Darzens Halogenation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Darzens in 1911.[1] It is the synthesis of alkyl halide from alcohols via the treatment of thionyl chloride or bromide in the presence of small amounts of tertiary amines such as pyridine. This is a general method with good yields for the preparation of alkyl halides,[2] without the disadvantage of using halogen derivatives of phosphorus that might cause the isomerization, polymerization,[1] and the *Walden Inversion* of certain optically active alcohols.[3] It is reported that when alcohols are treated with equivalent amounts of thionyl chloride in the presence of pyridine, it results in no chlorination[4] or yields the alkyl sulfite instead of the alkyl halide.[5] However, in a large excess of thionyl halide and a small amount of pyridine, alkyl halides will form upon reflux.[2] In a special case, alkyl halide can form in high yield even without a base in presence.[2]

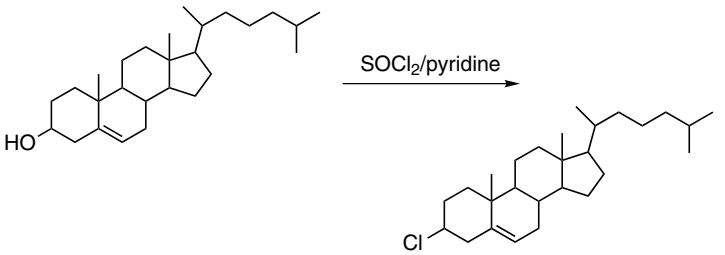
G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To a mixture of 5 g cholesterol and 1 mL pyridine was added 10 mL thionyl chloride rapidly. The reaction mixture was kept cool with running water and was refluxed for 1 h. Sulfur dioxide was liberated. The mixture was cooled, poured into water, and then extracted with ether. The ethereal solution was dried over anhydrous sodium carbonate. When the solvent was removed under reduced pressure a semicrystalline product remained. This was recrystallized from alcohol and identified as cholesteryl chloride; m.p. 95–96°C. The reaction was repeated without the addition of pyridine with identical results. The yield was almost quantitative.

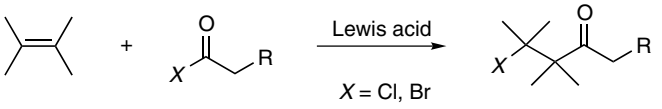
Darzens Olefin Acylation
(Kondakov Acylation)

A. GENERAL DESCRIPTION OF THE REACTION

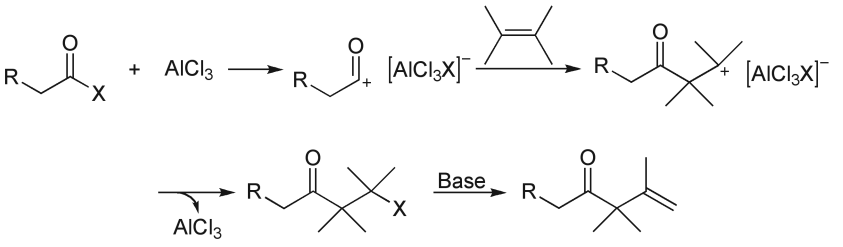
This reaction was first reported by Kondakov in 1892.[1] It is the preparation of β-haloketones via the direct condensation of acyl halides or acyl anhydride[2] and olefins in the presence of Lewis acid. Therefore, it is generally known as the Kondakov acylation[3] or Kondakov reaction.[4] However, this reaction is also known as the Darzens acylation of olefin[5] or the Darzens reaction[5] after Darzens's work in 1910.[6] The Lewis acid catalysts suitable for this condensation include $SnCl_4$, $AlCl_3$, $TiCl_4$, and BF_3. However, a subtle difference does exist between the Kondakov acylation and the original Darzens reaction condition in which acyl halides react with alicyclic olefins in the presence of $AlCl_3$ for the latter case. Different from the *Fridel-Crafts Acylation* in which the carbocation from acyl addition can be stabilized and the recurring of aromaticity leads to a high yield of acylation products, the Darzens olefin acylation, often fails due to the formation of various unstable intermediates from electrophilic addition, elimination, and isomerization.[7] In particular, the acylation of olefins from chloroformates fail almost exclusively,[7] except one example in which unexpected regiochemistry was obtained.[8] It is reported that in the presence of a base with low nucleophilicity, both α,β-unsaturated and β,γ-unsaturated ketones might form.[7]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

The addition of non-nucleophilic base will result in the formation of α,β- or β,γ-unsaturated ketones.

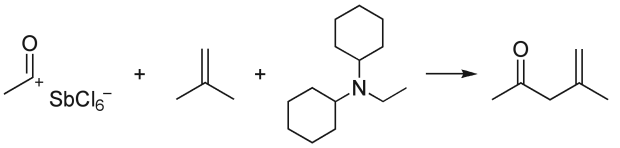
E. APPLICATIONS

This reaction has applications in the preparation of β-halo ketones and α,β- or β,γ-unsaturated ketones.

F. RELATED REACTIONS

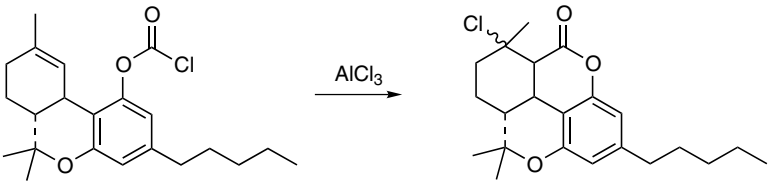
This reaction is related to the *Fridel-Crafts Acylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

Equimolar amounts of isobutene (5 mmol) and dicyclohexylethylamine (5 mmol), each dissolved in 5 mL CH_2C1_2, were mixed and quickly added to the partially dissolved acetyl hexachloroantimonate ($CH_3CO^+SbCl_6^-$) in 20 mL CH_2Cl_2 under vigorous stirring at –50°C. The temperature was kept at –50°C for 1 h. After the reaction was completed, the dark brown reaction mixture was immediately poured into 200 mL *n*-pentane containing 3 mL water to decompose any remaining acetyl hexachloroantimonate and shaken for 1 min, and the precipitate was removed by filtration. The precipitate was washed twice with *n*-pentane, and the combined organic layers were washed with water, dried over Na_2SO_4, and evaporated under reduced pressure to leave an oily product. The acetylated products were purified by preparative GLC in a yield of 90%.



Reference 5.

A solution of 16.5 Δ^9-tetrahydrocannabinol (Δ^9-THC) chloroformate (43.9 mmol) in 72 mL CH_2Cl_2 was added in one portion to a stirring suspension of 17.5 g $AlCl_3$ (132 mmol) in 231 mL dry CH_2Cl_2 under nitrogen. The reaction mixture turned dark red, and nearly all the $AlCl_3$ appeared to dissolve. After 40 min the reaction was quenched by the rapid addition of 36.4 g K_2CO_3 (264 mmol) in 35 mL H_2O with vigorous stirring. After the boiling subsided, the granular precipitate was filtered through a coarse fritted filter. The amount of H_2O employed in the quenching process was limited to avoid the formation of a difficult to filter pasty solid. The resin obtained after removing the solvent in vacuo was eluted from 600 g silica gel with 40% CH_2C1_2/hexane to yield 8.47 g 6-chloro-5a,7,8,8a,9,10c-hexahydro-6,9,9-trimethyl-2-pentyl-5H,6H-[2]benzopyrano[5,4,3-cde][1]benzopyran-5-one, in a yield of 51%.

Other references related to the Darzens olefin acylation are cited in the literature.[9]

Darzens-Nenitzescu Reaction

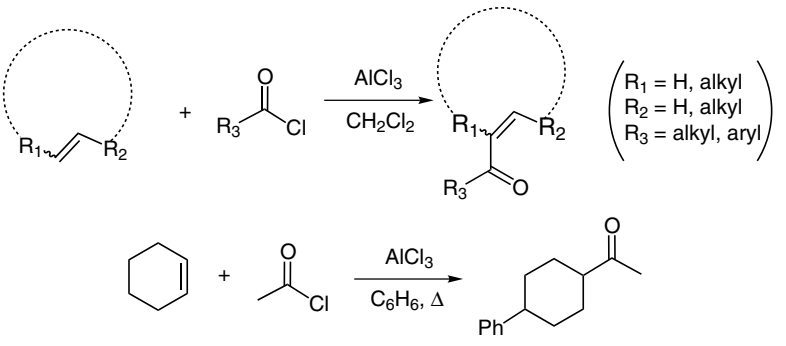
(Nenitzescu Acylation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Nenitzescu in 1931.[1] It is the formation of an α,β-unsaturated ketone directly by aluminum chloride–promoted acylation of alkenes with acyl halides. Therefore, it is known as the Darzens-Nenitzescu reaction (or Nenitzescu reductive acylation),[2] or Nenitzescu acylation.[3] Under such reaction conditions, Nenitzescu prepared 2-butenyl methyl ketone from acetyl chloride and 1-butene[4] and dimethylacetylcyclohexene from acetyl chloride and cyclooctene.[5] However, in the presence of benzene or hexane, the saturated ketones are often resolved, as supported by the preparation of 4-phenyl cyclohexyl methyl ketone from the reaction of cyclohexene and acetyl chloride in benzene,[6] and the synthesis of 3- or 4-methylcyclohexyl methyl ketone by refluxing the mixture of cycloheptene and acetyl chloride in cyclohexane or isopentane.[5b,7] This is probably caused by the intermolecular hydrogen transfer from the solvent.[8] In addition, owing to its intrinsic strain, cyclopropyl group reacts in a manner similar to an olefinic functionality so that it can be readily acylated.[9] It should be pointed out that under various reaction conditions, the Darzens-Nenitzescu reaction is often complicated by the formation of β-halo ketones, β,γ-enones, or β-acyloxy ketones.[8,10] This complication can be overcome by an aluminum chloride–promoted acylation with vinyl mercuric chloride, resulting in a high purity of stereochemistry.[11]

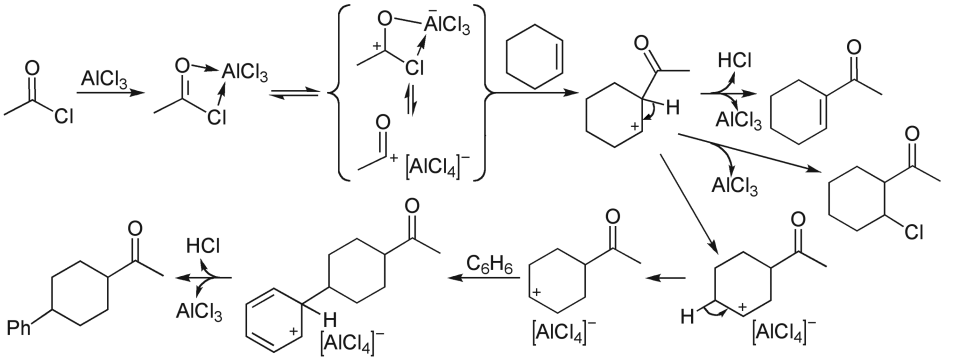
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the mechanism for the formation of acetylcyclohexane is known,[3] an alternative mechanism is proposed here for the acylation of cyclohexene with acetyl chloride. In this reaction, after the acyl cation adds to double bond, the elimination of the α-proton gives an α,β-unsaturated ketone, whereas the attack of chloride produces a β-chloroketone. Since acetyl is an electron-withdrawing group, it is plausible that the positive charge migrates to form a more stable carbocation, which electrophilically alkylates with benzene.



D. MODIFICATION

The formation of α,β-unsaturated ketones has been modified by the acylation of vinyl mercuric chloride.[11] In addition, this reaction has been extended to the acylation of alkynes[10] and a zinc chloride-promoted acylation of olefins.[12]

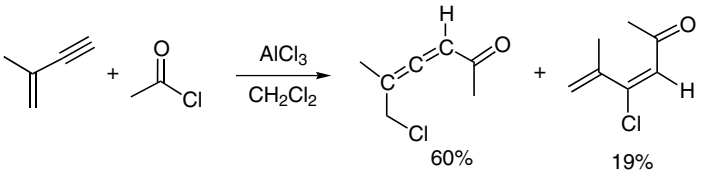
E. APPLICATIONS

This reaction has general application in the preparation of α,β-unsaturated ketones.

F. RELATED REACTIONS

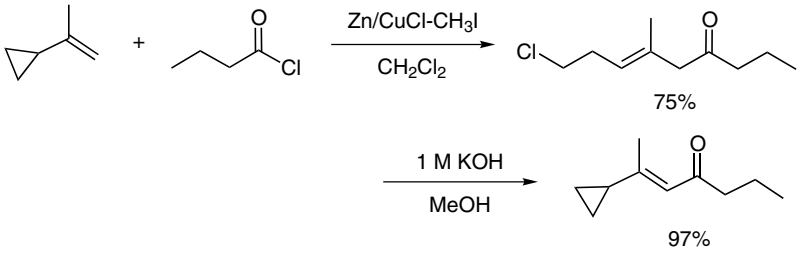
This reaction is related to the *Friedel-Crafts Acylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

A mixture of 3.33 g $AlCl_3$ (25 mmol), 1.96 mL acetyl chloride (27.5 mmol, 1.1 eq.), and 45 mL anhydrous CH_2Cl_2 was stirred until dissolution. The resulting solution was stirred for 3 min at 20 mmHg and cooled to –90°C; then 2.86 mL 2-methyl-1-buten-3-yne (30 mmol, 1.2 eq.) in 30 mL anhydrous CH_2Cl_2 was slowly added over 2 h. The solution was allowed to warm to –60°C, the mixture was stirred until the completion of reaction, as monitored by TLC, and then transferred to a vigorously stirring mixture of crushed ice and Et_2O. The organic layer was quickly stirred with a saturated solution of $NaHCO_3$ and dried using $MgSO_4$ and stored in a refrigerator. After filtration and concentration in vacuo at room temperature, the crude product was quickly flash chromatographed on silica gel, eluting with a gradient of pentane/ether to afford 60% 5-methyl-6-chloro-3,4-hexadien-2-one and 19% 5-methyl-4-chloro-3,5-hexadien-2-one, which were stored in refrigerator.



Reference 12.

A mixture of 6.54 g zinc dust (0.10 mol) and 0.99 g cuprous chloride (0.01 mol) in 30 mL CH_2Cl_2 was refluxed with stirring under nitrogen for 30 min. After the mixture was cooled to room temperature, 7.1 g iodomethane (0.05 mol) was added, and the mixture was then refluxed for an additional 1 h. Into the solution of the freshly prepared active zinc compounds was added 4.11 g 2-cyclopropyl-propene (0.05 mol) in 10 mL CH_2Cl_2 at 0–5°C under nitrogen with stirring. After a short period, 1.07 g butyryl chloride (0.010 mol) in 10 mL CH_2Cl_2 was added dropwise into the above stirred mixture in 15 min at 15–20°C with external cooling. An exothermic reaction took place, and the mixture gradually turned red-brown. The reaction mixture was stirred at room temperature for 2 h and then was refluxed for another 2 h. After that, 30 mL 10% H_2SO_4 was carefully added into the mixture under

cooling with an ice water bath. The reaction mixture was filtered with suction and extracted with ether (3×50 mL). The combined ethereal solution was washed with saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and concentrated to give a mixture of products, which was purified to give 75% 9-chloro-6-methyl-6-en-4-nanone. This product, upon treatment with 1 M KOH in methanol, gives 97% 1-cyclopropyl-2-en-hept-4-one.

Other references related to the Darzens-Nenitzescu reaction are cited in the literature.[13]

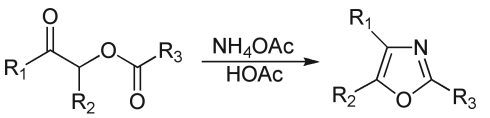
Davidson Oxazole Cyclization

(Davidson Cyclization)

A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction had been investigated by Japp in the early stage of its development,[1] it was Davidson and co-workers who studied both the mechanism and method of formulating a general procedure for the preparation of substituted oxazoles.[2] Therefore, this reaction is known as the Davidson cyclization[3] or Davidson oxazole cyclization.[3] It is the preparation of substituted oxazole by condensation of *O*-acylacylion with ammonia or ammonium acetate. The *O*-acylacyloin or *O*-acyl benzoin can be prepared from the reaction between acyloin or benzoin with carboxylic acid in the presence of DCC,[4] or from the reaction between α-haloketone with carboxylic acid under basic conditions.[5] It has been found that the cyclization to form oxazole does not occur when ammonia or ammonium acetate is replaced by organic amines.[6] This reaction is best for 2,4,5-trisubstituted oxazole or oxazoles with an aromatic substituent at C-5,[7] whereas it works poorly for the preparation of 2,4-disubstituted or monosubstituted oxazoles.[3]

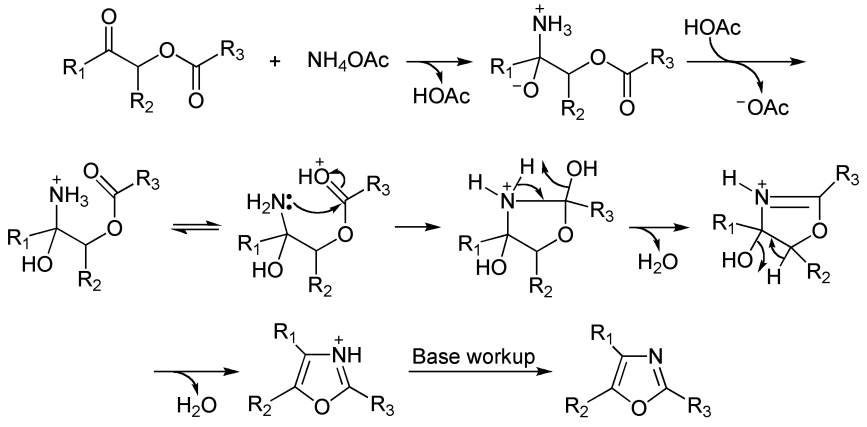
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The early mechanisms from both Japp[1] and Davidson[2] are not clear and an updated new mechanism is proposed here.



D. MODIFICATION

This reaction has been modified to generate *O*-acylacyloin via the reaction of α-haloketone with carboxylic acid under basic conditions.[5]

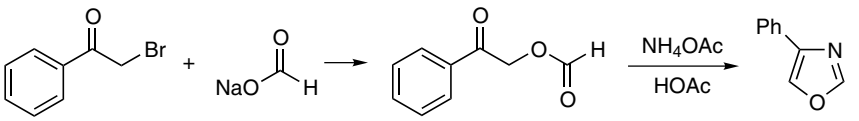
E. APPLICATIONS

This reaction has general application in the preparation of 2,4,5-trisubstituted oxazoles.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

A mixture of 20.0 g bromoacetophenone (0.100 mol) and 8.84 g sodium formate (0.13 mol) in 200 mL DMF was stirred for 12 h. The solution was then poured into 800 mL water and extracted with CH_2Cl_2 until the aqueous layer was colorless. The organic phase was washed with saturated brine, dried over Na_2SO_4, and evaporated. Residual DMF was removed by vacuum distillation, leaving 13.6 g α-(formy1oxy)acetophenone as a yellow oil, in a yield of 83%.

A mixture of 10.4 g of this crude α-(formyloxy) acetophenone (63.4 mmol) and 24.3 g ammonium acetate (315 mmol) in 125 mL acetic acid was refluxed for 1.5 h. After cooling, it was added to 500 mL water and extracted with CH_2Cl_2. The organic phase was neutralized by careful addition (foaming) of saturated $NaHCO_3$ solution, washed with brine, dried over Na_2SO_4, evaporated, and distilled to yield 4.52 g 2-phenyl-oxazole in a yield of 49.5%, b.p. 60–61°C (at 0.1 mmHg).

Other references related to the Davidson oxazole cyclization are cited in the literature.[8]

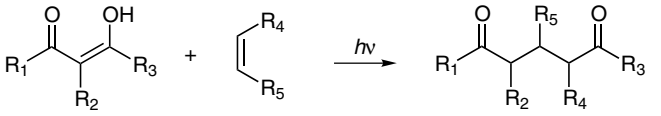
de Mayo Reaction

A. GENERAL DESCRIPTION OF THE REACTION

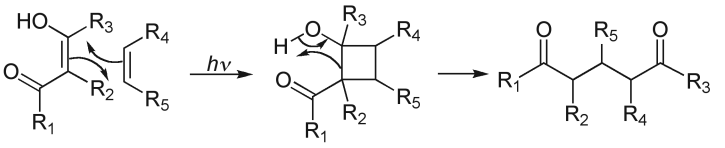
This reaction was initially reported by de Mayo in 1962.[1] It is a two-step process involving the [2+2] photocycloaddition of an enol of a 1,3-dicarbonyl compound (e.g., β-diketone,[1,2] β-dialdehyde,[3] or β-ketoaldehyde[4]) with an olefin to form a cyclobutanol intermediate and the *retro* aldol condensation of such a cyclobutanol to give 1,5-dicarbonyl compounds. Therefore, this reaction is generally known as the de Mayo reaction.[5] Occasionally, it is also referred to as the de Mayo photocycloaddition.[6] In this reaction, it is known that in the absence of extreme steric hindrance, the regiochemistry of cycloaddition is predictable,[7] and such regioselectivity will also be affected by a solvent.[8] When an electron-deficient, polarized olefin (CH_2=CHR, R = CN, Cl, $COCH_3$, CO_2CH_3, etc) is subjected to the [2+2] photocycloaddition with enol of 1,3-dicarbonyl compound, the so-called head-to-tail regioisomer with *exo*-orientation of R on such an olefin is the favored product.[9] However, in the case of unsymmetrical 1,3-dicarbonyl compound, regioselectivity of the enolization will result in a significant problem, and the original reaction pattern would be modified using β-keto esters.[5i] In addition, dioxolenones are used as a covalently locked enol form of a β-keto ester to avoid the competing *Paterno-Büchi Reaction* that forms oxetanes.[10] It should be pointed out that the cyclobutanol intermediate from cyclic 1,3-dicarbonyl compound can be transformed into either cyclooctanedione[5e] or cyclohexenone (via an *Aldol Reaction*).[9]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to form enols from β-keto esters.[5i,10]

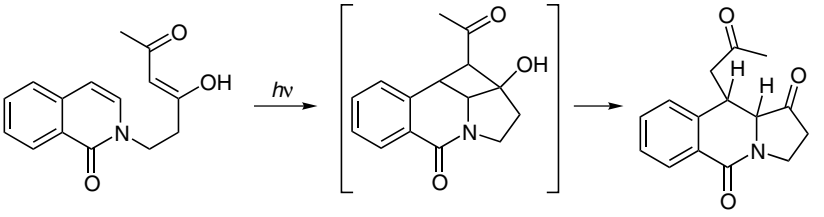
E. APPLICATIONS

This reaction has a wide range of application in the preparation of 1,5-dicarbonyl compounds, especially in regard to the synthesis of the smallest known bicyclic compound ([4.3.1] undecane) with *trans* bridgehead hydrogen.[10b]

F. RELATED REACTIONS

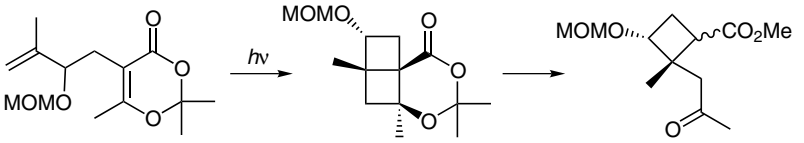
This reaction is related to *[2+2] Cycloaddition* and *Aldol Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A solution containing 101 mg 2-(3,5-dioxo-1-hexyl)isoquinolin-1(2*H*)-one (0.39 mmol) in 10 mL acetonitrile was purged with nitrogen for 15 min before irradiation through a Pyrex filter at ambient temperature for 1.5 h. The reaction mixture was concentrated under reduced pressure by rotary evaporation. Flash chromatography (silica, EtOAc/hexane, 2:1) gave 72.3 mg 10-(2-oxopropyl)-2,3,10,10a-tetrahydropyrrolo[1,2-*b*]-isoquinolin-1,5-dione as a white crystalline solid, in a yield of 71.6%, m.p. 184–185°C.



Reference 10a.

Irradiation of a solution of 277 mg 5-(2-methoxymethoxy-3-methylbut-3-enyl)-2,2,6-trimethyl-[1,3]dioxin-4-one (1.03 mmol) in 50 mL acetonitrile/acetone mixture (9:1 v/v) for 2–3 h afforded 130 mg 3-methoxymethoxy-4,6,8,8-tetramethyl-7,9-dioxatricyclo[4.4.0.0^{1,4}]decan-10-one as a colorless oil after purification (EtOAc/petroleum ether, 1:3, R_f = 0.24), in a yield of 47%. When 81 mg this photo-cycloadduct (0.3 mmol) was treated with base in refluxing THF for 30 min, 56 mg of a 30:70 mixture of 3-methoxymethoxy-2-methyl-2-(2-oxopropyl)cyclobutanecarboxylic acid methyl ester of diastereomers was obtained as a colorless oil after column chromatography (Et_2O/petroleum ether, 1:4), in a yield of 77%. Both isomers were separated by further chromatography.

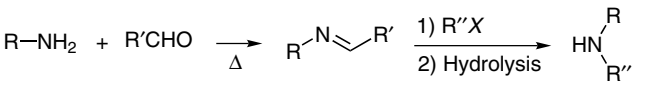
Decker-Becker Secondary Amine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

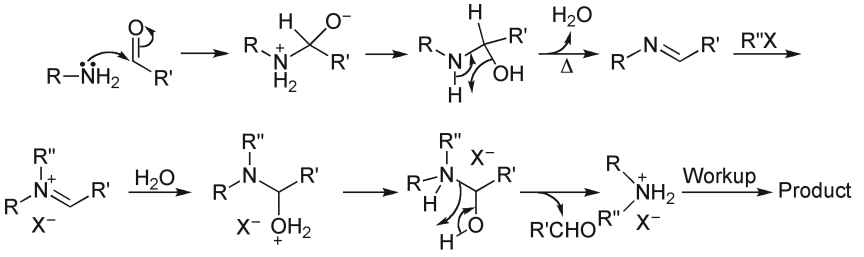
Although Forster initially reported this reaction,[1] it was Decker and Becker who investigated it in more depth and made this reaction an applicable route for the preparation of secondary amines.[2] Therefore, this reaction is known as the Decker-Becker method[3] or Forster reaction,[4] but it is named the Decker-Becker secondary amine synthesis in this book. It is the synthesis of secondary amine by the condensation of primary amines with aldehydes to form an imine intermediate, which then reacts with alkyl halides via alkylation to finally afford secondary amines after hydrolysis. This reaction gives good results when methyl halides are used but works poorly and unstably when larger alkyl halides are applied.[5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has general application in the preparation of secondary amines, especially for the alkyl (aryl) methyl amines.

General Method for Preparation of Schiff Base

After the mixture of equal amounts of primary amines and benzaldehyde in 95% ethanol was refluxed for 30 min, the solvent was removed and the Schiff base was obtained in roughly 95% via vacuum distillation. These Schiff bases were mostly yellow oils and were used directly without further purification.

Alkylation and Hydrolysis

To a thoroughly dried Carius tube were added equal amounts of Schiff base and the appropriate alkyl iodide. After sealing, the tube was heated at 100°C by steam for 4–24 h, the longer time being used for the higher halides. The reaction was considered complete

when the whole contents of the tube upon cooling was a red to orange viscous oil or a partially crystalline mass. A layer of mobile liquid above the viscous mass showed the reaction to be incomplete. After opening, the contents of the tube were washed out with an alcohol—methyl alcohol for the methylated product and ethyl alcohol for the higher alkylated product—to which had been added one eighth its volume of water. The mixture was refluxed for 30 min then the mixture was poured into an equal volume of water and boiled until the odor of benzaldehyde had disappeared. The solution was made weakly acid with acetic acid and extracted three times with ether. After basification with 30% sodium hydroxide, the amine was extracted with ether, the ethereal solution was dried with anhydrous magnesium sulfate, and after removal of the solvent, the residue was distilled in vacuo.The hydrochlorides of these secondary amines were prepared from an anhydrous ether solution by the addition of gaseous hydrogen chloride and were recrystallized from ether-alcohol mixtures. The yields vary from 29% to 93%.

Other references related to the Decker-Becker secondary amine synthesis are cited in the literature.[6]

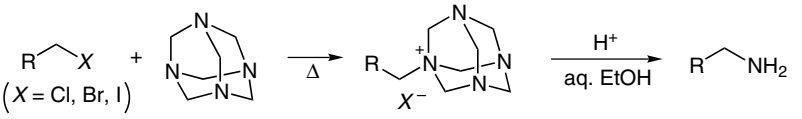
Delépine Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Delépine in 1895.[1] It is the preparation of primary aliphatic amines by acidic hydrolysis of quaternary amines formed from alkyl halides and urotropine (i.e., hexamethylene tetramine).[2] Therefore, this reaction is generally known as the Delépine reaction.[3]

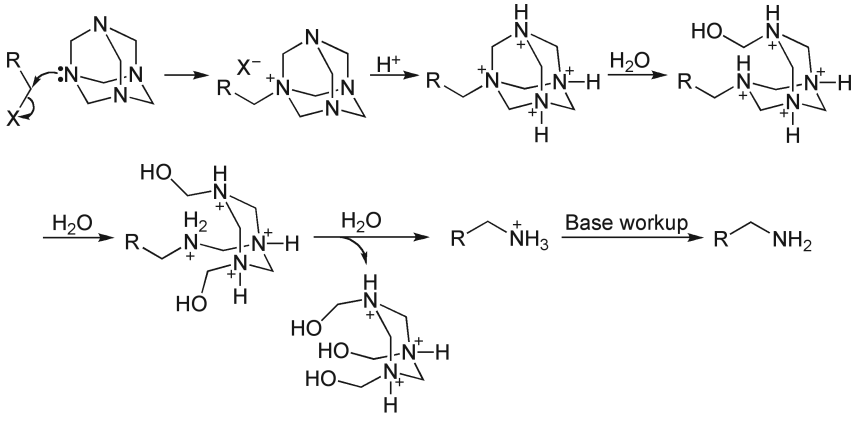
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is displayed here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

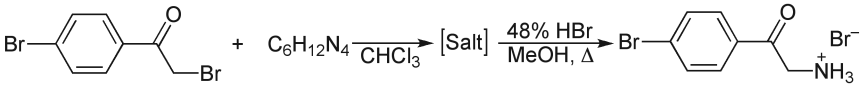
E. APPLICATIONS

This reaction has general applications in the conversion of alkyl halides into primary amines.

F. RELATED REACTIONS

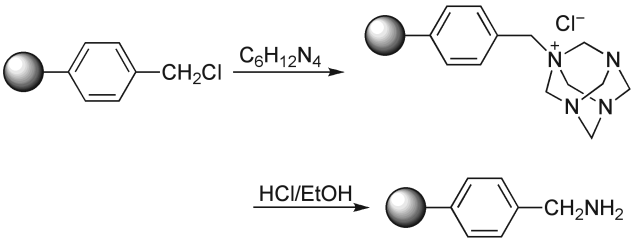
This reaction is related to the *Gabriel Primary Amine Synthesis* and *Sommelet Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

Hexamethylene tetramine (49.2 g, 0.350 mol) was dissolved in 750 mL chloroform, then 97.4 g 2,4′-dibromo-acetophenone (7.4 g, 0.350 mol) was added all at once; the suspension was stirred overnight and the quaternary salt was collected, washed with 750 mL chloroform, and dried at 60°C under reduced pressure (20 mmHg) for 4 h. The product was treated with 900 mL methanol and 120 mL 48% hydrobromic acid at 20°C for 2 days. Solid was always present, so 600 mL methanol was added, and the suspension was heated at 50°C overnight and then at reflux for 1.5 h, cooled to 20°C, and evaporated at a bath temperature of 50°C to obtain a mushy solid, which was recrystallized from 700 mL water to give 84.4 g 4-bromobenzoylmethylammonium bromide dihydrate, in a yield of 73%, m.p. 273–277°C (dec.)



Reference 3.

A tube containing 300 mg monolithic VBC/DVB PolyHIPE (1.23 mmol of chloromethyl groups) was set in an Argonaut Quest 210 apparatus and a 240 mL ethanol solution of reagents (hexamethylenetetramine and sodium iodide, five times excess relative to chloromethyl groups) was passed through at a flow rate of 20 mL/h and at 60°C. The product was washed with EtOH, EtOH/water (1:1), and water; subsequently, a solution of 240 mL conc. HCl/EtOH (1:15) was passed through at a flow rate of 20 mL/h and at 75°C. The product was washed with EtOH, EtOH/water (1:1), MeOH, NEt_3, and MeOH and dried at 50°C (10 mbar, 48 h).

Demjanov Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Demjanov (sometimes spelled Demjanow or Dem'yanov) in 1903.[1] It is the conversion of primary amines into alcohols by means of the diazotization of those amines with nitrous acid, accompanying the migration of the carbon atom when the primary amino groups are on the ring or at the α-position of the side chain. Therefore, this reaction is generally known as the Demjanov rearrangement[2] or Demjanov reaction.[3] In the case of cyclic aliphatic amines, alcohols with enlarged or contracted rings are formed, depending on the position of the amino group. If an amino group is directly attached to the ring, then ring contraction occurs;[4] in the case of primary amines, when the amino group is connected to the cyclic ring via a methylene group, the ring expands after diazotization.[2g,5] The Demjanov rearrangement under this condition is also referred to as the Demjanov ring expansion.[5a,6] If an aromatic group is attached to the same position where an aminomethylene sits, phenyl migration happens without ring enlargement.[2f]

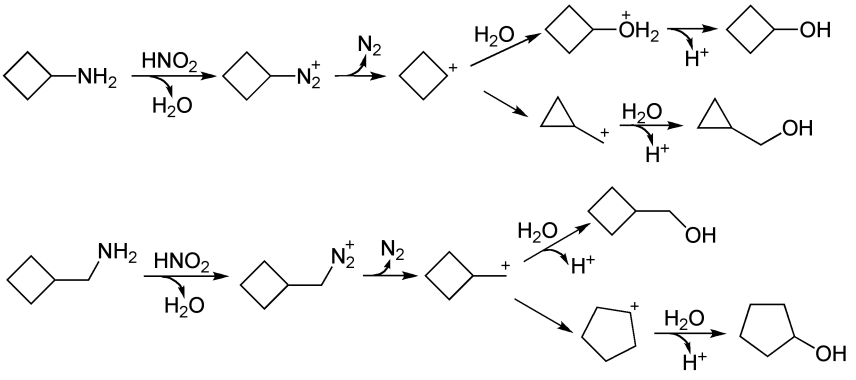
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

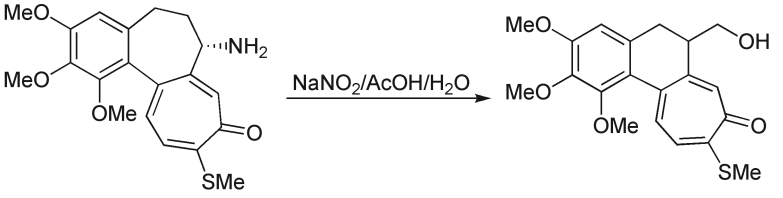
E. APPLICATIONS

This reaction has general application in the preparation of cyclic compounds with different sizes.

F. RELATED REACTIONS

This reaction is related to the *Tiffeneau-Demjanov Rearrangement* and *Wagner-Meerwein Rearrangement*, both involve carbocation intermediates.

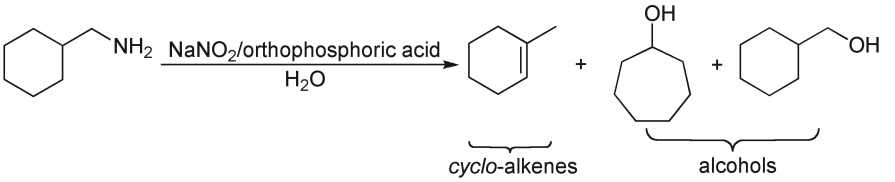
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a solution of 42.7 mg deacetylthiocolchicine (0.11 mmol) in 4 mL water was added 10.9 mg sodium nitrite in 1 mL water containing two drops of acetic acid. The reaction mixture was stirred at room temperature for 24 h and extracted with $CHCl_3$ (30 mL × 3). The extract was washed with 5% $NaHCO_3$ solution, water, and brine until pH = 7. It was dried over anhydrous Na_2SO_4 and concentrated. Purification of the residue by preparative TLC plates with $CHC1_3$/MeOH (95:5) as the eluant furnished 18.1 mg

pure 5,6-dihydro-6(*S*)-(hydroxymethyl)-1,2,3-trimethoxy-9-(methylthio)-8*H*-cyclohepta [a]naphthalene-8-one. Crystallization from CH_2Cl_2-Et_2O afforded yellow crystals, in a yield of 42%, m.p. 201–203°C.



Reference 2e.

Cyclohexanemethylamine (45.2 g, 0.4 mol) was treated with $NaNO_2$ in dilute aqueous orthophosphoric acid at room temperature for 1 h and then at 95°C for 1 h. Fractional distillation of the crude product gave 9.4 g cycloalkene mixtures (b.p. 90–115°C) and 26.6 g alcohol mixtures (b.p. 50–95°C at 20 mmHg).

Other references related to the Demjanov rearrangement are cited in the literature.[7]

Dess-Martin Periodinane Oxidation

(Dess-Martin Oxidation)

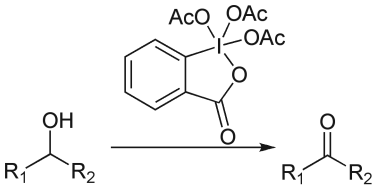
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Dess and Martin in 1983.[1] It is the conversion of primary and secondary alcohols into carbonyl compounds (aldehydes and ketones) by means of the oxidation with a hypervalent iodine compound (i.e., 12-I-5 triacetoxyperiodinane).[2] Therefore, this reaction is generally known as the Dess-Martin periodinane oxidation[3] or simply referred to as the Dess-Martin oxidation.[4] On the other hand, the hypervalent iodine compound is called the Dess-Martin periodinane (DMP),[2,5] Dess-Martin reagent,[6] Dess-Martin Periodinane reagent,[7] or Dess-Martin oxidant,[8] which tolerates a variety of functional groups.[2,5u,9] The actual oxidation condition is mild and normally completes within 2 h at room temperature and in a solvent with either slightly acidic or neutral pH.[5v] This oxidation normally gives high yields of products without overoxidation and can be easily worked up.[10] Therefore, this oxidation is suitable for the oxidation of substrates containing sensitive functionalities.[5v] The reaction has been carried out in different solvents but often in dichloromethane or chloroform. It was found that DMP might not be the actual oxidation reagent, while the substituted periodinane (the replacement of one or two acetyl groups by hydroxyl or ethoxy) oxidizes the alcohols faster than DMP. Therefore, addition of certain amounts of water to the reaction solution can accelerate the oxidation.[4c] It has been found that the oxidation of alcohols using DMP is faster in ionic liquids (either hydrophilic or hydrophobic) than in conventional solvents (e.g., DMSO, DMF, and EtOAc) and gives excellent yields with high selectivity.[11] Unfortunately, it is difficult to prepare

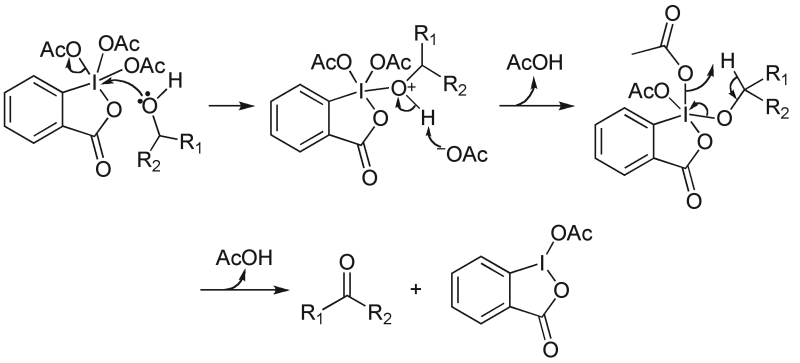
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

DMP with high purity by the original procedure;[5v,12] therefore, a few modifications have been suggested.[4c,5v,6b,13] In addition, DMP has been successfully used in the syntheses of polycyclic heterocycles[14] and in the removal of thioketals and thioacetals.[15] It should be mentioned that other hypervalent iodine compounds can be used as oxidants as well,[2] especially for the *o*-iodoxybenzoic acid (IBX), the precursor to DMP, which can oxidize tertiary cyclic allyl alcohol into α,β-unsaturated cyclic ketones[16] and secondary amines into imines[17] and can convert epoxides or aziridines into corresponding α-hydroxy ketones or α-amino ketones.[18]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

The preparation of DMP has been modified by substituting acetic acid with only a catalytic amount of TsOH during the acetylation step. By this modification, pure DMP can be easily obtained on a 100-g scale with an isolated yield of $> 90\%$.[5v] In addition, the oxidation itself has been accelerated by the addition of water to the reaction solution.[4c]

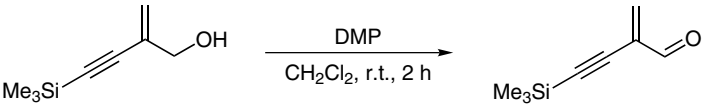
G. CITED EXPERIMENTAL EXAMPLES

Reference 19.

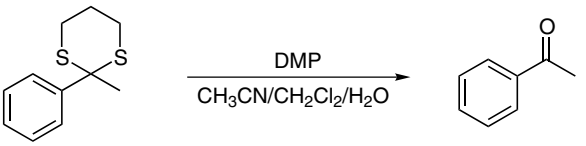
To a solution of 3 mL CH_2Cl_2 containing 111.4 mg forocidin (0.2 mmol) was added 101.8 mg Dess-Martin periodinane (0.24 mmol). After being stirred for 30 min at room temperature, a solution of 10 μL H_2O in 10 mL CH_2Cl_2 was added slowly via a dropping funnel. The pale yellow solution was stirred for 2–3 h until formation of a noticeable precipitate, then concentrated under reduced pressure; the residue was taken up in 30 mL ether. It was washed with 15 mL 10% $Na_2S_2O_3$/saturated aqueous $NaHCO_3$ (v/v 1:1), followed by 10 mL H_2O and 10 mL brine. The combined aqueous layers were extracted with $CHCl_3$ (3×10 mL). The combined organic layers were dried with Na_2SO_4 and concentrated. Column chromatography ($CHCl_3/CH_3OH$, v/v 9:1, 1% NH_3) of the residue afforded 61% of ketone as a pale yellow solid.



Reference 20.

A 50-mL, two-necked, pear-shaped flask fitted with an argon inlet adapter and a rubber septum was charged with a solution of 30 mL dichloromethane containing 0.942 g of the allylic alcohol (6.11 mmol). After the solution was cooled to 0°C, 2.856 g Dess-Martin periodinane (6.73 mmol) was added in one portion. The heterogeneous reaction mixture was stirred at 0°C for 5 min and then allowed to warm to room temperature. After 20 min, the reaction mixture was cooled to –78°C and diluted with 30 mL pentane, followed by the addition of 3.227 g poly(4-vinylpyridine) (30.69 mmol) in one portion. The resulting mixture was stirred at –78°C for 25 min. A 2.5-cm diameter jacketed column fitted with a rubber septum at the top and a short needle at the bottom was charged with a 6-cm plug of silica gel, which was cooled at –78°C by filling the jacket with dry ice acetone. The reaction mixture was transferred into the column by cannula and filtered through the silica gel under a positive pressure of argon into a 200-mL recovery flask fitted with a rubber septum with a short needle as a vent. The reaction flask and the column were rinsed with four 15-mL

portions of 4:1 pentane/ether. The filtrate was concentrated by rotary evaporation at 25°C (20 mmHg) to a volume of ∼3 mL and this solution was then cooled to –78°C and diluted with 5 mL toluene. The resulting solution was concentrated by rotary evaporation at 25°C to a volume of ∼3 mL. The resulting pale yellow solution was cooled to –78°C and further concentrated at 0.05 mmHg (∼15 min) to furnish 2-methylene-4-trimethylsilyl-but-3-ynal as a yellow oil, in a yield of 53%.



Reference 15.

To a sample of 210 mg 2-methyl-2-phenyl-1,3-dithiane (1.0 mmol) in 5.0 mL 8:1:1 $MeCN/CH_2Cl_2/H_2O$ (0.2 M) was added 424 mg Dess-Martin periodinane (2.0 mmol) in one portion. The reaction mixture was stirred at room temperature, and exposed to air for 2 h until the complete consumption of starting material as observed by TLC. The reaction was quenched with 20 mL 50% aqueous $NaHCO_3$. The layers were separated, and the aqueous layer was extracted three times into 50 mL CH_2Cl_2. The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (silica, 5% EtOAc/hexanes) afforded 112 mg (92%) of the desired acetophenone.

Other references related to the Dess-Martin periodinane oxidation are cited in the literature.[21]

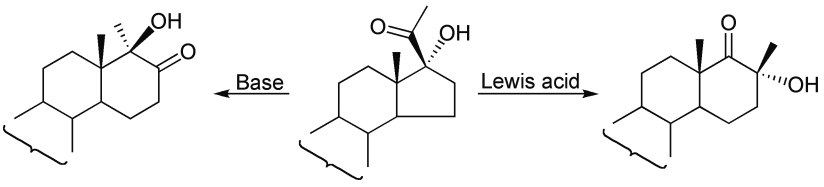
D-Homo Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This rearrangement can be traced back to 1938 when 17β-hydroxy-20-ketosteroid was treated with a base to give a ring-enlarged ketone.[1] As this rearrangement occurs at the D-ring of steroids without the loss of a carbon, it is known as D-homo rearrangement or D-homo annulation.[2] In this rearrangement, when 17-hydroxy-20-ketosteroids are treated with either bases or acids (Lewis acids), they will rearrange and give six-membered D-rings; the products resulting from the base treatment differ greatly from those caused by the acid treatment, showing characteristic stereospecificity.[2b,2j,2l] Explicitly, the 17α-hydroxy-20-ketosteroids will form products with 17aβ-hydroxy configurations when treated with base, and 17β-hydroxy compounds give 17aα-hydroxy-D-homo derivatives. In contrast, when 17aα-hydroxy compounds are treated with Lewis acids, the 17aα-hydroxy-D-homo derivatives form, and 17β-hydroxy compounds give corresponding 17aβ-derivatives.[2b,2j,2l] The Lewis acids or the combinations of acids tested for this rearrangement include $MgBr_2$, $BF_3/Ac_2O/AcOH$, $AlCl_3/Ac_2O/AcOH$, $ZnCl_2/Ac_2O/AcOH$, and $SnCl_4/Ac_2O/AcOH$. However, the stereospecificity might not hold in the presence of a proton donor when Lewis acid is used.[2l] The rearrangement also occurs when a carbocation forms at position 20 without a carbonyl group.[3]

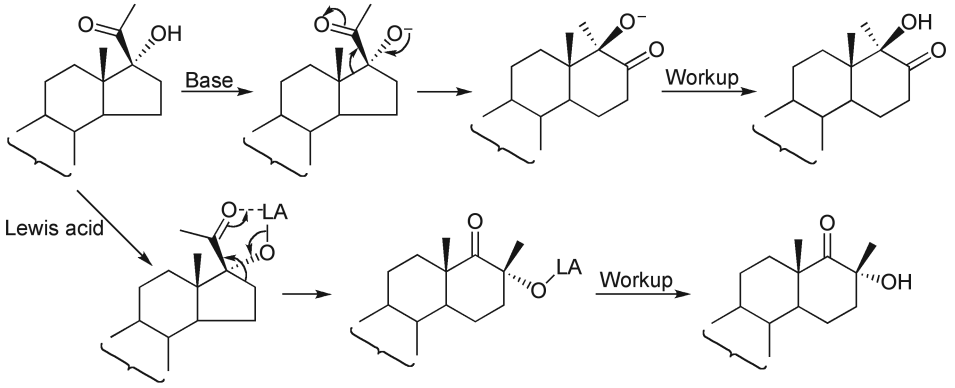
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is proposed that when 17α-hydroxy-20-ketosteroids are treated with a base, the oxygen atom on the carbonyl group will stay away from the oxygen anion originated from the hydroxy group; the migration will give a 17aβ-hydroxy derivative. In contrast, when the same molecule is treated with a Lewis acid, both oxygen atoms on the carbonyl and hydroxyl group will coordinate with the Lewis acid, and the migration of alkyl group results in a D-homo derivative with complete conservation of steric configuration, as illustrated here.



D. MODIFICATION

N/A

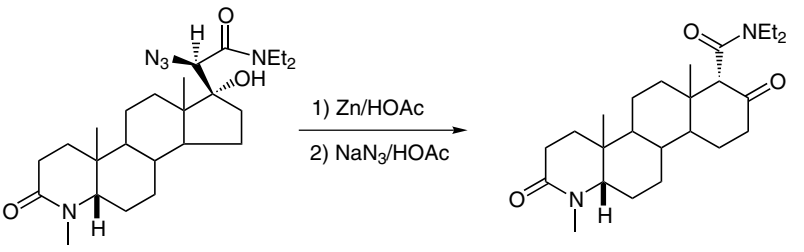
E. APPLICATIONS

This rearrangement has been used for the preparation of a series of steroid derivatives.

F. RELATED REACTIONS

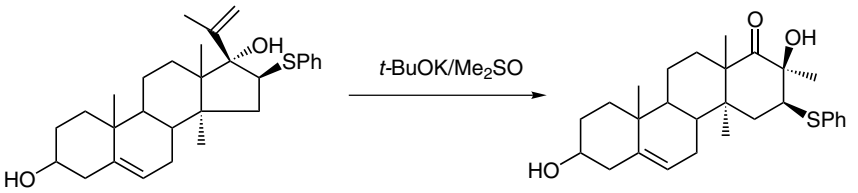
This reaction is related to the *Pinacol Rearrangement*.[2j]

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

To a solution of 1.37 g *N*,*N*-diethyl-4-methyl-3-oxo-17α-hydroxy-20α-azido-4-aza-5α-pregnane-21-carboxyamide in 35.0 mL acetic acid was added 1.37 g zinc powder in small portions over a period of 45 min at 20°C. The reaction mixture was stirred for 2 h at room temperature, after which gas evolution had ceased. The reaction mixture was filtered through Supercel and the excess of zinc was thoroughly washed with 27.8 mL of water containing 12.0 mL of acetic acid. The combined filtrates were diluted with 100 mL water and extracted with EtOAc. The extract was washed twice with water, and these washings were added to the acid layer. The latter was cooled in ice, and the pH was adjusted to 3–4; then 1.3 g sodium nitrite was added in portions. The diazotization was allowed to proceed overnight at 0–5°C with constant stirring. The reaction mixture was extracted four times with EtOAc, and the organic layers were combined and washed with water and brine, dried over $MgSO_4$, then filtered, and concentrated to give 1.07 g of a pale yellow oil. This oily material was then chromatographed on 60.0 g of EM silica gel with 3:2 acetone/hexane to give 683.0 mg 17α-(diethylcarbamoyl)-4-methyl-D-homo-4-aza-5α-androstane-3,17-dione as an amorphous material and 153.0 mg of a polar material as foam. Further purification of the former on HPLC followed by recrystallization afforded pure compound with melting point at 159–160°C.



Reference 2b.

To a solution of 196 mg 3β,17α-dihydroxy-16β-(phenylthio)pregn-5-en-20-one in 2 mL dry DMSO was added 2.6 mL 0.035 M *t*-BuOK in DMSO. After being stirred for 2 min at room temperature, the reaction mixture was quenched with concentrated HCl and worked up. After removal of the solvent, 200 mg 3β,17β-dihydroxy-17α-methyl-16β-(phenylthio)-D-homo-androst-5-en-17a-one was obtained. Recrystallization from ether afford pure product with melting point at 131–133°C.

Other references related to the D-homo rearrangement are cited in the literature.[4]

Dieckmann Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Dieckmann in 1894.[1] It is a base-promoted intramolecular condensation of α,ω-diesters to form cyclic β-ketoesters that can be further transformed into cyclic ketone upon hydrolysis and decarboxylation. Therefore, it is generally known as the Dieckmann condensation.[2] In addition, this reaction is often referred to as the Dieckmann reaction[3] or Dieckmann cyclization.[4] Occasionally, it is called Dieckmann ring closure.[5] It should be pointed out that this reaction is not only good for the preparation of 5- or 6-membered cyclic β-keto esters[1,6] but also an important tool for synthesizing even larger cyclic ketones.[7] Examples include the cyclization of various aminodiesters to 10-membered cyclic aminoketones and 16- and 20-membered cyclic diaminodiketones.[8] The formation of 5- to 6-membered cyclic β-keto esters is usually carried out in an alcoholic solvent by the treatment of sodium alkoxide; whereas the formation of large cyclic ketones take places in an aprotic solvent (e.g., xylene) under high dilution conditions when diesters are treated with potassium *t*-butoxide under nitrogen atmosphere,[7a] such as the formation of metacyclophanes from methyl esters of *meta*-benzenedialkanoic acids with carbonyl groups at the centers of the *meta*-bridges.[9] The importance of this reaction has been evidenced in the preparation of complicated cyclic compounds in a series of tandem reactions, as shown in the tandem [2+2] cycloaddition-Dieckmann condensation[10] and tandem conjugate addition- (or *Michael Addition*)-Dieckmann condensation.[11] Theoretically, the Dieckmann condensation is a special case of *Claisen Condensation*, and its mechanism is also similar to the *Claisen Condensation*. It has been proved that the Dieckmann con-

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

densation also occurs in the gas phase, with a mechanism analogous to the solution phase condensation.[12] However, the carbanion formed from proton abstraction in the solution phase is the actual intermediate for condensation, while the carbanion generated similarly in the gas phase may not necessarily be the intermediate of condensation.[12]

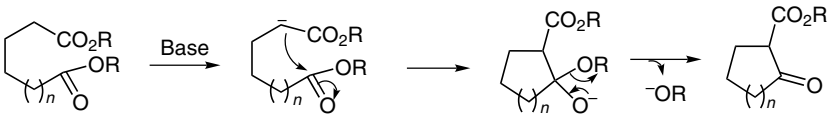
C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

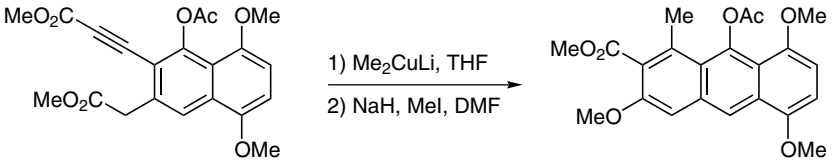
E. APPLICATIONS

This reaction has general application in the synthesis of cyclic ketones.

F. RELATED REACTIONS

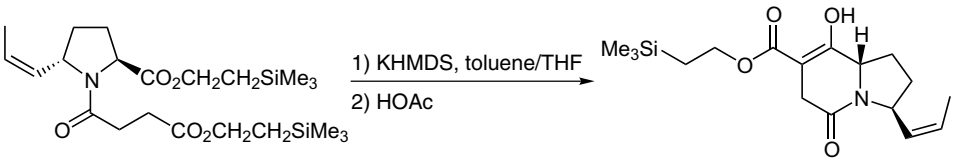
This reaction is related to the *Claisen Condensation.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

To an ice-cooled suspension of CuI (119 mg, 0.627 mmol) in 2 mL THF was added 0.78 mL 1.6 M ether solution of MeLi (1.255 mmol) during stirring. The mixture was stirred for 10 min, then 200 mg 3-(1-acetoxy-5,8-dimethoxy-3-methoxycarbonylmethyl-naphthalen-2-yl)-propynoic acid methyl ester (0.502 mmol) in 4 mL THF was introduced via cannulation. The reaction mixture was allowed to warm up to room temperature and then stirred overnight. Then it was quenched with 10% HCl, and the product was extracted with EtOAc. Organic layers were combined and washed with water, dried over Na_2SO_4, and concentrated in vacuo. The crude yellow product (160 mg, 84% crude yield) was used in the next step without purification. To a solution of crude phenol (160 mg, 0.41 mmol) in 2 mL DMF at room temperature was added 160 mg K_2CO_3 (1.16 mmol) followed by 0.05 mL MeI (0.8 mmol). The resulting suspension was stirred overnight; and then diluted with water. The product was extracted with EtOAc, and the combined organic layers were washed with water, dried over Na_2SO_4, and concentrated in vacuo. Silica gel chromatography (CH_2Cl_2) yielded 120 mg 9-acetoxy-3,5,8-trimethoxy-1-methyl-anthracene-2-carboxylic acid methyl ester as a yellow solid, in a yield of 60% over two steps, m.p. 227–228°C.



Reference 4d.

To a solution of 0.486 g (2*S*,5*S*)-5-*cis*-propenyl-1-[3-(2-trimethylsilanylethoxy-carbonyl)propionyl]pyrrolidine-2-carboxylic acid 2-trimethylsilanylethyl ester (1.07 mmol) in 100 mL THF at –78°C under argon was slowly added 3.21 mL 0.5 M potassium bis(trimethylsilyl)amide in toluene (1.61 mmol). A pale orange solution was formed, which was allowed to warm to room temperature over 2 h. The reaction was then quenched with 0.31 mL glacial acetic acid (5.5 mmol), and the solvent was evaporated. The residue was triturated with Et_2O and filtered, and the filtrate was dried over sodium sulfate and evaporated to yield an orange oil, which was purified by column chromatography (EtOAc/hexanes, 1:4) to yield 0.188 g (3*S*,9*R*)-8-hydroxy-5-oxo-3-*cis*-propenyl-1,2,3,5,6,8a-hexahydroindolizine-7-carboxylic acid 2-trimethylsilanylethyl ester as an unstable colorless solid, in a yield of 52%.

Diels-Alder Reaction
(Diels-Alder Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Diels and Alder in 1928.[1] It is an electrocyclic [4+2]-cycloaddition between a conjugated diene and a dienophile (either alkene or alkyne) for the synthesis of an unsaturated six-membered ring. Therefore, it is generally known as the Diels-Alder reaction[2] or Diels-Alder cycloaddition.[3] However, it was also referred to as the Diels-Alder diene synthesis,[4] and the Diels-Alder synthesis[5] during the early development stage of this reaction. The products from this reaction are called cycloadducts. As numerous publications on Diels-Alder reaction appear each year, it is impossible to review all of them.[6] For example, the Diels-Alder reaction probably is one of the most commonly applied reactions in organic synthesis, as indicated by the 637 papers published from 1990 to 2000 on ACS. In addition, there are many monographs (or books[7]) and reviews[2l-2p,3m,4-6,8] available for the Diels-Alder reaction. In this reaction, the substituents on diene and dienophile both play very important roles, as they all affect the electron densities and orbital energy of the reactants. Generally speaking, a diene can react with a dienophile using diene's HOMO (highest occupied molecular orbital) and dienophile's LUMO (lowest unoccupied molecular orbital) or vice versa. According to the Woodward-Hofman's rule[9] and Fukui's frontier molecular orbital theory (FMO),[10] the Diels-Alder reaction can be divided into three types: the normal Diels-Alder reaction ($HOMO_{diene}$+ $LUMO_{dienophile}$), the inverse electron demand Diels-Alder reaction or simply the inverse Diels-Alder reaction ($LUMO_{diene}$+ $HOMO_{dienophile}$), and the neutral Diels-Alder reaction.[8n] The reaction rate is related to the magnitude of the lowest HOMO–LUMO energy separation attainable by the diene-dienophile components. For the normal Diels-Alder reaction, electron-donating groups on dienes will level up the HOMO energy of dienes, and the electron-withdrawing group will lower the LUMO energy of dienophile; as a result, the magnitude between the HOMO–LUMO gaps is reduced, and the Diels-Alder reaction is

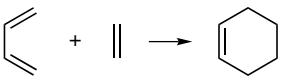
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

accelerated. Similarly, the electron demanding will be reversed on dienes and dienophiles in the inverse electron demand Diels-Alder reaction. For the neutral Diels-Alder reaction, the energy gap between $HOMO_{diene}$- $LUMO_{dienophile}$ and $LUMO_{diene}$ - $HOMO_{dienophile}$ does not differ too much, and either combination will lead to the formation of product, as in the case of ethylene and 1,3-butadiene.[11]

It is important to note that the Diels-Alder reaction shows high regioselectivity, diastereoselectivity and enantioselectivity, which are controlled by the compatibility between the HOMO–LUMO pairs of dienes and dienophiles. During the cycloaddition, dienes can take s-*cis* or s-*trans* conformation (*cisoid* or *transoid*); however, only the s-*cis* conformation can participate in the cycloaddition.[8s,12] If dienes are restricted to s-*trans* conformation, almost no Diels-Alder reactions occur from these dienes.[13] The small cyclic dienes have been forced to take the s-*cis* conformation (e.g., cyclopentadienes and cyclohexadienes); they are very good candidates for such reaction.[14] For the case of dienophiles, *cis*-dienophiles give *cis*-substitution, and *trans*-dienophiles result in *trans*-substitution in the cycloadducts. The major product for cyclic diene is an *endo* product, in which the electron-withdrawing groups will be on the same side as the double bond of the bicyclic ring, because it is favored by secondary orbital interactions via kinetic control.[15] Overall, the product formed from the suprafacial–suprafacial interaction with the *endo* approach will be the most favored product.[2m]

The introduction of an atom other than carbon to either dienes or dienophiles will result in the hetero-Diels-Alder reaction.[16] Owing to the nature (steric effect, electronic effect, etc.) of substituents on dienes and dienophiles, the Diels-Alder reaction might occur through a synchronous concerted, an asynchronous concerted, or a stepwise reaction mechanism.[17] The stepwise and asynchronous concerted Diels-Alder reactions proceed via diradical intermediates,[18] whereas the synchronous concerted mechanisms does not. It should be pointed out that most of the Diels-Alder reactions are concerted; as a result, both the rate constants and the stereoselectivities of Diels-Alder reaction are only moderately sensitive to the changes in the nature of organic solvents.[8i] However, it has been clearly shown that the applications of water to the reaction system can greatly accelerate such reactions.[19] Other modifications on this reactions include the application of high pressure,[2e] Lewis acid,[20] and ultrasound radiation.[8i] More information about this reaction can be easily attained from reviews and relevant books.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Provided here is a simple illustration for the Diels-Alder reaction proceeding through a synchronous concerted mechanism.

D. MODIFICATION

There are many modifications on this reaction, including the application of Lewis acids, aqueous media, high pressure, and ultrasonic radiation.

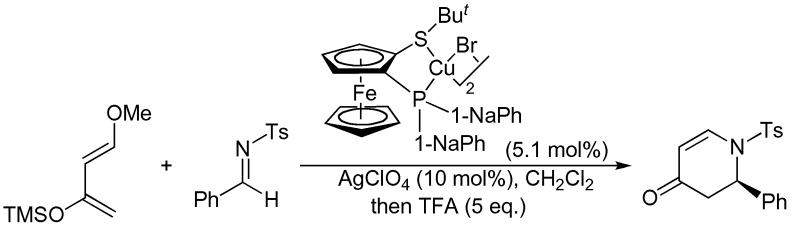
E. APPLICATIONS

This reaction has very broad application in organic synthesis, regarding the preparation of cyclic compounds.

F. RELATED REACTIONS

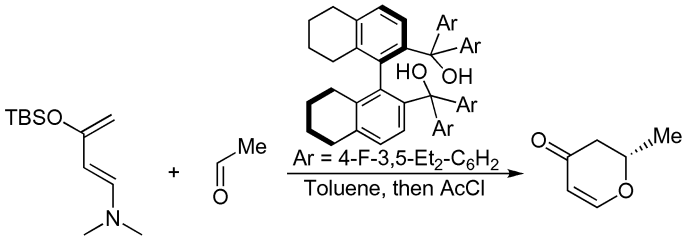
This reaction is related to *Retro-Diels-Alder Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 21.

A solution of 0.0056 mmol ferrocene catalyst and 0.011 mmol $AgClO_4$ in 0.6 mL CH_2Cl_2 was stirred in the dark at room temperature under argon for 2 h and treated with a solution of 0.11 mmol imine in 1 mL CH_2Cl_2. The reaction mixture was stirred at room temperature for 5 min before it was treated with 0.15 mmol diene at room temperature. Once the starting material was consumed, 0.1–0.2 mL TFA was added, and the mixture was stirred at room temperature for 30–60 min. The reaction mixture was neutralized with saturated aqueous $NaHCO_3$, extracted with CH_2Cl_2, dried over $MgSO_4$ and filtered. After evaporation of the solvent, the residue was purified by flash chromatography (*n*-hexane/EtOAc, 4:1) to give (*R*)-2-phenyl-1-(*p*-tolylsulfonyl)-2,3-dihydro-4-1*H*-pyridone [(*R*)-5a] as a white solide, in a yield of 87%, 97% e.e., m.p., 122–123°C (CH_2Cl_2/*n*-hexane).



Reference 22.

To a solution of 1.0 mmol aldehyde and 0.1 mmol diol in 0.5 mL toluene at –40°C (temperature of the cooling bath) was added 0.5 mmol (*E*)-1-dimethylamino-3-*tert*-butyldimethylsiloxy-1,3-butadiene dropwise (5–10 s). The reaction was maintained at the temperature for 1 day. The reaction was then brought to –78°C (dry ice/acetone) before dilution with 1.0 mL CH_2Cl_2 and subsequent addition of 1.0 mmol acetyl chloride. This was allowed to stir for 30 min at –78°C before the crude mixture was transferred directly on top of a silica gel column and eluted with hexanes/EtOAc to afford 75% 2,3-dihydro-2-methyl-4*H*-pyran-4-one as a pale yellow oil, with 97% e.e.

Other references related to the Diels-Alder reactions are cited in the literature.[23]

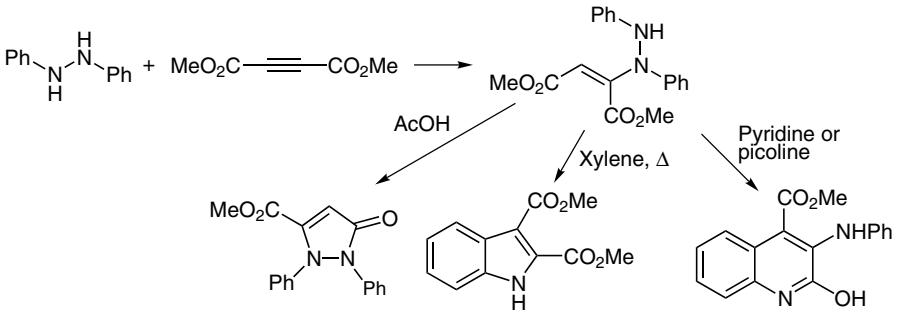
Diels-Reese Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Diels and Reese in 1934.[1] It is the conjugate addition between hydroazobenzene and dimethyl acetylene-dicarboxylate. The resulting adduct can be transformed into three different heterocyclic compounds under various experimental conditions (i.e., pyrazolones with acid, indoles upon heating in xylene, and quinolones with base[2]). For example, 1,2-diphenyl-3-carbomethoxy-5-pyrazolone will be generated from the adduct in acetic acid (acidic condition), whereas dimethyl indole-2,3-dicarboxylate is produced in xylene (neutral condition) and 2-hydroxy-3-anilino-4-carbomethoxy-quinoline is yielded in pyridine (basic condition).[1,3] The latter can be further converted into 2,3-dihydroquinoline upon decarboxylation and hydrolysis.[4] This reaction has been extended to heat the 1:1 adduct in picoline.[3]

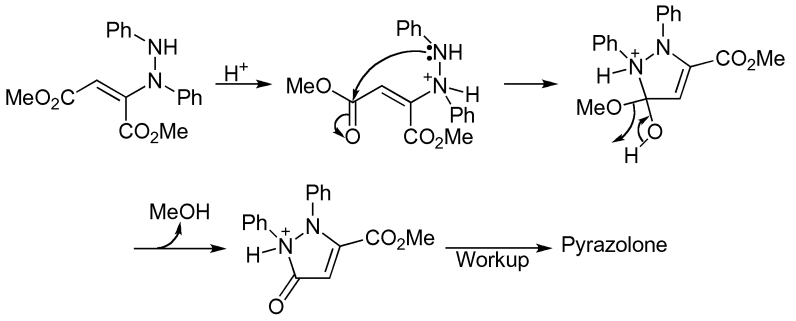
B. GENERAL REACTION SCHEME



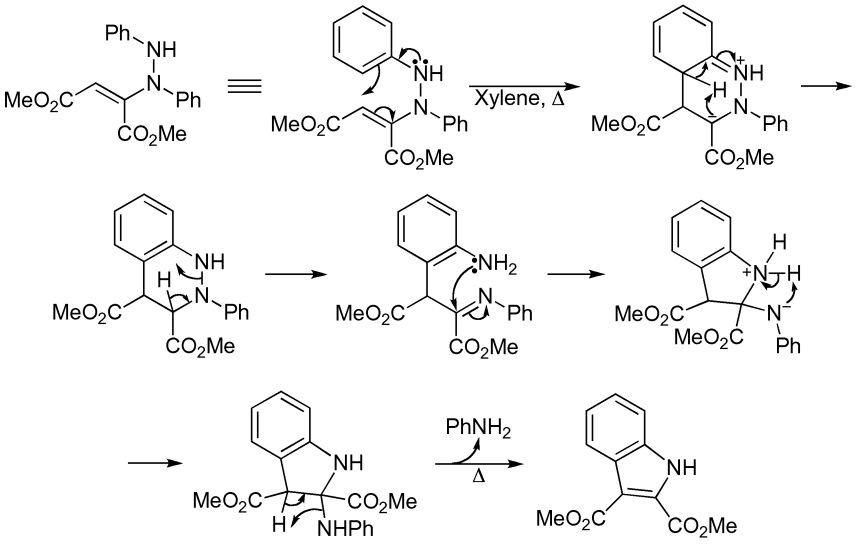
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

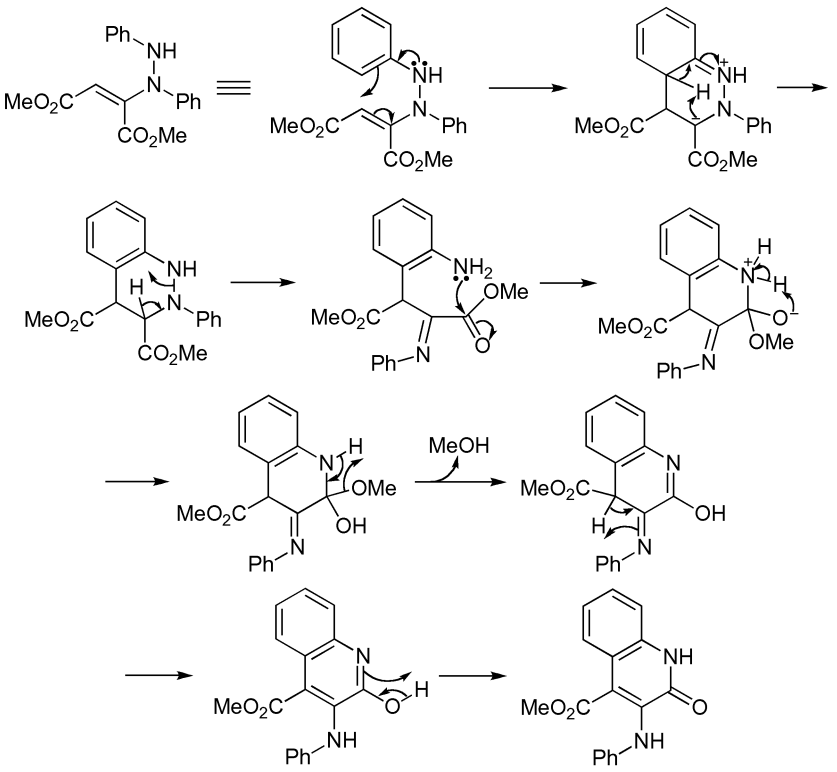
Because no mechanistic information about this reaction is available, the routes to form the three different products are tentatively outlined (Schemes 1–3.)



SCHEME 1. *Formation of pyrazolone by the Diels-Reese reaction.*



SCHEME 2. *Formation of indole derivative in xylene.*



SCHEME 3. *Formation of quinolone derivative.*

D. MODIFICATION

The refluxing of the adduct in α-picoline provides a higher yield of quinoline than that in pyridine.[3]

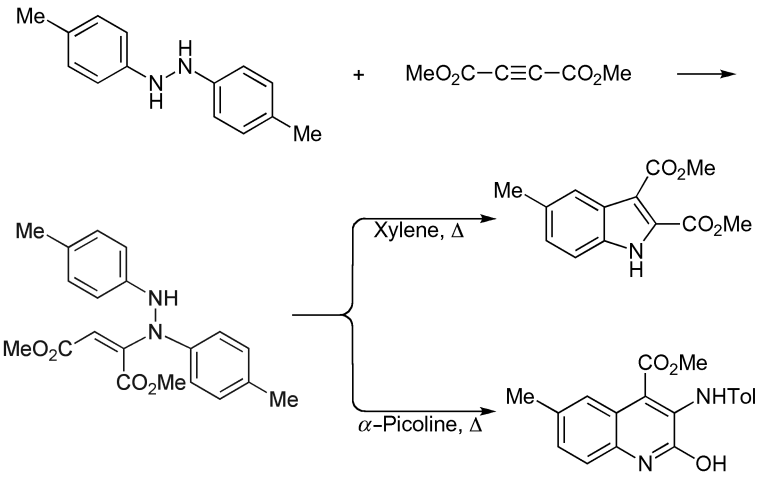
E. APPLICATIONS

This reaction can be used for the preparation of pyrazolones, indoles, and quinolines.

F. RELATED REACTIONS

This reaction is related to the *Fischer Indole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

Preparation of Adducts

A mixture of 6.5 g freshly prepared 4,4-dimethylhydrazobenzene (0.031 mol), 20 mL methanol and 5.5 g dimethyl acetylenedicarboxylate (0.038 mol) was refluxed. Within 1 min, the solid dissolved to form an orange-red solution that boiled spontaneously for 4 min. The mixture was refluxed for an additional 90 min. After standing in the ice-box overnight, the mixture had set to a yellow mash, which was filtered and washed with 5 mL cold ether to afford 7.1 g light yellow powder after dryness, in a yield of 66%. The adduct was pure enough for further reaction, m.p. 138–140°C (dec.)

Preparation of Quinoline

A solution of 10.0 g of the adduct (0.028 mol) in 20 mL α-picoline was refluxed for 1 h. The excess picoline was evaporated at room temperature. The brown residue, which was permeated with crystals, was stirred with 10 mL methanol, filtered, and washed with a little methanol. After drying under vacuum, 5.5 g 2-hydroxy-3-(p-toluino)-4-carbomethoxy-6-methylquinoline was obtained, in a yield of 61%, m.p. 236–237°C. Gold yellow needles can form after recrystallization in acetic acid, with a melting point of 237–238°C.

Preparation of Indole

A suspension of 2.0 g adduct (0.057 mol) in 4 mL xylene was refluxed for 1 h. The brown solution on cooling deposited a yellow solid, which was filtered and washed with methanol to give 1.1 g dimethyl 5-methylindole-2,3-dicarboxylate, in a yield of 66%. Recrystallization from acetic acid gave small golden yellow needles, melting at 236–237°C.

No other references for the Diels-Reese reaction are found from available literature sources.

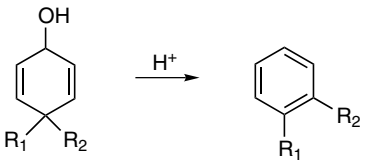
Dienol-Benzene Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

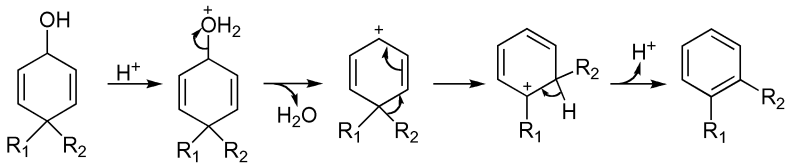
This reaction can be traced back to 1956.[1] It is an acid-promoted conversion of 4,4-disubstituted cyclohex-2,5-dienol into substituted benzene and is generally known as the dienol-benzene rearrangement.[2] It has been clearly shown that both the transition state and intermediate in this rearrangement have substantial carbonium ion characters.[2c] However, this reaction is catalyzed only by H^+ in acetate, formate, and phosphate buffers. In aqueous solution of $HClO_4$ and H_2SO_4, the rearrangement has been found to be first-order kinetics for 4-methyl-4-trichloromethyl cyclohex-2,5-dienol. In addition, the rearrangement of 4,4-dimethyl cyclohex-2,5-dienol is complicated with the isomerization to 6,6-dimethylcyclohex-2,4-dienol, leading to *o*-xylene.[2c] This reaction is useful for introducing aromaticity into the A-ring of steroids.[2m]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

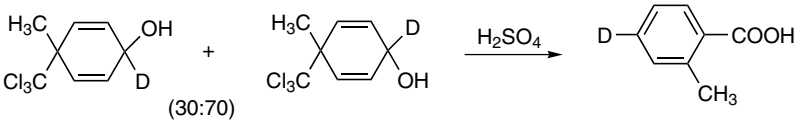
E. APPLICATIONS

This reaction has general application in the conversion of 4,4-disubstituted cyclohex-2,5-dienol (or dienone) into aromatic compounds.

F. RELATED REACTIONS

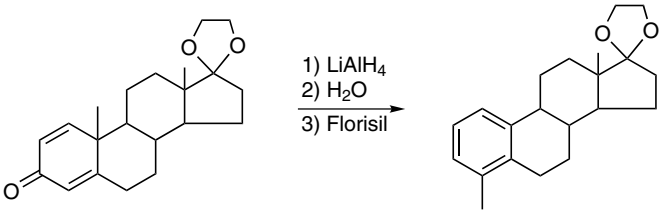
This reaction is closely related to the *Dienone-Phenol Rearrangement* but is not as common.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

A sample of 200 mg 1-D-4-methyl-4′-trichloromethyl-cyclohex-2,5-dienol (30:70 ratio) was treated with 1 mL conc. H_2SO_4 at 0°C for 25 min. The addition of ice gave 4-D-*o*-toluic acid, m.p. 96–100°C.



Reference 2m.

To a mixture of 1.0 g 1,4-androstadiene-3,17-dione-17-ethylene ketal and 1.0 g $LiAlH_4$ was added slowly 100 mL dry ether, while the temperature was maintained at 0–5°C under mechanical agitation. The reaction mixture was then refluxed for 2 h, cooled again to 0–5°C and 10 mL acetone was added cautiously with agitation. Then 10 mL water was added dropwise under stirring. The mixture was filtered, and the hydrated alumina was washed with ether. The combined filtrates were washed with water, dried over Na_2SO_4, and concentrated to give 990 mg of a colorless oil. The oil was taken up in hexane and chromatographed on 15 g Florisil. The hexane fractions were pooled and crystallized from hexane at –78°C to afford 250 mg 4-methylestra-1,3,5(10)-triene-17-one 17 ethylene ketal, m.p. 115–116.5°C.

Other references related to the dienol-benzene rearrangement are cited in the literature.[3]

193

Dienone-Phenol Rearrangement

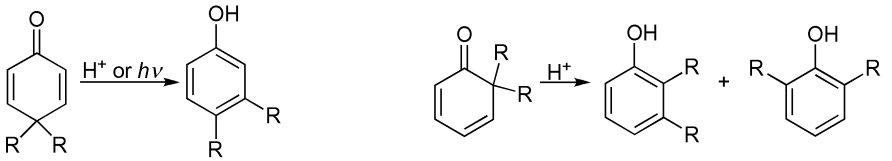
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Auwers and Ziegler in 1921.[1] In most cases, it is the transformation of 4,4-disubstituted cyclohexadienone into a 3,4-disubstituted phenol upon treatment of acid; however, 2,2-disubstituted cyclohexadienone[2] and cyclohexadienone with exocyclic double bond[3] can also be converted into the corresponding disubstituted phenol under similar conditions. Therefore, this kind of transformation is generally known as the dienone-phenol rearrangement.[4] It is interesting that the rearrangement of endocyclic cyclohexadienone to its phenolic derivative is spontaneous[3] unless a dichloromethyl group presents at position 4[5] or the process is blocked in some manner,[3] such as by the presence of a bulky substituent (e.g., *tert*-butyl) at both positions 2 and 6 for cyclohexa-2,5-dienones[6] or position 6 for cyclohexa-3,5-dienones.[7] In these cases, the elimination of the bulky group is also accompanied by the migration of the alkyl group,[6,7] and the alkyl group might rearrange to position 6 for cyclohexa-3,5-dienone.[7] It has been shown that the driving force for all of these rearrangements is aromatization.[8] For the acid-promoted dienone-phenol rearrangement, the reaction media used are either aqueous mineral acids or anhydrous media[9] (e.g., acetic anhydride or ether[10]) with an acid catalyst. It has been found that the reaction media have strong effects on the rearrangement;[11] however, for one case of santonin, a general acid-catalyzed reaction holds, as the same product was formed from both media.[9] Because this reaction occurs via a carbocation transition state, it has been clearly shown that the regioselectivity is completely controlled by the electronic factors, not the steric

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

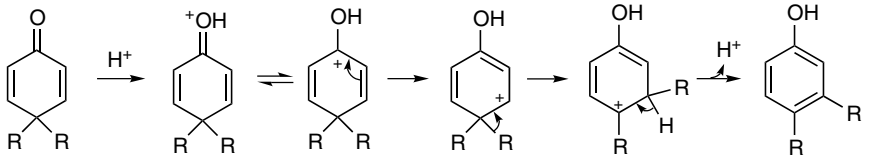
hindrance;[12] in addition, the stability of the final carbocation is the determining mechanistic element in such rearrangement.[13] Therefore, the migration tendency for two different groups at either 4,4 position or 2,2 position can be determined by comparing the relative stability of the carbocation formed via rearrangement. Under acid-promoted conditions, a few migration tendencies include CO_2Et > Ph (or alkyl),[13] Ph > Me,[14] vinyl > Me,[8] Me > OR,[15] and OR > Ph.[16] For the special cases of allyl and benzyl group, the actual rearrangement might undergo through the *Cope Rearrangement*.[7,17] Two successive *Allylic Rearrangements* are found for the rearrangement of quinamines.[18] Besides the acid promotion, the dienone-phenol rearrangement can also be catalyzed by base (NaOH for conversion phenol to dienone[19] and ammonia, primary, secondary, and tertiary amines for dienone to phenol[20]) or promoted photochemically.[21] Overall, the dienone-phenol rearrangement has proven valuable in the syntheses of steroids,[22] anthracene,[3] phenanthrene,[23] and a variety of phenols.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is illustrated by the rearrangement of 4,4-disubstituted cyclohexadienones to 3,4-disubstituted phenols, as displayed here.



D. MODIFICATION

The original rearrangement pattern has been modified by promoting the reaction photochemically[20] or by initializing the reaction via base.[19]

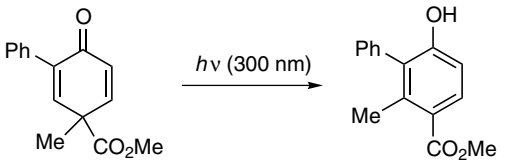
E. APPLICATIONS

This reaction has wide applications in the preparation of a variety of phenols; more important, this rearrangement has other uses in the syntheses of steroids, anthracene, and phenanthrene.

F. RELATED REACTIONS

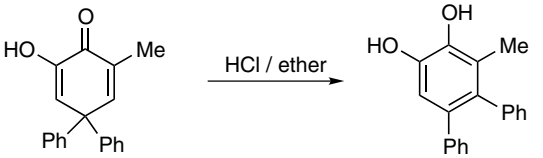
This reaction is related to the *Dienol-Benzene Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 21a.

A 0.06–0.08 M solution of 1-methyl-4-oxo-3-phenyl-cyclohexa-2,5-dienecarboxylic acid methyl ester in benzene was degassed by bubbling argon through the solution for 15 min. Irradiation through uranyl or Pyrex glass was carried out, and the final product of 6-hydroxy-2-methyl-biphenyl-3-carboxylic acid methyl ester was separated from chromatography on silica gel (4:1, hexane/EtOAc), in a yield of 85%.



Reference 12.

A 10-mL round-bottomed flask was fitted with a magnetic stirrer and charged with 0.7 mmol of 2-hydroxy-6-methyl-4,4-diphenylcyclohexa-2,5-dienone, 5 mL ether, and 2 mL conc. HCl. The mixture was stirred for 29 h, neutralized with a saturated $NaHCO_3$ solution, washed with water, and dried over $MgSO_4$. Upon removal of solvent, the residue was purified on preparative TLC and finally recrystallized from acetone/hexane to give white crystals, in a yield of 93%, m.p. 147–148°C, $R_f = 0.24$ (acetone/hexane, 1:4).

Dimroth Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Dimroth in 1909.[1] It is the base-catalyzed rearrangement or translocation of *exo*- and *endo*-cyclic heteroatoms on a heterocyclic ring and is generally known as the Dimroth rearrangement.[2] In quite a few cases, it is also referred to as the Dimroth-type rearrangement[3] or Dimroth reaction.[4] This type of rearrangement often occurs on a six-membered ring[5] but is also possible for five-membered rings.[6] Many Dimroth rearrangements involve 1H-1,2,3-triazoles.[6] In fact, this rearrangement undergoes a ring opening followed by a ring reclosure along with the translocation of heteroatoms.[5a] In most cases, the heteroatom is nitrogen, as indicated in the Section G.

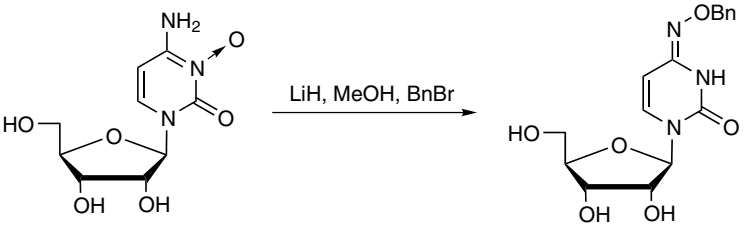
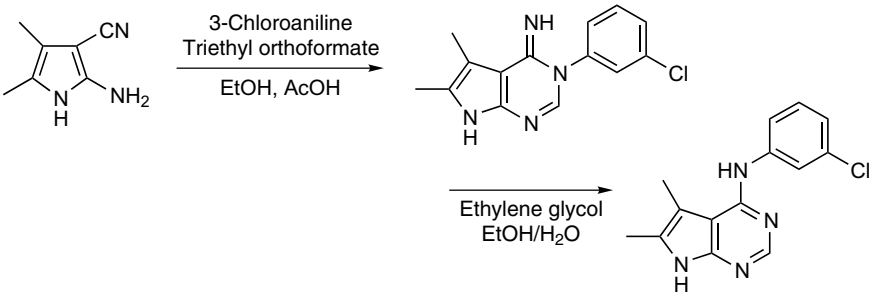
This reaction is related to the *ANRORC Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a suspension of 77.7 mg 4-amino-1-(3,4-dihydroxy-5-hydroxymethyltetrahydrofuran-2-yl)-1*H*-pyrimidin-2-one 3-oxide (cytidine N^3-oxide, 0.30 mmol) and 12.6 mg 95% pure lithium hydride (1.5 mmol) in 5 mL dry methanol was added 40 μL 98% pure benzyl bromide (0.33 mmol); the mixture was stirred at 37°C for 1 day under an argon atmosphere. TLC analysis of the reaction mixtures with chloroform/methanol/acetic acid (16:6:3) and chloroform/methanol (10:1) as the developing solvents showed complete consumption of the starting material for almost quantitative conversion to a less polar compound. After being neutralized with 1 N HCl solution and subsequent removal of the solvent under reduced pressure, the resulting residue was subjected to a short silica gel column by eluting with chloroform/methanol (20:1) to isolate 99.5 mg 1-(3,4-dihydroxy-5-hydroxymethyltetrahydrofuran-2-yl)-1*H*-pyrimidin-2,4-dione 4-*O*-benzyloxime (uridine 4-*O*-benzyloxime) as a colorless amorphous powder, in a yield of 95%, m.p. 123–125°C (from methanol).



Reference 8.

The mixture of 204.5 g triethyl orthoformate (1.35 mol), 700 mL absolute ethanol, and 222.0 g 3-chloroaniline (1.72 mol) was charged in a reaction vessel, and the pH was adjusted to 5–5.5 by addition of 6.65 g acetic acid (0.11 mol). The mixture was warmed to 50°C and stirred for 1 h. Then 166.0 g 2-amino-3-cyano-4,5-dimethylpyrrole (1.23 mol) was added as a solid over 6 h, while maintaining the temperature at 45–50°C. After completion of the addition, the mixture was kept at 50°C for additional 4 h and then for another 8 h at room temperature. After the addition of 100 mL water, the mixture was cooled to 0°C, and this temperature was maintained for 30 min. The resulting suspension was filtered, washed with ethanol/water (4:1), and dried in a vacuum at 50°C to yield 261 g 3-(3-chlorophenyl)-5,6-dimethyl-4H-pyrrolo[2,3-*d*]pyrimidine-4-imine, in a yield of 78%, m.p. > 150°C (dec).

A suspension of 300.0 g pyrrolopyrimidine (1.1 mmol) in 750 mL water, 750 mL absolute ethanol, and 1500 mL ethylene glycol was heated to 95°C for 4 h. The mixture was cooled to room temperature within 90 min. After the temperature was maintained at room temperature for an additional 1 h, the suspension was filtered, washed with water, and dried under vacuum at 50°C to yield 277 g 4-(3-chlorophenylamino)-5,6-dimethyl-7H-pyrrolo-[2,3-*d*]pyrimidine in a yield of 92%, m.p., 240–255°C.

Di-Π-Methane Rearrangement

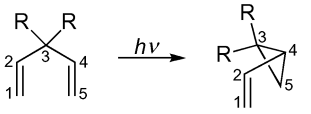
A. GENERAL DESCRIPTION OF THE REACTION

This rearrangement was initially investigated by Zimmerman in 1966.[1] It is a photochemical reaction of a molecular entity comprising two π-systems separated by a saturated carbon atom (a sp^3 carbon, e.g., a methylene group) involving the migration of one π-moiety bonded to the saturated carbon to other π moiety accompanied by the concomitant formation of a cyclopropane ring from the remaining π-moiety and methylene group.[2] Therefore, this reaction is known as the Zimmerman rearrangement,[3] di-π-methane rearrangement,[4] di-π-methane photorearrangement,[5] or simply the di-π-methane reaction.[6] Currently, this rearrangement has at least six versions: the divinylmethane variant,[7] the arylvinylmethane variant,[8] the *oxa*-di-π-methane rearrangement[9] (or ODPM rearrangement[10]), the *aza*-di-π-methane rearrangement,[11]and two less common variants, (barrelene di-π-methane rearrangement[12] and metalla di-π-methane rearrangement[13]). The *oxa*-di-π-methane rearrangement is the photochemical reaction of a β,γ-unsaturated ketone to an α-cyclopropyl ketone via a 1,2-acyl shift.[14] All these variants differ from each other. For example, the divinylmethane and arylvinylmethane rearrangement involves both singlets and triplets[2] and are favored from the triplet state for bicyclic molecules and the excited singlet for acyclic compounds,[16] whereas the *oxa*-di-π-methane rearrangement occurs solely through triplets,[2] with only a few exceptions.[9j] In addition, the divinylmethane rearrangement readily occurs when the sp^3 carbon between the vinyls is substituted, but the arylvinyl methane rearrangement does not have such a requirement. The di-π-methane rearrangement has high regiospecificity, with a strong preference for migration of the less conjugated π-moiety to the more conjugated one,[16] which contains two important stages as a "bridge"

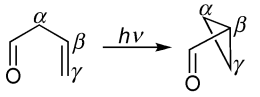
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

step and a "break" step.[17] It should be pointed out that the di-π-methane rearrangement can also be promoted by the application of plasma;[18] under certain conditions, the di-π-methane rearrangement is reversible.[19]

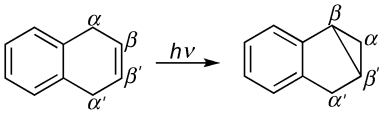
B. GENERAL REACTION SCHEME



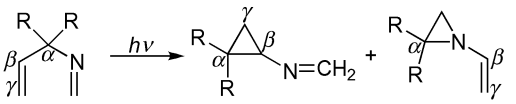
Divinyl type di-π-methane rearrangement.



Oxa-di-π-methane rearrangement.



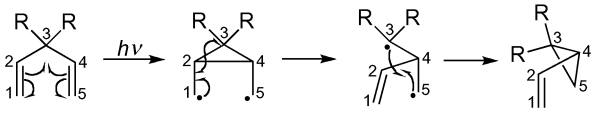
Arylvinyl type di-π-methane rearrangement.



Aza-di-π-methane rearrangement.

C. PROPOSED MECHANISMS

It is proposed that this rearrangement proceeds via the formation of the cyclopropane ring along with the generation of a biradical, followed by the ring opening of cyclopropane and the ring closure to form a new cyclopropane ring,[2,15] as illustrated here.



D. MODIFICATION

The original di-π-methane rearrangement has been modified to *oxa*-di-π-methane and *aza*-di-π-methane rearrangements.

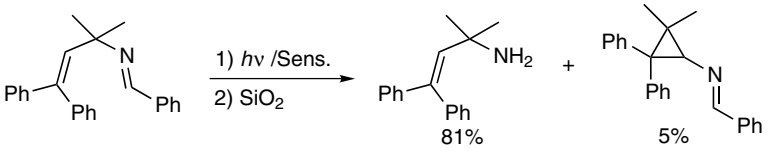
E. APPLICATIONS

This reaction can be used for the preparation of substituted cyclopropanes.

F. RELATED REACTIONS

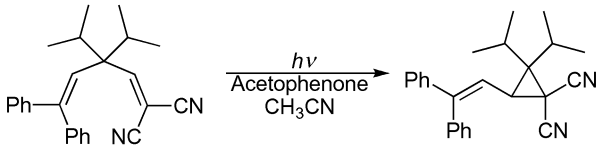
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 11b.

A mixture of 250 mg 3,3-dimethyl-1,5,5-triphenyl-2-aza-1,4-pentadiene (0.80 mmol), 550 mg *m*-methoxyacetophenone (3.7 mmol) and 450 mL dry *t*-BuOH was put into a quartz immersion well apparatus with a Pyrex filter. The solution was purged with argon for 1 h and was irradiated with a 400-W medium-pressure mercury arc lamp for 6 h. After completion of the irradiation, the solvent and the sensitizer were removed under reduced pressure, the residue was chromatographed with hexane/Et_2O (99:1) as an eluent to afford 65.0 mg benzaldehyde, and 13.0 mg of cyclopropylimine as a colorless oil, in a yield of 5%. Further elution with Et_2O yielded 25 mg of a highly polar material. Final elution with EtOH afforded 148 mg 1,1-dimethyl-3,3-diphenyl-2-propenylamine, in a yield of 81%.



Reference 20.

A solution of 51.0 mg 1,l-dicyano-5,5-diphenyl-3,3-diisopropyl-1,4-pentadiene (0.144 mmol) and 10 mL acetophenone (86 mmol) in 170 mL acetonitrile was irradiated with a 405-W Hanovia for 10 min after being purged with argon for 10 min. Concentration in vacuo and removal of acetophenone by bulb-to-bulb distillation (40°C at 0.1 mmHg) gave 56.2 mg of a pale yellow oil, which was further purified on HPLC. Elution with 1% ether in hexane gave 31.6 mg of starting material as fraction 1 and 17.8 mg 1,1-dicyano-2-(2,2-diphenylvinyl)-3,3-diisopropylcyclopropane as a colorless oil, which was recrystallized from pentane to give 9.3 mg of pure product, m.p. 76–77°C.

Other references related to the di-π-methane rearrangement are cited in the literature.[21]

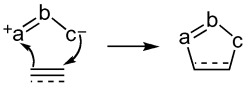
1,3-Dipolar Cycloaddition

A. GENERAL DESCRIPTION OF THE REACTION

The 1,3-dipolar cycloaddition[1] is a kind of cycloaddition reaction that involves the 1,3-dipolar molecules (called 1,3-dipoles) and dipolarophiles in analogues to the diene and dienophiles in *Diels-Alder Cycloadditions*. This reaction was first explored by Huisgen in 1960s[2,3] and was then extensively studied by Huisgen, Padwa,[4] Zecchi,[5] etc. Generally, the 1,3-dipolar molecules come from the combinations of carbon, nitrogen, and oxygen and can be divided into two categories: the propargyl-allenyl type and the allyl type, which are shown in Section B. The dipolarophiles can be either alkenes or alkynes. The outcome of this reaction will be a variety of five-membered heterocyclic molecules, which have been widely applied in medicinal/pharmaceutical chemistry.

B. GENERAL REACTION SCHEME

For the reaction of the allyl-type 1,3-dipoles, the reaction scheme can be generally presented as shown in Figure 1.



(a, b, c = N, O, C)

FIGURE 1. *Allyl type 1,3-Dipolar Cycloaddition.*

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

Whereas in the propargyl-allenyl type 1,3-dipoles, with the existence of *sp* orbital, the reaction scheme will be generally shown in Figure 2.

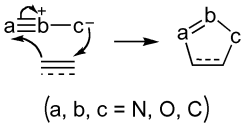


FIGURE 2. *Propargyl-allenyl type 1,3-Dipolar Cycloaddition.*

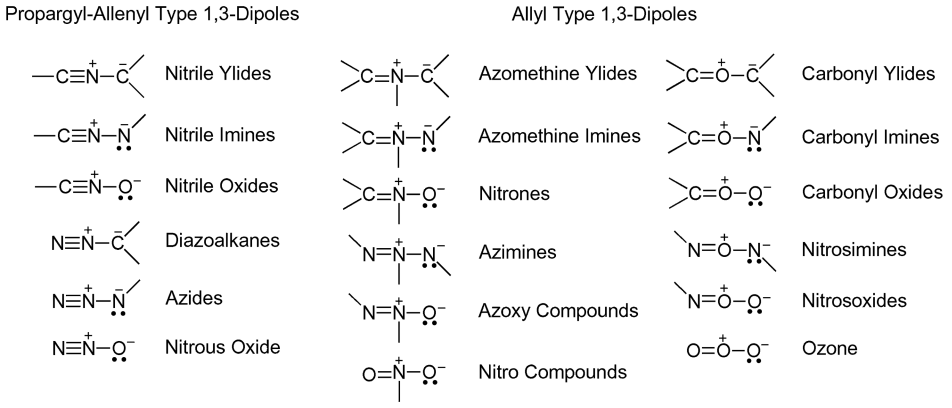
All the possible 1,3-dipolar molecules coming from carbon, nitrogen, and oxygen are summarized in Table 1.[3b] Sustmann presented a historical account for the 1,3-dipolar cycloaddition.[6] Other reviews about 1,3-dipolar cycloaddition are also available in the literature.[7]



C. PROPOSED MECHANISMS

Although only five atoms participate in the 1,3-dipolar cycloaddition, there are still six electrons ($4\pi + 2\pi$) involved in this reaction to form two new σ-bonds, similar to that in the *Diels-Alder Cycloaddition*. Mechanistically, most of the 1,3-dipolar cycloadditions are thought to undergo a concerted one-step process via a cyclic mechanism, as shown earlier. Although the transition state of 1,3-dipolar cycloaddition is more polar than that of the *Diels-Alder Cycloaddition*, the symmetry of the frontier orbitals is similar.

D. MODIFICATION

N/A

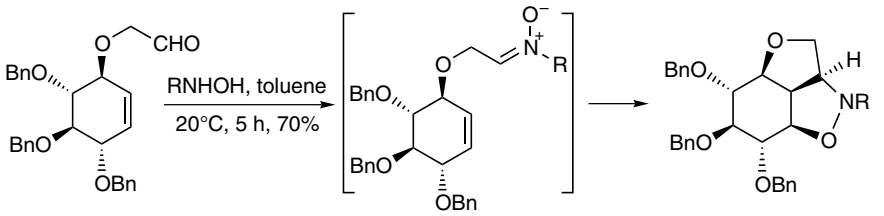
E. APPLICATIONS

This reaction has broad application in the preparation of a variety of five-membered heterocycles, by means of the combination of different dipolar molecules summarized earlier with either alkenes or alkynes.

F. RELATED REACTIONS

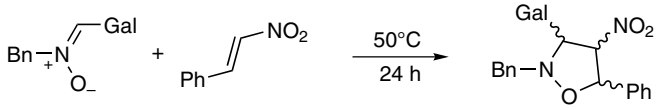
Besides 1,3-dipolar cycloaddition, there are many other types of cycloadditions. One of the most important cycloadditions is the *Diels-Alder Cycloaddition*, which gives six-membered cyclic compounds, in either heterocyclic or homocyclic. Two other important cycloadditions are *[2+2] Cycloaddition* and *Paterno-Büchi Reaction*. In addition, there are many other types of cycloadditions, such as [2+1], [2+2+1], [2+2+2], [2+2+2+1], [3+2+1], [3+2+2], [3+2+2+2], [3+3], [4+1], [4+2+1], [4+2+2], [4+3], [4+4], [5+1], [5+1+2+1], [5+2], [5+2+1], [5+3], [5+4], [6+2], [6+3], [6+4], [6+6] and [8+2] cycloadditions, which are summarized as a general *[m+n(+...)] Cycloaddition*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

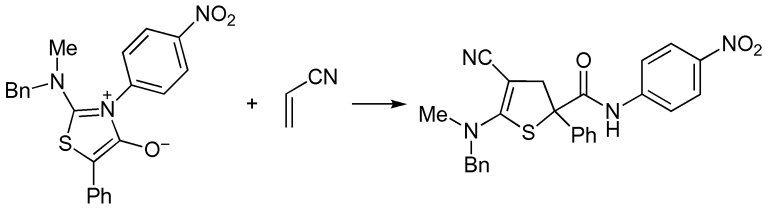
To a solution 0.46 g 2-[(1S,4S,5R,6S)-4,5,6-tris(benzyloxy)cyclohex-2-enyloxy]-acetaldehyde (1 mmol) in 5 mL anhydrous toluene was added a solution of 0.12 g *N*-benzyl-hydroxylamine (1.1 mmol, prepared from the hydrochloride acid with 0.1 mL triethylamine) in 2 mL anhydrous dichloromethane. The reaction mixture was stirred at 20°C for 2 h. Removal of the solvents under reduced pressure furnished a residue, which was chromatographed to give 0.4 g (2*aS*,4*a*S,5S,6S,7R,7*a*R,7*b*R)-2-benzyl-5,6,7-tris(benzyl-oxy)octa-hydro-2H-furo[4,3,2-c,d][1,2]benzisoxazole as a colorless wax, in a yield of 70%. $R_f = 0.45$ (toluene/ethyl acetate, 5:1). $[\alpha]_D^{22} = 86.14$ ($c = 1.0$, $CHCl_3$).



Reference 9.

A solution of 0.235 g (*Z*)-*N*-benzyl-(1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranos-6-ylidene)amine *N*-oxide (0.65 mmol) and 0.385 g β-nitrostyrene (2.60 mmol) in 0.5 mL toluene was stirred at 50°C. After 24 h, the conversion was complete, as indicated by

^{1}H NMR, which showed the formation of two diastereomers of 2-benzyl-3-(1,2:3,4-di-*O*-isopropylidene-α-D-galacto-pentopyranos-5-yl)-4-nitro-5-phenylisoxazolidines(65:35).



Reference 10.

To a solution of 0.84 g thioisomünchnones (2.0 mmol) in 10 mL dry CH_2Cl_2 was added 0.11 g acrylonitrile (2.0 mmol) and the reaction mixture was stirred at room temperature for 24 h. The solvent was then evaporated under reduced pressure, and the residue was treated with EtOAc to give 0.55 g 5-[benzyl-(methyl)amino]-4-cyano-N-(4-nitrophenyl)-2-phenyl-2,3-dihydrothiophene-2-carboxamide as crystals, in a yield of 58%, m.p. 167–169°C.

Other references related to 1,3-dipolar cycloaddition are cited in the literature.[11]

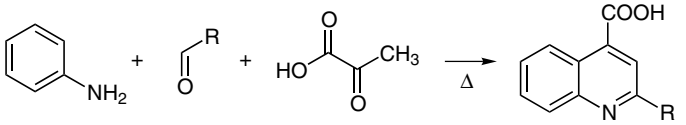
197

Doebner Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Doebner in 1887.[1] It is the synthesis of cinchoninic acid[2] (or quinolinic acid[3]) derivatives from the reaction of aromatic amines, aldehydes, and pyruvic acid, involving the removal of hydrogen from the aromatic ring.[3] However, the Doebner reaction failed when 2-chloro-5-aminopyridine,[3] 3-aminopyridine,[3] and 2-aminopyridine[4] were applied as the aromatic amines.

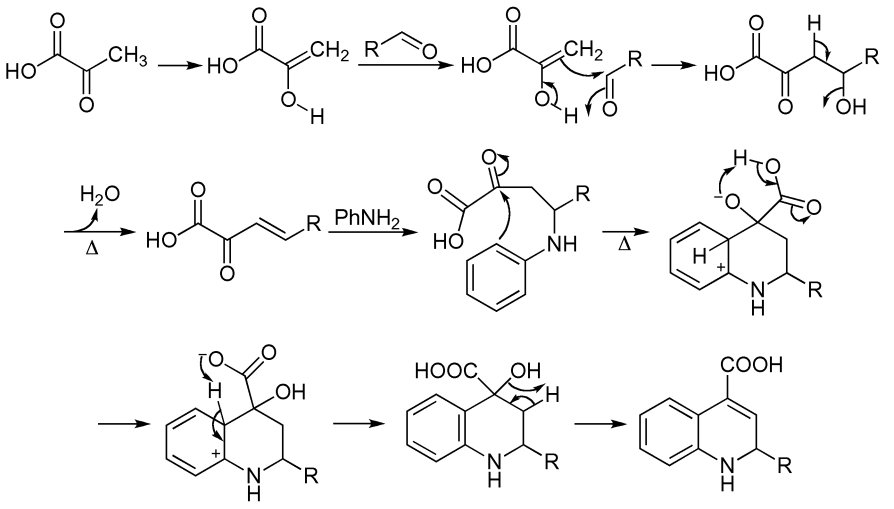
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

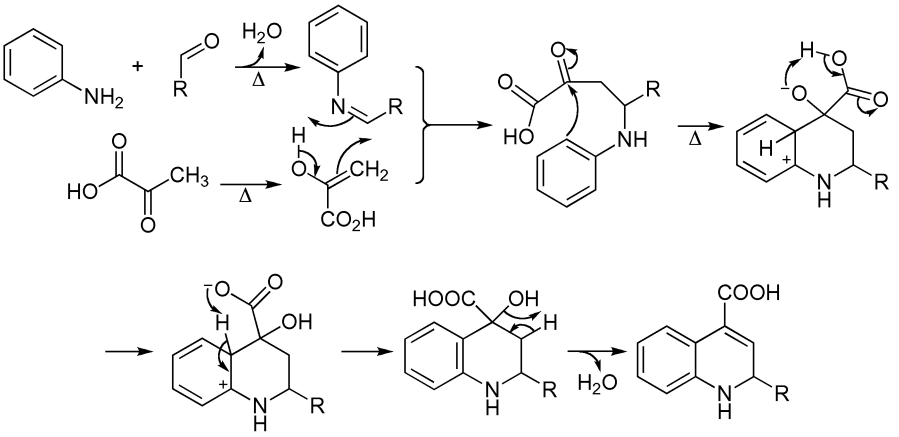
This reaction may involve an *Aldol Condensation* between the aldehyde and pyruvic acid to afford a β,γ-unsaturated α-keto acid that then undergoes the *Michael Addition* with aniline, as shown in Scheme 1.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



SCHEME 1. *Doebner reaction via aldol condensation.*

Alternatively, this reaction might involve the formation of a Schiff base between aniline and aldehyde, which then couples with pyruvic acid, as illustrated in Scheme 2.



SCHEME 2. *Doebner reaction involving Schiff base intermediate.*

D. MODIFICATION

N/A

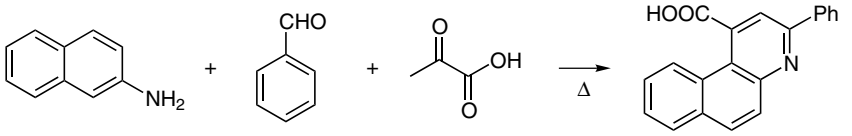
E. APPLICATIONS

This reaction has been applied to the synthesis of quinolinic acids and cinchoninic acids.

F. RELATED REACTIONS

The reaction is related to the *Combes Quinoline Synthesis* and *Conrad-Limpach Quinoline Synthesis.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

The anil was first prepared from the reaction between benzaldehyde and 2-naphthylamine. Then the suspension of 0.2 mol anil and 0.1 mol pyruvic acid in 250 mL 95% ethanol was refluxed for 4 h. The benzocinchoninic acid separated as a crystalline insoluble precipitate, which was filtered out of the hot mixture, washed thoroughly with alcohol and ether, and dried to give 40% of product. The compound was a pale yellow solid that decomposed at 247°C.

Other references related to the Doebner reaction are cited in the literature.[5]

Doebner-Miller Reaction

(Doebner-Miller Synthesis, Doebner-von Miller Quinoline Synthesis, Skraup-Doebner-von Miller Quinoline Synthesis)

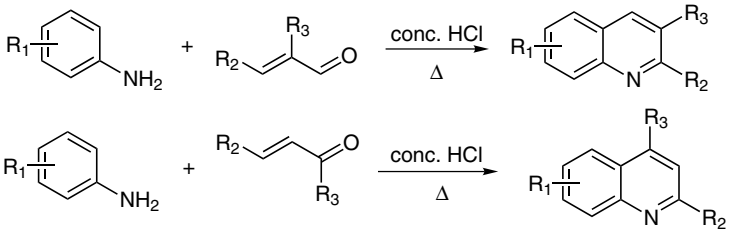
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Doebner and von Miller in 1881[1] as a modification of the original *Skraup Reaction*, and it was subsequently modified by Beyer in 1886.[2] It is an acidic condensation between primary aromatic amines (e.g., anilines) and α,β-unsaturated carbonyl compounds (mostly α,β-unsaturated aldehydes) to give 2,3-disubstituted quinolines. Therefore, this reaction is generally known as the Doebner-Miller reaction,[3] or Doebner-Miller synthesis.[4] In addition, this reaction is also referred to as the Doebner-von Miller quinoline synthesis,[5] Skraup-Doebner-von Miller reaction,[6] Skraup-Doebner-von Miller quinoline synthesis,[7] Doebner-Miller condensation,[8] and Doebner-Miller Quinaldine Synthesis.[9] For comparison, the modification from Beyer, known as the Beyer method[10] for quinoline, is an acidic condensation between anilines and α,β-unsaturated carbonyl compounds generated *in situ* from aldehyde or aldehyde and methyl ketone to afford 2,4-disubstituted quinolines.[11] The optimal condition of this reaction is to heat the mixture of aniline/aldehyde (1:2) at 100°C for 6 h with hydrochloric acid and zinc chloride; in addition, an oxidizing reagent is also needed in this reaction, such as nitrobenzene.[12] However, it has been reported that *N*-alkylanilines are also formed in this reaction.[13] The nature and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

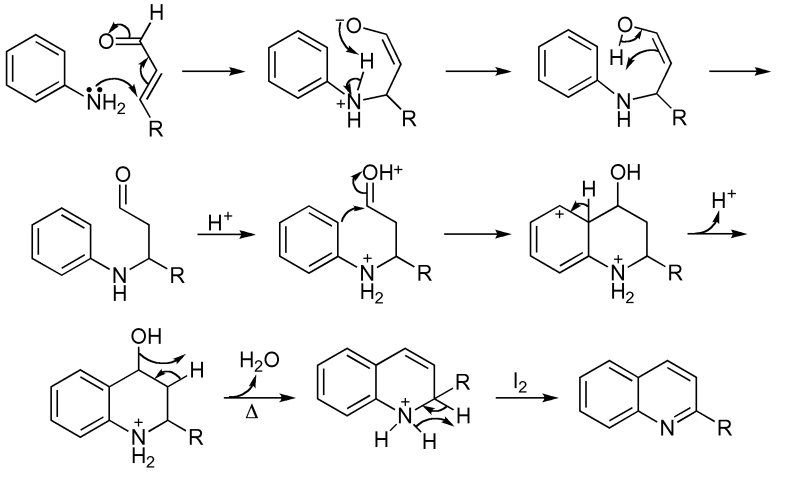
positions of substituents in anilines were found to have a sufficient effect on the reaction direction and quinoline yields, which the anilines with electron-donating groups normally afford higher yields of quinolines, whereas those with electron-withdrawing groups impede product formation.[14] For example, *o*- and *p*-substituted anilines form six- and eight-substituted quinolines,[15] respectively, *m*-substituted anilines (with *ortho-para* directing substituents) give a hardly separated mixture of five- and seven-substituted quinolines in low yields,[16] and *o*-nitro-*p*-methoxyaniline leads to no ring closure.[17] The generation of seven-substituted quinolines in high yields was observed in the application of (Pr^{+3}–PPh_3–DMF) as a catalyst in this reaction.[16] This reaction has been extensively reviewed.[18]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is evident that the condensation of aniline with a substituted acrolein to yield quinoline involves the loss not only of water but of two hydrogen atoms as well.[19] Therefore, the illustrative mechanism is proposed here for the reaction between a simple aniline and acrolein using iodine as an oxidizing reagent.



D. MODIFICATION

A catalytic amount of iodine is applied as a condensation reagent to form α,β-unsaturated carbonyl compound *in situ* in the formation of benzopyrano[3,4-f]quinolines.[20] In addition, the fume sulfuric acid is also a good reagent for this reaction, together with $FeSO_4$ and H_3BO_3.[21]

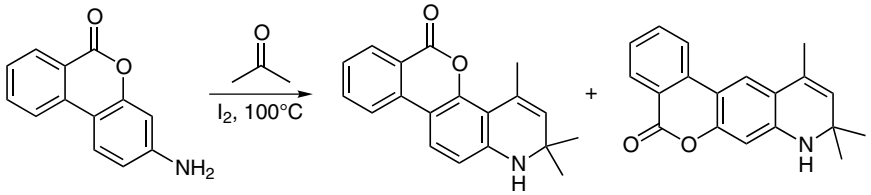
E. APPLICATIONS

This reaction is generally used for the synthesis of quinolines with substituents on the pyridinoid ring.

F. RELATED REACTIONS

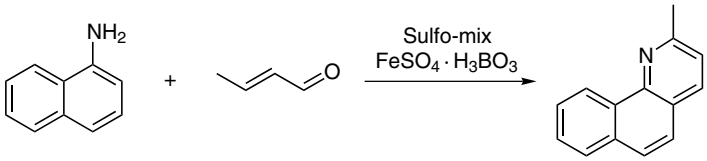
This reaction is related to the *Skraup Reaction*, but is used for the synthesis of quinolines bearing substitutents in the pyridinoid ring. This reaction is also related to the *Gould-Jacobs Quinoline Synthesis* and *Knorr Quinoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 20c

A solution of 185 mg 3-amino-6*H*-dibenzo[*b*,*d*]-pyran-6-one (0.87 mmol) and 25 mg iodine (0.10 mmol, 11 mol %) in 20 mL acetone was heated at 100°C in a sealed tube for 15 h. The mixture was concentrated and chromatographed (30–150 mm column, hexane/EtOAc, 10:1 to 2:1 gradient) to afford 150 mg 1,2-dihydro-2,2,4-trimethyl-10-isocoumarino[3,4-*f*]quinoline (60% yield, m.p. 197–199°C) and 75 mg 1,2-dihydro-2,2,4-trimethyl-10-isocoumarino-[4,3-*g*]quinoline (30% yield, m.p. 246–248°C).



Reference 21

To a warmed (110°C), homogeneous mixture of 58.5 g sulfo-mix [prepared from 48.0 g $H_2SO_4 \bullet SO_3$ (20%) and 10.5 g nitrogenzene], 1.4 g $FeSO_4 \cdot 7H_2O$, 2.4 g H_3BO_3, 25 mL water, and 5.72 g 1-naphthylamine (0.04 mol), was added dropwise over 30 min 3.5 g crotonaldehyde (0.05 mol). The bath temperature was raised to 130°C, and the reaction mixture was stirred for 5 h. The cooled solution was made basic with aqueous 20% NaOH and extracted with four 100-mL portions of $CHCl_3$. The combined $CHC1_3$ extracts were washed with water, dried over $MgSO_4$, and evaporated to dryness. The brown liquid residue was chromatographed on 100 g alumina. The elution with benzene was evaporated to give a yellow oil. Distillation gave 2.8 g 2-methylbenzo[h]quinoline as a pale yellow liquid, in a yield of 36%, b.p. 322–324°C.

Other references related to the Doebner-Miller reaction are cited in the literature.[22]

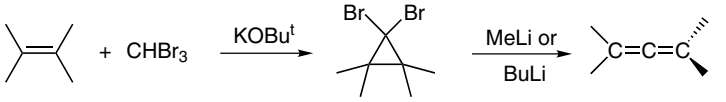
Doering-Moore-Skattebøl Reaction

A. GENERAL DESCRIPTION OF THE REACTION

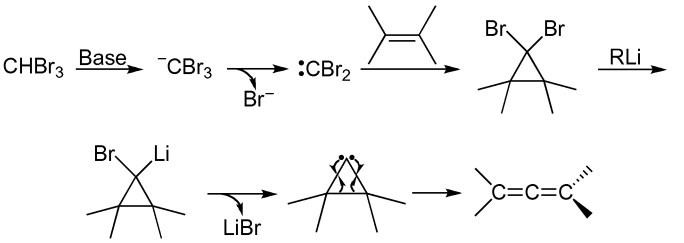
This reaction was initially reported by Doering and LaFlamme in 1958[1] but subsequently improved by both Moore in 1960[2] and Skettebøl in 1961.[3] It is a two-step preparation of allene via the addition of dibromocarbene to olefin,[4] followed by the treatment of the corresponding geminal cyclopropyl dibromide with alkyllithium under low temperature.[2,3] Therefore, this reaction is called the Doering-Moore-Skettebøl reaction,[5] Doering-Moore-Skettebøl-like reaction,[6] Doering-Moore-Skettebøl procedure,[5c] or Doering-Moore-Skettebøl method.[7] However, the original Doering method is to treat the geminal cyclopropyl dibromide with magnesium to give pure allene in a 16–35% yield or with high-surface sodium to give a high yield of allene but complicated with different isomers.[1] It was found that the alkyllithiums, including butyllithium and methyllithium, work equally well in the preparation of internal allenes without either cyclic or acyclic isomerization.[8] It has been proven that this reaction involves a carbene-like intermediate (a carbenoid) or a free carbene (cyclopropylidene).[5c] The transient carbenes can undergo either ring opening to allenes[9] or possibly a specific C-H bond insertion.[7,10] A potential side product of this reaction is the alkylation product from 1-halo-1-lithiocyclopropane when carried out at very low temperatures.[11] It is interesting that the conversion from anti-substituted cyclopropylidenes proceeds with a high degree of stereospecificity, whereas the *syn*-substituted cyclopropylidenes retain very low stereoselectivity in this process.[12]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

The original procedure of Doering and LaFlamme was modified and improved by Moore and Skattebøl.

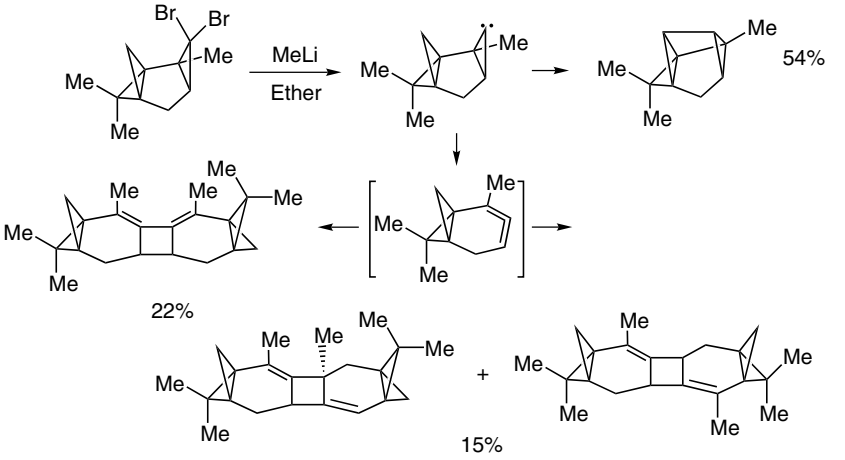
E. APPLICATIONS

This reaction has become a general method for the preparation of allene derivatives.

F. RELATED REACTIONS

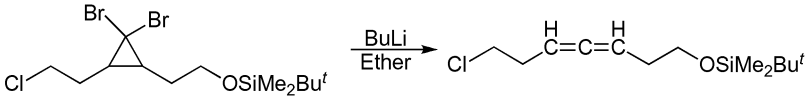
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a solution of 15.40 g 3,3-dibromo-2,7,7-trimethyl-tricyclo[4.1.1.$0^{2,4}$]octane (50.0 mmol) in 100 mL dry ether was added dropwise 37.5 mL 1.6 M MeLi in ether (60 mmol) at room temperature, and the resulting solution was stirred for 2 h. The reaction mixture was quenched with water. The mixture was extracted with ether, and the organic layer was washed with saturated NaCl and dried over $MgSO_4$. After the removal of the solvent (20°C, 15 mmHg), the product mixture (8.77 g) was distilled at 38°C (5 mmHg) to provide 4.04 g the insertion product 3,7,7-trimethyltetracyclo[4.2.0.0^{2,4}.0^{3,8}]octane as a colorless liquid, in a yield of 54%. The residue was passed through silica gel (70 g), eluting with hexane to yield the head-to-head allene dimer 1*R*,6*R*,8*S*,10*R*,11*R*,13*S*-2,5,7,7,14,14-hexamethylpentacyclo [11.1.1.1^{6,8}.0^{3,11}.0^{4,10}]hexadeca-2,4-diene, which was further purified by recrystallization from ethanol to yield 1.62 g of colorless crystals in a yield of 22%, m.p., 122.5–123.0°C. The oily second fraction was 1.19 g of a diastereomeric mixture of the head-to-tail dimer 7,7,9,11,14,14-hexamethylpentacyclo-[11.1.1.1^{6,8}.0^{3,11}.0^{4,10}]hexadeca-2,9-diene and head-to-head allene dimer 2,7,7,9,14,14-hexamethylpentacyclo-[11.1.1.1^{6,8}.0^{3,11}.0^{4,10}]hexadeca-2,9-diene, in a yield of 15%.



Reference 13.

A solution of 21.14 g dibromocyclopropane (50 mmol) in 80 mL ether was cooled to –70°C in a three-necked flask equipped with a mechanical stirrer and then treated with 33.4 mL 1.5 N *n*-butyllithium (50 mmol) over 25 min. The reaction mixture was stirred at –70°C for another 60 min and then poured into ice water and extracted with ether. The ethereal solution was washed with brine, dried over K_2CO_3, and concentrated. The residue was distilled to give 11.02 g 7-chlorohepta-3,4-diene-1-yl *tert*-butyldimethylsilyl ether in a yield of 84%, b.p., 80°C at 0.5 mmHg.

Dötz Benzannulation

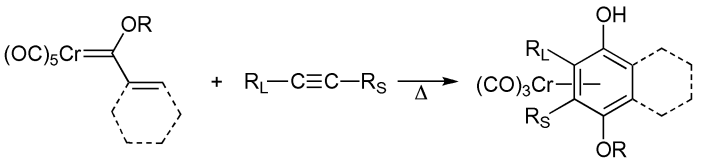
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Dötz in 1975.[1] It is a thermal reaction for preparing phenol derivatives from an aromatic or vinylic alkoxy pentacarbonyl chromium carbene complex (often called a Fischer carbene complex[2] or chromium carbene complex[3]) and an alkyne. It is known that this reaction involves the initial insertion of an alkyne to the Fischer carbene complex to form a dienylcarbene complex intermediate (called metallahexatrienes),[4] the carbon monoxide insertion to give vinylketene, and a final electrocyclization.[5] Therefore, this reaction is generally known as the Dötz benzannulation.[5,6] In addition, this reaction is also referred to as the Dötz reaction,[4,5,7] Dötz annulation,[8] Dötz annulation process,[6j] and Dötz chromium carbene benzannulation.[9] The Fischer chromium carbene complex can be easily prepared from chromium hexacarbonyl and organolithium reagent, followed by the *O*-alkylation.[3b,10] It has been found that this reaction is optimal with neutral alkynes (neutral alkynes > electron-deficient alkynes),[11] by which the isomers of the alkyne insertion intermediates form an equilibrium.[12] However, the isomer, of which the larger substituent on alkynes is *ortho* to the phenolic group, predominates in the equilibrium.[5,11] Because there are many possible branching points for the side reactions, twelve[13] to twenty-one[7e] distinct types of products (depending on the reaction conditions and substituents) have been identified, including indenes,[14] furans,[15] and cyclopentenones.[16] It has been reported that the optimal condition of this reaction is to perform the reaction in heptane instead of ethereal solvents (Et_2O, THF) at a chromium carbene complex concentration of 0.3 M, with a slight excess of alkyne (1.0–1.5 eq.).[11] On the other hand, a reaction involving the cleavage of the vinylic carbon-carbon bond in original Fischer carbene complex is also known.[17] In addition, transition metals other than chromium

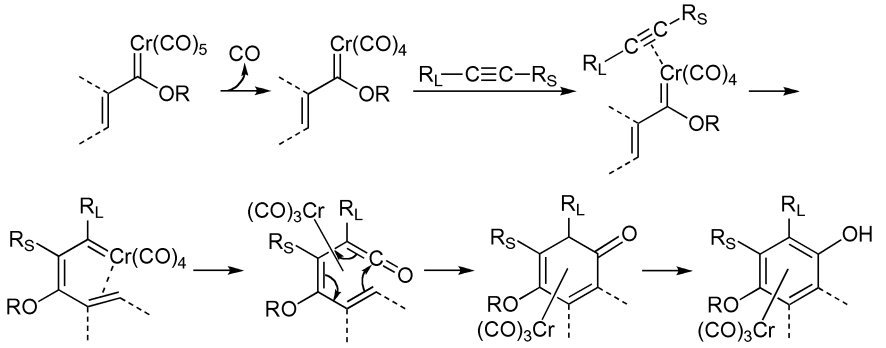
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

have also been found to undergo a similar reaction, such as manganese.[18] This reaction has been used for the preparation of biaryls,[2b] with central-to-central,[19] central-to-planar,[20] planar-to-axial,[21] and central-to-axial chirality transfer.[22]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

The chromium has been replaced by other transition metals, such as manganese.[18]

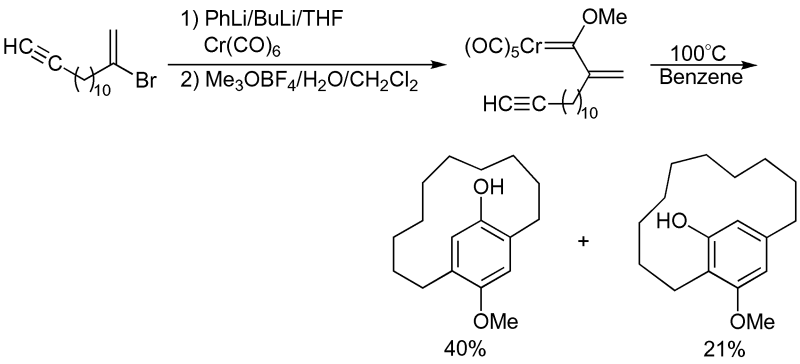
E. APPLICATIONS

This reaction has general application in the preparation of phenol derivatives; in addition, other types of molecules (indenes, furans, cyclopentenones, etc.) can be prepared.

F. RELATED REACTIONS

This reaction is related to the *Fischer Carbene Complexes*.

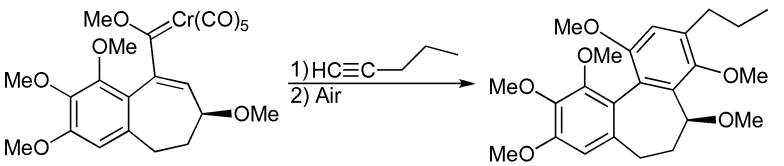
G. CITED EXPERIMENTAL EXAMPLES



Reference 17.

2-Bromo-1-decen-9-yne (167.3 mg, 0.778 mmol) was dissolved in 18 mL THF and cooled to −78°C. PhLi (0.782 mmol) was added dropwise, and the mixture was stirred at −78°C for 1.5 h. Then 1.57 mmol *t*-BuLi was added; the resultant solution turned yellow immediately and then green. The reaction mixture was stirred at –78°C for 30 min and then was transferred to 35 mL THF at –78°C containing 172.2 mg $Cr(CO)_6$ (0.782 mmol). This reaction mixture was warmed to room temperature and stirred for 2 h. The solvent was removed, and the residue was dried on high vacuum for 40 min and then taken up in H_2O/CH_2Cl_2 (10 mL/10 mL). Me_3OBF_4 (230 mg, 1.55 mmol) was added, and the yellow suspension turned orange immediately. The mixture was stirred at room temperature for 80 min and quenched with saturated aqueous $NaHCO_3$. The mixture was extracted with ether, and the organic layer was washed with brine, dried over $MgSO_4$, concentrated, and chromatographed (pentane) to give 128.5 mg pentacarbonyl (1-methoxy-2-methylene-9-decynylidene) chromium(0) as a red oil, in a yield of 44%, R_f = 0.14 (hexanes).

Alkenyl carbene complex was dissolved in benzene at a concentration of 0.002 M. The red solution was deoxygenated by the freeze-pump-thaw method (four cycles) and heated in an oil bath to 100°C. The solution turned from red to yellow during the reaction. After the completion of the reaction, the solvent was removed, and the residue was taken up in CH_2Cl_2/ether, and stirred in air overnight. The mixture was then loaded on silica gel and chromatographed to give 40% of *p*-methoxy phenol derivative and 21% of *m*-methoxy phenol derivative.



Reference 22.

To an approximately 0.33 M solution of the carbene complex in dry benzene was added a threefold excess of 1-pentyne. The resulting solution was deoxygenated by the freeze-pump-thaw method (–196°C/25°C, three cycles). The flask was back-filled with argon at

room temperature, sealed, and then heated at 55–58°C for 36 h. The red clear solution gradually changed to a dark mixture. The reaction mixture was opened to air and stirred in the open flask for 12 h. The solvent was removed in vacuo, and the crude product was diluted with 50% EtOAc in hexane and filtered through a layer of silica gel. The crude product was purified by flash chromatography on silica gel (15–25% gradient of EtOAc in hexane) to give 40% of yellowish crystal as the only diastereomer, m.p. 148–148.5°C.

Other references related to the Dötz benzannulation are cited in the literature.[23,24]

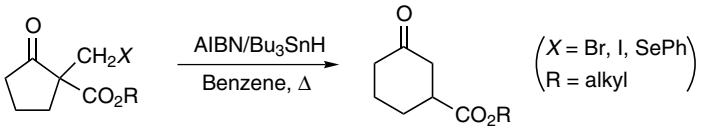
Dowd-Beckwith Ring Expansion

A. GENERAL DESCRIPTION OF THE REACTION

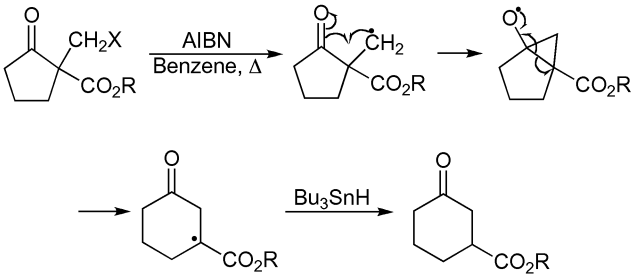
This reaction was first reported by Dowd[1] and Beckwith[2] concurrently in 1987. It is a general method for one-carbon ring expansion of cycloketone via the introduction of a halomethyl group to cyclic β-keto esters followed by radical dehalogenation (e.g., through the addition of a mixture of tributyltin hydride and AIBN in refluxing benzene solution). After radical dehalogenation, the carbon radical adds to the neighboring carbonyl group, leading to a cyclopropyloxy radical that is unstable and forces the cyclopropyl ring to break and form a larger cycloketone. Therefore, this reaction is generally known as the Dowd-Beckwith ring expansion.[3] In addition, it is also referred to as the Dowd-Beckwith type ring expansion,[4] Beckwith-Dowd type rearrangement,[5] Beckwith-Dowd expansion,[5] Dowd-Beckwith rearrangement,[4] Beckwith-Dowd ring expansion,[5,6] and Beckwith-Dowd ring enlargement.[7] It is proposed that the ester group in the cyclic β-keto ester can facilitate the alkylation, activate the radical addition to carbonyl group, and assist the ring opening of the cyclopropyloxy radical.[8] It has been found that the acyl radical cyclization is irreversible on any kinetically significant time scale;[5] however, the radical cyclization to the carbonyl group may fail if a highly congested transition state is involved.[4] This reaction has been studied extensively[8] and extended for preparing middle-size cycloketones via four-carbon ring expansion by Dowd.[9]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

Tributyltin hydride has been replaced by the silylated cyclohexadienes as the proton source.[7] In addition, zinc and indium have been applied to initiate similar ring-expansion reactions.[10]

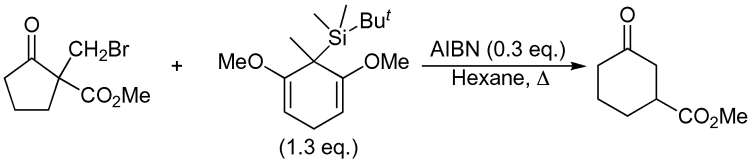
E. APPLICATIONS

This reaction has been widely used for the preparation of cyclic ketones.

F. RELATED REACTIONS

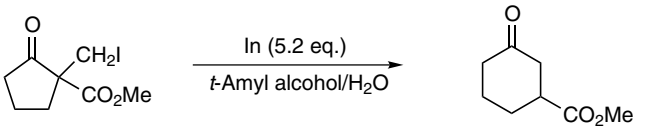
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

Methyl 1-bromomethyl-2-oxo-cyclopentanoate (235 mg, 1 mmol), 349 mg silylated cyclohexadiene (1.3 mmol), and 50 mg AIBN (0.3 mmol) were dissolved in 5 mL hexane under argon. The reaction mixture was refluxed for 7 h. Removal of the solvent in vacuo and purification by flash chromatography (Et_2O/pentane, 3:8) afforded 76 mg methyl 3-oxo-cyclohexane-1-carboxylate as a colorless oil, in a yield of 49%.



Reference 10.

Indium powder (2.08 mmol) was added to a refluxing solution of 0.4 mmol α-iodomethyl cyclic β-keto ester in a mixed solvent of 2 mL *tert*-amyl alcohol and 1 mL water under an argon atmosphere. The mixture was refluxed for 2 h under stirring. After the reaction, the mixture was filtered through Celite, then the solvent was removed, and the residue was purified by silica gel column chromatography to afford 59% methyl 3-oxo-cyclohexane-1-carboxylate as a colorless oil.

Other references related to the Dowd-Beckwith ring expansion are cited in the literature.[11]

202

Duff Reaction

A. GENERAL DESCRIPTION OF THE REACTION

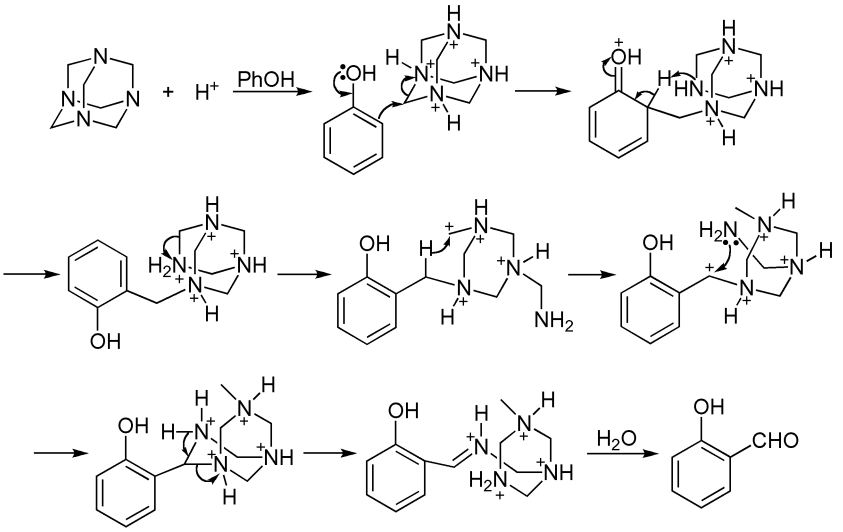
This reaction was initially reported by Duff and Bills in 1932.[1] It is the formylation of phenols or aromatic amines in a mixture of hexamethylenetetramine, boric acid, and glycerol. Therefore, it is generally known as the Duff reaction.[2] In a few cases, it is also referred to as the Duff formylation[3] and Duff synthesis.[4] This reaction is normally very fast and usually gives only *ortho*-formylated (or a small amounts of *ortho*, *para*-disubstituted) product[5] (e.g., in the case of phenols); however, this procedure gives *para*-products in the case of anilines. It is found that electron-withdrawing groups hinder or prevent the reaction from taking place;[5] therefore, hydroxypyridines and hydroxyquinolines cannot be formylated.[5] Though they do not work with glycerol/boric acid, the *N*,*N*-dialkylanilines can be formylated in a mixture of formic acid and acetic acid but not in either one alone.[5] Further modification of this reaction by conducting the reaction in anhydrous trifluoroacetic acid results in a milder reaction condition,[2q,6] with a high yield and no detectable isomer or dialdehydes.[2q] This modification gives a high order of *para*-formylation product; even simple hydrocarbons can be converted to imine products, which are transformed to aryl aldehydes on hydrolysis.[2q] However, this modification may also give *ortho*-formylated products,[2l] and a dimmer of aniline in cyclic form may result instead of the normal formylation.[2g] In addition, reactions in a mixed solvent of THF/HMPA also provide relatively high yield.[2h]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

A tentative mechanism is proposed below, although no mechanistic details are available from the cited literature.



D. MODIFICATION

The original Duff reaction condition has been modified to run in trifluoroacetic acid.

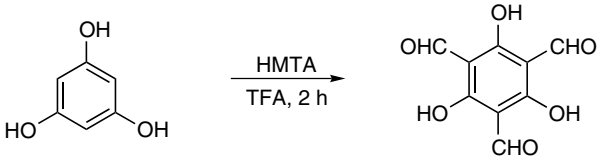
E. APPLICATIONS

This reaction has general applications in the formylation of aromatic compounds.

F. RELATED REACTIONS

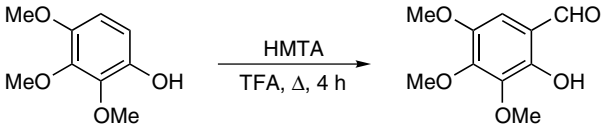
This reaction is related to the *Reimer-Tiemann Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a mixture of 15.098 g hexamethylenetetramine (108 mmol) and 6.014 g dried phloroglucinol (49 mmol) under nitrogen was added 90 mL trifluoroacetic acid. The solution was heated at 100°C for ∼2.5 h. Approximately 150 mL 3 M HCl was added, and the solution was heated at 100°C for 1 h. After cooling to room temperature, the solution was filtered through Celite, extracted with ∼350 mL dichloromethane, dried over magnesium sulfate, and filtered. Rotary evaporation of the solution afforded 1.48 g triformylphloroglucinol as an off-white powder, in a yield of 14% with 99% purity by ^{1}H NMR. Further purification has been conducted by sublimation.



Reference 2c.

A solution of 100 mg 2,3,4-trimethoxyphenol (0.54 mmol) and 75.7 mg hexamethylenetetramine (0.54 mmol) in 0.5 mL trifluoroacetic acid was refluxed for 4 h. After the reaction was quenched with the addition of ice, the resulting mixture was further stirred for 15 min and extracted with ether. The combined organic extracts were washed with saturated $NaHCO_3$ solution and brine, dried over anhydrous Na_2SO_4, filtered, and then concentrated in vacuo. Flash chromatography (benzene/acetone, 10:1) of the residue gave 79.4 mg 2-hydroxyl-3,4,5-trimethoxy benzaldehyde as a powder, in a yield of 69%, m.p.: 41–43°C (recrystallized from hexane).

Other references related to the Duff reaction are cited in the literature.[7]

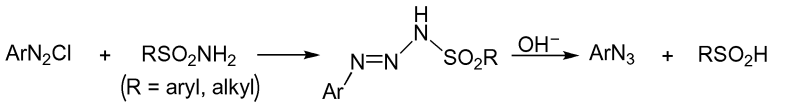
Dutt-Wormall Reaction

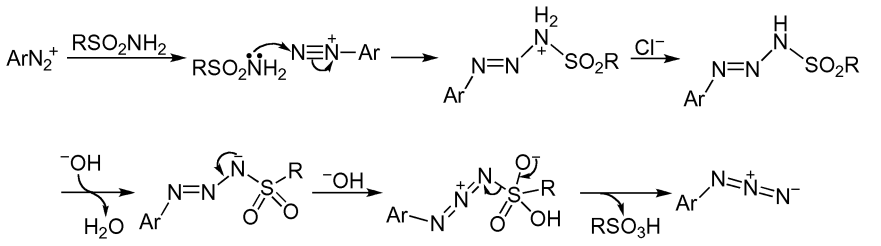
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Dutt, Whitehead, and Wormall in 1921.[1] It is the preparation of aromatic azide via the basic hydrolysis of aromatic diazoaminosulfinate that can be easily synthesized from aromatic diazonium salt and arylsulfonamide or alkylsulfonamide. Therefore, this reaction is known as the Dutt-Wormall reaction.[2] Similarly, azides can be prepared via the cleavage of compounds from diazonium salt with ammonia,[3] hydrazine,[4] hydroxylamine,[4c,4d,5] etc.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

N/A

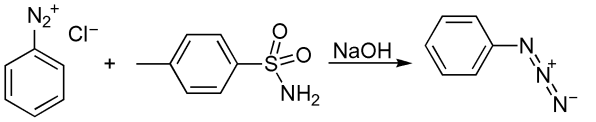
E. APPLICATIONS

This reaction has been used for the preparation of aromatic azides.

F. RELATED REACTIONS

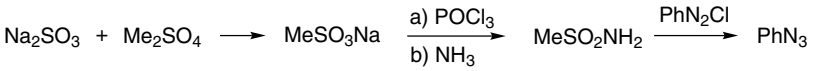
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 1.

Benzenediazonium chloride (made from 9.3 g aniline) was slowly added to a solution of 17 g *p*-toluenesulfonamide and 15 g NaOH in 350 mL water. In this case no precipitate was formed, but an orange, opalescent liquid was obtained that smelled strongly of phenylazoimide. A drop of the liquid produced a deep red coloration on β-naphthol test paper. The mixture was kept overnight in the ice box, and a considerable amount of oil had accumulated at the bottom of the vessel, but the liquid still gave the red coloration with β-naphthol test paper. Sodium hydroxide (15 g) was then added, and the mixture was stirred until no color reaction was obtained with β-naphthol test paper. It was then extracted with ether, the ether was distilled off, and the residue was distilled in steam. The steam distillate was again extracted with ether, and the extract was dried over $CaCl_2$ and distilled in a vacuum from a water bath. The yield of phenylazoimide was 9 g, and the calculated yield was 11.9 g. It was a clear yellow liquid, with a characteristic, penetrating, but not unpleasant smell. It exploded when heated in a test tube over a Bensen flame but distilled at 81°C at 44 mmHg.



Reference 6.

Preparation of Methanesulfonamide

Methyl sulfate (100 g) was slowly dropped over 1 h into a mixture of 300 g Na_2SO_3, 375 mL water, and 125 mL MeOH, while boiling under reflux. The solid residue obtained by evaporation of the filtered solution was extracted with 80% alcohol and crystallized. The yield of sodium methanesulfonate, which contained a small proportion of sodium methyl

sulfate was ~94%. The sulfonyl chloride was prepared by heating 100 g sulfonate and 200 g phosphoryl chloride (phosphorus pentachloride may be used, but the reaction is rather vigorous) at 130–150°C for 2 h. The liquid was purified by fractional distillation and the portion that had a boiling point between 152° and 159°C was collected, in amount of 60 g. The methanesulfonamide was prepared by saturating a cold benzene solution of the methanesulfonyl chloride with dry ammonia gas. The mixture was finally warmed and filtered and the solvent was distilled off. The residue was crystallized from benzene/alcohol as colorless, monoclinic plates, m.p. 84–85°C.

Preparation of Phenylazide

To a mixture of 19 g methanesulfonamide, 16 g NaOH, and 400 mL water was added slowly a benzenediazonium chloride prepared by mixing a solution of 18.6 g aniline, 60 mL of concentrated HCl and 100 mL water with 14 g $NaNO_2$ in 60 mL water. The yellow solid that first appeared soon decomposed, and the phenylazide thereby produced was extracted with ether and purified in the usual way, in amount of 19.0 g.

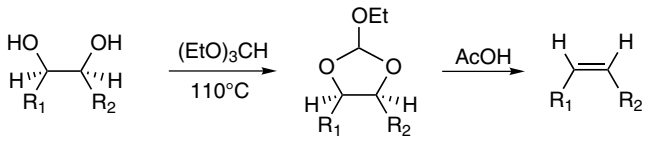
204

Eastwood Olefination

A. GENERAL DESCRIPTION OF THE REACTION

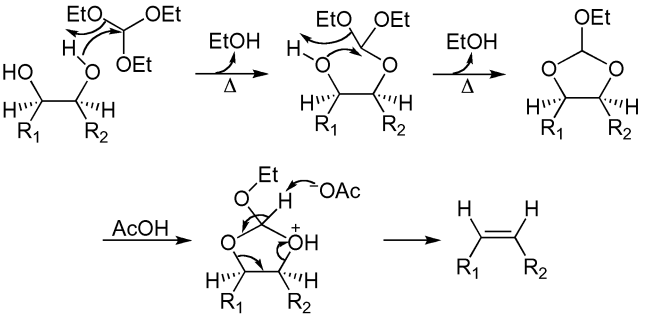
This reaction was initially reported by Grank and Eastwood in 1964.[1] It is the stereospecific preparation of olefin from vicinal diol by means of the thermal decomposition of a five-membered cyclic orthoformate of the diol in the presence of a catalytic amount of acid (e.g., acetic acid). Therefore, this reaction is known as the Eastwood procedure[2] or Eastwood deoxygenation procedure,[2,3] but is called Eastwood Olefination in this book. It has been reported that using acetic anhydride as a solvent, the cyclic orthoformate can be converted into olefin in a high yield.[4] This improvement is referred to as Ando's modification.[3b] The Eastwood olefination is especially good in the preparation of dideoxy nucleosides and nucleotides.[5] Because acetic anhydride might cause the cleavage of the *N*-glycosyl bond,[5] dideoxy thymidine has been prepared using hydrous zirconium oxide as the catalyst and tributylamine as the stabilizer.[3b]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

The decomposition of cyclic orthoformate of vicinal diol has been carried out in acetic anhydride.[4]

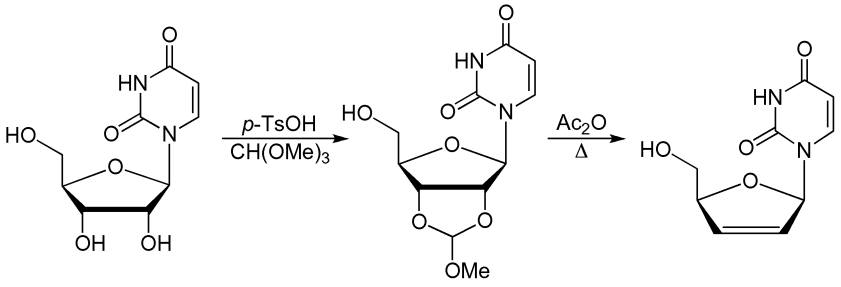
E. APPLICATIONS

This reaction has been applied in the preparation of olefin, dideoxy nucleosides, and nucleotides.

F. RELATED REACTIONS

This reaction is related to the *Corey-Winter Olefination*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To a solution of 100 g uridine (410 mmol) in 250 mL trimethyl orthoformate was added 3.0 g *p*-toluenesulfonic acid monohydrate (15.8 mmol). The solution was stirred at room temperature for l6 h and then cooled to 10°C. Sodium methoxide in methanol (28%, 3.39 g,

17.6 mmol) and 100 mL toluene was added, and the resulting mixture was stirred for 1 h at 10°C. The reaction mixture was filtered, and the separated crystal was washed with 100 mL toluene and dried to yield 113.6 g 2′,3′-*O*-(methoxymethylene) uridine as a white crystal, in a yield of 96%. $R_f = 0.34$ ($CHCl_3$/MeOH = 10/1).

A solution of 5.0 g 2′,3′-*O*-(methoxymethylene) uridine (17.5 mmol) in 50 mL acetic anhydride was stirred for 3 h at 132°C. The reaction mixture was cooled to room temperature and evaporated. Chloroform (50 mL) was added, and the mixture was washed with 50 mL aqueous $NaHCO_3$. Aqueous layer was extracted with 50 mL $CHCl_3$, and the combined organic layers were dried over Na_2SO_4, concentrated, and purified by silica gel column chromatography ($CHCl_3$/MeOH, 10:1) to give 1.87 g 1-(5-*O*-acetyl-2′,3′-dideoxy)-β-D-glycero-pent-2-enofuranosyl)uracil, in a yield of 42%, m.p. 128–128.5°C (recrystallized from EtOH).

Eder Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Eder in 1880.[1] It is the photochemical reduction of mercuric chloride to calomel by oxalates and is generally known as the Eder reaction.[2] This reaction has been proved to be a chain reaction[3] of great energy efficiency,[3] with a chain length of nearly 1,000,000,[4] so that it is often used in actinometry, including x-ray actinometry.[5] This reaction can be induced at room temperature[2d] by illumination,[2d] oxidizing reagents (e.g., $KMnO_4$, MnO_2),[2d,6] and reducing reagents;[4] however, it can also be inhibited by a few substances, including oxygen,[3,6,7] phenols,[2e] and other inorganic chlorides.[8] Some fluorescent dyes,[7b] potassium trioxalatocobaltiate,[7a] quinine,[4] and $FeCl_3$[4] function as photochemical sensitizers.

206

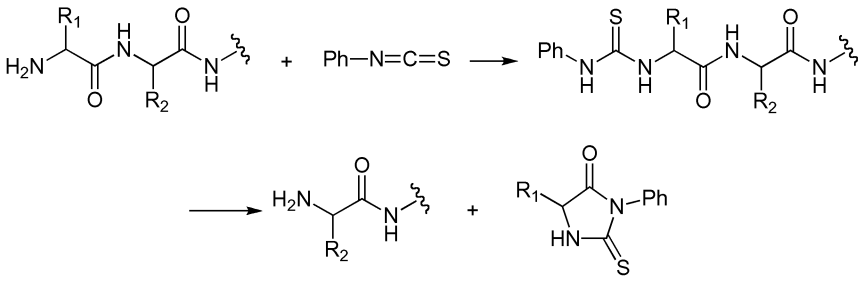
Edman Degradation

A. GENERAL DESCRIPTION OF THE REACTION

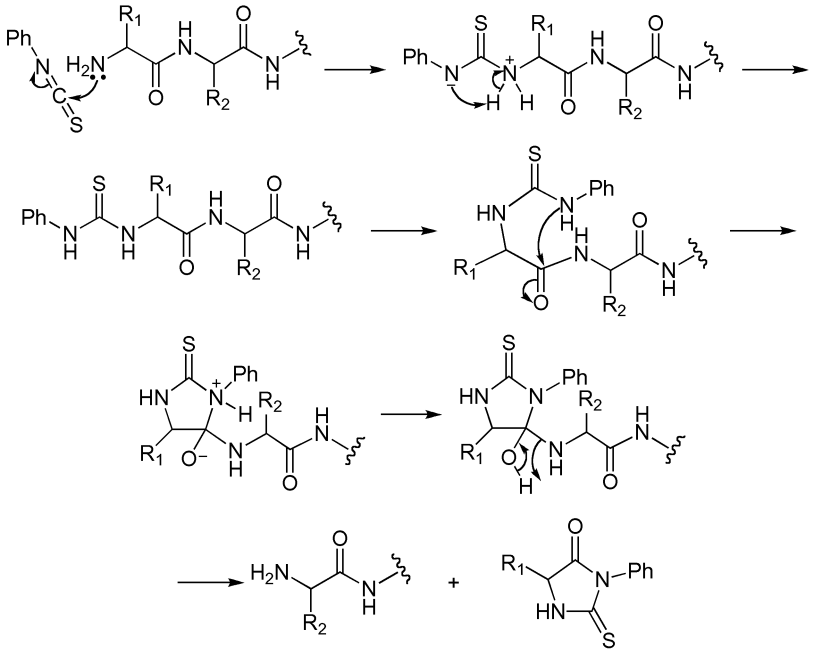
This reaction was initially reported by Edman in 1949.[1] It is the reaction between phenyl isothiocyanate and the free amino group of the *N*-terminal amino acid within a polypeptide to generate a thiourea, which upon the intramolecular cyclization via the nucleophilic addition of the amino group to adjacent amide carbonyl cleaves the *N*-terminal amino acids as a phenylthiohydantoin derivative and leaves the second amino acid as the *N*-terminus again.[2] Therefore, this reaction is generally known as the Edman degradation.[3] The cleaved phenylthiohydantoin derivatives of the amino acids can be identified by using chromatography.[4] This process can be repeated many times until the whole sequence of the peptide is determined. The advantages of this method include well-characterized conditions for the derivatization and cleavage reactions, high stepwise yields, and simple identification of the cleaved phenylthiohydantoin derivative by chromatography.[4] However, this method does have a few disadvantages, including the difficult separation of the phenylthiohydantoin derivative from the residual peptide segment in the solution phase during the sequencing of a small peptide,[5] low sensitivity,[4] the need for highly purified samples,[4] the long cycle times[4,6] and the high cost.[6] To overcome these weaknesses, the reaction can be carried out by means of solid-phase support synthesis (SPSS), so that a small protein or peptide can be sequenced automatically. However, providing that each cycle of the Edman degradation is 99% complete, this reaction is good for identifying only the first 50 amino acids in a sequence. Considering the degradative nature of this reaction, the Edman degradation has not often been adapted for normal organic synthesis.[2] Further development has made this degradation useful for sequencing the C-terminal segments of hydroxyethylamine-derived peptides[7] and an efficient method for the synthesis of 2-iminohydantoins.[2]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to a solid-state reaction, and polypeptides can be sequenced automatically.[5] In addition, this degradation can be used to sequence C-terminal segments of hydroxyethylamine-derived peptides[7] and for the preparation of 2-iminohydantoins.[2]

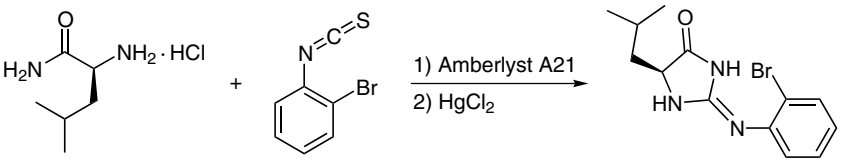
E. APPLICATIONS

This reaction has general application in protein sequencing.

F. RELATED REACTIONS

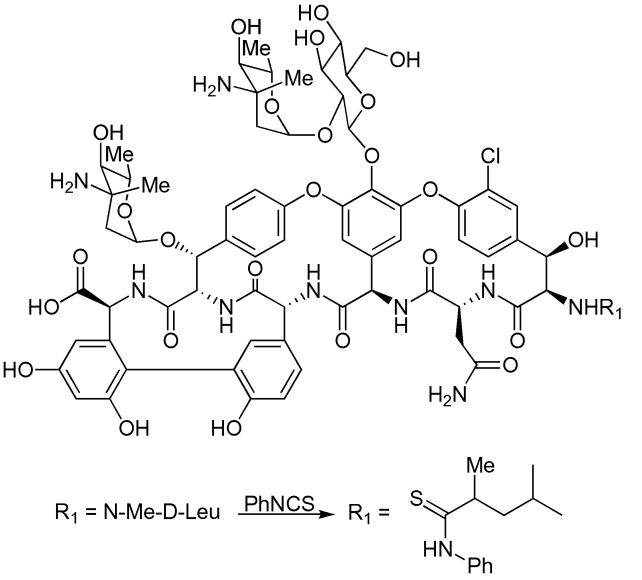
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To a mixture of 0.38 mmol of L-leucine amide and 0.5 g weakly basic amberlyst-A21 ion-exchange resin in 2.0 mL MeCN was added 0.38 mmol 2-bromophenyl isothiocyanate; the mixture was stirred at room temperature for 1 h. To the reaction mixture was added 0.42 mmol $HgCl_2$, and the mixture was then stirred overnight. The reaction mixture was diluted with 2.0 mL EtOAc and filtered through a pre-packed Celite column, using 4 mL EtOAc to remove the amberlyst-A21 resin and HgS by-product. The solution was added to the Celite column and allowed to sit in the column for 1 min before suction was applied to the column. After column chromatography, 99% yield of iminohydantoin with 98% of purity was obtained.



Reference 8.

Duolite basic anion-exchanger A 30 (OH^- form) was added to a solution of 500 mg eremomycin sulfate (0.3 mmol) in 100 mL water, and the mixture was left at room temperature for 3 h. Eremomycin base solution was filtered off and concentrated in vacuo with the addition of *n*-BuOH; then 50 mL acetone was added to give a precipitate. The latter was filtered off, washed with acetone, and dried in vacuo to give 410 mg eremomycin base (0.26 mmol). It was dissolved in 5 mL of a pyridine/water (1:1) mixture, and 0.02 mL PhNCS (0.2 mmol) was added under argon. The reaction mixture was stirred at room temperature for 16 h, concentrated in vacuo with the addition of *n*-BuOH, and applied to a column with silanized silica gel (2 × 100 mL), previously equilibrated with 0.001 M acetic acid. Acetic acid solution (0.001 M) was used for elution to give fractions containing nonreacted eremomycin. A mixture of MeOH/0.001 M AcOH (2:8) at a rate of 30 mL/h was used to give fractions containing *N*-phenylaminothiocarbonyleremomycin. The fractions were pooled and concentrated with the addition of *n*-BuOH in vacuo, and 50 mL acetone was added to yield the precipitate, which was filtered off, washed with acetone, and dried to yield 303 mg *N*-phenylaminothiocarbonyleremomycin, in a yield of 68%.

Other references related to the Edman degradation are cited in the literature.[9]

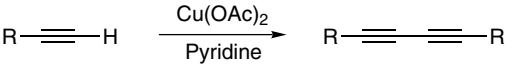
Eglinton Coupling

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Eglinton in 1956.[1] It is an oxidative coupling of terminal alkynes[2] by means of the treatment of the alkynes with a stoichiometric amounts of copper (II) acetate [$Cu(OAc)_2$] in pyridine.[1,3] Therefore, this reaction is generally known as the Eglinton coupling.[3,4] In addition, this reaction is also referred to as the Eglinton method,[5] Eglinton methodology,[2a] Eglinton coupling reaction,[3] Eglinton oxidative coupling,[2c,6] Eglinton-Glaser reaction,[7] Eglinton reaction,[2a,8] and Eglinton condition.[9] It can be homogenous when the reaction is carried out in methanolic pyridine.[10] This reaction is especially useful for the preparation of linearly conjugated all-carbon chains (polyacetylenes)[11] or cyclic dimmer, trimer, tetramer and even pentamer of compounds with two terminal alkynyl groups.[2a] It is interesting that the homocoupling of 3,6-di-(*t*-butyl)-3,6-dihydroxyl-1,4,7-octa-triynes with $Cu(OAc)_2$ gives cyclic dimmer in pyridine, whereas the solid state reaction with $Cu(OAc)_2 \cdot 2Py$ affords linear coupling product.[12]

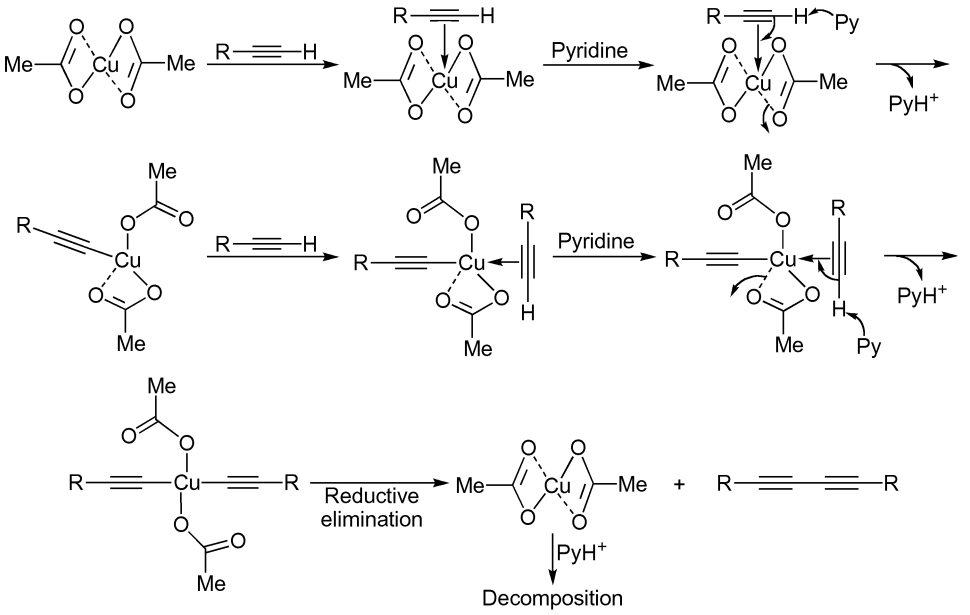
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

As no mechanism can be found for this reaction, a tentative mechanism is provided here. It is known that Cu(II) will form square-pyramidal geometry, whereas Cu(I) forms tetrahedral geometry.[13] In $Cu(OAc)_2$, copper (II) has nine out-shell electrons and can form five coordination bonds, like that in $CuSO_4 \cdot 5H_2O$.



D. MODIFICATION

This reaction has been modified to use a mixture of $Cu_2Cl_2/CuCl_2$ in pyridine for the coupling.[14] In addition, terminal alkynes protected by trimethylsilyl group can also couple under this reaction conditions via prior deprotection by K_2CO_3.[5a]

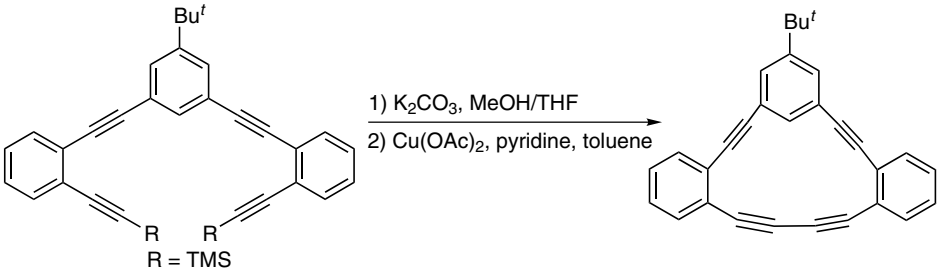
E. APPLICATIONS

This reaction has wide application in coupling terminal alkynes, especially in the formation of cyclic alkynes.

F. RELATED REACTIONS

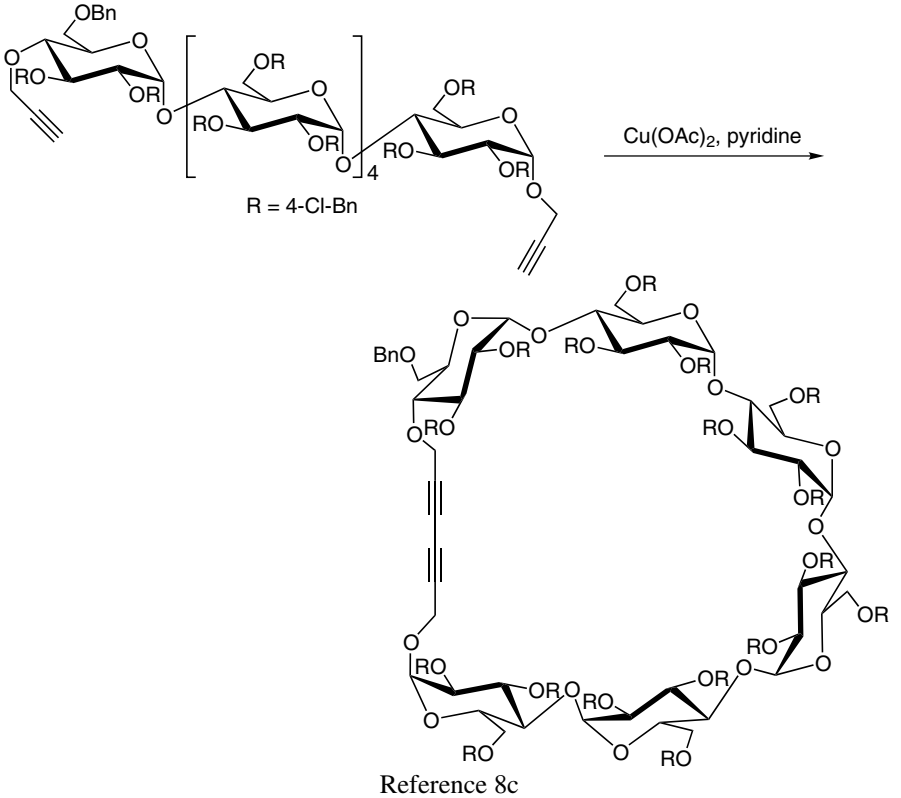
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5a

A total of 158 mg TMS-protected alkynes (0.30 mmol) in 20 mL methanol/THF mixture (1:1) was treated with 83 mg K_2CO_3 (0.60 mmol). After TMS was deprotected, the solvent was evaporated on a rotatory evaporator, and 100 mL toluene was added to dissolve the residue. To an another flask charged with 5.45 g $Cu(OAc)_2$ (30.0 mmol), 450 mL pyridine, and 100 mL toluene under a nitrogen atmosphere was added dropwise 100 mL toluene containing the alkyne through a Hershberg dropping funnel at room temperature over 32 h, and the mixture was stirred for additional 10 h. During the reaction, the flask was wrapped with aluminum foil to protect the product from light. After removal of the solvent in vacuo, the residue was purified by flash chromatography followed by preparative HPLC to give 95 mg dibenzo[12]metacyclophanetetrayne as a colorless solid in a yield of 83%, m.p., $>220^\circ$C (dec).



Reference 8c

A solution of 110 mg $Cu(OAc)_2$ (0.611 mmol) in 110 mL pyridine was added at 60°C under argon to a solution of 200 mg 6-*O*-benzyl-2,3-*bis*-*O*-(4-chlorobenzyl)-4-*O*-(prop-2-yn-1-yl)-α-D-glucopyranosyl-[(1→4)-2,3,6-*tris*-*O*-(4-chlorobenzyl)-α-D-glucopyranosyl]$_4$-(1→4)-2,3,6-*tris*-*O*-(4-chlorobenzyl)-α-D-glucopyranoside (0.061 mmol) in 12 mL pyridine within 3 h. The mixture was then stirred for an additional hour and evaporated. The residue was dissolved in 80 mL EtOAc and washed with an aqueous solution of Na_4TMEDA (367 μL, 2.44 mmol), 40 mL water, and 40 mL brine and dried over $MgSO_4$. Evaporation and flash chromatography (toluene/EtOAc, 40:1 → 20:1) gave 166 mg 6-*O*-benzyl-2,3-*bis*-*O*-(4-chlorobenzyl)-α-D-glucopyranosyl-[(1→4)-2,3,6-*tris*-*O*-(4-chlorobenzyl)-α-D-glucopyranosyl]$_4$-(1→4)-2,3,6-*tris*-*O*-(4-chlorobenzyl)-α-D-glucopyranoside 6:4^{VI}-anhydride as a white foam, in a yield of 83%, R_f = 0.41 (toluene/EtOAc, 9:1), m.p. 55–58°C.

Other references related to the Eglinton coupling are cited in the literature.[15]

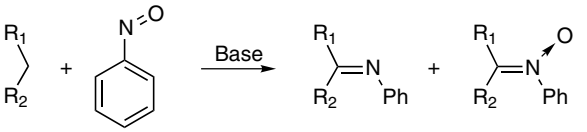
Ehrlich-Sachs Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Ehrlich and Sachs in 1899.[1] It is the condensation between compounds of active methylene groups and aromatic nitroso molecules and is generally known as the Ehrlich-Sachs reaction.[2] This reaction can be initiated by base, acid, or simply heating,[3] but in most cases, it is triggered by a base. In this reaction, two competing products are formed[4]—the dehydrate azomethine derivative (or Schiff base) and the oxidized nitrone derivative. As the actual reaction mechanism has not been well understood, it is difficult to predict which product will eventually form. However, it is known that the reaction condition, the acidity of the methylene group, and the structure of compounds with the methylene group all affect the reaction outcome.[4] It is plausible that the reaction of the base-generated enolate from 1,3-dicarbonyl compound or aryl alkyl ketones predominantly gives the azomethine derivatives[5] with a few exceptions.[6] The base applicable for this reaction can be as weak as sodium carbonate.[7]

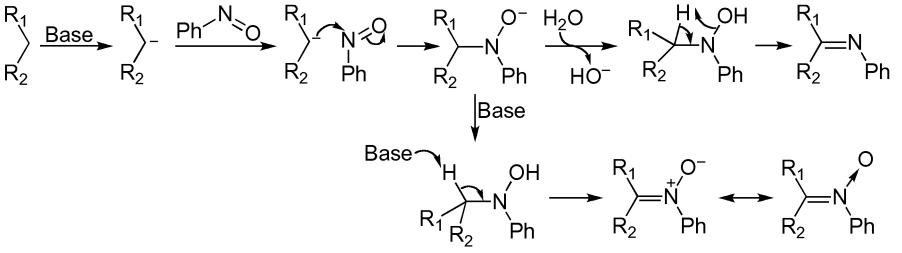
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Because the mechanism of this reaction is not quite clear, a tentative mechanism is outlined here.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction is generally used in the preparation of azomethine derivatives, which are used in the dye and drug industry.

Reference 7.

To a solution of 7.0 g 1-(4-oxo-1,4H-5,8-dimethoxyfuro-4′,5′,6,7-chromene-2-ylmethyl)pyridinium iodide in 240 mL aqueous ethanol (50%) at 40°C was added a solution of 2.8 g *p*-nitrosodimethylaniline hydrochloride in 50 mL water. The reaction mixture was

then treated dropwise, while stirring, with a solution of 2.0 g Na_2CO_3 in 20 mL water over 15 min; then the solution was kept aside at room temperature for 4 h. The solid separated. On addition of 400 mL water, the reaction mixture was extracted with $CHCl_3$ and washed with dilute H_2SO_4 (1%) and finally with water. The organic layer was dried and concentrated to afford a solid that was crystallized from 2.5 L ethanol to give 2.5 g of 5,8-dimethoxyfuro-4′,5′,6,7-chromone-2-*p*-dimethylamino-phenylazomethine as golden yellow needles, m.p. 212°C (dec.).

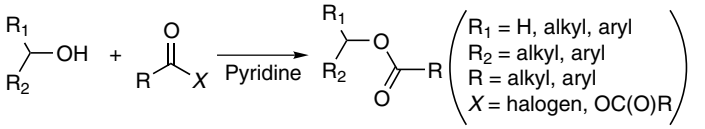
Einhorn Acylation

A. GENERAL DESCRIPTION OF THE REACTION

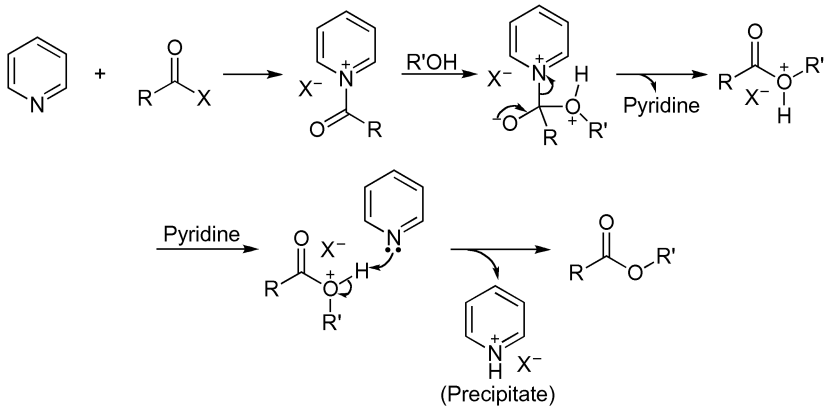
This reaction was initially reported by Einhorn and Hollandt in 1898.[1] It is the acylation of alcohols using anhydride or acyl halide in a tertiary amine such as pyridine. Therefore, this reaction is known as the Einhorn acylation,[2] Einhorn reaction,[3] and Deninger-Einhorn method.[4] The function of tertiary amines in this reaction have been identified as both nucleophilic acylation catalyst[5] and acid scavenger.[6] The solid evidence of nucleophilic catalyst is to record the UV spectrum of the intermediate acetylpyridinium salt in water.[7] Subsequently, a number of highly nucleophilic tertiary amines have been employed for the acylation of alcohols. These tertiary amines include triethylamine,[8] 4-(dimethylamino)pyridine (DMAP),[9] 1,4-diazabicyclo[2.2.2]octane (DABCO),[3b,3c,10] and 1,2,2,6,6-pentamethylpiperidine (PMP).[11] In addition, when chiral tertiary amines are used as catalysts, secondary alcohols can be selectively acylated to afford the chiral ester.[2]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified by adding 4-(dimethylamino)pyridine (DMAP) as a catalyst during the acylation in pyridine.[3c]

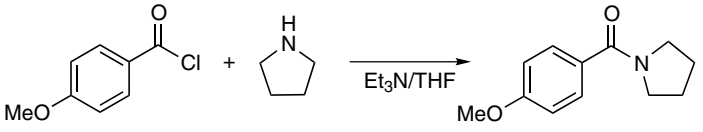
E. APPLICATIONS

This reaction has wide application in the preparation of esters from alcohols and acylation reagents (e.g., acyl halides and anhydrides).

F. RELATED REACTIONS

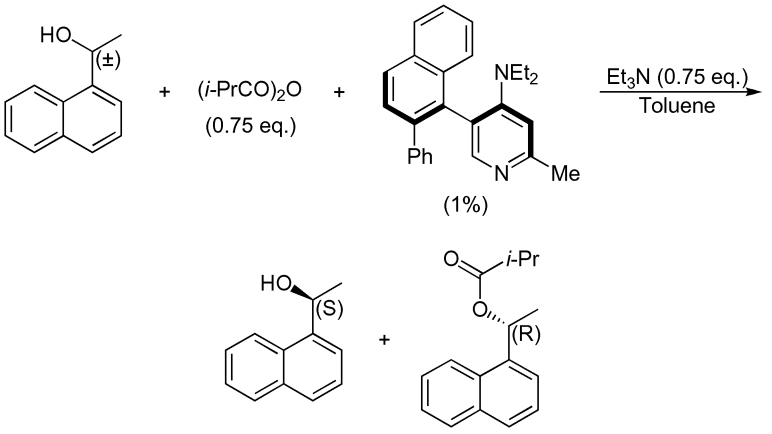
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To the solution of 4.20 g 4-methoxybenzoyl chloride (24.0 mmol) and 32 mL Et_3N in 30 mL THF was added a solution of 2 mL pyrrolidine (24 mmol) in 5 mL THF. The mixture was refluxed for 1 h. After cooling to ambient temperature, the solution was filtered and the filtrate was concentrated. The crude product was purified by column chromatography (CH_2Cl_2) to afford 75% of 1-(4-methoxybenzoyl)pyrrolidine.



Reference 2.

A solution of 172.0 mg (±)-1-(1-naphthyl)ethanol (1.00 mmol), 104 mL Et_3N (0.75 mmol), and 3.7 mg of the catalyst (10 μmol, > 99.9% e.e.) in 2.0 mL toluene was cooled to 0°C. Under vigorous stirring, 331 μL $(i\text{-PrCO})_2O$ (2.00 mmol) was added dropwise. After 24 h at 0°C, the reaction was quenched by 10 mL MeOH at 0°C. The mixture was allowed to warm to room temperature over 15 min, and the solvents were evaporated in vacuo. 1-(1-Naphthyl)ethanol and its isobutyric ester were separated by flash chromatography (petroleum ether/CH_2Cl_2 from 1:1 to pure CH_2Cl_2) to give 35.9% e.e. of (S)-ester.

Other references related to the Einhorn acylation are cited in the literature.[12]

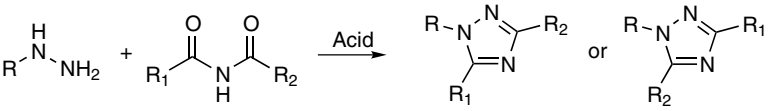
Einhorn-Brunner Reaction

A. GENERAL DESCRIPTION OF THE REACTION

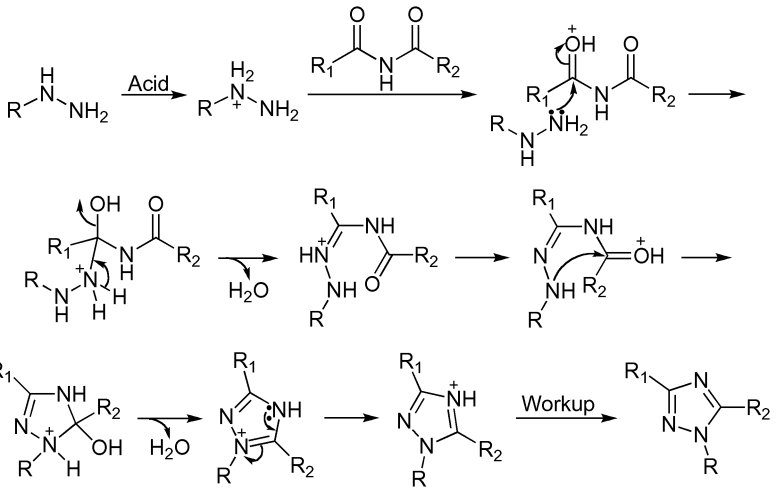
This reaction was initially reported by Einhorn in 1905[1] and was extended by Brunner in 1914,[2] therefore, it is known as the Einhorn-Brunner reaction.[3] It is the synthesis of 1,2,4-triazoles by acid-catalyzed condensation between hydrazines (or semicarbazides) and diacylamines. It should be pointed out when two side chains in diacylamine are different, two isomeric triazoles will form. It was found that the substituent in the diacylamine derived from the stronger acid would appear in position 3 of the resulting triazole,[3e] indicating that the reaction is initiated by the attack of the free amino group of hydrazine on the more electrophilic carbonyl group of the stronger acid moiety.[3c]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

A new preparation of 1,2,4-triazoles has been developed using tosylmethyl isocyanide and a diazonium salt.[3b]

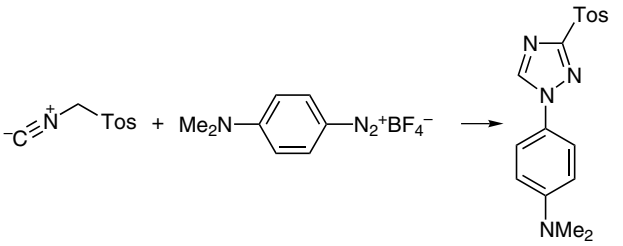
E. APPLICATIONS

This reaction has been used in the preparation of 1,2,4-triazoles (the most successful method[3c]).

F. RELATED REACTIONS

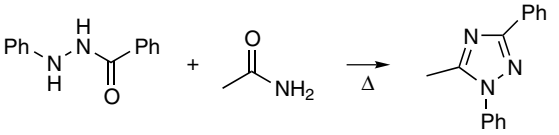
This reaction is related to the *Pellizzari Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

A solution of 9.75 g tosyl methyl isocynide (50 mmol) and 23.5 g *p*-dimethylaminobenzenediazonium tetrafluoroborate (100 mmol) in a mixture of 200 mL Me_2SO, 160 mL MeOH, and 80 mL H_2O was cooled in ice salt. To the stirred solution was added over 45 min a solution of 10.5 g K_2CO_3 in 100 mL cold water. After being stirred for another 10 min, the reaction mixture was poured in 4 L ice water that was almost saturated with NaCl. The precipitate was collected, washed with water and dried. Column chromatography (alumina, CH_2C1_2/THF, 3:2) gave 16.0 g 1-*p*-dimethylaminophenyl-3-tosyl-1,2,4-triazole, in a yield of 94%, m.p. 172–175°C. An analytically pure sample was obtained by preparative TLC (alumina, CH_2Cl_2) followed by crystallization from hot ethanol, with a melting point of 177–178.5°C.



Reference 3e.

1-Benzoyl-2-phenylhydrazine (6.0 g) and 15.0 g dry, freshly distilled acetamide were refluxed in an oil bath at 250°C for 4 h. The acetamide was distilled off at atmospheric pressure, and the residue was extracted with ether (2 × 50 mL), leaving 2.1 g undissolved 1-benzoyl-2-phenylhydrazine (m.p. 166°C). The crude triazole extract (3.8 g) was fractionated to give the main fraction as a pale yellow oil, b.p. 210–215°C (25 mmHg), which solidified after several months (2.1 g). Recrystallization from light petroleum (b.p. 40–60°C) removed 1-acetyl-2-phenylhydrazine (0.08 g, m.p. 129°C). The petroleum extract was sublimed at 40°C (2 mmHg) to afford oily crystals, m.p. 80–85°C. The compound was identified as 5-methyl-1,3-diphenyl-1,2,4-triazole.

Other references related to the Einhorn-Brunner reaction are cited in the literature.[4]

Eisleb Alkylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Eisleb in 1941.[1] It is the alkylation of compounds of active hydrogen with alkyl halide via the treatment of sodium amide. The compounds with active hydrogens include deoxybenzoin,[1a] diphenylmethane,[2] phenylacetonitrile,[3] fluorene,[2,4] benzyl phenyl sulfone,[5] and 2-pyridyl acetonitrile.[6] This reaction normally gives a satisfactory yield of introducing *N*,*N*-dialkylamino alkyl group to compounds with an active proton.[4]

A solution of 120 g fluorene (0.72 mol) in 250 mL toluene was refluxed with 15 g sodium amide (0.575 mol) for 1.5 h, then a solution of β-dimethylaminoethyl chloride in toluene (base liberated from 57.0 g β-dimethylaminoethyl chloride hydrochloride in 150 mL toluene) was added. The mixture was refluxed for another 4 h, then cooled and decomposed with sufficient 4 *N* HCl to render it acid to Congo red. The organic layer was washed twice with dilute hydrochloric acid and evaporated to leave about 50 g unreacted fluorene. The aqueous acidic layers were combined, made alkaline, and extracted with ether. Fractional distillation of the dried ethereal extract gave 44.2 g crude 9-(β-dimethylaminoethyl)-fluorene, in a yield of 41%, b.p, 156–165°C (at 2 mmHg). This product was further purified by the following process. The product, dissolved in 200 mL warm alcohol, was treated with 400 mL hot 5% $HClO_4$ solution; the perchlorate was purified by recrystallization from water, m.p. 206–208°C. The recrystallized perchlorate was dispersed in a mixture of 300 mL hot water and 100 mL hot benzene, the mixture was basified and vigorously mixed, and the benzene layer was separated. The aqueous layer was extracted with hot benzene again, and the benzene layers were combined,and distilled to give 28.0 g pure 9-(β-dimethaminoethyl)-fluorene, in an overall yield of 34%, b.p. 153–154°C (1.7 mmHg).

Other references related to the Eisleb alkylation are cited in the literature.[7]

Elbs Persulfate Oxidation

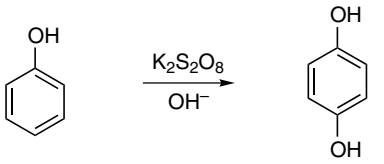
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Elbs in 1893.[1] It is the oxidative hydroxylation of aromatic compounds via the treatment of persulfate salt in the presence of alkali. Therefore, this reaction is generally known as the Elbs persulfate oxidation.[2] Occasionally, this reaction is also referred to as the Elbs alkaline persulfate oxidation,[3] Elbs oxidation,[4] Elbs peroxydisulfate oxidation,[5] Elbs persulphate oxidation,[6] Elbs reaction[2l,7] or Elbs-Seshadri persulfate oxidation.[8] In this oxidation, a hydroxyl group is mounted onto an aromatic ring predominantly in the *para*-position of a preexisting group;[3,5b] however, if the *para*-position has already been blocked, then hydroxylation at *ortho*-position occurs with much lower yield;[2s] no *meta*- hydroxylation has been reported yet.[5b] The persulfate is also called peroxydisulfate or peroxodisulfate.[5b] The persulfate salts suitable for this reaction include ammonium persulfate[2s] and potassium persulfate;[2s] all of them give similar results,[2s] indicating that the actual component in this oxidation is the persulfate ion. Although the yield of this oxidation is generally low, it normally affords a product with high purity.[2s] It has been reported that the yield can be improved by carrying out the oxidation in a solution saturated with NaCl or Na_2SO_4[2s] or when oxygen is purged off by nitrogen.[9] The aromatics suitable for this reaction include phenols, naphthols, coumarins, and flavones.[2s] It is assumed that this reaction occurs through a radical mechanism,[2h,2s,2w,3] because ammonium persulfate often initiates a radical reaction in aqueous solution; however, some evidence indicates that this oxidation predominantly involves the ionic nucleophilic substitution,[5] in which the electron-donating group facilitates the reaction and the electron-withdrawing group retards the reaction. In addition, it was found that the oxidation of phenol from the mixture of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

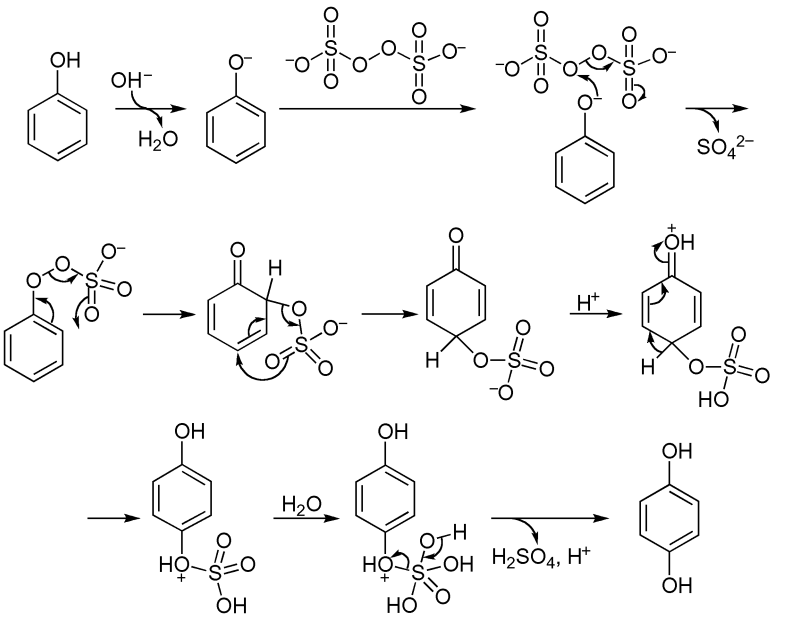
$KHSO_5$-$KHSO_4$-K_2SO_4 gives similar results to those from potassium persulfate.[2h] This reaction has been modified as oxidation from hydrogen peroxide in the presence of alkali.[10] Another modification is the application of a quaternary ammonium hydroxide as the base, such as tetramethylammonium hydroxide or tetraethylammonium hydroxide; the later gives a better yield.[9] Overall, this reaction is often used for the preparation of the aromatics with alkoxy groups by the alkylation after the hydroxylation.[2f,7a,11]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because both radical and ionic mechanisms have been proposed for this reaction and no mechanistic detail has been given in the literature, a new ionic mechanism similar to the *Abnormal Claisen Rearrangement* is proposed and outlined here.



D. MODIFICATION

This reaction has been modified to oxidize the aromatics using hydrogen peroxide in the presence of an alkali.[2s] Other modifications include the application of tetramethylammonium hydroxide or tetraethylammonium hydroxide as a base during the oxidation.[9]

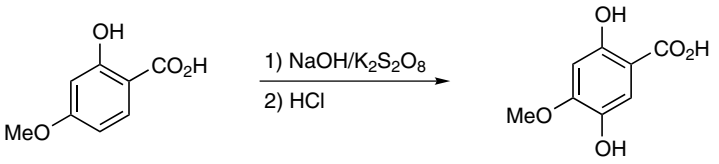
E. APPLICATIONS

This reaction has been widely applied in the preparation of hydroxyl aromatics and alkoxylated aromatics.

F. RELATED REACTIONS

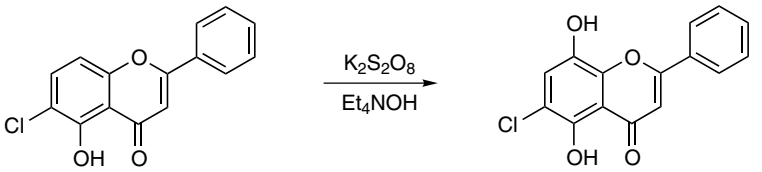
This reaction is related to the *Boyland-Sims Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2d.

To a solution of 10.0 g 2-hydroxy-4-methoxybenzoic acid (59.5 mmol) and 8.0 g NaOH (200 mmol) in 90 mL water at 10°C was added a solution of 17.0 g potassium persulfate (62.9 mmol) in 300 mL water over a 4-h period. The reaction mixture was then allowed to warm to room temperature and was stirred for 24 h, resulting in a purple solution. The mixture was neutralized with 1 N hydrochloric acid and extracted with ether (3 × 150 mL). The combined organic extracts were washed with brine and dried over $MgSO_4$. Concentration and recrystallization from ethanol and water afforded 3.21 g 2,5-dihydroxy-4-methoxybenzoic acid as colorless rectangular rods, in a yield of 30%, m.p. 200–202°C (dec).



Reference 9.

To a 1-L, three-necked flask equipped with dropping funnel, stirrer, and fritted-glass gas dispersion rod was added 4.0 g 6-chloro-5-hydroxyflavone dissolved in 280 mL of a 10% aqueous solution of tetraethylammonium hydroxide and 9 mL pyridine. The resulting solution was purged with nitrogen for 1.5 h at 30–35°C. Then followed the dropwise addition to the stirred solution of 6.85 g potassium peroxydisulfate in 150 mL oxygen-free water over a 4-h period. An additional 9 mL pyridine was added after 2 h to maintain a homogeneous mixture. The reaction mixture was stirred for an additional 20 h at 30–35°C and filtered to give 1.25 g potassium salt of 6-chloro-5-hydroxyflavone; the filtrate was acidified with concentrated HCl to Congo red. The filtrate was neutralized with very dilute sodium hydroxide (∼1%), and the resulting 3.4 g of tan precipitate was collected by filtration. The

tan precipitate was dissolved in 40 mL cold 5% NaOH and filtered; ~200 mg of dark solid was collected and discarded. The filtrate was acidified to Congo red with concentrated HC1, and the resulting tan precipitate was collected and dried. The tan material then was placed in 80 mL hot water, and the pH was adjusted to 7.5–8.0 with 1% sodium hydroxide solution. The resulting mixture was stirred for 15 min and filtered, and the dark brown precipitate was discarded. To the filtrate was added 25 mL concentrated HC1, and the acidified filtrate was heated 2 h on a steam bath. 6-Chloro-5,8-dihydroxyflavone was obtained as a yellow powder and collected by filtration in a yield of 1.02 g (34% based on 2.84 g of starting material), m.p. 244–247°C. One crystallization from ethanol gave the pure substance (mp. 248–249°C). The filtrate from the original crude product isolation was acidified with 25 mL concentrated HCl and heated on a steam bath; and 360 mg crude substance was collected. Chromatography of the latter on a column of Florex/Celite (5:l wt.) with EtOAc as the solvent, gave an additional 30 mg 6-chloro-5,8-dihydroxyflavone, thus making the total yield 1.05 g.

Other references related to the Elbs persulfate oxidation are cited in the literature.[12]

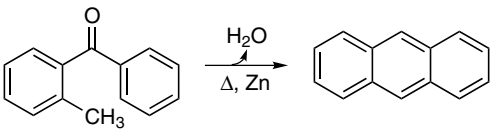
Elbs Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although the thermal decomposition of *o*-methylbenzophenones had been studied by Behr and van Dorp in 1873[1] and Ador and Rilliet in 1878,[2] it was Elbs who extensively investigated this reaction beginning in 1884.[3] Therefore, it is generally referred to as the Elbs reaction[4] or Elbs pyrolysis.[5] This reaction is the preparation of polyaromatics (especially anthracene) by intramolecular condensation of diaryl ketones containing a methyl or methylene substituent *ortho* to the carbonyl group. This reaction is usually carried out by means of high-temperature pyrolysis in the absence of a solvent or catalyst.[4a,4c] In some cases, it is accompanied by the elimination of substituents before the pyrolysis, such as fluoro,[4b,6] methyl,[4b] and methoxy.[4b] As a result, the Elbs reaction is not a perfect method for the preparation of polyaromatics with substituents,[7] although it is by far the most rapid and economical method for the synthesis of parent polyaromatics.[7] It has been proposed that hydrogen transfer is involved in this reaction.[4b] In addition, the yield of the Elbs reaction can be improved by removing the formed anthracene derivatives at intervals from the reaction zone.[8]

B. GENERAL REACTION SCHEME

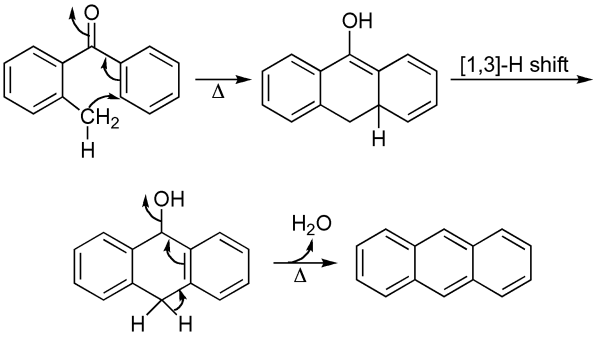


Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

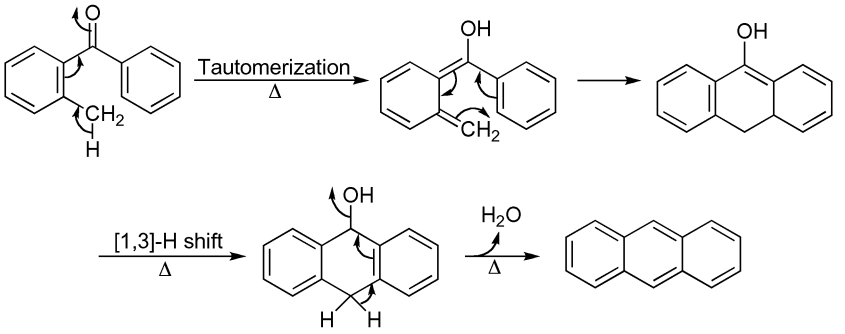
C. PROPOSED MECHANISMS

At least three different mechanisms have been proposed for this reaction. Displayed here are two of the most plausible mechanisms from Fieser and Cook.

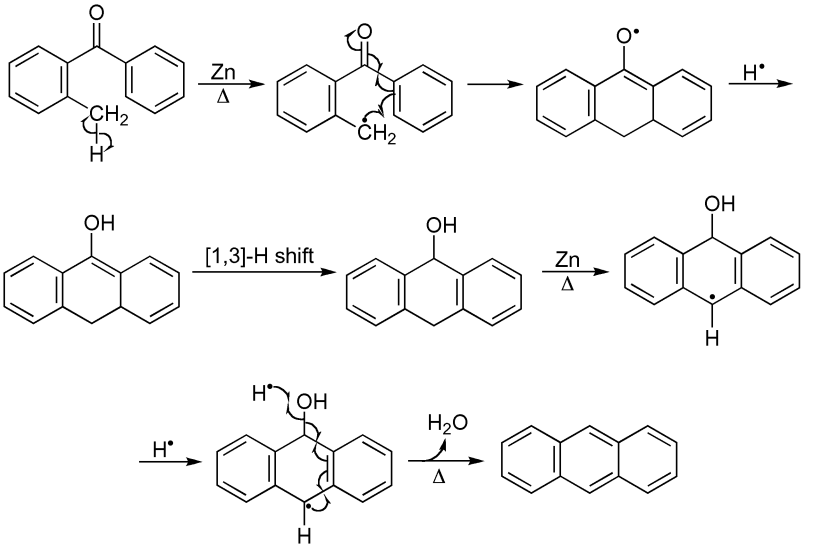
Fieser's mechanism.[9]



Cook's mechanism:[10]



In addition, an alternative mechanism is proposed here involving the generation of radical by high-temperature pyrolysis, as illustrated below.



D. MODIFICATION

N/A

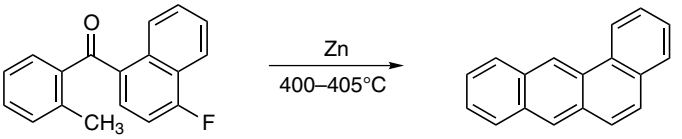
E. APPLICATIONS

This reaction has been widely used in the preparation of polyaromatic compounds.

F. RELATED REACTIONS

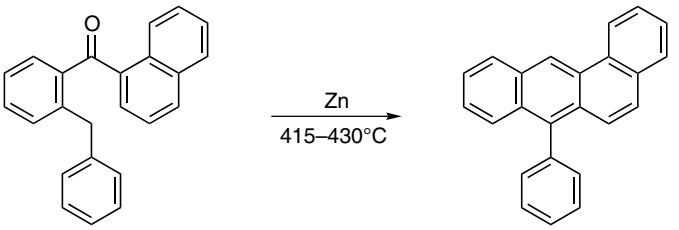
This reaction is related to the *Bradsher Cyclization*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4c.

A mixture of 4.0 g 1-fluoro-4-(*o*-toluoyl)naphthalene and 2.0 g zinc dust was heated at 400–405°C for 2 h and flash distilled under 1 mmHg. The distillate was brought to crystallization by treatment with a mixture of ethanol and benzene, and the product was chromatographed on alumina (benzene/petroleum ether, 3:1) to afford 1.1 g 1,2-benzanthracene, in a yield of 32%, m.p. 160°C.



Reference 4b.

A mixture of 3.0 g of 2-benzylphenyl 1-naphthyl ketone and 1.0 g powdered zinc was heated at 415–430°C for 3 hours in an atmosphere of nitrogen. The product was flash-distilled under vacuum and purified by chromatography on alumina with petroleum ether, and 0.9 g 7-phenylbenz[a]anthracene was obtained, in a yield of 32%, m.p. 182–183°C. No other products were isolated.

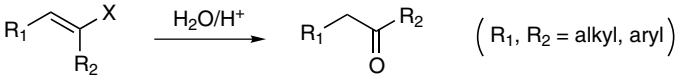
Eltekoff Hydrolysis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Eltekoff in 1873.[1] It is the hydrolysis of olefinic halides in aqueous alkali solution to generate glycol that further forms carbonyl compounds (aldehyde or ketone). In the original procedure,[2] Eltekoff heated the olefinic halides with lead oxide and water to 140–150°C and obtained acetaldehyde and ethylene glycol from ethylene bromide (or chloride), acetone and propionaldehyde from the propylene halides, etc. At the same time, Eltekoff found that the yield of the carbonyl compound was directly related to the reaction time—that is, the longer the halide was heated with lead oxide and water, the higher the yield of carbonyl compounds and the lower the amount of glycol formed.[3] This result indicates that the carbonyl compounds were generated from the dehydration of glycols in the slightly acidic solution. However, it was found that lead oxide or a high temperature was unnecessary for this reaction,[4] and olefinic halides could be easily hydrolyzed to glycols[3,5] but not directly to carbonyl compounds when treated with the aqueous alkali solution. If the alkali is omitted, then the glycols might rearrange into carbonyl compounds[6] (a kind of *Pinacol Rearrangement* in a slightly acidic solution). It is assumed that this reaction under acidic condition occurs via an $A_{SE}2$ mechanism.[7] This reaction has become one of the most convenient methods for the production of ketones.[3]

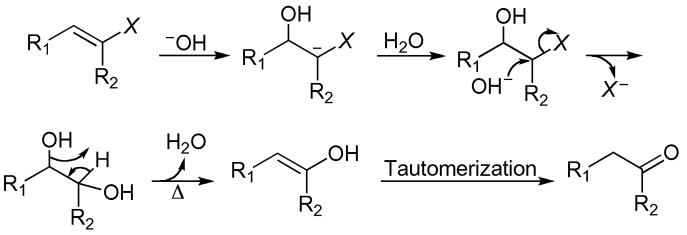
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

In slightly acidic conditions, the hydration of olefin gives halo-alcohol, which decomposes to carbonyl compound, as outlined below.[7]



D. MODIFICATION

This reaction has been modified for treating vicinal dihalides with an aqueous alkali solution to produce glycols and carbonyl compounds.

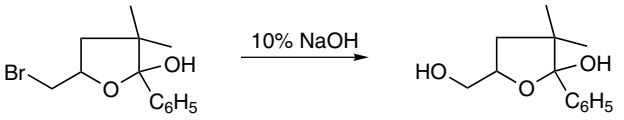
E. APPLICATIONS

This reaction has been used to prepare glycols, aldehydes, and ketones.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 6a.

A mixture of 1.5 g 5-bromomethyl-3,3-dimethyl-2-phenyltetrahydro-2-furanol ("bromohydrin"), 2.5 mL 10% NaOH, and 50 mL dioxane was stirred and refluxed for 4 h and then poured into 1 L water. The mixture was extracted with four 200-mL portions of ether. The organic layers were combined and washed with 100 mL water (five times) and 40 mL brine (three times). Removal of the ether at room temperature left 1.22 g orange oil, which was chromatogrphed from petroleum ether on 37.0 g alumina. Elution with petroleum ether and 10:1 petroleum ether/ether gave 0.75 g of a white solid (the starting material) and 0.36 g 2-hydroxy-5-hydroxymethyl-3,3-dimethyl-2-phenyltetrahydrofuran as a white solid, in a yield of 30%.

Other references related to the Eltekoff hydrolysis are cited in the literature.[8]

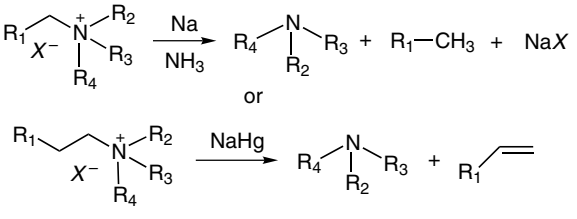
Emde Degradation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Emde in 1906.[1] It is the reductive cleavage of quaternary ammonium salt of nitrogen-containing compounds (especially in heterocyclic forms) by means of the treatment with an excess of sodium amalgam in an alcoholic or aqueous solution.[2] In fact, this reaction is the modification of *Hofmann Degradation*; therefore, it is sometimes known as the Hofmann and Emde degradation[3] or the Emde-Birch fission.[4] However, this reaction is generally referred to as the Emde degradation[5,6] or Emde reduction,[5a,5b,5e,5f,7] and the corresponding products are called the Emde products.[5d,5e] The order of groups to be cleaved was found to be: $RC(O)CH_2$, $PhCH{=}CHCH_2$ > benzyl > allyl > phenyl > methyl.[2] It was found that the position of the scission for the nitrogenous heterocyclic ring depended on the reaction condition,[7c] affording one product[7f] or two products.[5a] This reaction has been modified to treat the quaternary ammonium salt with sodium/dry ammonia,[5f,7g] sodium/ammonia/0.5% water,[8] or by electrolytic reduction in dry ammonia (or with 0.5% water present)[9] or to degrade the ammonium salt by photo irradiation.[10]

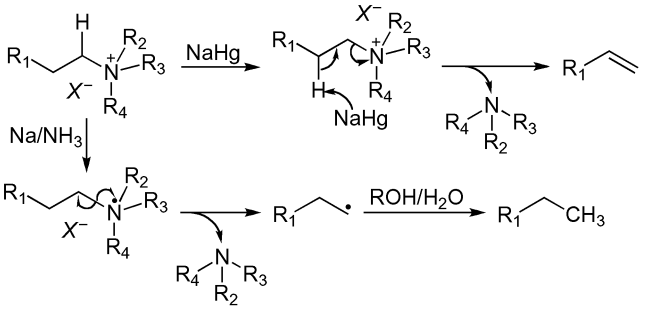
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Because not much mechanistic information is available for this reaction, a tentative mechanism is outlined here to indicate the formation of different types of products (e.g., alkenes and alkanes).



D. MODIFICATION

This reaction has been modified to occur in liquid ammonia by treatment of sodium alone.[5f,7g] In addition, a photo-Edme degradation has been developed.[10]

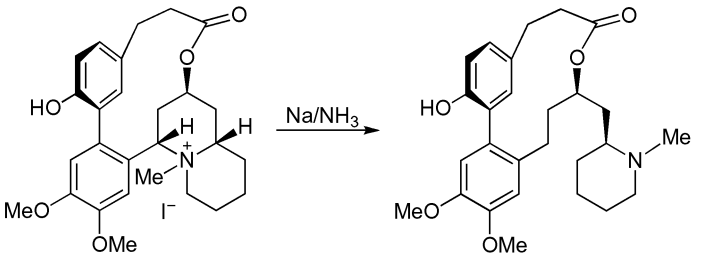
E. APPLICATIONS

This reaction has been successfully applied in the degradation of nitrogenous heterocyclic compounds and the elucidation of many alkaloids structures.

F. RELATED REACTIONS

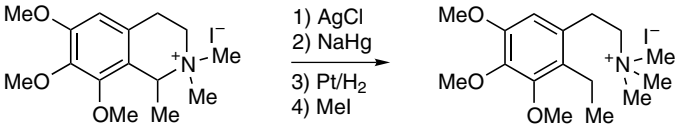
This reaction is related to the *Hofmann Degradation* and *von Braun Degradation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5b.

To a solution of 2.05 g decinine methiodide (3.55 mmol) in 175 mL liquid ammonia was added 0.29 g sodium. When the blue color had disappeared, the ammonia was allowed to evaporate. The residue was dissolved in water, the pH was adjusted to 10, and the mixture was extracted with chloroform. The chloroform extract was dried and diluted with 95% ethanol, and the volume was reduced until crystallization ensued. A yield of 1.19 g *N*-methyldihydrodecinine was obtained, in a yield of 74%, m.p. 230–231°C.



Reference 7d.

To 10 mL hot water containing 460 mg *O*,*N*-dimethyl-DL-anhalonidine methiodide was added 0.5 g freshly precipitated silver chloride (from 0.5 g silver nitrate). After being shaken in the dark for 30 min, the mixture was filtered, and 20 g 3% sodium amalgam was added. After being heats on a steam bath for 18 h, the oil floating on the surface was extracted with ether. The dried ether extract was evaporated, and the residue was dissolved in 30 mL ethanol. Then 40 mg of platinum oxide was added, and the mixture was hydrogenated for 12 h at 30 psi. The residue obtained on evaporation of the filtered solution was dissolved in 30 mL methanol, and 0.3 mL methyl iodide was added. After standing overnight, the solution was evaporated to small bulk, and EtOAc was added when colorless needles of 2-ethyl-3,4,5-trimethoxy-phenylethyltrimethylammonium iodide was obtained (84 mg), m.p., 216–218°C. Fine needles (m.p. 218–219°C) were obtained on recrystallization from ethanol.

Other references related to the Emde degradation are cited in the literature.[11]

Emmert Reaction

A. GENERAL DESCRIPTION OF THE REACTION

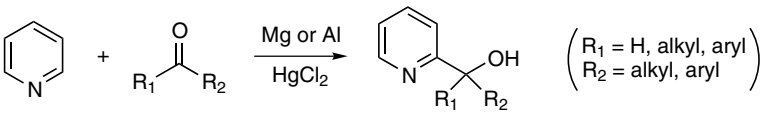
This reaction was initially reported by Emmert and Asendorf in 1939.[1] It is the formation of pyridylalkyl or pyridyldialkyl carbinols by condensation of pyridine (or its analogues) with aldehydes or ketones in the presence of aluminum or magnesium amalgam. Therefore, it is generally known as the Emmert reaction.[2] Pyridine and its analogues are assumed nonreactive toward alkylation or acylation, due to the C=N bond in pyridine ring.[3] However, the alkylation of pyridine can occur when aldehyes or ketones are treated with aluminum or magnesium, mercuric chloride, and iodine[4] or treated with very small amounts of mercuric chloride with few drops of mercury.[4] It was found that other metals with low reduction potentials do not work in this reaction, and the metals of high reduction potentials and poor coordinating power do not offer the alkylation product but the pinacols of ketones.[2e] It is magnesium or aluminum that combines both characters of high reduction potential (2.4 V and 1.7 V, respectively) and coordinating power functions well for this reaction.[2e] Beryllium (1.69 V) functions similarly, but gives very poor yields.[2e] In this reaction, pyridine might react with dialkyl, diaryl, alkyl aryl, and cyclic ketones, while steric effects from *ortho* substituent on pyridine might inhibit the reaction between such pyridine and aryl ketones.[2e] Although the exact function of the metal is not quite clear,[2f] it is assumed that the metal supplies two electrons to the carbonyl compound, resulting in a carbanion that attacks the pyridine ring.[2e] Therefore, the electron-donating group on ketones can increase the negativity of a carbanion to facilitate the addition to the pyridine ring; likewise, ketone gives a better yield than aldehyde as of the hyperconjugation of alkyl group on ketone.[2e] In this reaction, moisture will inhibit the reaction, and solvents such as carboxylic acids and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

alcohols that donate a proton through ionization are not feasible for this reaction either.[2e] Under reductive conditions, no hydrogenated pyridines are formed, indicating that air is the oxidizing agent.[2e] Other nitrogenous heterocycles, including picolines, can be similarly alkylated.[2f] Although both magnesium and aluminum work for this reaction, there exist some subtle differences between magnesium and aluminum. For example, when magnesium is used in the absence of mercuric chloride, the reaction is very slow and any variation of the reactants ratio gives a low yield of the desired product;[4] however, when aluminum is used, increasing the proportions of pyridine or aluminum increases the yields of the desired product.[4] In addition, aluminum may give 4-alkylated pyridyl carbinol, as larger aluminum might form a transannular bridge between the nitrogen atom and the 4-position of pyridine.[2e]

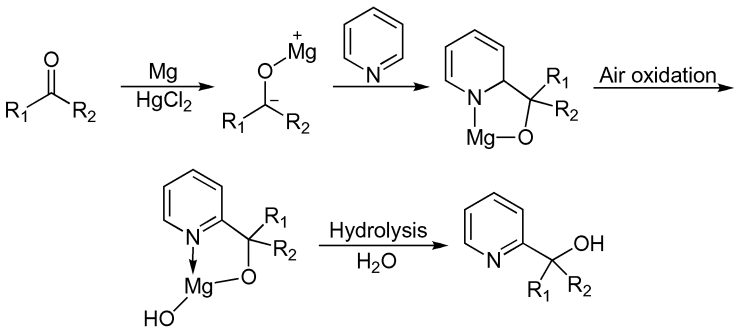
Moreover, magnesium and aluminum can also be applied for the acylation of pyridine derivatives with acid esters via a similar mechanism, involving a two-electron transfer process, with the activity order of Al > Mg > Be.[5] Other acid derivatives (e.g., *N*,*N*-dialkylamides and nitriles) also react with pyridines in lower yields; however, the low-boiling acid derivatives may give low yields too, as the reaction is normally carried out at 100°C.[5] In general, aromatic esters afford higher yields than aliphatic esters, because the carbanion intermediates can be stabilized via resonance.[5]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that the metal donates two electrons at a time to form the carbanion, which adds to pyridine ring,[2e] as illustrated by the reaction of Mg.



D. MODIFICATION

This reaction has been modified to form acylated pyridine derivatives.[5]

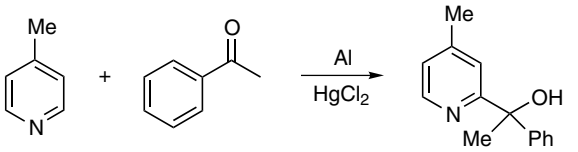
E. APPLICATIONS

This reaction is very useful in the preparation of 2-alkylated or 2-acylated pyridine derivatives as well as picoline and quinoline derivatives.

F. RELATED REACTIONS

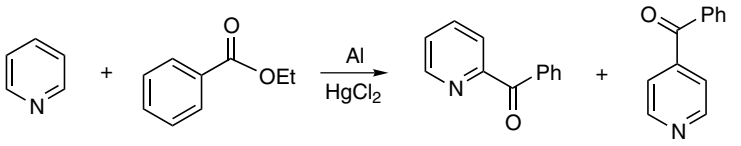
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2e.

Granular (30-mesh) aluminum (27 g, 1 mol), 0.5 g mercuric chloride, and a few drops of mercury were preheated together for 30 min at 100°C in a 1-L, three-necked flask fitted with a dropping funnel, condenser, and mercury sealed stirrer. A mixture of 25 g each 4-picoline and acetophenone was added in one portion and stirred until the reaction began. The beginning of the reaction was accompanied by an evolution of heat and a color change to dark green. The remaining picoline (290 g, 3.5 mol total) was added in one portion, and 185 g acetophenone (1.75 mol total) was added dropwise under vigorous stirring within 5.5 h. The temperature was kept at 130°C during the addition with the aid of a heating mantle. After that, the mixture was stirred for additional 3.5 h at 130°C, and then cooled and decomposed by being poured into 1 L 3 N NaOH solution. The separating oil was extracted successively with 200-mL portions of 6 N HCl. The acid extract was made basic with a NaOH solution. The organic layer was dried over $CaSO_4$ and distilled. The fraction boiling at 130–135°C (0.8 mmHg) was collected in a total amount of 85 g and in a yield of 30%; it was recrystallized from petroleum ether to yield a colorless solid, m.p. 69.5 −70°C.



Reference 5.

Granular (30-mesh) aluminum (27 g, 1 mol), 5 g mercuric chloride, and several drops of mercury were preheated together for 2 h at 100°C in a 1-L, three-necked flask fitted with a dropping funnel, condenser, and stirrer. Ethyl benzoate (25 g) and 25 g pyridine were added to the metallic mixture to initiate the reaction. A green color developed immediately and turned to a muddy brown within a few minutes. Then 250 g pyridine (3.5 mol total) was added dropwise over a period of 2 h during refluxing. At the end of this addition

the reaction mixture was dark colored. Ethyl benzoate (425 g, 3.0 mol total) was added dropwise to the reaction mixture over a period of 24 h at which time all of the aluminum metal had reacted. The cooled reaction mixture was stripped of unreacted pyridine using an aspirator and mild heating, and then the remaining viscous oil (350–400 mL) was poured into 1500 mL petroleum ether (90–100°C). This addition resulted in the precipitation of a brown solid (286 g), which could be filtered, dried, and allowed to stand in the presence of air without any noticeable decomposition. This complex was hydrolyzed with 6 N HCl, the oil layer was distilled under vacuum through a 30-cm glass helix–packed column, and the following fractions were collected: 2-benzoylpyridine (87.0 g, 32.5%, 124–126°C at 1.5 mmHg), 4-benzoylpyridine (19.4 g, 7.1%, 126–146°C at 1.9 mmHg, m.p.,72.5–73°C), and mixture of benzil and benzoin (26.7 g, 12.7%).

Other references related to the Emmert reaction are cited in the literature.[6]

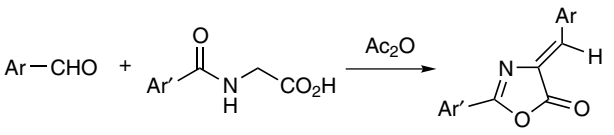
Erlenmeyer-Plöchl Azlactone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

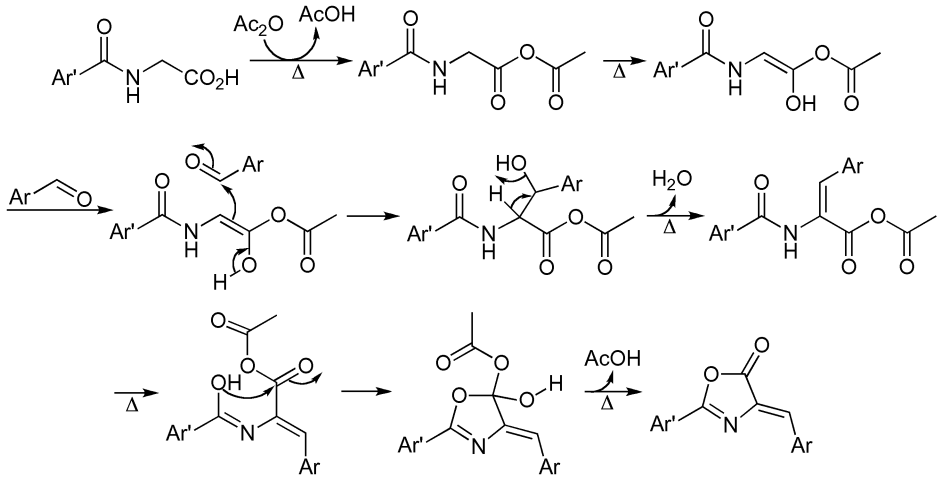
The condensation between aromatic aldehydes and hippuric acid in the presence of acetic anhydride was initially reported by Plöchl in 1883[1] and was studied extensively by Erlenmeyer in 1892.[2] In addition, Erlenmeyer corrected the original assigned structure of a product containing a three-membered ring and coined the word *azlactone* for the formed product.[3] Therefore, this reaction is known as the Plöchl-Erlenmeyer reaction,[4] Erlenmeyer-Plöchl reaction,[5] Erlenmeyer-Plöchl synthesis,[6] Erlenmeyer-Plöchl oxazolone synthesis,[7] Erlenmeyer-Plöchl method,[8] Erlenmeyer synthesis,[9] and Erlenmeyer azlactone synthesis.[10] In detail, the Erlenmeyer-Plöchl azlactone synthesis is the preparation of azlactones (also called oxazolones[11]) in a *Z* configuration (originally assigned to the *E* configuration)[10b] by condensation of aromatic aldehydes with hippuric acid (the benzoyl glycine derivatives[12]) in the presence of acetic anhydride. The formed azlactones have found many applications in organic synthesis, especially for α-ketos, α-amino acids[2c,2d] and peptides.[13] This reaction normally gives one product: the thermodynamically stable one;[10b] however, two products are also formed in some cases.[7] In addition, transacylation often occurs in this reaction, especially when the reaction mixture is refluxed.[5b,6] Thus the yields of desired products are not very high, and extensive purification of crude azlactones should be avoided to generate higher yields.[5b]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur in polyphosphoric acid (PPA) to form the azlactones in the *E* configuration.[10b]

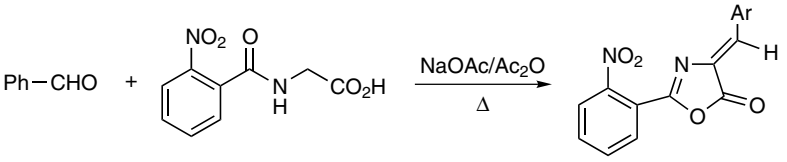
E. APPLICATIONS

This reaction has been used for the synthesis of α-keto, α-amino acids,[2c,2d] and peptides.[13]

F. RELATED REACTIONS

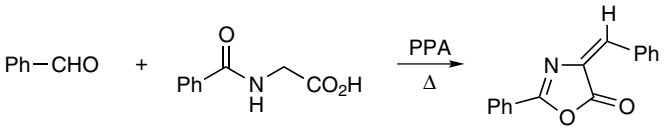
This reaction is related to the *Bergmann-Stern Azlactone Synthesis*, *Claisen Condensation*, and *Perkin Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

To a flask equipped with a condenser, were added 1.07 mmol *ortho*-nitrobenzoylglycine, 0.96 mmol benzaldehyde, 0.96 mmol fused NaOAc, and 3 mmol acetic anhydride. The mixture was heated in a boiling water bath for 1 h. After cooling, 2 mL 95% ethanol was added to the flask, and the mixture was left at 5°C for 4–6 h. The precipitate formed was filtered and washed with cold ethanol, then with boiling water, and again with cold ethanol. The dried precipitate was recrystallized to a constant melting point in acetic acid to give 57% product as yellow needles, m.p. 210°C.



Reference 10b.

To a sample of polyphosphoric acid prepared from 20 mL phosphoric acid and 32 g phosphoric anhydride was added 5.3 g benzaldehyde (50 mmol) and 8.95 g hippuric acid (50 mmol). The mixture was then heated on a steam bath (80–95°C) for 90 min and then poured into water. The resultant solid product was collected and repeatedly washed with water. Finally, 12.0 g 2-phenyl-4-phenylmethylene-2-oxazolin-5-one was recrystallized from a mixture of benzene-Skellysolve B, in a yield of 90%, m.p. 146–147°C.

Other references related to the Erlenmeyer-Plöchel azlactone synthesis are cited in the literature.[14]

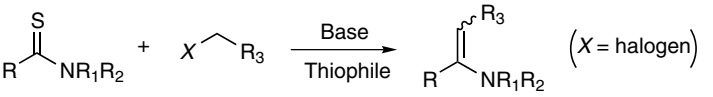
Eschenmoser Coupling

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fischli and Eschenmoser in 1967 during the synthesis of vitamin B_{12}.[1] It is the formation of vinylogous amides and urethanes by alkylation of secondary or tertiary thioamides with an electrophilic reagent followed by the extrusion of sulfur. Therefore, it is known as the Eschenmoser coupling,[2] Eschenmoser coupling reaction,[3] Eschenmoser's method,[4] Eschenmoser sulfide contraction,[5] Eschenmoser sulfide contraction methodology,[6] or Eschenmoser sulfide reaction.[7] Essentially, this reaction is analogous to the *aza Claisen-Schmidt Condensation*;[5c] however, it is not well suited for introducing the *meso* substituents.[8]

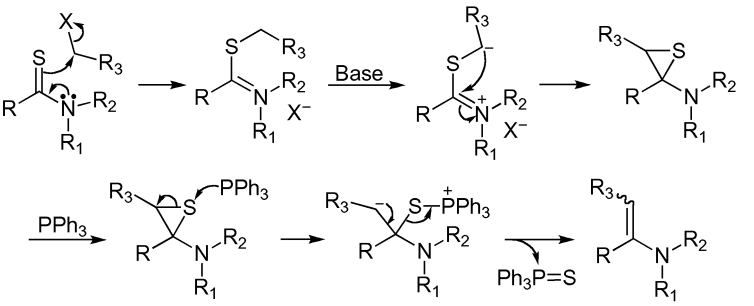
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Provided here is a tentative mechanism for the Eschenmoser coupling.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified to form vinyl thioether through peroxide initiation.[5c]

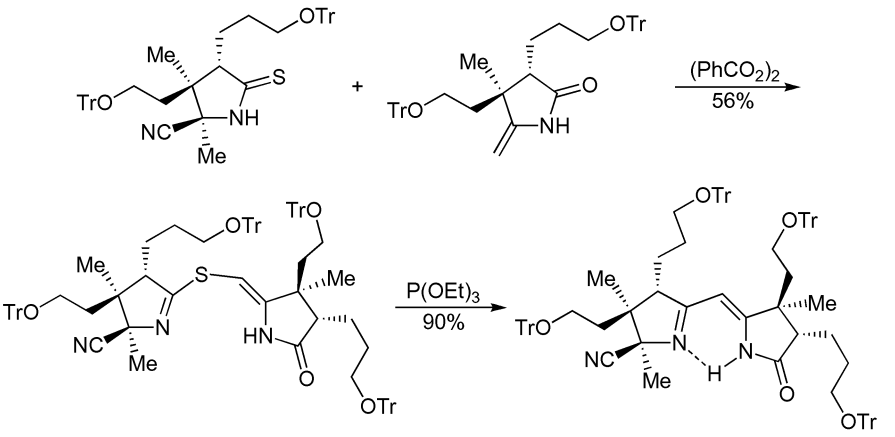
E. APPLICATIONS

This reaction has general application in the preparation of vinylogous amides, especially for vitamin B_{12}.

F. RELATED REACTIONS

This reaction is related to the *Claisen-Schmidt Condensation*.

G. CITED EXPERIMENTAL EXAMPLES

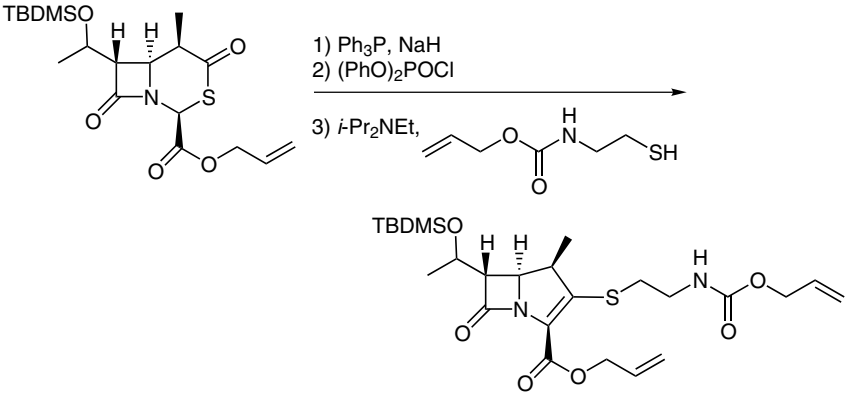


Reference 5c.

A solution of 1.74 g (2R,3S,4S)-2,3-dimethyl-5-thioxo-3-(2-(trityloxy)ethyl)-4-(3-(trityloxy)propyl)pyrrolidine-2-carbonitrile (1.00 mmol) in 5 mL dry benzene was added to freshly prepared (3S,4S)-4-methyl-5-methylene-4-(2-(trityloxy)ethyl)-3-(3-(trityloxy)-

propyl)pyrrolidin-2-one (1.50 mmol, 1.047 g). At 0°C, benzoyl peroxide (415 mg, 1.20 mmol) was added. The mixture was stirred in the dark and under argon for 24 h and poured into a mixture of diethyl ether and saturated aqueous $NaHCO_3$. The organic layer was dried over $MgSO_4$, filtered, and concentrated. Purification by silica gel chromatography (linear gradient of 10–20% EtOAc/hexane) afforded 804 mg [2*R*, 3*S*,4*S*,5(2*Z*,3*S*,4*S*)]-2,3-dimethyl-5-[(3-methyl-5-oxo-3-(2-(trityloxy)-ethyl)-4-(3-(trityloxy)propyl)pyrrolidin-2-ylidene)methanesulfonyl]-3-(2-(trityloxy)ethyl)-4-(3-(trityloxy)propyl)-3,4-dihydro-2*H*-pyrrole-2-carbonitrile, in a yield of 56%.

A solution of 200 mg sulfide (139 μmol) and 0.148 mL triethyl phosphite (142 mg, 850 μmol) in 2 mL dry benzene was degassed and heated to 120 °C for 72 h in a sealed tube. The mixture was concentrated and chromatographed on aluminium oxide (activity III–IV, linear gradient of 10–20% EtOAc/hexane) to give 177 mg [2*R*,3*S*,4*S*,5(2*Z*,3*S*,4*S*)]-2,3-dimethyl-5-[(3-methyl-5-oxo-3-(2-(trityloxy)ethyl)-4-(3-(trityloxy)propyl)pyrrolidin-2-ylidene)methyl]-3-(2-(trityloxy)ethyl)-4-(3-(trityloxy)-propyl)-3,4-dihydro-2*H*-pyrrole-2-carbonitrile as a mixture of diastereoisomers (~36:6:6:1), in a yield of 90%. Diastereomerically pure material was obtained by HPLC (Nuc 50–10, 10:1:2 hexane/MeOAc/diethyl ether, +20% hexane, 10 mL/min) to give 130 mg pure A-B-semicorrin as an amorphous solid, in a yield of 67%.



Reference 4.

To a stirred solution of 300 mg allyl (2*S*,5*R*,6*S*,7*S*)-7-[(1*R*)-1-[(*tert*-butyldimethylsilyl)-oxy]ethyl]-5-methyl-4,8-dioxo-1-aza-3-thiabicyclo[4.2.0]-octane-2-carboxylate (0.726 mmol) and 186 mg Ph_3P (0.726 mmol) in 6 mL DMF at −20°C under nitrogen was added 32 mg 60% NaH (0.798 mmol). After the reaction mixture was stirred for 2 h, 0.165 mL $(PhO)_2POCl$ (0.709 mmol) and 9 mg DMAP (0.07 mmol) were added to the mixture, and the stirring was continued at 0°C for 2 h. *N*-[(Allyloxy)carbonyl]cysteamine (152 mg, 0.944 mmol) and 0.165 mL *i*-Pr_2NEt (0.944 mmol) were added to the mixture, which was allowed to stand at 0°C in the refrigerator for 3 days. The reaction mixture was poured into water and extracted with EtOAc. The organic layer was washed with brine, dried, and evaporated. The residue was purified by silica gel column chromatography (elution with *n*-hexane/EtOAc, 3:1) to afford 250 mg allyl (1*R*,5*S*, 6*S*)-6-[(1*R*)-1-[(*tert*-butyldimethylsilyl)-oxy]ethyl]-2-[[[2-[(allyloxy)-carbonyl]amino]-ethyl]thio]-1-methylcarbapen-2-em-3-carboxylate as a yellowish syrup, in a yield of 66%.

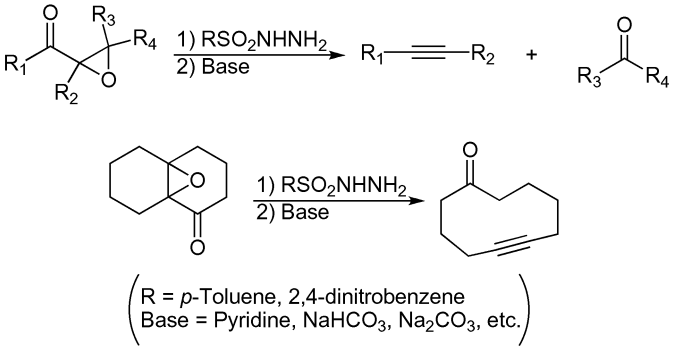
Eschenmoser Fragmentation

A. GENERAL DESCRIPTION OF THE REACTION

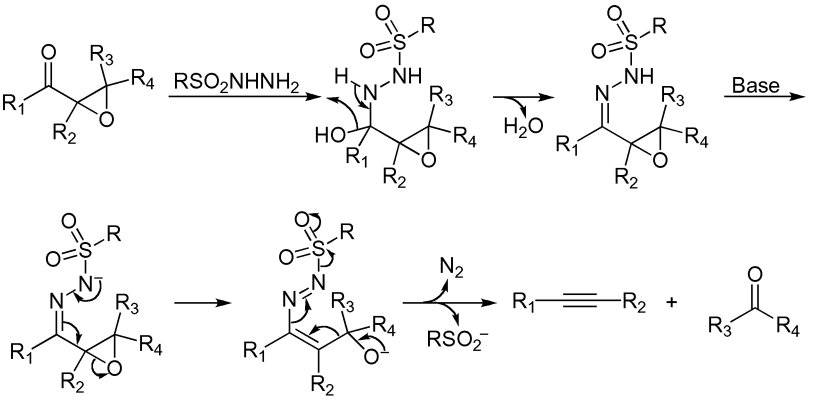
This reaction was initially reported concurrently by Eschenmoser[1] and Tanabe[2] in 1967. It is the cleavage of α,β-epoxyketones under mild conditions to acetylenic aldehydes or ketones with *p*-toluenesulfonylhydrazine using pyridine, $NaHCO_3$, or Na_2CO_3 as a catalyst.[3] Therefore, this reaction is generally known as the Eschenmoser fragmentation.[4] Occasionally, it is also referred to as the Eschenmoser-Tanabe Fragmentation[5] or α,β-epoxy ketone cleavage reaction.[3] It is interesting that more and more experimental evidence indicates that *p*-toluenesulfonylhydrazine is not a satisfactory reagent for the cleavage of α,β-epoxy ketones,[3,4a] thus alternative sulfonylhydrazines are applied to this reaction, including *p*-nitrobenzenesulfonylhydrazine.[4a] This reaction provides an alternative and spectacular type of ring expansion for the cyclic ketones.[4c] The driving force of this reaction arises from both enthalpic and entropic contributions, due to the formation of toluene sulfinate and the evolution of nitrogen gas, respectively. This reaction is assumed to proceed via a concerted mechanism.[5b]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

p-Nitrobenzenesulfonylhydrazine[3] and mesitylene-sulfonylhydrazine[4c] have been substituted for *p*-toluenesulfonylhydrazine for the Eschenmoser fragmentation.

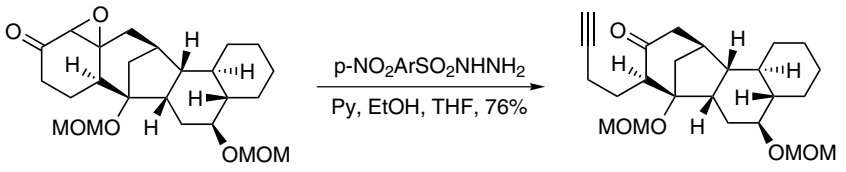
E. APPLICATIONS

This reaction has been used in the preparation of acetylenic aldehydes and ketones; in addition, it has been used to synthesize middle-size cyclic ketones.

F. RELATED REACTIONS

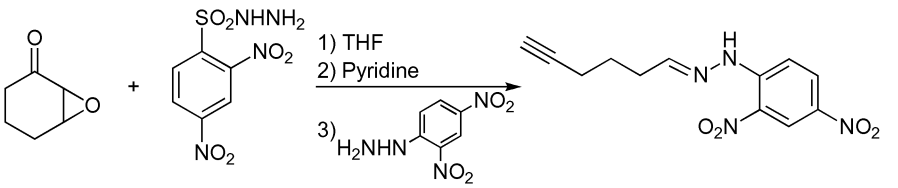
This reaction is related to the *Bamford-Stevens Reaction*, *Grob Fragmentation* and *Wharton Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

(4a*SR*,5*SR*,6a*SR*,7*SR*,7a*RS*,13*RS*,13a*RS*,13b*RS*)-1,2,3,4,4a,5,6,6a,7,7a,8,9,11,11a,12,13,13a,13b–Octadecahydro-11,11a-epoxy-5,7-bismethoxymethoxy-7,13-methano-10*H*-benzo[4,5]cyclohepta[1,2-a]-naphthalen-10-one(60 mg, 0.14 mmol) was dissolved in a mixture of 2 mL THF and 5 mL ethanol, and the solution was cooled to −78°C. 4-Nitrobenzenesulfonyl hydrazide (34 mg, 0.16 mmol) was dissolved in 2 mL THF, and this solution was added to the cooled solution. The resulting solution was placed in an ice bath and stirred for 1 h. After which, 14 mg pyridine (0.18 mmol) was added, and the solution was allowed to warm to room temperature and the stirring was continued for a further 8 h. The resulting yellow solution was diluted with 10 mL 1 M NaOH and then extracted with EtOAc (3 × 15 mL). The organic layers were combined and washed with water (2 × 25 mL) and then brine (25 mL), and dried and evaporated in vacuo to give the crude alkynyl ketone. The crude product was purified by column chromatography (EtOAc/petroleum spirit, 1:3) to give 44 mg (4a*SR*,5*SR*,6a*SR*,7*SR*,8*RS*,11*SR*,11a*RS*,11b*RS*)-1,2,3,4,4a,5,6,6a,7,8,10,11,11a,11b-tetradecahydro-8-(but-3′-ynyl)-5,7-bismethoxymethoxy-7,11-methano-9*H*-cyclohepta[a]naphthalen-9-one as a clear oil that solidified on standing, in a yield of 76%, $R_f = 0.50$ (EtOAc/petroleum spirit 1:3).



Reference 3.

To a solution of 0.576 g 2,4-dinitrophenylsulfonylhydrazine (2.2 mmol) in 20 mL THF cooled to −25°C was added 0.224 g 2,3-epoxy cyclohexan-1-one (2 mmol). The reaction mixture was kept at −25 to −30°C for 30 min and then at −10°C for 30 min. The mixture was allowed to warm to 0°C, dried at this temperature over anhydrous magnesium sulfate for 20 min, and filtered below 0°C. After being stirred for 1 min a drop of pyridine was added and the stirring was continued. The mixture was taken out of the ice bath, and after 2 min another drop of pyridine was added. This caused an extensive effervescence, and the mixture turned deep orange in color. After 2 min, more pyridine (a total of 0.16 g, 2 mmol) was added, and the stirring was continued for 5 min. The mixture was filtered through Celite 545, and the filtrate was stirred with 1 g powdered $CuSO_4 \cdot 5H_2O$ for 25 min. It was filtered, and the volatile substances from the filtrate were transferred under vacuum (0.03 mmHg) at ambient temperature into a receiver containing 0.792 g 2,4-dinitrophenylhydrazine (4 mmol) in 75 mL THF. The mixture was stored at 25–30°C for 48 h. The solvent was removed by

rotary evaporation, and the residue was purified by preparative TLC on silica gel (methylene chloride, $R_f = 0.8$) to give 342 mg of the orange crystalline 2,4-dinitrophenylhydrazone of 5-hexynal, in a yield of 62%, m.p. 90–9l°C.

Other references related to the Eschenmoser fragmentation are cited in the literature.[6]

Eschweiler-Clarke Methylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Eschweiler in 1905,[1] and subsequently by Clarke and co-workers in 1933.[2] It is the preparation of tertiary methylamines from primary or secondary amines by means of the treatment of those amines with an excess amount of aqueous formaldehyde and formic acid. Therefore, it is generally known as the Eschweiler-Clarke methylation.[3] In addition, this reaction is also referred to as the Eschweiler-Clarke condition,[4] Eschweiler-Clarke *N*-methylation,[5] Eschweiler-Clarke procedure,[3j,6] Eschweiler-Clarke reaction,[3d,3g,3j,7] Eschweiler-Clarke reductive methylation,[8] Eschweiler-Clarke reductive *N*-methylation,[9] Clarke-Eschweiler methylation,[10] Clarke-Eschweiler reaction,[10b,10c,11] or Clarke-Eschweiler procedure.[11] In this reaction, the formate anion donates its proton to reduce the imine or iminium salt, so that carbon dioxide is evolved. Thus the whole process is a reductive amination of formaldehyde. This reaction is very useful for the reductive amination, without the application of hydrogen gas, catalyst (e.g., Pd/C), and high-pressure apparatus and has been widely applied to alkaloid chemistry. A special case of such reductive amination that occurs on phenylethylamine and results in the formation of tetrahydroisoquinolines is also referred to as the Clarke-Eschweiler cyclization.[7d,10b,10c] In a few cases, the methylation also occurs on an aromatic ring during the reductive amination.[3j]

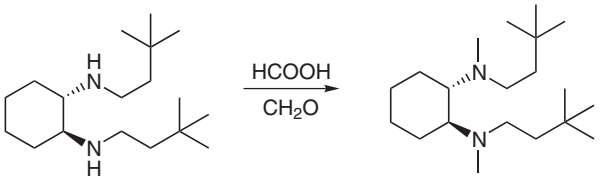
E. APPLICATIONS

This reaction has wide application in the methylation of primary and secondary amines.

F. RELATED REACTIONS

This reaction is related to the *Leuckart Reaction*.

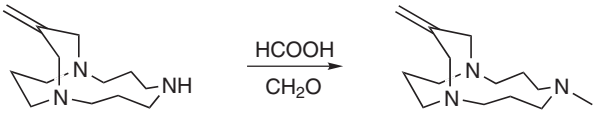
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

Formic acid (96% aqueous solution, 0.69 mL, 17.5 mmol, 5 eq.) was cooled to 0°C in an ice water bath, and 0.99 g (1*S*,2*S*)-(+)-*N*,*N*′-bis(3,3-dimethylbutyl)-1,2-cyclohexanediamine (3.5 mmol, 1 eq.) was added slowly. A 37% aqueous formaldehyde

solution (7.7 mmol) was then added in one portion, and the solution was heated until carbon dioxide evolution began, at which time heating was discontinued. Once the formation of gas was no longer apparent, heating was resumed for 14–22 h. The cooled reaction mixture was then poured onto ice-cooled 10% aqueous hydrochloric acid (3.85 mmol, 1.1 eq.) and washed with four portions of diethyl ether. The pH of the aqueous phase was adjusted to 10 by the addition of solid NaOH pellets, and the solution was extracted with two portions of diethyl ether. The combined organic portions were dried over a potassium hydroxide-sodium sulfate mixture and concentrated by rotary evaporation. Rigorous drying of the product by heating with sodium metal and subsequent Kugelrohr distillation from fresh sodium provided 0.75 g (1*S*,2*S*)-(+)-*N*,*N*′-bis(3,3-dimethylbutyl)-*N*,*N*′-dimethyl-1,2-diaminocyclohexane as a clear, colorless oil, in a yield of 68%, b.p., 140–145°C (5 mmHg).



Reference 3d.

A mixture of 0.14 g 11-methylene-1,5,9-triazabicyclo[7.3.3]pentadecane (0.63 mmol), 78 μL 90% formic acid (1.5 mmol), and 54 μL 37% aqueous formaldehyde (0.66 mmol) was heated in an oil bath at 120°C for 16 h. The reaction mixture was basified with 10 M aqueous KOH solution and extracted with $CHCl_3$. The $CHCl_3$ layer was dried over $MgSO_4$ and filtered. The filtrate was concentrated by rotary evaporation and dried under vacuum. The crude oily product was distilled from powdered KOH, yielding 65 mg 5-methyl-11-methylene-1,5,9-triazabicyclo[7.3.3]pentadecane as a colorless oil, in a yield of 43%, b.p. 100–110°C (0.3 mmHg).

Ester Pyrolysis

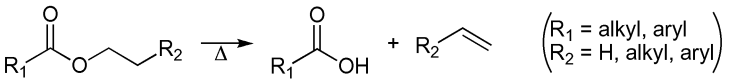
A. GENERAL DESCRIPTION OF THE REACTION

It is said that this reaction was initially observed by Smith in 1842[1] or Heintz in 1854.[2] It is the unimolecular thermal cleavage of esters that hold β-hydrogen(s) on the alcoholic moiety via *cis*-elimination to form olefins without a carbon skeleton isomerization or double bond shift.[2b] Carboxylic acids are the by-products in this reaction. This reaction is good for esters containing volatile components of either acid or alcohol.[1b] It is assumed that the major controlling factor in ester pyrolysis is the difficulty to form a p-π conjugation between carbonyl oxygen and β-hydrogen in the ground state of the ester, that is, the stronger the conjugation (in the manner of semipolar six-membered cyclic ring), the easier for the pyrolysis to occur.[3] Therefore, it is found that γ-lactones are stable at 600°C, whereas larger lactones that can form a transient six-membered ring decompose at 500°C.[4] Although this reaction was thought to be concerted initially,[5] more experimental evidence indicates that it occurs via a semipolar six-membered transition state, with a partial negative charge on the departing oxygen atom.[6] It was found that the *Hofmann Rule* is followed in pyrolysis of the esters with aliphatic alcohols, in which the olefinic mixtures show a similar ratio of available β-hydrogens in the alcoholic component.[2b,7] As a result, the more primary protons, the easier for the pyrolysis; to an extreme extent, even *tert*-butyl acetate pyrolyzes at 360°C.[5b] For the case of *tert*-butyl esters, the pyrolysis rate is linear to the pKa of the corresponding

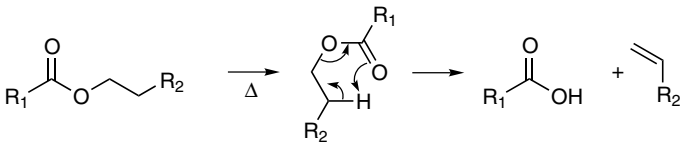
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

acids;[8] in contrast, the pyrolysis rate of isopropyl α-haloacetates is on the order of I > Br > Cl > F.[8] It was reported that when the acyl portion is varied within a series of esters, the pyrolysis temperature decreases in a zigzag fashion, by which the esters from acids with an even number of carbon atoms are slightly more stable than their neighboring analogues.[9] This reaction is especially important in thermal modification, recycling, and degradation of polyesters (poly ε-caprolactone)[10] and the synthesis of olefins that are difficult to obtain,[2b] such as the highly unsaturated compounds (e.g., 2-vinylbutadiene).[11] A few examples of ester pyrolysis that give special products are the formation of methylenecyclobutenone from the flash vacuum pyrolysis of furfuryl benzoate,[12] alkyl or aryl phenyl 2-methylene-1,3-diones from 3-phenylpropargyl esters,[13] and cyclic ethers containing three- to six-membered rings from cyclic carbonates with one or two hydroxyl groups.[14]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

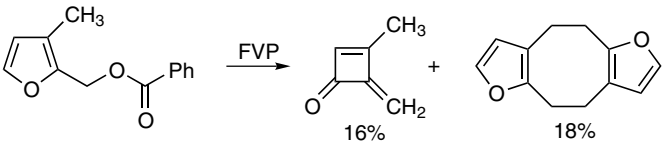
E. APPLICATIONS

This reaction has been widely applied to the synthesis of a variety of olefins and other special compounds (e.g., cyclic ethers).

F. RELATED REACTIONS

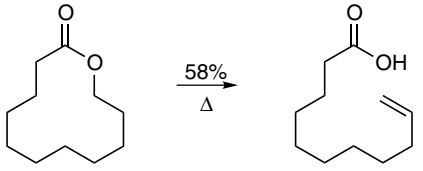
This reaction is related to the *Chugaev Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 12.

A 2.0 g 3-methylfurfuryl benzoate (9.25 mmol) was flash vacuum pyrolyzed at 630°C in the normal manner. A quantitative ^{1}H NMR analysis of the pyrolysate indicated the presence of 3-methyl-4-methylenecyclobutenone in a 21% yield and its dimmer in a 24% yield. Thick layer chromatography on silica gel plates (2000 μ) using two elutions with 20% EtOAc in hexanes afforded two major bands. The upper band consisted of 0.313 g 4*H*,5*H*,9*H*,10*H*-cycloocta[1,2-b:6,5-b′]difuran, in a yield of 18%, m.p. 49–52°C. The lower band was concentrated to give 0.139 g 3-methyl-4-methylenecyclobutenone, in a yield of 16%.



Reference 15.

A pyrolysis tube packed with Vycor Raschig rings was used in the standard pyrolysis apparatus, and 7.59 g 11-hydroxyhendecanoic acid lactone (41.2 mmol) was dropped through the pyrolysis tube at 520°C at a rate of 0.95 g/min to yield 6.87 g pale yellow liquid pyrolysate. A small amount of carbon was deposited in the pyrolysis tube. Titration at 0°C of a small portion of the pyrolysate dissolved in 95% ethanol indicated that the pyrolysate contained 86% of hendecenoic acid. The acid was separated from the lactone by 0.5 N sodium bicarbonate solution, then 0.5 N HCl and ether. The solvent was removed from the final ether extracts by distillation under reduced pressure, and the residue was dried in a vacuum desiccator to give 3.98 g 10-hendecenoic acid, in a yield of 58% (based on the weight of the pyrolysate), m.p. 17–19.6°C.

Other references related to the ester pyrolysis are cited in the literature.[16]

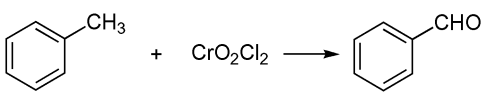
Étard Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Étard in 1880.[1] It is the oxidation of hydrocarbons by hexavalent chromium compounds (chromyl chloride,[2] i.e., chromatic acid chloride) to form a mixture of alcohol, carbonyl compounds (aldehyde or ketones), chloro-ketones, or aldehydes and the starting material.[3] Therefore, this reaction is generally known as the Étard reaction.[2,4] In this reaction, a highly hygroscopic brown powder forms[3b] which is called the Étard Complex[3a,3b,5] and is a heterogenous, oligomeric material[3a] containing carbonyl compounds and at least 2 equivences of chromium atom in a valence of IV and VI.[4i,6] It was found that the carbonyl compound functions as a ligand in the Étard complex[3a,3b] and can be displaced by other coordinating solvents, such as acetonitrile, acetone, and water.[3b] The wide distribution of products[3] (alcohols, ketones, chloroketones, and even epoxides[7]) and the lack of specificity[8] at the reaction site reduce the yields of the desired compounds.[9] As a result, this reaction is almost useless for organic synthesis, and the corresponding reaction mechanism is not clear either.[8] However, the oxidation of methylated homologs of benzene using chromyl chloride is an effective method for preparing aromatic aldehydes.[6,9,10]

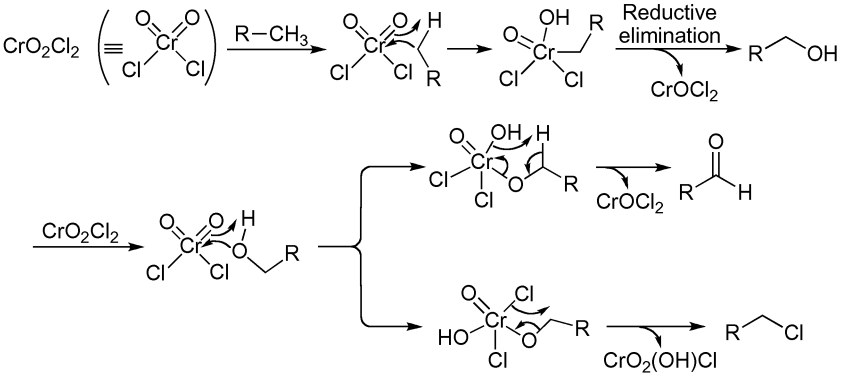
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is assumed that chromium (VI) is reduced by hydrocarbons via the formation of a Cr-C bond in the Étard reaction,[8] as outlined below.



D. MODIFICATION

N/A

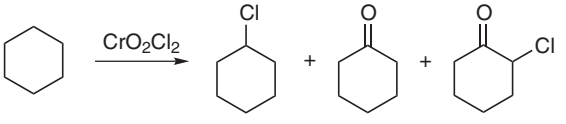
E. APPLICATIONS

This reaction has been used to prepare aromatic aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Corey-Schmidt Oxidation* and *Corey-Suggs Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

The setup of thus reaction was done inside a glove box. To a greaseless Pyrex reaction vessel with small stir bar sealed with a Teflon valve with a ground, glass joint attachment was added 1 mL purified cyclohexane using a volumetric flask. Into the flask was syringed 20.0 ± 0.3 μL of CrO_2Cl_2 (0.247 mmol). The needle valve on the reaction flask was quickly closed, and the reaction vessel was removed from the glove box. The flask was then placed in a light-free, temperature-controlled circulating water bath at 80°C, and the reaction

mixture was set stirring. Over approximately 8 h, a brown solid formed on the bottom of the reaction vessel, while the solution turned from clear red to colorless. The reaction vessel was removed from the hot water and immediately frozen in a dry ice–acetone bath followed by the addition of 1.5 mL 0.1 M $Na_2S_2O_3$, yielding a clear green aqueous layer and a colorless organic phase. Chloroform (4 mL) and 10.0 $\pm$ 0.3 μL of *n*-heptane standard were added. After being stirred for 10–15 min, a 1 mL aliquot of the organic layer was pipetted into a vial followed by 30 mL TMEDA. The resulting solution was analyzed by GC/FID and GC/MS, indicating 10% chlorocyclohexane, 8.0% cyclohexanone, and 2.5% chlorocyclohexanone.

Evans Aldol Reaction

A. GENERAL DESCRIPTION OF THE REACTION

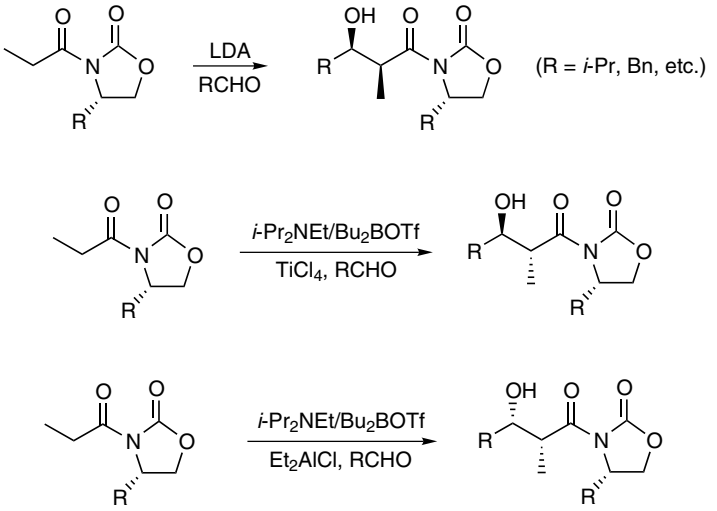
This reaction was initially reported by Evans and co-workers in 1979.[1] It is the diastereoselective addition of the dibutylboryl enolate of chiral *N*-acyl-oxazolidone to aldehydes. In this reaction, the chiral auxiliary will help the generated enolate from the acyl part to take different conformations, depending on the presence or absence of oxophilic metal, to form the chelated coordination between the metal cation and the oxygens of two carbonyl groups.[2] The chiral *N*-acyl-oxazolidone is called the Evans reagent.[2] Because this reaction provides the most reliable means for controlling the vicinal *syn* stereogenic centers (especially for the case of propionate, with a diastereoselectivity of $> 140{:}1$ to $500{:}1$[3]), irrespective of the absolute configuration of α-branched aldehydes (i.e., a tolerance for a broad range of aldehydes, either alkyl or aryl, hindered or unhindered),[4] it has been successfully applied to the syntheses of many natural products (e.g., phyllanthocin,[5] and tautomycin[6]), especially the macrolides (amphidinolide B1,[7] tedanolide,[8] (+)-rhizoxin D,[9] altohyrtin A,[10] salicylihalamides,[11] bafilomycin A1,[12] aplyronine A,[13] etc.). It has been modified extensively to different variations, including the application of Lewis acid,[2,14] the modification of chiral auxiliaries (e.g., replacement of oxazolidone with 3,4,5,6-tetrahydro-2H-1,3,4-oxadiazin-2-ones (oxadiazinones)[15] or thiazolidinethione[14]), the application of different chelating metals.[16] Because of these modifications, this reaction gradually gained different names, including the Evans asymmetric aldol reaction,[2,17] Evans aldol condensation,[9,18] Evans aldol methodology,[19] Evans aldol process,[19] Evans aldol reaction,[4,5,9,11,13,20] Evans catalytic asymmetric aldol reaction,[21] Evans *syn*-aldol addition,[14] Evans-Tischenko reaction,[22] and Tischenko-Evans reaction.[23] For the special

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

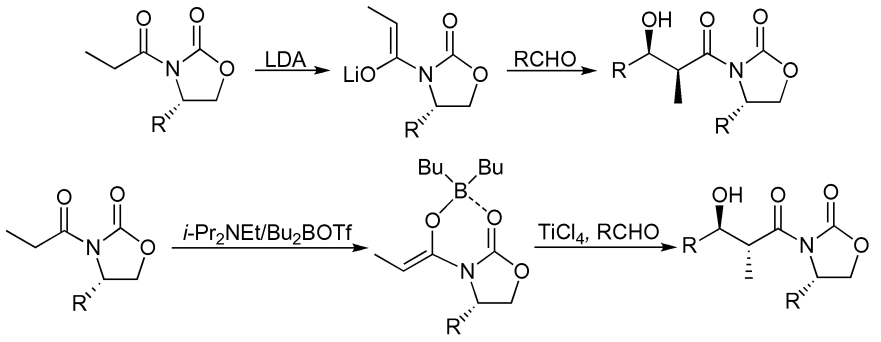
case of an aldol reaction in the presence of a Lewis acid, both "non-Evans" *syn*- and *anti*-aldol products can be generated, depending on the size of the applied Lewis acid (e.g., $TiCl_4$ and Et_2AlCl) or the experimental procedure (slow addition of $SnCl_4$ or $TiCl_4$).[2] The non-Evans *anti*-aldol product predominates if a large Lewis acid is used, such as Et_2AlCl, or the formation of a reactive 2:1 complex via the slow addition of $TiCl_4$; the non-Evans *syn*-aldol product will be formed favorably if a small Lewis acid such as $SnCl_4$ is applied. Coupling with the original Evans condition, three out of four aldol products can be produced selectively. Although the diastereoselectivity is not perfect, a product with high enantiomeric purity can be easily purified via crystallization.[2]

In addition, under the help of a chiral auxiliary group, the generated enolate can also react with electrophiles to form α-alkylated ketones,[4] and this specific reaction is called Evans alkylation[24] (such as in the case for the preparation of discodermolide[4]).

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

As for the characteristic controlling of stereochemistry during aldol reaction, the Evans aldol reaction has been extensively modified through the application of Lewis acids,[2,14] chiral auxiliaries (e.g., oxazolidone,[1,2] oxadiazinones,[15] thiazolidinethione[14]), chelating metals,[16] etc.

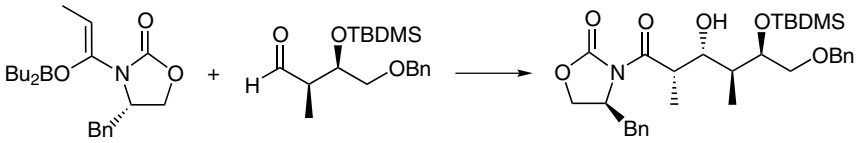
E. APPLICATIONS

This reaction is very useful for the preparation of the compounds with specific vicinal stereogenic centers.

F. RELATED REACTIONS

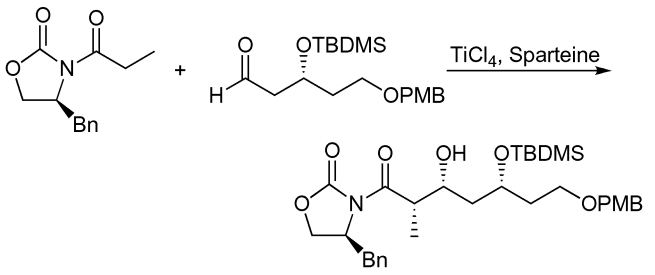
This reaction is related to the *Aldol Reaction*, *Mukaiyama Aldol Reaction,* and *Tischenko Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 12.

To a solution of 0.160 g propionyl (5*S*)-5-benzyl oxazolidinone (0.688 mmol) in 1.5 mL CH_2Cl_2 at 0°C were added dropwise 0.206 mL Bu_2BOTf (0.812 mmol, 1.18 eq.) and 0.125 mL Et_3N (0.908 mmol, 1.32 eq.). After 20 min, the reaction mixture was cooled to −78°C, and 0.246 g (-)-phenyl (2*R*,3*R*)-4-benzyloxy-3-(tert-butyldimethylsiloxy)-2-methylbutyrate (0.764 mmol, 1.1 eq.) in 0.3 mL CH_2Cl_2 was added dropwise. After 1 h at −78°C and 2 h at 0°C, 0.756 mL of a buffered phosphate solution (pH = 7) was added followed by the addition of 2.27 mL MeOH and a mixture of 30% H_2O_2/MeOH (2:1 ratio). After 1 h at 0°C, the reaction mixture was concentrated under vacuum, and ether was added followed by a saturated aqueous $Na_2S_2O_4$ solution. The aqueous solution was extracted with ether (four times), and the organic phases were washed with a saturated aqueous $NaHCO_3$ solution and then with brine. The resulting solution was dried over $MgSO_4$, filtered, and evaporated and the residue was purified by flash chromatography on silica gel (petroleum ether/EtOAc, 4:1) to give 0.305 g (+)-(4*S*)-3-[(2*S*,3*R*,4*S*,5*R*)-6-benzyloxy-5-(*tert*-butyldimethylsiloxy)-3-hydroxy-2,4-dimethyl-hexanoyl]-4-benzyloxalidin-2-one as a colorless oil, in a yield of 80%, $R_f = 0.33$ (petroleum ether/EtOAc, 4:1).



Reference 11.

To a stirred, cooled (0°C) solution of 2.86 g (4*S*)-4-(phenylmethyl)-3-propanoyl-1,3-oxazolidin-2-one (12.3 mmol) in 100 mL CH_2Cl_2 was added dropwise 1.42 mL titanium(IV) chloride (2.44 g, 12.9 mmol); the mixture was allowed to stir for 5 min. Subsequently, 7.04 mL (-)-sparteine (7.19 g, 30.7 mmol) was added to the yellow slurry. The dark red enolate solution was stirred for 20 min at 0°C before a solution of 4.76 g (3*R*)-3-{[*tert*-butyl(dimethyl)silyl]oxy}-5-[(4-methoxy-benzyl)oxy]pentanal (13.5 mmol) in 50 mL CH_2Cl_2 was added dropwise, and the mixture was stirred for 1 h at 0°C. The reaction was quenched with 20 mL half-saturated ammonium chloride. After separation of the layers, the organic layer was dried over Na_2SO_4, filtered, and concentrated in vacuo. Purification of the residue by flash chromatography afforded 5.67 g (4*R*)-4-benzyl-3-{(2*R*,3*R*,5*R*)-5-{[*tert*-butyl(dimethyl)silyl]oxy}-3-hydroxy-7-[(4-methoxybenzyl)oxy]-2-methylheptanoyl}-1,3-oxazolidin-2-one as a colorless oil, in a yield of 79%. $R_f = 0.33$ (petroleum ether/Et_2O, 2:3).

Favorskii Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

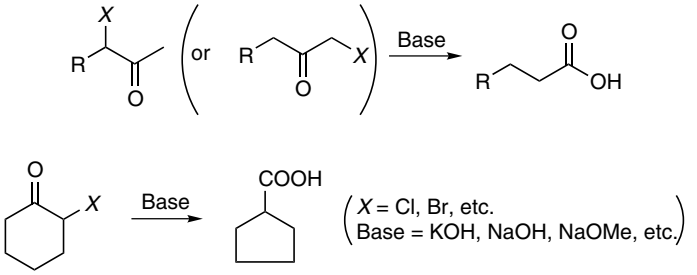
This reaction was initially reported by Favorskii in 1894.[1] It is a base-induced rearrangement of α-halo ketones to the corresponding carboxylic acid derivatives (e.g., acids, esters, and amides) with the same number of carbon atoms in the skeletons; and the bases can be hydroxide, alkoxide, or amines.[2] Therefore, it is generally known as the Favorskii rearrangement.[3] Occasionally, it is also referred to as the Favorskii reaction.[4]

There have been at least six different mechanisms proposed for this rearrangement: (*a*) the addition of alkoxide to the carbonyl group with the concomitant extrusion of a halide ion to form a final product via the intermediate of epoxide;[5] (*b*) the reaction of a nucleophile with a ketene generated by the base-induced elimination of hydrogen halide;[6] (*c*) the addition of alkoxide to the carbonyl group followed by the 1,2-migration of an alkyl group (similar to the *Benzilic Acid Rearrangement*; therefore, it is also called the semibenzilic acid mechanism[7] or abnormal or quasi-Favorskii rearrangement[8]); (*d*) the unimolecular dissociation of an α-halo ketone to a carbonium ion, which tautomerizes to isomeric carbonium then rearranges to product;[9] (*e*) the generation of a carbanion by deprotonation of α'-hydrogen followed by a nucleophilic substitution to form cyclopropanone, which undergoes rearrangement to a final product during alkoxide attacks[10] (this mechanism is also called the Loftfield mechanism[11] or cyclopropanone mechanism[12]); and (*f*) the formation of an oxyallylic anion that undergoes [4+3] cycloaddition.[13] Among these mechanisms, the semibenzilic acid mechanism and cyclopropanone mechanisms are most plausible.[7b,12a] When α'-hydrogens are available, the cyclopropanone mechanism is preferred,[10–12] whereas semibenzilic acid mechanism comes into play in the absence of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

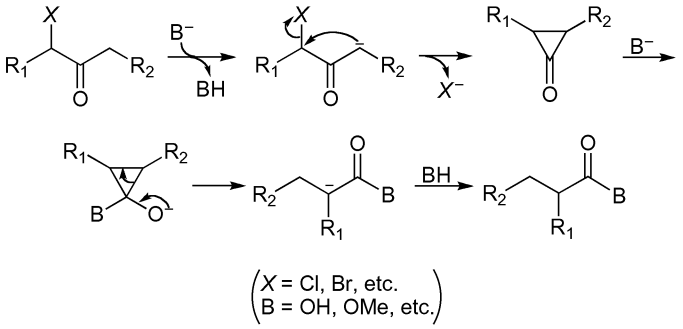
α'-hydrogens (e.g., in nonenolizable ketones[7b,14a]) or when the formation of cyclopropanone is prevented.[14] However, it has been reported that in the gas phase the semibenzilic acid mechanism is more favorable,[7b,12a] and the oxyallylic mechanism can be limited using a non-nucleophilic solvent such as trifluoroethanol.[13a] Similarly, many experimental results have shown that the actual reaction mechanisms depend on the reaction conditions.[15] Even the cyclopropanone mechanism can be concerted or unconcerted.[16] In this reaction, the deprotonation is the rate-limiting step, followed by a quick halo extrusion.[17] In the case of cyclic α-halo ketones, ring contraction occurs.[13b,18] A similar reaction occurs on β-halo ketones via the elimination of a hydrogen halide to cyclobutanone followed by the scission of cyclobutanone, known as the homo-Favorskii rearrangement.[11,19] This reaction has been proved to be a useful tool for synthesizing the highly strained esters, bicyclic esters,[13b] and some steroids,[20] norsteriods,[21] etc. In addition, this reaction has been successfully applied to the synthesis of saturated pyrollidine derivatives.[18a] Similarly, the base-induced rearrangement of ketimines will afford imidates or amides.[12b] More details about this reaction are described in reviews.[22]

B. GENERAL REACTION SCHEME

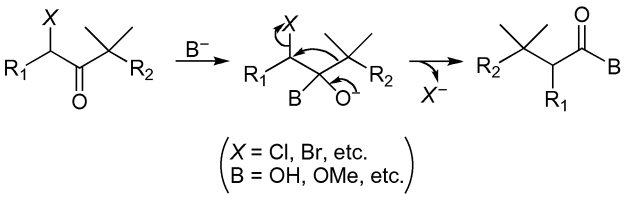


C. PROPOSED MECHANISMS

Although several mechanisms have been proposed for this reaction, only cyclopropanone mechanism (Scheme 1) and benzilic acid mechanism (Scheme 2) are displayed here.



SCHEME 1. *Favorskii rearrangement via cyclopropanone mechanism.*



SCHEME 2. *Favorskii rearrangement occurring a benzilic acid mechanism.*

D. MODIFICATION

N/A

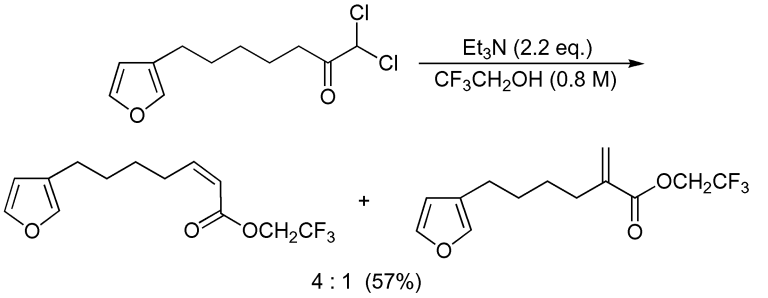
E. APPLICATIONS

This reaction has been successfully used to prepare bicyclic esters, steroids, norsteroids, pyrollidine, etc.

F. RELATED REACTIONS

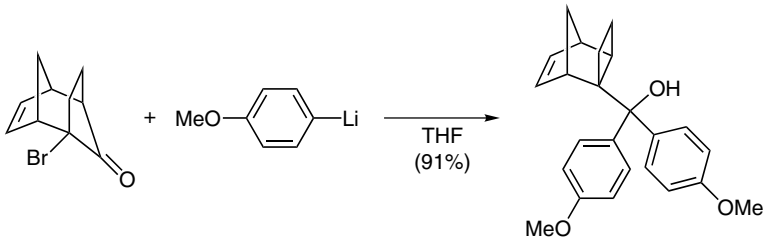
This reaction is related to *Benzilic Acid Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 13a.

To a solution of 50 mg 1,1-dichloro-7-furan-3′-yl-heptan-2-one (0.20 mmol) in 0.25 mL 1,1,1-trifluoroethanol (0.8 M) was added 60 μL triethylamine (0.44 mmol) at room temperature. The reaction mixture was heated at 50°C (oil bath) for 24 h before quenching with water and extracting with CH_2Cl_2. The organic layer was dried over $MgSO_4$ and concentrated to give a residue that was purified by column chromatography (5:1, hexane/EtOAc) to give 31.3 mg an inseparable mixture of trifluoroethyl acrylic esters in a 4:1 ratio, in a yield of 57%, $R_f = 0.68$ (hexane/EtOAc, 5:1).



Reference 8a.

To a cooled solution of 100 mg bromoketone (0.44 mmol) in 4.4 mL THF at −78°C was added 2.2 eq. of 4-methoxyphenyl lithium solution dropwise. After being stirred at −78°C for 1 h, the reaction mixture was warmed to room temperature over 2 h and then stirred for an additional 4 h. It was quenched with distilled water, extracted by ether (3 × 10 mL), washed with brine (5 mL), dried over $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by flash chromatography with 5% EtOAc in hexane to yield 91% of bis(4-methoxyphenyl)tricyclo[4.2.1.$0^{2,5}$]non-7-en-2-ylmethanol as an oil.

Other references related to the Favorskii rearrangement are cited in the literature.[23]

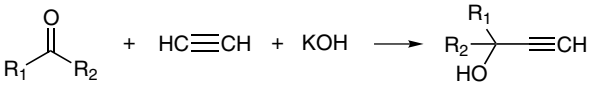
Favorskii-Babayan Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Favorskii in 1905[1] and subsequently extended by Babayan in 1939.[2] It is a base-promoted or -catalyzed ethynylation of aldehydes and ketones to produce secondary or tertiary acetylenic alcohols or glycols using anhydrous KOH or NaOH.[3] Therefore, it is generally known as the Favorskii-Babayan reaction[4] or Favorskii reaction.[5] Although it has been proposed that this reaction might involve a reaction between acetylene and the adduct from the ketone and KOH[1] or a coupling of potassium acetylide with the carbonyl compounds,[6] the most recent experimental results indicate that potassium hydroxide and acetylene first form a complex, rather than potassium acetylide in liquid ammonia, which then reacts with carbonyl compounds to form the acetylenic alcohols, where ammonia functions as a co-catalyst.[3] The experimental evidence includes (*a*) the loss of acetylene by the thermal decomposition of the formed dry complex at 1 mmHg and 100˚C within 4 h, whereas almost no decomposition occurs on potassium acetylide; (*b*) no stretch peak of the carbon-carbon triple bond and C−H bond on infrared spectra, indicating the contribution of the carbon-carbon triple bond and acetylic proton into the complex; and (*c*) strong association of the complex with an electron-donating solvent, such as ammonia or diisopropyl ether, and a part of the solvent remains after prolonged vacuum drying for the solvent-associated complex. The formed acetylenic alcohols can be used as nonionic surfactants.[7] It has been reported that NaOH also works for this reaction, although it is not as effective as KOH; moreover, LiOH is almost inert for this reaction.[3] It should be pointed out that the Favorskii-Babayan reaction also occurs in the presence of a catalytic amount of KOH.[8]

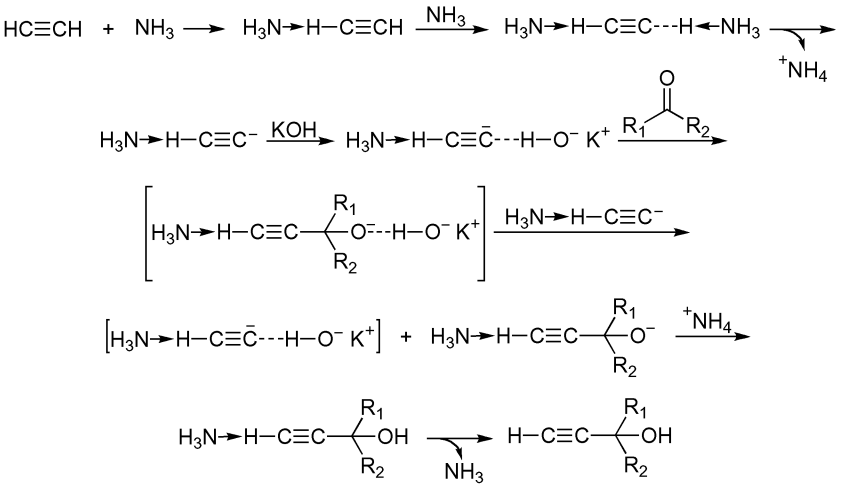
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the reaction mechanism modified from Tedschi's work.[3]



D. MODIFICATION

This reaction has been modified by using a catalytic amount of KOH.[8]

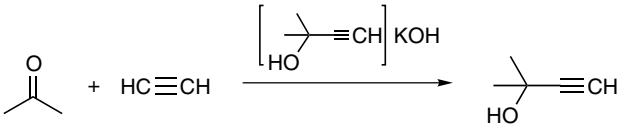
E. APPLICATIONS

This reaction has been used in the preparation of acetylenic alcohols that are used for nonionic surfactants.[7]

F. RELATED REACTIONS

This reaction is related to the *Arens-van Dorp Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

Note: The preparation of methylbutynol-KOH adduct is written according to the preparation of the corresponding sodium adduct. Into a 1-L stainless-steel autoclave liner, under anhydrous conditions, was weighed 16.8 g finely ground potassium hydroxide (0.30 mol). The tightly sealed liner was quickly transferred to a standard 1-L stirred autoclave under a positive flow of dry nitrogen. To the sealed autoclave then was added 320 mL liquid ammonia followed by 40 g methylbutynol (0.48 mol) at a temperature of 14–20°C. The reaction mixture was stirred for 3.5 h and isolated in the usual manner using hexane as the inert diluent. The isolated adduct was dried under vacuum to constant weight.

To a 1-L stirred autoclave was added 0.10 mol methylbutynol-KOH adduct, 1.6 mol acetylene, and 200 mL liquid ammonia. Then 1.6 mol acetone was introduced into the autoclave within 30 min at 30–32°C. The total pressure in the autoclave averaged 160–185 psi. After 1.5 h, ammonia was vented, and dry CO_2 gas was introduced into autoclave to neutralize the catalyst complex to $KHCO_3$ and methylbutynol. The total conversion to methylbutynol before distillation was 97%, the catalytic conversion was 1170%, and the conversion to pure methylbutynol was 88%, b.p., 103–104°C.

Feist-Bénary Reaction

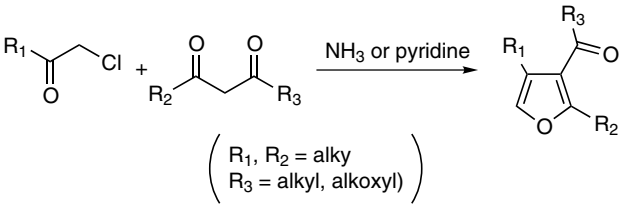
(Feist-Bénary Furan Synthesis, Feist-Bénary Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

It was first reported by Feist in 1901[1] for preparing furan derivatives via the base-promoted condensation of β-dicarbonyl compounds with α-haloketones, and subsequently extended by Bénary in 1911 using 1,2-dichloroethyl ether and acetoacetic acid esters.[2] Therefore, the synthesis of furan derivatives by treatment of an α-halo ketone and β-dicarbonyl compound with a base is known as the Feist-Bénary condensation,[3] Feist-Bénary furan synthesis,[4] Feist-Bénary cyclocondensation,[5] or Feist-Bénary reaction.[6] The bases used are normally ammonia and pyridine, however, it was found advantageous to use aqueous pyridine to effect this reaction instead of ammonia, because the production of pyrrole derivative is obviated and the yield of the furan derivative is increased.[7] It was found that the first step is an *Aldol Condensation*,[6e] and the regioselectivity could be inverted if the alkylation of β-keto esters is carried out followed by the acid treatment.[8] In addition, the intermediate dihydrofuran can be isolated with good diastereoselectivity under mild conditions, and normally *cis* isomer is yielded when moderately acidic nucleophiles are used, whereas *trans*-isomers will be generated when highly acidic dicarbonyl compounds are used as nucleophiles.[5c,5d] This reaction has been extended to prepare furan from α,β-dichloroethyl ether and β-ketoester in aqueous pyridine solution to reduce the formation of pyrrole.[7,9]

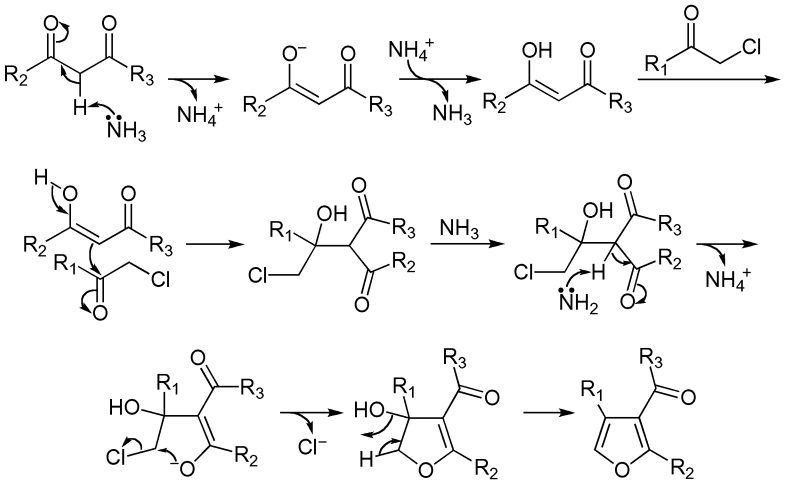
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the reaction mechanism using ammonia as the base.



D. MODIFICATION

This reaction has been modified by temporarily terminating the reaction to obtain the dihydrofuran derivatives.[6c,6d] In addition, this reaction has been carried out under an acidic conditions, such as in the presence of TFA,[5e] and by using 10% Et_3N as the base.[6d] Moreover, α,β-dichloroethyl ether has been used to substitute for the α-halo ketones.[7,9] Other modifications include the reaction of dicarbonyl compounds with acetylenes[10] and aldehydes.[11] Furthermore, a general preparation of five-membered heterocycles, including furans—although not related to the Feist-Bénary reaction—is also considered as a relevant modification.[3a]

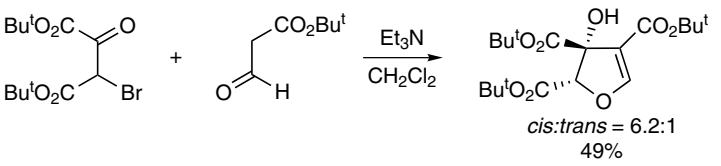
E. APPLICATIONS

This reaction has general applications in the preparation of furan derivatives.

F. RELATED REACTIONS

This reaction is related to the *Hantzsch Pyrrole Synthesis*.

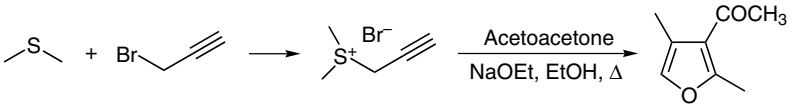
G. CITED EXPERIMENTAL EXAMPLES



Reference 6c.

To a solution of 6.59 g di-*t*-butyl oxalacetate (27.0 mmol) and 2.66 g NaOAc (27.0 mmol) in 40 mL acetic acid at room temperature was added slowly a solution of 1.38 mL Br_2 (4.31g, 27.0 mmol) in 14 mL acetic acid by cannula over 10 min. After being stirred at room temperature for 30 min, the reaction mixture was diluted with 150 mL water and extracted with CH_2Cl_2 (100 mL, 50 mL, 50 mL). The combined organic layers were washed with 150 mL saturated $NaHCO_3$. The layers were separated and the aqueous layer was extracted with CH_2Cl_2 (2 × 50 mL). The organic layers were combined, dried over Na_2SO_4, filtered, and concentrated in vacuo to afford 8.64 g unpurified α-bromo di-*t*-butyl oxalacetate as a yellow oil, in a yield of 99%. This product was used directly for the next step reaction without further purification.

To a solution 6.61 g formyl Meldrum's acids (38.4 mmol) in 77 mL benzene was added 3.62 mL (2.85g, 38.4 mmol) of *tert*-butanol. The reaction mixture was refluxed for 30 min and then cooled to room temperature. The resulting unpurified *tert*-butyl formylacetate solution was transferred via cannula to 8.63 g of the prepared α-bromo di-*t*-butyl oxalacetate (26.7 mmol). The resulting solution was cooled to 0°C, and then treated with 3.72 mL (2.70 g, 26.7 mmol) of Et_3N. After being stirred at 0°C for 14 h, the reaction was quenched by the addition of 80 mL Et_2O and 40 mL brine. The layers were separated, and the aqueous layer was extracted with Et_2O (2 × 80 mL). The organic layers were combined, dried over Na_2SO_4, filtered, and concentrated in vacuo. Purification of the residue by column chromatography (9:1 then 6:1 hexane/EtOAc) gave 5.08 g [2*S**,3*R**]-2,3-dihydro-3-hydroxy-2,3,4-furantricarboxylic acid tri-*t*-butyl ester as a mixture of two diastereomers in ratio of 6.2:1. The mixture was a pale yellow oil; crystallization from hexane at −20°C afforded 2.72 g of such product as a white powder, m.p. 97–98.5°C.



Reference 10.

Caution! These reactions should be performed in a hood because of the noxious odors. A mixture of 6.2 g dimethyl sulfide (0.10 mol), 11.9 g 3-bromopropyne (0.10 mol), and 10 mL acetonitrile was stirred magnetically for 20 h in a darkened, 100-mL round-bottomed

flask fitted with a calcium chloride drying tube. The resulting white, crystalline mass was filtered with suction and washed with three 50-mL portions of dry diethyl ether, giving 16.4 g sulfonium salt (in a yield of 90%, m.p. 105–106°C). This material may be used in the next step without purification but, if desired, it may be recrystallized from ethanol-ether with minimal loss, m.p. 109–110°C.

To a solution of 8.7 g acetylacetone (0.087 mol) in 175 mL 0.5 *M* ethanolic sodium ethoxide (0.087 mol), contained in a 500-mL, round-bottomed flask fitted with a condenser topped with a calcium chloride drying tube, was added a solution of 15.75 g dimethyl-2-propynylsulfonium bromide (0.087 mol) in 150 mL ethanol. The mixture was refluxed until the odor of dimethyl sulfide was no longer appreciable. The reaction flask was then fitted with a 30-cm, helix-packed column; by heating the flask with a water bath, ethanol was distilled through the column. The residue was treated with 200 mL ether, and the suspension was filtered. Ether was distilled from the filtrate at atmospheric pressure, and the residue was distilled, giving 9.7 g 3-acetyl-2,4-dimethylfuran, in a yield of 81%, b.p., 90–95°C (12 mmHg).

Fenton Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fenton in 1893.[1] It is the generation of a hydroxyl radical by the decomposition of hydrogen peroxide in the presence of ferrous salt and is generally known as the Fenton reaction.[2] Although the Fenton reaction itself cannot be considered as a real organic reaction, it has found a wide application in organic, bio-organic, and environmental chemistry. It was found that the hydroxyl radical can be quickly generated[3] at the initial stage of the reaction,[4] which is very reactive[5] with a high oxidation potential.[5c] Many organic molecules can be oxidized using the hydroxyl radicals–for example, oxidation of α-hydroxy acids to α-keto acids and benzene to phenol and biphenyl,[6] the formation of methane and ethane by proton abstraction from DMSO,[3] and the degradation of single-stranded and double-stranded DNA.[7] Especially important is the application of this reaction in the degradation of organic pollutants (including Orange II,[8] 2,4,6-trinitrotoluene (TNT),[9] pentachlorophenol (PCP),[5a] and aniline[5c,10]) in groundwater and soils. In addition, the photo induced reaction called the photo-Fenton reaction[11] has been reported to enhance the iron cycling and degradation of contaminants.[11b] It was found that the oxidation of malachite green can be catalyzed by various aromatic additives, which can be transformed into hydroquinone-like structures; the reaction order follows hydroquinone > salicyclic acid > *p*-hydroxybenzoic acid > *m*-hydroxybenzoic acid > *p*-benzoquinone > carboxylic aromatics > amindo aromatics.[12] In addition, it was also found that other additives can also enhance such reactions—for example, the strong bidentate or tridentate ligands, such as bis(picolinate), ethylenediamine-*N*,*N*′-diacetate, and nitrilotriacetate.[13] Even the substitution of phosphate buffer by sodium trifluoroacetate will increase the amount of trapped

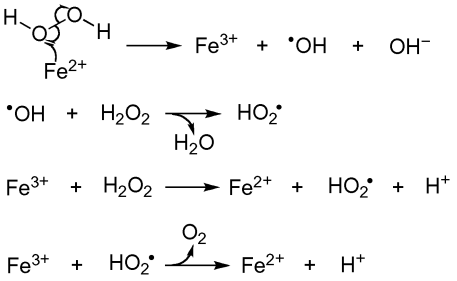
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

hydroxyl radical $\sim$ 300 times.[14] Similarly, ADP and ATP show a similar effect on this reaction.[15] It was found that the metallic Fenton reaction was more effective than the classical one,[5a] and other metal ions that function in the same manner are called Fenton-like reagents, including V^{4+}, Ti^{3+}, and Cr^{2+}.[16] This reaction is sometimes called the *Haber-Weiss Reaction*.[5b,17]

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

It has been proved that this reaction involves both hydroxyl and hydroperoxyl radicals,[18] with a pH usually less than 3.[9] Displayed below is the reaction mechanism.



D. MODIFICATION

This reaction has been modified to occur at a neutral pH using chelating agents.[9] Other modifications include the photo-Fenton reaction[11] and the initiation by other metal cations (e.g., Cr^{2+} and V^{4+}).[16]

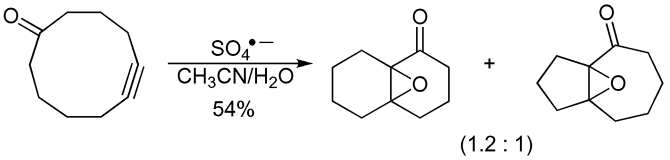
E. APPLICATIONS

This reaction has wide application in the degradation of organic waste in soil and groundwater.

F. RELATED REACTIONS

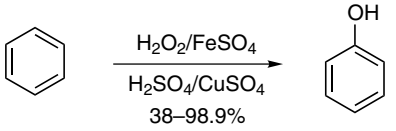
This reaction is related to the *Haber-Weiss Reaction.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 19.

To 30 mL CH_3CN solution containing 1 mmol 5-cyclodecynone was added 3 mmol persulfate dissolved in 10 mL water. To this heterogeneous reaction mixture, 3 mmol $Fe(EDTA)(SO_4)_2 \cdot 4H_2O$ in 30 mL water was quickly added under vigorous stirring through a dropping funnel. The reaction completed after $\sim$ 15 min (monitored by TLC), and the mixture was dilutes with water and extracted with EtOAc. The combined organic fractions were dried and evaporated. The residue was purified by chromatography (diethyl ether/pentane, 1:2) to afford 52% α,β-epoxy ketones in a ratio of 1.2:1. (*Note*: The molecular formula of $Fe(EDTA)(SO_4)_2 \cdot 4H_2O$ cannot be balanced by charge).



Reference 6.

Into a 100-mL Erlenmeyer flask with a rubber stopper equipped with four glass tubings was placed 25 mL of a solution that contained 50 mM H_2SO_4, 10 mM $FeSO_4$, and 30 mM $CuSO_4$. After air was purged from the flask with nitrogen through two glass tubings fitted to the rubber stopper, 0.75 mL benzene (8.4 mmol) was added through the third tubing using a microfeeder. Under magnetic stirring, a solution containing 100 mM H_2O_2 and 50 mM H_2SO_4 was added dropwise using another microfeeder at a rate of 0.2759 mL/min. After the addition of the precalculated amount of H_2O_2 at 25°C, the reaction mixture was allowed to stand for 30 min with stirring. After the remaining benzene was evaporated with a stream of nitrogen, 5 mL of the reaction mixture was diluted to 50 mL with 25 mM EDTA, and the yield of phenol, which varied from 38% to 98.9%, was analyzed using HPLC.

Other references related to the Fenton reaction are cited in the literature.[20]

Ferrier Reaction

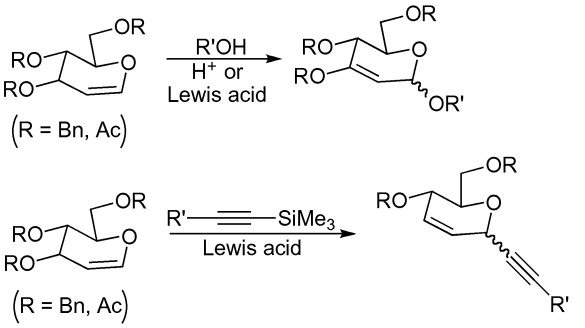
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Ferrier and co-workers in 1962.[1] It is an acid-catalyzed or induced rearrangement of glycals[2] in the presence of different nucleophiles (or aglycons).[3] The acids used in this reaction include the protic acids[4] such as methanolic hydrochloric acid,[5] sulfuric acid,[6] and Lewis acids such as $SnBr_4$,[4,7] $EtAlCl_2$,[4,8] $SnCl_4$,[9] $Pd(CH_3CN)_2Cl_2$,[10] $NbCl_5$,[11] $ZnCl_2$,[12] $InCl_3$,[13] $Er(OTf)_3$,[14] $Bi(OTf)_3$,[15] $ZrCl_4$,[16] $Sc(OTf)_3$,[17] $LiBF_4$,[18] iodine,[4,19] and the most often used $BF_3{\cdot}Et_2O$.[2a,4,20] As for the acidic nature of this reaction, substrates sensitive to acidic conditions are precluded;[21] therefore, some neutral catalysts have been developed for this reaction, including iodonium dicollidinium perchlorate,[22] 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ),[23] and montmorillonite K-10 (a clay catalyst).[24] Among these catalysts, it has been found that $InCl_3$ has a superior catalytic activity relative to many other Lewis acid catalysts[9] and can be recovered without loss of any activity;[13a] however, $InCl_3$ should be used in combination with TMSCl, otherwise a stoichiometric amount of $InCl_3$ is needed.[13a] The nucleophiles in this reaction could be alcohols (to form alkyl glycosides),[2a] thio-alcohols (for thio-glycosides),[25] amino acids (for *O*- or *S*-glycopeptides),[3] monosaccharides (for disaccharide)[9] and even carbo-nucleophiles (to form allylic *C*-glycosides).[13b,26] Overall, this reaction has become an important synthetic tool,[27] which predominantly produces α-anomer[3,13a] in good to excellent yield.[9,13a] Although the mechanism of this reaction is still unclear,[4] an allylic isomerization of the glycal to a 2,3-dideoxy sugar followed by a S_N1-type reaction[4] through a cyclic allylic oxocarbenium ion in quasi-axial orientation is proposed.[28] Similarly, the *Allylic Rearrangement* also occurs on *exo*-rings,[29] and even works for 1,2-cyclopropanated

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

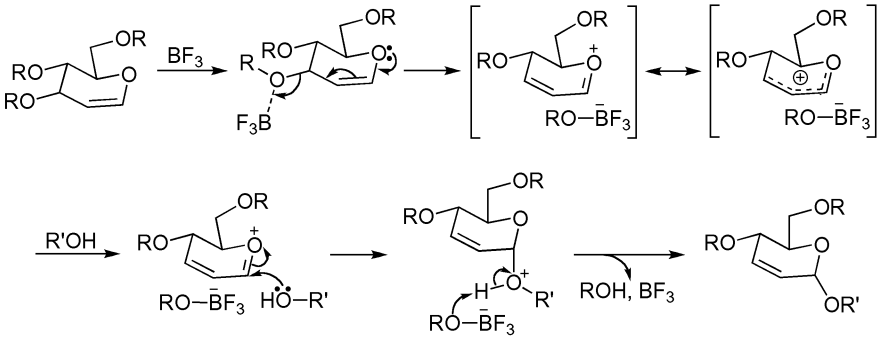
sugars.[10b] This reaction is most commonly cited as the Ferrier rearrangement,[2,4,10b,13a,21,30] Ferrier-type rearrangement,[2a,4,10b] or Ferrier reaction,[2a,3,26b,27,30d,31] but is called the Ferrier reaction in this book to differentiate it from another type of rearrangement also developed by Ferrier and co-workers.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction occurs via the intermediacy of a cyclic allylic oxocarbenium ion, as outlined here.



D. MODIFICATION

This reaction has been modified extensively by using different acids as catalyst, as described earlier. In addition, this reaction has been extended to the preparation of *C*-glycosides.

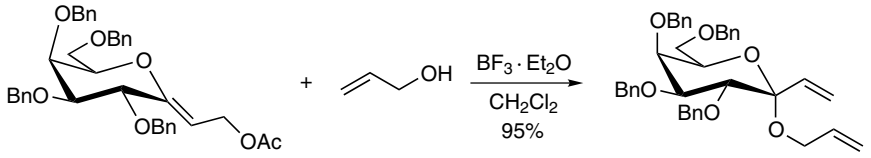
E. APPLICATIONS

This reaction has general applications in carbohydrate transformation.

F. RELATED REACTIONS

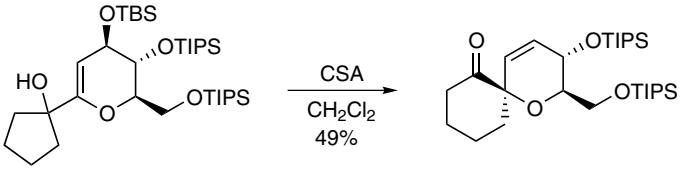
N/A

G. CITED EXPERIMENTAL EXAMPLES



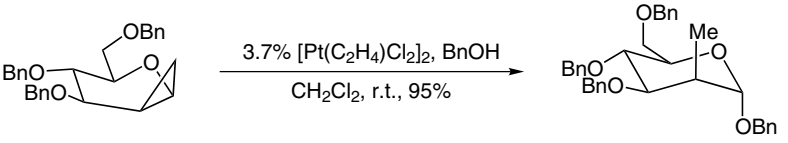
Reference 29.

To a stirred solution of an *exo*-glycal (1.0 eq.) and allyl alcohol (2.0 eq.) in anhydrous CH_2Cl_2 at 0°C was added 1.0 eq. $BF_3{\cdot}Et_2O$ dropwise in the presence of 4-Å molecular sieves. The reaction was usually complete within 1 h. The reaction mixture was quenched by the addition of saturated $NaHCO_3$ and extracted with CH_2Cl_2 (three times). The collected organic layers were washed with brine, dried over $MgSO_4$, and evaporated in vacuo. The resulting residue was subjected to silica gel chromatography (with hexanes and EtOAc) to afford 95% of the listed product.



Reference 32.

A solution of 60 mg 1,5-anhydro-2-deoxy-1-*C*-(1-hydroxycyclopentyl)-3,4,6-tris-*O*-(triisopropylsilyl)-D-*arabino*-hex-1-enitol (0.09 mmol) in 40 mL dry CH_2Cl_2 was stirred in the presence of a catalytic quantity of camphorsulfonic acid for 1 h. Following the addition of 25 mL saturated $NaHCO_3$ solution, the aqueous phase was extracted with CH_2Cl_2 (3×50 mL), and the combined organic layers were dried and evaporated. The crude product was purified by flash chromatography on silica gel (elution with 2% EtOAc in hexanes) to give 22 mg of the listed product as a colorless oil, in a yield of 49%.



Reference 10b.

Zeise's dimmer ($[Pt(C_2H_4)Cl_2]_2$ (21.5 mg, 0.0366 mmol) was dissolved in 5 mL CH_2Cl_2 under an atmosphere of nitrogen. The solution was then transferred by syringe to a flask containing 1.0 mmol cyclopropane ring-fused sugar and 2.0 mmol benzyl alcohol. The

mixture was stirred under nitrogen at room temperature for 15 h. After removal of the solvent in vacuo, the crude mixture was purified by flash chromatography to give 95% benzyl 3,4,6-tri-*O*-benzyl-2-deoxy-2-*C*-methyl-D-mannopyranoside with α:β anomeric ratio of 12:1.

Other references related to the Ferrier reaction are cited in the literature.[33]

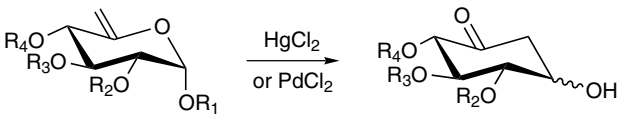
229

Ferrier-II Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Ferrier in 1979.[1] It is a mercury (II) salt[2]-induced or promoted conversion of 5-enopyranosides into cyclohexanones[3] with stereochemical control, by which substituents at positions 3 and 5 are predominantly in a *trans* relationship. To differentiate from another reaction also discovered by Ferrier (called the *Ferrier Reaction)*, this reaction is known as the Ferrier-II rearrangement,[3,4] Ferrier-II carbocyclization,[3,5] Ferrier carbocyclization,[6] or Ferrier-II reaction.[7] Occasionally, it is also referred to as the *Ferrier Reaction*.[8] Therefore, it is called the Ferrier-II rearrangement in this book. It is useful in the conversion of carbohydrates into carbosugars,[2a] *myo*-inositols,[9] and other natural products.[10]

B. GENERAL REACTION SCHEME

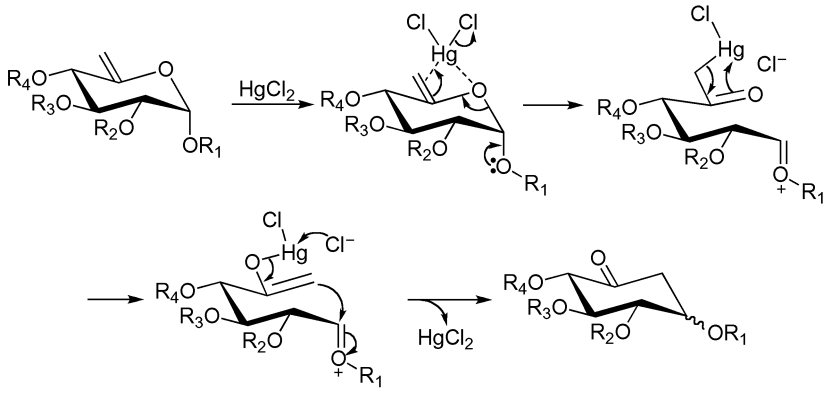


(R_1, R_2, R_3, R_4 = alkyl, benzyl, etc.)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A simple mechanism is illustrated here.[11]



D. MODIFICATION

This reaction has been modified to occur under microwave irradiation[2a] and using palladium dichloride as a catalyst.[2a,3,4]

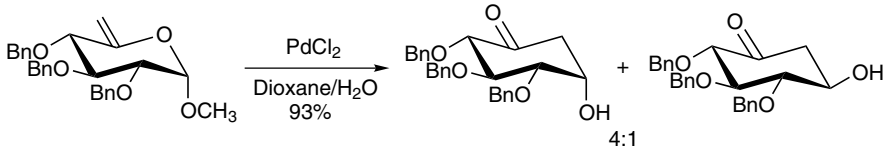
E. APPLICATIONS

This reaction has wide and important applications in the preparation of carbosugars and inositols.

F. RELATED REACTIONS

This reaction is related to the *Petasis-Ferrier Rearrangement*.

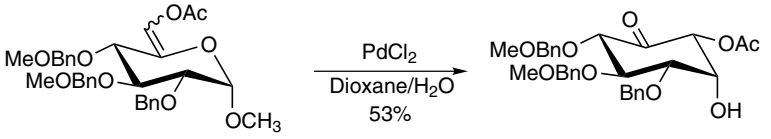
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To a solution of 2.3 g methyl-6-deoxy-2,3,4-tri-*O*-benzyl-α-D-hex-5-enopyranose (5.2 mmol) in 20 mL 1,4-dioxane and 10 mL water was added 0.37 g $PdCl_2$ (2.0 mmol) at room temperature. The mixture was stirred at 60°C with 300-W power in the microwave

for 5 min. The mixture was diluted with 60 mL EtOAc and washed with saturated aqueous $NaHCO_3$ (2 × 50 mL) and water (2 × 50 mL). The organic solvent was removed under reduced pressure. The product was purified by silica gel column chromatography (EtOAc/hexane, 2:3) to afford a 93% yield of α/β mixtures of 2,3,4-tri-*O*-benzyl-D-cyclohexanones, where the α-anomer is 1.7 g [3.8 mmol, 80% of the mixture, white solid, $R_f = 0.27$ (EtOAc/hexane, 3:7)] and the β-anomer is 0.41 g (0.95 mmol, 20% of the mixture).



Reference 3.

A mixture of 96.5 mg (*E*)-methyl 6-*O*-acetyl-2-*O*-benzyl-3,4-*O*-di-methoxybenzyl-α-D-*gluco*-hex-5-enopyranoside and (*Z*)-methyl 6-*O*-acetyl-2-*O*-benzyl-3,4-*O*-dimethoxybenzyl-α-D-*gluco*-hex-5-enopyranoside (0.171 mmol) and 3.0 mg $PdCl_2$ (0.017 mmol) in 3.3 mL of a dioxane-water mixture (2:1) was stirred at 60°C for 8 h. After the reaction was finished, water was added, and the mixture was extracted with EtOAc. The organic layer was dried over Na_2SO_4 and evaporated to dryness. Chromatography using EtOAc/hexane (1:2) gave 49.9 mg (1*R*,2*R*,3*S*,4*R*,5*S*)-3-benzyloxy-2-hydroxy-4,5-bis(4-methoxybenzyloxy)-6-oxocyclohexyl acetate as a solid (0.091 mmol), in a yield of 53.0%, $R_f = 0.33$ (EtOAc/hexane, 1:1).

Other references related to the Ferrier Rearrangement are cited in the literature.[12]

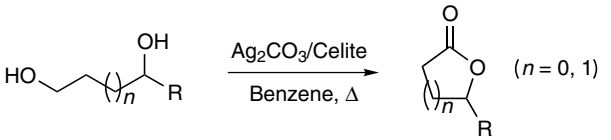
Fétizon Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fétizon and Golfier in 1968.[1] It is a mild oxidation of alcohols into carbonyl compounds in refluxing benzene using silver carbonate absorbed on Celite as the oxidant. Therefore, it is known as the Fétizon oxidation,[2] and the silver carbonate on Celite is often called Fétizon's reagent.[2c,3] Fétizon's reagent is a very mild oxidant (e.g., even milder than Ag_2O),[4] and usually oxidizes the 1,4-diols,[5] 1,5-diols[2b,3c,6] and lactols[2c,3b,3d,6a,7] into lactone. Thus this reaction is also called Fétizon cyclization.[2b] In addition, the Fetizon's reagent also oxidizes geminal diols into α-hydroxyl ketones (or aldehydes),[3m] and sometimes cleaves the diols.[8] In the cases of 1,4-hydroquinones[3j,9] and catechols,[3i,10] they are oxidized into quinone by the Fétizon's reagent. Other applications of the Fétizon's reagent include the deprotection of the benzyl group on carbohydrate along with sodium sulfate,[11] conversion of halide into alcohol,[3g] generation of an aromatic radical,[3i,10b] coupling of indole to chloroquinone,[3a] one-pot synthesis of medium to large ring-fused furans from 1,3-dicarbonyl compounds and vinyl sulfides,[3f] and quinoxaline derivatives from catechol and α-amino anilines or naphthalenes.[4] The advantage of this reaction is that the reagent can be simply removed by filtration.[3a,3f]

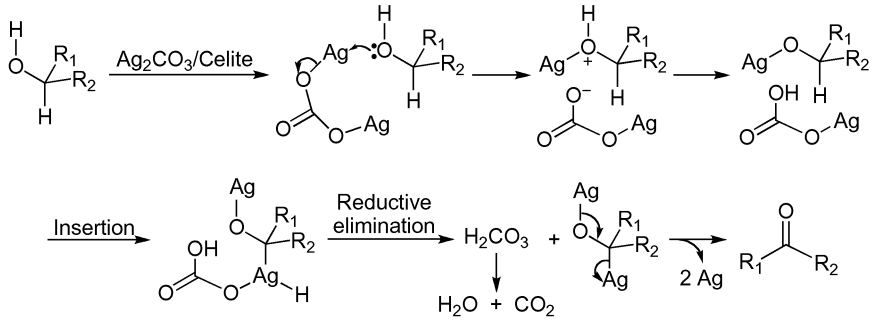
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Displayed here is the reaction mechanism modified from the one reported by Fétizon.[13]



D. MODIFICATION

This reaction has been modified to remove water via azeotropic distillation with toluene.

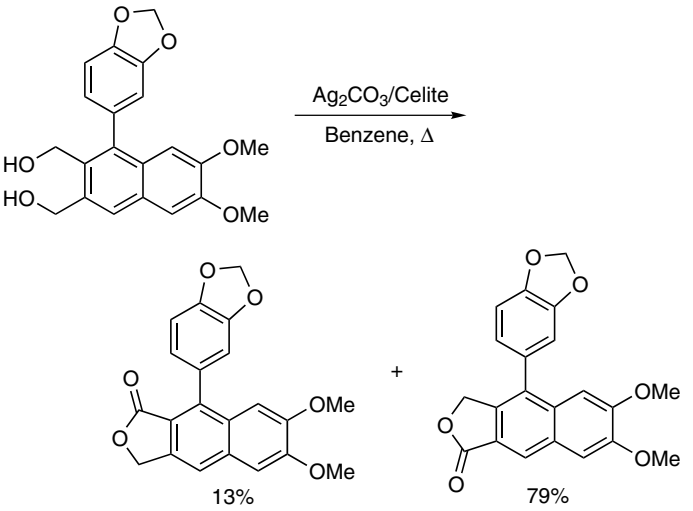
E. APPLICATIONS

This reaction has wide application in the preparation of aldehydes, ketones, lactones, quinones, and quinoxalines.

F. RELATED REACTIONS

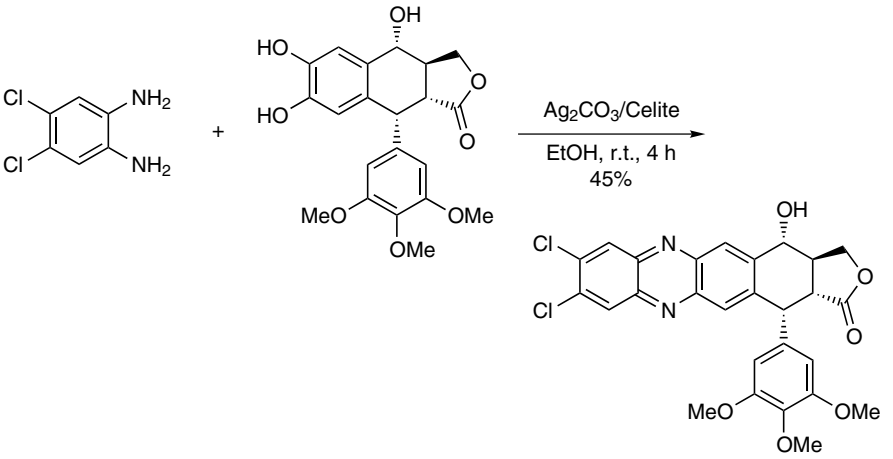
This reaction is related to the *Adkins Catalyst*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5a.

A stirred suspension of 115 mg 1-(3,4-methylenedioxyphenyl)-6,7-dimethoxynaphthalene-2,3-diyldimethanol (0.312 mmol) and 3.12 g Fétizon's reagent (Ag_2CO_3-Celite) in 50 mL benzene was refluxed for 1.5 h with azeotropic removal of water using a Dean-Stark apparatus. After cooling to room temperature, the mixture was concentrated. The obtained crude product was purified by SiO_2-column chromatography ($CHCl_3$/EtOAc, 30:1) to give 15 mg justicidin B as a colorless crystal (m.p. 240–242°C), in a yield of 13%, and 90 mg retrojusticidin B as a colorless crystal (m.p. 217–219°C), in a yield of 79%.



Reference 4.

Commercially available 4,5-dichloro-1,2-phenylenediamine (44 mg, 0.25 mmol) and 50 mg 7-*O*,*O*-demethylenepodophyllotoxin (0.12 mmol) were dissolved in 5 mL dry ethanol. To this solution was added 357 mg freshly prepared Ag_2CO_3/Celite reagent (0.62 mmol). The reaction mixture was stirred for 4 h at room temperature. The reaction mixture was filtered, and the filtrate was evaporated under reduced pressure. The desired product was purified by silica gel column chromatography ($CHCl_3$:MeOH, 60:1) to give 30 mg 2″,3″-dichloropodophenazine as yellow granules crystallized from methanol, in a yield of 45%, m.p. 270°C (dec.).

Other references related to the Fétizon oxidation are cited in the literature.[14]

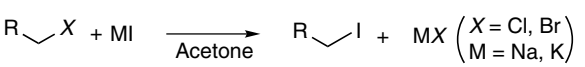
Finkelstein Reaction

A. GENERAL DESCRIPTION OF THE REACTION

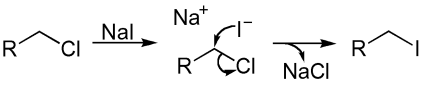
This reaction was initially reported by Finkelstein in 1910.[1] It is a preparation of alkyl iodide from alkyl bromide or chloride with potassium or sodium iodide in acetone. Therefore, this reaction is generally known as the Finkelstein reaction.[2,3] Occasionally, it is also referred to as the Finkelstein halide exchange,[4] Finkelstein displacement,[5] or Conant-Finkelstein reaction.[6] Mechanistically, this reaction is a simple nucleophilic substitution (often via S_N2), as iodide is a stronger nucleophile than bromide or chloride. The yield of this reaction is very high and can be quantitative if occurs in DMF.[2a] It was found that the trifluoromethyl group retards the displacement of bromide when it presents as an α- or β-substituent but accelerates the reaction as a substituent in an allylic chloride.[2h] Under normal conditions, this type of halide displacement does not occur for aryl halides.[7] For dihalides, unsaturated or cyclic compounds may form via carbocation intermediates, which form transient covalent iodides or are reduced directly by iodide to free radicals.[2g,7] However, the aromatic halide exchange reacts smoothly when 10% CuI is present in the reaction mixture as a catalyst,[2d] and such halide substitution can even occur at $-40^{\circ}C$.[2b]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur in DMF;[2a] in addition, CuI has been used to catalyze this reaction for aromatic halides.[2d]

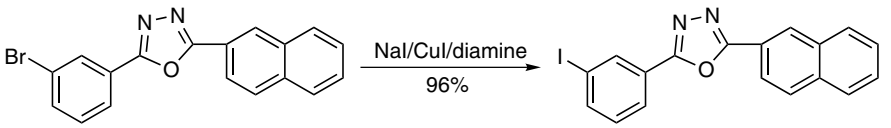
E. APPLICATIONS

This reaction has general applications in the preparation of alkyl and aryl iodides.

F. RELATED REACTIONS

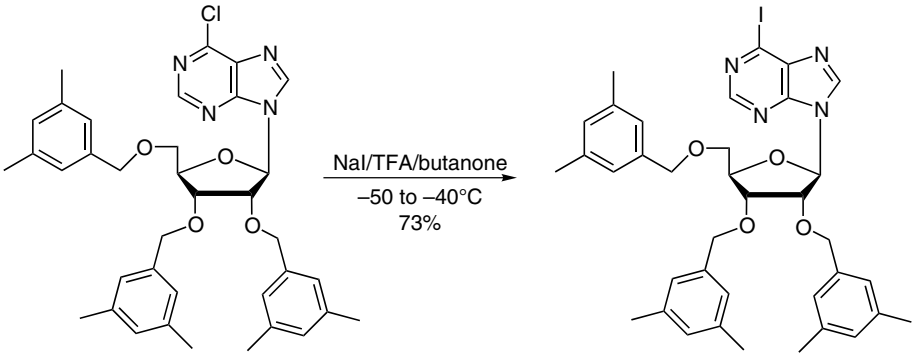
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2d.

A Schlenk tube charged with 9.6 mg CuI (0.050 mmol, 5.0 mol%), 352 mg 2-(3-bromophenyl)-5-(2-naphthyl)-1,3,4-oxadiazole (1.00 mmol), and 300 mg NaI (2.00 mmol), was briefly evacuated and backfilled with argon. Then 16 μL racemic *trans*-*N*,*N*′-dimethyl-1,2-cyclohexanediamine (0.10 mmol, 10 mol %) and 1.0 mL dioxane were added under argon. The Schlenk tube was sealed with a Teflon valve, and the reaction mixture was stirred at 110°C for 24 h. The resulting light green-gray suspension was allowed to reach room temperature and then was diluted with 5 mL 30% aqueous ammonia, poured into 20 mL water, and extracted with dichloromethane (3 × 15 mL). The combined organic phases were dried over Na_2SO_4 and concentrated to ~ 2 mL volume. The product was allowed to crystallize at room temperature. After 15 min, 20 mL hexane was added; the mixture was kept at room temperature for 15 h and finally filtered to provide 382 mg 2-(3-iodophenyl)-5-(2-naphthyl)-1,3,4-oxadiazole as white, fine needles, in a yield of 96%, m.p., 156–158°C.



Reference 2b.

A mixture of 0.50 g 6-chloro-9-[2,3,5-tri-*O*-(2,4,6-trimethylbenzoyl)-β-D-ribofuranosyl]purine (0.7 mmol), 0.57 g trifluoroacetic acid (5 mmol), and 3.0 g sodium iodide (20 mmol) in 20 mL butanone was stirred at –40 to –50°C for 5 h. The reaction mixture was poured into a saturated $NaHCO_3$ solution and extracted with 50 mL CH_2Cl_2. The organic layer was washed with $NaHSO_3$ solution, H_2O, and brine and dried over Na_2SO_4. Volatiles were evaporated, and the residue was recrystallized from EtOH to afford 0.41 g 6-iodo-9-[2,3,5-tri-*O*-(2,4,6-trimethylbenzoyl)-β-D-ribofuranosyl]purine, in a yield of 73%, m.p. 143–145°C.

Fischer Carbene Complexes

A. GENERAL DESCRIPTION OF THE REACTION

These types of complexes were first reported by Fischer and Maasböl in 1964.[1] The complexes contain a low-valent transition metal (often group VIB), an organic moiety (e.g., alkenyl,[2] alkynyl,[3] and aryl), several strong electron-withdrawing ligands (e.g., CO) and an electron-donating group (OR or NRR′). The combination of these characteristics enhances the stability of the complexes, which are stable even in aqueous solution.[4] In addition, these types of complexes also have metal-carbon multiple bonds, of which the electron configuration of carbon attaching to metal is similar to that of a carbene structure; therefore, these complexes are called Fischer carbene complexes[5] or Fischer-type carbene complexes.[6] Gradually, the Fischer carbene complexes, consisting of a few functionalities, found enormous applications in organic synthesis, as listed below.

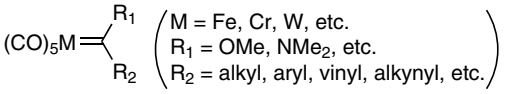
- Participation in [2+1] cycloaddition to form cyclopropane derivatives;[5v,7] *Diels-Alder Cycloaddition*;[8] *1,3-Dipolar Cycloaddition*;[9] [3+2+1] cycloaddition (i.e., the *Dötz Benzannulation* to form functionalized phenol derivatives[5u,10]), [3+2+2+1] cycloaddition to give cyclopenta[*b*]-pyrans;[11] and [3+1+1],[12] [3+2+2],[13] [3+2+2+2],[14] and [4+1] cycloaddition.[15]
- Insertion of carbonyl (CO) to form esters or amides upon extrusion of metal.[5v,16]
- Substitution of an alkoxy group by other substituents to generate more derivatives.[4,5r]
- Substitution of metal by nucleophiles (e.g., alkyl anion to form allyl sulfoxide).[17]
- Hegedus photochemical ketene synthesis.[5u,18]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

- Transmetallation of a group VI element to other transition metal.[19]
- Reaction of an olefinic or alkynyl group bound to metal.[5v,5x,7b,10b]

More information on the reactivities of such types of complexes are provided in reviews.[5s,18,19a,20]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

No mechanism is necessary for the Fischer carbene complexes.

D. MODIFICATION

N/A

E. APPLICATIONS

These types of complexes have found wide application in organic synthesis as summarized in Section A.

F. RELATED REACTIONS

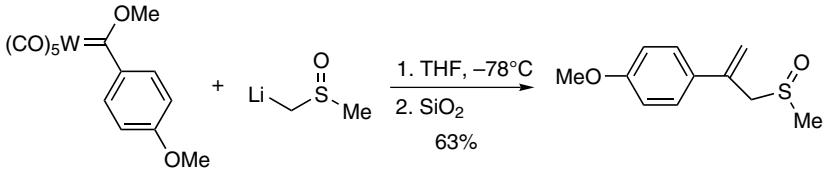
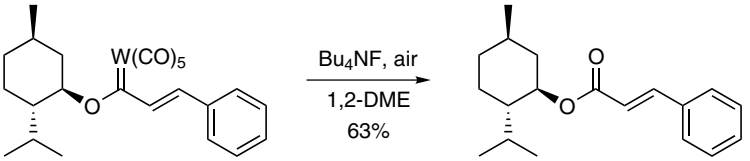
G. CITED EXPERIMENTAL EXAMPLES



Reference 17.

To a solution of 0.195 g DMSO (2.5 mmol) in 15 mL THF cooled at −20°C was added 1.7 mL 1.5 M MeLi in pentane. The resulting mixture was allowed to warm to

room temperature and was added dropwise to a solution of carbene complexe (1 mmol) in 20 mL THF at −78°C. The mixture was stirred at −78°C for 30 min and then warmed to room temperature. Silica gel was added and the solvents were evaporated under reduced pressure. The remaining material was loaded onto a column for chromatography, and 63% 2-(4-methoxyphenyl)allyl methyl sulfoxide was obtained as a yellow oil, $R_f = 0.15$ (EtOAc).



Reference 5w.

Tetrabutylammonium fluoride (1.5 mmol) was added at room temperature to a solution of 1.0 mmol pentacarbonyl[1-(1*R**,3*R**,4*S**)-menthyloxy-*trans*-3-phenyl-2-propenylidene]tungsten(0) in 30 mL 1,2-DME at room temperature. The reaction mixture was stirred at the same temperature and monitored by TLC. When disappearance of the starting material was observed, 1 g silica gel was added. Upon evaporation of solvent under vacuum, the residue adsorbed on silica gel was purified by flash chromatography to afford 63% *trans*-cinnamic acid menthyl ester.

Other references related to the Fischer carbene complexes are cited in the literature.[21]

Fischer Indole Synthesis
(Fischer Indolization)

A. GENERAL DESCRIPTION OF THE REACTION

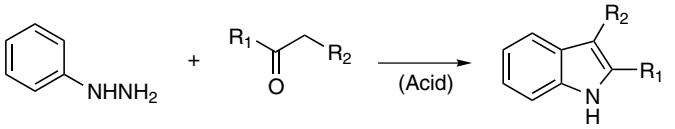
This reaction was first reported by Fischer and Jourdan in 1883.[1] It is a synthesis of indole derivatives by the treatment of aryl hydrazones coupled from aromatic hydrazines and ketones or aldehydes with either a mineral or Lewis acid. Therefore, it is generally known as the Fischer indole synthesis.[2] In addition, it is also referred to as Fischer cyclization,[3] Fischer indole cyclization,[4] Fischer indole reaction,[5] Fischer indolization,[6] Fischer reaction,[7] and Fischer indole annulation.[8] Although the mechanism has been extensively studied,[5e,9] the one formulated by Robinson and Robinson is now generally accepted.[10] It involves the following steps: (*a*) initial acid-catalyzed tautomerization of an aromatic hydrazone to an *ene*-hydrazine, (*b*) a [3,3]-sigmatropic rearrangement of *ene*-hydrazine to a *bis*-imine intermediate, (*c*) re-aromatization to aniline, (*d*) intramolecular nucleophilic attack to form aminal, and (*e*) extrusion of an ammonia to afford the indole.

This reaction is often catalyzed by acids, including mineral acids (e.g., PPA[3b]) and Lewis acids. $ZnCl_2$ is found to be a very effective Lewis acid catalyst,[11] and the special case of indole synthesis using 1% $ZnCl_2$ as catalyst is known as the Fischer-Arbuzov reaction.[2z] However, much experimental evidence also indicates that an acidic catalyst is not necessary for this reaction;[2t,2bb,12] in addition, the formation of indole from aromatic hydrazone can occur at high temperatures (e.g., 222°C).[2t] These reaction conditions are called non-catalytic Fischer indole syntheses.[2ac] Even though the Fischer indole synthesis is one of the most common methods for indole, it also has some potential problems. For example, indole isomers[13] and even quinolone[2bb] derivatives will form if unsymmetrical ketones are used to form the aromatic hydrazones. Furthermore, because the Fischer indole synthesis involves a [3,3]-sigmatropic rearrangement and nucleophilic attack, if both the 2 and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

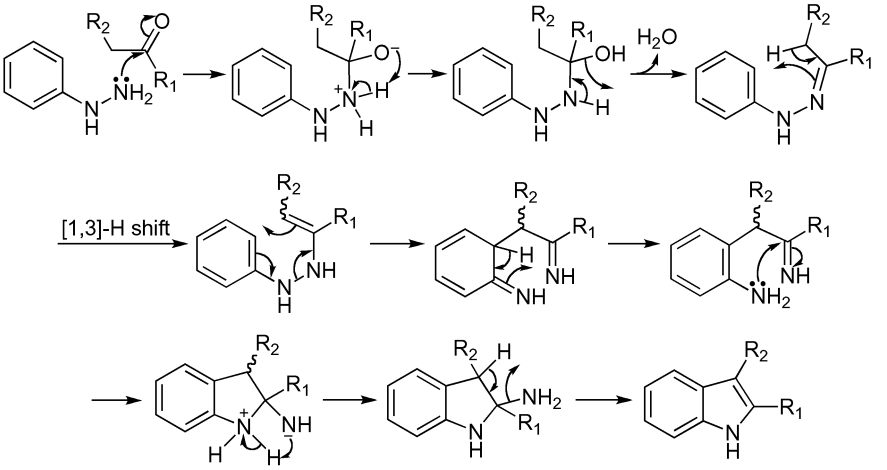
6 positions of the aromatic hydrazines are blocked by substituents, then non-indole product (e.g., carbazole[4b,14]) or abnormal indole product (via 1,4-migration) is obtained,[7,9b,15] usually in poor to fair yield.[16] To overcome this problem, thioether is often used to direct the regiochemistry and is then removed at a later stage;[17] in addition, it was found that Eaton's reagent (P_2O_5/$MeSO_3H$)[13] and diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP)[18] can facilitate the regioselectivity. As the formed indole is subjected to degradation under acidic conditions, a two-phase reaction was designed for the indole synthesis.[6e] Moreover, a solid-phase supported synthesis of indole has also been developed,[2n,19] and the traceless synthesis of indole is probably the most advanced technique for solid-phase synthesis.[2m,2q,20] Furthermore, as ketones and aldehydes tautomerize under acidic conditions, the dialkyl acetals are used for the indole preparation.[21] It is interesting that a new preparation of aromatic hydrazones with substituted benzaldehydes have been developed from aromatic halides and hydrazines.[6d] Further modifications of this reaction include the reaction in gas phase[2w] and in ionic liquid,[2p] the application of organoaluminium amide as a catalyst,[18] and the generation of hydrazone from aldehydes by hydroformylation of olefins with carbon monoxide.[21a] Because of the importance of indole moiety in alkaloids, this reaction has been extensively investigated and widely applied to pharmaceutical and medicinal chemistry as well as in organic synthesis.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The detailed mechanism in the absence of an acid is illustrated here.



D. MODIFICATION

This reaction has been extensively modified to various conditions, including a reaction without a catalyst,[2t,2cc,12c] the generation of aldehydes by hydroformylation of olefin,[21aa] two-phase reaction,[6e] and—more important—the solid phase-supported reactions.[2m,2n,2q,19,20]

E. APPLICATIONS

This reaction has wide application in the synthesis of indole derivatives.

F. RELATED REACTIONS

This reaction is related to the *Borsche-Drechsel Reaction, Madelung Indole Synthesis*, and *Piloty-Robinson Pyrrole Synthesis*.

Procedure for Hydrazone Formation

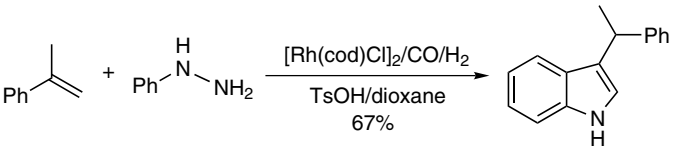
The aldehyde resin (0.5 g, 0.55 mmol) was dried in high vacuum overnight and suspended in 5 mL dichloroethane. To this suspension, 2.75 mmol (5 eq.) *p*-methoxybenzenehydrazine hydrochloride and 194 μL triethylamine (6 eq.) were added under argon atmosphere. The mixture was shaken at 45°C overnight. After cooling, the resin was filtered and washed three times each with 5 mL *N*,*N*-dimethylformamide, DMF/H_2O (v/v = 90/10), DMF, dichloromethane, ethyl acetate, and methanol.

Procedure for Hydrazone Acylation

The hydrazone resin (0.5 g, 0.45 mmol) was dried in high vacuum overnight and suspended in 5 mL pyridine. To this suspension was added 1.35 mmol *p*-bromobenzoyl chloride (3 eq.) under argon. The mixture was shaken at 80°C overnight. After cooling, the resin was filtered and washed three times with DMF, DMF/H_2O (v/v = 90/10), DMF, dichloromethane, ethyl acetate, and methanol.

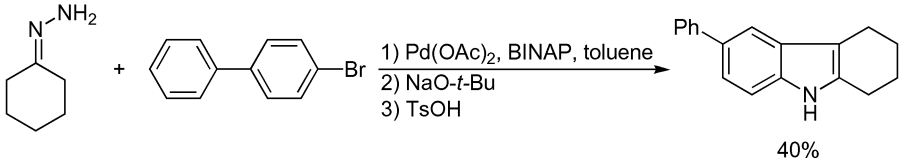
Procedure for Cleavage and Indole Rearrangement

The benzoylated hydrazone resin (150 mg, 0.11 mmol) was suspended in 6 mL dichloroethane/trifluoroacetic acid (1/1). Then 10 eq. laevulinic acid was added, and the mixture was heated for 15 min to 2 h at 70°C. After cooling, the mixture was quenched with methanol, and the resin was filtered and washed with 5 mL dichloromethane, methanol, ethyl acetate, and methanol. The filtrate was evaporated to dryness, and the crude product was purified by preparative HPLC. Finally, [1-(4-bromobenzoyl)-5-methoxy-2-methyl-1*H*-indol-3-yl]acetic acid was obtained as white solid, in a yield of 57% with a purity of > 99% (HPLC), m.p. 151°C.



Reference 21a.

To an autoclave were added 0.60 g α-methylstyrene (5.1 mmol), 0.58 g phenylhydrazine (5.3 mmol), 10 mg $[Rh(cod)Cl]_2$ (0.5 mol %), 0.95 g *p*-toluenesulfonic acid (5.0 mmol), and 30 mL anhydrous dioxane. Then the autoclave was pressurized with 50 bar CO and 20 bar H_2. After being stirred for 2 days at 120°C, the mixture was filtered over alumina. The solvent was evaporated, and the residue was purified by flash chromatography on silica to yield 0.74 g 3-(1-phenylethyl)-indole, in a yield of 67%.



Reference 2r.

To an oven-dried test tube were added 112 mg cyclohexanone hydrazone (1.0 mmol), 0.5 mL toluene, 233 mg 4-bromobiphenyl (1.0 mmol), 11 mg $Pd(OAc)_2$ (0.05 mmol), and 31 mg (±) BINAP (0.05 mmol), followed by an additional 0.5 mL of toluene. The test tube was capped with a septum, purged briefly with argon, and heated to 100°C for 2 min (the reaction mixture turned green and then black during this period). The reaction mixture was cooled to room temperature, the septum was removed, and 134 mg sodium *tert*-butoxide (1.4 mmol) was added, followed by 1 mL toluene. The test tube was recapped with the septum and purged briefly with argon; the resulting purple solution was heated

at 100°C for 8 h (*Caution!* Hydrazine may be evolved during this reaction). The reaction mixture was cooled to room temperature, diluted with 10 mL Et_2O, and filtered through a short pad of Celite. The filter cake was rinsed with 20 mL Et_2O. The filtrate was then concentrated to afford the crude product. The crude product was then refluxed with 380 mg *p*-toluenesulfonic acid monohydrate (*p*-TsOH·H_2O) (2.0 mmol) in 5 mL EtOH for 48 h. The reaction mixture was then cooled to room temperature, the septum was removed, and the reaction mixture was diluted with 15 mL Et_2O. The resulting heterogeneous mixture was then filtered through a pad of silica gel (1 inch), and the silica gel was rinsed with an additional portion of Et_2O (20–50 mL). The filtrate was concentrated, and the crude product was purified by flash chromatography (5 → 10% EtOAc/hexanes) to afford 98 mg 6-phenyl-1,2,3,4,-tetrahydrocarbazole, in a yield of 40%, m.p. 142–143°C.

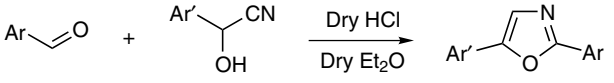
Fischer Oxazole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Fischer in 1896.[1] It is a synthesis of oxazole derivatives by treatment of equimolar amounts of aldehyde cyanohydrin and aromatic aldehyde in anhydrous ether with dry hydrochloride. Therefore, it is known as the Fischer oxazole synthesis[2] or Fischer synthesis.[3] This method is good for the preparation of 2,5-diaryloxazoles[4] and is usually carried out in dry ether by dissolving aromatic aldehydes and aldehyde cyanohydrins and passing in dry HCl gas.[4] The synthesized oxazole precipitates as its hydrochloride salt, which can be converted into free oxazoles by the addition of water[5] or by boiling with alcohol.[1,6] However, some minor byproducts also form in this reaction, including 4-chlorooxazoles,[7] oxazolidinone,[7] arylenemandeloamide,[8] and diazine.[8] This reaction has been further modified by using aroyl cyanide and aromatic aldehyde in the presence of dry HCl or HBr gas to give 4-chloro- or 4-bromo-oxazoles;[3] another modification is to add $SOCl_2$ to the reaction mixture of nitrile, aromatic aldehyde, and HCl gas to form oxazoles in one step[9] instead of preparing cyanohydrin before reacting with aldehyde.

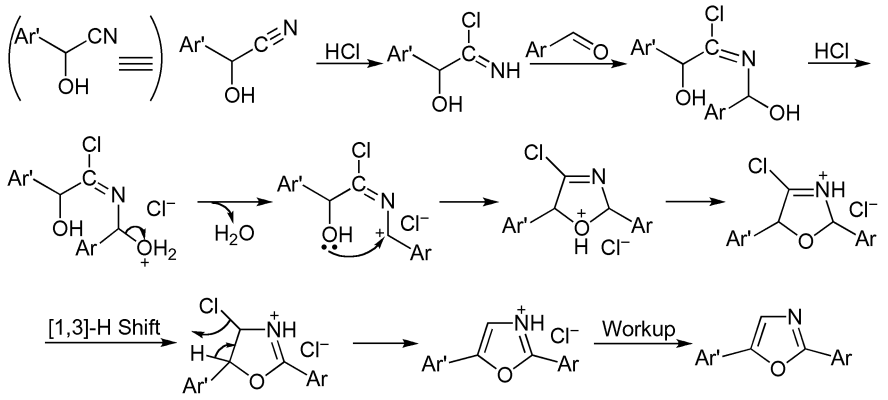
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A mechanism similar to that of Ingham[8a] but with much more detail is given here.



D. MODIFICATION

The modifications of this reaction include the reaction between aroyl cyanide and aromatic aldehyde in the presence of HCl gas[8] and the reaction of nitrile with aromatic aldehyde, HCl and $SOCl_2$.[3]

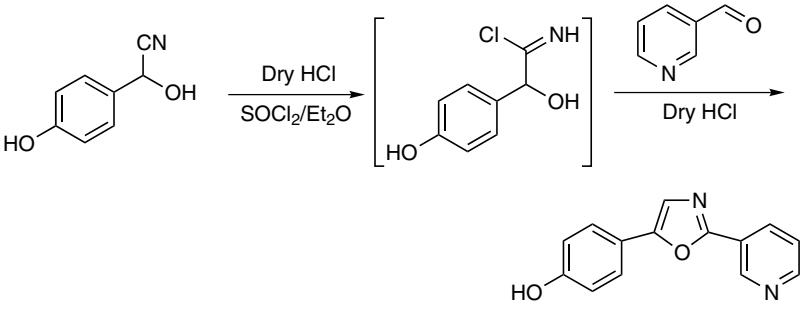
E. APPLICATIONS

This reaction has a general application in the preparation of 2,5-diaryl-oxazoles.

F. RELATED REACTIONS

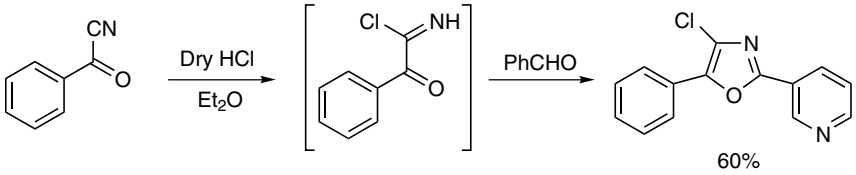
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9b.

The solution of 0.94 g freshly prepared *p*-hydroxymandelonitrile in 45 mL anhydrous ether was saturated with HCl by bubbling the dry HCl gas into the solution. After an addition of 1.12 g $SOCl_2$, the reaction mixture was stirred for 10 min with external cooling. Then an addition of 0.75 g nicotinaldehyde was followed, and the reaction mixture was saturated with dry HCl once again. After standing at room temperature for 2 days, the reaction solution was poured into water, and the separated organic layer was further washed with aqueous HCl. Neutralization of the combined aqueous layers with Na_2CO_3 resulted in the precipitation of halfordinol, which was collected on a filter and recrystallized from methanol to fine cream needles, in amount of 248 mg (16.5%), m.p. 254–255°C.



Reference 3.

Benzoyl cyanide was prepared by heating a mixture of benzoyl chloride and cuprous cyanide, then 13.1 g purified benzoyl cyanide (0.10 mol), 11.67 g benzaldehyde (0.11 mol), and 100 mL dry ether were cooled in an ice bath and saturated with dry hydrogen chloride. The mixture was kept at 0°C overnight, then transferred onto 300 g crushed ice and extracted with ether (2 × 100 mL). The combined organic layers were washed with water, saturated $NaHSO_3$, and water and dried over Na_2SO_4. Upon removal of the solvent, the residue was recrystallized from acetone or an acetone/methanol mixture to give 15.34 g 2,5-diphenyl-4-chloro-oxazole, in a yield of 60%, m.p. 71–72°C.

Other references related to the Fischer oxazole synthesis are cited in the literature.[10]

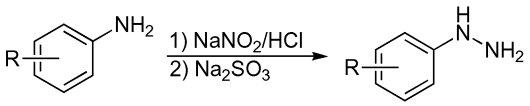
235

Fischer Phenylhydrazine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fischer in 1875.[1] It is a synthesis of phenylhydrazine involving the diazotization of aniline, the reduction of the resulting diazonium salt with an excess amount of sodium sulfite, and the hydrolysis of phenylhydrazine sulfonic acid salt with hydrochloric acid. In addition, the diazonium salt can also be reduced by zinc dust in acetic acid.[2] This process has become a standard industrial method for the production of arylhydrazines.

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that sodium sulfite adds to the diazonium salt to form an azo group, which is further reduced to hydrazine by sulfite as outlined here.

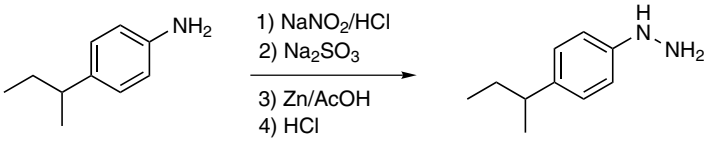
E. APPLICATIONS

This reaction is the general method for preparing arylhydrazines, from a small scale to an industrial scale.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

The *p-sec*-butyl aniline was first treated with concentrated hydrochloric acid followed by the slow addition of a $NaNO_2$ solution to maintain the temperature below 0°C. The diazonium salt solution was poured at once into a cold solution of sodium sulfite, giving a

rich red solution, a sample of which was only slightly cloudy after having been boiled for 1 min. This solution was then reduced in the usual way by the Fischer method with zinc dust and acetic acid. The reaction mixture was heated nearly to the boiling point during the reduction to secure completeness of the reduction. From the cooled solution, the solid sulfonate was separated by filtration. The *p-sec*-butyl-phenylhydrazine sodium sulfonate crystallized from a water solution in beautiful white plates with a pearly luster. These are stable in the air for $\sim$ 2 h when they darkened slightly. After one crystallization from 95% alcohol, the crystals were well dried in a vacuum desiccator over sulfuric acid. To obtain the hydrochloride of the hydrazine, the sulfonate was covered with concentrated hydrochloric acid, and the mixture was boiled for 8 h, during which time fresh acid was supplied as needed. The solid hydrochloride was obtained as a mass of white crystals from the cooled solution. These were treated with sodium hydroxide and so on, to give the hydrazine. The pure *p-sec*-butyl-phenylhydrazine can be obtained by vacuum distillation in the atmosphere of hydrogen.

Fischer Phenylhydrazone and Osazone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

The formation of phenylhydrazone was initially reported by Fischer in 1875.[1] It is a condensation between phenylhydrazine and a carbonyl compound (aldehyde or ketone) to form phenylhydrazone. The compounds condensed from carbohydrates and 2 eq. of phenylhydrazine are generally known as osazones[2] or specifically referred to as glycosazones.[3] Both the phenylhydrazones of carbonyl compounds and glycosazones from carbohydrates often readily crystallize[4] and show sharp melting points; therefore, formation of phenylhydrazone derivatives from carbonyl compounds was a routine method in traditional structure analysis before modern instruments (MS and NMR) came into play. Similarly, the glycosazones were employed by Fischer to elucidate the configuration of sugars.[3a] However, it was found that the phenylhydrazones of aliphatic ketones and aldehydes rapidly tautomerize to the more stable azo isomers in solution;[5] in addition, the glycosazones of carbohydrates also exist as chelated acyclic forms.[6] The phenylhydrazones have been applied as ligand for the coupling reaction,[7] to generate nitrones along with nitrosobenzene,[8] and to prepare *N*-phenylphthalimidine along with carbon monoxide in the presence of a cobalt catalyst.[9] In addition, the acetyl glycosazones can be reduced to amino sugar with zinc dust and acetic acid,[10] or converted into multifunctional hexane via the elimination of acetic acid.[11]

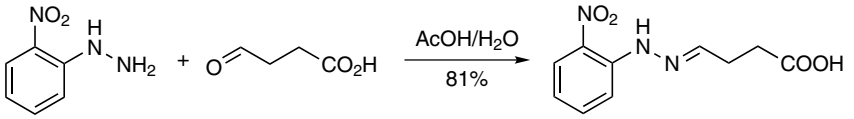
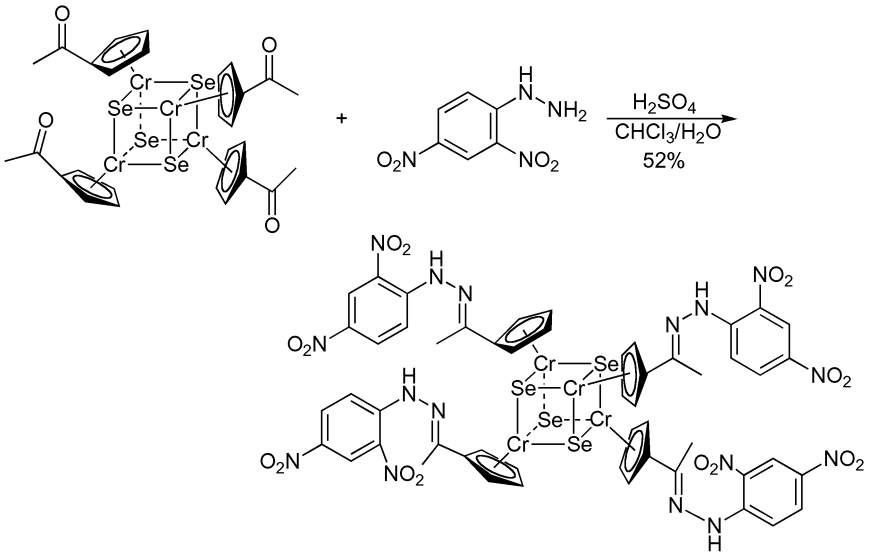
This reaction is related to the *Bamford-Stevens Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



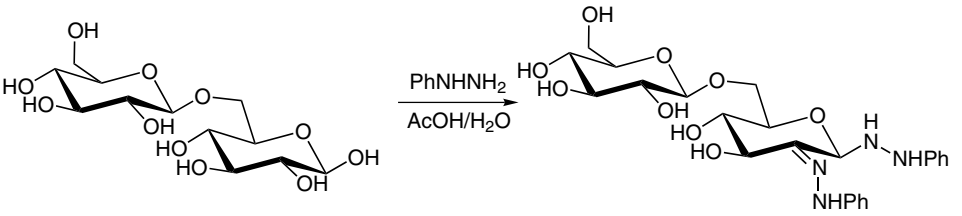
Reference 13.

A hot solution of 7.65 g *o*-nitrophenylhydrazines (0.05 mol) in 150 mL 20% acetic acid was added to 200 mL hot water containing 5.8 g levulinic acid (0.05 mol). The red-orange oil that precipitated crystallized on cooling, affording 10.2 g hydrazone in a yield of 81%. The solid was recrystallized from ethanol with the addition of water, m.p. 150–150.5°C.



Reference 14.

To a deep green solution of 0.190 g $[\eta^5\text{-MeC(O)C}_5\text{H}_4]_4\text{Cr}_4\text{Se}_4$ (0.20 mmol) in 20 mL $CHCl_3$ was added 9.6 mL 2,4-dinitrophenylhydrazine solution ($\sim$ 1.60 mmol, prepared by dissolving 1.0 g 2,4-dinitrophenylhydrazine in 5 mL 98% H_2SO_4, 10 mL H_2O, and 35 mL 95% EtOH). The mixture was stirred at reflux for 2 h, then 30 mL water was added after cooling to room temperature. The organic layer was separated, dried over Na_2SO_4, concentrated, and purified by preparative TLC with acetone/petroleum ether/CH_2Cl_2 (1:2:3) as the eluent to give 0.174 g $[\eta^5\text{-2,4-(NO}_2)_2\text{C}_6\text{H}_3\text{NHNC(Me)-C}_5\text{H}_4]_4\text{Cr}_4\text{Se}_4$ as a brown solid, in a yield of 52%, m.p. $> 280^\circ$C.



Reference 15.

A suspension of 7.2 g β-gentiobiose octa-acetate in 50 mL absolute methyl alcohol was saponified by adding a solution of 0.36 g metallic sodium in 10 mL absolute methyl alcohol; the mixture was allowed to stand for 15 min with occasional shaking. Then 25 mL water, 4.0 g glacial acetic acid, and 6.0 g phenylhydrazine were added, and the mixture was heated on a water bath for 1.5 h. On cooling, the solution deposited crystals of gentiobiose phenylosazone, which were filtered off, washed with cold water, and dried in a vacuum desiccator over sulfuric acid at room temperature to a constant weight (2.1 g). On the addition of water to the filtrate, 0.8 g more of the osazone separated. The total amount of osazone was 2.9 g, in a yield of 52.5%, m.p. 156–158°C. After recrystallization from hydrous ethyl acetate, the osazone, consisting of long needles, melted at 179–181°C.

Other references related to the Fischer phenylhydrazone and osazone synthesis are cited in the literature.[16]

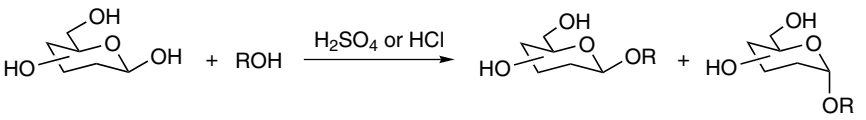
Fischer-Helferich Glycosylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fischer in 1893[1] and modified subsequently by his student Helferich.[2] It is a preparation of *O*- or *S*-alkyl glycosides from unprotected carbohydrates and alcohols or thiols using mineral acid (H_2SO_4, HCl, etc.) as a promoter or catalyst. Therefore, this reaction is generally known as the Fischer-Helferich glycosylation.[3] Occasionally, it is referred to as the Fischer-Helferich procedure.[4] This reaction involves the formation of oxocarbenium ion or its reactive equivalent.[5] A variety of simple *O*- or *S*-glycosides have been prepared by this method, including methyl, benzyl, and allyl glycosides.[6] In addition, urea and alkyl-substituted urea also react with carbohydrate in the presence of sulfuric acid.[7] It was found that "solid" alcohol or sugar derivatives are not suitable for this particular glycosylation reaction.[5] This reaction has been modified to use different acids, including Lewis acids, as promoters.[8] Unfortunately, this reaction always gives a mixture of both pyranosides and furanosides, along with their anomeric mixtures.

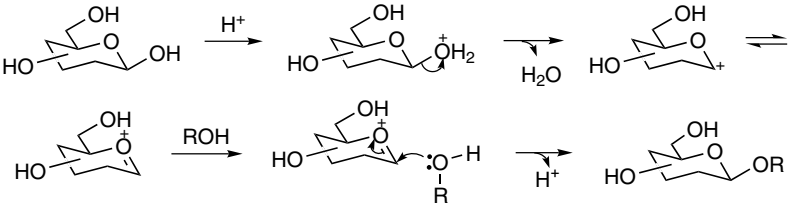
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A mechanism to form alkyl β-D-glycoside using mineral acid as a promoter is illustrated below.



D. MODIFICATION

This reaction has been modified using a Lewis acid as the catalyst or promoter.

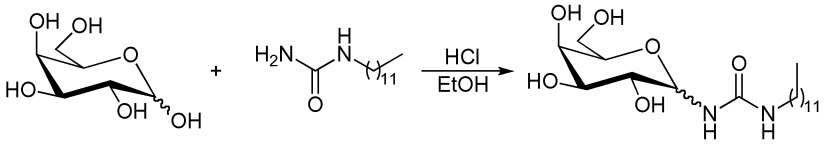
E. APPLICATIONS

This reaction has been used in the preparation of alkyl *O*- or *S*- glycosides.

F. RELATED REACTIONS

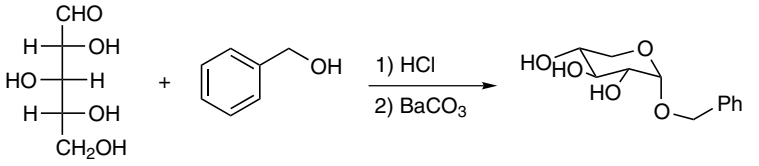
This reaction is related to the *Koenigs-Knorr Glycosylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

A mixture of 22.8 g dodecylurea (0.1 mol), 19.8 g galactose (0.11 mol), 2.5 g concentrated hydrochloric acid, and 200 mL 95% ethanol was stirred and heated at 50°C for 100 h, it was then cooled and filtered. Washing with water and hot benzene gave 15.6 g dodecylurea *N*-galactoside as a white solid, in a yield of 40%, m.p. 165–188°C.



Reference 9.

A mixture of 50.0 g D-xylose in 250 mL benzyl alcohol was cooled in an ice salt bath and saturated with dry hydrogen chloride gas. The mixture was shaken for 24 h at room temperature, after which a dark solution was obtained. This was poured into 500 mL water,

and solid barium carbonate was added to neutralize the acid. The solid material was removed by filtration, and the excess benzyl alcohol in the filtrate was separated from the water layer by ether extraction. The water layer was concentrated to dryness in vacuo at 50°C, and the mixture of salt and syrup was extracted three times with absolute ethanol. The alcohol layer was then concentrated to a thick syrup, which was dissolved in 40 mL absolute ethanol and left at 5°C in the refrigerator. Crystals formed readily to give 10.0 g benzyl α-D-xylopyranoside after filtration and being washed with ether. The product was recrystallized by dissolving it in a warm absolute ethanol and adding ether to turbidity to form needles with a constant melting point of 127–128.5°C.

Other references related to the Fischer-Helferich glycosylation are cited in the literature.[10]

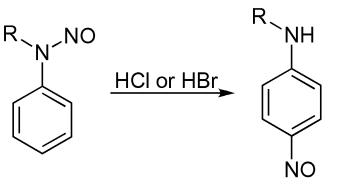
Fischer-Hepp Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fischer and Hepp in 1886.[1] It is a conversion of *N*-nitroso aromatic amines into *p*-nitroso aromatic amines in the presence of HCl or HBr and is generally known as the Fischer-Hepp rearrangement.[2] Originally, the Fischer-Hepp rearrangement was thought to be intramolecular;[3] however, much experimental evidence indicates that this rearrangement is actually intermolecular. For example, the nitroso group has been found to migrate onto a more reactive aromatic compound,[4] but no rearrangement occurs in the presence of urea.[5] It should be pointed out that the rearrangement is much less effective when sulfuric acid is used rather than HCl or HBr,[2y] because HCl or HBr can easily form a nitroso halide that quickly replaces the proton at the *para*-position of the amino group by electrophilic substitution.[2y]

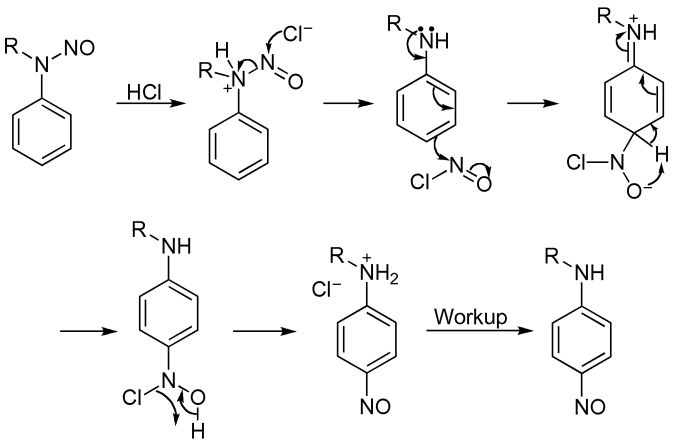
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Illustrated here is the rearrangement of *N*-alkyl-*N*-nitroso aniline with HCl.



D. MODIFICATION

N/A

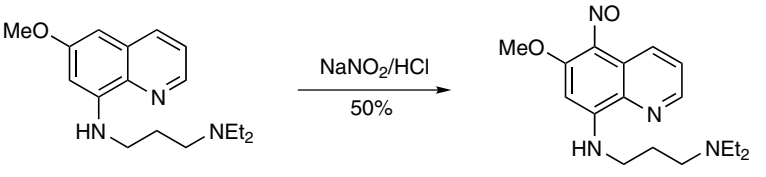
E. APPLICATIONS

This reaction has been used in the preparation of *p*-nitroso arylamines.

F. RELATED REACTIONS

N/A

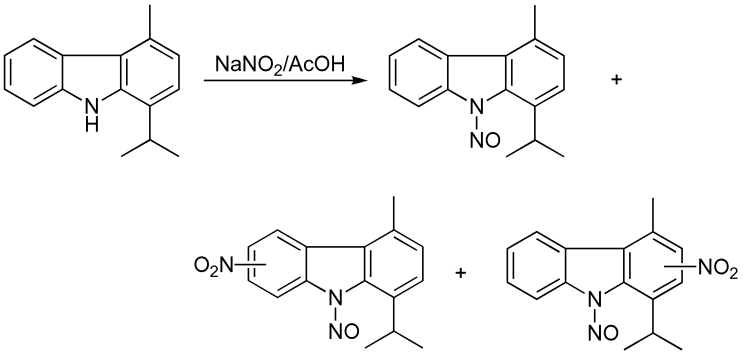
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A solution of 17.3 g sodium nitrite (0.25 mol) in 40 mL water was added dropwise with stirring to 72 g 6-methoxy-8-(3-diethylaminopropylamino)-quinoline in 37 mL concentrated HCl and 100 g ice at 3°C. After 1.5 h, the reaction mixture was made slightly basic,

and extracted with warm benzene. Green felt-like lustrous needles (17.5 g) crystallized from the dried, concentrated benzene extract. The dark, oily residue (50 g) that could not be crystallized was recovered as starting material; b.p. 170–180°C (0.2 mmHg); hydrochloride: m.p. 191–192°C. This was reworked to give a total of 41 g nitroso plasmocid, in a yield of 50%.



Reference 2bb.

To a cooled solution of 2.25 g 1-isopropyl-4-methylcarbazole in 45 mL glacial acetic acid (distilled from phosphorus pentoxide) was added 2.5 g sodium nitrite in 4 mL water while the reaction flask was cooled in ice water. A yellow solid separated after 10 min; precipitation was completed by addition of 50 mL water. The solid was separated by filtration, thoroughly washed with water, and pressed dry. Recrystallization from petroleum ether gave 1-isopropyl-4-methyl-9-nitrosocarbazole, m.p. 97–98°C. Attempted recrystallization from petroleum ether containing residual acetic acid yielded a solid with melting point of 158–160°C. Chromatography of this solid on alumina afforded two fractions: 1-isopropyl-4-methyl-6 (or 7)-nitrocarbazole, eluted by benzene, m.p. 204–205°C, and 1-isopropyl-2(or 3)-nitro-4-methylcarbazole, m.p. 210°C (no yield was given in the original paper).

Other references related to the Fischer-Hepp rearrangement are cited in the literature.[7]

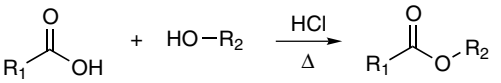
Fischer-Speier Esterification

A. GENERAL DESCRIPTION OF THE REACTION

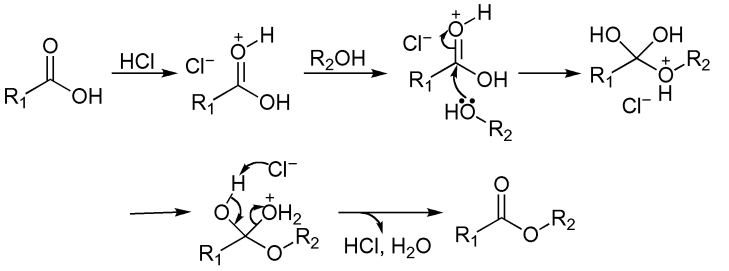
This reaction was initially reported by Fischer and Speier in 1895.[1] It is the synthesis of ester by refluxing carboxylic acid with an excess amount of alcohol in the presence of an acidic catalyst (e.g., HCl), and is known as the Fischer-Speier esterification.[2] It is known that the formation of ester from alcohol and carboxylic acid is reversible, and an equilibrium always exists between the ester and carboxylic acid. To drive the equilibrium toward ester side, azeotropic refluxing is always applied to remove the newly formed water.[3] At the same time, an acidic catalyst is added to accelerate the esterification, often by passing dry HCl gas into the solution.[1] Compared to the sulfuric acid–promoted esterification, the reaction promoted by HCl does not produce olefin (from alcohol), and does not undergo electrophilic substitution with benzene either. For the special case of preparing methyl esters, it was found that the methyl esters can be synthesized in almost quantitative yield with acetone dimethyl acetal, which functions as a water scavenger, resulting in a self-accelerating reaction. This is because whenever a water molecule is formed after the esterification, two more methanol molecules will be generated by hydrolysis of acetone dimethyl acetal.[3]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

More convenient *p*-toluenesulfonic acid (TsOH) is often used when dry HCl is not available.

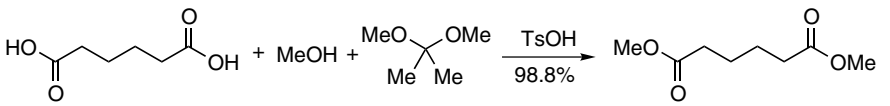
E. APPLICATIONS

N/A

F. RELATED REACTIONS

N/A

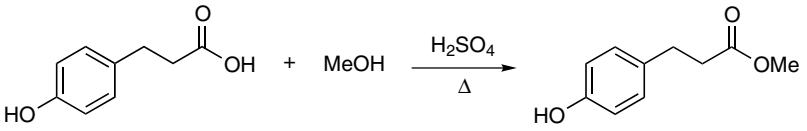
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

Adipic acid (585 g, 4 mol) was added to 200 mL methanol containing 5 g *p*-toluenesulfonic acid. This mixture was stirred in a 2-L flask and maintained at 40–60°C. As the reaction progressed, acetone dimethyl acetal was added in increments. By the end of 30 min, 200 mL had been added, by the end of 1 h, 600 mL total had been added (at this point, all adipic acid was in solution), and by the end of 1.5 h, a total of 1 L of the acetone dimethyl acetal (8 mol) had been added. At the end of 2 h, only 10% of the acid remained unreacted. After 4 h, the reaction was 99% complete. One half of the crude solution was then distilled at a rate such that by the end of 3 h, all of the acetone and methanol had been removed. This left a 98.8% yield of crude, straw-colored dimethyl adipate. On further distillation, a 94% yield of pure dimethyl adipate with a boiling point of 109°C was recovered.

A similar experiment in which all of the reactants were mixed at one time and left overnight at room temperature (with stirring) resulted in 100% conversion of the adipic acid.



Reference 2a.

The mixture of 1.1 g 3-(*p*-hydroxyphenyl) propionic acid, 5 mL concentrated H_2SO_4, and 100 mL MeOH was refluxed for 4 h. Then the mixture was poured into 200 mL cold $CHCl_3$ and washed with 300 mL 5% $NaHCO_3$ three times and water two times. The organic layer was dried and evaporated, and the residue was distilled under vacuum to give 0.9 g methyl 3-(*p*-hydroxyphenyl) propinate.

Other references related to the Fischer-Speier esterification are cited in the literature.[4]

Fischer-Tropsch Synthesis

(Fischer-Tropsch Technology, Fischer-Tropsch Process)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fischer and Tropsch at the Kaiser Wilhelm Institute in Germany in 1923.[1] It is the conversion of synthesis gas, a mixture of hydrogen and carbon monoxide, into a mixture of high-value hydrocarbons and their derivatives (e.g., aliphatic alcohols, olefins, aldehydes, and ketones) and some by-products such as water and CO_2. Therefore, this reaction is generally known as the Fischer-Tropsch synthesis,[2,3] Fischer-Tropsch technology,[4] or Fischer-Tropsch process.[5] Occasionally, it is also referred to as the Fischer-Tropsch reaction.[6] In this reaction, the synthesis gas is passed through a reactor containing a solid supported metal catalyst, such as, Ru/SiO_2,[7] Co/Nb_2O_5,[8] Co/TiO_2,[9] Co/Al_2O_3,[10] Co/SiO_2,[11] $Co\text{-}CeO_2/SiO_2$,[12] and Fe/SiO_2,[13] at 200–350°C and a pressure of 15–40 bar. Although the metals with catalytic activity for this reaction are ruthenium, cobalt, and iron,[14] cobalt and iron are the most used ones due to the high cost of ruthenium. However, the cheapest iron-based catalysts also suffer from a low wax selectivity[14] and are deactivated about as high as 4.8% per week[15] and are good for $\sim$ 8 weeks;[16] in contrast, cobalt-based catalysts "are stable and allow high syn-gas conversions,"[14] which can produce heavy wax ($\sim$ C100)[17] and can be used up to 5 years.[18] It was found that the rate of CO conversion increases linearly with cobalt's dispersion rate, regardless of solid support.[2g] This reaction has been practically used for making odorless, colorless, clean diesel fuel containing low levels of sulfur and other impurities.[4i,19] The application of this reaction in the fuel industry is so important that it might solve the energy crisis after we run out of crude oil, because this reaction uses much more enriched coal and sustainable biomass as starting materials.

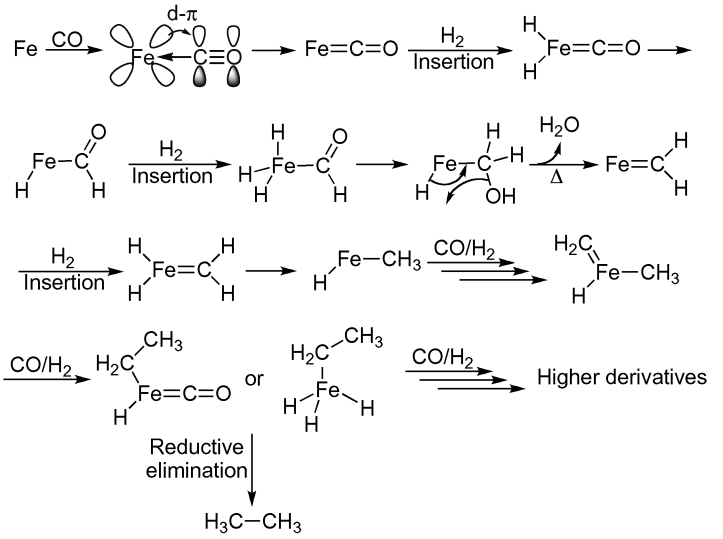
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

$$CO + H_2 \xrightarrow[200\text{–}350^\circ C]{\text{Co or Fe}} CH_3(CH_2)_n\text{-}H \quad (n = 0, \ldots > 100)$$

C. PROPOSED MECHANISMS

The mechanism is very complicated, as more than 36 reactions have been proposed.[2m] Illustrated here is a simple demonstration of this reaction, where iron is used to indicate the catalytic center only, no other bonds are shown except for the necessary ones. This mechanism is similar to the one in Brady and Pettit.[20]



D. MODIFICATION

This reaction has been modified using a variety of catalysts and different reactors.

E. APPLICATIONS

This reaction has a very important application in industry to produce clean fuels.

F. RELATED REACTIONS

This reaction is related to the *Bergius Process*.

G. CITED EXPERIMENTAL EXAMPLES

No experimental details are given here, because the cited papers provide only the procedures for preparing a particular catalyst and the analysis of product distribution.

Other references related to the Fischer-Tropsch synthesis are cited in the literature.[21]

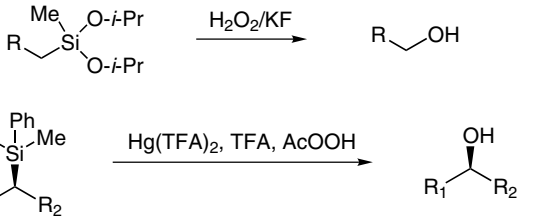
Fleming-Tamao Oxidation
(Tamao Oxidation, Tamao-Fleming Oxidation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Tamao and co-workers in 1983[1] and Fleming and co-workers in 1984.[2] It is the conversion of a silyl group into a hydroxyl group by means of an oxidative desilylation using either hydrogen peroxide or peracetic acid as an oxidant and KF or KHF_2 as an additivie (Tamao's procedure for di-isopropyl-methylalkylsilanes) or using a peroxy acid as an oxidant under acidic conditions (Fleming's procedure for phenyldimethyl-alkylsilanes). Therefore, this reaction is known as the Fleming-Tamao oxidation[3] but more commonly as the Tamao oxidation[4] or Tamao-Fleming oxidation.[4b,5] For the cases of dialkylsilanes, two alcohols can be generated from oxidative desilylation; therefore, this is an important method for the preparation of diols from cyclic silanes.[3b,3d,5c,5g,6] This oxidation has shown its versatility and importance in modern organic synthesis, beacuse organosilicon molecules can be easily prepared from the hydrosilylation of alkenes and alkynes with *cis*[7] or *trans*[8] stereochemistry, and alcohols or other derivatives can be obtained by the oxidative desilylation of the introduced silyl groups. It was found that the phenyldimethylsilyl group can be converted into an hydroxyl group with retention of stereochemistry,[3d,5d] except for cases when allylsilanes are present in the reaction solution.[3d] Unfortunately, this reaction is not feasible for removing the trimethylsilyl group.[3b]

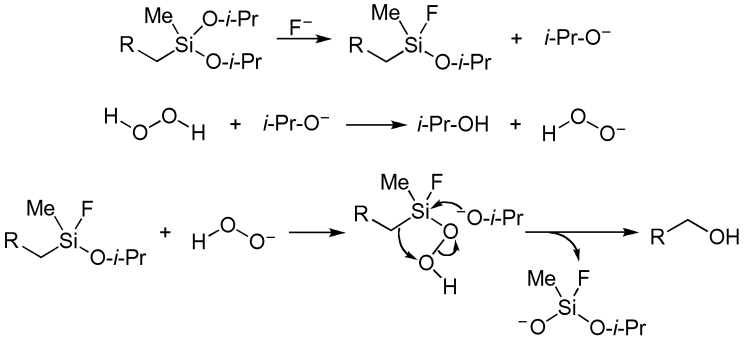
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Listed here is a demonstration of the mechanism using H_2O_2 as an oxidant to yield the alcohol. It is known that fluoride is silicon philic, which can liberate the isopropanol anion and deprotonate the hydrogen peroxide.



D. MODIFICATION

This reaction has been modified by the addition of $KHCO_3$ to further facilitate the reaction.[3d]

E. APPLICATIONS

This reaction has wide application in the removal of silyl groups and alcohol preparations.

F. RELATED REACTIONS

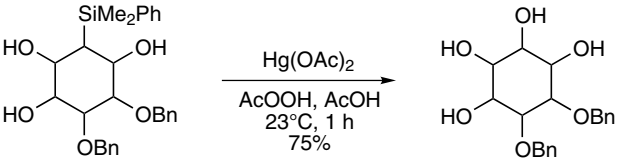
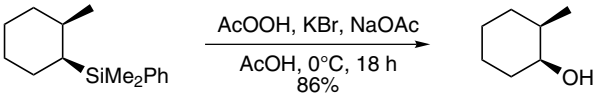
G. CITED EXPERIMENTAL EXAMPLES



Reference 3a.

To a solution of 16 mg (1*S*,2*S*,3*S*,4*R*,5*S*,6*R*)-5,6-dibenzyloxy-3-(dimethylphenylsilanyl)-cyclohexane-1,2,4-triol (0.03 mmol) in 0.3 mL AcOH were added 12 mg $Hg(OAc)_2$ (0.04 mmol) and 0.2 mL 32% AcOOH (1.0 mmol) at 23°C. After 1 h, the mixture was cooled to 0°C and quenched with 2 mL saturated aqueous $Na_2S_2O_3$ and 3 mL EtOAc. The mixture was stirred for 30 min and the two phases were separated. The aqueous layer was extracted with EtOAc (2 × 5 mL) and the combined organic extracts were washed with saturated aqueous $NaHCO_3$, dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified by gradient flash chromatography (10 g SiO_2, 5% MeOH/CH_2Cl_2) to yield 9 mg (1*S*,2*S*,3*S*,4*R*,5*S*,6*R*)-5,6-dibenzyloxy-cyclohexane-1,2,3,4-tetrol, in a yield of 75%.



Reference 5f.

Peracetic acid (Aldrich, 32% solution in acetic acid, 5 mL) was added dropwise at 0°C to a stirred mixture of 3 mmol *cis*-1-(phenyldimethylsilyl)-2-methyl cyclohexane, 500 mg potassium bromide, and 1.2 g anhydrous sodium acetate in 15 mL glacial acetic acid. The mixture was allowed to warm to room temperature and stirred for an additional 18 h. Then the reaction mixture was diluted with ether and carefully neutralized with saturated aqueous $NaHCO_3$ solution. The ethereal layer was washed with saturated aqueous Na_2SO_3 and brine and dried over $MgSO_4$. Ether was removed at ambient pressure, and the residue was purified by preparative column chromatography (eluent hexane, then hexanes/ether, 5:1) to give 294 mg *cis*-2-methylcyclohexanol as a colorless oil, in a yield of 86%.

242

Flood Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Flood in 1933.[1] It is a synthesis of trialkylsilyl halide involving the treatment of the mixture of di-trialkylsilyl oxide and concentrated sulfuric acid with sodium halide or ammonium halide.[2] The resulting trialkylsilyl halide can be extracted by petroleum ether and then purified via distillation.[1] It was found that when di-trimethylsilyl oxide is mixed with concentrated sulfuric acid, trimethylsilyl sulfate can be isolated as a white crystalline (m.p., 56–58°C), which forms trimethylsilyl halide when it reacts with ammonium halide.[3] The reaction has been improved by continuous extraction of the reaction mixture with pentane to yield more and purer trialkylsilyl halide[3] and by the addition of ammonium bisulfate to the reaction mixture.[3]

B. GENERAL REACTION SCHEME

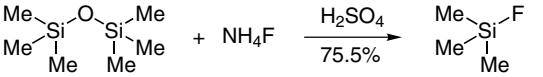
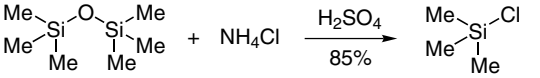
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To an ice-cold stirred solution of 32.4 g hexamethyldisiloxane (0.2 mol) in 60 mL concentrated sulfuric acid was added 24.2 g ammonium fluoride (0.7 mol) through a dropping bottle within 1 h. Warming gave 31.0 g distillate of clear colorless liquid. Two fractions were collected from fractional distillation: 3.2 g fraction 1, b.p. 15.4°C; and 27.8 g fraction 2, b.p. 15.8°C at 734 mmHg (the pure trimethylfluorosilane), in a yield of 75.5%.



Reference 4.

To a vigorous stirred solution of 324.0 g hexamethyldisiloxane (2 mol) and 1000 g concentrated sulfuric acid cooled in an ice bath was added 321.0 g dry powdered ammonium chloride (6 mol) within 3 h. Upon completion of the addition, the upper layer was separated as quickly as possible. Fraction distillation gave 369.0 g trimethylchlorosilane (3.4 mol), in a yield of 85%, b.p. 58°C.

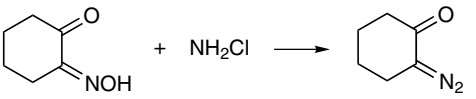
243

Forster Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Forster in 1915.[1] It is the synthesis of diazoketones, especially for the cyclic diazoketones[2] from α-keto oximes by the reaction with chloramines. Therefore, it is known as the Forster reaction.[3] Although two mechanisms have been proposed for this reaction,[3c] experimental evidence favors the one involving the attack of NH_2Cl by the lone-pair electrons of the oxime nitrogen.[3c,4] This reaction has been modified via the generation of chloramine *in situ*, which is used in the preparation of 2-diazo-1-indanones.[2a]

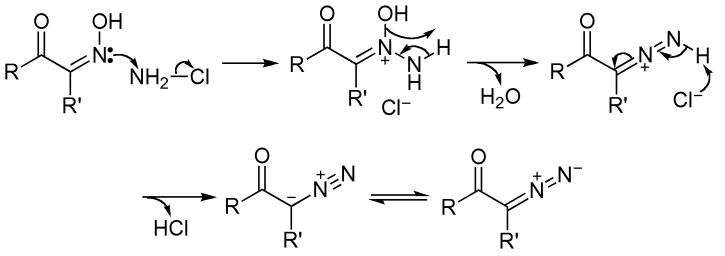
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction involves the attack of the nitrogen atom of oxime to chloramine.[3c,4]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified to generate chloramine *in situ* via the reaction of ammonia with sodium hypochlorite.[2a]

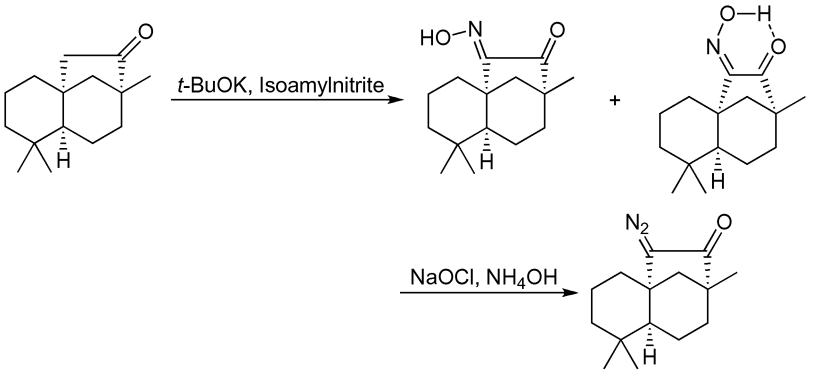
E. APPLICATIONS

This reaction is used to prepare diazoketones, especially for the cyclic diazoketones.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES

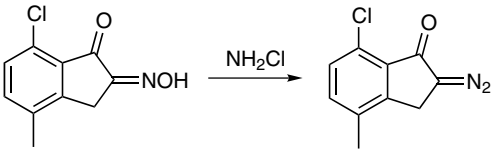


Reference 4.

To a solution of 0.08 M *t*-BuOK in 5.4 mL THF cooled to –78°C in dry ice–acetone bath was added dropwise a solution of 16 mg (1*S*,9*R*)-5,5,9-trimethyltricyclo[7.2.1.$0^{1,6}$]dodecan-10-one (0.073 mmol) and 13 mg isoamyl nitrite (0.11 mmol) in 1 mL THF. Shortly, a reddish color developed. After stirring at –78°C for 1 h, the reaction was allowed to warm up slowly to room temperature over a 30 min period and then was stirred at room temperature for another 30 min. The reaction mixture was then diluted with 20 mL Et_2O and quenched with 5 mL saturated NH_4Cl. The two phases were separated, and the aqueous phase was extracted with Et_2O (3 × 5 mL). The combined

organic phases were washed with 10 mL water, saturated aqueous $NaHCO_3$, and brine and dried over $MgSO_4$. After filtration and concentration, the residue was purified through silica gel column chromatography (EtOAc/hexanes, 1:4 to 1:2) to gave (1*R*,6*S*,9*R*,11*Z*)-5,5,9-trimethyltricyclo[7.2.1.$0^{1,6}$]dodecane-10,11-dione 11-oxime in two isomeric forms: *syn*, 5 mg, *anti*, 11 mg (88.4% combined yield).

To a vigorously stirred solution of 6.6 mg *anti*-oxime (0.027 mmol) in 2 mL THF at 0°C was added 0.37 mL 15 M $NH_3 \cdot H_2O$. The mixture was treated with 0.37 mL Clorox (a commercial bleach) dropwise. After the addition, the reaction mixture was stirred for 5 min and then worked up by dilution with Et_2O and water (10 mL each). The resulting two layers were separated, and the aqueous layer was back extracted with ether (2 × 10 mL). The combined organic layers were dried over $MgSO_4$ and concentrated under reduced pressure. The residue was purified by silica gel column chromatography (8:1 hexanes/EtOAc) to afford 3.6 mg diazo ketone, in a yield of 55%.



Reference 2a.

In a 1 L, three-necked flask equipped with a mechanical stirrer, dropping funnel, and thermometer and cooled in an ice bath was placed a solution of 6.3 g oximinoketone (0.03 mol) in a mixture of 200 mL water and 30 mL 1 *N* sodium hydroxide (0.03 mol). The stirred solution was cooled to 2°C, when a portion of the sodium salt of the oxime separated. Then 4 mL 15 *N* ammonium hydroxide (0.60 mol) was added. Next, 100 mL 5.25% sodium hypochlorite solution (0.071 mol) was added dropwise over a period of 20 min. At 1 h after the completion of the addition of the hypochlorite, the ice bath was removed, and stirring was continued for an additional 5 h. The precipitated brown solid was filtered, washed well with water, and dissolved in methylene chloride. The resulting deep red solution was treated with charcoal until orange in color; it was then filtered, concentrated, and chilled to give 3.9 g diazoketone as fine yellow needles, in a yield of 63%, m.p. 173–180°C (dec.).

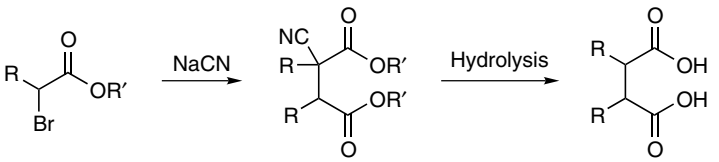
Franchimont Condensation

A. GENERAL DESCRIPTION OF THE REACTION

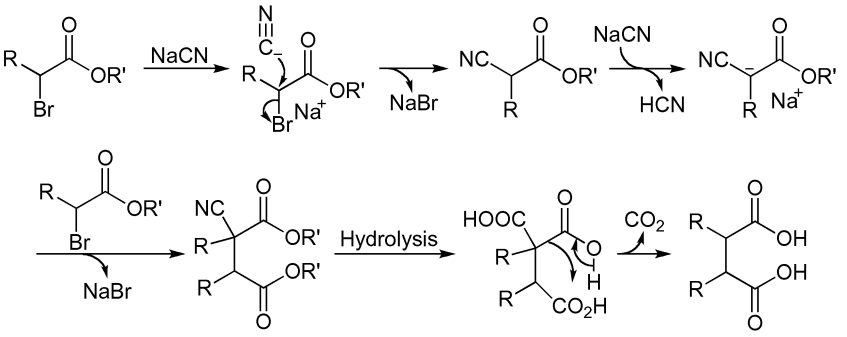
This reaction was initially reported by Franchimont in 1872.[1] It is a condensation of two α-bromocarboxylic acids in absolute alcohol in the presence of sodium cyanide to give 1,2-dicarboxylic acids after hydrolysis and decarboxylation. In the case of α-bromoketones, 1,4-diketones are produced similarly after hydrolysis with phosphoric acid.[2] It was found that the bulky group at the ester end prevents condensation, as in the case of phenyl and naphthyl esters.[3] Although the substituent at β-position does not prevent such condensation, it reduces the overall yield.[3] In addition, a compound with two ester groups at proper position will form cyclic diacid under such reaction conditions; and cyclobutane,[3,4] cyclopentane[5] and cyclohexane[5] dicarboxylic acid have been prepared in such a way. In the case of 1,4-dibromo-1,4-dibenzoylbutane, a derivative of cyclopentanone is produced after acidic hydrolysis.[2] It should be pointed out that other common solvents—including acetone, ether, and acetonitrile– are not good for this reaction.[3]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

The original condensation of two α-bromocarboxylic acids has been extended to the condensation of compounds with two α-bromocarbonyl groups.

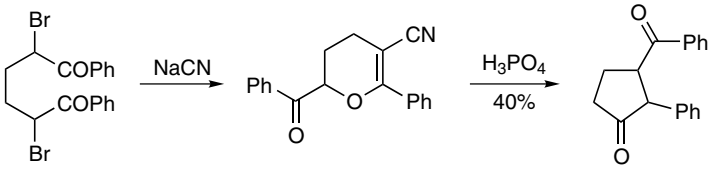
E. APPLICATIONS

This reaction has been used in the synthesis of cyclobutane, cyclopentane, and cyclohexane dicarboxylic acids.

F. RELATED REACTIONS

This reaction is related to the *Acyloin Condensation* and *Benzoin Condensation*.

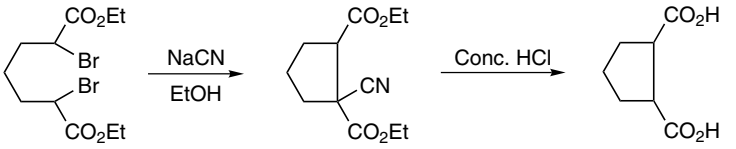
G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To a mixture of 300 mL 85% phosphoric acid and 25 mL 95% ethanol was added 10.0 g cyano dihydropyran prepared from 1,4-dibromo-1,4-dibenzoylbutane and sodium cyanide. The solution was stirred for 18 h at room temperature and then refluxed for 8 h. When the solution was cooled down, it was diluted to a volume of 1800 mL in a 2-L

beaker by the addition of water. The yellow solid was filtrated after a few hours, and 40% 2-phenyl-3-benzoylcyclopentanone was recrystallized from ethanol, m.p. 159.0–159.5°C.



Reference 5.

A mixture of 50.0 g ethyl α,α'-dibromopimelate, 25.0 g powdered sodium cyanide, and 30 mL absolute ethanol was refluxed for 60 h. Sodium bromide and excess sodium cyanide were removed from the cooled mixture by filtration and washed with 10 mL ethanol. The filtrate, when distilled in vacuo, gave a colorless distillate boiling at 125–130°C at 2 mmHg. Redistillation gave 25–29 g ethyl 1-cyano-1,2-cyclopentanedicarboxylate at 135–136°C at 3.5 mmHg or 126–128°C at 2 mmHg pressure, with a corresponding yield of 80–88%.

Ethyl 1-cyano-1,2-cyclopentanedicarboxylate (15.0 g) was hydrolyzed by refluxing with 75 mL concentrated HCl for 30 h. The ester dissolved completely, giving a light brown solution that deposited, on cooling, 5 g crude *trans*-1,2-cyclopentanedicarboxylic acid with a melting point at 155–158°C. This was converted into the pure *trans* acid by being heated to 160°C with 1 mL concentrated HCl in a sealed tube for 1 h. The pure *trans* acid melted at 161°C.

Other references related to the Franchimont condensation are cited in the literature.[6]

Frankland Reaction

A. GENERAL DESCRIPTION OF THE REACTION

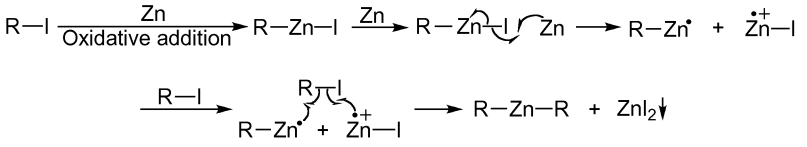
This reaction was initially reported in 1848 by Frankland,[1] who tried to prepare ethyl radical from zinc and ethyl iodide in a sealed tube.[2] However, he obtained diethyl zinc. This event is probably the origin of organometallic chemistry,[2,3] because diethyl zinc was the first synthetic organometallic compound.[2,4] Therefore, the preparation of dialkyl zinc from zinc and alkyl iodide is called the Frankland reaction.[5] Currently, alkyl zinc has found many applications in organic synthesis,[6] because the addition of alkyl zinc to aldehydes in the presence of a chiral catalyst affords secondary alcohols with a high level of enantioselectivity;[7] in addition, organic zinc reagents can tolerate a broad range of functionalities.[8] It should be pointed out that dialkyl zinc forms a complicated complex rather than a simple zinc alkoxide when it is exposed to oxygen.[9] Moreover, the direct preparation of dialkyl zinc from alkyl iodide and zinc followed by distillation is best for compounds with a short hydrocarbon chain (e.g., from C1 to C4).[10] Besides the Frankland reaction, other methods for preparing dialkyl zinc compounds have been developed, including the reactions between the activated zinc and the alkyl halide,[11] the reaction of zinc with a mixture of alkyl iodide and alkyl bromide,[8a] the transmetalation of lithium[11,12] or magnesium[9] organometallics with zinc salts, and the iodine-zinc exchange.[6]

B. GENERAL REACTION SCHEME

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is suggested that the reaction between zinc and alkyl bromide involves an electron transfer, but the details of the mechanism are not given.[8a] Therefore, it is reasonable to assume that the reaction between zinc and alkyl iodide also involves electron transfer, as outlined here.



D. MODIFICATION

A few modifications of this reaction are the reaction between alkyl iodide and copper-zinc alloy,[3c,11] the reaction between zinc and a mixture of alkyl iodide and alkyl bromide,[8a] the transmetalation between zinc and lithium,[11,12] magnesium,[9] or tin,[5d] and the iodine-zinc exchange.[6]

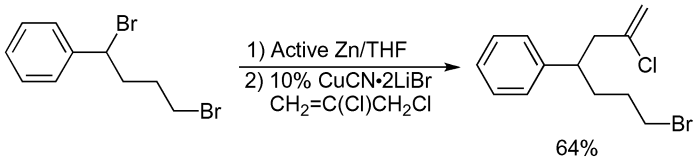
E. APPLICATIONS

The prepared organozinc reagents have wide application in organic synthesis.

F. RELATED REACTIONS

This reaction is related to the *Grignard Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8a.

To a 50-mL centrifuge tube containing 584.1 mg 1,4-dibromo-1-phenylbutane (2.0 mmol) in 10 mL anhydrous THF at 0°C (equipped with a stirring bar and septum) was added 1.5 mL active zinc suspension of THF (2.2 mmol, 10 g/100 mL) via a disposable syringe under argon atmosphere. The mixture was stirred at 0°C for 10 min, then the organozinc reagent was centrifuged for 2 min at 2500 rpm, and the content of the tube was

cannulated to a 100-mL, two-necked flask at –30°C containing 17.9 mg copper (I) cyanide (0.2 mmol) and 17.4 mg LiBr (0.4 mmol) in 10 mL THF. 2,3-Dichloropropene (222 mg, 2.0 mmol) was added immediately to the flask. After 3 h, the temperature was allowed to rise to room temperature, and stirring was maintained for an additional 3 h. After this, 50 mL hexanes was added, the mixture was hydrolyzed with 1 M HBr and extracted with hexanes (2 × 50 mL), the organic phases were dried over magnesium sulfate, and the solvents were removed at 30°C and a pressure of 15 mmHg. Kugelrohr distillation afforded 64% 7-bromo-2-chloro-4-phenyl-1-heptane.

Reference 3c.

To a 1-L round-bottomed flask equipped with a reflux condenser and a heavy stirrer was placed 130.0 g fine turnings of a zinc-copper alloy containing 5–8% copper (~2 mol), 0.5 mol *n*-butyl iodide, and 0.5 mol *n*-butyl bromide. The mixture was gently refluxed with slow stirring. In case the reaction became too vigorous, the flask was cooled with ice water, but only to the point at which the reaction was again under control. At the end of 30 min from the time the heat was removed, the reaction was usually over. The flask was allowed to cool and was connected with a distilling head and condenser; the di-*n*-butyl zinc was distilled directly from the reaction flask at 9 mmHg at 81–82°C. The apparatus need not be swept out with an inert gas before starting the distillation, but at the end, when the vacuum was released, dry carbon dioxide was admitted to the apparatus instead of air. Finally 78–79% of di-*n*-butyl zinc was obtained, and an equal weight of the desired dry solvent was added to the receiving flask. The resulting solution was ready for subsequent reaction of such zinc reagent.

Other references related to the Frankland reaction are cited in the literature.[14]

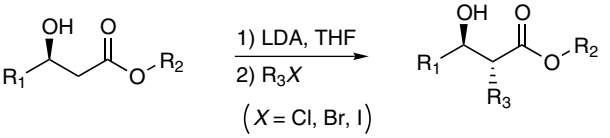
Fráter-Seebach Alkylation

A. GENERAL DESCRIPTION OF THE REACTION

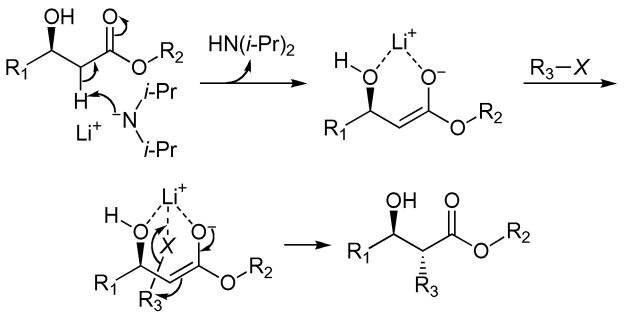
This reaction was initially reported by Fráter in 1979[1] and subsequently by Seebach and Wasmuth in 1980.[2] It is a reaction between a lithium enolate of an enantiomerically pure β-hydroxyl carboxylate and a alkyl halide to give α-alkyl-β-hydroxyl-carboxylate with high diastereoselectivity (> 10:1 of *anti*- preference).[3] Therefore, this special type of alkylation is generally known as the Fráter-Seebach alkylation.[3,4] Occasionally, it is also referred to as the Fráter-Seebach protocol.[5] The high diastereoselectivity is clearly evidenced in one experimental condition, in which only the *anti*-diasteromer forms.[4f,5] The resulting α-alkyl-β-hydroxy-carboxylate is often an important intermediate in natural product synthesis;[3,4d,4h] in addition, it can also be reduced by lithium aluminum hydride (LAH) to form diastereomerically pure 1,3-diol,[4g] which forms 1,3-dioxane with a carbonyl compound (acetal or ketal),[4b,4g] an important intermediate in organic synthesis. It is assumed that the high diastereoselectivity arises from the chelation.[5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This stereoselective alkylation has been extended to γ-hydroxyl-carboxylic acid that exists as a lactone.[4h]

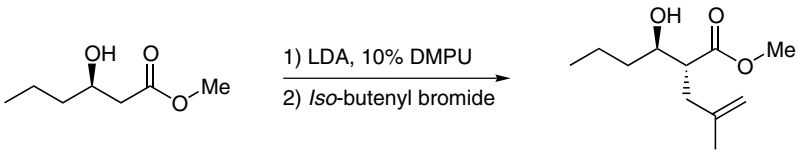
E. APPLICATIONS

This reaction has certain application in the preparation of multifunctional chiral compounds.

F. RELATED REACTIONS

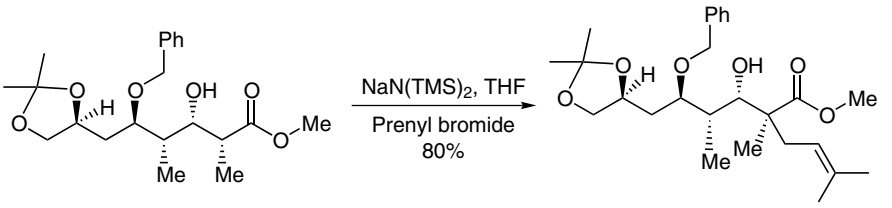
This reaction is related to the *Aldol Reaction* and *Evans Aldol Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

LDA (2.1 eq.) was generated by the addition of 2.55 M *n*-BuLi in THF to a 1.0 M solution of diisopropylamine (2.1 eq.) in THF at 0°C. After 15 min, the LDA solution was cooled to –78°C and 1.0 eq. THF solution of β-hydroxy ester was added dropwise via syringe such that the internal temperature was maintained at or below –65°C. Then 1.1 eq. *iso*-butenyl bromide was added via syringe followed by DMPU (10% v/v). The reaction mixture was stirred at –78°C for 5 min then allowed to come to 0°C over 24–48 h until the reaction was complete by TLC. The reaction mixture was then quenched with saturated NH_4Cl and extracted with ether, the organic layers were combined and washed with 1 N HCl, 5% $NaHCO_3$, and brine and dried over $MgSO_4$. Removal of the solvent and silica gel chromatography afford the product. (No yield was given for this reaction.)



Reference 4f.

To 33.5 mL 1.0 M sodium hexamethyldisilazide in hexane (33.5 mmol) at −78°C was added 2.55 g 2,4,6-trideoxy-2,4-dimethyl-7,8-*O*-(1-methylethylidene)-5-*O*-(phenylmethyl)-D-*glycero*-D-*gluco*-octanoic acid methyl ester (6.70 mmol) in 35 mL THF dropwise via cannula. Once the addition of the ester was complete, the mixture was warmed to –20°C (internal thermometer) for 30 min and was then recooled to –78°C. Prenyl bromide (10 g, 70 mmol, 7.8 mL), freshly distilled from anhydrous K_2CO_3, was added, and stirring was continued at –78°C for 3 h. The reaction mixture was gradually warmed to 0°C over 3 h and was maintained at that temperature for an additional 9 h. The reaction was quenched by the addition of 50 mL saturated aqueous NH_4Cl, followed by the addition of 200 mL Et_2O. The organic layer was washed with 75 mL water and 75 mL brine, and the combined aqueous layers were back extracted with Et_2O (2 × 50 mL). The ethereal extracts were dried over $MgSO_4$, filtered, and concentrated. Silica gel chromatography (23% EtOAc/hexane) gave 2.41 g (2*S*)-2,4,6-trideoxy-2,4-dimethyl-2-(3-methyl-2-butenyl)-7,8-*O*-(1-methylethylidene)-D-*altro*-octonic acid methyl ester as a viscous yellow oil, in a yield of 80%, $R_f = 0.48$ (EtOAc/hexanes, 2:3).

Other references related to the Fráter-Seebach alkylation are cited in the literature.[6]

Freund Reaction
(Hass Cyclopropane Process)

A. GENERAL DESCRIPTION OF THE REACTION

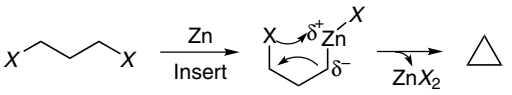
This reaction was initially reported by Freund in 1881.[1] It is a preparation of cyclopropane derivatives from internal nucleophilic displacement of 1,3-dihalopropanes with the treatment of sodium. The further modification of this reaction by treatment of 1,3-dihalopropane with zinc dust is called the Gustavson reaction,[2] whereas treatment with zinc dust in aqueous alcohol in the presence of a catalytic amount of NaI is called the Hass cyclopropane process.[3] Although the Freund condition is challenged because of its similarity to the *Wurtz Reaction*,[4] the preparation of cyclopropane from 1,3-dihalopropane is more often called the Freund reaction,[4,5] including the condition of Gustavson.[5e,6] Similar to zinc, magnesium also reacts with 1,3-dihalopropane to give cyclopropane.[6] In this reaction, metal zinc or magnesium inserts into a carbon-halogen bond, and the resulting carbanion attacks the nearby alkyl halide to form the cyclopropane ring. It has been reported that 1,3-diiodopropane also cyclizes under radical conditions.[7] Due to the steric effect, the primary, primary 1,3-dibromides give high yields of cyclopropanes; primary, secondary dibromides give fair yields of cyclopropanes; and secondary, secondary dibromides afford poor yields.[5e] In some cases, olefin is produced as the principal or sole product.[5e]

B. GENERAL REACTION SCHEME

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Illustrated here is the mechanism for the reaction between zinc and 1,3-dibromopropane.



D. MODIFICATION

The Gustavson and Hass conditions are the further modifications of the original Freund procedure.

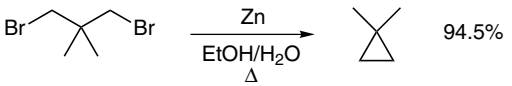
E. APPLICATIONS

This reaction has general application in the preparation of cyclopropanes and probably for cyclobutanes and cyclopentanes as well.

F. RELATED REACTIONS

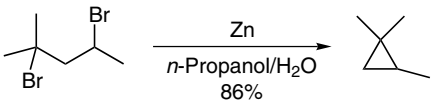
This reaction is related to the *Wurtz Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

In a 2-L, three-necked flask equipped with a dropping funnel, mercury-sealed stirrer, and reflux condenser (connected to a trap surrounded by a dry ice–acetone bath) were placed 900 mL 95% ethanol, 90 mL distilled water, and 628 g zinc dust (9.6 mol). It was necessary to maintain vigorous stirring at all times to prevent caking of the zinc. The mixture was brought to gentle reflux, and 562 g 1,3-dibromo-2,2-dimethylpropane (2.4 mol) was added dropwise at this temperature. Heating and stirring were continued for 24 h after the last of the dibromide had been added; the bulk of the hydrocarbon was collected in the trap during this period. The remaining 1,1-dimethylcyclopropane (along with some alcohol) was then distilled from the reaction flask and was collected in the trap. The crude 1,1-dimethylcyclopropane (162 g) was washed with ice water and dried, in a crude yield of 94.5%.



Reference 5e.

To a 1-L, three-necked flask fitted with a reflux condenser, thermometer, dropping funnel, and mercury sealed stirrer was added 100 mL water, 300 mL *n*-propyl alcohol, and 196.0 g oxygen-free zinc dust (3.0 mol, prepared from commercial grade zinc dust). The flask was placed in an ice bath, and 214 g freshly distilled 2-methyl-2,4-dibromopentane (1 mol) was added dropwise with efficient stirring over a period of ~ 90 min. The ice bath was then removed, and the mixture was stirred at room temperature for ~ 32 h. After ~10 h an immiscible layer of hydrocarbon had formed. At the end of the reaction, the hydrocarbon product was separated by distillation. 1,1,2-Trimethylcyclopropane was collected over a temperature range of 49–51°C and weighed 78.1 g, in a yield of 86%. The distillate contained a small amount (2 or 3 mL) propyl alcohol and water; therefore, it was washed twice with 100-mL portions of ice water to remove the alcohol and cooled to freeze the aqueous layer. The hydrocarbon was poured off. The crude 1,1,2-trimethylcyclopropane was purified by distillation in a vertical surface column operating under conditions that gave an efficiency of 100 theoretical plates calculated by the method of Calingaert and Beatty.

Other references related to the Freund reaction are cited in the literature.[8]

248

Friedel-Crafts Acylation

A. GENERAL DESCRIPTION OF THE REACTION

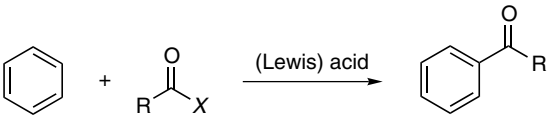
This reaction was initially reported by Friedel and Crafts in 1877.[1] It is an electrophilic aromatic substitution by an acyl group derived from carboxylic acid derivatives in the presence of a Lewis acid or Brønsted acid. Therefore, this reaction is generally known as the Friedel-Crafts acylation.[2] Generally speaking, this reaction involves four basic elements: the aromatics, acylating agents, catalysts, and solvents. As of the electrophilic nature, the more enriched the electron is on the aromatic ring, the easier the reaction occurs; therefore, electron-donating groups on aromatic rings usually facilitate the reaction, whereas electron-withdrawing groups normally impede the reaction. Nitrobenzene, with its strong electron-withdrawing nitro group that usually inhibits acylation,[3] is often used as the solvent for Friedel-Crafts acylation.[4] On the other hand, the acylating agents of carboxylic acid derivatives also influence this acylation; the more the electrophilic the acylating agent, the faster the acylation proceeds. Consequently, the commonly used acylating agents are acyl halides (mostly acyl chloride) and acyl anhydrides, though other derivatives—including carboxylic acids,[5] esters,[4,6] and lactams[7]—are also used in the direct acylation. In addition, to increase the electrophilicity of acylating agents, at least 1 eq. of Lewis acid is used in this reaction.[4] The Lewis acids used in the acylation with acyl halides include $AlCl_3$, $AlBr_3$, $BeCl_2$, $CuCl_2$, $FeBr_3$, $HgCl_2$, $MbCl_5$, $SbBr_3$, $SbCl_5$, $TiCl_4$, UCl_4, WCl_6, and $ZrCl_4$.[4] When acyl anhydrides are used as acylating agents, effective catalysts are $AgClO_4$, BF_3, CF_3CO_2H, $(CF_3CO)_2O$, $HClO_4$, HF, H_3PO_4, $SnCl_4$, $SOCl_2$, $ZnCl_2$, etc.[4] Although many compounds that do not undergo the Friedel-Crafts acylation can be used as the solvent, the commonly used solvents are nonpolar carbon disulfide for heterogeneous acylation and polar nitrobenzene for homogenous acylation.[4] It is known that the Lewis acid forms a complex with the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

acylating agent that is sufficiently electrophilic to react with an aromatic ring,[8] resulting in a ketone–Lewis acid complex as the actual reaction product, which prevents further reaction (e.g., rearrangement) and gives high yields of pure product. Therefore, water or dilute HCl is often used to decompose the ketone–Lewis acid complex. This is the reason at least 1 eq. of Lewis acid is needed for the acylation with acyl halide. Other acylating agents might need more than 1 eq. of Lewis acid.[4] From this point of view, the Lewis acids are the promoters, not the catalysts, although recent developments have made this acylation catalytic.[6a,9]

The Friedel-Craft acylation is usually considered irreversible; however, if the acyl group is tilted out of the plane of the aromatic ring by a neighboring bulky group, isomers form from the reversible acylation.[10] The intermolecular acylation can provide the aromatics with long hydrocarbon chains without rearrangement after reduction of the carbonyl groups, whereas intramolecular acylation can synthesize benzocyclic ketones including 1-indanones, 1-tetralones, and 1-benzosuberones.[6a] The direction of acylation follows the *Crum-Brown-Gibson Substitution Rule*—that is, the acylation occurs often at the *para*-position of the electron-donating group, and occurs much less at the *ortho*-position because of steric hindrance. It was found that when both amino and thioether groups exist on the same aromatic ring, the amino group is the determining group for acylation direction.[11] Other developments for the Friedel-Crafts acylation include (*a*) application of ionic liquids as recyclable catalyst and media for acylation;[9b,12] (*b*) application of $AgSbF_6$,[13] Bi_2O_3,[9b] $Bi(OTf)_3$,[9b] $[(CuOTf)_2PhH]$,[14] Envirocats,[15] $EtAlCl_2$,[16] Nafion-H,[9a,17] zeolite,[18] and ZnO[19] as new catalysts; (*c*) application of acylals as acylating agents, giving different products depending on the conditions and the amount of catalysts;[20] and (*d*) acylation of alkenes to make β,γ-unsaturated ketones.[16] Further information about the Friedel-Crafts acylation can be found in reviews.[4,21]

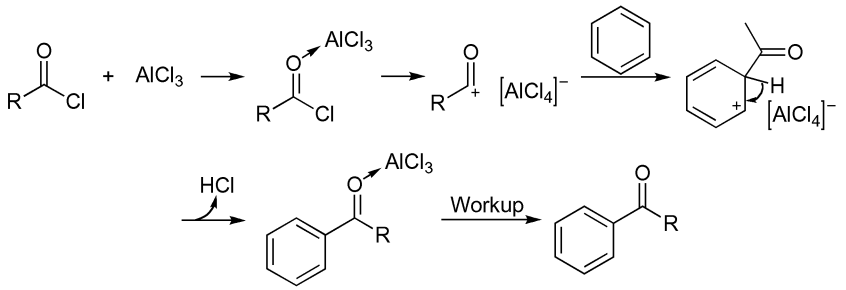
B. GENERAL REACTION SCHEME



(*X* = halogen, OC(O)R′, OR′, NHR′, OH, etc.)

C. PROPOSED MECHANISMS

Demonstrated here is the mechanism of the acylation of benzene using acyl chloride as the acylating agent and $AlCl_3$ as an acylation promoter.



D. MODIFICATION

Because of its importance in aromatic chemistry, the Friedel-Crafts acylation has been extensively modified, including the use of different acylating agents and different acylation promoters.

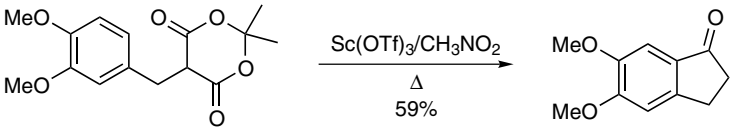
E. APPLICATIONS

This reaction has wide application in the preparation of aromatic derivatives.

F. RELATED REACTIONS

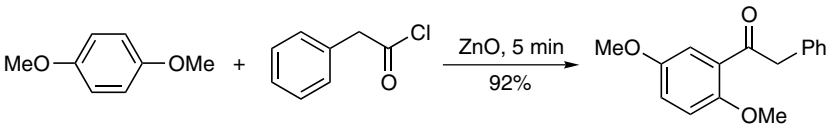
This reaction is related to the *Friedel-Crafts Alkylation, Darzens Olefin Acylation, Fries Rearrangement, Haworth Phenanthrene Synthesis*, and *Nencki Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 6a.

In a flame-dried, round bottomed flask equipped with a magnetic stir bar and a reflux condenser and under inert atmosphere were placed 200 mg 5-(3,4-dimethoxybenzyl)-2,2-dimethyl-1,3-dioxane-4,6-dione and 0.1 eq. $Sc(OTf)_3$. Nitromethane was added in one portion by syringe, and the resulting suspension was immediately placed into an oil bath preheated to 100°C. The reaction was maintained at this temperature and monitored by TLC until complete consumption of the starting material was observed (~ 45 min). The reaction mixture was then concentrated under vacuum and directly subjected to flash chromatography, using a small quantity of CH_2Cl_2 to assist column loading, using hexane/EtOAc (6:5) as an eluent to afforded 59% 5,6-dimethoxy-1-indanone as a white solid, m.p. 116–118°C after crystallization from CH_2Cl_2.



Reference 18.

1,4-Dimethoxybenzene (1 mmol) was added to a mixture of 0.04 g ZnO powder (0.5 mmol) and 1 mmol phenyl acetyl chloride at room temperature and stirred with a magnetic stirrer. Color (usually pink) developed immediately and darkened with the progress

of the reaction. The reaction mixture was kept at room temperature with occasional stirring for 5 min as required to complete the reaction (monitored by TLC). The solid mass was then eluted with 20 mL dichloromethane, and the dichloromethane extract was then washed with an aqueous solution of sodium bicarbonate and dried over anhydrous sodium sulfate. Evaporation of solvent furnished practically pure (phenyl)-acetyl-(2,5-dimethoxy)-benzene in 92% of yield.

Friedel-Crafts Alkylation

A. GENERAL DESCRIPTION OF THE REACTION

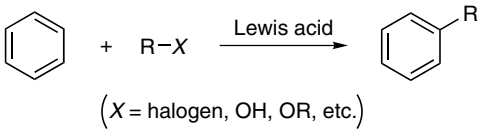
Although this reaction was first discovered by Wurtz,[1] it is generally known as the Friedel-Craft alkylation[2] after Friedel and Crafts reported their work in 1877.[3] It is a special class of electrophilic aromatic substitution in which the electrophile is a carbocation.[4] Similar to the *Friedel-Crafts Acylation*, the electron-donating groups facilitate the alkylation, whereas the electron-withdrawing groups impede the alkylation. In addition, an acidic catalyst (either a Brønsted acid or a Lewis acid) is needed to enhance the electrophilicity of the alkylating agent. Often this alkylation is carried out between the aromatics and alkyl halides in the presence of a Lewis acid.[5] The Lewis acid generally polarizes the alkyl halide, making the hydrocarbon part to bear a more positive charge and become more electrophilic, which then saturates its electron deficiency from electron-rich aromatics by forming a π-complex that further transforms into a σ-complex while sacrificing the aromaticity. Extrusion of proton in such σ-complex will regain the aromaticity.

Besides the most common alkylating agents of alkyl halides, other types of organic compounds—including alcohols,[6] aldehydes,[6b,7] esters,[8] ethers,[6b] imines,[9] hydrozones,[10] olefins[11]—also react with the aromatics to give the alkylated products. Among these alkylating agents, the esters have shown their advantage over alkyl halides and have been extensively explored. So far, the esters used in alkylation include alkyl sulfates, sulfites, phosphates, orthosilicates, carbonates, borates, chloroformates, hypochlorites, halosulfates, chlorosulfites, arenesulfonates, perchlorate, arenesulfinates, chloro- and fluorosulfates, triflates, pentafluorobenzenesulfonates, trifluoroacetates, acetates, formates, oxalate, silicate, and carboxylate.[8] The solvents can be nitromethane, methylene chloride, carbon disulfide,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

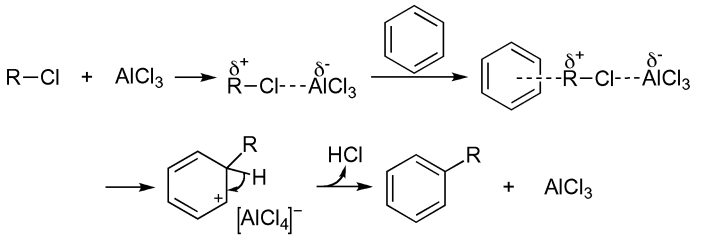
1,1,2-trichlorotrifluormethane, etc.[8a,12] The generally used Lewis acid catalysts in alkylation are arranged in the following order of decreasing Lewis acidity: $Al_2Br_6 > Al_2Cl_6 > Al_2I_6 > Ga_2Br_6 > Ga_2Cl_6 > Fe_2Cl_6 > SbCl_5 > ZrCl_4$, $SnCl_4 > BCl_3$, BF_3, $SbCl_3$.[13] However, the Friedel-Crafts alkylation is also different from the *Friedel-Crafts Acylation*, with its characteristic limitations such as disproportionation,[14] isomerization,[6d,6f,15] over alkylation,[16] sensitivity to trace amounts of water,[17] and side reactions of alkylating agents. All these disadvantages can be linked to the character of carbocation in this reaction. For example, the disproportionation originates from the isomerization of a σ-complex to a more stable σ-complex during the alkylation if more than one alkyl group exist on the aromatic ring; the isomerization of an alkylated group comes from the rearrangement of a carbocation to form a more stable carbocation, as shown in the preparation of *t*-butyl aromatics from *sec*-butyl halide;[15a,15c] in addition, the alkyl group on the alkylated aromatics is normally an electron-donating group that enriches the electron density on the aromatics and facilitates further alkylations; when olefins are used as the alkylating agents, they can polymerize in the presence of a strong Lewis acid. Because of the acidic nature of this alkylation, the acid-labile aromatics are not feasible for this reaction, such as many heterocycles. Although nitrobenzene is known to be inert for the *Friedel-Crafts Acylation*, it can undergo the alkylation with ethanol in sulfuric acid;[18] similarly, many moderately inert aromatics also undergo the alkylation with ethyl, *n*-propyl, isopropyl, and *n*-butyl alcohol (except for methanol and *t*-butyl alcohol) when sulfuric acid, PPA, or 85% phosphoric acid is used as the catalyst.[6c] Even the highly electron deficient pentafluorobenzene can react with methylene chloride or chloroform.[19] Recent advances in the Friedel-Crafts alkylation include (*a*) development of new alkylating catalysts, such as zeolite,[20] cation-exchanged Montmorillonite,[21] hetereobimetallic,[6a] and rare earth metal salts;[6b] (*b*) application of new reaction media, such as supercritical CO_2;[22] (*c*) development of new alkylating agents, such as vinyl chlorosilanes,[16a,23] nitrosoamide,[5] and benzyl *N*-sulfamoylcarbamates,[24] (among which the benzyl *N*-sulfamoylcarbamates can react with aromatics even in the absence of an acidic catalyst); and (*d*) development of an unsymmetrical alkylation system using chiral catalysts to form enantiomerically pure products.[9,10,11a,11c,25] Further information about the Friedel-Crafts alkylation are provided in reviews.[26]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Demonstrated here is the mechanism for the alkylation of benzene with alkyl halide using $AlCl_3$ as the catalyst.



D. MODIFICATION

This reaction has been extensively modified by the application of different catalysts, reaction media, and alkylating agents.

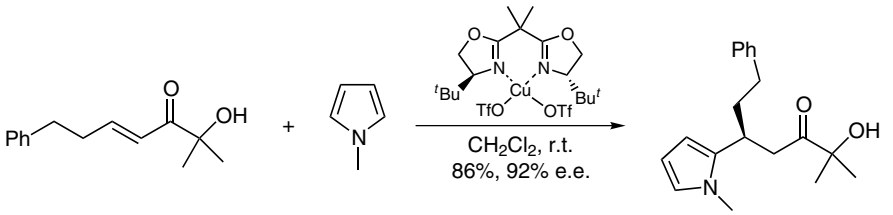
E. APPLICATIONS

This reaction has wide application in the preparation of substituted aromatics.

F. RELATED REACTIONS

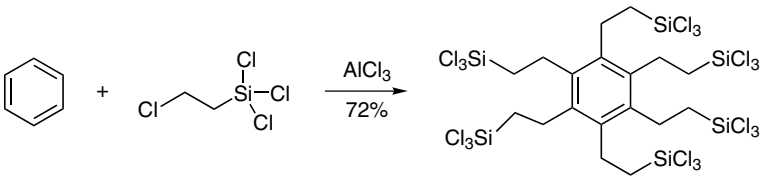
This reaction is related to the *Friedel-Crafts Acylation* and *Baddeley Isomerization*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 11a.

2,2′-Isopropylidene bis[(4*S*)-4-*tert*-butyl-2-oxazoline] (0.06 mmol) was weighed in a flame-dried flask and placed under nitrogen, followed by the addition of 18.0 mg $Cu(OTf)_2$ (0.05 mmol) by rinsing with 1.0 mL dry CH_2Cl_2 from a weighing boat. After stirred at room temperature for 3 h, 0.5 mmol hydroxy enone in 0.5 mL dry CH_2Cl_2 was cannulated into the solution followed by a rinse using 0.5 mL CH_2Cl_2; the resulting mixture was stirred for a further 10 min at room temperature. Then 109 mg *N*-methyl pyrrole (89 μL, 1 mmol) was added dropwise by syringe directly into the reaction, and the mixture was stirred at room temperature under nitrogen for 2 h. The resulting reaction mixture was diluted with 10 mL NH_4Cl and extracted with CH_2Cl_2 (3×10 mL). The CH_2Cl_2 layers were combined, dried over anhydrous $MgSO_4$, and concentrated. The crude product was purified by column chromatography on SiO_2 (hexane/EtOAc, 9:1) to afford 129 mg 2-hydroxy-2-methyl-5-(1-methyl-1H-pyrrol-2-yl)-7-phenyl-heptan-3-one as a thick yellow oil, in a yield of 86% with 92% e.e.



Reference 16a.

To a stirring suspension of 1.0 g benzene (12.8 mmol) and 1.0 g $AlCl_3$ (7.5 mmol) was added 16.7 g 2′-chloroethyl-trichlorosilane (84.4 mmol) at a pumping rate of 0.3 mL/min using a syringe pump at 70°C. A moderately exothermic reaction was observed. The reaction mixture was stirred for additional 3 h at 70°C. Dried hexane (100 mL) and 1.9 g NaCl (32.5 mmol) were added to the reaction mixture, and the mixture was then stirred at the reflux temperature of hexane for 2 h. Solid products and NaCl-$AlCl_3$ complex insoluble in hexane were filtered out, washed three times with hexane (20 mL × 3), and dissolved in dried THF. The NaCl-$AlCl_3$ complex insoluble in THF was filtered off. The filtrate was concentrated by evaporation and cooled to −30°C to afford yellowish white crystals. These crystals were powdered and then kept under vacuum conditions (150°C at 0.2 mmHg) for 24 h to give 9.7 g of a mixture of hexa-(trichlorosilylethyl) benzene and THF (∼ 10 mol %), in a yield of 72% , m.p. 260°C (dec. slowly).

Other references related to the Friedel-Crafts alkylation are cited in the literature.[27]

Friedländer Condensation

(Friedländer Synthesis, Friedländer Reaction, Friedländer Quinoline Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

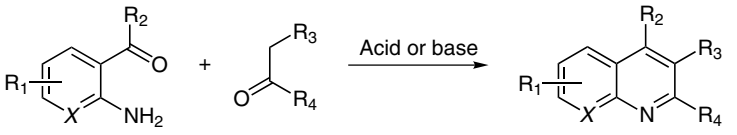
This reaction was initially reported by Friedländer in 1882.[1] It is a preparation of nitrogen-containing heterocycle (mostly, 2,3-disubstituted quinolines) from an aromatic *ortho*-aminoaldehyde (or ketone) and an aldehyde (or ketone) bearing an active α-methylene functionality. This reaction is considered to be one of the most successful methods for preparing quinoline derivatives,[2] often in high yield.[2c,3] Therefore, it is generally known as the Friedländer condensation,[4] Friedländer synthesis,[2b,4k,5] or Friedländer reaction.[2a,2c,4i,4o,6] In addition, over the past 120 years, this reaction has been referred to as the Friedländer annulation,[2a,5m,7] Friedländer heteroannulation,[5m,8] Friedländer methodology,[4n,9] and Friedländer quinoline synthesis.[2a,5m,5t,10]

This reaction often occurs in one pot[4c] and involves two distinct steps:[6o] (*a*) condensation between the amino group and the carbonyl group of the aldehyde or ketone to form anil, and (*b*) an irreversible intramolecular condensation between the active methylene or α-methyl group and the carbonyl group attached to the aromatic ring. Therefore, it is assumed that aldol type condensation is involved at a certain stage of the overall condensation.[2a,2d] Consequently, both acid and base can catalyze this reaction; HCl, H_2SO_4, *p*-TsOH, and PPA were widely applied as acid catalysts,[2a,4l,4o,5m] and NaOH and NaOEt were employed as base catalysts.[2a,4m] It has been suggested that an acid catalyst is better than a base catalyst for this condensation.[2d] In addition, this reaction is usually carried out in a polar solvent, such as CH_3CN, THF, DMF, and DMSO;[5m] otherwise, the reaction

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

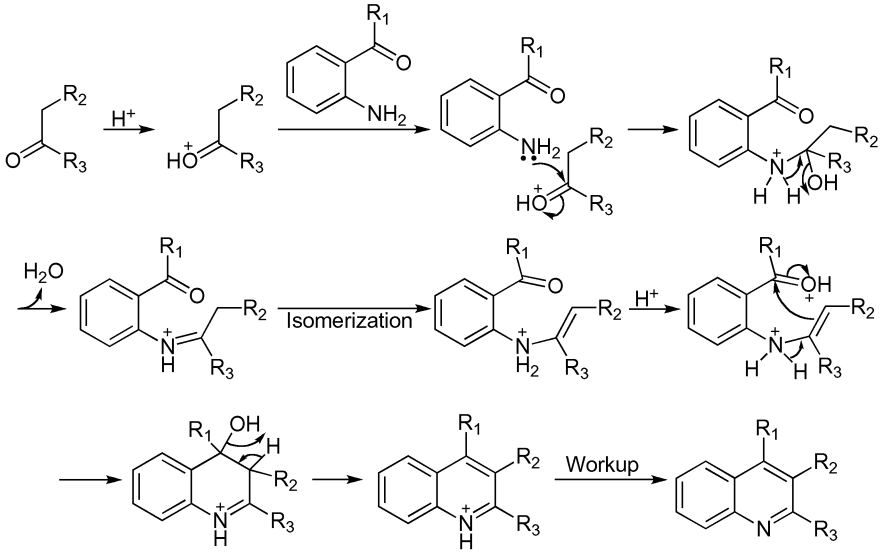
will occur in drastic conditions (e.g., 150–220°C) in the absence of a catalyst and solvent.[2d,5m] Although the Friedländer condensation indeed has some limitations when unsymmetrical ketones participate in the condensation with aromatic *o*-aminoaldehyde or ketones,[2a,2c,2d,5m] it has been extended to occur under various conditions, including the employment of microwaves,[11] gold(III) compounds,[12] NaF (in solid state),[4e] $FeCl_3 \cdot 6H_2O$ in ionic liquids,[6k] $FeCl_3$,[5i] $Mg(ClO_4)_2$,[5i] $SnCl_2 \cdot 2H_2O$,[5k] sulfamic acid,[10b] Lewis acidic ionic liquid,[5l] and pyrrolidine[2a] as promoters or catalysts. Other modifications involve traceless solid phase synthesis[5n] and preparation of polymers containing quinoline moieties.[3,4j,10d] The application of pyrrolidine in particular provides a mild, wide functionality tolerated reaction that occurs even for the unactivated methyl ketone.[2a] So far, this reaction has been used in the synthesis of quinolines, 1,8-naphthyridines,[2a,4c,4i,13] huprines,[6m] and chromeno[2,3-b]pyridines derivatives.[2a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Demonstrated here is the mechanism for an acid-catalyzed Friedländer condensation between an aromatic *o*-aminoketone and a ketone.



D. MODIFICATION

This reaction has been extensively modified to occur under various conditions as described in Section A.

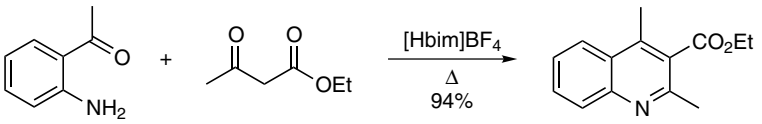
E. APPLICATIONS

This reaction has been used in the preparation of quinolines, naphthyridines, huprines, and other polycyclic heterocycle derivatives.

F. RELATED REACTIONS

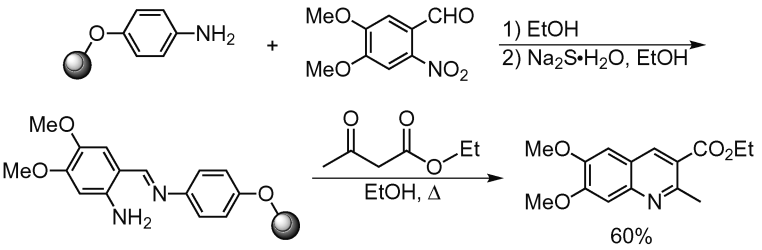
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5m.

A mixture of 1 mmol *o*-amino-acetophenone, 1 mmol ethyl acetoacetate, and 1 mmol 1-butylimidazolium tetrafluoroborate [Hbim]BF_4 was heated at 100°C with good stirring for 3 h. The completion of reaction was monitored by TLC (EtOAc/petroleum ether, 1:4). After completion of the reaction, the reaction mixture was diluted with 25 mL water. The ethyl 2,4-dimethylquinoline-3-carboxylate was extracted with EtOAc (2 × 10 mL) and dried over Na_2SO_4. After removal of solvent, the crude product was purified by column chromatography (EtOAc/petroleum ether, 1:4), to afford 94% ethyl 2,4-dimethylquinoline-3-carboxylate as oil. The aqueous layer consisting of the ionic liquid was distilled (80°C at 10 mmHg) for 2 h to remove water and recycle 98% of the ionic liquid [Hbim]BF_4.



Reference 5n.

TentaGel resin containing aniline residue (0.25 mmol/g, 1 g, 0.25 mmol) and 211 mg 3,4-dimethoxy-6-nitrobenzaldehyde (1 mmol) were weighed into a 16 × 115 mm test tube. After adding 20 mL ethanol, the test tube was equipped with an agitation magnet, topped with a Teflon cap, and fitted with the parallel reflux bar (First Mate). The resulting mixture was stirred at reflux for 3 h. After being cooled to room temperature, the beads were filtered, successively washed with ethanol (2 × 30 mL) and CH_2Cl_2 (2 × 30 mL), and dried at room temperature under vacuum overnight to afford 1.050 g of resin containing nitrobenzene.

The nitrobenzene-containing resin (0.25 mmol/g, 1 g, 0.25 mmol) and 240 mg $Na_2S{\cdot}H_2O$ (2.5 mmol) were weighed into a 16 × 115 mm test tube. After the addition of 15 mL ethanol, the reaction vessel was equipped with an agitation magnet, topped with a Teflon cap, and fitted with the parallel reflux bar (First Mate). The resulting mixture was stirred at reflux for 20 min. After the reaction vessel was cooled to 0°C for 4 h, the beads were filtered; successively washed with ethanol (2 × 30 mL), water (2 × 40 mL), ethanol (2 × 30 mL), and CH_2Cl_2 (2 × 30 mL); and dried at room temperature under vacuum overnight to afford 1.00 g resin-containing aniline.

The reduced resin (300 mg, 0.25 mmol/g, 0.075 mmol) was placed in a 5-mL Teflon vessel (Quest 210), followed by 1.1 eq. ethyl acetoacetate and 5 mL ethanol. The mixture was heated at 75°C under stirring for 12 h. The resin was filtrated and washed with ethanol (2 × 5 mL), and the combined ethanol phases were concentrated. Column chromatography (EtOAc/cyclohexane, 1:5) and recrystallization from EtOAc afforded 60% ethyl 6,7-dimethoxy-2-methyl-3-quinolinecarboxylate as a beige solid.

Regeneration of Original Resin. The collected resin (3 g) was placed into a 10-mL Teflon reaction vessel on the Quest 210. After adding 3 mL 2 M HCl and 3 mL 1:1 water/THF mixture, the resulting suspension was stirred for 12 h at room temperature. The reaction vessel was drained using nitrogen pressure and subsequently washed in the following order: ethanol, water, 2 M solution of triethylamine in ethanol, water, ethanol, and dichloromethane. The resulting resin was dried under vacuum for 12 h at 40°C before the next use.

Other references related to the Friedländer condensation are cited in the literature.[14]

Fries Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fries and co-workers in 1908.[1] It is a Lewis acid–promoted rearrangement of phenolic esters to *ortho*- and/or *para*-acyl phenols and is generally known as the Fries rearrangement.[2] On the basis of extensive investigations, it is known that both Lewis acids[3] (e.g., $AlCl_3$, BCl_3, BF_3,[4] $Bi(OTf)_3$,[5] $FeCl_3$, $HgCl_2$, $SnCl_4$, $ZrCl_4$,[6] and lanthanide triflates.[7]) and Brønsted acids (TsOH, H_3PO_4, HF, etc.) work equally well for this reaction.[3] Among these catalysts, the lanthanide triflates, having high catalytic activity and low toxicity, are both air and moisture tolerant;[5] but $AlCl_3$ is the most commonly used catalyst.[3] During this rearrangement, a mixture of phenolic ester and an equivalent amount of acidic promoter is heated either neat or in a solvent suitable for *Friedel-Crafts Acylation* (e.g., nitrobenzene) to 80–180°C, the subsequent decomposition of the Lewis acid–acyl phenol complex leads to the rearranged product.[3] Depending on the structure of the starting material[8] and the reaction conditions (e.g., reaction temperature[9]), *para*- and/or *ortho*-acyl phenols and simple phenol can be obtained in various ratios. This is because the *para*- and *ortho*-acyl phenols are generated in different reaction pathways. For example, an *ortho* or 1,2-path of intramolecular rearrangement gives an *ortho*-acyl phenol, whereas a *para* or 1,4-path of intermolecular rearrangement produces a *para*-acyl phenol, and the migration of the oxocarbonium ion gives both isomers.[10] Some interesting Fries rearrangements include $Bi(OTf)_3$-promoted direct acylation of phenol,[5] the $BF_3{\cdot}OEt_2$-catalyzed rearrangement of diacyl hydroquinone to 4-ethoxy-2-acyl phenol,[4] and the rearrangement of acyl *p*-phenyl phenol to 4′-acyl 4-hydroxy biphenyl.[11] A similar rearrangement also occurs on acyloxyheteroarenes[9a] (e.g., *N*-acetylcarbazole), and this

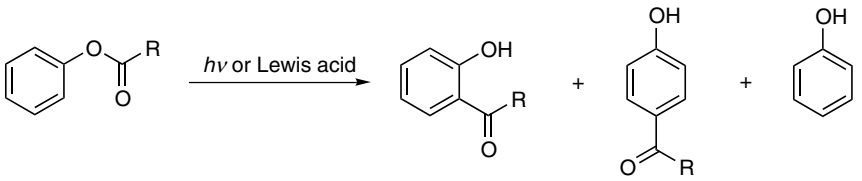
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

rearrangement is called the Fries-Rosenmund rearrangement.[12] Unfortunately, thioesters do not undergo such rearrangements even if they are treated under harsh conditions.[13] As for the limitation on regioselectivity, a metal-promoted Fries rearrangement[13] or anionic *ortho*-Fries rearrangement[14] was developed by Snieckus in 1983,[15] by which *O*-aryl carbamates are converted only into *ortho*-hydroxy aryl amides,[11,15] and the *N*-aryl carbamates are transformed into *ortho*-amino aryl amides. The latter transformation is called the anionic *N*-Fries rearrangement.[16] A similar migration of a phosphoryl group is referred to as the anionic phospho-Fries rearrangement.[17] Further modifications of this procedure include the lithium-bromo or lithium-iodo exchange to facilitate the *ortho*-lithiation.[13,18]

It should be pointed out that arylsulfonates also undergo a similar rearrangement to afford hydroxyaryl sulfones, and such rearrangement is known as the thia-Fries rearrangement (promoted by $Al_2O_3/MeSO_3H$[19a] or graphite/$MeSO_3H$[19b]). It is surprising that such rearrangement may involve an anionic intermediate, and the corresponding rearrangement is referred to as the anionic thia-Fries rearrangement.[20]

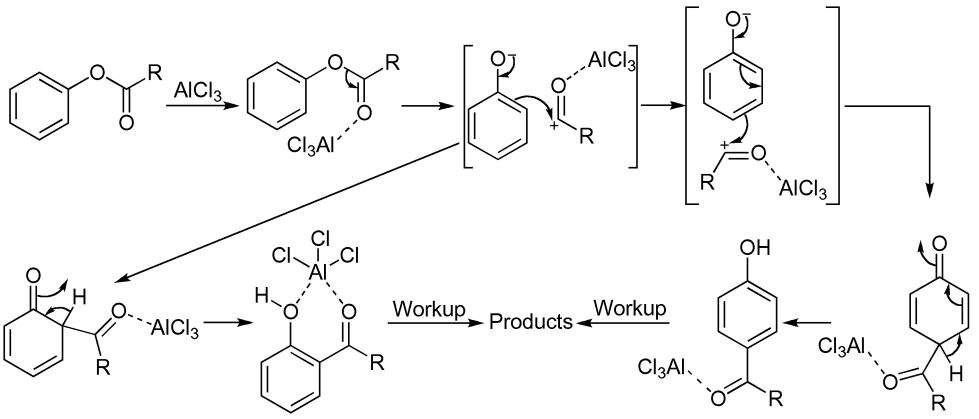
Comparable rearrangement of aryl esters under photo-irradiation were developed in 1960 by Anderson and Reese,[21] which are known as the *Photo-Fries Rearrangement*[22] or *Photo-Fries Reaction*.[23] Similarly, the photo-initiated rearrangement of aryl anilides to amino acyl aromatics is called the photo-anilide rearrangement.[22n] In addition, aryl sulfonanilides,[24] sulfonates,[25] carbamates,[26] sulfamates[27] and cinnamates[28] all undergo a similar rearrangement under photo-irradiation. It is known that the *Photo-Fries Rearrangement* is intramolecular[22k] and occurs through either an excited singlet state[22l,29] (because quantaum yields are not affected by either triplet quenchers[30] or sensitizers[25b]) or an upper triplet state.[27,28] After excitation, the homolytic cleavage of aryl ester leads to the radicals being restrained by a solvent cage that combines to the rearrangement products and starting material.[22k] In addition, the aryloxy radical might escape from the solvent cage and abstract a hydrogen to form a phenol.[22a,22k,23a] It was found that the presence of oxygen[22d,22h,31] or the addition of pentasil zeolite,[22c] Nafion membrane[22c] or β-cyclodextrin[22h,30] all affect the product distribution. Finally, the *Photo-Fries Rearrangement* has been extended to simple vinyl esters[32] as well as 1,3-dienyl esters,[33] by which both 1,3- and 1,5-acyl migration occurs on 1,3-dienyl esters.

B. GENERAL REACTION SCHEME

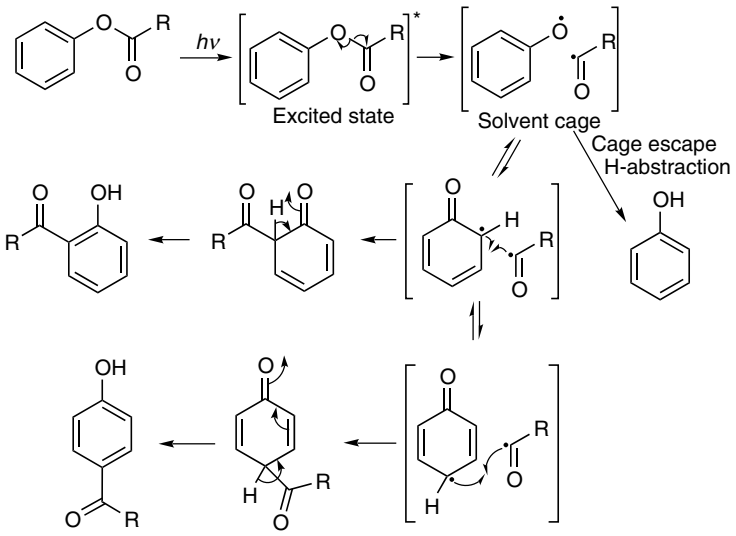


C. PROPOSED MECHANISMS

The mechanism of the Fries rearrangement catalyzed by a Lewis acid (e.g., $AlCl_3$) is demonstrated in Scheme 1, and the mechanism for a *Photo-Fries Rearrangement* is displayed in Scheme 2.



SCHEME 1. *Mechanism for a Lewis acid–promoted Fries rearrangement.*



SCHEME 2. *Mechanism for a photo-Fries rearrangement.*

D. MODIFICATION

The original Fries procedure has been modified extensively to occur under either UV irradiation (*Photo-Fries Rearrangement*) or anionic lithiation or lithium-bromo exchange (anionic ortho-Fries rearrangement). Other modifications include the application of microwaves,[2b,2i,34] electron beam,[2e,2g] BF_3-H_2O,[2a] Y zeolite,[35] zinc powder,[2f] $Bi(OTf)_3$,[2h] and solid acid catalyst[2o] as the promoters.

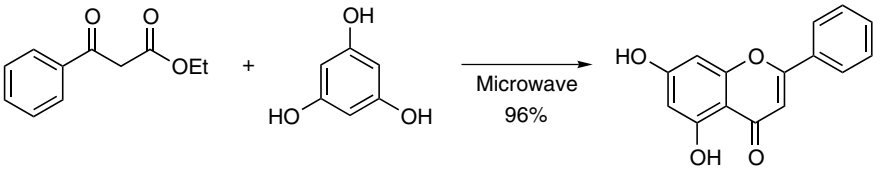
E. APPLICATIONS

This reaction has general application in the preparation of hydroxyl acyl phenols or heteroarenes (coumarin,[8,9a] carbazole,[12] etc.)

F. RELATED REACTIONS

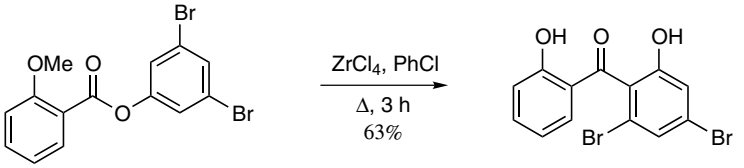
This reaction is related to the *Friedel-Crafts Acylation*.

G. CITED EXPERIMENTAL EXAMPLES



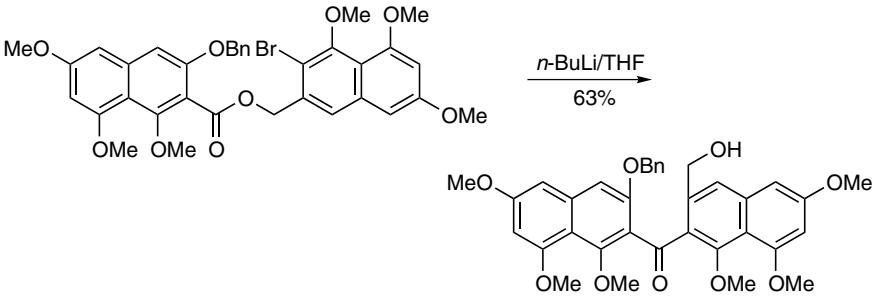
Reference 35.

A mixture of 384 mg ethyl benzoyl acetate (2 mmol) and 126 mg phloroglucinol (1 mmol) was irradiated with microwaves (ETHOS D, Millestone, at 80% of a total output of 1000 W or with the temperature control set to 240°C) for 3 min. The crude product was dissolved in 20 mL 10% aqueous NaOH and washed with diethyl ether (2 × 20 mL); the product was precipitated by adding concentrated HCl. The product was filtered, washed with water, and vacuum dried to give 243 mg chrysin, in a yield of 96%. Pure chrysin can be obtained by crystallization from dichloromethane-methanol, m.p. 288–290°C.



Reference 6.

In a sealed tube, a solution of 200 mg anisic acid 3,5-dibromophenyl ester (0.52 mmol) and 780 mg $ZrCl_4$ (3.1 mmol) in 2 mL chlorobenzene was quickly heated at 160°C and stirred for 3 h. The reaction mixture was cooled to room temperature, hydrolyzed with 5% HCl (which was added dropwise), and finally extracted with ether. The organic layers were combined and washed with 5% HCl, water, and brine and then dried over magnesium sulfate. Chromatography on silica gel (ether/hexane, 1/4) provided 120.9 mg (2,4-dibromo-6-hydroxy-phenyl)-(2-hydroxy-phenyl)-methanone, in a yield of 63%. R_f = 0.25 (ether/hexane,1:9), m.p. 180–183°C.



Reference 19a.

Under argon, 269 mg 3-benzyloxy-1,6,8-trimethoxy-naphthalene-2-carboxylic acid 3-bromo-4,5,7-trimethoxy-naphthalen-2-yl methyl ester was dissolved in 1.59 mL THF (0.25 M), from which residual water had been removed with *n*-butyllithium and *o*-phenanthroline), and cooled to –45 to –55°C. *n*-Butyllithium (203 μL, 0.437 mmol) was then added dropwise. After the solution was stirred for 2 h, the reaction mixture was quenched by the addition of saturated aqueous NH_4Cl, allowed to warm to ambient temperature, and diluted with EtOAc. After the usual workup, the crude product was purified by radial thin-layer chromatography (hexane/EtOAc, 9:1, 8:2, 7:3, and then 5:5) to give 130 mg 1-(3-benzyloxy-1,6,8-trimethoxy-naphthalen-2-yl)-1-(3-hydroxymethyl-1,6,8-trimethoxy-naphthalen-2-yl)-methanone as a white solid, in a yield of 55%. Further purification was executed by crystallization from cyclohexane-dichloromethane, m.p., 220–224°C.

Other references related to the Fries rearrangement and the *Photo-Fries Rearrangement* are cited in literature 37 and 38, respectively.

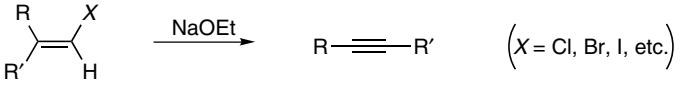
Fritsch-Buttenberg-Wiechell Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fritsch[1] and Buttenberg,[2] coincidently with Wiechell,[3] in 1894. It is a strong base (e.g., NaOEt) promoted rearrangement of 2,2-diaryl-1-halo-alkenes into diarylacetylenes.[4] Therefore, it is generally known as the Fritsch-Buttenberg-Wiechell rearrangement.[5] This reaction has been found to occur via a carbenoid intermediate[4,5n,5q,5r] rather than the α-elimination of metal halide;[5j] in addition, the electron-donating groups normally facilitate or accelerate the migration of aryl moiety.[5j] It is the aryl moiety *trans* to the halide that undergoes the 1,2-migration,[6] thus this reaction is also called 1,2-Fritsch-Buttenberg-Weichell rearrangement.[5c] Currently, this reaction has been extended to the rearrangement of aryl or alkyl olefinic halides,[5l] and the most recent development for this reaction is the mild transformation of alkyl olefinic dibromides or alkyl alkoxy olefinic halides into alkyne derivatives proceeding via zinc carbenoids with broad tolerance of functionalities.[5e] For the reaction of alkyl alkoxy olefinic halides, the alkoxyalkyl moiety migrates exclusively;[5g,5l] in addition, this rearrangement occurs only when a hydrogen, alkoxy, or aryl moiety is involved in the migration step.[5g] This reaction has been widely used in the synthesis of polyalkynes containing 2–10 acetylene units.[5a]

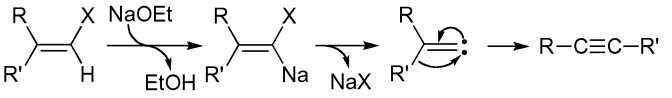
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that a carbenoid intermediate is involved in this reaction, as displayed below.



D. MODIFICATION

This reaction has been modified via the formation of zinc carbenoids, which undergo a mild rearrangement,[5e] with the retention of the configuration of the migrating group.[5m] In addition, this reaction has been extended to occur under electrochemical[5n] and photochemical conditions. The rearrangement occurs under photo irradiation is known as photo-Fritsch-Buttenberg-Wiechell rearrangement.[7]

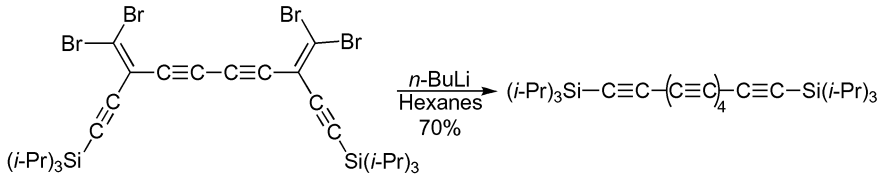
E. APPLICATIONS

This reaction has been used in the synthesis of polyalkynes that contain different acetylene units.

F. RELATED REACTIONS

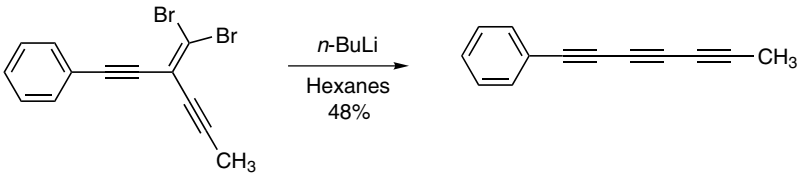
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 5a.

A 0.010–0.016 M solution of the dibromoolefin in hexanes under nitrogen was cooled to −78°C, and 1.1–1.2 eq. *n*-BuLi per dibromoolefin moiety was slowly added over a period of ∼2 min. Reactions were allowed to warm to −10 to −5°C over a period of 30–60 min. The reaction was quenched with 10 mL aqueous NH_4Cl at about −5°C. Diethyl ether was added (20 mL), the organic layer was separated, and washed with aqueous NH_4Cl solution (2 × 20 mL), and dried over $MgSO_4$. The solvent was removed in vacuo to give 70% 1,12-bis(triisopropylsilyl)-1,3,5,7,9,11-dodecahexayne, m.p. 78–80°C, R_f = 0.87 (hexanes).



Reference 5d.

To 10 mL cooled dry hexanes (−78°C) containing 0.131 g dibromoolefin (0.404 mmol) was added dropwise 0.15 mL 2.5 M *n*-BuLi in hexane (0.38 mmol) over 10 min. The mixture was warmed to −40°C for 30 min, recooled to −78°C, and quenched with a saturated aqueous solution of NH_4Cl. Et_2O was added (50 mL), and the organic layer was separated, washed with brine, and dried over magnesium sulfate. Solvent removal in vacuo and by passing the residue through a short plug of silica gel gave 31.9 mg 2-non-1-en-3,5,7-1-phenylhepta-1,3,5-triyne as a white solid, in a yield of 48%, m.p. 58°C, $R_f = 0.40$ (hexanes).

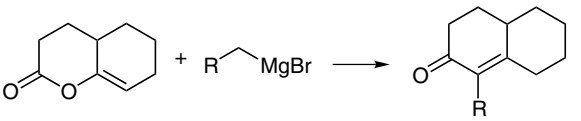
Fujimoto-Belleau Reaction

A. GENERAL DESCRIPTION OF THE REACTION

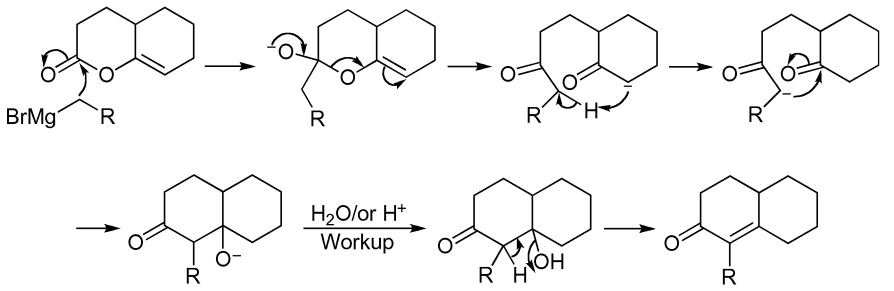
This reaction was initially reported by Fujimoto[1] coincidentally with Belleau in 1951.[2] It is a synthesis of five- or six-membered α-substituted-α,β-enones by the addition of a Grignard reagent prepared from a primary halide to an enol lactone followed by an *Aldol Reaction*.[3] Therefore, it is generally known as the Fujimoto-Belleau reaction.[4] This reaction is especially useful for the transformation of a steroid scaffold[3,5] in which an isotopic carbon can be imbedded using isotopic methyl iodide.[5b,6] In addition, this reaction has been extended to imbed isotopic carbon into the benzo ring, such as in benzazepine.[3] Besides the Grignard reagent, the comparable lithium reagent is also feasible for this reaction and forms cyclic enones.[7]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been extended to occur with comparable lithium reagents.[7]

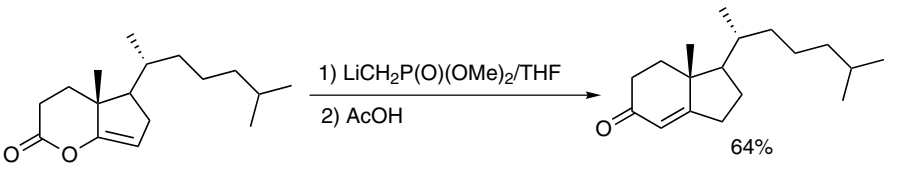
E. APPLICATIONS

This reaction is useful in steroid chemistry that imbeds an isotopic carbon into the cyclic rings.

F. RELATED REACTIONS

This reaction is related to the *Aldol Reaction* and *Grignard Reaction*.

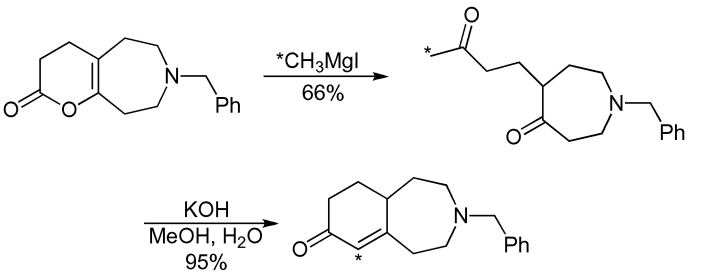
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a 60 mL THF solution containing 0.43 mL $MePO(OMe)_2$ (4 mmol) was added 2.9 mL 1.4 M *n*-BuLi in hexanes (4.1 mmol) at −78°C. After the solution was stirred for 1 h, 0.53 g (1*R**,1′*R**,7a*R**)-1-(1,5-dimethylhexyl)-2,3,4,5,6,7-hexahydro-7aβ-methyl-4-oxaindan-5-one (2 mmol) in 8 mL THF was added, and the solution was stirred for an additional 30 min and warmed to −20°C over 2.5 h. Then 0.11 mL AcOH (1.92 mmol) was added dropwise. The mixture was heated at 55°C for 3 h, then cooled to 0°C; and 1 M HCl was added, followed by water. The aqueous solution was extracted with EtOAc and dried; the solvent was removed. The residue was chromatographed on SiO_2 (3% EtOAc in

hexane) to give 335 mg (1*R**,1′*R**,7a*R*)-1-(1,5-dimethylhexyl)-7aβ-methyl-2,3,5,6,7,7a-hexahydro-1*H*-inden-5-one, in a yield of 64%.



Reference 3.

To 6 mL ether solution containing 153 mg magnesium turnings was added 4.46 mmol [^{14}C] methyl iodide (250 mCi, 56 mCi/mmol) by static vacuum transfer, and the mixture was stirred for 30 min to generate the Grignard reagent. Then the ethereal solution was added dropwise by cannula over 5 min to a vigorously stirred solution of 1.15 g 7-benzyl-4,5,6,7,8,9-hexahydropyranol[2,3-d]azepin-2-(3H)-one (4.47 mmol) in 100 mL ether maintained between -20° and -30°C, resulting in the formation of a voluminous white precipitate. The mixture was allowed to warm to near 0°C over 30 min, then 15 mL water was added. Volatile radioactivity was removed by static vacuum transfer. The organic phase was separated from the aqueous phase, and the latter was extracted twice with ether. The combined organic layers were dried over magnesium sulfate and evaporated in vacuo to provide 1.15 g 1-benzyl-1,2,3,5,6,7-hexahydro-5-(3-oxo[4-^{14}C]butyl)-4H-azepin-4-one as a clear oil, containing 164 mCi radioactivity, in a yield of 66%.

This compound was dissolved in a solution of 517 mg KOH (10.8 mmol) in 4 mL water and 10 mL methanol under an argon atmosphere. The solution was allowed to stand at room temperature for 3 h. Then 25 mL water was added, and the mixture was extracted four times with ether. The combined extracts were washed twice with brine, dried over $MgSO_4$, and evaporated in vacuo to give 760 mg 3-benzyl-1,2,3,4,5,8,9,9a-octahydro-[6-^{14}C]-7H-3-benzazepin-7-one as a pale yellow oil, containing 156 mCi of radioactivity, in a yield of 95%.

Fukuyama Amine Synthesis

(Fukuyama-Mitsunobu *N*-Alkylation, Fukuyama-Mitsunobu Alkylation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Fukuyama and co-workers in 1995.[1] It is a two-step conversion of primary amines into secondary amines via *ortho*-nitrobenzenesulfonation in conjunction with the *Mitsunobu Reaction* and subsequent removal of the *o*-nitrobenzenesulfonyl group by thiophenol.[2] Therefore, this reaction is generally known as the Fukuyama amine synthesis.[3] In addition, it is also referred to as the Fukuyama-Mitsunobu *N*-alkylation,[4] Fukuyama-Mitsunobu alkylation,[5] Fukuyama-Mitsunobu condition,[6] Fukuyama-Mitsunobu procedure,[7] or Fukuyama-Mitsunobu Reaction.[2] In this reaction, the *o*-nitrobenzenesulfonyl-protected amine is alkylated with alcohol in the presence of PPh_3 and diethyl azodicarboxylate (DEAD)[8] or diisopropyl azodicarboxylate (DIAD),[2] and the deprotection occurs in a very mild condition[2,8a] (almost neutral[9]). The *o*-nitrobenzenesulfonyl group is simply called the *Fukuyama sulfonamide protecting group*.[10] This reaction has become a versatile method for the synthesis of secondary amines,[11] polyamines,[12] and even tertiary amines[2,4a,13] via a solid-support, in which DIAD is superior to DEAD.[2]

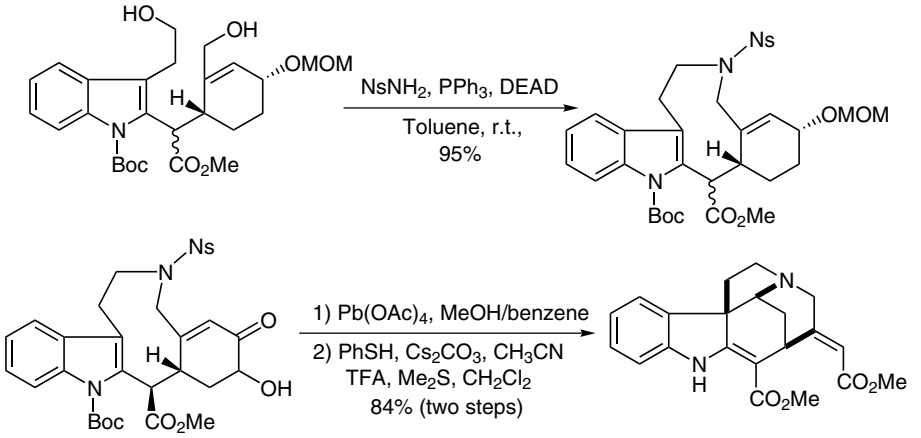
G. CITED EXPERIMENTAL EXAMPLES

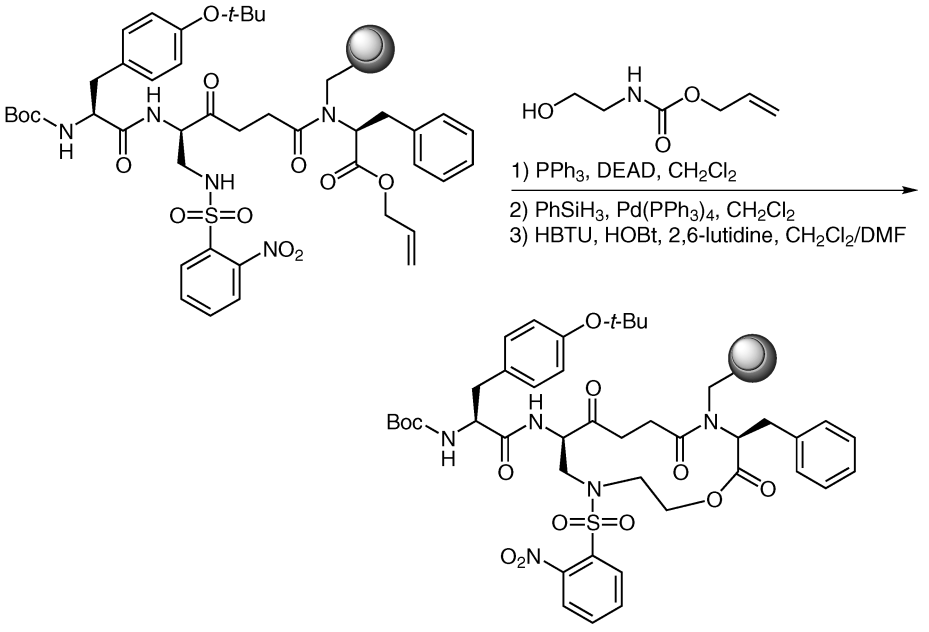


Reference 14.

To a stirred suspension of 663 mg *tert*-butyl 2-((methoxycarbonyl)((1*R*,4*R*)-2-(hydroxymethyl)-4-(methoxymethoxy)-cyclohex-2-enyl)-methyl)-3-(2-hydroxyethyl)-1*H*-indole-1-carboxylate (1.32 mmol), 692 mg PPh_3 (2.64 mmol), and 534 mg $NsNH_2$ (2.64 mmol) in 53 mL toluene at room temperature was added DEAD (40% in toluene, 1.20 mL, 2.65 mmol), and the mixture was stirred for 5 min, at which time the solvent was removed under reduced pressure. Et_2O was added to the residue, and the precipitate was removed by filtration through a pad of Celite. The filter cake was rinsed with Et_2O, and the filtrate was concentrated under reduced pressure. The residue was purified by column chromatography on silica gel eluting with CH_2Cl_2-Et_2O-hexane (40:30:30) to afford 837 mg (3*R*,14a*R*)-13-*tert*-butyl 14-methyl 1,2,3,5,6,7,8,14,14a-nonahydro-3-(methoxymethoxy)-6-(2-nitrobenzenesulfonyl)benzo-[7,8]azonino[5,4-*b*]indole-13,14(1*H*)-dicarboxylate as a white foam, in a yield of 95%. The diastereomers could be separated by preparative TLC.

To a solution of 249 mg (14*R*,14a*R*)-13-*tert*-butyl 14-methyl 1,2,3,5,6,7,8,14,14a-nonahydro-3-oxo-2-hydroxy-6-(2-nitrobenzenesulfonyl)benzo[7,8]azonino[5,4-*b*]indole-13,14(1*H*)-dicarboxylate (0.389 mmol) in 4 mL MeOH and 4 mL benzene at 0°C was added 345 mg $Pb(OAc)_4$ (0.778 mmol). After being stirred for 10 min, the reaction mixture was quenched with saturated $NaHCO_3$ and extracted with EtOAc. The organic layer was washed with brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was passed through a pad of silica gel eluting with EtOAc/hexane (70:30). Removal of the solvent gave aldehyde, which was dissolved in 3.9 mL acetonitrile. To this solution at room temperature were added 190 mg Cs_2CO_3 (0.583 mmol) and 47.9 μL PhSH (0.484 mmol). The suspension was stirred for 30 min, at which time 2.0 mL Me_2S, 4.0 mL CH_2Cl_2, and 2.0 mL TFA were added. The mixture was heated to 50°C and stirred for 7 h. After being cooled to room temperature, it was

diluted with EtOAc, washed with saturated $NaHCO_3$ and brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel eluting with hexane/CH_2Cl_2/Et_3N (60:40:5 then 0:100:5) to give 120 mg (3a*R*,10*R*,11a*S*)-methyl 1,2,3,10,11,11a-hexahydro-13-(*E*)-[(methoxycarbonyl)methylene]-1,10-ethanopyrrolo[2,3-*d*]carbazole-9-carboxylate as a pale yellow oil, in an overall yield of 84% in two steps.



Reference 2.

To an argon-agitated suspension of the peptide-bound resin (2.06 mmol) and *N*-(allyloxycarbonyl) ethanolamine (5 eq.) in 80 mL THF were added carefully 5.0 eq. DIAD and PPh_3 each at 0°C, and the reaction was agitated at room temperature for 12 h. After successive washings with DMF, MeOH, and CH_2Cl_2 (three times), a solution of $PhSiH_3$ (24 eq.) and a solution of $Pd(PPh_3)_4$ (0.1 eq.) in 20 mL CH_2Cl_2 were added to the resin under argon. The resin was shaken for 10 min, the peptide resin was washed with DMF, MeOH, and CH_2Cl_2 (three times); then the deprotection process was repeated once. The deprotected peptide resin was suspended again in 15 mL DMF/CH_2Cl_2 (v/v = 1:1) and treated with 3.0 eq. of HBTU, 3.0 eq. HOBt, and 4.0 eq. 2,6-lutidine for 12 h. After being washed successively with DMF, MeOH, and CH_2Cl_2 (three times), the resin was dried in vacuo to provide 5.67 g peptide resin (1.95 mmol), in a yield of 95%.

Fukuyama Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Fukuyama in 1994.[1] It is a unique synthesis of 3-substituted or 2,3-disubstituted indole derivatives from a tributyltin-based intramolecular radical cyclization of *o*-alkenylphenylisocyanides[2] (or isonitriles or 2-isocyanostyrene derivatives[1,3]). Therefore, this reaction is generally referred to as the Fukuyama indole synthesis.[4]

It should be pointed out that the Fukuyama indole synthesis has already been upgraded to a second generation.[3] The initial reaction protocol (Scheme 1) involves the treatment of 2-isocyanostyrene derivatives with tributyltin hydride in the presence of a radical initiator (e.g., AIBN), giving a (2-alkenyl)phenylstannoimidoyl radical, which cyclizes intramolecularly and tautomerizes subsequently to afford 3-substituted-2-tributylstannyl indoles.[1] Acidic treatment of the indole tin derivatives will afford simple 3-alkyl-substituted indole derivatives.[1] Moreover, in conjunction with the *Stille Coupling*,[5] 2-alkenyl (or alkynyl, aryl)-3-alkyl-indole derivatives can be obtained, and the *Stille Coupling* can be performed in a one-pot manner.[1] This version of the reaction allows for the preparation of indoles with both acid- and base-sensitive functionalities at positions 2 and 3 from readily accessible phenylisonitriles; however, it would be very difficult to form 2-alkyl-substituted indoles directly.[1] In addition, the reaction from 2-isocyanostyrenes with a *trans*-β-alkyl group might be complicated with the formation of tetrahydroquinolines, while 2-isocyanostyrenes with a *cis*-β-alkyl group will give much less tetrahydroquinolines.[1]

The second generation of the Fukuyama indole synthesis (Scheme 2) generally involves the intramolecular radical cyclization of 2-alkenylthioanilides, which can be readily accessed in a modular fashion from at least three different methods.[3] In the first method, tetrahydropyran-protected *o*-(3-hydroxyallyl)thioanilides are prepared from quinolines by

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

means of thiophsogene decomposition, $NaBH_4$ reduction, tetrahydropyran protection, and nucleophilic addition on the isothiocyanate moiety by a carbon nucleophile (e.g., enolate or Grignard reagent).[3] In the second modular reaction, quinolines are treated analogously with thiophosgene followed by $NaBH_4$ reduction; the resulting *o*-(3-hydroxyallyl)phenyl isothiocyantes are converted into *o*-(3-hydroxyallyl)anilines, which are then acylated with acyl chloride and subsequently treated with *Lawesson's Reagent*.[3] The third method involves a *Sonogashira Coupling* of 2-iodoaniline, with terminal alkynes to afford 2-alkynylanilines, which are reduced by activated zinc to give exclusively *o*-aminostyrenes with a β-substituent in *cis*-configuration. Then the anilines are transformed into thioanilides by acylation and subsequent treatment with the *Lawesson's Reagent*.[3] The thioanilides can be easily converted into a variety of 2-substituted and 2,3-disubstituted indoles by tributyltin hydride, followed by desulfurization with Raney nickel.[4b]

It was found that triethylborane (Et_3B) is an effective radical initiator,[5] from which a wide range of both acid- and base-sensitive groups—such as ester, THP ether, and β-lactam—can be implemented at indole's 2- or 3-position.[3] Under such radical reaction conditions, no racemization has been detected for a thioanilide derived from a chiral α-amino acid.[3] In addition, hypophosphorus acid, being a radical reducing reagent, has also been used as a substitute for tin hydride.[3] Overall, the Fukuyama indole synthesis has been successfully applied to the total synthesis of several natural alkaloids containing indole moieties, including aspidophytine,[6] haplophytine,[6] catharanthine,[7] vindoline[8] and the antineoplastic agent of (+)-vinblastine,[8] as shown in Figure 1.

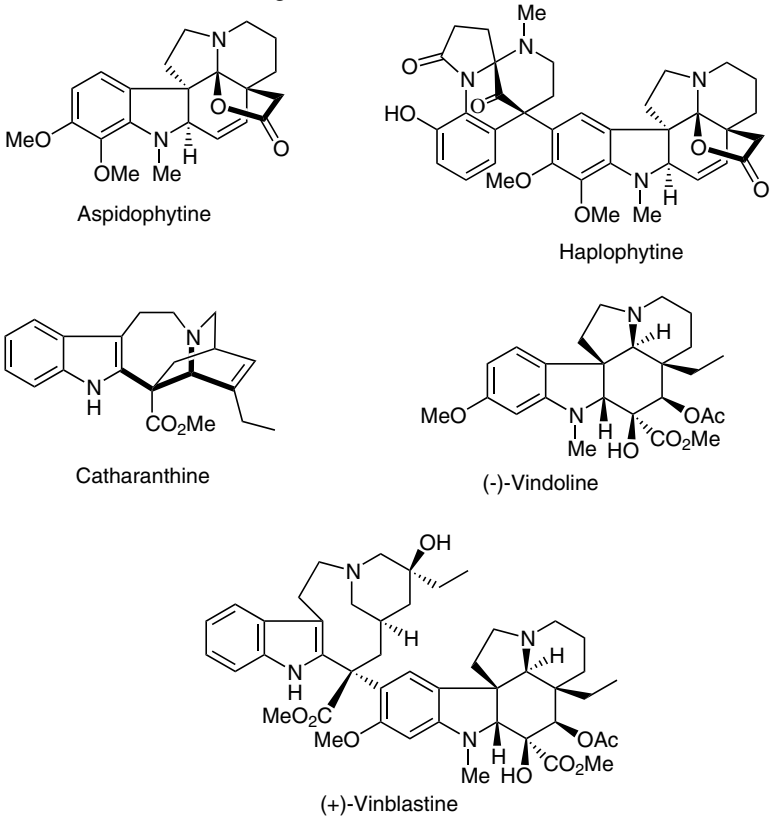

FIGURE 1. *Indole-containing alkaloids that are accessible by the Fukuyama indole synthesis.*

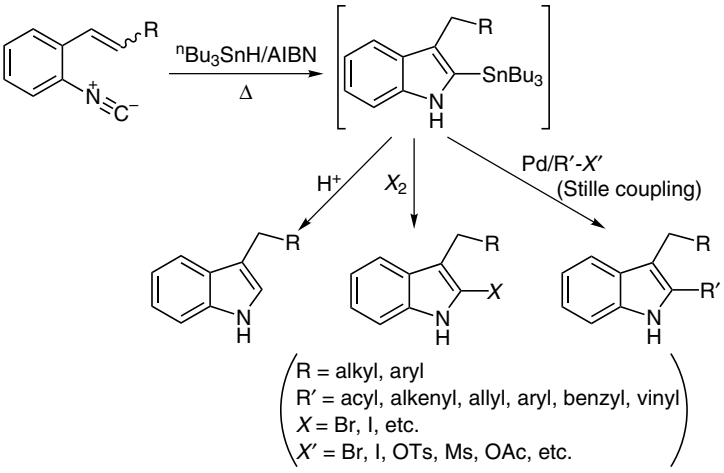
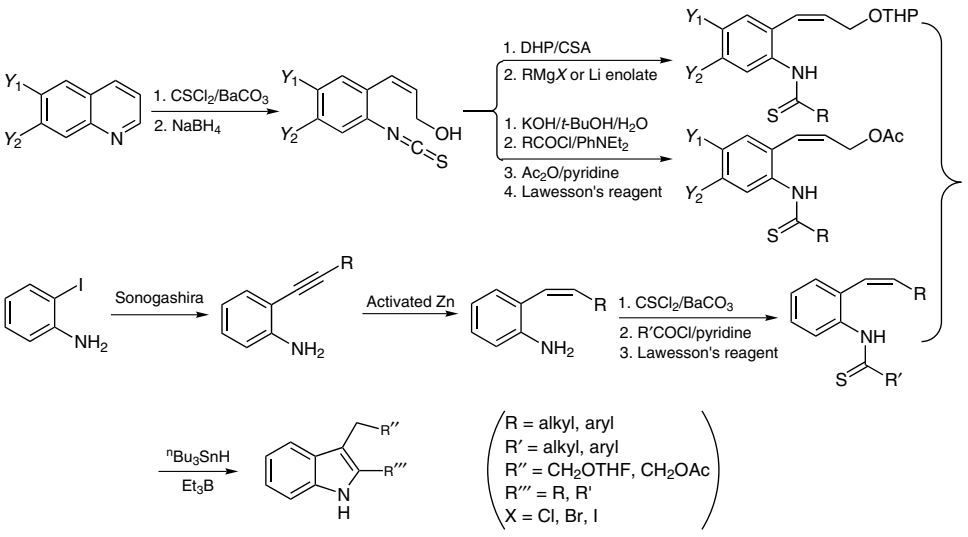
B. GENERAL REACTION SCHEME



SCHEME 1. *First-generation Fukuyama indole synthesis.*

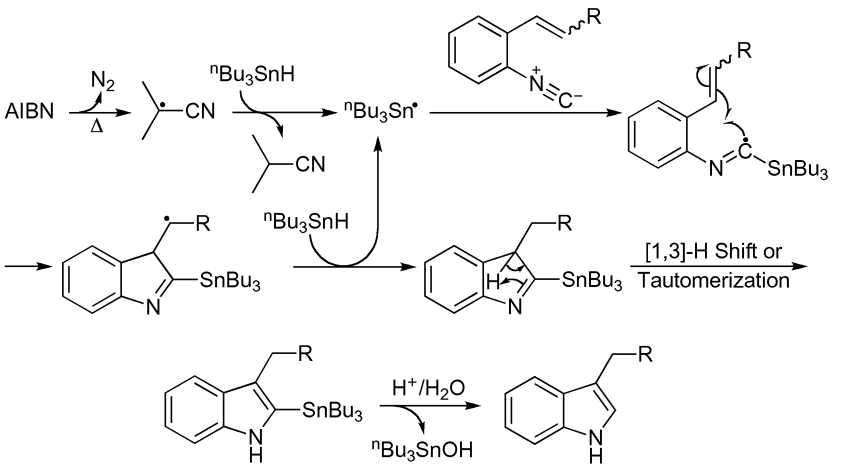


SCHEME 2. *Second-generation Fukuyama indole synthesis.*

C. PROPOSED MECHANISMS

Because both the first and the second generations of Fukuyama indole synthesis involve the intramolecular radical cyclization, only the mechanism for the first generation is pro-

vided here.



D. MODIFICATION

The 2-isocyanostyrene derivatives have also been prepared by the *Pudovik Reaction* with a variety of aldehydes.[4b] In addition, a variant of the 5-*exo-dig* radical cyclization of 2-alkynylphenylisonitriles using thiols as both radical initiators and nucleophiles has been developed. Under these conditions, quinolines can be obtained by a potentially competitive 6-*endo-dig* radical cyclization.[9]

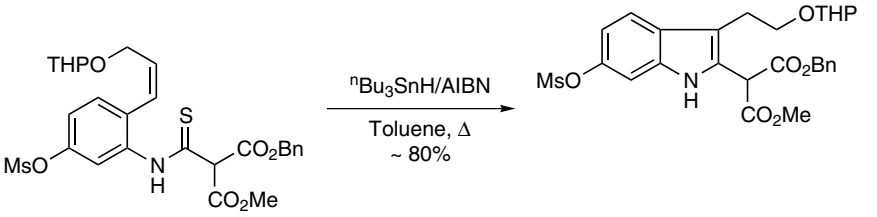
E. APPLICATIONS

This reaction has an important application in the preparation of indole-containing alkaloids.

F. RELATED REACTIONS

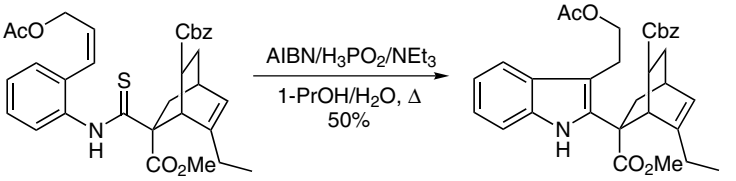
This reaction is related to the *Fürstner Indole Synthesis*, both give the 2,3-disubstituted indole derivatives.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

A 3.0-L toluene solution containing 43.3 g 2-{5-methanesulfonyloxy-2-[(*Z*)-3-(tetrahydropyran-2-yloxy)propenyl]-phenylthiocarbamoyl} malonic acid benzyl ester methyl ester (75.0 mmol), 22.2 mL tri-*n*-butyltin hydride (82.5 mmol), and 1.23 g 2,2′-azobisisobutyronitrile (7.50 mmol) was degassed at room temperature with argon for 10 min and then stirred at 110°C for 10 min. After being cooled to room temperature, to the resulting suspension was added 1.0 L half-saturated aqueous potassium fluoride. The resulting two-phase mixture was stirred vigorously for 3 h. After removal of the organic layer, the aqueous layer was extracted with EtOAc twice. The combined organic extracts were dried over anhydrous $MgSO_4$, filtered through a pad of Celite, and concentrated in vacuo to give ~75 g crude syrup, which was purified with flash chromatography using 20–40% EtOAc in hexane to afford 80% 2-{6-methanesulfonyloxy-3-[2-(tetrahydropyran-2-yloxy)ethyl]-1*H*-indol-2-yl}malonic acid benzyl ester methyl ester as a slightly yellow oil.



Reference 9.

To 5 mL 1-propanol were added 414 mg thioanilide (0.74 mmol), 133 mg AIBN (0.81 mmol), 1.4 mL 30% aqueous hypophosphorus acid (7.4 mmol), and 1.55 mL triethylamine (11.1 mmol) under argon. The mixture was first warmed slightly, and then stirred at 90°C under a reflux condenser with an argon balloon. After 45 min, TLC analysis indicated the completion of reaction. The reaction mixture was cooled down to room temperature and diluted with 20 mL ether. The organic solution was then washed with 1 *N* HCl, 1 *N* NaOH, and brine; dried and concentrated to give a yellow oil, which was purified by flash column chromatography using hexanes/EtOAc (10:1 to 5:1) with 0.5% Et_3N as the eluent to afford 198 mg indole product as a clear, faintly yellow oil, in a yield of 50%.

Fürstner Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Fürstner in 1991.[1] It is a low-valent titanium-induced or -mediated intramolecular reductive alkylidenation of alkyl (or aryl) 2-*N*-acylamidophenyl ketones to afford 2,3-disubstituted indoles, also known as titanium-induced intramolecular oxoamide coupling[2] or the zipper reaction.[3] Therefore, this reaction is referred to as the Fürstner indole synthesis.[3a,4]

This reaction is best performed with highly reactive titanium on graphite[5] that is prepared from $TiCl_3$ and 2 eq. of KC_8[6,7] (or from $TiCl_3$ and 3 eq. of KC_8[8]), which can produce the corresponding indole derivatives in up to 93% yield in DME.[6] In theory, the Fürstner indole synthesis is an extension of the *McMurry Coupling*,[9] which is usually performed in two steps, involving the reduction of $TiCl_3$ or $TiCl_4$ with a strong reducing agent followed by the addition of a carbonyl compound to the activated titanium slurry.[2,9] In the regular *McMurry Coupling*, the active titanium species vary, depending on the activation conditions, such as $[TiHCl{\cdot}THF_{1/2}]_n$ from an $LiAlH_4$ reduction or [TiCl(MgCl)·*n*THF] or [Ti(MgCl)$_2$) · *n*THF] by magnesium reduction.[10] However, the Fürstner indole synthesis is different from the normal *McMurry Coupling* in both reaction scope and mechanism. For example, the *McMurry Coupling* is assumed to proceed via a radical mechanism in general, whereas a dianion mechanism fits most of the experimental aspects of the Fürstner indole synthesis.[9] For a particular reaction condition, the activated titanium species prepared from $TiCl_3$ with 2 eq. KC_8 gives the most favorable results, whereas other titanium species in the *McMurry Coupling* fail for this reaction.[9] In fact, it was found that in the Fürstner indole synthesis, a series of titanium species at different oxidation states (e.g., 0, +1, +2), such as $Cp_2Ti(PMe_3)_2$, Ti(arene)$_2$ (arene = toluene, biphenyl), and a few non-titanium low-valent metallic species (e.g., $NbCl_5$/Zn), are also suitable coupling reagents.[9] Moreover, the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

Fürstner indole synthesis is not necessarily performed in a two-step fashion, instead it can be efficiently carried out via an "instant" method.[2,3a,9] Under such conditions, $TiCl_3$ is added to form a complex with oxoamide substrates before the addition of an excess amount of zinc; once $TiCl_3$ is reduced to an active oxidation state, it immediately mediates the alkylidenation of two adjacent carbonyl functionalities.[9] Furthermore, unlike the *McMurry Coupling*, the Fürstner indole synthesis is not restricted to THF or DME, it can also be performed in solvents such as EtOAc, DMF, and CH_3CN, although it does not work in toluene and MeOH.[9] What is more, a variety of reducible and acid or base-labile functionalities at other sites of the substrates can sustain the Fürstner indole synthesis.[9] For example, 2-*N*-α-ketoacylamidophenyl ketone with a more electrophilic α-keto group cyclizes only to a indole derivative.[9] In addition, a pair of phenyl/mesityl or benzyl/*tert*-butyl groups at C-2 and C-3 in either possible arrangement does not affect the overall yield of indole derivatives to a noticeable extent.[9]

Overall, the versatility of the Fürstner indole synthesis is probably due to the ready formation of a five-membered ring, the proximity of the two carbonyl groups, the high oxophilicity of low-valent titanium species, and the generation of a new aromatic moiety.[9] So far, the Fürstner indole synthesis has been successfully used in the preparation of 2,3-disubstituted indoles on a multigram scale[5] as well as a series of indole-containing compounds, such as camelexin, indolopyridocolin, flavopereirine, secofascaplysin, aristoleline, and lukianol (Figure 1).[11] However, the Fürstner indole synthesis is also problematic for substrates with two branched alkyl groups at C-2 and C-3, and for the preparation of 3-unsubstituted indoles from *o*-*N*-acylated benzaldehydes.[9]

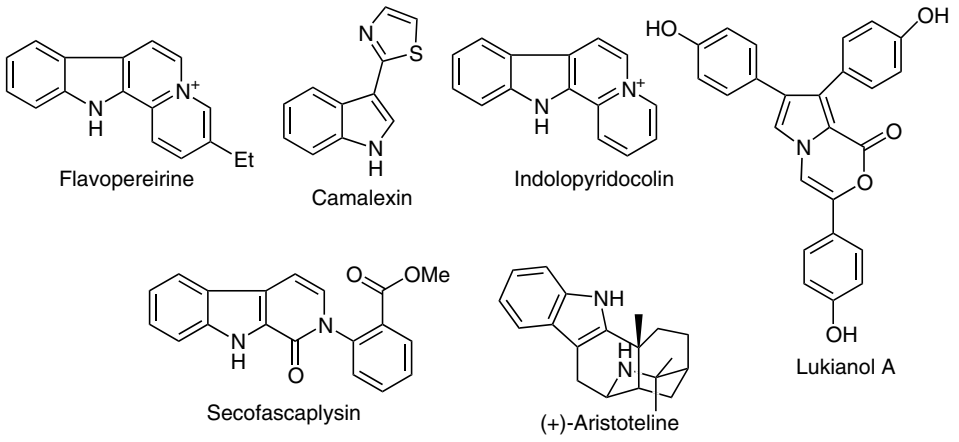

FIGURE 1. *Some indole and pyrrole derivatives accessible from the Fürstner indole synthesis.*

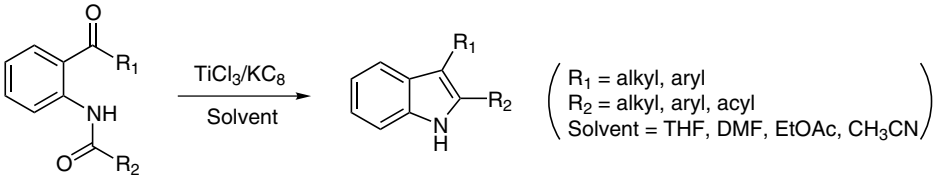
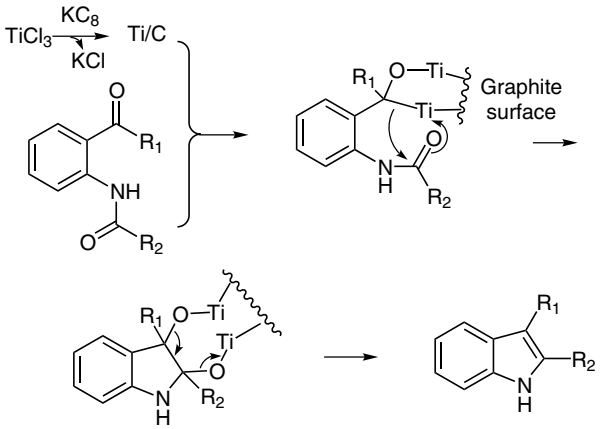
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the *McMurry Coupling* proceeds via a single-electron transfer (SET) mechanism involving ketal radical intermediates, the Fürstner indole synthesis does not occur through SET process, due to a series of experimental facts as follows.[9] (*a*) Diaryl ketones react faster than aryl alkyl ketones, and only amido and ester groups in the vicinity of keto group will undergo the reductive cyclization, indicating that the Fürstner indole synthesis occurs initially at the keto group. (*b*) If the reaction occurs via SET, then solvents such as DMF and EtOAc would be unsuitable for this reaction, because the amido or ester group is an electron acceptor. (*c*) In addition, the C-2 and C-3 substituent with different electron properties should greatly affect the reaction; however, all types of amides of a given parent 2-aminophenyl ketone (e.g., formamides, alkanoyl, aroyl, and heteroaroyl and fatty acid amides) react at comparable rates. (*d*) Neither the dimerization product of the ketal anion radical nor the ring-opening product of cyclopropyl group has been observed in the reaction. On the other hand, although Tebbe reagent[12] has been extensively applied to the conversion of esters and amides into vinyl ethers and amines via a titanium carbene intermediate, the Fürstner indole synthesis is not likely to involve a titanium carbene intermediate either, owing to the observation of a substantial amount of *Pinacol Rearrangement* products and the unsuccessful conversion of *gem*-dibromide into the expected indole with a variety of titanium reagents.[9]

However, it is more promising that the Fürstner indole synthesis proceeds through a dianion mechanism, according to the following experimental phenomena.[9] (*a*) The reaction initially takes place at keto group as shown earlier, and once the ketone dianion forms, it attacks on the vicinal ester or amido group equally well by a common titanium template, whereas other distal functionalities are intact. (*b*) *N*-Phenylbenzamide is electrochemically inactive, clearly showing the formation of a ketone dianion before any electron transfer to an amido group. (*c*) The electrochemically generated dianion of diphenyl ketone can be added to admixed acetic anhydride to give 1,1-diphenyl-1-acetoxy-2-propanone, validating the dianion mechanism for the Fürstner indole synthesis. In addition, titanium species have been proved to convert α-hydroxyketones into olefins. Therefore, the Fürstner indole synthesis should involve the transfer of two electrons to keto group to give a titanium alkoxide carbanion in which the carbanion nucleophilically adds to the vicinal carbonyl group to give pinacol intermediate that is then cleaved to give 2,3-disubstituted indole derivatives, as displayed here.



D. MODIFICATION

This reaction has been improved to a catalytic version by heating the mixture of zinc dust, a catalytic amount of $TiCl_3$, the oxoamides, and an excess amount of silane (such as R_3SiCl in MeCN or DME).[2] The scope of such version of Fürstner indole synthesis depends on the competition by uncatalyzed zinc-induced reduction. It is found that bis(chlorosilane)—Such as $(ClSi(Me)_2CH_2CH_2Si(Me)_2Cl$—gives a better turnover number due to the intramolecular siloxane formation.[2] In addition, SmI_2 has been successfully applied to the Fürstner indole synthesis.[13] Moreover, in terms of intramolecular cyclization, the Fürstner indole synthesis has been extended to the preparation of benzofurans.[8c]

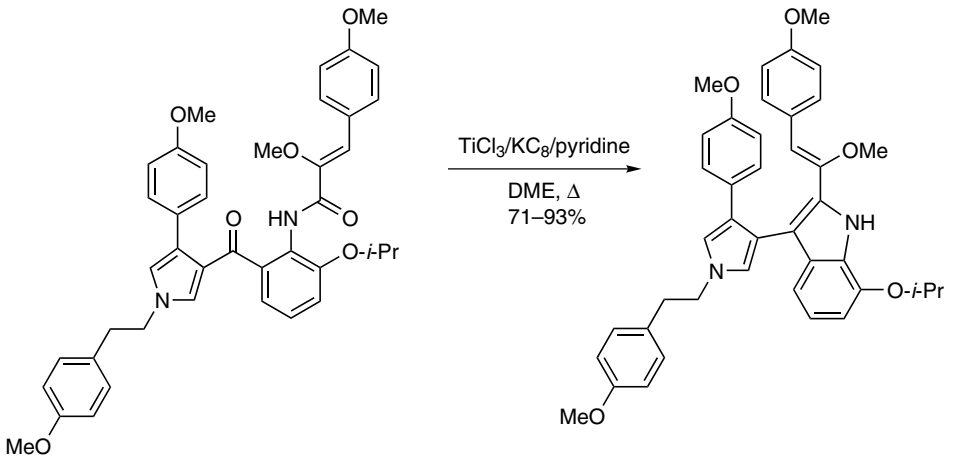
E. APPLICATIONS

This reaction has very broad applications in the preparation of the 2,3-disubstituted indole derivatives as well as pyrrole and benzofuran derivatives.

F. RELATED REACTIONS

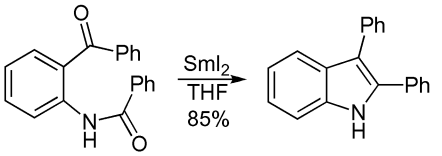
This reaction is related to the *Fukuyama Indole Synthesis*, both give 2,3-disubstituted indole derivatives. In addition, this reaction is very closely related to *McMurry Coupling* in mechanism.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

Caution! KC_8 is pyrophoric and must be handled under argon with care! To a mixture of 2.85 g $TiCl_3$ (18.5 mmol) and 4.96 g KC_8 (36.7 mmol) at 0°C under argon was added 40 mL dry DME (exothermic!), and the resulting suspension was refluxed for 1.5 h. After the addition of 1.5 mL dry pyridine (18.5 mmol), the mixture was refluxed for another 15 min. Then 2.49 g 2-*N*-[2-isopropoxy-6-({4-(4-methoxyphenyl)-1-[2-(4-methoxyphenyl)-ethyl]-1*H*-pyrrol-3-yl}carbonyl)phenyl]-2-methoxy-3-(4-methoxyphenyl)-2-propenamide (3.69 mmol) in 10 mL dry DME was introduced, and the mixture was refluxed until the completion of the reaction as monitored by TLC (∼ 1.5 h). After being cooled to ambient temperature, the mixture was filtered through a plug of Celite layered on silica, which was carefully rinsed with 150 mL EtOAc/toluene (1:1); the combined filtrates were concentrated in vacuo. The residue was purified by flash chromatography using EtOAc/hexanes (1:6) with 1% 6 M NH_3/MeOH added, to afford 1.68 g 7-isopropoxy-2-[methoxy-2-(4-methoxyphenyl)ethenyl]-3-{4-(4-methoxyphenyl)-1-[2-(4-methoxyphenyl)-ethyl]-1*H*-pyrrol-3-yl}-1*H*-indole as a yellow oil, in a yield of 71%. The yield was raised to 93% when this reaction was performed on a somewhat smaller scale from 278 mg ketoamide.



Reference 13.

A mixture of 0.6 g pulverized samarium (4.0 mmol) and 1.0 g iodine (4.0 mmol) in 20 mL anhydrous THF was stirred at room temperature until the samarium disappeared. To the resulting dark blue suspension of SmI_2 was added 0.3 g benzoyl 2-*N*-benzoylphenone (1.0 mmol). The mixture was stirred at 65°C for 30 min and then poured into 10 mL H_2O. The aqueous solution was extracted with EtOAc (3 × 15 mL), and the combined extracts were washed subsequently with 15 mL saturated aqueous $Na_2S_2O_3$ solution and 15 mL brine and then dried over anhydrous Na_2SO_4. Upon removal of solvent under reduced pressure, the residue was purified by preparative TLC on silica gel using EtOAc/cyclohexane (1:7) as the eluent, to afford 0.229 g 2,3-diphenylindole as a colorless crystal, in a yield of 85%, m.p. 121–123°C.

Gabriel Primary Amine Synthesis

(Gabriel Synthesis, Gabriel Reaction)

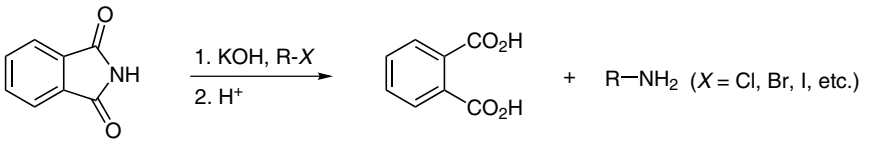
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gabriel in 1887.[1] It is a two-step synthesis of primary aliphatic amines involving the *N*-alkylation of phthalimide followed by acidic or basic hydrolysis of *N*-alkyl-phthalimides. In this reaction, phthalimide can be easily deprotonated by KOH or NaOH because of the two electron-withdrawing groups (i.e., carbonyl), resulting in a good nucleophile; after the *N*-alkylation, the *N*-alkyl phthalimide can be decomposed to provide pure primary amines. Therefore, this reaction is known as the Gabriel synthesis,[2] Gabriel synthesis of primary amine,[2a,3] or Gabriel reaction.[4] The major advantage of this reaction is to avoid over alkylation on the nitrogen atom; because the primary or secondary amine is more nucleophilic than ammonia, the direct reaction between ammonia and an alkyl halide would give the mixtures of primary amine, secondary amine, tertiary amine, and even quaternary ammonium salt. It is found that under basic conditions for the hydrolysis of *N*-alkyl phthalimide, the second step is the rate-limiting step, with a $t_{1/2}$ of 264 h in 0.1 M NaOH at 60°C; in contrast, under acidic hydrolysis conditions, the first step is the rate-determining step, with a $t_{1/2}$ of 175 h in 0.1 M HCl at 60°C.[2a] Because the hydrolysis of *N*-alkyl phthalimide in the original protocol takes too much time, the hydrolysis has been modified by using hydrazine to accelerate the hydrolysis,[5] which is known as hydrazinolysis or the Ing-Manske procedure.[2a,3a] In addition, a two-step procedure including a $NaBH_4$/isopropanol reduction and acetic acid hydrolysis has been developed for the generation of primary amines.[6] On the basis of the known mechanism,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

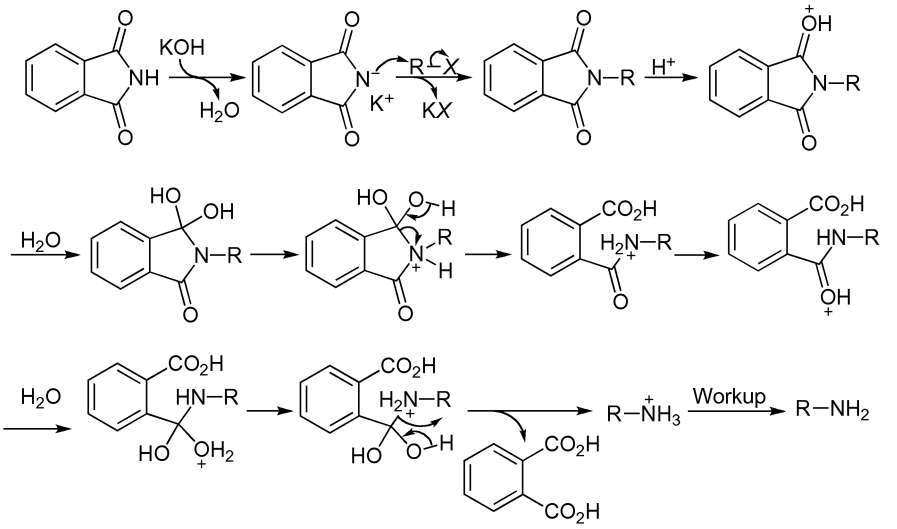
it has been suggested that this reaction be run under a mild acid-base condition within a shorter reaction time.[2a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The acidic hydrolysis of *N*-alkyl phthalimide is proposed here to illustrate the reaction mechanism.



D. MODIFICATION

This reaction has been modified using hydrazinolysis[5] or hydrolysis after the $NaBH_4$/isopropanol reduction.[6] In addition, other amide,[7] phosphoramidate,[3b] and sulfonamide[8] derivatives have been applied to the preparation of primary amines in a similar manner.

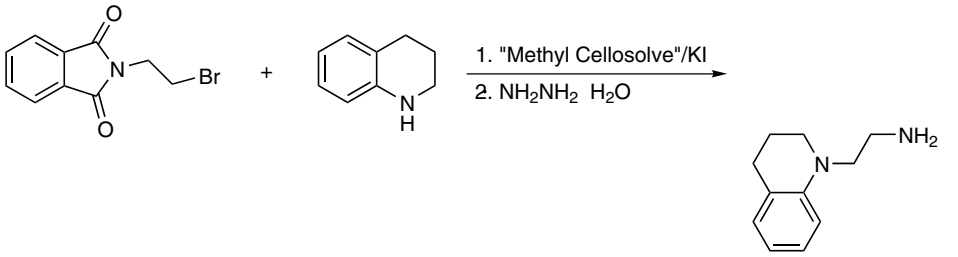
E. APPLICATIONS

This reaction is generally used for the synthesis of aliphatic primary amines.

F. RELATED REACTIONS

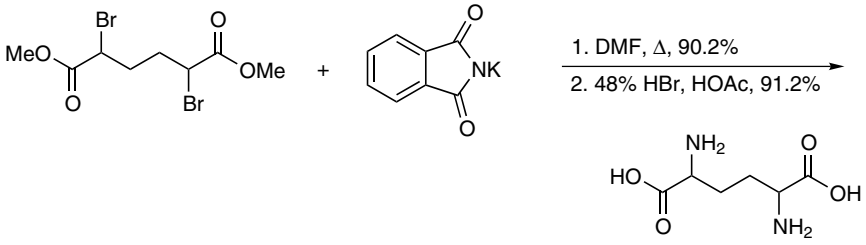
This reaction is related to the *Fukuyama Amine Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A mixture of 20 g 1,2,3,4-tetrahydroquinoline, 25 mL methyl Cellosolve, 2 g potassium iodide, and 28.1 g 2-bromoethylphthalimide was heated overnight on a steam bath. The solvent was evaporated in vacuo from the dark reaction product, and the residue was dissolved in dilute hydrochloric acid, filtered from insoluble material, and then made alkaline with a sodium carbonate solution. The resulting 2-(1′,2′,3′,4′-tetrahydroquinolino)-ethylphthalimide that recrystallized from aqueous alcohol (m.p. 131–133°C), was suspended in 50 mL absolute alcohol, and 2.4 g 85% hydrazine hydrate was added. After the mixture was warmed gently for 5 h, an excess of dilute hydrochloric acid was added, and the mixture was filtered after standing for 1 h. An excess of 12.5 *N* NaOH was added to the filtrate, and a small amount of oily 2-(1′,2′,3′,4′-tetrahydroquino-1ino)-ethylamine was taken up in methyl acetate.



Reference 10.

A mixture of 69.0 g dimethyl α, δ-dibromoadipate (0.21 mol), 87.0 g potassium phthalimide, and 260 mL DMF was heated to 90°C (a mild exothermic reaction starts at 50°C) and maintained at this temperature for 40 min. The cooled reaction mixture was diluted with 300 mL $CHCl_3$ and poured into 1200 mL water. The chloroform layer was separated, and the aqueous phase was extracted twice with 100 mL chloroform. The combined organic layers were washed with 200 mL cold 0.1 N NaOH and 200 mL water and dried over Na_2SO_4. The chloroform was removed by concentration under reduced pressure to the point of incipient crystallization, the immediate addition of 300 mL ether induced a rapid crystallization. The ether-washed product weighed 87.0 g, in a yield of 90.2%, with a wide melting point (160–185°C). After three recrystallizations from EtOAc and benzene, a pure stereoisomer was obtained with a normal melting point (210.7–211.4°C).

A mixture of 100 mL 48% HBr, 100 mL acetic acid, and 50.0 g dimethyl α,δ-diphthalimidoadipate was refluxed until a clear solution resulted (10 days). On cooling,

the filtrate and water washes were concentrated under reduced pressure practically to dryness. The residue was dissolved in 100 mL water, filtered, and neutralized with concentrated ammonia. After crystallization at 0°C for 12 h, 17.3 g α,δ-diaminoadipic acid was obtained, in a yield of 91.2%.

258

Gabriel Reaction

A. GENERAL DESCRIPTION OF THE REACTION

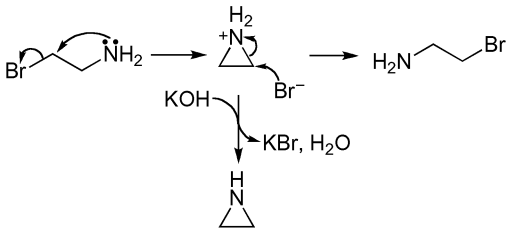
This reaction was initially reported by Gabriel in 1888[1] and subsequently by Marckwald in 1889.[2] It is the synthesis of ethylenimines (now called aziridines) from aliphatic α-haloamines. Therefore, it is known as the Gabriel reaction.[3] The original Gabriel's procedure is to treat α-bromoethylamine hydrobromide with silver oxide in water;[1] however, the commonly used method is to treat α-haloethylamine hydrohalide with NaOH or KOH in water;[4] and the most successful method is to treat α-aminoethyl hydrogen sulfate with NaOH[5] as α-aminoethyl hydrogen sulfate can be easily prepared from ethanolamine and sulfuric acid.[6] This reaction can be extended for preparing four- (azetidines),[7] five-, and six-membered cyclic amines. The aziridine and substituted aziridines are important intermediates for complicated organic syntheses[8] and monomers for polyamines.[9]

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

It is known that alkyl amine is a stronger base than water; therefore, NaOH or KOH cannot deprotonate the amino group. On the other hand, the amino group is a good nucleophile that attacks the β-carbon to form an aziridinium cation and then quickly decomposes back to the starting material in the absence of a base. A representative mechanism is illustrated here using 2-bromoethylamine and KOH.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

A convenient method starting from α-aminoethyl sulfate has been adapted for the preparation of aziridines.[5,6]

E. APPLICATIONS

This reaction has general application in the preparation of cyclic amines, including aziridines and azetidines.

F. RELATED REACTIONS

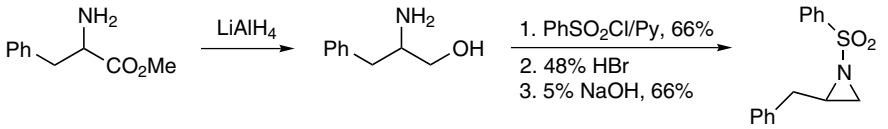
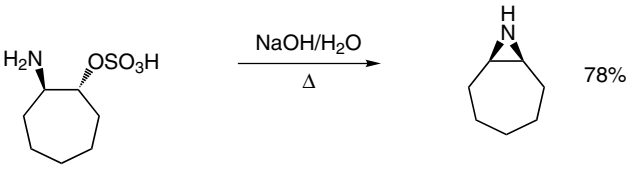
G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

The methyl ester of DL-phenylalanine was recovered from its hydrochloride salt and was reduced with $LiAlH_4$ to 3-phenyl-2-amino-1-hydroxypropane. Then 1.0 g such an alcohol (6.6 mmol) was dissolved in 20 mL cold pyridine containing 2.9 g benzenesulfonyl chloride (16.0 mmol); the solution was held at 5°C overnight. Ice was added (50 g) followed by cold 4 N HCl. The resulting solid was collected and crystallized from 95% ethanol to give 1.9 g 3-phenyl-2-benzenesulfonamido-l-(benzene-sulfonyloxy)propane, in a yield of 66%, m.p., 104.5–106.5°C.

A mixture of 5.0 g dibenzenesulfonyl derivative (10 mmol), 30 mL 48% HBr, and 200 mL ethanol was refluxed for 3 h. The cooled reaction mixture, containing 3-phenyl-2-benzenesulfonamido-1-bromopropane was neutralized with 5% NaOH diluted with 300 mL cold water, and then treated with 185 mL 5% NaOH. After the alkaline mixture was stirred for 15 min, the white precipitate was collected and crystallized from alcohol to furnish 2.2 g 1-benzenesulfonyl-2-benzylethylenimine as needles, in a yield of 66%, m.p., 51–53°C.



Reference 11.

A solution of 12.0 g *trans*-2-aminocycloheptyl hydrogen sulfate and 24.0 g NaOH in 30 mL water was heated in a distilling flask until the residue was nearly dry. The distillate was collected in a cooled receiver containing a little ether and sodium hydroxide pellets. The ethereal solution was separated, and the aqueous solution was extracted with ether (3 × 15 mL). The combined ether solution was dried over solid NaOH and distilled to give 5.0 g cycloheptenimine as a colorless liquid, in a yield of 78%, b.p., 171–172°C.

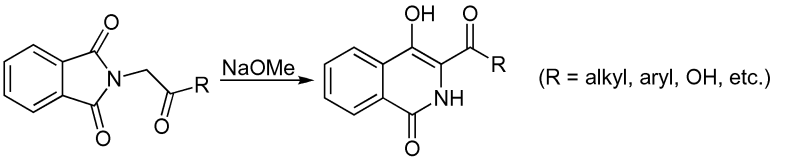
Gabriel-Colman Rearrangement

(Gabriel Isoquinoline Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gabriel and Colman in 1900.[1] It is the rearrangement of alkyl phthalimidoacetate into isoquinoline derivatives by means of alkoxide treatment. Therefore, it is generally known as the Gabriel-Colman rearrangement.[2] In addition, this reaction is also referred to as Gabriel isoquinoline synthesis.[3] However, this reaction is limited to the phthalimido derivatives containing an enolizable carbon attached to nitrogen.[2e,4] In this reaction, the phthalimido ring is first cleaved and then closed at the methylene carbon to give the ultimate 3-carboethoxy-4-hydroxyisocarbostyril.[4] For the phthalyl derivatives of amino acids other than glycine, the corresponding products are 3-alkyl (or aryl)-4-hydroxyisocarbostyrils.[5] It has been reported that under acidic conditions, the 3-carboethoxyl-4-hydroxyisocarbostyril predominates, whereas in neutral conditions, the tetrahydroisoquinolinedione is the dominating structure of the product.[6]

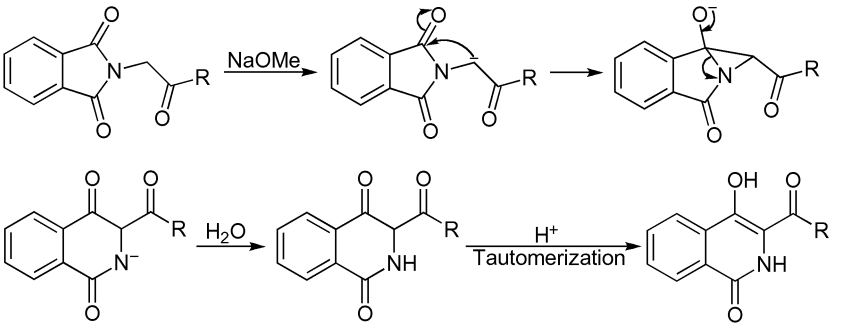
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

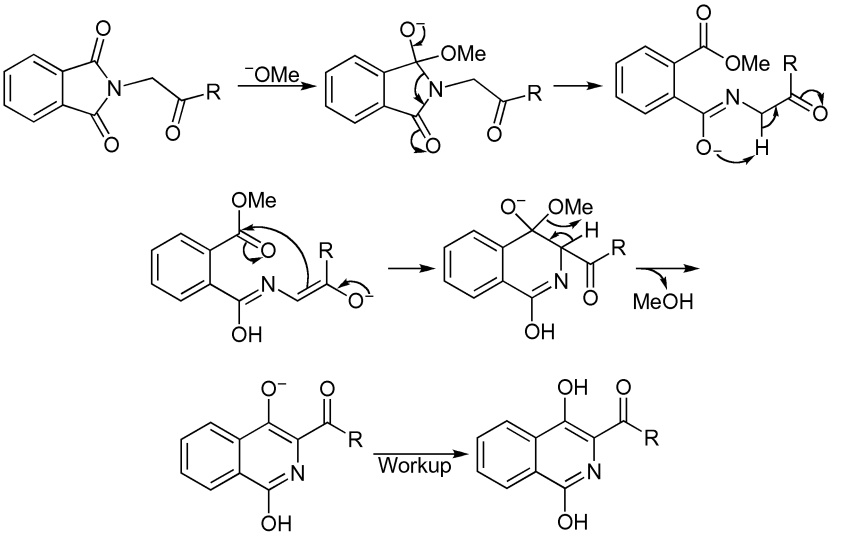
C. PROPOSED MECHANISMS

It is assumed that this reaction involves an α-deprotonation, the formation of aziridine ring, ring opening, and tautomerization to form an isoquinoline skeleton, as shown here in Scheme 1.



SCHEME 1. *Possible mechanism for the Gabriel-Colman rearrangement involving the formation of the aziridine intermediate.*

Alternatively, this reaction may involve the addition of methoxy to the amido group, the opening of the five-membered ring to give an iminol intermediate, followed by the formation of enolate and the final ring closure, as illustrated here in Scheme 2.



SCHEME 2. *Possible mechanism for the Gabriel-Colman rearrangement involving the formation of an iminol intermediate.*

D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has relatively limited application in isoquinoline syntheses.

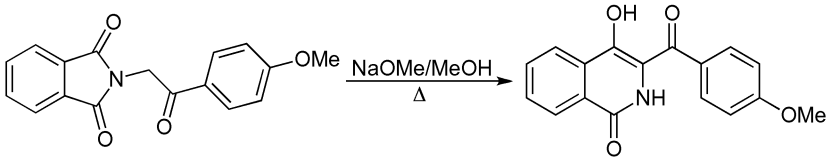
To a 1-L, three-neck, round-bottomed flask, fitted with a mercury-seal stirrer and a Friedrichs condenser equipped with a drying tube with CaO were added 21.9 g methyl phthalimidoacetate (0.1 mol), 21.6 g NaOMe, and 200 mL absolute methanol. Stirring and heating were initiated, and the mixture became dark yellow. In ~15 min, a yellow precipitate began to form. At the end of 1 h, the heating was stopped, the mixture was cooled to room temperature, and 100 mL 6 N HCl was added with stirring and cooling. The grayish precipitate was filtered by suction and washed on the filter with 0.1 N HCl until the washings were colorless, then with distilled water until the washings were neutral. The resulting mass was extracted with 500 mL boiling water, and the mixture was filtered through a funnel with a hot water jacket. After the solution cooled down, 13.8 g 3-carbomethoxy-1,2,3,4-tetrahydroisoquinoline-1,4-dione was obtained by filtration, which at dryness melted at 219–220°C (corrected).



Reference 2e.

A solution of *N*-phenacylphthalimide (4 mmol) was added to a flask containing 50 mL 2 M NaOMe in absolute methanol. The mixture was refluxed in the absence of

moisture and carbon dioxide until homogeneous and then for an additional 2 h. After that, the mixture was cooled, and neutralized with dilute HCl. The solid was filtered, washed with water, and crystallized several times from glacial acetic acid to give *p*-methoxybenzoyl-4-hydroisocarbostyril. (No yield was given.)

Garner Aldehyde

A. GENERAL DESCRIPTION OF THE REACTION

The Garner aldehyde[1]—that is, 1,1-dimethylethyl 4-formyl-2,2-dimethyloxazolidine-3-carboxylate[2] or *N*-Boc D-serinal acetonide[3]—was initially reported by Garner in 1984,[4] and is now commercially available.[2] This compound, a versatile synthon, has wide application in organic synthesis due to its chemical and optical stability, high enantiopurity, and multifunctionality,[5] in which the 4-formyl group can participate in most reactions that occur on regular aldehydes (e.g., *Aldol Reaction, Wittig Reaction*), introducing the contiguous amino-hydroxy functionality that exists in many natural products. In addition, this aldehyde can be readily prepared in the laboratory in multigram quantities[6] without partial racemization.[7] However, it has been reported that the aldehyde itself does epimerize under *Wittig Reaction* conditions when BuLi is used as the base.[3a] To enhance the stability under acidic conditions, the Garner aldehyde is protected by Cbz instead of Boc.[8] It has been reported that olefin predominating in either the *Z*-,[9] or the *E*-configuration[10] can be prepared from this aldehyde, and the allylation with allylindium reagent gives a diastereoselective product in *anti*-form.[11] Some other applications of the Garner aldehyde include the synthesis of glycosyl amino acids,[3a,12] sphingosines,[13] piperidine,[14] and the proteasome inhibitor TMC-95A.[15] The corresponding ester of Garner aldehyde is called the Garner ester.[16]

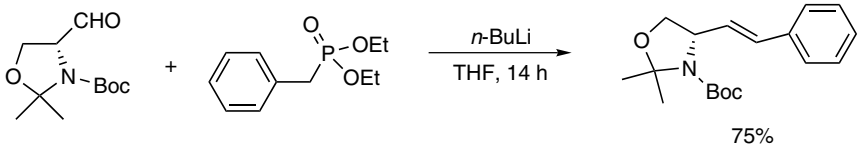
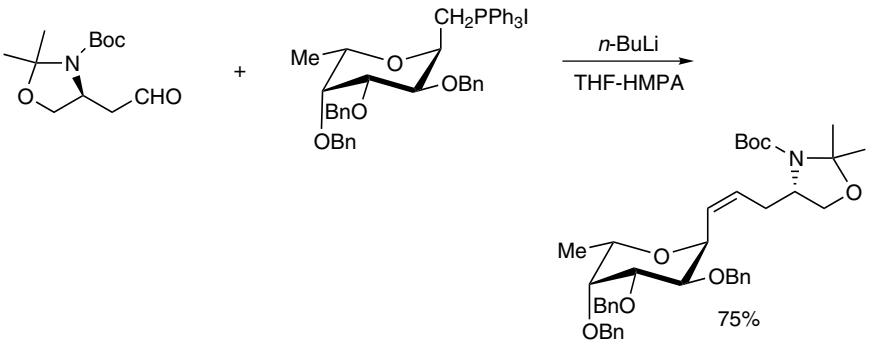
G. CITED EXPERIMENTAL EXAMPLES



Reference 10a.

A solution of 6.95 g diethyl benzylphosphonate (30.48 mmol) in 100 mL THF was treated with 15.24 mL 1.6 M BuLi in hexane (24.38 mmol) at −78°C. The resulting mixture was stirred for 30 min at −78°C, and then a 35 mL THF solution containing 3.49 g Garner aldehyde (15.24 mmol) was slowly added over 30 min. After the addition, the mixture was stirred for 2 h at −78°C and 12 h at room temperature. Then the mixture was quenched with water and diluted with Et_2O; the aqueous phase was extracted with Et_2O three times. The combined organic extracts were washed with brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Purification by flash chromatography (5% EtOAc in petroleum ether) and crystallization in petroleum ether gave 3.46 g (4*S*,1*E*)-2,2-dimethyl-4-styryl-3-*tert*-butyloxycarbonyloxazolidine as colorless crystals, in a yield of 75%, m.p., 85°C.



Reference 3a.

A mixture of 760 mg of phosphonium salt (0.92 mmol), 0.90 g activated 4-Å powdered molecular sieves, 7.1 mL anhydrous THF, and 4.7 mL anhydrous HMPA was stirred at room temperature for 10 min and then cooled to -20°C. The stirred mixture was treated with 580 μL 1.6 M *n*-BuLi in hexanes (0.92 mmol), warmed to 0°C, stirred for an additional 30 min, and then cooled to -20°C. To the stirred mixture was added 336 mg Garner aldehyde in 7.1 mL anhydrous THF over a 15-min period. The mixture was allowed to reach 0°C in 2.5 h, stirred at 0°C for an additional 1 h, and then diluted with 200 mL Et_2O and filtered through a pad of Celite. The ethereal solution was washed with 1 M phosphate buffer at pH 7 (3×30 mL), dried over Na_2SO_4, and concentrated. The residue was eluted from a column of silica gel with 5:1 cyclohexane/EtOAc to give 457 mg 6,10-anhydro-7,8,9-tri-*O*-benzyl-2-*tert*-butoxycarbonylamino-2,3,4,5,11-pentadeoxy-1,2-*N*,*O*-isopropylidene-L-*threo*-D-*ido*-undec-4-(*Z*)-enitol as a syrup, in a yield of 75%.

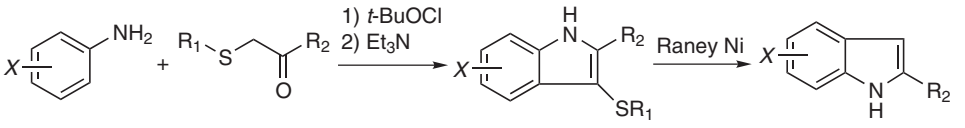
Gassman Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gassman and co-workers in 1973.[1] It is a versatile method used to prepare many types of substituted indoles via a sequential treatment of anilines by *tert*-butyl chlorite, β-keto sulfide, triethylamine, and Raney nickel if desulfurization is needed.[1a] Although this is a multistep reaction, it essentially is a one-pot reaction[2] and can be applied to synthesize either 1- or 2- substituted and 2,7-disubstituted indoles in good yields.[1a] This method has a few demonstrated advantages over the most common methods for the preparation of indoles, e.g., *Fischer Indole Synthesis*. These advantages include the application of a cheap and readily available starting material; accessibility for 1-, 2-, 4-, 5-, 6-, or 7-substituted indoles; mild reaction conditions without involving a strong acid or base; and higher yield than the average yields from the *Fischer Indole Synthesis*.[1a] In contrast, the common *Fischer Indole Synthesis* needs the appropriately substituted phenylhydrazine or 1,1-disubstituted hydrazine to make the desired indole derivatives.[3] A general mechanism was provided in 1974,[4] and the application of this reaction has been reviewed.[5]

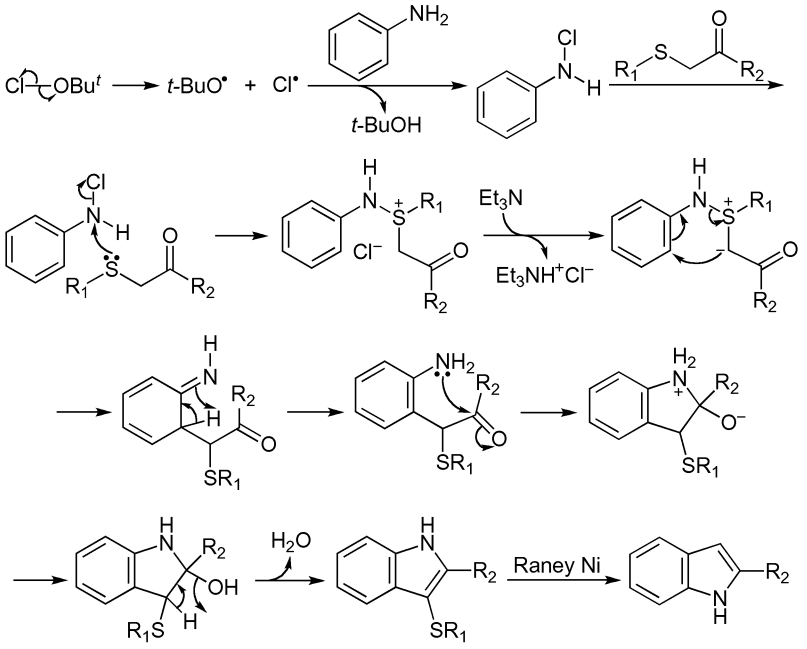
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction is assumed to begin with the proton abstraction by a *t*-butoxy radical, as shown here.



D. MODIFICATION

N/A

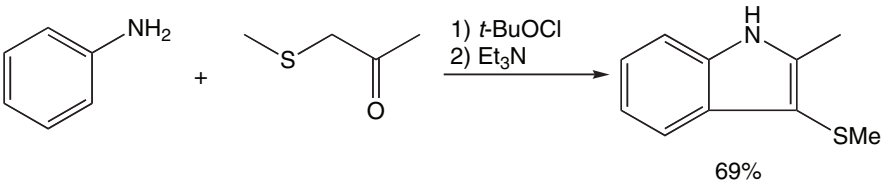
E. APPLICATIONS

This reaction has broad application in the preparation of a variety of substituted indoles.

F. RELATED REACTIONS

This reaction is closely related to the *Gassman Reaction* and *Gassman Oxindole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a vigorously stirred solution of 2.05 g aniline (0.022 mol) in 150 mL CH_2Cl_2 at −65°C was added dropwise 2.4 g *tert*-butyl hypochlorite (0.022 mol) in 20 mL CH_2Cl_2. After 5–10 min, 2.3 g methyl acetylmethylene sulfide (0.022 mol) in 20 mL CH_2Cl_2 was added, causing an exotherm; and the mixture was stirred for an additional hour. Subsequently, 2.22 g triethylamine (0.022 mol) in 20 mL CH_2Cl_2 was added. After the addition was completed, the cooling bath was removed and the solution was allowed to warm to room temperature. Water (50 mL) was added, and the organic layer was separated, dried, filtrated, and evaporated. The residue was then purified by column chromatography over silica gel using methylene chloride. Recrystallization then gave 2.68 g 2-methyl-3-methylthioindole, in a yield of 69%, m.p. 58–59°C, b.p. 140–142°C (0.85 mmHg).

Other references related to the Gassman indole synthesis are cited in the literature.[6]

262

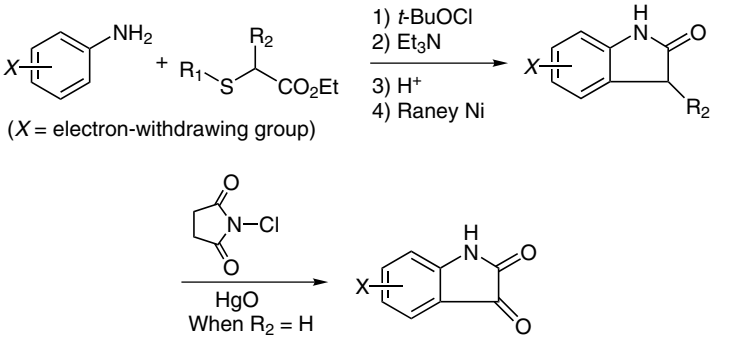
Gassman Oxindole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gassman and co-workers in 1973.[1] It is a multistep process (but a one-pot reaction[2]) for preparing oxindole with an electron-withdrawing group involving sequential treatment of aniline with *tert*-butyl hypochlorite, ethyl (methylthio)acetate, triethylamine, and hydrochloric acid and final treatment with zinc or Raney nickel for the desulfurization.[1,3] Therefore, this reaction is often known as the Gassman oxindole synthesis.[4] For the anilines with an electron-donating group, the nucleophilic attack by a sulfur atom on the nitrogen atom is disfavored, thus an alternative approach is used to prepare the corresponding oxindoles by treatment of the anilines with chlorosulfonium salt.[5] Further oxidation of the resulting oxindole by *N*-chlorosuccinamide/HgO or by direct air oxidation gives relevant isatin.[6] This reaction can tolerate a variety of functional groups, which differ in electron character;[1] in addition, *N*-alkylanilines are also suitable for this reaction.[7] It should be pointed out that when sulfide with a substituent at the active methylene moiety is used, a 3-substituted oxindole will be produced.[1]

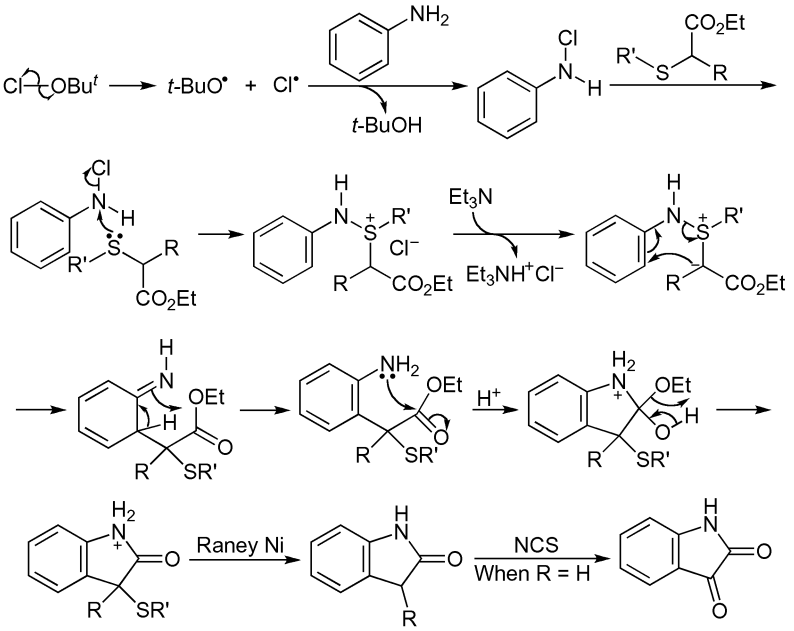
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism emphasizing the formation of oxindole is illustrated here.



D. MODIFICATION

This reaction has been modified to use a sulfoxide as a synthetic equivalent of a sulfenyl halide.[8] In addition, a procedure that involves the initial mixing of ethyl (methylthio)acetate and sulfuryl chloride, followed by the addition of aniline with one equivalent of proton sponge and final Et_3N treatment can be used to prepare oxindole that is not accessible via the initial Gassman protocol.[2]

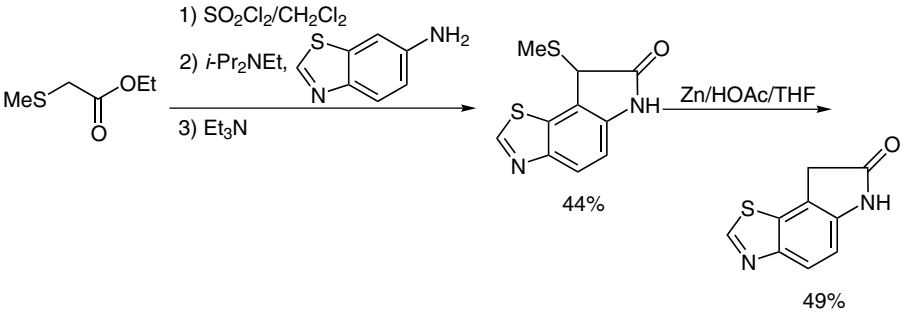
E. APPLICATIONS

This reaction has general application in the preparation of oxindoles and isatins.

F. RELATED REACTIONS

This reaction is closely related to the *Gassman Reaction* and *Gassman Indole Synthesis*.

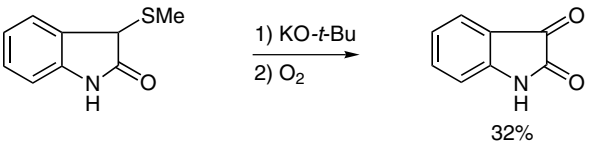
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

Under a nitrogen atmosphere, a mixture of 121 g ethyl methylthioacetate (116 mL, 0.9 mol) and 1.33 L CH_2Cl_2 was cooled to −74°C with a dry ice acetone bath. Sulfuryl chloride (70.0 mL, 118 g, 0.870 mol) was added over a 5-min period, with the temperature maintained between −70° and −74°C, and the clear colorless solution was stirred at −70° to −74°C for 25 min. Then a mixture of 117 g *N*-ethyl-diisopropylamine (157 mL, 0.9 mol), 131 g 6-aminobenzothiazole (0.87 mol), and 1 L CH_2Cl_2 was added over a period of 100 min with the temperature maintained between −69° and −74°C. An additional 0.9 L CH_2Cl_2 was added to dissolve a cream-colored precipitate, and the solution was stirred for 30 min. Triethylamine was added over a 2-min period, causing a temperature rise to −48°C. After 15 min the cooling bath was removed, and the brown-orange solution was warmed to −30°C over a 45-min period with a heat gun. The solution was concentrated under vacuum at 20°C, and the resulting dark orange oil was treated with 1.4 L 0.5-inch N HCl and 1.3 L *tert*-butylmethyl ether. The mixture was stirred for 2.5 h at room temperature. The golden precipitate was isolated by filtration and dried in a vacuum at room temperature to furnish 92 g 8-(methylsulfanyl)-6,8-dihydro-7*H*-[1,3]thiazolo[5,4-*e*]-indol-7-one, in a yield of 44%.

A mixture of 2.7 g 8-(methylsulfanyl)-6,8-dihydro-7*H*-[1,3]thiazolo[5,4-*e*]indol-7-one (11 mmol), 3.0 g activated zinc, 41 mL acetic acid, and 41 mL THF was heated at 60–65°C for 3.5 h. The gray-green mixture was filtered through a sintered glass funnel containing a 0.5-inch pad of Celite, and the pad was washed with 40 mL hot THF/acetic acid (1:1). Water (200 mL) was added to the filtrate, and the pale yellow mixture was stirred for 10 min. The resulting solid was isolated by filtration, washed with 25 mL water, and dried under vacuum at 70°C to furnish 1.05 g 6,8-dihydro-7*H*-[1,3]thiazolo[5,4-*e*]indol-7-one as a pale yellow solid, in a yield of 49%.



Reference 6.

A mixture of 0.48 g 3-methylthiooxindole and an equimolar amount of sublimed potassium *tert*-butoxide was suspended in 200 mL dry ether at 0°C. The solution immediately became colored. The reaction mixture was then stirred and aerated at 0°C for 4 h and then at 25°C for 20 h. Acidification with diluted HCl prepared from 0.22 mL conc. HCl and 25 mL water followed by extraction with ether, drying of the extracts over $MgSO_4$, filtration, and evaporation of the filtrate gave an orange solid. Recrystallization from chloroform gave 0.13 g pure isatin, in a yield of 32%, m.p., 199–200°C.

Other references related to the Gassman oxindole synthesis are cited in the literature.[9]

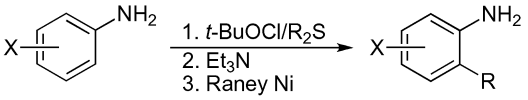
Gassman Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gassman in 1972.[1] It is a multistep preparation of *ortho*-alkylated anilines by sequential treatment of the anilines with *tert*-butyl hypochlorite, dialkylsulfide, and triethylamine followed by Raney nickel desulfurization. Therefore, it is known as the Gassman reaction.[2] Although it is a multistep process, it is actually a one-pot reaction.[2] In addition, this reaction can be adapted to prepare anilines with vinyl, formyl, and benzyl groups at the *ortho*-position.[3] Furthermore, *para*-substituted anilines can be prepared as well via a modified process by which *N*-*t*-butyl-*N*-chloro anilines, generated from the chlorination of anilines from *tert*-butyl hypochlorite, are treated with silver salt and a nucleophile such as methanol.[4]

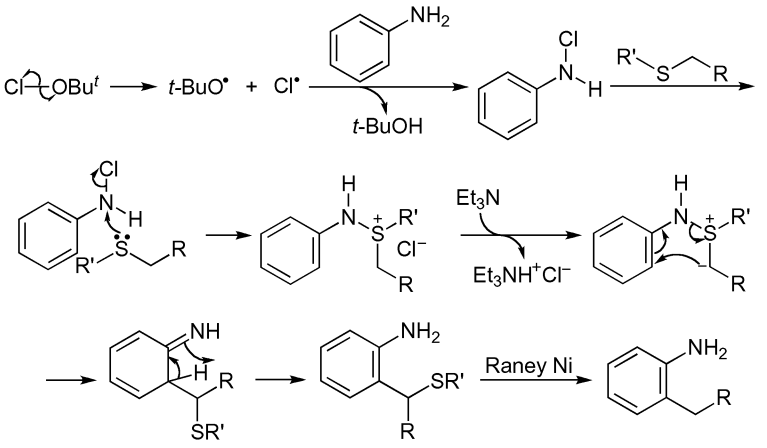
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves the proton abstraction by a *t*-butoxy radical, followed by the coupling between a S_N2 reaction with thioether, as shown here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been improved by using sulfuryl chloride as the chlorination reagent.[2]

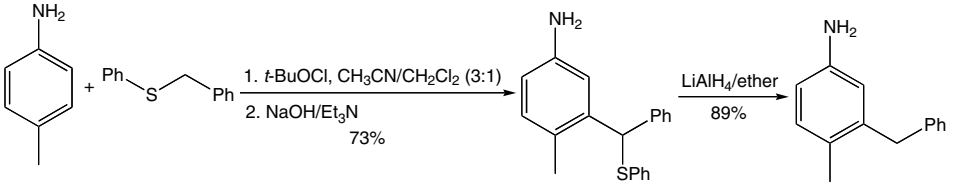
E. APPLICATIONS

This reaction has been used for the preparation of anilines with alkyl, vinyl, formyl, and benzyl groups at the *ortho*-position.

F. RELATED REACTIONS

This reaction is closely related to the *Gassman Indole Synthesis* and *Gassman Oxindole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES

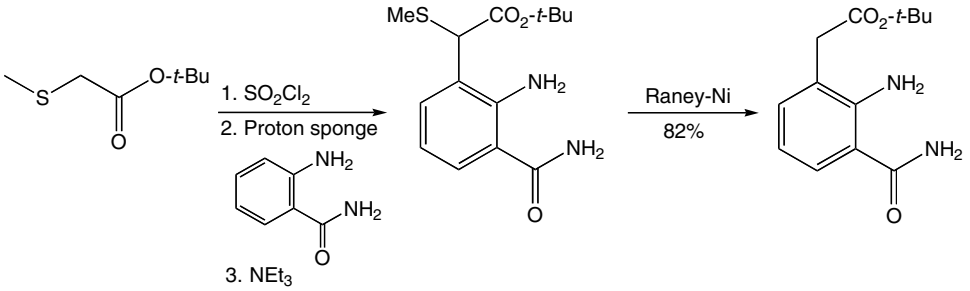


Reference 3.

To a rapidly stirred solution of 2.7 g *p*-tolulidine (0.025 mol) and 0.050–0.080 mol benzyl phenyl sulfide in 300 mL dry acetonitrile and 100 mL methylene chloride under nitrogen at

−40°C was added dropwise 3.5 g *tert*-butyl hypochlorite (0.032 mol) in 25 mL methylene chloride at −78°C in diffuse light. The reaction mixture was stirred for 4 h at −40°C, then allowed to warm slowly to −20°C over a 3-h period. Sodium methoxide (7.0 g, 0.13 mo1) in 50 mL methanol at 25°C was added, and the reaction mixture was stirred for 1 h, during which the reaction mixture warmed to room temperature. The solution was concentrated in vacuo; 250–500 mL dry toluene and 30–50 mL triethylamine were added, and the solution was refluxed for 12 h. The solution was concentrated in vacuo, 100 mL water was added, and the reaction mixture was extracted with CH_2Cl_2 (5 × 100 mL). The combined organic phases were washed with 50 mL 5% aqueous sodium hydroxide and 100 mL brine, dried over $MgSO_4$, and filtered. The solvent was removed in vacuo, leaving an oil that was chromatographed on 300–500 g Fisher basic alumina (activity I) using ether/pentane or ether as the eluant to give 5.7 g 2-amino-5-methyldiphenylthiophenoxymethane as a yellow oil, in a yield of 73%.

To a rapidly stirred suspension of 0.50 g $LiAlH_4$(13.2 mmol) in 100 mL dry ether under nitrogen at room temperature was added 2.0 g 2-amino-5-methyldiphenylthiophenoxymethane (6.6 mmol) in 30 mL ether. The suspension was stirred for 12 h at 25°C. Sulfuric acid (0.5 N, 100 mL) was added, and the product was extracted with ether (5 × 100 mL). The combined organic phases were washed with 50 mL 5% aqueous sodium hydroxide and 100 mL brine, dried over $MgSO_4$, filtered, and concentrated. Distillation of the residue gave 1.16 g 2-amino-5-methyldiphenylmethane, in a yield of 89%, b.p., 124–127°C (0.27 mmHg).



Reference 2.

tert-Butyl (methy1thio)acetate (12.0 g, 74 mmol) in 800 mL methylene chloride at −70°C was treated dropwise with 5.9 mL sulfuryl chloride (73 mmol), and stirred for 30 min, then treated dropwise with a solution of 16 g proton sponge (75 mmol) and 10.0 g anthranilamide (73 mmol) in 1000 mL methylene chloride over 1 h. The resulting pink slurry was then treated with 12 mL triethylamine (86 mmol) and allowed to warm to room temperature. The mixture was washed with water (3 × 250 mL) and brine, dried over Na_2SO_4, filtered, and concentrated by rotary evaporation. Flash chromatography on 200 g silica gel, eluting with EtOAc/hexane (1:1) gave 19.5 g *t*-butyl *m*-amido-*o*-amino-α-methylthiophenylacetate as a pale yellow oil.

A solution of 14.5 g of the yellow oil (49 mmol) in 400 mL absolute ethanol was stirred with 50 mL Raney nickel (washed to neutrality with water then with ethanol) at room temperature for 30 minutes and filtered through Celite; the filter cake was washed with THF (2 × 50 mL). The combined filtrates were concentrated in vacuo, and the resulting solid was triturated with EtOAc/hexane (1:1) to give 10.0 g *t*-butyl *m*-amido-*o*-amino-phenylacetate, in a yield of 82%.

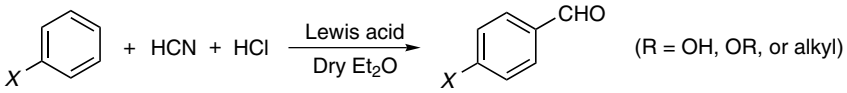
Gattermann Aldehyde Synthesis

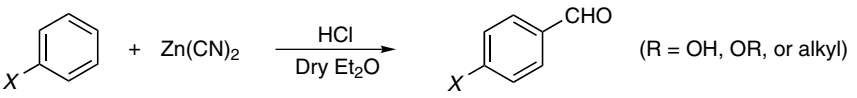
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gattermann in 1898.[1] It is the preparation of aromatic aldehydes containing hydroxyl or alkyloxyl groups on the aromatic ring by treatment of the aromatics with hydrogen cyanide and hydrogen chloride in anhydrous solvent (e.g., ether) with or without the presence of a Lewis acid (e.g., $ZnCl_2$, $AlCl_3$) as a catalyst,[2] in which aldimine hydrochloride functions as an intermediate.[2,3] Therefore, it is generally known as the Gattermann aldehyde synthesis[3,4] or simply as the Gatterman synthesis.[5] However, because the application of anhydrous hydrogen cyanide needs extensive precaution and skill during the whole process,[5c] a new condition was adapted by Adams by treating the aromatics in dry ether with zinc cyanide and then passing them in dry hydrogen chloride, in which hydrogen cyanide forms *in situ* and the new formed zinc chloride functions as a catalyst.[5b,5c] It is known that pure zinc cyanide is ineffective for this reaction, but it will work properly in the presence of a trace amount of KCl or NaCl.[2] Currently, this reaction is probably still the only available process for preparing some phenolic aldehydes[5c] and is even suitable for making aromatic aldehydes with multi-alkyl groups, such as mesitaldehyde.[6]

B. GENERAL REACTION SCHEME



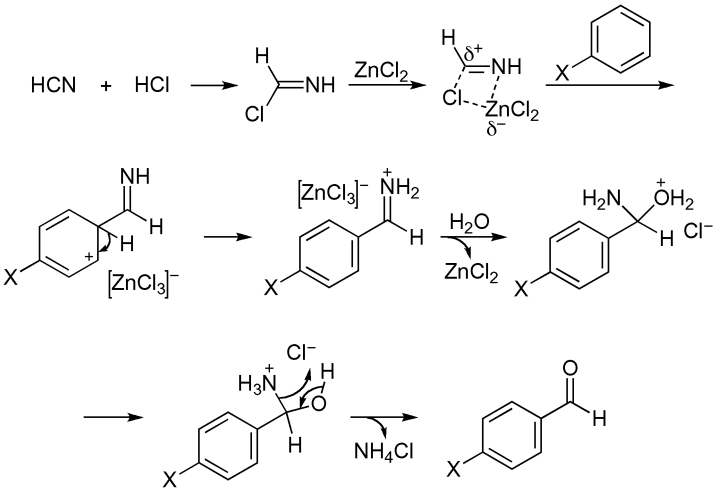
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



Adam-modified condition

C. PROPOSED MECHANISMS

Because no mechanistic details are available, a mechanism is proposed and illustrated here.



D. MODIFICATION

This reaction has been modified by treating aromatic compounds with zinc cyanide and anhydrous hydrogen chloride.[5b,5c]

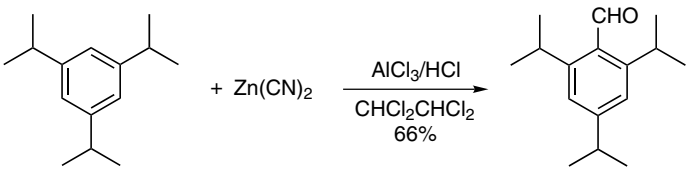
E. APPLICATIONS

This reaction is useful in the preparation of aromatic aldehydes with hydroxyl, alkoxyl, and even mutli-alkyl groups.

F. RELATED REACTIONS

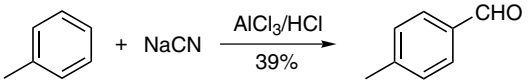
This reaction is related to the *Friedel-Crafts Acylation, Reimer-Tiemann Reaction, Houben-Hoesch Acylation,* and *Vilsmeier-Haack Formylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A rapid stream of dry hydrogen chloride was passed into a mixture of 100 g 1,3,5-triisopropylbenzene, 102 g zinc cyanide, and 400 mL tetrachloroethane until the cyanide was decomposed. The mixture was cooled to 0°C, and to it was added 134 g $AlCl_3$ with vigorous stirring. Introduction of hydrogen chloride was resumed and continued for 8 h at 70°C. The mixture was poured into a mixture of ice and hydrochloric acid and allowed to stand for overnight. It was then heated under reflux for 3 h. Final distillation afforded 75.0 g 2,4,6-triisopropylbenzaldehyde, in a yield of 66%.



Reference 3.

Dry hydrogen chloride was passed at a slow rate into a well-stirred mixture of 25 g reagent sodium cyanide (0.4 mol), 100 g anhydrous aluminum chloride (0.77 mol), and 100 mL toluene (in excess amount) at room temperature for 15 min, after which the bath temperature was brought up gradually to 100°C, and the passage of dry hydrogen chloride was maintained for 7 h. The reaction mixture was hydrolyzed by pouring it into 300 mL ice–conc. HCl, and subjected to steam distillation. The distillate was extracted with ether, neutralized, and dried. It was submitted to fractionation, whereby 35 g unreacted toluene was recovered and 26 g *p*-tolualdehyde was obtained, in a yield of 39%, b.p. 204–207°C. It was noticed that the yield of *p*-tolualdehyde was appreciably lower when the reaction was carried out below 100°C.

Other references related to the Gattermann aldehyde synthesis are cited in the literature.[7]

265

Gattermann Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gattermann in 1890.[1] It is the preparation of aromatic halides or aromatic cyanides by decomposition of corresponding diazo salts in the presence of copper powder, in which copper powder is freshly obtained from a copper (II) sulfate aqueous solution. Therefore, it is generally known as the Gattermann reaction.[2] Occasionally, it is also referred to as the Gattermann method.[3] It should be pointed out that this reaction is almost equivalent to the *Sandmeyer Reaction*.[2b] It is believed that a radical mechanism might be involved in this reaction,[2c] by which electron transfer occurs at the surface of metallic copper.[2b] However, this reaction is not applicable for the preparation of aromatic fluorides because HF exists as H_2F_2 and ionized as H^+ and HF_2^-.[2e]

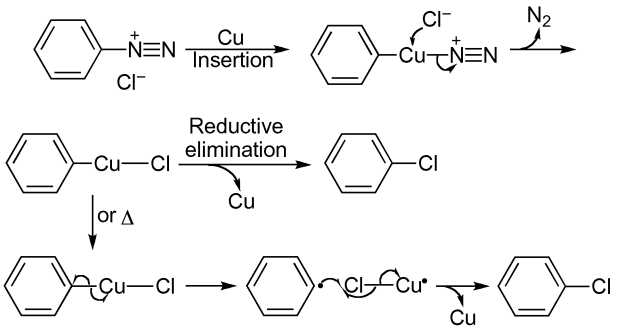
B. GENERAL REACTION SCHEME

$$ArN_2X \xrightarrow[\Delta]{\text{Cu/HCl (aq.)}} ArX \quad (X = \text{Cl, Br, I, CN, etc.})$$

C. PROPOSED MECHANISMS

It is known that this reaction involves unstable aryl cupric halide,[2h] therefore, a tentative mechanism involving a radical process is outlined here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

This reaction has been modified for preparing aromatic mercuric halide.[2h] In addition, a similar procedure for preparing aryl halides from dry arenediazonium *o*-benzenedisulfonimides and quaternary ammonium halides in the presence of copper can be considered a further modification of the Gattermann reaction.[2a]

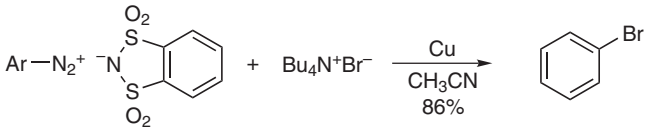
E. APPLICATIONS

This reaction is useful for the preparation of aromatic halides and cyanides.

F. RELATED REACTIONS

This reaction is related to the *Sandmeyer Reaction, Balz-Schiemann Reaction,* and *Bart Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To a suspension of 3.23 g dry benzenediazonium *o*−benzenedisulfonimide (10 mmol) in 20 mL anhydrous CH_3CN maintained at 20°C was added 0.02 g copper powder and 8.06 g tetrabutylammonium bromide (25 mmol) in one portion under vigorous stirring. A rapid evolution of nitrogen took place at once. The salt dissolved, and the solution became red and then cleared to pale orange. The solution was stirred for an additional 45 min, the reaction mixture was filtered to remove the copper, and the solution was then poured into 200 mL Et_2O/water (1:1). The aqueous layer, containing CH_3CN and a suspension of a fine

white solid substance, was separated and extracted again with 80 mL Et_2O. The combined organic extracts were washed several times with water (4 × 50 mL) to eliminate all the CH_3CN, dried over Na_2SO_4, and evaporated under reduced pressure. The crude residue was column chromatographed, eluting with petroleum ether/CH_2Cl_2 (9:1, v/v), to afford 1.35 g bromobenzene as a colorless oil, in a yield of 86%.

Other references related to the Gattermann reaction are cited in the literature.[4]

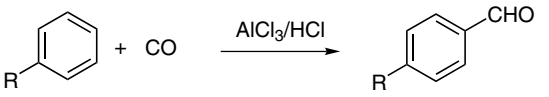
Gattermann-Koch Formylation

A. GENERAL DESCRIPTION OF THE REACTION

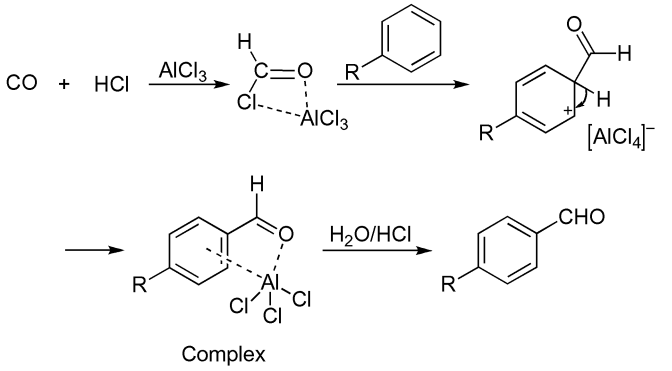
This reaction was originally reported by Gattermann and Koch in 1897.[1] It is the preparation of aromatic aldehydes by the treatment of aromatic compounds with CO and HCl in the presence of $AlCl_3$ and cuprous chloride, by which CO and HCl behave like the hypothetical formyl chloride and react in a fashion similar to other acyl chlorides. Therefore, this reaction is generally known as the Gattermann-Koch formylation.[2] Occasionally, it is also referred to as the Gattermann-Koch aldehyde synthesis,[3] Gattermann-Koch reaction,[4] or Gattermann-Koch synthesis.[5] It is known that this reaction can be carried out in two major types of conditions: at atmospheric pressure of CO with Cu_2Cl_2 present and at high-pressure in absence of Cu_2Cl_2,[6] in which the optimal temperature for high-pressure synthesis of benzaldehyde is 35°C.[7] It is found that the $AlCl_3$-benzaldehyde complex can reduce the induction period in the high pressure synthesis of benzaldehyde with $AlCl_3$,[8] although $AlBr_3$ works better than $AlCl_3$ for the synthesis of benzaldehyde.[9] This reaction is highly *para*-regioselective,[10] as reflected both in the observed toluene/benzene rate ratio ($k_T/k_B = 155 \sim 860$) and in the high degree of *para*-substitution (88.7 ~ 96%);[10d] however, if the *para*-position has been blocked by another group, then migration of such substituent might occur.[11] Besides the system of HCl-$AlCl_3$, the Gattermann-Koch formylation also occurs in superacid conditions, such as HF-BF_3,[12] CF_3SO_3H,[13] HSO_3F-SbF_5,[10c,14] HF-SbF_5,[3c,3d,10a,10b,10e] CF_3SO_3H-SbF_5,[3a,3c,3e,13a] and HF-CF_3SO_3H-BF_3,[10d,13a] in which both kinetic features and regioselectivity indicate a typical intra-complex reaction,[3a,3c] and formylation occurs at atmospheric CO pressure and 0°C in HSO_3F-SbF_5.[10c] However, this reaction is not applicable for phenols or their alkyl ethers where *Gattermann Aldehyde Synthesis* takes place.[6]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



Complex

D. MODIFICATION

This reaction has been modified to occur in a variety of superacid systems as mentioned earlier.

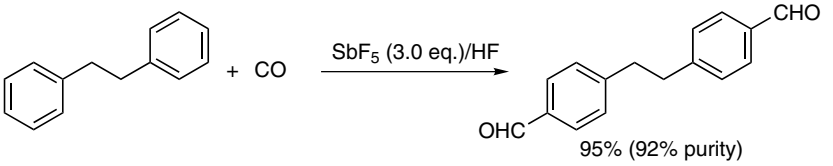
E. APPLICATIONS

This reaction has wide application in the preparation of aromatic aldehydes and is still the major process used to synthesize aromatic aldehydes in industry.

F. RELATED REACTIONS

This reaction is related to the *Friedel-Crafts Acylation, Reimer-Tiemann Reaction*, *Houben-Hoesch Reaction*, *Gatterman Aldehyde Synthesis*, and *Vilsmeier-Haack Formylation*.

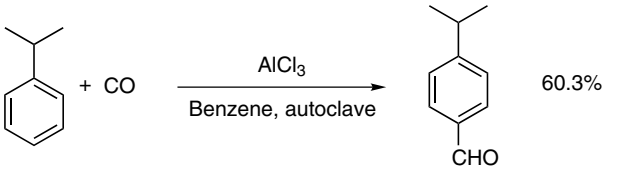
G. CITED EXPERIMENTAL EXAMPLES



95% (92% purity)

Reference 2a.

Dibenzyl (1.82 g, 10 mmol) was added to a solution of Lewis acids with HF or CF_3SO_3H in a Hastelloy autoclave (100 mL) equipped with a Hastelloy magnetic stir bar under temperature control. The autoclave was sealed, and CO was introduced with vigorous stirring until reaching the pressure of 20 atm. After the reaction was over, the autoclave was depressurized and opened. The reaction was quenched with ice water and extracted with benzene. After removal of the solvent, 95% aromatic aldehyde was obtained, where 92% of the aldehyde was p,p'-bisformyl dibenzyl.



Reference 15.

To mixture of 210 g isopropylbenzene (1.75 mol) and 315 g benzene (4.05 mol) saturated with hydrogen chloride in a lead-lined rocking autoclave was added 255 g aluminum chloride (technical, 1.92 mol), which previously had been ground to pass a 20 mesh and exposed in a 1-in. layer to air for 2 h with frequent stirring. The autoclave was then purged with carbon monoxide (commercial) from a cylinder, and carbon monoxide was added to a pressure of 500 psi at 25–30°C. After the pressure dropped to 300 psi, it was again raised to 500 psi. This was repeated until no drop occurred ($\sim$ 2.5 h), whereafter the pressure was maintained for 1 h longer. The reaction mixture was poured onto 2600 g ice acidified with 5 mL conc. HCl and separated. The oil layer was washed with 500-mL portions of water and 55 mL Na_2CO_3 solution and filtered to break the emulsion. After separation, the oil layer was washed twice with 500-mL portions water. The oil was charged to a round-bottomed flask headed by a 36-in. fractionating column packed with glass helices. Distillation was continued under atmospheric pressure until the pot temperature reached 131°C; the distillate was benzene. Then, under a vacuum of 135 mmHg, 40.5 g isopropylbenzene (b.p. 95°C) was recovered. Distillation at 35 mmHg gave 11 g benzaldehyde (b.p., 83–88°C at 35) contaminated with a small amount of isopropylbenzene, 126 g *p*-isopropylbenzaldehyde (b.p., 131–135°C), and 25 g 2,4-diisopropylbenzaldehyde. There was $\sim$ 25 g of residue left after the fractionation. The yield of *p*-isopropylbenzaldehyde was 60.3%, based on the recovered isopropylbenzene.

Other references related to the Gattermann-Koch formylation are cited in the literature.[16]

Gewald Reaction

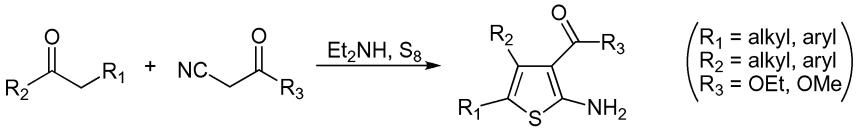
(Gewald Aminothiophene Synthesis, Gewald Synthesis of 2-Aminothiophene)

A. GENERAL DESCRIPTION OF THE REACTION

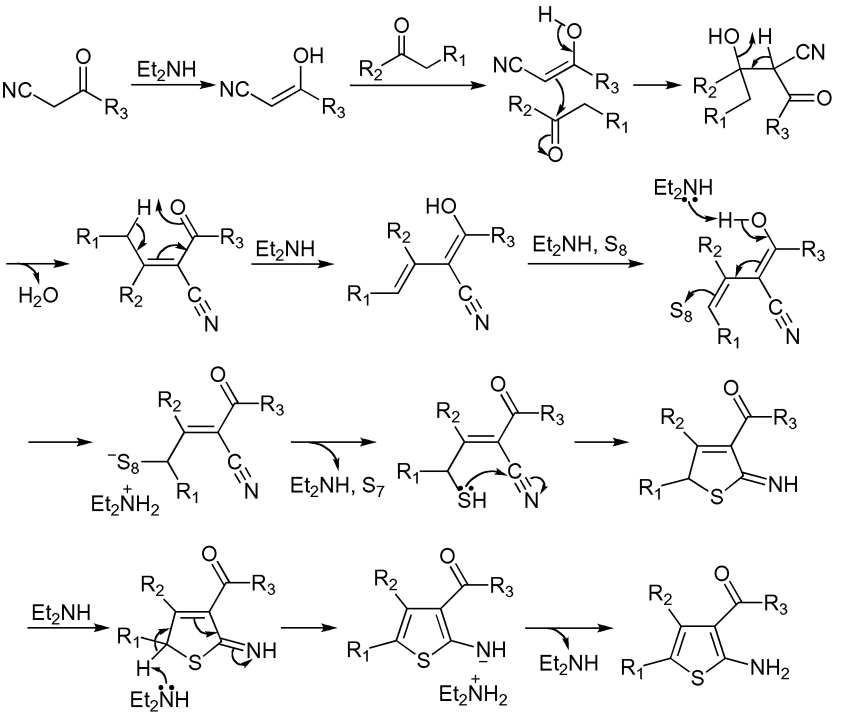
This reaction was initially reported by Gewald in 1965.[1] It is the usual route for synthesizing 2-aminothiophene involving a base-catalyzed condensation of a ketone having an active CH_2 group with α-ketonitrile to form an olefin that cyclizes with sulfur.[2] Therefore, this reaction is known as the Gewald reaction,[3] Gewald synthesis,[2a,3g,3l,4] Gewald thiophene synthesis,[3j] Gewald aminothiophene synthesis,[3g,3j,5] or Gewald synthesis of 2-aminothiophene.[4a,6] This reaction has two major types of variants: a two-step synthesis and a one-pot synthesis. The two-step variant involves the isolation of the olefin intermediate and is primarily used for large-scale synthesis, whereas most current syntheses use the one-pot variant by adding all the reactants and catalyst at once.[2b] In this reaction, diethyl amine is usually the catalyst,[2b] although a solid-phase catalyst has been reported for such reaction.[7] This reaction provides a route for thieno[2,3-d][1,3]-oxazin-4-ones,[3j,3l] a useful moiety for the serine protease inhibitor.[3l] This reaction has been modified to synthesize 2-aminothiophene with a substituent at the 3-, 4-, or 5-position.[2a] Unfortunately, this reaction is limited to the preparation of 2-aminothiophenes with electron-withdrawing groups at the 3-position.[3h] In addition, it produces a significant amount of isomeric by-product if two active CH_2 groups are available.[3g]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has recently been modified for preparing 2-aminothiophenes with a substituent at the 3-, 4-, or 5-position.[2a]

E. APPLICATIONS

This reaction is the usual method used to synthesize 2-aminothiophenes.

F. RELATED REACTIONS

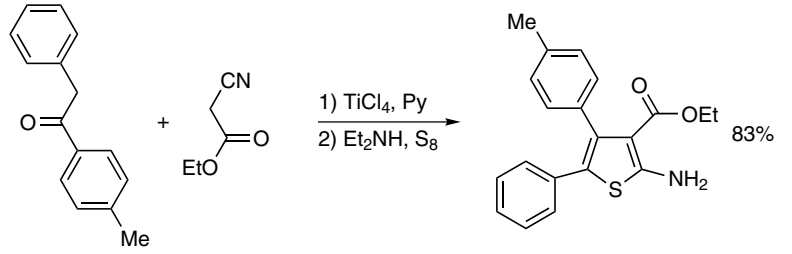
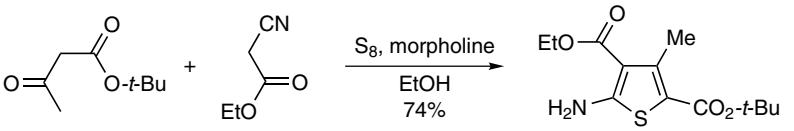
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To 60 mL anhydrous THF at 0°C was added 4.9 mL neat $TiCl_4$ (45 mmol) dropwise, followed by a THF solution of 4.33 g deoxybenzoin (22 mmol) and 30 mmol ethyl cyanoacetate. The ice bath was removed, and 1.5 mL dry pyridine was added. The dark blue solution was stirred for 1 h, after the addition of an additional 4.5 mL pyridine, the reaction mixture was stirred overnight at room temperature. The reaction mixture was neutralized with 10% HCl and extracted with EtOAc. The combined organic layers were washed with 2 M NaOH and dried over $MgSO_4$. Evaporation of the solvent afforded a crude Knoevenagel product, which was taken up in 20 mL THF and stirred at room temperature with 710 mg sulfur (22.2 mmol) and 4 mL diethylamine for 1 h. The volatiles were removed in vacuo to afford the crude ethyl 2-amino-4-(4-methylphenyl)-5-phenylthiophene-3-carboxylate, which was recrystallized from hot ethanol in a yield of 83%.



Reference 3j.

A mixture of 15.8 g *tert*-butyl acetoacetate (100 mmol), 11.3 g ethyl cyanoacetate (100 mmol), 3.5 g sulfur (110 mmol), and 25 mL EtOH was stirred at 45°C. Morpholine (10 g, 115 mmol) was added dropwise over 15 min. Then the mixture was stirred at 60°C for 5 h and filtered. The filtrate was diluted with 50 mL water and cooled. The precipitate was collected by filtration, washed with 30% EtOH, and dried to obtain 21.2 g ethyl 2-amino-4-methyl-5-(*tert*-butoxycarbonyl)thiophene-3-carboxlate, in a yield of 74%, m.p., 116–117°C (cyclohexane/hexane).

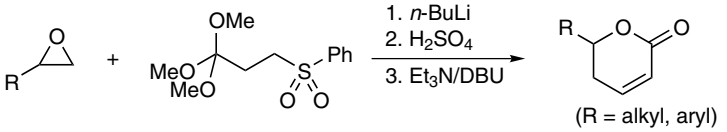
Ghosez Cyclization
(Ghosez Lactonization)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Ghosez and co-workers in 1988.[1] It is the synthesis of α,β-unsaturated δ-lactone and the corresponding dihydropyran reduced from such lactone derivative, involving the reaction of epoxide with the lithio derivative of methyl 3-(phenylsulfonyl)orthopropionate and subsequent acid hydrolysis and base-induced elimination of phenylsulfinic acid. This reaction is thus known as the Ghosez cyclization[2] or the Ghosez lactonization.[3]

In this reaction, methyl 3-(phenylsulfonyl)orthopropionate functioning as a 1,3-dipole equivalent, contains a potential carbanion center at C-3 that is stabilized by a phenylsulfonyl group, and has a masked cationic character at C-1 in the form of an *ortho*-ester.[4] Upon treatment of the base, the carbanion is generated at C-3, which nucleophilically attacks the epoxide ring via a S_N2 reaction; the resulting alkoxide anion undergoes the second S_N2 reaction by replacement of a methoxide to give the cyclic orthoester. Acidic hydrolysis of the cyclic orthoester forms δ-lactone, and the subsequent base-induced elimination of phenylsulfinic acid generates the α,β-unsaturated δ-lactone.

B. GENERAL REACTION SCHEME

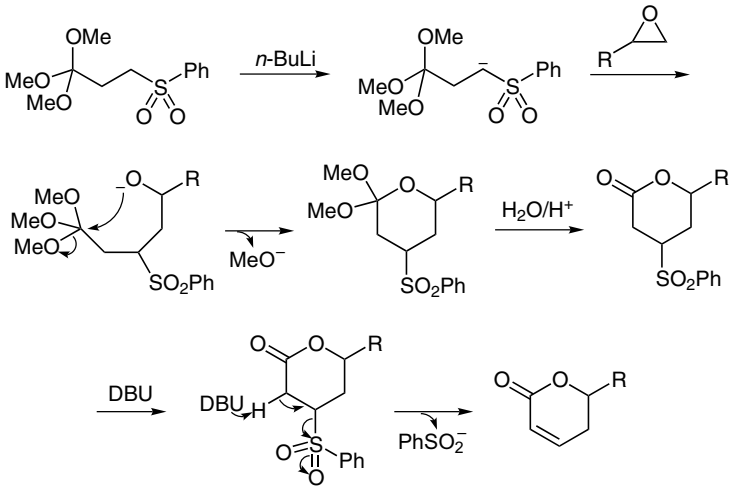


(R = alkyl, aryl)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A simple illustration of the reaction mechanism is provided here.



D. MODIFICATION

A similar reaction involving 2,3-dibromo-1-phenylsulfonyl-1-propene and a carbanion from acetoacetone or 3-methylacetoacetone to form the corresponding 2-methyl-4-[(phenylsulfonyl)methyl]furan or 2-methyl-3-[(phenylsulfonyl)methyl]-2-cyclopenten-1-one could be considered as an extension of this reaction.[5]

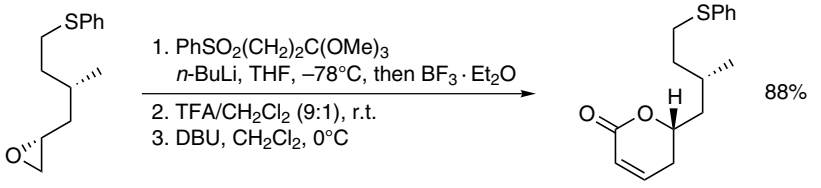
E. APPLICATIONS

This reaction has certain applications in organic synthesis, such as the preparation of hydrindan,[4] glycoside,[3a] and natural product swinholide A.[2b,2c]

F. RELATED REACTIONS

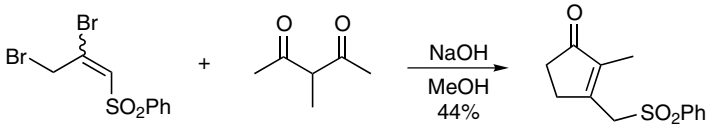
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3b.

To a solution of 3.29 g methyl 3-phenylsulfonyl orthopropionate (12.0 mmol) in 40 mL THF cooled at –78°C was added 7.76 mL 1.6 M *n*-BuLi (12.4 mmol) in hexanes dropwise. After being stirred for 30 min, 1.54 mL $BF_3{\cdot}Et_2O$ (12.1 mmol) was added, followed by 888 mg (2*R*)-2-[(2*R*)-(2-methyl-4-phenylsulfanyl-butyl)]oxirane (4.0 mmol) in 6 mL dry THF. After being stirred for 1.5 h at –78°C, the reaction mixture was poured into a mixture of cold saturated aqueous $NaHCO_3$ (60 mL) and Et_2O (160 mL) with vigorous stirring. The phases were separated, and the aqueous layer was extracted with Et_2O three times. The combined organic phases were dried over $MgSO_4$ and concentrated. The residue was stirred with 40 mL 90% aqueous TFA at room temperature for 3 h and concentrated. The remaining material was dried by repeated co-evaporation with toluene (3 × 50 mL), dissolved in 40 mL dry CH_2Cl_2, and cooled (0°–5°C). To this cold solution was added 2.0 mL DBU (13.4 mmol) dropwise via syringe. The elimination of phenylsulfinic acid completed in 30 min as monitored by TLC (CH_2Cl_2/hexanes/EtOAc, 16:15:1, R_f = 0.39). The solution was concentrated, and the residue was purified by flash chromatography to afford 973 mg (6*R*)-6-[(2*R*)-(2-methyl-4-phenylsulfanyl-butyl)]-5,6-dihydro-2*H*-pyran-2-one as a bright yellow oil, in a yield of 88%.



Reference 5a.

In a 1-L, flame-dried, round-bottomed flask equipped with an addition funnel under a nitrogen atmosphere were placed 20.0 g 2,3-dibromo-1-(phenylsulfonyl)-1-propene (58.8 mmol) and 7.0 mL 3-methyl-2,4-pentanedione (60.0 mmol) in 300 mL methanol. The flask was cooled in an ice water bath. To this mixture was added 140 mL 0.5 *N* NaOH (70.0 mmol) in methanol dropwise over 30 min. The solution was then stirred at 25°C for 5 h and cooled to 0°C. Another 140 mL 0.5 *N* NaOH in methanol was added over 20 min. After being stirred at 25°C for 10 h, the reaction was quenched by 50 mL saturated NH_4Cl solution. The solvent was removed with a rotary evaporator at aspirator vacuum, and the resulting residue was taken up in 100 mL water and 200 mL dichloromethane. The aqueous layer was extracted with dichloromethane (2 × 200 mL). The combined organic layers were washed with 100 mL water, 100 mL brine, and dried over anhydrous $MgSO_4$. After filtration and concentration, the residue was recrystallized from EtOAc to give 6.5 g 2-methyl-3-[(phenylsulfonyl)methyl]-2-cyclopenten-1-one, in a yield of 44%. (*Note*: NaOH was displayed as NaOMe in the original reaction scheme.)

Ghosez Keteniminium-Olefin Cyclization

(Ghosez [2+2] Keteniminium-Olefin Cycloaddition)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Ghosez as early as 1972.[1] It is the synthesis of cyclobutanones from the reaction of alkenes and keteniminium ions. The keteniminium ions are usually generated from tertiary amides by reacting with triflic anhydride and a hindered pyridine base[2] or by the dechlorination of 1-chloro-*N*,*N*,2-trimethyl-1-propylenamine with $AgBF_4$[1,3] followed by the hydrolysis of the resulting iminium salts under biphasic conditions. Therefore, this reaction is known as Ghosez keteniminium-olefin cyclization or Ghosez [2+2] keteniminium-olefin cycloaddition;[4] and 1-chloro-*N*,*N*,2-trimethyl-1-propylenamine, generated by the treatment of *N*,*N*-dimethyl 2-methylpropionamide with phosgene and triethylamine,[3] is known as the Ghosez reagent.[5]

The keteniminium salt, being a ketene equivalent,[6] is superior to ketene in [2+2] cycloaddtion, due to the higher electrophilicity (with a positive charge) and the absence of dimerization owing to charge-charge repulsion;[7] in comparison, ketenes are known to dimerize.[8] As a result, the reaction conditions for keteniminium salt are very mild, and the yields are often satisfactory.[1] In addition, the keteniminium salt with a chiral inducer on the carbon atom usually leads to the formation of cyclobutanone, with the configuration following the known chirality of the inducer.[6] Although the intermolecular reaction of a keteniminium salt with 1,1-disubstituted alkenes gives very low yields of product, the intramolecular cycloaddition occurs with three-, four-, five- and seven-atom tethers; in

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

contrast, the corresponding reaction of ketenes normally proceed with three- or four-atom tethers.[7]

It should be pointed out that the *[2+2] Cycloaddition* between keteniminium and imines to form β-lactams was reported by Ghosez even earlier (1970),[9] and azetidiniminium salts are generated from this cycloaddition, which can be converted into many different molecules besides β-lactams, including 2-acetidinethiones, azetidinimines, oxazolidin-2-ones, and 2-amino-1-azetines as well as 1,2-amino alcohols and α-amino acids.[10] In such modifications, the keteniminium salts can be simply prepared from *N*,*N*-dialkyl amides by means of phosgene; the resulting *N*,*N*-dialkyl-2-chloroiminium chloride might take three different routes to give azetidiniminium salts: (*a*) direct reaction with imine in the presence of triethylamine; (*b*) formation of enamine in the presence of Et_3N and coupling with imine; and (*c*) formation of enamine in the presence of Et_3N, conversion of resulting enamine into keteniminium salt by a Lewis acid (e.g., $ZnCl_2$ or $TiCl_4$), and subsequent reaction with imine.[11] In this reaction, path *a* is more practical; however, only path *c* affords 4-alkyl azetidiniminium salts.[11] Although chiral iminium salts usually give chiral azetidiniminium salts of high optical purity, the large α-substituents on the carboxyl moiety play a decisive role on the diastereoselectivity of the reaction, whereas the diastereoselectivity is rather independent of the substituents on corresponding imines.[11]

Upon treatment with base (e.g., hydroxide) followed by acidic hydrolysis, either β-lactams or β-amino amides are obtained from azetidiniminium salts via an exocyclic or endocyclic C-N bond cleavage.[11] It has been reported that the ratio of β-lactams to β-amino amides depends on the relative rate of protonation on the exocyclic and endocyclic nitrogen atom of the tetrahedral intermediate.[11] Likewise, thiolysis or aminolysis by treatment of azetidiniminium salts with sodium hydrosulfide or primary amines (including ammonia and hydroxylamine) affords the corresponding azetidinethiones or azetidinimines (Figure 1).[11] However, during the formation of azetidinimines, the azetidiniminium salts with hydrogen at the α-carbon give a much lower yield of product; in this case, the corresponding azetidinimines can be prepared by the formation of azetidine-2-thione and further reaction with amine in the presence of mercuric acetate.[11] In addition, the *Baeyer-Villiger Oxidation* of azetidiniminium salts give oxazolidinones; similarly, oxidation of azetidiniminium salts with *bis*-trimethylsilyl peroxide in the presence of fluoride affords the five-membered carbamates, which are then hydrolyzed to aminoalcohols (Scheme 1).[11]

B. GENERAL REACTION SCHEME

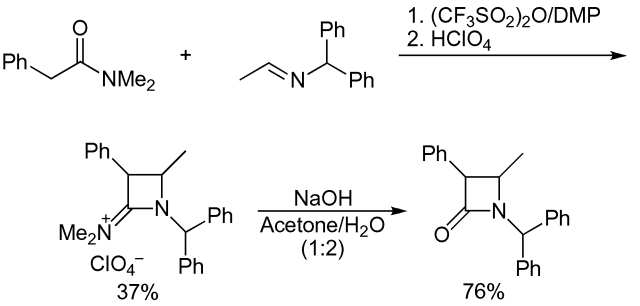
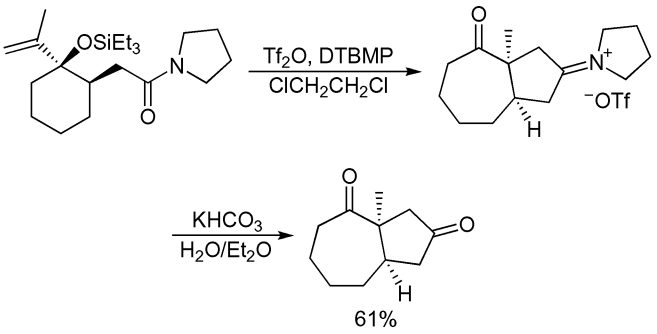
G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

To a mixture of 0.40 g *N*,*N*-dimethyl phenylacetamide (2.45 mmol) and 0.41 mL triflic anhydride was added a solution of 0.5 g imine prepared from the corresponding acetaldehyde and benzhydrylamine (2.44 mmol) and 0.5 g 2,6-dimethylpyridine (DMP) in 6 mL 1,2-dichloroethane. The solution was stirred at –20°C for 1 h and then at 25°C for 2 h. After conversion of the azetidiniminium triflate to the corresponding perchlorate, the residue was purified by silica gel column chromatography using CH_2Cl_2/CH_3CN (5:1) as the eluent to afford 0.41 g *cis*-3-phenyl-4-methyl-1-benzhydrylazetidine-2-(*N*-dimethyliminium perchlorate), in a yield of 37%. This compound was then dissolved in 10 mL acetone/water (1:2), and 10 mL 1 N NaOH aqueous solution was added. The resulting mixture was stirred at 25°C for 1 h. Acetone was removed under vacuum, and the product was extracted with CH_2Cl_2. The organic layers were dried over Na_2SO_4 and concentrated. The residue was purified by column chromatography using *n*-pentane/EtOAc (13:2) as the eluent to give 0.22 g *cis*-3-phenyl-4-methyl-1-benzydrylazetidin-2-one as an oil, in a yield of 76%.



Reference 2.

To a 0.1 M solution of 1-pyrrolidin-1-yl-2-[2-triethylsiloxy-2-isopropenylcyclohexyl]-ethanone (95 mg, 0.26 mmol) in 2.6 mL 1,2-dichloroethane containing 66.7 mg 2,6-di-*tert*-butyl-4-methylpyridine (DTBMP, 0.33 mmol, 1.25 eq.) cooled to –20°C was added 92 mg trifluoromethanesulfonic anhydride (0.33 mmol, 1.25 eq.) dropwise. The mixture was allowed to slowly warm to room temperature and then was stirred at 65°C for 18 h. The reaction mixture was cooled to room temperature and concentrated; the resulting residue was dissolved in a mixture of 3 mL aqueous $KHCO_3$ and 3 mL ether, and the mixture was stirred vigorously at room temperature for 5 h. After extraction of the product with ether (3×20 mL), the combined organic extracts were dried over Na_2SO_4, filtered, and concentrated. The residue was purified by silica gel flash chromatography using EtOAc/hexanes (1:9 to 2:8) as the eluent to give 29 mg (3a*R*,5a*R*)-3a-(methyl)octahydroazulene-2,4-dione as a colorless oil, in a yield of 61% and > 20:1 of diasteroselectivity.

Gibbs-Wohl Naphthalene Oxidation

(Gibbs Phthalic Anhydride Process)

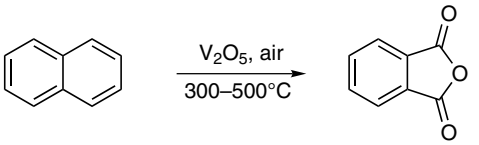
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gibbs and Conover in 1918,[1] based on a laboratory process in 1917.[2] It is a simple and direct vapor-phase oxidation of naphthalene to phthalic anhydride in the presence of a catalyst made from Group VB or VIB transition metals. This process was highly supported by the U.S. government[2] in 1910s because phthalic anhydride was an important intermediate for dyes (e.g., indigo) and medicinal molecules.[3] All phthalic anhydride was imported exclusively from Germany and was unfortunately cut off due to World War I.[2] This process is the modification of a German patent by Sapper at Badische Anilin und Soda Fabrik in 1896,[4] in which sulfuric acid was used to oxidize naphthalene with a mercury salt as the catalyst.[3] It was obvious that many disadvantages were associated with the 1896 process, which involves an expensive apparatus to convert SO_2 to SO_3,[5] though it was the primary method to produce phthalic anhydride at that time. The new process uses air and naphthalene and produces phthalic anhydride as the only product,[2] a much more efficient way of carrying out chemical reactions, which has directed inventions of other oxidation of aromatic compounds, such as the production of anthraquinone from anthracene,[6] and phenanthraquinone from phenanthrene.[7] Therefore, this process is known as Gibbs phthalic anhydride process. In the original patent, Gibbs and Conover tested the catalytic efficiency of many metal oxides—including MgO, Al_2O_3, TiO_2, ZrO_2, CeO_2, Cb_2O_5, Cr_2O_3, WO_3, UO_3, Mn_2O_3, Fe_2O_3, NiO, MoO_3, Co_2O_3, Cu_2O, and V_2O_5—by passing a mixture of naphthalene and air through the reaction tube; they found that V_2O_5 was the best catalyst, with 3.7% conversion and 7.5% yield,[5] and MoO_3 was the second best

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

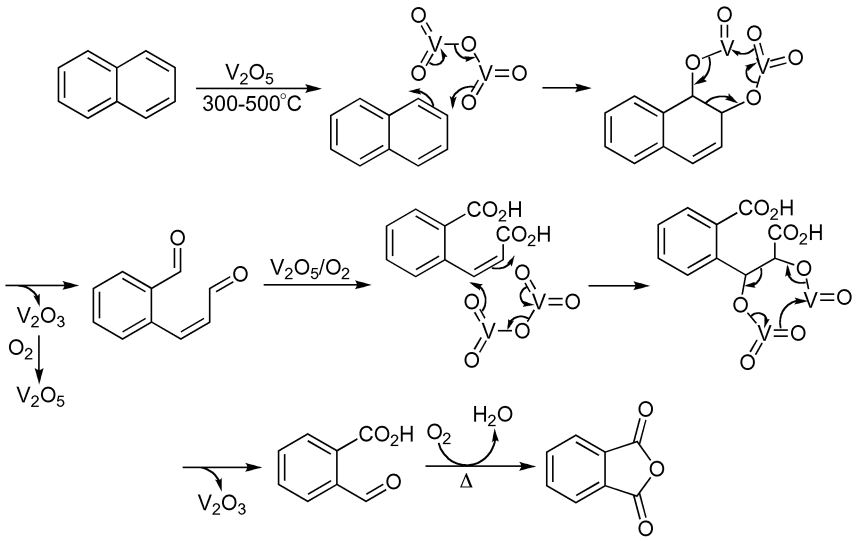
catalyst with a yield of phthalic anhydride at 31.1% and 10.2% conversion.[5] (This should indicate that MoO_3 is the best catalyst!) It was found that the reaction temperature was critical in this reaction, and it reacted at 275°C for V_2O_5 and 325°C for MoO_3 when pure oxygen was used; naphthalene started to combust at 300°C and 350°C, respectively. However, the reaction temperature could be raised to 500°C without the ignition of naphthalene when air was directly used, giving a higher yield of product.[5] It was found that V_2O_5, fused and then finely powdered, was a better catalyst than the light powder obtained from decomposing ammonium metavanadate at low temperature, of which the catalytic efficiency is not effectively lowered by AsO_3 or SO_2 but is lowered by sodium compounds. In this case, phthalic acid was the major product, and CO_2 was the major gaseous product. Benzoic acid and naphthols might exist as minor products, but no CO was detected.[5] It is interesting that Wohl in Germany invented the same synthesis 2–3 months earlier than Gibbs, and he was finally granted the U.S. patent in the 1930s[8] with a validation on August 28, 1951.[2] Therefore, this reaction is also referred to as Gibbs-Wohl oxidation of naphthalene. Unfortunately, Andrews, who claimed an article of manufacturing "phthalic anhydride substantially chemically pure and having a melting point above 130°C., corrected" and "phthalic anhydride in the form of colorless, needle-like crystals substantially chemically pure and having a melting point above 130°C., corrected," was granted a U.S. patent[9] that was later claimed to be not patentable.[10]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This is a very complicated process, therefore, a tentative mechanism is proposed here.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction is the primary method for the production of phthalic anhydride in industry.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES

Because this is used in the industrial production of phthalic anhydride, no preparation on a laboratory scale is available; thus no experimental details are collected here.

Other references related to the Gibbs-Wohl naphthalene oxidation are cited in the literature.[11]

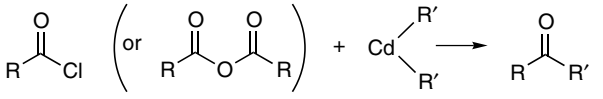
Gilman-Cason Ketone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gilman in 1936[1] and was later extensively explored by Cason.[2] It is the preparation of ketones from alkyl (or aryl) cadmium and acyl chloride or anhydride, and is called the Gilman-Cason ketone synthesis. In this reaction, the cadmium reagent is preferentially prepared from a lithium derivative rather than a Grignard reagent,[1] although the aromatic Grignard reagents form cadmium derivatives readily and give good yields of aromatic ketones.[1,2b,3] For the scope of this reaction, it was found that in the case of *n*-butyl halides the chloride is somewhat inferior to the bromide, although it is much better than the corresponding iodide;[2b] in addition, reaction with anhydride seems to be uniformly inferior to that obtained with acid chlorides.[2b–2d,3b] The order of relative reactivity of acyl halides is ArCOI > ArCOBr > ArCOCl > ArCOF.[4] Cadmium chloride is at least as effective as cadmium bromide for preparing the cadmium reagents,[1] and secondary or tertiary alkylcadmium reagents are too unstable to allow their effective use in synthesis, even at a temperature as low as 0°C.[5] It was reported that alkyl cadmium can dissociate and form alkyl radical upon heating.[5] For example, butenylcadmium reagents rapidly dissociate at the boiling temperature of ether and results in the coupling products.[5]

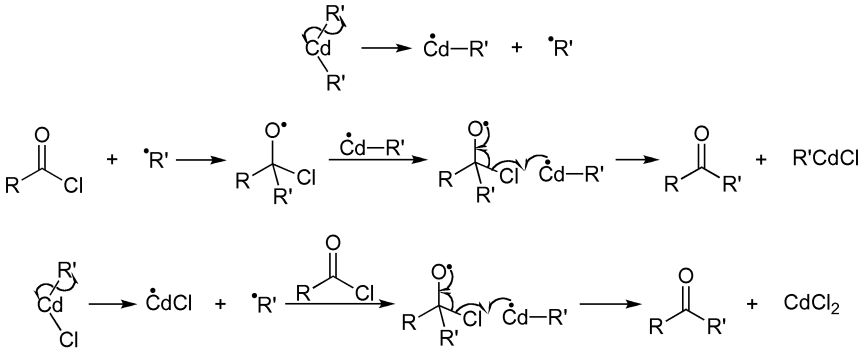
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Cadmium reagent is much milder than corresponding Grignard reagent, and it is believed that cadmium reagent can dissociate into radicals,[5] therefore, the mechanism is tentatively proposed here.



If no radical is involved in this reaction, then the mechanism should be very similar to that of the *Grignard Reaction*. However, as cadmium reagents are much milder than Grignard reagents, they will not further attack the formed ketones.

D. MODIFICATION

N/A

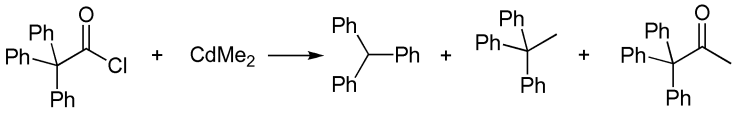
E. APPLICATIONS

This reaction can be used in the synthesis of ketones with multifunctional groups, including carbonyl and esters.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES

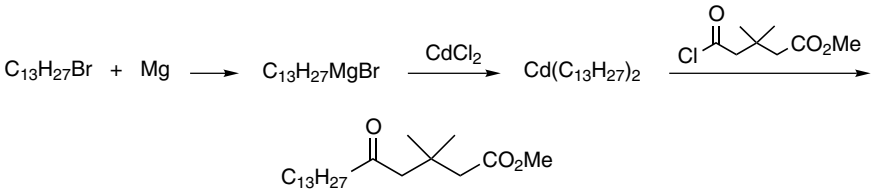


Reference 6.

A Grignard reagent was prepared in 18 mL ether from 0.16 g magnesium turnings and excess methyl bromide, which had been bubbled through sulfuric acid. This reagent

was converted to the cadmium reagent in usual fashion[7] with 0.60 g anhydrous cadmium chloride. After distillation of ether and the addition of 15 mL benzene, a solution of 1.0 g triphenylacetyl chloride in 5 mL benzene was added at 10°C over ~2 min. After the cooling bath had been removed, there was no observable exothermic reaction as the mixture warmed to room temperature.

The reaction was continued with stirring for 1 h at 43°C, then caked solid was scraped from the sides of the flask, and the mixture was heated to reflux for 1 h. As the temperature was raised, sudden boiling occurred, and the mixture turned a bright yellow. The reaction mixture was worked up in the usual fashion for cadmium reactions, and 0.54 g of a yellow oil was obtained, from which no significant crystallization could be obtained in ethanol. Chromatography on alumina of activity III gave 18% triphenylmethane, 33% triphenylethane, and 12% methyl trityl ketone. The melting point of methyl trityl ketone was 137.5–139°C after recrystallization.



Reference 8.

A Grignard reagent was prepared in a nitrogen atmosphere in the usual manner from 4.9 g magnesium turnings (0.2 mol) and 52.7 g *n*-tridecyl bromide (0.2 mol). This was converted to the cadmium reagent with 29.2 g anhydrous cadmium chloride (0.16 mol). Ether was distilled until distillation on a steam bath became slow, then 65 mL benzene was added immediately, and an additional 10 mL distillate was collected. This mixture was cooled to 20°C, and then to the stirred mixture in one portion was added a solution of 19.3 g γ-carbomethoxy-β,β-dimethylbutyryl chloride (0.1 mol) in 70 mL benzene. The temperature of the mixture rose rapidly to 40°C and was maintained at 38–40°C for 80 min, cooling being necessary during the first 20 min. The temperature was then raised to 65°C over 1 h, after which time the mixture was worked up as usual. On distillation, there was obtained 14.5 g of fore run consisting mostly of tridecane, b.p. 115°C (15.5 mmHg), and 30.1 g methyl-3,3-dimethyl-5-ketooctadecanoate (88%), b.p. 191–193°C (2.5 mmHg.)

Gilman-Speeter Reaction
(Gilman-Speeter Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

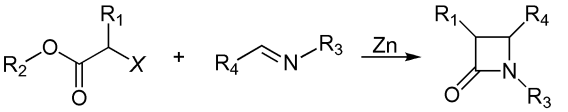
This reaction was first reported by Gilman and Speeter in 1943.[1] It is an efficient preparation of 3-alkyl-substituted or unsubstituted β-lactams by the condensation of a Reformatsky reagent and an imine. Therefore, this reaction is generally known as the Gilman-Speeter reaction[2] or Gilman-Speeter condensation.[2e] In addition, the extended reactions between lithium ester enolate or lithium thioester enolate and imine are also considered as the Gilman-Speeter reaction.

This reaction usually works for nonenolizable imines (e.g., *N*-aryl aldimines)[2g] and has the features of readily accessible starting materials, and simple preparation of 3-substituted or unsubstituted 2-azetidinones (i.e., β-lactams) with direct control of stereoselectivities.[2h] It has been reported that the yield of this reaction depends on the activation and the type of zinc.[3] The stereochemistry of β-lactams depends on the α-substituent of bromoacetates, the solvent, and the alkyl portion of the esters.[2g] For example, when the α-substituent is an alkyl group (e.g., Me, Et, *i*-Pr, cyclohexyl, *t*-Bu), the major product has *cis* geometry, such a trend is especially prevailing for the reaction of acetate with a branched α-substituent (e.g., *i*-Pr, cyclohexyl, *t*-Bu) in THF.[2g] For comparison, the reaction of isopropyl acetate in toluene tends to form β-lactams of *trans* geometry. In addition, phenyl acetates favor the *trans* isomers regardless of the solvents.[2g]

It was found that ultrasound can facilitate the reaction and increase the yields of β-lactams.[2g] However, the Gilman-Speeter reaction has not yet been extensively explored, probably due to the slow reaction rate and relatively low yields[2h] that usually appear at 20–50%.[2h]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

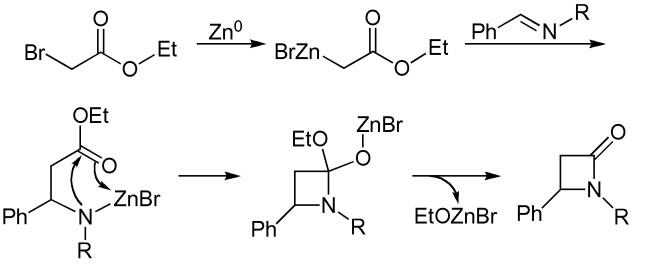
B. GENERAL REACTION SCHEME



R_1 = Me, Et, *i*-Pr, Cy, *t*-Bu, etc.
R_2 = *i*-Pr, *t*-Bu, Cy
R_3 = alkyl, aryl
R_4 = aryl, Me, H, etc.

C. PROPOSED MECHANISMS

The Gilman-Speeter reaction involves the formation of a Reformatsky reagent from α-haloester, nucleophilic addition of the Reformatsky reagent to an imine, and subsequent intramolecular cyclization to form β-lactam, as displayed below.



D. MODIFICATION

The modifications of the Gilman-Speeter reaction include the activation of zinc by trimethylsilyl chloride (TMSCl)[2h] and the application of lithium ester enolate[4] or lithium thioester enolate[5] as the substitute for the traditional Reformatsky reagent. In these modifications, it was found that TMSCl-activated zinc is much more effective in promoting the reaction between ethyl bromoacetate and Schiff bases.[2h] In addition, in the presence of a chiral ether ligand, the reaction between lithium ester enolate and imines affords β-lactams of high enantiomeric excess, probably due to the formation of a ternary complex reagent.[2e,4] The enantioselectivity and reactivity of the ternary complex depend on the size and nature of the lithium amide used. For example, the lithium amide from 2,2,6,6-tetramethylpiperidine (LTMP) is unfavorable for this reaction.[4]

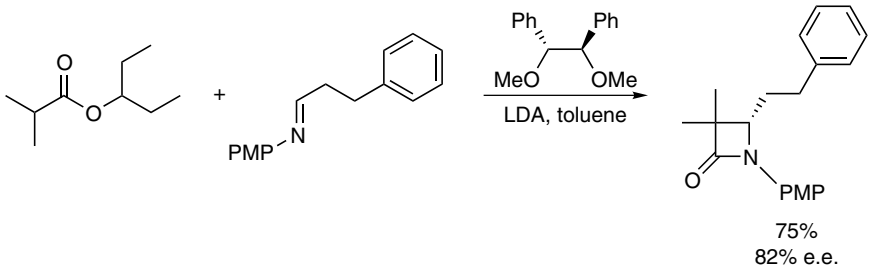
E. APPLICATIONS

This reaction has general application in the synthesis of β-lactams, but has not yet been applied extensively.

F. RELATED REACTIONS

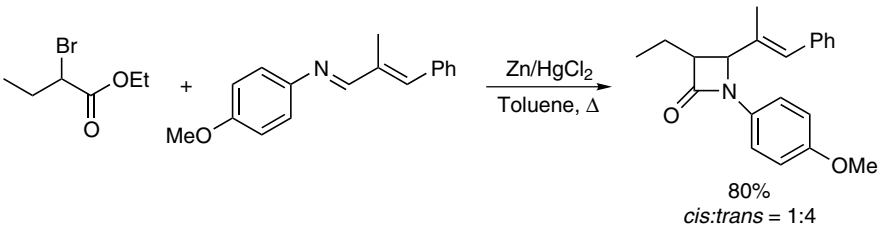
This reaction is related to the *Ghosez Keteniminium-Olefin Cyclization* and *Staudinger Cycloaddition*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

To a preformed LDA solution (4.4 mmol) in 9 mL toluene at −78°C was added a solution of 0.31 g 3-pentyl isobutyrate (2.0 mmol) and 48 mg (1*R*,2*R*)-1,2-dimethoxy-1,2-diphenylethane (0.2 mmol) in 3 mL toluene. The mixture was stirred at −25°C for 1.5 h and cooled to −78°C, to this solution was then added a solution of 0.24 g imine (1.0 mmol) prepared from 3-phenylpropinaldehyde and 4-methoxyaniline in 1.5 mL toluene. After being stirred at −78°C for 20 h, the solution was quenched with aqueous NH_4Cl and extracted with EtOAc. The combined organic layers were washed with brine and dried over $MgSO_4$. Upon removal of the solvent, the residue was purified by silica gel column chromatography using EtOAc/hexanes (1:5) as the eluent to afford 75% of (*S*)-α,α-dimethyl-β-(2′-phenyl)ethyl-*N*-(*p*-methoxy)phenyl-β-lactam in 82% e.e. The chiral ligand was recovered for reuse in 99% yield.



Reference 2h.

A mixture of 2.51 g *N*-(α-methylcinnamy1idene)-*p*-anisidine (10 mmol), 0.78 g zinc dust (12.0 mmol), 1.38 mL *dl*-methyl 2-bromobutyrate (12.0 mmol), and a catalytic amount of $HgCl_2$ in 20 mL toluene was refluxed under nitrogen for 8 h. The resulting mixture was cooled to room temperature and poured into an aqueous solution prepared from 20 mL saturated NH_4Cl and 20 mL 25% NH_4OH. The mixture was then extracted with CH_2Cl_2, and the combined organic layers were washed with 20 mL 0.1 *N* HCl and 20 mL water, and dried over $MgSO_4$. Upon removal of the solvent, the residue was purified by column

chromatography using CH_2Cl_2/hexanes (1:2) as the eluent to give 2.57 g 3-ethyl-4-(α-methylstyryl)-l-(4-methoxyphenyl)azetidin-2-one as a 1:4 mixture of *cis* and *trans*-isomers, in a yield of 80%. The *cis*-isomer was separated by trituration in hexane and further crystallization from EtOH, m.p. 99–100°C, and the *trans*-isomer was isolated as an oil.

Other references related to the Gilman-Speeter reaction are cited in the literature.[6]

Gomberg Free Radical Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Free radical chemistry can be traced back to the initial preparation of a triphenylmethyl radical from Gomberg in 1900 by halogen abstraction of triphenylmethyl halide with metals,[1] when he stated that he wished to reserve the field for himself.[1a,2] Thus the generation of triphenylmethyl radical is referred to as the Gomberg reaction.[3] This initial work shifted people's attention to trivalent carbon,[4] the so-called free radical. Since then, the generation of radicals and the reactions involving radicals have been extensively explored and has become a part of free radical chemistry. It is known that the triarylmethyl radicals demonstrate different colors while changing temperature,[5] as in quinonoidation.[6] It has been reported that radicals might even be formed during the preparation of Grignard reagents at the initial stage when iodine was used as a catalyst.[7] Up to now, many efficient and convenient methods have been developed to generate free radicals, such as reduction;[8] oxidation;[9] pyrolysis of peroxides, acyl peroxides, and azo compounds;[10] photo irradiation;[11] and trialkylaluminium[12] or trialkylboranes.[12,13] The compounds, which easily decompose and form free radical species, are used as free radical initiators, and the commonly used free radical initiators are summarized in Table 1. On the other hand, compounds that contain one weak bond linking to hydrogen are prepared as proton donors in radical chain reactions, and these compounds are known as hydride transfer reagents; the most common ones are silanes,[14] germanes,[15] and stannanes[16] (Table 2). Because of their reactive nature, radicals are normally transient intermediates in chemical transformations. The lifetime of other radicals can be determined by careful analysis of the product distribution, if these radicals react with the compound that undergoes an intramolecular radical rearrangement with known lifetime. This is a new field in free radical chemistry developed since 1980—the so-called

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

TABLE 1. Common Free Radical Initiators

Structure	Name	Structure	Name
	2,2′-Azobis(2,4-dimethyl-4-methoxyvarelonitrile) (V-70)[10b]		Benzoyl peroxide[10d]
	*tert*-Butyl peroxybenzoate[10d]		*tert*-Butyl peroxide[10d]
	Azoisobutyronitrile (AIBN)[10a]		Triethylborane[12,13]

TABLE 2. Common Hydrogen-Transfer Reagents in Free Radical Reactions

n-Bu_3SnH[16]	*n*-Bu_3GeH[15b,15c]	$(Me_3Si)_3GeH$[15a]
$(Me_3Si)_2Si(Me)H$[14a]	$(Me_3Si)_3SiH$[14b]	Et_3SiH[14c]
$PhSiMe_2H$[14c]	$PhSiH_3$[14c]	$Me_3SiSiMe_2H$[14c]

radical-molecule reaction kinetics[17]—and the radicals with a known lifetime are called free radical clocks.[18] Although most of the radicals have short lifetimes, some radicals, like Gomberg's triphenylmethyl radical, with bulky substituents may have longer lifetimes, and these radicals fall into two categories: persistent radicals and stable radicals. A persistent radical has a relatively long lifetime (e.g., minutes) allowing its characterization under the conditions it is generated,[8a] whereas a stable radical is inherently stable and can be isolated without signs of decomposition under inert atmosphere at room temperature.[8a,8b] Some radicals are extremely stable in air, with half-lives of decades, and can withstand typical radical reagents (e.g., nitric oxide) and even highly reactive chemical species (e.g., halogens and sodium hydroxide). In addition, these radicals even possess a very high thermal stability (up to 300°C).[19] Therefore, these types of radicals are called inert free radicals.[4,19,20] Some representative long-living radicals are summarized in Table 3, including the persistent, stable, and inert radicals.[9a,20,21] Overall, the radicals are involved in almost every aspect of organic chemistry, as indicated in reviews about free radical chemistry.[22]

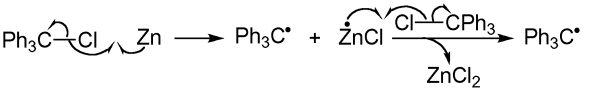
B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS



D. MODIFICATION

The original initiation of a free radical has been modified extensively, as mentioned earlier.

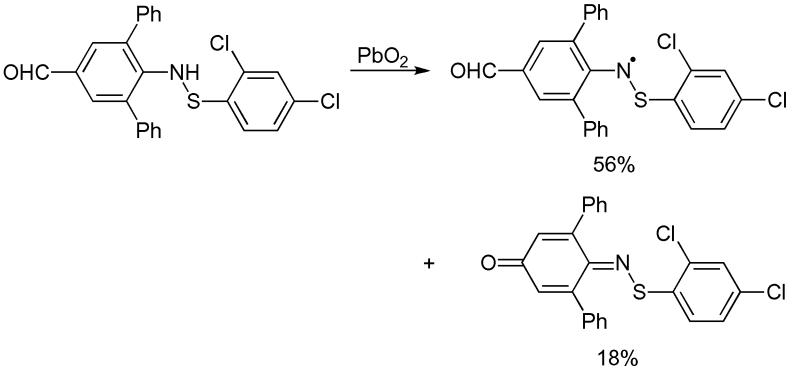
E. APPLICATIONS

The free radical reaction has extremely broad applications in organic synthesis.

F. RELATED REACTIONS

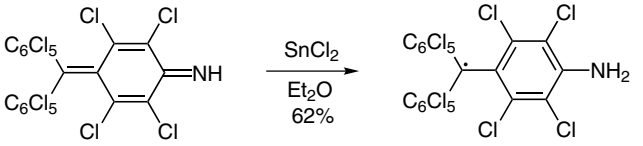
This reaction is related to the *Benkeser Reduction* and *Birch Reduction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 9a.

A mixture of 100 mg *N*-[(2,4-dichlorophenyl)thio]-4-formyl-2,6-diphenylaniline and 300 mg K_2CO_3 in 10 mL benzene was vigorously stirred. Within 30 min, 2.5 g PbO_2 was added in portions; after that, the mixture was further stirred for 1 min and filtered. After the benzene was removed by freeze-drying, the residue was subjected to chromatography on alumina. Elution of the green zone with benzene gave *N*-[(2,4-dichlorophenyl)thio]-4-formyl-2,6-diphenylphenylaminyl in 56% yield in the form of dark green needles from hexane/EtOAc, m.p., 128–130°C. In addition, further elution of the orange zone with EtOAc afforded 18% *N*-[(2,4-dichlorophenyl)thio]-2,6-diphenyl-*p*-benzoquinone monoimine in the form of orange prisms from hexane/EtOAc, m.p., 185–186°C.



Reference 23.

Anhydrous $SnCl_2$ (0.040 g) was added to a solution of 0.080 g crude fuchsonimine in 18 mL anhydrous diethyl ether, and the mixture was stirred in the dark under argon overnight. The green solution was then filtered, washed with aqueous HCl and water, dried, and evaporated. The residue was purified by column flash chromatography (silica gel hexane/CCl_4) to give 0.050 g 4-aminotetradecachlorotriphenylmethyl radical as dark green needles, in a yield of 62%.

Other references related to the Gomberg free radical reaction are cited in the literature.[24]

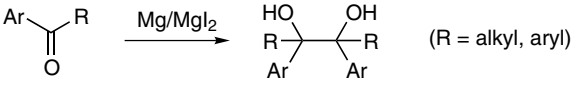
Gomberg-Bachmann Pinacol Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gomberg and Bachmann in 1927.[1] It is the preparation of pinacols from aromatic aldehyde or ketones in the presence of magnesium and magnesium iodide and is known as the Gomberg-Bachmann pinacol synthesis.[2] It is known that a radical mechanism is involved in this reaction as indicated by the green and brown colors of the reaction solution, which disappear when the solution is exposed to air and reappear when air is removed.[1] During this reaction, the ketone was first reduced to a ketyl radical, then the ketyl radicals combine to give pinacol after workup.[1] This reaction produces pinacols in almost quantitative yields[2] and is especially good for stable ketones, such as xanthone and fluorenone, whose corresponding pinacols have not be prepared by alternative methods yet.[2] It is known in the cases of pyridyl ketones, 2 eq. magnesium iodide is needed for the completion of reduction, where one magnesium iodide complexes with the nitrogen atom of the pyridyl ring, and the second magnesium iodide actually reduces the ketone in combination with magnesium.[2]

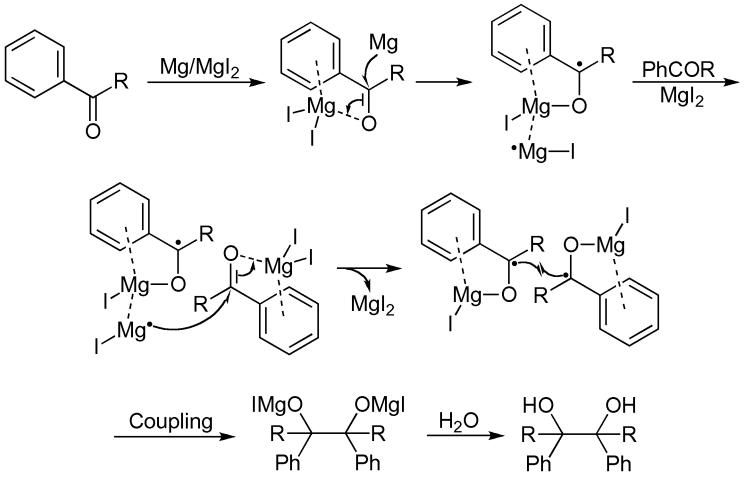
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Illustrated here is the tentative mechanism, using acyl phenone as an example.



D. MODIFICATION

This reaction has been modified using 2 eq. magnesium iodide for heteroaromatic ketones.[2]

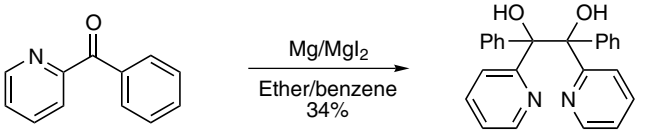
E. APPLICATIONS

This reaction is very useful in the preparation of pinacols from aromatic aldehydes and ketones.

F. RELATED REACTIONS

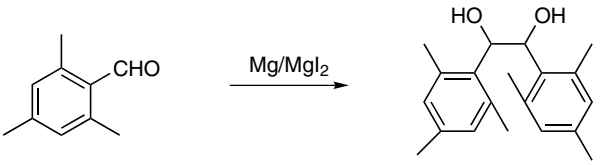
This reaction is related to the *Pinacol Coupling Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

To 5 g powdered magnesium (0.21 mol) in 35 mL ether and 50 mL benzene was added with shaking 14 g iodine (0.055 mol) in portions to keep the solution boiling. After the complete addition, the mixture was shaken until the liquid was practically colorless. To this mixture was added 18.3 g phenyl 2-pyridyl ketone (0.1 mol) dissolved in 30 mL benzene. A green precipitate separated, which on shaking slowly turned to a yellow solid. The mixture was shaken and heated on a water bath for 1 h, but no visible change occurred. A small portion of the mixture was withdrawn and hydrolyzed with water. The benzene-ether layer was dried and then evaporated to dryness to give a pale yellow solid, m.p. $< 40^{\circ}$C. To the mixture was added an additional quantity of magnesium and magnesium iodide (prepared from 5 g magnesium and 14 g iodine) and on shaking, the yellow precipitate changed to a green precipitate. The mixture was refluxed on a water bath for 4 h, and then allowed to stand at room temperature for 1 week, after which time no visible change had taken place. The mixture was added to water, and the benzene-ether layer separated. The water layer was washed several times with ether, and the benzene-ether solution was combined with the ether washings and dried over magnesium sulfate. Distillation of the solution yielded an orange oily solid, which on washing with ethanol yielded 7.0 g α,α-di-2-pyridylhydrobenzoin, in a yield of 38%, m.p., 141–142°C, after recrystallization twice from EtOAc. The filtrate on evaporation yielded 4.3 g phenyl 2-pyridyl ketone.



Reference 3.

To the mixture of 15 g magnesium turnings, 100 mL dry ether, 150 mL dry benzene, and 60 g iodine, was added a solution of 67 g mesitaldehyde in 75 mL dry benzene over a period of 1.5 h. The mixture was stirred vigorously and refluxed for 12 h. The product was isolated in a usual manner. The solid was warmed with high-boiling petroleum ether, and the undissolved material was separated and recrystallized from methanol. This yielded the pinacol of mesitaldehyde, m.p. 214–215°C.

Other references related to the Gomberg-Bachmann pinacol synthesis are cited in the literature.[4]

Gomberg-Bachmann Reaction

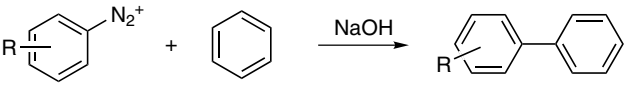
(Gomberg-Bachmann-Hey Reaction)

A. GENERAL DESCRIPTION OF THE REACTION

Although this reaction was initially discovered almost concurrently by Kühling[1] and by Bamberger[2] in 1895, it is generally known as the Gomberg-Bachmann reaction[3] after a convenient and much safer experimental procedure was developed by Gomberg and Bachmann in 1924.[4] It is the synthesis of diaryls (mostly unsymmetrical diaryls) by condensation of aryl diazonium salts with aromatic or heterocyclic compounds in the presence of aqueous NaOH. Therefore, this reaction is sometimes referred to as the Gomberg-Bachmann alkaline reaction,[3a] Gomberg arylation,[3a] or Gomberg-Bachmann biaryl synthesis.[5] Hey and co-workers extensively studied the mechanism of this reaction, indicating the involvement of free radicals in this reaction;[6] thus this reaction is also called the Gomberg-Bachmann-Hey reaction,[7] Gomberg-Bachmann-Hey arylation,[8] and Gomberg-Bachmann-Hey aryl coupling.[9] It is known that this reaction is rapid and easy to carry out, especially for the aromatic diazonium salts containing an electron-withdrawing group.[4] However, this reaction does have inherent drawbacks, such as the instability of diazonium salt[3c] and the accompanying side reactions to form tar residue;[3j] therefore, this reaction has been modified to use stable aromatic diazonium tetrafluoroborate under phase transfer conditions.[3c]

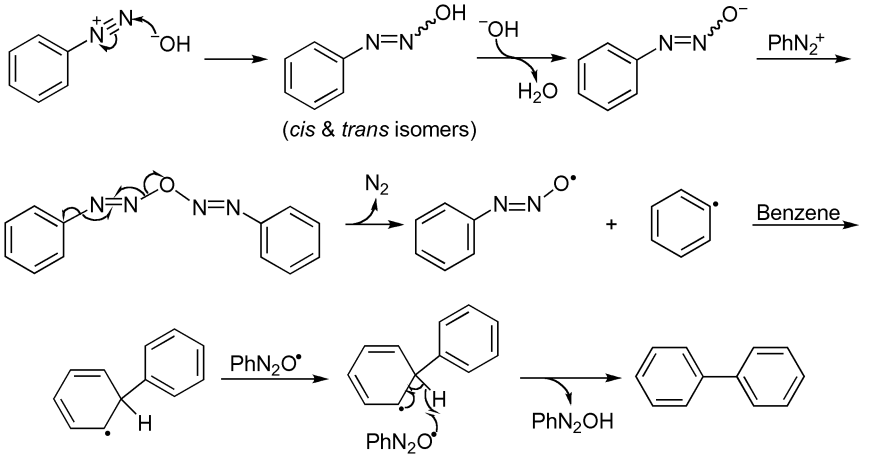
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is demonstrated by the coupling between phenyldiazonium salt and benzene as displayed here.



D. MODIFICATION

This reaction has been modified using aryldiazonium tetrafluoroborate under phase transfer conditions to enhance the stability of diazonium salt.[3c]

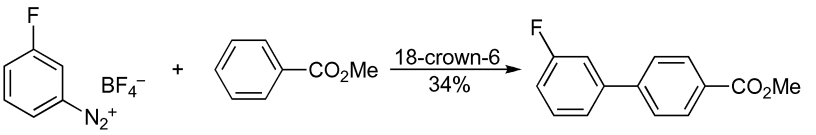
E. APPLICATIONS

This reaction has wide applications in the coupling of aryl compounds or aryl and heteroaromatics.

F. RELATED REACTIONS

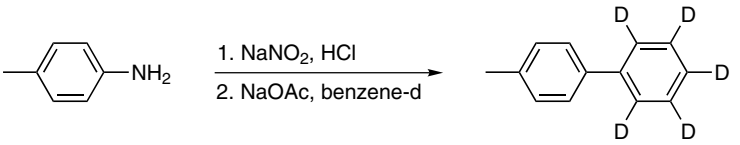
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

Potassium acetate (1.20 g, 12.2 mmol, 2 eq.) was added at ambient temperature to a magnetically stirred mixture of 1.28 g 3-fluorophenyldiazonium tetrafluoroborate (6.0 mmol) and 5 mol % 18-crown-6 in 60 mL methyl benzoate. Stirring was continued for 90 min. The red mixture was filtered, and the filtrate was washed with brine and water. The organic layer was dried over Na_2SO_4 and evaporated, and the residue was chromatographed over alumina (30–50 g) using 10% ether/hexane as the eluent, the collected fraction was further distilled to afford 0.48 g methyl 3′-fluorobiphenyl-2-carboxylate as oil, in a yield of 34%.



Reference 3g.

p-Toluidine (0.58 g, 5.4 mmol) was dissolved in 2 mL concentrated hydrochloric acid and diazotized at 0–5°C with 0.6 g $NaNO_2$ dissolved in 2 mL water. The solution of the resulting diazonium salt was added slowly, with vigorous stirring, to a mixture of 30 g benzene-d (97.02% isotopically pure by mass spectrometry at reduced ionizing voltage, 0.38 mol) and 7.0 mL NaOAc solution containing 3.0 g NaOAc maintained at 6–10°C. After completion of the addition, the mixture was stirred at 6–10°C for 30 min and then at room temperature for 6 h. The dark benzene layer was separated, washed three times with aqueous $NaHCO_3$ followed by water, dried over $CaCl_2$, and concentrated on a steam bath. The residue was dissolved in 5 mL ether, mixed with 2 g activated alumina, and dried in a film evaporator. The residue, impregnated on alumina, was placed on top of an alumina column (25 g) and was extracted repeatedly with petroleum ether (b.p. 60–90°C). The first 100 mL of eluate on concentration gave 350 mg 4-methylbiphenyl, m.p. 42–44.5°C, raised to 46.5–47°C by sublimation under reduced pressure and crystallization from methanol.

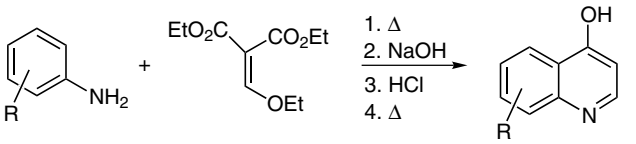
Gould-Jacobs Reaction

(Gould-Jacobs Quinoline Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gould and Jacobs in 1939.[1] It is the synthesis of 4-hydroxyquinolines from anilines and diethyl ethoxymethylenemalonate involving the condensation to anilinomethylenemalonate, cyclo-acylation to quinolin-4-one nucleus, and subsequent hydrolysis and decarboxylation. Therefore, this reaction is generally known as the Gould-Jacobs reaction.[2] Occasionally, it is also referred to as the Gould-Jacobs cyclization,[3] Gould-Jacobs quinoline synthesis,[4] or Gould-Jacobs synthesis.[5] This reaction works well for anilines with electron-donating groups at the *meta*-position, whereas the electron-withdrawing groups reduce the overall yield.[2k] This reaction can be applied to the synthesis of piperazine and pyrrolidine analogues.[2a]

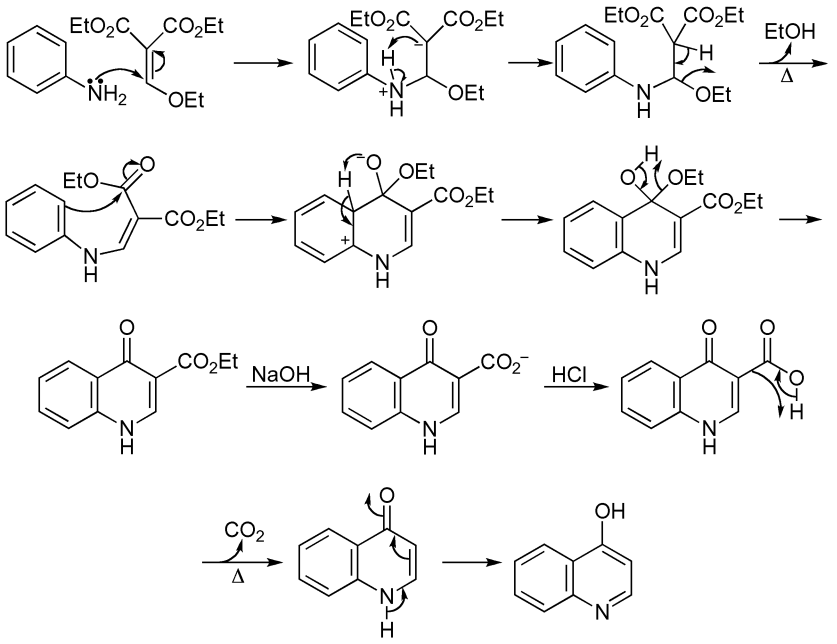
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed here is the demonstration of the reaction mechanism using aniline as example.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

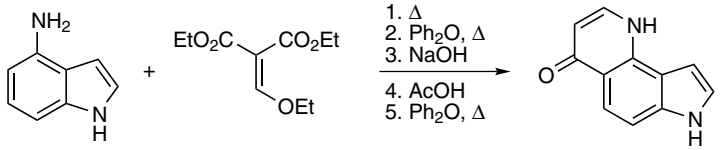
E. APPLICATIONS

This reaction is very useful for preparing 4-hydroxyquinoline derivatives. In addition, *N*-alkyl-quinolin-4-one derivatives can also be prepared if an electrophile is added before the hydrolysis and decarboxylation.[2a]

F. RELATED REACTIONS

This reaction is related to the *Doebner-von Miller Quinoline Synthesis* and *Knorr Quinoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES

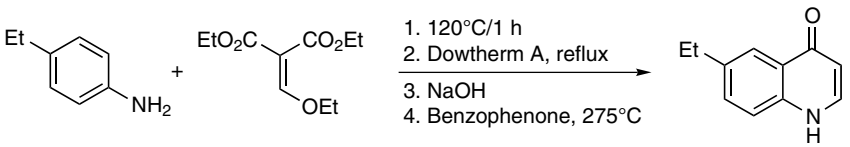


Reference 6.

In a 50-mL round-bottomed flask were placed 0.265 g 4-aminoindole (2.0 mmol) and 0.405 mL diethyl ethoxymethylenemalonate (2.0 mmol, $d = 1.07$); the mixture was heated at 130°C for 3 h. Any unreacted diethyl ethoxymethylenemalonate was removed under vacuum, leaving 0.50 g 2-[(1*H*-indol-4-ylamino)methylene]malonic acid diethyl ester as a brown solid, in a yield of 83%, m.p., 122°C (ethanol). Then 0.50 g of the solid diester (1.7 mmol) was added to 50 mL boiling diphenyl ether in portions; after 20 min of refluxing, the precipitate formed by cooling was collected by filtration, washed many times with diethyl ether, and recrystallized from ethanol, yielding 0.360 g ethyl 4-oxo-4,7-dihydro-1*H*-pyrrolo[2,3-*h*]quinolin-3-carboxylate, in a yield of 83%, m.p. 280°C (dec.), $R_f = 0.45$ (EtOAc/MeOH, 8:2).

In a 100-mL round-bottomed flask were placed 0.260 g of the above ester (1.01 mmol) and 30 mL 2 N NaOH; the suspension was heated to complete solution and was then refluxed for 6 h, the reaction was monitored by TLC analysis (EtOAc/MeOH, 8:2). After cooling, the reaction mixture was acidified to pH 5 by acetic acid/water (1:2). A brown precipitate formed, which was collected, washed with water, and dried at 60°C, affording 0.185 g 4-oxo-4,7-dihydro-1*H*-pyrrolo[2,3-*h*]quinolin-3-carboxylic acid as a crystalline solid, in a yield of 80%, m.p., 320°C (dec.), $R_f = 0.71$ (EtOAc/MeOH, 8:2).

In a two-necked, 100-mL round-bottomed flask, 50 mL diphenyl ether was heated to the boiling temperature. After the portionwise addition of 0.185 g quinolin-3-carboxylic acid (0.81 mmol), the solution was refluxed for 20 min. After cooling, the formed precipitate was collected, washed many times with diethyl ether and dried, providing 0.120 g 1*H*,7*H*-pyrrolo[2,3-*h*]quinolin-4-one, in a yield of 80%, m.p., 351°C (dec.), $R_f = 0.38$ (EtOAc/MeOH, 8:2).



Reference 4h.

Equimolar amounts of 4-ethylaniline and diethyl (ethoxymethylene)-malonate were heated together at 120°C for 1 h and then heated under reflux in Dowtherm A to effect cyclization. The resulting crude ester was saponified to give 6-ethyl-4(1*H*)-quinolone-3-carboxylic acid in an overall yield of 81%, m.p., (DMF) 257°C (dec.). This acid was decarboxylated in benzophenone at 275°C to give 6-ethyl-4(1*H*)-quinolone, in a yield of 77%, m.p., (H_2O) 197.5–198.5°C.

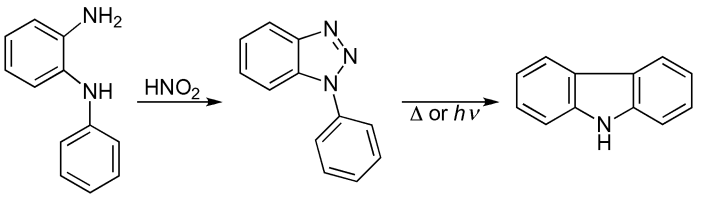
Graebe-Ullmann Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

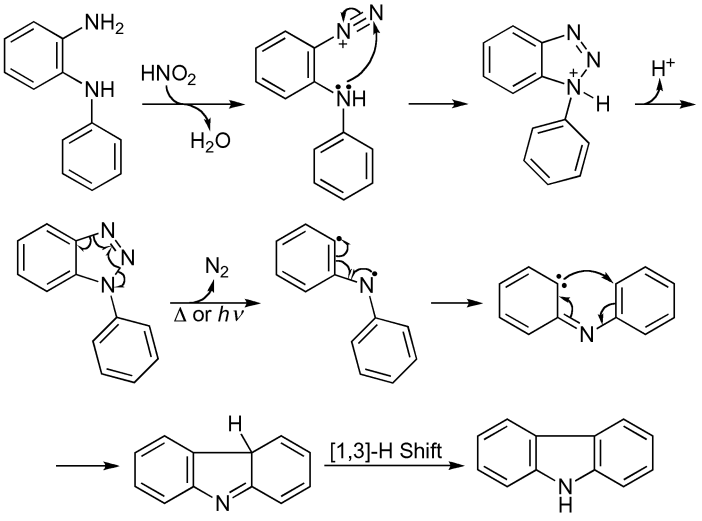
This reaction was initially reported by Graebe and Ullmann in 1896.[1] It is the preparation of carbazoles involving the pyrolysis of 1-phenyl-1,2,3-benzotriazole prepared from *ortho*-amino-diphenylamine and nitrous acid.[2] Therefore, it is known as the Graebe-Ullmann reaction,[3] Graebe-Ullmann thermolysis,[4] Graebe-Ullmann synthesis,[5] or Graebe-Ullmann carbazole synthesis.[6] It is known that this reaction involves the cyclization of a diradical or iminocarbene intermediate to 4aH-carbzole, which isomerizes to carbazole via a [1,3] hydrogen shift.[5b] Besides the pyrolysis of benzotriazoles to carbazoles, the photolysis[7] and microwave irradiation[8] of triazoles also produce carbazoles accordingly. In addition, some more complicated heterocycles containing pyrrole moiety can be prepared from this reaction.[9]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified using microwave irradiation.[8]

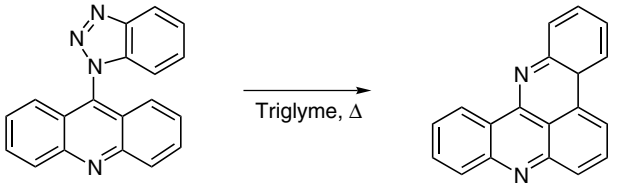
E. APPLICATIONS

This reaction has general application in the preparation of carbazole derivatives.

F. RELATED REACTIONS

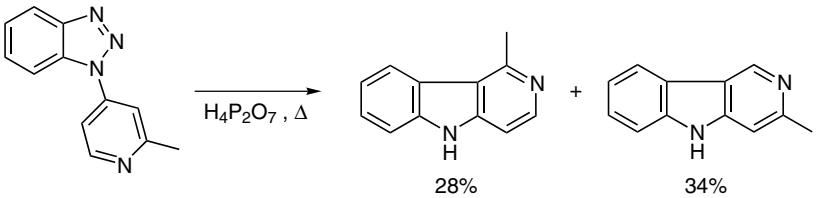
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 10.

A suspension of 1.0 g 9-(1,2,3-benzotriazol-1-yl)acridine in 5 mL triglyme was boiled for 4 h, and the cooled solution was diluted with excess water. The product was collected and washed with water to yield 87% 8H-quino[4,3,2-kl]acridine.



Reference 8.

A mixture of 2 mmol 1-(2-methylpyridin-4-yl)-1*H*-benzotriazole and 6 mmol $H_4P_2O_7$ was heated at 150°C until the evolution of nitrogen ceased (1.5–2 h). The reaction mixture was then triturated with water and basified with a 15% solution of NaOH. The precipitate formed was filtered off and purified by column chromatography to give 102 mg 1-methyl-5*H*-pyrido[4,3-*b*]indole in a yield of 28% (CH_2Cl_2/acetone, 9.5:0.5), m.p., 248–249°C (CH_3CN, cream-colored powder), and 124 mg 3-methyl-5*H*-pyrido[4,3-*b*]-indole, in a yield of 34% (CH_2Cl_2/acetone, 7:3), m.p., 226–227°C (EtOAc, orange prisms).

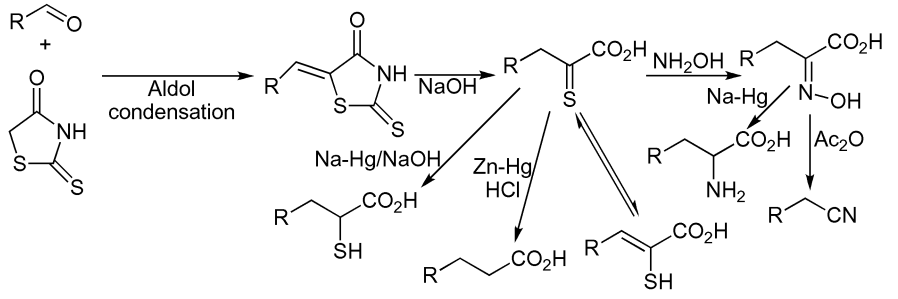
Gränacher Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gränacher in 1922.[1] It is the preparation of thionic acid by the treatment of *Aldol Condensation* product from an aldehyde and rhodanine with a base (e.g., NaOH).[2] Therefore, this reaction is known as the Gränacher synthesis[3] or Gränacher reaction.[4] The prepared thionic acid in this reaction can be further converted into a variety of derivatives under different conditions.[3,5] For example, it can be transformed into α-thiol acid under a basic sodium amalgam reduction, whereas aliphatic acid is formed under an acidic zinc amalgam reduction. In addition, when the thionic acid is treated with ammonia, α-keto acid is generated, and the thionic acid can be converted into α-carboxyl oxime in reaction with hydroxylamine, from which either α-amino acid or aliphatic nitrile forms via the treatment of sodium amalgam reduction[6] or acetic anhydride, respectively.

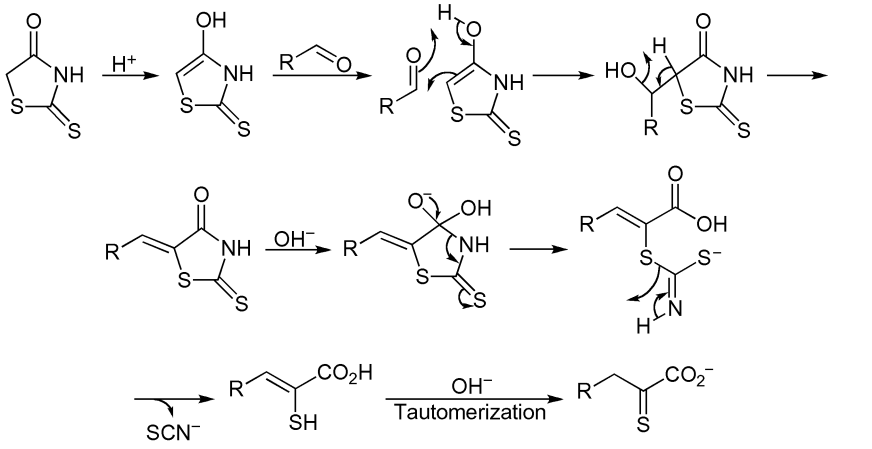
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The possible reaction pathway for the conversion of rhodanine and aldehyde into thionic acid is displayed here. The further transformations of thionic acid into other derivatives, including α-amino acid, aliphatic nitrile, and aliphatic acid, are not provided.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has general application in the preparation of α-keto acids, nitriles, α-amino acids, etc.

F. RELATED REACTIONS

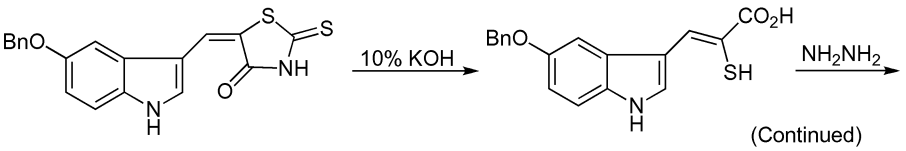
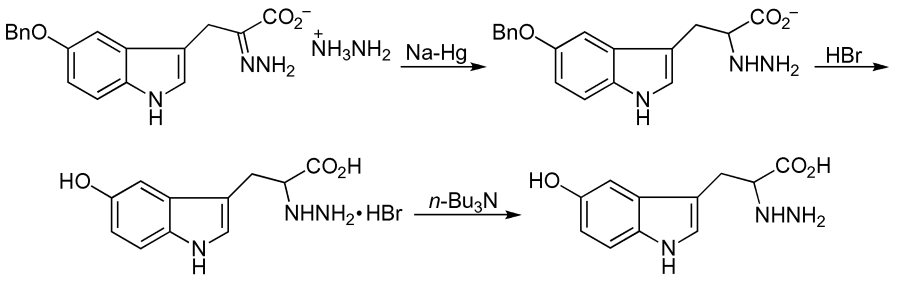
G. CITED EXPERIMENTAL EXAMPLES



(Continued)



Reference 7.

A stirred mixture of 3.67 g 5-(5-benzyloxyindole-3-methylene)rhodanine (10 mmol) and 112 mL 10% KOH was refluxed under nitrogen for 1 h. The reaction was cooled to room temperature, and 0.82 g 5-benzyloxy-3-indolecarboxaldehyde was removed by filtration. The stirred filtrate was cooled to 0°C and acidified with 2.5 N HCl. The yellow product that separated was filtered, washed with water (2 × 20 mL), and then dried to afford 2.05 g β-(5-benzyloxy-3-indolyl)-α-sulfhydrylacrylic acid.

A stirred slurry of 2.93 g β-(5-benzyloxy-3-indolyl)-α-sulfhydrylacrylic acid (9 mmol) in 10 mL absolute ethanol was treated with 2.4 mL 99–100% hydrazine hydrate (0.048 mol), and the mixture was heated under nitrogen. Reaction occurred at 60°C, accompanied by vigorous evolution of H_2S. After the mixture was refluxed for 2 h, the liberation of H_2S had ceased (no black precipitate when a stream of nitrogen was passed through the reaction solution and exited into aqueous lead acetate), and the flask was allowed to cool to room temperature. The crystalline product, the hydrazine salt of β-(5-benzyloxy-3-indolyl)pyruvic acid hydrazone, was filtered, washed with cold ethanol (3 × 8 mL), and then dried. It weighed 2.35 g and was found to be analytically pure.

To a well-stirred suspension of 1.07 g hydrazine salt (3 mmol) in 15 mL water was added 14 g pulverized 3% NaHg. The system was purged and stirred under nitrogen for 2 days. The aqueous phase was then decanted from the pool of mercury, filtered through Supercel, and treated dropwise with 1.5 mL acetic acid. The zwitterions precipitated voluminously and was filtered, washed with water (2 × 4 mL), and then dried to give 0.75 g β-(5-benzyloxy-3-indolyl)-α-hydrazinopropionic acid, m.p. 217°C (dec.).

A dry flask containing 7.50 g β-(5-benzyloxy-3-indolyl)-α-hydrazinopropionic acid (0.023 mol) was cooled to −75°C in a dry ice–acetone bath, and anhydrous HBr was passed in until 50 mL had condensed. The mixture was stirred at −75°C for 1 h, then all volatile liquid was evaporated via a stream of dry nitrogen (1 h) after the cold bath had been removed. When the flask had warmed to room temperature, the HBr salt was stirred with 50 mL dry ether, filtered, and washed well with ether (5 × 10 mL) to remove traces of HBr and benzyl bromide. The hygroscopic tan powder so obtained was dissolved in 50 mL alcohol and filtered; the pH of the filtrate was adjusted to 3.5 by the addition of 7–8 mL of tri-n-butylamine. The precipitated zwitterion was collected, washed with 5 mL cold ethanol, and then dried to yield 3.60 g DL-β-(5-hydroxy-3-indolyl)-α-hydrazinopropionic acid, m.p., 227–231°C (dec.). This off-white powder was purified by dissolving it in 15 mL 2.5 N HCl and diluting the solution with 25 mL ethanol. After being stirred with 0.36 g charcoal, the mixture was filtered, and the pH of the filtrate was adjusted to 5.5 by the slow addition of tri-*n*-butylamine. The white microcrystalline product was filtered, washed with 7 mL ethanol, and then dried to give 3.00 g pure product.

More experimental details are available in literature,[8] and other references related to the Gränacher synthesis are cited in the literature.[9]

Gribble Reductive Amination

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Gribble and co-workers in 1974.[1] It is the synthesis of indolines or *N*-alkylated indolines from the direct acidic reduction of indoles using $NaBH_4$ or $NaBH_3CN$ in acetic acid or trifluoroacetic acid. Therefore, it is known as the Gribble reductive amination.[2] Under these conditions, an indole derivative can be purely reduced to indoline or further to *N*-ethyl indoline[1] without polymerization that exists in other methods of reduction.[3] It is found that the reduction by $NaBH_4$ in formic acid affords an indole dimmer and other side products besides the normal indoline, whereas the same reduction in trifluoroacetic acid (TFA) gives only the indoline without *N*-alkylation.[1] It has been proven that this reaction involves the protonation at 3-position followed by the reduction of the formed indolenium interemdiate.[1] This reducing method has been extended to reduce primary and secondary aromatic amines and to synthesize unsymmetrical tertiary amines directly from primary amines.[1] In addition, other heterocycles can be reduced by this reduction, such as the conversion of quinoxaline to 1,2,3,4-tetrahydroquinoxaline,[4] quinazoline to 1,2-dihydroquinazoline,[4] and pyrazine to piperazine.[5] Moreover, even some aryl alcohols can be directly converted into their corresponding arylalkanes.[6]

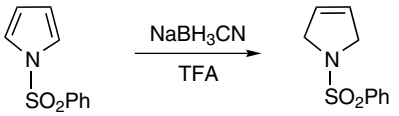
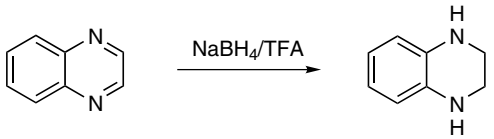
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To 10 mL magnetically stirred TFA at room temperature was added 0.45 g $NaBH_3CN$ (7.25 mmol) slowly and in portions. (*Caution*! $NaBH_3CN$ reacts with TFA with vigorous evolution of hydrogen, so that minor explosions are possible.) The resulting mixture was stirred for an additional 15 min, and 0.50 g *N*-phenylsulfonylpyrrole (2.41 mmol) was added slowly as a solid. After 1 h, an additional 0.45 g $NaBH_3CN$ (7.25 mmol) was added. The mixture was stirred overnight, quenched with water, and extracted with methylene chloride. The combined organic layers were washed with saturated $NaHCO_3$ and water, dried over Na_2SO_4, filtered, and evaporated in vacuo. Chromatography on silica gel using hexanes/CH_2Cl_2 provided 0.45 g 1-phenylsulfonyl-3-pyrroline, which slowly crystallized in vacuo. Recrystallization from methanol provided 0.38 g pure product, m.p., 120–121°C.



Reference 4.

To 10 mL THF solution containing 1.0 g quinoxaline was added 1.0 g $NaBH_4$, then 10 mL TFA was added over 15 min without cooling, and the mixture was stirred an additional 45 min. Water (5 mL) was added, and the pH was adjusted with a 50% NaOH to pH 7. Dichloroethane (50 mL) was added to the solution, and vigorous stirring was begun. The organic layer was separated, dried over Na_2SO_4, and concentrated at reduced pressure, yielding an oil that solidified when cooled. The formed solid was recrystallized from EtOAc to afford 910 mg 1,2,3,4-tetrahydroquinoxaline as colorless crystals, m.p., 95–96°C.

Other references related to the Gribble reductive amination are cited in the literature.[8]

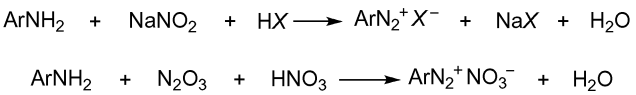
Griess Diazotization

(Knoevenagel Method, Witt Method)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Griess in 1858.[1] It is the preparation of aromatic diazonium salts from primary aromatic amines, N_2O_3, and nitric acid and is generally known as the Griess diazotization[2] or Griess reaction.[3] Subsequently, the preparation of diazonium salt was extended by Knoevenagel in 1890 using organic nitrite as diazotization agent under acidic conditions,[4] by Witt in 1909 using $Na_2S_2O_5$ and nitric acid as the diazotization agents[5] (known as Witt method[6]), and by Houston and Johnson in 1925 using N_2O_4 as the diazotization agent.[7] Recently, other reagents have also been developed for the purpose of diazotization: NOCl,[8] $NaNO_2/HBF_4$,[9] $NaNO_2/CuCl_2$,[10] and $NO^+BF_4^-$[11] (or $NO^+PF_6^-$,[11b] $NO^+SbF_6^-$,[11b] etc.). However, the most popular method of forming diazonium salt is to use nitrous acid generated *in situ* from sodium nitrite and an acid (HCl,[12] H_2SO_4,[13] HCO_2H,[14] AcOH,[15] etc.), although the Knoevenagel's method is also quite popular.[16] The generated diazonium salt is useful for many other reactions, including the *Gatterman Reaction* and *Balz-Schiemann Reaction*.

B. GENERAL REACTION SCHEME



Griess Diazotization

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

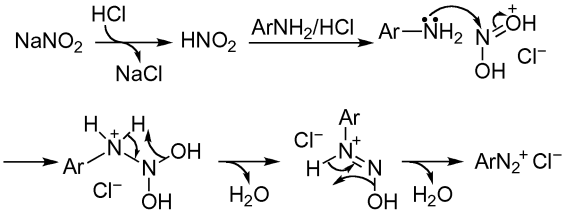
Knoevenagel Modification

Witt Modification

Houston-Johnson Modification

C. PROPOSED MECHANISMS

The mechanism of diazotization from sodium nitrite and hydrochloric acid is given here.



D. MODIFICATION

The original Griess diazotization has been modified to use different diazotization reagents as noted in Section A.[4,5,7–11]

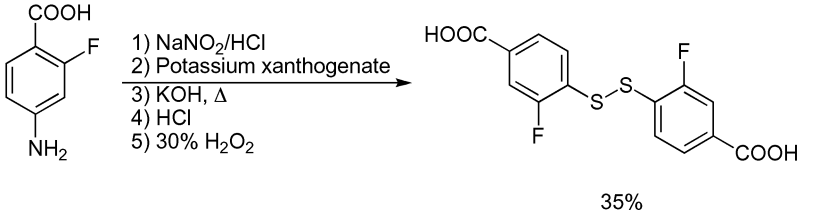
E. APPLICATIONS

This reaction is very useful in the preparation of aromatic diazonium salts.

F. RELATED REACTIONS

This reaction is related to the *Gatterman Reaction* and *Balz-Schiemann Reaction*.

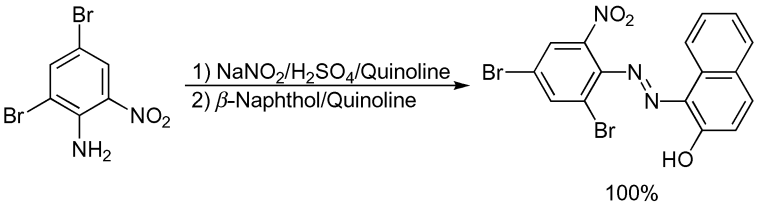
G. CITED EXPERIMENTAL EXAMPLES



35%

Reference 12a.

To a mixture of 12.5 mL concentrated HCl and 12.5 mL water was added 5.0 g substituted 4-amino-2-fluorobenzoic acid (32 mmol) under stirring, and the suspension was warmed to 70°C. After this, the solution was cooled to 0°C and diazotized with 2.2 g $NaNO_2$ (32 mmol) over 20 min. This solution was then added dropwise over 1 h to a solution of 19.0 g potassium xanthogenate (117 mmol) at 80°C, after which the oil that separated was extracted with diethyl ether, dried over $MgSO_4$ for 2 hours, and then evaporated under low pressure to give a brownish oil. This oil was then dissolved in 50 mL ethanol to which 10 g KOH in ethanol was added slowly over 30 min. The solution was heated at 80°C for 8 h. The ethanol was removed under reduced pressure. The residue was dissolved in water and slowly neutralized with concentrated HCl at 0°C to pH 5 and then extracted with EtOAc; dried over $MgSO_4$ and removed under low pressure to give the aryl thiol as a solid with strong thiol odor. The thiol obtained was suspended in ethanol. To this suspension was added 3.8 mL 30% H_2O_2, and the mixture was stirred at room temperature under nitrogen for 24 h. The solvent was then removed, and the residue was chromatographed on silica gel with 1–3% MeOH in $CHCl_3$ to give 1.95 g 2,2′-difluoro-4,4′-dithiobis(benzoic acid) as a light cream solid, in a yield of 35%, m.p., > 245°C (dec.), $R_f = 0.76$ ($CHCl_3$/MeOH, 5:1).



Reference 17.

A solution of 5.91 g 4,6-dibromo-2-nitroaniline in 15 mL quinoline was diazotized with a mixture of 3 g $NaNO_2$ in 40 mL conc. H_2SO_4 and 15 mL water. Coupling took place when to the clear diazonium salt solution was added a solution of 2.88 g β-naphthol in 10 mL quinoline. The coupled product was filtered, washed, and digested with 25% alcohol. The yield was quantitative. Recrystallization of the 4,6-dibromo-2-nitrobenzene-azo-β-naphthol from toluene gave red crystals, m.p., 250°C.

Other references related to the Griess diazotization are cited in the literature.[18]

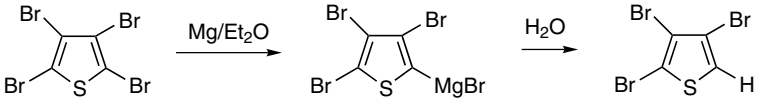
Grignard Degradation

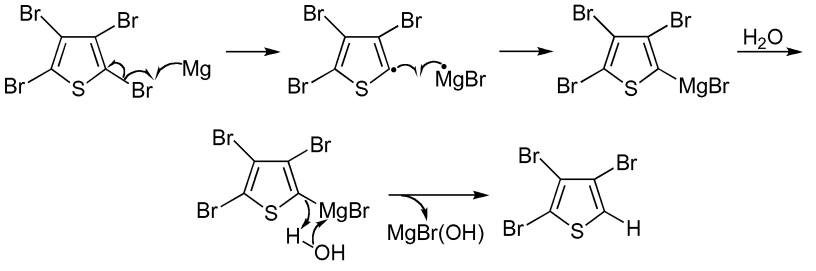
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Steinkopf in 1934.[1] It is the dehalogenation of polyhalo-compounds via the treatment of the corresponding Grignard reagents with water to produce compounds with one less halogen atom. This reaction primarily works for aromatic compounds.[2] In addition, the dehalogenation of aromatic halides also occurs when the halides are treated with other Grignard reagents in the presence of catalytic amounts of cobaltous chloride[3] or Et_2TiCl_2.[2a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

D. MODIFICATION

This reaction has been modified using other Grignard reagents to dehalogenate the aromatic halides in the presence of cobaltous chloride[3] or Et_2TiCl_2.[2a]

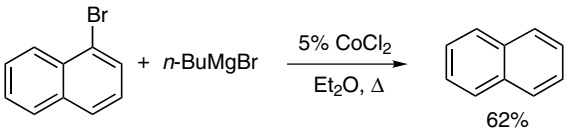
E. APPLICATIONS

This reaction can be applied to the dehalogenation of aryl or alkyl halides.

F. RELATED REACTIONS

This reaction is related to the *Grignard Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

To an ether solution containing 0.05 mol *n*-butylmagnesium bromide (*n*-BuMgBr) was added 5% cobaltous chloride at low temperature; then a solution of 0.05 mol 1-bromonaphthalene in ether was added at a rate sufficient to maintain a gentle refluxing of the ether solution. The mixture was thoroughly agitated throughout the addition. After the addition was complete, the reaction mixture was refluxed for 2 h on a water bath; it was allowed to stand overnight and was poured onto ice. The product was extracted by ether, washed, and dried over $MgSO_4$. Upon removal of solvent via evaporation, the residue was purified to give 62% naphthalene.

Other references related to the Grignard degradation are cited in the literature.[4]

Grignard Reaction

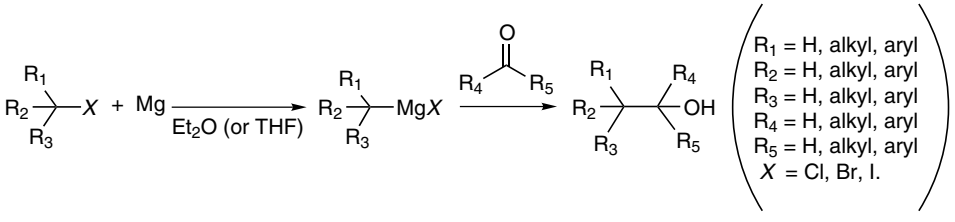
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Grignard in 1900.[1] Traditionally, it is the preparation of alkyl or aryl magnesium halides (RMg*X* or ArMg*X*) from corresponding organohalides and magnesium in ethereal solvents (Et_2O or THF) and their nucleophilic addition to carbonyl compounds to form alcohols. Thus the organomagnesium halides are generally known as the Grignard reagents; however, the updated broad meaning of Grignard reaction refers to the reaction of Grignard reagents with many kinds of electrophiles, including CO_2 to form carboxylic acid and nitriles or acyl halides to form ketones, carbonyl compounds to form alcohols (primary alchol from formaldehyde, secondary alcohols from other aldehydes, and tertiary alcohols from ketones). Because the Grignard reagent is equivalent to a carbanion, the preparation of Grignard reagent must be carried out in an anhydrous solvent that can dissolve but not react with the generated carbanion species. Only the ethereal solvents (Et_2O, THF, etc.) that can complex with the Grignard reagent are good for this reaction, and among these ethereal solvents, Et_2O is the best one. On the other hand, as the formation of the Grignard reagents is heterogeneous, a catalytic amount of iodine and 1,2-dibromoethane are often added to the reaction system to initiate the generation of Grignard reagents. It is reported that the reaction rate for the formation of Grignard reagent is proportional to the concentration of organic halide and the surface area of magnesium, and all organic iodides and many secondary alkyl bromides react at a mass transport or diffusion-controlled rate in Et_2O; other less reactive organic bromides (neopentyl, phenyl, etc.) and most organic chlorides react at lower rates.[2] However, since the 1920s,[3] more and more experimental results have indicated that the formation of Grignard reagents involves a free radical[4] or single-electron transfer (SET) process,[5] such as the formation of pinacol via a ketyl radical during the addition of the Grignard reagent to ketone.[5a–5c] The concept that

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

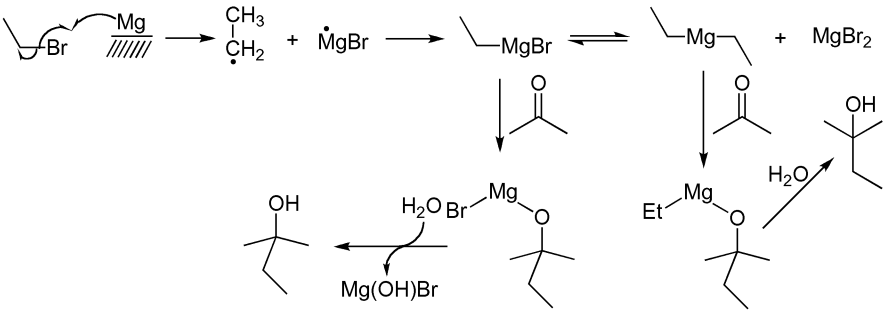
the radicals diffuse freely in solutiuon at all times is called the D-Model,[6] which is consistent with the formation of Grignard reagents from primary alkyl halides.[7] In addition, it is known that the Grignard reagents form an equilibrium with dialkyl (or diaryl) magnesium and magnesium halide,[8] and such an equilibrium is called the Schlenk equilibrium,[9] in which the dialkyl (or diaryl) magnesium is considered to be more reactive.[10] During the addition of a Grignard reagent to ketones, the resulting tertiary alkoxy magnesium halides are often worked up by aqueous ammonium chloride if at least one alkyl groups is present. Other alkoxy magnesium halides from aldehydes can be hydrolyzed using a strong acid, as the tertiary alcohols are easy to dehydrate under acidic conditions. It is interesting that the reaction of benzyl or 1-naphthylmethyl magnesium bromide with ketone form both the normal alcohol and ortho alcohol[11] and PhMgBr with highly hindered cyclobutanones gives both 1,3-butadiene and allene instead of alcohol.[12] For the reaction with acyl halides to form ketones, a reversed order of reactivity of halide displacement applies: acyl fluoride > chloride > bromide.[13] However, in the reaction between CH_3MgI and mesitoyl chloride, mesitil and ethane were found to be the products.[14] Although the reaction between Grignard reagents and esters normally produce tertiary alcohols, different products might form in the special case of allyl esters if the steric effect is strong enough to inhibit the addition of RMg*X* to the carbonyl group,[15] such as the formation of pure *n*-crotylbenzene from the reaction of PhMgBr with *n*-crotyl mesitoate.[16] On the other hand, in the presence of some transition metal salts, the reaction course and mechanism of Grignard reagents with alkyl (or aryl) halides might be altered, as shown by the addition of a silver complex[17] (AgBr works even in a trace amount, e.g., 10^{-5}M[17a]), manganous salts,[18] nickel chloride[19] ($NiCl_2$ + 1,3-butadiene[20]), iron salt,[21] or cobaltous chloride ($CoCl_2$)[22] to the Grignard reaction. Kharasch has elaborated the details of Grignard reaction by addition of cobaltous chloride.[22] It was found that the reaction between Grignard reagent and terminal propargylic chloride leads to the formation of 1,3-butadiene.[23] Finally, the carbenoid homologation of Grignard reagents generated by an iodine/magnesium exchange from the diiodoalkane opens the opportunity to generate secondary Grignard reagents that avoid free radicals as intermediates.[9a]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is represented by the reaction between ethyl magnesium bromide and acetone as shown here.



D. MODIFICATION

The original procedure has been extensively modified and improved by the addition of different transition metal salts[17–22] and additives (e.g., 1,3-butadiene).[20]

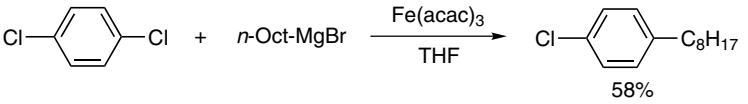
E. APPLICATIONS

This reaction has wide application in organic synthesis and is one of the most popular reactions to form carbon-carbon bonds.

F. RELATED REACTIONS

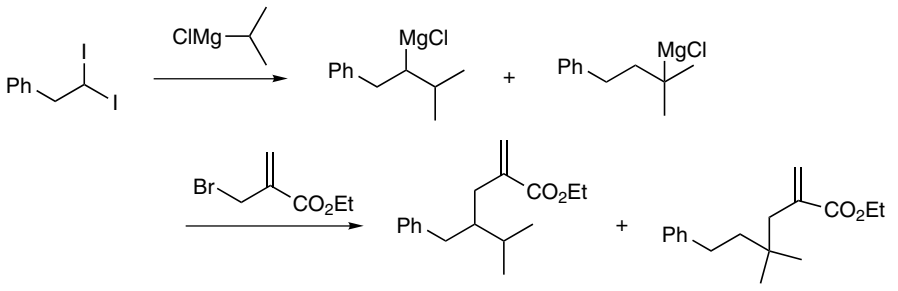
This reaction is related to the *Grignard Degradation* and *Barbier Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 21.

A solution of 120 mL 0.4 M octylmagnesium bromide in THF was added over 15 min to a solution of 4.67 g 1,4-dichlorobenzene (31.8 mmol) and 1.13 g $Fe(acac)_3$ (3.2 mmol) in 200 mL THF and 15 mL NMP, causing an immediate color change from red to dark brown/black and a slight increase in temperature (~40°C). After the mixture was stirred for 30 min, an additional 22 mL 0.4 M octylmagnesium bromide in THF and 565 mg $Fe(acac)_3$ (1.6 mmol) were introduced, and stirring was continued for 30 min. The reaction was quenched with dilute HCl, the aqueous phase was repeatedly extracted with *tert*-butyl methyl ether, the combined organic layers were dried over Na_2SO_4 and evaporated, and the residue was purified by vacuum distillation to give 4.34 g 1-chloro-4-octylbenzene (b.p., 65°C, 10–4 mmHg) as a colorless liquid, in a yield of 58% with 95% GC purity (remainder is hexadecane).



Reference 9a.

A solution of 254 mg ethyl 3-bromo-2-methylenepropanoate (1.32 mmol) in 0.7 mL THF was cooled to −90°C. A Grignard solution of 236 mg 1,1-diiodo-2-phenylethane (0.66 mmol) in ∼2.7 mL THF at −20°C (prepared by the addition of such a compound into a stirred solution of 1.1 mL 1.80 M isopropylmagnesium chloride in Et_2O [2.04 mmol] in 1.5 mL of THF) was added via cannula. The flask of the Grignard reagent was rinsed twice with 0.5 mL THF. The washings were again transferred via cannula into the reagent solution. The latter was allowed to reach −78°C over 30 min. Saturated aqueous NH_4Cl solution (2 mL) was added. The layers were separated, and the aqueous layer was extracted with Et_2O (3 × 4 mL). The combined organic layers were dried over $MgSO_4$ and concentrated. Volatile coproducts were removed by bulb to bulb distillation at 4 mmHg from a bath at 100°C. The residue was then subjected to flash chromatography with pentane/*tert*-butyl methyl ether (30:1) to furnish 136 mg ethyl 4-benzyl-5-methyl-2-methylenehexanoate (79%) and 21 mg ethyl 4,4-dimethyl-2-methylene-6-phenylhexanoate (12%).

Grob Fragmentation

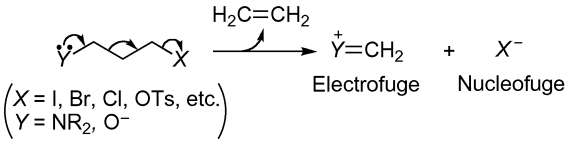
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Grob and Baumann in 1955.[1] It is the cleavage of an amine of a suitable β-leaving group in the presence of a base, where the leaving group is a halogen or tosyl group. Therefore, it is generally known as the Grob fragmentation.[2] Occasionally, it is also referred to as the Grob reaction.[3] In this reaction, the halogen or tosyl group is called a "nucleofuge," and the moiety of the amino group together with the carbon attached to the nitrogen is referred to as an "electrofuge."[4] The difference of the cleavage rate between β-halo (or tosyl) amines and the halides (or tosylate) without a β-amino group results from the frangiomeric acceleration, which can be quantified as the frangiomeric effect, and the largest one recorded so far is as big as 10^5.[5] This reaction occurs via either a concerted[6] or stepwise mechanism,[5] depending on the stereochemical and stereoelectronic factors,[7] but primarily through the concerted one. However, an example of a two-step concerted mechanism with zero activation energy for the second step has also been reported.[4b] Under basic conditions, this reaction has been challenged by nucleophilic substitution, elimination, and cyclization; therefore, some modifications have been developed to carry out such fragmentation under milder conditions, such as to initiate the fragmentation by fluoride,[8] cuprous ion,[9] samarium iodide,[10] and oxidative electron transfer from photo irradiation.[11] In addition, the first example of gas phase fragmentation has recently been reported.[12] The intramolecular version of this reaction has been extensively applied to the synthesis of compounds with medium-size rings.[10a,13] In addition to substituted amines, other types of structures can also undergo fragmentation in a similar manner, such as the oxidative cleavage of β-tributylstannyl alcohol,[6] decomposition of dioxirane and α-peroxy lactone by pyridine *N*-oxide,[14] acid-promoted cleavage of acetonide,[7] and removal of the ether-protecting group (e.g., methoxyethoxymethyl, [trimethylsilyl]ethoxymethyl, benzyloxymethyl).[15] When the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

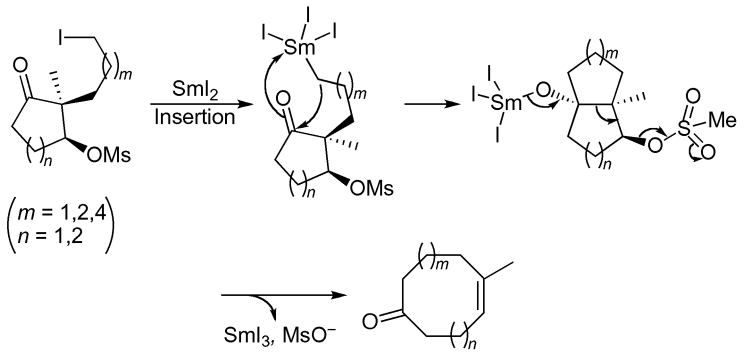
central carbon atom is replaced by a nitrogen atom, the comparable cleavage is called *aza*-Grob fragmentation.[16] It has been found that the fragmentation of *N*-halo-α-amino acid is independent of pH.[4b]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Because this reaction occurs via different mechanisms, depending on the stereochemical and stereoelectronic factors, only the one that results in the enlargement of the ring using SmI_2 is illustrated here.[10]



D. MODIFICATION

This reaction has been modified to different variants, including the initiation from fluoride,[8] cuprous ion,[9] samarium iodide,[10] and oxidative electron transfer[11] and the cleavage of acetonide,[7] β-tributylstannyl alcohol,[6] and different ether protecting groups.[15]

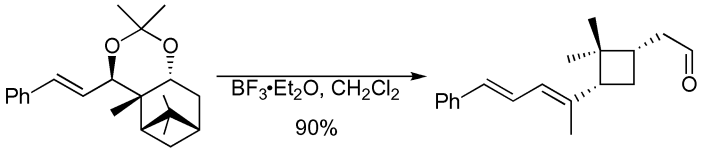
E. APPLICATIONS

This reaction has wide application in natural product synthesis and in the preparation of cyclic compounds with medium-size rings.

F. RELATED REACTIONS

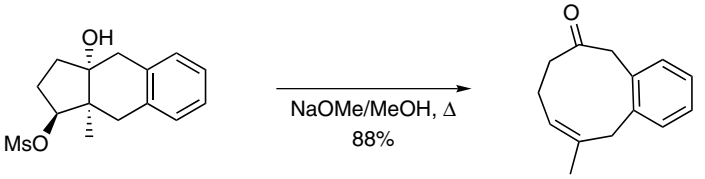
This reaction is related to the *Eschenmoser Fragmentation* and *Wharton Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a solution of 163 mg acetonide (0.5 mmol) in 5 mL dried CH_2Cl_2 cooled at $-15^{\circ}C$ was added 12 mL 0.017 M $BF_3{\cdot}OEt_2$ in CH_2Cl_2 (0.2 mmol) under nitrogen. After 10 min, the reaction completed as monitored by TLC. The reaction was quenched at the same temperature with 10 mL saturated $NaHCO_3$ solution. The mixture was extracted with CH_2Cl_2 (2×10 mL), and the combined organic layers were washed with saturated $NaHCO_3$ solution (2×10 mL) and dried over anhydrous sodium sulfate. Upon removal of the solvent under vacuum, the residue was purified by silica gel flash chromatography (hexane/diethyl ether) to afford 120 mg 2-{(1*S*,3*R*)-2,2-dimethyl-3-[(*E*,*E*)-1-methyl-4-phenyl-1,3-butadienyl]cyclobutyl}ethanal as a colorless liquid, in a yield of 90%, $R_f =$ 0.26 (hexane/diethyl ether, 6:1).



Reference 10a.

To a solution of 11 mg NaOMe (0.2 mmol) in 3 mL MeOH was added 60 mg alcohol (0.2 mmol), and the solution was refluxed for 1 h. After evaporation of MeOH, 3 mL water was added, and the aqueous phase was extracted with EtOAc. The combined organic phases were washed with brine and dried over $MgSO_4$. After evaporation of the solvent, the resulting solid was recrystallized from Et_2O/petroleum ether to yield 34 mg (*Z*)-10-methyl-5,7,8,11-tetrahydrobenzocyclononen-6-one as colorless crystals, in a yield of 88%, m.p., 118–120°C.

Other references related to the Grob fragmentation are cited in the literature.[17]

Grosheintz-Fischer-Reissert Aldehyde Synthesis

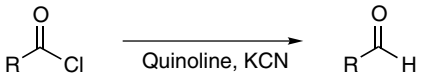
(Reissert Aldehyde Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Reissert in 1905[1] and extended by Grosheintz and Fischer in 1941.[2] It is the synthesis of aldehyde involving the formation of 1-acyl-2-cyano-1,2-dihydroquinoline derivatives from acyl chlorides, quinoline, and potassium cyanide and the subsequent hydrolysis of said dihydroquinoline derivatives under acidic conditions to produce quinaldic acid and aldehydes.[3] The original procedure occurs smoothly for aroyl or cinnamoyl chloride in liquid SO_2 but not in benzonitrile, ether, dioxane, acetone, or $CHCl_3$.[4] However, the modification from Grosheintz and Fischer using hydrogen cyanide and 2 eq. quinoline in absolute benzene is also adaptable for aliphatic acid chlorides.[2] This is one of the methods that converts acyl chlorides into aldehydes and is found to be superior to the normal *Rosenmund Reduction*. For example, *o*-nitrobenzoyl chloride has been converted into *o*-nitrobenzaldehyde in 60% yield by the current reaction, whereas the *Rosenmund Reduction* is not suitable for such conversion.[5] Therefore, this reaction is referred to as the Grosheintz-Fischer-Reissert aldehyde synthesis or Reissert aldehyde synthesis.[6]

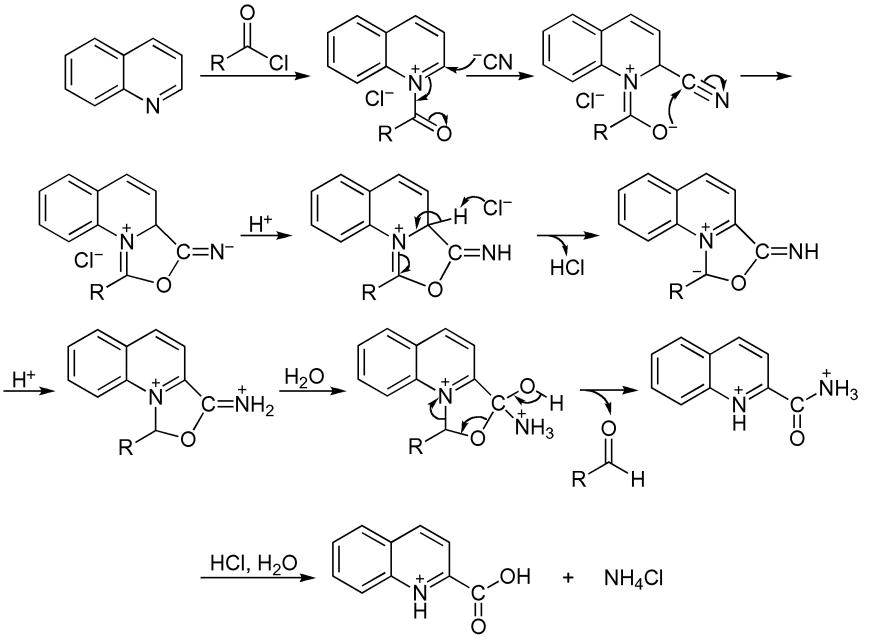
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Many mechanisms have been proposed for this reaction, however, shown here is likely to be correct, according to the literature.[3a]



D. MODIFICATION

This reaction has been modified to improve the yield in a two-phase system.[6]

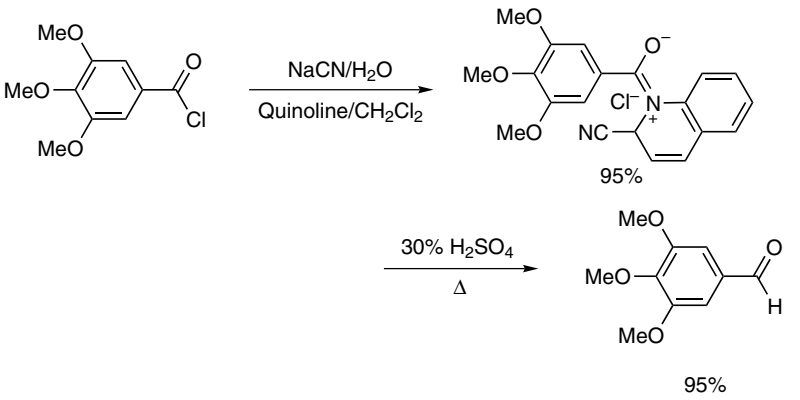
E. APPLICATIONS

This reaction has general application in the synthesis of aldehydes, especially the aromatic aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Reissert Compound*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

To a 250-mL, three-necked round-bottomed flask equipped with mechanical stirrer, baffle, addition funnel, and nitrogen inlet (vented through a safety bubbler) was added 8.3 g NaCN (160 mmol) and 25 mL water. The suspension was stirred to dissolve the salt. Then 22.0 g quinoline (170 mmol) in 50 mL CH_2Cl_2 was added. As the mixture was briskly stirred, 38.6 g 3,4,5-trimethoxybenzoyl chloride (167 mmol) in 75 mL CH_2Cl_2 was added via the addition funnel over 2.5 h. Initially the mixture became orange and then turned yellow. TLC showed that only trace amounts of the acid chloride remained (Et_2O/hexane). After being stirred for an additional 2 h, the mixture was poured into a separatory funnel, and the CH_2Cl_2 layer was withdrawn. The aqueous layer was extracted with CH_2Cl_2 (2×100 mL) and discarded. The combined CH_2Cl_2 layers were extracted first with saturated Na_2CO_3 solution (2×100 mL), then with 10% HCl (2×100 mL), and finally with H_2O (2×100 mL). The CH_2Cl_2 solution was dried over K_2CO_3 and placed in a 500-mL distillation flask with 250 mL EtOH. The solvent was distilled through a Vigreux column to a temperature of 80°C. Crystallization began, and after cooling to 0°C, the crystals were collected, washed with 50 mL EtOH, and vacuum dried at 80°C to give 35.0 g white crystals, m.p. 184–187°C. A second crop of crystals (17.8 g) was obtained from the mother liquors, m.p. 159–161°C. The combined weight (52.8 g) represents a 95% yield of the *Reissert Compound*.

Then 10.5 g *Reissert Compound* was added to a 500-mL three-necked, round-bottomed flask equipped with a thermometer, mechanical stirrer, condenser, baffle, and nitrogen inlet (vented through a safety bubbler); afterwards, 400 mL 30% H_2SO_4 was added. The suspension was heated to 107°C (reflux) with rapid stirring until the mixture became a homogeneous orange solution (∼1 h). Then 1.0 g SG extra charcoal was added, and the mixture was heated at reflux for 15 min, filtered over Celite, and then cooled to room temperature, whereupon the organic product was extracted into CH_2Cl_2 (3×100 mL). This CH_2Cl_2 solution was extracted first with a 10% Na_2CO_3 solution (2×25 mL) and then with H_2O (2×25 mL) and dried over K_2CO_3. The dried solution was placed in a 500-mL distillation flask with 100 mL hexane. Atmospheric distillation of ∼ 350 mL solvent, followed by cooling to 0°C, produced crude solid 3,4,5-trimethoxybenzaldehyde. The crude solid was dissolved in boiling hexane. Insolubles (0.5 g) were filtered and identified as

the *Reissert Compound* (accounting for ∼ %5). The filtered hexane solution was cooled, producing 5.6 g white 3,4,5-trimethoxybenzaldehyde, in a yield of 95%, m.p., 75–77°C.

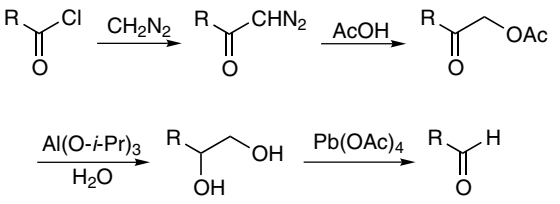
285

Grundmann Aldehyde Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

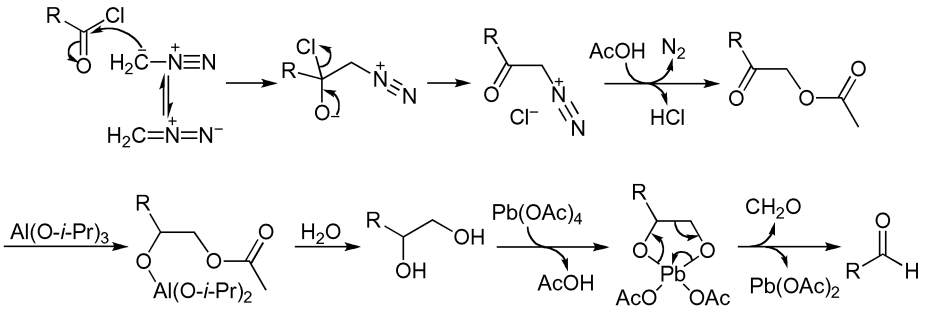
This reaction was initially reported by Grundmann in 1936.[1] It is the conversion of acyl chloride into aldehyde with the exact same carbon skeleton via the following consecutive steps: (*a*) treatment of acyl chloride with diazomethane to form a ketone, (*b*) conversion of such a ketone into ketol acetate with acetic acid, (*c*) reduction of ketol acetate with aluminum isopropylate, and (*d*) hydrolysis and oxidation with lead tetraacetate. This method is especially useful in the preparation of aliphatic aldehydes with methylene-interrupted double bond(s).[2] Although polymers might form in the preparation of highly unsaturated aldehydes during the reduction with aluminum isopropylate, the reduction from lithium aluminum hydride can eliminate such drawbacks.[2]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to reduce the ketol acetate from $LiAlH_4$.[2]

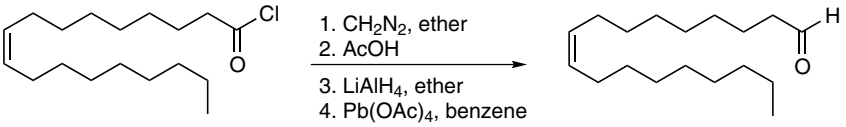
E. APPLICATIONS

This reaction has general application in the conversion of acyl chloride into aldehyde, especially for the unsaturated and isotopic labeled aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Sonn-Müller Reaction* and *Stephen Aldehyde Synthesis.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

Preparation of Glycols

Oleoyl chloride (0.1 mol, 30 g) in 100 mL ether was added during a period of 10 min to a stirred solution of 0.25 mol diazomethane in 590 mL ether kept at 0–5°C. After the mixture warmed to room temperature and stood for 2–4 h, the excess diazomethane and most of the solvent were removed by a stream of nitrogen. The remaining yellow oil was added slowly to 50 mL acetic acid at 50–60°C. After 2 h at this temperature, the decomposition

of the diazo ketone was completed by refluxing for 10 min. The slightly yellow solution was poured into water and the ketol acetate was extracted with ether. The product was washed with water to neutrality and then dried over sodium sulfate. The ether was removed, first by evaporation and finally by heating the residual oil to 50°C under high vacuum. The crude ketol acetate contained ~ 10% chloroketone. The crude ketol acetate in 200 mL ether was treated with an unfiltered solution of 4.0 g $LiAlH_4$ (0.1 mol) in 350 mL ether. The mixture was refluxed for 1 h; after the addition of a little EtOAc, it was poured over 200 g crushed ice. The milky suspension was acidified with dilute H_2SO_4 and extracted several times with ether. The product can be checked for complete reduction by warming a few milligrams with several drops of 50% KOH bath. Residual ketol is indicated by a yellow or brown color. Paper chromatography indicated that these crude preparations contained 10–15% of primary C_{18} alcohol and ~ 5% secondary C_{19} alcohol and/or free acid. The mono alcohols and glycols have boiling points of ~170°C and 190–195°C at 2 mmHg respectively, which can be separated by distillation. A pear-shaped Claisen flask with a modified Pyros-Glover type receiver was used for this purpose. To keep the length of exposure to heat at a minimum, the products were distilled in portions of 0.1 mol or smaller from a bath preheated to 180°C. Additional amounts of pure glycol were obtained by chromatographing the intermediate distilled fractions (6.5 g in 15 mL petroleum ether, 35–60°C) on alumina (40 g, activated, Harshaw) in a tube (2 × 30 cm). The chromatogram was developed successively with 100 mL methylene chloride, 100 mL ether, and 200 mL ethanol. A total of 24 fractions (15 mL each) were collected, and each was spot tested on paper. The first peak of the column chromatogram represented primary and secondary alcohols, which were not separated from each other, and 1.5–2 g pure glycol was recovered from the second peak.

Preparation of Aldehydes

$Pb(OAc)_4$ (0.1 mol, 40–45 g), and 0.5 mL acetic acid were added to a solution of 15 g nonadecene-10-diol-1,2 (0.05 mol) in 100 mL benzene and kept at 60°C for 3 h. Excess of $Pb(OAc)_4$ was destroyed by the addition of ethylene glycol. The solution was cooled to room temperature, poured into 500 mL 20% acetic acid in water, and extracted several times with benzene. The combined extracts were washed first with dilute acetic acid to remove the lead salts and finally with water to neutrality. Such preparations contain small amounts of free acids, which are removed by extracting the benzene solution with 1% Na_2CO_3. The aldehydes obtained in this manner are chromatographically pure and remain as liquid at –20°C, and can be distillated between 150 and 160°C at 2 mmHg.

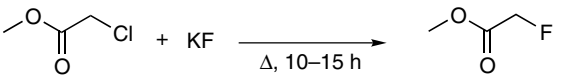
Gryszkiewicz-Trochimowski and McCombie Fluorination

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported almost concurrently by McCombie and co-workers in 1946[1] and Gryszkiewicz-Trochimowski and co-workers in 1947.[2] It is the preparation of methyl fluoroacetate by the treatment of methyl chloroacetate with potassium fluoride at high temperatures (e.g., 190°C) for 10–15 h, with a yield of 60%[3] to 90%.[2] This method has been used to prepare other fluoroacetates[4] and ω-fluoro-alcohols;[5] however, sodium fluoride is not suitable for this reaction because of a very low yield.[4] The best conditions for this reaction require a vigorous agitation of completely dried starting materials at high temperature with potassium fluoride in large excess.[4] This reaction has been scaled up in a pilot plant to prepare methyl fluoroacetate in the United States.[6]

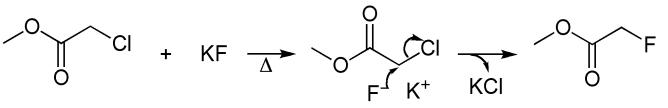
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that there is more ionic character in KF than that in KCl, and the dissociation constant of KCl is smaller than that of KF, according to the electronegativities and sizes of ions. This reaction might occur via a S_N2 mechanism.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

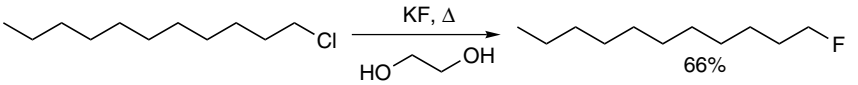
E. APPLICATIONS

This reaction has been used in the preparation of some alkyl fluoroacetates, ω-fluoroalcohols, etc.

F. RELATED REACTIONS

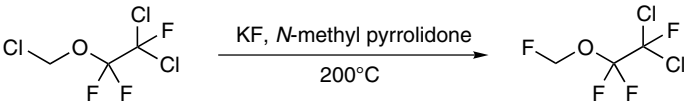
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

A mixture of 15.0 g anhydrous KF (0.26 mol), 80.0 g diethylene glycol and 34.0 g 1-chloroundecane (0.18 mol) was heated at 135°C for 23 h with vigorous stirring. The period of heating may be reduced, with slight diminution of yield. The mixture was cooled and diluted with an equal volume of water. The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer and extracts were treated with bromine in ether until a faint orange color persisted, and then were washed successively with water, aqueous sodium carbonate and water again. The product, after being dried over sodium sulfate and removal of the ether, was fractionally distilled, yielding 15.0 g 1-fluoroundecane, b.p. 102–102.5°C at 23 mmHg and 9.0 g unchanged 1-chloroundecane. The yield was 66%, based on the consumed 1-chloroundecane.



Reference 8.

KF (100 g) was added to 500 mL *N*-methylpyrrolidone, and the mixture was dried by distilling out 50 mL solvent. Then 100 g chloromethyl 1,1,2-trifluoro-2,2-dichloroethyl ether was added slowly with stirring while keeping the reaction temperature at 200°C. A

mixture of product and starting material was distilled out from the reaction mixture, and the distillate was washed with water, dried, and purified by fractional distillation or preparative gas chromatography to give 5–10% fluoromethyl 1,1,2-trifluoro-2,2-dichloroethyl ether.

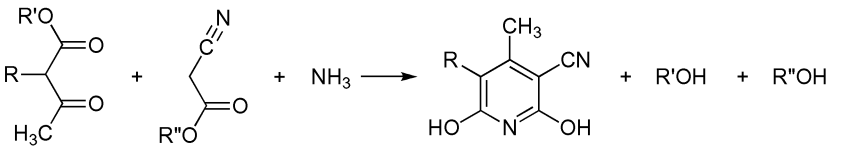
Guareschi Reaction

(Guareschi-Thorpe Pyridine Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

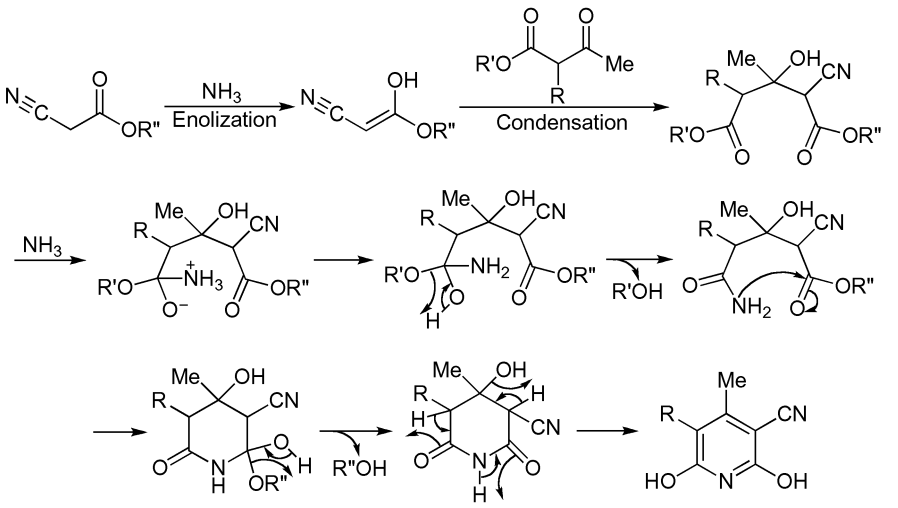
This reaction was initially reported by Guareschi in 1896[1] and fully extended by Thorpe beginning in 1911.[2] It is the preparation of pyridine derivatives by condensation of acetoacetic esters and cyanoacetic acids (or its esters and amides) in the presence of ammonia. The formed cyclic dicyano-imides are called the Guareschi products[3] or Guareschi imides,[4] and this reaction is known as the Guareschi reaction.[3,4a] It was found that ketones can also condense with cyanoacetic esters or amides in aqueous solution in the presence of piperidine or alkali,[5] but this condensation is limited to methyl alkyl ketones only, including acetone.[6] Ketones with carbonyl group adjacent to a ring junction do not condense with cyanoacetic acid.[2b,2d,5b] Unlike cyanoacetic acid, malonic acid and its esters do not undergo this reaction.[3] This reaction has been adopted to prepare β-alkyl glutaric acid from aldehydes and cyanoacetamide.[7]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

A two-step process has been adopted to replace the one-pot synthesis from other ketones that do not regularly undergo this reaction.[4a]

E. APPLICATIONS

This reaction has been used for the synthesis of pyridine derivatives and β-alkyl glutaric acid.

F. RELATED REACTIONS

This reaction is related to the *Hantzsch Dihydropyridine Synthesis* and *Kröhnke Pyridine Synthesis*.

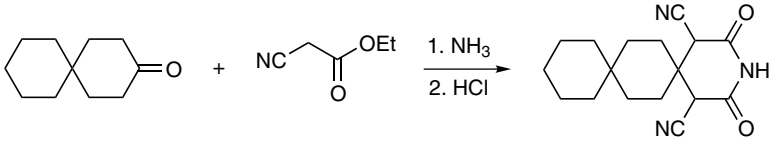
To a 500-mL round-bottomed flask were added 34.45 g 3-pentanone (0.41 mol), 66.31 g ethyl cyanoacetate (0.59 mol), 8.51 g ammonium acetate (0.11 mol), 28.40 g acetic acid (0.47 mol), and 105 mL benzene. The flask was equipped with a Dean-Stark tube fitted to an efficient condenser attached to a $CaCl_2$ drying tube. The solution was refluxed for 45 h while 17.5 mL water was separated (> 100%). The cooled benzene solution was washed three times with 75 mL water, dried over $CaCl_2$, filtered, and concentrated by rotary evaporation to an orange-red oil. Distillation through a 10-cm Vigreux column afforded 60.51 g ethyl 2-cyano-3-ethyl-2-ene-pentate in a yield of 84%.

To a 500-mL, three-necked, round-bottomed flask equipped with overhead stirrer, water-cooled reflux condenser fitted with a $CaCl_2$ tube, and dropping funnel were added 180 mL absolute ethanol and 10.29 g clean sodium (0.45 mol). After the sodium had disappeared, 84.08 g cyanoacetamide (0.45 mol) was added, and the resulting slurry was refluxed for 15 min while another 20 mL ethanol was added. The mixture was cooled, and a solution of 40.54 g ethyl 2-cyano-3-ethyl-2-ene-pentate (0.224 mol) in 40 mL ethanol was added as a thin stream. The reaction was mildly exothermic, resulting a very thick, yellow-orange mixture. Stirring was continued overnight, and then the slurry was poured into 950 mL water, forming a homogeneous orange solution. With cooling, 47 mL concentrated hydrochloric acid was added, forcing out a heavy precipitate. After cooling thoroughly in an ice water bath, the solid was collected by suction filtration, washed with cold water, air dried for 12 h, and further dried at 100°C for 2 h to afford 44.96 g 2,4-dicyano-3,3-diethylpentanimide as a white fluffy solid, in a yield of 91.7%.



40%

Reference 4b.

Spiro[5.5]undecan-3-one (33.2 g, 0.2 mol) and 47.5 g ethyl cyanoacetate (0.42 mol) were placed in a 500-mL thick-walled flask. The mixture was cooled to 0°C, and 100 mL ethanol saturated with anhydrous ammonia at 0°C was added. A stopper was wedged and the mixture was stored at 0–5°C for 1 week. The precipitated ammonium salt of the Guareschi imide was filtered, dissolved in boiling water, filtered, and acidified with HCl. The Guareschi imide was filtered, washed with water, and dried. It melted at 230–233°C and 232–233°C after recrystallization from alcohol-water. 1,5-Dicyano-3-azadispiro[5.2.5.2] hexadecane-2,4-dione (24 g) was obtained, in a yield of 40%.

Guerbet Condensation

A. GENERAL DESCRIPTION OF THE REACTION

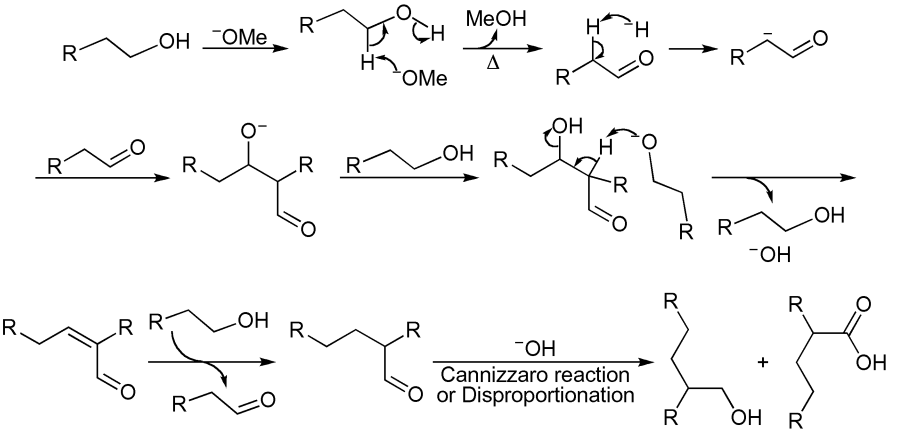
This reaction was initially reported by Guerbet in 1899.[1] It is the condensation of primary or secondary alcohols at high temperature and pressure in the presence of alkali metal hydroxide or alkoxide. It was reported that this reaction occurs via dehydrogenation to form aldehyde that condenses with a second molecule of aldehyde to give the aldol product, which subsequently is reduced by alcohol to form a higher order of alcohol,[2] known as the Guerbet alcohol.[3] Therefore, this reaction is referred to as the Guerbet condensation,[2a,4] Guerbet dimerization[3] or Guerbet reaction.[2b,4e,5] In this reaction, acid is formed in a yield comparable to alcohol,[2a] so that different reagents have been tried to improve the reaction conditions. Tripotassium phosphate was found to be the best condensation reagent for this reaction.[2a] It was found that 0.225 mol potassium alkoxide is the best ratio for the reaction.[4f] The surfactant made from Guerbet alcohol is known as the Guerbet surfactant.[3,6] Recent developments of this reaction have used solid-state catalysts[7] and copper-supported NaOMe as catalyst.[5a] It is interesting that the primary amines are also found to condense under similar conditions.[4e]

B. GENERAL REACTION SCHEME

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is assumed that under these reaction conditions (e.g., high pressure, high temperature), metal alkoxide is strong enough to deprotonate the α-hydrogen. Because no mechanistic details are available, a tentative mechanism, consisting of dehydrogenation to form an aldehyde and subsequent *Aldol Reaction*, is outlined here.



D. MODIFICATION

This reaction has been modified using solid-state catalysts.[5a,7]

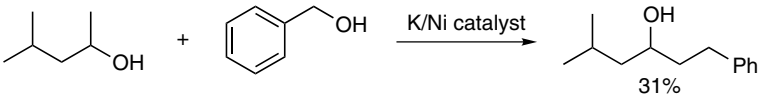
E. APPLICATIONS

This reaction has general application in the preparation of higher-order alcohols from cheap alcohols.

F. RELATED REACTIONS

This reaction is related to the *Lebedev Process* and *Ostromislensky Process*.

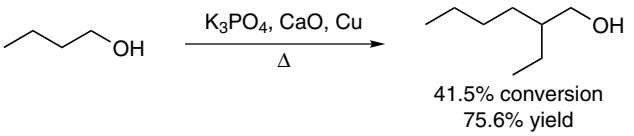
G. CITED EXPERIMENTAL EXAMPLES



Reference 4f.

Total alcohols (benzyl alcohol and 4-methyl-pentanol-2 in ratio of 2:1, 1 mol) was placed in a 500-mL three-necked flask fitted with a stirrer, a thermometer, and a Dean-Stark water trap surmounted by a reflux condenser. The trap was wrapped with asbestos cord for

insulation. After sweeping out the reaction system with a nitrogen flow for several minutes (to reduce the chance of explosion), potassium was added in small portions with slow stirring. Upon the disappearance of potassium, 0.5 g U.O.P nickel catalyst was added, the stirrer was set at a more rapid rate, and the mixture was heated to reflux (143–187°C) with a hemispherical mantle. The temperature and volume of water collected were read at frequent intervals. After 4 h, the reaction mixture was cooled < 100°C and quenched with ∼150 mL water. The catalyst was filtered off, and the layers were separated. The alcohol layer was washed with 10% NaOH, and the combined aqueous layers were extracted with ether. The combined non-aqueous layers were dried over sodium sulfate. After ether was removed at the water aspirator, the product was isolated by vacuum distillation through an 8-in. Vigreux column to give 31% 1-phenyl-5-methyl hexanol-3. The by-product acid was recovered from the combined aqueous layers by acidification with dilute hydrochloric acid, extraction into benzene, and distillation.



Reference 2a.

To a stainless-steel autoclave was added 544.0 g *n*-butanol-1, 53.0 g potassium phosphate, 84.0 g calcium oxide, and 20.0 g activated copper. The autoclave was sealed and tested for leaks with 1000 psi nitrogen. When the autoclave was secure, the nitrogen pressure was slowly bled off through the vent. When the vent valve was closed, the heat was applied with stirring. The reaction attained the desired temperature within 1 h and was maintained at 293–295°C for 4.5 h. The maximum pressure developed during the reaction was 2250 psi. After the reaction was cooled to room temperature, the residual pressure (93 psi) was vented, and the autoclave was emptied. The contents were filtered, and the filtrate was washed with water to remove salts and extracted with benzene. The benzene extracts were combined with the organic materials and dried over $MgSO_4$. Distillation of the mixture yielded 45.5 g *n*-butyl alcohol-water azeotrope, 185.0 g *n*-butyl alcohol, and 162.0 g 2-ethylhexanol distilling at 181–185°C. A residue of 24.5 g remained after distillation. The conversion to 2-ethylhexanol was 41.5%, and the yield was 75.6%.

Other references related to the Guerbet condensation are cited in the literature.[8]

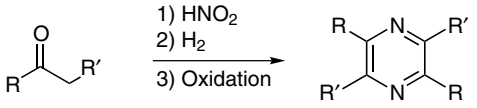
Gutknecht Condensation
(Gutknecht Pyrazine Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

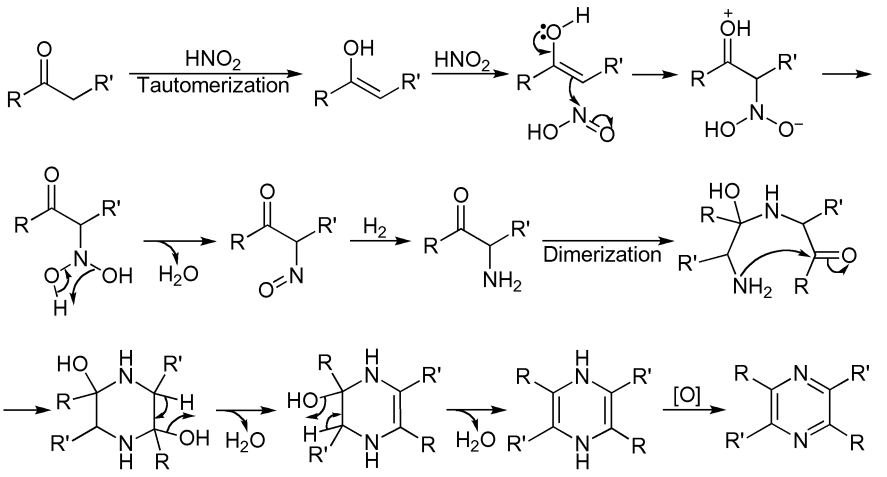
This reaction was initially reported by Gutknecht in 1879.[1] It is a synthesis of pyrazine involving the treatment of a ketone with nitrous acid to form an oximino ketone[2] followed by reduction to an α-amino ketone that dimerizes to dihydropyrazine via a pinacol-like process.[3] The formed dihydropyrazine is then converted into the pyrazine from the dehydrogenation (or oxidation) with mercury (I) oxide, copper (II) sulfate, or atmospheric oxygen.[4] This reaction is thus known as the Gutknecht condensation[5] or Gutknecht pyrazine synthesis.[6] For example, the α-amino acetone in ammonia solution is converted into dimethylpyrazine by the oxidation of mercuric chloride;[4b] likewise, *p*-methyl-α-aminoacetophenone[7] and α-aminopropiophenone[8] are converted into 2,5-di-*p*-toylypyrazine and 3,6-diphenyl-2,5-dimethylpyrazine, respectively. It should be pointed out that pyrazines were once named ketines, as suggested by Treadwell to indicate their origin, but the structures were falsely presented.[2]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified by the treatment of an α-amino ketone with a base (e.g., NH_3,[4a] Grignard reagent[9]) to afford the pyrazine derivative.

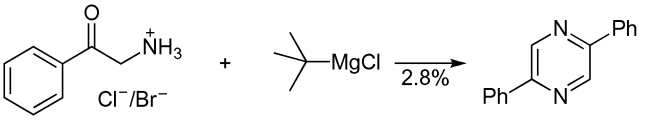
E. APPLICATIONS

This reaction has a general application in the preparation of pyrazine derivatives.

F. RELATED REACTIONS

N/A

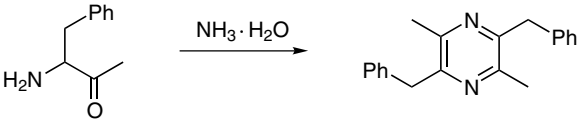
G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To an ethereal solution of *t*-butylmagnesium chloride prepared from 78.7 g *t*-butyl chloride (0.850 mol) and 20.8 g magnesium (0.855 mol) was added, in portions and with stirring, 30 g of the mixed hydrobromide-hydrochloride salt of α-aminoacetophenone ($\sim$ 0.14 mol). After the mixture was boiled under reflux with stirring for 7 h, it was allowed to stand

overnight under a nitrogen atmosphere and then poured into 50 mL saturated, aqueous solution of ammonium chloride. The mixture was filtered, and the two-phase filtrate was made alkaline with aqueous sodium hydroxide solution, heated to boil, cooled and extracted with ether (5 × 200 mL). The combined extracts were dried over $MgSO_4$ and concentrated. An ethanolic solution of the residue deposited 0.46 g crude 2,5-diphenylpyrazine, in a yield of 2.8%, m.p. 191–194°C. Two additional crystallizations from ether afforded the pure pyrazine as colorless plates, m.p. 197.3–198°C.



Reference 4a.

To a solution of 1.0 g α-benzyl-α-aminoacetone hydrochloride in 5 mL water was added 5 mL concentrated aqueous ammonia. The mixture was allowed to stand in an open dish overnight to afford 2,5-dibenzyl-3,6-dimethylpyrazine. Oily droplets separated out, which later changed to long silky needles. The crystals were dissolved in an excess of hydrochloric acid, filtered from a little oily impurity, and then extracted with ether. The acid extract was disregarded, and the solution again was extracted with ether after being made alkaline with sodium hydroxide. The ether on evaporation left a mass of crystals, which melted in a crude condition at ~ 85°C. After being dried on a porous plate and recrystallized from a few drops of alcohol, a small yield of good crystals, both plates and needles, melting at 92–94°C, was obtained.

Other references related to the Gutknecht condensation are cited in the literature.[10]

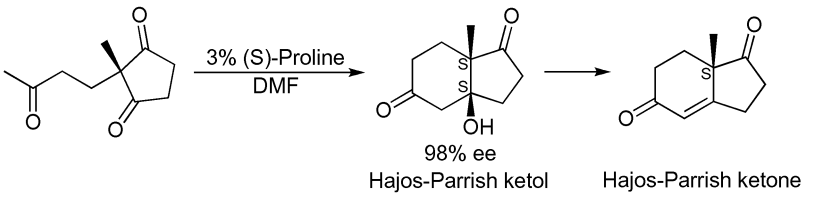
Hajos-Parrish-Eder-Sauer-Wiechert Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was independently reported by two groups in 1971: the group of Hajos and Parrish[1] and the group of Eder, Sauer, and Wiechert.[2] It is an enantioselective *Aldol Reaction* catalyzed by (S)-proline, one of the earliest enantioselectively catalyzed reactions of practical use in synthetic organic chemistry. Owing to its wide application in organic synthesis, it has been extensively explored and extended to asymmetric *Aldol Reaction*,[3] α-alkylation,[4] *Mannich Reaction*,[5] *Michael Addition*,[6] and α-amination[7] of carbonyl compounds. In the literature, this reaction has been referred to by different names: Hajos-Parrish-Eder-Sauer-Wiechert reaction,[8] Hajos-Eder-Sauer-Wiechert reaction,[9] Hajos-Wiechert reaction,[10] and Hajos-Parrish-Wiechert reaction.[11] The asymmetric version of the *Robinson Annulation* catalyzed by (S)-proline is known as the Hajos-Parrish reaction,[12] Hajos-Parrish-Robinson annulation,[13] or Hajos-Wiechert aldol reaction.[14] The resulting cyclic aldol product is called the Hajos-Parrish ketol.[15] In addition, the cyclic (S)-enedione—(7aS)-2,3,7,7a-tetrahydro-7a-methyl-1H-indene-1(5,6H)-dione[16]—is referred to as Hajos-Parrish ketone,[17] Hajos-Parrish diketone,[18] or Hajos-Wiechert ketone.[19] Initially, this reaction was assumed to "involve the formation of a carbinolamine intermediate followed by the displacement of the proline moiety by nucleophilic attack of the enol from ketone,"[8d,20] but more experimental and theoretical evidence indicate that this reaction involves "nucleophilic addition of the neutral enamine to the carbonyl group together with hydrogen transfer from the proline carboxylic acid moiety to the developing alkoxide".[8d]

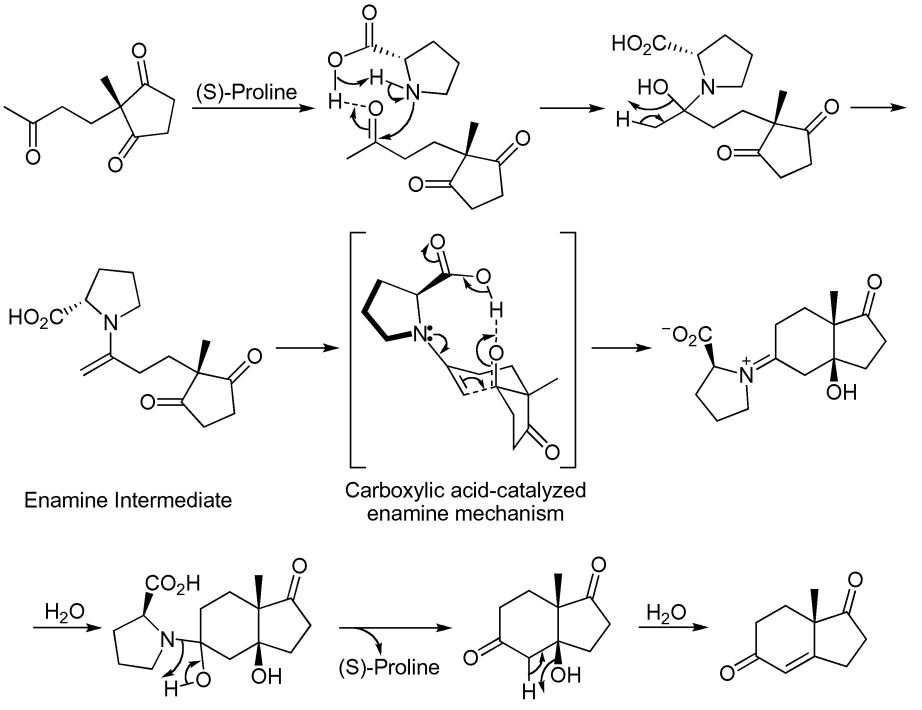
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Illustrated here is the mechanism involved in the nucleophilic addition of the neutral enamine to carbonyl group.[8d]



D. MODIFICATION

This reaction has been extended to other reactions, including α-alkylation,[4] *Mannich Reaction*,[5] *Michael Addition*,[6] and α-amination[7] of ketones.

E. APPLICATIONS

This reaction has wide use in the synthesis of enantiomerically pure molecules involving ketones.

Haller-Bauer Cleavage

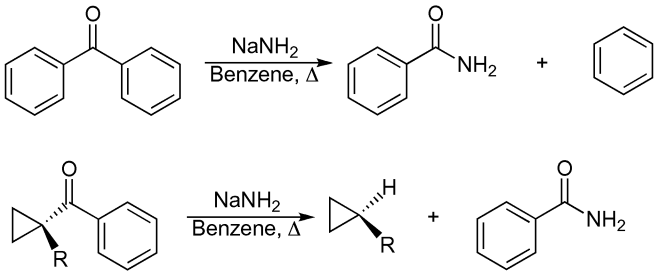
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Haller and Bauer in 1909.[1] It is the base-induced cleavage of a carbon-carbon bond of a nonenolizable ketone to give a carboxylic acid derivative (i.e., an amide) and a neutral fragment in which the carbonyl group is replaced by hydrogen. Therefore, it is generally known as the Haller-Bauer cleavage.[2,3] In addition, this reaction is also referred to as the Haller-Bauer reaction,[2g,2j,2n,4] Haller-Bauer fragmentation,[5] Haller-Bauer decarboxylation,[2j] or Haller-Bauer process.[2f,4c,6] The nonenolizable ketones studied include biaryl ketones, and aryl cyclopropyl ketones, and aryl trifluoromethyl ketones. It was found that this reaction overwhelmingly involves a carbanion, with only minor incursions of a competing free-radical pathway,[6a] and the mode of cleavage depends on the relative stability of the carbanions involved.[2n] Therefore, the cleavage is particularly effective when the incipient carbanion is stabilized;[2j] otherwise, the cleavage might fail if at least one of the groups cannot assist in stabilization of the carbanion.[2h] Exceptions are the cleavage of 1-methyl-2,2-diphenylcyclopropyl phenyl ketone[2o,7] and *Z*-2-phenylcyclopropyl phenyl ketone,[2n] which result in reverse cleavage because of the steric interaction between the phenyl group on 2-position and the carbonyl group.[2m] In addition, this reaction occurs with retention of configuration, not only in the cyclopropyl anion[2o,6b,7,8] where the inversion of configuration is impossible[2j] but also in the open chain.[2j,9] Silane has a higher ability to stabilize the anion than normal alkyl groups, thus higher retention of stereochemistry is found during the preparation of chiral tertiary silanes.[2a,2g,2h] On the other hand, the metal cation of used bases also affects this reaction, and it was found that reaction with potassium amide is faster than that with sodium amide.[2g] When other strong bases such as alkoxides are used for this reaction, the LiO-*t*-Bu does not induce this reaction, showing the reactivity trend of KO-*t*-Bu > NaO-*t*-Bu > LiO-*t*-Bu.[4d]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

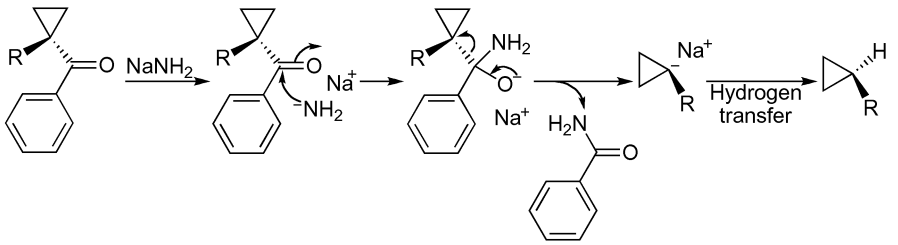
In addition, solvents affect the reaction. Traditionally, this reaction is carried out in boiling benzene with excess amounts of sodium or potassium amide.[9] Substitution of benzene by *t*-BuOH results in the kinetic retardation and modest lowering of stereoselectivity of proton transfer.[4e] It is interesting that a case of cleavage for biaryl ketone is successfully triggered by KO-*t*-Bu but fails when $NaNH_2$ is used.[9] This reaction is useful for preparing chiral compounds[2e,2h,6a] and tertiary carboxamides.[9] Recent modification of this reaction is to induce the cleavage with *N*-alkylamines and *N*,*N*-dialkylamines,[9] and extend the reaction to cyclobutyl ketone.[10]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown below is the mechanism according to Paquette and Maynard,[6a] and Ishihara and Yano.[9]



D. MODIFICATION

This reaction has been extended to use potassium *t*-butoxide[11] or *N*-alkylamines and *N*,*N*-dialkylamines[9] to induce the cleavage.

E. APPLICATIONS

This reaction has wide use in the preparation of tertiary carboxamides, tertiary alcohols, and debenzoylation.

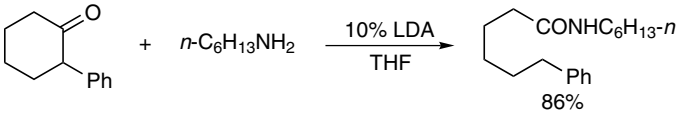
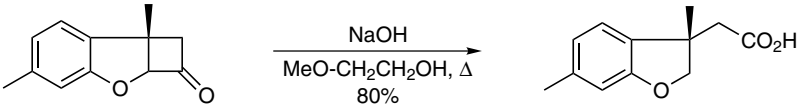
G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To 2 mL THF containing 2.2 mmol hexamine and 28 mL *N*,*N*-diisopropylamine (0.2 mmol) at 0°C under nitrogen atmosphere was added 1.51 mL 1.58 M BuLi in hexane solution (2.4 mmol) dropwise. After being stirred for 15 min, a solution of 2.0 mmol 2-phenyl cyclohexanone in 2.0 mL THF was added, and the mixture was stirred for 30 min at 0°C and at room temperature for 5 h. The reaction was then quenched with 25 mL 1 M HCl, and the mixture was extracted with EtOAc (3 × 20 mL). The organic layer was dried over Na_2SO_4 and concentrated. The residue was purified by column chromatography on silica gel to give 86% *N*-hexyl-6-phenylhexanamide.



Reference 10.

A mixture of 250 mg cyclobutabenzofuranone, 4 mL 15% NaOH, and 10 mL 2-methoxyethanol was refluxed for 10 h. It was then cooled and extracted once with ether. The ethereal layer left no residue. The aqueous portion was acidified with cold 6 N HCl and extracted with ether. The ethereal extracts were washed with water, dried, and concentrated to afford 220 mg of an acid that crystallized from ether-petroleum ether, m.p. 104–105°C, in a yield of 80%.

Hammick Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hammick and co-workers in 1937.[1] It is the synthesis of α-pyridylcarbinols by the decarboxylation of picolinic acid with excess amount of carbonyl compounds (aldehydes or ketones). Therefore, it is generally known as the Hammick reaction.[2] Occasionally, it is also referred to as the Hammick coupling.[2j] It was found that four types of molecules—picolinic acids,[1] quinaldinic acids,[2k] isoquinaldinic acids,[2k] and isonicotinic acids[2k]—all undergo this reaction. In addition, quaternization (e.g., alkylation[3] or formation of *N*-oxide[4]) of the nitrogen atom in these compounds lead to molecules that decarboxylate especially easily.[5] The solvents feasible for this reaction can be either acidic, basic, or neutral. The acidic solvents include phenol and *p*-nitrophenol, and the basic solvents are aniline, *p*-nitroaniline, *N*,*N*-diethylaniline, quinoline, and tributylamine. The neutral solvents include *o*-, *m*- and *p*-dimethoxybenzene, and *o*-, *m*-, and *p*-nitrotoluene and *p*-cymene.[2h] Therefore, this reaction is not affected strongly by the acidity or basicity of the solvent,[6] and it was found that *p*-cymene is the best solvent for this reaction.[2i] The carbonyl compounds, including benzaldehyde, benzophenone, acetophenone, *m*-nitrobenzaldehyde, and *m*-nitroacetophenone, all couple with the heterocyclic moiety upon decarboxylation; however, *p*-nitrobenzaldehyde, 2,4-dinitrobenzaldehyde, cinnamaldehyde, and *p*-dimethylaminobenzaldehyde do not react in the presence or absence of solvents.[2i] This reaction has been proposed to involve three kinds of intermediates: the cyclic form,[2h,4] zwitterions form,[2h,5] and carbene form.[5,7] Each intermediate is favored by certain experimental results, as shown in the cited literature. In addition, the intermediate can also react with other electrophiles instead of carbonyl compounds.[8] Similar to the structure of picolinic acid, the Schiff bases of α-keto acids also decarboxylate accordingly.[5]

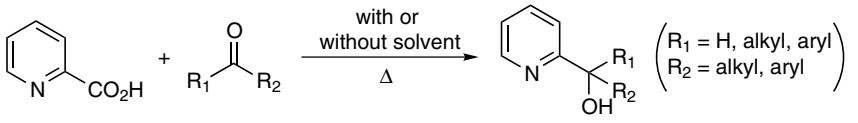
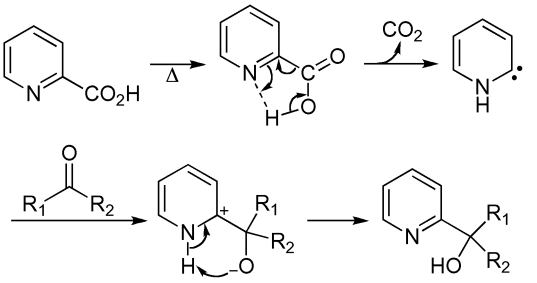
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown below is the mechanism involving a carbene intermediate, which then couples with carbonyl compounds.



D. MODIFICATION

N/A

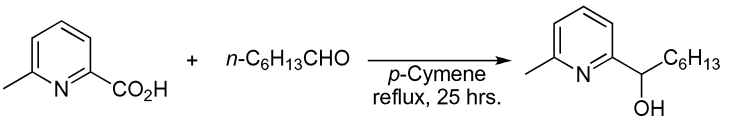
E. APPLICATIONS

This reaction has general application in the preparation of pyridylcarbinols.

F. RELATED REACTIONS

N/A

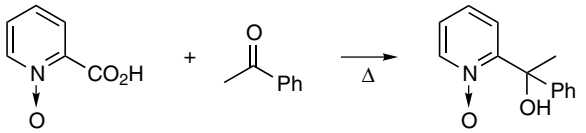
G. CITED EXPERIMENTAL EXAMPLES



24%

Reference 2g.

A solution of 10 g 6-methylpicolinic acid (73 mmol) and 10.0 g *n*-heptaldehyde (87 mmol) in 60 mL *p*-cymene was refluxed for 25 h, after which carbon dioxide evolution ceased (90% of theoretical). The cooled solution was extracted with 2 M HCl (2 × 50 mL), the combined acid extracts were alkalinized and extracted with ether, and the ether extract was dried and distilled to give 24% 1-(6′-methyl-2′-pyridy1)-1-heptanol, b.p. 122–124°C (2 mmHg).



30%

Reference 4.

A solution of 5.0 g 2-carboxypyridine *N*-oxide in 60 mL acetophenone was heated at 150°C until carbon dioxide evolution ceased (1 h). The cold solution was then extracted with 50 mL 2 N HCl; the aqueous layer was made basic and extracted with ether. Concentration of the dried ether extract gave a yellow oil that, on treatment with a mixture of ether-chloroform-petroleum ether, crystallized to give 2.32 g *N*-oxide pyridylcarbinol as white needles, in a yield of 30%, m.p. 112–113°C.

Other references related to the Hammick reaction are cited in the literature.[9]

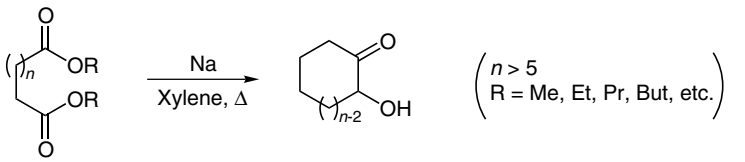
Hansley-Prelog Acyloin Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction, originating from the preparation of open-chain α-ketols,[1] was first reported by Hansley in 1935,[2] and subsequently extended by Prelog in the 1940s–1950s.[3] It is the preparation of cyclic acyloins of 8 or more carbon atoms (e.g., more than 20 carbon atoms) from the reaction of colloidal sodium with esters of saturated or unsaturated dicarboxylic acids in high dilution.[1] The resulting cyclic acyloins can be further converted into cyclic ketones with the same carbon numbers by the reduction of zinc and hydrochloric acid in acetic acid.[4] This reaction is normally carried out above the melting point of sodium[2] while maintaining sodium in colloidal dispersion and then adding the esters of dicarboxylic acid in very diluted concentrations.[5] Toluene and xylene are equally good solvents for this reaction.[2] For the esters of dicarboxylic acids with fewer carbon, the corresponding *t*-butyl or *sec*-butyl esters are preferred, which give higher yields than the methyl esters per unit volume of solvents.[2]

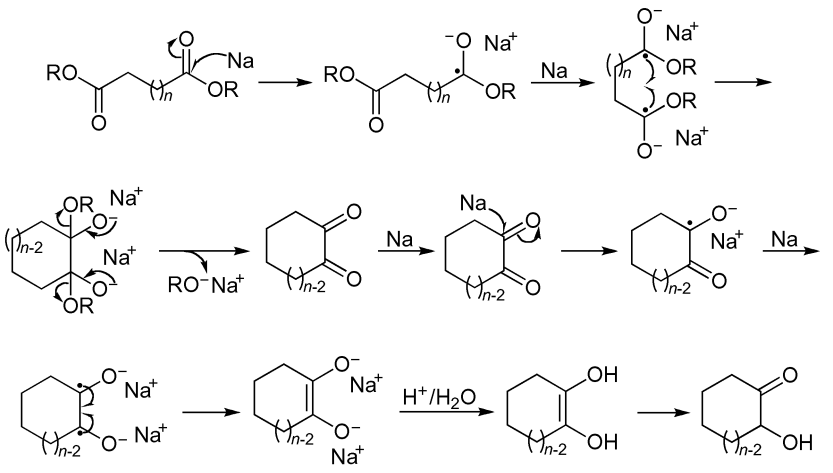
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A radical mechanism is involved in this reaction as shown below.



D. MODIFICATION

N/A

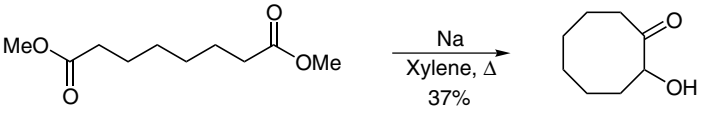
E. APPLICATIONS

This reaction has general application in the preparation of medium to large cyclic ketones.

F. RELATED REACTIONS

This reaction is related to the *Dieckmann Condensation* and *Acyloin Condensation*.

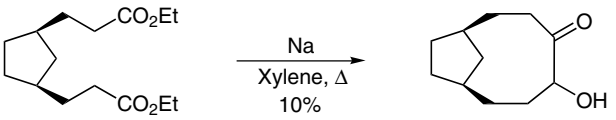
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A 250 mL Morton flask was equipped with a high-speed, stainless-steel stirrer and a high-speed (20,000 rpm) stirrer motor. In one of the necks of the flask was placed a Claissen adapter holding a West condenser directly over the flask and a 250-mL Hershberg dropping funnel in the outer arm. In the other neck of the flask was placed a second Claissen adapter,

one arm of which was stoppered and one arm of which held a gas inlet. A gas outlet attached to a U-tube with a small head of mercury was placed in the top of the reflux condenser. The Claissen adapters were wired securely to the necks of the Morton flask. To remove the last traces of moisture, the entire system was heated with a flame while flushing with argon. Then 125 mL xylene, dried over sodium, was placed in the Morton flask, and the last traces of moisture were removed from the solvent by distilling a small amount through the condenser, which was temporarily placed in distilling position; during the distillation, the air in the flask was replaced by argon. The condenser was replaced in reflux position, and 4.9 g freshly cut sodium metal (0.21 mol) was added through the top of the reflux condenser under a stream of argon. After reheating the xylene to reflux, the stirrer was started, and the molten sodium was dispersed by stirring at an estimated rate of 2000 rpm for 15 min. Addition of a solution of 13.9 g *cis*-1,3-bis-(ethoxycarbonyl)ethyl cyclopentane (0.052 mol) in 25 mL dry xylene to the sodium dispersion was completed in 45 h. The reaction mixture was heated with continued stirring for an additional 3 h. After cooling in an ice bath, 14 g glacial acetic acid (0.24 mol) was added dropwise to decompose excess sodium. During the addition of acetic acid, it was necessary to add an additional 50 mL xylene to suspend the sodium acetate formed. Sodium acetate was removed by vacuum filtration and returned to the reaction flask with 50 mL fresh xylene. After being stirred vigorously for several minutes, the solid was again filtered, and the xylene filtrates were combined. The xylene solution was washed with water and dilute sodium bicarbonate solution and dried over anhydrous magnesium sulfate. Xylene was removed by distillation through a 10-cm Vigreux column. Additional product was recovered by dissolving the sodium acetate in 200 mL water and extracting with ether several times. The washed and dried ethereal extract afforded a residue upon evaporation of the solvent. The two samples were combined (4.1 g total) and chromatographed on a 14 × 1.5 cm column of activity grade V Woelm neutral alumina. Evaporation of the benzene eluate gave 0.9 g crude acyloin product, in a yield of 10%.



Reference 7.

A 5-L three-necked flask was equipped with mercury-sealed Hershberg stirrer and a simple high dilution apparatus, to which was attached a reflux condenser and a Hershberg dropping funnel. Sodium (46 g, 2 mol) was powdered by stirring under 1 L refluxing xylene, and a solution of 101 g dimethyl suberate (0.5 mol) in 80 mL xylene was added through the dilution apparatus over a period of 8 h in an atmosphere of dry nitrogen, with stirring and refluxing during that period plus an additional 2 h. The mixture was allowed to stand overnight, and then was cooled with an ice bath. Absolute ethanol (50 mL) was added to destroy any remaining sodium followed by a solution of 120 g glacial acetic acid (2 mol) in 800 mL dry ether, added slowly with stirring to neutralize the mixture. The nitrogen atmosphere was maintained to this point. Sodium acetate was separated by filtration and washed well with ether, and the filtrate was concentrated under reduced pressure in a nitrogen atmosphere. The residue was distilled from a Hickman molecular-type pot still at 60–133°C (0.5 mmHg), and the distillate was fractionated through a 15 × 1-cm Vigreux column under nitrogen, yielding 26 g suberoin, in a yield of 37%, b.p., 66–71°C (1.3 mmHg). The nearly

colorless product crystallized and was purified by redistillation and crystallization from a mixture of ether and pentane, b.p., 64°C (0.3 mmHg), m.p., 37–38.5°C.

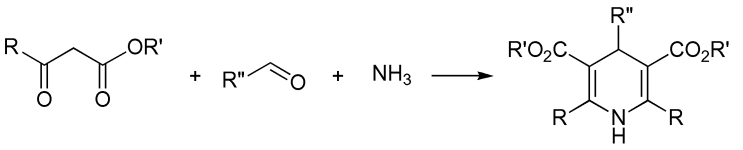
Hantzsch Dihydropyridine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hantzsch in 1882.[1] It is the synthesis of dihydropyridine dicarboxylate by condensation of an aldehyde with 2 eq. β-ketoester in the presence of ammonia. Therefore, this reaction is generally known as the Hantzsch dihydropyridine synthesis.[2] In addition, this reaction is also referred to as Hantzsch condensation[2f,3] or Hantzsch reaction;[4] and the formed dihydropyridine dicarboxylate is called the Hantzsch ester.[3a,5] Subsequent oxidation (or dehydrogenation) of the Hantzsch ester gives pyridine-3,5-dicarboxylates, which may also be decarboxylated to yield the corresponding pyridines.[2f,4a,5b,6] The Hantzsch ester, as a calcium antagonist,[3a,7] has important applications in drug design;[8] in addition, it can also be used as a hydrogen source.[9] This reaction has been modified to take place under microwave irradiation with high reaction rate and overall yields.[2b] Other modifications on this reaction include (*a*) the condensation of alkylidene or arylidene 1,3-dicarbonyl compounds with a β-amino-α,β-unsaturated carbonyl compound to form unsymmetrical 1,4-dihydropyridines[10] and (*b*) condensation of aminocrotonic ester with aldehyde under acidic conditions.[11] The latter modification is a useful process for the synthesis of 3,5-dicyanodihydropyidines.[4f] It should be pointed out that the special synthesis of 2,4,6-trimethylpyridine (collidine) is referred to as Hantzsch collidine synthesis.[12]

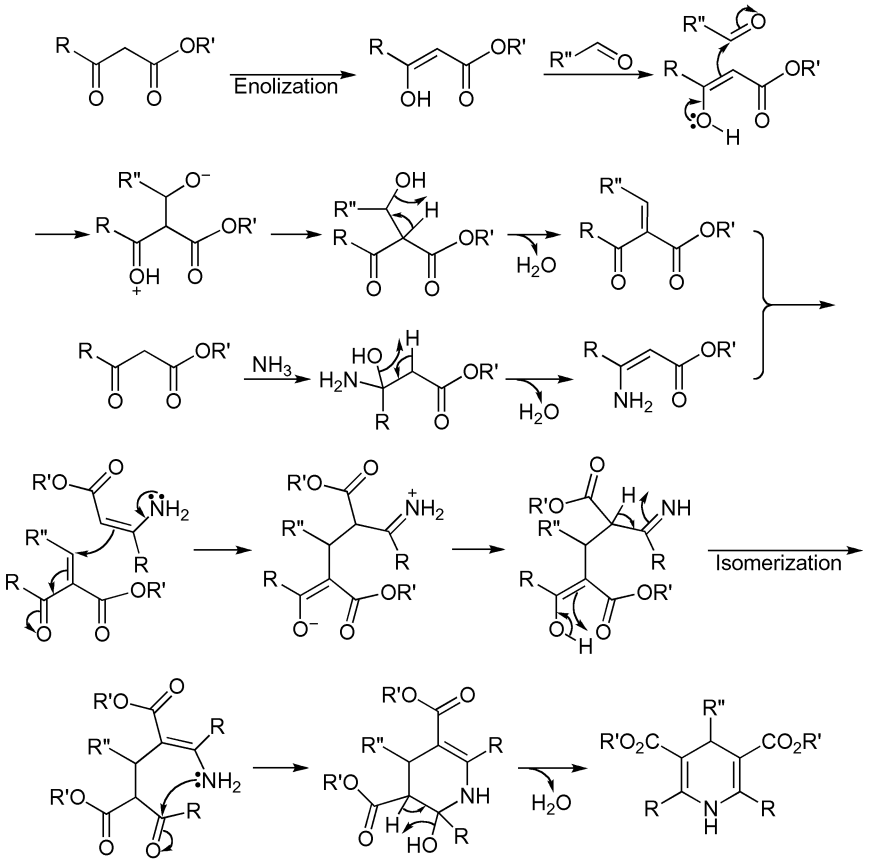
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves the condensation of two important intermediates: the α-alkylidene or α-arylidene β-keto ester condensed from the β-keto ester and aldehyde, and the ester enamine originated from the β-keto ester and amine, as shown below.



D. MODIFICATION

This reaction has been modified to prepare unsymmetrical 1,4-dihydropyridine[10] and 3,5-dicyanodihydropyridine.[4f] In addition, this reaction has been adapted to occur under microwave irradiation.[2b]

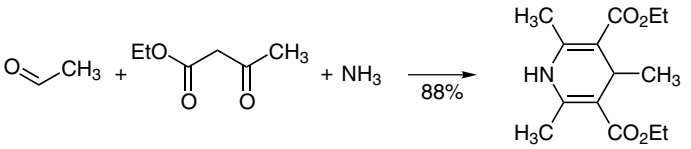
E. APPLICATIONS

This reaction has wide application in the synthesis of substituted 1,4-dihydropyridines and corresponding pyridines.

F. RELATED REACTIONS

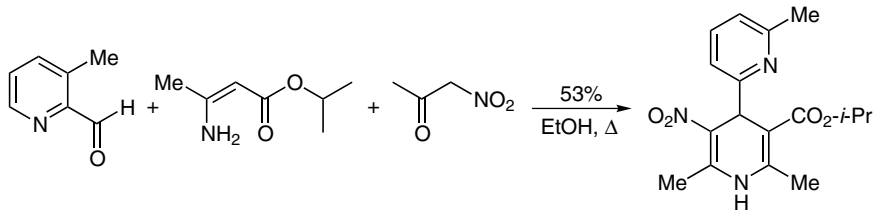
This reaction is related to the *Guareschi-Thorpe Pyridine Synthesis*, *Chichibabin Pyridine Synthesis, Kröhnke Pyridine Synthesis*, and *Petrenko-Kritschenko Piperidone Synthesis.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

The mixture of 26.0 g ethyl acetoacetate (0.2 mol), 4.4 g acetaldehyde (0.1 mol), and 1.7 g ammonia (0.1 mol) in 20 mL ethanol was refluxed for 2 h. The reaction was monitored by TLC. After the completion of the reaction, the mixture was cooled to room temperature; the yellow solid was isolated by filtration and recrystallized from 95% ethanol to give 23.0 g diethyl 2,4,6-trimethyl-1,4-dihydropyridine-3,5-dicarboxylate, in a yield of 88%.



Reference 4c.

A mixture of 1 mmol 3-methyl-2-formyl-pyridine, 1 mmol isopropyl 3-aminocrotonate, and 103 mg nitroacetone (1 mmol) in 5 mL ethanol was stirred at 25°C for 1 h and then refluxed for 16 h. After that, the solvent was removed

in vacuo, and the residue was purified by silica gel column chromatography using EtOAc/hexane (70:30, v/v) to give 53% isopropyl 1,4-dihydro-2,6-dimethyl-3-nitro-4-(6-methyl-2-pyridyl)-5-pyridinecarboxylate, m.p. 189–190°C (recrystallized from EtOAc/hexane).

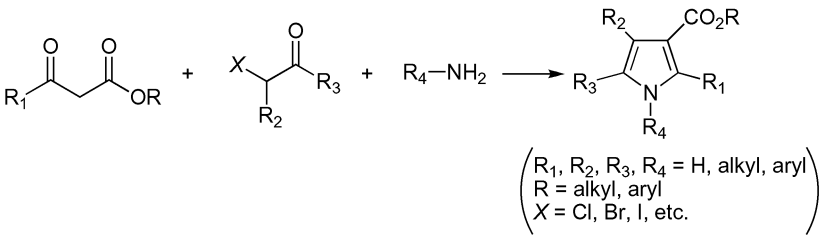
Hantzsch Pyrrole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

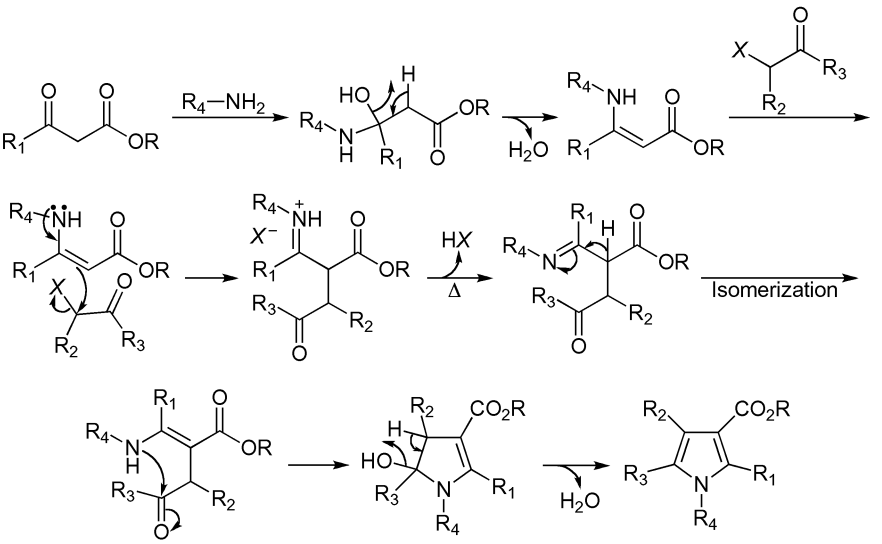
This reaction was first reported by Hantzsch in 1890.[1] It is the preparation of 2,5-dialkyl or 2,4,5-trialkylpyrrole derivatives from the condensation of α-halo-ketones, β-ketoesters and ammonia or amines. Therefore, it is often known as the Hantzsch pyrrole synthesis[2] or simply the Hantzsch synthesis.[3] During this synthesis, ammonia or amine reacts quickly with β-keto esters to form enamine esters or 3-amino crotonates that cyclize with α-halo-ketones to form pyrrole derivatives upon heating, and the regioselectivity strongly depends on the substituents on the starting materials.[4] Thus, this reaction can directly start from 3-amino crotonates[1,5] or enamines of β-keto esters.[6] Further extension of this reaction from aromatic amines results in the formation of indole derivatives,[7] or carbazole derivatives if cyclized with α-halo-cyclohexanones.[8] The synthesized pyrroles have wide application in medicinal chemistry,[9] conducting polymers,[10] molecular optics,[11] sensors,[12] etc.

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to the direct reaction between enamine of β-keto ester[6] or 3-amino crotonate[1,5] and α-halo-ketones; in addition, this reaction has been extended to prepare indole[7] and carbazole[8] derivatives.

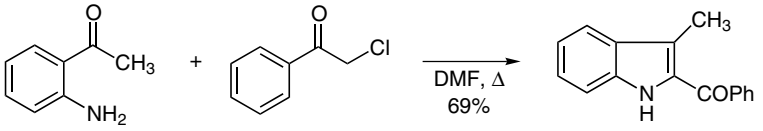
E. APPLICATIONS

This reaction has general applications in the preparation of 2,5-dialkyl- or 2,4,5-trialkyl-substituted pyrrole derivatives.

F. RELATED REACTIONS

This reaction is related to the *Paal-Knorr Pyrrole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7g.

The mixture of 2.7 g *o*-amino acetophenone (0.02 mol) and 3.08 g α-chloro-acetophenone (0.02 mol) in 50 mL anhydrous DMF was heated in an oil bath (80–90°C) for 16 h. The reaction mixture was then poured over 1500 mL ice water, and the crystalline 2-benzoyl-3-methyl-indole was isolated by filtration and was further purified by recrystallization from methanol, giving 69% yield, m.p., 138–139°C.

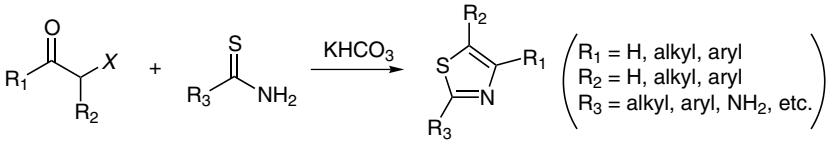
Hantzsch Thiazole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

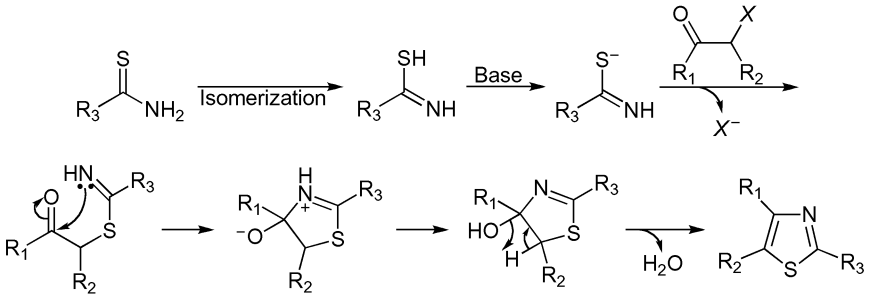
This reaction was first reported by Hantzsch and Weber in 1887.[1] It is the formation of thiazole derivatives by means of condensation of α-haloketones (or aldehydes) and thioamides. Therefore, it is generally known as the Hantzsch thiazole synthesis.[2] In addition, other names, including the Hantzsch synthesis,[2k,3] Hantzsch reaction,[2m,3a,4] and Hantzsch thiazole reaction[5] are also used from time to time. Besides thioamides, other thio-ketone derivatives such as thiourea,[3b,4a,6] dithiocarbamates,[2k] and ketone thiosemicarbazone[2k] can also condense with α-halo ketones (or aldehydes) to form thiazoles. This reaction occurs because of the strong nucleophilicity of the sulfur atom in thioamides or thioureas,[6] and normally gives excellent yields for simple thiazoles but low yields for some substituted thiazoles, as of dehalogenation.[7] This reaction has been proven to be a multistep reaction, and the intermediates have been isolated at low temperatures,[3c] in which the dehydration of cyclic intermediates seems to be the slow step.[2k] It is found that a variety of reaction conditions might result in the racemized thiazoles that contain an enolizable proton at their chiral center, and it is the intermediate not the final product that is involved in the racemization.[2k] Therefore, some modifications have been made to reduce or even eliminate the epimerization upon thiazole formation.[8] In addition, this reaction has been modified using α-tosyloxy ketones to replace α-haloketones.[9]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to reduce the epimerization upon the formation of thiazole.[8] In addition, α-tosyloxy ketones have been used to replace α-haloketones for such reactions.[9]

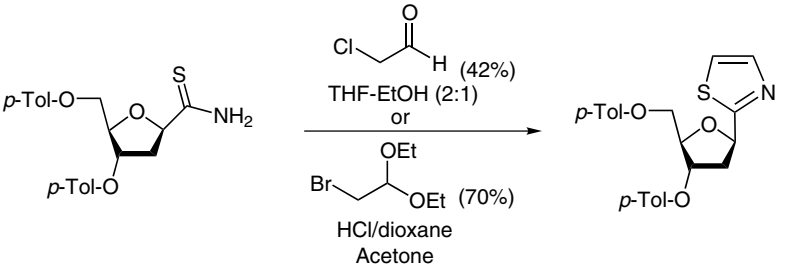
E. APPLICATIONS

This reaction, the classic method for thiazoles, has wide application in the preparation of thiazole derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



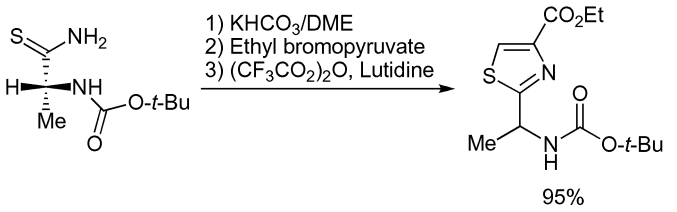
Reference 10.

Method A

2,5-Anhydro-3-deoxy-4,6-di-*O*-*p*-toluoyl-D-*ribo*-hexonthioamide (1.16 g, 3.0 mmol) was dissolved in a mixture of 33 mL THF and 16 mL EtOH. Then 50% chloroacetaldehyde solution (3.18 mL, 25 mmol) was added, and the reaction mixture was refluxed for 24 h. Another equivalent of chloroacetaldehyde solution (3.18 mL, 25 mmol) was added, and the reaction mixture was refluxed for another 24 h. The solvents were evaporated, and the residue was dissolved in EtOAc, washed with saturated $NaHCO_3$ and brine, and dried over $MgSO_4$. Silica gel column chromotography (EtOAc/hexanes) yielded 42% 2-(2′-deoxy-3′,5′-di-*O*-*p*-toluoyl-β-D-ribofuranosyl)thiazole as a light yellow solid.

Method B

2,5-Anhydro-3-deoxy-4,6-di-*O*-*p*-toluoyl-D-*ribo*-hexonthioamide (0.50 g, 1.21 mmol) was dissolved in 7.1 mL dry acetone and 0.9 mL bromoacetaldehyde diethyl acetal (0.69 g, 3.5 mmol); then 13 mL of a 4 M HCl/dioxane solution was added. The resulting clear solution was refluxed under argon for 24 h. The brown-colored solution was evaporated to a dark oil, then dissolved in 100 mL EtOAc and washed with 100 mL saturated aqueous $NaHCO_3$ and 100 mL brine. The organic layer was dried over Na_2SO_4, filtered, and evaporated to a dark brown liquid. Purification by silica gel chromatography (EtOAc/hexanes) provided 0.370 g 2-(2′-deoxy-3′,5′-di-*O*-*p*-toluoyl-β-D-ribofuranosyl)thiazole as a light brown gum, in a yield of 70%. Crystallization from ethanol converted the compound as a solid.



Reference 4b.

A solution of Boc-D-alanine thioamide (1.17 g, 5.74 mmol) in 35 mL DME was cooled to −13°C, followed by the addition of 4.97 g $KHCO_3$ (49.7 mmol) under a nitrogen atmosphere. The suspension was vigorously stirred for 15 min, followed by the addition of 2.4 mL ethyl bromopyruvate (19.1 mmol) under the inert atmosphere at −13°C. The reaction mixture was further incubated at −13°C for 0.5 h, and then at room temperature for 0.5 h. After the reactants were cooled to −13°C again, a solution of 3.6 mL trifluoroacetic anhydride (25.5 mmol) and 6.2 mL lutidine (53.2 mmol) in 10 mL DME was added dropwise. The reaction mixture was allowed to warm from 0°C to room temperature and incubated for 12 h. After removal of the volatile components in vacuo and the addition of 100 mL water, the solution was extracted with $CHCl_3$ (3 × 50 mL). The $CHCl_3$ phase was dried over Na_2SO_4, and after the removal of the solvent, the residue was chromatographed on a silica gel column ($CHCl_3$/EtOAc, 2:1) to afford 1.64 g ethyl (*R*)-2-(1-*N*-Boc-amino)ethylthiazole-4-carboxylate as a yellow semisolid, in a yield of 95%, $R_f = 0.53$ ($CHCl_3$/EtOAc, 2:1).

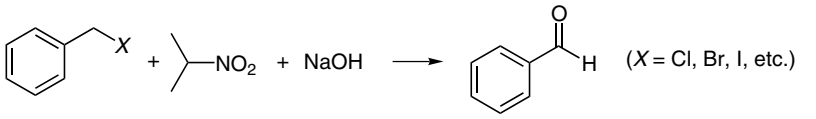
Hass-Bender Oxidation

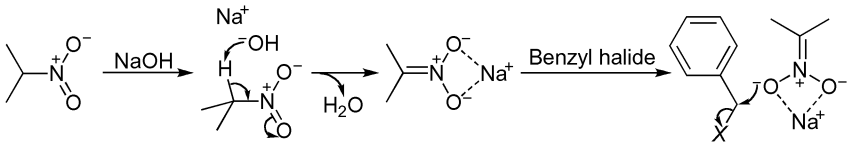
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Hass and Bender in 1949.[1] It is the synthesis of aromatic aldehydes by treatment of substituted benzyl halides with sodium nitropropane salt (also called sodium propane-nitronate[2]). Therefore, this reaction is called the Hass-Bender reaction[3] or Hass-Bender oxidation.[4] This reaction also takes place on aromatic polycyclic compounds.[5]

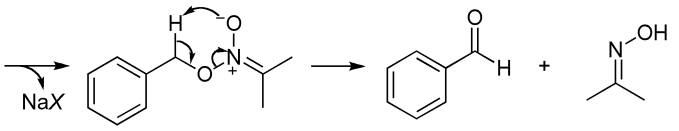
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

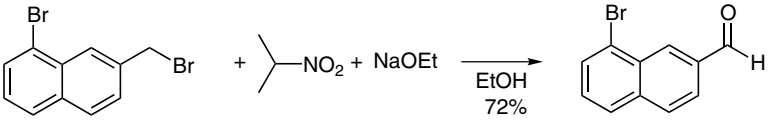
E. APPLICATIONS

This reaction is useful for the conversion of the α-halomethylene group on an aromatic nucleus into a formyl group (i.e., in the synthesis of aromatic aldehydes.)

F. RELATED REACTIONS

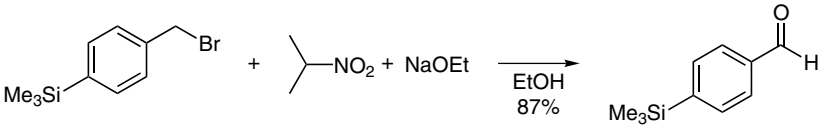
This reaction is related to *Sommelet Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

2-Nitropropane (350 μL, 3.9 mmol) was added to a solution of NaOEt (3.8 mmol) in 8 mL EtOH. A colorless precipitate was formed immediately. Then 1.13 g 1-bromo-7-bromomethylnaphthalene (3.8 mmol) was added to the mixture and stirred for 65 h at room temperature. The reaction mixture was filtered, and the liquid was concentrated on an evaporator. To the residue were added 100 mL Et_2O and 15 mL water. The organic phase was washed with 10% aqueous NaOH solution (2 $\times$ 10 mL) and 10 mL water, dried and evaporated. Column chromatography of the residue gave 640 mg 8-bromonaphthalene-2-carbaldehyde as colorless crystal, in a yield of 72%, m.p. 83–84°C.



Reference 3b.

Under a nitrogen atmosphere, 2.3 g sodium (0.1 mol) was dissolved in 100 mL absolute ethanol. After the sodium had dissolved, 11.6 g 2-nitropropane (0.13 mol) was added followed by 24.3 g *p*-trimethylsilylbenzyl bromide (0.1 mol). After thorough mixing, the reaction mixture was allowed to stand at room temperature under a nitrogen atmosphere for 15 h. The precipitated sodium bromide was removed by filtration, and the filtrate was concentrated by evaporation (*Note*: The original procedure was to remove the ethanol at atmospheric pressure). During this process, additional sodium bromide precipitated. The residue was mixed with ether and the water. The ethereal solution was washed with 10% sodium hydroxide, followed by water, and was then dried over Drierite. The ether was removed by distillation, and the residue was fractionally distilled through a small Vigreux column, giving 13.87 g *p*-trimethylsilylbenzaldehyde, in a yield of 87%, b.p. 118–119°C (16 mmHg).

Other references related to the Hass-Bender oxidation are cited in the literature.[6]

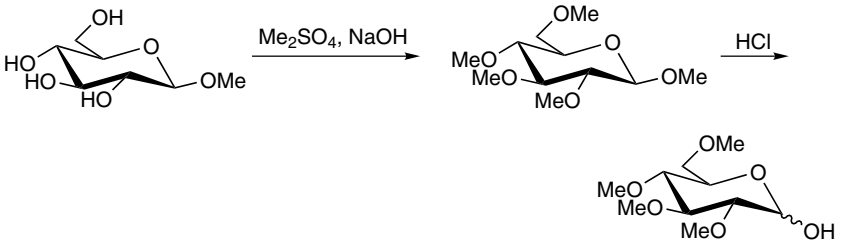
Haworth Methylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Denham and Woodhouse in 1913,[1a] and extended by Haworth in 1915.[1b–1d] It is the preparation of the methylated methyl glycoside from methyl glycosides with dimethyl sulfate and 30% sodium hydroxide. The glycosidic methyl group of the methylated glycosides can be removed via hydrolysis in hydrochloric acid. This reaction is very useful at earlier stages of carbohydrate chemistry to elucidate the sugar structures, including the linkages between monosaccharide units in disaccharides or oligosaccharides and the ring structures. This reaction was optimized by West and Holden by means of the treatment of concentrated sugar or a methyl glycosides solution and carbon tetrachloride solution of methyl sulfate with 60% sodium hydroxide for 8–10 h. Then the crude or isolated methylated glycosides were hydrolyzed with 2 N HCl through steam distillation to give pure crystalline tetramethyl-monosaccharides.[2]

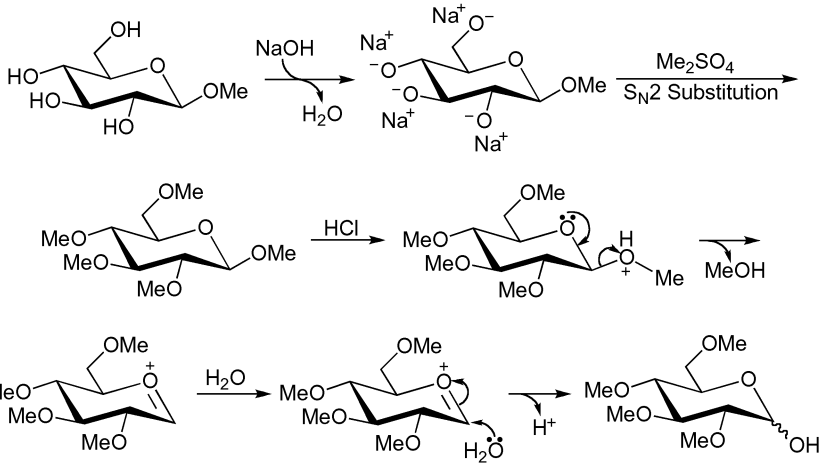
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Under these conditions, the sodium hydroxide is strong enough to deprotonate the hydroxyl groups on glycosides. It should be pointed out that such deprotonation should be stepwise; however, only one step of deprotonation is provided here to illustrate the methylation process.



D. MODIFICATION

This reaction has been modified by West and Holden by means of the treatment of glycosides with carbon tetrachloride solution of methyl sulfate and 60% sodium hydroxide.[2]

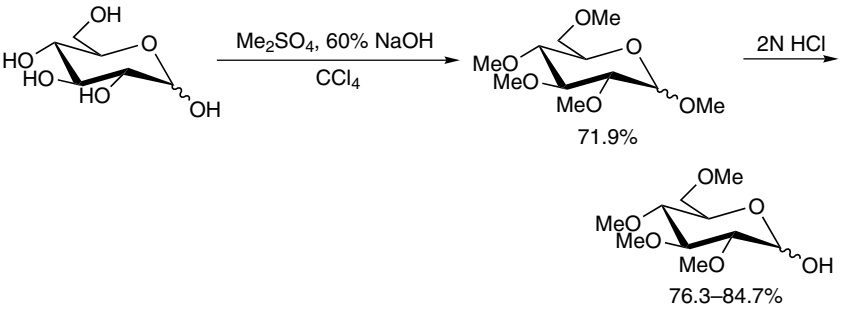
E. APPLICATIONS

This reaction has wide application at earlier stages of carbohydrate chemistry, for the sake of structural analysis of carbohydrates.

F. RELATED REACTIONS

This reaction is related to *Irvine-Purdie Methylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

Glucose (25 g) and 15 mL water were placed in a methylating flask in a water bath at 55°C under rapid stirring, which was maintained throughout the reaction. Then 90 mL methyl sulfate in 125 mL carbon tetrachloride was added quickly through the dropping tube, followed by the addition of 400 mL 60% NaOH at the rate of 1 drop in 2 seconds for 5 min, then 1 drop for 5 min, and then 3 drops until the distillation of carbon tetrachloride slackened or ceased, which was usually accomplished in 20 min, and after the addition of 70–90 mL NaOH solution. The heat of reaction generally maintained the proper temperature of 50–55°C throughout this stage, and it was not necessary to heat the bath externally. The remainder of the alkali was added to the flask as quickly as possible, and the bath temperature was raised rapidly to and maintained at 70–75°C. Then 160 mL methyl sulfate was placed in the reservoir and added at 3–4 drops/second (slower if the mixture foamed seriously). After the addition of all the methyl sulfate, the bath was heated to boil for 30 min (stirring continued), after which the contents of the flask were cooled, diluted with sufficient water to dissolve most of the separated sodium sulfate, and extracted with chloroform (4 × 150 mL). The combined chloroform extracts were dried with sodium sulfate and filtered; the chloroform was distilled off. The syrup distilled at 88–90°C at 0.15 mmHg to give 25 g α,β-tetramethylmethylglucose, in a yield of 71.9%

The undried, filtered chloroform solution of α,β-tetramethylmethylglucoside (or the isolated syrup) obtained in the direct methylation of glucose was placed in a 2–3 L distilling flask with 400 mL 2 N hydrochloric acid, and the chloroform was distilled off. A vigorous current of steam was then passed through the solution for 1 h, care being taken to maintain the volume of solution approximately constant by heating the flask. Norit (5 g) was added to the hot solution, which was then cooled and filtered. The filtrate was saturated with sodium sulfate and extracted with $CHCl_3$ (4 × 150 mL). The combined chloroform extracts were dried with sodium sulfate; 1 g Norit was added and filtered. Chloroform was distilled off as much as possible without vacuum and then in a boiling water bath at the water pump. The syrup was treated with 40–50 mL petroleum ether (30–60°C) and shaken for a short time, whereupon it set to a mass of crystals. After cooling in an ice bath for 30 min, the crystals were filtered off, washed with a little cold petroleum ether, and dried over calcium chloride in a vacuum, yielding 18–20 g tetramethylglucose, in a yield of 76.3% to 84.7%.

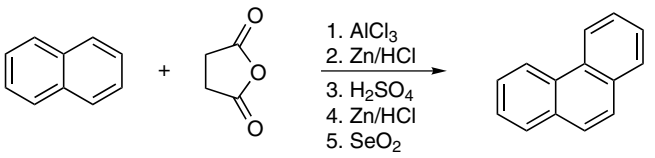
Haworth Synthesis
(Haworth Phenanthrene Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

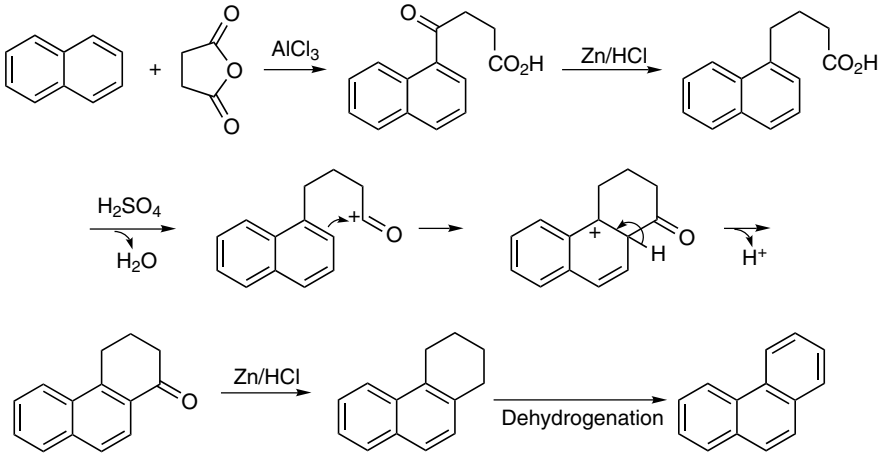
This reaction was first reported by Haworth in 1932.[1] It is a multistep preparation of phenanthrenes from naphthalenes by means of the *Friedel-Crafts Acylation* with succinic anhydride, followed by a *Clemmensen Reduction* or *Wolff-Kishner Reduction*, cyclization, reduction, and dehydrogenation. Therefore, it is generally known as the Haworth synthesis.[2] Occasionally, it is also referred to as the Haworth phenanthrene synthesis.[3] In addition, the same procedure used for the preparation of naphthalenes[2b,4] from benzenes is called the Haworth reaction.[4a] It is known that naphthalene also reacts with mono or symmetrical dialkyl derivatives of succinic anhydride.[3] Substituted naphthalenes often give only one naphthoylpropionic acid derivative, as of the directive effect of the substituent.[3] The cyclization is often executed by the direct reaction of naphthalene-butyric acid with sulfuric acid,[4b,5] HF,[6] or polyphosphoric acid (PPA)[2b] or by intramolecular *Friedel-Crafts Acylation* from the corresponding acyl chloride. The dehydrogenation reagents used include 2,3-dichloro-5,6-dicyano-benzoquinone (DDQ),[4a] 3,4,5,6-tetrachloro-1,2-benzoquinone (TCQ),[2b] triphenylmethanol (TPM),[2b] sulfur,[2b] and SeO_2.[7] This reaction has been modified by alkylation with 4-pentenoic acid ester in the presence of HCl, from which the phenanthrenes with alkyl substituents can be synthesized directly.[8] In addition, the first step of the *Friedel-Crafts Acylation* with succinic anhydride has been substituted by the *Grignard Reaction* between succinic anhydride and the naphthalene Grignard reagent.[6] This reaction has been used for the synthesis of optically active polysubstituted naphthalene derivatives[2b] and the isotopic-labeled naphthalene and phenanthrene derivatives.[4a]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to react with 4-pentenoic acid ester to form alkyl-substituted phenanthrenes directly.[8] In addition, the first step of acylation has alternatively been carried out by the reaction of succinic anhydride with an aryl Grignard reagent.[6]

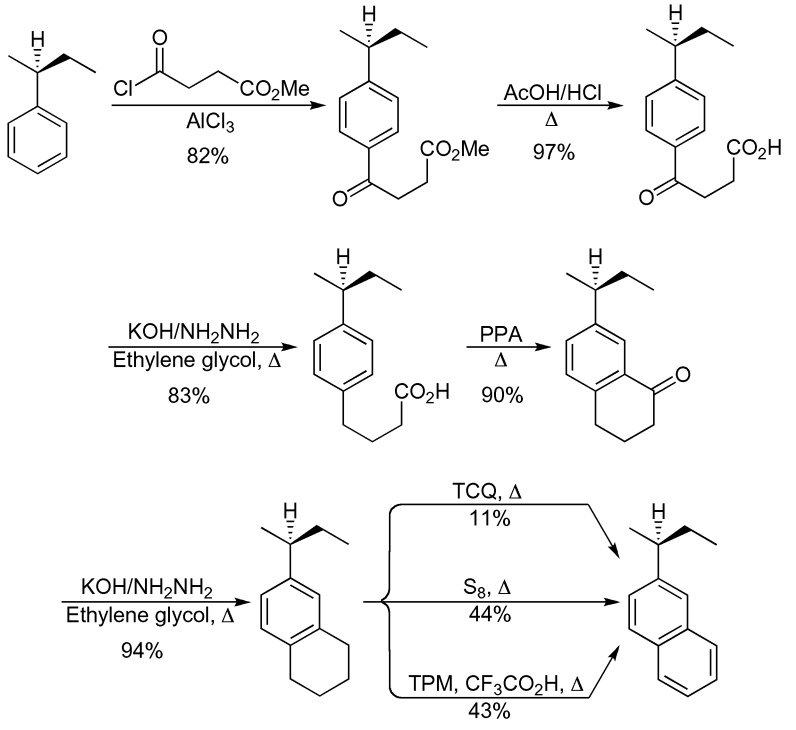
E. APPLICATIONS

This reaction has general application in the preparation of fused aromatics, including naphthalenes and phenanthrenes.

F. RELATED REACTIONS

This reaction is related to *Friedel-Crafts Acylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a filtered solution prepared from 35.6 g $AlCl_3$ (0.266 mol) and 27.2 g 3-(carbomethoxy)propionyl chloride (0.180 mol) in 150 mL dry CH_2Cl_2 was added 27.5 g (S)-isobutyl-benzene (0.205 mol) in 70 mL dry CH_2Cl_2 at 0°C. The mixture was stirred at 0°C for 1 h and hydrolyzed with ice and 10% HCl. Then the organic layer was dried and evaporated, and the residue was distilled to give 36.6 g 99% pure methyl (S)-3-[4-(1-methylpropyl)benzoyl]propionate in 82% yield with respect to the acyl chloride, besides 4.1 g 99% pure (S)-isobutyl-benzene.

A mixture of 36.5 g methyl (S)-3-[4-(1-methylpropyl)benzoyl]propionate (0.147 mol) dissolved in 600 mL glacial acetic acid and 725 mL 36% HCl was heated at 70°C for 8 h. After the mixture was cooled, 10 L of water was added; the organic product was extracted with ether, washed by water and dried; evaporation gave 33.6 g (S)-3-[4-(1-methylpropyl)benzoyl]propionic acid, in a yield of 97%, m.p. 94–95°C.

A mixture of 34.5 g (S)-3-[4-(1-methylpropyl)benzoyl]propionic acid (0.147 mol) and 30.0 g KOH (0.535 mol) in 200 mL diethylene glycol was heated at 50°C for 30 min; after cooling, 21.7 g 85% hydrazine hydrate (0.434 mol) was added. After the mixture was refluxed for 15 h, the water and the excess of hydrazine were removed under reduced pressure (18 mmHg), and the residue was heated at 180°C for 6 h. The reaction mixture was diluted with 2 L water, neutralized with HC1, and extracted with ether. The solvent was removed, and the residue was distilled to give 27.0 g 99% pure (S)-4-[4-(1-methylpropyl)phenyl]butanoic acid, in a yield of 83%, b.p. 138°C (0.3 mmHg).

To a hot solution (90–100°C) of PPA, obtained from 672.5 g P_2O_5 (4.75 mol) and 727.0 g 85% H_3PO_4 (7.42 mol) was added 26.0 g (S)-4-[4-(1-methylpropyl)phenyl]butanoic acid (0.118 mol). After 2 h, the mixture was cooled, diluted with ice water, and extracted with ether. The ethereal extracts were washed with 10% NaOH and water and dried over Na_2SO_4. The solvent was removed, and 21.5 g 99% pure 7-(1-methylpropyl)-1-tetralone was obtained, in a yield of 90%, b.p. 111°C (0.3 mmHg).

To a solution of 16.0 g 7-(1-methylpropyl)-1-tetralone (79.1 mmol) in 40 mL diethylene glycol was added 11.6 g 85% hydrazine hydrate (0.231 mol) at 0°C. After the mixture had been refluxed for 1 h, 7.1 g KOH (0.126 mol) dissolved in 25 mL diethylene glycol was added; then the mixture was refluxed for an additional hour. The water and excess of hydrazine were removed under reduced pressure (18 mmHg), and the residue was heated at 180°C for 4 h. The mixture was worked up as usual to give 14.0 g 99% pure (S)-1,2,3,4-tetrahydro-6-(1-methylpropyl)naphthalene, in a yield of 94%, b.p. 83°C (0.5 mmHg).

A mixture of 0.62 g sulfur (19.3 mmol) and 1.4 g (S)-1,2,3,4-tetrahydro-6-(1-methylpropyl)naphthalene was heated at 250°C for 2 h. By distillation under reduced pressure, 0.6 g 98% of (S)-2-(1-methylpropyl)naphthalene was obtained.

The aromatization of tetralin can also be completed by the following two methods. (a) aromatization with TCQ. To a solution of 12.0 g TCQ (51.4 mmol) in 25 mL dry benzene, was added at 80°C 4.0 g (S)-1,2,3,4-tetrahydro-6-(1-methylpropyl)naphthalene (21.2 mmol) dissolved in 15 mL dry benzene. After being refluxed for 4 h, the mixture was diluted with water and extracted with pentane. The organic phase was washed with 30% NaOH and water and dried over Na_2SO_4. The solvent was removed, and the crude product was distilled to give 2.7 g of a 2.2:1 mixture of (S)-1,2,3,4-tetrahydro-6-(1-methylpropyl)naphthalene and (S)-2-(1-methylpropyl)naphthalene. By GLC purification (2-m column, BDS; 140°C), 0.43 g 98% pure (S)-2-(1-methylpropyl)naphthalene was obtained, b.p. 90°C (0.8 mmHg).

(b) Aromatization with triphenylmethanol. A solution of 1.5 g (S)-1,2,3,4-tetrahydro-6-(1-methylpropyl)naphthalene (8.0 mmol) and 4.6 g triphenylmethanol (17.7 mmol) in 20 mL trifluoroacetic acid was refluxed under nitrogen for 18 h. The reaction mixture was cooled, diluted with ice water, and extracted with ether. The ethereal solution was washed with 10% NaOH and water, and dried over Na_2SO_4. In the crude product, no trace of the starting material was detected. After accurate distillation to remove the triphenylmethane, 0.6 g 99% pure (S)-2-(1-methylpropyl)naphthalene was obtained, in a yield of 40%.

Hayashi Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hayashi in 1927.[1] It is the rearrangement of substituted *o*-benzoylbenzoic acids in the presence of sulfuric acid or phosphorous pentoxide. Therefore, it is referred to as the Hayashi rearrangement.[2] Under normal conditions, the *o*-benzoylbenzoic acid cyclizes to form anthraquinones in the presence of acylating reagents, including sulfuric acid;[2b] however, when the aryl group is activated[2b] through conjugation or hyperconjugation,[2c] 1,4-aryl migration involving an acyl carbonium ion occurs.[2b] It has been found that the direction of carbonium center transfer is determined by sulfuric acid concentration and reaction temperature.[2a] Catalysts such as trifluoroacetic acid, methanesulfonic acid, and PPA have no effect on this rearrangement.[2a] Similar reactions also occur in other aromatic compounds, such as naphthalenes[3] and benzhydryls.[2b]

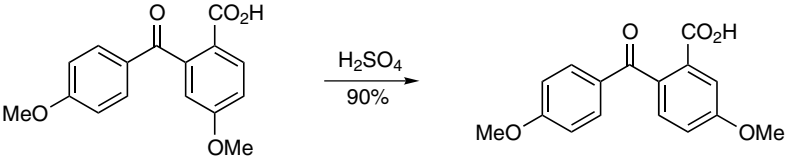
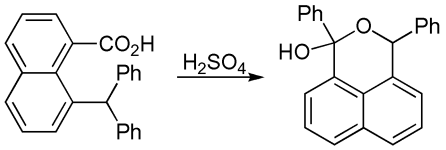
G. CITED EXPERIMENTAL EXAMPLES



Reference 2c.

2-(4′-Methoxybenzoyl)-4-methoxybenzoic acid (0.5 g) in 3 mL conc. H_2SO_4 was heated at 65°C for 6 h; then the mixture was cooled and diluted with ice and water. The reaction mixture was made basic with NaOH, and any cyclized material was separated. The filtrate was acidified to yield unchanged or rearranged keto acid. It was found that 0.5 g keto acid was obtained, m.p. 170–172°C; after crystallization from dilute alcohol, 0.45 g pure keto acid was obtained, m.p. 173–175°C.



Reference 2b.

8-Benzhydryl-1-naphthoic acid (0.50 g) was heated on a steam bath for 2 h with 16 mL H_2SO_4 and 4 mL H_2O (not all of the solid went into solution). The orange mixture was then cooled and poured onto crushed ice; the precipitate was taken up in ether. After extraction with 10% Na_2CO_3 solution, it was acidified with HCl to give 0.3 g starting material (60% recovery). After the ether layer was washed and treated with petroleum ether (b.p. 60–70°C), the residue solid was recrystallized from $CHCl_3$-petroleum ether to give 0.10 g colorless, crystalline 1-phenylhydroxymethyl-8-benzoylnaphthanlene, m.p. 136.5–137°C.

Heck Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Heck in 1968.[1] It is the palladium-catalyzed coupling between an aryl (or vinyl) halide and an alkene without an allylic hydrogen. Accordingly, this reaction is generally known as the Heck reaction.[2] Occasionally, this reaction is also referred to as the Heck arylation,[3] Heck coupling,[4] Heck ethylenation,[5] Heck insertion,[6] Heck olefination,[7] and Heck vinylation.[8] In addition, the intramolecular version of this reaction to form cyclic olefin is called the Heck cyclization.[9] Unfortunately, the terms Heck-Mizoroki reaction,[7] Mizoroki-Heck reaction,[10] and Mizoroki-Heck arylation[11] are also used for this reaction, because people have mistakenly cited Mizoroki's 1971 work[12] and Heck's 1972 paper.[13] The Heck reaction is a powerful tool for constructing a C-C bond in a single transformation employing a variety of aryl or vinyl halides and alkenes, which tolerate almost any sensitive functionalities, including amino, hydroxy, aldehyde, ketone, carboxy, ester, cyano, and nitro groups.[14] The traditional Heck reaction uses 1–5 mol % of a palladium catalyst along with a phosphine ligand (PPh_3) in the presence of a suitable base (soluble as Et_3N or insoluble as K_2CO_3, Ag_2CO_3), which scavenges the generated hydrogen halide in the β-elimination step of the catalytic cycle. Although it is known that this reaction involves a Pd(0)/Pd(II) catalytic cycle, in which Pd(II) is reduced by a phophsine to Pd(0), a few cases that involve the catalytic cycle of Pd(II)/Pd(IV) also exist with some ligands.[15] The palladium complex in the former case is known as a neutral palladium complex, in which regiochemistry is controlled by steric effect; whereas in the latter Pd(II)/Pd(IV) catalytic cycle, it is known as the *cationic palladium complex*, in which regiochemistry is influenced by an electric effect and the cationic Pd complex increases the polarization of the alkene in favor of the transfer of the vinyl or aryl group to the site of least electron density. In addition, the Heck reaction catalyzed by a neutral palladium complex

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

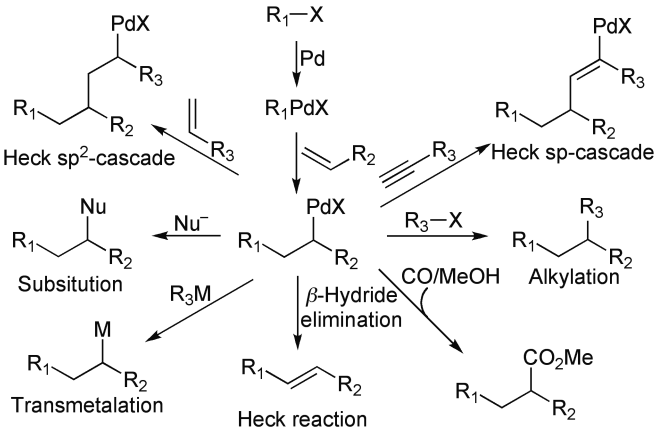

FIGURE 1. *Possible Heck-tandem product under various conditions.*

or cationic palladium complex can give different stereochemical outcomes.[16] The reaction mechanism is illustrated by a catalytic cycle, in which the palladium complex is reduced to a Pd(0) complex with a 14-electron—that is the active species, which inserts into aryl halide via oxidative addition—and the resulting palladium complex then adds to the C=C bond of an alkene on the same face; the addition product then rotates to have the β-hydride and the palladium in *syn*-coplanar geometry to undergo elimination and complete the catalytic cycle. Reversible β-hydride elimination can lead to alkene isomerization, which is minimized in the presence of silver salt.[17] If the addition product does not (or cannot) decompose via elimination, the tandem reaction occurs (Figure 1). Likewise, alkyl halides having hydrogen at the β-position to halide atom are not suitable for the Heck reaction due to the β-hydride elimination.[2u,18] The palladium complex is so efficient in this reaction and with high turnover number that only a small amount of palladium is required to complete the coupling. For active aryl halide (aryl iodide), the concentration of the palladium complex can be down to the ppm level;[19] and in aqueous solution under microwave radiation, the concentration of Pd can be even lowered to 500 ppb.[4b] The ligands suitable for this reaction include triaryl phosphine,[5] *N*,*N*-bis(2,6-diisopropyl-phenyl)dihydroimidazolium,[10e] *N*-acyl-substituted dipyridyl,[20] *N*-acyl-substituted dipyrimidylamines,[21] Pfaltz ligand,[2w,22] and ketopinic acid–based ligands.[2w] In addition, the palladium has been enclosed in silica[10b] or NaY-zeolite[23] as a heterogeneous catalyst or bound to a fluoros tail.[11] Some representative palladium complexes used for the Heck reaction are listed in Figure 2.

On the other hand, it is known that the combination of a phase transfer reagent (e.g., tetraalkylammonium salt) and an insoluble base can accelerate the reaction rate, which lowers the reaction temperature.[24]

Besides the traditional coupling between alkenes and aryl (vinyl) halides, other functionalized aryl derivatives can also couple with alkenes in the Heck reaction, including aryl silanes,[10c,10g,25] stannanes,[26] bismuth,[27] antimony,[28] triflates,[4a,9b,29] boric acid,[30] phosphonic acid,[31] carboxylic acid,[32] and diazonium salt.[33]

Furthermore, the Heck reaction also takes place under some unconventional conditions, such as superheated water (e.g., 260°C),[4e] aqueous solution,[6] ionic liquid,[34] and even without the presence of ligand .[10b,23] On the other hand, some other transition metals also catalyze the Heck reaction, such as cobalt,[18] copper,[34a] and rhodium.[10g]

This reaction has been extensively reviewed.[35]

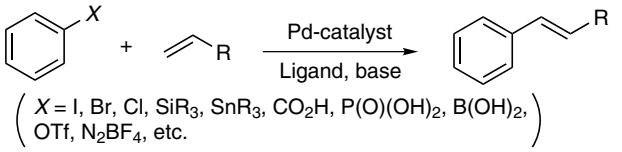
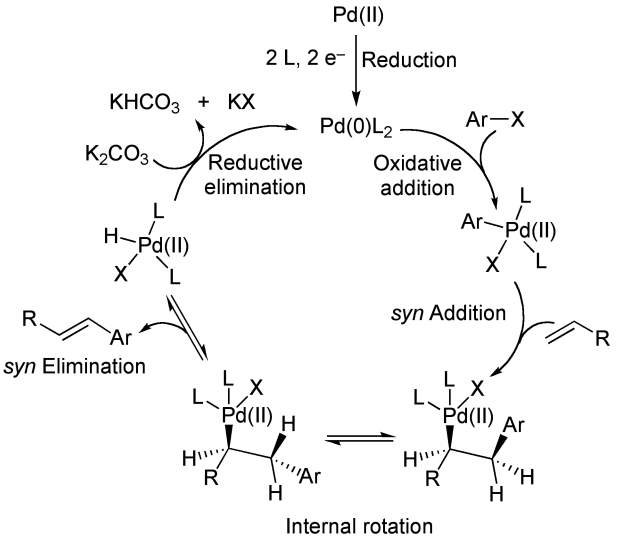
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism of the Heck reaction catalyzed by a neutral palladium complex is illustrated below.



D. MODIFICATION

This reaction has extensively been modified, including the modification of ligands and the substitution of transition metals (Cu, Rh, Co).

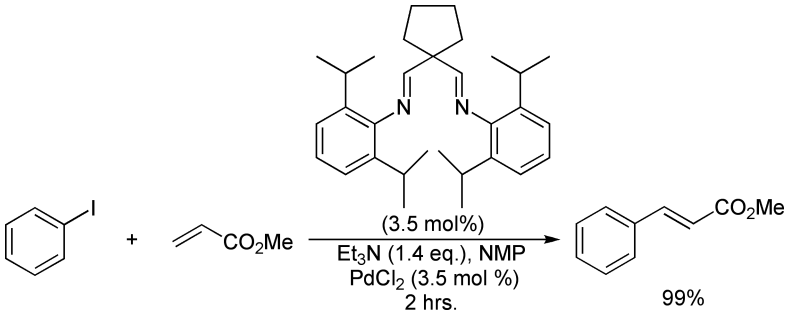
E. APPLICATIONS

This reaction has wide applications in organic synthesis.

F. RELATED REACTIONS

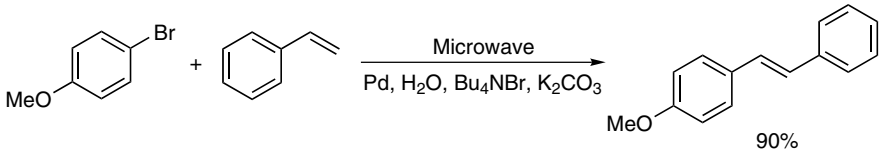
This reaction is related to the *Stille Coupling, Suzuki Coupling, Hiyama Coupling*, and *Sonogashira Coupling*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 38.

Under an atmosphere of argon, a solution of 0.035 mmol $PdCl_2$, 0.035 mmol *N*,*N*′-(1,1-cyclopentylidene-dimethylidyne)bis(2,6-bis-(1-methylethyl)benzenamine) in 3 mL 1-methyl-2-pyrrolidinone was stirred at 140°C for 30 min. Then 1.0 mmol iodobenzene, 1.2 mmol methyl acrylate, and 1.4 mmol Et_3N were added, and the mixture was stirred at 140°C. After completion of coupling (2 h), 10 mL saturated NH_4Cl solution was added, and the mixture was extracted with CH_2Cl_2 (3 ×10 mL). The combined organic layers were washed with 2 M HCl (5 × 10 mL), water (1 × 10 mL), and saturated NaCl solution (2 × 10 mL), dried over Na_2SO_4, and filtered. The solvent was evaporated, and the crude product was purified by flash chromatography to give 99% of methyl 2-*trans*-phenyl acrylate.



Reference 4b.

In a 10-mL glass tube were placed 187 mg 4-bromoanisole (0.125 mL, 1.0 mmol), 208 mg styrene (0.230 mL, 2.0 mmol), 511 mg K_2CO_3 (3.7 mmol), 322 mg tetrabutylammonium bromide (1.0 mmol), 0.4 mL palladium stock solution (a 1000 ppm solution in water), and 1.6 mL water to give a total volume of water to 2 mL and a total palladium concentration of 200 ppm. The vessel was sealed with a septum, shaken and placed into the microwave cavity. Initial microwave irradiation of 70 W was used, the temperature being ramped from room temperature to the desired temperature of 170°C. Once this was reached, the reaction mixture was held at this temperature for 10 min. After allowing the mixture to cool to room temperature, the reaction vessel was opened, and the contents were poured into a separating funnel. Water (30 mL) and 30 mL EtOAc were added, and the organic material was extracted and removed. After further extraction of the aqueous layer with EtOAc, combining the organic washings and drying them over $MgSO_4$, the ethyl acetate was removed in vacuo to give a crude product that was purified via chromatography, in a yield of 90%.

Other references related to the Heck reaction are cited in the literature.[39]

Hegedus Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

The Hegedus indole synthesis,[1] also known as the Hegedus reaction,[1b,1d] Hegedus-Mori-Heck indole synthesis,[1b,2] and Hegedus-Mori-Heck reaction,[1b,3] in general contains at least two types of reactions for indole derivatives. They are the palladium (II) complex–catalyzed oxidative *N*-heterocyclization of *o*-allylaniline (developed in 1976)[4] or *o*-aminostyrenes (reported in 1978)[5] and the palladium-catalyzed intramolecular cyclization of *o*-halo *N*-allylaniline (reported in 1980);[6] the latter preparation is also referred to as the Hegedus cyclization.[7]

A simple procedure for the Hegedus indole synthesis would be as follows: the addition of *o*-allylaniline to the THF solution of $PdCl_2(CH_3CN)_2$ affords a yellow-brown precipitate, which dissolves again on addition of triethylamine; the resulting cherry red solution starts to deposit metallic palladium. After the completion of palladium deposition, the solution is filtered, and the filtrate is concentrated to give 2-methylindole, which may be contaminated with a small amount of $Et_3N{\cdot}HCl$.[4] It is apparent that stoichiometric amounts of palladium dichloride are needed for this reaction,[8] which is reduced to metallic palladium. However, the Hegedus indole synthesis can be performed catalytically in the presence of an oxidant, which can convert Pd(0) to Pd(II). It has been found that benzoquinone is the oxidant of choice to reoxidize Pd(0) to Pd(II),[5] and in some cases, higher yields of indoles are obtained under catalytic conditions than those using a stoichiometric amount of catalyst.[8] In this reaction $Pd(OAc)_2$ and lithium chloropalladate are not effective catalysts.[8]

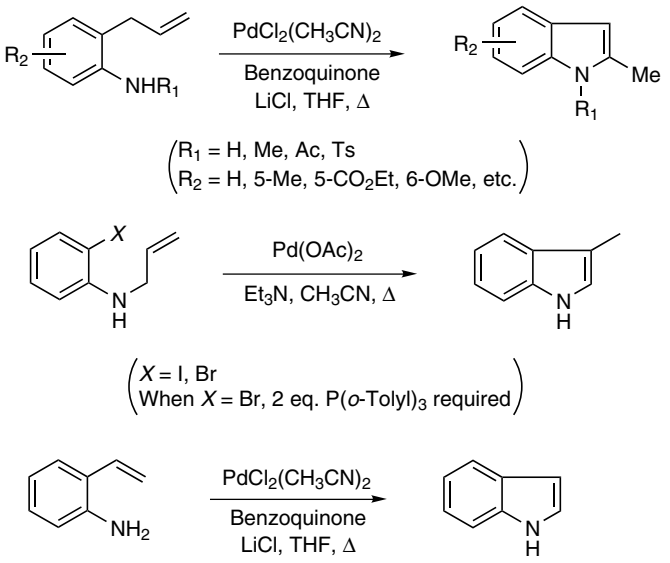
The Hegedus indole synthesis is not only compatible with a wide range of functional groups on the aromatic ring but is also tolerable for the alkyl groups at the 2 or 3 position of the allyl side chain.[4] Other features of this reaction include (*a*) general accessibility for the intramolecular amination of mono-olefin from primary amines and weakly basic

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

amines, such as aniline; (*b*) unnecessary removal of amine to form the olefin-palladium complex; and (*c*) intramolecular amination of cyclohexene and 2-methylbutene moiety.[4] All these reactions are generally unfeasible under other reaction conditions, and the failure for the amination of mono-olefin from primary amines is probably due to the strong linkage between nitrogen and palladium that eliminates the amine as an effective nucleophile.[1c] In addition, the reaction is not restricted to nitrogen nucleophiles; it works for oxygen nucleophiles as well. As an example, treatment of *o*-allylbenzoic acid with $PdCl_2$ and Na_2CO_3 in THF affords 3-methylisocoumarin in good yield.[4] Although *p*-toluenesulfonamides are not considered good nucleophiles, they are effective for the attack on Pd(II)-coordinated olefins. Indeed, the *N*-tosyl *o*-allylanilines cyclize much faster and more efficiently to give *N*-tosylindole derivatives.[9]

On the other hand, for the preparation of an indole from *o*-halo *N*-allylaniline, the iodo aromatics usually give good yields of indole in the presence of $Pd(OAc)_2$ and Et_3N in CH_3CN at 110°C for 72 h. However, due to the deactivation of the palladium catalyst, it is necessary to add fresh catalyst periodically.[6] For instance, during 72 h of reaction, better results are obtained by adding one third of the catalyst each day than the reactions using same amount of catalyst in one portion. However, for the less reactive bromo aromatics, 2 equivalents of tris(*o*-tolyl)phosphine per Pd is necessary for an acceptable yield.[6]

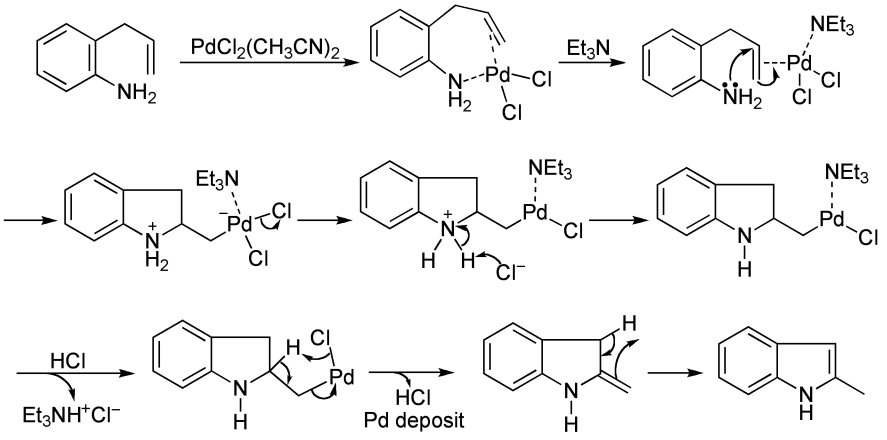
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The formation of indole from *o*-allylaniline with $PdCl_2$ is believed to involve the formation of palladium complex in which both the amino group and the olefinic moiety are

coordinated in a chelating fashion. Subsequently added triethylamine displaces the basic aromatic amine to form another complex in which the aromatic amine obtains a *trans*-geometry required for the amination of coordinated olefin. Attacking the coordinated olefin by the aromatic amines gives a σ-alkylpalladium complex, which upon elimination of HCl and β-elimination of "Pd-H", undergoes the spontaneous rearrangement to 2-methylindole via a [1,3]-H shift.[4,8] An illustrative scheme of the reaction course is provided below.



D. MODIFICATION

This reaction has been extended to form 3-methylindole in higher yields and under milder conditions without using a phosphine ligand.[10] In addition, the cyclization of *o*-halo-*N*-allylanilines has been performed in a homogeneous water/CH_3CN medium in the presence of a water soluble tris(3-sulfonatophenyl)phosphine sodium salt (TPPTS) ligand,[11] and in supercritical CO_2 in the presence of $Pd(OAc)_2$ and a fluorinated phosphine ligand, e.g., phenyl bis(2-perfluorohexyl)-ethylphosphine.[12]

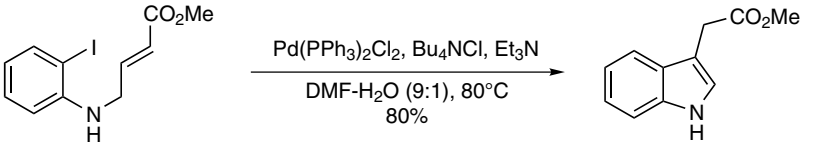
E. APPLICATIONS

The cyclization of *o*-halo *N*-allylaniline has been applied to the preparation of cycloprop[c]indol-5-ones,[7] indole-3-acetic acids and hetero analogs,[13] indole-3-pyruvic acid oxime ether,[14] 5-(sulfamoylmethyl)indoles,[15] the *anti*-migraine agent CP-122,288,[16] and the protected A-unit of CC-1065.[17] In addition, the cyclization of *o*-vinylaniline has been applied to *o*-vinyl-*N*-tosylanilines,[9,18] *o*-vinylacetanilides,[19] and *o*-vinyl-*N*-alkylanilines.[20]

F. RELATED REACTIONS

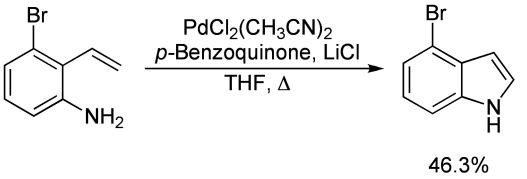
This reaction is related to the *Larock Indole Synthesis*, and mechanistically is relevant to the *Wacker Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 21.

To a 2 mL DMF-H_2O solution (9:1) containing 22 mg 4-[(2-iodophenyl)amino]but-2-enoic acid methyl ester (0.069 mmol), 29 mg tetrabutylammonium chloride (0.10 mmol), and 40 mg triethylamine (0.40 mmol) was added 5.0 mg bis(triphenylphosphine)palladium(II) chloride (0.007 mmol). The resulting mixture was stirred under nitrogen at 80°C for 2 days; the volatiles were then removed under vacuum. The residue was separated by preparative TLC using hexane/EtOAc (2:1) as the eluent to afford 10.5 mg indole-3-acetic acid methyl ester as a colorless viscous solid, in a yield of 80%. (*Note*: The yield has been given as 20% in reaction scheme but 80% in the experimental section.)



Reference 9.

A mixture of 0.606 g crude 3-bromo-2-ethenylaniline (3.06 mmol), 0.496 g *p*-benzoquinone (4.59 mmol), 0.616 g LiCl (15.0 mmol), 39 mg $PdCl_2(CH_3CN)_2$ (0.15 mmol), and 15 mL THF was purged with argon and then heated in a sealed tube at 100°C for 22 h. After cooling to room temperature, the solvent was removed in vacuo. The residue was chromatographed on silica gel by using hexanes as eluent to afford 0.277 g 4-bromoindole as a yellow oil, in a yield of 46.3%.

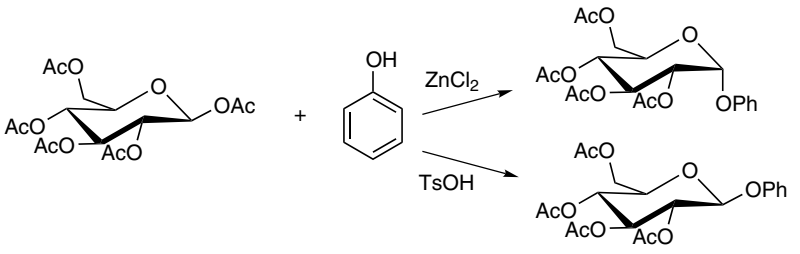
303

Helferich Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Helferich and Schmitz-Hillebrecht in 1933.[1] It is the direct synthesis of acetylated phenyl glycosides from the fusion of monosaccharide pentaacetate and phenol in the presence of an acidic catalyst. Therefore, this reaction is known as the Helferich condensation,[2] Helferich and Schmitz-Hillebrecht fusion,[3] or Helferich and Schmitz-Hillebrecht synthesis.[4] In the presence of fused $ZnCl_2$, the α-anomer is produced from the condensation, whereas in the presence of *p*-toluenesulfuric acid, the β-anomer is formed.[1] This reaction has been improved by carrying out the condensation under vacuum where released acetic acid is removed immediately from the reaction system;[5] however, in the presence of acetic acid and acetic anhydride, even higher yields are obtainable compared to the original procedure.[6] It should be pointed out that this reaction is not suitable for the less common or harder to obtain phenols, such as tetrahydrocannabinol; in such cases, a high yield of glycosylation occurs in benzene solution in the presence of moist phosphorus oxychloride.[7]

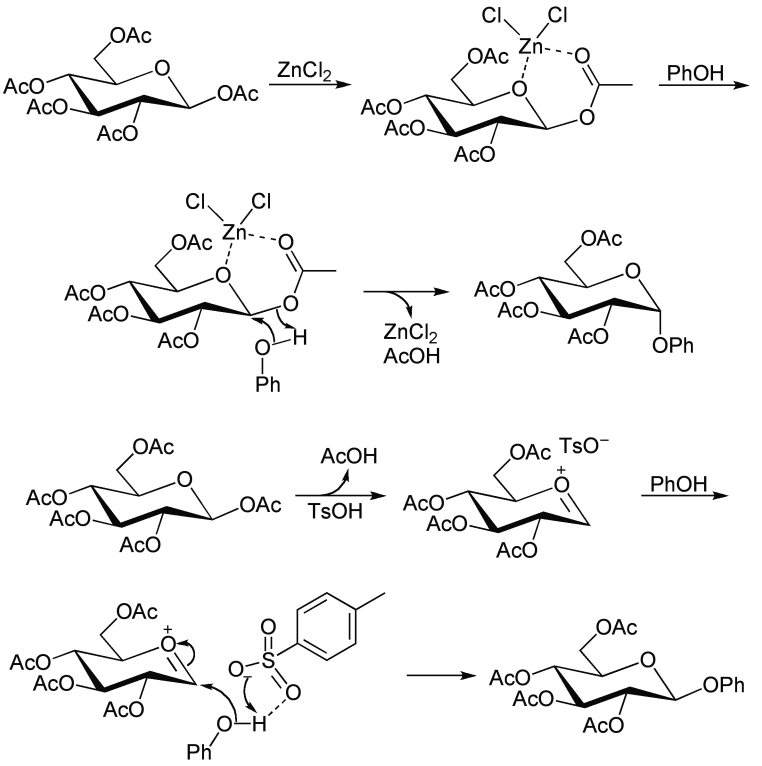
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Although no mechanistic study is reported about this reaction, it is possible that $ZnCl_2$ chelates with the oxygen from the carbohydrate ring and 1-acetyl group, favoring the attack of phenol from the bottom of the carbohydrate ring and resulting in a phenyl α-glycoside. In the presence of TsOH, the 1-acetyl group directly evolves from the ring, giving a cation associated with tosylate. When coupling with phenol, the hydrogen bond between the phenol and the sulfonic group favors the geometry to give phenol β-glycoside. The said mechanism is illustrated here.



D. MODIFICATION

This reaction has been modified to take place under vacuum to remove acetic acid,[5] or in the presence of acetic acid and acetic anhydride.[6] Furthermore, phosphorus oxychloride is used to condense the carbohydrate with difficultly attainable phenols.[7]

E. APPLICATIONS

This reaction has been used to prepare aryl glycosides.

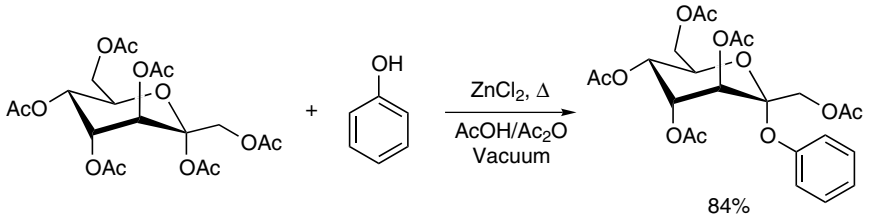
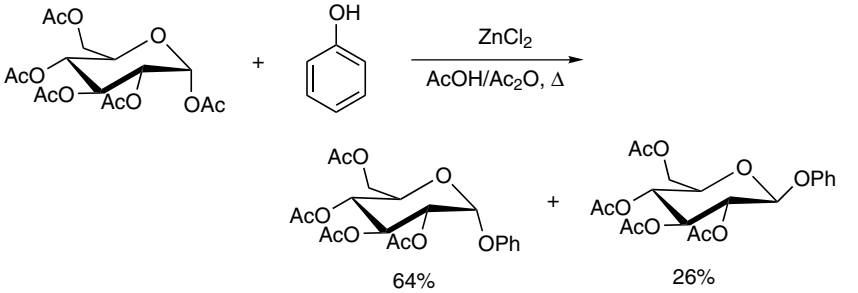
G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

A mixture of 4.0 g sedoheptulose hexaacetate, 8.0 g phenol, 2.0 g fused zinc chloride, 7.2 mL acetic acid, and 0.8 mL acetic anhydride was warmed until homogeneous and then heated in vacuo (water pump) for 2 h at 75–80°C. The residue was dissolved in 125 mL $CHCl_3$, and the extract was washed with water, twice with 3% aqueous NaOH and water. The washed extract was dried over Na_2SO_4, filtered through decolorizing carbon, and concentrated in a current of air. The crystalline residue was filtered and washed with pentane to yield 3.6 g phenyl α-D-altro-heptulopyranoside pentaacetate, in a yield of 84%. After two recrystallizations from aqueous acetone, the clusters of prismatic needles melted at 148–150°C.



Reference 6.

To a melt mass in a Claisen distilling flask from 25 g α-pentaacetylglucose (0.064 mol) and 24 g phenol (0.255 mol) was added 6.3 g fused $ZnCl_2$ dissolved in 20 mL of a 95:5 $AcOH/Ac_2O$ mixture. This homogeneous reaction mixture was heated in a bath at 120–125°C for 2 h. The acetic acid formed in the reaction, as well as that added with the zinc chloride, was removed by evacuating the flask with a water pump during the heating. The resulting red syrup was dissolved in 300 mL ethylene dichloride, and the zinc chloride and phenol were removed by washing with water and aqueous sodium hydroxide, respectively. The solution was dried with granular calcium chloride, concentrated in vacuo, and the product crystallized at 0°C from 150 mL ethanol. A dense mass of isomeric acetates was obtained, with a total yield of 92%. Separation of the α-form was effected

by allowing this mixture to crystallize slowly from 350 mL ethanol. After four recrystallizations, pure crystalline tetraacetyl-α-phenyl-D-glucoside, was isolated as shining needles with a total yield of 64%, m.p. 115°C. From the mother liquor was obtained the anomeric tetraacetyl-β-phenyl-D-glucoside in a yield of 26%.

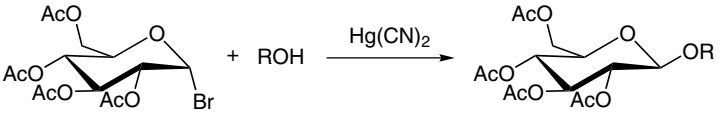
304

Helferich Glycosylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Helferich and Weiss in 1956.[1] It is the synthesis of *O*-glycosides from protected glycosyl bromide and alcohol (or another carbohydrate) in the presence of mercuric cyanide. Therefore, it is generally known as the Helferich glycosylation.[2] Occasionally, it is also referred to as the Helferich condition.[3] This reaction is especially suitable for the glycosylation of hindered secondary alcohols of allocyathin.[4] According to the anomeric effect, glycosyl bromide is primarily an α-anomer, so that the resulting glycoside is a β-glycoside[2a,2b,4b] via a S_N2 mechanism.

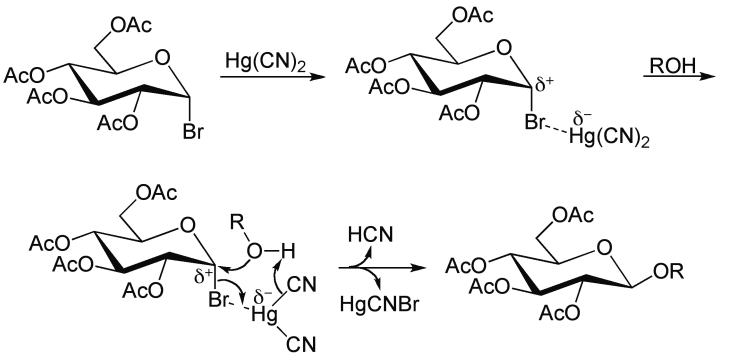
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Part of the mechanism is illustrated here, in which mercuric cyanide coordinates with a bromine atom from glycosyl bromide and polarizes the carbon-bromide bond, then S_N2 substitution occurs leading to the formation of β-glycoside and releasing HgCNBr, which might enter the glycosylation again.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

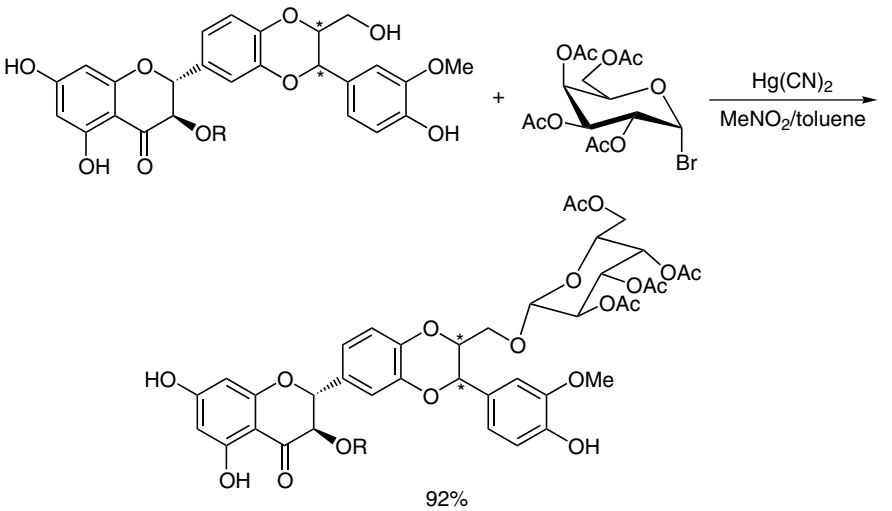
E. APPLICATIONS

This reaction has general application in the formation of glycosides.

F. RELATED REACTIONS

This reaction is related to the *Koenigs-Knorr Glycosylation*.

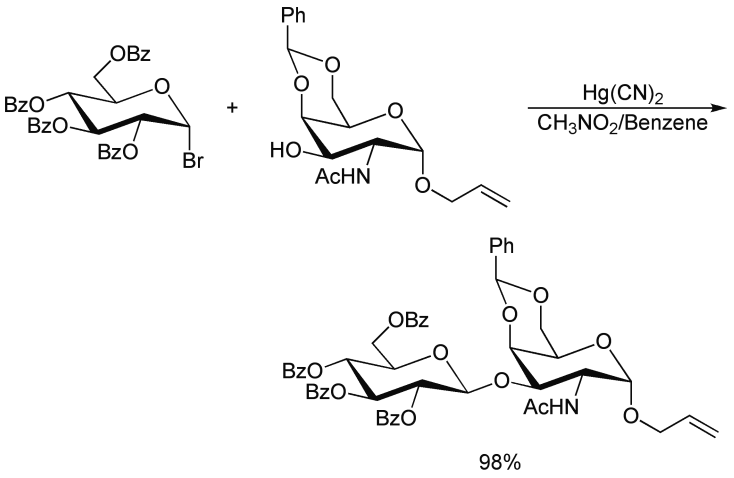
G. CITED EXPERIMENTAL EXAMPLES



92%

Reference 2d.

Silybin, dried by azeotropic distillation with toluene to remove crystal-bound water, (5.3 g, 11.0 mmol) was dissolved in a total of 450 mL mixed solvent of nitromethane and toluene (v/v = 14 : 11), from which 10–20 mL was distilled off using the Distler apparatus to remove traces of water. The mixture was stirred at 60°C under nitrogen and 2.8 g $Hg(CN)_2$ (11.0 mmol) was added. When all catalyst was dissolved, a solution of 5.2 g 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide (12.5 mmol) in a minimal amount of the solvent mixture was added, and stirring the mixture at 60°C was continued for 20 h. Then 2.1 g tetraacetyl-α-bromo-galactose (5 mmol) and 0.76 g $Hg(CN)_2$ (3 mmol) were added. The addition of 1.0 g carbohydrate and 0.25 g $Hg(CN)_2$ was repeated after another 20 h and the reaction was terminated after a total of 50 h. The mixture was evaporated to one fifth its original volume and cooled, and the bulk of precipitated $Hg(CN)_2$ was filtered off. The rest of the mercury was removed by extraction with 3% aqueous KI (3 × 100 mL). The organic phase was dried over Na_2SO_4. The crude mixture of per-acetylated silybin glycosides was separated from any unchanged silybin and glycosyl donor by flash chromatography on silica gel (toluene/dichloromethane/MeOH, 1:10:0.8). Final purification and separation of the per-acetylglycosides of two silybin diastereoisomers was achieved by medium-pressure liquid chromatography on a prepacked Lobar column (silica gel, size C) by the solvent mixture of toluene/HCO_2H/AcOH (40:0.7:0.7; 9.9 mL/min) with a linear acetone gradient of 12–20% (v/v). Before evaporation, pooled fractions were neutralized by successive washings with water, saturated aqueous $NaHCO_3$, and brine. The yield of crude silybin 23-*O*-β-D-2,3,4,6-tetraacetylgalactopyranoside was 8.3 g (92%).



Reference 2b.

A solution of 1.67 g allyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside (4.78 mmol) in 60 mL nitromethane/benzene mixture (v/v = 1:1) was stirred for a couple of hours at room temperature. To ensure dryness, the solution was concentrated under reduced pressure. This process was repeated three times by adding the same volume of solvent and then concentrated until one half the volume remained. The temperature was adjusted to 25°C and 4.70 g 2,3,4,6-tetra-*O*-benzoyl-α-D-galactopyranosyl bromide (7.13 mmol) and 1.80 g $Hg(CN)_2$ (7.13 mmol) were added successively at N_2

atmosphere. The resulting solution was stirred at room temperature for 18 h. The solvent was removed under vacuum. The residue was dissolved in 40 mL $CHCl_3$ and then filtered through a Celite pad. The filtrate was successively washed with 10% aqueous KI, saturated $NaHCO_3$, and distilled water, and then was dried over Na_2SO_4. After concentration, the residue was purified by silica gel column chromatography (benzene/EtOAc = 15:1) to give 4.31 g allyl (2,3,4,6-tetra-*O*-benzoyl-β-D-galactopyranosyl)-(1$\rightarrow$3)-2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside as a white foamy solid, in a yield of 98%, m.p. 109.7–111.0°C, $R_f = 0.59$ (benzene/EtOAc,1:2).

Other references related to the Helferich glycosylation are cited in the literature.[5]

Hell-Volhard-Zelinsky Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hell in 1881[1] and subsequently extended by Volhard[2] and Zelinsky[3] in 1887. It is the synthesis of α-bromocarboxylic acid by treatment of aliphatic acid containing at least one α-hydrogen with bromine in the presence of a catalytic amount of phosphorus or phosphorus tribromide. Therefore, this reaction is generally known as the Hell-Volhard-Zelinsky reaction[4] or simply referred to as the Zelinsky reaction.[5] Even though the same procedure can be applied to the chlorination of carboxylic acid[6]—the reaction known as the Hell-Volhard-Zelinsky chlorination[7]—appreciable amounts of carboxylic acids with chlorine atom at various positions rather than the α-position are also produced.[8] Therefore, the Hell-Volhard-Zelinsky reaction is primarily good for the bromination, that occurs smoothly even for the carboxylic acid with an alkyl substituent at the α-position;[9] in addition, phosphorous trichloride and thionyl chloride have also been used to catalyze the bromination of aliphatic acid.[10] However, it should be pointed out that thionyl chloride is usually used to convert carboxylic acid into acyl chloride, so the formation of acyl chloride can be combined with the bromination by performing the bromination in thionyl chloride.[11] Although a few mechanisms have been proposed for this bromination, the majority of experimental evidence supports the formation of an enol[8,12] instead of a ketene[6,7] intermediate, which is analogous to the acid-catalyzed halogenation of ketones.[12a] It is interesting that the bromination of levulinic acid with one equivalent of bromine in the presence of 1.6 mol% phosphorus gives rise to 3,5-dibromolevulinic acid as the major product.[13] This reaction is synthetically useful because the α-halogen can easily be replaced by other functional groups, such as CN, and the resulting α-cyano carboxylic acid yields malonic ester in the presence of aqueous acid and ethanol.

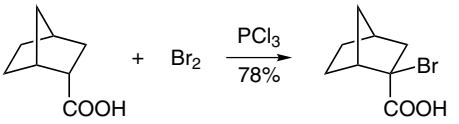
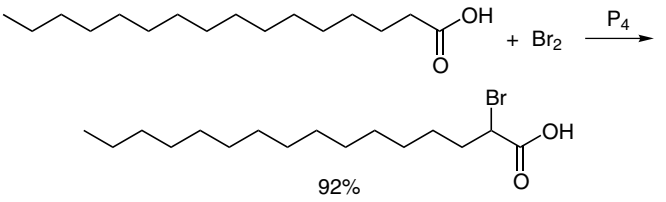
G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

A mixture of 49.2 g norbornane-2-endocarboxylic acid (0.35 mol), 63.8 g bromine (0.4 mol), and 1.5 mL phosphorus trichloride was heated on a steam bath at 80–90°C for 7.5 h. After being cooled, the mixture was taken up in Et_2O. The ether solution was washed with $NaHSO_3$ and then several times with water, and finally dried over $MgSO_4$. Upon removal of solvent, 60.4 g α-bromo-norbornane-2-endocarboxylic acid was obtained as a yellow crystalline solid, in a yield of 78%. The solid, after being washed with petroleum ether and decolorized with Norite, recrystallized from benzene or nitroethane with a melting point of 151°C.



Reference 15.

To a 1-L three-necked flask equipped with a stirrer, dropping funnel, and condenser protected with a calcium chloride tube were added 100 g palmitic acid (0.39 mol) and 5.0 g red phosphorus. The acid was melted on a water bath at 70°C, and 50 mL dry bromine (0.975 mol) was dropped in over 8 h with continuous stirring, then heated and stirred for an additional 4 h, at which time the evolution of HBr ceased. The clear, dark red reaction mixture was heated on a boiling water bath for 30 min until all the excess bromine had been removed, giving a clear straw-colored oil. Then the hot product was poured into 2 L water and allowed to stand overnight. The hydrolyzed acid was washed several times with water, and finally was heated in water with stirring. The cooled gel was taken up in 500 mL ether. The ether solution was washed until the washings were neutral to litmus and was dried over Na_2SO_4. Upon removal of ether, 121.0 g α-bromo palmitic acid was obtained, in a yield of 92%. After recrystallization from petroleum ether with Norite and finally from ethanol, the product had a melting point of 52.3–52.5°C.

Hemetsberger Indole Synthesis

(Hemetsberger Reaction, Hemetsberger-Knittel Indole Synthesis)

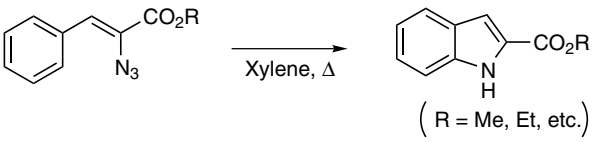
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hemetsberger and Knittel et al in 1969.[1] It is the synthesis of indole-2-carboxylic esters via the thermal decomposition of 3-aryl-2-azidopropenoic esters. Although this reaction has not been explored extensively due to the instability and difficult accessibility of the starting material, it has been given a variety of names, including the Hemetsberger azide pyrolysis,[2] Hemetsberger cyclization,[3] Hemetsberger reaction,[2–4] Hemetsberger rearrangement,[5] Hemetsberger-Rees styryl azide thermolysis,[6] Hemetsberger indole synthesis,[7] Hemetsberger-Knittel indole synthesis,[8] Hemetsberger-Knittel reaction,[9] and Hemetsberger synthesis.[7c,10]

In this reaction, the starting materials are usually prepared by the *Claisen-Schmidt Condensation*[11] between aromatic aldehydes and methyl azidoacetate; for example, upon treatment with 4 eq. ethyl azidoacetate and sodium methoxide in methanol, the corresponding azidocinnamic ester was prepared from 2-*O*-(1′-methyl)hexyl-5-bromo 2-hydroxylbenzaldehyde.[3] On the other hand, the thermal decomposition is usually carried out in refluxing xylene,[3,4a,4c,4d,7a] yielding indole derivatives of highly regiospecificity.[4d]

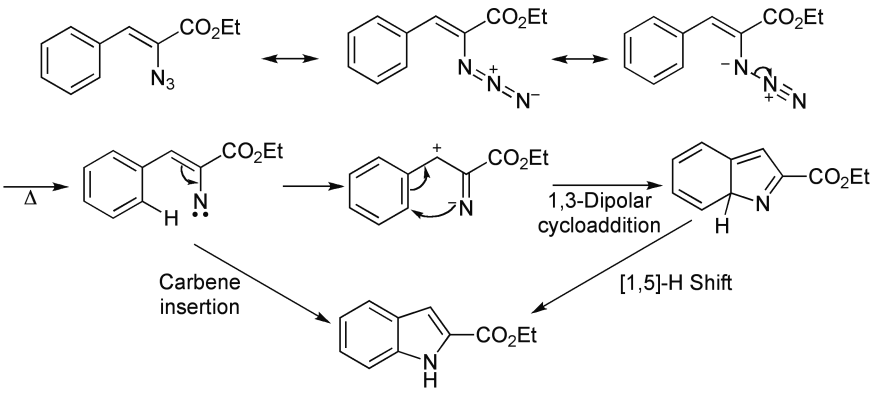
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Although the mechanism of Hemetsberger indole synthesis is not quite clear, the reaction is postulated to proceed via a highly electrophilic singlet nitrene species,[11] which then inserts into an aromatic ring to form the indole derivatives. In addition, 2H-azirines are also proposed as the intermediates for this reaction,[7b] arising from the insertion of nitrene to the adjacent double bond. A tentative mechanism is given below.



D. MODIFICATION

This reaction has been extended to the synthesis of thiophene[4b] and pyridine[7a] fused pyrrole derivatives.

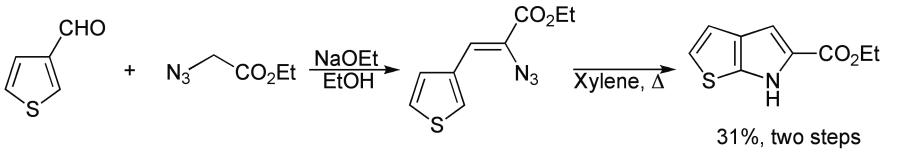
E. APPLICATIONS

This reaction has been successfully used for the synthesis of a number of indole alkaloids.[3,9b,12]

F. RELATED REACTIONS

N/A

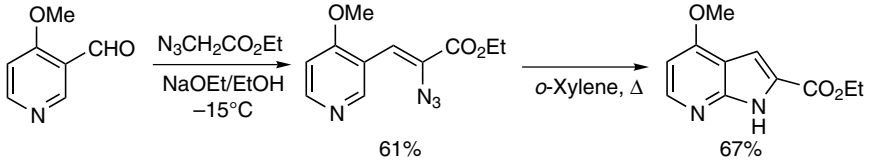
G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

To a 0.15 M NaOEt (4 eq.) solution in ethanol at 0°C was added dropwise a solution of 1 eq. 3-formylthiophene and 4 eq. ethyl azidoacetate. The resulting mixture was stirred at 0°C for 1 h and at room temperature for an additional 1 h; then it was poured into a saturated NH_4Cl solution. The product was extracted with ether, and the combined organic layers were dried over Na_2SO_4 and concentrated in vacuo. The residue was purified by silica gel column chromatography to provide ethyl α-azido-β-(3-thiophenyl) acrylate.

A 100-mL toluene solution of acrylate (0.2 M, 20 mmol) was heated at 145°C for 60 min and then cooled to room temperature. After evaporation of the solvent, the residue was purified by column chromatography to afford 1.2 g 6*H*-thieno[2,3-b]pyrrole-5-carboxylic acid ethyl ester as a white solid, in a yield of 31% for two steps, $R_f = 0.5$ (EtOAc/hexanes, 1:4).



Reference 7a.

A mixture of 4.15 g ethyl azidoacetate (32 mmol) and 1.1 g 3-formyl-4-methoxypyridine (8.02 mmol) in 50 mL anhydrous EtOH was added dropwise under nitrogen at –15°C to a 30 mL well-stirred solution containing 0.74 g Na (32.1 mmol). The mixture was stirred at –15°C for 72 h and poured into 50 mL 30% NH_4Cl aqueous solution. The separated solid was washed with H_2O, air-dried, and recrystallized from EtOAc/*n*-hexane (1:1) to give 1.21 g ethyl α-azido-β-(4-methoxypyrid-3-yl)-acrylate as colorless needles, in a yield of 61%, m.p. 106–108°C.

A stirred solution of 1.0 g ethyl α-azido-β-(4-methoxypyrid-3-yl)-acrylate (4.03 mmol) in 140 mL dry *o*-xylene was heated in a molten salts bath at 170°C for 25 min. After being cooled at −10°C, the precipitated white solid was collected by filtration, washed with Et_2O, and recrystallized from CH_2Cl_2 to give 0.59 g 2-ethoxycarbonyl-4-methoxypyrrolo-[2,3-b]pyridine as white needles, in a yield of 67%, m.p. 216–217°C.

Henkel Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Raecke from Henkel et Cie in 1952.[1] It is a thermal rearrangement or disproportionation of alkaline salts of aromatic acids to symmetrical diacids in the presence of a metallic salt and carbon dioxide. Therefore, it is generally known as the Henkel reaction.[2] Occasionally, it is also referred to as the Raecke process[2j] or Henkel process.[2b,2i,3] For this reaction, the alkaline salts of benzoic acids, including potassium, rubidium, and cesium benzoates, give satisfactory yields,[2i,2j] whereas sodium benzoate and lithium benzoate react at even higher temperatures and give much lower yields.[2b,2j] It should be pointed out that the disproportionated symmetrical diacids are the major products but not the sole products in this reaction; other possible products from the Henkel reaction of potassium benzoate include diphenylmethane, benzophenone, triphenylmethane, and 9-phenylfluorene.[2a] Although the alkaline earth metal salts of benzoic acid also pyrolyze at high temperatures, they might give different products. For example, the pyrolysis of calcium benzoate proceeds via an anionic mechanism to form benzene and benzophenone as the major products without formation of any calcium phthalate; in addition, even the formation of diphenylmethane, benzophenone, etc. was slowed down considerably.[2a] It has been reported that this reaction can be catalyzed by a cadmium[2a,2j] or zinc salt.[4] Under the high pressure of carbon dioxide, the yield is improved; in contrast, lowering the pressure of CO_2 or under high pressures of nitrogen, the yield is lowered as well.[2b] In addition, other gas components such as hydrogen, water, and oxygen are toxic to this reaction.[2j] The alkaline salt of other aromatic acids, besides benzoic acid, disproportionate similarly, as shown by the ZnI_2-catalyzed transformation of disodium naphthalenedicarboxylate to 2,3,6,7-naphthalenetetracarboxylic acid (NTC) dianhydride.[4]

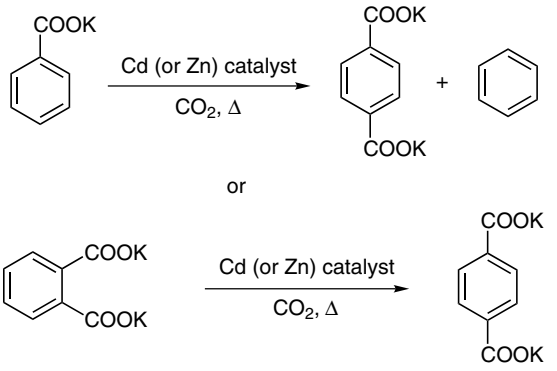
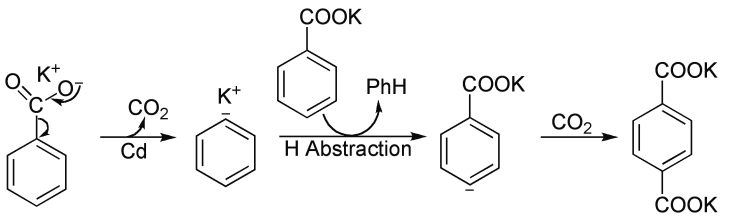
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A simple mechanism is proposed here for the disproportionation of potassium benzoate in the presence of cadmium catalyst.



D. MODIFICATION

N/A

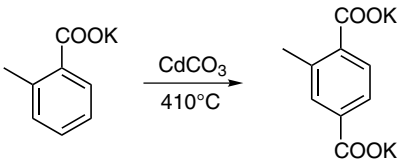
E. APPLICATIONS

This reaction has been used in the production of terephthalic acid at an industrial scale.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3d.

A mixture of 3.0 g finely powdered potassium *o*-toluate and 0.24 g cadmium carbonate in a test tube with a rubber stopper fitted with a constricted glass tube was heated for 1.5 h at 410°C in a metal bath. While heating, continuous evolution of toluene was observed. The toluene was collected by cooling and confirmed as 2,4-dinitrotoluene, m.p. 69.7°C. The solid product was dissolved in boiling water. Colloidal black material was removed by filtration with the aid of zinc sulfate, the filtrate being acidified with hydrochloric acid and then extracted with ether. After evaporation of ether, white solid was obtained. The petroleum ether–soluble portion of this material consisted of pure starting material, whereas the 0.13 g insoluble portion was shown to be 2-methylterephthalic acid by converting it into the dimethyl ester, m.p. 75.5°C. Better yields were obtained by using cadmium iodide rather than cadmium carbonate. (*Note*: I do not understand how 2,4-dinitrotoluene is formed in this reaction).

Other references related to the Henkel reaction are cited in the literature.[5]

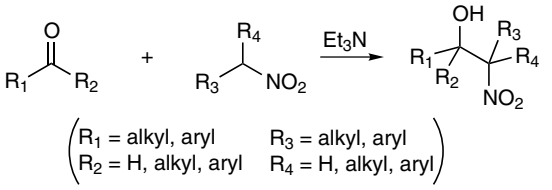
Henry Reaction

A. GENERAL DESCRIPTION OF THE REACTION

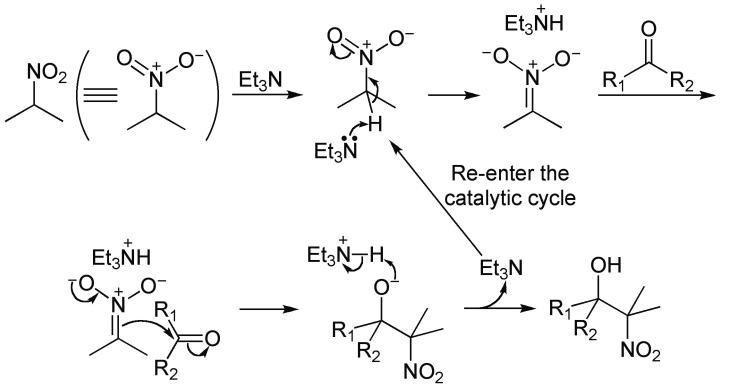
This reaction was initially reported by Henry in 1895.[1] It is the base-catalyzed condensation between a carbonyl compound (aldehyde or ketone) and a nitroalkane having at least one α-hydrogen atom to yield 1,2-nitroalcohol. This reaction, though commonly known as the Henry reaction,[2] is also referred to as the nitroaldol reaction.[2bb,2ff,3] Analogously, the condensation between nitroalkane and imine is known as the *aza*-Henry reaction[2cc,4] or nitro-Mannich reaction.[2cc] The resulting 1,2-nitroalcohol may further undergo reactions such as oxidation, reduction, and elimination.[2bb] During the condensation with aldehyde, the Henry reaction is also complicated with the *Cannizarro Reaction*,[2ff] though it can be suppressed under special conditions;[5] in addition, the condensation with aromatic aldehyde is often accompanied by dehydration to form nitroalkene.[2ff] Similar to the regular *Aldol Reaction*, the Henry reaction is also reversible[2x] and is an equilibrium-controlled reaction.[6] The most attractive feature of the Henry reaction is its potential for the control of stereochemistry, depending on the catalyst and solvent systems.[2x] Due to the strong electron-withdrawing ability of the nitro group, the α-hydrogen can easily be deprotonated, even in the presence of a weak base, so that Et_3N is often used for this purpose.[2bb] In addition, polymer-supported amines, such as KG-60-NEt_2 are also applied as catalysts.[2z] Other catalysts for this reaction include copper(II)-(*S*)-*tert*-butyl bisoxazoline,[2bb] chiral heterobimetallic catalyst,[3m] and ketoiminatocobalt complexes,[2y] which lead to asymmetric Henry reaction products. It is interesting that the electron-deficient aromatic aldehydes, but not the aliphatic aldehydes, undergo the Henry reaction in the presence of an acidic catalyst—such as $TiCl_3$(O-i-Pr)—at room temperature, leading to 2-nitro alcohols enriched in the *erythro* diastereoisomer.[7]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been improved to produce asymmetric 1,2-nitro alcohols.[2y,2z,3m]

E. APPLICATIONS

This reaction has wide application in organic synthesis, such as in the preparation of 1,2-nitro alcohol and 1,2-amino alcohol.

F. RELATED REACTIONS

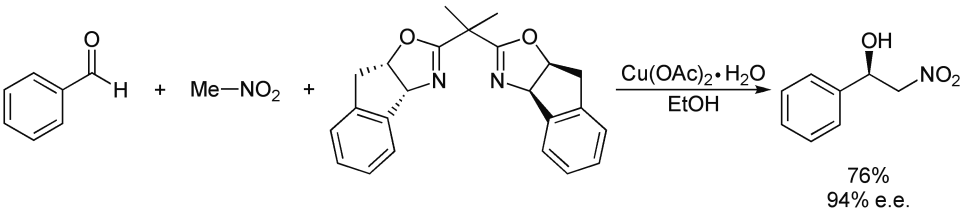
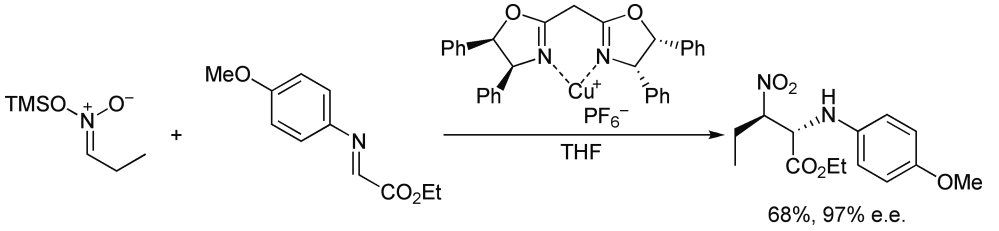
G. CITED EXPERIMENTAL EXAMPLES



Reference 3x.

To a screw-capped vial containing a stir bar were added 19.7 mg indabox ligand (0.055 mmol), 10.0 mg $Cu(OAc)_2 \cdot H_2O$ (0.05 mmol), and 1.5 mL ethanol; the mixture was stirred for 1 h. To the resulting clear blue solution were added 0.54 mL nitromethane (10 mmol) and 0.106 g benzaldehyde (1 mmol). After being stirred for 22 h, the volatile components were removed under reduced pressure, and the crude product was purified by column chromatography (10% Et_2O/CH_2Cl_2) to give 76% of product as a colorless oil, with 94% e.e.



Reference 2cc.

To a THF solution containing the shown catalyst was added 39.0 mg ethyl α-(4-methoxyphenyl)iminoacetate (0.2 mmol); the solution was cooled to -100°C using an ether/liquid N_2 cooling bath. A solution of 42.0 mg trimethylsilyl propanenitronate (0.3 mmol) in 1.0 mL THF was added over 1 h using a syringe pump. The reaction was left to warm to -20°C overnight and quenched with 0.5 mL ethanol. The crude material was purified by flash chromatography using CH_2Cl_2/pentane (1:1) as the eluent, giving 68% ethyl (2R,3R)-2-(4-methoxyphenyl)amino-3-nitropentanoate, with a diastereomeric ratio of 10:1, and 97% *e.e.* of *erythro* isomer and 88% *e.e.* of *threo* isomer.

Herbst-Engel Transamination

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Herbst and Engel in 1934.[1] It is the transfer of an amino group from an α-amino acid to an α-keto acid to form a new α-amino acid. The amino acids without α-hydrogen, such as α-aminoisobutyric acid, are inactive for this reaction.[2] It is believed that this reaction involves a few steps, including the formation of imino group between an amino and a carbonyl group, hydrogen transfer to the α-carbon of the ketonic acid moiety accompanied with the elimination of carbon dioxide, and the addition of water (hydrolysis) resulting in fission along with the formation of an aldehyde and the new α-amino acid.[3] It was found that the substituent on both α-amino acids and α-keto acids affect the extent of decarboxylation[3b] and that carbon dioxide evolution is much faster for transamination with arylaminoacetic acid than that with aliphatic amino acids.[3a] In addition, the evolution of carbon dioxide is even more rapid with arylaminoacetic acid with an *ortho*-substituent than that with a *para*-substituent, and the one with the electron-withdrawing group is faster than the one with the electron-donating group.[3a] A reaction similar to this transamination but catalyzed by enzymes under physiological conditions is also known,[4] which is an important process in amino acid metabolism.[2] However, no decarboxylation occurs for the enzyme-catalyzed reaction.[2,5] It has been reported that the transamination between α-amino acid and glyoxylate to form glycine and the corresponding keto acid without decarboxylation completes in about 10 min when the reaction is catalyzed by copper or iron salts.[6]

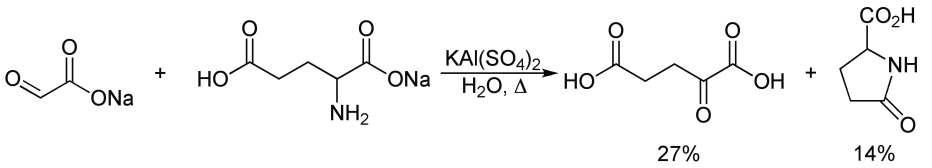
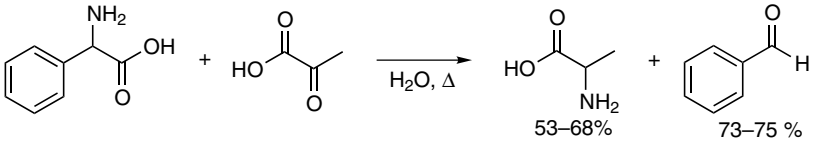
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A mixture of 0.025 mol sodium glyoxylate, 0.025 mol glutamic acid, and 0.0025 mol potassium aluminum sulfate was dissolved in 500 mL water, and the pH was adjusted to 5.0 with NaOH. The solution was heated in a boiling water bath to 100°C, held 10 min, and cooled. The pH was adjusted to 1.0 with H_2SO_4, and the solution was subjected to continuous ether extraction. The ether extract was evaporated in vacuo, the residue was taken up in boiling nitromethane, cooled, and held overnight in the refrigerator. A first crop of 0.52 g α-pyrrolidonecarboxylic acid was separated. Concentration of the mother liquors in vacuum and cooling yielded 1.01 g α-ketoglutaric acid, in a yield of 27%, m.p. 110–111°C (corr.)



Reference 7.

A mixture of 4.53 g α-aminophenylacetic acid (0.03 mol), 7.9 g pyruvic acid (0.09 mol), and 200 mL water (3.5% deuterium) was boiled under reflux for 3 h. A homogeneous solution was formed within a few minutes after the mixture began to boil. On completion of the reaction, benzaldehyde was removed by distillation through a declining condenser and extracted from the distillate with several small portions of chloroform. The aqueous portion of the distillate and the aqueous reaction mixture were reserved. After drying the chloroform solution over sodium sulfate, the solvent was evaporated and the residual benzaldehyde was converted into the phenylhydrazone by treatment with phenylhydrazine in 50% alcoholic solution. After recrystallization from 60% alcohol, the yield of benzaldehyde phenylhydrazone was 4.3–4.4 g, m.p. 155.5–157°C for various preparations.

After being thoroughly chilled, the aqueous reaction mixture was filtered to remove a trace amount of α-aminophenylacetic acid, which had separated. The filter was washed with the aqueous distillate from the benzaldehyde fraction. The entire filtrate was evaporated to a thick, syrupy consistency on the water bath under reduced pressure, care being taken to recover the aqueous distillate as completely as possible. The residual syrup was taken up in 100 mL ordinary water, and the evaporation was repeated. A second similar treatment with 100 mL water sufficed to easily remove the exchangeable deuterium completely. The residual syrup was then taken up in 10 mL hot 95% alcohol and transferred to a small Erlenmeyer flask; the distilling flask was rinsed with four 5-mL portions of hot 95% alcohol. Alanine crystallized spontaneously from the alcoholic solution on cooling; complete separation was ensured by the addition of 5 mL pyridine to the cold solution. After thorough chilling in the

refrigerator, the alanine was filtered by suction, washed thoroughly with cold 95% alcohol, and dried in a vacuum desiccator. The yield of crude alanine varied from 1.4 g to 1.8 g in different experiments.

310

Heron Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Glover at the Second Heron Island Conference on Reactive Intermediates and Unusual Molecules, Heron Island, Australia in 1994,[1] thus it was called the HERON rearrangement,[2] or HERON reaction.[1,3] HERON is an acronym for heteroatom rearrangements on nitrogen.[4] It is the rearrangement of amides, with two heteroatoms (e.g., oxygen) substituted at nitrogen (RC(O)NXY), to esters and 1,1-diazenes via the migration of oxygen from the nitrogen to the carbonyl carbon.[4] Amides of the type that can undergo such rearrangement are collectively called HERON amides.[4] In this rearrangement, a heteroatom (X) bearing a high-energy pair of electrons (i.e., oxygen) initiates rearrangement from nitrogen to carbon through a strong anomeric overlap with the σ^* orbial of the adjacent N-heteroatom bond (N-Y), and the so-called anomeric interactions at nitrogen are enhanced when the second heteroatom (Y) is strongly electronegative.[5] Analogues of N,N'-diacyl-N,N'-dialkoxyhydrazines thermally decompose to esters and nitrogen through two consecutive rearrangements.[6]

To a solution of 58 mg *N*-*tert*-butoxy-*N*-chlorobenzamide (0.0255 mmol) in 5 mL CH_3CN was added a solution of 0.20 g sodium azide (3.08 mmol) in 20 mL CH_3CN/H_2O (1:1). A pale pink color was formed immediately. The reaction mixture was stirred at room temperature for 2 h, during which time 9.7 mL nitrogen was collected (85%). The reaction solution was extracted with 50 mL CH_2Cl_2, and the solution was dried and concentrated to give 40 mg *tert*-butyl benzoate as a yellow oil, in a yield of 87%.

Other references related to the HERON rearrangement are cited in the literature.[7]

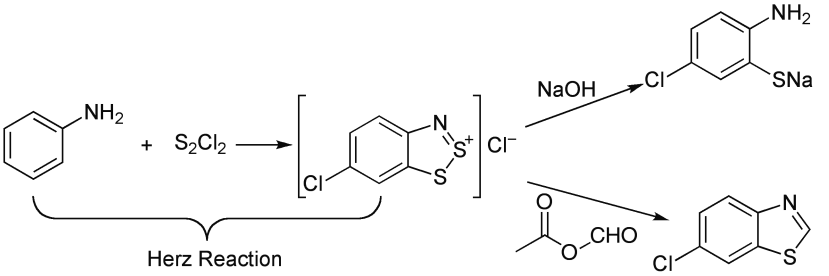
Herz Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Herz in 1914.[1] It is the reaction between primary aromatic amines, their salts, or *N*-acetyl derivatives with sulfur monochloride either in the presence or absence of an inert solvent (such as benzene, nitrobenzene, or acetic acid) to form 1,3,2-benzothiazathiolium chlorides,[2] known as the Herz compounds[3] or Herz salts.[3,4] Therefore, this reaction is generally referred to as the Herz reaction.[5] In addition, the terms Herz process[2] and Herz condensation[2] are also used for this reaction. The Herz compounds decompose on heating and are difficult to purify,[3] so that they are normally converted into other derivatives. For example, hydrolysis of these compounds results in 1,2,3-benzodithiazole 2-oxide,[3] whereas basic hydrolysis of these compounds by NaOH results in *o*-amino thiophenol,[2] and treatment of these compounds with acetic-formic anhydride leads to the synthesis of substituted benzothiozoles.[2] Furthermore, treatment of Herz compounds with chloroacetic acid leads to *o*-aminophenylthioglycolic acid derivatives, the intermediates used to produce thioindigo dyestuffs in industry.[6] It has been observed that this reaction is always accompanied with the chlorination on aromatic nucleus, primarily at the *para*-position of the amino group,[2,3,7] even the *para*-position is replaced by an NO_2, CO_2H, or SO_2 group.[2] For example, both *o*-nitroaniline and *o*-chloroaniline afforded only 4,6-dichlorobenzothiazole when their corresponding crude Herz compounds were treated with acetic-formic anhydride.[2]

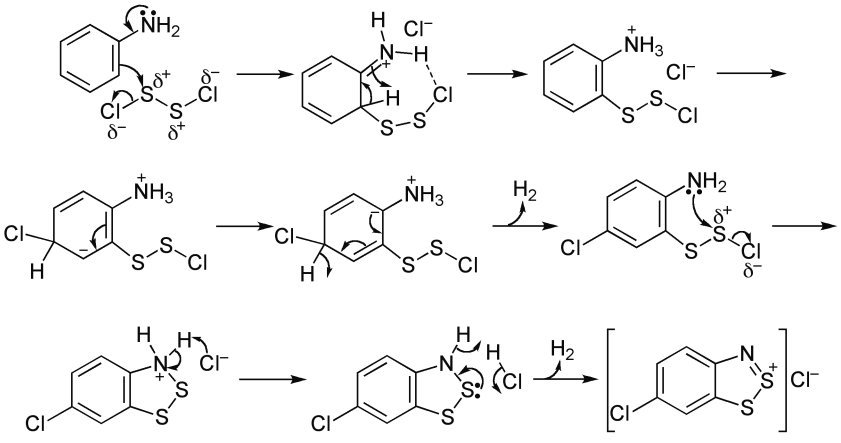
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It has been observed that no further chlorination occurs on Herz compounds in the presence of a chlorination reagent (e.g., $SOCl_2$), thus the chlorination on aromatic nucleus probably occurs before the formation of the Herz compounds. A tentative mechanism is outlined here.



D. MODIFICATION

N/A

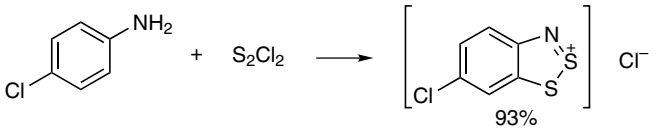
E. APPLICATIONS

This reaction is used to prepare *o*-amino thiophenols and benzothiozoles.

F. RELATED REACTIONS

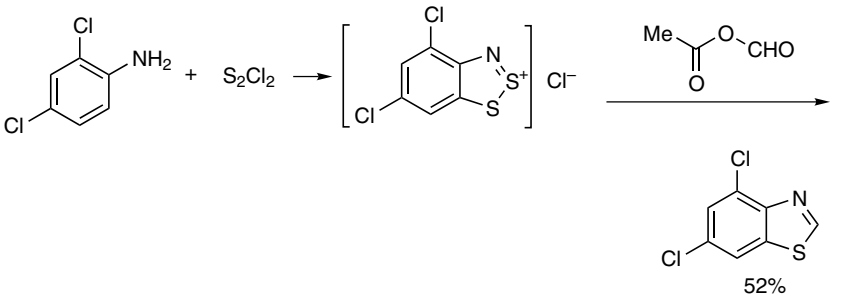
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A solution of 5.7 g *p*-chloroaniline (0.045 mol) in 7.0 mL anhydrous acetic acid was added to 25 mL cold redistilled sulfur monochloride (42.0 g, 0.31 mol). This mixture was stirred for 3 h at room temperature, and then at 70–80°C for 3 h. After being cooled to room temperature, the dark mixture was stirred with 50 mL dry benzene ($CaC1_2$) and then filtered. The solid was washed with dry benzene and then dried in vacuo to give 9.3 g 6-chloro-1,3,2-benzothiazathiolium chloride as a yellow-brown solid, which decomposed at 210–225°C. The yield was 93%.



Reference 2.

A solution of 32.0 g 2,4-dichloroaniline was mixed with sulfur monochloride to give an orange-red Herz condensation product, which was then treated with alkaline solution and filtered. The filtered alkaline solution was further treated with acetic-formic anhydride to gave a crude 4,6-dichlorobenzothiazole, m.p. 136–138°C. Recrystallization from ethanol gave 21.0 g pure 4,6-dichlorobenzothiazole as white needle-like crystals, in a yield of 52%, m.p., 142–142.5°C.

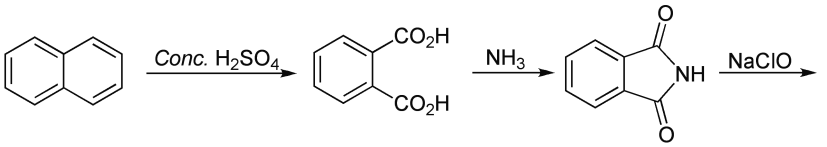
312

Heumann Indigo Process

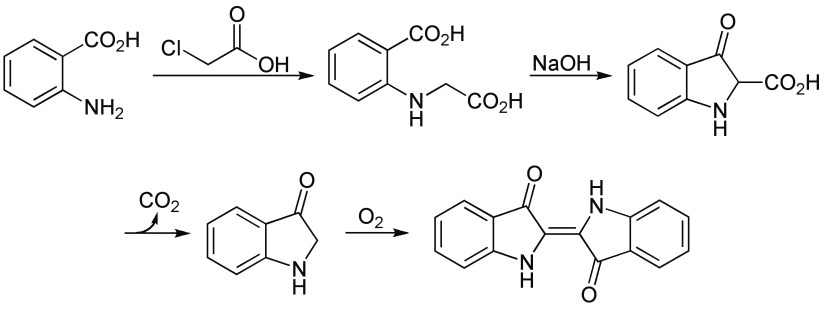
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Heumann in 1890.[1] It is the industrial production of indigo from basic fusion of *N*-phenylglycine-*o*-carboxylic acid into indoxylic acid, which decarboxylated to indoxyl; the latter is then oxidized into indigo by air. This process, which was modified by the Badische company[2] and commercialized in 1897 after Heumann died,[3] produced indigo from naphthalene via a sequential processes that included (a) the oxidation of naphthalene to phthalic acid by concentrated sulfuric acid, (b) the conversion of phthalic acid into phthalimide by ammonia, (c) the production of anthranilic acid by means of sodium hypochlorite oxidation of phthalimide, (d) the conversion of anthranilic acid into phenylglycocollorthocarboxylic acid by chloroacetic acid, (e) the fusion of phenylglycocollorthocarboxylic acid with caustic soda to produce indoxyl or indoxylic acid depending on conditions, and (f) oxidation of indoxyl into indigo by air in presence of alkaline.[4] This process resulted in an annual production of indigo of 3,000,000 lb from Badische, one quarter of world's supply in the 1900s,[4] leading to the monopoly of dyestuff of Germany in the early 20th century. The thioindigo analogues can be produced similarly from thiosalicylic acid,[5] which can be produced from the *Herz Reaction*.[6]

B. GENERAL REACTION SCHEME

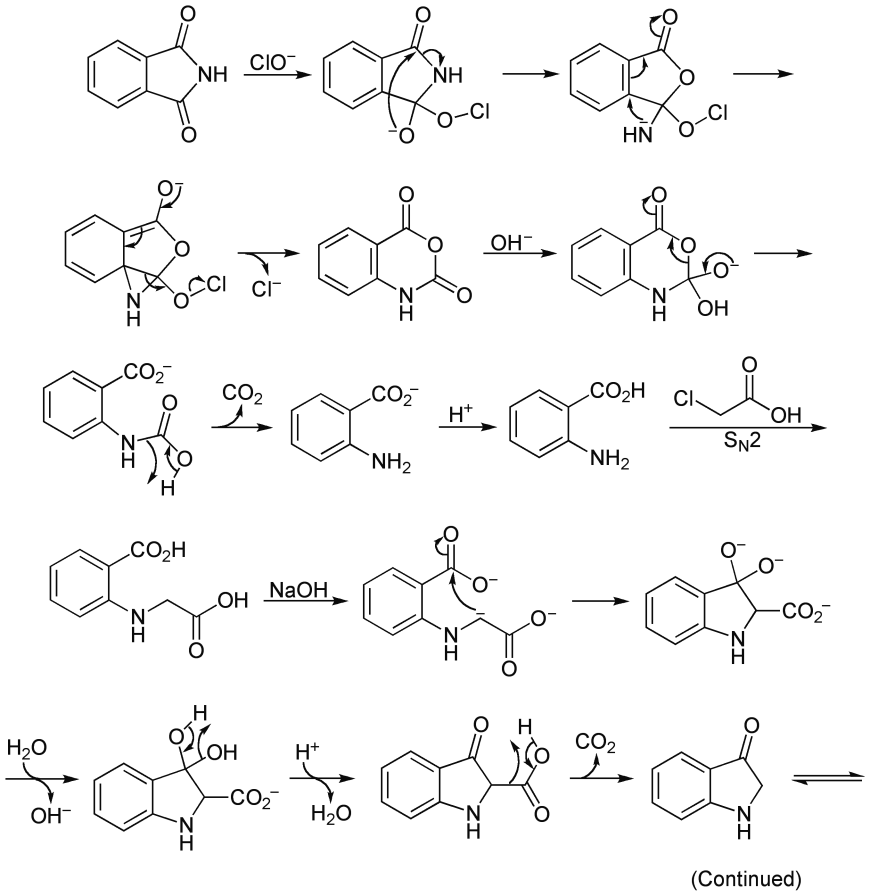


Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

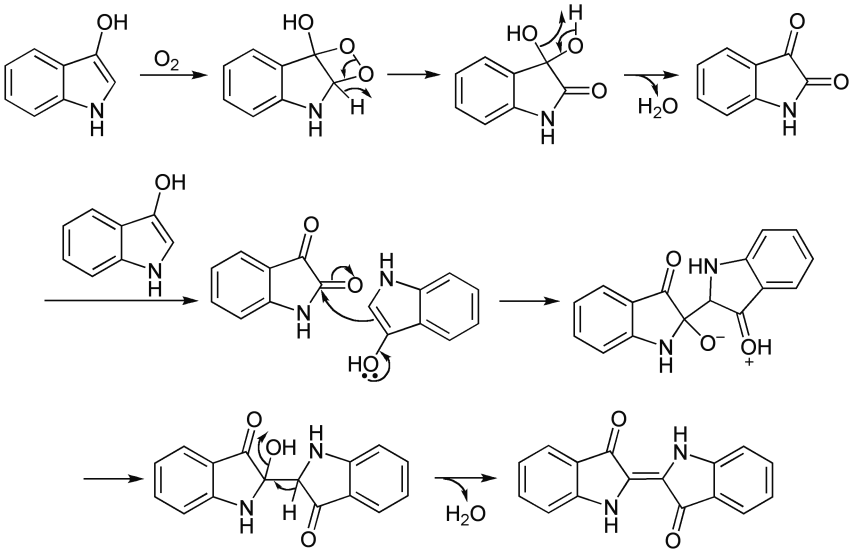


C. PROPOSED MECHANISMS

Because this is an industrial process, many of the reaction details have not been released to public,[4] the mechanism outlined here is a tentative one. This mechanism provides a possible reaction path from phthalimide because the oxidation of naphthalene to phthalic acid is well known and the formation of phthalimide is obvious.



(Continued)



D. MODIFICATION

The Badische process described here is a modification of the original Heumann process.

E. APPLICATIONS

This process has been extensively used in the production of indigo on an industrial scale.

F. RELATED REACTIONS

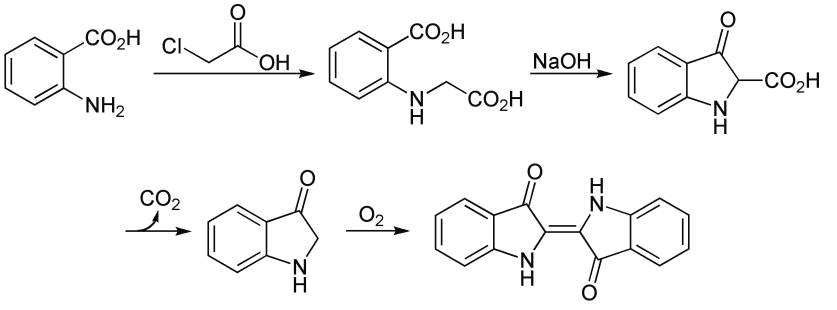
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To a 2-L flask equipped with a condenser were added 137 g anthranilic acid (1 mol), 94.5 g chloroacetic acid (1 mol), and 1 L water; the mixture was heated for 3 h. On cooling, crystals of phenylglycine-*o*-carboxylic acid were separated out. These were filtered off and recrystallized from hot water to give ~1000 g of such acid.

The mixture of 1 eq. phenylglycine-*o*-carboxylic acid, 3 eq. NaOH, and 1 eq. water was heated at 235–265°C in the absence of air until the alkaline mass assumed an intense orange color, whereupon it was allowed to cool and subsequently dissolved in water. Passing a stream of air through the aqueous solution resulted in the precipitation of indigo. No yield was given. (*Note*: This is a summary from Phillips.[7])

Heyns Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Heyns, probably as early as 1952.[1] It is a rapid[2] rearrangement of α-hydroxy imines (including α-hydroxy Schiff bases) into stable α-amino carbonyl compounds (i.e., α-ketoamines[3]) under nonreducing conditions and is generally known as the Heyns rearrangement.[4,5] The corresponding α-ketoamines are referred to as the Heyns rearrangement products[4b,4e,4m,4p,4r,4s,4v,6] or Heyns products.[2,4b,4m,4p,4s,6b]

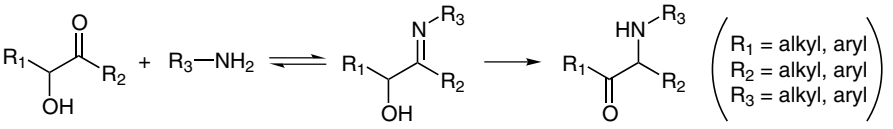
It should be pointed out that the formation of imines or Schiff base derivatives is thermodynamically reversible,[2,4f,4o] whereas the α-hydroxyl group facilitates the Heyns rearrangement, leading to the formation of stable α-ketoamines.[2,3,4c,4f,4x] In this reaction, the formation of Schiff base is the rate-limiting step, while the Heyns rearrangement is fast.[2] For example, the imine formed from an amine of lens protein and the C-20 carbonyl of corticoids undergoes Heyns rearrangement, and the resulting Heyns product is reported to be involved in the cataract formation.[4l,7] However, under reducing conditions, such as in the presence of sodium cyanoborohydride, the imine or Schiff base is reduced to secondary α-hydroxyamine and no Heyns rearrangement occurs.[2] In addition, the α-ketoamines can be destroyed by acidic hydrolysis, whereas α-hydroxyamines formed under reducing conditions are stable in acidic hydrolysis.[2]

With α-hydroxy carbonyl scaffold, carbohydrates undergo two different reactions with proteins requiring no group protection manipulations—that is, the *Amadori Rearrangement* and Heyns rearrangement. Aldoses give the Amadori products,[4g] existing only in the keto form with an α-hydroxy carbonyl function in the open chain form;[4m] in contrast, ketoses form several Heyns products,[4s] but mainly in the aldehyde form without the α-hydroxy carbonyl functionality[4m] (e.g., the conversion of lactoulose into different lactosamine derivatives[4n]). Both Amadori and Heyns products can undergo further reactions,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

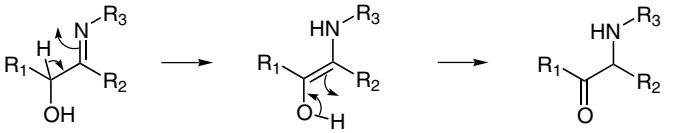
depending on the reactivity of the carbonyl group.[4m] The Amadori products, bearing an α-hydroxy carbonyl group, more readily undergo the enolization, dehydration, elimination, cyclization, migration of carbonyl group, and retro-aldol reaction.[4m] For instance, the Heyns products brown slower than those of Amadori products at 110°C under free access of oxygen.[4v] All these transformations make up the *Maillard Reaction*, leading to the formation of highly reactive compounds that may decompose into small volatile flavor compounds; polymerization into high molecular weight brown pigments known as mellanoidins,[4m] or the formation of fluorescent compounds widely applied in food, cosmetic, and pharmaceutical industries.[8]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The Heyns rearrangement is believed to take place via a hydroxy enamine intermediate, which is analogous to the enediol intermediate proposed in the internal rearrangement between aldoses and ketoses as displayed here.



Hydroxy enamine

D. MODIFICATION

N/A

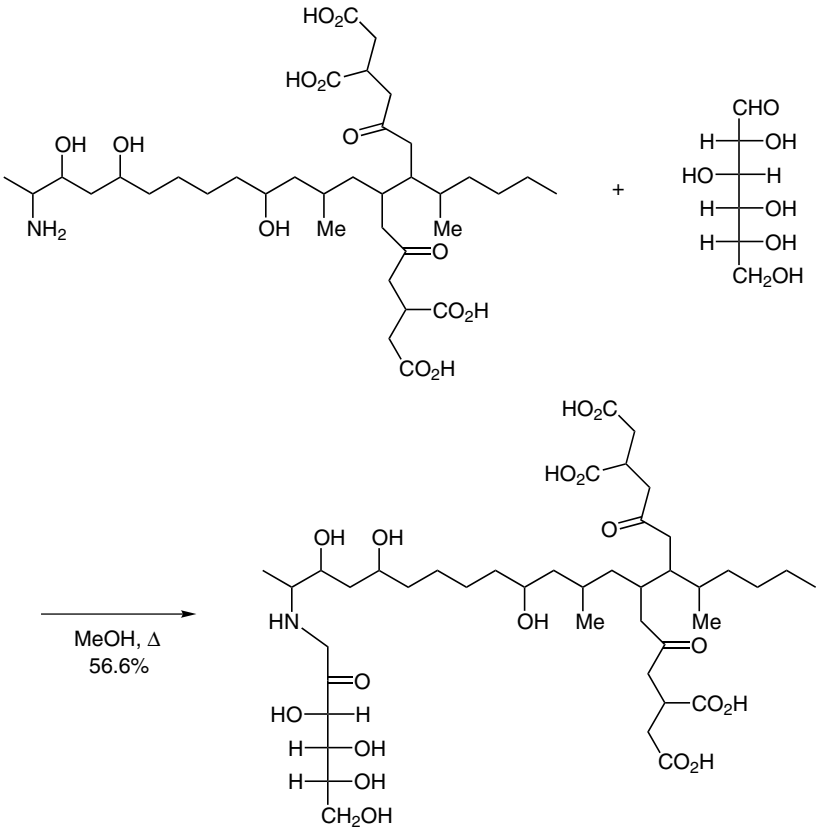
E. APPLICATIONS

This rearrangement is very popular in food chemistry.

F. RELATED REACTIONS

This reaction is related to the *Amadori Rearrangement* and *Maillard Reaction*.

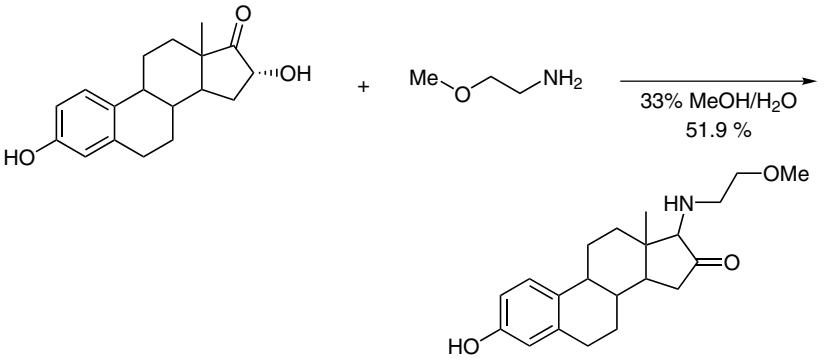
G. CITED EXPERIMENTAL EXAMPLES



Reference 4g.

Four 4.5-mL amber septum vials, each containing 12 mg fumonisin B_1 (16.6 μmol), D-glucose (108 mg, 600 μmol) and 4 mL methanol, were sealed and heated at 64°C for 6 h. The vials were removed briefly and shaken every 1–1.5 h. The glucose did not completely dissolve until the vials had been heated ~ 5 h. The contents of the vials were combined and diluted with 64 mL water (four times the volumes). The products were recovered from the diluted reaction mixture by passing it through a 2-g tC_{18} cartridge (Sep-Pak Vac 12 cm^3 [2 g] tC_{18} cartridge, Waters Corp., Milford, Mass.) that had been preconditioned with 20 mL MeOH, followed by 20 mL MeOH/H_2O (20:80). After the products were loaded, the cartridge was washed with 20 mL MeOH/H_2O (20:80) and then 20 mL CH_3CN/H_2O (10:90). The products were eluted with 20 mL 50:50 CH_3CN/H_2O. The procedure was then repeated using 8 vials, and the products were recovered using a 2-g tC_{18} cartridge. The 50:50 eluates from the 4- and 8-vial preparations were combined. A total of 153 mg fumonisin B_1 (212 mmol) were used for the 12 vials. Fumonisin B_1 and *N*-(1-deoxy-D-fructos-1-yl) fumonisin B_1 were separated using a 10-g strong cation exchange (SCX) Mega Bond Elut, 40 μm, SCX cartridge (Varian Sample Preparation Products, Harbor City, Califo). The cartridge was conditioned with 100 mL MeOH followed by 100 mL 50:50 CH_3CN/H_2O.

The combined 50:50 eluates were loaded onto the SCX cartridge. The cartridge was eluted with the following solvents, and the fractions were collected and analyzed: 100 mL 20:80 CH_3CN/H_2O, 100 mL 1% HCOOH in 20:80 CH_3CN/H_2O, and 2 × 100 mL and then 6 × 50 mL 5% HCOOH in 20:80 CH_3CN/H_2O. *N*-(1-Deoxy-D-fructos-1-yl)fumonisin B_1 started eluting in the first 100-mL portion of the latter solvent, whereas fumonisin B_1 did not start eluting until the second 50-mL portion. The first three portions were combined, diluted with an equal volume of water (250 mL), and loaded onto a 2-g tC_{18} cartridge that had been preconditioned with 20 mL MeOH, followed by 20 mL 10:90 CH_3CN/H_2O. The cartridge was washed with 20 mL of the latter solvent and eluted with 20 mL 50:50 CH_3CN/H_2O. The 50:50 CH_3CN/H_2O eluate was freeze-dried to give 106 mg *N*-(1-deoxy-D-fructos-1-yl) fumonisin B_1 (120 μmol), in a yield of 56.6%.



Reference 4t.

The mixture of 360 mg 3,16α-dihydroxy-estra-1,3,5(10)-trien-17-one and 4 mL 2-methoxy ethylamine was stirred at room temperature for 3 h. The formation of imine intermediate was monitored by the reduction of an aliquot of the reaction mixture with $NaBH_4$ and subsequent TLC analysis using $CHCl_3$/MeOH (10:1) as a developing solvent. After removing the excess reagent under reduced pressure, the residue was dissolved in 33% aqueous MeOH and stirred at room temperature for 2 h. The precipitate formed was collected by filtration. The filtrate was adjusted to pH 1 with 5% HCl, washed with EtOAc, readjusted to pH 11 with 10% NaOH, and extracted with $CHCl_3$. The combined organic layers were washed with half-saturated NaCl, dried over anhydrous Na_2SO_4, and evaporated. The residue was combined with the precipitate and recrystallized from methanol to give 224 mg 3-hydroxy-17β-(2-methoxyethylamino)estra-1,3,5(10)trine-16-one as colorless needles, in a yield of 65.5%, m.p. 190–191°C.

Other references related to the Heyns rearrangement are cited in the literature.[9]

Hilbert-Johnson Reaction

A. GENERAL DESCRIPTION OF THE REACTION

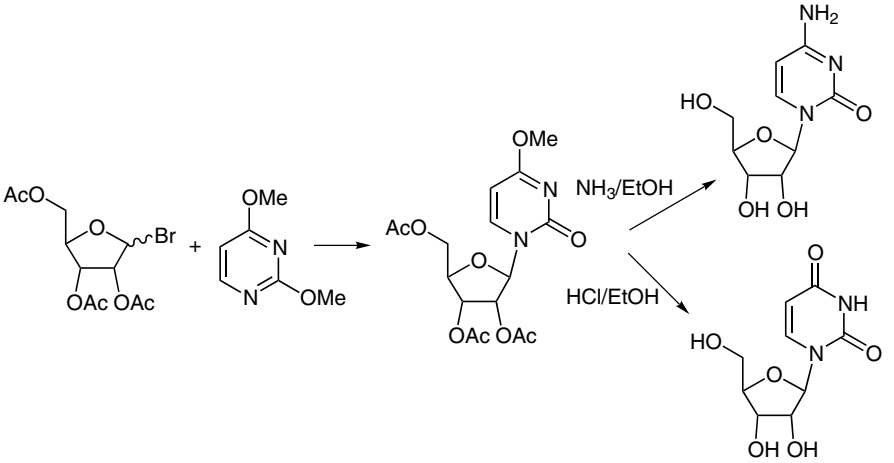
This reaction was first reported by Johnson and Hilbert in 1929.[1] It is the synthesis of pyrimidine nucleosides from the glycosylation of protected glycosyl halides with 2,4-dialkoxypyrimidines. Thus it is generally known as the Hilbert-Johnson reaction.[2] Occasionally, it is also referred to as the Hilbert-Johnson synthesis,[3] Hilbert-Johnson glycosylation,[2e,4] Hilbert-Johnson pyrimidine nucleoside synthesis[5] or Hilbert-Johnson method.[6] It should be pointed out that the Lewis acid ($SnCl_4$, TMSOTf, etc.) promoted glycosylation from labile trimethylsilyl-protected pyrimidine and glycosyl acetate, developed initially by Birkofer,[7] and greatly extended by Vorbrüggen,[8] is more versatile and successful for the preparation of pyrimidine nucleosides, which is generally referred to as silyl-Hilbert-Johnson reaction[8i,9] and, in a rare case, as the silyl-Hilbert-Johnson synthesis.[9f] On the other hand, 2-methylthio protected pyrimidine stops at the quaternization step, yielding an intermediate of glycosylpyrimidinium salt that can be converted into 2-oxo, 2-thio, and 2-aminopyrimidine nucleosides.[2t] This reaction is highly efficient and proceeds with high regioselectivity and stereoselectivity,[4c] by which β-anomer predominates in the products,[2r,4a] either condensed from α-glycosyl halide or β-glycosyl halide,[10] except for the case of condensation with 3,5-di-*O*-p-toluyl-2-*deoxy*-D-ribofuranosyl chloride into 2′-deoxyribofuranosylpyrimidines, which resulted in 66% of α-anomeric product.[3a] This reaction has been used for the synthesis of a variety of 2-oxo-pyridimine nucleosides, including uracil,[4c,9b,11] cytosine,[2t,11a,11d] and thymine[11a,11d] nucleosides. In addition, The Hilbert-Johnson reaction also works for nonaromatic aglycons, such as 6-oxadihydrouracil.[12] It was observed that suitably blocked pyranose derivatives also undergo such glycosylation, but under more stringent conditions at slower rates than their corresponding furanose isomers.[13] The protection

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

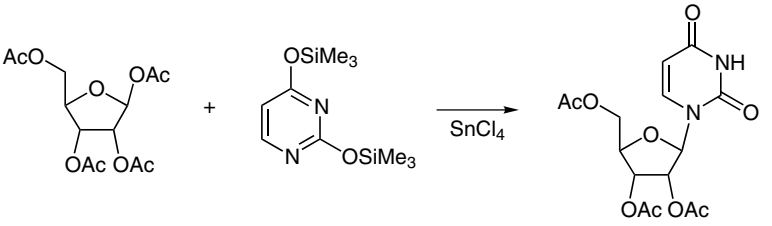
by acetyl rather than benzoyl group leads to an improved yield.[7e] Moreover, reaction in nitrobenzene is significantly faster than that in acetonitrile, the typical solvent used for this reaction.[9e] This reaction has been extended to the preparation of purine nucleosides.[14]

B. GENERAL REACTION SCHEME

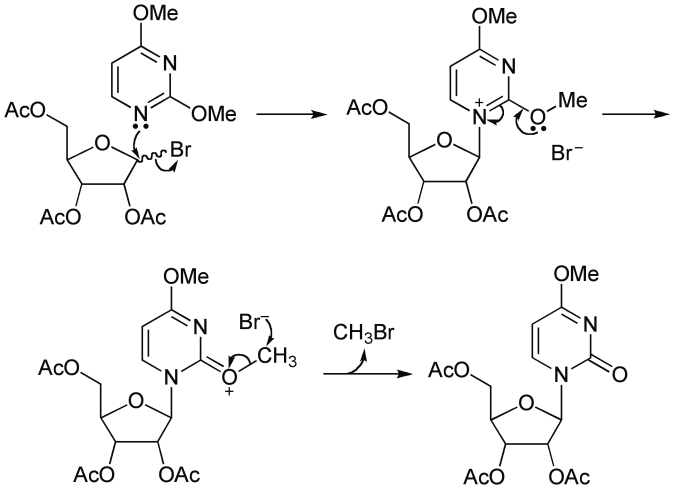
Hilbert-Johnson reaction.



Silyl Hilbert-Johnson reaction.



C. PROPOSED MECHANISMS



D. MODIFICATION

The original Hilbert-Johnson reaction has been modified using trimethylsilyl protected pyrimidine as aglycons to condense with glycosyl acetate and has been applied extensively to the synthesis of a variety of nucleoside derivatives. In addition, the substitution of 2-alkyl pyrimidine for 2-methylthio-protected pyrimidine allows the preparation of 2-oxo, 2-thio, and 2-aminopyrimidine nucleosides.

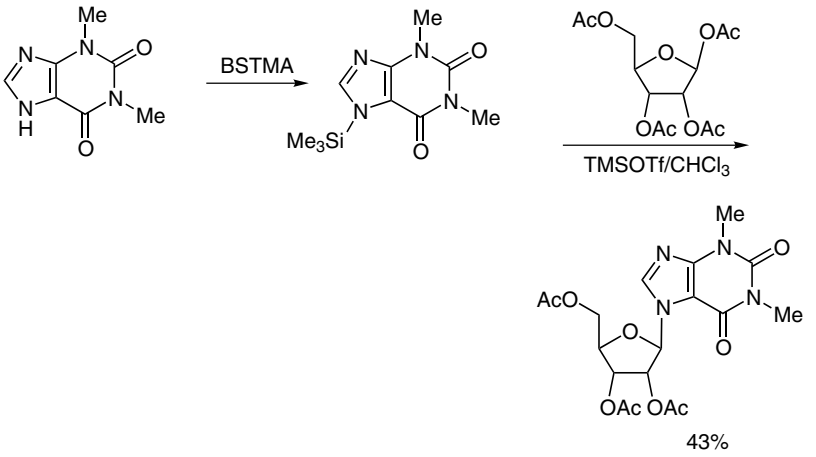
E. APPLICATIONS

This reaction has wide application in the synthesis of pyrimidine nucleosides and their analogues.

F. RELATED REACTIONS

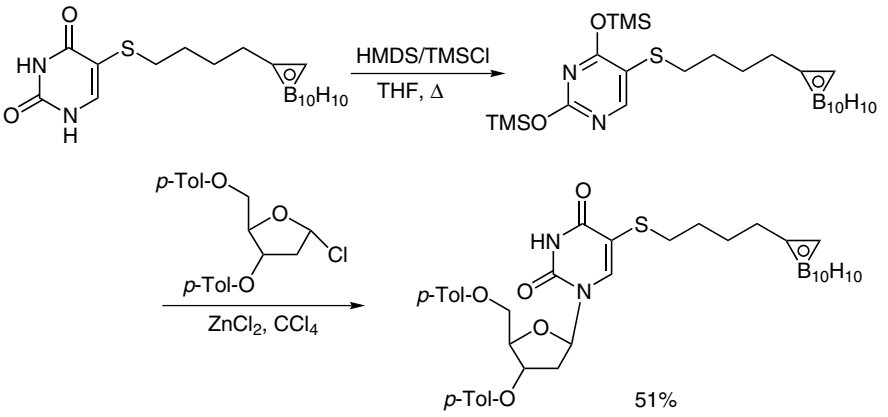
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

A mixture of 4.80 mmol theophylline and 1.4 mL *N*,*O*-bis(trimethylsilyl)acetamide (BSTMA, 5.80 mmol) in 15 mL dry $CHCl_3$ was stirred under nitrogen for 40 min at 20°C. A solution of 4.0 mmol tetraacetyl ribose and 0.1 mL trimethylsilyl trifluoromethanesulfonate (5.80 mmol) in 5 mL $CHCl_3$ was then added, and the reaction mixture was heated at reflux under nitrogen for 4 h. Saturated aqueous $NaHCO_3$ (120 mL) and dichloromethane were then added. After the system had been stirred for 15 min, the two layers were separated, and the aqueous one was extracted with dichloromethane (3 × 120 mL). The combined organic layers and extracts were combined and washed with brine, dried over anhydrous $MgSO_4$, and filtered. The solvents were evaporated to dryness. The residue was crystallized from MeOH to provide 43% 7-(2′,3′,4′-tri-*O*-acetyl-β-D-ribofuranosyl)theophylline as a white solid, m.p. 106°C.



Reference 9b.

5-[4-(*o*-Carboran-1-yl)butylmercapto]uracil (0.86 g, 2.5 mmol) was dissolved in 30 mL anhydrous THF, followed by the addition of 5.0 mmol hexamethyldisilazane (HMDS) and catalytic amounts of TMSCl (0.01 eq.). The mixture was refluxed under argon atmosphere. The byproduct, NH_4Cl, sublimed and was periodically removed from the condenser tips. The cessation of NH_4Cl sublimation indicated that the reactions were complete about 4–6 hours. Removal of THF and excess HMDS by evaporation left clear oil residues, which were immediately used for the condensation step. The oils were dissolved in 25 mL anhydrous CCl_4, and freshly prepared α-D-2-*deoxy*-3,5-di-*O*-*p*-toluoylribofuranosyl chloride (1.25 eq.) and $ZnCl_2$ (0.01 eq.) were added all at once. The reactions were stirred at room temperature for 2–4 days, and then CCl_4 was removed, leaving crude oils, which were purified by silica gel column chromatography, to give 0.90 g 5-[4-(*o*-carboran-1-yl)butylmercapto]-3′,5′-di-*O*-*p*-toluoyl-β-D-2′-deoxyuridine as a white foam, in a yield of 51%, m.p. 92–97°C, R_f = 0.35 (hexane/EtOAc, 3:2).

Other references related to the Hilbert-Johnson reaction are cited in the literature.[15]

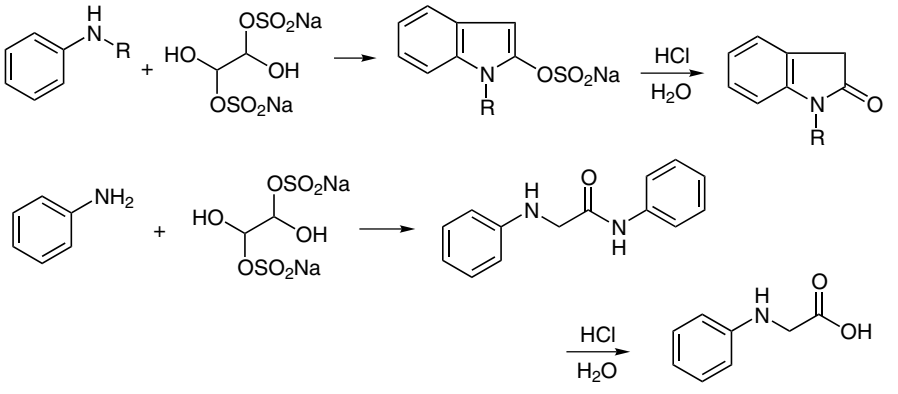
Hinsberg Oxindole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hinsberg in 1888.[1] It is the synthesis of *N*-alkyl-oxindole from *N*-alkyl aniline and the glyoxal-bisulfite adduct after hydrolysis by hydrochloric acid.[2] Similarly, the reaction of *N*-alkyl naphthylamine with glyoxal-bisulfite adduct leads to benzo-oxindole.[3] In contrast, the reaction between primary aryl amines and glyoxal-bisulfite adduct produces the substituted glycines.

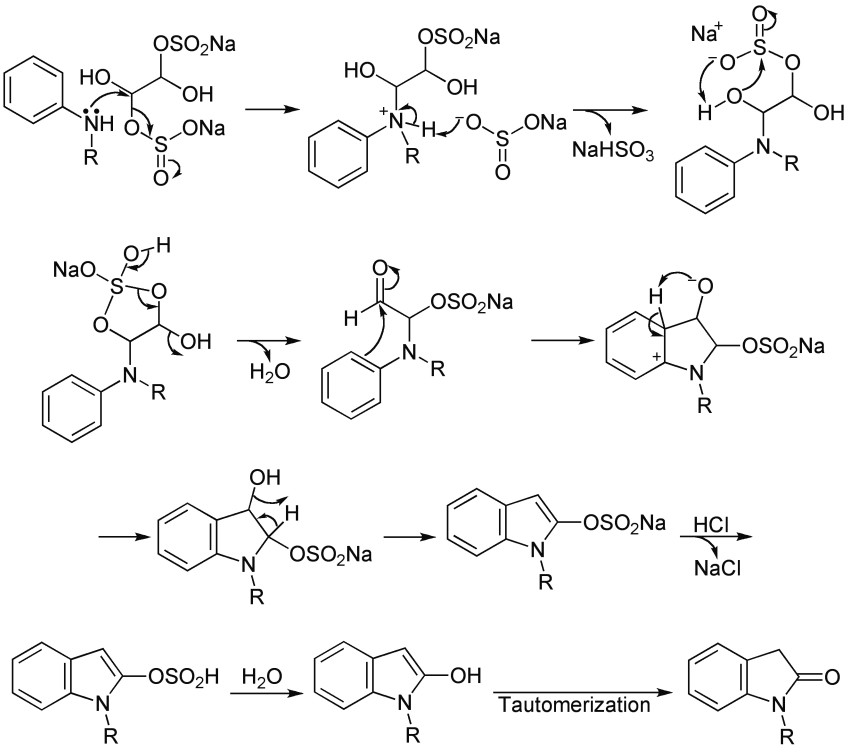
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

As this reaction has not been extensively studied and not much mechanistic information is available, a tentative mechanism is outlined here. It is possible that the primary aryl amine has less steric hindrance than the secondary aryl amine during the substitution, hence substituted glycine is produced as the product.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has certain applications in the preparation of oxindoles.

F. RELATED REACTIONS

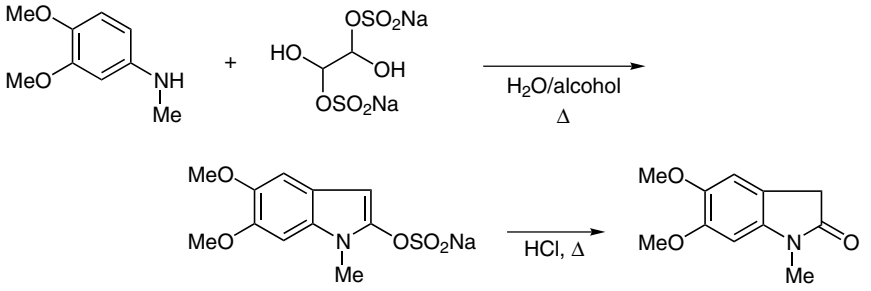
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

A solution of 32.0 g glyoxal sodium bisulfate in 250 mL water was mixed with a solution of 20.0 g 4-methyl aminoveratrole in 150 mL alcohol, and the resulting mixture was boiled under reflux for 48 h. The greenish yellow solution was filtered while hot and then cooled at $\sim 0^{\circ}$C. The solid was separated and crystallized from water to afford 19.0 g sodium 5,6-dimethoxy-1-methylindolyl 2-sulfite as small prisms, m.p. 187°C (dec.)

The mixture of 5.0 g sodium 5,6-dimethoxy-1-methylindolyl 2-sulfite, 25 mL water, and 50 mL HCl was boiled for 30 min, and the resulting solution was neutralized. A small amount of insoluble material separated. Extraction of the basified solution with ether afforded 5,6-dimethoxy-1-methyloxindole, which dissolved readily in water and crystallized from light petroleum ether (b.p. 100–120°C) in clusters of needles, m.p. 120–121°C.

Other references related to the Hinsberg oxindole synthesis are cited in the literature.[5]

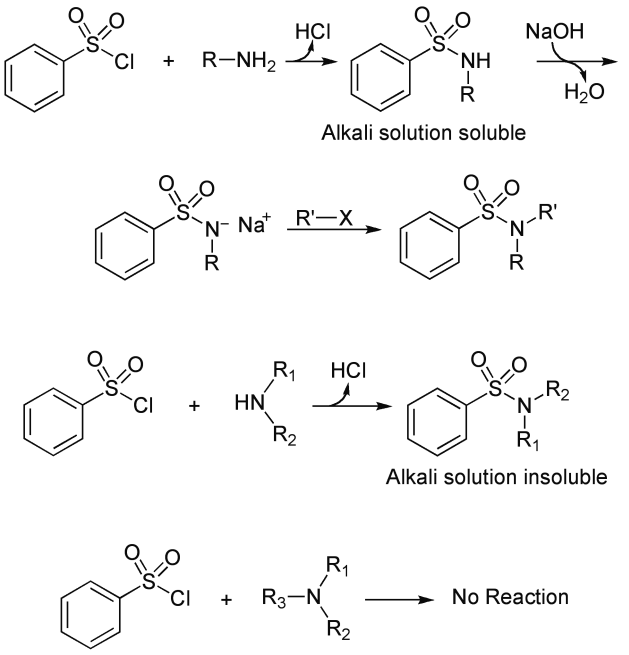
Hinsberg Reaction

A. GENERAL DESCRIPTION OF THE REACTION

Although the preparation of arenesulfonamides had been known since 1853,[1] it was Hinsberg who applied the method to prepare secondary amines in 1890[2] and explored the application of this reaction,[3] thus comes the name of the Hinsberg reaction[4] or Hinsberg method.[4b,5] It is the preparation of sulfonamides involving the treatment of primary or secondary amines with arenesulfonyl chloride, the further alkylation of resulting sulfonamides from primary amines, and the hydrolysis of sulfonamides into primary or secondary amines. With a quite acidic hydrogen attached to the nitrogen in the arenesulfonamides of primary amines,[6] the primary amines can be distinguished by observing the mode of reaction with a sulfonyl chloride and aqueous alkali, in which the primary amine forms an alkali-soluble sulfonamide, but the secondary amine results in an alkali insoluble sulfonamide, and the tertiary amine does not react with sulfonyl chloride.[4b] Therefore, arenesulfonyl chloride has been widely used to protect the amino group,[7] differentiate the type of amines,[4b] etc. It should be pointed out that in some cases, the primary amines (e.g., aniline and *m*-xylidine) might be oversulfonated to form disulfonylamides that are not soluble in alkali solution, and some monosulfonamides of primary amines are still not soluble in alkali solution.[5c] Therefore, the reaction using arenesulfonyl chloride to differentiate the types of amines (i.e., primary, secondary, and tertiary amines) is also known as the Hinsberg test.[8] Because the formed sulfonamides are very stable,[4b] different methods have been tried to hydrolyze the sulfonamides, including the treatment of sulfonamides with chlorosulfonic acid,[9] 80% sulfuric acid,[10] sulfuric acid, acetic acid,[11] hydrochloric acid,[12] and 48% hydrobromic acid in acetic acid in the presence of phenol.[5a,7] However, the sulfonation on the aromatic nucleus may occur along with the hydrolysis of sulfonamide of the aromatic amines;[13] and the hydrolysis of sulfonamides under basic conditions is not successful.[14]

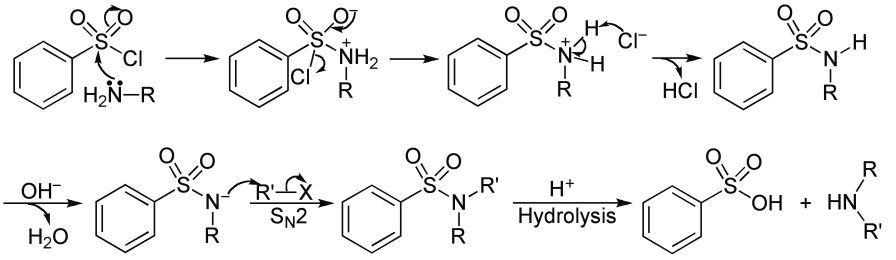
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism for the preparation of secondary amines from primary amines is given below.



D. MODIFICATION

This reaction has been modified to use *p*-phenylazobenzenesulfonyl chloride to react with amines to monitor the reaction.[15]

E. APPLICATIONS

This reaction has applications in the protection of primary and secondary amino groups and selective conversion of primary amines into secondary amines.

F. RELATED REACTIONS

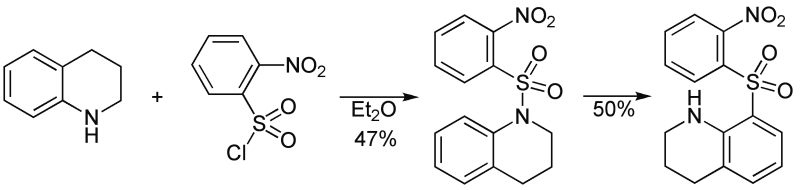
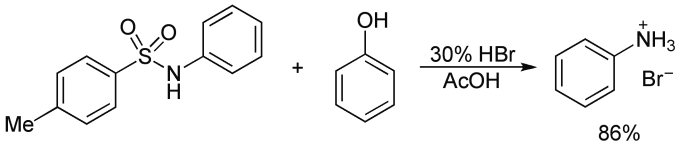
G. CITED EXPERIMENTAL EXAMPLES



Reference 15.

A solution of 67.0 g *o*-nitrobenzenesulfonyl chloride (0.3 mol) in 400 mL anhydrous ether was added gradually with stirring to a cooled solution of 80.0 g 1,2,3,4-tetrahydroquinoline (0.6 mol) in 120 mL anhydrous ether. After the addition was complete, the cooling bath was removed, and the mixture was refluxed for 1 h. The cooled reaction mixture was filtered, and the precipitate was washed with hot water to remove the amine hydrochloride. The residue was combined with the ether filtrate, and the solvent was stripped to give ~50 g crude product. The product was dissolved in ethanol, decolorized, and recrystallized to give 43 g 1-(phenylsulfonyl)-1,2,3,4-tetrahydroquinoline as a pale yellow solid, in a yield of 47%, m.p. 131–132°C.

A mixture of 2.0 g 1-(phenylsulfonyl)-1,2,3,4-tetrahydroquinoline with 6 mL concentrated sulfuric acid gradually colored; and when complete solution occurred, it was heated in a steam bath for 45 min, cooled, and poured over ice. A pale gummy solid precipitated, which was isolated, washed thoroughly with water, and recrystallized from ethanol to give 1.0 g 8-(phenylsulfonyl)-1,2,3,4-tetrahydroquinoline as pale yellow needles, in a yield of 50%.



Reference 7.

A solution of 2.5 g *p*-toluenesulfonanilide (0.01 mol) and 2.0 g phenol (0.02 mol) in 23 g 30% hydrogen bromide in acetic acid was permitted to stand at 26°C for 16 h. The reaction mixture was poured into 150 mL anhydrous ether. The precipitate was filtered, washed with 100 mL ether, and dried to give 1.48 g aniline bromide, in a yield of 86%, m.p. 283°C (dec.).

317

Hinsberg Sulfone Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hinsberg in 1894.[1] It is the formation of sulfonylquinol derivatives from the addition of sulfinic acids to quinones. This reaction can be carried out in both aqueous solutions[2] and nonaqueous aprotic solvents (e.g., THF).[3] However, the reaction of unsymmetric quinone will form two isomeric products in various ratios, depending on the solvent and acidity of the reaction system.[4] For example, the addition of phenylsulfinic acid to 2-methyl quinone results in 2-methyl-5-phenylsulfonylhydroquinone (i.e., the 2,5-adduct) and 2-methyl-6-phenylsulfonylhydroquinone (2,6-adduct), in which the 2,5-adduct predominates in acetic buffer at pH 4.5, and the 2,6-adduct dominates in either more acidic (e.g., pH 1) or more basic (e.g., pH 5.5) conditions.[4] In addition, the 2,6-adduct is also the major product in strong acidic two-phase systems[5] and aprotic solvent systems (e.g., THF, acetone, acetonitrile, or acetoacetone).[4] In the alcoholic aqueous solution, the percentage of 2,6-adduct increases along with the decreasing of alcohol percentage in the solution.[4] These results indicated that the protonated quinone is the actual species that sulfinic acid adds, and the product ratio reflects the selectivity of protonation on the carbonyl group.[4] Although both the resonance theory and frontier molecular orbital theory predict the preference of 2,5-adduct,[5] the substituents on quinones may inhibit the protonation in acidic condition, leading to the preferred 2,6-adduct.[4,5]

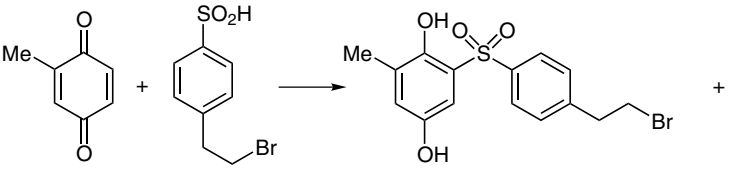
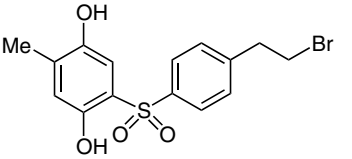
This reaction is related to *Thiele-Winter Acetoxylation*.

G. CITED EXPERIMENTAL EXAMPLES



Major product isolated when carried out in $AcOH/H_2O$ (1:1), 91%



Major product isolated when carried out in $EtOH/H_2O$ (5:7), 87%

Reference 4.

A solution of 1.2 g 2-methyl-1,4-benzoquinone (10 mmol) in 20 mL 95% ethanol was added dropwise to a stirred suspension of 3.0 g 4-(2-bromoethyl)benzenesulfinic acid (12 mmol) in 100 mL 30% aqueous ethanol. As the quinone color faded, a solid precipitate appeared and was filtered under vacuum. The filtrate was diluted with 300 mL ice water, and a second crop was obtained. After the mixture was allowed to stand overnight, a third crop was present. Each of the three fractions was a mixture of two sulfones as shown by TLC and NMR. A representative total crude yield was 11.0 g, in 87% yield. Recrystallization from aqueous ethanol yielded 2-[[4′-(2-bromoethyl)phenyl]sulfonyl]-5-methylhydroquinone, m.p. 119–121°C.

A solution of 410 mg 2-methyl-1,4-benzoquinone (3.4 mmol) in 10 mL AcOH was added, in one portion, to a stirred suspension of 1.2 g 4-(2-bromoethyl)benzenesulfinic acid (4.8 mmol) in 10 mL water. The quinone color disappeared along with the sulfinic acid. After stirring for 0.5 h, the light tan solid was suction filtered. After an additional 1 h of stirring, more tan solid was filtered. The reaction mixture was diluted with 200 mL ice water, and a third crop was obtained. Each of the three fractions was a mixture of two sulfones as shown by TLC and NMR. A representative total crude yield was 1.2 g, in a yield of 91%. Recrystallization from aqueous ethanol yielded 2-[[4′-(2-bromoethyl)phenyl]sulfonyl]-6-methylhydroquinone, m.p. 145–146°C.

Hinsberg Thiophene Synthesis

(Hinsberg Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hinsberg in 1910.[1] It is the synthesis of thiophene carboxylic acids from 1,2-diketones and dialkyl thiodiacetate (i.e., thiodiglycolate) via an intermediate of δ-lactone in the presence of sodium or potassium alkoxide. Therefore, it is known as the Hinsberg reaction,[2] Hinsberg method,[3] Hinsberg condensation,[4] Hinsberg thiophene synthesis,[5] or Hinsberg thiophene ring synthesis.[6] The reaction mixture is often worked up by diluting the alcoholic alkaline solution with water and boiling and isolating the free carboxylic acid thus formed;[4f] however, experimental evidence indicates that both diester[7] and half acid, half ester thiophene derivatives[4f] also form in this reaction. In addition, this reaction has been extended to 1,4-diketones, such as the reaction between *o*-phthalaldehyde and diethyl thiodiacetate to form 3-benzothiepin-2,4-dicarboxylic acid, which desulfurizes upon refluxing in ethanol, leading to the formation of naphthalene-2,3-dicarboxylic acid.[8] It is reported that the reaction of thiodiacetate with 1,2,3-triketone, such as indan-1,2,3-trione, is unsuccessful.[4e] Similarly, di-(trimethylsilyl)methyl sulfoxide when treated with bis-(trimethylsilyl)acetylene, also gives thiophene derivative after DDQ treatment.[9] The formed thiophene derivatives can be easily oxidized to sulfone derivatives by perbenzoic acid.[10]

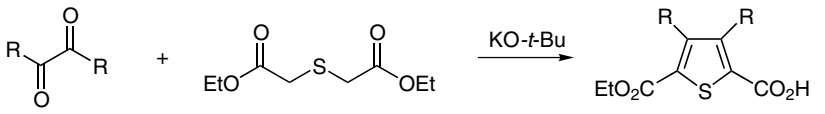
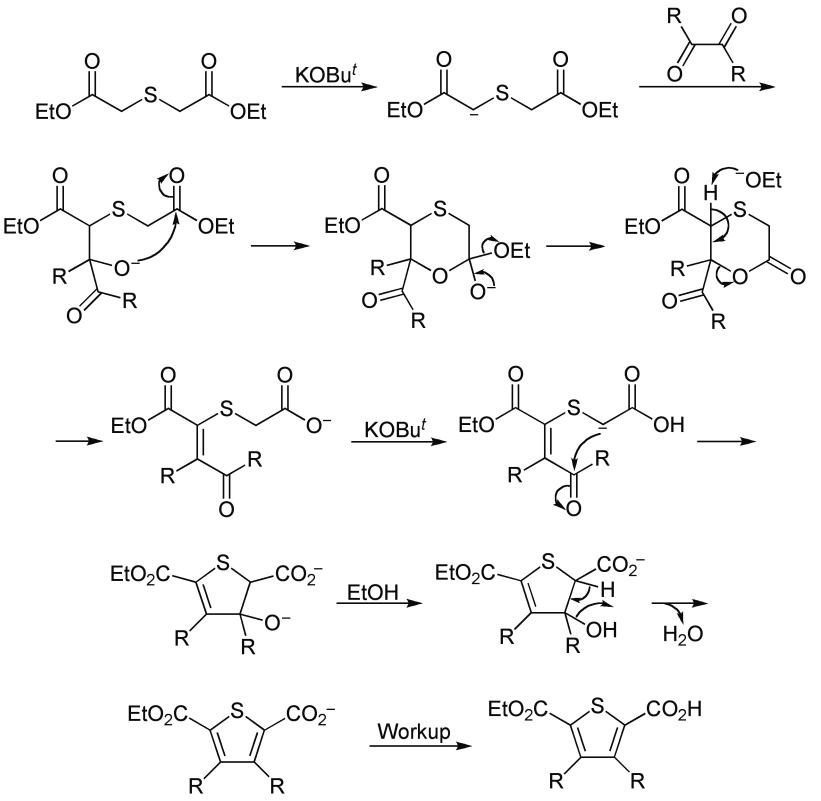
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

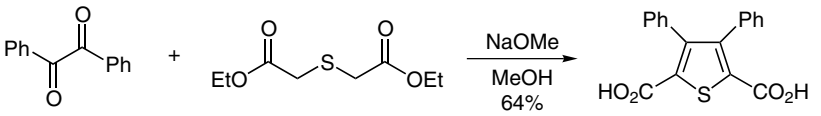
E. APPLICATIONS

This reaction has been used to synthesize thiophene derivatives as well as furan, selenophene, and pyrrole derivatives by varying the ester component from sulfur to oxygen, selenium, and nitrogen analogs.[11]

F. RELATED REACTIONS

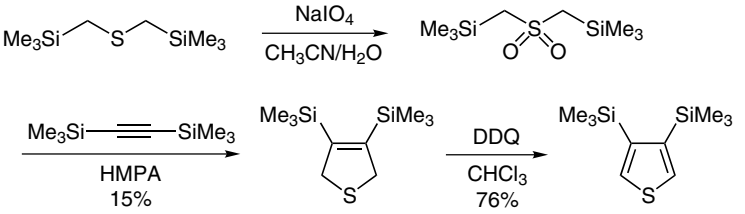
This reaction is related to the *Stobbe Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To a mixture of 2.0 g diethyl thiodiacetate (9.71 mmol) and 2.04 g benzil (9.71 mmol) in 15 mL methanol was added 1.57 g NaOMe (29.1 mmol). The mixture was stirred at ambient temperature for 3 days. After addition of water, the alcohol was evaporated. The formed solid (benzil) was filtered off, and the filtrate was acidified with HCl, upon which 3,4-diphenylthiophene-2,5-dicarboxylic acid precipitated. After filtration, 2.02 g of a white solid was obtained, in a yield of 64%.



Reference 9.

To a 50-mL flask were added 3 mL acetonitrile, 206 mg bis[(trimethylsilyl)methyl] sulfide (1 mmol), and 3 mL aqueous solution containing 257 mg sodium metaperiodate (1.2 mmol) at $-10°$C by ice salt bath cooling. The solution was stirred at $-10°$ to 0°C for 12 h and then the cold solution was filtered and extracted with cold dichloromethane (3×5 mL). The dichloromethane extracts were dried over Na_2SO_4 and concentrated under vacuum to yield bis(trimethylsilylmethyl)sulfoxide as a colorless oil that is pure enough for subsequent reaction.

To a 100-mL, flame-dried, three-necked flask equipped with a condenser and a dropping funnel was added a solution of 666 mg bis(trimethylsilylmethyl)sulfoxide (3.0 mmol) in 2 mL HMPA (distilled from CaH_2), then 340 mg bis(trimethylsilyl)-acetylene (2 mmol) in 2 mL HMPA was added rapidly from a dropping funnel. The resulting solution was warmed at 100°C and stirred at this temperature for 30 min under nitrogen atmosphere. The cooled reaction mixture was diluted with 40 mL benzene, washed with brine (4×15 mL), and dried over $MgSO_4$. The solvent was removed under reduced pressure. The residue was subjected to column chromatography on silica gel (50 g, hexanes) to give 69 mg 3,4-bis(trimethylsilyl)-2,5-dihydrothiophene as a colorless oil, in a yield of 15%.

To 8 mL chloroform solution containing 230 mg 3,4-bis(trimethylsilyl)-2,5-dihydrothiophene (1.0 mmol) was added a hot solution of 363 mg DDQ (1.6 mmol)

in 45 mL chloroform. The mixture was stirred at 60–65°C for 10 h. The cooled reaction mixture was washed with 10% aqueous sodium carbonate (3 × 10 mL) and 10 mL water, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel (30 g, hexanes) to afford 173 mg 3,4-bis(trimethylsilyl)thiophene as a colorless oil, in a yield of 76%.

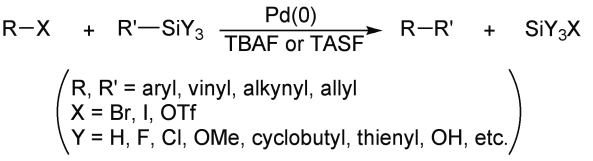
Hiyama Coupling

A. GENERAL DESCRIPTION OF THE REACTION

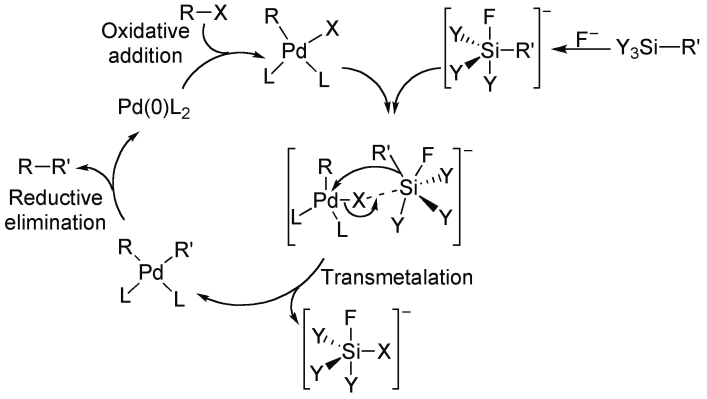
This reaction was first reported by Hatanaka and Hiyama in 1988.[1] It is a palladium-catalyzed cross-coupling reaction between organosilanes and aryl (or vinyl) halides or triflates. This reaction is known as the Hiyama coupling,[2] Hiyama cross-coupling,[3] or Hiyama reaction,[2f,3d,4] which tolerates a wide spectrum of functional groups including ethers, acetals, nitriles, esters, and amides,[2f] except for amino groups that might poison the palladium catalyst. Typically, the Hiyama coupling is promoted by the activation of the organosilanes with a stoichiometric amount of fluoride source,[3d] such as tetrabutylammonium fluoride (TBAF) or tris(dimethylamino)sulfur(trimethylsilyl)difluoride (TASF)[3d] and by using chlorosilancs or fluorosilanes instead of trimethylsilanes.[5] The presence of a fluoride source is essential to facilitate the transmetalation of the organic group through the formation of a five-coordinate silicate species.[6] This reaction is known to be accelerated by microwave.[7] On the other hand, this reaction is analogous to the *Stille Coupling* but with advantages of lower toxicity and easier handling.[3d] In the presence of Ag_2O and catalytic amount of $Pd(PPh_3)_4$, even organic silanols can couple with aryl iodide; however, TBAF fails to promote the reaction under this condition.[8] Recently, this reaction has been extended to the coupling of alkyl halides with silanes, using the combination of $PdBr_2$/$P(t\text{-}Bu)_2Me$/TBAF; this modification is especially good for electron-rich silanes. In addition, replacement of $P(t\text{-}Bu)_2Me$ with $[HP(t\text{-}Bu)_2Me]BF_4$ allows the coupling to occur in the presence of air or moisture.[2f]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to undergo the coupling with alkyl halides using the combination of $PdBr_2$/P(*t*-Bu)$_2$Me/TBAF as a catalytic system.[2f]

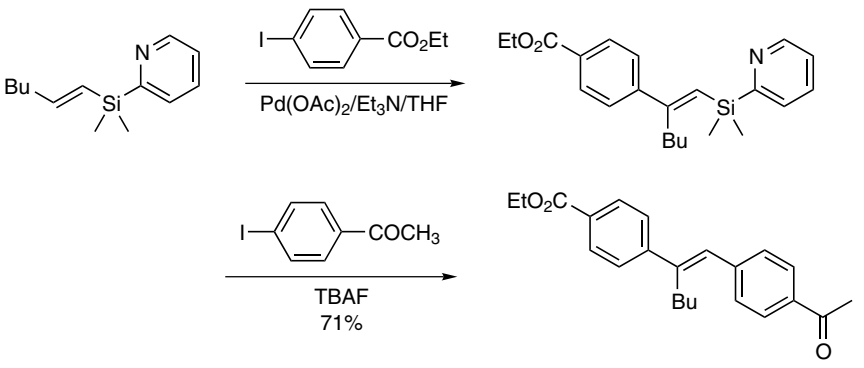
E. APPLICATIONS

This reaction has wide application in organic synthesis during the coupling of aryl and vinyl moieties.

F. RELATED REACTIONS

This reaction is closely related to the *Stille Coupling* and *Suzuki Coupling*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2g.

To a 0.9 mL THF solution containing 4.3 mg $Pd(OAc)_2$ (0.02 mmol, 10 mol %), tri-2-furylphosphine (5.1 mg, 0.02 mmol, 10 mol %), 32.7 mg triethylamine (0.32 mmol), and 75.2 mg 4-iodobenzoic acid ethyl ester (0.27 mmol), was added 65.7 mg (2-pyridyl)-1-hexenyl-dimethylsilane (0.30 mmol) under argon; the reaction mixture was stirred at 60°C for 3 h. After the mixture was cooled to room temperature, 48.2 mg 4-iodoacetophenone (0.20 mmol) and 0.46 mL 1 M TBAF solution in THF were added to the reaction mixture, and this reaction mixture was stirred at 60°C for 14 h. The catalyst was removed by filtration through a short silica gel pad (EtOAc). The filtrate was evaporated, and the residue was chromatographed on silica gel (hexane/EtOAc, 10/1) to afford 48.6 mg (*E*)-1-(4-acetyl)phenyl-2-(4-ethoxycarbonyl)phenyl-1-hexene as a colorless oil, in a yield of 71%.

Other references related to the Hiyama coupling are cited in the literature.[9]

Hoch-Campbell Reaction

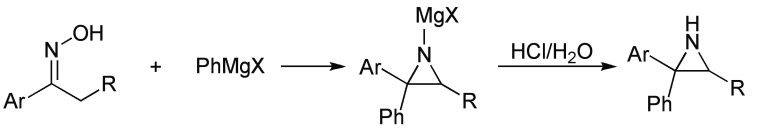
(Hoch-Campbell Aziridine Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

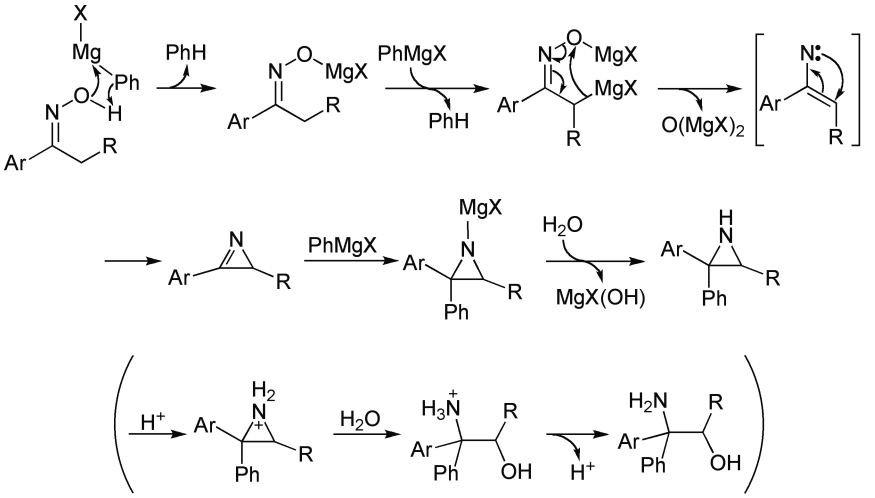
This reaction was first reported by Hoch in 1934[1] and subsequently extended by Campbell in the early 1940s.[2] It is the synthesis of aziridines (also known as ethylenimines[3]) by treatment of ketoximes with excess amounts of Grignard reagent followed by the hydrolysis of the resulting organometallic complex. Therefore, it is generally known as the Hoch-Campbell reaction.[4] Occasionally, this reaction is also referred to as the Hoch-Campbell aziridine synthesis or Hoch-Campbell ethylenimine synthesis,[5] and the formed aziridines are called the Hoch-Campbell products.[3,6] On the other hand, α-amino alcohols can also be the products instead of aziridines, depending on the conditions used in the hydrolysis of the organometallic complex.[2d,3,7] It is known that this reaction proceeds regiospecifically through a vinyl nitrene intermediate leading to an azirine,[8] and the subsequent addition of Grignard reagent occurs on the less hindered side of the azirine to give diastereomeric aziridines.[8b,8e,9] In this reaction, solvents also play an important role;[10] for example, reactions in toluene give one major product, whereas two isomers form in THF.[10a] Similarly, the aziridines can be prepared from oxime tosylate and organolithium reagents.[7,11] It is interesting that the ketoximes can be directly reduced to aziridines when cyclohexylmagnesium or isobutylmagnesium chloride is used as a Grignard reagent.[6] However, oximes from simple ketones such as acetone and 2-butanone do not undergo such reaction.[12]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

N/A

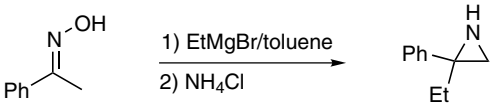
E. APPLICATIONS

This reaction has general application in the synthesis of aziridines, especially the fully substituted aziridines.

F. RELATED REACTIONS

This reaction is related to the *Neber Rearrangement*.

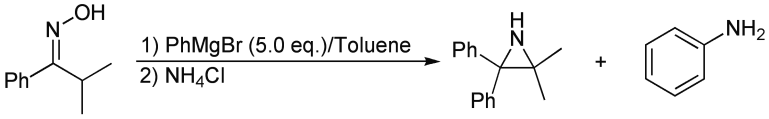
G. CITED EXPERIMENTAL EXAMPLES



37%

Reference 2a.

A solution of ethylmagnesium bromide prepared from 24 g magnesium turnings, 115 g ethyl bromide, and 350 mL dry ether was distilled until 200 mL ether was removed; dry toluene (200 mL) was added, and then a solution of 34 g acetophenone oxime (0.25 mol) in 200 mL dry toluene was added dropwise over a period of 2 h. The oil bath surrounding the flask was kept at 90–95°C during the addition, and continued for 30 min afterward. The mixture was hydrolyzed at once by pouring onto ice and a NH_4Cl solution; the water layer was extracted several times with ether, and the combined ether solutions were dried over magnesium sulfate. The residue remaining after removal of the ether and toluene was distilled under reduced pressure to yield 14.4 g 2-phenyl-2-ethyl aziridine, b.p. 85–86°C (7.0 mmHg), in a yield of 37%.



Reference 13.

The procedure is same as the one just described. Isobutyrophenone oxime (33 g; 0.2 mol) and 1 mol phenylmagnesium bromide were used. The reaction mixture was hydrolyzed with a solution of ammonium chloride and extracted with ether. The ethereal extracts were dried over calcium sulfate and saturated with hydrogen chloride. The precipitate that formed was filtered off, washed with ether, and recrystallized from dry acetone. It weighed 8 g and melted at 192–193°C. It was dissolved in 45 mL concentrated ammonium hydroxide, and the solution was extracted with ether. The ether solution after drying over calcium sulfate was concentrated by evaporation. The residual oil was fractionated to yield two substances. One boiled at 49–51°C (1 mmHg) (i.e., aniline) and gave a hydrochloride salt that, after one recrystallization from acetone, melted at 193–194°C, two more recrystallizations from the same solvent did not depress the melting point of aniline hydrochloride (196–198°C). The second fraction, 2,2-diphenyl-3,3-dimethylaziridine, distilled at 128–129°C (1 mmHg). On standing, this material crystallized partially to form large plates that melted at 181–185°C with softening at 60°C. A hydrochloride of this material was prepared in an ether solution saturated with hydrogen chloride. After recrystallization from acetone, this salt melted at 227–228°C. (No yields are given for either product.)

Hock Rearrangement
(Hock Cleavage)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hock and Schrader in 1936.[1] It is the protic or Lewis acid–promoted rearrangement of hydroperoxides that have unsaturated unit(s) attached to the carbon bearing the hydroperoxide group to oxycarbonium ion, which undergoes nucleophilic attack by water, leading to the cleavage of C-C bond and the formation of two carbonyl compounds. Therefore, this reaction is known as the Hock rearrangement,[2,3] or Hock cleavage.[2d,2e,4,5] This reaction occurs quite frequently on lipids and fatty acids[2d,4a,6] where allylic and dienylic hydroperoxides often form upon radical hydrogen abstraction in the presence of air or oxidation by singlet oxygen ($^1O_2$).[2c,4e] Although this reaction is generally promoted by acid, it also occurs in the absence of an added acid,[7] such as in the case where the *ene* reaction solution is injected onto a gas chromatography column for product isolation.[8] In addition, some Hock rearrangements even occur at temperatures substantially below room temperature.[9] Depending on the substrate structure and the choice of Lewis acid, dialkyl peroxide and ozonides might decompose via Hock rearrangement path, such as the decomposition of the substrate with groups of high migratory aptitude in the presence of $SnCl_4$ or $BF_3{\cdot}OEt_2$.[2e] The qualitative migratory aptitude of groups is generally in the order of cyclobutyl > aryl > vinyl > hydrogen > cyclopentyl $\approx$ cyclohexyl >> alkyl.[10] Moreover, the silver ion adducts of hydroperoxides and cyclic peroxides also undergo such rearrangement to give aldehydes and epoxides.[11] On the other hand, the intermediate oxycarbonium ion in this reaction might undergo another reaction path of β-proton elimination instead of attacking by a water molecule, affording a product of divinyl ether.[12]

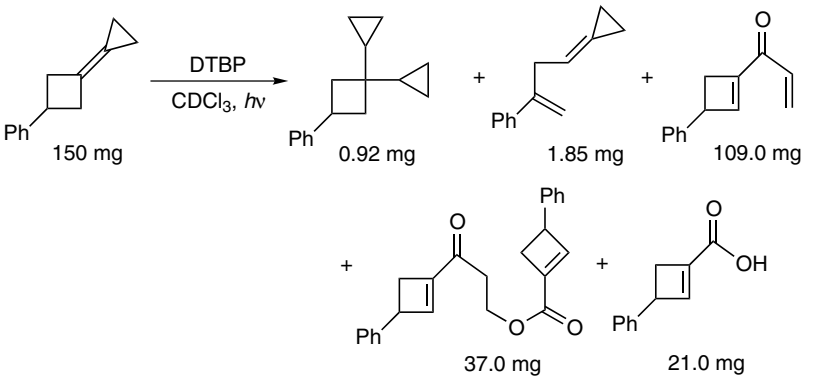
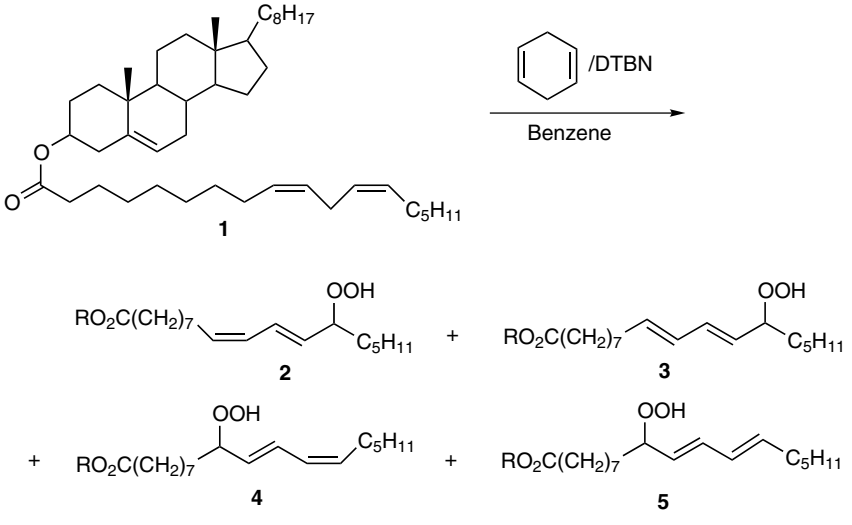
This reaction is related to the *Criegee Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

The water-cooled photooxidation on 150 mg 1-cyclopropylidene-3-phenylcyclobutane (0.88 mmol) in 3 mL $CDCl_3$ in the presence of a small amount of the radical inhibitor 2,6-di-*tert*-butylphenol (DTBP) proceeded essentially to completion within 2 h. Silica column chromatography, using a 0–20% gradient of EtOAc in hexane, yielded three fractions. The first one was 4 mg of a mixture (∼2% total) of 1-cyclopropylidene-3-phenylcyclobutane, 1,1-dicyclopropyl-3-phenylcyclobutane, 1-cyclopropylidene-3-phenyl-3-butene and 2,6-di-*tert*-butylphenol in a 1:1.5:3:1 ratio, respectively. Compounds 1,1-dicyclopropyl-3-phenylcyclobutane and 1-cyclopropylidene-3-phenyl-3-butene were impurities in the starting material (vide supra). This was followed by 109.0 mg 1-(3-phenylcyclobut-1-enyl)-propenone at higher eluent polarity (0.59 mmol, 67% yield) as a yellow liquid, 37.0 mg 3-oxo-3-(3-phenylcyclobut-1-enyl)propyl 3-phenylcyclobut-1-enecarboxylate (0.103 mmol, 12%) as a viscous yellow oil, and 21.0 mg 3-phenylcyclobut-1-enecarboxylic acid (0.12 mmol, 14% yield) as a white solid, m.p. 87°C.



Reference 11.

A round-bottomed flask was charged with 300 mg cholesteryl linoleate (0.462 mmol) and was diluted to 0.20 M with 0.876 mL 1,4-cyclohexadiene (9.26 mmol) and 1.43 mL dry benzene. DTBN (2 mg) was added to the solution, and the sealed flask was heated to 37°C under an oxygen atmosphere. After 24 h, TLC indicated the formation of peroxidic products. Butylated hydroxytoluene (BHT, 2 mg) was added to the reaction. Analytical HPLC (tandem silicon columns, 0.5% 2-propanol in hexanes, $\lambda = 234$ nm) indicated the formation of four major components in the mixture: **2**, $t_R = 15.0$ min; **3**, $t_R = 17.5$ min; **4**, $t_R = 20.1$ min; and **5**, $t_R = 20.5$ min. Semipreparative HPLC (0.66% 2-propanol in hexane) was used to separate the components. Compounds **4** and **5** were isolated as a mixture.

Other references related to the Hock rearrangement are cited in the literature.[14]

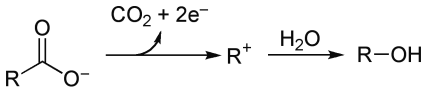
Hofer-Moest Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hofer and Moest in 1902.[1] It is the conversion of aliphatic acids into corresponding alcohols with one less carbon by electrolytic decarboxylation in neutral or alkaline solutions in the presence of an inert anion, such as sulfate, phosphate, perchlorate, carbonate, or bicarbonate.[2] This reaction is generally carried out with a platinum anode.[2] The added salt of the inert anion favors carbonium ion product relative to the normal radical product;[2] the latter leads to the formation of hydrocarbon (or paraffin),[3] a process known as the *Kolbe Electrolysis*.[4] Therefore, this reaction is generally known as the Hofer-Moest reaction.[5] Occasionally, this reaction is also referred to as the Hofer-Moest oxidation,[5i,6] abnormal Kolbe reaction,[7] etc. The alcohols produced in this reaction are called Hofer-Moest products.[5i] Besides the major product of alcohols, some minor products also form in this reaction, such as olefins,[5b] carbonyl compounds (e.g., ketone),[8] esters[2] and ethers,[2,4c] which originate from the proton elimination, further oxidation of alcohols, coupling of resulting alcohols with parent acids, and so on. In addition, the Hofer-Moest products are also favored by increasing the frequency in pulsed electrolysis.[5i] On the other hand, it was found that a carbon anode has some advantages over platinum anode, by which the Kolbe product is practically eliminated even without the help of added salts or increased pH.[2] This reaction has been extended to decarboxylation of amino acid derivatives, such as the stepwise degradation of polypeptides from the carboxyl terminal[9] and the anodic methoxylation of amides or carbamates to *N*-acyliminium ions[10] for amidoalkylation.

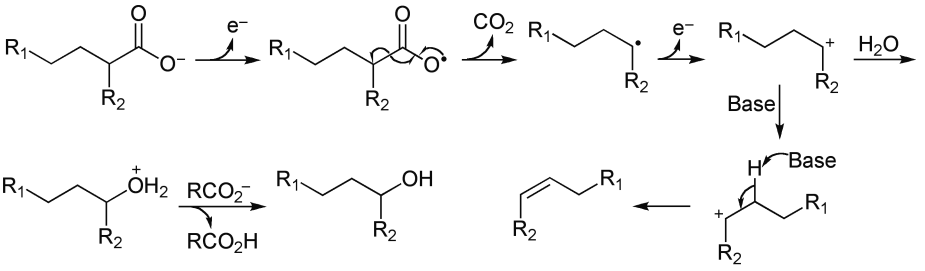
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the mechanism to form an alcohol or an olefin.



D. MODIFICATION

N/A

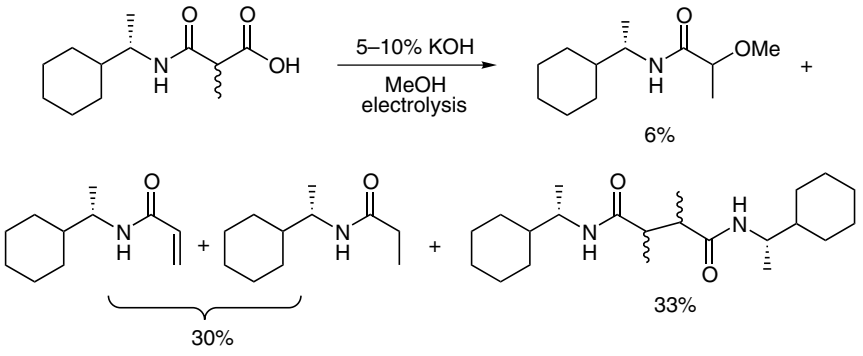
E. APPLICATIONS

This reaction is useful for the conversion of carboxylic acids into alcohols with one less carbon, and the decarboxylation of amino acids and polypeptides.

F. RELATED REACTIONS

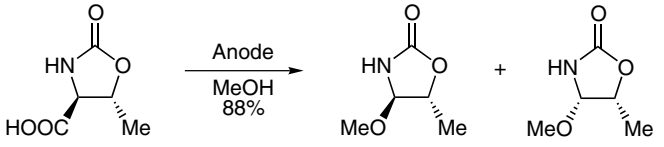
This reaction is closely related to *Kolbe Electrolysis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To an undivided jacketed cell with platinum as both anode and cathode were added 5–10% methanolic KOH with 0.5 mM *N*-[(1S)-cyclohexylethyl)-2-methylmalonamic acid. The cell was put into a cryostat precooled to –40°C and was charged with an electric current of 250 mA/cm^2, 1.7F/mol; the temperature was maintained between 10° and 60°C. The reaction was monitored by pH measurement (until acid to neutral). When passivation or coverage of electrodes was noticed, polarity inversion was used. After the reaction, the normal workup process and column chromatography yielded 6% *N*-[(1S)-1-cyclohexylethyl]-2-methoxypropanamide, 33% *N*-[(1S)-1-cyclohexylethyl]-acrylamide (white solid, m.p. 70–72°C), *N*-[(1S)-1-cyclohexylethyl]-propanamide (white solid, m.p. 107–110°C), and 30% *N*,*N*′-bis-(1-cyclohexylethyl)-2,3-dimethylsuccino-diamide (white solid, m.p. > 300°C), but only 0.7 % mixed Kolbe dimmer (the regular Kolbe product).



Reference 10.

A stirred solution of 2.9 g (4S,5R)-5-methyl-2-oxazolidinone-4-carboxylic acid (20 mmol) in 500 mL 0.02 N NaOAc/MeOH was electrolyzed at room temperature under galvanostatic conditions using graphite electrodes (3 × 30 × 100 mm) in an undivided cell. After consumption of 3F/mol at a current density of 5 mA/cm^2, the solvent was evaporated, the white residue was purified, and the diasteromers were separated by flash chromatography on silica gel with Et_2O as the eluent to afford 2.1 g (4R/S,5R)-4-methoxy-5-methyl-2-oxazolidinone as white crystals, in a yield of 88%, m.p. 87–90°C. The (4R,5R)-4-methoxy-5-methyl-2-oxazolidinone was formed with 77% ds.

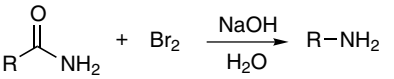
Hofmann Degradation
(Hofmann rearrangement)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hofmann in 1881.[1] It is the conversion of carboxylic amides into primary amines with one less carbon atom via the isocyanate intermediate by means of basic hypohalite treatment. Hence it is known as the Hofmann rearrangement,[2] Hofmann degradation,[2,3] or Hofmann reaction.[2,3y,3z] In this reaction, heat is needed; and in some cases, cyanate is also formed.[4] On the other hand, the Hofmann rearrangement of carboxylic amides with α-halogen yields a certain amount of ketones as well.[5] This reaction is often used as a method for cuting a single carbon atom out of a chain. In addition, the configuration of the hydrocarbon chain is retained during the migration.[6] However, the corresponding amide of pyrazine-2,5-dicarboxylic acid was found to be stable toward both hypochlorous and hypobromous acids.[3z]

B. GENERAL REACTION SCHEME

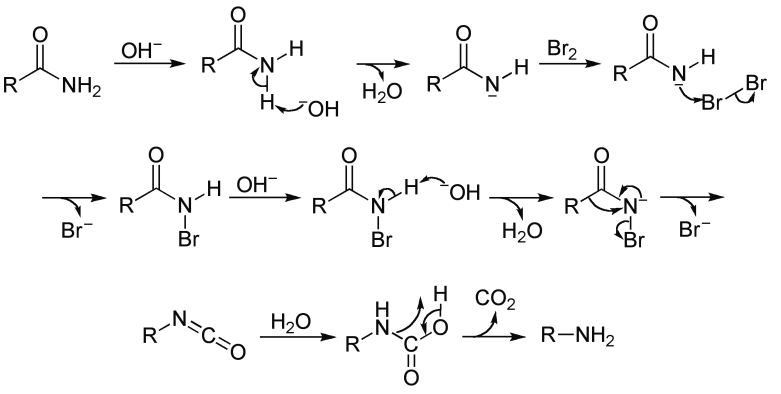


C. PROPOSED MECHANISMS

It is known that this reaction proceeds in the following steps: base abstraction of an acidic N-H proton to yield an anion, which reacts with bromine to form *N*-bromoamide; further base abstraction of the remaining N-H proton to give a bromoamide anion, which rearranges to isocyanate through the migration of an R group attaching to the carbonyl carbon and

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

cleavage of a bromide ion; nucleophilic addition of water to isocyanate affording a carbamic acid, which loses carbon dioxide spontaneously to yield the primary amine.



D. MODIFICATION

This reaction has been modified by the substitution of a hypohalite with (diacetoxyiodo)benzene.[7]

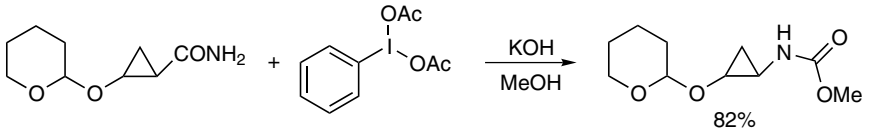
E. APPLICATIONS

This reaction has general application for the conversion of carboxylic amides into amines.

F. RELATED REACTIONS

This reaction is related to *Curtius Rearrangement*, *Lossen Rearrangement*, *Schmidt Reaction*, *Weerman Degradation*, and *Wolff Rearrangement*.

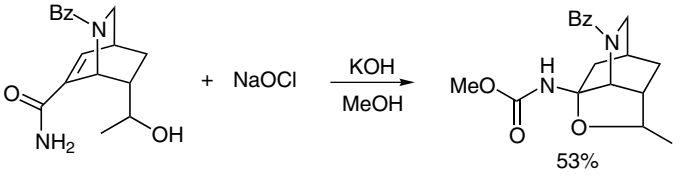
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To 100 mL methanol solution containing 7.75 g (±)-*trans*-2-tetrahydro-2H-2-pyranyloxy-1-cyclopropane carboxamide (41.84 mmol) and 6.03 g KOH (107.47 mmol) was added 13.42 g (diacetoxyiodo)benzene (41.66 mmol) at 5°C under stirring, and the stirring was continued at room temperature for an additional 2 h. The solvents were removed under reduced pressure, the residue was mixed with 70 mL water and 30 mL

dichloromethane, and the aqueous layer was extracted with dichloromethane (4 × 30 mL). The combined organic layers were washed with water and brine (50 mL each), dried, and evaporated. After column chromatography (hexane → EtOAc/hexane, 1:2), 7.37 g (±)-methyl *N*-[*trans*-2-tetrahydro-2H-2-pyranyloxycyclopropyl]carbamate was obtained as a colorless oil, in a yield of 82%, $R_f = 0.5$ (EtOAc/hexane, 1:1).



Reference 2.

The crystalline mixture of 2.30 g hydroxyamide and its epimer (8.05 mmol) in 65 mL methanol was treated with 0.85 g potassium hydroxide (15.2 mmol) in 15.7 mL 5.25% aqueous NaOCl solution (11.0 mmol). The resulting solution turned yellow and warmed spontaneously to ∼ 50°C. After 1 h it was poured into 300 mL brine, and the resulting mixture was extracted five times with chloroform. The dried extracts were evaporated to an oil, which crystallized from ether in colorless needles, 1.51 g tricyclic urethane was obtained, in a yield of 53%, m.p., 147.5–149°C.

Other references related to the Hofmann degradation are cited in the literature.[8]

Hofmann Elimination

A. GENERAL DESCRIPTION OF THE REACTION

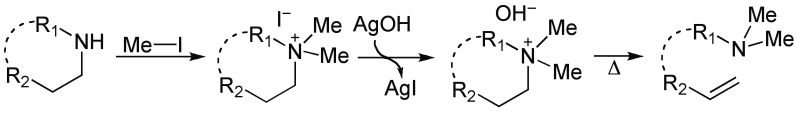
This reaction was first reported by Hofmann in 1851.[1] It is the thermal decomposition of tetraalkylammonium hydroxide to form an olefin and a tertiary amine. Therefore, this reaction is generally known as the Hofmann elimination[2,3] or Hofmann degradation.[2i,2l,2m,2aa,2gg,4] Sometimes, it is also referred to as the Hofmann decomposition,[5] Hofmann cleavage,[6] or Hofmann pyrolysis.[7] In addition, Hofmann elimination also includes the pyrolysis of tetraalkylammonium salts (often in the form of trimethylalkylammonium salt) to olefins and tertiary amines (e.g., trimethylamine) in the presence of a strong base. Thus the conversion of amines into quaternary ammonium salts maximized with methyl groups along with the formation of olefins and a tertiary amine (mostly trimethylamine) is known as the Hofmann exhaustive methylation.[2dd,2gg,8] As the nature of pyrolysis, the Hofmann elimination is often carried out in a solvent with a high boiling point,[2ee] involving a single-step (or one-step)[2hh,9] bimolecular E2 mechanism.[10] For most of aliphatic quaternary ammonium salts with a β-hydrogen atom *trans* to the amino group, stereochemical studies have shown that the Hofmann elimination proceeds almost exclusively by *anti*-elimination,[11] giving the olefins with less substituents unless a substituent on the β-carbon enhances the acidity of that particular proton (the *Hofmann Rule*).[2m] The *anti*-elimination also predominates on six-membered rings.[2o] However, a few exceptions that proceed E2 elimination via the *cis* transition state are also known, due to the enhanced acidity of proton, or conformational or steric hindrance. Examples for the violation of the *Hofmann Rule* via such elimination are the conversion of *trans*-2-phenylcyclohexyltrimethylammonium hydroxide into 1-phenylcyclohexene,[11b] the elimination of *N*,*N*,*N*-trimethyl-3,3-dimethylcyclopentylammonium hydroxide to

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

3,3-dimethylcyclopentene and 4,4-dimethylcyclopentene,[2o] the elimination of *N*,*N*,*N*-trimethyl-2-*exo*-norbornylammonium-3-*exo*-D iodide,[2y] and the *cis*-ylide elimination of *N*,*N*,*N*-trimethyl-2-*t*-butyl-3,3-dimethylbutylammonium hydroxide.[2y] It has been found that the mechanism is quite susceptible to alternation by steric factors for cyclic systems.[2o] For example, the *syn* elimination is dominated on four-membered rings, whereas *trans* elimination is favored on six-membered rings; however, steric and electronic factors can alter the elimination to a *syn* manner on six-membered rings.[2o] Furthermore, the eclipsing effects of substituents and the van der Waals interaction with bulky trimethylammonium groups can alter the mechanism as well.[12] The elimination of substituted 2-phenylethyltrimethylammonium ions gives a linear Hammett plot with ρ values usually greater than +3.0, indicating a substantial negative charge development at the β-carbon in the transition state.[11a] In addition, it has been reported that the proton transfer in the transition state is greater in the *syn* elimination than that in the *anti*-elimination.[2x] For the quaternary ammonium salts with a hydroxyl group on the β-carbon that is allowed to rotate into *anti*-coplanar to the leaving nitrogen, an epoxide forms upon the pyrolysis. If a proton occupies the position *anti*-coplanar to leaving nitrogen, however, an enol forms, which quickly tautomerizes to a ketone.[2m] In cases in which the hydroxyl group sits in the neighborhood of the ammonium group, the ether might form.[2q] For the quaternary ammonium salt with an allyl group, migration of the double bond takes place to give 1,3-diene during the elimination.[4k]

Although most of Hofmann eliminations are promoted by strong bases, some weak bases have also been reported to trigger the Hofmann elimination, such as diisopropylethylamine,[13] a mixture of diisopropylethylamine and potassium carbonate,[13] and gaseous ammonia (NH_3);[14] and ammonia has been found to be the ideal reagent for vapor-phase Hofmann elimination.[2g] On the other hand, some Hofmann eliminations are found to proceed under very mild conditions, such as the reaction in a concentrated aqueous solution of alkyltrimethylammonium hydroxide surfactants at room temperature.[2e] Furthermore, dried tetrabutylammonium fluoride (TBAF) has been reported to decompose at room temperature via the Hofmann elimination.[2a] Overall, the Hofmann elimination has been applied extensively for the structural elucidation of alkaloids[15] and analysis of alkylbenzyldimethylammonium chloride (ABDAC) in river water and sewage effluent.[4b] It is interesting that, for the alkaloid of apomorphinium system containing two β-carbons, there are two possible cleavage pathways that can be controlled under different conditions.[16]

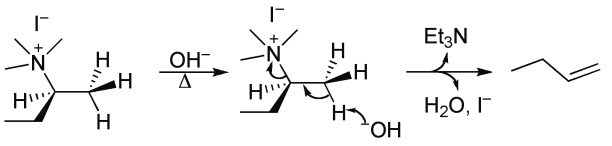
B. GENERAL REACTION SCHEME



(R_1 = H, alkyl; R_2 = H, alkyl, aryl)

C. PROPOSED MECHANISMS

Illustrated here is the elimination of isobutyl trimethylammonium iodide with hydroxide to give 1-butene.



D. MODIFICATION

This reaction has been extended to resin for the preparation of tertiary amine library.[6,13,17]

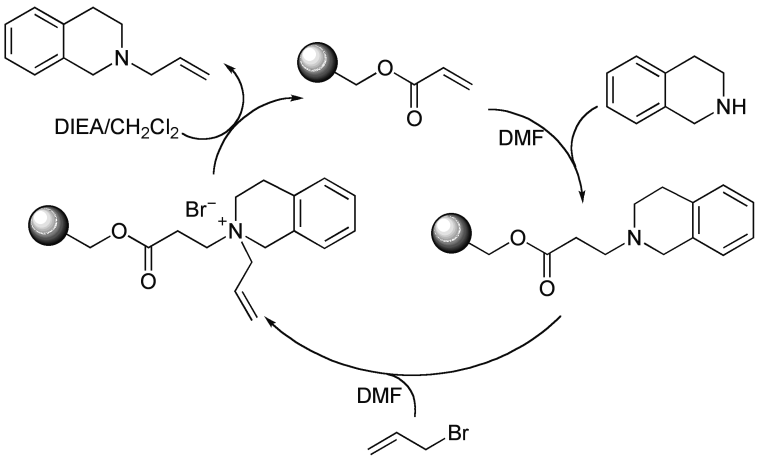
E. APPLICATIONS

This reaction has wide application in the structural elucidation of alkaloids and in the synthesis of olefins with less substituents.

F. RELATED REACTIONS

This reaction is related to the *Emde Degradation* and *Cope Elimination*.

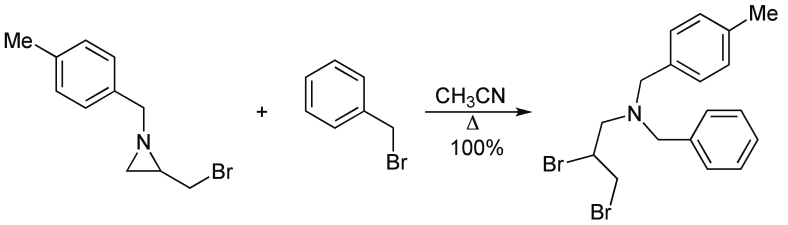
G. CITED EXPERIMENTAL EXAMPLES



Reference 13.

REM resin (a polystyrene resin) (1.0 g, 0.74 mmol) was suspended in a mixture of 927 μL 1,2,3,4-tetrahydroisoquinoline (7.4 mmol) and 7 mL DMF in a 15-mL polypropylene tube and agitated on a rotator for 2.5 h. The resin was drained and washed using a VacMaster station with DMF (4 × 2.5 mL) and then briefly dried under reduced pressure. The resin was resuspended in a solution of 326 μL allyl bromide (3.7 mmol) in 7 mL DMF and agitated on the rotator for 2.5 h. The resin was drained and washed using a VacMaster station with DMF (4 × 2.5 mL) and CH_2Cl_2 (4 × 2.5 mL), then briefly dried under reduced pressure.

The resin was resuspended in a solution of 266 μL diisopropylethylamine (1.48 mmol) in 7 mL CH_2Cl_2 and agitated on the rotator for 2.5 h. The resin was drained and washed using a VacMaster station with CH_2Cl_2 (3 $\times$ 3 mL). The filtrate was collected and evaporated. The residue was partitioned between diethyl ether (3 mL) and aqueous sodium carbonate (2 mL, 5% w/v). The organic layer was separated, and the aqueous layer was reextracted with ether (2 $\times$ 2 mL). The combined organic extracts were dried over K_2CO_3 and evaporated to dryness. 2-Allyl-1,2,3,4-tetrahydroisoquinoline was obtained as a colorless oil in a 88% yield and 99% purity. (*Note:* An aqueous extraction was used in this case for purification, because too much material was obtained for purification using a 500-mg silica SPE cartridge.)



Reference 2b.

To a solution of 3.60 g 2-(bromomethyl)-1-((4-methylphenyl)methyl)aziridine (15 mmol) in 50 mL acetonitrile was added 2.56 g benzyl bromide (15 mmol). After the solution was refluxed for 5 h, the solvent was removed in vacuo, resulting in 6.15 g *N*-benzyl-*N*-(2,3-dibromopropyl)-*N*-((4-methylphenyl)methyl)amine, in a crude yield of 100%. Pure compound can be obtained by column chromatography on silica gel using a mixture of hexane and EtOAc as an eluent.

Other references related to the Hofmann elimination are cited in the literature.[18]

Hofmann Isonitrile Synthesis
(Hofmann carbylamine reaction)

A. GENERAL DESCRIPTION OF THE REACTION

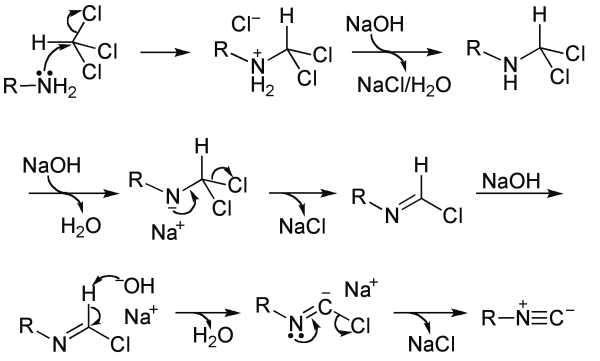
This reaction was first reported by Hofmann in 1868.[1] It is the synthesis of isonitriles (also known as isocyanides) from primary amines and chloroform in the presence of alkali and is known as the Hofmann isonitrile synthesis,[2] Hofmann carbylamine reaction,[3] or Hofmann carbylamine synthesis.[2] This reaction has been used to test the presence of primary amines from the order of isocyanides. Alternatively, the isonitriles can be prepared by means of the treatment of formamide of primary amines with toluenesulfonyl chloride[4] or phosphorus oxychloride ($POCl_3$).[4,5] Currently, the isonitriles have gained much attention in organic synthesis because of their application as versatile building blocks for heterocycles[6] and in multicomponent reactions to generate combinatorial libraries, such as that in the *Passerini reaction* and *Ugi reaction*.[7]

B. GENERAL REACTION SCHEME

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Shown below is a putative mechanism for this reaction.



D. MODIFICATION

This reaction has been modified using the conditions of phase transfer catalysis.[8]

E. APPLICATIONS

This reaction is generally used to convert primary amines into isonitriles.

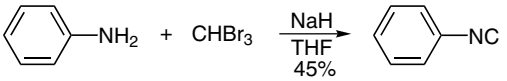
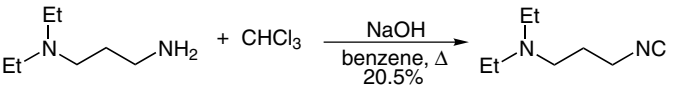
G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

The mixture of 0.1 mol aniline and 0.105 mol bromoform was added to a suspension of 0.33 mol sodium hydride (dispersed in mineral oil) in THF. After the reaction was complete, water was added dropwise to destroy any excess sodium hydride. Ether was added, and the ether solution was washed with H_2O (4 × 50 mL), dilute HCl solution (3 × 20 mL), and water. After drying over Na_2SO_4, the ether was evaporated and the residue was distilled to yield 4.65 g phenylisonitrile, in a yield of 45%, b.p., 50–55°C (13 mmHg). Redistillation gave 3.5 g of product, b.p. 52–53°C (13 mmHg). The material was light green but became colorless upon bulb-to-bulb distillation at 10^{-5} mmHg.



Reference 10.

A mixture of 40 g powdered potassium hydroxide and 100 mL benzene was placed in a 1-L round-bottomed flask equipped with a reflux condenser, drying tube, stirrer, and dropping funnel. The mixture was stirred and heated under reflux, and gradually a solution of 15.8 g 3-diethylaminopropylamine in 29 mL chloroform was added. At a point during the addition, the reaction became violently exothermic, heating was immediately discontinued, and the reaction was moderated (but not quenched) by cooling the mixture externally with ice water. The remainder of the chloroform solution was added at a rate to maintain vigorous refluxing, and the mixture was then allowed to stand until cool. It was then filtered, the brown, tarry precipitate was washed with benzene, and the washings were added to the filtrate. Solvent was removed, and further distillation gave a fraction of b.p. 87–107°C (45 mmHg), and a tarry residue. Attempted further distillation of this residue at 1.0 mmHg resulted only in decomposition. The distillate was redistilled to give 2.49 g 3-diethylaminopropylamine; 2.37 g of a mixture with a boiling point of 86–105°C (45 mmHg); and 2.99 g 3-diethylaminopropyl isocyanide (20.5%) as a clear, colorless liquid, b.p. 105–107°C at 45 mmHg.

Hofmann Rule

A. GENERAL DESCRIPTION OF THE REACTION

The Hofmann rule is formulated on the basis of product distribution in the decomposition of a quaternary ammonium hydroxide initially reported by Hofmann in 1851 (i.e., *Hofmann Elimination*).[1] The Hofmann rule[2] states that the major product will be an olefin having the smallest number of attached alkyl groups[3]—that is, the product of less thermodynamical stability.[4] This rule was extensively studied first by Hughes and Ingold, who proposed that the Hofmann rule was applicable to a bimolecular elimination (E2), which was controlled by the polar factor from the positive charge in the "onium ion," whereas the elimination (e.g., of the alkyl halides) that gives the most substituted olefin follows the *Saytzeff Rule*, which is controlled by the electronic factor.[5] However, Hughes and Ingold's proposition was challenged by a group of researchers including Brown,[2d,2e,4,6] Saunders,[7] Cope,[8] Baumgarten,[9] Bailey,[3,10] DePuy,[11] Bartsch,[12] and Brawerman.[13] In particular, the extensive experimental evidence from Brown, Saunders, Bailey, and Cope indicated that the elimination of quaternary ammoniums,[3,7b,7c,8,11] tertiary sulfonium salts,[2d,3,7c,11] pyrolysis of secondary and tertiary esters of acetic acid,[3,10b] and so on all follow the Hofmann rule and are primarily controlled by the steric effect, not the polar factor (e.g., the acidity of hydrogen to be eliminated[11]). These experiments also showed that except for the highly strained molecules, first-order elimination reactions tend to follow the *Saytzeff Rule*, but bimolecular elimination reactions may follow either the *Saytzeff Rule* or the Hofmann rule,[3] depending on the steric nature of the alkyl groups on the incipient double bond,[2d] the attacking base,[2d,13] and the leaving group.[2d] In addition, the hyperconjugative effect[11] and the strength of the base[7a,7b] used also affect the elimination direction. Only when the steric factors are canceled out, or the electronic effects become overwhelming, do Saytzeff products dominate.[11] Thus the formation of desired olefins can be controlled by choosing different attacking bases, as

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

in the case for the elimination of 2-haloalkane:1-alkene is obtained predominantly when potassium *t*-butoxide is used, whereas 2-alkene is the major product when an ethoxide base is applied.[13] However, the elimination of alkyl fluorides[7d] and the pyrolysis of cyclohexyl carbinol acetate always give Hofmann products; in the latter case, the formation of an *exo* double bond to the six-membered ring is avoided.[14] In addition, the functional groups that can conjugate with the forthcoming double bond might alter the direction of elimination too (e.g., as a carbonyl group or a nitro group[10b]); however, one phenyl group is not strong enough to turn over the preference in the elimination direction.[10b] On the other hand, the effect of the base on the *trans*:*cis* ratio depends on the stereochemistry of the reaction.[7b] For example, the stronger base in a pure *anti* elimination gives more *cis*-olefin, but, if a *syn* elimination competes with *anti*-elimination, the application of a stronger base results in a higher proportion of *trans*-olefin. In the former case, known as the "normal" pattern, the increase in the Hofmann rule product is accompanied by a decrease in the *trans*:*cis* ratio of the olefins. In the latter case, known as "abnormal" pattern, the Hofmann rule product and the *trans*:*cis* ratio of the olefins increase in the same direction.[7b]

B. GENERAL REACTION SCHEME

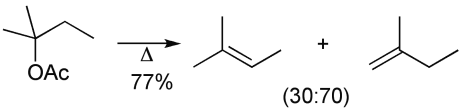
E. APPLICATIONS

This rule is useful in predicting and rationalizing the structures of elimination products.

F. RELATED REACTIONS

This rule is related to *Saytzeff Rule*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 10a.

To a pyrolysis apparatus consisting of a Vycor tube packed with Pyrex helices and externally heated with a 12-in. Hoskins furnace at 400°C was added dropwise 16.0 g *t*-amyl acetate (0.12 mol) at the rate of 1 g/min to the top of the tube. In the end of the pyrolysis, a small sample of the pyrolysate was immediately analyzed by GC, indicating a mixture of 70% 2-methyl-1-butene and 30% 2-methyl-2-butene. After the pyrolysate had been washed with water until neutral, the aqueous extracts were titrated with standard base to indicate that 77% of acetic acid has been librated.

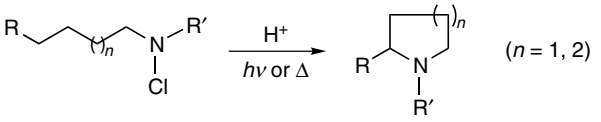
Hofmann-Löffler-Freytag Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hofmann in 1883,[1] and then extended by Löffler et al. after 1909.[2] It is the synthesis of pyrrolidine or piperidine derivatives by thermal or photochemical decomposition of the protonated aliphatic *N*-haloamines. Historically, this reaction has been known as the Löffler method,[3] Löffler-Freytag reaction,[4] Hofmann-Löffler reaction,[5] and Hofmann-Löffler-Freytag cyclization,[6] but the Hofmann-Löffler-Freytag reaction[7] is the most commonly used name today. Corey[5d,7p] and Wawzonek[8] provided many experimental evidences to support the radical mechanism of this reaction, such as the initiation of the reaction by either photo-irradiation or traditional radical initiators and the inhibition of reaction by oxygen. Without radical initiation (e.g., UV light), the *N*-haloamines are stable even in 85% sulfuric acid in the dark at room temperature;[5b] in contrast, the same protonated *N*-haloamines disappear within 3 h if irradiated by even a weak UV light source, such as a chromatography column scanner.[5d] In this reaction, hydrogen abstraction is the chain-propagating step.[7h] It is known that the bond energy of secondary C-H (e.g., Me_2CH-H) is 358 KJ/mol, and the bond energy of Me_2N-H is 383 KJ/mol.[7h] Obviously, it is mildly exothermic for hydrogen abstraction by aminyl radicals on hydrocarbons. Moreover, the protonation of aminyl radicals to give aminium radicals considerably enhances the electron deficiency of nitrogen, which would dramatically facilitate the hydrogen abstraction.[9] On the other hand, even though both pyrrolidines and piperidines are potential products of this reaction, pyrrolidines are the most favored products,[5c,5d,7p] possibly because of the kinetic factor. Currently, many other methods have been established to generated aminium radicals, including electrochemistry,[10] pulse radiolysis,[11] and the reduction of photosensitizers (e.g., ketone triplet, dicyanobenzene).[12] It should be pointed out that this reaction has been extended to amidyl radicals.[7c,13]

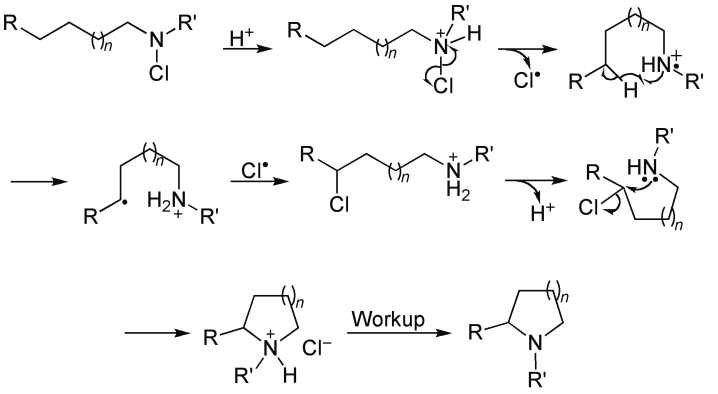
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Proposed here is a tentative mechanism for the Hofmann-Löffler-Freytag reaction.



D. MODIFICATION

This reaction has been extended to amidyl radical,[7c,13] sulfonamidyl radical,[7b] and other nitrogenous radicals.[14]

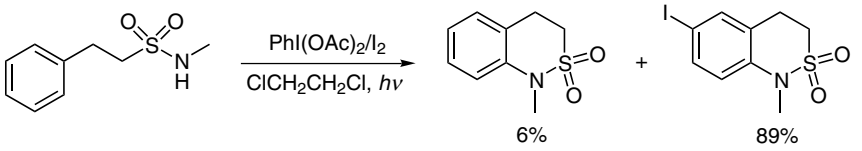
E. APPLICATIONS

This reaction has been widely used in the synthesis of substituted pyrrolidines and piperidines.

F. RELATED REACTIONS

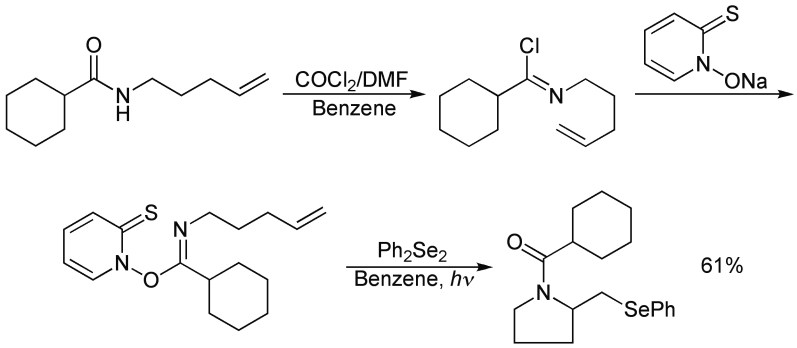
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7b.

(Diacetoxyiodo)benzene (0.8 mmol) and 0.5 mmol iodine were added to a solution of 0.5 mmol *N*-methyl phenylethylsulfonamide in 5 mL dichloroethane. The mixture was irradiated with a 500-W tungsten lamp at 20–30°C for 2 h under an argon atmosphere. After the reaction, the mixture was poured into a saturated aqueous sodium sulfite (Na_2SO_3) solution and extracted with $CHCl_3$ three times. The organic layers were combined and dried over Na_2SO_4. After removal of the solvent under reduced pressure, the residue was chromatographed by preparative TLC on silica gel using a mixture of hexane, EtOAc, and $CHCl_3$ (6:3:1) as the eluent, to give 6% *N*-methyl-3,4-dihydro-2,1-benzothiazine-2,2-dioxide, m.p. 77.0–79.0°C and 89% *N*-methyl-6-iodo-3,4-dihydro-2,1-benzothiazine-2,2-dioxide, m.p. 139.0–141.0°C.



Reference 13a.

To a solution of 402 mg *N*-(4-pentenyl)cycloyexanecarboxamide (2.15 mmol) in 21.5 mL benzene containing a catalytic amount of DMF at ~ 5°C was transferred 1.5 eq. phosgene (1.9 M of phosgene in toluene). The solution was allowed to warm slowly to ambient temperature with stirring. The slow evolution of CO_2 was monitored via a mineral oil bubbler. After ~ 12 h, the evolution of CO_2 was complete. Excess amounts of phosgene and solvent were removed by distillation at room temperature under reduced pressure to give the imidoyl chloride as a clear liquid. Dry ether was added to give a 0.1 M solution of imidoyl chloride. The flask was wrapped in aluminum foil, and 1.2 eq. anhydrous 2-mercaptopyridine *N*-oxide sodium salt was added via a solid addition tube under nitrogen. The mixture was stirred for 4–8 h. The residual salts were removed by filtration under nitrogen and were washed with dry ether. Concentration of the filtrate in vacuo gave 1-[(*N*-(4′-pentenyl)cyclohexanecarboximidyl)oxy-2(1H)-pyridinethione as a yellow oil.

The product was dissolved in benzene at 0.05 M concentration; then under a nitrogen atmosphere was added 1.2 g diphenyl diselenide (3.8 mmol). The solution was irradiated

for 10 h. Removal of the solvent and then radial chromatography (hexane/EtOAc, 4:1) gave 456 mg *N*-(cyclohexylcarbonyl)-2-[(phenylseleno)methyl]pyrrolidine, in a yield of 61%. Recrystallization from hexanes gave a material with a melting point of 81–83°C.

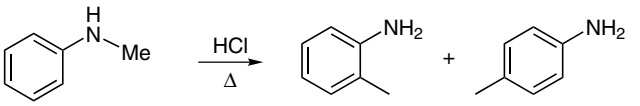
Hofmann-Martius Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hofmann and Martius in 1871.[1] It is the thermal conversion of hydrohalides of *N*-alkylated aromatic amines to *o*-alkylated and *p*-alkylated aromatic amine derivatives and is generally known as the Hofmann-Martius rearrangement.[2] It is known that the *N*-alkylated aromatic amine hydrochlorides dissociate upon heating[3] and then the new components undergo the intermolecular alkylation,[2h,4] involving the migration of an alkyl group in the form of free radical,[4b] olefin[3,4b] or carbocation.[3,4a] However, evidence also indicates the combination of both radical and olefin pathways.[4b] The Hofmann-Martius rearrangement in the solid state mostly gives *ortho*-alkylated products, possibly because of limited diffusion.[5] In addition, the Hofmann-Martius rearrangement can be triggered by photo-irradiation.[6]

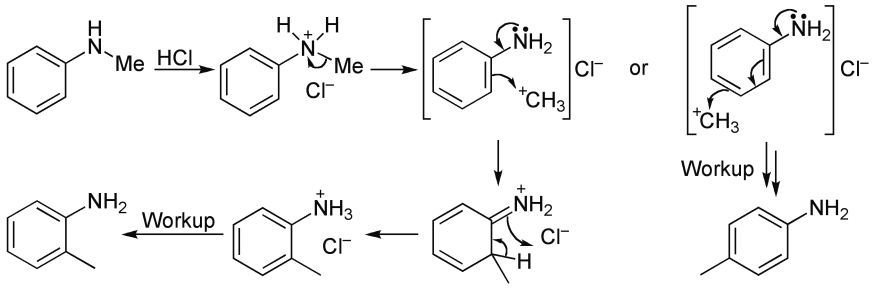
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A cationic mechanism is displayed here for the thermal rearrangement of *N*-methyl aniline hydrochloride, without the formation of methyl chloride as a reaction intermediate.



D. MODIFICATION

This reaction has been modified to the conditions promoted by photo-irradiation.[6]

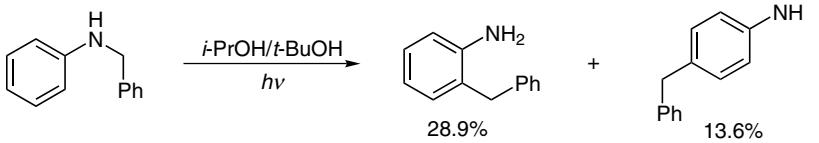
E. APPLICATIONS

This reaction is useful for the preparation of substituted aromatic amines.

F. RELATED REACTIONS

This reaction is related to *Fischer-Hepp Rearrangement*, *Orton Rearrangement*, and *Reilly-Rickinbottom Rearrangement.*

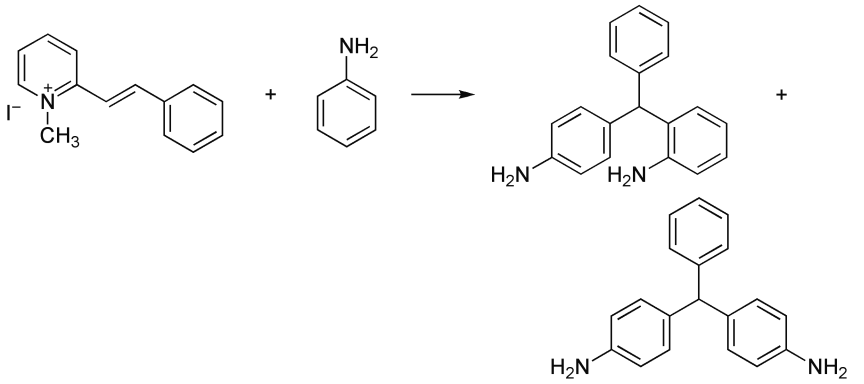
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A solution of 300 mL isopropyl alcohol/*t*-butyl alcohol containing 3.83 g *N*-phenylbenzylamine was irradiated under nitrogen gas for 30 h. The concentrated reaction mixture was chromatographed on a 15 × 300-mm column, slurry packed in benzene/3% acetone with 100-mesh silica gel, using benzene/3% acetone as the eluent. Three components

were obtained in the order of *N*-phenylbenzylamine, *o*-benzyl-aniline (28.9% yield), and *p*-benzyl-aniline (13.6% yield), in a total conversion of 55.4%.



Reference 7.

A mixture of 25.0 g *trans*-2-styrylpyridine methiodine and 50.0 g aniline was heated under reflux for 1 h. The cooled reaction mixture was washed with dilute ammonium hydroxide solution, and organic material was extracted with ether. The ether extract was washed with water and dried over $MgSO_4$. The excess aniline and ether was removed under reduced pressure to give a brown oil that crystallized from benzene to yield 15.0 g of colorless prisms. A portion of this material (4.25 g) was chromatographed on silica gel with an increasing percentage of EtOAc in benzene as the eluent. The desired portions were evaporated to yield 0.6 g 2,4′-diaminotriphenylmethane and 1.95 g 4,4′-diaminotriphenylmethane. An intermediate cut yielded 1.15 g of a mixture of these two compounds. Pure 4,4′-diaminotriphenylmethane (1.2 g) was obtained as colorless prisms from crystallization in benzene, m.p. 137–138°C, and a sublimed sample of this molecule had a melting point of 142–144°C. Similarly, 0.4 g pure 2,4′-diaminotriphenylmethane was obtained from the crystallization in benzene, m.p. 99–104°C (with benzene in presence), and the sublimed sample had a melting point of 131–132°C.

Other references related to the Hofmann-Martius rearrangement are cited in the literature.[8]

Hofmann-Sand Reaction

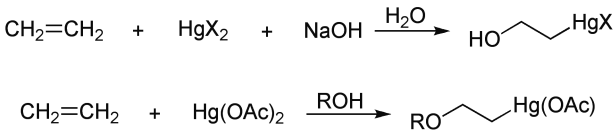
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hofmann and Sand in 1900.[1] It is the reaction between mercuric salt (acetates, halides, nitrates, or sulfates) and compounds containing a carbon-carbon double bond in aqueous or alcoholic solutions to form either addition products or coordination complexes or both. In addition, the solvents also participate in this reaction causing hydrolysis or alcoholysis to give products containing hydroxyl or alkoxyl groups. The formed compounds characteristically decompose to regenerate the olefins in the presence of hydrochloric acid, often in only 5% concentration, except for the product of dibenzoyl derivative and mercurated 1,2-dihydrobenzofurans.[2] For example, 1-chloromercurimethyl-1,2-dihydrobenzofuran is perfectly stable in boiling acetic acid and does not decompose after standing in 15% hydrochloric acid or 50% sulfuric acid for several days at ordinary temperatures;[2b] in addition, the corresponding sulfate is even more stable to acids than chloride.[2b] The overall reaction outcome depends on the following factors:[3] the structure of olefin, the acidity of the solution, the anion in mercuric salt, and the temperature and the concentration of solution. For example, allyl alcohol usually gives an internal ether product.[2,4] In this reaction, the *trans*-olefin normally reacts more sluggishly than the *cis*-isomers,[5] by which unsymmetrical olefins give products with the mercury atom attaching to the carbon of fewer substituents[3] and the existing negative group hinders and may even prevent the reaction.[3] On the other hand, mercuric nitrate and acetate are the best salts for general use, and the reaction usually completes when the solution of the reactants no longer gives a precipitate of mercuric oxide with caustic alkali.[3] It should be pointed out that the Hofmann-Sand reaction occurs most readily in methanol solution in which even *trans*-olefins with negative groups attached would react.[6] In this reaction, the mercuric salt-olefin adducts are crystalline substances with relatively high thermal stability[3]—for

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

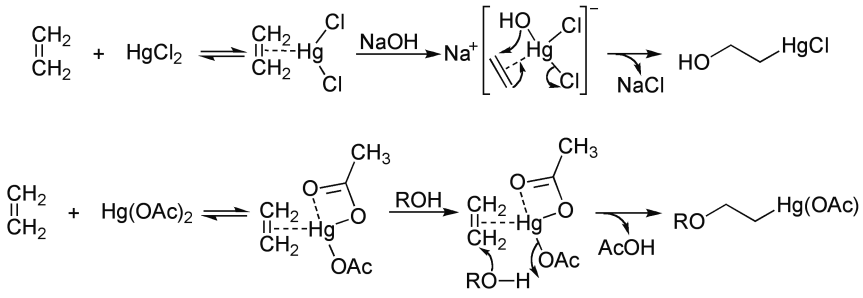
example, both *cis*- and *trans*-1-methoxy-2-(chlormercuri)-cyclohexanes can be distilled under vacuum without decomposition.[7] Except for their greater density, the mercurate salt-olefin adducts are typical organic compounds, which can further react with a variety of compounds.[3] Some of the reactions that the mercurate salt-olefin adducts undergo are (*a*) conversion into iodohydrin by treatment with iodine in KI solution,[2b] (*b*) reduction to alcohol by sodium amalgam,[3] (*c*) conversion into ether compound in 5% H_2SO_4,[8] (*d*) regeneration of olefin in aqueous solution of cyanides and thiocyanates,[1a] (*e*) conversion to sulfide from hydrogen sulfide,[1a,1b] (*f*) reaction with alkyl halide to form alkyl alcohol along with the evolution of the original olefin,[9] (*g*) liberation of olefin when reacting with Grignard reagent[5c] along with the isomerization of *cis*-olefin to *trans*-olefin,[10] and (*h*) formation of aldehyde when reacting with diazonium salt.[11]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Based on many experimental details, it is strongly believed that olefins form a coordination complex with mercuric salts in solution, which can decompose to release olefins again. As only 10 outer electrons are available for Hg^{2+}, the complexes from olefin and mercuric halides that do not have a stable 18-electron configuration require additional ligands of hydroxide in aqueous solution; for comparison, the complexes from olefin and mercuric acetate are stable because acetate is bidental. Olefin is activated as of coordination, so that the formation of an addition product is quite possible. A tentative mechanism is outlined here to show the dynamic equilibrium between the coordination complex and the addition product.



D. MODIFICATION

N/A

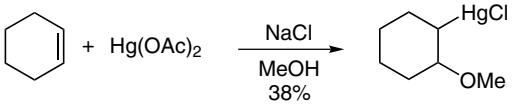
E. APPLICATIONS

This reaction is very useful for the determination of olefinic configuration and the conversion of *cis*-olefins into *trans*-olefins.

F. RELATED REACTIONS

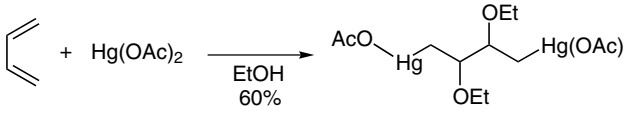
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

When 1.96 g cyclohexene (0.024 mol) and 3.19 g mercuric acetate (0.01 mol) were left to stand 11 days, a residue remained after 1 h of evaporation under 12 mmHg. This gummy residue was dissolved in 25 mL methanol. After 3 days, the solution was poured into dilute sodium chloride to yield 1.32 g α-1-chloromercuri-2-methoxycyclohexane, in a yield of 38%.



Reference 12.

Mercuric acetate (40 g; 0.125 mol) and 225 mL absolute ethanol were placed in a 500-mL filtering flask fitted with a large expansion bulb reaching nearly to the bottom of the flask. Gaseous 1,3-butadiene (0.067 mol) from the sulfone, or from a measured quantity of liquid butadiene in a test tube was introduced through the side tube of the filtering flask. The reaction mixture was shaken to facilitate absorption of the gas. After the absorption started, the flask was placed on a hot plate and maintained just below the boiling point of the ethanol. The mercuration can be carried out with good results at room temperature, but a longer time is required because the mercuric acetate dissolves quite slowly. When all of the butadiene had been absorbed, a test portion of the solution was withdrawn and made alkaline with aqueous sodium hydroxide. If a yellow precipitate of mercuric oxide formed, a small additional quantity of butadiene was introduced, and the absorption process continued until the sodium hydroxide test was negative. The mercuration mixture was allowed to cool

to 20°C, and the crystals of the less soluble product (α-isomer) were filtered with suction and washed twice with ether. The first crop of crystals weighed 20–23 g. The filtrate and washings were subjected to distillation on a steam bath until most of the alcohol had been removed. The residue was filtered when cold, and the filtrate was reserved for isolation of the more soluble product (β-isomer). The second crop of crystals of the α-isomer was washed with ether and combined with the first crop, giving a total amount of 25 g α-isomer (60% yield, based on mercuric acetate). The product formed colorless crystals from ethanol, m.p. 162–163°C.

Hooker Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hooker in 1936.[1] It is the oxidation of 2-hydroxy-3-alkyl (or alkenyl)-1,4-benzoquinones into its homologs with alternated hydroxy and alkyl groups of one less carbon by alkaline permanganate or the combination of hydrogen peroxide and sodium carbonate. Therefore, it is generally known as the Hooker oxidation.[2] This reaction is known to occur through at least three stages:[2d] initial cleavage of the C=C bond to form aromatics with keto acid and ketyl side chains, subsequent *Aldol Condensation* of an activated methylene group to a neighboring keto acid to form a six-membered ring, further decarboxylation and aromatization resulting in 1,4-hydroquinone with alternated hydroxy and alkyl groups of one less carbon, and the final oxidation of 1,4-benzohydroquinones into 1,4-benzoquinones. This mechanism has been proved either by comparison of oxidized derivatives with different substituents (e.g., Br)[2e] or isotopic labeling.[2a] It has been suggested that for the oxidation of quinones with saturated side chains a rather strong alkaline solution is required, and the reaction is normally conducted at 0–5°C by quickly mixing the solution of hydroxyquinone in 1% alkali and potassium permanganate in 10% alkali.[3] This reaction usually gives very pure products with yields generally in the range of 70–80%. In addition, in some cases, the yield is even better if the reaction is conducted in more concentrated alkali solution.[3] However, the oxidation of those benzoquinone with unsaturated side chains requires a much less strong alkaline medium—for example, using aqueous potassium permanganate without alkali—and gives much lower yields, in the range of 35–40% or even lower.[3] This reaction can be repeated until the side alkyl chain is completely cut off.[3] This reaction is a valuable tool for the preparation of substances that might otherwise be difficult to make and is also useful for the determination of the side chains of benzoquinones.[3]

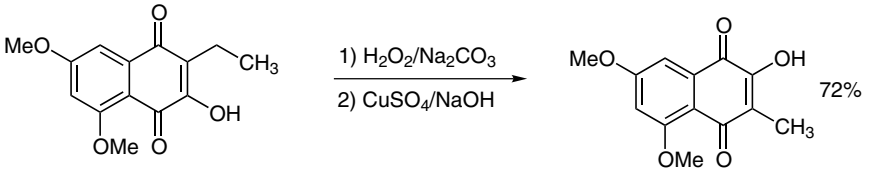
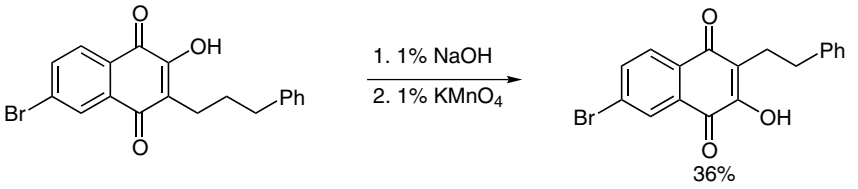
G. CITED EXPERIMENTAL EXAMPLES



Reference 2a.

To a 50-mL round-bottomed flask charged with 1.5 mL dioxane, 1.5 mL H_2O, and 64 mg Na_2CO_3 (0.6 mmol) was added 131 mg 2-ethyl-3-hydroxy-5,7-dimethoxy-1,4-naphthoquinone (0.5 mmol). The resulting burgundy colored mixture was heated with H_2O_2 (30%, 0.2 mL) at 60°C until the solution became colorless to pale yellow. Upon cooling in ice bath, the reaction mixture was treated with 5 drops 36% HCl and H_2O saturated with SO_2. A stream of nitrogen was then bubbled through the solution for 30 min. Next, the mixture was treated with 1 mL 25% NaOH solution and a solution containing 0.5 g $CuSO_4$ (3 mmol) in 4 mL H_2O; the mixture was heated at 70°C until the starting blue solution became red in color (∼ 1 h). The solid components were removed by vacuum filtration through a pad of Celite. The filtrate was then treated with conc. HC1, resulting in a yellow solution (pH 1–2). Extraction with $CHC1_3$ (3 × 50 mL) was followed by a back washing of the aqueous layer with $CHCl_3$ (2 × 25 mL). The combined organic portions were washed with 10 mL brine, dried over $MgSO_4$, and concentrated in vacuo. Flash column chromatography (3:l, hexanes/EtOAc) gave 89 mg 2-hydroxy-5,7-dimethoxy-3-methyl-1,4-naphthoquinone as a yellow solid, m.p. 223–225°C.



Reference 2e.

A solution of 3.0 g 2-hydroxy-3-(γ-phenyl)propyl-6-bromo-1,4-naphthoquinone in the required amount of benzene was stirred in 600 mL hot 1% NaOH solution, and the red solution was cooled to 0°C and treated with 189 mL 1% $KMnO_4$ also at 0°C. The solution becoming practically colorless (spot test) and then reaching a maximum intensity of red in 1 to 2 h. The yield of precipitated, nearly pure material was 36%. Crystallization from alcohol containing acetic acid afforded 3-hydroxy-2-(β-phenyl)ethyl-6-bromo-1,4-naphthoquinone as golden yellow needles, m.p. 173–175°C.

Horenstein-Pählicke Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Horenstein and Pählicke in 1938.[1] It is the reaction between substituted aryl carboxylic acid and *N*,*N*-dialkylamino alkyl halide to give a corresponding *N*,*N*-dialkylaminoalkyl arylcarboxylate hydrochloride,[2] specifically for the preparation of a group of molecules with anesthetic activity.[3] Therefore, this reaction is often known as the Horenstein-Pählicke reaction.[2b,4] In addition, it is also referred to as the Horenstein-Pählicke process[5] or Horenstein-Pählicke condensation.[2a] Under these reaction conditions, the common self-condensation of *N*,*N*-dialkylamino alkyl halides[4c] is minimized. Often, the aryl carboxylic acid, such as 2-hydroxy-4-nitrobenzoic acid, is refluxed with *N*,*N*-diakylamino alkyl chloride in isopropanol in the presence of a base (e.g., K_2CO_3). However, the protection of hydroxyl group by a benzyl other than acetyl will increase the yield.[2b] In addition, it has been found that the reaction in butanol will give a higher yield than that in isopropanol and the direct reaction between aryl carboxylic acid and alkyl halide will give even higher yields.[6] This reaction works mainly for primary alkyl halides and is not good for secondary alkyl halides, such as 1-methyl-3-chloro-pyrrolidine.[6] Besides the alcoholic solvent, this reaction is often carried out in dry toluene under basic conditions.[4c,7]

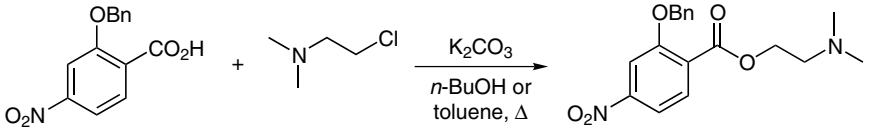
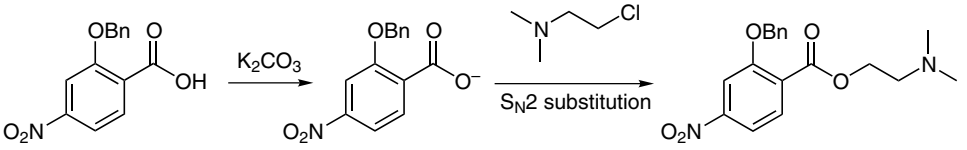
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur in sodium-dried toluene.[7]

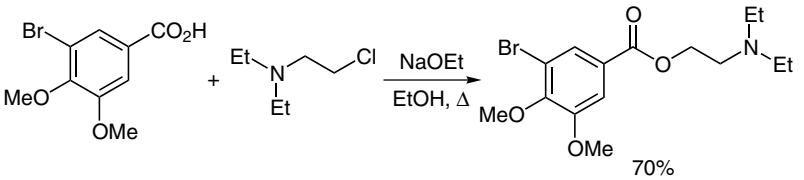
E. APPLICATIONS

This reaction is specifically used for the preparation of *N*,*N*-dialkyl alkyl arylcarboxylates.

F. RELATED REACTIONS

N/A

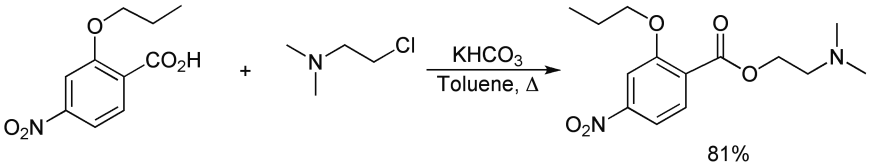
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

To 150 mL absolute ethanol containing 3.3 g clean, freshly cut sodium (0.15 mol) was added, with stirring, 13 g 5-bromomethylvanillic acid (0.05 mol). The mixture was

then stirred and refluxed for 30 min. After the mixture was cooled to room temperature, the salt was filtered off, washed with absolute ethanol, and allowed to dry. The dried salt was then suspended in 200 mL sodium-dried toluene and treated with 8.5 g β-diethylaminochloroethane hydrochloride (0.05 mol). The mixture was then stirred and refluxed for 18–20 h. The hot mixture was then filtered. On cooling, the filtrate was washed with 10% NaOH (2 × 75 mL) followed by water. The toluene layer of the basic ester was then dried for several hours over $MgSO_4$. Anhydrous HCl was then bubbled through the toluene solution until salt formation was complete. The product was filtered, allowed to dry in a desiccator, and then recrystallized from a mixture of absolute ethanol and anhydrous ether, to give 70% of a water-soluble product, which melted at 164–165°C.



Reference 4c.

A mixture of 22.5 g 4-nitro-2-*n*-propoxy benzoic acid (0.10 mol), 11.0 g $KHCO_3$, and 400 mL dry toluene was stirred and refluxed under a water trap until dehydration was complete (~ 2 h). The water trap was removed, and 12.9 g 2-dimethylaminoethyl chloride (0.12 mol) was added. Stirring and refluxing were continued for 20 h. The mixture was filtered while hot, and the filter cake was washed well with hot toluene. The toluene was removed from the combined filtrates in vacuo and the residual oil was dissolved in dilute hydrochloric acid. After decolorization, the solution was treated with solid K_2CO_3, and the liberated base was taken up in EtOAc. After drying over Drierite, EtOAc was evaporated in vacuo and 24.0 g 2-dimethylaminoethyl 4-nitro-2-*n*-propoxy benzoate was obtained as oil, in a yield of 81%.

Horner-Wadsworth-Emmons Olefination

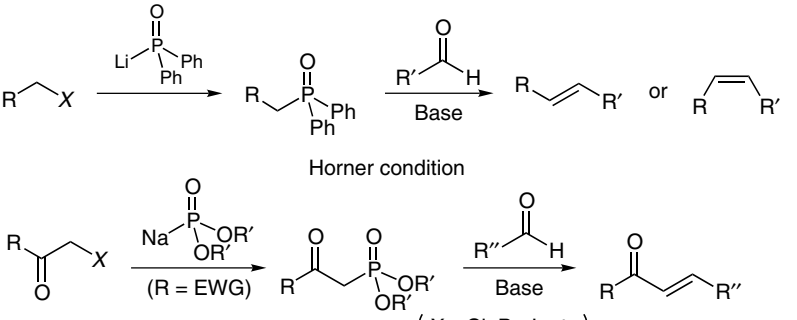
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Horner et al. in 1958[1] and subsequently modified by Wadsworth and Emmons in 1961.[2] In fact, it is the further modification of the *Wittig Reaction*.[3] The Horner-Wadsworth-Emmons (HWE) olefination is the synthesis of olefins from the condensation between carbonyl compounds (both aldehydes and ketones) and carboanions derived from alkyl phosphine oxides (Horner's condition),[1] phosphonates (Wadsworth and Emmons's condition),[2] phosphonamides (Corey),[4] and their thiono counterparts (Corey).[5] All these reaction conditions have obvious advantages over the original *Wittig Reaction*, such as the higher nucleophilicity and the basicity of phosphonate-stablized carbanion compared to the corresponding phosphonium ylides and the easy removal of dialkylphosphate salt (by-product of this reaction) by simple aqueous extraction. Historically, this reaction has been known as the Horner-Wadsworth-Emmons reaction (HWE reaction),[6,7] Horner-Wadsworth-Emmons olefination (HWE olefination),[8,9] Horner-Wadsworth-Emmons condensation,[6k,10] Horner-Wadsworth-Emmons coupling,[11] Horner-Wadsworth-Emmons homologation,[12] etc. The starting materials of dialkyl phosphonates can be prepared by the *Michaelis-Arbuzov Rearrangement*,[13] *Michaelis-Becker Reaction*,[14] acylation of alkyl phosphonate anion,[15] and phosphonate ester interchange.[16] In this reaction, the rate-determining step is the addition of phosphonate anion into the carbonyl group,[17] where the carbanion-stabilizing group is necessary for the elimination to occur;[5] otherwise, the β-hydroxyphosphonates form from the nonstabilized phosphonates.[18] During the elimination, both *Z*-olefins and *E*-olefins are possible, and the ratio depends on the stereochemical outcome of the initial addition and the ability of the intermediate to equilibrate. Generally speaking, for disubstituted olefins (from aldehydes), the $E : Z$ ratio increases when the reversibility of the nucleophilic addition increases (i.e., increasing of the retroaddition rate relative to the rate of elimination).[19] Other conditions that favor the

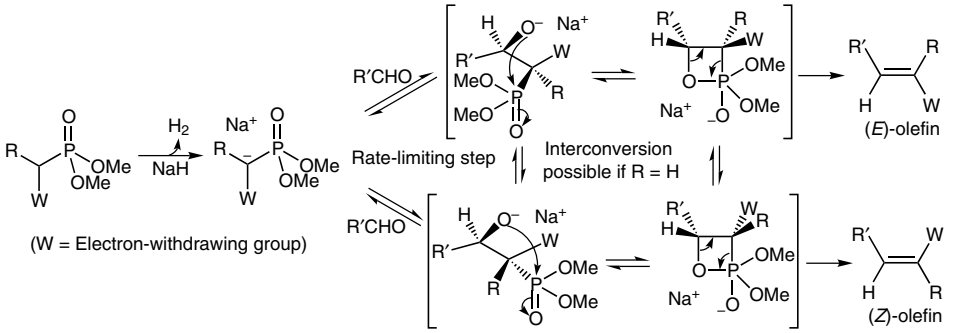
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

E-selectivity are: bulky phosphonate and ester substituents,[20] substitution solvent of THF with DME, higher reaction temperature, increased α-substitution of the aldehyde, and a cation order of $Li^+ > Na^+ > K^+$. For comparison, the trisubstituted olefins can be synthesized either from the α-branched phosphonates with aldehyde or phosphonates with ketones. Some hindered ketones do not undergo the original *Wittig Reaction* but do take place for the HWE olefination.[21] On the other hand, the HWE olefination is normally performed in the presence of a relatively strong base such as *n*-BuLi, KOBu^t, or NaH;[22] therefore, this reaction is complicated by the *Aldol Condensation*[6k,22] or other reactions that aldehydes and ketones normally undergo under such conditions. Therefore, Masamune and Roush introduced mild conditions (LiCl, amine base, ambient temperature) for the olefination of base-sensitive substrates or phosphonates.[23] In addition, Ando improved the condition to enhance the *Z*-selectivity by using a combination of NaI/DBU/THF.[6e,6h,22,24] Similarly, Still and Gennari reported the synthesis of trisubstituted olefins with high *Z*-selectivity from methyl [bis(trifluoroethyl)phosphono]propionate in THF in the presence of KHMDS/18-crown-6.[16a] Further modifications on this reaction include the application of chiral phosphonates (phosphonamides),[25] parallel kinetic resolution according to the difference in rates of enantiomeric aldehydes,[6c] control of the 1,4-asymmetric addition and 1,2-addition to α,β-unsaturated carbonyl compounds,[26] and synthesis of tetrahydrofuran and pyran derivatives.[27] This reaction has successfully been applied to the preparation of some macrolides, including (-)-Vermiculine,[28] (-)-Asperdiol,[29] Amphotericin B[30] FR182877,[31] and dactylolide.[32] This reaction has been extensively reviewed.[13,18,33]

B. GENERAL REACTION SCHEME

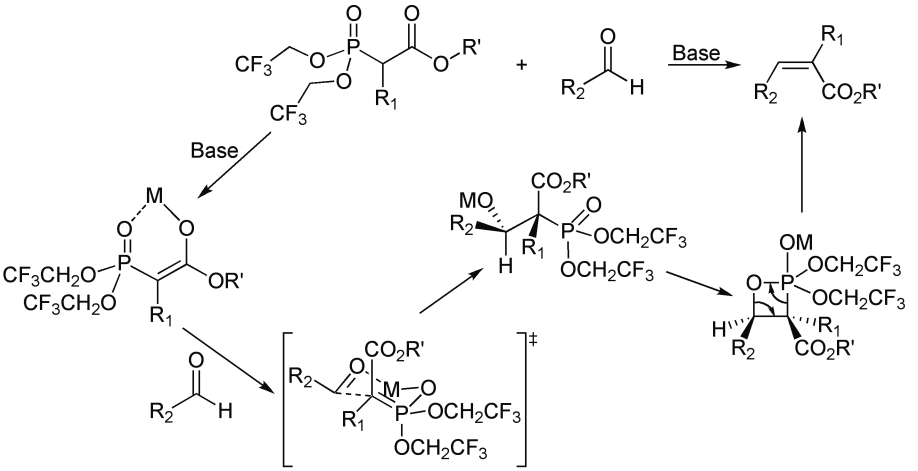


C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur under mild conditions such as those of Masamune and Roush, Still, and Ando. In addition, chiral phosphonates (or phosphonamides) have been used for this reaction. In particular, the method developed by Still and Gennari using [bis(trifluoroethyl)phosphono] esters, generally known as Gennari-Still phosphonates,[34] is very useful in the preparation of *Z*-olefins.[16a] Illustrated is the HWE reaction using Gennari-Still phosphonates to give *cis*-olefins, and its mechanism.



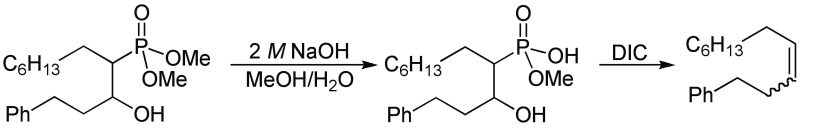
E. APPLICATIONS

This reaction has very wide application in the synthesis of compounds containing carbon-carbon double bond(s).

F. RELATED REACTIONS

This reaction is closely related to *Wittig Reaction*. This reaction is also related to *Peterson Reaction* and *Tebbe Reaction.*

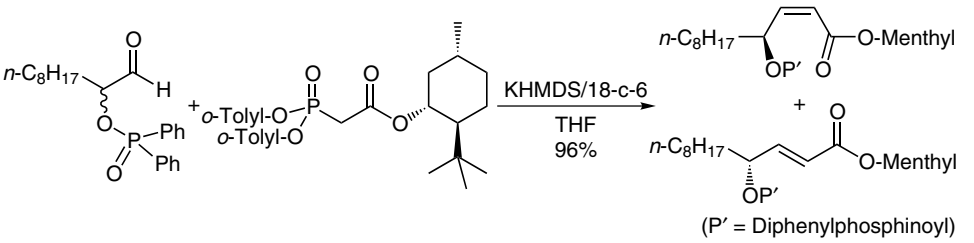
G. CITED EXPERIMENTAL EXAMPLES



Reference 35.

To a solution of 1.1 mmol [1-(1-hydroxy-3-phenyl-propyl)-octyl]-phosphonic acid dimethyl ester in 5.0 mL methanol was added 5.0 mL 4 M NaOH. After being stirred at room temperature for 16 h, the reaction mixture was acidified to pH < 2 with 1 M HCl, extracted with CH_2Cl_2, dried over $MgSO_4$, and concentrated in vacuo. The reaction residue

was dissolved in 5.0 mL $CHCl_3$ and treated with 2.2 mmol diisopropylcarbodiimide. After being stirred at room temperature for 4 h, the reaction mixture was concentrated in vacuo. Purification of the residue by flash chromatography (SiO_2, hexane) afforded 99.0 mg 1-phenyl-3-undecene (0.382 mmol) as a colorless oil, $R_f = 0.65$ (hexane).



Reference 36.

To a solution of phosphonate (1.0 eq. 0.02 M in THF) and 18-crown-6 (5 eq.), precooled to -78°C, was added KHMDS (1.0 eq.) under argon. The mixture was stirred for 30 min and then transferred via cannula to a precooled solution of 1.1–2.2 eq. of 2-diphenylphosphinoyloxy-n-deca-aldehyde. The mixture was stirred at -78°C under argon for 3 h, whereafter a 1 M solution of acetic acid in methanol was added. After the mixture was stirred for 5 min more, phosphate buffer at pH 7 was added, and the mixture was allowed to warm to room temperature. Extraction with EtOAc afforded a crude mixture that was purified by flash chromatography (twice; 20–25% EtOAc in hexanes) to give (1′*R*,2′*S*,5′*R*)-8–phenylmenthyl (2*Z*,4*S*)-4-diphenyl-phosphinoyloxy-2-dodecenoate and (1′*R*,2′*S*,5′*R*)-8′-phenylmenthyl (2*E*,4*R*)-4-diphenylphosphinoyloxy-2-dodecenoate, both as a colorless oil, in a combined yield of 96%.

Other references related to the Horner-Wadsworth-Emmons olefination[37] and to the Still-Gennari modification[38] are cited in the corresponding literature.

Hosomi-Sakurai Allylation

(Hosomi-Sakurai Reaction, Sakurai Allylation)

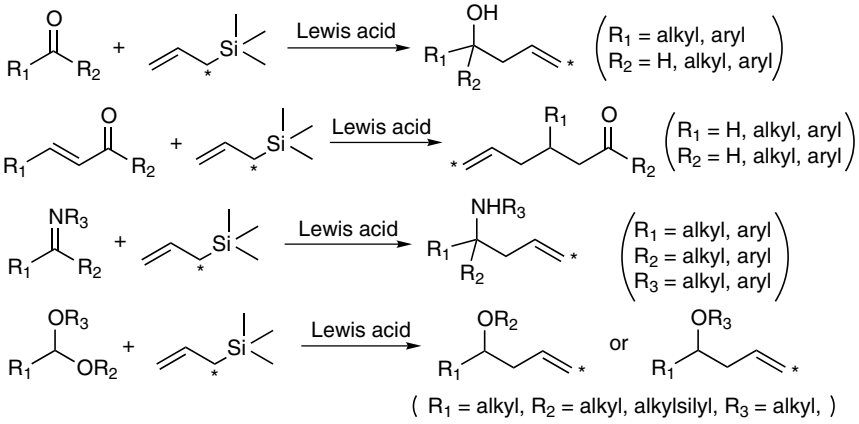
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hosomi and Sakurai in 1976.[1] It is the Lewis acid- or fluoride-promoted[2] allylation of various carbon electrophiles (e.g., aldehydes,[3] ketones,[2a] aldimines,[2a] alkenes,[4] imines,[5] α,β-unsaturated carbonyl compounds,[2b,5,6] acetals[3b,7]) with allyltrimethylsilane accompanied by the regiospecific transposition of allylic moiety and possible generation of new chiral center(s).[7c] This reaction is therefore known as the Homosi-Sakurai reaction,[3b,4,5,6,7d,8] Hosomi-Sakurai allylation,[2b,3a,8c,8e,9] Sakurai-Hosomi allylation,[10] Sakurai allylation,[11] and Sakurai addition.[12] When the electrophiles are acetals, the allylation might occur in the presence of a catalytic amount of Lewis acid, such as 2% $FeCl_3$.[7a] In addition, many other Lewis acids have been applied as promoters or catalysts for the allylation of acetals, including $TiCl_4$,[13] $BF_3{\cdot}Et_2O$,[3a] $SnCl_4$,[2b] $AlCl_3$,[7a] TMSI,[14] TMSOTf,[15] $TMSNTf_2$,[16] $Sc(OTf)_3$,[17] $Bi(OTf)_3$,[18] and trityl perchlorate.[19] On the other hand, the allylation of alkylsilyl mixed acetals leads to the replacement of either an alkoxyl or an alkylsiloxyl group, depending on the Lewis acid applied.[3b] For electrophiles of aldehydes, such as benzaldehyde, it has been found that even the use of an excess amount of Lewis acid ($BF_3{\cdot}Et_2O$) does not drastically increase the yield of homoallylic alcohol;[3a] in contrast, a catalytic amount of $FeCl_3$ can promote the allylation of aliphatic aldehydes.[7a] For the electrophiles of α,β-unsaturated ketones or aldehydes, it has been found that allylsilanes undergo regiospecific conjugate addition to double bond in the presence of strong Lewis acid catalyst,[2b] except for the application of auxiliaries;[20] however, all monoactivated α,β-unsaturated esters, nitriles, and amides do not undergo such allylation, regardless of the choice of catalyst.[2b] For the allylation of aldehydes with substituted allylsilane, such as

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

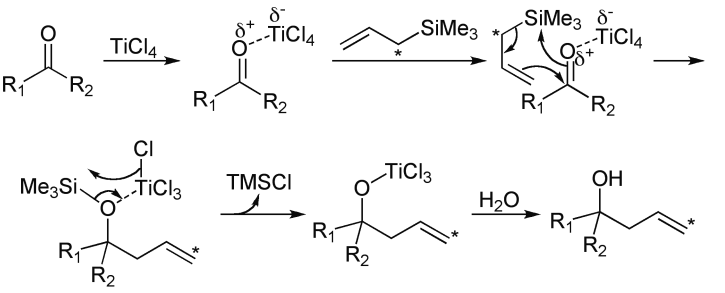
crotylsilane, the *syn*-homoallylic alcohols form predominantly from either *cis*-crotylsilane or *trans*-crotylsilane.[3b] In addition, the allylation of aldehydes also results in the formation of ether.[6b] This reaction has been improved to occur in the presence of a catalytic amount of Lewis acid using allylsilyl chlorides instead of allyltrimethylsilane.[21]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is a representative mechanism for the reaction between allyltrimethylsilane and ketone in the presence of Lewis acid $TiCl_4$.



D. MODIFICATION

This reaction has been extensively modified using different Lewis acids as catalysts.

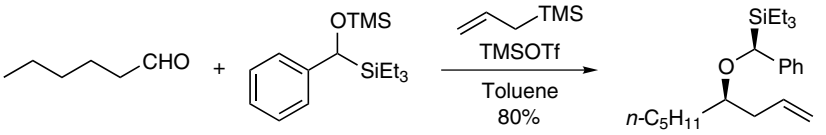
E. APPLICATIONS

This reaction has wide applications in organic synthesis.

F. RELATED REACTIONS

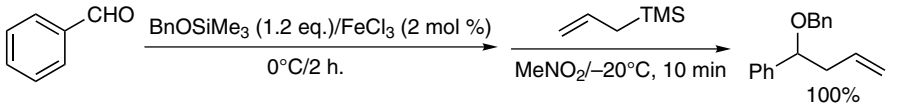
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 20.

To a 0.1 M toluene solution containing 0.11 g (±)-1-phenyl-1-(triethylsilyl)methanol TMS ether (0.38 mmol, 1.0 eq.) precooled to −78°C was added 52 μL hexanal (0.42 mmol, 1.1 eq.), allyltrimethylsilane (1.1 eq.), and TMSOTf (0.2 eq.). The mixture was maintained at −78°C for 1 h, and then the reaction was quenched by saturated aqueous $NaHCO_3$. The mixture was allowed to warm to ambient temperature, diluted with CH_2Cl_2, and washed once with saturated $NaHCO_3$ and then three times with brine. The combined aqueous phases were extracted twice with CH_2Cl_2, and the combined organic layers were dried over $MgSO_4$ and then concentrated in vacuo. Purification by flash chromatography (5% CH_2Cl_2/hexanes) afforded 0.10 g triethyl [(1-pentylbut-3-enyloxy)phenylmethyl]silane as a colorless oil, in a yield of 80%.



Reference 7a.

To a mixture of 2.0 mg $FeCl_3$ (0.012 mmol) and 63 μL benzaldehyde (0.62 mmol) was added 146 μL benzyloxytrimethylsilane (0.74 mmol) at 0°C under argon atmosphere. After the reaction mixture was stirred for 2 h, allyltrimethylsilane (112 μL, 0.71 mmol) in nitromethane was added at –20°C. The resultant mixture was stirred for 10 min and quenched with saturated aqueous $NaHCO_3$. The organic materials were extracted with Et_2O and dried over anhydrous $MgSO_4$. The solvent was evaporated, and 165.6 mg (1-benzyloxy-but-3-enyl)benzene was isolated by thin-layer chromatography on silica gel (ether/hexane, 1:30), in a yield of 100%.

Other references related to the Hosomi-Sakurai allylation are cited in the literature.[22]

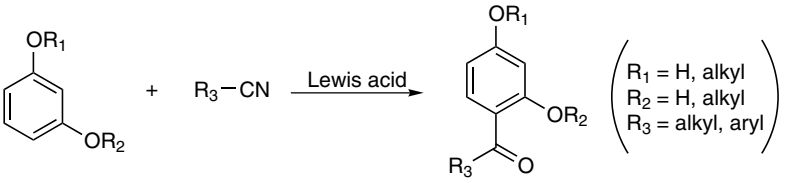
Houben-Hoesch Reaction
(Houben-Hoesch Acylation)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Hoesch in 1915[1] and was extended subsequently by Houben in 1926.[2] It is the acylation of electron-rich aromatics—such as multi-hydroxy phenols, their ethereal derivatives, and some heterocyclic compounds—from organic nitriles via the intermediate of ketimines in the presence of hydrochloric acid or Lewis acid or both. Therefore, this reaction is generally known as the Houben-Hoesch reaction.[3] In addition, this reaction is also referred to as the Hoesch synthesis,[4] Houben-Hoesch condensation,[5] Houben-Hoesch acylation,[6] Houben-Hoesch synthesis,[7] or Hoesch reaction.[8] Moreover, the intramolecular version of such reaction is also known as the Houben-Hoesch cyclization.[9] The acidic catalysts used for this reaction include $ZnCl_2$,[1a,3r] $AlCl_3$,[3r,3x,10] the combination of BCl_3 and $AlCl_3$,[3r] many superacids,[9,11] and even the cation-exchange resin (Amberlite IR-120).[12] It has been reported that simple phenol does not undergo acylation and forms only a salt of iminomethyl phenyl ether; however, phenol can be *ortho*-acylated from nitriles by using the combination of BCl_3 and $AlCl_3$ as the catalyst.[3r] It has been found that the dications—that is, the carbocation destabilized by an iminium cation group—are the real acylation species.[3i,3l] This reaction has been modified using a palladium-catalyzed approach, which is good for both intermolecular and intramolecular acylation of less electron-rich arenes.[3b] In addition, because protonated nitriles exist in very low concentration ($pKa \sim -10$),[6a] many current acylating reagents are Meerwein's alkylated nitrilium ions developed in 1956,[13] which show enhanced electrophilicity of the intermediate; under these conditions, the incoming aryl group is located in the position *cis* to the *N*-substituent.[14]

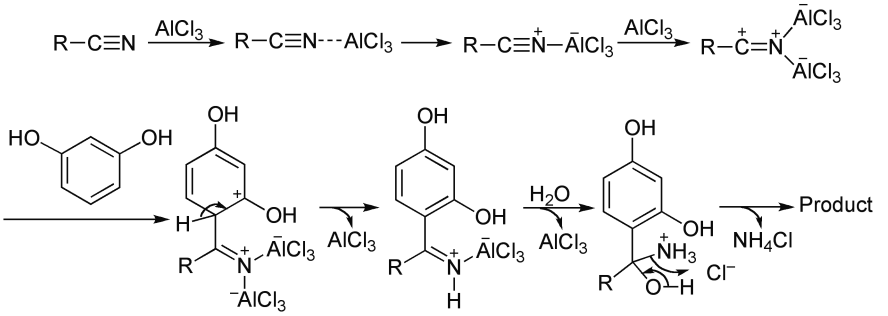
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Shown below is the reaction mechanism for the $AlCl_3$ catalyzed reaction between 1,3-dihydroxybenzene and a general nitrile.



D. MODIFICATION

This reaction has been modified using either a palladium-catalyzed approach,[3b] the combination of BCl_3 and $AlCl_3$ as the catalyst,[3r] and the *N*-alkylated nitrilium salt as the acylating reagent.[6a,14]

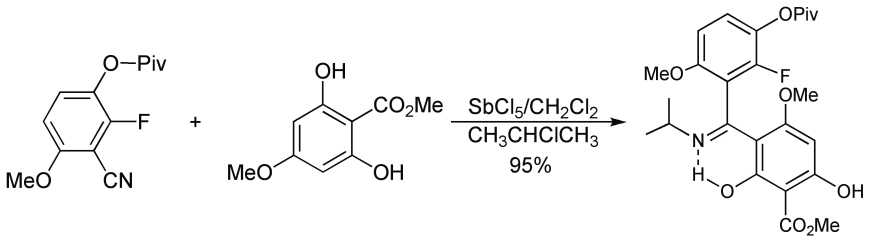
E. APPLICATIONS

This reaction has been applied to the acylation of phenols, their ethereal derivatives, and some heterocyclic compounds.

F. RELATED REACTIONS

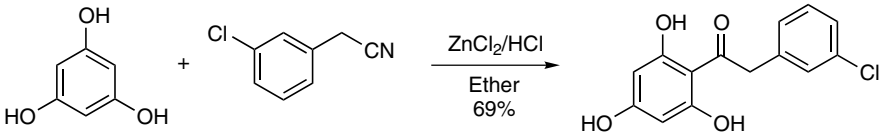
This reaction is related to the *Friedel-Crafts Acylation* and *Gatterman Aldehyde Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3e.

To 460 mL CH_2Cl_2 solution containing 7.0 g 2-fluoro-3-pivaloyl-6-methoxyl benzonitrile (27.89 mmol) and 25.5 mL 2-chloropropane (278.89 mmol) was added 27.9 mL $SbCl_5$ prepared as a 1 M CH_2Cl_2 solution (36.26 mmol) over 8 min. After 40 min, 13.81 g methyl 2,6-dihydroxy-4-methoxybenzoate (69.72 mmol) was added by cannula in 80 mL CH_2Cl_2 solution, and the reaction mixture was stirred for 2 h at room temperature. The volume was reduced to 200 mL, and the reaction mixture was filtered through a short silica pad and washed with 5% CH_3OH/CH_2Cl_2 to remove the antimony salts. Column chromatography (40→60% EtOAc/hexanes→20% CH_3CN/EtOAc) provided 12.98 g 2,4-dihydroxy-6,6′-dimethoxy-2′-fluoro-3-methoxycarbonyl-3′-pivaloylbenzophenone-*N*-(2-methylethyl)ketimine as a yellow oil, in a yield of 95%, R_f =0.6 (2% $MeOH/CH_2Cl_2$).



Reference 15.

Phloroglucinol (i.e., 1,3,5-trihydroxybenzene) (9.2 g; 72.9 mmol) and 11.05 g 3-chlorobenzyl cyanide (72.9 mmol) were dissolved in 70 mL anhydrous ether. Zinc chloride was added, and a stream of dry hydrogen chloride was bubbled through the reaction mixture for 4 h. A viscous yellowish mass separated from the slightly brown solution. The flask was left closed overnight, and then the ethereal layer was removed by decantation; HCl (2 M, 150 mL) was added, and the partly dissolved mass was heated to 100°C for 2.5 h. The hot solution was filtered, and the yellow solid was collected. A lower second phase formed in the filtrate as a brown oil, which crystallized upon cooling to give 14.05 g 2-(3-chlorophenyl)-1-(2,4,6-trihydroxyphenyl)ethanone, in a yield of 69%. Crystallization from EtOAc/pentane gave pure product as light yellow crystals, m.p. 182.6–184.7°C.

Houdry Cracking Process

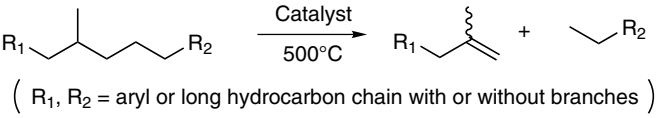
A. GENERAL DESCRIPTION OF THE REACTION

It was first reported by Eugene Houdry in 1934.[1] It is an industrial process to degrade petroleum or heavy petroleum fractions into more useful lower-boiling materials by heating the oil at 500°C and 30 psi, over a clay catalyst containing silica, alumina, and magnanese oxide. Therefore, it is known as the Houdry cracking process.[2] Soon after the invention of this process, the first commercial fixed-bed, three-case cracker was constructed (in 1936), which could crack 2000 barrels of oil daily.[3] By this time, the Houdry process corporation was founded, and its research branch—known as Houdry Laboratories—was also established in Marcus Hook, pennsylvania to concentrate on the studies of catalysts for such petroleum-cracking processes.[4] During the thermolytical degradation of oil, continuous coking occurs which deactivates the catalyst. Therefore, in the first three-case cracker, vaporized gas oil and air were passed alternately over the catalyst bed in each case, so that whenever the oil deposits coked on the catalyst, the coke after purging, would be burned off by the passage of air.[3] Thus in a single cycle of a three-case cracker, one case is cracking, another is burning carbon, and the third is being purged.[5] The typical cycle duration is ~10 min.[5] It has been found that a few factors affect the effectiveness of a catalyst, such as the chemical nature of the oil gas, the time and temperature for the exposure of the catalyst to oil gas, contamination of the catalyst by metals entrained in the stock, and the type of catalyst.[6] Heavy metals—such as iron, nickel, vanadium, and copper—are all harmful for the catalyst.[6] It is believed that at such high cracking temperatures, the decomposition of oil undergoes a radical mechanism.[7] More information about this process is available.[8]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME

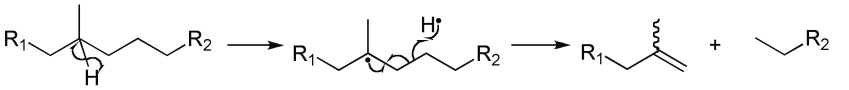
An example with branched hydrocarbon is used to illustrate this cracking process.



(R_1, R_2 = aryl or long hydrocarbon chain with or without branches)

C. PROPOSED MECHANISMS

A radical mechanism is proposed for this process, because the C-H bond at the allylic carbon, benzylic carbon, or tertiary carbon is relatively weaker than other C-H bonds, which can homolytically cleave and form radicals, as shown below.



D. MODIFICATION

This process has been modified for the thermofor process in which the catalyst bed is in continuous motion propelled by oil gas steam.[5]

E. APPLICATIONS

This process has been extensively used in oil refinery manufacturing plants to produce gas and other petrochemicals.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES

Because this is an industrial process for cracking petroleum oil, no practical experiments on the laboratory scale are provided here.

Huisgen Pyrrole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

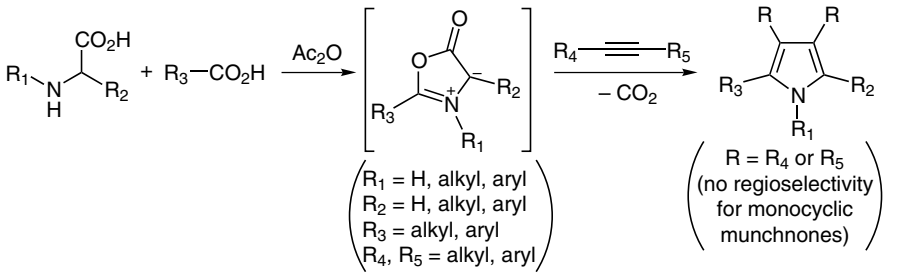
This reaction was first reported by Huisgen in 1960.[1] It is a general synthesis of pyrrole derivatives, especially *penta*-substituted pyrroles,[2] involving the *1,3-Dipolar Cycloaddition* of the mesoionic Δ^2-oxazilium-5-olates to the corresponding acetylenic or olefinic dipolarophiles, followed by carbon dioxide evolution and subsequent aromatization or tautomerization.[3] Therefore, this reaction is generally known as the Huisgen pyrrole synthesis.[2,4] It should be pointed out that the mesoionic Δ^2-oxazilium-5-olates, which behave like cyclic azomethine ylides,[3] are simply referred to as munchnones,[2,3,5] owing to their initial development in Munch, Germany. Depending on the nature of dipolarophiles, either pyrrolidines, dihydropyrroles, or pyrroles can be prepared from this reaction,[6] and the resulting dihydropyrroles can be converted into pyrroles directly by the oxidation from manganese dioxide[6a] or sulfur.[7]

In this reaction, the munchnones can be easily prepared by the acetic anhydride–induced dehydrative cyclization of *N*-alkyl-*N*-acyl-α-amino acids at high temperatures,[5] and such reactions can also be performed in a one-pot fashion in which the α-amino acids, the acylating agents, and acetylenic dipolarophiles are combined at once to give pyrroles by the way of the intermediate munchnones.[2] It has been found that the reaction between asymmetric electron-deficient dipolarophiles and monocyclic munchnones gives a mixture of regioisomers,[5] whereas the reaction between such dipolarophiles and polycyclic munchnones is regiospecific,[8] and the regioselectivity is controlled by the nature of substituents on the 1,3-dipoles.[9] On the other hand, the azomethine ylides can also be generated by the ring opening of aziridines,[6b,10] by which the *trans*-azomethine ylides combine stereospecifically with dipolarophiles, even with the weak dipolarophiles; in contrast, the *1,3-Dipolar Cycloaddition* of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

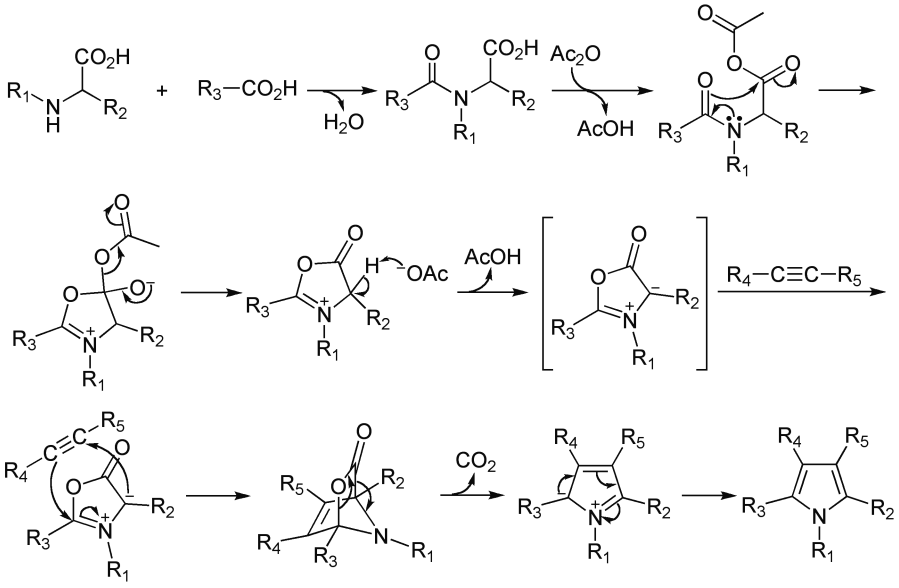
cis-azomethine ylides with dipolarophiles is competed by the isomerization to *trans*-azomethine ylides.[10]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

This reaction involves the formation of cyclic 1,3-dipoles, followed by *1,3-Dipolar Cycloaddition* with dipolarophiles, the evolution of carbon dioxide, and the subsequent tautomerization to give pyrroles, as shown below.



D. MODIFICATION

This reaction was extended by Huisgen to the reaction of proline, acetic anhydride, and dimethyl acetylenedicarboxylate to give pyrrole derivatives.[11] In addition, a method for generating the munchnone from 1,3-oxazolium perchlorate with triethylamine at low temperatures has been developed.[12] Moreover, an analogous pyrrole synthesis via a tran-

sient azomethine ylide involving a di-rhodium (II) salt–catalyzed three-component coupling between an imine, diazoacetonitrile, and activated alkynyl coupling partner to give 1,2-diarylpyrrole has been recently established.[13]

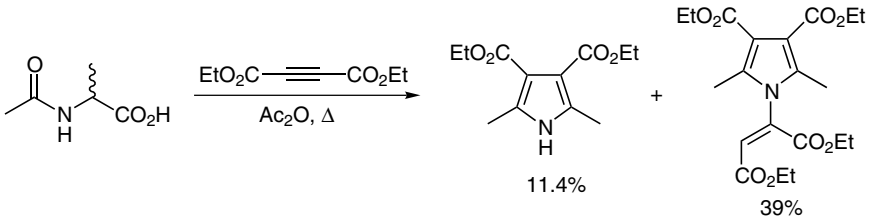
E. APPLICATIONS

This reaction has wide applications in the preparation of pyrrole derivatives.

F. RELATED REACTIONS

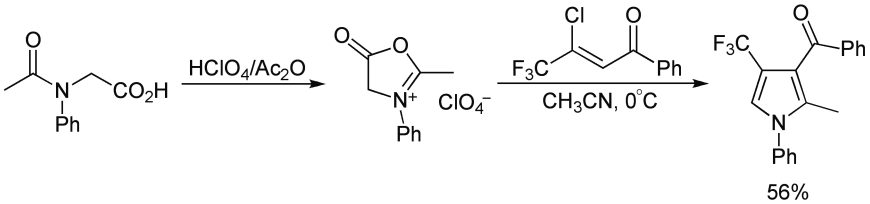
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

To a suspension of 1.31 g *N*-acetyl-D,L-alanine (10 mmol) in 10 mL acetic anhydride was added 3.2 mL diethyl acetylenedicarboxylate (20 mmol). The reaction mixture was maintained at 110°C for 2 h, cooled, and then evaporated under reduced pressure. The oily residue was dissolved in hot cyclohexane and left in the refrigerator overnight with crystal seeds. Diethyl 2,5-dimethyl pyrrole-3,4-dicarboxylate was isolated as white needles by filtration, in amount of 274 mg, in a yield of 11.4%. The filtrate was evaporated and chromatographed (dry column vacuum chromatography) using CH_2Cl_2 and then CH_2Cl_2/EtOH (99:1 to 98:2) to afford 1.58 g 2-(2,5-dimethyl-3,4-diethoxycarbonyl)-pyrrolyl maleic acid diethyl ester as a yellowish oil, in a yield of 39%.



Reference 5.

To a solution of 5 mL CH_3CN containing 505 mg Et_3N (5.0 mmol) at 0°C was added 117 mg 2-chloro-2-trifluoro-vinyl benzophenone (0.5 mmol) dropwise under a nitrogen atmosphere. Then a solution of 413 mg *N*-phenyl-2-methyl-1,3-oxazolium perchlorate (1.5 mmol) in 1 mL CH_3CN was slowly added while the temperature was maintained below 0°C. The resulting mixture was stirred at 0°C for 3 h and then at room temperature overnight. After evaporation of the solvent in vacuo, the residue was purified by silica gel column chromatography using *n*-hexane/EtOAc (5:1 then 5:2) as the eluent to afford 93 mg 3-benzoyl-2-methyl-1-phenyl-4-(trifluoromethyl)pyrrole as a pale yellow solid, in a yield of 56%, m.p. 73–7°C.

Other references related to the Huisgen pyrrole synthesis are cited in the literature.[15]

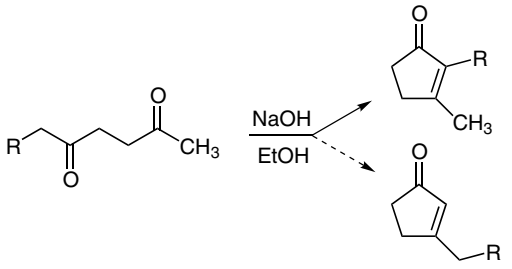
337

Hunsdiecker Condensation

A. GENERAL DESCRIPTION OF THE REACTION

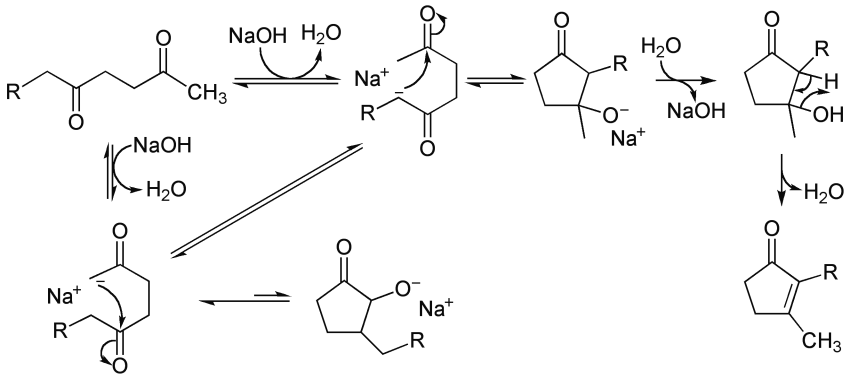
This reaction was first reported by Hunsdiecker in 1942.[1] It is the synthesis of 2,3-disubstituted cyclopentenones via an intramolecular condensation of 1,4-diketone (or γ-dicarbonyl compounds) by means of base treatment. When 2-acetyl ketone is treated with a base, two possible cyclopentenones—2-alkyl-3-methyl cyclopentenone and 3-alkyl cyclopentenone might form. However, only former has been reported as the isolated product[2] because the intramolecular condensation occurs via a reversible *Aldol Reaction*, and the transition state leading to the formation of 2-alkyl-3-methyl cyclopentenone is 2 Kcal/mol more stable than that needed to give 3-alkyl cyclopentenone.[3] This reaction has been modified to occur under the milder conditions of K_2CO_3/methanol.[4]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified using a mild basic system, such as K_2CO_3/MeOH.[4]

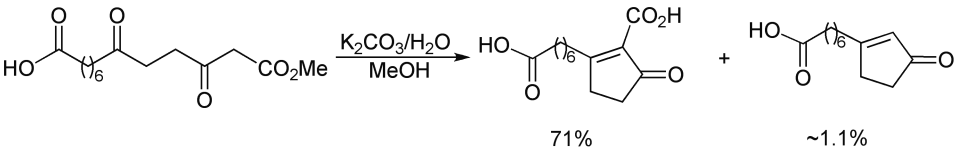
E. APPLICATIONS

This reaction is one of the general reactions used to prepare substituted cyclopentenones.[4]

F. RELATED REACTIONS

This reaction is related to *Aldol Condensation.*

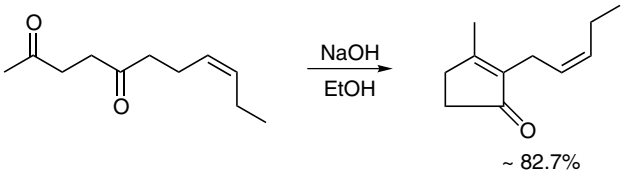
G. CITED EXPERIMENTAL EXAMPLES



Reference 4.

12-Methoxycarbonyl-8,11-dioxolauric acid (24.84 g, 82.8 mmol) was dissolved in 125 mL methanol, and 250 mL 20% aqueous K_2CO_3 solution was added. The mixture was refluxed for 1 h. After the solution was concentrated to one-third volume, cooled, and acidified with 2 *N*HCl, a crystalline precipitate (15.5 g) was separated. The filtrate was extracted with EtOAc, and the resulting 2.1 g extract was mixed with the crystalline precipitate. The mixture was recrystallized from ether to give 15.0 g 7-(2′-carboxy-3′-oxo-1′-cyclopentene)heptanoic acid, in a yield of 71%, m.p., 60–62°C.

Evaporation of the ethereal mother liquor gave 2.4 g of an oil that on trituration with ether gave 240 mg 7-(3′-oxo-1′-cyclopenten) heptanoic acid, m.p., 100–101°C.



Reference 5.

A mixture of 2.799 g *cis*-undec-8-ene-2,5-dione, 7 mL ethanol, and 25 mL 0.5 N NaOH was refluxed under nitrogen for 5 h. The mixture was cooled, extracted with pentane, washed with water, dried over Na_2SO_4, and evaporated. The remaining oil (2.522 g) was distilled through a microspinning-band column at 80–100°C (bath temperature) and 0.05 mmHg pressure, giving 2.087 g of *cis*-jasmone.

Hunsdiecker Reaction

A. GENERAL DESCRIPTION OF THE REACTION

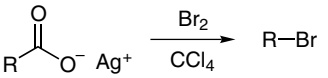
Although this reaction was first reported by Borodine in 1861[1] for the preparation of bromomethane from silver acetate and bromine, it was Hunsdiecker who extensively investigated this reaction and turned it into practice.[2] Therefore, the decomposition of carboxylic acid salts of Ag(I) in combination with halogen source (e.g., bromine) into organic halides with one less carbon atom than the original acids is generally known as the Hunsdiecker reaction.[3] In addition, this reaction is also referred to as the Borodine reaction,[4] Hunsdiecker-Borodine reaction,[5] Hunsdiecker decarboxylation,[6] Hunsdiecker bromodecarboxylation,[7] and Hunsdiecker degradation.[8] It should be pointed out that this reaction is also falsely called the *Simonini Reaction*.[9]

In this reaction, besides the often used silver salts, the corresponding Hg(II), Ti(I), or Pb(IV) salt of the carboxylic acids also undergoes a similar reaction.[5,10] This reaction works for aliphatic acids with either long or short hydrocarbon chains, by which the yields of halides decrease in the order of primary acid > secondary acid > tertiary acid.[3hh] However, this reaction is also accompanied with isomerization and racemization when the carboxylic acid salt group is attached to an asymmetric carbon of aliphatic acid.[3gg] Many experimental results support a free radical mechanism for this reaction,[3d,3y,3bb,3dd,3gg,6,11] involving the decomposition of intermediate hypohalite,[3m,3cc] although the ionic pathways are also favored by some experimental evidence.[3m,12] It should be pointed out that in a few cases, the Hunsdiecker reaction of corresponding carboxylic acid does not lead to the normal product of halides. For example, the reaction with iodine results in the formation of ester,[3hh] the decomposition of silver salts of α-hydroxy or α-amino acids produce aldehydes of one less carbon,[3hh] the decomposition of 1-hydroxycyclopentylacetic acid or 1-hydroxycyclohexylacetic acid leads to a product with a cleaved cyclic ring,[3y] and

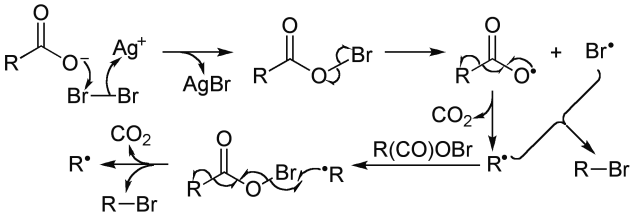
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

the Hunsdiecker reaction of β,β,β-triarylpropionic acid forms aryl β,β-diarylacrylate.[13] To address the moisture sensitivity and heat instability of silver salts,[3w] the original protocol was modified by Cristol and Firth by the addition of bromine into the slurry mixture of carboxylic acid and red mercuric oxide in carbon tetrachloride,[14] and this modification has been widely applied in organic synthesis because of its tolerance for moisture.[3z,3bb,13a,15] Other modifications of this reaction include the direct bromination of carboxylic acid with bromine at very high temperatures (e.g., 350°C),[3aa] photochemical initiation of ester bound to the *N*-hydroxy thiazole 2(3)-thione on a Wang resin,[3d] bromination or iodination from *N*-bromo-succinimide (NBS) or *N*-iodo-succinimide (NIS) in the presence of lithium acetate,[10] direct bromination of carboxylic acid from selectfluor,[5] triethylamine catalyzed bromination,[3c] and bromination of Barton's 2(1H)-thioxo-1-pyridyl ester in the presence of bromotrichloromethane or iodoform.[7,16] The last modification is also known as Barton-Hunsdiecker decarboxylation or Hunsdiecker-Barton decarboxylation.[16]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been extensively modified for various conditions as mentioned in section A. In addition, the α,β-unsaturated carboxylic acids, including cinnamic acids, can be converted into α,β-unsaturated nitro compounds when treated with nitric acid and a catalytic amount of AIBN in acetonitrile via nitrodecarboxylation.[17]

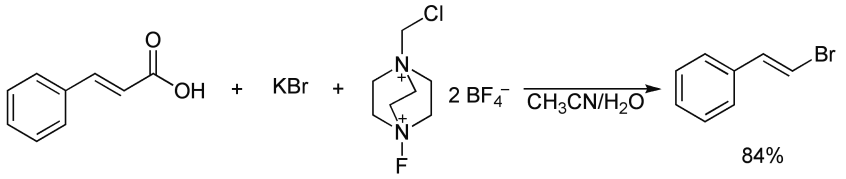
E. APPLICATIONS

This reaction has general application in the synthesis of aliphatic halides.

F. RELATED REACTIONS

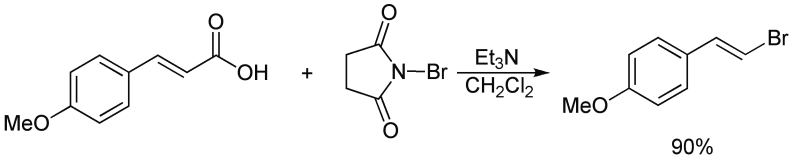
This reaction is related to *Kochi Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 5.

To a stirred mixture of 1.48 g *trans*-cinnamic acid (10.0 mmol), 4.20 g KBr (35.0 mmol), and 25.0 mL CH_3CN, were added 1 mL water and 4.24 g Selectfluor (13.0 mmol). The reaction was monitored by TLC. After completion of the reaction, it was diluted with water and extracted with CH_2Cl_2 (25 mL × 3). The organic layers were combined and washed with dilute solutions of $NaHCO_3$, Na_2SO_3, and brine. It was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to give crude products, which were purified by silica gel column chromatography to afford 1.54 g 1-(2-bromovinyl)benzene with an E/Z ratio of 95:5, in a yield of 84%.



Reference 3c.

Triethylamine (7 mL) was added to 3.0 mL dichloromethane containing 0.178 g 4-methoxy-*trans*-cinnamic acid (1.0 mmol). After the mixture was stirred for 5 min at room temperature, 1.2 mmol *N*-bromo-succinimide (1.2 mmol) was added. The solution was stirred for 5 min, and the solvent was removed under reduced pressure. The residue was subjected to silica gel column chromatography (1% EtOAc in hexanes) to afford 90% 4-methoxy-β-bromostyrene.

Other references related to the Hunsdiecker reaction are cited in the literature.[18]

Hydroformylation
(Oxo Reaction, Oxo Process, Oxo Synthesis)

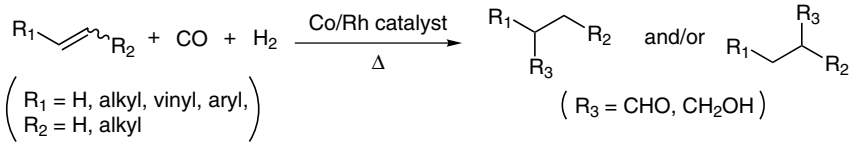
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Smith et al. in 1930[1] and subsequently by Roelen in 1938.[2] It is an industrial process for synthesizing aldehydes and alcohols from olefins and synthesis gas (i.e., carbon monoxide and hydrogen) in the presence of a cobalt or rhodium catalyst at high pressures (100–200 atm) and high temperatures (115–190°C) with the attachment of a new carbon to the less-substituted end of the double bonds.[3] In the literature, this reaction is often known as hydroformylation,[2b,2c,4] as well as oxo process,[2b,4i,4j,5] oxo reaction[2c,3,4l–4o,6] oxo synthesis,[4k,7] and Roelen reaction.[8] This reaction is one of the most extensively used reactions in the field of organometallic chemistry,[9] resulting in the production of 2.6 million metric tons of aldehydes and alcohols in 1969. Generally, aldehydes dominate in the product mixtures at relatively low temperatures (e.g., 115–125°C), whereas alcohols are almost the sole products at temperature >180°C.[3] This process is sometimes carried out in two stages: the production of aldehydes and the further reduction of aldehydes into alcohols. In addition, the straight-chain terminal olefins often lead to two isomeric aldehydes or alcohols,[4m] while ketones are the major product when ethylene is subjected to the hydroformylation.[4k] However, α,β-unsaturated aldehydes and ketones undergo direct reduction to saturated aldehydes and ketones without any hydroformylation at 120–125°C and 200–300 atm, yet these unsaturated carbonyl compounds are completely reduced under similar pressure, but at temperatures of 180–185°C. For comparison, conjugated dienes and furans undergo both types of reactions, by which one double bond is reduced and the other is extended by a formyl group; in contrast, thiophene and phenanthrene undergo only slow reductions, and benzene is inert under such hydroformylation

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

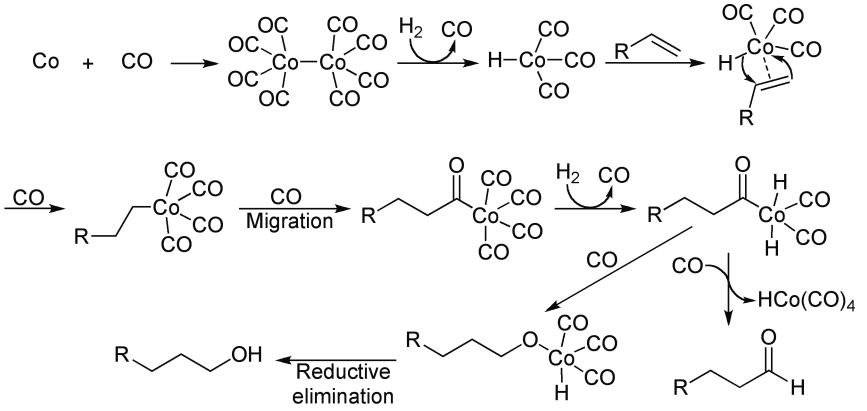
conditions. For vinyl aromatics or vinyl heteroaromatics, the corresponding aldehydes are the major products, except for 4-vinyl pyridine and 2-vinyl pyridine, which form either hydrogenation or hydroformylation products, depending on the catalyst employed.[10] For rhodium-catalyzed hydroformylation, it has been found that hydrogen and formyl groups add to both *cis* and *trans* internal olefins from the same side with high stereospecificity.[11] Because of the high cost of rhodium catalyst, this process has been modified using a VIB group metal (Cr, Mo, W) complex as the major component of the binary catalyst system in combination with trace amounts of cobalt or rhodium carbonyl, which can be adjusted in terms of catalytic activity and selectivity.[4i]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this process involves the following steps: (a) formation of dicobaltoctacarbonyl from cobalt and CO, which equilibrates with cobalt hydrocarbonyl by reaction with hydrogen; (b) substitution of one carbon monoxide by olefin to form a π-complex; (c) conversion of a π-complex to cobalt alkyltetracarbonyl via a cobalt tricarbonyl intermediate after the addition of carbon monoxide; and (d) fast rearrangement of the cobalt alkyltetracarbonyl compound into the acyl cobalt tricarbonyl compound, which reacts with hydrogen to give aldehyde and cobalt hydrocarbonyls.[4k] A detailed mechanism is shown below.



D. MODIFICATION

This reaction has been modified using a group VIB metal complex as catalyst in combination with trace amounts of cobalt or rhodium carbonyl complex.[4i]

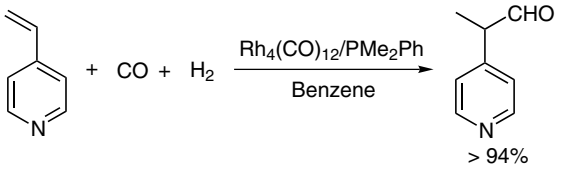
E. APPLICATIONS

This reaction has extensive application in the industrial production of aldehydes and alcohols with carbon chains from C_4 to C_{13}.[12]

F. RELATED REACTIONS

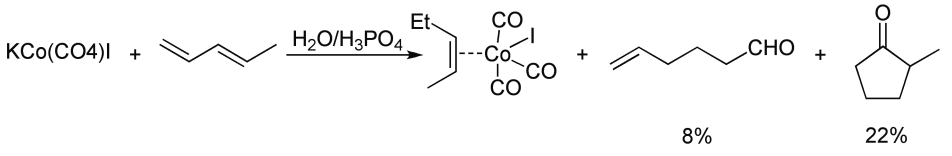
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

A solution of 0.8 mL 4-vinyl pyridine (7.42 mmol), 3.0 mg $Rh_4(CO)_{12}$ (0.004 mmol), and 9.0 mg PMe_2Ph (0.064 mmol) in 4.0 mL benzene was introduced by suction into an evacuated 25-mL stainless-steel autoclave equipped with a magnetic stirrer. The reactor was transferred to an oil bath, and carbon monoxide was introduced; the autoclave was then heated to 100°C (45 atm), and hydrogen was rapidly introduced up to 100 atm total pressure (CO/H_2,1:1). During the reaction, the drop in pressure was restored by injection of a carbon monoxide–hydrogen mixture (1:1 from a high-pressure container). After 75 min, GC analysis of a siphonated sample indicated that 4-vinyl pyridine had been completely transformed into branched and linear aldehydes (96:4 isomeric ratio), and the hydrogenation product was $< 2\%$. The reactor was cooled, and the CO/H_2 gas mixture was vented. After evaporation of the solvent, a pure sample was obtained as a yellow-green oil by distillation of the crude product at reduced pressure (0.1 mmHg, 120–125°C).



Reference 4k.

A solution of 0.2 mol potassium tetracarbonylcobaltate(-I) in 300 mL water was placed in a 1-L steel autoclave; then 120 mL concentrated phosphoric acid and 0.2 mol 1,4-pentadiene were added without mixing, and the autoclave was closed, inverted to mix the reactants, and rocked for 24 h. The vessel was opened under a stream of nitrogen, and 100 mL hexane was added to extract the products. The hexane layer was separated, washed with distilled water, dried over sodium sulfate, and transferred to a distillation apparatus. The hexane was removed by aspirator vacuum; the product was distilled under high vacuum. The material distilling at 45°C (1 mmHg) was collected as one fraction; the material distilling at 45°C was predominantly π-(l-ethylallyl) tricarbonylcobaltate(-I). The first fraction was further separated into two pure compounds in a Beckman Megchrom gas chromatograph equipped with a silicone rubber column. The first component (8% yield) was identified as 5-hexenal. The second component (22% yield) was identified as 2-methylcyclopentanone.

Other references related to the hydroformylation are cited in the literature.[13]

Iodolactonization

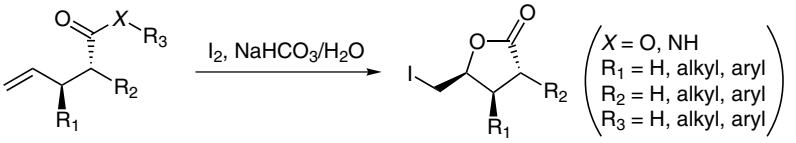
A. GENERAL DESCRIPTION OF THE REACTION

The halo cyclization was initially reported by Stobbe in 1902[1] and Fittig in 1904,[2] and the iodolactonization is believed to be established first by Bougault from 1904 to 1908.[3,4] It is the transformation of β,γ- or γ,δ-unsaturated carboxylic acid derivatives into either a five- or six-membered lactone in the presence of a positive iodine source with concomitant group and face selectivity. Therefore, this reaction is commonly known as the iodolactonization.[4–6] Occasionally, it is also referred to as the iodo cyclization.[7] Likewise, similar reactions with bromine sources are called bromolactonization.[5m] The iodine sources used for this reaction include $I_2 + NaHCO_3 + H_2O$,[5f,5o] $KI + I_2 + NaHCO_3$,[5k,8] $I_2 + AgOTF$,[5h] cyanogen iodide (CNI),[4c] ICl,[4a] IBr,[9] N-iodosuccinimide (NIS),[5a] iodonium dicollidine perchlorate,[4a,10] chalcogen iodine complex,[11] etc. On the other hand, the β,γ- or γ,δ-unsaturated carboxylic acid derivatives can be acids themselves,[5a,5c,5l,5m,5o,5p,8] their esters,[5h,9] amides,[4a,5e,7,12] or the phosphate.[4b] Although the β,γ- or γ,δ-unsaturated bonds are mostly double bonds, they could be triple bonds as well.[9] It has been reported that this reaction can occur in a two-phase system.[5d,5l] It is believed that this reaction involves the initial addition of positive iodine on the unsaturated bond followed by the carboxylate anion displacement on the resulting iodonium ion.[4c] The success of this reaction, therefore, depends on the ability to form either a five- or six-membered ring and on the electron density on the unsaturated bond.[4c] If the unsaturated bond is in conjugation with the carbonyl group, as in the case of α-keto-β,γ-unsaturated acid and α,β-γ,δ-unsaturated acid, there is an ineffectual addition of positive iodine to the unsaturated bond because of the reduction of electron density on the unsaturated bond.[4c] On the other hand, the increase of electron density on the carbonyl group[13] or the presence of substituents at the α position of carboxylic group facilitates this reaction and accelerates the reaction rate.[14] In particular, the substitution at the α position

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

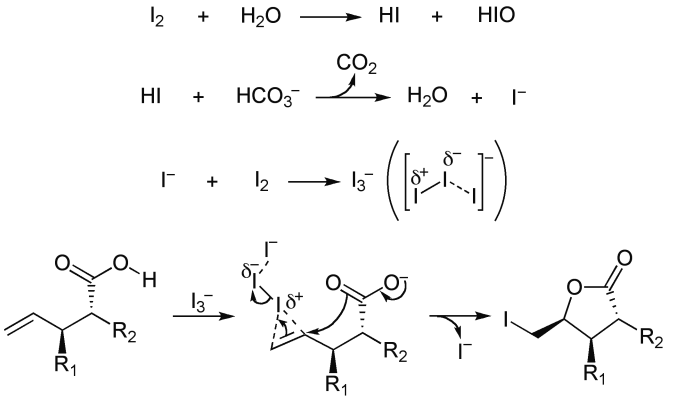
results in the high 1,3-asymmetric induction, where the *trans* selectivity is associated with amides and *cis* selectivity is associated with acids.[5b] The stereochemistry of the products, in most cases, depends on the substrates; however, in some cases, the reagents also control the outcome of the stereochemistry, such as when dihydroquinidine-iodine complex[15] or ICl[4a] is used as the source of I^+. Furthermore, the overall asymmetric induction can also be achieved in a thermodynamically[5m,16] or kinetically[17] controlled manner. This reaction has very broad applications in organic syntheses; some recent applications are the synthesis of nucleosides[18] and the change of stereochemistry of unsaturated carboxylic acid.[5i] In a special case, the iodolactonization is also competed by iodosultinization.[5h]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism is demonstrated by the reaction between γ,δ-unsaturated acid and $I_2/NaHCO_3$.



D. MODIFICATION

The original reaction protocol has been extensively modified using different positive iodine sources and different unsaturated acid derivatives, such as esters and amides, as mentioned.

E. APPLICATIONS

This reaction has wide application in organic synthesis, especially in the preparation of nucleosides and lactones with desired stereochemistry.

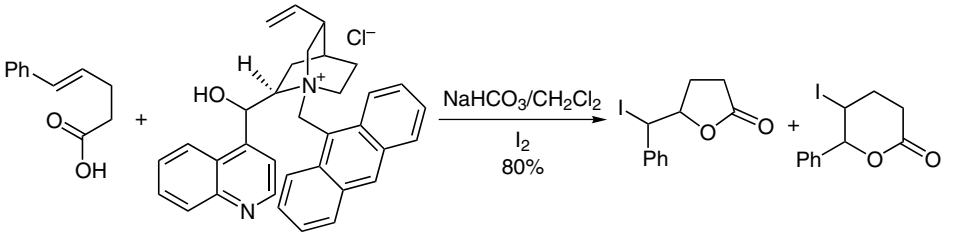
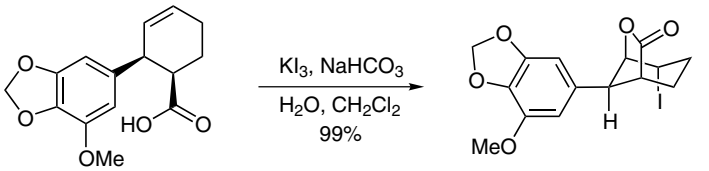
G. CITED EXPERIMENTAL EXAMPLES



Reference 19.

To a solution of 176 mg *trans*-5-phenyl-4-pentenoic acid (1 mmol) and 150 mg *N*-anthrancenyl cinchonidinium chloride (0.3 mmol, as chiral phase transfer catalyst) in 10 mL CH_2Cl_2, was added 5 mL saturated aqueous $NaHCO_3$. After the mixture was stirred for 10 min, 380 mg iodine (1.5 mmol) was added to this rapidly stirred two-phase reaction mixture at 0°C. The flask was protected from light and stirred at 0°C for 10 h. The reaction mixture was diluted with 100 mL CH_2Cl_2 and then quenched with saturated aqueous $Na_2S_2O_3$. The organic layer was separated and washed with saturated aqueous $NaHCO_3$ (2×60 mL) and brine (60 mL) and dried over $MgSO_4$. After removal of solvent in vacuo, the resulting crude iodolactones were purified by column chromatography (silica, ether-petroleum ether) to give 242 mg two regioisomeric products, in a total yield of 80%. The two isomers are identified as 5-(iodo-phenyl-methyl)-dihydrofuran-2-one, in 16.0% e.e. and 5-iodo-6-phenyl-tetrahydro-pyran-2-one, in 30.5% e.e.



Reference 5d.

At room temperature, to a solution of 863 mg 2-(7-methoxybenzo[1,3]dioxol-5-yl)cyclohex-3-enecarboxylic acid (3.12 mmol) in 10 mL CH_2Cl_2, were added 15 mL 1 *N* $NaHCO_3$ solution and 40 mL aqueous KI_3 solution containing 24.3 g KI, 12.1 g iodine. The mixture was stirred for 20 h and poured into a saturated aqueous $Na_2S_2O_3$ solution. The mixture was extracted with EtOAc (2×50 mL); the combined organic layers were washed with brine, drived over Na_2SO_4, and evaporated. The crude product was purified by column chromatography on silica gel (hexane/EtOAc, 1:1) to give 1.24 g 4-iodo-8-(7-methoxbenzo [1,3]dioxol-5-yl)-6-oxabicyclo-[3.2.1]octan-7-one as a colorless oil, in a yield of 99%.

Other references related to the iodolactonization are cited in literature.[20]

Irvine-Purdie Methylation

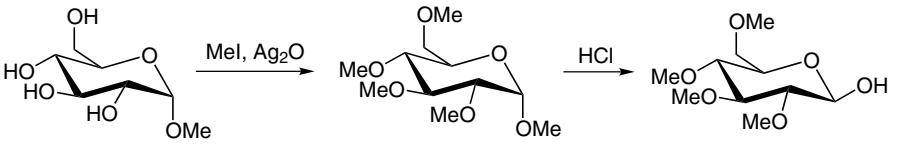
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Irvine and Purdie in 1903.[1] It is the exhaustive methylation of alkyl glycoside by repeated treatment of said glycoside with methyl iodide and silver oxide and the deprotection of anomeric alkyl group by hydrolysis of the resulting methyl saccharide ether with dilute acid. In addition, this reaction also stands for the mere methylation of sugars from methyl iodide and silver oxide. This reaction is often carried out in neutral solvent under mild conditions,[2] in which the profound side reactions, such as racemization, the *Walden Inversion*, or interconversion of glycosides (α- and β-forms), do not occur.[2] For example, the methylation of fructose tetraacetate by this reaction gives an almost quantitative yield of pure crystalline tetraacetyl monomethoxy fructose, without any affect on the acetyl groups in fructose tetraacetate.[3] However, bacause of the high cost of methyl iodide and silver oxide, and the limited solvents suitable for dissolving the initial glycosides,[2] this reaction has widely been replaced by the *Haworth Methylation* by treatment of sugar derivatives with methyl sulfate and sodium hydroxide,[4] and the *Haworth Methylation* has been further modified to occur in carbon tetrachloride using a high concentrated alkali base.[4] Nonetheless, both reactions do not yield the completely methylated glycosides, thus these two methods are often used together to yield the fully methylated glycosides for structural analysis, and the Irvine-Purdie methylation is often the last step. For example, the repeated four Irvine-Purdie methylations of sucrose yields a product with a methoxy content of 50.93%, smaller than the theoretical content of 54.63%. For comparison, one *Haworth Methylation* of sucrose gives a product with a methoxyl content of 50.5%, and further treatment of the product by *Haworth Methylation* does not increase the methoxyl content; however, two subsequent Irvine-Purdie methylations of such methyl sucrose can bring the methoxyl content up to 54.12%.[5] Overall, to fulfill the

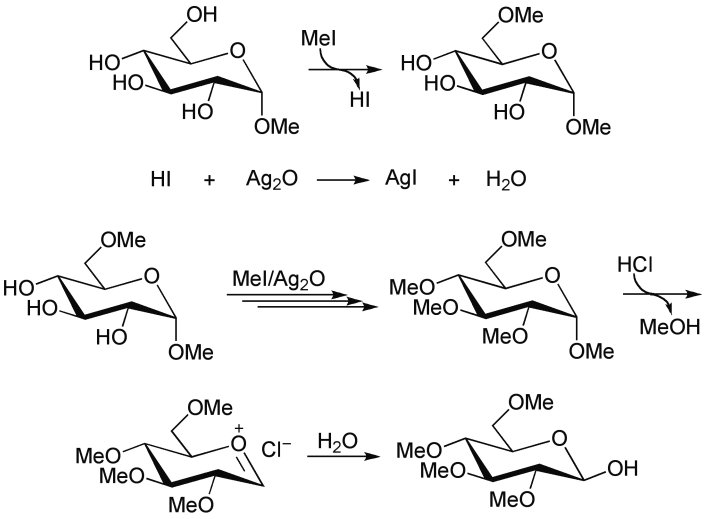
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

per-*O*-methylation for both methods, the repeated methylation on the materials recovered by extraction is necessary.[6] However, bacause per-*O*-methylation of sugars, especially the polysaccharides, is the prerequisite for the elucidation of polysaccharide structures,[6] this reaction has been further modified for a one-step per-*O*-methylation of polysaccharide by adding a solution of sodium methylsulfinyl carbanion (Na dimsyl) and methyl iodide to a DMSO solution of carbohydrate,[7] which has also been improved by adding potassium dimsyl and lithium dimsyl.[8]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to become the *Haworth Methylation*,[4] which was extended to treat sugars with sodium methylsulfinyl carbanion and methyl iodide for the purpose of per-*O*-methylation in one step.[7,8]

E. APPLICATIONS

This reaction has been used for the structural analysis of polysaccharide and the methylation of sugars.

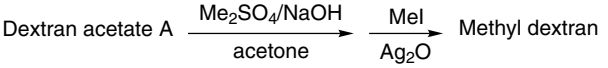
F. RELATED REACTIONS

This reaction is related to the *Haworth Methylation*.

G. CITED EXPERIMENTAL EXAMPLES

Reference 6.

Sodium dimsyl was prepared in a dry 500-mL, three-necked, round-bottom flask by adding 8 g dry sodium hydride to 100 mL anhydrous dimethyl sulfoxide under a dry nitrogen atmosphere. The magnetically stirred reaction mixture was heated slowly to 50°C and maintained at this temperature until hydrogen evolution had ceased. The mixture was centrifuged to produce a clear, gray-green solution. The solution was then aliquoted in 1-mL portions under nitrogen into Teflon-lined screw-capped vials and frozen at −20°C. For permethylation, the carbohydrates (5–7 mg) were introduced into a conical vial, which was dried overnight under vacuum, and then sealed with dry nitrogen. Dimethyl sulfoxide (1 mL) was added by dry syringe, followed by 0.3 mL nitrogen dimsyl solution (3 eq. per mol of replaceable hydrogen), and the reaction mixture was stirred at room temperature for 1 h. Methyl iodide (90 μL, 3 eq. per mol of replaceable hydrogen) was added after cooling the reaction mixture in an ice bath. After the mixture was fushed with dry nitrogen, stirring was continued at room temperature for 2 h.



Reference 9.

To 200 mL acetone was added 4.35 g dextran acetate A, which was methylated with NaOH (30%, 300 mL) and 110 mL dimethyl sulfate over a period of 3 h. The bath temperature was kept at 25°C for the first 2 h, and at 55°C for 1 h; it was then raised to 100°C for 0.5 h. The excess alkali was neutralized, and the reaction mixture was dialyzed. The dialyzed material was concentrated to a small volume, and the methylation was repeated four times in the same way with the bath temperature maintained at 55°C; acetone was added in to keep the product in solution. After the fifth methylation the product was extracted with chloroform, and the extract was washed with dilute acetic acid and water and concentrated to give 3.39 g syrup. The syrupy product was methylated with 50 mL methyl iodide (50 mL) and 6 g silver oxide, added in 12 portions under continual stirring and refluxing for 22 h. The product was extracted with chloroform, and after the removal of solvent it was remethylated four times in the same manner to give 1.96 g product with a methoxyl content of 44.93%. On fractionation of the methylated dextran from chloroform with petroleum ether, 90% of the product precipitated at 90–92% petroleum ether, a second

fraction recovered by concentration of the mother liquor was not investigated further. (*Note*: this procedure used a ridiculous amount of sodium hydroxide and methyl sulfate, and, later on, also used a great excess of methyl iodide and silver oxide to obtain the methylated dextran. It is an unacceptable practice in terms of cost-effectiveness. This procedure is cited for comparison).

Jacobsen Rearrangement
(Jacobsen Reaction)

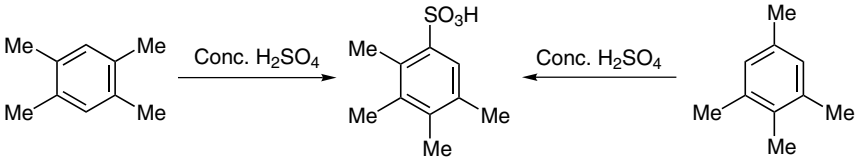
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was studied extensively by Jacobsen starting in 1886,[1] although the first reaction of this series was reported by Herzig in 1881.[2] It is the conversion of polysubstituted aromatics into corresponding sulfonated aromatics with the migration of substituents in contact with concentrated sulfuric acid. Under such conditions, the halogenated polyalkylaromatics undergo disproportionation of halogen atoms. Therefore, this reaction is generally known as the Jacobsen rearrangement[3] or Jacobsen reaction.[4,5] Generally speaking, among the polyalkyl benzenes, only the tetraalkyl or pentaalkyl benzenes undergo this reaction, in which the pentaalkyl benzenes give 1,2,3,4-tetraalkyl benzenesulfonic acid and hexaalkyl benzenes,[1b,4i] and the tetraalkyl benzenes intramolecularly rearrange to 1,2,3,4-tetralkyl benzene as the major product.[4d] In addition, it has been found that tetraethylbenzenes rearrange much more smoothly and quickly than tetramethylbenzenes; whereas pentamethylbenzene undergoes this reaction more readily than pentaethylbenzene.[4c] In contrast, hexaalkyl benzenes, as the end point of the reaction, are stable toward concentrated sulfuric acid, even if they are in contact with concentrated sulfuric acid for several months.[4i] However, for less alkyl-substituted benzenes, such as trialkyl benzenes and dialkyl benzenes, no rearrangement but the mere sulfonation of aromatics are found.[4i] Moreover, this reaction is always accompanied by the evolution of sulfur dioxide,[3f,4d,4e] together with the production of amorphous tarry byproducts in 30% of the weight of the starting material, which are soluble in excess amounts of acetone and show green fluorescence.[4d] Furthermore, only those primary alkyl groups on the aromatic rings migrate properly; both secondary and tertiary alkyl groups, such as isopropyl and *tert*-butyl groups are eliminated in this reaction.[3e] On the other hand, for the aromatics with cyclic alkyl substituents, such as the tetralins, the cyclic alkyl group almost always remains unchanged while other groups migrate;[3g,4b] however,

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

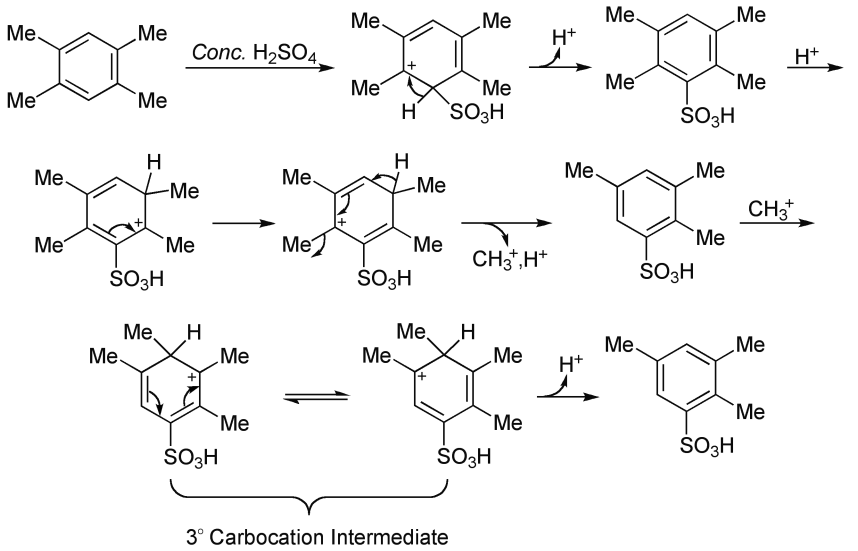
in pure cyclic alkyl–substituted aromatics, the group does migrate. For example, the octahydroanthrance rearranges into octahydrophenanthrene.[3i] In addition, the Jacobsen rearrangement not only works for polyalkyl aromatics but also works for halogenated aromatics as well,[3e,4d–4f,4j] even for mono-halogenated aromatics. The fluorinated aromatics are exceptions.[6] For the case of halogenated aromatic compounds, halogen atoms often migrate to give disproportionated products. For example, bromobenzene rearranges to dibromobenzene and presumably benzene when treated with concentrated sulfuric acid,[4i] dibromobenzene produces tetrabromobenzene and hexabromobenzene, and tribromobenzene yields hexabromobenzene.[4i] For chlorinated alkyl aromatics, the rearrangement does not always occur; chlorine migration might be either intramolecular or intermolecular. For example, 5- and 6-chloropseudocumenes rearrange to 3-chloropseudocumene; chloromesitylene and 4-chlorohemimellithene do not undergo this rearrangement but only the sulfonation.[4d] It has been found that concentrated sulfuric acid is used to reverse the desulfonation of aromatic sulfonic acids that occur in diluted sulfuric acid.[3f]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is proposed that this reaction involves the sulfonation and protonation of an aromatic ring as shown below.[3e]



D. MODIFICATION

N/A

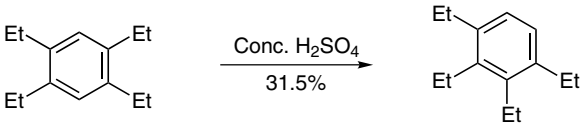
E. APPLICATIONS

This reaction has been used to prepare multisubstituted alkyl aromatics with substituents in the vicinal position, which might be more difficult to prepare from traditional *Friedel-Crafts Alkylation* with large amounts of *meta* alkyl substituent.[4e]

F. RELATED REACTIONS

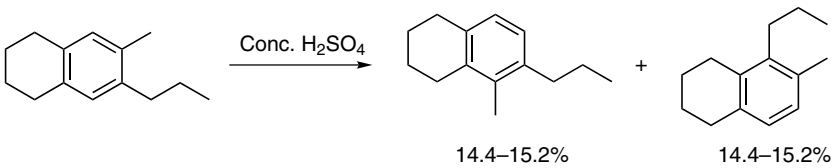
This reaction is related to the *Friedel-Crafts Alkylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3h.

Labeled tetraethylbenzene (8 g, 42 mmol) was mixed with 28.90 g reagent-grade sulfuric acid, and the mixture was heated rapidly to 100°C. Rapid mixing produced complete solution in ~ 30 min. This solution was maintained at 100°C for 10 min and was then poured onto 29 g crushed ice. Steam distillation of the diluted mixture at 140°C was carried out until only a few traces of insoluble residue remained in the still pot. The distillate was saturated with sodium chloride and extracted with ether. The ether solution was dried over calcium chloride, and the hydrocarbon was isolated by distillation through a 12-in. Vigreux column, b.p. 55–56°C (0.25 mmHg), in the amount of 2.52 g (13.3 mmol).



Reference 3g.

Pure 6-methyl-7-*n*-propyltetralin (20 g, 0.11 mol) was mixed with 125 mL concentrated sulfuric acid, and the rearrangement was performed according to Smith and Lo.[4b] Hydrolysis of the product with superheated steam at 155°C gave 6.7 g of a light oil, b.p. 60–66°C (0.2 mmHg), in a yield of 32%. Analysis by GPC showed 11 peaks with 2 major peaks retained at 52.5 and 61.0 min, respectively, made up 90–95% of the total; they are identified

as 6-methyl-5-*n*-propyltetralin and 5-methyl-6-*n*-propyltetralin, respectively, presenting as equivalent amounts.

Other references related to the Jacobsen rearrangement are cited in the literature.[7]

Jacobsen-Katsuki Epoxidation

A. GENERAL DESCRIPTION OF THE REACTION

Although the epoxidation of olefins catalyzed by oxomanganese salen *N*,*N*′-ethylene-bis(salicylideneaminato) complex was first reported by Kochi in 1980s,[1] it is Jacobsen[2] and Katsuki[3] who concurrently reported the improvement of such olefin epoxidation in 1990, using a sophisticated chiral salen ligand for manganese complexes, which resulted in high enantioselectivity. They extensively studied different aspects of this reaction[4,5] to convert it into one of the most useful and widely applicable methods for the epoxidation of unfunctionalized olefins.[6] Therefore, this reaction is often referred to as the Jacobsen-Katsuki epoxidation.[7] Occasionally, it is also known as the Jacobsen epoxidation,[8] Jacobsen oxidation,[9] Jacobsen asymmetric epoxidation,[10] or Kochi-Jacobsen-Katsuki oxygenation.[11] This reaction is usually carried out in dichloromethane or acetonitrile. Generally, Jacobsen's catalysts have two stereogenic centers, while Katsuki's catalysts have four.[3,5g–5j] Some of the Jacobsen-type catalysts (Figure 1) and Katsuki-type catalysts (Figure 2) are listed, respectively. It is known that the conformation of the chiral substituents attached to the C_8- and C_8'-positions have considerable influence on asymmetric induction.[3,5g–5j] In addition, the presence of a bulky group (e.g., *t*-butyl) at C_3- and C_3'-position of salen ligand achieves high enantioselectivity;[41] however, the groups larger than *t*-butyl have not shown apparent advantages for enhancing the enantioselectivity.[41] What is worse, the bulky trialkylsilyl group at C_3- and C_3'-position significantly lower the enantioselectivity, presumably because of the long carbon-silicon bond.[13] Furthermore, it is known

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

that this reaction is a strongly electrophilic one,[4c,7b] and the presence and properties of substituents at the C_5- and C_5'-position of salen ligand also affect the enantioselectivity, as well as the epoxidation rate.[14] It has been reported that electron-withdrawing groups accelerate the epoxidation reaction but lower the enantioselectivity via an early transition state, whereas the electron-donating substituents attenuate the reaction rate but enhance the enantioselectivity.[6a] On the other hand, the enantioselectivity of this epoxidation also depends on the structure of substrates. Generally, Jacobsen's catalysts work better for *cis*-olefins and Katsuki's catalysts are better for *trans*-olefins.[7d] The substrates with a *cis*-olefinic bond in conjugation with an aryl, alkenyl or alkynyl, or in connection with a bulky group or an allylic oxygen often result in high enantioselectivity when Jacobsen's catalysts are applied,[4j,15] especially for the epoxidation of 2,2-dialkylchromene derivatives with all terminal oxidants.[16] It has been found that simple nonconjugated olefins react slower than the conjugated ones and give both low yields and poor enantioselectivities.[4j,4k] Aryl-substituted alkenes often afford *cis*-epoxides, while conjugated dienes and enynes generally give *trans*-epoxides.[17] In addition, the counterion of Mn(salen)X complexes (Cl^-, PF_6^-, etc.),[7b] the additive as an axial ligand,[18] and the oxygen donors (i.e., oxidant)[7c] all have effects on the outcome of the asymmetric epoxidation. The oxidants used for this epoxidation include iodosylbenzene (PhIO) with chromium-salen complex,[19] sodium hypochlorite (NaOCl),[41,20] oxygen/reductant,[21] hydrogen peroxide (H_2O_2),[22] alkylhydroperoxide (e.g., *t*-butylperoxide),[23] peroxyacids (e.g., *m*CPBA),[18d,21b,23,24] potassium monoperoxysulfate ($KHSO_5$, oxone),[23,25] dimethyldioxirane,[26] and triphenyl phosphorus oxide (Ph_3PO).[27] Even though the mechanism of this reaction is controversial, it is generally agreed that this reaction consists of a two-step catalytic cycle—the formation of Mn(salen)^{v} complex and the transfer of activated oxygen to an olefinic double bond.[6a] To complete the catalytic cycle, at least three mechanisms have been proposed, including the concerted,[7b,7f] stepwise radical[7b,7f] and manganaoxetane pathways.[7i,28] In addition, a multichannel process including singlet, triplet and quintet spin states[7f] and proximal and distal approach (vectors) have been proposed to explain the stereochemical outcome of the epoxidation.[7b] Nevertheless, the transition state is held to be asynchronous;[4c] therefore, the order of mixing the reacting components is important for this reaction.[7h] This reaction has been extended to occur in the presence of the ionic liquid[7e,12,29] ($BMIMPF_6$), to resolve the racemic epoxides in a highly selective manner using a cobalt salen complex,[30] and then oxidize the stilbene into diarylacetaldehyde under basic conditions.[9]

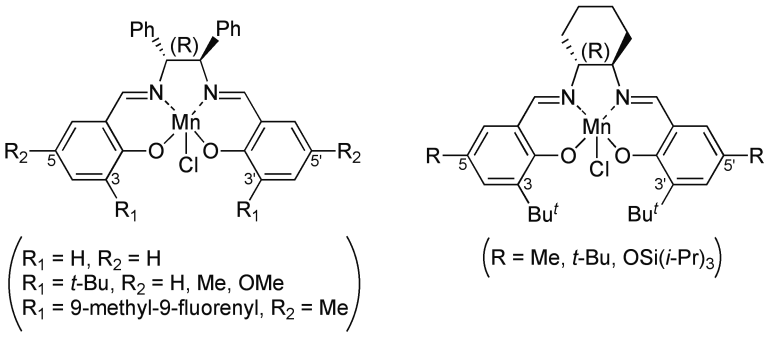

FIGURE 1. *Jacobsen-type catalysts.*

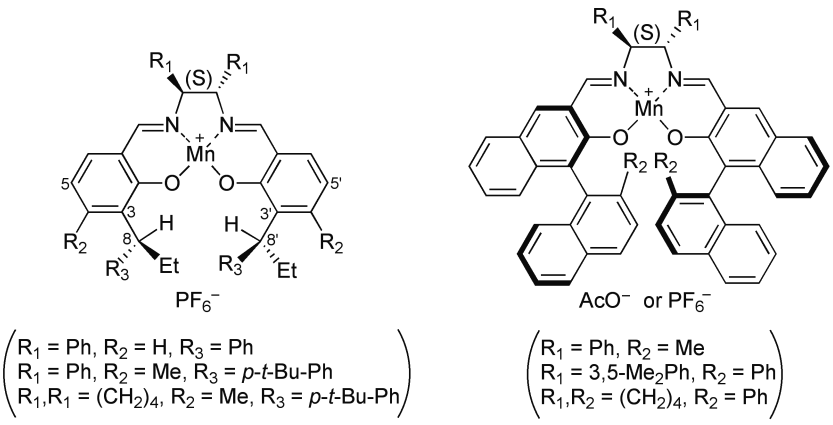

FIGURE 2. *Katsuki-type catalysts.*

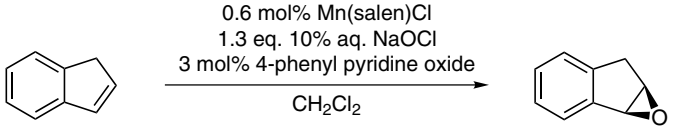
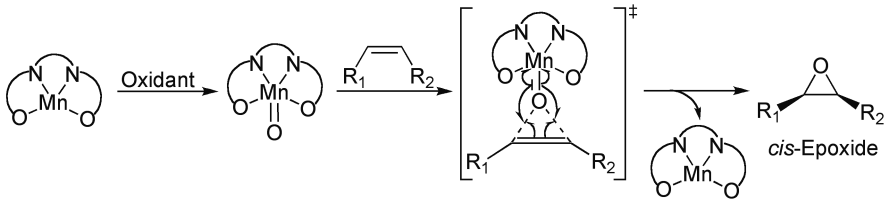
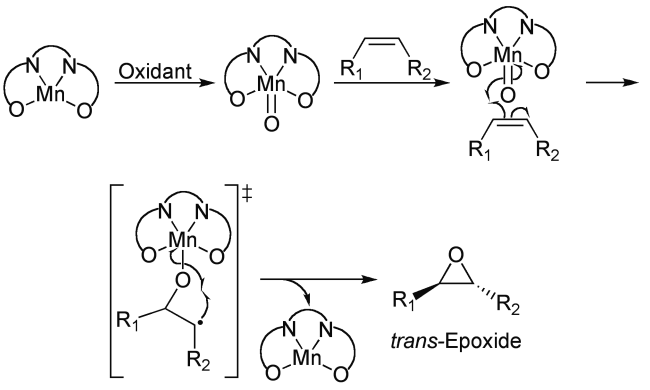
B. GENERAL REACTION SCHEME



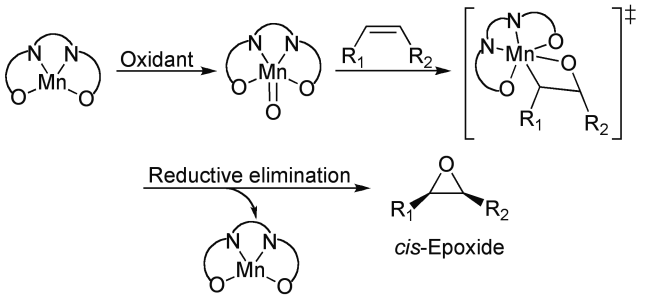
C. PROPOSED MECHANISMS

Outlined below is the proposed mechanism for the epoxidation in which the salen scaffold is simplified.





Radical mechanism



Mechanism involving manganaoxetane transition state

D. MODIFICATION

This reaction has been extended to occur in ionic liquid,[7e,12,29] and used for the highly selective hydrolytic kinetic resolution of epoxides.[30]

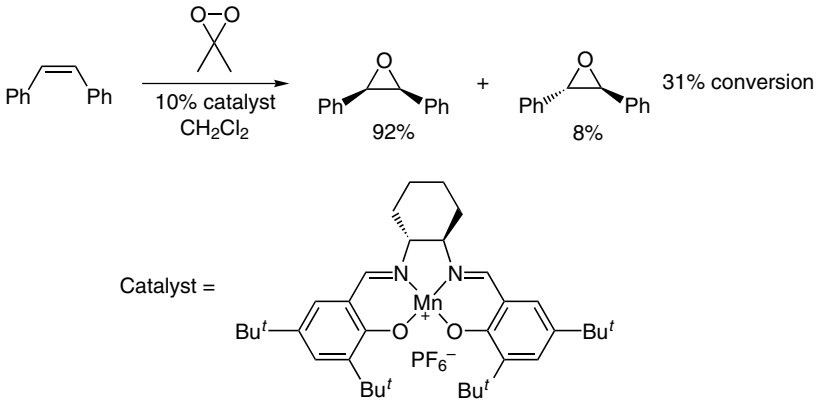
E. APPLICATIONS

This reaction has been widely used for the asymmetric epoxidation of olefins, especially for unfunctionalized olefins.

F. RELATED REACTIONS

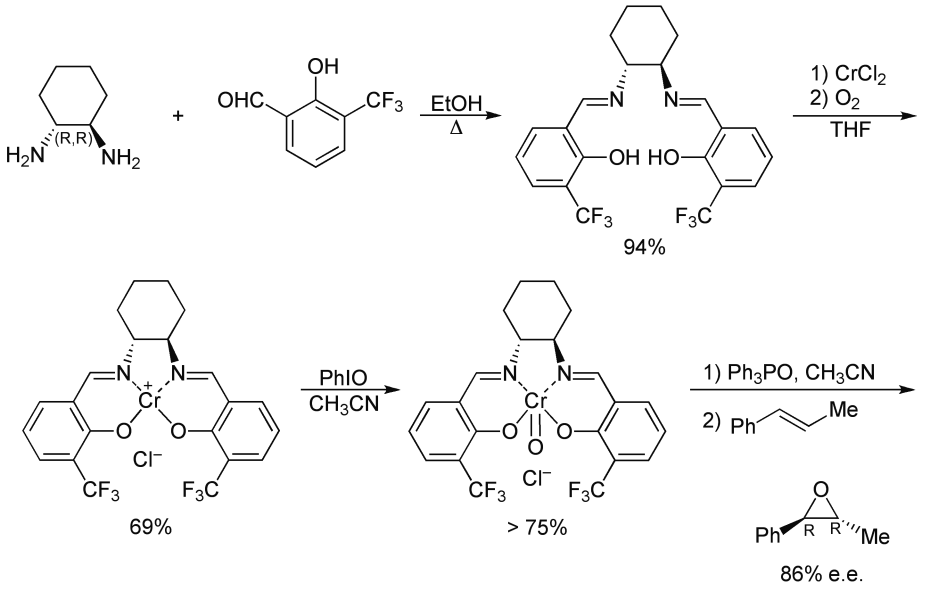
This reaction is related to the *Sharpless Epoxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7c.

A solution of 37.5 μmol (10 mol%) of the particular Mn(salen)PF_6 in 3.75 mL CH_2Cl_2 was stirred for 3 min at ~20°C. After addition of 375 μmol of *cis*-stilbene, the mixture was stirred for another 2 min and 375 μmol of acetone-free dimethyldioxirane in CH_2Cl_2 (0.185 M) was administered in small portions over 2 min. After the mixture was stirred for up to 16 h, the solvent was removed at 20°C at a pressure of 400 mbar, and the residue was transferred onto a short column of silica gel (~10 g) and eluted with 200 mL of a mixture of petroleum ether/Et_2O (1:1). The solvent was evaporated at 30°C and 10 mbar, to give 31% conversion in a 92:8 of *cis/trans*-epoxide.



Reference 27

To 70 mL of ethanol was added 2.30 g (*R*,*R*)-(-)-*trans*-cyclohexane-1,2-diamine (20.1 μmol) and 7.66 g 2-hydroxy-3-(trifluoromethyl)benzaldehyde (40.3 μmol). The resulting bright yellow mixture was refluxed for 2 h, and cooled; the solvent was removed

in vacuo to yield a solid that was recrystallized from hexane to give 8.65 g of (*R*,*R*)-(-)-*N*,*N*′-bis(3-trifluoromethylsalicylidene)-*trans*-cyclohexane-1,2-diamine as bright yellow needles, in a yield of 94%, m.p. 126–128°C.

To a 100 mL, two-necked, round-bottomed flask equipped with a nitrogen inlet and outlet was added 26 mL of dry and degassed THF containing 600 mg (*R*,*R*)-(-)-*N*,*N*′-bis(3-trifluoromethylsalicylidene)-*trans*-cyclohexane-1,2-diamine (1.31 mmol). To this yellow solution was then added 177 mg anhydrous chromium(II) chloride (1.44 mmol). The resulting brown solution was stirred for 3 h under a blanket of nitrogen and then exposed to air for a further 3 h. The brown solution was diluted with 120 mL *tert*-butyl methyl ether, washed with 80 mL saturated ammonium chloride, and 80 mL of brine. The organic phase was dried over sodium sulfate, and the solvent was removed *in vacuo* to yield 489 mg (*R*,*R*)-(-)-*N*,*N*′-bis(3-trifluoromethylsalicylidene)-*trans*-cyclohexane-1,2-diamine chromium(III) chloride as a brown solid, in a yield of 69%, m.p. > 230°C.

(*R*,*R*)-(-)-*N*,*N*′-Bis(3-trifluoromethylsalicylidene)-*trans*-cyclohexane-1,2-diamine chromium(III) chloride (435 μmol) was dissolved in CH_3CN, and 115 mg of iodosylbenzene (522 μmol) was added. After being stirred for 30 min, the reaction was filtered and the solvent was removed *in vacuo*. Addition of Et_2O precipitated a black solid that was collected by filtration, washed thoroughly with Et_2O, dried, and stored under a nitrogen atmosphere to give > 75% of (*R*,*R*)-(-)-*N*,*N*′-bis(3-trifluoromethyl-salicylidene)-*trans*-cyclohexane-1,2-diamine oxochromium(V) chloride.

To 5 mL of acetonitrile, was added 30 mg (*R*,*R*)-(-)-*N*,*N*′-bis(3-trifluoromethyl-salicylidene)-*trans*-cyclohexane-1,2-diamine oxochromium(V) chloride, under stirring, 1-2 eq. of iodosylbenzene was added, and a deep blue/black color appeared almost immediately. After stirring for 30 min, the solution was filtered, and the filtrate was cooled to 0°C using an ice/water bath. Then 1 eq. of triphenylphosporus oxide was added, and five min later, 1 eq. of *trans*-β-methyl styrene was added. The reaction mixture was stirred at 0°C until the brown color of the Cr(III)(salen) complex returned completely (∼1.5 h). The solvent was removed *in vacuo*, and the residue was treated with Et_2O. The Et_2O washings were flushed through a short alumina column using Et_2O as the eluant. The eluant was concentrated *in vacuo* to give (*R*,*R*)-1-phenyl-2-methyl-*trans*-ethylene oxide, in 86 ee%.

Janovsky Reaction

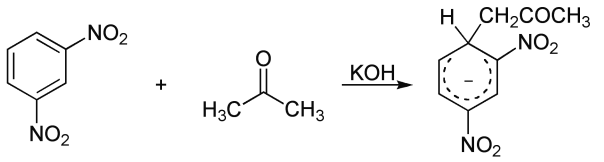
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Janovsky and Erb in 1886.[1] It is the reaction between aromatics containing multinitro groups and aldehydes or ketones with an activated α-proton in the presence of a strong base to form coloring molecules, for detection of both carbonyl compounds and nitroaromatics. Therefore, this reaction is generally known as the Janovsky reaction.[2,3] Occasionally, it is also referred to as the Janovsky test.[4] It is known that this reaction involves the addition of an enolate from the ketone or aldehyde to multinitro aromatics (the rate-determining step[2b]), resulting in the formation of a cyclohexadienate ion,[2b] an anionic σ complex[5] that is also known as Janovsky complex.[6] In addition, the product of this reaction is called Janovsky adduct[7] or Janovsky product.[8] It has been reported that substituents other than the nitro groups on the aromatic rings may influence the reactivity of substrates or alter the resonance of the nitro groups in the quinoid ion.[9] On the other hand, the relative location of the nitro groups also affect the outcome of this reaction. For example, *meta*-dinitrobenzene readily responds to this reaction, *para*-dinitrobenzene yields a reddish yellow color and quickly changes into a greenish yellow color, and *ortho*-dinitrobenzene does not yield any color.[10] When potassium hydroxide is applied as the base, the formation of the addition product is reversible, the color develops relatively slowly; however, when sodium methylate is used as the base, the successive color change is indistinct and too quick to follow, occurring via an irreversible pathway.[2g] A study on this reaction found that at very low temperatures (e.g., -40°C), the addition of enolate to the nitroaromatics is primarily through an *O*-attack, whereas at relatively high temperatures (e.g., -20°C), the *O*-attack intermediate gradually changes to the anion originated from *C*-attack, which is stable for days at room temperature.[2a] Although this reaction has not found much synthetic application, it has been widely used for the detection of nitroaromatics, in the fields of

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

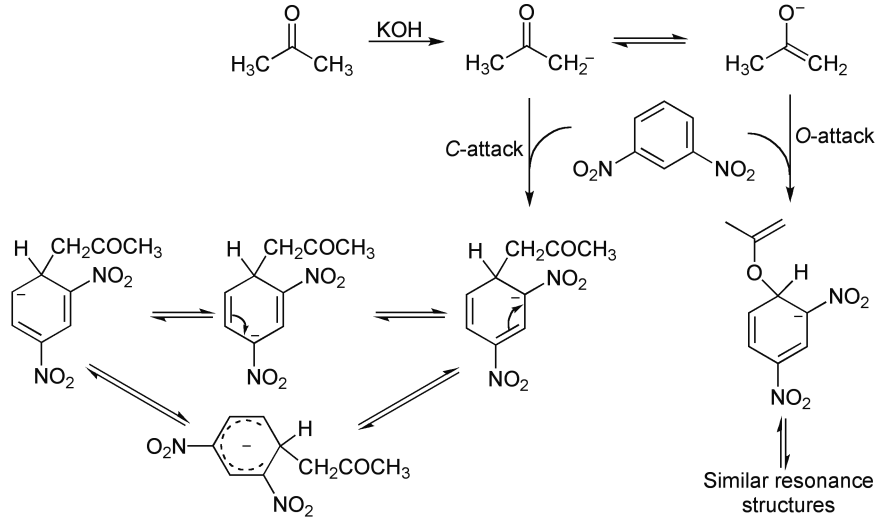
forensic toxicology,[2g] agriculture,[3z] etc. For example, 2,4-dinitrobenzene can be detected at concentration level of < 1 ppm,[10] while DDT can be detected as small as 1 μg.[2g] However, it is difficult to detect dinitro compounds in the presence of trinitro compounds.[10] It has been found that this reaction will behave differently in the presence of an excess amount of nitroaromatics, which will oxidize the Janovsky complex and reduce the excess nitro compounds.[2c] This reaction has been extended to measure 3,5-dinitrobenzamide using ammonium hydroxide as base.[3z]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A mechanism including both a *C*-attack and an *O*-attack of enolate is outlined here.



D. MODIFICATION

This reaction has been extended to 3,5-dinitrobenzamide using ammonium hydroxide as base.[3z]

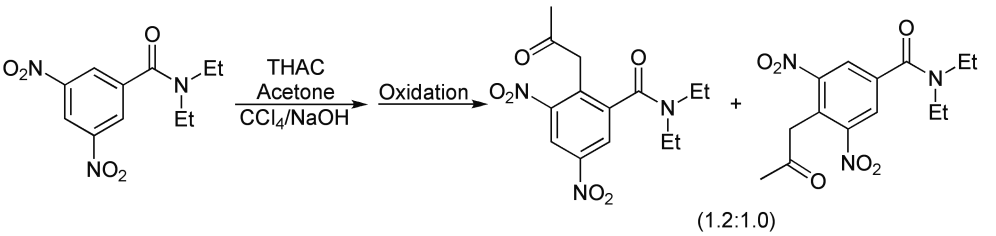
E. APPLICATIONS

This reaction has been widely used for forensic toxicology, and agriculture and pharmaceutical testing.

F. RELATED REACTIONS

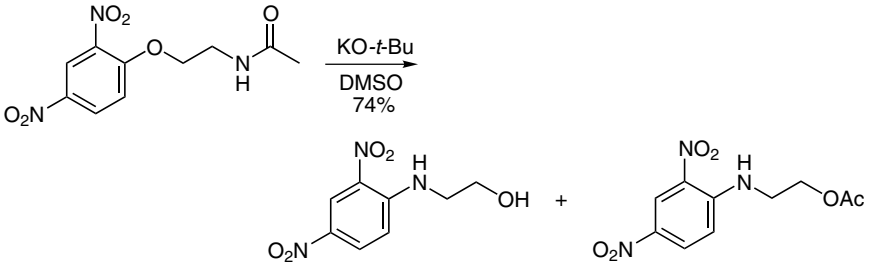
This reaction is related to the *Meisenheimer Complexes* and *Zimmermann Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

To a scintillation vial equipped with a stir bar were added 134 mg *N*,*N*-diethyl-3,5-dinitrobenzamide (0.5 mmol) and 196 mg tetrahexylammonium chloride (THAC, 0.5 mmol). The aluminum foil lining of the cap was replaced with a Teflon lining. To this vial was added 10 mL carbon tetrachloride, followed by 50 μL acetone via a syringe, and then 5 mL 2 M NaOH. The organic layer turned dark blue immediately upon addition of NaOH. The mixture was stirred vigorously for 4 h in the capped vial. Stirring was stopped to allow for phase separation. The organic layer was diluted with 10 mL CH_2Cl_2 and separated from the aqueous layer. The organic phase was combined with 10 mL 6 M HCl and stirred for an additional 10 min. The color of the organic phase changed from dark blue to yellow-orange. The organic phase was extracted sequentially with saturated solutions of $NaHCO_3$ and NaCl, dried over sodium sulfate, and concentrated under reduced pressure. The residue was purified through flash column chromatography using 10% Et_2O in CH_2Cl_2 to recover 53 mg *N*,*N*-diethyl-3,5-dinitrobenzamide (40%), 14 mg of an oily mixture of the *o*- and *p*-acetonate adducts in an *ortho*/*para* ratio of 1.2:1.0.



Reference 5.

To a stirred solution of 0.778 g *N*-acetyl-β-aminoethyl-2,4-dinitrophenyl ether (2.89 mmol) in 10 mL Me_2SO was added at room temperature 2.37 mL 1.22 N potassium *t*-butoxide (2.89 mmol). After the mixture had been stirred for 1 h and then 2.89 mL HCl (2.0 N) solution was added, the mixture was poured into 100 mL water, extracted with chloroform, and dried over anhydrous Na_2SO_4. The solvent was evaporated to produce the crude products, which were separated by column chromatography on silica gel with benzene as a developing solvent to give 74% *N*-β-hydroxylethyl 2,4-dinitroaniline and *N*-β-acetoxyethyl 2,4-dinitroaniline as a mixture.

Other references related to the Janovsky reaction are cited in the literature.[11]

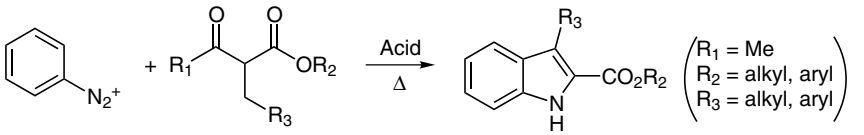
Japp-Klingemann Fischer Indole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction combines the *Japp-Klingemann Reaction* and *Fischer Indole Synthesis*, involving the condensation between aryldiazonium salt and an active methylene or methinyl compound under acidic or basic conditions to form a hydrazone derivative followed by cyclization to give a substituted indole. This reaction is therefore known as the Japp-Klingemann Fischer indole protocol,[1] Japp-Klingemann/Fischer indole process,[2] Japp-Klingemann Fischer indole synthesis,[3] or the Japp-Klingemann indole synthesis[4] or Japp-Klingemann indole formation.[5] This reaction was probably first reported by Findlay and Dougherty in 1948,[6] to avoid the use of arylhydrazines, which are difficult to prepare and handle in some cases.[7]

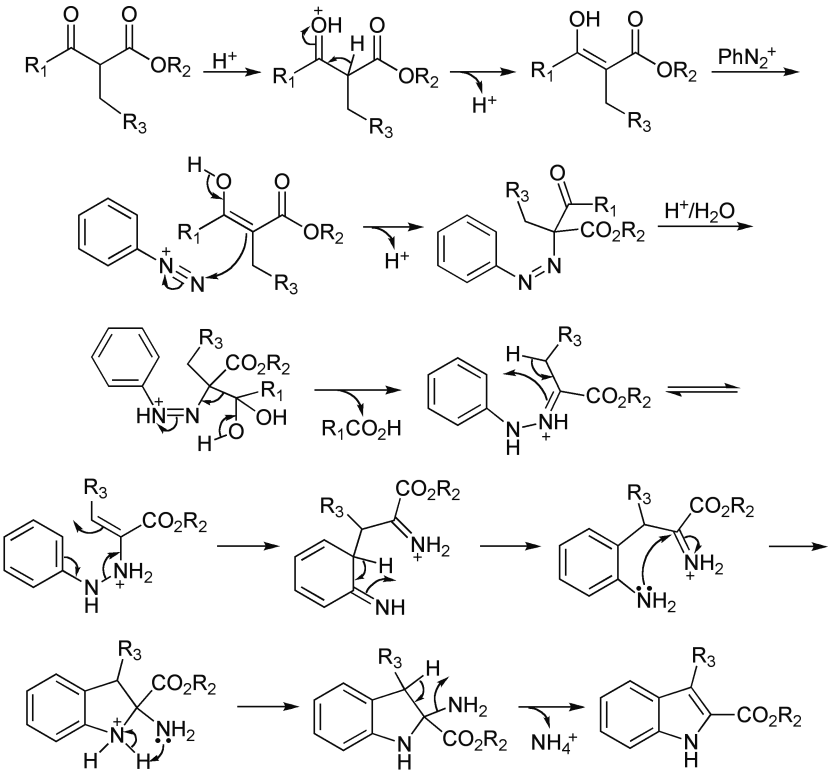
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

This reaction involves the elelctrophilic attack of an aryldiazonium cation on the enol carbon atom of an active methinyl compound to give an azo intermediate, which then hydrolyzes to form an arylhydrazone.[8] Tautomerization of aryl hydrazone yields the vinyl hydrazine, which undergoes [3,3] sigmatropic rearrangement and subsequently cyclizes to give an indoline derivative which, upon evolution of ammonium ion, yields the indole derivative, as shown below.



D. MODIFICATION

N/A

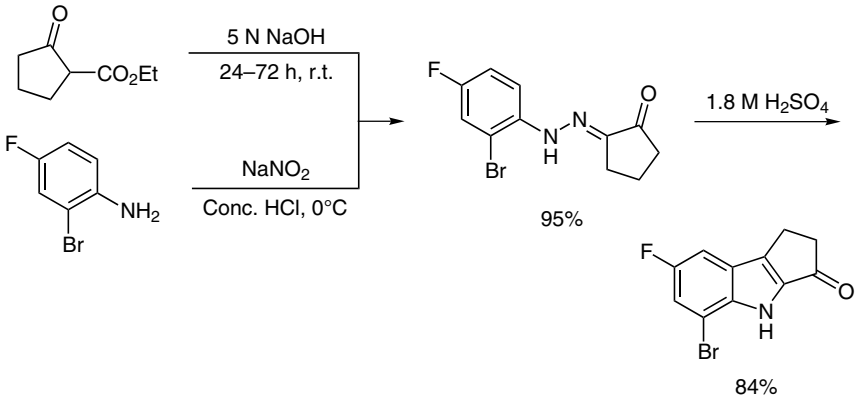
E. APPLICATIONS

This reaction is very useful for the preparation of indole derivatives.

F. RELATED REACTIONS

This reaction is related to the *Japp-Klingemann Reaction* and *Fischer Indole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES

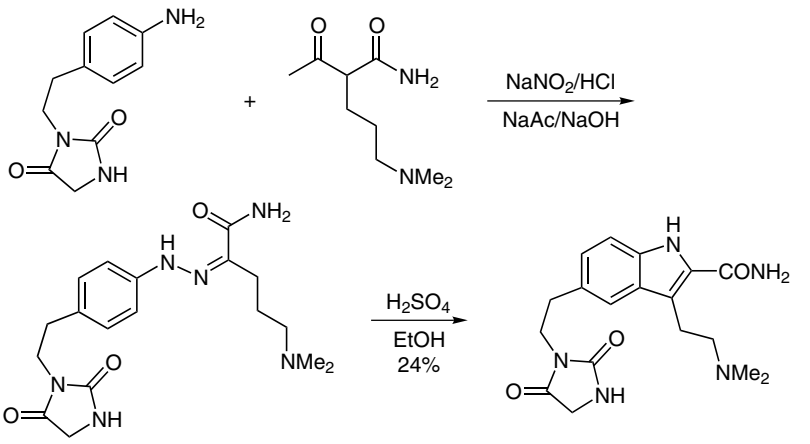


Reference 9.

To a three-necked flask were added 156.2 g ethyl 2-oxocyclopentanecarboxylate (1.0 mol), 2 L water, and 220 mL 5 N NaOH solution (1.1 mol); the resulting solution was stirred for 48 h at room temperature. This mixture was extracted with methyl *tert*-butyl ether (2 × 400 mL) to remove any residual unreacted starting material, and the aqueous phase containing the sodium carboxylate was returned to the original three-necked flask. This solution was cooled to 0°C, treated dropwise with concentrated HCl (1.1 mol) over 15 min, and aged at this temperature for 45 min.

Mean while, to a mixture of 190.0 g 2-bromo-4-fluoro-aniline (1 mol) and 0.6 L water at room temperature was added 3 mol concentrated HCl; the resulting thick white slurry was cooled to 0°C. A solution of 1 mol $NaNO_2$ in 0.7 L water was added slowly over 25 min, at such a rate as not to exceed an internal temperature of 10°C, and the reaction was aged for 30 min before filtration to remove any insoluble precipitate. This filtered diazonium solution was added to the prepared sodium carboxylate solution at 0°C dropwise over a period of 40 min (*Note*: If added to the solution of sodium carboxylate, then it was not necessary to acidify the sodium carboxylate with concentrated HCl.) The resulting thick yellow slurry was stirred to room temperature, filtered, and dried under a stream of nitrogen to give 270.9 g (4:1 ratio) 1-(*E*/*Z*)-cyclopentane-1,2-dione (2-bromo-4-fluorophenyl)hydrazone as a yellow solid, in a yield of 95%, m.p. 182–187°C.

To a three-necked, round-bottomed flask equipped with a mechanical stirrer, a condenser, and a nitrogen inlet were added 2.85 g of the hydrazone (10 mmol) and 25 mL CH_3CN. To this solution was then added 17 mL 1.8 M H_2SO_4 (30 mmol) in one portion. The resulting mixture was refluxed under stirring for 5–6 h. After the reaction was judged complete by HPLC analysis, 50 mL water was added, and the resultant slurry was stirred at room temperature for 1–2 h before filtration. The collected precipitate was washed with 50 mL CH_3CN/water (1:3), water (3 × 50 mL) and dried to give 3.24 g 5-bromo-7-fluoro-1,4-dihydrocyclopenta[*b*]indol-3(*2H*)-one, in a yield of 84%, m.p. 204–206°C.



Reference 4c.

To a mixture of 2.0 mL ethanol and 6.5 mL water, was added 1.0 g 3-(4-aminophenethyl) imidazolidine-2,4-dione (3.91 mmol), followed by 0.78 mL concentrated HCl (7.42 mol). The solution was cooled to 0˚C, and a solution of 0.54 g $NaNO_2$ (7.82 mmol) in 2.5 mL water was added. The solution was stirred for 30 min, after which the excess $NaNO_2$ was destroyed with 0.29 g urea (4.8 mmol). Meanwhile, 0.72 g 2-(3′-*N*,*N*-dimethylamino)propyl acetoacetamide (3.91 mmol) in 3.5 mL EtOH was stirred with 2.77 g sodium acetate trihydrate (20 mmol) in 3.5 mL water at 0°C for 20 min, after which the solution was added quickly to the cold diazonium solution. The resulting mixture was allowed to stir at 0°C for an additional 30 min and then allowed to stir up to room temperature for 1 h. The pH was adjusted to 9 with 10% NaOH solution, and the solution was left in the refrigerator overnight. The residue was extracted with ethyl acetate (3 × 30 mL); the combined organic layers were dried and filtered; and the solvent was evaporated to give a red gum, which was purified by column chromatography to afford 300 mg of the desired hydrazone intermediate, in 90% purity. A portion of the hydrazone (30 mg, 0.08 mmol) was dissolved in 3.0 mL ethanol, and 0.13 mL concentrated H_2SO_4 was added. After gentle refluxing overnight, the solution was cooled, and the solvent was evaporated under reduced pressure. The residue was mixed with water, and the pH was adjusted to 9 with K_2CO_3. The basic solution was extracted with EtOAc, and the combined organic layers were dried, filtered and evaporated. The yellow residue was purified by column chromatography using CH_2Cl_2/EtOH/NH_3 (50:8:1) as the eluent to afford 3-[2-(dimethylamino)ethyl]-5-[2-(2,5-dioxo-1-imidazolidinyl)ethyl]-1*H*-indole-2-carboxamide as an off white solid. Further purification using preparative HPLC gave 13.0 mg of the acetate salt of the indole as a white lyophylate, in a yield of 24%.

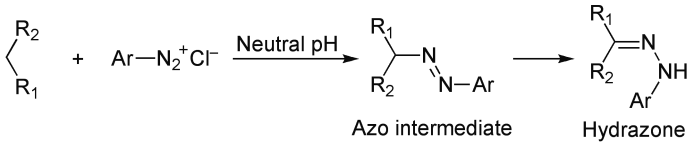
Japp-Klingemann Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Japp and Klingemann in 1887.[1] It is the reaction between aryldiazonium salt and compounds with methylene protons activitated by electron-withdrawing groups in which at least one of such activating groups is an acyl, carboxyl, or ester group to form an unstable azo intermediate that rearranges into a stable hydrazone derivative by expelling of the above acyl, carboxyl or ester group. Therefore, this reaction is often known as the Japp-Klingemann reaction.[2,3] Occasionally, it is also referred to as the Japp-Klingemann degradation,[4] Japp-Klingemann rearrangement,[5] Japp-Klingemann synthesis,[6] Japp-Klingemann condensation,[2a,7] Japp-Klingemann coupling,[8] or Japp-Klingemann cleavage.[9] This reaction is found to be very mild and occurs under almost neutral conditions,[2k] with an optimal pH of 6.2.[10] In most cases, the hydrazone can be isolated when a limited amount of diazonium salt is used or by working at a lower pH.[2k] In addition, the hydrazone formed might exist in a tautomeric form of ene-hydrazine.[11] Especially, under more alkaline conditions or when an excess of diazonium salt is used, the second diazonium ion can couple to the generated hydrazone.[11] In this reaction, the functional group of acyl (e.g., acetyl,[2k,12] benzoyl), carboxyl, ester[2k] and even hydrogen[2k] and bromonium ion[13] can be expelled during the formation of hydrazone. It has been found that the yield of such reaction can be improved dramatically by prior treatment of the extreme acidic diazonium salt with sodium acetate;[14] on the other hand, ammonium salts (e.g., NH_4Cl or NH_4Ac) are found to promote the coupling rate.[2j] This reaction has been extended to the coupling of diazonium salt with 2-pyridylacetic acids,[2m] and has been used in the syntheses of various amino acids,[2j] naphthazoleacetic acid,[2n] tetrahydrocarbazoles[15] and indole derivatives.[2c–2e,2l,2n,5,16]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

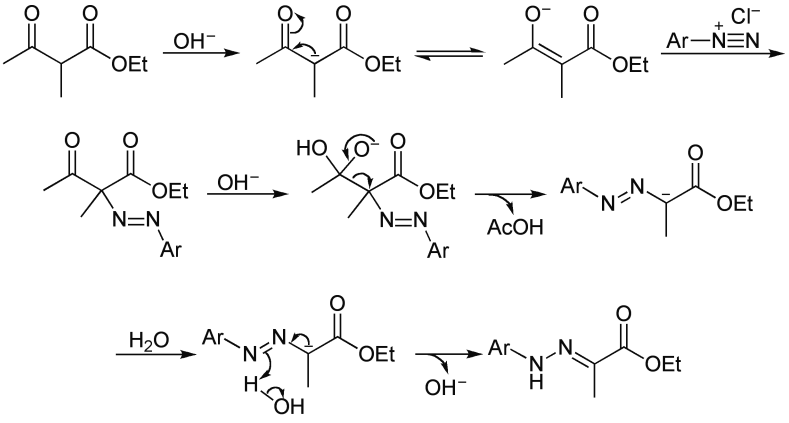
B. GENERAL REACTION SCHEME



$(R_1, R_2 = NO_2, CHO, C(O)R, C(O)NR_2, COOH, SOR, SO_2R, etc.)$

C. PROPOSED MECHANISMS

Displayed below is the reaction mechanism between ethyl α-methyl-acetoacetate and aryl diazonium chloride.



D. MODIFICATION

This reaction has been modified to treat the acidic diazonium salt with sodium acetate before the addition of compounds with active methylene groups.[14] In addition, this reaction has been carried out in the presence of an ammonium salt.[2j]

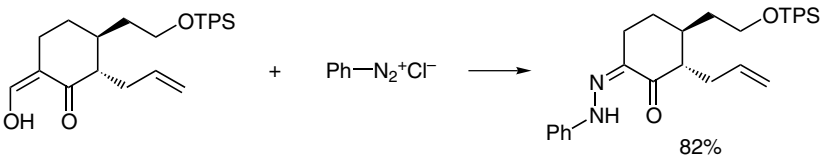
E. APPLICATIONS

This reaction has been used to synthesize a variety of amino acids and nitrogenous heterocycles, such as indole and tetrahydrocarbazole derivatives.

F. RELATED REACTIONS

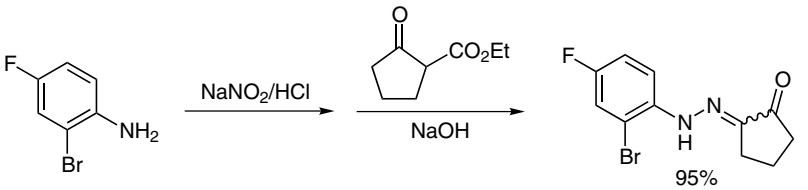
This reaction is related to the *Japp-Klingemann Fischer Indole Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 14.

Aniline (0.90 mL, 9.98 mmol) was added to a 3 mL 6 M HCl solution at 0°C. After the mixture was stirred for 10 min, 10 mL cold 0.998 M $NaNO_2$ solution (688 mg $NaNO_2$ in 10 mL H_2O) was added slowly at 0°C under temperature control. The solution was neutralized with NaOAc, followed by addition of an ice-chilled THF solution containing 2.985 g (2S,3S)-2-allyl-3-[2-(*tert*-butyldiphenylsilanyloxy)-ethyl]-6-hydroxymethylene-cyclohexanone (6.65 mmol). The reaction mixture was stirred for 1 h at 0°C, then diluted with methyl *tert*-butyl ether (MTBE). The aqueous layer was extracted twice with MTBE. The combined organic layers were washed with brine and dried over magnesium sulfate. The solvent was removed in vacuo and the crude oil was purified by column chromatography on silica, eluting with hexanes/MTBE (16:1) to give 2.86 g (2S,3S)-2-allyl-3-[2-(*tert*-butyl-diphenylsilanyloxy)-ethyl]-6-(phenyl-hydrazono)-cyclohexanone, as an orange oil, in a yield of 82%.



Reference 2a.

Sodium Carboxylate Preparation

A three-necked flask was charged with 156.2 g ethyl 2-oxocyclopentanecarboxylate (1 mol), 2 L water, and 220 mL 5 N NaOH (1.1 mol), and the resulting solution was stirred for 48 h at room temperature. This mixture was extracted with MTBE (2 × 400 mL) to remove any residual unreacted ester, and the aqueous phase containing the sodium carboxylate was returned to the original three-necked flask. This solution was cooled to 0°C.

Diazonium Salt Preparation

To a mixture of 190 g 2-bromo-4-fluoroaniline (1.0 mol) in 0.6 L water was added 250 mL concentrated HCl, and the resulting thick white slurry was cooled to 0°C. Aqueous solution (0.7 L) containing 69 g $NaNO_2$ (1 mol) was added slowly over 25 min, at such a rate as not to exceed an internal temperature of 10°C, and the reaction was aged for 30 min before filtration to remove any insoluble precipitate.

Japp-Klingemann Reaction

To the prepared sodium carboxylate solution at 0°C was added the filtered diazonium solution dropwise over 40 min at a temperature range of 0–4°C. The resulting thick yellow slurry was stirred to room temperature, filtered, and dried under a stream of nitrogen to give 95% (1*E*/*Z*)-cyclopentane-1,2-dione (2-bromo-4-fluorophenyl) hydrazone, as a yellow solid of steric mixture in 4:1 ratio, m.p. 182–187°C.

Other references related to the Japp-Klingemann reaction are cited in the literature.[17]

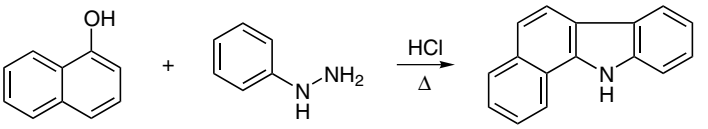
Japp-Maitland Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Japp and Maitland in 1903.[1] It is the acid promoted thermal condensation between arylhydrazine and aromatic compounds activated by a hydroxyl group to give carbazole derivatives. Therefore, this reaction is known as the Japp-Maitland condensation,[2] or Maitland-Japp reaction.[3] For example, the condensation between 6-alkyl-2-naphthols and phenylhydrazine affords 3-alkyl-7*H*-benzo-[c]carbazoles in good yield.[2] However, due to the heat sensitivity of naphthylhydrazines and their salts, the condensation with naphthylhydrazines gives corresponding carbazoles in very low yields.[4] In addition, the condensation with simple 2-naphthol also affords poor yields.[2]

B. GENERAL REACTION SCHEME

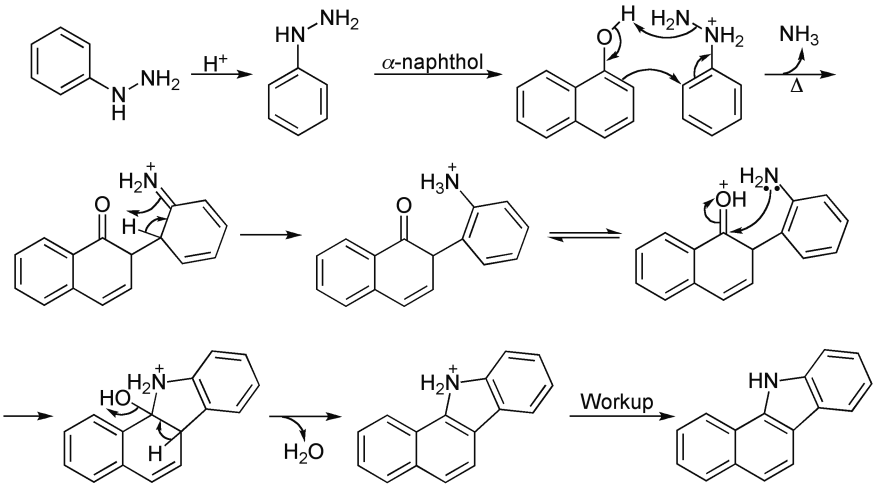


C. PROPOSED MECHANISMS

It is believed that α-naphthol, functioning as an enol, undergoes a semi-*Michael Addition* with protonated arylhydrazine while accompanying the evolution of ammonia during

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

heating. The amino group then attacks the carbonyl group and closes the ring. Upon extrusion of water, the benzocarbozole is produced as illustrated below.



D. MODIFICATION

N/A

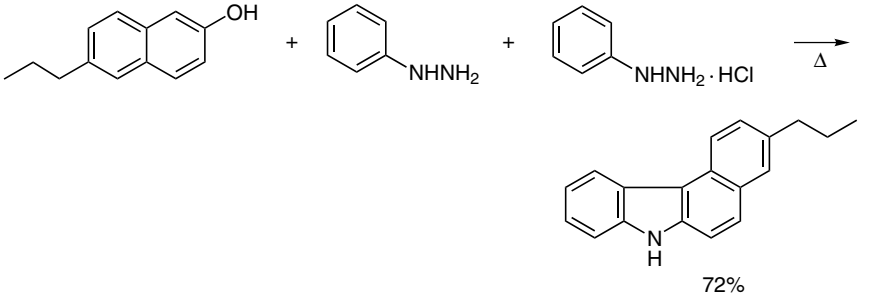
E. APPLICATIONS

This reaction is generally used for the preparation of carbazole derivatives.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 2.

A mixture of 4.0 g 6-propyl-2-naphthol, 4.0 g phenylhydrazine, and 4.0 g phenylhydrazine hydrochloride was cautiously refluxed for 1 h. After cooling, dilute aqueous NaOH was added, and the reaction product was taken up in toluene. The combined organic layers were washed with water and dried over Na_2SO_4. Upon removal of solvent, the residue was vacuum fractioned. The portion boiling at 280–305°C at 17 mmHg in a total of 4.0 g (72%) was recrystallized from cyclohexane to afford pure 3-propyl-7*H*-benzo[c]carbazole in lustrous colorless leaflets, m.p. 127°C.

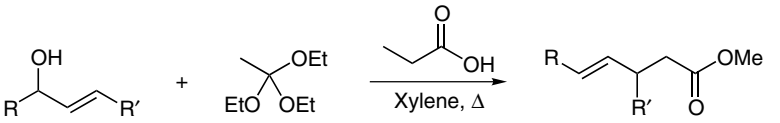
Johnson Orthoester Claisen Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

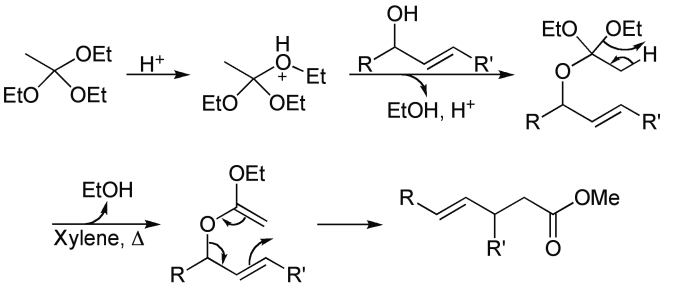
This reaction was first reported by Johnson et al. in 1970.[1] It is a highly stereoselective[2] synthesis of γ,δ-unsaturated esters from the reaction between allylic alcohols and an orthoester in the presence of a trace amount of weak acid, such as propionic acid.[1,2] Because this reaction is the modification or variant of the *Claisen Rearrangement*, it is often referred to as the Johnson orthoester Claisen rearrangement.[3] Occasionally, this reaction is also known as the Claisen-Johnson orthoester rearrangement,[2,4] or Johnson orthoester protocol.[5] This reaction involves the formation of mixed orthoester from allyl alcohol and the added orthoester, which loses an alcoholic component to form a ketene acetal[1] then migrates to unsaturated carbonyl compounds via the *Claisen Rearrnagement* with high *syn* selectivity.[3f] Posner further extended this reaction to use sulfonyl orthoester.[6] Overall, this reaction has been applied to the synthesis of a variety of complicated natural products, such as squalenes.[1,7]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been extended to start with sulfonyl orthoesters.[6]

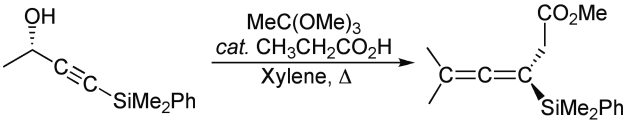
E. APPLICATIONS

This reaction has been used for the synthesis of a variety of natural products, including squalenes.[1,7]

F. RELATED REACTIONS

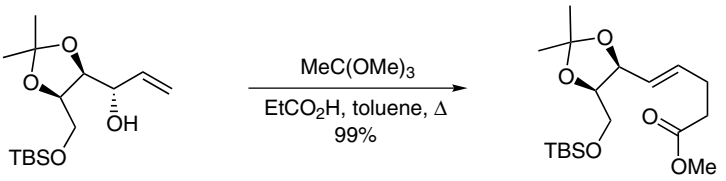
This reaction is related to the *Claisen Rearrangement*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3h.

A mixture of 5.0 g (*S*)-4-(dimethyl(phenyl)silyl)-but-3-yn-2-ol (24.46 mmol), 12.45 mL trimethylorthoacetate (97.84 mmol), 0.1 mL propionic acid (1.22 mmol), and 100 mL xylenes was refluxed for 24 h. An additional 6.23 mL trimethylorthoacetate (48.92 mmol) was added, and the solution was refluxed for 16 h longer. Then the solution was concentrated, and the residue was purified over silica gel using hexanes/EtOAc (95:5) as the eluent to give 5.0 g (*R*)-methyl 3-(dimethyl(phenyl)silyl)hexa-3,4-dienoate as a clear slightly yellow oil, in a yield of 78.5%.



Reference 3a.

To a 1-L round-bottomed flask equipped with distillation apparatus were added 500 mL toluene and 27.9 g (3*S*,4*S*,5*R*)-6-[(*tert*-butyldimethylsilyl)oxy]-4,5-(isopropylidenedioxy)-1-hexen-3-ol (92.3 mmol), followed by 77 mL trimethyl orthoacetate (640 mmol) and 1.9 mL propionic acid (26 mmol). The mixture was heated at reflux, distilling off methanol as it formed. Gas chromatography was used to monitor the disappearance of starting material (t_R = 4.0 min) and the appearance of product (t_R = 5.2 min). After 24 h, the mixture was cooled to room temperature and concentrated by rotary evaporation to give 32.7 g methyl (*E*)-(6*S*,7*R*)-8-[(*tert*-butyldimethylsilyl)oxy]-6,7-(isopropylidenedioxy)-4-octenoate as a pale yellow oil, in a yield of 99%, $R_f = 0.40$ (hexane/EtOAc, 6:1).

Other references related to the Johnson orthoester Claisen rearrangement are cited in the literature.[8]

349

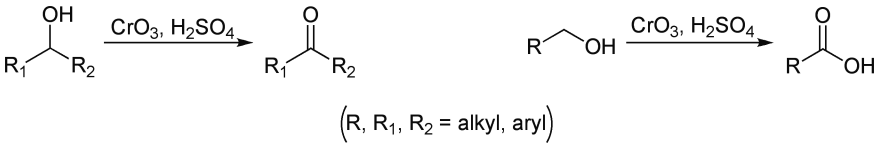
Jones Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Jones et al. in 1946.[1] It is the oxidation of primary alcohols into carboxylic acids or the conversion of secondary alcohols into ketones using acidic chromic acid. Therefore, this reaction is generally known as the Jones oxidation,[2,3] and the reagent of CrO_3-H_2SO_4-H_2O is called the Jones reagent.[2f,2k,4]Occasionally, the Jones oxidation is also referred to as Jones chromic acid oxidation.[5] This reaction is generally carried out in aqueous acetone[4a,4d] and is fast with low selectivity. Although it has been suggested that this reaction might involve a radical intermediate[6] or the conversion of Cr(IV) into Cr(II) species,[7] the predominant mechanism is the transformation of Cr(VI) into Cr(IV) species. If the hydroxylic group is protected by a silyl ether,[8] the deprotection and oxidation can be combined as a one-step reaction if the Jones reagent is applied. For example, the enediol bis-trimethylsilyl ether has been oxidized to α-diketone directly in high yield.[2f] Even though the 1,2-diols and α-hydroxy ketones are susceptible to cleavage,[9] the peroxide group is tolerable for this oxidation.[10] However, the benzylic group will be oxidized into carbonyl group when the Jones oxidation is carried out in acetic acid;[5] thus indans and tetralins can be oxidized to 1-indanones and 1-tetralones, respectively.[5] Furthermore, olefins in acetone can also be oxidized by the Jones reagent, especially in the presence of 20 mol % mercuric acetate or mercuric propionate, so that terminal olefins are oxidized to methyl ketones, and 1,2-disubstituted olefins are converted into ketones (but in low yields), respectively.[4d]

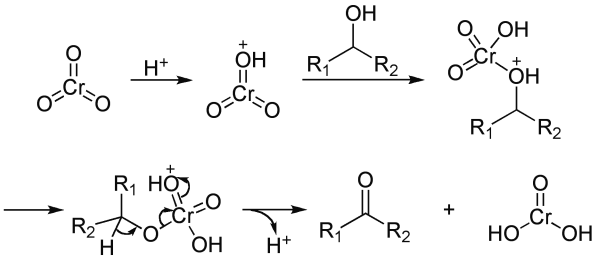
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism for the oxidation of a secondary alcohol is illustrated below.



D. MODIFICATION

Because this reaction is so fast and does not show much selectivity, more mild oxidation methods using chromium (VI) have been developed, such as the *Corey-Schmidt Oxidation* (PDC oxidation) and *Corey-Suggs Oxidation* (PCC oxidation)

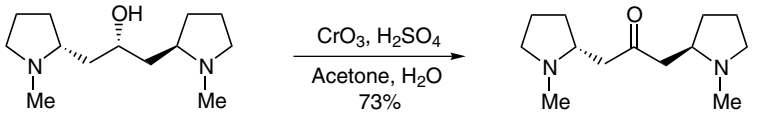
E. APPLICATIONS

This reaction has wide application in organic synthesis for preparing different ketones.

F. RELATED REACTIONS

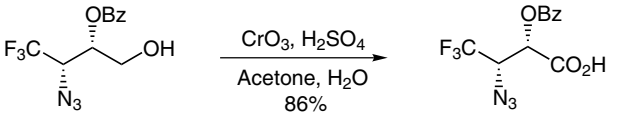
This reaction is related to the *Corey-Schmidt Oxidation* and *Corey-Suggs Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To a stirred solution of 30 mg (*R*,*R*)-dihydrocuscohygrine (0.13 mmol) in 1 mL acetone was added 0.2 mL 1.8 M Jones reagent at 0°C. After 2 h, the solution was cooled to 0°C and 1 mL ice-cold saturated $NaHSO_3$ solution was added. The solution was brought to pH 13 with ice-cold 5 N KOH. Then the solution was immediately extracted with precooled $CHCl_3$ (3 × 5 mL), and the combined organic layers were washed with cold brine and dried over $MgSO_4$. Evaporation of the solvent under reduced pressure at room temperature gave 22 mg racemic cuscohygrine as a colorless oil, in a yield of 73%, R_f = 0.27 (cyclohexane/$CHCl_3$/Et_2NH, 5:4:1).



Reference 1b.

To a mixture of 549 mg (2*S*,3*S*)-benzoic acid 2-azido-3,3,3-trifluoro-1-hydroxymethylpropyl ester (1.9 mmol) and 60 mL acetone was added 15 mL 1 M Jones reagent (15 mmol) at 0°C. The mixture was stirred for 20 min at 0°C under nitrogen. The reaction was quenched with 7 mL isopropyl alcohol and then diluted with 60 mL water and 60 mL ethyl acetate. The aqueous layer was then extracted with ethyl acetate. The combined organic layers were dried, filtered, and concentrated in vacuo. The residue was purified by column chromatography on silica gel (petroleum ether/EtOAc, 1:1) to give 495 mg (2*S*,3*S*)-benzoic acid 2-azido-1-carboxy-3,3,3-trifluoropropyl ester, in a yield of 86%.

Jourdan-Ullmann Reaction
(Ullmann Condensation)

A. GENERAL DESCRIPTION OF THE REACTION

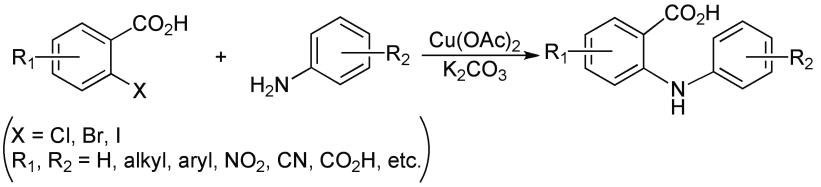
In 1885, Jourdan reported the reaction between aniline and activated aryl halides (e.g., 2,4-dinitro-chlorobenzene) to form diarylamine;[1] since 1902, Ullmann extended this reaction to unactivated or slightly activated aryl halides using copper or copper reagents as a catalyst and K_2CO_3 as the base.[2] At almost the same time, Ullmann's assistant and wife, Goldberg, reported the extension of this reaction from acetanilide to form diarylamines regardless of the degree of activation of the aryl halides.[3] Thus the copper-promoted amination of aryl halides with aniline to form diarylamines in the presence of a base is now known as the Jourdan-Ullmann condensation,[4] Jourdan-Ullmann diphenylamine synthesis,[5] Jourdan-Ullmann reaction,[4d,6] and Jourdan-Ullmann synthesis[6f,6h] as well as the Ullmann condensation,[7] Ullmann reaction,[7d,8] Ullmann-Goldberg condensation,[9] Ullmann-Goldberg coupling,[10] Ullmann-Goldberg reaction,[10b,11] and Ullmann-Jourdan reaction.[12] In general, the aryl halides of the electron-withdrawing groups work better than the ones of electron-donating substituents in the Jourdan-Ullmann condensation,[8c] and the reactivity of halides are in the order of I > Br > Cl > F;[7i] in comparison, anilines with electron-withdrawing groups proceed poorly in this reaction,[4b,4d] except for the reaction between *o*-chlorobenzoic acid and anthranilic acid, which occurs at 100–120°C to give 2,2′-dicarboxyl-diphenylamine in almost a quantitative yield within 30 min.[4d] Some of the reaction pairs between aryl halide and anilines are *o*-chlorobenzoic acid with *p*-iodoaniline,[7a] *o*-aminobenzoic acid,[7f] *p*-aminobenzoic acid,[10a] and *o*-anisidine;[8a] *o*-bromobenzoic acid with *o*-phenylenediamine;[13] *o*-bromotoluene with *m*-methylanthranilic acid;[14] and 3-bromo-2-naphthoic acid with 5-amino-2,2-dimethyl-2H-chromene.[7g]

It is known that both copper acetate and cuprous iodide are effective catalysts for this reaction, as well as pure copper metal in the presence of oxygen.[7m] In addition, the salts

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

of some other metals—such as iron, nickel, platinum, and zinc—are active catalysts in this reaction; the salts of tin and manganese are inactive reagents.[7m] The addition of a base such as K_2CO_3 is critical for this reaction, because the base will neutralize the generated hydrogen halide; especially for the reaction of *o*-halobenzoic, the base will convert the carboxyl group into carboxylate so that the chance for decarboxylation is reduced and the resinous by-products are dramatically diminished.[7m] Consequently, the overall yield and purity of diarylamines are enhanced. Because copper and copper salts are not soluble in organic solvents, the heterogeneous Jourdan-Ullmann reaction proceeds slowly in general;[7i] however, the application of high-boiling aprotic solvents containing oxygen, nitrogen, and sulfur atoms (e.g, nitrobenzene,[7m] amyl alcohol,[7a,7m,10b] pyridine,[7m,10b] quinoline,[7i] or DMSO[8e,15]) will facilitate the reaction by partially converting the reaction into homogenous reaction due to coordination. In particular, the mono-ether of ethylene glycol and its oligomers have shown considerable advantages for being solvents for this condensation, due to their different boiling points, their ability to accelerate the reaction rate because of high solubility for the reaction components, and their miscibility with water to simplify the workup process.[6i] One example is that the yield of the reaction between *o*-chlorobenzoic and *p*-aniline was increased from 20% to 48% when it was carried out in 2-methoxyethanol.[7a] However, all the solvents used for this reaction must be dry because the existing water may coordinate with copper and deplete the active catalyst,[7i] as evidenced by the lower yield by extraction of the reaction intermediate with 95% ethanol than that with absolute ethanol.[8i] Furthermore, under the conditions of the Jourdan-Ullmann condensation, many other nucleophiles can also couple with aryl halides, such as ammonia, potassium phenoxide, alkoxide, hydroxide, and even the sodium derivative of ethyl malonate and similar compounds of active methylene groups.[7m] However, this reaction suffers from high reaction and the need for a large excess of copper or copper salts.[12b] In addition, this reaction is often accompanied with reductive dehalogenation of aryl halides.[7m,8c]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Even though the Jourdan-Ullmann condensation has been known for more than a century, the mechanism is still not quite clear. On the one hand, the reaction may proceed via a free-radical mechanism, pertaining to the reductive dehalogenation of aryl halides and the acceleration of the reaction rate by ultraviolet irradiation,[7m] as outlined in Scheme 1. On the other hand, the reaction may involve halonium and proceed as a simple aromatic nucleophilic substitution,[7k,7m] as displayed in Scheme 2. However, for the reaction of *o*-halobenzoic acid, it is believed that the copper ion coordinates with both carboxyl and

o-halogen so that the carbon-halogen bond is weakened, and an aromatic nucleophilic substitution occurs subsequently, as illustrated in Scheme 3. This mechanism is supported by the evidence that neither ethyl *o*-bromobenzoate nor *p*-bromobenzoic acid can participate in the Jourdan-Ullmann condensation.[7m]

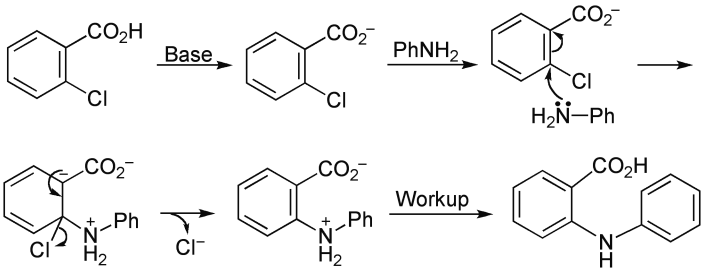
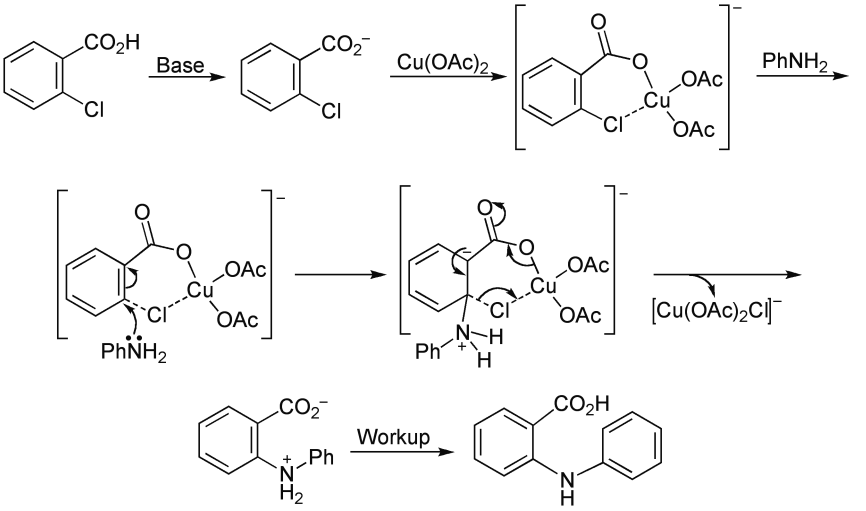


SCHEME 2. *Ionic aromatic nucleophilic substitution mechanism for the Jourdan-Ullmann reaction.*



SCHEME 3. *Alternative mechanism for the Jourdan-Ullmann reaction.*

D. MODIFICATION

Both ultrasound[12a] and microwave[7b,7c] have been applied to accelerate the reaction; the Jourdan-Ullmann condensation under microwave irradiation can be carried out in

either dry media[7b] or in aqueous solution.[7c] In addition, this reaction has been extended to *O*- and *S*-arylation in the presence of polycoordinate ligand,[8b] such as the application of 2-methylaminomethyl-3-hydroxypyridine for the preparation of diaryl ether.[8c] It should be mentioned that the reaction under Jourdan-Ullmann condensation to form diaryl ether is known as the *Ullmann Diaryl Ether Synthesis*.[16] Moreover, this reaction has been extended to the preparation of triarylamines using 10-phenanthroline as a ligand.[7h] Other modifications include the couplings of anilines with aryl amides (e.g., isatin),[15] diphenyliodonium-2-carboxylate,[4a,17] and arylboronic acids.[18] The condensation with arylboronic acids in particular is considerably versatile and is known as the Chan-Lam-Evans modified *Ullmann Condensation*.[19]

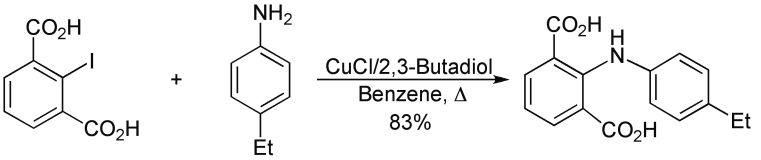
E. APPLICATIONS

This reaction has wide application in the preparation of diarylamines, many of the diarylamines have been converted into acridone and acridine derivatives.

F. RELATED REACTIONS

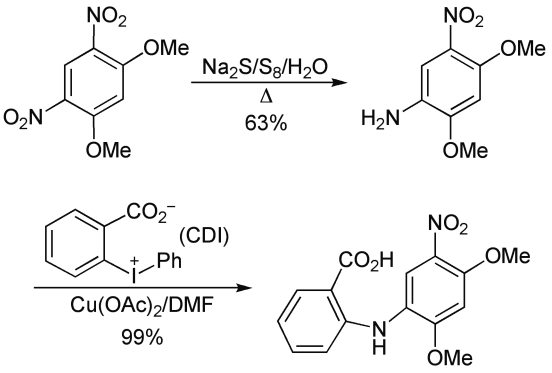
This reaction is related to the *Rosemound-von Braun Nitrile Synthesis, Ullman Diaryl Ether Synthesis*, and *Ullmann Acridine Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 15.

A mixture of 2.92 g 2-iodoisophthalic acid (10 mmol), 1.82 g 4-ethylaniline (15 mmol), 1 g CuCl, 12 mL 2,3-butanediol, and 10 mL benzene was heated and stirred, with the benzene being allowed to distill off. When the internal temperature of the reaction mixture reached 100°C, 6 mL *N*-ethylmorpholine was added, and the reaction mixture was stirred for an additional 4 h at 120°C. The reaction mixture was then diluted with 50 mL 0.5 M NH_4OH, treated with charcoal, and filtered through Celite. Acidification with 2 M HCl afforded a precipitate that was extracted into EtOAc (2 × 100 mL), filtered through Celite, and further extracted with 100 mL 0.5 M aqueous NH_3. Acidification with concentrated HCl and recrystallization of the isolated product gave 2.36 g 2-[(4-ethylphenyl)amino]isophthalic acid, in a yield of 83%, m.p. (EtOAc/petroleum ether) 194–195.5°C.



Reference 4a.

A suspension of 20.1 g 1,5-dimethoxy-2,4-dinitrobenzene (90.0 mmol) in 117 mL water was stirred under reflux and treated dropwise over 30 min with a solution of sodium polysulfide, prepared by heating 28.6 g $Na_2S{\cdot}9H_2O$ (119 mmol) and 6.8 g sulfur (213 mmol) in 120 mL water. The reaction mixture was stirred under reflux for a further 3 h and then cooled and evaporated under reduced pressure at 45°C to give a dark residue. This was extracted several times with warm EtOAc, and the combined extracts were filtered through a short column of silica gel. The eluates were washed with water and evaporated to dryness. The residue was dissolved in 1 N HCl, filtered, and basified with aqueous NaOH to give 11.0 g 1-amino-2,4-dimethoxy-5-nitrobenzene, in a yield of 63%, m.p. 126–128°C.

A mixture of 6.0 g 1-amino-2,4-dimethoxy-5-nitrobenzene (30.9 mmol), 20.0 g diphenyliodonium-2-carboxylate (61.4 mmol), and 0.4 g copper(II) acetate (2.2 mmol) in 180 mL dry DMF was stirred at 90°C (bath temperature) for 7 h and then at 20°C for overnight. Most of the DMF was evaporated under reduced pressure, and the residue was taken up into CH_2Cl_2, washed twice with water, and extracted into 0.5 N KOH. The alkaline layer was back extracted with CH_2Cl_2 and filtered, and the filtrate was acidified at 0°C to give 9.7 g 2-[(2,4-dimethoxy-5-nitrophenyl)amino]-benzoic acid, in a yield of 99%, m.p. ($CHCl_3$/MeOH) 283–285°C.

Julia Olefination

(Julia-Kocienski Olefination or Julia-Lythgoe Olefination)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Julia in 1973.[1] It is primarily a multistep preparation of *trans*-olefins involving the addition of phenylsulfonyl carbanion to aldehydes or ketones to form β-hydroxysulfones, followed by the esterification of hydroxyl group (benzoyl or acetyl) and reductive elimination of β-sulfonyl esters with sodium amalgam. Therefore, this reaction is generally known as the Julia olefination.[2,3] Occasionally, this reaction is also referred to as the Julia reaction[4] or Julia coupling.[2c,2h,2s,4b,5] Because of its intrinsic weaknesses—including multiple steps, low tolerance for reducible functional groups, and the presence of mercury reagent—the original protocol has been extensively modified and extended by researchers such as Kocienski (Kociensky) and Lythgoe,[6] Julia,[7] and Keck.[8] These modifications employ the one-step reaction between heterocyclic sulfonyl carbanion and aldehyde (or ketone) to give either *cis*- or *trans*-olefins or replace the reduction from the sodium amalgam by samarium iodide (SmI_2).[8] Therefore, the modified olefination methods are referred to as the Kocienski olefination,[2p] Julia-Kocienski olefination,[2a,9] Kocienski-Julia olefination,[10] Julia-Kociensky olefination,[9d] Kocienski-Julia coupling,[2d] Julia-Lythgoe olefination,[2r,4a,8b,11] Julia-Lythgoe reaction,[11f]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

or Julia-Lythgoe coupling.[2g,8b,11j] The applied heterocyclic sulfones in this olefination include benzothiazol-2-yl sulfones (BT), 1-phenyl-1*H*-tetrazol-5-yl sulfones (PT), 2-pyridinyl sulfones (Pyr), and *tert*-butyl-1*H*-tetrazol-5-yl sulfones (TBT), as shown in Figure 1. Besides improving the weakness associated with the original Julia protocol, the application of heterocyclic sulfones in this olefination provides extra advantages, such as enabling more or less pronounced complexation between the heterocycle and metal cation to influence the selectivity, and undergoing nucleophilic substitution at the carbon attached to the sulfonyl group, which then becomes a leaving group. It has been found that when benzothiazol-2-yl sulfones are applied as the carbanion source, the stereoselectivity is controlled by solvent.[12] In general, more *cis*-olefins are formed when this reaction is carried out in solvents such as toluene, methylene chloride and diethyl ether; more *trans*-olefins are produced in solvents such as DME and DMF.[12] In addition, the electronic and steric nature of such sulfones do not affect the yield and the selectivity of olefination.[2i] Unfortunately, the application of benzothiazol-2-yl sulfones is often accompanied with a side product from the nucleophilic addition of sulfonyl carbanion to a second benzothiazol-2-yl sulfone,[7c] thus the Julia olefination involving benzothiazol-2-yl sulfone is best carried out by adding base into the mixture of aldehyde and sulfone. Further modification for the application of benzothiazol-2-yl sulfone as the starting material is to trap the reaction with trimethylsilyl chloride to form a cyclic sulfone intermediate, which is then converted exclusively to *trans*-olefin under acidic conditions, or alternatively transformed into the mixture of *cis*- and *trans*-olefin with the treatment of a base, e.g., TBAF.[2f] On the other hand, both 2-pyridinyl sulfones[7b] and *tert*-butyl-1*H*-tetrazol-5-yl sulfones exhibit high *cis*-selectivity for olefins, in addition, *tert*-butyl-1*H*-tetrazol-5-yl sulfone is especially good for the synthesis of aliphatic olefins, resulting in a higher yield and selectivity than the application of PT or BT. In contrast, 1-phenyl-1*H*-tetrazol-5-yl sulfone gives somewhat better *trans*-selectivity than the BT sulfones because of the steric demands of the phenyl group.[2d,10b] In addition, PTs do not show the tendency of self-condensation like BT does, so that they can be deprotonated and then react with aldehydes. Thus PTs are suitable for coupling with base sensitive aldehydes. In addition, PT also shows the metal cation effect by which higher *cis*-selectivity is achieved when potassium is applied as the metal rather than lithium.[10b]

It has been found that the original Julia olefination protocol occurs via two mechanisms, depending heavily on the reducing agent.[4a] However, more recent experimental evidence prefers initial elimination of the ester to form vinyl sulfone, which would then undergo homolytic cleavage to give vinyl radical and finally transform into *trans*-olefin through vinyl anion, as illustrated in Scheme 2.[8b] However, modified Julia olefination using heterocyclic sulfones proceeds via a different mechanism, involving the reversible addition of carbanion to carbonyl group. A closed transition state forms from the chelation when lithium is used as the counterion and in nonpolar solvent, whereas an open transition state is possible in polar solvent and when a larger potassium cation is applied as the counterion, leading to either *cis*- or *trans*-olefins.[13] This reaction has been widely used to prepare predominantly *trans*-olefins, especially in convergent synthesis of complex structures of natural products.[8b] However, one should be aware that a potential problem exists during the preparation of allyl sulfones through the oxidation of allyl sulfide, by which allyl alcohol might be generated as a side product.[14]

B. GENERAL REACTION SCHEME

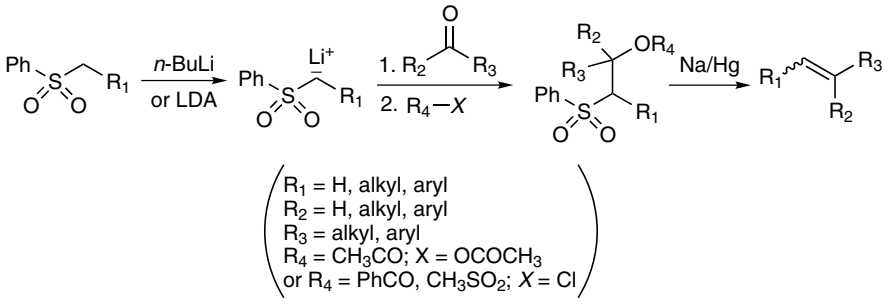

FIGURE 1. *Heterocyclic sulfones used in the modified Julia olefination.*

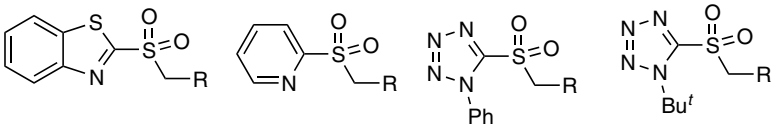
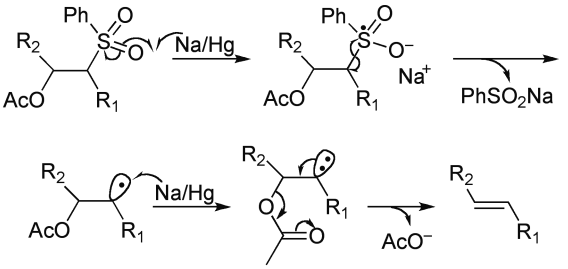
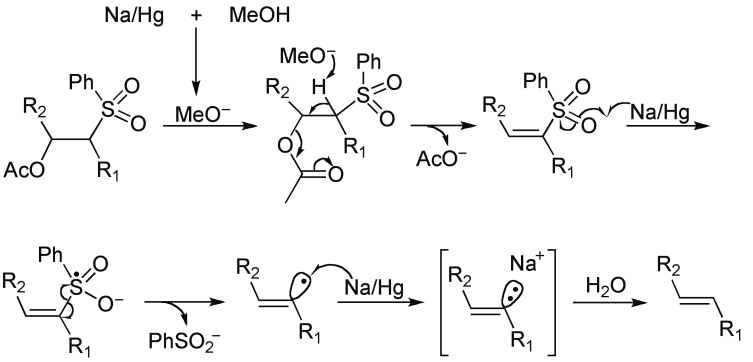


C. PROPOSED MECHANISMS

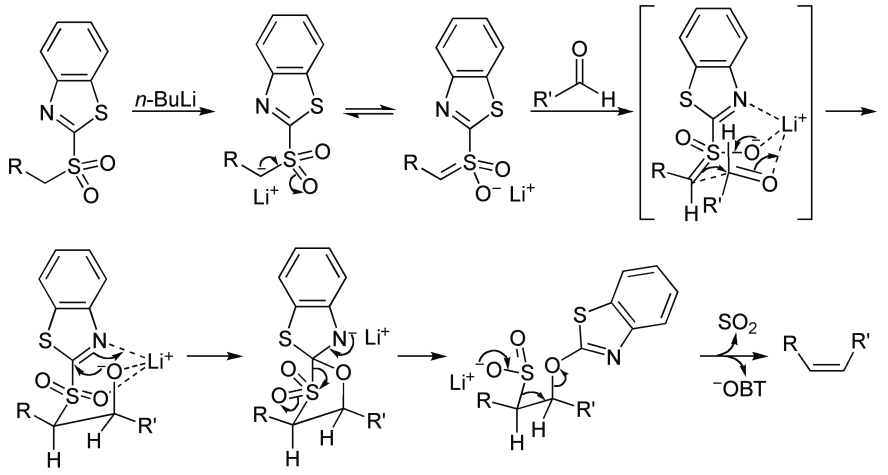
The original mechanism for the Julia olefination is shown in Scheme 1 (the reduction step only). The revised mechanism is shown in Scheme 2, and the mechanism for the modified Julia olefination (i.e., the Julia-Kocienski olefination) is shown in Scheme 3.



SCHEME 1. *Original mechanism for the Julia olefination (partial).*



SCHEME 2. *Revised mechanism for the Julia olefination.*



SCHEME 3. *Mechanism of the modified Julia olefination in a nonpolar solvent.*

D. MODIFICATION

The original Julia olefination protocol has been extensively modified using heterocyclic sulfones as the starting materials to control the stereochemistry.

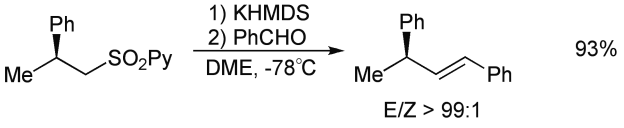
E. APPLICATIONS

This reaction has been widely used in the preparation of olefins, especially in the convergent synthesis of complex natural products.

F. RELATED REACTIONS

This reaction is related to the *Wittig Reaction* and *Petersen Olefination*.

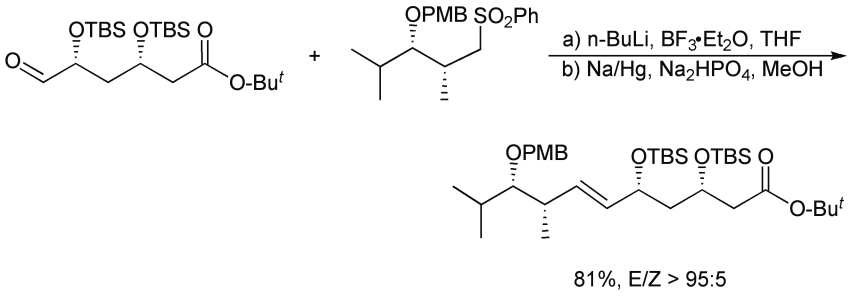
G. CITED EXPERIMENTAL EXAMPLES



Reference 9d.

To a stirred solution of 46 mg chiral (*S*)-2-phenyl-1-((2-pyridyl)sulfonyl)propane (0.176 mmol) dissolved in 4.6 mL anhydrous DME (0.033 M) under argon and cooled at –78°C were added 530 μL 0.5 M potassium hexamethyldisilazide in toluene via syringe.

The yellow-orange solution was stirred for 3 min, then 27 μL benzaldehyde (0.264 mmol) was added, and the mixture was stirred at –78°C for 2 h. The pale yellow solution was quenched with saturated NH_4Cl at the same temperature and diluted with 5 mL CH_2Cl_2, and the aqueous layer was extracted with CH_2Cl_2 (3 × 10 mL). The combined organic layers were dried over anhydrous Na_2SO_4, the solvent was removed in vacuo and the resulting pale yellow oil was purified by column chromatography (hexanes) to give 34 mg (1*E*,3*R*)-1,3-diphenyl-1-butene, in a yield of 93% with an E/Z ratio ~ 99:1.



Reference 2g.

To a solution of 673 mg ({(3*S*,2*R*)-3-[(4-methoxyphenyl)methoxy]-2,4-dimethyl-pentyl}sulfonyl)-benzene(1.80 mmol) in 17 mL THF at −78°C was added 1.2 mL 1.55 M *n*-BuLi in hexanes (1.90 mmol), and the canary yellow solution was stirred for 1 h before the addition of 0.22 mL $BF_3{\cdot}OEt_2$(1.80 mmol). After being stirred for 15 min, a −78°C solution of *tert*-butyl (3*S*,5*R*)-3,5-bis(*tert*-butyldimethylsilyloxy)-6-oxohexanoate in 5 mL THF was added dropwise via cannula. After an additional 1 h of stirring, the reaction mixture was quenched with 5 mL saturated aqueous NH_4Cl, diluted with 30 mL Et_2O, and allowed to warm to room temperature. The aqueous phase was extracted with Et_2O (2 × 30 mL), and the combined organic layers were washed with 60 mL each saturated aqueous $NaHCO_3$ and brine before being dried over $MgSO_4$ and concentrated in vacuo. To a solution of the residue in 17 mL CH_3OH at −40°C was added 1.20 g Na_2HPO_4 (8.60 mmol) followed by 4 g 5% Na/Hg amalgam (8.30 mmol) in two portions. The cold bath was removed, and the mixture was stirred vigourously for 1.5 h and then quenched by the addition of 5 mL saturated aqueous NH_4Cl and diluted with 50 mL Et_2O. The aqueous phase was extracted with Et_2O (2 × 50 mL), and the combined organic layers were washed with 75 mL each saturated aqueous $NaHCO_3$ and brine before being dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by flash chromatography (5% EtOAc/hexanes) to afford 470 mg *tert*-butyl (6*E*)(3*S*,8*S*,9*S*,5*R*)-3,5-bis(*tert*-butyldimethyl-silyloxy)-9-[(4-methoxyphenyl)methoxy]-8,10-dimethyl-undec-6-enoate as a clear colorless oil, in an overall yield of 81% for the two steps.

Other references related to the Julia olefination are cited in the literature.[15]

Juliá-Colonna Asymmetric Epoxidation

(Juliá Asymmetric Epoxidation)

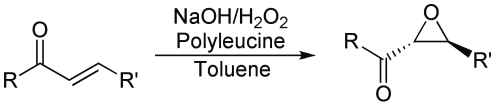
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Juliá in 1980[1] and was extended by Juliá and Colonna in 1982.[2] It is the oxidation of electron-deficient *trans*-α,β-enones into *trans*-α,β-epoxyketones by a hydroperoxide anion in the presence of polyamino acid. Therefore, this reaction is known as the Juliá epoxidation,[3] Juliá asymmetric epoxidation,[4] Juliá-Colonna epoxidation,[5] Juliá-Colonna reaction,[6] Juliá-Colonna oxidation,[7] or Juliá-Colonna stereoselective epoxidation;[8] however, it is more generally referred to as the Juliá-Colonna asymmetric epoxidation.[5f,6,9] The initial epoxidation protocol is limited to electron-deficient enones, such as chalcone in a three-phase reaction, by which the enones, dissolved in an organic solvent (such as hexane, CCl_4, or toluene), are oxidized by hydroperoxide anion (H_2O_2 + NaOH) in aqueous solution, under the catalysis of insoluble polyalanine or polyleucine.[2,10] This protocol has been extended to a two-phase reaction by dissolving enones in THF and using anhydrous urea-H_2O_2 as an oxidant in the presence of insoluble polyamino acid as the catalyst.[11] In addition, this reaction has also been carried out homogenously in a mixed solvent of water and DME, using sodium percarbonate as both base and oxidant.[12] Following this direction, further modification of this reaction has immobilized the catalyst of polyamino acid onto silica gel[8b,13] or polyethylene glycol (PEG).[5f] The modification by immobilizing the catalyst on silica gel bears the obvious advantages of improved filtration properties, high catalyst activity, ease of recycling, and higher stability.[6,8b,13] In this case, the best solvent is pyridine.[8b] It has been found that enones bind to the *N*-terminus

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

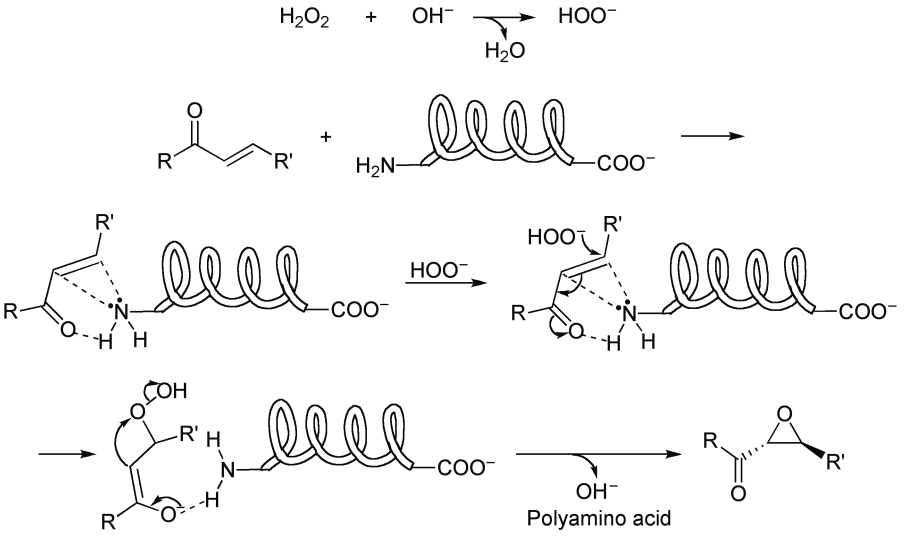
of the polypeptide, and it is the α-helicity of the polypeptide that determines the configuration of the epoxide through the face-selective delivery of a hydroperoxide anion.[5f,5g,9h] Furthermore, it has been reported that the peptide would be active as short as five amino acid residues, just enough to form one complete α-helix.[5g] Common polypeptides used for this reaction are $\sim$ 30 amino acid residues;[6] among these polypeptides, poly-neopentylglycine has higher catalytic activity than polyleucine.[6,14] It should be pointed out that this reaction is not suitable for the epoxidation of endocyclic enones, such as cyclohexenones or quinones and *cis*-enones.[5g]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is proposed here for the epoxidation of enone.



D. MODIFICATION

This reaction has been modified to occur in two phases using urea-H_2O_2 as the oxidant[11] or to take place homogenously using sodium percarbonate as the oxidant.[12] Further modifications of this reaction include the immobilization of catalyst onto PEG[5f] or silica gel[8b,13] to simplify the purification process.

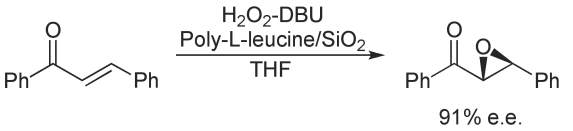
E. APPLICATIONS

This reaction has been widely used for the epoxidation of *trans*-enones.

F. RELATED REACTIONS

This reaction is related to the *Sharpless Epoxidation*.

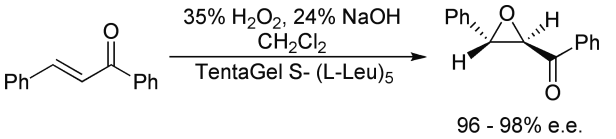
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

To a stirred 0.16 M solution of L-leucine NCA in anhydrous THF under a nitrogen atmosphere was added an initiator (0.0313 amino equivalents, either amino methyl polystyrene or 1,3-diaminopropane). The course of the reaction was followed by IR spectroscopy and TLC. After polymerization was judged complete, the reaction was filtered, and the solid poly-L-leucine was washed with further solvent and then dried in vacuo at 50°C. Then the poly-L-leucine was mounted on silica gel in THF according to Geller and Roberts.[8b]

To solution of chalcone (1 eq.) in anhydrous tetrahydrofuran was added urea-hydrogen peroxide (1.2 eq.), diazabicycloundecene (1.2 eq.), and poly-L-leucine (12 mol % optionally immobilized on silica, i.e., one part catalyst, three parts silica). The mixture was stirred at room temperature until the reaction was complete (TLC) ($\sim$ 7 days). The catalyst was removed by rapid filtration and washed with EtOAc. The combined organic fractions were evaporated in vacuo to yield crude epoxide. It was found that $\sim$ 45% of chalcone had been oxidized within the first 30 min, and the overall epoxyketone has 91% e.e.



Reference 5g.

To a stoppered test tube, equipped with a magnetic stir bar (10 × 3 mm) and thermostated to 20°C by a water jacket, was added 0.0219 mmol of penta-L-leucine on Tenta Gel S, and 1.6 mL dichloromethane containing 40.0 mg *trans*-chalcone (0.192 mmol). The reaction was started by the addition of 2.0 mL of a prethermostated mixture of three parts 24% NaOH and four parts 35% H_2O_2. The magnetic stirrer was set to 1200 rpm, and the test tubes were protected from light. After 24 h, 20 μL of the organic phase (lower layer) was withdrawn by means of a syringe, diluted with 1.0 mL dichloromethane, and analysized by HPLC, indicating that the product had a 96–98 % e.e.

Other references related to the Juliá-Colonna asymmetric epoxidation are cited in the literature.[15]

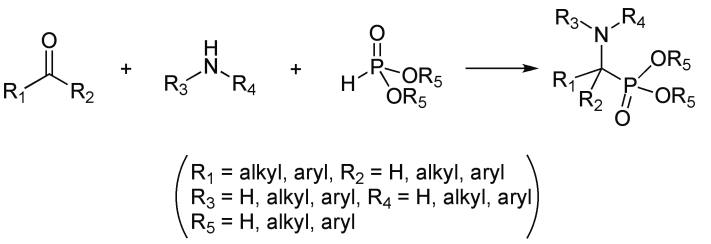
Kabachnik-Fields Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported concurrently in 1952 by Kabachnik and Medved[1] and Fields.[2] It is a one-pot synthesis of α-amino phosphonate via the three-component coupling of aldehyde (or ketone), an amine, and a dialkylphosphite. Therefore, it is generally known as the Kabachnik-Fields reaction.[3,4] Occasionally, it is also referred to as the Kabachnik-Fields synthesis.[5] It has been found that ketones undergo the coupling more readily than aldehydes, especially for aliphatic ketones that react vigorously with amine and phosphite.[6] However, alicyclic and aromatic-aliphatic ketones react with amine at a relatively slow rate, and aromatic ketones react with even more difficulty.[3m] On the other hand, both primary and secondary amines can undergo this reaction.[2] Even though some reactions are carried out without any catalysts,[7] in most cases, this reaction is catalyzed by an acid or promoted by a base, such as CF_3CO_2H,[8] $InCl_3$,[9] $La(OTf)_3$,[10] $LiClO_4$,[11] $Sc(O_3SOC_{12}H_{25})_3$,[12] SiO_2,[13] or $TaCl_5$-SiO_2.[14] In addition, this reaction can also be promoted by microwave.[3j] The resulting α-amino phosphonates are useful for chelating agents.[15] It has been found that the direct reaction between phosphonate and imine results in the same product as the three-component coupling from phosphite, amine, and carbonyl compound; high yields are achieved if the anhydrous ammonia and carbonyl compounds are mixed before the dialkyl phosphite is added.[16]

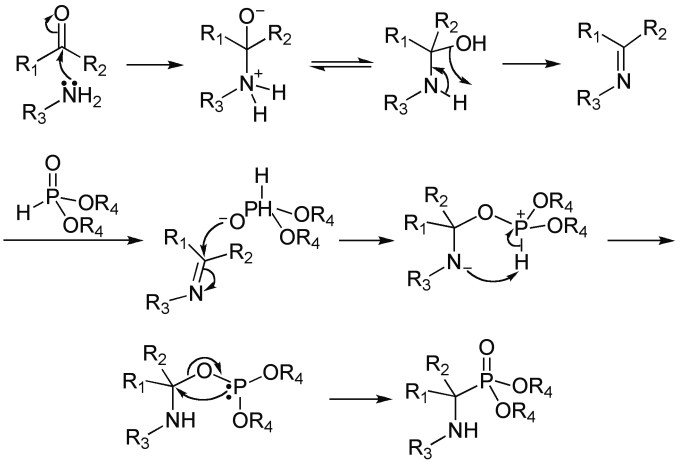
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed that this reaction occurs through the addition of dialkyl phosphite to the imine intermediate formed from the carbonyl compound and amine. It is known that both acid and base can accelerate the formation of the imine. Outlined here is a tentative mechanism for this reaction.



D. MODIFICATION

This reaction has been modified by using different catalysts as described in section A.

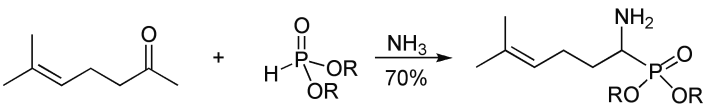
E. APPLICATIONS

This reaction has been used for the preparation of α-amino phosphonates.

F. RELATED REACTIONS

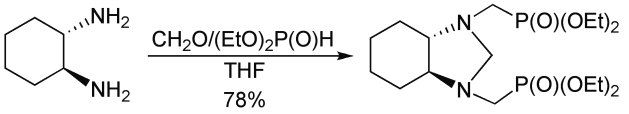
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 17.

Gaseous ammonia was bubbled through a stirred mixture of hept-5-en-2-one (0.10 mol) and dialkyl phosphite (0.11 mol) at 60°C. The reaction was monitored by TLC and generally finished within 4 h. The reaction mixture was then treated with 1 M aqueous HCl and extracted with ether. Aqueous NaOH was then added to adjust the pH to 10, and the mixture was then extracted with ether. The organic phase was washed with brine and dried over Na_2SO_4. Evaporation of the solvent under reduced pressure afforded 70% dialkyl (1-amino-1,5-dimethyl-4-enyl)phosphonate as a yellow oil.



Reference 3h.

To a magnetically stirred solution of 3.42 g *trans*-1,2-diaminocyclohexane (30 mmol) in 40 mL anhydrous THF was added slowly 8.3 g diethyl phosphite (60 mmol). The reaction mixture was refluxed before the addition of 2.8 g paraformaldehyde (93 mmol). After heating under reflux for 4 h, the solvent was evaporated under reduced pressure. The residue was dissolved in 50 mL $CHCl_3$, and the organic layer was washed twice with H_2O (2×10 mL) and dried over Na_2SO_4. The chloroform was evaporated under vacuum to obtain 10 g of a crude yellow oil that was purified by Kugelrohr distillation to yield 78% [3-(diethoxyphosphorylmethyl)-octohydro-benzoimidazol-1-ylmethyl]-phosphonic acid diethyl ester ($T = 280$°C, 0.1 mmHg).

Other references related to the Kabachnik-Fields reaction are cited in the literature.[18]

Kahne Glycosylation

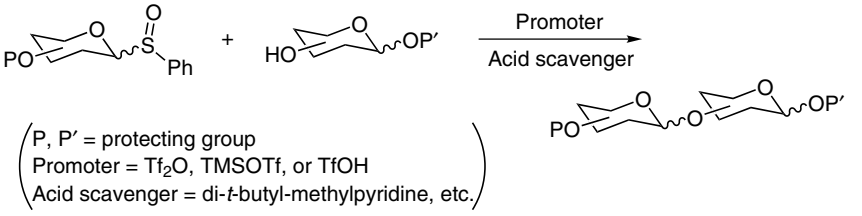
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Kahne in 1989.[1] It is a convenient synthesis of glycosides and disaccharides or oligosaccharides between glycosyl phenyl sulfoxide (i.e., the glycosyl donor) and an acceptor in the presence of a glycosylation promoter. Because of its obvious advantages, including the mild reaction condition,[2] good to excellent anomeric stereocontrol, compatibility with both solution and solid-phase glycosylation[3] and high reactivity of glycosyl donor, this reaction has been widely used for the synthesis of oligosaccharides. Therefore, this reaction is generally known as the Kahne glycosylation[4] and is especially useful for unreactive acceptors, or the most hindered alcohols.[5] So far, the glycosides of acetamide,[6] hindered bile acids,[1] hydroxylamines,[7] hydroxylated amino acids,[8] phenols,[1] tertiary alcohols,[9] and a variety of carbohydrates[1,10] have been prepared by this method. Alcohols have sometimes been converted into their tributylstannyl ether derivatives before being mixed with glycosyl sulfoxides (known as sulfinil glycosides[11]), presumably because of the enhanced nucleophilicity of the acceptors.[2] The promoters for this reaction are triflic anhydride (Tf_2O)[12] and trimethylsilyl triflate (TMSOTf)[13] in a stoichiometric amount or triflic acid in a catalytic amount.[11] In addition, this reaction is often carried out in a nonpolar solvent[11] at low temperature[14] in the presence of an acid scavenger (e.g. di-*t*-butyl methyl pyridine);[11] however, when a catalytic amount of triflic acid is used as the glycosylation promoter, methyl propionate is applied as the sulfenlic acid scavenger.[10a] It should be pointed out that the glycosylation is not restricted to glycosyl phenyl sulfoxides, glycosyl alkyl sulfoxides[2] and sulfimides[15] are suitable for glycosyl donors as well. It is found that the protecting groups on sulfinil glycosides have an apparent effect on the stereochemistry of glycosides. For example, the glycosylations of pivalate-protected glucosyl phenyl sulfoxide always give β-glycosides,[2] whereas reaction of the corresponding

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

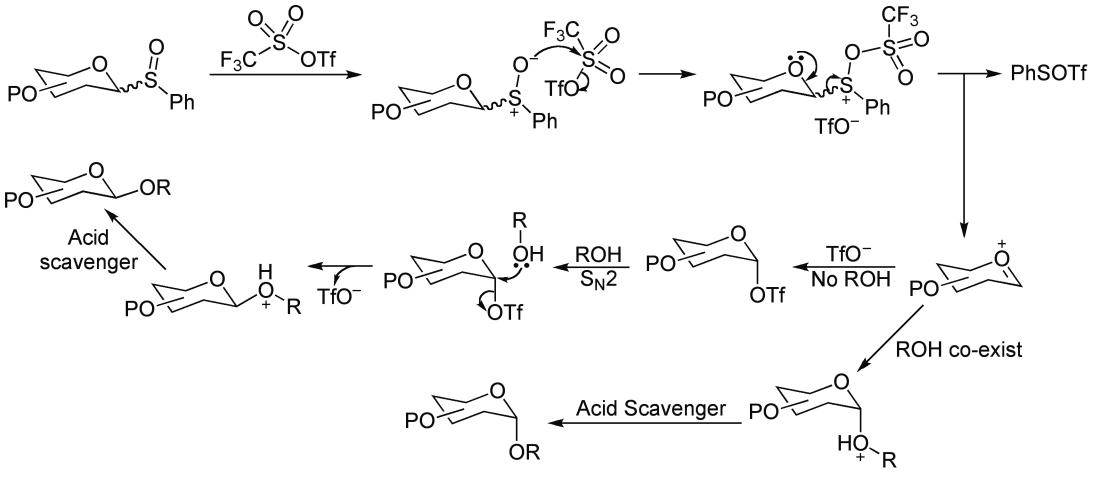
perbenzyl derivatives results in a mixture of α- and β-anomers by which the β:α ratio increases with solvent polarity and approaches the optimal selectivity in propionitrile.[2] It has also been found that even the mixing sequence of a promoter and acceptor can influence the stereochemical outcome, such as the formation of mainly α-anomer if the donor, acceptor, and base are mixed before the addition of triflic anhydride; prior activation of the donor with Tf_2O reverses the stereoselectivity.[16] Thus it is generally recommended to activate the sulfoxide donor with Tf_2O before the adding the glycosyl acceptor.[2]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It has been suggested[2] that glycosyl sulfoxide is converted into sulfonium salt, which collapses immediately to the oxacarbenium ion and the sulfenyl triflate. In the presence of a glycosyl acceptor, the oxacarbenium ion is trapped directly by the acceptor along the axial attack, leading to α-glycoside; in the absence of an acceptor, the oxacarbenium ion is trapped by triflate to form glycosyl triflate as an intermediate, which then couples with the following added acceptor to form β-glycoside, as shown below.



D. MODIFICATION

This reaction has been extended to glycosyl alkyl sulfoxide[2] and glycosyl disulfide.[17] In addition, reverse Kahne glycosylation has also been made possible by coupling between carbohydrate and alkyl sulfoxides.[4a]

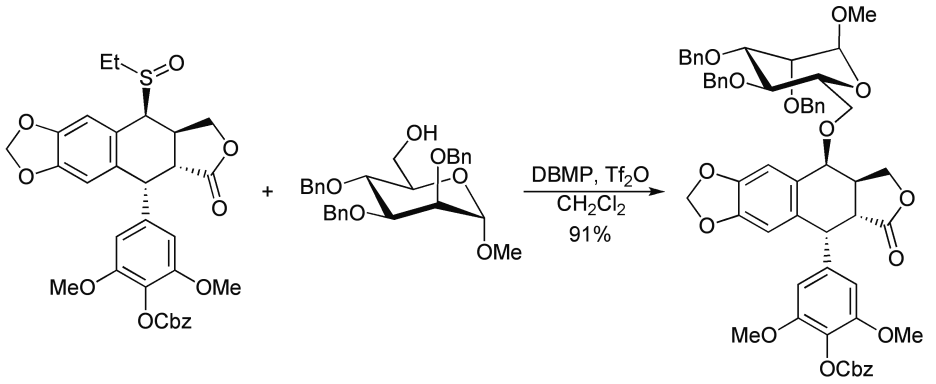
E. APPLICATIONS

This reaction has wide application in the preparation of glycosides, disaccharides, and oligosaccharides.

F. RELATED REACTIONS

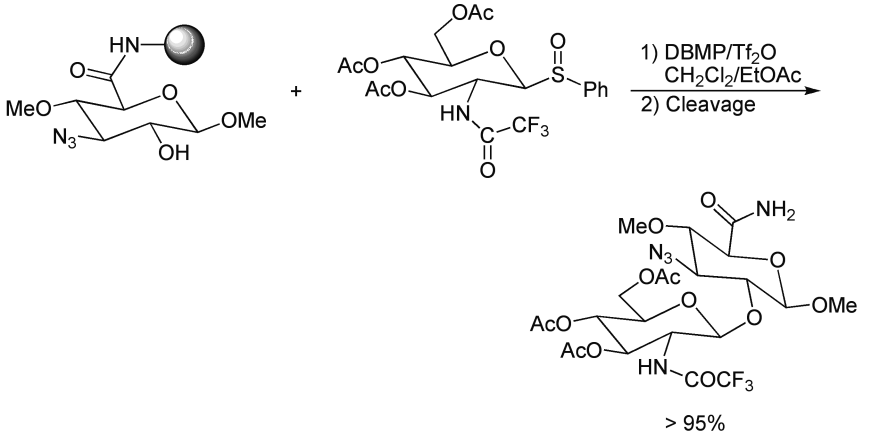
This reaction is related to the *Helferich Glycosylation*, *Hilbert-Johnson Reaction*, and *Koenigs-Knorr Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

To a solution of 10.0 mg sulfoxide (0.017 mmol) and 7.0 mg 2,6-di-*tert*-butyl-4-methylpyridine (DBMP, 0.034 mmol) in 1 mL CH_2Cl_2 at −78°C was added 5.0 μL trifluoromethanesulfonic anhydride (25 μmol). After 10 min, a solution of 24 mg methyl 2,3,4-tri-*O*-benzyl-α-D-mannopyranoside (50 μmol) in 0.5 mL CH_2Cl_2 was added via cannula, and the reaction mixture was left stirring at −78°C for 3 h. The reaction mixture was diluted with CH_2Cl_2 and washed with water, followed by drying over Na_2SO_4, filtration, and evaporation. Flash chromatography (0 ∼ 50% EtOAc/hexanes) afforded 15 mg of the desired compound as a single (C_4-*S*) diastereomer, in a yield of 91%, R_f = 0.4 (EtOAc/hexanes, 1:1).



Reference 3.

Rink amide resin (20 mg, 9 μmol) containing the glycosyl acceptor was dried under high vacuum and kept under argon. To the resin was added a solution of 2-deoxy-2-*N*-trifluoroacetyl-3,4,6-*O*-triacetyl-β-D-glucosyl phenyl sulfoxide (4 eq., in concentration of 0.14 M) and 4.5 mg 2,6-di-*tert*-butyl-4-methylpyridine (2 eq.) in 300 μL of mixed solvent of CH_2Cl_2/EtOAc (5:1). The mixture was stirred at room temperature for 5 min and cooled to -78°C. Trifluoromethanesulfonic anhydride (7 μL, 4 eq.) was slowly added, and the system was kept at -70°C for 1 h. The temperature was slowly raised to -45°C and kept constant for 5.5 h. The reaction was quenched with 100 μL of a 2:1 mixture of methanol and DIPEA at -45°C. The reaction mixture was allowed to warm to room temperature, and the resin was washed with DMF (three times), THF (twice), CH_3OH (twice), and CH_2Cl_2 (twice) and dried to give > 95% of product. The final glycoside was then cleaved with 20% TFA-CH_2Cl_2.

Other references related to the Kahne glycosylation are cited in the literature.[18]

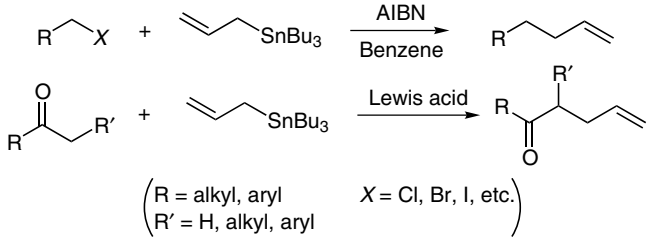
Keck Allylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Keck in 1982.[1] It is a three-carbon chain extension of alkyl halides with allyl tri-*n*-butylstannane in the presence of a radical initiator[2] or an extension of carbonyl compound with allyl tri-*n*-butylstannane in the presence of a Lewis acid.[3] Therefore, it is generally known as the Keck allylation.[2b,2c,3a,3b,4] Occasionally, it is also referred to as the Pereyre-Keck allylation,[5] Keck reaction,[6] or Keck radical coupling.[7] When allyl tri-*n*-butylstannane reacts with α-hydroxyaldehyde, either *erythro* or *threo* products can be controlled with excellent stereoselectivity,[3d] depending on the order of the addition of the reagent, solvent, and Lewis acid involved.[8] It has been found that the *threo* product is formed under chelation control, and the *erythro* product predominates in the absence of Lewis acid; however, a strong electron-donating solvent can overturn the stereochemistry.[8] The Lewis acids suitable for this reaction include $BF_3{\cdot}OEt_2$, $MgBr_2$, $MgCl_2$, $Mg(ClO_4)_2$, $ZnBr_2$, ZnI_2, $TiCl_4$, and $AlMe_3$.

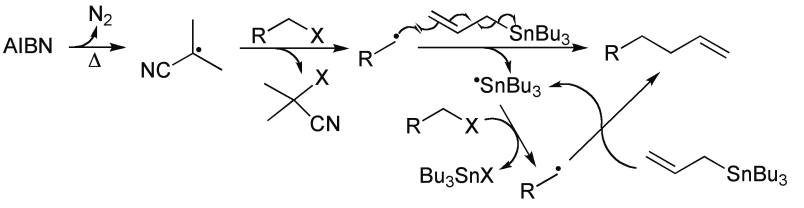
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

Demonstrated here is the mechanism of the Keck allylation proceeding via a radical pathway.



D. MODIFICATION

N/A

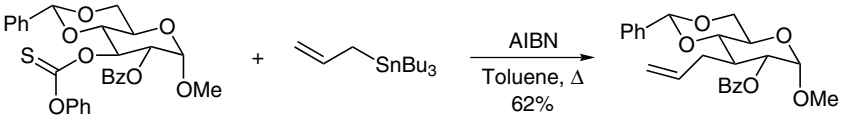
E. APPLICATIONS

This reaction has wide application in the extension of carbon chains in organic synthesis.

F. RELATED REACTIONS

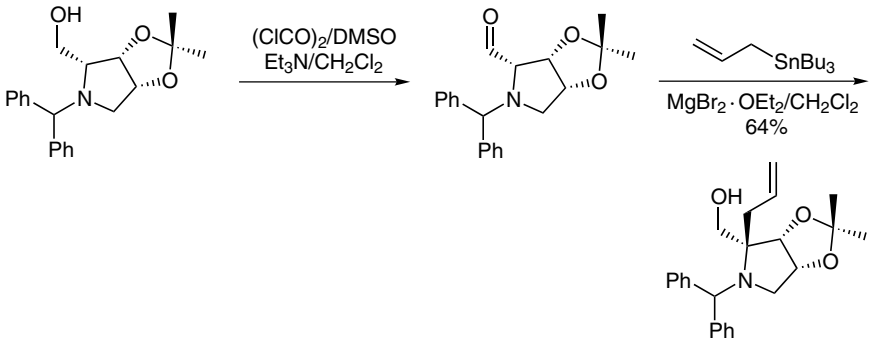
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 4b.

A mixture of 4.98 g methyl 2-benzoyl-3-phenoxythiocarbonyl-4,6-benzylidene-α-D-glucoside (9.5 mmol), 7.40 mL allyltributyltin (23.9 mmol), 313 mg AIBN, and 15 mL toluene was refluxed for 4 h at which point TLC showed complete consumption of the starting material. The solution was concentrated, and the residue was flash chromatographed on silica gel using 5% EtOAc in toluene as the eluent to give 3.48 g methyl (3S)-2-*O*-benzoyl-4,6-di-*O*-benzylidene-3-allyl-3-deoxy-α-D-glucopyranoside as a solid, in a yield of 62%, m.p. 138–139°C, R_f = 0.38 (EtOAc/hexanes, 1:9).



Reference 9.

2,3-*O*-Isopropylidene-*N*-diphenylmethyl-1,4-dideoxy-1,4-imino-D-lyxitol (139 mg, 0.411 mmol) was oxidized to aldehyde by Swern oxidation. Then the crude aldehyde was treated with 150 mg activated 4-Å molecular sieves and 6 mL CH_2Cl_2 containing 212 mg $MgBr_2{\cdot}OEt_2$ (0.822 mmol) at -20°C. The resulting mixture was stirred at -20°C for 30 min, and 140 μL allyltributylstannane (0.452 mmol) was added. The reaction mixture was stored at -23°C. After 20 h, ether (10 mL) and 1 mL aqueous KF prepared from 1 mL saturated KF and 4 mL H_2O were added, and the mixture was vigorously stirred at room temperature for 30 min. The phases were separated, and the aqueous layer was extracted with ether. The organic layers were pooled, washed with 5 mL $NaHCO_3$, dried over $MgSO_4$, filtered, and concentrated. The residue was purified on silica gel (10% EtOAc/hexanes) to afford 99.6 mg 4-*C*-allyl-2,3-*O*-isopropylidene-*N*-diphenylmethyl-1,4-dideoxy-1,4-imino-D-lyxitol as an oil, in a yield of 64% with > 20:1 dr.

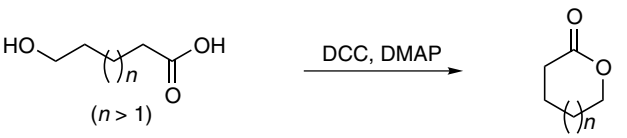
Keck Macrolactonization

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Keck in 1985.[1] It is a carbodiimide[2] (e.g., DCC[3]) promoted esterification to form a macrolactone in the presence of a nitrogenous base (e.g., DMAP,[4] *N*,*N*-dimethylalanine[5]). This reaction has been used in the preparation of a variety of macrolactones, thus is known as the Keck macrolactonization.[3,4b,6]

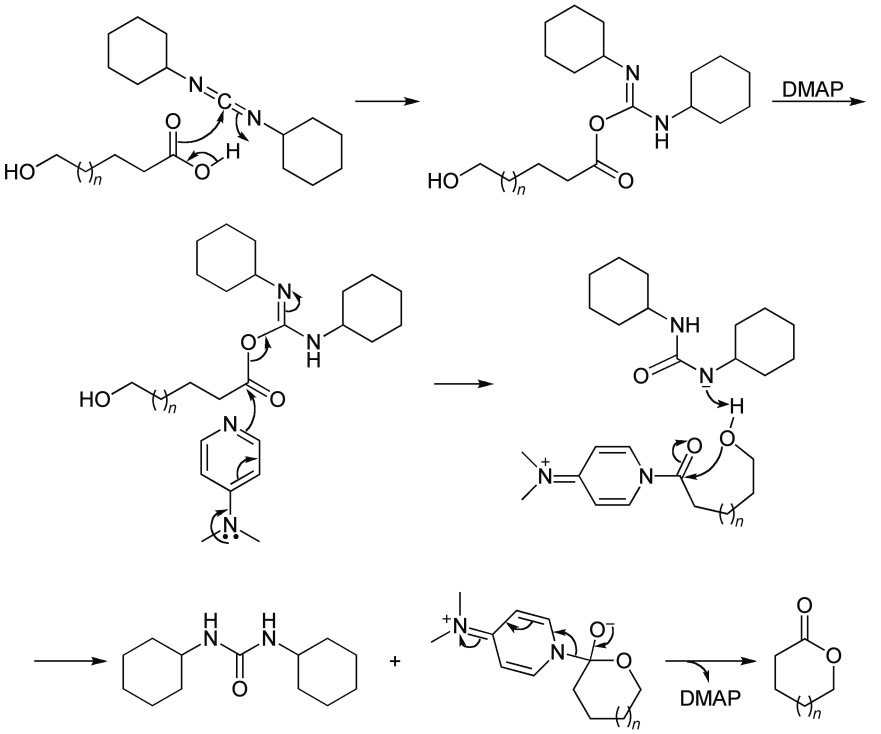
B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The reaction promoted by DCC in a catalytic amount of DMAP is outlined here.

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang



D. MODIFICATION

N/A

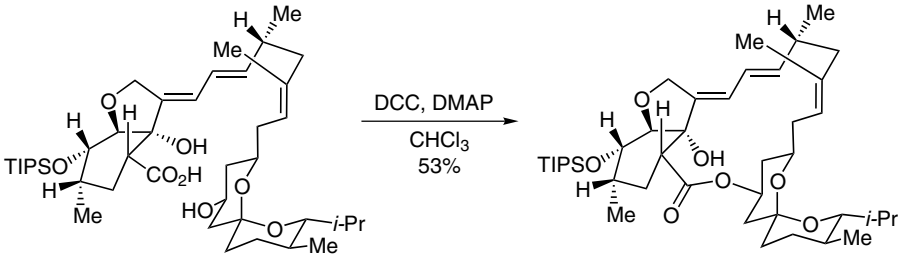
E. APPLICATIONS

This reaction has general application in the preparation of macrolactones.

F. RELATED REACTIONS

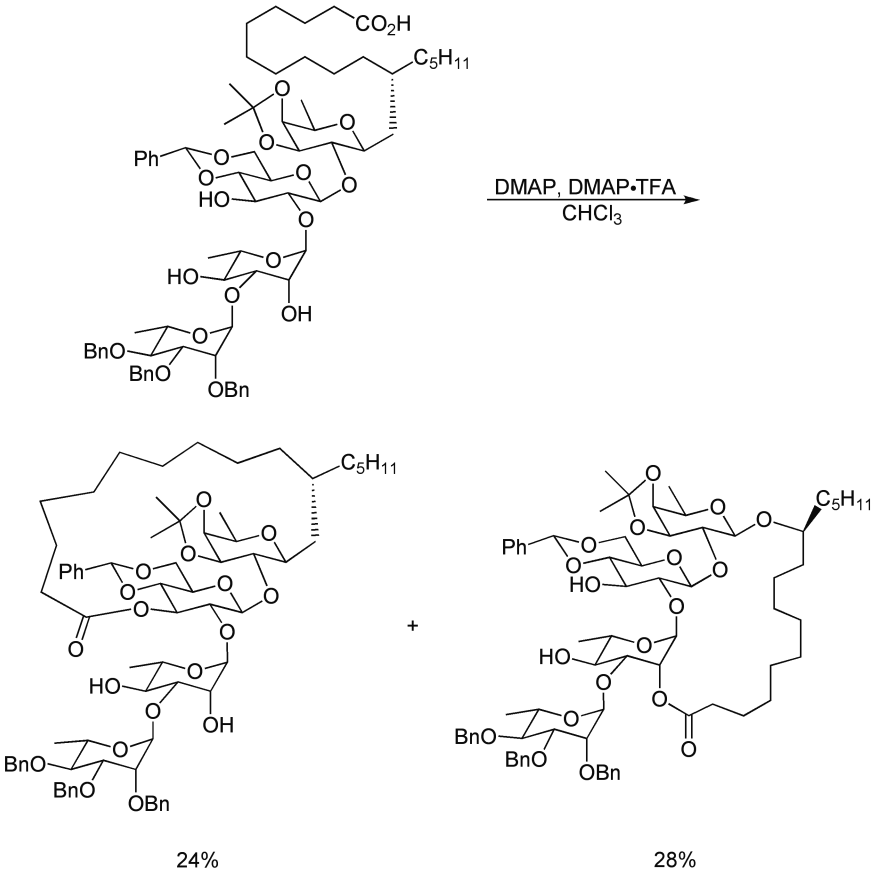
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

A solution of 0.138 g *N*,*N*-dicyclohexylcarbodiimide (DCC, 0.67 mmol), 0.122 g 4-(dimethylamino)pyridine (1.0 mmol), and 0.106 g DMAP·HCl (0.67 mmol) in 350 mL dry $CHCl_3$ (ethanol free) was heated to reflux. Hydroxy acid (0.240 g, 0.33 mmol) in 20 mL dry $CHCl_3$ (ethanol free) was added to the refluxing solution via a syringe pump over a period of 16 h. The long needle was inserted through the condenser and placed directly over the refluxing solution so that the refluxing chloroform washed the substrate droplets forming at its tip. Upon completion of the addition, the flask and syringe containing the substrate were washed by more chloroform (2 × 2 mL), and these solutions were delivered by syringe pump over a period of 1 h. The reaction mixture was cooled to room temperature, and excess DCC was consumed by adding 0.45 mL MeOH and 0.11 mL acetic acid. The resulting solution was stirred at room temperature for 2 h, concentrated in vacuo, and purified by column chromatography on silica gel (0–10% EtOAc/hexanes) to afford macrolactone (0.125 g) as a white foam, in a yield of 53%.



Reference 7.

DMAP (14 mg, 0.11 mmol) and 23 mg DMAP·TFA (0.097 mmol) were combined and azeotroped from benzene. To the dried reagents were added 20 mg DCC (0.097 mmol) and 25 mL EtOH-free $CHCl_3$. The reaction solution was then heated to reflux. In another flask, 25 mg (11*S*)-11-[[(2,3,4-tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→3)-(α-L-rhamnopyranosyl)-(1→2)-(4,6-*O*-benzylidene-β-D-glucopyranosyl)-(1→2)-3,4-*O*-isopro-

pylidene-β-D-fucopyranosyl]oxy]hexadecanoic acid (25 mg, 0.020 mmol) was azeotroped from benzene, dissolved in 7 mL EtOH-free $CHCl_3$, and added to the DMAP solution over 20 h. After the addition was complete, the reaction solution was heated at reflux for 1 h, cooled, and concentrated to 2 mL. The solution was diluted with 25 mL Et_2O, filtered, and concentrated. The residue was purified by chromatography on silica gel with 5 ~ 20% EtOAc in toluene as the eluent to give 6 mg (11*S*)-11-[[(2,3,4-tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→3)-(α-L-rhamnopyranosyl)-(1→2)-(4,6-*O*-benzylidene-β-D-glucopyranosyl)-(1→2)-3,4-*O*-isopropylidene-β-D-fucopyranosyl]oxy]hexadecanoic acid 2_{rha}-lactone as white solid (24%) and 7 mg (11*S*)-11-[[(2,3,4-tri-*O*-benzyl-α-L-rhamnopyranosyl)-(1→3)-(α-L-rhamnopyranosyl)-(1 → 2)-(4,6-*O*-benzylidene-β-D-glucopyranosyl)-(1 → 2)-3,4-*O*-isopropylidene-β-D-fucopyranosyl]oxy]hexadecanoic acid 3_{glu}-lactone (28%).

Kemp Elimination
(Kemp Decarboxylation)

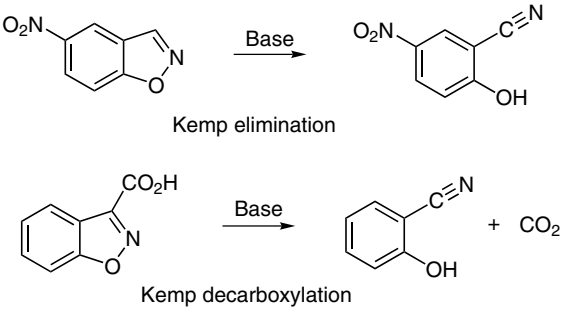
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kemp in 1973.[1] It is a general base-catalyzed ring-opening of a benzisoxazole by cleaving a *N*−*O* bond along with the deprotonation of carbon (C-3) to give *o*-cyano phenol derivatives. This reaction is an exothermic concerted reaction[2] involving an E2 mechanism;[2a] therefore, it is commonly known as the Kemp elimination.[2a,3] When a carboxyl group exists on carbon-3, the corresponding reaction also occurs by *N*−*O* cleavage accompanied by the decarboxylation,[3h,4] thus the Kemp elimination for this special case is referred to as Kemp decarboxylation.[3h,4] It has been found that this reaction is highly sensitive to medium effects. For example, the decarboxylation of 3-carboxy benzisoxazole is over 10^8 times faster in an aprotic dipolar solvent (e.g., CH_3CN) than that in an aqueous solution.[5] This dramatic rate enhancement is due to the destabilization of the carboxylate ion in microenvironments that are deficient in hydrogen bond donors (e.g., in CH_3CN).[3f] As a result, some other materials that can mimic the microenvironment to facilitate the deprotonation can be used as catalysts for the Kemp elimination, such as serum albumins,[2b,3a,3b,3g,3h,6] amino-cyclodextrins,[3i,7] antibody 38C2,[3g] commercially available coals (especially those of lower commercial value),[2a] and vesicles formed from dimethyldioctadecylammonium chloride.[3e] On the other hand, because the Kemp elimination is a simple, one-step transformation without any intermediate[2a] and is sensitive to the medium,[2] it has been selected as a model for studying many enzyme-catalyzed proton transfer reactions,[2a] in which the carboxylate, amino, and imidazole group of amino acid residues (histidine) on enzymes can function as general bases. Carboxyl, sulfurhydryl and hydroxyl groups, on the other hand, can function as general acids. Because of the effect of microenvironment, enzymes can catalyze many reactions that would not be possible under pure chemical conditions, such as the enolization of ketones,[8] of which the α-proton has

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

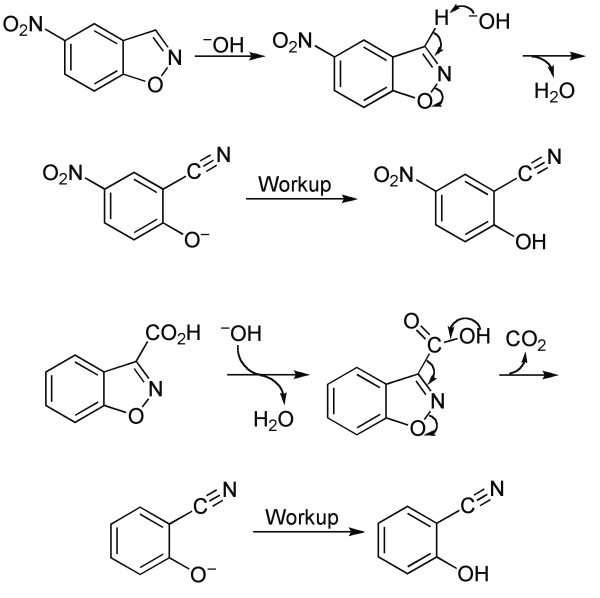
a pKa of 16–24,[1a,9] indicating the α-proton would not be deprotonated under neutral conditions. However, many reactions in which ketones or aldehydes participate in biological systems occur easily in the presence of an enzyme, such as *Aldol Reactions*. This phenomenon has become an interesting and extensively debated topic, known as the hard-soft acid-base (HSAB) theory.[10]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The mechanism of both the Kemp elimination and Kemp decarboxylation are outlined here.



D. MODIFICATION

This reaction has been modified for the use of different catalysts, such as albumin, cyclodextrin, and even commercial coals.

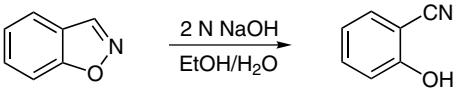
E. APPLICATIONS

This reaction does not show much application in actual organic synthesis but functions as an important model in enzyme studies.

F. RELATED REACTIONS

N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 1b.

A solution of 0.5 g benzisoxazole in 5–8 mL ethanol and 5 mL water was mixed with 2 *N* NaOH (15 mL) solution and allowed to stand for 10 min, at which time HC1 was added to bring the pH to 1. The solution was extracted with dichloromethane (3 × 10 mL), and the organic layers were combined, dried, and evaporated. The residue was recrystallized from water, water-ethanol, or acetonitrile; dried under vacuum for 6 h, and stored in foil-wrapped vials in a desiccator. No yield was given in the original reference.

Other references related to the Kemp elimination are cited in the literature.[11]

Kennedy Oxidative Cyclization

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kennedy in 1992.[1] It is a highly stereoselective conversion of 5-hydroxyl alkene into a *trans*-tetrahydrofuran derivative with *erythro* stereochemistry at the two vicinal carbinol centers via rhenium (VII) oxide (Re_2O_7) promoted *syn*-oxidative cyclization.[2] Therefore, it is referred to as the Kennedy oxidative cyclization.[3] During this reaction, the hydroxy group of substrate binds to Re_2O_7, and the substrate itself turns into an alkoxyperrhenate intermediate along with the formation of 1 eq. perrhenic acid ($HOReO_3$); then the Re=O double bond couples with carbon-carbon double bond via [2+2] addition and releases the tetrahydrofuran derivative via reductive elimination.[4] It is interesting that the comparable oxidative cyclization promoted with $VO(acac)_2$ yields a *cis*-tetrahydrofuran ring with *threo* stereochemistry at the two vicinal carbinol centers.[4] This reaction is very powerful in converting polyenes into polyoxygenated chiral derivatives, especially in combination with the Sharpless asymmetric oxidation,[3] and has been successfully applied to the synthesis of many acetogenins of the first and second subgroups, such as solamin, reticulatacin, asimicin, bullatacin, trilobacin, and trilobin.[3b]

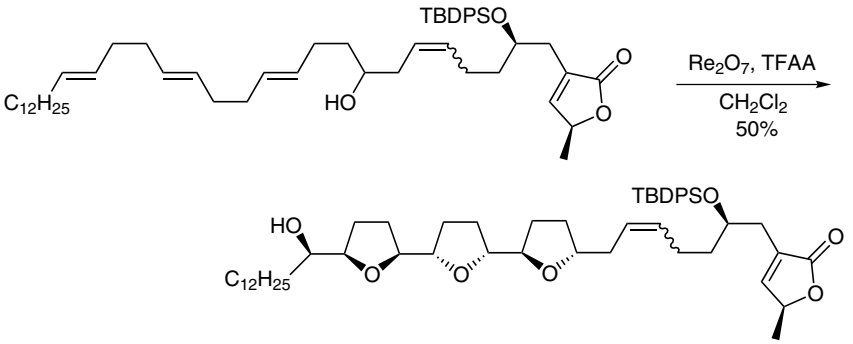
Reference 3a.

To a mixture of 20 mL dry CH_2Cl_2, 2.4 mL lutidine (20.4 mmol), and 1.0 g (*cis*-4*R*,5*R*,12*R*,13*R*)-5-hydroxy-12,13-isopropylidenedioxytricosa-8-en-1,4-olide (2.7 mmol) was added 3.3 g Re_2O_7 (6.81 mmol) in portions. The mixture was stirred overnight at room temperature and then quenched by dropwise addition of 8 mL saturated $NaHCO_3$ solution and 8 mL 35% H_2O_2. After being stirred for 20 min, the mixture was extracted with CH_2Cl_2, the organic layer was washed with water and dried over $MgSO_4$; the solvents were removed under reduced pressure, and the residue was purified by silica gel column chromatography using an eluent of hexanes/EtOAc (3:1) to give 0.654 g (4*R*,5*R*,8*R*,9*S*,12*R*,13*R*)-9-hydroxy-12,13-isopropylidenedioxy-5,8-oxidotricosa-1,4-olide as a colorless oil, in a yield of 64%.



Reference 3b.

Re_2O_7 (230 mg, 0.47 mmol) was placed in a dry flask under argon, then 10 mL dry THF was added followed by 0.12 mL TFAA (0.85 mmol), and the mixture was stirred at room temperature for 1 h. Solvents were removed under reduced pressure at 0°C, and the residue was washed twice with cold dry pentane. Then 5 mL CH_2Cl_2 and 0.09 mL TFAA (0.64 mmol) were added at 0°C, followed by 95 mg alcohol (0.12 mmol). The resulting mixture was stirred at 0°C to room temperature for 3 h and then quenched by the slow addition of 2 mL saturated $NaHCO_3$ solution, followed by 0.3 mL 35% H_2O_2. The aqueous solution was extracted with ether. Upon removal of the solvent under reduced pressure, the residue was purified on silica gel column chromatography using hexanes/EtOAc (4:1) as the eluent to afford 50 mg product, in a yield of 50%.

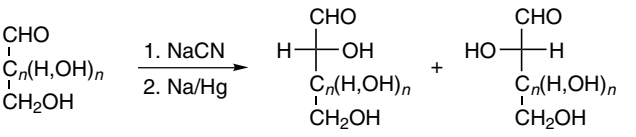
Kiliani-Fischer Cyanohydrin Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kiliani in 1885,[1] and then extended by Fischer in 1889.[2] It is the conversion of an aldose into two one-carbon-higher epimeric homologs, which involves a nucleophilic addition of a cyanide to the terminal carbonyl group of an aldose, hydrolysis of cyanohydrin, and reduction of the resulting lactone. Therefore, it is known as the Kiliani synthesis,[3] Kiliani-Fischer reaction,[4] Kiliani cyanohydrin synthesis,[5] Kiliani-Fischer synthesis,[3a,6] Kiliani-Fischer cyanohydrin synthesis,[3a,7] Fischer-Kiliani cyanohydrin synthesis,[8] or cyanohydrin reaction.[9] This reaction is carried out under alkaline conditions[9] (e.g., at pH > 9.1) to maintain a high effective concentration of cyanide ion;[6a] in addition, the resulting cyanohydrins are not isolated[6a] but hydrolyzed to aldonic acid lactones,[9] which are then reduced either by sodium amalgam[3b,4,5,6a,9] or catalytic hydrogenation[6a] or with $NaBH_4$ at pH 3–4 in an aqueous solution[6a] to yield higher homologs. This reaction is the traditional[9] and earliest[6a] carbohydrate synthesis without protection and is used commonly for the preparation of rare or unnatural carbohydrates as well as sugars labeled with ^{13}C or ^{14}C at the end.[3a,8]

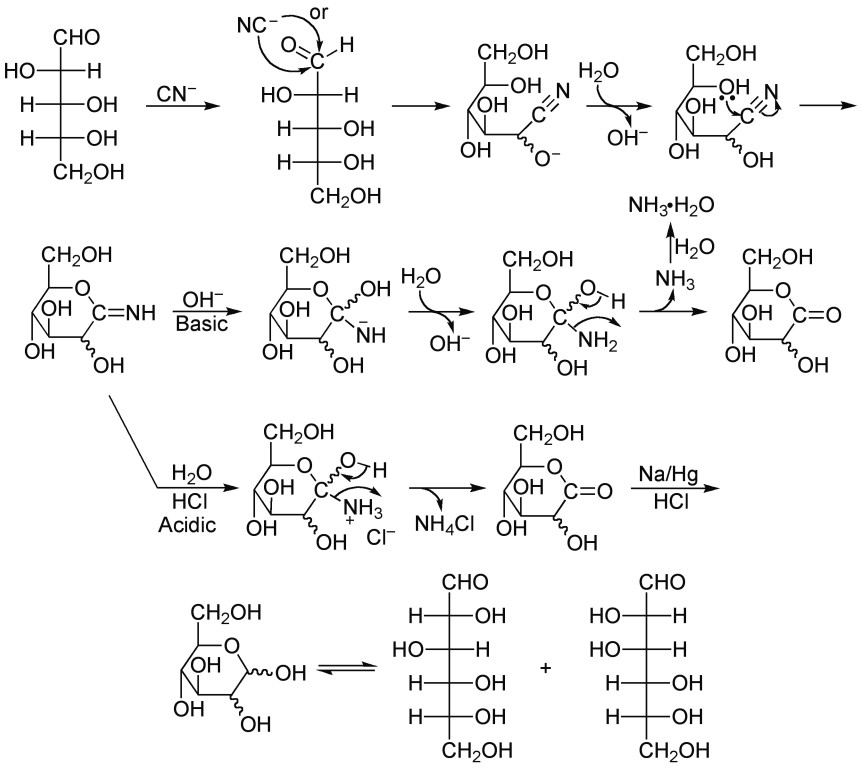
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

A reaction to prepare D-mannose and D-glucose from D-arabinose is used to demonstrate the mechanism.



D. MODIFICATION

This reaction is modified by replacing sodium cyanide with thiazole.[7a]

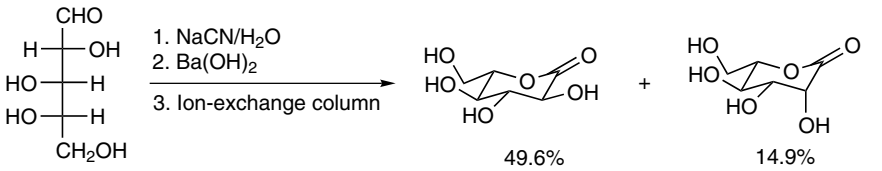
E. APPLICATIONS

This reaction has been used to prepare higher-order aldoses and isotope-labeled carbohydrates.

F. RELATED REACTIONS

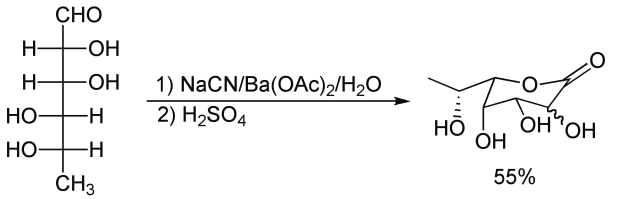
This reaction is related to the *Urech Cyanohydrin Method.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

An ice-cooled solution containing 30 g pure L-arabinose and 13 g NaCN in 300 mL water was kept near 5°C in a refrigerator until the Fehling test became faint (4 days). $Ba(OH)_2 \cdot 10H_2O$ (10 g) was added, and the solution was boiled with renewal of water to expel all ammonia for 3–4 h. The barium was then removed as carbonate after the addition of activated carbon, and the sodium ions were adsorbed by passing the solution through an ion-exchange column. Concentration to a syrup, lactonization, and solution of the residue in methyl cellosolve led to only 2.5 g crystalline L-mannoic γ-lactone. Removal of solvent from the mother liquor, conversion of the acidic residue to its neutral barium salt, and crystallization from aqueous ethanol produced 26.1 g barium L-gluconate. Removal of barium ion from the mother liquor permitted the recovery of 5 g L-mannonic lactone. By this treatment, 49.6% L-gluconic and 14.9% L-mannonic acid were prepared.



Reference 3e.

To 400 g ice were added successively 100 g rhamnose hydrate (200 mL), 105 g $Ba(OAc)_2$ (in 150 mL solution), and 32 g NaCN (100 mL). After the mixture was kept 1 h and then in the refrigerator for 70 h, 122 g $Ba(OH)_2 \cdot 8H_2O$ was added, and the mixture was boiled for 6 h. Water was then added to maintain about half the original volume. The barium was balanced with H_2SO_4, 15 g carbon was added, the mixture was boiled for 30 min. $BaSO_4$ was filtered off and washed with water. Then 141.6 mL 4.61 N H_2SO_4 was added to balance the sodium ions, and the combined solutions from three runs were distilled to dryness under reduced pressure. The residue was mixed with 500 mL 95% ethanol; the distillation was repeated, and the organic products were extracted from sodium sulfate by hot 95% ethanol followed by methanol. Concentration of the alcohol solution under reduced pressure gave several crops of colorless crystals and a syrup, which yielded more crystals with acetone as the solvent. A total of 200 g α-rhamnohexonic acid, its lactone, and ester were yielded after air-drying. To convert the acid and ester into lactone, a solution of the crystals in 2 L water was evaporated to dryness on the steam bath. The operation was repeated with less water, and the residue was heated at 100°C for several hours, washed with cold acetone, and dried at 95–100°C for 3 h, to give 175 g rhamnohexonic lactone, in a yield of 55%.

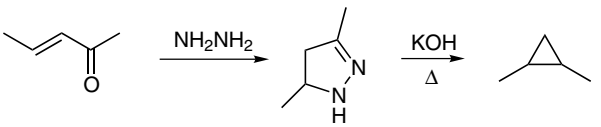
Kishner Decomposition

A. GENERAL DESCRIPTION OF THE REACTION

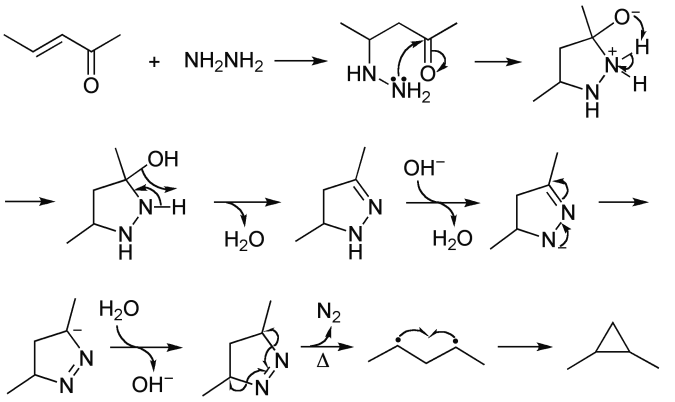
This reaction was first reported by Kishner in 1911.[1] It is the preparation of cyclopropane derivatives by decomposition of pyrazolines formed from hydrazine and α,β-unsaturated ketones or aldehydes. Therefore, it is known as the Kishner reaction,[2] Kishner decomposition,[3] or Kishner method.[4] In addition, this reaction has been modified to prepare pyrazoline intermediates from diazomethane and unsaturated carbonyl compounds, such as maleic and fumaric esters, resulting in an ester group in the *trans* position. However, when maleic anhydride or maleimide is used, the corresponding pyrazoline is formed with carbonyl groups in the *cis* configuration.[5] It has been found that the stability of pyrazolines varies considerably, decomposing to cyclopropanes at different rates.[5] Moreover, the transformation of pyrazolines into cyclopropanes can be catalyzed by a trace amount of mercuric ion.[5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

The preparation of pyrazoline has been modified by using unsaturated carbonyl compounds and diazomethane.[5]

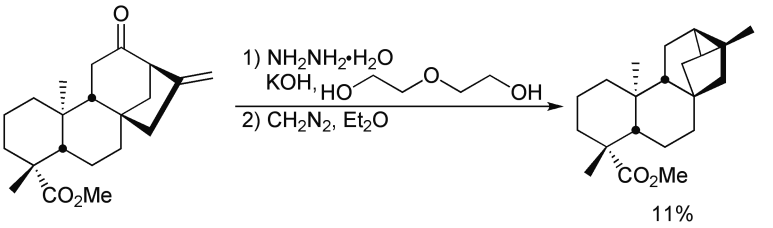
E. APPLICATIONS

This reaction has been used in the preparation of cyclopropane derivatives.

F. RELATED REACTIONS

N/A

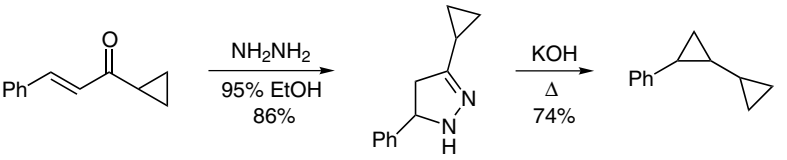
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

(±) Methyl 12-oxokaur-16-en-19-oate (43.7 mg, 0.132 mmol) was dissolved in 4 mL bis-(ethylene glycol), and then 1 mL $NH_2NH_2 \cdot H_2O$ (20.62 mmol) was added. The resulting mixture was refluxed at 135°C for 2 h. After the mixture was cooled to room temperature, 83.1 mg KOH (1.26 mmol) was added at room temperature, and the mixture was heated to 200°C over a period of 2 h. After being heated for 6.5 h, 4 mL 5% HCl was added at room

temperature, and then the resulting mixture was extracted with EtOAc. The organic layer was washed with 2 mL H_2O and brine, dried, and evaporated to leave 32.1 mg of a white solid, which was taken up into 2 mL Et_2O. The resulting solution was treated with an ethereal solution of diazomethane at room temperature. After 1 h of stirring at room temperature, AcOH was added until the evolution of nitrogen gas ceased. Saturated K_2CO_3 (1 mL) was added, and the mixture was extracted with Et_2O. The ethereal layer was washed with brine, dried, and evaporated to afford a white solid. Chromatography of the residue on a column of silica gel impregnated with 30% silver nitrate with a 1:3 mixture of benzene/petroleum ether as a solvent furnished 4.6 mg (±)-methyl trachyloban-19-oate, in a yield of 11%.



Reference 7.

Styryl cyclopropyl ketone (42 g, 0.245 mol) was added to a solution of 26 mL aqueous hydrazine (0.42 mol) in 70 mL 95% ethanol. The mixture became warm and acquired a green color. It was allowed to stand for 45 min, and then was warmed on the steam bath for 1 h, after which excess hydrazine and solvent were removed under reduced pressure. Distillation of the residue at 164°C (1 mmHg) gave 37.8 g 3-cyclopropyl-5-phenyl-2-pyrazoline as a light green liquid, in a yield of 86%. To a 100-mL round-bottomed flask equipped for distillation and immersed in a metal bath, was added 7.2 g KOH and 3.2 g platinized asbestos. When the bath was heated to 220°C, 37.8 g 3-cyclopropyl-5-phenyl-2-pyrazoline was added slowly. After the rapid evolution of nitrogen ceased, the product was distilled from the reaction mixture at 92–96°C (0.8 mmHg), and 22.5 g 2-phenylbicyclopropyl was obtained, in a yield of 74%.

Knoevenagel Condensation

A. GENERAL DESCRIPTION OF THE REACTION

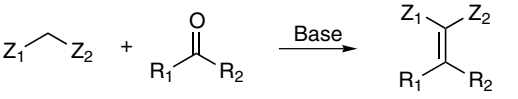
This reaction was first reported by Emil Knoevenagel in 1894.[1] It is a nucleophilic addition of a compound with an active methylene component to a ketone or aldehyde, followed by the elimination of water to form an olefin. Therefore, it is generally known as the Knoevenagel condensation.[2,3] Occasionally, it is also referred to as the Knoevenagel reaction.[2d,2x,2jj,2ll,4] For the condensation between compounds with two active methylene groups and two carbonyl groups to form polymers, the corresponding condensation is called the Knoevenagel condensation polymerization[2p,5] or Knoevenagel polycondensation.[6] This is an atom-economic and cleaner tool for the synthesis of α,β-unsaturated compounds.[2d] Theoretically, this reaction is an extension of aldol addition and is reversible.[2ll] The yield of this reaction depends not only on the relative reactivity of the reactants, the strength of the bases employed, and the nature of solvents,[2y] but also on the removal of the formed water during the reaction.[2ll] Essentially, the methylene group can be activated by at least one electron-withdrawing group, such as nitro, cyano, carbonyl, or sulfonyl group. As a result, the compounds with any combination of these electron-withdrawing groups adjacent to a methylene group can function as nucleophiles, including malonic acid,[2a,2w,2hh,7] malonic esters (diethyl malonate,[2b,4h] dimethyl malonate[8]), malonic amides,[2v] cyclohexa-1,3-dione,[9] Meldrum's acid,[2b,2i,2t] β-ketoacid,[2r] β-ketoester[2v] (ethyl acetoacetate[2ll]), β-ketoamide,[2x] ethyl cyanoacetate,[2jj,2ll] malononitrile,[2u,2bb,2jj] phenylcinnamonitriles,[2q] *o*-nitroarylacetonitriles,[2ee] cyanoacetamides,[2v] oxindole,[2ff] benzene-1,4-diacetonitrile, benzene-2,5-bis(methoxy)benzene-1,4-diacetonitrile,[2n,2p,2y] isatin,[10] homophthalic acid system,[11] α-perfluoroalkanesulfonyl acetate esters or α-keto aryl sulfones,[2m] α-keto sulfones,[2s] and keto-thioester.[12] On the other hand, the carbonyl compounds, mostly aldhydes, applied for this reaction are acrolein,[2a] citronellal,[2j]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

2-hydroxybenzaldehydes,[2b] (*R*)-2-(*tert*-butyldimethylsiloxymethoxy) propanal,[2f,2x] α-alkoxyaldehydes,[2x] benzaldehyde,[2bb,2x,4h] isobutyraldehyde,[2x] terephthaldialdehyde,[2hh] salicylaldehyde,[2y] crotonaldehyde[4f] and enaminones.[2i]

This reaction is generally catalyzed by weak bases, such as tetrabutylammonium hydroxide,[13] potassium phosphate,[2g,2z] morpholinium acetate,[14] K_2CO_3,[2ee] NH_4Ac,[8] ethylenediammonium diacetate,[2o] piperidine,[2g,2h,2j,2l,2m,2s,4h,4j] diethylamine,[4j] zinc chloride-aniline,[4j] pyridine,[2h,2t,2hh] amino acids,[15] aminophenols,[15] and strong bases (including NaOH,[2h] KOH,[2h] and sodium ethoxide[4j]). In addition, this reaction has been catalyzed by solid-state supported bases, such as KF/Al_2O_3,[2d] $AlPO_4$-Al_2O_3,[2aj] alumino-vanadate oxynitride,[2bb] amino group immobilized silica gel,[2ii] basic ion-exchange resins and their organic salts (such as Amberlite IR-4B, Deacidite, and Amberlite IRA-400[2ll]), and basic zeolites (such as Cs-exchanged NaX [CsNaX] and GeX[2h]). In addition, this reaction has been modified to undergo in ionic liquid[2o] or under microwave assistance.[2v,16] It is interesting that malononitrile can react directly with aromatic aldehydes under grinding in the absence of solvents and catalysts;[2u] furthermore, β-ketonitrile and β-ketothioester selectively afford the completely opposite stereoisomers when reacted with aldehydes, by which β-ketonitrile always give *E*-olefins.[2x] This reaction has been used to synthesize some interesting molecules, such as coumarin,[2b] indole,[2ae] quinoline,[2s,2ee] stilbenes,[2g] niphendipine,[2h] nitrendipine,[2h] and azepinones.[2i]

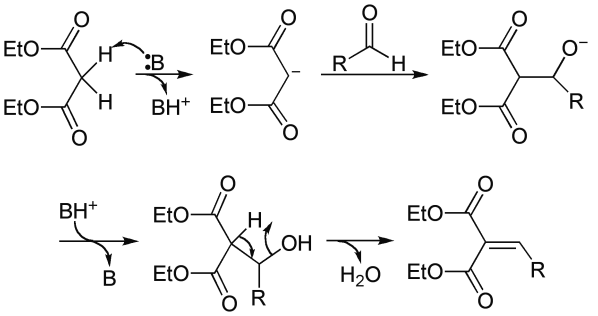
B. GENERAL REACTION SCHEME



(Z_1, Z_2 = NO_2, CN, CO_2R, COOH, SO_2R, COR, Ar
R_1 = alkyl, aryl
R_2 = H, alkyl, aryl)

C. PROPOSED MECHANISMS

Illustrated here is the mechanism for the condensation between diethyl malonate and a general aldehyde catalyzed by a weak base generally represented by B.



D. MODIFICATION

This reaction has been extensively modified for various conditions (as mentioned in Section A) by using different nucleophiles, different carbonyl compounds, and different bases as catalysts.

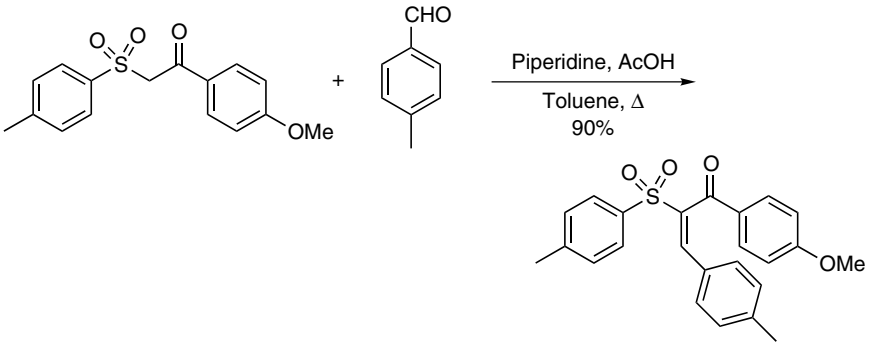
E. APPLICATIONS

This reaction has very broad application in organic synthesis.

F. RELATED REACTIONS

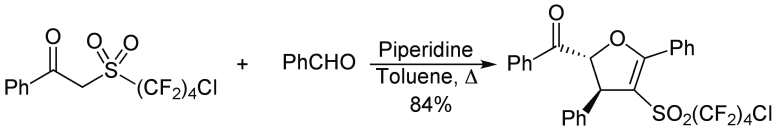
This reaction is related to the *Aldol Condensation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2s.

A mixture of 4.6 g 2-(*p*-toluenesulfonyl)-4′-methoxyacetophenone (15 mmol), 2.0 g *p*-tolualdehyde (16.5 mmol), 0.18 g piperidine (2 mmol), and 0.42 g acetic acid (7 mmol) in 40 mL toluene was refluxed for 2 h with azeotropic removal of water using a Dean-Stark trap. The mixture was cooled to room temperature and concentrated in vacuo. The residue was purified by flash chromatography (hexane/EtOAc/toluene, 3:1:1) to give 5.5 g pure 1-(4′-methoxyphenyl)-3-(4′-methylphenyl)-2-(*p*-toluenesulfonyl)-2-(*E*)-propen-1-one as a solid, in a yield of 90%, m.p. 141.0–142.0°C.



Reference 2m.

A mixture of 356 mg $ClC_4F_8SO_2CH_2COPh$ (0.84 mmol), 43 mg benzaldehyde (0.4 mmol), and 78 μL piperidine in 16 mL toluene was refluxed for 1 h with azeotropic removal of water using a Dean-Stark trap. TLC analysis indicated the reaction was completed. The mixture was cooled to room temperature, the solvent was removed under reduced pressure, and the residue was column chromatographed (hexane/ethyl ether, 10:1) to give 213 mg (2*R*,3*S*)-2-benzoyl-3-phenyl-4-(4′-chloro-perfluorobutylsulfonyl)-4-phenyl-2,3-dihydrofuran, in a yield of 84%.

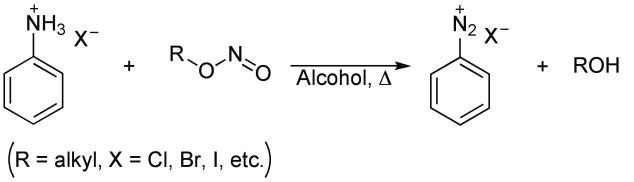
Knoevenagel Diazotization Method

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Knoevenagel in 1890.[1] It is the preparation of an anhydrous diazonium salt by the treatment of primary amine with amyl nitrite in an acidified absolute alcohol, by which a crystalline precipitate of the diazonium salt is formed on standing or on the addition of a small quantity of ether. Therefore, this reaction is known as the Knoevenagel diazotization method.[2] Under these conditions, nitrous acid is generated *in situ*, which then diazotizes the amines.[3] For example, the bisulfates of *p*-nitrobenzenediazonium, *p*-methoxybenzenediazonium, *p*-methylbenzenediazonium, and benzenediazonium ions can be made in an ethanol-sulfuric acid solution with amyl nitrite, which then crystallizes as colorless platelets from either absolute methanol or the mixture of methanol and ethanol.[4] However, the bisulfate of *m*-nitrobenzenediazonium will not crystallize under these conditions, so it is prepared in an acetic-sulfuric acid mixture with butyl nitrite.[4,5] It should be pointed out that the reaction of aromatic amine with amyl nitrite in aromatic solvents affords a moderate yield of biaryls, in which the variation of the reaction temperature, nitrite concentration, and the order of addition of the reagents do not affect the yield of biaryls, indicating the presence of aryl radicals.[6]

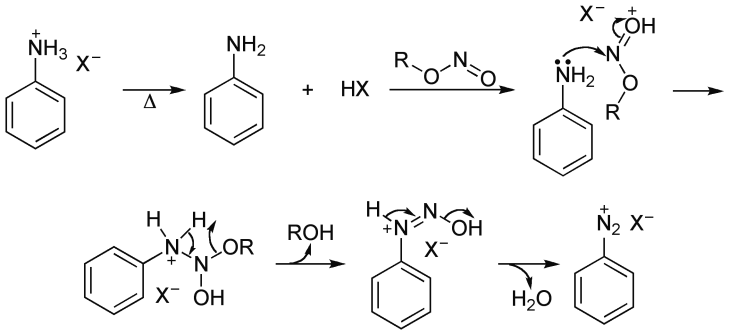
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is assumed that nitrous acid forms *in situ* under the Knoevenagel diazotizaiton condition,[3] which then combines with aniline to give a diazohydroxide, which can decomposes to yield the phenyl radical. However, in the presence of a strong acid, the diazohydroxide is further protonated and converted into the corresponding diazonium salt which may undergo a heterolytical or homolytical decomposition to give radicals or a cation intermediate,[6] as shown below.



D. MODIFICATION

The modifications of the Knoevenagel diazotization method include the addition of isoamyl nitrite to an appropriate amine salt suspended in cold acetic acid[7] and the diazotization of amine by the addition of a solution of N_2O_4 in ether.[8] In addition, a specific method for the preparation of anhydrous diazonium tetrafluoroborate has been developed in which the amine is mixed with an alkyl nitrite and an excess amount of $BF_3{\cdot}Et_2O$. For this preparation, the excess BF_3 can trap the alcohol and water produced during the diazotization, and the diazonium tetrafluoroborate precipitates from the reaction solution as it is formed.[9]

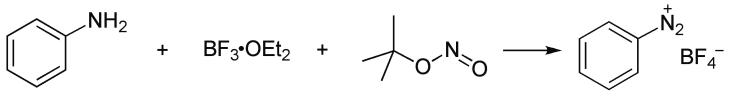
E. APPLICATIONS

This reaction is very useful for the preparation of anhydrous diazonium salts.

F. RELATED REACTIONS

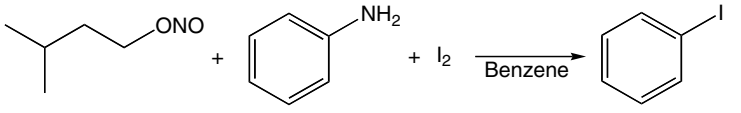
This reaction is related to the *Griess Diazotization*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 9.

To a three-necked, round-bottomed flask fitted with two addition funnels and a reflux condenser connected to a gas buret was added 1.06 g boron trifluoride etherate (7.5 mmol), which was then cooled to −15°C in an ice acetone bath. Then 5.0 mmol of the aromatic amine in a minimal volume of the anhydrous solvent (usually 10 mL) was added. If a solid of amine/BF_3 complex had formed, additional solvent or ethyl ether was added to produce homogeneous solution. *tert*-Butyl nitrite (0.618 g. 6.0 mmol) in 5 mL of the same solvent was added dropwise to the rapidly stirred solution over a period of 10 min. After the complete addition, the temperature of the reaction was maintained at –15°C for 10 min and then allowed to warm to 5°C in an ice water bath over a 20-min period. A crystalline precipitate usually formed during the addition of *tert*-butyl nitrite, and after 20 min at 5°C, precipitation was complete. Pentane (40 mL) was then added to the reaction solution, and the solid was suction filtered, washed with cold ether, air dried, and weighed.



Reference 6b.

Amyl nitrite (1.4 g, 0.012 mol) was added to a stirred mixture of 0.93 g aniline (0.01 mol), 1.26 g iodine (0.005 mol), and 30 mL benzene (or other aromatic solvent) in a 50-mL, round-bottomed flask equipped with a reflux condenser and gas bubbler. The flask was then placed in an oil bath and gradually heated to solvent reflux. The temperature of the oil bath was maintained at 100°C. The reaction was allowed to continue until gas evolution ceased. The mixture was then allowed to cool to room temperature and an internal standard was added. GC analysis indicated a composition of 78% iodobenzene, 21% 1,4-diiodobenzene, and 1% higher benzene oligomer, in a total yield of 60%.

Other references related to the Knoevenagel diazotization method are cited in the literature.[10]

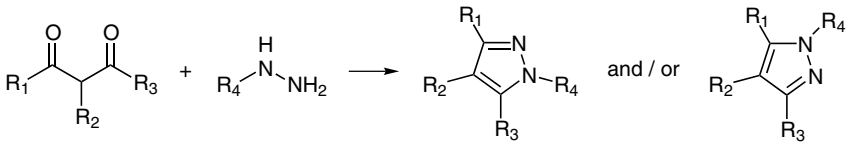
Knorr Pyrazole Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

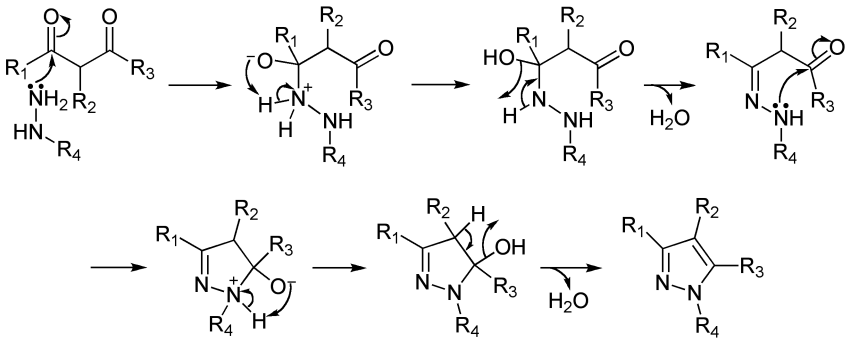
This reaction was first reported by Knorr in 1883.[1] It is the preparation of pyrazole derivatives from 1,3-dicarbonyl compounds and hydrazines. Similarly, pyrazole derivatives can also be prepared from hydrazines and equivalent molecules of 1,3-dicarbonyl compounds, such as α-ethoxymethylene α-phenylacetone.[2] In a special case, β-carbonyl aldehyde reacts with a simple hydrazine to afford tautomers of 3- and 5-substituted pyrazoles, of which the proton oscillates rapidly back and forth between two nitrogen atoms.[3] These two tautomers are distinguishable only at sufficiently low temperatures.[4] It should be pointed out that the reaction of hydrazine with β-carbonyl ester leads to the formation of pyrazolone.[2,5]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur between β-alkoxyl α,β-unsaturated carbonyl compounds and hydrazines.[2]

E. APPLICATIONS

This reaction has general application in the preparation of pyrazole derivatives.

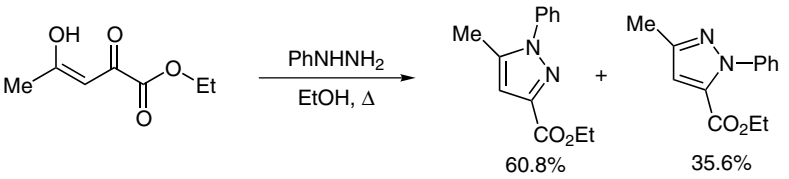
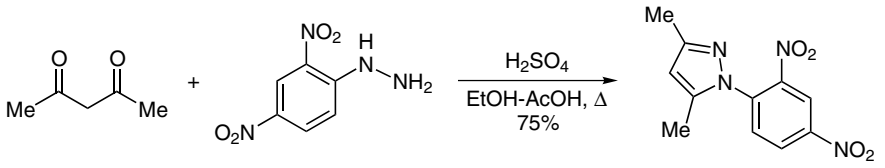
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

2,4-Dioxo-4-phenylbutyric acid ethyl ester (0.14 mL, 1.0 mmol) in 10 mL ethanol was treated dropwise with 0.12 mL phenyl hydrazine (1.2 mmol), and the resulting solution was refluxed over a period of 3 h. After the mixture was cooled to room temperature, the solvent was distilled off in vacuo. The residue was purified by means of silica gel column chromatography (petroleum ether/EtOAc, 4:1) to give 140 mg 5-methyl-1-phenyl-pyrazole-3-carboxylic acid ethyl ester as a pale brownish solid (0.61 mmol), in a yield of 60.8%, m.p.

37°C. In the meantime, 82 mg 5-methyl-2-phenyl-pyrazole-3-carboxylic acid ethyl ester was also obtained as a pale yellow solid (0.36 mmol), in a yield of 35.6%, m.p. 39–40°C.



Reference 7.

A solution of 1.98 g 2,4-dinitrophenylhydrazine (10 mmol) in 3 mL conc. H_2SO_4 was added to the solution of 10 mmol acetoacetone in EtOH-AcOH, and the mixture was heated on a water bath for several hours. On cooling and diluting, shining crystals of 1-(2,4-dinitrophenyl)-3,5-dimethyl-pyrazole was separated, which was recrystallized from EtOH or AcOH as a lemon yellow solid, in a yield of 75%, m.p. 114°C.

Knorr Pyrrole Synthesis
(Knorr Pyrrole Reaction)

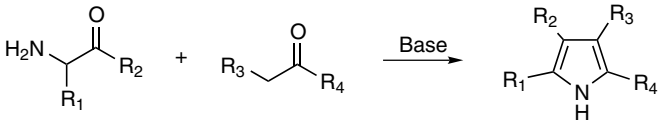
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was initially reported by Knorr in 1884.[1] It is the synthesis of pyrrole derivatives by the condensation of α-amino ketones with carbonyl compounds containing active α-methylene groups. Therefore, it is generally known as the Knorr pyrrole synthesis.[2] Occasionally, it is also referred to as the Knorr reaction,[3] Knorr pyrrole reaction,[2a] Knorr synthesis,[4] or Knorr condensation.[5] This reaction, as one of the principal routes for pyrroles, is highly regioselective[2a,6] and always gives high yields of pyrrole derivatives.[2a] Because α-amino ketones easily undergo a self-condensation, the α-amino ketones are often generated *in situ* from either isonitrosoketones, oximes,[3] or hydrazones[2a] in the presence of zinc dust, NaOAc and HOAc. However, such reduction results in an environmental problem when it is carried out on large scale, so the reduction has been improved by replacing the zinc reduction with hydrogenation.[2g] In addition, carbonyl groups can also be produced *in situ* by deprotection of the masked carbonyl group, such as ketal. It is interesting that it has been found that the oxygen atmosphere plays an important role in this reaction during the reduction of isonitrosoketones because no or a very low yield of expected pyrroles is obtained when oxygen is excluded under a helium or argon atmosphere.[2g] On the other hand, it has been reported that even more pyrrole derivatives could be yielded if α-amino ketone hydrochlorides are used directly rather than generated *in situ*.[2g] In the cases of a reaction

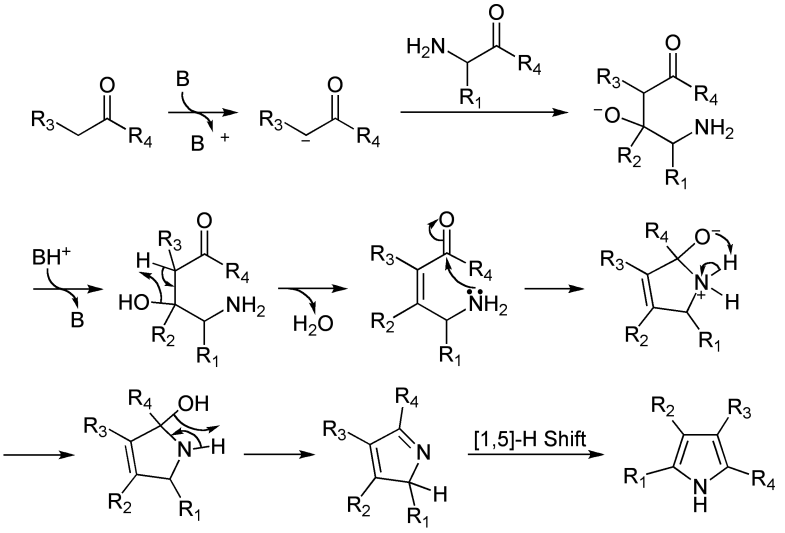
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

between α-amino ketones and β-ketoesters, the formed pyrroles are typically isolated by a water knockout.[3]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified by directly using α-amino ketone hydrochloride[2g] or reducing α-nitrosoketone or hydrazone via hydrogenation[3] to form pyrrole derivatives.

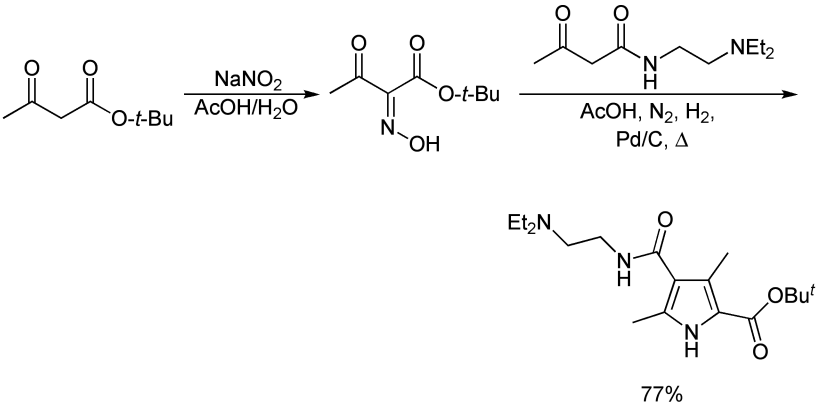
E. APPLICATIONS

This reaction has general application in the preparation of pyrrole derivatives, especially for the porphyrins with exocyclic rings.[7]

F. RELATED REACTIONS

This reaction is related to the *Hantzsch Pyrrole Synthesis* and *Paal-Knorr Pyrrole Synthesis*.

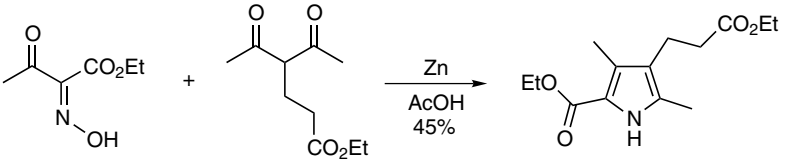
G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

To a three-necked, round-bottomed flask was added 30 g *tert*-butyl acetoacetate (190 mmol) along with 30 mL acetic acid. After the mixture was cooled to 0–3°C under nitrogen a solution of 18.3 g $NaNO_2$ (265 mmol) in 35 mL H_2O was added dropwise by maintaining the temperature < 10°C. Once the addition was complete, the reaction solution was slowly warmed to room temperature. When the reaction was deemed complete by TLC (2 h), the mixture was partitioned between 40 mL aqueous KCl solution and 50 mL diethyl ether. The aqueous layer was extracted further with diethyl ether (3 × 25 mL). The combined organics were washed with H_2O (3 × 35 mL), dried over Na_2SO_4, and concentrated in vacuo to afford oxime as a pale yellow oil, which was used in the next step without further purification.

To a 500-mL Parr hydrogenation vessel was added 20.0 g oxime (107 mmol), along with 2.0 g 5% dry Pd/C, followed by 21.4 g *N*-(2′-diethylamino-ethyl) acetoacetamide (107 mmol) dissolved in 220 mL acetic acid. The vessel was purged with nitrogen and hydrogen, and the mixture was hydrogenated at 45 psi by heating at 65°C for 7 h. After this time, the reaction mixture was cooled to room temperature and filtered to remove palladium, and the cake was washed with acetic acid. The filtrate was neutralized with 50% aqueous NaOH, and 500 mL CH_2Cl_2 was added, followed by more 50% aqueous NaOH until the pH of the aqueous phase was 13. The mixture was transferred to a separatory funnel, and the layers were separated. The aqueous layer was extracted with CH_2Cl_2 (3 × 350 mL), and the combined organics were washed with H_2O (2 × 250 mL). The washes were back extracted with 250 mL CH_2Cl_2, and the combined organics were concentrated in vacuo. The residue was dissolved in hot CH_3CN, and the resulting solution was filtered and cooled. The solids that formed were isolated by filtration to afford 27.7 g *tert*-butyl 4-[[[2-(diethylamino)ethyl]amino]carbonyl]-3,5-dimethyl-1*H*-pyrrole-2-carboxylate (83 mmol), in a yield of 77%.



Reference 8.

To a 250-mL three-necked flask was added 14.0 g methyl 4-acetyl-5-oxohexanoate (75 mmol) in 35 mL acetic acid. The internal temperature was maintained at 65–80°C while the oxime solution (preparation same as the one described for Reference 3) was added over 80 min, along with 12 g each of zinc dust and anhydrous sodium acetate in small portions. The mixture was stirred an additional 10 min and poured onto 400 g ice. The precipitate was collected and dissolved in benzene, unreacted zinc was removed, and the benzene solution was evaporated to dryness. The formed pyrroles were recrystallized from methanol, benzene-hexane, and carbon tetrachloride.

Other references related to the Knorr pyrrole synthesis are cited in the literature.[9]

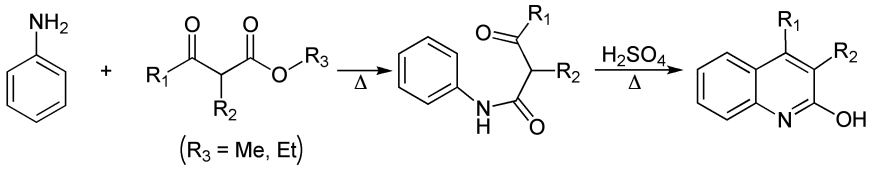
Knorr Quinoline Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Knorr in 1886.[1] It is the synthesis of 2-hydroxyquinolines via the cyclization and dehydration of an anilide intermediate condensed from β-ketoesters and anilines at a relatively high temperature. Right after this report, Conrad and Limpach also reported a similar reaction between anilines and β-ketoesters but at low temperatures, which resulted in the formation of 4-hydroxyquinolines from the intermediate of alkyl crotonate.[2] Thus this reaction is known as the Knorr synthesis,[3] Knorr-Limpach method,[4] Knorr cyclization,[5] Conrad-Limpach-Knorr reaction,[6] or Knorr quinoline synthesis.[7] It has been reported that the formation of an alkyl crotonate intermediate is favored at moderate or low temperature in the presence of iodine or an acid catalyst, whereas intermediate anilide is formed at high temperatures.[6b]

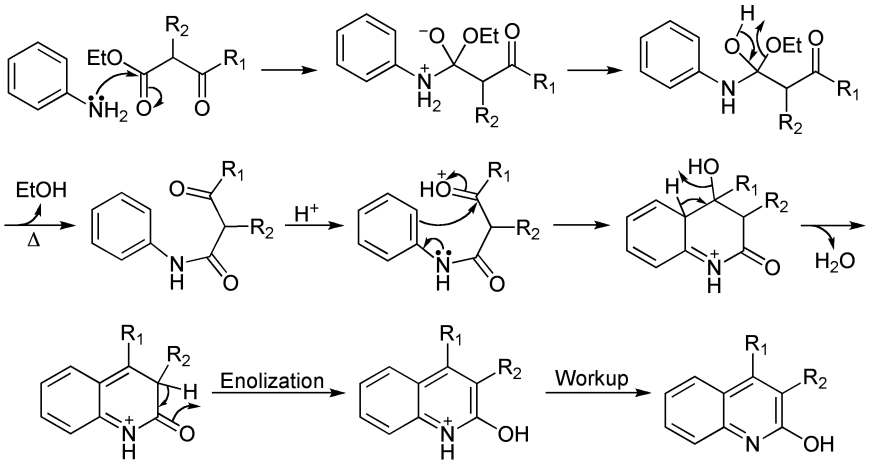
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is illustrated by the reaction between aniline and ethyl β-ketoester.



D. MODIFICATION

N/A

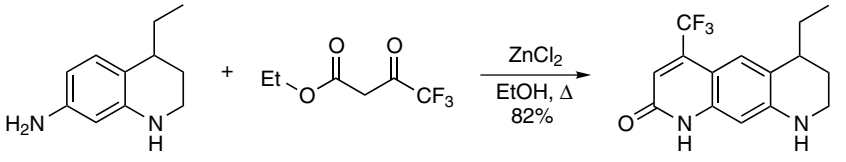
E. APPLICATIONS

This reaction has general application in the preparation of 2-hydroxyquinoline derivatives.

F. RELATED REACTIONS

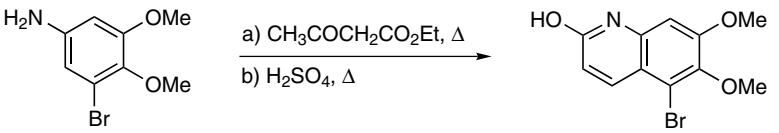
This reaction is related to the *Conrad-Limpach Quinoline Synthesis*, *Doebner-von Miller Quinoline Synthesis*, and *Gould-Jacobs Quinoline Synthesis*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 8.

To a flame-dried, 100-mL, round-bottomed flask containing 210 mg aminotetrahydroquinoline (1.19 mmol) and 20 mL ethanol at room temperature was added 190 μL ethyl-4,4,4-trifluoroacetoacetate (1.31 mmol, 1.10 eq.) and 244 mg $ZnCl_2$ (1.79 mmol, 1.50 eq.). The reaction mixture was heated to reflux for 6 h, at which time TLC analysis indicated complete consumption of the starting material. The reaction mixture was cooled to room temperature, and the solvent was removed under reduced pressure. Dichloromethane (20 mL) was added, and the organic phase was washed with saturated $NaHCO_3$ (2×10 mL) and brine (10 mL), then dried over Na_2SO_4 and concentrated under reduced pressure. The residue was purified by flash chromatography (CH_2Cl_2/MeOH, 15:1) to give 24.4 mg 4-ethyl-1,2,3,4-tetrahydro-6-(trifluoromethyl)-8-pyridono[5,6-g]quinoline as a yellow solid, in a yield of 82%, $R_f = 0.37$ (CH_2Cl_2/MeOH, 9:1). Recrystallization from EtOAc provided an analytically pure sample as yellow needles, m.p. 264–265°C.



Reference 6b.

To 20 mL ethyl acetoacetate heated to 160–165°C was added 5.5 g 4-amino-6-bromoveratrole over 3 min. After continuing the heating for an additional 30 min, the excess ethyl acetoacetate was distilled off under reduced pressure, and the residue was washed with light petroleum ether, leaving a thick oil in an apparently quantitative yield. This thick oil was mixed with 8 mL concentrated H_2SO_4, and the mixture was heated for 2 min at 60–70°C. The mixture immediately solidified, which was thrown into water. The solid was filtered out and crystallized from a mixture of chloroform and alcohol to give 60% 2-hydroxy-5-bromo-6,7-dimethoxylepidine as long white needles, m.p. 274–276°C (dec.).

Other references related to the Knorr quinoline synthesis are cited in the literature.[9]

Koch-Haaf Carboxylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Koch in 1955[1] and subsequently modified by Koch and Haaf.[2] It is the formation of tertiary carboxylic acids or esters by treatment of alcohols or alkenes with anhydrous formic acid that functions as both an acidic catalyst and a source of carbon monoxide.[3] This reaction was quickly modified to an industrial production of carboxylic acid from the reaction between alcohols or alkenes and carbon monoxide in the presence of a strong acid.[4] Therefore, this reaction is generally known as the Koch-Haaf reaction[4,5] or Koch-Haaf carboxylation.[5c,6] In one case, it is also referred to as Koch reaction.[7] The carboxylation of alcohols occurs in two steps: the formation of an acyl cation from carbon monoxide or carbocation generated from acidic dehydration followed by the coupling between the acyl cation and water or alcohol to form the acid or ester derivative.[4] For example, pivalic acid can be generated from isobutylene or *tert*-butyl alcohol and carbon monoxide.[4] In addition, the corresponding aryl esters are formed in the presence of phenol.[5a] It has been found that a variety of Brønsted and Lewis acids can catalyze this reaction,[5a] among these acids, BF_3 is the most effective catalyst.[8] However, in the presence of a super acid, it is possible to formylate isoalkanes to aldehydes that subsequently rearrange to the corresponding branched ketones.[4]

B. GENERAL REACTION SCHEME

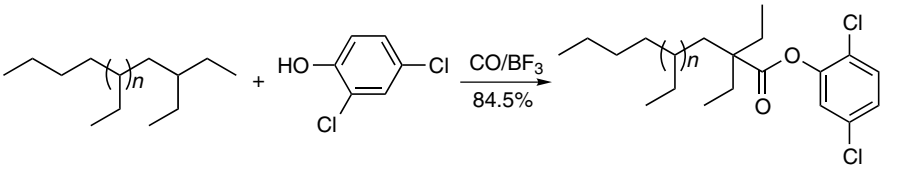
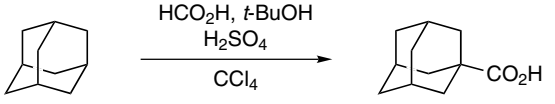
G. CITED EXPERIMENTAL EXAMPLES



Reference 5a.

An autoclave was pressured to 199 psi with BF_3 at 50°C, followed by 301 psi of CO to bring the total pressure to 500 psi. Ethylene-1-butene copolymer (EB, Mn = 4600, 20 wt % ethylene, 406 g) and 100.6 g 2,4-dichlorophenol (pKa = 7.85) at 50°C were charged to the autoclave and pressured to 1430 psi with CO. The autoclave contents were stirred under these conditions for 2 h and depressurized. The reaction product was stripped to remove the BF_3 gas and excess substituted phenol to give 84.5% EB copolymer aryl ester.



Reference 2.

To a 1-L three-necked flask equipped with a stirrer a thermometer, a dropping funnel, and a gas-outlet tube were added 255 mL 96% H_2SO_4 (4.8 mol), 100 mL CCl_4, and 13.6 g

adamantine (0.1 mol). The well-stirred mixture was cooled to 17–19°C in an ice bath, and 1 mL 98% formic acid was added. Then a mixture of 38 mL *t*-butyl alcohol (0.4 mol) and 55 g of 98–100% formic acid (1.2 mol) was added dropwise, during which the rate of addition and the cooling were regulated so that the temperature of the reaction mixture was kept at 17–25°C. After the completion of addition, the reaction mixture was stirred for an additional 30 min and poured onto 700 g crushed ice. The layers were separated, and the upper, acid layer was extracted with CCl_4 (3 × 100 mL). The combined carbon tetrachloride layers were shaken with 110 mL 15 *N* ammonium hydroxide, and the crystalline ammonium 1-adamantanecarboxlate that separated was collected on a Büchner funnel with a coarse fritted disk. The salt was washed with 20 mL cold acetone and suspended in 250 mL water. The suspension was made strongly acidic with 25 mL 12 *N* HCl and extracted with 100 mL chloroform. The chloroform layer was dried over anhydrous Na_2SO_4, and evaporated to dryness on a steam bath. The residue, in amount of 12–13 g, was crude 1-adamantanecarboxylic acid, in a yield of 67–72%, m.p. 173–174°C. Recrystallization of this product from a mixture of 30 mL methanol and 10 ∼mL water afforded 10–11 g pure 1-adamantanecarboxylic acid, in a yield of 56–61%, m.p. 175–176.5°C.

Kochi Reaction

(Kochi Oxidative Decarboxylation)

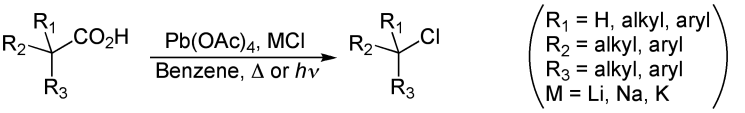
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kochi in 1965.[1] It is the conversion of carboxylic acids into corresponding halides via the oxidative degradation of carboxylic acid by lead tetraacetate (LTA) accompanied by a simultaneous replacement with a halogen under free-radical conditions in the presence of a stoichiometric amount of metal halide. Thus it is known as the Kochi reaction[2] or Kochi oxidative decarboxylation.[3] In the absence of metal halide, the carboxylic acids will be oxidized into various compounds, depending on the experimental conditions, either thermally or photochemically.[4] It has been found that for the photochemical reaction, the initial process involves the formation of an acyloxy radical, whereas under the thermal reaction conditions, the alkyl radical occurs directly;[4a] however, the photochemical reaction at 30°C and thermal reaction at 80°C give almost the same products.[4c] In addition, the structure of the substrates also affects the oxidation outcome, and the relative rates of oxidation by Pb(IV) determine the distribution of products.[4c] For example, tertiary and α-arylalkyl carboxylic acids are readily converted into alkenes and esters.[1d,5] In this reaction, the tertiary and secondary radicals undertake a long free-radical chain mechanism, whereas the primary radicals undergo a short-chain mechanism, due to the facile chain transfer of the primary radicals.[1c] Besides LTA, a variety of oxidants, such as manganese (III) salt,[5] and silver (II) salt,[6] are effective for oxidative decarboxylation. Moreover, it has been found that such oxidative decarboxylation can be enhanced by pyridine,[1c,1d] trialkylamines,[1d] or peroxides[1c] or catalyzed by a copper salt,[1c] but it will be inhibited by oxygen.[1c,1d] For the copper salt catalyzed reaction the thermal and pyridine-induced short free-radical chain reaction is replaced by a long-chain reaction because the alkyl radicals are oxidized by Cu(II).[1c] Consequently, the oxidation of valeric acid in benzene via the thermal and the pyridine-induced reactions yields butanes, butenes, butyl esters, and butylbenzenes, whereas only butenes are formed in the presence of a catalytic amount of copper salts.[1c] On the other hand, in the presence of metal halide, the alkyl halides form as major

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

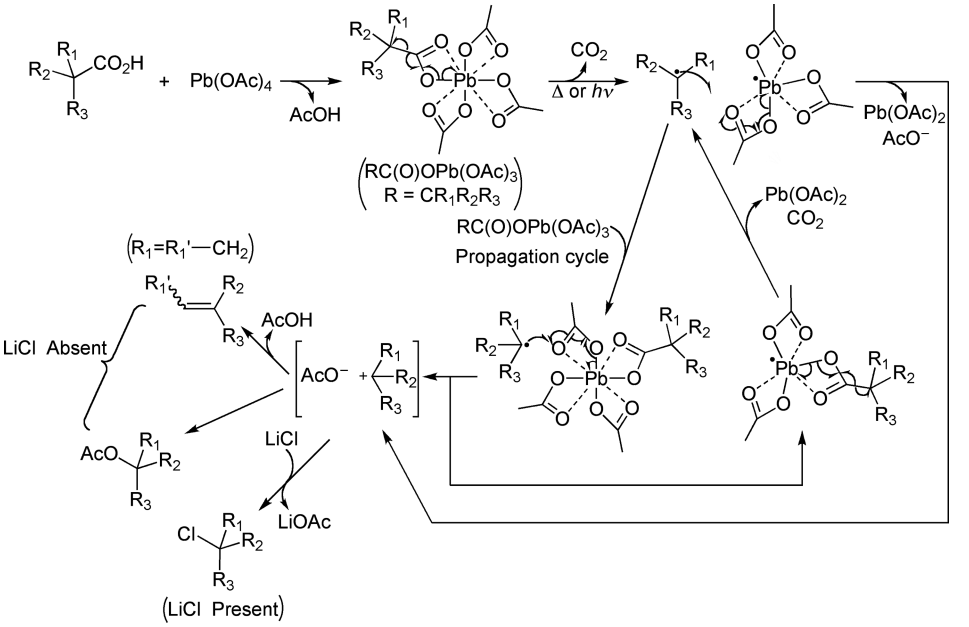
products, depending on the reaction conditions. In general, the yields of alkyl chlorides from secondary and tertiary acids are excellent, if a stoichiometric amount of metal chloride is present; whereas alkyl chlorides vanish if an excess amount of metal chlorides are present.[1d] Moreover, the chloride salts also affect the reaction results, and tetraalkyl ammonium chloride, being soluble, gives no expected product. Potassium or sodium chloride gives the best yield but a slower reaction rate than lithium chloride.[1d] It is interesting that no evidence for the rearrangement of the alkyl moiety has been observed for this reaction, as indicated from the formation of neopentyl chloride from β,β-dimethylbutyric acid. Similarly, alkyl bromides and iodides can also be formed from the oxidative decarboxylation in the presence of corresponding bromide and iodide salts, though relative low yields are obtained.[1d] Although this reaction does not work well for benzoic acid,[1d] the α,β-unsaturated carboxylic acids can undergo the oxidative decarboxylation to afford halogenated olefins using iodosylbenzene or iodosylbenzene diacetate and *N*-bromo, *N*-chloro, or *N*-iodosuccinimide as oxidants.[6] Such modification is especially feasible for the preparation of olefinic bromide with a phenyl group at the β-position.[6] In contrast, no detectable radical intermediate was found for the oxidative decarboxylations of 2-hydroxycarboxylic acids by lead tetraacetate in anhydrous acetic acid.[7]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A general mechanism for this reaction, including the metathesis, initiation by either heat or light, the propagation cycle, and the termination steps in the presence or absence of LiCl, is outlined below.



D. MODIFICATION

This reaction has been modified to occur using different oxidants, such as Mn (III)[5] and silver (II)[6] salts. In particular, the oxidation from iodosylbenzene or iodosylbenzene diacetate with NBS allows the easy preparation of olefinic bromides.[6]

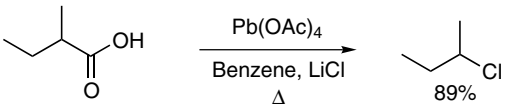
E. APPLICATIONS

This reaction is generally useful for the preparation of secondary and tertiary halides.

F. RELATED REACTIONS

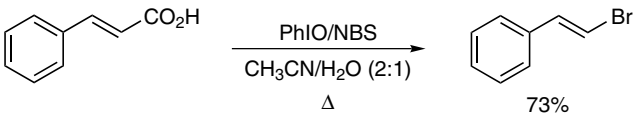
This reaction is related to the *Hunsdiecker Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 1d.

To 10 mL benzene solution containing 0.48 g α-methylbutyric acid (4.7 mmol) was added 2.0 g lead tetraacetate (4.5 mmol). The mixture was stirred at room temperature until homogeneous. Then 0.196 g LiCl (4.5 mmol) was added, and the mixture was immediately flushed with nitrogen to remove oxygen. The surface of the salt at room temperature rapidly achieved a yellow coloration with LiCl. The mixture was placed in a constant-temperature oil bath (81 $\pm$ 0.3°C), and the rate of gas evolution was followed volumetrically. The induction period was very short and gas evolution followed apace. The completion of the reaction resulted in a clear colorless solution and a colorless amorphous solid, and the solution was decanted and extracted with dilute aqueous perchloric acid, followed by a Na_2CO_3 wash. The organic layer was dried over Na_2SO_4. About 89% *sec*-butyl chloride was yielded from this reaction.



Reference 6.

Trans-cinnamic acid (1.0 mmol) and 0.5 mmol iodosylbenzene were dissolved in 10 mL CH_3CN and H_2O (2:1) at 60°C. This mixture was stirred for 10 min, and 1.0 mmol NBS was added. The mixture was stirred for additional 30 min at 60°C. After the reaction was complete, the solvent was evaporated. The aqueous phase was extracted three times with 10 mL ether. The ether phases were dried over $MgSO_4$ and evaporated. The crude reaction

mixture was separated by flash chromatography using petroleum ether as the eluent to afford 73% 2-*trans*-bromo styrene.

Other references related to the Kochi reaction are cited in the literature.[8]

Koenigs-Knorr Reaction

(Koenigs-Knorr Glycosidation, Koenigs-Knorr Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

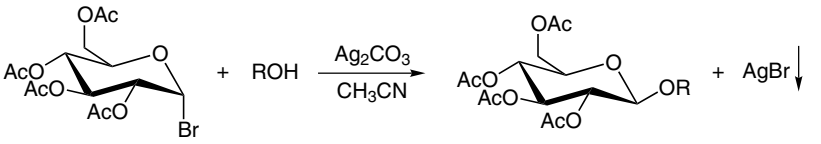
This reaction was first reported by Koenigs and Knorr in 1901.[1] It is the formation of *O*-glycosides from acetylated glycosyl halides and alcohols or phenols in the presence of a silver or mercury salt that functions as both promoter and halophile. As one of the most widely applied methods for *O*-glycosylation, this reaction has been extensively modified by means of using different promoters (e.g., Ag_2O,[2] Ag_2CO_3,[2] AgOTf,[2] $CdCO_3$,[3] $Hg(CN)_2^4$), different solvents of low polarity (e.g., dichloromethane, cyclohexane and petroleum ether),[4] and various desiccants (Na_2SO_4,[5] $CuSO_4$,[6] $CaCl_2$,[7] Drierite,[8] etc.) to remove the generated water. Therefore, this reaction is generally known as the Koenigs-Knorr method,[2,9] Koenigs-Knorr reaction,[2b,3,9a,10] Koenigs-Knorr synthesis,[2a,3,4b,11] Koenigs-Knorr glycosidation,[12] Koenigs-Knorr glycosylation,[13] or Koenigs-Knorr condensation.[14] Occasionally, this reaction is also referred to as Koenigs-Knorr-Zemplén method[2] or Koenigs-Knorr process.[15]

Under the modified conditions, the Koenigs-Knorr synthesis usually gives only β-*O*-glycosides,[2] except for certain conditions that use mercury salts as promoters.[4b] When carbohydrate itself is applied as an aglycone, the primary OH is considerably more reactive than the secondary OH,[4b] with a relative reactivity on the order of 6-OH >> 3-OH > 4-OH > 2-OH.[4b] For the preparation of alkyl *O*-glycosides, this reaction is generally a solvolysis with an excess amount of alcohol, and the generated water is negligible if compared with the amount of alcohol; therefore, a drying agent is not necessary.[4b] Other modifications of this reaction include the application of glycosyl fluorides as donors[4a] and silver trifluoromethanesulfonate as a promoter for the formation of glycosides from hindered alcohols.[2a]

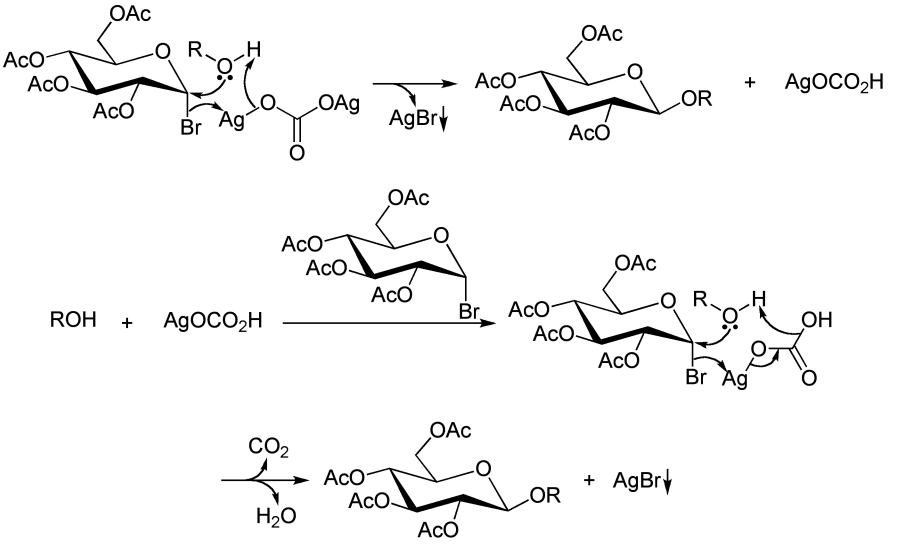
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

However, because this reaction always requires an excess amount of promoter, it has limited application in large-scale preparations.[2]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been extensively modified to various conditions, including the application of different promoters, solvent systems, and drying agents.

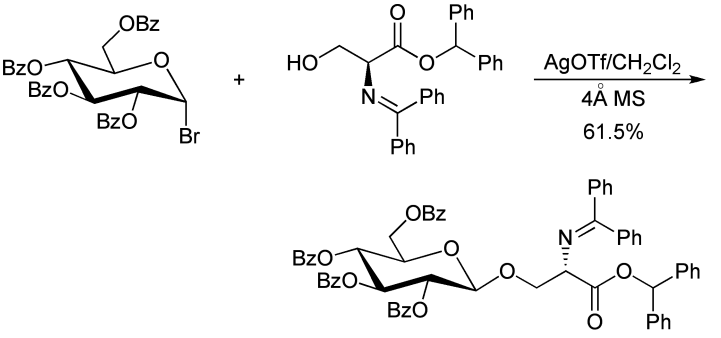
E. APPLICATIONS

This reaction has general application in the preparation of *O*-glycosides.

F. RELATED REACTIONS

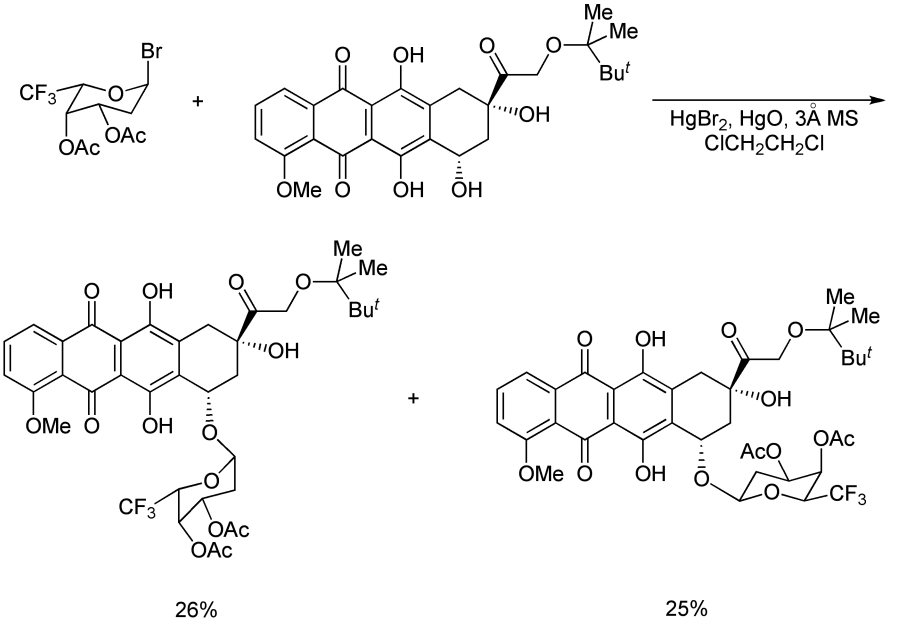
This reaction is related to the *Helferich Glycosylation*, *Hilbert-Johnson Reaction*, and *Kahne Glycosylation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 9a.

A mixture of 1.06 g 2,3,4,6-tetra-*O*-benzoyl-α-bromo-D-glucopyranose (1.61 mmol, 1.40 eq.) and 0.50 g benzhydryl *N*-(diphenylmethylene)-L-serinate (1.15 mmol, 1.0 eq.) was placed in a flame-dried RB flask with 50 mL CH_2Cl_2, along with 1.0 g powdered 4Å molecular sieves under argon and cooled to 0°C. Then 0.45 g AgOTf (1.73 mmol, 1.50 eq.) was added in portions over 45 min. After 14 h, the reaction was complete as monitored by TLC, and the reaction was quenched by the addition of 0.5 mL iPr_2NEt (2.5 eq.) and stirred for an additional 10 min. The solution was filtered through Celite, and the crude solution was washed twice with conc. $Na_2S_2O_3$, twice with conc. Na_2CO_3, and brine and dried over $MgSO_4$. After evaporation on a rotatory evaporator, the crude product was flash chromatographed using 25% EtOAc/hexanes (R_f = 0.33) to obtain 0.72 g diphenylmethyl *N*-diphenylmethylene-*O*-(2,3,4,6-tetra-*O*-benzoyl-β-D-glucopyranosyl)-L-serinate as a white foam, in a yield of 61.5%.



Reference 16.

A mixture of 85 mg 3,4-di-*O*-acetyl-2,6-dideoxy-6,6,6-trifluoro-α-L-*lyxo*-hexopyranosyl bromide (0.24 mmol) and 142 mg 14-*O*-(*tert*-butyldimethylsilyl)adriamycinone

(0.27 mmol) in 4 mL dry 1,2-dichloroethane (freshly distilled from CaH_2) was stirred in the dark in the presence of 498 mg yellow HgO (2.3 mmol), 174 mg $HgBr_2$ (0.48 mmol), and 700 mg 3-Å molecular sieves for 15 h at room temperature. After the addition of $CHCl_3$, the mixture was filtered through a pad of Celite, which was thoroughly washed with $CHCl_3$. The combined filtrates were washed successively with 30% aqueous KI, aqueous $NaHCO_3$, and water; dried over Na_2SO_4; and concentrated. TLC (10:1, toluene/acetone) of the residue showed three spots at $R_f = 0.17$ (an adriamycinone derivative), $R_f = 0.25$ (14-*O*-(*tert*-butyldimethylsilyl)-7-*O*-(3,4-di-*O*-acetyl-2,6-dideoxy-6,6,6-trifluoro-β-L-*lyxo*-hexo-pyranosyl)-adriamycinone), and $R_f = 0.28$ (14-*O*-(*tert*-butyldimethylsilyl)-7-*O*-(3,4-di-*O*-acetyl-2,6-dideoxy-6,6,6-trifluoro-α-L-*lyxo*-hexo-pyranosyl)-adriamycinone). Separation of the products by column chromatography twice (10:1 toluene/acedtone → 30:1 $CHCl_3$/acetone) gave 50 mg α-anomer (26% yield) and 49 mg β-anomer (25% yield) as red solids.

Other references related to the Koenigs-Knorr reaction are cited in the literature.[17]

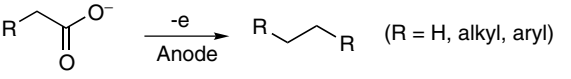
Kolbe Electrolysis

(Kolbe Synthesis, Kolbe Electrosynthesis, Kolbe Electrolytic Synthesis)

A. GENERAL DESCRIPTION OF THE REACTION

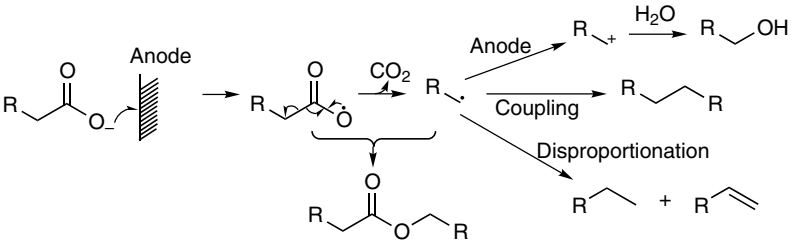
This reaction was first reported by Kolbe in 1849.[1] It is the formation of symmetrical hydrocarbons through the coupling of radicals generated from carboxylic acid at an anode via electrolysis. Therefore, it is generally known as the Kolbe electrolysis,[2] Kolbe synthesis,[3] Kolbe electrosynthesis,[4] or Kolbe electrolytic synthesis.[2aaa,5] Occasionally, this reaction is also referred to as Kolbe hydrocarbon synthesis.[3r,6] It is accepted that this reaction proceeds through a one-electron transfer process at the anode from the carboxylate to form an acyloxy radical, which then undergoes decarboxylation to form an alkyl radical that dimerizes in the end.[3l] In the presence of free radicals, this reaction has been used to initiate the polymerization to prepare low molecular weight polystyrene[7] as well as polymers from vinyl acetate, methyl methacrylate, and vinyl chloride.[2eee] However, under certain conditions, the generated radicals also disproportionate[5i] or lose one more electron to form carbocations; therefore olefins,[8] esters,[3l,5i] ethers[3l] and alcohols[3l] are also formed in this reaction. It is interesting that phenyl 1,2-shift, which occurs frequently for radical intermediates, is not observed during the electrolysis.[2xx]

B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS



D. MODIFICATION

This reaction has been modified to occur in liquid ammonia for the electrolysis of ammonium carboxylate.[3q]

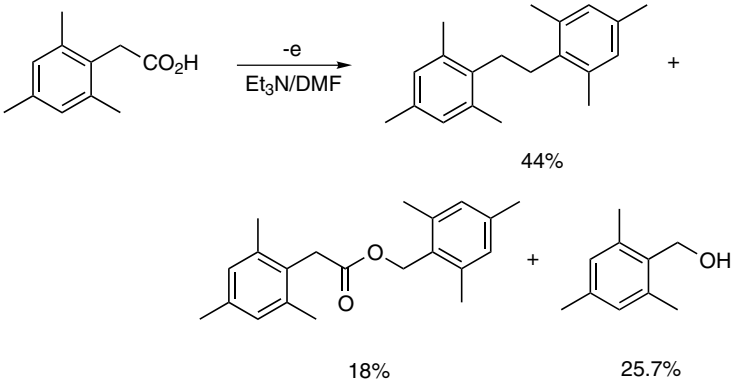
E. APPLICATIONS

This reaction has general application in the preparation of hydrocarbons, especially for the industrial production of special hydrocarbons.

F. RELATED REACTIONS

This reaction is related to the *Hofer-Moest Reaction*.

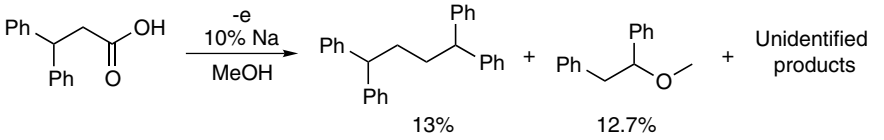
G. CITED EXPERIMENTAL EXAMPLES



Reference 31.

A solution of 3.56 g mesitylacetic acid (20 mmol), 0.6 mL triethylamine, and 30 mL DMF was electrolyzed at 35–50°C at a current density of 16.7–2.5 mA/cm^2 (140–150 V) for 6 h. A total of 0.670 g CO_2 was collected (76%). The solvent was removed under reduced pressure. No acid was recovered by extraction with Na_2CO_3. The reaction mixture was placed on an alumina column and eluted with *n*-hexane to yield 1.17 g 1,2-dimesitylethane,

in a yield of 44%, m.p. 117–119°C. Elution with hexane/benzene (3:2) gave 0.56 g 2,4,6-trimethylbenzyl mesitylacetate, in a yield 18%, m.p. 103–105°C. Further elution with benzene followed by ether gave 0.770 g 2,4,6-trimethylbenzyl alcohol as needles, in a yield of 25.7%, m.p. 89–90°C.



Reference 2xx.

A solution of 2.67 g 3,3-diphenylpropanoic acid in 25 mL absolute methanol containing 27 mg sodium was electrolyzed at 12 F/mol. It was not possible to maintain a constant current since a white precipitate, which obstructed the current flow, formed at the anode. This difficulty was largely overcome by reversing the electrode polarity every 5 min. The electrolysis was continued for a period of 20 h, whereupon the mixture was processed to yield 1.56 g crude syrup. This was chromatographed on 200 g silica gel, using benzene/hexane mixtures gradually enriched in benzene, and finally ether as the eluent. Residues from eluate evaporation, afforded five fractions totaling 97.3% of the charge. Fraction 1 was 1,1,4,4-tetraphenylbutane, which solidified and was recrystallized from hexane as white needles, in a yield of 13%, m.p. 119–122°C. Fraction 2 was an unidentified oil, in a yield of 4.5%. Fraction 3 crystallized and was recrystallized from hexane/benzene to provide a few milligrams of white solid, m.p. 137–139°C, in a yield of 1.1%. The low yield did not provide sufficient material for characterization. Fraction 4 proved to be methyl 1,2-diphenylethyl ether as a clear oil, in a yield of 12.7%. Fraction 5 (68.8% yield) was a crude oil containing at least four components as analyzed from TLC, one of them is similar to 4-phenyl-3,4-dihydrocoumarin, no further identifiable products were isolated from this fraction.

Other references related to the Kolbe electrolysis are cited in the literature.[9]

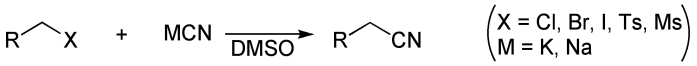
Kolbe Nitrile Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was reported by Kolbe before 1884.[1] It is the synthesis of nitriles via S_N2 substitution between an alkali metal cyanide and an alkyl halide, tosylate, or mesylate and is generally known as the Kolbe nitrile synthesis.[1,2] This reaction works best for primary alkylating agents in a polar aprotic solvent, such as DMSO,[3] HMPA,[4] or NMP.[5] The secondary bromides might give moderate yields of corresponding nitriles as well; however, the tertiary halides may end up with the elimination products, because the alkali metal cyanide functions as a base too. Because cyanide is a bident nucleophile, it can also result in an isonitrile as a by-product, especially when AgCN or CuCN is used as a nucleophile.[2b] This reaction has been modified to use a phase-transfer catalyst[6] and has recently been carried out in various ionic liquids, such as [bmim][BF_4] (1-butyl-3-methyl imidazolium tetrafluoroborate),[5] [bmim][PF_6], [bmim][$N(Tf)_2$] (1-butyl-3-methyl imidazolium bis(trifluoromethylsulfonyl) imide), and [hpyr][$N(Tf)_2$] (1-hexylpyridinium bis(trifluoromethylsulfonyl) imide).[7] This reaction has been applied to extend the carbon chain of carboxylic acid via the reduction of acid to alcohol followed by the hydrolysis of a new nitrile generated through substitution of the corresponding tosylate of the reduced alcohol. It should be pointed out that the configuration of a stereocenter adjacent to the carboxy function is retained in this reaction.[2c]

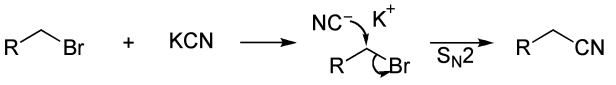
B. GENERAL REACTION SCHEME



Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

The mechanism is represented by the substitution between a primary bromide and potassium cyanide. The potassium cyanide may exist as contact or loose ion pairs or may even dissociate into free cyanide anion, depending on the reaction conditions, but mostly on the chosen solvents.



D. MODIFICATION

This reaction has been modified to occur under the conditions of either an ionic liquid[5,7] or in the presence of a phase-transfer catalyst.[6]

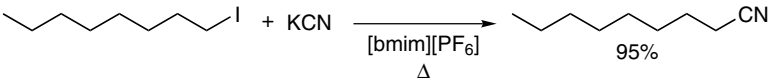
E. APPLICATIONS

This reaction has general application in the preparation of nitriles.

F. RELATED REACTIONS

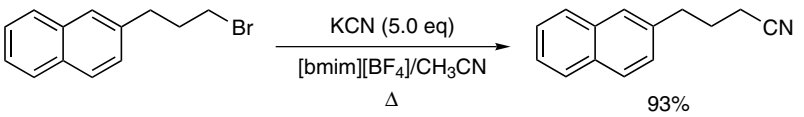
This reaction is related to the S_N2 *Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

Reactions were carried out in a screw cup with Teflon-faced rubber septum vials under magnetic stirring. To a suspension of 3 mmol KCN in 2 mL ionic liquid [bmim][PF_6], stirred overnight at 80°C was added 1 mmol 1-iodo-*n*-octane. The mixture was stirred at 80°C for 7 h, and then the product was extracted with Et_2O (1 mL × 5). The combined organic layers were dried over $MgSO_4$, and concentrated to give 95% 1-nanonitrile.



Reference 5.

Potassium cyanide (325 mg, 5 mmol) was added to a mixture of 249 mg 2-(3-bromopropyl)naphthalene (1.0 mmol) and 3.0 mL [bmim][BF_4] in 3.0 mL acetonitrile. The mixture was stirred at 50°C for 30 min. The reaction mixture was extracted from the ionic liquid phase with Et_2O (7 mL × 3). The ether layers were combined and dried over Na_2SO_4 and evaporated under reduced pressure. The residue was purified by flash column chromatography (10% EtOAc/hexane) to yield 181 mg 2-(3-cyanopropyl)naphthalene (0.93 mmol) as a white solid, in a yield of 93%.

Kolbe-Schmidt Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kolbe in 1860[1] and subsequently by Schmidt in 1886.[2] It is the preparation of *ortho*- or *para*-hydroxyl benzoic acid from carbon dioxide and sodium or potassium phenolate and is generally known as the Kolbe-Schmidt reaction.[3] In addition, this reaction is also referred to as the Kolbe-Schmidt carboxylation[3c] or Kolbe-Schmidt synthesis.[4] It has been found that heating the mixture of phenol, potassium carbonate, and carbon dioxide also results in the formation of hydroxyl benzoic acid.[3e] It is interesting that the sodium phenolate always leads to the formation of *ortho*-hydroxyl benzoic acid, (i.e., salicylic acid), whereas potassium phenolate often results in the production of *para*-hydroxyl benzoic acid. Even though the mechanism is not quite clear, it is possible that sodium phenolate exists as contact ion pairs, of which sodium cation coordinates with one oxygen of CO_2 that prefers the formation of salicyclic acid; in contrast, potassium phenolate forms dissociated ion pairs and thus attacks CO_2 through the *para*-position. Although in most cases, this reaction is feasible only with the highly activated phenols (with more electron-donating groups), some phenols with electron-withdrawing groups such as CF_3 also undergo this reaction,[3e] and such a reaction even occurs for 3-hydroxy pyridine[3c] and hydroxyl-2(1*H*)-pyridinone.[5]

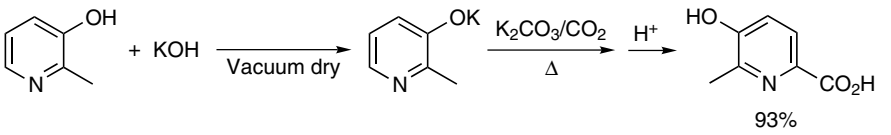
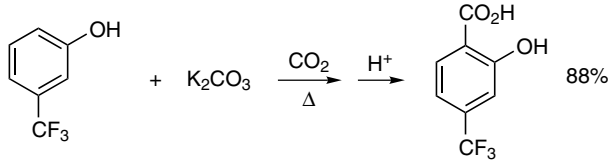
G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

The dry potassium salt of 2-methyl-3-hydroxypyridine was prepared by dissolving this compound in an equivalent amount of 2.5 *N* aqueous KOH, concentrating this solution to a thick glass on a steam bath under a nitrogen stream and completing the drying at 70°C in a vacuum oven. A mixture of 27 g of this potassium salt (0.18 mol) and 38 g anhydrous K_2CO_3 (0.28 mol) was thoroughly ground in a ball mill for 1 h. The resulting fine powder was quickly transferred to a hydrogenation bomb, which was charged to a pressure of 500 psi with CO_2 and heated with rocking at 250°C for 9 hours. Rocking was continued as the bomb was allowed to cool to room temperature. In a series of experiments, the pressure drop always amounted to 80–100% of that calculated for the absorption of 1 mol CO_2 per mole of 2-methyl-3-hydroxypyridine. Using 350 mL boiling water in portions, the contents of the bomb were removed, the mixture was heated to boiling and filtered hot, and the filtrate was acidified to pH = 2 with H_2SO_4. The CO_2 was driven off by boiling, and the mixture, cooled to room temperature, was rapidly adjusted to pH 7.3–7.4 with conc. NaOH solution. Filtration at this point gave 23 g 5-hydroxy-6-methylpicolinic acid, and continuous extraction of the filtrate with methylene chloride, maintaining the pH at 7.3, led to a recovery of 3 g 2-methyl-3-hydroxypyridine. The aqueous phase then was acidified to pH = 3 with H_2SO_4 and thoroughly extracted with *n*-butyl alcohol. Concentration of the *n*-butyl alcohol extracts gave an additional 4 g 5-hydroxy-6-methylpicolinic acid, bringing the total to 27 g of material (93% yield, based on consumed 2-methyl-3-hydroxypyridine), melting > 240°C (dec.)



Reference 3e.

The mixture of 48.6 g *m*-trifluoromethylphenol (0.3 mol) and 124.4 g anhydrous K_2CO_3 (0.90 mol) were intimately dispersed in a 250-mL copper bomb, and carbon dioxide gas from a commercial cylinder was introduced at 300 psi at room temperature. The temperature was allowed to rise very slowly over a period of 10 days to 220°C. It was noted that some carbon dioxide was absorbed even at room temperature and that at 140°C the reaction was essentially completed. As CO_2 was taken up, additional gas was introduced. The reaction time can be shortened by raising the temperature much more rapidly. However, there are indications that a fairly slow rise in temperature is beneficial, and an immediate increase of the temperature to > 140°C is not recommended. At the completion of the reaction, the bomb was cooled, vented, and opened. The product was a hard cake, which was dissolved

in hot water. The solution was extracted with ether, decolorized with charcoal, and acidified with concentrated HCl. An 88% yield of 4-trifluoromethylsalicylic acid was isolated with only a trace amount of detectable phenol. Crystallization from alcohol and water yielded pure compound as white needles, m.p. 178–178.5°C.

Kondrat'eva Pyridine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

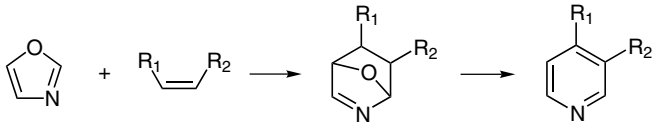
This reaction was first reported by Kondrat'eva in 1957.[1] It is a general method for synthesizing pyridine derivatives involving an inverse demand *Diels-Alder Cycloaddition* between an azadiene (especially the oxazoles) and a dienophile followed by an extrusion of the resulting bridge of the bicyclic intermediate. Thus this reaction is known as the Kondrat'eva pyridine synthesis,[2]Kondrat'eva reaction,[2a] Kondrat'eva cycloaddition,[2,3] or Kondrat'eva approach.[2a,4]

When substituted oxazole is applied as a diene, the dienophiles are usually derived from 2-butene-1,4-diols.[4] In addition, the derivatives of maleic acid and fumaric acid are also good dienophiles.[5] On the other hand, only certain isooxazoles of particular substituted patterns undergo cycloaddition to give pyridine derivatives. For example, 4-methyl-oxazole reacts with either electron-rich or electron-deficient alkenes, and the resulting bicycles can decompose via three different routes: loss of water to pyridine; expelling of a substituent (R) to form 3-pyridinol, depending on the substituent R on alkenes; or oxidative scission to give a different 3-pyridinol.[2b] In addition, an intramolecular version of Kondrat'eva pyridine synthesis between the tethered oxazole and the alkene generally proceeds smoothly.[6]

However, the extremely activated oxazoles, such as 5-amino-oxazole, can undergo different patterns of cycloaddition, including [2 + 4], [2 + 3], and even [2 + 2] cycloaddition, according to the reaction conditions.[7]

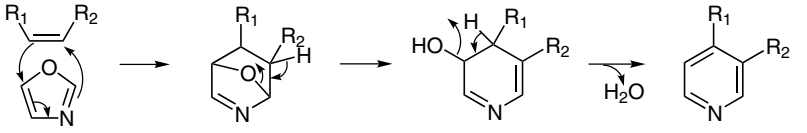
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

In general, the Kondrat'eva pyridine synthesis involves an inverse demand *Diels-Alder Cycloaddition* between an azadiene and a dienophile followed by the extrusion of a part of the resulting bicyclic intermediate to give a pyridine derivative, as illustrated here.



D. MODIFICATION

This reaction has been modified extensively to include the cycloaddition of pyrimidines,[8] pyrazines,[9] 1,2,3-triazene,[10] and 1,2,4-triazenes[11] with dienophiles to give a variety of pyridine derivatives.

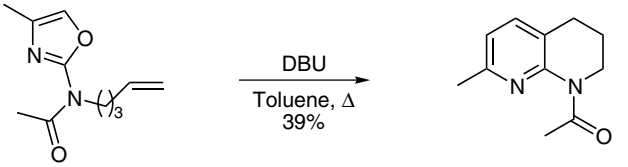
E. APPLICATIONS

This reaction has wide application in the preparation of pyridine derivatives and other heterocycles.

F. RELATED REACTIONS

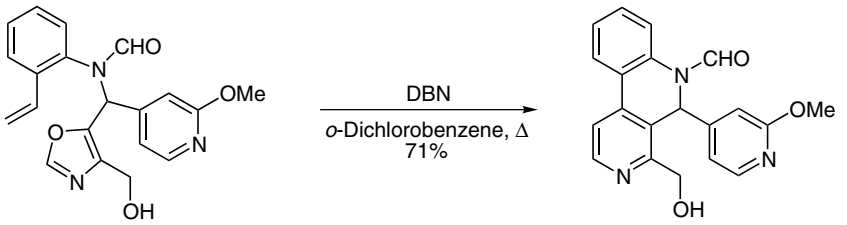
This reaction is related to the *Diels-Alder Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

A solution containing 0.1 g *N*-(4-methyloxazol-2-yl)-*N*-(pent-4-enyl)acetamide (0.5 mmol) and 0.06 g DBU (0.4 mmol) in 2 mL toluene in a sealed tube under an argon atmosphere was heated at 180°C for 20 h. Then the solvent was removed under reduced pressure, and the residue was purified by flash silica gel chromatography to give 0.3 g 1-acetyl-7-methyl-1,2,3,4-tetrahydro-1,8-naphthyridine as a pale yellow oil, in a yield of 39%. (*Note*: It requires 0.842 g starting material to afford 39% naphthyridine derivative in a yield of 39%, but it was stated as 0.1 g in the original article.)



Reference 2a.

A solution of 0.15 g oxazole alcohol (0.41 mmol) and 0.05 g DBN (0.41 mmol) in 60 mL anhydrous *o*-dichlorobenzene was deoxygenated with argon for 45 min. The mixture was heated at 150°C under an argon atmosphere for 1.5 h and then cooled to room temperature. Upon removal of solvent in vacuo, the residue was purified by flash chromatography using MeOH/EtOAc (1:49) as the eluent to afford 0.10 g pyridine alcohol as a pale yellow oil, in a yield of 71%.

373

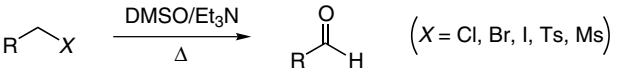
Kornblum Oxidation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kornblum in 1957.[1] It is the formation of aldehydes by treatment of primary alkyl halides with dimethylsulfoxide and a hydrogen acceptor. Thus it is often known as the Kornblum oxidation.[2] Occasionally, it is also referred to as the Kornblum reaction.[3] In fact, this is the first mild oxidation leading to a carbonyl compound using DMSO.[4] In this reaction, bases such as triethyl amine[2d] and sodium bicarbonate[5] are usually used as the proton acceptor; however, the oxidation of 4-chloro-3-methyl-2-buten-1-ol acetate does not proceed well when sodium bicarbonate is used as the proton scavenger, thus a sodium or potassium phosphate dibasic (Na_2HPO_4 or K_2HPO_4) is used.[3] Generally, this reaction works well for active alkyl halides, such as benzylic or allylic halides or alkyl iodide, because it initially involves the nucleophilic substitution of a halide into an alkoxysulphonium ion that transforms into an aldehyde when treated with a base.[6] Thus those nonactive alkyl halides are often converted into corresponding tosylates and are then treated with DMSO and a base.[1,7] On the other hand, it has been found that a nonnucleophilic silver salt such as $AgBF_4$[8] or zinc sulfide[2b] can assist the nucleophilic substitution that is added to the reaction system. Unfortunately, this reaction is less selective or is uncontrollable for the oxidation of multibenzylic halides[3a] and always requires high temperature treatments.[2a,2c,2d]

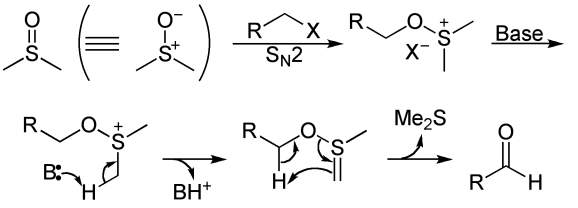
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Illustrated below is the mechanism, in which *B* represents a general base.



D. MODIFICATION

This reaction has been modified by adding nonnucleophilic silver salt[8] or zinc sulfide[2b] to facilitate the initial nucleophilic substitution. In addition, it has been modified to convert α-bromo alcohols into ketones.[2b]

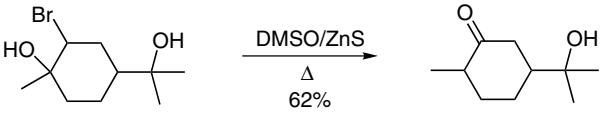
E. APPLICATIONS

This reaction is useful for converting primary alkyl halides into the corresponding aldehydes.

F. RELATED REACTIONS

This reaction is related to the *Swern Oxidation, Dess Martin Oxidation,* and *Moffatt-Swern Oxidation*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a flask, was added 2.51 g bromohydrin (10 mmol) and 15 mL dry DMSO. To this solution was added 0.97 g dry ZnS (10 mmol), and the mixture was stirred at 70°C. Reaction was monitored by injection of a worked-up aliquot on GC. In the end ($\sim$ 10 h), the reaction mixture was poured into 150 mL water and extracted into CH_2Cl_2 (10 mL $\times$ 3). The organic layer was dried over anhydrous Na_2SO_4, and solvent was evaporated. The residue was chromatographed over SiO_2 using a mixture of EtOAc/hexane (1:9) as the eluent to give 62% ketone.

Kornblum-Delamare Rearrangement

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kornblum and DeLaMare in 1951.[1] It is primarily a base-promoted rearrangement of a peroxide into a ketone and an alcohol and is thus known as the Kornblum-DeLaMare reaction[2] or Kornblum-DeLaMare rearrangement.[3]

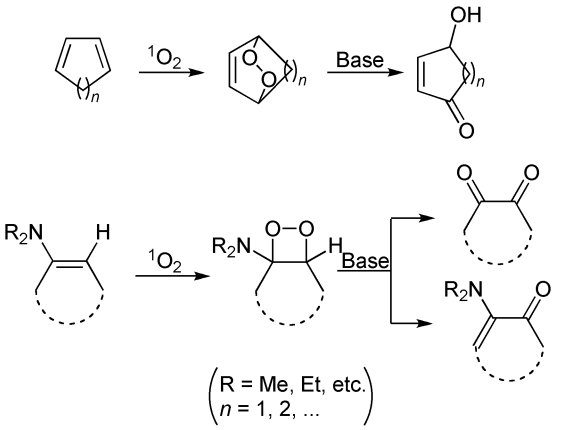
In its initial protocol, potassium *tert*-butyl peroxide and 1-phenylethyl bromide are eventually converted into *tert*-butanol and acetophenone in the presence of piperidine, KOH, or NaOEt.[1] However, in the case of symmetric bicyclic endoperoxides, enantioenriched γ-hydroxyenones form via desymmetrization in the presence of a catalytic amount of chiral base, especially for the cinchona, which gives the best results in terms of reactivity and enantioselectivity among the tested amines.[3b] Although organic bases such as trialkylamine (e.g., Et_3N[1,4]) are often used in this reaction, phosphorus ylide[5] and an inorganic base, such as KOH,[1] LiOH,[3c,6] or sodium ethoxide,[1] are also workable for this rearrangement. In addition, even acidic SiO_2 has recently been observed to promote the rearrangement.[3f]

On the other hand, besides the initial S_N2 substitution to form the peroxide,[1] peroxides are normally obtained by 1,4-dioxygenation of conjugated diene with singlet oxygen ($^1O_2$)[3b,3f,4a] or photo-[2+2] cycloaddition between singlet oxygen and alkenes, especially with alkenes activated with an amino or alkoxy group (i.e., enamines or vinyl ethers).[2b] For the special case of *N*-substituted 3-vinylindoles, photo-oxidation with $^1O_2$ occurs efficiently and stereospecifically to afford dioxacarbazole endoperoxides; however, *[2+2] Cycloaddition* would occur preferentially at the 3-vinyl double bond when the s-*cis* conformation is blocked by substituents at the position 2 of indole and the β-position of vinyl moiety.[3f] For *N*-substituted 3-vinylindoles, it is found that both the stability of endoperoxides and the reaction products depend on the *N*- and 3-vinyl β-substituents. For example, an electron-withdrawing group on the nitrogen atom of an indole will stabilize the resulting

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

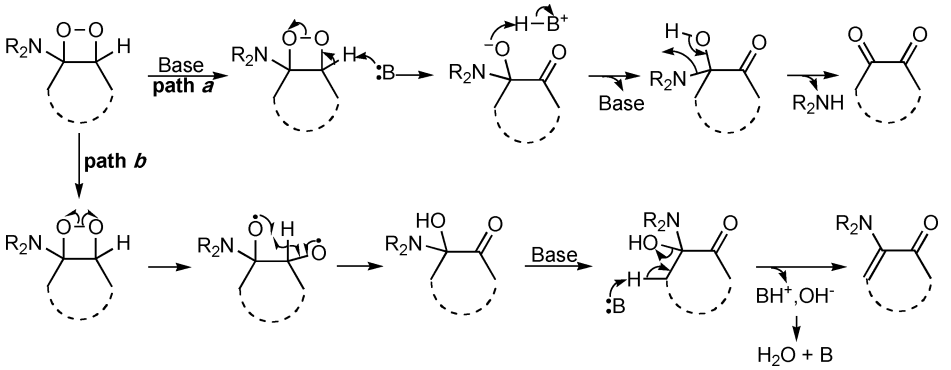
endoperoxide, whereas on the β-carbon of 3-vinyl moiety it will destabilize the endoperoxide and favor the Kornblum-DeLaMare rearrangement. In addition, endoperoxide arising from *N*-methyl 3-vinyl indole is sensitive to acid and will rearrange to dioxetane, which cleaves the 3-vinyl double bond. The β-methoxy group on 3-vinyl moiety has a strong directing effect on the reaction, which accelerates the endoperoxidation when the aromatic double bond is in a *cis*-configuration, while making the *ene* reaction occur exclusively when a *cis*-methyl group is present.[3f]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

In most cases of the Kornblum-DeLaMare rearrangement, an E2 elimination mechanism is involved in the presence of a base, to afford a ketone and an alcohol, as illustrated in path *a*.[2b,3b] However, in the rearrangement of dioxetanes arising from alkenes with electron-donating groups, such as enamines and vinyl ethers, a free-radical process consisting of initial O-O cleavage followed by an internal hydrogen transfer to give α-hydroxy ketones dominates, as shown in path *b*.[2b]



D. MODIFICATION

The enantioselective Kornblum-DeLaMare rearrangement based on the desymmetrization of *meso*-endoperoxides by a chiral base catalyst has recently been developed.[3b]

E. APPLICATIONS

This reaction has important applications in the preparation of γ-hydroxyenones.

F. RELATED REACTIONS

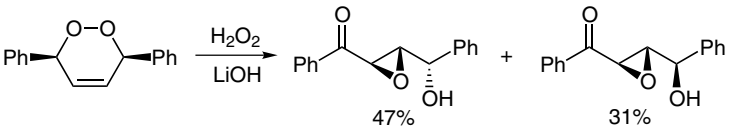
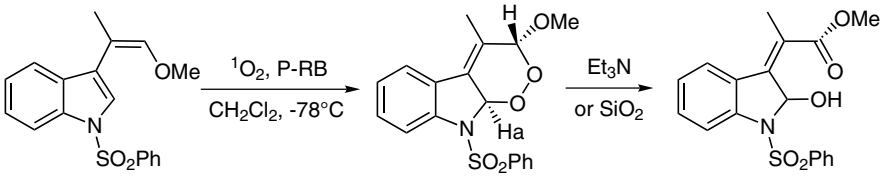
G. CITED EXPERIMENTAL EXAMPLES



Reference 3c.

To a stirred solution of 0.238 g 1,2-dioxine (1 mmol) in 5 mL THF was added 453 mg 30% aqueous hydrogen peroxide (4 mmol) followed by 23 mg lithium hydroxide (1 mmol). The resulting suspension was stirred vigorously until the reaction was completed as monitored by TLC ($\sim$16 h). A small portion (1–2 mg) of manganese dioxide was added to the mixture and allowed to stir until evolution of gas had ceased. The solution was then diluted with 15 mL water and extracted with CH_2Cl_2 (2 $\times$ 20 mL). The combined organic extracts were dried and evaporated, and the residue was purified by flash chromatography to afford 47% of ($\pm$)-{(2*R*,3*S*)-3-[(*S*)-1-hydroxy-1-phenylmethyl]oxiran-2-yl}(phenyl)methanone as a colorless solid [m.p. 106–107°C, R_f = 0.5 (hexane/EtOAc, 3:2)] and 31% of ($\pm$)-{(2*R*,3*S*)-3-[(*R*)-1-hydroxy-1-phenylmethyl]oxiran-2-yl}(phenyl)methanone as a colorless solid, m.p., 78–80°C, R_f = 0.38 (hexane/EtOAc, 3:2).



Reference 3f.

A solution of 60 mg *N*-phenylsulfonyl-3-(α-methyl-*cis*-β-methoxy)vinylindole (0.18 mmol) and 5 mg polymer-bound rose bengal in 2 mL CH_2Cl_2 was photooxygenated at -78°C for 40 min. After filtration of the polymer-bound rose bengal,

the solution was concentrated to give only *trans*-9,9a-dihydro-3-methoxy-4-methyl-9-(phenylsulfonyl)-3H-1,2-dioxion[3,4-b]indole, which was purified by recrystallization from CH_2Cl_2/hexane (1:1), m.p. 100–102°C. Further treatment of this compound with SiO_2 or Et_3N afforded the final ester compound, which was purified by preparative TLC (petroleum ether/CH_2Cl_2/acetone, 4:2:0.5).

Kostanecki-Robinson Reaction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kostanecki and Rozycki in 1901.[1] It is the formation of coumarins and chromones from alkyl *o*-hydroxyaryl ketone and aliphatic acid anhydride in the presence of the corresponding aliphatic acid sodium salt, via the *O*-acylation and *Aldol Condensation*. Because this reaction is similar to the *Robinson Annulation*, this reaction is generally known as the Kostanecki-Robinson reaction,[2] Kostanecki-Robinson acylation[2i,3] or Kostanecki-Robinson synthesis.[2i,4] In addition, a specific reaction between alkyl *o*-hydroxyaryl ketone and acetic anhydride is called the Kostanecki-Robinson acetylation;[5] likewise, the corresponding reaction with phenylacetic anhydride is referred to as the Kostanecki-Robinson phenylacetylation.[6] Depending on the actual reaction conditions and substituents, either coumarin or chromone or both can be produced,[2i] and normally, the application of acetic anhydride and sodium acetate gives chromone derivatives.[2b,7] It has been found that the existing α-pyrone ring on the aromatic ketone does not affect the Kostanecki-Robinson reaction.[3g]

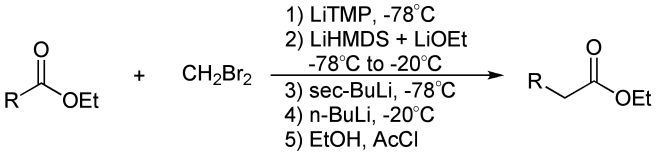
Kowalski Ester Homologation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kowalski et al. in 1985.[1] It is a one-carbon extension of a carboxylic acid chain of an ester with methylene dibromide by means of strong base treatment at very low temperature and quenched by an alcohol. Thus it is known as the Kowalski homologation,[2] Kowalski chain homologation,[2b,3] or Kowalski ester homologation.[2a,4] The original procedure involves the formation of dibromomethyllithium, to which the ester is added to form a tetrahedron species, which may undergo either of the two paths when treated with an excess amount of a base to form α-bromo-α-keto dianions through either dibromoenolate or bromoenolate; the dianion then rearranges to alkynolate anion, which is quenched by alcohol to give an ester with one more carbon via ketene.[1,5] This reaction has obvious advantages over the *Arndt-Eistert Synthesis* because the latter requires further activation and involves diazomethane and diazoketones.[2a,5] However, this procedure also bears some limitations, such as the moderate yield, small scale (< 2.5 mmol scale), and application of low temperature.[4c,5] On the basis of a mechanism study, this reaction has been modified by first formation of dibromoketone, which is then treated with LHMDS to form bromoenolate or dibromoenolate and further by an excess amount of butyl lithium to give the alkynolate anion. Such two-step modification not only increases the yield but also scales up the reaction to the 25-mmol level, and even 100-mmol level in one case.[5] It has been found that the R group of the carboxylic acid in the ester can be a primary, secondary, or tertiary alkyl group or an aryl, alkenyl, or alkynyl as well as some lactones.[1,5] In addition, the stereochemistry is retained during the migration of the R group.[2a,5]

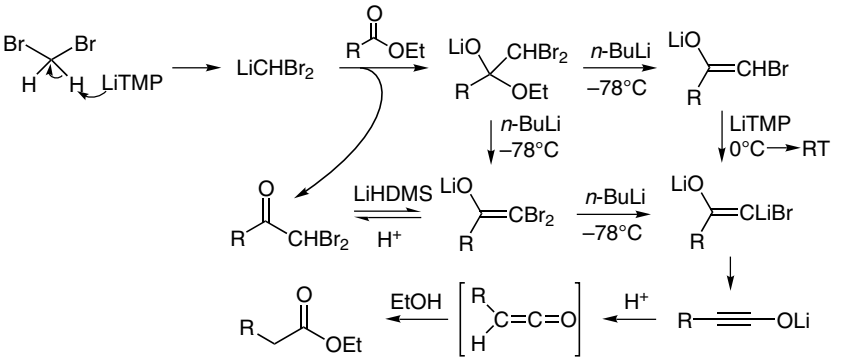
Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Displayed below is the modified mechanism proposed by Kowalski.[5]



D. MODIFICATION

This reaction has been modified from a one-pot synthesis to a two-step reaction so that both higher yields and larger reaction scales can be achieved.

E. APPLICATIONS

Besides the general extension of an ester carbon chain, this reaction has been used to synthesize β-amino acid ester with retention of stereochemistry[2a] and the siloxyacetylene derivatives.[2b]

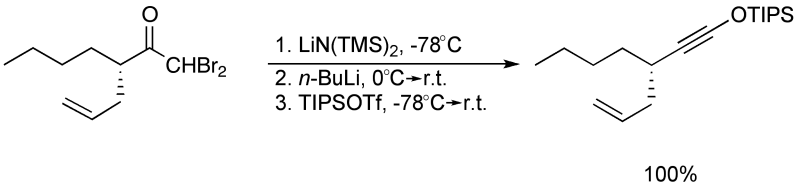
A solution of LiTMP was prepared as follows: 1.1 mL *n*-BuLi in hexanes (3.1 mmol) was added to a stirred, cold (0°C) solution of 0.6 mL TMP (3.3 mmol) in 4.3 mL THF. In a separate flask, a stirred mixture of 216 mg methyl (*S*)-*N*-benzylpipecolinate (0.9 mmol) and 0.2 mL CH_2Br_2 (3.1 mmol) in 4.3 mL THF was cooled to −78°C. After 30 min, the LiTMP solution was cooled to −78°C and added to the ester/CH_2Br_2 mixture dropwise via a double-ended needle. After 15 min, a cold (−78°C) solution of LiHMDS in THF (2.8 mL, 3.1 mmol) was added dropwise via a double-ended needle. The mixture was then allowed to warm to −20°C and was then recooled to −78°C. A solution of *s*-BuLi in hexanes (3.6 mL, 4.7 mmol) was added dropwise. The mixture was then warmed to −20°C, and a solution of *n*-BuLi in hexanes (1.1 mL, 2.8 mmol) was added. The mixture was warmed to room temperature, stirred for 1 h, and then quenched over a 20-min period into 12 mL stirred acidic methanol at 0°C. [Acidic methanol was prepared by the slow addition of acetyl chloride to ice-cooled dry methanol (1:5 volume ratio)]. The mixture was diluted with 150 mL ether and washed with saturated aqueous $NaHCO_3$. The aqueous phase was reextracted with ether (2 × 50 mL), and the combined organic extracts were washed with brine and dried over $MgSO_4$ and concentrated in vacuo. Purification by flash chromatography (hexane/EtOAc, 9:1→3:2) gave 195 mg methyl (*S*)-*N*-benzylpiperidin-2-ylacetate, in a yield of 85%, R_f = 0.55 (hexane/EtOAc, 1:1).



Reference 2b.

A solution of 1.50 g dibromoketone (4.78 mmol) in 27 mL THF was cooled to −78°C. In a separate flask, a 1.21-mL solution of hexamethyldisilazane (HMDS) (5.70 mmol) in 27 mL THF was cooled to 0°C and treated with 2.0 mL 2.5 M *n*-BuLi in hexanes (5.0 mmol). This colorless LiHMDS solution was immediately added dropwise via an addition funnel to the dibromoketone solution over a 25-min period. The reaction mixture was stirred for 20 min at −78°C and treated with 4.2 mL 2.5 M *n*-BuLi in hexanes (10.5 mmol) via syringe. After 30 min, 1.39 mL freshly distilled tri-isopropylsilyl trifluoromethylsulfonate (TIPSOTf) (5.18 mmol) was added. The reaction mixture was allowed to warm to 0°C, cooled to −78°C, quenched with 50 mL saturated aqueous $NaHCO_3$, extracted with hexanes (2 × 50 mL), dried over $MgSO_4$, filtered, and concentrated. The product was purified by bulb-to-bulb distillation (0.1 mmHg, oven temperature 80–120°C) to afford 1.48 g siloxyalkyne as a colorless oil, in a yield of 100%.

Other references related to the Kowalski ester homologation was cited in the literature.[6]

Krapcho Decarboxylation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was studied comprehensively by Krapcho beginning as early as 1967.[1] It is an alkali halide promoted alkylative decarboxylation of active esters (e.g., β-keto esters, β-diesters, α-cyano esters) in polar or dipolar aprotic solvents (e.g., DMF, DMSO, HMPA,)[1e] and is generally known as the Krapcho decarboxylation[2] or Krapcho condition.[3] Occasionally, it is also referred to as the Krapcho decarbalkoxylation.[4] In addition, the corresponding decarboxylation on methyl esters is known as the Krapcho decarbomethoxylation,[5] and the decarboxylation of ethyl esters is referred to as the Krapcho decarboethoxylation.[5a,6]

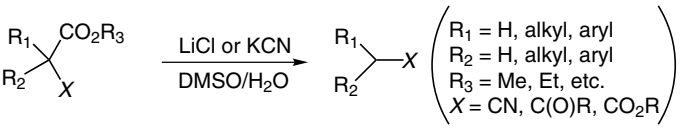
A few exemplary decarbalkoxylation systems are NaCN/DMSO,[7] LiCl/HMPA/H_2O,[8] LiCl/DMSO/H_2O,[9] LiBr/HMPA/H_2O,[10] LiI/NaCN/DMF/H_2O,[11] NaCl/DMF/H_2O,[12] and tetramethyl-ammonium acetate (Me_4NAc).[13] Among the halides salts, NaCl, NaBr, KCl, and Me_4NBr in solvents such as DMSO and HMPT have been used for the internal alkylative decarboxylation,[14] and LiCl in HMPT has been used for external alkylative decarboxylation.[15] In addition, it has been found that many β-keto esters with an α-hydrogen proceed decarboxylation rapidly in wet DMSO.[1e] Although the common use of iodides in this reaction is due to their prior application for cleavages of methyl ester,[1e] the application of tetramethylammonium acetate can avoid the loss of stereohomogenecity of the double bond; the latter condition is usually superior to the consecutive hydrolysis and decarboxylation.[13a] Among the alkali chlorides, LiCl works better than NaCl due to the difference in solubility of these two salts in DMSO.[1e] It should be pointed out that LiF is ineffective, presumably because LiF exists as contact ion pair in the solution;[1e] in contrast, LiCl or KCN is the most effective salt to remove ethyl ester in wet DMSO.[1e] When LiCl is used, the reaction is accompanied by the formation of lithium carbonate

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

(Li_2CO_3);[1e] in addition, even though the reaction rate depends on the concentration of LiCl, the reaction is not in first-order kinetics in terms of LiCl concentration, since the largest rate increase has been observed in the presence of 5 eq. LiCl, and a much smaller rate enhancement is noticeable afterward.[1e] Other than the listed alkali halides, $MgCl_2$, $Na_3PO_4 \cdot 12H_2O$ and lithium acetate (LiAc) are somewhat effective for the alkylative decarboxylation, and the effectiveness of $Na_3PO_4 \cdot 12H_2O$ is due to its high pH in aqueous solution.[1e]

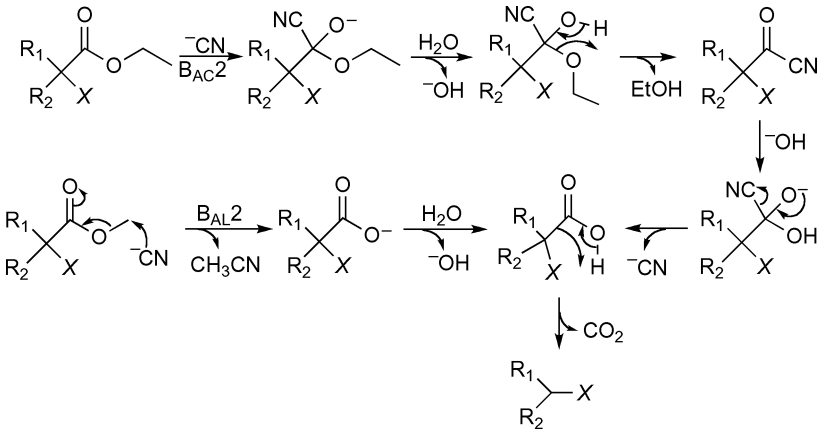
It has also been found that electron-withdrawing substituents facilitate the alkylative decarboxylation, whereas steric hindrance might retard the occurrence of such reaction. For example, diethyl and dimethyl disubstituted malonates do not practically undergo the decarboxylation when heated in $DMSO/H_2O$.[16]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

The insensitive isotopic effect observed in the presence of LiCl or KCN indicates a nucleophilic catalytic mechanism.[1e] However, due to steric hindrance, the decarboxylation may proceed via either $B_{AC}2$ or $B_{AL}2$ mechanism, where B_{AC} is for acyl cleavage and B_{AL} is for alkyl cleavage. $B_{AC}2$ mechanism involves a tetrahedral intermediate originating from the attack of a nucleophile on the carbonyl group, while $B_{AL}2$ takes place via a S_N2 pathway on the alkyl moiety.[17] For example, the isolation of ethanol from the reaction of diethyl diethylmalonate indicates that the $B_{AC}2$ mechanism is competitive,



whereas the absence of methanol in the reaction of dimethyl diethylmalonate by $KCN/H_2O/DMSO$ and the 35.1 times rate enhancement are consistent with a dominant $B_{AL}2$ pathway.[1e] Both $B_{AC}2$ and $B_{AL}2$ mechanisms are displayed using ethyl and methyl esters, respectively.

D. MODIFICATION

1,4-Diazabicyclo[2.2.2]octane (DABCO) has been used for the cleavage of β-keto esters.[18]

E. APPLICATIONS

This reaction has general application for the mild removal of ester groups from the activated esters.

F. RELATED REACTIONS

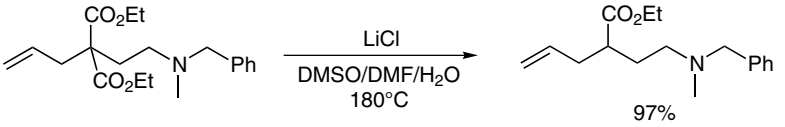
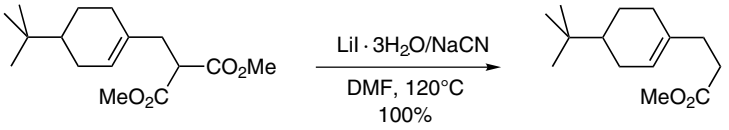
G. CITED EXPERIMENTAL EXAMPLES



Reference 5a.

A solution of 12.0 g 6-(*N*-benzyl-*N*-methylamino)-4,4-di(ethoxycarbonyl) hex-1-ene (34.6 mmol) and 3.2 g LiCl (76 mmol) in 32 mL DMSO, 6.5 mL DMF, and 0.5 mL water was heated at 180°C for 6 h under nitrogen. The resulting dark brown reaction mixture was cooled to room temperature and poured into 150 mL water. The mixture was extracted with dichloromethane (5 × 100 mL), and the combined organic phases were washed with ice water (3 × 100 mL) and brine (100 mL). Drying over sodium sulfate and condensation under reduced pressure gave a brown oil, which was purified by flash chromatography on silica gel, using hexane/EtOAc (1:1) as the eluent to afford 9.26 g 6-(*N*-benzyl-*N*-methylamino)-4-ethoxycarbonyl-1-ene, in a yield of 97%. This product was further purified by vacuum distillation at 143–146°C (0.11 mmHg), $R_f = 0.54$ (ether/hexanes, 1:1).



Reference 13a.

A mixture of 83 mg 1-(2′-dicarbomethoxyethyl)-4-*tert*-butylcyclohexene (0.294 mmol), 225 mg lithium iodide trihydrate (1.2 mmol), 13.3 mg NaCN (0.294 mmol), and 5 mL DMF was heated at 120°C for 12 h. After cooling to room temperature, the solution was poured into water and extracted with ether (2 × 75 mL). The combined ethereal solution was washed with water, 10% aqueous HCl solution, and brine. After drying and evaporation in vacuo, the crude oil was purified by preparative TLC using chloroform as the eluent to afford 66 mg 1-(2′-carbomethoxyethyl)-4-*tert*-butylcyclohexene, in a yield of 100%.

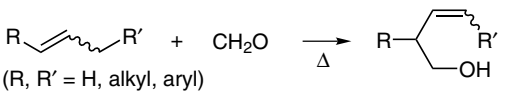
Kriewitz Condensation

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kriewitz in 1899.[1] It is the condensation between formaldehyde and olefins to form unsaturated primary alcohols under conditions of high temperature (e.g., 170°C). In this reaction, water or acetic acid is usually applied as the solvent, and an acid is added as a catalyst, such as sulfuric acid.[2] Under these conditions, formaldehyde and some ketones function as an enophile.[3] The double bond in the new unsaturated alcohol is adjacent to its original position in the starting olefin,[4] with the exception of camphene, which gives an allylic alcohol.[5] For the acylic olefins in this condensation, the isobutylene-type olefins are much more reactive than the monosubstituted olefins or 1,2-disubstituted olefins.[4] The further extension of this reaction involving an intramolecular condensation of an α-alkoxycarbenium ion with a double bond to form a hydropyran derivative is known as the Prins-Kriewitz cyclization.[6]

B. GENERAL REACTION SCHEME

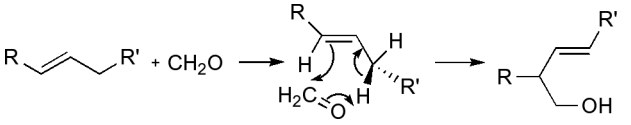


(R, R′ = H, alkyl, aryl)

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

C. PROPOSED MECHANISMS

It is believed that a six-membered ring like transition state is involved in this condensation, as shown here. It is predicted that in the presence of an acid, the carbonyl group would be protonated and even polarized to be more electrophilic, thus the condensation is accelerated. As for the steric hindrance, the major product should be in *trans*-configuration, as in the case of forming *trans*-3-octen-1-ol exclusively from 1-heptene.[4]



D. MODIFICATION

This reaction has been modified to form tetrahydropyran derivatives from the intramolecular condensation of α-alkoxycarbenium ion and internal double bond.[6]

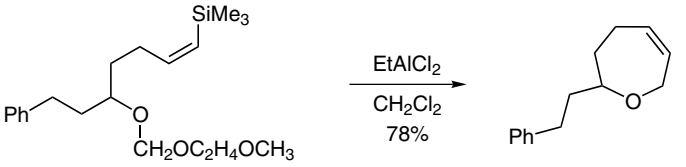
E. APPLICATIONS

This reaction has limited application in organic synthesis. Although it was once used in the production of butadiene or isoprene for the rubber industry, this reaction was found to be less attractive than dehydrogenation and the cracking processes.[2]

F. RELATED REACTIONS

This reaction is related to the *Prins Reaction*.

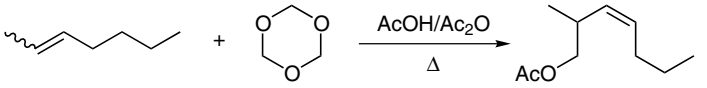
G. CITED EXPERIMENTAL EXAMPLES



Reference 6.

To a solution of 3.0 mL dry CH_2Cl_2 containing 32.3 mg olefin (0.0921 mmol) at -78°C was added 0.10 mL 25.9% $EtAlCl_2$ in heptane (0.28 mmol). The resulting solution was maintained at -78°C for 3 h, allowed to warm to room temperature, maintained there for 2 h, and then cooled to -78°C, and quenched with 5 mL cold (0°C) 2 M NaOH. The two layers were separated, and the aqueous layer was extracted with CH_2C1_2 (2×10 mL).

The combined organic fractions were washed with 10 mL brine, and dried over $MgSO_4$. Purification of the residue on silica gel (hexane/EtOAc 99:1 → 49:1) gave 15 mg of 2-(2-phenylethyl)-2,3,4,7-tetrahydrooxepin as a clear oil, in a yield of 78% with 95% purity by TLC analysis.



Reference 4.

A mixture of 200 g 2-heptene (2.04 mol), 55 g paraformaldehyde (1.83 mol), 96 g acetic acid (1.60 mol), and 18.4 g acetic anhydride (0.20 mol) was heated in a stainless-steel bomb at 180–190°C with agitation for 40 h. The reaction mixture was filtered and separated from 24 g of an aqueous layer. The organic layer was distilled to remove 182.5 g of starting materials, which contained 138.5 g unreacted 2-heptene. Continued distillation gave 62.3 g crude acetate in a yield of 60% (based on 2-heptene consumed), b.p. 98–107°C (30 mmHg).

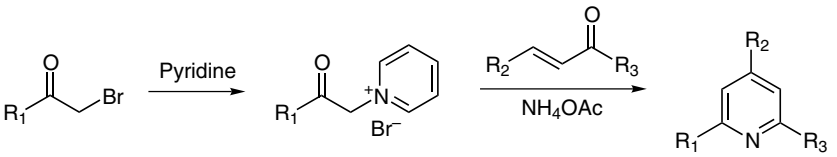
Kröhnke Pyridine Synthesis

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kröhnke et al. in 1961.[1] It is the synthesis of 2,4,6-trisubstituted pyridine derivatives involving the formation of pyridinium ylide from pyridine and α-bromoketone, which undergoes the 1,4-Michael addition to an α,β-unsaturated compound to form 1,5-dicarbonyl compounds and cyclizes with ammonium acetate. Therefore, it is generally known as the Kröhnke pyridine synthesis[2] or Kröhnke reaction.[2b,3] In this reaction, the intermediate 1,5-dicarbonyl compounds do not need to be isolated from reaction mixture.[2b,4] Because three different substituents can be introduced into pyridine ring, this reaction becomes the ideal model for combinatorial synthesis,[2b,4,5] and a library pool containing pyridine from 9^5 to over 200^{2b} has been generated by this reaction.

B. GENERAL REACTION SCHEME

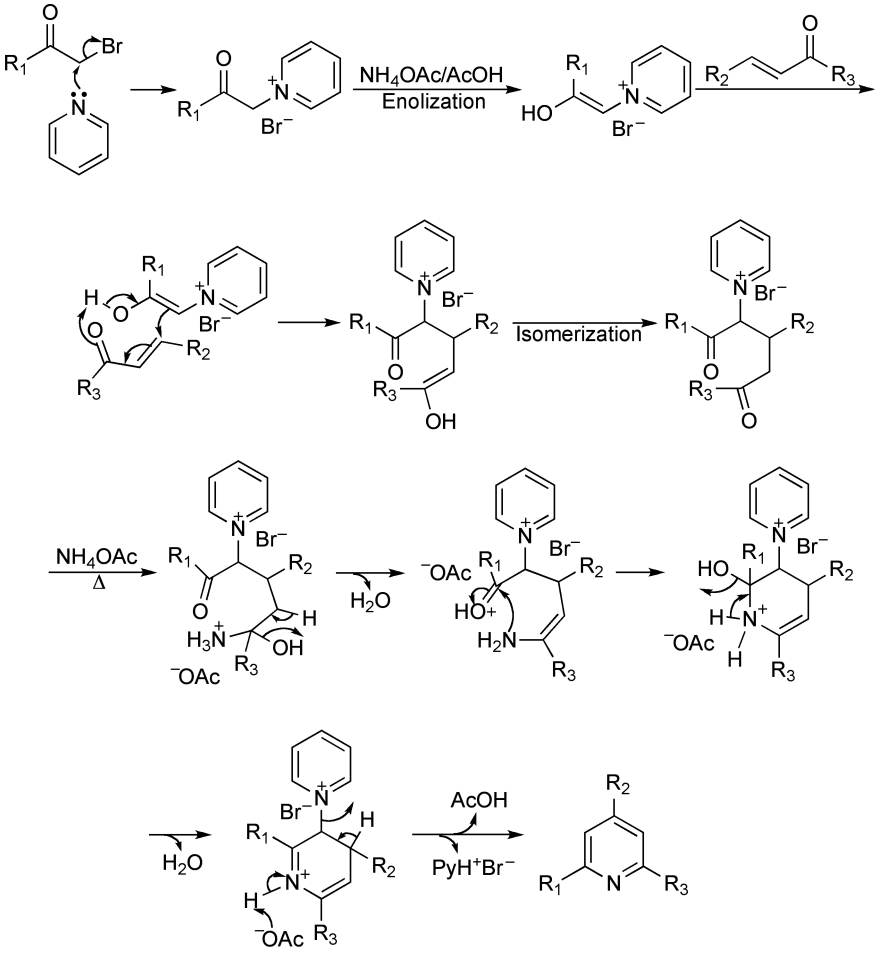


C. PROPOSED MECHANISMS

Illustrated below is the mechanism of the Kröhnke pyridine synthesis in which an ammonium ion attacks the carbonyl group close to R_3. It should be pointed out that the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

ammonium ion can also attack the carbonyl group adjacent to R_1 as the first step for the cyclization.



D. MODIFICATION

This reaction has been modified to produce 2,4,6-trisubstituted pyridines from isoquinolinium ylide instead of pyridinium ylide.[6]

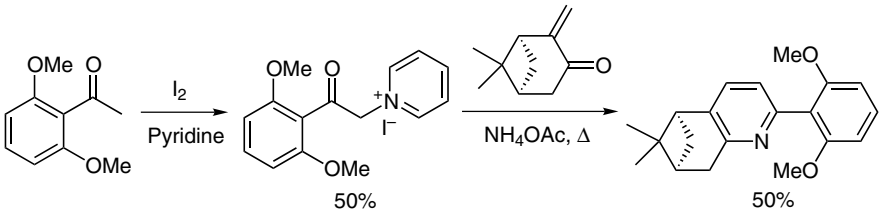
E. APPLICATIONS

This reaction has wide application in the preparation of substituted pyridine derivatives.

F. RELATED REACTIONS

This reaction is related to the *Chichibabin Pyridine Synthesis*, *Guareschi-Thorpe Condensation,* and *Hantzsch Dihydropyridine Synthesis*.

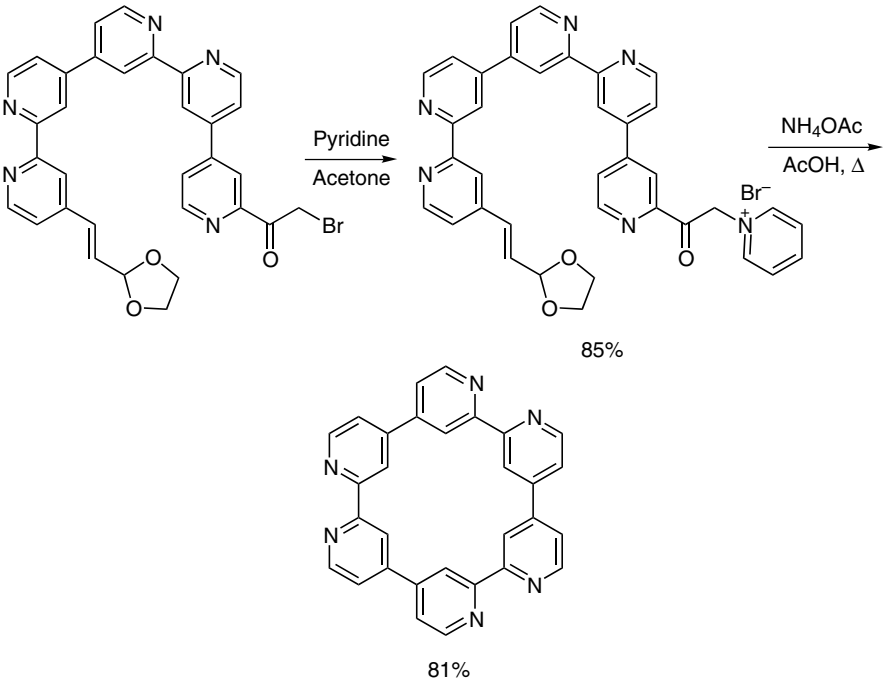
G. CITED EXPERIMENTAL EXAMPLES



Reference 7.

2,6-Dimethoxyacetophenone (48.0 mmol) was heated in 20 mL pyridine until a clear solution was obtained. Crystalline iodine (17.4 g, 57.0 mmol) was added portionwise, and the resulting solution was refluxed for 1 h and then cooled to room temperature. The brownish precipitate was filtered off and successively washed with absolute pyridine (3 × 15 mL) to give 9.29 g 1-[2-(2,6-dimethoxyphenyl)-2-oxo-ethyl]-pyridinium iodide as a pale yellow solid, in a yield of 50%, m.p. 201–203°C (water).

Anhydrous ammonium acetate (110.0 g) was heated in 100 mL acetic acid at 110°C until it dissolved. Then 18.19 g Kröhnke salt (47.0 mmol) was added, and the mixture was left at 110°C until the Kröhnke salt dissolved. (-)-Pinocarvone (43.0 mmol) was added, and the solution was stirred at 110°C for 48 h. Water (20 mL) was then added, and the mixture was extracted with EtOAc (3 × 50 mL). The combined organic layers were washed successively with water (3 × 50 mL) and 30 mL brine, and dried over $MgSO_4$. The solvent was removed in vacuo to afford an oil that was purified via flash chromatography on 25 g silica gel using petroleum ether, followed by a 9:1 mixture of petroleum ether and EtOAc to give 50% (+)-5-(2,6-dimethoxyphenyl)-10,10-dimethyl-6-aza-tricyclo[7.1.1.$0^{2,7}$]undeca-2(7),3,5-triene.



Reference 8.

A mixture of 0.032 g 2-(bromoacetyl)-4‴″-[2-(1,3-dioxolan-2-yl)ethenyl]-4,4′:2′,2″:4″,4‴:2‴,2‴″-quinquepyridine (0.053 mmol) and 0.010 mL pyridine (0.12 mmol) in 30 mL acetone was stirred at room temperature for 12 h. The solvent was evaporated in vacuo, and the residue was dissolved in $CHCl_3$ and then introduced dropwise to cyclohexane while being stirred. The resulting precipitate was collected by filtration and dried in vacuo to afford 0.031 g 4‴″-[2-(1,3-dioxolan-2-yl)ethenyl]-2-(2-pyridiniumylacetyl)-4,4′:2′,2″:4″,4‴:2‴,2‴″-quinquepyridine bromide as a light brown solid (unstable > 20–25°C) that was used immediately for the final step (85% yield)

A solution of 0.024 g pyridinium salt (0.035 mmol) and 0.170 g ammonium acetate (2.2 mmol) in 50 mL acetic acid was refluxed for 19 h. After cooling, the solvent was evaporated in vacuo and the resulting black solid was washed with $CHCl_3$ and isolated by filtration to give 0.013 g cyclo 2,2′:4′,4″:2″,2‴:4‴,4‴″:2‴″,2‴‴:4‴‴,4-hexipyridine as a dark brown solid, in a yield of 81%.

Kuhn-Roth Oxidation

(Kuhn-Roth C-Methyl Determination, Kuhn-Roth Degradation, Kuhn-Roth Determination)

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kuhn and Roth in 1933.[1] It is a method for quantifying the number of methyl groups attached to the carbon atom in an organic molecule, which involves the oxidation of such an organic compound with chromic acid in the presence of sulfuric acid, followed by steam distillation to collect the generated acetic acid and quantification of the acetic acid via acid/base titration.[2] In addition, the collected acetic acid can be further analyzed by conversion of acetic acid into lithium acetate, pyrolysis of lithium acetate to acetone, and transformation of acetone into iodoform by hypoiodite.[3] Therefore, this reaction is generally known as the Kuhn-Roth C-methyl determination,[4] Kuhn-Roth chromic acid oxidation,[5] Kuhn-Roth degradation,[2b,5,6] Kuhn-Roth determination,[2a,7] or Kuhn-Roth oxidation.[2b–2d,3,6e,8]

Depending on the nature of the organic molecules, the ratio of chromic acid and sulfuric acid varies, such as the use of 4 *N* chromic acid/H_2SO_4 in 4:1 (v/v),[3] or 5 *N* chromic acid/concentrated sulfuric acid (2:1).[7a] After acetic acid is separated from the reaction system by steam distillation, it can be quantified using alkali hydroxide of different concentrations, from as low as 0.07 *N*[2c] to 1.0 *N*.[2b] When 1.0 *N* NaOH is used, phenolphthalein can be applied as the end point indicator.[2b] Besides determining the number of methyl groups, this method can also measure the number of ethyl groups on the cyclic compounds, which will be separated in the form of propionate.[2b] After separation of acetic acid, the excess amount of chromic acid is usually reduced by hydrazine.[5]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

It should be pointed out that the Kuhn-Roth oxidation pertains only to the oxidation at an extra-nuclear carbon atom, with a general reactivity order of $C_6H_5\text{-}CH(R_2) > R_3CH > CH_2(R_2) > RCH_3$ (R = aliphatic chain).[4b] The Kuhn-Roth oxidation can determine the number of methyl groups in monoalkylbenzenes with acceptable accuracy up to 20 carbon atoms on the side chains,[7a] however, it fails in the oxidation of toluene, ethylbenzene, and isopropylbenzene to give the expected amount of acetic acid.[4b] In the case of *t*-butylbenzene, the oxidation occurs exclusively at the ring.[4b]

B. GENERAL REACTION SCHEME

C. PROPOSED MECHANISMS

Although no details of the mechanism are available for Kuhn-Roth oxidation, the reaction is proposed to involve the hydrogen abstraction and hydride abstraction mechanism.[4b] It is reasonable that the oxidation occurs initially at the location carrying the most active hydrogen, such as the tertiary proton in aliphatic compounds or the benzylic proton of alkylbenzenes. After such a proton is abstracted, alcohol is formed. Further oxidation of the resulting alcohol gives ketones, presumably accompanied by the cleavage of an alkyl group in the tertiary alcohol, and finally aliphatic acid is generated. Such an aliphatic acid holding an active α-hydrogen will undergo hydrogen abstraction, decarboxylation, and formation of a new aliphatic acid with a shortened carbon chain, until acetic acid is reached. However, a contradictive conclusion of the oxidation of ethylbenzene would be a potential challenge for this explanation.[4b,7a] An example of Kuhn-Roth oxidation on ethylcyclohexane to form propionic acid[2b] is displayed here.

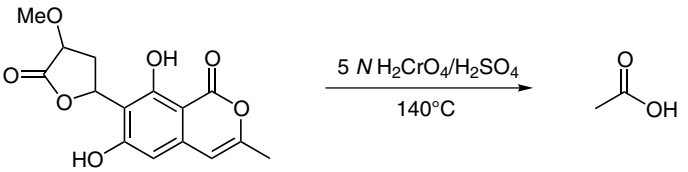
G. CITED EXPERIMENTAL EXAMPLES



Reference 8e.

To a 50-mL flask containing 90 mg ^{14}C labeled canescin were added 10 mL 5 *N* chromic acid and 2 mL concentrated sulfuric acid slowly. A slow stream of clinical oxygen was passed, and the flask was heated to 140°C for 4 h with reflux. On cooling, the condenser was washed down with a small amount of distilled water, then 30% hydrazine solution was added dropwise until the color was completely green. After acidification with 4 mL phosphoric acid, the solution was steam distilled, and the distillate was made slightly alkaline with 0.1 *N* NaOH, as indicated by phenolphthalein. Evaporation gave sodium acetate, which was either converted into the *p*-bromophenacyl ester by standard methods or degraded by the Schmidt procedure; the products being measured as barium carbonate and *N*-methyl-2,4-dinitroaniline. In this experiment, 1 equivalent of acetic acid was found.

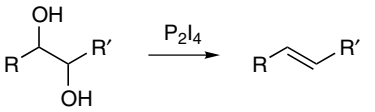
Kuhn-Winterstein Reduction

A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Kuhn and Winterstein in 1928.[1] It is the conversion of adjacent diols into corresponding olefins by means of a diphosphorus tetraiodide reduction and is known as the Kuhn-Winterstein reduction.[2] This reaction is tolerable for the diols with a terminal acetylene group if the experimental conditions are carefully handled,[3] such as the addition of diol in anhydrous pyridine to the supersaturated solution of diphosphorus tetraiodide in carbon disulfide.[2] In most cases, this reaction gives *trans*-olefins as major products,[3] unless the diol group is a part of a ring.[2]

B. GENERAL REACTION SCHEME

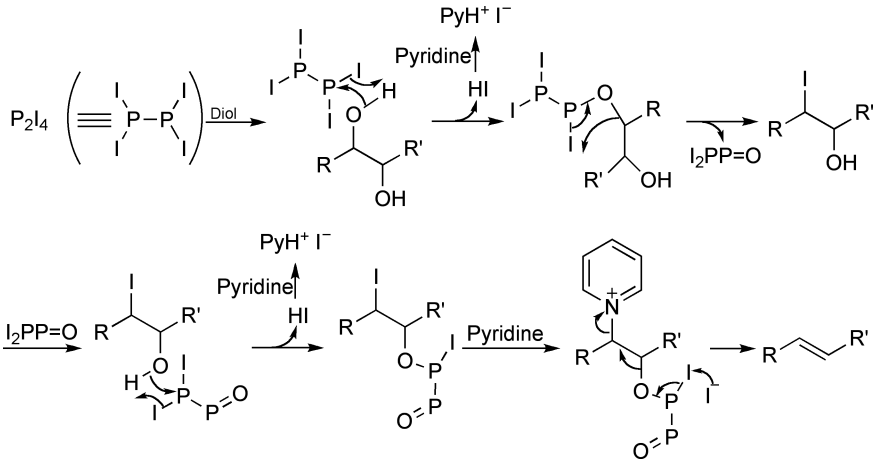


C. PROPOSED MECHANISMS

It is known that alcohols can be converted into halides when they are refluxed with red phosphorus and halogen (e.g., Br_2);[4] therefore, it is assumed that the diol is also converted into iodide as an intermediate that then undergoes the elimination in the presence of a base

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

(e.g., pyridine). The brown color indicates the formation of iodine.[2] Shown here is part of the tentative mechanism.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction can be used to convert the diols into corresponding olefins.

Diphosphorus tetraiodide (50 g, 88 mmol) was finely ground in a mortar, and extracted with 2.5 L dry carbon disulfide for 3 h in a Soxhlet extractor. *Trans*-1,2-diethynylcyclohexane-1,2-diol (10 g, 61 mmol) in 500 mL dry pyridine was added with

stirring over 10 min. The solution immediately turned brown and was then stirred at room temperature for 2 h. The carbon disulfide was removed under reduced pressure, and the residue was extracted with ether. The ether extract was washed successively with sodium hydroxide (2 *N*) solution, 12% sodium thiosulfate solution, 1.5 *N* sulfuric acid, water, saturated sodium bicarbonate solution, and saturated sodium chloride solution. The extract was dried over $MgSO_4$ and evaporated. The resulting brown residue (1.8 g) was chromatographed on 200 g silicic acid-Supercel using pentane as the eluent, to afford 1.48 g 1,2-diethynylcyclohexene as a colorless liquid, in a yield of 19%, b.p. 52–53°C (18 mmHg, under nitrogen).

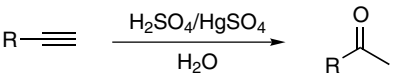
Kutscheroff Acetylene Hydration

A. GENERAL DESCRIPTION OF THE REACTION

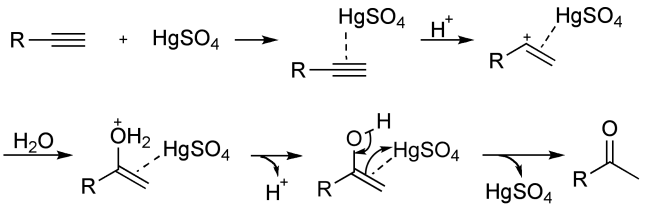
This reaction was first reported by Fittig and Schrohe in 1875[1] and subsequently extended by Kutscheroff in 1881.[2] It is an acid-catalyzed hydration of alkynes into ketones. In this reaction, dilute sulfuric acid and mercuric salt are used as catalysts,[3] and mercuric chloride can form a complex with acetylene in aqueous solution.[4] This reaction has been used to prepare ketones from higher alkynes, such as propyne,[5] and vinylacetylene[6] as well as in commercial production of acetaldehyde from acetylene.[3]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

A tentative mechanism is proposed for the hydration of acetylene, as shown below.



D. MODIFICATION

N/A

E. APPLICATIONS

This reaction has been used to prepare methyl alkyl ketones and for the commercial production of acetaldehyde.

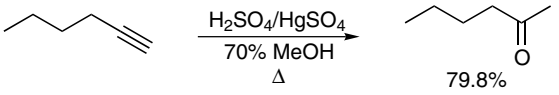
N/A

G. CITED EXPERIMENTAL EXAMPLES



Reference 3.

To a 500-mL three-necked flask equipped with a mercury-sealed stirrer, reflux condenser, and a dropping funnel were added 1.0 g $HgSO_4$, 1.0 g H_2SO_4, and 150.0 g 70% methanol. The mixture was kept at 60 ± 1°C, and 41.0 g 1-hexyne (0.5 mol) was added with good stirring over a period of 1 h. The reaction mixture was then stirred at 60°C for an additional 3 h and cooled to room temperature. The solvent methanol was removed by fractional distillation through an efficient double-jacketed column packed with a single monel wire spiral. The residue was saturated with solid NaCl, and the two layers were separated. The organic layer was washed with brine, Na_2CO_3, and brine again; dried over $CaCl_2$; and distilled from a modified Claisen flask. The portion of the distillate boiling between 124° and 128°C was retained as 2-hexanone, in a yield of 79.8%.

Other references related to the Kutscheroff acetylene hydration are cited in the literature.[7]

Lander Rearrangement

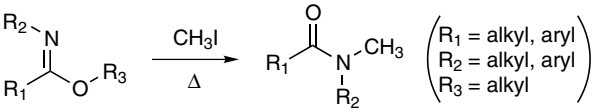
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Wheeler and Johnson in 1899[1] and was explored extensively by Lander starting in 1900.[2] It is a thermal conversion of alkyl imidates (also known as imino ethers[3]) into *N*-alkyl amides in the presence of an alkylting agent. Therefore, it is generally referred to as the Lander rearrangement.[4]

In this 1,3-shift process,[5] when the alkyl group of the alkylating agent is different from that of the substrate, mixed alkyl amides are obtained;[6] however, when the alkylating agent of a lower alkyl group is used for the pyrolysis of alkyl imidates, the *N*-alkyl amides more likely form, with the alkyl groups substituted by the lower one.[2e] Such trend of alkyl group replacement was postulated as early as in 1897 for the conversion of 2-methoxyquinoline or 2-ethoxyquinoline into *N*-methyl-2-quinolone with excess methyl iodide.[7]

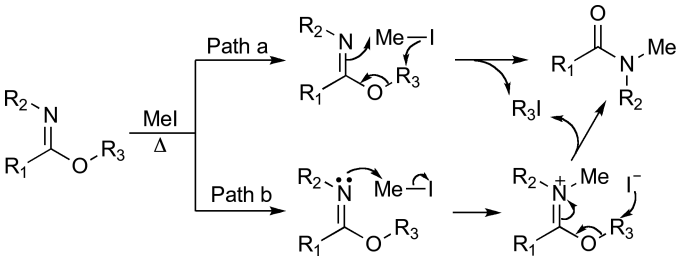
It should be pointed out that this rearrangement also occurs smoothly in the absence of an alkylting agent, as shown in the transformation of *N*-substitued imidates to *N*,*N*-disubstituted amides during the distillation in vacuo,[5] and the reaction under such condition is now known as the *Chapman Rearrangement*.[8]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Different mechanisms have been proposed for this reaction, including a radical process,[4b,8] an ionic proces[9] and even a concerted rearrangement.[10] In addition, experimental evidence indicates that this rearrangement is an intramolecular process.[5] An illustration of such rearrangement by two possible pathways is displayed below.



D. MODIFICATION

This reaction has been extended to the thermal conversion of 2-methylthiobenzthiazole to 2,3-dihydro-3-methylthiobenzthiazole-2-thione in the presence of a methiodide salt.[11] In addition, the *Chapman Rearrangement* and *Hilbert-Johnson Reaction* can be considered as the extensions of the Lander rearrangement.

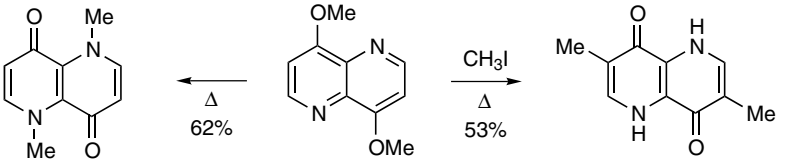
E. APPLICATIONS

This reaction is often used to convert methoxypyridines into *N*-methylpyridones.[12]

F. RELATED REACTIONS

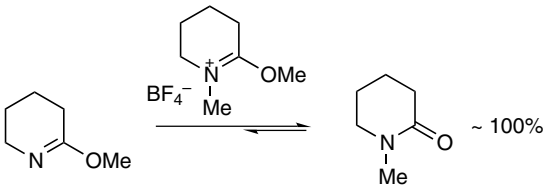
This reaction is closely related to the *Chapman Rearrangement* and *Hilbert-Johnson Reaction*.

G. CITED EXPERIMENTAL EXAMPLES



Reference 4a.

A mixture of 140 mg 4,8-dimethoxy-1,5-naphthyridine and 34 mg methyl iodide (molar ratio = 3:1) was heated at 220°C for 12 h. The resulting crude product was boiled with benzene to remove any 1,5-dimethyl-1,5-naphthyridine-4(1*H*),8(5*H*)-dione present and then gradient sublimed at 275°C. The white crystalline sublimate was dissolved in warm dilute aqueous NaOH, and the resulting violet solution was adjusted to pH 2 with concentrated HCl. The precipitate was collected and recrystallized from a large volume of water to afford 74 mg pure 3,7-dimethyl-1,5-naphthyridine-4(1*H*),8(5*H*)-dione, in a yield of 53%, m.p. > 300°C. However, when 280 mg pure 4,8-dimethoxy-1,5-naphthyridine was heated at 226°C for 10 h, and the crude product was dissolved in boiling benzene and filtered hot through a thin pad of Norit A on Celite, 174 mg 1,5-dimethyl-1,5-naphthyridine-4(1*H*),8(5*H*)-dione was obtained as a white crystalline after cooling and filtration, in a yield of 62%, m.p. 268.5–272°C.



Reference 4c.

A sealed tube containing 0.138 g *O*-methylvalerolactim and 0.029 g *N*-methyl-2-methoxy-3,4,5,6-tetrahydropyridinium fluoroborate was heated at 130°C for 2 h. After the reaction, the mixture was taken up by 1.2 mL CH_2Cl_2, and 0.019 g *N*-methyl-2-methoxy-3,4,5,6-tetrahydropyridinium fluoroborate was precipitated by the addition of 8.0 mL Et_2O. GLPC analysis of the solution using phenyl ether as an internal standard indicated a 104 ± 5% yield of *N*-methylvalerolactam.

Other references related to the Lander rearrangement are cited in the literature.[13]

Larock Indole Synthesis
(Larock Heteroannulation)

A. GENERAL DESCRIPTION OF THE REACTION

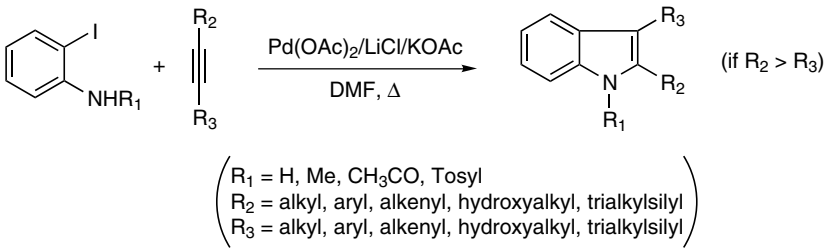
This reaction was first reported by Larock et al. in 1991.[1] It is a palladium-catalyzed chemoselective and "ligandless" heteroannulation between *ortho*-iodoanilines and disubstituted alkynes to form substituted indole derivatives. Therefore, this reaction is generally known as the Larock heteroannulation[2] or Larock indole synthesis.[3]

This reaction is affected by various factors, including an added base, lithium halide and its stoichiometry, the presence or absence of ligand PPh_3, and the reaction temperature.[1,4] Specifically, for the reaction of 0.25 mmol *ortho*-iodoaniline with 0.75 mmol alkyne (3 eq.), using 5 mol % of $Pd(OAc)_2$ as the catalyst and 5 eq. of base in 10 mL DMF, it is not at all necessary to have a ligand (e.g., PPh_3) present.[4] The bases tested for this reaction are KOAc, NaOAc, K_2CO_3, and Na_2CO_3; the potassium salts are obviously better than the sodium salts, and KOAc is always superior to K_2CO_3, except when no other reagent is added, such as LiCl.[4] For example, when KOAc is used as the base, only 1 eq. of LiCl is needed, and an excess amount of LiCl will result in a lower reaction rate, lower yield, and contamination from further insertion. Under these conditions, the reaction must be carried out at temperature $> 120^{\circ}C$ and the addition of 5 mol % of ligand will lower the yield.[4] However, when K_2CO_3 is used as a base, LiBr or LiI can be used as the LiCl substitute, and ligand has no effect on this reaction; in contrast, in the presence of 1 eq. LiCl, the reaction temperature can be lowered to $100^{\circ}C$. Therefore, the best condition for the Larock indole synthesis is to use 5 mol % $Pd(OAc)_2$ and either KOAc or K_2CO_3 as the base, with 1 eq. LiCl and 2–5 eq. alkynes.[4] On the other hand, this reaction is very versatile, as indicated by its tolerance of diversified substituents on the alkynes and nitrogen atom of anilines. For example, the substituents on the nitrogen atom of anilines can be methyl, acetyl, tosyl, etc.,[1]

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

and the alkynes can bear alkyl, aryl, alkenyl, hydroxyl, and silyl groups.[1] Even bulky tertiary alkyl or trimethylsilyl groups are readily accommodated by this reaction.[4] In addition, this reaction is highly regioselective, whereas the more sterically bulky group ends up at the 2-position.[1,4] However, for the case of diethyl acetal of 2-butynal, no regioselectivity was observed that may have been caused by an electronic effect.[4] It has been found that for the reaction between *o*-iodoacetylaniline and alkynes with hindered or unhindered hydroxyalkyl group, the migration of the *N*-acetyl group from nitrogen to the alcohol group does sometimes occur, which may arise from the base-catalyzed intramolecular transfer of acetyl group.[4]

B. GENERAL REACTION SCHEME

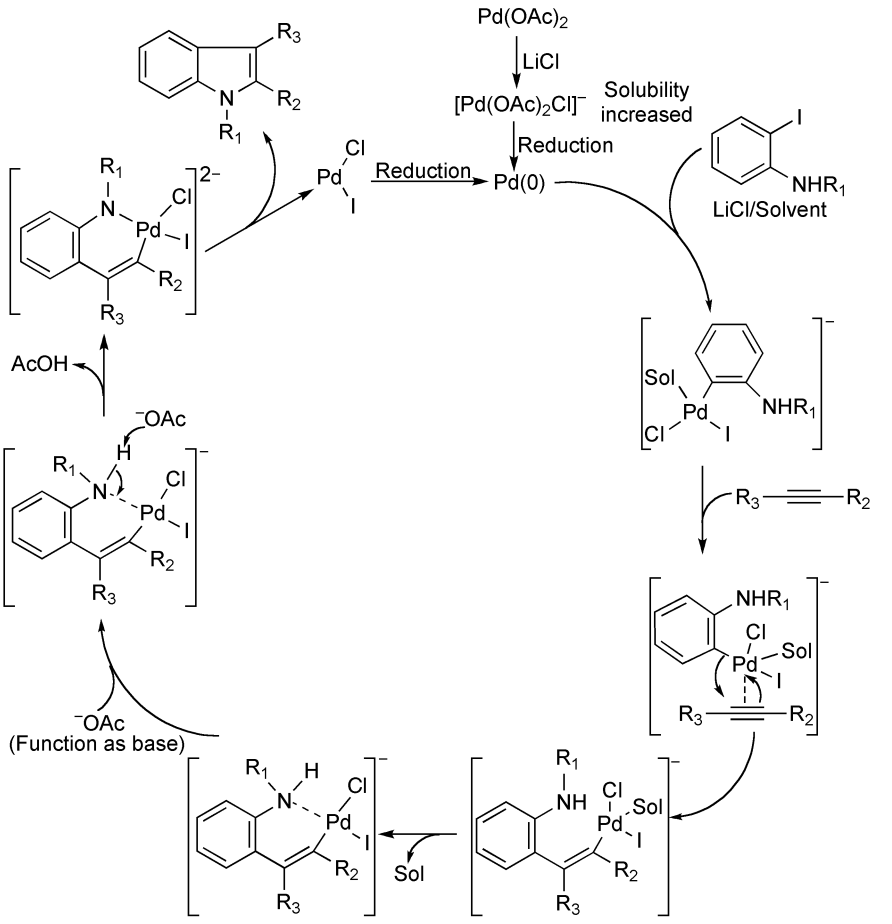


C. PROPOSED MECHANISMS

Although a mechanism has been proposed to rationalize the reaction that contains a several steps for the catalytic cycle,[1,4,5] a different mechanism is proposed here. The original mechanism includes the following steps in the catalytic cycle: (*a*) reduction of $Pd(OAc)_2$ to Pd(0) to initiate the catalytic cycle, (*b*) coordination of chloride to palladium, (*c*) oxidative addition of aryl iodide to Pd(0), (*d*) coordination of alkyne to palladium atom and subsequent regioselective *syn*-insertion into the arylpalladium bond, (*e*) nitrogen displacement of the halide in the resulting vinylic palldium intermediate to form a palladacycle, and (*f*) reductive elimination to form indole and the regenerated Pd(0) reenters the catalytic cycle.

As mentioned, this ligandless reaction proceeds in the presence of a base, 1 eq. LiCl, using a catalytic amount of $Pd(OAc)_2$. The presence of LiCl may have two effects: coordination with palladium and enhancement of solubility. In addition, the catalytic amount of $Pd(OAc)_2$ can be reduced to Pd(0) by any reducing reagent in the reaction solution, which then inserts into *o*-iodoaniline. At this stage, one or two solvent molecules may coordinate with palladium to stabilize the complex, and the role of the solvent in the complex can be replaced by ligand if a ligand presents. After that, an alkyne coordinates with the complex, and an alkenyl palladium species forms. When an *ortho* amino group coordinates with palladium, the proton on the nitrogen atom is more acidic than it's used to be, which can be deprotonated by the existing base. Finally, reductive elimination affords the substituted indole molecule, and Pd(II) species can be reduced to Pd(0) and enter the catalytic cycle again. This new mechanism is displayed here.

Carbonate is a stronger base than acetate, so when acetate is used as the base, the reaction occurs $> 120^{\circ}C$; whereas when K_2CO_3 is used as base, the reaction temperature can be lowered to $100^{\circ}C$.



D. MODIFICATION

This reaction has been modified to occur between *o*-iodoaniline and allene to form 3-methyleneindolines,[6] and between *o*-alkynylhaloarene and amines to form indole derivatives.[7] More importantly, this reaction has been successfully extended to *ortho*-bromoanilines or *ortho*-chloroanilines by carefully choosing ligand, base, solvent, and concentration.[5] For example, 1,1′-bis(di-*tert*-butylphosphino)ferrocene or tricyclohexylphosphine has been used as a ligand; the former is the best ligand discovered so far, whereas the latter does not result in normal by-products.[5]

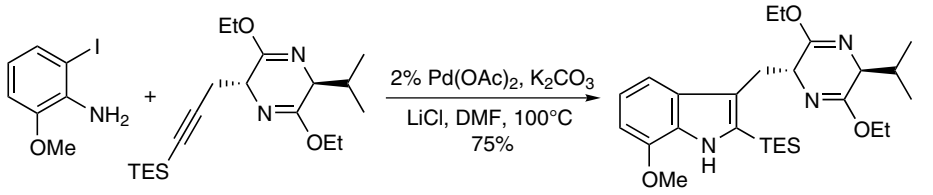
E. APPLICATIONS

This reaction has been used to prepare a variety of heterocycles, including 5-aza-indoles;[8] 5-,6-, and 7-aza-indoles;[9] pyrrolo[3,2-*c*]quinolines;[10] 12-methoxy-N_a-methyl-vellosimine;[2c] (+)-12-methoxyaffinisine;[2c] and (-)-fuchsiaefoline.[2c]

F. RELATED REACTIONS

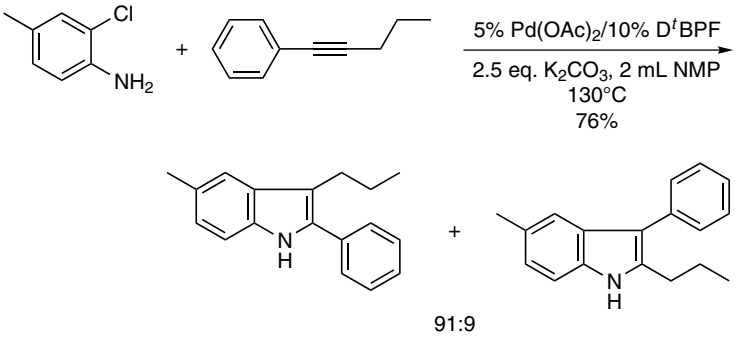
This reaction is related to the *Hegedus Indole Synthesis*, *Castro Indole Synthesis*, and *Mori-Ban Indole Synthesis.*

G. CITED EXPERIMENTAL EXAMPLES



Reference 2b.

To a 2-L round-bottomed flask were added 102 g 2-iodo-6-methoxyaniline (0.41 mol), 179 g Schöllkopf derivative (0.49 mol), 17.4 g LiCl (0.41 mol), 141.3 g K_2CO_3 (1.02 mol); 1.84 g $Pd(OAc)_2$ (8.2 mmol), and 700 mL anhydrous DMF. The mixture was then degassed with a vacuum pump three times at room temperature (with argon). The suspension that resulted was heated for 36 h at 100°C under an atmosphere of argon. After the consumption of iodoaniline, as monitored by TLC, the reaction mixture was cooled to room temperature and diluted with EtOAc. The mixture was washed with H_2O (5 × 20 mL) to remove DMF. The organic layer was washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. Purification by flash chromatography over silica gel (2% EtOAc/hexane) provided 149 g (5*R*,2*S*)-3,6-diethoxy-2-isopropyl-5-[7-methoxy-2-(triethylsilyl)-3-indolyl]methyl-2,5-dihydropyrazine as a yellow oil, in a yield of 75%.



Reference 5.

To an oven-dried reaction vial were added 11 mg $Pd(OAc)_2$ (0.05 mmol), 47 mg 1,1′-bis(di-*t*-butylphosphino)ferrocene (0.1 mmol), and 346 mg potassium carbonate (2.5 mmol). The vial was purged with argon. Then 123 μL 2-chloro-4-methylaniline (1 mmol), 192 μL 1-phenyl-1-pentyne (1.2 mmol), and 2 mL NMP were added via syringe. The reaction was heated to 130°C, stirred at the same temperature; and monitored by HPLC. The reaction was complete after 4 h. The ratio of the regioisomer was 91:9. The mixture

was filtered through a pad of Celite. The cake was washed with EtOAc. The organic solvent was washed with water and brine, dried over $MgSO_4$, filtered, and concentrated to give a brown residue. The product was purified via column chromatography.

Other references related to the Larock indole synthesis are cited in the literature.[11]

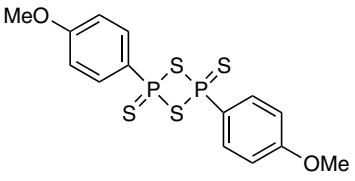
Lawesson's Reagent

A. GENERAL DESCRIPTION OF THE REACTION

The full name of this reagent is 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-disulfide (or -disulphide),[1] 2,4-bis(4-methoxyphenyl)-2,4-dithioxo-1,3,2,4-dithiadiphosphetane,[2] 4-methoxy-phenylthionophosphine sulphide dimmer,[2] or (*p*-methoxyphenyl)thionophosphine sulfide.[3] Although it was not initially invented by Lawesson,[4] it is known as the Lawesson's reagent (LR)[5] after Lawesson who extensively studied the reactivities of this reagent and made it a popular chemical reagent.[1a,6] Lawesson's reagent is a powerful, mild, and versatile[7] thiation[1a,8] (also called thionation[1b,3,9] or sulfuration[10]) agent that efficiently converts oxygen functionalities into their *thio*-analogs. First, it converts the carbonyl group into thiocarbonyl group, as shown in the transformation of ketone into thioketone,[6b,11] amide to thioamide,[11,12] ester to thioester,[13] urea to thiourea,[14] trimethylsilyl ferrocenoketone to analgous thioketone,[12b] enaminoaldehyde to enaminothioaldehyde,[9a] enaminoketone to enaminothioketone,[9a] oxalamide to oxala-thioamide,[10,15] flavones to thioflavones,[11] isoflavones to thioisoflavones,[11] lactones to thiolactone,[11] and coumarin to 2*H*-chromene-2-thione.[6d,16] Second, the Lawesson reagent also converts the carbon-oxygen single bond into a carbon-sulfur single bond, as indicated in the transformation of benzylic and related alcohols into corresponding thiols;[9e,17] β-lactone to β-thio lactone;[18] and orthoesters, acetals, or epoxides to their thio-analogues.[19] Third, because of the versatility in replacing oxygen functionalities, this reagent has been used for the cyclization of compounds containing at least two oxygen functionalities. This type of reaction includes the conversion of 1,4-dicarbonyl compounds into 2,5-disubstituted thiophenes;[20] 4-hydroxy enone[17a] or 4-keto enol[8a] into thiophene derivatives; α-keto amide into 1,3-thiazoles;[20a,21] nonenolizable 1,4-, 1,5-, 1,6-, and 1,7-diketones into 1,3-dithietanes;[22] and β-keto esters in combination with sulfur to dithiolethiones.[9c] More importantly, this reagent has been

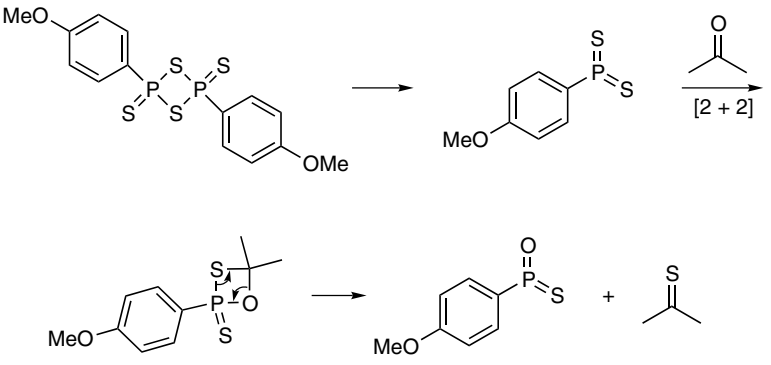
used to convert two ester groups into an olefinic bond in combination with 1,1,3,3-tetramethylthiourea, as demonstrated by the synthesis of hemibrevitoxin B and brevitoxin B.[13a,13b] If two oxygen functionalities coexist within a molecule, it has been found that the hydroxyl group is superior to amido group toward the Lawesson's reagent;[9e] similarly, an amido group is superior to an ester group in terms of reactivity.[23] This is parallel to the electron density on those groups, in which the oxygen functionality with more enriched electron should react faster with the Lawesson's reagent.[14] In some cases, the steric hindrance also influences the selectivity.[9d] It is interesting that the thionation of dibenzyl ketone ends up with styrenyl thiol as the major product.[24] Other applications of Lawesson's reagent are indicated by the reductive coupling of phenalenone to peropyrene,[25] the thionation of phosphonamidate oxygen (i.e., converting P=O bond to P=S bond),[9d] thionation of S-oxide in thioketene to form thiirane-2-thione,[26] thionation of S-oxide in thioketone to give dithiirane,[27] synthesis of β-lactams in combination with a Schiff base,[1b] and thionation on organometallic compounds[3,9b] such as converting the W=O bond to W=S.[28] Nevertheless, it is believed that the Lawessons reagent $(ArPS_2)_2$ breaks into 2 eq. active species ($ArPS_2$), which is involved in all the functional transformation.[8b] Although this reagent is very versatile, it does have some disadvantages during functional group transformation. For example, due to its relatively high molecular weight, this reagent is normally used for small-scale reactions.[9c] In addition, the by-products derived from this reagent generally cannot be separated by simple extraction but usually by column chromatography.[9c]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

Only the mechanism for the formation of thioketone from ketone is illustrated here.



D. MODIFICATION

The thionation from the Lawesson's reagent has been improved by using P_4S_{10} and hexamethyldisiloxane as the thionation reagent, from which the by-products can be easily removed by extraction and column chromatography after the thionation.[9c]

E. APPLICATIONS

Besides the extensive applications of the Lawesson's reagent as already mentioned, this reagent has been used to synthesize many five- and six-membered phosphorus heterocycles,[9e] and sulfur-containing heterocycles;[9e] in addition, this compound has also been used as the racemization-free coupling reagent in peptide synthesis,[29] and the 1,3-dipole indicator.[8b]

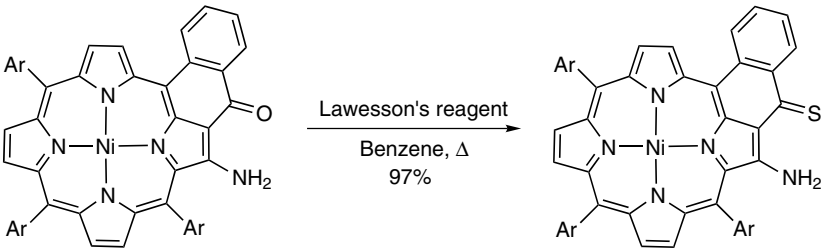
G. CITED EXPERIMENTAL EXAMPLES

Reference 8a.

To a solution of 0.834 g 1,2-C_5H_3(CTpOH)(COTp) (2.92 mmol) in 90 mL dry toluene was added 1.59 g Lawesson's reagent (3.94 mmol). The solution was refluxed for 8 h under stirring. After cooling to room temperature, the solution was concentrated to an oil via rotary evaporation and further dried on the Schlenk line for 2 h. The oil was cooled over liquid nitrogen, then extracted using cold pentane. The organics were filtered, and the volatiles were removed via rotary evaporation, giving an oil. The crude oil was purified by silica gel column chromatography (30:70, toluene/pentane) to yield 1,3-dithienyl-4*H*-cyclopenta[*c*]thiophene as a cream-colored solid. Rechromatographing the second fluorescent fraction, containing a mixture of 1,3-dithienyl-4*H*-cyclopenta[*c*]thiophene and an unknown compound (96:4, hexane/Et_2O) yielded another batch of 1,3-dithienyl-4*H*-cyclopenta[*c*]thiophene, in total amount of 0.125 g, in a yield of 15.0%. m.p. 98–101°C (MeOH).



Reference 9a.

A solution of 273 mg nickel enaminocetone (0.26 mmol) and 152 mg Lawesson's reagent (2.66 mmol) in 150 mL benzene was refluxed until consumption of all starting material (∼2 h). After evaporation of the solvent, the residue was chromatographed on a silica gel column (dichloromethane/hexane, 1:1). After crystallization from dichloromethane/methanol, 270 mg green nickel enaminothioketone (0.254 mmol) was isolated, in a yield of 97%.

Other references related to the Lawesson's reagent are cited in the literature.[30]

Lebedev Process

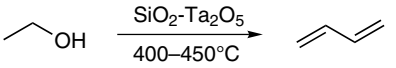
A. GENERAL DESCRIPTION OF THE REACTION

This reaction was first reported by Lebedev in 1928.[1] It is a one-step industrial production of butadiene from ethanol at temperature of 400–450°C in the presence of a catalyst with both dehydration and dehydrogenation processes. Therefore, this reaction is generally known as the Lebedev process.[2] Occasionally, it is also referred to as the Lebedev contact process,[3] Lebedev method,[4] Lebedev reaction,[2f] or Lebedev synthesis.[5] The butadiene produced by this process is used for production of synthetic rubber.[2f] The best catalyst for this process is a silica gel impregnated with tantalum oxide (SiO_2-Ta_2O_5),[2d] silica-magnesium-tantalum, and silica-magnesium-chromium.[6] Furthermore, it has been found that the addition of copper gives good results if sufficient acetaldehyde is maintained.[2d] On the other hand, it has been reported that diethyl acetal, vinyl ethyl ether, diethyl ether, *n*-butanol, *n*-butanediols, *n*-butyraldehyde, ethylene, acetylene, and tetrahydrofuran are not major intermediates in this process,[7] even though some of these chemicals have been proposed in the mechanism to rationalize this process. For example, Lebedev proposed a radical mechanism and claimed that acetaldehyde and ethylene were the intermediates to form 1,3-butadiene.[8] Some other mechanisms proposed are the dehydrogenation and dehydration of ethanol to both ethylene and acetylene, which form butadiene;[2f] the formation of butanediols from ethanol and acetaldehyde, which dehydrates to give butadiene;[9] and the formation of diethyl ether, which gives butadiene.[10] However, none of these mechanisms make sense from the advanced organic chemistry point of view, and the most important evidence for the real mechanism is that conversion of crotonaldehyde and ethanol to butadiene is easier than that of ethanol and acetaldehyde, and acetaldehyde is produced by the time the

Comprehensive Organic Name Reactions and Reagents, by Zerong Wang

crotonaldehyde is converted into butadiene.[2d,2e] It has been found that the silica component in the catalyst facilitates the condensation of acetaldehyde to crotonaldehyde, whereas tantalum promotes the deoxygenation of crotonaldehyde using ethanol as the hydrogen donor.[7]

B. GENERAL REACTION SCHEME



C. PROPOSED MECHANISMS

It is believed[2e] that this reaction involves the following consecutive steps: dehydrogenation of ethanol to acetaldehyde, condensation of acetaldehyde into acetaldol, dehydration of aldol product to crotonaldehyde, and deoxygenation of crotonaldehyde. This mechanism is illustrated here.
