with one more aldehyde molecule and cyclizes to give porphyrin and its analogues. Displayed here is an illustrative reaction route for the formation of porphyrin.



D. MODIFICATION

This reaction has been modified by Alder and Longo by heating the mixture of pyrrole and aldehyde in propionic acid at 141°C while open to air to give unhindered porphyrin derivatives.[13] However, such modification often causes problems such as the formation of a high level of tar material that complicates the purification process, the incompatibility with certain functional groups on aldehydes, and the low batch-to-batch reproducibility.[4i] On the other hand, Lindsey has carried out the reaction in the presence of a catalytic amount of BF_3 or TFA under equilibrium conditions, followed by oxidation with an electron-deficient quinone,[4i,14] such as DDQ.[2b,4a,4i] In addition, this reaction has been extended to the preparation of corrole by the application of an excess amount of pyrrole.[2e]

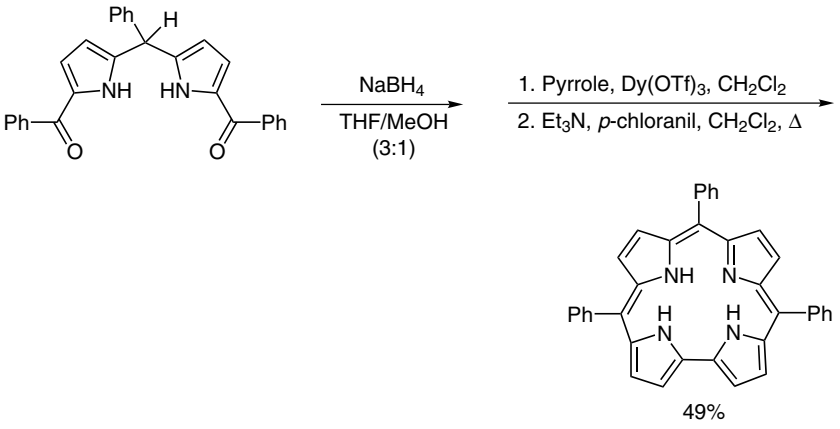
E. APPLICATIONS

This reaction is the primary method for the preparation of porphyrin derivatives and their analogues.

F. RELATED REACTIONS

This reaction is related to the *Bakelite Process*.

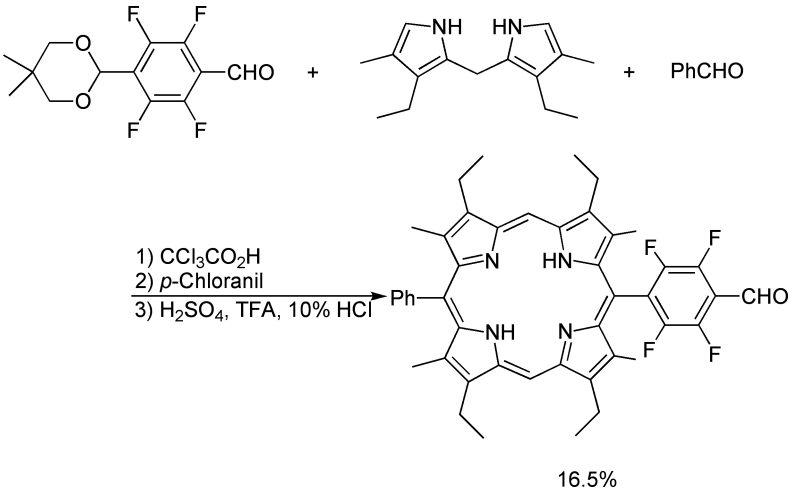
G. CITED EXPERIMENTAL EXAMPLES



Reference 15.

Phenyl-bis(2-(5-benzoyl)pyrrolyl) methane (215 mg, 0.5 mmol) in 40 mL THF/MeOH (3:1) was reduced by 946 mg $NaBH_4$ (25.0 mmol) to afford the corresponding carbinol, which upon being dried under vacuum for 30 min was immediately subjected to condense with 3.47 mL pyrrole (50 mmol) in the presence of 122 mg $Dy(OTf)_3$ (0.2 mmol) in 200 mL CH_2Cl_2 for 1.3 h at room temperature. After the addition of 0.139 mL triethylamine

(1.0 mmol) and 246 mg *p*-chloranil (1.00 mmol), the mixture was refluxed for 45 min. Then the entire reaction mixture was filtered through a pad of silica gel, and eluted with CH_2Cl_2. The filtrate was concentrated to dryness. The residue was then dissolved in 75 mL CH_2Cl_2, adsorbed onto 15 g silica gel, concentrated, and purified by silica gel column chromatography using CH_2Cl_2/hexanes (1:1) as the eluent to afford 128 mg 5,10,15-triphenylcorrole, in a yield of 49%.



16.5%

Reference 5.

Benzaldehyde (0.110 mL, 1.09 mmol) and 317 mg 2,3,5,6-tetrafluoro-4-(5,5-dimethyl-1,3-dioxan-2-yl)benzaldehyde (1.09 mmol) were dissolved in 15 mL dry acetonitrile. Then 2 mL dry acetonitrile containing 21.0 mg dry trichloroacetic acid (0.129 mmol) was added, and the resulting mixture was stirred under argon in the dark. After that, a solution of 500 mg bis(3-ethyl-4-methyl-2-pyrrolyl)methane (2.17 mmol) in 3 mL dry acetonitrile was added to the mixture, and the resulting mixture was stirred for 5.5 h. Then a suspension of 790 mg *p*-chloranil (3.21 mmol) in 15 mL dry THF was added, and the mixture was stirred overnight. The reaction mixture was passed through a short alumina column and washed by acetonitrile. Upon evaporation of the solvent, the residue was separated by silica gel column chromatography with CH_2Cl_2 as an eluent and was further separated by gel permeation chromatography (GPC) using THF as an eluent. The second fraction was collected and further purified by silica gel column chromatography using EtOAc/hexane (1:1) as the eluent to afford 146 mg 5-(4-(5,5-dimethyl-1,3-dioxan-2-yl)-2,3,5,6-tetrafluorophenyl)-2,8,12,18-tetraethyl-3,7,13,17-tetramethyl-15-phenylporphyrin, in a yield of 16.5%.

The acetal porphyrin (100 mg) was dissolved in a mixture of TFA (5 mL), 5 mL 10% HCl, and 1 drop concentrated H_2SO_4. The resulting mixture was moderately refluxed for 3 h. After being cooled to room temperature, the reaction mixture was neutralized with saturated $NaHCO_3$ aqueous solution. Then the aqueous solution was extracted with EtOAc, washed with brine, and dried over Na_2SO_4. Upon removal of the solvent, 5-(4-formyl-2,3,5,6-tetrafluorophenyl)-2,8,12,18-tetraethyl-3,7,13, 17-tetramethyl-15-phenylporphyrin was obtained, in a yield of 100%. (*Note:* The description of the original protocol is not clear; a few steps were omitted.)

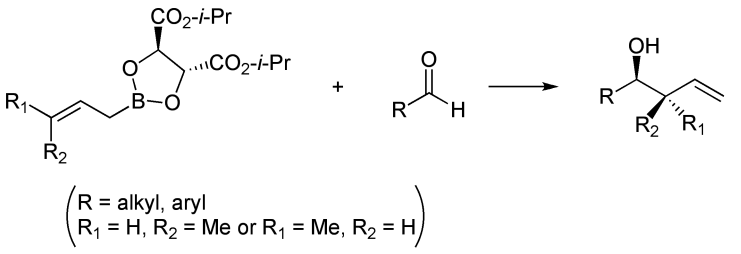
Roush Crotylboration

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Roush in 1985.[1] It is an enantioselective synthesis of a chiral alcohol by the condensation between a crotylboronate derived from diisopropyl-(*R*,*R*)-tartrate and an achiral aldehyde. Therefore, it is known as the Roush crotylboration,[2] Roush asymmetric crotylboration,[3] or Roush crotylboronate chemistry.[4] The (*Z*)- or (*E*)-crotylboronate derived from diisopropyl-(*R*,*R*)-tartrate can be readily prepared from *cis*-2-butene or *trans*-2-butene by a series of treatments on 2-butene with *n*-BuLi/KO-*t*-Bu, B(*i*-Pr)$_3$, acid and diisopropyl tartrate, respectively. The initial configuration of 2-butene is preserved during the preparation, and the resulting crotylboronates are referred to as the Roush crotylboranes[5] or Roush crotyl boronate reagents,[3] which are very convenient to use and can be stored in the freezer in toluene solution.[3] In addition, no extra oxidation step is necessary during the workup stage after the addition of the Roush crotylborane to aldehyde.[3] It has been found that the (*Z*)-crotylboronate results in a *syn*-homoallylic alcohol in preference,[6] whereas (*E*)-crotylboronate yields the corresponding *anti* allylic alcohol in favored amounts.[6b] However, these crotylboronates can yield only good to moderate enantioselectivity for the addition to most achiral aldehydes with a typical e.e. between 60% and $\sim$ 87%,[7] except for the reaction with metal carbonyl-complexed unsaturated aldehydes, which gives e.e. in the range of 83–98%.[8] Guided by the reaction mechanism, Roush's group has developed a second generation of crotylboronates with a chiral auxiliary of (*R*,*R*)-*N*,*N*′-bis-(2,2,2-trifluoroethyl)-*N*,*N*′-ethylenetartramide, which rank among the most highly enantioselective reagents. It should be pointed out that the auxiliary group can be easily recycled after the reaction.[9]

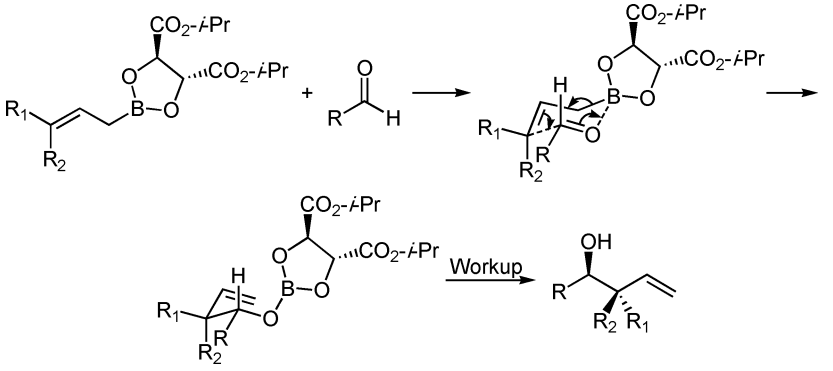
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

An illustrative mechanism is provided here for the addition of crotylboronate to aldehyde with control of stereochemistry.



D. MODIFICATION

This reaction has been modified by the application of (*R*,*R*)-*N*,*N*′-bis-(2,2,2-trifluoroethyl)-*N*,*N*′-ethylenetartramide as a chiral auxiliary to obtain the highest enantioselectivity.[9]

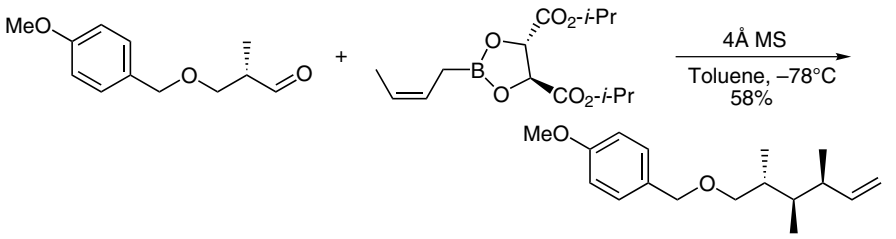
E. APPLICATIONS

This reaction has wide application in asymmetric synthesis.

F. RELATED REACTIONS

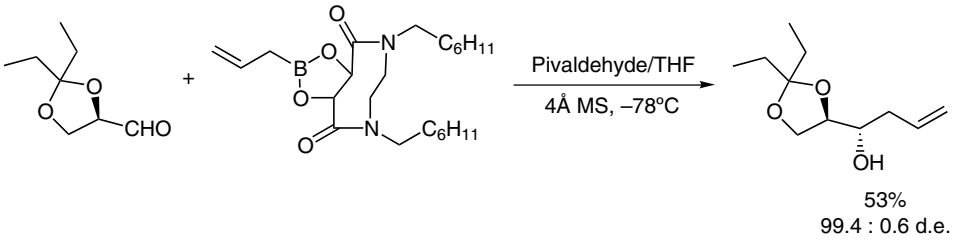
This reaction is related to the *Evans Aldol Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 6a.

A mixture of 32.2 g (4*S*,5*S*)-2-[(2*Z*)-2-butenyl]-1,3,2-dioxaborolane-4,5-dicarboxylic acid bis(1-methylethyl) ester (108.0 mmol), 450 mL anhydrous toluene, and 3.22 g 4Å molecular sieves was stirred at room temperature for 30 min under nitrogen and cooled to −78°C. Then 15.0 g (2*S*)-3-[(4-methoxyphenyl)methoxy]-2-methyl-propanal (72.0 mmol) in 50 mL anhydrous toluene was slowly added, while maintaining the temperature at −78°C. The resulting mixture was maintained at −78°C for 18 h, then carefully quenched with a suspension of 1 g $NaBH_4$ in 100 mL absolute ethanol. The mixture was warmed to 0°C, diluted with 500 mL 1 *N* NaOH, and stirred vigorously for 2 h. The layers were separated, and the aqueous layer was extracted with Et_2O (3 × 100 mL). The organic layers were combined, dried over K_2CO_3, and concentrated. The residue was purified by flash chromatography over SiO_2 using EtOAc/hexanes (1:9) to afford 11.0 g (2*S*,3*R*,4*S*)-1-[(4-methoxyphenyl)methoxy]-2,4-dimethyl-5-hexen-3-ol as a clear oil, in a yield of 58%.



Reference 9.

A mixture of 0.66 mmol allylboronate with (*R*,*R*)-*N*,*N*′-bis(cyclohexylmethyl)-*N*,*N*′-ethylenetartramide as chiral auxiliary, 1.0 mL THF, and 600 mg 4Å powdered molecular sieves was stirred at room temperature for 30 min and was cooled again to −78°C. A solution of 5.2 μL pivaldehyde (0.044 mmol) in 200 μL dry THF was added dropwise. After the addition was complete, the solution was warmed to room temperature and stirred for 30 min. The mixture was cooled to −78°C again and then a solution of 0.069 g D-glyceraldehyde pentylidene ketal (0.44 mmol) in 0.2 mL dry THF was added dropwise down the side of the flask. After the addition was complete, the solution was maintained at −78°C for 36 h. Excess acetaldehyde was then added dropwise via syringe, the cooling bath was removed, and the solution was warmed to room temperature. The mixture was filtered

through a plug of Celite, and the filtrate was concentrated under reduced pressure. The residue was purified by flash silica gel chromatography using hexane/Et_2O (9:1) to afford 0.047 g *erythro*-1,2-*O*-pentylidenehex-5-en-1,2,3-triol with 99.4:0.6 diastereoselectivity, as determined by capillary GC analysis, in a yield of 53%.

Other references related to the Roush crotylboration are cited in the literature[10].

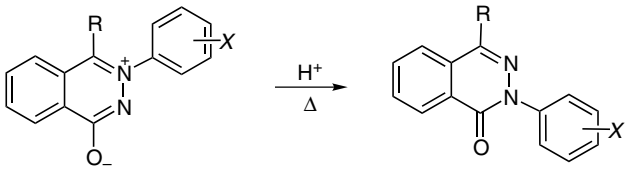
Rowe Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was reportd by Rowe et al. in 1926.[1] It is an acid-promoted thermal transformation of *pseudo*-phthalazones into phthalazones[2] and is commonly known as the Rowe rearrangement.[2,3] This reaction is generally carried out in a 1.2 *N* HCl solution at 180°C in a sealed tube for a few hours,[2,3] and the migratory attendance of the aryl group depends on its substituents and the nature of the substituent at the 4-position of the *pseudo*-phthalazone.[2] For example, an electron-withdrawing group at the 2- or 4-position of the aryl, such as nitro, facilitates the rearrangement of the aryl moiety, whereas an electron-donating group, such as methyl, at the 2- or 4-position retards such migration.[2] During this intramolecular rearrangement, the aryl group remains attached to the same nitrogen atom,[2] indicating the nitrogen atoms in diazonium ions are not equivalent.[3]

B. GENERAL REACTION SCHEME

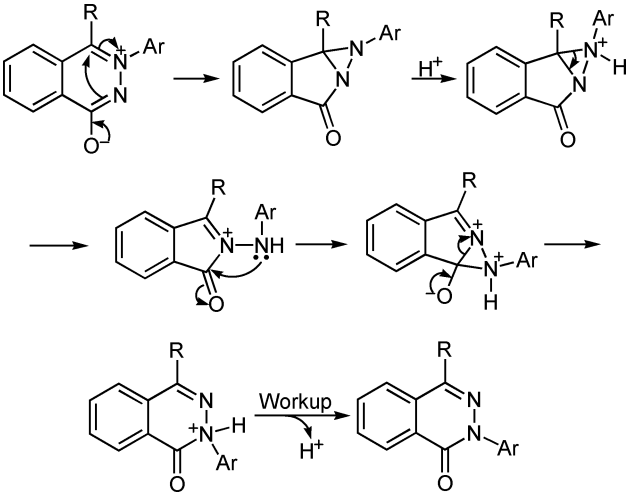


(*X* = 2- or 4-Me, Cl, NO_2, etc.)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although the reaction mechanism has been studied via an isotopic labeling experiment, the proposed mechanism is still not clear. Thus a revised and tentative mechanism is displayed here. In this mechanism, the initial addition of an amido nitrogen to the iminium ion eliminates the charge, but the protonation of nitrogen increases the ring strain, and the three-membered ring opens.



D. MODIFICATION

N/A

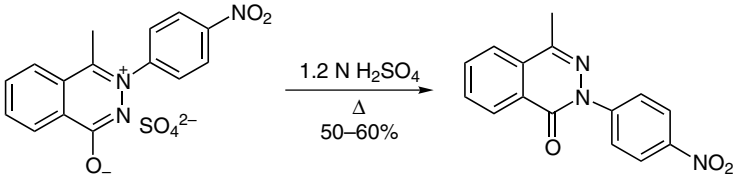
E. APPLICATIONS

This reaction has limited application in organic synthesis but is useful for mechanistic study.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A mixture of 2.5 g ψ-phthalazone sulfate and 36 mL 1.2 *N* H_2SO_4 was sealed in a glass tube, and heated at 180°C for 9 h to give 50–60% of 2-(4-nitrophenyl)-4-methylphthalazone, m.p. 215.5–216.5°C after recrystallization from acetic acid/water. Considering the actual content of free base in the sulfate mixture (65%), the yield was adjusted to 86–91%.

Other references related to the Rowe rearrangement are cited in the literature[4].

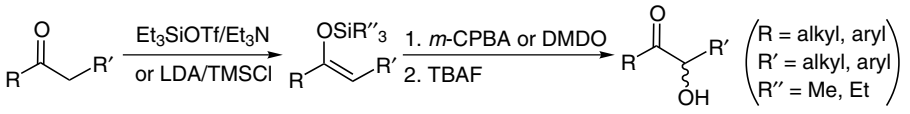
Rubottom Oxidation
(Rubottom Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rubottom[1] and Brook et al.[2] concurrently in 1974. It is the transformation of a ketone into the corresponding α-hydroxyketone by means of the epoxidation or dihydroxylation of a silyl enolate of the ketone with *m*-chloroperbenzoic acid (*m*-CPBA) or dimethyldioxirane (DMDO). Therefore, this reaction is generally known as the Rubottom reaction[3] or Rubottom oxidation.[3a,4] Under certain conditions, the Rubottom oxidation can establish a hydroxyl group enantioselectively, such as in the introduction of *cis*-hydroxyl group with respect to the isopropyl group in 8α,11β-dimethyl-13β-hydroxy-12β-isopropyl-5β,15-isopropylidenedioxy-14-keto-($\Delta^{1,2}$,$\Delta^{3,4}$)-tricycle.[4] The silyl group can be cleaved by means of tetra-*N*-butylammonium fluoride (TBAF).[4a]

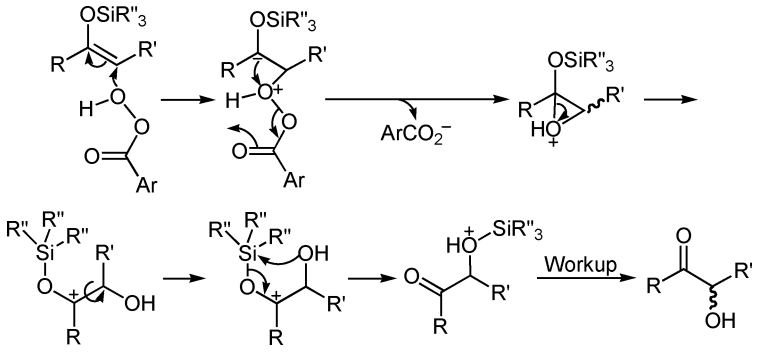
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that the epoxidation of the silyl enolate yields an anomeric effect-stabilized silyloxy carbocation, which transforms into α-silyloxy ketone via 1,4-silyl migration. Hydrolysis of such α-silyloxy ketone gives the α-hydroxy ketone. A general illustration of this reaction is provided here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

The oxidation of the silyl enolate has been extended by the application of DMDO rather than *m*-CPBA.

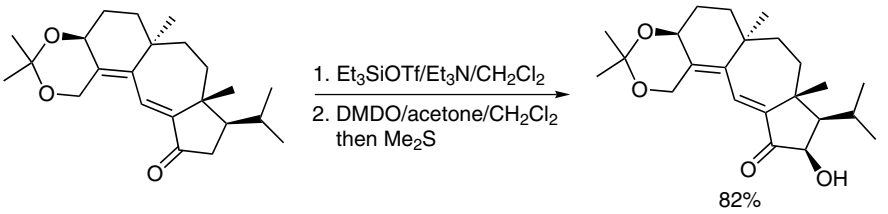
E. APPLICATIONS

This reaction has general application in the transformation of ketones into α-hydroxyl ketones.

F. RELATED REACTIONS

N/A

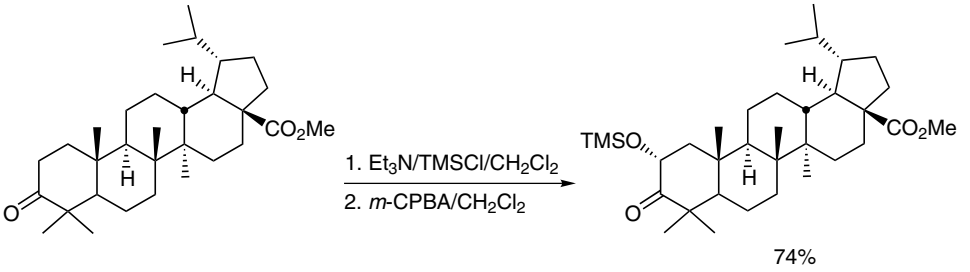
G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To a 10-mL pear-shaped flask were added 8.5 mg 8α,11β-dimethyl-12β-isopropyl-5β,15-isopropylidenedioxy-14-keto-($\Delta^{1,2}$,$\Delta^{3,4}$)-tricycle (0.024 mmol, 1.0 eq.) and 1 mL CH_2Cl_2 under argon, followed by 33 μL Et_3N (0.24 mmol, 10.0 eq.) and 27 μL Et_3SiOTf (0.12 mmol, 5.0 eq.). The mixture was stirred for 10 min and then diluted with 5 mL EtOAc, washed with 1 mL saturated $NaHCO_3$ solution, dried over Na_2SO_4, filtered, and concentrated under reduced pressure to give an oil. This oil was azeotropically dried with toluene,

then dissolved in 2.4 mL CH_2Cl_2 in a 10-mL pear-shaped flask, and cooled to −78°C under argon. A solution of 0.52 μL DMDO (0.036 mmol, 1.5 eq.) in CH_2Cl_2 was added dropwise down the side of the flask. The resulting solution was stirred for 15 min at −78°C, and 27 μL Me_2S (0.37 mmol, 15 eq.) was added to quench the excess amount of DMDO. The quenched reaction solution was stirred for 5 min at −78°C, allowed to warm to room temperature, and then concentrated under reduced pressure. The residue was purified by flash column chromatography using EtOAc/hexanes (1:19 to 1:4) to afford 7.3 mg 8α,11β-dimethyl-13β-hydroxy-12β-isopropyl-5β,15-isopropylidenedioxy-14-keto-($\Delta^{1,2}$,$\Delta^{3,4}$)-tricycle as a colorless oil, in a yield of 82%. This compound can be further purified by recrystallization via vapor diffusion between EtOAc and hexanes to provide white needles, m.p. 184.6–186.4°C, $R_f = 0.28$ (hexane/EtOAc, 4:1).



Reference 5.

To a solution of 183 mg methyl 3-oxo-28-lupanoate (0.389 mmol) in 8 mL CH_2Cl_2 at –78°C under argon was added with stirring 0.54 mL triethylamine (3.87 mmol) followed by 0.352 mL trimethylsilyl trifluoromethanesulfonate (TMSOTf, 1.95 mmol). After 1 h at –78°C, the reaction was quenched by 3 mL saturated aqueous $NaHCO_3$ solution, and extracted with hexanes (3 × 3 mL). The combined organic extracts were washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. The crude silyl enol ether was dissolved in 8 mL CH_2Cl_2 at 0°C, and 10 mL precooled CH_2Cl_2 solution containing 107 mg *m*-CPBA (0.434 mmol) was added. The mixture was stirred for 2 h and quenched by 5 mL saturated aqueous $NaHCO_3$ solution. The mixture was extracted with CH_2Cl_2 (3 × 5 mL), washed with brine, dried over Na_2SO_4, and concentrated. Flash chromatography on silica gel using hexanes/EtOAc (97:3) as the eluent afforded 156 mg methyl 2-*O*-trimethylsilyl-3-oxo-28-lupanoate as a colorless oil, in a yield of 74%, $R_f = 0.52$ (hexanes/EtOAc, 9:1).

Other references related to the Rubottom oxidation are cited in the literature.[6]

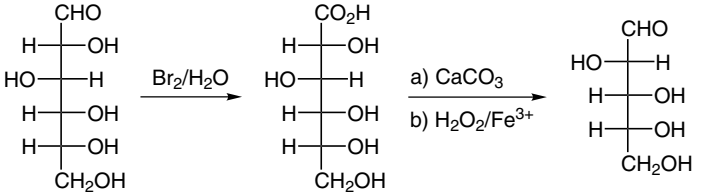
Ruff Degradation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ruff in 1892.[1] It is a transformation of an aldose to its analog of one less carbon atom by oxidation of the original aldose into aldonic acid followed by the decarboxylation of the corresponding calcium salt of aldonic acid with hydrogen peroxide in the presence of ferric acetate [$Fe(OAc)_3$]. Therefore, this reaction is generally known as the Ruff degradation.[2] Occasionally, it is also referred to as the Ruff oxidative degradation[3] or Ruff reaction.[2w] For example, D-arabinose is easily prepared from calcium D-gluconate,[2u,4] and D-lyxose is degraded from calcium D-galactonate.[2u] In addition, this reaction can be used for the general conversion of α-hydroxy acids into aldehydes.[2s] Although the Ruff degradation has been widely used for the structural determination and the preparation of new sugars, it suffers from difficulty in separating the sugar from the gross quantities of organic and inorganic materials presenting in the reaction mixture.[2u] It has been reported that this reaction can be catalyzed by titanium-containing zeolites.[3c]

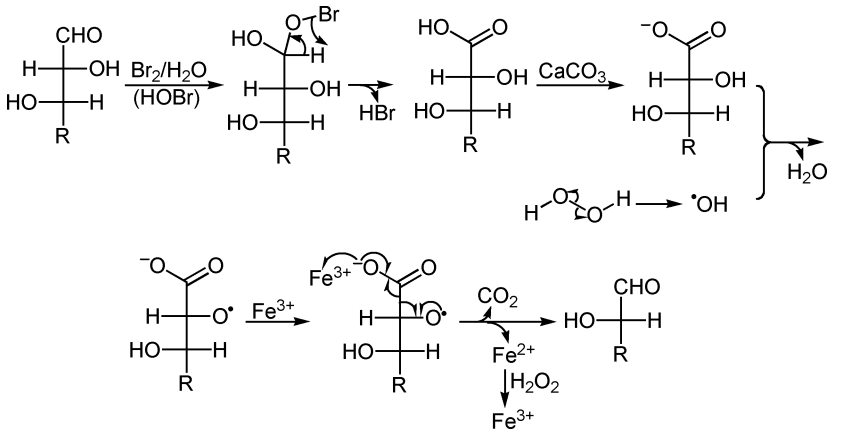
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is an illustration of the Ruff degradation.



D. MODIFICATION

This reaction has been optimized by the application of an active and reliable catalyst prepared by double decomposition of ferric sulfate with barium acetate.[5]

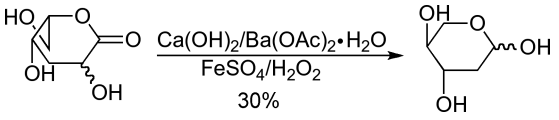
E. APPLICATIONS

This reaction has general application in the structural determination of carbohydrate.

F. RELATED REACTIONS

This reaction is related to the *Weerman Reaction*, *Wohl Degradation*, and *Fenton Reaction*.

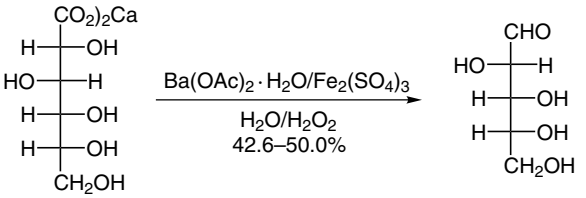
G. CITED EXPERIMENTAL EXAMPLES



Reference 2h.

To a stirred mixture of 1.716 g 3-deoxy-L-hexonolactone, 34 mL water, 442 mg calcium hydroxide, 272 mg barium acetate monohydrate, and 170 mg hydrous ferrous sulfate was added 2 mL 30% H_2O_2, and an additional 2 mL 30% H_2O_2 was added after 45 min of

stirring. Then the solution was kept at room temperature for 2 h with occasional stirring, and then treated with decolorizing carbon and filtered. The filtrate was passed successively through columns of Amberlite IR-120 (H^+) (40 mL) and Amberlite IR-4 (OH^-) (40 mL). Concentration in vacuo gave 430 mg of a yellow syrup, in a yield of 30%.



Reference 5.

A solution of 20.86 g barium acetate monohydrate (0.076 mol) in 60 mL water and a solution of 10.2 g ferric sulfate (0.0255 mol) in 60 mL water (equimolecular quantities) are poured into 2 L distilled water in a 4-L glass beaker. Calcium gluconate dihydrate (200 g, 0.43 mol) was then added, and the solution was heated to boil with stirring. The solution was then removed from the flame, allowed to settle, and filtered on a Buchner funnel precoated with filtercel. To the clear amber-colored filtrate, 1 L water was added, and the solution was cooled to 35°C, then 120 mL 30% H_2O_2 was added. Within a few minutes, an evolution of gas began, and the temperature rose spontaneously to ~ 55°C. The reaction was complete in about 30 min, as indicated by the sudden appearance of a dark purple color. After the mixture cooled to 40°C, an additional 120 mL 30% H_2O_2 was added, whereupon a new reaction took place very similarly. The dark turbid solution was then filtered through carbon on a Buchner funnel and concentrated to 250 mL under vacuum. To this solution was added 1500 mL methanol with shaking, and the granular precipitate was filtered on a Buchner funnel precoated with carbon and washed with 300 mL methanol. To the clear filtrate was added 900 mL ether with shaking. After 5 min of settling, the new granular precipitate was filtered on a carbon-coated Buchner funnel. The filtrate was concentrated to a syrup under vacuum. When it had become so stiff as barely to flow, it was taken up in ~100 mL warm methanol and poured out into an Erlenmeyer flask; another 25 mL methanol was used for rinsing. Crystallization took place readily without seeding. After a few hours in the refrigerator, the sugar was filtered, washed with MeOH and dried. The yield was 55–65 g or ~ 42.6–50% of the theoretical amount. It was recrystallized by being dissolved in two thirds its weight of water and filter with carbon rapidly while hot; five volumes of methanol was added. Sharp prisms of D-arabinose separated in a yield of 80% of the crude substance used. The product was dried at 60°C under vacuum for 2 h, m.p. 155.5–156.5°C.

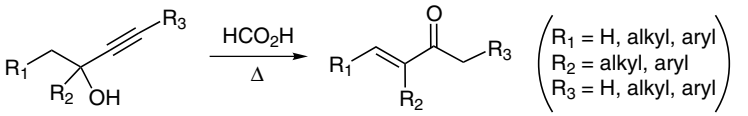
Rupe Rearrangement
(Rupe Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Rupe and Kambli in 1926.[1] It is a formic acid-promoted thermal transformation[2] of tertiary α-acetylenic alcohols into α,β-unsaturated ketones, and is generally known as the Rupe reaction[2c,3] or Rupe rearrangement.[2,3c,3e,4] Besides formic acid, other acids[2c] and even the salt of silver carbonate[4b] can trigger this reaction as well. In many cases, this reaction is competed by the *Meyer-Schuster Rearrangement*, which also leads to the formation of α,β-unsaturated ketones or aldehydes.[2a,3e,4d,5] However, there is a distinct difference between these two reactions. For example, the Rupe rearrangement involves dehydration to form a vinyl acetylene intermediate, and the hydration of this intermediate gives the α,β-unsaturated ketone;[2a,2c,3a,3d,3e,5] while the *Meyer-Schuster Rearrangement* is a 1,3- or allylic shift to form an allenic carbonium intermediate, and the hydration of this intermediate leads to a different α,β-unsaturated ketone,[2c] and an aldehyde from the rearrangement of a terminal acetylene.[2a] In certain cases, only the Rupe rearrangement takes place, as in the case of phenylethynylcarbinol with a methoxy group at the *para*-position of the phenyl group.[3e]

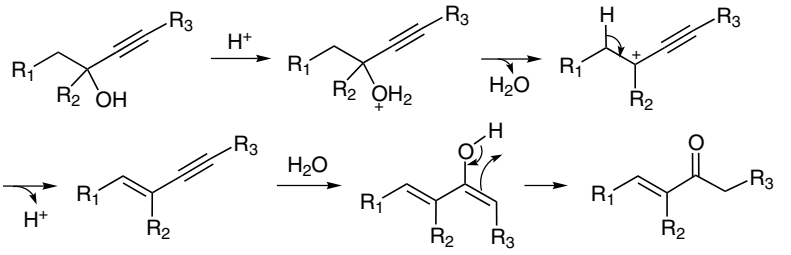
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction involves the protonation of a tertiary alcohol and dehydration to form a tertiary carbonium ion that expels the α-proton to form an enyne intermediate. Hydration of the acetylene moiety yields the α,β-unsaturated ketone.[2a] A general illustration of this reaction is provided below, as well as the possible competition to yield the *Meyer-Schuster Rearrangement* product.



D. MODIFICATION

This reaction has been initiated by the application of silver carbonate.[4b]

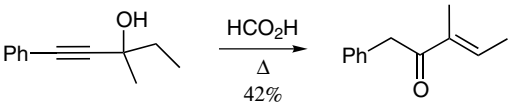
E. APPLICATIONS

This reaction has general application in the preparation of α,β-unsaturated ketones.

F. RELATED REACTIONS

This reaction is related to the *Meyer-Schuster Rearrangement.*

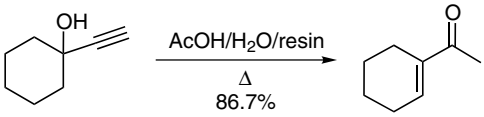
G. CITED EXPERIMENTAL EXAMPLES



Reference 3e.

The mixture of 38 g methylethyl-(phenylethynyl)carbinol (0.218 mol) and 300 mL 88% formic acid was refluxed vigorously for 3 h. The reaction mixture became cloudy and a clear red oil rose to the surface. After cooling, the mixture was transferred to a beaker and neutralized with solid $NaHCO_3$. The resulting neutral mixture was transferred into a separation funnel, and extracted with benzene (4×50 mL). The combined organic layers

were washed with brine and dried, and the benzene was removed by distillation. The residue was fractionated under reduced pressure using a modified Claisen flask to afford 16.1 g 1-phenyl-3-methyl-pent-3-ene-2-one as a pale yellow viscous liquid, in a yield of 42%, b.p., 154–157°C at 24 mmHg.



Reference 6.

A stirred mixture of 39.0 g 1-ethynylcyclohexanol, 100 mL acetic acid, 10 mL H_2O, and 20 g resin was refluxed for 45 min. As soon as the reflux temperature had been reached, the resin began to darken, and in a few min had changed from the original brown to almost black. After cooling, the resin was filtered off and washed with ether. The filtrate and washings were diluted with water and made slightly alkaline by the cautious addition of 40% NaOH solution. This mixture was extracted with ether, and the combined ether layers were washed with brine and filtered through anhydrous $MgSO_4$. Upon removal of ether, the residue was distilled to afford 33.8 g 1-acetyl cyclohexene, in a yield of 86.7%, b.p. 96–98°C at 22 mmHg.

Other references related to the Rupe rearrangement are cited in the literature.[7]

Sabatier-Senderens Reduction

A. GENERAL DESCRIPTION OF THE REACTION

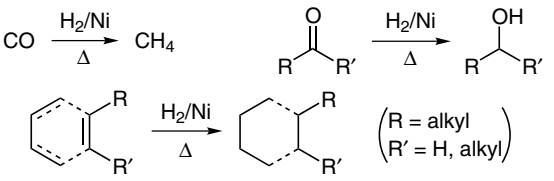
This reaction can be traced back to Debus's transformation of hydrocyanic acid into methylamine over platinum in 1863, De Wilde's hydrogenation of acetylene into ethylene and ethane in 1874,[1] and Mond's extensive work from 1890 to 1895.[2] However, it was in 1899 that Sabatier and Senderens established nickel-based hydrogenation[3] and converted the unsaturated organic molecules (e.g., ketones, aldehydes, alkenes and aromatics) into corresponding saturated compounds (i.e., alcohols, hydrocarbons) by passing the vapor of organic molecules and hydrogen over hot, finely divided nickel. This nickel-based vapor phase hydrogenation became one of the most practically useful reactions and won Sabatier the Nobel Prize in 1912.[1] It is generally known as the Sabatier-Senderens reduction.[4]

This reaction is different from reductions using nascent hydrogen as the reducing agent, such as amalgam of sodium in alcohol (alkaline condition) and or zinc or tin with hydrochloric acid (acidic medium). In this reaction, the purity of nickel and reaction temperature are found to be critical for successful hydrogenation.[1] For example, trace amounts of sulfur, bromine, or iodine will deactivate the nickel catalyst; in addition, it has been found that each hydrogenation process takes place only within a well-defined temperature range,[1] as evidenced by the hydrogenation of benzene to cyclohexane at temperatures ranging from 70° to 190°C, with an optimal temperature between 170° and 190°C, and the further reduction of benzene to methane accompanied by the deposited carbon on nickel at temperatures > 300°C.[5] Under the correct hydrogenation conditions, Sabatier et al. successfully converted oleic acid into stearic acid, acetone to isopropanol, carbon monoxide into methane or a gaseous mixture rich in methane, phenol and *p*-cresol into cyclohexanol and *p*-methylcyclohexanol, benzene to cyclohexane, and naphthalene to tetralin, etc.[1] All these reductions afford the expected products, except for the hydrogenation of naphthalene; other

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

reducing methods may lead to the unexpected products, as demonstrated by the reduction of benzene with hydroiodic acid at 250°C to afford methyl cyclopentane,[1] and the hydrogenation of only one phenyl group of triphenylcarbinol over the Adam's platinum oxide catalyst.[6] At the same time, Sabatier et al. also found that the reduced cobalt, iron, copper, and powdered platinum have catalytic activities similar to nickel. Copper in particular is known to be superior to nickel during the hydrogenation of nitrobenzene to aniline, due to its insensitivity to accidental impurities.[1] It is interesting that Sabatier was able to reduce naphthalene into only tetralin,[7,8] other researchers have successfully converted naphthalene into decalin over nickel.[9]

B. GENERAL REACTION SCHEME

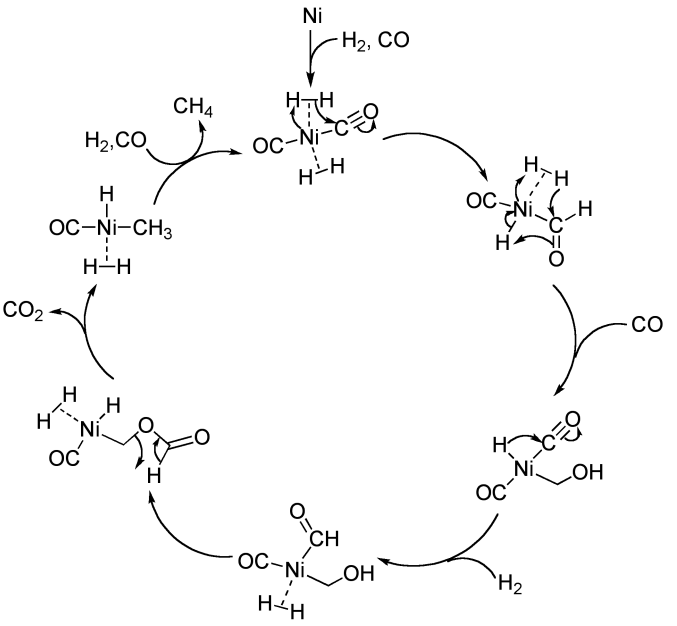


C. PROPOSED MECHANISMS

Although Sabatier proposed that the hydrogenation occurs via nickel perhydride (NiH_2) from the well-prepared and pure nickel, via a poorer hydride from nickel with impurities, or at a very high temperature,[1] it is clear that nickel can absorb a great deal of hydrogen, as indicated by the current use of the nickel hydrogen (Ni/H_2) battery cell.[10] On the other hand, the hydrogenation of carbon monoxide into methane is assumed to involve the formation of an intermediate complex, CHxO, on the nickel surface[11] or an active carbon intermediate from the dissociation of carbon monoxide,[11] which is hydrogenated into methane. In addition, it has been proposed that hydrogen or non-hydrogen gas assists the dissociation of carbon monoxide.[11a] Alternatively, the Sabatier-Senderens reduction may proceed in another route, in which nickel inserts into hydrogen via oxidative addition, and the resulting intermediate forms a coordination complex with carbon monoxide; then a series of transformations, including acyl transfer and reductive elimination, take place until the formation of methane. In addition, the deposited carbon on nickel might be caused by dehydrogenation occurring at an elevated temperature. Displayed here is a tentative mechanism (next page) to illustrate the formation of methane from carbon monoxide.

D. MODIFICATION

In terms of hydrogenation, the Sabatier-Senderens reduction has been extensively modified, as shown by the *Fischer-Tropsch Synthesis* (or process), the *Adkins Catalyst*, and *Raney-Nickel Catalyst*. In addition, the silica black-supported nickel catalyst,[12] and nickel-based complex reducing agents (Nic, e.g. NaH-RONa-$Ni(OAc)_2$),[13] have also been developed, the latter is a heterogeneous hydrogenation catalyst that works at atmospheric pressure.



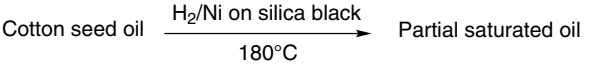
E. APPLICATIONS

This reaction has an important application in organic synthesis, especially in the transformation of carbon monoxide or carbon dioxide into organic compounds.

F. RELATED REACTIONS

This reaction is related to the *Fischer-Tropsch Synthesis* and *Raney-Nickel*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 12.

To a reaction flask were added 50 mL cotton seed oil and 2.5 g silica black-supported nickel catalyst, and the mixture was agitated until complete suspension was attained. Then the mixture was stirred with a mechanical stirrer for 10 min, and the flask was placed in a furnace and connected with a hydrogen tube that reached to the bottom of the flask. The flask was maintained at 180°C for different time intervals, while hydrogen was bubbled through at the rate of 400–450 bubbles/min at ordinary atmospheric pressure. At the end of hydrogenation period, the experiment was stopped, and the product was filtered through asbestos at 140°C. The degree of unsaturation for the oil was verified by iodine numbers.

Other references related to the Sabatier-Senderens reduction are cited in the literature.[14]

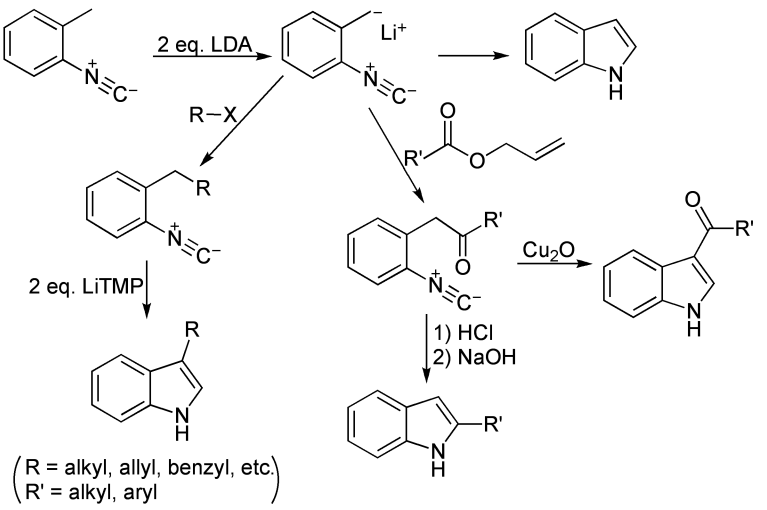
Saegusa Cyclization
(Saegusa Indole Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Saegusa, et al. in 1977.[1] It is the synthesis of indole and 2- or 3-substituted indole derivatives by means of the lithiation of *ortho*-alkyl phenyl isocyanide and subsequently intramolecular cyclization. Therefore, it is known as the Saegusa cyclization.[2] In this reaction, the treatment of *ortho*-alkyl phenyl isocyanide with two equivalents of base such as LDA or LiTMP in diglyme at low temperature followed by intramolecular cyclization leads to the formation of simple indole, while the reaction between *o*-lithomethylphenyl isocyanide and an electrophile (e.g., alkyl halide, epoxide, etc.) followed by lithiation and ring closure produces 3-substituted indoles.[1] This reaction is solvent dependent and can give indoles in quantitative yields.[1] For example, the lithiation of *o*-tolyl isocyanide by LDA in ether or THF results in the low yield of indole, along with the formation of a substantial amount of *N*,*N*-diisopropyl-*N*′-(*o*-tolyl)-formamidine.[1] This is probably attributed to the strong coordination from the two oxygen atoms in diglyme to the lithium cation, whereas only one oxygen atom exists in ether, THF, or monoglyme. Furthermore, *o*-(acylmethyl)phenyl isocyanides prepared from the acylation of *o*-lithomethylphenyl isocyanide with allyl carboxylates can yield 3-acyl indoles or 2-alkyl indoles by the treatment with cuprous oxide or acid.[3]

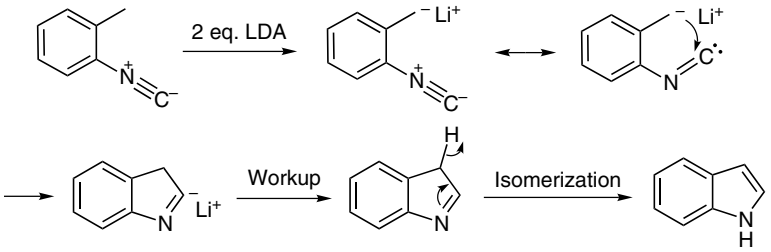
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple mechanism is provided below for the preparation of indole.



D. MODIFICATION

This reaction has been modified by the activation of the *ortho*-benzylic proton with ruthenium complexing to tetramethyl ethylene diphosphine.[4] In addition, the *o*-alkynyl phenylisocyanide has been converted into indolene or indole derivatives via radical initiated cyclization.[5]

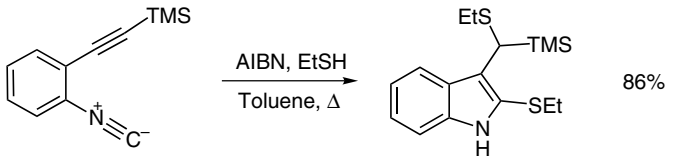
E. APPLICATIONS

This reaction has certain application in the preparation of indole derivatives.

F. RELATED REACTIONS

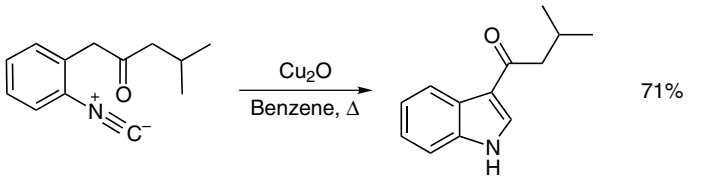
This reaction is related to the *Madelung Indole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

A mixture of 1.13 g *ortho*-isonitrile phenyl trimethylsilyl acetylene (5.68 mmol), 2.10 ethanethiol (28.4 mmol), 0.14 g AIBN (0.85 mmol), and 142.0 mL toluene was refluxed for 15 min and then concentrated in vacuo. The residue was purified by alumina column chromatography using hexanes/EtOAc (10:1) as the eluent to afford 1.57 g 2-ethylthio-3-(1-trimethylsilyl-1′-ethylthio)methyl indole as a pale yellow solid, in a yield of 86%, m.p. 94–96°C.



Reference 3.

A mixture of 302 mg *o*-[(3-methylbutyroyl)methyl]phenyl isocyanide (1.5 mmol) and 29 mg Cu_2O (0.2 mmol) in 5 mL benzene was refluxed under nitrogen for 2 h and monitored by IR for the characteristic IR peak of the isonitrile group. The reaction mixture was filtered, and the filtrate was concentrated. The residue was purified by silica gel column chromatography using $CHCl_3$/EtOAc (1:1) to afford 71% 3-(isobutyroyl)indole, m.p. 135.5–137.0°C, $R_f = 0.76$ ($CHCl_3$/EtOAc, 1:1).

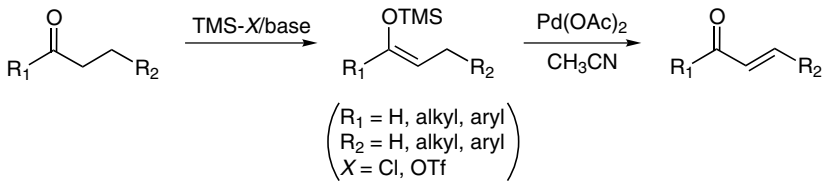
Saegusa Oxidation
(Saegusa-Ito Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Saegusa et al. in 1978.[1] It is a two-step process for the regioselective conversion of a ketone into an α,β-unsaturated ketone, involving the transformation of the ketone into a silyl enol ether and palladium (II) acetate (i.e., $Pd(OAc)_2$) mediated dehydrosilylation in acetonitrile. Therefore, this reaction is generally known as the Saegusa oxidation.[2] Occasionally, it is also referred to as the Saegusa-Ito oxidation[3] or Saegusa-Ito reaction.[4] Currently, a variety of protocols have been developed for the preparation of silyl enol ethers, including TMSCl/LHMDS,[5] TMSCl/LDA,[6] TMSCl/LDA/Et_3N,[2h] TMSCl/LiTMP,[4] TMSOTf/Et_3N,[7] TMSOTf/2,6-lutidine,[2d] and TMSOTf/EtN(i-Pr)$_2$.[3b] Although this reaction normally requires a stoichiometric amount of palladium (II) acetate,[1,8] it also takes place when less than an equivalent[1,9] of or even a catalytic amount of $Pd(OAc)_2$[2e,2h,4,8–10] is present, if an oxidating reagent exists in the reaction system. These oxidants include oxygen,[2e,8a] diallyl carbonate,[4] benzoquinone,[2h] iodoxybenzoic acid (IBX),[11] t-BuOOH,[10] and $Cu(OAc)_2$.[9] Even though this reaction has become one of the most convenient reactions for the preparation of α,β-unsaturated ketones,[8b] sometimes it still fails.[2a,3a,9,12] However, the modification of the standard protocol by the addition of water[9] or base[2g,3a] often works properly.

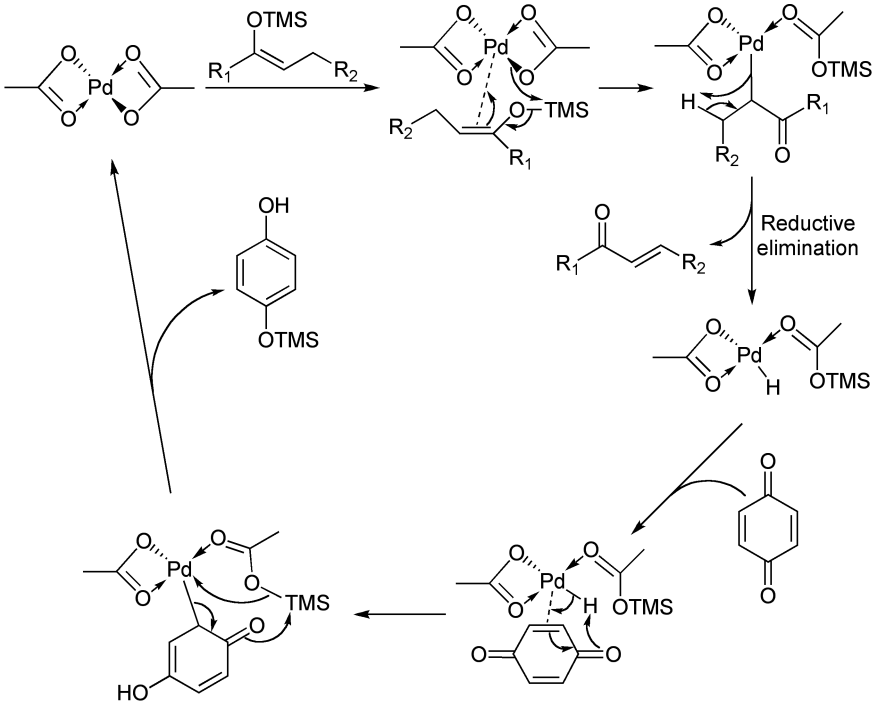
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

In $Pd(OAc)_2$, Pd(II) has 8 out-shell electrons in total, and requires 10 more electrons to satisfy the 18-e rule. Because acetate is a bidenate ligand, $Pd(OAc)_2$ itself can in fact bind to only one more ligand, which possibly is the double bond of the silyl enol ether. The migration of the silyl group leads to the addition of palladium to the double bond, and reductive elimination of palladium results in the α,β-unsaturated ketone. If an oxidant exists in the reaction system, the palladium species from the reductive elimination is oxidized to Pd(II), which enters the catalytic cycle again. An illustrative mechanism focusing on the dehydroxysilylation in CH_3CN is displayed below, using quinone as the oxidant.



D. MODIFICATION

This reaction has been extensively modified to a catalytic version by the use of different oxidants.[2e,2h,4,8–10] Especially, different α,β-unsaturated ketones can be obtained from the same silyl enol ether by the use of different bases, such as Na_2HPO_4 and $CsCO_3$.[10]

E. APPLICATIONS

This reaction has been widely used for the preparation of α,β-unsaturated ketones, and the cleavage of tertiary cyclobutanols.[8a]

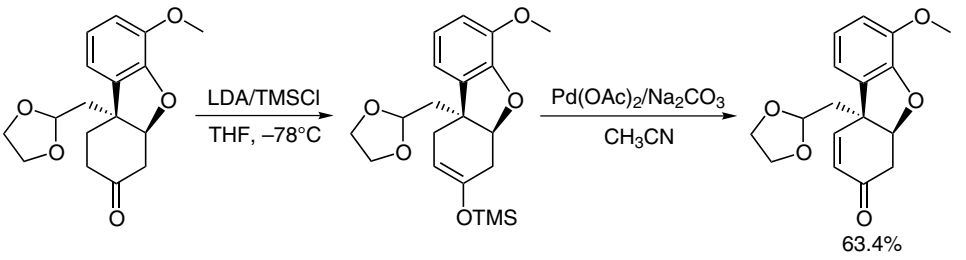
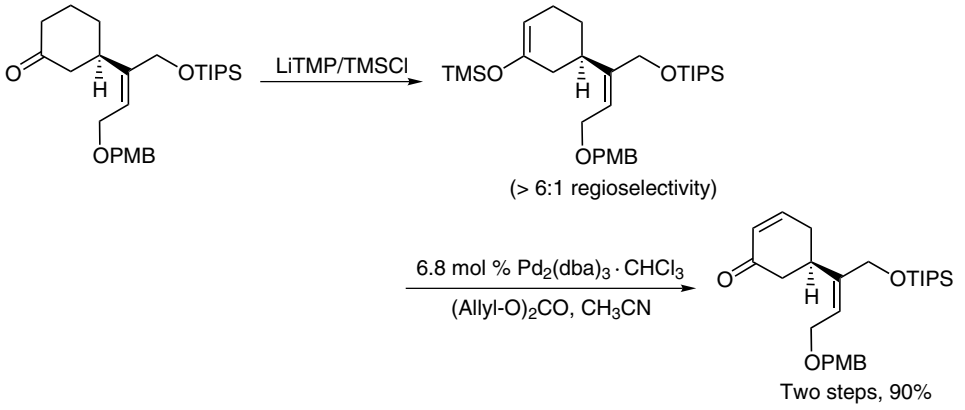
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a solution of LDA freshly prepared from 1.70 mL diisopropylamine (12 mmol) and 4 mL 1.5 M *n*-BuLi in hexane (6 mmol) in 10 mL THF at –78°C under argon was added dropwise a solution of 600 mg ketone (2 mmol) in 4 mL THF. After 15 min, 5 mL chlorotrimethylsilane (4 mmol) was added, and the reaction was allowed to warm to 0°C. The mixture was quenched with 8 mL H_2O, extracted with Et_2O (4 × 10 mL), dried over $MgSO_4$, and concentrated in vacuo. The resulting silyl enol ether was taken up by 30 mL acetonitrile; 275.6 mg anhydrous Na_2CO_3 (2.6 mmol) and 583.5 mg palladium acetate (2.6 mmol) were added in turn. The reaction mixture was stirred for 12 h under a nitrogen atmosphere. Then the mixture was filtered with a short gel column and washed by EtOAc. Upon removal of solvent, the residue was purified by silica gel column chromatography using petroleum ether/EtOAc (8:1) as the eluent to afford 378 mg enone (63.4%) along with 104 mg starting ketone (17.0% recovery).



Reference 4.

To a solution of 0.22 mL 2,2,6,6-tetramethylpiperidine (1.31 mmol, 1.5 eq.) in 6.0 mL THF was added 0.79 mL 1.48 M BuLi in hexane (1.22 mmol, 1.4 eq.) at 4°C (ice water bath). After being stirred for 1 h at the same temperature, the reaction mixture was cooled

to –78°C. TMSCl (0.17 mL, 1.22 mmol,1.4 eq.) was then added, followed by 402 mg starting material (0.873 mmol) in 6.0 mL THF via cannula. After being stirred for 2 h at –78°C, the reaction mixture was allowed to warm up, quenched by saturated $NaHCO_3$ aqueous solution, extracted with Et_2O, dried over Na_2SO_4, and concentrated. The residue was dissolved in 4.7 mL CH_3CN, then 0.17 mL diallyl carbonate (1.2 mmol, 1.4 eq.) and 61.0 mg $Pd_2(dba)_3{\cdot}CHCl_3$ (59 μmol, 6.8 mol %) were added at room temperature. After being stirred for 12 h at room temperature, the reaction mixture was quenched by saturated $NaHCO_3$ aqueous solution, extracted with CH_2Cl_2, dried over Na_2SO_4, and concentrated. The residue was purified by flash column chromatography using 15%–20% EtOAc in hexane as the eluent to afford 361.3 mg (*R*)-5-[(*E*)-3-(4-methoxybenzyloxy)-1-triisopropylsilyloxymethyl-1-propenyl]cyclohex-2-enone and its regioisomer (> 6:1) as a colorless oil (90% for two steps, $R_f = 0.43$ (hexane/EtOAc, 3:1)), and 35 mg starting material (9% recovery).

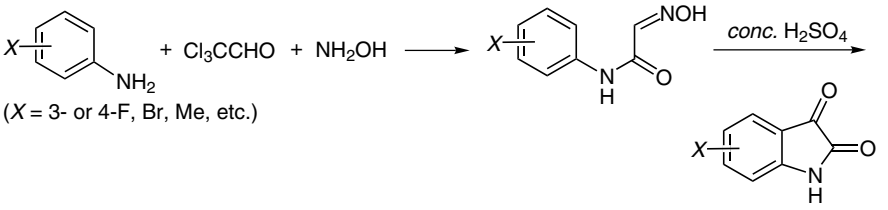
Sandmeyer Isatin Synthesis
(Sandmeyer Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Sandmeyer in 1919.[1] It is a synthesis of isatin derivative involving the condensation of chloral (i.e., trichloroacetaldehyde), hydroxylamine, and a primary aryl amine to an α-isonitrosoacetanilide and subsequent electrophilic cyclization of the latter in the presence of a strong acid such as concentrated sulfuric acid.[2] Therefore, this reaction is generally known as the Sandmeyer isatin synthesis[2a,3] or the Sandmeyer synthesis.[4] During this reaction, the oximino intermediate can be isolated by extraction with warm 2 *N* NaOH followed by the precipitation with a 2 *N* HCl solution and purified by recrystallization in ethanol.[5] The isatin derivatives from this reaction have been used as the starting material for quinolines, acridines, and indophenazines.[3c] It is possible that the oximino intermediate from the *meta*-substituted aryl amine may form two stereoisomers during electrophilic cyclization (i.e., the 4- and 6-substituted isatins), which cannot be separated completely by fractional crystallization.[6] It is interesting that these two stereoisomers could be completely and rapidly isolated by precipitation of 4-isomer (usually red needles) with acetic acid followed by the precipitation of 6-isomer (usually yellow plates) by concentrated HCl.[6] However, this reaction fails to convert the oximino intermediates arising from nitroanilines,[7] 2-fluoroanilines, and 2,4-difluoroanilines[3c] into the corresponding isatin derivatives.

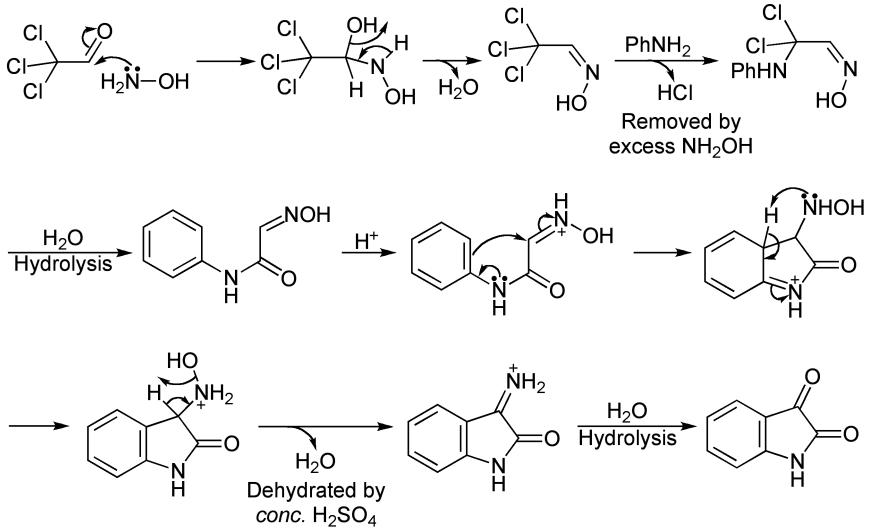
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that hydroxylamine condenses with chloral to give oxime, which then undergoes the nucleophilic substitution with aniline, and hydrolyzes to give oximino intermediate under basic conditions. In the presence of a strong acid, such as concentrated sulfuric acid, the oximino compound cyclizes via nucleophilic addition of aromatic ring to C=N double bond. An illustrative mechanism is provided below.



D. MODIFICATION

The oximino intermediate has been cyclized with PPA as the dehydrating reagent.[3a]

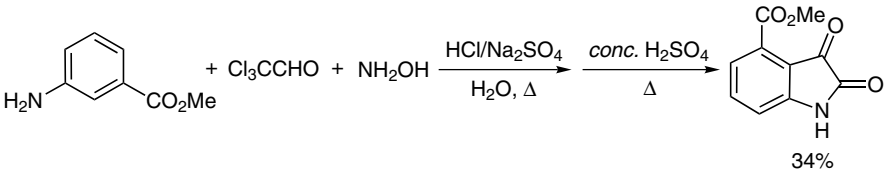
E. APPLICATIONS

This reaction has a general application in the synthesis of isatin derivatives, which could be used as the starting materials for quinolines, acridines and indophenazines etc.

F. RELATED REACTIONS

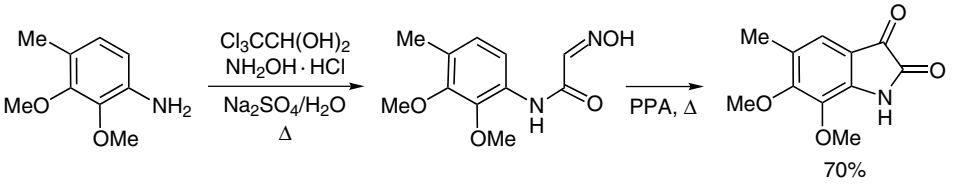
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

A mixture of 13.6 g methyl 3-aminobenzoate (0.09 mol), 16.1 g chloral hydrate (0.09 mol), 234.4 g Na_2SO_4, 19.8 g hydroxylamine hydrochloride (0.29 mol), 145 mL water, and 8 mL concentrated HCl was refluxed for 2 h and then kept at room temperature overnight. The cream color isonitroso intermediate was filtered off, washed with water, and dried to give 16.0 g intermediate, in a yield of 80%. This compound in a total of 16.0 g (0.07 mol), was added in portions to 70 mL *conc*. H_2SO_4 maintained at 70–75°C over a period of 30 min under stirring. The resulting mixture was then heated at 80°C until the reaction was complete, as monitored by TLC ($CHCl_3$/EtOH, 8:2). After being cooled to room temperature, the mixture was slowly poured onto ice. The aqueous phase was extracted with EtOAc; the combined organic layers were dried over $MgSO_4$, filtered, and evaporated. The resulting orange solid was purified by gradient flash column chromatography on silica gel, eluting with $CHCl_3$/EtOH (8:2) to give 5.0 g methyl 4-isatincarboxylate, in a yield of 34%, m.p. 215–217°C.



Reference 3a.

After a mixture of 1.68 g chloral hydrate (10.2 mmol), 2.03 g hydroxylamine hydrochloride (29.2 mmol), 13.4 g anhydrous Na_2SO_4, and 45 mL water was stirred at 45–50°C for 15 min, a 7.0 mL solution prepared from 1.517 g aniline, 0.75 mL *conc*. HCl, and water was added. The resulting mixture was heated for 1 h each at 45–50°C, 55–60°C and 65–70°C. An additional 0.45 g chloral hydrate and 4.1 g hydroxylamine hydrochloride were added, and the reaction mixture was heated at 75–80°C for another hour. When the mixture was cooled in ice water, a light brown precipitate formed, which was filtered to afford 1.58 g *N*-(2,3-dimethoxy-4-methylphenyl)-2-(hydroxyimino)-acetamide of sufficient purity, in a yield of 73%. To 20 mL polyphosphoric acid at 100°C was added 2.0 g *N*-(2,3-dimethoxy-4-methylphenyl)-2-(hydroxyimino)-acetamide (8.39 mmol) over a period of 5 min. After 20 min, the reaction mixture was cooled, and 40 mL water was carefully added to yield an orange precipitate, which was filtered to give 1.30 g 6,7-dimethoxy-5-methyl-1H-indole-2,3-dione, in a yield of 70%. This compound could be further purified by recrystallization in methanol, m.p. 180.5–181.5°C.

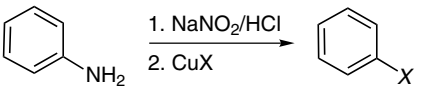
Sandmeyer Reaction
(Sandmeyer Transformation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Sandmeyer in 1884 during the preparation of phenylacetylene from benzenediazonium chloride and cuprous acetylide.[1] It is a two-step synthesis of aryl halides or cyanides from primary aryl amines involving the formation of diazonium salts of the corresponding amines with nitrous acid and the transformation of diazo intermediates into aryl halides or cyanides with cuprous halides or cyanide. This reaction is therefore generally referred to as the Sandmeyer reaction.[2,3] Occasionally, it is also known as the Sandmeyer transformation.[4] In addition, the preparation of aryl nitrile from this reaction is specifically known as the Sandmeyer nitrile synthesis.[2v] Likewise, the combination of the alkali halide and cuprous halide is known as the Sandmeyer reagent.[2v,5] It is clear that the halo group introduced into the aromatic ring originates from cuprous halide instead of the diazonium halide, as supported by the formation of *p*-dichlorobenzene from *p*-chlorobenzenediazonium bromide and cuprous chloride as well as the production of *p*-chloro-bromobenzene from *p*-chlorobenzenediazonium chloride and cuprous bromide.[6] In addition, the halogen exchange has also been observed in the Sandmeyer reaction.[3a,3n] Although cupric or ferrous chloride does not promote this reaction,[1a] it has been found that a saturated solution of $CaCl_2$, $ZnCl_2$, and zinc ammonia chloride [$Zn(NH_3)_2Cl_2$], with maximal concentration of chloride ions, reacts equally well with aryl diazonium salt to give aryl chloride.[1a] In contrast, the yield of aryl nitrile can be improved by a reaction of diazonium salt with nickel cyanide (i.e., $Ni(CN)_2$), rather than CuCN,[1a] whereas other salts of cyanide such as that with Fe, Cr, and Zn are not effective.[7] It should be pointed out that the iodonation of the aromatic diazonium salt does not need the presence of cuprous iodide.[1a,2e] Overall, this reaction usually gives less than a quantitative yield of aryl halide due to the formation of some side products, including biaryl, azobenzene, and phenol.[1a,2b,8]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

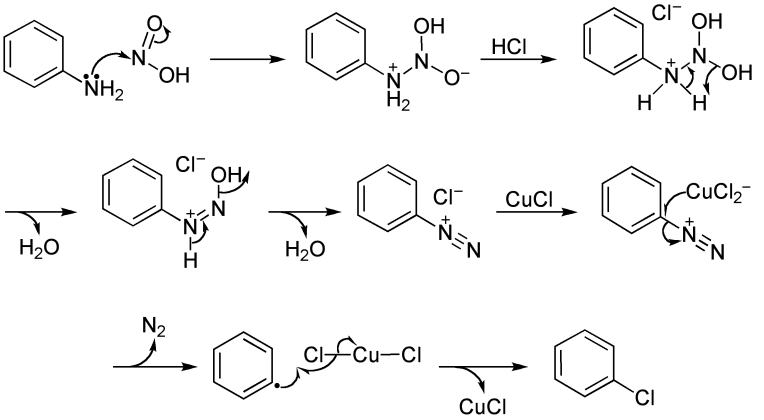
B. GENERAL REACTION SCHEME



(*X* = Cl, Br, I, CN, SCN, SeCN, etc.)

C. PROPOSED MECHANISMS

Although different mechanisms have been proposed for this reaction, including the addition of cuprous chloride to the N=N double bond, the formation of cupric salt from oxidation-reduction, the formation of copper complex $[CuCl_4]^{2-}$,[1a] and the isolation of $C_6H_5N_2Cu_2Br_3$ crystal as the reaction intermediate,[3l] more recent experimental evidence supports the concept that this reaction involves an aryl radical,[1a,2x,3f,3p] as illustrated below.



D. MODIFICATION

A standard condition has been optimized for this reaction, in which the aryl amine is diazotized in 10 times its amount of acetic acid, followed by the addition of one equivalent of cuprous halide in hydrohalic acid. Under these conditions, the acetate salt of aryl amine is relatively soluble, and less froth and tarry material are formed during diazo transformation.[9] In addition, chlorination, bromination, and iodonation of *p*-haloaniline to dihalobenzenes under such standard conditions give almost comparable average yields. Other modifications of this reaction include the formation of phenyl selenocyanate by the reaction with potassium selenocyanate,[2c] and aryl nitrile by the reaction with nickel cyanide.[1a] Moreover, this reaction has been extended to the preparation of phenyl thiocyanate, phenyl isothiocyanate[3h] and aromatic sulfonyl chloride.[3o]

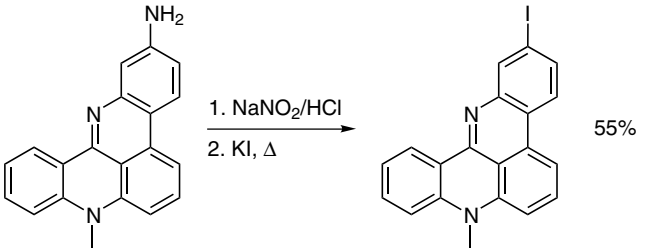
E. APPLICATIONS

This reaction has very general application in the preparation of aryl halides and nitriles.

F. RELATED REACTIONS

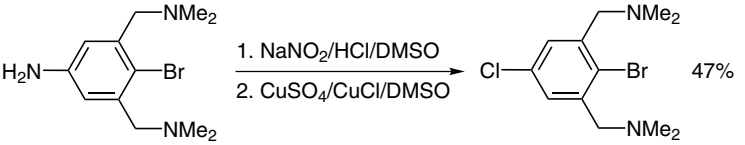
This reaction is related to the *Gattermann Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2e.

A solution of 87 mg $NaNO_2$ (1.26 mmol) in 2 mL water was added dropwise to a solution of 250 mg 2-amino-8-methyl-8*H*-quino[4,3,2-*kl*]acridine (0.84 mmol) in 50 mL 2 M HCl at 0°C. After the mixture was stirred at 0°C for 15 min, a solution of 0.24 g KI (1.47 mmol) in 10 mL water was added dropwise, and the resulting mixture was heated for 0.5 h at 80°C. After cooling, the reaction mixture was alkalinized to pH 12 with 10% NaOH, and the product was extracted with $CHCl_3$ (4 × 50 mL). Upon removal of solvent, the residue was purified by column chromatography using 0.25% MeOH in $CHCl_3$ as the eluent, to afford 190 mg 2-iodo-8-methyl-8*H*-quino[4,3,2-*kl*]acridine, as a yellow solid, in a yield of 55%, m.p. 265–268°C.



Reference 2q.

To a stirred solution of 9.0 g 5-amino-2-bromo-1,3-bis-[(dimethylamino)methyl] benzene (31.4 mmol) in 75 mL DMSO was added 15 mL concentrated HCl dropwise. The reaction mixture was cooled to 0°C, and subsequently, a mixture of 15 mL *conc*. HCl and 6.1 g $NaNO_2$ in 50 mL DMSO was added, while the temperature of the reaction mixture was maintained at 10°C. After this addition, 7.86 g $CuSO_4$ (31.4 mmol) and 1.55 g CuCl (15.7 mmol) were added. There was immediate gas evolution, and the greenish mixture was then stirred for an additional 16 h, while the temperature was slowly raised to room temperature. The reaction mixture was poured into 400 mL 2 M NaOH, whereupon the solution turned blue and then brown. To this heterogeneous mixture was added 200 mL CH_2Cl_2, and the whole mixture was filtered through a G4 glass frit with a layer of infusorial earth. The organic layer of the orange filtrate was separated, and the aqueous phase was extracted with CH_2Cl_2 (2 × 100 mL). The combined organic layers were washed with brine, dried over $MgSO_4$, and evaporated to afford a yellow oil. Fractional distillation under reduced pressure at 0.05 mmHg produced 4.56 g 2-bromo-5-chloro-1,3-bis[(dimethylamino)methyl]benzene, in a yield of 47%.

Other references related to the Sandmeyer reaction are cited in the literature.[10]

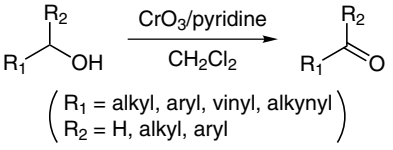
Sarett Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Sarett et al. in 1953[1] after the initial preparation of a relevant oxidation reagent in 1948.[2] It is a mild oxidation of primary or secondary alcohols into corresponding aldehydes or ketones using chromium trioxide and pyridine complex as the oxidant and is generally referred to as the Sarett oxidation.[3] Likewise, the complex from anhydrous chromium trioxide and pyridine is commonly termed the Sarett's reagent.[4] The advantage of using Sarett's reagent is its relatively high solubility in the chlorinated hydrocarbons,[5] in which the allylic oxidation[6] and α-oxidation of alkyne[4b] can be effectively performed. For example, methylene chloride, the most commonly used solvent for the Sarett oxidation, has a solubility of 12.5 g per 100 mL for the chromium trioxide-pyridine complex.[7] In addition, Sarett's reagent can be prepared directly in methylene chloride,[7] which is superior to pyridinium chlorochromate (PCC) in the α-oxidation of alkyne because of the rapid formation of product.[4b]

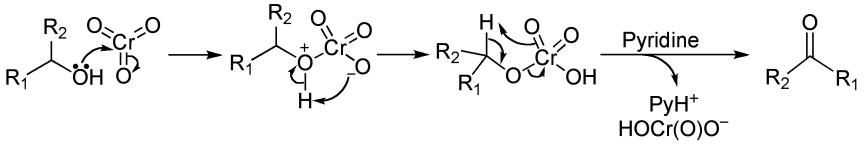
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

An illustrative mechanism is provided below for the Sarett oxidation.



D. MODIFICATION

This reaction has been modified by using methylene chloride as the reaction solvent.[5,7]

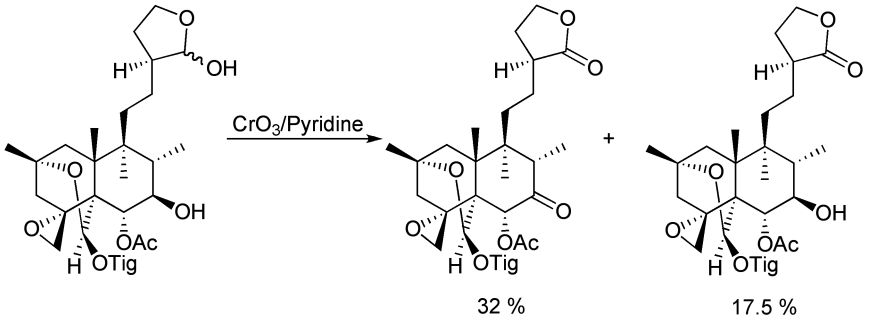
E. APPLICATIONS

This reaction has broad application in organic synthesis.

F. RELATED REACTIONS

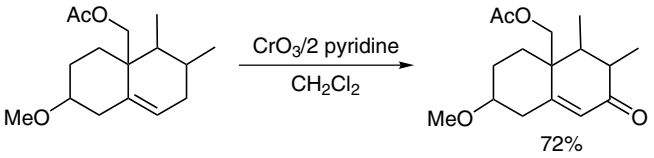
This reaction is related to *Corey-Schmidt Oxidation* and *Corey-Suggs Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a solution of 320 mg scutegalin B (0.63 mmol) in 17 mL pyridine was added a mixture of 1.7 g CrO_3 and 17 mL pyridine, and the mixture was left at room temperature for 24 hours. Then the mixture was poured into 100 mL water and extracted with Et_2O (5 × 25 mL). The combined organic layers were dried over Na_2SO_4, and evaporated. The residue was purified by silica gel column chromatography using petroleum ether/EtOAc (1:1) as the eluent, to afford 102 mg [(13*S*,19*R*)-6α-acetoxy-4α,18-epoxy-7-oxoneoclerodan-16,15-olide 19,2α-(19-*O*-tigloyl) hemiacetal] (an amorphous white solid, 32%, m.p. 115–120°C) and 56 mg of [(13*S*,19*R*)-6α-acetoxy-4α,18-epoxy-7β-hydroxyneoclerodan-16,15-olide 19,2α-(19-*O*-tigloyl) hemiacetal] as colorless needles, in a yield of 17.5%, m.p. 223–226°C (from EtOAc).



Reference 8.

To a rapidly stirred mixture of 7.75 g dry pyridine and 220 mL CH_2Cl_2, was added 4.9 g chromium trioxide, and the resulting mixture was stirred at room temperature for additional 20 min. Then, to this solution was added 2.5 g chloest-5-ene-3b-19-diol 3-methyl ether 19-acetate in 10 mL CH_2Cl_2 in one portion, and the mixture was stirred for 17 h. At the end of this period, an additional portion of $CrO_3 \cdot 2$pyridine complex, prepared from 1.52 g chromium trioxide and 2.4 g pyridine in 100 mL CH_2Cl_2, was added, and the mixture was stirred for another 7 h. The solution was diluted with 600 mL ether and washed with saturated $NaHCO_3$ solution (3 × 75 mL), 3% HCl (2 × 75 mL), saturated $NaHCO_3$ solution (1 × 100 mL) and brine (1 × 100 mL). The organic layer was dried over $MgSO_4$, and evaporated in vacuo. The resulting brown oil was purified by silica gel column chromatography using hexanes/EtOAc (3:1) as the eluent to afford 1.78 g 7-oxochloest-5-ene-3b,19-diol 3-methyl ether 19-acetate, in a yield of 72%, m.p. 95–96.5°C.

Other references related to the Sarett oxidation are cited in the literature.[9]

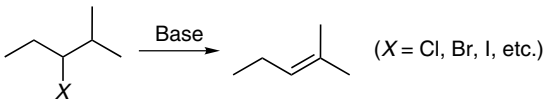
Saytzeff Rule
(Zaitsev Rule)

A. GENERAL DESCRIPTION OF THE REACTION

This rule was first formulated by Saytzeff (Zaitsev) in 1875.[1] It is a rule for predicting the regio-selectivity of olefin formation by the elimination of secondary or tertiary alkyl halides, in which the proton is eliminated preferentially from the carbon bearing the smallest number of protons; therefore, it is generally known as the Saytzeff rule[2] or Zaitsev rule.[3] Nowadays, it is more generally accepted that the elimination of aliphatic halides, alcohols, esters, etc. forms thermodynamically stable products,[4] and this elimination is termed as the Zaitsev elimination.[5] The regioselectivity to give a more stable olefin is referred to as the Saytzeff regiospecificity,[6] and the corresponding olefin is known as the Saytzeff product,[7] or Zaitsev product.[8] The Saytzeff rule does not apply to the pyrolysis of esters in the gas phase (e.g., $> 400^{o}C$)[9] and the elimination of onium salts,[2n] such as the quaternary ammonium salts and substituted sulfonium salts, of which the *Hofmann Rule* works and the least-substituted olefins predominate in the products.[2d,4b,10] The unimolecular elimination such as the *Chugaev Reaction*[11] and the pyrolysis of esters in the liquid phase (e.g., $< 200^{o}C$)[9] also follows the Saytzeff rule. Furthermore, the steric effect during the elimination may also lead to the product obeying the *Hofmann Rule*,[12] as indicated by the increased ratio of 1-/2-olefin from the elimination of a series compounds of $RCH_2CBr(CH_3)_2$, in which R varies from Me, Et, *i*-Pr to *t*-Bu.[13] Similarly, the size of the base applied in the elimination also affects the regioselectivity between the Saytzeff and Hofmann rules.[12a,14] It is interesting that the steric effect may also result in the Saytzeff product from the elimination of an ammonium salt.[2d]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is well known that in the absence of a significantly steric interaction, the formation of a more stable olefin during elimination is attributed to electronic stabilization (e.g., hyperconjugative factors) of the double bond in the transition state.[2f,10,12a,14] It is not necessary to illustrate the mechanism here.

D. MODIFICATION

The complexes of Group IVB (d0) metal with benzamidinate have been used for the transformation of olefins into the most stable isomers.[15]

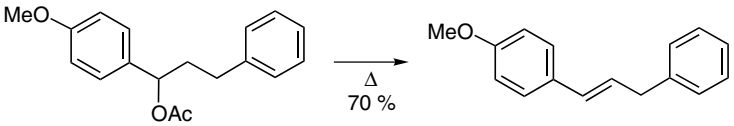
E. APPLICATIONS

This rule is very useful in predicting the regioselectivity of elimination.

F. RELATED REACTIONS

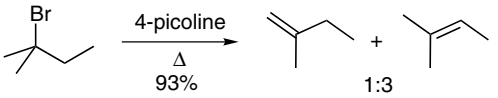
This rule is related to the *Hofmann Rule.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 10a.

To a small flask equipped with a short refractional column was added 10.0 g 1-(*p*-anisyl)-3-phenylpropyl acetate. The flask was heated with a soft Bunsen flame until acetic acid began to distil. Heating was continued at such a rate that the acetic acid distilled rapidly, until the calculated amount had been collected in a graduated centrifuge tube. The residue was then cooled, taken up in CH_2Cl_2, and washed free of any excess acid. Upon removal of the solvent, the residue was distilled under reduced pressure to afford 5.5 g 1-(*p*-anisyl)-3-phenylpropene, in a yield of 70%, b.p. 160°C at 1 mmHg.



Reference 14.

To a 200-mL round-bottomed flask equipped with a Todd microcolumn was placed 100 ml of 4-picoline and 15.10 g *t*-amyl bromide (0.1 mol). The mixture was rapidly heated to reflux. Olefin was removed at the top of the column as rapidly as it appeared there. The collected sample was washed with water and separated to give 6.46 g methyl butene, in a yield of 93%. The refractive index of 1.3850 indicated a composition of 25% 2-methyl-1-butene and 75% 2-methyl-2-butene.

Other references related to the Saytzeff rule are cited in the literature.[16]

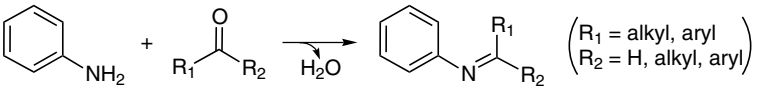
Schiff Base

A. GENERAL DESCRIPTION OF THE REACTION

The first Schiff base was reported by Schiff in 1864.[1] It is a special type of imine derivative formed by the condensation between a primary aromatic amine and an aldehyde or ketone, but sometimes the condensation products from aliphatic amine and ketone[2] or aldehyde[3] are also referred to as the Schiff bases.[4] It has been reported that under certain conditions, the formation of a Schiff base linkage proceeds reversibly without any additives.[5] In addition, imine formation is observed to take place faster in a slightly acidic conditions,[5] but the formed imine is subject to hydrolysis in a more acidic medium.[6] The prepared Schiff bases have found wide uses, such as to tune the metal-center electronic factors,[4b,7] the model compounds for the study of active sites of metalloenzymes,[8] and the chelators in coordination chemistry.[4d–4p,7,9,10] It should be pointed out that the salens (e.g., oxomanganese salen [*N*,*N*′-ethylene-bis(salicylideneaminato)] complex) are widely used in the *Jacobsen-Katsuki Epoxidation*,[10,11] and the chromium(III) complexes with chiral tridentate Schiff base is successfully used to catalyze the highly enantioselective and diastereoselective *hetero-Diels-Alder Cycloaddition*,[2a] etc. In addition, some Schiff bases have shown different biological activities, including antituberculous activity[12] and obstruction of the growth of animal tumors.[2d]

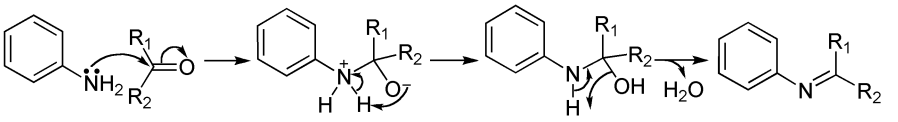
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

An illustrative mechanism for the formation of a Schiff base is given here.



D. MODIFICATION

N/A

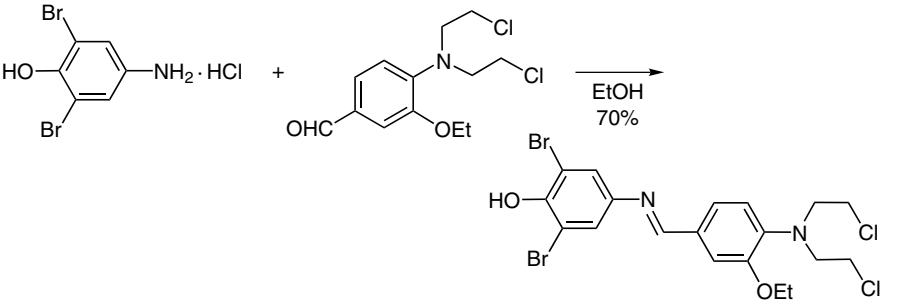
E. APPLICATIONS

The Schiff base has wide application in coordination chemistry as well as in organic synthesis.

F. RELATED REACTIONS

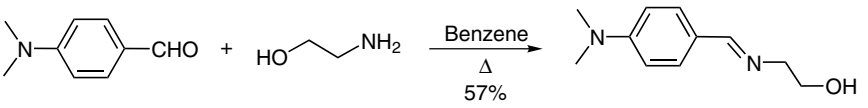
The Schiff base is related to the formation of imine.

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To a solution of 3.0 g 2,6-dibromo-4-aminophenol hydrochloride (10 mmol) in dry warm ethanol was added a *conc*. ethanol solution of 2.9 g 4-[*N*,*N*-bis(2-chloroethyl)amino]-3-ethoxybenzaldehyde (10 mmol). The resulting dark red solution was stirred for a few hours and then cooled in ice to deposit the crystal solid. The crystal was filtered and washed with absolute ethanol and diethyl ether, and dried to afford 3.4 g 4-({4-[*N*,*N*-bis(2-chloroethyl)amino]-3-ethoxybenzylidene}-amino)-2,6-dibromophenol hydrochloride, in a yield of 70%.



Reference 2e.

A mixture of 14.92 g *p-N,N*-dimethylaminobenzaldehyde (0.1 mol), 4.45 g ethanolamine, and 50 mL dry benzene in a Dean-Stark moisture determination apparatus was refluxed in an oil bath until the volume of water collected in the trap remained constant (2–3 h). The benzene was removed by distillation under reduced pressure, and the residual oil was poured onto an ice-water mixture. The solid crystalline mass was triturated with cold water, collected on a suction filter, and washed on the filter with several portions of cold water. After drying the crystals on the filter by use of a rubber dam followed by air drying, the crude material was dissolved in boiling petroleum ether (b.p. 30–60°C), treated with Norite A for 15 min, and filtered. The filtrate was cooled in an ice-water bath to induce crystallization. The crystals were collected on a suction filter and washed with several small portions of cold petroleum ether, in a yield of 57%, m.p. 103–104°C.

Other references related to the Schiff base are cited in the literature.[14]

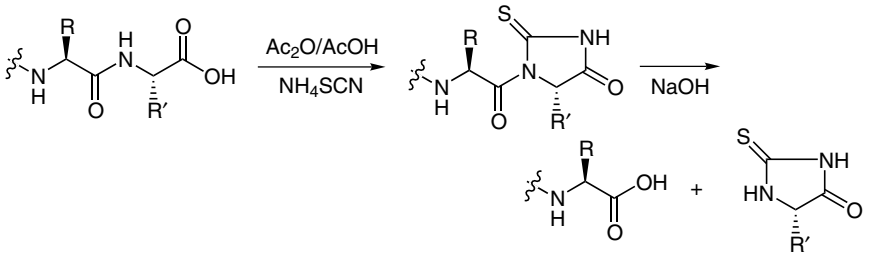
Schlack-Kumpf Reaction
(Johnson Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Johnson in 1911,[1] and subsequently used by Schlack and Kumpf in 1926[2] to sequence peptides and proteins from the C-terminal. It is the synthesis of 2-thiohydantoins from α-amino acids with thiocyanate and acetic anhydride; therefore, it is simply called the Johnson reaction;[3] however, because it has an important use for peptide and protein sequencing, this reaction is mostly known as the Schlack-Kumpf reaction.[4] In this reaction, the terminal carboxyl group is activated by the formation of a mixed anhydride with acetic anhydride,[5] which then reacts with ammonium thiocyanate to give a peptidyl 2-thiohydantoin, the 2-thiohydantoin is then cleaved from the peptide chain to expose the second carboxyl group as the new terminal carboxyl group by the treatment with a base. However, this reaction does have a few disadvantages: the severity of the conditions for the complete conversion of terminal carboxyl group into peptidyl 2-thiohydantoin and its cleavage.[6] In addition, the C-terminal aspartate, proline[3b,6,7]—as well as other amino acids such as lysine, glutamine, glutamate, and arginine[8]—all have difficulty forming the corresponding 2-thiohydantoin derivatives.

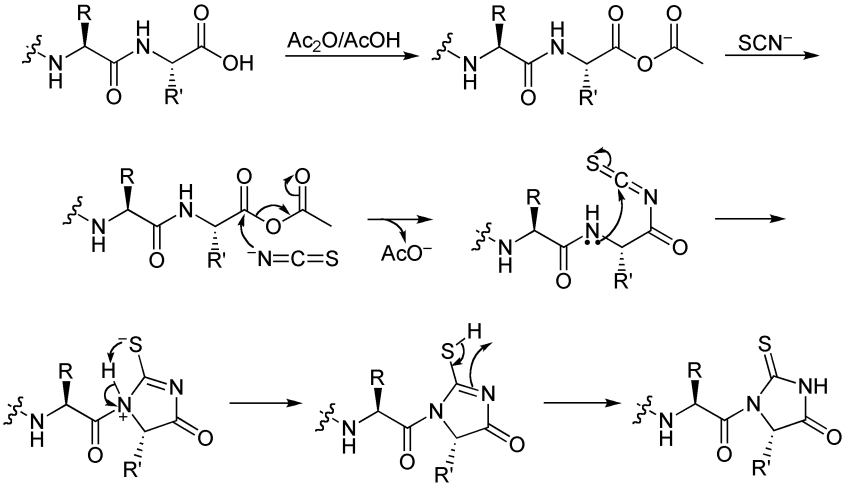
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Only the mechanism for the formation of peptidyl 2-thiohydantoin is illustrated here.



D. MODIFICATION

This reaction has been extended to the reaction of terminal amino acids with thiocyanic acid[7b,9] (also developed initially by Johnson[10]) and trimethylsilyl isothiocyanate[11] for the formation of thiohydantoin. In addition, 12 *N* HCl[11] and acetohydroxamate[8] have been used to cleave the 2-thiohydantoin from the peptide chain.

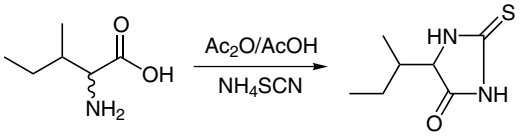
E. APPLICATIONS

This reaction has a general application in the preparation of 2-thiohydantoins from pure amino acids but mostly is used for the sequencing of peptide and protein starting from the C-terminal.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



DL-Isoleucine

Reference 8c.

A mixture of 10 mmol amino acid, 0.9 g ammonium thiocyanate, 10 mL acetic anhydride, and 1.3 mL acetic acid was heated at 100°C for 30 min. Then the mixture was poured into 50 mL water, and an oil separated from the water, which subsequently crystallized. Further purification was accomplished by recrystallization of the crude 2-thiohydantoin from ethanol. The 5-*sec*-butyl-2-thiohydantoin from racemic DL-isoleucine has melting point of 163°C. (no yield was given for this preparation).

Other references related to the Schlack-Kumpf reaction are cited in the literature.[12]

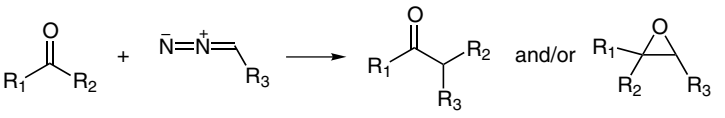
Schlotterbeck Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Meyer in 1905,[1] and was closely investigated by Schlotterbeck beginning in 1907.[2] It is the reaction between a carbonyl compound (aldehyde and ketone) and a diazoalkane to form a new ketone or oxirane (i.e., epoxide) and is generally referred to as the Schlotterbeck reaction.[3] This reaction is not always clean-cut, forming either a ketone or an epoxide.[4] For example, *m*- and *p*-nitrobenzaldehydes react with diazomethane to give corresponding acetophenones, whereas *o*-nitrobenzaldehyde affords *o*-nitrostyrene oxide.[3d] For another example, piperonal reacts with two equivalents of diazomethane to afford safrole oxide.[5] As a result, this reaction is currently of no general use in organic synthesis,[3d] and alternative methods have been used for the preparation of ketones. However, this reaction is useful for the preparation of β-keto ester from ethyl diazoacetate.[2b]

B. GENERAL REACTION SCHEME

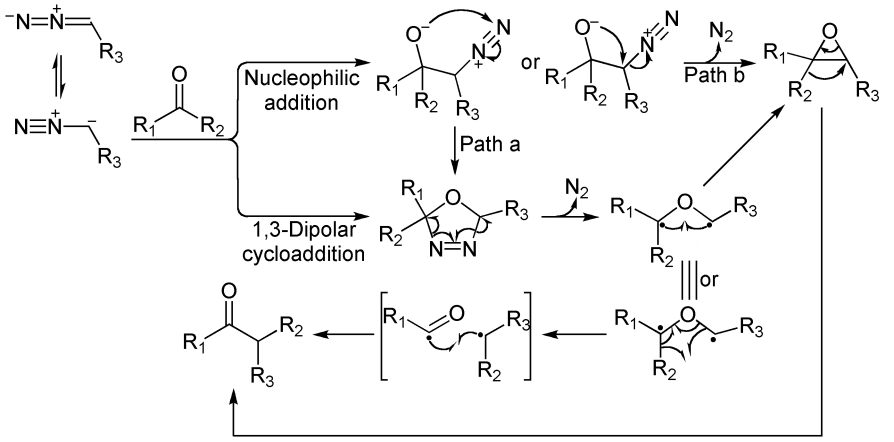


(R_1 = alkyl, aryl; R_2 = H, alkyl, aryl; R_3 = H, alkyl, CO_2Et, etc.)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although a free radical mechanism has been proposed for this reaction,[6] it is much more plausible that the Schlotterbeck reaction involves a nucleophilic attack of the diazoalkane[7] on the carbonyl group to form a diazonium betaine or neutral Δ^2-1,2,3-oxadiazoline intermediate, which then decomposes to give either a ketone or an epoxide[8] as illustrated here.



D. MODIFICATION

This reaction has been extended to directly convert aldehydes into β-keto esters by reacting with ethyl diazoacetate in the presence of a catalytic amount of $SnCl_2$.[9] In addition, the reaction between diazoalkanes and acyl halides to form α-halomethyl ketones, known as the *Nierenstein Reaction*, should be considered as another extension of the Schlotterbeck reaction.

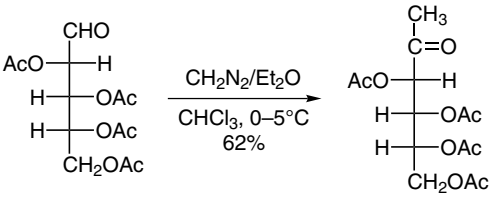
E. APPLICATIONS

This reaction is currently of limited application in organic synthesis.

F. RELATED REACTIONS

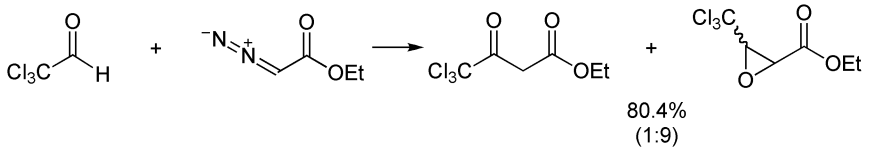
This reaction is closely related to the *Nierenstein Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

The diazomethane generated by the decomposition of 20 mL urethane was distilled in an ether stream directly into an absolute chloroform solution of 24 g *aldehydo*-D-arabinose tetraacetate cooled to 0–5°C. There was a steady, vigorous evolution of nitrogen as the reaction proceeded. The yellow color of the diazomethane was discharged very quickly until about three fourths of the total quantity had been added. The solution then acquired a permanent yellow tinge, indicating an excess of diazomethane. After the solution stood overnight at room temperature, the color vanished. The amorphous precipitate of polymethylenes was removed by filtration, and the solvent was removed by evaporation. The syrup was taken up in 50 mL absolute ethanol, and the solution made opalescent by the addition of petroleum ether. The product of 1-*deoxy*-keto-D-fructose tetraacetate on standing in an ice box (two crops) crystallized slowly to give 15.4 g beautiful cubic crystals, in a yield of 62%, m.p. 75–77°C. Pure product was obtained after four recrystallizations from 95% ethanol, m.p. 77–78°C.



Reference 3a.

Redistilled chloral (59.0 g, 0.4 mol) and 45.6 g ethyl diazoacetate (0.4 mol) were mixed according to Schlotterbeck's procedure. The yellow liquid obtained was fractionally distilled under reduced pressure to yield 75.0 g of a mixture of ethyl trichloroacetoacetate and ethyl 3-(trichloromethyl)glycidate in a ratio of 1:9, in a yield of 80.4%, b.p. 80°C at 1 mmHg. The product gave a positive ferric chloride test. This yellow liquid was then dissolved in ether and washed three times with ice-cooled 10% ammonium hydroxide solution and then with water until the water layer was neutral when tested with litmus paper. The ether layer was dried over anhydrous $MgSO_4$, and the ether was removed by distillation. The remaining yellow oil was fractionally distilled in vacuo to give 45 g ethyl 3-(trichloromethyl) glycidate, with a yield of 48.2% based on the original starting material, b.p. 85°C at 1.5 mmHg.

Other references related to the Schlotterbeck reaction are cited in the literature.[11]

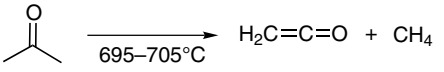
564

Schmidlin Ketene Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Schmidlin and Bergman in 1910.[1] It is a gaseous synthesis of ketene by thermal decomposition[2] or pyrogenic decomposition[3] of acetone through a combustion tube filled with pieces of clay,[2b,4] in a temperature range of 500–750°C. The optimal temperature is the maximum temperature that is compatible with the decomposition of ketene itself by heat,[4] and is found in the range of 695–705°C.[3b] At this temperature, acetone decomposes into ketene and methane.[4,5] In general, three major factors that will affect the yield of ketene in this reaction are the choice of the combustion tube, the reaction temperature, and the fraction of acetone decomposed. For example, this reaction cannot be conducted through a metal tube, either a copper tube[4] or an iron pipe[3b] because carbon may form via dehydrogenation in the presence of some metal oxides.[3b] Although the quartz static system is a suitable reaction environment for ketene synthesis,[6] the yield of ketenes is essentially similar to that conducted in the glass tube.[7] In addition, it has been observed that acetone decomposes into methane, carbon monoxide, and acetylene at 1000°C in a 1-m long copper tube,[4] whereas it yields mesityl oxide between 410° and 420°C over a thoria catalyst[8] as well as over alumina or zirconia.[4] At the optimal temperature in a glass tube, it has been found that the best yield of ketene obtainable is ∼ 35% when less than 40% of acetone is decomposed,[3b] indicating that a comparatively rapid flow of the acetone vapor is needed to carry the ketene out of the reaction chamber once it is generated.[4]

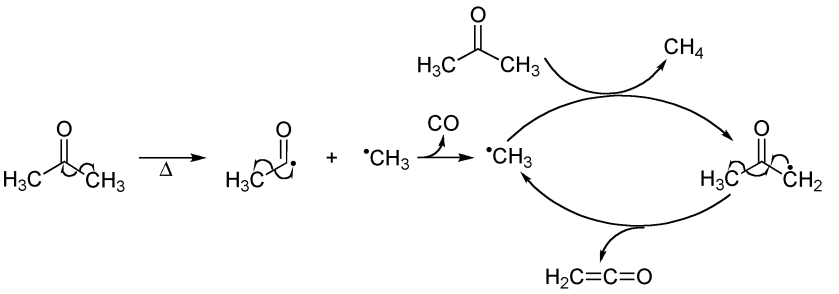
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is assumed that acetone at such high temperatures decomposes into methyl and acetyl radicals, and the latter further degrades into methyl radical and carbon monoxide. Then methyl radical abstracts one hydrogen atom from acetone to give methane and an acetylmethyl radical that decomposes into ketene and another methyl radical.[2b] Displayed here is the reaction mechanism for the Schmidlin ketene synthesis.



D. MODIFICATION

N/A

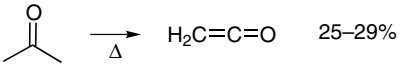
E. APPLICATIONS

This reaction is very useful for the production of ketene and is cheaper than the analogous thermal decomposition of acetic anhydride[9] and acetyl chloride.[4]

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

A 500-mL two-necked round-bottomed flask was equipped with a dropping funnel and an adaptor to a glass combustion tube filled with broken porcelain. The other end of the combustion tube was connected with a refluxing condenser through a three-way stopcock, one to a flask to collect the condensed acetone and the other for connecting with the condenser. The evolved gas from the condenser is led to another reactor to trap the ketene via a tube. To this reaction setup, 126 mL acetone (1.7 mol) was added to the dropping funnel, and the flask was heated by boiling water. The combustion tube was heated by 14 burners,

and tiles are placed over the burners and adjusted to yield a maximum temperature. When the combustion tube was fully heated, acetone was dropped into the flask at a rate of 3–4 mL/min, and about half the acetone was recovered from the condenser. The ketene was produced in 25–29%.

Other references related to the Schmidlin ketene synthesis are cited in the literature.[10]

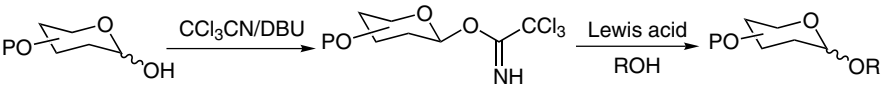
Schmidt Glycosylation
(Schmidt Glycosidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction, originating from Sinaÿ's glycosyl imidate donor reported in 1976,[1] has been extensively explored by Schmidt and co-workers since 1980.[2] It is a Lewis acid-catalyzed glycosylation using glycosyl trichloroacetimidate as the donor. Therefore, this reaction is generally known as the Schmidt glycosylation.[3] Occasionally, it is also referred to as the Schmidt glycosidation,[4] Schmidt coupling,[3h,5] or Schmidt trichloroacetimidate method.[6] Nowadays, it is one of the most popular methods for glycosylation, second only to the glycosylation with a thioglycoside donor.[7] In this reaction, the glycosyl trichloroacetimidate can be simply prepared by the treatment of a carbohydrate precursor with trichloroacetonitrile in the presence of a base, such as DBU, K_2CO_3, Cs_2CO_3, or NaH. When K_2CO_3[8] or DBU[9] is used as the base, β-glycosyl trichloroacetimidate predominates, even though the formation of α- and β-anomeric mixtures is also possible by the treatment of DBU.[10] In contrast, α-glycosyl trichloroacetimidate is formed in preference when Cs_2CO_3[11] or NaH[12] is used. The popularity of this reaction in carbohydrate transformations may be attributed to the mildly acidic coupling conditions and the opportunities to alter α/β selectivity via different glycosyl trichloroacetimidate donors and/or the coupling reagents.[3h] The mild acids compatible with this glycosylation include TMSOTf,[4b,10a,11,13] $BF_3{\cdot}Et_2O$,[10b,14] TBDMSOTf,[10a] TBSOTf,[7] and perchloric acid.[7] Among these promoters, TMSOTf,[10a,11,13d] TBDMSOTf,[10a] and AgOTf[11] often lead to the formation of a β-glycosidic linkage, especially when α-glycosyl trichloroacetimidate is used as the glycosyl donor;[11] in addition, the general 1,2-*trans* selectivity of glycosylation also applies to this reaction, as evidenced in the formation of β-glucoside and α-mannoside.[13e] However, in the presence of $BF_3{\cdot}Et_2O$ promoter, α-glycoside is favored,[10b] and such preference is even observed for the preparation of α-C-glycosides.[15]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

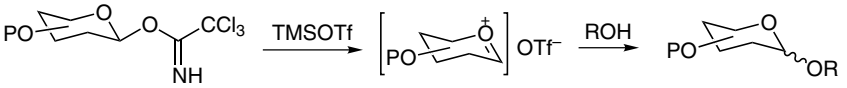
B. GENERAL REACTION SCHEME



(P = protecting group
R = alkyl, carbohydrate, etc.
Lewis acid = TMSOTf, $BF_3 \cdot Et_2O$, etc.)

C. PROPOSED MECHANISMS

Similar to the glycosylation from other types of glycol donors, it is assumed that glycosyl trichloroacetimidate is converted into glycosyl cation, which then couples with a glycosyl acceptor. However, the direct attack of glycosyl trichloroacetimidate by an acceptor (a S_N2 reaction) may also be involved in this reaction, where a higher amount of α-glycosides can be obtained from a β-glycosyl trichloroacetimidate.[13a] A general illustration of the glycosylation is displayed here.



D. MODIFICATION

Glycosyl trifluoroacetimidate has recently been developed as the glycosyl donor,[3f,16] which holds a particularly good reactivity for the glycosylation of sialic acid.[7] In addition, the Schmidt glycosylation has been extended to occur on a solid phase[12a,17] or column,[3] as well as in an ionic liquid (e.g., [emim][OTf] and [bmim][PF_6]).[13a] Especially, in ionic liquids, it has been found that under certain conditions, the Schmidt glycosylation takes place without a Lewis acid catalyst and yields preferentially the β-glycosides from trichloroacetimidate bearing a nonparticipating group at C-2 in [emim][OTf].[13a] Moreover, this reaction has been carried out under sonication, a condition with shortened reaction time, enhanced reactivity, and stereoselectivity.[18]

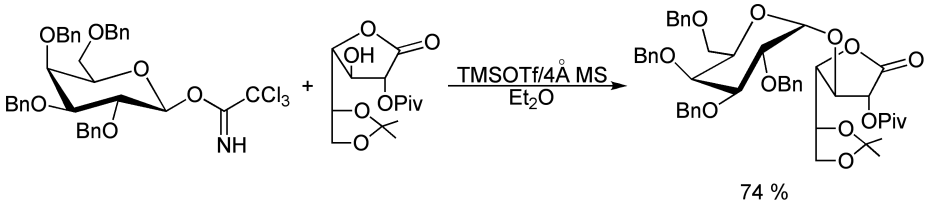
E. APPLICATIONS

This reaction has a very broad application in the carbohydrate transformation.

F. RELATED REACTIONS

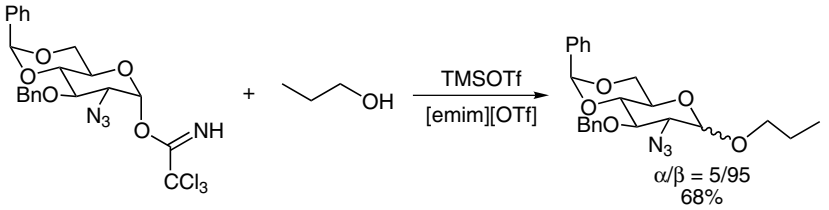
This reaction is related to the *Helferich Glycosylation*. In addition, many other glycol donors have also been developed, which include glycosyl fluorides,[19] 1,2-anhydrosugars,[20] glycosyl phosphates,[21] glycosyl sulfoxide,[22] *n*-pentenyl glycosides,[23] thioglycosides,[24] and thioimidates.[25]

G. CITED EXPERIMENTAL EXAMPLES



Reference 13c.

A mixture of 300 mg *O*-(2,3,4,6-tetra-*O*-benzyl-β-D-galactopyranosyl)-trichloroacetimidate (0.44 mmol), 141 mg 5,6-*O*-isopropylidene-2-*O*-pivaloyl-D-galactono-1,4-lactone (0.47 mmol), and 500 mg powdered 4Å molecular sieves in dry ether was vigorously stirred at 0°C under an argon atmosphere. After 20 min, 25 μL TMSOTf (0.14 mmol) was slowly added, and the stirring was continued for 2 h. The suspension was neutralized by the addition of *N*,*N*-diisopropyl-*N*-ethylamine, filtered through Celite, and concentrated under reduced pressure. The residue was purified by column chromatography using toluene/EtOAc (20:1) as the eluent to afford 269 mg 2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl-(1$\rightarrow$3)-5,6-*O*-isopropylidene-2-*O*-pivaloyl-D-galactono-1,4-lactone as a colorless syrup, in a yield of 74%, R_f = 0.71 (toluene/EtOAc, 5:1).



Reference 13a.

A mixture of 100 mg 2-deoxy-2-azido-3-*O*-benzyl-4,6-*O*-benziliden-α-D-glucopyranoside (0.23 mmol), and 275 mg 2-propanol (4.58 mmol, 20 eq.) was dissolved in 0.5 mL [emim][OTf]. Then 2.3 μmol TMSOTf (0.01 eq.) was added. The reaction was stirred at room temperature for 1 h, and water was added to quench the reaction. The resulting mixture was extracted with $CHCl_3$. Upon removal of the solvent, the residue was purified by flash column chromatography using hexane/EtOAc (9:1) as the eluent to afford 68% of *O*-isopropyl-2-deoxy-2-azido-3-*O*-benzyl-4,6-*O*-benziliden-β-D-glucopyranoside and its α-anomer in a 95:5 ratio.

Schmidt Reaction
(Schmidt Rearrangement)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Schmidt in 1923.[1] It is a reaction between a hydroazoic acid (i.e., azoimide) and a carboxylic acid or a carbonyl compound via an 1,2-migration to form a nitrogen-containing molecule such as primary amine or amide. Therefore, this reaction is generally known as the Schmidt reaction.[2] In particular, the reaction between a hydroazoic acid and a carboxylic acid to yield a primary amine with one less carbon atom by decarboxylation is referred to as the Schmidt rearrangement,[3] Schmidt degradation,[4] or Schmidt decarboxylation.[5] In comparison, the reaction between a hydroazoic acid and a carbonyl compound, generally yielding two possible amides from a ketone or formamide from an aldehyde, is known as the Schmidt rearrangement[6] or Schmidt transformation.[7] Today, the scope of the Schmidt reaction has been extended to include reactions between hydroazoic acid or alkyl azide and other molecules that can form carbocation intermediates under acidic conditions, such as olefins,[4o,8] tertiary alcohols,[9] and some secondary alcohols (e.g., benzhydrols).[3k] As a result, the Schmidt reaction is very versatile and has the advantages of simplicity, readily available reactants, mild reaction conditions, and a certain level of functional group tolerance.[2h] For example, this reaction is often carried out in sulfuric acid,[10] and hydroazoic acid can be generated *in situ* from sodium azide.[2h,4n,10a,10d]

For the degradation of carboxylic acid, factors that may affect the reaction outcome are the ratio of sulfuric acid/carboxylic acid, the reaction temperature and the dilution extent of sulfuric acid.[4o] Even though some of the Schmidt degradations of carboxylic

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

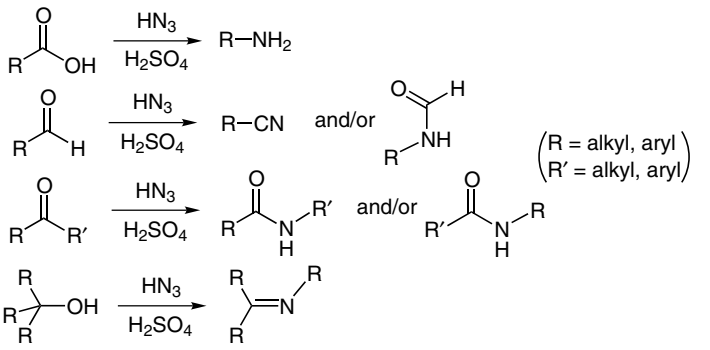
acids are known to be quantitative,[4n] the decarboxylation of carboxylic acids with chain branching at the α-position often gives amines in yields less than the theoretical values, along with the formation of some by-products, such as carbon monoxide, ketones, alcohols, and ammonia.[4o] However, it is intriguing that the reaction between sodium azide and 2-phenyl-2-methylhexanoic acid in sulfuric acid gives 55% aniline.[10a]

The Schmidt reaction between hydroazoic acid and aldehyde often gives formamide.[10d] However, the reaction with benzaldehyde produces both benzonitrile and formanilide, with the yields varying from 70% and 13% to 5% and 50%, respectively, when the ratio of sulfuric acid/benzaldehyde changes from 0.72 to 5.4.[11]

It should be pointed out that the reaction between hydroazoic acid and ketone is much more complicated, yielding two possible amides by the migration of different alkyl or aryl groups, and the ratio of two amides depends on the strength of acid and the migratory aptitude of the two groups. Generally speaking, the aryl group is preferred over the alkyl group for the migration from aminodiazonium ion,[12] and the migrating tendency correlates well with the Hammett substituent constant, in which an electron-donating group on aryl facilitates the migration while an electron-withdrawing group decreases the migrating ability.[13] For example, the migratory aptitude in diarylethylene is found in the order of *p*-anisyl > *p*-tolyl > *p*-biphenyl > phenyl > *p*-chlorophenyl > methyl.[8c] However, such a trend does not always apply to the Schmidt reaction of ketones, where the electronic effect might not be as apparent as that in diarylethylenes.[14] For example, both *p*-chloro-*p*′-methoxybenzophenone and *p*-nitro-*p*′-methoxybenzophenone give two amides in 1:1 ratio.[8b] In addition, the strength of acid also affects the constitution of products. For example, the Schmidt reaction of adamantan-2-one in methanesulfonic acid yields 88% 4(e)-methanesulfonoxyadamantan-2-one and 11% 4-azatricyclo[4.3.1.1^{1,8}]undecan-5-one whereas the same reaction in methanesulfonic acid-acetic acid, water, trichloroacetic acid or trifluoroacetic acid gives 40–61% of bicyclo[3.3.1]non-6-one-3-carbonitrile and 27–60% of 4-azatricyclo[4.3.1.1^{1,8}]undecan-5-one, and also produces 4-acetoxy-adamantan-2-one, 4-hydroxyadamantan-2-one, and 4-azatricyclo[4.3.1.1^{1,8}]-undecan-5-one in sulfuric acid–acetic acid.[15] Moreover, the particular reaction of benzyl azide may give a normal Schmidt reaction product and the unexpected *Mannich Reaction* product, and the ratio of these two products varies, depending on the acid applied.[16] For example, when $TiCl_4$ is used, the Schmidt product is favored, whereas in the presence of TfOH, the Mannich product predominates.[16b] Furthermore, solvent also affects the reaction outcome, even though most reactions are carried out in chloroform. For example, the reactions in ether or benzene in the presence of a 76% sulfuric acid take place in two different pathways, in which the reaction in benzene/76% sulfuric acid is fast and all the substrates remain in the sulfuric acid phase, whereas the reaction in ether is much slower and the reactants stay in the ether phase.[6e]

The Schmidt reaction of a simple cyclic ketone yields lactams with the ring expanded,[2g,2h] while the intramolecular Schmidt reaction of cyclic ketone with an azido group at the side chain leads to the formation of bicyclic lactams with nitrogen at the position of fusion.[2h,17] It is interesting that the reaction between a cyclic ketone and 2-azido ethanol can form either a lactam or a lactone by means of the treatment with a different base, in which the lactam is formed when the reaction system is treated with KOH, whereas lactone is generated when $NaHCO_3$ is used as the base.[18] Especially, the reaction between 4-*tert*-butylcyclohexanone and 3-azido-2-methyl-2-phenylpropanol gives lactam in 19:1 stereoselectivity.[19]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

For the degradation of carboxylic acid, it is known that the reaction involves an acyl azide intermediate, in a manner similar to the *Curtius Rearrangement*,[2g] as shown in Scheme 1. Similar to the acid-catalyzed esterification of alcohol, it is assumed that the carbonyl oxygen is protonated rather than the hydroxyl oxygen. However, for the Schmidt reaction of ketones, it is well accepted that the reaction undergoes in two different routes, both involve the α-hydroxyhydrazidium ion arising from the nucleophilic addition of hydroazoic acid to the protonated carbonyl group.[2m,20] The resulting α-hydroxyhydrazidium ion may rearrange to amides along with the evolution of nitrogen, and the ratio of amides produced depends on the inherent migratory aptitudes of both groups and the abilities of the group acting as the stationary group to stabilize the positive charge. Alternatively, the α-hydroxyhydrazidium ion undergoes dehydration to form iminodiazonium ion,[6d] and the stereospecific migration of the group *antiperiplanar* to the azido group produces an acylium ion, which upon hydration forms the corresponding amide,[2m] as shown in Scheme 2. In this mechanism, the ratio of amides depends on the population of *syn*- and *anti*-iminodiazonium ions arising from different steric repulsions in the transition state of dehydration, which cannot isomerize but may interchange into each other only through the hydration and dehydration process. If the hydration and dehydration process is fast enough, then two iminodiazonium ions can quickly reach an equilibrium, this situation is controlled by the migratory tendency of substituents in the hydroxyhydrazinium ion.[2m,14,20,21]

D. MODIFICATION

This reaction has been extensively modified. First, the Schmidt reaction is often carried out in a halogenated solvent, such as chloroform, so there exists a potential to form explosive multi-azides. For this matter, DME is suggested as the solvent,[22] or polyphosphoric acid is applied as both acid and reaction medium.[6e,7,23] Second, alkyl azide, retaining the important dipolar character of the azido group, has been widely used for the Schmidt reaction,[6c,16b,17,24] even though it is much less nucleophilic than hydroazoic acid.[2g] In addition, it has been suggested that a higher yield could be obtained for the degradation of succinic acid if it were converted into succinic anhydride before the degradation.[25] Other modifications include the photoinduced Schmidt reaction,[26] the P_2O_5/SiO_2 catalyzed one-pot reaction,[2e] the ionic exchange resin[2j] or silica sulfuric acid[2f] catalyzed Schmidt reaction, the trimethylsilyl azide[3h] or azidotrimethylsilane[2b,3g] mediated Schimdt reaction, and the transition metal activated Schmidt reaction. For example, the reaction between alkyl azide and gold (I) activated alkynes has been used in the preparation of multisubstituted pyrroles;[24a] likewise, mercury salt has been used to promote the Schmidt reaction,[8a] which has the following advantages: the wide applicability, e.g., to even 1,2-disubstituted olefins rather than to only tertiary, allylic, benzylic, or propargylic alcohol to form a stable carbocation intermediate under strong acid conditions as required by the normal Schmidt reaction; tolerance to acid-labile functionalities; and no carbocation rearrangement before the cyclization/rearrangement, which usually occurs in the acid-promoted Schmidt reactions.[2l,8a]

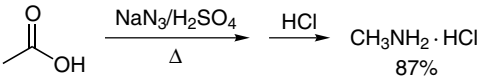
E. APPLICATIONS

The degradation of carboxylic acid has been used for the preparation of amines,[2l,4o,10a,27] amino acids,[28] and structural elucidation, especially via ^{14}C labeling.[4n] The reaction with carbonyl compounds has an even wider application in organic synthesis.

F. RELATED REACTIONS

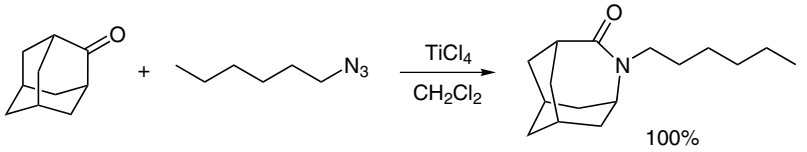
This reaction is related to the *Curtius Rearrangement*, *Hofmann Rearrangement*, *Lossen Rearrangement*, and *Stieglitz Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4o.

A mixture of 20.0 g 99.5% pure acetic acid (0.33 mol), 232 g concentrated sulfuric acid in chemical purity (2.37 mol), and 27.9 g NaN_3 (0.43 mol) was stirred at 60°C. The methylamine was collected in concentrated HCl, which was evaporated to afford 21.5 g crude methylamine hydrochloride, m.p. 186–220°C. The crude product was recrystallized from absolute ethanol to give 19.5 g beautiful plates without improvement for melting point, in a yield of 87%, in good agreement with the 89% yield of carbon dioxide obtained. In addition, sodium azide was found to decompose ~ 26%.



Reference 16b.

To a mixture of 119 mg 2-adamantanone (0.79 mmol), 200 mg 1-azidohexane (1.58 mmol), and 2.5 mL methylene chloride in an ice bath was added 380 mg $TiCl_4$ (2.0 mmol) dropwise. The reaction was allowed to warm to room temperature, with immediate gas evolution noted. A precipitate formed after 15 min, but the suspension was stirred for a total of 16 h, at which time it was diluted with 20 mL EtOAc and partitioned between 200 mL EtOAc and 30 mL saturated $NaHCO_3$ solution. The organic layer was washed with 30 mL brine and dried over anhydrous Na_2SO_4. Upon evaporation of the EtOAc, the residue was purified by flash column chromatography with EtOAc/hexane (1:4) as the eluent to give 197 mg 4-hexyl-4-azahomoadamantane, as a clear oil, in a yield of 100%.

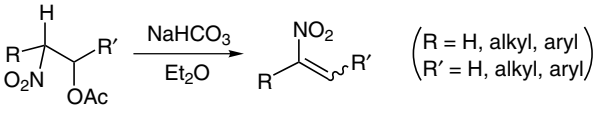
Schmidt-Rutz Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Schmidt and Rutz in 1928.[1] It is the synthesis of nitro-olefins by means of the treatment of acetates of α-nitro-alcohols with sodium bicarbonate and is generally known as the Schmidt-Rutz reaction.[2] Occasionally, it is also referred to as the Schmidt-Rutz degradation.[3] This reaction is suitable for the α-nitro esters with one proton at the α-carbon bonding to the nitro group;[4] however, such restriction is not strictly followed as shown in the formation of 1-nitro-olefins.[5] In addition, the Schmidt-Rutz reaction is applicable to the substrates without any other base-labile functional groups and usually gives nitro-olefins in good yields.[4b,4c,6,7] It has been reported that the best yields can be achieved from the esters of nitro-alcohols with nine or more than nine carbon atoms.[7b] Besides sodium bicarbonate, other mild bases such as potassium bicarbonate, sodium carbonate, and even sodium acetate can be used in this reaction.[2f,4c] The resulting nitro-olefins can be reduced to amines, so that the Schmidt-Rutz reaction has become one of the powerful methods for amines with a definite structure free of isomers.[4b] Moreover, this reaction has been widely used in carbohydrate chemistry, due to a good crystalline capability of nitro carbohydrate acetates, which easily crystallize even in the presence of a large amount of other carbohydrate acetates.[7a]

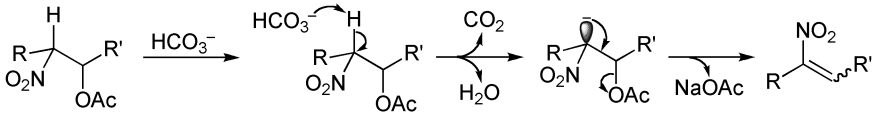
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Due to the presence of a nitro group, the α-proton in α-nitro-alcohol acetate is activated and can easily be deprotonated, so that subsequent elimination occurs once the carbanion is generated, as shown here.



D. MODIFICATION

This reaction has been extended to the sulfonate of α-nitro-alcohol, which undergoes the reaction in the presence of pyridine.[4a]

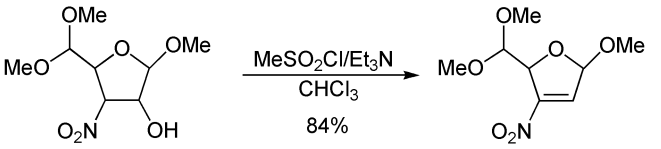
E. APPLICATIONS

This reaction has a general application in the preparation of nitro-olefins.

F. RELATED REACTIONS

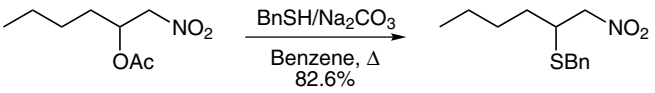
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

To a mixture of 0.508 g methyl 3-deoxy-3-nitro-β-D-ribofuranoside-1,4-dialdose 5,5-dimethyl acetal, 1.0 g triethylamine, and 7.0 mL $CHCl_3$, was gradually added 0.95 g methanesulfonyl chloride. After being stirred at 20°C for 1 h, 15 mL water was added, and the stirring was continued for 0.5 h. The $CHCl_3$ layer was separated, and the aqueous layer was extracted with CH_2Cl_2. The combined organic layers were washed with 1% HCl, saturated $NaHCO_3$ solution, and brine and then dried over $MgSO_4$. Vacuum evaporation of the solution afforded 430 mg methyl 2,3-dideoxy-2-ene-3-nitro-β-D-ribofuranoside-1,4-dialdose 5,5-dimethyl acetal as a brown gum, in a yield of 84%.



Reference 9.

A mixture of 18.9 g 2-acetoxy-1-nitrohexane (0.1 mol), 12.4 g benzyl mercaptan (0.1 mol), 5.3 g sodium carbonate (0.05 mol), and 25 mL benzene was refluxed for 3 h. The sodium acetate was filtered from the benzene and dissolved in water, and the aqueous solution was extracted with benzene. The combined benzene solution was dried over $MgSO_4$. Upon removal of benzene, 26.2 g 2-benzylthio-1-nitrohexane was obtained, which was further purified by vacuum distillation to give 20.9 g product, in a yield 82.6%, b.p. 140°C at 0.1 mmHg.

Other references related to the Schmidt-Rutz reaction are cited in the literature.[10]

Schmittel Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

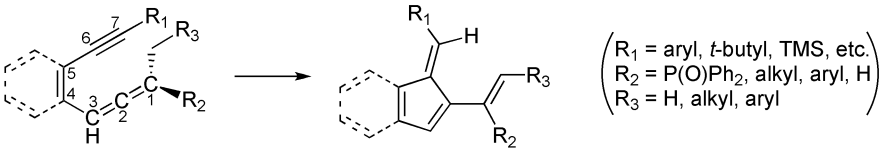
This reaction was first reported by Schmittel et al.[1a] and Gillmann et al.[1b] concurrently in 1995. It is an intramolecular C^2-C^6 cyclization of hepta-1,2,4-triene-6-yne (i.e., enyne-allene) to form a five-membered cyclic structure via a methyl fulvene biradical intermediate and is generally known as the Schmittel cyclization.[2] Occasionally, this reaction is also referred to as the Schmittel reaction[2i,2l,2m,2q,3] or Schmittel ring closure reaction.[2q]

Before the discovery of the Schmittel cyclization, the enyne-allenes were generally considered to undergo C^2-C^7 cyclization to give aromatic compounds, i.e., the *Myers-Saito Cyclization*.[4] Theoretical studies indicate that the Schmittel cyclization is disfavored by 25 Kcal/mol with respect to the *Myers-Saito Cyclization*,[2q] because aromaticity is attained in the *Myers-Saito Cyclization*,[2c] whereas the Schmittel cyclization proceeds via a not completely delocalized π-radical intermediate with a slightly alternating single and double bond.[2r] As a result, the Schmittel cyclization is endothermic at $\sim$10 Kcal/mol, with an activation barrier of 35 Kcal/mol.[2n,2p,2s,4] However, enyne-allenes with an aryl group at the alkynyl terminus can easily undergo the Schmittel cyclization,[1] due to the stabilization of biradical intermediate from the benzylic group.[5] Likewise, the Schmittel cyclization is also facilitated by benzannulation with enyne-allenes.[2q,6] In addition, enyne-allenes with a sterically bulky group (e.g., *t*-butyl, trimethylsilyl) at the alkynyl terminus[6b,7] or eight or nine-membered cyclic enyne-allenes[2s] also undergo the Schmittel cyclization because the steric hindrance burdens the occurrence of the *Myers-Saito Cyclization*. For example, benzannulation lowers the reaction barrier from 30 to 25.2 Kcal/mol for the Schmittel cyclization, whereas it lowers the activation energy only $\sim$ 1.2 Kcal/mol for the corresponding *Myers-Saito Cyclization*, although the endothermicity is lowered by only 1.0 Kcal/mol.[2l] To an extreme extent, the benzannulated enyne-allene with an aryl group

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

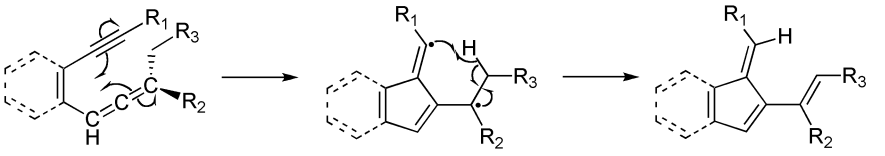
at the alkynyl terminus proceeds via the Schmittel cyclization in mild thermal condition.[6,8] The occurrence of the Schmittel cyclization is attributed to the formation of a strong sp^2-$sp^2\sigma$ bond from sp-hybridized carbons.[2c] Moreover, oxyanion substitute of enyne-allene also switches the preferences of product formation from a biradical to a polar closed-shell singlet, and this effect is more apparent for the Schmittel cyclization.[2p]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction, similar to the competing reaction of the *Myers-Saito Cyclization*, proceeds via a biradical intermediate,[2d,2j–2l,2n,2o,2q,3] as supported by the trapping of a biradical intermediate with 1,4-cyclohexadiene[10] and the experimental fact that the change of the polarity of solvent has no effect on the reaction rate and the ratio of products formed, indicating the absence of a zwitterionic intermediate.[2c] The proton abstraction by the vinyl radical leads to the formation of fulvene derivatives. An illustration of this reaction is provided here.



D. MODIFICATION

The benzannulation and oxyanion of enyne-allenes to facilitate the Schmittel cyclization can be considered as modifications of this reaction.

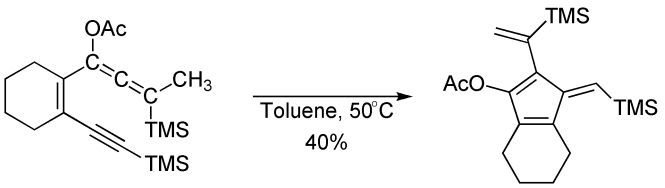
E. APPLICATIONS

This reaction has important application in organic synthesis[2c] as well as in double-stranded DNA cleavage.[2c,3]

F. RELATED REACTIONS

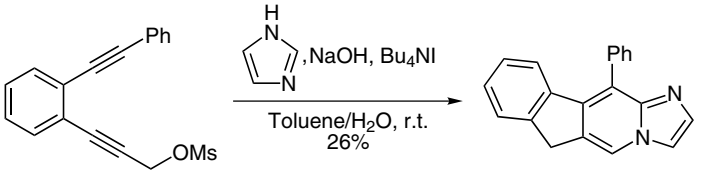
This reaction is related to the *Bergman Cyclization, Moore Cyclization,* and *Myers-Saito Cyclization.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

A solution of 45 mg 1-(1′-acetoxy-3′-methyl-3′-trimethylsilyl)-2-(2″-trimethylsilyl)-acetyenyl cyclohexene (0.13 mmol) in 0.42 mL toluene was heated to 50°C for 3 h. Then solvent was removed in vacuo, and the residue was purified by flash chromatography with 10% Et_2O/pentane to give 18 mg 4,5,6,7-tetrahydro-2-(1-trimethylsilylvinyl)-1-(trimethylsilylmethylidene) indenyl acetate, in a yield of 40%.



Reference 2d.

To a stirred mixture of 10 mg imidazole (0.15 mmol), 27 mg tetrabutylammonium iodide (0.073 mmol), and 0.52 mL 50% aqueous NaOH in 0.41 mL toluene was added 47 mg 3-(*o*-(2′-phenyl)acetyenyl) phenyl propargyl methanesulfonate (0.15 mmol). After the mixture was stirred at room temperature for 15 min, 0.5 mL toluene and 0.5 mL water were added. The organic layer was separated, washed with water, dried over $MgSO_4$, and concentrated. The residue was purified by column chromatography using Et_2O/MeOH (100:3) as the eluent to afford 11 mg 11-phenyl-6*H*-indeno[1,2-*d*]imidazo[1,2-*a*]pyridine as a pale yellow solid, in a yield of 26%.

Other references related to the Schmittel cyclization are cited in the literature.[10]

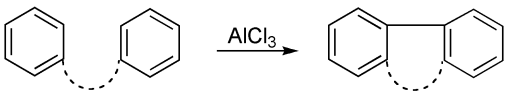
Scholl Reaction
(Scholl Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Scholl in 1910.[1] It is a Lewis acid-catalyzed coupling of aromatic compounds while eliminating two of the aryl-bound hydrogens.[2] Therefore, it is generally known as the Scholl reaction,[2,3] or Scholl condensation.[2a,4] Occasionally, this reaction is also referred to as the Scholl oxidation.[2a,3b] The commonly used Lewis acid is $AlCl_3$,[3c,3v,3x,3cc,3ii] because some other Lewis acids may lead to the formation of by-products. For example, the use of molten $SbCl_3$ results in the formation of a Scholl condensation product as well as some hydro-aromatics arising from hydrogen redistribution.[4g] In addition, the alumina pillars in the clay are also found to catalyze this reaction.[3k] Although this reaction does not take place in the presence of the most protic acids (e.g., 40% HF, benzenesulfonic acid, trifluoroacetic acid, FSO_3H, 98% sulfuric acid, liquid hydrochloric acid),[2b] it does occur in anhydrous HF.[5] Moreover, this reaction is facilitated by the addition of NaCl[2b,3c] or trace amounts of HCl or water.[6] Generally, the yield of this reaction is relatively low,[2b] except for some intramolecular reactions, as indicated by the 66% conversion of 1-phenylbenz[a]anthracene to dibenzo[a,1]pyrene.[7] Presumably, the most exciting result by the Scholl reaction is to form as many as 126 new aryl-aryl bonds in a single step from dendritic oligophenylenes.[8]

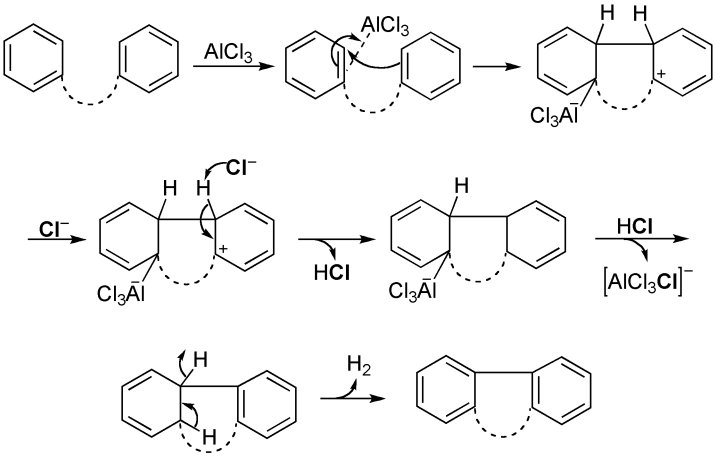
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although a mechanism involving a radical cation has been proposed for the Scholl reaction, as indicated by the paramagnetic properties of many polycyclic aromatic hydrocarbons (PAHs) when they are treated with Lewis acids or concentrated sulfuric acid,[3l] it is assumed that the Scholl reaction occurs in a manner similar to the *Friedel-Crafts Alkylation*,[9] involving an arenium cation instead of a radical cation.[3c,6] In detail, the Scholl reaction of hexaphenylbenzene involves the complexation between a Lewis acid and aromatic nucleus, electrophilic addition, and deprotonation,[2a] as illustrated here. In the presence of NaCl or HCl, chloride is beneficial for the elimination of aryl hydrogen by the formation of hydrogen chloride, as indicated by the bold chloride.



D. MODIFICATION

This reaction has been modified by the use of alumina pillars in the clay[3k] or anhydrous HF[5] as the promoter.

E. APPLICATIONS

This reaction has an important application in the production of polycyclic aromatic hydrocarbons[8] and carbon nanotube segments.[9]

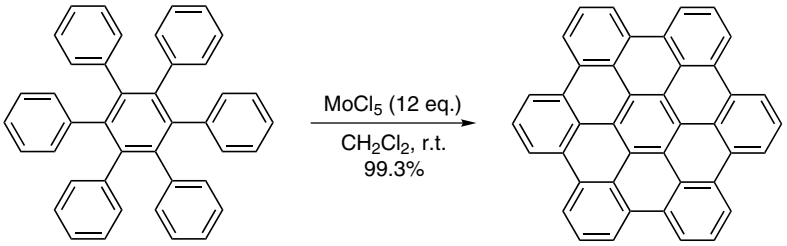
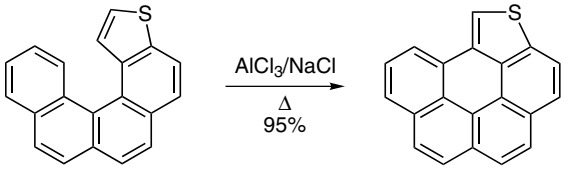
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To 10 mL dichloromethane containing 0.1022 g 1,2,3,4,5,6-hexaphenylbenzene (0.187 mmol) was added 0.613 g $MoCl_5$ (2.24 mmol, 12 eq.). The resulting mixture was stirred under nitrogen at ambient temperature for 12 h. Methanol (10 mL) was added to the solution, and the stirring was continued for an additional hour. The reaction mixture then was further diluted with dichloromethane and methanol. The resulting hexa-*peri*-benzocoronene was filtered through a high density sintered glass filter, and washed thoroughly with methanol, dichloromethane, methanol, distilled water, methanol, dichloromethane, tetrahydrofuran, benzene, and again dichloromethane. The crude hexabenzocoronene was dried in the air for 24 h and weighed. In addition, the filtrate was diluted with distilled water and extracted with dichloromethane. The organic layer was washed with distilled water, dried over $MgSO_4$, and evaporated to dryness. The combined weight of hexa-*peri*-benzocoronene was 0.0992 g, in a yield of 99.3%.



Reference 2b.

A mixture of 100 mg aromatic starting material (0.35 mmol), 300 mg NaCl (5.1 mmol), and 1.50 g $AlCl_3$ (11.2 mmol) was heated at 140°C (and the reaction might be monitored by TLC). When the reaction was complete, water was added slowly to the molten mixture under stirring to yield a yellow-orange precipitate, which was taken up by 200 mL benzene, The organic layer was washed with water and saturated $NaHCO_3$ solution, and dried over $MgSO_4$. Upon filtration and evaporation, the residue was purified by column chromatography on alumina using benzene as the eluent. The collected fraction was dried, and the residue was recrystallized twice from methylcyclohexane to afford 95 mg pyreno[5,4,3-cde]benzo[b]thiophene as long orange yellow needles, in a yield of 95%, m.p. 298–299°C.

Other references related to the Scholl reaction are cited in the literature.[10]

Schöllkopf Bis-Lactim Ether Method

(Schöllkopf Bis-Lactim Method)

A. GENERAL DESCRIPTION OF THE REACTION

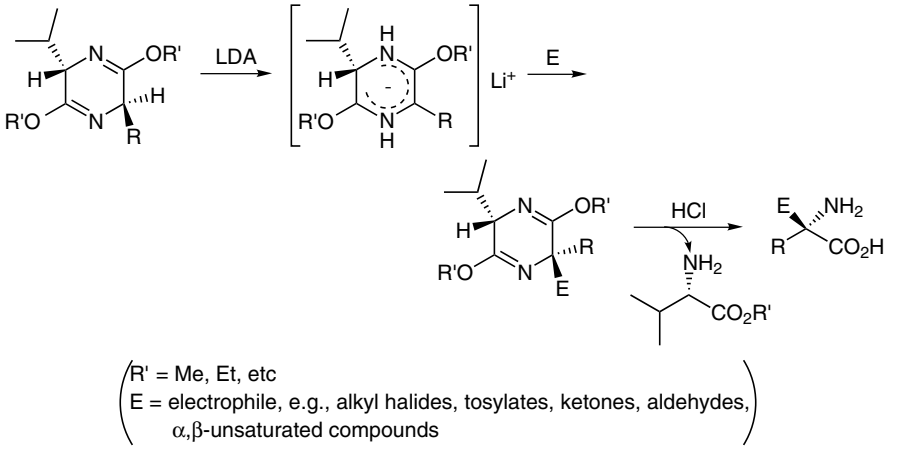
This reaction was first reported by Schöllkopf in 1979.[1] It is a synthesis of an unnatural nonproteinogenic amino acid from the lithiated enolate equivalent of a simple amino acid (e.g., glycine, alanine and valine), which involves the diastereoselective alkylation of the lithiated bis-lactim ether of an amino acid with an electrophile[2] or an *Aldol Reaction* or *Michael Addition* to an α,β-unsaturated molecule[3] and subsequent acidic hydrolysis. Therefore, the intermediate of the bis-lactim ether prepared from corresponding amino acids is generally referred to as the Schöllkopf bis-lactim ether,[3a,3b,4] Schöllkopf chiral auxiliary,[2,5] Schöllkopf reagent,[3a,3b,6] or Schöllkopf bis-lactim ether chiral auxiliary.[2a,7] Likewise, the Schöllkopf bis-lactim ether mediated synthesis of chiral nonproteinogenic amino acid is known as the Schöllkopf bis-lactim ether method,[2b,6b] Schöllkopf bis-lactim method,[6b] or Schöllkopf methodology.[6a] In addition, the reaction between a lithiated Schöllkopf bis-lactim ether and an electrophile is termed as the Schöllkopf alkylation,[8] while the addition of such lithiated intermediate to an α,β-unsaturated compound is referred to as the Schöllkopf-type addition.[8]

To smoothly prepare the Schöllkopf bis-lactim ether from an amino acid, it is important to add 2,6-di-*tert*-butylpyridine to the reaction system.[9] It has been reported that the alkylation of the lithiated Schöllkopf bis-lactim ether in diethyl ether contains high levels of π-facial discrimination,[3a,4m] where the tosylate or halide electrophile is introduced into the opposite side of the bulky group on the bis-lactim ether ring.[8] Such stereochemical outcome for the Schöllkopf alkylation is known as the Schöllkopf's rule or Schöllkopf's observation.[8] However, this rule is not always obeyed, and the reaction is probably controlled by both

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

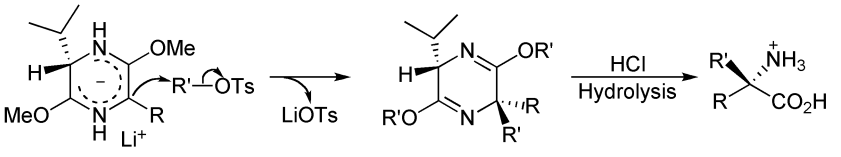
reagent and substrate.[3b] For example, the reaction between the Schöllkopf bis-lactim ether with a benzyl group at the 3-position and methyl iodide or deuterium chloride all give products in favor of *trans* isomers, with a *trans*/*cis* ratio of 4:1; whereas the alkylation with a triflate leads to the formation of a racemic mixture.[8] In addition, due to the low solubility of the lithiated Schöllkopf bis-lactim ether in diethyl ether, a small amount of THF is necessary to ensure a homogenous reaction condition.[4m] For comparison, the conjugated addition of the lithiated Schöllkopf bis-lactim ether to the α,β-unsaturated compounds may yield products with high levels of stereochemical control at both the α- and β-positions.[3b] Furthermore, the lithiated Schöllkopf bis-lactim ether can add to aldehydes or ketones to yield *threo* diastereomers.[4i] It should be emphasized that to ensure a complete hydrolysis of the Schöllkopf bis-lactim ether, it is better to use a higher concentration of HCl,[4d] rather than a mild acidic condition.[10]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that the alkylation can be considered as a simple nucleophilic substitution, probably via a S_N2 mechanism. For the case of alkylation, due to the steric effect of isopropyl group on the bis-lactim ether ring, the electrophile enters from the opposite side. However, for the alkylation with an alkyl triflate, the reaction could be too fast to display the facial discrimination. For comparison, a "compact" and "relaxed" transition state has been proposed to rationalize the stereochemical outcome for the conjugated addition of the lithiated Schöllkopf bis-lactim ether to an α,β-unsaturated compound, such as α,β-unsaturated phosphonate.[2c] An illustrative diagram is provided here for the alkylation with a general alkyl tosylate.



D. MODIFICATION

This reaction has been modified by exchanging the lithium ion of the Schöllkopf bis-lactim ether intermediate with Sn(II),[11] Cu(I),[12] or Ti(IV)[13] to enhance the diastereoselectivity in *Aldol Condensation* and the *Michael Addition*.

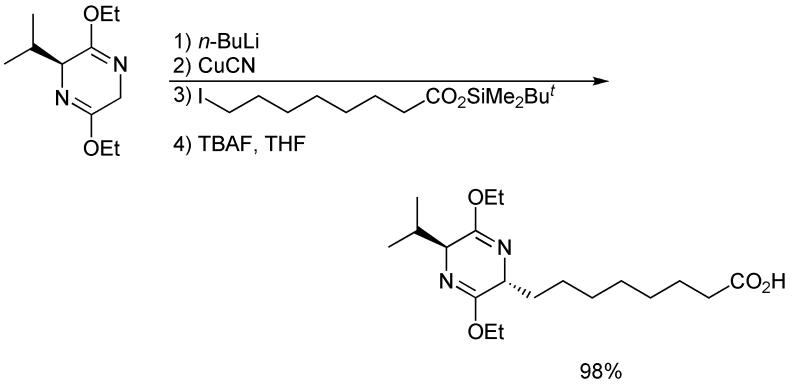
E. APPLICATIONS

This reaction is very useful for the preparation of unnatural, nonproteinogenic amino acids that are used for the synthesis of immunostimulants, hormones, synthetic enzymes, and peptide drugs with special biological properties.[4k]

F. RELATED REACTIONS

N/A

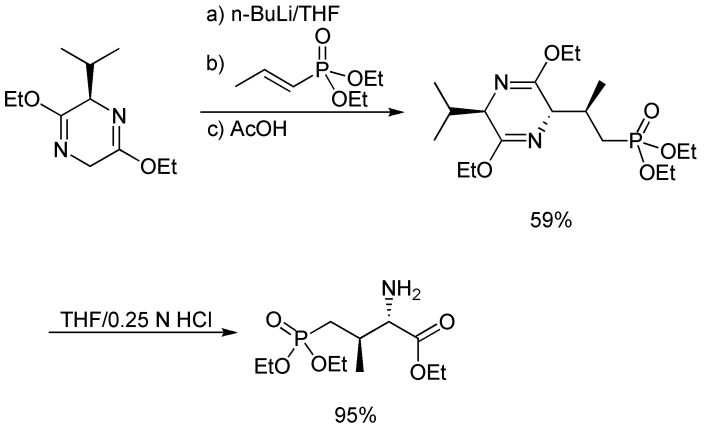
G. CITED EXPERIMENTAL EXAMPLES



Reference 4d.

To 20 mL THF solution containing 2.50 g 6(*S*)-isopropyl-2,5-diethoxy-3,6-dihydropyrazine (11.8 mmol) at −78°C, was added under argon 7.05 mL 1.67 M *n*-BuLi in hexane (1 eq.) dropwise over 10 min. After being stirred for an additional 20 min, the reaction mixture was transferred via a Teflon cannula to 20 mL THF solution of 0.527 g CuCN (5.89 mmol, 0.5 eq.) over 30 min, so that all of CuCN dissolved over this period. Then the solution was cooled to −78°C again, and 20 mL THF solution of 3.39 g *tert*-butyldimethylsilyl 8-iodooctanoate (8.83 mmol, 1.5 eq. with respect to CuCN) precooled to −78°C was transferred via a Teflon cannula. The reaction mixture was then warmed to −23°C and was stirred at this temperature for a further 5 h, after which time the reaction was stored at −23°C for 18 h. The reaction was then quenched with 30 mL concentrated NH_3/saturated NH_4Cl solution (1:9); the resulting mixture was extracted with 750 mL Et_2O in portions, and the combined organic layers were washed with concentrated

NH_3/saturated NH_4Cl solution (1:9, 3 × 300 mL) and dried over Na_2SO_4. Upon removal of solvent in vacuo, 1.44 g crude yellow oil was yielded. To this crude 8-(*R*)-(4(*S*)-isopropyl-3,6-diethoxy-2,5-dihydropyrazin-2-yl)-*tert*-butyldimethylsilyl octanoate (assumed to be 5.89 mmol based on CuCN) under argon was added 17.7 mL 1.0 M tetra-*n*-butylammonium fluoride (TBAF) THF solution, and the mixture was stirred at room temperature for 75 min and then quenched with 35 mL saturated NH_4Cl solution. The reaction mixture was extracted with Et_2O (2 × 125 mL), and the combined organic layers were dried over Na_2SO_4. Upon removal of solvent in vacuo, the 4.77 g white solid was purified by column chromatography using Et_2O/hexane (1:1) containing 0.1% formic acid as the eluent ($R_f = 0.4$) to afford 2.06 g 8-(*R*)-(5(*S*)-isopropyl-3,6-diethoxy-2,5-dihydropyrazin-2-yl)octanoic acid, in a yield of 98% (based on CuCN). The chiral purity was checked by chiral HPLC as single product. After hydrolysis of this product with 1.0 M HCl, the expected amino acid could be obtained. (*Note:* There is an inconsistency of weight in this experimental procedure: from 1.44 g 8-(*R*)-(4(*S*)-isopropyl-3,6-diethoxy-2,5-dihydropyrazin-2-yl)-*tert*-butyldimethylsilyl octanoate, it is impossible to produce 2.06 g 8-(*R*)-(5(*S*)-isopropyl-3,6-diethoxy-2,5-dihydropyrazin-2-yl)octanoic acid by removal of the dimethyl-*tert*-butylsilyl group.)



Reference 3b.

To 1050 mL THF solution containing 22.4 g 3(*R*)-isopropyl-2,5-diethoxy-3,6-dihydropyrazine (105.5 mmol) at −78°C, was added 42.2 mL 2.5 M *n*-BuLi in hexane, and the resulting solution was stirred for 1 h. Then 116 mL THF solution of 10.35 g propenylphosphonate (58.1 mmol) was added dropwise. After being stirred at −78°C until the completion of the reaction, the reaction mixture was quenched with AcOH and warmed to room temperature. Upon removal of the solvent in vacuo, the resulting material was diluted with water and extracted with EtOAc. The combined organic layers were dried over Na_2SO_4 and evaporated, and the residue was purified by flash column chromatography (silica gel, EtOAc/hexane, 2:1–4:1) to yield 13.4 g (2*S*,5*R*,1′*R*)-3,6-diethoxy-2-[2-(diethoxyphosphoryl)-1-(methyl)ethyl]-2,5-dihydro-5-isopropylpyrazine as a colorless oil, in a yield of 59%, $R_f = 0.46$ (EtOAc).

A mixture of 9.37 g (2*S*,5*R*,1′*R*)-3,6-diethoxy-2-[2-(diethoxyphosphoryl)-1-(methyl)-ethyl]-2,5-dihydro-5-isopropyl-pyrazine (24.0 mmol), 200 mL THF, and 240 mL 0.25 *N* HCl was stirred at room temperature for 24 h. Then the solvent was evaporated to half of its initial volume (< 40°C), and the aqueous solution was made basic (pH = 10) by the

addition of $NaHCO_3$ followed by concentrated ammonia. The aqueous layer was extracted with CH_2Cl_2, and the combined organic layers were dried over Na_2SO_4 and evaporated. The residue was purified by silica gel flash column chromatography (EtOAc to EtOAc/MeOH (8:1)) to afford 6.4 g ethyl (2*S*,3*R*)-2-amino-4-diethoxyphosphoryl-3-methylbutanoate as a colorless oil, in a yield of 95%, $R_f = 0.36$ (EtOAc/MeOH, 10:1).

Schöllkopf Oxazole Synthesis

(Schöllkopf Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

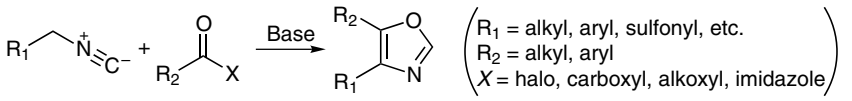
This reaction was first reported by Schöllkopf and Schröder in 1971.[1] It is the formation of a 2-unsubstituted oxazole derivative by the condensation of an α-metalated isocyanide with an acylating reagent. Therefore, this reaction is known as the Schöllkopf oxazole synthesis[2] or Schöllkopf reaction.[3]

In this reaction, the α-alkali metalated isocyanide, generated by the treatment of an isocyanide with an α-hydrogen by a regular base such as butyllithium, potassium *tert*-butoxide, sodium hydride, DBU, and even triethylamine, functions as both nucleophile and electrophile,[4] and reacts with a suitable acylating reagent, including acyl halide, amide,[1] ester,[4] anhydride,[5] and acyl imidzole.[6] During this reaction, the intermediate of α-isocyanoketone is not isolable, and cyclizes to give oxazole at the workup stage.[4] Among the formed oxazole derivatives, the substituent at the 4-position comes from the group on the methylene carbon of the isonitriles, while the substituent at the 5-position has the origin from the acylating reagent.[6] One important utility of the Schöllkopf oxazole synthesis is to prepare amino esters and amino ketones in high yields.[7]

Besides the formation of oxazole derivatives, Schöllkopf and the others have successfully extended the α-alkali metalated isocyanides to the formation of the chain-extended primary amines,[8] 2-oxazolines,[9] 2-thiazoline-4-carboxylic esters,[4] 2-imidazolines,[10] 2-pyrrolines and pyrroles,[11] thiazoles,[12] 2-imidazolin-5-ones,[4] 2-imidazolinones,[4] etc. For example, a simple reaction between lithiomethyl isocyanide with two equivalents of piperonal followed by acetylation of the intermediate with acetic anhydride affords the corresponding oxazoline.[13]

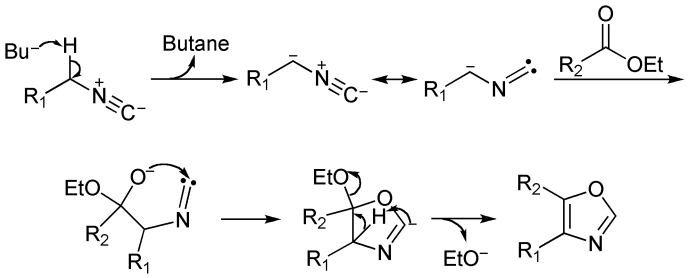
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that this reaction involves the deprotonation of an α-hydrogen to form an isocyano group stabilized carbanion that adds to the carbonyl group of the acylating agent followed by the cyclization via the attack of alkoxyl anion on the isocyano group, as illustrated here.



D. MODIFICATION

Kozikowski has extended this reaction by using selenol esters as the acylating reagent instead of the acyl chlorides, in which the activated isonitriles in the presence of a soft metal ion have shown a strong affinity for selenium.[2b] This modification is thus referred to as the Kozikowski modification.[2a]

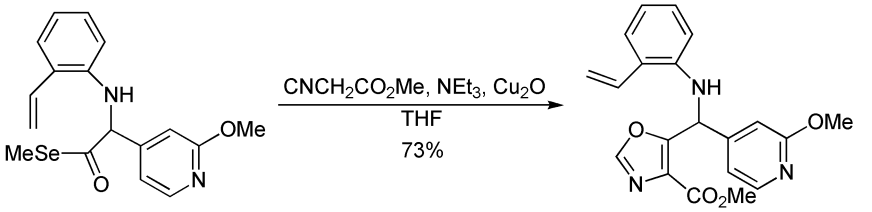
E. APPLICATIONS

This reaction has general application in the preparation of oxazole derivatives.

F. RELATED REACTIONS

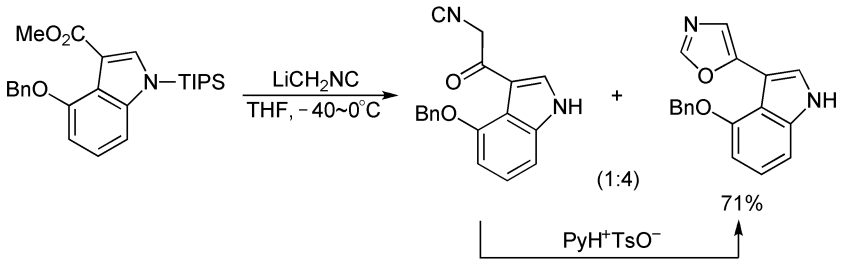
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To a mixture of 0.15 g selenol ester (0.41 mmol), 63 mg triethylamine (0.62 mmol), and 0.12 g methyl isocyanoacetate (1.21 mmol) in 5 mL anhydrous THF was added 92 mg anhydrous cuprous oxide (0.62 mmol). After being stirred at room temperature for 1 h, the reaction mixture was filtered through a pad of silica gel, which was eluted with EtOAc. The combined filtrate was concentrated in vacuo and the residue was purified by flash chromatography using EtOAc/hexane (1:3) as the eluent to afford 0.11 g oxazole ester as a colorless oil, in a yield of 73%.



Reference 3a.

To a solution of 0.827 mL methyl isocyanide (15.1 mmol) in 20 mL THF at −78°C was added 5.0 mL 1.5 M *n*-BuLi in hexanes (7.55 mmol). The mixture was stirred for 10 min and warmed to −45°C. To this solution was added 0.661 g 4-benzyloxy-3-methoxycarbonyl-1-(triisopropylsilyl)indole (1.51 mmol) in 5 mL THF dropwise. The resulting solution was stirred at −45°C for 30 min and warmed to 0°C for an additional 30 min. Then the mixture was poured into 50 mL saturated $NaHCO_3$ solution and extracted with EtOAc (3 × 30 mL). The combined extracts were dried over anhydrous $MgSO_4$, filtered, and concentrated. The residue was purified by silica gel column chromatography using ether/hexanes (2:1–3:1) to afford a 4:1 mixture of oxazole to keto isocyanide products (1:2 ratio in the original article, but 4:1 in the corresponding experimental section). The mixture of products was dissolved in 15 mL CH_2Cl_2 and treated with 0.076 g pyridinium *p*-toluenesulfonate (PPTS) (0.302 mmol) for 2 h. The mixture was concentrated and filtered through a plug of silica gel with ether as the eluent to afford 0.310 g 4-benzyloxy-3-(5-oxazolyl)indole as a white solid, in a yield of 71%, $R_f = 0.29$ (ether/hexane, 3:1). Pure material was obtained by crystallization from CH_2Cl_2, mp 167–168°C.

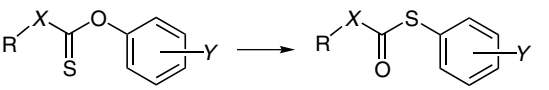
Schönberg Rearrangement
(Schönberg Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Freudenberg on the rearrangement of the methyl xanthate of diacetonehexose in 1927[1] and was subsequently studied by Schönberg on the thermal transformation of thioncarbonates (*O*-aryl) into thiolcarbonates (*S*-aryl) in 1930.[2] Therefore, it is generally known as the Schönberg rearrangement[3] or Schönberg reaction.[3a,4] This reaction has been well documented for aryl thioncarbonates (or xanthates) that lack a β-hydrogen atom,[3a,3i] whereas the thioncarbonates or xanthates with a β-hydrogen atom can also undergo the competing pyrolysis (e.g., *Chugaev Reaction*[5]) to afford olefins.[3a] It is assumed that the Schönberg rearrangement is driven by the higher nucleophilic character of the sulfur atom and the electron-donating capability of the aryl (or alkyl) group;[3i] as a result, the rearrangement is facilitated by electron-withdrawing groups at the *ortho*- and *para*-positions of the *O*-aryl moiety, which sulfur migrates to.[3h] This reaction has an important use in the conversion of phenols to thiophenols,[3i] especially for some substituted thiophenols that are difficult to attain when prepared by other methods.[3e]

B. GENERAL REACTION SCHEME

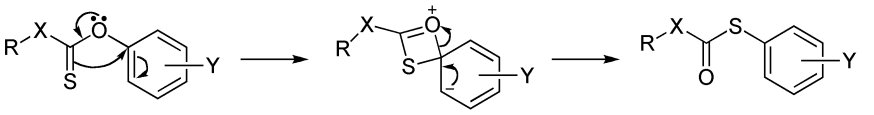


R = alkyl, aryl
X = O, S
When *Y* = ortho- or para-electron-withdrawing group, reaction is favored

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction has been found to be strictly first order in kinetics.[3h] In addition, experimental evidence has indicated that this reaction is an intramolecular reaction involving the attack of sulfur atom on the *O*-aryl ring via a four-membered cyclic transition state.[3d,3e,3g,3h] An illustrative mechanism is displayed here.



D. MODIFICATION

The yield of this reaction can be considerably improved by conducting a vapor phase pyrolysis.[3e]

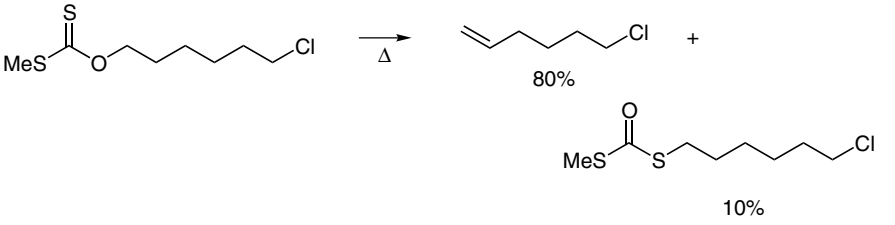
E. APPLICATIONS

This reaction has an important application in the synthesis of substituted thiophenols.

F. RELATED REACTIONS

This reaction is related to the *Chapman Rearrangement* and *Newman-Kwart Rearrangement*.

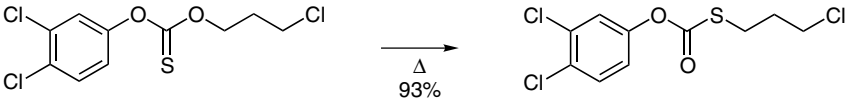
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

The yellow methyl 6-chloro-hexyl xanthate (60.0 g, 0.265 mol) was vacuum distilled at 525°C for 3.5 h in a quartz tube, which was, in advance, coupled with two traps cooled by liquid nitrogen. Still under vacuum, the first trap was warmed to room temperature, and the volatile fragments including carbonoxy sulfide and methylmercaptan were automatically transferred to the second trap, which was placed in the hood to allow the contents to

evaporate to avoid the odour. The crude pyrolysate (45 g) in the first trap was fractionated to give 25.3 g 6-chloro-1-hexene (0.21 mol, 81%), and 5.9 g S-(6-chloro-1-hexyl)-S′-methyl dithiocarbonate as a yellow liquid, in a yield of 10%, b.p. 175–176°C at 20 mmHg.



Reference 3g.

A solution of 4.83 g 3,4-dichlorophenyl chlorothionoformate (0.02 mol) in 15 mL $CHCl_3$ was added dropwise to a stirred solution of 2.83 g 3-chloro-1-propanol (0.03 mol) and 1.7 milliliters of pyridine in 15 mL $CHCl_3$ at 0–5°C. After the reaction completed, the solution was washed with 1 *N* NaOH and water, dried, and evaporated. The residue was heated at 170°C for 1 h, and the mixture was distilled at 171°C (0.6 mmHg) to yield 5.6 g 3,4-dichlorophenyl 3-chloropropanethiol carbonate, in a yield of 93%.

Other references related to the Schönberg rearrangement are cited in the literature.[5]

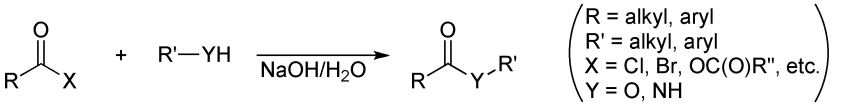
Schotten-Baumann Reaction
(Schotten-Baumann Acylation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Schotten in 1884[1] and subsequently extended by Baumann in 1886.[2] It is the acylation of alcohols and amines from acyl halide or anhydride in an aqueous alkaline solution (e.g., 1 *M* NaOH),[3] and is generally known as the Schotten-Baumann reaction[4] or Schotten-Baumann acylation.[4s,4u,5] Occasionally, it is also referred to as the Schotten-Baumann method,[4l,4o] or Schotten-Baumann esterification.[4h,4q] Likewise, the formation of benzoyl ester under these conditions is called the Schotten-Baumann benzoylation.[4i] It is assumed that the reaction would perform well if carried out in a biphasic system of water and an immiscible organic solvent (e.g., CH_2Cl_2), which has an important application in the acylation of amino acids.[4t,4x] For example, *p*-nitrohippuric acid and dibenzoylornithine (ornithuric acid) all can be prepared under these conditions.[4t] It is interesting that when tyrosine is acylated with benzoyl chloride under this condition, it forms a dibenzoyl derivative that cannot react with the diazotized sulfanilic acid; whereas histidine yields only a monobenzoyl derivative that can further react with diazonium acid.[4t] However, it has been found that when pyridine is added to scavenge the generated HCl, the reaction yield might be reduced.[4b]

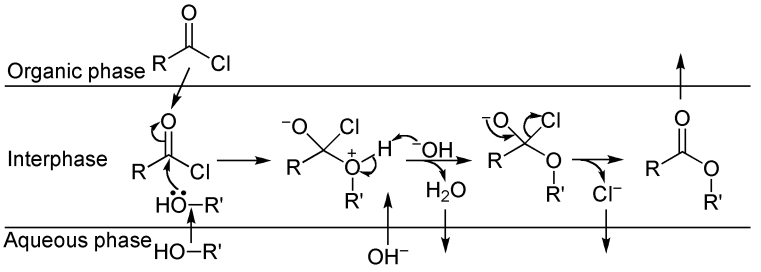
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction should occur in a manner similar to a regular acylation reaction. However, in the presence of a base, the hydrogen chloride is rapidly removed by the base, although the base may also react with acyl chloride or hydrolyze the new-formed ester. A general mechanism of the ester formation is illustrated here.



D. MODIFICATION

This reaction has been made feasible in an ionic liquid such as [bmim][BF_4]$_6$ in the presence of $KHCO_3$.[4a]

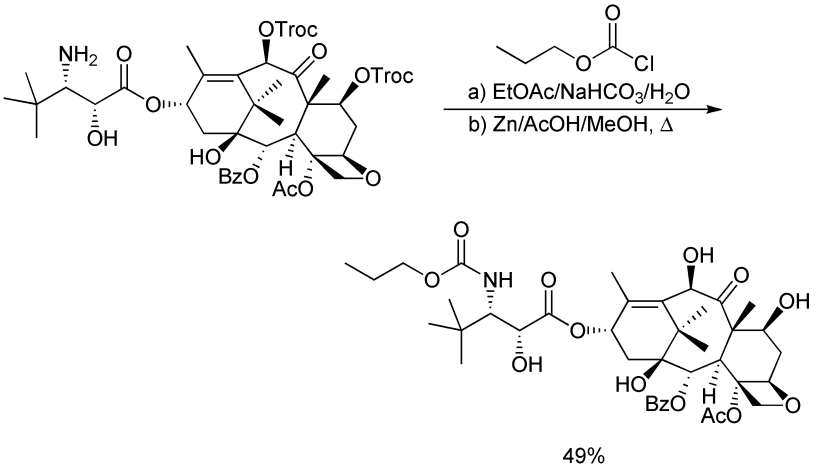
E. APPLICATIONS

This reaction has a certain application in the preparation of esters and amides.

F. RELATED REACTIONS

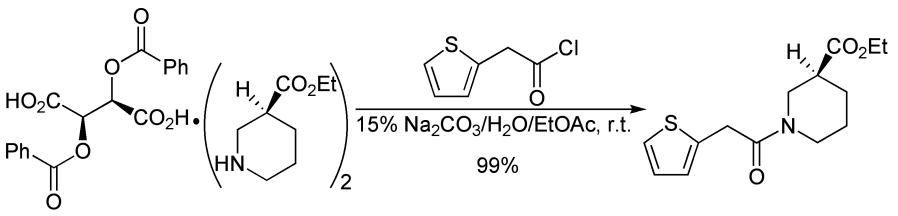
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5d.

To a mixture of 7 mL EtOAc, 10 mL saturated aqueous $NaHCO_3$ and 10 mL H_2O containing 0.10 g butitaxel starting material (0.096 mmol) was added dropwise a solution of 0.015 g propyl chloroformate (0.13 mmol, 1.3 eq.) in 1 mL EtOAc. The mixture was stirred at 24°C for 30 min and extracted with EtOAc (2 × 30 mL). The combined organic layers were washed with water and brine and dried over Na_2SO_4. Upon removal of solvent under reduced pressure, the residue was purified by silica gel flash column chromatography using EtOAc/hexane (1:3) as the eluent to afford 0.08 g carbamate. This carbamate was then mixed with 0.1 g zinc dust, 3 mL MeOH, and 3 mL acetic acid, and the mixture was heated at 60°C for 2 h. The reaction mixture was cooled to room temperature and filtered. The solvents were removed under reduced pressure, and the residue was dissolved in 15 mL EtOAc, washed with 10 mL saturated aqueous $NaHCO_3$ solution, 10 mL brine, and dried over Na_2SO_4. Upon removal of the solvent, the residue was purified by silica gel flash column chromatography using CH_2Cl_2/MeOH (20:1) as the eluent to afford 0.04 g *N*-debenzoyl-*N*-(propoxycarbonyl)butitaxel as a white solid, in a total yield of 49%, m.p. 155–157°C, $R_f = 0.49$ (EtOAc).



Reference 6.

A 5-L three-necked flask equipped with a mechanical stirrer and a dropping funnel was charged with 182 g ethyl nipecotate·dibenzoyl tartarate salt (271 mmol) followed by 590 mL EtOAc. To the rapidly stirring slurry was added 715 mL water followed by 482 mL 15% Na_2CO_3 (~2.5 eq.) over 15 min via a dropping funnel. After the mixture was stirred briefly, 91.3 g (2-thiophenyl)acetyl chloride (568 mmol) in 111 mL EtOAc was added over 10 min via a dropping funnel, during which time mild gas evolution was observed. Upon completion of the addition, the mixture was allowed to stir for 30 min., at which time the layers were separated, and the aqueous layer was extracted with EtOAc (2 × 350 mL). The combined organic layers were dried over Na_2SO_4, filtered, and concentrated in vacuo. The yellow residue was purified by silica gel flash column chromatography using hexane/EtOAc (1:1–1:3) to afford 150 g (*S*)-ethyl-1-(2-thiopheneacetyl)-3-piperidinecarboxylate as a faintly off-white oil, in a yield of 99%.

Schwartz Reagent
(Schwartz's Reagent)

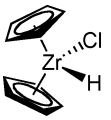
A. GENERAL DESCRIPTION OF THE REACTION

The organometallic compound, known as bis(cyclopentadienyl)zirconium(IV) chloride hydride,[1] [zirconium, chlorobis(η^5-2,4-cyclopentadien-1-yl)hydro],[2] or simply zirconocene hydrochloride (Cp_2ZrHCl)[3] was first introduced by Schwartz into organic synthesis in 1974,[4] and is thus referred to as the Schwartz's reagent[5] or Schwartz reagent.[1,3,5a,6] Although the Schwartz reagent is poorly soluble in commonly used solvents (e.g., toluene, THF, CH_2Cl_2)[5a,7] and is also difficult to purify because of its disproportionation,[7] it is still widely used in organic synthesis because of its easy preparation by the reduction of zirconocene dichloride with $LiAlH_4$,[2] compatibility with several functionalities,[6e] and special reactivity. Similar to other hydride reagents, the Schwartz reagent also undergoes reduction in which the carbonyl compounds including aldehydes, ketones, carboxylic acids, and esters are usually reduced to alcohols because of the strong hydridic character of the reagent;[1] in comparison, imines are reduced to amines,[1] dichlorophosphine and dicyano-phosphine are reduced to phosphines (or diketoimines);[8] and nitriles and tertiary amides are converted into corresponding aldehydes.[5a] In addition, the Schwartz reagent usually does not lead to the formation of a mixture as observed in the DIBAL reduction, due to the lack of a strong base.[5a] On the other hand, although the hydrozirconation of unsymmetrical alkynes is observed to proceed with complete stereoselectivity and high regioselectivity to give vinylic zirconium complexes,[3b] the regioselectivity actually depends on the reaction stoichiometry, temperature, solvent, and reaction duration.[3b] For example, the hydrozirconation of (4*S*,5*S*)-4-methyl-5-methoxy-5-benzyl-2-pentyne yields a mixture of vinylic zirconium complex with one equivalent of Schwartz reagent, whereas a thermodynamic vinylic zirconium complex is favored with an excess amount of Schwartz reagent; in addition, a longer reaction period and electron-donating solvent (e.g. THF) favor the thermodynamic product.[3b] Similar to tributyltin hydride, the Schwartz reagent is also known to be an

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

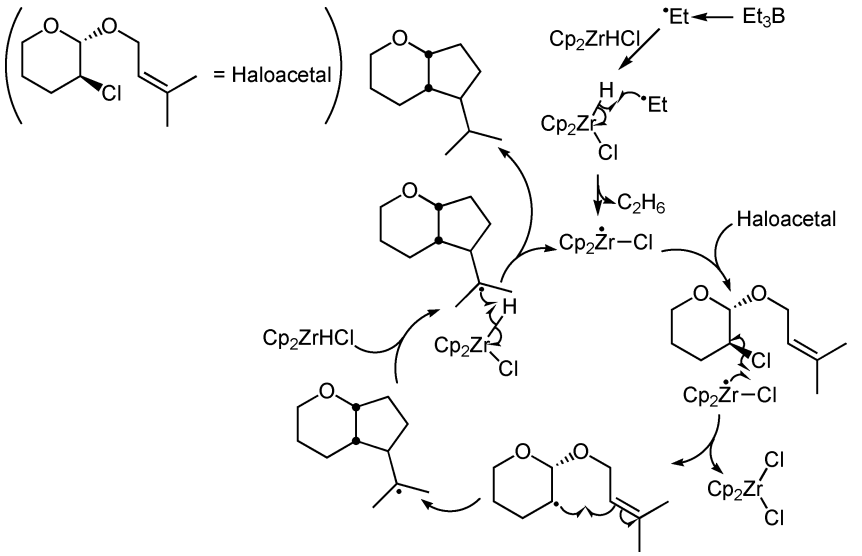
efficient radical chain carrier that can mediate a radical reduction process of alkyl halides,[1,6d] the cyclization of unsaturated haloacetals,[6c] etc. It should be pointed out that the radical cyclization can be performed in the presence of a catalytic amount of Schwartz reagent and sodium bis(2-methoxyethoxy)aluminium hydride (Red-Al).[6d] In addition, triethylborane (Et_3B) can be applied to depress the competitive hydrozirconation during the radical cyclization of terminal olefins, where the cyclization of internal olefins proceed smoothly.[6c]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reagent can participate in a variety of reactions, involving different reaction mechanisms. For the Schwartz reagent-mediated radical cyclization, it is proposed that the key step is the homolytic cleavage of the zirconium-hydrogen bond,[1] as illustrated here.



D. MODIFICATION

The Schwartz reagent has been replaced by bis(cyclopentadienyl)zirconium(IV) hydride triflate [$Cp_2Zr(H)OTf$], which displays the advantages over the Schwartz reagent, such as less tendency for aggregation and the higher reactivity of hydride due to the weak coordination ability of triflate anion.[7]

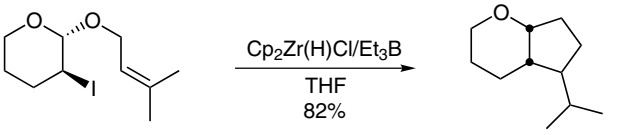
E. APPLICATIONS

This reagent is very useful in organic synthesis.

F. RELATED REACTIONS

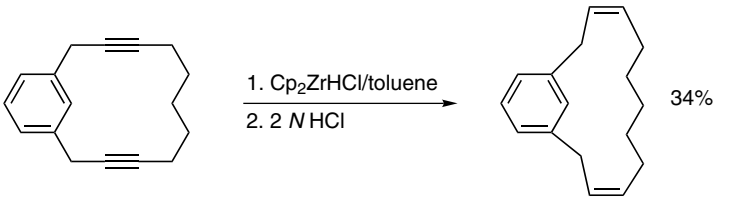
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 1.

To a 50-mL reaction flask were added 387 mg $Cp_2Zr(H)Cl$ (1.5 mmol) and 3.0 mL THF under argon. Then 148 mg (2*R*,3*S*)-3-iodo-2-(3-methyl-2-butenoxy)-tetrahydropyran (0.50 mmol) in 2.0 mL THF and 0.5 mL 1.0 M triethylborane in hexane (0.50 mmol) were added. The resulting heterogeneous mixture turned to a clear yellow solution after being stirred for 1 h at 25°C. After being stirred for an additional 2 h, the mixture was poured into a 30 mL 1 *N* HCl solution and stirred for 15 min. The mixture was extracted with hexane/EtOAc (10:1) (30 mL × 3). The combined organic layers were dried over Na_2SO_4 and concentrated in vacuo. The residue was purified by silica gel column chromatography using hexane/EtOAc (20:1) as the eluent to afford 70 mg product, in a yield of 82%.



Reference 5g.

To a solution of 222 mg [11]metacyclophane-2,9-diyne (1.0 mmol) in 25 mL dry toluene was added 1.30 g Schwartz's reagent (5.0 mmol) at once. The reaction was monitored by TLC. After 4 days, the solution was cooled to 0°C, and 3.0 mL 2.0 *N* HCl (6.0 mmol) was added at once, and the mixture was stirred for additional 10 min. The suspension was filtered, and the residue was washed several times with CH_2Cl_2. The combined filtrate was dried over Na_2SO_4, and the solvent was evaporated in vacuo. The residue was purified by silica gel column chromatography (petroleum ether) and further by Kugelrohr distillation to afford 76 mg (*Z*,*Z*)-[11]metacyclophane-2,9-diene as a colorless oil, in a yield of 34%, b.p. 115°C at 0.02 mbar.

Other references related to the Schwartz reagent are cited in the literature. [9]

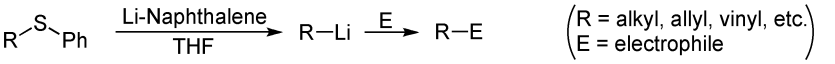
Screttas Lithiation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Screttas in 1978.[1] It is one of the most common methods for preparing an organic lithium reagent by reductive lithiation of an alkyl or aryl thioether[2] with an aromatic radical anion (e.g., lithium naphthalene) in THF, which is feasible for the preparation of primary, secondary, tertiary,[2a,2c,2d] and even vinyl lithium species.[2a] It has been found that the less stable the organic lithium is, the greater the ease of generating the organic lithium by reductive lithiation.[2a] The resulting lithium reagent can react with a variety of electrophiles, such as epoxides, aldehydes, ketones, α,β-unsaturated compounds, alkyl halides, etc. It has been found that in the presence of titanium isopropoxide or cerium chloride, the addition of allyl lithium to aldehydes or ketones shows high stereoselectivity.[3] In addition, the generated lithium species undergoes an intramolecular cyclization to form four- to six-membered ring structures,[2a,2c] with the reactivity order of secondary > tertiary > primary. In particular, the secondary lithium reagent leads to the formation of cyclobutane or cyclopentane derivatives with extremely high stereoselectivity; however, such cyclization is inhibited by a terminal olefinic methyl group.[2a] In most of the cases, the Screttas lithiation is carried out in THF,[2a,2c,2d,4] with only an exception of dimethyl ether.[2c]

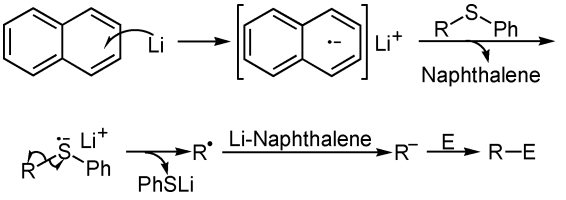
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is assumed that this reaction involves a radical reductive process. Displayed below is the lithiation of an alkyl phenyl thioether with lithium naphthalene.



D. MODIFICATION

The lithium naphthalene has been replaced by an even more reactive lithium 4,4′-di-*tert*-butylbiphenylyl (LDTBB) or lithium dimethylaminonaphthalene (LDMAN). LDTBB "not only is a more powerful reducing reagent but is less susceptible to radical attack";[2c] in addition, it can be applied in a catalytic amount (5 mol %) by suspension of an excess amount of lithium powder in THF.[2c] For comparison, the use of LDMAN has the advantage of easy removal of DMAN by a dilute acid wash, although LDMAN may decompose when the reaction temperature is above –45°C.[2d]

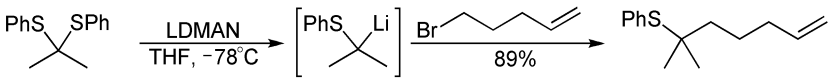
E. APPLICATIONS

This reaction has a very important application in carbanion chemistry and is one of the rare and general methods to prepare organolithium species.[2c]

F. RELATED REACTIONS

N/A

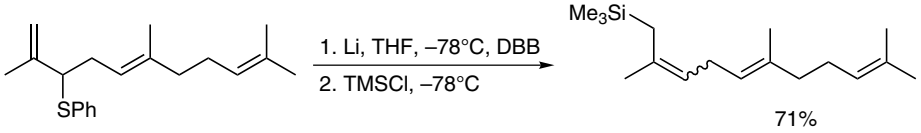
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

A LDMAN solution (45 mL, 0.51 M) in THF prepared from 3.8 mL DMAN (23.0 mmol) and 161 mg lithium (23.0 mmol), was cooled to –78°C; then a mixture of 2.90 g 2,2-bis(phenylthio)propane (11.2 mmol) and 10 mL THF was added. The dark green color of the solution turned into dark red. After 10 min of stirring, 1.39 mL 1-bromo-4-pentene (11.2 mmol) was added. The resulting mixture was stirred at –78°C for 2 h, and the

temperature was then raised to –20°C. After the solution had been stirred at –20°C for 30 min, 30 mL saturated aqueous $NaHCO_3$ was added. The reaction mixture was extracted with ether (50 mL × 3). The combined organic layers were washed with 30 mL 5% HCl (to remove DMAN) and 30 mL brine and then dried over anhydrous $MgSO_4$ and filtered through cotton. Upon removal of the solvent in vacuo, the residue was purified by flash chromatography using hexane as the eluent to give 2.19 g 6-methyl-6-phenylthio-1-heptene as a yellow oil, in a yield of 89%.



Reference 2b.

To a two-necked round-bottomed flask equipped with an argon inlet, were added 1.4 mL THF and 22 mg di-*tert*-butylbiphenyl (0.08 mmol). Small lithium pieces in a total amount of 288 mg (41.5 mmol)—prepared by scrapping the dark oxide coating off the surface while immersed in mineral oil and cut into small but shiny pieces and dipped in hexane—was quickly added to the solution of DBB while the flask was rapidly purged with argon. The mixture was sonicated for 5 min at room temperature, then cooled to –78°C. A solution of 200 mg allylthioether (0.83 mmol) in 1 mL THF was added to the preformed solution of LiDBB under argon, and the mixture was stirred until the originally dark green color reappeared; then 180 mg TMSCl (1.66 mmol) was added. The reaction was maintained at –78°C for an additional 5 min and the resulting solution was filtered to remove the excess lithium. The mixture was extracted three times with Et_2O. The combined organic layers were washed with water and brine, dried over $MgSO_4$, and concentrated to dryness. The residue was purified by column chromatography (hexane) to afford 184 mg *Z*-(trimethyl-(4-phenyl-3-(phenylthio)but-2-enyl)silane as a colorless oil, in a yield of 71%, $R_f = 0.26$ (hexane).

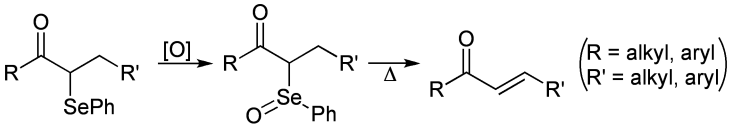
Selenoxide Elimination
(Selenoxide Pyrolysis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Jones et al. in 1970.[1] It is the synthesis of an olefin via the pyrolysis of an alkyl selenoxide and is generally known as selenoxide elimination[2] or selenoxide pyrolysis.[3] Occasionally, it is also referred to as the selenoxide *syn* elimination[2cc,4] or hydrolytic selenoxide elimination.[5] This reaction often takes place under very mild conditions, with few exceptions at a temperature $> 100^{\circ}C$.[2cc] Because the selenoxide is reluctant to undergo further oxidation, the preparation of selenoxide can be achieved by different oxidants,[2cc] including ozone,[3b,6] *m*CPBA,[2cc] H_2O_2,[7] and $NaIO_4$.[8] It has been found that an electron-withdrawing group accelerates the elimination process and lowers the reaction temperature.[9] For example, α-carbonyl selenoxides can decompose into α,β-unsaturated ketones around or even below room temperature.[2cc,9] In addition, the selenoxide elimination has shown good regioselectivity for the asymmetrical ketones.[2d] It should be pointed out that the selenoxides are extremely polar molecules and are highly hygroscopic.[2aa] Overall, this reaction is suitable for the preparation of allyl alcohols (from epoxide),[10] acetylenes, or allenes (from α-selenoxide alkyene),[2z] dienes,[11] α,β-unsaturated ketones,[2cc] esters,[12] and nitriles.[13]

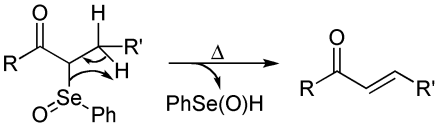
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A simple mechanism is illustrated here for the *syn*-elimination.



D. MODIFICATION

This reaction has been modified by the use of different oxidants to generate the selenoxides. In addition, an antibody-catalyzed selenoxide elimination has been developed.[2g] Moreover, this reaction has been performed under basic conditions.[14]

E. APPLICATIONS

This reaction has a very general application in organic synthesis to form olefinic derivatives.

F. RELATED REACTIONS

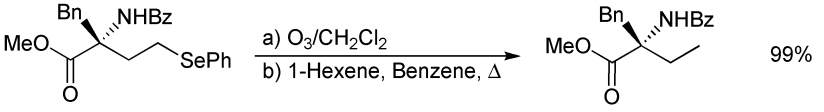
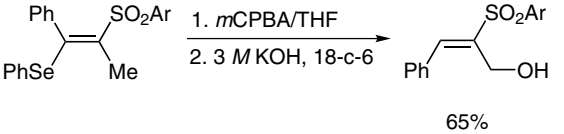
G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

A solution of 6.84 g methyl *N*-benzoyl-2-[2′-(phenylseleno)ethyl]phenylalaninate (14.7 mmol) in 150 mL CH_2Cl_2 at −78°C was bubbled through ozone until the blue color persisted. Then 31.7 mL 1-hexene (255 mmol) was added, and this cold mixture was added dropwise to 500 mL boiling benzene, and the refluxing was continued for 30 min. Upon evaporation of all the solvent, the residue was purified by flash column chromatography using EtOAc/hexane (0:1–1:9) to afford 4.48 g methyl *N*-benzoyl-2-vinylphenylalaninate as a white solid, in a yield of 99%, m.p. 116–117°C.



Reference 14.

A mixture of 298 mg selenide (0.70 mmol), 144 mg *m*CPBA (0.84 mmol), and 10 mL THF was stirred for 5 min. Then 5 mL 3 *M* KOH solution and a catalytic amount of 18-crown-6 were added, and the resulting mixture was stirred vigorously for 18 h at room temperature. The reaction mixture was then extracted with ether, and the combined organic layers were washed with water (2 × 10 mL) and brine (10 mL), and dried over anhydrous Na_2SO_4, and evaporated in vacuo. The residue was purified by preparative TLC using hexane/EtOAc (4:1) as the eluent to afford 130 mg 3-phenyl-2-(*p*-tolylsulfonyl)-2-propen-1-ol, which was further purified by crystallization from ether/hexane, in a yield of 65%, m.p. 95.5–96.5°C.

Other references related to the selenoxide elimination are cited in the literature.[15]

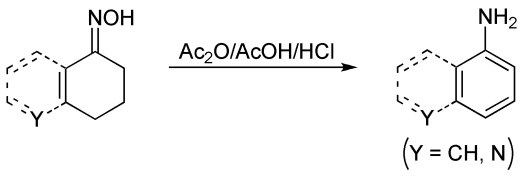
Semmler-Wolff Aromatization

(Semmler-Wolff Rearrangement, Semmler-Wolff Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Semmler in 1892[1] and subsequently studied by Wolff in 1902[2] and Schroeter in 1911.[3] It is the rearrangement of an oxime of an α,β-unsaturated cyclohexenone (or known as the α,β-unsaturated cyclohexenyl ketoxime) to an aromatic amine in a mixture of acetic anhydride and acetic acid saturated with HCl or HBr.[4] Therefore, this reaction is generally known as the Semmler-Wolff aromatization,[4b,5] Semmler-Wolff rearrangement,[5e,6] or Semmler-Wolff reaction.[7] Occasionally, it is also referred to as the Semmler-Wolff-Schroeter reaction.[8] It should be pointed out that the *Beckmann Rearrangement*,[4b,5d,5e,9] and the fragmentation to nitriles[5d] often compete with the Semmler-Wolff aromatization. In addition, the Semmler-Wolff aromatization is obstructed by the substituents close to the reaction center.[5e]

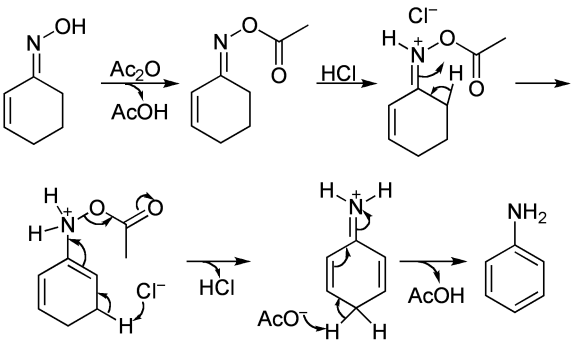
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Illustrated here is the mechanism for the aromatization of an α,β-unsaturated cyclohexenyl ketoxime.



D. MODIFICATION

This reaction has been modified by heating the oximes in acetic anhydride and anhydrous phosphoric acid at 80°C[4a] or heating the mixture of ketoxime and one equivalent of acetyl chloride in toluene in a sealed tube at 80°C[10] to improve the reaction yield.

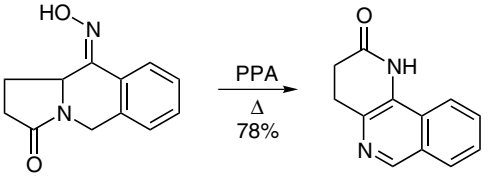
E. APPLICATIONS

This reaction has certain application in the preparation of aromatic amines.

F. RELATED REACTIONS

This reaction is related to the *Beckmann Rearrangement*.

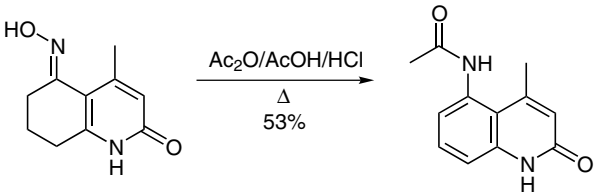
G. CITED EXPERIMENTAL EXAMPLES



Reference 5d.

Finely powdered (±)-(*Z*)-1,10a-dihydropyrrolo[1,2-b]isoquinoline-3,10-(2H,5H)-dione-10-oxime (30 g, 0.14 mol) was added quickly to 600 g hot polyphosphoric acid

(100°C) under stirring. The resulting mixture was vigorously stirred for 10 min during which period the internal temperature increased to 128°C. The hot mixture was decanted over 2.5 L crushed ice and diluted with water to give a solution, that was basified to pH 8–9 with 50% NaOH. Further dilution with water to keep the inorganic salts in solution was necessary. The yellow precipitate was collected by vacuum filtration, and the filter cake was washed thoroughly with water and dried in vacuo at 40°C over NaOH pellets to give 21.6 g crude 1,4-dihydrobenzo[c]-1,5-naphthyridin-2(3H)-one, in a yield of 78%. The product was further purified by preparative HPLC and recrystallization from 95% ethanol to afford yellow crystals, m.p. 227–228°C.



Reference 5e.

To a mixture of 4 mL acetic acid and 1.5 mL acetic anhydride was added 0.5 g 4-methyl-5,6,7,8-tetrahydro-5-(hydroxyimino)-2-hydroxyquinoline (3.0 mmol). The solution was saturated with anhydrous HCl gas and then held at reflux for 18 h. At the end of the reaction period, the solution had become dark, whereupon it was cooled, diluted with water, and allowed to stand for several hours. The white precipitate that formed was washed with water and crystallized from alcohol to provide 0.30 g 4-methyl-5-acetamido-2-quinolone, in a yield of 53%, m.p. 355°C.

Other references related to the Semmler-Wolff aromatization are cited in the literature.[11]

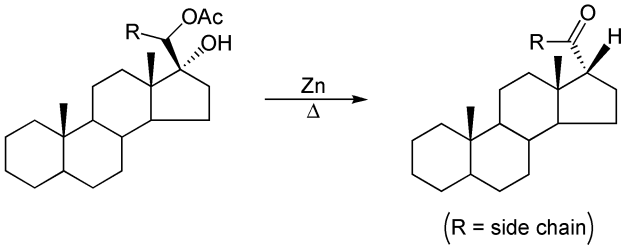
Serini Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Serini in 1939.[1] It is a zinc-promoted rearrangement of 17-hydroxy-20-acetoxy-steroids into 20-oxo-steroid derivatives with the complete inversion of stereochemistry at C-17 and is generally known as the Serini reaction.[2] Occasionally, it is also referred to as the Logemann-Serini reaction[3] or Serini-Logemann reaction.[4] It has been found that the treatment of steroid derivatives with anhydrous zinc acetate yields the results similar to that when refluxed with zinc, indicating that the function of zinc in the Serini reaction is to generate a Lewis acid.[2f] This reaction has been extended to other cyclic and open-chain 1,2-diol monoacetates as well as corresponding benzoates and *p*-nitrobenzoates.[2f] Under normal conditions, the 1,2-diol monobenzoates or *p*-nitrobenzoates offer better results than the corresponding monoacetates.[2f] If an aromatic ring is attached to the secondary carbon, the corresponding aldehyde might form because of the 1,2-aryl migration.[2f]

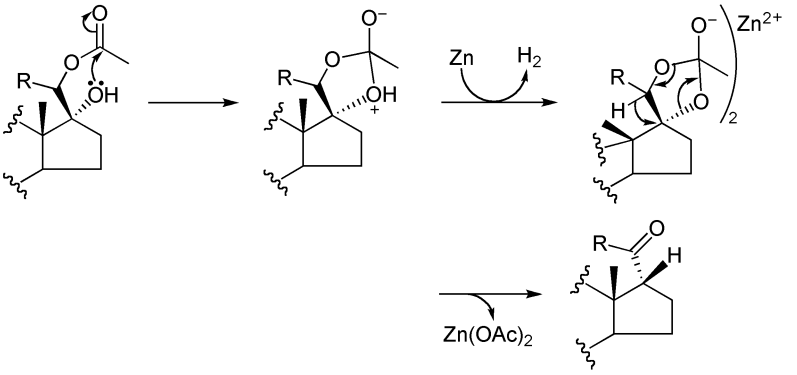
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism of this reaction has been studied to a certain extent.[2f,2l,4] It has been proposed that zinc is actually converted into a complexing Lewis acid. In addition, the C-O bond, as a part of the monoacetate at C-20, of these steroids never breaks and is transformed into the carbonyl group in the final product while the hydrogen at C-20 migrates to the C-17 position, accompanying with the inversion of stereochemistry at C-17, as illustrated here.[2f,2l]



D. MODIFICATION

This reaction has been extended to other cyclic and open-chain 1,2-diol monoesters.[2f]

E. APPLICATIONS

This reaction has certain application in steroid chemistry.

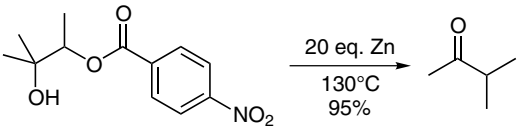
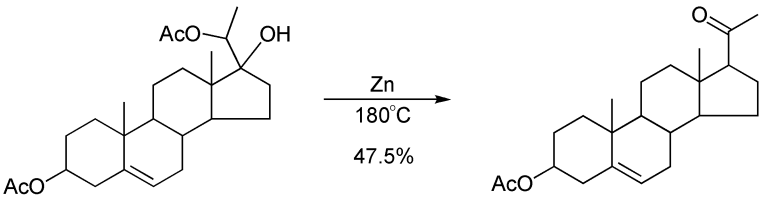
G. CITED EXPERIMENTAL EXAMPLES



Reference 2f.

To a special reaction vessel equipped with a nitrogen inlet and removal trap, was added powdered (3′-methyl-3′-hydroxyl)-2-butyl *p*-nitrobenzoate and 20 eq. of freshly activated zinc dust through a funnel. The reaction vessel was immersed into an oil bath at 130°C for 2.5 h and a steady nitrogen flow (60 bubbles/min) carried the volatile products or by-products

toward the trap, which was cooled with dry ice/acetone. At the end of the reaction, the volatile product (i.e., methyl isopropyl ketone) was collected in the trap, in a yield of 95%.



Reference 2q.

A mixture of 200 mg Δ^5-pregnene-3β,17α,20β-triol-3,20-diacetate and 4.0 g zinc dust was finely ground and heated slowly in an air bath to 180°C at 0.03 mmHg. The material that sublimed was extracted with $CHCl_3$, and the product so collected on crystallization from dilute acetone gave 78 mg 17-iso-Δ^5-pregnene-3β-ol-20-one-3-acetate, in a yield of 47.5%; on further crystallization from alcohol, the substance obtained melted at 159–164°C and 167–168°C. (*Note:* Two different melting points were given in the original work.)

Other references related to the Serini reaction are cited in literature 5.

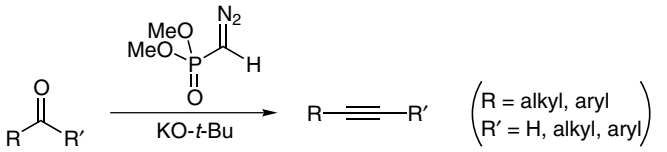
Seyferth-Gilbert Homologation

(Seyferth-Gilbert reaction)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Seyferth in 1970[1] and was subsequently extended by Gilbert et al. in 1979.[2] It is the transformation of aldehydes or ketones into alkynes with one more carbon atom by means of the reaction with dimethyl (diazomethyl)phosphonate in the presence of potassium *t*-butoxide. Therefore, it is known as the Seyferth-Gilbert reaction,[3] Seyferth-Gilbert homologation,[4] Gilbert-Seyferth homologation,[5] or Gilbert-Seyferth reaction.[6] Similarly, dimethyl (diazomethyl)phosphonate is referred to as the Seyferth reagent,[7] Seyferth-Gilbert reagent,[8] Seyferth-Gilbert diazophosphonate reagent, Gilbert-Seyferth diazo phosphonic reagent,[9] or simply the Gilbert-Seyferth reagent.[10]

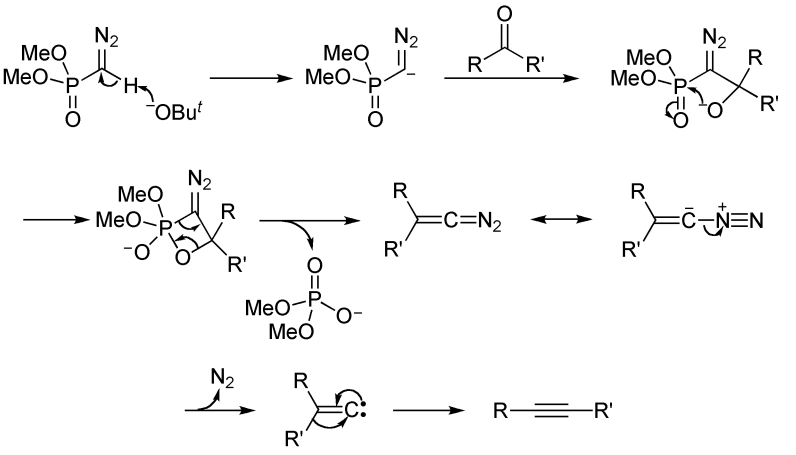
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is proposed that this reaction occurs via a mechanism similar to the *Wittig Reaction*.[11] In detail, deprotonation of the Seyferth-Gilbert reagent by potassium *t*-butoxide generates a carbanion, which adds to the carbonyl group to yield an oxaphosphatane; then subsequent elimination of dimethylphosphate leads to the formation of a vinyl diazo intermediate from which the vinyl carbene forms by evolution of nitrogen gas; final 1,2-migration of the substituent on vinyl carbene yields the alkyne. An illustrative mechanism is displayed here.



D. MODIFICATION

This reaction has been modified by Ohira[12] and Bestmann[13] via the generation of dimethyl(diazomethyl)phosphonate *in situ* by the treatment of dimethyl-1-diazo-2-oxopropylphosphonate with methanol and K_2CO_3. This method, often gives a very high yield of terminal alkynes from aldehydes and is also known as the Bestmann modification.[3a,6] Dimethyl-1-diazo-2-oxopropylphosphonate is referred to as Ohira's reagent.[8]

E. APPLICATIONS

This reaction should have a very wide application in organic synthesis, in terms of the preparation of alkynes.

F. RELATED REACTIONS

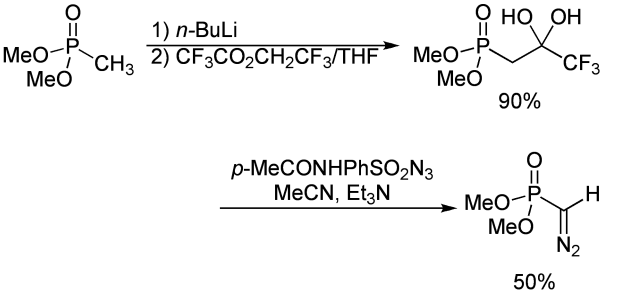
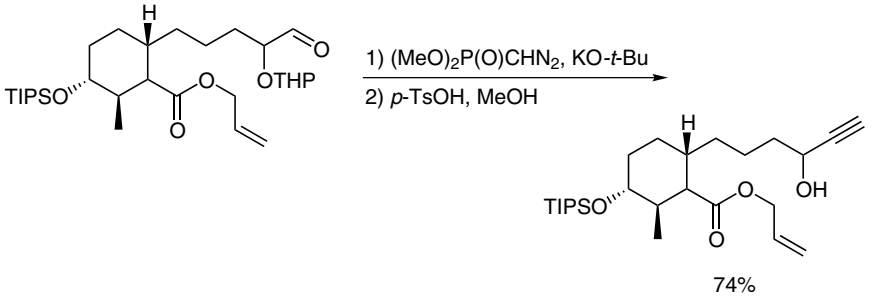
G. CITED EXPERIMENTAL EXAMPLES



Reference 11.

To a 250-mL, flame-dried, round-bottomed flask, were added 40 mL dry THF and 2.29 g dimethyl methylphosphonate (18.4 mmol), and the mixture was cooled to −78°C. Then 7.66 mL 2.4 M *n*-butyllithium in hexanes (18.4 mmol) was added over 5 min; after the solution was stirred at −78°C for 15–30 min, 5.41 g 2,2,2-trifluoroethyl trifluoroacetate (3.73 mL, 27.6 mmol) was added rapidly (1–2 s), and the resulting mixture was stirred at −78°C for 15 min and was then warmed to room temperature. The crude reaction mixture was partitioned between 250 mL Et_2O and 10 mL 3% HCl solution, the combined organic layers were washed with 10 mL saturated $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated to give 90% dimethyl (3,3,3-trifluoro-2,2-dihydroxypropyl)phosphonate, which upon purification from column chromatography had melting point of 57–61°C. This intermediate was immediately dissolved in 40 mL dry CH_3CN, then 3.97 g 4-acetamidobenzenesulfonyl azide (16.5 mmol) was added, and the solution was cooled to 0°C. Triethylamine (1.66 g, 2.29 mL, 16.5 mmol) was slowly added within 5 min. The mixture was allowed to warm to room temperature and was stirred overnight. Solvent was removed by rotary evaporation from the resulting slurry, which contained the precipitated 4-acetamidobenzenesulfonamide. The residual orange oily solid was suspended in $CHCl_3$ and filtered through a coarse glass frit to remove 4-acetamidobenzenesulfonamide, which was washed with a small portion of additional $CHCl_3$. Upon concentration of the filtrate, the residue was purified by column chromatography using EtOAc as the eluent and iodine for visualization to afford 1.23 g dimethyl (diazomethyl)phosphonate, in a yield of 50%.



Reference 4.

A solution of 63 mg dimethyl (diazomethyl)phosphonate (0.42 mmol) in 5 mL THF was treated with 0.42 mL 1 M KO-*t*-Bu at −78°C and stirred for 20 min at this temperature.

Then aldehyde in 5 mL THF was added slowly. The resulting mixture was allowed to slowly warm to 0°C and stirred at 0°C for an additional 8 h, then quenched with saturated aqueous NH_4Cl. The mixture was extracted with EtOAc (2 × 20 mL), the combined organic layers were washed with brine, dried over $MgSO_4$, and concentrated in vacuo. This crude acetylene was then dissolved in 10 mL MeOH, and a catalytic amount of *p*-toluenesulfonic acid was added. The mixture was stirred at room temperature for 5 h, and diluted with 20 mL EtOAc, washed sequentially with aqueous saturated $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated in vacuo. The residue was purified by column chromatography using hexane/EtOAc (4:1) as the eluent to afford 117 mg propargyl alcohol as a colorless oil, in a yield of 74%.

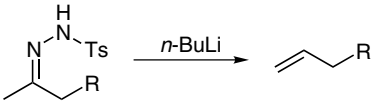
Shapiro Reaction
(Shapiro Elimination)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Shapiro in 1967.[1] It is a synthesis of olefins by means of a base-promoted decomposition of *p*-toluenesulfonylhydrazones of the corresponding ketones or aldehydes.[2] Therefore, it is generally known as the Shapiro reaction,[2b,3] or Shapiro elimination.[4] Occasionally, it is also referred to as the Shapiro olefination,[5] Shapiro lithiation reaction,[6] Shapiro fragmentation,[3d] or Shapiro degradation.[4d]

Normally, at least two equivalents of a strong base (typically an alkyllithium or lithium dialkylamide) are required to react with the hydrazones, and subsequent aqueous workup will give the expected alkenes.[3j] However, the Shapiro reaction has recently been reported to occur catalytically.[3k] This reaction is commonly carried out under very mild conditions compared to the *Bamford-Stevens Olefination*. In addition, due to the *syn*-dilithio effect,[7] the Shapiro reaction normally affords high yields of alkenes without rearrangement or other side reactions.[2c] Moreover, when the Grignard reagent is used as a base, substituted nitrile can be generated.[3d] The alkenes formed are kinetically controlled products—that is, less substituted alkenes.[2b] It should be pointed out that the Shapiro reaction does not work well with substrates containing only tertiary R-carbon atoms,[8] because the formation of the dianionic intermediate is problematic in this case and substitution at the imino carbon atom competes effectively with the elimination.[8a]

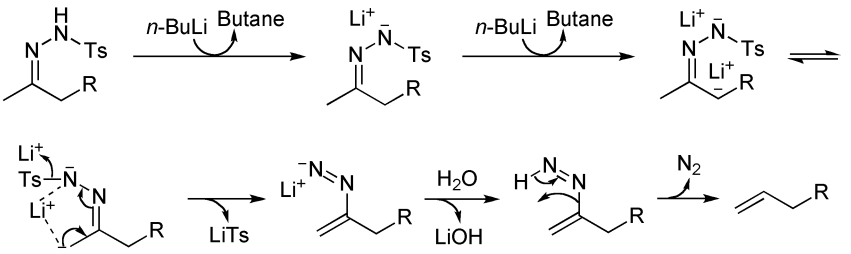
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is assumed that the Shapiro reaction involves the deprotonation of the hydrazone NH and subsequently of an α-CH group, the resultant dianion eliminates *p*-toluenesulfinate followed by the evolution of nitrogen, as illustrated here.[2b]



D. MODIFICATION

This reaction has been modified to occur with only a catalytic amount of lithium amide.[3k]

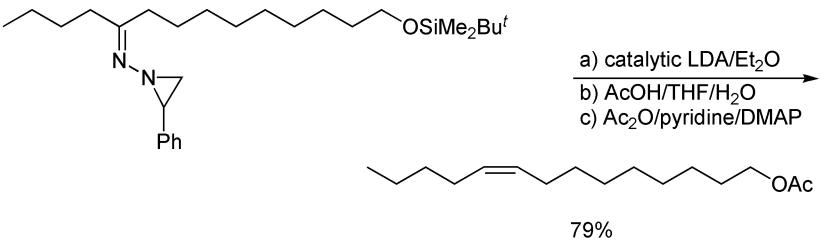
E. APPLICATIONS

This reaction has wide application in the preparation of alkenes or other derivatives.[2]

F. RELATED REACTIONS

This reaction is closely related to the *Bamford-Stevens Reaction*.

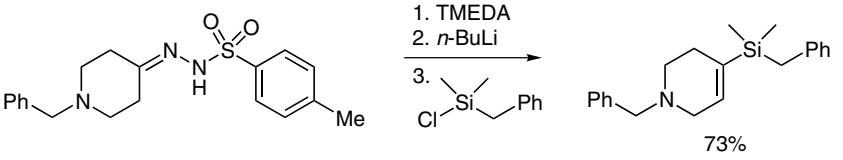
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

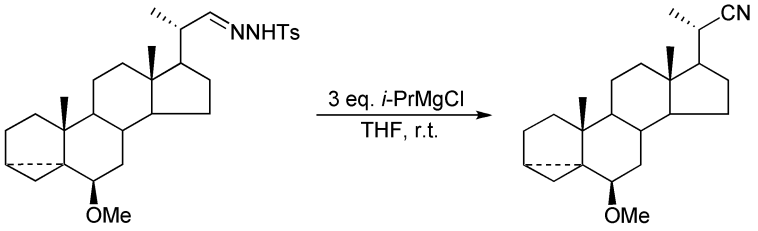
To a solution of 446 mg phenylaziriine (*Z*)-hydrazone of 14-(*tert*-butyldimethylsiloxy)-5-tetradecanone (1.0 mmol) in 1.0 mL dry ether at 0°C under argon atmosphere was added a solution of 0.2 mL 0.5 M LDA in ether/hexane. The mixture was stirred at 0°C for 1 h

and then poured into a mixture of AcOH/THF/H_2O (2:1:1, 40 mL). The mixture was stirred vigorously at room temperature for 3 h. Ether (50 mL) was added, and the organic layer was washed with saturated aqueous $NaHCO_3$ followed by brine, dried over Na_2SO_4, and concentrated. The crude (*Z*)-9-tetradecenol was treated with 142 μL Ac_2O (1.5 mmol) and 121 μL pyridine (1.5 mmol) in 3.0 mL dichloromethane, in the presence of a catalytic amount of DMAP at 25°C for 1 h. A standard workup and purification by column chromatography on silica gel (ether/hexane, 1:8) afforded 201 mg (*Z*)-9-tetradecenyl acetate, in a yield of 79%.



Reference 3b.

To a 1-L round-bottomed flask equipped with an addition funnel and an internal thermometer were added 18.6 g *N*-(1-benzyl-piperidin-4-ylidene)-*N*′-tosyl-hydrazine (52 mmol) and 260 mL hexanes. Under a nitrogen atmosphere, 40 mL TMEDA (267 mmol) was added and the mixture was cooled by dry ice/acetone bath and stirred for 25 min to resolve a white suspension. Then 160 mL 1.6 M *n*-butyllithium in hexanes (256 mmol) was added through the addition funnel dropwise over a period of 20 min, during which the reaction mixture turned into a yellow-orange suspension and the internal temperature rose by ~10°C. After the addition of *n*-BuLi completed, the solution was stirred at −78°C for 15 min and then was allowed to warm to room temperature (~18°C) within 1.5 h while being stirred. Over this time period, bubbling was observed, and the reaction slowly became reddish orange and then reddish brown. Then the solution was cooled by an ice bath for 10 min; after that, 14 mL benzyldimethylsilyl chloride (neat) (77 mmol) was added through a syringe over about 1 min. The reaction mixture quickly turned more reddish in color, and the internal temperature rose by ~15°C. After being stirred overnight, the reaction mixture was placed in an ice bath and quenched by 400 mL water, portionwise at first. The mixture turned from reddish brown to bright yellow, and the internal temperature rose by ~20°C. After separation of the organic phase, the aqueous layer was extracted with hexanes (2 × 150 mL). The combined organic layer was dried over Na_2SO_4 and concentrated in vacuo. The residue was purified by silica gel chromatography (automated column, 330 g SiO_2, 0%–20% EtOAc in hexanes gradient) to afford 12.19 g 1-benzyl-4-(benzyldimethylsilanyl)-1,2,3,6-tetrahydro-pyridine as an orange oil, in a yield of 73%.



Reference 3d.

To a solution of 205 mg (*E*)-tosylhydrazone of 3α,5-cyclo-23,24-dinor-6β-methoxy-5α-cholane-24-al (0.4 mmol) in 1.4 mL THF was added 0.6 mL 2 M *i*-PrMgCl in THF (1.2 mmol). The mixture was stirred at room temperature for 24 h. The excess Grignard reagent was quenched with aqueous NH_4Cl, and the product was extracted with Et_2O and purified via column chromatography, to give 143 mg starting material (70% recovery yield) and 19 milligrams of 20(S)-6β-methoxy-3,5-cyclo-5α-pregnane-20-carbonitrile, in a yield of 14%.

Other references related to the Shapiro reaction are cited in the literature.[9]
