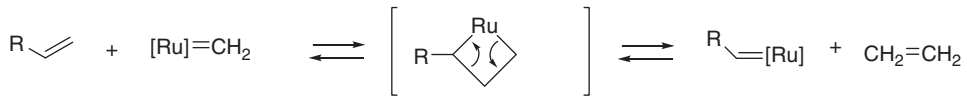
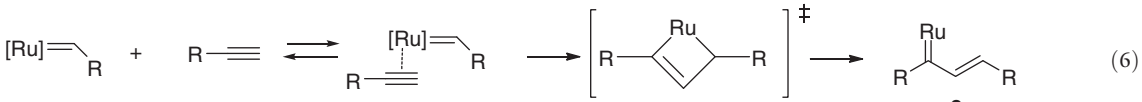
The EYM mechanism began as a source of controversy, but detailed mechanistic studies developed into a generally accepted mechanism. The confusion had been complicated by many factors: the use of different carbene catalysts (e.g., of different generations), differing reactivity of alkenes (e.g., 1-hexene vs. acrolein), 'borrowing' intermediates from alkene metathesis, the difficulty in differentiating mechanisms experimentally, and the propensity of any new synthetic application to ascribe a mechanism without decisive mechanistic experiments. (These problems arise partly due to the cross-fertilization of the literature from mechanistic organometallic chemistry to synthetic organic chemistry and partly from the pace at which new reactions can be synthetically exploited and published as compared with mechanistic studies. Mechanistic studies are usually much slower to performed.) Mostly these concerns have been dispelled; however with certain combinations of alkene and alkyne reactants, the mechanism may vary. With certain catalysts, the rate-determining steps may be different. Before a detailed catalytic cycle is presented, the authors will briefly discuss fundamental carbene pathways and the relationship to alkene metathesis (for the catalytic cycle, see Scheme 4 *vide infra*).



EYM is a catalytic process involving ruthenium carbene intermediates. Of course, ruthenium carbenes are well known to be reactive intermediates in alkene metathesis. From alkene metathesis, the benzylidene initiates with an added 1-alkene. Fundamentally, the metal carbene catalyst undergoes cycloaddition with the alkene in two different ways. This process may occur with regiochemistry indicated in equations 3–5.

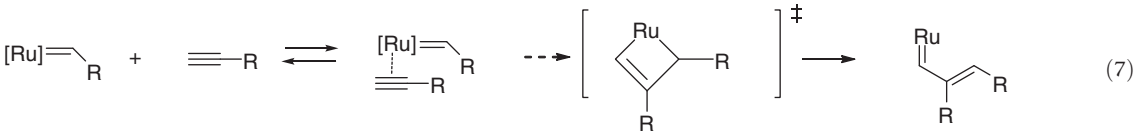
(3)

(4)



(5)

The pathway in equation 3 is called transalkylidenation, a process that transforms one alkylidene ligand (or in this case a benzylidene) into another alkylidene ligand. An alkylidene is the organic fragment of a metal carbene. This is the initiation step in alkene metathesis; the equilibrium lies to the right when the alkene is in excess of the catalyst, and in many cases styrene is the more stable alkene. This fundamental process generates the needed alkylidene that is required for cross-metathesis. Alternatively, the alkene may react with the opposite regiochemistry in a process that leads to alkene cross-metathesis (equation 4). In this case, the intermediate ruthenacyclobutane has 1,2-disubstitution. Retrograde [2 + 2] extrudes a 1,2-disubstituted alkene and a

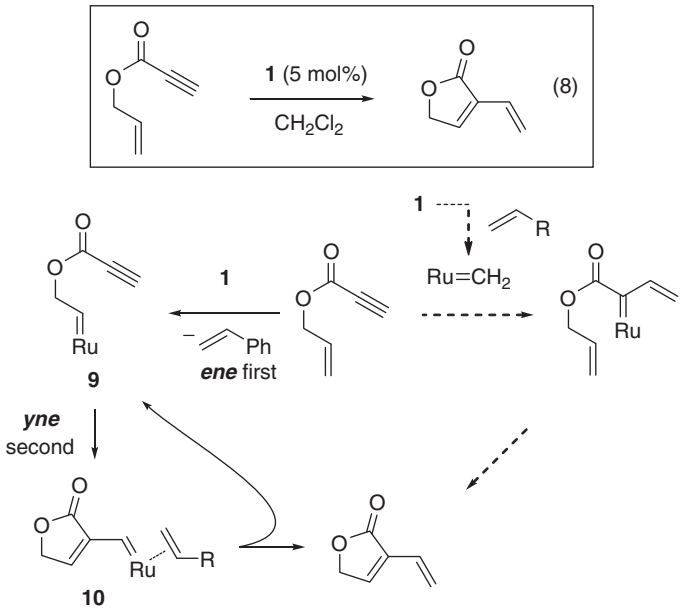


$Ru{=}CH_2$ species. Of these two pathways, the initiation step is faster than cross metathesis. Transalkylidenation of equation 3 is favored due to the lower energy 1,3-disposition of substituents on the metallacyle intermediate of equation 3. The cross-metathesis pathway is slower because the 1,2-disubstituted ruthenacyclobutane intermediate is higher in energy. These intermediates are relevant to the high-energy ruthenacycles encountered in EYM.

In terms of alkene metathesis, the methylidene plays an important catalytic role. Productive alkene cross-metathesis must follow the regiochemistry of equation 4 to give a 1,2-disubstituted alkene product. The methylidene is formed after a cross-metathesis, exemplified by the reaction of equation 4. The methylidene product of equation 4 is a reactive species that propagates catalysis. Subsequent transalkylidenation with excess 1-alkene ultimately releases ethylene (equation 5). Excess alkene and loss of ethylene help drive the equilibrium of equation 4 forward (to the right side). As it does, it regenerates the alkylidene, the reactive metal carbene intermediate that is needed for the next catalytic turnover.

The metallacycle reactive intermediates in EYM resemble those in alkene metathesis, but they are higher in energy. In fact, density functional theory (DFT) calculations suggest that ruthenacyclobutenes are actually transition states.[42] To access metallacyclobutenes, the metal carbene undergoes $2\pi + 2\pi$ cycloaddition with the alkyne. As in the case of metal carbene cycloadditions with 1-alkene, this reaction can follow two different pathways that differ in regiochemistry (equations 6–7). Alkyne binding occurs by ligand exchange with the tricyclohexylphosphine ligand (note that the Cy_3P ligand is omitted for clarity in the equations). The resulting η^2 complex reorganizes via the ruthenacyclobutene to give a vinyl carbene **8**. As in the above examples, the alkyl groups can be either 1,3- or 1,2-substituted on the ring. Though alkyne binding is more favorable than alkene binding, the high energy of the ruthenacyclobutene transition states allow preequilibrium events such as ligand exchange and metal carbene exchange reactions. Metal carbene exchange reactions such as initiation and transalkylidenation are described in equations 3–5. Because the alkene is typically in molar excess, formation of the alkylidene tends to be dominated by equations 3 and 5, and this populates the alkylidene 'resting state.' This sets the stage for an alkylidene-first mechanism. (When the alkene is ethylene, the reaction proceeds through the $Ru{=}CH_2$ intermediate. The Grubbs benzylidene carbene complexes form the $Ru{=}CH_2$ intermediate when exposed to ethylene. The methylene species is highly reactive and not selective. In the second-generation Grubbs carbene, it becomes kinetically deactivated by coordination to tricyclohexylphosphine. Higher ethylene concentrations may help protect the reactive carbene from kinetic deactivation by phosphine coordination.)

(6)

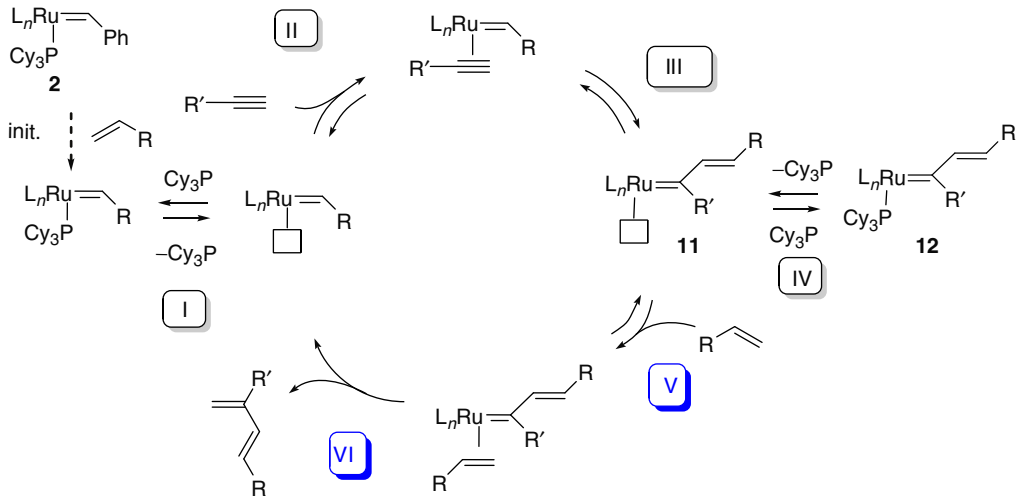


(7)

Current mechanistic and kinetic evidence points to an alkylidene-first mechanism. Mechanistic studies were done because of inconsistencies in the literature, partly due to mechanistic assertions in the synthetic literature and the fact that different catalysts were being used. The mechanistic controversy surrounded the question as to which occurs first – reaction of the metal carbene with the alkene or alkyne. Though alkene reactivity varies considerably, it is generally believed that the Grubbs initiator reacts with the alkene first to produce an alkylidene. The alkylidene is the reactive intermediate that reacts with the alkyne. (Some of the confusion is due to a reasonable assumption that a terminal alkyne should bind better to the Grubbs benzylidene complex such that the alkyne should react first. The alkyne does bind better in preequilibrium,[43] but reorganization via ruthenacyclobutene intermediates is a higher energy process than transalkylidenation via 1,3-disubstituted ruthenacyclobutanes. It is a Curtin–Hammett scenario where facile alkyne binding does not dictate alkyne insertion.)[43] Reaction with the alkene is called the 'alkylidene-first' mechanism; it is rooted in the transalkylidenation of alkene metathesis. The metal alkylidene reacts with a 1-alkyne via the regiochemistry of equation 6. This mechanistic scenario is to be differentiated from the alkyne-first mechanism where a ruthenium methylidene (methylene) is the reactive metal carbene intermediate, and reacts with the alkyne with the opposite regiochemistry. (In some cases, ene–yne cross-metathesis does begin by reaction with an alkyne in cases where the alkene may be particularly unreactive. For instance, alkynes can react exclusively with the initiator in a oligomerization reaction).[44,45]

Early mechanistic studies of RCEYM suggested an 'alkylidene-first' reaction mechanism based on NMR studies. In RCM depicted in equation 8, Hoye recognized that there were two possibilities: reaction of $[Ru]{=}CH_2$ with the alkyne directly or initial transalkylidenation to generate an alkylidene **9** (**Scheme 3**).[46] These two possibilities invoke different metal carbenes as reactive species and suggest an order of reactivity. The reaction of $Ru{=}CH_2$ with the alkyne is called the methylidene-first pathway. The initiation of the alkene moiety with the Grubbs catalyst gives rise to an alkylidene; since the alkylidene forms first, it is called the alkylidene-first mechanism. The difference distills down to what metal carbene is reacting with the alkyne.

If the ene-then-yne pathway is followed, it was predicted that vinyl carbene intermediate **10** should accumulate. ^1H NMR experiments showed the buildup of an alkylidene concomitant with initiation by the Grubbs benzylidene **1**, as evidenced by the



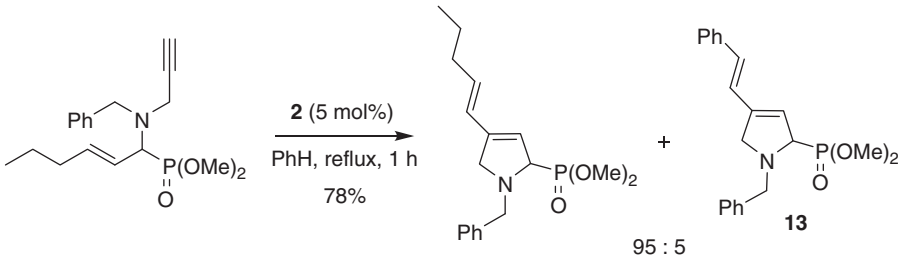
Scheme 3 Alkylidenation-first mechanism in a bifunctional enyne substrate (RCEYM).[46]

loss of the benzylidene CH signal and the production of styrene. Styrene could only be formed if the Grubbs catalyst reacted with the alkene present in the bifunctional substrate. In the last critical step, the alkene reacts with the vinyl carbene to generate the product and more alkylidene, which continues in catalysis. Hoye and Vos refer to this as an 'ene-then-yne' pathway; this terminology is widely used in the literature for describing the mechanism of RCEYM. Similarly, using carbene **2** in an RCEYM, Kozmin et al. suggested that an 'alkylidene-first' mechanism was operative.[47] These authors examined the reactivity of each unsaturated fragment of the enyne and found that the alkene reacted to give the corresponding alkylidene, whereas the alkyne did not react. These two studies suggested that alkylidenes formed faster than the reaction rate between [Ru]=CH_2 and alkynes. These studies were performed with the first- and second-generation Grubbs carbene complex and arrived at the same conclusion in support of an alkylidene-first mechanism. This is presumed to be the basic mechanism, with perturbations depending on the relative reactivity of the unsaturated reactants.

An accepted mechanism has emerged based on mechanistic investigations and kinetic studies of the reaction mechanism (Scheme 4). Direct mechanistic evidence of the EYM is derived from kinetic analysis using the second-generation Grubbs catalyst **2**. Zero-order dependence on the alkyne concentration indicates that the alkyne is not involved in the rate-determining step. First-order dependence was found for both the ruthenium complex and the terminal alkene. This kinetic evidence suggested that either step V or step VI was the rate-determining step (alkene binding or metallacycle formation/collapse). Based on DFT calculations, Lippstreu and Straub suggested that the cycloreversion step VI is rate limiting,[42] which is consistent with experimental kinetic data. Supporting evidence for the alkylidene-first mechanism was presented above and is supported by another critical study of the regiochemistry of vinyl carbene reactions with styrenes.[49] The mechanism shown in Scheme 4 is based on this kinetic study. The kinetic study was performed on a limited set of alkyne and alkene substrates, and a large excess of the alkene was employed for pseudo-order conditions. These conditions resemble those normally used for intermolecular EYM. Typically the alkene is used in molar excess, but not always.[50]

A modest increase in propargylic substitution gave faster reaction rates. An increase in steric bulk resulted in faster reaction for propargylic benzoates. To test whether chelation by oxygen atoms located in the propargylic position was inhibiting the reaction rate, the corresponding hydrocarbons were examined, devoid of oxygen functionality. In comparison with their lower hydrocarbon analogs, it was found that secondary substitution at the propargylic center resulted in faster reaction rate than a primary carbon chain. Alkynes with the same propargyl substitution reacted with similar rates. In contrast, tertiary substitution at the propargylic site resulted in diminished reaction rates. With the second-generation Grubbs catalyst, there is not a chelation effect for ester functionality located at the propargylic position.

The resting state at the vinyl carbene intermediate explains the effect of propargyl substitution on reaction rate. The mechanistic picture brings into focus the partitioning of the 14-electron vinyl carbene intermediate **11**. Greater substitution at the propargylic position may increase the rate of catalysis by destabilizing unproductive resting state **12**. Substitution of **12** at the site labeled R′ in Scheme 4 might destabilize the phosphine complex, increasing the concentration of the vinyl carbene **11**. With EYM promoted by phosphine-free catalysts like the Hoveyda–Blechert complex, there is no phosphine-bound resting state that may partly explain their high activity once initiated. However, phosphine-bound resting states can also protect the highly reactive intermediate **11** when alkene concentration is low (e.g., near the end of the reaction). Thus, a subtle balance is needed for a good



Scheme 4 Mechanism for intermolecular enyne metathesis based on kinetic studies.[48]

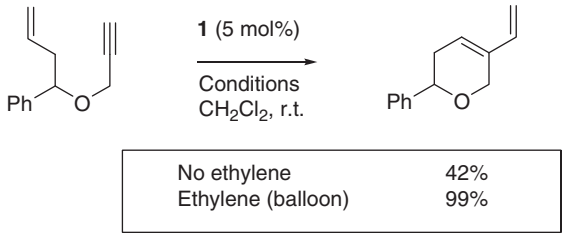
catalyst – high activity but protection from decomposition. Since decomposition pathways are only partly understood, the optimal structural features of a superior catalyst are not completely clear.

Which catalyst is used and under what reaction conditions can result in a change in the rate-determining step or divert the EYM to another pathway. For example, different kinetic orders for reactants and catalysts were found for the first-generation Grubbs complex.[51] Although this does not change the sequence of events of the catalytic mechanism, it shows that the rate-determining step can change. This is governed by the 'resting state' of the catalyst and the intrinsic barriers of the fundamental processes. One of the most rapid areas of growth has been in catalyst development. In recent years, there has been an increased use of the Hoveyda–Blechert 'phosphine-free' catalyst, largely due to its thermally robust nature. The higher reactivity of the catalysts can lead to alkyne oligomerization either at low alkene concentrations or with alkenes that are not very reactive with the Grubbs complex.[45] (This can be gauged from inspection of the Grubbs selectivity model for alkene metathesis. The less reactive alkenes are in the type III and type IV family. With these less reactive alkenes, one may expect greater competition from alkyne oligomerization reactions, similar to what one observes with the traditional Schrock catalyst.) In other words, the effectiveness of EYM is determined by a balance of reactivity between the alkene and the alkyne.

In RCEYM, the general reactivity appears to be ene-then-yne by an alkylidene-first mechanism. However, with less reactive alkenes, the timing may switch leading to an yne-then-ene pathway. One case that appears to react at the alkyne-first is shown in equation 9.[52] In this case, the alkene is internal and substituted with an allylic heteroatom, which suggests that its reactivity will be diminished considerably compared with 1-hexene. In addition to the expected RCEYM product, a new product **13** was obtained. The styrene-transfer product **13** in equation 9 supports the viability of the alkyne-first pathway because the Grubbs benzylidene catalyst **2** gave alkyne insertion followed by RCEYM. This initiation step would furnish a Ru=CHC$_3$H$_7$ species that would propagate catalysis. Importantly, it reveals that intermolecular reactions are kinetically feasible compared with alkene initiation and intramolecular ring closing onto the pendant alkyne, which is understood as the 'normal' or most common pathway. The latter pathway is thought to dominate in RCEYM. This example points out that more challenging bifunctional substrates, which possess unsaturated functionality of vastly different reactivity, may diverge from the normal processes.

(9)

It is difficult to reliably (or quantitatively) predict alkene versus alkyne reactivity. Though the example in equation 9 is not too surprising given the alkene's steric and electronic properties, a reactivity model is lacking to predict the outcome in more complex cases. In equation 9, which reacts first is not a major concern as long as the RCEYM provides the expected product. In Section 5.27.7, the site selectivity for initiation on a dienyne is controlled by relative alkene reactivity, which directly influences the ring sizes formed. More importantly, as reactivity is retarded on each unsaturated component, a complete loss of enyne metathesis reactivity will be observed, which neither higher temperatures nor higher catalyst loadings will remedy. Less reactive unsaturated



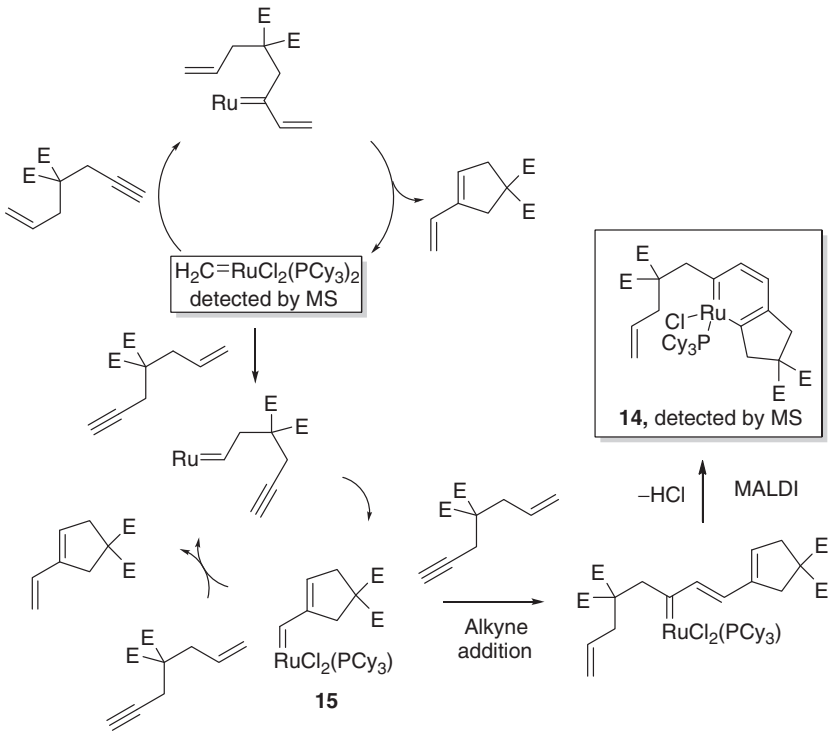
functionality will be encountered increasingly as chemists wish to push the reaction into more challenging cases or those with an increased number of electron-withdrawing groups. What is still missing in ene–yne or enyne metathesis is a predictive model of alkyne versus alkene reactivity. In the next few years, hopefully a model will emerge from the current body of literature and guide future applications.

The mechanism of EYM commonly follows an alkylidene-first pathway that defines the order of reactivity as ene-then-yne. For reactions catalyzed by **2**, the rate-determining step involves alkene association such that higher alkene concentrations (or molar excesses) contribute to a productive EYM. Importantly, the alkene concentration and the intrinsic reactivity of the alkene are important determinants of 'manifold selectivity': maintaining the catalytic EYM over competing reactions such as alkyne oligomerization. This helps explain the beneficial role of ethylene. The role of ethylene in promoting RCEYM under Mori's conditions is a combination of mode selectivity, stabilization of reactive intermediates with respect to decomposition, and more favorable turnover of the vinyl carbene intermediate.

Continued discussion of the mechanism of RCEYM will follow in the next section describing the role of ethylene. The observations related to the ethylene effect are directly relevant to the mechanism of the intramolecular enyne metathesis.

5.27.2.1 Role of Ethylene in Ring-Closing Enyne Metathesis (Mori's Conditions)

The helpful effect of ethylene on RCM of 1,ω-enynes is known as 'Mori's conditions.'[14] Ethylene exerts a subtle effect because it does not seem to appear in the products. Ethylene is not necessary for 'atom economy' since the alkene of the enyne is able to contribute both the alkylidene and methylene moieties in the metathetical union with alkyne. For example, RCM of a simple enyne gave low yield under inert atmosphere, but under an atmosphere of ethylene (an ethylene balloon) a high yield was obtained (equation 10). The exact role played by ethylene is probably the combination of stabilization of reactive intermediates, acceleration of catalyst turnover, and interdiction of alkyne oligomerization pathways. Catalyst turnover can be accelerated at higher alkene concentration. The importance of alkene concentration had been noted in earlier studies by Hoye[46] and Lee,[53] and a mechanistic and kinetic explanation offered by Diver and Keister.[48] Because enyne metathesis is dependent on alkene concentration and proceeds best with molar excess of alkene, it proves useful to provide an 'auxiliary alkene' such as ethylene, especially where higher enyne concentrations cannot be used for fear of enyne oligomerization/polymerization.



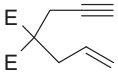
(10)

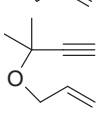
The ethylene effect is primarily due to the need for higher concentrations of alkene to maintain catalysis. The sagely study by Hoye clearly showed that alkene concentration was critical for the success of an RCEYM. The authors found that increased enyne concentration (0.1 mol l^{-1}) gave an efficient RCM.[46] This is counterintuitive since high dilution is employed in bifunctional substrates to encourage ring closure and to limit oligomerization. This is the first example showing that solution concentration of the enyne affects the 'rate' of RCEYM.

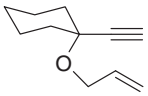
The role of ethylene in RCEYM has been addressed in mechanistic and kinetic studies. Due to the uncertainty regarding the role of ethylene, a detailed study was needed. First, an elegant mechanistic study was conducted by Lloyd-Jones.[54] In this investigation, the authors showed that ^{13}C-labeled ethylene produced vinyl carbene turnover, showing that ethylene turns over the vinyl carbene by what the authors termed a 'second cycle,' via reaction with the auxiliary alkene, ethylene. In other words, ethylene assists the turnover of the intermediate vinyl carbene (see **Scheme 3**, where R=CH_2). This is consistent with the concentration effect observation by Hoye and Vos[46] and the mechanistic proposal by Diver et al. in CEYM with ethylene speeding up the turnover step.[55]

Further insight into the ethylene effect has been provided by observations made using matrix-assisted laser desorption/ionization (MALDI) mass spectral analysis under inert atmosphere conditions.[44] Fogg and coworkers had developed mass spectral analysis as a tool for studying intermediates and decomposition products of ruthenium carbenes relevant to metathesis. The RCEYM of the malonate shown in **Scheme 5** was considered in terms of both the ene-then-yne and the yne-then-ene pathway. The RCM was investigated under nitrogen or ethylene. Under an ethylene atmosphere, a Ru=CH_2 resting state was detected by MALDI MS analysis. (The authors suggest that this is due to initiation with the alkene end of the enyne. The high molar concentration of ethylene populated the Ru=CH_2 species. Note that these mass spectral data were observed with the first-generation Grubbs catalyst **1**.) Under nitrogen, a decomposition species was found which had incorporated two molecules of enyne substrate **14**. At longer reaction times, a molecular ion was observed consistent with six enynes having reacted with the ruthenium carbene. The dimer and oligomer observed under nitrogen (in the absence of ethylene) are suggestive of alkyne oligomerization through a vinyl carbene intermediate.

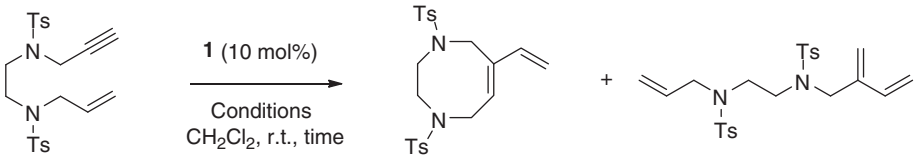
This study sheds further light on the role of ethylene because it limits intermolecular pathways. It was recognized that vinyl carbene reactions may proceed with alkene through RCEYM (intramolecular) or with alkyne by an intermolecular process. The reaction with an alkyne can repeat itself giving rise to higher molecular weight species. This helps explain the low mass recoveries







Scheme 5 Evidence of alkyne dimerization/oligomerization pathways in RCEYM.[44]



in simple RCEYM reactions without the use of 'Mori's conditions.' In the absence of added ethylene, intermediate **15** prefers to react with additional alkyne subunits of enynes in *inter*molecular EYM. This pathway leads to higher molecular weight products that are intractable and explains the low mass balance observed in these reactions. (Fogg et al.[44] also showed that the oligomerizations are not reversible using the first-generation Grubbs carbene **1**. The observation of higher molecular weight oligomers obtained from alkyne oligomerization provides critical insight into the dichotomy of enyne metathesis versus alkyne oligomerization.) In the presence of ethylene, these pathways are shut down and ethylene assists in turning over vinyl carbenes. This is consistent with previous suggestions.

Increased propargylic substitution results in better mass balance and decreased need for ethylene. Under conditions without ethylene (Table 1), comparison of the first- and the second-generation Grubbs catalyst shows that each is susceptible to alkyne oligomerization (entries 1 and 2).[44] Alkyne oligomerization has been observed in EYM using the Hoveyda–Blechert catalyst.[45] Low conversions were seen after 24 h and remarkably very low yields of dienes were found, suggesting that little conversion to product had occurred. Monosubstitution on the alkyne propargylic position enhanced conversion, but did not appreciably increase the yield (entries 3 and 4). Only disubstitution gives significantly enhanced conversions and yields (entries 5–8). In the more hindered cases, the second-generation Grubbs complexes are needed due to their higher reactivity with sterically hindered substrates.

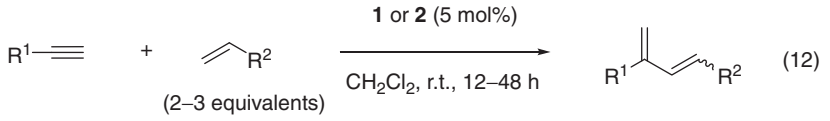
Table 1 Ring-closing ene–yne metathesis yields vs. propargylic substitution (without ethylene)

Entry		*Catalyst*	*Time (h)*	*Alkyne conversion (%)*	*Diene yield (%)*
1		1	24	33	18
2		2	24	17	3
3		1	–	–	–
4		2	24	42	3
5		1	–	–	–
6		2	20	>99	67
7		1	–	–	–
8		2	20	>99	71

For RCM, the use of ethylene is not always beneficial as it can lead to intermolecular EYM. For example, if ring closure is slow, the competitive ethylene–alkyne cross-metathesis can be expected. Formation of eight-membered rings is particularly difficult. Ring closing under standard inert atmosphere conditions gave a low yield of the RCM product (equation 11); resorting to ethylene atmosphere gave none of the desired ring closure product, but produced solely the ethylene cross-metathesis product, a 2-substituted butadiene (equation 11).[56]

(11)

No ethylene	35%	–
Ethylene (balloon)	–	84%



5.27.3 Cross-EYM

Cross-metathesis between alkene and alkyne generates acyclic 1,3-dienes. This carbon–carbon bond coupling can be described as a cross-coupling of alkyne and alkene with π-bond reorganization. These unsaturated reactants do not require preactivation for carbon–carbon bond coupling: They are generally reactive with the ruthenium carbene. The metathesis is thought to initiate from the alkene, so it is critical that the alkene is reactive with the Grubbs ruthenium carbene initiator. The cross-metathesis produces a 1,3-disubstitution pattern on the resulting diene. A limitation of the EYM cross-coupling is the production of *E*/*Z* mixtures in these acyclic reactions. High concentration or molar excess (2–6 equivalents based on alkyne) of the alkene is favored, but it is not absolutely required. When reactivity of each unsaturated reactant is high, it is possible to use equimolar amounts of the alkene and alkyne. Though terminal alkynes are employed most of the time, internal alkynes are sufficiently reactive for cross-metathesis. However, internal alkyne–alkene couplings are plagued with regiochemistry problems and best reserved for reactions with symmetrical alkene/alkyne substrates (see Section 5.27.3.2).

5.27.3.1 Cross-EYM with 1-Alkenes

Simple aliphatic 1-alkenes, used in molar excess, perform best in cross-enyne metathesis with either generation Grubbs complex. Blechert reported the first cross-enyne metathesis using the first-generation Grubbs carbene complex (equation 12).[57] Several terminal alkynes were examined and led to products with a 1,3-disubstitution pattern. A variety of different 1-alkenes were found to participate in the reaction, giving the conjugated 1,3-diene products as *E*/*Z* mixtures (Table 2).

Table 2 Cross-enyne metathesis[57,58]

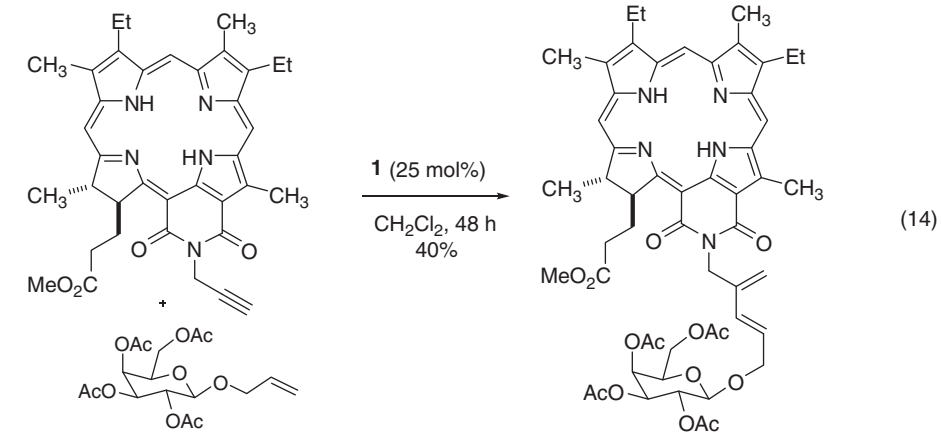
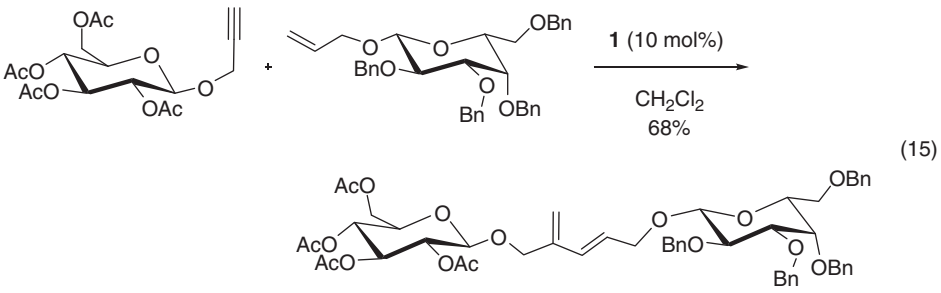
5	Me_3Si–	$–CH_2SiMe_3$	2	77
6	$TrOCH_2CH_2$–	$–CH_2SiMe_3$	2	98



Follow-up studies using the second-generation Grubbs complex showed substantial improvements in propargylic substituted alkynes and trimethylsilyl (TMS) acetylene (entries 4–6).[58] Entries 4 and 5 shown in Table 1 did not give products using the first-generation carbene complex **1**. An *E*/*Z* mixture of stereoisomers in the vicinally disubstituted bond of the 1,3-diene is typical of the intermolecular (ene–yne) metathesis. In some cases, higher *E*-selectivity has been achieved by secondary metathesis[59] or by the use of ethylene additive.[60] The acyclic 1,3-diene products are useful building blocks in ring

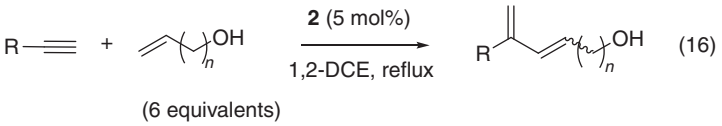
construction. Not surprisingly, they give cycloaddition; an example of a high-pressure hetero Diels–Alder reaction is illustrated in equation 13.[61]



(13)

Fairly complex functional groups can be carried in the alkene or alkyne reactant so long as they are removed from the reacting sites (Scheme 6). For example, a porphyrin attached to the alkyne via a propargylic imide proved to be an effective way to conjugate the *O*-allyl galactoside (equation 14).[62] Similarly, a 1,3-diene-linked disaccharide could be prepared from unsaturated reactants with acetal functionality in the allylic and propargylic positions (equations 14 and 15).[63]

(14)



(15)

Scheme 6 Some complex substrates in CEYM.[62,63]

CEYM can be performed with free hydroxyl functionality in the alkene reactant. Though allylic alcohols were found to be problematic in early metathesis studies, they have been found to react efficiently in CEYM (equation 16).[64] Catalyst decomposition to ruthenium hydride species occurs when heating with primary alcohols, so the metathesis had to be accelerated by higher temperature and the use of excess alcohol reactant. These two experimental parameters are the easiest to change, and often the most successful. The CEYM was successful for an assortment of homologous unsaturated alcohols. With respect to the alkyne, oxygen-containing functional groups were tolerated at the propargylic and homopropargylic position (Table 3). Notably, a free hydroxyl group in the alkyne reactant is not permitted in this reaction. The reactions were quenched using the polar isocyanide[39] that assisted in the purification of products.

Under optimized conditions, it is possible to conduct EYM cross-coupling with equimolar amounts of unsaturated reactants. As previously noted, CEYM has typically been done with an excess of the alkene reactant. Since the rate-determining step of CEYM showed alkene dependence, it was understandable that a CEYM should benefit from a molar excess of the alkene. To make CEYM truly 'atom economical,'[65,66] a reactive alkyne would have to be paired with a reactive alkene in equimolar amounts. Diver and Clark found that equimolar amounts of very reactive alkene and alkyne substrates with 10 mol% of catalyst **2** or **3** gave a high-yielding diene synthesis (Table 4).[50] Several alkenes were examined, including a series of protected and unprotected alkenols. Additionally, enantiopure *syn*-allylic alcohols were shown to perform well in the cross-metathesis with branched alkynes. The allylic chiral center was preserved in product **16** which in this case was found to be solely the *E*-isomer. Under atom economy,

slower cross-metatheses can lead to unwanted by-products arising from 1,5-hydride shift. Benzoquinone was added to suppress an undesirable 1,5-hydride shift in all CEYM cases involving unprotected alkenols. 1,5-Hydride shift was not found in cases where nonalcohol-containing functionalities were present in the alkene.

16, 55%, All E

CEYM has been used successfully in the total synthesis of amphidinolide K.[67] The macrocyclic ring of the natural product features a 1,3-diene with trisubstitution on one of the alkene moieties. Though this could be directly accessed by CEYM using an internal alkyne, a mixture of regioisomers was expected. Lee et al. devised a bold solution using a two-step sequence using a boronate to direct the regiochemistry of the EYM step. Starting with a terminal alkyne, the boronate is installed and directly subjected to cross-metathesis with excess alkene, giving a single regioisomer of the product (**Scheme 7**). It is worth noting that the alkene bears secondary allylic substitution and a chiral center; this is rare in CEYM. The boronate was converted to the trisubstituted alkene through Suzuki coupling using MeI. In addition to providing an elegant solution to carbon–carbon bond coupling in the total synthesis, this approach may prove generally useful to access higher substitution on the diene substructure. (The regiochemistry is guided by steric and electronic factors from the alkyne. Sterically, the ligands on the metal avoid the boronate. Electronically, it is unfavorable to place the carbene on the carbon bearing the electropositive boron atom.)

Strain can be used to promote reaction of geminally substituted alkenes with 1-alkynes.[68] Normally, geminal (1,1-disubstituted) alkenes are nonreactive in EYM because they do not initiate with **2** and cannot participate in the alkylidene-first mechanism. According to the alkylidene-first mechanism of enyne metathesis,[44,46–49,51,69] the alkene must be able to react with the Grubbs catalyst. Yet by the Grubbs model,[70] 1,1-disubstituted alkenes are unreactive with the second-generation Grubbs carbene. To overcome this lack of reactivity, ring strain in the alkene can be used to drive the initiation (this principle was used by Grubbs to form geminally substituted ruthenium carbenes)[71] and give CEYM (**Scheme 8**). A variety of initiators were screened for this reaction, with the best reactivity registered by the phosphine-free Hoveyda–Blechert-type catalysts. Interestingly, these reactions could be conducted at low temperatures. Typical CEYM are run at ambient temperature (25 °C); more difficult ones are performed over extended periods in refluxing toluene. The strain relief that drives the cycloaddition with the metal carbene also drives cycloaddition, permitting low-temperature cycloaddition chemistry.

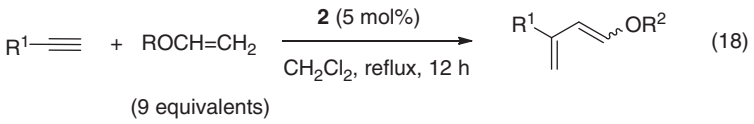

Scheme 8 Strain-assisted EYM (and cycloaddition step).[68]

An important distinction between alkene and EYM is highlighted in the case of enol ethers. Though less reactive than aliphatic alkenes, enol ethers participate in EYM.[37] Enol ethers such as ethyl vinyl ether are commonly used to quench alkene metatheses before isolation of product (equation 1). The resulting ruthenium Fischer carbenes are not sufficiently reactive to give further alkene metathesis. Yet EYM is different than alkene metathesis because it benefits from an enthalpic driving force in forming the conjugated diene products. A critical variable that can be optimized when employing reluctant alkenes is molar excess. The mechanistic study with **2** suggests why this is helpful.[48] Accordingly, a large excess of enol ether gives EYM that is complete in a matter of minutes (equation 18; **Table 5**). Vinylogous ruthenium Fischer carbenes are likely to be intermediates in the reaction. Despite the stability of these intermediate Fischer carbenes, excess alkene helps accelerate catalysis in the turnover step (see Section 5.27.2). A variety of terminal alkynes participate in this transformation, though the reaction proved sensitive to substitution at the propargylic position.

5.27.3.2 Internal Alkynes

Since the earliest examples of enyne metathesis, internal alkynes were shown to have good reactivity.[12] However, the major limitation in their use has been lack of control of regiochemistry. The orientation preference of the metal carbene (metal

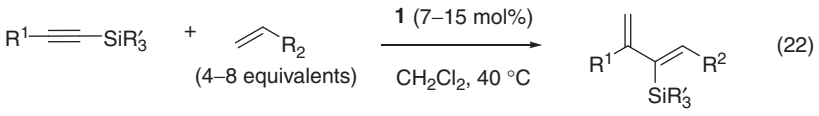
alkylidene) is determined by differential alkyne substitution and stability of the resulting vinyl carbenes. With internal alkynes bearing two different alkyl groups, there is poor distinction between the two ends. Nonetheless, cross-metathesis has been successfully employed with internal alkynes using a symmetrical alkyne[49] (equation 19), a symmetrical alkene[15] (equation 20), or both (not shown). If each of the two components is not symmetrically substituted, then a mixture of regioisomers results (equation 21).

(19)



(20)

(21)

A slight steric difference in internal alkyne substitution gives a regioselective EYM. Lee and coworkers developed a regioselective cross-enyne metathesis between TMS-substituted alkynes and a wide variety of 1-alkenes (**Table 6**).[69]

Table 6 Regioselective cross ene–yne metathesis of internal alkynes[69]

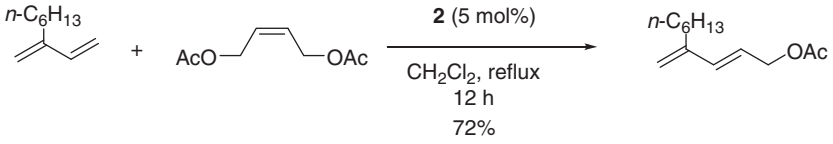
In addition, $(RO)Ph_2Si$-substitution was effectively tolerated on the alkyne. The newly formed bond was produced with high *Z*-selectivity. The origin of the high regio- and stereoselectivity is probably due to an alkylidene-first mechanism, which leads to the preferential formation of one metallacycle intermediate.

5.27.3.3 Ethylene-Assisted CEYM

Ethylene has been used in the CEYM involving higher alkenes. There are two principal reasons justifying its use. First, ethylene may improve the *E*-selectivity. Second, ethylene may allow milder reaction conditions. However, using ethylene must be done with good judgment, for ethylene is itself a reactive alkene and can give ethylene–alkyne cross-metathesis. There are few cases where ethylene can be used with another alkene – in this combination the other alkene should dominate reactions with the Grubbs carbene. (Mori's conditions refer to the use of ethylene in promoting an RCM of a 1,ω-enyne, not ethylene as a reactant in cross-metathesis.)



Ethylene as an additive enhances stereoselectivity in cross-metathesis of 1-alkynes with select alkenes.[60] Simple aliphatic alkenes such as 1-hexene give *E*-diene with ethylene present in a closed system (equation 23; **Table 7**). Though a variety of alkenes successfully produce the *E*-diene, some alkenes do not give high selectivity.[59,72] The relationship of alkene reactivity to *E*-selectivity is not completely understood. Though many possible roles of ethylene are imaginable, the most likely explanation for the most *E*-selective examples is the intermediacy of 2-substituted-1,3-butadienes. These would be the product of ethylene cross-metathesis. Grubbs has also described a highly *E*-stereoselective alkene–diene cross-metathesis using 2-substituted-1,3-butadienes.[73] The 2-butadiene starting materials can be accessed by ethylene–alkyne cross-metathesis (equation 24).

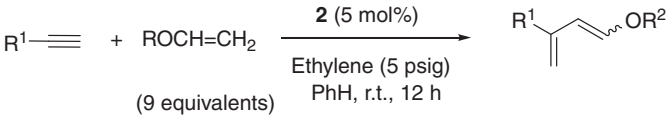
(24)



Lee and coworkers synthesized the macrolide amphidinolide E using a CEYM to introduce the C_{19}–C_{26} triene segment of the highly unsaturated natural product isolated from the dinoflagellate *Amphidinium* sp.[74] In the metathesis step, the authors first conducted an ethylene cross-metathesis to give an intermediate butadiene (3 h), the ethylene balloon was removed and a large excess of the skipped 1,4-diene was added and the vial sealed (**Scheme 9**). Because of the two different substitution patterns on each alkene, the less substituted alkene is more reactive and the geminal alkene does not give rise to any cross-metathesis products. Higher stereoselectivity was obtained by conducting the cross-metathesis as a diene–alkene cross-metathesis. Nonetheless, the butadiene is not completely reactive and 19% yield of the ethylene cross-metathesis product was obtained after 24 h. This synthesis stands as an important milestone in the use of stereoselective cross-metathesis in total synthesis.

To improve the effectiveness of enol ether–alkyne cross-metathesis, ethylene was used as a coadditive.[55] Because the enol ether–alkyne cross-metathesis is demanding, these reactions are heated to speed up the ligand exchange processes and accelerate the vinyl carbene turnover step. However, heating results in destruction of the metal carbene and the concomitant formation of ruthenium hydride species.[75,76] Instead of higher temperatures, other means of accelerating the slow catalytic step was desired. An auxiliary alkene, ethylene, was used to speed up the vinyl carbene turnover step, which was presumed to be the slow step of the catalytic cycle. This led to improved reaction scope and resulted in lower reaction temperatures (**Table 8**). Silyl enol ethers could be coaxed to react since the temperatures were lower. Previously, it had been found that heating silyl enol ethers with the Grubbs catalyst gave decomposition to a hydrocarbonyl ruthenium complex.[77] Since lower temperatures can be used with ethylene assistance, this catalyst deactivation pathway can be averted. As a result, the ethylene/enol ether–alkyne 'cometathesis' could be used to generate Danishefsky-type dienes that are extremely useful in thermal and Lewis acid-promoted cycloaddition (another important cross-metathesis method to make electron-rich dienes uses alkynyl ethers).[47,78]

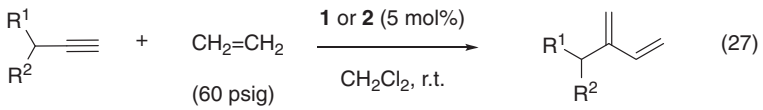
5.27.3.4 CEYM with Ethylene

The CEYM between alkynes and ethylene is an effective way to synthesize substituted 1,3-butadienes. Using an atmosphere of ethylene gas supplied through a balloon, Mori demonstrated an effective cross-metathesis with a variety of terminal and internal alkynes.[15] The procedure produces 2-substituted-1,3-butadienes from terminal alkynes and 2,3-disubstituted-1,3-butadienes from internal alkynes. The cross-metathesis has seen many more examples of terminal alkyne reactions than those of internal alkynes, though each substituted alkyne is reactive. Though the intramolecular RCM with Grubbs' carbenes demonstrates excellent functional group tolerance, intermolecular reactions are more demanding. Ethylene has the advantage that it can be employed in molar excess at ambient or moderately elevated pressures. Moreover, the excess ethylene reactant is easy to remove at the end of the reaction.

An example of ethylene–alkyne cross-metathesis is shown in equation 26.[15] The ethylene is supplied through the use of a balloon. Good reactivity was found with both terminal and internal alkynes, though none of the substrates had additional propargylic substitution. Under these conditions using carbene **1**, long reaction times are generally needed.



(26)

To tackle higher propargylic substitution and additional functionality on the alkyne, there are additional requirements (equation 27). Improvement in substrate scope was possible through either increased ethylene concentration[79] or use of the second-generation Grubbs complex.[80] Modest increase in ethylene pressure results in higher solution concentration of ethylene.

Due to the dependence of EYM on alkene concentration, this resulted in an improvement in reaction rate. Faster cross-metathesis helped the less reactive α-branched terminal alkynes to react (Table 9). In these cases, no purification of ethylene was needed. It should be noted that 60 psig (pounds per square inch gauge) is approximately 4 bar (4×10^5 Pa), easily achievable using pressure glassware that is available in most synthesis labs (stainless steel autoclaves are not needed).

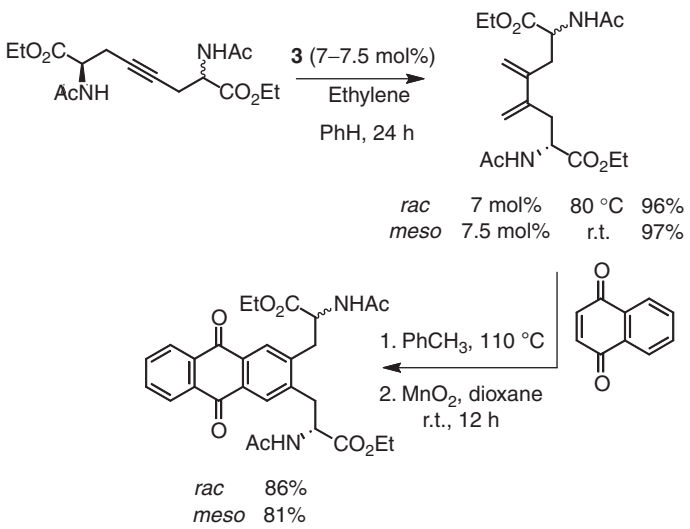
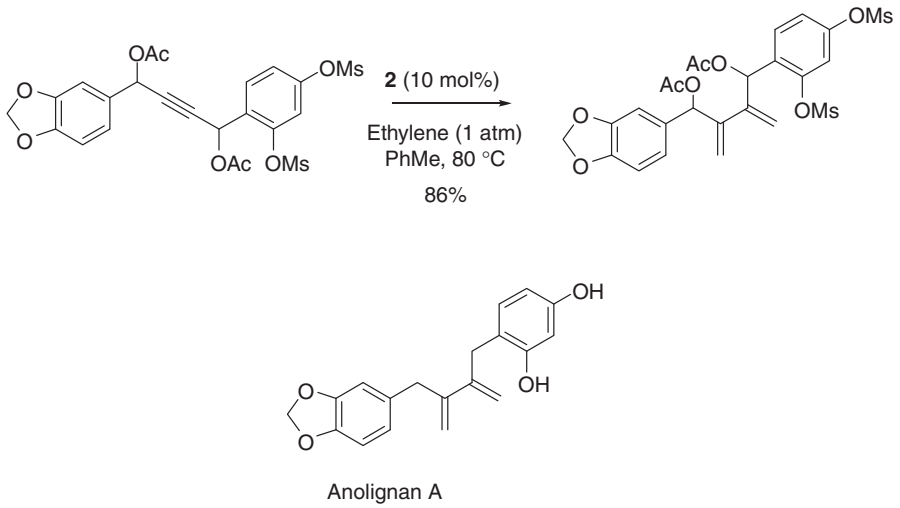
Oxygen functionality and additional substitution in the alkyne can be overcome by the use of the second-generation Grubbs catalyst at higher ethylene pressures.[80] When there are Lewis basic and potentially coordinating heteroatoms positioned in close proximity to the alkyne, the intermediate vinyl carbene may become kinetically trapped by chelation (entry 4). Chelation slows down the rate of catalysis because the coordinating group has to be exchanged for ethylene to complete the catalytic cycle. Improved reactivity was achieved by joining high ethylene pressure with the more reactive second-generation carbene (entries 4 vs. 6 and 5 vs. 7). As the previous discussion of mechanism indicates, higher concentrations of alkene benefit rate, but high ethylene concentration may also help stabilize reactive intermediates. In the case of the second-generation Grubbs carbene, higher solution concentration of ethylene may prevent both decomposition and rebinding of the Cy_3P ligand, which generates a dormant form of the methylidene.[81] For a planned ethylene–alkyne cross-metathesis with sterically hindered alkynes rich with oxygen functionality, higher pressure of ethylene and the second-generation Grubbs catalyst is recommended.



For metathesis with the Grubbs carbenes, sulfur functionality in the unsaturated reactant has presented a difficulty. The affinity of sulfur for late transition metals is well known. During catalysis, the metal carbene can become ligated by sulfur and therefore discourage further reactions such as productive EYM. Use of thiol ester protecting groups proved successful in attenuating the basicity of the sulfur lone pair, resulting in a successful ethylene cross-metathesis (entries 8–11).[82] Thiol acetates and thiol benzoates were prepared by Mitsunobu reaction of the corresponding alkynols. In entry 10, it can be seen that the first-generation carbene **1** as well as the second-generation complex **2** did not perform. For alkynes containing sulfur functionality, higher ethylene pressures proved helpful.

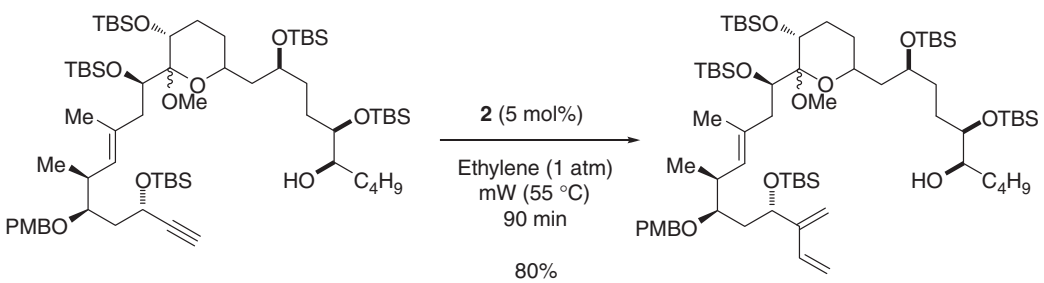
Kotha and coworkers developed a novel CEYM/Diels–Alder sequence to apply to the synthesis of substituted phenylalanines.[83,84] In this example, ethylene CEYM using the Hoveyda–Blechert second-generation catalyst was followed by a Diels–Alder reaction (Scheme 10).[85] The cycloadduct was oxidatively aromatized with MnO_2. This simple and effective method was used to make several other analogs of cystine mimetics in good yields.

EYM is often used in conjunction with subsequent [4 + 2] cycloaddition. This tandem approach was used to access taxol hybrid structures. With several unsuccessful RCM approaches to the central eight-membered ring, Kaliappan and coworkers sought a tandem approach accentuating the utility of each individual reaction.[86] In the metathesis event, an ethylene cross-metathesis was employed to access the substrate for a type II intramolecular Diels–Alder reaction (equation 28).

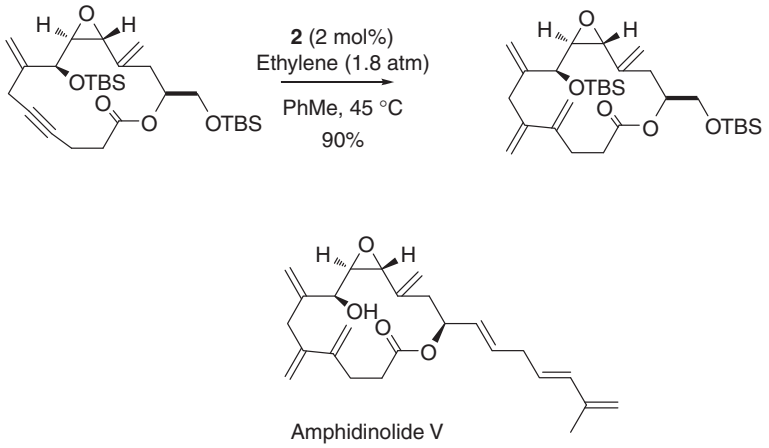


(28)

Scheme 10 Synthesis of amino acid analogs by metathesis/cycloaddition/oxidation.[85]



Ethylene–alkyne cross-metathesis has been used in natural product synthesis. Anolignan was prepared using an ethylene metathesis with the second-generation Grubbs complex performed at higher temperature (**Scheme 11**).[87]



Scheme 11 Mori's approach to anolignan by ethylene–alkyne cross-metathesis.[87]

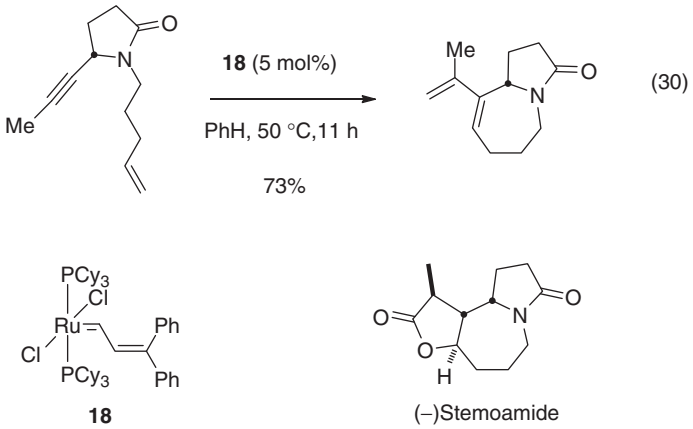
Fürstner demonstrated an impressive use of ethylene–alkyne metathesis on an unsaturated cycloalkyne to furnish the macrocyclic framework of amphidinolide V (**Scheme 12**).[88,89]

While scouting routes to amphidinolide N, Nicolaou and coworkers carried out a successful ethylene metathesis on a complex synthetic intermediate (equation 29).[90] For this same substrate, other EYM proved problematic.

(29)

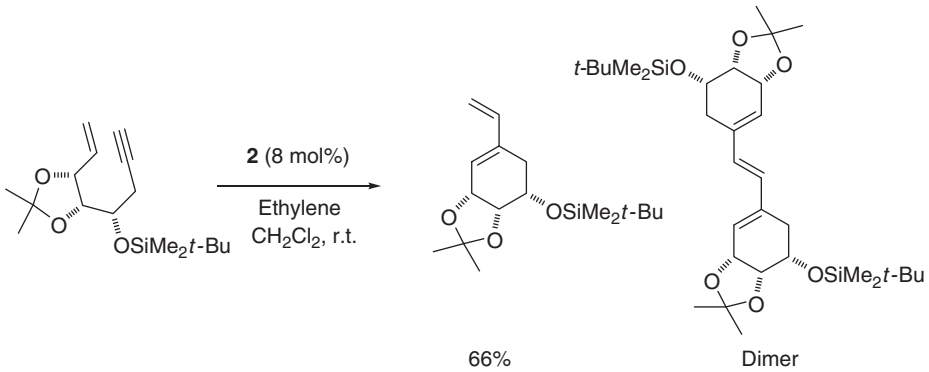
Scheme 12 Fürstner's synthesis of Amphidinolide V by ethylene–alkyne cross-metathesis.[88]

In summary, both the first- and second-generation Grubbs catalysts can be used in ethylene–alkyne cross-metathesis. Ethylene as the simplest and lowest molecular weight alkene is easy to use in excess and easy to remove. For more difficult cases, such as those with α-branching in the propargylic position or those alkynes replete with oxygen-containing functionality (such as alkyl ethers), the reactions benefit from higher ethylene pressure. Given the wide availability of the second-generation Grubbs carbene, it is advisable to employ this catalyst in combination with slightly elevated ethylene pressures if the cross-metathesis is difficult. Though the terminally unsubstituted 1,3-dienes are somewhat rare, they can be found in Nature. To that end, the use of ethylene–alkyne cross-metathesis has been successfully used in total synthesis.



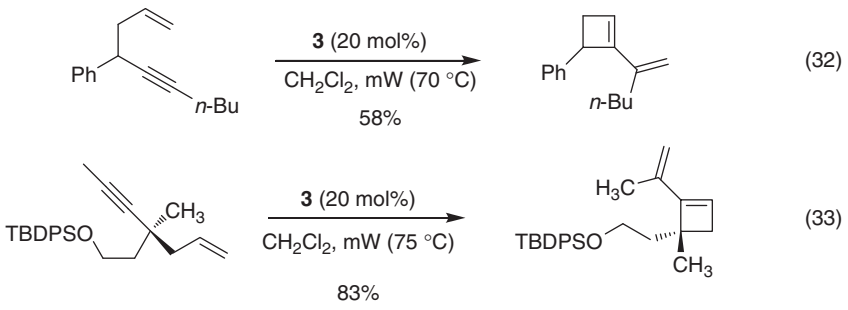
5.27.4 Ring-Closing Applications

5.27.4.1 Ring-Closing Enyne Metathesis with Ruthenium Carbenes



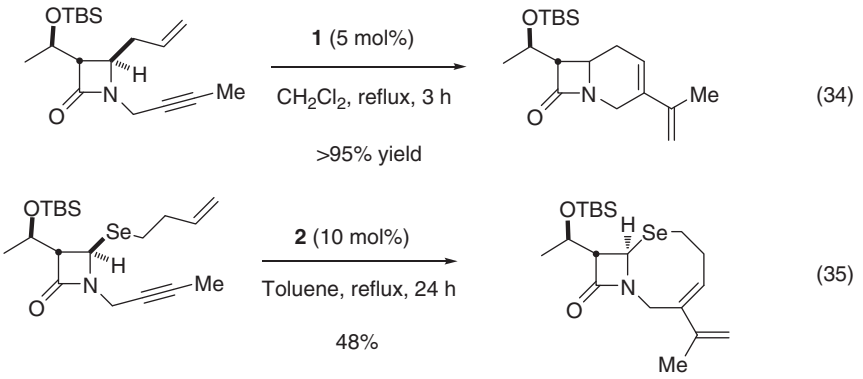
RCEYM is a well-established method for the synthesis of rings. A variety of carbocyclic and heterocyclic rings can be formed using this protocol. The synthesis of small rings is relatively straightforward using metathesis methods.[3,16] Larger rings can also be formed under typical macrocyclization conditions involving high dilution of the enyne reactant. The RCEYM is used to form carbocycles and heterocycles, and is successful even in the presence of a high density of functional groups such as those found in carbohydrates and natural products. RCEYM has been used in natural product synthesis. More applications utilize the RCEYM in tandem with other processes, such as cycloaddition or a second cross-metathesis reaction. These have become attractive due to their ability to rapidly assemble polycyclic structures. Reactions that involve metathesis cascades are discussed in greater detail in Section 5.27.7. During the development of RCEYM methods and applications to a range of small molecules, there are distinct phases where different generations of catalysts were used. Currently, the second-generation Grubbs carbene is widely employed for RCEYM, though in earlier examples and for the simplest cases, the first-generation Grubbs complex was successfully used. Modern use of this chemistry may employ either Grubbs catalyst, depending on the application. The most difficult ring closures to make small rings or those containing highly substituted alkenes require longer lived and thermally robust catalysts like the Hoveyda–Blechert catalyst. Lastly, RCEYM with the first-generation Grubbs carbene benefits from the presence of ethylene. Many early examples used 'Mori conditions' to improve the yield of the 1,3-diene product. The role of ethylene has been explained in Section 5.27.2.1.

Mori and Kinoshita illustrated a beautiful use of RCEYM as a key step in their synthesis of the *Stemona* alkaloid stemoamide (Scheme 13).[91] This was a landmark contribution because it demonstrated that the new Grubbs carbenes could be used to promote enyne metathesis in complex molecule synthesis. The Grubbs catalyst **18** was a tremendous advance over early transition metal Fischer carbenes, which lacked the activity, selectivity, and functional group tolerance of the well-defined ruthenium carbene complex.



RCEYM has been used successfully in many oxygen-rich environments. In particular, the second-generation Grubbs carbenes feature a combination of increased reactivity and high chemoselectivity; significant attributes in oxygen-rich environments, where induction and chelation reduce reactivity. Accordingly, ring closure with the second-generation Grubbs complex gives the vinylcyclohexene product in good yield.[92] Without ethylene, the vinyl carbene dimerizes, illustrating another dimension to the ethylene effect in RCEYM. Ethylene limits the formation of an undesired dimeric by-product by 'turning over' the vinyl carbene intermediate to product. This prevents an intermolecular reaction with the alkyne of another enyne reactant, which leads to the dimer (equation 31).

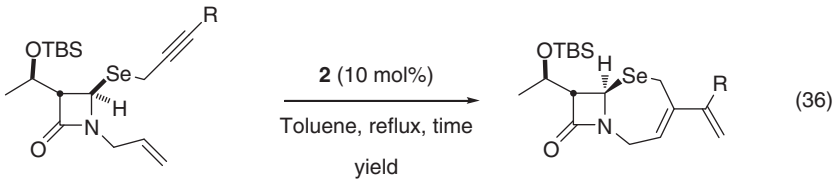
Scheme 13 RCEYM en route to Stemoamide.[91]



Formation of strained four-membered rings is possible by RCEYM. Reactivity gains have been achieved with the second-generation Grubbs carbenes simply due to the ability to heat difficult reactions for a longer period. However, at refluxing toluene temperatures, thermal decomposition of **2** becomes problematic. For difficult metatheses that require higher temperatures, the Hoveyda–Blechert complex **3** has distinguished itself. Recently, microwaves have been used to bring about metathesis. Use of the complex **3** under microwave heating promoted RCEYM to form strained cyclobutene rings (equation 32; **Scheme 14**).[93]

Scheme 14 Four-membered rings by microwave-assisted ring-closing enyne metathesis.[93,94]

A similar approach was employed by Goess et al. to make grandisol (equation 33).[94] The use of high catalyst loading and microwaves promoted the difficult ring-closing step. Notably, a quaternary carbon center resides at the propargylic position, which is unusual even for intramolecular enyne metathesis.



RCEYM can be used to access privileged heterocyclic ring systems such as the carbapenams and their structural analogs. The RCM conditions are mild such that the delicate β-lactam ring system remains intact during annulation (**Scheme 15**).[95,97] Larger B rings were made with selenium present in the nascent ring using the second-generation Grubbs catalyst (equation 34).[96] This reaction proved quite challenging due to the ring size and the presence of the selenium atom (see Section 5.27.3.4 for an example of sulfur in CEYM). Neither the first-generation Grubbs carbene or lower reaction temperatures were sufficient to promote this

Scheme 15 RCEYM to form β-lactams.[95,96]

reaction (equation 35). Internal alkynes performed well in the RCM, but a terminal alkyne failed (equation 36; Table 10) possibly due to alkyne polymerization under the forcing reaction conditions.

Polyhydroxylated carbocyclic rings are found in biologically important molecules and natural products. Due to their importance, Madsen and Poulsen developed an RCEYM strategy to readily access carbocyclic rings from carbohydrates (equation 37).[92] The authors attempted the RCEYM in the presence of an unprotected alcohol located at the homopropargylic position. At room temperature and in the presence of ethylene, they found no reaction (N.R.) with catalyst **1** or **2**. Raising the temperature to 40 °C gave decomposition of the enyne. Blocking this position with a *t*-butyldimethylsilyl (TBS) protecting group gave RCEYM under ethylene to form the desired carbocycle in good yield (Table 11).

Highly oxygenated enynes undergo RCEYM to form six-membered carbocycles. Similar to the examples above, polyhydroxylated enynes bearing homopropargylic and propargylic oxygen functionality were subjected to ring closing with the

second-generation Grubbs carbene **2**.[98,99] Interestingly, either benzyl or acetyl protecting groups were tolerated (equation 38, Table 12); these protecting groups are commonly used in sugar chemistry. In addition, each diastereomer was evaluated separately and found to give efficient RCM.

As a means of ring fusion toward bicyclic dienes, van Boom and coworkers performed RCEYM on protected 2-vinyl pyranose and 2-vinyl furanose.[100] These readily available carbohydrates were transformed into pyranopyrans and pyranofurans in the presence of the first-generation Grubbs catalyst **1**. Low conversion was observed with a terminal alkyne; however an internal alkyne gave good yield (equation 39; Table 13). A similar difference in yield was also found in the furanose case (equation 40; Table 14).

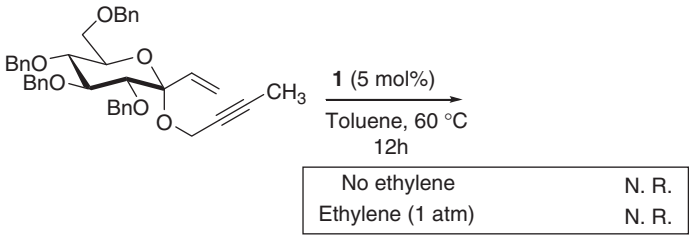
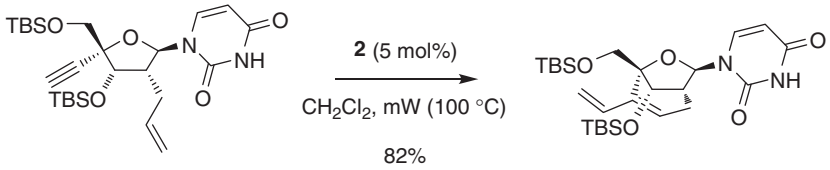
Highly functionalized spirofused oxacycles are accessible from carbohydrate-based enynes by RCEYM. van Boom et al. converted ketoglycosidic enynes into dienyl spiroacetals in the presence of the first-generation Grubbs carbene.[101] The



first two reactions (equations 41 and 42) were successful, producing the desired spirocycles in good yields, whereas the third reaction (equation 43) proved unsuccessful as the starting enyne was found to be unreactive. Conversion to product did not improve in the last case under extended reaction times or increased catalyst loadings. The ability of the catalyst **1** to initiate at the alkene may be diminished due to the steric hindrance associated with the highly substituted anomeric center.

(41)

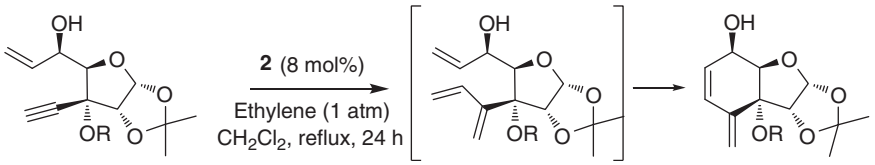


(42)

(43)

RCEYM can be used to synthesize bicyclic structures in the presence of nitrogen heterocycles such as pyrimidines. Nielson and coworkers recognized the potential of enyne metathesis in their synthesis of a bicyclic 2′-deoxynucleoside, a carbocyclic-locked nucleic acid analog (equation 44).[102] The enyne was subjected to the second-generation Grubbs catalyst using microwave heating for 2 h, giving the bicyclic structure in 82% yield.

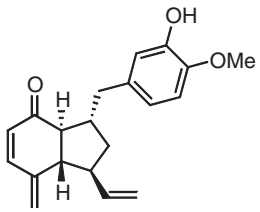
(44)



A tandem metathesis sequence allowed access to an unusual ring-closure mode. In an RCEYM, forming a new ring by closure onto the proximate carbon of an alkyne would lead to a smaller ring. If a pendant alkene could be made to close onto the distal carbon, a larger ring would result. This is called *endo*-selectivity and is atypical of small ring closures using ruthenium carbene intermediates. *Endo*-selectivity was achieved by Kaliappan and coworkers who envisioned a tandem ethylene cross-metathesis/RCM sequence as a means to access 4-methylene-2-cyclohexanols.[103] This substructure obtained from equation 45 is contained in the natural products otteliones and loloanolides (**Table 15**). The reaction was conducted under ethylene, triggering an ethylene–alkyne metathesis first. The intermediate vinyl appendage of the 1,3-diene can combine in an alkene RCM to furnish the product. Subsequent Dess–Martin oxidation of the alcohol resulted in the 4-methylene-2-cyclohexenone framework.

5.27.4.1.1 Nitrogen-containing heterocycles

The RCEYM has been used to furnish a variety of nitrogen-containing heterocycles. Nitrogen heterocycles pose a challenge to metal carbene-mediated chemistry because of the electron-withdrawing nature of the nitrogen atom and because nitrogen protecting groups may coordinate to the carbene intermediates. In this section, some challenging examples are provided, mostly employing the second-generation Grubbs catalyst **2**. Bicyclic nitrogen heterocycles are also obtained using metathesis methods.



The use of a sulfoximine linker in the enyne leads to a heterocyclic sulfoximine by RCEYM (equation 46).[104] In the case of terminal alkynes, good yields were also obtained along with a dimeric product that could not be completely eliminated by

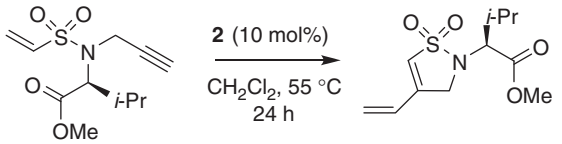
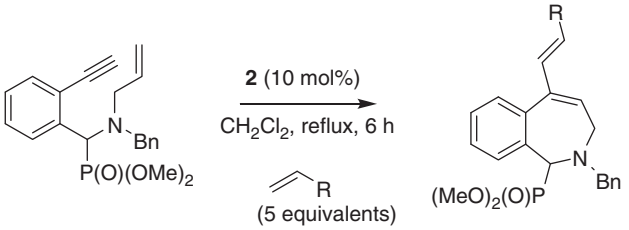
dilution or use of ethylene. The resulting 1,3-dienes underwent further transformation such as a Diels–Alder aromatization with benzoquinone, allowing access to benzofused sulfoximines. Attempts to perform further RCEYM reactions on enynes with longer tether lengths to produce larger heterocyclic rings were unsuccessful.



(46)

RCEYM can be performed with a vinyl sulfonamide and a terminal alkyne to produce an endocyclic sultam; this is an unusual heterocycle. Heterocyclic ring systems appear in many pharmaceutical agents and are extremely important in drug development. Given this and their versatility, heterocycle synthesis has become a major focus for chemical library synthesis by diversity-oriented synthesis (DOS). With this goal in mind, Hanson and coworkers synthesized skeletally diverse sultams (equations 47 and 48).[105] RCEYM reactions provide unique access to functionalized heterocyclic ring systems from linear unsaturated elements with heteroatom linkers. Initiating metathesis at an electron-deficient site or near coordinating heteroatoms can be difficult. In this case, vinyl sulfonamides are difficult substrates due to the electron-poor nature of the alkene. Generally, this problem can be solved using the more active Hoveyda–Blechert catalyst **3**, but in this case longer periods of heating with Grubbs carbene **2** proved successful.



(47)

(48)

Cyclic α-aminophosphonates are accessible by RCEYM. Benzofused seven-membered ring systems have received much attention in the synthetic community due to their appearance in a variety of natural products and similarity to privileged structures such as to the benzodiazepines. Moreover, benzofused heterocycles bearing phosphonates have interesting biological properties. Stevens and coworkers planned the synthesis of phosphono-substituted benzazepines using RCEYM as their key strategy (equation 49; Table 16).[52] Obtaining the desired 1,3-diene posed a challenge due to the slow conversion of the initially formed butadiene to the 1,3-diene. To speed up conversion to the 1,3-diene, an additional 5 equivalents of alkene were added after the first 2 h of reaction. At the end of the reaction, approximately 10% of butadiene remained unreacted but proved separable by flash chromatography.

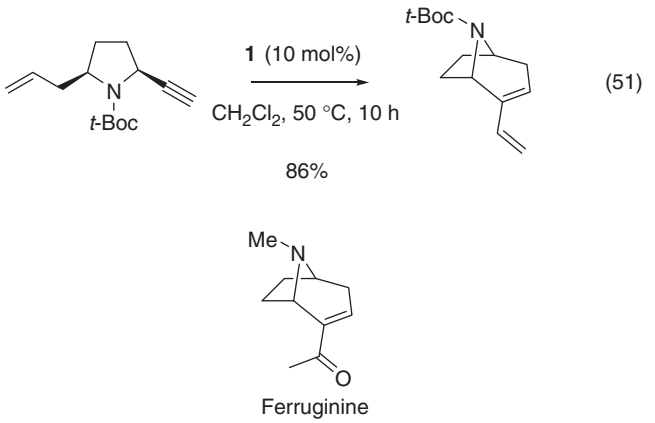
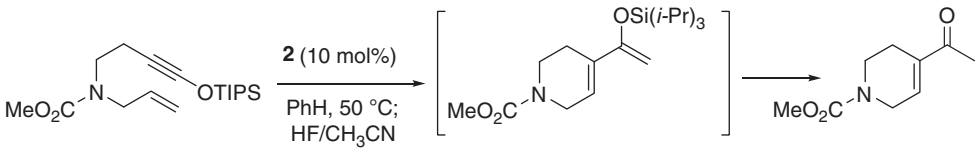
Bicyclic nitrogen heterocycles have been synthesized by RCEYM. The groups of Martin[106] and Mori[107] had independently pursued two closely related strategies toward anatoxin-a. For brevity, the Martin approach is detailed. The enyne precursor was synthesized from D-methyl pyroglutamate.[106] In the RCEYM step, the enyne was found to cyclize efficiently (under Ar) to give the bridged azabicycle under nominal conditions (equation 50). The exocyclic geminal alkene of the diene product was elaborated by osmylation and oxidative cleavage of the 1,2-diol. After protecting group removal (TMSI), the natural enantiomer of (+)-anatoxin was formed (Scheme 16).

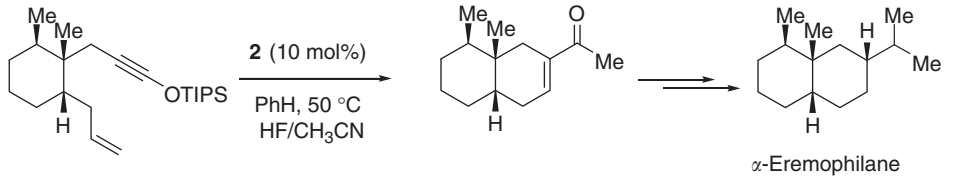


(50)

Scheme 16 Ring-closing approach to the aza bicyclic ring system of anatoxin.



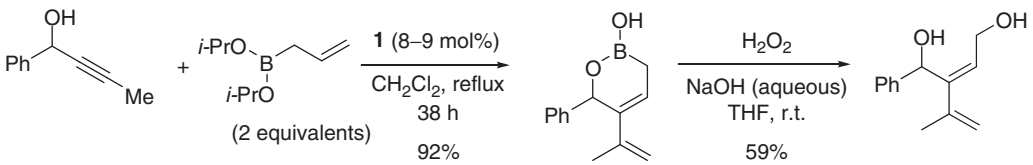
The bicyclic ring system of the alkaloid (+)-ferruginine was assembled by RCEYM (Scheme 17). Aggarwal et al. screened catalysts **1**, **3**, and **5** in this reaction, but monitoring reaction progress indicated that these more active catalysts were destroying the 1,3-diene product after its initial formation.[108] This is an unusual example of an RCEYM that occurs better with the less reactive first-generation carbene **1**. A Wacker-type oxidation sequence was used to transform the exocyclic geminal alkene to a methyl ketone.



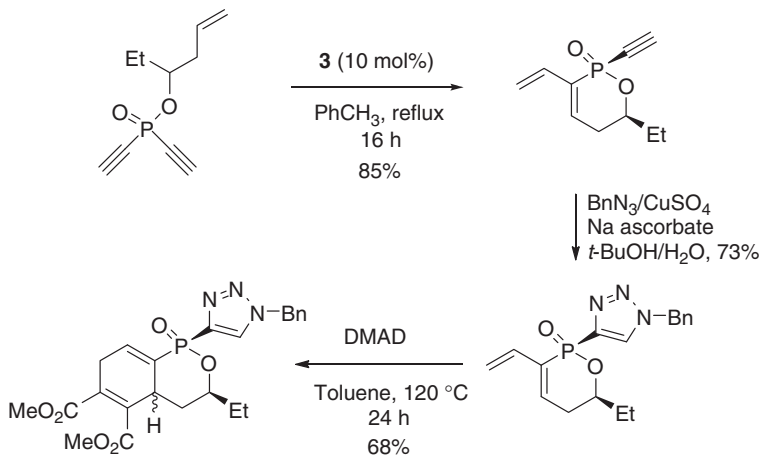
RCEYM can be used to access other functionality besides 1,3-dienes. Coupling a tandem transformation with the enyne metathesis provides access to enones in a 'one-pot' process. Normally, enyne metathesis produces a vinyl cyclohexene; however, Kozmin et al. recognized that if the alkyne bore an oxygen atom, the product could be converted into a methyl ketone.[47] Use of silyl alkynyl ethers in the RCM followed by deprotection of the intermediate silyl enol ether gives the product methyl ketones after

Scheme 17 RCEYM approach to [3.2.1] azabicycle.[108]

acid-catalyzed enol-keto tautomerization (equation 52). This metathesis/deprotection/tautomerization sequence was applied to the synthesis of α-eremophilane (equation 53).[109]

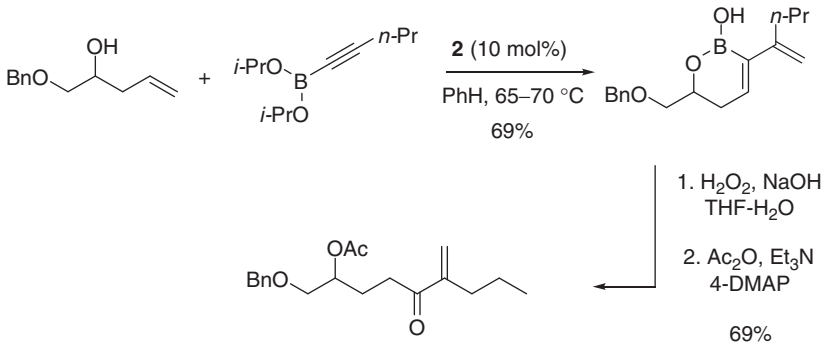


5.27.4.1.2 Other heterocycles



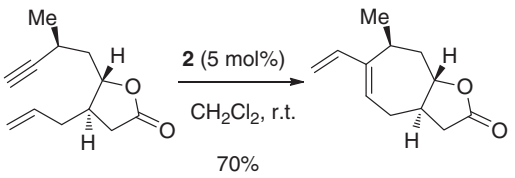
Though they had previously shown that phosphorus-containing compounds are suitable for metathesis, Gouverneur and coworkers developed the first example of a diastereoselective ene-diyne metathesis to form various chiral P-stereogenic heterocycles (Scheme 18).[110] To achieve full conversion, 10 mol% of the Grubbs catalyst **2** or the Hoveyda–Grubbs catalyst **3** was necessary, in conjunction with elevated reaction temperature. Through optimization, it was also found that the second-generation Hoveyda–Blechert catalyst in refluxing toluene gave the highest diastereoselectivity (18:1). This was much higher than with the first-generation Grubbs catalyst **1** (3:1) or Grubbs catalyst **2** (10:1). These stereochemically distinct phosphorus heterocycles are unique stereogenic templates and could lend themselves to further functionalization on either the alkyne (Huisgen 3 + 2 cycloaddition) or 1,3-diene moieties (Diels–Alder reaction).

The use of a transient linker to bring together the unsaturated elements was elegantly employed by Schreiber and Micalizio to furnish boroxines (Scheme 19).[111,112] However, the cyclic boronate could be oxidized to the enol that produced the corresponding enone after enol-keto tautomerization. The cyclic boronates could also be subsequently hydrolyzed to provide acyclic dienes (equation 54). The use of a linker switches a slower intermolecular EYM to the intramolecular manifold, increasing the reaction rate and enforcing the endocyclic alkene geometry. The mixed boronate ester offers functionality that can be harnessed for subsequent C–C bond formation.

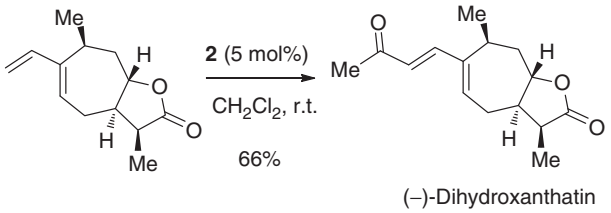


5.27.4.1.3 Application to carbocyclic natural products

Morken constructed the seven-membered ring found in dihydroxanthatin by RCEYM (equation 55).[113] The treatment of the requisite enyne with 5 mol% of **2** produced the expected RCEYM product. After enolate alkylation, the diene was subjected to

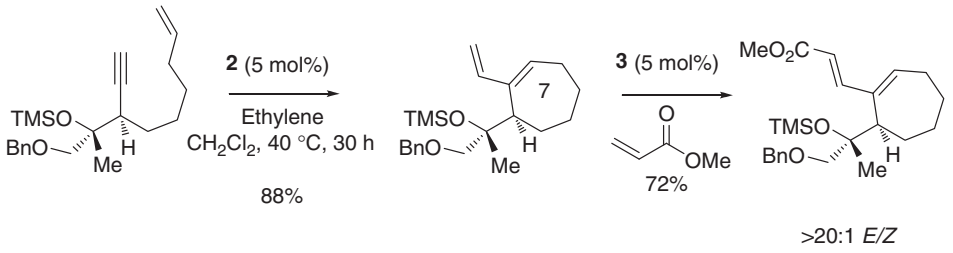


Scheme 18 Desymmetrization RCM on diyne.[110]



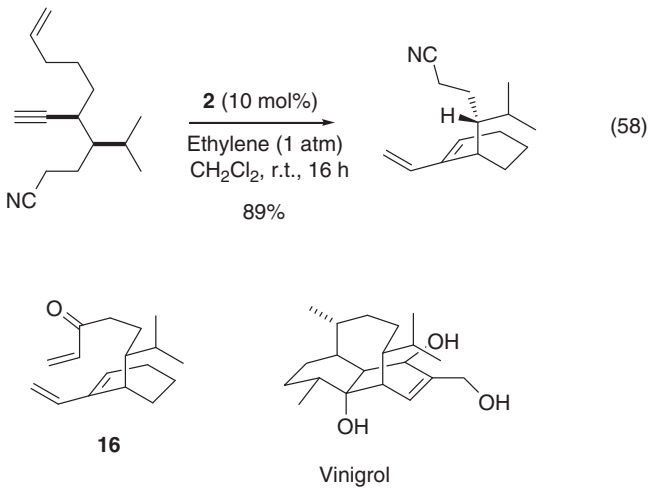
Scheme 19 Transient boronate linker organizing RCEYM.[111,112]

cross-metathesis with methyl vinyl ketone (equation 56). This procedure could have been achieved in one pot using **3**; however, the authors found it tactically superior to perform the metathesis stepwise to selectively enolize the lactone.



(55)

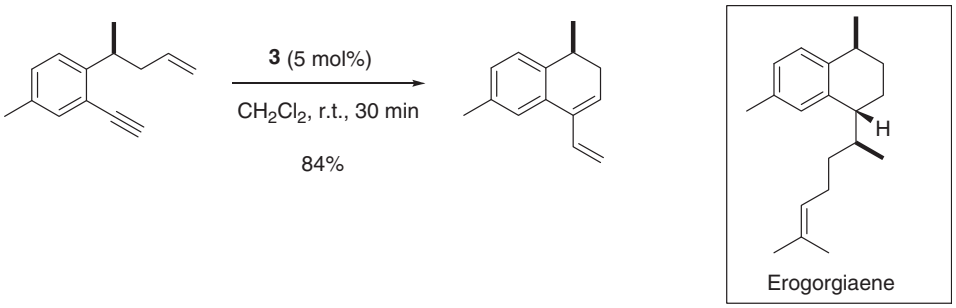
(56)



(–)-Dihydroxanthatin

An efficient RCM was used to make the seven-membered C-ring of lancifodilactone.[114] In this case, a rather hindered homopropargylic alkyne underwent reaction with carbene **2**, as long as the homopropargylic alcohol was protected as the TMS ether (equation 57). In the second cross-metathesis with methyl acrylate, the Hoveyda–Blechert complex **3** was employed to achieve good yield and high *E*-selectivity. This example serves to illustrate different strengths of the carbene promoters **2** and **3**.

(57)

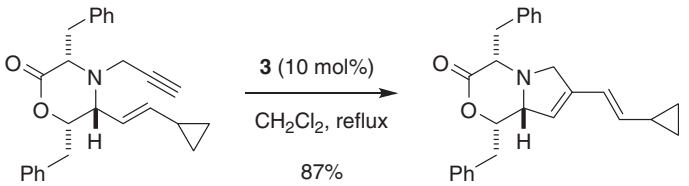


Access to six-membered rings using metathesis is advantageous because it can be used to set up subsequent annulation. For example, the resulting vinyl cyclohexene is capable of Diels–Alder cycloaddition (Scheme 20).[115] In subsequent transformations, Barriault and coworkers converted the nitrile into the enone **16**, which underwent a Lewis acid-catalyzed Diels–Alder reaction to provide the carbon framework of the tricyclic core of the diterpenoid vinigrol.

(58)

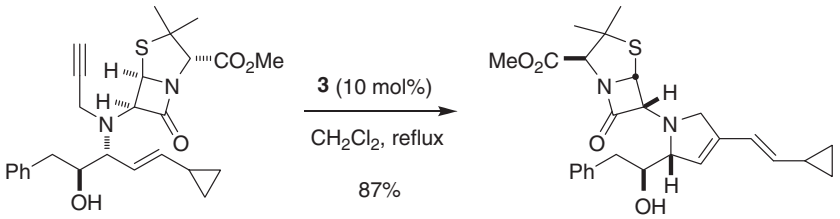
Scheme 20 RCEYM used to set up intramolecular cycloaddition.[115]

The Hoveyda–Blechert complex also promotes simple RCEYM. In their synthesis of erogorgiaene, Hoveyda and coworkers employed an RCEYM using complex **3** (equation 59).[116]



(59)

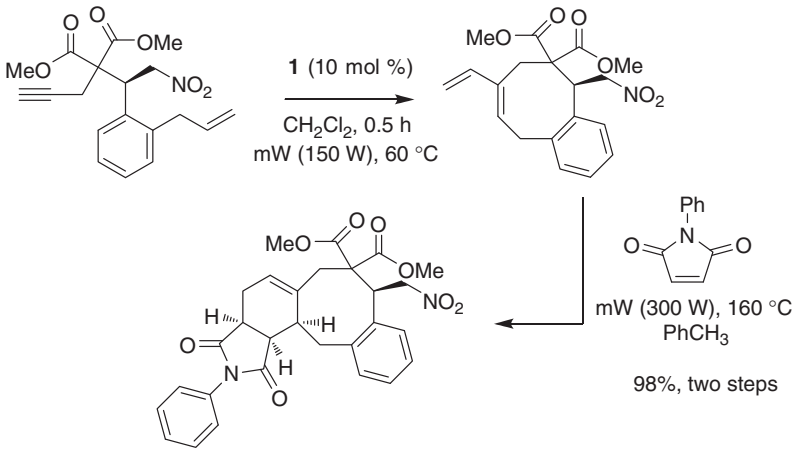
5.27.4.1.4 For diversity generation and in diversity-oriented synthesis



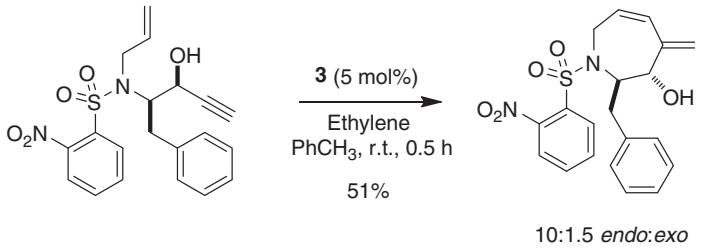
The EYM is well suited to DOS. The DOS aims to create various cyclic or polycyclic templates to project functional groups to give a quasi systematic and wide representation of three-dimensional space. This approach is inspired by complex natural products, which evolved for a particular function. Enyne metathesis is a very attractive enabling technology for the rapid assembly of the core structures because it can be used to make a wide variety of ring sizes, tolerates many functional groups, and supplies products that are amenable to subsequent transformation (e.g., cycloaddition). In this section, a few reactions that fall into this family are highlighted. In Section 5.27.7, cascade reactions are also utilized for the assembly of polycyclic arrays and are detailed in that section.

Two representative examples from DOS illustrate the functional group tolerance of the RCEYM (equations 60 and 61). Chiral scaffolds can be employed to generate heterocyclic rings bearing chiral centers, and the alkene does not need to be terminal. Many

examples in this section include terminal alkenes closing onto alkynes. In this case, Schreiber et al. showed that an alkene bearing a cyclopropyl group participates in RCEYM onto an alkyne that contains a basic amine in the propargylic position (equation 60).[117] In the second example, a privileged heterocyclic ring, that of the penicillin ring (with a divalent sulfur atom and a β-lactam ring), is carried as a spectator during a remarkably efficient RCEYM (equation 61). These two examples illustrate that the enynes can be adorned with a rich array of functionality without deleterious effect on the catalytic enyne metathesis.



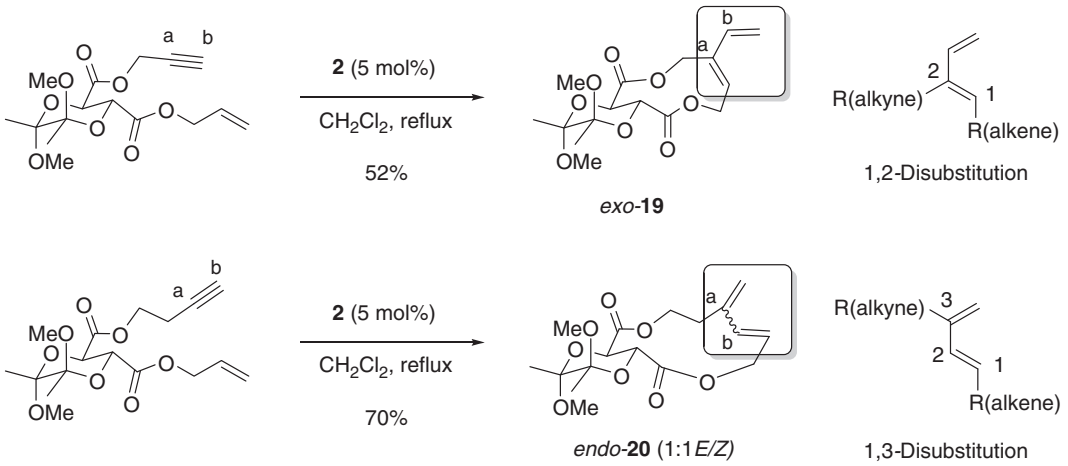
(60)



(61)

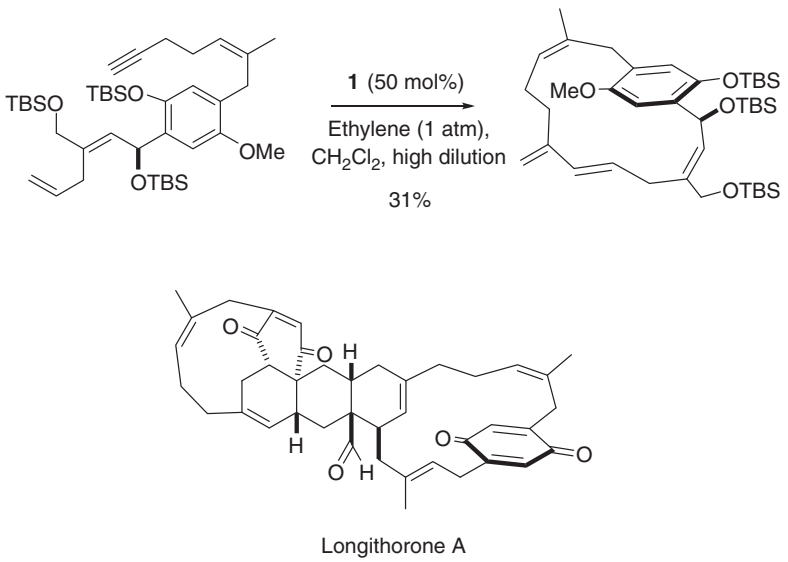
Multifunctional diene scaffolds were accessed through RCEYM as a means of generating skeletal diversity. Porco and coworkers conducted the RCM step under Mori's conditions using ethylene and microwave heating (**Scheme 21**).[118] The 1,3-diene was not isolated but directly subjected to a thermal [4 + 2] cycloaddition with *N*-phenylmaleimide. The microwave heating allows rapid throughput and high chemical yield (98% over two steps).

Scheme 21 Skeletal diversity by enyne metathesis and cycloaddition.[118]



Schreiber et al. built stereochemical and skeletal diversity into a set of small molecules using multiple approaches involving RCEYM (equation 62).[119] The RCEYM in Equation 62 gave an unusual result, proceeding with *endo*-selectivity when using the Hoveyda–Grubbs catalyst under an ethylene atmosphere. Significantly, a free hydroxyl group is present at the propargylic position. Free alcohols in the propargyl position tend to be problematic in CEYM, except those involving ethylene. The free hydroxyl group was important for the high *endo*:*exo* selectivity; if it was protected, the *exo*-mode RCM dominated.

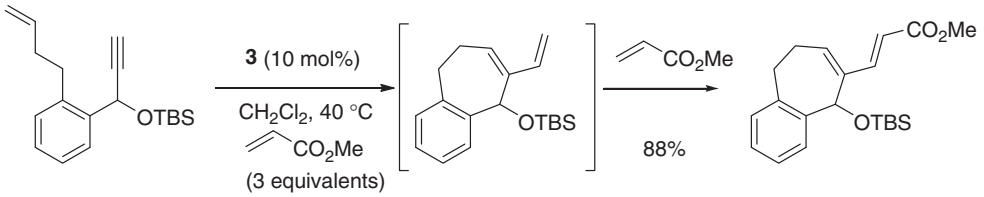
(62)



5.27.4.1.5 Macrocyclic ring closure

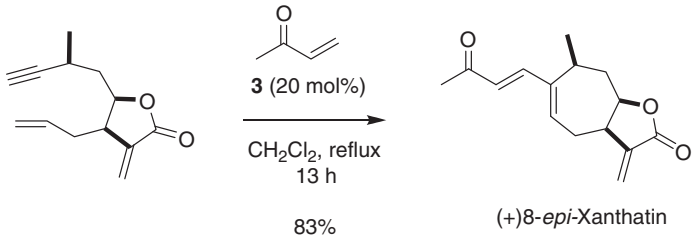
In larger RCEYM, there are two orientations that can be obtained, which affect the ring size formed. If the ring is smaller than 10 members, then ring constraint forces the enyne to come together with the 1,2-disubstitution pattern (**19**, Scheme 22). This is called *exo*-selectivity because the intermediate vinyl carbene leading to *exo*-**19** features the ruthenium exocyclic to the newly formed ring. However, if the ring is very large, the ene and yne react with the regiochemistry observed for the intermolecular reaction (as in **20**). In this case, the vinyl carbene forms endocyclic to the macroring formed. Lee and Hansen studied this in a systematic way and rationalized the data in terms of reactive intermediate stabilities.[120] With slightly greater flexibility in the enyne tether, the ring closure may result in the larger ring size by switching regiochemical preference. In general, rings smaller than 10 members will form with the 1,2-disubstitution pattern (*exo*-selectivity); rings in the 10–11 range are borderline cases, and larger rings result in the 1,3-disubstitution pattern on the 1,3-diene (*endo*-selectivity). The 1,3-disubstitution results from CEYM. A study of macrocyclization in a related system has also appeared, with an emphasis on DOS.[121]

Scheme 22 Ring-closure mode selectivity.[120]



In a remarkable macroring-closing enyne metathesis, Shair and coworkers produced two cyclophanes that were used to assemble the seven ring systems found in longithorone A.[122] Due to the difficulty of the ring closure, high loading of the Grubbs catalyst was used along with ethylene. The synthesis of one cyclophane is illustrated in Scheme 23. This cyclophane comprised the right half of longithorone A.

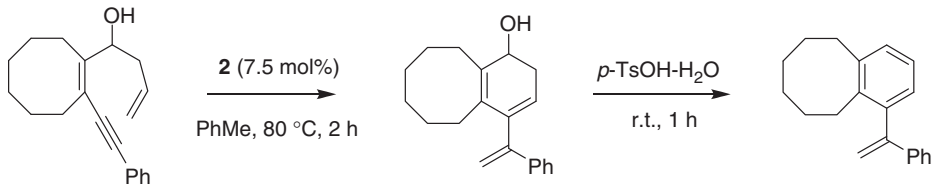
Scheme 23 Macroring closure en route to Longithorone A.[122]



5.27.4.1.6 With tandem cross-metathesis

Since the Hoveyda complex is well suited to reactions employing electron-deficient alkenes, tandem reactions are possible using these alkenes subsequent to RCEYM.[123] Though carbene **3** is capable of reaction with enoates, it is more reactive with simple aliphatic alkenes. In equation 63, the initial reaction occurs on the alkene of the enyne that undergoes ring closure to give an intermediate vinyl cycloheptene species. With complex **3**, both the ring closing and the cross-metathesis with the added alkene took place in a single-reaction flask without further addition of catalyst. The second step can be regarded as a slower and more difficult diene-enoic ester cross-metathesis. It is interesting to note that the reaction temperature can be controlled in this example so as to limit possible Diels–Alder reaction between the intermediate and the excess electron-poor alkene.

(63)



Martin used a tandem cross-metathesis-based approach to make the related diterpene 8-*epi*-xanthatin using the Hoveyda–Blechert complex **3** (equation 64).[124]

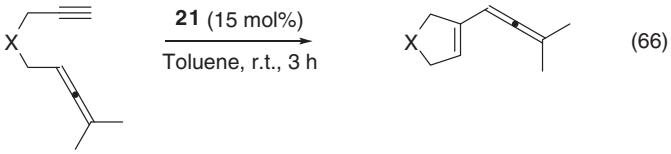
(64)

5.27.4.1.7 Ring-closing/aromatization

Substituted arenes can be prepared by an RCEYM/dehydration sequence. RCEYM was carried out with a 1,5-octadien-7-yn-4-ol and second-generation Grubbs carbene (equation 65).[125] On formation of the triene, the alcohol was subjected to mild dehydration conditions (*p*-toluenesulfonic acid (*p*-TsOH)) to trigger elimination and engender aromaticity in the six-membered ring. This novel one-pot process was carried out with a large repertoire of substrates offering an efficient one-pot access to substituted styrenes. A related RCEYM/keto-to-enol tautomerization is also described.[125]

(65)

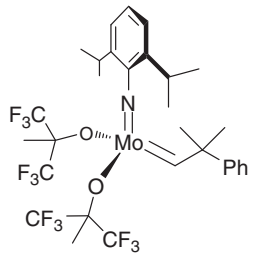
Ethylene	Yield
None	74%
(1 atm)	96%



RCEYM has seen wide application as a ring-forming method. It is tolerant of a variety of functional groups and can accommodate electron-withdrawing functionality positioned within or residing outside the newly formed ring. For carbocycles, the scope is wide, tolerant of oxygen substitution, and used in complex molecule synthesis. The Grubbs catalysts typically cause ring-closing of 1,*n*-enynes in the *exo* mode. Use of ethylene in some cases leads to *endo*-ring closure. The next section details more examples of *endo*-selectivity using Schrock–Hoveyda molybdenum carbene catalysts. The use of RCEYM in alkaloid synthesis has a long history dating back to Mori's landmark synthesis of stemoamide. Applications to more unusual nitrogen heterocycles and use in DOS are modern themes. Though the Hoveyda–Blechert complex can be used to promote enyne metathesis just as the second-generation Grubbs complex, its niche application is electron-deficient alkenes and forcing reaction conditions needed to make small rings. This complex is the most widely used phosphine-free variation of the Grubbs ruthenium carbenes, but variants such as the Grela catalyst **4** are also useful for enyne metathesis. Complex **3** has proven particularly effective under demanding metathesis conditions or those involving enones, enoates, or enals.

5.27.4.2 Ring-Closing Applications with the Molybdenum Carbene Catalysts

The Schrock molybdenum catalyst has not been widely used in enyne metathesis. This can be attributed to the catalysts' high reactivity with terminal alkynes: Alkyne polymerization outcompetes enyne metathesis. In the best cases, 1,ω-enyne substrates may undergo RCEYM with competitive polymerization taking place. A few years ago, there were no examples of RCEYM using the Schrock catalyst.[3] In recent years, the Schrock catalyst has seen far greater application in asymmetric alkene metathesis applications and in *Z*-selective alkene metathesis. Improving the design of asymmetric catalysts has led to a collateral benefit for enyne metathesis: improved cross-selectivity. (This refers to the cross-reaction between an alkene and an alkyne as opposed to homopolymerization of alkynes.) This highlights that major developments often follow from improvements in catalyst design. As any student of organometallic chemistry might expect, subtle changes in catalyst structure may have a profound effect on reactivity and selectivity.



The parent Schrock catalyst was found to promote the RCEYM of an allene–yne.[126] This is a well-balanced case of intramolecular reactivity over alkyne polymerization (**Table 17**). Based on initiation studies, the authors favored a mechanism where the molybdenum allenylidene formed and then reacted with the alkyne, followed by ring closure. Though the ether linkage failed due to chelation with the oxophilic metal, a basic amine gave successful enyne metathesis.

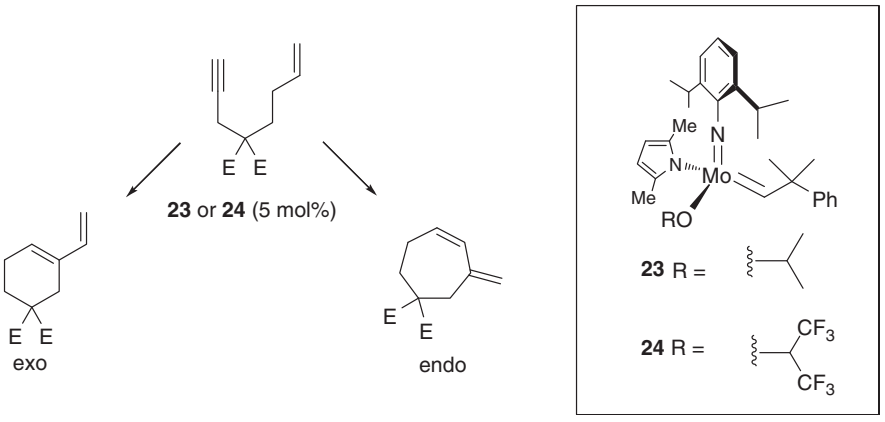
21 (Schrock catalyst)

By changing the ligands in the Schrock complex, RCM of 1,ω-enynes is possible.[127] Chirality in the Schrock molybdenum carbene environment is achievable by either substituting the two alkoxy groups for a chiral diol,[128] or using four different ligands to make the metal center stereogenic. In both ways, the Schrock and Hoveyda research team has generated highly selective catalysts for asymmetric RCM applications[129,130] and *Z*-selective alkene metathesis.[131–133] The Schrock complex **21** has two alkoxy groups bound to the molybdenum center. The chiral-at-molybdenum carbene complex **22** bears one alkoxy group and one pyrrolide ligand directly bound to the metal.[127,134] This slight alteration in ligand environment (changing one alcohol ligand to a pyrrole ligand) resulted in enyne metathesis reactivity. Mono pyrrolide catalyst **22** promotes RCM (equation 67).[127] Interestingly, the ring size formed from a 1,6-enyne is not the same as would be expected based on RCEYM promoted by ruthenium carbenes. The mode selectivity observed in equation 67 is called *endo*-selectivity (it has also been called the β-addition mode). Interestingly, this ring closure 'mode selectivity' is different from that observed with the Grubbs ruthenium carbene, where *exo*-selectivity is observed in small-membered rings. With ruthenium carbenes, the five-membered ring **23** would have been produced by *exo*-addition (**Scheme 24**). This complementary mode selectivity suggests a niche for the molybdenum (and tungsten catalysts).[135] In rare cases where ruthenium catalysts have been used, an initial ethylene cross-metathesis is required to guide *endo*-selectivity. Use of the stereogenic-at-metal complex has provided two asymmetric applications in RCEYM.[134]

The catalyst structure in the Schrock–Hoveyda catalysts influences 'mode selectivity' of ring closure. With one pyrrolide ligand already in place, changing the alkoxy group in the four-coordinate molybdenum catalyst has a profound effect on the ring closure mode selectivity (**Table 18**). For instance, the heteroleptic catalyst **23** gives primarily the *exo* ring closure mode, but changing to catalyst **24** results in exclusively *endo*-mode. This example illustrates how the ligands surrounding the metal atom determine



Scheme 24 Schrock–Hoveyda molybdenum carbene-promoted RCEYM.[127]

reactivity profile and how a class of catalysts once dismissed for enyne metathesis has emerged with both the reactivity and a degree of selectivity previously unseen.

Table 18 Molybdenum ligand environment affects the mode of ring closure[75]

Entry	*Catalyst*	*Ratio*(exo:endo)	*Yield (%)*

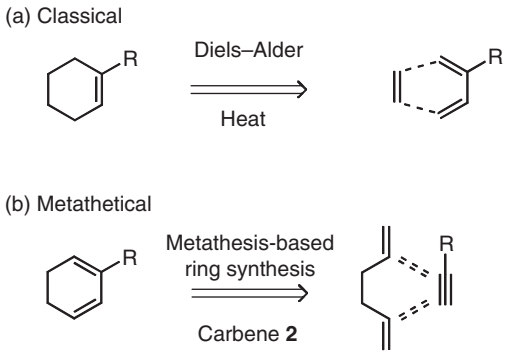
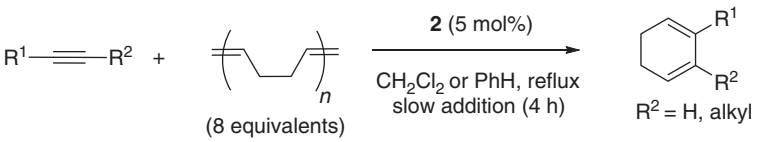
2	24	0:100	70



The new Schrock catalysts have improved selectivity and may have improved functional group tolerance compared with the parent Schrock catalyst. Although the outlook is hopeful, there has been a higher barrier to the use of the Schrock complex due to its moisture sensitivity and its lower functional group tolerance for alcohols and ethers. Recently, the Schrock catalysts have been rendered significantly more bench stable through complexation with 2,2′-bipyridine.[136] This practical advance will facilitate the use of these catalysts in synthetic laboratories. For RCEYM, the reactivity issue has been solved through tailored catalyst design. With continued improvements in the synthesis of *in situ* catalysts and their recognized versatility, the perceived barrier to using these complexes is expected to be less significant. Though one can argue that Mo(IV) is too oxophilic to use in complex molecule total synthesis, one is reminded of the early, successful ring-closing alkene metathesis approach to fluvirucin (Sch 38516) by Hoveyda,[137] where a protected sugar and amide withstood the metathesis conditions. Most likely, immediate use of the Schrock subfamily of catalysts will capitalize on the unusual enyne metathesis ring closure mode selectivity and the potential for enantioselectivity, due to the unique stereogenic environment at the metal center.

5.27.5 Ring Synthesis

Rings can be formed by EYM between 1,ω-dienes and alkynes.[138] To accomplish this ring synthesis, both a CEYM and *in situ* RCM would occur in the same reaction. The use of a 1,5-diene such as 1,5-hexadiene as a four-carbon donor to an alkyne results in the synthesis of 1,3-cyclohexadienes. Larger rings can be formed by cross-metathesis/ring closing performed on enyne substrates.



Cross-metathesis between dienes and alkynes provides a powerful ring synthesis of 1,3-cyclohexadienes. For example, the venerable Diels–Alder reaction forms a six-membered ring by a cycloaddition between an alkene and 1,3-diene. In a similar vein, a two-carbon plus four-carbon additive metathesis reaction would form the six-membered ring with a conjugated diene present. To take the analogy with the Diels–Alder reaction one step further, the newly formed six-membered ring contains a 1,3-diene rather than a cyclohexene, the 'residual unsaturation' characteristic of the Diels–Alder cycloadducts (**Scheme 25**). Of course, the Diels–Alder reaction is superior due to its simplicity: It only requires heat to bring the reactants together in the ordered transition state. The methylene-free ring synthesis joins two carbons from the alkyne with four carbons from the diene reactant. The ring synthesis is promoted by the Grubbs carbene **2** and is favored by π-reorganization. Unlike the Diels–Alder reaction, the ring synthesis results from several discrete metathesis steps and is not concerted. The products of methylene-free ring synthesis are themselves amenable to subsequent Diels–Alder reaction serving in the capacity of 1,3-diene.

Scheme 25 Six-membered ring-building approaches.

The methylene-free tandem metathesis approach offers a synthetically useful ring synthesis (**Table 19**). The reaction is preparatively useful and can be conducted on a larger scale at reduced catalyst loadings.[141] Either 1,5-cyclooctadiene or polybutadiene can be used as the alkene reactant. Because there are no terminal methylene groups, this is termed 'methylene-free conditions.' These conditions are thought to permit equilibration between *E*- and *Z*-vinyl carbene intermediates. In more difficult cases, such as those employing coordinating heteroatoms on the alkyne or internal alkynes, higher concentrations of 1,5-cyclooctadiene or the polymer polybutadiene are needed.[139] Some representative products are illustrated in **Table 19**.

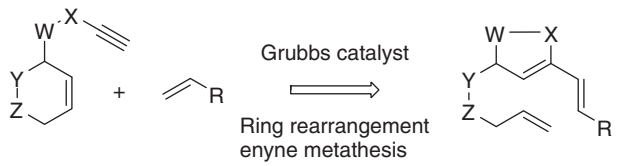
EYM has been used as a key step in a diversity-oriented approach to macrocyclic structures through a cross-metathesis/ring-closing ring synthesis. Kotha and Singh generated a diverse collection of macroheterocyclic derivatives by CEYM with 1,5-hexadiene followed by a macroring-closing metathesis (equation 69). This cascade reaction is effective in producing macroheterocycles. In addition, a tetraene product was isolated due to *E*-diene formation. The mixture of products reflects the nonstereoselective cross-metathesis. The isolated *E*-tetraene was resubjected to the second-generation Grubbs catalyst **2**, but failed to undergo RCM.

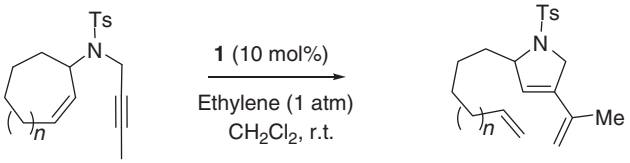


(69)

5.27.6 Ring-to-Ring Conversions by EYM

5.27.6.1 Ring Rearrangement Enyne Metathesis

RCEYM onto a pendant cycloalkene shuffles the ring. In the process, the existing cycloalkene (YZ linker atoms) is converted into a new ring incorporating the atoms that separated the cycloalkene and alkyne in the first place (linker atoms W–X, equation 70). Often the linker W–X includes a heteroatom, which distinguishes this metathesis as a useful conversion of carbocyclic rings to heterocyclic rings.



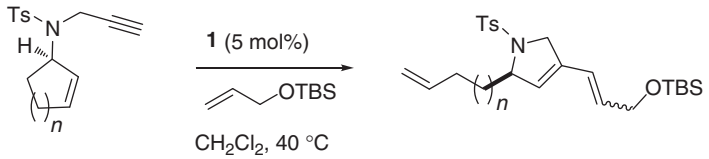
(70)

To the best of the authors' knowledge, the reaction was developed independently by Blechert[142] and Mori.[143] Blechert dubbed the process to be a 'ring rearrangement;[142,144–147] this terminology will be used throughout this section. The ring rearrangement is driven forward to products by π-bond reorganization, the same enthalpic driving force of enyne metathesis. Typically, a carbocycle is broken, whereas a heterocycle is formed.

The ring rearrangement enyne metathesis occurs in the presence of added ethylene. To a first approximation, the mildness of the rearrangement inversely correlates with the stability of the cycloalkene. Seven- and eight-membered cycloalkenes perform well in the ring rearrangement promoted by the first-generation Grubbs complex **1** (Table 20).[143] Though the carbocycle to heterocycle forward reaction may seem surprising, it is driven by the π-bond reorganization of the enyne metathesis, and it is not due to the stability of the new ring system formed.

Table 20 Ring rearrangement with added ethylene[143]

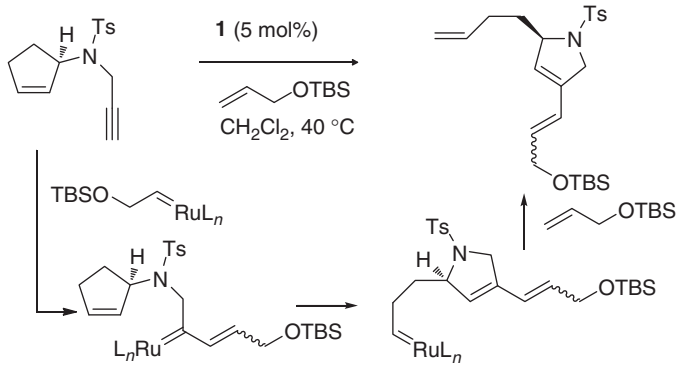
(71)



Entry	n	*Time (h)*	*Yield (%)*
1	1	24	56
2	2	1	75

Other alkenes can be added in the ring rearrangement enyne metathesis. Initial studies by Mori had focused on ethylene,[143] yet Blechert found that other alkenes could be incorporated into the resulting 1,3-diene (Table 21).[142]

In this example, the alkylidene is formed from the added silyl allyl ether that reacts with the alkyne, then triggers ring rearrangement onto the pendant cycloalkene to produce the triene product (Scheme 26). The site of reaction by the metal carbene can be influenced by propargylic ethers, which lead to alkene incorporation on the cycloalkene if propargylic ethers are present (not shown).[142]



Mori observed diastereospecific ring rearrangements with cyclohexenes bearing an endocyclic chiral center.[143] In these two examples, each conducted under ethylene, initial ethylene–alkyne metathesis produces a vinyl carbene (see inset of Scheme 27). To undergo ring rearrangement, the vinyl carbene must approach the pseudoaxial silylether to access the ruthenacyclobutane giving ring closing. This is impeded in the conformer shown. In the *trans*-diastereomer, this interaction is not present because the silylether resides in a pseudoequatorial position. The absence of this steric interaction allows the RCM onto the cyclohexene ring to proceed uneventfully (equation 74). The resulting triene is poised for intramolecular Diels–Alder cycloaddition after oxidation of the allylic alcohol.

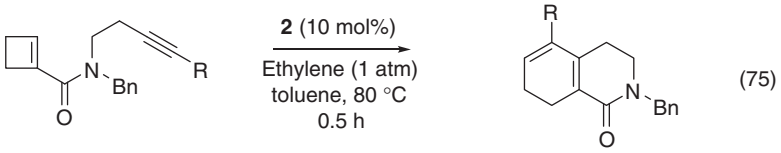
(73)

(74)

Scheme 27 Diastereospecific ring rearrangement enyne metathesis.[143]



The increased reactivity of the second-generation Grubbs carbene permitted more difficult ring rearrangements onto more highly substituted cyclohexenes. The first-generation carbene **1** could not open the cyclohexene and instead promoted ethylene cross-metathesis. Under more forcing conditions possible with **2**, a seven-membered ring carbocycle was obtained along with a trace dimeric product (Scheme 28).[148] The seven-membered ring was not expected; addition of the six-membered ring to the alkyne should have formed an eight-membered ring. The forcing conditions caused alkene isomerization via the intermediate triene **26**. Ruthenium hydride-promoted alkene isomerization is followed by reinitiation and RCM on the pendant diene, which resulted in the truncated ring rearrangement product. Under less forcing conditions (refluxing CH_2Cl_2), the desired eight-membered ring product was obtained as a minor coproduct along with the 1,3-cycloheptadiene and dimer.

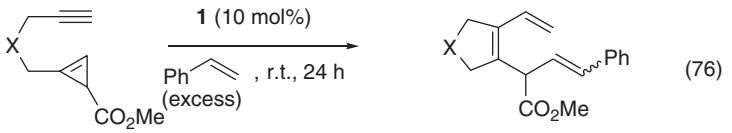
Scheme 28 Unexpected truncation product under more forcing ring rearrangement.[148]

Strained cycloalkenes also give the ring rearrangement (Table 22).[149] Given the potential for the cyclobutene to undergo competing ring-opening metathesis polymerization, ethylene is added. This is quite typical in RCM or metathesis cascades involving strained cycloalkenes. The added ethylene helps suppress polymerization of the strained cycloalkene. This net process is similar to the intermolecular synthesis of 1,3-cyclohexadienes using methylene-free conditions.[140]

Table 22 Ring rearrangement to form isoquinoline derivatives[149]

(75)

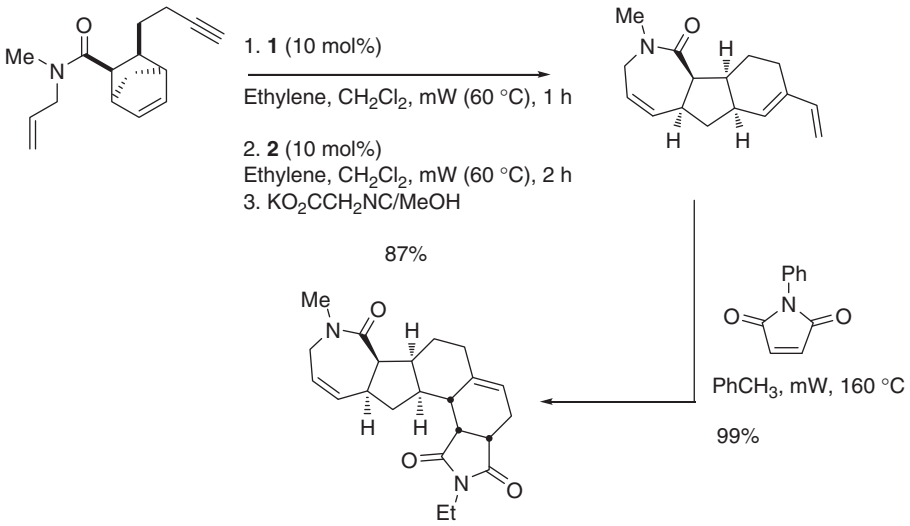
Entry	*R*	*Yield (%)*
1	H	61
2	Me	56
3	Ph	82



Ring rearrangement with cyclopropene-containing reactants provides skipped triene products. Ring opening of the cyclopropene is triggered by an external alkene such as styrene (equation 76; Table 23). As in the example above, an added alkene used in molar excess helps prevent homopolymerization of the strained cycloalkane, as demonstrated previously by Snapper et al. in selective ring-opening cycloalkene-alkene cross-metathesis.[150] The regioselectivity of the cyclopropene ring opening positions the carbene proximal to the alkyne. Ring closing onto the pendant alkyne results in the ring-rearranged product (equation 76).[151]

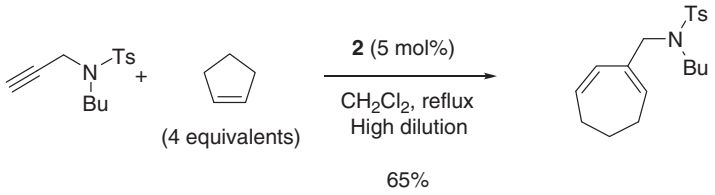
Metathesis cascades are extremely efficient for rapidly generating skeletal diversity. In Scheme 29, metathesis events are controlled in a stepwise process that capitalizes on catalyst attributes.[152] The overall process most likely begins with ethylene cross-metathesis joining the strained norbornene with the alkyne. The second-generation Grubbs catalyst would broker the formation of the seven-membered ring. To facilitate purification of the intermediate triene from the ruthenium catalysts, a polar isocyanide[39] is used to quench the catalysts and facilitate the removal of the organometallic impurities. Using microwave irradiation allowed Spring et al. to accelerate the metathesis and conduct a cycloaddition on the diene subunit to gain access to an additional ring.

5.27.6.2 Synthesis of 1,3-Cycloheptadienes



Like the ring rearrangement, an existing ring can be converted into a larger ring by net alkyne insertion. This is a ring expansion EYM that occurs as a result of a cascade process. In contrast to the ring rearrangement described in Section 5.27.6.1, ring

Table 23 Ring rearrangement involving cyclopropenes



(76)

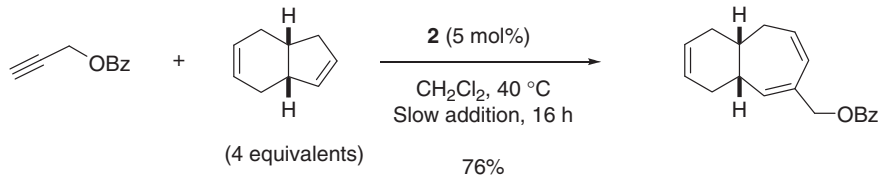
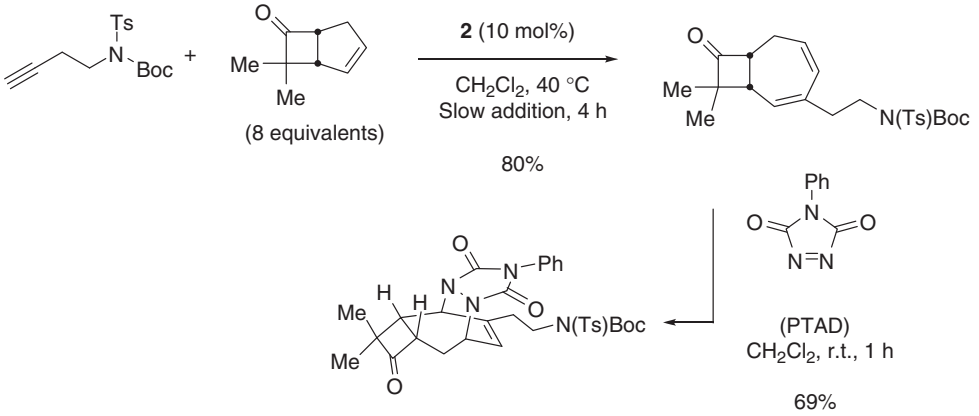
1	NTs	60	1:1.5
2	O	55	1:1.4



Scheme 29 Cascade metathesis to generate skeletal diversity.[152]

expansion is an intermolecular process. This makes the reaction more challenging. Moreover, because of the decreased reactivity with cycloalkenes in the intermolecular manifold, competing reactions such as alkyne polymerization become problematic. As a result, high dilution of the alkyne is needed along with a molar excess of the cycloalkene. An example of the ring expansion with cyclopentene is shown in equation 77. [153]

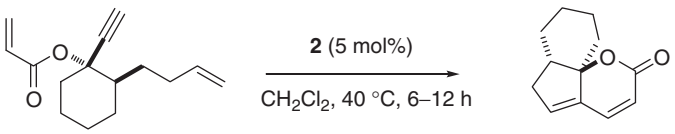


(77)

In bicyclic systems, the double bond in the five-membered ring reacts selectively. There are two issues: which alkene will react (site selectivity) and what is the orientation of the alkyne substituent in the product (regioselectivity). The ring opening of bicyclic diene proved highly selective and produced a single product[154] (equation 78). To obtain the desired product, slow addition of the reactive components to the Grubbs catalyst was needed via syringe pump addition. These reaction conditions benefit from a robust second-generation Grubbs catalyst, which must survive for an extended period of heating. Because ruthenacyclobutane ring openings are not generally stereoselective, the origin of the stereoselectivity is thought to arise from *E*/*Z* isomerization of vinyl carbenes occurring *in situ*.

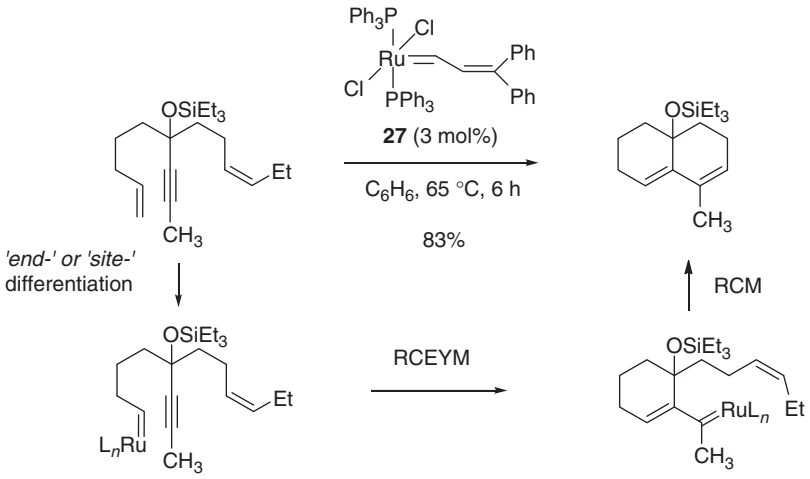
(78)

To guide regioselectivity in bicyclic systems, a bulky group at the allylic position is required. In the bicyclic ketone shown, the geminal dimethyl substituents guide the ring opening of the cyclopentene and give a single cycloheptadiene product (Scheme 30). Facile [4 + 2] cycloaddition with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) gives a crystalline tetracyclic product.



Scheme 30 Regioselectivity in the ring expansion of a bicyclic cyclopentene.[154]

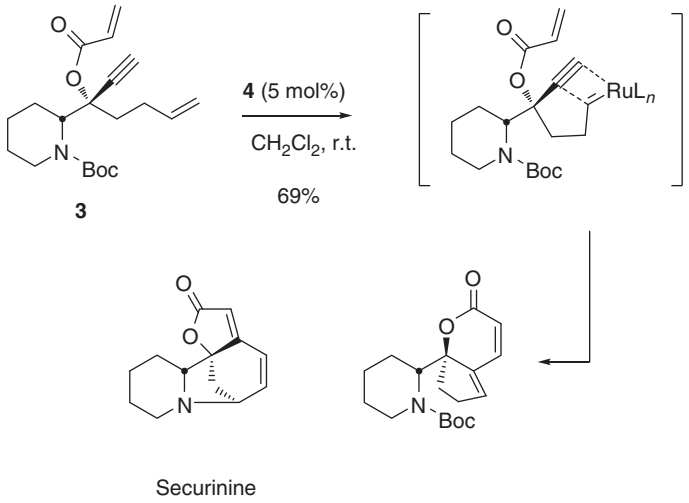
5.27.7 Cascade Enyne Metathesis



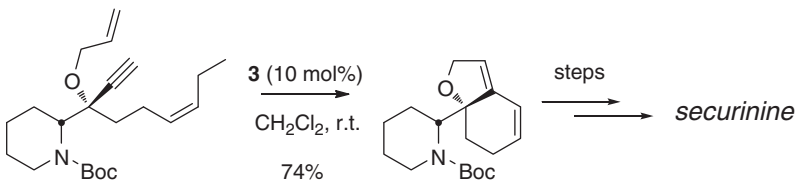
Cascade dienyne metathesis is a powerful ring-building method that furnishes multiple rings from acyclic precursors. Ring-forming reactions are very powerful transformations since many biologically active molecules contain one or several ring systems. The potential of cascade metathesis to produce different polycyclic ring systems from common precursors by using differential alkene reactivity has become an important method of generating skeletal diversity. A common theme in these reactions is the exploitation of the different reactivity of the alkenes, an important concept that borrows heavily from mechanistic understanding of alkene metathesis (the Grubbs model). The metathesis cascade begins with reaction of one alkene, ring closure onto the alkyne, and the next ring-forming metathesis by closure on the other alkene. Control can be achieved in unsymmetrical dienynes by rendering one alkene more reactive toward the metal carbene. Higher reactivity is achieved in less substituted alkenes that are not electron deficient. This serves to orchestrate the first ring closure onto the alkyne. The alkyne serves as a 'relay' linking the two ring closure events. Interestingly, the RCEYM is generally favored over a possible alkene–alkene RCM. The most commonly used catalysts are the Grubbs ruthenium benzylidene complexes **1** and **2**. A variety of small and medium-sized rings can be formed in this metathesis cascade. However, bulky groups may significantly slow down the RCEYM and attempted the eight-membered ring formation may lead to truncation products arising from undesired alkene isomerization side reactions.

The differential substitution of the pendant alkenes controls the ring size of the bicyclic system formed. Dienyne undergoes cascade metathesis with an earlier Grubbs catalyst **27** to provide the bicyclo[4.4.0]decane (Scheme 31).[155,156] This process begins by metal carbene formation on the 1-alkene, which achieves end differentiation. Had the other more substituted *cis*-alkene initiated, a bicyclo[5.3.0]decane would have resulted. Experimentally, these intramolecular metathesis cascades can be favored over intermolecular reactions by conducting the reaction at high dilution.

The same concepts of end differentiation apply to electronically distinct alkenes. In this case, the more electron-rich alkene initiates the cascade reaction (equation 79). The electron-poor acrylate reacts more slowly.[157] Interestingly, this study found that the initial RCEYM always out competed the ring-closing alkene–alkene metathesis. Along with the approach to securinine in the previous section, relative alkene reactivity provides useful information when planning metathesis cascades. In this case, the metathesis sequence produces bicyclic lactones containing the conjugated 1,3-diene.

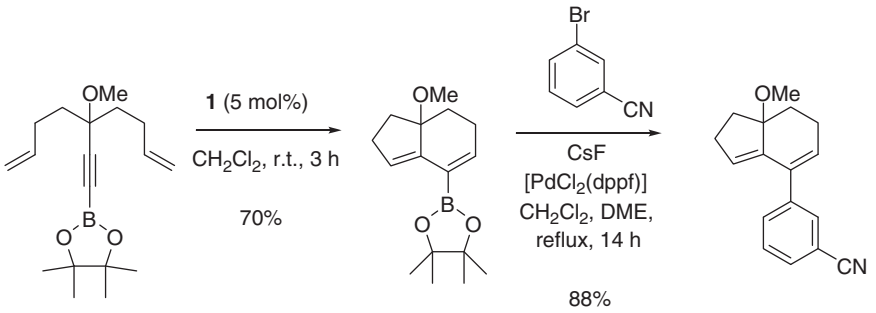


(79)



Scheme 31 Metathesis polycyclization and end group differentiation.[155]

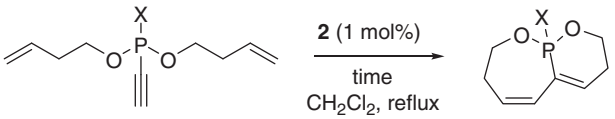
A tandem RCEYM that involves an electron-deficient alkene benefits from phosphine-free catalysts. Honda and coworkers prepared the *securinega* alkaloid securinine by a tandem enyne metathesis. The reaction began at the more electron-rich terminal alkene to give the observed product, which does not have the same bicyclic ring system found in securinine (**Scheme 32**).[158] The initial ring closure produced the five-membered ring rather than the desired six-membered ring present in securinine.



Scheme 32 Site differentiation with phosphine-free grela catalyst **4**.[158]

To obtain the desired bicycle, the initiation profile had to be reversed. In other words, the alkene of the enoate had to be rendered more reactive so it would initiate the cascade. From the Grubbs reactivity model of alkene cross-metathesis, terminal aliphatic alkenes are the most reactive with the Grubbs catalysts.[70] Dienyne bearing an allyl ether was used to initiate the cascade (equation 80). Simultaneously, the 'lower' alkene's reactivity had been tempered by converting it to a less reactive internal alkene. After a series of allylic oxidations, the synthesis of the alkaloid securinine was completed.

(80)



Boron-substituted alkynes participate in cascade cyclization to give products amenable to Suzuki coupling. Cascade metathesis with first-generation carbene **1** gave the bicyclic diene, which was cross-coupled with an aromatic ring under Pd(0) catalysis (equation 81).[159]

(81)

Phosphorus heterocycles can be accessed by a tandem ring-closing dienyne metathesis (equation 82; Table 24). The phosphorus-substituted alkyne proved reactive, despite its electron-deficient nature. Interestingly, the phosphine borane underwent successful RCEYM without reduction of the Grubbs catalyst. In this example, the equivalent reactivity of the terminal alkene means that the cascade can start at either end to produce the observed heterocycle.

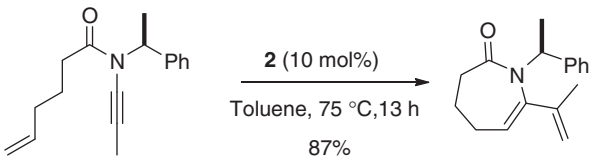


Table 24 Phosphorus-containing oxa-bicyclics

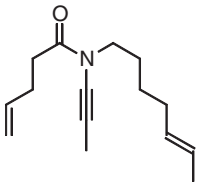
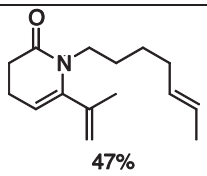
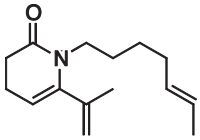
(82)

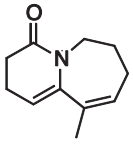
Entry	*X*	*Time (h)*	*Yield (%)*
1	O	0.5	76
2	BH_3	16	75

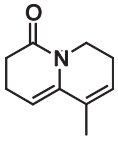
Electron-rich alkynes also participate in cascade ring-closing dienyne metathesis to bicyclic dienes with a nitrogen atom at a bridgehead position (equation 83).[160] These heterocycles are unsaturated homologs of the indolizidine alkaloids. If the second ring closure is difficult, such as in the eight-membered ring formation, the reaction may terminate after a single RCEYM to give a monocyclic product (entry 1; Table 25). When the second ring-forming step is slow, the by-products associated with double-bond migration are observed (entry 2). Competing reactions leading to by-products can be anticipated due to high temperatures required to form eight-membered rings, a process disfavored due to the negative entropy associated with ring closure. With two similar ends of dienyne, the reaction cascade begins at either side to give a 1:1 mixture of bicyclic products. If the initiation is inhibited at one site, the other more reactive terminal alkene triggers the cascade giving predominantly one bicyclic product. A similar example can be found in Section 5.27.6.1.

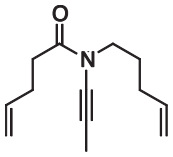


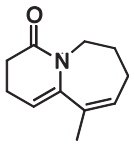


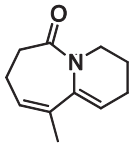


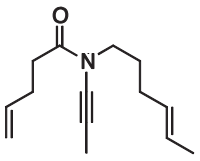


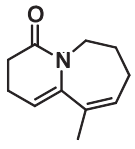


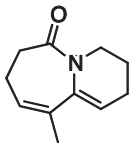






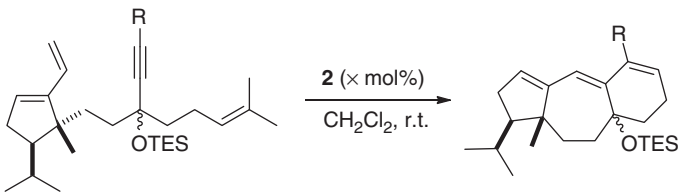






(83)

The cascade metathesis has also been used as an entry point to bicyclic ring systems that contain seven-membered rings. Seven-membered rings can be found in a variety of natural products. The polycyclization has been employed to gain access to the guanacastepene carbotricyclic framework[161,162] (equation 84; Table 26). A variety of substituents on the alkyne were tolerated in the metathesis, with the exception of a TMS group that is presumably too bulky to permit the alkyne insertion step. Interestingly the ring-closing cascade begins from the vinyl appendage of the diene, and this requires the use of the more reactive second-generation Grubbs catalyst.



The unsaturated tricyclic ring system of colchicine was made through a polycyclization by cascade metathesis[163] (Scheme 33). A free propargylic hydroxyl group prevented the metathesis, so protection as the TMS ether was required (a similar solution has been used in a related RCEYM).[114] (To the authors' knowledge, the only cases where a free propargylic hydroxyl group is allowed is ethylene–alkyne cross-metathesis.) In this case, a clever oxidative [3,3] sigmatropic rearrangement was used to alter the diene substitution pattern and accomplish the oxidation of the secondary chromate ester. The epimers proved inconsequential as the oxidative rearrangement converged to the enone product. The PCC oxidative rearrangement is an interesting organic transformation applied to the dienes obtained through enyne metathesis.

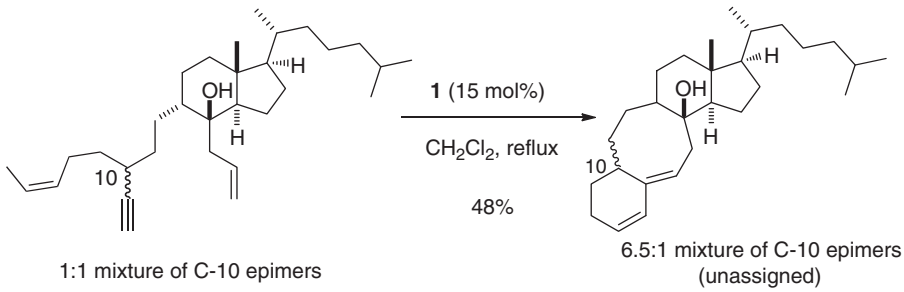
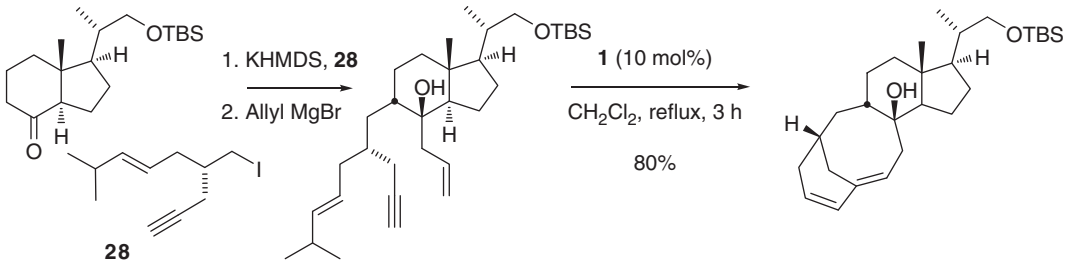
Guanacastepene A



In the above two examples, the introduction of the alkyne into the reactant is difficult to control, which required that the diastereomeric mixture be carried through the synthesis. This serves to highlight one of the difficulties in the synthetic preparation of the required polyunsaturated substrates (dienynes in this case). In more rigid systems with existing stereocenters, the presence

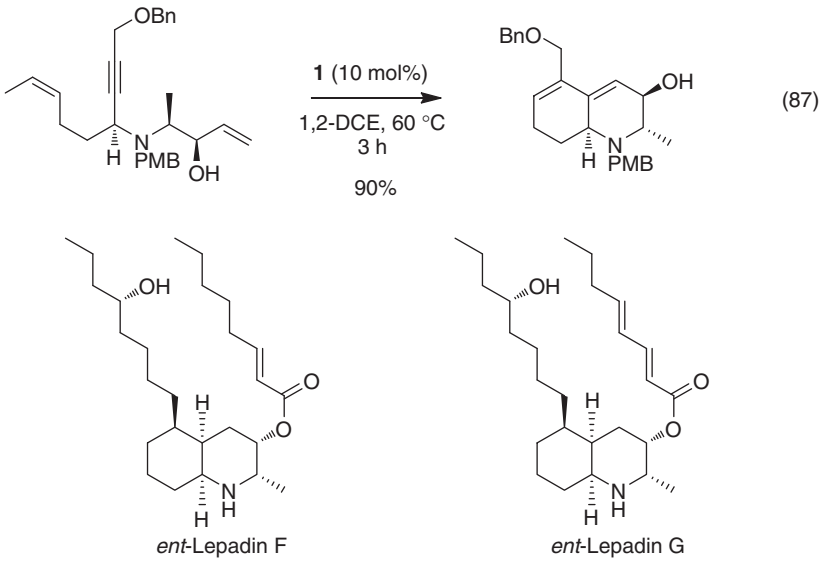
Scheme 33 Polycyclization approach to colchicines.[163]



of epimers might result in kinetic differentiation, as observed by Clark et al. previously.[164] Some evidence of this diastereodifferentiation can be found in the next example.

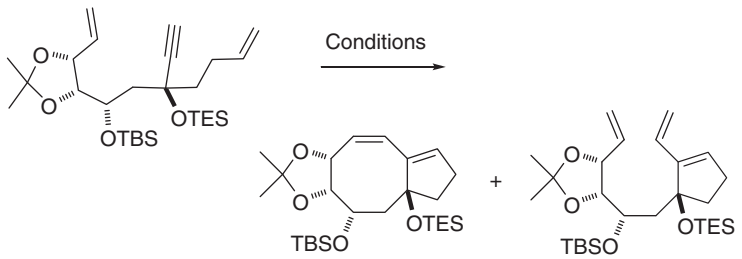
The metathesis cascade can also furnish eight-membered rings. In the first ring closure, an eight-membered ring is formed in the synthesis of a vitamin D_3 transition-state analog[165] (equation 85). In this case, the first-generation Grubbs carbene was employed, and the cyclization was conducted under high-dilution conditions (4.7 mM in CH_2Cl_2). A 1.7:1.0 mixture of diasteromers resulted in a product consisting of a 6.5:1 mixture of C-10 diastereomers yield, which suggests that one epimer cyclized more favorably than the other.

(85)



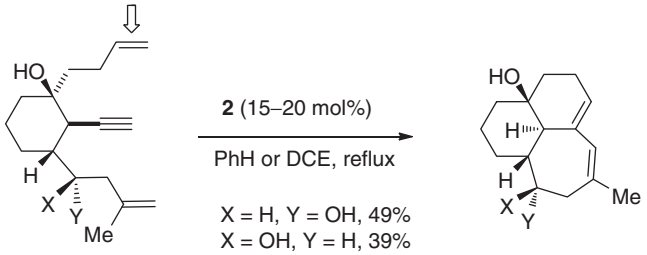
Remarkably, the strained bicyclic [5.3.1] ring system found in taxol can be formed by a metathesis cascade. In this study, Granja et al.[166,167] found that the catalyst **1** gave the best results in their approach to 'taxosteroids' (equation 86). The cascade is initiated at the homoallylic alcohol to form the eight-membered ring in the initial enyne metathesis ring closure. To ensure end differentiation of the alkenes and to avoid formation of the alternative bicycle starting from a five-membered ring, the kinetic decelerating substitution of the pendant alkene was systematically evaluated. An optimum balance of reactivity was achieved by the use of the isopropyl-substituted alkene, as a trisubstituted alkene did not undergo the second ring closure. This study shows that a successful bicyclization depends on the proper choice of alkene substitution to achieve end differentiation.

(86)

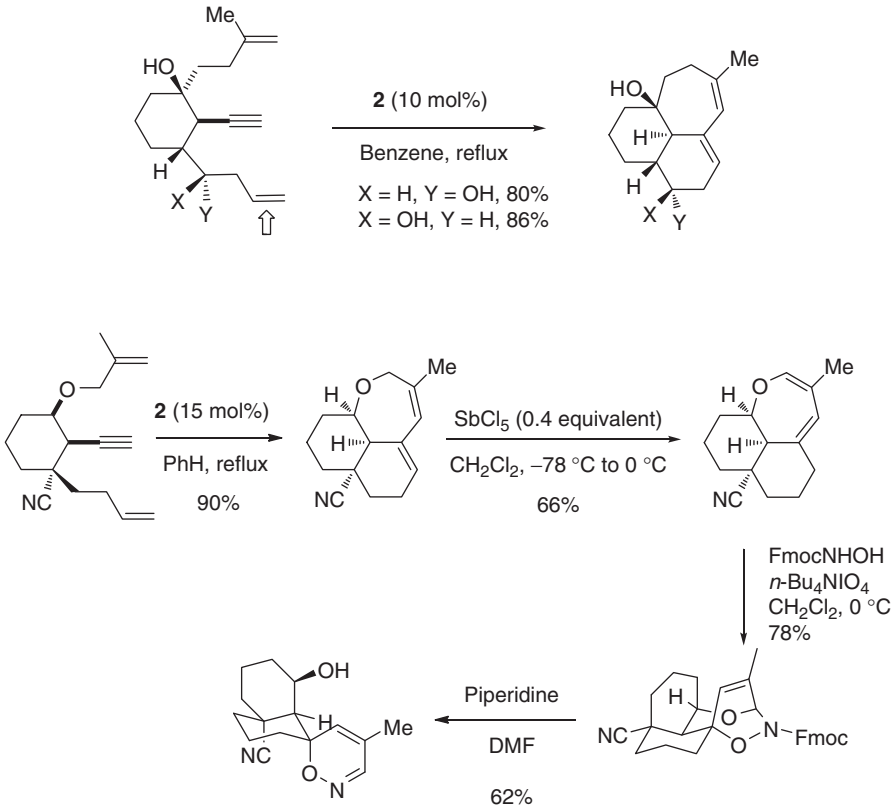


Tandem dienyne RCM can access bicyclic systems containing a heterocyclic ring. As a key step in their synthesis of lepadin F and G, the skeletal synthesis by tandem dienyne metathesis was achieved in a 90% yield (equation 87, Scheme 34).[168] The hexahydroquinoline ring system was carried forward to provide the first total synthesis of lepadin F and G.

In a highly oxygenated environment, the reactivity difference between the first- and second-generation Grubbs carbenes determined the success of the second ring closure. The first-generation catalyst **1** gave RCEYM beginning with the most reactive



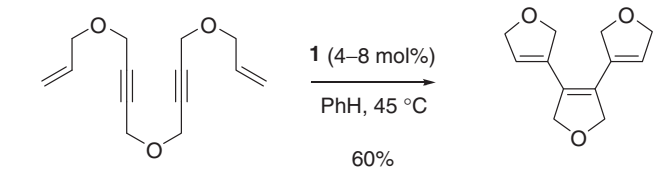
Scheme 34 Dienyne metathesis cascade approach to the lepadins.[168]

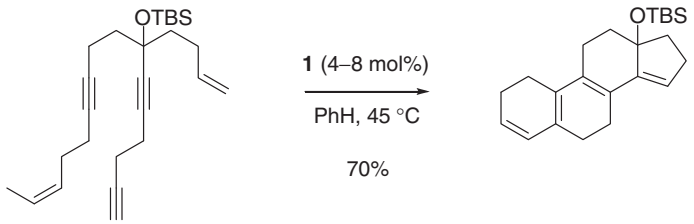


alkene and the reaction stopped at the triene stage (equation 88).[169] To encourage the second cyclization, the more reactive Grubbs complex **2** was employed.

1 (20 mol%), PhH, reflux, 17 h	–	85%
2 (10 mol%), CH_2Cl_2, reflux, 24 h	94%	–

Polycyclization using tandem RCEYM proved to be an effective strategy to generate diverse structural analogs of the anti-trypanosomal agent artemisinin. An advantage of the site differentiation is the ability to access different cyclic core structures, depending on the placement of the initiating alkene (equations 89 and 90).[170] This approach is highly attractive for the construction of unique polycyclic frameworks that could be used in directed library synthesis or DOS. To complete the synthesis of structural analogs, dienyl isomerization was required. After screening several different Brønsted and Lewis acids, catalytic SbF_5 was used to produce the endocyclic diene (**Scheme 35**). The endocyclic diene underwent cycloaddition with an *in situ*-generated acyl nitroso dienophile giving a cycloadduct, which rearranged during Fmoc deprotection to the unusual spirofused oxazine.

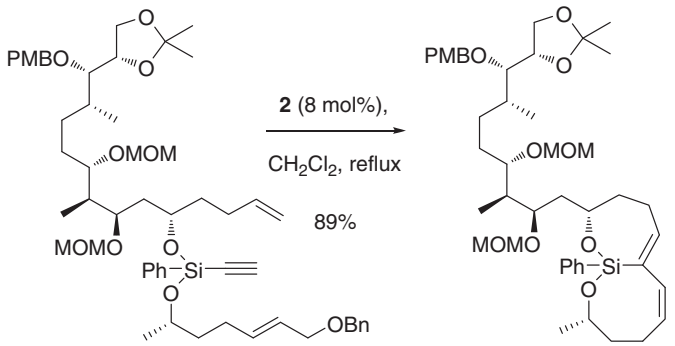




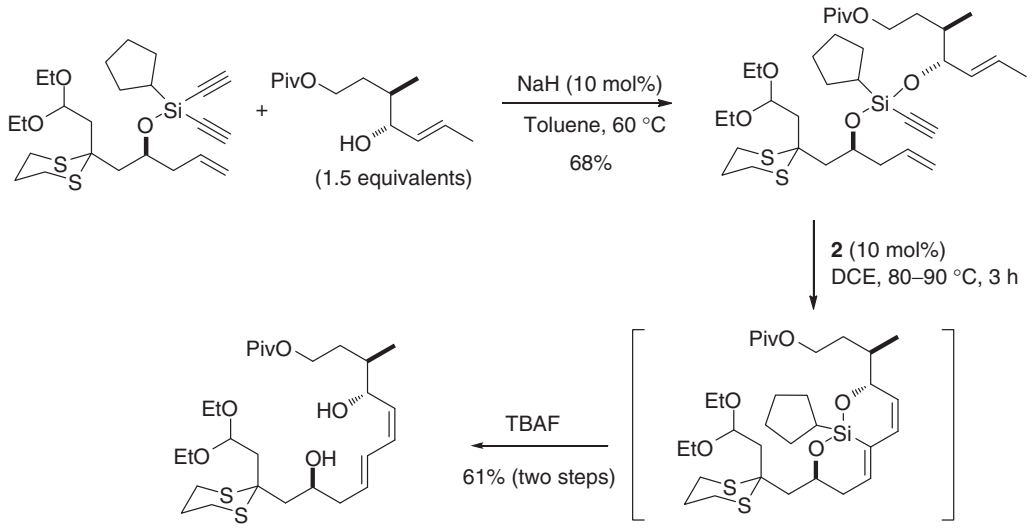
(90)

Scheme 35 Cascade metathesis and dienyl isomerization sequence.[170]

Polycyclization by cascade metathesis proceeds with multiple alkynes situated in between the starting and terminating alkenes. Arranged in this way, the additional alkyne(s) react with the intermediate vinyl carbenes to produce new vinyl carbenes, which eventually terminate. Oxygen heterocycles (equation 91) are easily made as well as the steroid-like tetracycle (equation 92).[171]



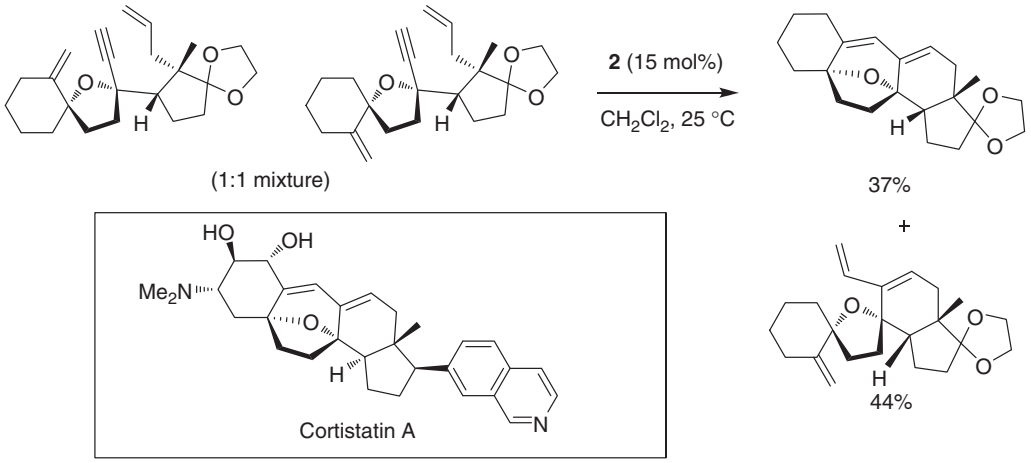
(91)



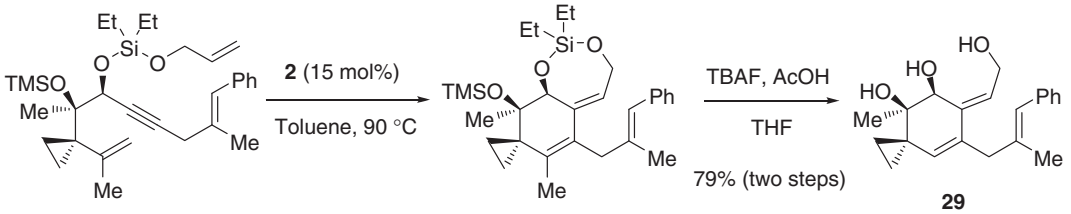
(92)

Siloxane linkers can be used to preorganize unsaturated reactants and then removed to provide stereocontrolled synthesis of 1,3-dienes.[172] This strategy was employed by Kim and Lee for the construction of the unsaturated carbon framework of tartrolon B (equation 93). The silicon atom is used to temporarily connect the alkyne and alkene fragments, similar to the use of boronate linkers by Schreiber and Micalizio.[111,112] Reactivity differences in the two alkenes achieve site differentiation, which resulted in the initial formation of the seven-membered ring. Once the cascade RCM has occurred, the silicon is removed by desilylation using a fluoride source such as TBAF. In this tandem sequence of reactions, various end substitutions on the 1,3-diene can be obtained.

(93)

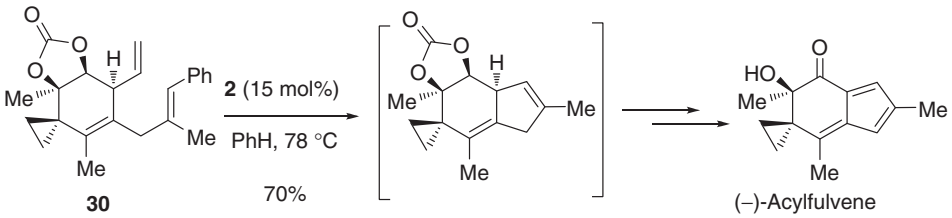


The temporary siloxane linker was used to furnish the 1,3-diene segment of cochleamycin. Access to the mixed silaketal is provided by base-catalyzed replacement of an acetylide with the secondary alcohol. The mixed silaketal sets the stage for the cascade EYM. The control of the rings formed utilized end differentiation, where the more reactive unsubstituted alkene triggered the cascade process (**Scheme 36**). Stereospecific removal of the siloxane was accomplished with TBAF. More recent approaches to the stereoselective synthesis of macrocyclic dienes include the use of site-specific ring-closing alkene–diene metathesis,[173] but this is not detailed in this chapter.



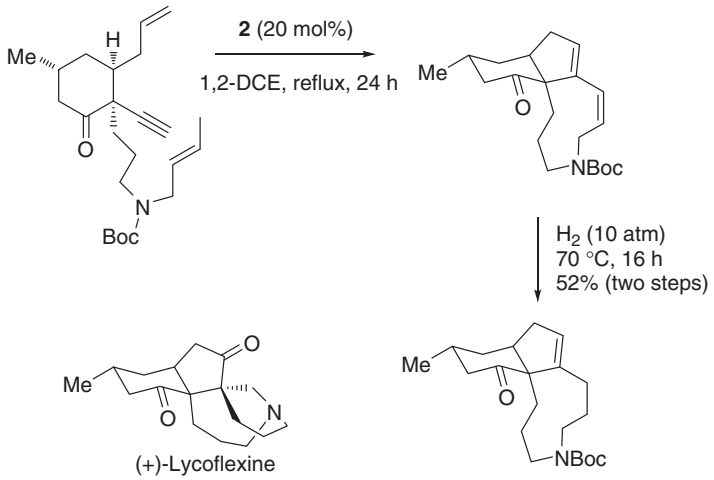
Scheme 36 Siloxane-mediated cascade EYM for stereocontrolled diene synthesis.

The polycyclic core of cortistatin A was accessible by cascade dieneyne RCM. Stolz and coworkers utilized a 1:1 mixture of diastereomers in the cascade metathesis that was triggered by the second-generation Grubbs carbene (**Scheme 37**).[174] As a result, a 37% isolated yield of the desired core ring system was obtained, along with 44% yield of a by-product arising from the other diastereomer. Interestingly, the alternate diastereomer gives a single RCM since the geminal alkene is not able to capture the vinyl carbene intermediate. This shows that cascade enyne metathesis is a rapid method for the construction of the carbocyclic core of cortistatin A.



A casacade RCM was used to assemble the core ring system of the spirotricyclic natural product acylfulvene.[175] The metathesis cascade (which was studied extensively in model systems)[176] was initiated by the second-generation Grubbs complex to afford an intermediate tricyclic diene, which was deprotected *in situ* to give the triol **29** (equation 94). The bond-forming events are orchestrated by alkene reactivity; the most reactive allyl ether initiated the cascade and the less reactive geminally disubstituted alkene terminated it. After the tandem reaction, the 1,3-diene was reductively transposed using the Myers protocol for the *in situ* generation of the diazene, giving **30**. This synthetic tactic manages to convert the conjugated 1,3-diene into a 1,4-diene. After the transposition, a ring-closing alkene metathesis of **30** gained access to all three rings of the natural product (–)-acylfulvene (equation 95). This combination of tandem enyne metathesis and a clever diene isomerization stands as an inspiring example of cascade metathesis in the service of total synthesis.

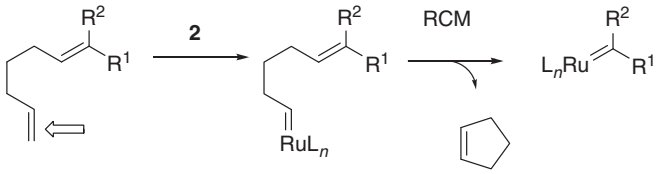
Scheme 37 Cascade metathesis approach to Cortistatin A.[174]



(94)

(95)

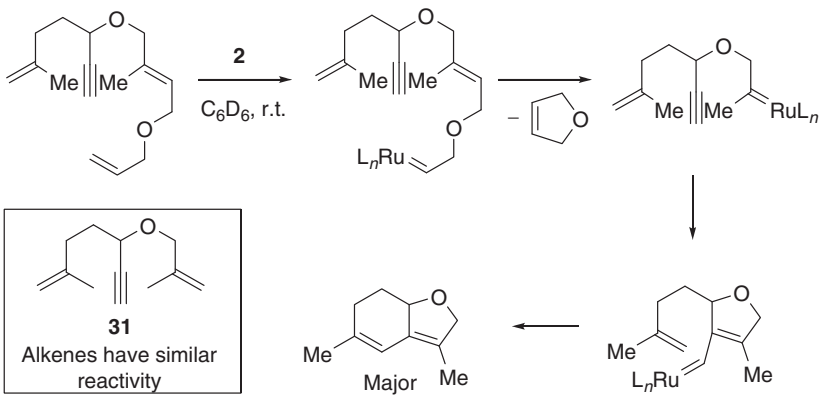
A concise tandem ring-closing dienyne metathesis was used to assemble the core polycyclic framework of the alkaloid lycoflexine.[177] The ring-closing event was initiated at the more reactive terminal alkene to first form the five-membered ring (Scheme 38). Strikingly, the second ring closure generated the nine-membered azacyclic ring. The 1,3-diene was semihydrogenated in a site-selective reduction step where the residual Grubbs catalyst was transformed into a ruthenium hydride, giving a ruthenium hydride catalyst that selectively reduced the diene fragment. Such use of tandem catalysis under hydrogenation (H_2) or transfer hydrogenation conditions has been previously employed in ring-closing alkene metathesis/hydrogenation tandem reactions.[75]



Scheme 38 Cascade metathesis approach to the alkaloid lycoflexine.[177]

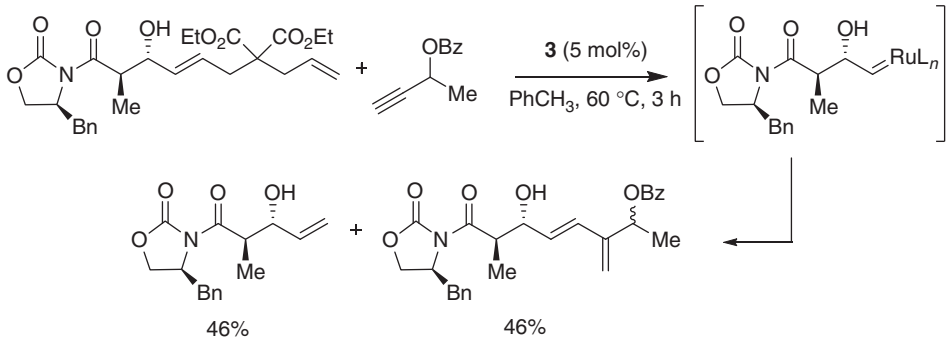
5.27.8 Choreographed Movement of Metal Carbenes in Enyne Metathesis Cascades

In the previous section, differential alkene reactivity guided the movement of the carbene to the alkyne, thereby controlling ring size in the resulting bi- or polycyclic frameworks (end differentiation). In this section, a directing alkene is used to guide the metal carbene to a less reactive site through RCM. In the process, the five-membered ring is extruded and lost. This tactic allows for the formation of a metal carbene that would otherwise be difficult or impossible to form. This choreographed movement of metal carbenes is called 'relay RCM' (rRCM). It has been used several times in alkene metathesis literature to guide RCM. The applications to enyne metathesis are somewhat fewer, but ironically it is here that the reaction was discovered. Some recent applications have conjoined rRCM in tandem with distinct reactions such as metallotropic shift.



5.27.8.1 Relay Metathesis or rRCM

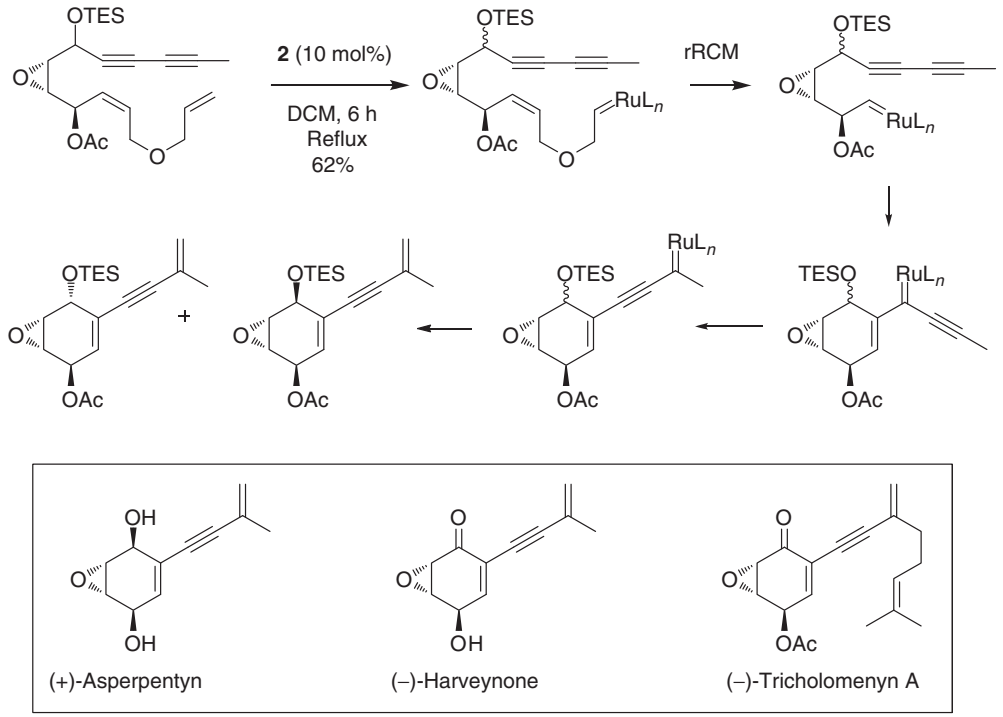
The relay ring-forming metathesis strategy developed by Hoye is designed to use a favorable RCM to position the metal carbene, usually at a less reactive alkene site. The relay metathesis strategy overcomes the problem of generating reactivity at an unreactive or less reactive alkene site. Hoye and coworkers[178] developed a procedure where a pendant alkene serves as an initiation locus (equation 96). The strategy cleverly exploits alkene reactivity preferences to orchestrate a metathesis cascade. Initiation at the terminal alkene leads to the intermediate metal carbene that undergoes RCM. The RCM step is associated with the loss of a cyclic alkene that translocates the carbene to a site that was not accessible by direct, intermolecular catalyst initiation.



(96)

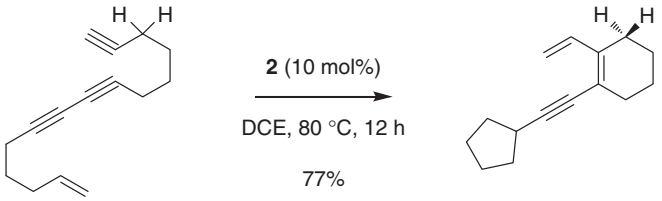
In addition to its utility for cyclizing unreactive dienes, this strategy can be used to steer metathesis when more than one option is available. The dienyne **31** shown in the inset of Scheme 39 contains two relatively unreactive alkenes. Cascade metathesis is triggered nearly equally at each site, giving a mixture of two products. By adding a terminal alkene three atoms away from the desired site of reaction, higher selectivity is obtained to give one major product due to choreographed metathesis as depicted in Scheme 39. The terminal alkene is the initiating point and through the RCM positions the metal carbene appropriately. Geminally substituted alkenes are difficult to initiate with the Grubbs carbenes; one case of strain assistance was seen previously.[68] The rRCM achieves site selectivity when the starting material has two reactive alkenes. If the relay is triggered on the other side, the opposite site selectivity is obtained producing the alternate bicyclic ring system that contains a pyran ring (product not shown).

Scheme 39 Site selectivity with rRCM.[178]



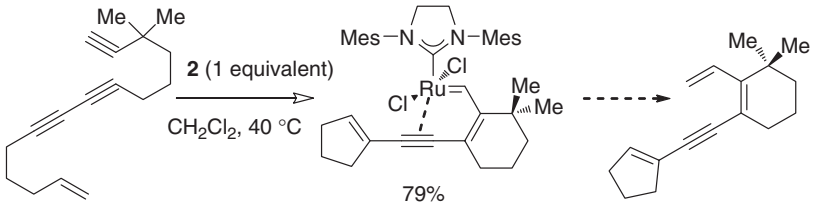
Using the rRCM strategy, Diver and coworkers set the stage for a CEYM.[179] A dienal underwent a catalytic Evans aldol reaction (reaction not shown), and subsequently the Hoveyda–Blechert carbene **3** was used to trigger the relay metathesis in the presence of an external alkyne. The rRCM extrudes a cycloalkene to form an intermediate metal carbene (Scheme 40). In this way, ene–yne cross-metathesis occurs *in situ* with butynyl benzoate, providing a highly functionalized 1,3-diene in a good yield. With 1:1 stoichiometry of alkene and alkyne, the intermediate metal carbene did not completely react with butynyl benzoate such that some *anti*-allylic alcohol was isolated as a coproduct.

Scheme 40 rRCM/CEYM sequence.[179]



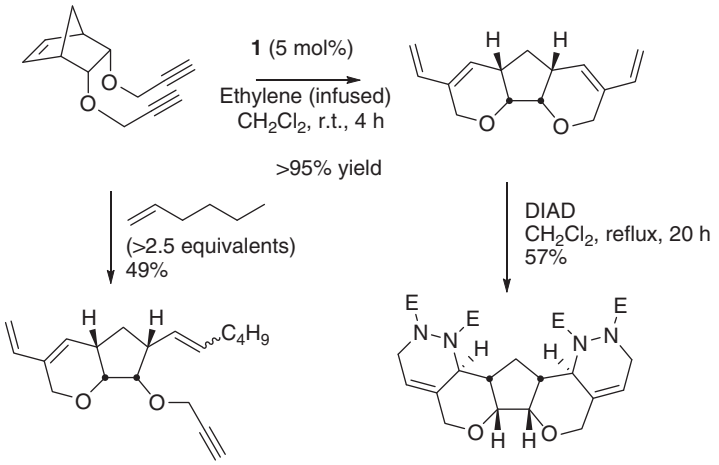
5.27.8.2 Ring-Closing Enyne Metathesis with Metallatropic Shift

Relay ring closing has been conjoined with RCEYM and metallatropic shift as an approach to oxygenated natural products containing an unsaturated sidechain. Lee and coworkers began with a mixture of diastereomers and subjected them to tandem enyne metathesis metallotropic [1,3]-shift for a concise total syntheses of (+)-aperpentyn, (–)-harveynone, and (–)-tricholomenyn A (Scheme 41).[180] The two diastereomers were formed collectively in 62% yield and proved separable by flash chromatography. These were carried forward to give the desired natural products.



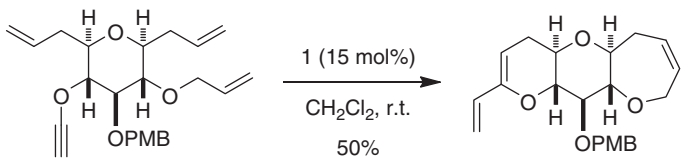
Scheme 41 Access to natural products using polycyclization/metallatropy cascade.[180]

While studying metathesis cascades involving metallatropic shift, Lee and coworkers identified a stable ruthenium alkylidene complex bearing a coordinated alkyne.[181] In one case, a diendiyne gave the expected cascade product (equation 97). With the geminally substituted dimethyl analog, exposure of the entriyne to 1 equivalent of catalyst **2** in refluxing DCM for 6 h gave an alkyne-chelated ruthenium alkylidene complex instead of the expected metathesis product (equation 98). This stable metal carbene was formed through an RCEYM, metallatropic shift, and another RCEYM to produce the vinyl carbene. The rigidity of the cyclohexene ring enforces a favorable coordination geometry that discourages ligand exchange and hence limits the last step of metathesis.



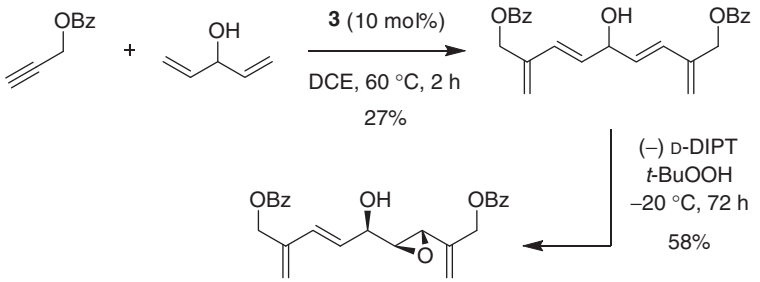
(97)

(98)



5.27.9 Double-Directional Synthesis

A particularly dramatic example of the ring rearrangement enyne metathesis employed a strained norbornene that reacted with two alkynes in a two-directional manner. In this case, each alkyne underwent RCM with the proximate end of the cycloalkene, giving the linear tricycle (Scheme 42).[182,183] The two 1,3-dienes were subsequently trapped in a cycloaddition step to form the linear pentacycle. With an added aliphatic alkene, ring opening of the norbornene takes place first and only one alkyne participates in ring closure, giving the bicyclic diene.



Scheme 42 Double-ring rearrangement enyne metathesis.[182]

Double-directional synthesis involving enyne and alkene metathesis was employed to access the polyether framework found in the ciguatoxins and brevetoxins. Polycyclic ethers such as those found in CTX-30 are a synthetic challenge due to the complexity of their polycyclic ring system. Clark and Hamelin found a two-directional double RCM to be a useful strategy in the synthesis of polycyclic ethers containing complex medium-sized rings (equation 99).[184] The example depicted below uses 15 mol% of the first-generation Grubbs catalyst to perform RCEYM and a ring-closing alkene metathesis simultaneously. This resulted in an efficient synthesis of the ABC ring system found in CTX-3C.

(99)

Achieving stoichiometric equivalency in CEYM permits the use of a bifunctional alkene substrate for a linear two-directional synthesis. Under standard cross metathesis conditions, this would be inconceivable because the alkene is used in molar excess. An excess of the alkene would have prevented double substitution of a diene reactant. In this case, divinyl carbinol was reacted with a twofold excess of propargyl benzoate to give the resulting tetraene in 27% yield (Scheme 43).[50] With the unprotected hydroxyl group present in the product, a site-selective desymmetrization was achieved through a directed sharpless asymmetric epoxidation.

Scheme 43 Two-directional EYM with divinylcarbinol.[50]

5.27.10 Conclusion and Outlook

EYM provides an efficient catalytic method for diene synthesis using simple unsaturated reactants. The reaction shows excellent functional group tolerance characteristic of the Grubbs ruthenium carbenes. That the ruthenium carbenes are widely available and easy to use can explain the wide range of applications in organic synthesis. Some of the appeal is the accessibility of the simple reactants and the reactivity of the resulting 1,3-dienes. The unique reactivity of 1,3-dienes can be harnessed in cycloaddition reactions. This sequence translates into a rapid gain in structural complexity. Interest in enyne metathesis has closely followed interest in complex molecules and heterocycles, and there has been increasing use of metathesis in total synthesis. These successes have helped to maintain momentum in the field, further emboldened by successful EYM used in tandem with other bond-forming processes. These successes, combined with continuing improvements in substrate scope and a refined understanding of reaction mechanism, have made EYM a useful synthetic method for C–C bond construction.

RCM has seen diverse applications to a variety of ring sizes and for the construction of different heterocyclic rings. Some recent topics that utilize the economy of the enyne metathesis and recognize the utility of the 1,3-diene product include DOS, or the synthesis of platforms that array functional groups in a stereodefined way. It was also seen that a number of tandem reactions are joined with the enyne metathesis, some distinct bond-forming processes such as cycloaddition or metallotropic shift, and others involving additional metathesis steps. The cascade metathesis applications have tremendous potential to generate polycyclic structures in one step. The potential chemistry here is expansive and is open to the imagination and limited perhaps only by the level of difficulty in obtaining the acyclic polyeneyne precursors. Control of the formed ring in polypendant dienynes is controlled through alkene reactivity, which in turn achieves site differentiation. Control of carbene positioning has been achieved through orchestrated movement of carbenes known as relay enyne metathesis.

In CEYM applications, a molar excess of the alkene is typically used to drive the EYM forward. However, in the best cases, nearly equimolar amounts of the alkene and alkyne can be used. In these cases, the EYM is a carbon–carbon cross-coupling, with a reorganization of the π-bonds. Some of the other exciting applications include the ring rearrangements to form heterocyclic rings, and ring construction and ring expansion methods.

There are still growth areas for EYM. Some of the unresolved difficulties in EYM include poor control of alkene geometry, high catalyst loadings, and oftentimes the need for a large excess of alkene reactant. Some applications such as ring building capitalize on *in situ* isomerization to access the *Z*-geometry. *Z*-Selectivity is unsolved in acyclic EYM and there are currently no catalysts to overcome this shortcoming, despite the very recent advances in *Z*-selective alkene metathesis catalysts. Though the mechanism has been studied, the rate profile with a wide assortment of alkynes and alkenes has not been fully elucidated. This will be useful to guide future synthetic efforts with less reactive unsaturated reactants.

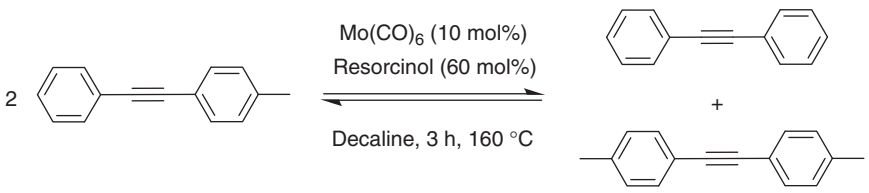
Glossary

Alkyne metathesis Reaction leading to the mutual exchange of the alkylidyne units between a pair of (nonterminal) acetylene derivatives.

Ancillary ligands Permanent ligands to a transition metal catalyst that are not directly involved in the catalytic process, yet may exert a strong influence on activity and stability.



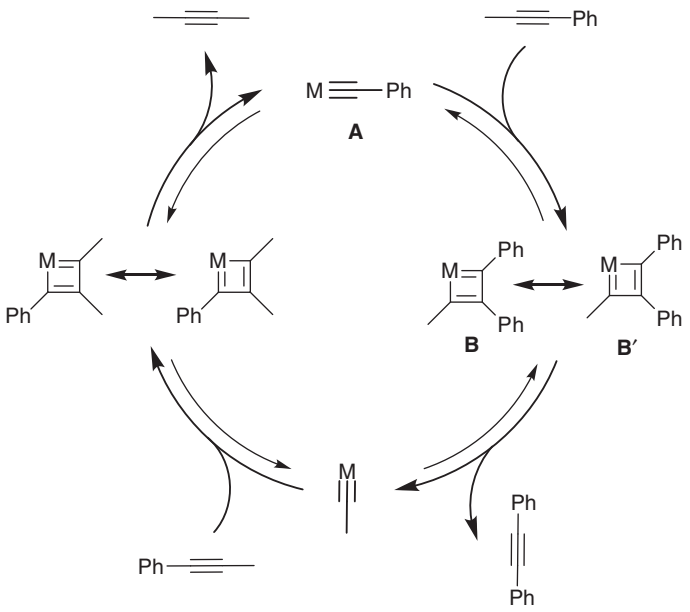
Ate-complex Salt, the anion of which is a negatively charged transition metal complex.

Fischer carbyne Transition metal complexes discovered by Prof. E. O. Fischer, which are distinguished by a triple bond between a carbon-based ligand and a transition metal in a low oxidation state; prototype examples are $[Br(CO)_4M{\equiv}CPh]$ (M = Cr, Mo, W); their LUMO is largely made up by the π^*-orbitals of the metal–carbon bond, which renders such complexes susceptible to nucleophilic attack at the carbyne carbon atom.

Schrock alkylidyne Transition-metal complexes discovered by Prof. R. R. Schrock, featuring a triple bond between a carbon-based ligand and a transition metal in (usually) the highest possible formal oxidation state (d°). The tungsten complex $[(t\text{-BuO})_3W{\equiv}CCMe_3]$ serving as a standard catalyst for alkyne metathesis represents a prototype example; Schrock alkylidyne complexes are nucleophilic at the alkylidyne carbon atom.

5.28.1 Introduction

The tremendous success of alkene metathesis during the past two decades[1–3] has overshadowed the fact that π-systems other than olefins can also be scrambled by related mutual exchange processes with the aid of transition metal catalysts. For nonterminal alkynes, this is known since 1968, when Penella and coworkers disclosed that the two inequivalent alkylidyne units of 2-pentyne get statistically redistributed on exposure of this substrate to a heterogeneous catalyst consisting of WO_3 (6.8% *w*/*w*) on silica.[4] The impact of this discovery on synthesis remained limited, not least because of the very harsh reaction conditions (200–450 °C) that led to competing polymerization. A few years later, Mortreux and coworkers showed that the same type of transformation, which was called 'alkyne metathesis' from there on, can also be achieved in homogeneous phase (**Scheme 1**).[5] Specifically, a mixture of $Mo(CO)_6$ (10 mol%) and resorcinol (60 mol%) in decaline at 160 °C was found to equilibrate 1-methyl-4-(phenylethynyl)benzene within 3 h to a mixture comprising the substrate (55%), diphenylacetylene (23.5%), and bis(*p*-tolyl)acetylene



Scheme 1 Original discovery of alkyne metathesis in homogeneous phase.

(21.5%). The fact that the products were formed in equal amounts, within the limits of detection, was taken as an indication that a metathetic process must have taken place in solution.[5,6]

Many variants of this original catalyst recipe were explored later on by changing the molybdenum source, the phenol activator, the solvent, and/or by using additional additives. Although the actual catalyst species formed *in situ* has not been unambiguously characterized so far, it is highly likely that it is a molybdenum alkylidyne endowed with one or more phenolate ligands (or a blend of several such species). This open question notwithstanding, 'Mortreux-type' mixtures still enjoy some popularity because of the preparative convenience and the use of cheap and bench-stable ingredients. Their scope, however, is limited by the typically harsh conditions and a restricted functional group tolerance (see Section 5.28.2).

A significant leap forward was made when the mechanism of alkyne metathesis could be established beyond doubt. Penella et al. originally envisaged a scenario based on direct [2 + 2] cycloadditions/cycloreversions of the two alkyne substrate molecules;[4] in contrast to this proposal, Katz and McGinnis advocated a mechanism following the logic of the Chauvin cycle of olefin metathesis (Scheme 2).[7] Specifically, they suggested that a catalyst species **A** comprising a carbon–metal triple bond as the reactive unit undergoes a formal [2 + 2] cycloaddition with the substrate to give a metallacyclobutadiene complex that is adequately described by the two mesomeric extremes **B** and **B′**. Cycloreversion of **B′** forms the product and regenerates a competent catalyst entity, which then undergoes the exact same steps to close the catalytic cycle.

Scheme 2 Generally accepted mechanism of alkyne metathesis spelled out for the conversion of 1-phenyl-1-propyne to tolane and 2-butyne; the latter needs to be removed from the mixture to drive the reaction forward, otherwise an equilibrium is reached.

Somewhat surprisingly however, the Fischer–carbyne complexes[8] known at the time when this mechanistic proposal was published were essentially inactive, even though they comprise a carbon–metal triple bond. According to the conventions of organometallic chemistry, the metal center in Fischer–carbynes is usually considered 'low-valent' and the carbyne unit counted as a monoanionic ligand.[9] It was only after the discovery of their 'high-valent' relatives, the so-called Schrock alkylidynes,[2,10,11] that the mechanistic hypothesis depicted in Scheme 2 could be brilliantly validated.[12,13] Many Schrock alkylidynes of tungsten, molybdenum, and rhenium exhibit good-to-excellent catalytic activities; the corresponding metallacyclobutadiene complexes formed in the [2 + 2] cycloaddition step were shown to be intermediates rather than transition states. They actually represent the catalyst resting state since the loss of the product alkyne from the metallacycle is rate-determining, at least for the specific tungsten complexes invesigated. Details are outlined in Section 5.28.3.

The catalytic activity and the functional group tolerance of Schrock alkylidynes is largely determined by the chosen ancillary ligands. Whereas alkylidynes bearing halide-, (branched) alkyl-, carboxylate-, or thiolate ligands were found by and large inadequate, the use of *tert*-alkoxides, branched fluorinated alkoxides, sterically hindered phenolates, certain amides, imidazoline-2-iminato groups, and in particular, silanolates have been employed with great success in various formats. Figure 1 displays the most common Schrock alkylidynes, although other variants have also been described. All of these complexes are quite sensitive to moisture and need to be handled and stored under inert atmosphere.

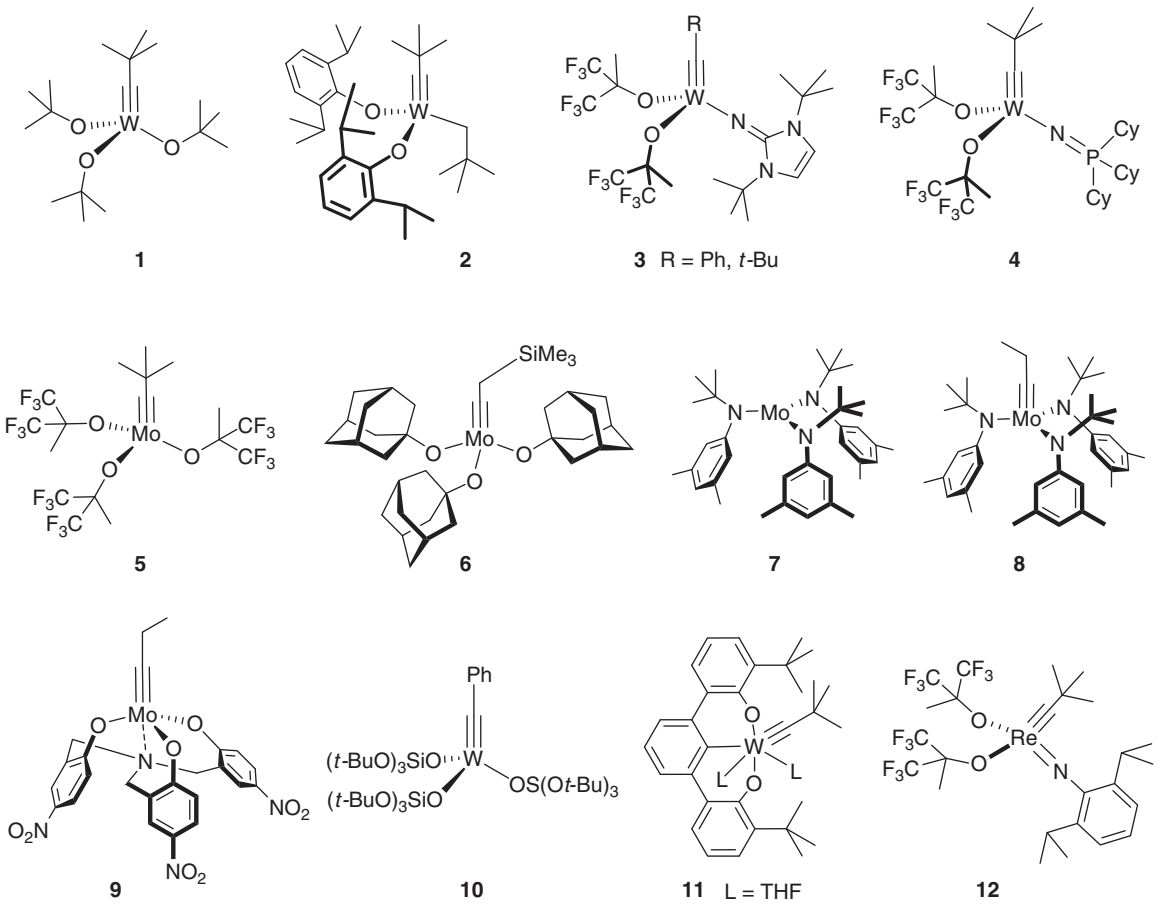


Figure 1 Assortment of established alkyne metathesis catalysts bearing *tert*-alkoxides, fluorinated alkoxides, amides, phenolates, or neopentyl groups as ancillary ligands; in case of complex **7**, the alkylidyne unit is generated *in situ* on treatment with CH_2Cl_2 and exposure to the alkyne substrate, see Section 5.28.3.2.

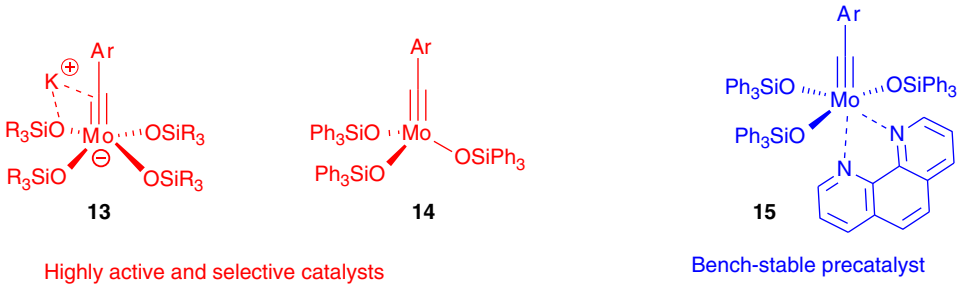
The list of possible ancillary ligands was recently extended to cheap triarylsilanolates, which impart particularly favorable properties onto the corresponding alkylidynes (see Sections 5.28.3.2 and 5.28.3.3). Complexes such as **13** and **14** belong to the most active metathesis catalysts known to date (Figure 2).[14,15] At the same time, such alkylidyne complexes can be rendered bench-stable on complexation with 1,10-phenanthroline or 2,2′-bipyridine; the active species is easily regenerated from the resulting adducts on treatment with metal salts as simple as $ZnCl_2$ or $MnCl_2$.[14,15] Therefore, phenanthroline complexes such as **15** combine an excellent performance and application profile with a much improved user-friendliness, and should lend themselves to broad applications in organic chemistry and polymer science.

This chapter will focus on the preparative aspects of alkyne metathesis, whereas the organometallic background is touched only to the extent that the reader can put the recent catalyst development into proper perspective.[16–22] For more information, the comprehensive and authoritative reviews of the preparation, structure, and reactivity of metal alkylidyne complexes should be consulted.[2,10,11] In analogy to alkene metathesis, several distinctly different application modes of alkyne metathesis can be envisaged, which demonstrate that this methodology is relevant for small molecule chemistry and polymer science alike (Scheme 3). Among them, ring-closing alkyne metathesis (RCAM),[23,24] alkyne cross metathesis (ACM, $R^1 \neq R^2$),[25–27] alkyne-self-metathesis (ACM, $R^1 = R^2$), and the stepwise acyclic diyne metathesis polymerization (ADIMET)[28] have so far gained the greatest relevance.



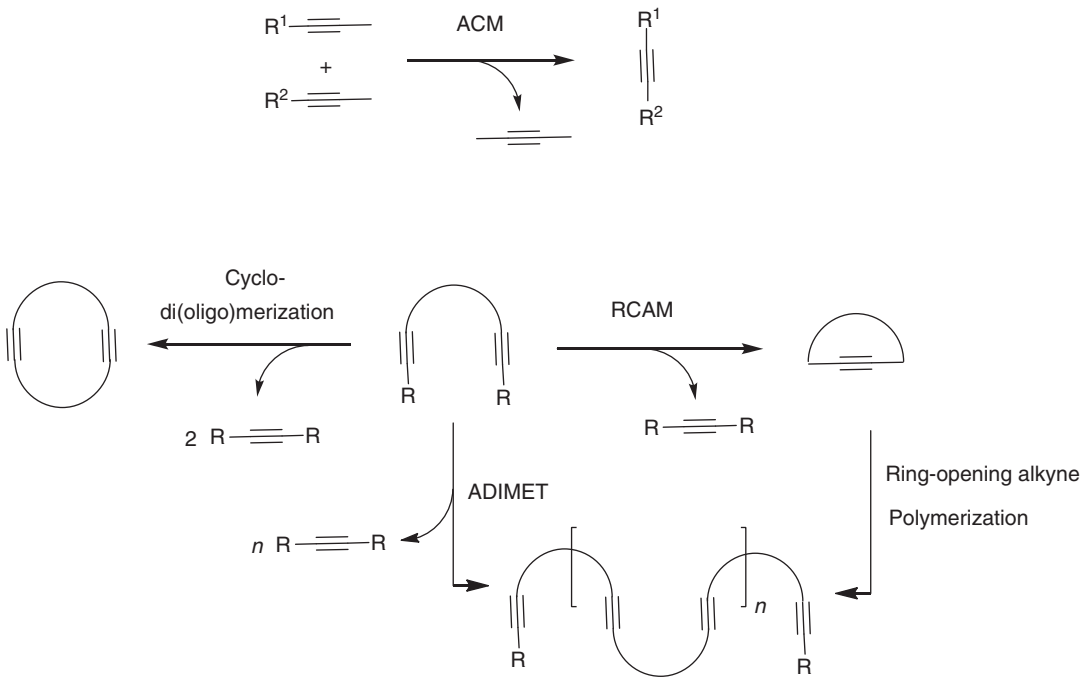


Figure 2 Sample of the bench-stable molybdenum alkylidyne/1,10-phenanthroline adduct **15b** (Ar = *p*-$MeOC_6H_4$–), which serves as a convenient precatalyst for alkyne metathesis reactions of all sorts and is compatible with a host of polar and unpolar functional groups; adduct **15** derives from the parent complexes **13** and **14**, which are arguably the most active and selective alkyne metathesis catalysts known to date (see Section 5.28.3.2).

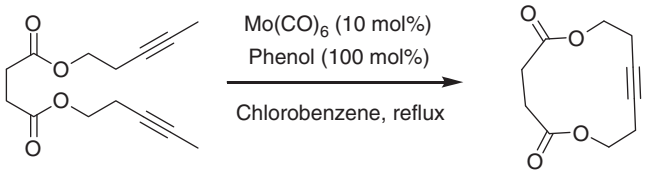

Scheme 3 Basic modes of alkyne metathesis.

5.28.2 Mortreux-Type Catalysts

As mentioned in Section 5.28.1, a mixture of $Mo(CO)_6$ and resorcinol accounted for the first alkyne metathesis reaction in homogeneous phase; this system operated at 160 °C in decaline as the solvent.[5] Soon after this important discovery had been disclosed, it was shown that other molybdenum sources can also be used, although $Mo(CO)_6$ remained the most popular choice for its convenience and ready availablity.[29] Although structurally undefined species generated *in situ* from $MoO_2(acac)_2$ and alkylaluminum reagents showed higher activity on modification with phenol additives, such catalysts were hardly used in later investigations.[30] Scattered reports on the use of $W(CO)_6$ instead of $Mo(CO)_6$ can also be found.[31]

Over the years, the performance of a large variety of substituted phenols was tested in combination with $Mo(CO)_6$.[29,32–34] The data suggest that electron-withdrawing substituents are generally advantageous and allow the necessary reaction temperature to be lowered, at least to some extent. Based on the results of simple RCAM experiments, 2-fluorophenol, and 2-fluoro-5-methylphenol were proposed as being optimal, whereas pentafluorophenol failed completely (**Table 1**).[35,36] In striking contrast to these results, however, pentafluorophenol scored best in a related screening exercise based on an ACM reaction of propynyl ferrocene, whereas 2-fluorophenol was clearly suboptimal (**Table 2**).[37,38] No obvious explanation for these disparate findings can be given nor could any correlation between the pK_A of the phenol and the activity of the resulting catalyst be established. It is also of note that *ortho*-, *meta*-, and *para*-nitrophenol performed either poorly or gave no conversion at all in either assay. This result stands in striking contrast to the widespread use of nitrophenolates as ancillary ligands for structurally defined molybdenum alkylidynes, which will be discussed in more detail in Section 5.28.3.2.

[b]After 6 h reaction time.

Further attempts were made to allow Mortreux-type mixture to operate under milder conditions by the use of additional coligands. In this context, 1,2-di(phenyloxy)ethane[39] and 1,2-dichloroethane[40] were reported to exert beneficial effects, although their mode of action remains speculative. Furthermore, it was recommended to generate the as yet unknown active species before the addition of the actual substrate by heating the molybdenum source and the chosen phenol in the presence of a sacrificial alkyne; after this activation step, the temperature can be lowered before the actual substrate is introduced.[41] Although these empirical protocols showed some promise, they did not yet find widespread application; therefore the knowledge base about their scope remains narrow.

The phenol additive is always used in excess relative to $Mo(CO)_6$ and even more than 1 equivalent compared to the substrate is not uncommon (**Scheme 4**). At temperatures ≥ 100 °C, however, free phenol in solution is by no means innocent and can damage various functional groups. Therefore, many of the reported applications of Mortreux-type mixtures deal with substrates that are barely functionalized or carry only rather stable substituents. Noteworthy examples include early applications of RCAM to the synthesis of various macrocyclic ethers and lactones including the valuable perfume ingredients ambrettolide and civetone (see Section 5.28.6.4.2),[24,42–44] the insect repellant aza-macrolide epilachnene,[24] the cytotoxic alkaloid motuporamine C (see Section 5.28.6.4.6),[45] and some naturally occurring cyclophanes of the turrinane series;[46] in the latter case, it was shown that ultrasonication of the reaction mixture leads to a significant rate acceleration without affecting the yield by much. A more recent

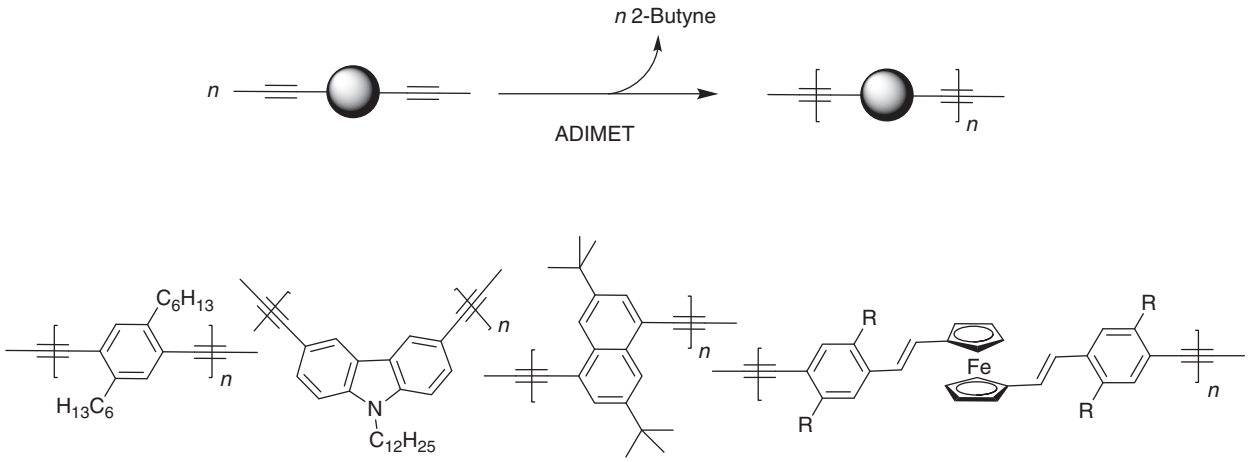
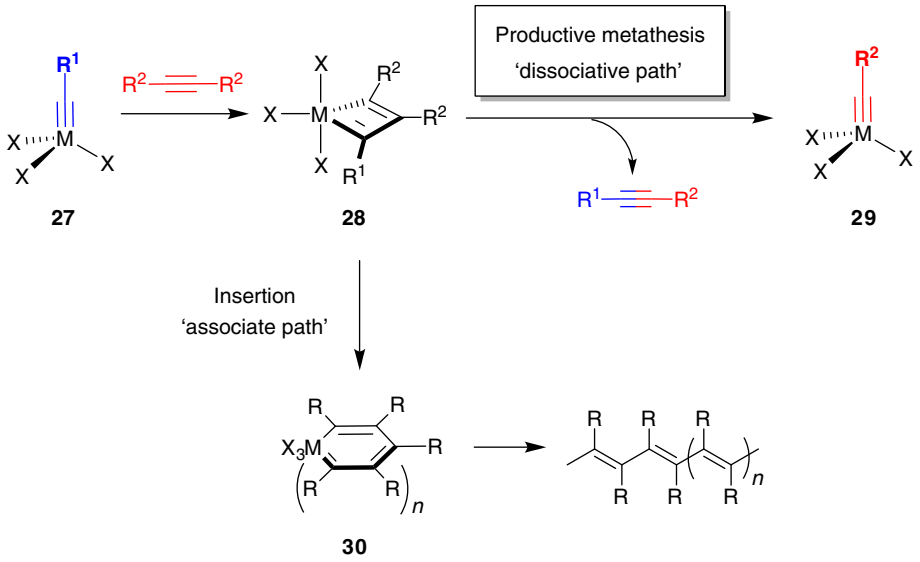
case refers to a total synthesis of the complex alkaloid nakadomarin A, even though the yield of the desired cycloalkyne **23** was only modest despite the high catalyst loading.[47] Likewise, the productivity was poor in an application to the glycolipidic array **25**.[48] The attempted cyclization of the arguably more sensitive prostaglandin derivative **26** by a Mortreux-type catalyst failed since the substrate was merely decomposed. In contrast, this particular diyne could be cyclized without incident and in good-to-excellent yields with the molecularly defined catalysts **1** (65%) or **7**/CH_2Cl_2 (81%).[49]

Whereas the limited compatibility of Mortreux-type mixtures with polar groups is a severely limiting factor for applications in advanced organic synthesis, they turned out highly enabling for material science where less functionalized substrates can still lead to valuable products. Of particular interest are various poly(arylene-ethynylene) (PAE) derivatives with promising electronic and optical properties (**Scheme 5**). The PAE's obtained by ADIMET tend to show fewer defects and higher molecular weights than the corresponding materials prepared by traditional Sonogashira-type cross coupling.[50] The nature of the side chains attached to the monomers is the prime determinant for solubility of the growing chain and hence for the attainable degree of polymerization. Although a detailed discussion of this topic (as well as of other applications of alkyne metathesis to polymer chemistry)[51] is beyond the scope of this chapter, the representative repeat units depicted in **Scheme 5** clearly indicate that ADIMET powered by Mortreux catalyst mixtures allowed various carbo- and heterocyclic arene-building blocks to be processed, including carbazole- and ferrocene-based units. In this context, however, it is of note that other authors found propynylated ferrocene derivatives to undergo competing addition of the *p*-chlorophenol to the triple bond when subjected to mixtures of $Mo(CO)_6$/*p*-ClC_6H_4OH in chlorobenzene under the standard conditions.[52] This result shows again that the presence of excess phenol is a seriously limiting factor for applications of Mortreux-type catalyst mixtures in general. Yet another sidetrack is the possible consumption of the alkyne substrate by a [2 + 2 + 2] cycloaddition process, which actually became the major reaction pathway for certain substrates when Mortreux-type mixtures are employed.[26,53]



5.28.3 Schrock Alkylidyne Complexes

5.28.3.1 General Characteristics



The advent of complexes containing a triple bond between a carbon ligand and a high-valent metal center, commonly called Schrock alkylidynes after their inventor,[2,10,11] allowed the mechanistic proposal originally made by Katz[7] to be elegantly confirmed. Specifically, it was shown that certain high-valent alkylidynes of tungsten, molybdenum, and rhenium exhibit good-to-excellent catalytic activity, which was far higher than that of any Mortreux-type mixture known at the time. Moreover, several representative metallacyclobutadiene complexes of the general structure **28** formed in the elementary [2 + 2] cycloaddition step between an alkylidyne **27** and an alkyne substrate could be isolated and fully characterized (**Scheme 6**).[54,55] Kinetic studies indicated that they might actually be the catalyst resting states, since the release of the product from such metallacyclobutadiene complexes was found to be rate determining, at least for the specific examples of tungsten complexes investigated. Although metallacyclobutadienes of molybdenum (**28**, M = Mo) are less well characterized, they are believed to be isostructural with but likely less stable than their tungsten analogs (**28**, M = W). Overall, these early classical investigations into Schrock alkylidynes formed a sound basis for the development of ever more active and selective catalysts for alkyne metathesis.

Scheme 4 Applications of Mortreux-type catalyst mixtures to natural product chemistry.

Scheme 5 Repeat units of representative PAE derivatives prepared by acyclic diyne metathesis polymerization using Mortreux-type catalyst mixtures.

Scheme 6 Possible competition between a dissociative pathway and an associative channel, which may result in substrate polymerization.

In addition to the nature of the central metal, the ancillary ligands turned out to be of utmost importance for the performance of the catalysts. The nature of the substituent R^1 on the alkylidyne unit of **27**, which is lost in the first turn of the catalytic cycle, affects the onset rate of the reaction, the stability of the complex and the ease of its preparation. However, the inherent catalytic activity of a given alkylidyne is largely determined by the anionic ancillary ligands X.[56] Although an in-depth discussion is beyond the scope of this chapter, the available data suggest that the anionic ligands must be sterically demanding as well as moderately electron-withdrawing. Metal neopentylidyne complexes **27** ($R^1 = CMe_3$) endowed with X = chloride, neopentyl, -SR, -NR_2, or certain carboxylate groups were found by and large inactive;[57,58,75] in contrast, the use of either bulky phenolates or branched alkoxides afforded catalysts of appreciable activity.[59] Among them, [(*t*-BuO)$_3$W≡CCMe$_3$] (**1**) served as the valuable lead compound and continues to represent a benchmark in the field of alkyne metathesis;[12,13] this complex is also commercially available. The use of branched fluorinated alkoxides instead of *tert*-butoxides leads to even more active species.[60] This effect is particularly evident from the molybdenum series, where the parent complex [(*t*-BuO)$_3$Mo≡CCMe$_3$] showed little, if any, activity, whereas its fluorinated cousin with $-OC(Me)(CF_3)_2$ ligands in lieu of the *tert*-butoxides exhibits appreciable catalytic performance.[61–63] If the ancillary groups are too small and the central metal quite Lewis acidic, however, as is the case for M = W and X = $-OCH(CF_3)_2$, the productive metathesis channel can be outperformed by an associative pathway (**27** → **28** → **30**), which ultimately result in polyacetylene formation.[60] This course is particularly easy for small, unhindered alkynes and therefore potentially relevant for the fate of 2-butyne formed as the generic byproduct in all alkyne metathesis reactions of acetylene substrates capped by a methyl group. Polymerization of 2-butyne, however, keeps the catalyst busy and away from doing its actual

job ('pseudo-poisoning effect');[64] successful catalyst design must close this associative channel by proper adjustment of the steric and electronic environment about the chosen central metal.

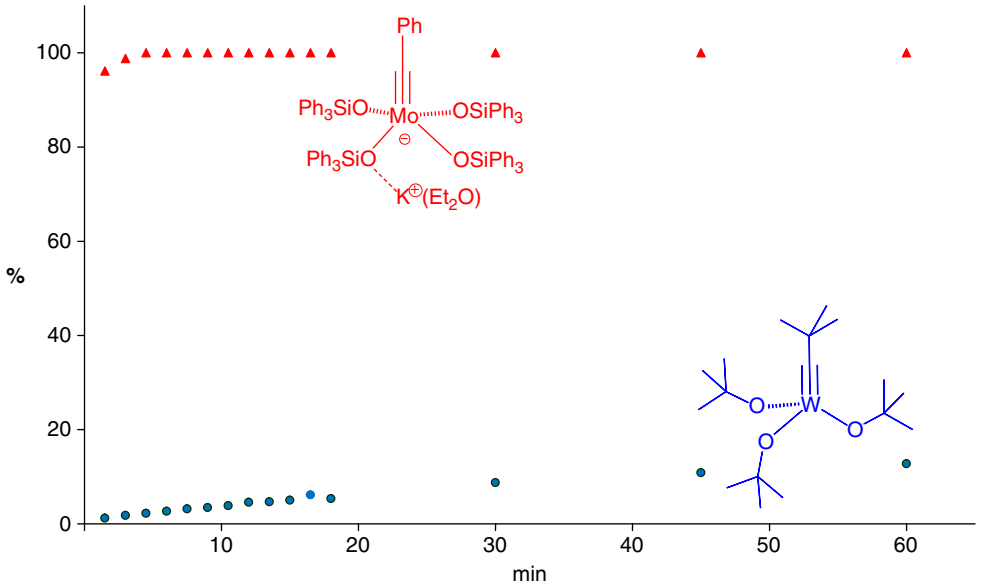
Another important factor is the Lewis acidity of the central metal, which can be regulated via the ancillary ligands X. One has to note, for example, that even the parent complex [(*t*-BuO)$_3$W≡CCMe$_3$] (**1**) is incompatible with substrates containing (moderately) basic nitrogen or divalent sulfur.[24] This limitation is likely caused by coordination of such donor sites onto the high-valent metal center with a formal d^0 electron count (not considering π-back donation). Because of this pronounced Lewis acidic character, complex **1** was also found to deprotect certain acetal groups and can seriously damage or even destroy acid-sensitive substrates (for representative examples, see Section 5.28.6.4). At the same time, however, the alkylidyne carbon atom of this and related complexes shows nucleophilic character, which is sufficiently high for reactions with the carbonyl groups of benzaldehyde, acetone, ethyl formate, and even DMF.[65]

The combination of a fairly Lewis acidic metal center and a markedly nucleophilic alkylidyne unit seriously limits the applicability and scope of [(*t*-BuO)$_3$W≡CCMe$_3$] (**1**) and relatives, since advanced organic chemistry is all about the ability to manipulate functional groups with the highest possible level of chemoselectivity. To increase the scope of alkyne metathesis in general, it was therefore mandatory to develop more tolerant catalysts without compromising their activity. To this end, different approaches have been pursued, the most prominent of which can be summarized as follows:

1. The Lewis-acidity imparted onto the W^{VI} center of pertinent alkylidynes by branched (fluorinated) alkoxides can be counterbalanced with the aid of electron-releasing substituents. To this end, complexes such as **2**–**4** characterized by a mixed ligand sphere with a push/pull environment have been prepared (**Figure 1**).[66–69] Complex **3** in particular was reported to be highly active and compatible with esters, ethers, thioethers, nitro groups, and aryl chlorides. A more comprehensive picture of its performance, however, cannot yet be drawn from the limited dataset currently available.[70]
2. Replacement of tungsten by the inherently less Lewis acidic molybdenum seems to pay dividends when it comes to the design of chemoselective alkyne metathesis catalysts for organic synthesis and polymer chemistry. A successful and widely used precatalyst is the molybdenum trisamide [(Ar)(*t*-Bu)N]$_3$Mo (**7**, Ar=3,5-dimethylphenyl) which is activated with CH_2Cl_2 to generate a molybdenum alkylidyne *in situ* (see Section 5.28.3.2).[71,72] Closely related is the complex [(Ar)(*t*-Bu)N]$_3$Mo≡CCH$_2$CH$_3$ (**8**),[73,74] which derives from the same precursor **7** on treatment with higher *gem*-dichlorides (Section 5.28.3.2). Exchange of the bulky amide ligands by nitrophenol has been used to fine-tune the Lewis acidity even further, which enabled many interesting applications, notably in material science.
3. Molybdenum alkylidyne complexes endowed with triarylsilanolate groups as the ancillary ligands arguably show the best application profile known to date.[14,15] As will become evident from the discussion in Section 5.28.3.2, the silanolates synergize with the high-valent molybdenum center, leading to highly active and, at the same time, remarkably selective catalysts. A raft of complexes of this type has been prepared, amongst which the ate-species **13** and its neutral analog **14** are the most practical and useful variants, which are easy to make on a multigram scale (**Figure 2**); such complexes are currently about to be commercialized. Their performance was carefully investigated with a large set of inter- as well as intramolecular alkyne metathesis reactions.[14,15] The direct comparison of **13a** · Et$_2$O with the standard Schrock alkylidyne [(*t*-BuO)$_3$W≡CCMe$_3$] (**1**) depicted in **Figure 3** demonstrates the far superior performance of the molybdenum silanolate complex; at the same time, **13** and relatives tolerate a host of functional groups, including very sensitive ones that are incompatible with e.g., [(*t*-BuO)$_3$W≡CCMe$_3$]. Specifically, esters, ethers, silyl ethers (TESO-, TBSO-, TBDPSO-, TIPSO-), thioethers, sulfonates, ketones, amides, carbamates (Boc, Fmoc, Teoc), aldols, acetals (including MOM- and THP- groups), spiroketals, epoxides, vinyl epoxides, aryl-X groups (X=F, Cl, Br), aldols, alkyl chlorides, propargyl acetates as well as trifluoromethyl- and nitro groups pose no problem; even the triple bond of nitriles is kinetically inert. All kinds of alkenes are fully compatible, independent of whether they are terminal, internal, or conjugated to a carbonyl group; 1,3-dienes as well as skipped alkenes are inert too. Moreover, various types of heterocycles such as pyridine, thiophene, thiazole, indole, carbazole, pyrone, and so on are tolerated. In view of this excellent profile, complexes of type **13** and **14** are ideally suited for advanced synthetic applications. For the practitioner it is also important to note that such complexes are rendered bench-stable on complexation with 1,10-phenanthroline or 2,2′-bipyridine; the active principle is easily released from the resulting adducts **15** with the aid of cheap metal salts such as $MnCl_2$ or $ZnCl_2$ (for a more detailed discussion, see Section 5.28.3.2).[14,15]

5.28.3.2 Preparation of the Standard Schrock Alkylidyne Complexes

The classical route to Schrock alkylidynes consists in the alkylation of a high-valent metal salt such as WCl_6 or – preferably – [(MeO)$_3$WCl$_3$] with a sterically hindered alkylmetal reagent, typically neopentylmagnesium chloride.[75,76] The intermediate primarily formed is unstable and undergoes two consecutive α-elimination reactions with formation of the neopentylidyne entity (**Scheme 7**). The resulting air-sensitive product **32** is treated with anhydrous HCl to give the corresponding trichloro–alkylidyne complex **33**, which itself is catalytically inert but serves as a valuable starting material for the preparation of various active complexes by salt metathesis with suitable ancillary ligands as exemplified for **1a–e**. Although this chemistry – a priori – also works in the molybdenum series, the yields tend to be lower and problems with the scale-up have been documented in the literature.[61,62]



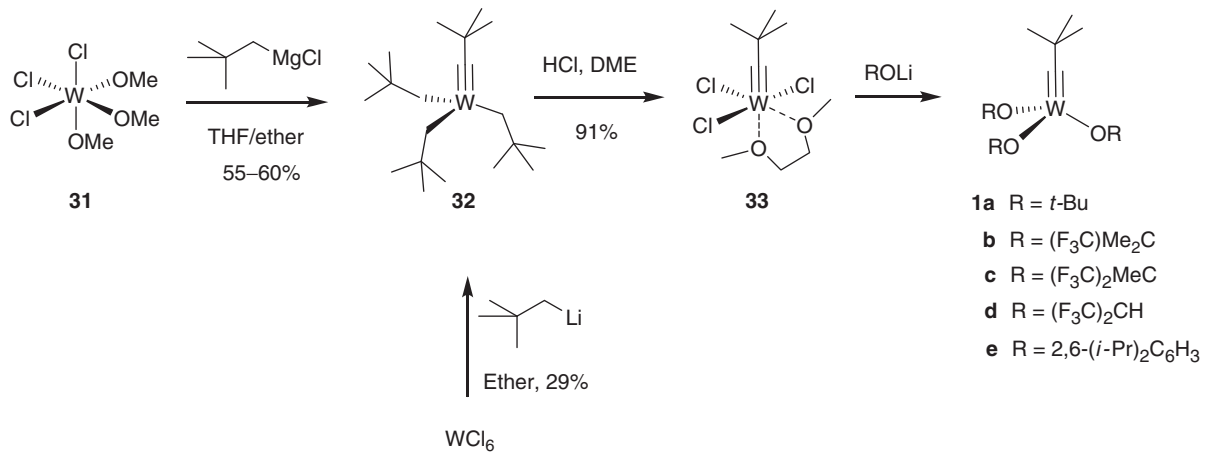


Figure 3 Comparison of the performance of the Mo-alkylidyne ate-complex **13a** · Et_2O (red) with the tungsten alkylidyne **1** (blue) in the conversion of 1-phenyl-1-propyne to tolane. The reaction was performed at ambient temperature with 1 mol% catalyst loading in the presence of MS 5 Å to trap the released 2-butyne (see Section 5.28.5).

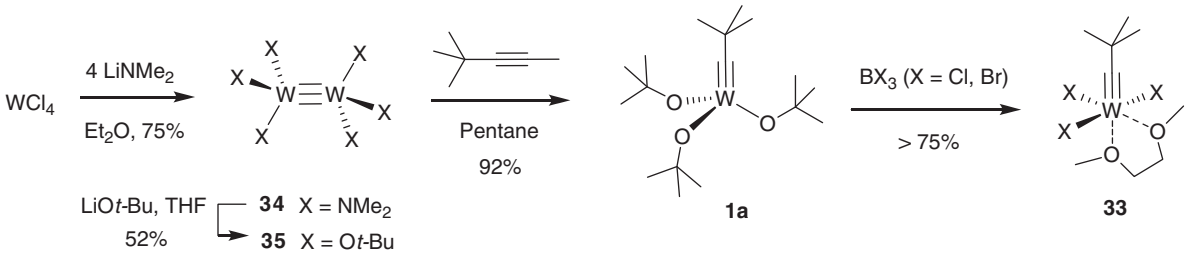
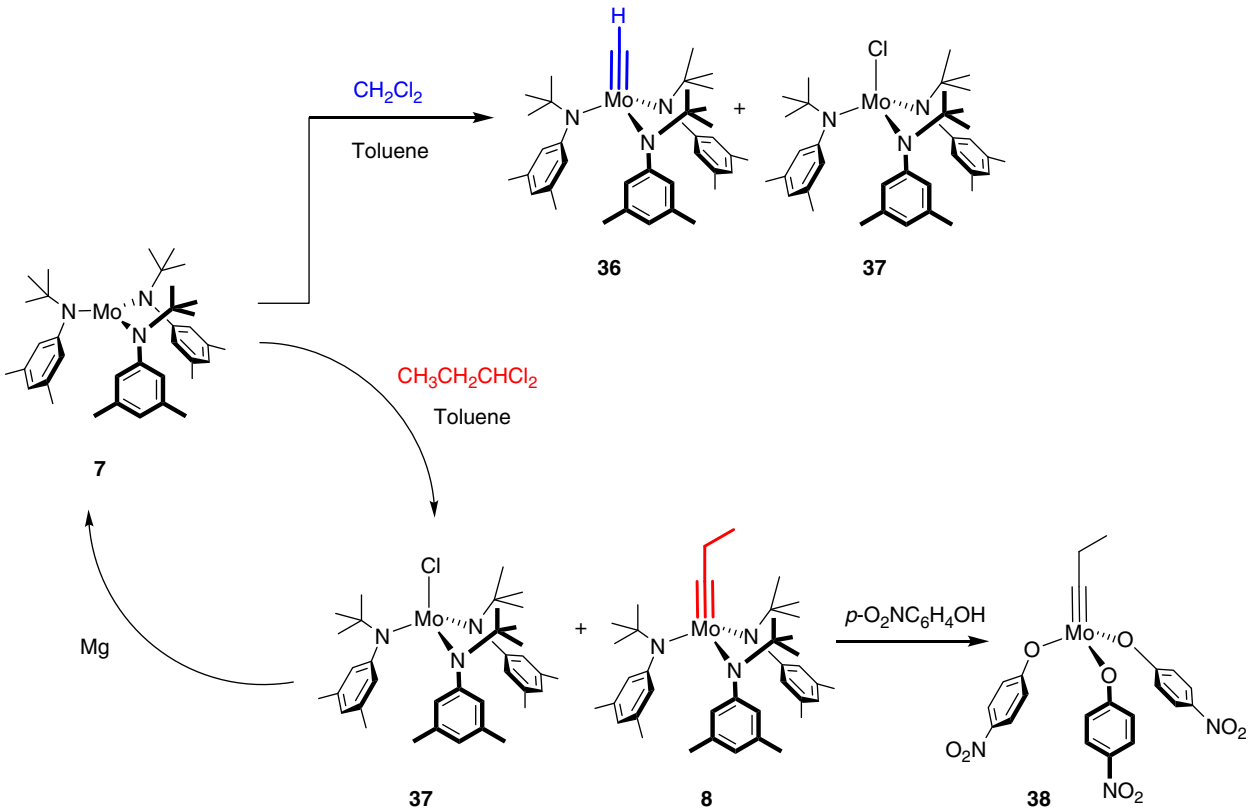


Scheme 7 The classical 'Schrock route' for the preparation of tungsten neopentylidyne complexes.

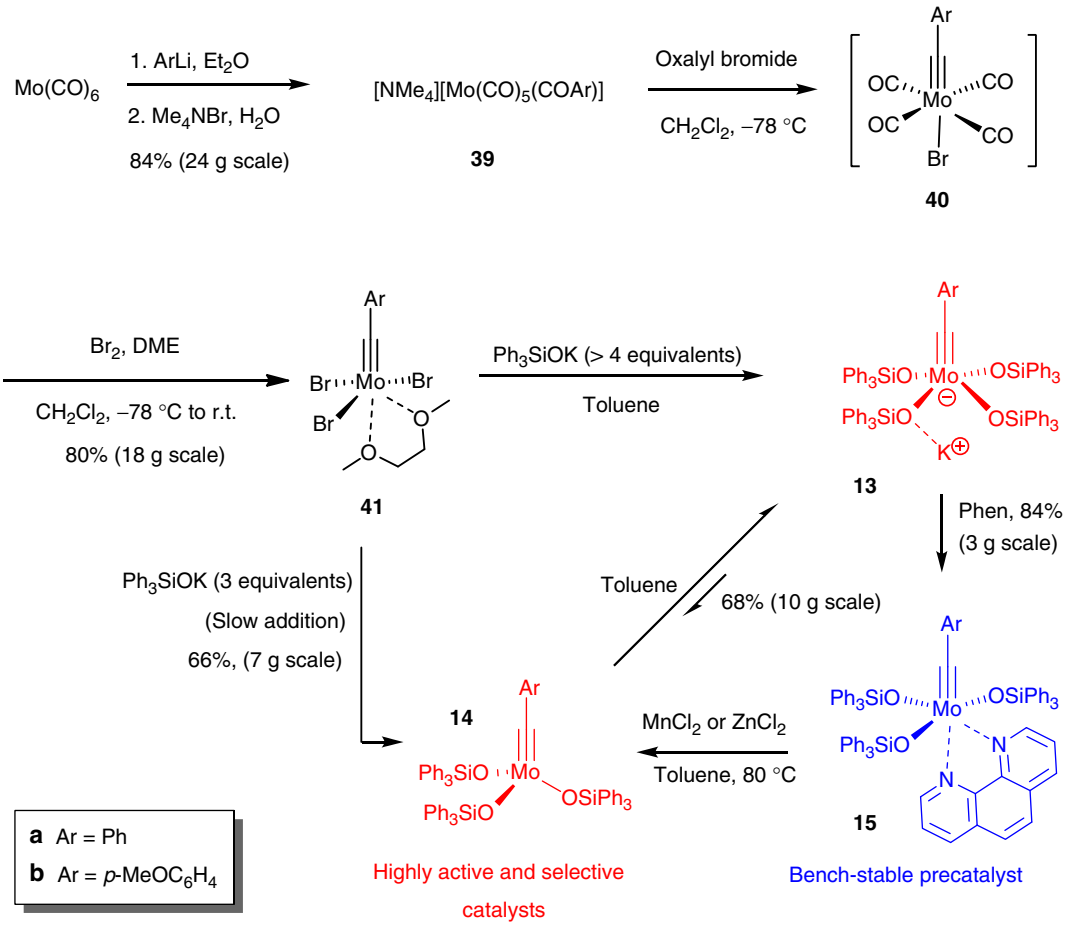


An alternative route to complex **1** relies on the metathetic cleavage of the tungsten–tungsten triple bond of the precursor complex $[(t\text{-BuO})_3W{\equiv}W(Ot\text{-Bu})_3]$ (**35**) with neoheptyne,[77] which in turn is available on a multigram scale from WCl_4 and $LiNMe_2$ (Scheme 8).[78] Unfortunately, this chemistry is once again not easily translated into the molybdenum series, where it is unclean and low yielding. If desirable, **1** can be converted into $[X_3W{\equiv}CCMe_3(dme)]$ (**33**, X = Cl, Br) using BX_3 as the reagent, which provides another access route to this valuable building block.[79]

For the exploration of the potential of molybdenum alkylidynes, it was necessary to develop alternative synthesis routes. Among the different solutions proposed in the literature,[80] the conversion of the trisamido Mo(+3) complex **7** into Mo(+6) alkylidyne complexes represented an important advance.[71,72] This development was triggered by the observation that the treatment of **7** with CH_2Cl_2 leads to a mixture of different molybdenum species, of which the methylidyne complex **36** and the monochloride complex **37** are the major constituents (Scheme 9). This mixture does not need to be separated but is metathesis-active as such;[71,72] therefore, the combination **7**/CH_2Cl_2 found numerous applications in the past, because of its excellent activity and remarkable functional group tolerance (see Sections 5.28.6.3 and 5.28.6.4).

Replacement of CH_2Cl_2 by other *gem*-dihalides provides nonterminal molybdenum alkylidynes, which are more robust and allow for the reconversion of the accompanying chloride **37** into the starting complex **7** on reduction with magnesium turnings (Scheme 9). This 'reductive recycle strategy' ultimately transforms the entire substrate into the desired molybdenum alkylidyne.[73,74,81] Propylidyne **8** thus formed from **7** and 1,1-dichloropropane can be isolated and its catalytic activity adjusted on

Scheme 8



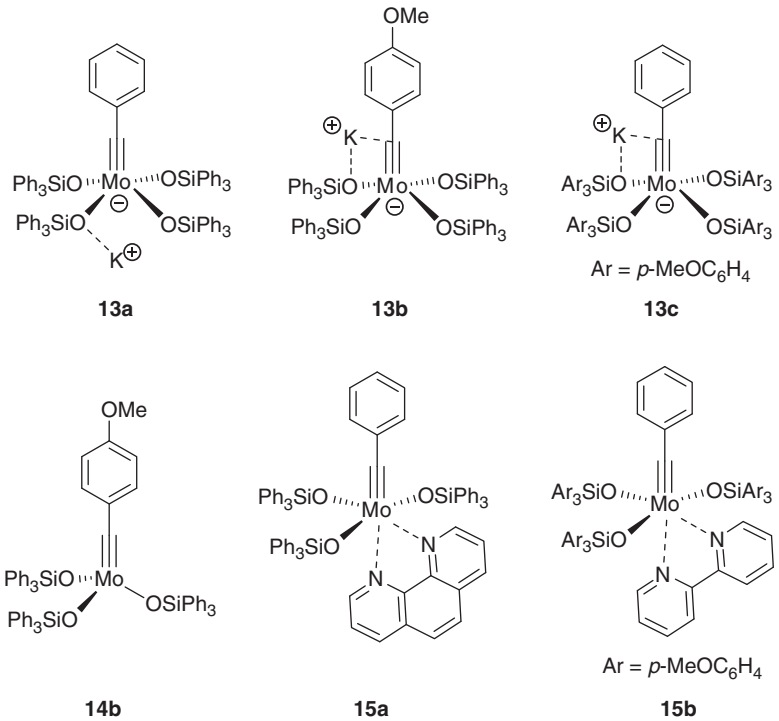
Scheme 9

mixing with electron-deficient phenol additives, preferably 2-nitro-, or 4-nitrophenol. These additives replace the amide groups by nitrophenolates and hence afford more electron-deficient catalyst species such as **38**. An analogous ligand exchange process has been used to introduce the chelate ligand of complex **9** (Figure 1), which was also described as highly metathesis active.[82] Moreover, immobilized catalyst variants could be made from complex **8** on reaction with the surface –OH groups of silica.[83]

The combinations **7**/CH_2Cl_2 or **8**/nitrophenol found widespread use in alkyne metathesis, both in the realm of natural product synthesis as well as in the material science arena. However, the popularity of these powerful catalysts is limited by the fact that complex **7** serving as the starting material in either case is exceptionally sensitive. Not only is this species instantaneously destroyed by air or moisture, but it even reacts with molecular nitrogen at ambient temperature.[84] Therefore it is mandatory to work under Argon in rigorously dried and purified solvents using proper organometallic techniques (Schlenk-lines, glove box).

This handicap was recently overcome by a new type of catalysts for alkyne metathesis, which are much more user-friendly. As has already been mentioned, 1,10-phenanthroline- or 2,2′-bipyridine adducts such as **15** are bench-stable and can be handled without any particular precautions (Scheme 10).[14,15] They are prepared on multigram scale by adapting a sequence that links the chemistry of low-valent Fischer-carbyne complexes with that of their high-valent Schrock alkylidyne relatives.[85,86] Specifically, the reaction of $Mo(CO)_6$ with an aryllithium reagent followed by cation exchange provides the Fischer carbene **39**, which converts into the corresponding Fischer-carbyne **40** on treatment with oxalyl bromide. **40** does not need to be isolated but is best oxidized directly to the tribromo alkylidyne complex **41** with Br_2 in CH_2Cl_2 in the presence of 1,2-dimethoxyethane (DME). These

transformations are high yielding and nicely scalable as long as the reaction temperature during the oxidation steps is properly controlled.[15] In practical terms, the use of *p*-methoxyphenyl lithium in the first step turned out to be optimal, because it imparts advantageous solubility properties onto all downstream complexes (**13b–15b**, **41b**), which are easy to isolate and purify.[15] It should be mentioned that a similar sequence of reactions is also successful in the tungsten series.[70]



Scheme 10 Scalable and modular preparation of molybdenum alkylidyne complexes endowed with triarylsilanolate complexes; the yields are specified for Ar = *p*-MeO-C_6H_4 (**b** series). The same route can also be followed using other ArLi reagents and silanolates other than Ph_3SiO–, cf. Ref. 15. For specific examples of preferred catalysts prepared by this route, see **Figure 4**.

Complexes **41a**,**b** and relatives serve as convenient starting materials for the preparation of highly metathesis-active molybdenum alkylidyne complexes by ligand exchange via salt metathesis. A thorough screening campaign showed that triarylsilanolates are privileged ancillary ligands, with triphenylsilanolate and tris(*p*-methoxyphenyl)silanolate being optimal in practical terms (**Scheme 10** and **Figure 4**).[14,15] They are cheap and provide highly active catalysts, which are nicely crystalline and hence easy to isolate. Complexes **14b** and **13a**,**b** are the most reactive ones, whereas the use of complex **13c** is advantageous when working with highly unpolar alkyne substrates; the *p*-methoxy groups render the silicon-containing byproducts formed on work-up of the reaction mixtures quite polar and hence facilitate the product isolation in such cases. If desirable, however, other silanolates can also be used and lead to complexes with tailor-made properties and impressive activities.[15]

The reaction of **41** with Ph_3SiOK in toluene forms the ate-complex **13** as the preferred product independent of the chosen stoichiometry. For preparative purposes, it is therefore recommended to use ≥ 4 equivalents of Ph_3SiOK to ensure high yields. The fourth silanolate ligand on **13**, however, is sufficiently labile to get lost when treated with 1,10-phenanthroline or 2,2′-bipyridine. The resulting adducts of type **15** are air-stable for extended periods of time (> 2 years) and hence easy to handle.[14,15] Although **15** itself is inactive (all coordination sites of the molybdenum center are blocked), the stabilizing chelate ligand can be readily removed with $MnCl_2$ or $ZnCl_2$ in anhydrous toluene to deliver the catalytically active neutral alkylidyne template **14** (**Scheme 10**). Although this activation will occur even at ambient temperature, it is recommended to perform this step at ≈60–80 °C to ensure fast rates.

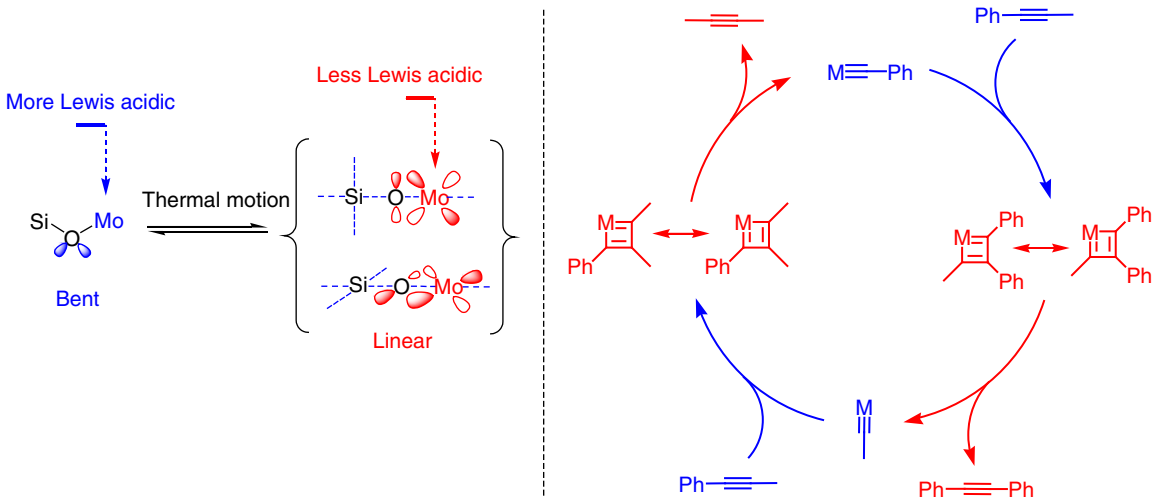
The lability of the fourth silanolate of the ate-complex **13** is also deemed responsible for the fact that this species itself is highly metathesis-active. In solution, **13** equilibrates with a small amount of the corresponding neutral complex of type **14**, which is thought to represent the actual catalyst (**Scheme 10**). Access to these exquisitely active neutral alkylidyne species in analytically

13a 13b 13c

14b 15a 15b

Figure 4 Specific examples of molybdenum alkylidyne complexes endowed with silanolate ligands prepared by the route shown in **Scheme 10**, which are preferred catalysts for alkyne metathesis (see Section 5.28.6). For the ate-complexes **13**, the location of the potassium counterion is drawn as found in the crystal structures of the complexes, see Ref. 15.

pure form has also been achieved, albeit only in a few select cases.[15] Specifically, slow addition of 3 equivalents of Ph_3SiOK to a solution of precursor complex **41b** carrying a *p*-methoxybenzylidyne unit allowed the neutral product **14b** to be formed in decent yield on a multigram scale (**Scheme 10**). The structures of this complex and of many of its relatives have been unambiguously determined by X-ray diffraction. Molybdenum alkylidynes endowed with silanolate ligands are about to be commercialized for use in alkyne metathesis.



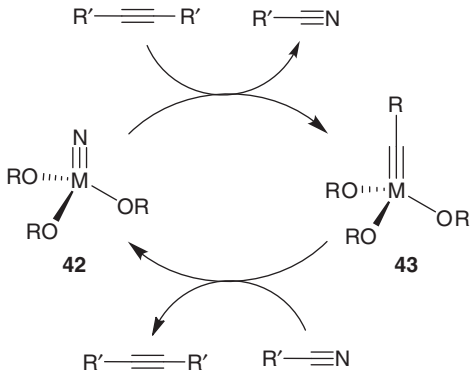
5.28.3.3 Silanolate Effect and the Fate of the Catalysts

Although a detailed discussion of the organometallic background is beyond the scope of this review, a few comments on the beneficial effects of triarylsilanolates on the stability, activity, and functional group tolerance of molybdenum alkylidyne complexes seem appropriate. One might perceive Ph_3SiO-groups as being very bulky, but the available crystallographic information actually shows that the Mo-center in a complex of type $[(Ph_3SiO)_3Mo{\equiv}CAr]$ (**14**) remains well accessible for neutral (and anionic) donors.[14,15] Therefore, one may conclude that the silanolate ligand sphere does not impede substrate binding and hence presents no serious kinetic barrier for productive alkyne metathesis.

However, triarylsilanolates render the periphery crowed enough to disfavor the collision of two alkylidynes. Because bimolecular decomposition pathways account for much of the thermal decay of alkylidyne catalysts, the effective shielding provided by the greasy rim of the triarylsilanolates increases the catalyst lifetime and, as a consequence, the total turnover number.[15] Similarly important is the fact that $R_3Si–O$ bonds are quite robust when bound to a Lewis acidic metal center such as Mo^{VI}, whereas the analogous $R_3C–O$ bonds of tertiary alcohols (a class of ligands with a long history in alkyne metathesis, cf. **Figure 1**) break much more readily with formation of stabilized tertiary cations. Hydrolysis constitutes the most serious threat for complexes of the general type $[(R_3SiO)_3Mo{\equiv}CAr]$ and adducts thereof, independent of whether they are anionic (**13**) or neutral (**14**).[15]

In addition to these steric arguments, triarylsilanolates exert a very unique electronic effect, which renders the derived alkyne metathesis catalysts particularly productive. Siloxides are weaker net donors than alkoxides because $p_\pi \rightarrow d$ donation has to compete with backbonding of the two electron pairs of oxygen into the low lying Si-C $\sigma*$ orbitals.[87,88] Furthermore, the donor capacity is innately angle-dependent: electron donation into the vacant metal d-orbitals is maximized when the Mo–O–Si bond angle Θ is close to 180 °C, because both orthogonal electron pairs of oxygen can then engage in $O \rightarrow Mo$ bonding (**Scheme 11**). In contrast, bending of the Si–O–Mo hinge gives only one O-lone pair the chance to overlap with an empty metal d-orbital and should therefore lead to higher Lewis acidity at the central atom.

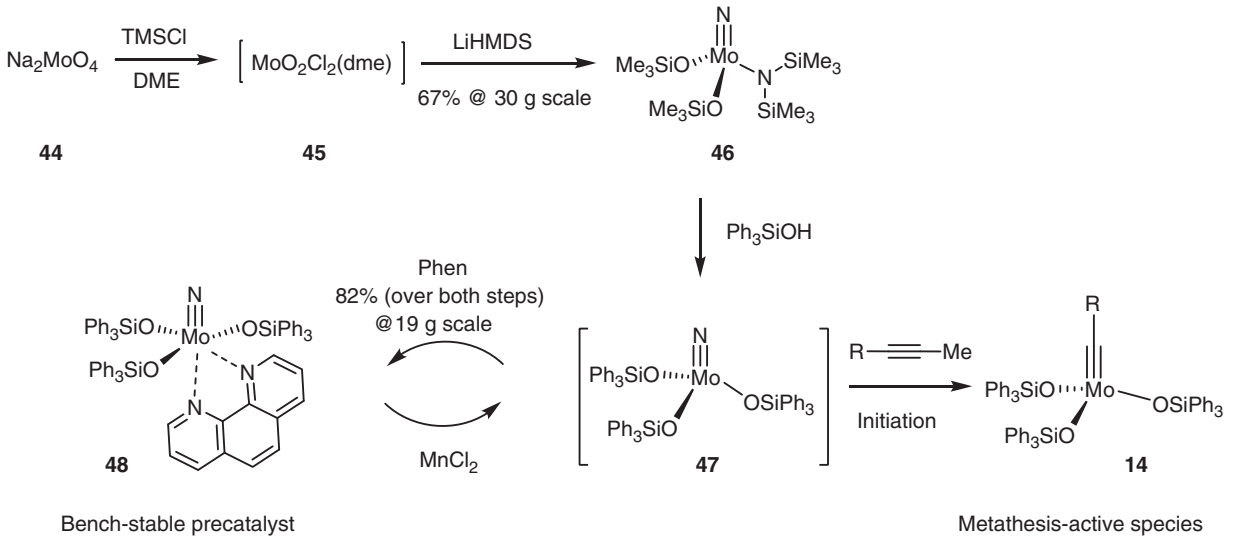
The available crystallographic data for a host of neutral and anionic molybdenum alkylidyne complexes indicate that the bending and stretching of the Mo–O–Si hinges is very facile and the silanolate ligand sphere therefore unusually floppy.[14,15] This



Scheme 11 The floppiness of the silanolate ligand sphere is thought to translate into a gentle up- and downregulation of the Lewis acidity of the molybdenum center, which may help the catalyst to meet the alternating electronic demands during the catalytic cycle.

thermal motion, however, means that the electronic influence of the R_3SiO-ligand sphere is not static either: on bending, the Lewis acidity of the Mo^{VI} center is gently increased which favors uptake of an alkyne substrate as well as the subsequent metallacycle formation; in contrast, stretching of the Si–O–Mo hinge assists the release of the product. In this context, it is important to recognize that any metathesis catalyst has to meet opposing electronic requirements during a single turn-over, as color coded in Scheme 11. By virtue of their suppleness, silanolates are thought to help the operative alkylidyne unit in adjusting to these alternating electronic demands along the reaction coordinate.[15]

5.28.4 Metal–Nitride Complexes as Precatalysts

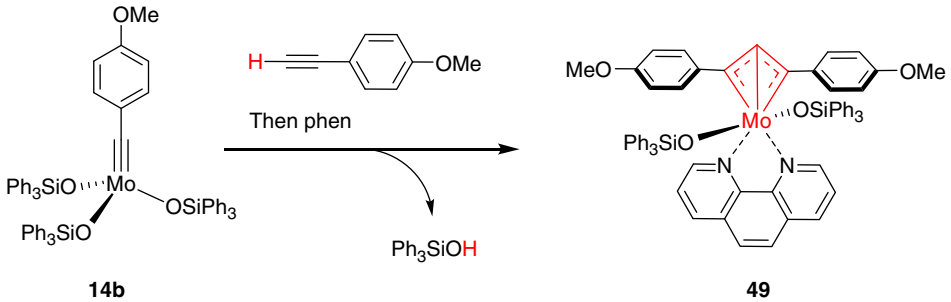


It is known for a long time that certain metal alkylidynes eventually react with nitriles in a metathetic process that is largely driven by the high thermodynamic stability of the resulting nitride complexes.[65,89] Strikingly, however, it was recently shown that the reaction can be reversed, provided that electron-withdrawing ancillary ligands are bound to the metal (Scheme 12).[90,91] Such ligands are thought to destabilize the more polarized M≡N bond of a nitride more than the rather unpolar M≡CR bond of a Schrock alkylidyne. In line with this notion, molybdenum- and tungsten nitrides **42** (M = Mo, W) endowed with fluorinated branched alkoxide ligands were found to react with 3-hexyne at elevated temperatures to give the corresponding propylidyne complexes **43**.

Scheme 12 The discovery of a reversible interchange between certain metal nitrides **42** (M = Mo, W, R = $-C(Me)(CF_3)_2$, $-CMe_2(CF_3)$) and the corresponding metal alkylidynes **43** opened the door for the use of metal nitrides as precatalysts for alkyne metathesis and alkyne-nitrile cross metathesis reactions.

The originally used nitride species **42** were prepared by azide decomposition and the fluorinated alcohols are rather expensive.[90,91] Gratifyingly though, a much more practical alternative could be found with nitride **46**, which is available on multigram scale, without recourse to any dangerous azide precursors, from cheap sodium molybdate, trimethylchlorosilane (TMSCl), and

lithium hexamethyldisilazide (LiHMDS) (Scheme 13). Reaction of this material with commercial Ph_3SiOH exchanges the ligands to give **47**, which turned out to be a competent precatalyst for alkyne metathesis reactions of all sorts.[14,15,92] **47** slowly converts into an alkylidyne of the general type $[(Ph_3SiO)_3Mo{\equiv}CR]$ on treatment with an alkyne substrate. Therefore, this particular precatalyst exhibits by and large the same excellent scope and functional group tolerance as the preformed alkylidyne complexes **13** and **14** discussed above. The necessary nitride-to-alkylidyne conversion, however, is best accomplished at somewhat elevated temperatures. Thus, reactions catalyzed by **47** are typically carried out at 80 °C, whereas the analogous reactions effected by prefomed alkylidynes such as **14** usually proceed at ambient temperature.[14,15]

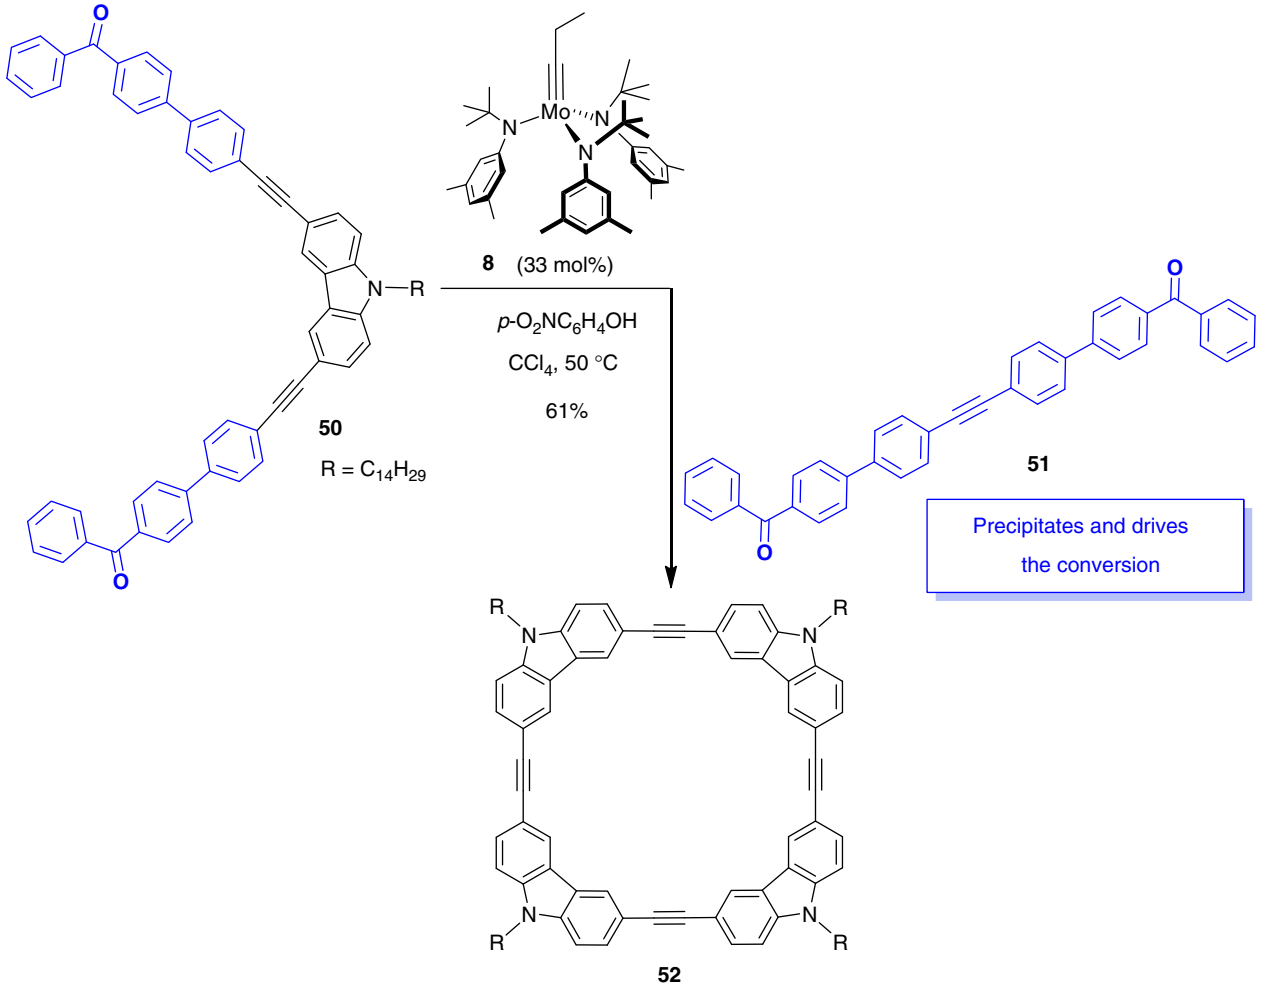


Scheme 13 Convenient and scalable preparation of molybdenum nitride complexes endowed with silanolate ligands, which qualify as effective precatalysts for alkyne metathesis.

As expected, nitride **47** can also be stabilized by complexation with 1,10-phenanthroline or 2,2′-bipyridine.[14,15] The resulting adducts such as **48** are indefinitely air stable and therefore very convenient to work with. As in the alkylidyne series, the stabilizing nitrogen chelate ligand can be removed and the metathesis-active template released on treatment of **48** with $MnCl_2$ or $ZnCl_2$ in anhydrous toluene. Since the preparation of **48** is straightforward, scalable, and requires only very cheap starting materials, this complex constitutes a serious alternative choice for the practitioner of alkyne metathesis.[14,15] Very much like its alkylidyne siblings, it has already passed the test of natural product total synthesis (see Section 5.28.6.4).

5.28.5 Reaction Set-up

At the present stage of development, terminal alkynes cannot be used as the substrates for catalytic alkyne metathesis; they do not lead to sustained turn-over but destroy Schrock alkylidyne complexes by a peculiar C–H activation mechanism at the stage of the metallacyclobutadiene. This has been confirmed crystallographically on more than one occasion (Scheme 14).[15,62,93–95]

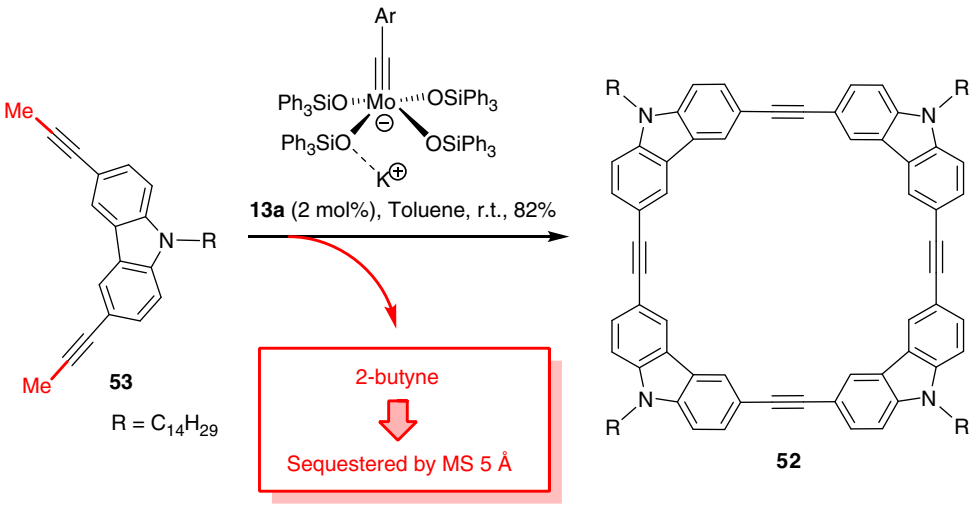


Scheme 14 Established pathway leading to the deactivation of metal alkylidynes on exposure to terminal alkyne substrates; the structure of the product was established by X-ray diffraction, see Ref. 15.

As a consequence, internal alkynes must be used, among which acetylenes capped with a methyl group are most readily accessible and hence most common. Their use leads to the formation of 2-butyne as one of the products, which has to be removed

from the mixture in order to drive the reaction forward and make it preparatively meaningful. In view of the low boiling point of 2-butyne of 27 °C, most of it will evaporate if the reactions are carried out at elevated temperatures and/or if gentle vacuum is applied. Vacuum-driven reactions, however, are not convenient as the solvent will also distill off, at least in part, which changes the concentration of the reaction mixture and may require monitoring and occasional replenishing. High boiling solvents can compensate for this inconvenience, but they usually render the work-up and product isolation more tedious.

In addition to the possible impact on the overall conversion, the accumulation of 2-butyne is also potentially detrimental for the catalyst. Certain Schrock alkylidynes are capable of engaging in a competing associative mechanism, in which further insertion of a given substrate into the metallacycle is faster than cycloreversion with release of the metathesis product (**Scheme 6**). This polymerization manifold is obviously more likely for smaller alkyne substrates and hence most probable for 2-butyne. Because it prevents the catalyst from doing its actual job, 2-butyne may exert a so-called 'pseudo-poisoning' effect.[64]

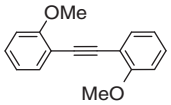


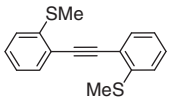
An obvious way around the problem is the use of alkyne substrates carrying larger end-groups than methyl; this strategy, however, is less attractive from the viewpoint of 'atom economy' as more of the material input ultimately ends up in the waste stream. Yet, it has been carried to the extreme in what is called 'precipitation-driven alkyne metathesis' (**Scheme 15**).[64,96] To this end, tailor-made substrates such as **50** were used; on metathesis, the contained 4-benzoyl-biphenyl termini end up in compound **51**. Since this product is only sparingly soluble in either CCl_4 or 1,2,4-trichlorobenzene, the conversion is driven to completion by its precipitation and the desired shape persistent macrocycle **52** isolated in good yields (61–81%).[64,97] Note, however, that the byproduct **51** has a molecular weight of no less than 538 and the preparation of the required substrate **50** mandates more than one extra step.

Scheme 15 Prototype example of a precipitation-driven alkyne metathesis reaction.

A much more practical alternative relies on the use of molecular sieves, in particular MS 5 Å.[14] The pores of this material are able to entrap 2-butyne without getting blocked by the toluene solvent molecules. As a consequence, methyl-capped alkynes can be used as the substrates and the reactions be performed at ambient temperature (or even below), where 2-butyne will hardly evaporate; yet, quantitative conversion is reached since the added MS 5 Å effectively sequesters this byproduct and thereby drives

the conversion to completion.[14] As an additional bonus, the molecular sieves keep the reaction medium dry and hence retard or even stop the deleterious hydrolysis of the catalysts, which remains a serious decomposition pathway for molybdenum alkylidynes carrying silanolate ligands. Furthermore, MS 5 Å binds traces of water that might be inadvertently introduced when $ZnCl_2$ or $MnCl_2$ are employed to activate bench-stable precatalysts such as the phenanthroline or bipyridine adducts **15a**,**b**, respectively. Since molecular sieves are cheap and, if desirable, can be recovered and reactivated, their use is recommended independent of the chosen catalyst. Out of the many successful applications of the use of MS 5 Å, some of which are featured in the later sections of this chapter, the preparation of the very same cyclotetramer **52** is quoted here. As can be seen from Scheme 16, the yield of this particular product was even better than that obtained under precipitation-driven conditions, on exposure of the methyl-capped substrate **53** to catalyst **13a** (or alternatively, to either the nitride- or alkylidyne-phenanthroline adducts **48** or **15** in combination with $MnCl_2$).[14] It is also of note that the required catalyst loading of **13a** (2 mol%) was significantly lower than that in case of catalyst **8** (33 mol%) used in Scheme 15.

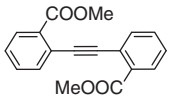


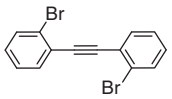


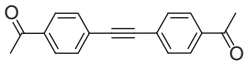
Scheme 16 Molecular sieves allow 2-butyne (bp = 27 °C) formed as the byproduct in metathesis reactions of alkynes capped with methyl groups to be conveniently sequestered and hence the reactions to be performed at (or even below) ambient temperature.

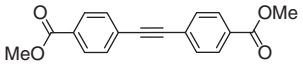
5.28.6 Synthetic Applications of Alkyne Metathesis

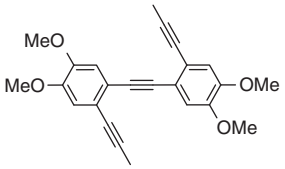
5.28.6.1 Alkyne Self-Metathesis Reactions

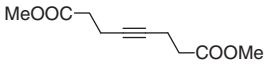


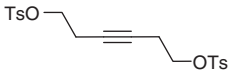


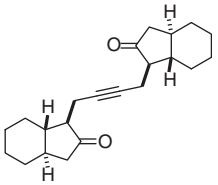


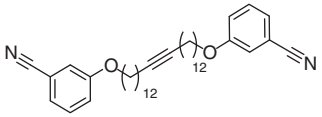












With the advent of ever more effective catalysts, the number of reactions in which alkyne substrates were 'dimerized' (with loss of 2-butyne) has considerably grown. Although by no means comprehensive, the examples compiled in Table 3 provide an overview and attest to the excellent state of the art. As can be seen, aliphatic and aromatic substrates are equally amenable to this reaction, and a considerable number of functional groups were found compatible with the latest generation of catalysts represented by complexes **13**, **15**, or **48**.[14,15] This included heterocyclic motifs as well as potential donor sites comprised of divalent sulfur or moderately basic nitrogen atoms, showing that these complexes fare extremely tolerant to catalyt poisoning. It also makes little

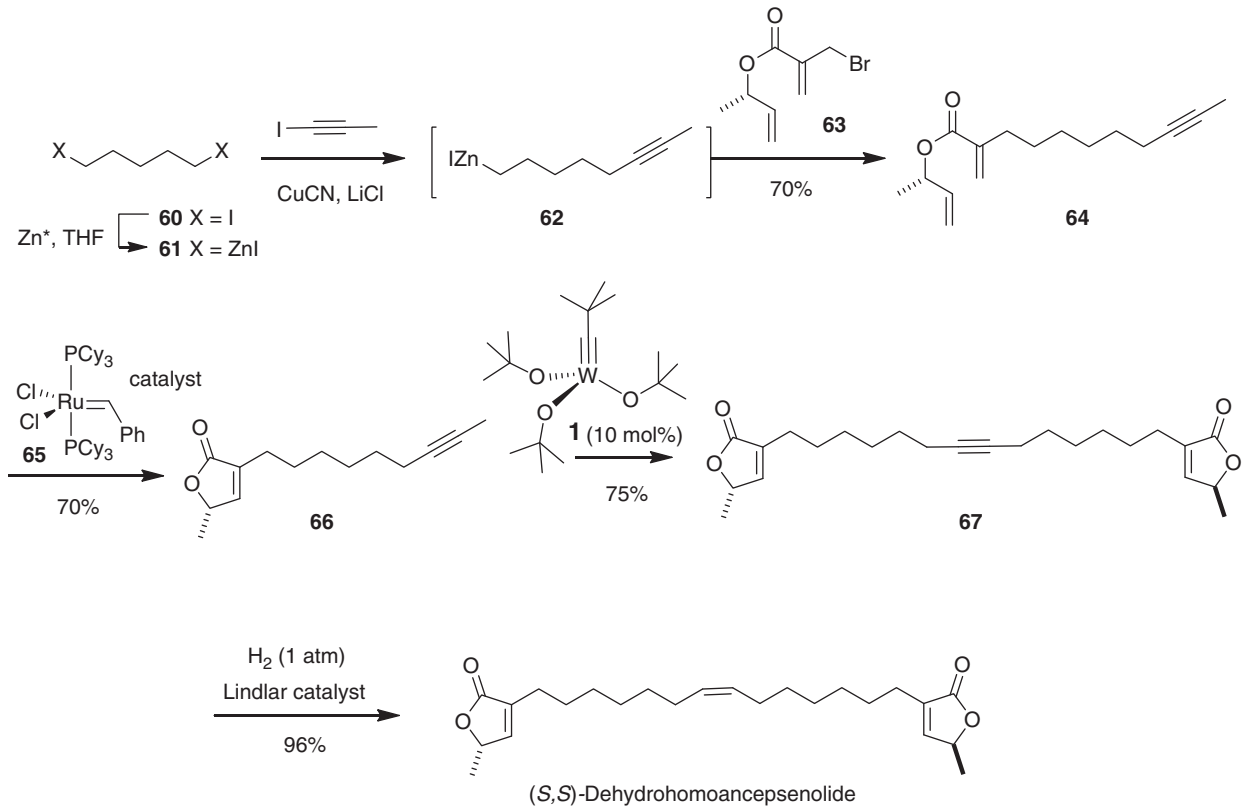
difference if the polar substituent resides *ortho*-, *meta*-, or *para*- to the alkyne group to be metathesized. In the same context, the kinetic stability of nitriles has to be emphasized (entries 9 and 17), as such groups may by cleaved by Schrock alkylidyne complexes as already outlined in Section 5.28.4. The example shown in entry 16 illustrates that chiral centers next to an enolizable carbonyl group are not racemized (for further illustrations of this aspect, see Section 5.28.6.4), and an elimination-prone primary tosylate remained untouched (entry 15). Aromatic aldehydes, however, still represent a challenge, although some examples are known in which this group remained intact.[27] Interestingly, when working with nitride precatalysts such as **46**–**48**, aldehydes actually get transformed into the corresponding nitriles by an as yet unknown mechanism, which represents a potentially valuable transformation in its own right.[92]



The data also suggest that molybdenum alkylidynes endowed with triarylsilanole ligands and their molybdenum nitride counterparts exhibit essentially the same application profile in chemical terms. It should be noted, however, that the initiation of **47** by nitride-to-alkylidyne exchange is best performed at slightly elevated temperatures and the reactions therefore usually carried out at $\geq 80\ ^{\circ}C$ (see Section 5.28.4). This boundary does not exist for preformed alkylidynes, which can be used at ambient temperature if the intrinsic activity of the chosen substrate permits.[14,15] Moreover, the necessary catalyst loading is typically higher when working with nitride precatalysts such as **48**. As expected, however, it makes no difference whether the active species is released from a bench-stable phenanthroline (bipyridine) adduct with the aid of $MnCl_2$, or whether an unstabilized complex is used (compare the performance of **15** vs. **13a**,**b**).

In addition to the examples shown in **Table 3**, a few other peculiar cases deserve mentioning at this point (**Scheme 17**). Propynylated ruthenocene (**54**) for instance reacted quite efficiently under Mortreux conditions to give the corresponding dinuclear product **55**.[98] Conjugated enynes such as **56** and **58** also behaved well under similar conditions, with or without preactivation of the Mortreux-type catalyst by sacrificial 3-hexyne before the addition of the substrate (see Section 5.28.2).[41,99]

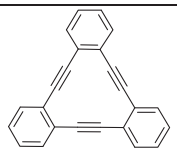
Scheme 17

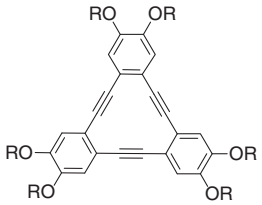
An early application of an alkyne self-metathesis reaction to natural product total synthesis is shown in **Scheme 18**.[100] The C_2-symmetric acetogenin (*S*,*S*)-dehydrohomoancepsenolide could be made available by a concise sequence of reactions, starting with a zinc-induced, copper-mediated three-component coupling reaction.[101] To this end, insertion of activated zinc into both C–I bonds of 1,5-diiodopentane (**60**) followed by addition of only 1 equivalent of CuCN to the resulting diorganozinc intermediate **61** gave a 1,5-heterobimetallic species, which was first reacted with 1-iodo-1-propyne at the copper end, followed by addition of the bromomethyl acrylate ester **63** to provide product **64** in 70% yield in a single operation. This material was treated with the first-generation Grubbs catalyst **65** to forge the corresponding butenolide **66**, which was then subjected to alkyne metathesis in the presence of the standard tungsten alkylidyne complex **1**. A final Lindlar reduction of the dimeric product **67** thus formed completed the total synthesis of this particular target of marine origin.[101] The most noteworthy chemical feature of this productive sequence is the chemical orthogonality of alkene- and alkyne metathesis, which transpires from the consecutive manipulation of the olefinic and acetylenic sites in **64** with the aid of an alkylidene and an alkylidyne complex. This characteristic is highly enabling, as will become evident from several more intricate examples described in Section 5.28.6.4.

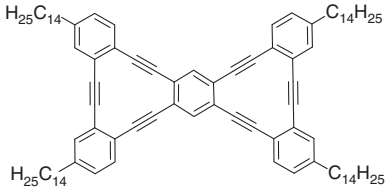
Scheme 18

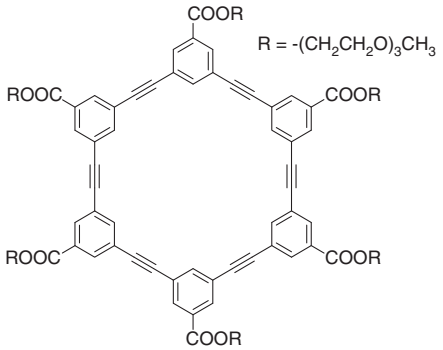
5.28.6.2 Cyclodimerization and Cyclooligomerization Reactions

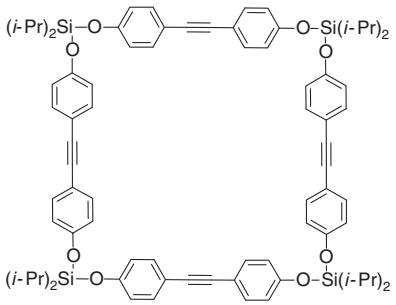
A special case of self-metathesis relates to the cyclo-oligomerization of suitable bis-propynylated arene derivatives, which leads to shape-persistent macrocycles with interesting material properties. The carbazole tetramer **52** as a prototype example has already been discussed in Section 5.28.5 in the context of precipitation-driven alkyne metathesis. Many related cases are known in the literature; a few representative examples are compiled in Table 4. The fact that alkyne metathesis is inherently reversible arguably constitutes the biggest advantage of this methodology over alternative syntheses of such cyclooligomeric products. This dynamic covalent character allows the initially formed product mixture to equilibrate and hence the thermodynamically most favorable product to accumulate in solution. To this end, however, it is necessary that the different products initially formed *in situ* do not precipitate from the mixture. The solubility of such polyaromatic compounds is largely determined by the length and nature of the alkyl chains attached to the monomeric building blocks, which therefore need to be carefully chosen.

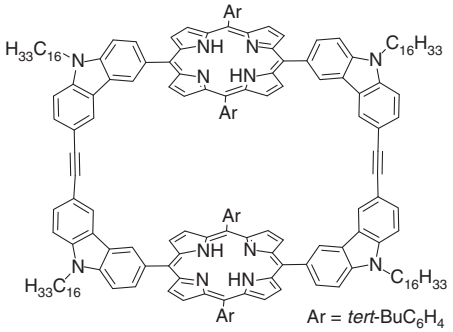












The cyclodimerization of a homologous series of conformationally unrestricted and unfunctionalized diynes has also been reported using a mixture of $Mo(CO)_6$ and 4-(trifluoromethyl)phenol in boiling toluene.[107] The yields remained rather low in most cases, except for the formation of cyclooctadeca-1,10-diyne (**69**) and cyclotetracosa-1,13-diyne, which formed quite efficiently (Scheme 19). The reasons why these particular cyclic diynes are generated much more productively than their immediate homologs are not obvious.

5.28.6.3 Alkyne Cross Metathesis

For ACM to be productive, it is necessary that the two reaction partners are sufficiently different in steric and/or electronic terms;[14,25–27] otherwise, a statistical mixture of products is formed, which is usually difficult to separate. In many of the reported cases, a couple comprising one aromatic and one aliphatic alkyne partner was crossed, and the corresponding products were obtained in good to excellent yields. Even alkynes terminated by a TMS-group could be employed, which are much less reactive than their analogs terminated by a methyl cap and therefore do not react with themselves to any significant degree.[27] The same argument holds true for propargylic alcohol derivatives, which undergo self-metathesis only very reluctantly and therefore cross well.[14] Table 5 shows a selection of representative cases.

Several applications of ACM to natural product chemistry have been reported, among which the preparation of a library of prostaglandin derivatives (Scheme 20)[27,49] and the synthesis of gallicynoic acid I (**78**, Scheme 21)[92] are noteworthy. ACM also

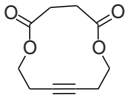
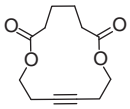
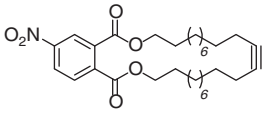
5.28.6.4 Ring-Closing Alkyne Metathesis

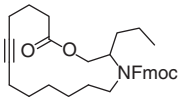
5.28.6.4.1 General aspects

The advent of RCAM shortly before the turn of the millennium increased the preparative significance of alkyne metathesis to a large extent.[23,24,72] The reaction was originally developed to address a stereochemical problem that conventional ring-closing alkene metathesis (RCM) was unable to solve, but it has evolved since then into a much more general tool for organic synthesis.









It is now common knowledge that RCM provides access to cyclic products of virtually all ring sizes but tends to afford *E*/*Z*-mixtures when applied to medium and macrocyclic rings.[109–112] The isomer ratio is difficult to predict; it depends on the chosen catalyst, the particular reaction conditions, and even the reaction time since the reversible nature of RCM engenders a (slow) equilibration. A priori, this process should accumulate the thermodynamically more stable isomer in solution, which is often – but not always – the *E*-configured cycloalkene. Many examples are documented in the literature, however, which demonstrate that even remote substituents and/or the nature of the chosen protecting groups exert a pronounced influence on the

isomer ratio in RCM-based macrocyclizations.[109–112] Inherently *E*-selective alkene metathesis catalysts are currently unknown, and the first-generation of *Z*-selective catalysts has been published only very recently.[113,114]

RCAM was originally developed as a reliable entry point into stereodefined macrocyclic alkenes of either series.[23,24] The cycloalkynes formed by RCAM can either be subjected to Lindlar-type reductions to give *Z*-alkenes or to a Birch-type reduction process, which opens access to the complementary *E*-alkene series with good to excellent levels of selectivity. As will become apparent from the discussion below, this concept has worked out very well and was scrutinized by many applications to the total synthesis of natural products of different levels of complexity. It should be noted at this point, however, that the classical Birch reduction can be advantageously replaced by a ruthenium-catalyzed *trans*-selective hydrosilylation followed by protodesilylation;[115] this methodology is compatible with many functional groups.

Despite the original strategic goal of making stereodefined cycloalkenes accessible by an RCAM/semireduction sequence, it is obvious that the scope of RCAM is by no means limited to this particular type of application. Cycloalkynes can be converted into a host of other structural motifs by taking advantage of different alkyne-selective postmetathesis transformations. The recent progress in the development of alkynophilic π-acid catalysts, notably those based on platinum and gold, provide ample opportunities in this regard.[116–118] Some illustrative case studies along these lines have already been published and many more can be awaited. Table 6 displays a few selected examples of RCAM reactions used to test the different catalyst systems.

Table 6 Screening of different catalysts in model RCAM reactions

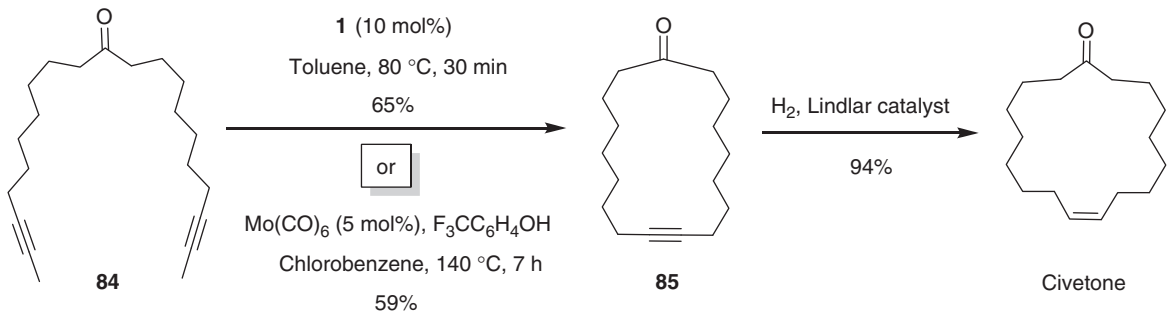
Another highly advantageous characteristic, which paid already many dividends in synthesis, is the orthogonal character of alkyne- and alkene metathesis. It has been demonstrated on many occasions that the available alkyne metathesis catalysts, in particular those of the latest generation, do not touch C–C double bonds of any kind, be they terminal, internal, or conjugated with electron-withdrawing or -donating groups;[14,15] 1,3-dienes are equally tolerated and even highly sensitive skipped 1,4-dienes were shown to survive undamaged. As a consequence, RCAM is predestined for applications to target molecules that present more than one π-system, as will become evident from some of the examples compiled below.

In terms of ring size, RCAM has allowed carbo- and heterocycles of ring sizes ≥ 11 to be formed, with the strain of the cycloalkynes being the limiting factor. In case of an 11-membered ring, the cyclodimerization of the substrate was a major side reaction (see Section 5.28.6.2.),[23,24] which completely takes over in attempted formations of even smaller cycles.

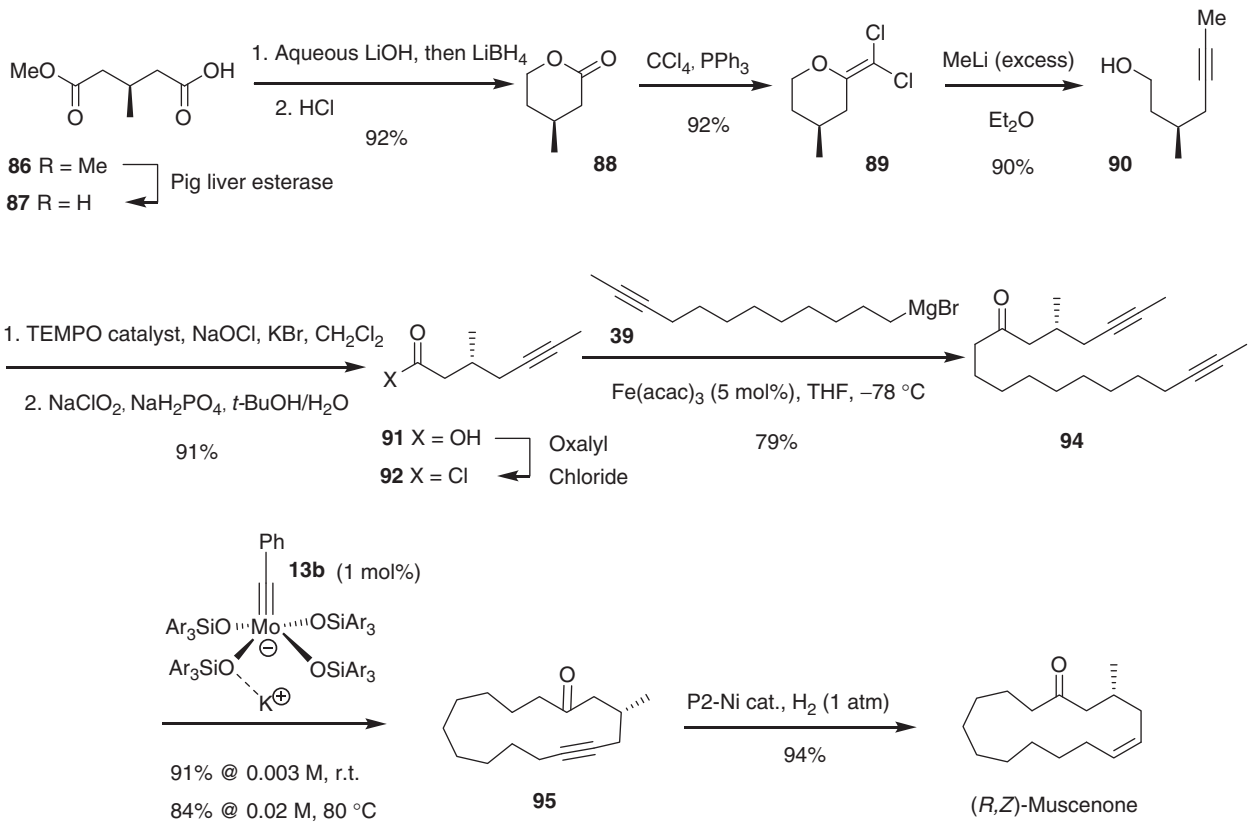


Very recently, catalytic ring-closing metathesis reactions of conjugated diyne substrates have also been accomplished in which dimethyldiacetylene is cleaved off and cyclic 1,3-diyne products are formed (Scheme 23).[119] The reaction was again best performed in the presence of MS 5 Å, using the tungsten alkylidyne **10** modified by siloxide ligands.[120]

Scheme 23

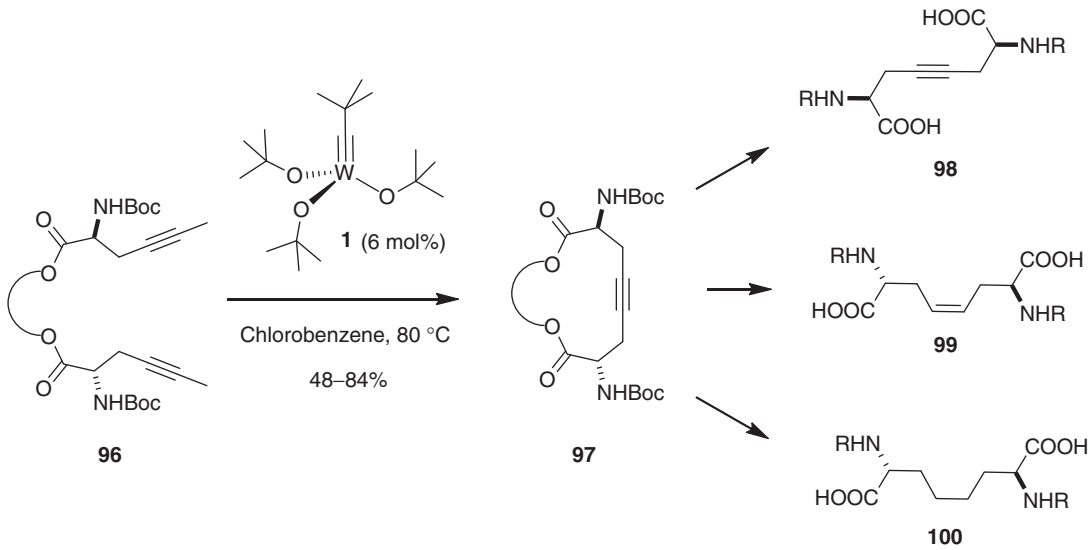
5.28.6.4.2 Olfactory compounds

Many unsaturated macrocyclic lactones and ketones exhibit pleasant olfactory properties, which are often determined by the configuration of the double bonds embedded into the macrocyclic frames. Prominent examples are the perfume ingredients civetone and (*R*,*Z*)-5-Muscenone®, the musk-odored lactone ambrettolide or the camphor- and minty-odored yuzu lactone. Because of their rather simple structures yet industrial relevance, these and related compounds frequently served as testing grounds for the various generations of alkyne metathesis catalysts.[24,42,121] As already mentioned in Section 5.28.2, several such targets could be made in respectable yields even with Mortreux-type catalyst mixtures, although the tungsten alkylidyne **1** was at least as effective but required much shorter reaction times, as exemplified in Scheme 24 for the case of civetone.[42]



Scheme 24

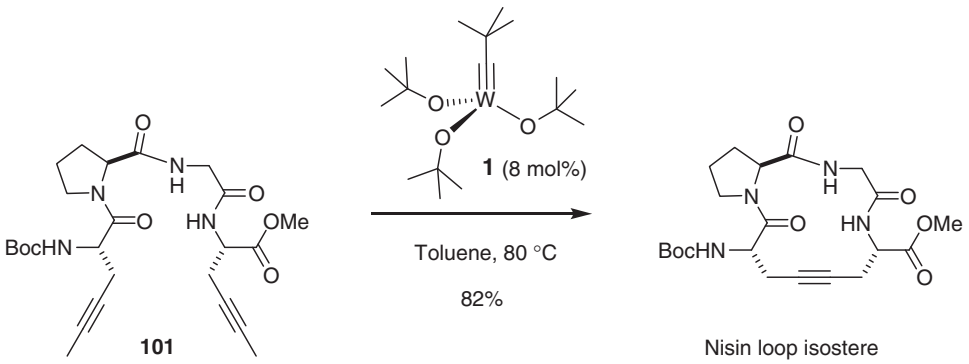
A comparison of the civetone synthesis with the preparation of the commercially used perfume ingredient (*R*,*Z*)-5-Muscenone® presented in Scheme 25 is instructive as it gives a feeling for the advances in catalyst design during the last decade.[122] Interestingly, the preparation of Mucenone was solely built on base-metal catalysis (Fe, Mo, Ni), featuring an iron-catalyzed cross coupling reaction for the formation of the necessary substrate **94** from acid chloride **92** and the alkyl Grignard reagent **93**.[123,124] The cyclization of diyne **94** to the 15-membered cycloalkyne **95** was effected within 30 min at ambient temperature using only 1 mol% of the molybdenum alkylidyne ate-complex **13b**, when the reaction was carried out under high-dilution conditions (0.003 mol l^{-1}). Interestingly, it was possible to increase the substrate concentration by almost one order of magnitude to 0.02 mol l^{-1} without much loss in yield, provided that the cyclization was performed at 80 °C.[122] Under these conditions, the substrate initially converts into a product mixture comprising **95** and various dimeric and oligomeric compounds. Due to the covalent dynamic character of alkyne metathesis, however, this mixture eventually converges to the desired cyclic monomer at the chosen higher temperature.



5.28.6.4.3 Amino acid derivatives

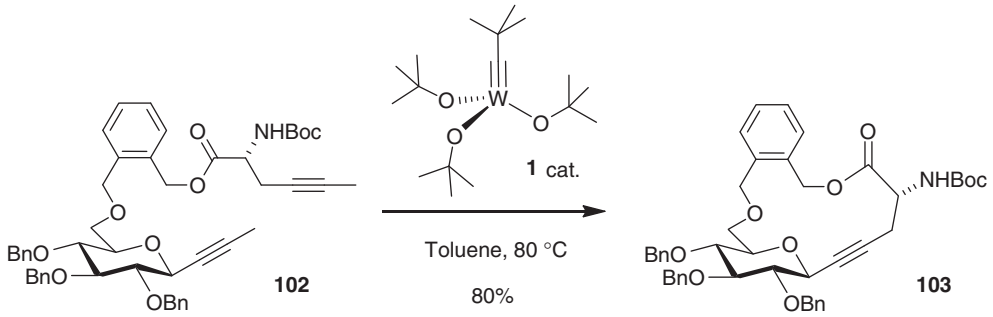
The functionality presented by protected amino acids and peptides poses no problem for the tungsten alkylidyne complex **1**. This excellent compatibility transpires from the successful applications to a small set of cystine isosteres **98**–**100**, in which the chemically and metabolically labile disulfide bridge of the natural product was replaced by either a carbon–carbon triple-, double-, or single bond; the efficiency of ring closure, however, depended on the chosen diol tether (Scheme 26).[125] The same

Scheme 25



tactics could also be applied to the preparation of orthogonally protected cystine isosteres for incorporation into larger peptides, as well as to variety of other acetylene-containing amino acid derivatives.[126]

Scheme 26

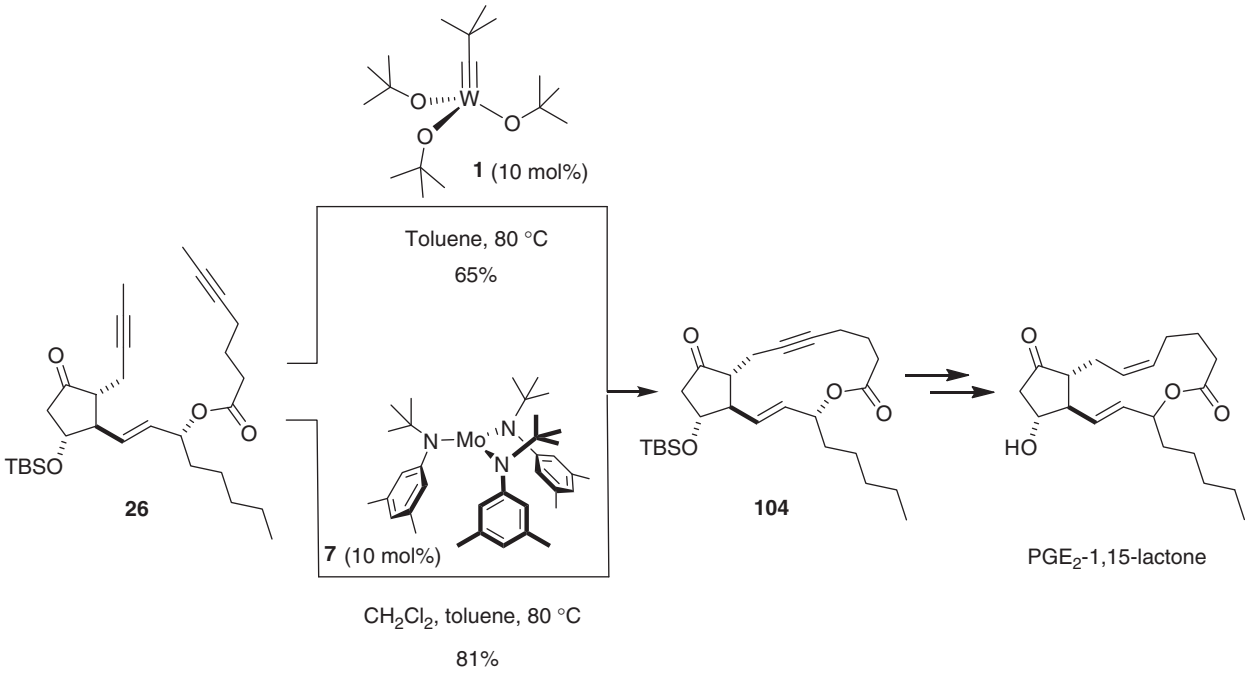


RCAM also served the preparation of several isosteres of the individual loops of the lantibiotic nysin Z.[127,128] The most effective case is shown in Scheme 27, which benefits from a certain degree of conformational preorganization of the substrate **101** by the turn-inducing proline unit. Peptidic diynes devoid of such a cyclization-friendly conformation gave lower yields and

required longer reaction times. The beneficial effect of proline was later used to prepare various other cyclic β-turn motifs by a similar strategy.[129]

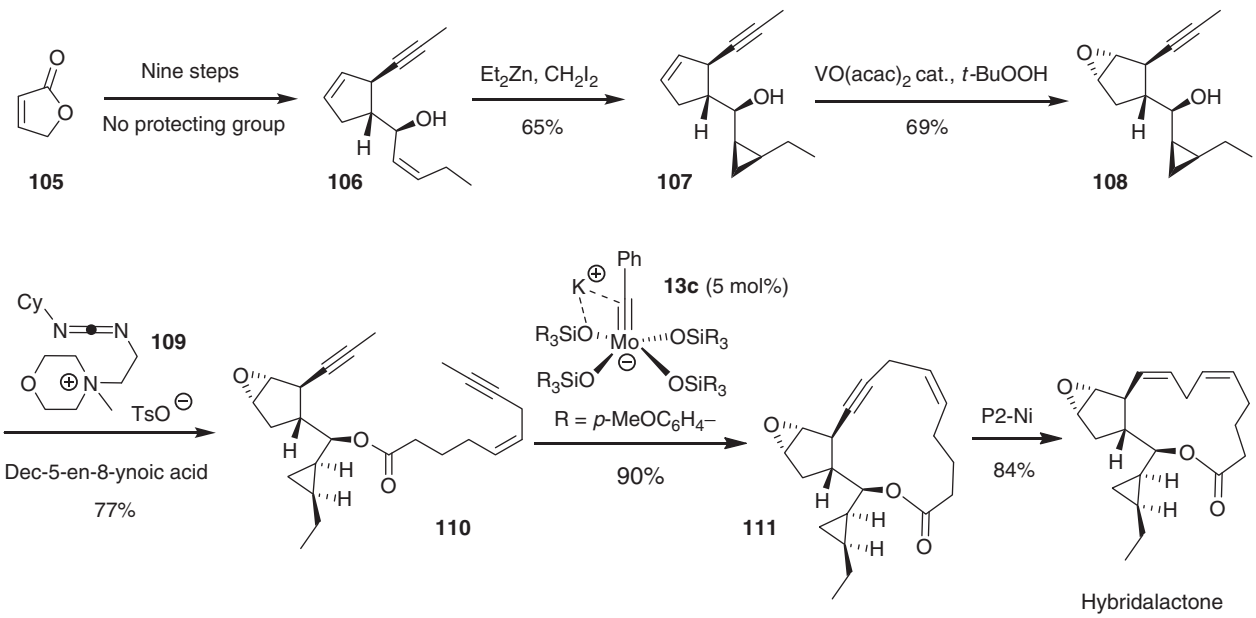
Scheme 27

Related cyclization reactions were successfully applied to the preparation of glycopeptide isosteres starting with substrates, in which *C*-glycosidic acetylenes such as **102** reacted intramolecularly with a tethered 2-butynyl glycine entity.[130] Depending on the particular connectivity pattern, either the desired cyclic monomers such as **103** or cyclodimeric products were obtained with the aid of the tungsten catalyst **1** (Scheme 28).



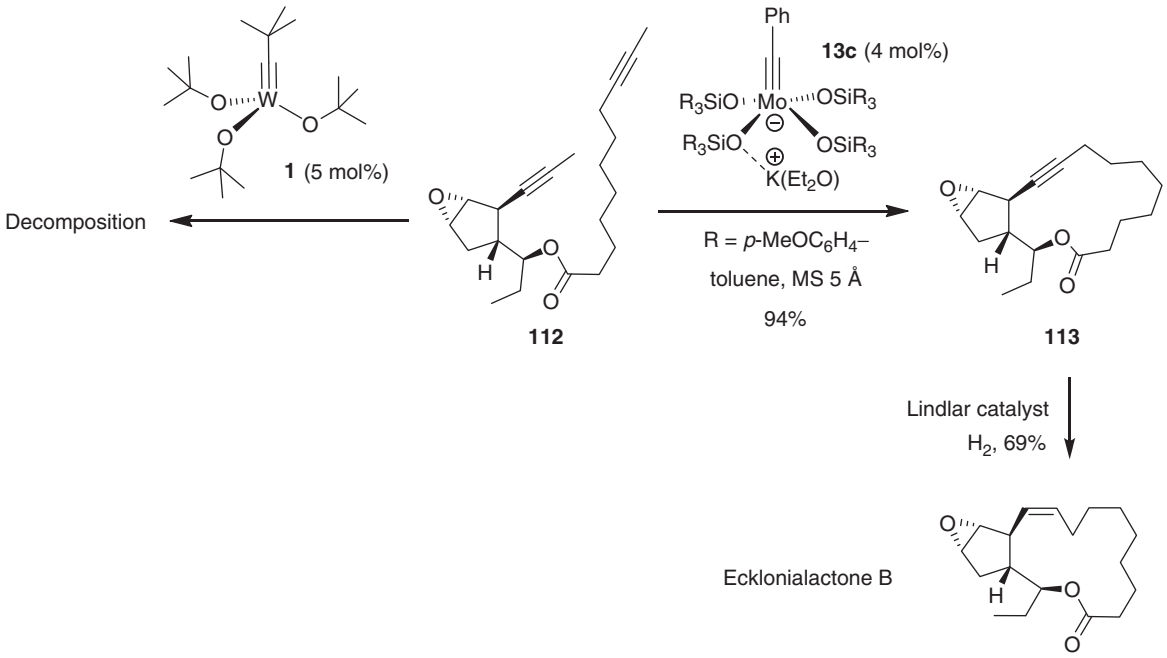
Scheme 28

5.28.6.4.4 Prostaglandins and oxylipins



The intrinsic lability of prostaglandins renders this product class a formidable testing ground for the efficiency of the various alkyne metathesis catalysts available to the practitioner. The significant differences in their performance are evident from an early application to the total synthesis of prostaglandin E_2–1,15-lactone, a naturally occurring prodrug that is hydrolyzed on demand to the parent prostaglandin E_2 by various esterases (Scheme 29).[49,131] Attempts to cyclize diyne **26** by Mortreux-type catalysts met with failure as the substrate was destroyed (Scheme 4). In contrast, the use of the classical tungsten alkylidyne **1** afforded the desired cycloalkyne **104** as the immediate precursor of the target in appreciable yield but was outperformed by the combination **7**/CH_2Cl_2. A small set of nonnatural prostaglandin analogs could be obtained analogously by varying the length and substitution pattern of the acid segment in the cyclization precursor.[49]

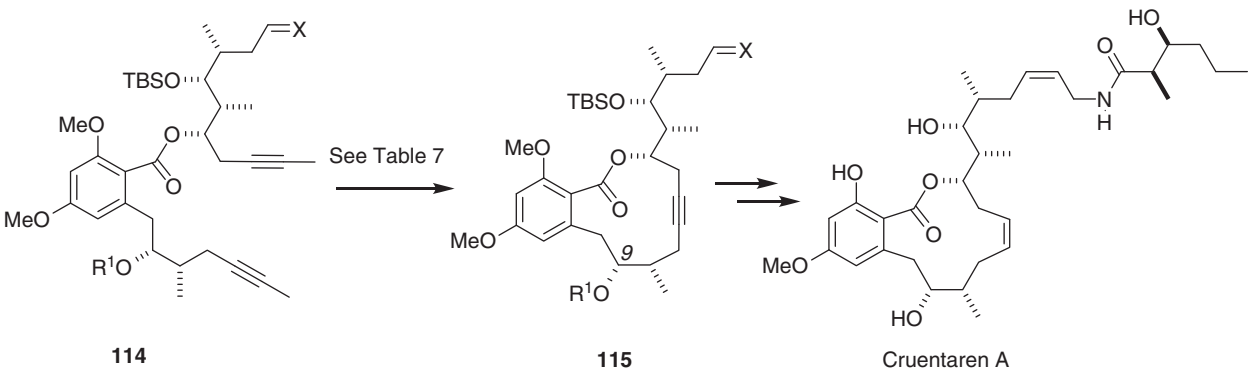
The structurally rather unusual marine eicosanolid hybridalactone constitutes an even more demanding case (Scheme 30).[132] In an attempt to adhere to the most stringent conditions imposed on contemporary total synthesis, the required cyclization precursor **110** was prepared without recourse to any protecting group maneuvers in excellent overall yield starting from the commercial butenolide **105**. Key to success were two consecutive and highly chemo- and stereoselective functionalizations of the alkene sites in **106**, both of which were guided by the allylic –OH group serving as a relay substituent. First, this group assured a β-selective cyclopropanation of the *Z*-configured allylic alcohol to give product **107** before it directed the subsequent vanadium-catalyzed epoxidation to the α-face of the endocyclic olefin. With all seven contiguous chiral centers of the target being set, the stage for macrocyclization was reached on esterification of **108** with dec-5-en-8-ynoic acid. This seemingly routine step was actually rather difficult and worked well only when mediated by a specially modified cationic carbodiimide **109** escorted by a tosylate counterion. Any more nucleophilic anion present in the mixture (for instance, the chloride released when using the respective acid chloride for the acylation) was found to open the epoxide ring of **108**, which is unusually reactive. Gratifyingly, the resulting diyne **110** was cyclized with exceptional ease using catalyst **13c**, whereas the classical tungsten alkylidyne **1** destroyed this



Scheme 29

fragile substrate (and related compounds, see Scheme 31).[132] The *p*-methoxyphenyl groups on the silanolate ligands of **13c** facilitate the purification of the resulting cycloalkyne **111**, because they render the silicon-containing residues formed on work up rather polar and hence easy to remove from the fairly lipidic product. A selective reduction of **111** over nickel boride (P2-Ni made from $Ni(OAc)_2 \cdot 4\,H_2O$ and $NaBH_4$) installed the skipped 1,4-diene unit and completed the total synthesis of this interesting marine natural product.[132] Various natural and nonnatural analogs were also obtained by analogous routes, including the C18-oxylipin derivatives ecklonialactone A, B, and C. The approach to these latter compounds also highlighted the much improved application profile of the molybdenum alkylidynes of type **13** as compared with the classical Schrock catalyst **1** (Scheme 31).[132,133]

Scheme 30



Scheme 31

5.28.6.4.5 Macrolides incorporating Z- or E-configured alkenes

The fact that three research groups independently pursued the total synthesis of the highly cytotoxic F-ATPase inhibitor cruentaren A via RCAM/semireduction as the key strategic transformation may reflect the growing popularity of the method within the synthetic community. At the same time, the three approaches nicely feature the rapid advance in catalyst development made in recent years.

Specifically, Vintonyak and Maier forged the highly functionalized 12-membered ring **115a** with the aid of the Schrock tungsten alkylidyne catalyst **1** (Scheme 32 and Table 7, entry 1)[134,135] and then carried the cycloalkyne trough to the very end of the synthesis. It served to keep the –OH group at C.9 away from the transannular lactone and hence effectively prevented undesirable ring contraction with formation of a δ-lactone from occurring. After attachment of the lateral chain, a Lindlar reduction revealed the two *Z*-olefins residing in the ring and the tether in a single operation. This successful blueprint was promptly extended to the preparation of a set of cruentaren-analogs for biological testing.[136]

Scheme 32

In parallel work, the Fürstner group was able to cyclize the even more decorated precursor **114b** to product **115b**, which already contained the *Z*-alkene in the lateral chain (X=CHCH$_2$OTHP).[137,138] Attempts to perform this reaction with the tungsten alkylidyne **1a**, however, only led to cleavage of the THP-acetal due to the significant Lewis acidity of this particular catalyst (Table 7, entry 2). Gratifyingly, the combination **7**/CH_2Cl_2 was found more chemoselective, furnishing the desired product in 87% yield (entry 3). This transformation was revisited when the latest generation catalysts endowed with siloxide ligands became available. As expected, complex **13a** furnished product **115b** with similar efficiency but required a significantly lower loading of

Table 7 RCAM reactions en route to cruentaren A as shown in **Scheme 32**

Entry		*R^1*	*X*	*Catalyst*	*T (°C)*	*Yield (%)*	*References*
1	**115a**	TIPS	H, ODMB	**1** (10 mol%)	85	91	134
2	**115b**	TBDPS	$CHCH_2OTHP$	**1** (10 mol%)	80	–[a]	137
3	**115b**	TBDPS	$CHCH_2OTHP$	**7** (10 mol%)[b]	80	87	137

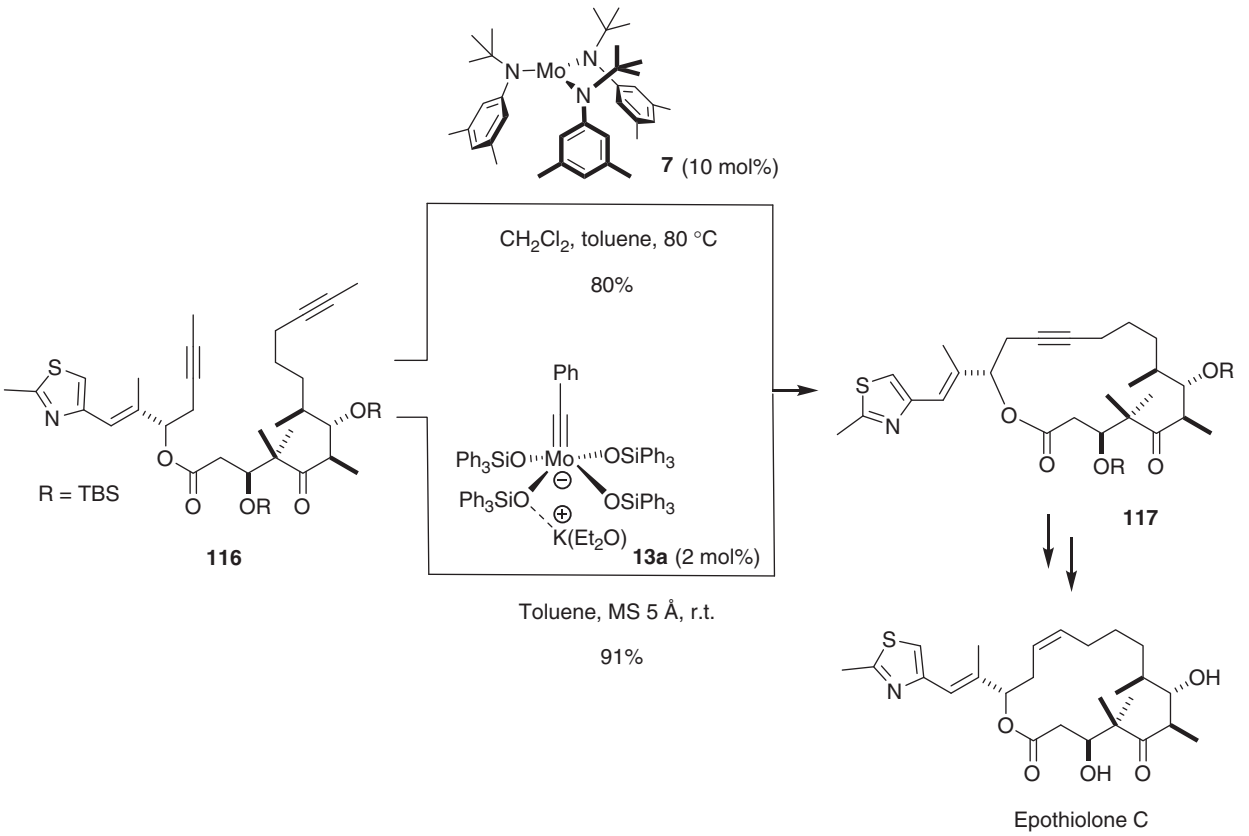
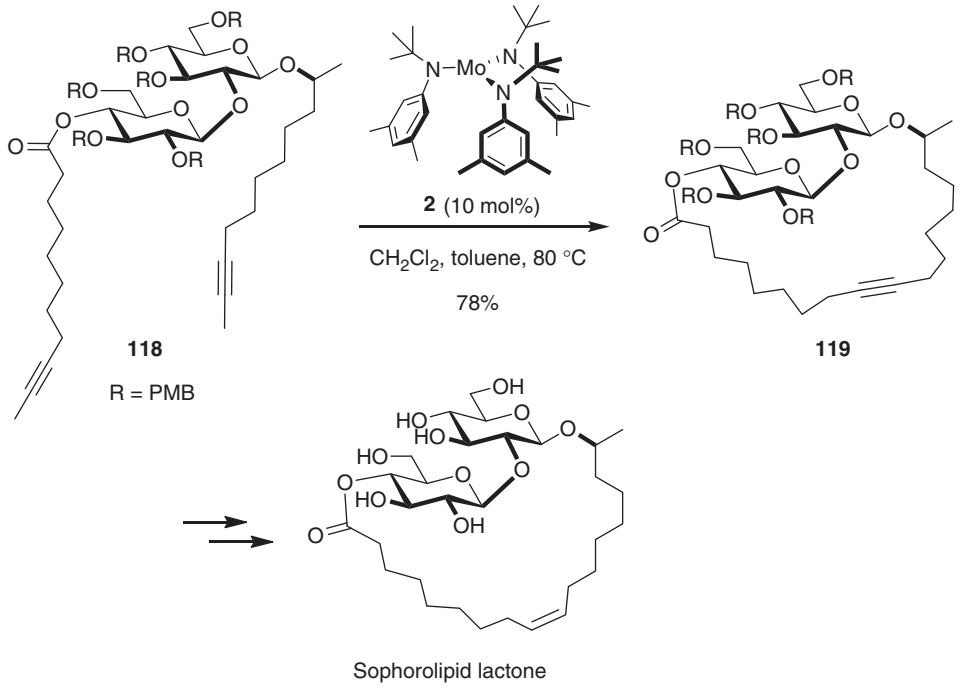
only 2 mol% (entry 4). A few standard operations then allowed **115b** to be converted into cruentaren A in high overall yield. In the next stage of the project, the approach could be successfully reprogrammed to the preparation of a collection of designer-analogs of this potent cytotoxic agent, all of which contained deep-seated structural point mutations.[138] Gratifyingly, three of these fully synthetic compounds turned out to be as or even more cytotoxic than the parent natural product cruentaren A itself against L-929 mouse fibroblast cells, reaching IC_{50} values as low as 0.7 ng ml^{-1}.



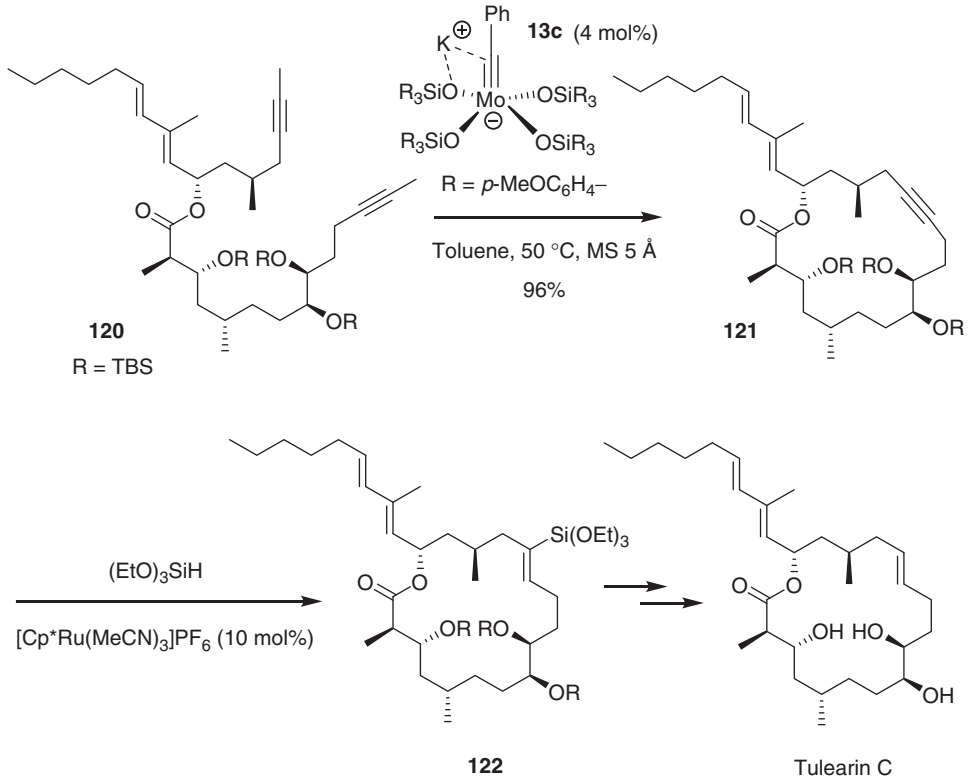
Barrett and coworkers reported yet another synthesis of cruentaren A via RCAM using the pyridine adduct of the molybdenum nitride **47** as the precatalyst to forge the macrocycle.[139] Because the initiation of this precatalyst by nitride-to-alkylidyne exchange is slow and requires heating, a fairly high loading (40%) was used to ensure a sufficient concentration of the active species in solution and hence a short reaction time in order to minimize the thermal decomposition of the polyfunctionalized substrate (Table 7, entry 5). Although this key step resembles the earlier syntheses of **115**, the innovative preparation of the cyclization precursor **114c** by a biomimetic *de novo* synthesis of the resorcyclide unit deserves particular mentioning.

A similar comparison of the productivity of the different available catalysts can also be made in the case of epothilone C, a prominent target in natural product synthesis in general and metathesis chemistry in particular (**Scheme 33**). The first synthetic approaches toward the epothilones based on RCM were all facing the same problem that the macrocycle could be closed in high yields but with little – if any – selectivity in favor of the required *Z*-alkene.[140] Since this selectivity issue arose only in the final stages of the multistep sequences leading to the target and the produced isomer mixtures were found difficult to separate, the epothilones showcased the urgent need for the development of more stereoselective metathesis catalysts. To this end, the combination of RCAM/Lindlar reduction provided the first viable solution (**Scheme 33**).[72,141] It was the then brand new trisamido complex **7** in combination with CH_2Cl_2, which allowed the polyfunctionalized diyne **116** to be cyclized in high yield in toluene at 80 °C. Neither was the aldol substructure damaged nor was the sulfur- and nitrogen donor sites present in this substrate interfering with the catalyst. After the development of the molybdenum alkylidyne complexes endowed with triarylsilanolate ligands, this particular transformation was reinvestigated.[14] As expected, catalyst **13a** was not only even more productive but also required a lower loading even when operated at ambient temperature. Semireduction of the resulting cycloalkyne **117** followed by global deprotection gave epothione C in excellent yield and isomerically pure form. It is, however, fair to say at this point that the very recent progress in the design of *Z*-selective olefin metathesis catalysts has also enabled a stereoselective synthesis of epothilone C by conventional RCM.[113]



Another challenging application from a different area relates to the stereoselective total synthesis of the glycoconjugate sophorolipid lactone, which comprises an isolated *Z*-alkene within its fatty acid tether (**Scheme 34**). Once again, RCAM followed by semihydrogenation provided a satisfactory solution and showed at the same time that polyoxygenated substrates and glycosidic linkages pose no problems for molybdenum-based catalysts.[142,143]

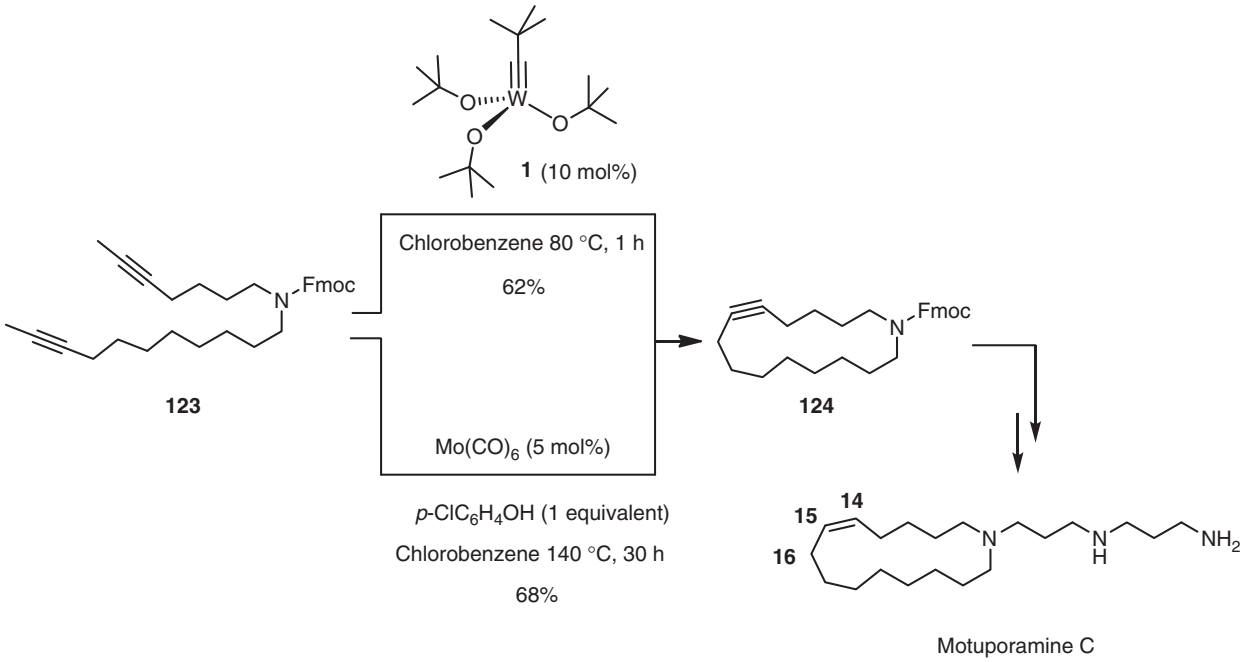
A recent total synthesis of the sponge metabolite tulearin C shows that RCAM/semireduction also excels in the stereocomplementary formation of *E*-olefins from adequate cycloalkyne precursors (**Scheme 35**).[144] This result must be seen in the light of a previous investigation, in which the macrocyclic frame of a tulearin had been forged by conventional RCM, but with an unfavorable *E*/*Z*-ratio of 1.9:1.[145] This outcome shows that the lack of inherently *E*-selective olefin metathesis catalysts can be a serious setback for target-oriented synthesis, in particular since all attempts to improve on the result by changing the reaction parameters or modifying the substrate were to no avail.



This shortcoming of RCM can be circumvented by an RCAM/semireduction sequence. As shown in **Scheme 35**, this tactics furnished tulearin C with exquisite stereochemical purity. Specifically, cyclization of diyne **120** using the highly active and selective ate-complex **13c** as precatalyst in the presence of MS 5 Å as additive gave the corresponding cycloalkyne **121** in almost quantitative yield, although the contained dienyl-alcohol motif as well as the aldol subunit are both fairly sensitive. A subsequent *trans*-hydrosilylation catalyzed by $[Cp^*Ru(MeCN)_3]PF_6$ followed by global deprotection of **122** furnished tulearin C in a very satisfactory yield and excellent *E*-selectivity. The formal *trans*-reduction of the alkyne by a ruthenium-catalyzed hydrosilylation followed by cleavage of the resulting alkenyl silane with a mild fluoride source, originally developed by Trost and coworkers,[115] is widely applicable in the context of cycloalkynes and cyclic enynes and tolerates many relevant functionalities, as this and other studies from the author's laboratory have demonstrated.[146–148]

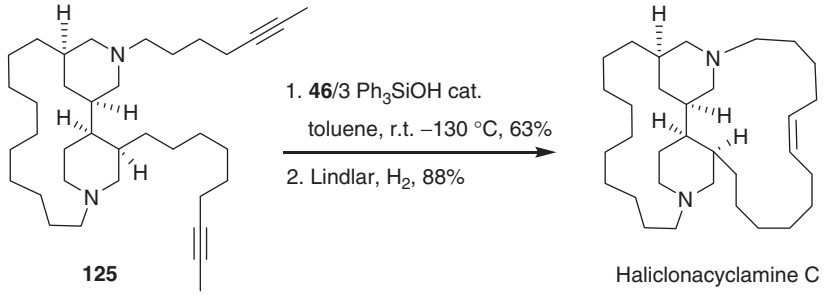
Scheme 33

Scheme 34



Scheme 35

5.28.6.4.6 Alkaloids

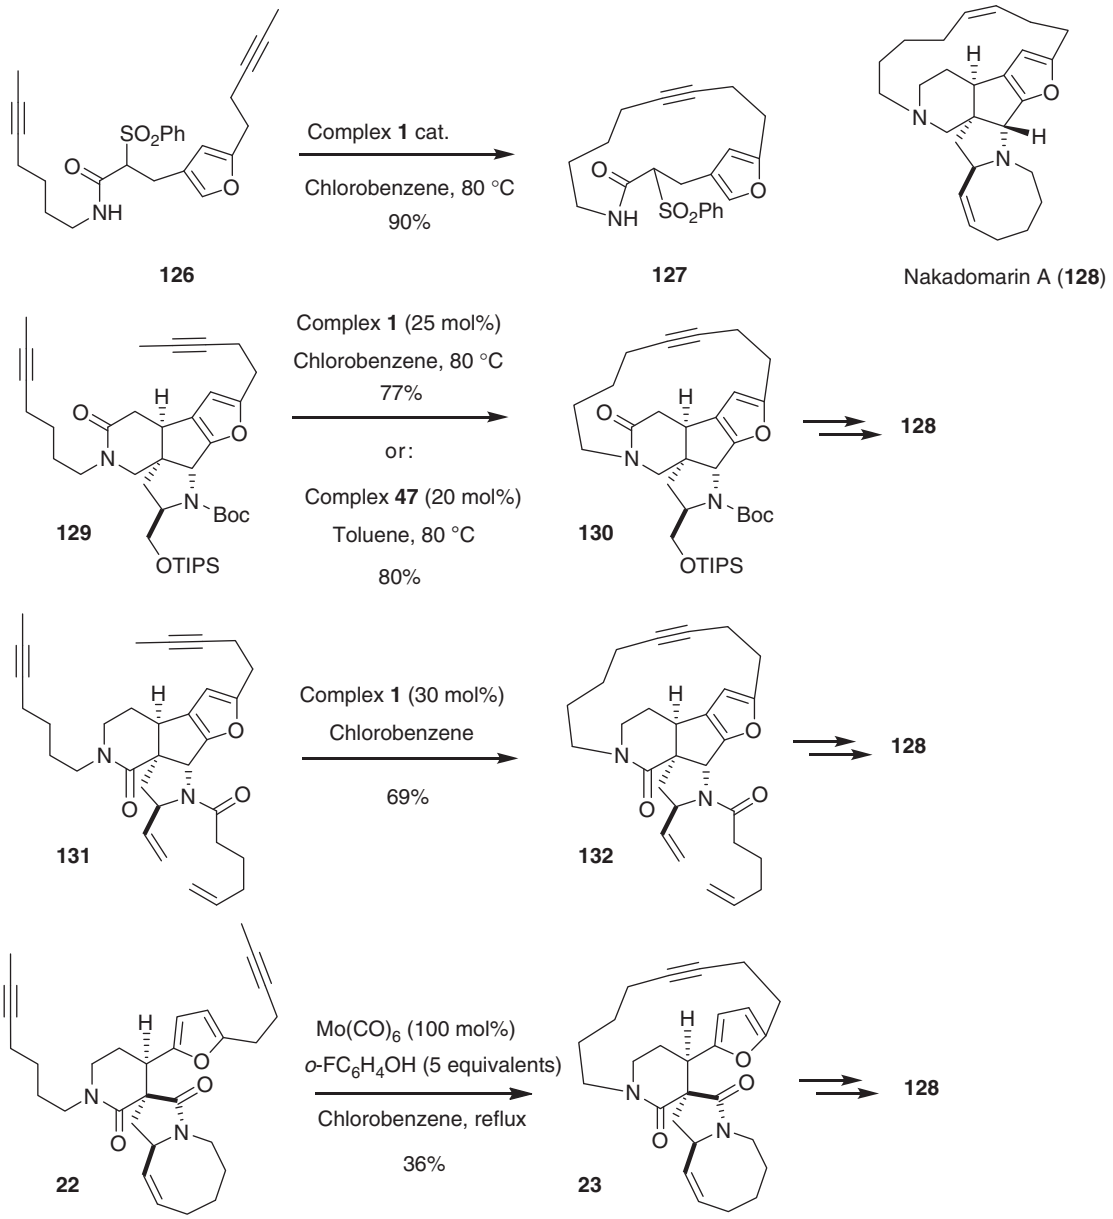


The structurally rather simple but biologically very promising spermine alkaloid motuporamine C served as an early testing ground.[45] Since the isolation team had been unable to determine whether the $\Delta^{14,15}$-alkene or the $\Delta^{15,16}$-isomer represented the natural product, both compounds were selectively prepared as depicted in **Scheme 36** for one of them. RCAM forged the macrocycle either with the aid of the tungsten alkylidyne **1** or with an *in situ* Mortreux-type mixture, which were similarly effective in case of this barely functionalized substrate. A subsequent Lindlar reduction then gave the required *Z*-alkene, which was easily advanced into the target. With both positional isomers in hand, it was possible to show that the $\Delta^{14,15}$-alkene depicted in **Scheme 36** was identical with natural motuporamine C in all spectroscopic and analytical regards.[45]

Whereas the early and more Lewis acidic alkyne metathesis catalysts such as **1** are inhibited by coordination to basic N-atoms, the new molybdenum nitride and alkylidyne complexes bearing silanolate ligands are usually compatible with such donor sites and hence qualify particularly well for applications in the alkaloid series. This notion is exemplified by a total synthesis of the tetracyclic alkylpiperidine alkaloid haliclonacyclamine (**Scheme 37**).[149] In the penultimate step, the elaborate substrate **125** containing two *tert*-amines was successfully cyclized and the resulting product swiftly advanced to the targeted natural product. Of all the catalysts tested, only $[(Ph_3SiO)_3Mo{\equiv}N]$ (**47**) generated *in situ* from nitride **46** and Ph_3SiOH was able to effect this transformation without getting blocked by the tertiary amines. Since **47** must convert into an alkylidyne *in situ* in order to exert its catalytic activity (see Section 5.28.4, **Scheme 13**), it is reasonable to assume that preformed molybdenum alkylidynes such as **13**–**15** would be equally or even more effective in this particular transformation.[14,15]

The macrocyclic perimeter of the complex marine alkaloid nakadomarin A (**128**) has invited many teams to scrutinize the performance of RCAM in target-oriented synthesis (**Scheme 38**). After an early model study had suggested that the ring can be closed by this reaction in excellent yield (**126**→**127**),[24] several teams succeeded in implementing this strategy into actual total synthesis endeavors. Specifically, the group of Funk showed that the tungsten alkylidyne **1** and the molybdenum nitride complex **47** are roughly equipotent in the conversion of **129** into **130**, but the latter is much cheaper and easier to handle.[150] Dixon and coworkers employed the tungsten catalyst **1** to cyclize the somewhat more elaborate substrate **131**, which contained two additional double bonds; once again, the alkylidyne was found to select exclusively for the alkynes and left the olefins unchanged.[151] Somewhat surprisingly, the most elaborate substrate **22** with the strained eight-membered ring already in place, was cyclized by the Dixon group in a second approach with the aid of a more archetypic Mortreux-type catalyst, which required very harsh conditions.[47] Although the desired product **23** could be isolated, the yield remained low despite the very high catalyst loading (see Section 5.28.2).

Scheme 36



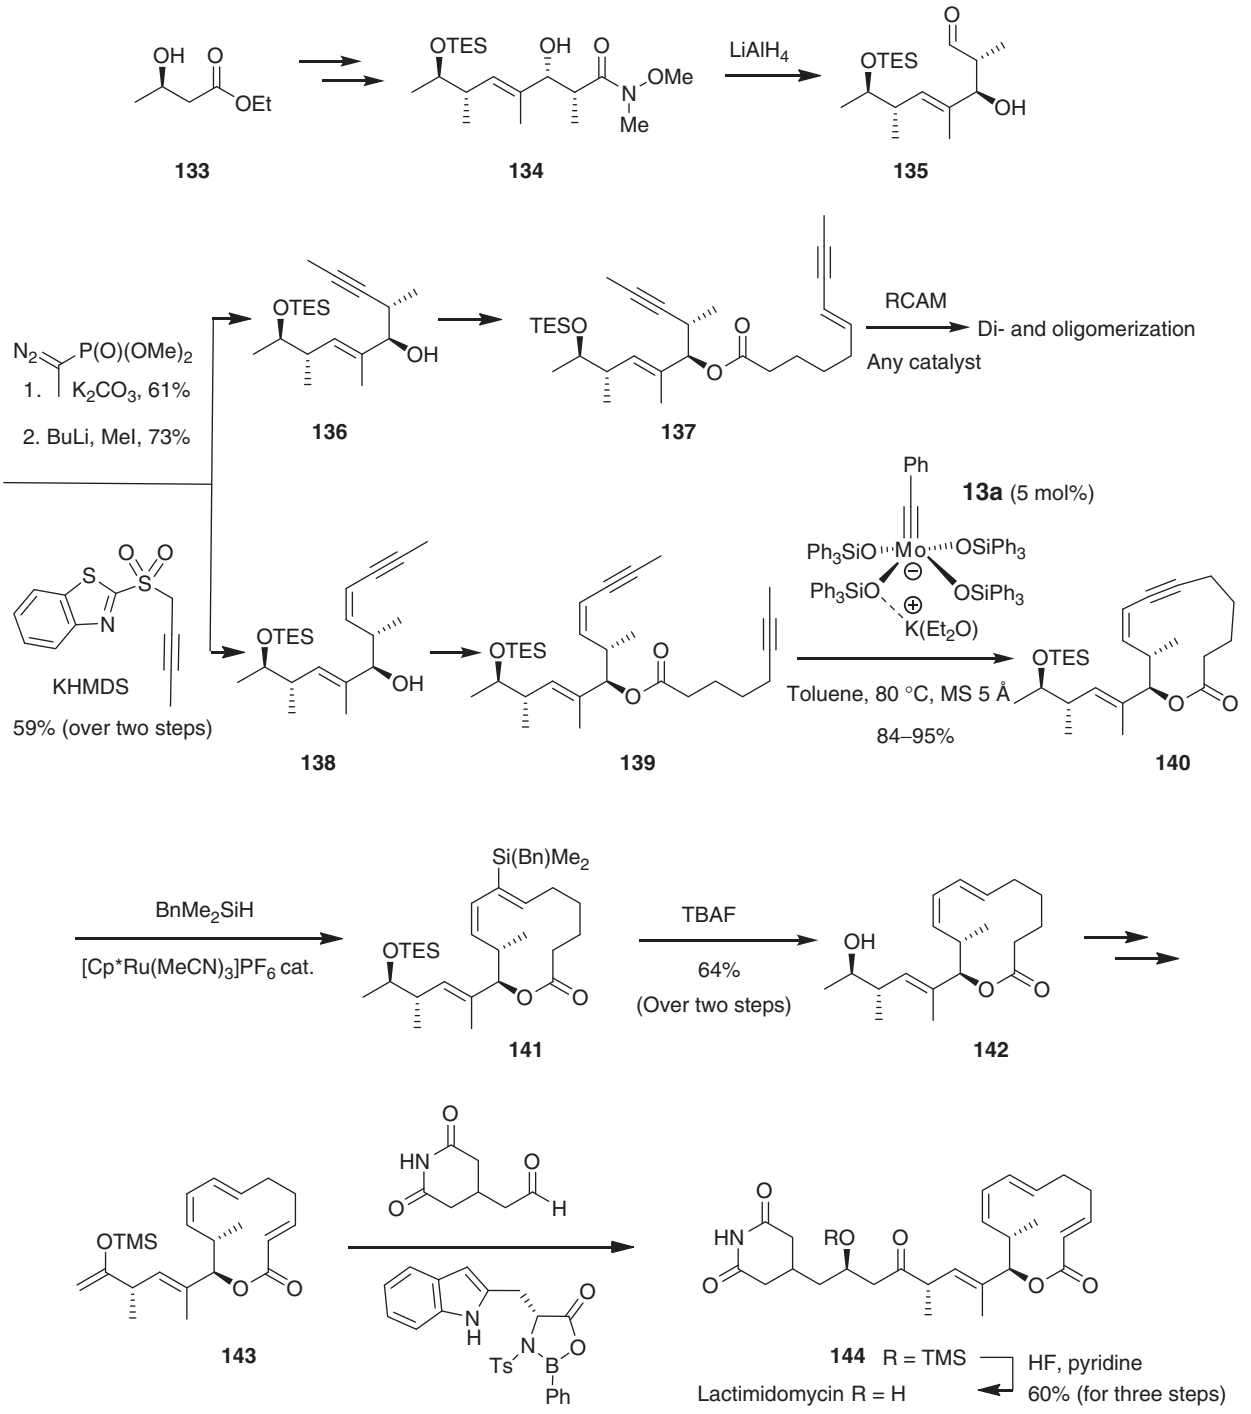
Scheme 37 The compatibility of the molybdenum catalysts bearing silanolate ligands with basic amines was the key enabling feature for a total synthesis of the alkylpiperidine alkaloid halichlonacyclamine C.

5.28.6.4.7 Conjugated dienes

An important limitation of contemporary alkene metathesis relates to the stereoselective formation of conjugated dienes or polyenes, because the standard catalysts do not properly distinguish between the different double bonds of the required substrates. Although a couple of successful examples are known in the literature, many attempted syntheses of cyclic 1,3-dienes were plagued by the preferential activation of the inner double bond of a given substrate, which ultimately results in ring contraction. Moreover, the newly formed bonds are usually formed as *E*/*Z*-isomer mixtures, which complicates matters even further and makes cumbersome separations necessary. Only recently has a more rational RCM-based approach to 1,3-dienes been devised, in which the inner double bond of a given substrate is substituted by a silyl group that serves as a protecting and as a stereodirecting group alike.[152]

The proven orthogonal character of alkyne metathesis provides a serious alternative. Early model studies had shown that only the two acetylene units of an enyne–yne substrate will react, whereas the conjugated alkene site passes uncompromised.[147,148] The resulting enyne product can then be stereoselectively transformed into the desired diene, which allows the regio- and stereochemistry of the product to be reliably dialed in. This notion is illustrated by the total syntheses of lactimidomycin (Scheme 39) and latrunculin A (Scheme 40). Both targets contain an *E*,*Z*-configured diene; in the former case, this motif was formed at the *E*-olefinic site, whereas in the latter case, it was the *Z*-alkene substructure, which served as the site of disconnection, thus showing the flexibility of the RCAM-chemistry.

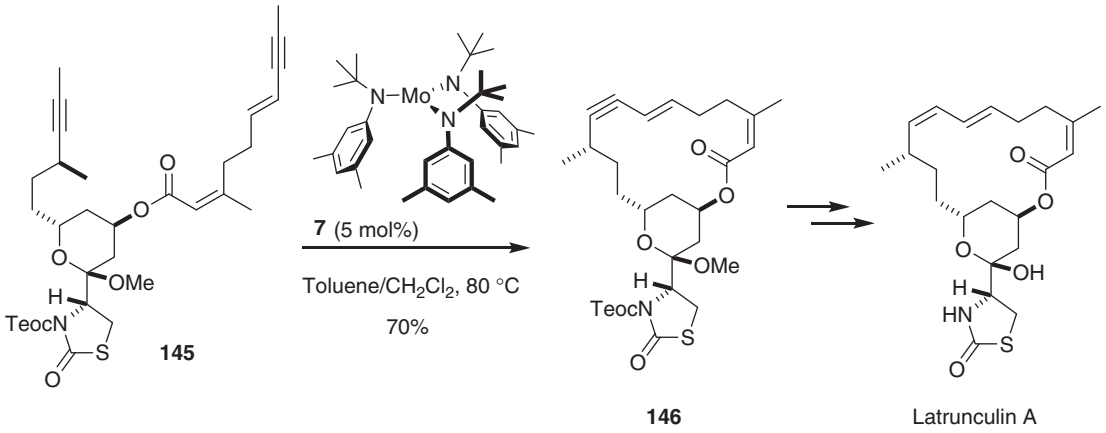
The major challenge in the total synthesis of the cell-migration inhibitor lactimidomycin is related to the significant strain inherent to the 12-membered head group that comprises seven sp^2-hybridized C-atoms (Scheme 39). Although it may seem counterintuitive at first sight to try to forge this substructure via alkyne metathesis, this plan could be reduced to practice on counterbalancing the extra strain by editing the enoate double bond out at the stage of ring closure.[153] The success of this tactics,



Scheme 38 Comparison of different RCAM-based approaches to nakadomarin A.

however, depended on the site of ring closure, whereas compound **137** afforded only di- and oligomeric products but no significant amount of the desired cyclic monomer, the isomeric substrate **139** cyclized smoothly; this different pattern is readily understood if one considers that **137** would lead to a 12-membered lactone comprising a supposedly linear alkyne and an *E*-alkene, whereas product **140** is somewhat less strained because the preexisiting alkene in the ring is *Z*-configured.

In any case, compound **139** was ring closed in excellent yield on a gram scale to cycloalkyne **140** by recourse to the powerful molybdenum ate-complex **13a** in the presence of MS 5 Å. Although this catalyst is metathesis-active at or even below room temperature, this particular transformation had to be carried out at 80 °C, which is ascribed to the strain that has to be built up.[153] A subsequent ruthenium-catalyzed *trans*-hydrosilylation followed by a simultaneous C- and O-desilyation of the resulting product **141** gave **142**, which was then elaborated into the target. The final stages of the synthesis relied on an asymmetric Mukaiyama aldol reaction of silyl enolether **143** to complete the lateral chain of **144** while setting the as yet missing chiral center.



As outlined above, considerations of ring strain had dictated the choice of the *E*-alkene as the optimal assembly point for lactimidomycin. No such superordinate aspects need to be considered in the case of the potent actin-binding macrolide latrunculin A (Scheme 40).[154,155] This valuable tool for chemical biology was made available by a convergent approach via the elaborate enyne **145** decorated by an unusual thiazolidinone unit. Gratifyingly, neither this rare sulfur-containing heterocycle nor the elimination-prone tertiary glycoside posed any problem in the macrocyclization, which was catalyzed by the combination

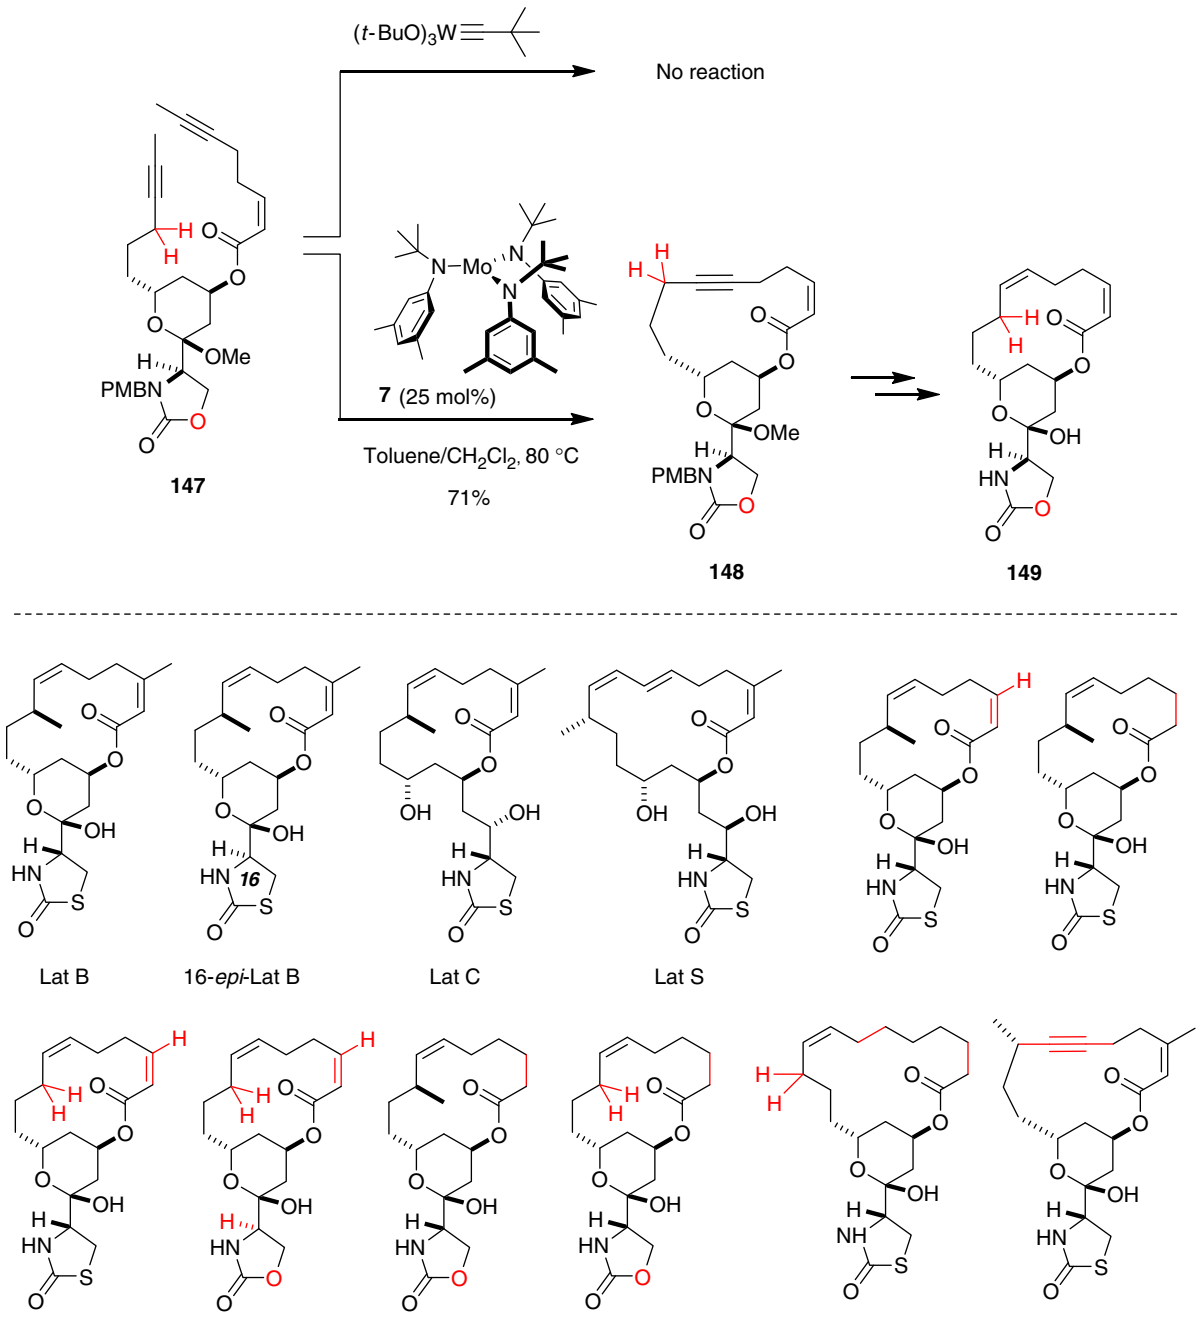
Scheme 39

7/CH_2Cl_2 in toluene as the then most effective catalyst. A series of routine protecting group manipulations and a Lindlar reduction allowed **146** to be transformed into the targeted natural product in high yield.

This project was then extended to the total synthesis latrunculin B, C, S, and 16-*epi*-latrunculin B, as well as to the preparation of a set of nonnatural analogs comprising deep-seated structural 'point mutations' within their framework that would not be easily available otherwise; the produced compounds are summarized in Scheme 41, with structural modifications relative to the parent natural lead being indicated in red.[155,156] Even though the sulfur atom was edited out in some members of this panel (e.g., **147**), the cyclization would not proceed with the tungsten alkylidyne complex **1** (Scheme 41). Therefore, these and other examples clearly attest to the superior functional group tolerance of molybdenum-based catalysts for alkyne metathesis. A detailed

Scheme 40

biological assessment of the compound collection shown in Scheme 41 allowed us to demonstrate that the excision of two seemingly innocent peripheral methyl branches from the latrunculin backbone results in increased potency of these actin microfilament-disrupting agents while streamlining the synthesis.[156,157] This investigation is therefore deemed a good example for the power of 'diverted total synthesis' in general.[158]

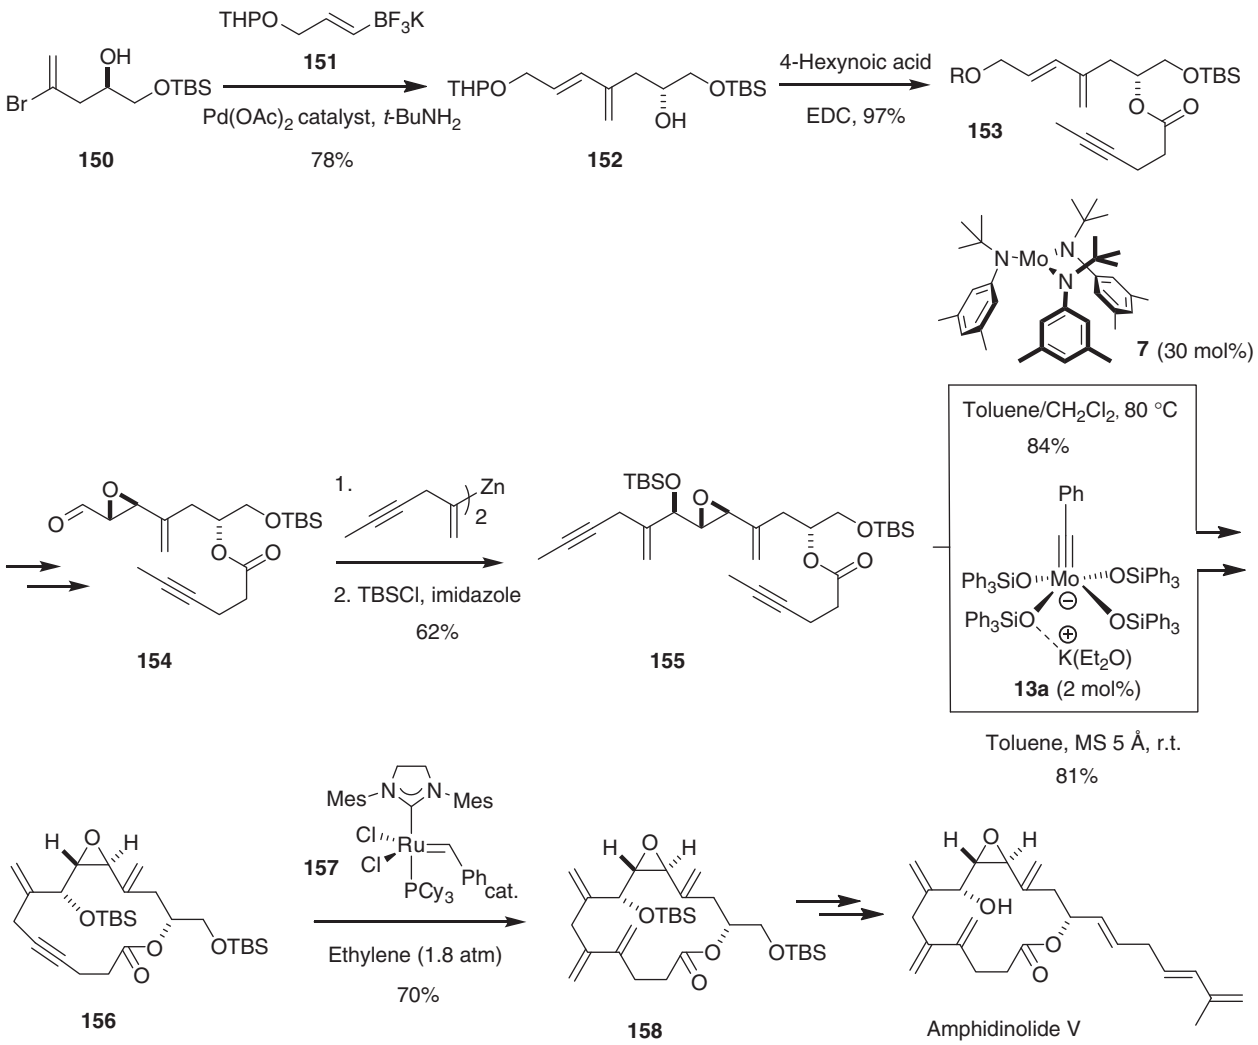


The total synthesis of the rare marine metabolite amphidinolide V at the conspicuous 1,3-diene substructure made up by the two vicinal *exo*-methylene branches of this target inspired a conceptually very different application of alkyne metathesis (Scheme 42).[159] It was reasoned that a sequence of RCAM followed by enyne cross metathesis might allow this motif to be built up by an unconventional approach. To this end, the required cyclization precursor **155** was prepared by a convergent route starting from bromide **150** and trifluoroborate **151** as the building blocks. After their merger by a Suzuki coupling followed by elaboration of the allylic alcohol subunit in **153** to the corresponding epoxy-aldehyde **154**, a stereoselective addition of a functionalized dialkenylzinc reagent followed by protection of the newly formed –OH group as a TBS-ether gave the required diyne **155**. This sensitive material, which incorporates an alkenyl epoxide, an alkoxy epoxide, and a skipped, nonthermodynamic enyne motif, could be cyclized in excellent yield with the aid of **7**/CH_2Cl_2. None of these fragile structural elements suffered any harm during this transformation, which highlights the outstanding functional group tolerance of the catalyst. The resulting cycloalkyne **156** was then subjected to an enyne cross metathesis with ethylene gas, which was effected by the second-generation Grubbs ruthenium carbene **157** to set the vicinal methylene branches decorating the macrocyclic frame of this particular target. The resulting product **158** was cleanly transformed into amphidinolide V by means of a few standard operations.[159]

Since the structure originally assigned to amphidinolide V by the isolation team left some ambiguity, all conceivable stereomers of this compound were prepared following the same synthesis blueprint.[159,160] In addition to solving a structural conundrum and providing precious material for biological testing, the success of this campaign confirms the reliability of alkyne metathesis in general. Moreover, after the advent of the new siloxide-bearing molybdenum alkylidynes, the ring closure of **155** to **156** was revisited as a particularly stringent test reaction. As expected, the ate-complex **13a** was not only similarly effective in terms of yield (81%) as the combination **7**/CH_2Cl_2 originally used, but also required a much lower loading (2 mol% vs. 30 mol% of **7**).[14]

5.28.6.4.8 Alkyne metathesis in the heterocyclic series

The total synthesis of neurymenolide A, an unusually sensitive pyrone derivative of eicosanoid origin, is deemed one of the most stringent tests for the performance of RCAM published to date (Scheme 43).[161] This compound contains three *Z*-alkenes as well as one *E*-configured olefin in its lipidic chain and would hardly withstand any of the known alkene metathesis catalysts. By virtue of the skipped arrangement of the unsaturations, this target compound and all of its immediate precursors are exceptionally sensitive and may even decompose on contact with silica. Yet, neurymenolide A could be formed in high yield by a sequence comprising a new gold-catalyzed hydroxy-pyrone synthesis and a subsequent alkyne metathesis as the key operations.[161] It is of note that the gold catalyst **162** activates only the alkyne that is conjugated to the carbonyl for the formation of the heterocyclic ring within substrate **161** that contains no less than six different sites of unsaturation (not counting the enolized *β*-keto ester). Equally remarkable is the chemoselectivity of the subsequent RCAM of the resulting compound **163**. Alkylidyne **13c** was absolutely critical because it operates under very mild conditions and selectively activates the alkynes, but leaves the truly fragile olefinic array untouched. This example therefore nicely underscores the outstanding tolerance and activity of the new molybdenum alkylidyne complexes ligated with triarylsilanolate groups and features at the same time that alkyne metathesis is strictly orthogonal to olefin chemistry. This very property allowed the site of ring closure as well as the configuration of the newly formed double bond derived from the cycloalkyne precursor to be unambiguously predetermined, which was critical for success.[161]

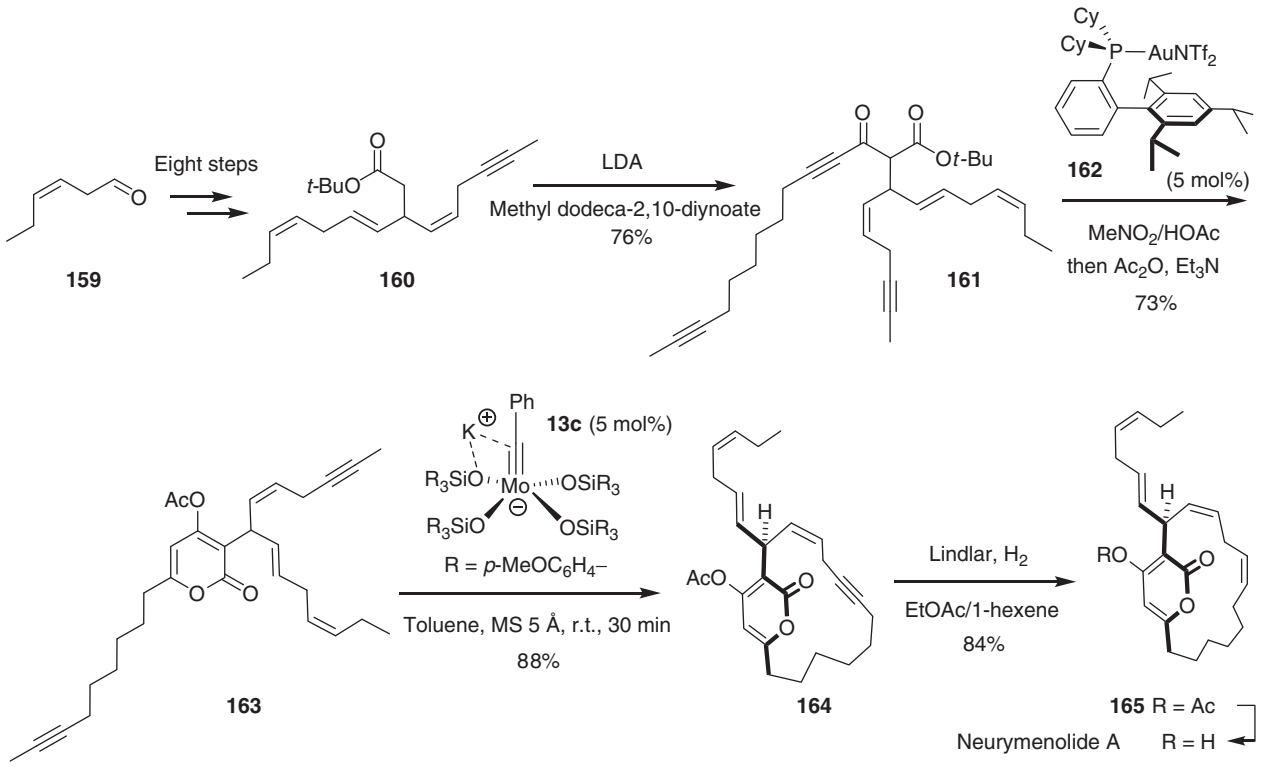


The cycloalkynes formed by RCAM can also be used as carbonyl equivalents for the preparation of heterocyclic motifs. A concise total synthesis of citreofuran illustrates this notion, in that product **167** formed by cyclization of diyne **166** with the

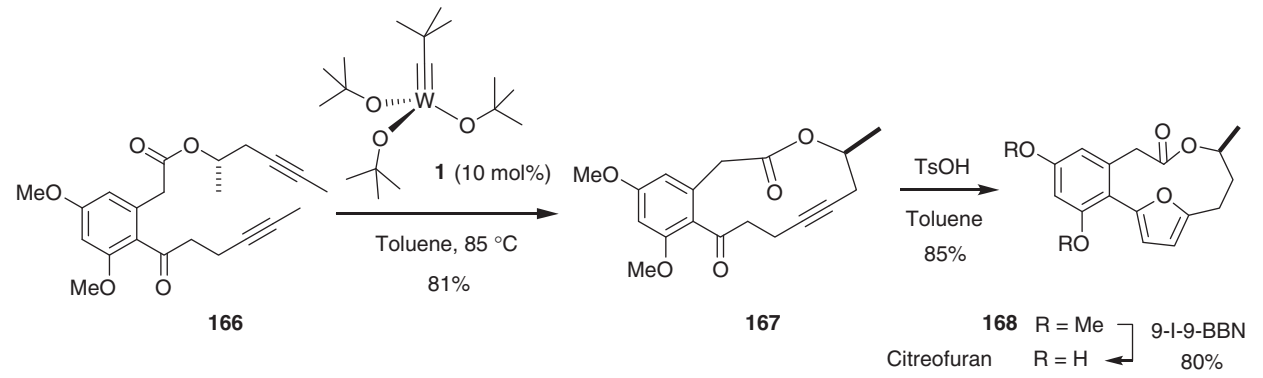
Scheme 41 Catalyst dependence in the preparation of a fully synthetic analog of latrunculin B together with the set of naturally occurring latrunculins and latrunculin-related compounds prepared via RCAM; structural point mutations relative to the parent natural products are indicated in red.

tungsten alkylidyne **1** was gently converted into the macrotricyclic scaffold of the target on exposure to mildly acidic conditions (Scheme 44).[162] It is believed that the ketone undergoes a transannular 5-*exo*-*dig* attack onto the slightly strained triple bond in vicinity, followed by aromatization of the resulting intermediate. A final deprotection of compound **168** thus formed unmasked optically active citreofuran.

A much more sophisticated example can be found in a recent total synthesis of the potent phosphatase inhibitor spirastrellolide F (Scheme 45).[163] In this particular case, the highly decorated macrocyclic perimeter was forged at the 'southern' spiroketal site made up by the B- and C-rings. The necessary substrate was obtained in high overall yield from the three building blocks **169**–**171**, which were assembled by hydroboration of **170**, Suzuki coupling of the resulting alkylborane with triflate **171**, and esterification of the resulting product with the elaborate acid segment **169**. Diyne **172** thus formed underwent an essentially quantitative RCAM in 30 min reaction time at ambient temperature when exposed to 8 mol% of the molybdenum alkylidyne ate-complex **13a** in the



Scheme 42



presence of MS 5 Å. Product **173** was isolated from the mixture in 87% yield, which illustrates the outstanding performance and functional group tolerance of this latest generation of alkyne metathesis catalysts.[163] After deprotection of the two *p*-methoxybenzyl (PMB) ether groups, the necessary transannular ketalization of **174** was accomplished in two consecutive operations. In the event, treatment of **174** with the bulky cationic gold catalyst **175** enforced a regioselective 6-*endo-dig* attack of the C.13–OH group onto the alkyne, which gave enol ether **177** in respectable yield. Acid treatment of this labile intermediate prompted the sterically more hindered hydroxyl group at C.21 to engage in the necessary second cyclization with formation of ketal **178**. The integrity of this compound was confirmed by X-ray diffraction before it was elaborated into spirastrellolide F by stereoselective reduction of the *exo*-methylene group and attachment of the lateral chain via a Kocienski olefination as the key steps.[163]

5.28.6.4.9 RCAM in the organometallic series

Collectively, the examples discussed above illustrate the outstanding compatibility of alkyne metathesis catalysts with all sorts of polar and unpolar functional groups as displayed by natural products and nonnatural compounds of interest for life sciences or material research. This gratifying profile is further completed by a number of examples, in which RCAM was used to tailor the ligand sphere of unsaturated coordination compounds. This allowed a set of unusual chelate complexes of rhenium, ruthenium, and platinum to be forged, which would be difficult to make otherwise; a few representative cases are compiled in Scheme 46. The example of the rhenium complex **179** is particularly noteworthy, whereas the tungsten alkylidyne **1** allowed the kinetic product *fac*-**180** to be formed, a rearrangement to the thermodynamically more stable *mer*-disposed product **181** could not be avoided when working with a Mortreux-type mixture, which mandates a much higher reaction temperature to become operative.[164,165]

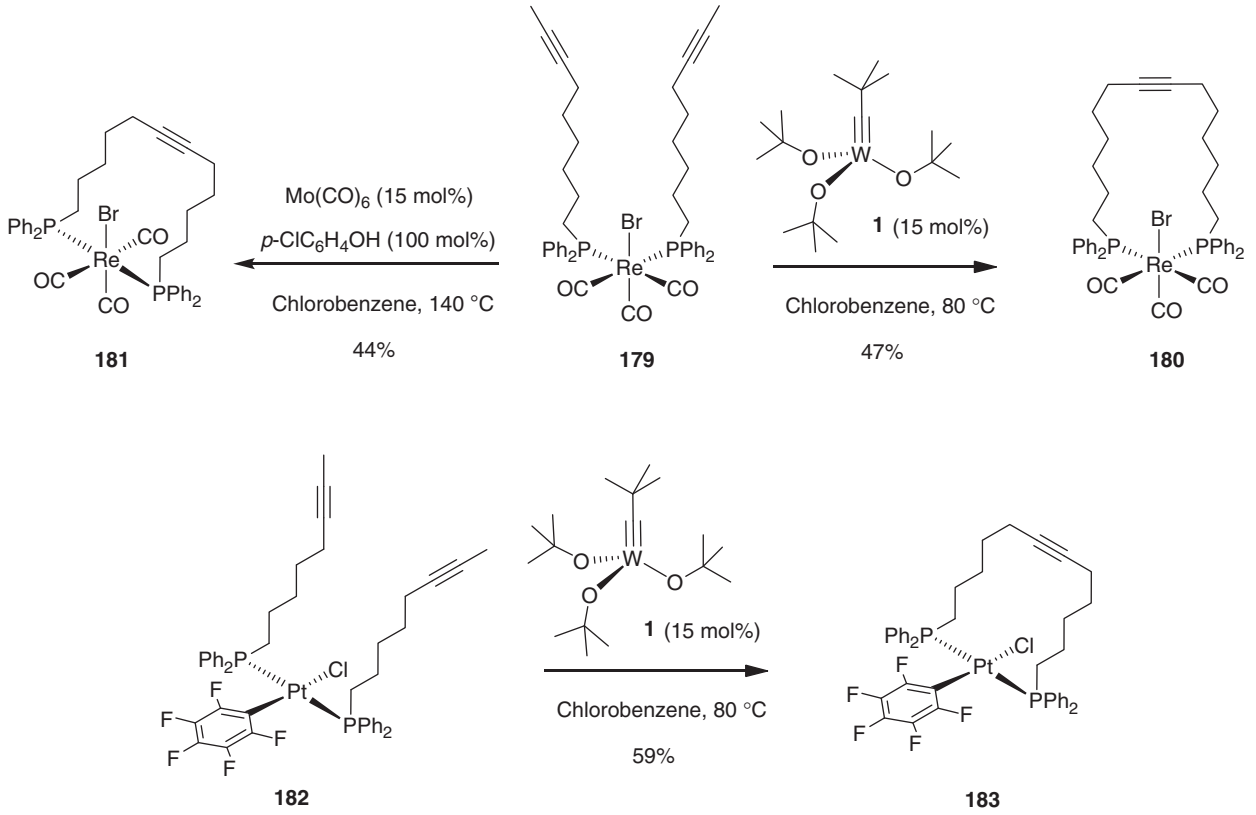

Scheme 44

5.28.7 Conclusions and Outlook

It is fair to say that alkyne metathesis did not play a significant role in preparative chemistry for several decades after its discovery, even though the mechanism of this reaction had been elucidated early on and effective catalyst were available following simple-to-use *in situ* protocols. Yet, the limited compatibility of some of these catalyst preparations together with the harsh reaction conditions were not overly attractive. As in the olefin metathesis arena, the decisive impulse for the development of this method into a useful preparative tool came from fundamental studies into the organometallic chemistry of transition metal alkylidynes. Catalysts based on such mechanistically well-behaved entities show remarkable performance and acquired, with a certain lag time, a truly outstanding compatibility with functional groups that rivals the rightfully praised tolerance of the very best alkene metathesis catalysts known to date. At the same time, the catalysts became user-friendly, as bench-stable variants have been described that are easy to work with. Therefore alkyne metathesis should find many more applications in the future, as there is now little barrier left for its use even by practitioners who are less familiar with organometallic techniques. Since alkynes can be

converted into many different structural motifs, the structural space that can be covered by alkyne metathesis in concert with creative postmetathesis transformations is expected to be large and many opportunities for explorative investigations along these lines can be envisaged.

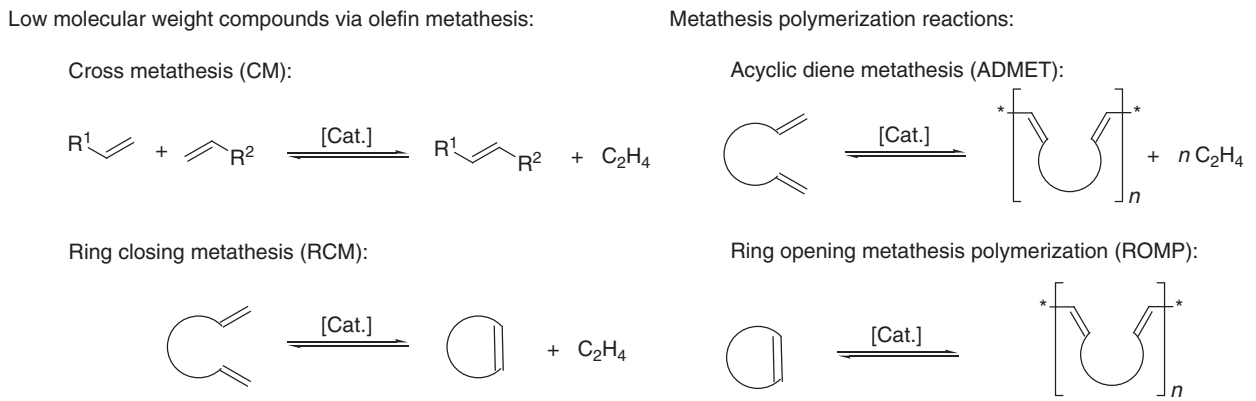
Glossary

Alkylidene complex Transition metal complex with an alkylidene or carbene ligand. Alkylidene complexes are characterized by a metal–carbon double bond.

Backbite mechanism Describes the attack of a reactive center at the terminus of a growing chain onto a reactive functional group at an inner position.

Chiral pool The entity of natural products occurring in enantiomerically pure form. Compounds from the chiral pool are often used as starting materials in the synthesis of enantiomerically pure target molecules.



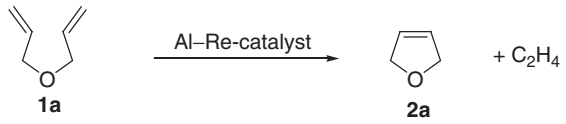
Multicomponent reaction Reaction leading from three or more starting materials to one single product in a defined and controlled order of events.

***N*-Heterocyclic carbene (NHC)** Unusually stable carbenes, in which the divalent carbon atom is part of a heterocycle. NHCs are often highly nucleophilic and good σ-donor ligands in complexes with transition metals.

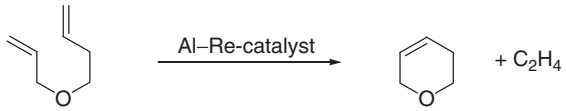
Tethered reaction A synthetic strategy that involves the temporary connection of two molecules via a labile bond (the tether) and a subsequent, facilitated, cyclization. Cleavage of the tether liberates the desired acyclic molecule.

5.29.1 Introduction

Olefin metathesis reactions can be described as a transition metal catalyzed mutual exchange of alkylidenes, resulting in the formation of alkenes from other alkenes by formal scission of carbon–carbon double bonds and recombination of the alkylidene units. In principle, every olefin metathesis reaction is reversible, although numerous examples exist where the back reaction is merely a theoretical option. After its incidental discovery in the 1950s during investigations into Ziegler–Natta-type olefin polymerization reactions, olefin metathesis rapidly emerged as an important topic in polymer and industrial chemistry.[1] Investigations into the mechanism[2] and the nature of the actual catalysts became a domain of organometallic chemistry and stimulated many projects dealing with the synthesis and reactivity of transition metal–carbene complexes. Olefin metathesis reactions can take place in an inter- or intramolecular fashion and yield low molecular weight compounds or polymers (Scheme 1).



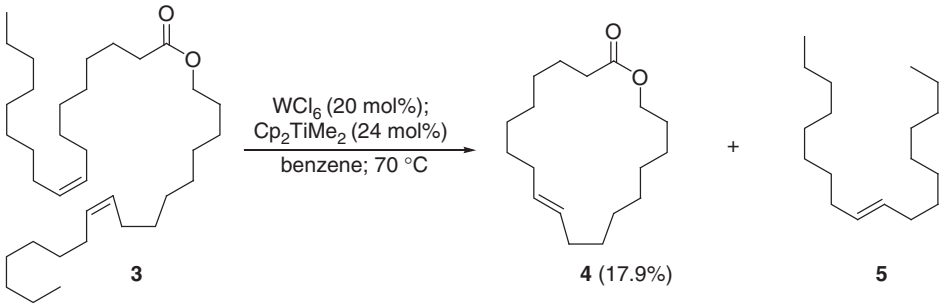
Scheme 1 Inter- and intramolecular olefin metathesis reactions.



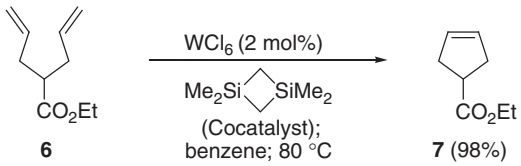
For the intermolecular version, the term cross metathesis (CM) is commonly used;[3] and in those cases where $R^1 = R^2$, occasionally the term self-metathesis or homodimerization can be found in the literature. For intramolecular olefin metathesis reactions, α,ω-dienes are required as starting materials. These reactions result in the formation of carbo- or heterocycles and are therefore named ring-closing metathesis (RCM) reactions. Both enthalpic and entropic factors contribute to the success of these reactions. RCM reactions that involve the buildup of ring strain are disfavored and, consequently, the reverse reaction, called ring opening metathesis (ROM), will be preferred.[4] Beneficial for RCM reactions is the formation of a volatile alkene, normally ethene or propene, which is removed from the reaction mixture, thereby shifting the equilibrium to the side of the cyclic product. Two metathesis polymerization reactions[5] may interfere with the RCM and ROM reactions: acyclic diene metathesis (ADMET)[6] is the polymerization of α,ω-dienes and thus, in principle, a competing reaction of RCM, whereas the ROM polymerization[7] occurs with strained cyclic olefins. This chapter focuses on RCM reactions (*see* Chapter 5.26). CM reactions are covered in a separate chapter and will therefore only be mentioned if they are relevant in the context of a particular RCM reaction. Ring closure reactions involving the metathesis of C–C triple bonds, ring closing enyne metathesis (*see* Chapter 5.27),[8] and ring closing alkyne metathesis[9] reactions (*see* Chapter 5.28) are also discussed in separate chapters in this volume.

A search for the topics 'ring-closing metathesis' or 'ring-closing olefin metathesis' in the ISI-Web of Science, conducted in August 2012, reveals that either of these terms has been used in more than 6000 publications, which have been cited more than 173 000 times. These figures are even more impressive if one considers that the term 'ring closing olefin metathesis' has been used

for just 20 years, when it was introduced by Fu and Grubbs.[10] However, there have been earlier reports describing the cyclizative olefin metathesis of α,ω-dienes, albeit without using the term 'ring-closing metathesis'. For example, Bashkirov et al. reported in 1978 that two simple allyl ethers **1a,b** react in the presence of an unspecified Al–Re-catalyst to 2,5-dihydrofuran and α-2,3-dihydropyran, respectively in 'high rate and a selectivity of 100%',[11] unfortunately without stating an yield (equations 1, 2). The RCM of diallyl silanes with the same heterogeneous catalyst system was reported shortly afterward as a side reaction in the ADMET of these substrates, yielding silacyclopentenes in low yields.[12–15]



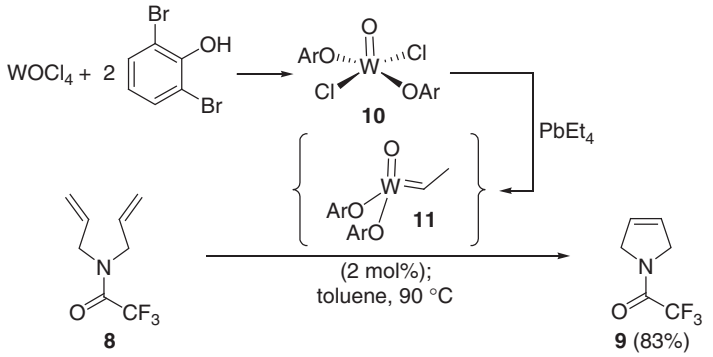
1a **2a** (1)



1b **2b** (2)

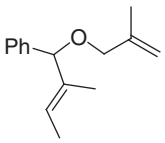
In 1980, Tsuji and Hashiguchi[16] and Villemin[17] independently reported the first synthesis of macrocycles using RCM. These researchers used WCl_6/Cp_2TiMe_2 and $WCl_6/SnMe_4$, respectively; both catalyst systems are clearly inspired by Ziegler-type catalysts used for olefin polymerization. As highlighted in equation 3, Tsuji and Hashiguchi could obtain the macrolactone **4** from the fatty acid-derived precursor **3** only in a moderate yield, which was attributed by the researchers to a rather low tolerance of the catalyst system against functional groups.

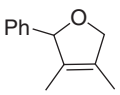
3 **4** (17.9%) **5** (3)

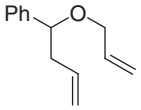


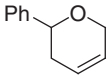
A few reports published in the early 1990s suggest, however, that the limitations of these tungsten-catalyzed RCM reactions are more likely caused by the particular challenges of macrocyclization reactions rather than poor functional group tolerance. For example, Bespalova et al.[18] were able to synthesize cyclopentene **7** via RCM of the diallyl compound **6** in the presence of 2 mol% of a WCl_6/silacyclobutane catalyst system in nearly quantitative yields (equation 4).

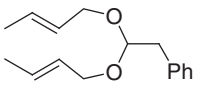
6 **7** (98%) (4)

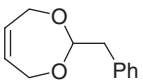


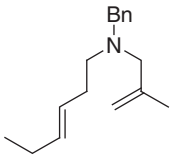


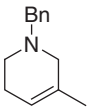


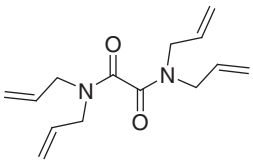


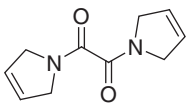


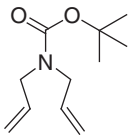


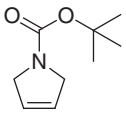


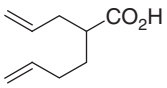


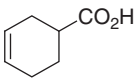


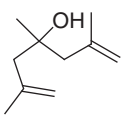


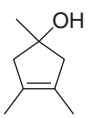






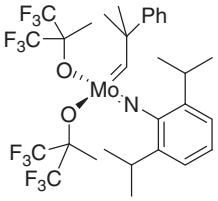


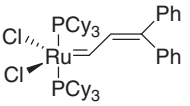


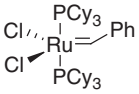


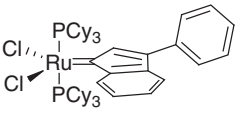
Shortly afterward, Nugent et al. disclosed their catalytic system for 'cyclic metathesis, a combination of $WOCl_4$, 2,6-dibromophenol, and $PbEt_4$'.[19] Using this catalytic system, numerous five- and six-membered carbo- and heterocycles, such as **9**, were synthesized in high yields. The actual catalyst was also investigated in some detail: $WOCl_4$ and 2,6-dibromophenol react under nucleophilic displacement of two chlorides to a bis-phenoxy tungsten complex **10**, which is activated *in situ* by the addition of the cocatalyst $PbEt_4$. The researchers propose that the actual catalyst is a tungsten ethylidene complex **11**, which was, however, not isolated and characterized (**Scheme 2**).

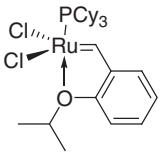
Although interesting and synthetically valuable results were achieved in RCM reactions using the two-component tungsten-based catalytic systems mentioned above, these could not prevail against the structurally defined homogeneous Mo (**C1**)[20] and Ru-catalyst (**C2**)[21,22] discovered shortly before by Schrock et al. and Grubbs et al. The structural formulae of these catalysts are depicted in Section 5.29.2 (**Table 2**), together with those of the commonly used derivatives of **C2**. In the context of this historical discussion, only a few representative examples published in the early days of Mo- and Ru-catalyzed RCM will be mentioned (**Table 1**). These seminal examples already reveal some of the most characteristic differences between Mo- and Ru-catalyzed RCM

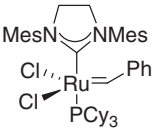


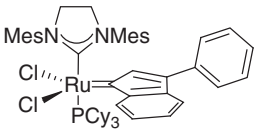


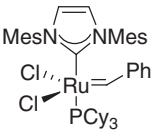


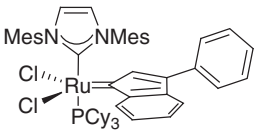


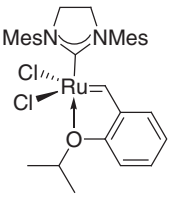


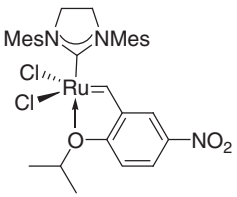


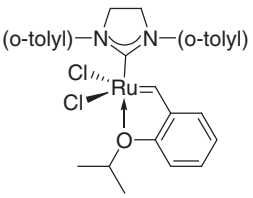












Scheme 2 Tungsten-catalyzed RCM reaction.

Table 1 Early days RCM reactions catalyzed with **C1** or **C2**[a]

Entry	*α,ω-Diene*	*RCM product*	*Catalyst (mol%)*	*Yield (%)*	*References*

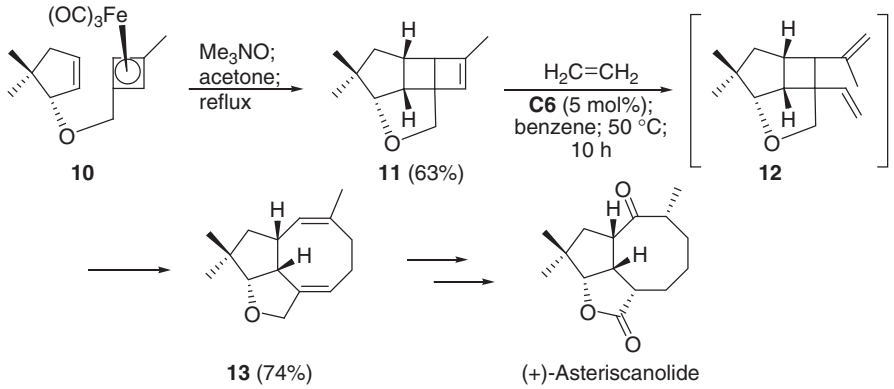
reactions. The Mo-catalyst **C1** is very active and, in contrast to **C2**, tolerates tertiary amines, and is capable of forming tetrasubstituted double bonds. On the contrary, RCM reactions catalyzed with **C2** can be performed in nonpurified solvents under air (which is impossible for **C1**). An additional advantage of **C2** is a significantly higher tolerance toward functional groups, in particular protic functional groups, which are normally not tolerated by **C1** (for a notable exception, see **Table 1**, entry 8).

Over the past two decades, catalyst evolution has led to the development of a plethora of new Mo- and Ru-alkylidene complexes with beneficial properties in RCM and olefin metathesis in general. One of the most notable advancements is the discovery of Ru-alkylidenes with one *N*-heterocyclic carbene ligand, which show reactivities comparable to those observed for **C1** while maintaining the functional group tolerance of **C2**.[26] The objective of this chapter is to provide an overview of synthetic applications of RCM and to highlight the general synthetic strategies involving RCM steps. Therefore, the mechanistic aspects and progress in catalyst development will not be discussed in detail; however, fundamental mechanistic considerations and an overview of common catalysts used in RCM are provided in the following section.

5.29.2 The Mechanism of RCM and a Selection of Commonly Used Catalysts

The accepted mechanism of RCM reactions is an adaptation of Chauvin's orginal mechanism for olefin metathesis reactions in general.[2] This mechanism accounts for the alkylidene structure of the actual catalysts and for the reversibility of RCM reactions.

The catalytic cycle involves the formation of metallacyclobutane **C** from the alkylidene complex **A** and an α,ω-diene **B**, which then undergoes cycloreversion to a new alkylidene complex **D**, and intramolecular cycloaddition to a bicyclic metallacyclobutane **E**, which reacts in a final cycloreversion with regeneration of the catalytically active species **A** and formation of the RCM product **F** (Scheme 3).

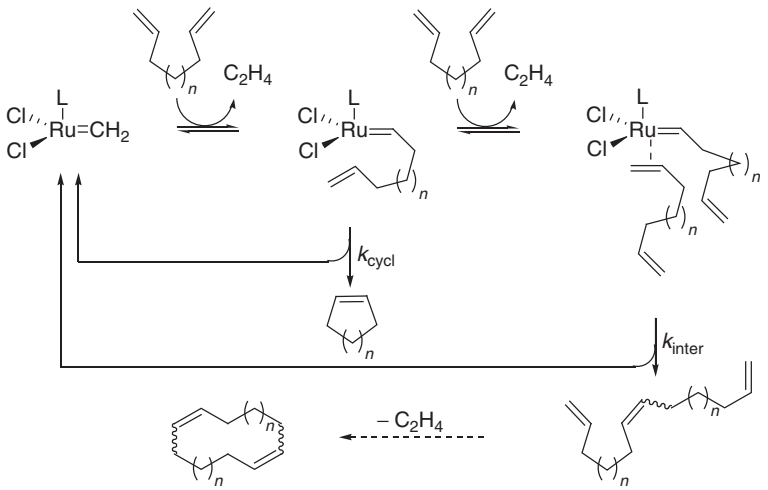


Scheme 3 Mechanism of RCM reactions.

Numerous important details of Mo- and Ru-catalyzed RCM reactions are not considered in this simplified mechanistic scenario and the reader is referred to more specialized review articles for this information.[27–30] In lieu of a comprehensive discussion of catalyst development, just the structures and references for the most common catalysts used in RCM reactions are listed in Table 2 and correlated with a numbering scheme, which will be used throughout this chapter. Structures of other catalysts will be shown in the appropriate section.

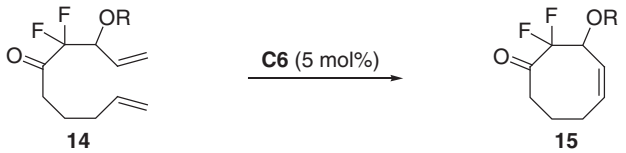
Apart from the choice of the best catalyst, a number of other questions arise when an RCM reaction is implemented in a synthesis: Is the intended ring size conveniently accessible, or are certain ring sizes disfavored? In which way will substituents affect the cyclization rate? Which is the ideal solvent for a given RCM? Is it necessary to consider dimerization or ADMET as a side reaction? If so, do these reactions occur under thermodynamic or kinetic control, and are there opportunities to avoid them and favor the RCM reaction? Answers to these questions are mostly based on empirical data, gathered in the literature over the past two decades. However, over the past few years first steps toward simulation approaches have been undertaken which rely on spectroscopic investigations, kinetic measurements, and computational methods. Although these approaches cannot yet replace the consideration of literature precedence, they might perspectively assist in planning and executing RCM reactions by suggesting parameters such as the substrate concentration and the preferred solvent, choice of catalyst, (minimum) catalyst loading, and reaction temperature. Some aspects of general importance are briefly discussed below:

1. Effects of ring size on cyclization rates.[44] Due to the reversibility of the olefin metathesis reaction, cyclopropenes and cyclobutenes are not formed in RCM reactions but undergo the reverse reaction, ROM, with the release of ring strain.[4] Such ROM reactions can be combined with an RCM step, resulting in synthetically very useful domino reactions, which will be discussed in detail in Section 5.29.11. The combination of ROM with a CM reaction is strictly speaking beyond the scope of this chapter, but such reactions have evolved as synthetically valuable methods. Therefore, Snapper's total synthesis of (+)-asteriscanolide is discussed as an instructive example,[45] outlined in Scheme 4. The cyclobutene **11** required as a starting material was obtained from Fe–cyclobutadienyl complex **10** by oxidative decomplexation. Treatment of **11** with the second-generation catalyst **C6**



Scheme 4 Synthesis of (+)-asteriscanolide via ROM–CM.

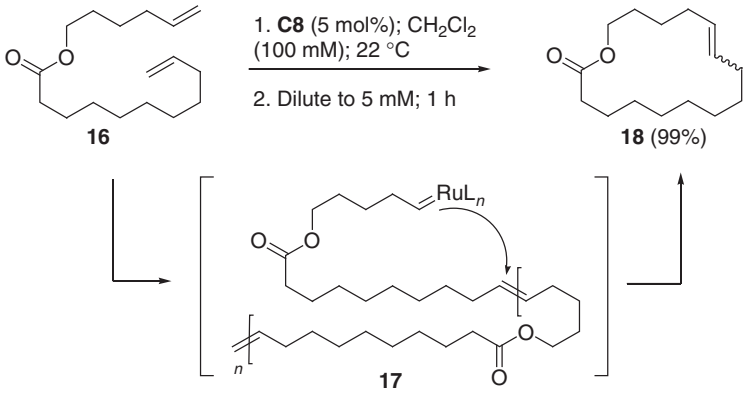
under an ethylene atmosphere and at slightly elevated temperatures gave cyclooctadiene **13** via a sequence of ROM–CM and a thermal Cope rearrangement.



As for many other cyclization reactions, the formation of five- and six-membered rings by RCM is normally fast. However, to rank the RCM-rates for these two ring sizes is not simple; based on the literature precendence it has generally been assumed that five-membered ring systems are formed more rapidly than six-membered rings, but a recent electrospray ionization mass spectrometry study on the RCM of unsubstituted α,ω-dienes suggests that the formation of cyclohexene from 1,6-octadiene is significantly faster than the corresponding reaction giving cyclopentene and cycloheptene.[46] This ranking has been corroborated by an nuclear magnetic resonance (NMR)-spectroscopical investigation into the kinetics of RCM reactions for these simple substrates,[47] and by computational methods, which also suggest that the formation of cyclohexene is thermodynamically more favorable than cyclopentene formation by several orders of magnitude.[48] In contrast, the formation of medium-sized rings (ring sizes from 7 to 11) using RCM can be difficult,[49] because, as for many other cyclization methods, enthalpic (ring strain) and entropic constraints have to be overcome. For macrocyclizations (ring size ≥ 11), the buildup of ring strain is normally not a major problem, but cyclization may be retarded due to a larger distance between the chain ends.

2. Metathesis cyclization versus ADMET. Over the past few years the application of the concept of 'effective molarities' (EM) to olefin metathesis reactions has been discussed in the literature. The kinetic effective molarity EM^k is defined as the ratio of the rate constants for cyclization (k_{cycl}) and intermolecular reaction (k_{inter}): for the thermodynamic effective molarity, the ratios of the corresponding equilibrium constants K are considered.[50] These parameters have been proposed to evaluate the overall efficiency of RCM reactions by taking the competition between ADMET and RCM into account. The mechanistic scenario might be further complicated by a cyclization of dimers or oligomers, as outlined in **Scheme 5**.

Scheme 5 RCM versus dimerization.



The competition between inter- and intramolecular olefin metathesis is normally limited to medium-sized rings and macrocycles. It is possible to suppress undesired dimerization in many cases by applying high dilution conditions; however, scale up becomes a serious problem in such cases. Percy et al. could show for the RCM-based synthesis of a set of cyclooctenones **15** that the rate and efficiency can be modulated by a protecting group R. These researchers also succeeded in measuring EM for different substrates (equation 5).[51]

(5)

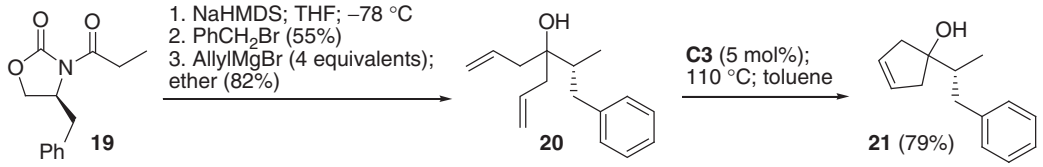
Although the fastest RCM was observed for allylic alcohol (R=H), this reaction was not the most efficient, because introduction of a benzoate (R=Bz) could very effectively suppress dimerization, although the reaction rate was lower than for the free alcohol. The experimental determination of EM for the RCM of dienes **14** could be directly translated into a synthetically advantageous experimental protocol, because it was found that precursor **14** with R=Bz undergoes RCM at an initial

substrate concentration of 20 mM, which is unusually high for this particular ring size. However, the initial formation of dimers or oligomers in an intended RCM does not necessarily mean that the reaction is not feasible or that the initial substrate concentration is too high. Fogg et al. discovered that for many α,ω-diene precursors leading to medium-sized rings or macrocycles, oligomer formation is dominant in the early phase of the reaction, but that ring closure to the desired RCM product can occur via a backbite mechanism. Owing to this possibility, oligomer formation might even be advantageous; if substrate **16** was exposed to catalyst **C8** at 100 mM, rapid oligomerization occurred. Subsequently, diluting the reaction mixture to 5 mM induced cyclization via a backbite mechanism, resulting in the efficient formation of macrocycle **18**. This protocol turned out to be more efficient than conducting the RCM under high dilution conditions from the beginning, because this decelerates the reaction between substrate **16** and the catalyst, which can result in a decreased overall yield due to competing catalyst decomposition (Scheme 6).[52]

Scheme 6 Backbite mechanism for RCM from oligomers.

3. Solvent effects. The most commonly used solvents for RCM reactions are dichloromethane, 1,2-dichloroethane, benzene, and toluene. Recently, the RCM of diallyl malonate, a commonly used test substrate, has been investigated in different solvents including uncommon ones such as acetic acid and acetone using the second-generation catalyst **C6**.[53] The researchers proposed a kinetic model that considers the individual steps of the RCM, i.e., phosphine dissociation to give the catalytically active 14-e species, the subsequent metathesis reaction as one single step, and the irreversible catalyst decomposition[54] as a deactivating step. Determination of kinetic data for the individual steps in different solvents allows the simulation of product formation versus reaction time. This study reveals that the overall productivity of a certain metathesis reaction in a particular solvent is governed by a 'fine balance between initiation, catalytic turnover, and catalyst deactivation'.[53] For instance, dichloromethane is a good solvent for RCM reactions because decomposition of the catalytically active species is very slow. Quite surprisingly, acetic acid was identified as an even better solvent for the RCM reaction studied, albeit for different reasons. In acetic acid, catalyst decomposition is faster than in dichloromethane, but initiation and catalytic turnover also occur much more rapidly, resulting in an overall superior performance. This result was corroborated by experiments on preparative scale.[53,55] The underlying kinetic model, proposed by Adjiman, Taylor et al., has recently been criticized as 'significantly simplified' in certain points by Percy et al., who published a refined approach for the simulation of RCM reactions based on the kinetic data for the individual steps.[56] Significantly improved yields have been observed for several 'difficult' metathesis reactions with second-generation catalysts, if the common solvents were replaced by fluorinated aromatic hydrocarbons (e.g., C_6F_6 or $C_6F_5CF_3$).[57–59] On the basis of X-ray structure data, Grela et al. suggested that the effect is caused by an enhanced initiation, which might in turn result from π–π-stacking interactions between the aromatic substituents of the *N*-heterocyclic carbine (NHC) ligand and the fluorinated aromatic hydrocarbons.[60]

5.29.3 Five-Membered Ring Systems

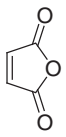


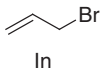
5.29.3.1 Five-Membered Carbocycles

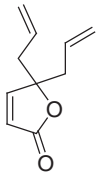
Over the past two decades numerous RCM reactions of α,ω-heptadienes leading to functionalized cyclopentenes have been described. In particular, hydroxylated derivatives, cyclopentitols, play an important role as natural and nonnatural target molecules. Specialized current review articles on cyclization approaches to cyclopentitols[61] and metathesis approaches to carbanucleosides[62] are available.

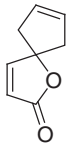
5.29.3.1.1 Synthesis of precursors by addition of organometallics to carbonyl compounds

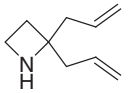
Addition of excess allyl metal compounds to carboxylic acid derivatives is a straightforward route to diallyl carbinols with identical allyl groups, which serve as precursors for symmetrical cyclopentenols. Apart from esters, amides have also been used as

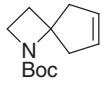


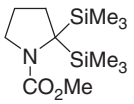


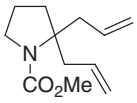


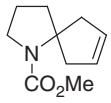


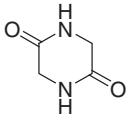


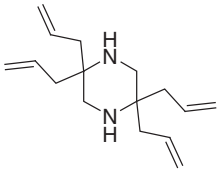


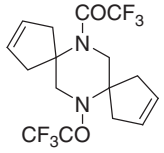


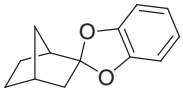


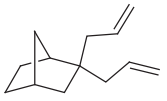


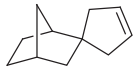


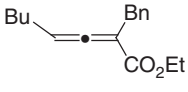


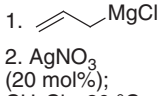


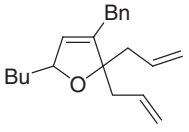


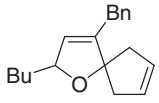






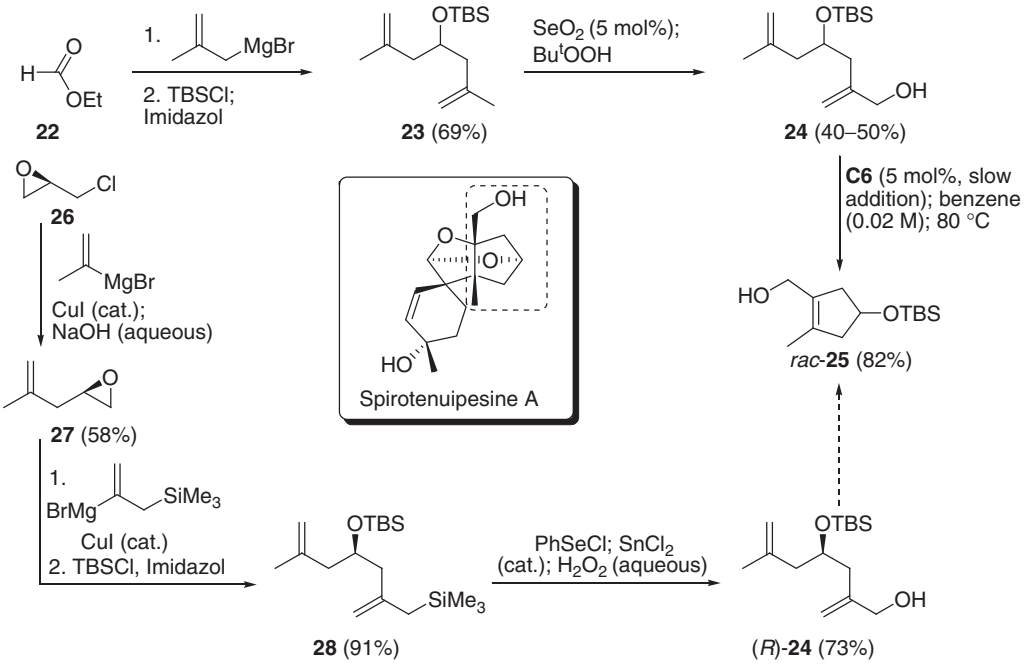






precursors, for example, the acylated Evans auxiliary resulting from a diastereoselective alkylation of **19**. Cleavage of the auxiliary with excess allyl-Grignard reagent yields **20**, which undergoes RCM to cyclopentenol **21** with the first-generation catalyst **C3** only at elevated temperatures, whereas no reaction was observed at ambient temperatures (Scheme 7).[63]

Scheme 7 Enantiopure cyclopentenols via Evans alkylation.



Occasionally, undesired double bond isomerization reactions occur when RCM reactions are conducted in refluxing toluene. For the RCM of **20** and several derivatives, this can be avoided by using the more reactive second-generation catalyst **C6**, which catalyzes this reaction at an ambient temperature with catalyst loadings as low as 1 mol%.[64] The double allylation of carbonyl compounds and subsequent RCM has also been used for the synthesis of spirocyclopentenes and representative examples are listed in Table 3. Remarkably, in contrast to the RCM of diallyl carbinols with an unprotected OH group, for most examples listed in Table 3 the less reactive first-generation catalyst **C3** gives satisfactory results at ambient or slightly elevated temperatures. For the example listed in entry 6 a rather high amount of catalyst **C6** has been used at 40 °C. However, it is not clear whether these conditions are mandatory or if comparable results could have been obtained with a first-generation catalyst.

Table 3 Diallylmetalation and subsequent spirocyclization via RCM

Entry	*Substrate*	*Allyl metal compound*	*RCM precursor*	*Yield (%)*	*RCM conditions*	*RCM product*	*Yield*	*References*
1				64	**C3** (5 mol%); CH_2Cl_2; 20 °C		87	65

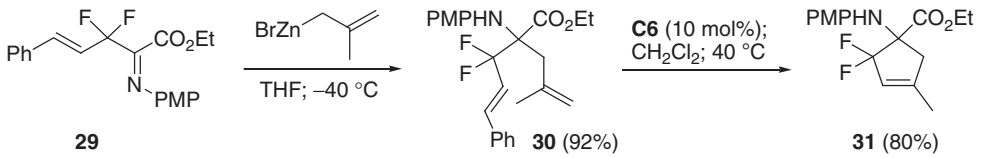
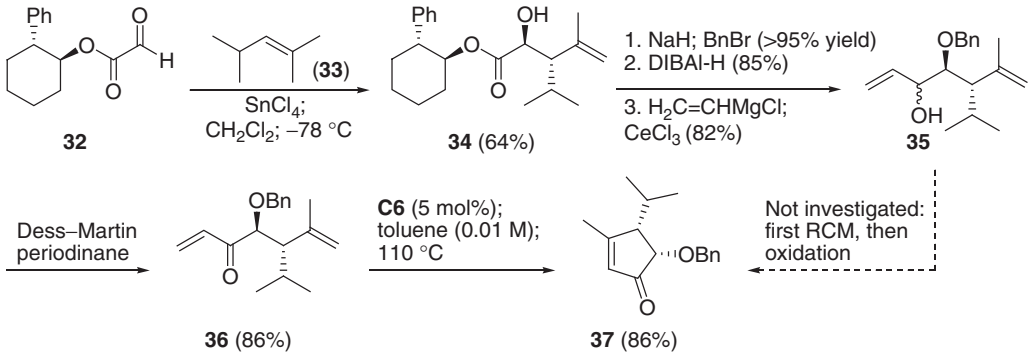
5				65	**C3** (5 mol%); CH_2Cl_2 (0.05 M); 20 °C		80	69
6				98	**C6** (5 mol%); CH_2Cl_2; 40 °C		86	70



Although double allylation of esters, amides, or nitriles, as described above, is a straightforward route to RCM precursors, it has only rarely been used in actual target molecule syntheses, because for such applications symmetrical cyclopentenes are normally

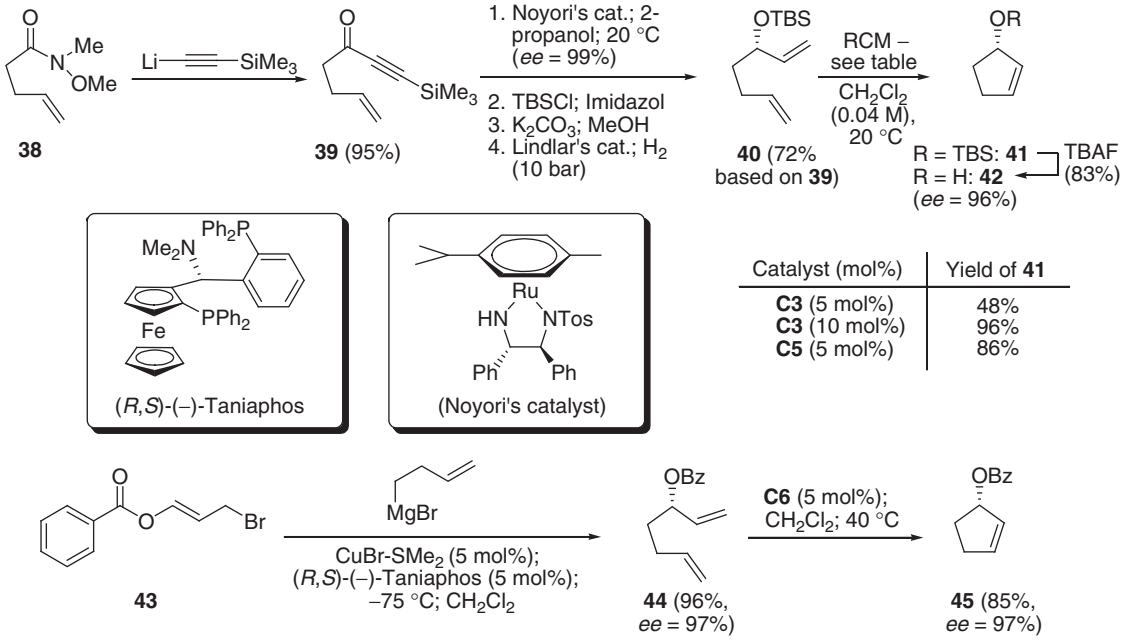
not required, and the differentiation between enantiotopic or diastereotopic allyl groups is often difficult. This point has been illustrated by Danishefsky et al., who required enantiomerically pure cyclopentene **25** in a total synthesis of the fungal metabolites spirotenuipesines A and B (Scheme 8).[71,72]

Scheme 8 Two syntheses of the cyclopentene building block for spirotenuipesines A and B.



The shortest route starts from ethyl formiate (**22**), which is converted to **23** by double addition of methallylmagnesium chloride. Selenium catalyzed allylic oxidation yields racemic **24**, which undergoes RCM to the required cyclopentene **25** using **C6** in refluxing benzene. The construction of tetrasubstituted double bonds via RCM is challenging and normally requires significantly higher catalyst loadings or even more reactive catalysts. In this case, rather high dilution was combined with a slow addition of the precatalyst to the reaction mixture, resulting in a good yield of 82%.[71] Alternatively, a route to enantiomerically pure (*R*)-**24** from *R*-epichlorohydrine (**26**) was pursued, which involves the subsequent Cu-catalyzed addition of two vinyl-Grignard reagents and a final oxidative cleavage of the allylsilane **28**.[72] Other strategies toward unsymmetrical cyclopentenes are based on the addition of organometallic reagents to aldehydes, ketones, or imines. Fustero et al.[73] exploited this approach in a synthesis of fluorinated cyclopentene-α-amino acids, which are potentially useful building blocks for the synthesis of conformationally constrained peptides (Scheme 9). The required precursors, for example **30**, were obtained by chemoselective addition of allylic zinc reagents to imines such as **29**. RCM of **30** requires 10 mol% of the second-generation catalyst **C6** and proceeds with loss of styrene. This example illustrates that the formation of volatile alkenes such as ethene or propene is not necessarily required to shift the equilibrium toward product formation.

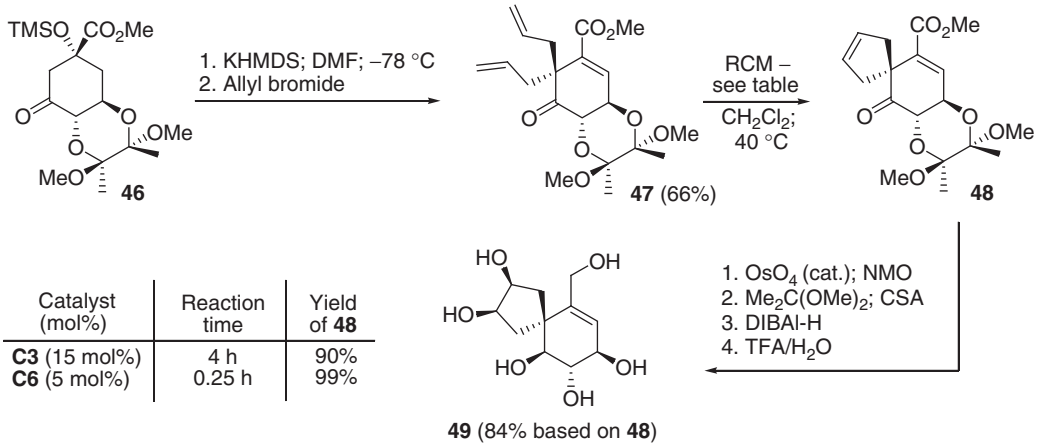
Scheme 9 Synthesis of fluorinated cyclic amino acids.



A challenging cyclopentenone formation has been reported by Trauner et al. in the course of a total synthesis of guanacastepene E (Scheme 10).[74] In this example, the chirally modified glyoxylate **32** reacts with 2,4-dimethyl-2-pentene (**33**) in the presence of a Lewis acid to homoallylic alcohol **34**, which is converted by a sequence of benzylation, reduction of the ester with diisobutylaluminumhydride (DIBAl-H), and addition of vinyl magnesium bromide to allylic alcohol **35**. Oxidation of **35** gave enone **36**, which underwent RCM in the presence of **C6** in refluxing toluene. An alternative strategy, which has not been reported for this particular example, would rely on a reversed order of the two final steps, i.e., RCM of the allylic alcohol **35**, followed by oxidation of the resulting cyclopentenol. This order of events turned out to be advantageous in some cases, for

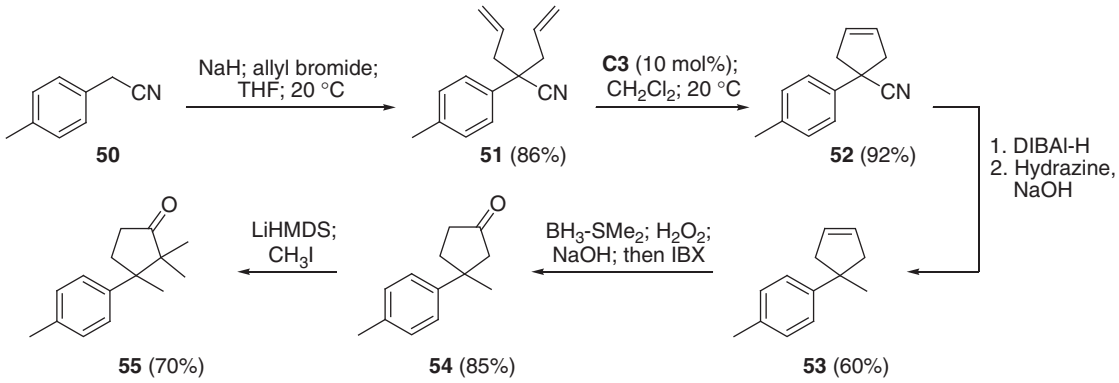
example, Nay's synthesis of a harringtonolide fragment,[75] because RCM of an electron-deficient double bond is avoided, and OH-directing and activating effects[76] might facilitate the metathesis step. However, if the metathesis reaction is slow (which has to be expected in the case of **35**) rapid isomerization to ethyl ketones will most likely occur.[77]

Scheme 10 Synthesis of cyclopentenone fragment in the total synthesis of guanacastepene E.



An RCM-based synthesis of enantiopure 2-cyclopentenol (**42**), a useful building block for several target molecule syntheses, relies on the addition of an alkynyl lithium reagent to a Weinreb amide **38**, followed by enantioselective reduction of ketone **39**[78] and Lindlar reduction of the alkyne (Scheme 11). RCM of the *tert*-butyldimethylsilyl (TBS)-protected precursor **40** was investigated using the first-generation Grubbs' catalyst **C3** and first-generation Grubbs–Hoveyda catalyst **C5** in CH_2Cl_2 at an ambient temperature. With a catalyst loading of 5 mol%, the conversion remained incomplete for **C3**, whereas quantitative conversion and synthetically useful yields were obtained with 10 mol% of **C3** or 5 mol% of **C5**.[79] An alternative approach to a protected *S*-2-cyclopentenol **45** uses a Cu-catalyzed enantioselective allylic substitution with butenyl magnesium bromide as a nucleophile and benzoate **43** as a starting material. RCM precursor **44** was obtained in nearly quantitative yields and high *ee*, and subsequently cyclized to **45** using the second-generation catalyst **C6** (Scheme 11). The modest reactivity of the TBS- or benzoate-protected precursors **40** and **44** might be attributed to steric reasons. In particular, TBS-protecting groups attached to allylic OH-groups were found to retard the rate of RCM reactions, and it is therefore often advantageous to remove the protecting group before the RCM step.[80] The enantioselective Cu-catalyzed allylic substitution with butenyl-Grignard reagents and phosphoramidite ligands, and subsequent RCM have also been conducted as one-pot reactions, giving various enantiopure cyclopentenes.[81]

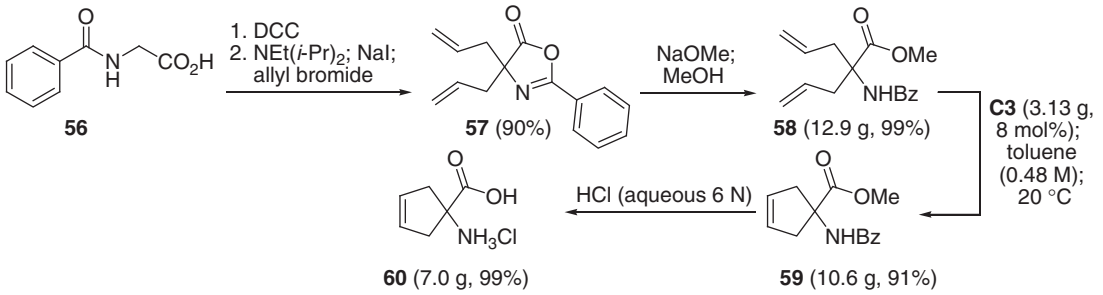
Scheme 11 Alternative syntheses of protected *S*-2-cyclopentenol.



5.29.3.1.2 Synthesis of precursors by α-functionalization of carbonyl compounds

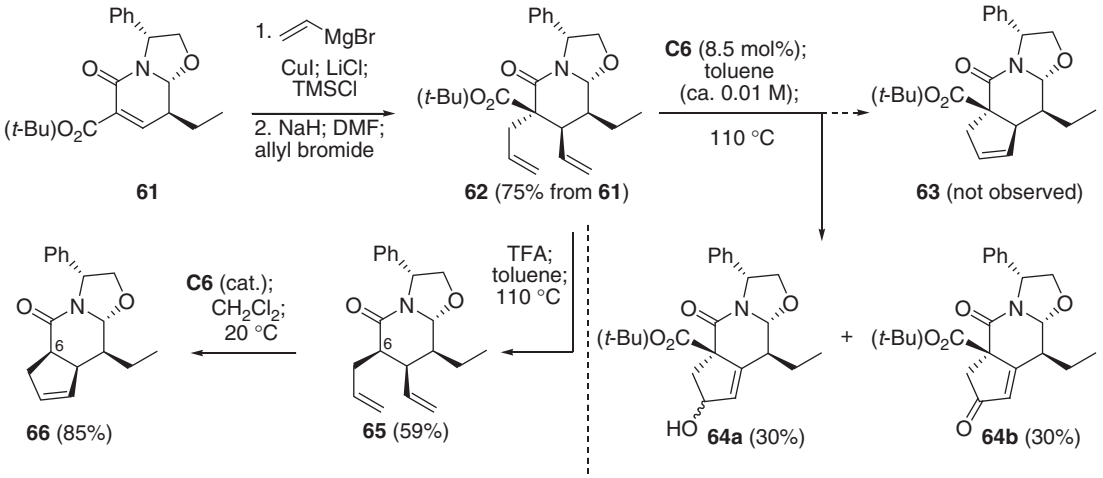
A straightforward route to symmetric cyclopentenes is the double allylation of enolates, in particular those derived from 1,3-dicarbonyl compounds, followed by RCM. The synthesis of conformationally constrained spirocyclic glycosidase inhibitors is a typical example for this approach (Scheme 12).[82] Dicarbonyl compound **46**, derived from quinic acid, was converted by deprotonation and treatment with excess allyl bromide to the RCM precursor **47**. RCM of **47** using the less reactive catalyst **C3** did not give satisfactory results, because an excessively high catalyst loading was required. In contrast, with **C6** a quantitative yield of **48** was obtained within considerably shorter reaction times and with lower catalyst loading. Spirocyclopentene **48** was then converted stereoselectively in four steps to product **49**, which showed a moderate inhibitory activity of a β-galactosidase.

Scheme 12 Synthesis of potential glycosidase inhibitors.



The problem of cyclopentene desymmetrization remains for other target molecule syntheses using double allylation and subsequent RCM. In the syntheses of *rac*-cuparenone[83] and *rac*-1,13-herbertenediol[84] this has been solved by hydroboration–oxidation and by allylic oxidation using pyridinium dichromate (PDC), respectively. The cuparenone synthesis is outlined as a representative example in Scheme 13.[83] As for the previous example, the catalyst loading required for this spirocyclization is very high, which might not only be attributed to steric constraints but also to partial catalyst deactivation by the cyano group.

Scheme 13 Synthesis of *rac*-cuparenone (**55**).

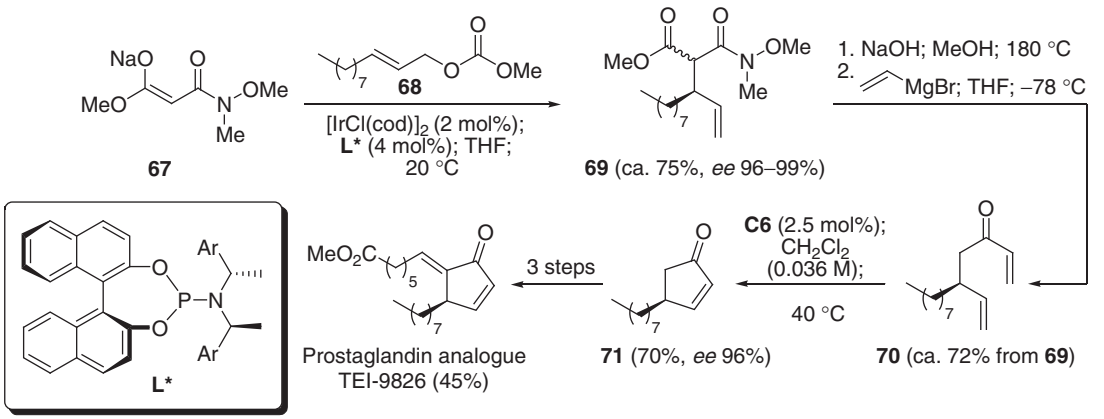


Similar approaches have been pursued by several groups for the synthesis of conformationally constrained cyclopentene α-amino acids **60** (see also Scheme 9 and discussion). As starting materials for the double allylation, Schöllkopf' bis-lactim ethers,[85] isocyanoacetate,[86] or a hippuric acid-derived oxazolone have been used. The synthesis starting from hippuric acid (**56**) was performed on multigram scale and is summarized in Scheme 14.[87] Notably, and particularly important for reactions on larger scale, an initial substrate concentration of approximately 0.5 M can be used.

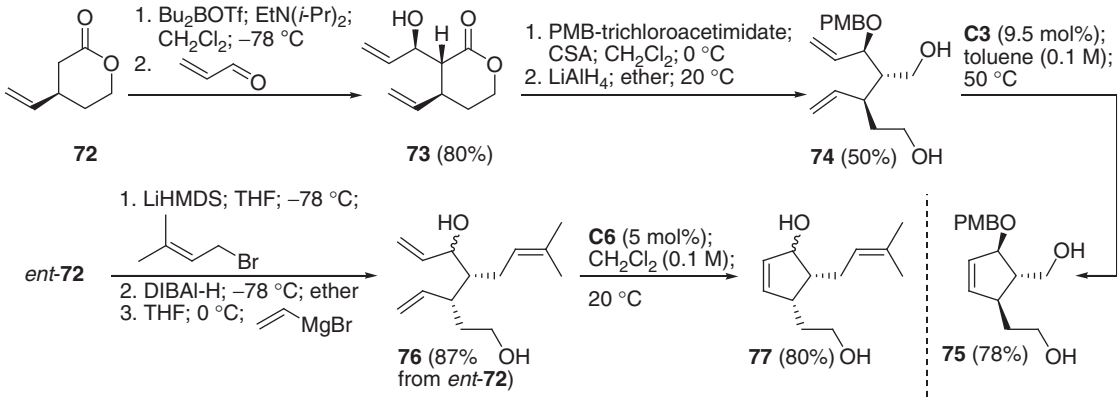
An alternative route to cyclopentene precursors relies on a sequence of conjugate addition of a vinyl metal compound to an α,β-unsaturated carbonyl or dicarbonyl compound, followed by mono-α-allylation. This approach makes unsymmetrical cyclopentene units accessible and is particularly useful for bicyclic systems. Bosch et al. investigated a route along these lines with a

Scheme 14 Multigram scale synthesis of 1-aminocyclopent-3-ene-1-carboxylic acid hydrochloride (**60**).

view toward the synthesis of enantiomerically pure polysubstituted piperidine libraries (Scheme 15).[88] Starting from **61**, the required metathesis precursor **62** was obtained by Cu-mediated addition of vinyl magnesium bromide, followed by α-allylation. Interestingly, the desired RCM product **63** was not observed, instead two products **64a** and **64b** resulting from allylic oxidation of **63** were isolated in equal amounts. The researchers attribute the formation of these products to residual oxygen in the reaction mixture and a release of strain associated with the migration of the double bond. It is not fully clear whether the allylic oxidation occurs spontaneously or Ru-catalyzed; however, it is evident that the bulky ester group at the 6-position is responsible for this outcome, because a precursor **65** resulting from ester cleavage and decarboxylation reacts smoothly to cyclopentene **66** without concommitant or subsequent allylic oxidation. A comparable result was observed for the 6-epimer of **65**, giving the *trans*-configured diastereomer of **66**.



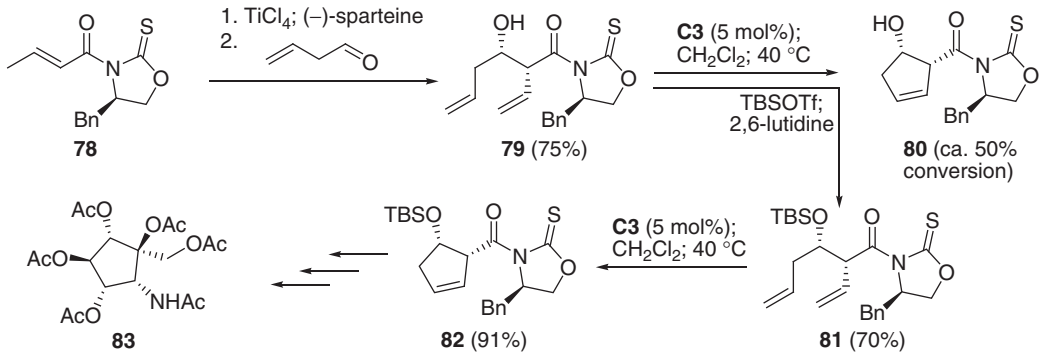
Scheme 15 Conjugate addition/α-allylation sequence for the synthesis of RCM precursors.



The Cu-catalyzed enantioselective allylic substitution with alkenyl metal compounds has been discussed in the previous section. A related strategy toward RCM precursors was developed by Helmchen et al. It involves the Ir-catalyzed allylation of enolates derived from 1,3-dicarbonyl compounds, for example, Weinreb-amide **67** (Scheme 16).[89] The strategy has, inter alia, been applied to the synthesis of the cytotoxic prostaglandin analog TEI-9826. In the first step, enolate **67** was allylated with carbonate **68** in the presence of an Ir-(I)-precatalyst and chiral phosphoramidite ligand L*. The resulting product **69** was obtained in very high *ee*, and subsequently converted by saponification/decarboxylation and addition of the vinyl-Grignard reagent to the RCM precursor **70**. RCM of **70** yields the required cyclopentenone **71** in good yield and excellent optical purity. The synthesis of the target molecule TEI-9826 was accomplished by aldol addition and elimination. The sequence can be conveniently modified for the synthesis of 2-methyl-2-cyclopentenones by replacing vinyl magnesium bromide by the Grignard reagent resulting from 2-bromopropene. In these cases, the RCM step was performed with comparable catalyst loadings, dilution, and isolated yields.

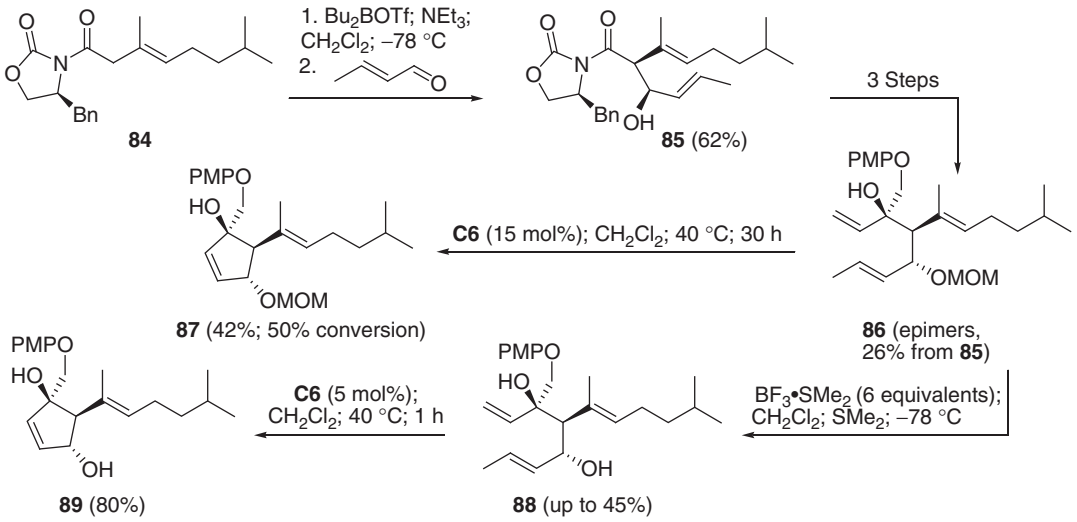
Stereoselective aldol addition reactions of enolates and enals have also emerged as a useful method for the synthesis of RCM precursors. An example is the synthesis of preclavulone-A methyl ester, which starts from lactone **72**, obtained in enantiomerically pure form by resolution (Scheme 17).[90]

Conversion of **72** into the corresponding boron enolate and subsequent treatment with acrolein gave aldol adduct **73** as a single diastereomer in good yields. The RCM precursor **74** was obtained by protection of the secondary alcohol and reductive cleavage of the lactone. RCM was accomplished in good yield with the first-generation catalyst **C3** at slightly elevated temperatures. In the same study, the researchers investigated a route to the *cis*-epimer, which involved a ring-closing metathesis of precursor **76**. Surprisingly, this reaction failed with **C3**. It is not clear whether this failure must be attributed to the allylic OH



Scheme 16 Cyclopentenones via enantioselective allylic substitution and RCM.

Scheme 17 Diastereoselective aldol addition using a boron enolate.

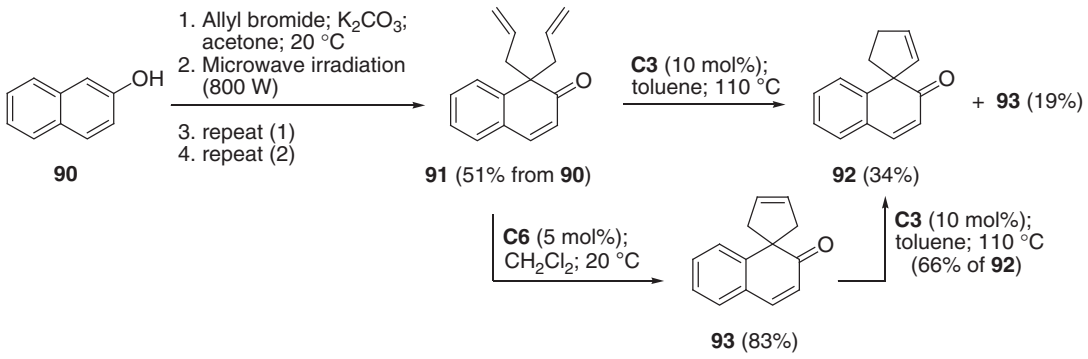


group or the pendant prenyl side chain. Gratifyingly, however, with the aid of the second-generation catalyst **C6** the cyclization proceeds at an ambient temperature.

The asymmetric aldol addition-RCM strategy has been applied to the synthesis of several target molecules with densely functionalized cyclopentane cores by Crimmins et al. One example is their approach to the trehalase inhibitor trehazolin, which is outlined in Scheme 18.[91] Starting from oxazolidinthione **78**, a stereoselective aldol addition was achieved with 3-butenal in the presence of $TiCl_4$/(–)-sparteine with high *syn*-selectivity and in good yields. Attempted RCM of aldol adduct **79** did not proceed to completion, but stopped at ca. 50% conversion. Interestingly, the same result was observed for the analogous oxazolidinone (synthesized from the corresponding boron enolate); thus, catalyst inhibition by coordination to the sulfur can be excluded. However, after protection of the hydroxy group as a TBS ether the RCM proceeded smoothly to yield cyclopentene **82**, which was functionalized in several steps to the advanced trehazoline precursor **83**.

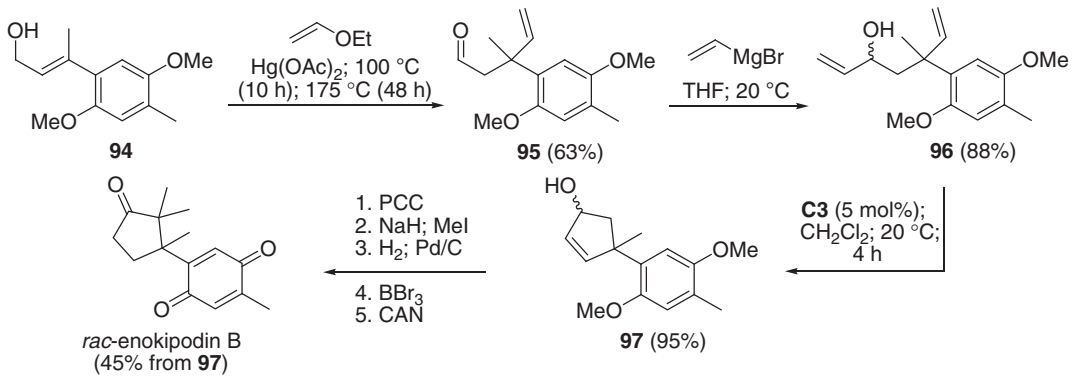
Scheme 18 Auxiliary controlled asymmetric aldol addition and RCM.

It should be noted that it is not possible to draw the general conclusion that protection of allylic hydroxy groups is always beneficial. Eustache et al. investigated several cyclopentene forming RCM reactions in the course of a project directed at the elucidation of structure–activity relationships of potential angiogenesis inhibitors based on the fumagillin structure (Scheme 19).[92] Evans-aldol methodology was used to synthesize **85**, which was then converted in three steps to two epimers of the methoxymethyl (MOM)-protected RCM precursor **86**. Separation of the epimers was possible, and both were found to undergo cyclization only slowly, requiring very high catalyst loadings of 15 mol% of **C6**. Nevertheless, the reaction stopped at 50% conversion after 30 h, and an isolated yield of just 42% of **87** could be obtained. The researchers suspected that the low reactivity of **86** was caused by the MOM-protecting group, which was therefore removed and the resulting allylic alcohol **88** was then subjected to RCM. Remarkably, this reaction went to completion in the presence of a considerably lower amount of the second-generation catalyst **C6** within 1 h, resulting in an isolated yield of 80% of cyclopentene **89**.



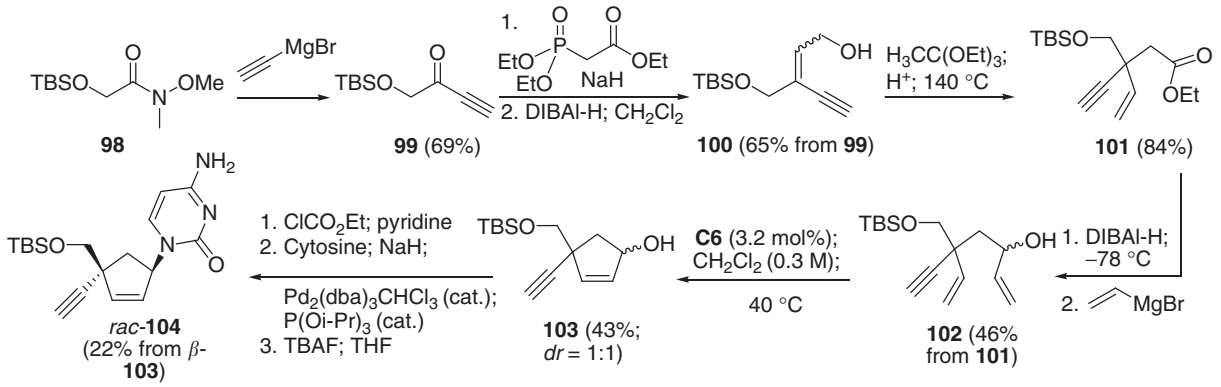
Scheme 19 Protecting group effects in the RCM-approach toward fumagillin analogs.

5.29.3.1.3 Synthesis of precursors involving Claisen rearrangement



The Claisen rearrangement (*see* Chapter 5.20) and its variants are very useful for the synthesis of cyclopentene precursors, and numerous applications have been published. For example, the iterative O-allylation/Claisen rearrangement of 2-naphthol (**90**) yields the diallylated ketone **91** under microwave irradiation in good yields (Scheme 20).[93] RCM of **91** was found to be very slow in the presence of catalyst **C3**, making a high catalyst loading and elevated temperatures necessary. Under these conditions an undesired double bond isomerization occurs, and **92** was identified as the major product. In contrast, with the second-generation catalyst **C6** the reaction proceeds smoothly at an ambient temperature and with a lower amount of precatalyst. The researchers demonstrated that the double-bond migration is indeed Ru-catalyzed, because **93** can be converted to its isomer **92** in the presence of the first-generation catalyst **C3**, whereas no isomerization occurs in the absence of a Ru-catalyst.

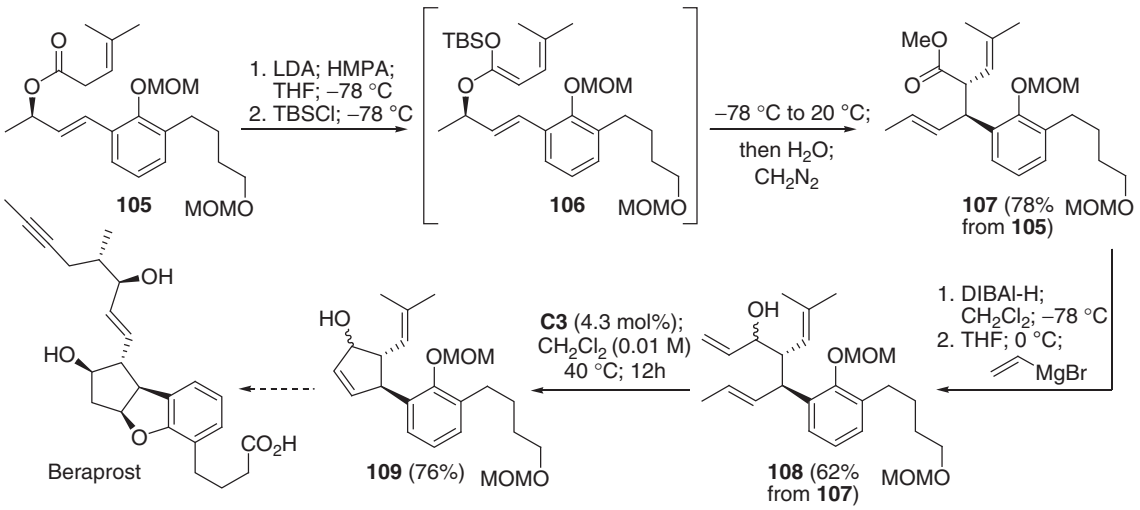
Srikrishna et al. have used the combination of Claisen rearrangement and RCM in a manifold of sesquiterpene syntheses.[94] As an example, the synthesis of enokipodin B is outlined in Scheme 21:[95] starting from allyl alcohol **94**, a one-pot vinylation/Claisen



Scheme 20 O-Allylation/Claisen rearrangement/RCM sequence to spirocycles.

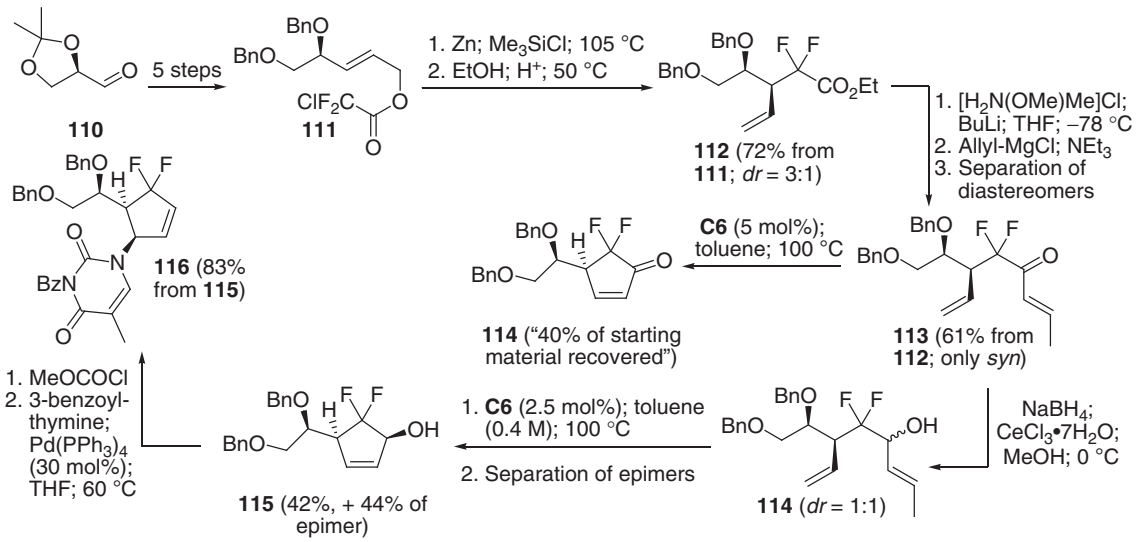
rearrangement to give the substituted pent-4-enal **95** was performed. By addition of vinyl magnesium bromide the RCM precursor **96** was obtained, which underwent smooth ring closure in the presence of **C3** to give cyclopentenol **97** in nearly quantitative yields. Compound **97** was then converted in five steps to the target molecule enokipodin B.

Scheme 21 Claisen rearrangement/RCM toward enokipodin B.



In many syntheses, the Johnson variant or the orthoester variant of the Claisen rearrangement has been advantageously used instead of the Claisen rearrangement itself. This has been exemplified in several contributions by Hong et al., who investigated synthetic approaches to carbonucleosides that rely on Johnson–Claisen rearrangement, RCM, and Pd-catalyzed allylic alkylation (Scheme 22);[96] starting from the glycolate-derived Weinreb amide **98**, precursor **100** was obtained through alkinyl Grignard addition, Horner–Wadsworth–Emmons (HWE)-reaction, and reduction. Treatment with triethyl orthoacetate at 140 °C in the presence of acid gave the Claisen rearrangement product **101**, which was converted by reduction and addition of vinyl magnesium bromide into a mixture of diastereomeric alcohols **102**. RCM of **102** was accomplished using the second-generation catalyst **C6** and resulted in the formation of diastereomeric cyclopentenols **103** in a moderate yield of 43%. The modest yield can be attributed to a competing ring closing enyne metathesis; unfortunately, no yield was reported for this product. The sequence was completed with single diastereomers of **103**, by conversion of the hydroxy group into a carbonate leaving group and Pd-catalyzed allylic substitution using deprotonated cytosine as a nucleophile.

Scheme 22 Carbonucleosides via Claisen rearrangement, RCM, and allylic alkylation.

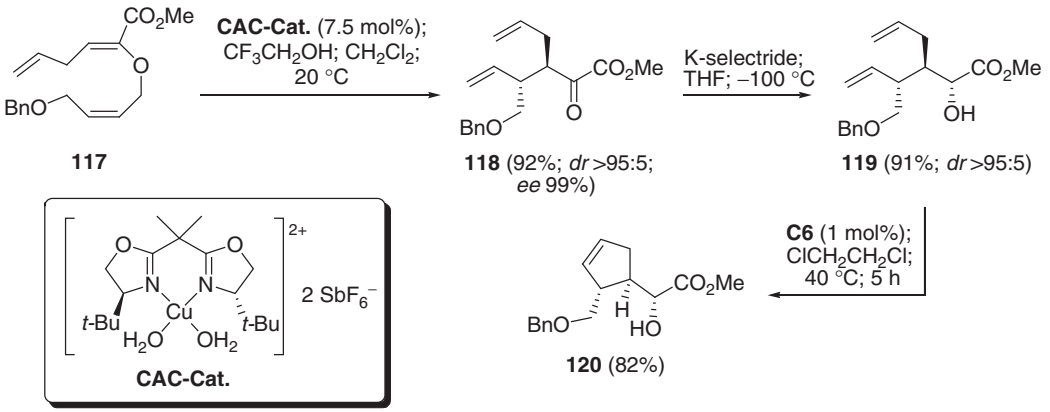


Variants of the Claisen rearrangement, which can be performed under milder conditions and in a stereoselective fashion, have been developed and combined with RCM in synthetic sequences. Among these, the Ireland–Claisen rearrangement is the most commonly used method, which is exemplified by a synthesis of the antiplatelet drug, beraprost (Scheme 23).[97] Allyl ester **105** was first converted into the (*Z*)-silyl ketene acetal **106**, which underwent stereospecific rearrangement on warming to an ambient temperature. Aqueous workup, followed by treatment with diazomethane provided ester **107** as a single diastereomer. The RCM precursor **108** was obtained through reduction with DIBAl-H and Grignard addition. It was cyclized to cyclopentenol **109**, without OH-protection, using a moderate amount of the first-generation catalyst **C3** at 40 °C.

The Reformatsky–Claisen reaction has been exploited for the synthesis of fluorinated carbonucleosides (Scheme 24).[98] The required precursor **111** was synthesized in five steps from protected glyceraldehyde **110**. The Reformatsky–Claisen rearrangement required the presence of zinc as a reducing agent at elevated temperatures and resulted in the formation of ester **112** in moderate diastereoselectivity. This compound was converted into the RCM precursor **113**; however, RCM did not proceed with satisfactory

Scheme 23 Synthesis of beraprost via Ireland–Claisen rearrangement/RCM.

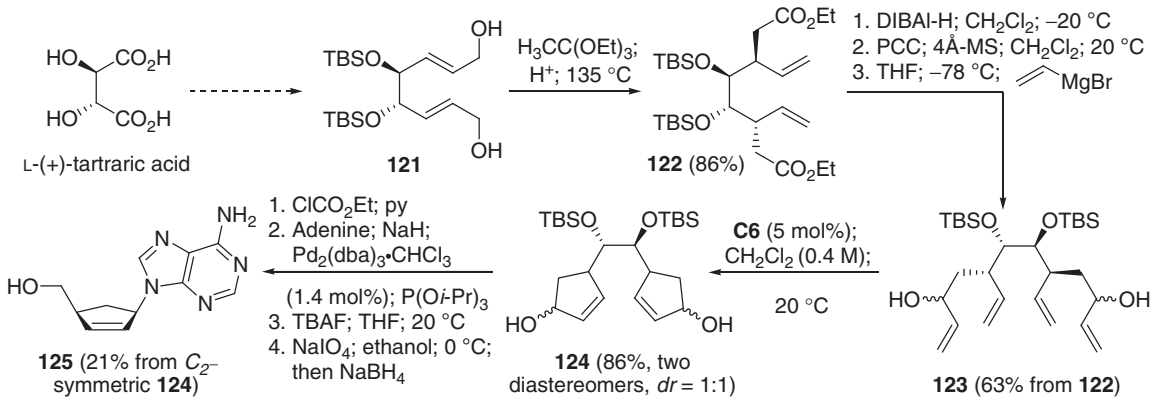
conversion, which was attributed to the highly electron-deficient nature of one C–C double bond. Therefore a Luche reduction was used to obtain an allylic alcohol **114**. Both epimers of **114** underwent RCM smoothly at a remarkably high initial substrate concentration of 0.4 M to give cyclopentenol **115** and *epi*-**115** in equal amounts. Palladium-catalyzed allylic alkylation was used for the introduction of the protected nucleobase 3-benzoyl thymine, which proceeded to give a good yield but required a rather high loading of the Pd-precatalyst.



Scheme 24 Carbonucleosides via Reformatsky–Claisen reaction and RCM.

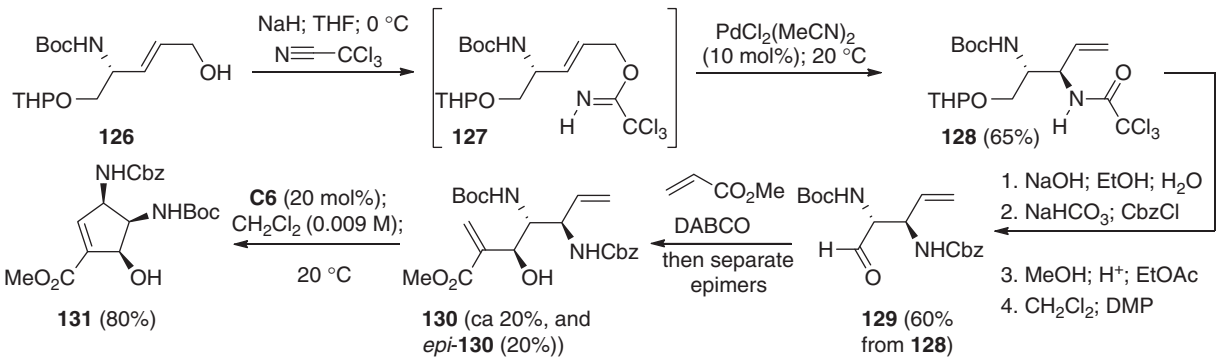
The catalytic asymmetric Claisen rearrangement, developed by Hiersemann et al., was combined with RCM in the synthesis of a cyclopentane fragment of (–)-ecklonialactone B (Scheme 25).[99] Starting from ketene acetal **117**, the rearrangement product **118** was obtained in a high yield as a single stereoisomer. Stereoselective reduction gave the RCM precursor **119**, which was converted to cyclopentene **120** in good yield with a comparatively low catalyst loading.

5.29.3.1.4 Synthesis of precursors from 'chiral pool' starting materials



In the preceding sections, the authors focused on synthetic methods for the construction of appropriate metathesis precursors. Although in some of the examples discussed so far, starting materials derived from natural products have been used, this section will be dedicated specifically to the exploitation of chiral pool compounds. In particular, α-hydroxy acids, α-amino acids, and carbohydrates have been used for the stereoselective synthesis of many RCM precursors.

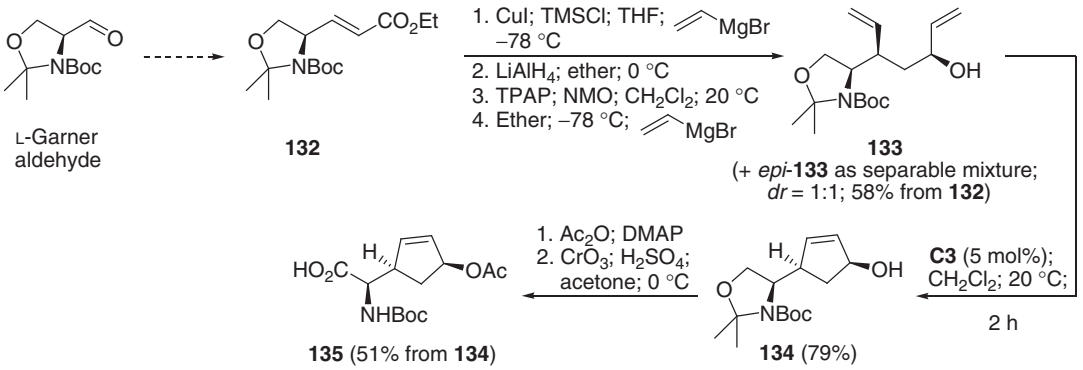
An example for the efficient use of L-(+)-tartrate has been published by Fang and Hong (Scheme 26).[100] Conversion into diol **121** was achieved through routine steps. Subsequently, **121** was subjected to the conditions of a Johnson–Claisen rearrangement, resulting in the highly diastereoselective formation of **122**. Elaboration of the diester into the diallylic alcohol **123** gave a mixture



Scheme 25 Catalytic asymmetric Claisen rearrangement and RCM.

of two diastereomers, which underwent RCM smoothly to afford bis-cyclopentenol **124**. Separation of the C_2-symmetric epimer, conversion of the OH-groups into carbonate groups, Pd-catalyzed allylic substitution with deprotonated adenine, and desilylation gave a C_2-symmetric diol, which was finally subjected to a periodate cleavage, giving two equivalents of carbonucleoside **125** after reductive workup.

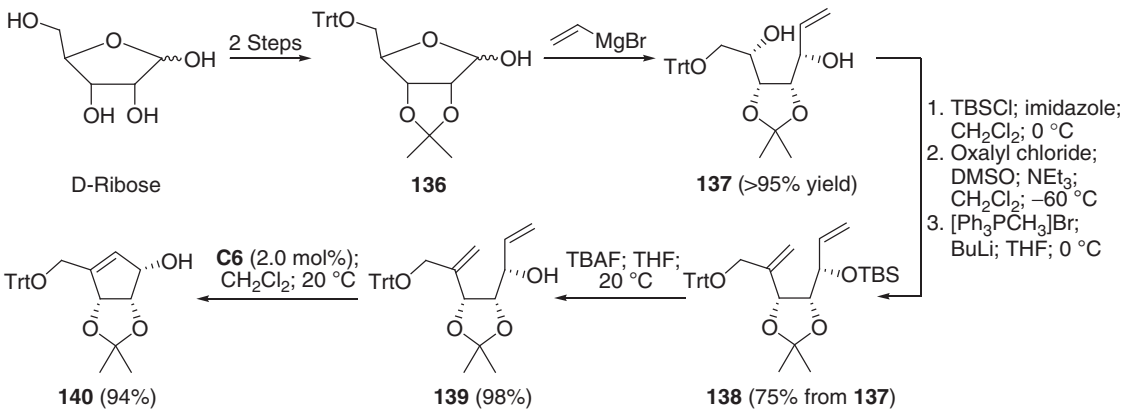
Scheme 26 Enantiopure carbonucleosides from L-(+)-tartrate.



L-serine is one of the most commonly used amino acids in organic synthesis. Here, two examples of how serine-derived starting materials can be used in the synthesis of aminocyclitols will be discussed. With a view toward diaminocyclitols as potential neuraminidase inhibitors, the serine-derived allylic alcohol **126** was converted to the vicinal *anti*-diamine **128** by treatment of the alkoxide with trichloroacetonitrile followed by a Pd-catalyzed aza-Claisen rearrangement of the initially formed trichloroacetimidate **127** (Scheme 27).[101] Aldehyde **129** is available in four steps from **128**, which is then subjected to a Baylis–Hilman reaction to furnish the RCM precursor **130** and its epimer. The epimers were separated and subjected individually to RCM conditions. Not surprisingly, considering the electron-deficient nature of one of the double bonds involved and the

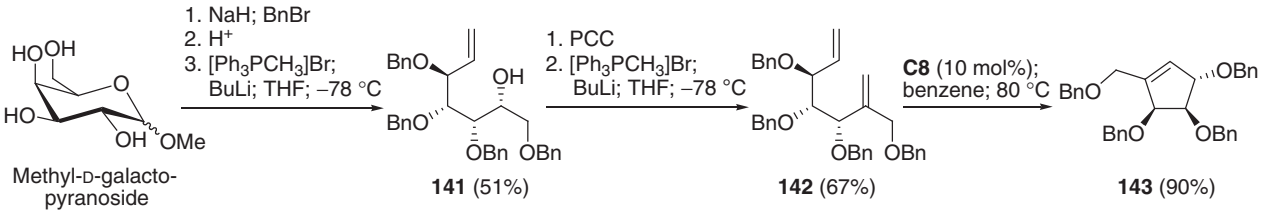
Scheme 27 Diaminocyclitols from L-serine.

required formation of a trisubstituted double bond, the first-generation catalyst **C3** was found to be inactive; however, by using the second-generation catalyst **C6** (albeit with a very high catalyst loading and at rather high dilution) cyclization to both **131** and its epimer were accomplished in good yields. Interestingly, by thermal aza-Claisen rearrangement the *syn*-diastereomer of **128** becomes available, and the researchers also repeated the entire sequence for *syn*-**128**. Thus, all diastereomeric RCM precursors of **130** were separately synthesized and individually subjected to RCM. All RCM reactions proceeded under similar conditions and the products were obtained in comparable yields.



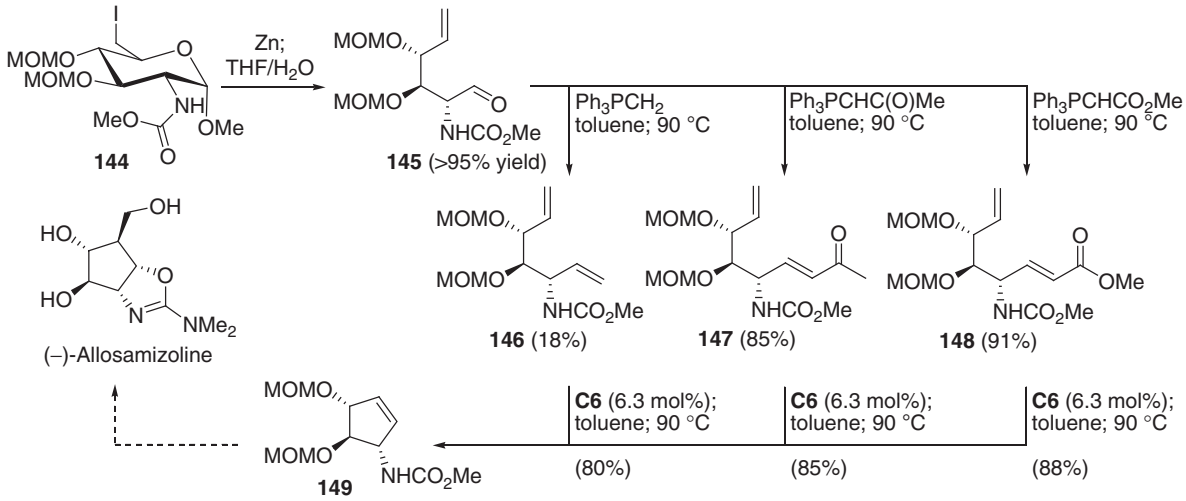
A commonly used building block derived from L-serine is Garner's aldehyde, which has been used in several syntheses of enantiopure cyclopentenol derivatives. A recent example is outlined in Scheme 28.[102] The starting point is ester **132**, which is converted through conjugate addition, reduction of the ester group, oxidation to the aldehyde, and addition of vinyl magnesium bromide into a 1:1 mixture of allylic alcohols **133** and *epi*-**133**. The epimers were separated and subjected to RCM, which proceeded smoothly without protection of the OH-group. Under the reported RCM conditions, both diastereomers reacted with a comparable rate and yield to the corresponding cyclopentenols **134** and *epi*-**134** (not shown). By acetylation and Jones oxidation the desired *N*-*tert*-butyloxycarbonyl (Boc)-protected amino acid **135** and its epimer could be obtained. The researchers also devised a route to the enantiomers of **135** and *epi*-**135** from cheap L-serine, which was converted to D-Garner aldehyde in five steps.

Scheme 28 Stereodivergent route to cyclopentenyl glycine derivatives.



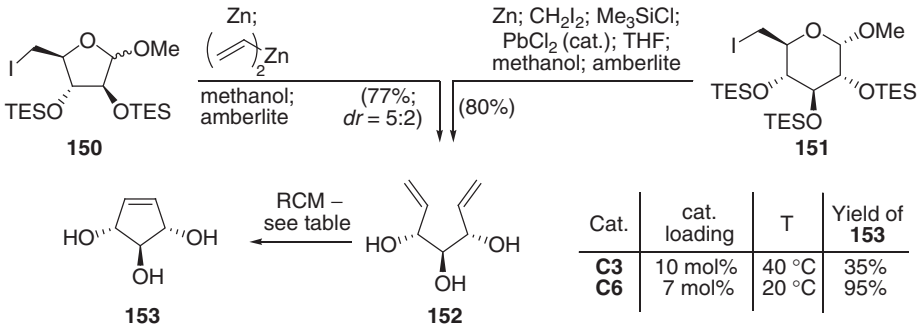
By far the most important chiral pool starting materials for RCM-based syntheses of cyclopentenes (and cyclohexenes, see Section 5.29.4.1) are carbohydrates.[103] Three important methods for the synthesis of the required RCM precursors have emerged: (i) addition of vinyl metal compounds to the carbonyl carbon of a carbohydrate; (ii) Wittig and other olefination reactions; and (iii) reductive elimination of iodoglycosides.

The addition of vinyl metal compounds to protected lactols often proceeds with high or even perfect diastereoselectivity. A representative example is highlighted in the following: aiming at the synthesis of carbonucleosides as potential antiviral agents, D-ribose was converted to the protected furanose **136**, which reacted quantitatively with vinyl magnesium bromide to allylic alcohol **137** as a single diastereomer.[104] After regioselective TBS protection and oxidation of the remaining secondary alcohol to a ketone, the second C–C double bond was introduced using a Wittig olefination. The TBS-protected precursor **138** did not undergo RCM, even if excessive amounts of first- or second-generation catalysts were used. However, after desilylation, the resulting allylic alcohol **139** underwent RCM smoothly on a 10 g scale in the presence of 2 mol% of the second-generation catalyst **C6** (Scheme 29).



Scheme 29 Synthesis of RCM precursor from D-ribose.

An example for a dual application of the Wittig olefination is summarized in Scheme 30.[105] The sequence, starting from D-galactose, leads to a protected cyclopentitol **143** with a diastereomeric substitution pattern relative to **140** (Scheme 29). In this example, the RCM step was conducted with the tetrabenzylated precursor **142**, making significantly higher catalyst loadings and elevated temperatures necessary.

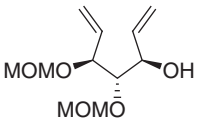


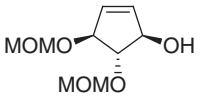
Scheme 30 Synthesis of RCM precursor from D-galactose.

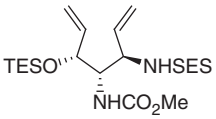
The third method often used for the construction of alkenes from carbohydrates, the zinc-mediated elimination of iodoglycosides, has been combined with an olefination of carbonyl groups in most examples. This is illustrated in the RCM-based synthesis of (–)-allosamizoline, the aglycon of the chitinase inhibitor allosamidin (Scheme 31).[106] The aldehyde **145** obtained on treatment of iodoglycoside **144** (derived from D-glucosamine) with zinc was then subjected to a Wittig olefination. As the supposedly most reactive precursor **146** was obtained in only 18% yield, the Wittig reaction was repeated with stabilized ylides to give precursors **147** and **148** in high yields. In spite of the electron-deficient nature of one of the double bonds participating in the RCM step, cyclopentene **149** was obtained from all three precursors in preparatively useful yields with acceptable amounts of precatalyst **C6**.

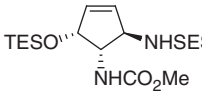
Scheme 31 Synthesis of the cyclopentene core of (–)-allosamizoline.

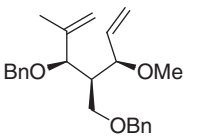
Madsen et al. devised protocols for sequential one-pot reductive elimination/vinylation and reductive elimination/olefination syntheses of polyhydroxylated α,ω-dienes from deoxy-iodo carbohydrates (Scheme 32).[107]

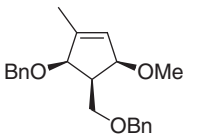


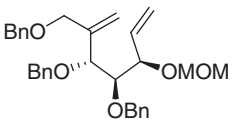


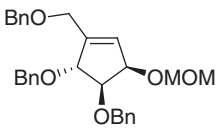


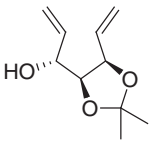


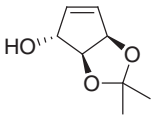


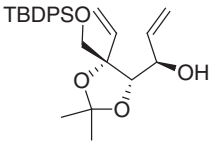


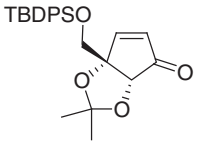


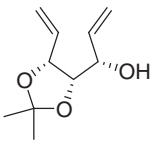


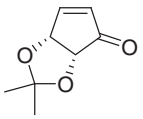


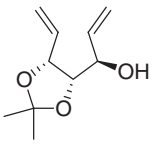


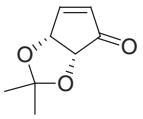












Cat.	cat. loading	T	Yield of **153**
C3	10 mol%	40 °C	35%
C6	7 mol%	20 °C	95%

Scheme 32 Sequential zinc-mediated elimination toward RCM precursors.

From arabino derivative **150**, diene **152** is available in moderate diastereoselectivity through reduction with zinc, addition of divinylzinc, and final acidic workup. The same diene was obtained from the gluco derivative **151** as a single isomer by zinc-mediated reduction for the formation of one double bond and Takai-type olefination of the aldehyde for the construction of the second C–C double bond. Both protocols involve acidic workup with methanol, resulting in the removal of the TES-protecting groups. Subsequent RCM was accomplished with the unprotected triol **152**, which underwent smooth cyclization to cyclopentene **153** only in the presence of the second-generation catalyst **C6**, whereas incomplete conversion was observed with **C3** even with higher amounts of catalyst and at elevated temperatures. Additional instructive examples for the RCM-based syntheses of cyclopentenes from carbohydrates are listed in Table 4.

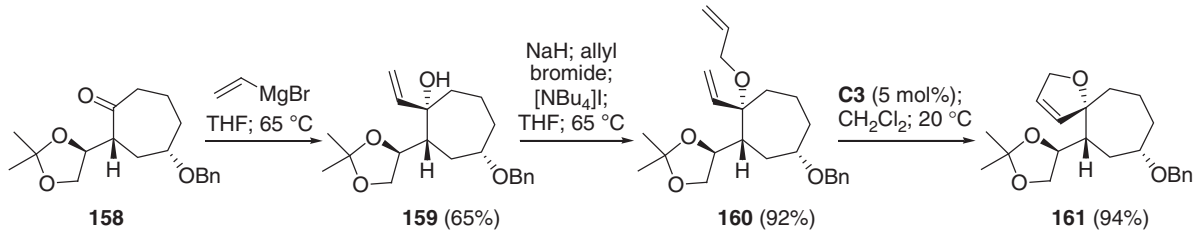
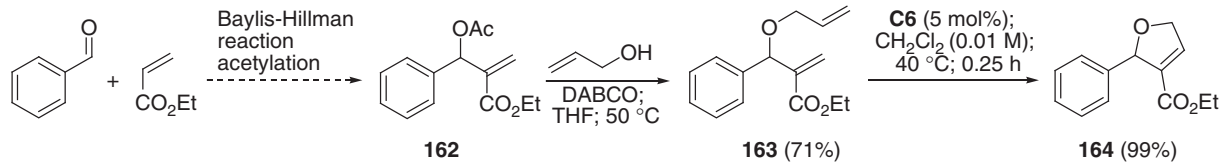
5.29.3.2 Five-Membered Heterocycles

5.29.3.2.1 Five-membered oxacycles



5.29.3.2.1.1 α-Substituted dihydrofurans

Monosubstituted diallylethers are normally highly reactive substrates in RCM reactions, and in most cases the first-generation catalyst **C3** should be sufficiently active to convert the precursors into 2-substituted 2,5-dihydrofurans in high yields at ambient or only slightly elevated temperatures. An example is the synthesis of enantiomerically pure (–)-gloeosporiol, a secondary metabolite of a phytopathogenic fungus (Scheme 33).[116] Routinely, the synthesis of RCM precursors such as **156** starts from aldehydes or ketones, which react with vinyl-Grignard reagents to racemic homoallylic alcohols. Often a kinetic resolution with lipases is used to obtain enantiopure alcohols,[117] which are then allylated to the desired RCM precursors. In the present case, **156** underwent RCM to 2-aryl-2,5-dihydrofuran **157** smoothly, which was then diastereoselectively dihydroxylated, resulting – after desilylation – in the formation of (–)-gloeosporiol with an optical purity higher than 99%.

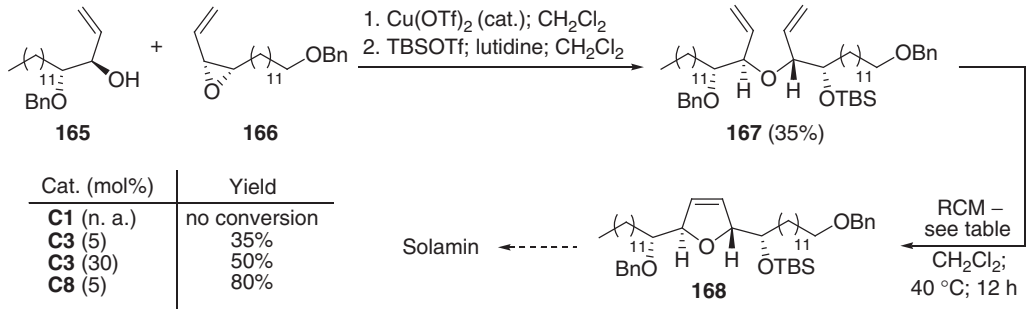


Scheme 33 Synthesis of (–)-gloeosporiol through RCM of a diallyl ether.

In the course of a study directed at the synthesis of Schisandra nortriterpenoids, a highly diastereoselective addition of vinylmagnesium bromide to a substituted cycloheptanone **158** was exploited for the synthesis of the RCM precursor **160** (Scheme 34).[118] Although this precursor is sterically more congested than **156** (Scheme 33), RCM to the spirocyclic compound **161** proceeded in nearly quantitative yields with the same catalyst loading.

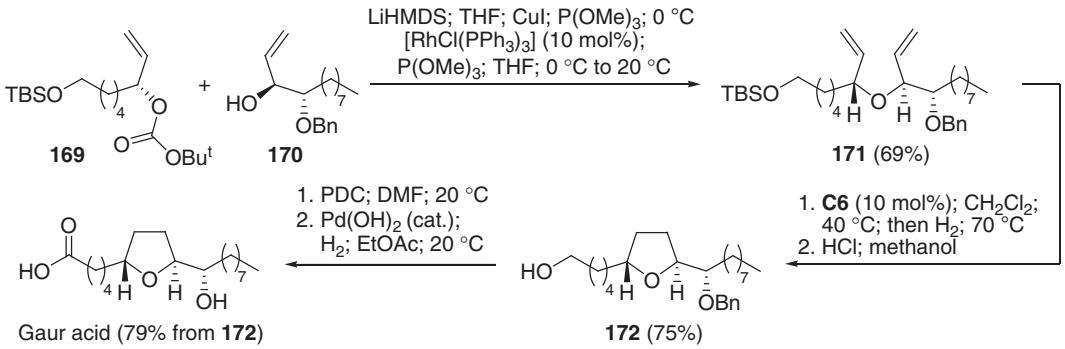
Scheme 34 Synthesis of a Schisandra-nortriterpenoid building block through RCM.

As for the synthesis of cyclopentenes, RCM reactions leading to dihydrofurans with a triple-substituted double bond require higher catalyst loadings, elevated temperatures, or the use of more active second-generation catalysts. In particular, this is necessary if electron-deficient double bonds are involved in the RCM step, as outlined in Scheme 35.[119] In this example, one of the two double bonds of the precursor comes from an acetate of a Baylis–Hillman adduct (**162**). The second double bond is introduced by nucleophilic substitution with allyl alcohol to give the RCM precursor **163**, which underwent RCM in the presence of **C6**. As in most cases when a triple-substituted double bond is formed in the RCM step, comparatively high dilution has been



Scheme 35 2,3-Disubstituted 2,5-dihydrofurans through RCM of Baylis–Hillman-adducts.

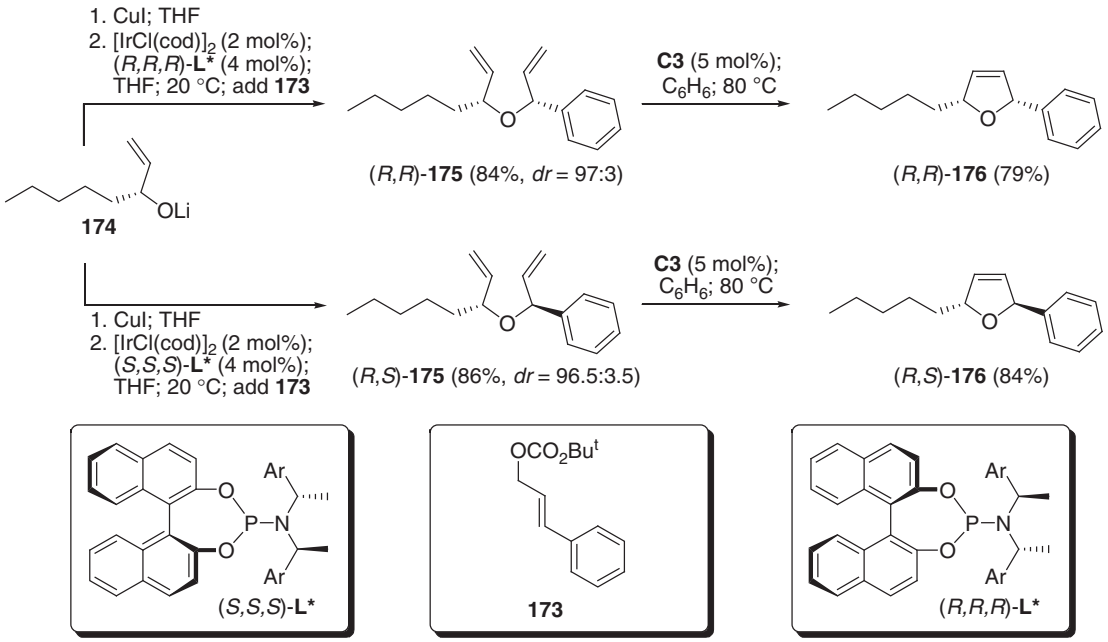
applied to suppress competing dimerization through self-metathesis. In a related strategy, Baylis–Hillman-adducts have been used by Donohoe et al. to synthesize dihydrofurans equipped with a leaving group, which undergo elimination of ethanol leading to furans.[120]



5.29.3.2.1.2 α,α′-Disubstituted dihydrofurans

For quite some time, the synthesis of appropriately substituted precursors has been a major obstacle in accessing 2,5-disubstituted dihydrofurans through RCM. One solution relies on a regio- and stereoselective opening of vinyl epoxides with allyl alcohols, and a representative example is outlined in the following (**Scheme 36**).[121] Aiming at the synthesis of the *Annona* acetogenin solamin, alcohol **165** and vinyl epoxide **166** were coupled in the presence of catalytic amounts of Cu-(II)-triflate to furnish diene **167** in moderate yields after TBS protection. Various catalysts and conditions were tested to accomplish RCM, but only low yields could be obtained with **C3** at reasonable catalyst loadings. Surprisingly, the highly active molybdenum catalyst **C1** failed completely, which might be attributed to its high sensitivity toward air and moisture, whereas the second-generation catalyst **C8** worked well, providing the desired dihydrofuran **168** in good yields at acceptable catalyst loadings. A similar strategy has been pursued in the synthesis of an amphidinolide C segment, where the crucial RCM step was accomplished with catalyst **C6**.[122]

Scheme 36 2,5-Disubstituted dihydrofurans through RCM.

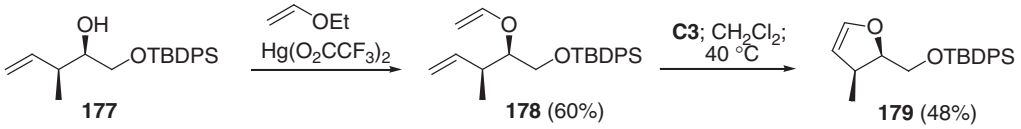


The discovery that Rh- and Ir-catalyzed allylic nucleophilic substitution reactions provide a convenient access to products with a terminal C–C double bond has been a major advantage in the synthesis of RCM precursors. The approach reported by Evans et al.[123] to the natural product gaur acid illustrates how a stereo- and regiospecific Rh-catalyzed allylic substitution and an RCM can be advantageously combined in the synthesis of target molecules (**Scheme 37**). The enantiomerically pure carbonate **169** undergoes a regio- and stereospecific Rh-catalyzed nucleophilic substitution with the Cu-alkoxide of allylic alcohol **170** to give the RCM precursor **171** as a single diastereomer. RCM was achieved with the second-generation catalyst **C6**, and the newly formed double bond was *in-situ* hydrogenated, using the metathesis catalyst in a tandem transformation (see Section 5.29.12 for a more detailed discussion of such transformations). After desilylation, the resulting *trans*-configured tetrahydrofuran **172** was converted into the natural product in two steps.

Scheme 37 Synthesis of Gaur acid through Rh-catalyzed allylation and RCM.

Alternatively, achiral carbonates can be used with chiral catalysts. To this end, Hartwig et al. introduced the combination of Ir(I)-precatalysts and phosphoramidite ligands (**Scheme 38**).[124] For example, Li-alkoxide **174** reacts with the achiral carbonate **173** in the presence of enantiomeric Ir-catalysts (generated *in situ* from all-*R* or all-*S* phosphoramidites, respectively) to the diastereomeric precursors (*R*, *R*)-**175** and (*R*, *S*)-**175** in high regio- and stereoselectivity. In contrast to the examples

quoted above, both undergo smooth RCM in the presence of 5 mol% of the first-generation catalyst **C3** in refluxing benzene.

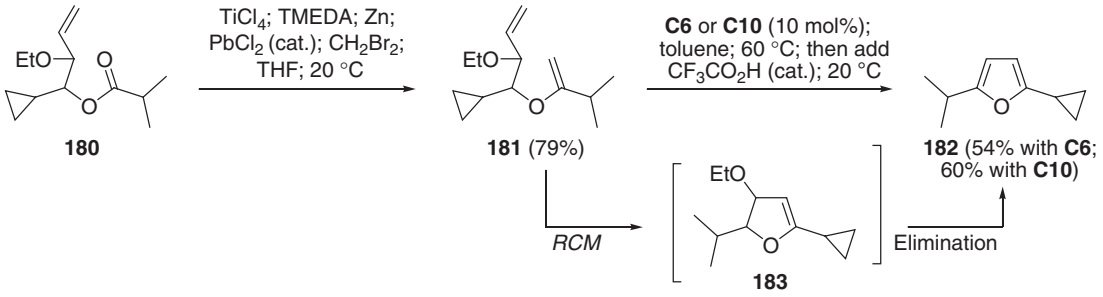


Scheme 38 Synthesis of RCM precursors through enantioselective Ir-catalyzed allylation.

More recently, Kocovský et al. exploited the Ir-catalyzed allylic substitution-RCM sequence for the synthesis of various aryl-C-ribonucleosides. For substrates that are sterically similarly congested as **175** it was found that the amount of catalyst **C3** can be reduced to 1 mol%, and that the temperature can be reduced to 40 °C for the RCM step.[125]

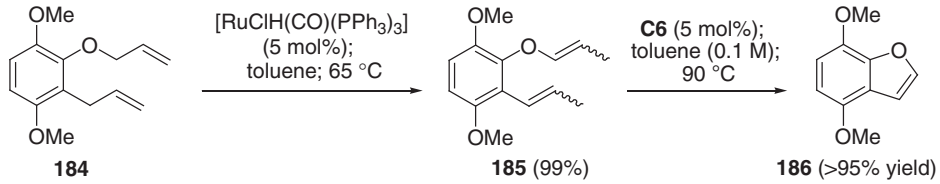
5.29.3.2.1.3 Five-membered cyclic enol ethers

In contrast to the RCM of diallyl ethers, vinyl ethers react slower and often require increased catalyst loadings, more active catalysts, higher dilution, and elevated temperatures. The decreased reactivity is commonly attributed to the intermediate formation of Fischer-type carbene complexes, if initiation occurs at the electron rich C–C double bond.[126] Another obstacle in the RCM of enol ethers is the synthesis of the precursors, which is often achieved by Hg^{2+}-mediated vinylation of homoallylic alcohols with ethyl vinyl ether. An example has been described by Williams et al., who required the 4,5-dihydrofuran **179** in the course of their lankacyclinol synthesis (Scheme 39).[127] Unfortunately, no catalyst loading was reported for this example.



Scheme 39 Vinylation of homoallylic alcohols and enolether RCM toward lankacyclinol.

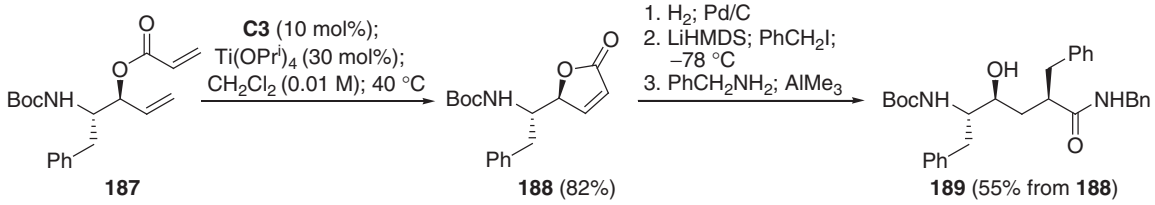
A different approach to enol ethers was pursued by Donohoe et al. in their one-pot synthesis of furans (e.g., **182**) via RCM and acid-catalyzed elimination (Scheme 40).[128] They used a modified Takai olefination to obtain the required precursors, for example, **181**, from esters such as **180**.



The RCM step was catalyzed by **C6**, and the resulting dihydrofurans **183** were treated, without isolation, with catalytic amounts of acid to promote the elimination of ethanol. The researchers report that in some cases the chromatographic purification of the product was hampered by the presence of phosphine, but this problem could be solved by using the phosphine-free catalyst **C10**. Apart from the simplified workup, better yields and shorter reaction times were observed with this catalyst.

Sometimes it is advantageous to synthesize the required RCM precursors from allyl compounds via isomerization. A significant number of examples for this strategy have been published by van Otterlo et al. In the following a synthesis of benzo[b]furans based on Ru-hydride catalyzed double-bond migration and subsequent RCM is highlighted (Scheme 41).[129] Allyl ether **184** was

Scheme 40 One-pot enolether RCM elimination for the synthesis of furans.

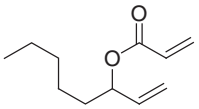


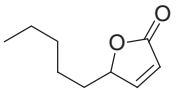
treated with a catalytic amount of a Ru-hydride complex to undergo quantiative isomerization to the vinyl ether **185**, which was then cyclized to the benzo[b]furan **186** with moderate loadings of catalyst **C6**.

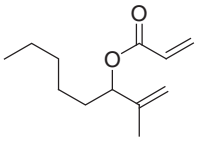
Scheme 41 Ru-catalyzed isomerization and RCM for the synthesis of benzofurans.

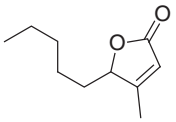
5.29.3.2.1.4 α,β-Unsaturated five-membered lactones (butenolides)

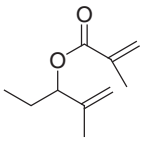
Like substrates with one electron-rich double bond, for example, enol ethers, substrates with an electron-deficient double bond are significantly less reactive than allyl ethers. The problems associated with this type of RCM and its high synthetic value become evident from an early example published by Ghosh et al. in 1998 (Scheme 42).[130] They discovered that the RCM of acrylates such as **187** proceeds only very slowly, making rather high catalyst loadings of **C3** necessary. It should be taken into account that at this time the second-generation NHC-ligated catalysts were not yet available, and therefore alternative measures were investigated to improve the rate of the RCM. The researchers reasoned, supported by the previous observations published by Fürstner and Langemann in the course of macrocyclizations,[131] that the decreased reactivity originates from the formation of rather stable chelates after initiation. It is in line with this assumption that the addition of the Lewis acid $Ti(OPr^i)_4$ as a cocatalyst significantly accelerates the cyclization, resulting in the formation of butenolide **188** in 82% yield. Lactone **188** was diastereoselectively converted into the dipeptide isostere **189**, a useful intermediate in the synthesis of protease inhibitors.

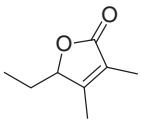


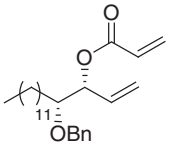


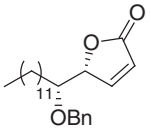


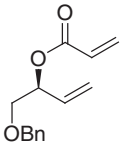


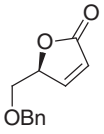


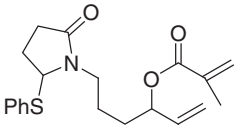


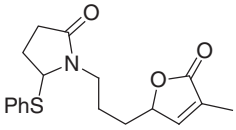


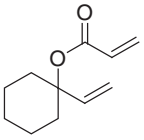


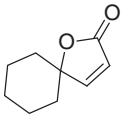












Scheme 42 Toward dipeptide isosteres through acrylate RCM.

In spite of the significant acceleration achieved by the addition of a Lewis acidic cocatalyst, the amount of first-generation Ru-catalysts (such as **C3**) required for useful rates of conversion is still very high, typically in the range of 10 mol% (occasionally in the range of 5 mol%).[132] In this regard, a significant progress was achieved with the discovery of second-generation catalysts. Shortly after the NHC-complexes **C6**–**C9** were first described in the literature, Fürstner et al. published an extensive study on the performance of these novel catalysts in 'difficult' RCM reactions, including the cyclization of various acrylates listed in Table 5 (entries 1–3).[39] In many cases, in particular if both the double bonds of the starting material are monosubstituted, catalyst loadings of 5 mol% or less are sufficient to obtain high yields of the desired butenolide. However, an obstacle that could not be overcome with the more active second-generation catalysts is the necessity to use rather low initial substrate concentrations, typically in the range of 0.01–0.05 M. A systematic study on the effect of catalyst loading and dilution in the RCM of acrylates suggests that, regardless of the catalyst loading, a critical initial substrate concentration exists for each RCM precursor.[133]

If this concentration is exceeded, the rate of conversion will decrease significantly, and this cannot be corrected by increased catalyst loadings. In contrast to some reports in the literature,[137] competing homodimerization is not the reason for the decreased

Table 5 Synthesis of butenolides through RCM of acrylates

Entry	Precursor	Conditions	Butenolide	Yield (%)	References

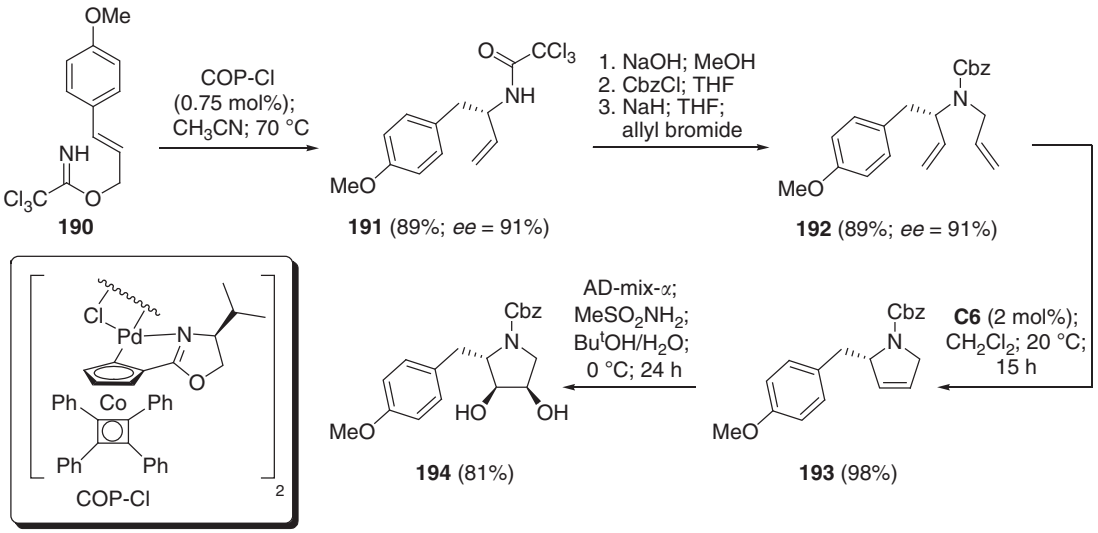
7		**C7** (2.5 mol%); toluene (0.02 M); 80 °C; 1.5 h		85	133



rate of RCM at higher concentrations in this particular case, because, whenever incomplete conversion was observed, only unreacted starting material and RCM products could be detected. Interestingly, higher initial substrate concentrations are tolerated with increasing degree of substitution of the double bonds (Table 5, entries 2, 3, 6).

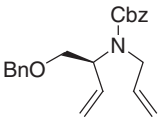
5.29.3.2.2 Five-membered azacycles

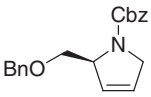
5.29.3.2.2.1 α-Substituted dihydropyrroles

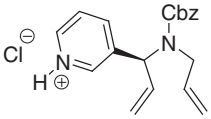
The most striking difference between oxa- and azacycle formation via RCM is that precautions have to be taken in the latter case to reduce the nucleophilicity of the heteroatom. In most cases this is achieved with electron-withdrawing groups such as the acetates, carbonates, or tosylates. Occasionally, however, synthetically useful results are obtained with tertiary amines, in particular benzyl amines, or after temporary conversion of a secondary amine into the corresponding hydrochloride.[138] For the synthesis of enantiomerically pure RCM precursors, diastereoselective transformations of carbohydrates,[139–141] enantio- or diastereoselective transformations of amino acid derivatives,[142,143] enantioselective allylic amination,[144,145] diastereoselective addition of organometallics to oximes,[146] or enantioselective imidate rearrangements[147] have been used. Synthetic strategies and methods for stereocontrol used in these precursor syntheses resemble those used for the synthesis of other RCM precursors (see Sections 5.29.3.1 and 5.29.3.2). Therefore, only an example for the successful implementation of an Overman- or imidate rearrangement catalyzed by a cobalt oxazoline palladacycle (COP-Cl, Scheme 43) will be discussed.[147]

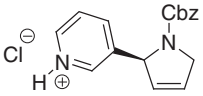
Starting from prochiral imidate **190**, an enantioselective imidate rearrangement to the allyl amine **191** is achieved with the dimeric Pd-catalyst COP-Cl. Introduction of the benzyloxycarbonyl (Cbz)-protecting group and allylation yields diallyl amide **192**, which cyclizes smoothly in the presence of **C6** at an ambient temperature to dihydropyrrole **193**. Dihydroxylation with

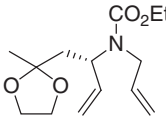
Scheme 43 Toward dihydropyrroles via enantioselective imidate rearrangement and RCM.

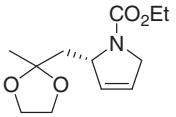


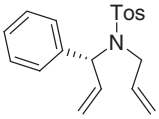


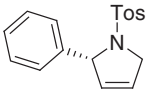


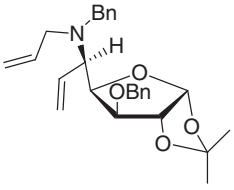


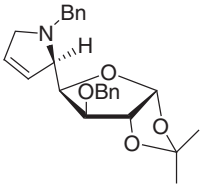


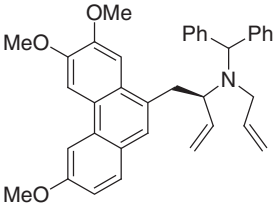


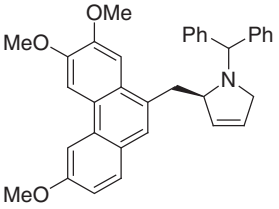


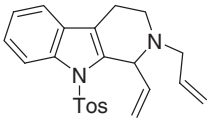


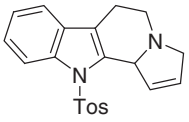


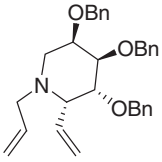


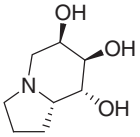


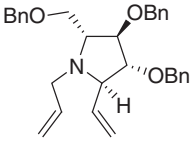


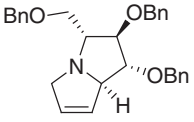












AD-mix-α proceeds with high diastereoselectivity, giving product **194**, a Cbz-protected epimer of the naturally occurring antibiotic anisomycin. In Table 6 some representative examples for RCM reactions leading to 1,2-disubstituted 2,5-dihydropyrroles are summarized. The commonly used electron-withdrawing N-protecting groups are Cbz (entries 1 and 2) or ethoxy carbonate (entry 3). In the case of the example listed in entry 2, pyridine was converted into hydrochloride before RCM. This RCM product was then converted in few steps into nicotine in > 99% *ee*,[144] whereas the dihydropyrrole in entry 3 served as a precursor for the alkaloid (+)-hygrine.[143] Tosylates (entry 4) are the less commonly used N-protecting groups in RCM reactions, although it could be demonstrated that the yields are comparable to those obtained with an ethoxy carbonate group for analogous RCM precursors.[145] In entries 5 and 6, examples for the successful conversion of tertiary amines are given. Although RCM of the benzyl-protected diallyl amine in entry 5 requires a rather high catalyst loading of 10 mol% of **C3**,[139] just 2 mol% of the same catalyst are sufficient to convert the diphenylmethyl-protected diallyl amine listed in entry 6 into the corresponding dihydropyrrole, an intermediate en route to the phenanthroindolizidine alkaloid (–)-antofine.[142] Obviously, sterically more demanding protecting groups reduce the unfavorable coordination of nitrogen to the metathesis catalyst, resulting in higher turnover numbers and lower catalyst loadings. Successful RCM reactions of diallyl amines have also been reported with sterically less demanding substituents at the nitrogen atom, in particular when nitrogen is part of a ring. In the example listed in entry 7, a long reaction time of 3 days was required for a good yield of the RCM product, but the amount of catalyst could be limited to 5 mol%.[148] In contrast, by using 10 mol% of the same catalyst, the reaction time could be significantly reduced for the structurally similar example in the entry 9.[140] A successful cyclization of an unhindered tertiary amine using a first-generation catalyst was achieved after temporary conversion of the precursor into the hydrochloride (entry 8). In this example, a very high catalyst loading of 25 mol% of **C3** was required, and the RCM product was hydrogenated *in situ* to give the bicyclic amine in 82% overall yield.

5.29.3.2.2.2 α,α′-Disubstituted dihydropyrroles

For the synthesis of precursors for 1,2,5-trisubstituted dihydropyrroles, regioselective nucleophilic opening of butadiene oxides with amines have been used in several syntheses. As a representative example, Trost's synthesis of the naturally occurring unusual amino acid (–)-bulgecinine is outlined below (Scheme 44).[150]

Starting from racemic butadiene oxide **195** and enantiomerically pure oxazolidinone **196** the RCM precursor **197** was obtained in good diastereoselectivities and overall yields using a Pd-catalyzed dynamic kinetic asymmetric transformation (DYKAT) followed by benzylation of the primary alcohol. Protection of the primary alcohol was found to be mandatory for successful RCM. Even with benzyl ether **197** the RCM reaction proceeded slowly, and the best yields of **198** were obtained by portionwise addition of catalyst **C6**. For the synthesis of the target molecule a regio- and stereoselective hydroboration of the double bond was required, which was accomplished using 9-*H*-9-borabicyclononane (9-H-9-BBN). The synthesis of (–)-bulgecinine was completed in five further steps. Additional examples for RCM reactions leading to 1,2,5-trisubstituted dihydropyrroles are listed in Table 7. The example in entry 1 shows the RCM of an epimer of **197** (see Scheme 44). A significantly higher catalyst loading and longer reaction times are required, although the effect of the relative configuration on the rate of the RCM step has not been explicitly investigated for this example. In entry 2, the RCM of the unprotected analog of **197** with **C6** is reported, which apparently contradicts the results reported by Trost et al. (see above). It should, however, be noted that for this example no catalyst loading was reported. From the example in entry 3 it becomes obvious that less active first-generation catalysts such as **C3** are only of limited value for this type of transformation, because no less than 50 mol% of catalyst are required to obtain 73% yield of product. In the last example in entry 4, the formation of an azabicyclooctane is reported. Ring closure proceeds with

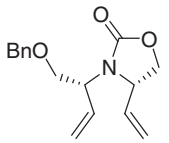
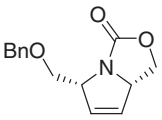
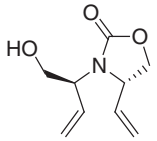
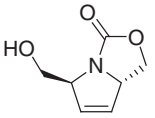
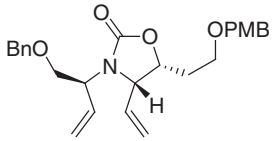
surprising efficiency, considering that a strained bicyclic product is formed, and requires only 10 mol% of the first-generation catalyst **C3**.

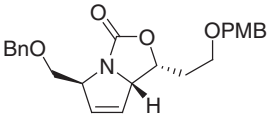


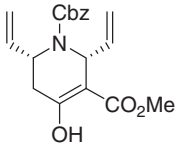












5.29.3.2.2.3 Five-membered cyclic enamides

Five-membered cyclic enamides are also accessible by RCM. The required starting materials can be synthesized by Tebbe olefination of acetamides or by isomerization of allylic amides. Examples for the synthesis of dihydropyrroles and indoles have been described. As for the oxa-analogs more active catalysts are required in most cases, but for sterically

unconstrained substrates, first-generation catalysts might also give satisfactory results. Some representative examples are listed in Table 8.

5.29.3.2.2.4 α,β-Unsaturated five-membered lactams

Ring-closing metathesis of acrylamides is associated with similar problems as RCM of acrylates (Table 9). To obtain good yields of unsaturated γ-lactams, normally high amounts of first-generation catalysts (entry 1), or moderate loadings of second-generation catalysts are required. Initial substrate concentrations normally do not exceed 0.1 M. For the example shown in entry 2, microwave irradiation and standard oil bath heating were compared. The researchers found that microwave irradiation reduces the reaction time to 30 min, compared with the 20 h taken under conventional heating conditions.

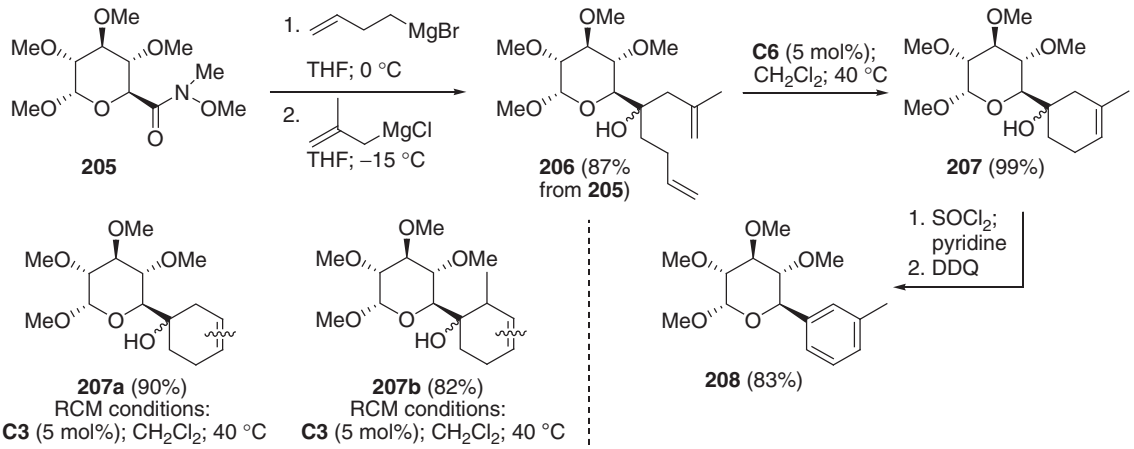
5.29.4 Six-Membered Ring Systems

5.29.4.1 Six-Membered Carbocycles

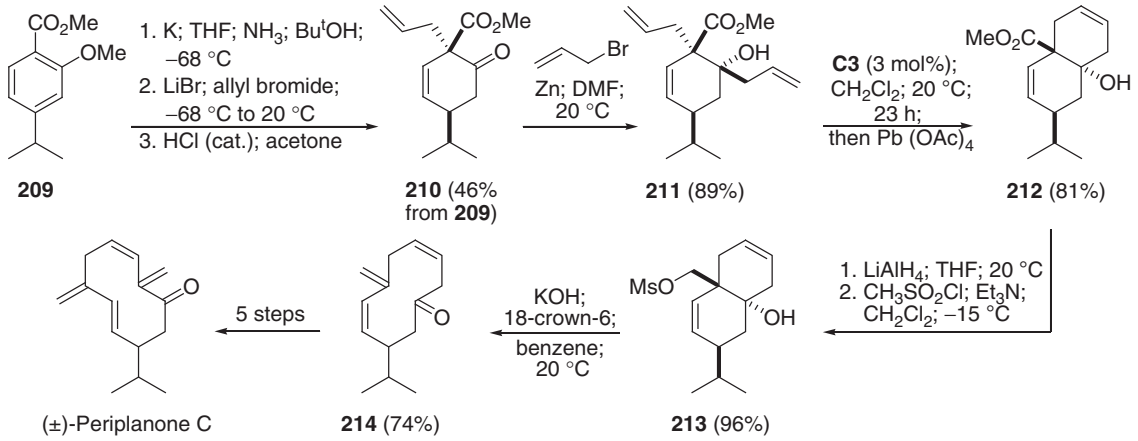
To a certain extent the methods used for the synthesis of RCM precursors for functionalized cyclohexenes resemble those for five-membered carbocycles. Therefore, they will not be covered in the same depths as in Section 5.29.3.1, but representative examples will be discussed to illustrate how the methods can be adapted to access RCM precursors for functionalized cyclohexenes.



5.29.4.1.1 Synthesis of precursors by the addition of organometallics to carbonyl compounds

One approach to cyclohexene precursors involves the sequential addition of two different organometallics to a carboxylic acid derivative. Useful chemo- and stereoselectivities can, for instance, be achieved with the cyclic ephedrine derivative **200** (Scheme 45).[162] En route to the quinic acid precursor **204**, the morpholine derivative **200** was first treated with butenyl magnesium bromide, followed by a highly diastereoselective Lewis-acid mediated allylation of hemiacetal **201** with allyltrimethylsilane. RCM of diene **202** was fast with the first-generation catalyst **C3** at an ambient temperature and provided spirocycle **203** in nearly quantitative yields. Reduction with Na in liquid ammonia furnished **204**, which was further elaborated to quinic acid.

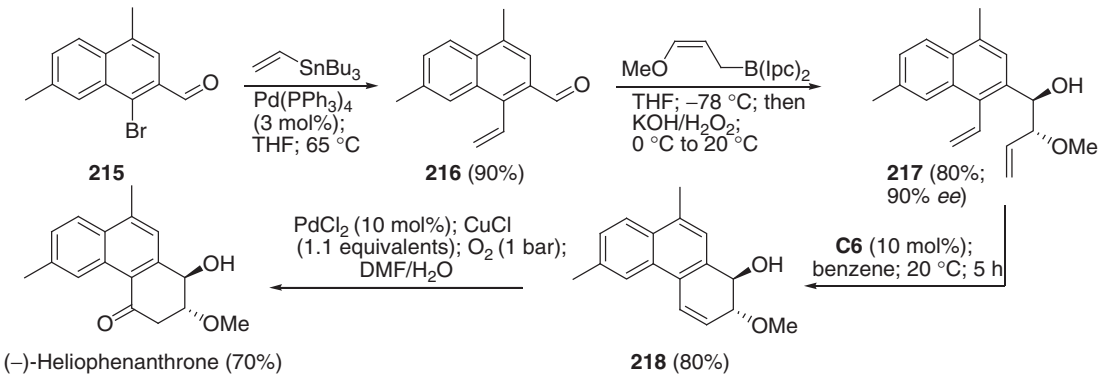
Scheme 45 Sequential butenylation/allylation for the synthesis of cyclohexene precursors.



Weinreb amides also allow the selective sequential addition of two different organometallic reagents. This has been used for the synthesis of cyclohexenols, which were then converted to substituted benzenes by elimination and oxidation (Scheme 46).[163] The sequence is illustrated for the synthesis of a *C*-aryl glycoside **208**: starting from Weinreb amide **205**; a butenyl and a 2-methylpropenyl Grignard reagent are successively added to give the RCM precursor **206**. For the RCM of **206**, comprising one geminally disubstituted double bond, the second-generation catalyst **C6** was used. Cyclohexenol **207** was obtained in nearly quantitative yields. It underwent aromatization by elimination, followed by oxidation with DDQ to give *C*-aryl glycoside **208**. For the RCM reactions leading to **207a** and **207b**, which did not involve the construction of a trisubstituted double bond, the less active catalyst **C3** gave good yields under otherwise identical conditions.

Scheme 46 From Weinreb amides to benzenes via RCM and elimination/oxidation.

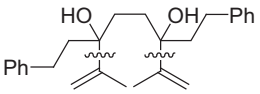
An alternative strategy toward cyclohexene precursors involves sequential trapping of an enolate with an allyl electrophile, followed by addition of an allyl nucleophile to the adjacent carbonyl group. This tactic is illustrated by the first steps of a synthesis of periplanone C (Scheme 47).[164] Interestingly, in this example the RCM is used to set the stage for a ring enlargement, giving access to a ring size that is normally difficult to obtain in a stereoselective manner.

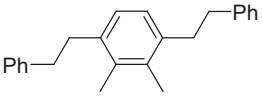


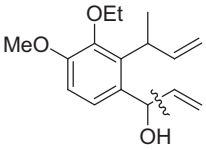
The sequence starts with a stereoselective Birch-reduction/allylation of the substituted benzene **209**, which proceeds with a *dr* of 7:1. An allyl zinc reagent is added to the resulting ketone **210** to give the RCM precursor **211** as a single diastereomer. RCM was

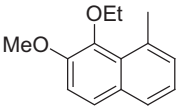
Scheme 47 From benzenes to decaline derivatives through Birch reduction and RCM.

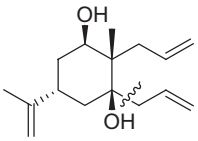
accomplished in a good yield using a moderate amount of **C3** at ambient temperatures. To facilitate chromatographic purification of cyclohexene **212**, Ru-residues were oxidized with $Pb(OAc)_4$ after the RCM had been completed.[165] Reduction of the ester and conversion of the primary alcohol into the mesylate set the stage for the base-induced fragmentation of **213** to the 10-membered cyclic ketone **214**. From **214**, the synthesis of (±)-periplanone C was completed in five further steps.

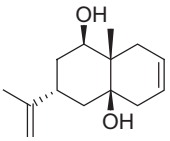


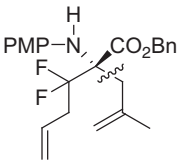


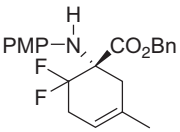


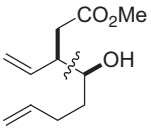


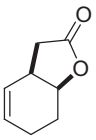


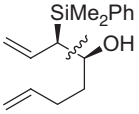


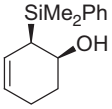


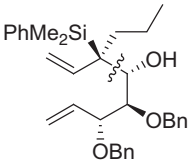


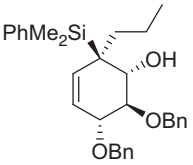


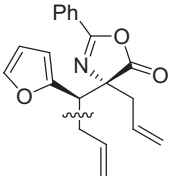


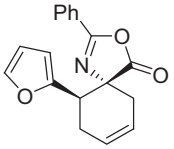


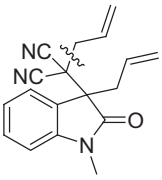


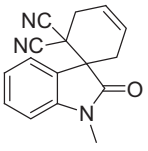


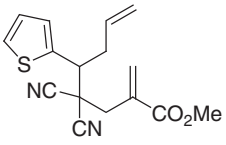


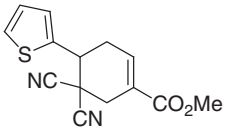






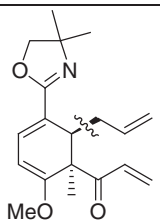


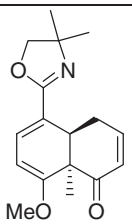


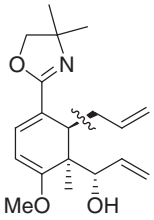


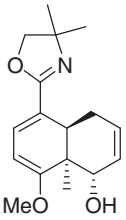
Apart from polar allyl metal compounds, allyl boron, allyl tin, and allyl silicon compounds were found to be particularly useful for constructing RCM precursors. A recent example is the protecting group-free synthesis of the plant constituent (–)-heliophenanthrone (Scheme 48).[166] Starting from naphthalene **215**, the first C–C double bond was introduced via Stille coupling, followed by a highly diastereoselective and enantioselective allylboration to give the RCM precursor **217** in 80% yield. RCM was accomplished using a surprisingly high loading of catalyst **C6**. The resulting cyclohexene **218** was then converted in one step to the target molecule via a regioselective Wacker oxidation.

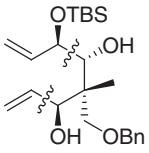
Scheme 48 Synthesis of (–)-heliophenanthrone.

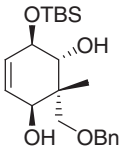


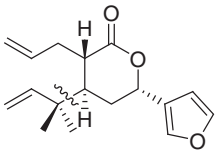


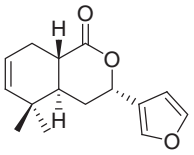












Some additional examples for the RCM of functionalized 1,7-octadienes, which were synthesized from carbonyl compounds through the addition of organometallics and enolate alkylation, are listed in Table 10. The authors wish to comment only on a few examples. The *in situ* RCM-aromatization listed in entry 1 is hampered because the formation of a tetrasubstituted double bond through RCM is a notoriously difficult process. No conversion was observed with precatalysts **C6** or **C10**, and the necessity to use excessively high catalyst loadings of Schrock's catalyst (**C1**) might be attributed to its sensitivity toward protic functional groups. For the example listed in entry 5, the RCM precursor was synthesized *in situ* via allylboration of pent-4-enal, and the allyl boronate was in turn generated *in situ* via a Pd-catalyzed borylation with bis-(pinacolato)diborane (B_2pin_2). The entire sequence, including the RCM step, was conducted in one flask in the presence of dimethyl sulfoxide (DMSO) and methanol, which might explain the unconventional choice of catalyst. The two examples shown in entries 6 and 7 illustrate how steric congestion both at the reacting double bonds, and also at the adjacent positions can lead to a decreased reactivity, necessitating higher catalyst loadings and prolonged reaction times. In the example listed in entry 11, RCM proceeded with unsatisfactory yields even if a second-generation catalyst **C9** was used, due to the presence of an electron-deficient double bond. This problem could be overcome by reducing the ketone, and subjecting the secondary alcohol shown in entry 12 to RCM. In this case, **C3** was sufficiently reactive to promote cyclization to cyclohexene in very good yield.

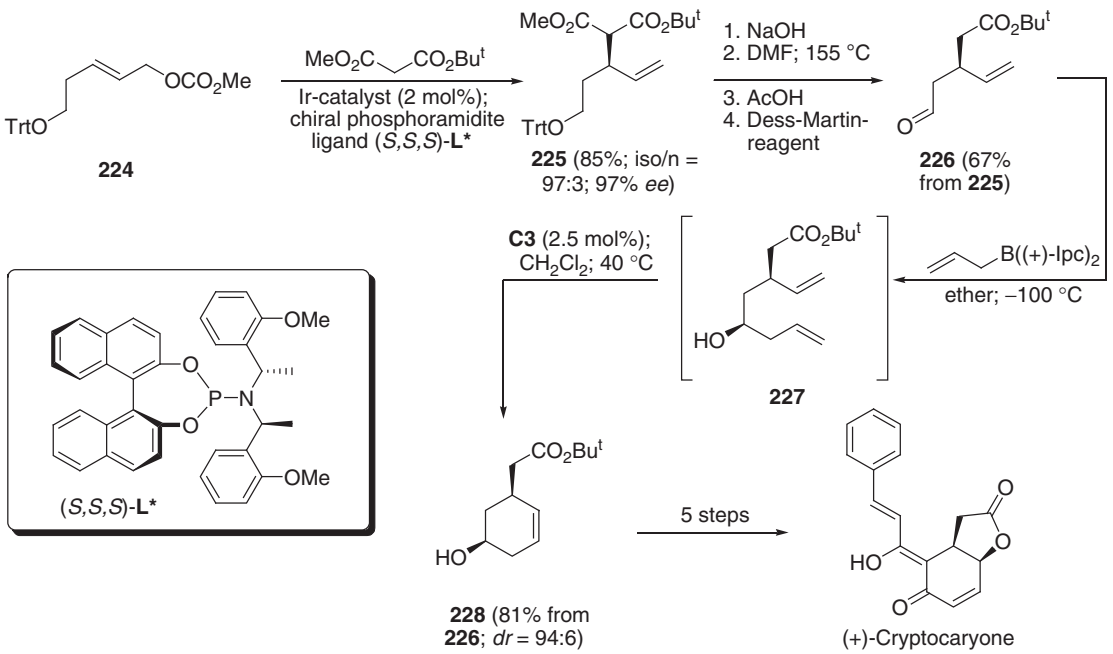
5.29.4.1.2 Synthesis of precursors by α-functionalization of carbonyl compounds

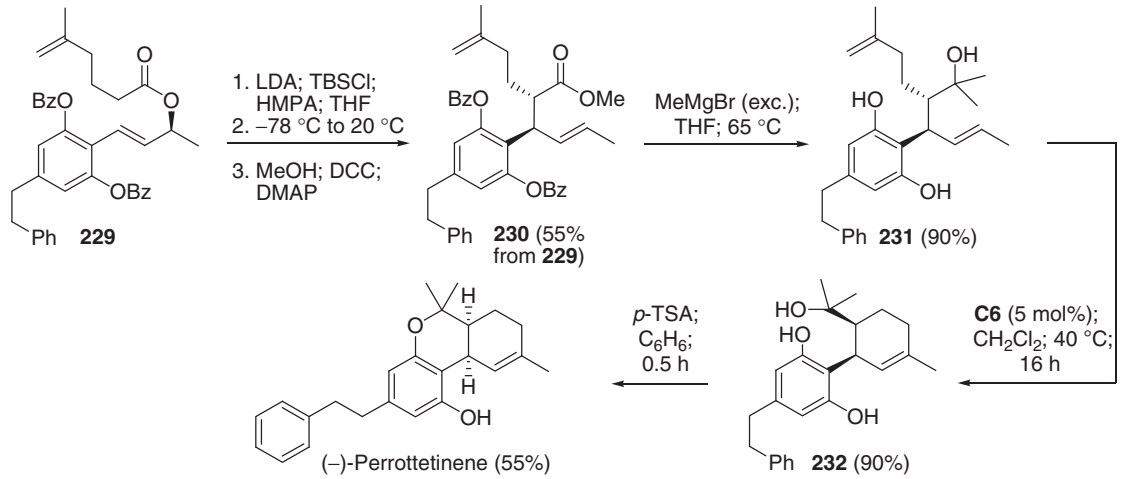
As described for the synthesis of cyclopentene precursors in Section 5.29.3.1.2, asymmetric transition metal-catalyzed enolate allylation has also emerged as a useful approach toward functionalized 1,7-octadienes, which can be subsequently cyclized to functionalized cyclohexenes. One example to illustrate this strategy is Trost's tetrahydrocannabinol synthesis (Scheme 49),[179] which relies on an Mo-catalyzed allylation of Na-malonate leading to the terminal alkene **220** with high regio- and enantioselectivities. Compound **220** was converted to acid **221** by saponification and decarboxylation. Alkylation of the enolate obtained from **221** with 4-iodo-2-methylbut-1-ene, followed by esterification, gave the RCM precursor **222** in good yields as a mixture of diastereomers. The mixture was subjected to RCM using 2 mol% of **C6** in dichloromethane at 20 °C, but the conversion was found to be incomplete and therefore an additional 1 mol% portion of **C6** was added. After base-mediated epimerization, the *trans*-configured cyclohexene **223** was isolated, which was then converted in four further steps to the target molecule, *trans*-tetrahydrocannabinol.



The combination of Ir-precatalysts and chiral phosphoramidite ligands is also very useful for the regio- and enantioselective synthesis of branched allylic substitution products, as illustrated by Helmchen's synthesis of the natural product (+)-cryptocaryone (Scheme 50).[180] The substitution product **225** was converted into aldehyde **226** in four steps, and the second alkene moiety was introduced via Brown allylboration. Diene **227** was then subjected to RCM without complete removal of the byproducts from the previous step. Nevertheless, cyclization proceeded smoothly with a moderate catalyst loading of **C3** to furnish the *cis*-configured cyclohexene **228** in good yield, which was elaborated in five steps into the target molecule.

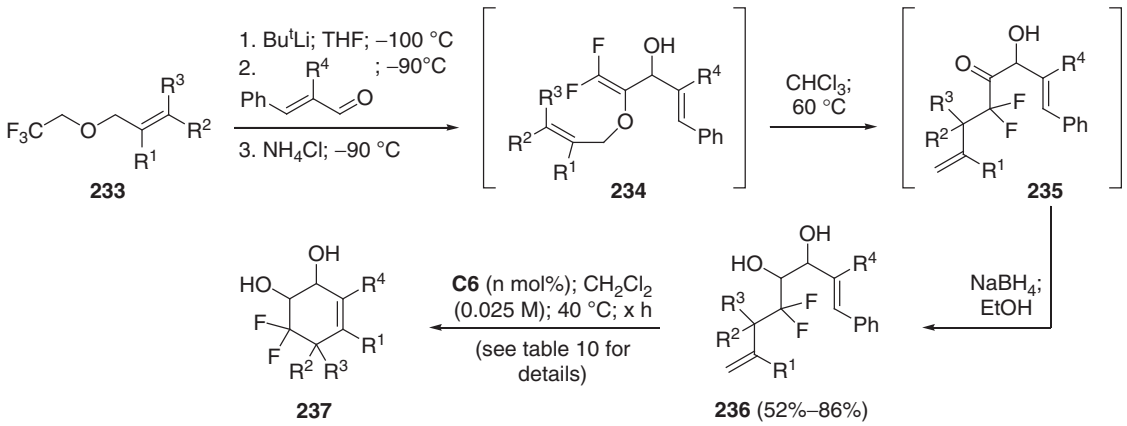
5.29.4.1.3 Synthesis of precursors involving Claisen rearrangement

The Claisen rearrangement and its variants have already been discussed in some detail in Section 5.29.3.1.3 as a method for the synthesis of cyclopentene RCM precursors. Therefore, only two examples will be discussed in this section to illustrate how synthetic strategies based on Claisen rearrangements can be adapted to obtain cyclohexene precursors. The first example is a total



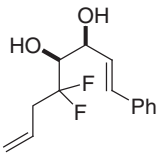
Scheme 49 Trost's tetrahydrocannabinol synthesis via Mo-catalyzed allylation/RCM.

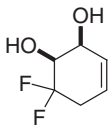
Scheme 50 Helmchen's (+)-cryptocaryone synthesis via Ir-catalyzed allylation/RCM.

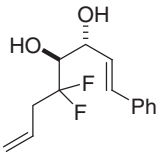


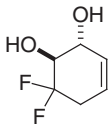
synthesis of the natural product (–)-perrottetinene, which relies on the combination of an Ireland–Claisen rearrangement of ester **229** and an RCM reaction as the key steps (Scheme 51).[181]

Before RCM, the Ireland–Claisen rearrangement product **230** was treated with excess MeMgBr to convert the methyl ester into the tertiary alcohol, and to cleave the benzoate groups. The RCM precursor **231** then underwent cyclization smoothly with 5 mol% of **C6** to give cyclohexene **232** in high yields. From **232**, the target molecule was obtained in one step by acid-catalyzed dehydration. The researchers point out that catalyst inhibition by coordination of the phenol to the Ru-center, a complication which has been observed for CM reactions of ortho-hydroxy styrenes,[182] is apparently not a problem in this case. The second



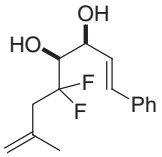


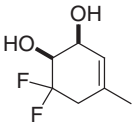


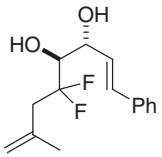


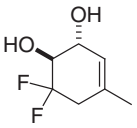
Scheme 51 Total synthesis of (–)-perrottetinene through Ireland–Claisen rearrangement/RCM.

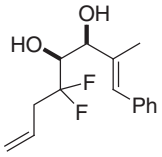
example to be discussed in some detail is a concise route to difluorinated, polysubstituted cyclohexenes based on Claisen rearrangement and RCM (Scheme 52 and Table 11).[183] A set of precursors **233** was converted by metallation and addition of α,β-unsaturated aldehydes into *gem*-difluorinated enol ethers **234**, which underwent Claisen rearrangement to ketones **235** on heating. These were reduced to a set of RCM precursors **236** with a *vic*-diol structure. The RCM reactions were accomplished with the second-generation catalyst **C6** in refluxing dichloromethane. The researchers found that in all examples the initial substrate concentration should not exceed 0.025 M, because otherwise significant amounts of byproducts were formed.

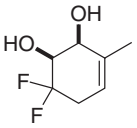


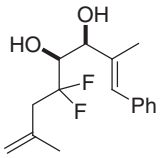


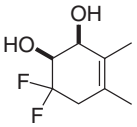


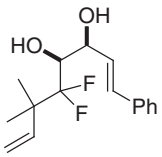


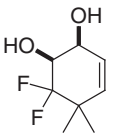


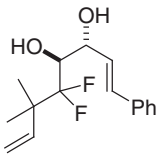


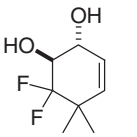


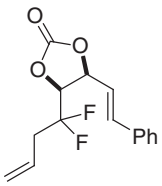


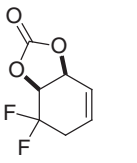


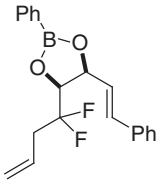


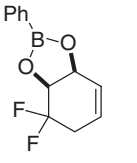












Scheme 52 RCM precursors via metallation/Claisen rearrangement of fluorinated ethers.

[d]Conversion of starting material remained incomplete.
[e]Full conversion of starting material.

The RCM reactions of precursors **236** were studied in considerable detail and valuable information on the interconnection of catalyst loading, reaction time, and steric constraints could be gathered. Representative examples from this study and the experimentally determined minimum catalyst loadings and reaction times are summarized in Table 11.[183] For the sterically less constrained epimeric dienes in entries 1 and 2, full conversion was observed in short reaction times at a remarkably low catalyst

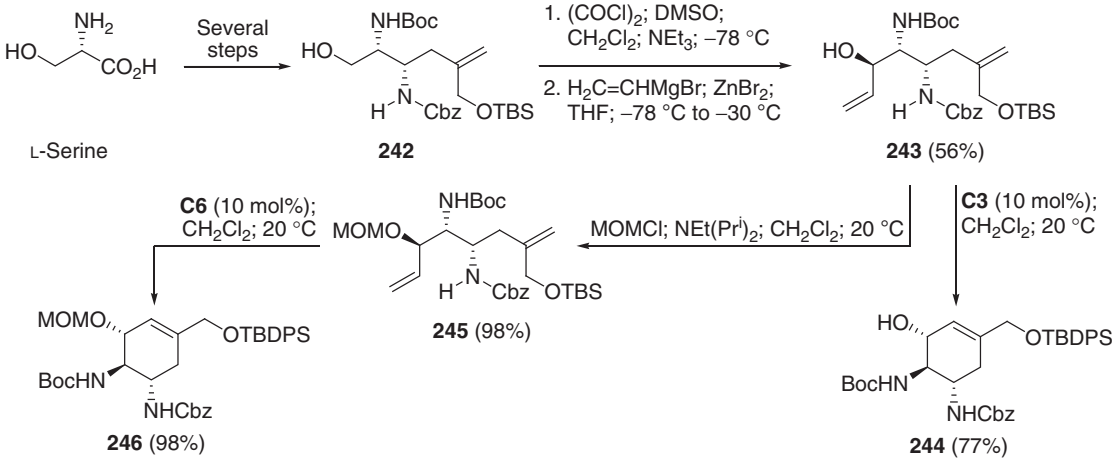
loading of 0.5 mol%. The researchers report that reducing the catalyst loading further to 0.25 mol% is possible, but only at the expense of dramatically increasing reaction times. In those cases leading to cyclohexenes with trisubstituted double bonds, catalyst loadings in the range of 2.5–5 mol% are equired, and reaction times are between 1 and 2 days. Particularly challenging are RCM reactions resulting in the construction of tetrasubstituted double bonds, as illustrated by the example in entry 6. Not surprisingly, this example requires a comparatively high catalyst loading and a prolonged reaction time. The two examples listed in entries 7 and 8 suggest that an expected rate acceleration by the *gem*-dimethyl effect is probably outweighed by additional steric hindrance, as these substrates require significantly higher catalyst loadings and longer reaction times compared with the examples in entries 1 and 2. Similarly, incorporating the two OH-groups in an annellated five-membered ring leads to a strongly decreased cyclization rate, which has been rationalized by the buildup of ring strain in the RCM step. Remarkable in these examples is the persistence of the catalytic activity over comparatively long periods of time. This has been attributed to the terminal phenyl substituent in the starting dienes, which will result in the regeneration of a more stable Ru-benzylidene species, rather than a Ru-methylidene species, after each catalytic cyle.

5.29.4.1.4 Synthesis of precursors from 'chiral pool'-starting materials

As for the stereoselective synthesis of cyclopentene precursors, starting materials from the chiral pool are also very important for accessing α,ω-octadienes. Once again α-hydroxy acids, α-amino acids, and carbohydrates have been extensively used for this purpose. One example to illustrate the use of carbohydrates is a formal total synthesis of the drug oseltamivir phosphate (Tamiflu™) from D-ribose (Scheme 53).[184] First, D-ribose was converted into iodide **238**, which underwent Zn-mediated reductive fragmentation to a substituted pent-4-enal. Addition of the allyl-Zn-reagent generated *in situ* from **239** proceeded in a *dr* of 5:1 to provide **240** in 78% yield after separation from the minor epimer. RCM of **240** to cyclohexene **241** went to completion within just 2 h in the presence of a comparatively small amount of the Grubbs–Hoveyda catalyst **C10** in refluxing dichloroethane. From the RCM product **241** the antiinfluenza drug oseltamivir phosphate is available in eight steps.

Scheme 53 Formal RCM-based total synthesis of oseltamivir phosphate from D-ribose.

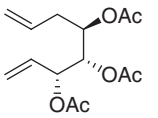
An alternative approach to the same target molecule starts from L-serine (Scheme 54),[185] which was converted in several known steps to **242**. Swern oxidation, followed by moderately diastereoselective addition of vinyl magnesium bromide ($dr = 5:1$) furnished the RCM precursor **243**. The first-generation catalyst **C3** was sufficiently active for the formation of cyclohexenol **244** with a trisubstituted double bond, even though a rather large amount of catalyst was used. Remarkably, after MOM protection of the secondary alcohol, precursor **245** required the more active second-generation catalyst **C6** to obtain the desired cyclohexene **246** in synthetically useful yields. Further examples for the utilization of ex-chiral pool compounds for the RCM-based synthesis of functionalized cyclohexenes are summarized in Table 12.

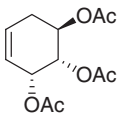


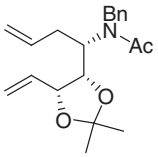
5.29.4.2 Six-Membered Heterocycles

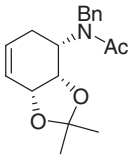
5.29.4.2.1 Six-membered oxacycles

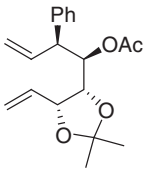
As for the synthesis of five-membered oxacycles in Section 5.29.3.2.1, reactions leading to dihydropyrans with only one substituent α to the ether oxygen (general structure **248**) will be discussed first, and then transformations yielding α,α'-disubstituted dihydropyrans, followed by examples for the synthesis of six-membered cyclic enol ethers. Finally, the formation of α,β-unsaturated δ-lactones through RCM will be discussed.

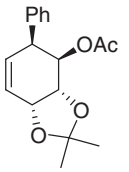


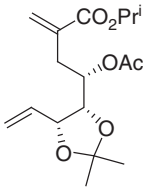


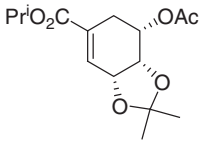


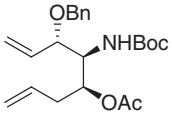


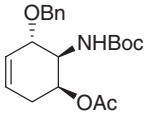


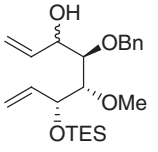


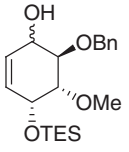












5.29.4.2.1.1 α-Substituted dihydropyrans

In most cases, RCM reactions leading to 2,3-disubstituted 3,6-dihydro-2*H*-pyrans (**248**), lacking a substituent at the 6-position, proceed smoothly with moderate catalyst loadings of first-generation catalysts at ambient or only slightly elevated temperatures. More active catalysts, higher catalyst loadings, and higher temperatures might be necessary if trisubstituted or even tetrasubstituted

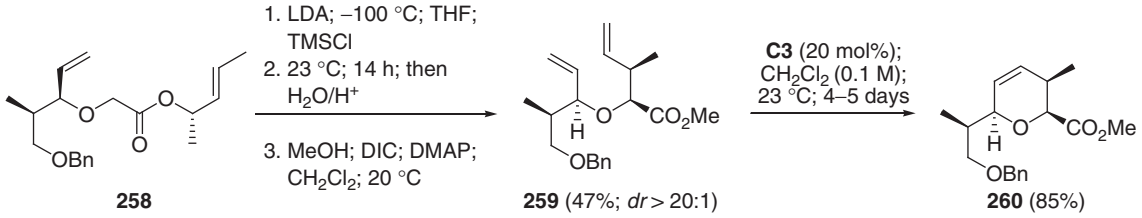
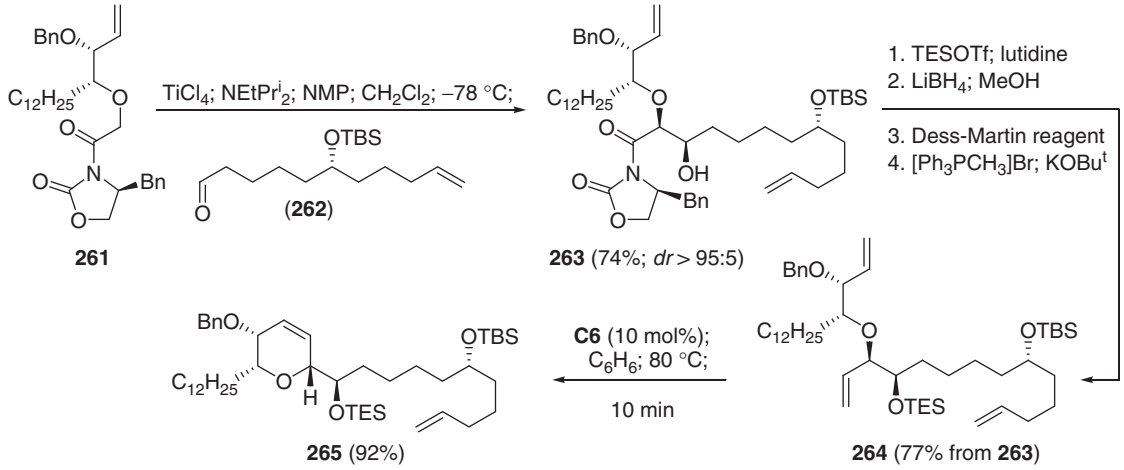
(route A).[195,196] One reason for the popularity of this approach is the availability of several reliable enantioselective allylation methods, such as Brown-allylboration (*see* Chapter 2.01) (entry 6)[197] or Leighton's allylation (*see* Chapter 2.02) (entry 2).[196] Alternatively, epoxides **250** are cleaved with appropriate vinyl metal compounds, again followed by allylation of the intermediate homoallylic alcohol (route B).[198] For the example listed in entry 7, a glycal epoxide was used as a starting material, which was cleaved with an acetylide, followed by Lindlar reduction and O-allylation to provide the RCM precursor.[199] In the case of entry 9, a laulimalide side chain precursor was obtained from enantiomerically pure glycidol by nucleophilic opening with a 2-propenyl cuprate. Notably, the tetrazole sulfone moiety does not interfere with the RCM reaction.[200] A third method starts from α-hydroxy carbonyl compounds **251**, which are first allylated and then treated with a vinyl metal compound (route C, entries 10, 11).[201] For this route the choice of the etherification method is often crucial, because α-hydroxycarbonyl compounds tend to undergo racemization or Wittig rearrangement to carbinols under the strongly basic conditions of a Williamson ether synthesis.[202] These problems can be circumvented by using either Ag_2O as a base in combination with allyl halides,[201] or by Pd-catalyzed allylation of aliphatic alcohols with allyl carbonates.[203] A less general but highly stereospecific and synthetically useful route to RCM precursors involves sigmatropic rearrangements, for example, of silyl ketene acetals such as **252**, followed by etherification of the resulting homoallyl alcohols (route D, entries 12,13).[204,205] A fifth class of precursor syntheses starts from β-hydroxy aldehydes or ketones and involves O-allylation followed by olefination of the carbonyl group (route E). This sequence has often been used for benzoannellated systems and therefore salicylic aldehydes **253** are common starting materials (entries 14–16),[206] but application of this route to the synthesis of aliphatic derivatives has also been described, for example, toward the *de-novo* synthesis of carbohydrates (entry 19).[207]



5.29.4.2.1.2 α,α′-Substituted dihydropyrans

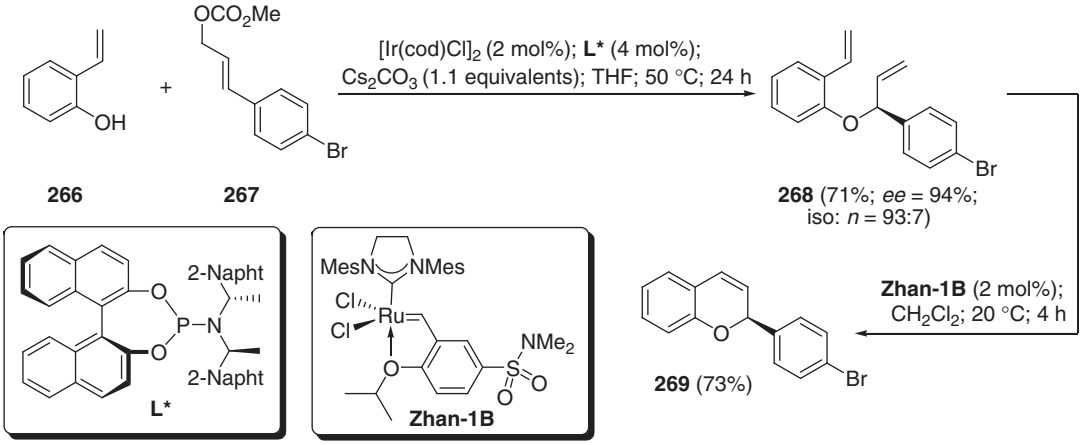
The synthesis of 2,6-disubstituted dihydropyrans was initially hampered by a lack of synthetic methods to access the required precursors stereoselectively. An early approach starts with the etherification of homoallylic alcohols such as **254** with 2-bromopropionates (**Scheme 56**).[214] Separation of the diastereomeric esters, reduction to the aldehyde followed by Wittig olefination furnished the diastereomeric RCM precursors **255** and **256** separately. The reactivity in the subsequent RCM depends on the relative configuration; interestingly, the formation of *trans*-**257** occurs significantly faster and with a lower amount of catalyst than the formation of the *cis*-epimer.

Scheme 56 RCM-based approach to 2,6-disubstituted dihydropyrans.



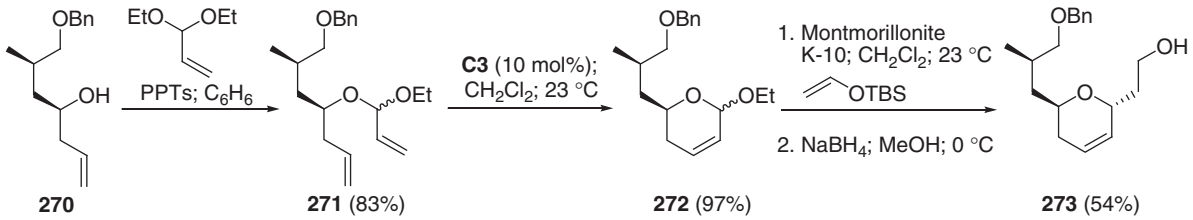
Shortly afterwards, Burke et al. described a diastereoselective approach to dihydropyrans based on a sequence of Ireland–Claisen rearrangement of glycolates and RCM (**Scheme 57**).[205] This example was published in 1998, shortly before the more active second-generation catalysts were discovered, and it illustrates how steric congestion leads to decreased reaction rates

Scheme 57 Synthesis of dihydropyrans via Ireland–Claisen rearrangement and RCM.



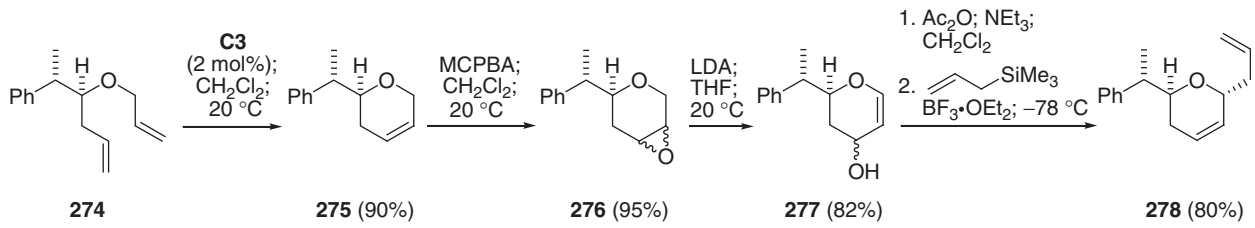
with first-generation catalysts, resulting in long reaction times (several days) and excessively high catalyst loadings of up to 20 mol%.

Another route, intensively investigated by Crimmins et al., also relies on glycolates as starting materials (Scheme 58).[215] For example, the synthesis of a fragment of the annonaceous acetogenin pyragonicin starts from glycolate **261**, which was reacted with aldehyde **262** to the aldol addition product **263** in high diastereoselectivity. Reductive removal of the oxazolidinone, followed by Dess–Martin oxidation and Wittig olefination, gave the RCM precursor **264**, which was cyclized within 10 min to dihydropyran **265** using the second-generation catalyst **C6**. A comparison with the example outlined in Scheme 57 underlines the significant improvement that can be achieved for the cyclization of highly substituted precursors if the more active second-generation catalysts are used.



Scheme 58 Auxiliary controlled aldol addition of glycolates and RCM.

Transition metal catalyzed O-allylation reactions have also been used to access α,α′-disubstituted dihydropyrans stereoselectively. This is illustrated by an Ir-catalyzed regio- and enantioselective allylation of phenols such as **266**, which, in combination with RCM, furnishes 2-substituted chromenes **269** (Scheme 59).[216] In this example, the less common Zhan-1B catalyst has been used. It should be noted that chromenes with very similar substitution patterns had previously been obtained by others using 4 mol% of **C6**.[217]



Scheme 59 Synthesis of chromenes via Ir-catalyzed allylation and RCM.

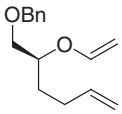
An alternative RCM-based approach to α,α′-disubstituted dihydropyrans relies on a subsequent introduction of one side chain. Via this strategy, it is possible to circumvent the stereoselective synthesis of acyclic precursors and exploit the normally more rigorous stereocontrol for substitution reactions of cyclic molecules. Such an approach has been pursued in Ghosh's total synthesis of laulimalide for the construction of the *trans*-configured 2,6-disubstituted dihydropyran fragment (Scheme 60).[218]

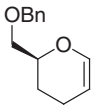
Scheme 60 Toward laulimalide via RCM and *trans*-selective nucleophilic substitution.

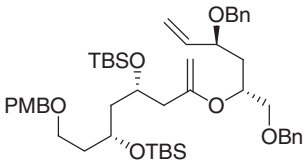
First, the homoallylic alcohol **270** was converted into a diastereomeric mixture of the mixed acrolein acetals **271** by treatment with acrolein diethyl acetal in the presence of acid. Alternatively, homoallylic alcohols can be reacted with methoxy allene in the presence of catalytic amounts of $Pd(OAc)_2$, as previously described by Rutjes et al., to give similar RCM precursors.[219] Dienes **271** underwent RCM in the presence of **C3** to yield a mixture of the epimeric cyclic acetals **272** in nearly quantitative yields. Under Lewis-acidic conditions, attack of the silyl enol ether occurs as expected from a pseudoaxial orientation, to provide – after reduction of the intermediate aldehyde – the *trans*-configured dihydropyran **273** as a single diastereomer. Alternatively, dihydropyrans such as **275**, lacking a substituent at the 6-position, have been epoxidized and subjected to a regioselective base-induced epoxide opening, giving cyclic enol ethers **277** with a hydroxy group at the 4-position. Converting the OH-group into a leaving group, and subjecting these derivatives *in situ* to the conditions of a carbon-Ferrier rearrangement gives access to *trans*-configured dihydropyrans such as **278** (Scheme 61).[201]

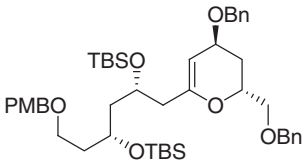
Scheme 61 RCM/epoxidation/base-induced rearrangement sequence.

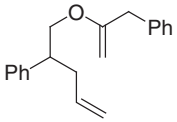
5.29.4.2.1.3 Six-membered cyclic enol ethers

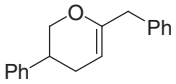


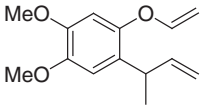


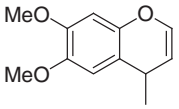


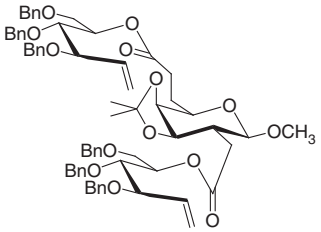


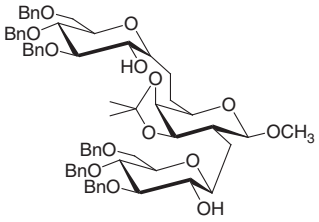






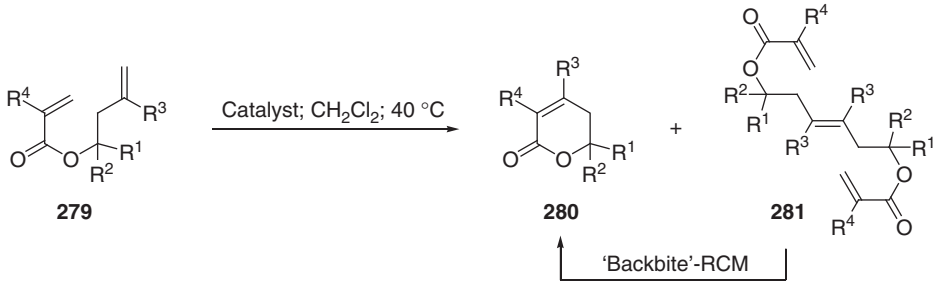






Similar to five-membered cyclic enol ethers, the formation of six-membered cyclic enol ethers is significantly slower compared with allyl ether metathesis. Consequently, more active catalysts, higher catalyst loadings, elevated temperatures, and comparatively low initial substrate concentrations are required. Table 14 provides an overview of some representative examples. As outlined for the example in entry 5, the precursors are often synthesized from esters using Tebbe or Takai-olefination reactions. First-generation catalysts, for example, **C3**, can be used only for sterically less congested substrates and are not suitable for the construction of cyclic enol ethers with trisubstituted double bonds.

5.29.4.2.1.4 α,β-Unsaturated six-membered lactones



A fourth group of reactions to be discussed in this section is the RCM of acrylates derived from homoallylic alcohols, resulting in the formation of α,β-unsaturated δ-lactones. These transformations, like the RCM of allyl alcohol acrylates (Section 5.29.3.2.1), also suffer from a comparatively low reactivity of the electron-deficient double bond, resulting in the necessity to apply high catalyst loadings, more active catalysts or Lewis-acidic additives, and normally high dilution conditions. Owing to the ubiquitous occurrence of α,β-unsaturated δ-lactones as structural elements in various natural products, the RCM of homoallylic acrylates has nevertheless been intensively investigated and numerous examples have been published. A detailed study by D'Annibale et al.[137] revealed that in contrast to common preconceptions first-generation catalysts can promote this particular type of RCM in many cases, albeit at the expense of rather high catalyst loadings (Scheme 62). The researchers could prove by NMR-experiments that initiation occurs at the homoallylic double bond of precursors **279**, and that – in particular with first-generation catalysts **C3** and **C5** – substantial amounts of self-metathesis products **281** are formed along with the desired RCM products **280**. Notably, these dimers cyclize via a backbite mechanism (see Section 5.29.2 for a more general discussion) to lactones **280** on addition of the second-generation catalysts **C6** or **C10**. In some cases, a substituent R^1 or R^2 was found to facilitate the RCM, in particular if a tetrasubstituted double bond ($R^3 = R^4 = Me$) is formed in the metathesis step.

The RCM step used in the synthesis of (+)-cryptocarya diacetate is an example for a comparatively facile homoallylic acrylate RCM, as it proceeds efficiently with just 3 mol% of **C6** at a remarkably high initial substrate concentration of 0.3 M (Scheme 63).[224] The *syn*-1,3-diol motif found in the target structure was synthesized via a highly diastereoselective aldol addition of 'super-silyl'-protected enol ether **283** to aldehyde **282**, catalyzed by triflimide. Subsequent diastereoselective addition of allyl

Scheme 63 Homoallylic acrylate RCM in the synthesis of cryptocarya diacetate.

magnesium chloride, followed by conversion of the intermediate homoallylic alcohol into the acrylate furnished the RCM precursor **284**. After RCM, both silyl groups in **285** were removed and the hydroxy groups acylated to give the target compound (+)-cryptocarya diacetate.

A synthesis of the natural product (–)-cleistenolide illustrates how sterically demanding substituents in the γ-position adversely influence the rate of the RCM step (**Scheme 64**).[225]

Cat. (mol%)	Solvent/T/time	c_0 of **287**	Additive (equivalent)	Conversion	Yield
C6 (5)	toluene/110 °C/16 h	0.005 M	none	<30%	n. d.

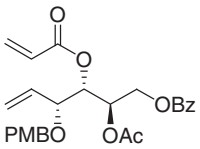
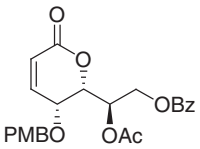
C6 (10)	toluene/70 °C/6 h	0.003 M	phenol (0.5)	80%	75%

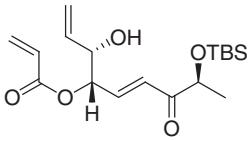
Scheme 64 Homoallylic acrylate RCM in the synthesis of (–)-cleistenolide.

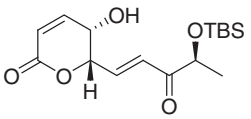
In this example, the required homoallylic acrylate **287** was obtained from the C_2-symmetric mannitol-derived diene **286** in four steps, i.e., monosilylation, Sharpless epoxidation, acrylate formation, and epoxide opening with benzoic acid. For the RCM of **287** numerous conditions were tested, and a selection is highlighted in the table inserted in **Scheme 64**. With 5 mol% of the second-generation catalyst **C6**, the conversion remained unsatisfactory even after 16 h. Inspired by a literature report describing the beneficial effect of added phenol in CM reactions,[226] this option was tested next. The conversion improved significantly to 50% in a considerably shorter period of time. Eventually, the use of 10 mol% of **C6** in combination with added phenol at a very low initial substrate concentration of 0.003 M turned out to be the optimum, resulting in an isolated yield of 75%. The synthesis of cleistenolide was completed by a one-pot desilylation–acetylation reaction. A comparison with related examples reveals that the choice of γ-OH-protecting groups has a significant impact on the rate of the RCM step (**Table 15**). Unfortunately, a removal or exchange of protecting groups before the RCM is not always possible; for example, in the case of the cleistenolide synthesis discussed above, all attempts to cleave the TBS group in **287** resulted in an extensive scrambling of the acrylate group. As can be seen from entry 1, taken from a different synthesis of cleistenolide, a sterically less demanding *para*-methoxybenzyl (PMB)-protecting group allows the RCM to be performed with lower amounts of catalyst and at a higher substrate concentration. In many cases unprotected allylic hydroxy groups are tolerated (entry 2), although it should be noted that allyl alcohols are sometimes prone to irreversible double-bond migration to the corresponding ethyl ketones or fragmentation to methyl ketones under metathesis conditions.[77] The RCM listed in entry 3 is hampered not only by a sterically demanding TBSO-group in the allylic position, but also by the presence of a dithiane moiety. Nevertheless, a synthetically useful yield could be obtained with the phosphine-free catalyst **C10** under microwave irradiation. RCM of acrylates without any substituent in the allylic position (entries 7, 8) is normally facile with comparatively low loadings of second-generation catalysts or first-generation catalysts in combination with $Ti(OPr^i)_4$ as a Lewis-acidic additive, even if, as in entry 9, a trisubstituted double bond is formed.

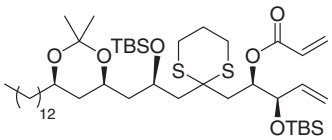
5.29.4.2.2 Six-membered azacycles

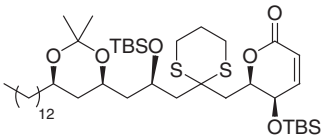


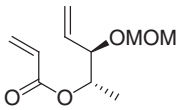


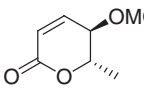


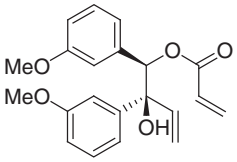


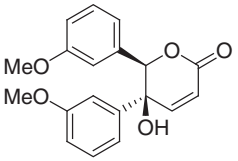


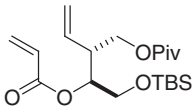


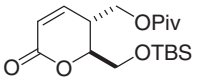


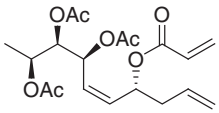


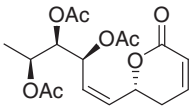


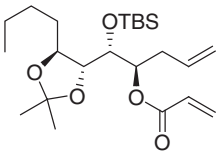


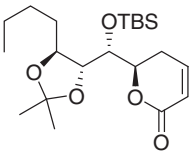


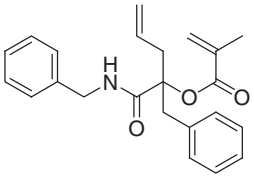


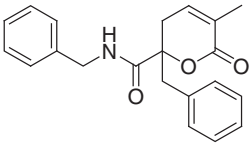








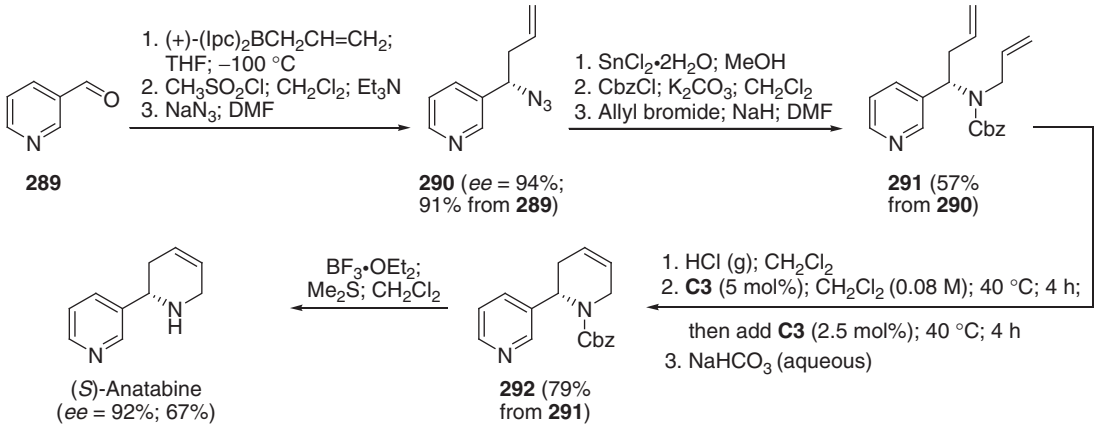




Six-membered azacycles are, together with six-membered oxacycles and their five-membered counterparts, the most important heterocycles accessible through RCM. Consequently, a plethora of examples have been described and only a representative selection can be shown here. Similar to the formation of five-membered azacycles, the donor capacity of the nitrogen has to be reduced to prevent catalyst inhibition.

5.29.4.2.2.1 Substituted tetrahydropyridines

Enantiomerically pure RCM precursors for substituted tetrahydropyridines have been obtained through enantioselective transformations or via modification of chiral pool starting materials. An example for the former approach is Felpin's synthesis of (*S*)-anatabine and various other tobacco alkaloids (**Scheme 65**).[233]



Starting from pyridine-3-carbaldehyde (**289**), azide **290** was obtained through enantioselective allylboration, conversion of the homoallylic alcohol into the mesylate and S_N2-reaction with NaN_3 in 94% *ee*. Conversion of **290** into the required RCM precursor **291** was achieved in three steps. RCM was successful after intermediate conversion of the pyridine into the hydrochloride; under these conditions, tetrahydropyridine **292** was isolated after basic workup in 79%, using catalyst **C3** in a total amount of 7.5 mol%. Addition of the catalyst in two portions turned out to be crucial, as incomplete conversion was observed if 10 mol% of the catalyst were added in one portion under otherwise identical conditions. The researchers reasoned that this might be caused by the acidic

Table 15 Homoallylic acrylate RCM

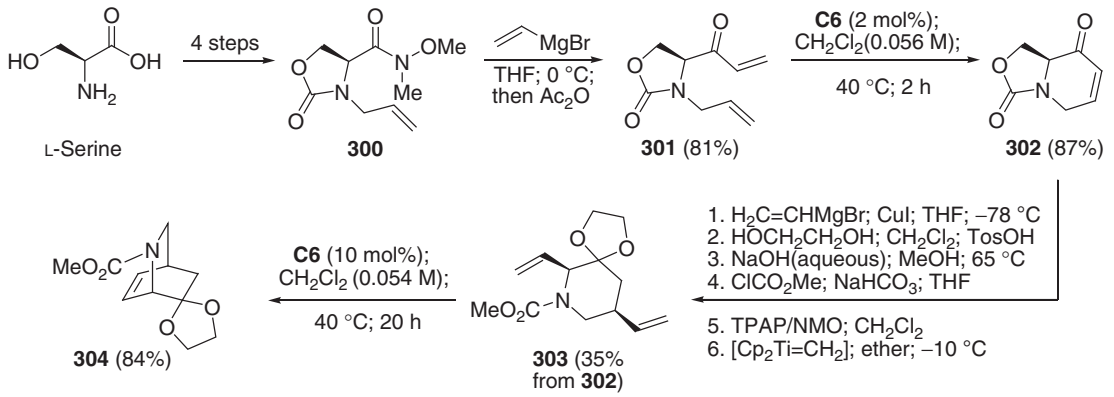
9		**C9** (5 mol%); toluene (0.1 M); 70 °C		62	232

conditions, which are presumbably detrimental for the stability of the metathesis catalyst. An enantioselective Rh-catalyzed α-amination of an *in-situ* generated silyl enol ether has been used, in combination with a challenging RCM as the key steps in a formal total synthesis of (–)-metazocine (Scheme 66).[234] In a sequential catalytic transformation, enone **293** underwent conjugate addition of triethylsilane, and the *in-situ* generated silyl enol ether **294** was then enantioselectively α-aminated, catalyzed by the depicted chiral catalyst. The RCM precursor **297** was obtained via Mitsunobu reaction and Wittig olefination.

RCM of **297** requires 10 mol% of **C6** and results in the formation of tetrahydropyridine **298**, with a tetrasubstituted double bond. Such transformations are generally considered to be challenging but manageable, provided that the more active second-generation catalysts are used. Grubbs et al. described several examples of reactions that proceed with comparable yields but lower catalyst loadings using less common NHC-alkylidene complexes.[43] The RCM product **298** was subsequently converted

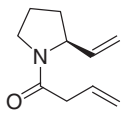
Scheme 65 Synthesis of (*S*)-anatabine via allylboration.

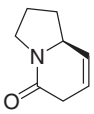


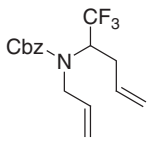
Scheme 66 Metazocine via enantioselective Rh-catalyzed α-amination and RCM.

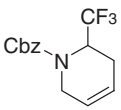
in two steps into the tetraalkylated tetrahydropyridine **299**, which had previously been used as a precursor for the synthesis of the target molecule.

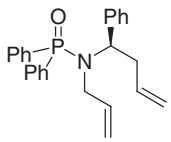
Amino acids are obviously well suited ex-chiral-pool starting materials for the synthesis of RCM precursors. In particular, proline and serine have found numerous applications, and one example, the synthesis of the azabicyclooctane fragment of the vinca alkaloid (+)-catharanthine from L-serine, is highlighted below (Scheme 67).[235]

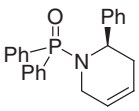


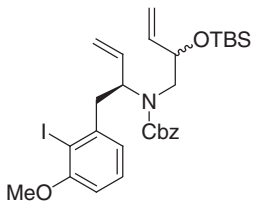


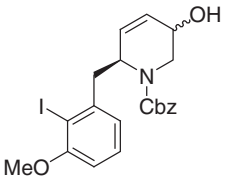


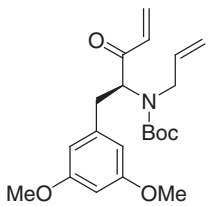


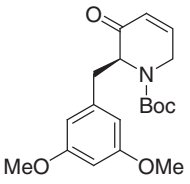


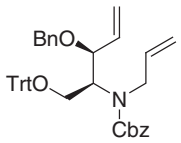


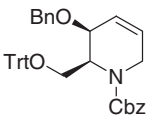






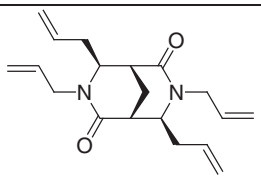


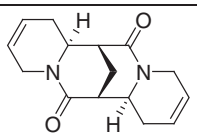


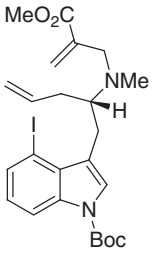


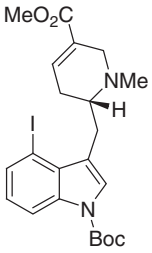
Thus, L-serine was converted in four steps into the Weinreb amide **300**, which served as a precursor for enone **301**. The first RCM step of the sequence was accomplished with a comparatively low amount of **C6** in just 2 h. The resulting RCM product **302** was then converted into the precursor **303** for the second, more challenging RCM step. The crucial step of the sequence leading to **303** is the conjugate addition of a vinyl cuprate to enone **302**, which proceeds with the desired high *cis*-diastereoselectivity. The second double bond required for the next RCM was established via hydrolysis of the oxazolidinone, oxidation of the primary alcohol, and Tebbe olefination. RCM of **303** was successful with a significantly increased catalyst loading of **C6** and a prolonged

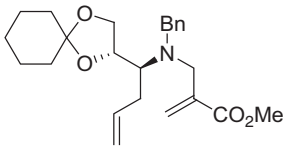
Scheme 67 Synthesis of a (+)-catharanthine fragment through dual RCM.

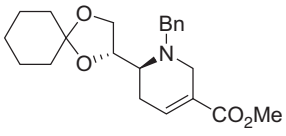


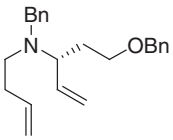


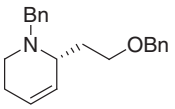


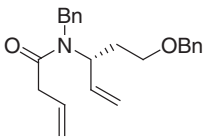


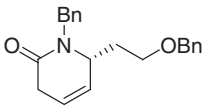


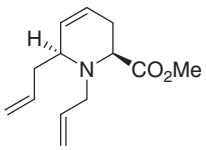


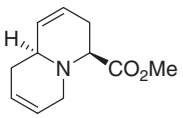


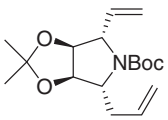


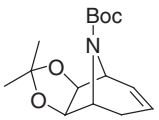












reaction time of 20 h. The researchers reasoned that the piperidine ring in precursor **303** needs to adopt an unfavorable boat conformation for the RCM to proceed. In Table 16, some additional examples for RCM reactions leading to variously substituted tetrahydropyridines are summarized.

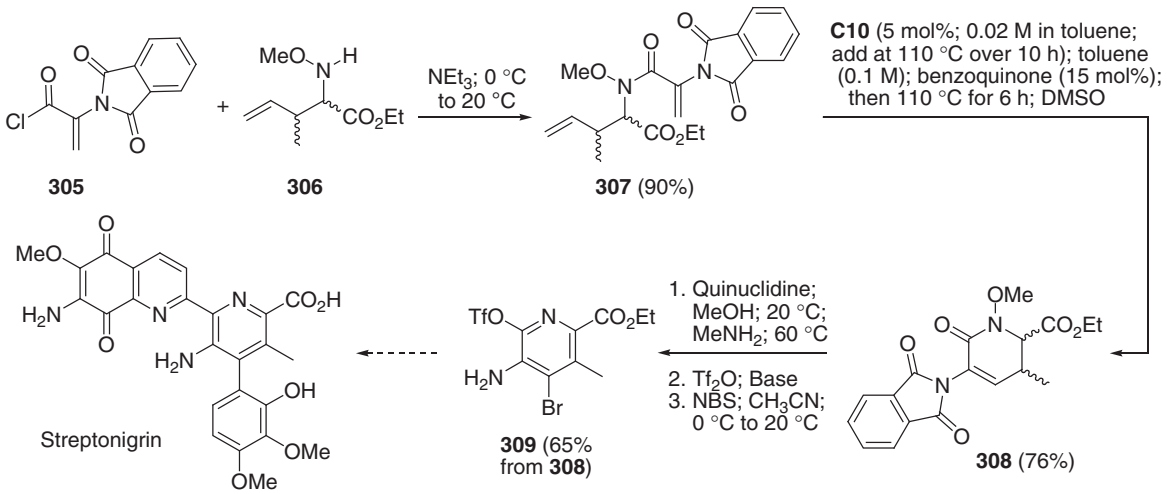
5.29.4.2.2.2 Six-membered cyclic enamides

As previously discussed for five-membered cyclic enamides, the RCM leading to their six-membered counterparts normally requires more active second-generation catalysts and often elevated temperatures. A selection of examples is presented in **Table 17**.



5.29.4.2.2.3 α,β-Unsaturated six-membered lactams

In many cases where homoallylic acrylamides were subjected to RCM, the resulting α,β-unsaturated lactams were not the actual target structures but intermediates en route to substituted piperidines or pyridines, as outlined below for Donohoe's synthesis of the pyridine core of the aminoquinone antitumor antibiotic streptonigrin (**Scheme 68**).[249]

Table 17 Synthesis of six-membered cyclic enamides through RCM

[a]Product was obtained along with the starting material (22%). In the absence of benzoquinone, extensive isomerization of the starting material to the MOM-enol ether was observed.

Scheme 68 Toward streptonigrin via homoallylic acrylamide RCM, followed by elimination.

The RCM precursor **307** was obtained by condensation of the *in-situ* generated acyl chloride **305** and the *O*-methyl hydroxyl amine **306**. The cyclization of **307** required optimization, but eventually the phosphine-free catalyst **C10** was found to catalyze this reaction when added slowly as a solution in toluene with a syringe pump over a period of 10 h. Addition of benzoquinone

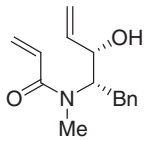
was required to suppress undesired double-bond isomerization reactions of the substrate, and DMSO was used to oxidatively destroy the metathesis catalyst after completion of the RCM in order to facilitate the chromatographic purification. Lactam **308**, obtained in gram quantities via this route, was then converted into the pentasubstituted pyridine **309** by elimination of methanol, aromatization by trapping of the enol form as a triflate, and bromination. It should be noted that this is a particularly challenging example, and that numerous other derivatives are accessible using less carefully controlled conditions. Some representative examples are listed in Table 18. Entries 1 and 2 once again illustrate the superior reactivity of second-generation catalysts if electron-deficient double bonds are involved in the RCM step. However, if the more reactive double bond is sterically encumbered, for example, due to a bulky protecting group in the allylic position (entry 3), even highly reactive catalysts such as **C6** often fail to give satisfactory results. For the same reasons the RCM of the isomeric precursors in entries 4 and 5 or 6, respectively, proceeds with a significantly different rate, although in both cases a trisubstituted double bond is formed. For the example listed in entry 4, a sterically less constrained styrene double bond facilitates initiation at this position, which is followed by rapid cyclization, resulting in a nearly quantitative yield. In contrast, the regioisomer in entry 5 undergoes RCM only very slowly, resulting in a poor yield even if a significantly higher amount of catalyst is used. This result can most likely be explained by assuming that the initiation at both double bonds is unfavorable for steric or electronic reasons, respectively. For this particular example, the yield can be improved by a solvent switch from dichloromethane to benzene (for a general discussion on solvent effects, see Section 5.29.2). The examples shown in entries 9 and 10 illustrate that in certain cases good results can be obtained even with the first-generation catalysts, but that a nitrogen-protecting group and a sterically unencumbered initiation site are mandatory.

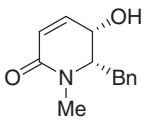
5.29.4.2.2.4 Combinations of multicomponent reactions and RCM

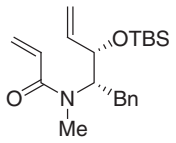
Azacycles are among the most important structural motifs in medicinal chemistry and play a major role as target structures for the synthesis of combinatorial libraries. A combination of multicomponent reactions with transition metal-catalyzed transformations, in particular RCM, has emerged as a useful strategy for generating structural complexity and diversity. In this section, two examples will be outlined briefly. An approach toward bridged bicyclic lactams has been published by researchers from Abbott (Scheme 69),[255] who obtained RCM precursors, for example, **314**, through Ugi multicomponent reactions. The double bonds required for the subsequent RCM were introduced in this example by using ω-unsaturated carboxylic acids, for example, **312**, and amines, for example, allyl amine (**311**). In other examples, one of the double bonds participating in the RCM came from the aldehyde component. RCM of **314** was accomplished with 10 mol% of **C6**; after completion of the RCM reaction, DMSO was added to facilitate chromatographic removal of catalyst residues. Lactam **315** was eventually subjected to a diastereoselective intramolecular Heck reaction to the bridged bicyclic lactam **316**, using a Pd-precatalyst immobilized on a polystyrene backbone.

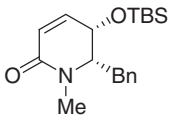
The second example illustrates the combination of a van Leusen three-component reaction and RCM for the synthesis of structurally diverse bicyclic imidazoles (Scheme 70).[256]

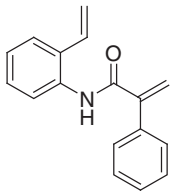
The RCM precursor **318** was obtained through coupling of tosyl methyl isocyanide (**317**), carboxylic acid **312,** and allyl amine (**311**) under basic conditions. RCM of **318** proceeded smoothly, in spite of the nucleophilic imidazole present in the precursor, when catalyst **C6** was used. Replacing 3-butenoic acid (**312**) with 4-pentenoic acid leads to precursors for azepine derivatives.

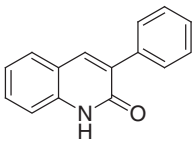


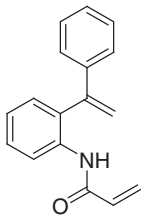


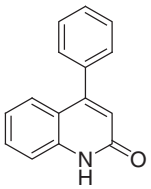


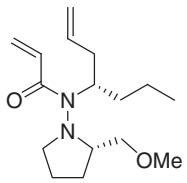


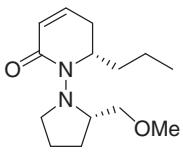


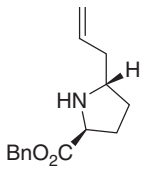


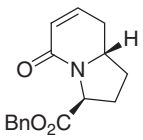


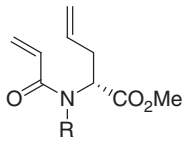


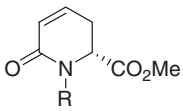


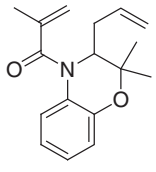


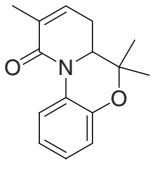






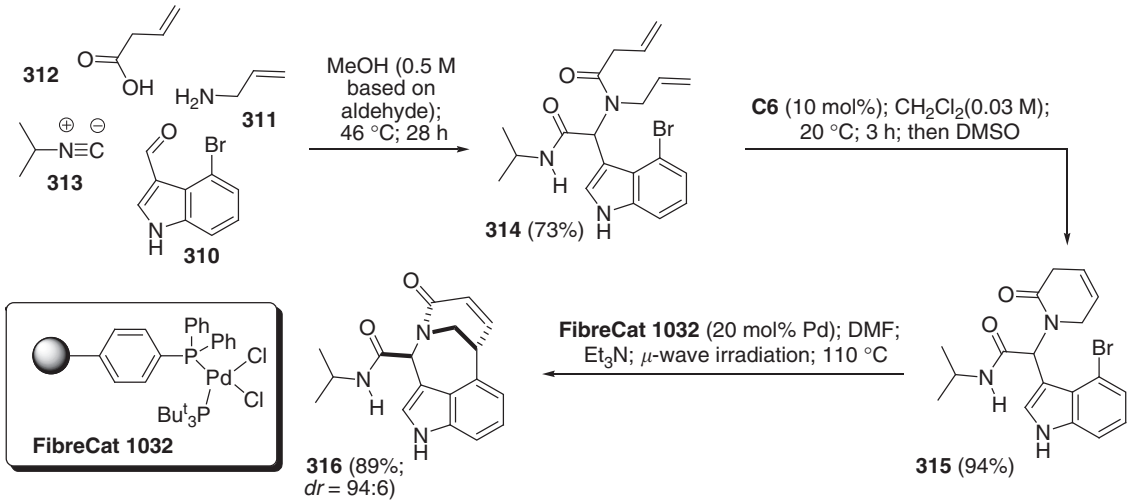






5.29.5 Medium-Sized Ring Systems and Macrocycles

The formation of medium-sized rings is generally hampered by enthalpic and entropic constraints,[49] and this is also true for most RCM reactions leading to seven- to ten-membered carbo- or heterocycles. As a consequence, lower initial substrate concentrations (to suppress undesired self-metathesis) and higher catalyst loadings than for similarly substituted five- or six-membered rings are normally required. Although the number of examples is considerably smaller than that for five- and six-membered rings, a plethora of reactions has been published over the past 20 years. This section is subdivided only according to the ring size, and carbo- and heterocycles are, in contrast to the previous sections, discussed under the same subheading.



5.29.5.1 Seven-Membered Ring Systems

Over the past decade, after the discovery of the more active and robust second-generation metathesis catalysts, RCM has been applied in the synthesis of several terpenoid natural products comprising seven-membered carbocycles, including strained bridged or polycyclic systems. The RCM step is occasionally highly challenging, making very high catalyst loadings, high reaction temperatures, and long reaction times necessary, which might induce undesired side reactions. For these reasons, synthetic modifications of the RCM precursor are sometimes inevitable to facilitate the subsequent RCM reaction. As a very recent example, the RCM step of Kigoshi's (–)-13-oxyingenol synthesis and attempts toward its optimization are outlined below (Scheme 71).[257]

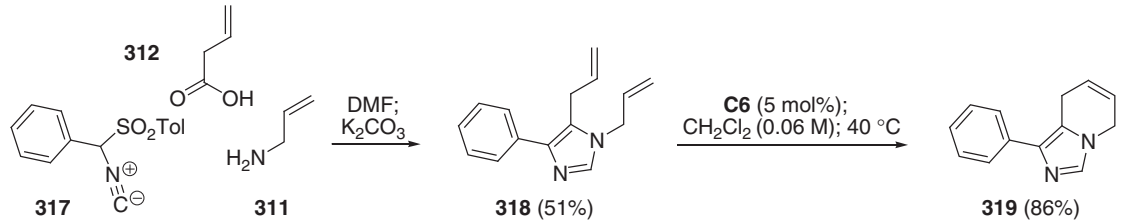


Table 18 Synthesis of α,β-unsaturated six-membered lactams through RCM

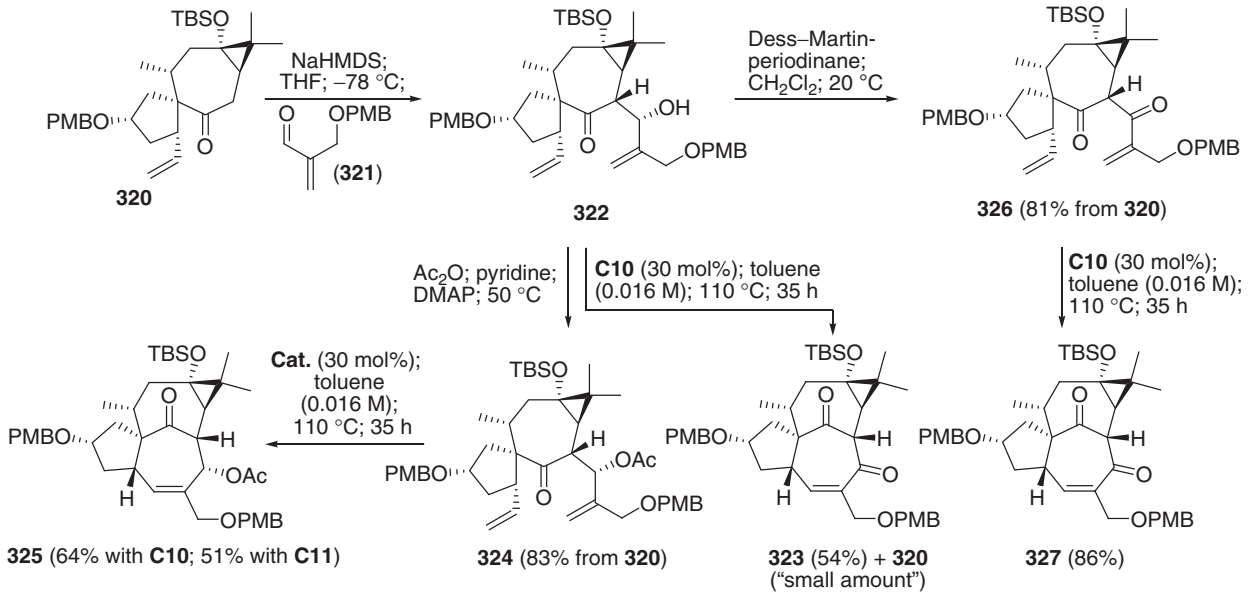
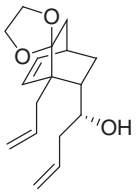
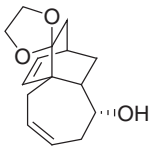
11		**C9** (5 mol%); toluene; 70 °C		76	254

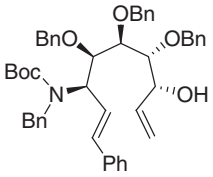


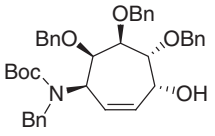
The first RCM precursor tested in this study, diene **322**, was directly obtained from a highly diastereoselective aldol addition of **320** and aldehyde **321**. Under the standard RCM conditions, the desired product **323** was obtained in 54% yield, but a retro-aldol reaction occurred to some extent. This could be avoided by protection of the hydroxy group as acetate **324**; however, neither the Grubbs–Hoveyda catalyst **C10** nor Grela's nitro-substituted catalyst **C11** gave satisfactory yields of **325**. The best yield was

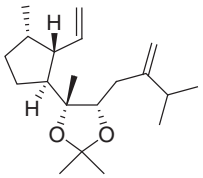
Scheme 69 Bridged bicyclic lactams via Ugi reaction, RCM, and Heck reaction.

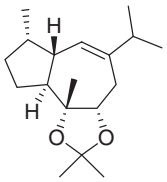


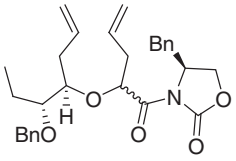


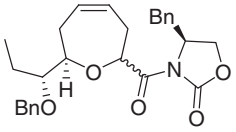


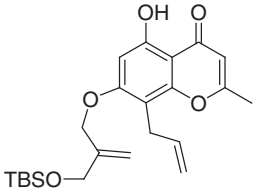


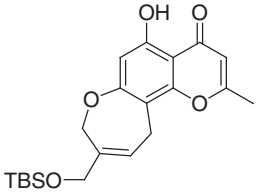


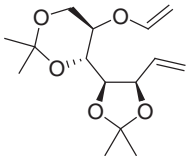


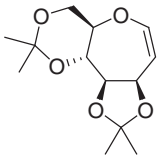


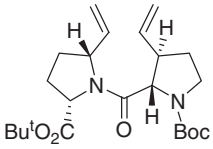


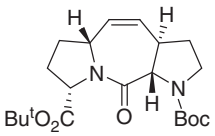


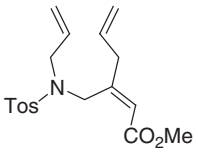


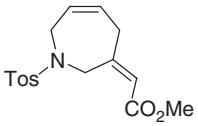












Scheme 70 Bicyclic imidazoles via van Leusen reaction and RCM.

Scheme 71 Toward 13-oxyingenol through RCM.

eventually obtained after oxidation of the secondary alcohol to the enone **326**, which underwent RCM in high yields to furnish the 1,3-diketone **327**. Obviously, conversion of the alcohol into the ketone results in reduced steric and conformational constraints during the RCM step, which outweighs the reduced reactivity of the electron-deficient double bond. Table 19 provides a representative selection of further examples for RCM reactions leading to seven-membered rings.

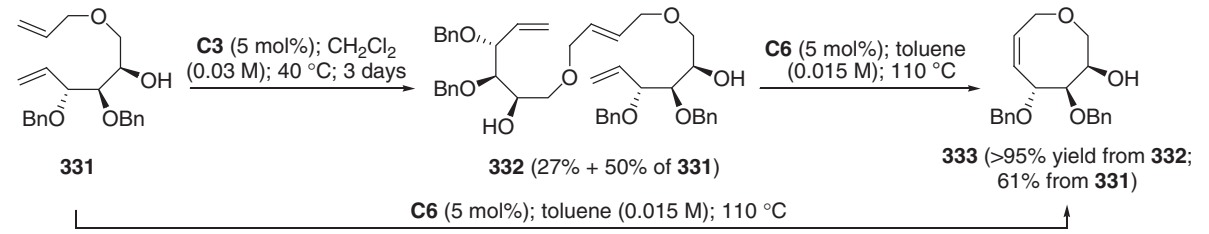
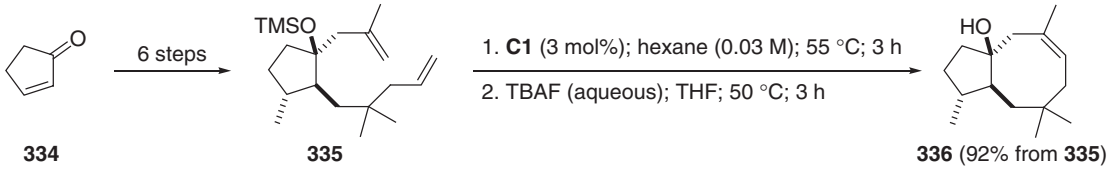
5.29.5.2 Eight-Membered Ring Systems



The formation of eight-membered carbo- and heterocycles is often complicated by competing self-metathesis of the precursors or by the formation of cycles with a more favorable ring size, if alternative double bonds are available for RCM. An example for the

latter complication has been observed during the synthesis of octalactin A (Scheme 72).[266] In this case, cyclopentene **330** was formed as a side product during RCM of **328**, caused by initiation of the catalyst at the double bond adjacent to the acyl substituent and subsequent intramolecular attack of the trisubstituted double bond next to the unprotected secondary hydroxy group. Interestingly, this cyclization was completely suppressed by the addition of $Ti(OPr^i)_4$ as a cocatalyst, resulting in the exclusive formation of **329** in good yields.

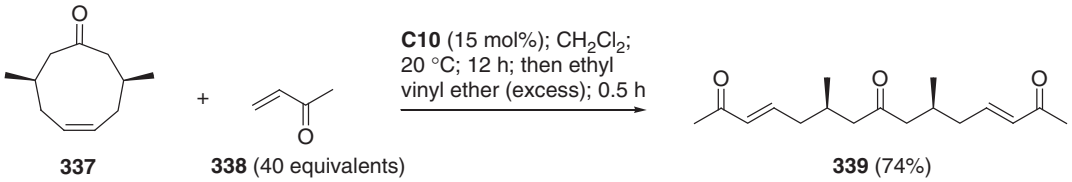


Scheme 72 Competing cyclization modes in the synthesis of octalactin A.

In contrast to the formation of ring-contracted products, as outlined in Scheme 72, self-metathesis of the RCM precursor does not necessarily mean a complete failure of the desired RCM reaction, because the formation of the cyclic product might still be possible via a backbite mechanism (Scheme 73).[267] For example, precursor **331** undergoes selective dimerization via the sterically less demanding allyl ether to give **332**, which does not react in a subsequent RCM if first-generation catalyst **C3** is used, even after a prolonged reaction time of 3 days. In the presence of **C6**, however, **332** cyclizes via backbite metathesis to the desired product **333** in quantitative yields. The same product could be obtained directly from **331** when the second-generation catalyst **C6** was used from the outset.

Scheme 73 Competing self- and ring-closing metathesis, and RCM via backbite mechanism.

Nevertheless, it should be noted that RCM is a useful method for the synthesis of eight-membered rings and that in certain cases even trisubstituted double bonds can be constructed. An early example is Fürstner's dactylol synthesis (Scheme 74),[268] which starts from cyclopentenone (**334**). In six steps, comprising a one-pot conjugate addition–aldol condensation, precursor **335** and its epimer were obtained. With Schrock's catalyst **C1** RCM proceeded smoothly with moderate catalyst loadings; however, protection of the tertiary alcohol turned out to be mandatory as the RCM failed completely for the carbinol.

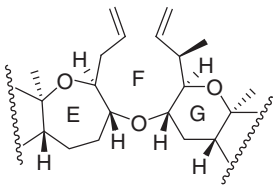


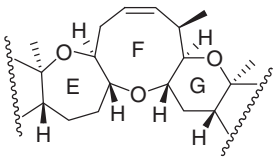
Scheme 74 Final steps of a dactylol synthesis.

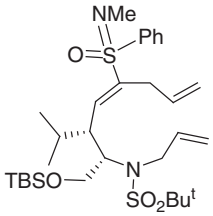
5.29.5.3 Nine-Membered Ring Systems

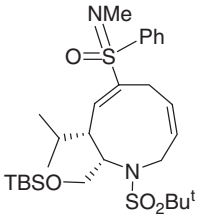
The considerable ring strain of medium-sized rings in general and nine-membered rings in particular becomes evident from a recently published example, in which a clean ROM of a cyclononene in the presence of methyl vinyl ketone was exploited for the synthesis of a meso-triketone (Scheme 75).[269] Cyclononenone **337** was obtained via an anionic oxy-Cope rearrangement, and

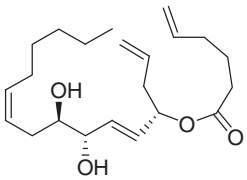
ROM to triketone **339** proceeded smoothly with **C10** and a significant excess of methyl vinyl ketone (**338**). In this example, the metathesis activity of the catalyst was quenched by the addition of ethyl vinyl ether before isolation of the product.

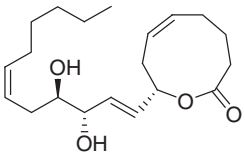












337 **338** (40 equivalents) **339** (74%)

Scheme 75 Toward bidirectional synthesis via ROM of a cyclononene.

In some other examples, RCM reactions leading to nine-membered rings have been shown to proceed in synthetically useful yields, although sometimes at the expense of rather high catalyst loadings (Table 20). In particular, these RCM reactions have been used for constructing the central oxacyclononene ring of several polyether toxins, for example, gambieric acid. This subject has been reviewed,[270] and a recent example is listed in entry 1.

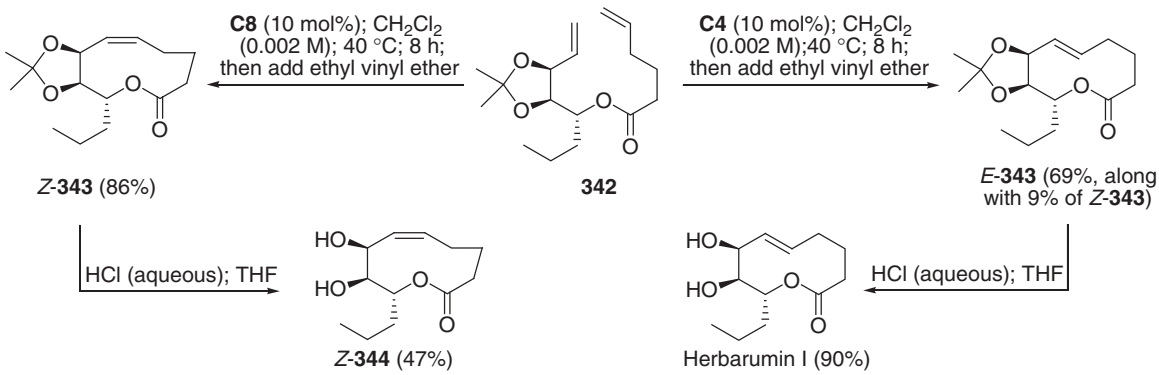
5.29.5.4 Ten-Membered Ring Systems



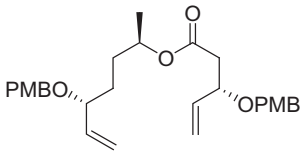
For this ring size control of the configuration of the newly formed double bond is a major issue. Several examples have been investigated, because the ten-membered lactone pattern is a common structural element in many natural products, which have attracted considerable attention over the past few years. In an early example for this type of RCM reaction, Kalesse et al. presented experimental and theoretical evidence that the control of *E*/*Z*-selectivity is subject to thermodynamic versus kinetic control (Scheme 76).[274] In the course of an epothilone synthesis, **340** was subjected to RCM using the first-generation catalyst **C3**, as the second-generation catalysts were not yet available at that time. The researchers discovered that with a rather high amount of the catalyst cycloalkene *Z*-**341** is the predominant product, but that the *E*-isomer, after chromatographic separation, can be completely converted into the *Z*-isomer on renewed exposure to the metathesis catalyst through a sequence of ring opening and ring-closing metathesis. From this observation, it was concluded that *Z*-**341** is the thermodynamically favored RCM product, and this was corroborated by computational methods, revealing that *Z*-**341** should be 9 kcal mol^{-1} more stable than *E*-**341**.

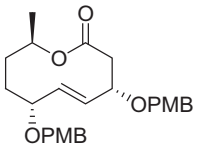
The advent of the significantly more active NHC-ligated Ru-catalysts in 1999 opened new opportunities for controlling the stereochemical course of an RCM reaction through a choice of the catalyst. Examples for this catalyst-controlled approach were

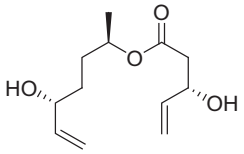
Scheme 76 Control of *E*/*Z*-selectivity for a 10-membered lactone formation.

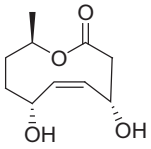
presented by Carda, Marco et al. for the synthesis of microcarpalide[275] and by Fürstner et al. for the synthesis of herbarumins I and II (Scheme 77).[276] In the latter example, semiempirical calculations revealed that the RCM product *Z*-**343**, leading to the nonnatural herbarumin analog *Z*-**344**, should be 3.5 kcal mol^{-1} more stable than *E*-**343**, which on deprotection gives the natural product herbarumin I. Consequently, formation of the thermodynamically more stable product had to be expected with the more active second-generation catalysts, whereas use of a less active first-generation catalyst might furnish the kinetically preferred product, i.e., *E*-**343**. The experimental results are indeed in line with these assumptions, as the desired *E*-isomer was obtained using the first-generation indenylidene complex **C4**, whereas the second-generation catalyst **C8** cleanly provided the *Z*-isomer. In both cases, the metathesis activities of the catalysts were quenched by the addition of ethyl vinyl ether after complete consumption of the starting material.

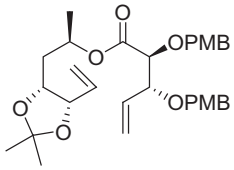
Scheme 77 Control of *E*/*Z*-selectivity through choice of the catalyst.

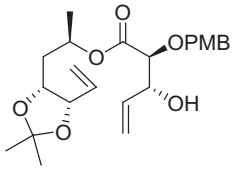


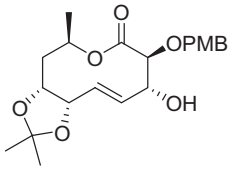


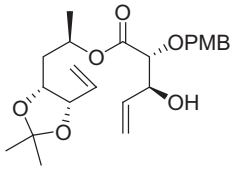


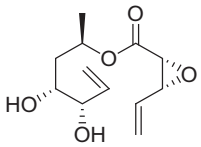


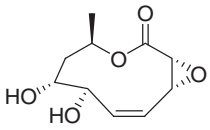




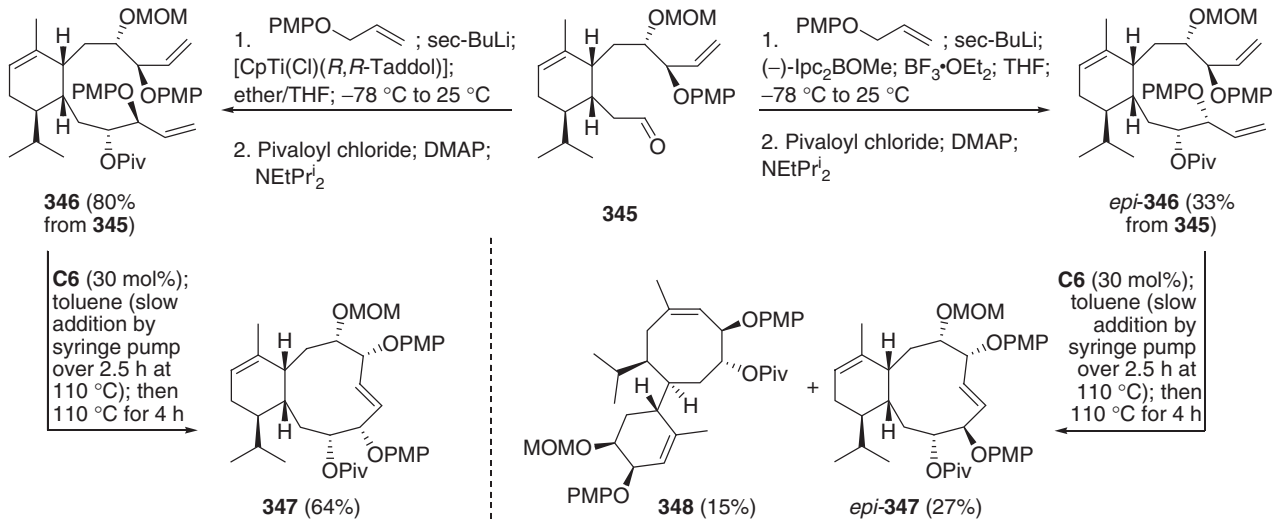








If a catalyst controlled stereoselective formation of the newly formed double bond is not feasible, modification of the RCM precursor is often the last resort to obtain the desired RCM product and to avoid a complete revision of the synthetic strategy. Sometimes, removal or introduction of a protecting group has already a significant impact on the outcome of an RCM reaction. Some examples are compiled in Table 21.



Although the identification of the thermodynamically preferred geometrical isomer by theoretical methods may assist in choosing the appropriate catalyst in many cases, there are examples where this approach fails. Gennari et al. discovered, during a study directed at the synthesis of the marine natural product eleutherobin, that the RCM of diene **346** proceeded with complete *E*-selectivity even under forcing conditions, although computational methods revealed that the *Z*-isomer of **346** should be more stable (Scheme 78).[279] On the basis of the DFT calculations, the researchers reasoned that the preferred *E*-selectivity originates from lower energies of the intermediate *trans*-ruthenacyclobutanes compared with their *cis*-analogs, and that – once the cycloalkene is formed – a ROM is no longer possible due to the sterically constrained environment of the C–C double bond. A further remarkable outcome of this study is that even minor configurational changes can have a significant impact on the result of the metathesis reaction. Apart from **346**, which was obtained from **345** via Duthaler–Hafner oxyallylation, the researchers also examined the RCM of its epimer, *epi*-**346**, which was the major product of a Brown-allylboration of the same precursor **345**. Application of the same RCM-protocol gave *E*-configured *epi*-**347** in significantly lower yields, along with a considerable amount of **348**, resulting from a ring opening/double RCM sequence.

5.29.5.5 Macrocycles (Ring Size > 10)

As for most synthetic methods used for macrocyclization, macro-RCM requires normally high dilution or pseudo-high dilution conditions to suppress the formation of dimers or oligomers. However, as outlined in Section 5.29.2, extremely high dilution

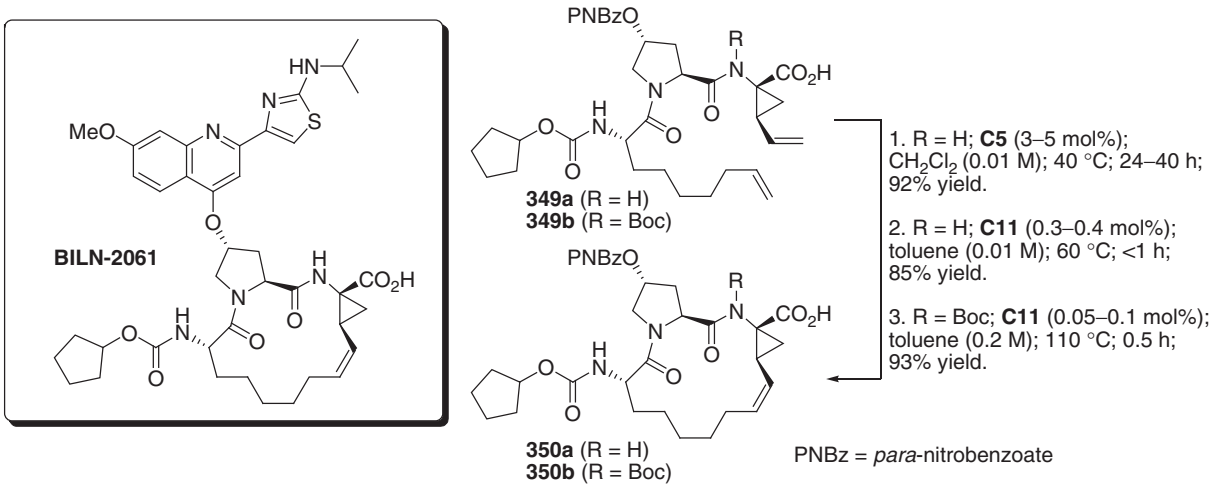


Table 21 Control of double-bond geometry through modification of the RCM precursor

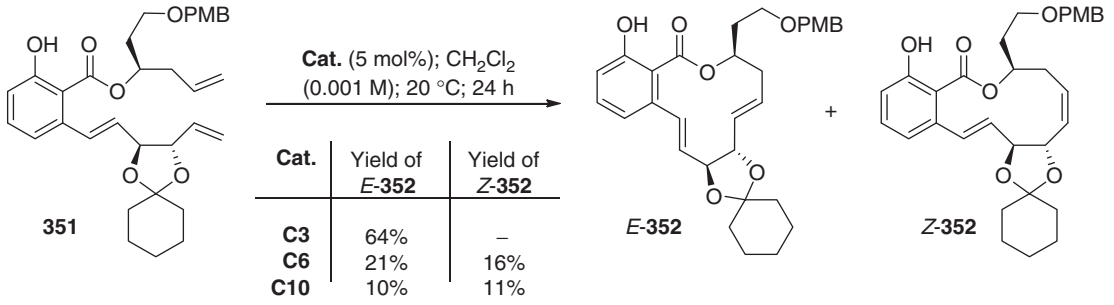
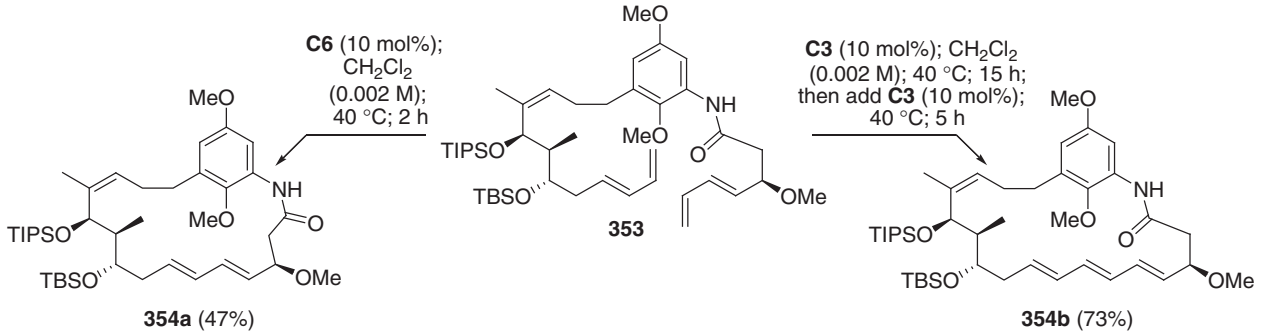
Scheme 78 Toward eleutherobin via RCM.

might be counterproductive in some cases, because often a considerable proportion of the RCM product is formed from dimers or oligomers via a backbite mechanism, and using low initial substrate concentrations will not only reduce the extent of self-metathesis, but also intermolecular reactions of the catalyst and the substrate. This will result in an overall reduced rate for the RCM. The application of RCM to the synthesis of macrocyclic natural products has been reviewed by Gradillas and Pérez-Castells, and their review includes an extensive compilation of reaction conditions such as catalyst, catalyst loading, solvent, substrate concentration, and reaction temperature.[280] These data show that most macro-RCM reactions are conducted with initial solvent concentrations in the low millimolar range and with catalyst loadings of up to 20 mol%. For these reasons, it is not surprising that RCM was not considered in drug development and production beyond the laboratory scale, because implementation into process development will be extremely challenging. It can, however, be safely assumed that in the majority of target molecule syntheses using macrocyclic RCM these critical parameters have not been fully optimized, because the RCM precursors require laborious multistep syntheses, and are therefore available only in small quantities. In addition, kinetic and thermodynamic data for ring closing and self-metathesis reactions have rarely been obtained. These data can be used for the calculation of kinetic and thermodynamic EM, which have recently emerged as a useful guiding principle for planning and optimizing macrocyclic RCM (see Section 5.29.2 for a brief general discussion).[51] An instructive example in this regard comes from a group at Boehringer Ingelheim, who developed a large-scale synthesis of the hepatitis-C protease inhibitor BILN-2061 (**Scheme 79**).[281]



Scheme 79 Development of a metathesis-based large-scale synthesis of BILN-2061.

In the original first-generation process, precursor **349a** with R=H was used in combination with the first-generation catalyst **C5** (RCM condition 1) in Scheme 79. Although the yields of **350a** were quite good, the high dilution, the large amount of catalyst, and the long reaction times were not acceptable on pilot plant scale. Two of these problems could be solved by using Grela's *para*-nitro-substituted catalyst **C11**, which made a reduction of the catalyst loading well below 1 mol% possible, and lead to a reaction time shorter than 1 h (RCM condition 2) in Scheme 79. The high dilution problem, however, remained, and prompted the researchers to measure EM for the RCM of **349a** by running the reaction at various initial substrate concentrations. This investigation revealed that EMs for **349a** are quite unfavorable and lead to the introduction of Boc as a bulky, electron-withdrawing protecting group at the nitrogen adjacent to the cyclopropane moiety. It turned out that for this modified precursor **349b** initiation of the metathesis exclusively occurs at the sterically less hindered double bond, whereas the unprotected precursor **349a** initiates at the double bond adjacent to the cyclopropane ring, which might lead to a chelation of the Ru and a retardation of the RCM. In addition, various computational methods revealed that introduction of a Boc group significantly reduces the ring strain of **350b** compared with **350a**, presumably because rotation around the neighboring endocyclic amide bond is no longer frozen.[282] This effect translates into a 19-fold increased thermodynamic effective molarity for the RCM of **349b** compared with **349a**, and even a 27-fold increase could be realized by conducting the RCM at 110 °C. In practice, this means that high yields of the RCM product **350b** are obtained at concentrations as high as 0.2 M, which is probably unprecedented for RCM macrocyclizations.



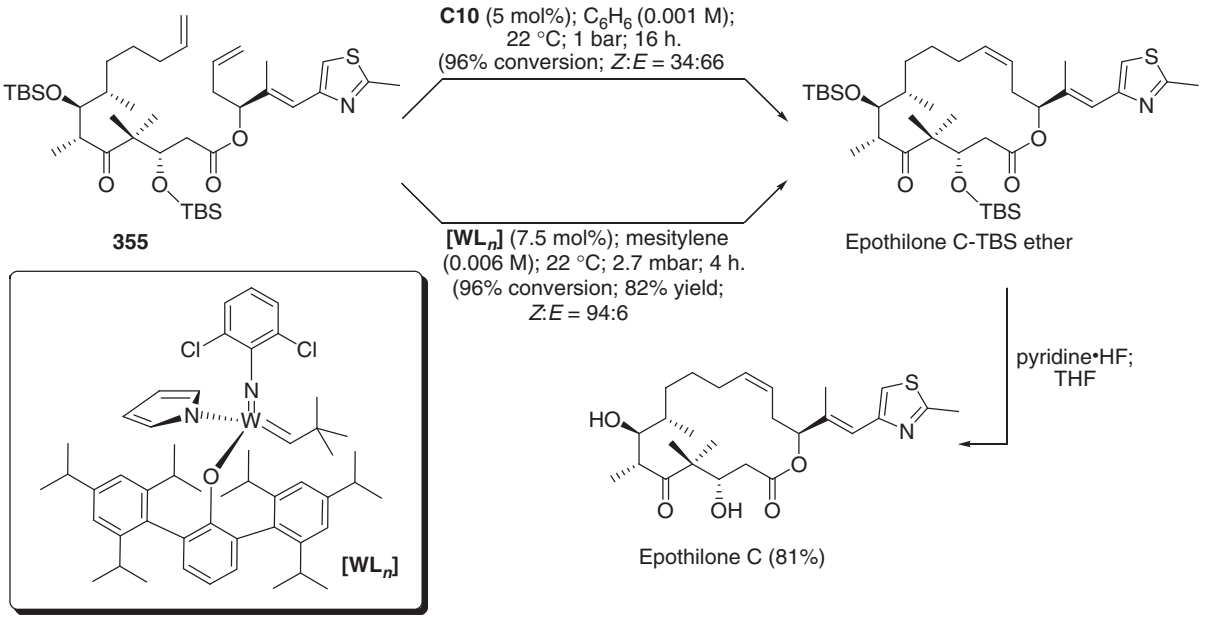
Other problems associated with macrocycle formation via RCM resemble to some extent those discussed above for medium-sized rings. In particular, control of *E*/*Z*-selectivity is often an issue, as outlined below for the example of a study directed at the synthesis of 12-membered salicylic macrolides (**Scheme 80**).[283] Interestingly, the highest yield and the best stereoselectivity was observed with a comparatively low amount of first-generation catalyst **C3**, whereas both **C6** and **C10** resulted in lower yields of cyclic products and poor *E*/*Z*-selectivity. One might assume that the reaction proceeds under kinetic control with the first-generation catalyst **C3** but under thermodynamic control with the more active second-generation catalysts. However, the researchers present evidence that even RCM reactions catalyzed by **C6** and **C10** are kinetically controlled. They reason that the observed selectivity arises from (i) a higher stability of the intermediate *trans*-ruthenacyclobutane (which fragments to *E*-**352**)

compared with the *cis*-ruthenacyclobutane (the mechanistic precursor for *Z*-**352**) and (ii) different rate determining steps for the first- and second-generation catalysts.

Scheme 80 *E*/*Z*-Selectivity control in macrocycle formation.

Another problem, which might occur if cyclic polyenes are the target molecules, is ring contraction, as outlined below (Scheme 81).[284] With the more active catalyst **C6**, the internal double bond of one conjugated diene is attacked with release of butadiene, resulting in the formation of **354a** instead of the desired target molecule **354b**. Gratifyingly, the conjugated triene moiety in **354b** became available with the first-generation catalyst **C3**.

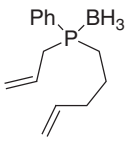
Scheme 81 Ring contraction in the synthesis of cyclopolyenes.

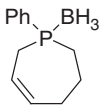


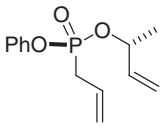
Recently, it was shown that stereoselectivity problems and undesired ring contraction can in many cases be efficiently suppressed if a sterically demanding silyl group is temporarily attached to a diene moiety participating in an RCM reaction. This strategy makes *E*,*Z*-configured conjugated macrocyclic dienes accessible.[285] Apart from these substrate-controlled solutions for the *E*,*Z*-selectivity problem, recently there has been significant progress made using a catalyst-controlled approach. Schrock, Hoveyda et al. developed a series of 'stereogenic-at-metal' catalysts which can not only be used for the efficient differentiation of enantiotopic vinyl groups (see Section 5.29.10, Scheme 92),[286] but also for *Z*-selective CM[287] and RCM.[288] This application is illustrated for a long-standing problem in the metathesis-based natural product synthesis, the *Z*-selective syntheses of the epothilones[289–292] (Scheme 82).

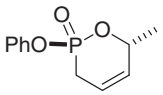
5.29.6 Heterocycles with Less Common Heteroatoms

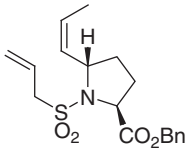
The majority of heterocycles synthesized via RCM are five- or six-membered and contain just one oxygen or nitrogen ring atom. Other heteroatoms are by far less common (Table 22): these include phosphorus (entries 1, 2) and sulfur (entries 3–10) in various oxidation states, and some examples for boron heterocycles, mostly in combination with other electron-donating heteroatoms (entries 11, 12) and silacycloalkenes (entries 13, 14). The synthesis of P- and S-heterocycles based on RCM has been reviewed by Hanson et al.[293] Examples for metathesis-based formation of heterocycles with more than one heteroatom (entries 15, 16) are also comparatively rare.

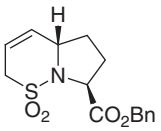


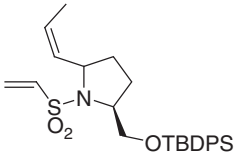


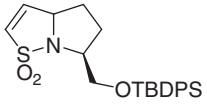


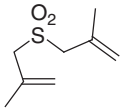


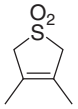


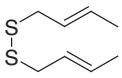












5.29.7 RCM Reactions Involving Heteroatom-Substituted Double Bonds

In this section, the authors discuss only examples where a heteroatom is attached to a double bond participating in an RCM and where this heteroatom is not an endocyclic part of the newly formed ring (Table 23). Metathesis reactions of

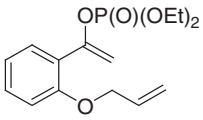
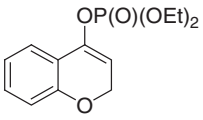
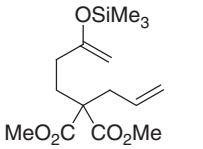
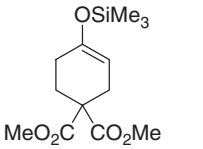
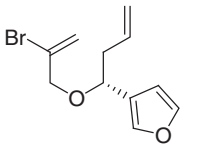
[c]Formation of 40% of the self-metathesis product.

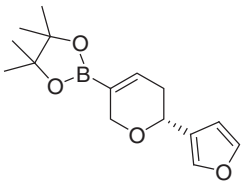


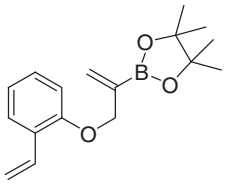


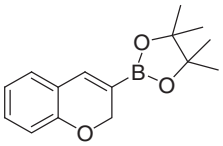












heteroatom-substituted double bonds have previously been reviewed by Brown and Satcharoen[305] and by Eustache et al.[306] Potentially highly useful from a synthetic point of view are metathetical cyclizations of vinyl halides; although RCM of vinyl fluorides might provide a convenient entry into fluorinated heterocycles as potential pharmaceutically active molecules (entries 1–3), the heavier halides offer the opportunity for further functionalization of the RCM products via cross-coupling reactions. Unfortunately, vinyl chlorides, which undergo RCM reactions at synthetically useful rates and selectivities (entries 4–6), are less reactive in this respect, whereas the more reactive vinyl bromides were for many years believed to be unreactive in olefin metathesis reactions. Recently, a surprising solution for this problem was devised by Dorta et al.,[307] who discovered that terminally unsubstituted vinyl bromides, such as the precursor in entry 7, decompose the second-generation catalyst **C6** with concommitant formation of styrene, when both are mixed in equimolar amounts. This observation explains why attempted catalytic RCM reactions of vinyl bromides failed. Remarkably, a quantitative conversion to the RCM product with liberation of styrene was observed when a phenyl substituent was introduced *Z* to the bromine (entry 8), whereas no conversion was observed for the *E*-isomer (entry 9). In their communication, the researchers present a plausible mechanistic rationale to explain this surprising outcome, along with 16 other examples to highlight the scope of the method; one of these is listed in entry 10. Apart from vinyl halides, enol ethers and enamides can also participate in RCM reactions. An example for the successful conversion of an enamide has been discussed in Section 5.29.4.2.2.3 in the course of Donohoe's streptonigrin synthesis.[249] Examples for the RCM of enol ethers are listed in entries 11 and 12. Enol phosphates are potentially useful as substrates for cross-coupling reactions, whereas the RCM of a silyl enol ether will, after desilylation, furnish a cyclic ketone. In entries 13 and 14, two examples for the RCM of vinyl pinacolatoboronates are given. The first successful RCM reactions of vinyl boronic acids and vinyl boronates were published by Renaud et al. in 1998 using the first-generation catalysts **C2** and **C3**.[308] The researchers discovered that the free boronic acids require longer reaction times and higher catalyst loadings than the analogous boronates. Later, second-generation catalysts were preferably used for this type of transformation, although occasionally still very long reaction times are necessary. The example

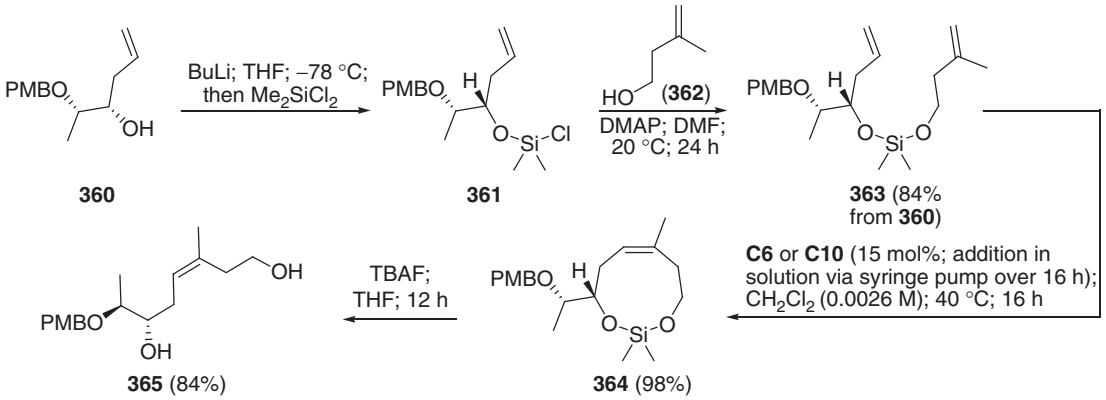
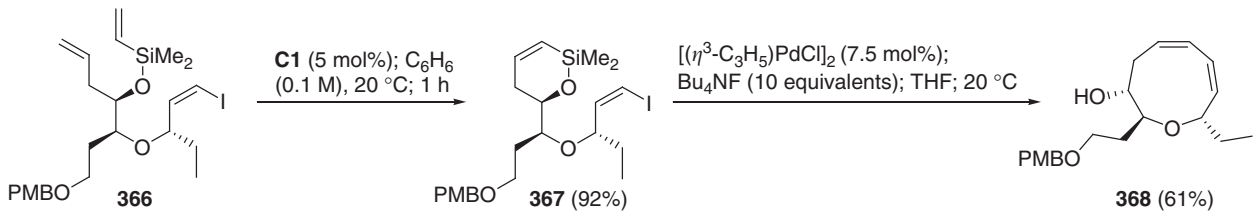
listed in entry 13 is taken from Snapper's synthesis of cacospongiolide B analogs;[308] in this case the reported yield refers to the vinyl bromide used to synthesize the actual RCM precursor via halogen–lithium exchange and subsequent borylation. The precursor in the last example in entry 14 was synthesized using a Cu–NHC-complex catalyzed borylation of a propargyl ether with pinacolatodiboron.

5.29.8 Tethered RCM



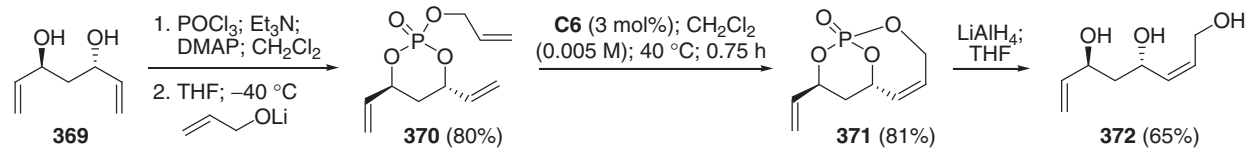
Tethered reactions are an important strategy to overcome entropic and selectivity drawbacks of many intermolecular reactions. The strategy involves the temporary connection of two molecules via a labile bond and a subsequent cyclization, which occurs ideally with improved yields and stereoselectivities compared with the intermolecular variant. Eventually, cleavage of the tether liberates the desired acyclic product. Particularly useful tethers contain silicon–carbon or silicon–oxygen bonds and were originally developed for radical cyclization reactions.[317] Later, these silicon tethers have been used to solve the *E*/*Z*-selectivity problem normally associated with olefin CM reactions.[3] Although RCM reactions leading to five- to eight-membered cycloalkenes necessarily proceed *Z*-selectively, CM reactions normally show moderate to high *E*-selectivity. An early application of the tether concept in olefin metathesis was published by Evans et al. and addresses this particular problem (**Scheme 83**).[318] Silylation of

Scheme 83 Silicon-tethered RCM-dihydroxylation sequence.



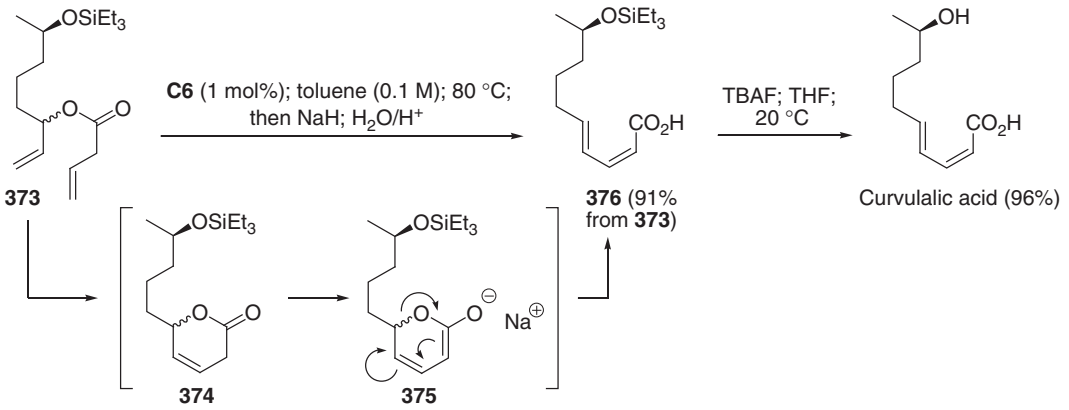
allylic alcohol **356** with dichlorodiphenyl silane gave silyl ether **357**, which underwent RCM with **C3** to the C_2-symmetric seven-membered cycle **358**. Osmium-catalyzed dihydroxylation, followed by cleavage of the tether with fluoride and treatment with acetic anhydride lead to the isolation of peracetylated D-altritol **359**.

Another problem of CM reactions is the formation of homodimers if olefins of the same type are used. In these cases, a statistical distribution of products must be expected. It has been demonstrated by several groups that temporary silicon-tethered RCM is a suitable method to circumvent this particular obstacle as well. For example, the C10–C15 fragment of epothilones B and D has been synthesized using a silicon-tethered RCM of an unsymmetrical silyl acetal **363**, which was obtained from alcohols **360** and **362** by stepwise condensation with dichloro dimethyl silane (Scheme 84).[319] The researchers point out that carefully controlled conditions for the RCM step are crucial in this example; quantitative yields of the RCM product **364** could only be obtained by extremely slow addition of catalysts **C6** or **C10** to a solution of **363**. Addition of the catalyst in one portion always resulted in yields of only 50%.



Scheme 84 Synthesis of C10–C15 fragment of epothilones B and D via silicon-tethered RCM.

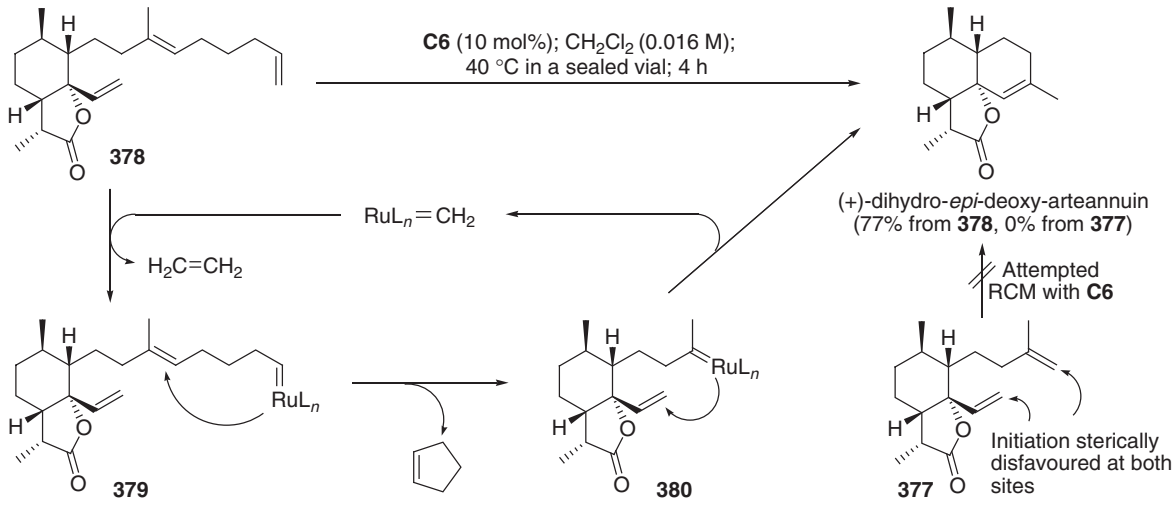
As mentioned above, silicon tethers may also rely on Si–C bonds, which offer additional opportunities for the post-RCM cleavage of the tether. For example, Denmark and Yang used the cyclic vinylsiloxane **367**, synthesized via RCM of **366** using Schrock's catalyst **C1**, for a Pd-catalyzed intramolecular cross-coupling reaction en route to the natural product (+)-brasilenyne (Scheme 85).[320]



Scheme 85 Silicon-tethered RCM and subsequent cross coupling.

Over the past few years several examples for the efficient use of phosphate-tethered RCM reactions were published by Hanson et al. (Scheme 86).[321,322] For example, phosphate **370**, obtained via condensation of the C_2-symmetric diol **369** with $POCl_3$ and subsequent substitution of the remaining chloride with a Li-alkoxide, was cyclized to the bicyclic phosphate **371** in high yields. Reduction of **371** furnished triol **372** as a single *Z*-isomer. The phosphate-tethered RCM can be extended to a bidirectional synthesis by subjecting **371** to a CM before cleavage of the tether.[323]

Scheme 86 Temporary phosphate-tethered RCM.



In most tethered RCM reactions the tether is removed tracelessly at some point after the cyclization by reduction or hydrolysis. It might, however, be an interesting option to keep the tether in the molecule as a functional group after cleavage. An example of this approach is outlined for the synthesis of the natural product curvulalic acid (Scheme 87)[324] via a one-flask RCM-deprotonation-electrocyclic ring opening sequence of butenoate **373**, which proceeds cleanly and highly stereoselectively to give the (2*Z*,4*E*)-configured dienoic acid **376**. After deprotection, the target molecule was obtained in nearly quantitative yields.

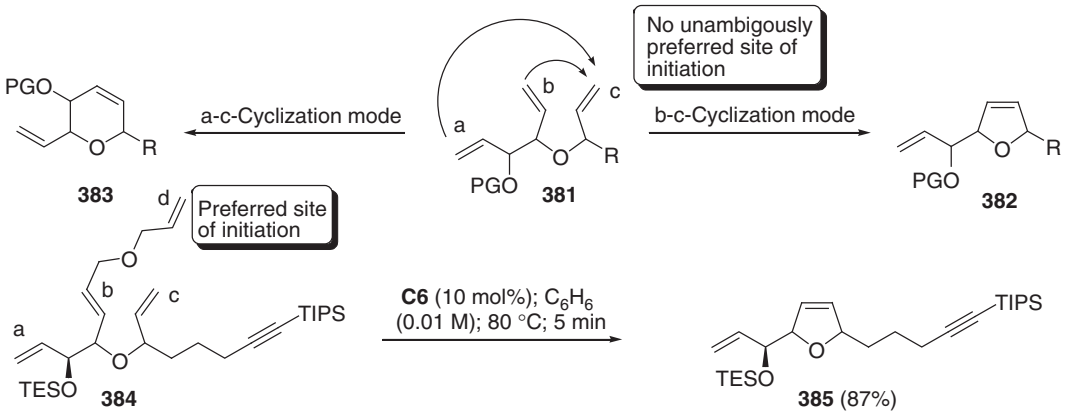
Scheme 87 Synthesis of *Z*,*E*-dienes via one-flask tethered RCM/electrocyclic ring opening.

5.29.9 Relay Ring-Closing Metathesis

The examples of RCM reactions presented in the previous sections suggest that at least one double bond of the diene precursor should be sterically and electronically unencumbered for the RCM to proceed at a reasonable rate and hence with a synthetically useful catalyst loading. It can be concluded that in these cases the initial attack of the metal–carbene species will occur at the sterically less hindered and electronically neutral site, but that – once initiation took place – the subsequent steps are reasonably fast and less influenced by steric or electronic drawbacks of the second double bond. This reasoning is the basis for the relay RCM (RRCM) concept originally developed by Hoye et al. to overcome reactivity problems in RCM reactions arising from insufficient rates of initiation.[325] The concept and some early applications have been reviewed by Wallace.[326] Here, the method is illustrated by the example of the total synthesis of the sesquiterpene dihydro-*epi*-deoxyarteannuin B (Scheme 88).[327]

Scheme 88 Illustrative example of an application of the RRCM concept.

Precursor **377** was found to be completely unreactive in attempted RCM reactions because both the terminal double bonds are sterically congested and the initial attack of the Ru-carbene at either site is hindered. However, the extended precursor **378** reacts smoothly to the target molecule, because initiation at the least hindered double bond is facile, the resulting Ru-carbene **379** then attacks the internal trisubstituted double bond via a backbite mechanism with concommitant formation of cyclopentene and a new Ru-carbene intermediate **380**. Once this Ru-carbene is formed, the catalytic cycle of the RCM can proceed, ethene is liberated,

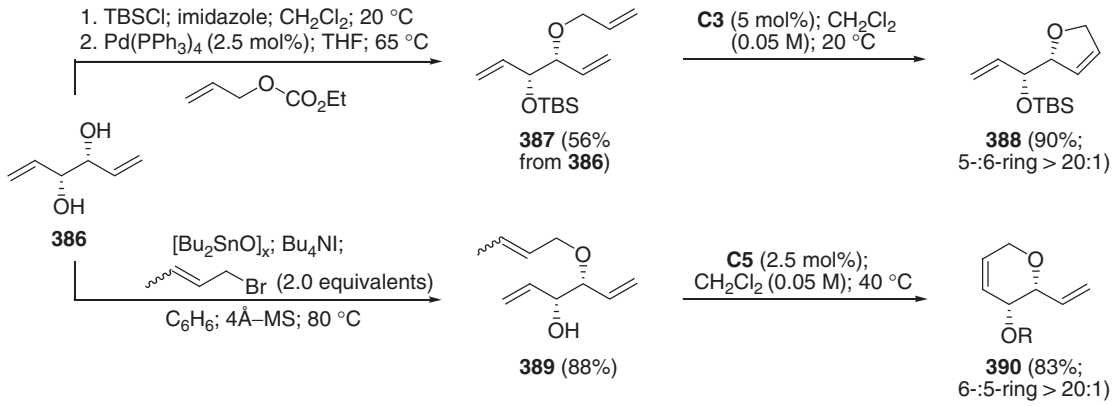


and the catalytically active species is regenerated. Apart from this example several interesting applications of RRCM have been published since the original disclosure[325] of the concept by Hoye et al. Recent examples include a RRCM-assisted macrocyclization in the synthesis of peloruside A[328] and a synthesis of the natural product penostatin B, where RRCM is used to trigger initiation at an electron-deficient acrylate moiety.[329] RRCM strategies can also help to overcome selectivity problems observed for certain RCM substrates with more than two double bonds. This aspect is covered in Section 5.29.10.

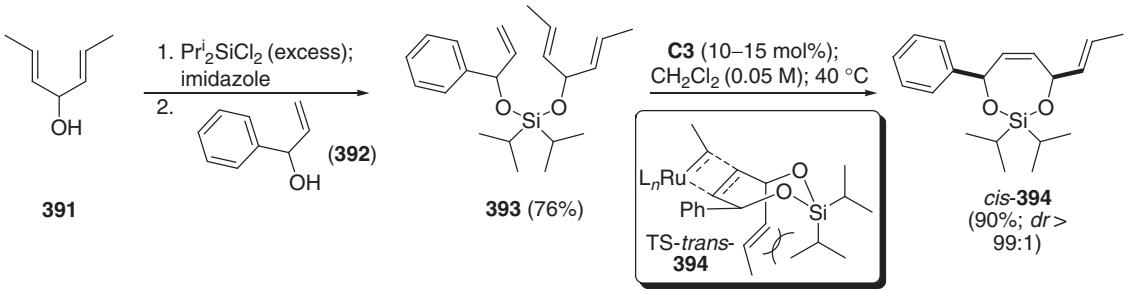
One should, however, bear in mind that in spite of numerous highly effective applications of the RRCM concept, the 'use of an RRCM strategy by no means guarantees a successful outcome',[330] as was recently stated by Hoye et al. in a very instructive account of synthetic approaches toward callipeltoside A.

5.29.10 Control of Regio- and Stereochemistry Issues Through RCM Reactions

Regio- and stereoselectivity issues may arise for substrates with more than two double bonds amenable for RCM. The subject has been reviewed,[331,332] and in this section different selectivity issues and their solutions are exemplified.



Regioselectivity of a given RCM reaction may affect the resulting ring size; for this reason, the term 'ring size selectivity' has been occasionally used. The following example to illustrate the problem and strategies to its solution comes from Crimmins' synthesis of the acetogenin natural product (–)-mucocin (Scheme 89).[333] In preliminary experiments it was discovered that precursors of the general structure **381** undergo RCM only with insufficient regioselectivity, leading to mixtures of the five- and six-membered rings **382** and **383**. This observation suggests that there is no preference for initiation at one of the three double bonds a, b, and c. A selective formation of the desired five-membered ring might be accomplished if the catalyst is directed exclusively to double bond b, because from this point only the cyclization mode b-c is feasible. Indeed, a ring size selective synthesis of the dihydrofuran fragment **385** could be realized through an RRCM strategy (see Section 5.29.9 for details) using precursor **384**, which preferentially initiates at the least hindered double bond d and then undergoes transfer of the Ru to position b with the formation of the 2,5-dihydrofuran **385**.

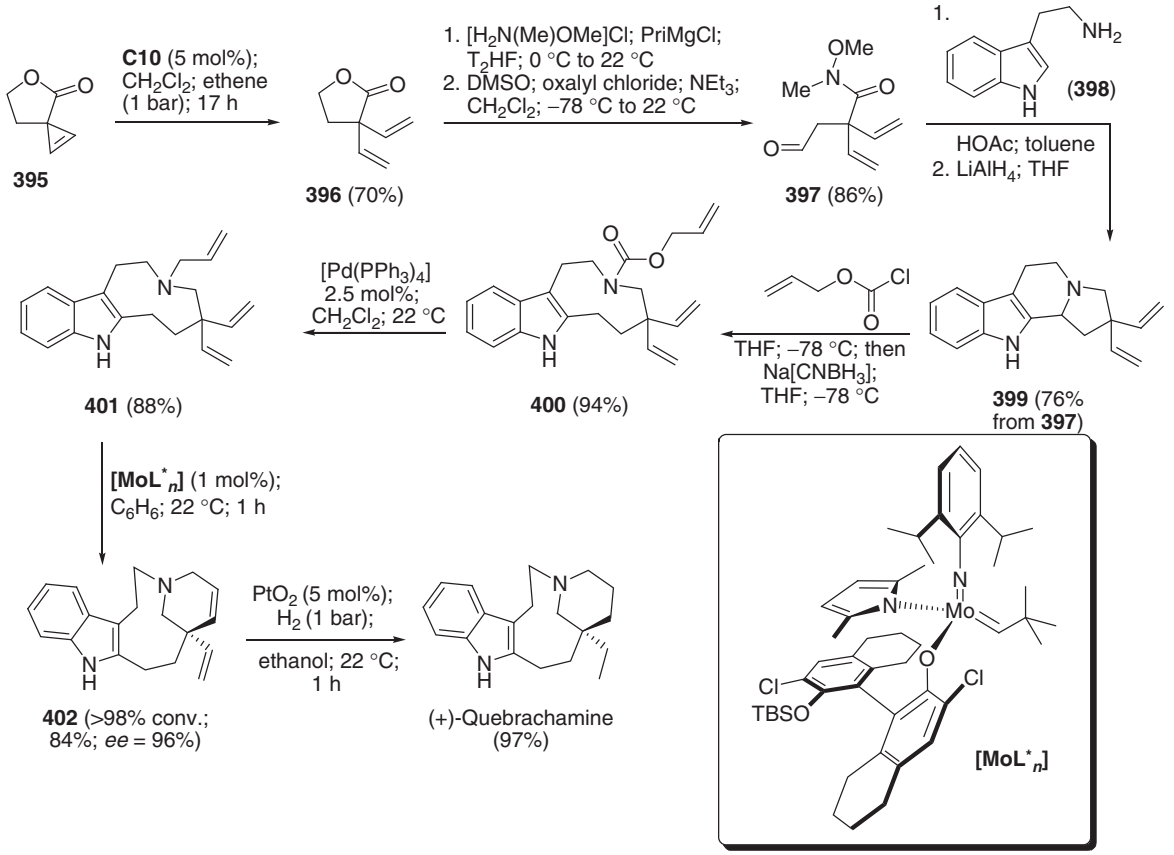


Scheme 89 Ring size selectivity issue in the synthesis of (–)-mucocin.

Another strategy to effectively influence ring size selectivity relies on hydroxyl group-directing effects. Such effects have also been exploited and rationalized by mechanistic considerations for diastereoselective ROM–CM sequences by Hoveyda et al., who proposed an H-bonding interaction between allylic OH-groups and the chloro ligands of the Ru-catalyst.[76] In the example outlined below, enantiopure dihydrofurans and dihydropyrans were synthesized selectively starting from the C_2-symmetric diene **386** (Scheme 90).[334] The TBS-protected allyl ether **387** reacts in high yield and selectivity exclusively to the dihydrofuran **388**, presumably due to initiation at the linear allyl ether and subsequent cyclization at the less hindered double bond. In contrast, the crotyl ether **389** cyclizes with similar yield and selectivity to the dihydropyran **390**, which can be rationalized by assuming that the OH-group steers the catalyst (most likely via H-bonding with the chloro ligands, *vide supra*) to the adjacent C–C double bond. In this case, a crotyl ether was used instead of an allyl ether to additionally increase the steric demand of the linear allyloxy substituent and suppress initiation at this site. Without the terminal methyl group, five- and six-membered oxacycles are formed in equal amounts. However, the first-generation Hoveyda–Grubbs catalyst **C5** had to be used for this substrate, because conversion remained incomplete with the less active catalyst **C3**. Interestingly, all NHC–Ru-catalysts tested in this study were unsuitable to mend the problem, because a complete erosion of selectivity was observed.

Diastereoselectivity becomes an issue in RCM reactions of trienes with two diastereotopic double bonds. The first examples for this type of RCM were published by Huwe and Blechert, who obtained up to 92% *de* and found that opposite relative configurations of the RCM products were obtained with the Ru-catalyst **C3** and the Mo-catalyst **C1**.[335] To illustrate the principle, an interesting example is highlighted below, in which a diastereoselective differentiation of diastereotopic groups is achieved through a tethered RCM (Scheme 91).[336]

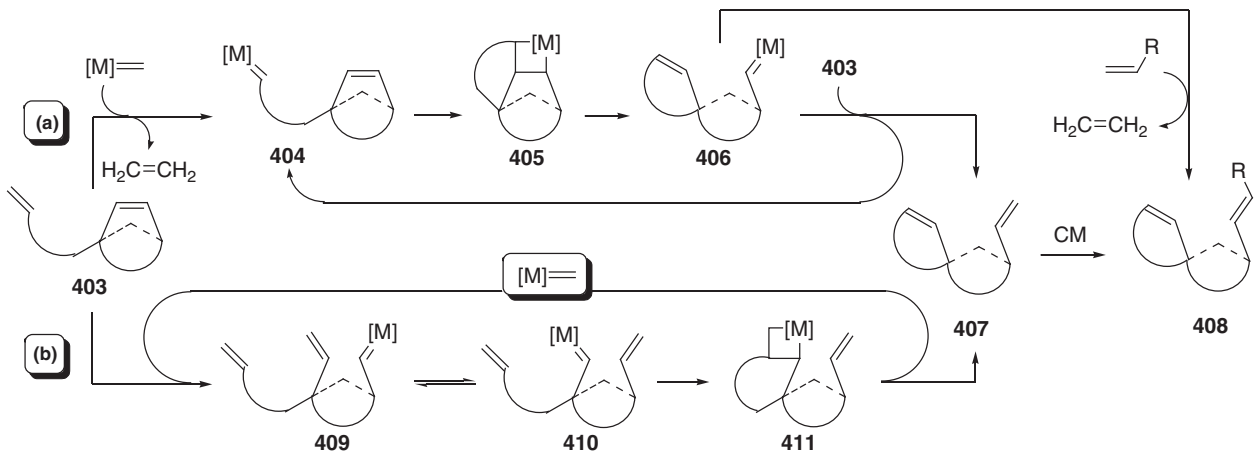
Scheme 90 Control of ring size selectivity through OH-directing effects.



Scheme 91 Highly diastereoselective tethered RCM.

As for other tethered RCM reactions, precursor **393** was synthesized via stepwise condensation of alcohol **391** with a dichlorodialkyl silane and allylic alcohol **392**. With catalyst **C3**, which needs to be added to the reaction mixture in portions over a period of several hours, the *cis*-configured product **394** (and several related examples) were obtained in diastereomeric ratios generally better than 20:1. The steric demand of the alkyl substituents at the silicon is crucial for the success of the reaction, which can be understood from the proposed transition state (see Inset in Scheme 91). The disfavored transition state TS-*trans*-**394** is presumably destabilized by steric repulsion between the vinyl substituent not participating in the RCM and the pseudoaxially oriented isopropyl substituent at the silicon.

Enantioselective RCM can be considered as the ultimate challenge in the field discussed in this section. Considerable efforts were made to obtain chirally modified catalysts that are highly active, yield high enantioselectivities, and are applicable to a broad range of substrates at the same time. The topic has been the subject of very instructive and up-to-date reviews by Hoveyda et al. (with a focus on applications in natural product synthesis)[337] and Kress and Blechert (a recently published tutorial review that outlines general construction principles of the catalysts and mechanistic considerations to rationalize the observed enantioselectivities).[338] In the context of this overview, we illustrate for one example, the enantioselective synthesis of the alkaloid quebrachamine and how the differentiation of enantiotopic vinyl groups by RCM using a chiral Mo-catalyst can be implemented in a total synthesis (Scheme 92).[286] The synthesis of the RCM precursor starts from a γ-butyrolactone, which is converted in a few steps to the spirocyclic lactone **395**. At this stage the two enantiotopic vinyl groups (to be differentiated several steps later) are introduced by a ROM using catalyst **C10**. By nucleophilic ring opening with an *in-situ* generated Mg-amide and subsequent Swern oxidation aldehyde **397** was obtained, which reacts with tryptamine (**398**) in a Pictet–Spengler reaction to give the tertiary amine **399**. Acylation of nitrogen with allyl chloroformiate, followed by reduction furnished amide **400**, which was then subjected to an intramolecular Pd-catalyzed N-allylation, giving the required precursor **401** for the enantioselective RCM, which was successful with the chiral Mo-catalyst depicted in the Insert. Notably, in contrast to many other chiral metathesis catalysts, this complex does not only contain a chiral ligand, but the metal itself is a stereocenter ('stereogenic-at-Mo-complexes'), accounting for the high levels of enantioselectivity observed. The synthesis of (+)-quebrachamine is completed by hydrogenation of the two double bonds of the RCM product **402**.

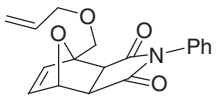


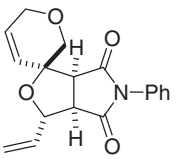
5.29.11 Ring Rearrangement Metathesis (Domino Reactions)

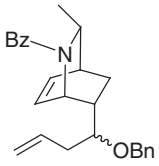
According to Tietze's definition, a domino reaction is understood as 'a process involving two or more consecutive reactions in which subsequent reactions result as a consequence of the functionality formed by bond formation or fragmentation in the

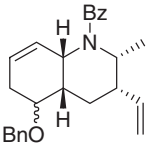
Scheme 92 Total synthesis of (+)-quebrachamine via enantioselective RCM.

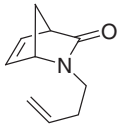
previous step.'[339] Homogeneous olefin metathesis catalyzed by Mo- and Ru-complexes was still in its infancy when this definition was published in 1993, but shortly afterwards a group of metathesis reactions was discovered that fits the above definition of a domino reaction perfectly, the ring rearrangement metathesis reactions (RRM). The field has been extensively reviewed,[340,341] and the authors will therefore limit themselves to discussing the concept with a few representative examples. In a typical RRM, a strained cycloalkene (bridged or monocyclic) with a pendant ω-unsaturated alkyl substituent (**403**) reacts to another less strained cycloalkene with a different ω-unsaturated side chain (**407**). The driving force for these reactions can be a release of ring strain, decreased steric interactions of other substituents attached to the starting carbo- or heterocycle, and/or removal of a volatile alkene from the reaction mixture. In principle, two mechanisms are conceivable (Scheme 93).

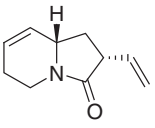


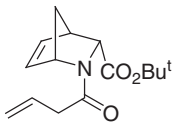


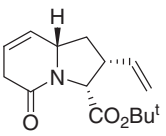








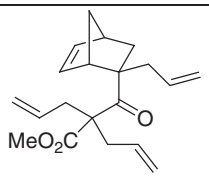


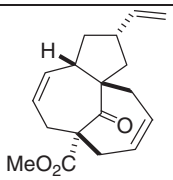


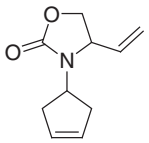
Scheme 93 Schematic presentation of different mechanistic scenarios for RRM reactions.

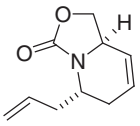
Mechanism (*a*): Initiation occurs at the least hindered double bond (typically the pendant side chain) to give a carbene complex **404**, followed by intramolecular attack of the carbene at the endocyclic double bond of the strained cycloalkene (metallacyclobutane **405**), resulting in a ring opening of the strained ring with release of ring strain and concomitant formation of a new, less strained cycle (ROM/RCM sequence) with a pendant metal–carbene moiety (**406**). Termination of the sequence occurs either by transfer of the carbene to the next substrate **403** (no small molecule alkene formed) with the formation of **404**, or by a CM with an added alkene (giving **408**) or by a second RCM event (not shown in the general scheme). In the latter cases a volatile alkene is released.

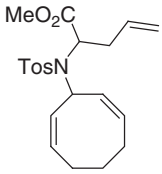
Mechanism (*b*): The catalyst initially attacks the strained cycle with immediate loss of ring strain, leading to the new metal carbenes **409** and/or **410**. These carbene complexes are interconvertible, but **410** can be removed from the equilibrium by a subsequent 'normal' RCM with the pendant ω-unsaturated side chain via metallacyclobutane **411**. Again, no volatile alkene is set free unless the new ω-unsaturated substituent is engaged in a subsequent metathesis reaction (either CM or RCM).

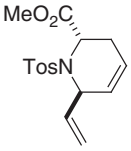


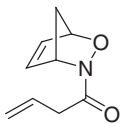


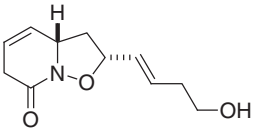


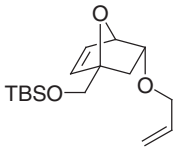


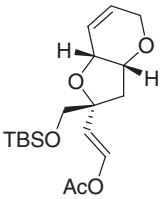


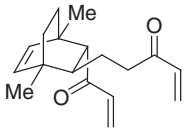


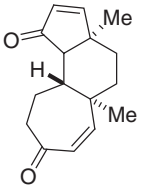


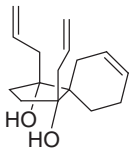


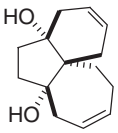












Metathesis transformations proceeding along these lines offer vast opportunities for the rapid and highly stereoselective construction of hetero- and polycyclic systems, because very often norbornenes and heteronorbornenes can be used as substrates, which are conveniently available via stereoselective Diels–Alder reactions. The absolute and relative configuration of the starting materials is then transferred through the RRM sequence into the desired products. It should be noted that a considerable number of transformations classified as ring rearrangement metathesis reactions involve one or two C–C triple bonds. These enyne metathesis reactions are beyond the scope of this chapter and covered separately in this volume (*see* Chapter 5.27). For these reasons, the principle of RRM is illustrated in Table 24 exclusively for alkenes. In the example listed in entry 1, the ω-unsaturated side chain is attached to the bridgehead of the strained bicyclic system. As can be deduced from the general scheme outlined above, spirocycles are the products in these cases. If, as in entry 2, the pendant side chain is attached to an atom adjacent to the bridgehead of the bicyclic starting material, annellated bicyclic products will result. As can be seen from entries 3–7, the RRM is frequently conducted under an atmosphere of ethene. In practice, this is often accomplished by saturation of the solvent with ethene before the reaction. For the example in entry 5, an additional 'conventional' RCM step occurs, resulting in the formation of an additional cycloheptenone ring. Entries 6 and 7 nicely illustrate that diastereoselective RCM can also be combined with an RRM sequence. In these examples, the halves of the cyclopentene and cycloheptadiene ring are diastereotopic, and the RRM sequence consequently becomes diastereoselective, with the *dr* of 14:1 observed for the example in entry 7 being remarkably high for this type of reactions. This example deserves another comment: after the RRM sequence one would expect a hepta-1,6-dienyl side chain α to the ring nitrogen; however, cyclopentene is cleaved off via a backbite mechanism and a vinyl side chain remains. Entries 8 and 9 illustrate the elongation of the ROM/RCM sequence by a CM step with pent-4-ene-1-ol (entry 8) and vinyl acetate (entry 9), respectively. Entries 10 and 11 show examples of RCM/ROM/RCM-sequences. Notably, for the example in entry 10, both pendant double bonds are electron deficient, making initiation at these sites less likely and suggesting a preferred pathway via general intermediate **409** (Scheme 93), which may also account for the comparatively high catalyst loading that was required.

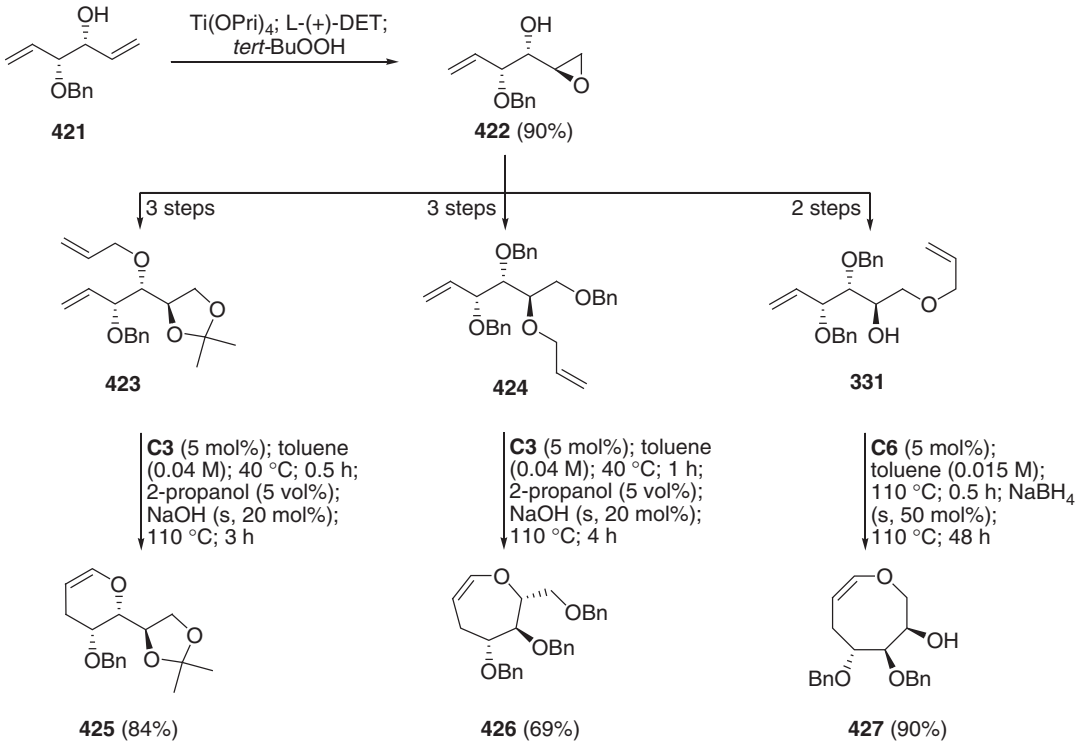
[d]*dr* = 14:1 in favor of the *trans*-isomer; cyclopentene is released after ROM/RCM step.
[e]Isolated together with 10% of the ethenolysis product.
[f]Yield also refers to the two previous steps.

5.29.12 Sequential RCM–Non Metathesis Transformations (Tandem reactions)

The domino metathesis reactions discussed in the previous section are characterized by the presence of just one catalytically active species (i.e., a metal–carbene complex), which promotes all steps of the sequence via essentially the same mechanism (i.e., the Chauvin mechanism). In addition, no functional group interconversion occurs during the sequence, which means that alkenes are converted via a domino metathesis transformation into other alkenes. Apart from these reactions, a second class of sequential metathesis reactions has emerged over the past decade, which are conceptually different from the domino or ring rearrangement

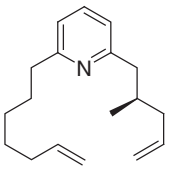


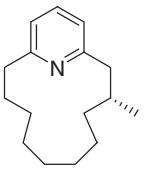
metathesis reactions. This second class includes transformations, which combine an olefin metathesis step with a subsequent nonmetathesis transformation of the primary product. These reaction sequences differ from simple one-pot reactions because the nonmetathesis step is also metal catalyzed and just one precatalyst is required. This implies that an organometallic transformation of the metal–carbene into a different species is triggered *in situ* by a change of the reaction conditions, which then catalyzes the nonmetathesis transformation. To distinguish between domino transformations such as RRM and sequential reactions such as those described above, Fogg and dos Santos have introduced the term 'assisted tandem catalytic transformation'. These are characterized by the presence of just one precatalyst, but more than one catalytic mechanism.[352] For reagents added to induce the organometallic transformation of one catalytically active species into the other, the researchers used the term 'chemical trigger'. To illustrate the principle, the mechanistic basis of the RCM isomerization sequence[353] will be first discussed as a representative example (Scheme 94), some of its applications will be highlighted and finally other RCM–nonmetathesis reaction sequences falling into this category will be summarized.

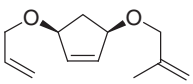
Scheme 94 Assisted tandem catalytic RCM isomerization sequence.

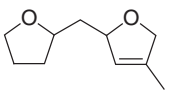
In the particular case of the Ru-catalyzed RCM-isomerization sequence, an α,ω-diene **412** undergoes RCM to the cycloalkene or heterocycloalkene **416** catalyzed by a Ru-carbene species via the expected intermediates **413**–**415**. After completion of the metathesis reaction, the conversion of the Ru-carbene species into a Ru-hydride species, which are well known isomerization catalysts,[354] is induced by the addition of a reagent[355,356] or – in the case of second-generation catalysts – occasionally already by heating the reaction mixture.[357,358] The product of the RCM reaction (**416**) then enters the next catalytic cycle via coordination to the Ru-hydride (**417**), hydroruthenation (**418**), β-hydride elimination (**419**) and dissociation into the Ru-hydride and the isomerized product **420**. Such an isomerization can be expected to proceed selectively into one direction whenever there is a thermodynamic driving force for a migration of the double bond.

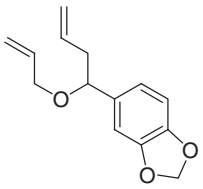
Obvious advantages of such sequences are a reduced number of unproductive work-up steps and consequently a reduced amount of solvents, waste and labor cost. In addition, the multipurpose use of precious metal catalysts improves the overall efficiency of a synthesis. In some cases, the option to circumvent notoriously difficult RCM steps, which might require excessively high catalyst loadings, highly active but expensive precatalysts, and high dilution conditions, is an additional benefit of the sequences discussed in this section. This point is illustrated for the application of the RCM-isomerization sequence to the synthesis of ring-expanded glycals (Scheme 95).[267] As can be seen from the discussion and the examples presented in Sections 5.29.3.2.1.3, 5.29.3.2.2.3, 5.29.4.2.1.3, and 5.29.4.2.2.2, RCM becomes significantly more difficult if an enol ether or enamide moiety is involved, compared with the analogous allyl precursors leading to the same ring size. The problem becomes even more pronounced if medium-sized rings have to be synthesized via enol ether or enamide metathesis (see, for instance, Section 5.29.5.1, Table 19 entries 7 and 8). An alternative route to glycal-type compounds of different ring sizes starts from allyl ethers **423**, **424**, and **331**, which are all available from diene **421** via epoxide **422**. In the case of **423** and **424**, the first-generation catalyst **C3** is sufficiently active to achieve rapid RCM. Conversion of the metathesis-active carbene into the isomerization-active Ru-hydride is then accomplished by the addition of 2-propanol and a base as a 'chemical trigger', presumably via the formation of a Ru-alkoxide that undergoes β-hydride elimination with the formation of acetone. Under these conditions, clean and irreversible isomerization to the desired glycals **425** and **426** occurs. In the case of precursor **331**, leading to an eight-membered oxacycle, the reactivity of **C3** in the metathesis step was insufficient and **C6** had to be used instead (see Scheme 73 in Section 5.29.5.2). In this particular case, an alternative 'chemical trigger', $NaBH_4$ in substoichiometric amounts, turned out to be advantageous and lead to the isolation of the eight-membered cyclic enol ether **427**. Alternative chemical triggers that have been used to deliberately induce isomerization activity of Ru-based metathesis catalysts are silanes,[356] enol ethers,[157,356] or a hydrogen atmosphere diluted with nitrogen.[355]

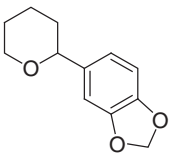


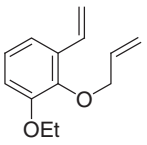


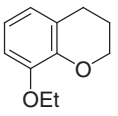


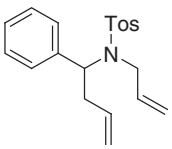


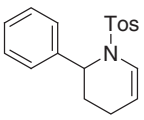


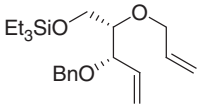


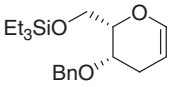


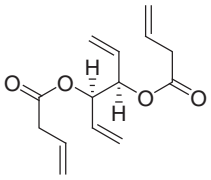


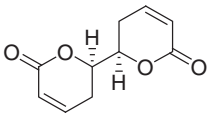


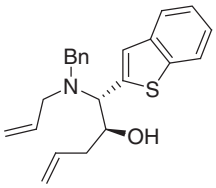


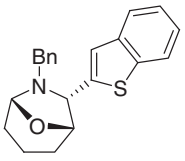


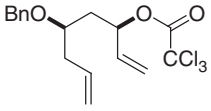


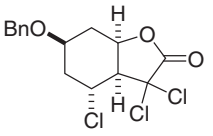


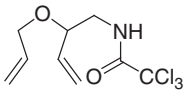


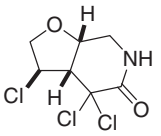






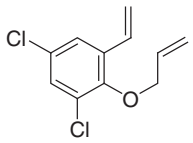


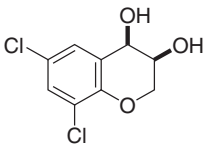


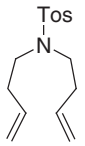


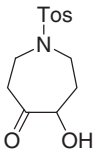
Scheme 95 RCM isomerization for the synthesis of ring-expanded glycols.

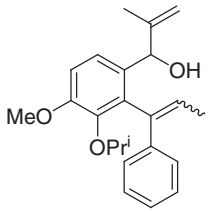
It should be noted that sometimes isomerization reactions may occur as highly undesirable side reactions in 'normal' RCM reactions.[359] The reasons for this complication can be diverse: sometimes the precatalyst contains small but highly active impurities of Ru-hydrides formed during the preparation of the catalyst, in particular if alcohols were used for washing the precipitated precatalyst.[360] However, the formation of a Ru-hydride through decomposition under the conditions of the metathesis reaction has also been observed, especially for second-generation catalysts. Some of these are known to decompose thermally via a bimolecular pathway, which explains why undesired isomerization occurs often with slowly reacting substrates that require high catalyst loadings and elevated temperatures.[357] In these cases, addition of benzoquinones often solves the problem[361] (see, for instance, the examples discussed in Table 17, entry 4 and Scheme 68).

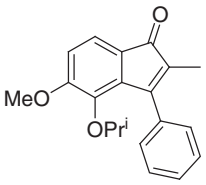


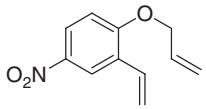


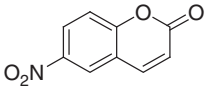


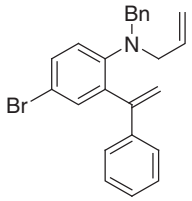


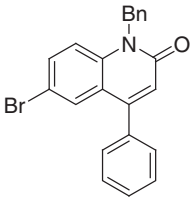


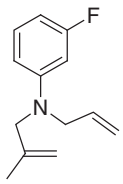


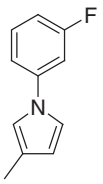


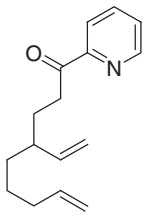


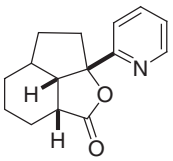


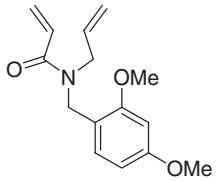


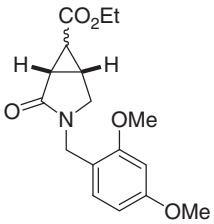












Apart from the RCM-isomerization sequence, several other RCM–nonmetathesis reactions have appeared in the literature. The subject has been reviewed comprehensively,[362] and has partially been covered in reviews[353,363,364] focusing on nonmetathesis reactivities of Ru-carbene complexes. To conclude this section, some of these sequences are highlighted with representative examples (Table 25). Historically, RCM-hydrogenation sequences triggered by molecular hydrogen were the first examples of assisted tandem catalytic sequences involving RCM steps. The formation of Ru-hydrides by hydrogenolysis of Ru-carbenes has been investigated from a mechanistic point of view.[365] Entries 1 and 2 show examples for these sequences; typically, hydrogen pressures of 50 bar have to be applied, as for the example in entry 1. The example in entry 2 is somewhat unusual, as it combines a domino sequence, as discussed in Section 5.29.11, with an assisted tandem catalytic sequence. In this example, hydrogenation is unusually facile and occurs at 1 bar of hydrogen, which allows the two double bonds formed during the preceding RCM/ROM/RCM sequence to be differentiated. Entries 3 and 4 show examples of RCM-hydrogenation sequences with reducing agents other than molecular hydrogen, i.e., triethyl silane (entry 3) and 2-propanol (entry 4). Both reagents have also been used to trigger isomerization reactions; however, isomerization occurs with significantly lower amounts of reagent and in shorter reaction times (entries 6 and 7). A way to use hydrogen as a chemical trigger for an isomerization reaction was discovered by Snapper et al. (entry 5). In this case it is important to apply a highly diluted hydrogen atmosphere to suppress competing hydrogenation. As mentioned above, RCM isomerization may also proceed without any additive just by heating the reaction mixture, if comparatively high loadings of second-generation catalysts are used, because these are known to decompose via a bimolecular pathway into a dinuclear Ru-hydride. An example is shown in entry 8, in which the resulting enamine is trapped by intramolecular addition of the hydroxy group with formation of the bicyclic *N,O*-acetal. In entries 9 and 10, examples of an RCM–Kharasch-addition sequence are shown. Ring closure of the α,ω-diene occurs typically at an ambient temperature; on heating, a Ru-catalyzed atom transfer radical cyclization reaction occurs with homolytic cleavage of one C–Cl bond and addition of the resulting carbon-centered radical to the double bond formed in the previous RCM step. In entries 11 and 12, the combination of RCM with dihydroxylation and ketohydroxylation, respectively, is presented. Protocols for conducting these Ru-catalyzed oxidative alkene transformations using $RuCl_3$ as a precatalyst and Lewis-acidic metal halides as cocatalysts have been extensively investigated by Plietker et al.[366] Most likely, under the conditions of the RCM-oxidation sequence, the Ru-carbene species is converted to RuO_4,

which then promotes the alkene oxidation step. The Ru-catalyzed oxidative double-bond functionalization requires special solvent mixtures consisting of ethyl acetate, acetonitrile, and water in carefully controlled ratios. Normally, these solvents are considered to be incompatible with RCM reactions. For this reason a solvent switch from dichloromethane to the above mentioned mixture was performed for the example in entry 11.[367] Alternatively, conducting the RCM step in ethyl acetate is also possible, but in this case acetonitrile and water have to be added together with the oxidant.[368] This protocol was established for the dihydroxylation sequence (not shown in the Table) and the ketohydroxylation sequence (entry 12). In the example in entry 13, the postmetathesis functionalization does not occur at the double bond but at the allylic position; presumably, conversion of the metathesis catalyst to a Ru-hydride is thermally triggered, which then catalyzes a dehydrogenation. This process is unusually facile, which might be explained by the dual activation of the allylic/benzylic position. Two different types of RCM/oxidative transformation sequences are highlighted in entries 14–16. These examples have in common that alkyl hydroperoxides are used as oxidants and chemical triggers. For the examples in entries 14 and 15, RCM is coupled with a Ru-catalyzed allylic oxidation, a reaction that has been extensively investigated by Murahashi et al.[369] It should be noted that the products of this sequence could also have been accessed through the RCM of the corresponding acrylates or acrylamides, respectively; but these electron-deficient double bonds would have been significantly less reactive. In entry 16, an example for an RCM/oxidative aromatization sequence leading to *N*-aryl pyrroles is shown. It was demonstrated by control experiments that the aromatization step indeed requires the presence of Ru. The last examples, shown in entries 17 and 18, are combinations of RCM and a Pauson–Khand reaction and RCM cyclopropanation, respectively, which allow for the rapid assembly of complex polycyclic structures.

Glossary

Alkoxycyclization Organic process involving a cyclization reaction and concomitant addition of an alcohol with formation of an ether moiety.

Atom economy Description of the efficiency of an organic reaction in terms of all atoms involved; the ideal reaction shows a full conservation of atoms of the starting material into the resulting product, with no atom being wasted.

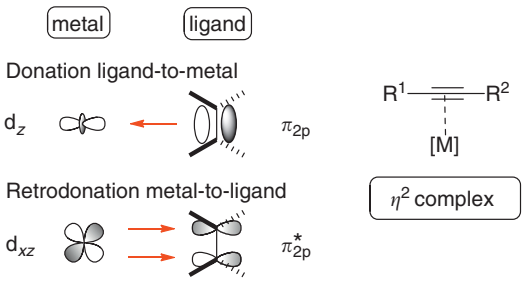
Cycloaddition Transformation involving several unsaturated molecules that combine to form a cyclic derivative.

Cycloisomerization Chemical transformation of an acyclic derivate to a cyclic isomer.

Dewar–Chatt–Duncanson model Model describing the bonding of π-conjugated ligands (alkene, alkyne, etc.), involving a donation from the ligand and back-donation from the metal.

Domino process Consecutive series of transformations involving the formation of multiple bonds.

5.30.1 Introduction

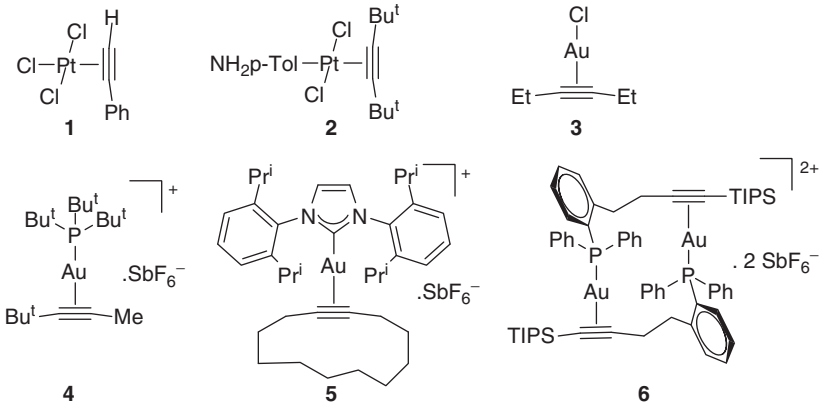


Metal-catalyzed cycloisomerization and related reactions of enynes have appeared as conceptually and chemically highly fascinating processes, as they contribute to the stimulating atom-economy research field. The predominant contribution of catalysis to the concepts of atom economy and green chemistry of the twenty-first century presented by Sheldon as well as by Anastas and Warner has reinforced the international demand on clean and straightforward processes.[1] Metal-catalyzed cycloisomerization reactions of 1,*n*-enynes fulfill such requests on atom-economical and step-economical reactions. Moreover, the presence of various functionalities such as alcohols, aldehydes, ethers, alkenes, or alkynes has led to the discovery of novel original processes that enhance the molecular complexity of the products. Historically, the group of Trost[2] paved the way of cycloisomerization reactions in the mid-1980s using palladium complexes. Since this pioneering work, several other organometallic complexes have 'entered

the dance,' including noble metals such as gold and platinum. The definition of a noble metal is that it is chemically inert and inactive especially toward oxygen or most acids (no corrosion). After a time lag for rationalization of the observed processes, unified mechanistic scenarios have been announced from the catalysis community, and these proposals have been scrutinized by sophisticated density functional theory (DFT) studies,[3] therefore contributing to the understanding of plausible reaction pathways. Still some speculations exist, but the main rationale has allowed predictions, optimizations, and the design of new efficient catalysts.

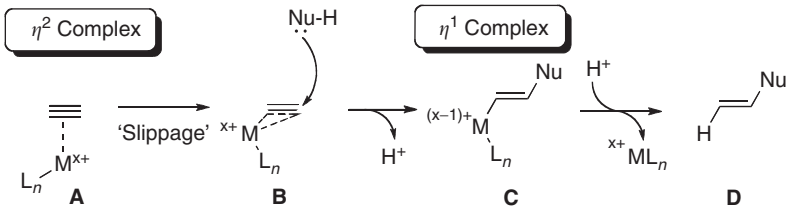
In this chapter, the main contributions in the field of cycloisomerization and related reactions of enynes will be highlighted, emphasizing the recent reports on gold and platinum catalysts.[4] The presentation starts from a historical background and the general mechanistic framework relying on the carbophilic Lewis acids properties of the organometallic species. The cycloisomerization and related reactions will be presented, starting from classical skeletal rearrangements leading to 1,*n*-dienes and bicyclic derivatives. The second part will be dedicated to related reactions, implying domino processes with the intervention of an internal or external nucleophile. In each part, the presentation of asymmetric versions[5,6] and applications of these rearrangements to natural products synthesis[7] will be highlighted.

5.30.2 Generalities and Unified Mechanism



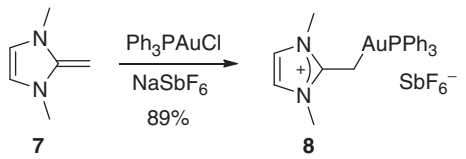
The Dewar–Chatt–Duncanson model is usually used to describe the mode of coordination of an unsaturated ligand (carbon–carbon double or triple bond) to a transition metal complex.[8] It postulates the formation of σ-bond by recovery of the ligand π_{2p} system with an empty orbital of the metal center, a phenomenon known as ligand-to-metal donation (Scheme 1). The formation of this bond is supplemented by π-back-donation from a filled orbital of the metal toward the empty $\pi*$ antibonding 2p orbital of the alkene or alkyne. Theoretical calculations were used to determine the mechanism of coordination of a gold complex on an alkyne. According to the particular calculation methods, a weak or strong σ-donor character of the alkyne is invoked by different groups to explain the mode of coordination to the metal. The η^2-complexation is accompanied by a rehybridization and a deformation of the carbon–carbon triple bond according to the model of Dewar–Chatt–Duncanson. The electron density around the alkyne is therefore reduced, which results in a possible nucleophilic attack onto the latter.

Scheme 1

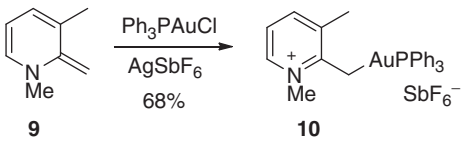


The isolation and characterization of platinum(II)– or gold(I)–alkyne complexes recently revealed that the alkyne adopts a perpendicular arrangement to the plane defined by the L_3Pt^{2+} fragment in the case of platinum.[9] The dicoordinated gold complexes follow a linear geometry, the second ligand being generally a chloride,[10] a phosphane or an *N*-heterocyclic carbene (NHC). X-ray analyses of complexes **1**–**6** have been obtained at various temperatures depending on the stability of the complexes (Scheme 2).[11] In complex **3** for example, Au–C distances of 2.152 and 2.172 Å and a C≡C distance of 1.224 Å have been determined and correlations have been established between experimental and calculated data, which show a strong alkyne-to-metal σ-bonding and a weak metal-to-alkyne π-back donation.[12] The cationic gold(I) species **4** is an ion-separated complex with symmetrical coordination of the alkyne to Au (distances of 2.238 and 2.239 Å). The *t*-butyl and methyl groups are bent away from the linear arrangement, with C–C≡C angles of 165.6° and 168.1°. Coordination of cyclododecyne to a $[(NHC)Au]^+$ complex resulted in a very stable complex **5**.[13] The C≡T bond is slightly elongated (1.213 Å compared with 1.196 Å in the alkyne), but this effect is less pronounced than that in the corresponding neutral chloride complex. The C–C≡C bond angles are significantly reduced from 175.9° to 168°. Association of these data to other spectroscopic data (NMR or IR spectra) suggests that the imidazole ring accounts for the electron withdrawal from the alkyne. The presence of an alkyne-containing triarylphosphane allowed for the isolation and characterization of the dinuclear Au(I) complex **6**.[14] The alkynes are η^2-bonded to gold and the Au–C and C≡C bond distances are 2.197/2.270 Å and 1.221 Å, respectively. It is noteworthy that Ag(I) behaves more like Au(I), whereas Cu(I) forms a mononuclear species with pseudotrigonal planar geometry. Another important feature in complex **6** is that the metal center is 'slipped' to one side of the π-bond.

In most cases, in the presence of noble metals, the σ-donation to the metal is dominant, which enhances the electrophilicity of the alkyne and therefore the addition of nucleophiles to the η^2-bonded alkyne.[14,15]

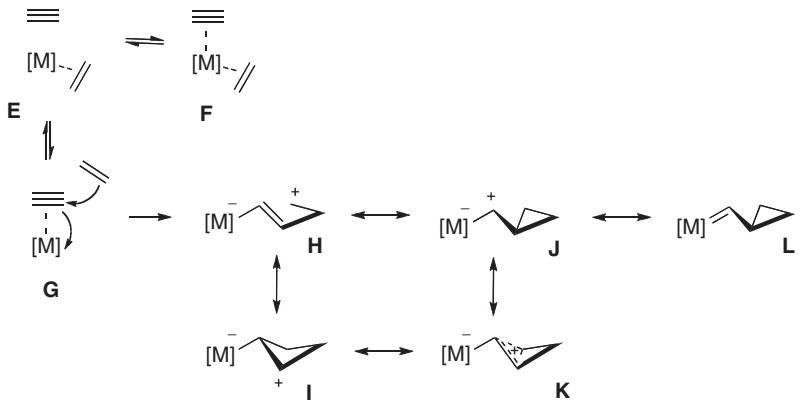


Scheme 2



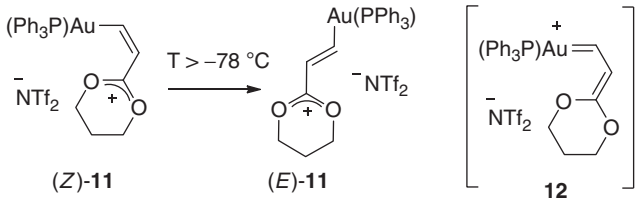
This carbophilic activation promotes *anti* nucleophilic addition on the complex **A** and the creation of a new carbon–carbon or carbon–heteroatom bond, depending on the nature of the nucleophile (carbon, oxygen, nitrogen, carbo-, or heterocyclic ring aromatic). The geometry of the formed η^1-complex **C** depends on the degree of oxidation of the metal center: the complex is linear at a low oxidation state (Au^+), but square-planar at a higher oxidation state (Pt^{2+}, Au^{3+}). A final step of protodemetallation on complex **C** completes the addition reaction (Scheme 3). The 'slippage' phenomenon and the addition of the nucleophile on the η^2-complex **B** may not be so trivial, and it was recently investigated theoretically and experimentally (equations 1 and 2).[16] The addition of triphenylphosphine gold chloride and sodium hexafluoroantimonate to 1,3-dimethyl-2-methyleneimidazoline **7** led to the cationic gold complex **8**, where the Au–C bond distance is 2.087 (longer than the Au–C bond in $AuPh(PPh_3)$) which confirms the 'carbon ylide' behavior of the olefin. The imidazolium unit could be replaced by an *N*-alkyl pyridinium moiety, as 1,3-dimethyl-2-methylene-1,2-dihydropyridine **9** reacted similarly and afforded a stabilized complex **10**. These two cationic complexes are representative examples arguing in favor of a η^2–η^1 complex deformation.

Scheme 3

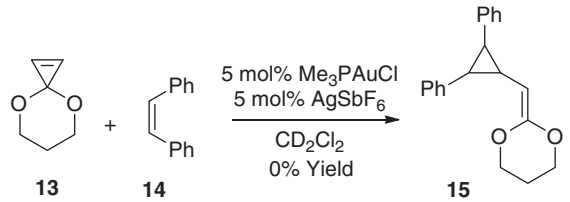


(1)

(2)

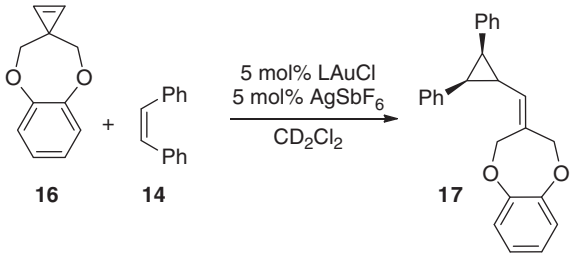


The case of enynes as substrates is highly intriguing, as originally mono- and dicomplexations of their alkenyl and alkynyl moieties may be envisaged. A higher stabilization for the Au(I)–ethylene complex over the ethyne analog has been established, with a calculated energy difference of 10 kcal mol^{-1} (complex **E** vs. **G**, Scheme 4).[17] Nevertheless, the observed reactivity brings out the selective π-complexation of the alkyne followed by nucleophilic addition of the alkene moiety. This behavior may be a consequence of the fact that the highest occupied molecular orbitals (HOMO) and the lowest unoccupied orbitals (LUMO) of alkynes are lower in energy than those of the corresponding alkenes (approximately 0.5 eV); alkynes are therefore more electrophilic and less nucleophilic.[18] One may anticipate a lower LUMO for the Au(I)–alkyne complex **G** than for the Au(I)–alkene



Scheme 4

complex **E**, which illustrates the observed 'alkynophilicity' of Au(I) and the reactivity of the resulting complex **A** (Scheme 3). The *trans* addition of the alkene to the π-complex **G** results in the formation of a cationic nonclassical intermediate, potentially depicted by the mesomeric structures **H–K**. If back-donation of electron density from the metal to the ligand is involved, the electrophilic metal carbenoid **L** may be considered. All the representations are probably mental projections, especially in the case of gold, and several theoretical and experimental data have been recently assembled to shed light on this mechanistic rationale.



The carbenic versus carbocationic descriptions have been studied mainly by the Fürstner and Toste groups, by measuring experimentally and theoretically the rotational barrier of bonds adjacent to gold. Indeed, NMR studies attempting to generate a gold carbene by rearrangement of a 3,3-disubstituted cyclopropene afforded the cationic products (*Z*)-**11** and (*E*)-**11** (equations 3–5).[19] The rotational barrier of the C–C bond in **11** has been determined to be in the same range as the barrier of the C–C bond between the phenyl ring and the carbonyl group of benzaldehyde, which preclude any significant contribution of the carbene **12** in the ground state structure. Computational experiments confirmed these conclusions, and additionally highlighted the importance of the carbocation-stabilizing heteroatoms such as oxygen atoms.[15h] The gold-catalyzed cyclopropanation reaction of **13** in the presence of *cis*-stilbene **14** did not produce the expected cyclopropane **15**, confirming the hypothesis of a carbocationic intermediate. On the contrary, the reaction of cyclopropene **16** allowed the stereospecific formation of product **17**, via a gold-stabilized carbene as potential intermediate. The study of such reactivity also highlighted the influence of the ligand on the stabilization of such intermediates. Indeed, lower yields were observed in the case of π-acidic ligands, which are prone to carbocationic stabilization. The best activity was obtained in the case of the electron-donating heterocyclic imidazole ligand (IPr, strong σ-donor, and weak π-acid) as 80% of the cyclopropane **17** was isolated in this case. The behavior of phosphine was found to be in between both extremes (carbenic vs. carbocationic). These studies have been supplemented by recent data dealing with the synthesis and reactivity of (NHC)gold(I) carbenes in the gas phase.[20] A recent study also highlighted the importance and influence of ligands by examining the kinetics of nucleophilic additions on unsaturated derivatives.[21] Based on all these pioneering studies, a certain consensus exists in the literature and the carbenic versus carbocationic representation or 'carbene-like' versus 'carbocation-like' reactivity of gold intermediates are summarized in the terms 'carbenoid' and 'carbenoid-like,' suggesting an intermediate situation.

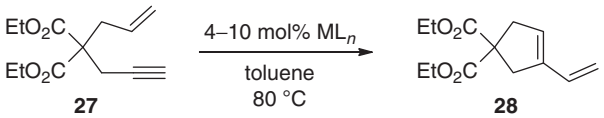
5.30.3 Enyne Cycloisomerization Reactions in the Absence of Nucleophiles

Cycloisomerization reactions of 1,*n*-enynes are by definition a skeletal rearrangement of the substrate without incorporation of external atoms or production of waste.[22,4] These transformations, responding to the concept of atom economy, allow for the stereoselective synthesis of functionalized carbo- and heterocycles. Various pathways are possible for the skeletal rearrangements as depicted in Scheme 5 for the example of 1,6-enynes. The cyclization of 1,6-enyne **18** (that can be a carbon-, oxygen-, or nitrogen-tethered enyne) involves, as a first step, the activation of the alkyne by the metal complex, leading to η^2-complex **19**. The stereoselective addition of the alkene to the activated carbon–carbon triple bond (as presented in the last paragraph, Scheme 3) may occur via two different pathways, a 5-*exo-dig* or 6-*endo-dig* one. The cyclopropyl carbenoid species **20** and **21** may be considered as key intermediates, as their rearrangements (e.g., cleavage or migration of C–C and C–H bonds) lead to the formation of unsaturated five- (**22**, **23**) or six-membered (**25**) cyclic structures, bicyclo[3.2.0]heptenes (**24**), and bicyclo[4.1.0] heptenes (**26**).

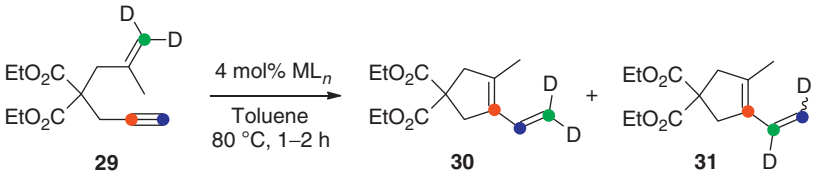


Scheme 5

The authors will present successively the catalytic preparation of 1,3- and 1,4-dienes, followed by bicyclo [3.2.0]heptenes and bicyclo[4.1.0] heptenes, presenting, in each case, the mechanistic proposals which have helped to rationalize the observed structures. The cycloisomerization reactions will be presented by the type of 1,*n*-enynes. The section will be limited to carbophilic mechanisms, involving an η^2–alkyne metal complex: neither examples of cycloisomerization involving a metallacycle type intermediate[23] nor cyclization reactions of enynes with propargylic acetates will be discussed.[24] Asymmetric cycloisomerization reactions catalyzed by chiral complexes of iridium, platinum, and gold will also be presented.

5.30.3.1 Formation of 1,3- and 1,4-Dienes

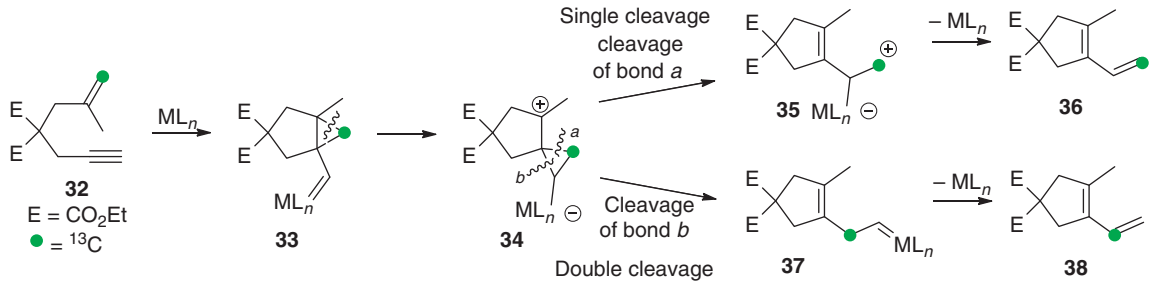
5.30.3.1.1 Reactivity of 1,6- and 1,7-enynes



Since the first examples catalyzed by palladium(II), the synthesis of 1,3-dienes has been demonstrated for a large number of transition metal complexes of platinum(II),[25] platinum(IV),[26] gold(I) and gold(III),[27] gallium(III),[28] indium(III),[29] ruthenium(II),[30] and iridium(I).[31] The cycloisomerization of 1,6-enyne **27** leading to vinylcyclopentène **28** is one of the most-studied rearrangements in the presence of organometallic complexes (equation 6). This rearrangement has been described in the presence of many carbophilic metal complexes, such as chlorides of platinum(II) and(IV), gold(III), and indium(III),[32] leading to the synthesis of the derivative **28** with yields between 42% and 68%.

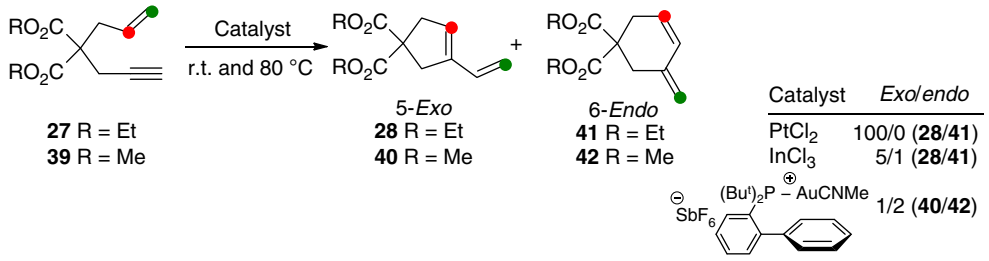
ML_n	t, Yield
$PtCl_2$	2 h, 53%
$PtCl_4$	20 h, 57%
$AuCl_3$	12 h, 42%
$InCl_3$	1 h, 68%

(6)



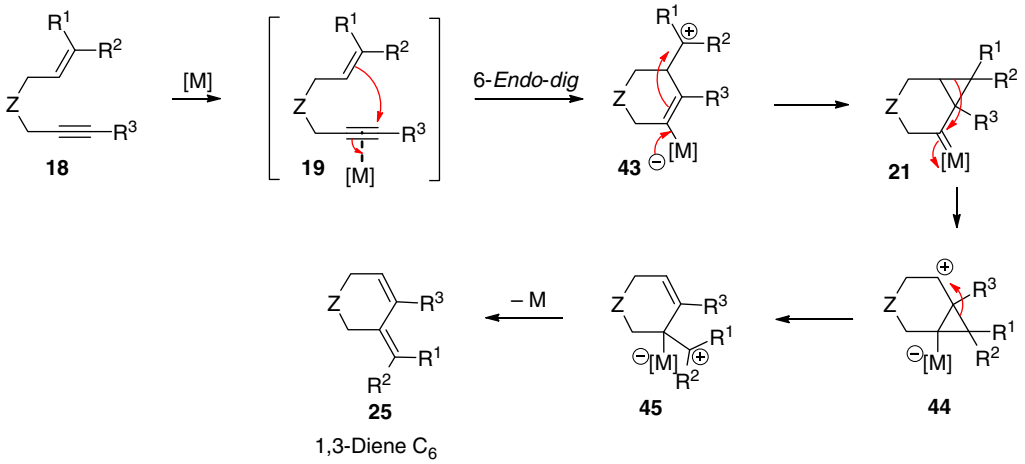
Chatani's group has focused on the isomer distribution obtained in the cycloisomerization of the carbon-tethered enyne **29**, bearing an internal methyl group on the alkene chain, in which the olefinic hydrogen atoms had been replaced by deuterium (equation 7).[32a] Several carbophilic metal complexes have been used in this study. The results show that isomer **31**, coming from a dual cleavage is obtained in great majority, irrespective of the nature of the complex used.

	ratio **30/31**
$PtCl_2$	1/99
$PtCl_4$	> 1/99
$AuCl_3$	4/96



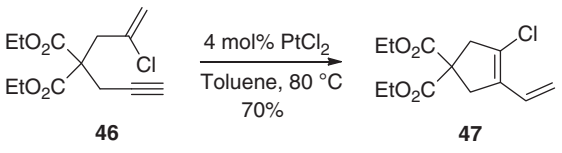
(7)

This selectivity in favor of the isomer obtained by 'double cleavage' can be rationalized by the following mechanism, which has been studied with a ^{13}C-labeled substrate (Scheme 6). The cyclopropylcarbenoid-like intermediate **33**, obtained by 5-*endo-dig* cyclization of the enyne **32**, undergoes a first carbon–carbon bond cleavage leading to the zwitterionic intermediate **34**. This latter can then rearrange in two ways: the cleavage of the carbon–carbon single bond *a* leads to the zwitterion **35** with a primary unstable carbocation ('simple cleavage' process). Subsequent protodemetallation gave diene **36**, having the labeled ^{13}C on the external carbon of the exocyclic unsaturation. In contrast, the cleavage of the bond *b* allows the formation of the intermediate **37**, which is more stable ('double cleavage' process). The diene **38** is therefore formed preferentially.



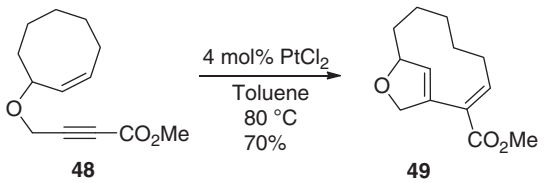
Scheme 6

The structure of 1,3-dienes obtained via the cycloisomerization of 1,6-enynes strongly depends on the metal complex used. The cyclization of enyne **27** leads in the presence of platinum chloride(II) at 80 °C exclusively to the 5-*exo* diene **28** via a double cleavage process (equation 8).[27e] The use of indium chloride(III) leads to a 5/1 mixture of the 5-*exo*/6-*endo* dienes **28**/**41**.[32] The gold(I) complex bearing an electron-rich and hindered phosphine ligand derived from biphenyl, allows the implementation of mild conditions (reactions carried out at room temperature) and leads to a reversed mixture of 5-*exo*/6-*endo* products **40**/**42**.[33] The use of gold nanoparticles supported on TiO_2 showed interesting selectivity in favor of 'single cleavage' pathway, which contrasts to general observation in homogeneous gold catalysis.[34] Finally, one may note that diene formation by a 6-*endo-dig* pathway is not described in the case of catalytic cyclizations effected by many other transition metals (palladium, platinum, iridium, gallium).

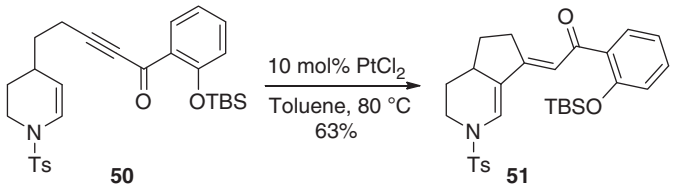


(8)

The mechanism of diene formation by a 6-*endo-dig* process completes the pattern of 1,3-diene syntheses presented earlier in this chapter (Schemes 5 and 7). The intramolecular addition of the alkene to the η^2 complex **19** leads, after rearrangement, to the metallacyclopropylcarbenoid intermediate **21**. The 1,3-alkyl migration provides intermediate **44**, which in turn undergoes a 1,2-alkyl migration to give the zwitterionic species **45**. The final step implies the demetallation leading to the unsaturated six-membered ring **25** bearing a 1,3-diene.

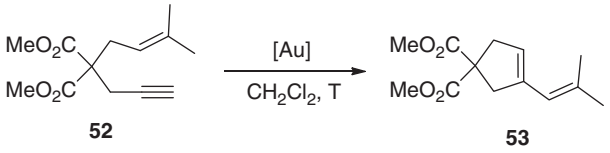


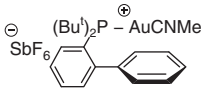
Scheme 7

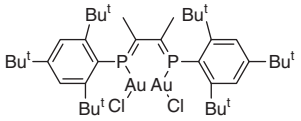


The preparation of 1,3-dienes by rearrangement of 1,6-enynes catalyzed by platinum(II) dichloride was studied by the team of Murai.[25] Among the variety of structures that have been synthesized, these rearrangements were also used for the preparation of vinyl halides. The cycloisomerization of enyne **46** gave the endocyclic halide **47** with a yield of 70% (equation 9). Fürstner's group has shown that this methodology could be applied to oxygen-tethered enynes possessing a large ring (equation 10).[25e] The unsaturated derivative **49** having a methyl ester group on the diene is efficiently prepared from the ether substrate **48**. Dake's group conducted the cyclization of sulfonamide-substituted enyne **50** and obtained azabicyclic derivative **51** with 63% yield (equation 11).[143] Some applications to the total synthesis of natural products will be detailed in Section 5.30.3.1.3.

(9)

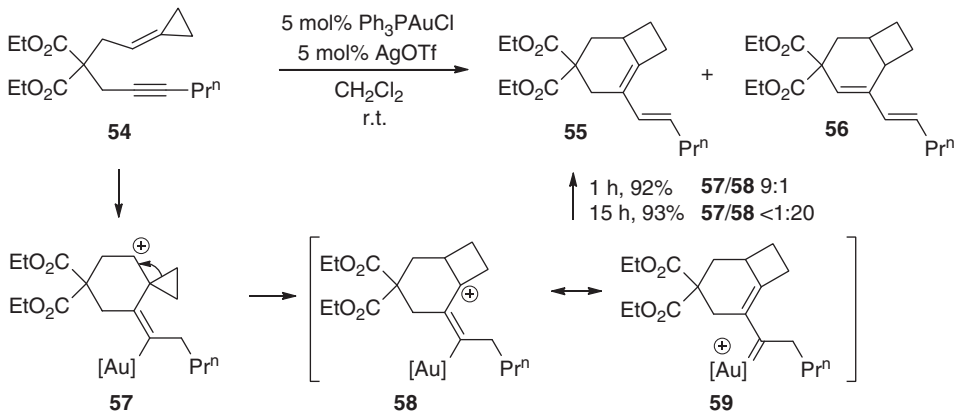






(10)

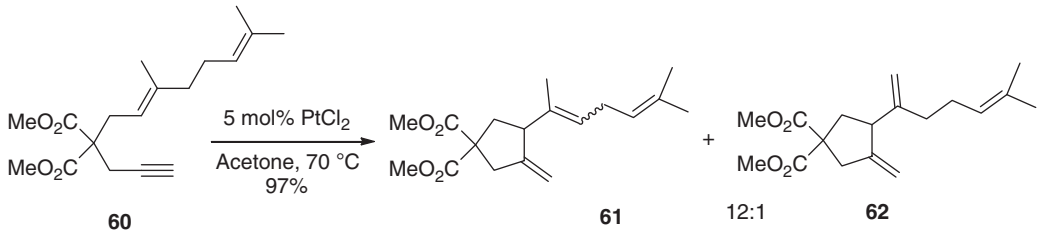
(11)



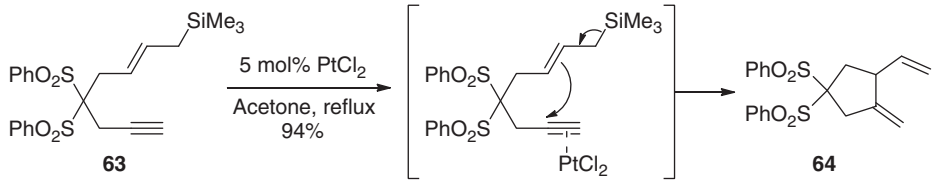
The use of gold(I) complexes is also noteworthy. The cycloisomerization of enyne **52** leading to 1,3-diene **53** has been effected with the gold(I) complex Ph_3PAuCl and silver hexafluoroantimonate $AgSbF_6$, allowing for the *in situ* formation of the reactive cationic species $[Ph_3PAu^+]$ (equation 12). The development of novel complexes, such as the bistriflimidate gold(I) species $[Ph_3PAuNTf_2]$,[27c] eliminates the handling of silver salts. The replacement of PPh_3 by a larger and electron-richer ligand further increases the catalyst activity, such that the cyclization is quantitative at temperatures less than $-26\ ^\circ C$.[35] The preparation of a bimetallic bridged complex has also been recently described and this Au complex was found to be effective too.[36]

[Au]	Temperature, Yield
$Ph_3PAuSbF_6$	r.t., 91%
$Ph_3PAuNTf_2$	r.t., 97%
	−63 to −26 °C, 99%
	r.t., 100%

(12)

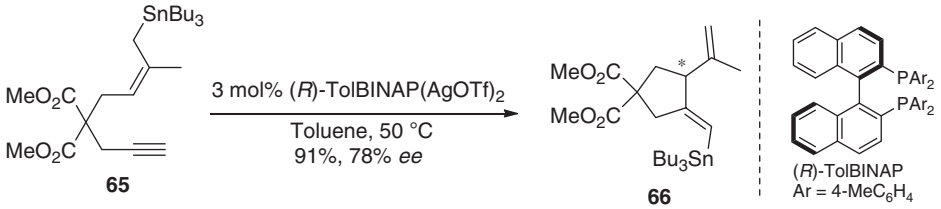


Toste's group has recently described the synthesis of endocyclic 1,3-dienes by gold(I)-catalyzed rearrangement of alkylidenecyclopropanes **54** in dichloromethane at room temperature.[37] The mechanism of the cyclization of enyne **54** is identical to that proposed for other 1,6-enynes. Nevertheless, the presence of the cyclopropane leads to a rearrangement by migration of a carbon–carbon bond in intermediate **57**. Two cyclobutane intermediates **58** and **59** are representative of the process, leading to the mixture **55**/**56** in which diene **55** prevails. When the reaction time is extended to 15 h, the isomerization of diene **55** to **56** is observed **Scheme 8**.



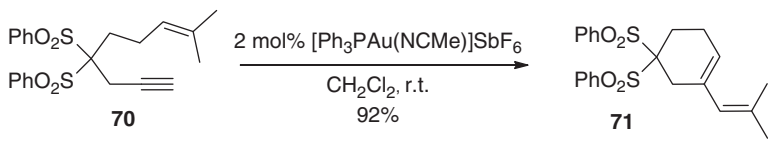
Scheme 8

Few examples of the synthesis of 1,4-dienes are reported in the literature with carbophilic Lewis acids: most of them have been described in the presence of palladium catalysts and rely on metallacycle intermediate.[2] Echavarren's group has described the synthesis of a 1,4-diene via the 5-*exo* cyclization of 1,6-enyne **60**. In the presence of a catalytic amount of platinum dichloride in

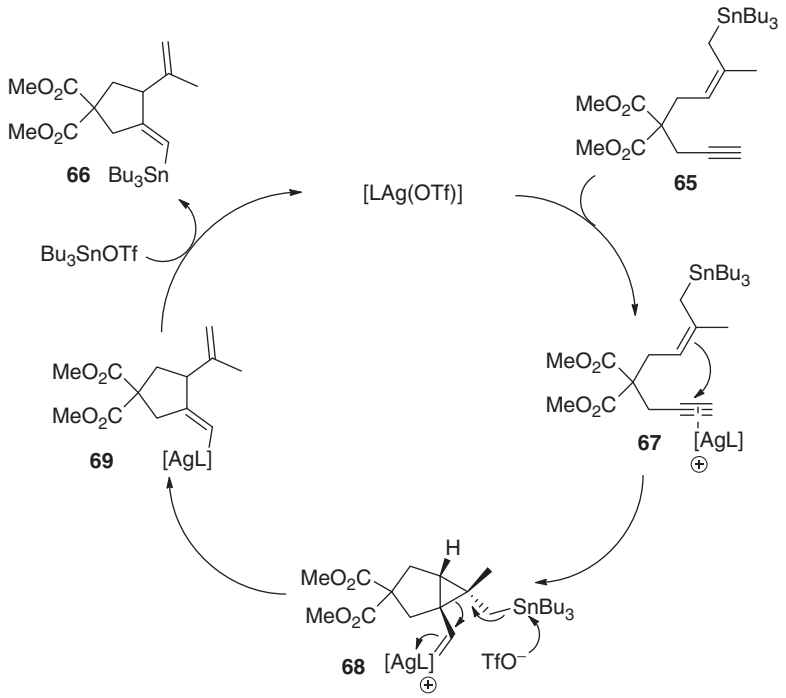


acetone at 70 °C, the substrate **60** is converted to a mixture of the 1,4-dienes **61** and **62** with 97% yield, the ratio of the two isomers being 12:1 (equation 13).[38] This regioselectivity in favor of the compound **61**, obtained after a *β*-elimination step is in complete agreement with the observed selectivity in the presence of a palladium complex.[2] However, the main limitation of this reaction is the use of a specific substrate since only 1,6-enynes bearing a trisubstituted alkene are transformed to 1,4-dienes. Other substrates such as allylic silanes or stannanes have also been cyclized in the presence of platinum or silver complexes. In refluxing acetone, 1,6-enyne **63** is converted in the presence of 5 mol% of platinum dichloride to the silylated 1,4-diene **64** in 94% yield (equation 14).[39] The mechanism of the reaction involves the *anti* attack of the allylsilane on the activated alkyne; this elemental step is promoted by the elimination of the silyl group. The same type of transformation is achievable with allylstannanes: starting, for example, with 1,6-enyne **65**, the use of a bimetallic chiral silver complex afforded the vinylstannane **66** in 91% yield and 78% enantiomeric excess (*ee*) (equation 15).[40] This constitutes the best *ee* for such a transformation, as only moderate results were obtained for the cycloisomerization of nitrogen-tethered 1,6-enynes in the presence of a bimetallic cationic gold catalyst.[41]

(13)

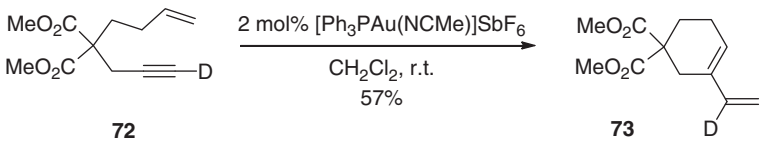


(14)

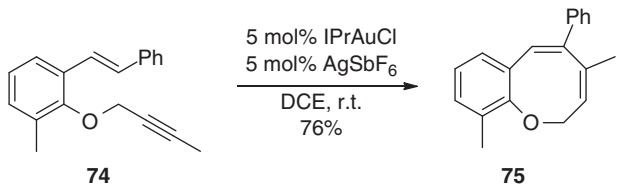


(15)

The authors proposed a mechanism based on the initial η^2-coordination of the alkyne by the silver complex leading to **67** followed by intramolecular nucleophilic addition of the alkene to form the *anti* cyclopropylcarbenoid intermediate **68**. The elimination of the tributylstannyl group and 1,2-migration of an alkyl moiety form the vinyl silver intermediate **69** that leads to the desired product **66** after protodemetallation (**Scheme 9**).

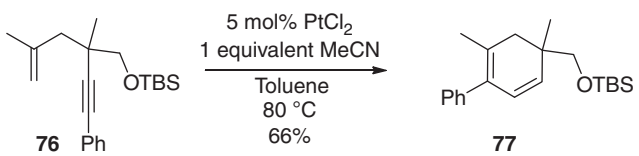


Cationic gold(I) complexes were also used for the rearrangement of 1,7-enynes.[42] In the presence of 2 mol% of the complex $[Ph_3PAu(NCMe)]SbF_6$, the cyclization of enyne **70** embodying a bis(phenylsulfonyl)methane unit led, via a 6-*exo-dig* process, to the diene **71** in 92% yield (equation 16). The activity of such complexes is noteworthy since the reactions are completed within 5 min at room temperature. It was also shown that the cyclization of 1,7-enyne **72** with a deuterium on the alkyne provides only the diene **73**, corresponding to a 6-*exo-dig*-type addition (equation 17). Larger rings are very difficult to obtain under catalytic conditions: one may cite an example from Porco's group, relying on a cycloisomerization of 1,9-enynes in the presence of an almost stoichiometric amount of a gold complex.[43] Recently, a 8-*endo* cyclization has been described for the cycloisomerization of 1,7-enynes such as **74** (equation 18) which cleanly gave the benzoxocine **75** in 76% yield.[44]

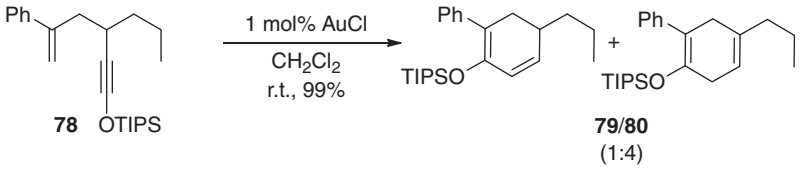


(16)

Scheme 9



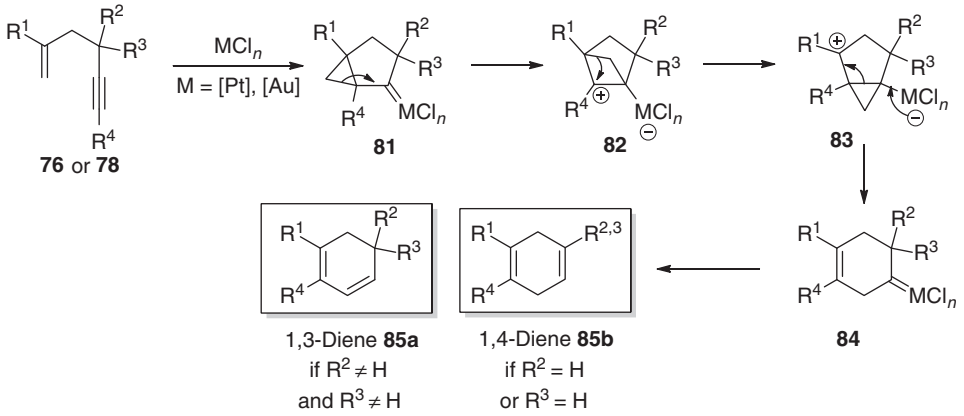
(17)



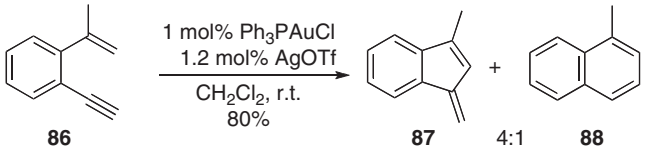
(18)

5.30.3.1.2 Reactivity of 1,5-enynes

Kozmin's group described the cyclization of 1,5-enynes to 1-cyclohexadienes in the presence of platinum(II) and gold(I).[45] The use of 5 mol% of platinum dichloride in a mixture of toluene and a stoichiometric amount of acetonitrile at 80 °C allows the cyclization of enyne **76**, having a quaternary carbon at the propargylic position to proceed; 1,3-diene **77** is synthesized with a yield of 66% (equation 19). When the carbon atom at the propargylic position is not quaternary, the cyclization leads to a mixture of dienes. The use of gold chloride(I) at a low loading (1 mol%) in dichloromethane represents an effective catalytic system, since the cyclic silyl derivatives **79** and **80** are formed in 99% yield as a mixture of the 1,3- and 1,4-diene obtained in a 1/4 ratio (equation 20).

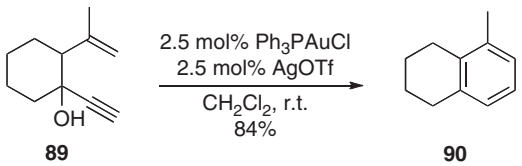


(19)

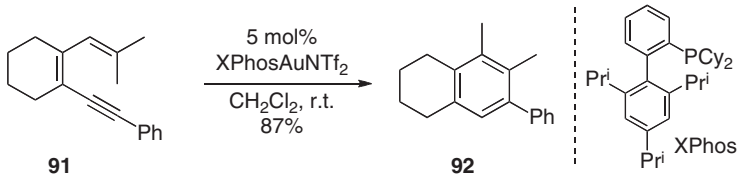


(20)

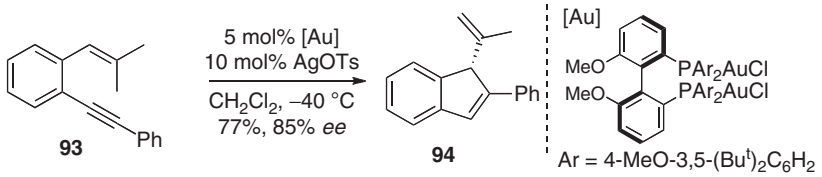
The proposed mechanism involves the coordination of the metal complex on the alkyne followed by formation of cyclopropylcarbenoid **81** (having a similar structure as the intermediate **20** formed from 1,6-enynes – Scheme 5). The 1,2-migration of an alkyl group allow for the production of the carbocationic intermediate **82**, which can be stabilized by the presence of an electron-donor group R^4. It is followed by a new 1,2-migration and demetallation, which leads to 1,3-diene **85** (exclusively obtained if R^2, $R^3 \neq H$), or a mixture of the 1,3- and 1,4-dienes (**85a** and **85b**) if R^2 and/or $R^3 = H$ (Scheme 10). Recent DFT calculations were in excellent agreement with the experimental observations and could explain the effect of alkynyl, alkenyl, and propargylic substituents on the outcome of the reaction.[46]



Scheme 10

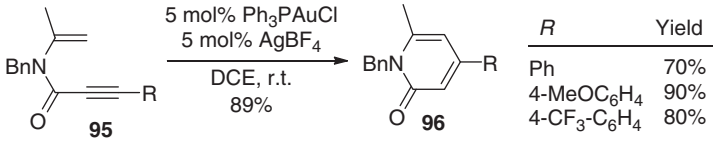


The synthesis of indenes, naphthalenes, and aromatic derivatives has also been described via cycloisomerization reactions of substituted 1,5-enynes with aromatic backbones. Following initial work of Dankwardt using silyl enol ethers in the presence of a platinum catalyst,[47] the synthesis of indenes and aromatic substituted rings was performed in the presence of gold. Cycloisomerization of the 1,5-enyne **86** in the presence of a cationic Au(I) complex led to a mixture of the indenyl and naphthyl derivatives **87** and **88** (resulting from 5-*exo* and 6-*endo* cyclization processes) in a 4:1 ratio and in 80% yield (equation 21).[48] Similarly, the tetrahydronaphthalene derivative **90** could be obtained starting from 3-hydroxy-5-ene-1-yne **89** in 84% yield according to a procedure implying a cyclization followed by water elimination (equation 22).[49] This methodology was recently applied to the synthesis of highly substituted benzenes. Substrate **91** is cleanly converted to the phenyl derivative **92** via a 6-*endo* cycloisomerization in 87% yield in the presence of a gold(I) complex derived from the XPhos ligand (equation 23).[50] It is noteworthy that a similar approach had been used in the specific case of cycloisomerization of 1,5-enynes derived from arene–chromium complexes.[51] The synthesis of indenes was nicely performed enantioselectively in the presence of a chiral gold(I) complex derived from a hindered MeOBIPHEP analog. The *ortho*-(alkynyl)styrene **93** thus provided 1*H*-indene **94** in 77% yield and 85% *ee* (equation 24).[52]

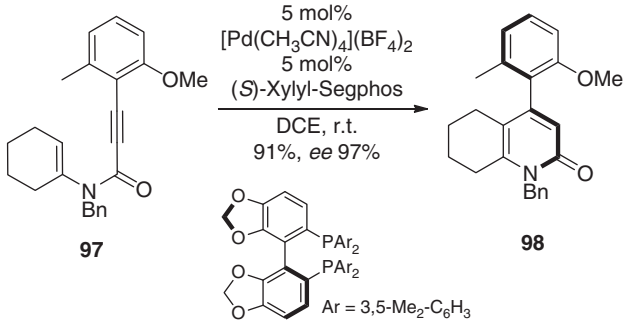


(21)

(22)

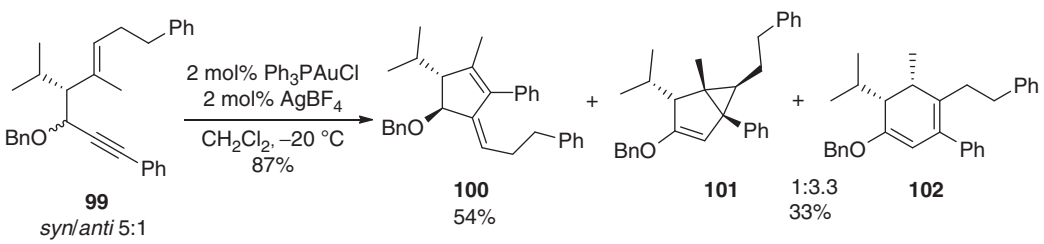


(23)



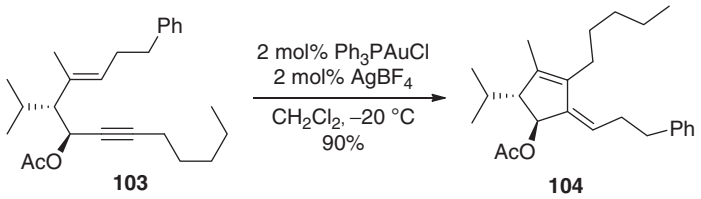
(24)

The cycloisomerization reaction of 1,5-enynes of the *N*-alkenylalkynylamide type has only recently been described by the group of Tanaka.[53] The synthesis of 2-pyridones **96** is performed via 6-*endo* cyclization and is catalyzed by cationic complexes of gold(I) in good to excellent yields (equation 25). The same authors also developed an enantioselective version of this reaction leading to chiral 2-pyridones in the presence of a dicationic palladium catalyst bearing a chiral atropisomeric diphosphine. Thus, the 1,5-enyne **97** is converted into compound **98** in 96% yield and 94% *ee* (equation 26).[54] Recently studies implying chiral gold catalysts instead of palladium ones have been performed in order to find suitable complexes for such enantioselective transformations. The use of cationic gold(I) complexes derived from DTBM-Segphos were suitable and afforded the axially chiral 4-aryl-2-quinolinones in *ee*s of up to 61%.[55]



R	Yield
Ph	70%
4-$MeOC_6H_4$	90%
4-CF_3-C_6H_4	80%

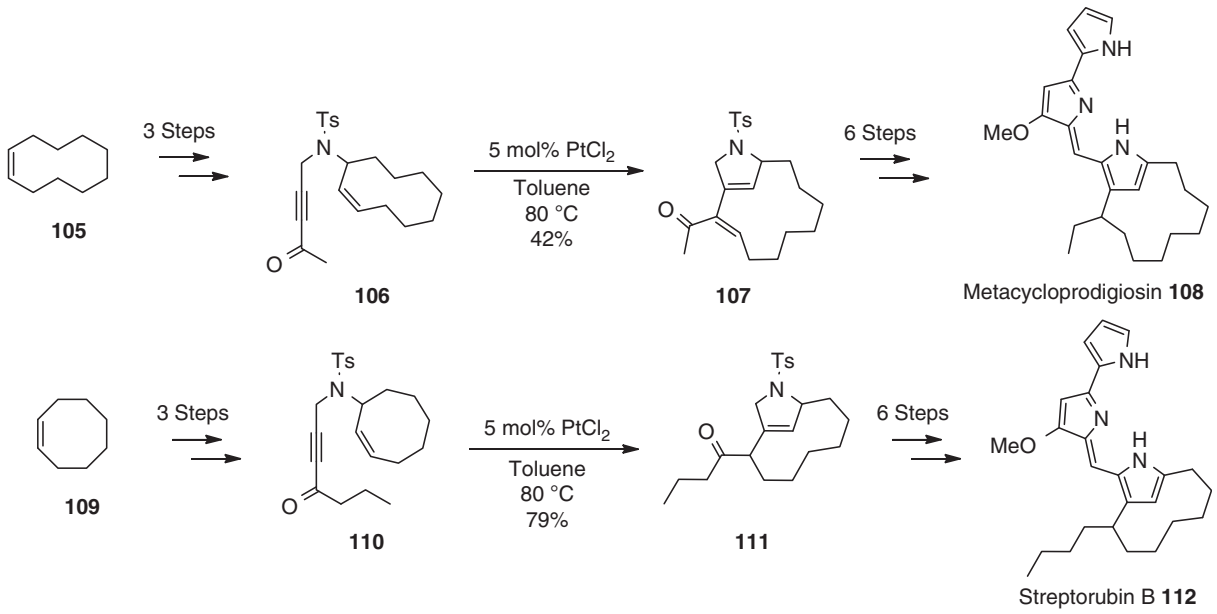
(25)



(26)

However cycloisomerization reactions are very substrate-dependent and often lead to mixtures of products resulting from competitive cyclization mechanisms. The case of the cycloisomerization of the 1,5-enyne **99** illustrates this observation.[56] The cyclization of **99** in the presence of a cationic gold complex gives a mixture of three products: a five-membered cyclic 1,3-diene **100**, a bicyclo[3.1.0]hexene derivative **101**, and a cyclohexadiene **102**. The cyclic 1,3-diene was obtained as a major compound in 54% yield, whereas **101** and **102** were isolated together with a 33% yield and in a ratio of 1:3.3 in favor of the cyclohexadiene **102** (equation 27).

(27)

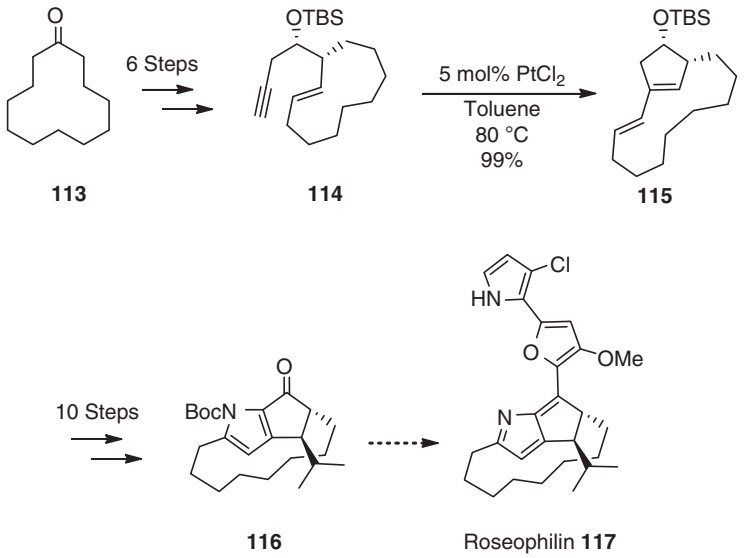


(28)

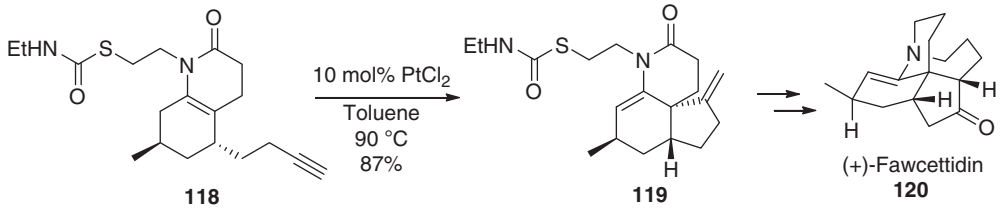
It is noteworthy that small modifications of the substrate may influence the outcome of the reaction. Indeed, compound **103** is converted to the functionalized cyclopentene **104** in 90% yield via a 5-*exo* cycloisomerization process.[56]

5.30.3.1.3 Applications in total synthesis

Cycloisomerization reactions have found several applications in total synthesis. The preparation of a 1,3-diene, as described in Section 5.30.3.1.1, was determined as a key step by Fürstner's group for the synthesis of two tetracyclic molecules bearing three pyrroles moieties, metacycloprodigiosin **108** and streptorubin B **112** (Scheme 11).[57] These two analogous molecules show *in vitro* antibiotic and immunomodulatory activities. Metacycloprodigiosin **108** and streptorubin B **112** were prepared in 10 steps from commercial alkenes, cyclodecene **105** and cyclooctene **109**, respectively. The synthetic routes involve a cycloisomerization step of the nitrogen-tethered 1,6-enynes **106** and **110** catalyzed by platinum dichloride. Dienes **107** and **111** are obtained in good yields (42% and 79%, respectively). Six additional steps then lead to the synthesis of the heterocyclic compounds **108** and **112**.

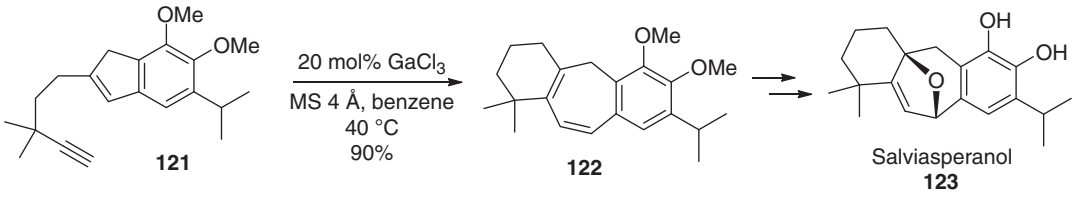


Scheme 11



This strategy of obtaining a 1,3-diene was subsequently also used in the formal synthesis of roseophilin **117**, a pentacycle with conjugated pyrroles and a furan ring (Scheme 12).[58] This molecule produced by *Streptomyces griseoviridis* shows some antitumoral properties, particularly in the treatment of leukemia and cancers of the skin. The enantioselective synthesis of 1,6-enyne **114** occurs in six steps from the commercial dodecanone **113**. The cycloisomerization key step was performed in the presence of a catalytic amount of platinum dichloride, leading quantitatively to 1,3-diene **115**, which could be converted into a key derivative **116** via a 10-step synthetic sequence. The activity of platinum complexes in such a clean cyclization process was also illustrated in the synthetic approach of botrydial, an antibiotic produced by a sesquiterpene fungus *Botrytis cinerea*.[59]

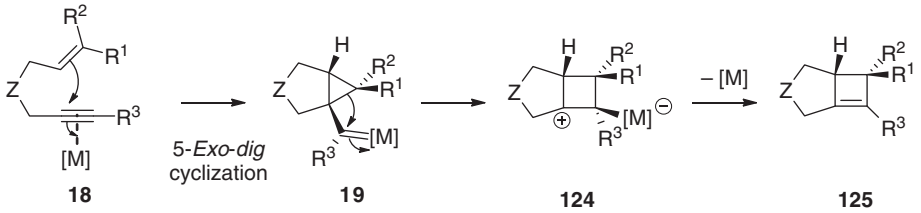
The formation of a 1,4-diene in the presence of a platinum complex also found an application in total synthesis as illustrated by the example given in Scheme 13.[60] The total synthesis of (+)-fawcettidin is described and implies the cycloisomerization of enyne **118**, leading very cleanly to the tricyclic structure **119** in 87% yield.



The applications of the cycloisomerization of enynes were not limited to the use of platinum complexes. The total synthesis of (±)-salviasperanol **123** was described by the Sarpong group and nicely takes advantage of the chemistry developed in the presence of gallium.[61] The key step of this synthesis is the reaction of enyne **121** in the presence of gallium trichloride, which leads to the tricyclic 1,3-diene **122** in an excellent yield of 90% (Scheme 14). The same group has described the formal synthesis of cortistatin A according to the same methodology, implying this time platinum dichloride as the catalyst.[62]

Scheme 12

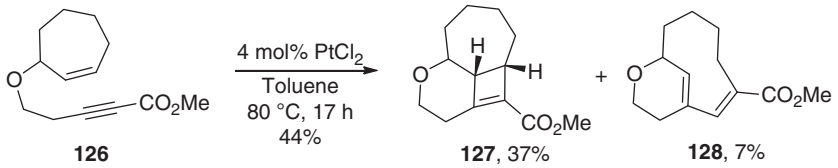
Scheme 13



Scheme 14

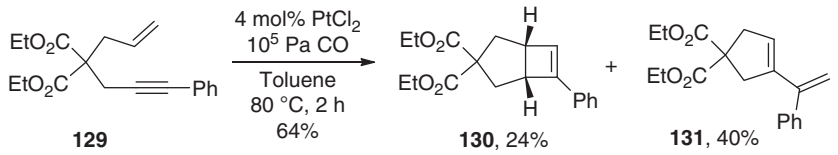
5.30.3.2 Formation of Bicyclic Derivatives via Cycloisomerization Reactions

5.30.3.2.1 Bicyclo[3.2.0]heptene formation

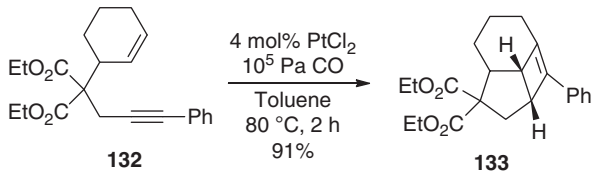


In addition to the formation of 1,3-dienes by single or double cleavage, the cyclization of 1,6-enynes by a 5-*exo-dig* process can lead to the synthesis of bicyclo[3.2.0]heptenes, which formally may be considered as a [2 + 2] cycloaddition (Scheme 15). As presented at the beginning of this chapter (Scheme 7), the postulated mechanism involves a classic addition of the alkene to the activated alkyne **18** (η^2-complex formation) via a 5-*exo-dig* process in the classic case of 1,6-enynes. The resulting cyclopropylcarbenoid intermediate **19** undergoes a 1,2-migration of an alkyl group, leading to the cationic intermediate **124**. The demetallation step leads to the formation of bicyclo[3.2.0]heptene **125**. A theoretical study by DFT calculations of the cycloisomerization of 1,6-enynes with $(PH_3)AuCl$ or $PtCl_2$ was conducted and confirms this hypothesis.[63]

Fürstner's group first highlighted the activity of platinum dichloride in the synthesis of tetrahydropyranic derivatives.[25e] The cyclization of the oxygen-tethered enyne **126** led to the formation of a mixture consisting of a polycyclic derivative **127** (isolated in 37% yield) and the 1,3-diene **128** (7%) (equation 29). The reactivity of the catalytic system could be increased by performing the reaction under an atmosphere of carbon monoxide (σ-donor and π-acid ligand), which contributes to the enhancement of the

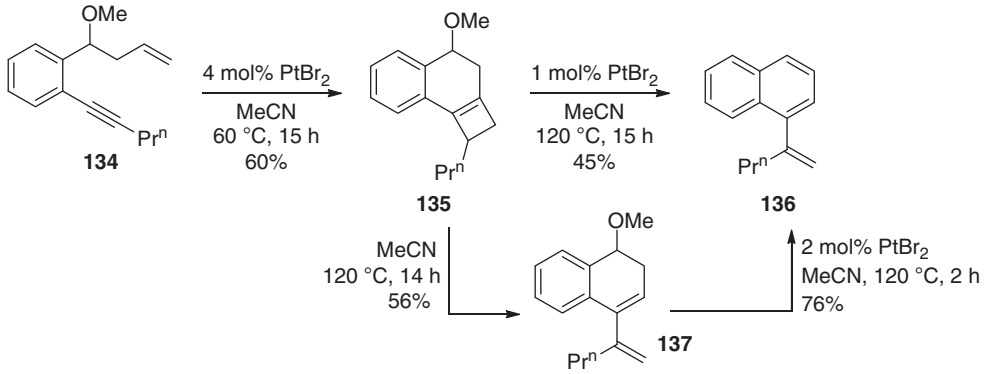


Scheme 15

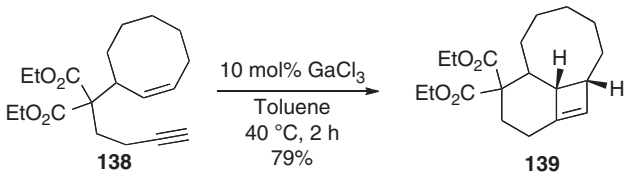


electrophilicity of the platinum complex.[64] The cyclobutene **130** and diene **131** were thus synthesized in 24% and 40% yield, respectively, from the substrate **129**.[65] High selectivity in favor of the tricyclic derivative **133** was observed in the cycloisomerization reaction of **132** (equation 31).

(29)

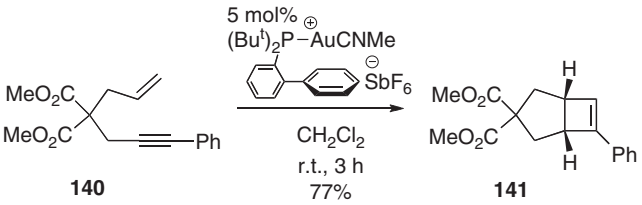


(30)

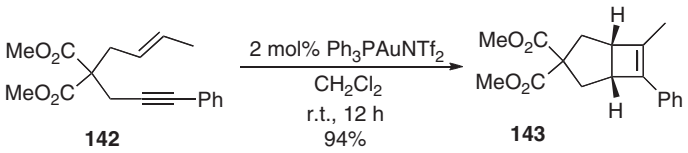


(31)

The Trost group has hypothesized that the synthesis of 1,3-dienes might proceed via a cyclobutenyl intermediate.[66] This hypothesis has been confirmed by the team of Yamamoto in the study of the cycloisomerization of enyne **134** in the presence of platinum dibromide (Scheme 16). This substrate is initially converted into cyclobutene **135** in 60% yield. The opening of the latter via [2 + 2] cycloreversion was performed without metal at high temperature giving the 1,3-diene **136**, which undergoes methanol elimination in the presence of 2 mol% of $PtBr_2$ to form the naphthalene **137**. It is also possible to obtain product **136** directly from the cyclobutene **135** in the presence of a catalytic amount of platinum(II).

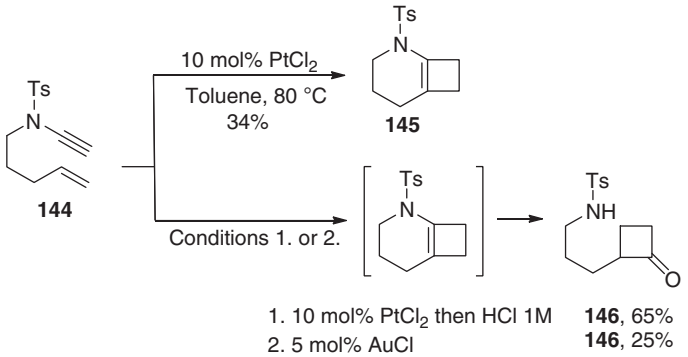


Scheme 16



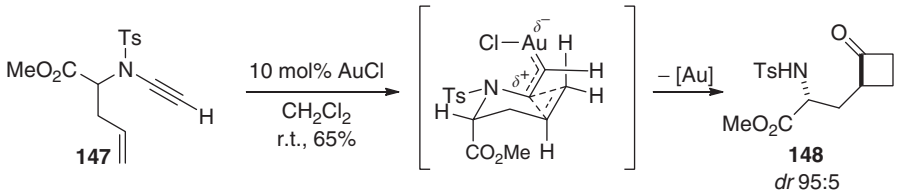
The cycloisomerization of 1,7-enynes has also been described with other carbophilic metal complexes. For example, Murai's group has efficiently obtained the tricyclic derivative **139** under mild conditions via the cycloisomerization reaction of enyne **138** in the presence of 10 mol% of gallium trichloride (equation 32).[67] The use of gold(I) complexes is also very effective: the cationic complex **43** allows for the rapid preparation of bicyclic derivative **141** from the enyne **140** in 77% yield.[68] Another cationic catalyst, the gold(I) bistriflimidate, could be used for the highly efficient cyclization of enyne **142** to the methyl-substituted bicyclic derivative **143**.

(32)

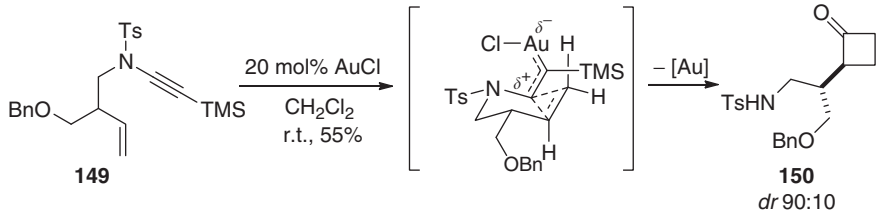


(33)

(34)



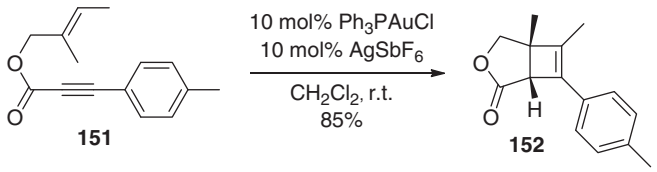
The nitrogen-tethered enynes exhibit specific reactivity as depicted in equations 35 and 36. The cyclization of a 1,7-enyne in the presence of 10 mol% platinum dichloride gives the tosyl-protected 2-azabicyclo [4.2.0] octene **145** in 34% yield.[69] The addition of a 1 mol l^{-1} solution of hydrochloric acid to the crude reaction then allows for the preparation of a wide variety of cyclobutanone-amine derivatives formed by hydrolysis; for example, ketone **146** was synthesized with an overall yield of 65%. The use of a catalytic amount of gold(I) chloride also allows for the direct production of cyclobutanone **146** in moderate yield (equation 36).[70]



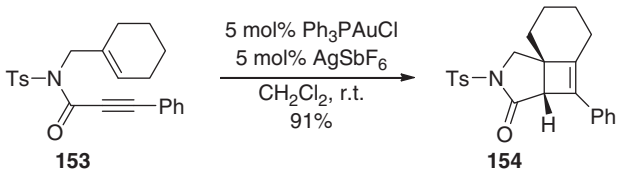
(35)

(36)

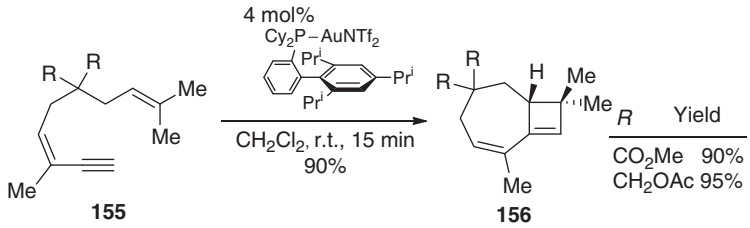
When a nitrogen-tethered enyne is substituted at the α- or β-position to the nitrogen atom, the reaction was found to be highly diastereoselective.[70] For example, ketone **148**, prepared efficiently by cyclization of substrate **147**, is obtained in excellent 90% diastereomeric excess (*de*). The same trend is observed for the cycloisomerization of compound **149** bearing benzyl ether at the β-position to the nitrogen atom: the reaction conducted in the presence of 20 mol% of gold(I) chloride leads to the derivative **150** with a yield of 55% and a *de* of 80%. In both cases, chair-like transition state models have been proposed and may account for the observed diastereoselectivity.



(37)

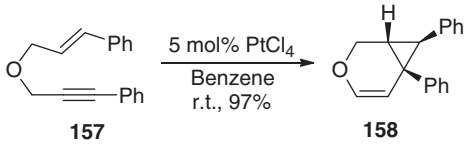


(38)

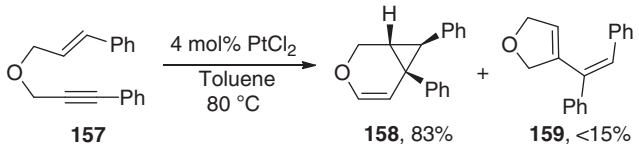


Cycloisomerizations of 1,6-enynes bearing an ester or amide function were also recently studied in the presence of gold catalysts.[71] The use of 10 mol% of a catalyst system combining the precursor gold(I) complex Ph_3PAuCl and $AgSbF_6$ in dichloromethane at room temperature allows ester **151** to be converted into bicyclo[3.2.0]hept-6-en-2-one **152** in 85% yield (equation 39). Compound **153** bearing an endocyclic alkenyl moiety has also been stereoselectively transformed into the tricyclic derivative **154** with a very good performance (equation 40). Once again, large rings are difficult to obtain via cycloisomerization reactions of enynes. The reaction of 1,8-enyne **155** in the presence of a highly hindered cationic biaryl-phosphine gold catalyst afforded the bicyclic derivative **156** in up to 90% yield (equation 41).[72] It is noteworthy that the substitution of the alkynyl side chain is important, as a mixture of stereoisomers was obtained when the alkynyl moiety carries a *n*-pentyl group.

(39)

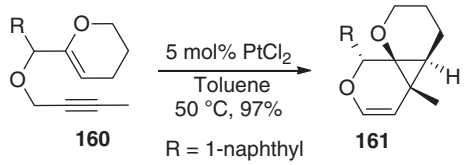


(40)



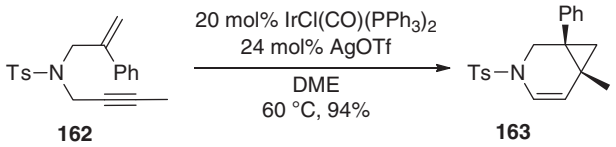
(41)

5.30.3.2.2 Bicyclo[4.1.0]heptenes and bicyclo[3.1.0]hexenes formations

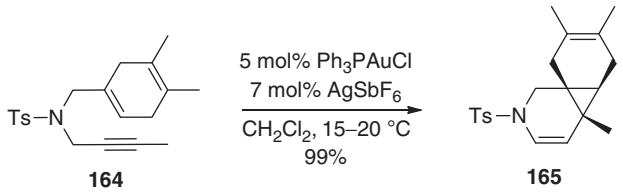


The reaction of oxygen-tethered 1,6-enynes in the presence of platinum tetrachloride at room temperature in benzene was originally described by Blum's group, leading to derivatives of 3-oxabicyclo[4.1.0]heptene.[73] For example, as presented in equation 42, the bicyclic derivative **158**, derived from the ether **157** was synthesized in 97% yield. Following this work, the group of Fürstner studied the activity of platinum dichloride in the synthesis of heterocyclic functionalized cyclopropanes, highlighting the importance of the nature of the enyne for the course of the reaction. Unlike carbon-tethered enynes, whose cyclization leads exclusively to the formation of 1,3-dienes, the cyclization of enyne **157** afforded a mixture of bicycle **158** as the major product and a small amount of 1,3-diene **159** (equation 43).[74] The group of Echavarren also described the synthesis of **161** by a completely diastereoselective rearrangement of ether **160** (equation 44).[75]

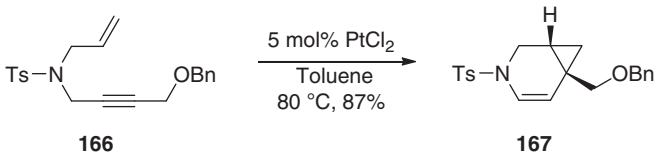
157 **158** (42)



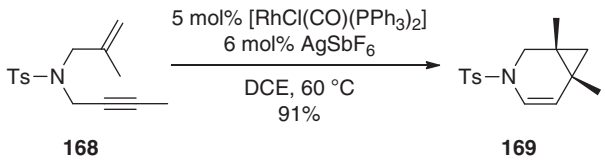
157 **158**, 83% **159**, <15% (43)



160 **161** (44)

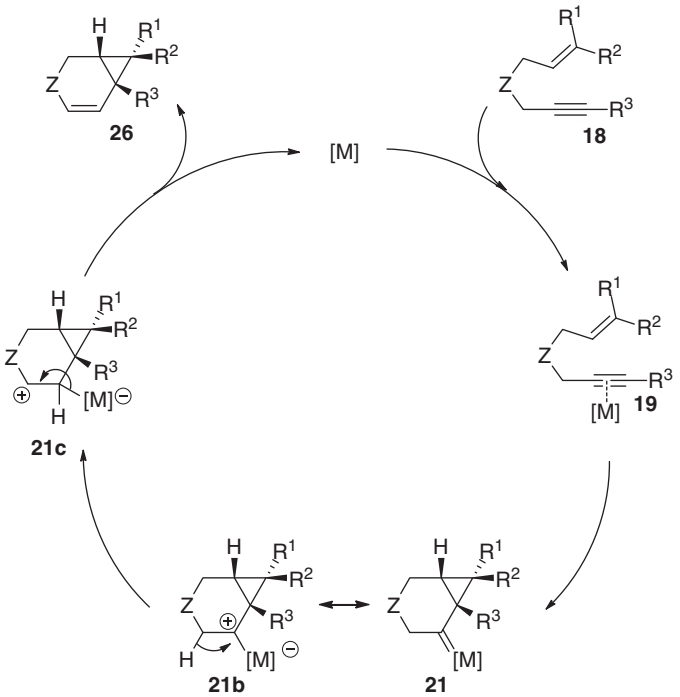


Iridium(I) complexes have also proven effective in the synthesis of bicyclo[4.1.0] heptenes. The use of a catalyst system combining $[IrCl(CO)(PPh_3)_2]$ and silver triflate in the cyclization reaction of the sulfonamide-based 1,6-enyne **162** in dimethoxyethane at 60 °C afforded the bicyclic derivative **163** in excellent 94% yield (equation 45).[76] The preparation of such polycyclic compounds was also catalyzed by gold(I) complexes.[27a] Indeed, it has recently been described that a rapid and quantitative conversion of compound **164** into azatricyclic diene **165** takes place in the presence of the catalyst system $Ph_3PAuCl/AgSbF_6$ in dichloromethane at room temperature (equation 46).[77] Another enyne such as **166**, bearing a heteroatom at the propargylic position could be efficiently transformed to the bicyclic derivative **167** (equation 47).[78] A rhodium complex associated with silver salts showed an activity similar to that of the iridium complexes.[79] For example, the cycloisomerization of **168** led to the bicyclic derivative **169** in 91% yield.



162 **163** (45)

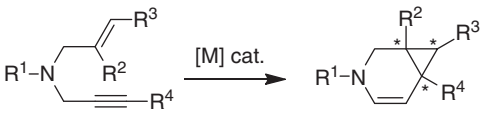
164 **165** (46)



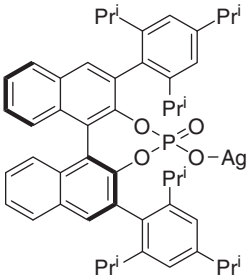
166 **167** (47)

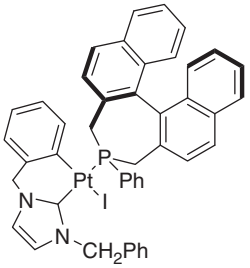
168 **169** (48)

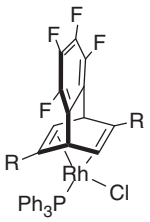
The observed stereoselectivity in the reaction can be rationalized by considering the following catalytic cycle (Scheme 17), which is reminiscent of the intermediates depicted in Scheme 5. In a first step, the coordination of the metal center leads to the η^2-alkyne complex **19**. The nucleophilic attack via a 6-*endo-dig* process of the alkyne allows for the completely diastereoselective formation of the cyclopropylmetalcarbenoid intermediate **21**, which may also be represented in the form of the zwitterion **21b**. The next step is a 1,2-hydride transfer leading to the cationic intermediate **21c**. The stabilization of **21c** in the presence of a heteroatom, by participation of a lone pair of the latter, has been hypothesized. Modeling by DFT calculations, performed by the group of Soriano and Marco-Contelles, confirms this participation of the heteroatom.[80,81] This intermediate then evolves to the bicyclic product **26** after the elimination and regeneration of the metal complex.

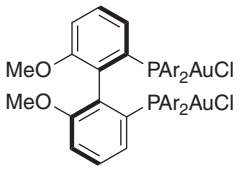


Scheme 17









Enantioselective versions of the synthesis of bicyclo[4.1.0]heptenes have been reported in the literature in the presence of platinum, rhodium, iridium, or gold complexes and some examples are presented in Table 1. The first stereoselective synthesis of bicyclo[4.1.0]heptenes was described by Shibata's group in the presence of iridium complexes for nitrogen-tethered 1,6-enynes.[76] A chiral catalytic system consisting of the $[Ir(cod)Cl]_2$ dimer, a silver salt, and (*R*)-Tol-BINAP led to the bicyclic product in moderate to good enantioselectivities, depending on the substrate (Table 1, entries 1–3). However, this method only applies to nitrogen-tethered 1,6-enynes. Another approach for the synthesis of the same derivatives using Vaska's catalyst and a chiral silver salt (AgTRIP) gave better results in terms of enantioselectivity (Table 1, entry 4).[82]

Other chiral catalytic systems using platinum, rhodium, and gold have also been reported in the literature. In the presence of a square-planar platinum complex with an achiral bidentate ligand and the monodentate ligand (*S*)-PhBINEPINE, Marinetti's group described the synthesis of nitrogen-containing bicyclic adducts in 90% yield and an *ee* of 96% (Table 1, entry 5).[83] Taking advantage of chiral dienes bearing electron-poor substituents as ligands to Rh(I), the group of Hayashi has recently developed a synthesis of bicyclo[4.1.0]heptenes in good to excellent *ee* (Table 1, entry 6).[84] Meanwhile, either a gold bimetallic complex bearing a bulky ligand derived from MeOBIPHEP[85] or monometallic gold complexes carrying a Taddol-related ligand[86] were particularly efficient for such asymmetric transformations (Table 1, entries 7 and 8).

Rhodium- and gold-based catalytic systems were also compatible with oxygen-tethered 1,6-enynes. Substrate **170** was converted into the bicyclo[4.1.0] heptene **171** in 56% yield and an *ee* of 96% (equation 49). The use of a bimetallic gold complex also allowed the synthesis of pentasubstituted bicyclo[4.1.0]heptenes starting from trisubstituted alkenes. When the reaction was carried out at 0 °C in the presence of $AgNTf_2$, product **173** was obtained in a yield of 36% and excellent *ee* of 99% (equation 50). Although yields are modest, it is important to note that this methodology is one of the few to obtain pentasubstituted cyclopropanes with such high *ee*'s.[87] The use of a chiral gold complex related to Taddol allowed for the preparation of bicyclo[4.1.0]heptenes **158** in 72% yield and 83% *ee* (equation 51). In the presence of a chiral rhodium catalyst, the bicyclic compound **175** bearing a *gem* diphenyl group at the allylic position could be synthesized from the enyne **174** in 86% yield and an *ee* of 90% (equation 52).

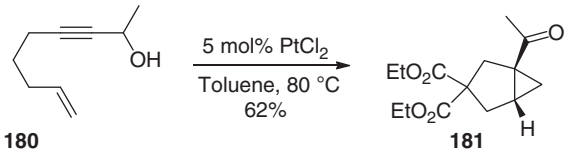
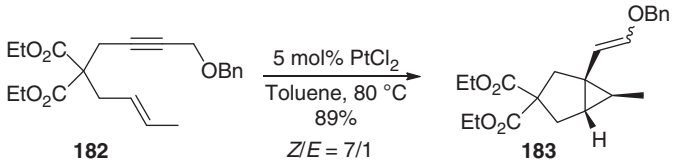
(52)

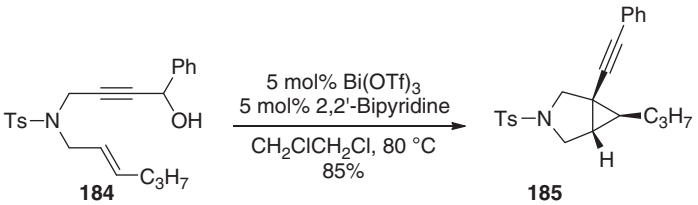


One remarkable total synthesis has recently appeared in the literature based on this methodology (**Scheme 18**). GSK1360707 (**179**), developed by the pharmaceutical company GlaxoSmithKline, is a potent inhibitor of reuptake of the neurotransmitters serotonin, norepinephrine, and dopamine.[88] Inspired by the strategy developed by the group of Elitzin,[89] Fürstner's team proposed a total synthesis in four steps starting from 3-chloro-2-(chloromethyl)prop-1-ene **176**. The preparation of 1,6-enyne **177** was followed by asymmetric cyclopropanation in the presence of the chiral gold(I) complex carrying a Taddol-related ligand.[90] The cyclic Cbz-protected derivative **178** was obtained in high yield and 95% *ee*. The synthesis ends via a hydrogenation/deprotection of the Cbz group step followed by the formation of the hydrochloride salt GSK1360707 **179**.

In the case of 1,6-enynes bearing a carbon- or nitrogen-tethered chain, the 6-*endo* cyclization is not always observed and a 5-*exo* cycloisomerization may occur. The modification of the substituents, especially the propargylic position, may therefore induce the formation of bicyclic cyclopropanes. The formation of functionalized bicyclo[4.1.0]hexanes such as **181** and **183** has been performed in the presence of platinum dichloride in toluene. Depending on the substitution, the cycloisomerization reaction leads either to the bicyclic aldehyde **181**[91] or the enol ether **183**[78] (as a *Z*/*E* mixture) (equations 53 and 54). The alkynylbicyclohexene **185** was synthesized in the presence of a combination of $Bi(OTf)_3$ and 2,2′-bipyridine in good yield. This rare example of a 5-*exo* cycloisomerization mode with an *N*-tethered 1,6-enyne may be rationalized by a dual complexation of

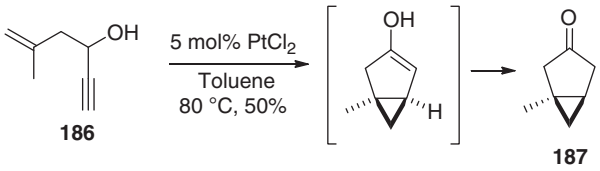


Scheme 18

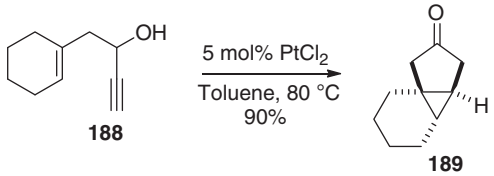


the bismuth catalyst to the alkyne and the alcohol, the whole process being considered as a dehydrative alkynylcyclopropanation (equation 55).[92]

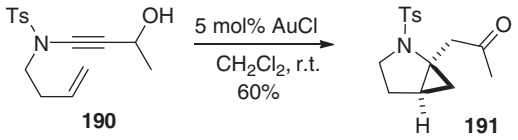
(53)



(54)

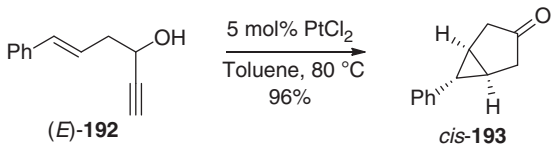


(55)

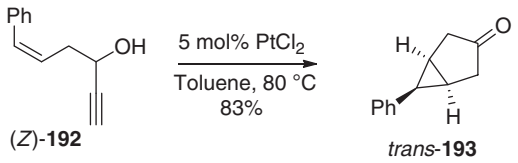


In the particular case of 1,5-enynes, cycloisomerization is observed even in the absence of a linking heteroatom. The cyclization of enynes substituted in the propargylic position has been independently studied by the groups of Fürstner and Malacria.[91,93] In the presence of platinum dichloride in toluene at 80 °C, the unprotected propargyl alcohol **186** has been converted to cyclopentanone **187**, via the enol intermediate, in 50% yield (equation 56). The substrate **188**, which has an endocyclic alkenyl function is transformed into the tricyclic compound **189** in excellent yield under the same reaction conditions (equation 57). The activity of gold chloride was also highlighted, the nitrogen bicyclic derivative **191** being obtained from the enyne **190** (equation 58).[70]

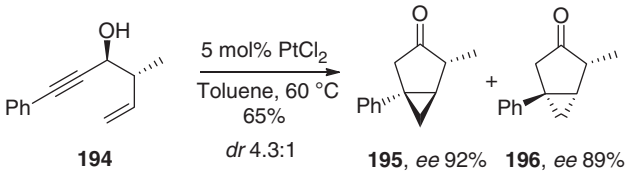
(56)



(57)

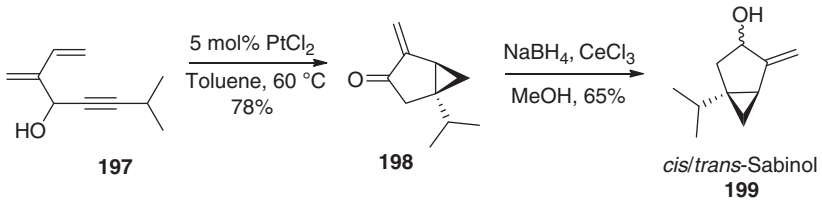


(58)

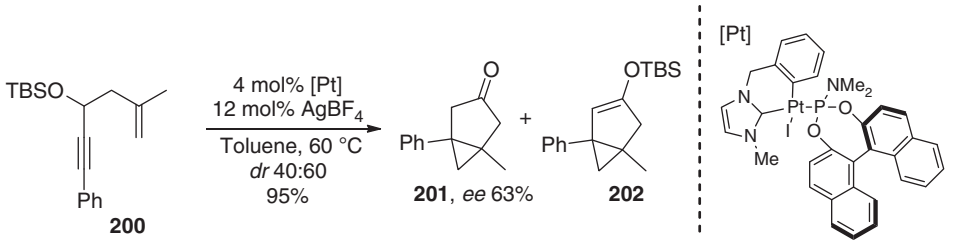


This reaction is totally stereospecific as illustrated in equations 59–61. Indeed, one may observe a direct correlation between the stereochemistry of the double bond within the starting alkene and the stereostructure of the final bicyclic compound. The alcohol (*E*)-**192** could be transformed into the bicyclo[3.1.0]hexanone *cis*-**193** in 96% yield, whereas its counterpart (*Z*)-**192** is cleanly cyclized into *trans*-**193** with a yield of 83%.[93] Optically pure bicyclic derivatives such as **194** were also engaged in the cycloisomerization process and led to diastereomers **195** and **196** in a ratio of 4.3:1 and *ee*'s of 92% and 89%, respectively (equation 59).[91]

(59)

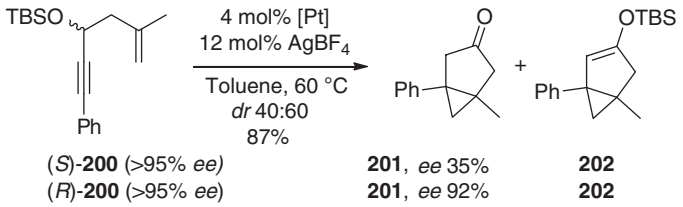


(60)



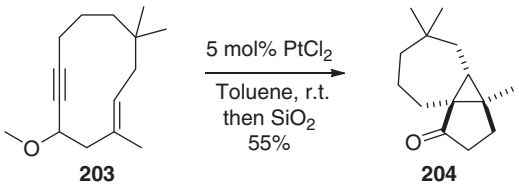
(61)

This reaction has been applied to the total synthesis of *cis* and *trans* sabinols, which are characteristic of the terpenes present in many *Artemisia*, *Juniperus*, and *Thuja* species (Scheme 19). The key step of the three-step process starting from 4-methylpent-2-ynal implies a Pt-catalyzed cycloisomerization reaction of **197** and leads to bicycle **198** in 73% yield. Further reduction affords product **199**, either as the *cis* or the *trans* isomer.

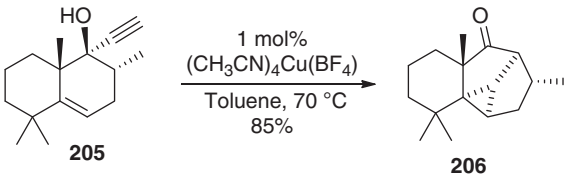


Scheme 19

An enantioselective version of this reaction has been proposed in the presence of chiral platinum complexes for the 1,5-enyne **200** bearing a silyl-protected alcohol at the propargylic position.[94] The reaction of **200** afforded a mixture of two products, the bicyclo [3.1.0]hexanone **201** and the corresponding silylated enol ether **202** in a 40:60 ratio and in 95% yield. The *ee* measured for the ketone **201** was found to be 63% (equation 62). Inspired by some results from the groups of Fürstner and Fehr,[91,95] the cycloisomerization reaction was then initiated with the (*R*) and (*S*)-configured substrate in the presence of the same chiral platinum catalyst, respectively. Starting from (*S*)-**200**, the ketone **201** was obtained in a modest *ee* of 35%, whereas it is formed with a much better *ee* of 92% from (*R*)-**200**. This outcome highlights a strong match/mismatch effect between the substrate and the platinum catalyst (equation 63).

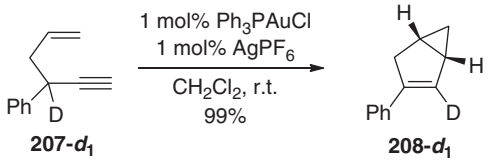


(62)

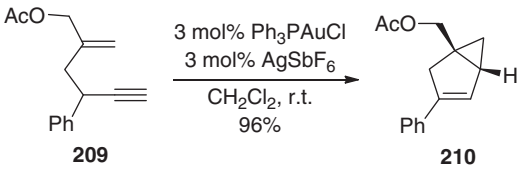


(63)

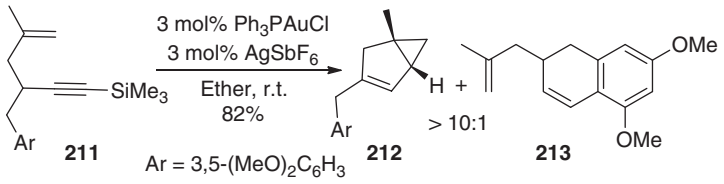
A transannular version of the cyclopropanation reaction has been performed in the presence of platinum dichloride in toluene at room temperature.[93b] The tricyclic compound **204** was synthesized from the 1,5-enyne **203** in 55% yield (equation 64). Another elegant example has been described for the cyclization of 5-en-1-yn-3-ols in the presence of a Cu(I) catalyst.[95b] The reaction of enyne **205** in the presence of $[Cu(CH_3CN)_4](BF_4)$ cleanly led to the formation of the tetracyclic ketone **206** in 85% yield.



(64)

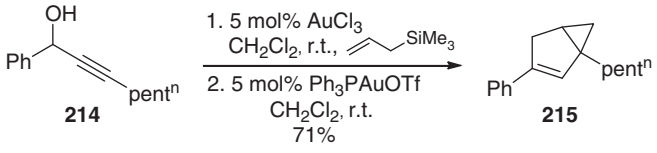


(65)

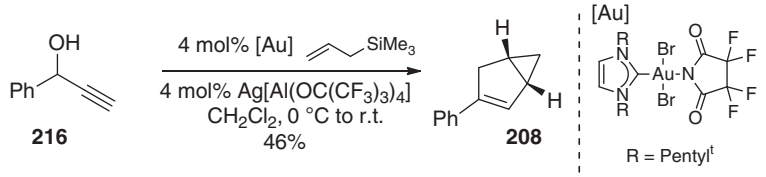


The formation of bicyclo[3.1.0]hexenes is not limited to 1,5-enynes substituted by hydroxyl or methoxy moieties. The enynes **207** and **209** are converted into bicyclo[3.1.0]hexenes **208** and **210** in the presence of triphenylphosphine gold(I) chloride and silver salts in dichloromethane at room temperature in 99% and 96% yields, respectively (equations 66 and 67).[96] In addition, the rearrangement of enyne **207-*d*$_1$**, which is monodeuterated at the propargylic position, leads to the product **208-*d*$_1$** whose structure reveals the 1,2-migration of the deuterium atom. The cycloisomerization of **211** bearing an electron-rich benzyl substituent leads to the formation of the bicyclic derivative **212** in good yield (equation 68).[97] It is noteworthy that the trimethylsilyl group was cleaved under these reaction conditions and that a byproduct **213**, resulting from the gold-catalyzed hydroarylation of the alkynyl part[98] was detected as a minor product.

(66)

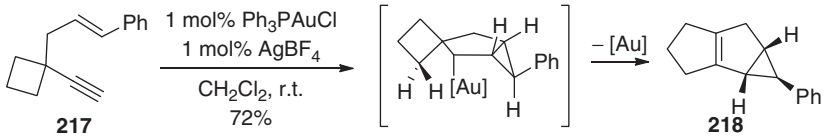


(67)

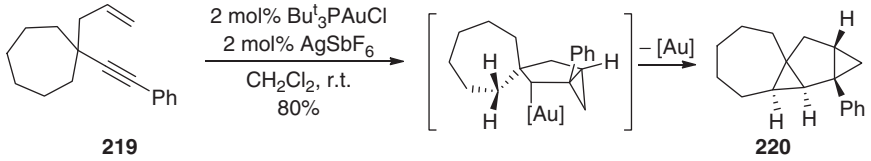


(68)

Similar carbon-tethered substrates may be involved in cycloisomerization reactions, which are synthesized *in situ* by nucleophilic substitution of allylsilanes on propargylic alcohols in the presence of a gold complex.[99] For example, the propargylic alcohol **214** is converted into the bicyclo[3.1.0]hexene compound **215** in 71% yield via substitution followed by the cyclization (equation 69).[100] Similarly, a catalytic system based on gold(III) has proven efficient for the same transformation.[101] The propargylic alcohol **216** was transformed into the bicyclic adduct **208** in 46% yield in the presence of allyltrimethylsilane (equation 70).



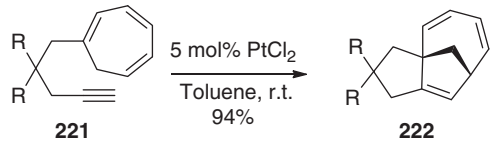
(69)



(70)

More complex enynes such as substrates bearing a spirocycloalkyl chain at the propargylic position may evolve according to various pathways. Indeed, migrations of various groups are not limited to hydrogen atoms, but may imply carbon–carbon bonds. A ring expansion of the cyclic adduct **217** takes place by migration of a carbon–carbon bond according to a Wagner–Meerwein transposition, leading to tricyclic compound **218** in 72% yield (equation 71).[96a] The rearrangement of the carbenoid intermediate involves a 1,2-migration of the alkyl group which is favored by the ring strain of the spirocycloalkyl group. A different reactivity was observed for 1,5-enynes such as **219** bearing a larger spirocycloalkyl substituent (at least seven carbon atoms).[102] In this case, a CH bond insertion step and simultaneous creation of three C–C bonds was observed. The reaction afforded the tetracyclic derivative **220** in 80% yield, the proposed intermediate being a tricyclic gold σ-complex (equation 72).

(71)

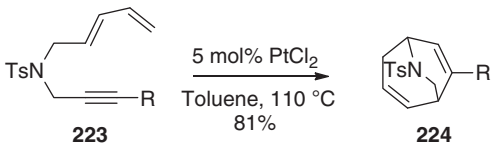


(72)

5.30.3.2.3 Formation of other cycles via enyne rearrangements

Depending on the substitution pattern of the enyne, the use of carbophilic catalysts allow for the formation of other cyclic derivatives, the size of the resulting rings being obviously substrate dependent. A platinum-catalyzed intramolecular formal [6 + 2] cycloaddition of the alkyne tethered to a cycloheptatrienes in compound **221** led to bicyclo[4.2.1]nona-2,4,7-trienes **222** in good to excellent yields (equation 73).[103] Various malonic-type trienynes were compatible with the mild reaction conditions. The authors propose an exocyclic cyclization mode followed by a 'concerted' electron redistribution releasing the cyclic trienes **222**.

In the presence of dienynes, the expected [4 + 2] cycloaddition is followed by a Cope rearrangement (equation 74).[104] Indeed nitrogen-tethered enynes **223** with various substitution on the alkynyl moiety are cleanly transformed to bicyclo[3.2.2]nona-2,8-dienes **224** in the presence of platinum catalysts at 110 °C. A metalla-Cope type rearrangement was proposed as the second



elemental step in the cycloisomerization reaction of dienynes **225**.[105] The generality of the pattern (e.g., carbon- or nitrogen-tethered derivatives) was remarkable and led to the cyclic dienes **226** in good to excellent yields (equation 75). One may note that the use of gold complexes allowed the cyclizations to proceed at room temperature; the silyl group was cleaved on work up.

(75)

The cycloisomerization of 3-silyloxy-1,5-enynes **227** implies an elegant design of the substrates that would be suitable for pinacol rearrangements after the cyclization step.[106] Substrates **227** were engaged in the presence of cationic gold complexes and allowed for the formation of formyl-substituted cyclopentenes **230** in good to excellent yields (**Scheme 20**). According to the authors, the mechanism may proceed through an initial activation of the alkyne moiety, leading to **228**, followed by a 6-*endo* cyclization of the 1,5-enyne giving the vinyl gold intermediate **229**. A pinacol rearrangement (1,2-alkyl migration) of the intermediate would terminate the catalytic cycle, releasing the products on protodesilylation.

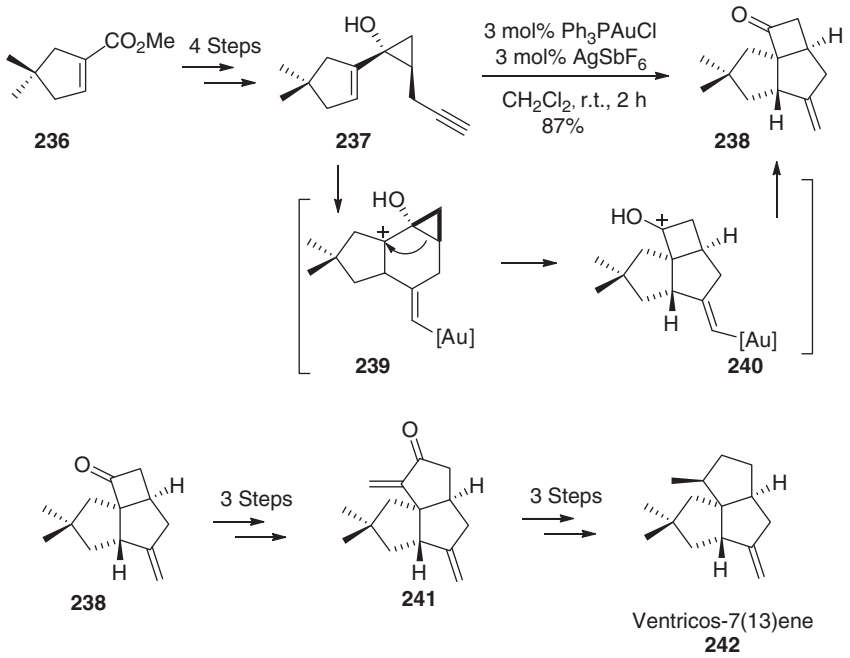
228 **229**

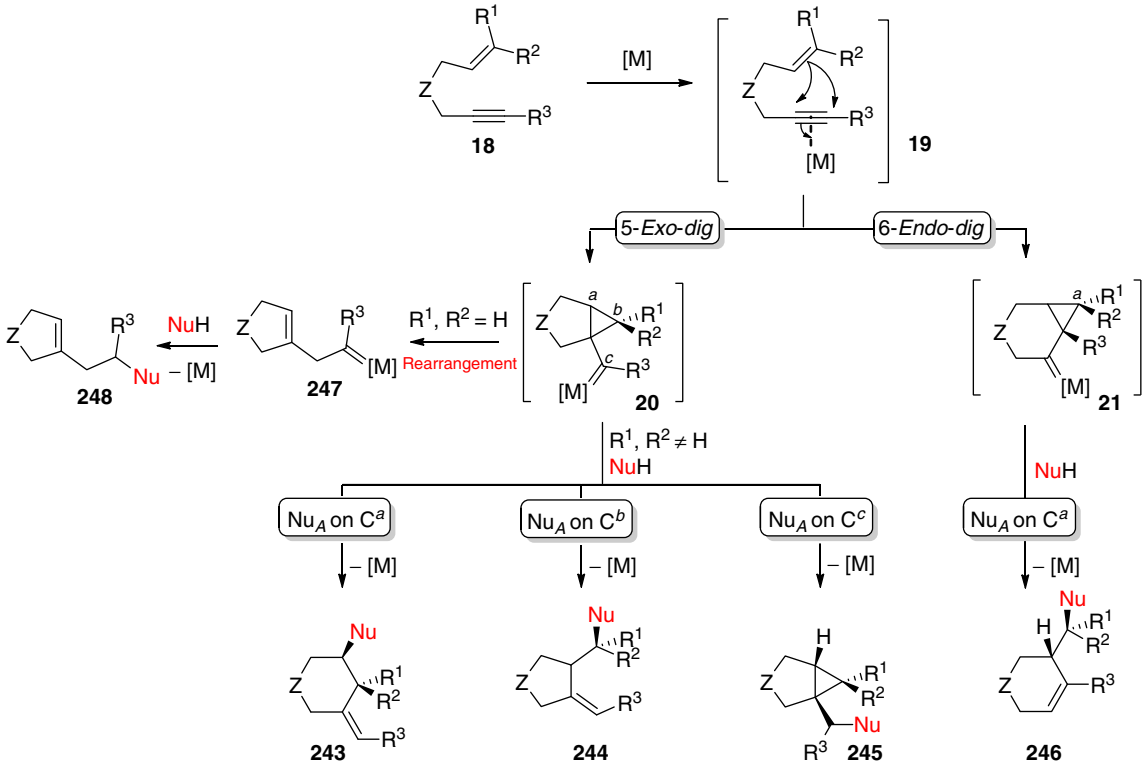
Scheme 20

The transfer of chirality was recently studied and could be applied to the preparation of **232** in high *ee* (equation 76); however, the process could not be generalized to encompass a broad range of substrates.[107] Although studying the rearrangement of enynes containing a tetrasubstituted alkene moiety, a novel carbon–carbon bond scission was observed that was rationalized via a Grob-type fragmentation instead of a pinacol-type 1,2-migration. The best result was obtained in the presence of gold(III) trichloride, which promoted the cyclization/fragmentation of 1,5-enyne **233** to derivative **234** in 51% yield; 3% of the bicyclic adduct **235** were isolated too (equation 77). The use of platinum dichloride in the presence of carbon monoxide afforded the aldehyde **234** in 67% yield.



(76)

(77)



The pinacol-type rearrangement was applied to the total synthesis of ventricos-7(13)-ene **242** (Scheme 21).[37] The cyclopropyl alcohol-containing 1,6-enyne **237** was classically prepared starting from the commercially available ester **236** in four steps. The cycloisomerization was performed in the presence of the cationic gold(I) complex $Ph_3PAuSbF_6$ under mild conditions and afforded the tricyclic ketone **238** in 87% yield. The reaction presumably proceeds via a 6-*exo* cyclization giving the vinyl aurate intermediate **239**, followed by a 1,2-alkyl shift and protodemetalation. The total synthesis of ventricos-7(13)-ene **242** was then accomplished via a six-step sequence involving a Pd-catalyzed ring expansion (leading to **241**) and a Barton–McCombie reduction of a xanthate ester.

Scheme 21

5.30.4 Domino Enyne Cycloisomerization–Nucleophile Addition Reactions

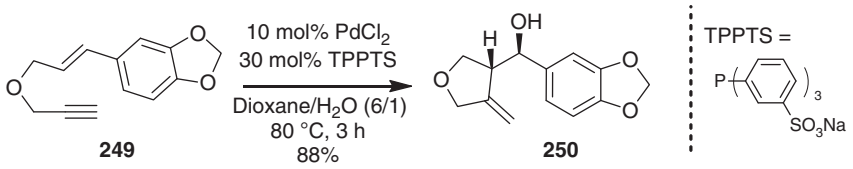
The enyne cycloisomerization reaction may also be associated with various inter- or intramolcular processes implying carbon or heteroatom nucleophiles. One general scheme trying to summarize the different possible pathways is presented in Scheme 22. In relation with Scheme 5, where the skeletal rearrangements were presented, one may envision the trapping of the carbenoid intermediates **20** and **21** resulting from 5-*exo-dig* and 6-*endo-dig* cycloisomerization processes.

Scheme 22

Depending on the nature of the nucleophile and the stabilization of the organometallic intermediate, the addition of the nucleophile can then be performed:

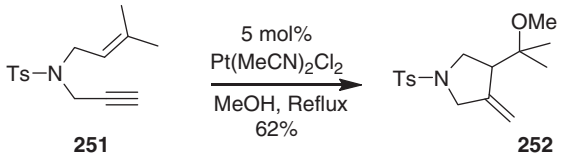
- On the cyclopropanyl moiety (carbons a and b), giving after rearrangement and protodemetallation, the unsaturated derivatives **243**, **244** (5-*exo-dig*), and **246** (6-*endo-dig*);
- On the carbenoid moiety (c) allowing the formation of the bicyclic compound **245**;
- On the carbenoid intermediate **247**, formed by rearrangement of intermediate **20** when the alkenyl function of the enyne is monosubstituted; this leads to the compound **248**.

A variety of nucleophiles could be used in the context of these cyclizations, including oxygen nucleophiles (water, alcohols, sulfoxides, and carbonyl derivatives), unsaturated carbon compounds (electron-rich aromatic rings, 1,3-dicarbonyl malonic derivatives, alkenes), and nitrogen compounds (amines and carbamates). The following Sections 5.30.4.1, 5.30.4.2 and 5.30.4.3 will give seminal examples.



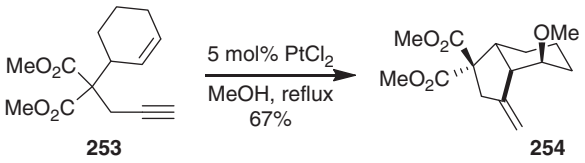
5.30.4.1 Oxygen Nucleophiles

5.30.4.1.1 Hydroxy- and alkoxycyclization reactions

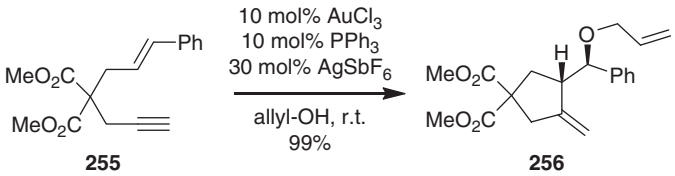


5.30.4.1.1.1 Reactivity of 1,6- and 1,5-enynes

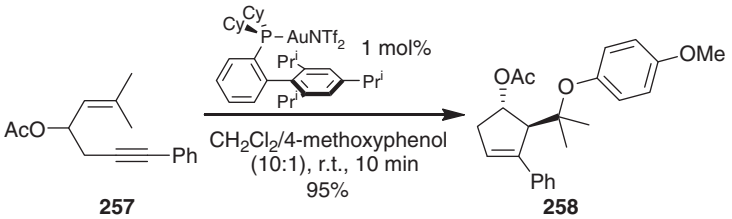
The addition of oxygen nucleophiles is probably the most-studied domino cycloisomerization/functionalization process. The first example of the addition of a protic oxygen nucleophile on 1,6-enyne catalyzed by an organometallic complex has been described by the group of Genêt.[108] The catalytic system, consisting of palladium dichloride and a water-soluble phosphine ligand (triphenylphosphino tris-*meta* sulfonate sodium salt, TPPTS), in 1,4-dioxane/water afforded alcohol **250** in a diastereoselective process (equation 85); starting from enyne **249**, the addition of water occurs on carbon b of intermediate **20** (Scheme 22).



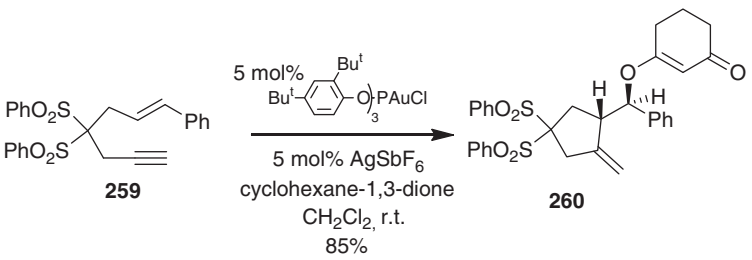
The synthesis of carbo- and heterocycles by cyclization of 1,6-enynes and domino addition of water or alcohol has been widely described using platinum(II) and gold(I) catalysts, which showed higher activities.[109] The addition of methanol on the nitrogen-tethered enyne **251** gave, for example, compound **252** in 62% yield. The cyclization of enyne **253**, which bears an endocyclic alkenyl pattern, leads to the completely diastereoselective formation of the bicyclic compound **254** in good yield (equation 80). Allylic alcohol, phenols, or 1,3-dicarbonyl nucleophiles may be employed in these processes as exemplified by the preparations of **256** (starting from 1,6-enyne **255**),[110] **258** (starting from 1,5-enyne **257**)[111] and **260** (starting from 1,6-enyne **259**)[112] (equations 81–83). An original variant consists of a 6-*endo-dig* type rearrangement, followed by the addition of benzyl alcohol to furnish the vinylsilane **262** from the silylated enyne **261**.[113] The introduction of alcohol occurs preferentially on the more substituted carbon (equation 84).



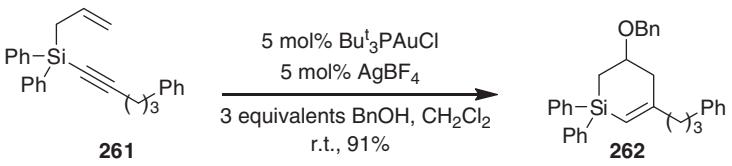
(78)



(79)

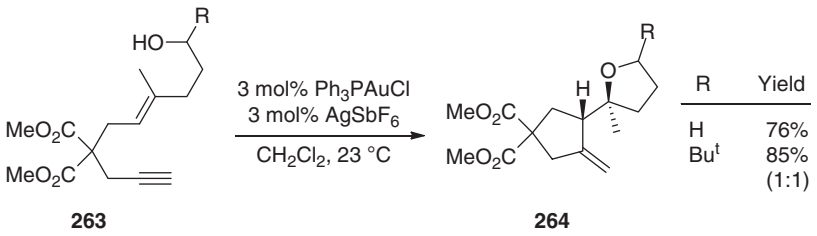


(80)

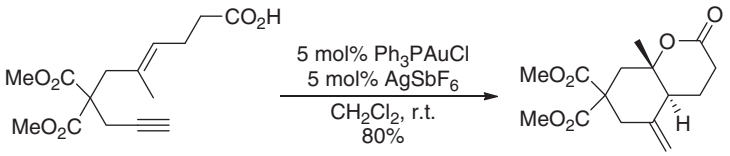


(81)

(82)

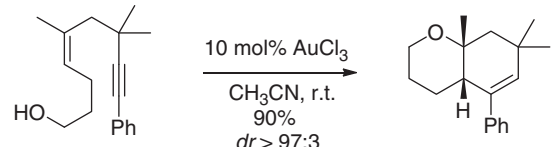


(83)

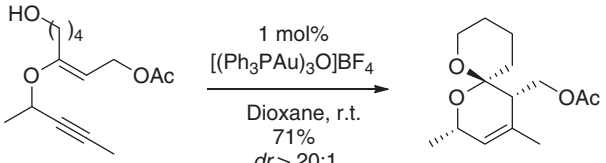


(84)

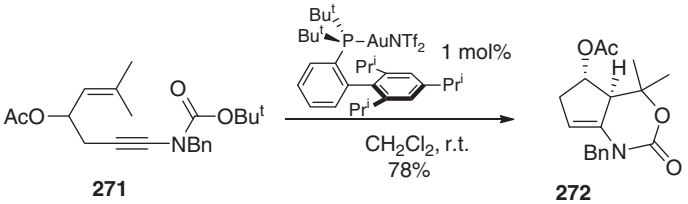
Intramolecular cyclizations of 1,6-enynes having a hydroxyl substituent on the alkene moiety have also been studied.[27d] In the presence of a catalytic amount of $Ph_3PAuCl/AgSbF_6$, the enynols **263** are converted via a 5-*exo*-*dig* process into bicyclic derivatives **264** in good yields (equation 85). In the case of the *tert*-butyl substituted alcohol (R = *tert*-Bu), a 1/1 mixture of diastereoisomers



was obtained. Other nucleophiles such as carboxylic acids are suitable for the transformation of 1,6-enynes (equation 86).[114] The authors showed that the reaction is stereospecific by preparing and reacting with both stereoisomers of **265**. The (*E*)-isomer is cleanly transformed to the *trans* bicyclic adduct **266**, whereas the (*Z*)-isomer is giving the respective *cis*-configured isomer of **266**. Moreover, the addition of the nucleophile is dictated by the substitution pattern of the double bond, which is in full agreement with the carbenoid type intermediates that have been discussed in Section 5.30.4. As for the intramolecular domino cyclization/functionalization reaction, this process could be applied to 1,5-enynes (equations 87–91). The group of Kozmin has reported one of the preliminary examples of a tandem intramolecular bicyclization.[115] In the presence of 10 mol% of gold(III) trichloride, the intramolecular addition of the hydroxyl group from **267** leads to the bicyclic adduct **268** through 6-*endo-dig* cyclization, with an excellent *cis* diastereoselectivity (equation 87). A similar transformation has been described modifying the structure of the enyne. The 6-*endo-dig* cyclization of the enyne **269** is followed by the addition of the hydroxyl group as nucleophile, leading to the ether spiroketal **270** in high yield (equation 88). The selectivity of the nucleophilic addition can be further rationalized by considering the formation of a tertiary carbocation that is more stable than a secondary one. A formal [4 + 2] cycloaddition of an *N*-alkynyl *tert*-butyloxycarbamate with an alkene has been recently described in the presence of cationic gold(I) catalyst. Cycloisomerization of **271** leads to the bicyclic functionalized adduct **272** in 78% yield, the process being totally diastereoselective.[116]

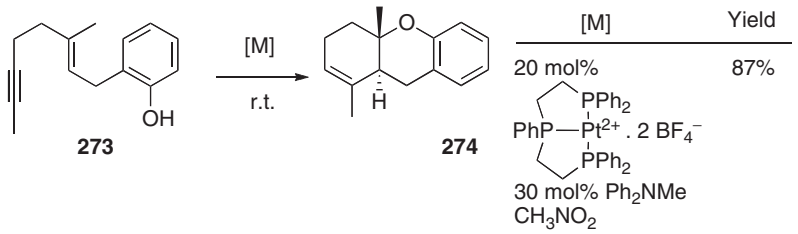


263 **264** (85)

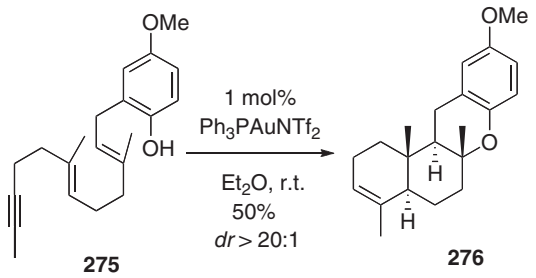


265 **266** (86)

267 **268** (87)



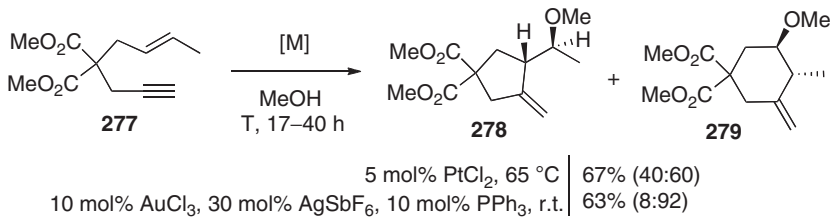
269 **270** (88)



271 **272** (89)

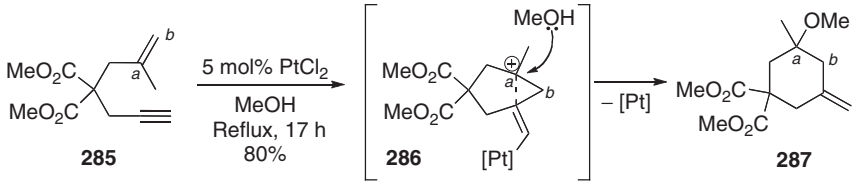
The intramolecular phenoxycyclization of 1,5-enynes was recently described either in the presence of a dicationic platinum(II) complex or of a gold catalyst (equation 90).[117] The enyne **273** is converted in the presence of the platinum complex to the tricyclic

derivative **274** in 76% yield. The use of the cationic gold(I) complex $Ph_3PAuNTf_2$ at a low loading (1 mol%) allowed this cyclization to occur more efficiently and faster. This cyclization proceeds as 6-*endo-dig* process; the *trans* relationship between the groups on both sides of the junction of the ring formed may be rationalized by a chair-type reactive intermediate. The same gold cationic precursor is also effective for the addition/tandem cyclization of dienynol **275**, leading diastereoselectively to the tetracyclic compound **276** in moderate yield (equation 91).

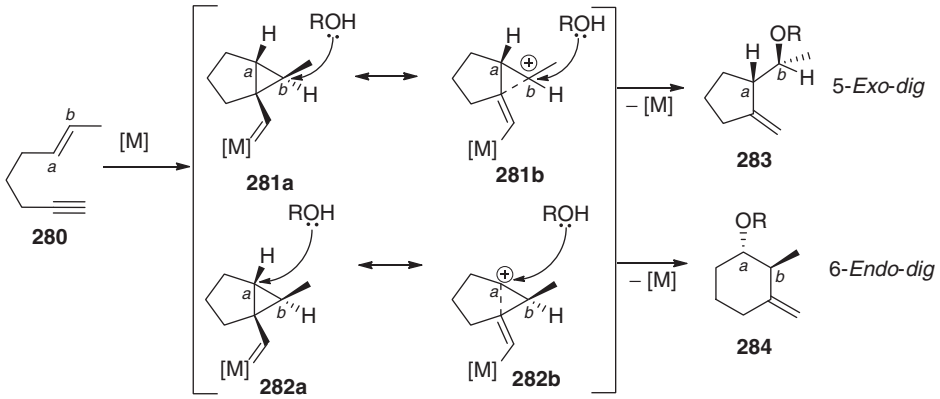


(90)

(91)



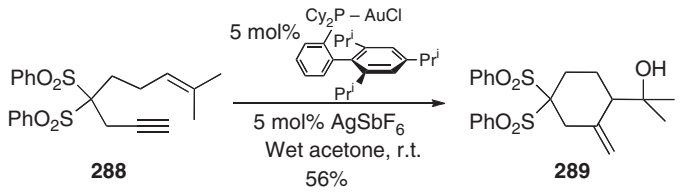
The cyclization/functionalization of some enynes leads to the formation of derivatives from the competitive 5-*exo-dig* and 6-*endo-dig* processes. In the presence of a catalytic amount of platinum dichloride, enyne **277**, bearing a methyl substituent on the external carbon of the alkene is converted to a mixture of the cyclization products **278** and **279** according to the two possible pathways (equation 92).[38] The electrophilicity of the chosen organometallic complex seems to influence the ratio of the two products in favor of the compound coming from the 6-*endo-dig* cyclization, since the use of a catalytic system based on gold leads to a ratio of **278**/**279** of 8/92.[110a]



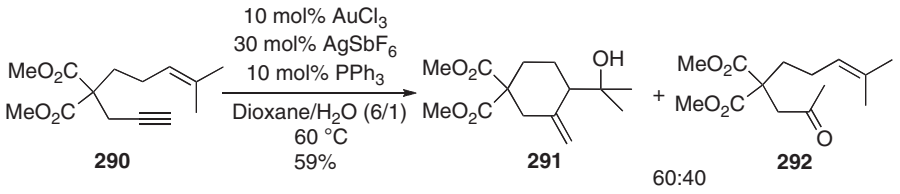
(92)

The influence of the electrophilicity of the metal center on the structural parameters of the cyclopropylcarbenoid intermediates (proposed in the cyclization of 1,6-enynes) has been studied by the group of Echavarren (**Scheme 23**).[27,35] DFT calculations for the cyclization of enyne **280** suggests that the intermediate obtained by nucleophilic addition of the alkene to the alkyne in the presence of platinum dichloride is best described by a cyclopropylcarbenic form (intermediates **281a** and **282a**), whereas the species obtained by the reaction in the presence of gold complex has a carbocationic character, represented by the intermediates **281b** and **282b**. Thus, the stereoselective attack (intermediate **282b**) by a protic oxygen nucleophile takes place preferentially to form a six-membered ring.

The cyclization according to a 6-*endo-dig* process may therefore be favored when there is substitution on the internal carbon of the alkene. In the presence of 5 mol% of platinum dichloride, enyne **285** is thus converted into the six-membered cyclic derivative **287** (equation 93). The regioselective addition of methanol occurs on the tertiary carbon of the transient intermediate **286**.[109b]

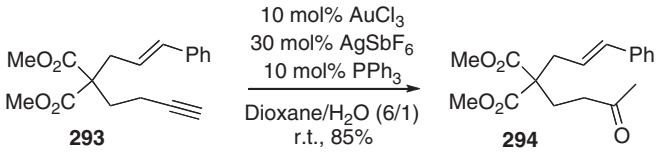


(93)



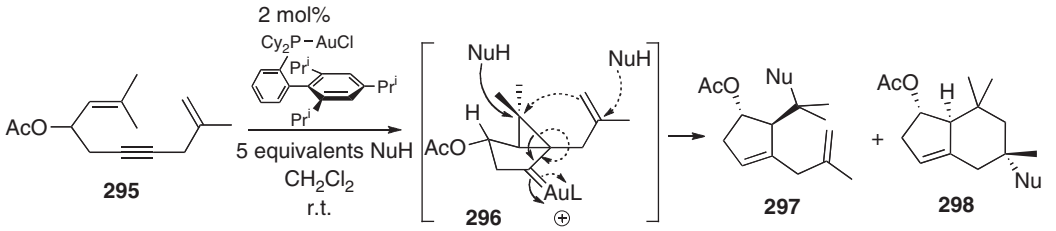
Scheme 23

5.30.4.1.1.2 Reactivity of 1,7-enynes and dienynes



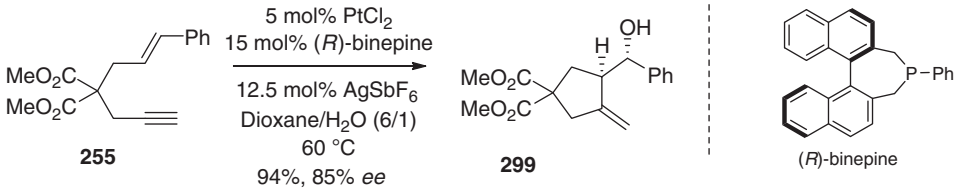
Apart from 1,5- and 1,6-enynes, few other substrates have been engaged in domino cycloisomerization/functionalization reactions. The activity of gold complexes has been studied in the alkoxycyclization of 1,7-enynes. The hydroxycyclization of enyne **288**, substituted by a disulfonate moiety in position C-4, leads to the alcohol **289** in 56% yield (equation 94).[42] Similar results were obtained in the case of the malonic analog **290**, despite the fact that competitive hydration of the alkyne moiety with formation of the ketone **292** was observed (equation 95).[110a] This competitive process may be predominant in the case of the 1,7-enyne **293**, where the general conditions led exclusively to the ketone **294** in 85% yield (equation 96).

(94)

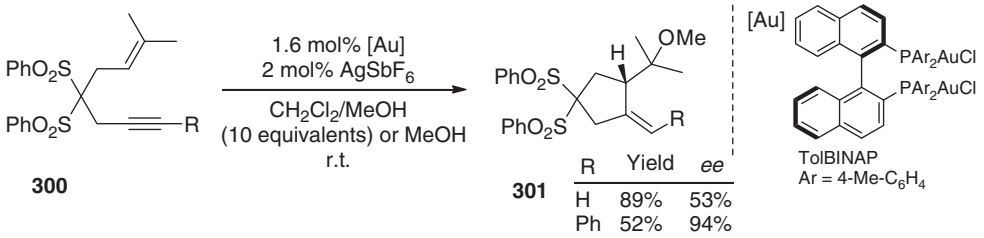


(95)

(96)

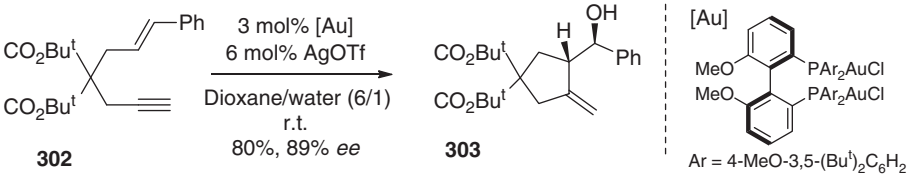


When the enyne bears another unsaturation, two nucleophilic sites are present and may participate in the cyclization/functionalization process. The competition between the oxygen and carbon nucleophiles has been highlighted while studying the reaction of dienyne **295** (equation 97).[118] A mixture of products was obtained with a preferential formation of **298**, the common intermediate being the carbenoid species **296**. The dilution seems to play an important role, as a very dilute medium leads to the formation of adducts **297** and **298** in almost equal proportions. The strength of the nucleophile is another criterion and the use of 4-methoxyphenol, less nucleophilic than methanol, has led to the exclusive double addition product **298**, in a completely diastereoselective manner and in 70% yield.



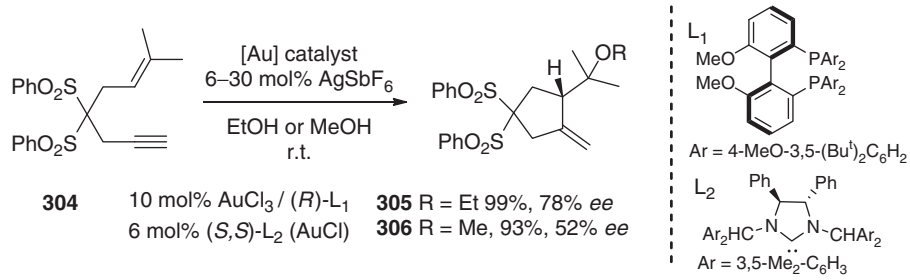
(97)

5.30.4.1.1.3 Asymmetric catalysis

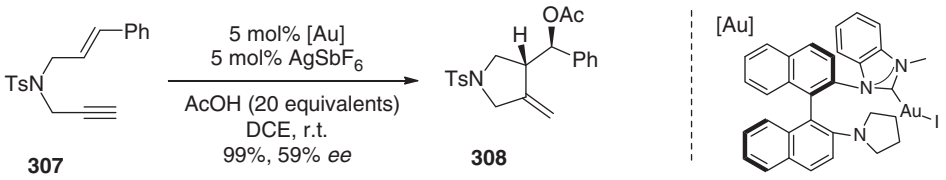


The first example of an enantioselective tandem hydroxycyclization involved a catalytic system generated *in situ* from 5 mol% platinum dichloride, 12.5 mol% of $AgSbF_6$, and 15 mol% of an atropisomeric monophosphine ligand (equation 98).[119] The carbon-tethered enyne **255** was thus converted into the secondary alcohol **299** via a 5-*exo-dig* cyclization in 94% yield and 85% *ee*. A similar system was proposed involving ligands such as (*R*)-BINAP or (*S*)-Tol-BINAP, but did not give any better results.[120] The use of bimetallic complexes of gold(I), with a atropisomeric bidentate ligand, has also shown efficacy in the methoxycyclization of disulfonated enyne **300** leading to ether **301** in 53–94% *ee*, depending on the substitution of the alkyne moiety (equation 99).[120] Recently, the use of a chiral NHC ligand led to *ee*'s of up to 72%.[121] However the platinum and gold systems (equations 98 and 99) have shown limited effectiveness since these rearrangements were found highly dependent on small structural modifications of the substrate. Other catalytic systems and substrate skeletons have therefore been designed, implying cationic bimetallic gold(I) complexes (equations 100–103). For example the use of a hindered malonic-type substituted 1,6-enyne such as **302**, allowed for a clean and selective hydroxycyclization reaction leading to **303** in 89% *ee*; for comparison, only 58% *ee* was observed for the methyl ester analog of **302** (equation 100).[122]

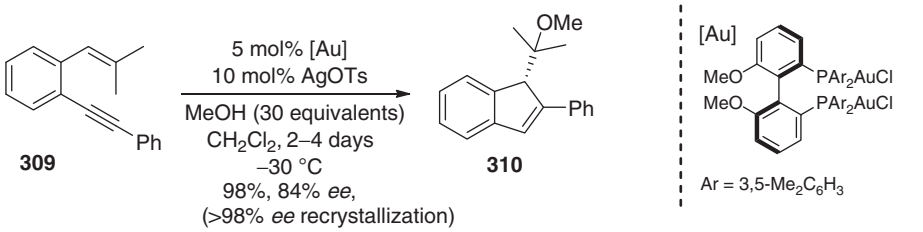
(98)



(99)

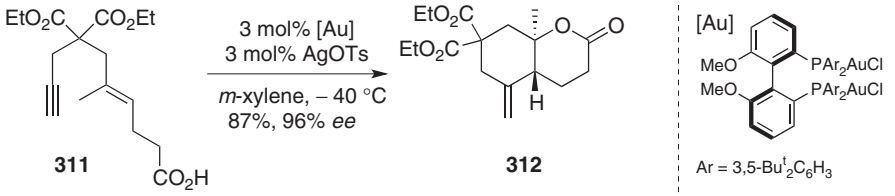


(100)

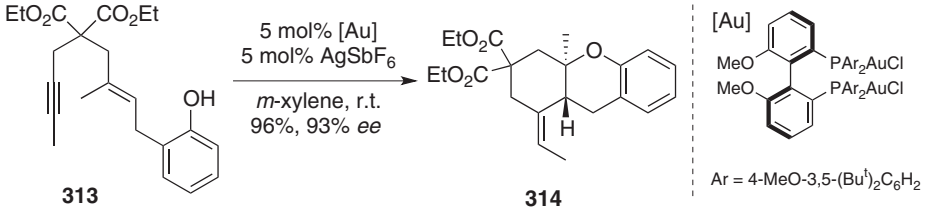


The alkoxycyclization reactions of enyne **304** were also dependent on the structure of the ligand as a better *ee* was obtained in the presence of a bimetallic gold complex derived from MeOBIPHEP analog[123] compared with the use of a monometallic chiral NHC ligand[124] (equation 101). The addition of acetic acid followed by the cyclization has been accomplished asymmetrically in the presence of an axially chiral NHC ligand (equation 102).[125] The nitrogen-linked enyne **307** was transformed to the functionalized pyrrolidine **308** in excellent yield and 59% *ee*. Recently, the synthesis of functionalized indene derivatives was described using a cationic bimetallic gold complex (equation 103); for example, the ether **310** was obtained in 84% *ee*.[52a]

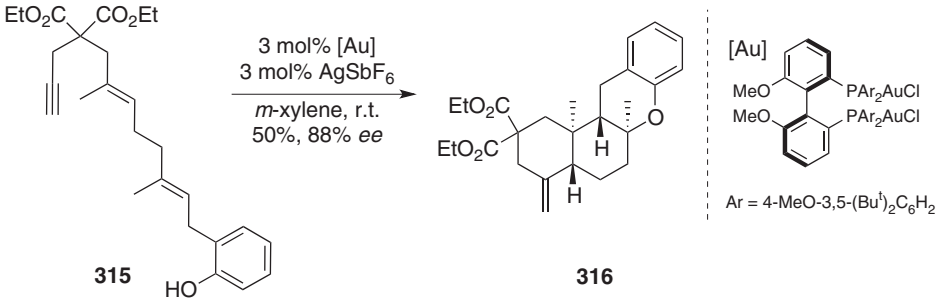
(101)



(102)



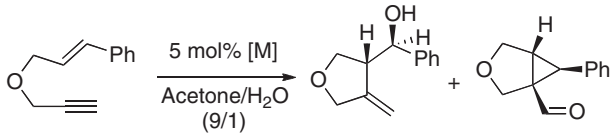
(103)



Intramolecular asymmetric versions of the carboxy- and phenoxycyclization appeared only recently in the literature (equations 104–106).[126]

(104)

(105)

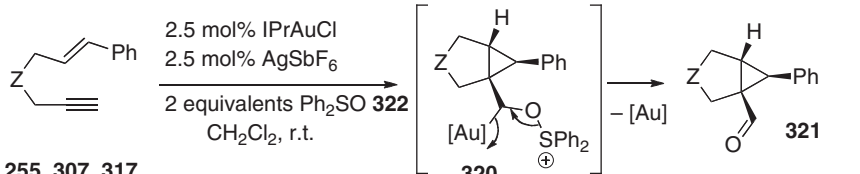


(106)

The reaction conditions of the bicyclization reactions involving either a carboxylic acid (substrate **311**) or a phenol (substrate **312**) were optimized in the presence of various chiral atropisomeric ligands. The best results were obtained with di-*tert*-butyl- and

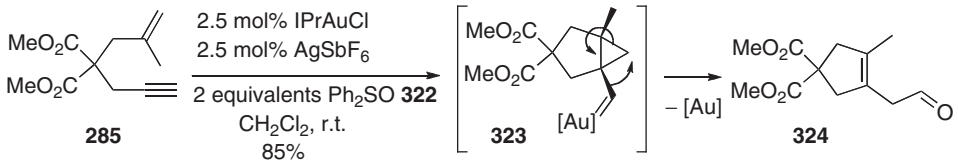
di-*tert*-butyl-methoxy-MeOBIPHEP as ligands, respectively, affording compounds **312** and **314** in 96% and 93% *ee*. As the stereochemistry is fully consistent with the Stork–Eschenmoser postulate, the tricyclization of dienyne **315** successfully gave the tetracyclic adduct **316** in good yield and 88% *ee* (equation 106).

5.30.4.1.2 Oxidative rearrangements



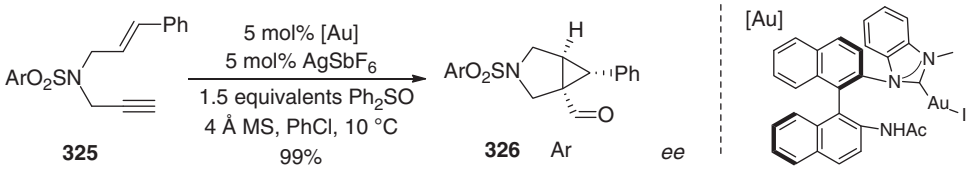
An interesting reactivity of carbenoid intermediates (e.g., **20** in Scheme 22) was garnered in the presence of unsaturated oxygen derivatives such as sulfoxides or oxygen. The first example of an oxidative rearrangement catalyzed by a carbophilic metal complex was described when the enyne **317** was cyclized in oxygenated aqueous acetone in the presence of 5 mol% of platinum dichloride (equation 107). The alcohol **318** was formed according to the conventional hydroxycyclization, but the bicyclic aldehyde **319** was also obtained in 12% yield. The use of palladium dichloride also leads to the mixture **318**/**319**, with **319** still being the minor product.[38] Toste's group has recently described a similar oxidative rearrangement by addition of diphenylsulfoxide **322**.[127]

[M]	Yield	**318**:**319**
$PtCl_2$	12%	12%
$PdCl_2$	40%	10%



(107)

The cyclization of enynes **255**, **307**, and **317**, in the presence of *N*-heterocyclic gold(I) complex IPrAuCl, a silver salt and 2 equivalents of diphenylsulfoxide, led to the formation of the bicycles **321** with a very good performance (equation 108). This reaction gave high yields starting from carbon-, oxygen-, or nitrogen-tethered enynes. The mechanism most probably involves the addition of the sulfoxide to the carbon bound to the gold(I) complex. Elimination of the metal complex and of diphenylsulfide (intermediate **320**) explains the formation of the bicyclopropanic carbonyl derivative (equation 108). An isomerization process may also occur on the cyclopropyl carbenoid species before the addition of the nucleophile (intermediate **247**, Scheme 22); this process is favored for alkenes that are unsubstituted at the terminal position. This reaction pathway can account for the structure of cyclopentene **324** obtained by cyclization of enyne **285** in 85% yield (equation 109).



Z	Yield
$C(CO_2Me)_2$	90%
O	94%
NTs	91%

(108)

(109)

The first example of an asymmetric variant appeared in 2011 in the presence of an axially chiral NHC ligand (equation 110).[125] The reaction of nitrogen-tethered enynes **325** led to the bicyclic adducts **326** in excellent yield and *ee*'s of up to 70%. It is noteworthy that this process has only been described for nitrogen-linked 1,6-enynes and that the *ee*'s are highly dependent on the substitution of the alkene and the protective group on the nitrogen atom.

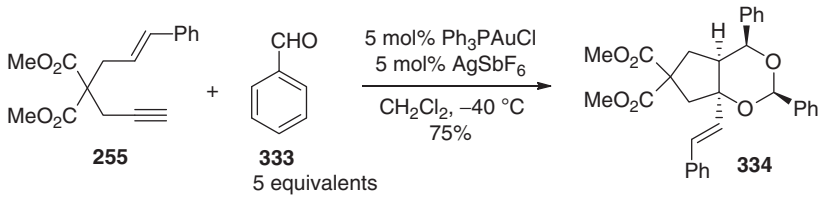
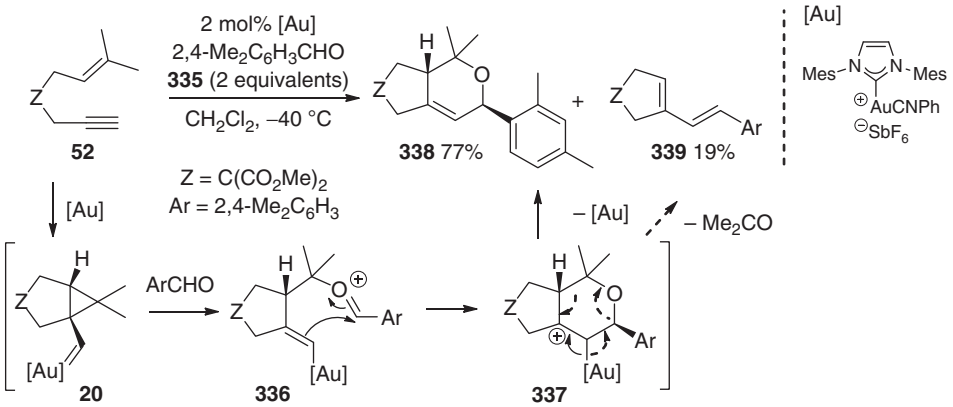
(110)

5.30.4.1.3 Prins rearrangements



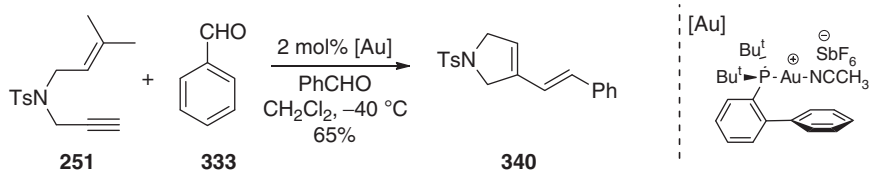
Helmchen's group described for the first time the intermolecular addition of carbonyl compounds onto enynes bearing monosubstituted alkene units. This domino process, in which two C–C and one C–O bonds are assembled, is a formal [2 + 2 + 2] alkyne/alkene/carbonyl cycloaddition. In the presence of the catalyst system $Ph_3PAuCl/AgSbF_6$ and *o*-nitrobenzaldehyde, the cyclization of enyne **327** leads to the tricyclic compound **332** in 66% yield (Scheme 24).[128]



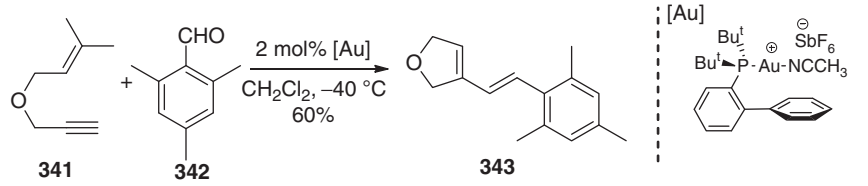
Scheme 24

The proposed mechanism involves a first isomerization step of the carbene intermediate according to the process presented above in the discussion of the oxidative rearrangement (equation 109) (Section 5.30.4.1.2) and in general Scheme 22. The addition of the carbonyl compound on the carbon bonded to the metal complex **329** leads to **330**. Subsequent attack by the alkene results in the formation of the bicycle **331**, which evolves to the tricyclic adduct **332**; the whole process is totally diastereoselective.

The substitution of the carbon–carbon double bond of the enyne plays a crucial role, since the intermolecular addition of carbonyl compounds onto 1,6-enynes with a substituted alkene unit leads to dioxolanes[129] or unsaturated pyranic bicycles[130] (equation 111 and Scheme 25) depending on the reaction conditions. The addition of 5 equivalents of benzaldehyde to 1,6-enyne **255**, under the conditions used for the preparation of ether **332**, gives dioxolane **334** by a totally diastereoselective process (equation 111).

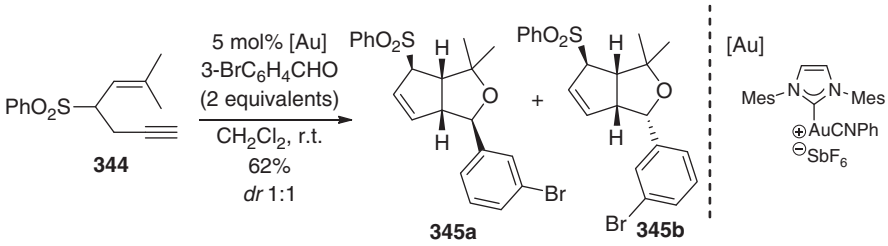


(111)



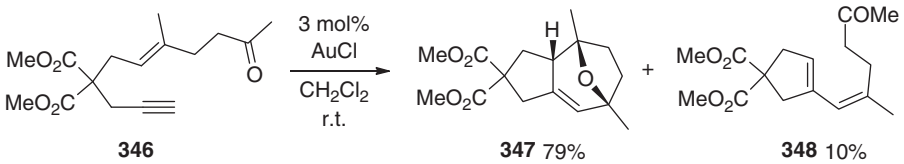
Scheme 25

Under modified conditions (catalyst and equivalents of aldehyde), the addition of 2,4-dimethylbenzaldehyde to the enyne **52** leads to the formation of a mixture of the ether **338** (77% yield) and the 1,3-diene **339** (19% yield). The ratio of the two products varies depending on the substitution of the aldehyde and the catalyst, the best result being generally obtained in the presence of the NHC gold(I) catalyst. The proposed mechanism includes the formation of the cyclopropylcarbenoid species **20**, followed by the direct addition of the aldehyde on the cyclopropane ring. The Prins cyclization, which occurs on the oxonium cation **336**, gives the tetrahydropyranyl derivative **337**. The elimination of the metal complex can then form the unsaturated bicycle **338**. Another competitive pathway is the elimination of acetone from intermediate **337**, explaining the formation of diene **339**. The substitution of the alkene function therefore modifies the reactivity of the enyne since the isomerization step of the carbenoid **20** is not observed here. The nucleophilic addition/cyclization Prins sequence is common to both mechanisms that are presented in Schemes 24 and 25.

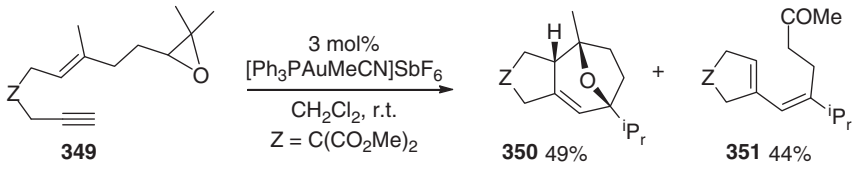


Interestingly, for nitrogen and oxygen-tethered enynes, the formation of the ether is not observed and the reaction results in the exclusive formation of the corresponding diene, in which an aromatic ring has been incorporated (equations 112 and 113).[130] For example, 1,6-enynes **251** and **341** were cleanly transformed to dienes **340** and **343** in 65% and 60% yields, respectively, with no traces of the corresponding ethers. Further investigations into the scope of the reaction showed that gold-catalyzed domino cycloisomerization/Prins reactions could also be applied to 1,5-enynes.[130] The sulfone compound **344** is cyclized according to a 5-*endo-dig* process in the presence of 2 equivalents of 3-bromobenzaldehyde and leads to a 1/1 mixture of the unsaturated bicyclic epimers **345a,b** in 78% yield (equation 114).

251 **333** **340** (112)

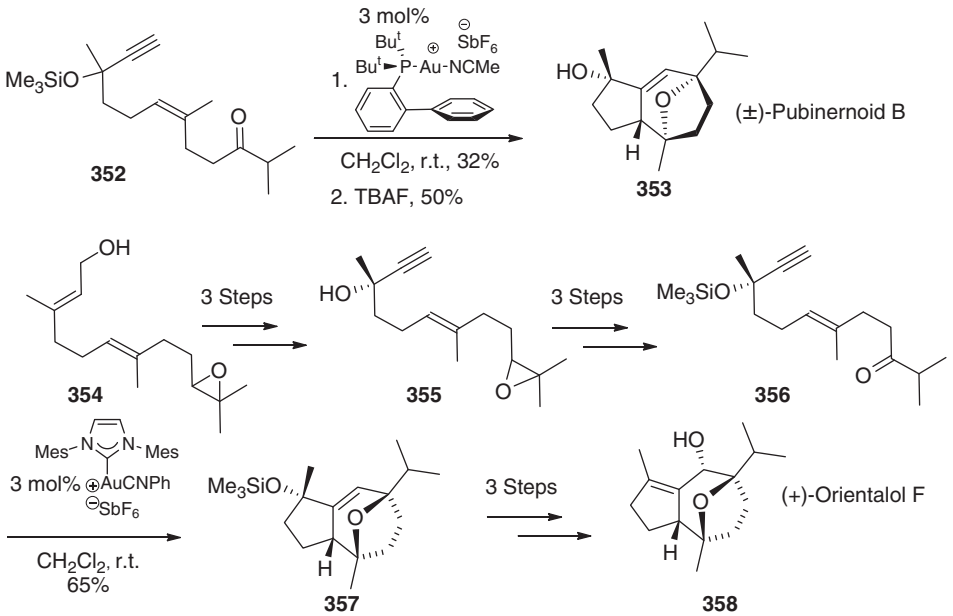


341 **342** **343** (113)



344 **345a** **345b** (114)

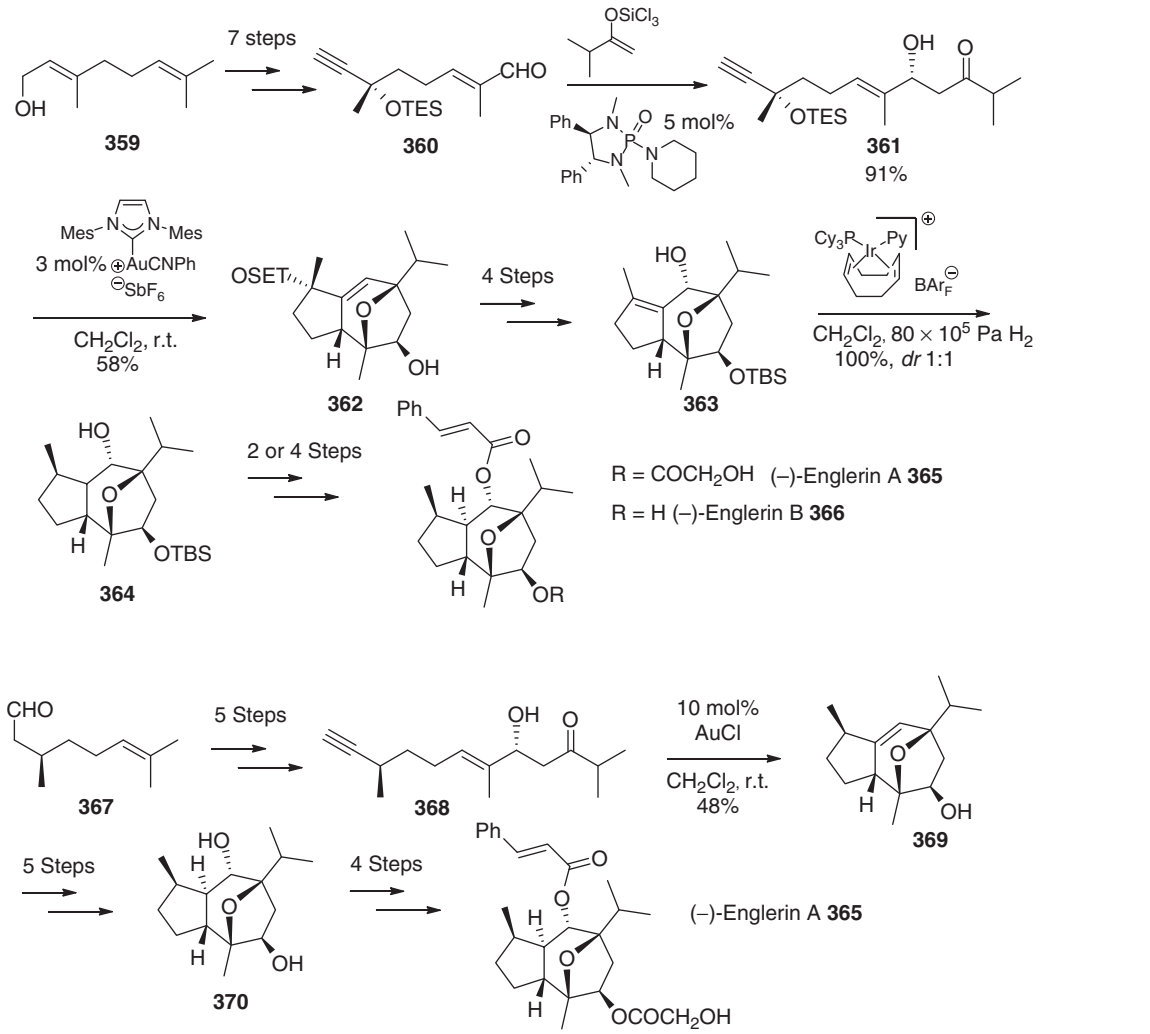
Cyclizations associated with a Prins reaction were studied for 1,6-enynes (equation 115). The reaction of substrate **346**, bearing a carbonyl substituent on the alkenyl side chain, leads to the oxatricyclic derivative **347** in 79% yield and 1,3-diene **348** in 10% yield.[131] Catalysts other than gold chloride were found to be efficient too, but generally gave mixtures of **347** and **348** with a higher amount of the 1,3-diene. The proposed mechanism is similar as the one presented for the intermolecular variant. The higher selectivity for the formation of the oxatricyclic adduct **347** using AuCl as the catalyst relative to classic cationic complexes is proposed to be due to a faster elimination of the metal center. Interestingly, the process could be applied to epoxides such as **349** (equation 116). Similar structures as in the case of ketone **346** were obtained: the 1,6-enyne **349** was transformed into a mixture of the oxatricyclic derivative **350** and the diene **351** in a ≈1:1 ratio.



346 **347** 79% **348** 10% (115)

349 **350** 49% **351** 44% (116)

The domino process cycloisomerization/Prins reaction has found very powerful applications in the total syntheses of pubinernoid B, (+)-orientol F,[132] and the (–)-englerins A and B.[133] The syntheses of pubinernoid B and (+)-orientalol F are presented in Scheme 26. The synthesis of pubinernoid B **353** relies on the preparation of enyne **352**, whose double-bond configuration had been adapted as necessary for the particular target. The synthesis of **353** was performed in modest yield in two steps but allowed the correct stereochemistry of the oxa-bridge of pubinernoid B to be determined.

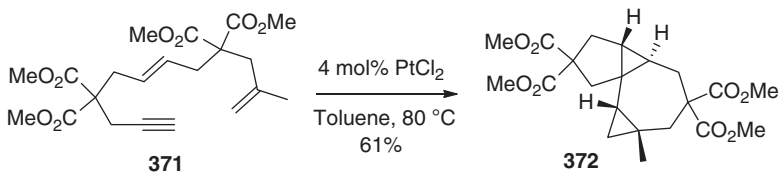


Scheme 26

The preparation of (+)-orientalol F starts from the known epoxyfarnesol **354**, which furnishes the chiral alkyne **355** via a three-step synthesis implying a Sharpless asymmetric epoxidation. The propargylic alcohol **355** was then efficiently transformed to ketone **356** via a regioselective reduction of the epoxide. The cyclization of enantiomerically enriched **356** using the NHC gold(I) complex gave **357** in 65% yield; the reaction was totally diastereoselective. (+)-Orientalol F **358** was then obtained after a three-step sequence involving an oxidative allylic rearrangement and a Luche-type reduction.

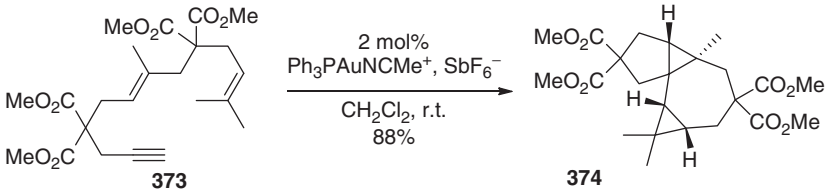
Two other sesquiterpenes, (–)-englerin A and B, were independently prepared by the cycloisomerization/Prins methodology by the groups of Echavarren and Ma (Scheme 27).[133] They differ in the precursor that was used for the rearrangement. The first synthesis is very similar to the one described for (+)-orientalol F, as the aldehyde **360** is prepared from geraniol **359** via a seven-step sequence involving a Sharpless asymmetric epoxidation, an oxidative cleavage of the trisubstituted double bond and a Wittig reaction. A stereoselective Denmark aldol reaction affords the allylic alcohol **361** in 91% yield and an excellent diastereomeric ratio (*dr*) (>14:1, 86% of **361**). The oxatricyclic derivative **362** was then cleanly synthesized, the best result being obtained in the presence of $IPrAuSbF_6$ as the catalyst and the unprotected allylic alcohol. The isomerization of **362** into **363** was realized after deprotection of the triethylsilyl group via an oxidation/reduction process and leads to the allylic alcohol **363** in good yield. The catalytic hydrogenation of the tetrasubstituted double bond was tricky but could be realized in the presence of a cationic iridium catalyst under high pressure of dihydrogen, although with a low selectivity. The desired isomer **364** was then transformed either to (–)-englerin B **366** in two steps or to (–)-englerin A **365** in four steps (in fact, (–)-englerin A was obtained from its B congener **366**).

The synthesis of (–)-englerin A **365** was also accomplished starting from (*R*)-citronellal **367**. Its transformation to the allylic alcohol **368** was performed via a five-step sequence, the key step being a boron-mediated aldol reaction to control the stereochemistry of the secondary allylic alcohol. The gold-catalyzed cycloisomerization/Prins reaction was optimized but the best results were obtained with the free alcohol **368** (in agreement with the results of the total synthesis described by Echavarren's group) and with simple gold chloride as the catalyst. The oxo bridged tricyclic derivative **369** was isolated in 48% yield and then transformed to diol **370** in a five-step procedure implying an epoxidation, reduction and oxidation reaction. It is noteworthy that the



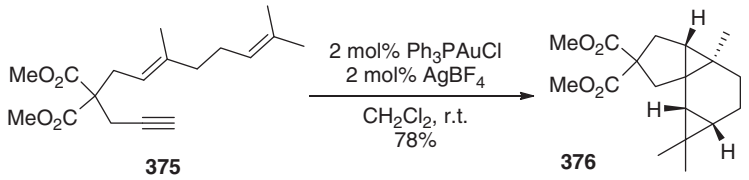
Scheme 27

hydrogenation of the tetrasubstituted double bond of the precursor of **370** was performed in the presence of Raney nickel at 90×10^5 Pa of dihydrogen. The completion of the synthesis of (–)-englerin **365** was then realized via protection/oxidation/reduction of the hydroxyl functions.



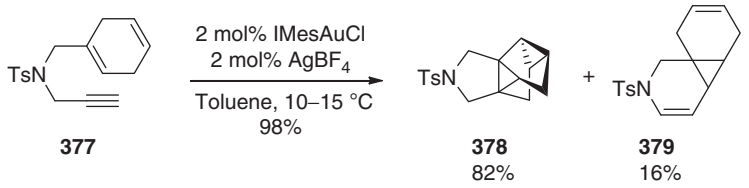
5.30.4.2 Carbon Nucleophiles

5.30.4.2.1 Alkenes as nucleophiles

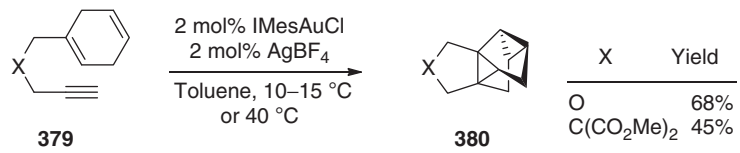


Murai's group examined the behavior of linear acyclic dienynes in the presence of organometallic complexes in order to trap the carbenoid intermediate (represented by **20** in Scheme 22) obtained from the cyclization of 1,6-enyne systems by the additional unsaturation.[134] The use of catalytic amount of platinum dichloride in toluene furnished the polycyclic derivative **372** in 61% yield from dienyne **371** (equation 117). It is noteworthy that a ruthenium catalyst also demonstrated excellent activity. With a gold catalyst, the same transformation occurred under milder conditions at room temperature.[135] For example, the tetracyclic derivatives **374** and **376** were obtained in 88% and 78% yields, respectively (equations 118 and 119).

(117)

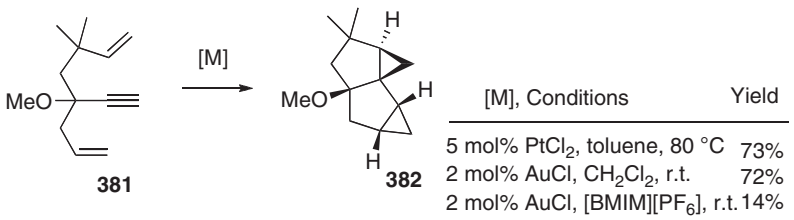


(118)

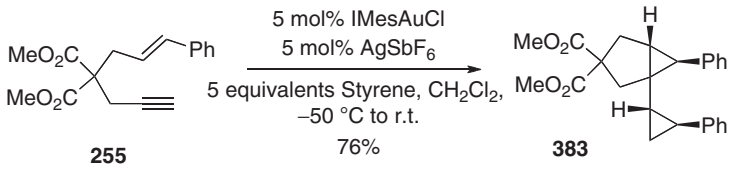


(119)

Switching from 1,6- or 1,5-dienes to 1,4-dienes on the side chain of the substrate did not obstruct the reactivity of the enyne, as illustrated in equations 120 and 121.[136] The preparation of tetracyclo[3.3.0.0^{2,8}.0^{4,6}]octane derivatives such as **378** and **380** has been described starting from the cyclohexadienyl substituted enynes **377** and **379**, respectively. Change of the tether group from *N*-tosyl to oxygen or malonate did not influence the reaction pattern (equation 121), the tetracyclic adducts being isolated in moderate to good yields.

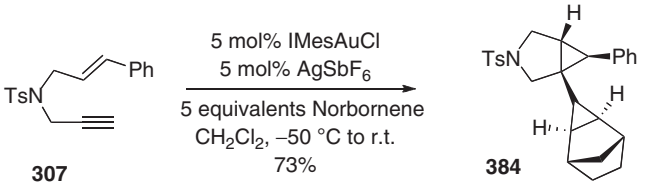


(120)

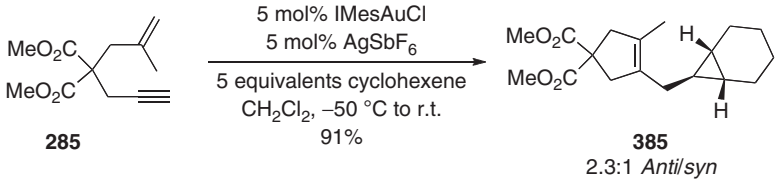


(121)

This reactivity was not limited to 1,6-enynes. The polycyclization reaction was also accomplished with 1,5-enynes (equation 122).[137] Various reaction conditions were adequate: specifically, the tetracyclic adduct **382** was isolated in 73% in the case of a Pt-catalyzed process and in 72% yield in the case of a gold-catalyzed reaction. Alternative solvents such as ionic liquids were tested but gave **382** only in a modest yield. The mechanism of this transformation has been recently studied using computational methods.[138]

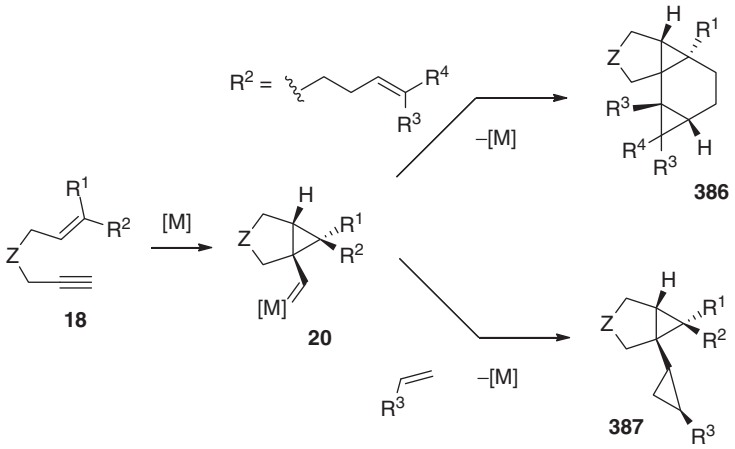


(122)

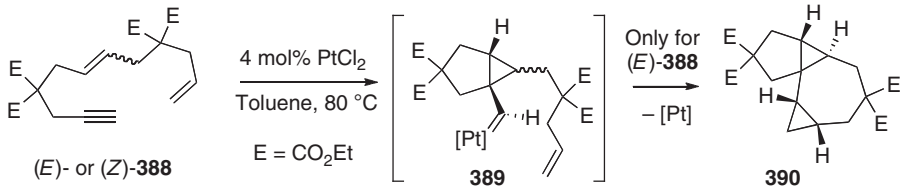


Echavarren's group showed that the reaction could be performed in an intermolecular manner.[139] If the enyne is substituted on the external carbon of the alkene, the cyclopropanation occurs after the first 5-*exo*-type cyclization. In the presence of 5 equivalents of styrene or norbornene, the gold(I) complex IMesAuSbF$_6$ promotes the rearrangement of enynes **255** and **358** into the bicyclic adducts **383** and **384** in very good yields (equations 123 and 124). Rearrangement also takes place when the alkenyl side chain bears an internal substituted carbon. The enyne **285** was converted into the cyclic compound **385** in the presence of cyclohexene under the same catalytic conditions with a very good yield of 91% (equation 125).

(123)

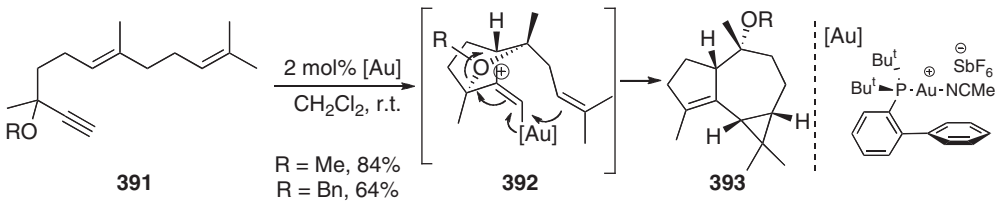


(124)



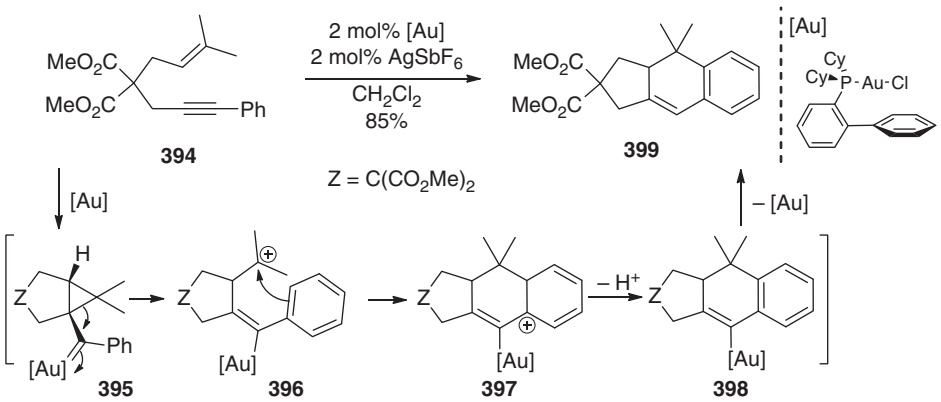
(125)

From a mechanistic point of view, the cycloisomerization reactions of polyunsaturated 1,*n*-enynes are related to a combination of two cyclopropanation steps, allowing for the formation of four carbon–carbon bonds (Scheme 28). The cyclization of the basic 1,6-enyne system **18** provides the carbenoid intermediate **20**, as previously seen in Scheme 22. This intermediate can be trapped by the addition of the remaining unsaturated side chain (for the intramolecular version) on the carbon bonded to the metal and is thus converted, after rearrangement, to the polycyclic product **386**. The case of the intermolecular version is very similar, as the addition of the carbenoid species to the external alkene leads to the cyclic adduct **387**.



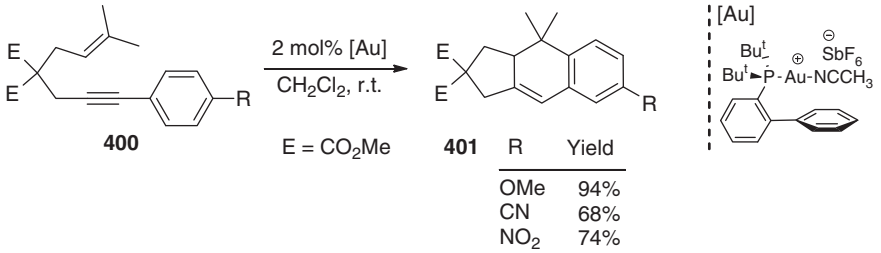
Scheme 28

It is noteworthy that the stereochemistry of the alkenyl side chain is crucial in the case of intramolecular reactions. Indeed, the rearrangement of (*Z*)-**388** affords a mixture of products, whereas the reaction of (*E*)-**388** leads cleanly to the tetracyclic derivative **390** via the intermediate **389** (equation 126). Other elemental steps may occur during the process of cyclopropanation, such as 1,5-migration of the ether groups.[140] The cycloisomerization of enyne **391** illustrates the structural complexity: the cyclopropyl carbenoid intermediate, formed by nucleophilic *anti* attack of the alkene to the alkyne, may react intramolecularly via an *anti* 1,5-migration of a methoxy or benzyloxy group on the cyclopropane skeleton. The intramolecular cyclopropanation with the alkene on the side chain then gives the tricyclic compounds **393** in 84% and 64% yields, respectively (equation 127).



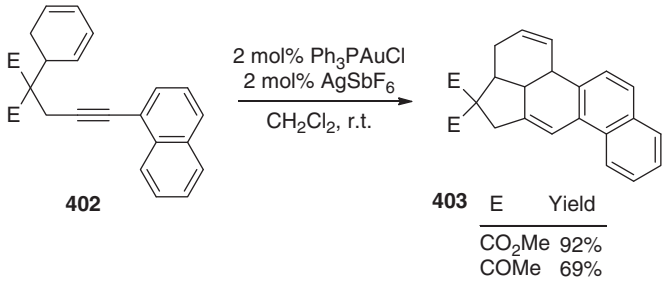
(126)

(127)



5.30.4.2.2 Aromatic rings as nucleophiles

Electron-rich aromatic compounds can also be good partners in cycloisomerizations of enynes. The process of tandem hydroarylation/cyclization allows aromatic C–H bonds to be functionalized in the presence of carbophilic transition metal complexes. The first example of an intramolecular hydroarylation/cyclization of 1,6-enynes has been described by the Echavarren group.[141] The use of substrates where the alkyne function is substituted by an aromatic ring leads to a variety of polycyclic compounds. For example, the synthesis of the tricyclic derivative **399** from the enyne **394** with a prenyl side chain was very efficient (Scheme 29). The mechanism of this reaction, consisting of a formal [4 + 2] cycloaddition, has been studied by DFT. These calculations support a stepwise mechanism for the cycloaddition by the initial formation of an *anti*-cyclopropyl intermediate **395**, followed by its opening (1,2-alkyl migration) to form a carbocation stabilized by a π-interaction with the aryl ring, which undergoes a Friedel–Crafts-type reaction. Aryl substituents stabilize gold carbenoid intermediates, which results in higher barriers for their skeletal rearrangement and lower ones for their *anti* to *syn* isomerization. The following aromatic electrophilic substitution yields the tricyclic system **397**; rearomatization and removal of the metal complex leads to the polycyclic product **399**.



Scheme 29

1,6-Enynes with an aryl ring at the alkyne position give 2,3,9,9a-tetrahydro-1*H*-cyclopenta[b]naphthalenes by a 5-*exo* cyclization followed by a Friedel–Crafts-type addition. This process gives access to the tricyclic derivatives **401** (starting from **400**) bearing electron-donating and withdrawing groups (equation 128). This methodology has recently been applied to the cyclization of 1-aryl-6,8-dien-1-ynes. Specifically, enyne **402** was converted to the tetracyclic product **403** via a 5-*exo* type cycloisomerization reaction in 94% yield (equation 129).[142]

R	Yield

(129)

As expected, substrates such as **404** with a *meta* substituent gave mixtures of regioisomeric cycloadducts **405a** and **405b**. The 6-*endo* cyclization is also observed in this case as a minor process (equation 130). Changing the reaction conditions allowed the formation of a new adduct **407**, resulting from an initial *endo-dig* cyclization followed by the isomerization of the alkene to the internal position. This adduct was obtained as a single regioisomer in excellent yield either under microwave heating or in the presence of a gold complex with tris(2,6-di-*tert*-butylphenyl)phosphite as the ligand (equation 131). This latter complex is an exceptionally reactive catalyst for this reaction.

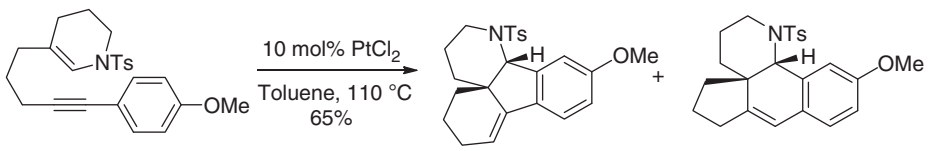
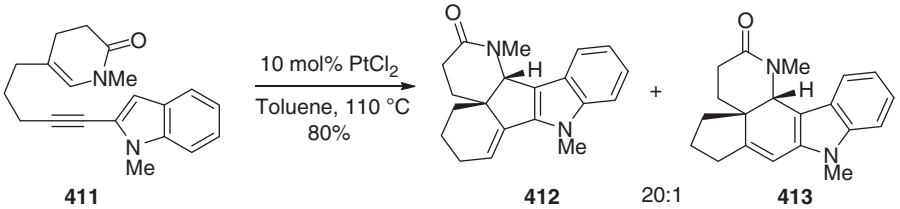
(130)



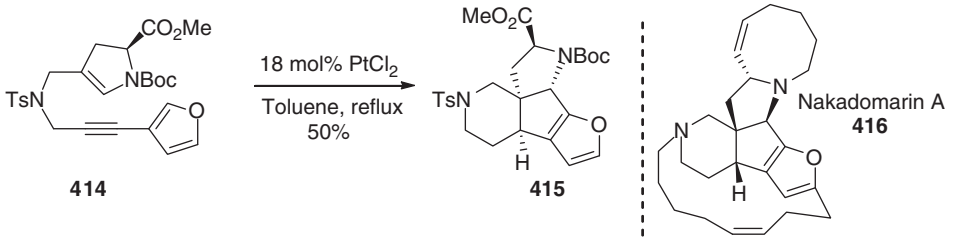
404

407

(131)



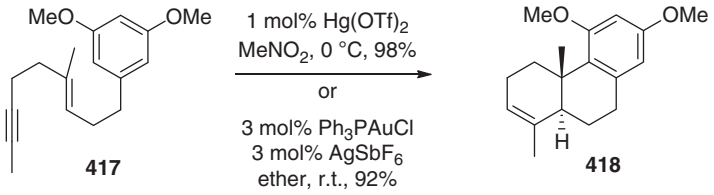
Cyclic enesulfonamides or enamides tethered to an alkyne moiety cyclize readily on exposure to platinum chloride (equations 132–134).[143] This reaction generates quaternary-substituted carbon centers within complex tetracyclic heterocyclic ring systems. Depending on the substitution on the aromatic ring, isomers resulting from an initial 6-*endo* or 5-*exo* process are obtained. The case of electron-donating groups in *para*-position is particularly rewarding, as a 19:1 mixture of isomers **409** and **410** was obtained starting from enyne **408**. Replacement of the benzene moiety with an indole fragment and of the enesulfonamides by enamides also gave excellent results. The treatment of enesulfonamide **411** with platinum dichloride generated **412** an **413** as a 20:1 mixture of isomers in 80% yield. A straightforward approach to *ent*-nakadomarin[144] was described and implied the cycloisomerization of enyne **414** to product **415**.



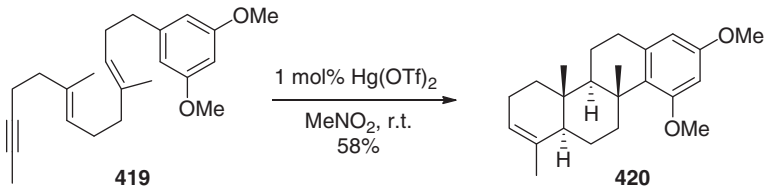
408

409 19:1 410

(132)

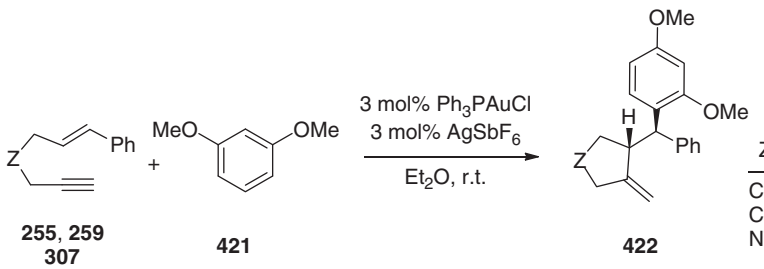


(133)

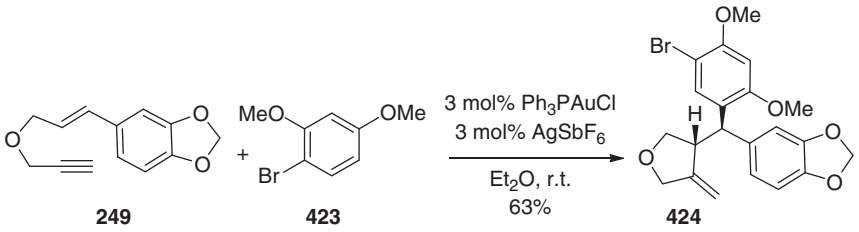


(134)

Cycloisomerization reactions involving an internal aromatic nucleophile have also been described for 1,5-enynes, with the aromatic part being linked on the alkenyl moiety. The use of either mercury or gold salts led to hexahydrophenanthrene **418** starting from **417** in excellent yields with perfect stereoselectivity (equation 135).[97,145] A polycyclization could also be performed in the presence of $Hg(OAc)_2$ that led to **420** in 58% yield; this process creates three carbon–carbon bonds (equation 136).

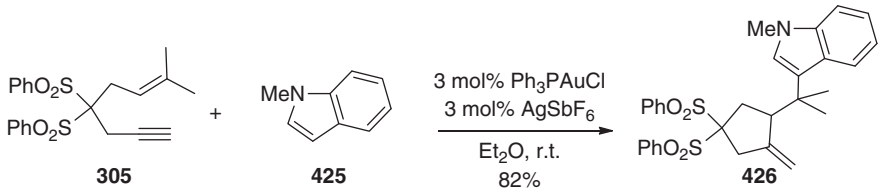


(135)

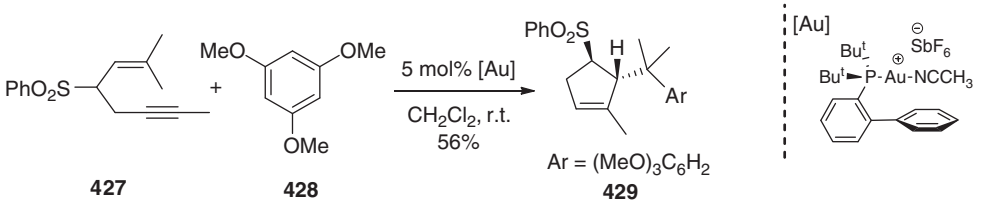


(136)

An intermolecular hydroarylation reaction/cyclization has also been developed, combining Ph_3PAuCl and $AgSbF_6$ in diethyl ether at room temperature.[146] The introduction of electron-rich aromatic compounds such as dimethoxybenzene afforded the corresponding 5-*exo* adducts **422** in good to excellent yields (equation 137). The diastereoselectivity of the reaction is in full accord with the alkoxycyclization processes presented in the last section. The mild conditions are compatible with 4-bromo-1,3-dimethoxybenzene **423** and 1-methylindole **425**. Under these conditions, ether **249** was converted into alkene **424** with a yield of 63%, and the cyclization of enyne **305** endowed with a *gem*-disulfone moiety was achieved quantitatively, leading to adduct **252** (equations 138 and 139). A moderate activity was observed in the case of 1,5-enynes.[147] The addition of trimethoxybenzene **428** to enyne **427** gave the functionalized cyclopentenyl adduct **428** in 56% yield (equation 140).

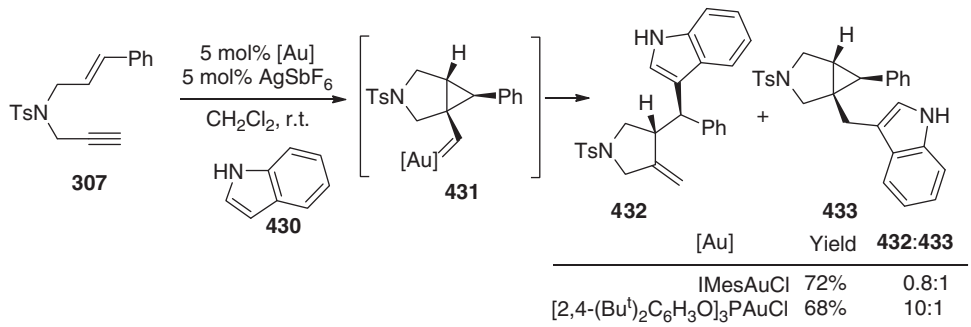


Z	Yield
$C(CO_2Me)_2$	73%
$C(SO_2Ph)_2$	99%
NTs	60%

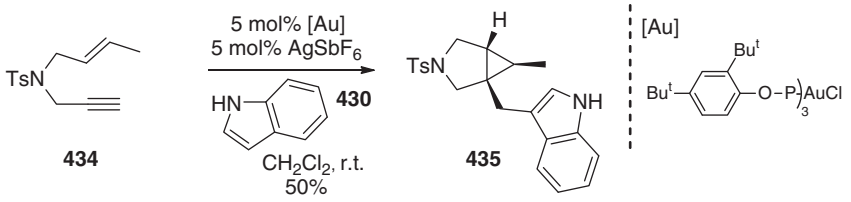


(137)

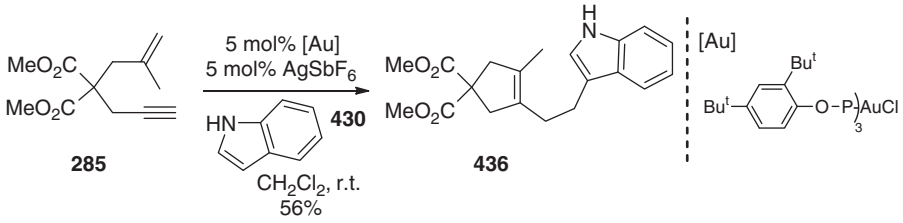
(138)



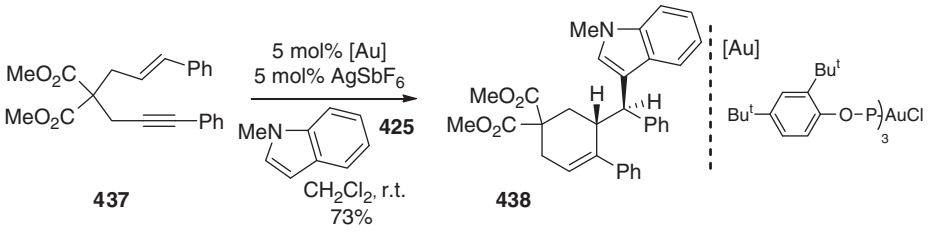
(139)



(140)

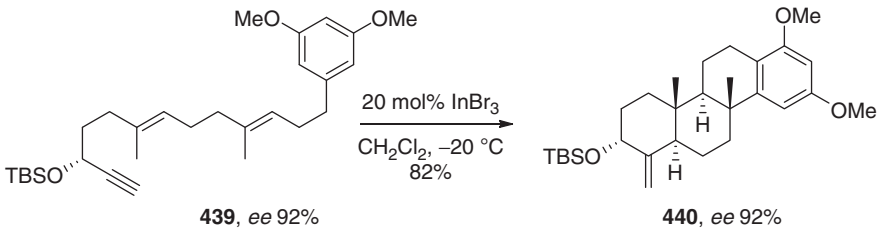


Equations 141–144 illustrate the importance of the substitution on the enynes as well as the dependence on the gold catalyst. The substrate **307**, having a nitrogen-atom that links the alkyne and alkene chains, has been engaged in a reaction in the presence of indole **430** and different gold complexes: the production of two products **432** and **433** resulting from the nucleophilic attack on either the cyclopropane (product **432**) or the cyclopropyl carbenoid moiety (product **433**) were observed (equation 141).[147] With the gold complex IMesAuCl carrying a NHC, a ratio of 0.8:1 was obtained, which shows that the addition is equally facile on either position of intermediate **431**. When the cationic gold complex [2,4-$(Bu^t)_2C_6H_3O$]$PAuSbF_6$ with a phosphite ligand was used, the major product was **432**, resulting from the nucleophilic attack of the indole on the cyclopropane. The addition of indole **430** to the sulfonamide-type enyne **307**, carrying a methyl on the alkene, in the presence of the same catalytic system, gives the azabicyclic derivative **435** resulting from the addition of the aromatic moiety to the carbenoid species (equation 142). The case of 1,6-enyne **285** is particularly instructive as its implication in cycloisomerization/functionalization processes has been detailed previously (equations 93, 109, and 125). Except for the case of the intervention of an alcohol (or water), which are present in large excess, the cycloisomerization of **285** leads to the rearrangement of cyclopropyl carbenoid intermediate **323** and therefore addition of various nucleophiles occurs on the carbenic moiety, which shows that the outcome of the transformation is mainly dictated by the substrate. Therefore similar structures are observed for the addition of aldehydes, alkenes or aromatic nucleophiles; for example, cyclopentene **436** was obtained in 56% yield (equation 143). The 6-*endo* cyclization mode is also possible, as illustrated by the reaction of the substituted 1,6-enyne **437**. The tandem addition of 1-methylindole (**425**)/cycloisomerization afforded product **438** in 73% yield.[147]

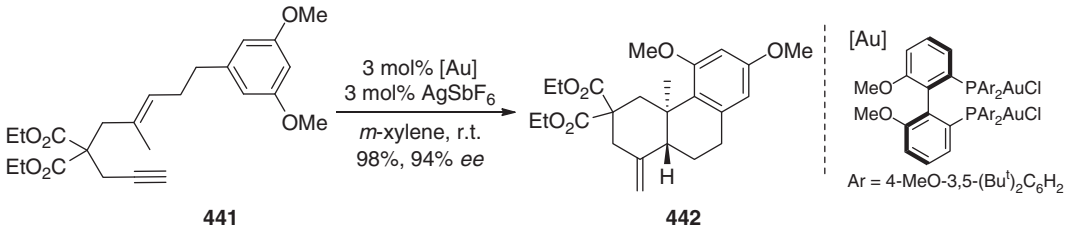


(141)

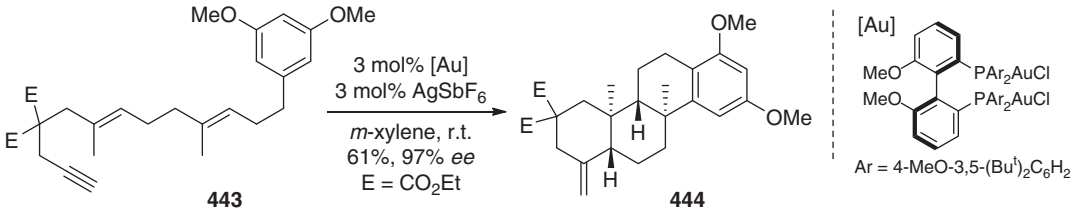
(142)



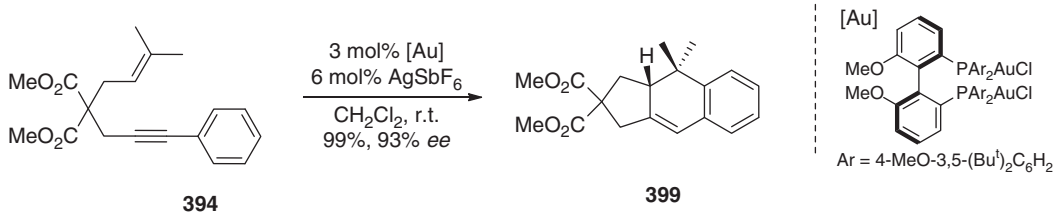
(143)



(144)

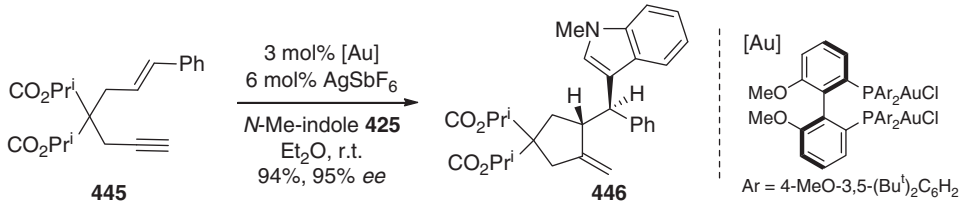


Few asymmetric examples are described in the literature.[5] The stereospecific intramolecular addition of electron-rich aromatic rings has been carried out on 1,6-enynes. The first process implies the enantiomerically enriched carbon-tethered enyne **439** and indium trichloride as the carbophilic catalyst.[148] In the presence of 20 mol% of the indium(III) salt at $-20\,^{\circ}C$, the synthesis of the tetracyclic derivative **440** was highly efficient. The resulting configuration of the created chiral centers is in line with the stereospecificity of the reaction and depends on the stereochemistry of the silyl ether at the propargylic position (equation 145). The authors also highlighted the superior activity of indium compared with silver, and the lower cost and toxicity compared with gold or mercury salts. Enantioselective versions implying a chiral gold bimetallic complex derived from an atropisomeric MeOBIPHEP analog have also been described (equations 146–148). The synthesis of the tri- or tetracyclic derivatives **442** and **444** (analogous to **440**) was performed in good to excellent yields and, more importantly, with excellent *ee*s (94% and 97%, respectively).[126] The cycloisomerization/functionalization reaction of 1,6-enyne **394** (already disclosed under racemic conditions, Scheme 29) led to **399** in 99% yield and 93% *ee* (equation 148).[122,149]

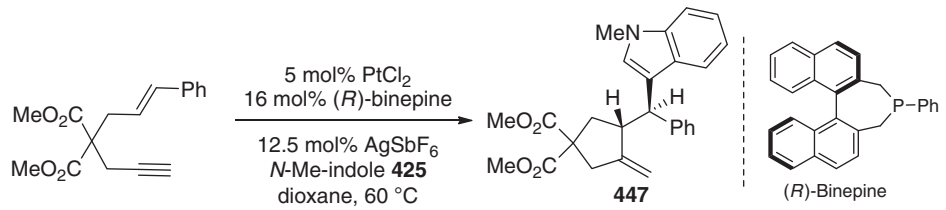


(145)

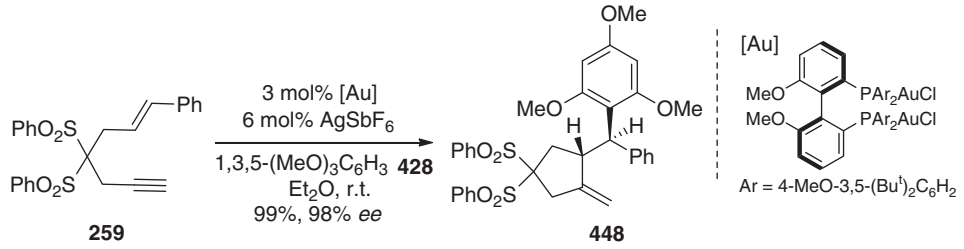
(146)



(147)



(148)



Intramolecular asymmetric processes have been designed either in the presence of chiral gold or platinum complexes (equations 149 and 150). The use of hindered malonate-type 1,6-enynes **445** allowed for the addition of *N*-methylindole **425** and cyclization in 94% yield and 95% *ee* (equation 149). A square-planar chiral Pt(II) catalyst with an atropisomeric monophosphane binepine led to excellent results too, despite the fact that the reaction occurs at higher temperature (equation 150).[150] This system had already proved efficient in the alkoxyclization of 1,6-enynes (equation 98).[119] The gold-catalyzed process was generalized to other enynes and nucleophiles (equations 151 and 152), the best results being obtained in the case of carbon-tethered 1,6-enynes such as **259** whereas oxygen-tethered analogs such as **249** reacted less selectively.

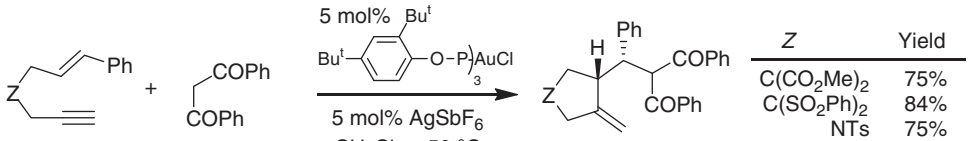
(151)

(152)

5.30.4.2.3 1,3-Dicarbonyl derivatives or allylsilanes as nucleophiles



Apart from alkenes and aromatic nucleophiles, few other carbon nucleophiles have been used as partners in the tandem processes. The reaction of allylsilanes gave rise to the formation of a carbon–carbon bond according to an S_N2' addition/cyclization.[112] Sulfonated derivatives such as **451** were prepared, according to a 'classic' rearrangement of the enyne **259** implying the cyclopropyl carbenoid species **20** as depicted in Scheme 22 and addition to the allyl moiety (equation 153). 1,3-Dicarbonyl derivatives may also be used in the rearrangement/functionalization procedure to form carbon–carbon bonds. Whereas cyclohexane-1,3-dione led to the formation of a new carbon–oxygen bond (alkoxycyclization process, equation 83), the use of dibenzoylmethane **452** afforded the corresponding five-membered ring derivatives **453** via cycloisomerization followed by the addition of the activated nucleophile (equation 154).

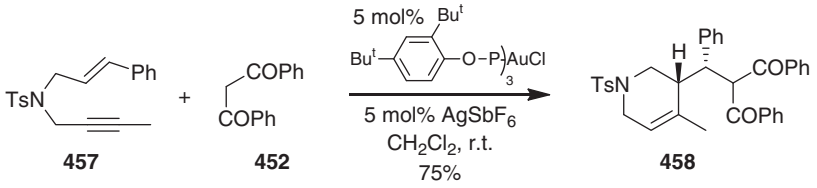
(154)

255 **452** **454**

(155)



The reaction conditions were found to be crucial, as further rearrangement occurs at room temperature in the case of 1,6-enyne **255**. Indeed, after formation of **453**, the remaining 1,3-dicarbonyl moiety acts as an oxygen nucleophile and the whole process leads to bicyclic **454** in 65% yield. As previously observed in equation 141, the reaction of the nitrogen-tethered enyne **407** gave a mixture of products **455** and **456**, with various ratios depending on the catalyst employed. The difference between IMesAuSbF$_6$ and [2,4-(Bu^t)$_2$C$_6$H$_3$O]PAuSbF$_6$ is more pronounced in the case of 1,3-dicarbonyl nucleophiles than in the case of indole as reaction partner (compare equations 141 and 156). The reactivity of enynes substituted at the alkynyl position also follows the same trend as previously observed for **437** (equation 144). The tandem addition/cyclization of **457** furnished the corresponding six-membered ring **458**, obtained via a 6-*endo* cyclization process (equation 157). The scope of this transformation is still limited, as cyclopentane-1,3-dione, indane-1,3-dione, dimethyl malonate, and Meldrum acid were not suitable nucleophiles.

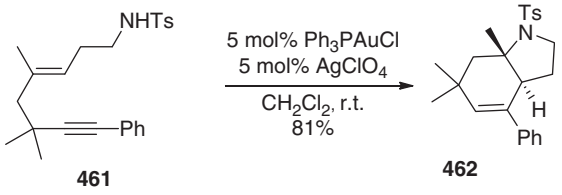
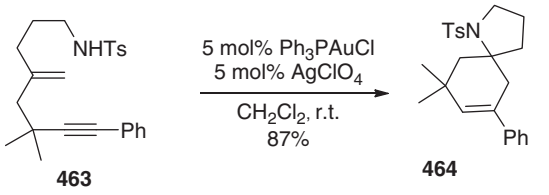
(156)

457 **452** **458** (157)



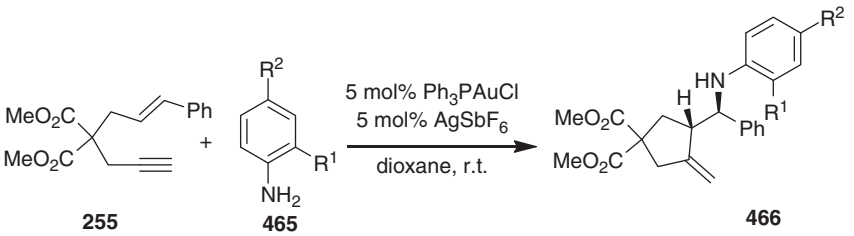
5.30.4.3 Nitrogen Nucleophiles

The team of Kozmin described in 2005 the first example of a tandem cyclization of 1,5-enynes involving a nitrogen nucleophile.[115] The use of 5 mol% of gold trichloride cleanly converted substrate **459** into bicycle **460** at room temperature with a yield of 82% (equation 158). The cyclization mechanism is similar to the previously developed alkoxycyclization of enynes. This completely diastereoselective intramolecular cyclization proceeds through 6-*endo-dig* process.



459 **460** (158)

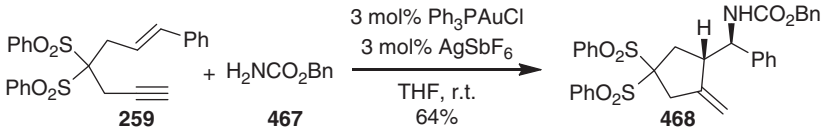
The same group has described the synthesis of the *trans*-azabicyclo[4.3.0]nonene **462** from the enyne **461** with an amino side chain according to a 6-*endo* cycloisomerization in the presence of a cationic gold catalytic system in 81% yield (equation 159). Depending on the substitution of the alkene, spiro compounds may also be formed by the intramolecular domino process. The enyne **463** rearranges in the presence of the same catalytic system to give the desired spiro compound **464** with an excellent yield of 87% (equation 160).



461 **462** (159)

463 **464** (160)

The intermolecular addition of nitrogen nucleophiles during the cycloisomerization of 1,6-enynes was developed more recently.[151]



Weakly nucleophilic amines such as sulfonamides, carbamates, or electron-poor anilines have been successfully introduced to a wide range of 1,6-enynes. For example, the addition of substituted anilines **465** bearing chloride, trifluoromethyl, or cyano groups afforded the corresponding functionalized cyclopentanes **466** in good to excellent yields (equation 162). In the presence of benzyl carbamate **467**, the cyclization of the disulfone derivative **259** led to amine **468** with a yield of 64% (equation 163). Oxygen-linked enynes are also good candidates for these domino reactions. The addition of allyloxy carbamate **471** on 1,6-enyne **470** gave the heterocycle **472** in 92% yield (equation 164). In all cases studied, only one diastereomer was formed. The proposed mechanism combines the stereospecific attack of the alkene to the alkyne to yield the cyclopropyl carbenoid intermediate, followed by the addition of the nucleophilic nitrogen.

$CbzNH_2$	7%	36%

(164)

Two examples of intermolecular addition of carbamates on dienynes with a 1,5-enyne as key motif have recently been described (equation 164).[118] As in the case of oxygen nucleophiles (equation 97), the addition of the nucleophile on the cyclopropane is in competition with the addition of the terminal alkene function present on the substrate **472**. In the presence of *tert*-butyl or benzyl carbamates and a catalytic amount of a cationic gold(I) complex, dienyne **472** was converted into a mixture of products **473** and **474** resulting from 5-*endo-dig* mono- and bicyclization, respectively, with preferential formation of isomer **474**.

In line with asymmetric cycloisomerization reactions using chiral gold catalysts, the group of Toste has reported a single stereoselective reaction of 1,6-enyne bearing an amino group as nucleophile.[126] The substrate **475** was transformed into bicyclo[4.4.0] decane **476** with a good 75% yield and an excellent *ee* of 92% (equation 165).

475 **476**

(165)

5.30.5 Conclusion

The field of cycloisomerization of enynes has been in constant expansion during the past 15 years. Based on the precept of π-activation of an alkyne by a carbophilic transition metal, several new rearrangements have been discovered, involving the alkene as the unique nucleophilic moiety or as the first partner in the presence of other nucleophiles. The diversity in terms on enyne skeletons and the simplicity to conduct a reaction with carbophilic and generally air-stable catalysts have contributed to the expansion of the field. Depending on the length of the tether between the alkyne and alkene moieties, various modes of cyclization have been highlighted. Moreover, the potential complexity of the resulting polycyclic structures resulting from enyne skeletal rearrangements has been heightened by the intervention of other nucleophiles (oxygen, carbon, and nitrogen nucleophiles), favoring domino processes. A multitude of diversified pathways have therefore been discovered. The interpretation and mechanistic rationale of each rearrangement or domino process is not always clear, but the emergence of theoretical studies has highly enriched the field and helped in interpreting the experimental results. The association of experimental and theoretical studies has also stimulated the discovery of new transformations.

As some reactivity trends have been established on the basis of experimental and theoretical studies, further applications such as the use of rearrangements and domino processes in total synthesis have appeared in the literature. This is the sign that this chemistry gains maturity and that 'prediction' takes precedence over 'understanding'. Platinum and gold complexes have shown high efficiency and tolerance for applications to functionalized systems, as previously palladium had.

The knowledge of the structure of the organometallic complexes from newly designed ligands has allowed for the discovery of highly efficient catalysts and has opened the door to asymmetric catalysis. Although some substantial advances have already been made in the past few years, it is still not possible to perform each and every asymmetric enyne rearrangement with success. Mechanistic rationalization associated with the ligand tailoring will certainly help to sustain future advances.

Glossary

Cooligomerization The oligomerization of two different compounds.

Crossed cyclotrimerization The addition of three components in which at least two are different to form a ring.

Cyclotrimerization The addition of three components to form a ring.

Helicenes Ortho-condensed polycyclic aromatic compounds in which the rings give helically-shaped molecules.

Homo-Diels-Alder A [2 + 2 + 2] cycloaddition between a strained nonconjugated diene and a dienophile resulting in the formation of tetracyclic structures of considerable strain known as deltacyclanes.

Thorpe–Ingold effect or angle compression The effect observed when increasing the size of two substituents on a tetrahedral center which leads to enhanced reactions between parts of the other two substituents.

5.31.1 Introduction

This chapter deals with [2 + 2 + 2] cycloaddition reactions in which three components contribute with two electrons each. Most examples involve three multiple bonds which are combined to form six-membered carbo- or heterocycles. However, a brief section will cover those reactions in which CO, isonitriles, or heteroatoms participate in the cycloaddition with two electrons to form four- or five-membered rings through a (2 + 1 + 1) or a (2 + 2 + 1) process. Pauson–Khand-type reactions (*see* Chapter 5.24), metal carbene cycloadditions (*see* Chapter 5.25), or zirconium-mediated bicyclization of enynes (*see* Chapter 5.30) will not be addressed as they are covered in other chapters. After some general remarks, this introductory section

will show the most important catalytic systems used. Then, a mechanistic discussion will provide a summary of the current knowledge on the reaction pathways of the different versions of this process.

The generation of new ring systems is a key part of organic synthesis which is many times accomplished through cycloaddition reactions. The [2 + 2 + 2] cycloaddition is remarkable in terms of synthetic power and scope; starting from various unsaturated substrates such as alkynes, nitriles, alkenes, allenes, imines, aldehydes, ketones, isocyanates, and isothiocyanates, sometimes in combination with CO, CO_2, CS_2, isonitriles, or heteroatoms, it allows the synthesis of a great variety of highly substituted cyclic molecules such as five-membered carbo- and heterocycles, benzenes, pyridines, pyridones, and 1,3-cyclohexadienes (Figure 1).

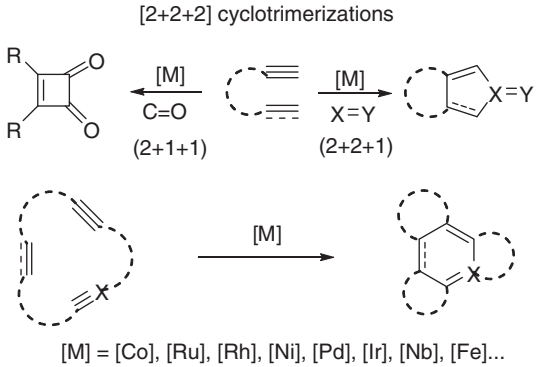

Figure 1 General scheme for [2 + 2 + 2] cyclotrimerizations.

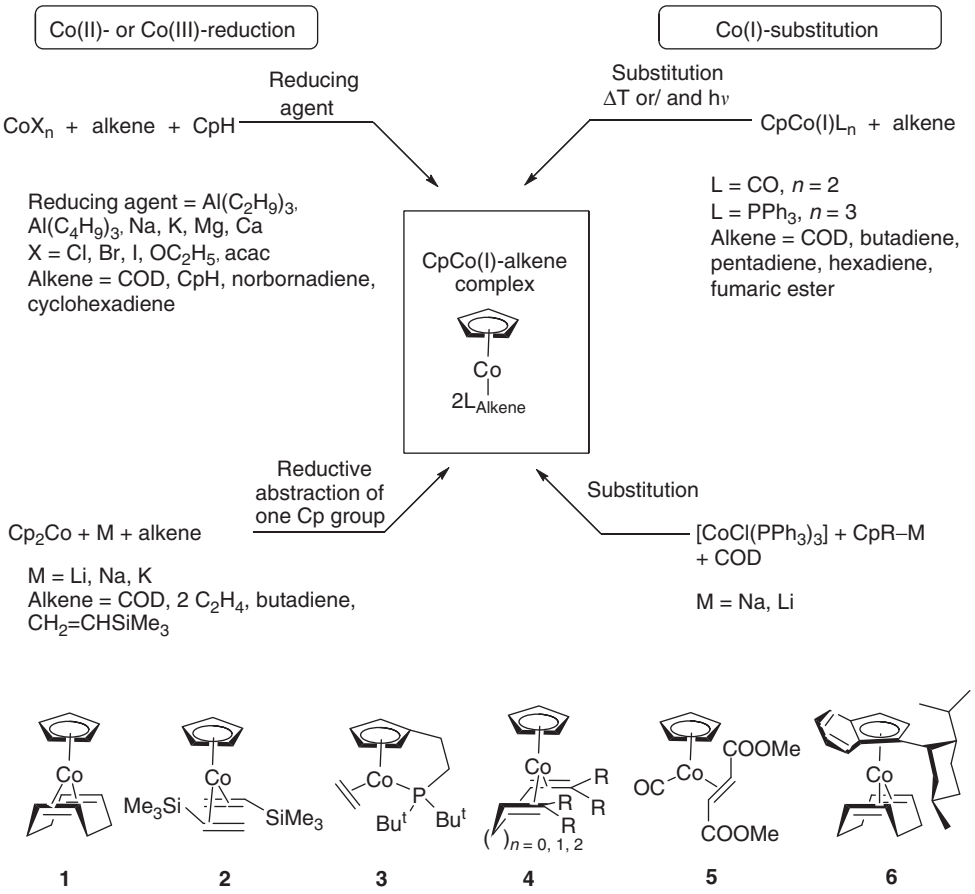
The metal-mediated [2 + 2 + 2] cycloaddition reaction began with the discovery of Reppe's trimerization of acetylenes nearly 60 years ago.[1] Nowadays the [2 + 2 + 2] cycloaddition reaction has reached such a mature state of the art that many densely functionalized aromatic compounds can be constructed with this methodology. For instance, polysubstituted benzenes and pyridines are highly useful compounds which are widely used in industry and in the laboratory. In addition these motifs are present in numerous natural products. Traditionally, aromatic compounds were constructed by stepwise introduction of the substituents via electrophilic substitution reactions. The [2 + 2 + 2] process is now an alternative to these methodologies applicable to the synthesis of natural products, axially chiral compounds, or molecules with fragile functionalities.

5.31.1.1 Catalysts

Catalysts based at least on 17 transition metals have been used to produce the [2 + 2 + 2] cyclization reaction. Most of them correspond to late transition metals especially those of group 9 (Co, Rh, Ir).[2] In addition, Ni and Pd are many times chosen as the catalyst followed by some ruthenium complexes including Grubbs' type carbenes. Niobium salts and zirconium complexes also have found use in these reactions, and examples of [2 + 2 + 2] reactions can be found in the literature with V, Ta, Mo, Fe, Os, In, and even lanthanides such as Eu, Dy, or Yb.[3] However, the current trend is to use Co, Rh, Ir, and Ru complexes or in a smaller number of contributions, Pd-, Ni-, Ti-, and Nb-based catalysts.

Despite the great development of the metal-catalyzed [2 + 2 + 2] cyclization process for laboratory uses, this process is still in its beginnings with respect to the development of environmentally friendly and scalable procedures that could be industrially applied. These reactions are generally performed in organic solvents with soluble catalysts. However, some contributions have described [2 + 2 + 2] reactions in water[4] and a recent report used nitrile-functionalized ionic liquids as solvents for cobalt-catalyzed cyclotrimerization reactions of terminal aromatic alkynes.[5]



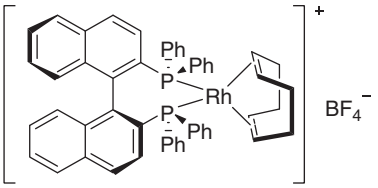
In addition, many reactions need thermal initiation and various groups have used microwaves (MW) heating for transition metal-catalyzed [2 + 2 + 2] cycloadditions. The claimed advantage of MWs (improved yields in shorter reaction times and lower catalyst loadings) has been discussed in a recent study that has compared MW-assisted reactions with conventional heated processes. With an accurate measurement of temperature using fiber-optic probes, the authors have reproduced exactly the same results both with and without MW. This fact discards the so-called wall effects (nonuniform heating of flasks when using conventional oil baths) and nonthermal MW effects as the lifetime of the catalyst was not altered.[6]

5.31.1.1.1 Cobalt catalysts

Most of the early literature used cobalt complexes to mediate or catalyze [2 + 2 + 2] cycloadditions.[7] The ability of cobalt complexes is well known to promote powerful synthetic transformations, and continues to be a nonexpensive and efficient option in many cases. Cobalt acts in a double role, as it is used in stoichiometric as well as catalytic complexes. Among all the available catalysts, η^5-cyclopentadienyldicarbonyl cobalt [$CpCo(CO)_2$] has proved the most popular and versatile reagent for the [2 + 2 + 2] cyclotrimerization of alkynes followed by [$CpCo(PPh_3)_2$]. Vollhardt's group has reported numerous applications of cobalt-catalyzed reactions including total syntheses of different natural products and compounds of theoretical interest. These complexes contain relatively strongly bound neutral ligands, requiring thermal or radiation energy for activation. Some cases require 1 equivalent or even an excess of cobalt complex. For intermolecular stoichiometric reactions $Co_2(CO)_8$ has also been used.[8]

There are several synthetic pathways to obtain Co(I)–alkene complexes, consisting of either reduction of Co(II) or Co(III) species in the presence of stabilizing alkene ligands or ligand substitution by alkenes in Co(I) complexes. As well-established examples of the first approach, [CpCo(COD)] **1** is obtained from $Co(acac)_3$ using organoaluminum reagents for reduction.[9] Another approach is the reductive abstraction of a cyclopentadienyl fragment from cobaltocene promoted by lithium or sodium in the presence of alkenes.[10] This approach allowed access to **2**, a very active catalyst.[11] One interesting variation consisted of a reaction of a Co(II)-salt with a metallated Cp fragment and further reduction in the presence of ethylene to give **3**, a complex able to produce cyclotrimerization reactions in water.[12] Other carbonyl-free catalytic systems are simple cobalt halides such as a $CoBr_2$, generally in combination with Zn powder as reducing agent, and other additives like diimines or phosphines.[13] For instance, $CoCl_2 \cdot 6H_2O$/Zn is an inexpensive and easy to handle reagent that, combined with additives like diimines or phosphines, has given excellent results in alkyne cyclotrimerization. The addition of silver triflate (AgOTf) or silver hexafluoroantimonate ($AgSbF_6$) significantly increased the activity of the catalytic system, if 2-(2,6-diisopropylphenyl)iminomethylpyridine (dipimp) was the additive. For the synthesis of pyridines with all types of nitriles, reactions catalyzed by 1,2-bis(diphenylphosphino)ethane (dppe)/ $CoCl_26H_2O$ in the presence of Zn powder were described to proceed with high regioselectivity.[14]

The other synthetic approach to prepare Co(I)–alkene complexes generally involves heating or irradiation of $[CpCo(CO)_2]$ which allows substitutions of both CO ligands or only one of them giving access to complexes such as **4** and **5**, respectively.[15] Another starting material is $[CoCl(PPh_3)_3]$, a suitable precursor for the introduction of a functionalized Cp ligand and subsequent coordination with COD, to form **6**.[11] **Scheme 1** summarizes the main Co-based catalysts currently used.



Scheme 1

5.31.1.1.2 Rhodium and iridium catalysts

The first reported uses of rhodium complexes in [2 + 2 + 2] chemistry, consisted of the formation of rhodacyclopentadienes by the reaction of stoichiometric amounts of Wilkinson's catalyst $[RhCl(PPh_3)_3]$ with α,ω-diynes, and further reaction with alkynes.[16] In addition to Wilkinson's catalyst and other similar derivatives like $[RhCl(COD)]_2$, many catalytic systems consist of a combination of a cationic rhodium species such as $[Rh(COD)_2]BF_4$ and a spectator ligand, generally a phosphine. Chiral 2,2′-Bis(diphenylphosphino)-1,1′-binaphthyl (BINAP)-type ligands have been successfully used in recent times (see Sections 5.31.3.2, 5.31.3.3, and 5.31.4 for representative examples). The final active complex with structure **7** as depicted in **Figure 2** may be prepared separately,

but currently these complexes are formed *in situ*. In addition, some groups have reported $RhCl_3 \cdot 3H_2O/Pr^i_2NEt$-catalyzed [2 + 2 + 2] cyclotrimerizations of alkynes,[17] and the use of a rhodium-*N*-heterocyclic carbene ligand (NHC) complex [RhCl(COD)(NHC)], in a [2 + 2 + 2]-cycloaddition reaction of three alkynes.[18]

[Rh((*aS*)-BINAP)(COD)]BF_4

7

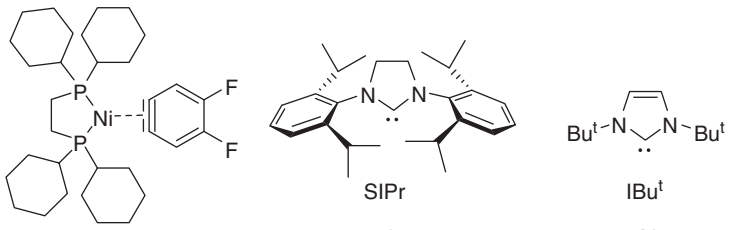


Figure 2 Structure of a cationic rhodium catalyst.

A recent report accounts for the synthesis and performance of a solid-supported catalyst made from $[Rh(C_2H_4)_2(acac)]$ and dealuminated Y-zeolite. The authors show X-ray absorption fine structure (EXAFS) spectra in which $\{Rh\text{-}(C_2H_4)_2\}$ groups appear covalently anchored to two zeolite oxygen ions.[19]

The first preparation of a iridacyclopentadiene consisted of a reaction of $[IrCl(N_2)(PPh_3)_2]$ with dimethyl acetylene dicarboxylate (DMAD).[20] Since then, iridium-based catalytic systems consist generally of an *in situ* mixture of $[IrCl(COD)]_2$ or $[IrCl(C_2H_4)_2]_2$ with a phosphine like dppe or 1,1′-bis(diphenylphosphino)ferrocene (dppf).[21] The nature of the ligand affects the regioselectivity in crossed cyclotrimerizations of diynes with nonsymmetric alkynes, and in intermolecular reactions.

5.31.1.1.3 Nickel and palladium catalysts

The pioneering cyclotrimerization of alkynes reported by Reppe was performed using a mixture of $NiBr_2$ and CaC_2.[1] Since then, $NiBr_2$/dppe, 1,1-bis(diphenylphosphino)methane (dppm), [1,4-bis(diphenylphosphino)butane] (dppb) complexes in combination with Zn powder have been used especially for the cyclizations of diynes with aryne precursors, which are thought to go through aryne intermediates such as **8**.[22] In addition, nickel (0) complexes such as $Ni(COD)_2$ have been applied to many substrates. Louie's group has extensively studied combinations of Ni(0)/NHC such as Ni(COD)/SIPr (**9**) or Ni(COD)/IBu^t (**10**) (Figure 3) as catalysts for the cycloaddition of unactivated nitriles, isocyanates, ketones, CO_2, and cyanamides with alkynes and diynes.[23]

8 **9** **10**

Figure 3 Structures of Ni-aryne intermediate **8** and of NHC ligands **9** and **10** used in combination with Ni(COD) as catalysts.

Several palladium complexes are reactive toward alkynes. In intermolecular versions, these Pd-catalyzed cyclizations are complex processes and appear to operate with a different mechanism, even though the formation of the arenes is the end result in some of these processes. The mostly used compounds are $Pd_2(dba)_3$, $Pd(PPh_3)_4$, and $Pd(OAc)_2/PPh_3$ *(vide infra)*. Heterogeneous catalysis would be useful as it facilitates elimination and reutilization of the catalyst. Gold nanoparticle-supported palladium(II) interphase catalysts were used to perform an alkyne cyclotrimerization reaction in ionic liquids.[24] Palladium complexes were immobilized onto Au nanoparticles through chelation to the surface-bound dipyridyls. Hybrid catalysts of this type were dissolvable and precipitable, and proved to be highly effective catalysts for [2 + 2 + 2] alkyne cyclotrimerization reactions with fairly good selectivity. The nanoparticles can be easily separated, quantitatively recovered by simple filtration, and reused effectively many times (Figure 4).

5.31.1.1.4 Ruthenium catalysts

With regard to ruthenium complexes, [CpRuCl(COD)], is a well-documented catalyst that forms benzene, pyridines, pyridones, and thiopyridones from diynes and alkenes, activated nitriles, isocyanates, and isothiocyanates, generally acting at ambient temperature.[25] In addition, $[CpRu(CH_3CN)_3]PF_6$ and $[CpRu(CH_3CN)_3]PF_6$ have also been used.[26] Recently a combination of $Ru_3(CO)_{12}$ with 2-(diphenylphosphino)benzonitrile (2-dppbn) was efficiently used to cyclotrimerize trifluoromethylalkynes.[27] Grubbs' catalysts have proven to be useful in mediating in [2 + 2 + 2] cycloadditions. After some early reports that used **[Ru]-I** as

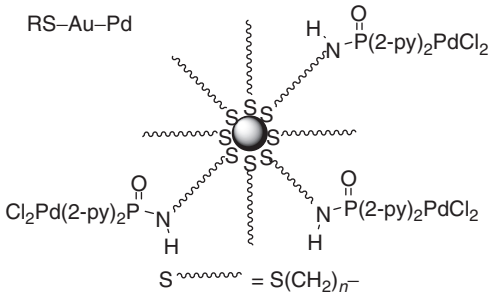

Figure 4 Schematic representation of palladium complexes immobilized onto Au nanoparticles. Represented nitrogen atoms belong to surface-bound dipyridyls.

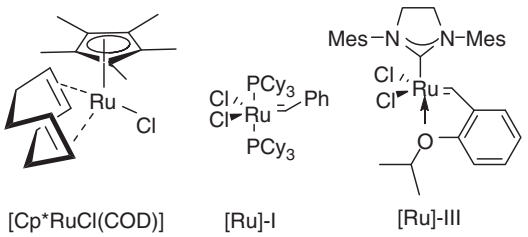
the catalyst, the authors recently disclosed a new protocol for crossed diyne–alkyne cyclotrimerizations mediated by Hoveyda–Grubbs' complex **[Ru]-III** (Figure 5).[28]



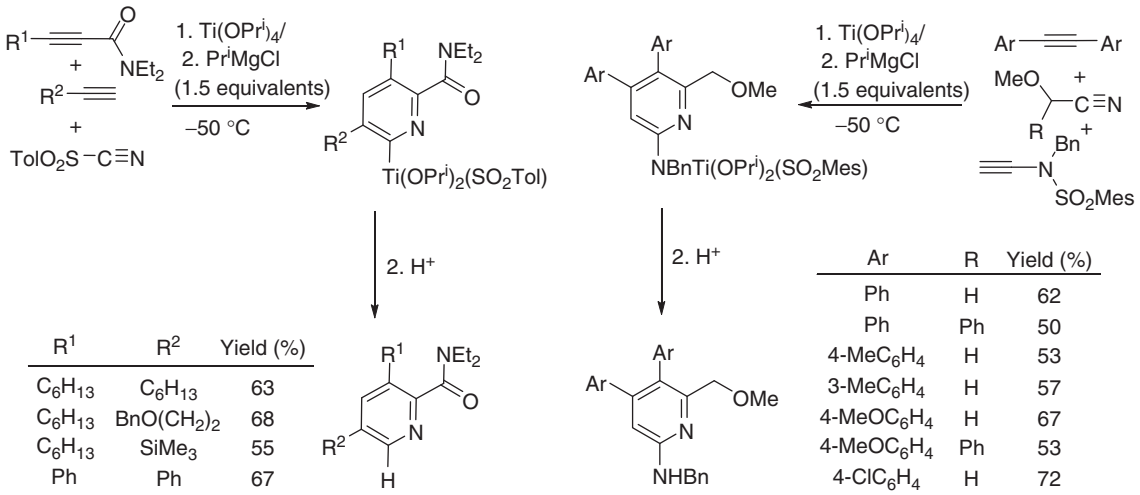


Figure 5 Structure of some ruthenium complexes used as catalysts in [2 + 2 + 2] cycloadditions.

5.31.1.1.5 Titanium and other metal-based catalysts

Titanium catalysis has received less attention in recent times in the cyclotrimerization chemistry as it generally works stoichiometrically. Urabe and Sato's group disclosed a four-component coupling process involving two acetylenes, a nitrile and a divalent titanium alkoxide reagent, $Ti(OPr^i)_4/2\text{-}Pr^iMgCl$, which directly yielded titanated pyridines in a highly selective manner. The key feature was the presence of a leaving group in the nitrile which allowed the titanium to finish the reaction attached to the pyridine. The pyridylmetal species formed enabled subsequent transformations (Scheme 2).[29]

Scheme 2

Other metal complexes have found utility in the [2 + 2 + 2] cyclotrimerization chemistry. Examples include V, Ta, and Os catalyzed reactions.[3] Zirconacyclopentadienes are still used in certain cases to react stoichiometrically with alkynes to give aromatic compounds.[30] More recently a $DyCl_3$-catalyzed silyl-radical cyclotrimerization of alkynes was reported[31] and rhenium and manganese salts were used as catalyst for [2 + 2 + 2] cyclizations and other cycloadditions between 1,3-dicarbonyl

compounds and alkynes.[32] Intermolecular [2 + 2 + 2] cycloaddition of alkynes and α,ω-dienes or alkenes was successfully achieved by [$NbCl_3$(DME)] (DME = dimethoxyethane) to afford 1,3,4,5-substituted-1,3-cyclohexadienes in excellent yields with high chemo- and regioselectivity (Scheme 3).[33]

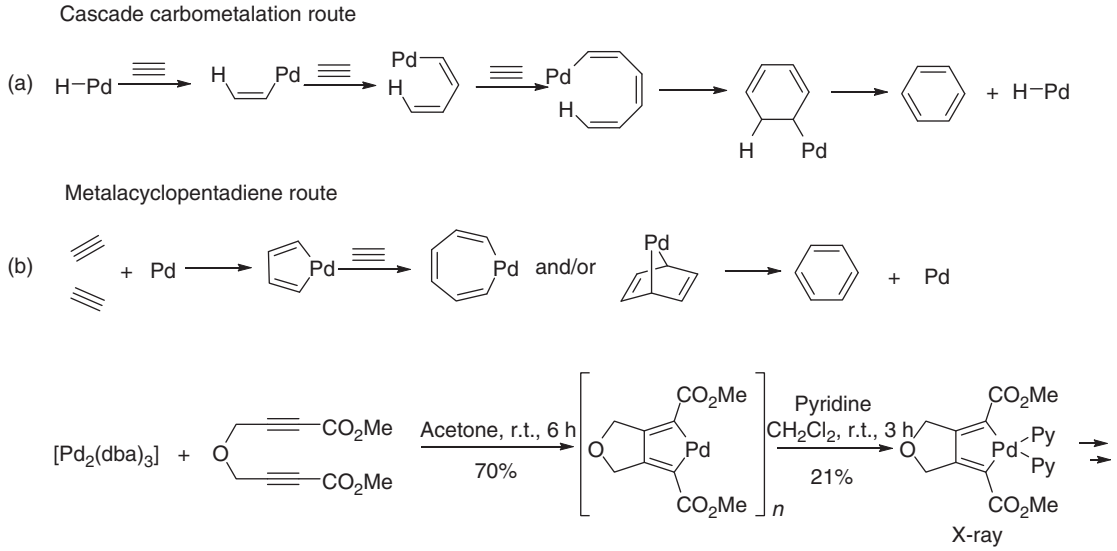
Scheme 3

Finally, iron-catalyzed syntheses of pyridines have been reported. The combination of $Fe(OAc)_2$ and an electron-donating, sterically hindered pyridyl bisimine ligand catalyzed the cycloaddition of alkynenitriles and alkynes.[34] In addition, simple iron salts combined with phosphines ($FeBr_3$/dppe) in the presence of Zn powder catalyzed the cycloaddition of diynes and unactivated nitriles leading to pyridine compounds at room temperature.[35]

Although this chapter is dedicated to metal-catalyzed [2 + 2 + 2] cycloaddition reactions, the authors will mention briefly recent reports that perform these transformations in the absence of metal catalysis. Sakai and Danheiser have described non-catalyzed formal [2 + 2 + 2] cycloaddition of diynes with electron-deficient alkenes to give cyclohexadienes and, in addition, of diyne–nitrile substrates to form functionalized pyridines. The transformation is based on pericyclic cascade reactions and requires thermal energy (more than 115 °C) to proceed successfully (Scheme 4).[36]

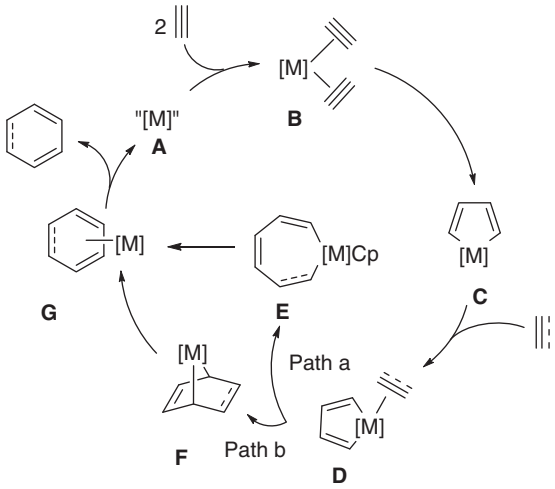


Scheme 4

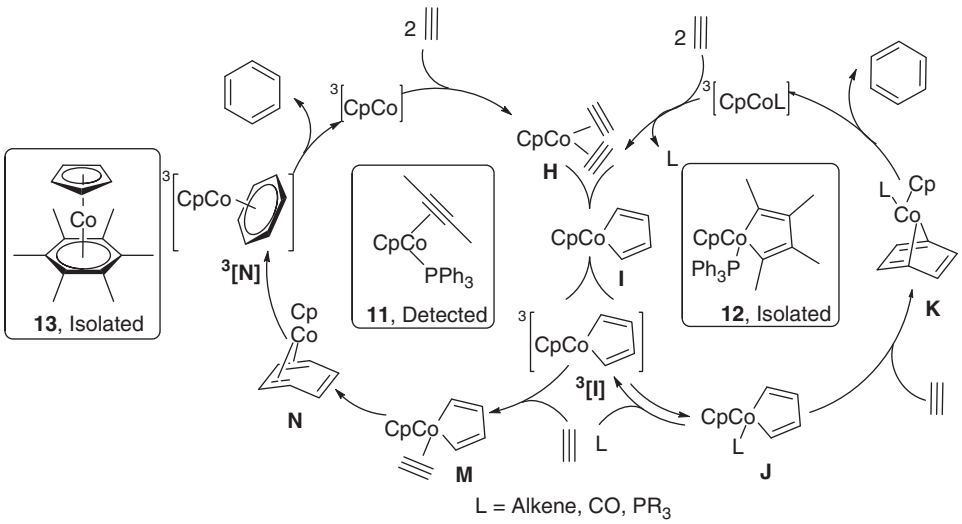
Another example used an organocatalytic procedure for the cyclotrimerization of alkynylketones which gave 1,3,5-trisubstituted benzenes. The reaction was catalyzed by 4-dimethylaminopyridine in the presence of 2,4-pentanedione as a cocatalyst.[37] A similar reaction was performed recently in pressurized hot water without any catalyst.[38]

5.31.1.2 Mechanism

The mechanism of the [2 + 2 + 2] cycloaddition is well established and its basic features are shared by most catalytic systems. Exceptions are the palladium catalyzed reaction and the ruthenium carbene process. Both cases are not very clear. With regard to palladium-catalyzed reactions it has been postulated that hydropalladation followed by two carbopalladations give an intermediate which follows ring closure to the benzene derivative through a 6-*endo-trig*-cyclization or an electrocyclic closure (Scheme 5a).[24] However, Yamamoto's group was able to isolate and characterize by X-ray diffraction analysis a palladacyclopentadiene formed in the reaction of $Pd_2(dba)_3$ with electron deficient diynes. This complex produced the final arene on reaction with an alkyne, which supports a metallacyclopentadiene route (Scheme 5b).[39] However, Grubbs' carbenes are thought to produce the benzene rings through a cascade metathesis process.[28]



Scheme 5

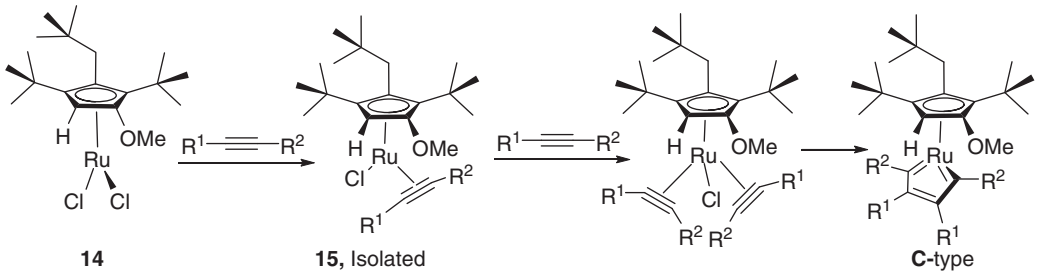


The [2 + 2 + 2] reaction was studied mainly through computational procedures. Experimental results are difficult to obtain and following the course of the reaction by nuclear magnetic resonance (NMR) is generally not possible due to the presence of paramagnetic species. However, isolation of reaction intermediates has been described in a few cases. The authors have currently quite a complete panorama of the most important mechanistic features of the transition metal-catalyzed or -mediated cyclotrimerization of alkynes and [2 + 2 + 2] cycloaddition of alkynes to alkenes because of the various excellent studies that have been published.[40] The mechanistic rationale of these processes depends on the nature of the metal, ligands, and substrate partners but a general pathway can be proposed and is represented in Scheme 6. Initially, two alkyne partners coordinate to the metal **A** and the resulting complex **B** forms a metallacyclopentadiene **C** by subsequent oxidative coupling. Then, the third unsaturated partner coordinates to give **D**, which follows two possible paths: insertion into the M–C bond to give metallacycloheptatriene **E**, which after reductive elimination gives complex **G**, or intramolecular [4 + 2] cycloaddition to form bicyclic complex **F**, which after isomerization affords complex **G**. Finally, decoordination of the metal produces the cycloadduct (Scheme 6).[40]

A particularly exhaustive and in-depth study was carried out on the mechanism of the $CpCoL_2$-catalyzed cyclotrimerization of ethyne.[41] This study concludes that after the formation of the cobaltacyclopentadiene **I** from **H**, this intermediate spontaneously relaxes to the triplet ground state ^{3}**[I]**. From this point on, two pathways are possible, depending on the nature of the ligands and the alkynes. In case of strong σ-donor solvents or ligands such as PR_3 or CO and electron-poor alkynes, complex ^{3}**[I]** is trapped to give the 18 e^- complex **J**, which undergoes the [4 + 2] cycloaddition to give complex **K**. In the absence of strong σ-donors and electron-poor alkynes, ^{3}**[I]** is transformed on alkyne ligation into a cobaltacyclopentadiene-(alkyne) intermediate **M**, which subsequently evolves to the CpCo(γ^4-arene) complex **N** through an intramolecular metal-assisted [4 + 2] cycloaddition. A spin change affords the 20-electron sandwich complex ^{3}**[N]** and dissociation of this species provides the free arene and CpCo. This study rules out the formation of metallacycloheptatriene intermediates in these alkyne cyclotrimerizations. Previous experimental works had isolated/detected intermediates of type **11** (**H**-type), **12** (**I**-type), and **13** (**N**-type) (Scheme 7).[41]

The ruthenium-catalyzed reaction is thought to follow a similar pathway. A recent work studied in detail the first steps of the reaction of a ruthenium catalyst (**14**) with alkynes until the formation of intermediates of type **C**. The authors isolated

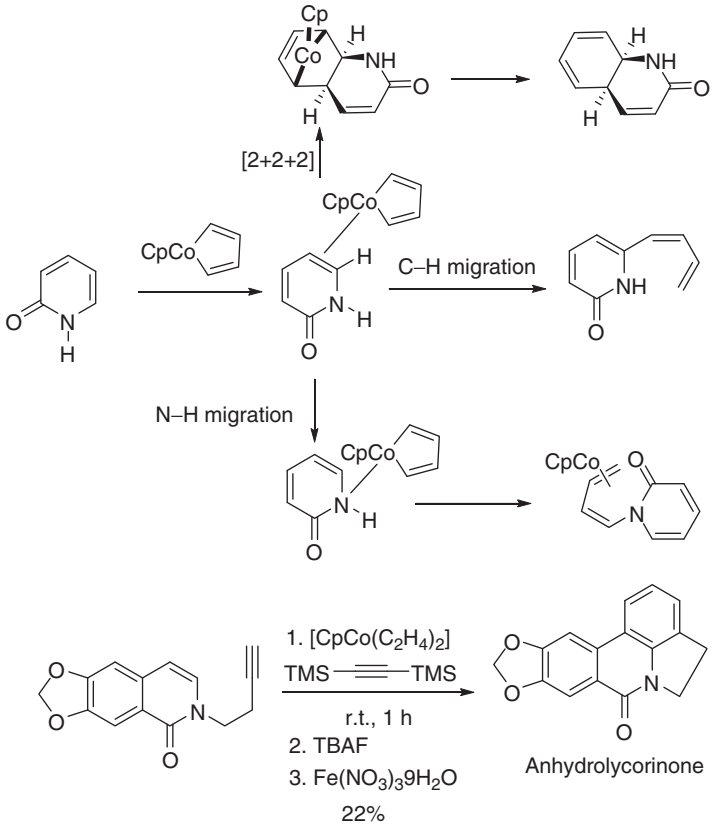
Scheme 6



Scheme 7

compounds **15a–d** and their calculations showed that alkyne addition to the [Ru(η^2-alkyne)Cl(Cp)] complex is strongly dependent on steric effects between the alkyne and the π-ligand. They also predicted that the subsequent C–C coupling process to form the ruthenacycle takes place following a two-step reaction mechanism via a metallabicyclic intermediate (Scheme 8).[42]

Certain competitive reactions may take place. Vollhardt's group studied the cobalt-mediated [2 + 2 + 2] cycloaddition of diynes with heterocycles such as pyridones, pyrazinones, and pyrimidines. In this approach, they observed a competition between the desired cycloaddition process and a dienylation at carbon or nitrogen through C–H or N–H activation. An experimental study, combined with density functional theory (DFT) calculations, concluded that the structure of the substrate determined which process was favored. Substrates-containing N–H bonds followed an N–H activation pathway, whereas cycloaddition or C–H activation predominated with *N*-protected derivatives. The diversity of the resulting products is due to the energetically close-lying trajectories available for the metal, a finding that is corroborated by DFT calculations. The usefulness of this reaction was demonstrated by a short synthesis of the natural product anhydrolycorinone (Scheme 9).[43]



Linear 2:1 cooligomerization of alkynes was observed by this group when using enolethers as partners in the cycloaddition with certain enynes. Minor variations such as lengthening the diyne tether or introducing electron-withdrawing (EWG) substituents caused reversion to the standard [2 + 2 + 2] mechanism (Scheme 10).[44]

The groups of Vollhardt and Saa independently studied by DFT computations the mechanism of the parent cobalt and ruthenium-mediated [2 + 2 + 2] cycloaddition of two alkynes and one alkene to give 1,3-cyclohexadienes. The main difference to the mechanism of alkyne cyclotrimerization is the way in which the alkene is included into the common cobaltacyclopentadiene

Scheme 9

O. Instead of an inter- or intramolecular [4 + 2] cycloaddition, alkene incorporation proceeds via insertion into an M–C σ-bond. The resulting key intermediate is metallacycloheptadiene **P** which leads to either a metallanorbornene derivative **Q** or hexatriene **R**, depending on the nature of the alkene. The formation of this hexatriene has been proven by NMR studies in certain cases. After the formation of **R**, a thermal disrotatory 6e-π electrocyclization may lead to the final 1,3-cyclohexadienes **S** completing a formal [2 + 2 + 2] cycloaddition (Scheme 11).[45]

Finally, the rhodium-catalyzed process has been investigated by DFT and kinetic studies, showing a pathway similar to that of Co and Ru. The authors were able to characterize the intermediate rhodacyclopentadiene Rh^{III} complexes type **C** by cyclic voltammetry, conductivity measurements, ^{31}P NMR, and electrospray ionization mass spectrometry. Furthermore, the totally intramolecular reaction of two types of enediynes, catalyzed by the Wilkinson's catalyst [$RhCl(PPh_3)_3$], was studied experimentally and with DFT calculations.[46]

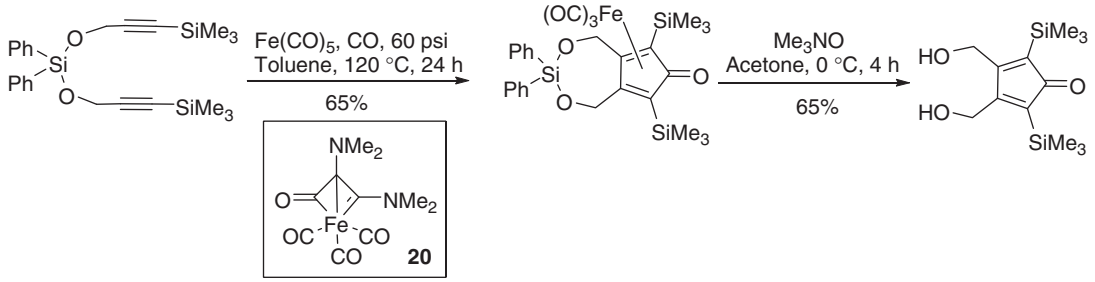
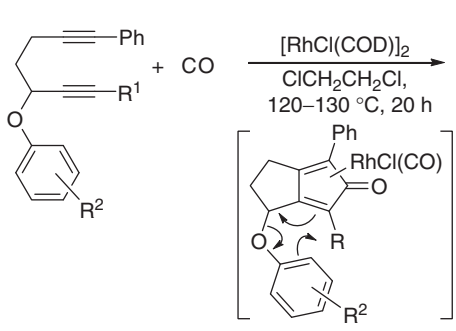
5.31.2 Synthesis of Four- and Five-Membered Rings



5.31.2.1 Carbocyclic Rings

Certain iron complexes have been used to produce cyclobutenediones on reaction with alkynes. Periasamy's group has developed several reactive iron carbonyl intermediates from iron carbonyls $Fe(CO)_5$ and $Fe_3(CO)_{12}$ in the presence of various promoters such as NaH, $NaBH_4$, Me_3NO, and amines. The coordinatively unsaturated '$Fe(CO)_4$' species generated *in situ* reacts with alkynes followed by $CuCl_2$ oxidation of iron-containing intermediates of type **18** (Scheme 12a). More recently they changed the catalytic system to a combination of $Fe(CO)_5$ with metal alkoxides which gives better results in terms of yields under milder conditions. With this new system intermediates are thought to be 1,2-dicarbonyliron complexes of type **19** (Scheme 12b).[47]

Similar catalytic iron-carbonyl-based reactions of diynes have been used for the synthesis of cyclopentadienones. The process is in general stepwise as an oxidative demetallation step is needed after the formation of a metal-complexed cyclopentanedione. Thus, 'silicon-tethered' $Fe(CO)_5$-promoted cyclocarbonylation and oxidation with Me_3NO was used as an effective method for carbonylative cross-coupling of alkynes to furnish cyclopentadienones with variable substituents. The reaction pathway seems to go through ferrabicyclobutenones of type **20** which have been isolated by another group in the reaction of $[Fe(CO)_5]$ with *bis*-dimethylaminoacetylene (Scheme 13).[48]



Scheme 12

Scheme 13

In addition, $[CpCo(PPh_3)_2]$, $[CpCo(CO)_2]$, and $[RhCl(PPh_3)_3]$ mediate alkyne–alkyne couplings to give metallacyclopentadienes, which can be transformed into cyclopentadienones by insertion of carbon monoxide and elimination of the metal. Recently, the structure of $[RhCl(CO)(cyclopentadienone)]_2$, which was formed by the reaction of $[RhCl(COD)]_2$ with a 1,6-diyne under CO, was determined and a new catalytic tandem reaction consisting of a $[2 + 2 + 1]$ carbonylative cycloaddition of phenoxy substituted diynes and Claisen rearrangement was described (**Scheme 14**).[49]

The first catalytic carbonylative alkyne–alkyne coupling for the synthesis of cyclopentadienones was achieved using iridium–phosphine complexes. To this end, $[IrCl(COD)]_2$ combined with a phosphine ligand under carbon monoxide at atmospheric pressure or a partial pressure of 20 000 Pa (0.2 atm) was able to catalyze cyclizations of enynes and CO providing cyclopentadienones in high isolated yields.[50]

In general, [2 + 2 + 1] cycloaddition reactions involving one double bond, one triple carbon–carbon bond, and a CO unit fall into the Pauson–Khand chemistry which is covered in Chapter 5.24 Nickel carbonyl-catalyzed cyclizations of allyl halides with alkynes is an exception as it follows a rather different mechanism. This reaction was originally performed with hazardous $Ni(CO)_4$ reagent. Moretó's group has succeeded in developing a highly efficient catalytic version using a stoichiometric amount of iron, acetone, and a catalytic amount of nickel halide. Cyclopentenones were obtained intermolecularly in high yields and with controlled stereochemistry (Scheme 15).[51]

5.31.2.2 Heterocyclic Rings

Cycloaddition reactions utilizing two carbon monoxide units and one alkyne or the carbonylative cycloaddition of aldehydes, ketones, and imines with alkynes have also been addressed because of their great potential for the preparation of heterocycles. However, recent reports are scarce. Chatani has shown the synthesis of different butyrolactones based on ruthenium carbonyl catalysis. The application of this methodology to benzofuran-diones allowed the synthesis of spirolactone derivatives **21** and **22** (Scheme 16).[52]

Starting from metallacyclopentadienes, the synthesis of various five-membered ring heteroaromatics is possible. Although in early times iron and cobaltacyclopentadienes were used as precursors, most recent contributions have involved the synthesis of zirconacycles formed from alkynes, diynes, or dienes. These zirconacyclopentadienes can easily be converted into heterocycles such as thiophenes, siloles, phospholes, germoles, pyrroles, and thiophene oxides (Scheme 17).[53] However, possibly due to the stoichiometric nature of these methodologies, they have received less attention in recent years.

5.31.3 Synthesis of Six-Membered Carbocyclic Rings

The cyclotrimerization reaction is mostly used for the synthesis of six-membered rings. Carbocyclic aromatic rings arising from cycloadditions of three triple bonds are the most common, and will be covered first classified by totally inter-, partially inter-, and totally intramolecular reactions. Then, the authors will address reactions with participation of carbon–carbon double bonds.

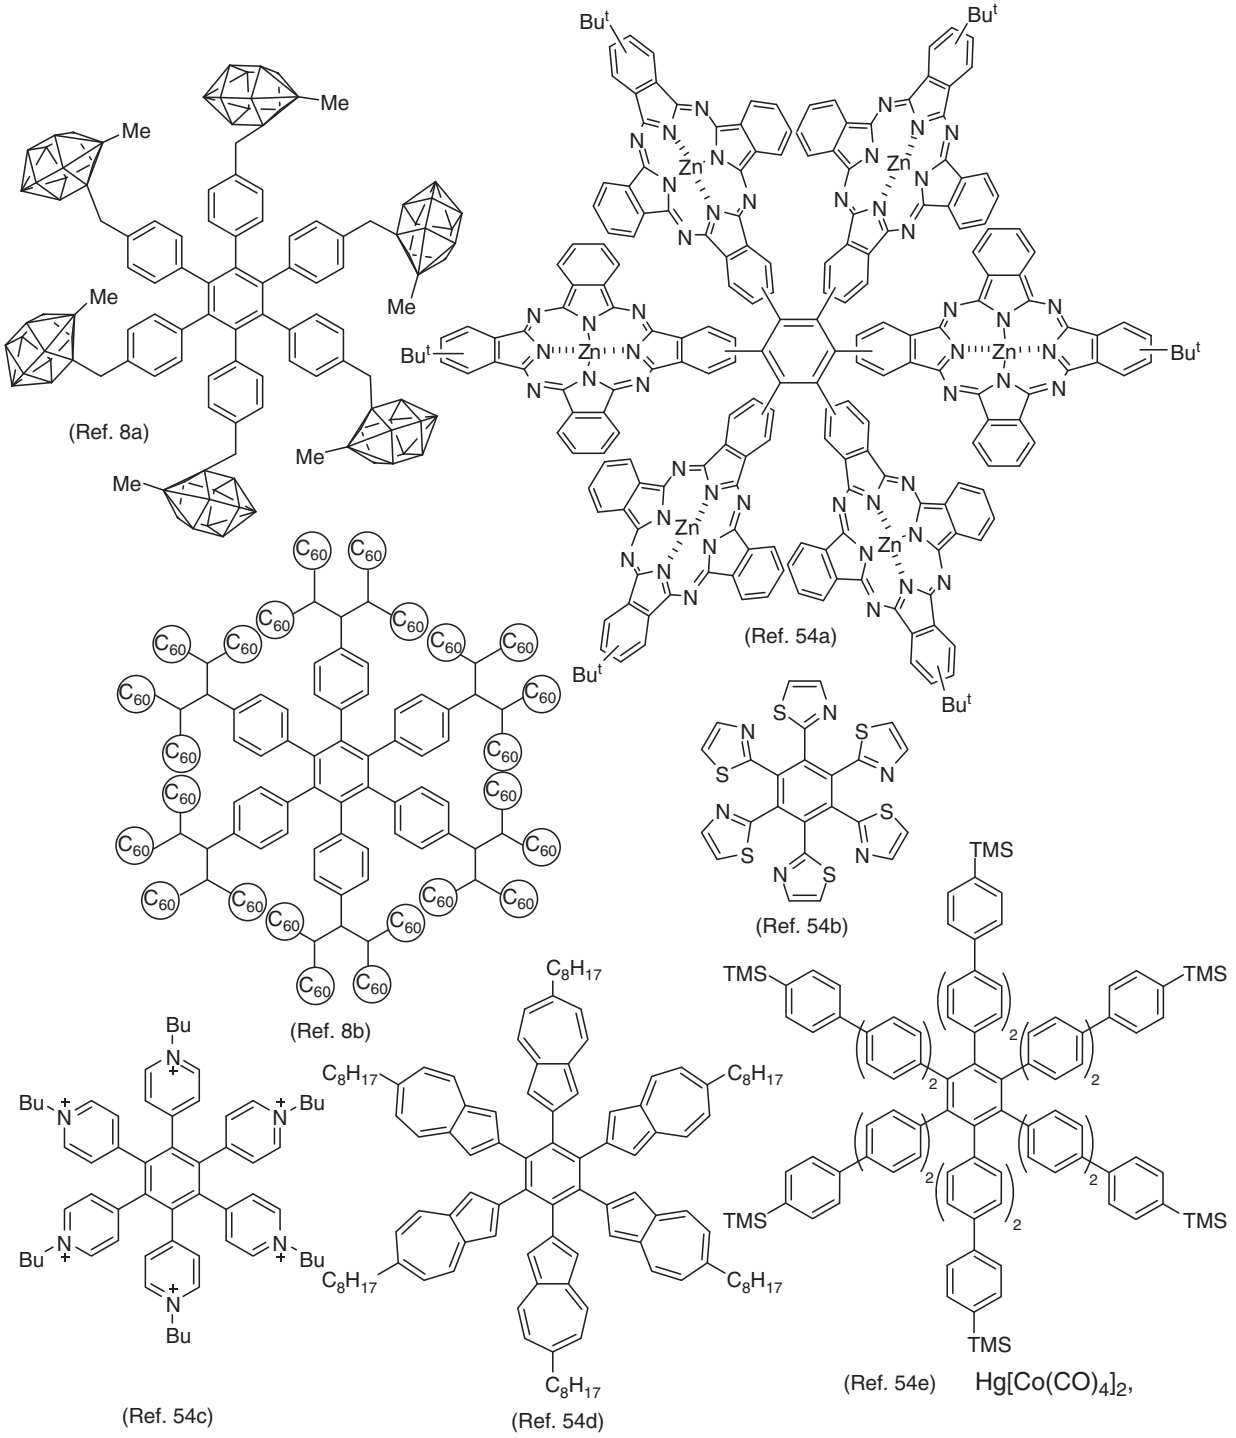
5.31.3.1 Totally Intermolecular Cyclotrimerizations of Alkynes. Synthesis of Nonfused Benzenes

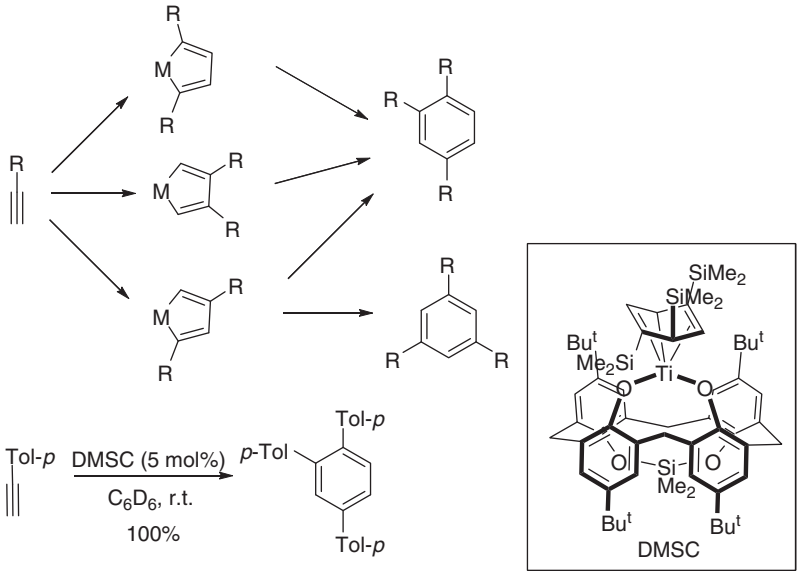
Most totally intermolecular reactions reported to date are trimerizations of internal alkynes with which syntheses of star-shaped per-substituted benzenes is possible. Symmetrically hexasubstituted benzenes have found applications in many fields such as main-group chemistry, organometallic chemistry, and organic material science. Thus, molecular devices, dendrimers, multi-electron redox systems, host molecules, etc., were prepared using in most cases cobalt-, nickel-, or palladium catalysts. In Figure 6 the authors show several recent examples synthesized from alkynes with inexpensive $Co_2(CO)_8$ as the catalyst except otherwise indicated.[54]

A more difficult case is the control of regiochemistry in the trimerization of unsymmetrical alkynes. This reaction generally gives mixtures of 1,2,4- and 1,3,5-trisubstituted benzenes. Although the symmetrical 1,3,5-trisubstituted aromatic is the less sterically hindered derivative, this isomer is often the minor product because only one of the possible three initially formed metallacycle intermediates provides the symmetrical aromatic ring (Scheme 18). Among the few successful methods reported for the totally selective formation of 1,2,4-trisubstituted benzenes is the use of a calixarene-bound titanium complex. The high selectivity may be understood in terms of the directing influence of the calixarene ligand which favors the formation of the 2,4-disubstituted titanacyclopentadiene and also sterically controls the approach of the third alkyne unit (Scheme 18).[55] Selective formation of 1,3,5-trisubstituted benzenes has been described although exclusive formation of this isomer is rare and generally achieved with ethynyl aryl ketones.[56]

Attempts at heterotrimerization (use of two or more different alkynes) lead generally to complex mixtures. The authors are still rather far from a truly general, intermolecular [2 + 2 + 2] cycloaddition and the controlled cyclization of two or three different alkynes to give only one final product continues to be a challenge. There is a double problem here: first, controlling the chemoselectivity during the metallacycle formation and second, the regioselectivity of the insertion of the third alkyne. It is worth remembering that combination of all chemo- and regiochemical possibilities gives 9 or 38 isomers when reacting two or three different monosubstituted alkynes, respectively. One first approach to this complex problem is the use of stoichiometric amounts of transition-metal complexes, for example, zirconium- or titanium-based systems. The problem of chemoselectivity is circumvented through stepwise addition of all reagents. Thus, the cycloaddition reaction of zirconacyclopentadienes to alkynes proved a highly selective method for forming benzene derivatives. (η^5-Cyclopentadienyl) zirconacyclopentane, formed from Cp_2ZrBu_2 and ethylene, was regioselectively transformed into a single unsymmetrical zirconacyclopentadiene after successive addition of two different alkynes. This was made possible by the presence of trimethylsilyl or aryl groups which are well known for giving α-silyl- or α-arylzirconium complexes. The reaction of the intermediate zirconacyclopentadiene with DMAD in the presence of copper(I) chloride gave hexasubstituted benzenes in good yields (Scheme 19).[56]

One strategy used to achieve chemoselectivity under catalytic conditions consists of using electronically extremely different alkyne components to control the initial metallacycle formation. Acetylene dicarboxylates are good partners for





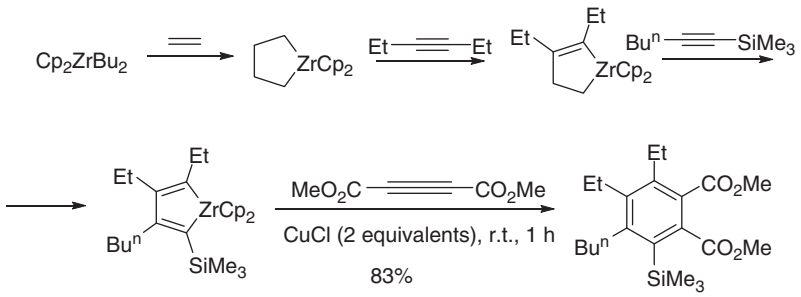


Figure 6 Examples of star-shaped products synthesized by totally intermolecular alkyne [2 + 2 + 2] cyclotrimerizations.

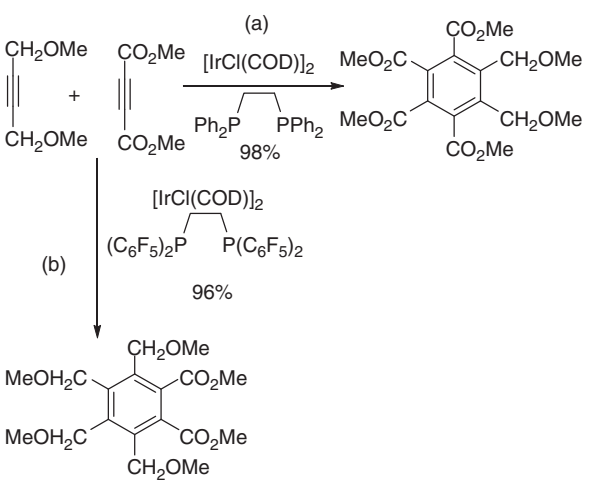

heterotrimerization with terminal alkynes as they do not usually form the initial metallacyclopentane and thus are the last C2 unit to be incorporated. Takeuchi and Nakaya used neutral iridium(I) systems combined with phosphines to cyclize DMAD with alkynes. When dppe was used as the ligand, two molecules of DMAD were incorporated into the product (Scheme 20a), whereas when the perfluoroaryl derivative of dppe is used as the ligand, one molecule of DMAD reacted with two molecules of the acetylene (Scheme 20b). In addition, they reacted three different alkynes under the latter conditions giving a single product in high yields (Scheme 20c).[57]

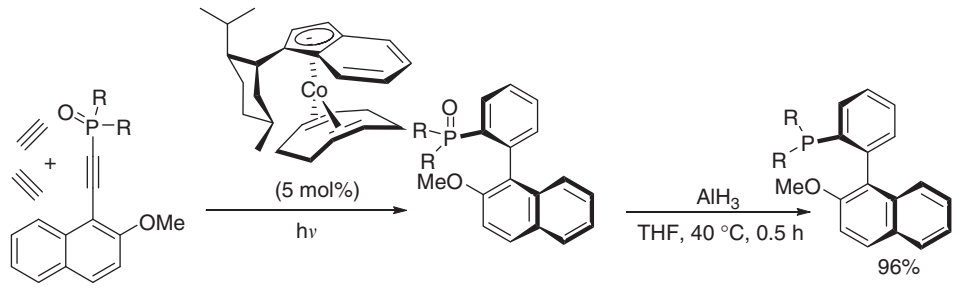
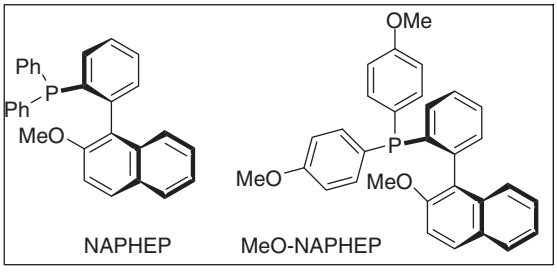
Scheme 20



Benzynes and benzyne-analogs are also excellent partners for cyclotrimerization reactions generally catalyzed by palladium or nickel complexes. Thus, the palladium-catalyzed cyclotrimerization of arynes is an efficient way to produce triphenylenes. In this reaction, a trimethylsilylaryl triflate is treated with fluoride in the presence of a Pd(0) catalyst, and the aryne generated *in situ* undergoes cyclotrimerization. The scope of this methodology is quite broad and has been applied to the synthesis of a wide variety of polycyclic aromatic hydrocarbons (PAHs) which are of considerable interest in materials science because of their charge transport properties. Scheme 21 shows representative examples reported by the groups of Peña and Perez.[58]



Scheme 21

o-Carboryne (1,2-dehydro-*o*-carborane), is a three-dimensional relative of benzyne that can react with alkenes, dienes, alkynes, and aromatics in [2 + 2], [4 + 2] cycloaddition and ene-reactions. Xie's group generated recently this reactive intermediate which was trapped by alkynes via Pd/Ni-cocatalyzed [2 + 2 + 2] cycloaddition reactions, leading to the formation of C,B-substituted-*o*-carborane derivatives.[59]

Heller's group developed chiral cobalt complexes with which they prepared chiral biaryls bearing phosphoryl moieties. By subsequent reduction to the corresponding phosphine, a very efficient and atom-economical approach to chiral monodentate *P*- or bidentate *P,O*-ligands was described (Scheme 22).[60]

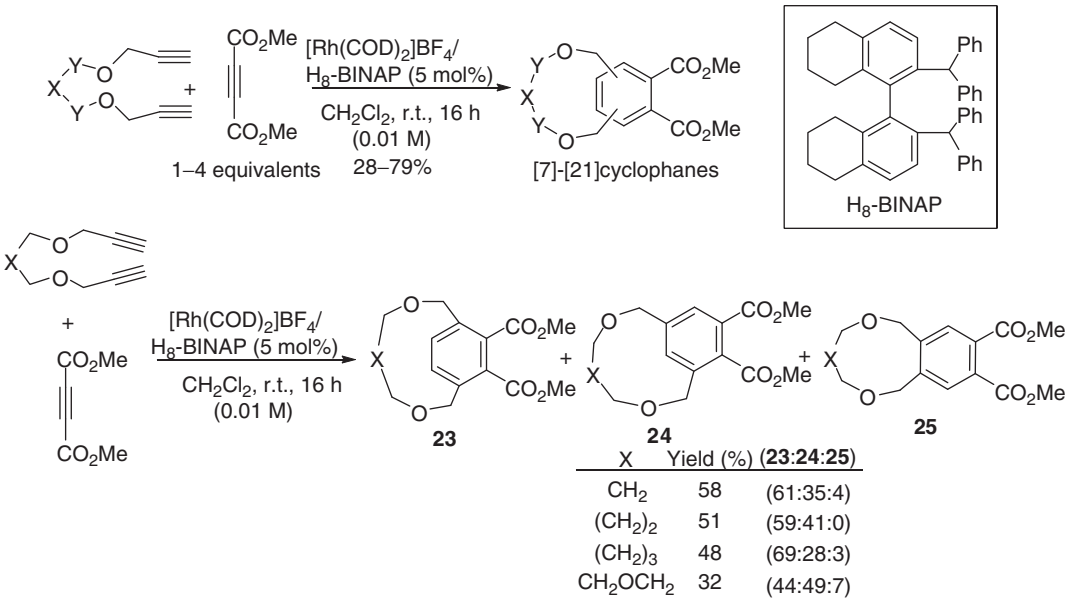
5.31.3.2 [2 + 2 + 2] Cycloaddition of Diynes and Triynes. Synthesis of Fused Benzenes

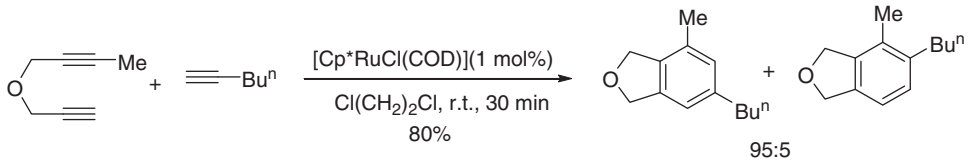
5.31.3.2.1 Scope, chemo-, and regioselectivity

The crossed version using a diyne and an alkyne has become the most common strategy used to overcome the problems with regio- and chemoselectivity. This version produces an additional cycle fused to the aromatic ring. One elegant way to avoid the formation of this additional ring is to tether temporarily two alkyne components. Yamamoto's group has succeeded in controlling the metallacycle formation by the geometric restrictions imparted by a boron temporary tether. [CpRuCl(COD)] catalyzed the cyclotrimerization of alkynylboronates, propargyl alcohols, and terminal alkynes producing an intermediate arylboronate that could be isolated or submitted to further transformations. Thus, they have described the synthesis of highly substituted phthalides by a palladium(II)-catalyzed carbonylation of the arylboronates. In a different contribution, the arylboronates were further converted to highly substituted biaryls via the Suzuki–Miyaura coupling with various aryl iodides using $Pd_2(dba)_3/PCy_3$ as the catalyst (Scheme 23).[61]



Scheme 23

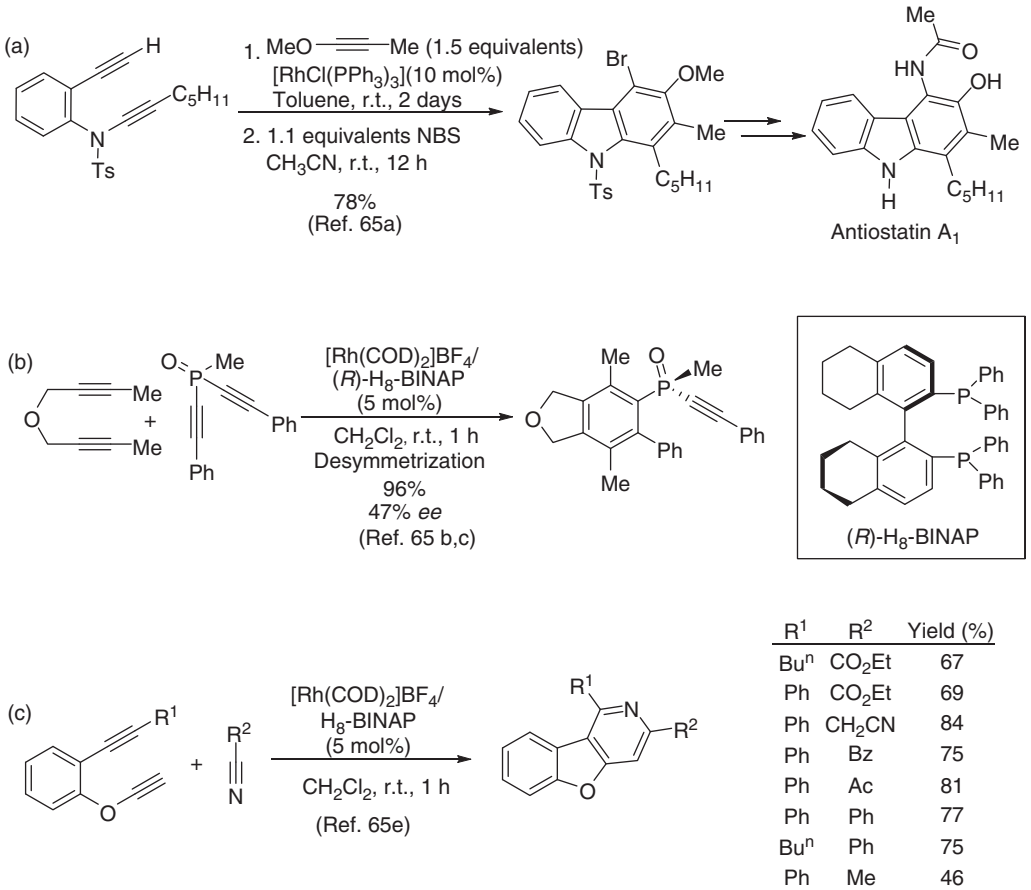
The scope of the crossed [2 + 2 + 2] cycloaddition of alkynes with diynes has been the subject of numerous works and is covered by various reviews.[1,2] The authors will summarize first the allowed structures of the starting materials and then will show some recent examples. Many types of diynes react efficiently. In principle, the additional ring fused to the emerging aromatic unit may have almost any size. Most examples, however, show the formation of five-membered carbo- or heterocycles from 1,6-diynes. A *gem* disubstitution at position 4 of the diyne is thought to favour the reaction and a Thorpe–Ingold effect is many times claimed to justify this. However, six-membered fused cycles are readily obtained from 1,7-diynes and there are examples of the synthesis of benzocyclobutanes.[62] Heteroatoms are allowed in the connecting tether so that benzofuranes, indoles, and isoindoles can be synthesized. Diynes connected through aromatic rings give good results possibly as a consequence of conformational restrictions.



Moreover, the formation of macrocycles and *ansa*-connected cycles is possible. Long-chain α,ω-diynes are known to react with acetylene dicarboxylates to yield pyridine-containing *ansa*-macrocycles and cyclophanes. The reaction has been catalyzed with a cationic rhodium(I)/H_8–BINAP complex by Tanaka's group for the synthesis of polyether cyclophanes (Scheme 24).

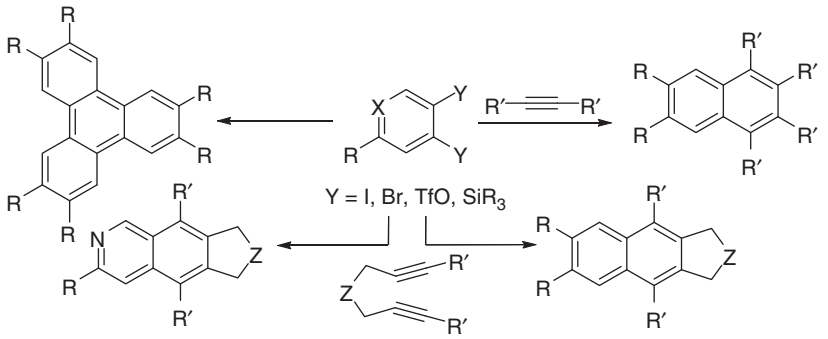
The regioselectivity of these reactions was affected by the length and type of linker unit between the alkyne groups, as well as by certain stereoelectronic effects.[63]

Scheme 24



Regioselectivity problems arise in reactions of nonsymmetrical diynes with monosubstituted alkynes. In this case *ortho* and *meta* products are possible, with the general tendency to obtain *meta* as the major product. Excellent *meta*-selectivities were observed in reactions of 1,6-diynes with terminal alkynes catalyzed by [CpRuCl(COD)]. A DFT study on the mechanism indicated that the alkyne insertion appears to take place as a formal [2 + 2] cycloaddition and the pathway leading to a *meta*-product goes through the lowest *trans–anti* transition state (Scheme 25).[64]

Scheme 25



Alkynes with heteroatoms directly bonded to the triple bond are valid substrates in [2 + 2 + 2] cycloadditions. Therefore, functionalized ynamides, phosphine derivatives, and phenol-linked 1,6-diynes react readily with alkynes and nitriles giving carbazole structures, bulky phosphines, and benzofuran derivatives, respectively. For these transformations rhodium catalysis is preferred. Thus, Scheme 26a shows a crossed cyclotrimerization reaction with a methoxyalkyne which gave a carbazole. Antioxidant antiostatin A_1 was synthesized using this reaction as the key step followed by a palladium-catalyzed arylamidation reaction. Production of central chirality, which is a nonfrequent issue in the [2 + 2 + 2] chemistry, was accomplished by desymmetrization of a dialkynylphosphine oxide reaching good enantiomeric excess in the P-stereogenic-containing product (Scheme 26b). Finally, benzofuranes and benzopyridines were readily obtained from phenoxy-connected diynes (Scheme 26c).[65] Yamamoto's group reported a terminal diiodination of a diyne and subsequent reaction with alkynes under [CpRu(COD)] catalysis to produce diiodobenzenes.[66]

A wide variety of terminal or internal alkynes with alkyl or aryl substituents participate in crossed cyclizations with diynes. These include alkoxyacetylenes, silylacetylenes, alkoxycarbonylacetylenes, alkynylboronates, propargyl alcohols, etc. In addition, arynes and pyridynes have been utilized as substrates in crossed [2 + 2 + 2] cycloadditions with diynes, alkynes, alkenes, allenes, and nitriles. Recent works described that arynes, formed from *o*-dihaloarenes or silyl triflates, react with acetylenes and nitriles catalyzed by the $NiBr_2$/dppe/Zn system to give substituted naphthalene, phenanthridine, or triphenylene derivatives depending on the reaction conditions (Scheme 27).[22a]

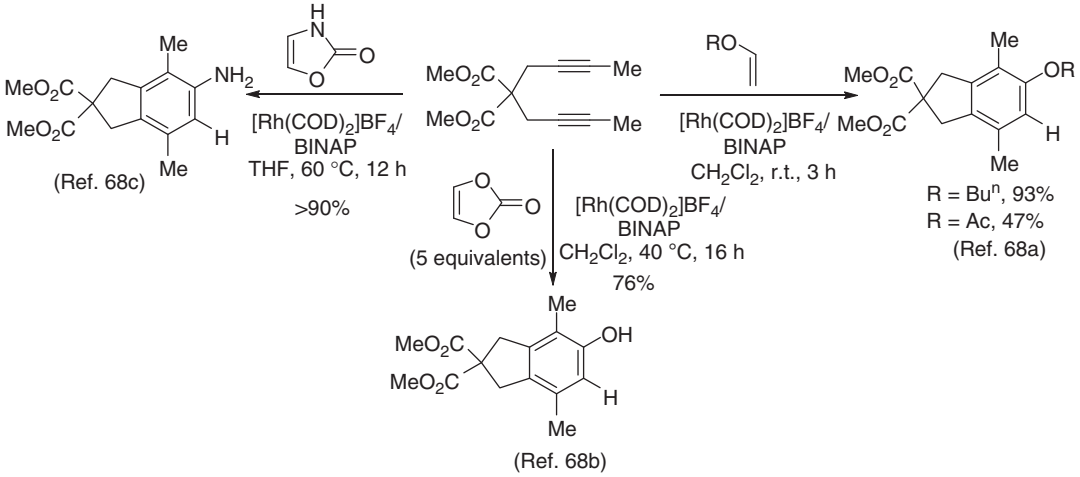
Scheme 27



Pyridynes gave isoquinoline-containing polycycles under $Ni(COD)_2/PPh_3$ catalysis, albeit the yields were in some cases moderate (Scheme 28).[67]

Synthesis of fused benzene rings can also be accomplished using alkyne surrogates in the reaction with diynes. This is a different and elegant way to avoid selectivity problems. Several groups have reported the use of enol ethers or easily enolizable ketones as an alkyne equivalent that suffers dehydration after the cyclotrimerization giving the aromatic final product. Some recent examples, depicted in Scheme 29 show diynes reacting under cationic rhodium(I)/BINAP catalysis with enol ethers, vinylene carbonates, or 2-oxazolones. The regioselectivity of the enol ether insertion is postulated to be controlled by coordination of the enol carbonyl moiety to the cationic Rh center in the metallacyclopentadiene intermediate. If the enol ether component is replaced by vinylene carbonate, a phenol is obtained, whereas the reaction with 2-oxazolones gives anilines.[68]

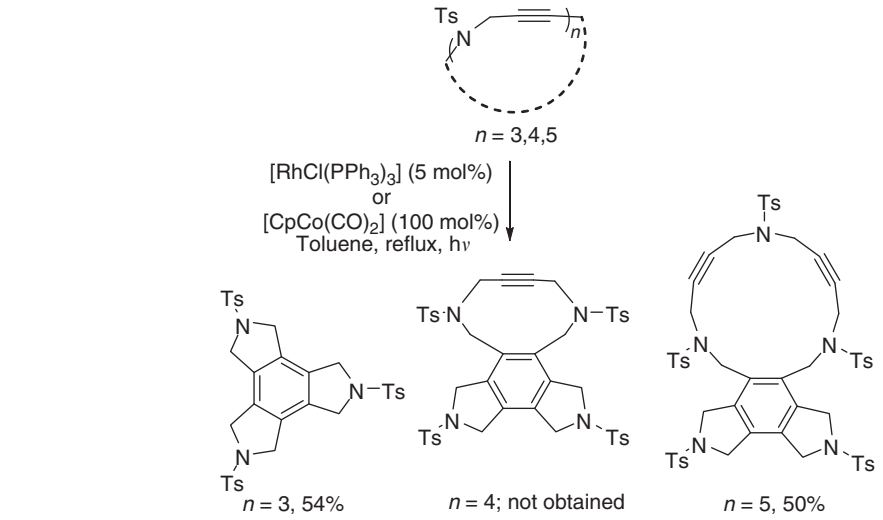
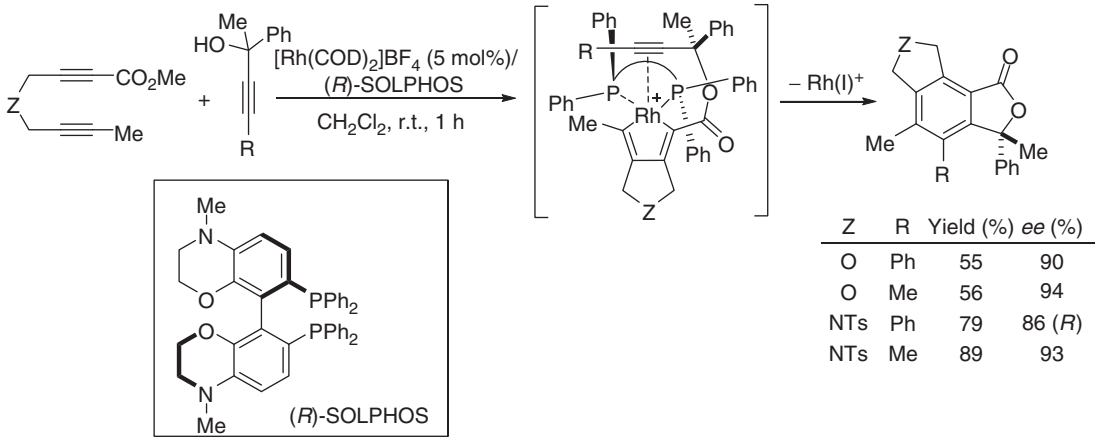
Scheme 29



The totally intramolecular version of the [2 + 2 + 2] cycloaddition, really a cycloisomerization process, has the disadvantage of requiring a highly functionalized starting material. However, the obvious control of the selectivity makes this version attractive and with high synthetic potential.

A recent study addressed the problem of the number of members of the triyne substrate and its influence on the results. Thus, 15-, 20-, and 25-membered polyacetylenic azamacrocycles were submitted to [2 + 2 + 2] cyclotrimerization processes catalyzed by the Wilkinson's catalyst. The 15- and the 25-membered azamacrocycles led to the expected cyclotrimerized compounds in contrast to the 20-membered azamacrocycle, which was characterized by its lack of reactivity. The difference in reactivity of these substrates was rationalized through DFT calculations. The lack of reactivity of the 20-membered substrate was attributed to its more stable and delocalized higher occupied molecular orbital and to the formation of a strained 10-membered ring during the cyclotrimerization (Scheme 30).[69]



5.31.3.2.2 Domino reactions. Combining the [2 + 2 + 2] cycloaddition with other transformations

Domino reactions are receiving huge attention in organic synthesis as they provide great molecular complexity in one step. Combination of the [2 + 2 + 2] cycloaddition with other reactions is highly desirable but has yet received scarce attention. Early examples showed reactions in which two cycloaddition reactions were performed in a single operational step. These included Pauson–Khand/[2 + 2 + 2] and [2 + 2 + 2]/Diels–Alder processes. Cyclotrimerization of alkynyl alcohols or amines with propiolates, acetylenedicarboxylates, or diynecarboxylates is a known way to produce benzolactones and benzolactam derivatives with regio- and chemoselectivity in good-to-excellent yields. In a recent work, this strategy was used to desymmetrize a double propargylic alcohol on reaction with a diyne ester under rhodium catalysis (Scheme 31).[70]

Li's group has recently prepared tetrasubstituted isoindolines from three alkyne units, two aldehyde units, and a primary amine via three consecutive reactions. First, a double aldehyde–amine–alkyne coupling (A^3-coupling) gives the starting diyne which on cocycloaddition with a third alkyne unit gives the final product in a single synthetic operation. The A^3-couplings are catalyzed by copper bromide and the cycloaddition is catalyzed by Wilkinson's catalyst but both catalytic systems are present in the reaction from the beginning (Scheme 32).[71]

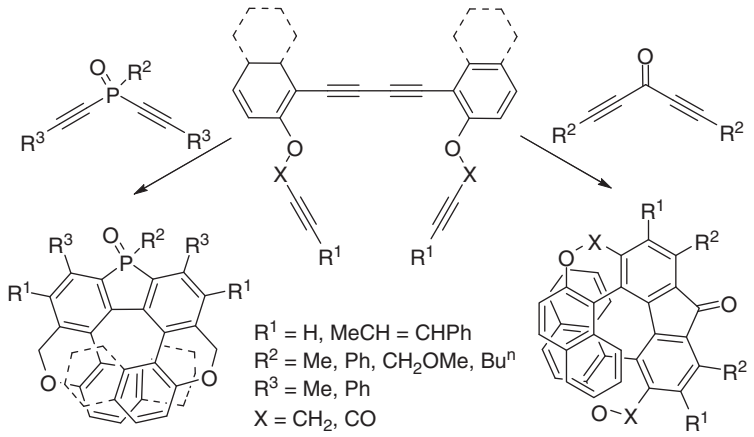
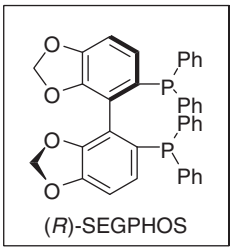
5.31.3.2.3 Asymmetric crossed cyclotrimerization reactions. Synthesis of axially chiral helicenes



Stary and coworkers were the first to use a chiral cobalt complex-catalyzed intramolecular cycloaddition of a triyne, to generate helical chirality. In a recent contribution, they improved the experimental procedure: after the cyclotrimerization of a triyne they assisted the aromatization of the second ring constructed with MWs, resulting in a practical synthesis of racemic diaza[5]helicene

and aza[6]helicenes which were resolved (Scheme 33).[72] Previously, numerous angular [*N*]phenylenes were constructed from the intramolecular version of the cotrimerization of alkynes. In addition to [4] and [5]phenylenes, helical [7], [8], and [9]phenylenes (heliphenes) have been obtained via cobalt-mediated multiple cycloisomerization of polyynes in racemic form, which could be resolved.[73]



Scheme 33

Other groups described the direct syntheses of enantio-enriched mixtures of chiral helicenes using iridium/BINAP and palladium/BINAP complexes. Tanaka's group has recently synthesized benzopyrano- and naphthopyrano-fused helical phosphafluorenes by the rhodium-catalyzed enantioselective double [2 + 2 + 2] cycloaddition of dialkynyl phosphorus compounds with phenol- or naphthol-linked tetraynes. These helical structures bear interesting photochemical and photophysical properties (Scheme 34).[74]

Tetraphenylene is a saddle-shaped molecule, wherein four benzene rings are *ortho* annulated to construct an eight-membered ring system. If the benzene rings have substituents, due to the D_{2d} point symmetry, the molecule becomes chiral because of a high barrier to inversion. Dimerization of triynes, possessing a phenylene-bridged 1,5-diyne moiety, by consecutive inter- and intramolecular cycloadditions was used to access chiral tetraphenylenes with high *ee* (Scheme 35).[75]

5.31.3.2.4 Axial chirality. Atropisomeric compounds

Bipyridine *N*,*N*′-dioxides, biaryl diphosphines, *N*,*N*-dialkylbenzamides, and other biaryls are known to exist as atropisomers due to the high rotational barrier around the aryl–aryl or aryl–carbonyl single bonds. Their role as chiral reagents has prompted

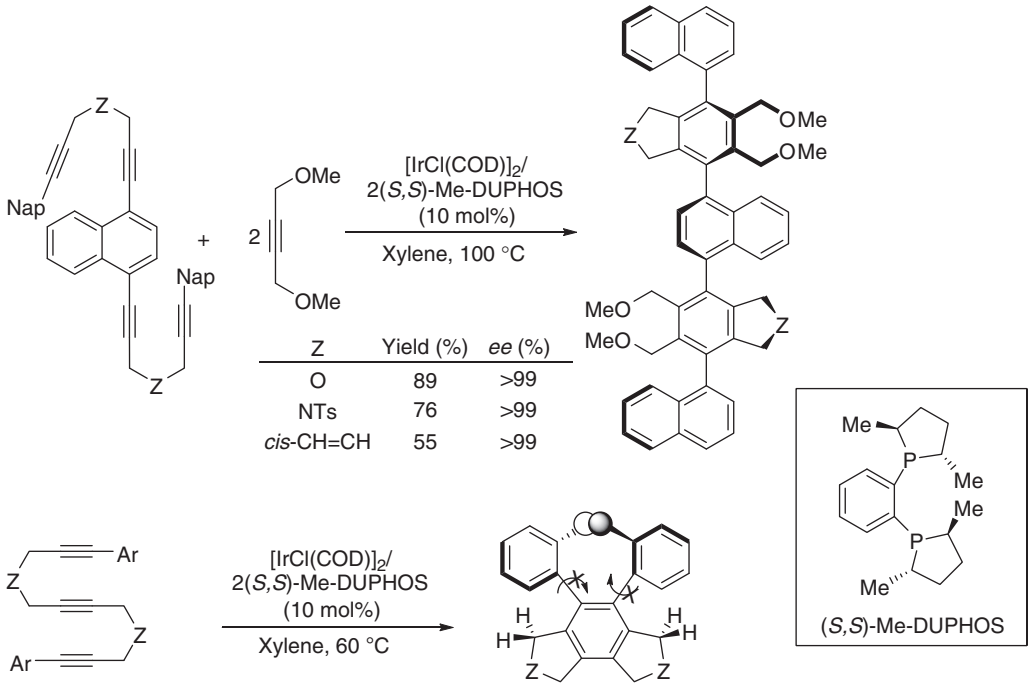
Scheme 35

organic chemists to explore their asymmetric synthesis but a straightforward catalytic enantioselective method remained elusive until the development of metal-catalyzed cycloaddition reactions such as the [2 + 2 + 2] cyclotrimerization. In 2004, the groups of Heller, Shibata, and Tanaka independently reported enantioselective [2 + 2 + 2] cycloadditions using different transition metal catalysts in succession, where axial chirality was generated along with benzannulation. During their work on the asymmetric Pauson–Khand reaction with chiral iridium complexes, Shibata's group observed the formation of [2 + 2 + 2] cycloaddition subproducts. This result prompted them to develop new inter- and intramolecular enantioselective [2 + 2 + 2] cycloadditions of alkynes for the generation of axial chirality. Scheme 36 shows some examples from this group.[76]

Tanaka's group reported the enantioselective synthesis of different axially chiral compounds like anilides, biphenyls, *N*-aryl-2-pyridones, and biaryl diphosphonates by cationic rhodium(I)/modified-BINAP-catalyzed [2 + 2 + 2] cycloadditions. In one of their most recent contributions they disclosed the catalytic enantioselective construction of aryl-carbonyl axial chirality of *N*,*N*-dialkylbenzamides in high yields and outstanding *ee*'s (Scheme 37).[77]

As part of their extensive studies on the chemistry of ynamides, the group of Hsung has succeeded in controlling both the C–C and C–N axial chirality in the synthesis of chiral *N*,*O*-biaryls and chiral anilides from achiral conjugated aryl ynamides. They used rhodium(I)-xylyl-BINAP catalysis, reaching good-to-excellent *ee*'s (Scheme 38).[78]



5.31.3.2.5 Synthesis of planar chiral compounds

Planar chiral *ansa*-cyclophanes are beautifully shaped compounds with potential utility in the area of asymmetric synthesis, host–guest chemistry, and material science. The groups of Tanaka and Shibata have independently disclosed catalytic enantioselective syntheses of planar-chiral metacyclophanes via cationic rhodium(I) complex-catalyzed cyclotrimerization (Scheme 39).[79]

5.31.3.2.6 Synthetic applications and natural product syntheses

Very recently it was demonstrated that the [2 + 2 + 2] cycloaddition reaction is usable for polymerization. Thus, a triyne monomer reacted under dipimp/$CoCl_2$ $6H_2O$/Zn catalysis yielding linear polymers involving a selective cross-cyclotrimerization reaction that occurred in a chain growth manner (Scheme 40).[80]

Cyclotrimerization of alkynes can be used for the synthesis of *C*-arylglycosides and other carbohydrate derivatives. This class of compounds is of considerable interest for pharmaceutical reasons, because of their stability toward enzymatic and chemical hydrolysis. Thus, *C*-aryl-deoxy-ribosides, 6-arylpurine ribonucleosides, isochroman-containing nucleosides, or spirocyclic *C*-arylribosides have been prepared through [2 + 2 + 2] cycloadditions by different groups. Figure 7 shows the structures of these potentially active compounds.[81]

There has been a recent increase in the use of the [2 + 2 + 2] cycloaddition for the synthesis of natural products as densely functionalized aromatic rings are common in natural products and in closely related bioactive compounds. Figure 8 shows some natural products in which the [2 + 2 + 2] cycloaddition reaction was used as the key step for their syntheses.[82] In general, elaboration of a functionalized triyne and cyclization is the preferred strategy, albeit different catalysts are used. Thus, various members of the alcyopterosin family of sesquiterpenes were constructed from enantiopure triynes under rhodium catalysis.[82a] An MW-promoted Co- or Rh-catalyzed intramolecular [2 + 2 + 2] cycloaddition served for the construction of ring C of the core of colchicine. 6-Oxa-allocolchicinoids were efficiently synthesized and were found to exhibit significant and selective apoptosis-inducing activities against B-type human lymphoma line tumor cells.[82b] Cobalt-mediated cyclization of a triyne was the strategy of choice for the synthesis of a series of angucyclinone antibiotics.[82c] Ruthenium catalysis was efficient in the synthesis of terpene natural product cryptoacetalide which was obtained in 12 steps in 26% overall yield.[82d] Finally, a crossed cyclotrimerization catalyzed by ruthenium was used for the synthesis of various cannabinoids.[82e]

A recent contribution from Nicolaou's group accounts for the total synthesis of the highly oxygenated, marine-derived, natural product sporolide B. The convergent strategy involved a ruthenium-catalyzed [2 + 2 + 2] cycloaddition to assemble the indene structural motif. Once this complex intermediate was constructed, a thermally induced Diels–Alder-type reaction formed the macrocycle (Scheme 41).[83]

5.31.3.3 Double Bonds as Partners of the [2 + 2 + 2] Cycloaddition Reaction. Synthesis of Cyclohexadienes and Cyclohexenes

The metal-catalyzed [2 + 2 + 2] cycloadditions between alkynes and alkenes or allenes to give 1,3-cyclohexadienes or cyclohexenes, are less developed but have triggered much attention in the very recent years. In principle, the field opens a great variety of possibilities which not all are feasible when using three triple bonds. These include asymmetric induction, use of allenes, enynes, endiynes, etc. Scheme 42 shows a summary of the different versions of a [2 + 2 + 2] cycloaddition between triple- and double bonds.

One of the first processes widely developed was the Vollhardt reaction consisting of a cobalt-mediated activation of double bonds that needs equimolar amounts of the metal promoter, generally cyclopentadienylcobalt carbonyl or ethene [$CpCoL_2$ (L=CO, C_2H_4)]. This group has used, among others, 'double bonds' in aromatic heterocycles such as furans, thiophenes, indoles,

pyrroles, imidazoles, pyridones, and pyrimidines in [2 + 2 + 2] cycloadditions with alkynes. Remarkably, even though resonance stabilized, these systems participate readily in such cyclizations giving rise to fused dihydroheteroaromatics. In one of their latest contributions they have developed new reaction conditions with cobalt(II) iodide (CoI_2), manganese and an *N*-heterocyclic carbene (IPr) generated *in situ* from the corresponding imidazolium salt and butyllithium. This avoids the former use of the air

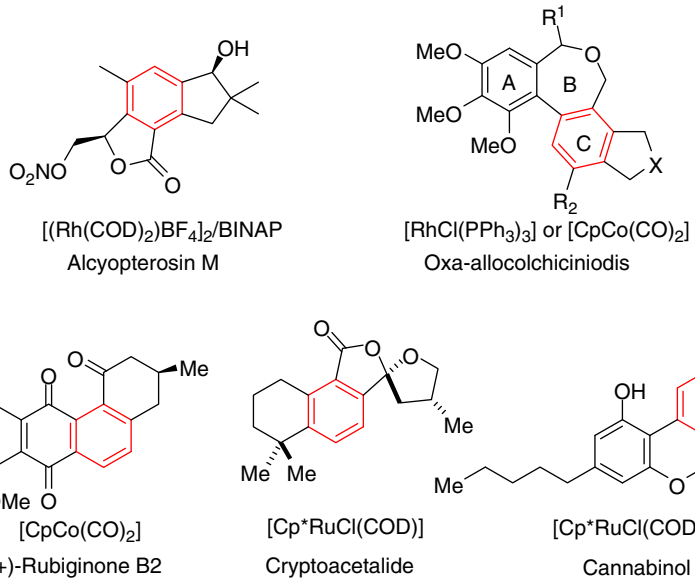
sensitive catalysts. The *N*-heterocyclic carbene can be used catalytically, which is a significant improvement compared with the corresponding phosphine-based system which requires an excess of ligand. Enediynes underwent intramolecular [2 + 2 + 2] under these conditions giving selectively polycyclic cyclohexadienes (Scheme 43).[14c,45b]

Focusing on catalytic protocols, several metal complexes of ruthenium, iridium, nickel, niobium, and rhodium are able to mediate these kinds of transformations. As commented above, [$NbCl_3$(DME)] (DME = dimethoxyethane) was used to effect intermolecular [2 + 2 + 2] cycloadditions of alkynes and α,ω-dienes or alkenes giving 1,3-cyclohexadienes with high chemo- and



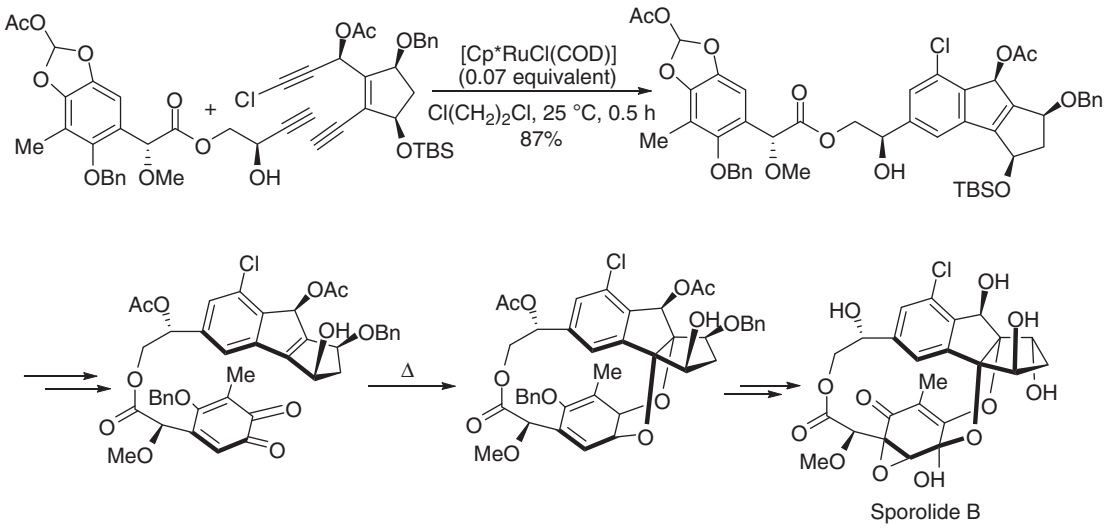


Figure 8 Natural products synthesized using the [2 + 2 + 2] cycloaddition reaction as the key step.

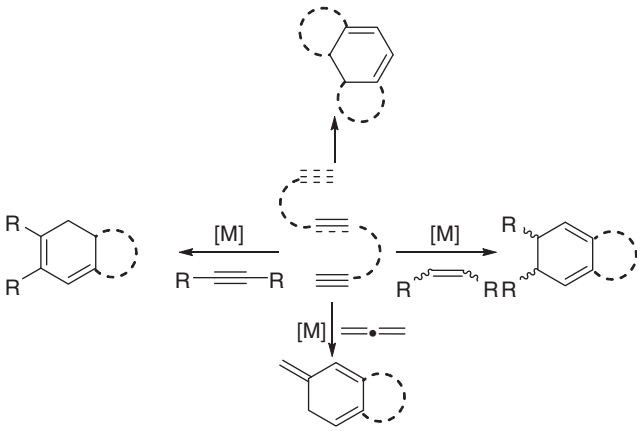
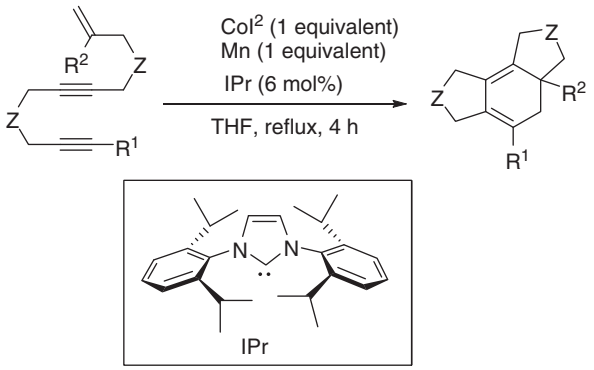


Scheme 41



regioselectivity (Scheme 3).[33] A remarkable three-in-one reaction was reported recently using nickel catalysis. Readily available arynes, activated alkenes, and alkynes gave a series of substituted 1,2-dihydronaphthalenes in moderate to very good yields with excellent chemo- and regioselectivity. The authors propose a reaction course starting with an oxidative coupling of benzyne and alkene on Ni to form a nickelacycle, which is probably stabilized by an intramolecular coordination of the heteroatom. Subsequent insertion of the alkyne into the Ni-C(aryl) bond gives a seven-membered intermediate which suffers reductive elimination to yield the final product (Scheme 44).[84]

With regard to bimolecular reactions, ruthenium (II) has been used for the reaction of 1,6-diynes with alkenes. The [2 + 2 + 2] cycloaddition was found to compete with double cyclopropanation processes which showcased the double carbenic nature of the metallacyclopentadiene intermediate. The nature of the catalyst was crucial to direct the reaction to either pathway (Scheme 45).[85]

A recent study focused on the regio- and stereochemical outcome of the reaction which depends on the substitution of the 1,6-diyne and the nature of the alkene. When acyclic alkenes were used, a cascade process took place that represents a formal Ru(II)-catalyzed [2 + 2 + 2] cycloaddition. Initially, a Ru-catalyzed linear coupling occurs to give open 1,3,5-trienes, which after a thermal disrotatory $6e^-$ π-electrocyclization led to the final 1,3-cyclohexadienes. In addition, new *exo*-methylene cyclohexadienes arose from a competitive reaction pathway when using electron-deficient alkenes (Scheme 46).[86]

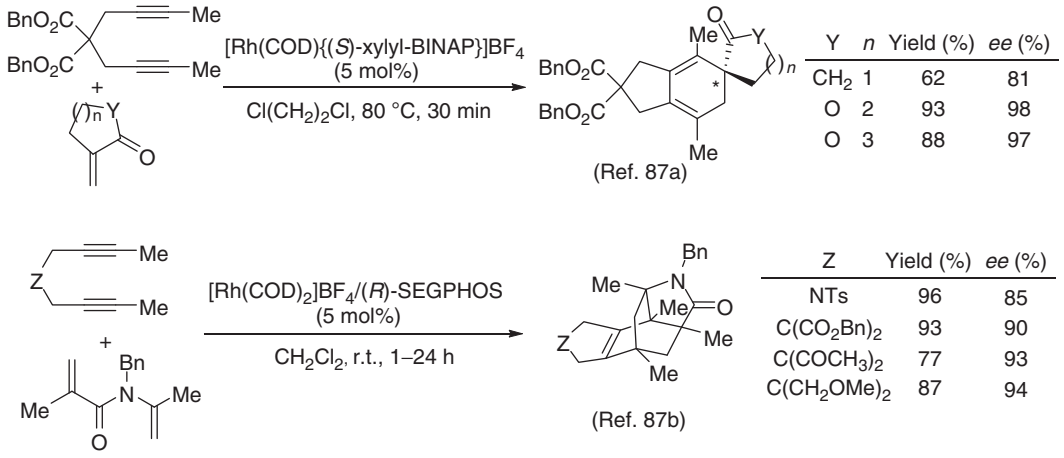
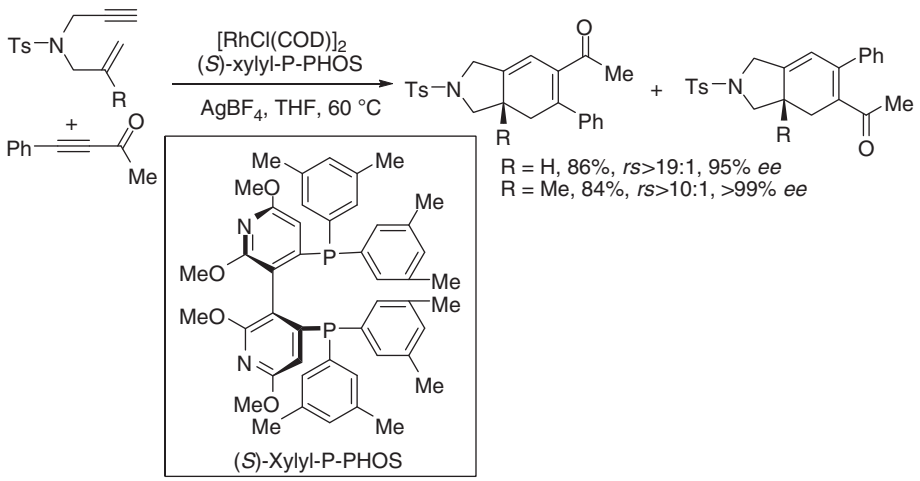
Scheme 44



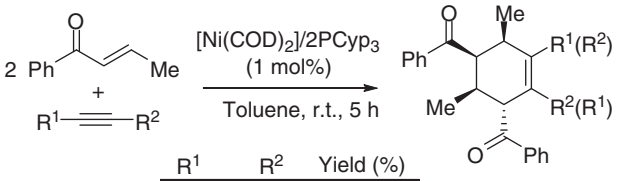
Scheme 47 shows two examples in which chiral rhodium-based catalytic systems catalyzed highly enantioselective [2 + 2 + 2] cycloaddition of diynes and alkenes. The first example shows the use of cyclic compounds with *exo*-methylene groups as a new protocol for the synthesis of chiral spirocyclic structures. Depicted below is a cascade bimolecular [2 + 2 + 2] cycloaddition/intramolecular Diels–Alder reaction using amide-linked 1,5-dienes.[87]

Scheme 45

Scheme 46



Scheme 47



The first rhodium-catalyzed [2 + 2 + 2] carbocyclization of 1,6-enynes with alkynes was disclosed in 2005. In this reaction, specific ligands were required for obtaining excellent regio- and enantioselectivities. The methodology allowed introducing quaternary carbon stereogenic centers (Scheme 48).[88] More recently, the enyne/alkyne reactions have been catalyzed by iridium, cobalt, and nickel.[89]

Catalytic enantioselective [2 + 2 + 2] cycloadditions of one alkyne unit and two alkene units are scarce. One contribution from Ogoshi's group described a fully intermolecular [2 + 2 + 2] cycloaddition of two enones and an alkyne, a reaction that proceeded stereoselectively to give only one diastereomer (Scheme 49).[90]

Intramolecular reactions with dienynes allowed the synthesis of fused tri- and tetracyclic cyclohexenes bearing two tertiary or quaternary carbon centers in high yields with high enantio- and diastereoselectivity. Cationic rhodium(I)/(*R*)-H_8-BINAP or (*R*)-SEGPHOS complexes were used as the catalytic systems (Scheme 50).[91]

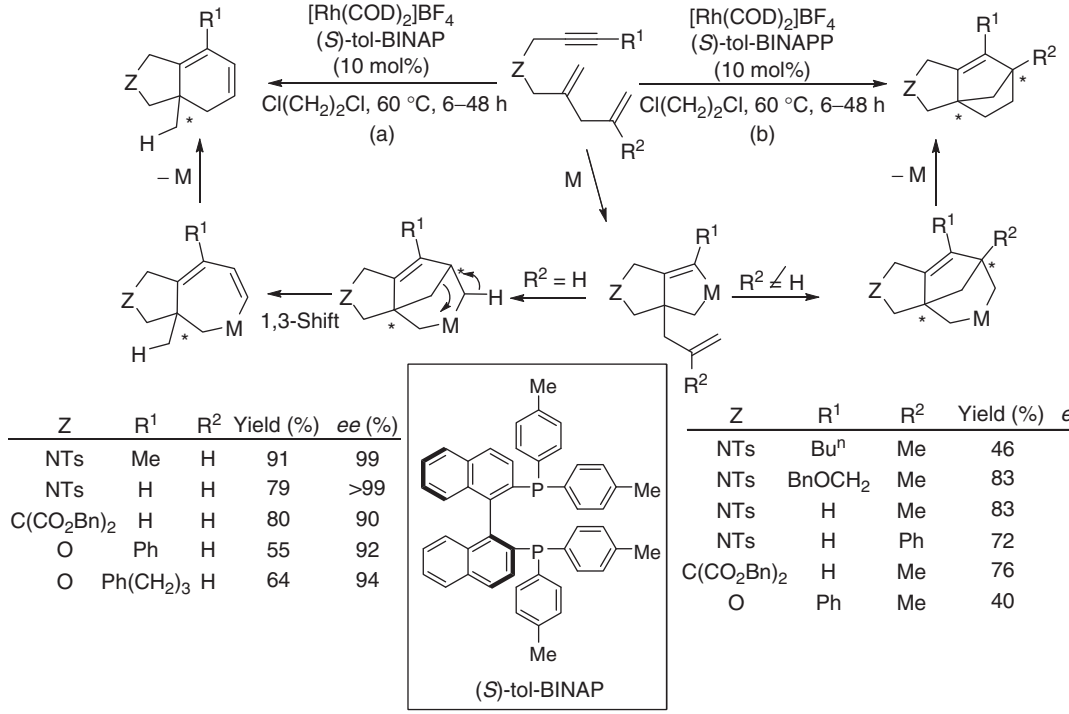
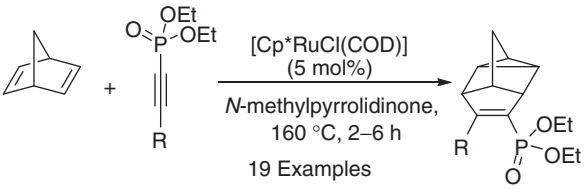
Scheme 49



Scheme 50

The reaction of a dienyne catalyzed by rhodium gave either cyclohexadienes or strained multicyclic compounds, both with quaternary carbon stereocenters, depending on the substitution pattern of the starting dienyne (Scheme 51). After the formation of the typical metallacyclopentene an olefin insertion followed. Then, for $R^2 = H$, a 1,3-hydrogen shift accompanied by ring cleavage proceeded to provide a metallacycloheptadiene and subsequent reductive elimination gave a cyclohexa-1,3-diene (path a). On the contrary, when $R^2 \neq H$, a tricyclic compound was obtained by reductive elimination (path b).[92]

The homo-Diels–Alder (HDA) cycloaddition is described as [2 + 2 + 2] cycloaddition resulting in the formation of tetracyclic structures of considerable strain known as deltacyclanes. The use of transition metals to catalyze this reaction has been well documented, and cycloadditions involving alkynyl dienophiles have been promoted by cobalt, rhodium, and ruthenium catalysts. Examples of ruthenium-catalyzed HAD [2 + 2 + 2] cycloadditions between alkynyl phosphonates and bicyclic alkenes were recently disclosed (Scheme 52).[93]



Allenes may be components in the [2 + 2 + 2] cycloaddition reaction. Examples include totally intermolecular reactions, crossed cyclizations with diynes, or reactions of allenynes with alkynes or arynes. Catalytic systems cover the general spectra for these reactions but nickel and cobalt salts are commonly used. Cheng's group has reported a highly regio- and chemoselective [2 + 2 + 2] cycloaddition of electron-deficient diynes with allenes catalyzed by the Ni(dppe)Br_2/Zn system and cycloadditions of electronically neutral 1,6-heptadiynes with allenes catalyzed by cobalt complexes leading to polysubstituted benzene derivatives

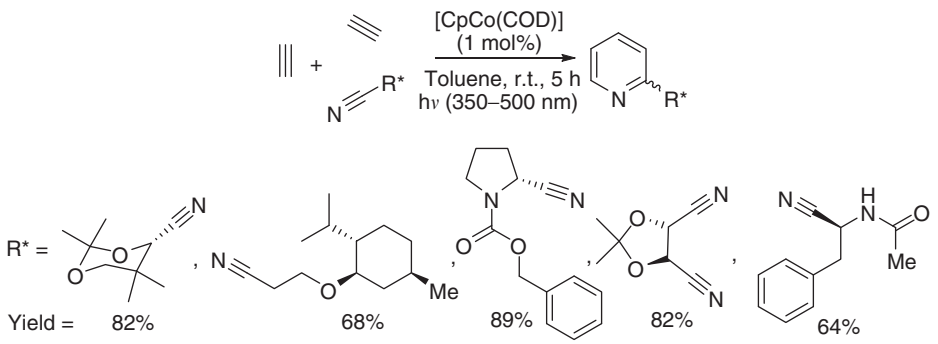
There is an outstanding contribution which shows one of the first examples of [2 + 2 + 2] cycloadditions with three double bonds, one of them belonging to an allene system. Thus, by means of rhodium(I)-catalysis, simple alkenes and allenes delivered

carbocycles with construction of up to four contiguous stereogenic centers, including quaternary stereocenters, in a single synthetic step albeit with moderate enantiomeric ratios (Scheme 54).[95]

Scheme 54

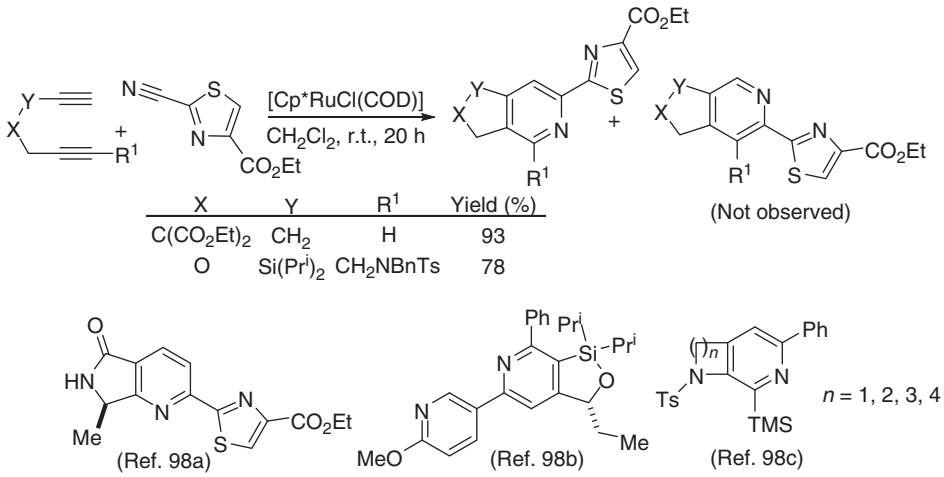


5.31.4 Synthesis of Nitrogen-Containing Six-Membered Heterocycles

The transition metal-mediated cyclocotrimerization of alkynes with carbon–heteroatom multiple bonds was first pioneered by Wakatsuki and Yamazaki followed by Bönnemann.[96] They disclosed stoichiometric reactions of cobaltacyclopentadienes with nitriles, carbon disulfide, and methyl isothiocyanate, leading to pyridines, dithiopyrones, and thiopyridones, respectively. Afterwards Vollhardt's group reported intramolecular cycloadditions of diynes and alkynenitriles leading to pyridines, mediated by cobalt. These early contributions were followed by works on new mild and catalytic reaction conditions using other metals and by asymmetric reactions mainly en route to axially chiral products.

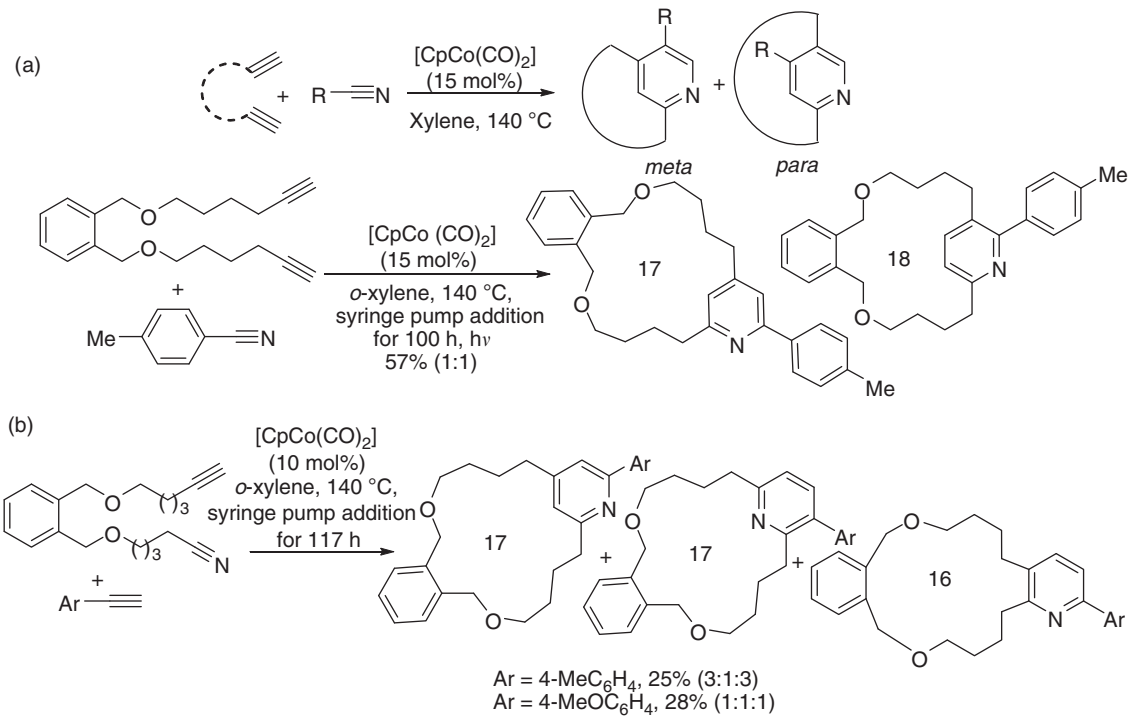
5.31.4.1 Synthesis of Pyridines

The transition-metal-catalyzed [2 + 2 + 2] cycloaddition reaction constitutes an important tool for the synthesis of pyridines. *De novo* construction of pyridine ring systems has evolved in recent years from the intramolecular assembly of pyridines by reaction of diynes and oligoynes with nitriles to some completely intermolecular reactions between acetylenes and nitriles and reactions with alkynenitriles and alkynes. The reaction tolerates a wide variety of functional groups in the substrates, giving access to densely functionalized pyridinic products.[96]



Cobalt complexes of the type [$CpCoL_2$] (L = CO, PR_3, olefin) have been extensively studied as catalysts in the [2 + 2 + 2] cycloadditions of alkynes with nitriles to afford pyridines. Among the scarce examples of totally intermolecular cycloadditions of a nitrile and two alkynes, the authors can remark the racemization-free conversion of chiral nitriles into pyridine derivatives disclosed by the group of Heller. The cobalt(I)-complex [CpCo(COD)] was the catalyst of choice and the reaction could be performed in organic solvents (toluene or hexane) or even in water. A broad variety of functionalized (e.g., ester, ketones, amines) chiral mono- as well as dinitriles were used as substrates for the reaction with acetylene or internal alkynes (Scheme 55).[97]

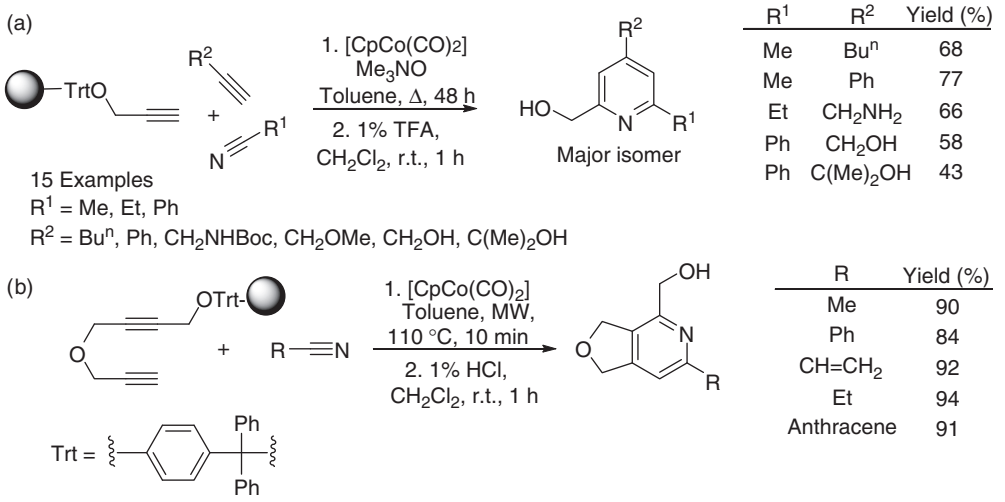
Scheme 55



Most syntheses of pyridines use diynes as starting materials. Terminal and internal diynes react with various types of nitriles. Nonsymmetric diynes give selectively the pyridine with the nitrogen adjacent to the more bulky substituent. This predictable regioselectivity has been used in synthetic applications as shown in Scheme 56. Thus, under cobalt catalysis, (1) a part of the natural product cyclothiazomycin, (2) an intermediate en route to bioactive neurite outgrowth inhibitors, and (3) various bicyclic aminopyridines were regioselectively synthesized.[98]

Diynes with different tether lengths are reactive toward nitriles. In this sense, long-chain α,ω-diynes are known to react with acetylene dicarboxylates, yielding pyridine-containing *ansa*-macrocycles and cyclophanes. The reaction has been catalyzed with

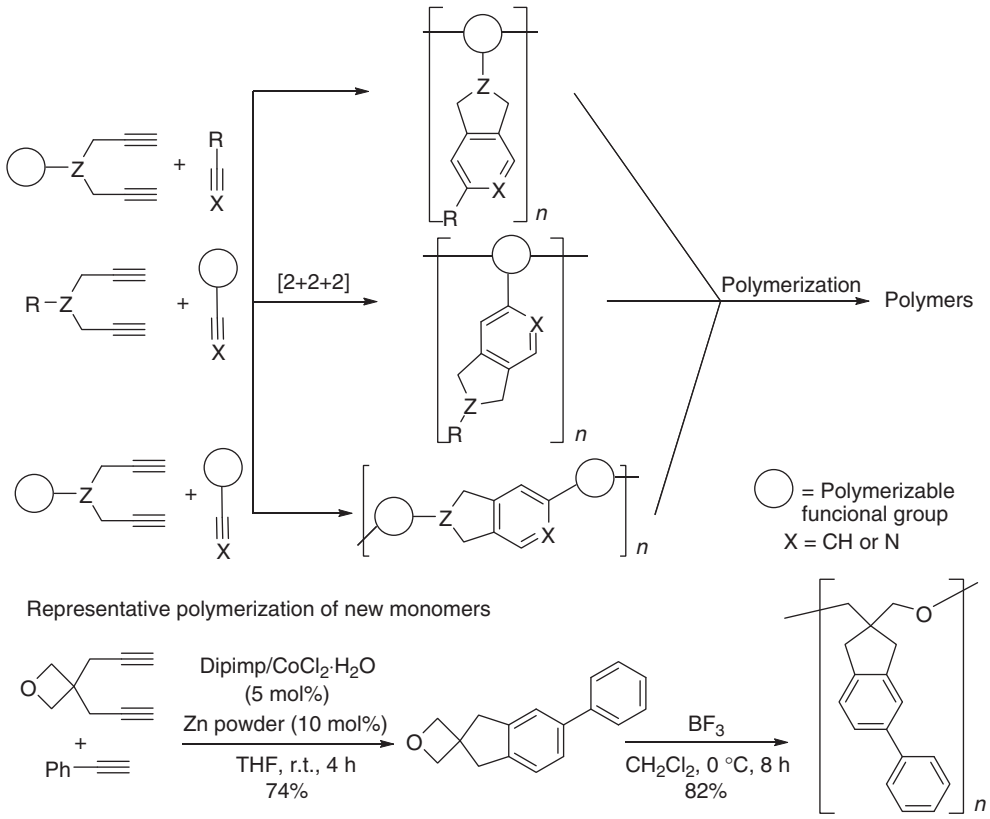
Scheme 56



$[CpCo(CO)_2]$. These type of macrocyclic pyridines were also obtained on reaction of ω-alkynyl-α-nitriles with alkynes (Scheme 57).[99]

Scheme 57

If conducted on a solid-support, [2 + 2 + 2] cycloaddition reactions enable rapid combinatorial access to diverse sets of carbo- and heterocyclic small-molecule arrays, solving partly the regio- and chemoselectivity problems. After the first work by Sun's group on the synthesis of isoindolines, Deiters' group has investigated different immobilization strategies, different diyne precursors, and a variety of functionalized alkyne and nitrile reaction partners.[100] A totally intermolecular method was disclosed first where an alkyne was anchored to the resin and reacted with a nitrile and a second alkyne (Scheme 58a).[100a] Afterwards, isoindoline, phthalan, pyridines, triphenylenes, and indanes were assembled in good-to-excellent yields using cobalt-catalysis under MW irradiation. In this second approach different diynes were anchored to a solid support (Scheme 58b).[100b]



Okamoto's group obtained a variety of polymerizable molecules having a 2,3-dihydro-1*H*-indene or 6,7-dihydro-5*H*-cyclopenta[*c*]pyridine core structures using [2 + 2 + 2] cycloaddition reactions. Some of the monomers were then polymerized in the presence of BF_3 as the catalyst (Scheme 59).[101]

Scheme 59

In addition to cobalt catalysis, ruthenium, rhodium, iron, and nickel-catalyzed syntheses of pyridines have been published. In particular, dicyanides, cyanamides, and halonitriles exhibited exceptionally high reactivity toward the ruthenium-catalyzed cycloaddition with 1,6-diynes leading to bicyclic pyridines under mild conditions. This especially good performance, which is in contrast to the behavior of benzonitriles or simple aliphatic nitriles, is thought to be due to an assisting effect of the additional functional group. Methoxy and methylthio groups also behave as assisting groups (Scheme 60).[25,26]

Production of central chirality was achieved in a cationic rhodium(I)/modified-BINAP complex-catalyzed reaction used to generate spirobipyridine ligands through an intramolecular double [2 + 2 + 2] cycloaddition of bis-diynenitriles (Scheme 61).[65c]

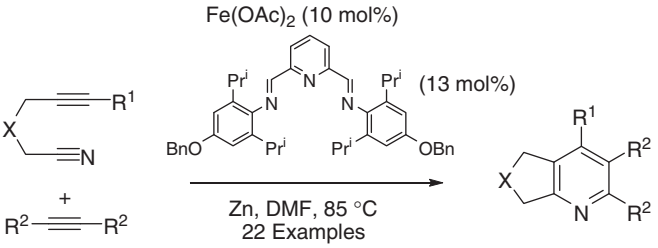
A combination of a nickel(0) precursor and an imidazolylidene ligand has been described as an efficient catalyst for the preparation of a wide range of pyridines from α,ω-diynes and nitriles. With this methodology, as with other catalytic systems, cyanamides were found to give excellent results (Scheme 62).[23]

In addition, iron complexes catalyzed the synthesis of pyridines. Cycloaddition of alkynenitriles and alkynes proceeded with high yields, as were some totally intramolecular examples in which diyne-nitriles were cycloisomerized (Scheme 63).[34]



One interesting and recent example of totally intramolecular reaction described the synthesis of tricyclic fused 3-aminopyridines through a very efficient cobalt-catalyzed [2 + 2 + 2] cycloaddition of a polyunsaturated compound displaying an ynamide, an alkyne, and a nitrile functionality. Particularly interesting was the synthesis with moderate yield of a stable 1,2-dihydro-1*H*-azeto[3,4-c]pyridine. This synthesis, which remarkably formed a four-membered ring, required heating, with $[CpCo(C_2H_4)_2]$ as the catalyst, which was added in two portions every 3 h (Scheme 64).[102]

Indole-containing alkaloids are a challenge in organic synthesis due to their complex and highly connected polycyclic structures. The presence of aromatic rings in their structures makes the [2 + 2 + 2] cycloaddition a good candidate for the construction of these compounds. The citrinadines are recently isolated marine-derived pentacyclic spiroindolinone alkaloids exhibiting important cytotoxic activities against various cancer cell lines. Deiters' group developed an approach to their tricyclic alkaloid core structures by conducting a MW-mediated [2 + 2 + 2] cyclotrimerization/intramolecular nucleophilic substitution/reduction sequence. The central pyridine ring was efficiently built and subsequently alkylated and reduced (Scheme 65).[103]

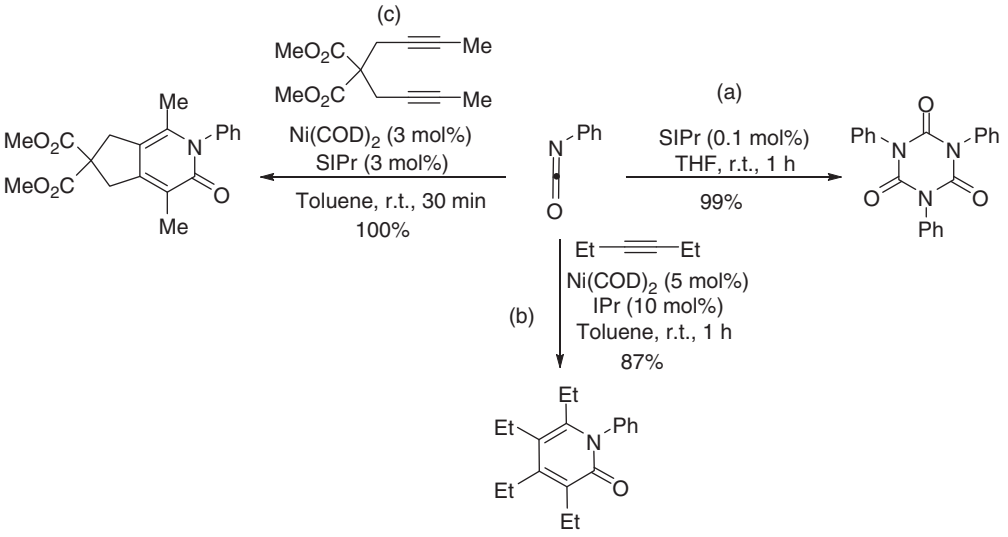
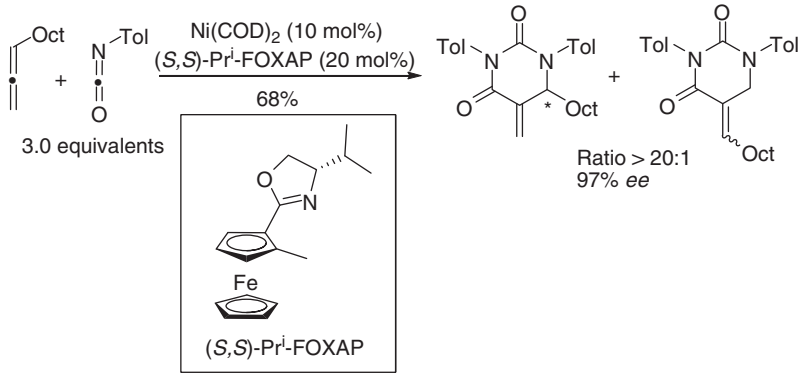
Two late-stage Co(I)-mediated [2 + 2 + 2] cycloadditions were the key steps for the synthesis of complanadine A, a member of the large family of lycopodium alkaloids. The first cycloaddition proceeded with excellent regioselectivity. However, it was necessary to add an excess of triphenylphosphine to get the desired 2,3′-bipyrimidyl product as the major isomer in the second [2 + 2 + 2] cycloaddition, albeit with 3:1 selectivity against the undesired 2,2′-isomer (Scheme 66).[104]

Scheme 65



Scheme 66

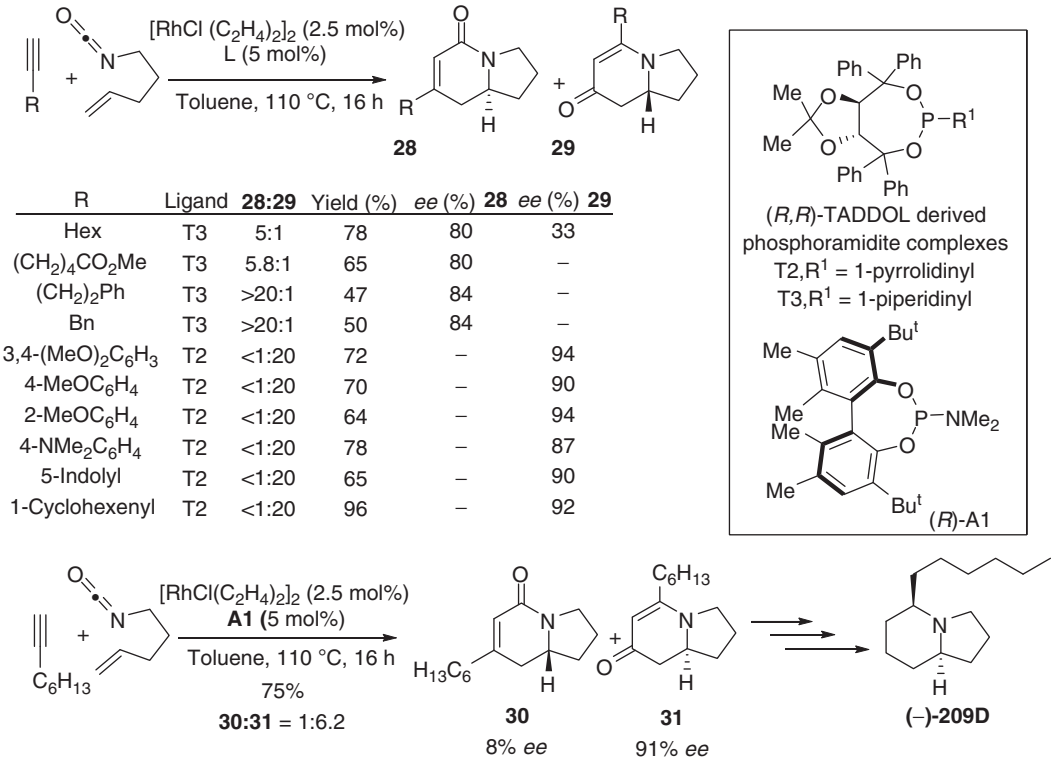
5.31.4.2 Synthesis of Pyridones Pirimidindiones and Dihydropyridine. Nitrogen-Containing Double Bonds as Partners for the [2 + 2 + 2] Cycloaddition



Nitrogen-containing heterocycles can be assembled using one C=N unit as partner for the [2 + 2 + 2] cycloaddition. Due to their modest basicity, isocyanates have been shown to be the best choice. These compounds can cyclotrimerize to form triazintriones, or cotrimerize with alkynes, diynes, allenes, or alkenes. Some cycloadditions of isothiocyanates have also been reported. In general, rhodium, cobalt, nickel, and ruthenium are able to catalyze [2 + 2 + 2] cycloadditions of alkynes and isocyanates, forming pyridones. Louie's group has described cyclotrimerizations of three isocyanate molecules, cotrimerizations of two isocyanates and one alkyne, and crossed cyclotrimerizations of diynes with isocyanates. NHCs alone were able to catalyze the

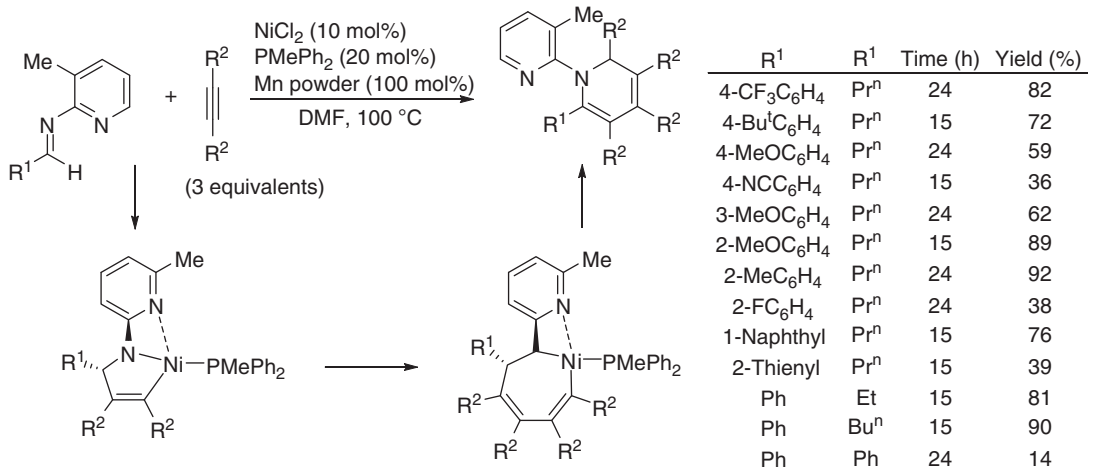
cyclotrimerization of isocyanates (Scheme 67a), whereas nickel complexes generated from NHCs and $Ni(COD)_2$ mediated the reaction of isocyanates with alkynes or diynes (Scheme 67b and c).[105]

Scheme 67



If an alkene is incorporated in place of one of the alkynes a new stereocenter is formed and the reaction could be rendered asymmetric using a chiral catalyst. Thus a cycloaddition of two molecules of isocyanate and one molecule of allene, catalyzed by a nickel complex provided an efficient access to enantiomerically enriched dihydropyrimidine-2,4-diones. Careful selection of the chiral ligand allowed for excellent enantioselectivity (Scheme 68).[106]

Scheme 68



After many contributions to the synthesis of indolizinones, quinolizinones, and pyridones, the group of Rovis has recently described an enantioselective rhodium-catalyzed [2 + 2 + 2] cycloaddition of terminal alkynes and alkenyl isocyanates leading to the formation of indolizidine and quinolizidine scaffolds. Single regioisomeric products are obtained in good yields and excellent enantioselectivities. The use of phosphoramidite ligands proved crucial for avoiding competitive terminal alkyne dimerization. α,α,α,α-tetraphenyll-1,3-dioxolane-4,5-dimethanol (TADDOL)-derived phosphoramidite ligands provided the best enantioselectivities for aryl alkynes, whereas 1,1′-bi-2-naphthol- and other biaryl-based phosphoramidite ligands gave higher enantioselectivity for alkyl alkynes. Interestingly, the major reaction pathway involved a CO migration which facilitated a rapid four-step asymmetric synthesis of the naturally occurring indolizidine **(–)-209D** (Scheme 69).[107]

Although imines can potentially participate in [2 + 2 + 2] cycloadditions to afford dihydropyridine derivatives, few examples have been reported possibly due to lack of stability of these substrates. After pioneering results by Ogoshi's group on nickel-catalyzed cycloaddition reaction of alkynes and an *N*-sulfonylimines, Yoshikai's group used the directing effect of a pyridyl group to achieve a reaction of an aldimine bearing a 3-methyl-2-pyridyl group with alkynes under nickel-catalysis. The reaction gave a 1,2-dihydropyridine derivative in moderate-to-good yield, presumably through 1,5-hydrogen shift of the initially formed cycloadduct (Scheme 70).[108]

5.31.5 Other Six-Membered Heterocycles

In recent times, the [2 + 2 + 2] cycloaddition reaction has expanded its scope to new unsaturated substrates such as ketenes, ketones or aldehydes, carbon dioxide, and carbon disulfide enabling the synthesis of nonnitrogenated six-membered heterocycles.

After the pioneering works by Vollhardt using cobalt catalysis, Yamamoto's group reported the [CpRuCl(COD)]-catalyzed cycloadditions of diynes with electron-deficient carbon–heteroatom multiple bonds resulting in various heterocyclic compounds with significant chemo- and regioselectivity. In addition to activated nitriles and isocyanates, they introduced isothiocyanates,

carbon disulfide and *N*-thionylamides as new partners for the cocyclization with diynes. Under mild conditions, the corresponding sulfur-containing heterocycles were synthesized in good yields. When using unsymmetrical diyne substrates, the regiochemistry of these cycloadditions was successfully controlled by the steric and electronic influence of the substituents (Scheme 71).[109]

Z	EWG	Yield (%)
$C(CO_2Me)_2$	COMe	90
$C(COMe)_2$	CO_2Et	90

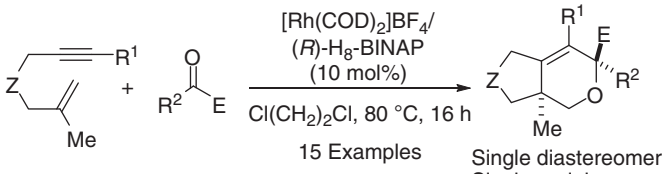
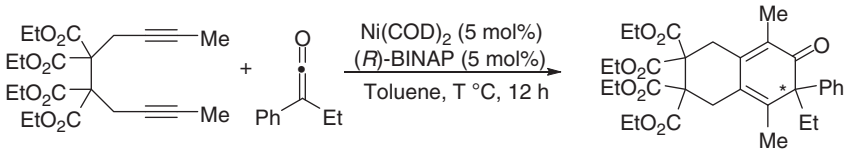


Scheme 71

Tanaka's group has contributed to the extension of the [2 + 2 + 2] cycloaddition process to carbon–heteroatom double-bond substrates. They have applied their cationic rhodium-catalyzed methodology to reactions of diynes with isocyanates for the synthesis of axially chiral 2-pyridones from unsymmetrical α,ω-diynes. An extension of the process using carbon disulfide also proceeded to give bicyclic dithiopyrones. More recently, they described a [2 + 2 + 2] cycloaddition of 1,6-enynes with electron-deficient ketones. Two quaternary carbon centers were created in the reaction to form fused dihydropyrans with excellent regio- and enantioselectivity (Scheme 72).[110]

Finally, ketenes were introduced as new substrates for [2 + 2 + 2] cycloaddition reactions. Ketenes have two possible modes of coordination to the metal and have the propensity to undergo decarbonylation with formation of stable, unreactive metal carbonyl complexes. They often suffer homodimerization under thermal conditions. Despite these pitfalls, it was reported that a nickel-phosphine catalyst mediated the cycloaddition of ketenes and diynes to afford cyclohexadienones in good yield without observing decarbonylation of the ketene starting materials. An enantiopure cyclohexadienone product was obtained when (*R*)-BINAP was used as the ligand (Scheme 73).[111]

5.31.6 Conclusions and Outlook



The [2 + 2 + 2] cycloaddition reaction is an atom economic and synthetically powerful reaction with a huge scope and great synthetic utility. The catalysts utilized in these reactions are easily handled. The original cobalt-carbonyl-mediated stoichiometric methodologies have evolved into active cobalt–alkene complexes, which are able to perform catalytically at low temperatures; alternatively Rh(I) or Ir(I)–diphosphane complexes are now regularly applied by mixing alkene precursor complexes and ligands *in situ*. Although zirconium- and titanium-mediated reactions are generally not catalytic, they are still used to circumvent selectivity problems; moreover, they can be used in combination with other reactions. Palladium-based catalysis is specifically effective for the synthesis of polycyclic aromatic hydrocarbons and for reactions with arynes. Ruthenium cyclopentadienyl–COD complexes have emerged as general catalysts for all types of [2 + 2 + 2] cycloaddition under mild

conditions. In addition, nickel complexes formed on combination of an Ni(0) adduct and an NHC ligand catalyze efficiently cycloadditions of alkynes with various unsaturated partners. Other metals such as niobium or iron appear as promising new alternatives to the usual methodologies.

The synthesis of functionalized arenes used to be achieved through classical transformations based mainly on electrophilic substitution reactions on preformed aromatic rings. However, once the [2 + 2 + 2] cycloaddition of alkynes has reached a mature state with many catalytic systems available, and great understanding of mechanistic aspects, it is becoming an efficient alternative, especially for the synthesis of natural products. This includes excellent ways to build pyridines when a nitrile is cocyclized with two alkynes.

In addition, the literature provides many procedures to carry out asymmetric reactions en route to axially or planarly chiral products. Axially chiral biaryl compounds are important as chiral auxiliaries and ligands for asymmetric synthesis and as the structurally decisive element in bioactive natural products. There is probably no reliable and generally applicable atropselective synthesis that gives excellent chemical yields and optical purities under mild and convenient reaction conditions. However, the use of commercially available and stable chiral bisphosphine ligands in iridium(I) and rhodium(I) catalyst systems or other combinations of chiral ligands with metals for [2 + 2 + 2] reactions is advantageous and allows catalyst tuning and convenient handling. Thus the enantioselective synthesis of many axially chiral biaryl compounds has successfully been described by several groups and applied in natural product syntheses.

Cocyclotrimerizations of alkenes, isocyanates, carbon dioxide, ketenes, ketones, imines etc. with alkynes affords cyclohexadienes and different heterocycles involving many times the generation of asymmetric centers. Various groups have used chiral catalysts to achieve enantioselective syntheses of these compounds.

Significant challenges still remain. For example, it is desirable to expand the substrate scope to include more diverse alkynes and alkyne surrogates as well as to solve the regioselectivity problem in reactions of aliphatic alkynes. Completely controlled intermolecular reactions between three alkynes or one nitrile/isocyanate and two alkynes, and new applications in synthesis are also yet to be realized.

In summary, the [2 + 2 + 2] cycloaddition reaction is today a strategic reaction because it is able to perform various bond connections in only one step, resulting in a significant increase of structural complexity. This area is clearly expanding in several

aspects and will reveal spectacular applications in the near future, ranging from new asymmetric synthesis of axial or planar chiral products and chiral cyclohexadienes/pyridones to the synthesis of natural compounds (Chart 1).

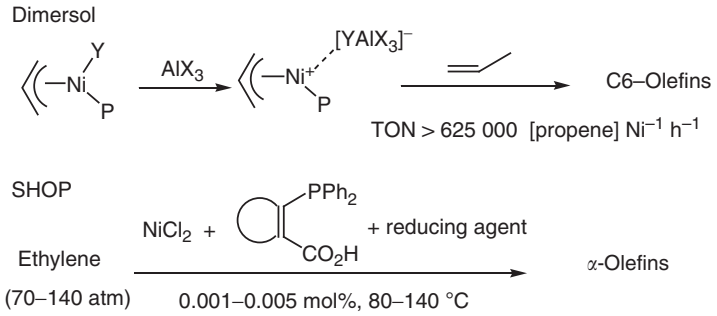
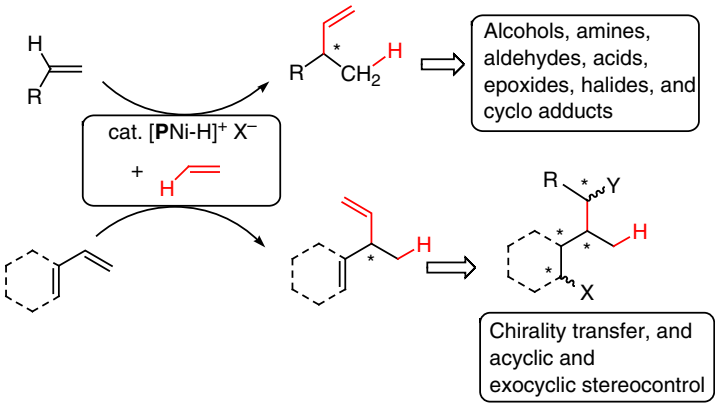
Glossary

Exocyclic stereocontrol Control of the absolute and/or relative configuration of a stereogenic center attached to a carbo- or heterocyclic ring.



Hemilabile ligand A ligand containing a weakly coordinating group such as an ether oxygen usually containing also a strongly coordinating group such as a phosphine.

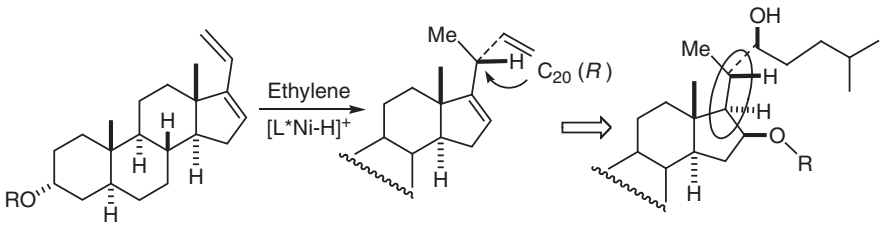
 doi:10.1016/B978-0-08-097742-3.00533-4



Hydroalkenylation Addition of an alkene to another unsaturated moiety as a hydrogen and an alkenyl group.
Phospholane Another name for a phosphacyclopentane ring system. 2,5-Dialkylphospholanes are extensively used chiral ligands.
Phosphoramidite A phosphorus(III) compound with two P–O bonds and a P–N bond. Such ligands from axially chiral binaphthols, known as Feringa ligands, are among the most widely used ligands in asymmetric catalysis.
Turnover frequency Number of moles of starting material converted into product per mole of the catalyst at unit time. A measure of the efficiency of a catalyst.

5.32.1 Introduction

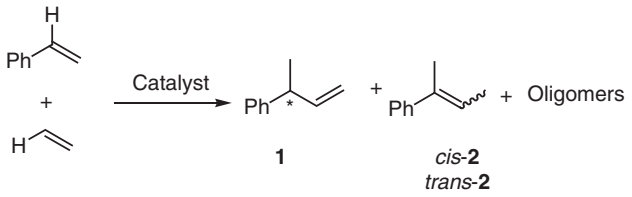
The astonishingly high turnover frequency ($>625\,000$ [propylene][Ni]$^{-1}$[h]$^{-1}$) observed for Ni(phosphine)(allyl)X as a catalyst in the homodimerization of propene makes this one of the most active homogeneous catalysts known for C–C bond formation.[1,2] This or related chemistry forms the basis of the Dimersol and the Shell higher olefin processes (SHOPs) (Scheme 1). Application of this chemistry for fine chemical synthesis would be especially attractive if the reaction can be extended to heterodimerizations (i.e., dimerization of two different olefins), and sufficient regio- and stereoselectivity can be achieved. Among such reactions, codimerization of ethylene and other alkenes (hydrovinylation, Scheme 2) would have the highest impact since the vinyl group in the product can be transformed into a number of other useful functional groups.



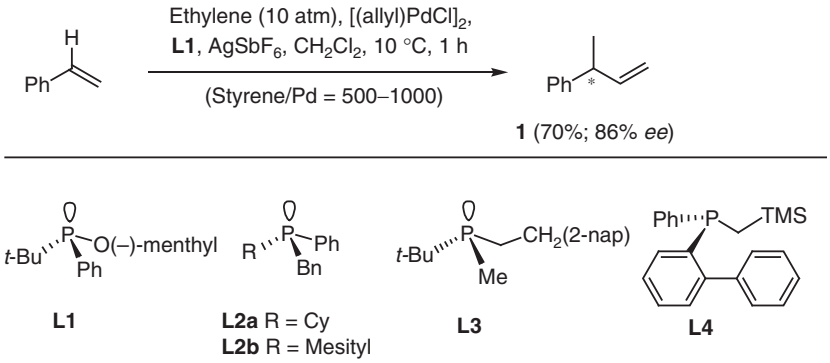
Scheme 1 Ni(II)-catalyzed reactions of propylene and ethylene.

Scheme 2 Selective hydrovinylation reactions.

From a synthetic perspective, this chemistry provides a very attractive solution to the long-standing problem of exocyclic stereochemical control, an example of which is illustrated in Scheme 3 in the context of steroid D-ring functionalization. As seen in steroids, a chiral side chain carrying a methyl-bearing carbon (C_{20}) that is attached to a chiral center in the D-ring is a very common structural motif in many important natural products. The installation of these centers via classical chemistry has often been quite circuitous.



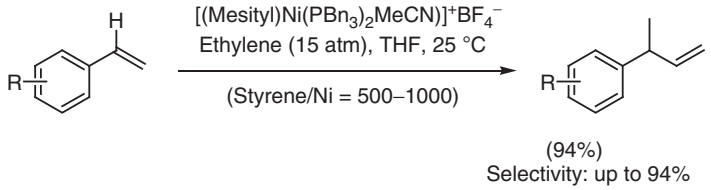
This review will primarily deal with the most recent aspects of the metal-catalyzed hydrovinylation and related reactions. The reader is urged to consult other reviews[3–7] for details of the early history and development of this class of reactions. The literature on hydrovinylation and related hydroalkenylation reactions up to the end of May 2012 is covered here.



Scheme 3 Hydrovinylation reactions for installation of exocyclic stereocenters.

5.32.2 Early History of the Hydrovinylation Reaction

The first report of hydrovinylation in the open literature appears in a 1964 paper by Hata,[8] who used Fe(acetylacetonate)$_3$ and triethylaluminum to effect additions of ethylene to 1,3-butadiene, 1,3-pentadiene, and isoprene to get a mixture of various adducts. Approximately the same time, Alderson, Jenner, and Lindsey at DuPont Central Research reported the use of hydrated rhodium and ruthenium chlorides to effect the dimerization of ethylene and various olefins, such as styrene and 1,3-butadiene, at high pressures (1000 psi).[9] Cobalt-catalyzed dimerization of ethylene using $(N_2)Co(H)(PPh_3)_3$ is another notable early result.[10] To date, styrene has served as the prototypical substrate for many of the initial investigations of this reaction, and, as illustrated in equation 1, the reaction is complicated by concomitant side reactions such as isomerization reactions of the initially formed product and oligomerizations of styrene as well as ethylene. In early studies, apart from rhodium[9,11] and ruthenium,[9,12] uses of other metals such as cobalt,[10,13] palladium,[14–16] and nickel [17–22] have also been reported. However, in most cases, the reactions yielded mixtures of products. Initial reports of the palladium-catalyzed hydrovinylation indicated that mostly linear products were formed and extensive isomerizations of the primary products were observed. More recent studies have shown that under carefully chosen reaction conditions and with the use of ligands such as **L1**,[23] **L2a**,[24] **L2b**,[25] **L3**,[26] and **L4**,[26,27] the isolation of predominantly the branched product can be achieved. Among these ligands, phosphinite **L1** is particularly noteworthy, for producing 3-phenylbut-1-ene (**1**) under the appropriate conditions (equation 2) in moderate yield (79%) with good selectivity (70% 3-phenyl-1-butene, 86% *ee*).[23] This paper also reports the beneficial effects of dissociating counterions such as SbF_6^-.

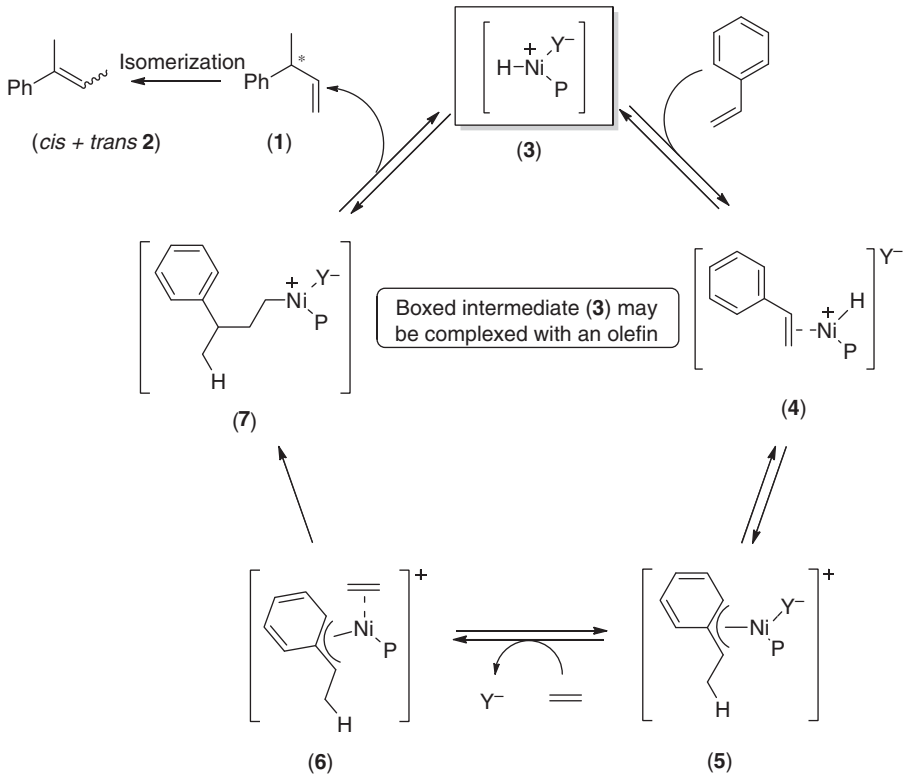


(1)

(2)

Due to the persistent isomerization of the primary product, low conversion, and poor selectivity, more recent work has focused on improving ligands and reaction conditions to afford a more viable protocol that is amenable to large-scale synthesis. By modifying the conditions originally reported by Kawata et al.,[17–19] Muller recently disclosed that Ni-catalyzed hydrovinylation of vinylarenes can be carried out (equation 3) using $[ArNi(PR_3)_2(MeCN)]^+BF_4^-$ [Ar = mesityl, R = benzyl] as precatalysts.[28,29] This catalyst system is able to achieve high turnover frequencies ($\sim$1900 [vinylarene][catalyst]$^{-1}$[h]$^{-1}$) and high selectivities under 15 atm of ethylene for a variety of vinylarenes. Although heteroatoms are well tolerated in this system, ring-alkylated vinylarenes were poor substrates, failing to react with ethylene. Additionally, an increase in reaction temperature (to promote reaction between ethylene and slow-reacting substrates) was accompanied by an undesired increase in isomerized product. Finally,

replacement of the tribenzylphosphine ligand with a chiral *cis*-myrtanyldiphenylphosphine ligand gives excellent selectivity for the branched product; however, only discouraging enantioselectivity (~7% *ee*) was observed.

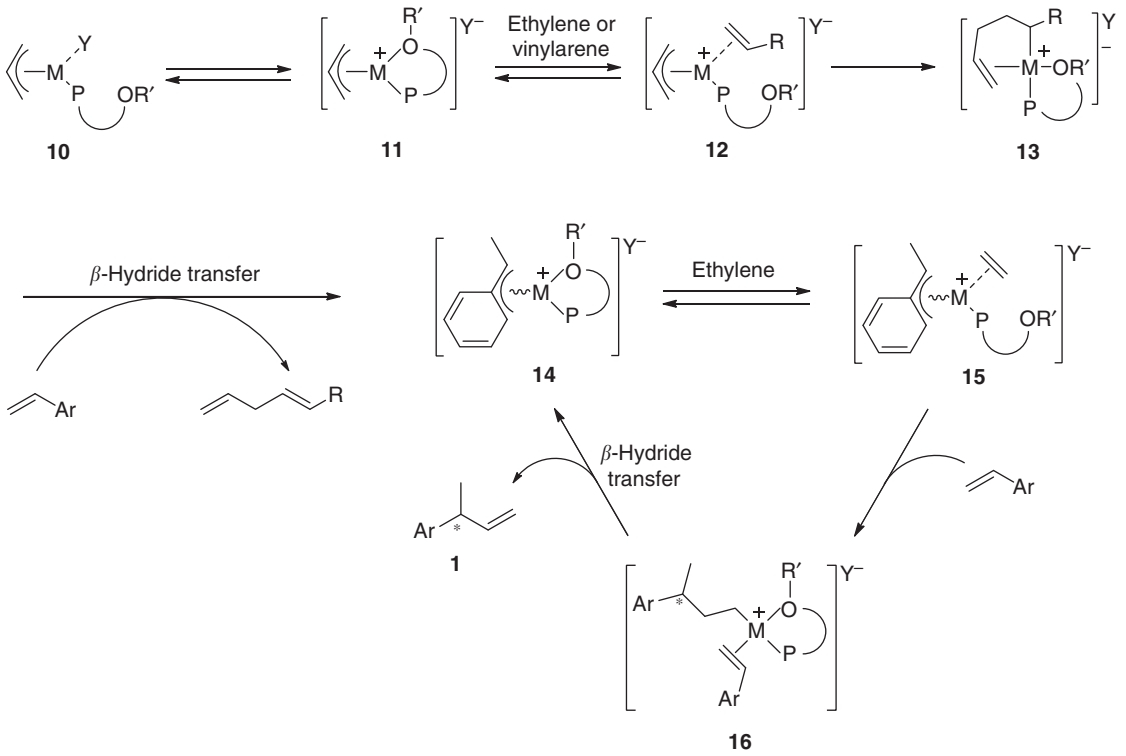


(3)

Since an exothermic polymerization of ethylene is a background reaction in all of these reactions (more prominent at the end of the facile heterodimerization reaction), the ability to control the temperature is crucial to achieve reliable selectivities and/or avoid the isomerization of the primary products. Monteiro et al.[30,31] have developed a catalyst system that circumvents the problem of isomerization by maintaining higher pressures (>10 atm) of ethylene in the reactor. They reported the use of dicationic nickel complexes ($[Ni(CH_3CN)_6]^{2+}2[BF_4]^-/Ph_3P/Et_2AlCl$) for the hydrovinylation of a variety of vinylarenes in moderate to good yields (68–87%).

5.32.3 Mechanistic Considerations

Although much of the early studies on the hydrovinylation of styrene with ethylene resulted in poor selectivities and rampant oligomerization, they have provided significant insights into the reaction mechanism. For instance, deuterium distribution studies using deuterated ethylene (C_2D_4) have provided evidence for the involvement of a cationic nickel hydride or equivalent.[19–22] Kinetic and solvent effect studies have provided early indications of coordination of ethylene to styrene and subsequent addition.[20] The deactivating effect of solvent was also observed and found to increase in the order of CH_2Cl_2, PhF, PhCl, PhMe, $PhNO_2$, Et_2O, consistent with the adverse effect of Lewis basic coordination. In the absence of an in-depth, meaningful mechanistic study, all available experimental evidences[19,32–35] support a mechanism involving a cationic nickel hydride intermediate associated with a weakly coordinated counterion and the phosphine ligand, represented by complex **3** (Scheme 4). Although the structures of none of the nickel complexes proposed in Scheme 4 have been confirmed by X-ray diffraction or any



Scheme 4 A hypothetical mechanism of Ni(II)-catalyzed hydrovinylation of styrene.

other methods, the structures of several compounds related to the allylnickel species [(allyl)Ni(phosphine) (X)] have been reported, including those with ligands dimenthyl(methyl)phosphine (X=Me),[36] *tert*-butyl(menthyl)methylphosphine (X=Cl),[37] and tricyclohexylphosphine ($X=MeAlCl_3$).[38]

Assuming that the functional equivalent of the active catalyst is a cationic nickel hydride, represented by complex **3**, the addition of styrene across the vinylarene would lead to intermediate **5**, depicted as a 16-electron η^3-complex. Coordination of ethylene with concomitant loss of the counterion leads to the formation of cationic intermediate **6**, which is poised for a subsequent insertion step to generate **7**. The catalytic cycle is then propagated by the η-hydride elimination to afford the primary product **1** and the active catalyst **3**. Strong evidence for intermediate **6** has been provided by Brookhart and DiRenzo[33,34] in an analog system with palladium, using the precatalyst $[(allyl)Pd(PCy_3)]^+$ $[BARF]^-$ (tetrakis[(3,5-trifluoromethyl)phenyl]borate (BARF)) that is employed for styrene dimerization reactions. Other significant mechanistic observations were the inability of chelating, bidentate phosphines to effect the reaction under standard protocols and the synergistic effect between the ligand and counterion.[35] Any valid mechanistic proposal must accommodate the following observations:

1. Electron-deficient vinylarenes exhibit diminished reactivity, which could be explained by the slower rate of nickel hydride addition (**4**→**5**).
2. Substrates possessing heteroatoms exhibit diminished reactivity when R_2AlX-type Lewis acids are employed, possibly from deactivation of the Lewis acid by coordination of the substrate to aluminum.
3. The deactivating effects of coordinating solvents.
4. The isomerization of the primary product (**1**→*cis*- and *trans*-**2**), possibly mediated by the nickel hydride via addition–elimination reactions.
5. The total inhibition of the reaction by chelating, bidentate phosphines.

Recently, two detailed computational studies have been reported, which focused on a better understanding of the mechanism of the hydrovinylation reaction, including the nature of the active catalyst, the catalyst resting state, role of a hemilabile ligand (more on this later), and the transition state leading to asymmetric induction.[39,40] The conclusions drawn in one of these papers[40] is at variance with the proposed working model. After a critical examination of the originally proposed mechanism (**Scheme 4**), this study found little support for a free-standing cationic nickel hydride (**3**), citing an exceedingly high barrier (>30 kcal mol^{-1}) for its formation via β-hydride elimination. Similarly, formations of all intermediate nickel complexes possessing only three coordinating groups seemed to have prohibitively high activation energies. To accommodate these new findings, a modification of the original mechanism was proposed and its salient features are presented in **Scheme 5** using a generic phospholane ligand with a hemilabile oxygen.[40] Thus, it was proposed that the coordination of an olefin, forming a pentacoordinate square pyramidal intermediate (**8**, **Figure 1**: Intermediate involving the initial allyl group with ethylene is shown for the sake of clarity) is involved

Scheme 5 Modified mechanism of Ni(II)-catalyzed hydrovinylation of styrene.

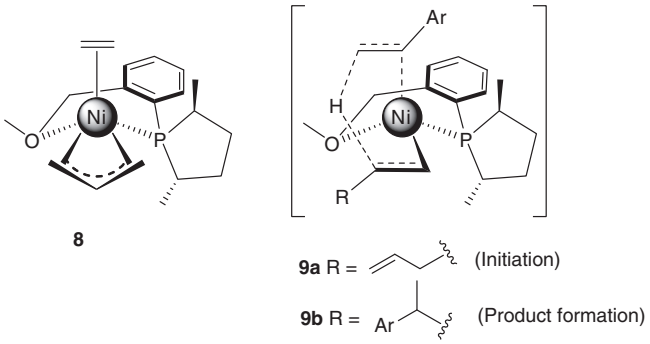


Figure 1 Calculated structures of two species in an energetically viable catalytic cycle.

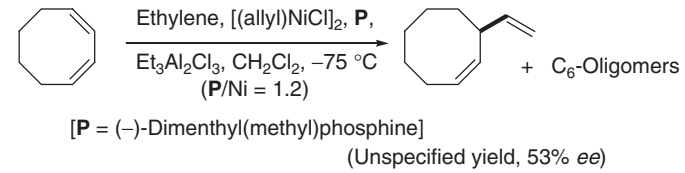
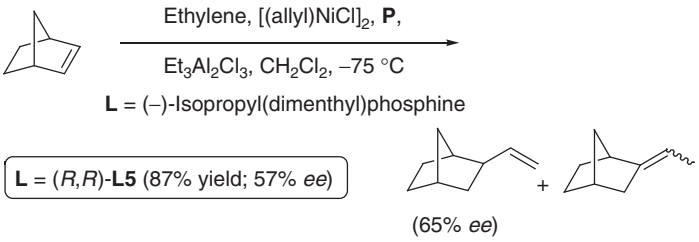


in the lowest energy path. The activation energy for the carbon–carbon bond forming step from this intermediate seems within reach at low temperature. Instead of a β-hydride elimination, the computational study supports the idea of a β-hydride transfer (via TS **9a** or **9b**, Figure 1) in both the turnover- and enantioselectivity-determining steps of the reaction (Scheme 5). The transfer of the β-hydride to the prochiral face of styrene proceeding through transition state **9**, leading to the η^3-benzylnickel complex (e.g., **13**–>**14** or **16**–>**14**), is shown to be 16 kcal mol^{-1} lower in energy compared to the formation of a free metal hydride. Apart from the β-hydride transfer step, most of the major conjectures of the original proposal remain intact.

5.32.4 Asymmetric Hydrovinylation Reactions

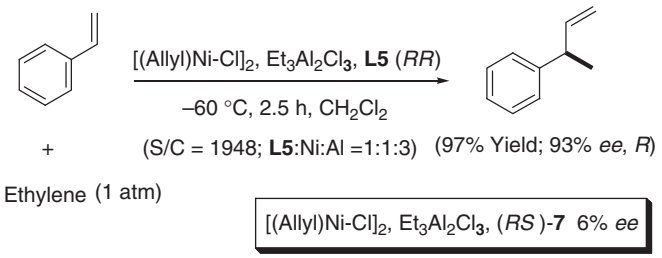


5.32.4.1 Notable Early Results

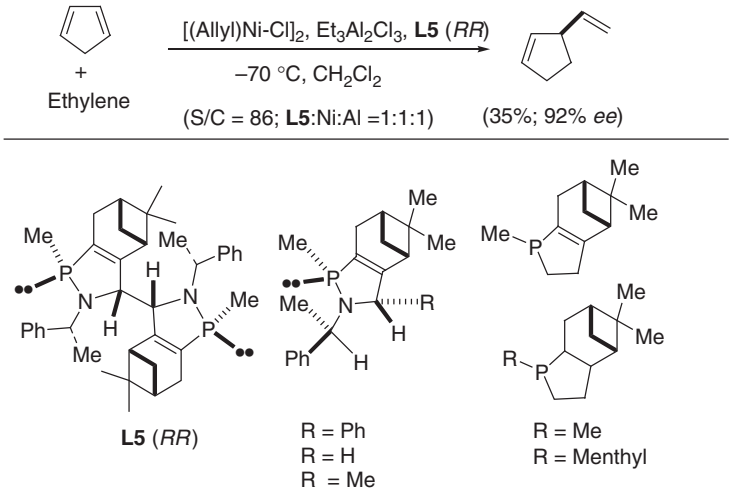
5.32.4.1.1 Menthylphosphine ligands for Ni

The asymmetric hydrovinylation of 1,3-cyclooctadiene (equation 4) using (–)-dimenthyl(methyl)phosphine as the ligand was among the first reported examples[41] of a metal-catalyzed asymmetric carbon–carbon bond forming reaction. The observed selectivities were unacceptably low by current standards (~53% *ee*). Under similar conditions, norbornene and norbornadiene yielded the corresponding 2-*exo*-vinylproducts in 65% *ee* (at −70 °C) and 78% *ee* (at −65 °C), respectively (equation 5).[38]

(4)



(5)

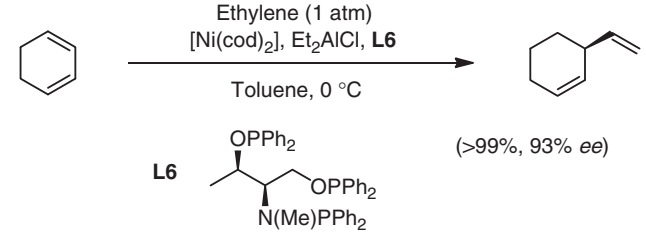


5.32.4.1.2 Azaphospholene ligands for Ni

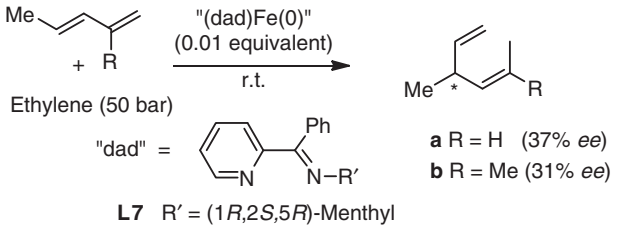
A critical analysis of the work published before 1994 reveals that only Wilke's nickel-based system afforded acceptable levels of activities and enantioselectivities in several asymmetric hydrovinylation reactions. As reported in a patent,[42] a variety of vinylarenes were subjected to asymmetric hydrovinylation using [η^3-(allyl)NiCl]$_2$/(*R,R*)-(**L5**),/$Et_3Al_2Cl_3$ (equation 6). This catalyst system yielded the best enantioselectivities reported until then for several vinylarene substrates, including styrene (93% *ee*, *R*), 4-isobutylstyrene (85% *ee*, *R*), 4-chlorostyrene (95% *ee*, *R*), and 2-methylstyrene (83% *ee*, *R*).[5,42] This catalyst system also affords high enantioselectivities for asymmetric hydrovinylation of norbornene (equation 5) and selected cyclic 1,3-dienes (equation 7). The azaphospholene (*R,R*)-**L5** ligand was prepared from (–)-(*R*)-myrtenal and (+)-(*R*)-1-phenylethylamine in a multistep process.

One other congener of this compound, the diastereomer (*R*,*S*)-**L5** (prepared from (–)-(*R*)-myrtenal and (–)-(*S*)-1-phenylethylamine) is much less active and selective for the hydrovinylation of styrene. Monomeric and structurally related versions of this ligand have been prepared[5,43] in an attempt to simplify the synthesis (see equation 7 for examples), but it has been found that catalytic activity and enantioselectivity invariably fall below useful levels. Much of the details of the pioneering work have appeared in review articles, dissertations, and patents[5] with few experimental details in the open literature, making meaningful comparisons with more recent work difficult. However, it appears that the esoteric nature of the azaphospholene ligand (**L5**) and the need for highly Lewis acidic aluminum salts limit the utility of this system for broadly applicable hydrovinylation reactions.

(6)



(7)

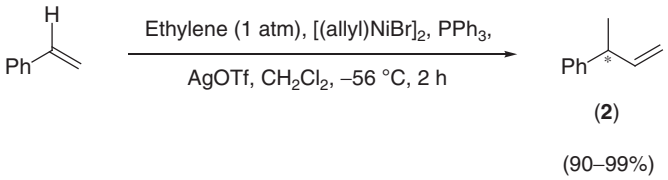


Recently, Wegner and Leitner used the azaphospholene-Ni(II) complex (allyl)(Cl)Ni(**L5**) to effect asymmetric hydrovinylation of styrene, 4-chlorostyrene, and 4-*t*-butylstyrene in supercritical CO_2 in the presence of the BARF counter ion at 40–60 °C.[44] Enantioselectivities for the 3-arylbutene up to 92% were obtained, even though, at high conversion, isomerization of the primary product ensues.

5.32.4.1.3 Aminophosphine-phosphinite (AMPP) ligands for Ni

Nickel complexes bearing AMPP ligands have been generated *in situ* for the efficient hydrovinylation of 1,3-cyclohexadiene (equation 8).[45] Although AMPP ligand **L6** derived from (2*S*,3*R*)-threonine exhibits high levels of enantioselectivity, AMPP ligands derived from other amino alcohols give lower selectivities. AMPP ligands have been extensively studied in the area of Rh-catalyzed asymmetric hydrogenation,[46] but surprisingly few studies on the hydrovinylation have appeared in the literature.[47]

(8)



(9)

5.32.4.1.4 N-menthylpyridylarylimine ligand for Fe

High pressure hydrovinylations of (*E*)-1,3-pentadiene (37% *ee*) and 2-methyl-1,3-pentadiene (31% *ee*) catalyzed by an Fe(0)-pyridylimine catalyst (ligand **L7**) has been disclosed.[48] No further advances on this promising result have been reported.

5.32.4.2 A New Protocol for Ni(II)-Catalyzed Hydrovinylation Amenable to Asymmetric Catalysis

As alluded previously, before 1994 only Wilke's system utilizing the ligand **[(*R*,*R*)-L5]** gave acceptable yields and selectivities for the hydrovinylation (HV) of vinylarenes and cyclic dienes.[42] However, subsequent studies have shown that the azaphospholene class of ligands have limited value for the development of a broadly applicable hydrovinylation reaction. Initially, it was envisioned[49] that the strong Lewis acid in the Wilke system could be replaced with a silver salt possessing a weakly coordinating anion that could be easily displaced from the coordination sphere of nickel by an olefin before the migratory insertion step in the mechanism (**5**–>**6**–>**7** in Scheme 4). Further, from the seminal ligand-tuning studies carried out by the Wilke group, it was already clear that the phosphine ligand played a crucial role in determining the selectivity of the reaction.[3] However, the relationship between the counterion (Y^- in Scheme 4) and phosphine ligand remained uncertain as the selectivities varied considerably based on their specific combinations. For example, anions such as $Et_2AlCl_2^-$, OTf^-, and BF_4^- typically produced higher *ee* values with Wilke's ligand **[(*R*,*R*)-L5]**,[5] whereas an opposite effect was observed with more basic ligands (e.g., isopropyl(dimenthyl)phosphine), where the highest *ee* values were observed in combination with highly dissociative anions (e.g., SbF_6^- and PF_6^-).[3] The RajanBabu group undertook an extensive, systematic investigation of the various parameters contributing to the observed selectivities in the hydrovinylation of vinylarenes. Various parameters including the metal, ligand, counterion, the solvent, and reaction conditions were examined, and a new, broadly applicable protocol for the Ni-catalyzed hydrovinylation reaction was discovered (equation 10).[49,50]

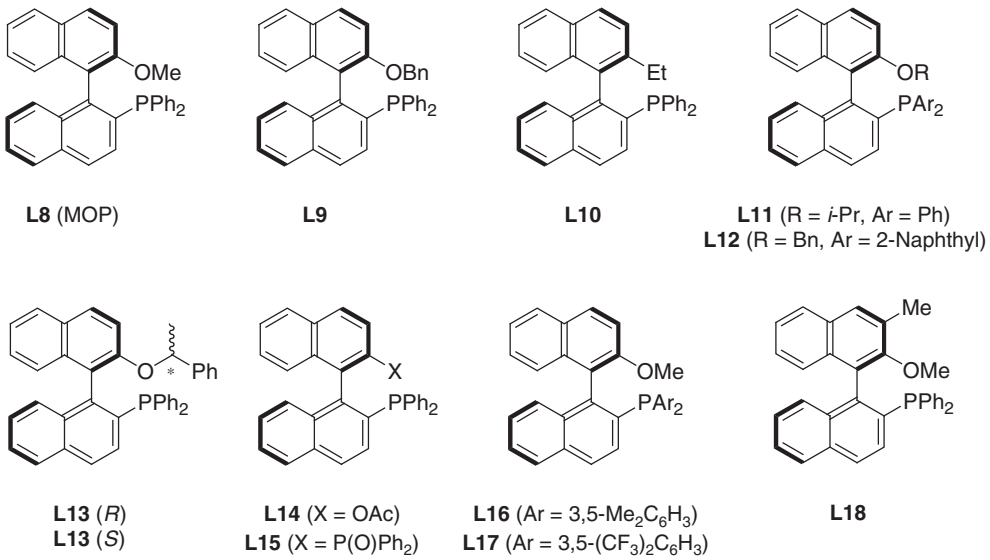
(10)

A series of substituted vinylarenes were subjected to the new protocol, resulting in the highest chemical yields and selectivities reported at that time (Table 1). The reactions were typically carried out under 1 atm of ethylene at low temperatures (−56 °C) in dichloromethane, using 0.7 mol% of a catalyst generated from Ph_3P and $[(allyl)NiBr]_2$. In contrast to the previous methods, no oligomerization of styrene or ethylene, or isomerization of the primary product was observed. These conditions were found suitable even for substrates containing Lewis basic centers (Table 1, entries 4, 5, and 10). The 3-aryl-1-butene derivatives from 4-isobutylstyrene, 6-methoxy-2-vinylnaphthalene (MVN), 3-fluoro-4-phenylstyrene, and 3-benzoylstyrene are particularly useful, as they are precursors to the important nonsteroidal antiinflammatory drugs (Table 1, entries 2, 4, 8, and 10).

Although the new protocol has expanded the substrate scope and applicability of the hydrovinylation reaction, several key challenges still remain in this area, especially with respect to enantioselectivity. As mentioned previously, the use of a number of chelating, bidentate phosphines, aminophosphines, and 1,2-bis-diarylphosphinites resulted in complete inhibition of the reaction under otherwise identical conditions.

5.32.4.2.1 Asymmetric hydrovinylation using hemilabile ligands

5.32.4.2.1.1 2-Alkoxy-2′-diphenylphosphino-1,1′-binaphthyl derivatives as ligands for nickel



Considering the requirement for an open coordination site during the critical steps of the reaction, it was proposed[49] that a monophosphine, bearing the right hemilabile group,[51,52] would not only be capable of stabilizing the putative cationic intermediates via internal coordination but also undergo facile displacement of this group by an olefin during the

appropriate stages of the catalytic cycle (Scheme 5). The use of a number of 'hemilabile' groups, including carboxylates, ester carbonyl, diarylphoryl, and thioether moieties, has been reported in a variety of reactions.[53–57] In the context of an asymmetric variant, the chiral ligand, 2-diphenylphosphino-2′-methoxy-1,1′-binaphthyl [(**L8**), MOP, Figure 2] received early attention due to its flexibility with respect to structural modifications. For example, variations of the 2′-substituents would permit further evaluation of the hemilabile coordination as a control element in the Ni-catalyzed asymmetric hydrovinylation reaction.

Figure 2 Binaphthyl phosphine ligands for asymmetric hydrovinylation.

Initial studies using **L8** indicated that the use of AgOTf was detrimental to the hydrovinylation reaction when the MOP ligand was employed. Although this observation has not been thoroughly investigated, it is hypothesized that the counterion (OTf^-) may be involved in a demethylation-degradation pathway of the ether linkage (i.e., resulting in the formation of a stable Ni(II) chelate). Supporting this conjecture, the use of a bulky, nonnucleophilic counterion BARF,[58] completely restored the activity of the catalyst system (equation 11).[49,50]

(11)

Ligand	Conditions	% *ee*
L8	–56 °C	62
L9	–70 °C	80
L10	–56 °C	13 (5% conversion)

Since use of the hemilabile coordination to enhance the enantioselectivity of a reaction was a novel idea at the time of its original discovery, a systematic evaluation of the 2′-substituents of the binaphthyl scaffold was conducted under standard reaction conditions with MVN as the substrate and BARF as the counterion (Table 2). With respect to the steric bulk of the 2′-*O*-alkyl substituents, little effect on the enantioselectivity was observed, but the yield of the reaction was reduced by larger substituents (entries 1, 2, and 5). Involvement of the hemilabile oxygen atom may be inferred from the MOP derivatives containing (*R*)- and (*S*)-phenylethoxy side chains, **L13** (*R*) (entry 6) and **L13** (*S*) (entry 7), respectively. Although **L13** (*R*) gives the product in excellent yield and good enantioselectivity (>98%, 71% *ee*), the reaction with **L13** (*S*) results in only 79% yield and 65% *ee*, suggesting an important role of the hemilabile oxygen with respect to the activity of the catalyst.

[c]−70 °C.

The effect of the hemilabile group was further demonstrated by the preparation of 2′-ethyl MOP-derivative (**L10**), which does not have a weakly coordinating heteroatom. The hydrovinylation of MVN with **L10** using the BARF counterion resulted in only 13% yield and 3% *ee* (entry 4), whereas the corresponding reaction involving AgOTf gave less than 2% conversion. Furthermore, if hemilabile coordination is important, the varying donor properties of the ligands should produce differences in the reactivity of the complexes. Therefore, allylnickel complexes of **L14** and **L15** were subjected to the standard reaction conditions. As expected, both analogs failed to give any desired hydrovinylation products (entries 8 and 9, respectively). Finally, a limited effort was made to examine the electronic effects of diaryl modifications (analogs **L16** and **L17**, entries 10 and 11).[50] MOP-type ligands possessing electron-donating and withdrawing substituents on the phosphorus were examined by comparing the enantioselectivities observed in the hydrovinylation reaction (Table 2, entries 1, 10, and 11). In sharp contrast to the nickel(0)-catalyzed hydrocyanation,[59,60] rhodium(I)-catalyzed hydrogenation,[61] and the palladium(0)-catalyzed allylation,[62] the electronic properties of the ligands appear to have a negligible effect on the hydrovinylation.[50] It is important to note that unlike the aforementioned reactions, the hydrovinylation is proposed to maintain the same oxidation state of the metal (Ni^{2+}) throughout the entire catalytic cycle. Essentially, the nickel(II) complex functions as a complex Lewis acid. Addition of a methyl group at the 3′-position (analog **L18**, entry 12)[63] did result in an improvement in the *ee* of the product from MVN. An explanation based on the working model for the asymmetric induction has been proposed for this observation.[63]

5.32.4.2.1.2 1-[(2-Alkoxy or alkoxyalkyl)aryl]-2,5-dialkylphospholanes

Based on the success of MOP-type ligands (Figure 2), it was presumed that chirality present near the hemilabile atom or the strongly chelating atom might have an influence on the selectivity of the hydrovinylation, even though the nature of such an influence was purely speculative at that time. A series of phospholane ligands carrying a hemilabile oxygen functionality (Figure 3) was synthesized and screened for the hydrovinylation reaction.[35] These hemilabile phospholanes, readily amenable to modifications of several key structural elements (Figure 3), proved to be excellent candidates as ligands for the asymmetric hydrovinylation.

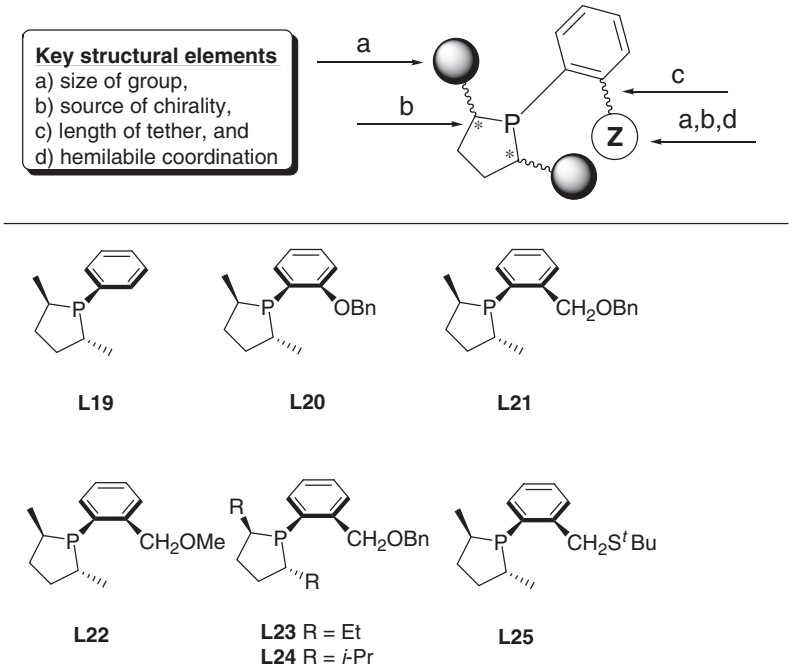

Figure 3 Phospholane ligands for asymmetric Ni(II)-catalyzed asymmetric hydrovinylation.

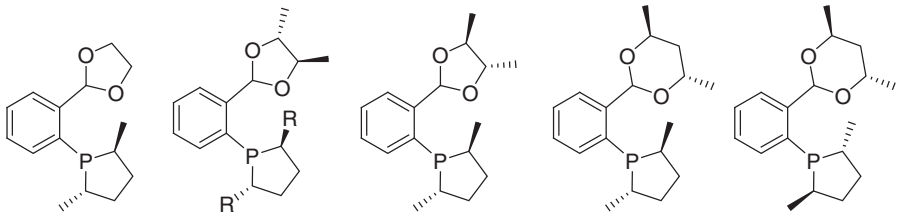

The evaluation started with ligand **L19** and hemilabile ligand **L20**. As expected from previous observations, ligand **L19** (possessing no hemilabile functionality) was competent in the hydrovinylation reaction, but only when AgOTf was used as a promoter. Initial results with **L20**, under standard conditions with BARF counterion, showed an extremely active catalyst that led to significant isomerization of the primary product, even at $-55\ ^{\circ}C$. In comparison to the successful MOP ligand **L8**, it was conjectured that the distance between the chelating phosphorus atom and the hemilabile group might influence the catalyst activity. In the MOP ligand (**L8**), placement of the hemilabile group is on the δ-carbon with respect to the phosphorus, whereas the hemilabile group is on the β-carbon in ligand **L20**, resulting in seven- versus five-membered nickel chelated complexes, respectively. Therefore, analog **L21** was prepared to probe the effect of the relative positioning of the hemilabile group. Gratifyingly, this ligand proved to be one of the best ones for the selective hydrovinylation reactions. Under the optimized conditions, no traces of any isomerized products were detected with this ligand.[35]

The effect of the size of the substituents at the 2- and 5-positions of the phospholane was also evaluated. An increase in size from methyl-(**L21**) to ethyl-(**L23**) improved the enantioselectivity, giving *ee* values of 63–67% for the hydrovinylations of styrene and 4-isobutylstyrene, respectively. The result represented one of the highest overall selectivities reported at the time for the substrate 4-isobutylstyrene, an important precursor to ibuprofen. Further increasing the size of the 2- and 5-substituents to isopropyl groups (**L24**), however, appeared to result in inhibition of the hydrovinylation reaction, even at elevated temperatures (25 °C). Finally, the *o*-(benzyloxy)methyl group was replaced with the sulfur analog *o*-(*t*-butylsulfanyl)methyl group (**L25**). No hydrovinylation products were observed with **L25**, most likely caused by the strong donor properties of the sulfur atom.

In order to examine the effect of additional chiral elements near the hemilabile position, a series of phospholane ligands possessing chiral acetal motifs were synthesized (Figure 4).[64] The ligands were investigated in the hydrovinylation reaction of 4-isobutylstyrene using 0.07 mol% catalyst, under an atmosphere of ethylene at $-55\ ^{\circ}C$, and the results are tabulated in Table 3. The acetal-containing phospholanes (**L26–L31**) in general, produced excellent results for the asymmetric hydrovinylation, resulting in nearly quantitative yields and perfect selectivities for the variety of 3-arylbut-1-ene products.

The phospholane ligand possessing an achiral acetal moiety (**L26**) gives the desired product in 85% *ee* (entry 1). Ligand **L27** exhibited the best selectivity for this transformation, improving the enantioselectivity to 91% *ee* (entry 2).

Increasing the size of the 2- and 5-substituents (**L28**) resulted in only minor effects on the selectivity, whereas significantly deteriorating the overall rate of the reaction (entry 3). A change in the configuration of the 4- and 5-substituents of the 1,3-dioxalane ring (**L29**) led to the isomerization of the primary product, accompanied by erosion of enantioselectivity

(71% *ee*, entry 4). The structurally related 1,3-dioxane derivatives (**L30** and **L31**) exhibited results comparable to the dioxalane ligands (entries 5 and 6), suggesting that the stereochemical outcome of the reaction is largely dictated by the chirality contained in the phospholane ring (e.g., the (*S*,*S*)-phospholane favoring formation of (*R*)-3-arylbut-1-ene products).

5.32.4.2.1.3 β-Acetamido-diarylphosphinite ligands

A number of carbohydrate-derived diarylphosphinites with a β-acetamido group (but not dialkylamino) have been found to be competent ligands for the asymmetric hydrovinylation of styrene derivatives.[47,65]

5.32.4.2.1.4 Phosphoramidite ligands

In 1996, Feringa et al.[66,67] disclosed novel phosphoramidite ligands derived from 2,2′-binaphthols (**Figure 5**) for the copper-catalyzed asymmetric conjugate additions of dialkylzinc reagents to enones, and these ligands have become immensely popular for a variety of metal-catalyzed reactions.[68] Leitner and coworkers[69] found that one of the original phosphoramidites (**L33a**) is an excellent ligand for the Ni(II)-catalyzed hydrovinylation of vinylarenes under the protocol reported by RajanBabu et al. (equation 11),[49] giving >90% *ee* for styrene, 4-bromostyrene and 4-chlorostyrene, and ~68% *ee* for 4-isobutylstyrene. Independently, the RajanBabu group found that phosphoramidites are effective ligands for the asymmetric hydrovinylation of norbornene derivatives (vide infra).[70,71] Optimization of the phosphoramidite ligands for asymmetric hydrovinylation has been undertaken by the RajanBabu[72,73] and Leitner[74] groups and this has led to significant improvements of activities and enantioselectivities in these reactions. Structures of some of the best ligands in this series are shown in **Figure 5**, and the results of the asymmetric hydrovinylation of various vinylarene substrates are summarized in **Table 4**.

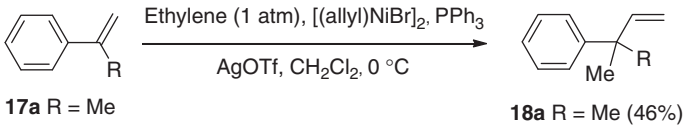
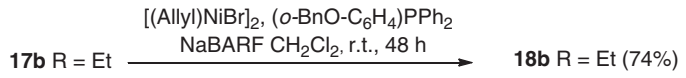
[c]With InI_3 instead of NaBARF: 89% *ee*.
[d]With InI_3: 90% *ee*.



The feasibility of fine-tuning phosphoramidite ligands to control stereoselectivity in the hydrovinylation reaction was initially investigated[72] using 4-methoxystyrene, an electron-rich substrate that consistently gave poor results with other ligands. The initial screening of ligands resulted in the identification of three phosphoramidite ligands (**L33**, **L34**, **L35**), which showed excellent levels of enantioselectivity. Interestingly, ligand **L34** (and its enantiomer), possessing only a biphenyl backbone, yields similar selectivities and conversions as the more expensive ligand carrying the chiral binaphthyl moiety **L33** (Table 4, entries 1 and 2). The crystal structure of a Ni complex [(**L34**)(allyl)NiBr] (Figure 5) clearly shows that the (*S*)-benzylamines induce helical chirality in the biphenyl moiety (*R*) and this in turn may be responsible for the nearly identical behavior of **L33a** and **L34** in the asymmetric hydrovinylation of vinylarenes. Since it has been realized that the sterically less demanding biphenyl ligands have some added advantages in some situations.

From this study, the ligand **L35** carrying 2-(1-naphthyl)ethylamine moiety was identified as having the broadest applicability across a wide spectrum of vinylarenes including 4-isobutylstyrene, MVN, 3-fluoro-4-phenylstyrene, and 3-phenoxystyrene, all precursors for enantioselective syntheses of the most popular nonsteroidal antiinflammatory agents, ibuprofen, naproxen, flurbiprofen, and fenoprofen, respectively. Indeed, full details of the synthesis of these compounds via asymmetric hydrovinylation followed by oxidative degradation of the alkene to the 2-arylpropionic acid have since been published.[75]

In addition to **L35**, Leitner's group has reported the utility of other phosphoramidites carrying the 2-(1-naphthyl)-ethylamine.[74] Thus, phosphoramidite **L36** is a competent ligand to effect the asymmetric hydrovinylation at room temperature with no isomerization of the terminal double bond in the product, an occasional complication in many such reactions run at higher temperatures (entries 8, 13, 23, and 26). Leitner also introduced InI_3 as a useful replacement for NaBARF.[76]



5.32.5 Generation of All-Carbon Quaternary Centers

The stereoselective generation of all-carbon quaternary centers is a subject of considerable topical interest.[77] The hydrovinylation reaction of an α-substituted styrene is a convenient method for the synthesis of such compounds with a benzylic carbon, selectively generating a quaternary center attached to a highly versatile vinyl group suitable for further functionalization. Following the first demonstration of the hydrovinylation of α-methylstyrene (**17a**, equation 13a),[50] several reports of the use of phosphoramidite ligands for asymmetric variations of this reaction have appeared.[78–82] Full experimental details of a large-scale (0.05 mol) asymmetric hydrovinylation of 2-phenyl-1-butene (**17b**) have also been published.[83]

For the hydrovinylation of a prototypical substrate, 2-phenylbut-1-ene (**17b**), Ni-catalysts derived from MOP ligand (**L8**, Figure 2) showed no reactivity, whereas those derived from phospholane ligand **L27** (Figure 4) showed only moderate reactivity.[79,80] Among the chiral ligands examined, phosphoramidites **L33a**, **L34**, **L35**, and **L38** were found to give the best results (Table 5). Although substrates **17b**, **26**, **27**, and **30** gave excellent selectivities, others like **32**, **19**, and **23** gave varying amounts of products resulting from migration of the double bond of the starting olefin. Up to 30% isomerization is seen in the HV of the tetraline derivative **32**, yet the chiral product is formed in ~99% *ee*. Surprisingly no such isomerization is seen in the oxygenated analog **33**, but a dimeric side product (~15%) is formed in the reaction. Substrates with heteroatom-containing side chains generally gave lower selectivities (entries 11[80] and 12[82]), except for allyl alcohol derivatives **23** (entry 13).[81] In this connection, the use of a phosphonite ligand **L39** is noteworthy, which yields nearly quantitative yield of the hydrovinylation product from **21** (equation 16).

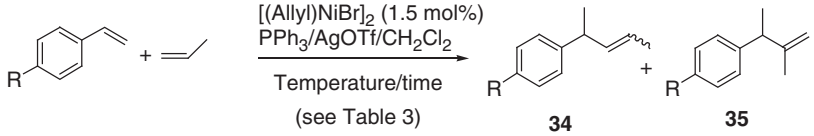
(15)

(16)



(17)

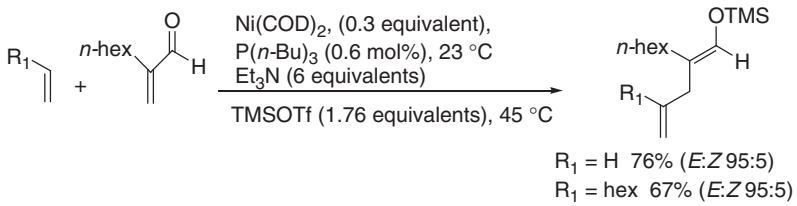
A brief examination of the origin of asymmetric induction in the chroman (3,4-dihydro-2*H*-1-benzopyran) **33** using diastereomeric phosphoramidites shows that the chirality of the product is determined by the axial chirality of the biaryl moiety of the ligand, not by the chirality of the amine.[80] As shown in entry 9, both **L33a** (R_a,S_c,S_c) ligand and a diastereomer with a different configuration **L33b** (R_a,R_c,R_c) gave the (*R*)-product in comparable *ee*'s (94% and 89%). Since the phosphoramidite **L34** (S_c,S_c), a ligand derived from flexible biphenyl scaffolding also gives the (*R*)-configuration in the product, it should be presumed that the chirality of the bis-amine (S_c,S_c) induces the *R*-configuration in the biphenyl unit. Although other procedures have been reported[84–86] for the synthesis of products of entries 8 and 9, the asymmetric hydrovinylation reaction provides the shortest and operationally simplest route available to these compounds, which have served as intermediates for pyrrolidinoindolines[87] and the benzomorphane analgesics (–)-eptacozine[84,85] and (+)-aphanorphine.[85]

5.32.6 Other Related Ni-Catalyzed Hydroalkenylation Reactions Including Hydrovinylation

5.32.6.1 Codimerization of Propene and Vinylarenes

A number of other Ni-catalyzed heterodimerization reactions using alkenes other than ethylene are known, even though no enantioselective versions of these useful reactions have been reported.[88] Propene reacts with styrene and substituted styrenes under the recent protocol developed by RajanBabu,[49] at higher temperature, yielding the expected products, **34** and **35** (equation 18 and Table 6).[89] As expected, a mixture of regioisomeric products is formed with the predominant addition of the C_1-carbon of propene (**34**) to the benzylic position. These reactions also established the remarkable functional group tolerance of the Ni(II)-catalyzed HV reaction conditions.

(18)



5.32.6.2 Addition of Alkenes to Enones

In 2008 Jamison reported[90] catalytic conditions under which alkenes including ethylene can act as alkenylmetal precursors in conjugate addition reactions (equation 19). Similar conjugate additions of alkenes to enones (equation 20) have been reported by Ogushi at much higher temperatures under different conditions.[91] These results, although maybe not significant from a synthetic perspective, raise very interesting mechanistic questions, since the regioselectivity in the two reactions are quite different.

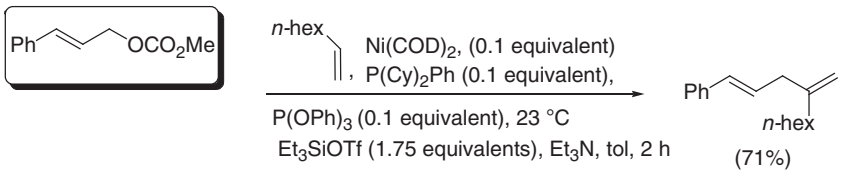
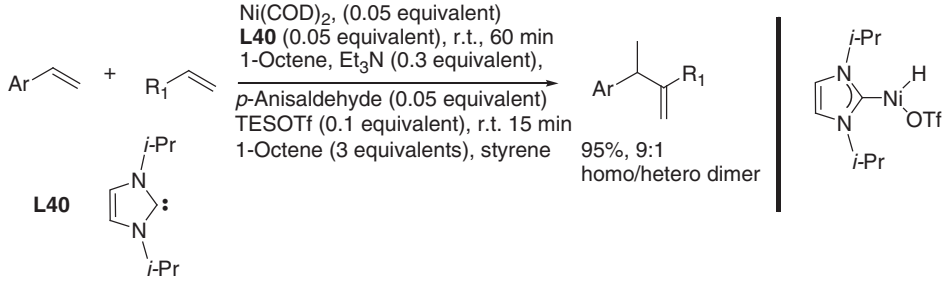
(19)



(20)

5.32.6.3 Addition of 1-Alkenes to Allylic Substrates

Jamison also reported a new reaction of allylic substrates with ethylene under the conditions shown in equation 21a.[92] Slight modification of the reaction, in which an additional equivalent of $P(OPh)_3$ is added, facilitated the codimerization of cinnamyl derivatives with linear alkenes (equation 21b). Note that in the case of the 1-alkenes, the C–C bond formation occurs at the more substituted carbon.

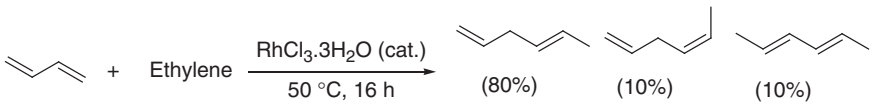


(21a)

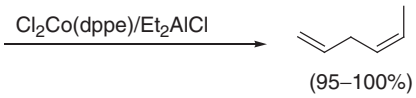
(21b)

5.32.6.4 Addition of Alkenes to Vinylarenes

An unprecedented tail-to-tail hydroalkenylation of styrene, using an *N*-heterocyclic carbene (**L40**)-nickel complex as a catalyst, has been reported by Ho et al. (equation 22).[93] The mechanisms of these reactions remain largely speculative and the reader is urged to consult the original publications for reasonable proposals.

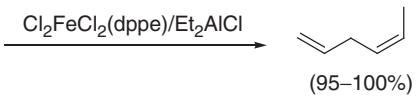


(22)



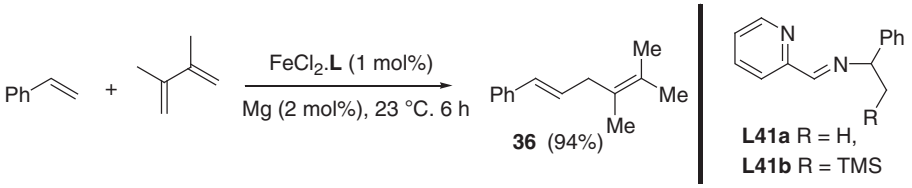
5.32.7 Hydrovinylation and Hydroalkenylation of 1,3-Dienes Catalyzed by Rh, Fe, Co, and Ru

5.32.7.1 Rhodium- and Iron-Catalyzed Reactions

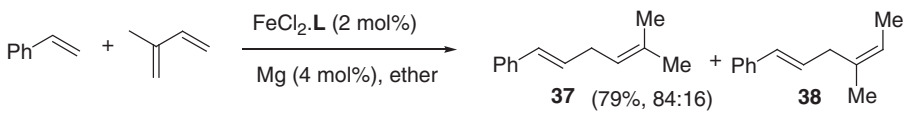


Rhodium-catalyzed linear dimerization of 1,3-butadiene and ethylene (equation 23) is an industrially important process for the synthesis of hexadienes.[4] Research in related cobalt (equation 24)[94,95] and iron (equation 25)[8,96] catalyzed processes has seen a resurgence of activity recently.

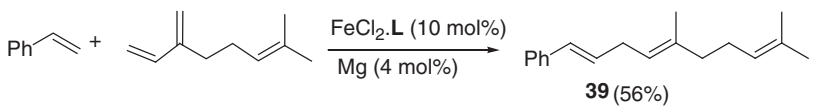
(23)



(24)



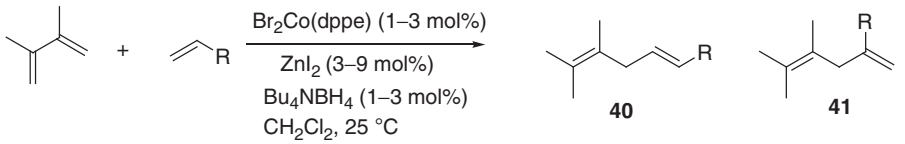
(25)



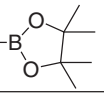
α-Olefins (especially styrene derivatives) undergo highly stereo- and regioselective 1,4-addition to 1,3-dienes in the presence of 1 mol% of iminopyridine-Fe(0)-complex (ligand **L41a**) to give exclusively the linear product **36** (equations 26, 27, and 28).[97] Unsymmetrical dienes such as isoprene produces two regioisomers (**37** and **38**) resulting from additions at either terminal position of the diene (equation 27), even though the selectivity can be improved by ligand tuning (e.g., switching to ligand **L41b)**. The geometry of both double bonds formed is controlled in this reaction, and formation of an η^4-complex, coupling with the alkene and a *syn*-β-hydride elimination may be responsible for this stereochemical outcome. Aliphatic α-olefins generally give mixture of products and the synthetically useful reactions are limited to styrene derivatives.

(26)

(27)



(28)



5.32.7.2 Cobalt-Catalyzed Reactions

Co(I)-catalyzed 1,4-hydroalkenylations of 1,3-dienes have been extensively developed by Hilt.[98–100] The optimum conditions for the addition to 2,3-dimethylbutadiene use ZnI_2 and a chelating phosphine with $CoBr_2$ in the presence of a reducing agent such as Bu_4NBH_4 or activated Zn dust (equation 29).[101] Under these conditions, terminal alkenes such as 1-hexene, cyclohexylethylene, or vinyltrimethylsilane gave almost exclusively the branched product(s) **41**, whereas terminal alkenes with an electron-withdrawing alkoxycarbonyl group (e.g., ethyl or *t*-butylacrylate) on the double bond give linear product(s) **40**.

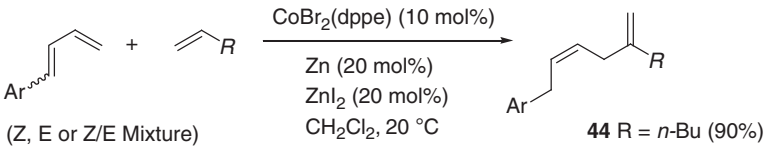
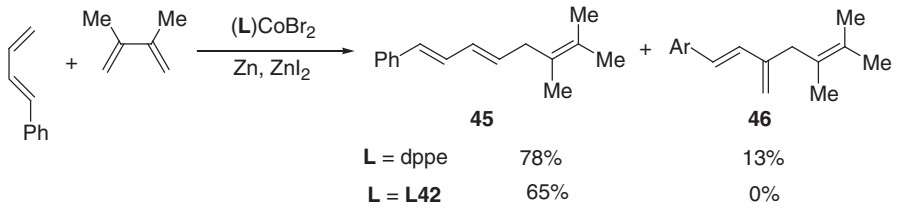
[a]See equation 29. [b] Br_2Co(**L42**) (5 mol%), Zn (10 mol%) ZnI_2 (10 mol%), CH_2Cl_2, r.t. (29)



The regioselectivity of addition to the alkene can be controlled by judicious choice of ligands for the reaction, under otherwise identical conditions.[99] Thus, dppe gives the branched 1,4-HV products (**41**) with unactivated alkenes, whereas SchmalzPhos (**L42**) gives the linear products (**40**). Activated alkenes such as acrylates give linear products using both sets of ligands. Reactions with unsymmetrical 1,3-diene are less selective, giving addition at both C1 and C4 positions of the diene (equation 30). The addition at the less hindered C4 position (**42**) of isoprene predominates (equation 30). In the original studies, bis-1,2-diphenylphosphinoethane was found to be the best ligand for this transformation. Control of the C_1 versus C_4 addition to the diene as a function of the nature of the C_2 and C_3 substituent has been examined.[102] Reaction with styrene and other vinylarenes using Co, unlike the excellent Fe-catalyzed reaction (see equation 26), gives a mixture of branched and linear addition products resulting from addition at the C_1 and C_2 positions of the vinylarenes.[103] However, addition of terminal alkenes to 1-aryl-1,3-butadiene proceeds in excellent yields to give the branched product **44** (equation 31). Irrespective of the starting geometry of the butadiene double bond, only the *Z*-product (**44**) is observed.

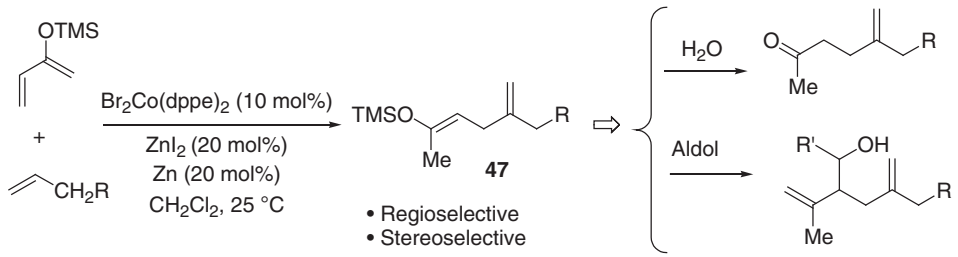
42 C_4 - Product **43** C_1 - Product

R = *n*-Bu	(84:16)
R = TMS	(92:8)



(30)

(Z, E or Z/E Mixture) **44** R = *n*-Bu (90%)

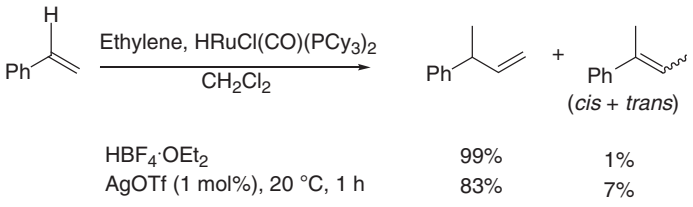


also: R = Benzyl, CH_2PHT, CH_2TMS; Ar = Ferrocenyl, R = *n*-Bu (31)

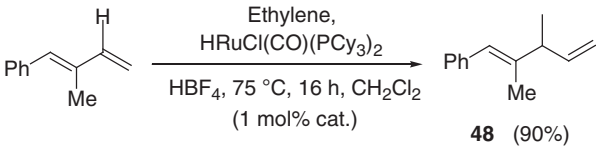
As shown in equation 32, ligand effects are also important in the 1,4-hydrobutadienylation of 1-aryl-1,3-dienes giving mostly linear products (**45**).[104]

(32)

A particularly noteworthy example of the cocatalyzed hydroalkenylation is the reaction of a 2-siloxydiene.[105] The hydrovinylation product **47** is formed exclusively as a single isomer with (*E*)-silylether geometry and C–C bond formation at the C_4 position of the diene and C_2 position of the alkene (equation 33). Since the reaction is tolerant to a number of functional groups (ethers, esters, phtalimide, aromatic, thiophenyl, substituted alkenyl), this is a very powerful reaction to produce a highly functionalized enolate equivalent. Subsequent transformations using electrophiles (e.g., acidic hydrolysis, Mukaiyama aldol, ozonolysis) should give valuable intermediates for organic synthesis.

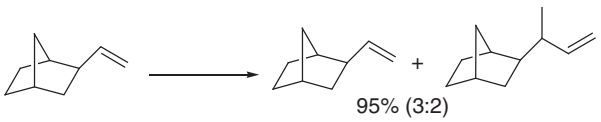


(33)

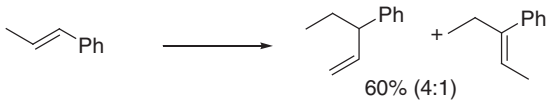


The cocatalyzed hydroalkenylation has been used as a key step in several diastereoselective multicomponent reaction sequences,[106] in one case forming as many as five carbon–carbon bonds in one pot.[107] These reactions attest to the power of cocatalysis and the remarkable functional group tolerance toward the reagents and the reaction conditions.

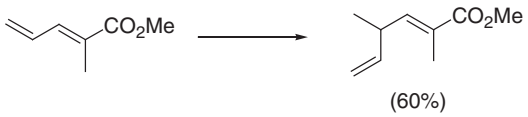
5.32.7.3 Ruthenium-Catalyzed Reactions



Even though ruthenium chloride was among the first metal salts reported for hydrovinylations,[9,12] useful levels of selectivity in these reactions were attained only recently. Yi and coworkers have disclosed a ruthenium catalyst system consisting of $HRuCl(CO)(PCy_3)_2$ and $HBF_4 \cdot OEt_2$ for the hydrovinylation of styrene and selected 1,3-dienes (equations 34 and 35).[108,109] It has also been found that the HV of styrene can be carried out under one atmosphere of ethylene when silver(I) triflate is used as an additive, all other conditions being the same.[50,110] Good yields of 1,2-adducts (e.g., **48**) can be obtained from 1,2-disubstituted dienes, 1-vinylcycloalkenes and norbornene (equations 35a, 35b, 35c and 35d).

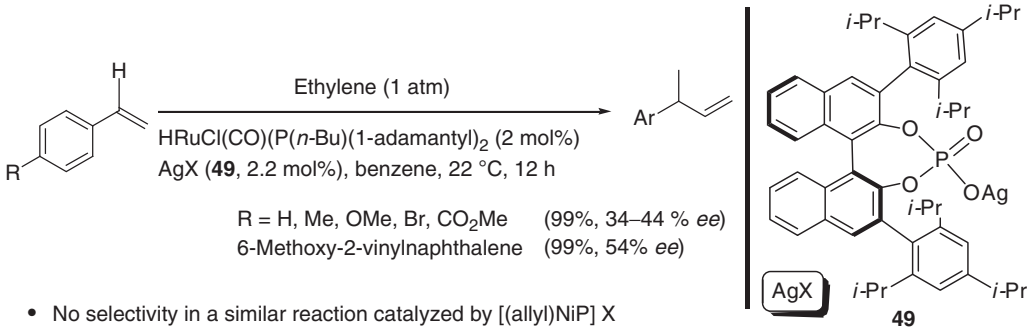


(34)

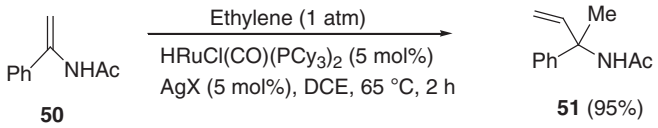


(35a)

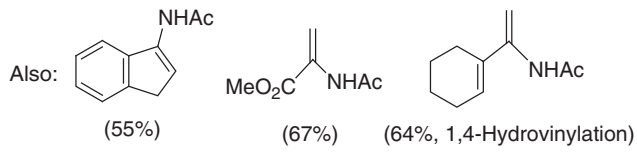
(35b)



(35c)

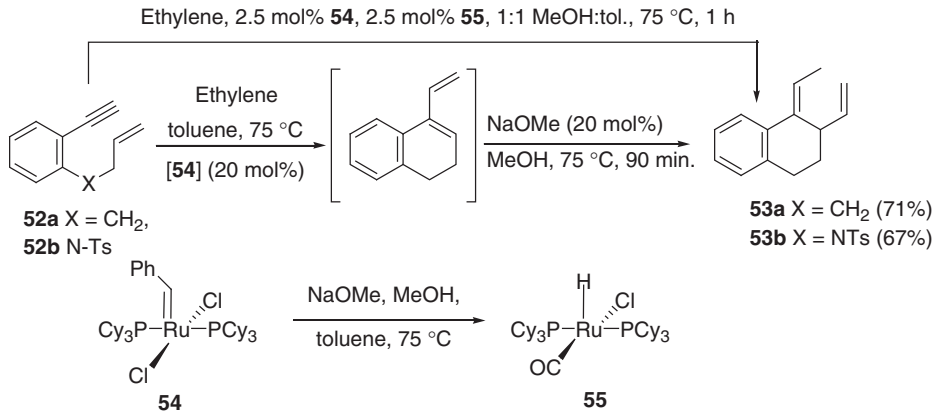


(35d)

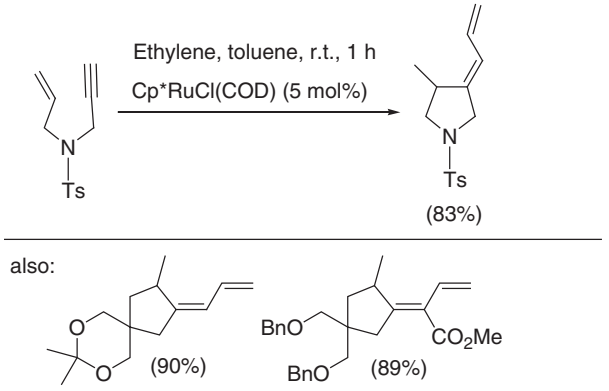


List reported an enantioselective version of the Ru-catalyzed reaction by using a binaphthol-derived chiral anion (**49**) as an additive. Enantioselectivities up to 54% were realized in a quantitative hydrovinylation of MVN (equation 36).[111]

(36)



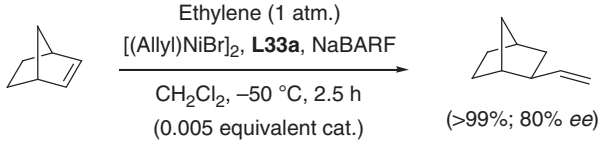
The Ru-catalyzed reaction can also be used for the hydrovinylation of enamides (e.g., **50**) that carry an activating group (aryl, carboalkoxy, or alkenyl group) on the α-carbon, giving products (e.g., **51**) with a quaternary carbon (equation 37).[112] The reaction is done at elevated temperatures for these sluggishly reactive substrates. Use of a [dialkylmenthylphosphine]Ru(II) complex gave low yields and poor enantioselectivities.



(37)

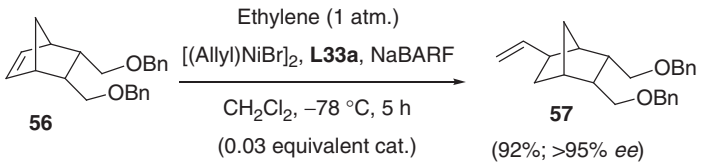
A connection[113] between Grubbs' metathesis catalyst **54** and Yi's hydrovinylation catalyst **55** was cleverly exploited by Snapper et al. in a tandem enyne metathesis/hydrovinylation protocol in which the metathesis catalyst was converted into the HV-catalyst after the first stage, by addition of more methanol, and continuing the reaction under an atmosphere of ethylene (**Scheme 6**). Because of the favorable relative rates of the various processes involved, the overall transformation from the enyne to the HV-product can be carried out in a single flask, in one step, by adding equimolar mixtures of both catalysts (2.5 mol% each) at the beginning of the reaction. A mechanistically different tandem reaction, shown in equation 38, employs an enyne cyclization followed by ethylene addition to give a diene. The alkylidenecyclopentene formed in this sequence can be formally thought of as an HV product.[114]

Scheme 6 A tandem metathesis/hydrovinylation sequence using Ru complexes.



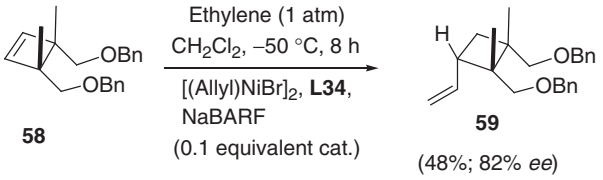
(38)

A number of related ruthenium-catalyzed heterodimerization reactions of methyl acrylate with norbornene, dihydrofuran, and various *N*-vinylamides have been reported, even though asymmetric variations are not known.[115–117] Ruthenium catalysts also affect either linear homodimerization of styrene or linear codimerization of styrene and ethylene.[118]

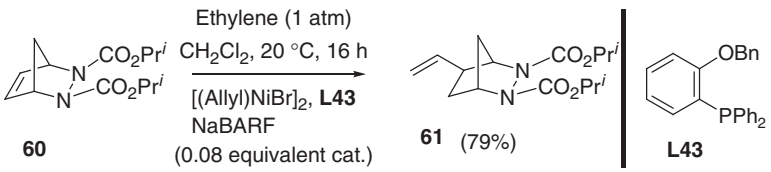


Linear codimers between styrene and ethylene are also formed as the major products by chromium catalysts supported by bis(arylphosphino)amine ligands on activation with methylaluminoxane (MAO).[119]

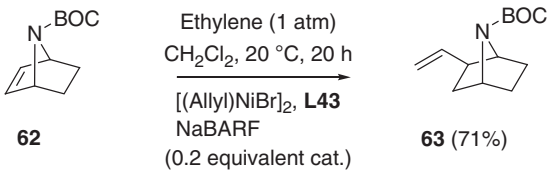
5.32.8 Ni-Catalyzed Hydrovinylation of Norbornene and Other Strained Alkenes



The viability of norbornene and other similar bicyclic molecules as substrates for hydrovinylation suggests that strain, in addition to electronic factors, can be used to promote highly selective codimerization reactions.[70,71] Hydrovinylations of norbornene and a 4,5-dibenzyloxymethyl derivative **56** using the phosphoramidite **L33a** as a ligand for Ni(II) gave very high yields and good to excellent enantioselectivities (equations 39 and 40). The cyclobutene **58** undergoes Ni-catalyzed hydrovinylation as shown in equation 41, even though the enantioselectivity remains modest. The hetero[2.2.1]bicyclic substrates **60** and **62** undergo hydrovinylation with ligand **L43**. Surprisingly, in these reactions, there is no ring-opening observed as is the case with most organometallic additions to the double-bonds of these types of molecules. The phosphoramidites are poor ligands for this class of substrates. For example, the adduct **63** is produced in $<15\%$ yield using 10 mol% of a Ni-complex of the phosphoramidite **L33a**, but with a very high enantioselectivity ($\sim 87\%$). Further work is needed to achieve synthetically useful levels of yield and selectivity in reactions of this class of substrates.



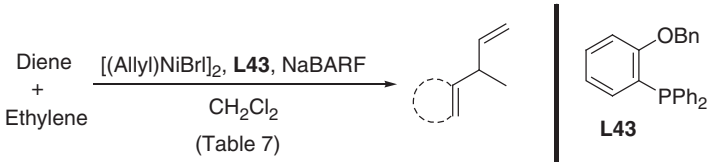
(39)



(40)

(41)

(42)

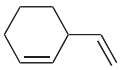


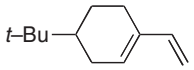
(43)

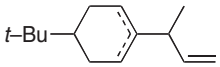
5.32.9 Asymmetric Hydrovinylation of 1,3-Dienes

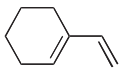
The asymmetric hydrovinylation of 1,3-cyclooctadiene (equation 4) using the ligand (–)-dimenthyl(methyl)phosphine was among the first reported examples[41] of metal-catalyzed asymmetric carbon–carbon bond forming reactions. However, the observed selectivities were unacceptably low by current standards. Other reactions where modest selectivities are obtained, include HV of cyclopentadiene (equation 7), 1,3-cyclohexadiene (equations 8), and 1,3-(E)-pentadiene (equation 9).

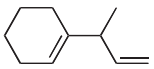
5.32.9.1 Ni(II)-Catalyzed Asymmetric Hydrovinylation of 1,3-Dienes

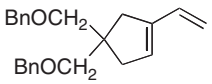


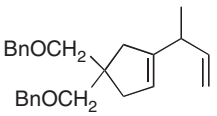


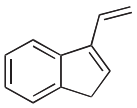


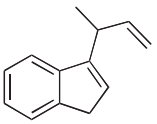


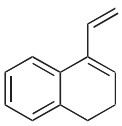


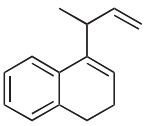


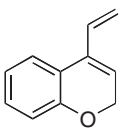


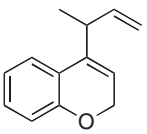


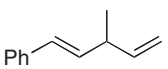


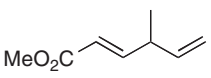




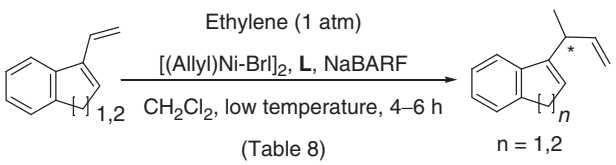








Recent investigations of the ligand effects on the hydrovinylation of 1,3-dienes show that the beneficial effects of hemilabile coordination seen in the context of vinylarenes[35,49] extend to this class of substrates as well. The best ligand for this transformation was identified as 2-benzyloxyphenyldiphenylphosphine **L43**.[120] Under the optimized conditions (equation 44), using this ligand, high yield and selectivities for the 1,2-hydrovinylation product were observed for a series of 1,3-dienes (Table 7). In general, the hydrovinylation of both cyclic and acyclic dienes resulted in high yields (>97%) and selectivities (>95%), giving the 1,2-addition product at the less hindered olefin. The cyclohexene and cyclopentene derivatives gave small amounts of 1,4-adducts (entries 3 and 4).



(44)

Table 8 shows the results of asymmetric hydrovinylations of 1,3-dienes (equations 45 and 46) using ligands **L27**, **L33a**, *ent*-**L33a**, **L34**, and **L43**. Hydrovinylation of substrate **80** (entry 5) using the ligands **L43** (an achiral ligand), **L33a,** and *ent*-**L33a** shows the power of enantioselective catalysis in overcoming the inherent selectivity of a chiral substrate with the judicious choice of ligands. Either diastereomer of the product (**81** or **82**) can be prepared in excellent *ee*'s using the appropriate ligand (equation 46).

5.32.9.2 Cobalt(II)-Catalyzed Hydrovinylation of 1,3-Dienes

The high levels of regioselectivities in the nickel-catalyzed hydrovinylations of arene- and carboalkoxy-substituted 1,3-dienes notwithstanding (Scheme 7, Table 8, entry 4), the corresponding reaction of unactivated, linear 1,3-diene substrates (e.g., **83a**) gave a mixture of products consisting of 1,2- and 1,4-adducts, accompanied by isomerization of these primary products. This is not surprising since between 1,2- and 1,4-HV reactions up to a maximum of 11 isomers (including the enantiomers) of the 1:1 addition are possible in this reaction (Figure 6).

5.32.9.2.1 Cobalt-catalyzed asymmetric hydrovinylation of vinylarenes and unactivated linear 1,3-dienes

Although the iron- and cobalt-catalyzed linear codimerizations of 1,3-butadiene and α-olefins have seen a resurgence of activity recently (vide infra), except for a lone report of asymmetric hydrovinylation of styrene (equation 47),[122] surprisingly little attention has been paid to the cobalt-catalyzed hydrovinylation reaction in which chiral, branched products are formed.

[a]For 3-phenyl-1-butene

Systematic studies were conducted with (*E*)-1,3-nonadiene (**83a**) and $LCoX_2$ complexes [$L=Ph_2P(CH_2)_nPPh_2$, n = 1–4] in the presence of various Lewis acids including trialkylaluminum as promoters.[123] The results suggested that these complexes, when used with a 3:1 ratio of $AlMe_3$:Co, were suitable for effective hydrovinylation of 1,3-dienes (equation 48). This is in sharp contrast to a previous report that $AlMe_3$ and MAO were ineffective in the hydrovinylation of styrene.[122]

(48)

On examining several bis-phosphine ligands, the product distribution was found to be highly dependent on the bite angle of the ligand and the reaction temperature (Table 9).

Table 9 Cobalt-catalyzed hydrovinylation of (*E*)-1,3-nonadiene (**83a**)[a]

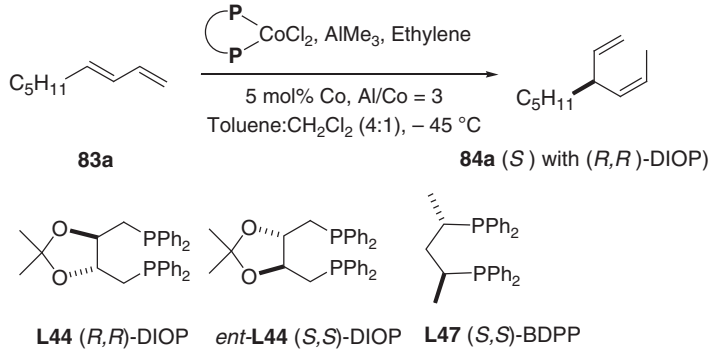
[e]Only linear adduct [(*Z*)-2-methyl-6-(3-propenyl)-octa-2,6-diene] was formed in 78% isolated yield.

5.32.9.2.1.1 A possible mechanism of the cocatalyzed hydrovinylation



Under the nonreducing conditions used for the hydrovinylation,[124,125] a hydride, $[(L)Co(II)\text{-}H]^+$ (**89**), is possibly the active catalytic species.[126,127] This species could be formed by metathesis of the Al–Me/Co–Cl bonds, abstraction of a Cl^- by Me_2AlCl,

alkene coordination, migratory insertion of the alkene into the Co–Me bond, followed finally by a reductive elimination (Scheme 8). Addition of the Co–H group via an η^4-diene complex **90** would produce a *syn-anti*(allyl)cospecies **91** which would undergo coupling with ethylene to give **93**. β-Hydride elimination from **93** regenerates the catalyst, giving the major product **84**. Intermediacy of the η^3-allylic intermediate **92**, which is capable of *syn-/anti*-isomerization, would also explain the temperature dependence of the product distribution. For example, in the Co(dppp)Cl_2-mediated HV of **83a**, none of the product **84a**, which is the major component at –20 °C (formed via the (*syn-anti*-(allyl) intermediate **91**), is observed at 23 °C. At low temperature, where the asymmetric catalyzed reactions are carried out, **91** must be configurationally stable to give the high selectivities observed. From the solid state structures of the tetrahedral complexes involved,[123] (*R,R*)-[DIOP]$CoCl_2$ and (*S,S*)-[BDPP]$CoCl_2$, it would appear that these complexes can overcome one of the serious limitations of catalysis by Ni(II)-complexes, where only monodentate ligands have been successful. Cobalt with the possibility of higher coordination numbers can support more flexible geometries for the intermediates in the catalytic cycle.

Scheme 8 A possible mechanism of Co(II)-catalyzed hydrovinylation of a 1,3-diene.

Realization of a synthetically useful chemo-, regio- and diastereoselective methods led to the investigation of an asymmetric variant (equation 49). Among the ligands that were evaluated, the best results were achieved with the simplest chiral analogs of dppb and dppp that are commercially available: (*R,R*)-(2,2-dimethyl-1,3-dioxalane-4,5-diylbismethylene)-bis-diphenylphosphine [(*R,R*)-DIOP, (**L44**)] and (*S,S*)-2,4-*bis*-diphenylphosphinopentane [(*S,S*)-BDPP, (**L47**)]. Under the optimized conditions (equation 49), (*E*)-1,3-nonadiene (**83a**) gave nearly quantitative yield of (*S*)-(*Z*)-4-vinylnon-2-ene (**84a**) with 95% *ee* (equation 49, Table 11, entry 1). In general, high levels of regio- and enantioselectivities were observed for a series of linear 1,3-dienes (Table 11, entries 1–10).

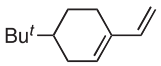
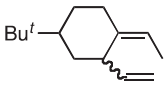
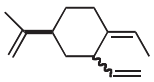
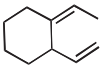
5.32.9.2.2 Cobalt-catalyzed asymmetric hydrovinylation of 1-vinylcycloalkenes

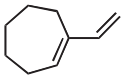
Hydrovinylation of racemic 4-*t*-butyl-1-vinylcyclohex-1-ene (**64**, Scheme 9) revealed that, in sharp contrast to the corresponding Ni(II)-catalyzed reaction (see equation 44, Table 7, entry 2),[120] the (dppp)$CoCl_2$/Me_3Al-mediated reaction gives almost exclusively the 1,4-adducts as a mixture of *cis*- (**94**) and *trans*- (**95**) isomers (81:17).[128] During these studies it was also recognized that MAO[129] can serve as an effective replacement of the hydrocarbon solutions of Me_3Al. Both the Ni(II) and Co(II) reactions are highly regioselective in the formation of the respective 1,2-(**65a**/**65b**) and 1,4-(**94**/**95**) adducts with less than 4% of the regioisomeric products formed in each case.

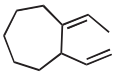


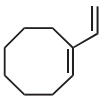


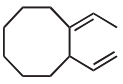


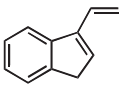


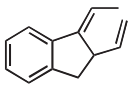


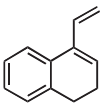


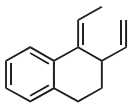


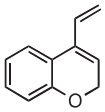


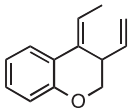






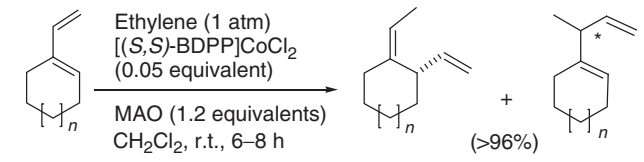






Scheme 9 1,2- Versus 1,4-hydrovinylation of a 1-vinylcyclohexene.

The scope of the reaction is illustrated with the examples shown in Table 12. Under the standard reaction conditions, the hydrovinylation is highly chemoselective for the 1,3-diene moiety, as shown by the reaction of the enantiopure triene **96**, which was prepared from commercially available (–)-perrilaldehyde (entry 2). The 1,4-adducts **97** and **98** (ratio of 4:1) are obtained in excellent yield. Conformationally flexible 1-vinylcyclohexene (entry 3) also gave predominantly the 1,4-adduct (**99**), with up to 22% of the 1,2-HV product **67** (see also Table 7). The Co(II)-catalyzed 1,4-hydrovinylations are particularly effective for 1-vinylcycloheptene (entry 4) and 1-vinylcyclooctene (entry 5), under the typical reaction conditions using dppp as the ligand.



Substrates **70**, **72**, and **74**, which gave exclusive 1,2-hydrovinylation under the Ni-catalyzed reaction conditions described in Scheme 9,[120] gave quantitative yields of the 1,4-adduct (1,4-HV: 1,2-HV>99:1) in the Co(II)-mediated reactions (entries 6–8).

The successful development of a useful and simple protocol for the cobalt-catalyzed hydrovinylation of 1-vinylcycloalkenes led to the exploration of an asymmetric version.[128] Reactions of two prototypical dienes, 1-vinylcyclohexene and 1-vinylcycloheptene, are shown in equation 50. These reactions with (BDPP)$CoCl_2$ closely parallel the results obtained with the corresponding (dppp)$CoCl_2$, except that the proportion of the 1,4-HV product is slightly more in the former case than what was found with dppp. The 1,4-HV products **99** and **101** are obtained essentially as single enantiomers, whereas the 1,2-HV products **67** and **102** are formed in much lower *ee*'s. Ligand (*S*,*S*)-BDPP (**L47**) was used to effect the asymmetric hydrovinylation of a series of other 1-vinylcycloalkenes with excellent yields and regio- and enantioselectivities and the results are shown in Table 13.

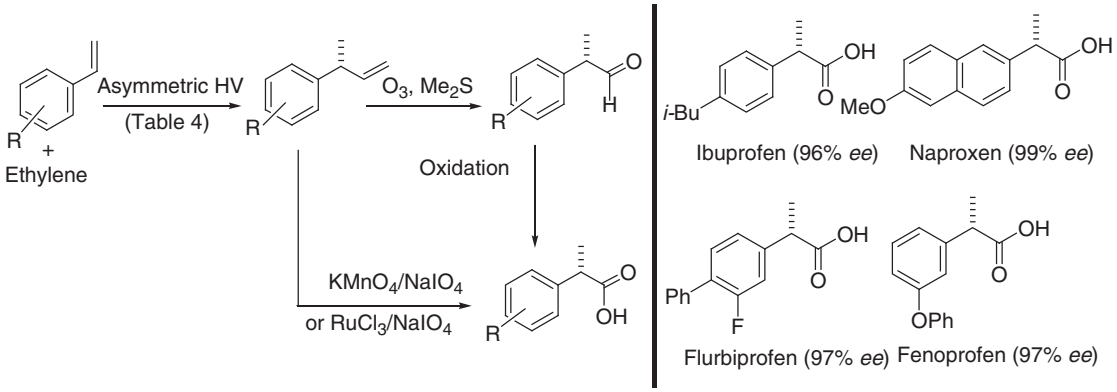
As illustrated by the examples in Table 13, the (BDPP)$CoCl_2$-catalyzed asymmetric 1,4-hydrovinylation is a broadly applicable reaction, proceeding in nearly quantitative yields and exceptional enantioselectivities for the respective 1,4-adducts. The enantiopure skipped 1,4-dienes are valuable intermediates for further synthetic applications, possessing two double bonds that can be differentiated by reactivities toward electrophilic reagents (e.g., faster reaction with the trisubstituted olefin) and steric effects (e.g., Rh-catalyzed hydrogenation and hydroboration, metathesis reactions of monosubstituted alkenes).

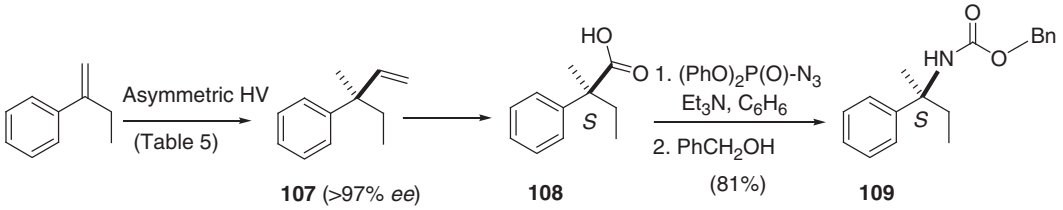


5.32.10 Applications of Asymmetric Hydrovinylation Reactions: Exocyclic Stereocontrol

A chiral side chain carrying a methyl group is a very common structural motif in many terpenoids, and this side chain is often attached to a sterogenic center in the ring. Examples can be found in simple compounds such as the juvenile hormone juvabione, and in more complex structures such as serrulatanes, pseudopterosins, colombiasin, elisabethin A, ophiobolin C, and steroid hormones like calcitrol and their analogs. Many pharmaceutically relevant compounds such as the hugely popular 2-arylpropionic acids have a benzylic chiral center. Asymmetric hydrovinylation offers an attractive solution for the enantioselective installation of the key stereogenic centers in these molecules starting with simple prochiral alkene precursors.

5.32.10.1 Synthesis of (*R*)- and (*S*)-2-Arylpropionic Acids

The 2-arylpropionic acids are the most widely used class of nonsteroidal anti-inflammatory drugs (NSAIDs). Naproxen, (*S*)-2-(6-methoxy-2-naphthyl)propionic acid, is the only NSAID that is sold in enantiomerically pure form, and it is currently prepared by a classical resolution. Most members of this class of compounds can be synthesized by the oxidative cleavage of the



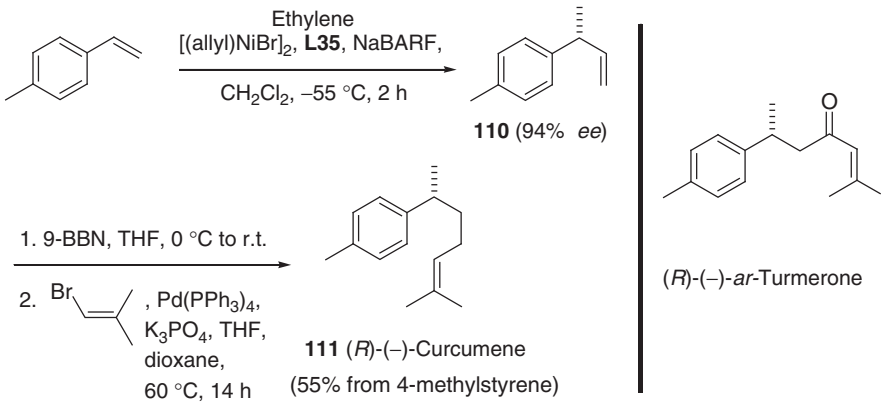
hydrovinylation products of vinylarenes. With the recent advances in the enantioselective synthesis of 3-arylbut-1-enes via hydrovinylation giving enantioselectivities >96% *ee*, using catalysts that give high turnovers (substrate/catalyst ~7000); this approach could provide a practical route to this important class of compounds (Scheme 10). Optimized oxidative protocols for the conversion of the 3-arylbutenes into various profen drugs have recently been reported.[75]

Scheme 10 Synthesis of enantiopure 2-arylpropionic acids via asymmetric hydrovinylation.

5.32.10.2 Enantiopure Primary Amines with Quaternary Benzylic Center

Application of a Curtius reaction to (*S*)-2-methyl-2-phenylbutanoic acid (**108**), prepared via the asymmetric hydrovinylation product (**107**) of 1-ethylstyrene, gives enantiopure amine derivative **109** (Scheme 11).[75] This route should allow the syntheses of a wide variety of compounds of similar structure starting with a styrene derivative.

Scheme 11 Synthesis of enantiopure primary amine with an α-tertiary center.



5.32.10.3 (*R*)-α-Curcumene and (*R*)-*ar*-Turmerone

The benzylic stereogenic center in bisabolanes (*R*)-α-curcumene and (*R*)-*ar*-turmerone poses a significant challenge in asymmetric synthesis. No less than 12 nonracemic synthesis of (*R*)-curcumene, a molecule often used to showcase newly developed asymmetric methodology, had been reported. The best among these involve a minimum of six steps and multiple chromatographic separations.[130,131] The asymmetric hydrovinylation product (**110**, prepared in 94% *ee* using ligand **L35**) of 4-methylstyrene can be converted into curcumene in two subsequent steps, both done in one pot (Scheme 12).[132] Treatment of **110** with 9-borabicyclo[3.3.1]nonane (1.2 equivalents) in THF, followed by Suzuki coupling with bromo-2-methylpropene gives (−)-α-curcumene (**111**) as a colorless oil in 55% overall yield from 4-methylstyrene in three steps. Similarly, the synthesis of (*R*)-(−)-*ar*-turmerone was accomplished in six steps from 4-methylstyrene.

5.32.10.4 Control of the Configuration of C_{20} on the Steroidal D-Ring Side Chain

Diastereoselective hydrovinylation provides a broadly applicable method for the control of the C_{20} configuration (**115**) of a steroid starting with a D-ring diene (Figure 7). This problem is of special interest for the synthesis of the unnatural $C_{20}(S)$ epimers, which are typically prepared by circuitous routes involving epimerization of the C_{20}-aldehyde (**114**) and a tedious separation. Steroid-derived dienes **112** and **113** (Figure 7), readily available from the corresponding D-ring ketones, have been subjected to hydrovinylation reactions. As shown in equation 51, a ruthenium-catalyzed hydrovinylation of **112** proceeds in a highly selective fashion to give the $C_{20}(S)$-isomer.[109] The Ni(II)-catalyzed hydrovinylation has been explored with the goal of preparing the specific epimer of the C_{20}-derivative.[133] Highly tunable phosphoramidites provide an excellent opportunity to address the effect of catalyst tuning in this context, and the results are shown in Scheme 13. Hydrovinylation of the steroid diene **112**, using *ent*-**L33a**

and **L34**, gave the $C_{20}(R)$- and $C_{20}(S)$-derivatives, respectively, along with minor amounts of the 1,4-adduct **118** (Scheme 13). The nonaromatic steroid **113** also behaves similarly.

Scheme 12 Synthesis of (–)-curcumene via asymmetric hydrovinylation.

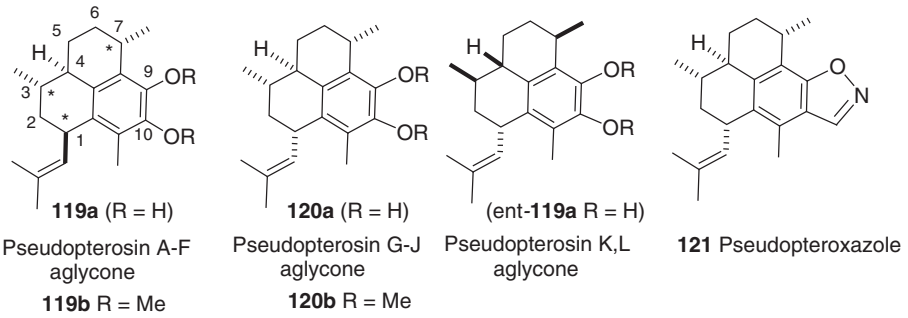
(51)

Scheme 13 Diastereoselective hydrovinylation for installation of C_{20}-configuration.

5.32.10.5 Enantioselective Synthesis of Pseudopterosins

Pseudopteropsins (Figure 8), with three exocyclic chiral centers, provide a challenging opportunity to showcase the power of asymmetric hydrovinylation to control the absolute and relative configuration of the various chiral centers. This class of compounds has attracted considerable attention because of their diverse biological activities, including antiinflammatory, antiviral, cytotoxic, and, especially, antimycobacterial properties.[134] A general approach to these compounds should address the thorny issue of how to control the configuration at each of the disparate chiral centers in these molecules. Previously reported syntheses of pseudopterosins invariably rely on chirality borrowed from nature, starting with limonene (Broka,[135] Corey[136]), menthol



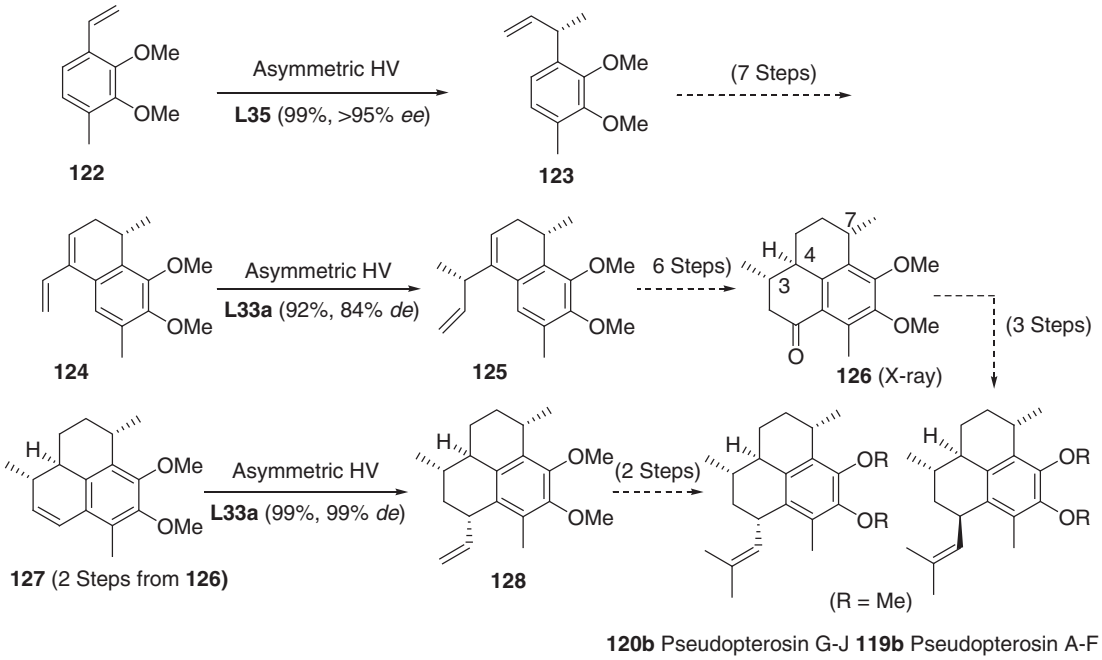


Figure 8 Structures of pseudoptereosins and related compounds.

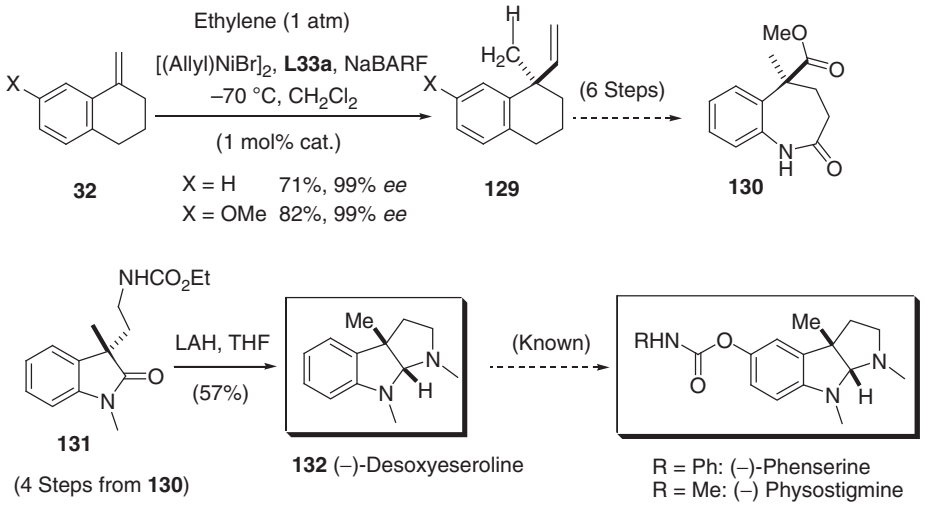
(Corey[137]), or (+)-isopulegol (Kocienski[138]), somewhat limiting the scope of this approach for the syntheses of various diastereomers. All these approaches rely on substrate control for the installation of the stereocenters, and significant changes in the overall synthetic strategy will be required for the synthesis of any particular diastereomer. Hydrovinylation, however, allows reagent-based selectivity at each step in which a chiral center is generated, and thus it should, in principle, be possible to make any of the diastereomers. This is illustrated in Scheme 14 with the syntheses of the pseudopterosin A–F and G–J aglycones.[121] The pseudopteosin K–L aglycone is enantiomeric to the A–F aglycone, thus accessible using the corresponding enantiomeric ligands.

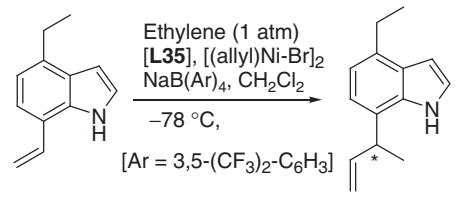
Scheme 14 Asymmetric hydrovinylation reactions in the syntheses of pseudopterosins.



As shown in Scheme 14, the synthesis starts with the hydrovinylation of a vinylarene **122** to get **123** in excellent yield and >95% *ee*. The product **123** could be easily converted into a diene **124** in seven steps. This diene was subjected to yet another asymmetric hydrovinylation under the standard protocol to get the product **125** in 92% yield and 84% de. Hydroboration followed by Li/NH_3 reduction and subsequent annulation gave the ketone **126**, which can be recrystallized to get a single enantiomer of this key intermediate. A solid-state structure of this compound established the relative configurations of all chiral centers in the molecule. Ketone **126** is converted into the vinylarene **127**, which was subjected to the final hydrovinylation to install the correct configuration of the C1 carbon of pseudopterosin G–J aglycone. The vinyl derivative **128** is readily converted into the methyl ether of pseudopterosin G–J aglycone (**120b**) via ozonolysis followed by a Wittig olefination. Under the reaction conditions, the aldehyde undergoes some epimerization to give, after the Wittig reaction, up to 13% of the pseudopetrosin A–F derivative in addition to the major expected product **120b**. Ketone **126** can been converted into **119b** by a procedure reported by Corey.[137]

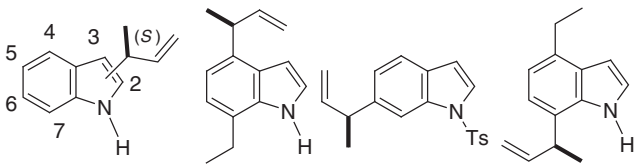
Even though we have not explored possibilities of making different diastereomers of pseudopterosins, previous work with the steroid side chains (Scheme 13) and a limited study of the hydrovinylation of the pseudopterosin precursors **122**, **124**, and **127** using various Ni(II)-phosphoramidite complexes suggest that there is considerable flexibility in the HV route for assembling these molecules.

The pseudopteosin K–L aglycone, which is the enantiomer of pseudopterosin A–F aglycone, can be synthesized from the same starting vinylarenes through the same chemistry using the appropriate ligands. Likewise a minor modification of this scheme should allow for the preparation of the antituberculotic pseudopteroxazole **121** (Figure 8). In addition, the stereochemical features associated with some of the advanced intermediates in the pseudopterosin synthesis are common to a number of important diterpenes including colombiasin A, elisabethin A, elisapterosin B, and several helioporins. With the stereochemical issues largely resolved, it should now be possible to design expeditious entry into these molecules and their congeners.



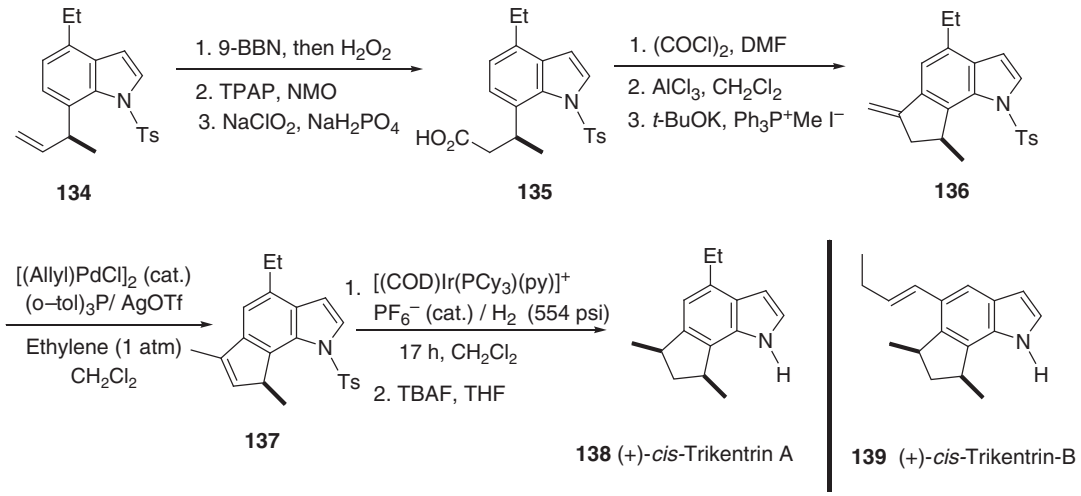
5.32.10.6 Enantioselective Synthesis of Desoxyeseroline, a Pyrrolidinoindoline with an Asymmetric All-Carbon Quaternary Center

(–)-Physostigmine (Scheme 15) is one of the major alkaloids isolated from African Calabar bean, which has an all-carbon quaternary benzylic chiral center, and this class of molecules has been the subject of intense interest, thanks to their anticholinestrase activity. The major challenge in the synthesis of this molecule and other useful analogs is the installation of the all-carbon quaternary center.



Scheme 15 Synthesis of pyrrolidinoindoles with an all-carbon quaternary center.

Asymmetric hydrovinylation of α-substituted alkenes provides a facile entry into compounds with all-carbon quaternary centers (equation 14, Table 5). One of the best substrates for this reaction is methylenetetralene **32**, which can be transformed into the benzoazepinone **130** by a highly enantioselective hydrovinylation followed by a series of oxidations and a Beckmann rearrangement (Scheme 15).[87] Methylation, hydrolysis, and a Curtius rearrangement gives the urethane **131**, which is easily converted into (–)-desoxyseroline (**132**), a common intermediate for the syntheses of a variety of pyrrolidinoindolines including physostigmine and phenserine.



(52)

Vinylindoles prepared in 94–99% *ee*:

5.32.10.7 Synthesis of Trikentrins

Vinylindoles undergo Ni(II)-catalyzed asymmetric hydrovinylation under very mild conditions (−78 °C, 1 atm ethylene, 1–4 mol% catalyst) to give the corresponding 2-but-3-enyl derivatives in excellent yields and enantioselectivities (equation 52).[139] Hydroboration of the alkene in the hydrovinylation product **133** derived from 4-ethyl-7-vinylindole, oxidation to an acid, followed by Friedel–Crafts annulation and a Wittig reaction gives an indole-annulated cyclopentene (**136**) that is a suitable precursor for the syntheses of *cis*-trikentrins and all known herbindoles (Scheme 16).[139] For example, this compound has been transformed into (+)-*cis*-trikentin A (**138**) in three steps (alkene isomerization,[140] diastereoselective hydrogenation, and nitrogen deprotection). The previous synthesis of this molecule from (*S*)-(−)-malic acid involved more than 20 steps and a preparative high performance liquid chromatography separation of diastereomeric intermediates.[141] A similar sequence can also be used for the preparation of other members of this class of compound, including unsaturated derivatives like (+)-*cis*-trikentrin-B, **139**.

Scheme 16 Synthesis of trikentrins via asymmetric hydrovinylation.

5.32.11 Conclusions and Future Prospects

Selective heterodimerization of olefins depends on different reactivities of the precursor and the product alkenes. Origin of this difference could be size, electronic factors (e.g., vinylarenes, dienes), or strain (e.g., bicyclo[2.2.1]heptenes and cyclobutenes). Many of the reactions are tolerant to a wide variety of functional groups, and substrate/catalyst ratios >7000 have been realized for some of the hydrovinylation reactions. The reaction has been shown to proceed under catalysis of Ni, Pd, Ru, Co, and Fe, and a number of tunable ligand systems for each of these metals have been identified. Recent results imply that Ru and Co would have their own unique features that are complementary to that of nickel, which appears by far to be the most active metal. The next major challenges in this area are expansion of scope of the substrates to include heterofunctionalized alkenes and higher olefins in the place of ethylene, and development of intramolecular versions.[142,143] Since most reactions involve a single oxidation state of the metal throughout the catalytic cycle, development of tandem catalytic processes[144] that involve hydrovinylation in one of the steps can also be envisioned. Applications for the syntheses of complex natural products and medicinally relevant targets are beginning to appear in the literature. With increased attention from several leading researchers further rapid progress in the area can be expected.

Acknowledgments

Financial assistance for the research conducted at the Ohio State University by US National Science Foundation (CHE-0610349, CHE-1057818) and the National Institutes of Health (General Medical Sciences, R01 GM075107) is gratefully acknowledged. Schering Plough Corporation provided a graduate fellowship (administered by the American Chemical Society) to Craig Smith. He and Adam Cox were also the recipients of NIH CBIP fellowships.

5.33 Hydroarylation Reactions

T de Haro and C Nevado, University of Zürich, Zürich, Switzerland

© 2014 Elsevier Ltd. All rights reserved.

5.33.1	**Introduction**	1621
5.33.2	**Hydroarylation of Alkynes**	1621
5.33.2.1	Late Transition Metal-Catalyzed Hydroarylations of Alkynes	1622
5.33.2.1.1	Palladium-catalyzed hydroarylations of alkynes	1622
5.33.2.1.1.1	Intermolecular hydroarylations	1622
5.33.2.1.1.2	Intramolecular hydroarylations	1623
5.33.2.1.2	Gold- and platinum-catalyzed hydroarylation of alkynes	1625
5.33.2.1.2.1	Intermolecular hydroarylations	1625
5.33.2.1.2.2	Intramolecular hydroarylations	1626
5.33.2.1.3	Ruthenium-catalyzed hydroarylation of alkynes	1628
5.33.2.1.3.1	Intermolecular hydroarylations	1628
5.33.2.1.3.2	Intramolecular hydroarylations	1629
5.33.2.1.4	Other metals (Cu, Fe, Co, Rh, Ni)-catalyzed hydroarylation of alkynes	1630
5.33.2.2	Nonlate Transition Metal-Catalyzed Hydroarylation of Alkynes	1630
5.33.2.2.1	Brønsted acid-catalyzed hydroarylation of alkynes	1632
5.33.3	**Hydroarylation of Alkenes**	1633
5.33.3.1	Transition Metal-Catalyzed Hydroarylation of Alkenes	1634
5.33.3.1.1	Ruthenium-catalyzed hydroarylation of alkenes	1634
5.33.3.1.1.1	Intermolecular hydroarylations	1634
5.33.3.1.1.2	Intramolecular hydroarylations	1636
5.33.3.1.2	Iridium-catalyzed hydroarylation of alkenes	1637
5.33.3.1.3	Rhodium-catalyzed hydroarylation of alkenes	1637
5.33.3.1.3.1	Intermolecular hydroarylations	1637
5.33.3.1.3.2	Intramolecular hydroarylations	1638
5.33.3.1.4	Palladium-catalyzed hydroarylation of alkenes	1639
5.33.3.1.5	Platinum-catalyzed hydroarylation of alkenes	1641
5.33.3.1.5.1	Intermolecular hydroarylations	1641
5.33.3.1.5.2	Intramolecular hydroarylations	1642
5.33.3.1.6	Gold-catalyzed hydroarylation of alkenes	1643
5.33.3.1.6.1	Intermolecular hydroarylations	1643
5.33.3.1.6.2	Intramolecular hydroarylations	1645
5.33.3.1.7	Other metals (Mo, W, Re, Fe, Co)-catalyzed hydroarylation of alkenes	1645
5.33.3.2	Nontransition Metal-Catalyzed Hydroarylation of Alkenes	1646
5.33.3.2.1	Brønsted acid-catalyzed hydroarylations	1648
5.33.4	**Hydroarylation of Allenes**	1652
5.33.4.1	Transition Metal-Catalyzed Hydroarylations of Allenes	1652

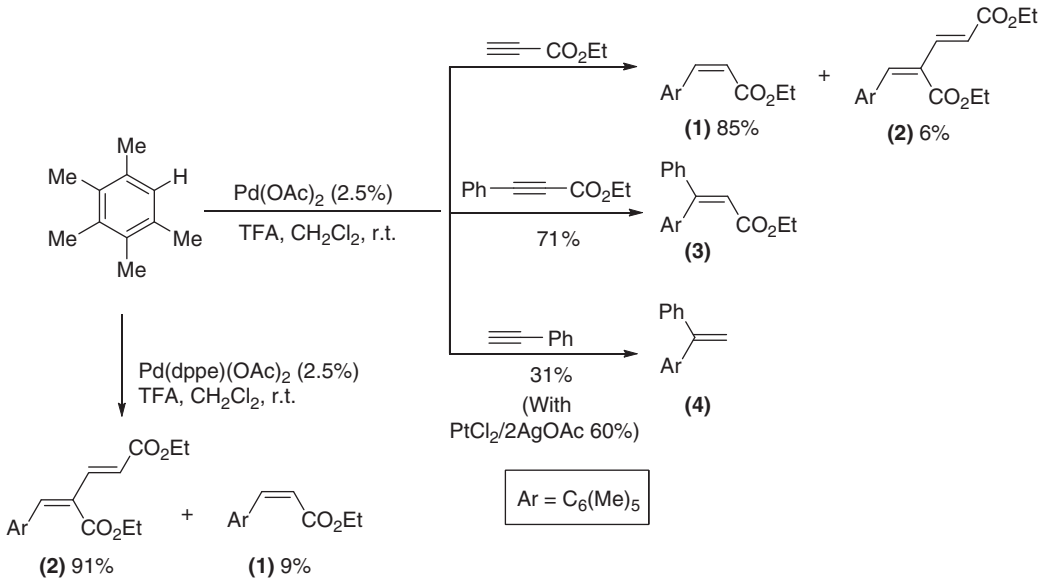
5.33.1 Introduction

Hydroarylation can be defined as the addition of an aryl group and a hydrogen atom across an unsaturated moiety (either alkene or alkyne) yielding a new Csp^2–Csp^3 or Csp^2–Csp^2 bond, respectively. Additionally, hydroarylations can also be rationalized as a result of the Csp^2–H functionalization of an aromatic substrate via insertion of an alkene or alkyne into the C–H bond. In this regard, hydroarylation reactions are atom economical and thus compare advantageously to classical cross-coupling processes in which formal hydroarylation products are formed from prefunctionalized aromatic substrates (e.g., aryl halide, triflates, boranes, etc.). In this account, the authors will focus on the examples obeying the most restricted definition of hydroarylation including alkynes, alkenes, and allenes. Within these three reaction partners, transition metal and nontransition metal-catalyzed processes will be described separately and intermolecular examples will be always introduced before intramolecular ones.[1] When available, details about the potential reaction intermediates and/or reaction mechanisms will also be briefly discussed.

5.33.2 Hydroarylation of Alkynes

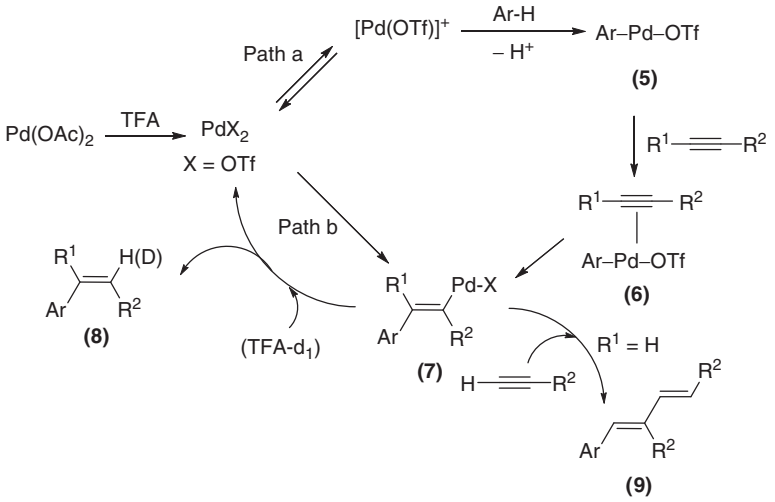


The hydroarylation of alkynes is one of the most efficient methods for the synthesis of functionalized alkenes. Two main reaction pathways have been proposed for this transformation: (1) the activation of the triple bond by an electrophile, E^+ (a metal complex, Lewis or Brønsted acid, etc.) followed by a Friedel–Crafts reaction with an aromatic counterpart or (2) activation of the Csp^2–H bond in the arene by the metal center before the addition onto the alkyne.

5.33.2.1 Late Transition Metal-Catalyzed Hydroarylations of Alkynes

5.33.2.1.1 Palladium-catalyzed hydroarylations of alkynes

5.33.2.1.1.1 Intermolecular hydroarylations

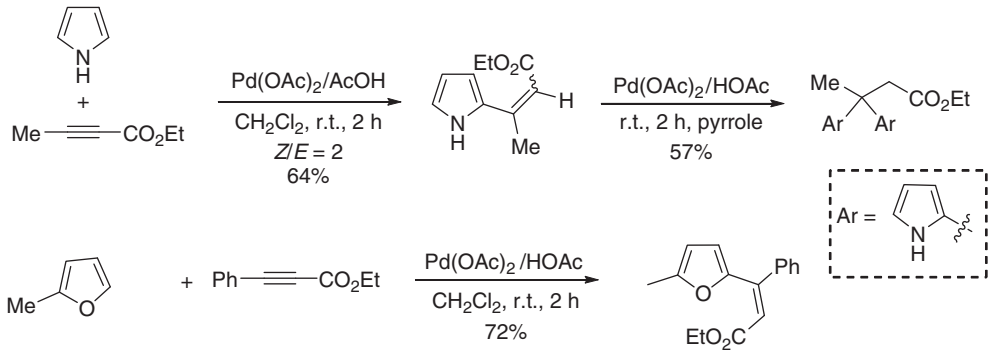


Fujiwara described the efficient hydroarylation of alkynes in the presence of highly electrophilic Pd(II) cationic complexes generated *in situ* from $Pd(OAc)_2$ and trifluoroacetic acid (TFA) (Scheme 1, right).[2] Electron-rich arenes and electron-deficient alkynes react smoothly, to give predominantly thermodynamically unfavorable *Z*-arylalkenes. Thus, the reaction of pentamethyl benzene with ethyl propiolate leads to *cis*-cinnamate **1** and diene **2** in 85% and 6% yield, respectively. Internal alkynes with an aromatic substituent such as phenyl ethyl propiolate, react in a Michael-type manner to give *cis*-1,1-diaryl substituted olefins **3** in good yields. However, phenylacetylene behaves differently, giving 1,1-diarylalkene **4** in only 31% yield. In this case, the combination of platinum dichloride and silver acetate increased the yield of **4** to 60%.

Scheme 1

In this context, further catalytic systems have been reported to improve the selectivity of the reaction and also to enable the use of less drastic conditions. Pd(II) catalysts with *N*-heterocyclic ligands such as IPr-Pd$(OCOCF_3)_2$ and IPr-Pd$(OAc)_2$ with TFA as solvent further improved the selectivity favoring, almost exclusively, monoaddition products **1**.[3] In contrast, palladium complexes with bidentate phosphine ligands in TFA afforded selectively dienes **2** in high yields (Scheme 1, down).[4] Interestingly, palladium(II) complexes bearing a chelating *N*-heterocyclic dicarbene ligand and two weakly coordinating anions (introduced *in situ* on addition of 2 equivalents of a suitable silver salt) could be tuned by the use of additives to afford products **1** or **2** selectively.[5] $Pd(OAc)_2$ combined with silver acetate in acetonitrile as solvent effectively generated highly substituted naphthalenes from internal alkynes via twofold hydroarylation products of type **2**.[6]

Two different mechanistic proposals have been outlined for these transformations (Scheme 2). In the case of Pd(II) (and Pt(II)) cationic complexes reported by Fujiwara,[2] an arene metalation is proposed to give σ-aryl metal species **5**, which simultaneously activate the alkyne through coordination via complex **6** (path a). Insertion of the alkyne in the Csp^2–metal bond was proposed to take place in an unusual *trans*-fashion yielding the thermodinamically unfavorable *cis*-vinyl intermediate **7**. Deutero- or protodepalladation affords the observed products **8**. The formation of aryl-palladium species **5** in these transformations is supported by the disappearance of the aryl hydrogen of pentamethylbenzene on reaction with 1 equivalent of $Pd(OAc)_2$ in TFA after a few minutes at room temperature. One of the alkenyl hydrogen in the adduct comes from the acidic solvent, presumably as a result of the protonation of alkenyl complex **7** by TFA (or TFA-d_1). The fact that hydroarylation reaction fails in acetic acid, indicates that cationic Pd(II) species are involved in the palladation and/or that protonation of the alkenyl-Pd intermediate to

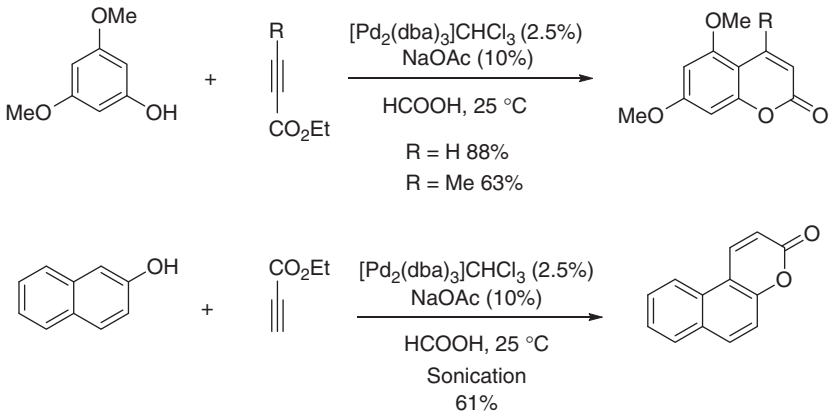


Scheme 2

complete the catalytic cycle only occurs with stronger acids such as TFA. The formation of adducts stemming from the reaction of two alkynes and one arene **9** would proceed through vinylpalladium intermediate **7**.

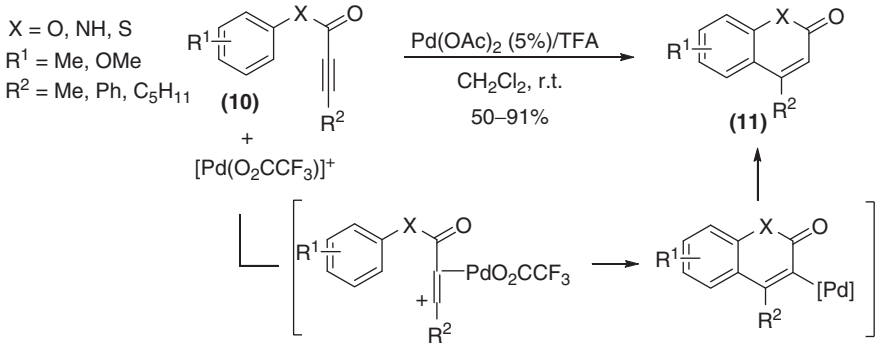
In the case of noncationic Pd(II) catalysts, the hydroarylation reaction is proposed to proceed via alkenyl-palladium **7**, which would be directly formed from the neutral palladium precatalyst by an electrophilic aromatic substitution process (path b).

Electron-rich heteroarenes such as pyrroles, indoles, and furans readily undergo addition to alkynoates at room temperature with catalytic amounts of $Pd(OAc)_2$ in acetic acid to give *Z*-alkenes in most cases (Scheme 3).[7] In this case, the reaction was carried out in dichloromethane as solvent to obtain selectively monoaddition adducts.



Scheme 3

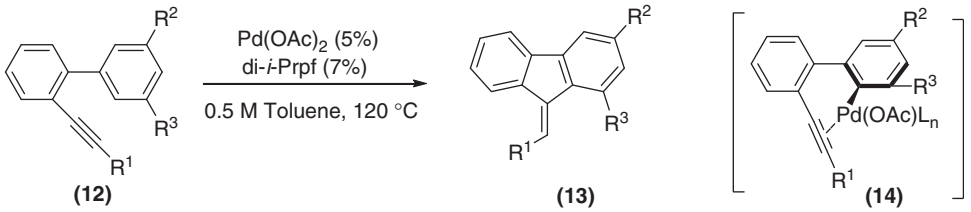
In addition to cationic Pd(II) complexes, Pd(0)-catalyzed intermolecular hydroarylations have also been reported. Thus, Trost described the synthesis of coumarins by addition of phenols to alkynoates (Scheme 4).[8] The original mechanistic proposal was based on the idea that electrophilic Pd(II) species could *ortho*-palladate an electron-rich phenol. However, after extensive experimentation, a mechanism was assumed in which the formation of hydridopalladium intermediates from the reaction of Pd(0) and formic acid are proposed as the initial productive species of the catalytic cycle. These intermediates trigger the addition of the arene onto the electron-deficient alkyne followed by lactonization to give the observed products.



5.33.2.1.1.2 Intramolecular hydroarylations

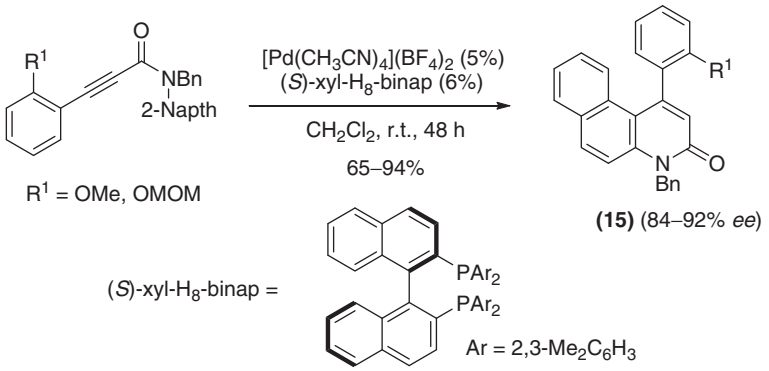
The catalytic system based on $Pd(OAc)_2$ and TFA has been successfully applied in the intramolecular hydroarylation of alkynes.[9] Aryl-alkynoates and alkynanilides **10** are efficiently transformed, in good-to-excellent yields, into coumarins and quinolin-2(1*H*)-ones **11**, respectively (Scheme 5). It was initially suggested that, in analogy to the intermolecular reaction presented in Section 5.33.2.1.1.1, a metalation of the arene takes place in these transformations. However, a detailed deuterium-labeling study supported a reaction mechanism involving an activation of the alkyne followed by an electrophilic aromatic substitution as shown in Scheme 5.[10]

The nature of the catalyst exerts a key influence not only in the reaction mechanism, but also in the regioselectivity of these transformations. Thus, related substrates such as *N*-arylpropiolamides, in the presence of $Pd(OAc)_2$ and dppf undergo 5-*exo*-*dig*



Scheme 4

Scheme 5

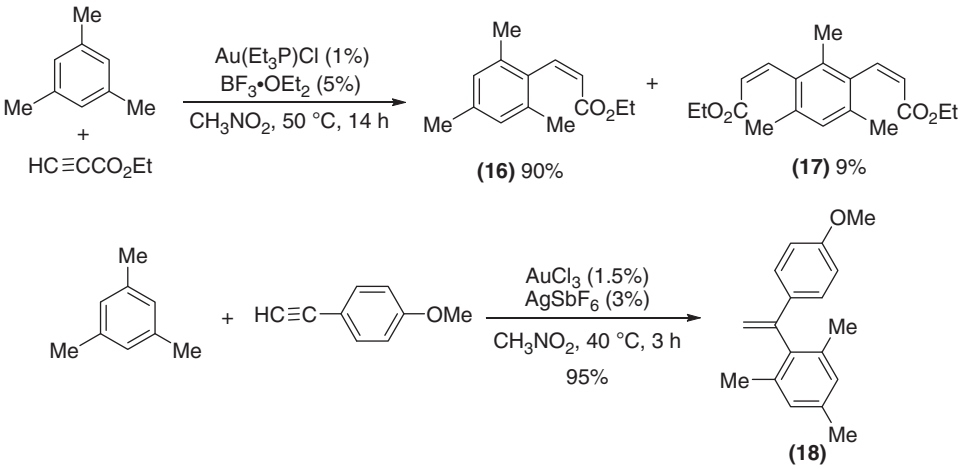


hydroarylations to give 3-methyleneoxindoles.[11] In addition, *ortho*-alkynyl biaryls **12** react in the presence of $Pd(OAc)_2$ and 1,1′-bis(diisopropylphosphino)ferrocene to form fluorene derivatives **13**.[12] Mechanistic studies support the involvement of an α-aryl-palladium intermediate **14**, formed by activation of the Csp^2–H bond, in these transformations (Table 1).

Table 1 Pd(II)-catalyzed synthesis of fluorenes

R^1	R^2	R^3	*Reaction time (h)*	*Yield (%)*
Ph	H	H	2.5	98
p-$NO_2(C_6H_4)$	H	H	4.0	89
Ph	F	F	3.0	93
p-$NO_2(C_6H_4)$	CF_3	CF_3	1.0	93

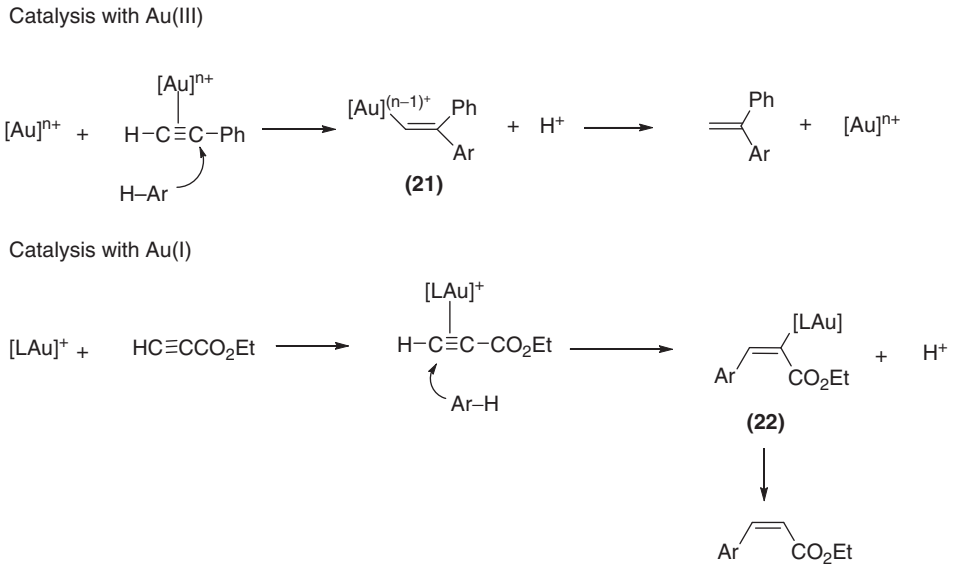
Asymmetric palladium-catalyzed hydroarylations have also been reported (Scheme 6).[13] In the presence of a cationic palladium(II)/(*S*)-xyl-H8-binap complex as catalyst at room temperature, axially chiral 4-aryl 2-quinolinones **15** were obtained in good yields and high enantiomeric excess.



Scheme 6

5.33.2.1.2 Gold- and platinum-catalyzed hydroarylation of alkynes

5.33.2.1.2.1 Intermolecular hydroarylations

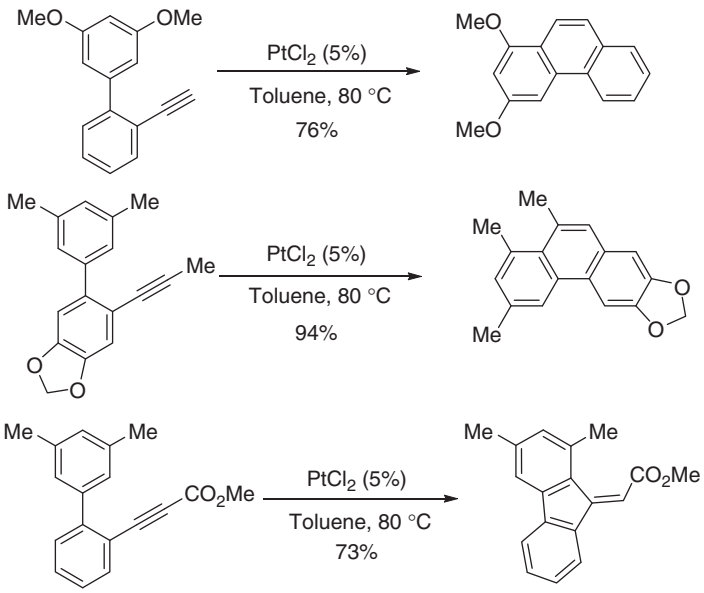


Cationic Pt(II) species have been used as effective catalysts for intermolecular alkyne hydroarylations offering comparable or in some cases, improved performances to those of Pd(II) catalysts. In addition to the examples reported by Fujiwara,[2] arenes and heteroarenes react with propiolic acid and esters to give *cis*-cinnamic derivatives in the presence of a catalyst generated *in situ* from K_2PtCl_4 and AgOTf.[14] $PtCl_2$ has also been proved to catalyze a multistep reaction of indoles with alkynyl alcohols involving an intermolecular hydroarylation in the first step of the catalytic cycle.[15]

However, gold has become the metal of choice to expand the scope of intermolecular hydroarylations of alkynes. Thus, Reetz found that gold(III) and gold(I) complexes catalyzed the intermolecular hydroarylation of electron-poor alkynes such as ethyl propiolate with electron-rich arenes in a regio- and stereoselective manner (Scheme 7).[16] In this case, 1,2-disubstituted alkenes were obtained with exclusive or predominant *Z* configuration. Thus, mesitylene and ethyl propiolate react with a cationic gold(I) complex formed *in situ* from [Au(PEt_3)Cl] and BF_3 to form *Z*-cinnamate **16** in 90% yield along with small amounts of double hydroarylation product **17**. Similar results were obtained by He in the reaction of arenes with ethyl propiolate and related electron-poor alkynes using $AuCl_3$/3AgX (X = OTf, SbF_6) in CH_2Cl_2.[17] However, aryl-substituted terminal alkynes react with electron-rich arenes in the presence of $AuCl_3$ and $AgSbF_6$ to give 1,1-diarylethenes such as **18** in good-to-excellent yields. In contrast, internal electron-poor alkynes failed to give the desired products under these conditions. Regarding the alkenylation of heteroarenes, indole[18] and furan[19] additions to alkynes catalyzed by gold(III) and gold(I) complexes respectively, have also been reported.

Scheme 7

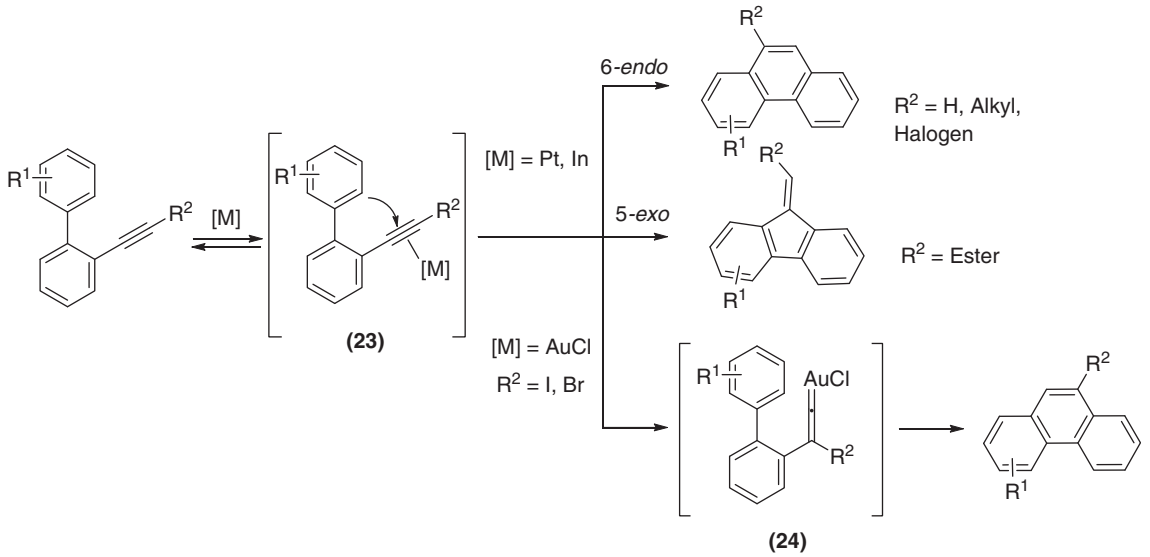
Although cationic gold(III) or gold(I) complexes are required for a successful outcome in the abovementioned transformations, an auration of the arene during the catalytic cycle seems unlikely, in contrast with the cationic-Pd(II)-catalyzed reactions described in Section 5.33.2.1.1.1. Aryl-gold(III) species ($ArAuX_2L$, **19**) react with alkynes to give Csp^2–Csp cross-coupling rather than hydroarylation products.[20] Furthermore, aryl-gold(I) complexes (Ar–Au–L, **20**) react with alkynes in the presence of palladium catalysts to give carboauration products.[21] Thus, gold-catalyzed hydroarylations seem to proceed by activation of the triple bond by π-complexation with the metal center (Scheme 8). In the case of aryl-substituted alkynes, the π-complex undergoes electrophilic aromatic substitution with the electron-rich arene to give alkenyl-gold(III) intermediate (**21**), which is immediately



Scheme 8

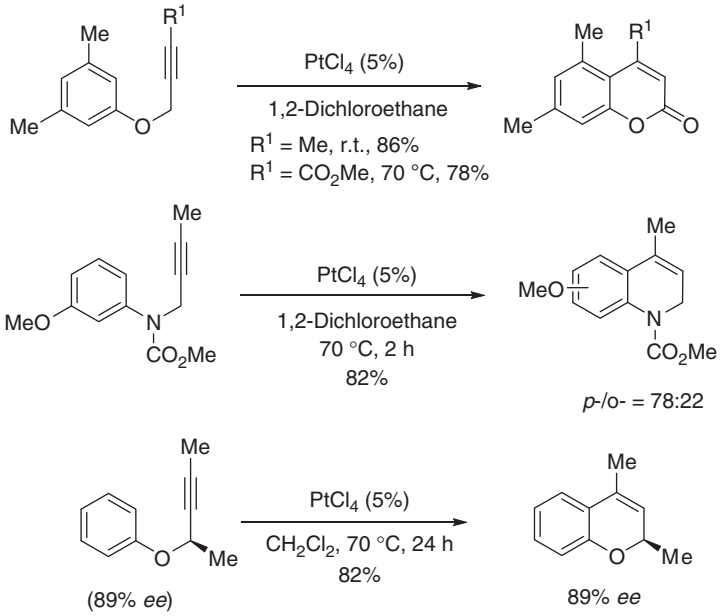
protonated by the H^+ generated in the previous step. For the gold(I)-catalyzed processes, the cationic complex coordinates the alkyne and the nucleophilic attack of the aromatic from the opposite face leads to alkenyl-Au(I) complex **22**, which undergoes protonation to give conjugated products. The regioselectivity seems to be thus determined by electronic rather than steric factors.

5.33.2.1.2.2 Intramolecular hydroarylations



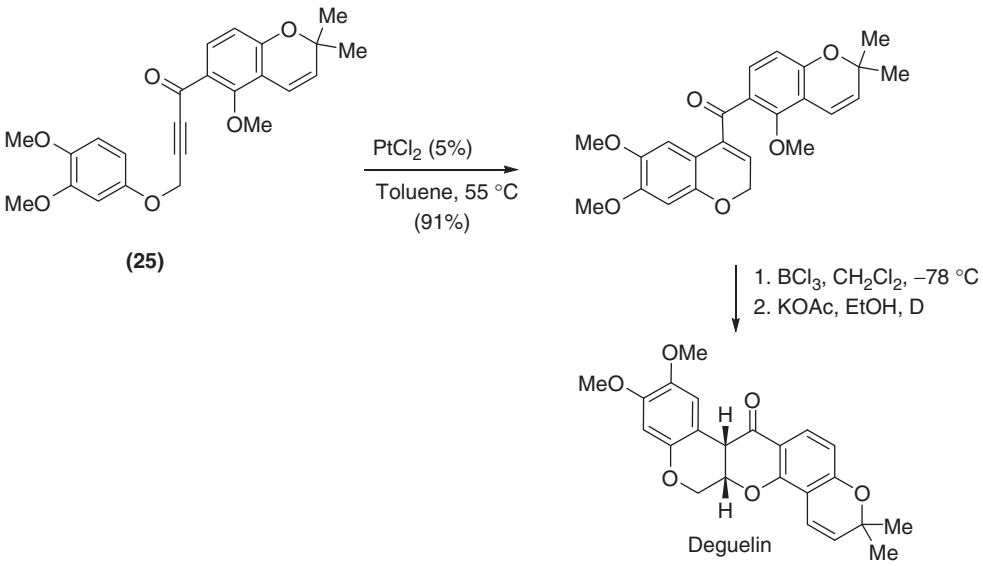
Pt(II) and Pt(IV) catalysts have found wider application in intramolecular alkyne hydroarylation processes. Fürstner reported a synthesis of phenanthrenes from biphenyl compounds bearing a triple bond at the *ortho*-position (**Scheme 9**).[22] This transformation has been applied in the synthesis of the aporphine family of natural products.[23] The 6-*endo* cyclization mode is preferred in both terminal and internal alkynes, although those bearing an electron-withdrawing group cyclized by a 5-*exo-dig* pathway.

Scheme 9



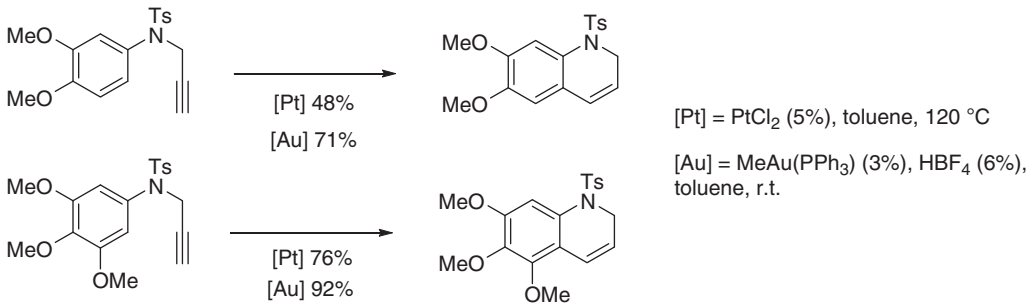
In addition to $PtCl_2$, other metal halides such as $AuCl_3$, $GaCl_3$, or $InCl_3$ catalyze this transformation.[22] As the Pt-catalyzed synthesis of phenantrenes also proceeds with nonterminal alkynes, a general mechanism involving activation of the triple bond by coordination of the metal (**23**) is strongly suggested.[24] Depending on the substitution pattern on the alkyne, the subsequent nucleophilic attack can take place in a 6-*endo* or a 5-*exo* manner. When halo-substituted alkynes were submitted to the reaction with In(III) salts, 10-halophenanthrenes were obtained in excellent yields. In contrast, when AuCl was used as catalyst,

9-halo-phenanthrenes were formed instead, thus pointing toward a different mechanism for this particular combination of substrates and catalyst, involving the formation of a metal vinylidene intermediate **24** via 1,2-halogen shift (Scheme 10).[22]



Scheme 10

$PtCl_4$ has also been reported to catalyze intramolecular alkyne hydroarylations enabling the synthesis of 2*H*-chromenes, 1,2-dihydroquinolines, and coumarins (Scheme 11).[25] In all cases, 6-*endo-dig* cyclizations were observed regardless of the electronic nature of the alkyne, in contrast to the Pt(II)-catalyzed transformation shown in Scheme 9. Stereogenic centers are compatible with the reaction conditions, which exclude a Claisen rearrangement followed by electrocyclic ring closure as the reaction course; thus, activation of the alkyne via coordination to the metal followed by electrophilic aromatic substitution suffices to explain the observed reactivity. Similar cycloisomerizations have also been carried out in the presence of $Hg(OTf_2)(TMU)_3$ with catalyst loadings below 0.5 mol%.[26]



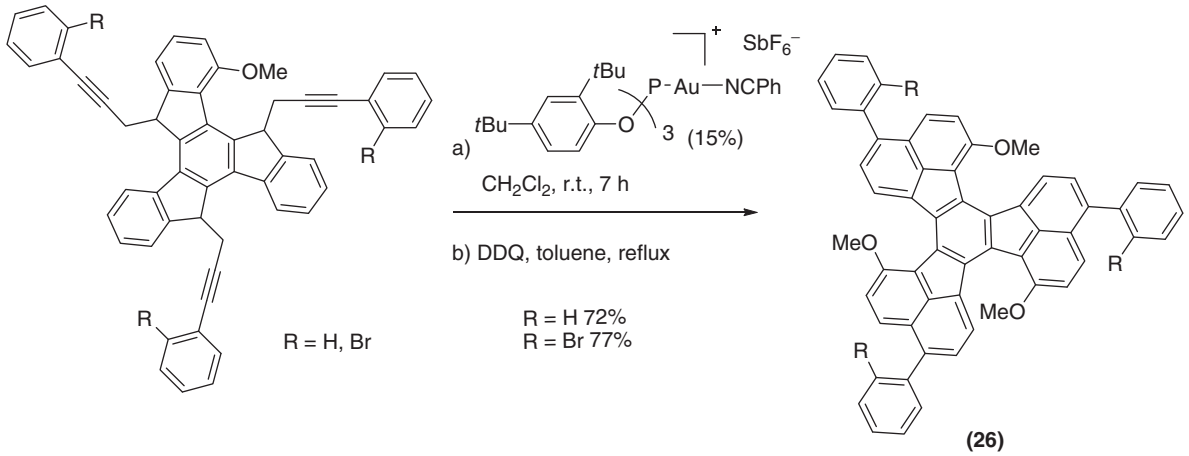
Scheme 11

A platinum-catalyzed hydroarylation has been applied in the total synthesis of deguelin, a rotenoid with promising chemopreventive properties.[27] After a $PtCl_2$-catalyzed 6-*endo* hydroarylation of **25**, a selective demethylation with boron trichloride, followed by base-catalyzed intramolecular oxo-Michael addition delivered the desired product (Scheme 12).

Scheme 12

Echavarren and coworkers also showed that 4-aryl-1-alkynes cyclized in a 6-*endo-dig* fashion with cationic gold(I) catalysts (generated *in situ* from [Au(PPh_3)Me] and a strong acid or from Ph_3PAuCl by chloride abstraction in presence of a silver salt) (Scheme 13).[28] $PtCl_2$ in refluxing toluene could also be used as catalyst although lower yields were reported for these transformations (Scheme 13).[29] As in the previous cases, π-activation of the alkyne is proposed to trigger the 6-*endo*-hydroarylations through a Friedel–Crafts mechanism although density functional theory (DFT) calculations showed that metal carbene intermediates can also be the effective precursors of Wheland-type species in these transformations.[28] This chemistry has also been expanded enabling the synthesis of chromenes and coumarins,[30] benzopyranes,[31] and cinnolines,[32] respectively.

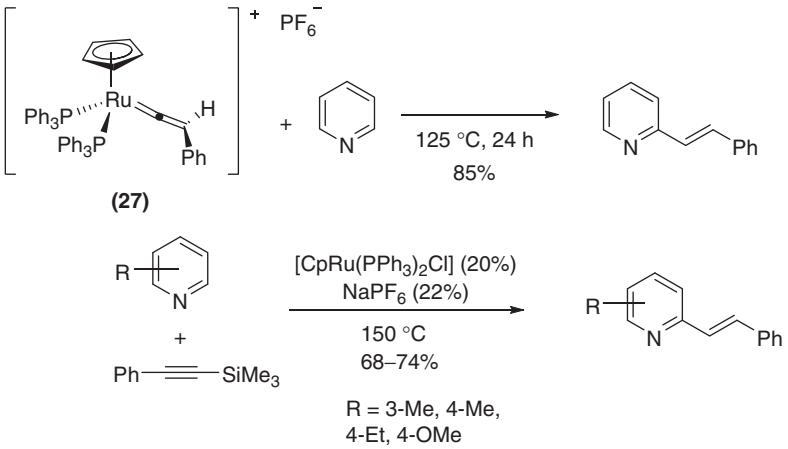
Scheme 13



The ability of gold to trigger intramolecular hydroarylations has been further tested in the construction of polyarenes as illustrated by the synthesis of two functionalized decacyclenes **26**. In a one-pot reaction, three C–C bonds are formed with high efficiency (Scheme 14).[33] AgOTf has also been used to promote multiple intramolecular hydroarylation processes to give perylene derivatives.[34]

In terms of heteroarenes as reaction partners, C3-substituted indoles undergo intramolecular hydroarylation processes catalyzed by gold(I) or gold(III) salts leading selectively to seven- or eight-membered ring, respectively.[35] In addition, (C2-enynyl)-indoles produce carbazoles by reaction with cationic gold(I) complexes.[36] The intramolecular hydroarylation of pyrrole-2-propargylcarboxamides to give pyrroloazepinones by a 6-*endo-dig* cyclization has been reported both with H_2PtCl_6 and $AuCl_3$ as catalysts.[37] Hg(II) efficiently catalyzes the 6-*exo* or 6-*endo-dig* cyclization of alkynyl furans depending on the substitution pattern on the alkynes.[38] In the latter transformation, neither platinum nor gold affords hydroarylation products but instead produce phenols as a result of a complex skeletal reorganization process.[39]

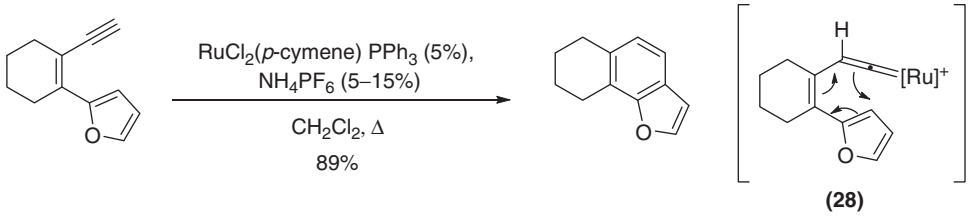
5.33.2.1.3 Ruthenium-catalyzed hydroarylation of alkynes



5.33.2.1.3.1 Intermolecular hydroarylations

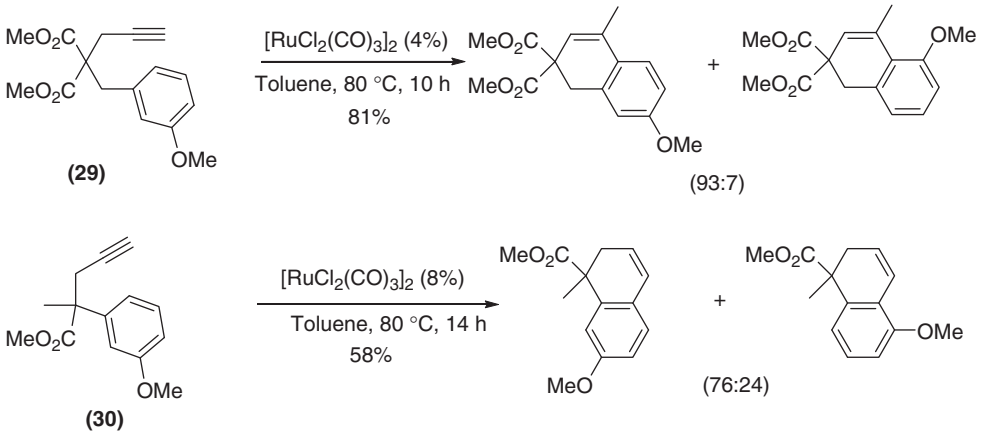
In contrast to the general mechanistic rationale described for platinum and gold-catalyzed arylation processes based on the π-activation of the triple bond by the metal, ruthenium-catalyzed hydroarylations of alkynes are oftentimes explained through

Scheme 14



ruthenium vinylidene intermediates. As for most late transition metals, the central carbon of the Ru-vinylidene moiety is electrophilic and thus susceptible of attack by a suitable nucleophile. Thus, pyridine reacts with Ru(II)-vinylidene complex **27** to give (*E*)-2-styrylpyridine (Scheme 15).[40] Although the *Z* isomer is formed first, it seems to evolve to the more stable *E* isomer under the reaction conditions. A catalytic version of this intermolecular alkenylation of pyridines at C-2 was carried out using $[CpRu(PPh_3)Cl_2]$ and $NaPF_6$, although an excess of pyridine and rather harsh conditions were required for a successful reaction outcome.

Scheme 15



5.33.2.1.3.2 Intramolecular hydroarylations

As shown in Scheme 16, intramolecular hydroarylations of heteroaromatic rings can be efficiently catalyzed by Ru(II) complexes as Ru-vinylidene intermediates **28** can be excellent substrates for 6π-electrocyclization reactions.[41] Deuteration experiments show that formation of the Ru-vinylidene **28** takes place via migration of the acetylenic hydrogen. A related 6π-electrocyclization of aromatic imines has been reported proceeding via W(0)-vinylidenes.[42]

Scheme 16

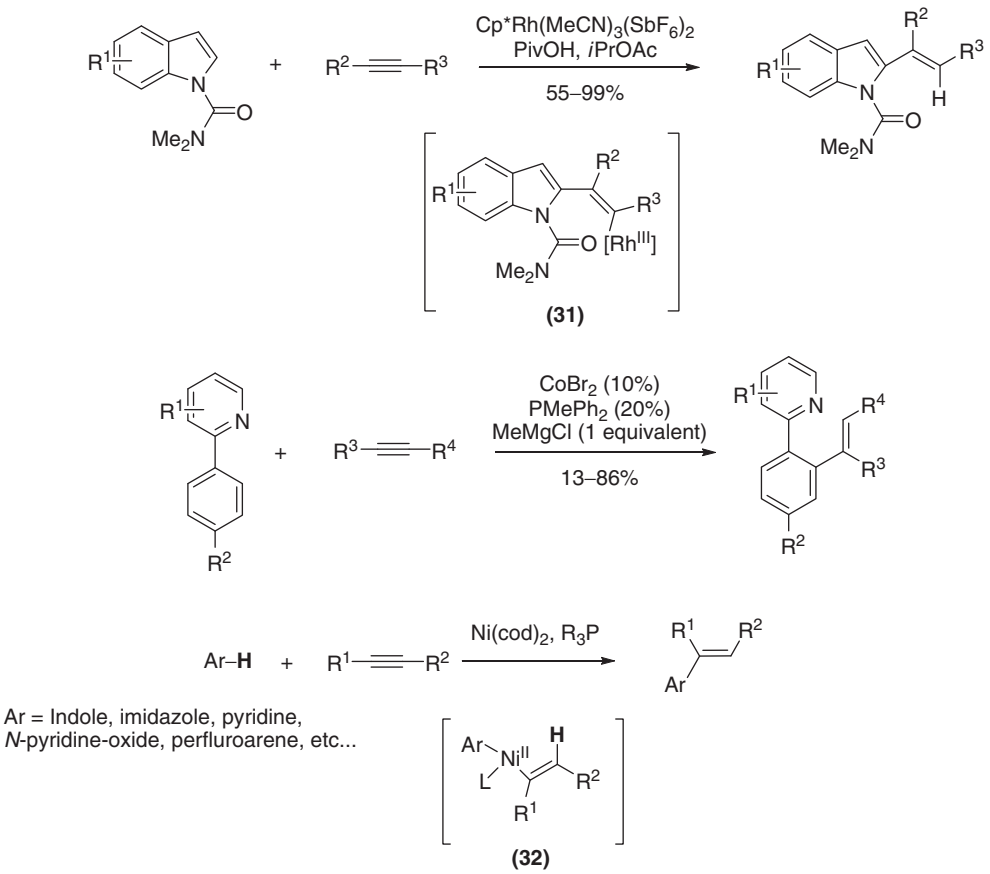
Interestingly, other Ru-catalyzed intramolecular alkyne hydroarylations are proposed to proceed via π-Lewis acid activation of the alkyne. Thus, Murai reported the cycloisomerization of ω-aryl-1-alkynes to give dihydronaphthalenes or dihydrobenzocycloheptenes (Scheme 17).[43] Different cyclization modes were observed depending on the length of the tethers: an *exo-dig* cyclization was preferred in substrate **29** where the alkyne and arene are separated by three (or up to four) carbon atoms, whereas an *endo-dig* mode was observed in substrates with two carbon atoms in the tether (**30**). This transformation, which can also be catalyzed by Pt(II), is limited to substrates bearing an electron-rich aromatic ring. More recently, the scope of the reaction was extended to substrates where the arene moiety does not possess strong electron-donating groups by using $GaCl_3$[44] or $FeCl_3$[45] catalysts.

Scheme 17

5.33.2.1.4 Other metals (Cu, Fe, Co, Rh, Ni)-catalyzed hydroarylation of alkynes

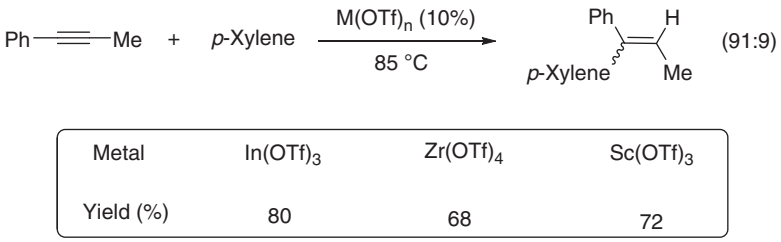
Recently, other metals such as iron,[46] cobalt, rhodium, and nickel have been explored in the context of alkyne hydroarylations, complementing the reactivity offered by the previously described systems. Thus, a rhodium(III)-catalyzed intermolecular hydroarylation of alkynes with *N*,*N*-dimethylcarbamoyl *N*-protected indoles at C2 was reported by Fagnou in 2010.[47] This transformation is proposed to proceed via directed metalation of the indole at C2, coordination of the alkyne to the Rh(III) center followed by *syn*-migratory alkyne insertion into the Csp^2–Rh bond to give **31**. Protonolysis of the carbon–rhodium bond would then give the observed products (Scheme 18).

The key role of a directing group has also been exploited in the cobalt-catalyzed hydroarylation of alkynes via chelation-assisted C–H bond activation.[48] Cobalt salts, phosphine ligands, and stoichiometric amounts of Grignard reagents promote the addition of arylpyridines and imines to unactivated internal alkynes with high regio- and stereoselectivity. Mechanistic studies involving deuterium-labeling experiments support a reaction mechanism in which chelation-assisted oxidative addition of the aryl C–H bond to the cobalt center is followed by insertion of the C–C triple bond into the Co–H bond. Reductive elimination affords the observed products (Scheme 18).



A wide variety of heterocycles, including C-3 substituted indoles, 1,3,4-oxadiazoles, imidazoles, pyridines, and pyridine *N*-oxides, 2-pyridones, pyrimidones, quinazolones, and also fluoroarenes have been efficiently alkenylated in the presence of $[Ni(cod)_2]$ combined with bulky alkylic phosphines (and Lewis Acid cocatalysts in certain cases).[49] A general mechanism for this palette of transformations involves an oxidative addition on the Ni(0) complexes into the Csp^2–H bonds followed by migratory insertion of the alkyne into the Ni–H bond to give **32**. The new Csp^2–Csp^2 bond is formed via reductive elimination on the diorganonickel(II) intermediate (Scheme 18).

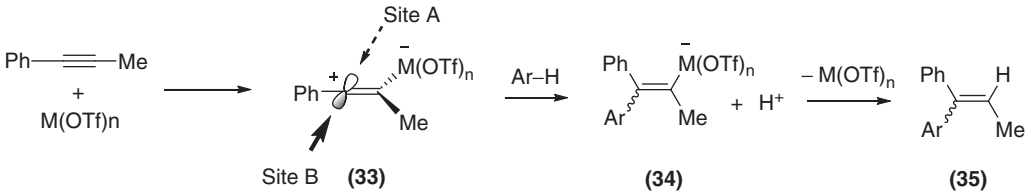
5.33.2.2 Nonlate Transition Metal-Catalyzed Hydroarylation of Alkynes



Electrophilic Ga(III)[44,50] and In(III)[22,51] complexes have also been used in alkyne hydroarylations. Metal trifluoromethanesulfonates such as $[M(OTf)_n$; M = Sc, Zr, In] catalyze the Friedel–Crafts alkenylation of arenes with internal alkynes to give 1,1-diarylalkenes in high-to-excellent yields (Scheme 19).[52]

Although different mechanistic hypotheses have been proposed, it is widely accepted that the attack of the arene to the initially formed zwitterionic intermediate **33**, from both A and B sites, affords an *E*/*Z*-mixture of **34**, which is transformed by protonation to the corresponding diastereoisomers **35** (Scheme 20). Kinetic studies revealed that the *Z* and *E* isomer of **34** are present in the mixture at the early stage of the reaction, strongly supporting this mechanism.

A double cyclization of bis(biaryl)acetylenes **36** occurs in the presence of $SbCl_5$ in CH_2Cl_2 at room temperature leading to dibenzo[*g*,*p*]chrysene derivatives **37** (Scheme 21).[53] The reaction involves the oxidation of the diphenylacetylene moiety by the



Scheme 18

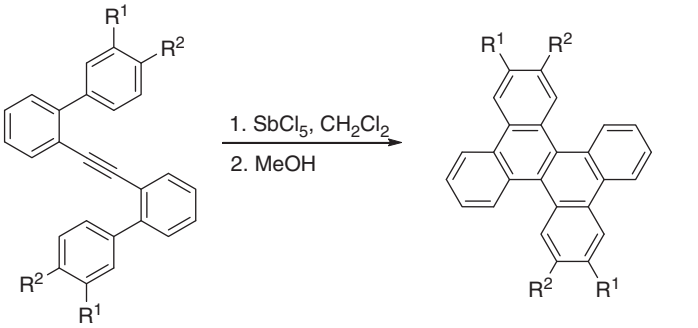
Yield (%)	80	68	72



Scheme 19

Scheme 20

one-electron oxidant $SbCl_5$ to form acetylene cation radicals, which undergo electrophilic and radical cyclization with the biaryl moieties.

Zeolite HSZ-360 is an efficient promoter for the regioselective monoalkenylation of phenol with phenylacetylene (Scheme 22). The observed *ortho*-regioselectivity was proposed to be due to the formation of a hydrogen bond between the

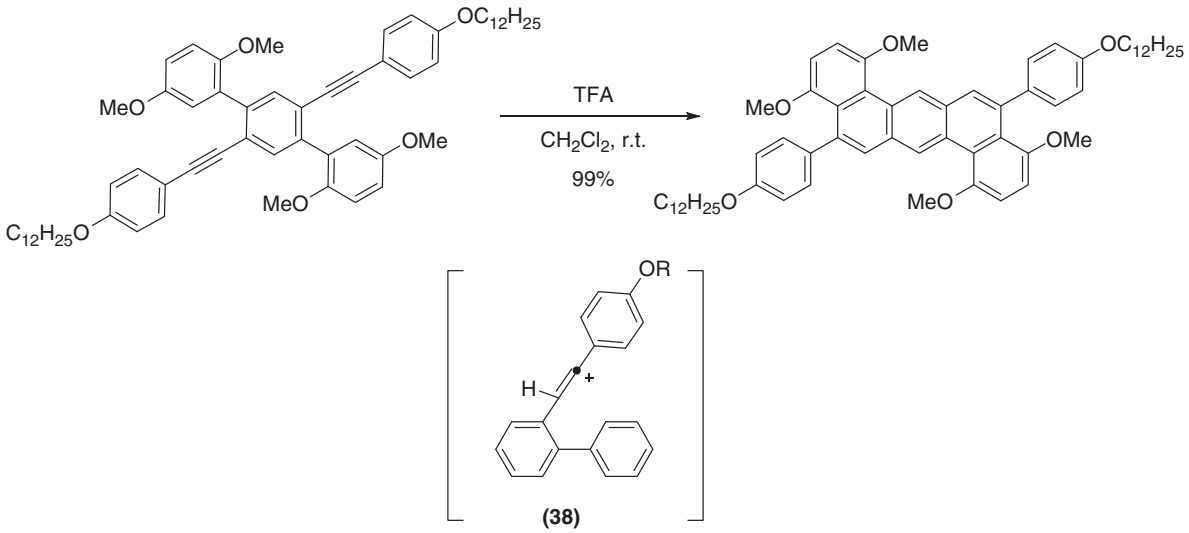
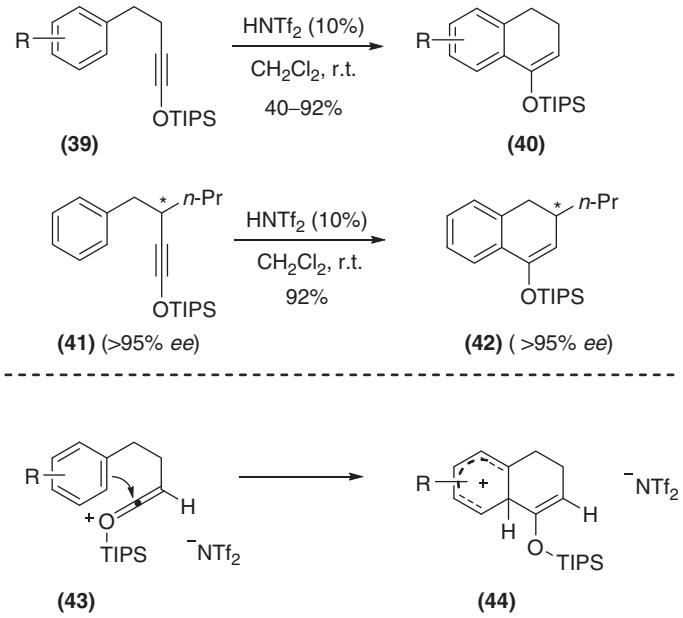
hydroxy group and the alkyne. In fact, when anisole reacted under the same conditions, a 1:1 mixture of *ortho*- and *para*-phenylethenylanisoles was obtained.[54]

5.33.2.2.1 Brønsted acid-catalyzed hydroarylation of alkynes

Brønsted acids can also efficiently catalyze the intermolecular hydroarylation of aryl-substituted alkynes with benzene derivatives. In the presence of TFA in dichloromethane and without any metal catalysts or additives, electron-rich arenes coupled with aryl-substituted alkynes to give 1,1-diarylalkenes in moderate-to-high yields (Scheme 23).[55]



Ar = Pentamethylbenzene, xylene, mesitylene...



Scheme 23

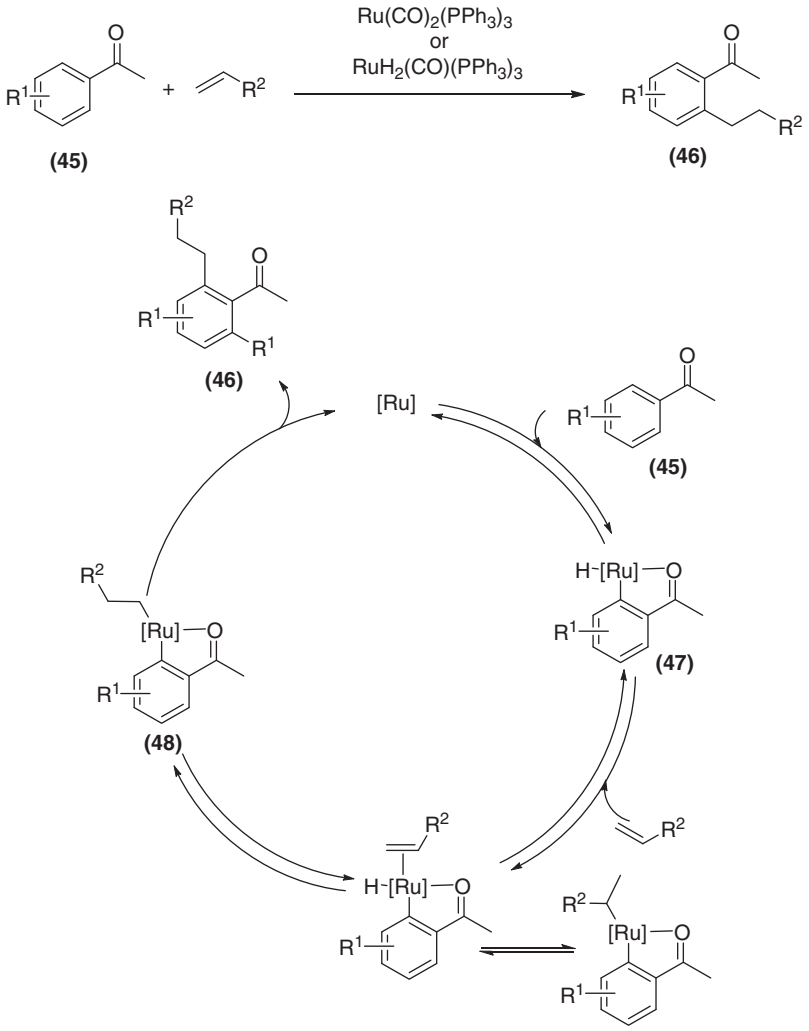
TFA has also been used to promote the synthesis of fused polycyclic aromatics (Scheme 24).[56,57] The presence of strong donors on the arylalkyne is critical for the success of the reaction. This is consistent with the formation of alkenyl carbocation species **38**. Selective electrophilic attack at the alkynylic moiety is driven by the stabilization provided by the *p*-alkoxy directing group. The cyclization then proceeds by Friedel–Crafts type reaction. Although the protic acid-promoted process is, in principle, catalytic, as the last step is a proton loss, the reactions are driven to completion in the presence of a large excess of acid.

An intramolecular hydroarylation of triisopropylsiloxyalkynes **39** catalyzed by Tf_2NH was reported by Kozmin to give silyl enol ethers **40** (Scheme 25).[58] In addition, $AgNTf_2$ also catalyzed the reaction, although with lower efficiency. A possible mechanism involving a [3,3]-sigmatropic rearrangement and electrocyclic ring closure was excluded, as optically active **41** (>95% *ee*) was cleanly transformed into **42** with full retention of configuration. The reaction most likely proceeds by protonation of the alkyne to form a ketenium ion **43**, which then reacts with the arene to give Wheland intermediate **44**.

Scheme 24

Scheme 25

5.33.3 Hydroarylation of Alkenes



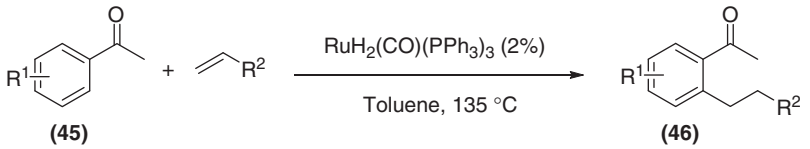
The addition of aromatic rings across alkenes is an atom-economic approach to synthesize alkylated arenes or heteroarenes, which are important structural motifs commonly found in many pharmaceuticals, agro-, and fine chemicals.[59] Two major reaction types can be used to achieve these transformations. Traditionally, Lewis (or Brønsted) acid Friedel–Crafts catalysis has been employed to make simple alkyl arenes.[60] This reaction takes place with electron-rich arenes and selectively affords branched adducts. However, this method suffers from several drawbacks including the propensity toward polyalkylation, the lack of regioselectivity for disubstituted arenes or the inability to recycle the catalyst, among others.[61] In recent years, transition metal-catalyzed hydroarylations through C–H bond activation have grown exponentially due to their high selectivity, efficiency, and environmental friendliness. These systems usually require a directing group or other electronic perturbation (electron-withdrawing groups) on the arene and preferentially afford the linear products due to the steric factors governing the insertion of the double bond into the M–H bond.[1a]

5.33.3.1 Transition Metal-Catalyzed Hydroarylation of Alkenes

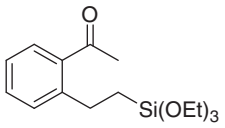
5.33.3.1.1 Ruthenium-catalyzed hydroarylation of alkenes

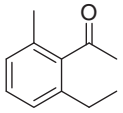
5.33.3.1.1.1 Intermolecular hydroarylations

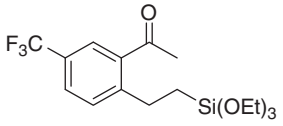
Murai's group pioneered the use of ruthenium catalysts such as $RuH_2(CO)(PPh_3)_3$ or $Ru(CO)_2(PPH_3)_3$ to activate the C–H bond at the *ortho*-position of aromatic ketones **45** triggering the addition of olefins to form aryl-alkanes **46** in nearly quantitative yields.[62] The key for the success of this reaction relies on the chelation assistance of the directing carbonyl group. The low-valent ruthenium complex coordinates to the C═O, enabling the subsequent cleavage of the adjacent aromatic C–H bond to give aryl-ruthenium complex **47** (Scheme 26). Coordination of the olefin in **47** is followed by addition of the Ru–H bond across the double bond to give intermediate **48**. Reductive elimination leads the final alkylated product **46** (Scheme 26).

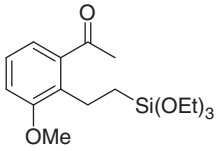


Scheme 26





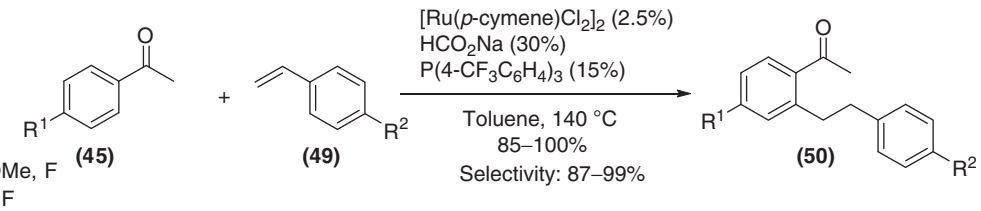




The scope of this transformation has been extensively investigated (Table 2). Olefins such as ethylene, *tert*-buthylethylene, vinylsilanes, and 1,1-disubstituted olefins were efficiently hydroarylated. In contrast, alkenes with allylic hydrogens rapidly isomerize affording the desired product in low yield.[63] Aromatic and heteroaromatic ketones with electron-donating and electron-withdrawing groups were well tolerated.[64] Aromatic substrates bearing an ester group and an electron-withdrawing group at the *meta*-position, could also participate in a chelation-assisted C–H/olefin coupling.[65] Other directing groups in the aromatic ring such as imines,[66] nitriles,[67] and aldehydes[68] have been successfully employed.

The reaction selectivity has also been studied in depth. *meta*-Substituted acetophenones **45** with two different reaction sites undergo C–H activation in the less congested position. However, when the substituent in the *meta*-position is a methoxy group, the C–C bond formation takes place at the sterically less favorable *ortho*-position due to electronic interaction between the oxygen lone pair and the ruthenium.[69]

Table 2 Ruthenium-catalyzed hydroarylation of olefins with aromatic ketones



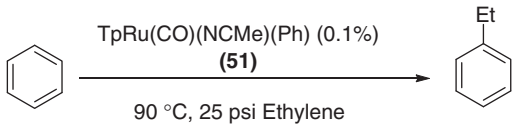
(45) (46)

R^1	R^2	Product	Yield (%)
H	$Si(OEt)_3$		75
o-Me	H		66
m-CF_3	$Si(OEt)_3$		82
m-OMe	$Si(OEt)_3$		100

When $RuH_2(H_2)_2(PCy_3)_2$ was used as catalyst by Chaudret[70] and Leitner,[71] the hydroarylation of olefins occurred at room temperature. Moreover, the alkylation of acetylpyridine,[72] 2-aryl pyridine,[73] and *N*-methylanilines[74] catalyzed by $RuH_2CO(PPh_3)_2$ and $Ru(CO)_{12}$, respectively, has also been reported.

The hydroarylation of styrenes **49** with *para*-substituted acetophenones **45** catalyzed by dimeric $[Ru(p\text{-cymene})Cl_2]_2$ complex has also been reported by Darses and coworkers. AntiMarkovnikov adducts **50** were obtained in a straightforward manner involving regioselective C–H bond activation (**Scheme 27**).[75]

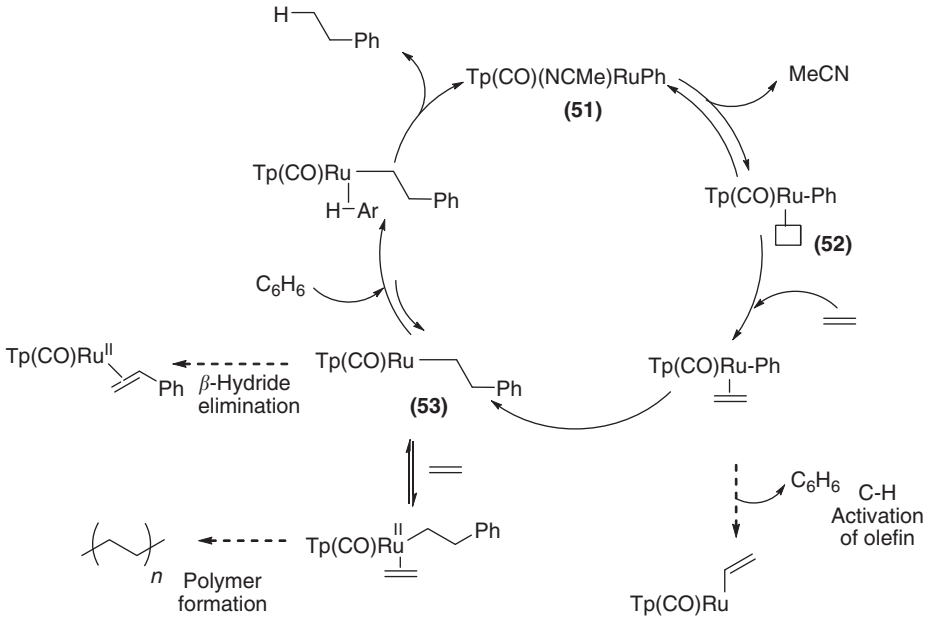
(45) (49) (50)



R^1= H, Me, OMe, F
R^2= H, OMe, F

Scheme 27

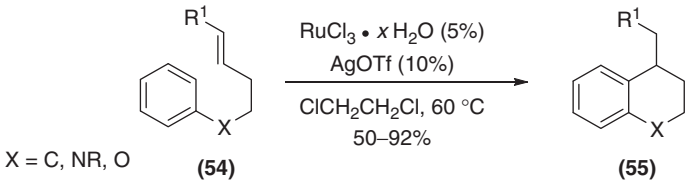
These reaction conditions have been efficiently applied to the hydroarylation of vinylsilanes using isopropanol as an inexpensive and nontoxic solvent, which constituted the first Csp^2–H activation under protic conditions with low-valent ruthenium complexes.[76] The same group reported the addition of olefins into aromatic ketones and Michael acceptors catalyzed by ruthenium trichloride.[77]



Mechanistic studies of this transformation carried out by Murai[63,67,78] and others,[79] revealed that the C–C bond formation is the rate-limiting step and the H/D exchange occurred only at the *ortho*-position highlighting the importance of the chelation assistance in the C–H bond cleavage by the ruthenium species.

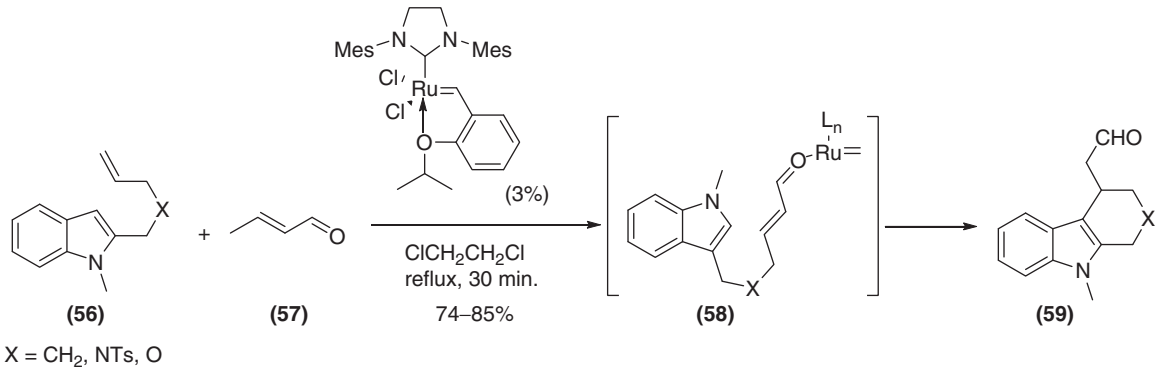
In 2003, Gunnoe and coworkers reported the first hydroarylation of olefins catalyzed by Ru(II) complex without chelating groups.[80] Under nitrogen atmosphere, the combination of 0.1 mol% of TpRu(CO)(NCMe)(Ph) **51** in dry benzene under 25 psi of ethylene at 90 °C resulted in the formation of ethylbenzene (equation 1). Fifty one turnovers of the catalyst were achieved in 4 h, with minimal quantities of 1,3- and 1,4-diethylbenzene products.

(1)



The reaction mechanism of this transformation is depicted in Scheme 28. Acetonitrile decoordination in **51** generates complex **52**, which undergoes olefin insertion leading to intermediate **53**. Subsequent C–H activation of the arene allows the elimination of alkyl benzene and the catalyst is recovered. Quantum mechanical calculations support this mechanistic proposal.[81] Labeling experiments in the hydrophenylation of ethylene with C_6H_6 and C_6D_6 showed a kinetic isotope effect of 2.1 suggesting that benzene C–H activation is the rate-limiting step of the reaction.[82] In addition, the rate of the catalyst is reduced with increasing ethylene pressure supporting that TpRu(CO)(CH_2CH_2Ph)(η^2-C_2H_4) is the catalyst's resting state.

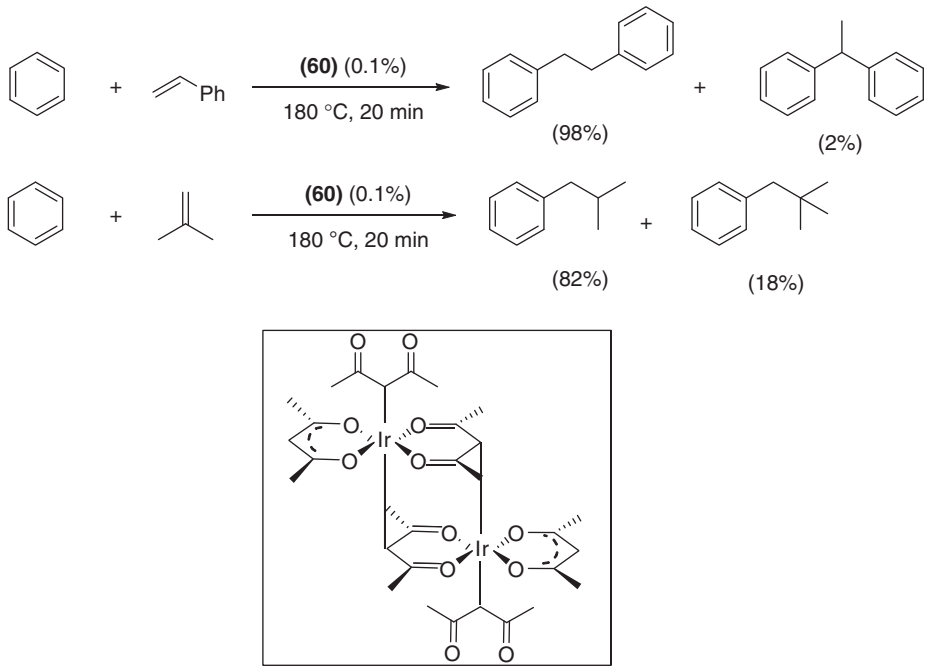
Scheme 28



5.33.3.1.1.2 Intramolecular hydroarylations

The intramolecular hydroarylation of a broad range of arene-ene substrates **54** catalyzed by $RuCl_3$/AgOTf under mild conditions was reported by Sames and coworkers in 2004.[83] This transformation provides, in good-to-excellent yields, chromanes, tetralins, terpenoids, dihydrocoumarins, and indolocyclohexane and cyclopentane systems **55** (Scheme 29). A mechanism involving π-alkene activation, C–C bond formation and protonation of the C–Ru intermediate has been proposed to explain the observed reactivity.

Scheme 29



A very efficient ruthenium alkylidene-catalyzed tandem cross-metathesis/intramolecular hydroarylation reaction of ω-indolyl alkenes **56** with electron-deficient alkenes **57** led to structurally complex tetrahydrocarbazoles **59** through intermediate **58** (Scheme 30).[84]

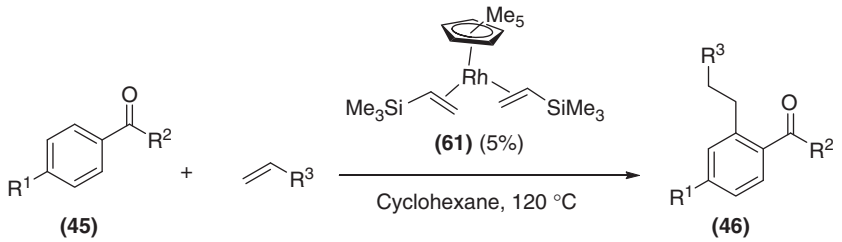
Scheme 30

5.33.3.1.2 Iridium-catalyzed hydroarylation of alkenes

Periana and coworkers reported an Ir(III)-catalyzed alkylation reaction of arenes[85] in which, as in the case of Ru or Rh complexes, antiMarkovnikov adducts were selectively obtained using [Ir(μ-acac-*O,O*)-(acac-C^3)]$_2$ (**60**) as catalyst (Scheme 31).

[Ir(μ-acac-O,O′,C^3)(acac-O,O′)(acac-C^3)]$_2$ **(60)**

Scheme 31



Experimental evidence and DFT calculations suggest that monomeric Ir complexes are the active catalysts in this transformation.[86] The reaction mechanism is similar to the one proposed for ruthenium systems although in this case, the rate-determining step is proposed to be the olefin insertion rather than the reductive elimination step. As with Ru(II) catalysts, an increase in the donor ability of the ancillary ligands is consistent with an increased rate of benzene C–H activation. In contrast, increasing the electron density on the metal (Ru or Ir) increases the activation barrier for olefin insertion.[87]

5.33.3.1.3 Rhodium-catalyzed hydroarylation of alkenes

5.33.3.1.3.1 Intermolecular hydroarylations

The hydroarylation of olefins with aromatic ketones **45** to give *ortho*-alkylation products **46** using bis-olefin rhodium complex [$C_5Me_5Rh(C_2H_3SiMe_3)_2$] (**61**) has also been reported (Table 3).[88] As for the analogous Ru-catalyzed process, a high anti-Markovnikov regioselectivity is observed. However, although in the ruthenium protocol the carbonyl coordination is presumed to occur first, allowing the C–H activation at the *ortho*-position, in the rhodium case there is no discrimination between the Csp^2–H

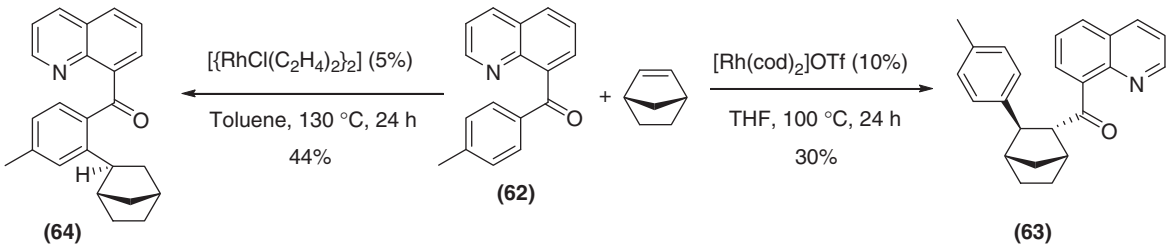


Table 3 Hydroarylation of olefins catalyzed by bis-olefin-rhodium complexes

R^1	R^2	R^3	*Conversion (%)*

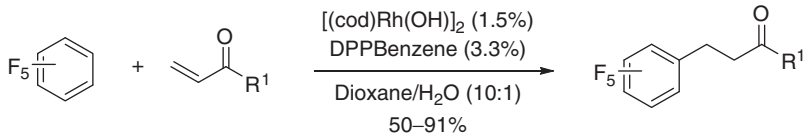
H	Ph	C_3H_7	60
H	Ph	OEt	10

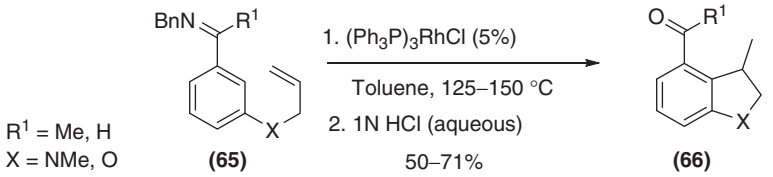


bonds of the aromatic ring and activation of all sites (*meta*, *ortho*, and *para*) is observed. In both processes though, the reductive elimination seems to be the rate-determining step.

A $[\{RhCl(C_2H_4)_2\}_2]$-catalyzed addition of quinolines **62** to olefins was reported by Douglas and coworkers.[89] Interestingly, by controlling the reaction conditions exclusive C–C or C–H activation can be selected to form hydroacylation or hydroarylation products **63** and **64**, respectively (**Scheme 32**). The $RhCl(PPh_3)_3$-catalyzed alkylation of arylpyridines[90] and aromatic imines[91] with olefins has also been realized.

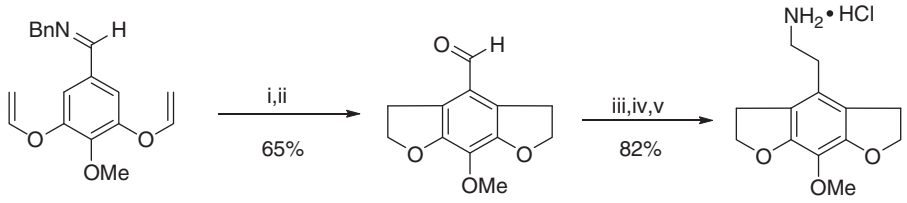
Scheme 32

In addition, an effective Rh-catalyzed coupling between highly fluorinated and α,β-unsaturated carbonyl derivatives to form the antiMarkovnikov alkylated products in high yields has also been disclosed (**Scheme 33**).[92]



R^1 = OEt, OBu, OBu^i, OBu^t, Me, Et, NMe_2, NH_2

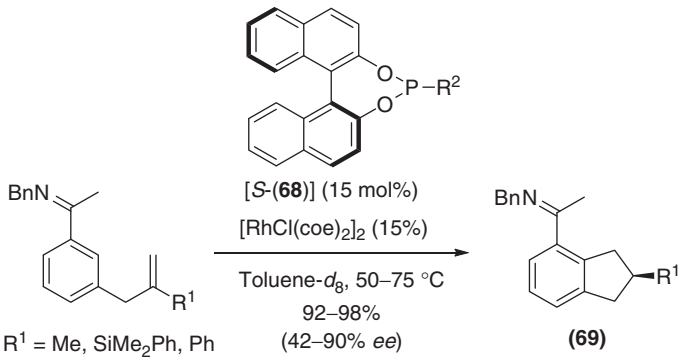
Scheme 33



5.33.3.1.3.2 Intramolecular hydroarylations

The annulation of aromatic imines or aldimines **65** in which the alkene is tethered *meta* to the directing group, led to functionalized indane, tetralanes, dihydrobenzofurans, and dihydroindoles **66** in the presence of Wilkinson's catalyst (**Scheme 34**).[93] The coupling proceeds selectively to the more hindered *ortho*-site to provide functionalized bicyclic systems **66**. Linear or branched coupling products were obtained depending on the length of the alkene tether. This annulation strategy has been applied in the total synthesis of tetrahydrobis(benzofuran) mescaline analog **67** (**Scheme 35**).[94]

An asymmetric variant of this protocol has also been developed in one of the first examples of highly enantioselective catalytic hydroarylation of alkenes through aromatic C–H bond activation.[95] The combination of $[RhCl(coe)_2]_2$ and chiral

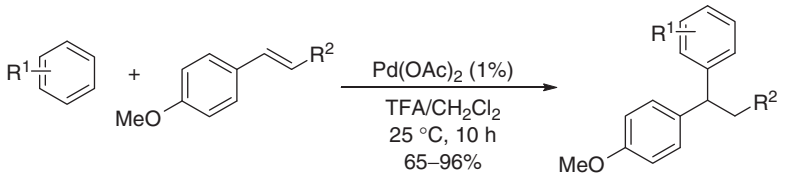


Scheme 34

i, $[RhCl(coe)_2]_2$ (10%), $FcPCy_2$ (20%), toluene, 150 °C, 2 h; ii, 1 N HCl, 3 h; iii, $MeNO_2$, NaOAc, AcOH, reflux; iv, $LiAlH_4$, THF, 23 °C; v, HCl, Et_2O

Scheme 35

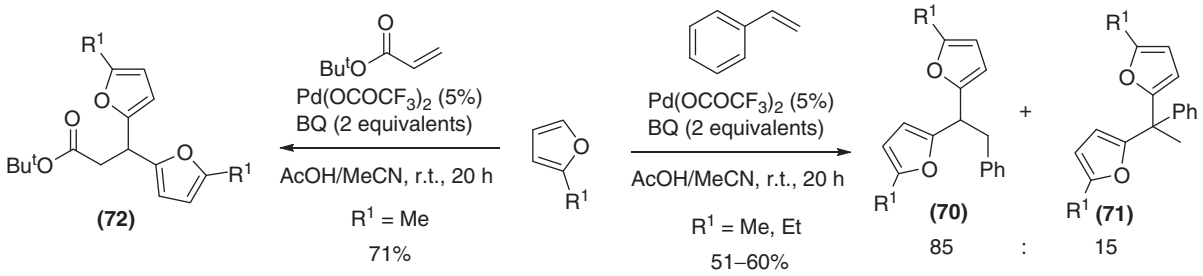
(*S*)-binol-derived phosphoramidite ligands [*S*-(**68**)] afforded the corresponding cyclic adducts **69** in excellent yields and moderate-to-good enantioselectivities (Scheme 36).



Scheme 36

5.33.3.1.4 Palladium-catalyzed hydroarylation of alkenes

Electrophilic Pd(II) cationic species, analogous to the ones reported for the hydroarylation of alkynes (Section 5.33.2.1.1) were used by Fujiwara's group to trigger a regioselective addition of alkoxyarenes to activated alkenes in TFA.[2a] $Pd(OAc)_2$ and $Pd(PPh_3)_2(O_2CCF_3)_2$ were equally active, whereas Pd(0) species such as $Pd(PPh_3)_4$ were much less efficient, indicating that the reaction may not involve Pd(0) species in the catalytic cycle (Scheme 37).



A palladium-catalyzed coupling of 2-alkylfurans with olefins in a mixture AcOH/MeCN has also been described.[96] Allylarenes and styrenes led to the formation of *β*,*β*-difurylalkanes (**70** and **71**) as major products, whereas acrylates afforded *β*,*β*-difurylesters (**72**) in high yields (Scheme 38).

ESI–MS spectrometry and labeling experiments support the reaction mechanism shown in Scheme 39. Two consecutive C–H bond activations in the 2-alkylfurans by L_2PdX_2 species followed by insertion of the olefin delivers alkyl-Pd(II) complexes **73**. These intermediates undergo *β*-elimination and insertion to form the new alkyl-Pd(II) complexes **74**. Reductive elimination affords the difurylalkanes **70**. Oxidation of the resulting Pd(0) with benzoquinone and AcOH regenerates the active catalytic species (Scheme 39).

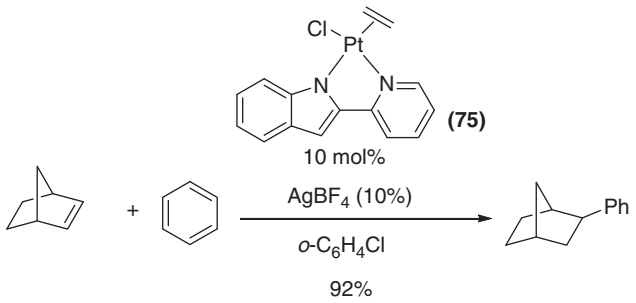
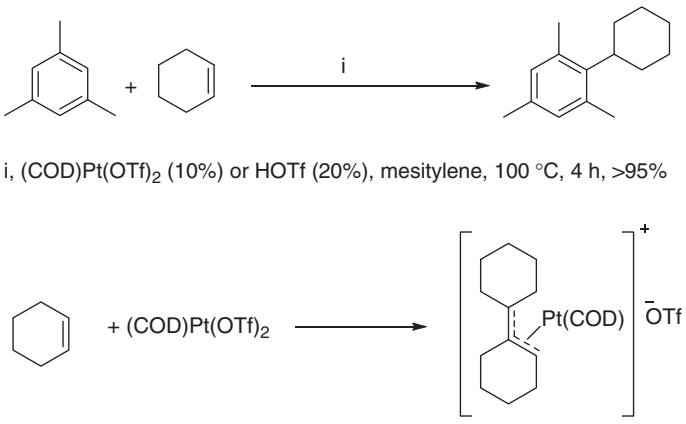
Scheme 37

Scheme 38



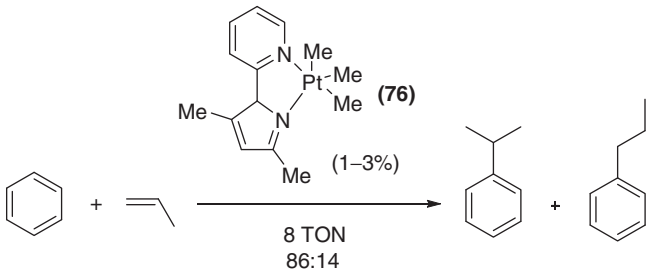
Scheme 39

5.33.3.1.5 Platinum-catalyzed hydroarylation of alkenes



5.33.3.1.5.1 Intermolecular hydroarylations

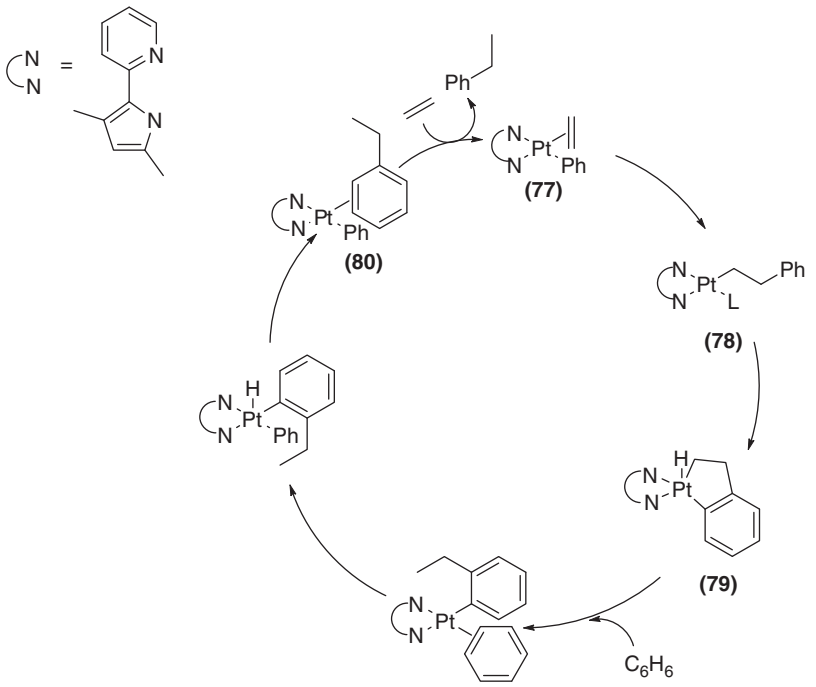
Platinum(II) complexes have shown an excellent ability to catalyze the hydroarylation of olefins. The combination of Pt-Ag ({2-(2-pyridyl)indole}Pt(Cl)(η^2-C_2H_4) **75** and AgOTf or $AgBF_4$) has been applied in the hydroarylation of unactivated alkenes such as norbornene, 2-butene, propylene, cyclopentene, or cyclohexene with benzene to give the corresponding aryl-alkanes in good yields (equation 2).[97] The reaction is regioselective affording exclusively *iso*-propylbenzene when 1-propene was used, which points toward a Friedel–Craft type alkylation pathway. Other cationic platinum systems such as the combination of (^{t}bpy)Pt(Ph)Cl and $NaBAr'_4$ have been investigated in this context.[98]



(2)

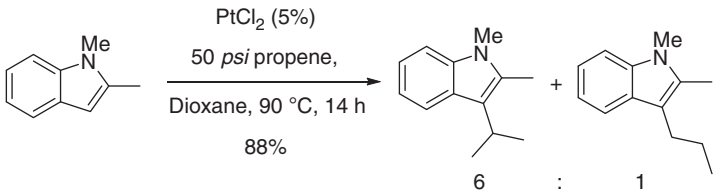
Dicationic platinum(II) complexes such as [Pt(PNP)(C_2H_4)(SbF_6)$_2$] are electrophilic enough to react with aromatic rings activated by electron-donating substituents.[99] Recently, Tilley and Bergman have gathered evidence for a Friedel–Crafts alkylation mechanism in which the acid generated by interaction between the cationic platinum species and the alkene is the active catalyst of the reaction (**Scheme 40**).[100]

Scheme 40



Neutral platinum(II) species with monoanionic 2-(2-pyridyl)pyrrolidine ligands (**76**) have been applied in reactions with unactivated arenes affording Markovnikov aryl alkane products in a regioselective manner (equation 3).[101] However, *para*-substituted arenes afforded a complex mixture of *ortho*-, *meta*-, and *para*-regioisomers.

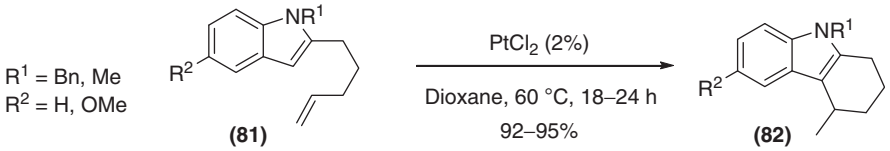
(3)



Mechanistic studies including deuterium-labeling experiments were consistent with a reaction pathway involving the olefin insertion into the Pt(II)-aryl bond (**78**) followed by C–H activation at the Pt(II) center to form cyclometalated Pt-H intermediate **79**.[102] Subsequent C–H reductive elimination followed by coordination of a new molecule of benzene and Csp^2–H bond

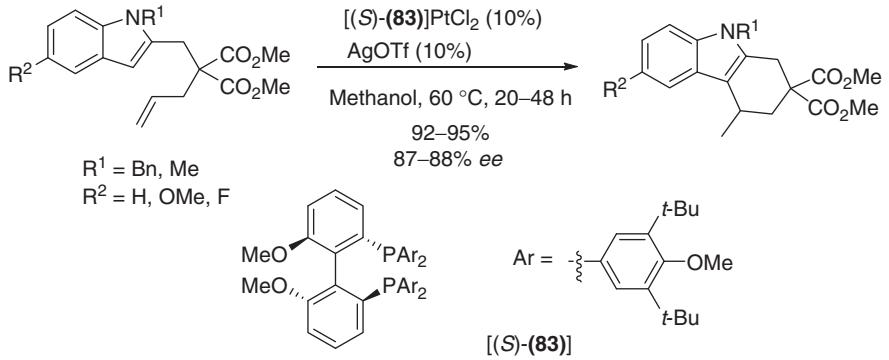
activation leads to platinum species **80**. On ethylbenzene ligand exchange in the presence of ethylene, the arylalkane is formed and the catalytic specie **77** is regenerated (Scheme 41).

Scheme 41



The addition of indoles to ethylene, α-olefins, and styrenes catalyzed by platinum dichloride has been reported.[103] This system affords the Markovnikov adducts as major products in the reaction mixture (equation 4).

(4)

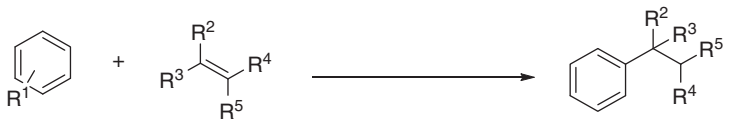


5.33.3.1.5.2 *Intramolecular hydroarylations*

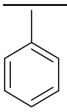
In a related example to the one shown in equation 4, Widenhoefer's group has developed an intramolecular alkylation of C2-substituted indoles **81** catalyzed by $PtCl_2$.[103b,104] The hydroarylation reaction was carried out in dioxane, which contained a trace of HCl (5 mol%) to lead to the corresponding tricyclic products **82** in excellent yields (Scheme 42).

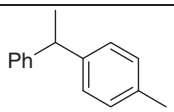
Scheme 42

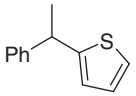
A 1:1 mixture of platinum bis(phosphine) complex [(*S*)-(**83**)]$PtCl_2$ ([(*S*)-(**83**)]= (*S*)-3,5-*t*-Bu-4-OMe-MeOBIPHEP) and silver triflate catalyzed the asymmetric version of this reaction (Scheme 43).[105] The enantioselective hydroarylation of disubstituted internal olefins in these systems was recently reported by Peters and coworkers.[106]

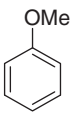


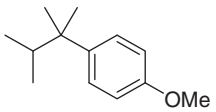
Scheme 43

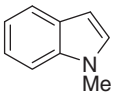


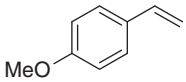


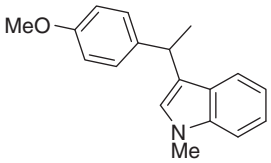


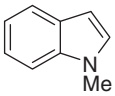


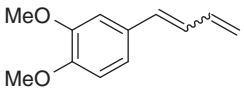


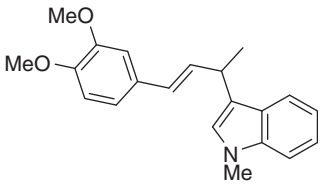










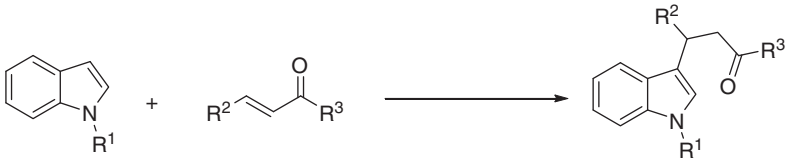


5.33.3.1.6 Gold-catalyzed hydroarylation of alkenes

5.33.3.1.6.1 Intermolecular hydroarylations

Gold(I) and gold(III) complexes combined with silver salts catalyze the addition of electron-rich arenes to olefins.[107] Substituted styrenes as well as unactivated aliphatic olefins and dienes were successfully hydroarylated as summarized in **Table 4**. The hydroarylation reaction with indoles was limited to *N*-phenylsulfonyl-protected ones when a $AuCl_3$/AgOTf catalytic system was applied.[108] However, the reaction can also be catalyzed by cationic gold(I) species ([(PR_3)PAuCl/AgOTf]) to give C-3 alkylated indoles with Markovnikov selectivity in thermal and microwave assisted conditions.[109]

Table 4 Gold-catalyzed hydroarylation of alkenes



Arene	*Alkene*	*Conditions*	*Selectivity (p-;o-)*	*Major product*	*Yield (%)*

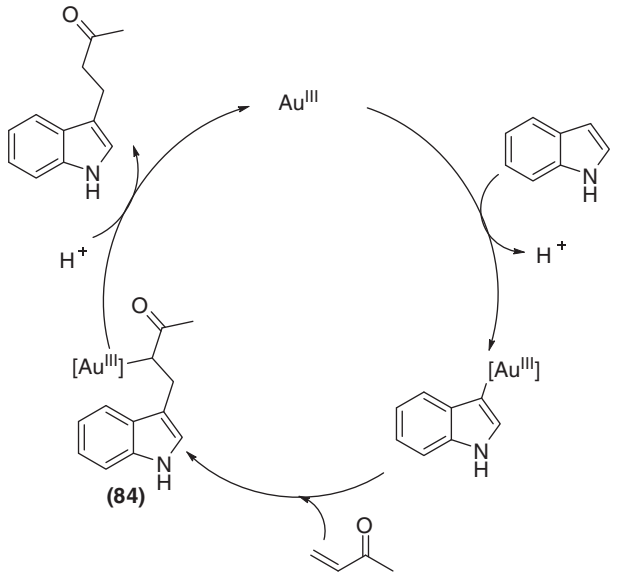
		PPh_3AuCl (5%), AgOTf (15%), toluene, 70 °C, 16 h			81

Gold(III) complexes have shown an exceptional activity in the conjugate addition of arenes and heteroarenes across α,β-unsaturated carbonyl compounds.[110] Complexes such as $NaAuCl_4 \cdot 2\ H_2O$[111] or $AuCl_3$[112] have been successfully employed in the



hydroarylation of substituted and unsubstituted enones with indoles (Table 5). Interestingly, if the C-3 position of the indole is substituted, the substrate can undergo a C-2 alkylation.[111] The alkylation of less electron-rich azaindoles[113] and a gold(III)-catalyzed one-pot reaction of 2-alkynyl-phenylamines with α,β-enones to form C-3-alkyl-indoles by sequential reactions such as cyclization/alkylation, *N*-alkylation/cyclization, or *N*-alkylation/cyclization/alkylation have also been developed.[114]

Table 5 Conjugate addition of indoles to α,β-unsaturated ketones

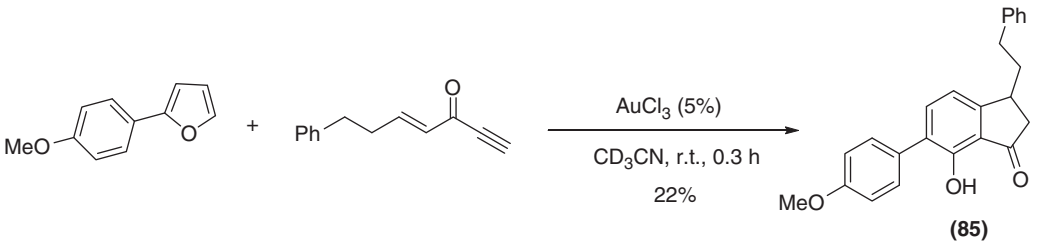
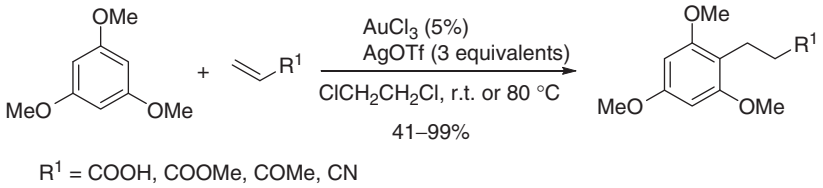
The regioselective auration of the indole at position 3 followed by a conjugate addition reaction to the electron-deficient alkene is suggested to yield alkyl–gold complex **84** (Scheme 44). On protodeauration of **84**, the alkylated indoles is obtained. This proposal is based on the detection of the arene aurated species $[indol\text{-}AuCl]^+$ by mass spectrometry (ESI–MS) in a stoichiometric reaction between the indole and $NaAuCl_4 \cdot H_2O$ in MeCN. However, a Friedel–Crafts type mechanism cannot be ruled out.



Scheme 44

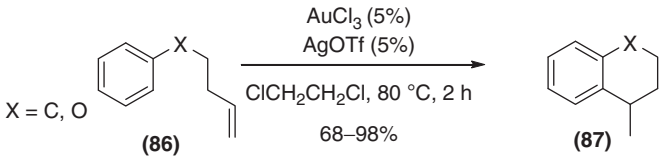
The gold-catalyzed addition of furans to α,β-enones was first reported by Hashmi[115,116] and further developed by Urriolabeitia, Contel, and coworkers (equation 5).[117,118] This reaction was also catalyzed by Brønsted acids such as *p*-TsOH and HCl, although the latter systems displayed different selectivities than the gold-catalyzed processes. The gold(III)-catalyzed addition of pyrroles to methyl vinyl ketones was studied, although the high reactivity of the pyrrole led to multiple substitution products and a selective pyrrole's substitution could not be achieved.[119]



(5)

Addition of furans to electron-deficient olefins catalyzed by gold followed by cycloisomerization delivered highly substituted phenols **85** in relatively low yields, which are nevertheless comparable to those obtained from known multistep-routes (equation 6).[120]

(6)



The addition of electron-rich arenes to α,β-unsaturated ketones in the presence of catalytic amounts of $AuCl_3$ and three equivalents of AgOTf gave the corresponding alkyl arenes in good yields. The silver salt is thought to help removing the chloride ions from the gold catalyst and generate a more electrophilic gold complex. The reaction was found to be compatible with a broad scope of Michael acceptors (Scheme 45).[12]

Scheme 45

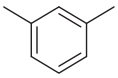
5.33.3.1.6.2 Intramolecular hydroarylations

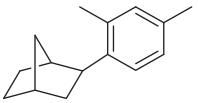
The combination of $AuCl_3$ with AgOTf catalyzed the intramolecular hydroarylation of olefins in a variety of functionalized arene derivatives **86** to form dihydrobenzopyrans, tetralins, and tetrahydroquinolines **87** in good yields (Scheme 46).[121]

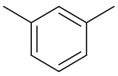
Scheme 46

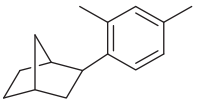
In addition, the gold(III)-catalyzed annulation of phenols and naphthols with dienes efficiently generated a broad scope of benzohydrofurans.[122] The presence of electron-donating groups on the arenes promoted the reaction whereas electron-withdrawing groups gave lower conversions. Furthermore, a gold(I)-catalyzed synthesis of phenanthrene and cyclohepta[*a*]-naphthalene skeletons through intramolecular hydroarylation of cyclic 5-(2-arylethyl)1,3-dienes has been recently reported.[123]

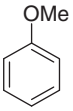
5.33.3.1.7 Other metals (Mo, W, Re, Fe, Co)-catalyzed hydroarylation of alkenes

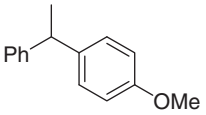


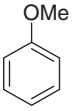


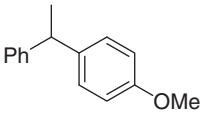




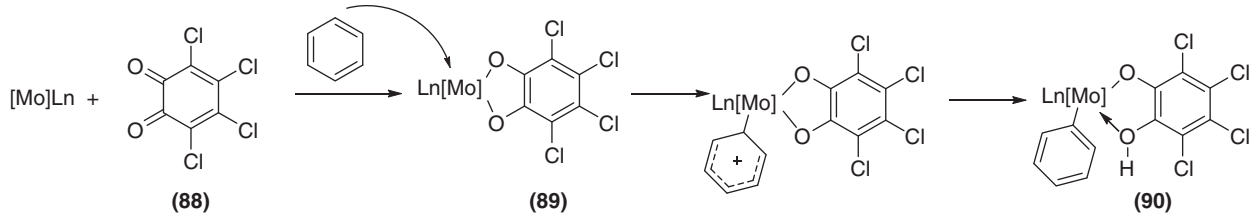






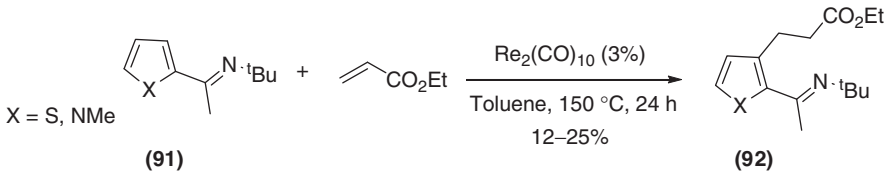


The combination of a molybdenum(II) complex ($[CpMoCl(CO)_3]$) and an organic oxidant (*o*-chloranil, **88**)[124] has been used in a Friedel–Crafts alkylation of norbornene and styrene to produce aryl-alkanes in moderate-to-high yields. The use of microwave irradiation at 150 °C afforded the hydroarylation products in comparable yields and shorter reaction times (Table 6).



Due to the Markovnikov- and *ortho*/*para*-selectivities, the authors propose the oxidation of the molybdenum complex by *o*-chloranil (**88**) to generate an intermediate molybdenum catecholate **89**. The electrophilic addition of the aromatic substrates gives **90**, a Brønsted acid catalytic species that behaves as a proton donor to trigger the arene alkylation (Scheme 47).

Tungsten(II) chlorocarbonyl complexes, obtained by photochemical oxidation of $W(CO)_6$ with CCl_4, are highly active catalysts for the transformation of alkenes to alkyltoluenes.[125] In addition, $[(CO)_4W(\mu\text{-}Cl)_3W(SnCl_3)(CO)_3]$ catalyzed an efficient addition of simples arenes, such as benzene, toluene, or *p*-xylene, to norbornene affording *exo*-2-aryl-norbornanes.[126]



The hydroarylation of acrylates with heteroaromatic aldimines **91** using $Re_2(CO)_{10}$ as catalyst has been reported.[127] However, the yields of the alkylated products **92** were very low and the reactions afforded complex mixtures (Scheme 48).

Table 6 [CpMoCl(CO)$_3$]/*o*-chloranil-catalyzed hydroarylation of alkenes with arenes

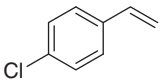
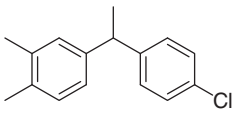
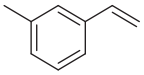
Scheme 47

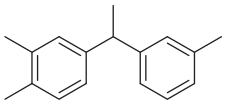
Scheme 48

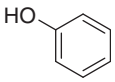
An easy and efficient synthesis of 1,1-diarylalkanes and 1-aryl-1-heteroarylalkanes was attained by hydroarylation of styrenes with electron-rich arenes and heteroarenes catalyzed by $FeCl_3$ (Table 7).[128] This transformation is especially attractive due to the cheap and easy-to-handle catalyst.

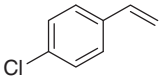


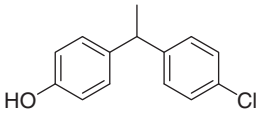


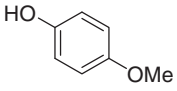


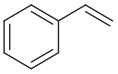


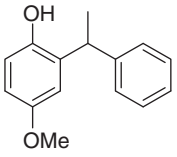






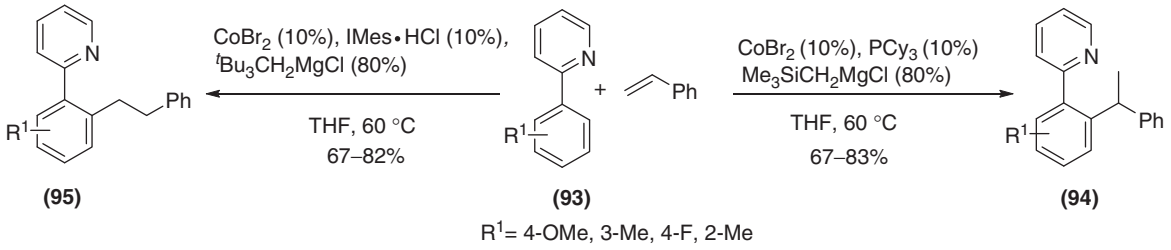






In analogy to the cocatalyzed hydroarylation of alkynes described in Section 5.33.2.1.2, the cobalt-catalyzed hydroarylation of styrenes with 2-arylpyridine derivatives **93** and aryl imines has also been reported.[129] Interestingly, the branched and the linear adducts could be obtained selectively by ligand control. A cobalt-catalyst generated from $CoBr_2$ (10 mol%), PCy_3 (10 mol%) and Me_3SiCH_2MgCl (80 mol%) in THF at 60 °C afforded the branched product **94** whereas, when the reaction was carried out with IMes · HCl instead of PCy_3, the linear adduct **95** was regioselectively obtained (Scheme 49).

5.33.3.2 Nontransition Metal-Catalyzed Hydroarylation of Alkenes



Friedel–Crafts hydroarylation processes are usually assisted by either protic acid or Lewis acids. On the basis of the reaction mode, these transformations can be divided into (1) reactions of arenes with normal alkenes via carbocation-like intermediates or (2) reactions of electron-deficient alkenes via Michael-type 1,4 addition.

The Friedel–Crafts alkylation of arenes with alkenes was previously reviewed in this series.[60] The C-3 alkylation of indoles with suitable Michael acceptors catalyzed by Lewis acids such as ytterbium triflate ($Yb(OTf)_3$)[130] or indium tribromide ($InBr_3$)[131] was reported by Kerr and Umani-Ronchi, respectively. A variety of Michael acceptors such as α,β-unsaturated ketones or esters and nitroalkenes afforded the alkylated indoles in moderate-to-good yields. These reactions are easily performed and remarkably

Table 7 $FeCl_3$-Catalyzed hydroarylation of styrenes[a]

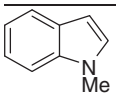
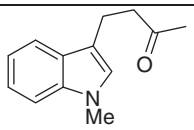
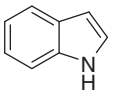
Scheme 49

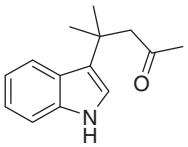
tolerant of substituents at different positions of the indole ring (Table 8). The addition of electron-rich arenes and heteroarenes to β-nitrostyrenes could also be mediated by aluminum trichloride in dichloromethane at −78 °C.[132]

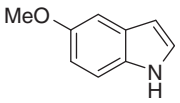
Bismuth(III) chloride and bismuth(III) triflate have also been reported to catalyze the hydroarylation of styrenes with electron-rich arenes to give Markovnikov adducts in good yields (equation 7).[133]

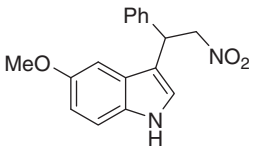


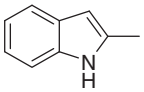


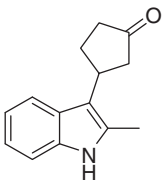


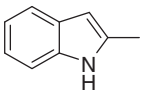


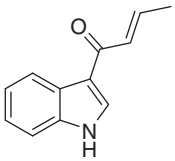


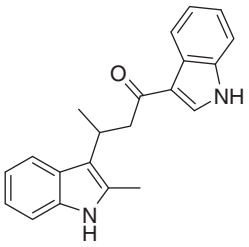




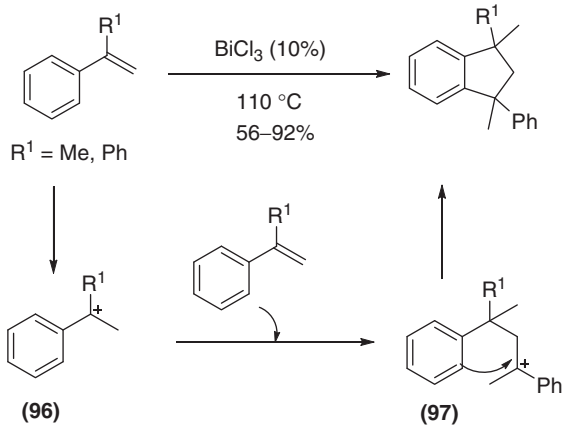








(7)



In these systems, the excess of α-substituted styrenes underwent inter- and intramolecular double hydroarylation as a result of styrene dimerization under the reaction conditions (Scheme 50). Such dimerization may proceed through an intermolecular ene-reaction between styrene and the carbocationic intermediate **96** followed by an intramolecular Friedel–Crafts alkylation of the resulting carbocationic 1,3-diarylpropane **97**. Intramolecular olefin hydroarylations catalyzed by Bi(III) triflate have also been reported.[134]

A highly efficient calcium-catalyzed intermolecular hydroarylation of aryl and aliphatic olefins was reported by Niggemann in 2010.[135] The hydroarylation of di- and trisubstituted styrenes, cyclic, and linear dienes as well as cyclic trisubstituted alkenes was found to proceed smoothly at room temperature in the presence of the highly reactive $Ca(NTf_2)_2/Bu_4NPF_6$ system. Free phenolic hydroxyl groups, furans, and thiophenes were well tolerated (Table 9).

Molecular iodine (I_2) has been applied as catalyst in the hydroarylation of styrenes with electron-rich arenes and heteroarenes under solvent-free conditions.[136] The reaction favors the Markovnikov adduct although in several cases mixture of regioisomers were observed (Scheme 51).

5.33.3.2.1 Brønsted acid-catalyzed hydroarylations

Strong acids have long been known to catalyze reactions involving alkenes.[60] When an alkene is mixed with a strong acid, the proton is transferred to the double bond affording a very reactive carbocation intermediate, which can react with external nucleophiles such as electron-rich arenes. The reaction affords Markovnikov adducts as the proton is added to the less substituted carbon of the double bond, leading the stabilized positive charge at the more substituted carbon atom.

Table 9 Hydroarylation of alkenes catalyzed by $Ca(NTf_2)_2/Bu_4NPF_6$

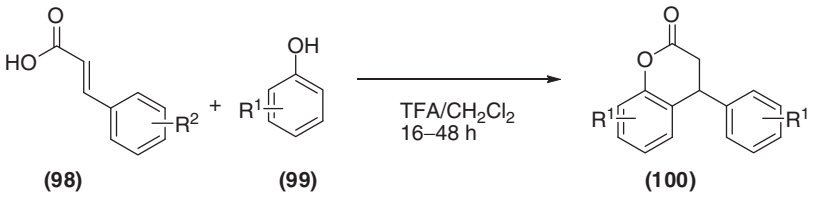
Scheme 51



The hydroarylation of electron-deficient alkenes has been investigated with various Brønsted acids such as TFA and *p*-toluenesulfonic acid. TFA enabled the synthesis of dihydrocoumarins (**100**) in excellent yields under very mild conditions from cinnamic acid derivatives **98** and phenols **99** (Table 10).[137] Nonactivated cinnamic acids required elevated reaction temperatures to achieve good yield. The reaction was regioselective when unsymmetrical 3-methyl-4-chlorophenol was used. In this case, the cyclohydroarylation led the product of addition at the less substituted *ortho*-carbon. An intramolecular version of this reaction starting from aryl cinnamates was also successfully developed.

In contrast, the synthesis of dihydroquinolones (**102**) could only be obtained by an intramolecular hydroarylation of aryl cinnamides (**101**) (Scheme 52).

p-Toluenesulfonic acid can also mediate the synthesis of dihydrocoumarins and the hydroarylation of anisole with cinnamic acid derivatives to form 3-(4-methoxyphenyl)-3-phenylpropanoic acids.[138] Hydroarylations of styrenes in heterogeneous fashion using Amberlyst-15[139] and $KHSO_4$[140] have also been reported.

Asymmetric Friedel–Crafts reactions involving nitroolefins mediated by chiral Brønsted acids have been investigated due to the versatility of the nitro functional group (Table 11). The first catalytic enantioselective addition of indoles to nitroalkenes was reported by Ricci and coworkers in 2005.[141] The reaction was catalyzed by thiourea derivative **103** and moderate-to-good yields and enantioselectivities were obtained. The catalytic process involves nitroalkene activation by the two NH hydrogen atoms of the thiourea and a weak hydrogen bonding between the indolic proton and the oxygen of the hydroxyl group. Other organocatalysts such as chiral-bis-sulfonamides **104**,[142] bis-arylthiourea **105**,[143] protonated quinolinum thioamide **106**,[144] and chiral phosphoric acid **107**[145] were successfully used affording the alkylated indoles in a highly enantioselective manner. In addition to indoles, the asymmetric addition of 1- and 2-naphthols to nitroalkenes has also been reported by employing the chiral Brønsted acid **108**.[146]

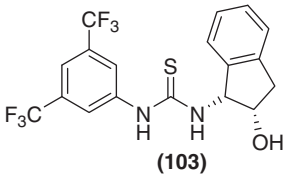
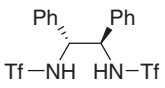


Scheme 52

Asymmetric Friedel–Craft reactions between indoles or 2-naphthols and α,β-unsaturated carbonyl compounds have been successfully described using Brønsted chiral acids.[147–151]



The hydroarylation of unactivated alkenes with anilines has attracted considerable attention in recent years. Thus, the *ortho*-alkylation of anilines with styrenes has been investigated by various groups. Hart and Kosak found aniline could be *ortho*-alkylated to 2-(*sec*-phenethyl)aniline at 220 °C in 82% yield in the presence of aniline hydrochloride and excess of styrene and aniline.[152] Bergman and Arnold applied $[PhNH_3][B(C_6F_5)_4]$ as catalyst in the hydroamination and hydroarylation of several styrene derivatives with anilines.[153] *Ortho*-alkylation of substituted anilines with styrene catalyzed by TFA was reported by Coates and coworkers in 2005 (**Scheme 53**).[154] The *ortho*-alkylation of anilines combined with chiral chromatography separation techniques provides a facile route to anilines with chiral *ortho*-substituents.

Catalytic amounts of aqueous HI led a mixture of hydroarylation and hydroamination products in the alkylation of anilines with styrene derivatives and simples alkenes such as norbornene and cyclohexane. However, the hydroamination process was generally favored over the hydroarylation reaction.[155]

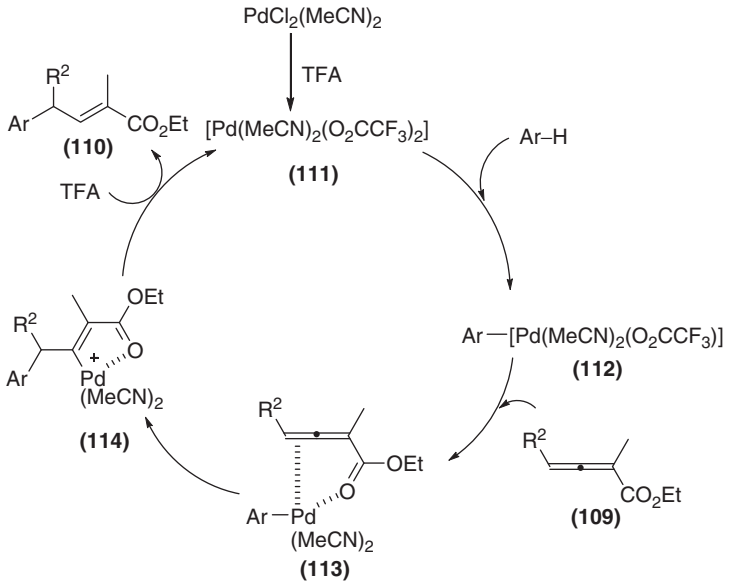
5.33.4 Hydroarylation of Allenes

5.33.4.1 Transition Metal-Catalyzed Hydroarylations of Allenes

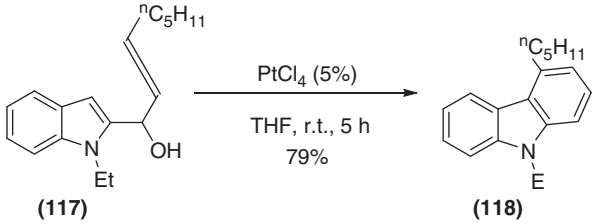


5.33.4.1.1 Palladium-catalyzed hydroarylation of allenes

A highly regio- and stereoselective hydroarylation of 2,3-allenoates **109** catalyzed by $[PdCl_2(MeCN)_2]$ was reported by Ma and coworkers.[156] Allylation of 1,3,5-trimethoxybenzene, anisole, phenol, and *N*-Ts or *N*-Ac-indoles in TFA afforded the corresponding 4,4-diarylbut-2(*E*)-enoates (**110**) in moderate yields (Scheme 54).

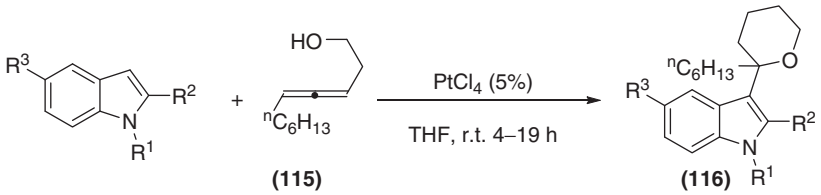
Scheme 54

The mechanism for this transformation involves the formation of $Pd(MeCN)_2(O_2CCF_3)_2$ (**111**) as the active catalytic species from the reaction between the $PdCl_2(MeCN)_2$ precatalyst and TFA. Complex **111** triggers the electrophilic C–H activation of the aromatic ring to form the aryl-palladium intermediate **112**. On coordination of **112** with the 2,3-allenoate **109**, *syn*-insertion of the relatively electron-rich C–C double bond affords intermediate **114**. Protonation of **114** under acidic conditions gives the allylic arene **110** (Scheme 55).



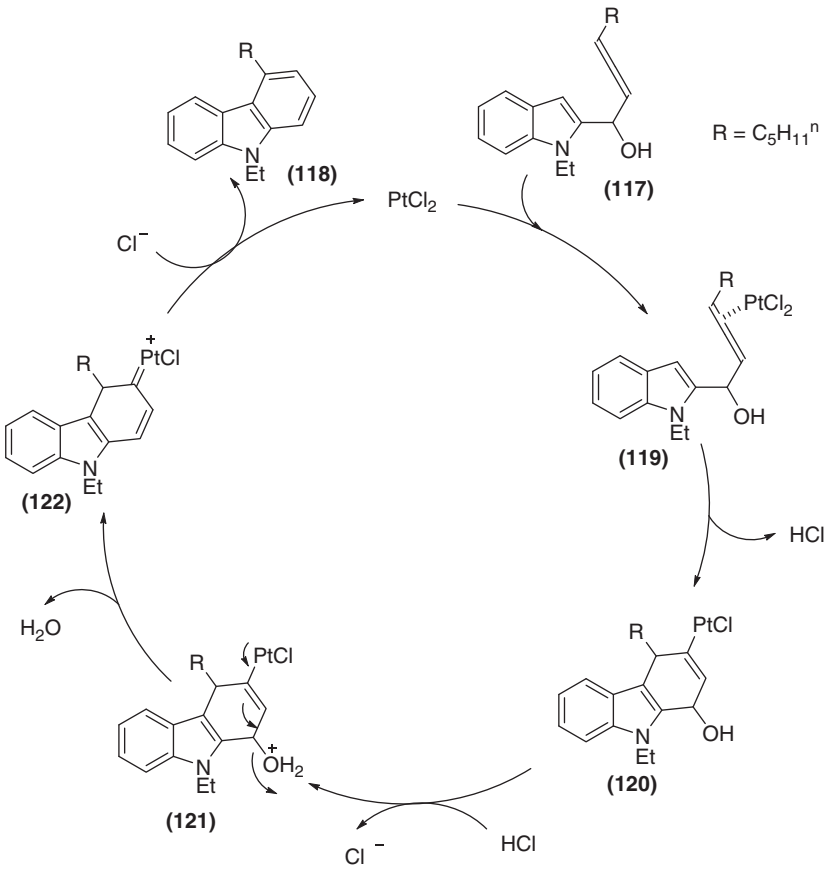
Scheme 55

5.33.4.1.2 Platinum-catalyzed hydroarylation of allenes



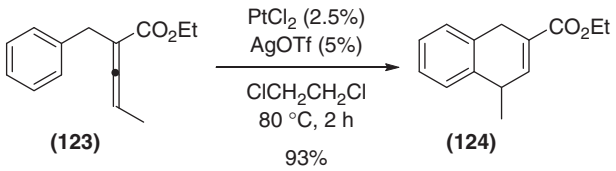
The $PtCl_4$-catalyzed regioselective intermolecular domino hydroarylation/hydroxylation of *β*-allenols **115** to form alkylated indoles containing a six-membered ether ring at the C-3 position **116** has been reported (Table 12).[157]

Based on this results, the Ma group reported an intramolecular $PtCl_2$-catalyzed cyclization of 1-(indol-2-yl)-2,3-allenols **117** in toluene at room temperature to give substituted carbazoles **118** in good yield (equation 8).[158]



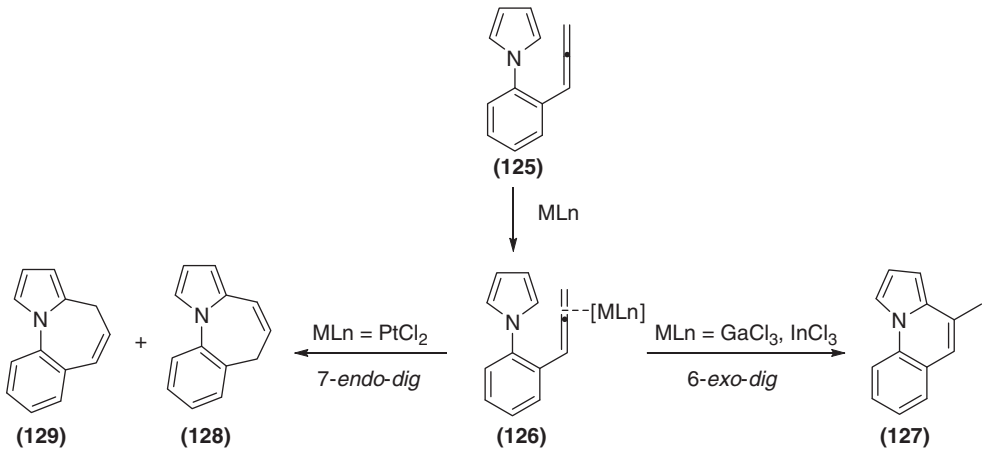
(8)

Table 12 $PtCl_4$-Catalyzed cyclization reaction of β-allenols with indoles



R^1	R^2	R^3	Yield (%)
H	H	H	74
Me	H	H	70
H	H	OH	67
H	Me	Cl	42

The proposed mechanism involving a metal carbene intermediate **122** is depicted in Scheme 56. Nucleophilic attack of the indole onto the activated allene **119** affords the vinylplatinum intermediate **120**, which undergoes protonation of the hydroxyl group to give **121**. The metal carbene intermediate **122**, obtained by elimination of water from **121**, undergoes a 1,2-H shift to form the final product **118**.



Scheme 56

A related synthesis of 1,4-dihydronaphtalenes **124** through a $PtCl_4$-catalyzed 6-*endo*-cyclohydroarylation of ethyl-2-benzyl-2,3-alkadienoates (**123**) was reported by Lee's group (equation 9).[159]

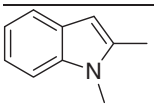
(123) **(124)** (9)

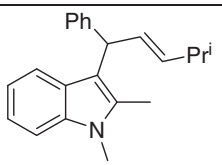
Further examples of allene intramolecular hydroarylations were reported in the context of the phenantrenes synthesis published by Fürstner and discussed in Section 5.33.2.1.1.1.[22b] When $GaCl_3$ or $InCl_3$ were used, aryl allene **125** gave phenantrene **127** as a single product. In contrast, when $PtCl_2$ was employed a mixture of isomeric pyrrolo-azepines **128** and **129** was isolated from the reaction. These results suggest a 6-*exo-dig*- and a 7-*endo-dig*-cyclization pathway, respectively (Scheme 57). DFT calculations showed that the cyclization depends on subtle structural effects of the reactant complex **126**.[24a] This specie is preferably formed by coordination of the terminal double bond of the allene. The metal complex ligand may develop unfavorable interactions with the substituent at the internal allene carbon. This effect leads to an improvement of electrophilicity for the central carbon affording selective *exo-dig*-cyclization. However, the $PtCl_2$-reactant complex **126**, with a trans-halide arrangement, lacks this effect and the reaction is preferentially guided to the unusual 7-*endo-dig*-cyclization.

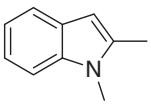
Scheme 57

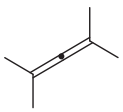
5.33.4.1.3 Gold-catalyzed hydroarylation of allenes

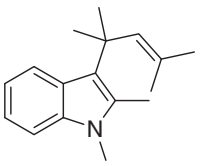
The gold-catalyzed addition of arenes and heteroarenes to allenes in an intra- and intermolecular manner has attracted a lot of attention in the past years.

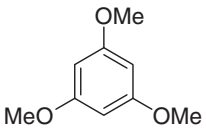


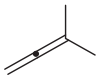


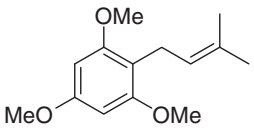




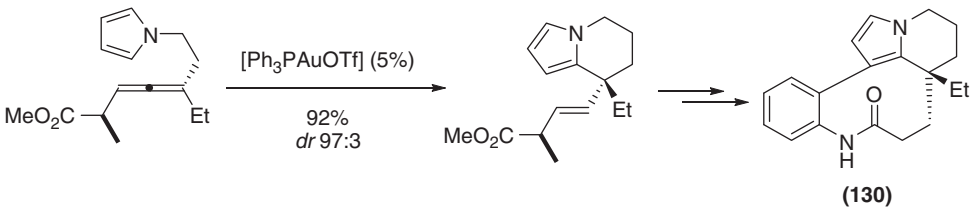






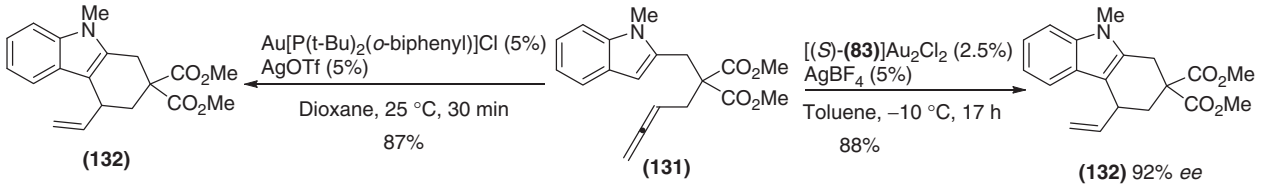


Although the intermolecular version still could be improved, initial investigations have been carried out by the groups of Widenhoefer[160] and Gagné.[161] The former group reported the intermolecular addition of monosubstituted, 1,3-disubstituted, and tetrasubstituted allenes with indoles catalyzed by a mixture of IPrAuCl and AgOTf to give, selectively, C-3-allylic indoles. Gagné and coworkers further applied simple arenes in this reaction. However, only di- and tri-alkoxyarenes afforded the allylic arenes (Table 13).



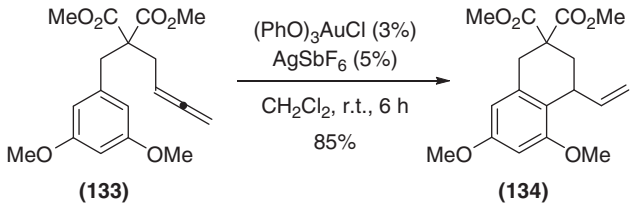
Nelson and coworkers pioneered the gold(I)-catalyzed intramolecular addition of pyrroles to enantioenriched allenes, which afforded optically active heterocycles.[162] This approach was applied in the total synthesis of (–)-rhazinilam (**130**) (Scheme 58). Recently, Toste and coworkers reported the synthesis of flinderoles B and C by a related gold-catalyzed intramolecular allene hydroarylation.[163]

Au[P(t-Bu)$_2$(*o*-biphenyl)]Cl activated by AgOTf or AgOTs triggered the intramolecular hydroarylation of 2-allenyl indoles **131** in a highly selective manner to give tetrahydrocarbazoles **132**.[164] Allenyl indoles that possessed an axially chiral allenyl moiety underwent cyclization with transfer of chirality from the allene to the newly formed stereogenic carbon atom with selective formation of *E*-alkenes. Moreover, the chiral bis(gold)phosphine complex [(*S*)-(**83**)]Au_2Cl_2 combined with $AgBF_4$ proved to be a very efficient system to catalyze the enantioselective hydroarylation of achiral 2-allenyl indoles **131**. Tetrahydrocarbazoles **132** were obtained in very high yields and enantioselectivities (Scheme 59).[165]



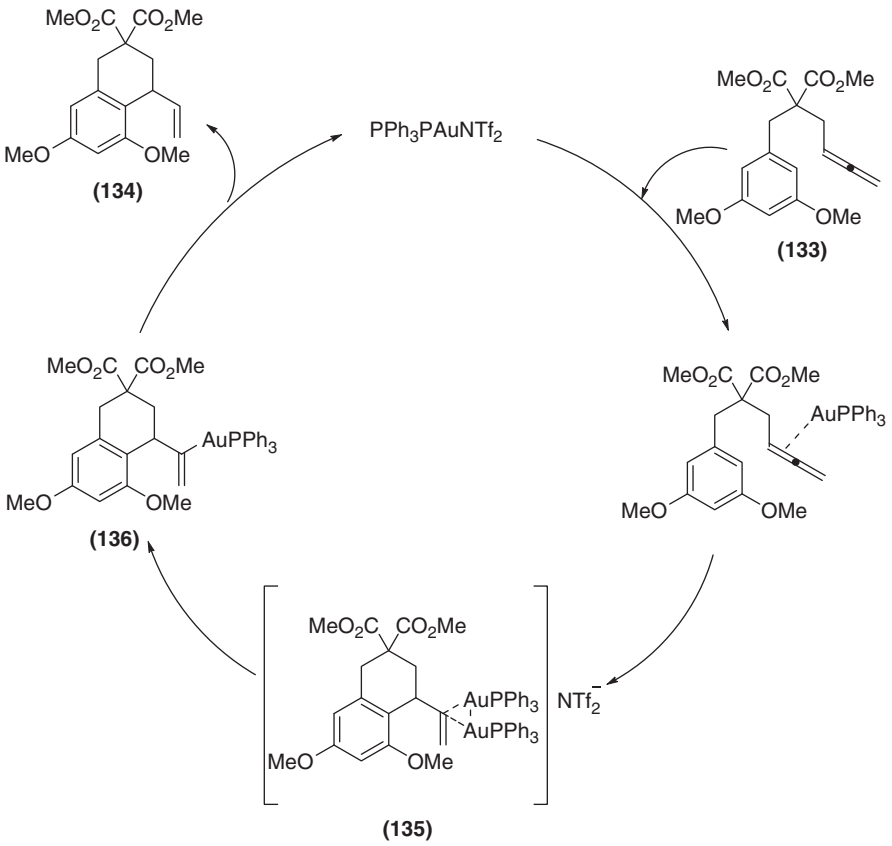
Almost simultaneously, Gagné and coworkers reported the intramolecular hydroarylation of 4-allenyl arenes bearing electron-rich arenes **133** catalyzed by highly electrophilic phosphite gold(I)-catalyst, which produced vinylbenzocycles **134** in high yields under mild conditions (equation 10).[166]

Table 13 Gold-catalyzed intermolecular hydroarylation of allenes



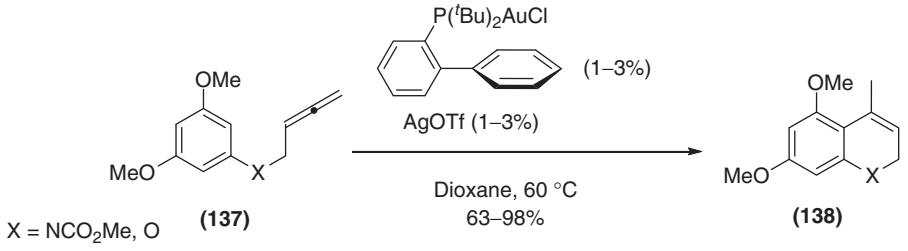
Aromatic ring	*Allene*	*Conditions*	*Product*	*Yield (%)*
		IPrAuCl/AgOTf (5%), dioxane, r.t., 48 h		82
		IPrAuCl/AgOTf (5%), dioxane, r.t., 48 h		56
		$(4\text{-Cl-PhO})_3PAuCl/AgBF_4$ (5%), CH_2Cl_2, r.t., 4 h		67

Scheme 58



Scheme 59

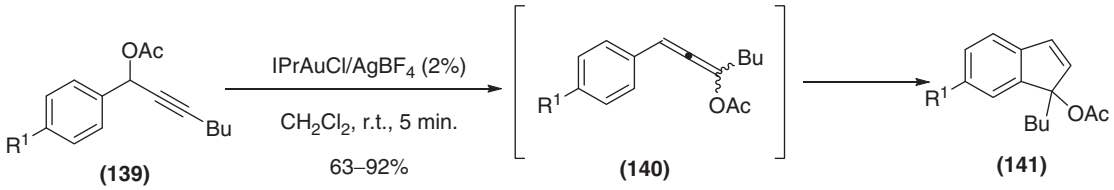
(10)



In-depth mechanistic studies suggested that the resting state of the catalyst was a doubly metalated variant of **136**. In fact, the dinuclear gold intermediate **135** was transformed into **136** on column chromatography in neural alumina. In contrast, the purification of intermediate **135** by silica gel or fluorosil chromatography led to the formation of the final product **134**. With these data, the authors propose the reaction mechanism depicted in Scheme 60.[167] Interestingly, the resting state of the

Scheme 60

gold(I)-catalyzed hydroarylation of **133** changes in the presence of a silver salt. Silver ions intercept the dinuclear organogold intermediate **135** as the silver likely replaces one of the gold atoms without significantly perturbing the gold vinyl structure.[168]



A related gold(I)-catalyzed hydroarylation of allenyl anilines and phenols **137** proceeded in a highly regioselective manner to form dihydroquinolines and chromenes **138**, respectively (Scheme 61).[169]

Scheme 61

The formation of substituted indenes **141** from aryl propargyl alkynes **139** via [3,3]-acetoxy rearrangement and intramolecular hydroarylation of an allene intermediate was reported by Nolan in 2006.[170] A *N*-heterocyclic carbene gold complex IPrAuCl combined with $AgBF_4$ efficiently catalyzed the synthesis of indenes **141** under very mild conditions in only 5 min. Interestingly, when the corresponding allene intermediate **140** was synthetized and submitted to the reaction conditions, the corresponding indene **141** was formed in slightly longer reaction times. This could be consequence of the higher alkynophilicity than allenophilicity of the $[IPrAu]^+$ fragment (Scheme 62).

The intermolecular version of this reaction was reported by Echavarren and coworkers 1 year later as propargyl carboxylates reacted with electron-rich arenes such as indole and 1,3–5-trimethoxybenzene.[171]

5.34 Early Transition Metal Mediated Reductive Coupling Reactions

GC Micalizio, Dartmouth College, Hanover, NH, USA

© 2014 Elsevier Ltd. All rights reserved.

This chapter is a revision of the previous edition chapter by E. Negishi, Vol. 5, pp 1163–1184, © 1991, Elsevier Ltd.

5.34.1	**Introduction**	1661
5.34.2	**Early Transition Metal-Mediated Cyclization of Polyunsaturated Substrates**	1662
5.34.2.1	Bicyclization of Diynes	1663
5.34.2.1.1	$Ti(OR)_4$-based reagent precursors for metallacycle-mediated intramolecular diyne coupling chemistry	1663
5.34.2.1.2	Development of new Ti-mediated cyclization/functionalization processes that harnesses the reactivity of intermediate metallacyclopentadienes formed from diyne cyclization	1664
5.34.2.2	Bicyclization of Enynes	1665
5.34.2.2.1	Development of more practical titanocene reagents for the cyclization of enynes	1667
5.34.2.2.2	Stereoselective synthesis via Zr-promoted enyne cyclization, including applications in natural product synthesis	1668
5.34.2.2.2.1	Heterocycle synthesis	1668
5.34.2.2.2.2	Natural product synthesis	1668
5.34.2.2.3	Catalysis in metallocene-promoted enyne cyclization	1668
5.34.2.2.4	Ti-alkoxide-promoted enyne cyclization	1673
5.34.2.2.4.1	Development of new Ti-mediated cyclization/functionalization processes that harnesses the reactivity of intermediate metallacyclopentenes formed from enyne cyclization	1674
5.34.2.3	Bicyclization of Dienes	1677
5.34.2.3.1	Stereochemistry in Zr-promoted enyne cyclization	1677
5.34.2.3.2	Catalysis in Zr-promoted diene cyclization	1679
5.34.2.3.3	Substrate scope limitations in Zr-promoted diene cyclization	1680
5.34.2.3.4	Titanium alkoxide-promoted diene cyclization	1680
5.34.2.3.4.1	Development of new Ti-mediated cyclization/functionalization processes that harnesses the reactivity of intermediate metallacyclopentanes formed from diene cyclization	1684
5.34.2.3.5	Titanium aryloxide-catalyzed diene cyclization	1684
5.34.2.4	Bicyclizations Involving Allenes	1684
5.34.2.5	Bicyclizations Involving a Carbonyl-Based Functional Group	1686
5.34.2.5.1	Cyclization reactions mediated by metallocenes	1686
5.34.2.5.2	Cyclization reactions mediated by Ti-alkoxides	1686
5.34.2.6	Summary of Advances in Early Transition Metal Metallacycle-Mediated Cyclization	1686
5.34.3	**Early Transition Metal-Mediated Cross-Coupling (Intermolecular C–C Bond Formation)**	1692
5.34.3.1	Introduction to Early Transition Metal Metallacycle-Mediated Cross-Coupling	1692
5.34.3.2	Alkyne–Aldehyde, Alkyne–Imine, and Alkyne–Nitrile Cross-Coupling (via Preformed Metal–Alkyne Complexes)	1692
5.34.3.2.1	Alkyne–aldehyde and alkyne–ketone coupling	1694
5.34.3.2.1.1	Control of regioselection	1694
5.34.3.2.1.2	Development of heteroatom-directed alkyne–aldehyde-coupling chemistry	1694
5.34.3.2.1.3	Control of allylic alcohol stereochemistry	1694
5.34.3.2.2	Alkyne–imine and related coupling reactions	1694
5.34.3.2.3	Alkyne–nitrile coupling	1698
5.34.3.3	Alkenes in Coupling Reactions with Carbonyl Systems	1700
5.34.3.4	Alkyne–Alkyne Cross-Coupling	1700
5.34.3.4.1	Internal alkyne + terminal alkyne	1700
5.34.3.4.2	Internal alkyne + internal alkyne	1705
5.34.3.5	Alkyne–Alkene Cross-Coupling	1707
5.34.3.5.1	Simple directed carbometalation	1707
5.34.3.5.2	Coupling via formal metallo[3,3] rearrangement	1707
5.34.3.6	Allene–Alkyne Cross-Coupling	1711
5.34.3.7	Imine–Alkyne Cross-Coupling (via Preformed Metal–Imine Complexes)	1711
5.34.3.8	Imine–Alkene Cross-Coupling (via Preformed Metal–Imine Complexes)	1719
5.34.3.8.1	Simple hydroxyl-directed Ti-mediated imine–alkene coupling	1719
5.34.3.8.2	Single and double asymmetric hydroxyl-directed imine–alkene coupling	1719
5.34.3.8.3	Imine–alkene coupling by formal metallo[3,3] rearrangement (convergent synthesis of homoallylic amines)	1722
5.34.3.8.3.1	Applications of imine–allylic alcohol coupling	1722
5.34.3.9	Alkene–Alkene Coupling	1727

 doi:10.1016/B978-0-08-097742-3.00535-8

5.34.3.10	Chemoselective Coupling Reactions of Polyenes	1727
5.34.3.10.1	Site and stereoselective coupling reactions of 1,5-dienes	1730
5.34.3.10.2	Site and stereoselective coupling reactions of 1,6-enynes	1730
5.34.3.10.3	A unique and highly stereoselective [2 + 2 + 2] annulation in a subset of alkyne–enyne-coupling reactions	1730
5.34.3.11	Other Coupling Reactions that Proceed via [2 + 2 + 2] Annulation	1730

Glossary

Chemoselectivity A preference for reactivity at a particular functional group of a molecule possessing multiple functional groups. When this term is used to describe selective reaction at one functional group in a molecule possessing other similar groups (one alkene of a polyene), the term 'site selectivity' is used.

Diastereomeric ratio (*dr*) It is the ratio of isomers observed in the product after purification.

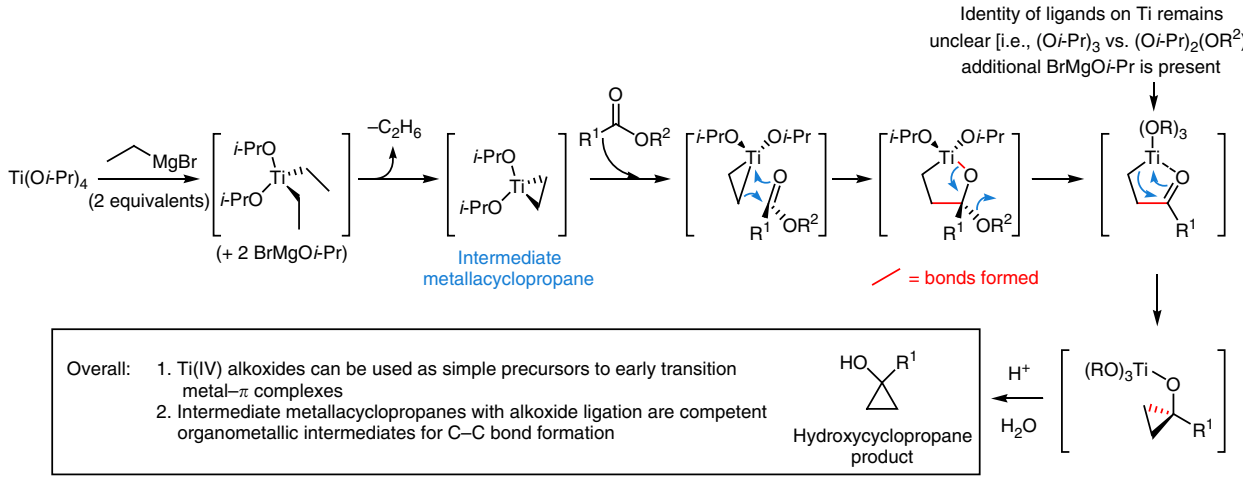
Diastereoselectivity (*ds*) It is a measurement of the selectivity of a reaction – assessed from analysis of the crude reaction mixture.

Pair selectivity A term employed by Prof. Negishi in the first edition of *Comprehensive Organic Synthesis* (Zirconium-promoted Bicyclization of Enynes) that relates to the preference for hetero- versus homocoupling in intermolecular versions of early transition metal metallacycle-mediated bond-forming processes (i.e., A + B → A–B + A–A + B–B).

Regioselectivity In the metallacycle-mediated coupling chemistry discussed, regioselectivity refers to the directionality of net carbometalation across each participating π-system.

Transfer epimetalation A term employed to describe the transfer of low-valent metal from a preformed organometallic complex (i.e., that is generated from the combination of Cp_2ZrCl_2 and *n*-BuLi (two equivalents)) to an unsaturated substrate of interest.

5.34.1 Introduction



Since the publication of the first edition of *Comprehensive Organic Synthesis* in 1991, substantial advances have been made in the chemistry of early transition metal metallacycle-mediated bond-forming processes. These include (1) the introduction of simple Ti(IV)-alkoxides to replace metallocene species (i.e., Cp_2ZrX_2 and Cp_2TiX_2); (2) the development of intramolecular chemistry that proceeds with catalytic quantities of a Group IV metal, albeit typically requiring stoichiometric additives; (3) the establishment of strategies to control relative and absolute stereochemistry in the course of C–C bond formation; and (4) the development of a caste of 'cross-coupling' technology based on controlling the course of metallacycle-mediated bond construction in intermolecular settings.

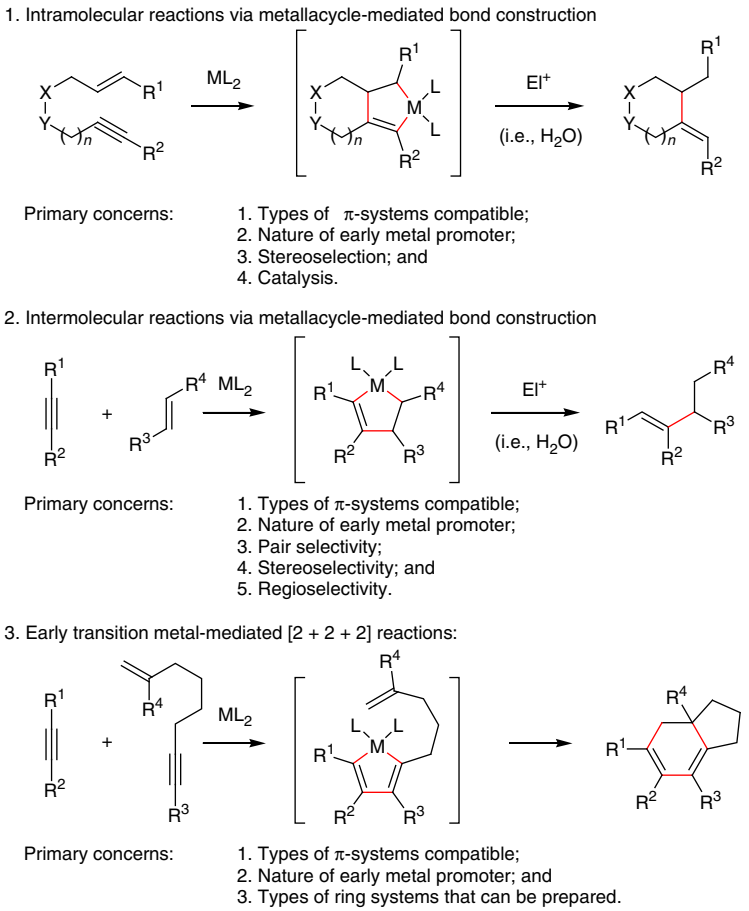
The chapter, 'Zirconium-promoted Bicyclization of Enynes,' provided relevant background regarding the basic reactivity central to early transition metal metallacycle-mediated bond construction (Chapter 9.5, 1st edition). Specifically, general strategies to access Cp_2Zr- and Cp_2Ti-π complexes were described, and the propensity of these species to undergo carbometalation with a second reactive π-system was discussed throughout. At the time, the state of the art in this area was largely limited to intramolecular reactions of polyunsaturated substrates, with a few exceptions demonstrating that a small subset of 'cross-coupling' or 'intermolecular' reactions was possible. In short, the utility of metallacycle-mediated coupling chemistry for convergent C–C bond formation was significantly constrained due to the great difficulties associated with controlling reactivity in intermolecular settings. Specific challenges in this regard included the following: (1) overcoming low levels of reactivity of substituted and electronically unactivated π-systems, (2) controlling pair selectivity (homodimerization vs. cross-coupling), and (3) simultaneously controlling regio- and stereoselection.

At the time of this earlier review, it was thought that Zr-promoted cyclization processes may be superior to Ti-promoted reactions, as evidence was mounting for the increased sensitivity of Cp_2Ti-mediated cyclization reactions to steric environment and ring strain. These conclusions, based on early observations of metallocene-based reactivity, should be reevaluated based on the substantial body of work that has emerged over the past 20 years – not the least of which includes the wealth of bond-forming processes mediated by Ti(IV) alkoxides.

The emergence of Ti-alkoxides as reagent precursors for metallacycle-mediated reductive coupling: Originating from the early contributions of Prof. Oleg Kulinkovich, it has become evident that synthetically useful early transition metal–π complexes can be generated from simple, inexpensive, and nontoxic Ti(IV) alkoxides (i.e., Ti(O*i*-Pr)$_4$) – reagents that can often be purified by distillation, transferred by syringe, and are easily handled outside of a glovebox. This finding stemmed from the discovery and development of a new hydroxycyclopropane-forming reaction, now termed the Kulinkovich reaction,[1] where the addition of two equivalents of a suitable Grignard reagent to Ti(O*i*-Pr)$_4$ results in an activated organometallic complex that ultimately adds to a carboxylic ester en route to the formation of a hydroxycyclopropane (Scheme 1).[2] Like the established reactivity of the 'Negishi reagent' (*n*-Bu_2ZrCp_2),[3,4] it has been proposed that the Kulinkovich reaction proceeds through the intermediacy of a similar

metallacyclopropane, formed from decomposition of the initially formed (alkyl)$_2$Ti(O*i*-Pr)$_2$ species.[5] In short, each σ_{C-Ti} bond of the resulting metallacyclopropane engages in nucleophilic addition to the carboxylic ester, resulting in the formation of a hydroxycyclopropane. At the current time, more substantial data exist to support the sequence of events that proceed from (n-Bu)$_2$ZrCp$_2$ to the corresponding butene–ZrCp$_2$ complex than the sequence of events that proceed from the R$_2$Ti(O*i*-Pr)$_2$ intermediate proposed in the Kulinkovich reaction.

Scheme 1



Being focused on the utility of metallacycle-mediated coupling reactions in organic synthesis, this review will not delve into the mechanistic hypotheses regarding the fate of the initial R$_2$Ti(OR)$_2$ species formed in the Kulinkovich reaction.[6–10] Rather, this chapter is presented in a manner that simply accepts that the fate of R$_2$Ti(OR)$_2$ can be manipulated to generate new organometallic complexes of alkynes, imines, and alkenes by net transfer epititanation – the reactive intermediates that are central to the powerful organic transformations discussed in this chapter.

This chapter is organized as depicted in **Scheme 2**. First, an update on intramolecular transformations mediated by early transition metals is provided. The primary organization within this section is based on the type of π-systems employed in the metallacycle-mediated cyclization (alkyne–alkyne, alkyne–alkene, alkene–carbonyl, etc.), and attention is given to the nature of the metal mediator (metallocene or metal alkoxide), stereoselection, and catalysis. Furthermore, within each mode of reactivity discussed, effort has been taken to highlight the utility of the method in stereoselective synthesis. The discussion then shifts to cover advances that have established a caste of intermolecular, or 'cross-coupling,' reactions made possible by advances in the manner in which metallacycle-mediated carbometalation chemistry can be controlled. Again, the primary organization of this section is based on the type of π-systems that are engaged in C–C bond formation. Care has been taken to convey a clear picture of the scope and limitations of each coupling process, with particular emphasis on considerations regarding the control of regio- and stereoselection. Applications of each reaction class are presented in stereoselective synthesis when deemed appropriate. Finally, the chapter concludes with a survey of early transition metal metallacycle-mediated [2 + 2 + 2] chemistry for the synthesis of carbo- and heterocyclic systems.

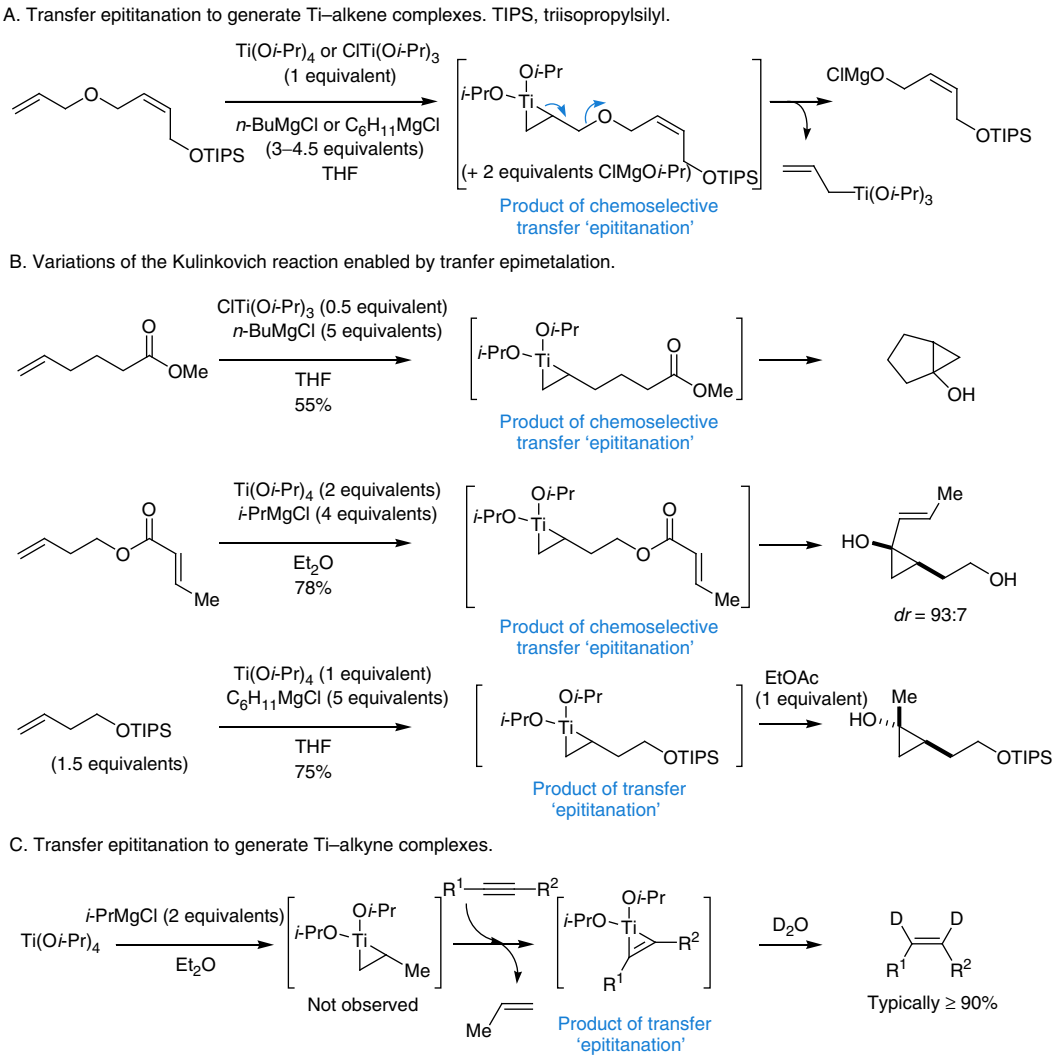
It is important to recognize that over the past 20 years a substantial body of chemistry has emerged that is based on exploiting the unique reactivity of early transition metals in novel C–C bond-forming processes. This chapter is focused on the subset of advances in this area that deal with the coupling of two π-systems. Developments not presented in this chapter include (1) Zr- and Ti-promoted addition reactions of Grignard reagents to alkenes and carbonyl systems, (2) Ti-mediated addition of alkenes to esters (i.e., the Kulinkovich reaction),[11] and (3) reactions that proceed through the conversion of alkenes and alkynes to allylic and propargylic organometallic reagents of utility in carbonyl addition chemistry.

5.34.2 Early Transition Metal-Mediated Cyclization of Polyunsaturated Substrates

After the initial observation that low-valent early transition metals promote the homocoupling of internal alkynes via the formation of metallacyclopentadienes,[12] cyclization reactions of polyunsaturated substrates were among the first powerful synthetic transformations to emerge from this mode of reactivity. Early accomplishments, mostly before 1991, established a foundation of chemistry that supports the conclusion that metallacycle-mediated bond construction defines a powerful means for ring formation via engaging simple π-unsaturations in C–C bond formation. Distinct from other transition metal-mediated methods that engage simple π-unsaturation in ring formation (i.e., diene and enyne metathesis), these early transition metal-mediated processes have the power to engage a vast array of π-systems and have secured a complementary portfolio of bond constructions of great potential utility in chemical synthesis. Following is a brief survey of developments in early transition metal-mediated

Scheme 2

cyclization of polyunsaturated substrates that aims to communicate the great power that this mode of reactivity has in ring formation. The discussion is organized based on the type of π-unsaturations employed in the intramolecular process: (1) alkyne–alkyne, (2) alkene–alkyne, (3) alkene–alkene, (4) allene–alkyne, (5) alkyne–carbonyl, (6) alkene–carbonyl, and (7) allene–carbonyl.



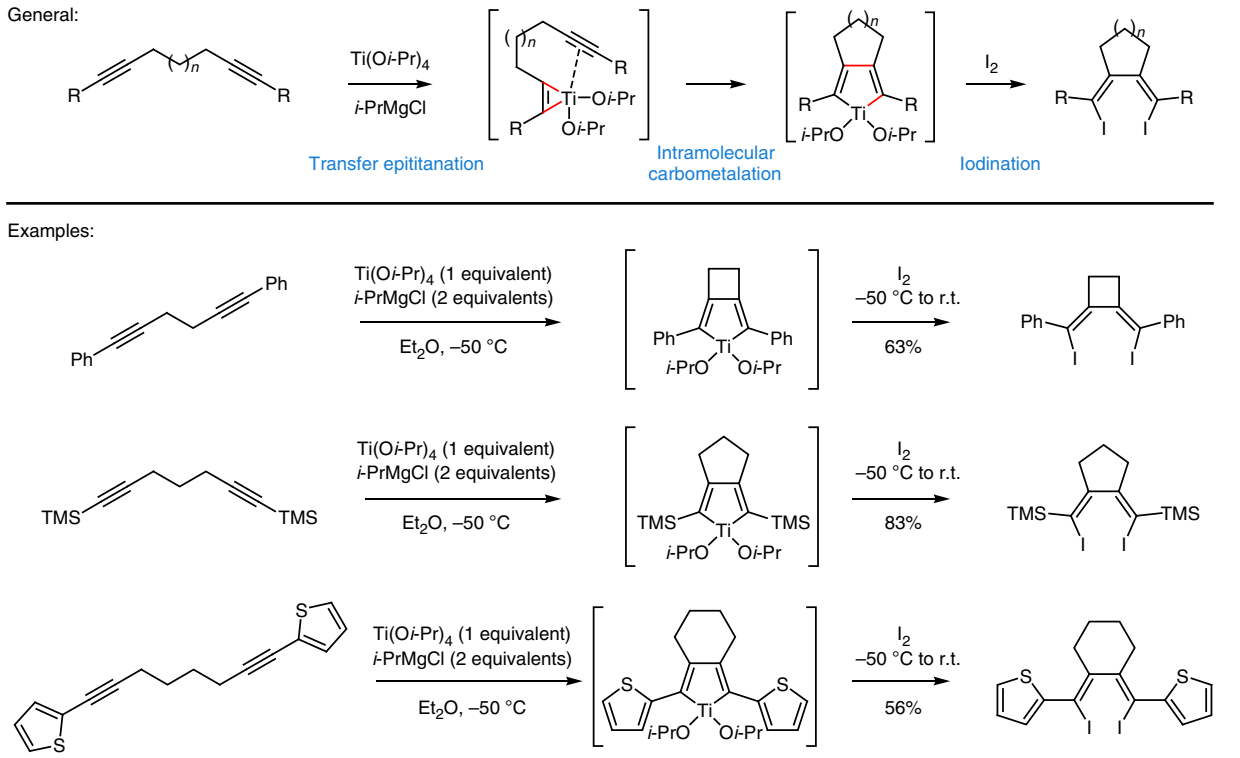
5.34.2.1 Bicyclization of Diynes

Among the earliest examples of metallacycle-mediated ring formation were cyclization reactions of diynes promoted by Cp_2Ti- and Cp_2Zr-based systems (before 1991).[13,14] Examples included the generation of carbo- and heterocyclic rings from four- to seven-membered systems and, through comparison of the relative efficiencies of cyclization promoted by Cp_2Zr- and Cp_2Ti-based systems, conclusions were made regarding the potential superiority of Zr-based systems for such cyclization processes.[14] Over the past 20 years, Ti(IV) alkoxides have emerged as new reagent precursors suitable for this class of cyclization reaction, and a number of new synthetic variations of this cyclization have been reported.

5.34.2.1.1 $Ti(OR)_4$-based reagent precursors for metallacycle-mediated intramolecular diyne coupling chemistry

In the years spanning 1995–96, Prof. Fumie Sato and Prof. Jin K. Cha independently described studies where the 'Kulinkovich' reagent (defined by the combination of a Ti(IV) alkoxide with two equivalents of a Grignard reagent) was employed to generate new Ti–alkene and Ti–alkyne complexes of unsaturated substrates (this process is referred to as transfer 'epititanation'). These observations were initially presented in the context of new methods for allyl deprotection and the generation of allylic titanium reagents from allylic esters, ethers, halides, and related substrates (**Scheme 3A**).[15,16] Subsequent studies explored the use of transfer epimetallation to enable intra- and intermolecular variations of the Kulinkovich hydroxycyclopropanation reaction (**Scheme 3B**),[17–19] and finally to generate Ti–alkyne complexes (**Scheme 3C**).[20] It is this latter mode of reactivity that is central to the development of new Ti-alkoxide-promoted diyne-based cyclization reactions.

Building on the demonstrated ability to access Ti–alkyne complexes via transfer epititanation from $Ti(Oi\text{-}Pr)_4/2i\text{-}PrMgCl$, Sato has revealed that bicyclization reactions of diynes are readily achieved with the use of Ti-alkoxides in place of established Cp_2Zr- and Cp_2Ti-based reagents.[21] As illustrated generally in **Scheme 4**, treatment of a diyne with $Ti(Oi\text{-}Pr)_4/2i\text{-}PrMgCl$ is thought to



Scheme 3

result in initial transfer epititanation and formation of a Ti–alkyne complex (or metallacyclopropene). Intramolecular coordination of the pendant alkyne is followed by intramolecular carbometalation to furnish a bicyclic metallacyclopentadiene intermediate which, on exposure to I_2, is converted to a functionalized 1,4-dihalobutadiene product.[22] Although previous conclusions have been made about the sensitivity of Cp_2Ti-mediated bicyclization reactions to ring strain, and the potential superiority of Cp_2Zr-based systems for bicyclization chemistry, it is apparent that this Ti-alkoxide-mediated procedure is useful for the generation of a variety of ring systems.

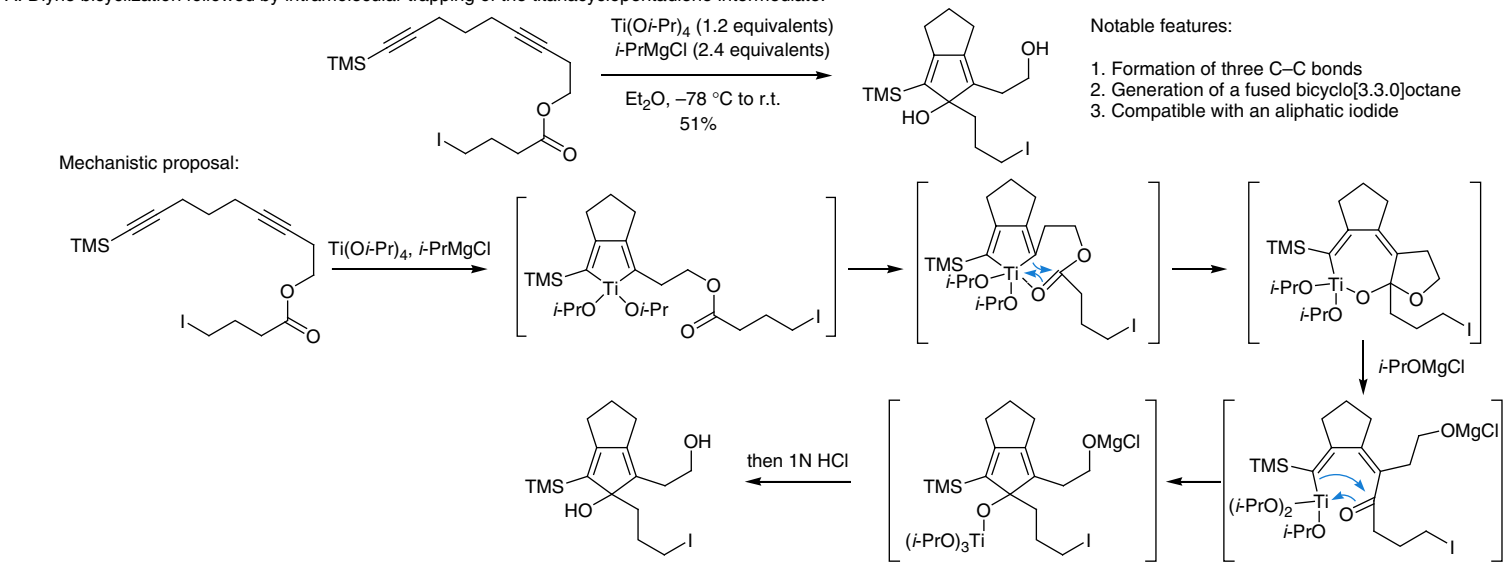
5.34.2.1.2 Development of new Ti-mediated cyclization/functionalization processes that harnesses the reactivity of intermediate metallacyclopentadienes formed from diyne cyclization

Instead of quenching the intermediate metallacyclopentadiene with a proton source, or reagents capable of halogenation, Sato has demonstrated that C–C bond formation can proceed in either an intra- or intermolecular fashion (Scheme 5). As depicted in Scheme 5A, bicyclic carbocycles are produced from $Ti(Oi\text{-}Pr)_4$-mediated cyclization and intramolecular trapping of the intermediate metallacyclopentadiene by engaging the reactivity of the proximal carboxylic ester.[23]

Illustrated in Scheme 5B, regioselective intermolecular trapping of unsymmetrical metallacyclopentadienes is also possible.[24,25] Here, formation of a titanacyclopentadiene intermediate is followed by addition of $Cl_2Ti(Oi\text{-}Pr)_2$ and an aldehyde (the use of $Cl_2Ti(Oi\text{-}Pr)_2$ was found to increase the yield of the addition reaction). Site-selective reaction of the metallacyclopentadiene occurs at the carbon bearing the silyl substituent – a selectivity that has been proposed based on a stabilization of charge in the transition state imparted by the silyl substituent. Most interestingly, subtle steric differences of silyl substituents about the titanacyclopentadiene intermediate can also be harnessed to control site-selectivity of C–C bond formation. As shown, the substrate bearing a trimethylsilyl (TMS)- and *t*-butyldimethylsilyl (TBDMS or TBS)-substituent undergoes cyclization/aldehyde addition to deliver a product where C–C bond formation has occurred at the site α- to the TMS group (in preference to the TBDMS group).

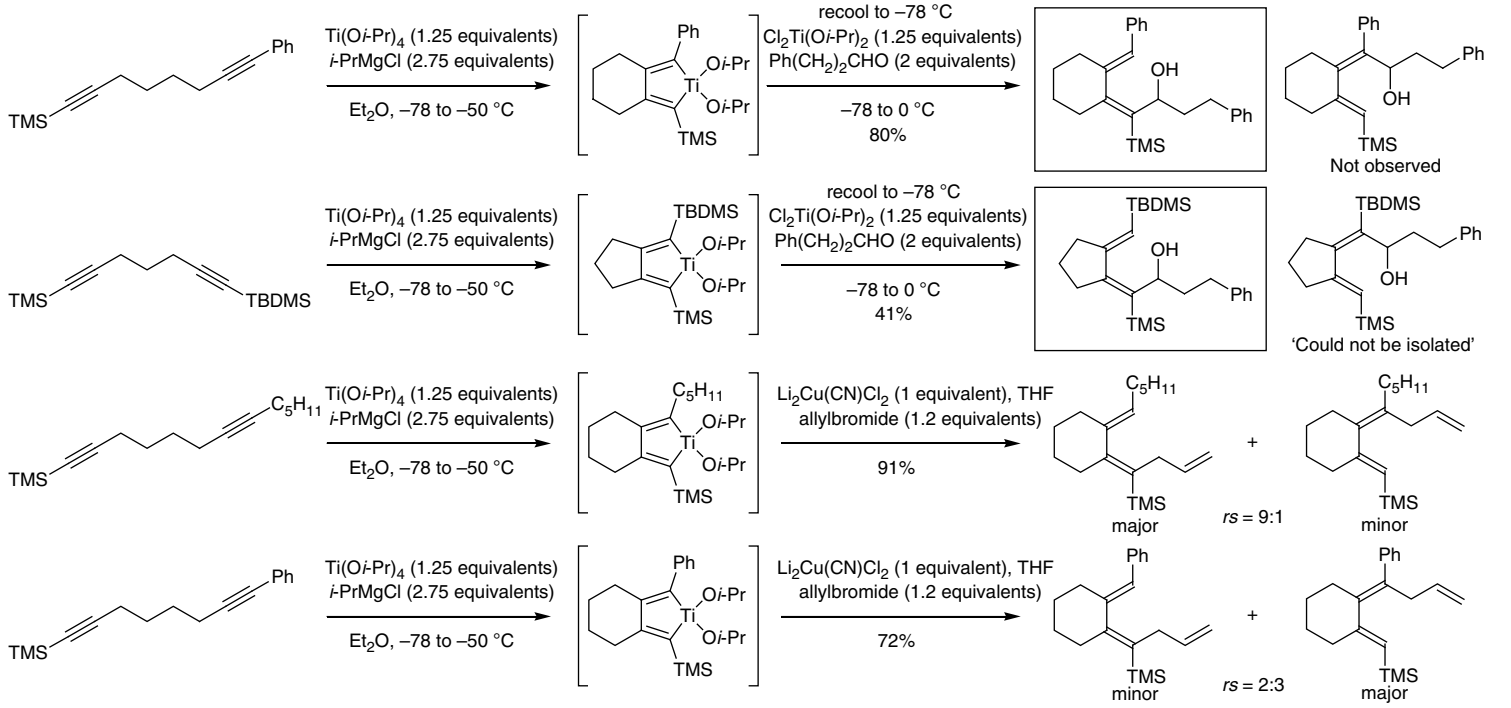
Scheme 4

Although the yield for the product was reported to be only 41% (half of that observed for other examples), and a precise selectivity was not given for this process, the authors report that the other possible regioisomer 'could not be isolated.'



In related studies targeting intermolecular functionalization of metallacyclopentadienes generated from Ti-mediated diyne cyclization, it has been demonstrated that site-selective allylation is possible (Scheme 5B). As is the case with aldehyde addition chemistry, site-selective coupling typically proceeds at the carbon bearing the TMS group. That said, in cases where the TMS-substituted unsymmetrical metallacyclopentadiene also bears a Ph-group, the major product from Cu-promoted allylation derives from C–C bond formation α- to the Ph-group, albeit proceeding with very low levels of selectivity (*rs* = 3:2).

In other studies exploring the fate of intermediate metallacyclopentadienes derived from bicyclization reactions of diynes, Sato reported that elimination chemistry can be accessed en route to ring systems bearing exocyclic conjugated allenes (Scheme 6A).[26,27] Surprisingly, it was found that the stability of bis-allene products derived from this tandem process was a function of ring size. With four- and five-membered systems, the conjugated bis-allene could be isolated, whereas with six- and seven-membered systems, cyclobutene products are formed (presumably via four-electron electrocyclization of the bis-allene intermediates). While delivering products of potentially useful reactivity in synthesis, the efficiencies of these processes vary greatly, with the best yields for conjugated bis-allenes being in the five-membered series (25–45% isolated yields), and cyclobutenes in the six-membered series (15–80% isolated yields).



5.34.2.2 Bicyclization of Enynes

A significant number of advances have been reported in the area of enyne cyclization. This section is organized to first describe advances made in metallocene chemistry (Cp_2M–), followed by those that derive from cyclization induced by early transition metal alkoxides ($(RO)_2Ti$–). Metallocene-based methods have been advanced as more practical methods to accomplish cyclization (see Section 5.34.2.2.1), applications of metallocene-based methods have appeared as central features of new routes to heterocycles and as key steps in natural product synthesis (see Section 5.34.2.2.2), and methods have emerged that proceed with catalytic quantities of metallocene reagent (see Section 5.34.2.2.3). Ti-alkoxide-mediated cyclization chemistry has emerged as an alternative means of enyne cyclization (see Section 5.34.2.2.4), where substantial increases in complexity are possible in cyclization reactions that deliver intermediate titanacyclopentenes that have rich reactivity profiles. Controlling the fate of this reactive intermediate has resulted in an impressive collection of complexity-generating processes that ensue from initial enyne cyclization and terminate by distinct intra- or intermolecular bond-forming processes of these titanacyclopentene intermediates.

5.34.2.2.1 Development of more practical titanocene reagents for the cyclization of enynes

The practical simplicity of the Negishi reagent (prepared by the addition of two equivalents of BuLi to Cp_2ZrCl_2) marked a substantial advance in metallocene chemistry, as one no longer needed to reduce a metallocene reagent precursor (Cp_2MCl_2) with Na/Hg (in the presence of $PhPMe_2$), or Mg/$HgCl_2$. In efforts to identify a similarly practical procedure to access titanocene species, Prof. Buchwald described a protocol based on the addition of two equivalents of EtMgBr to Cl_2TiCp_2.[28] Studies have led to the conclusion that this titanocene reagent system may be more tolerant of oxygen functionality than the zirconium system, and examples have demonstrated that this reagent combination is useful for the synthesis of bicyclic cyclopentenones and imino-cyclopentenes (Scheme 7) that proceed through initial Ti-mediated enyne cyclization and subsequent one-carbon insertion. Although the procedure for metal-centered bicyclization of the enyne substrate is straightforward, insertion of the one-carbon component requires removal of the ethereal solvent – a requirement that is complicated owing to the air and moisture sensitivity of the organometallic intermediate.

A related reagent formed from the addition of two equivalents of BuLi to Cp^*Ti(O-2,6-diphenylphenyl)Cl_2 has also been shown to affect cyclization reactions of more sterically encumbered substrates.[29]

Scheme 7

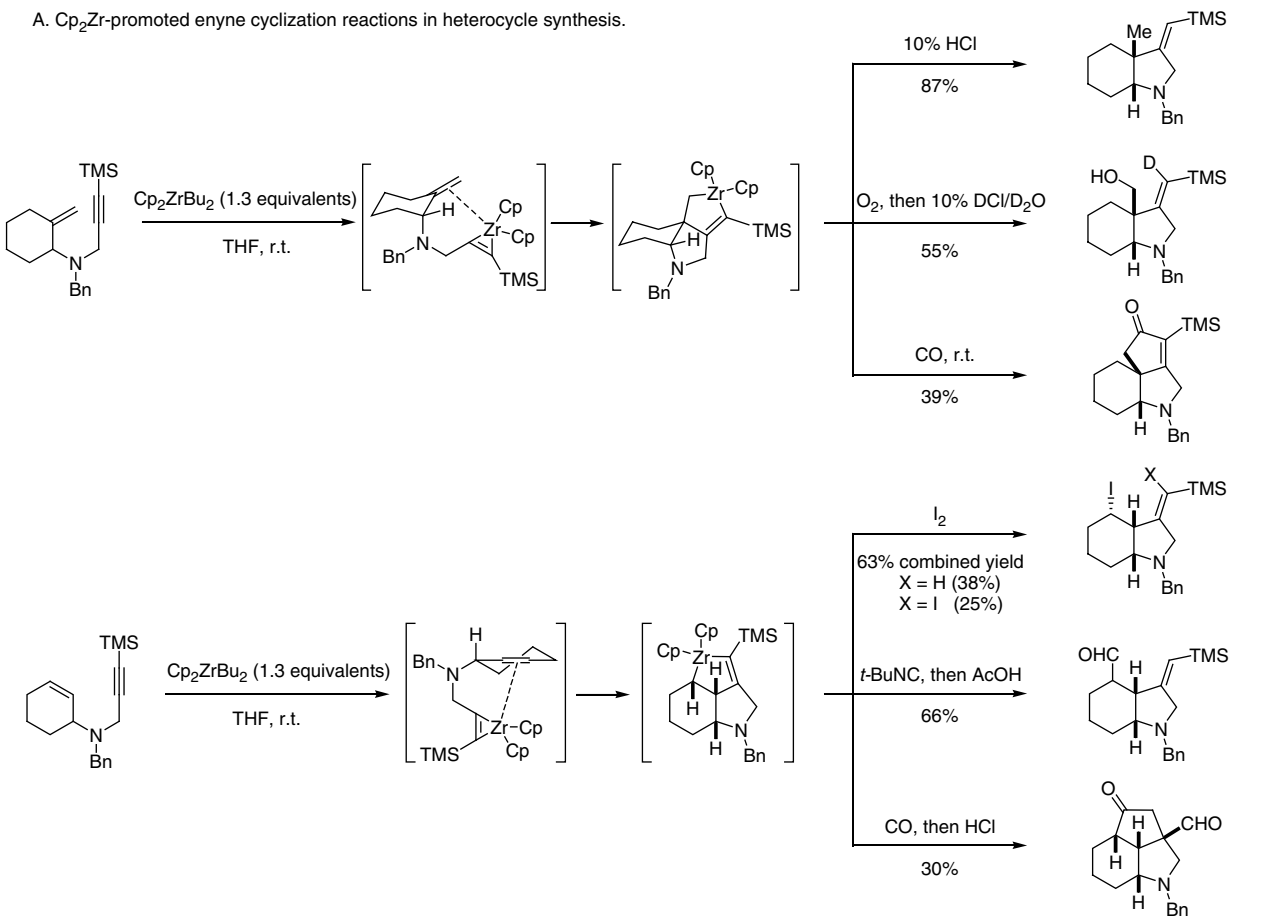
5.34.2.2.2 Stereoselective synthesis via Zr-promoted enyne cyclization, including applications in natural product synthesis

5.34.2.2.2.1 Heterocycle synthesis

Stereoselective variants of zirconocene-based enyne cyclization have emerged for the synthesis of perhydroindole derivatives (Scheme 8A).[30] Here, carbocyclic allylic amines serve as the starting materials for cyclization, and functionalization of the intermediate zirconacyclopentenes defines a means to access a range of stereodefined heterocyclic systems. In addition to validating the potential utility of Zr-promoted cyclization chemistry in heterocycle synthesis, these studies have also revealed an interesting reactivity profile of the intermediate zirconacycles. Overall, functionalization of the sp^3 C–Zr bond is more facile than the sp^2 C–Zr bond, as evidenced by (1) oxidation of the sp^3 C–Zr bond (with O_2), then deuteration of the remaining C–Zr bond; (2) isonitrile insertion, followed by treatment with acetic acid; and (3) the product mixture derived from iodination. These studies also demonstrated that carbonylation of tricyclic zirconocyclopentene intermediates can deliver products where one or two equivalents of CO have been incorporated – selectivity in this process is apparently derived from the nature of the ring system formed.

5.34.2.2.2.2 Natural product synthesis

Zr-promoted enyne bicyclization has been explored in natural product synthesis, with examples including a formal total synthesis of phorbol and the total synthesis of pentalenic acid (Scheme 8B).[31,32]



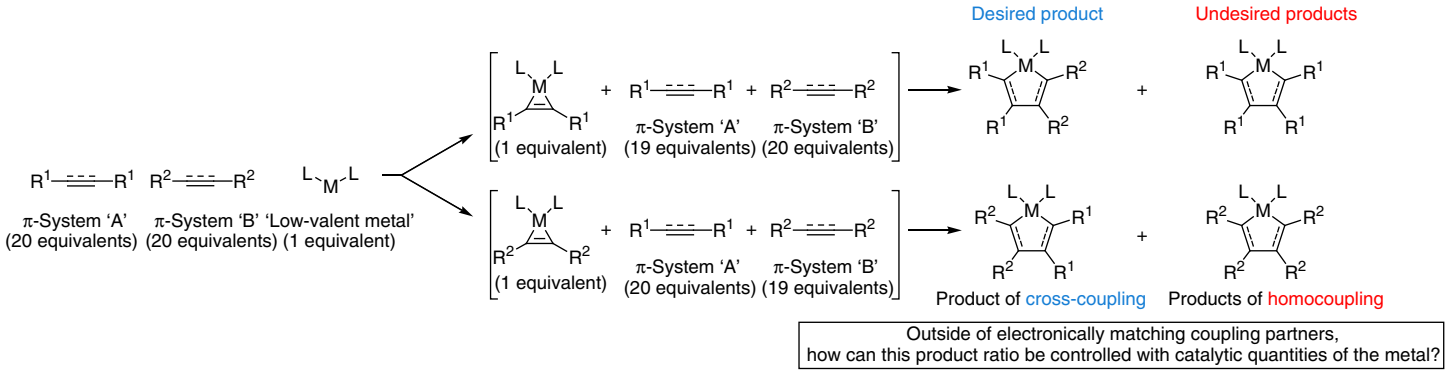
5.34.2.2.3 Catalysis in metallocene-promoted enyne cyclization

A number of metallacycle-mediated C–C bond-forming reactions have been described that proceed with substoichiometric quantities of a Zr-reagent along with excess Grignard or trialkylaluminum reagent. These reactions proceed by Zr-promoted addition of preformed organometallic reagents to a π-bond.[33] Although demonstrating conceptually novel approaches to catalytic C–C bond formation, these reactions do not proceed by coupling of two unsaturated organic substrates and, as such, will not be discussed further here.

Catalysis in early transition metal metallacycle-mediated coupling chemistry is complex owing to the mechanistic pathway by which these reactions proceed (Scheme 9). A primary concern in all potential catalytic processes is the excess quantities of unsaturated substrate present throughout the reaction. As illustrated in Scheme 9A, a general coupling reaction run with 5 mol% of a low-valent metal (ML_2) can proceed by initial activation of either coupling partner (π-system 'A' or 'B'). Independent of which π-system is engaged by the low-valent metal, the resulting L_2M–π complex is surrounded by large relative quantities of each substrate (π-system 'A' and π-system 'B'). Given an equal chance of this metal–π complex engaging either system in a carbometalation event, a complex product mixture can result that is contaminated by the undesired products of homo-coupling. Although matching the electronic and/or steric properties of the two substrates may provide a solution to a subset of coupling reactions, finding a general catalytic solution capable of cross-coupling any two unsaturated substrates is fundamentally limited by this problem in 'pair selectivity.'

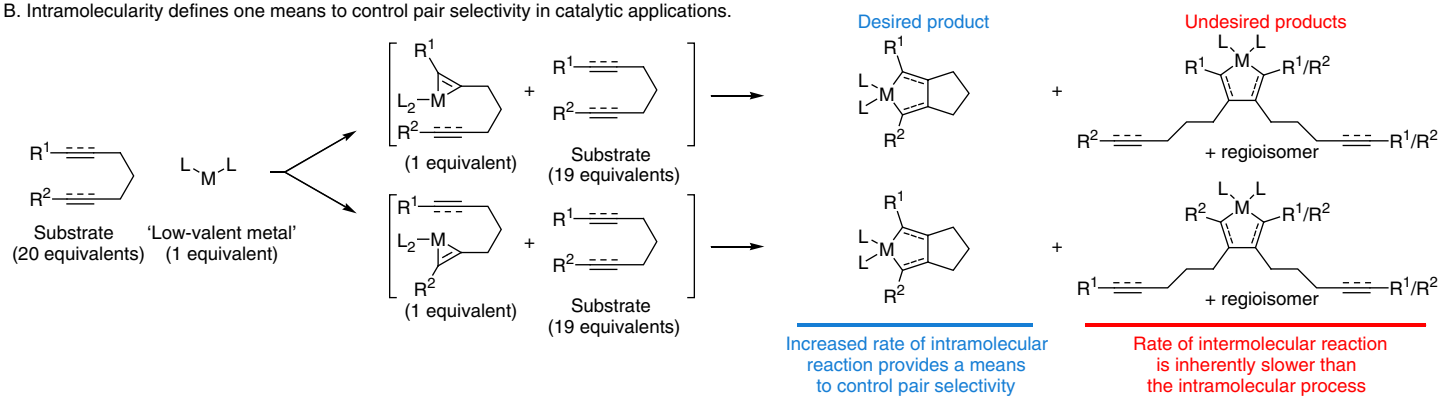
That said, catalytic processes for early transition metal metallacycle-mediated cyclization, where the C–C bond-forming event proceeds in an intramolecular fashion, are quite reasonable. As illustrated in Scheme 9B, complexation of a catalytic quantity of ML_2 to a polyunsaturated substrate leads to the generation of a small quantity of activated metallacyclopropane that, while surrounded by an excess polyunsaturated substrate, reacts through a unimolecular pathway (intramolecular formation of a metallacyclopentane) to kinetically outcompete intermolecular processes. Nevertheless, like all intramolecular processes, such reactions are sensitive to factors that diminish the rate of cyclization and result in competition with intermolecular bond-forming processes (including ring size, sterics, and stereochemical considerations that impact preferred conformation).

In 1993, Prof. Buchwald described a titanocene-catalyzed enyne cyclization for the synthesis of cyclopentenones where 10 mol% of $Cp_2Ti(PMe_3)_2$ (or 10 mol% Cp_2TiCl_2 and 20 mol% *n*-BuLi) is used alongside a slight excess of a (trialkylsilyl)cyanide (Scheme 10A).[34,35] Taking advantage of the equilibrium between the silylcyanide and the silylisonitrile, this protocol provided a means to turn over the titanocene by a protocol that does not require the presence of stoichiometric quantities of an isonitrile (this was essential to the success of this catalytic procedure). Overall, these reactions require careful exclusion of air and moisture (Schlenk technique and/or dry box reaction setup) and have proven to be effective for generating bicyclo[3.3.0]octene and



Scheme 8

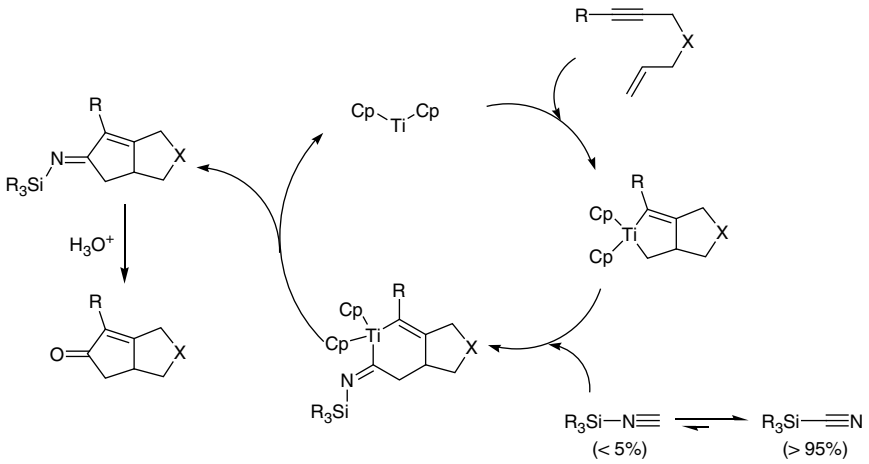
bicyclo[4.3.0]nonene systems. After hydrolysis of the iminocyclopentene products, cyclopentenones can be generated in 42–80% yield (Scheme 10B). Cyclization reactions of stereodefined enynes were also demonstrated to proceed with a range of stereoselectivity (from 1.6:1 to 12:1, depending on the position and nature of the substitution present in the tether). Although defining an important advance in enyne cyclization chemistry, this reaction remains limited in scope, being ineffective for cyclization reactions that engage 1,2-disubstituted alkenes, trialkylsilyl-substituted, or terminal alkynes, and all of the substrates depicted in Scheme 10C.



Since the initial report of a titanocene-catalyzed enyne cyclization for the synthesis of bicyclic cyclopentenones with $Cp_2Ti(PMe_3)_2$ and *t*-$BuMe_2SiCN$, significant advances have emerged:

1. The air-stable precatalyst Cp_2TiCl_2 has been shown to be competent in cyclization chemistry. Here, cyclization of enynes to bicyclic iminocyclopentenes proceeds with 10 mol% of 'finely ground' Cp_2TiCl_2, 20 mol% *n*-BuLi, and 115 mol% Et_3SiCN in toluene at 45 °C.[36]

A. The general challenge of pair selectivity in catalytic variants of early transition metal metallacyle-mediated coupling chemistry.



B. Intramolecularity defines one means to control pair selectivity in catalytic applications.

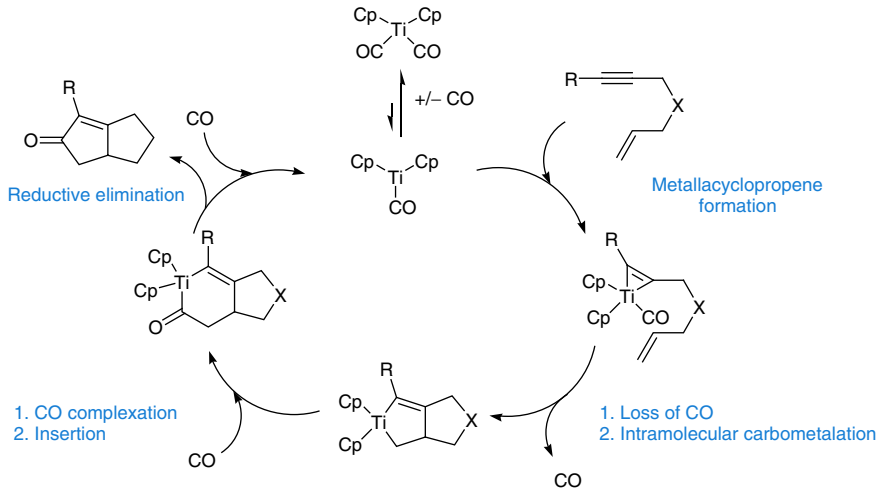
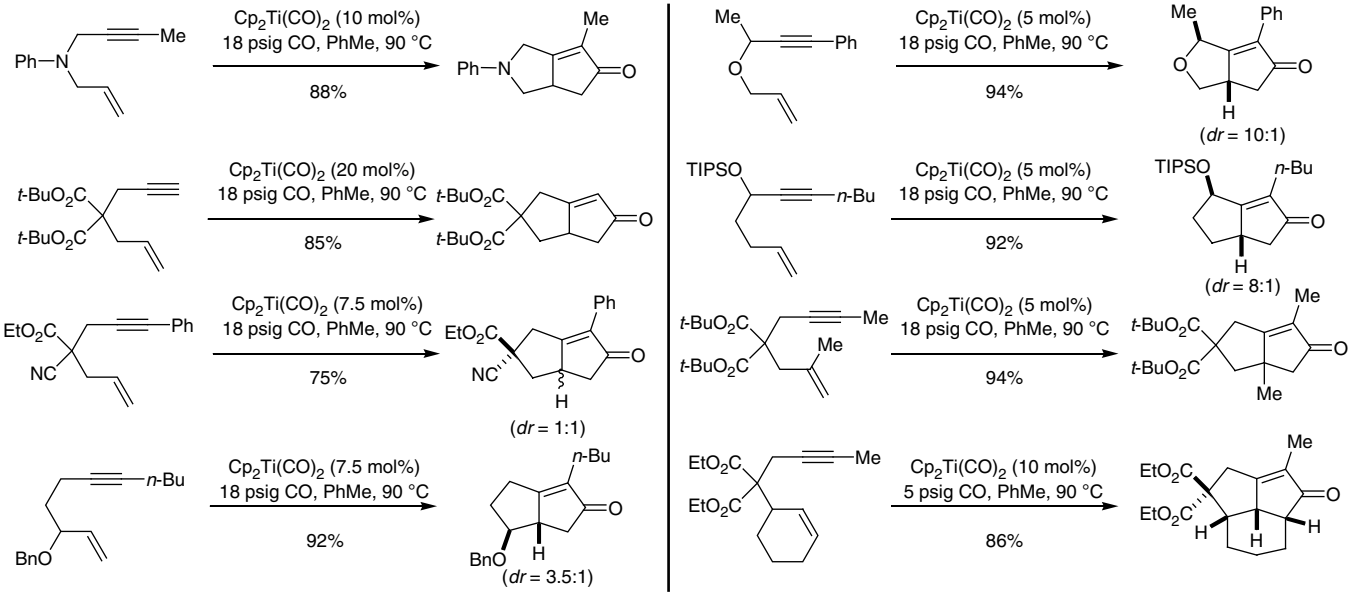
B. Titanocene-catalyzed enyne cyclization en route to cyclopentenones: Examples.



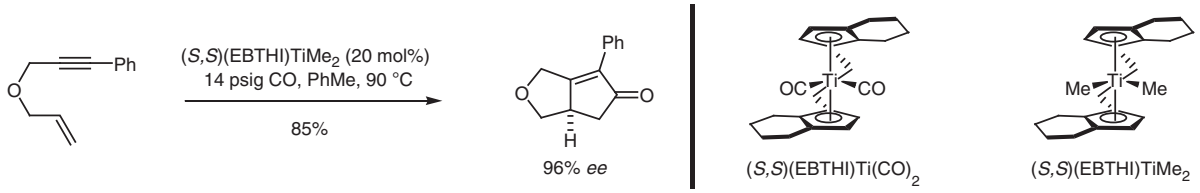
C. Titanocene-catalyzed enyne cyclization: Substrates that did not lead to cyclopentenone products.



Scheme 10

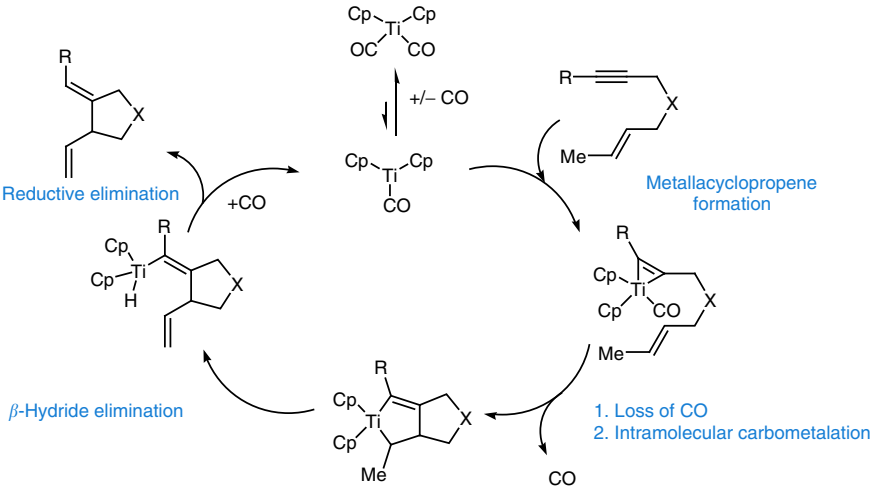
2. Although previous attempts to accomplish CO insertion into intermediate titanacyclopentenes derived from enyne cyclization with Cp_2TiCl_2/2EtMgBr in tetrahydrofuran (THF) met with failure,[28,37,38] it has been found that the commercially available precatalyst $Cp_2Ti(CO)_2$ can be employed to catalyze cyclization and carbonylation to deliver bicyclic cyclopentenones (5–20 mol% $Cp_2Ti(CO)_2$, 18 psig CO, PhMe, 90 °C). This procedure defines a means to avoid the often moderate yielding hydrolysis step required in the related reactions with R_3SiCN, offers additional functional group tolerance (i.e., nitrile- and ketone-containing substrates are effectively converted to bicyclic cyclopentenones), and enhanced substrate scope. For example, terminal alkynes, 1,1- and 1,2-disubstituted alkenes can be engaged in the cyclization reaction, albeit in these latter cases conformational biasing (via geminal diester substitution in the tether; Thorpe–Ingold effect) is required for cyclization to ensue (Scheme 11). In a related set of experiments, it was also found that six-membered rings could be formed in this cyclopentenone annulation, yet successful examples still require substantial conformational biasing of the acyclic system to enforce cyclization. Overall, many advantages are associated with this $Cp_2Ti(CO)_2$-catalyzed cyclization, yet the reported experimental procedure still requires careful reaction setup to avoid contamination with air and moisture (argon-filled glovebox) – a requirement that impacts the practicality of this advance in catalysis.

A. $Cp_2Ti(CO)_2$-catalyzed Pauson–Khand-type cyclization: Proposed catalytic cycle.

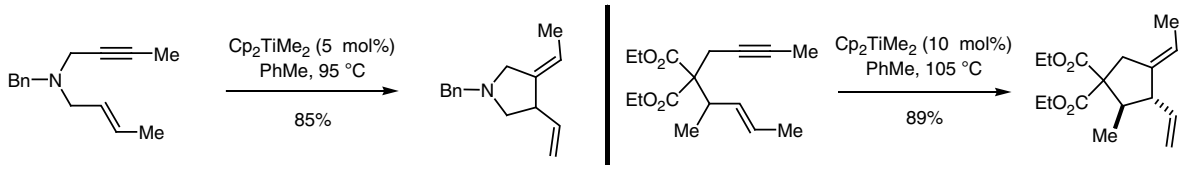


B. $Cp_2Ti(CO)_2$-catalyzed Pauson–Khand-type cyclization: Examples.

Scheme 11



3. A catalytic asymmetric enyne cyclization for the synthesis of bicyclic cyclopentenones has been described (Scheme 12).[39–41] Although representing an impressive advance in early transition metal-mediated asymmetric catalysis, this reaction process is similarly limited in substrate scope to previous titanocene-catalyzed enyne cyclization reactions and often requires higher catalyst loadings than the achiral system ($Cp_2Ti(CO)_2$).



Scheme 12

Moving beyond catalytic applications of enyne cyclization that are limited to the generation of bicyclic cyclopentenones (and related species), it has been demonstrated that titanocene-catalyzed enyne cyclization can be turned over by β-hydride elimination rather than stoichiometric additives that induce ring formation (i.e., CO and R_3SiCN) (Scheme 13A).[42] These advances stem from the ability of the $Cp_2Ti(CO)_2$ system to induce metallacyclopentene formation with substrates bearing 1,2-disubstituted alkenes and results in the formation of cyclopentanes bearing pendant 1,4-diene functionality (Scheme 13B).

A. $Cp_2Ti(CO)_2$-catalyzed intramolecular ene reaction: Proposed catalytic cycle.

B. $Cp_2Ti(CO)_2$-catalyzed intramolecular ene reaction: Examples.

Scheme 13

5.34.2.2.4 Ti-alkoxide-promoted enyne cyclization

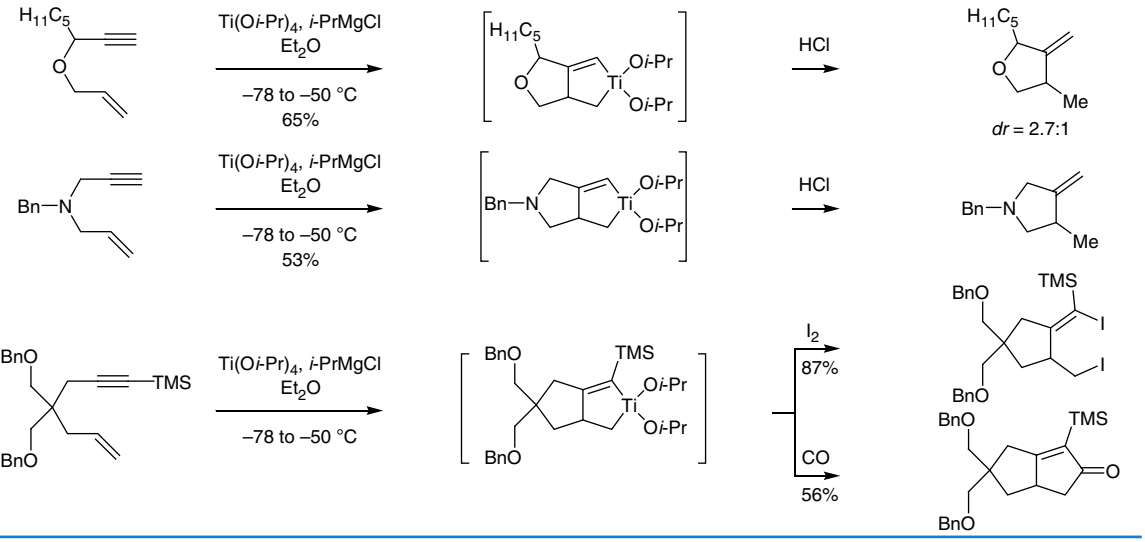
Exploring alternatives to the use of Cp_2ZrCl_2 and Cp_2TiCl_2 in metallacycle-mediated bicyclization reactions, Prof. Sato described the application of a simple inexpensive Ti(IV) alkoxide [Ti(O*i*-Pr)$_4$] in combination with Grignard reagents as a system suitable for enyne cyclization. In addition to defining that such a reagent combination defines a practical solution for this class of cyclization reaction, a rich body of reactivity has emerged that is unique to this system.

Among the first set of observations reported in this area was the ability of the reagent combination Ti(O*i*-Pr)$_4$/2RMgX to promote cyclization of enynes containing ethers and basic nitrogen (Scheme 14A).[21] These initial successes in cyclization were accompanied by demonstrations of functionalization reactions of the intermediate titanacyclopentene with protic acid, I_2, or CO.

As depicted in Scheme 14B, by employing substrates with appropriate heteroatom functionality, this cyclization reaction can be used to generate products related to that observed with metallo-ene chemistry (i.e., Scheme 13). Here, the reactivity of the titanacyclopentene intermediate formed from enyne cyclization is harnessed in elimination chemistry en route to substituted 1,4-diene-containing carbocyclic products.[27] In addition to demonstrating that functionalization of the remaining metal–carbon bond provides a means to increase product complexity, this process has also been rendered asymmetric via use of a chiral acetal as an auxiliary.[43]

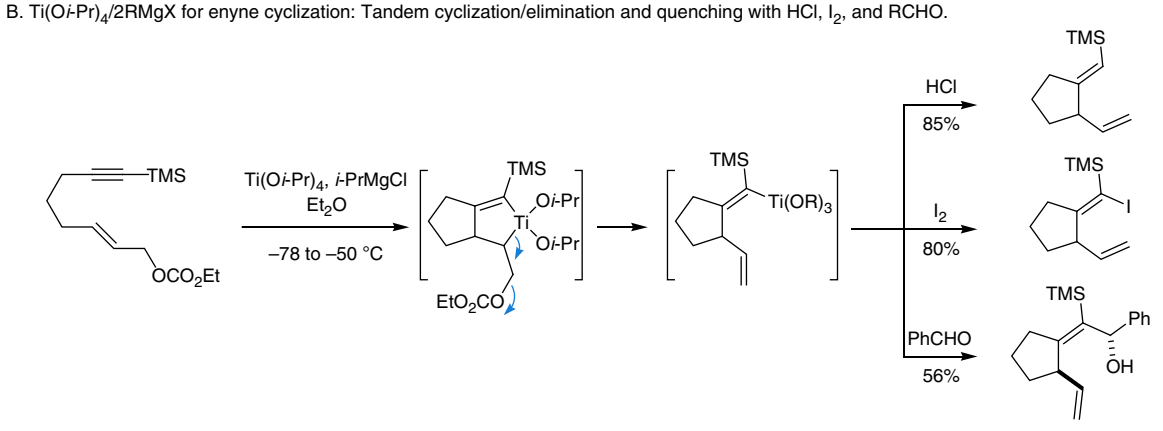
Finally, the compatibility of this metallacycle-mediated enyne cyclization reaction with metal alkoxides has led to the identification of a unique means to control the stereoselective course of ring closure.[44] As illustrated in Scheme 14C, cyclization reactions proceed to deliver stereodefined five- and six-membered rings with diastereomeric ratios (*dr*) ranging from 82:18 to >98:2. Interestingly, it was found that the free hydroxy group in these substrates was essential to obtain high levels of selectivity (protection as the corresponding TBS ethers led to substantial decreases in stereoselection). The authors suggest that the 'metal alkoxide behaves as a more sterically demanding group, at least superficially, than the TBS ether.'

5.34.2.2.4.1 Development of new Ti-mediated cyclization/functionalization processes that harnesses the reactivity of intermediate metallacyclopentenes formed from enyne cyclization



The titanacyclopentene intermediates derived from Ti(O*i*-Pr)$_4$/2*i*-PrMgCl-mediated enyne cyclization can be functionalized by selectively engaging each σ_{C-Ti} bond in subsequent bond-forming processes. Interestingly, addition reactions to aldehydes proceed with stereocontrol, yet with an opposite sense of regioselection compared with zirconacyclopentenes (Scheme 15A).[24,45,46] As depicted in Scheme 15B, it was found that a Lewis acidic additive [Cl$_2$Ti(O*i*-Pr)$_2$] increases both yield and stereoselection for this process – the proposed empirical model for stereoselection in the aldehyde addition reaction is depicted and is based on minimization of nonbonded steric interactions between the aldehyde (R^2)- and alkene (R^1)-substituents.

Despite the disparate regioselection observed in the addition of aldehydes to preformed metallacyclopentenes derived from Ti(O*i*-Pr)$_4$/2*i*-PrMgCl or Cl$_2$ZrCp$_2$/2BuLi, these species behave similarly in Cu-promoted allylation chemistry.[24,47] As illustrated in Scheme 15C, reactions proceed at the sp^2, rather than sp^3, carbon of the intermediate organometallic.



A variety of interesting new modes of reactivity have surfaced in recent years that take advantage of the instability of the organometallic intermediates formed from Ti(O*i*-Pr)$_4$-promoted bicyclization of enynes. In short, reactions have surfaced that are based on Grignard-mediated dehydrogenation/isomerization to a Ti-enolate/intermolecular trapping, intramolecular addition of a σ_{C-Ti} bond to a saturated or unsaturated ester, and elimination:

1. Dehydrogenation and trapping of intermediate metallacyclopentenes with aldehydes (Scheme 16): Treatment of bicyclic metallacyclopentenes with an additional equivalent of *i*-PrMgCl, followed by an aldehyde results in the stereoselective generation of functionalized 1,3-dienes.[24] This process has been proposed to occur by a sequence involving Ti(III) and radical intermediates that results in the formation of an allylic Ti(IV) species.
2. Stereoselective trapping and/or cyclization of enynes bearing one polarized π-bond (Scheme 17): Enyne substrates bearing an enoate are substrates for Ti(O*i*-Pr)$_4$/2*i*-PrMgCl-mediated ring closure, and these electronically activated systems deliver titanacyclopentene intermediates that have the potential to engage in a different collection of C–C bond-forming processes.[48,49] Illustrated in Scheme 17A, enyne cyclization followed by addition of formaldehyde delivers a carbocyclic product with high levels of stereoselection. Here, the site of aldehyde addition is different than that previously discussed in Scheme 15A, likely due to the reactivity profile imparted to the ring-expanded titanium enolate intermediate. This process is equally effective for the addition of an aliphatic aldehyde, yet stereoselection at the newly formed secondary hydroxyl group remains relatively low (*dr*=3:1).
3. These cyclization/alkylation reactions can take a different form if the nature of the ester is modified to accommodate late-stage organometallic addition to the carbonyl (ethyl ester rather than a *t*-Bu ester). As depicted in Scheme 17B, this portfolio of reactivity is quite useful in generation of a variety of bicyclic carbocycles, and use of a chiral auxiliary has been reported as a means to control absolute stereochemistry in the course of cyclization.[50] Finally, this sequence can accommodate other electrophiles to enable the formation of an additional C–C bond in the course of annulation. This is highlighted in Scheme 17C, where an aldol reaction with propionaldehyde leads eventually to the bicyclic carbocycle possessing a β-hydroketone.
4. As illustrated in Scheme 18, if the polarized π-bond in the enyne is the alkyne (in the form of an alkynoate), a different reaction path is observed.[48,49] Here, the intermediate metallacyclopentene rearranges to form a fused bicyclo[3.1.0]hexane system. Interestingly, quenching of the organometallic intermediate with a ketone results in the formation of a functionalized vinylcyclopropane.
5. Carbocyclization stemming from Ti-mediated cyclization of (*Z*)-enol ester-containing enynes (Scheme 19): Adding to the collection of interesting cyclization reactions that result from controlling the fate of the titanacyclopentene intermediate generated via enyne cyclization, it has been demonstrated that enol ester-containing enynes react by a unique stereoselective tandem reaction that takes advantage of the nucleophilicity of each σ_{Ti-C} bond present in the titanacyclopentene intermediate and the electrophilicity of the neighboring carbonyl.[51] As illustrated in Scheme 19, the simple reaction conditions employed for Ti(O*i*-Pr)$_4$/2*i*-PrMgCl-mediated enyne cyclization of a (*Z*)-enol acetate-containing enyne deliver a stereodefined oxygenated bicyclo[3.3.0]octene system. Although the isomeric (*E*)-enol acetate derivatives do not participate in this tandem process, it has been speculated that the course of this process follows initial nucleophilic addition of the proximal σ_{C-Ti} bond to the ester

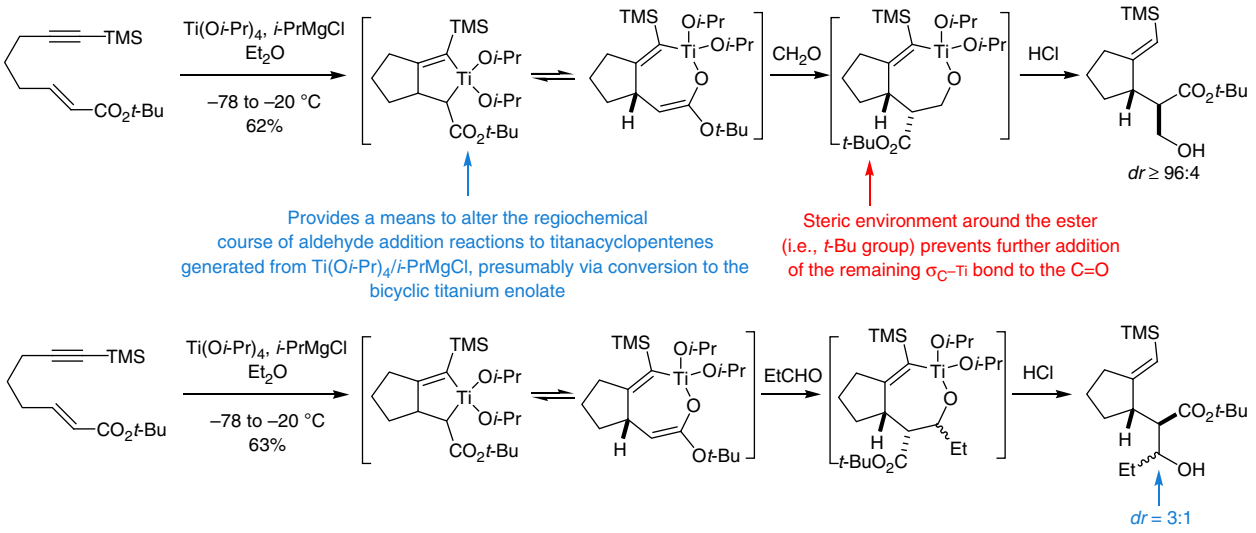
(to generate an epoxy-oxatitanacycloheptene intermediate), followed by rearrangement to the corresponding oxatitanacyclohexene, and a second intramolecular nucleophilic addition of the remaining σ_{C-Ti} bond to the pendant ketone. Based on the stereoselective course of the initial carbometalation process (generating the first metallacyclopentene intermediate), the subsequent steps proceed in a highly stereocontrolled manner – no evidence was found for the production of isomeric products.

6. Enyne cyclization followed by Pummerer rearrangement (Scheme 20): Cyclization of enynes bearing chiral vinylsulfoxides results in the formation of cyclopentanes adorned with a β,γ-unsaturated aldehyde.[52] It has been proposed that stereoselection in this process derives from an association of the sulfoxide oxygen with titanium in the transition state for carbometalation. This stereochemistry-determining step is then thought to be followed by elimination and intramolecular addition to generate a fused bicyclic oxatitanacyclohexene, hydrolysis of which delivers the stereodefined β,γ-unsaturated aldehyde product.

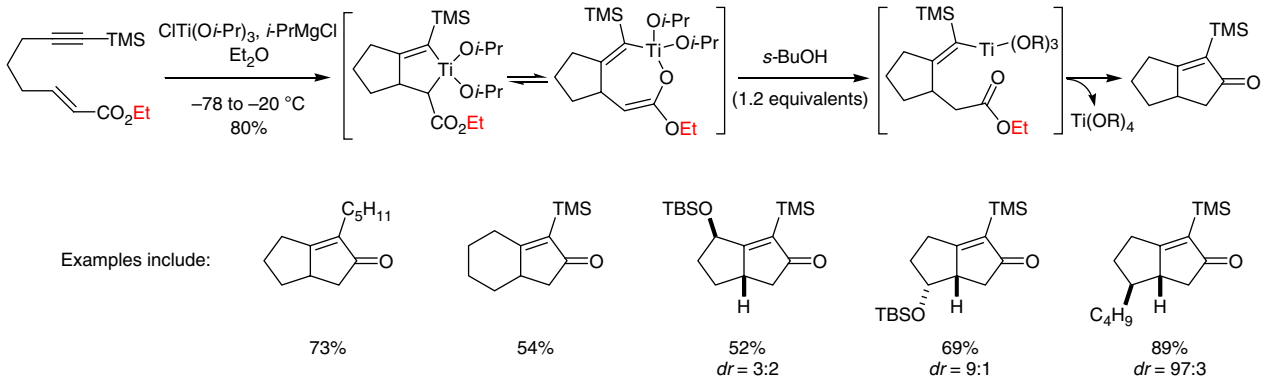
In addition to these unique cyclization reactions that derive from funneling the reactivity of intermediate metallacyclopentenes down different pathways, the utility of metallacycle-mediated enyne cyclization has recently been harnessed in acyclic stereocontrol. Specifically, studies directed toward the synthesis of dictyostatin stimulated the design of a new stereoselective version of the Ti(O*i*-Pr)$_4$/2*i*-PrMgCl-promoted enyne cyclization.[53,54] As depicted in Scheme 21, cyclization of a silyl ether-tethered enyne proved effective for establishing the C15–C16 *anti*-stereochemical relationship in this target with a high degree of stereochemical control – the cyclized product was produced as a single stereoisomer.

5.34.2.3 Bicyclization of Dienes



Cyclization of dienes has been studied with a variety of early transition metals. This section introduces advances that stemmed from investigations of metallocene-based chemistry, including the study of stereochemical control in such cyclizations (see Section 5.34.2.3.1) and catalysis (see Section 5.34.2.3.2), whereas also presenting some limitations in substrate scope (see Section 5.34.2.3.3). Titanium alkoxide-mediated diene cyclization chemistry is then discussed (see Section 5.34.2.3.4), first in a manner to support that Ti-alkoxides can be employed to realize diene cyclization, then to feature a variety of interesting functionalization reactions of the intermediate titanacyclopentanes that define unique and powerful tandem reactions for organic synthesis. Finally, this section is concluded with a discussion of a recently described Ti-catalyzed diene cyclization (see Section 5.34.2.3.5).

5.34.2.3.1 Stereochemistry in Zr-promoted enyne cyclization



Stereochemical control of early transition metal metallacycle-mediated diene cyclization has been a topic of considerable interest, with reports describing achievements in reactions that proceed with both stoichiometric and catalytic quantities of zirconocene reagents. A variety of cyclization chemistry has been described whereby the stereochemistry of the products can be established by kinetic or thermodynamic control – in the latter case, thermal instability of the intermediate metallacyclopentane[55–58] is harnessed as a mechanism to alter the stereochemical course of cyclization.

As illustrated in Scheme 22A, cyclization of 1,6-heptadiene can proceed with high selectivity for the formation of both 1,2-*trans*- or 1,2-*cis*-substituted cyclopentane products. When promoting the reaction with Cp_2ZrCl_2/*n*-BuLi, initial conversion proceeds with poor kinetic selectivity, but on prolonged stirring at r.t., bromination results in the selective formation of the *trans*-1,2-disubstituted cyclopentane (*dr* = 97:3).[59,60] If this reaction is run with Cp*$TiCl_3$/Na(Hg) amalgam, the *cis*-1,2-disubstituted isomer

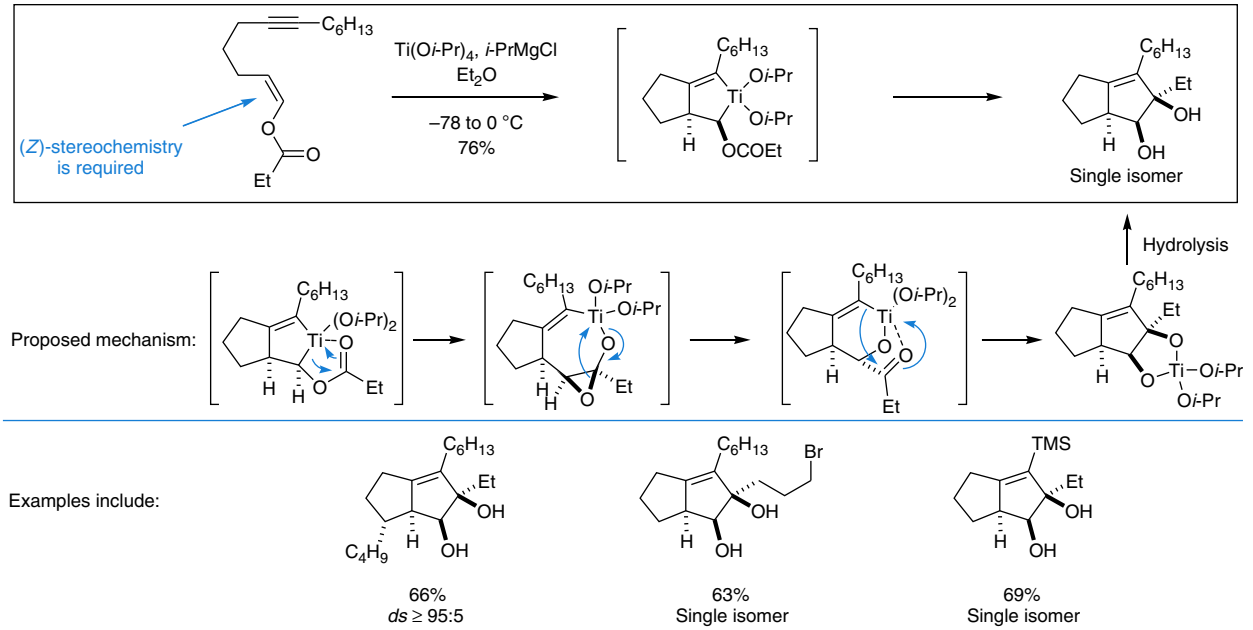
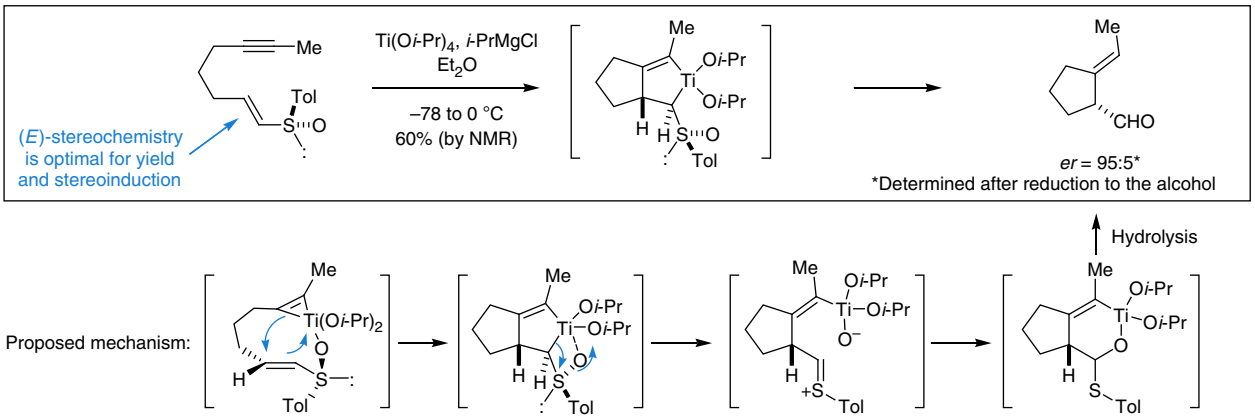


Scheme 17

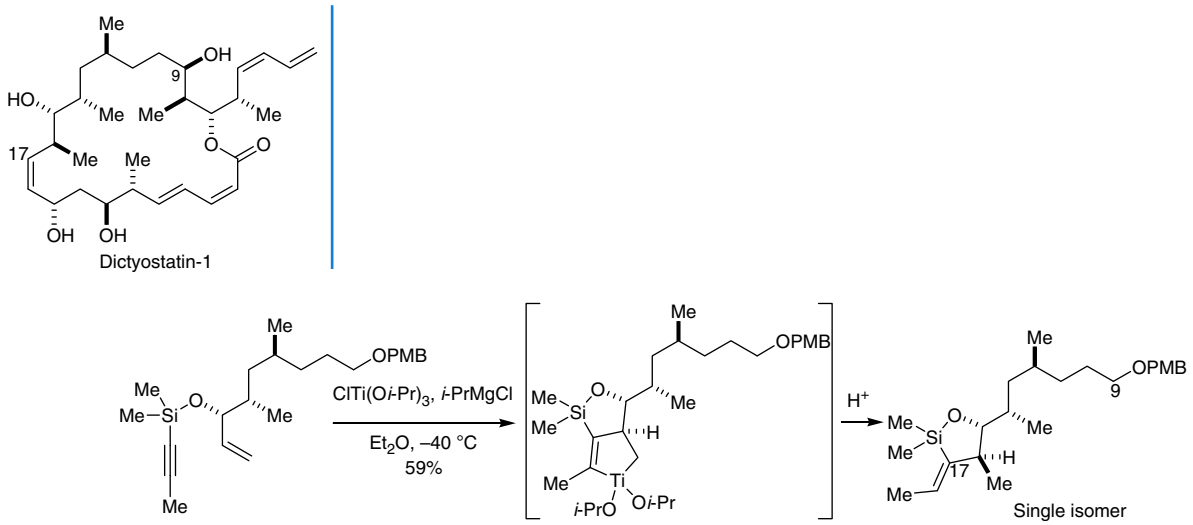
is produced with outstanding levels of stereochemical control – an observation that has been attributed to high kinetic selectivity and a decreased tendency for equilibration at r.t.

A similar trend is observed in the cyclization of 1,7-octadiene, where kinetic selectivity favors the formation of the 1,2-*cis*-disubstituted cyclohexane product (*dr* = 3:1) and prolonged heating at 75 °C results in the selective formation of the 1,2-*trans*-disubstituted product (*dr* = 99:1) (Scheme 22B).

Scheme 18



Scheme 19



In addition to the design of cyclization protocols that proceed with catalytic quantities of Zr reagent and excess Grignard,[60,61] a variety of stereoselective cyclization reactions have been described that provide a glimpse of the potential power of this type of cyclization in stereoselective synthesis (Scheme 23). Shown are three examples of stoichiometric Cp_2Zr-mediated cyclization reactions that proceed via thermodynamic control and deliver products with varying levels of stereoselectivity.[59,62,63] Interestingly, in catalytic variants, where excess Grignard is employed to turn over Cp_2Zr, kinetic trapping of the metallacyclopentane products can offer a complementary selectivity profile.[60,62]

5.34.2.3.2 Catalysis in Zr-promoted diene cyclization

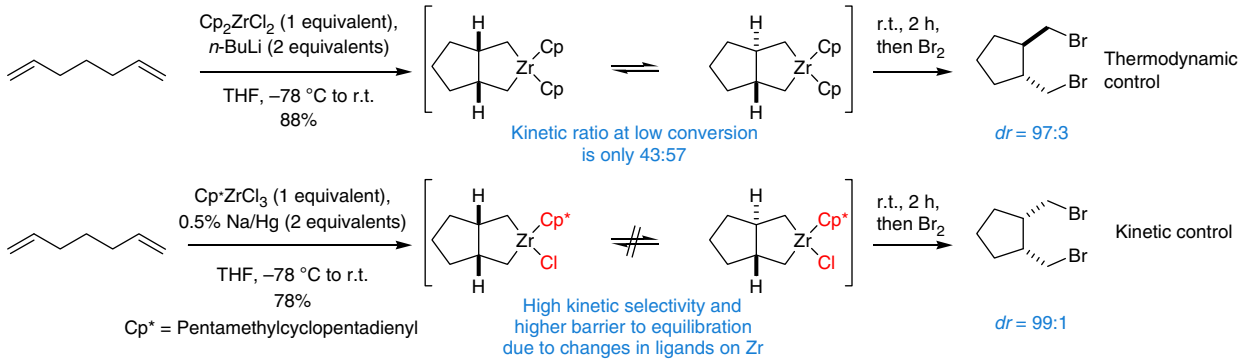
As mentioned in Section 5.34.2.2.3, an elegant means of rendering diene cyclization chemistry substoichiometric in Cp_2Zr– has been described.[64] These cyclization reactions, while proceeding through similar zirconacyclopentanes, are mechanistically complex with stereochemistry being influenced by a variety of factors including (1) the interplay between kinetic and thermodynamic stereoselectivity, (2) the rate of metallacycle isomerization, and (3) the rate of transmetalation of the metallacycle intermediates (Scheme 24A).[60] As illustrated in Scheme 24B, remarkable examples are shown that support the notion that

Scheme 20

Scheme 21

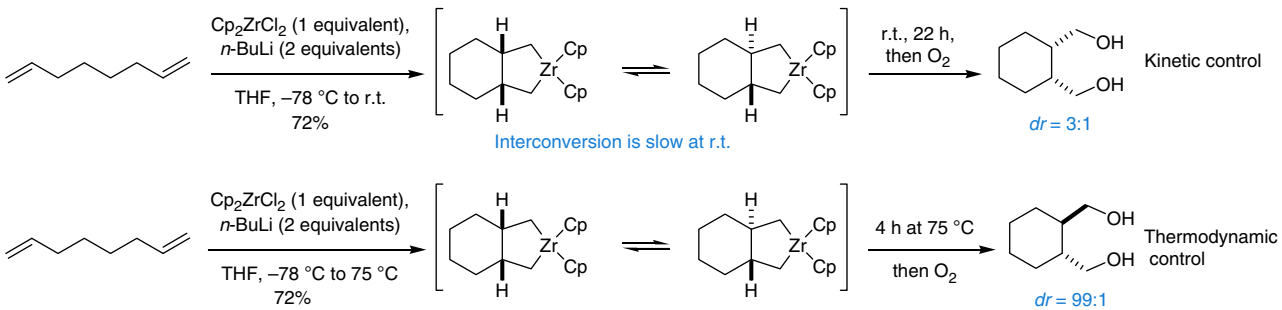
selective cleavage of intermediate metallacyclopentanes is possible and that demonstrate that changes in reaction conditions lead to a shifting of reaction course to generate mono- rather than diorganomagnesium intermediates.[61,62]

5.34.2.3.3 Substrate scope limitations in Zr-promoted diene cyclization



Exploration of the scope of Cp_2Zr-promoted diene cyclization has led to the discovery of a competing reaction process which results in isomerization of the diene starting material.[65] As illustrated in Scheme 25A, simple unsaturated hydrocarbon substrates containing substituted alkenes rapidly isomerize to conjugated dienes rather than undergoing cyclization. Interestingly, it has been demonstrated that substitution in the tether between the two alkenes can result in regaining the ability to accomplish cyclization. Although this process has not yet been extensively studied, a substrate bearing a 1,1-disubstituted olefin and a quaternary center (likely supporting a conformation that facilitates ring closure via the Thorpe–Ingold effect) has been shown to provide a carbocyclic product (Scheme 25B) in 85% yield, whereas the parent substrate lacking the geminal methyl substitution delivers the product of alkene isomerization (Scheme 25A).

Notably, heteroatom substitution in the tether between the two alkenes also can be employed to regain the ability to cyclize (Scheme 25B). Such features played a prominent role in a Cp_2Zr-promoted cyclization en route to a formal total synthesis of dendrobine (Scheme 25C).[66]



5.34.2.3.4 Titanium alkoxide-promoted diene cyclization

Study of early transition metal metallacycle-mediated diene cyclization reactions has resulted in the discovery of different selectivity patterns observed for reactions promoted by Negishi's reagent (Cp_2ZrBu_2) versus $Ti(Oi\text{-}Pr)_4/2i\text{-}PrMgCl$. As illustrated in Scheme 26, Prof. Whitby's study of the cyclization reactions of silyl-tethered 1,6-dienes has resulted in the discovery that the Zr-promoted process is highly selective for the *anti*-isomer (a minor isomer was not identified), whereas the Ti-alkoxide-promoted

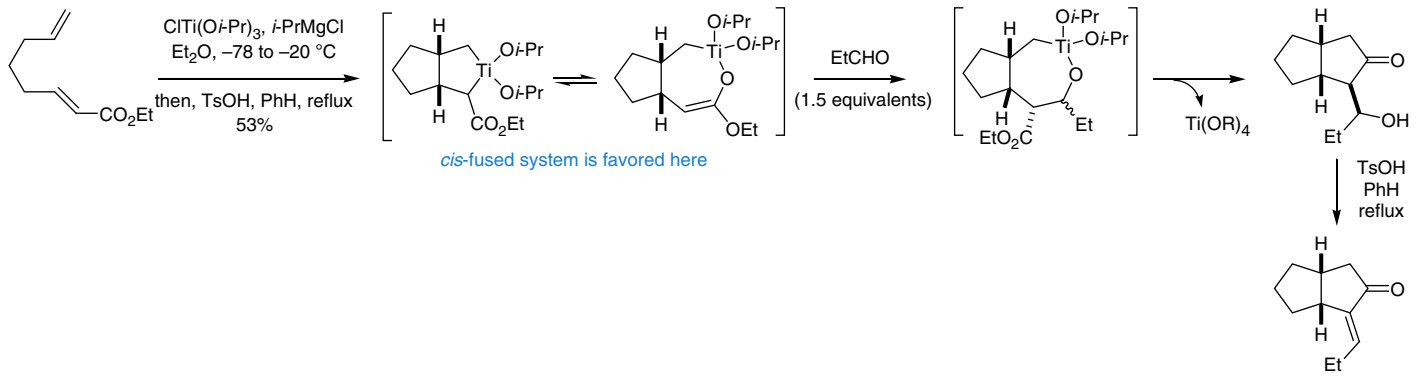
cyclization proceeds with an opposite sense of selectivity favoring the production of the *syn*-isomer, albeit with diminished levels of stereoselectivity (ds = 4:1).[67]

5.34.2.3.4.1 *Development of new Ti-mediated cyclization/functionalization processes that harnesses the reactivity of intermediate metallacyclopentanes formed from diene cyclization*

Consistent with trends in reactivity already discussed for titanacyclopentenes generated from enyne cyclization with Ti(O*i*-Pr)$_4$/2*i*-PrMgCl, diene cyclization reactions also deliver intermediate metallacyclic products that can be employed in subsequent bond-forming processes. As depicted in Scheme 27A, cyclization of diene substrates containing an enoate, followed by addition of one equivalent of an electrophile promotes monofunctionalization of the intermediate bicyclic titanium enolate, ring opening, and intramolecular C–C bond formation to deliver cyclic ketones. Interestingly, this process delivers carbocyclic products that have related stereochemistry to those derived from the Ti-promoted cyclization reactions depicted in Scheme 26, but opposite to that reported for the cyclization of a simple diene substrate (Scheme 27B). Perhaps these observations support the conclusion that the factors that control stereoselection in these processes are complex. Nevertheless, the tandem Ti-promoted diene cyclization/aldol/intramolecular nucleophilic addition reaction has recently been employed in a concise total synthesis of carbacyclin (Scheme 27C).[68]

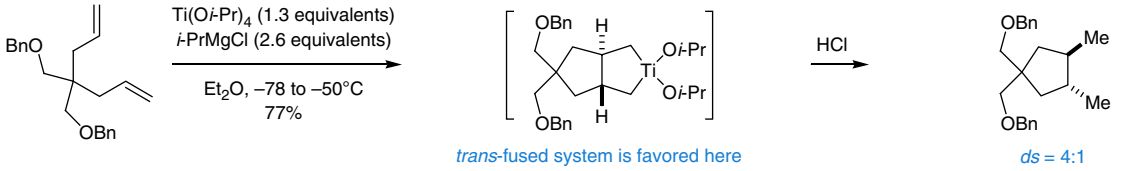
5.34.2.3.5 *Titanium aryloxide-catalyzed diene cyclization*

Defining a different net transformation, Ti(IV) aryloxides have been described as effective catalysts for cycloisomerization of 1,6- and 1,7-dienes en route to substituted five- and six-membered rings (Scheme 28).[69] Notably, this process has been found to be quite sensitive to alkene substitution – only terminal (monosubstituted) alkenes participate in the cyclization.



5.34.2.4 Bicyclizations Involving Allenes

Early transition metal metallacycle-mediated cyclization reactions of allenynes are complex owing to the availability of two different π-systems of the allene to engage in intramolecular reaction with the pendant alkyne. Titanium alkoxide-mediated reaction of 1,2-dien-7-ynes results in regioselective cyclization to deliver 1,4-diene-containing products, whereby C–C bond formation occurs at a terminus of the cumulated π-system (Scheme 29A).[70] Stereoselective variants of this cyclization have been established, where axial chirality of the allene is translated to point chirality in the cyclopentane product. Here, highest stereoselectivities are seen with silyl-substituted allenes (Scheme 29B).



Interestingly, the regiochemical course of this enyne cyclization changes with 1,2-dien-6-ynes (Scheme 29C). Here, C–C bond formation occurs at the central carbon of the allene and delivers a bicyclic allyltitanium species that can be intercepted with carbonyl electrophiles. The stereochemical course of the resulting SE2′ addition process is dependent on the nature of the substituent on the sp^3 carbon α- to Ti. With a linear pentyl side chain, C–C bond formation occurs *syn*- to the pentyl substituent. With a TMS group at the α-position, C–C bond formation occurs primarily *anti*- to the TMS group through a process that delivers a (*Z*,*E*)-1,3-diene.

Finally, as previously discussed in the related cyclization reactions of enynes and diynes, the intermediate metallacycles generated from these allenyne cyclization reactions can be induced to undergo elimination or CO insertion. In the current context, such processes provide a means to access cross-conjugated trienes and bicyclic cyclopentenones, respectively (Scheme 29D).[71] Related to this latter example, it has been demonstrated that $Cp_2Ti(CO)_2$ can be employed to catalyze a related enyne cyclization/CO insertion to generate bicyclic cyclopentenones from 1,2-diene-6-ynes (10 mol% $Cp_2Ti(CO)_2$, 18 psig CO, PhMe, 90 °C).[38]

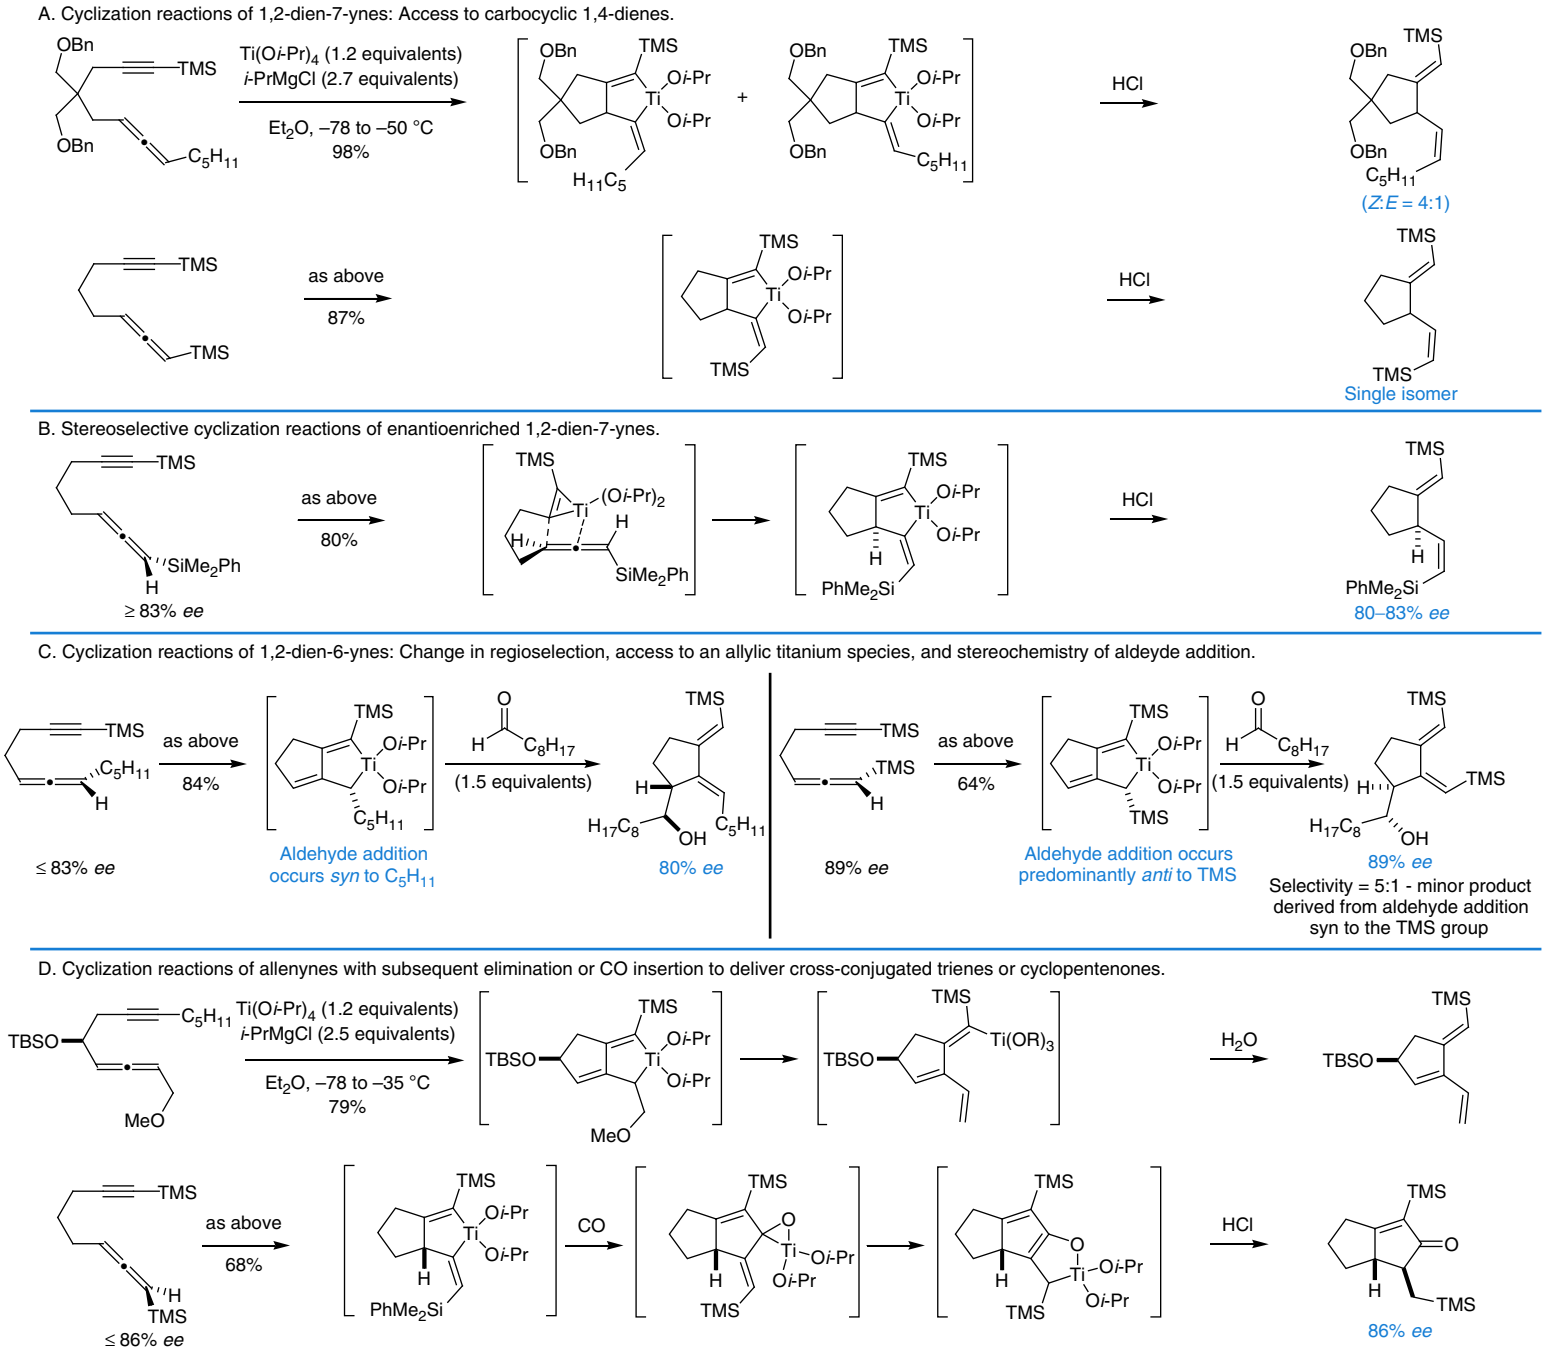
5.34.2.5 Bicyclizations Involving a Carbonyl-Based Functional Group

A variety of early transition metal metallacycle-mediated coupling chemistry has been described that engages the reactivity of carbonyl-based functional groups. This section is organized to first present advances in metallocene-based methods (see Section 5.34.2.5.1), then to describe relevant examples that proceed via the action of Ti-alkoxides (see Section 5.34.2.5.2). In this latter case, a variety of bond-forming processes are described that proceed through intramolecular reaction of a Ti–π complex with a pendant carbonyl system. In some cases, such processes result in the formation of a cyclic system, whereas in others nucleophilic addition is followed by ring opening to define a net acyl transfer process.

5.34.2.5.1 Cyclization reactions mediated by metallocenes

Building on the discovery of a titanium-catalyzed silane-mediated reduction of carbonyl compounds,[72] conditions have been found that enable reductive cyclization of unsaturated ketones and aldehydes that proceed with 10–20 mol% of $Cp_2Ti(PMe_3)_2$ and one equivalent of a silane or siloxane (Scheme 30A).[73–75] As previously discussed in the context of early transition metal-catalyzed diene cyclization reactions, stereoselection is often more challenging to control in these cyclization reactions due to competitive kinetic trapping of the intermediate metallacyclopentene before thermodynamic equilibration.

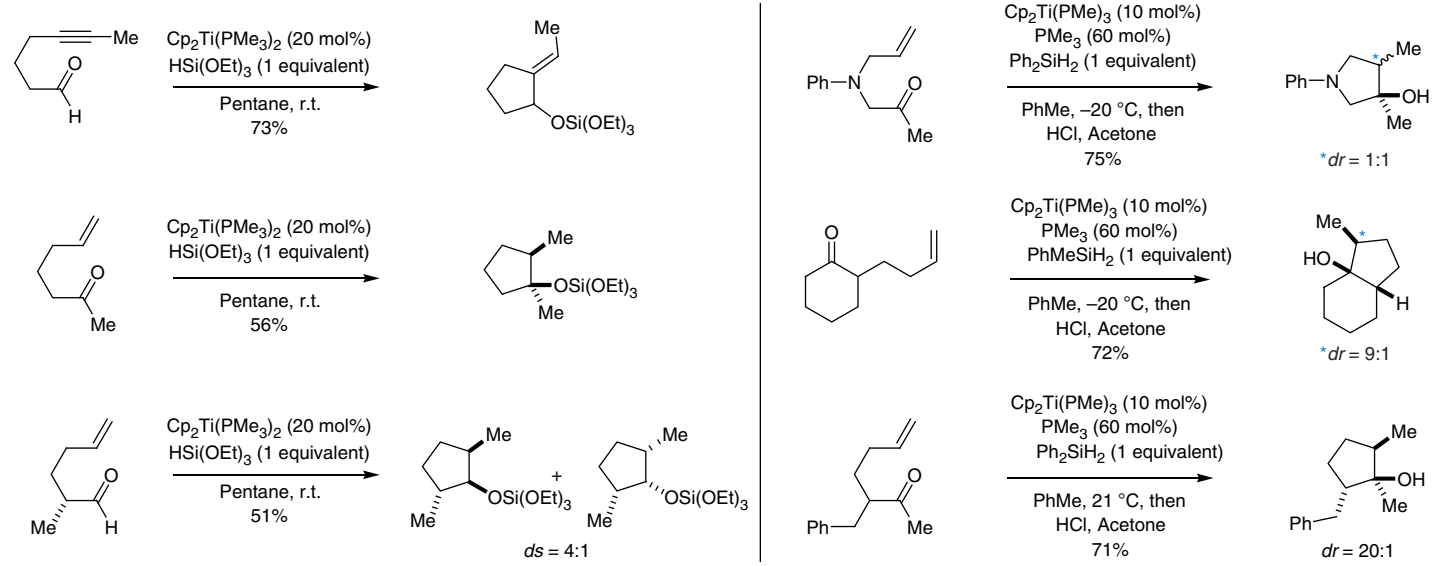
As has been highlighted with other cyclization processes, this class of early transition metal metallacycle-mediated cyclization reaction is compatible with intermediate-functionalization processes for the establishment of bicyclic products. As illustrated in Scheme 30B, a variety of carbocyclization reactions have been reported to deliver bicyclic lactones with high levels of stereochemical control.[76,77] Notably, this reaction process has been rendered substoichiometric in the early transition metal[77] – an accomplishment that has led to the discovery of a catalytic asymmetric variant.[78]



5.34.2.5.2 Cyclization reactions mediated by Ti-alkoxides

Ti-alkoxide reagents are useful for the cyclization of unsaturated carbonyl compounds, establishing parallel methods for cyclization chemistry to those observed with metallocene reagents (Scheme 31A).[79,80]

In addition to simple cyclization chemistry akin to that seen in diyne, enyne, and diene cyclization reactions, Ti-alkoxides have also been shown to affect a variety of other interesting transformations that derive from intramolecular addition of a Ti–π complex to an ester or a carbonate. As generally depicted in Scheme 31B, Ti–π complex formation is thought to be followed by intramolecular nucleophilic attack to deliver an intermediate bicyclic product, the fate of which is dictated by the nature of the unsaturated system (alkene, alkyne, allene, or 1,3-diene), the substituents X and Y, and the ring size.[81–86] These processes have been termed, 'intramolecular nucleophilic acyl substitution' (INAS) reactions and have been explored as a means to prepare a variety of nitrogen-containing heterocycles (Scheme 32A). Recently, this type of early transition metal-mediated process has appeared as a key step in the total synthesis of allopumiliotoxin 267A (Scheme 32B).[87]



5.34.2.6 Summary of Advances in Early Transition Metal Metallacycle-Mediated Cyclization

The preceding sections have presented a great deal of science that has surfaced from efforts aimed at understanding and controlling early transition metal metallacycle-mediated cyclization chemistry. In summary of these contributions, basic advances include the following: (1) Ti-alkoxides offer a complementary means to accomplish bicyclization of polyunsaturated substrates (Scheme 33A-1) and (2) procedures have been advanced to enable metallacycle-mediated cyclization chemistry to proceed with substoichiometric quantities of Group (IV) metals (Scheme 33A-2).

In addition to these, a great variety of novel complexity-generating reactions have emerged from harnessing the reactivity of metallacyclic intermediates generated from cyclization reactions promoted by $XTi(O\textit{i}\text{-}Pr)_3/\textit{i}\text{-}PrMgX$. As illustrated in Scheme 33B, these include the following:

1. Elimination reactions (Scheme 33-B1);
2. Regioselective nucleophilic addition reactions (Scheme 33-B2);
3. Isomerization to a Ti-enolate/enolate functionalization/intramolecular carbonyl addition (Scheme 33-B3);
4. Dehydrogenation/aldehyde addition (Scheme 33-B4); and
5. Rearrangement by intramolecular addition to a polarized π-bond (Scheme 33-B5).

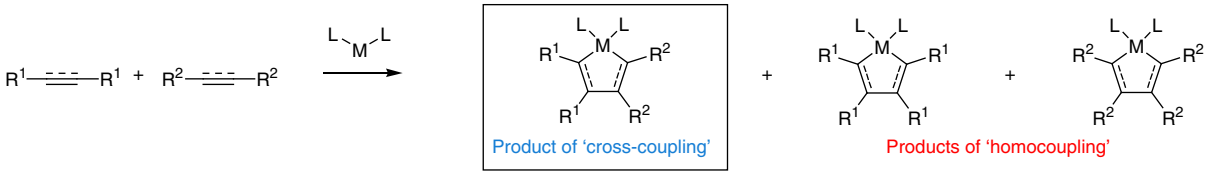
5.34.3 Early Transition Metal-Mediated Cross-Coupling (Intermolecular C–C Bond Formation)

5.34.3.1 Introduction to Early Transition Metal Metallacycle-Mediated Cross-Coupling

In the early 1990s, the emerging body of science associated with early metal metallacycle-mediated cross-coupling could be summarized in the following manner: A number of observations had been made that confirmed the viability of a subset of intermolecular coupling reactions of preformed metal–π complexes (i.e., Zr–alkyne, Zr–benzyne, Zr–imine, and Zr–alkene) with unsaturated systems (i.e., alkynes, alkenes, aldehydes, ketones, and imines). These accomplishments served to define the potential utility of metallacycle-mediated C–C bond formation in intermolecular settings but were frequently accomplished with only the simplest of systems (i.e., symmetrical alkynes and ketones and unhindered/unfunctionalized terminal alkenes/ethylene) of restricted relevance to complex molecule synthesis. Over the past 20 years, a substantial body of work has emerged that confirms the great potential that metallacycle-mediated cross-coupling has in organic synthesis, with recent accomplishments defining solutions to the major barriers that have existed in controlling the course of this class of bimolecular C–C bond-forming reaction.

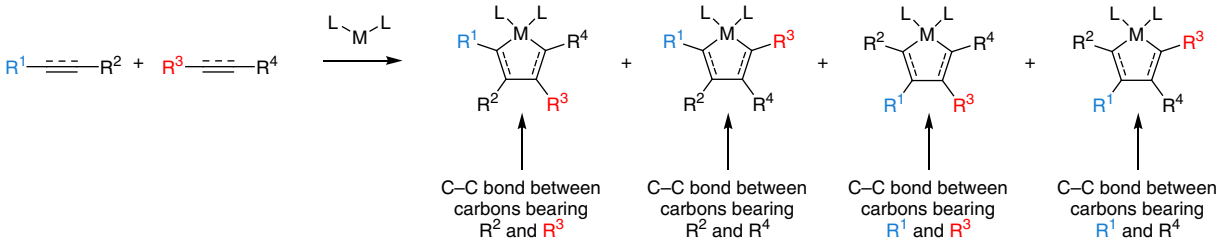
The factors that have limited the development of metallacycle-mediated cross-coupling lie not in the pursuit of catalytic methods, but rather relate to fundamental challenges associated with the control of reactivity and selectivity in the bimolecular C–C bond-forming event. Without a tether to position the two reactive π-systems in a defined orientation for intramolecular formation of a metallacyclopentane, intermolecular applications of this reactivity are substantially more difficult to control than their intramolecular counterparts. Outside of the low levels of reactivity for coupling processes between highly substituted alkenes and hindered alkynes, and the potential reversibility of the coupling process that is ever more significant with increasing temperature, major hurdles surface in the control of pair selectivity (**Scheme 34A**), regioselectivity (**Scheme 34B**), and *ds* (**Scheme 34C**). The great complexity that results when combining these issues is summarized in **Scheme 34D** and supports the impressive challenges associated with efforts aimed at controlling this area of chemical reactivity.

Moving beyond metallocene-based coupling chemistry, significant advances have surfaced from harnessing the reactivity of Ti–π complexes generated *in situ* from $Ti(O\textit{i}\text{-}Pr)_4/2RMgX$. Initial studies described bond constructions that mirrored those possible with metallocene chemistry (i.e., alkyne–aldehyde, alkyne–imine, and internal alkyne–terminal alkyne), with recent advances describing coupling reactions not possible with any other metallacycle-mediated coupling chemistry. These latter advances build on the demonstrated significance of initial stoichiometric activation of one coupling partner in the absence of the other (to achieve pair selectivity) and provide a means to simultaneously (1) overcome the typical low reactivity that has limited substrate scope in all metallacycle-mediated intermolecular C–C bond-forming reactions, (2) control regioselectivity with respect to both unsaturated reaction partners, and (3) control diastereoselectivity.



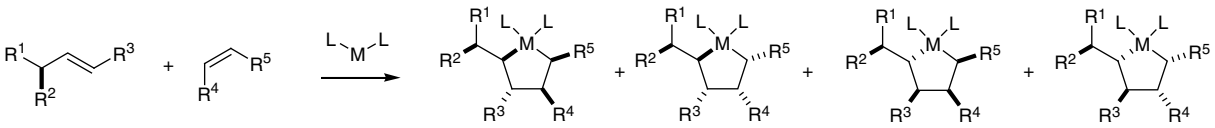
The most significant advance that has led to an explosion of new cross-coupling technology based on early transition metal metallacycle-mediated C–C bond formation has derived from a pursuit focused on rendering these reactions 'substrate directed.' It is well accepted that directing strategies provide a powerful means to control chemo-, regio-, and stereoselection in a host of other bond-forming processes.[88] Recognizing that Ti-alkoxides are compatible with metallacycle-mediated C–C bond formation and that alkoxide ligand exchange should be fast and reversible at Ti, led to a broad exploration of the use of tethered alkoxides as directing groups to control the course of metallacycle-mediated C–C bond formation.[89,90] These pursuits have indeed defined a collection of unique and complex coupling reactions not possible with other metal systems (catalytic or stoichiometric), while establishing a suite of technology capable of forging C–C bonds in the presence of free hydroxyls – a particularly compelling feature of this class of convergent coupling chemistry.

The organization of this section is similar to Section 5.34.2 on cyclization reactions, being subdivided by the nature of the π-systems that participate in the metallacycle-mediated bond construction. Within each subsection, attention is given to the nature of the initial Ti–π complex employed in each coupling process, as reactivity and selectivity are greatly influenced by this consideration. Also, effort has been taken throughout to highlight the demonstrated utility of these reactions in stereoselective organic synthesis. The discussion begins with a summary of alkyne–carbonyl coupling processes mediated by preformed metal–alkyne complexes that includes a discussion of the challenges associated with the control of regioselection in these processes, as well as state of the art means to achieve regio- and stereochemical control in alkyne–aldehyde coupling processes that proceed via the intermediacy of preformed metal–alkyne complexes (see Section 5.34.3.2). This discussion begins with addition reactions to aldehydes and ketones (see Section 5.34.3.2.1), and continues with addition reactions of alkynes to C═N (see Section 5.34.3.2.2) and nitriles (see Section 5.34.3.2.3). Moving on, the discussion shifts to include more challenging coupling reactions, including: alkyne–alkyne (see Section 5.34.3.4), alkyne–alkene (see Section 5.34.3.5), allene–alkyne (see Section 5.34.3.6), imine–alkyne (via the intermediacy of metal–imine complexes; see Section 5.34.3.7), imine–alkene (also via the intermediacy of metal–imine complexes; see Section 5.34.3.8), alkene–alkene (see Section 5.34.3.9), chemoselective coupling of polyunsaturated substrates (see Section 5.34.3.10), and other coupling reactions that proceed by [2 + 2 + 2] annulation (see Section 5.34.3.11).

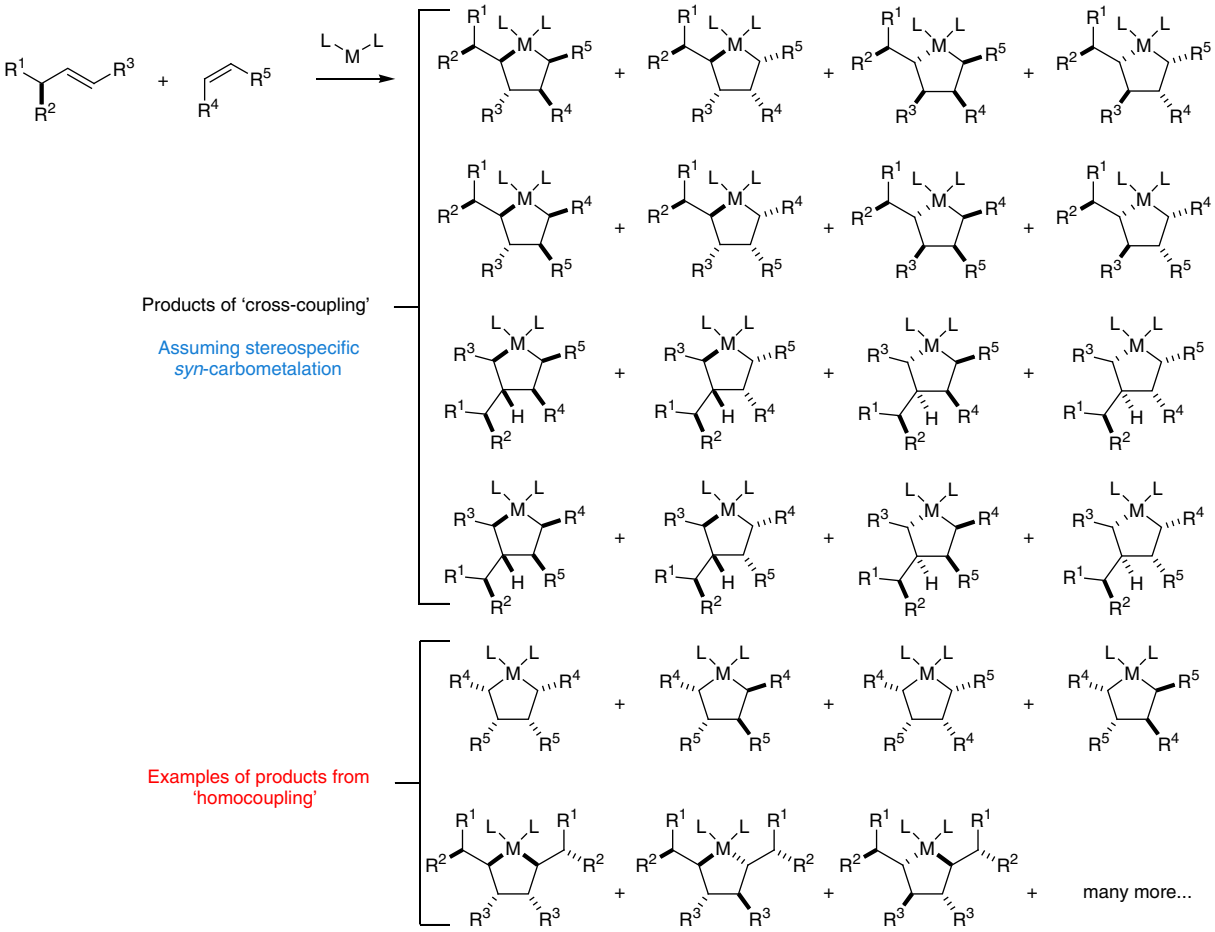


5.34.3.2 Alkyne–Aldehyde, Alkyne–Imine, and Alkyne–Nitrile Cross-Coupling (via Preformed Metal–Alkyne Complexes)

Since the early demonstrations of Cp_2Zr- and Cp_2Ti-based metallacyclopropene addition reactions to polarized π-bonds (i.e., aldehydes, ketones, and imines), titanium alkoxide-based methods have emerged that offer a complementary approach to achieve related chemical reactivity. Following is a brief survey of developments that have secured strategies to control regio- and stereoselection in this class of metallacycle-mediated cross-coupling.



A. The challenge of pair selectivity in metallacycle-mediated cross-coupling.



B. The challenge associated with control of regioselection in metallacycle-mediated cross-coupling.

C. The challenge associated with control of diastereoselection in metallacycle-mediated cross-coupling.

D. Combined challenges of pair selectivity, regioselectivity, and diastereoselectivity greatly complicate metallacycle-mediated cross-coupling.

Scheme 34

5.34.3.2.1 Alkyne–aldehyde and alkyne–ketone coupling

5.34.3.2.1.1 Control of regioselection

As illustrated in Scheme 35, it is often challenging to achieve regioselection in metallacycle-mediated coupling reactions of unsymmetrical alkynes with carbonyl systems. To date, factors that are known to influence the regiochemical course of C–C bond formation include alkyne substitution, nature of the electrophile, and solvent.[20,91,92] Moderate selectivity has been observed in coupling reactions of aromatic alkynes, propargylic ethers, and alkynoates – the major product of coupling reactions with such systems is derived from C–C bond formation α to these groups. With TMS-substituted alkynes, C–C bond formation occurs preferentially at the site distal to the TMS group. Here, it is clear to see that the degree of regioselection in these coupling reactions is also a factor of the nature of the electrophile (highest regioselection is observed with ketones). Finally, when the alkyne-coupling partner possesses a TMS group in combination with another 'directing' group that reinforces the selectivity imparted by the silyl substituent (i.e., propargylic ether or ester), very high levels of regiochemical control are observed.

While documenting the ability to accomplish alkyne–aldehyde and alkyne–ketone coupling chemistry under simple and straightforward reaction conditions, these early reports defined the substantial challenge that surfaces with respect to regioselectivity in metallacycle-mediated cross-coupling reactions of unsymmetrical alkynes. Notably, not even being concerned yet with absolute or relative stereochemistry, or having to worry about regioselectivity with respect to the carbonyl π-system (C–C bond formation is uniformly favored over C–O bond formation), the difficulties associated with controlling regiochemistry with respect to the alkyne-coupling partner relegates the synthetic utility of this coupling reaction to a small substrate scope.

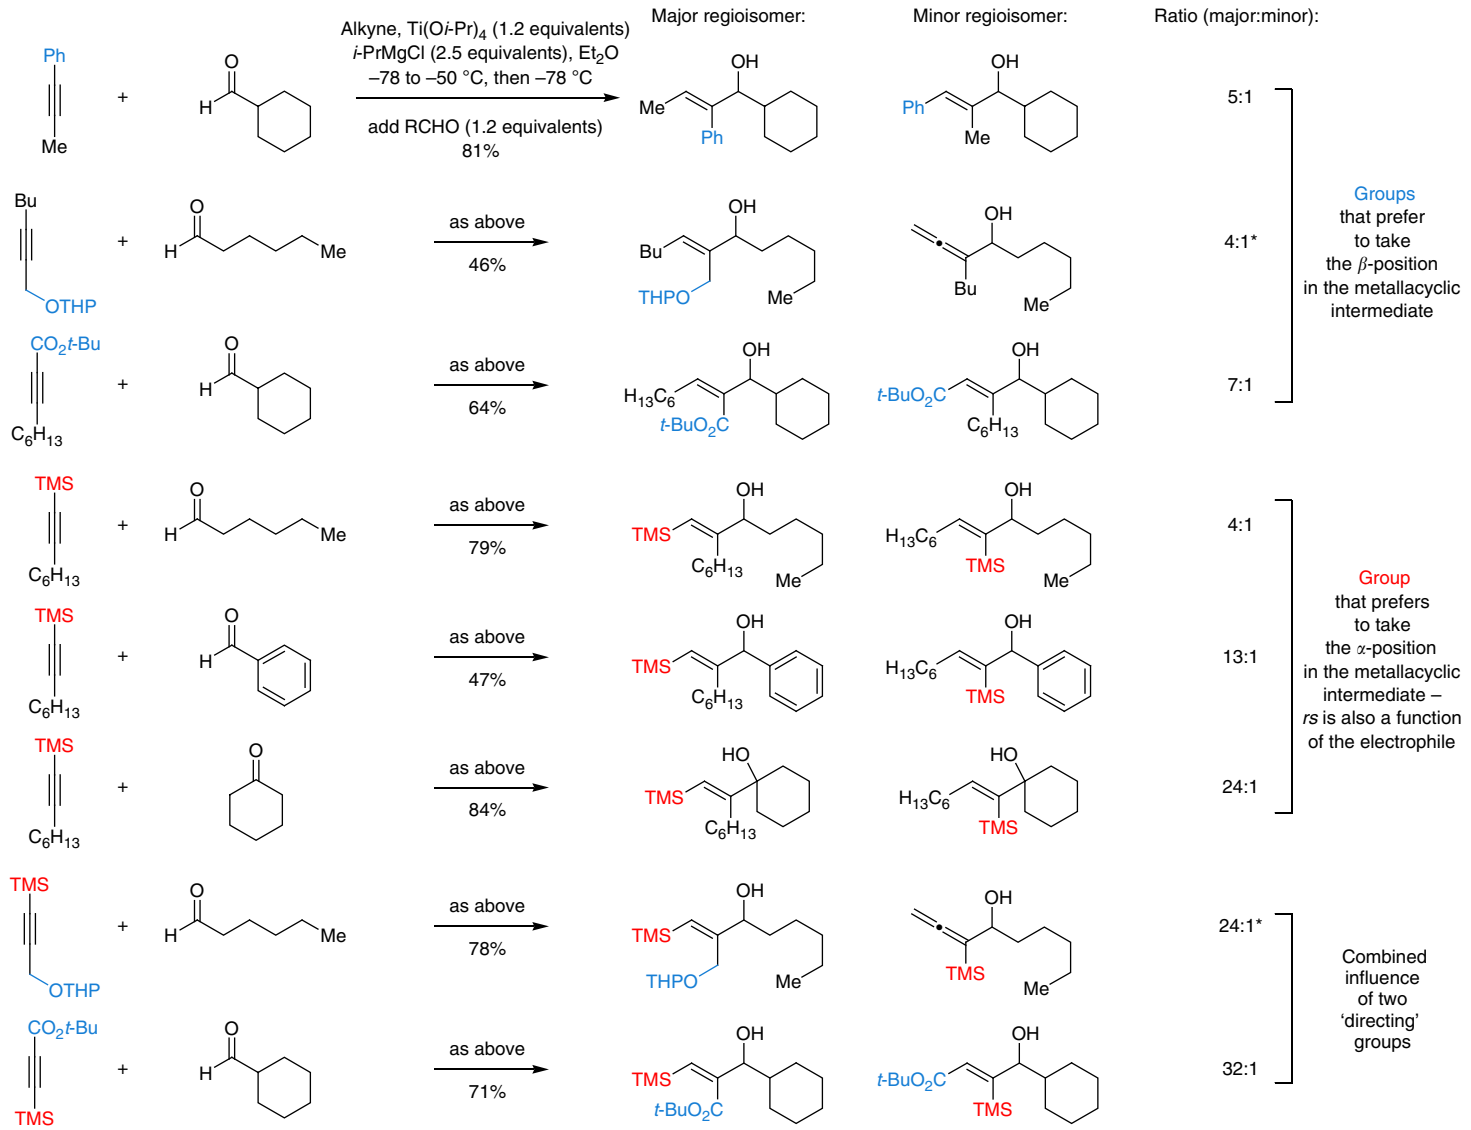
5.34.3.2.1.2 Development of heteroatom-directed alkyne–aldehyde-coupling chemistry

Aiming to establish the utility of Ti-mediated alkyne–aldehyde-coupling chemistry in polyketide synthesis, a new strategy for the control of regioselection in this subclass of metallacycle-mediated cross-coupling has been advanced. As illustrated in Scheme 36A, coupling reactions of fully protected branched alkynes with chiral aldehydes typically proceeds with low levels of regioselectivity, despite the significant difference in steric character of the alkyne substituents (Me- vs. branched alkyl).[89,93] As summarized in Scheme 36B, when the distal hydroxyl group is unprotected (a tris-homopropargylic alcohol), these coupling reactions uniformly proceed with much higher levels of regiochemical control.

Although stereochemical features also clearly play a role in regioselectivity, these results are consistent with an empirical model based on site-selective reaction of a fused bicyclic metallacyclopropene with the aldehyde component (Scheme 37). Important structural features that impact regiochemical control in these processes include the branched architecture of the side chain and the precise location of the free hydroxyl. For example, substrates of similar composition to that depicted in Scheme 37, but lacking the substantial branching of the side chain do not couple with high levels of regiochemical control. In addition, if the free hydroxy group is located at the homopropargylic position (rather than the tris-homopropargylic position), regioselectivity is uniformly compromised.

Although not without significant limitations, including relatively low diastereoselection, this hydroxyl-directed approach to alkyne–aldehyde coupling makes possible the use of metallacycle-mediated cross-coupling for the assembly of complex unsaturated polypropionates. Before this development, directing groups of the nature depicted in Scheme 35 were an absolute requirement for controlling site selectivity in alkyne–aldehyde-coupling chemistry.

5.34.3.2.1.3 Control of allylic alcohol stereochemistry



Two general strategies have been pursued to control the stereochemical course of metallacycle-mediated alkyne–aldehyde-coupling reactions. As illustrated in Scheme 38A, reagent control has been explored with chiral titanium alkoxides. Here, products are produced with relatively low levels of selectivity.[94] Alternatively, substrate control has been employed to control the stereochemical course of alkyne–aldehyde-coupling reactions.[92,95,96] Aldehydes and alkynes bearing chiral substituents have been shown to influence the stereochemical course of reductive coupling (Scheme 38B). With respect to the utility of these processes in target-oriented synthesis, note that all examples presented proceed with very high levels of regiochemical control as a result of the specialized alkyne substitution patterns employed.

5.34.3.2.2 Alkyne–imine and related coupling reactions

Preformed Ti–alkyne complexes have been demonstrated to be useful in a range of cross-coupling reactions with C=N systems. Interestingly, the regiochemical course of this coupling differs from that seen in the related coupling reactions of aldehydes. As illustrated in Scheme 39, coupling of phenyl propyne with a simple imine proceeds with very low levels of regiochemical control and favors the product possessing the Ph substituent at the alkenyl site distal to the amine (this is the minor isomer in the related coupling reaction with cyclohexane carboxaldehyde illustrated in Scheme 35). Of particular interest in chemical synthesis, this coupling process proceeds with exquisite levels of regiochemical control when TMS-alkynes are employed. Here, C–C bond formation occurs at the site of the alkyne distal to the TMS group (minor isomers were not reported; a similar sense of regiochemical control has also been observed with alkynylphoshponates).[97] Notably, the Ti-promoted coupling reaction also proceeds with ketimines and hydrazones.

Ti-promoted alkyne–imine coupling has been employed as a key convergent step in the synthesis of lactams and pyrroles. As illustrated in Scheme 40, treatment of the intermediate azametallacyclopentene with CO results in the formation of pyrroles, whereas exposure to CO_2 delivers substituted α,β-unsaturated γ-lactams.[98,99] Notably, regioselectivity in these processes is achieved by the use of a TMS-alkyne.

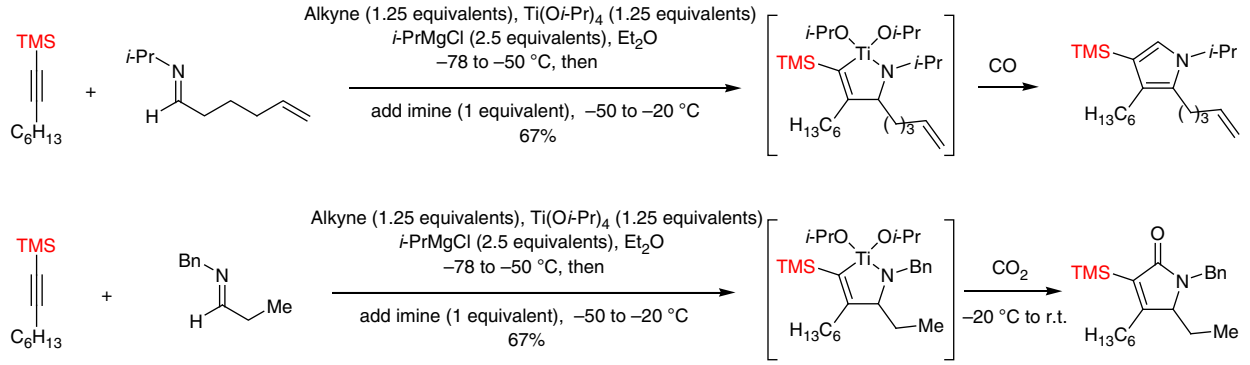
5.34.3.2.3 Alkyne–nitrile coupling

Building on the observations that $(RO)_2Ti$–alkyne complexes are effective nucleophilic species in addition reactions to aldehydes, ketones, imines, and hydrazones. It has recently been established that these species are also effective in coupling reactions with a subset of nitriles.[100] Although simple alkanenitrile or benzonitrile species are not viable substrates for this process, α-alkoxy, α-silyloxy, and α-chloro nitriles appear to be generally useful coupling partners en route to substituted azatitanacyclopentadienes (Scheme 41). In the first example depicted in Scheme 41A, addition of a sulfonylacetylene to an intermediate azatitanacyclopentadiene results in an annulation reaction that delivers a metallated pyridine intermediate. Quenching of this species with I_2 then delivers the tetrasubstituted pyridine as a single regioisomer in 50% yield. Regioselectivity in this complex coupling process deserves further comment. As in previous examples discussed, the use of silyl-substituted alkynes is important for regiochemical control in the first coupling process en route to the azametallacyclopentadiene intermediate. Subsequent reaction with the sulfonylacetylene also proceeds in a regioselective fashion, with C–N bond formation occurring at the carbon containing the sulfonyl group.

As illustrated in Scheme 41B and C, alternative pathways for functionalizing the azametallacyclopentadiene intermediates afford other aromatic heterocycles. In Scheme 41B, aldehyde addition followed by treatment with 1N HCl results in hydrolysis, intramolecular cyclization, and aromatization. Similarly, as illustrated in Scheme 41C, addition of a second α-alkoxy nitrile results in C–C bond formation, and subsequent treatment with 1N HCl results in hydrolysis and selective ring closure to generate the tetrasubstituted pyrrole. Here, the first C–C bond-forming process appears to proceed in a highly regioselective manner, with C–C bond formation occurring at the carbon possessing the aryl substituent. This observation is interesting, as aryl-substituted alkynes lacking another directing group (i.e., TMS) do not couple to aldehydes or imines in a highly regioselective manner. Next, ring closure proceeds through selective processing of a bis-imine intermediate – the major product being derived from selective enolization of the imine lacking an α-branch.



Overall, alkyne–nitrile cross-coupling chemistry has been described as a strategy to generate azametallacyclopentadienes, and these intermediates have been advanced to pyridines, furans, and pyrroles. Despite these interesting observations that define convergent solutions to heterocycle synthesis, this collection of coupling reactions remains limited by (1) the requirement of TMS- or Ar-substituted alkynes to control regioselectivity and (2) the use of α-heteroatom-substituted nitriles.

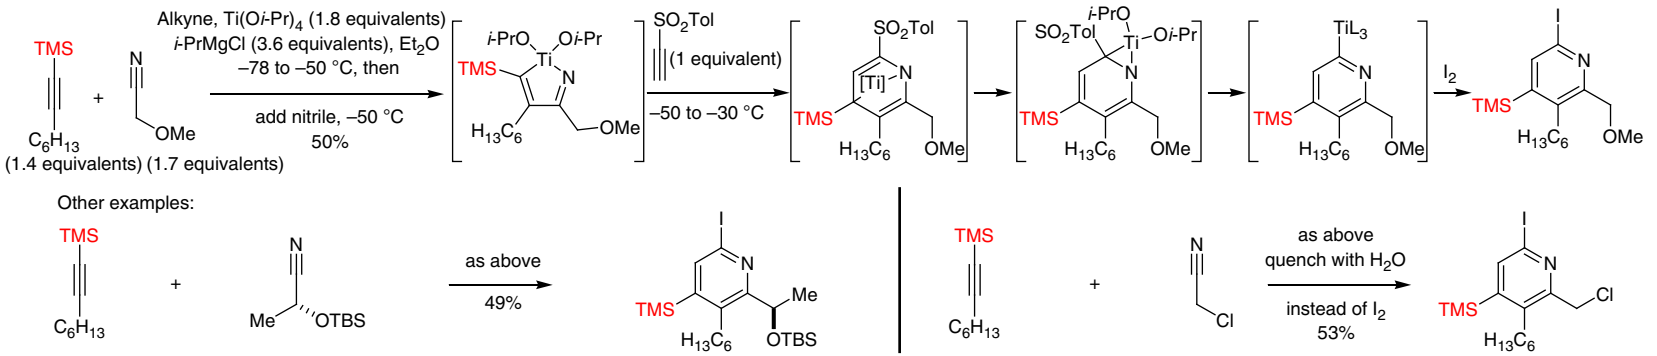
5.34.3.3 Alkenes in Coupling Reactions with Carbonyl Systems

Early transition metal metallacycle-mediated cross-coupling between alkenes and aldehydes is a complex and challenging reaction. The primary problem derives from the inability to accomplish transfer epimetalation from $R_2Ti(Oi\text{-}Pr)_2$ to many alkene substrates of interest. Although such transfer epimetalation chemistry is possible in the Kulinkovich reaction (alkene + ester), where the generation of the alkene–Ti complex is accomplished in the presence of the ester acceptor, such is not feasible in related alkene–aldehyde-coupling processes due to the markedly enhanced electrophilicity of aldehydes in comparison to esters. Requiring that the alkene–Ti complex be generated before addition of the aldehyde-coupling partner defines the major challenge in accomplishing this subclass of metallacycle-mediated cross-coupling.

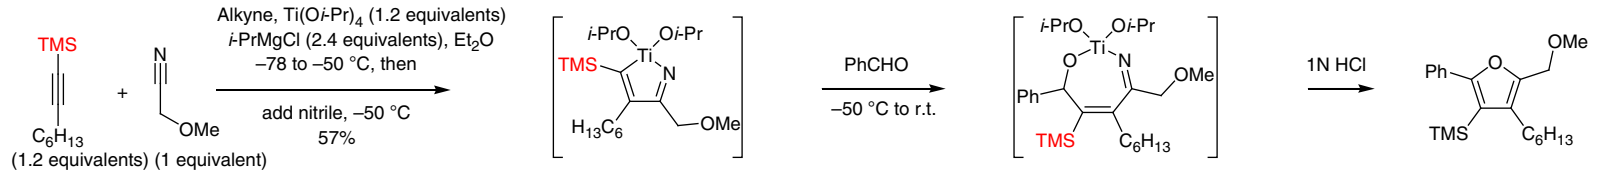
Two strategies have emerged to accomplish early transition metal metallacycle-mediated coupling between alkenes and aldehydes, each of which are significantly limited in substrate scope (Scheme 42A and B): (1) use of silylethylenes ($TMSCHCH_2$ or $ROMe_2SiCHCH_2$) as the alkene-coupling partner[101] and (2) generating a Ti–alkene complex from a 1,3-diene.[102]

Notably, in addition to the processes depicted in Scheme 42, a variety of alkene–aldehyde-coupling reactions have been accomplished through the defined intermediacy of an allyltitanium or allylzirconium species generated from an initial metal–alkene complex. These processes are outside of the scope of this chapter, as the process by which C–C bond formation ensues is from allyl transfer chemistry. Also, a few isolated examples of metallacycle-mediated cross-coupling of a terminal alkene with an *N*-acylpyrrole have been described, where the reaction is enabled by the presence of a free homoallylic alcohol.[103] The generality of this approach to preparing Ti–alkene complexes and the potential utility of this approach in accessing other metallacycle-mediated intermolecular C–C bond-forming processes with alkenes has not yet been established.



5.34.3.4 Alkyne–Alkyne Cross-Coupling

Early transition metal metallacycle-mediated alkyne–alkyne coupling defines a convenient, convergent, and stereospecific entry to substituted 1,3-dienes. Here, the challenge of regioselection is more complex than in the reactions described between alkynes and carbonyl compounds, as neither reactive π-system has an inherent electronic preference to control the regiochemical course of C–C bond formation. As such, coupling of two unsymmetrical alkynes can result in the generation of four different regioisomeric products (Scheme 34B). In Sections 5.34.3.4.1 and 5.34.3.4.2, below is a discussion of two different classes of alkyne-based coupling processes that are distinguished by the substitution of the alkynes. Coupling reactions that engage terminal alkynes are discussed first and are followed by the more demanding coupling reactions between two internal alkynes.



5.34.3.4.1 Internal alkyne + terminal alkyne

Ti-alkoxides have been found to be suitable reagent precursors to accomplish cross-coupling reactions between internal alkynes and terminal alkynes (Scheme 43).[104] In short, exposure of an internal alkyne to the combination of $Ti(Oi\text{-}Pr)_4/2i\text{-}PrMgCl$ results in the *in situ* generation of a Ti–alkyne complex. Addition of a terminal alkyne then results in intermolecular carbometalation en route to a metallacyclopentadiene, protonation of which furnishes stereodefined 1,3-dienes. Although four regioisomeric products are possible in this coupling process, it has been shown that terminal alkynes react in a regioselective fashion to favor the formation of intermediate 2,3,5-trisubstituted titanacyclopentadienes. As such, the challenge of controlling the course of this coupling process boils down to simply controlling regioselection in the functionalization of the internal alkyne (i.e., C–C bond formation α- to R^1 or R^2).

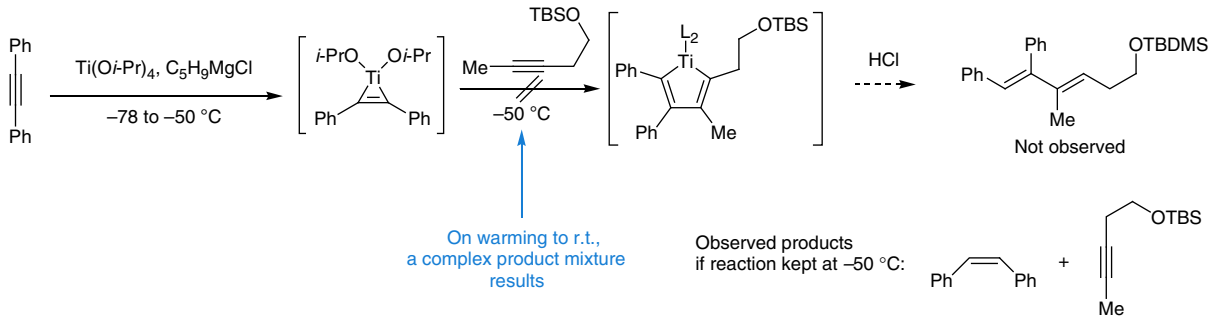
B. Hydroxyl-directed alkyne–alkyne coupling.

Examples:

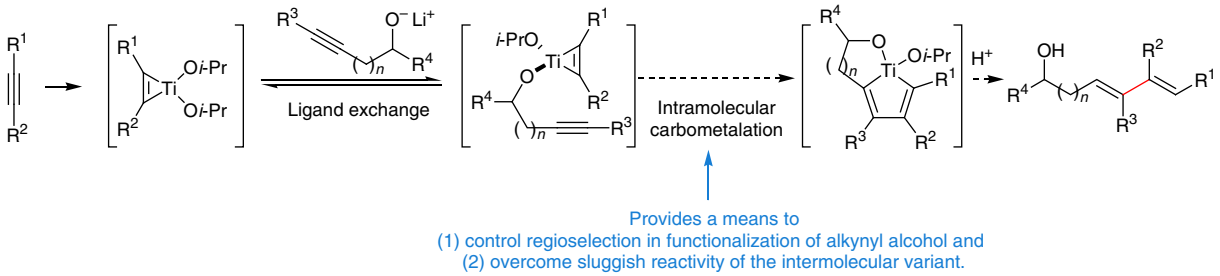
Scheme 44

As illustrated in Scheme 43A, a variety of coupling reactions in this class have been demonstrated that proceed with regiochemical control. That said, the structural features required to achieve high levels of regioselection limit the utility of this bond construction to a relatively small subset of coupling partners (Scheme 43B).



In efforts targeting the convergent synthesis of polyunsaturated polypropionate-derived natural products (Scheme 44A), hydroxyl-group direction has proven to be an effective alternative means of controlling the regiochemical course of this coupling reaction (Scheme 44B). As observed in the related hydroxyl-directed reductive cross-coupling between alkynes and aldehydes, regioselection is uniformly high with substrates possessing a tris-homopropargylic hydroxyl-directing group ($rs \geq 17{:}1$). Studies have shown that if the hydroxy-directing group is relocated to the homopropargylic position, or if there is no hydroxyl-directing group available, selectivity drops (substantially in some cases).[105] Overall, the broad utility of this directing group strategy has not been explored outside of polypropionate assembly. As such, it is not yet clear if this strategy will be useful for regioselective cross-coupling reactions of less substituted substrates. That said, this hydroxyl-directing group strategy has defined a new class of alkynes as useful coupling partners in metallacycle-mediated cross-coupling and has established a useful bond construction for natural product synthesis.[89,106,107]

Although modern Pd-catalyzed cross-coupling chemistry is routinely embraced to access stereodefined 1,3-dienes in a convergent manner, it is important to note that such methods require the use of coupling partners with stereodefined vinyl halides and vinyl organometallics to setup the Pd-catalyzed coupling process. In comparison, this Ti-mediated coupling process employs stereo-undefined π-systems (alkynes) and proceeds through a process that simultaneously establishes the central C–C bond of the diene in concert with securing the stereochemistry of each alkene.

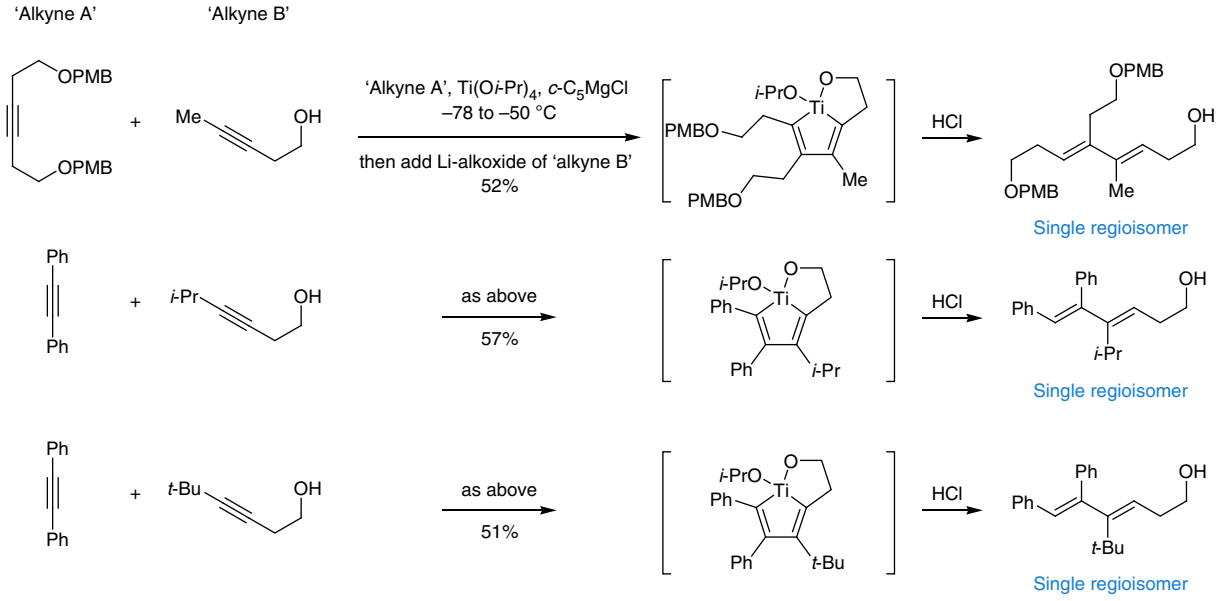


5.34.3.4.2 Internal alkyne + internal alkyne

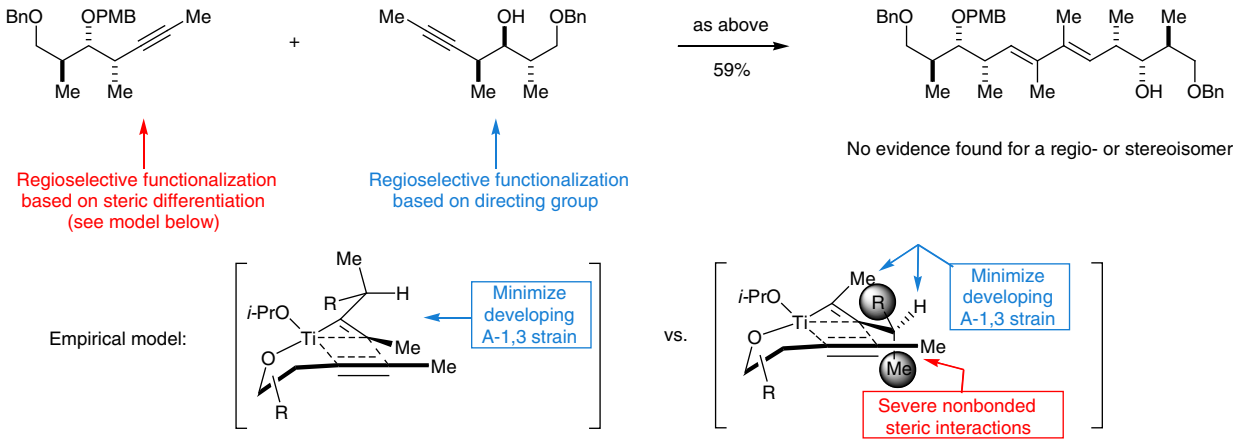
Although it has long been established that preformed early transition metal–alkyne complexes can add across terminal alkynes to generate trisubstituted 1,3-dienes, the related addition reaction to internal alkynes represents a much more challenging process. Not only more complex due to the aforementioned problems associated with the control of regioselection (i.e., Scheme 34B), this class of cross-coupling has proven difficult to accomplish with internal alkynes as a result of their decreased reactivity in carbometalation reactions with preformed metal–π complexes (Scheme 45A). Illustrated in Scheme 45B, a different hydroxyl-directing group strategy has been established to achieve suitable reactivity, whereas also providing a means to control regioselection in this class of early transition metal metallacycle-mediated cross-coupling reaction.[108] Distinct from the substrate-directing group strategies described previously (for the coupling of internal alkynes with aldehydes or for the coupling of internal alkynes with terminal alkynes), a unique hydroxyl-directing group strategy is employed here to render the carbometalation event intramolecular.

A. Low levels of reactivity broadly constrain the potential utility of early transition metal metallacycle-mediated cross-coupling between internal alkynes.

B. A different hydroxyl-directing strategy to enable cross-coupling between internal alkynes.



Scheme 45



As illustrated in Scheme 46A, hydroxyl-directed titanium-mediated reductive cross-coupling reactions of internal alkynes proceed in a highly regioselective manner. Early examples employed one symmetrical alkyne ('alkyne A'), so that regioselection could easily be assessed for the functionalization of the alkynyl alcohol component ('alkyne B'). In all cases explored to date, C–C bond formation occurs distal to the hydroxyl-directing group, consistent with the proposed intermediacy of fused bicyclic metallacyclopentadienes.

This directing group strategy has been employed as a strategy to accomplish highly regioselective reductive cross-coupling between two unsymmetrically substituted internal alkynes (Scheme 46B). Although regioselective functionalization of the alkynyl alcohol substrate occurs as anticipated based on the results summarized in Scheme 46A, functionalization of the sterically differentiated alkyne also proceeds with exquisite levels of regiochemical control. This is in contrast to previous studies that document the often inferior levels of regioselection observed in coupling reactions of such alkynes with aldehydes and terminal alkynes. It has been speculated that coupling reactions of the sort depicted in Scheme 46 likely proceed by a later transition state than previously discussed coupling reactions with aldehydes and terminal alkynes and, as such, the steric differences of the alkyne substituents play a more substantial role in dictating the regiochemical course of C–C bond formation. In short, as the transition state shifts to resemble the product, the Ti–alkyne complex appears more alkene like. Therefore, minimization of A-1,3 strain results in gearing of the propargylic substituents such that carbometalation is favored from proximal to the small Me-substituent (Scheme 46B).

Scheme 46

5.34.3.5 Alkyne–Alkene Cross-Coupling

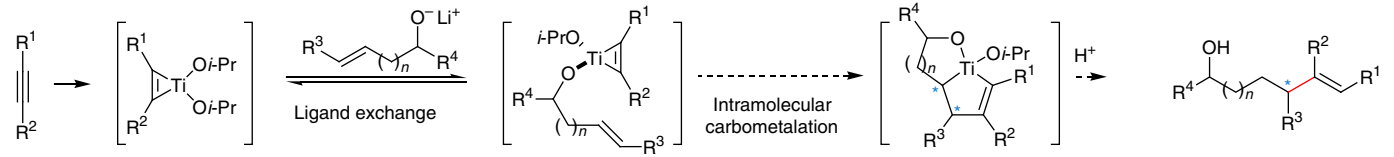
Metallacycle-mediated cross-coupling of alkynes with alkenes represents a significantly more challenging process than alkyne–alkyne coupling. In addition to the established difficulties associated with engaging a substituted alkene in metallacycle-mediated coupling chemistry (due to low levels of reactivity and potential reversibility of carbometalation), synthetically useful reactions in this class must also address regio- and stereoselection (Scheme 34B and C). Since 1991, reactions have emerged for alkyne–alkene coupling that proceed by treatment of preformed metal–alkyne complexes with alkenes. Many of these are substantially restricted in scope based on challenges controlling regioselection and issues relating to low reactivity (restricted to unhindered terminal alkenes).[101,109–111] These contributions will not be discussed here, rather the focus of this section is on advances that offer fine control over regio- and stereoselection, while providing a means to employ 1,2-disubstituted alkenes in this class of metallacycle-mediated cross-coupling.

5.34.3.5.1 Simple directed carbometalation

Representing an adoption of the general strategy described to control reductive cross-coupling of two internal alkynes, Scheme 47A depicts a hydroxyl-directed approach to controlling the course of alkene–alkyne-coupling chemistry. Here, preformation of a monocyclic metal–alkyne complex is followed by introduction of an unsaturated alkoxide. Rapid and reversible ligand exchange provides access to a transient intermediate capable of undergoing intramolecular carbometalation. If the intermediate metallacyclopentene is stable under the reaction conditions (i.e., previous studies of early transition metal complexes of this nature support the ability of such species to undergo cycloreversion with expulsion of the alkene and regeneration of a Ti–alkyne complex), then protonation would deliver the olefinic product in a regioselective fashion.

As illustrated in Scheme 47B, this approach to controlling the course of metallacycle-mediated cross-coupling is quite effective in realizing highly selective alkyne–alkene-coupling reactions.[90,112] In the first case depicted, one can see that the hydroxymethyl substituent on the cyclohexene offers a means to control both the regio- and stereochemical course of cross-coupling. Here, C–C bond formation occurs distal to the hydroxymethyl group, with complete control of stereoselection (C–C bond formation occurs on the same face of the cyclohexene as the directing group). Moving on, this coupling process is effective for the union of two unsymmetrical systems. As previously seen in Scheme 46B, steric differentiation of the alkyne component defines an effective means for controlling regioselection with respect to its functionalization. Similarly, use of homoallylic alcohols that react by way of a stereochemically biased pathway (as a result of the minimization of A-1,3 strain) in reactions with preformed Ti–alkyne complexes define extremely complex and unique convergent coupling reactions. Overall, this metallacycle-mediated alkene –alkyne coupling proceeds with complete regiochemical control with respect to the functionalization of each π-component, whereas also occurring with complete stereochemical control.

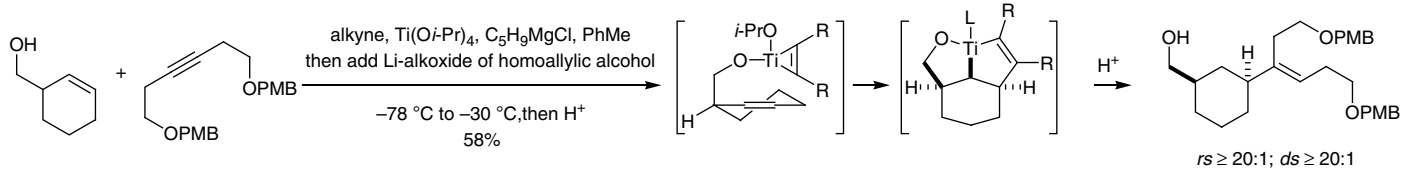
The realization of a highly selective alkene–alkyne cross-coupling process represents a significant advance in this broad area of chemical reactivity. Now, it is becoming evident that metallacycle-mediated cross-coupling can be designed to occur in a highly controlled fashion, offering convergent bond-forming processes unavailable with other modes of chemical reactivity (this particular bond construction has recently been described as a key convergent step in the synthesis of densely functionalized spiroketals).[113] That said, this early demonstration marked only the beginning of advances that have recently emerged in metallacycle-mediated reductive cross-coupling chemistry that have defined a broad collection of powerful and unique coupling reactions suitable for stereoselective synthesis.



5.34.3.5.2 Coupling via formal metallo[3,3] rearrangement

A variety of reports have appeared that describe the utility of early transition metal metallacycle-mediated coupling for the union of alkynes with allylic electrophiles (Scheme 48A). Formation of a metallacyclopentene is followed by elimination to deliver a vinyl organometallic intermediate which, after exposure to a protic acid, is converted to a 1,4-diene product. Although this process has been demonstrated to be useful for addition of a C_3-unit to an alkyne, where issues regarding stereoselection are absent,[27,114,115] the class of cross-coupling has only recently been rendered stereoselective in reactions that employ highly substituted allylic alcohols.[116,117]

As illustrated in Scheme 48B, hydroxyl-directed cross-coupling provides a means to translate stereochemical information from the allylic alcohol starting material to the intermediate metallacyclopentene. Stereospecific elimination then parlays the stereochemistry of this intermediate to the stereochemistry of the functionalized 1,4-diene product. Overall, the sequence of bond-forming events in this hydroxyl-directed coupling process can be summarized as a formal metallo[3,3] rearrangement (Scheme 48C).



As depicted in Scheme 49A, Ti-mediated hydroxyl-directed coupling of allylic alcohols with alkynes proceeds in a regio- and stereoselective manner. C–C bond formation occurs with allylic transposition and in a suprafacial manner. Further study of this process in acyclic settings has led to the conclusion that one can achieve (*E*)- or (*Z*)-selective coupling reactions. For example, using an allylic alcohol with a (*Z*)-disubstituted alkene results in a stereoselective coupling reaction to deliver a product possessing an (*E*)-disubstituted alkene [(*E*):(*Z*) = 8:1]. Here, minimization of A-1,3 strain results in positioning the allylic substituent in the equatorial position during the carbometalation event. Subsequent *syn*-elimination and protonation delivers the 1,4-diene in 59% yield. Taking a step back to appreciate the complexity of this coupling reaction based on the previous discussion regarding the course of all metallacycle-mediated cross-coupling processes (i.e., Scheme 34), regioselection is controlled in the functionalization of each reaction component: (1) the allylic alcohol is employed to gain control over site-selective functionalization of the

Scheme 49

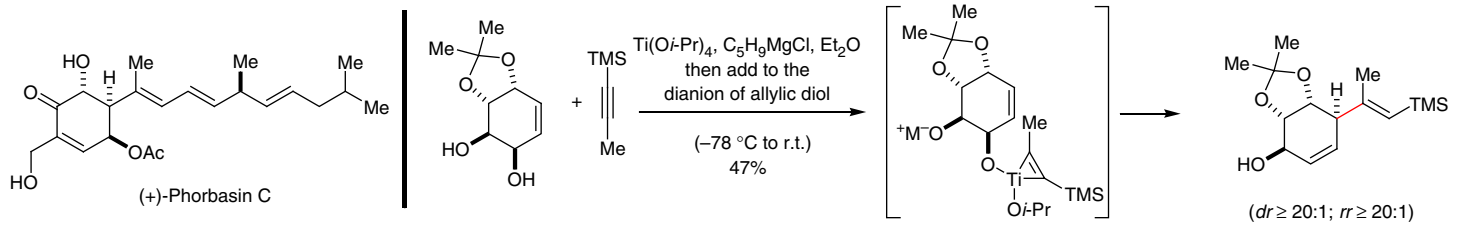
alkene and (2) a TMS group is employed to gain control over the regioselective functionalization of the alkyne. Next, minimization of nonbonded steric interactions in a boat-like transition state for carbometalation results in fine control over stereoselection. Note that a boat-like orientation is proposed based on two considerations: (1) requirement of an intramolecular carbometalation – docking of the allylic alcohol at Ti to enable an intramolecular pathway for carbometalation and (2) the stereoelectronic preferences for carbometalation – alignment of the σ_{Ti-C} bond with $\pi_{C=C}$.

To date, a limitation of this stereoselective coupling has been documented in acyclic settings where, without the substantial influence of A-1,3 or A-1,2 strain, the coupling of secondary allylic alcohols bearing terminal- or (*E*)-disubstituted alkenes does not proceed with significant levels of stereoselection. That said, this hydroxyl-directed allylic alcohol–alkyne-coupling reaction has already been demonstrated in a number of natural product syntheses. The first total synthesis and structure elucidation of phorbasin C was accomplished using a Ti-mediated allylic alcohol–alkyne-coupling reaction to establish the stereodefined carbocyclic core of the diterpene (**Scheme 50A**).[118] Interestingly, a second coupling process with the allylic alcohol product of this reaction was not observed. Presumably, the steric impediment introduced on the *β*-face (as drawn) is sufficient to dissuade a second C–C bond-forming process that would need to occur *syn*- to this substituent. Another application of this coupling reaction appeared in the first total synthesis of the marine-derived cytotoxic agent lehualide B (**Scheme 50B**).[119] Here, a late-stage Ti-mediated allylic alcohol–alkyne-coupling reaction was employed to establish the stereodefined skipped diene motif resident in the lipophilic tail of the natural product. Most recently, this class of metallacycle-mediated cross-coupling has been demonstrated to be of great utility for the stereoselective convergent synthesis of deoxypropionates. As illustrated in **Scheme 50C**, this process was employed in a total synthesis of the insect pheromone vittatalactone.[120]

5.34.3.6 Allene–Alkyne Cross-Coupling

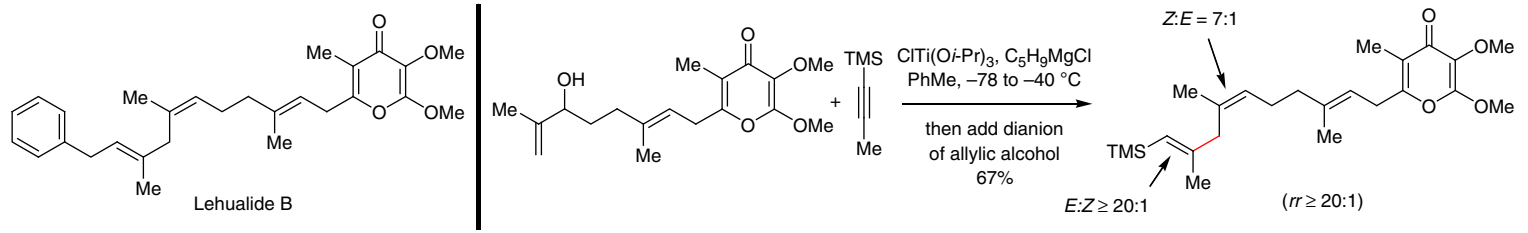
Metallacycle-mediated union of allenes with alkynes is a complex problem owing not only to the different π-systems available on the allene, but also due to the now familiar challenge of addressing regioselection with respect to this π-component. As illustrated in **Scheme 51A**, a variety of metallacyclopentenes are possible from the coupling of a disubstituted allene with an alkyne. These species derive from reaction pathways that engage either π-system of the allene (termed π-system 'A' or 'B'), the regiochemical course of functionalization of that π-system, the stereochemical course of carbometalation (*syn*- or *anti*- to the distal allene substituent), and the regiochemical course of alkyne functionalization. Given this, it is not surprising that only a few examples of this type of coupling reaction have been described. Early cases include those depicted in **Scheme 51B**.[121] Even with these minimally substituted systems, it is apparent that the control of stereochemistry in this coupling reaction is quite complex. Although the simple silyl-substituted allene is the best substrate to enforce carbometalation *anti*- to the $PhMe_2Si$ substituent, even chelating substituents on the allene lead to unpredictable and uniformly low levels of stereoselection.

Hydroxyl-directed metallacycle-mediated coupling has emerged as a potentially useful means of controlling the course of allene–alkyne coupling.[122,123] As illustrated in **Scheme 52A**, coupling of allenes possessing simple 1,1-disubstitution with internal alkynes proceeds with very high levels of stereoselection (delivering products containing an *E*-trisubstituted alkene). That said, this class of coupling presents problems unlike any reaction class previously discussed. Although related coupling reactions that employ TMS-alkynes proceed with very high levels of regiochemical control, the allene–alkyne-coupling process does not proceed with similarly high levels of selectivity. For example, metallacycle-mediated cross-coupling of allenes with TMS-alkynes typically delivers a 4:1 mixture of regioisomeric products (the major product of which derives from C–C bond formation preferentially occurring *β*- to the TMS group). Similarly, sterically differentiated substrates (Me vs. branched alkyl) are also problematic in this coupling process (in the example shown, products are formed as 2:1 mixtures of regioisomers).



An interesting feature of these processes is that the alkoxide-directed process changes course in coupling reactions with 1,3-disubstituted allenes (**Scheme 52B**). Here, carbometalation takes place with C–C bond formation occurring at the central carbon of the allene with concomitant allylic transposition (similar to that seen in the coupling reaction of alkynes with allylic alcohols). Highest levels of stereoselection (*E*:*Z*) are observed with allenic alcohols bearing branched alkyl substitution at the distal carbon (i.e., *i*-Pr). In these cases, C–C bond formation occurs *anti*- to the bulky branched substituent and delivers stereodefined cross-conjugated trienes ($E{:}Z \geq 20{:}1$). As previously seen in the coupling reactions depicted in **Scheme 52A**, regiochemical control in these cross-conjugated triene-forming reactions is also difficult to control. For example, coupling of a sterically differentiated internal alkyne (Me vs. branched alkyl) proceeds with only 2:1 regioselection.

5.34.3.7 Imine–Alkyne Cross-Coupling (via Preformed Metal–Imine Complexes)



Although Section 5.34.3.2.2 has already addressed metallacycle-mediated coupling reactions between alkynes and imines, the reactions presented previously were based on the addition of preformed metal–alkyne complexes to carbonyl electrophiles. Here, a discussion follows that derives from a different pathway to achieve reactivity, where metal–imine complexes are employed in carbometalation reactions with alkynes. This variation in the order of substrate activation results in a different set of reactions that can be controlled by unique features.

The generation of early transition metal–π complexes was discussed in the first volume of this series, with emphasis given to Prof. Buchwald's contributions demonstrating that Zr-complexes generated by the established thermal decomposition of Zr–alkyl complexes (with loss of CH_4) can be employed in a variety of metallacycle-mediated bond-forming processes. This mode of

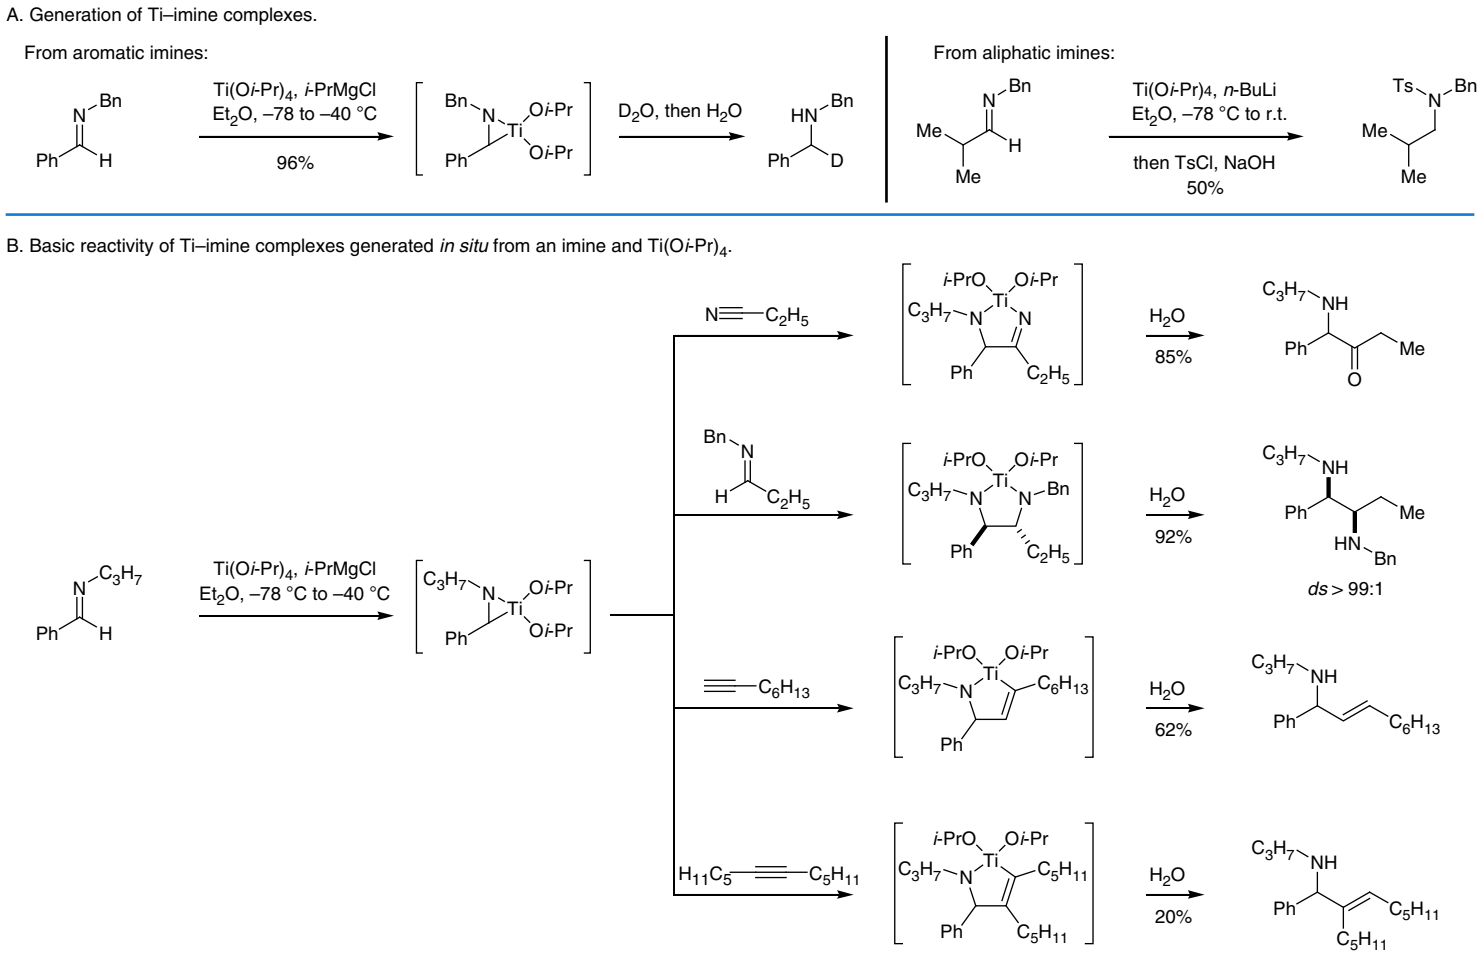
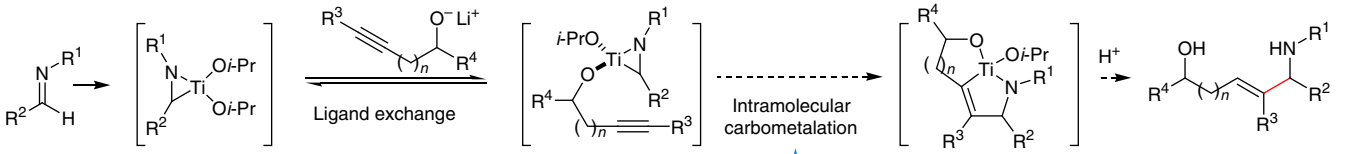
Scheme 53



activation was shown to be useful for the formation of Zr–imine complexes, and it has been documented that these species engage a variety of π-systems in carbometalation chemistry (i.e., nitriles, terminal alkenes, aldehydes, TMS-imines, terminal alkynes, and symmetrical internal alkynes; Scheme 53A).[124] These contributions established a foundation on which a subsequent asymmetric process was built (employing (ethylene-1,2-bis(η5-4,5,6,7-tetrahydro-1-indenyl) (EBTHI))ZrMeOTf; Scheme 53B).[125] Although establishing a foundation of reactivity associated with early transition metal–imine complexes, these contributions have not yet been investigated in complex settings, nor have they been demonstrated to be compatible with more functionalized substrates.

In 1997, Prof. Sato described a convenient method for the direct conversion of imines to Ti–imine complexes by the action of Ti(O*i*-Pr)$_4$/2*i*-PrMgCl (Scheme 54A).[126] Although originally limited to aromatic imines, recent advances have led to the establishment of a complementary procedure for the generation of Ti-complexes of aliphatic imines that proceeds by the reagent combination of Ti(O*i*-Pr)$_4$/2*n*BuLi.[127] As depicted in Scheme 54B, the reactivity profile of the intermediate azametallacyclopropanes mirrors that of other early transition metal-based metallacycles where addition reactions to electronically activated and/or unhindered terminal alkynes are straightforward. That said, attempted reaction with a simple internal alkyne was not efficient (generating allylic amine product in only 20% yield), reflecting the great difficulty associated with intermolecular addition reactions of early transition metal–π complexes to electronically unactivated and substituted π-systems.

Hydroxyl-directed Ti-mediated coupling provides a convenient means to accomplish highly regioselective addition reactions of unsymmetrical internal alkynes to aromatic imines.[128] As illustrated in Scheme 55A, Ti–imine complex formation is followed by addition of the alkyne-containing lithium alkoxide. Rapid and reversible ligand exchange at Ti then results in a fleeting intermediate that can undergo intramolecular carbometalation to generate a fused bicyclic azametallacyclopentene in a highly regioselective manner. Protonation of the resulting organometallic intermediate then delivers unsaturated amino alcohol products. As depicted in Scheme 55B, this reaction design is effective for controlling the course of reductive cross-coupling of imines with a range of substituted alkynes. In all cases, C–C bond formation occurs distal to the hydroxyl tether, consistent with the proposed intermediacy of a fused bicyclic azametallacyclopentene intermediate. Interestingly, this hydroxyl-directing group strategy overcomes the well-established selectivity profile of TMS-alkynes in reductive cross-coupling chemistry. Here, C–C bond formation occurs α- to the TMS group to deliver the stereodefined trisubstituted vinylsilane product in 55% yield as a single regioisomer.



This hydroxyl-directed reductive cross-coupling process is compatible with alternative quenching procedures that result in orthogonal functionalization of the intermediate azametallacyclopentene. As has been shown with azazirconacyclopentenes, as well as monocyclic azatitanacyclopentenes, the reactive intermediates generated in this coupling process can be advanced to γ-lactams by insertion of carbon dioxide. As illustrated in Scheme 55C, formation of a Ti–imine complex occurs in the usual manner – notably, this organometallic reaction is compatible with aromatic halides. Hydroxyl-directed C–C bond formation then delivers the fused bicyclic azatitanacyclopentene intermediate that is converted to the tetrasubstituted γ-lactam product by exposure to 20 psig CO_2 and heating to 90 °C.

With a glimpse of the potential power of hydroxyl direction to control the course of alkyne–imine cross-coupling, recent studies have explored this process as a means to gain access to complex heterocyclic motifs.[129] Scheme 56A depicts the design of a hydroxyl-directed coupling between substituted enynes and imines en route to a potentially useful amino alcohol for heterocycle synthesis. Here, substrate direction is proposed as a means to reinforce C–C bond formation to occur at the carbon α- to the preexisting alkene. Subsequent acid-promoted formation of an iminium ion followed by cationic annulation was anticipated to define a path to densely functionalized heterocyclic systems. Although other metallacycle-mediated reductive coupling reactions of enynes proceeds to deliver an isomeric product to that targeted in this heterocycle-forming process (Scheme 56B), the hydroxyl-directed coupling reaction provides for C–C bond formation with exquisite levels of regiochemical control

(Scheme 56C; only a single regioisomer was observed). Treatment of the polyunsaturated product with camphor sulfonic acid (CSA) then results in iminium ion generation and annulation to provide the fused tetracyclic product in 52% yield ($dr \geq 20{:}1$).

5.34.3.8 Imine–Alkene Cross-Coupling (via Preformed Metal–Imine Complexes)

Metallacycle-mediated union of imines with alkenes represents among the most challenging cross-coupling reactions in metallacycle chemistry. Recalling the general challenges to controlling the course of metallacycle-mediated cross-coupling that were depicted in Scheme 34, coupling reactions of alkenes with imines are complicated by the following:

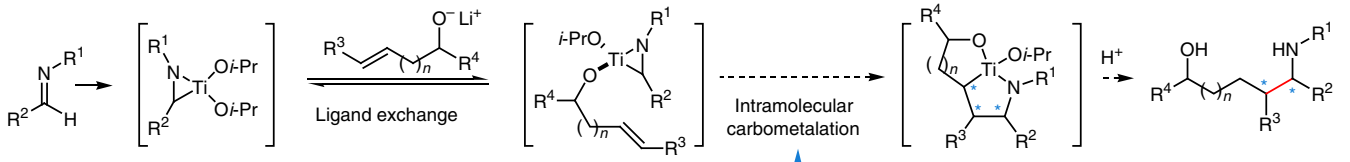
1. Pair selectivity: Given the established reactivity of saturated early transition metal metallacyclopropanes, where alkene expulsion defines a pathway to regenerate a metal–alkene complex, alkene–imine-coupling chemistry is anticipated to be complicated by the potential instability of the saturated azatitanacyclopentane (i.e., alkene extrusion would regenerate a Ti–imine complex). If free imine is present in the reaction mixture, the potential for imine homocoupling exists.
2. Low reactivity of alkenes: As previously discussed, early transition metal–π complexes often do not possess sufficient reactivity to add across substituted and electronically unactivated alkenes.
3. Regioselectivity: If one were able to achieve the desired cross-coupling, concerns regarding the control of regioselection in the functionalization of the alkene arise.
4. Diastereoselectivity: In these cases, two new stereocenters are generated in the course of C–C bond formation. How does one control simple and/or relative diastereoselection when stereodefined substrates are employed?

5.34.3.8.1 Simple hydroxyl-directed Ti-mediated imine–alkene coupling

It has recently been discovered that hydroxyl-directed titanium-mediated coupling provides an exceptionally powerful means to control the course of imine–alkene coupling. As previously discussed in association with Scheme 42 (alkene–alkyne coupling), the generation of Ti–alkene complexes is quite challenging and the viability of such activation is currently substantially limited in substrate scope. As such, alkene–imine reductive cross-coupling chemistry has been pursued through the initial formation of a metal–imine complex, followed by introduction of a suitably functionalized alkene-coupling partner to enable C–C bond formation (Scheme 57A).

As illustrated in Scheme 57B-1, this hydroxyl-directed early transition metal metallacycle-mediated coupling proceeds with exquisite levels of regiochemical control and often outstanding stereoselectivity.[130] The coupling process is stereoconvergent, providing a pathway to convert both (*E*)- and (*Z*)-disubstituted alkenes to the *anti*-products ($ds \geq 95{:}5$; $rs \geq 95{:}5$). This sense of stereochemical control is believed to derive from preferred reaction by way of a transition state that minimizes nonbonded steric interactions about the developing C–C bond (as in structures A and D of Scheme 57B-2). Notably, the coupling process is also selective in coupling reactions of terminal alkenes (monosubstituted; not shown) and 1,1-disubstituted alkenes. In this latter case, the reaction proceeds with modest levels of stereochemical control, delivering the 1,3-*syn* isomer as the major product ($ds = 4{:}1$) in 57% yield (Scheme 57-B1). A model has been proposed that justifies this sense of stereoselection based on progression through a transition state that positions the aromatic substituent of the imine 'outside' the developing *cis*-fused bicyclo[3.3.0] system (as in F of Scheme 57B-2).

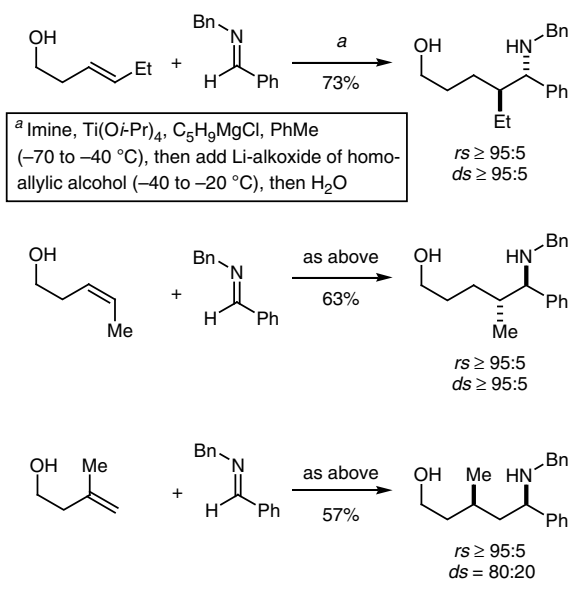
In efforts to explore the origin of stereoselectivity in this class of coupling reaction (i.e., kinetic vs. thermodynamic control), crossover experiments have been performed with D-labeled substrates.[131] Overall, these studies of hydroxyl-directed Ti-mediated cross-coupling between aromatic imines and terminal alkenes support the conclusion that the coupling process proceeds under kinetic control (i.e., no evidence was found to support the reversibility of C–C bond formation under the reaction conditions).



5.34.3.8.2 Single and double asymmetric hydroxyl-directed imine–alkene coupling

This hydroxyl-directed imine–alkene-coupling process can proceed in a manner that offers outstanding levels of substrate control when employing chiral imines and chiral homoallylic alcohols.[130] As illustrated in Scheme 58A, phenylglycine-derived imines undergo hydroxyl-directed coupling with alkenes with good levels of stereochemical control. That said, coupling with (*Z*)-alkenes proceeds with the highest levels of stereochemical control in this single asymmetric coupling process ($ds = 20{:}1$; no evidence for the production of a regioisomer was found).

In efforts to explore the factors that influence stereoselection in this process, it was reported that the coupling reaction is quite sensitive to double asymmetric relationships. As depicted in Scheme 58B-1, matched double asymmetric reactions have been reported en route to 1,4-*anti*-4,5-*anti*-1,5-aminoalcohols ($dr \geq 50{:}1$) and 1,4-*syn*-4,5-*anti*-1,5-aminoalcohols ($dr = 35{:}4{:}1$). The different levels of stereoselection observed for these matched double asymmetric transformations have been proposed to result from a varying nature of the transition states through which these processes proceed. As summarized for each case, the homoallylic substituent adopts a position outside of the developing *cis*-fused bicyclo[3.3.0] system, whereas minimization of nonbonded steric interactions about the developing C–C bond ensures a 4,5-*anti*-stereochemical relationship. As seen in the single asymmetric examples depicted in Scheme 58A, highest levels of stereochemical control in these double asymmetric coupling processes are observed in the coupling reactions of (*Z*)-disubstituted alkenes.



Mismatched double asymmetric reactions in this class are depicted in Scheme 58B-2 and demonstrate a substantial drop in stereoselection observed when the stereochemistry of coupling partners do not reinforce one another.

C. Use of 1,5-aminoalcohol products for piperidine synthesis. DMAP, 4-dimethylaminopyridine.

Scheme 58

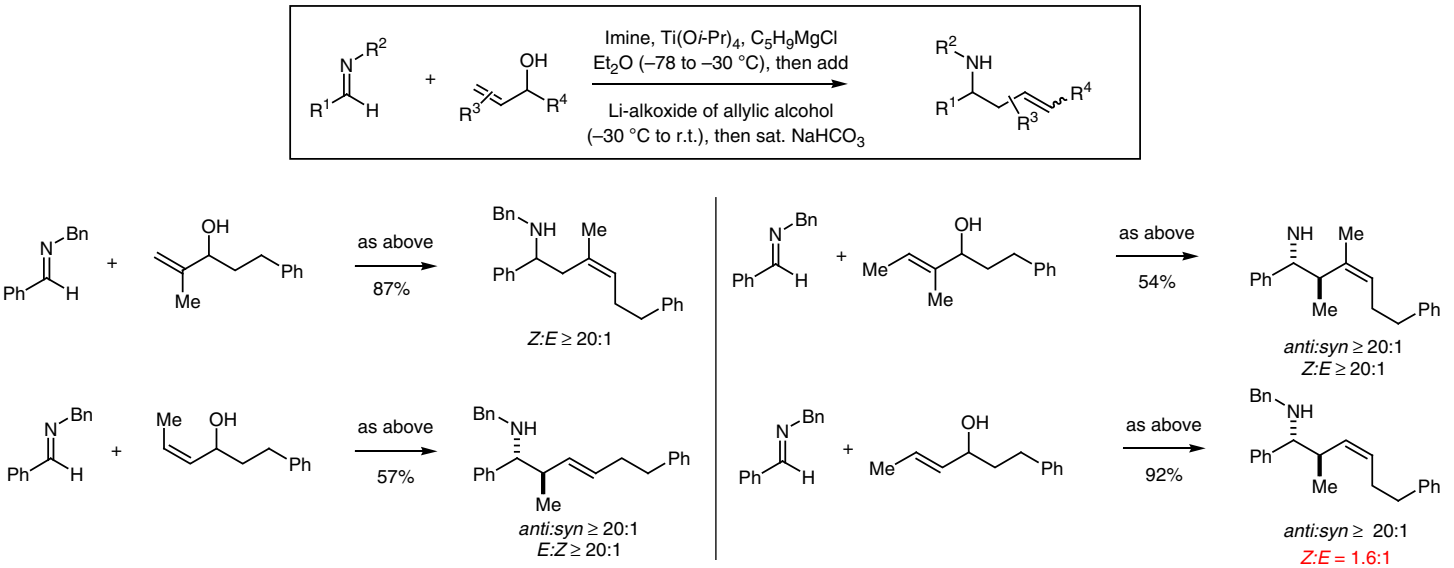
The utility of this coupling process has recently been demonstrated in the context of the stereoselective synthesis of substituted piperidines. As illustrated in Scheme 58C, cyclization of substrates bearing a primary alcohol proceeds without the need for removal of the phenylglycine auxiliary, whereas cyclization of substrates bearing a secondary hydroxyl requires initial selective hydrogenolysis of the phenylglycine auxiliary followed by stereoselective cyclization. In both cases, one can access stereodefined piperidines in a concise, convergent, and highly stereoselective fashion.

5.34.3.8.3 Imine–alkene coupling by formal metallo[3,3] rearrangement (convergent synthesis of homoallylic amines)

As discussed in Section 5.34.3.5.2 for the coupling of preformed metal–alkyne complexes with allylic alcohols, where C–C bond formation occurs with allylic transposition, a similar mode of reactivity is observed in the union of preformed Ti–imine complexes with allylic alcohols.[132,133] As illustrated in Scheme 59, coupling reactions of 1,1-disubstituted alkenes proceed to deliver homoallylic amine products possessing a (*Z*)-trisubstituted alkene with high levels of stereochemical control. As previously discussed, this selectivity likely derives from minimization of A-1,2 strain in a boat-like transition state (Scheme 49B). In a similar fashion, coupling reactions of allylic alcohols bearing (*Z*)-disubstituted alkenes deliver homoallylic amines with high levels of (*E*)-selectivity. Here, minimization of A-1,3-strain in the transition state is assumed to result in the production of the (*E*)-isomer, whereas minimization of nonbonded steric interactions about the developing C–C bond results in the establishment of the *anti*-stereochemical relationship between the allylic and homoallylic stereocenters (this second feature plays a prominent role in the coupling reactions of homoallylic alcohols with imines; Scheme 57).

Trisubstituted alkenes can also be employed in this coupling process. As illustrated, the (*E*)-trisubstituted allylic alcohol is an outstanding substrate for this reaction – delivering an *anti*-homoallylic amine product possessing a (*Z*)-trisubstituted alkene as a single isomer. Finally, as is observed in the related coupling reaction of alkynes with allylic alcohols, simple terminal alkenes or (*E*)-disubstituted alkenes do not react in a highly stereoselective manner (likely due to the lack of substantial bias in the transition state based on the minimization of allylic strain (A-1,2 or A-1,3)).

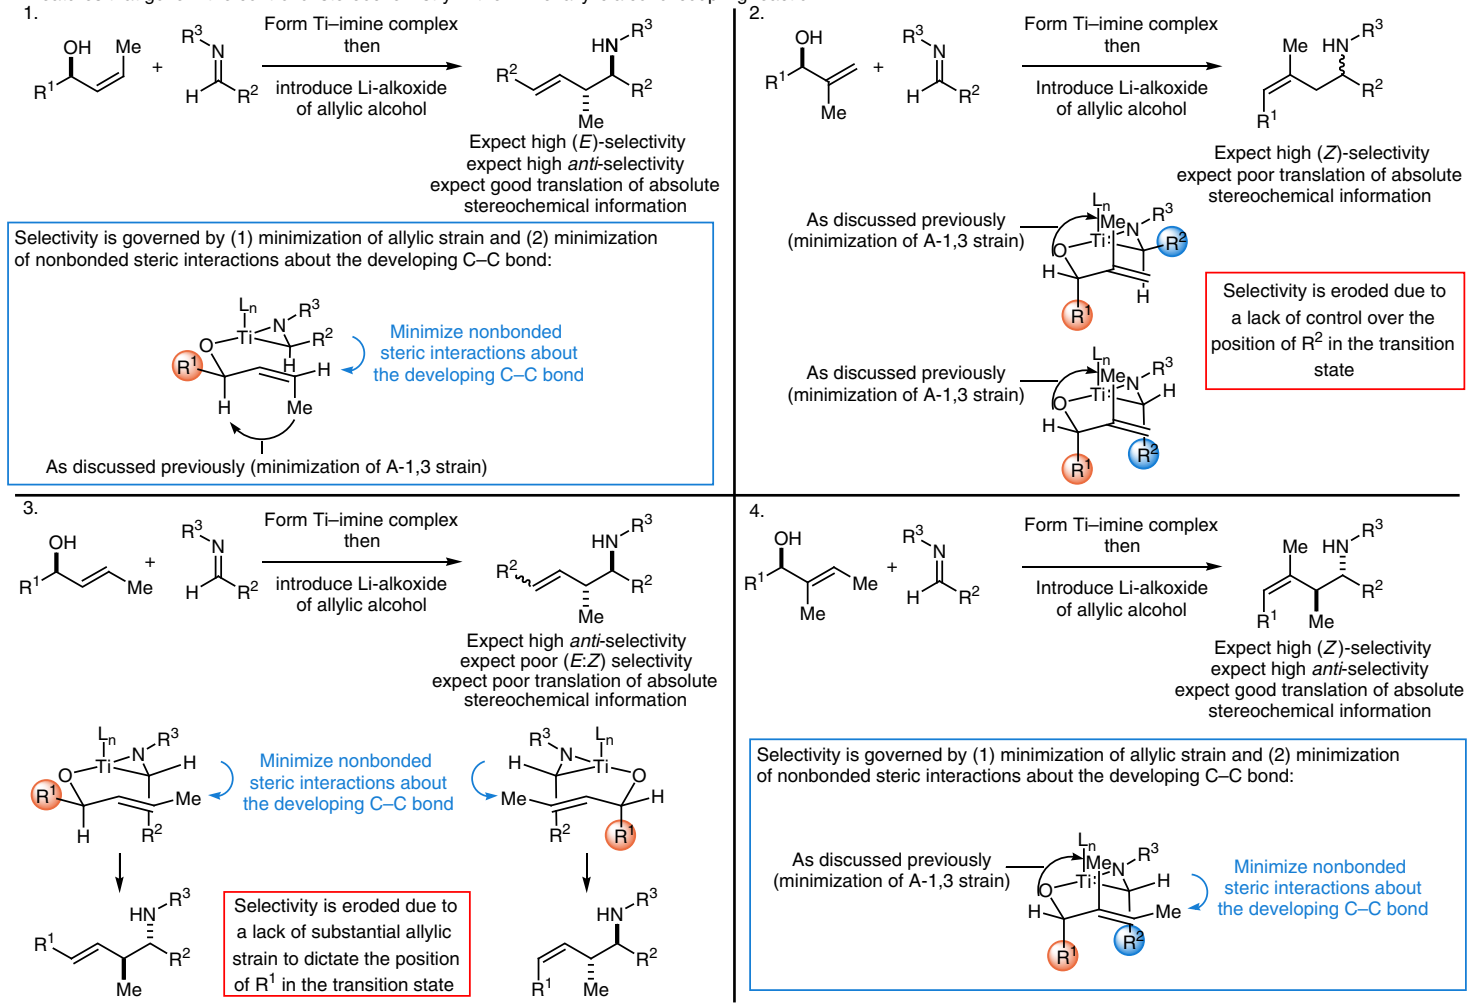
Although the issues that govern alkene selectivity are identical to the alkyne–allylic alcohol-coupling process previously discussed, the imine–allylic alcohol-coupling process is more complex owing to challenges associated with the control of absolute stereochemistry. As illustrated in Scheme 60A, consideration of this coupling process in a kinetic resolution mode (where both *R*- and *S*-azametallacyclopropanes are present, or potentially if there is a means for rapid equilibration between these isomers)[134] leads to the prediction that those reactions that are organized by both the minimization of allylic strain and nonbonded steric interactions about the developing C–C bond should proceed with a high degree of stereochemical control (panels 1 and 4). Those that proceed without both of these features are not expected to proceed with a high degree of stereochemical control (panels 2 and 3).



Examples of asymmetric allylic alcohol–imine-coupling reactions are depicted in Scheme 60B.[135] Here, allylic alcohols bearing (*Z*)-disubstituted alkenes are shown to undergo highly enantio- and diastereoselective coupling reactions with aromatic and aliphatic imines. In all examples reported, products are produced with retention of optical purity and are generated as single diastereomers (*anti*- and (*E*)). Also included in this Scheme is an example that proceeds with compromised levels of enantioselectivity. Here, union of an optically enriched allylic alcohol possessing a 1,1-disubstituted alkene delivers a (*Z*)-trisubstituted alkene-containing homoallylic amine with high levels of selectivity ($Z{:}E \geq 20{:}1$), yet a substantial drop in enantiomeric excess (*ee*) is observed (80–46% *ee*). As illustrated in Scheme 60A-panel 2, this observation is consistent with reaction by way of competing transition states that position the imine substituent (R^2) in a pseudo equatorial versus pseudo axial fashion.

Alternative means of controlling the stereochemical course of allylic alcohol–imine coupling chemistry have recently been described in double asymmetric synthesis.[135] As depicted in Scheme 61A, matched double asymmetric reactions of (*E*)-disubstituted allylic alcohols with phenylglycine-derived imines provides a means to access (*Z*)-alkene-containing *anti*-homoallylic amine products with outstanding levels of stereochemical control ($Z{:}E \geq 95{:}5$, $anti{:}syn \geq 95{:}5$). Interestingly, mismatched double asymmetric coupling reactions in this series lead to product mixtures that favor the formation of (*Z*)-alkene-containing *syn*-homoallylic amine products, albeit contaminated by a substantial quantity of the (*E*)-*anti*-isomer (selectivity = 2.3:1). A detailed empirical model has been proposed to account for these interesting observations.[135]

5.34.3.8.3.1 Applications of imine–allylic alcohol coupling



The ability to generate substituted homoallylic amines from metallacycle-mediated cross-coupling of carbonyl-containing systems with allylic alcohols, rather than the addition of allylic organometallic species to such systems has been recognized as a powerful and synthetically useful advance.[132] Recent applications have explored the utility of this process to access a range of functionalized systems. Scheme 62A illustrates the use of this coupling process as a means to generate substituted *exo*-alkylidene γ-lactams via a one-pot two-step process that engages a brominated allylic alcohol in Ti-mediated reductive cross-coupling and Pd-catalyzed carbonylation chemistry.[136] Scheme 62B depicts a reaction process that was recently established as a concise stereoselective entry to indolizidine and quinolizidines. Here, chemoselective engagement of the allylic alcohol (rather than the allylsilane) in C–C bond formation with a functionalized imine delivers substituted allylic silane intermediates.[137] Subsequent treatment with protic acid results in removal of the dimethyl acetal, intramolecular formation of an iminium ion, and stereoselective intramolecular aza-Sakurai allylation.

Scheme 62C highlights the ability to employ imine–allylic alcohol coupling chemistry with TMS-imines, generated *in situ* from treatment of aldehydes with lithium hexamethyldisilazide (LiHMDS) at low temperature.[138] This reaction process was recently

employed to define an entry to stereodefined homoallylic nitrones that undergo stereoselective intramolecular annulation en route to densely functionalize 1-aza-7-oxabicyclo[2.2.1]heptanes.

Finally, this Ti-mediated cross-coupling process has been employed to realize a regiospecific entry to densely functionalized pyridines (Scheme 62D).[139] Here, the three-component Ti-mediated coupling of allylic alcohols, aldehydes, and LiHMDS delivers functionalized primary homoallylic amines that can be converted to pyridines by the combined action of HgO, BF_3•OEt_2, and HCl in THF.

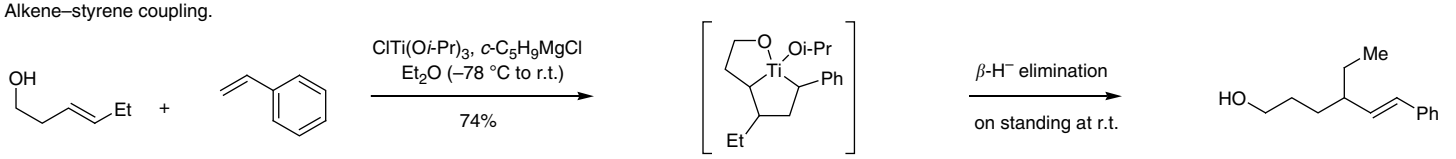
5.34.3.9 Alkene–Alkene Coupling

Early transition metal metallacycle-mediated cross-coupling reactions of alkenes are quite rare due to (1) the instability of saturated metallacyclopentanes – they routinely fragment to Ti–alkene complexes with loss of one alkene substrate and (2) the difficulty of forming early transition metal complexes with substituted alkenes. Early examples in this area noted the particular stability of titanacyclopentanes generated from the coupling of a Cp_2Ti–ethylene complex with methylenecyclopropanes,[140] and in the hydroxyl-directed homocoupling of homoallylic alcohols.[141] More recent advances have included hydroxyl-directed coupling of homoallylic alcohols to styrenes possessing monosubstituted alkenes (Scheme 63A).[142]

Scheme 63B describes an allylic alcohol–vinylsilane coupling that was employed to establish a stereochemically complementary process to the Claisen rearrangement.[143] Although [3,3]-based rearrangement chemistry of allylic alcohol derivatives typically proceeds with high stereoselectivity in favor of generating a product possessing an (*E*)-trisubstituted alkene, this Ti-mediated coupling process delivers the (*Z*)-trisubstituted alkene-containing product with very high levels of stereoselectivity ($\geq$95:5).

Efforts focused on exploring the reactivity of vinylcyclopropanes in hydroxyl-directed Ti-mediated reductive cross-coupling have led to the realization of a unique alkene–alkene-coupling process. As illustrated in Scheme 63C, initial formation of a vinylsilane–Ti complex is followed by addition of the lithium alkoxide of a substituted vinylcyclopropane. Directed carbometalation then proceeds in a stereoselective manner to deliver an unstable tricyclic metallacyclopentane that promptly fragments in a stereospecific manner. Oxidation of the C–Si bond then delivers the primary carbinol products that possess stereodefined skipped dienes.[144] Notably, these studies described the utility of vinylcyclopropanes in alkene–alkyne-coupling chemistry, defining convergent coupling reactions that deliver skipped trienes in a highly stereoselective fashion (not depicted).

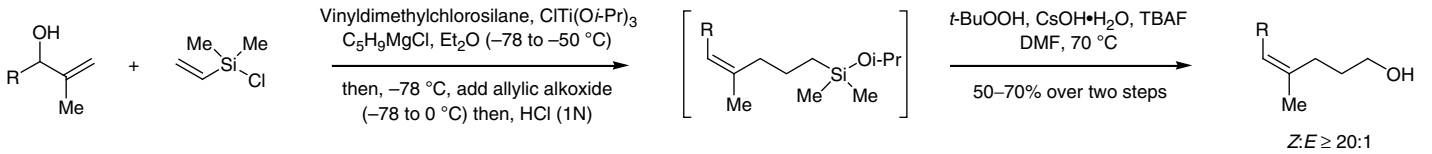
5.34.3.10 Chemoselective Coupling Reactions of Polyenes



Throughout Section 5.34.3, efforts have been taken to describe a collection of intermolecular early transition metal metallacycle-mediated coupling chemistry that proceeds with fine control over regio- and stereoselection. With the goal to achieve a collection of powerful coupling reactions of utility in complex molecule synthesis, it is important to understand and control chemoselectivity in coupling reactions of polyunsaturated substrates.

Early examples that provide a glimpse of the potential selectivity of early transition metal-mediated coupling processes with polyunsaturated substrates have appeared in the intramolecular Kulinkovich reaction, where treatment of an unsaturated ester with Ti(O*i*-Pr)$_4$/2RMgX results in initial transfer epititanation to a terminal alkene of the substrate, followed by intramolecular nucleophilic addition of this complex to the ester. Other examples include:

1. Ti-mediated cyclization of alkynyl esters or carbonates where transfer epititanation results in initial formation of a Ti–alkyne complex that adds to the tethered carboxylic ester or carbonate in an intramolecular fashion (Scheme 64A; also discussed in Schemes 31 and 32),[81,87]
2. Ti-mediated cyclization of allenyl carbonates where transfer epititanation generates a Ti–allene complex that adds to the carbonate in an intramolecular fashion (Scheme 64A),[83]
3. Reaction of a preformed Ti–alkyne complex with an imine in the presence of a tethered terminal alkene (this is a common mode of selectivity that favors addition of the preformed complex to the polarized π-bond of the aldehyde or imine; Scheme 64B),[98]
4. Addition of a preformed Ti–alkyne complex to an enyne that contains a terminal alkyne typically occurs at the alkyne rather than the alkene (Scheme 64C),[104] and
5. Transfer epititanation occurs selectively at an internal alkyne with enyne substrates bearing disubstituted alkenes (Scheme 64D) – interestingly, this example also demonstrates selective reactions of conjugated Ti–alkyne complexes, where protonation delivers a 1,3-diene but reaction with an aldehyde engages the alkene of the conjugated complex such that bond formation occurs in a manner typical of allylic metal reagents.[145]



Hydroxyl-directed early transition metal metallacycle-mediated coupling chemistry has also been explored in contexts that illustrate a great degree of chemoselectivity in functionalization reactions of polyunsaturated substrates. Scheme 50A and B have already presented some interesting observations with respect to chemoselectivity in a complex setting, and recent explorations have defined additional processes that enable site- and stereoselective functionalization of polyenes by metallacycle-mediated bond construction.

B. Alkyne–imine or alkyne–aldehyde coupling is typically faster than alkyne–alkene coupling.

C. Addition of preformed Ti–alkyne complexes to enynes bearing a terminal alkyne typically occur at the alkyne terminus.

D. Transfer epititanation occurs preferentially at an internal alkyne vs. and internal alkene.

Scheme 64

5.34.3.10.1 Site and stereoselective coupling reactions of 1,5-dienes

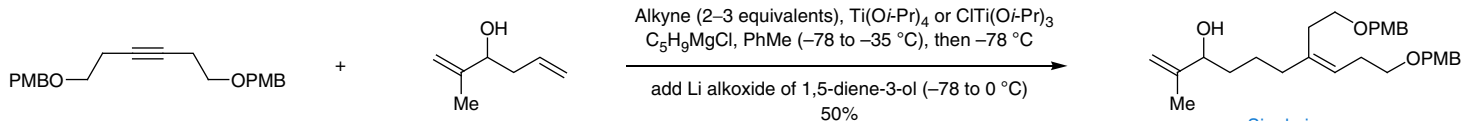
Scheme 65 illustrates the ability to control the site of C–C bond formation based on the nature of alkene substitution in a 1,5-diene.[146] Here, the diene is unsymmetrically disposed about a secondary alcohol such that one π-system is part of an allylic alcohol functional group, whereas the other is part of a homoallylic alcohol functional group. Although little selectivity is observed if both alkenes are terminal monosubstituted π-systems, substrate substitution can be used to gain full control over chemoselectivity. As illustrated in Scheme 65A, coupling between an internal alkyne and an unsymmetrically substituted 1,5-diene results in selective reaction at the least substituted alkene and in the formation of a 1,7-diene product. Interestingly, if both alkenes of the 1,5-diene are disubsituted, high selectivity is uniformly seen for reaction at the allylic alcohol (Scheme 65B). In the first case, the 1,5-diene substrate contains two (*Z*)-disubstituted alkenes, and regio-/stereoselective coupling ensues to deliver a skipped triene product containing a central (*E*)-disubstituted alkene as a single isomer. In the next two examples depicted, chemoselective reactions at the allylic alcohol termini result in highly (*Z*)-selective coupling process and deliver extremely complex stereodefined skipped trienes. Note that skipped trienes that possess trisubstituted alkenes, varying alkene stereochemistries, and sp^3 stereochemistry at the central position of the skipped polyene architecture are quite difficult to prepare using other methods.

5.34.3.10.2 Site and stereoselective coupling reactions of 1,6-enynes

Efforts to understand chemoselectivity in addition reactions of preformed Ti–alkyne complexes to enynes possessing a central hydroxyl-directing group have led to the discovery of unique and powerful coupling technologies. Scheme 66A depicts two coupling reactions that demonstrate the ability to selectively functionalize the enyne at the alkene or alkyne motif.[147] To date, only enyne substrates bearing both an internal alkyne and a terminal alkene are capable of selective hydroxyl-directed reaction at the terminal alkene – this selectivity is different than that previously reported for intermolecular coupling of a preformed Ti–alkyne complex to an enyne containing both a terminal alkyne and a terminal monosubstituted alkene (i.e., Scheme 64C).

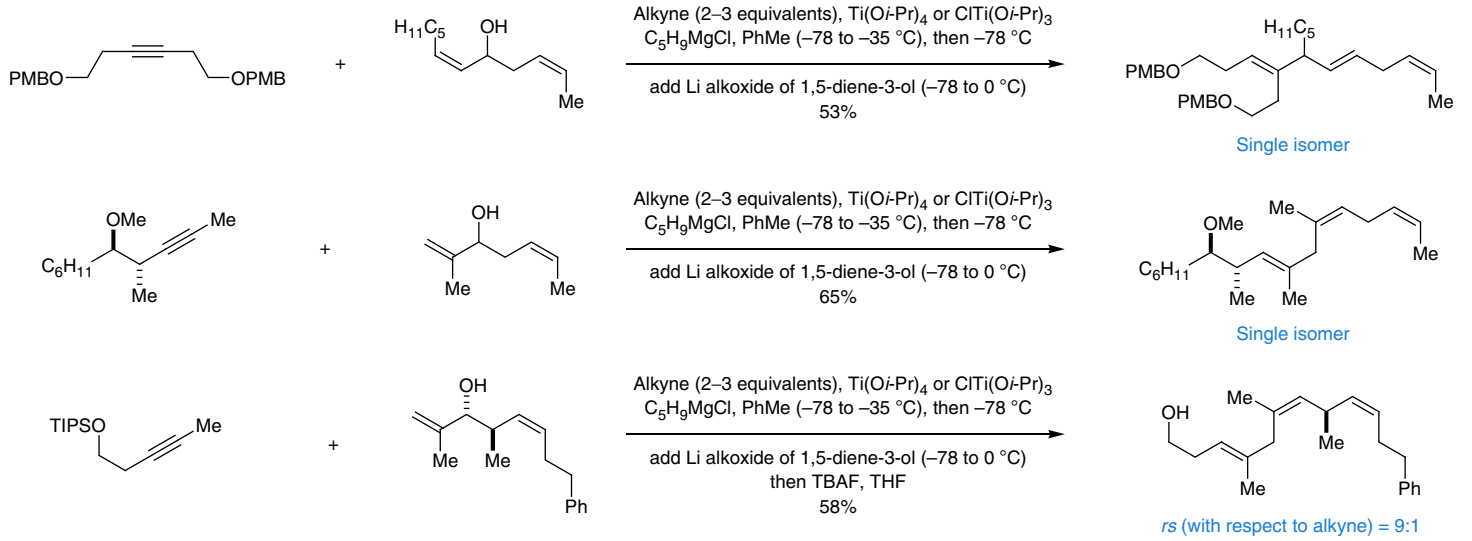
5.34.3.10.3 A unique and highly stereoselective [2 + 2 + 2] annulation in a subset of alkyne–enyne-coupling reactions

Scheme 66B shows a rather powerful coupling process between alkynes and enynes that delivers stereochemically defined hydroindanes by [2 + 2 + 2] annulation.[147] This result has proven unique to enyne substrates bearing 1,1-disubstituted alkenes and furnishes a useful stereoselective entry to densely functionalized hydroindane motifs.



As illustrated in Scheme 66C, a diyne–alkene [2 + 2 + 2] annulation process has also been described that secures an alternative entry to substituted carbocycles.[148] Here, intramolecular alkyne–alkyne coupling produces a metallacyclopentadiene that, through ligand exchange, reacts with the homoallylic alcohol to generate a transient species capable of undergoing annulation. Although the symmetry of the diyne substrate renders these coupling reactions a bit simpler than those described in Scheme 66B (as regioselectivity is not an issue here), these coupling processes proceed with exquisite levels of 1,3-stereochemical control.

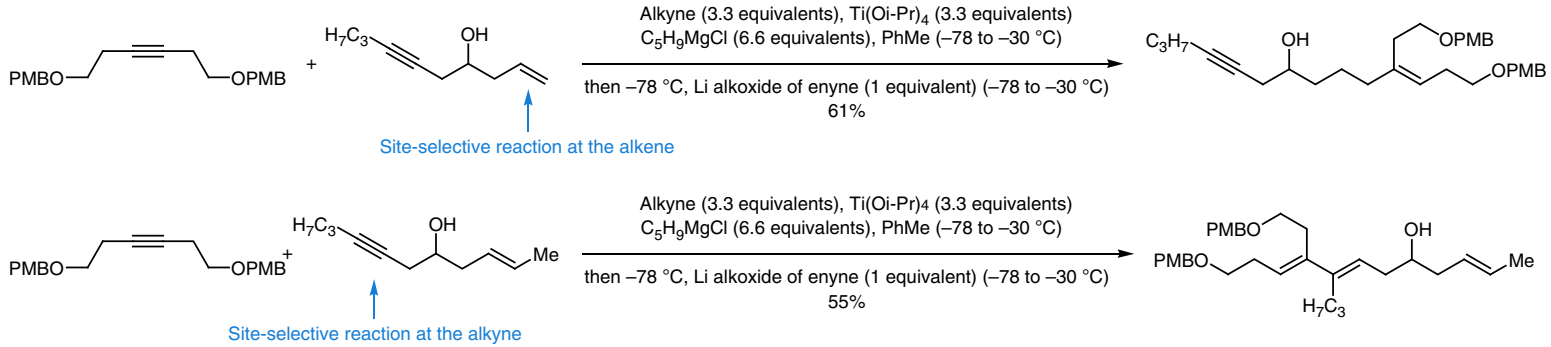
5.34.3.11 Other Coupling Reactions that Proceed via [2 + 2 + 2] Annulation



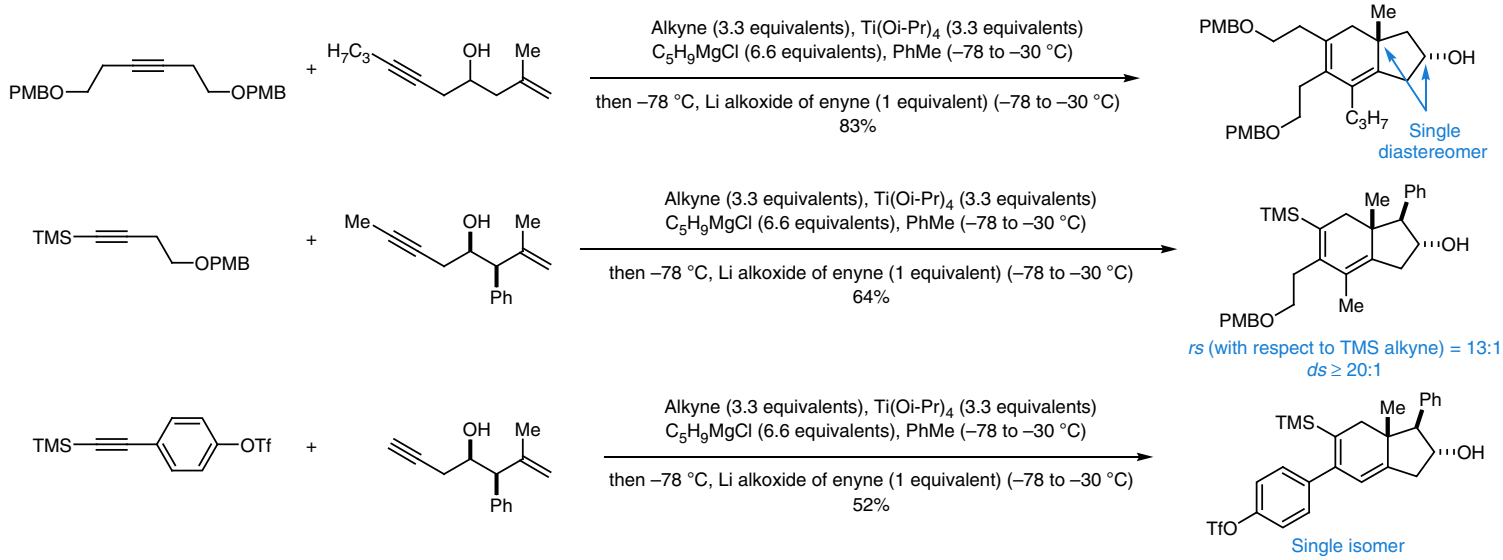
Section 5.34.3.10 that was focused on chemoselectivity in Ti-mediated coupling reactions of polyunsaturated substrates concluded with a brief discussion of some observations in [2 + 2 + 2] annulation chemistry. This section builds on that discussion, as recent advances have described a variety of Ti-mediated [2 + 2 + 2] annulation reactions for the synthesis of aromatic systems. Scheme 67A shows two reactions for the selective cross-coupling of three different alkynes en route to substituted benzenes. The first proceeds via regioselective generation of a metallacyclopentadiene (regioselection for this process was already discussed in association with Scheme 43). Addition of the ethyl sulfone then results in the formation of a metalated benzene by a sequence that has been proposed to proceed through regioselective [4 + 2] cycloaddition, isomerization, and then elimination.[149] In a related report, it was also demonstrated that addition of propargyl bromide to a metallacyclopentadiene intermediate results in regioselective [4 + 2] cycloaddition and elimination to deliver a benzylic organometallic.[150]

Ti-mediated [2 + 2 + 2] annulation has emerged as a powerful approach to the synthesis of substituted pyridines.[100,151,152] As illustrated in Scheme 67B, the collection of reactions defined for [2 + 2 + 2]-based entry to substituted pyridines employ two carbon-based π-systems (alkynes) and one C–N-based π-system (nitrile). Although a variety of distinct approaches to this aromatic heterocycle has been described, they proceed by one of two general pathways. The first of these follows from generation of a metallacyclopentadiene or azametallacyclopentadiene, with subsequent addition of a third sp-based π-system (alkyne or nitrile). Annulation then results in the generation of an organometallic intermediate that can isomerize and ultimately eliminate to generate a metalated pyridine. As illustrated in the first two examples of Scheme 67B, this can proceed through the addition of a sulfonyl nitrile or an ethynyl sulfone. Alternatively, as illustrated in the third example, generation of a metallacyclopentadiene by the coupling of a TMS-alkyne with an aminoacetylene can be followed by addition of a nitrile. Here, annulation delivers an intermediate that can eliminate the sulfonamide moiety – again, generating a metalated pyridine product. As illustrated in the fourth example depicted in Scheme 67B, pyridine synthesis can also proceed by coupling a metallacyclopentadiene with a nitrile. Here, annulation proceeds to deliver an intermediate that rearranges to a Ti–amide complex, protonation of which delivers 2-formyl-substituted pyridine products.

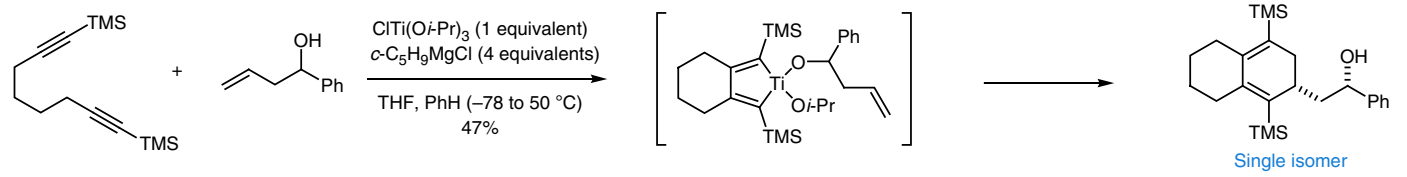
A. Coupling of preformed Ti–alkyne complexes with polyenes: Selective engagement of a terminal alkene via homoallylic alcohol–alkyne coupling:



B. Coupling of preformed Ti–alkyne complexes with polyenes: Selective engagement of a subsituted alkene via allylic alcohol–alkyne coupling in preference to homoallylic alcohol–alkyne coupling:

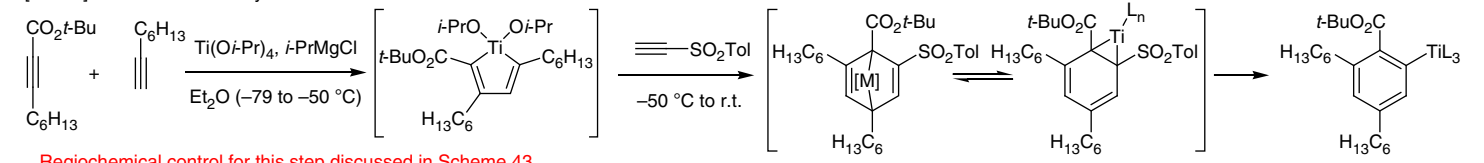


Scheme 65

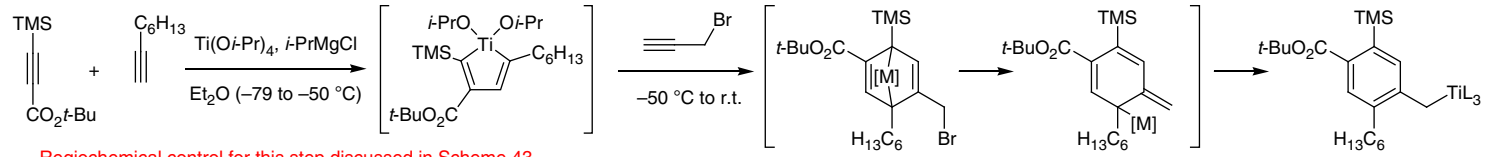


A. Coupling of preformed Ti–alkyne complexes with enynes: Selectivity is a function of the substitution of the π-system.

B. Coupling of preformed Ti–alkyne complexes with enynes: Enynes with 1,1-disubstituted alkenes take part in a highly controlled intermolecular [2+2+2] annulation.

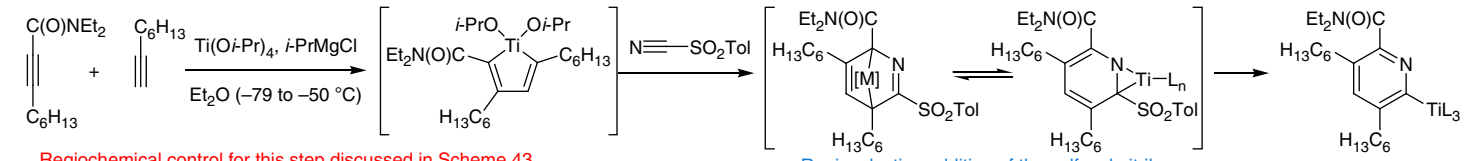


C. Coupling of preformed titanacyclopentadienes with homoallylic alkoxides: A different intermolecular [2+2+2] annulation.

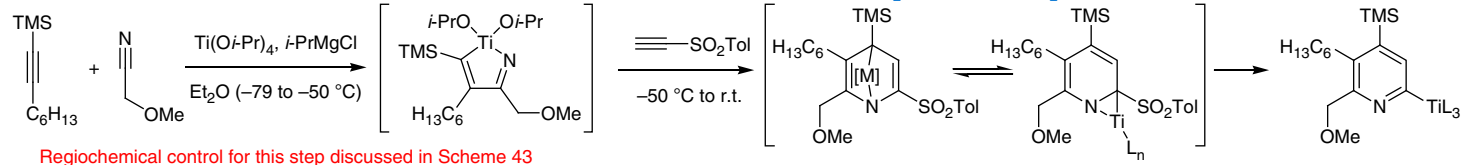


Scheme 66

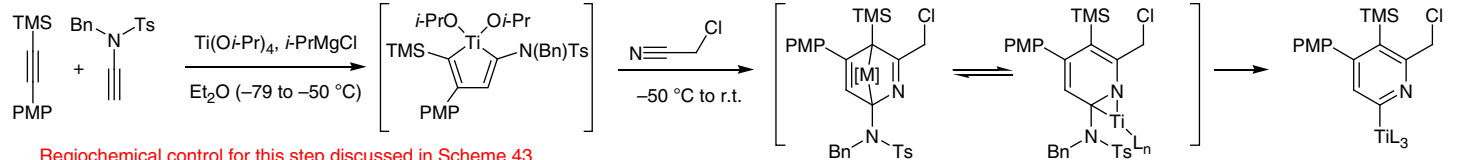
A. [2+2+2] Annulation for the synthesis of substituted benzenes.



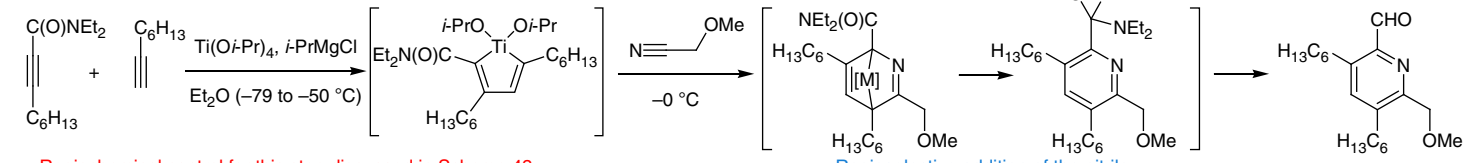
Regiochemical control for this step discussed in Scheme 43 and is based on the CO_2t-Bu group



Regiochemical control for this step discussed in Scheme 43 and is based on the TMS group

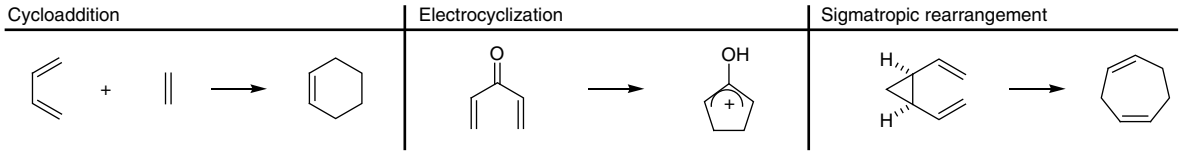


B. [2+2+2] Annulation for the synthesis of substituted pyridines.

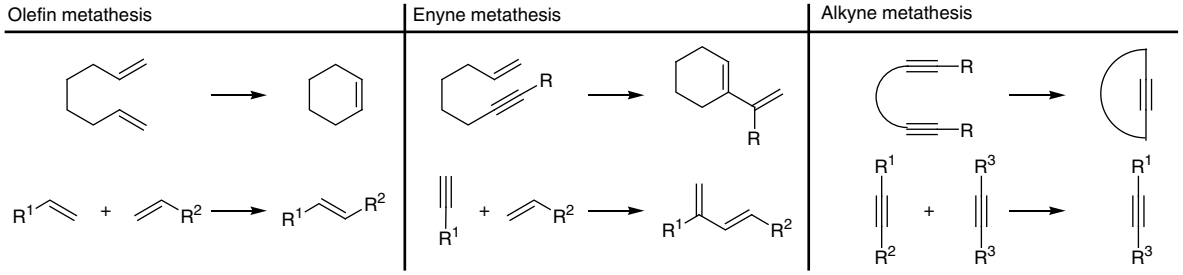


Regiochemical control for this step discussed in Scheme 43 and is based on the $C(O)NEt_2$ group

Regiochemical control for this step discussed in Scheme 43 and is based on the TMS group

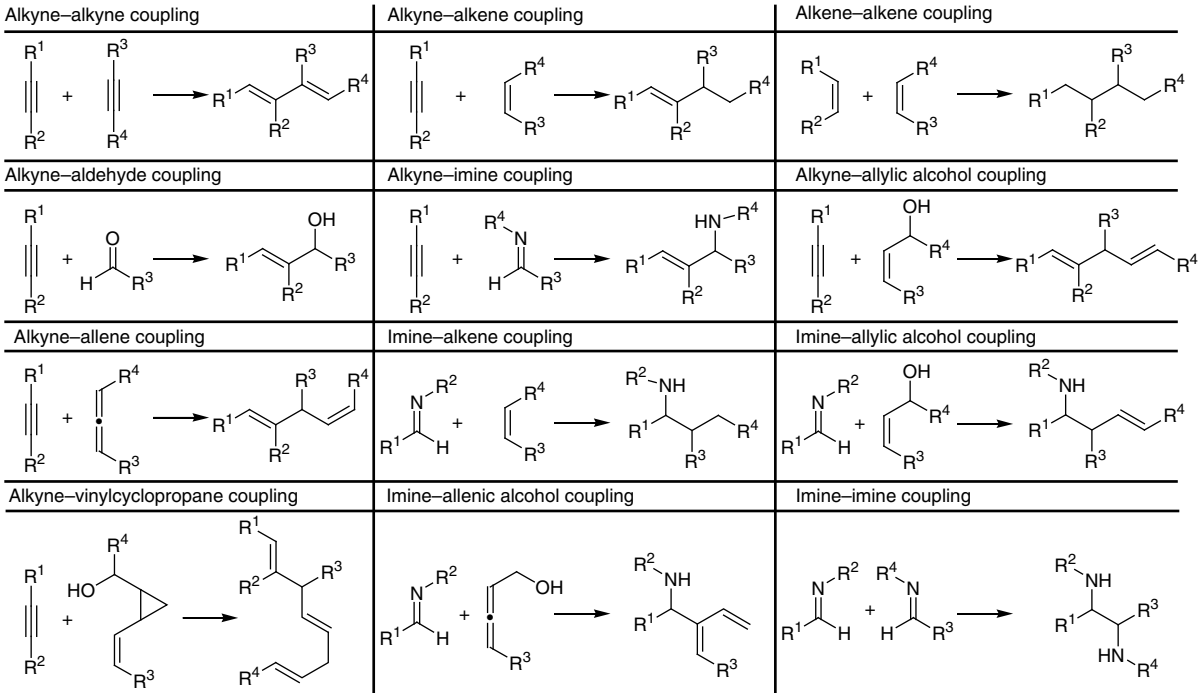


Regiochemical control for this step discussed in Scheme 43 and is based on the TMS group



Regiochemical control for this step discussed in Scheme 43 and is based on the $C(O)NEt_2$ group

Scheme 67



A. Concerted chemistry as a means of accomplishing C–C bond-forming reactions at sites of π-unsaturation.

B. Metathesis as a means of accomplishing C–C bond-forming reactions at sites of π-unsaturation.

C. Early transition metal metallacycle-mediated coupling as a means of accomplishing C–C bond-forming reactions at sites of π-unsaturation.

Scheme 68

5.34.4 Conclusion

Since the initial publication of the first edition of *Comprehensive Organic Synthesis* in 1991, substantial advances have been made in the control of metallacycle-mediated cross-coupling technology. Twenty years ago, the intramolecular versions of this chemistry were secured as a means to generate carbo- and heterocyclic systems, whereas intermolecular variations were substantially limited by (1) the lack of general strategies to control the course of metallacyclopentane formation (i.e., low reactivity, challenges controlling regioselectivity, diastereoselectivity, and pair selectivity) and (2) the functional group compatibility associated with Cp_2Zr- and Cp_2Ti-based systems. As such, only the simplest examples of cross-coupling by metallacycle-mediated coupling chemistry had appeared with a small subset of sparsely functionalized systems.

Major advances since 1991 include the discovery that inexpensive, nontoxic, and easy-to-work-with Ti-alkoxides can be employed as the central metal component. Building on this advance, a collection of heteroatom-directing group strategies have been put forth that offer fine control over reactivity, regio- and stereoselection in intermolecular variants of metallacycle-mediated coupling.

5.34.5 Perspective

Reactions that enable C–C bond formation at sites of π-unsaturation are incredibly important in modern organic synthesis. To date, it has been well accepted that cycloaddition, electrocyclization, and sigmatropic rearrangement chemistry have had a transformative effect in chemical synthesis (**Scheme 68A**). The same can be said for the growing significance of metathesis chemistry (**Scheme 68B**). Given the great diversity of π-systems that can be engaged in early transition metal metallacycle-mediated coupling (a subset of these are depicted in **Scheme 68C**), and the growing body of literature describing general strategies to control reactivity and selectivity for such coupling chemistry, a very bright future for the role of this chemistry in organic synthesis is likely. The emerging power of this chemistry is already becoming evident in the growing number of advances that embrace the chemical reactivity of early transition metals to accomplish the synthesis of a great variety of stereodefined functional groups, aromatic carbo- and heterocyclic systems, and natural product motifs of relevance to the synthesis of terpenes, alkaloids, and fatty acids. Important future advances in this area will include (1) broadening the substrate scope for early transition metal metallacycle-mediated coupling reactions, (2) increasing the scope of π-systems that can be employed in transfer epimetalation chemistry, (3) establishing new strategies to control regio- and stereoselection in metallacycle formation and functionalization, and (4) identifying methods that allow for cross-coupling of notoriously unreactive π-systems without the need of a directing group.

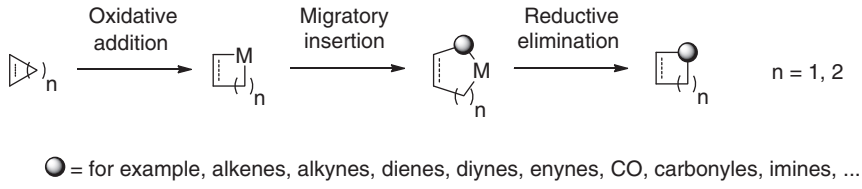
Glossary

Migratory insertion The insertion ion of a multiple bond AB into a covalent bond XY with concomitant creation of two covalent bonds AX and BY. X or Y is usually a metal. In the case of carbon monoxide, both new covalent bonds are formed with the carbon atom. Also more simply called insertion.

Oxidative addition The insertion of a metal complex into a covalent bond with concomitant formal loss of two electrons on the metal.

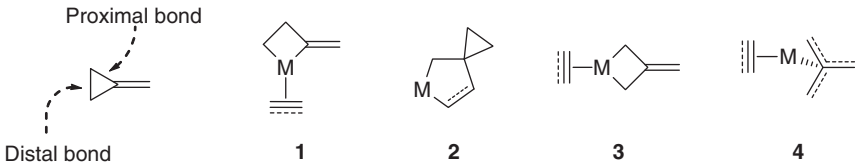


Reductive elimination An elementary step in organometallic chemistry; chemically speaking, a reductive elimination is the reverse of an oxidative addition.

Steric congestion Nonbonded repulsions and deviation from ideal geometry incurred by the substituents on atoms.

Strain energy Additional energy brought to a molecule by unfavorable bond angles and lengths and dihedral angles.

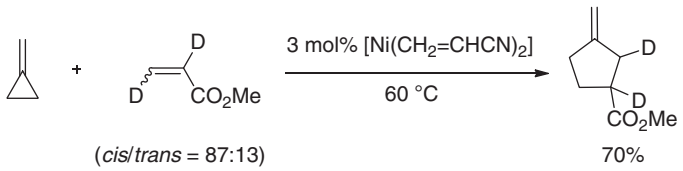
5.35.1 Introduction



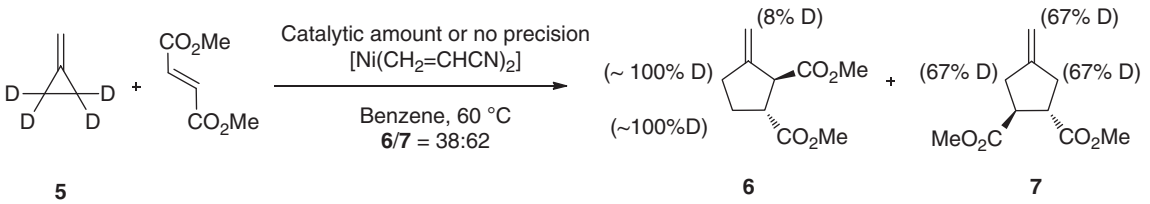
The strain energy of small ring compounds makes them particularly prone to undergo oxidative addition with transition-metal complexes.[1] The intermediates thus formed can react with unsaturated substrates via migratory insertion and give a broad variety of cycloaddition products after reductive elimination (Scheme 1). In the vast majority of transition-metal-catalyzed cycloadditions of small ring compounds, at least one carbon–carbon or carbon–heteroatom multiple bond is present in the substrate and facilitates or directs the oxidative addition.

Scheme 1

5.35.2 Cycloadditions of Methylene- and Alkylidenecyclopropanes



Although highly strained, methylene- and alkylidenecyclopropanes are stable at room temperature. Cleavage of the proximal bond, via metallacyclobutane **1** and α-cyclopropylmethylmetal **2**, or the distal bond, via metallacyclobutane **3** or a trimethylenemethane metal complex **4**, has been observed in the transition-metal-catalyzed cycloadditions of those substrates (Scheme 2).[2]

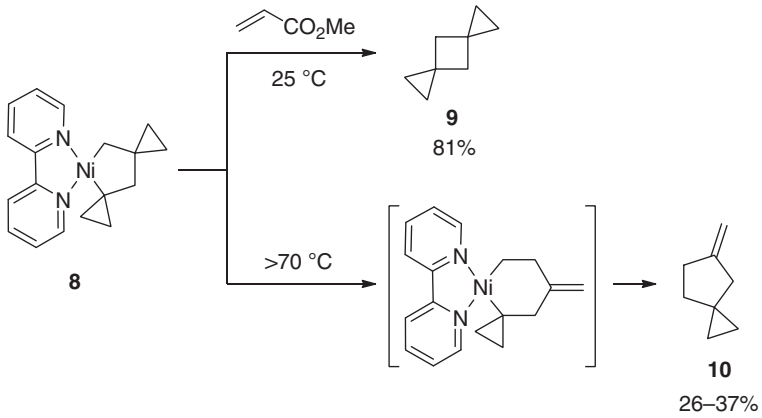


Scheme 2

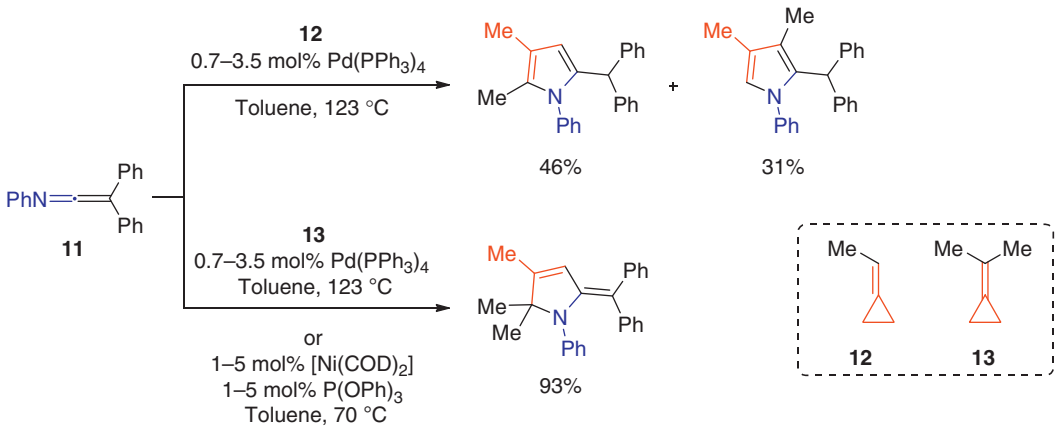
5.35.2.1 Intermolecular Cycloadditions

The reactions catalyzed by nickel complexes are very sensitive to the ligand sphere and the substrates. Both proximal and distal cleavages are possible. For example, it was shown that an intermediate of type **1** is plausible in the [3 + 2] cycloaddition of methylenecyclopropane with deuterated methyl acrylate (equation 1).[3] Conversely, the reaction of deuterated methylenecyclopropane **5** with dimethyl fumarate gave compound **6**, resulting from a proximal cleavage, and compound **7**, likely formed via an intermediate of type **4**, as indicated by the statistical scrambling of deuterium over three carbon atoms (equation 2).[4]

(1)

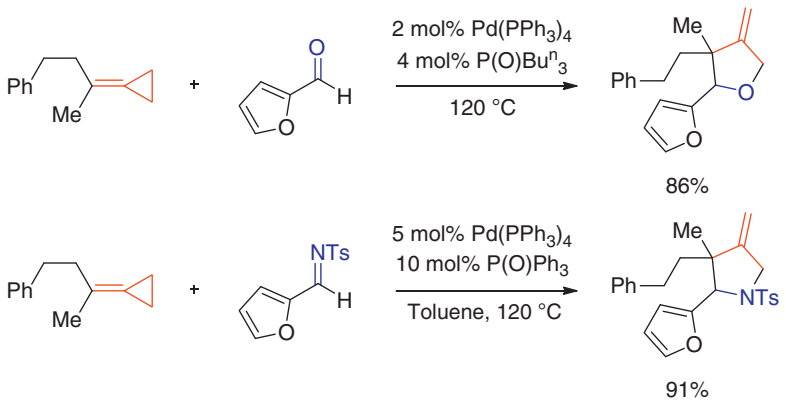


(2)

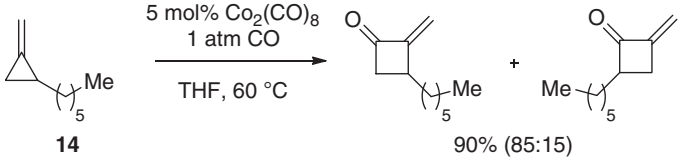


Moreover, the possibility of intermediates of type **2** in nickel-catalyzed dimerizations of methylenecyclopropane[5] has been demonstrated experimentally.[6] Hence, treatment of nickelacyclopentane **8** with an excess of methyl acrylate at room temperature led to the formation of the [2 + 2] dimerization product **9**, whereas heating of **8** above 70 °C afforded the [3 + 2] dimerization product **10** after rearrangement (Scheme 3).

In contrast to the nickel-catalyzed reactions, the regioselectivity of the ring cleavage of methylenecyclopropanes in [3 + 2] cycloadditions catalyzed by palladium complexes is much more consistent and likely proceeds through intermediates **3**.[7] In accordance with experimental results, computational investigations suggest that distal oxidative addition should be preferred over proximal addition.[8] Nevertheless, even if the cleavage of the small ring is completely regioselective, intermolecular reactions with substituted methylenecyclopropanes can lead to mixtures of products in certain cases.[2] For example, a mixture of regioisomers was obtained in the palladium-catalyzed cycloaddition of triphenylketimine **11** with **12**, whereas both palladium- and nickel-catalysts led to selective reactions with **13** (Scheme 4).[9] All products resulted from cleavage of the distal carbon–carbon bond in **12** and **13**. Palladium-catalyzed [3 + 2] cycloaddition of alkylidenecyclopropanes have also been described with aldehydes[10] and aldimines[11] (Scheme 5), giving products of distal bond cleavage in almost equimolar diastereomeric ratio.

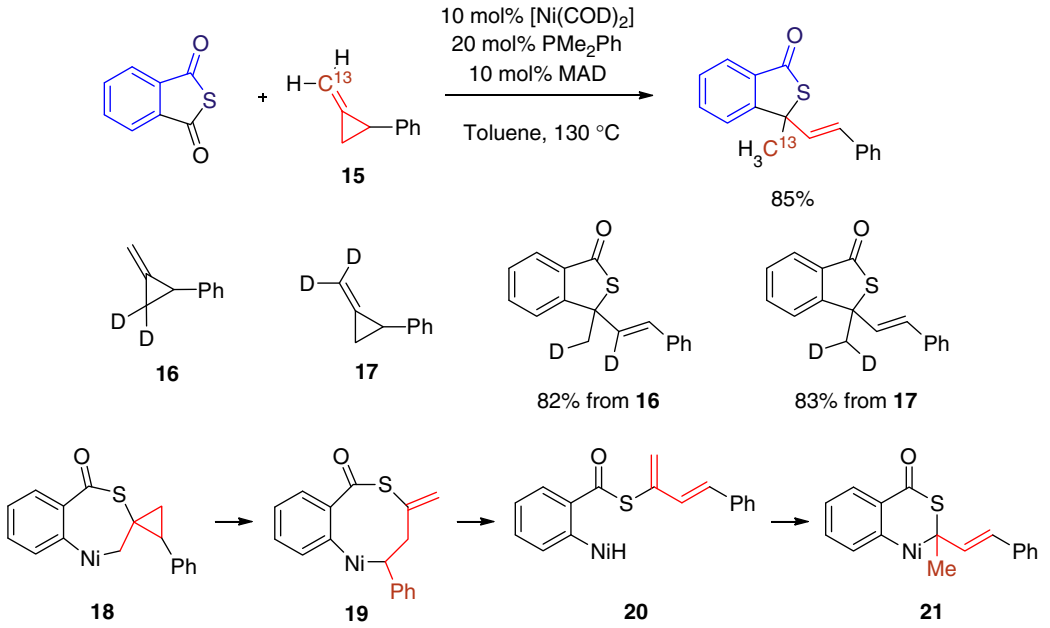


As mentioned in the introduction, the scope of reactants in transition-metal-catalyzed cycloadditions of small rings compounds is vast.[2] For example, cleavage of the less substituted carbon–carbon bond of the cyclopropane afforded the major product in the cobalt-catalyzed [3 + 1] carbonylative cycloaddition of **14** (equation 3).[12]

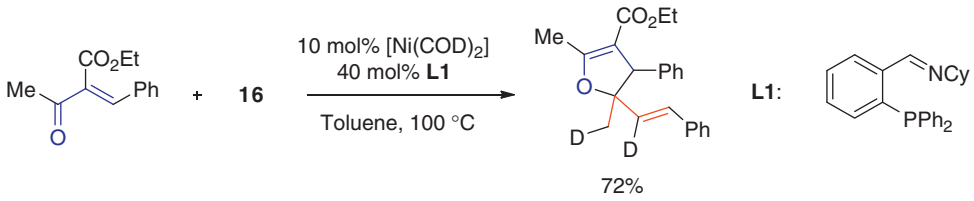


Scheme 3

Scheme 4



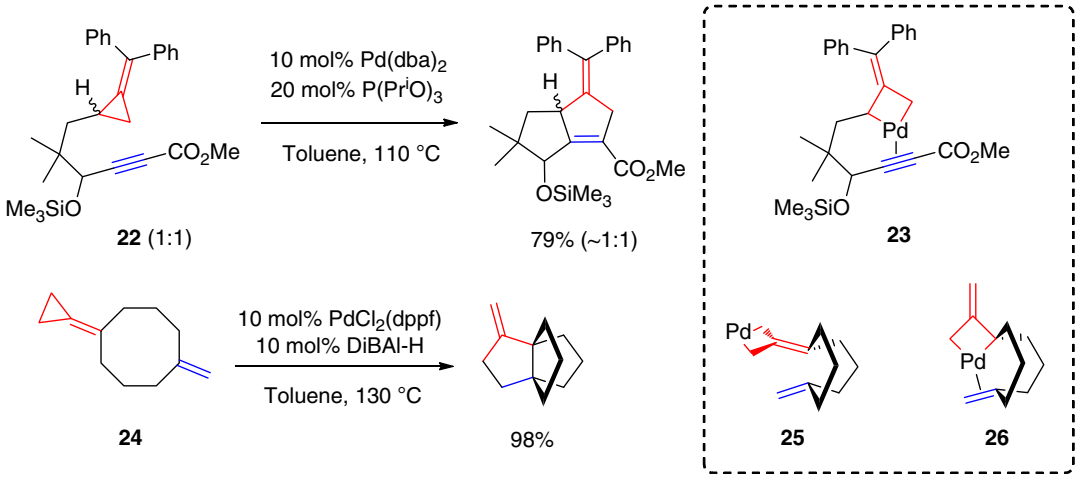
Scheme 5



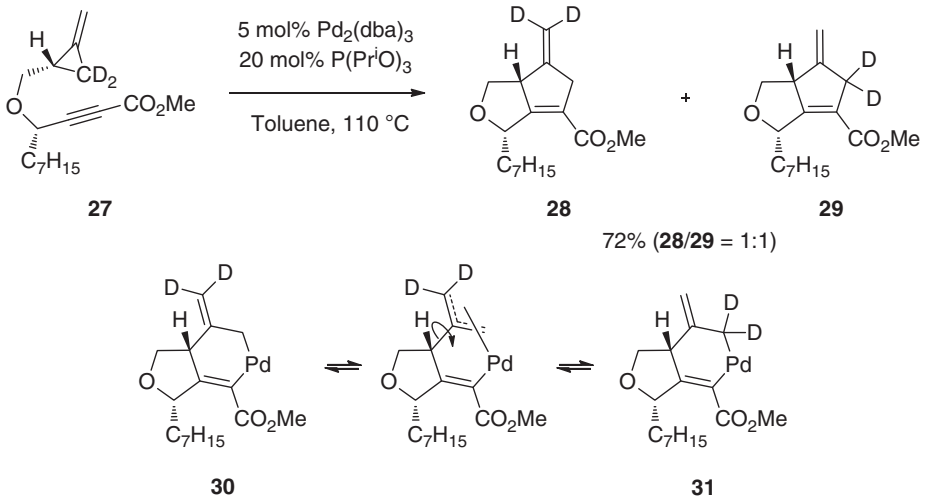
(3)

In addition, recent reports disclosed the use of methylenecyclopropanes as one-carbon unit in nickel-catalyzed cycloaddition reactions,[13,14] in contrast to the examples previously commented in this section, which all involved reactions where this motif was used as a three-carbon unit. Results of mechanistic studies with isotope-labeled compounds **15**–**17** (Scheme 6) were in good agreement with a catalytic cycle involving the rearrangement of α-cyclopropylcarbinylnickel intermediate **18** to homoallylnickel **19** with concomitant cleavage of the more sterically hindered carbon–carbon bond of the cyclopropane ring, followed by β-hydride elimination toward **20** and hydrometallation to give **21** before final reductive elimination.[13] A similar mechanism is likely operative in the [4 + 1] cycloadditions with α,β-unsaturated enones (equation 4).[14]

Scheme 6

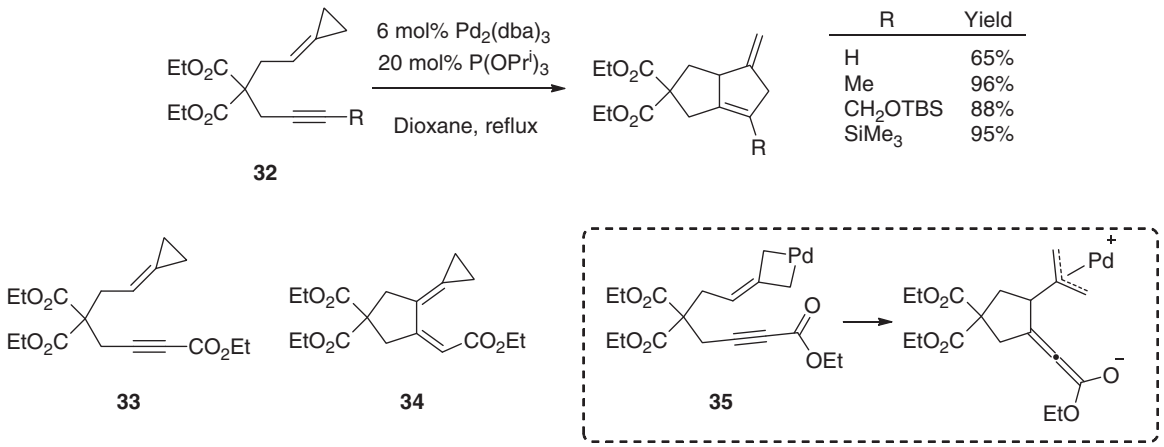


(4)



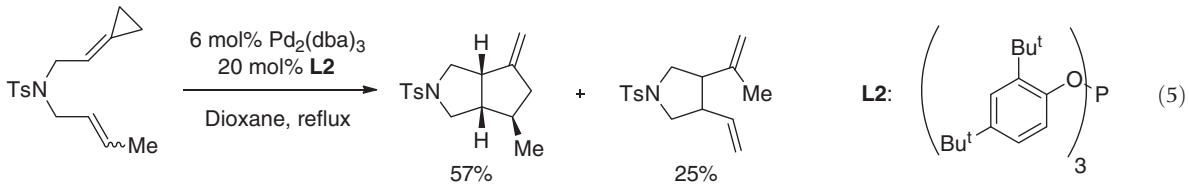
5.35.2.2 [3 + 2] Intramolecular Cycloadditions

The tether, placed between the methylenecyclopropane moiety and a carbon–carbon multiple bond, allows the regioselectivity of intramolecular [3 + 2] cycloadditions to be improved. For example, cleavage of the proximal bond in **22** presumably leads to intermediate **23**, which is poised for a high-yielding cycloaddition,[15] whereas the reaction of **24** likely proceeds through **25**, which can rearrange into **26** (Scheme 7).[16] It was also shown that the ratio of compounds **28** and **29** was constant during the conversion of **27**, whereas no deuterium scrambling was observed in recovered starting material (Scheme 8).[17] This is in agreement with a rapid alkyne insertion toward palladacycles **30** and **31**, followed by a rate-limiting reductive elimination. Presumably, intramolecular coordination to the metal stabilizes the metallacyclobutane intermediates in these reactions. Importantly, the observed retention of configuration at the cyclopropane carbon atom in **27** rules out a mechanism involving a trimethylenemethane intermediate, as this would lead to an inversion of the configuration.

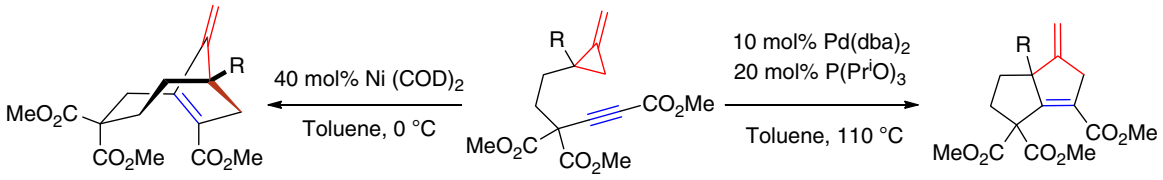


However, computational studies[18] suggest that trimethylenemethane intermediates are plausible in the reaction of substrates **32** (Scheme 9).[19] Moreover, it is noticeable that alkylidenecyclopropane **33** did not afford any [3 + 2] cycloaddition products. Instead, compound **34** was identified in the crude reaction mixtures, which could be formed by intramolecular conjugate addition to the electron-poor alkyne **35**.[18] This result is in striking contrast with the reactions of ester-substituted alkynes **22** and **27**.[15,17]

Scheme 7



Scheme 8



Scheme 9

Bicyclic products of distal bond cleavage were also obtained in rhodium[20] and ruthenium-catalyzed[21] intramolecular [3 + 2] cycloadditions, albeit the latter reaction likely follows a different mechanistic manifold. In palladium-catalyzed reactions, the alkyne moiety could be replaced with an allene.[22] However, replacement with an electron-poor or terminal alkene caused stereoselectivity issues, whereas a methyl-substituted alkene afforded a product by competitive β-hydride elimination in addition to the desired bicyclic product (equation 5).[23]

(5)

It was established early on that a nickel catalyst could lead via proximal bond cleavage to antiBredt products **36**, albeit in incomplete conversions and moderate isolated yields, whereas treatment of the same starting material with a palladium catalyst led to formation of **37**, resulting from the expected cleavage of the distal C–C bond of the methylenecyclopropane moiety (Scheme 10).[24] As illustrated in a recent study (equation 6),[25] nickel-catalysts tend to afford only products resulting from proximal bond cleavage in an intramolecular [3 + 2] cycloaddition.

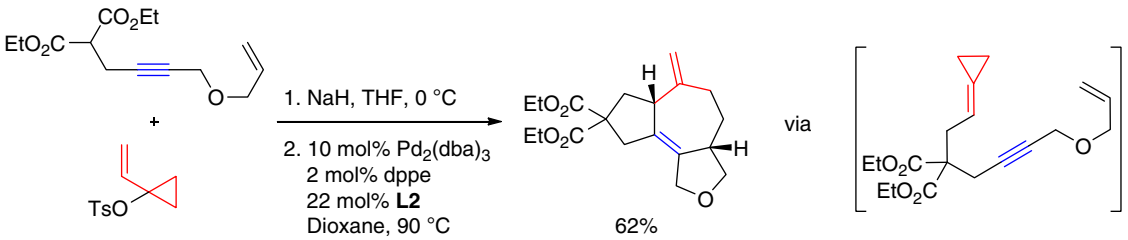
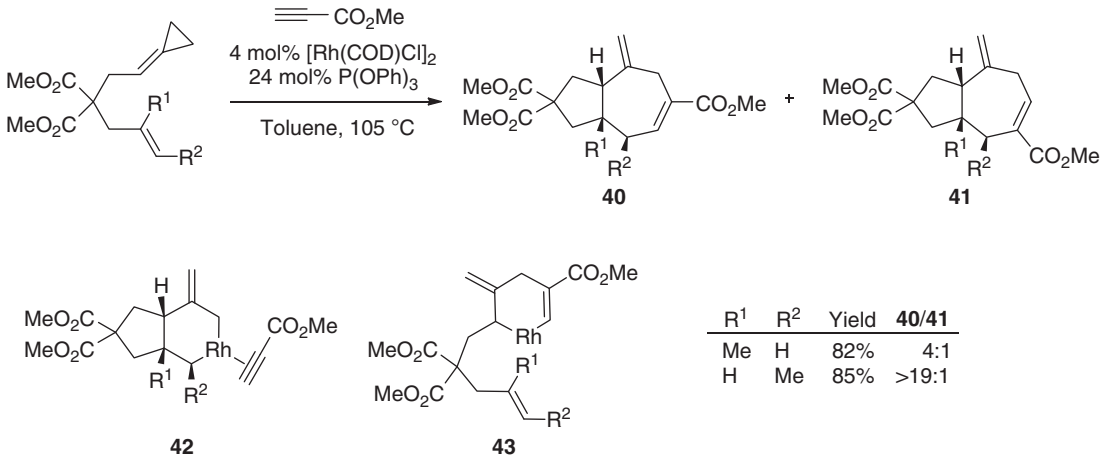
5.35.2.3 Higher Order Cycloadditions



In the last decade, increasingly complex combinations of unsaturated compounds have been used in transition-metal-catalyzed higher order inter- and intramolecular cycloadditions of alkylidenecyclopropanes, which serve as a three-carbon unit in those reactions. For example, seven-membered ring compounds could be prepared enantioselectively in a palladium-catalyzed [4 + 3] cycloaddition of alkylidenecyclopropanes tethered to a 1,3-diene (Scheme 11).[26] The reductive elimination of the putative palladacycle intermediates **38** and **39** could not be made completely selective in favor of the latter and mixtures of five- and seven-membered rings were typically obtained. Nevertheless, this approach enabled the rapid assembly of polycyclic compounds (Scheme 12).[27]

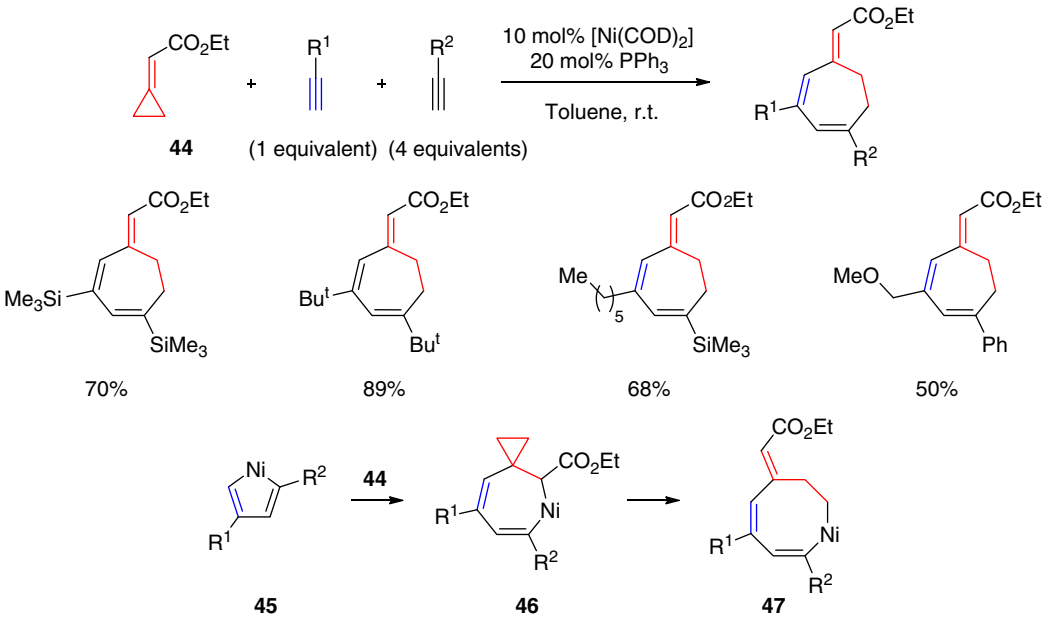
A rapid increase of complexity is also evident in the intermolecular [3 + 2 + 2] cycloadditions depicted in Scheme 13.[28] The seven-membered rings **40** and **41** were obtained as single diastereomers ($ds \geq 19{:}1$). Comparison of the **40**/**41** ratios suggest that intermediate **42** is more likely than **43** because the steric influence of the group R^2 on the regioselectivity of the migratory insertion of the alkyne is likely to be stronger in **42** than in the intermediate leading to **43**.



Two-[29] and three-component[30] nickel-catalyzed [3 + 2 + 2] cycloadditions of alkylidenecyclopropane **44** have also been reported (Scheme 14). The reaction is only possible with electron-poor **44**, which is in good accordance with a mechanistic sequence consisting of a conjugated addition of intermediate **45**, followed by a rearrangement of the α-cyclopropylcarbinylnickel **46** to homoallylnickel **47**.[31] In certain cases, conformational flexibility of the intermediates led to a mixture of stereoisomers through cleavage of both proximal bonds *a* and *b* of the cyclopropane ring, as exemplified in the spectacular [4 + 3 + 2] cycloaddition depicted in Scheme 15.[32] Similar observations have been made in the nickel-catalyzed reactions of 1,5- and 1,6-diynes with **44**.[33]

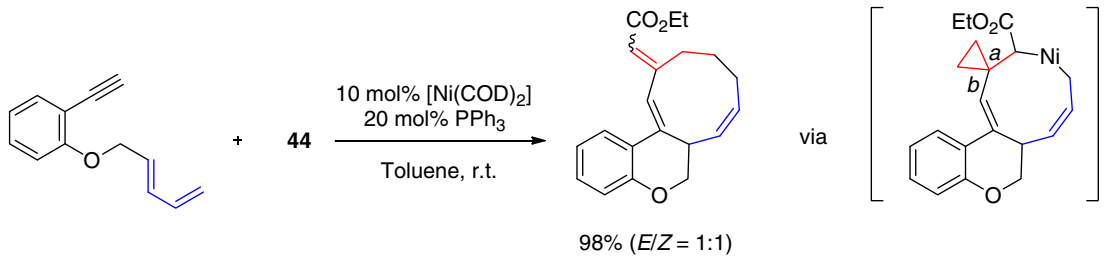
Scheme 11

Scheme 12



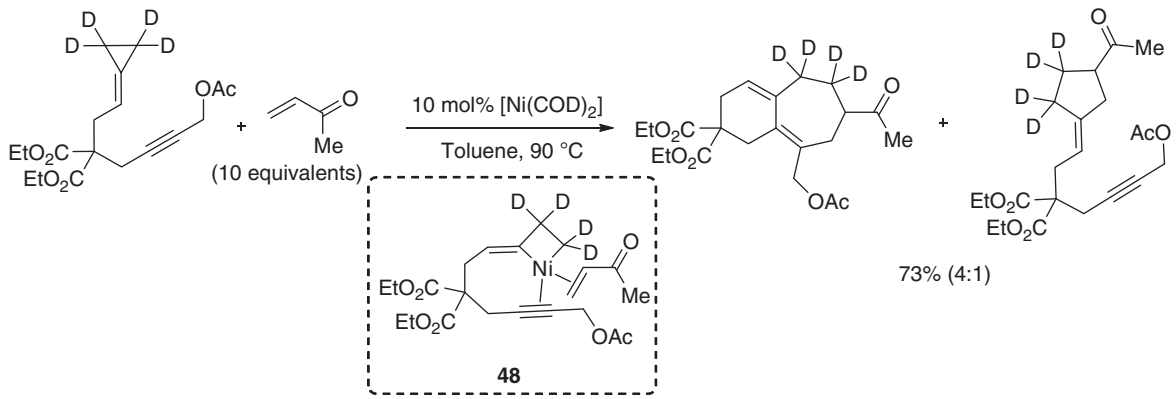
R^1	R^2	Yield	**40/41**
Me	H	82%	4:1
H	Me	85%	>19:1

Scheme 13



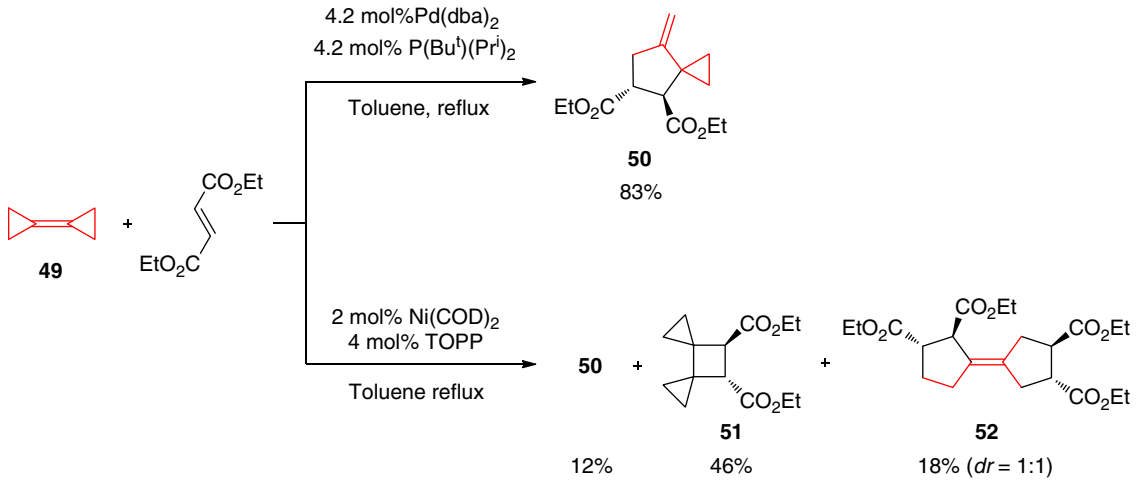
The proposed intermediate **48** is in good agreement with the results of experimental studies conducted with an isotope-labeled substrate (Scheme 16).[34] Importantly, calculations indicate that intramolecular alkyne coordination to the metal, as depicted in **48**, is essential to the process. Moreover, coordination of electron-poor alkenes (α,β-unsaturated ketone, ester, and phenylsulfone) would also facilitate migratory insertion of the alkyne into the carbon–nickel bond.

5.35.2.4 Cycloadditions of Bicyclopropylidene

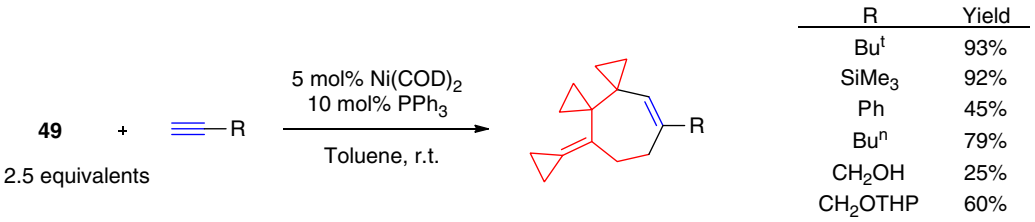


Although the major product of the palladium-catalyzed [3 + 2] cycloaddition of dimethylmethylenecyclopropane with diethyl fumarate displayed an intact alkylidene group, a similar cycloaddition with bicyclopropylidene **49** gave spirocyclic compound **50**

Scheme 14

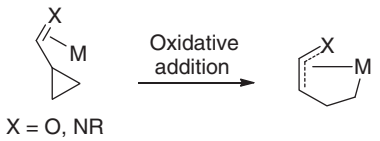


Scheme 15



Scheme 16

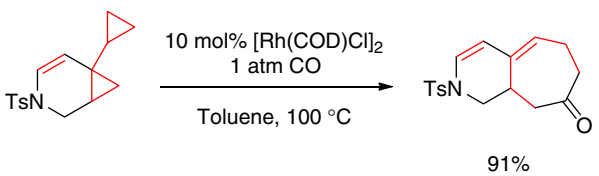
(Scheme 17).[35] The reaction catalyzed by a nickel complex led to the formation of **50–52**, illustrating the often observed lack of regioselectivity of purely intermolecular nickel-catalyzed reactions of methylenecylopropanes and their derivatives. As a rare exception, a nickel-catalyzed [3 + 2 + 2] between two molecules of bicyclopropylidene and terminal alkynes proceeded only by proximal bond cleavage (equation 7).[36]



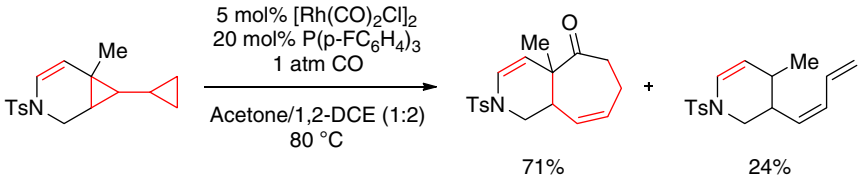
Scheme 17

(7)

5.35.3 Cycloadditions of Other Cyclopropane Derivatives



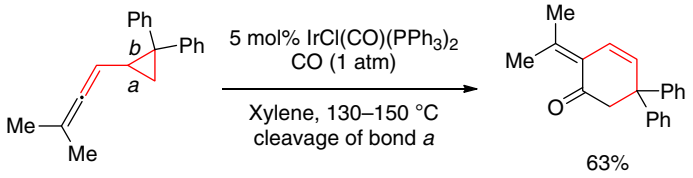
Besides methylene- and alkylidenecyclopropanes, vinylcyclopropanes represent the most versatile class of compounds used in transition-metal-catalyzed cycloaddition reactions and this chemistry has been reviewed extensively.[2c,37] A common principle underlies the reactions of vinyl, allenyl-, and propargylcyclopropanes, as well as reactions involving cyclopropylketones and imines. Namely, these compounds are prone to undergo oxidative ring opening on coordination of a metal complex to the carbon–carbon or carbon–heteroatom multiple bond of the substrate (Scheme 18). Hence, such compounds are useful as three- or five-atom building blocks in cycloaddition reactions.



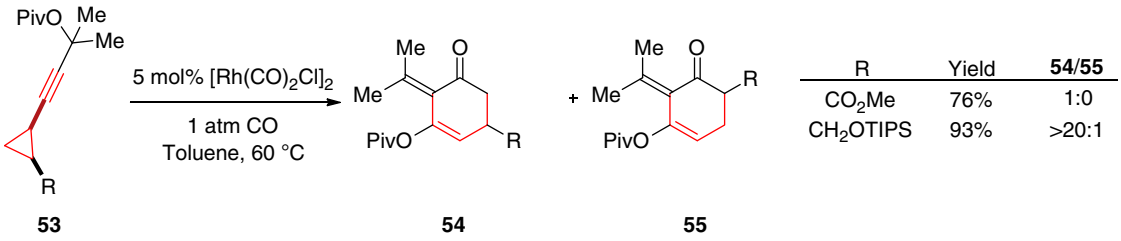
Scheme 18

5.35.3.1 Carbonylative [6 + 1] Cycloaddition of Biscyclopropanes

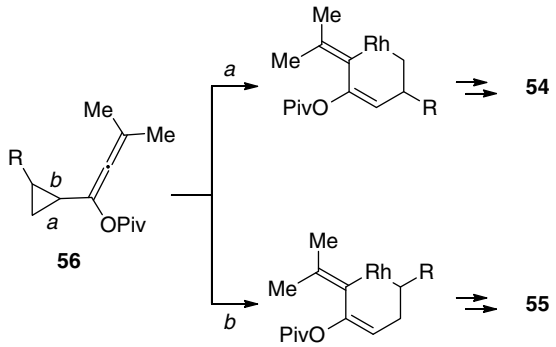
In line with the general principle depicted in Scheme 18, biscyclopropane derivatives with a vinyl substituent can undergo rhodium-catalyzed [6 + 1] (or [3 + 3 + 1]) carbonylative cycloadditions to give bicyclic compounds (equations 8 and 9).[38]



(8)



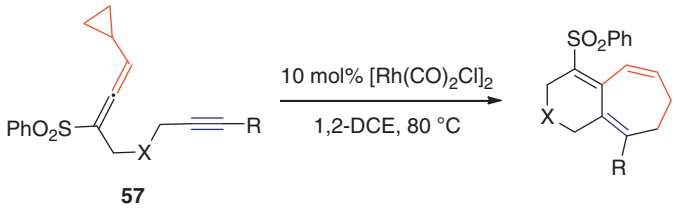
(9)



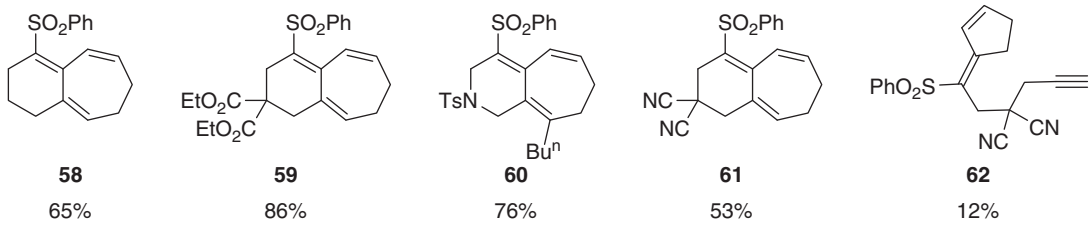
5.35.3.2 Carbonylative [5 + 1] Cycloadditions of Propargyl- and Allenylcyclopropanes

A neutral iridium catalyst was used to promote the regioselective [5 + 1] cycloaddition of allenylcyclopropanes with cleavage of the less sterically congested carbon–carbon bond of the cyclopropane ring (equation 10).[39] Similarly, it was shown that allenylcyclopropanes were plausible intermediates in the rhodium-catalyzed cycloaddition of propargylcyclopropanes **53** toward cyclohexenones **54** and **55** (Scheme 19).[40] Hence, minimization of steric congestion and cleavage of the less sterically hindered bond in intermediate **56** would again explain the regioselectivity observed for this reaction. However, aromatic or vinyl substituents showed a strong directing effect on the regioselectivity of the reaction, overcoming the effects of steric congestion.

(10)

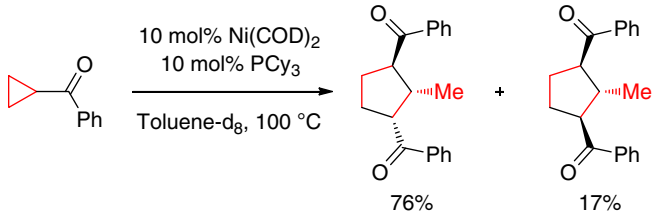


Scheme 19



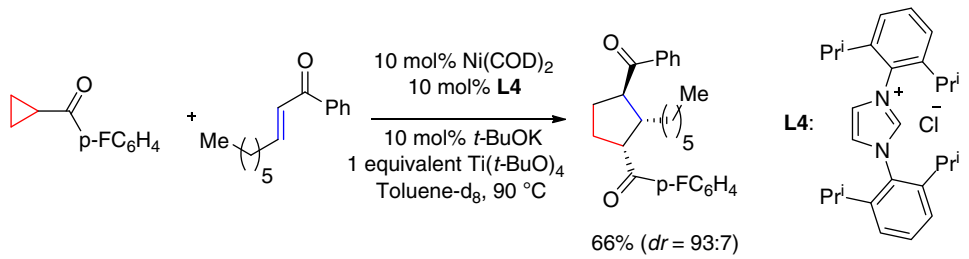
5.35.3.3 [5 + 2] Cycloaddition of Allenylcyclopropanes

Under similar reaction conditions but without carbon monoxide atmosphere, alkyne-tethered allenylcyclopropanes **57** can undergo intramolecular [5 + 2] cycloadditions and afford bicyclic compounds **58**–**60** in good yields, even at room temperature (Scheme 20).[41] The cycloisomerization of the allenylcyclopropane moiety can become a significant side reaction in some cases, as illustrated with the isolation of **62** alongside **61**. Nevertheless, the reaction is general and tethers extended by one methylene unit were tolerated, although they required the use of a modified catalyst. Moreover, it was demonstrated that the phenylsulfonyl substituent on the allene moiety is not essential.



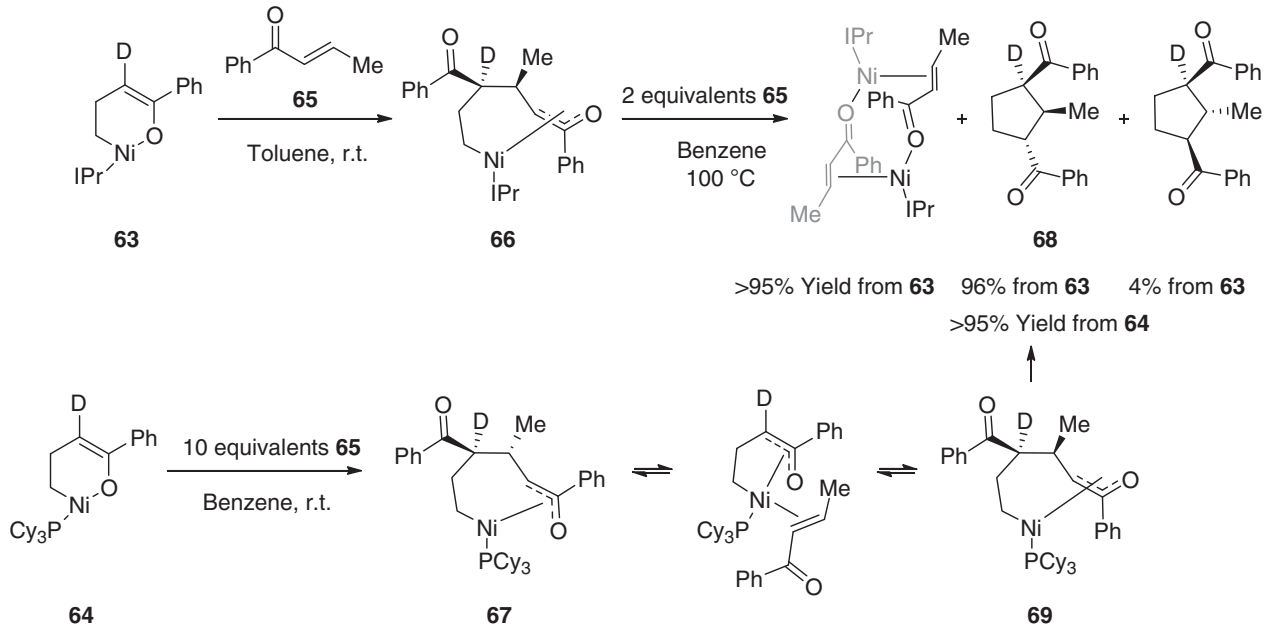
5.35.3.4 [3 + 2] and [5 + 2] Cycloaddition Reactions of Cyclopropyl Ketones and Imines

In the presence of nickel catalysts, cyclopropylketones underwent dimerization (equation 11)[42] or [3 + 2] cycloaddition with enones (equation 12),[43] which must be added slowly using a syringe pump.



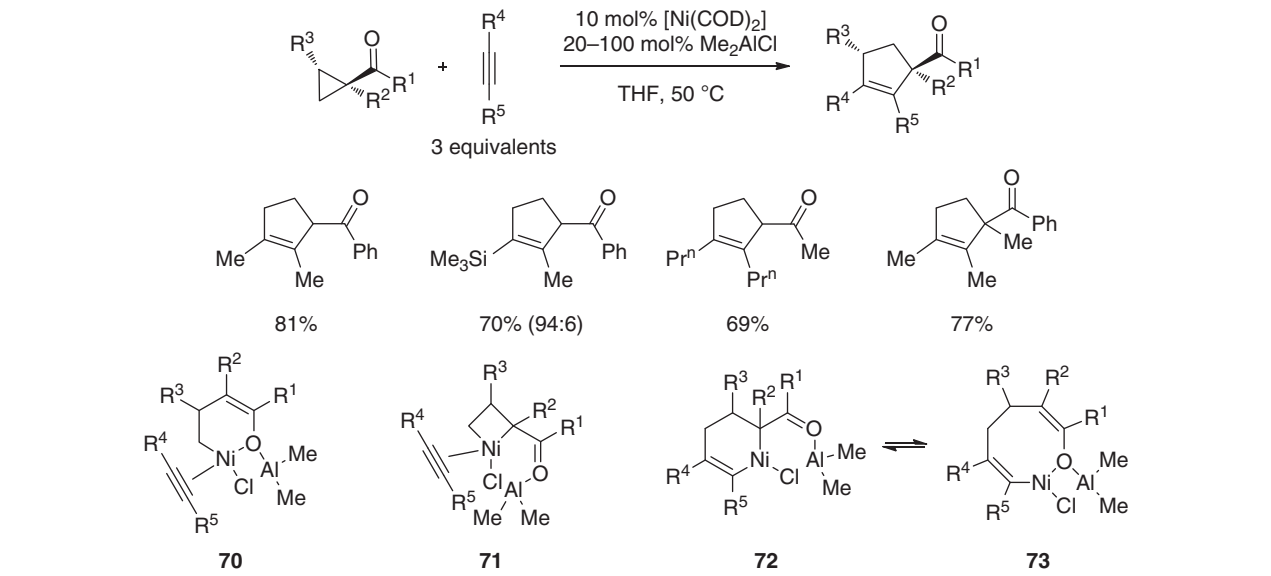
Scheme 20

(11)



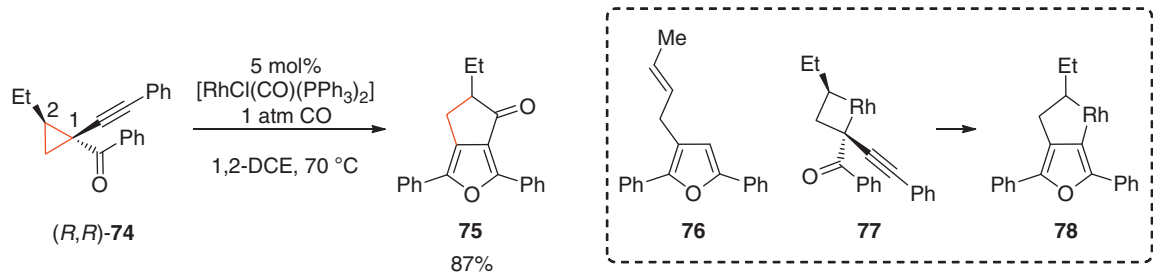
(12)

Careful mechanistic studies with isolated nickel complexes have recently revealed that six-membered hetero-nickelacycles, such as **63** and **64**, are key intermediates of the reactions (Scheme 21).[44] Interestingly, both intermediates reacted with enone **65** as nickel enolates, giving **66** and **67**, respectively. However, the nickel-*N*-heterocarbene complex **63** gave *syn*-**66** whereas the nickel–phosphine complex **64** gave *anti*-**67**. The reductive elimination of **63** afforded **68** as major diastereomer in the presence of an excess of enone **65** at elevated temperature, whereas the same diastereomer was obtained quantitatively at room temperature after isomerization of *anti*-**67** into *syn*-**69**.

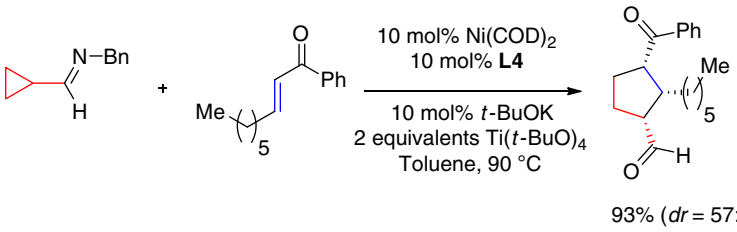


Addition of Me_2AlCl was crucial for the [3 + 2] cycloaddition of cyclopropylketones and various alkynes to occur in the presence of $[Ni(COD)_2]$ (Scheme 22).[45] In contrast to the cycloaddition reactions with enones,[42–44] mechanistic studies suggest that the six-membered heteronickelacycle **70** is unlikely as an intermediate.[45] The reaction is thought to proceed instead through intermediate **71** which would undergo alkyne migratory insertion to give **72**. The scope of the reaction indicates that the regioselectivity of this insertion is governed by steric factors. Moreover, the epimerizations observed with substituted cyclopropanes ($R^3 \neq H$) suggest the possibility of equilibrium between **72** and **73**.

The rhodium-catalyzed regio- and stereospecific carbonylation of cyclopropyl ketone (1*R*,2*R*)-**74** gave bicyclic furanone **75** in good yield (Scheme 23).[46] Interestingly, the (1*R*,2*S*)-diastereomer of **74** gave only the isomerization product **76** in 72% yield. Intermediates **77** and **78** have been proposed to explain the formation of **75**. However, the oxidative addition of the catalyst to the more sterically congested bond of the cyclopropane ring seems counterintuitive and in contradiction with the general trend observed with nickel-catalyzed [3 + 2] cycloadditions of cyclopropylketones and their dimerization.[42–45]

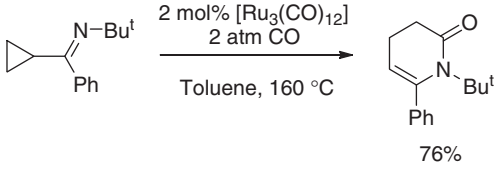


Cyclopropyl aldimines also underwent nickel-catalyzed [3 + 2] cycloaddition with enones (equation 13).[47] Yields were generally higher than those obtained from cyclopropylketones.[43] It was shown that the dimerization of cyclopropylaldimines does not occur in the absence of enone, in stark contrast to the dimerization of cyclopropylketones.[42] The diastereoselectivity of the reaction was altered by epimerization during imine hydrolysis, although it was demonstrated that the same diastereomer is kinetically formed in the reactions of cyclopropylketones and imines.

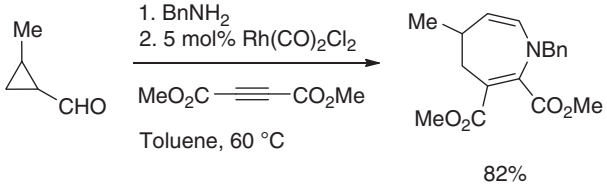


Scheme 21

Scheme 22

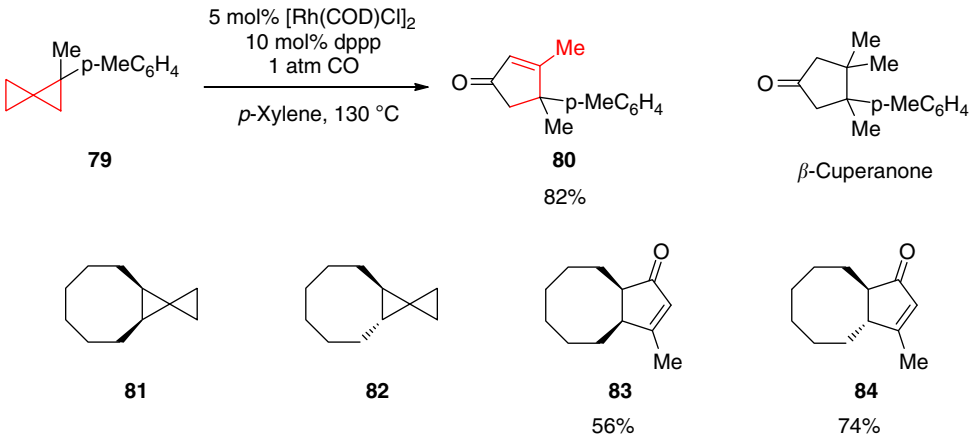


Scheme 23



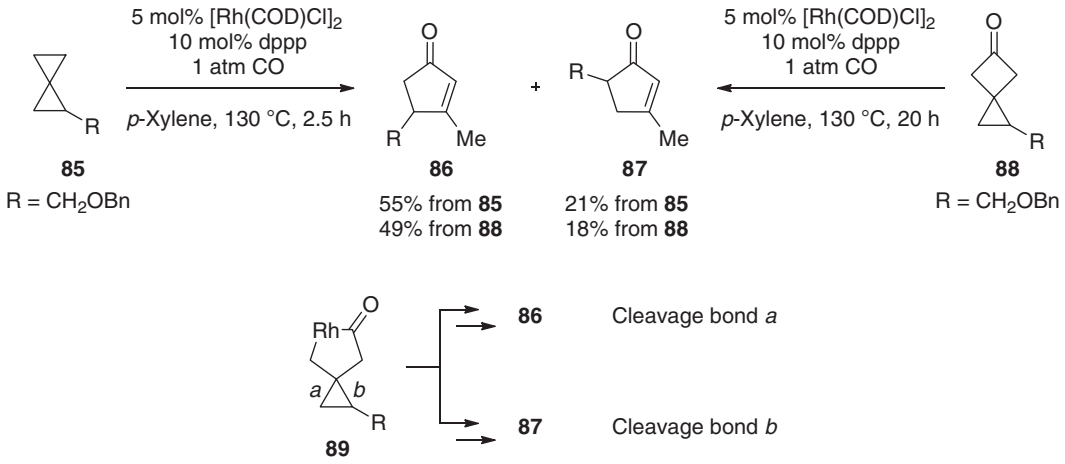
(13)

Cyclopropylimines are also good substrates for ruthenium-catalyzed [5 + 1] carbonylative cycloadditions (equation 14)[48] and rhodium-catalyzed [5 + 2] cycloadditions[49] with dimethyl acetylenedicarboxylate (DMAD) (equation 15).



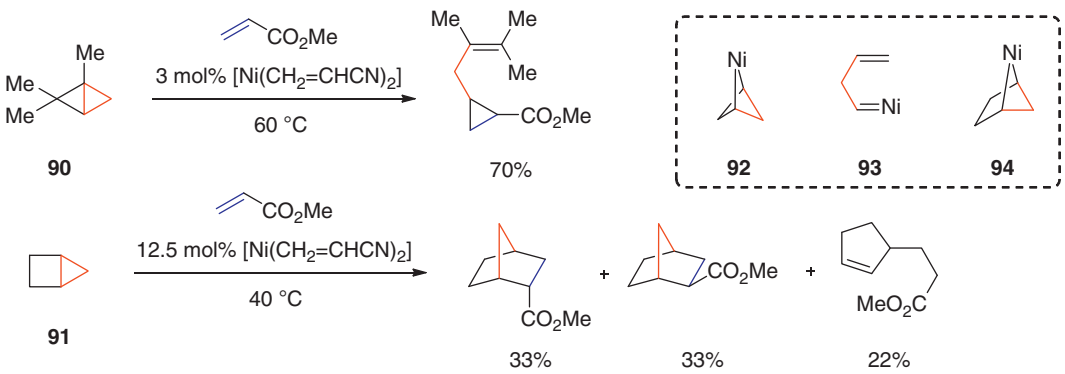
(14)

(15)



5.35.3.5 Cycloadditions of Highly Strained Cyclopropanes

Because of their great strain energy, spiropentanes can undergo oxidative addition without intervention of a carbon–carbon or carbon–heteroatom multiple bond. For example, the rhodium-catalyzed carbonylation of spiropentane **79** led to the regioselective formation of cyclopentenone **80**, a precursor of racemic *β*-cuparenone (Scheme 24).[50] Diastereomers **81** and **82** gave **83** and **84**, respectively, which indicates that the reaction is stereospecific. Monosubstituted spiropentane **85** gave a mixture of regioisomers **86** and **87** in almost the same ratio as the ratio obtained in the isomerization of spirocyclopropanecyclobutanone **88** (Scheme 25).[51] This result is in support of a mechanistic rationale featuring intermediate **89** which would preferentially undergo cleavage of the less sterically hindered carbon–carbon bond.

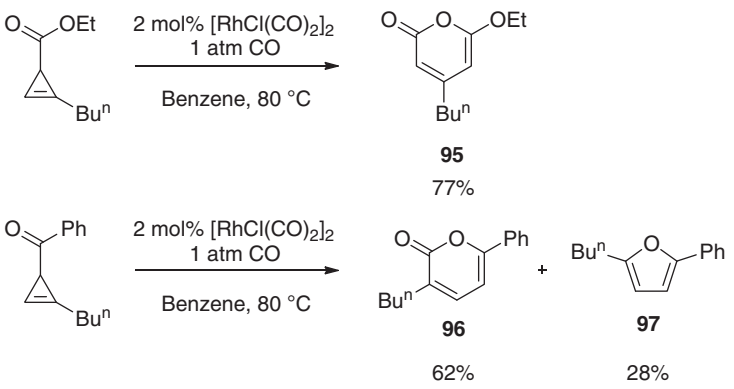


Scheme 24

Similarly, the high-strain energy of bicyclo[1.1.0]butane **90** and bicyclo[2.1.0]pentane **91** facilitates their use in metal-catalyzed cycloadditions (Scheme 26).[52] Experiments with deuterium-labeled substrates indicated the likeliness of oxidative addition intermediates **92** and **94**. The allyl-cyclopropanes obtained from **90** probably resulted from a rearrangement of **92** into a nickel-carbene **93**. It was shown with dimethyl fumarate and maleate that the reactions are stereospecific.

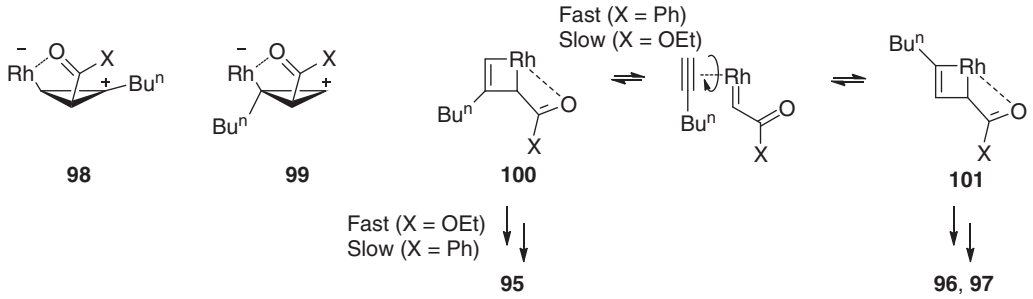
Scheme 25

Scheme 26



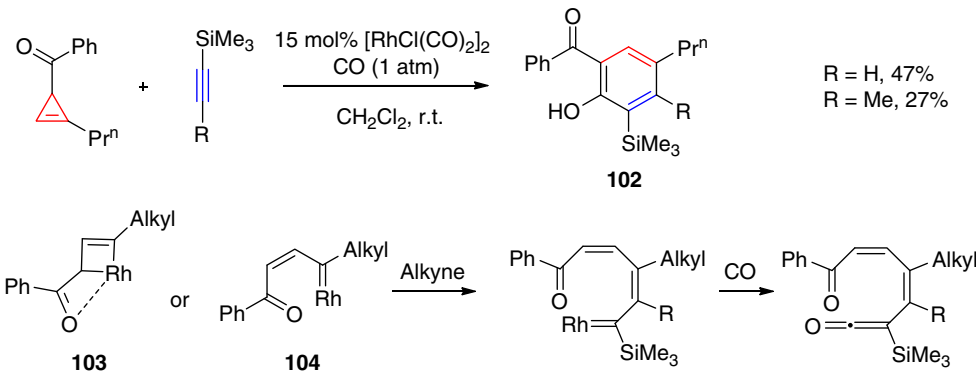
5.35.4 Cycloadditions of Cyclopropenes

Cyclopropenes are another class of small ring compounds prone to react with transition-metal complexes. The carbon–carbon double bond embedded into the three-membered ring can act as an anchor in a formal oxidative addition which likely proceeds through disrotatory ring opening to give a vinyl-carbene or metalacyclobutene. As exemplified in this section, this mode of reactivity seems prevalent in rhodium(I)-catalyzed reactions. Conversely, palladium(0)-catalysts tend to promote cycloaddition in which the integrity of the small ring is maintained. Nickel(0)-catalysts can promote both reactivities.



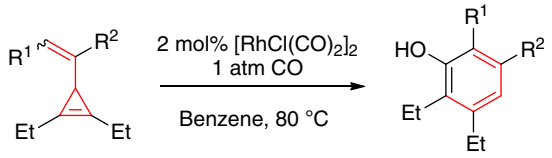
5.35.4.1 Cycloadditions Involving Ring Opening

Cyclopropene esters and ketones underwent rhodium-catalyzed [5+1] cycloadditions, yielding pyranones with opposite regioselectivity (Scheme 27).[53] The formation of compounds **95** on the one hand, and **96** and **97** on the other hand, could be ascribed to steric and electronic effects, respectively. Hence, it was proposed that charged intermediate **98** is more stabilized than **99** and would undergo a disrotatory ring opening to give **100** (Scheme 28).[53] The relative rates of carbon monoxide insertion and equilibration of **99** toward **101** would then control the regioselectivity of the reactions. In the case of cyclopropene-esters, this equilibration would be slower than carbon monoxide insertion, leading to the formation of **95** as the major product. In the case of cyclopropene-ketones, equilibration would be faster than carbon monoxide insertion and minimization of steric hindrance would favor **97**, explaining the predominant formation of **96** and **97**.[53] In the case of similar [5+1] cycloadditions catalyzed by molybdenum–carbonyl complexes, the regioselectivity of the reaction was dominated by steric effects.[54]



Comparing the reactions leading to pyranone **96** (Scheme 27) and phenols **102** (Scheme 29),[55] an identical mechanism could be proposed to explain the observed regioselectivity. Hence, it is plausible that intermediate **103** or its carbene equivalent **104** are formed in both cases. Without added alkyne, carbon monoxide insertion would lead to pyranones. In the presence of an alkyne, its insertion would precede the reaction with carbon monoxide, to give a nonmetallic intermediate which would eventually afford phenols after electrocyclization in a reaction appearing as a formal rhodium-catalyzed [3+2+1] cycloaddition. Minimization of

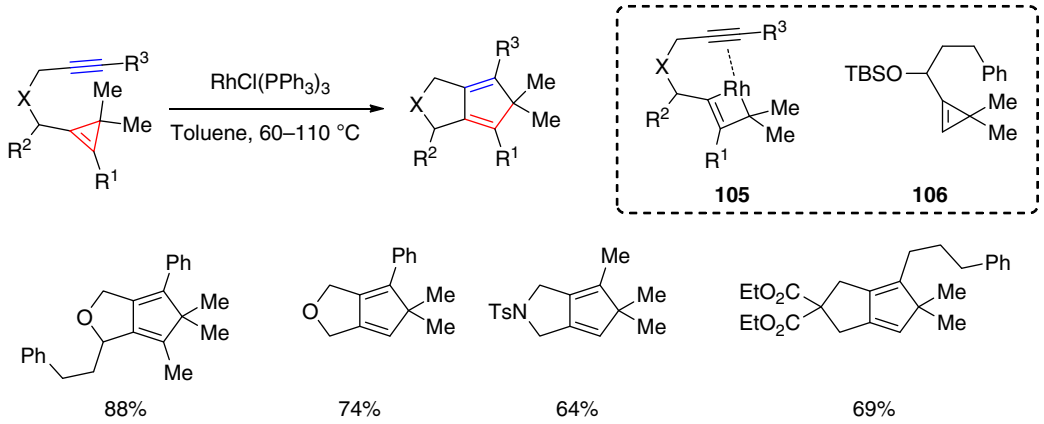
Scheme 27



Scheme 28

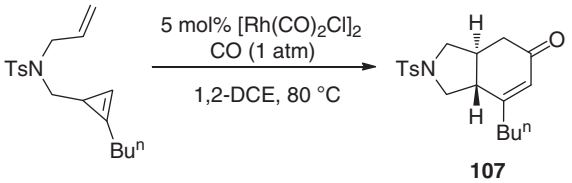
Scheme 29

steric congestion would control the regioselectivity of the alkyne insertion. Rhodium-carbene intermediates such as **104** would also nicely explain the formation of furans (e.g., **97**) in those reactions. Phenols could also be obtained through intermolecular [5 + 1] carbonylative cycloaddition of vinylcyclopropenes (equation 16).[53]



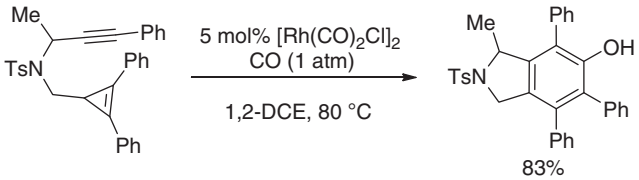
R^1	R^2	Yield
H	Ph	31%
Ph	Ph	51%
Pr^n	Ph	82%
H	Pr^i	46%

(16)



The tether is obviously an important bias in determining the regioselectivity of the rhodium-catalyzed intramolecular [3 + 2] cycloadditions depicted in Scheme 30.[56] Complex **105** is a likely intermediate, whereas compound **106**, lacking the alkyne moiety, did not undergo any reaction in the presence of one equivalent of rhodium catalyst, even at 80 °C. This observation suggests that

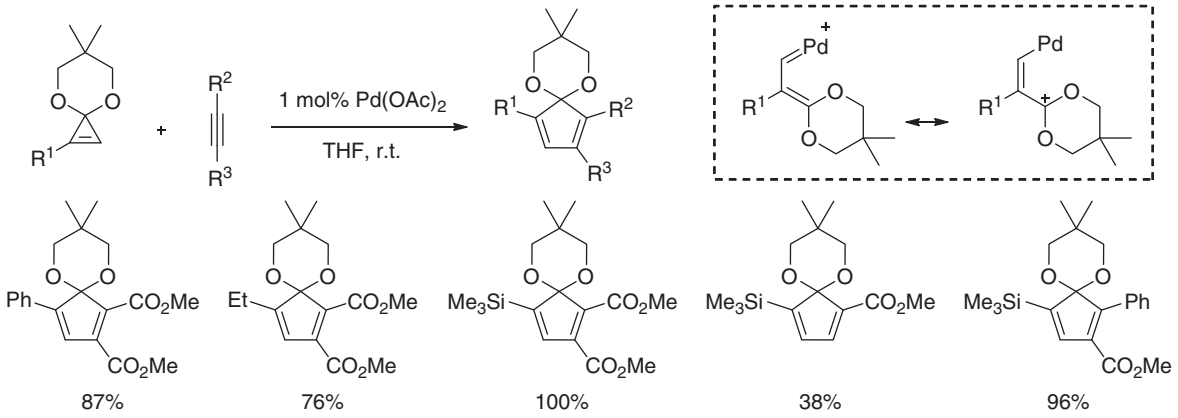
105 is formed as a result of alkyne precoordination, and is reminiscent of similar observations in [3 + 2][17] and [3 + 2 + 2][34] cycloadditions of alkylidenecyclopropanes.



Scheme 30

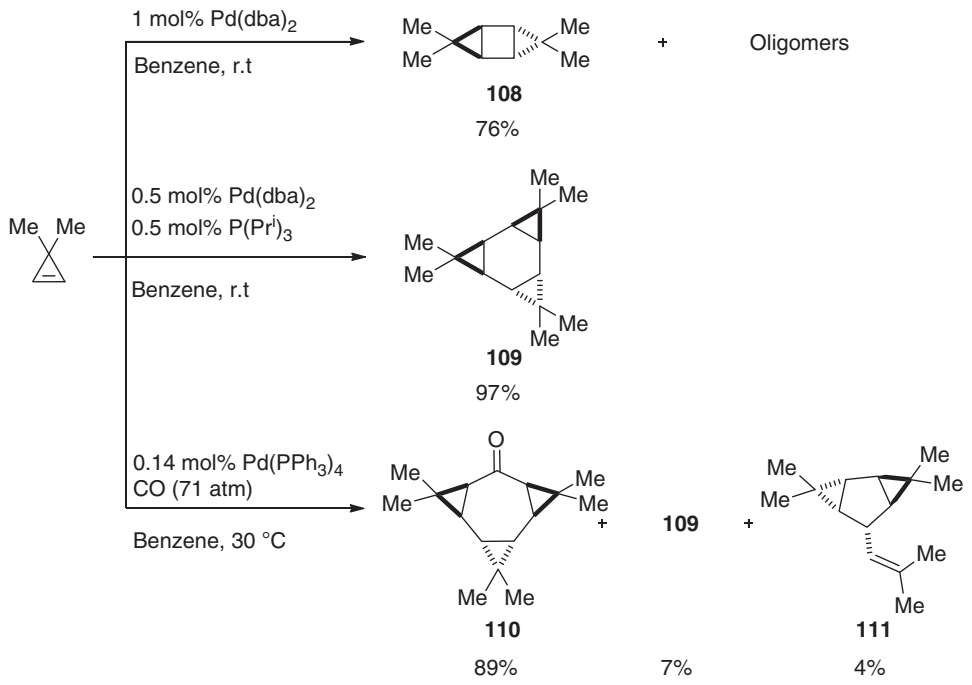
The rhodium-catalyzed carbonylative [3 + 2 + 1] cycloaddition leading to the formation of bicyclic cyclohexenone **107** delivered compounds with a *trans*-ring junction only (equation 17).[57] Importantly, the selective formation of compound **107** suggests that the proposed formal direct oxidative addition into the less sterically congested carbon–carbon bond of unsymmetrically substituted cyclopropenes probably involves intermediates similar to those depicted in Schemes 28 and 29. Moreover, the smooth conversion of substrates embedding a tethered alkyne led to the formation of phenols (equation 18). Conversely, replacing the tethered alkenes with a terminal allene gave the corresponding cycloaddition product in only modest yield.

(17)



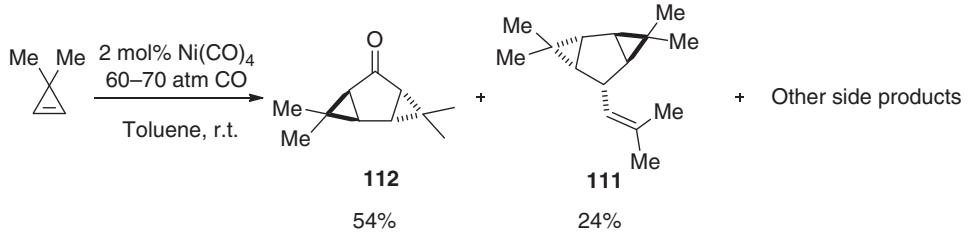
(18)

Besides those rhodium(I)-catalyzed reactions, it is noteworthy that palladium(II)-salts were reported to catalyze the regioselective [3 + 2] cycloaddition of cyclopropene acetals with electron-poor alkynes (Scheme 31).[58] The reaction also took place at elevated temperature in the absence of catalyst, but with opposite regioselectivity. Side products of the reaction suggest that vinyl-palladium intermediates are involved in the catalyzed version of this transformation. Such intermediates could result from the generation of a metal carbene and concomitant ring opening of the cyclopropene.



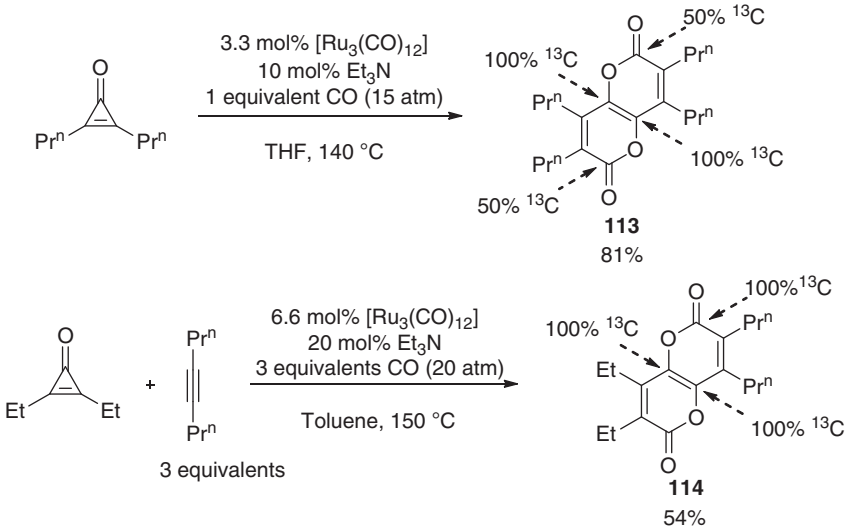
5.35.4.2 Cycloadditions not Involving Ring Opening

Palladium(0)-catalysts are particularly effective at triggering cycloaddition reactions of 3,3-dimethylcyclopropene at ambient temperature with preservation of the three-membered ring. For example, the selective formation of **108** and **109** has been reported (Scheme 32).[59] Under high carbon monoxide pressure, carbonylation led to polycyclic cycloheptanone **110**.[60]



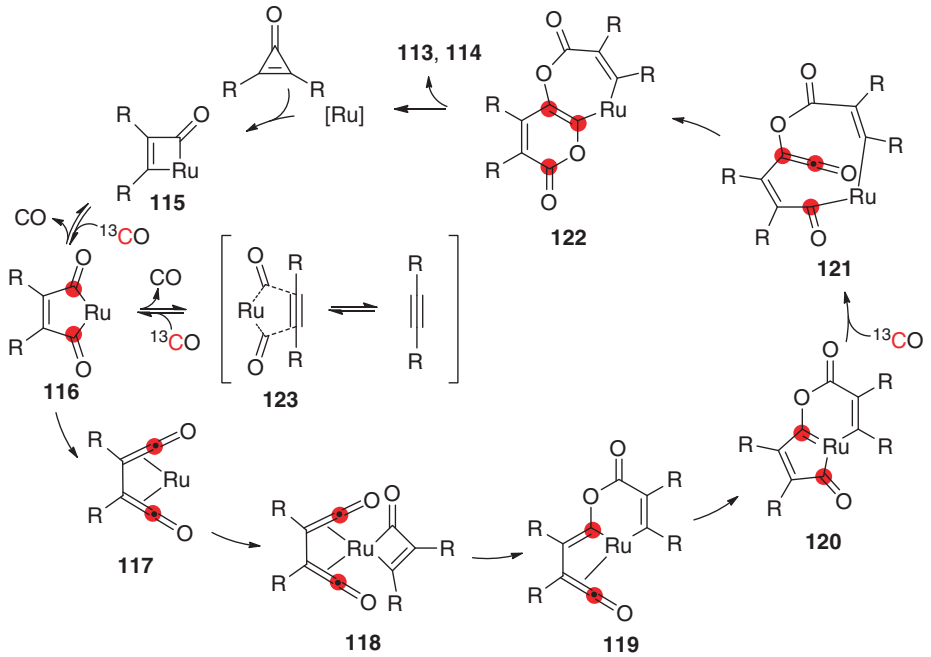
Besides palladium(0)-complexes, carbonyl-metals such as $Mo(CO)_6$ and $W(CO)_6$ are known to catalyze the dimerization of 3,3-dimethylpropene into **108**.[61] As mentioned in the introduction of this section, in the presence of cyclopropenes, nickel(0)-catalysts display a reactivity which is intermediate between palladium(0)- and rhodium(I)-catalysts. For example, the [2 + 2 + 1] trimerization product **111** was obtained as trace in addition to **110** in the presence of a palladium(0)-catalyst (Scheme 32)[60] whereas it became the main side product besides **112** in a similar reaction catalyzed by $Ni(CO)_4$ (equation 19).[62] Confirming this trend, the clean formation of vinyl-carbenes in the $[Ni(COD)_2]$-catalyzed [2 + 1] cycloadditions of cyclopropenes with electron-poor olefins led to the formation of vinyl-cyclopropanes in high yields.[63]

Scheme 31



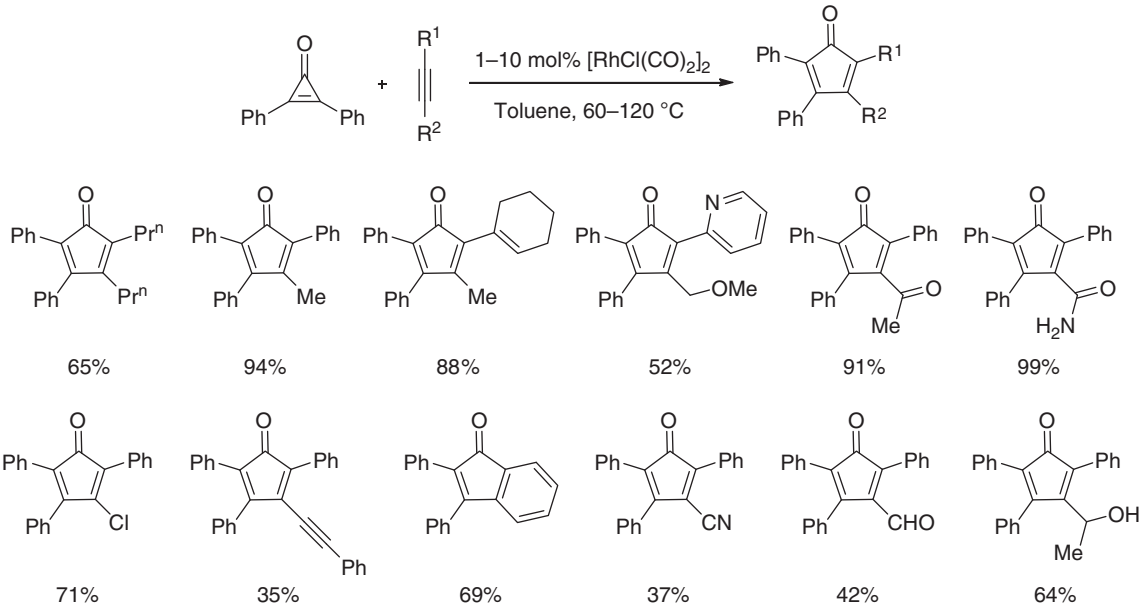
Scheme 32

(19)



5.35.5 Cycloadditions of Cyclopropenones

Transition-metal-catalyzed cycloadditions of cyclopropenones are rare. For example, it has been shown that $Ru_3(CO)_{12}$ catalyzes the carbonylative dimerization of cyclopropenones as well as their intermolecular cycloaddition with alkynes into pyranopyrandiones **113** and **114**, respectively (Scheme 33).[64]

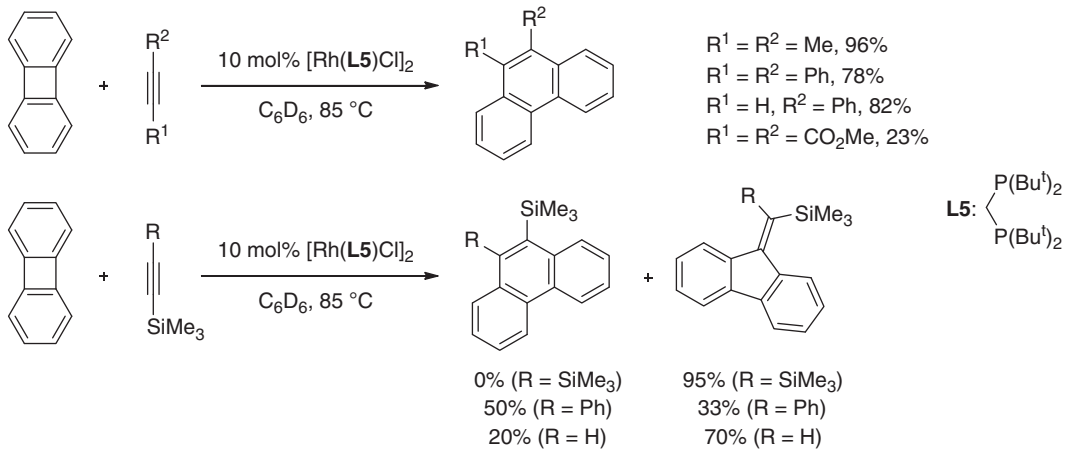


Scheme 33

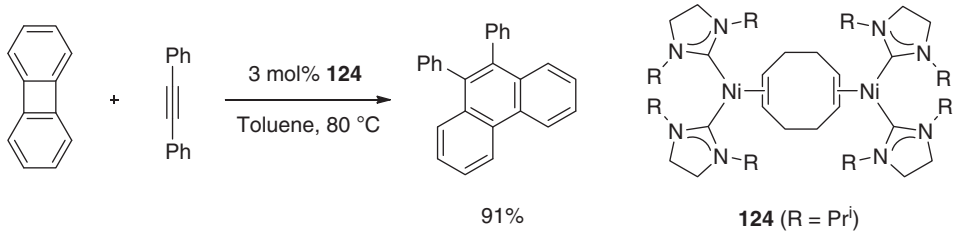
The results of experiments with isotope-labeled carbon monoxide provided an insight into a plausible mechanism (Scheme 34). After oxidative addition giving **115**, carbon monoxide insertion would lead to maleoylruthenium **116**. In the absence of alkyne, this intermediate would rearrange into the bisketene ruthenium(0)-complex **117**. Oxidative addition would then afford **118** and insertion of one of the carbon–oxygen double bond give **119** or its tautomer **120**. Isotope incorporation is in agreement with the trapping of carbene **120** by carbon monoxide. Finally, insertion of the carbon–oxygen double bond of ketene **121** into the acyl–ruthenium bond would lead to **122**, poised for the reductive elimination which would close this catalytic cycle. Importantly, in the presence of an excess of alkyne, **116** could be formed by carbonylative cyclization through intermediate **123**.

Scheme 34

Another important example is the rhodium-catalyzed [3 + 2] cycloaddition of cyclopropenones with alkynes (Scheme 35).[65] The functional group tolerance and the regioselectivity were remarkable. Among the limitations of the reaction, it is noteworthy that diphenyl acetylene reacted only slowly whereas reactions with terminal alkynes and DMAD led to decarbonylation of the cyclopropenones and trimerization of the alkynes instead of the expected [3 + 2] cycloaddition.



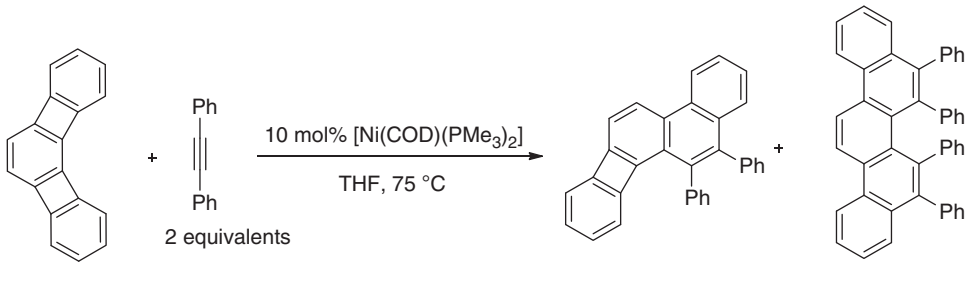
Scheme 35



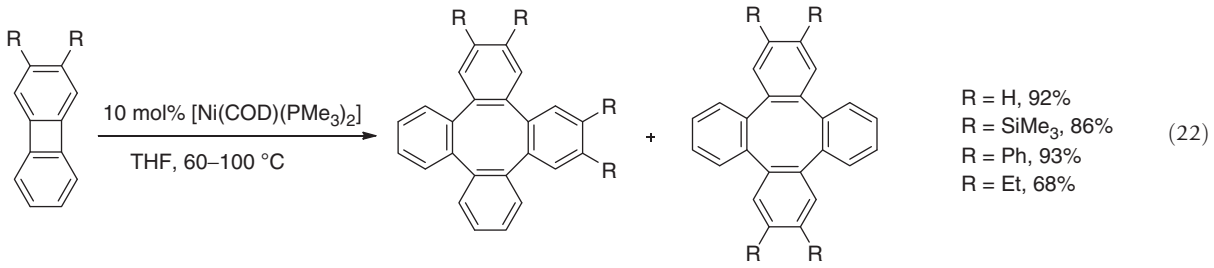
5.35.6 Cycloadditions of Cyclobutane Derivatives

5.35.6.1 Cycloadditions of Biphenylenes

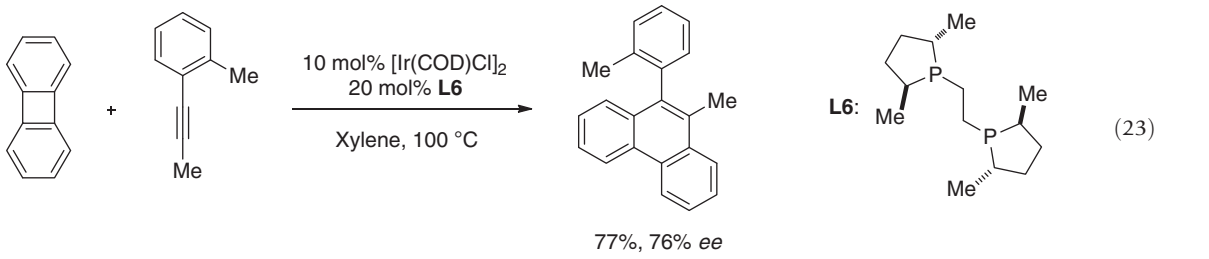
The strained central four-membered ring of biphenylene is prone to undergo oxidative addition to transition-metal complexes, which should make this class of compounds well suited for metal-catalyzed cycloaddition reactions with a variety of unsaturated reactants, following the general design discussed in the introduction. However, efficient catalytic reactions are mostly limited to [4 + 2] cycloadditions with alkynes. After initial studies,[66] phenanthrenes could be obtained in good yields in the presence of a rhodium catalyst (Scheme 36),[67] although cyclotrimerization of the alkynes was also observed, especially with electron-poor DMAD. With trimethylsilyl-substituted alkynes, the formation of fluorenes is significant and can even prevail over the formation of phenanthrenes. Carbene–nickel complex **124** has also been reported to catalyze the formation of phenanthrenes (equation 20).[68]



Scheme 36



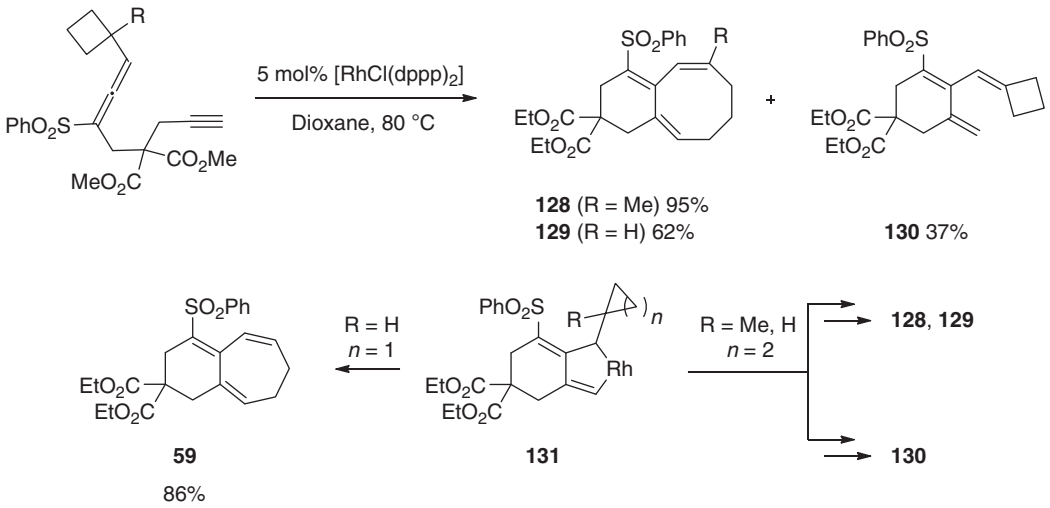
(20)



Phenacene **127** could be obtained in high yield in addition to compound **126** when bisphenylacetylene was added slowly to a solution of phenylene **125** and a phosphine–nickel catalyst (equation 21),[69] whereas the same phosphine–nickel complex catalyzed the dimerization of biphenylenes in the absence of alkyne (equation 22).[70] Although done with variable success, one of the most advanced applications of the [4 + 2] cycloaddition of biphenylene is the enantioselective formation of the axially chiral phenanthrene in the presence of chiral iridium catalyst (equation 23).[71]

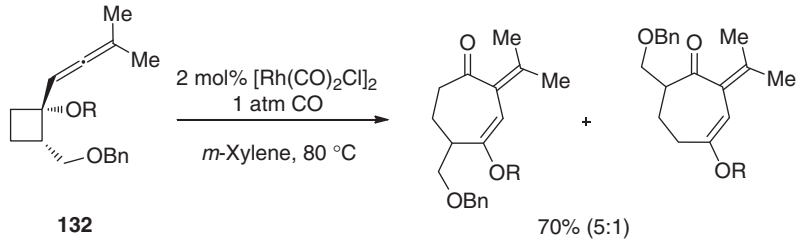
125 **126** 13% **127** 87% (21)

(22)



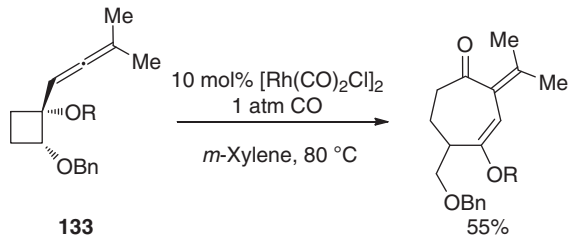
77%, 76% *ee* (23)

Known catalytic reactions in the presence of carbon monoxide or its isonitrile surrogates are still limited by low turnover numbers and frequencies.[66a,b]

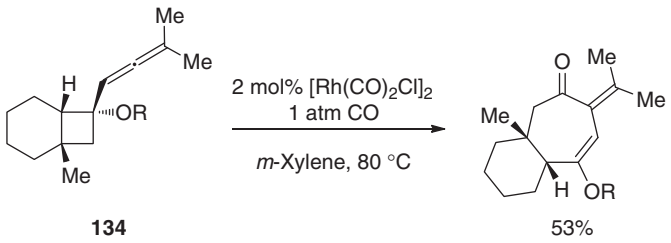


5.35.6.2 Cycloadditions of Allenylcyclobutanes

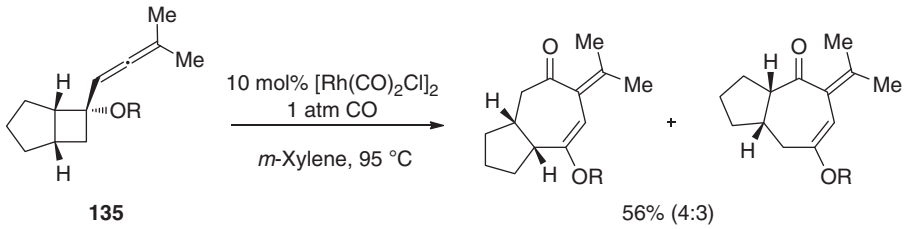
It was possible to extend the scope of the intramolecular [5 + 2] cycloaddition of alkyne-tethered allenylcyclopropanes (Scheme 20)[41] to the parent allenylcyclobutanes in a rhodium-catalyzed [6 + 2] cycloaddition (Scheme 37).[72] Whereas compounds **128** and **129** resulted from the intended ring enlargement of putative intermediate **131**, the β-hydride elimination product **130** was also obtained when R = H. This observation is noteworthy when compared with the neat formation of compound **59** from an allenylcyclopropane precursor (Scheme 20).[41] Hence, although cyclopropane and cyclobutane have similar strain energies, β-hydride elimination becomes competitive with the ring opening of **131**. Importantly, **59** was obtained by using $[Rh(CO)_2Cl]_2$ whereas this catalyst led to a larger proportion of β-hydride elimination product as compared with $[RhCl(dppp)_2]$ in the optimization study of the [6 + 2] cycloaddition of alkyne-tethered allenylcyclobutanes.[72] Hence, the rate of β-carbon elimination does not correlate with the relative strain energies of cyclopropane and cyclobutanes, but other factors must intervene.



Further mechanistic studies also appear necessary to explain the regioselectivity of the ring cleavage in the rhodium-catalyzed carbonylative [6 + 1] cycloaddition of allenylcyclobutanes (equations 24–27 ($R = (CH_2)_2OMe$)).[73] Considering the two different carbon–carbon bonds of the cyclobutane ring which can be broken in the cycloaddition, cleavage of the more electron-rich bond was preferred in precursors **132** and **133**. However, the influence of steric factors on the reactions of **134** and **135** is not clear.



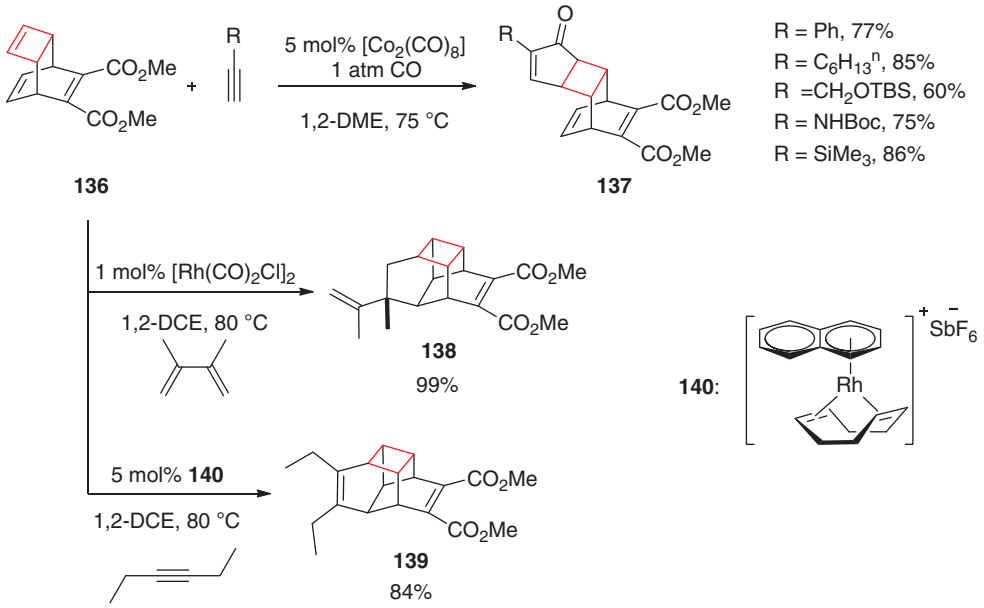
Scheme 37



(24)

(25)

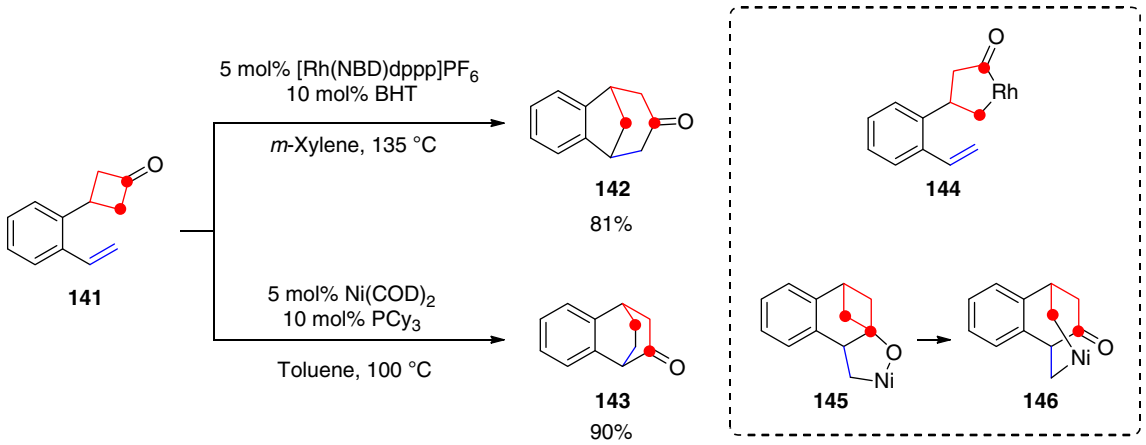
(26)



(27)

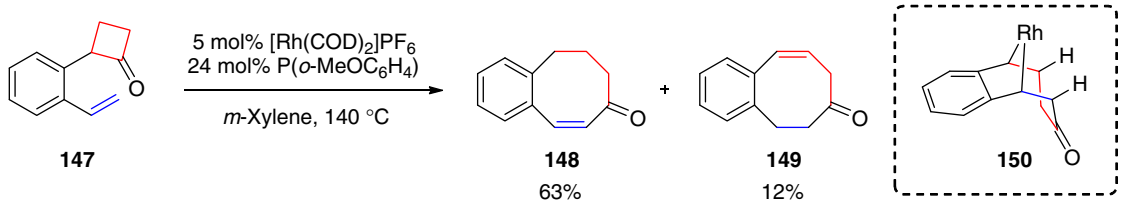
5.35.7 Cycloadditions of Cyclobutenes

Examples of transition-metal-catalyzed cycloaddition of cyclobutenes are extremely scarce and are limited to the study of the reactivity of the tricyclic compound **136** (Scheme 34).[74,75] Hence, a Pauson–Khand reaction afforded the fused cyclopentenones



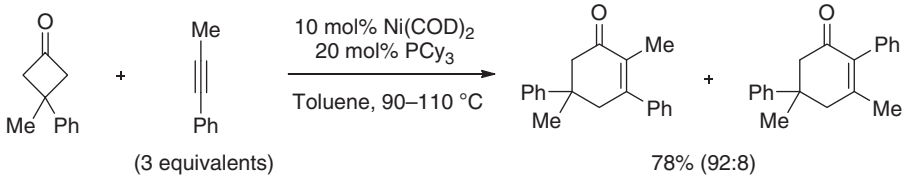
137,[74] whereas rhodium complexes catalyzed a [2 + 2 + 2] cycloaddition with 2,3-dimethylbutadiene or 3-hexyne to give **138** and **139**, respectively.[75] The four-membered ring remains intact in all cases Scheme 38.

Scheme 38



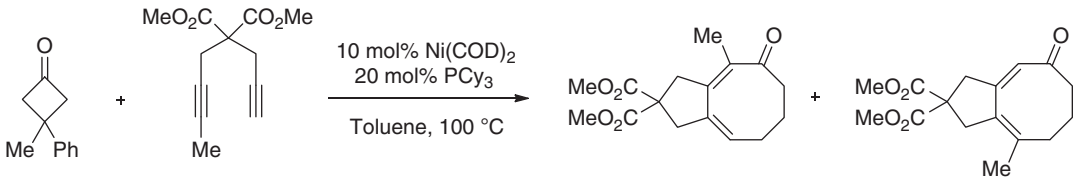
5.35.8 Cycloadditions of Cyclobutanones, Cyclobutenones, and Cyclobutenediones

The carbon–oxygen double bond of cyclobutanones makes them particularly apt to undergo transition-metal-catalyzed cycloadditions. For example, this functional group can serve as anchor in formal [4 + 2] cycloadditions of **141** leading to bridged polycyclic ketones **142** and **143** (Scheme 39). Isotope-labeling indicated that the rhodium-catalyzed formation of **142** likely involved intermediate **144**, resulting from the oxidative addition of the metal into the cyclobutanone ring.[76] In contrast, a nickel$^{(0)}$–phosphine complex catalyzed the formation of **143**, likely after transient formation of **145** and carbon–carbon bond cleavage toward **146**.[77] In a recent development of this nickel-catalyzed transformation, the enantioselective desymmetrization of cyclobutanones has been achieved under mild reaction conditions.[78]

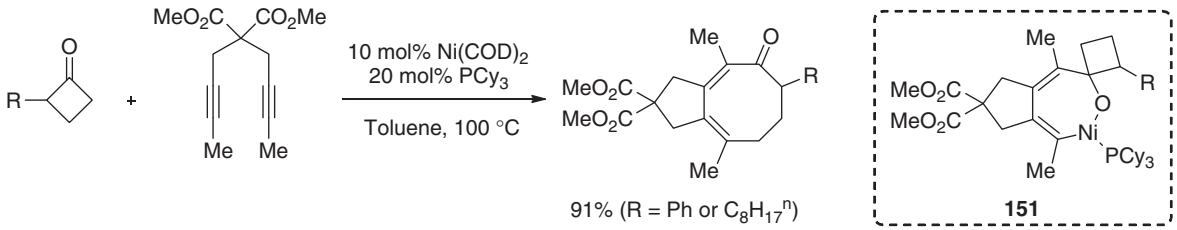


Scheme 39

The aromatic tether in **141** was required to observe its transformation into **143**. Modifying the regiochemistry of **141**, as borne out in **147**, also led to a failure of the nickel-catalyzed reaction. In contrast, this precursor was converted into **148** and **149** in the presence of a rhodium catalyst (Scheme 40).[79] Both cyclooctenones probably resulted from the formation of a common intermediate **150**.

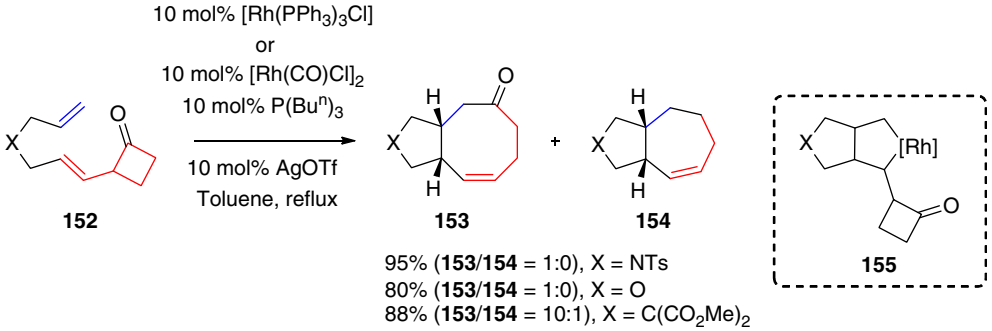


Scheme 40

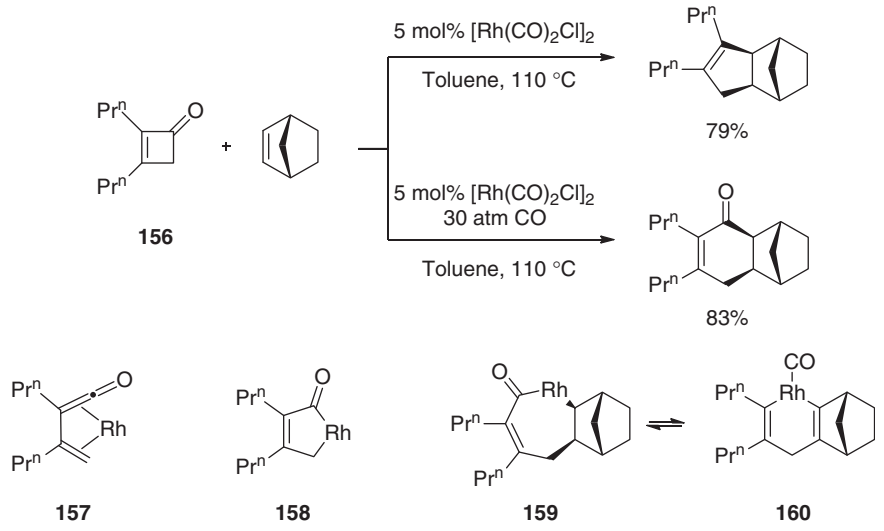


Nickel catalysts also enabled intermolecular [4 + 2] cycloadditions of cyclobutanones with alkynes (equation 28)[80] and their [4 + 2 + 2] cycloaddition with 1,6-diynes (equation 29 and Scheme 41).[81] The regioselectivity of the insertion of alkynes and diynes was likely dominated by steric factors, in line with nickel-catalyzed reductive coupling reactions.[82] Similarly, cleavage of the less sterically congested bond in the cyclobutane ring of **151** is a likely explanation for the observed transformation of α-substituted cyclobutanes.

(28)

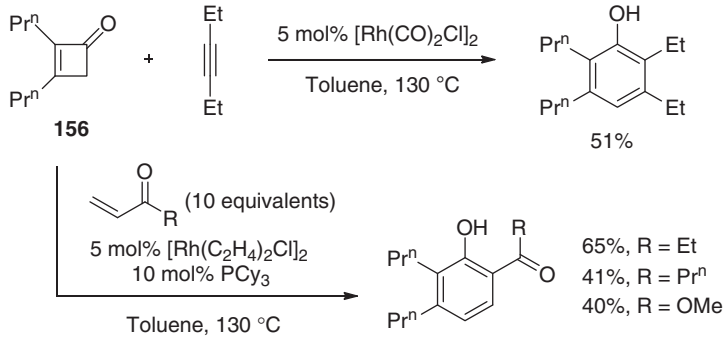


(29)



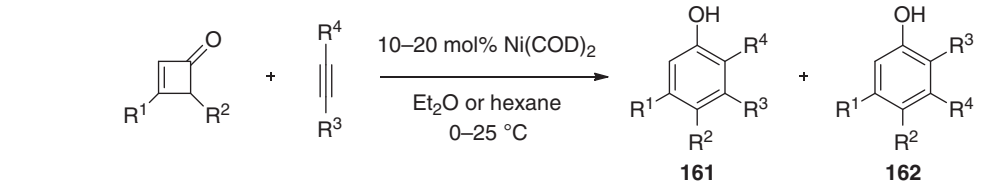
Scheme 41

The ability of cyclobutanones to undergo oxidative addition in the presence of a rhodium catalyst and the additional strain energy brought by the carbon–oxygen double bond, as compared with a nonfunctionalized cyclobutane, likely contribute to the intramolecular [6 + 2] cycloaddition of precursors **152** into bicyclic compounds **153** and **154** (Scheme 42).[83] Results from theoretical investigations indicated that **155** was a likely intermediate of the reactions.[84]

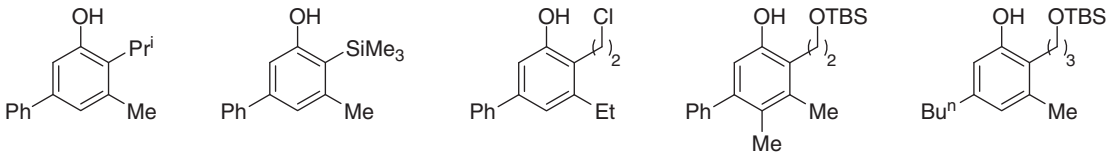


Scheme 42

Although decarbonylation of large metallacycles was only a side reaction in the cycloaddition of vinylcyclobutanones (Scheme 42), this tendency became much more pronounced in the cycloadditions of cyclobutenones with norbornene (Scheme 43).[85] Hence, after initial formation of either of the vinylketene complexes **157** or **158** from **156** and subsequent alkene insertion, intermediate **159** would be in rapid equilibrium with carbonyl-complex **160**. In the absence of carbon monoxide, reductive elimination would lead to the formation of cyclopentenes, whereas strong pressure of carbon monoxide would favor the formation of cyclohexenones. Investigations using isotope-labeled carbon monoxide came in support of these conclusions. Rhodium-catalyzed [4 + 2] cycloadditions of cyclobutenones with an alkyne or electron-poor alkenes have also been described in moderate yields, but decarbonylation was not reported (Scheme 44).[86] The formation of phenols in the reaction of electron-poor alkenes could possibly be ascribed to rhodium-catalyzed dehydrogenation, the excess of alkene being used to regenerate the active rhodium(I) catalyst.

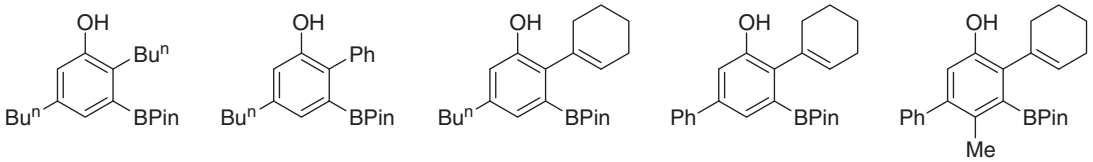


Scheme 43



Scheme 44

The formation of a phenol in the rhodium-catalyzed cycloaddition of cyclobutenone **156** and 3-hexyne is noteworthy, considering that η^2-vinylketene complexes similar to **158** were isolated after stoichiometric reaction with cyclobutenones but did not deliver phenols when heated in the presence of alkynes.[87] In contrast, regioisomeric phenols **161** and **162** were obtained in nickel-catalyzed cycloadditions with cyclobutenones (Scheme 45).[88,89] The regioselectivity of the reaction was not strongly influenced by the steric differentiation of the alkyne substituents. However, polar groups at the homopropargylic position appeared capable of exerting a modest directing effect, presumably by coordination to η^2-vinylketene nickel intermediate **163**.[88] Much better regioselectivity was obtained with alkyl-substituted alkynylboronates,[89] and one could perhaps again invoke lone pair coordination, as depicted in intermediate **164**, to explain the experimental results. Similarly, π-coordination, as depicted in **165**, could explain the reversal of regioselectivity observed with phenyl and cyclohexenyl-substituted alkynylboronates. However, these intermediates are purely speculative and more experiments are required in order to establish the mechanism of these reactions.



In the absence of alkynes, cyclobutenones afforded a mixture of 2-pyranones **166** and **167** when treated with $[RuCl_2(CO)_3]_2$ (equation 30), whereas only **167** was obtained in excellent yield when treated with $[Rh(CO)_2Cl]_2$.[85] Interestingly, in the presence of an alkynylboronate, the same catalyst promoted the formation of an equimolar mixture of **166** and **167**.[89]

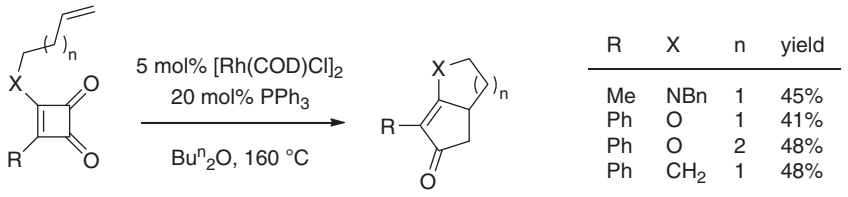
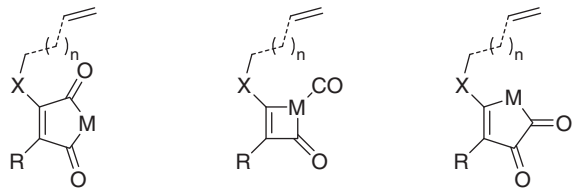
(30)

Oxidative addition of cyclobutenediones to transition-metal complexes is also well established. This enabled the development of cycloadditions with alkenes (equations 31 and 32).[90] It is noteworthy that not only a strained alkene like norbornene, but also ethylene participated to this reaction. The pressure of carbon monoxide was optimized in order to control the monodecarbonylation of the substrates.

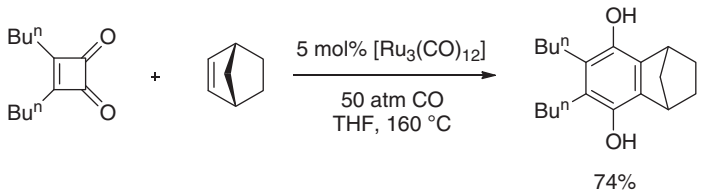


75%, R = OPr^i
60%, R = OBu^n
47%, R = OEt

(31)



(32)



Interestingly, $RhCl(PPh_3)_3$ could not effect these reactions, whereas a related rhodium–triphenylphosphine complex prepared *in situ* could catalyze the intramolecular variant of those decarbonylative cycloadditions without requiring the addition of carbon monoxide (equation 33).[91] The mechanism of the reactions depicted in equations 31–33 remains to be established. $RhCl(PPh_3)_3$ is known to react with cyclobutenediones to give maleoylmetal complexes,[92] hence **168** is a plausible intermediate in the intramolecular reactions (Scheme 46), whereas further decarbonylation of **169** could possibly be prevented by coordination of the tethered olefin. The ruthenium-catalyzed intermolecular reaction of 3,4-dibutylcyclobutenedione under high pressure of carbon monoxide gave a hydroquinone, and proceeded presumably via a maleoylmetal intermediate. In contrast, the intermolecular reactions of alkoxy-substituted cyclobutenediones, depicted in equations 31 and 32, are best explained by invoking metallacyclopentenedione **170**. Importantly, it has been shown in the case of stoichiometric reactions with $RhCl(PPh_3)_3$ that rhodacyclopentenediones are formed as kinetic products before undergoing a rearrangement to the more stable maleoylrhodium isomers.[93]

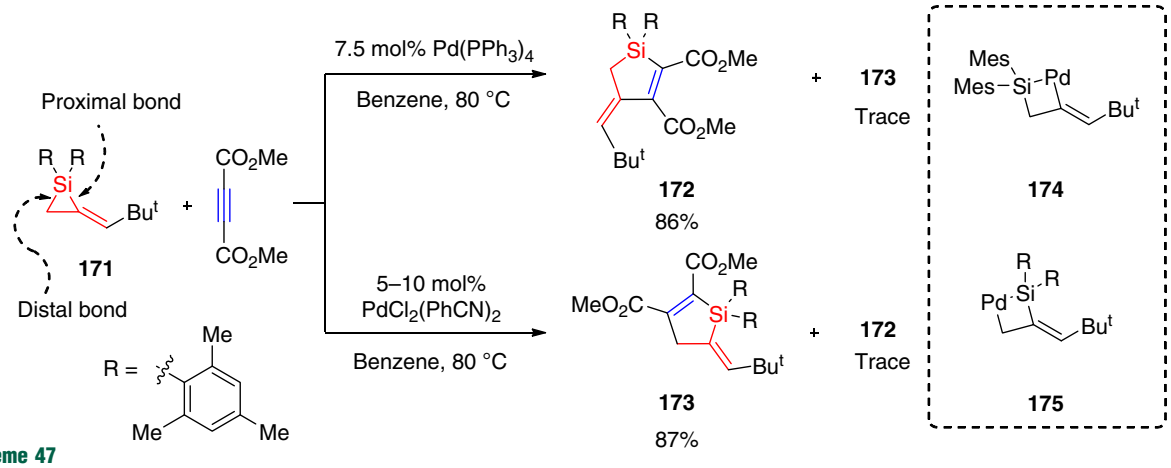
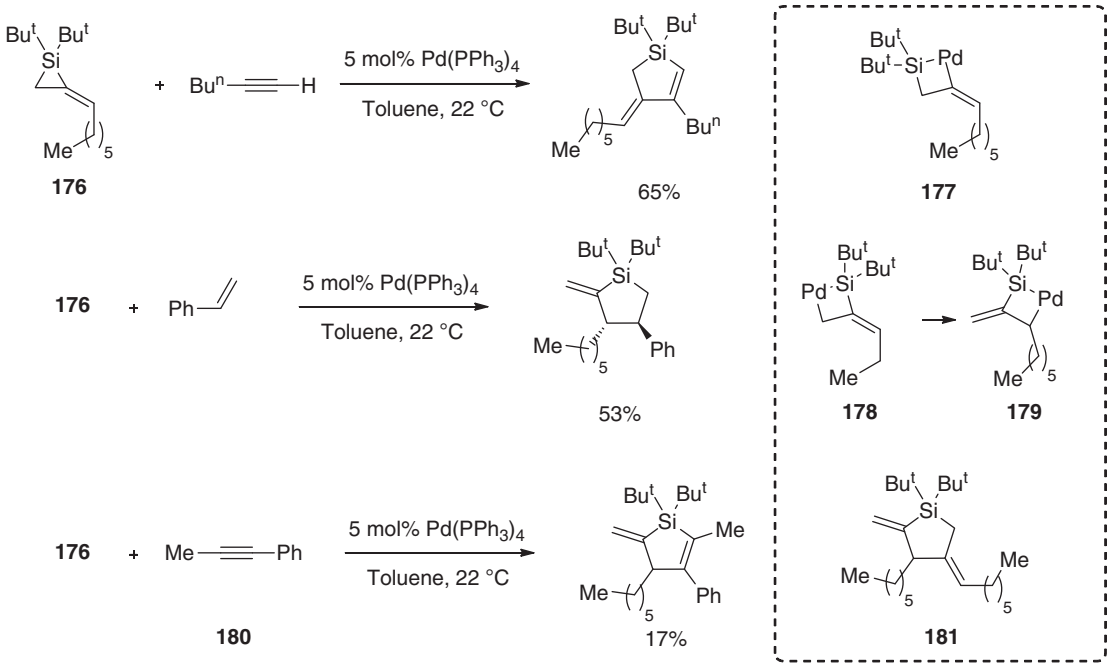
5.35.9 Cycloadditions of Small Heterocyclic Compounds



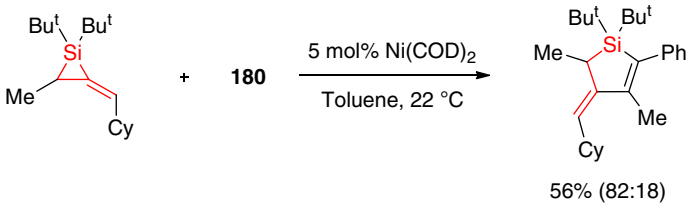
5.35.9.1 Cycloadditions Involving Cleavage of a Carbon–Heteroatom Bond

5.35.9.1.1 Cycloadditions of small ring compounds embedding a silicon atom

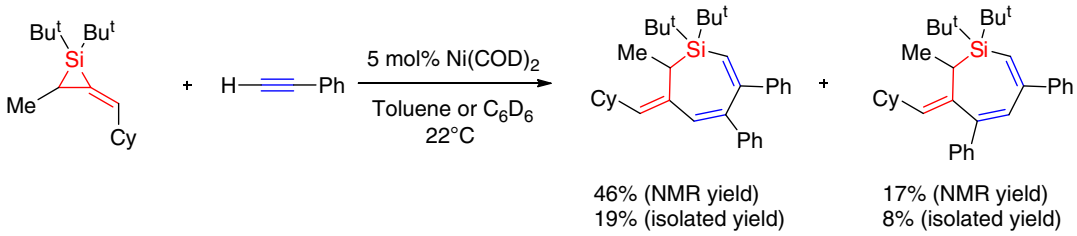


The transition-metal-catalyzed cycloadditions of alkylidenesilacyclopropanes are reminiscent of the reactivity of alkylidenecyclopropanes (Section 5.35.2), as cleavage of either the proximal or distal carbon–silicon bond can be observed.

For example, palladium-catalyzed [3 + 2] cycloaddition of **171** with DMAD afforded the five-membered ring compounds **172** and **173** (Scheme 47).[94] Intermediates **174** and **175** could be proposed to explain the formation of either intermediate. However, one could also argue that they are unlikely on the basis of strongly destabilizing steric interactions between the *tert*-butyl group and either the ligand sphere, in the case of **174**, or the substituents on the silicon atom, in the case of **175**. More recent examples confirmed that the cleavage of either the proximal or the distal carbon–silicon bond of **176** depended on the nature of the unsaturated partner (Scheme 48).[95] In contrast to the currently admitted mechanism of the palladium-catalyzed cycloadditions of alkylidenecyclopropanes (Section 5.35.2), it was proposed that reversible oxidative addition of the active palladium catalyst to the proximal carbon–silicon bond of **176**, giving **177**, would be preferred to the distal addition forming **178**. Rapid migratory

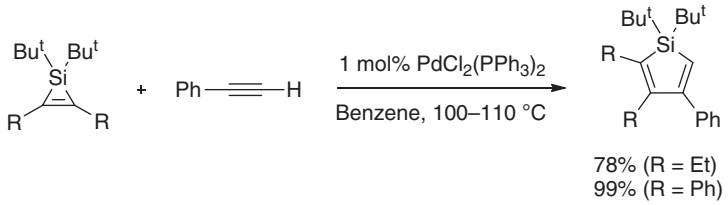


insertion of terminal alkynes or allenes would then lead to cycloaddition products of proximal bond cleavage after reductive elimination. The formation of **177** would be reversible, and internal alkynes or terminal alkenes would undergo slow migratory insertion with **179**, leading to cycloaddition products of distal bond cleavage after reductive elimination. Arguably, the formation of **177** is more favorable as compared with the formation of **174** or **175**. It is noteworthy that the reaction of the internal alkyne **180** led to the formation of **181** as the major product, suggesting the decomposition of intermediates **177**–**179** into a palladium-silirene. Using a nickel catalyst to promote the [3 + 2] cycloaddition of **180** was more effective, albeit isomerization of the carbon–carbon double bond of the substrate could not be avoided (equation 34).[95] The same catalyst also promoted the formation of a regioisomeric mixture of [3 + 2 + 2] cycloadditions products in low isolated yields (equation 35).[95]

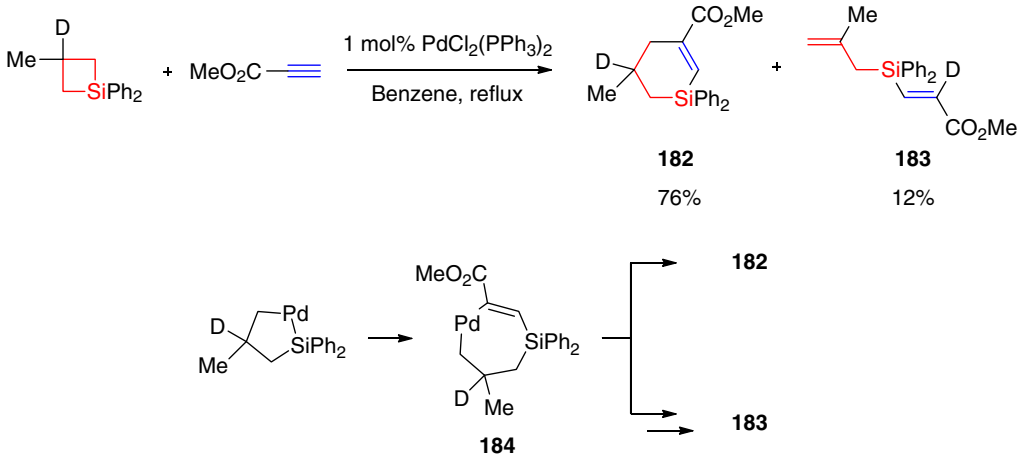


Scheme 47

Scheme 48



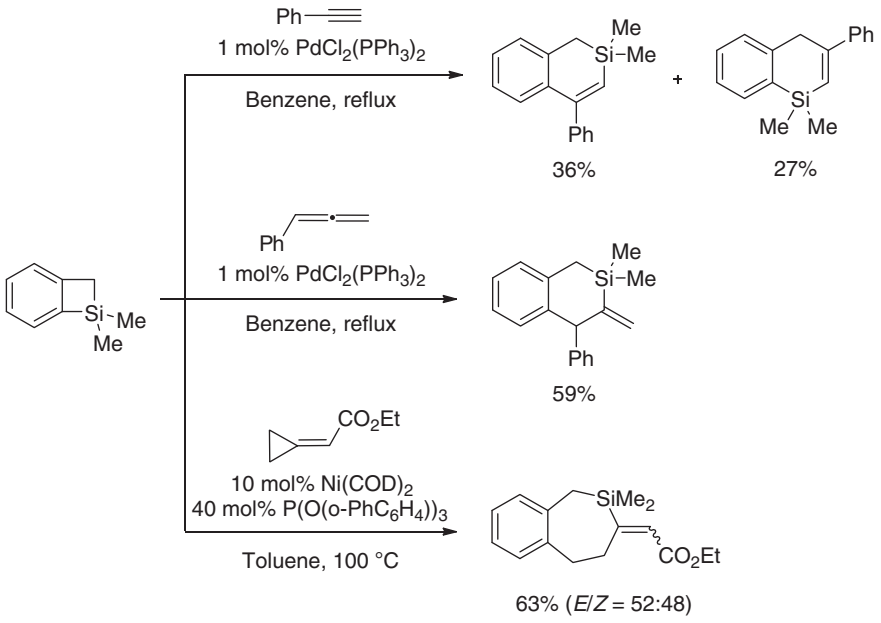
(34)



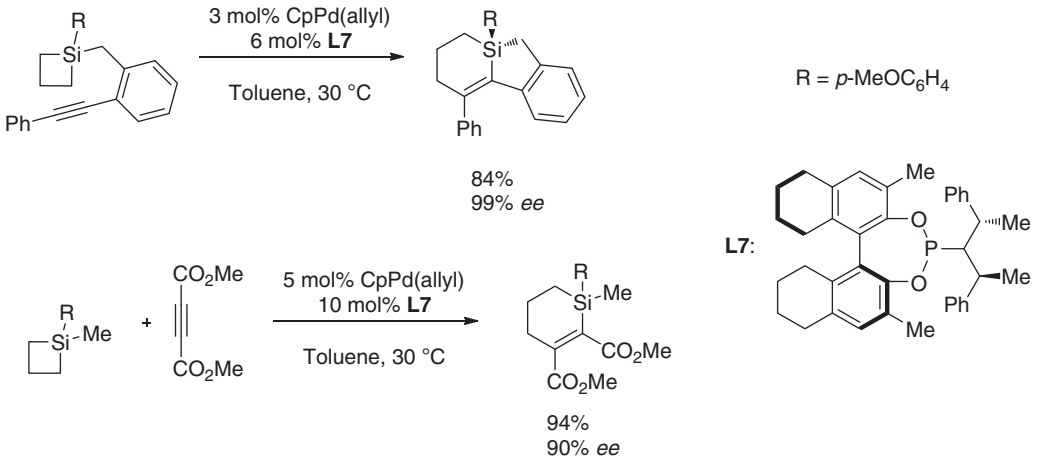
(35)

Following previous studies,[96] a recent example of a [3 + 2] cycloaddition of silirenes with alkynes has been reported (equation 36).[97] This reaction, as other reactions of small ring compounds embedding a silicon atom, is likely catalyzed by a palladium(0)-complex formed *in situ* by reaction of the starting material and the palladium(II) precatalysts.[96d]

(36)

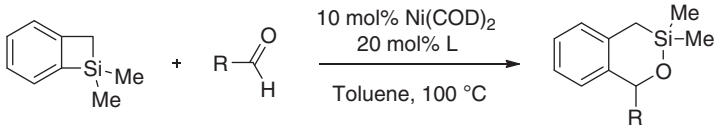


Four-membered ring compounds embedding a silicon atom can also undergo transition-metal-catalyzed cycloaddition reactions. For example, a reinvestigation of earlier results[98] has shown that the competition between reductive elimination and β–H elimination from intermediate **184** could account for the formation of the products **182** and **183** obtained in the palladium-catalyzed intermolecular [4 + 2] cycloaddition of silacyclobutanes with alkynes (Scheme 49).[99] Not surprisingly, the reductive elimination was faster in the presence of electron-poor alkynes and best results were obtained with DMAD.



Scheme 49

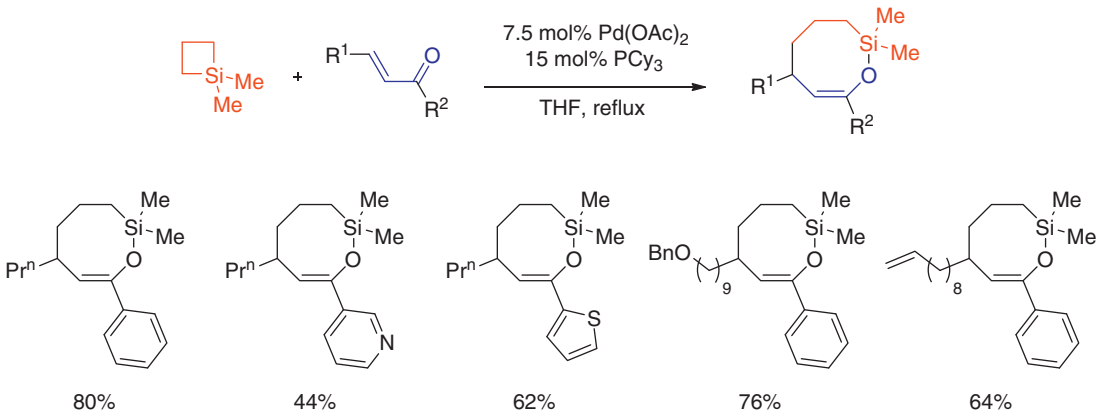
This undesirable β–H elimination being impossible with benzosilacyclobutanes, only cycloaddition products were obtained. However, the regioselectivity of the insertion of the metal catalyst into the strained four-membered ring appears to depend on the reaction partner (Scheme 50).[99,100] In a recent development, the enantioselective desymmetrization of prochiral silacyclobutanes has been reported (Scheme 51).[101]



The scope of transition-metal-catalyzed cycloadditions of silacyclobutanes and benzosilacyclobutanes is expanding. Hence, heterocylic compounds could be obtained by nickel-catalyzed [4 + 2] cycloadditions of benzosilacyclobutanes with aldehydes (equation 37)[102] and a palladium-catalyzed [4 + 4] cycloaddition of silacyclobutanes with α,β-unsaturated ketones (Scheme 52).[103] Although undesirable β–H elimination remained a problem with some substrates and competed against reductive elimination of a putative nine-membered palladacycle, this formal [4 + 4] cycloaddition is remarkable.

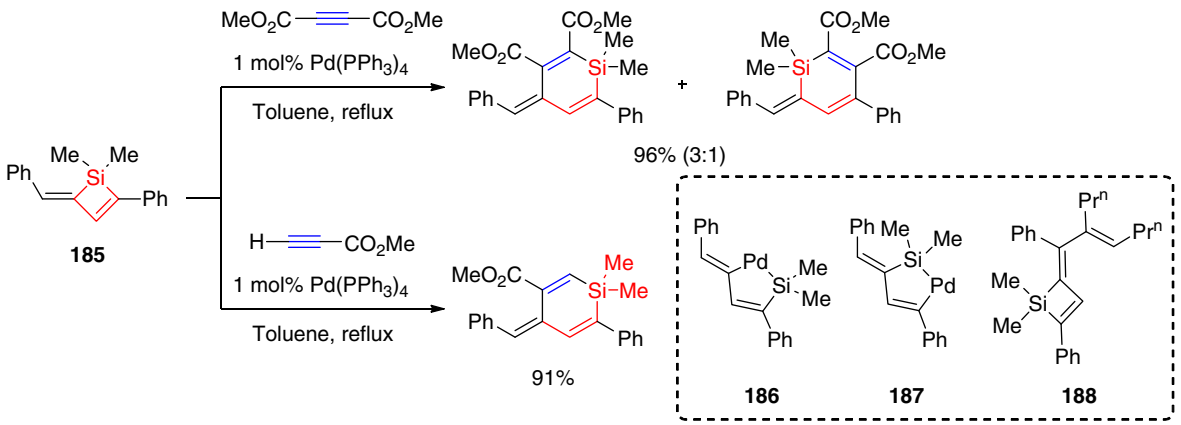
Scheme 50

Scheme 51



L	R	Yield
PPh_2Me	Ph	65%
PPh_2Me	o-MeC_6H_4	67%
$P(Bu^n)_3$	p-$CF_3C_6H_4$	75%
$P(Bu^n)_3$	$(CH_2)_2Ph$	50%

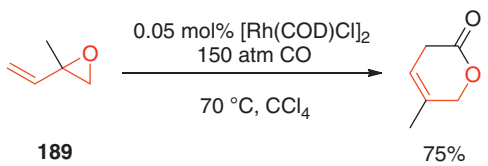
(37)



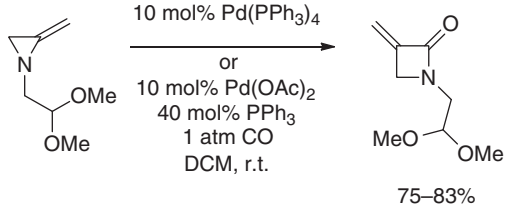
In addition to silacyclobutanes and benzosilacyclobutanes, the scope of transition-metal-catalyzed cycloadditions of four-membered ring compounds embedding a silicon atom is limited to the report of a regioselective carbon–silicon bond cleavage of alkylidene silacyclobutenes (Scheme 53).[104] On reaction with **185**, bis-substituted electron-poor alkynes gave a mixture of regioisomeric products, whereas their monosubstituted counterparts afforded a single isomer. Hence, if intermediates **186** and **187** were formed reversibly and rapidly, the control of the regioselectivity would take place during the migratory insertion. Alternatively, one could hypothesize that the alkyne could be coordinated to the metal and would influence the regioselectivity of the oxidative addition. Intriguingly, catalyzed reactions of the same alkynes with substrate **188** showed the opposite trend, the reaction with DMAD being completely selective, whereas the reaction with methyl propiolate gave a mixture of regioisomers.

5.35.9.1.2 Cycloadditions of small ring compounds embedding a nitrogen or oxygen atom

The carbonylation of epoxides and aziridines catalyzed by zwitterionic cobalt–carbonyl complexes and the associated mechanisms are well established (*see* Chapter 3.22).[105] However, one could speculate that the rhodium-catalyzed [5 + 1] carbonylative

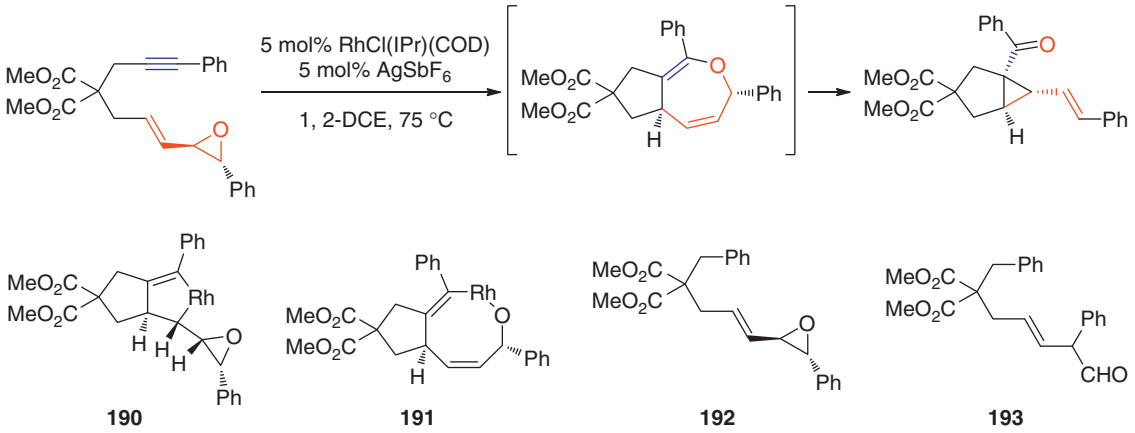


Scheme 52



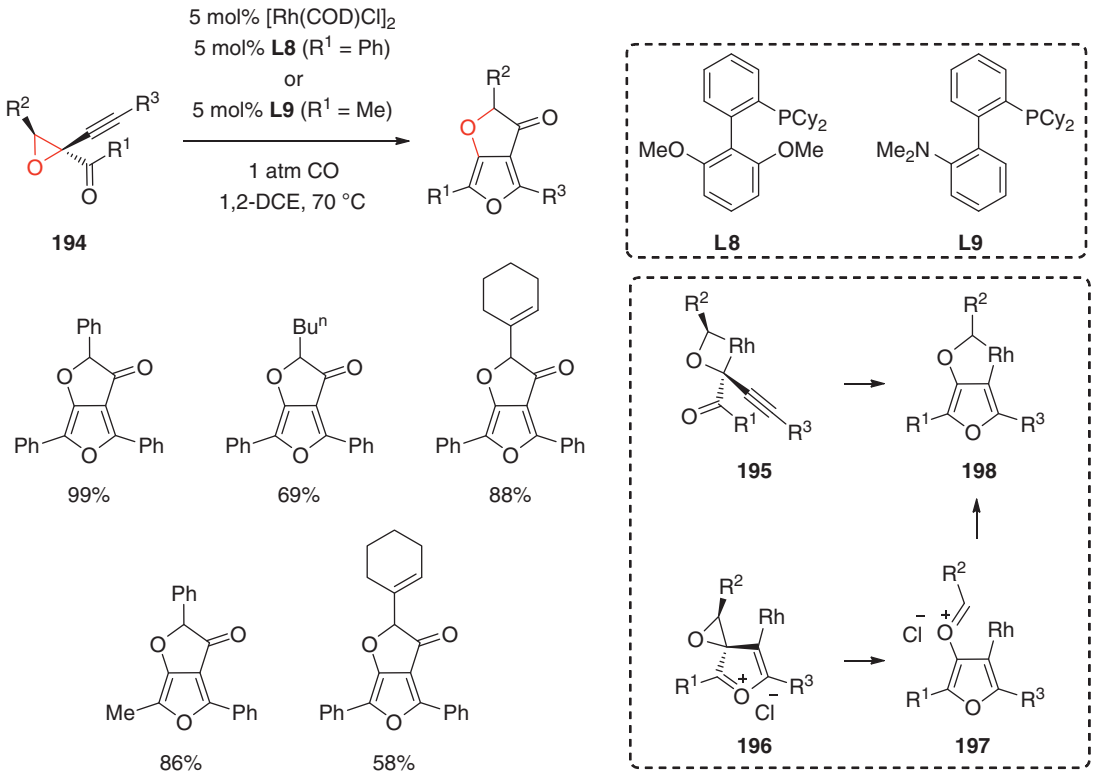
Scheme 53

cycloaddition of vinyl epoxide **189** (equation 38)[106] proceeds according to a mechanism similar to the mechanism governing the rhodium-catalyzed cycloadditions of vinylcyclopropanes (See **Scheme 18**, Section 5.35.3). The same hypothesis could be made to explain the intramolecular [5 + 2] cycloaddition/Claisen rearrangement of vinyl epoxides with alkynes (**Scheme 54**).[107] Hence, cyclooxidative addition intermediate **190** would undergo *syn*-coplanar elimination toward **191**; reductive elimination of this heterometalacycle would afford the precursor of the final sigmatropic rearrangement. Interestingly, it was shown that the alkyne moiety was likely crucial to the overall process, since the absence of this functional group in **192** led to the formation of unstable aldehyde **193** under the reaction conditions.



(38)

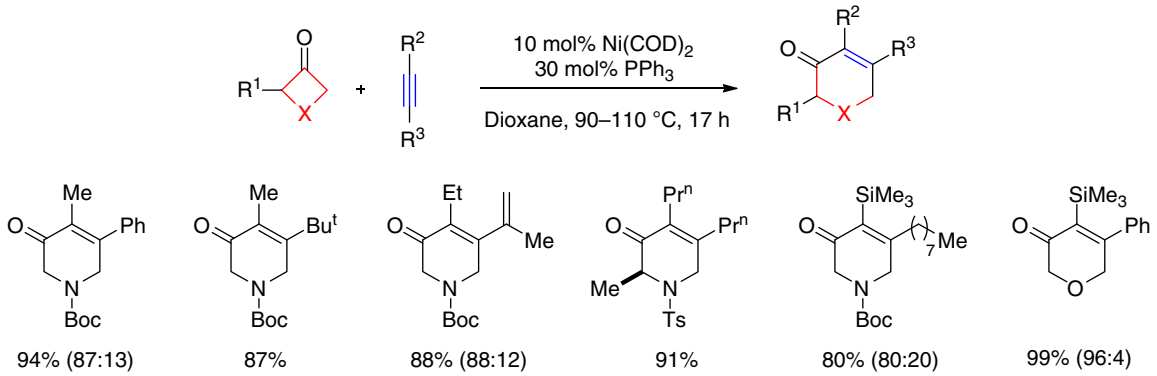
The palladium-catalyzed carbonylation of methylene-aziridines (equation 39)[108] is also likely to proceed according to another mechanism than the cobalt-catalyzed carbonylation of epoxides and aziridines.[105]



(39)

Scheme 54

5.35.9.2 Cycloadditions Involving Cleavage of a Carbon–Carbon Bond



In contrast to the previous examples of transition-metal-catalyzed cycloadditions of small heterocyclic compounds, which all involved the cleavage of a carbon–heteroatom bond, examples of cycloaddition involving the cleavage of a carbon–carbon bond are extremely scarce. Hence, the rhodium-catalyzed [4 + 1] carbonylative cycloaddition of alkynyl epoxides **194** has been reported recently (Scheme 55).[109] It was not established which of the intermediates **195–198** is the most pertinent to explain the results. However, as previously mentioned for the rhodium-catalyzed carbonylation of cyclopropyl ketone **74** to bicyclic furanone **75** (see Scheme 23, Section 5.35.3.4),[46] the oxidative addition of the catalyst to the more sterically congested bond of the epoxide ring seems counterintuitive. Therefore, intermediate **195** may be less likely.

Scheme 55

Moreover, the first examples of transition-metal-catalyzed carbon–carbon bond activation of 3-azetidinones and 3-oxetanones were reported recently (Scheme 56).[110] In the presence of a nickel catalyst and alkynes, a regioselective and high-yielding

intermolecular [4 + 2] cycloaddition occurred, leading to the formation of pyridinones and pyranones. In good accordance with nickel-catalyzed reductive coupling reactions of alkynes with aldehydes,[82] and with the [4 + 2] cycloaddition of cyclobutanones with alkynes,[80] the regioselectivity of the reactions depicted in Scheme 56 is likely controlled by steric factors in the case of alkyl–aryl-substituted alkynes. Conversely, electronic factors appeared to predominate in the case of the more polarized trimethylsilyl-substituted alkynes.[111]

Scheme 56

5.35.10 Conclusions

In most of the reactions discussed in this chapter, the small ring compounds are used as a three- or four-atom building block in the construction of a larger ring, embedding up to nine atoms. A chemical handle, mostly in the form of a carbon–carbon or carbon–heteroatom multiple bond, facilitates or even directs the cleavage of the small ring by an active catalyst. The reaction partners are varied, although alkynes, alkenes, and carbon monoxide are prominent. Currently, the most efficient catalysts are palladium, nickel, or rhodium complexes, with only few exceptions. Considering that the combination of more than two components has only been attempted in few cases, there is no doubt that new atom-efficient reactions will be developed in the future.

Glossary

Aziridine A three-membered cyclic compound containing a nitrogen and two carbons.

Coordinatively unsaturated complex A metal complex containing less than 18 electrons as the sum of its valence electrons and electrons from the attached ligands.

Organocatalyst Typically a low-molecular weight organic compound that is capable of catalyzing a reaction through its acid–base or hydrogen-bonding characteristics.

Oxynitrilase An enzyme that catalyzes the addition of hydrogen cyanide to aldehydes and ketones.

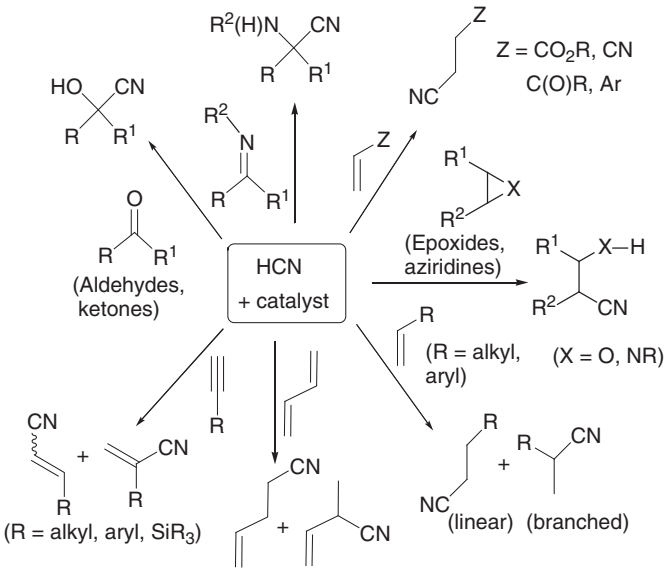
Parallel kinetic resolution A reaction in which each enantiomer of a racemic compound in a mixture undergoes separate reactions to give two different products.

Salen It is the imine from salicylaldehyde (2-hydroxybenzaldehyde).

Turnover frequency Number of moles of starting material converted into product per mole of the catalyst at unit time. A measure of the efficiency of a catalyst.

5.36.1 Introduction

Hydrogen cyanide (HCN) is one of the most abundant feedstocks[1] that is useful in the preparation of organic intermediates with a versatile nitrile functional group. These intermediates can be readily transformed into other valuable compounds for further applications in the manufacture of agrichemicals, cosmetics, pharmaceuticals, and polymers. Because HCN is relatively unreactive, especially in reactions with other unsaturated substrates, these reactions are best carried out under the influence of a catalyst, and catalyst-dependent selectivities can be brought to bear on the course of these reactions. This chapter will cover the most salient aspects of hydrocyanation of various organic compounds.[2–4] Although the major emphasis will be on hydrocyanation of alkenes and alkynes, the subject is introduced through a short section on hydrocyanation of carbonyl compounds, imines, epoxides, and aziridines, mostly for the sake of completeness. The review is meant to be illustrative than exhaustive. The many reviews and original publications cited herein should be consulted for further details. The literature on hydrocyanation till the end of March 2012 is reviewed.



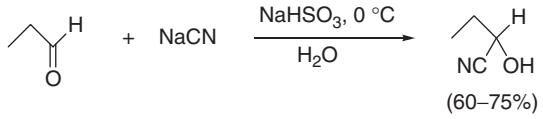
5.36.1.1 Safety

HCN is a highly toxic, volatile liquid (bp 26 °C) that is also susceptible to explosive polymerization in the presence of base catalysts. It is conveniently prepared by acidifying $K_4Fe(CN)_6$ or NaCN.[5] Considering its extensive use in the industry, reports of

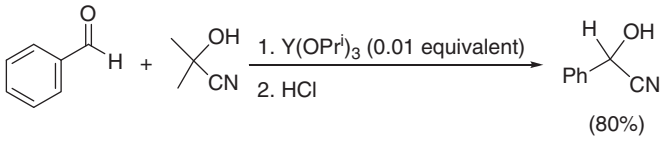
 doi:10.1016/B978-0-08-097742-3.00537-1

accidents are rare, pointing to the extreme diligence and attention paid during the manufacturing processes. In the laboratory it should be used only in small quantities in a well-ventilated hood. Other sensible precautions include not working alone and having available proper first aid equipments, HCN monitors, and professional respiratory protection devices (e.g., Scott Air Packs). Large quantities of HCN should only be handled by a team of at least two technically qualified experts, who have received appropriate medical training for treating HCN poisoning. On an industrial scale, HCN is disposed of by burning. In case of smaller amounts such as in a typical laboratory setting, it can be disposed of by adding it to an equimolar mixture of sodium hydroxide and sodium hypochlorite (which converts it to the cyanate). This is a highly exothermic reaction and the quenching should be carried out in high dilution and with extreme care (see Prudent Practices for Handling Hazardous Chemicals in Laboratories; National Academy Press: Washington, DC, USA, 1981).

In the presence of a catalyst, HCN adds to carbonyl compounds and imines,[2] epoxides (see citation 15 in Ref. 6 for previous reports that deal with ring-opening reactions of epoxides with various metals; depending on the metal either a nitrile or an isonitrile is formed),[6] aziridines,[7] alkenes,[8,9] and alkynes,[10] offering a direct and economic way to organonitrile intermediates (Scheme 1).

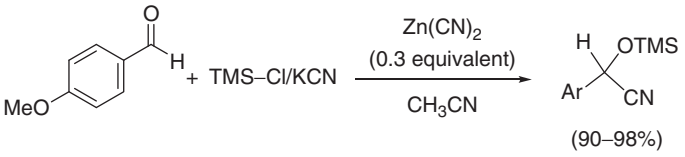


Scheme 1 Catalyzed additions of HCN.



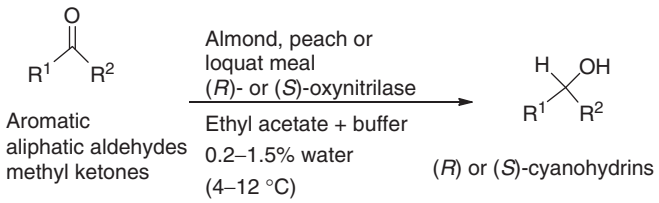
Hydrocyanation of activated polar substrates, such as carbonyl compounds, imines, and electron-deficient alkenes (C=C–Y, Y=CO_2R, CN, C(O)R, and C(O)H), usually occurs in the presence of a base, including cyanide ion itself and historical aspects of this topic have been extensively reviewed.[11–13] Conjugate addition of HCN to α,β-unsaturated carbonyl compounds also occur in the presence of Lewis acids such as alkylaluminum reagents ('Nagata Reaction'). An exhaustive review of this transformation has appeared in *Organic Reactions*.[14] This chapter will concentrate on the more recent aspects of these reactions of HCN. Reactions of readily available surrogates, trimethylsilyl cyanide (TMSCN) and acetone cyanohydrin, with various electrophilic partners are also included since they give similar products, and often are easier and safer to carry out in the laboratory.

5.36.2 Addition of HCN to Aldehydes and Ketones

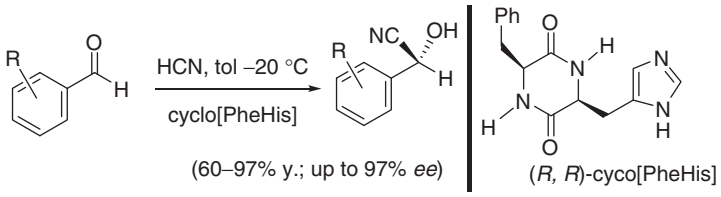


The addition of HCN to carbonyl compounds[2,15] is a reversible reaction with the cyanohydrin as the favored product in aldehydes and nonaromatic ketones. Direct reactions of aldehydes with neat HCN or of the reagent prepared *in situ* from metals and a mineral acid is a classical way of preparing a cyanohydrin (equation 1).[16] Cyanohydrins prepared in this way can be directly oxidized *in situ* using MnO_2 into an acyl cyanide, which may be converted into a methyl ester.[17] Lanthanide alkoxides, such as ytterbium isopropoxide, are excellent catalysts in the preparation of cyanohydrins from aldehydes and ketones (equation 2).[18] Many other metal catalysts, among them, $Cu(OTf)_2$, $Yb(CN)_3$, KCN/18-crown-6, Bu_2SnCl_2, and InF_3, have been used for the addition of TMSCN to aldehydes. A comparison of these methods has been provided in a recent review.[2] Silyl ethers of cyanohydrins can be prepared directly from a mixture of sodium or potassium cyanide, a trialkylsilyl chloride, and a suitable catalyst, thus avoiding the toxic silyl cyanides (equation 3).[19]

(1)



(2)



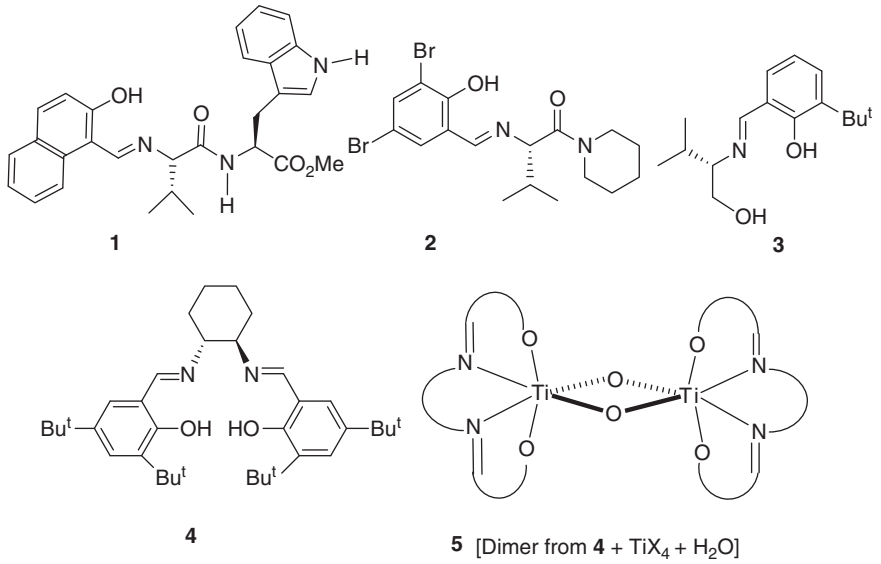
(3)

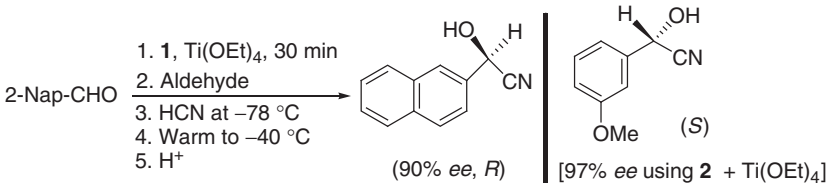
An interesting variation is a biochemical method using oxynitrilase enzyme-catalyzed addition of HCN to various aliphatic and aromatic aldehydes and ketones. Both (*R*)- and (*S*)-oxynitrilases have been isolated from plant sources (e.g., almonds, sorghum shoots, peach, loquat, and rubber plant) and provide a practical way of preparing enantiopure cyanohydrins.[20,21] The example shown in equation 4 is taken from a comparative study of the use of various protocols for oxynitrilase enzymes in the syntheses of cyanohydrins.[22] A broad class of organocatalysts that effect the addition of HCN to aldehydes are the cyclopeptides derived from readily available amino acids (equation 5).[20] It is believed that the morphology of the solid catalyst is important for a successful reaction, often carried out in a heterogeneous medium, and careful control of reaction conditions are needed to get high yields (y.) and selectivities.[23]

(4)

(5)

Titanium complexes of salicylaldehyde imines (salen) derived from dipeptides **1** and **2** (**Figure 1**) catalyze the addition of HCN to a variety of aldehydes to give either the (*R*) or the (*S*) cyanohydrin (equation 6).[24] Imines from *β*-aminoalcohols (**3**)[25] and C_2-symmetric diamines such as 1,2-diaminocyclohexane (**4**)[26] also serve as ligands for Ti(IV) in TMSCN additions to aldehydes. The isolated, purified complexes from **4** gave some of the best selectivities for aromatic aldehydes. Intermediacy of a dimeric complex **5** has been implicated in some of the most active ($\sim$0.1 mol%) catalysts.[26] Catalyst **5** also uniquely effects the addition of KCN in the presence of an anhydride to give cyanohydrin acetates.[27] Aluminum complexes derived from 2,2′-binaphthols (e.g., **6**, equation 7) or carbohydrate diols that carry additional Lewis basic sites (e.g., the $-Ph_2P{=}O$[28] or $-NR_2$[29] group) have also been used for the addition of TMSCN to aldehydes (equation 7).[28,30] These reactions are some of the best documented examples of bifunctional catalysis. Among other useful catalysts, the complexes of vanadium[31] and yttrium[32,33] are noteworthy.





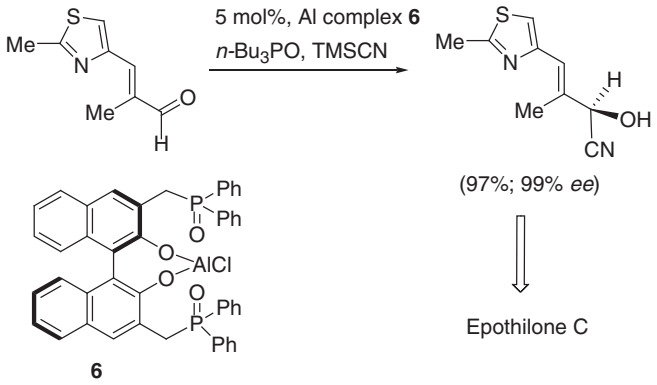


Figure 1 Salicylaldehyde imines as ligands.

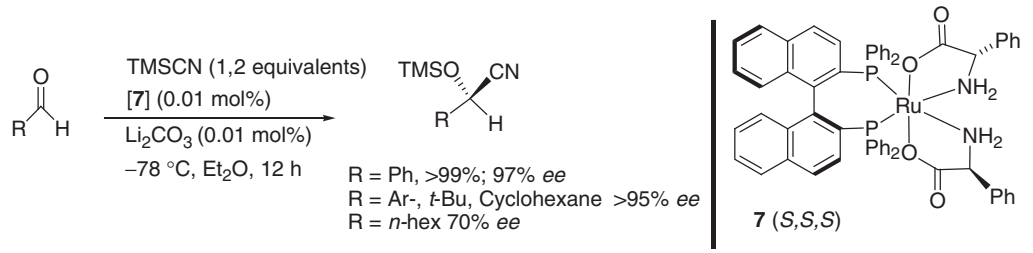
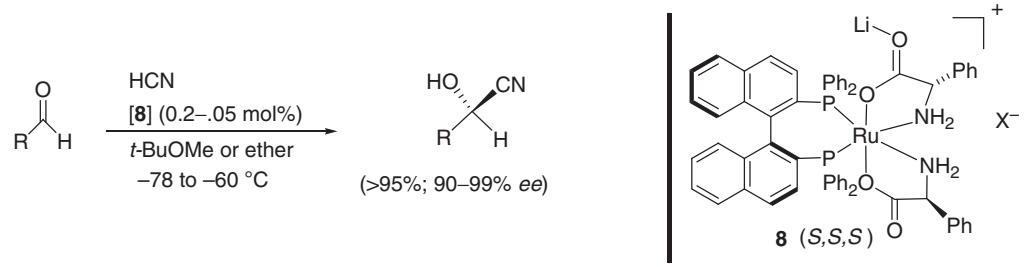
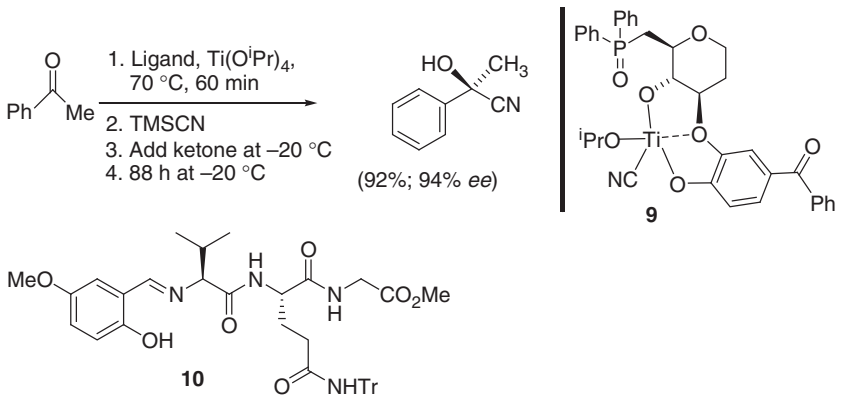


(6)



(7)

Late transition metals have rarely been used successfully for the hydrocyanation of aldehydes until Ohkuma reported[34] that Ru(2,2-bis-(diphenylphosphino)-1,1-binaphthyl (BINAP)) complex **7** for the silylcyanation of aldehydes (equation 8). A more recent application (equation 9)[35] in the use of a similar isolated bimetallic complex **8** represents the most efficient hydrocyanation of aldehydes using HCN reported to date. The complex [Li(Ru[(*S*)-(Phe)]$_2$[(*S*)-BINAP])]Br is readily synthesized by mixing Ru[(*S*)-Phenylglycine]$_2$[(*S*)-BINAP] and LiBr, and, it efficiently catalyzes asymmetric hydrocyanation of aldehydes with a substrate-to-catalyst ratio of 500–2000 at -78 to $-60\,^{\circ}C$. A range of aromatic, heteroaromatic, and α,β-unsaturated aldehydes as well as a *tert*-alkyl aldehyde is converted into cyanohydrins in high enantiomeric excess (*ee*) (up to 99%).

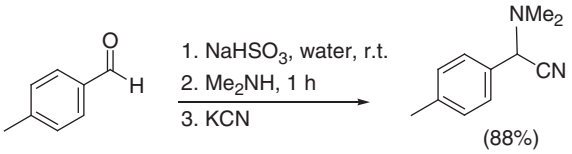


(8)

(9)

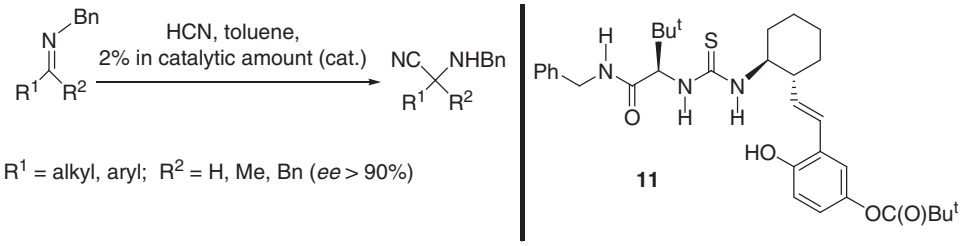
The equilibrium in case of the addition of HCN to ketones does not favor the cyanohydrin, and most successful reactions use TMSCN to prepare these intermediates. Historically, ZnI_2 has been the reagent of choice, even though a number of other catalysts have been reported for this reaction.[36] These include $TMSN(SO_2F)_2$, $InBr_3$, $Cu(OTf)_2$, $Y(OTf)_2$, $BiBr_3$, and Et_2AlCN, all of which have been found to give acceptable y. of the product.

Dimeric Ti complex **5** (**Figure 1**) catalyzes the addition of TMSCN to acetophenone[31] even though *ee*'s are unacceptably low. Carbohydrate-derived phosphine-oxide–Ti complex **9** (equation 10) catalyzes the addition of TMSCN to both aromatic and aliphatic ketones.[37] In this case, depending on the metal that is used, one can get either of the enantiomers.[38] An aluminum complex of a peptide–imine ligand **10** has also been used for this reaction.[39] Aluminum salen complexes in conjunction with *N*-oxide additives (double activation)[40] have also been reported for this reaction. Other notable results include the use of H-bonding catalysis[41] and the use of amino acid salts in the syntheses of ketone cyanohydrins.[42] Several examples of related additions of methyl cyanoformate to aliphatic ketones in the presence of modified cinchona alkaloids have also been reported.[43]



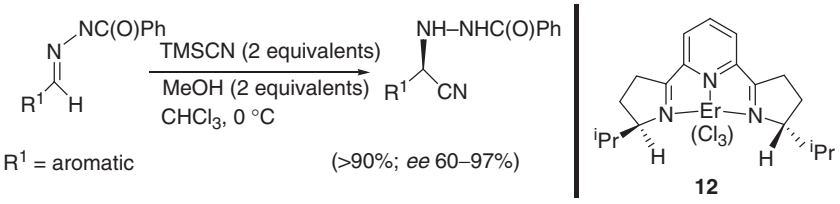
(10)

Many oxynitrilase enzymes, which generally use aldehydes as their natural substrates, will accept methyl and ethyl ketones and even some substituted cyclohexanones. Under buffered conditions these catalyze the addition of HCN.[20,44,45]

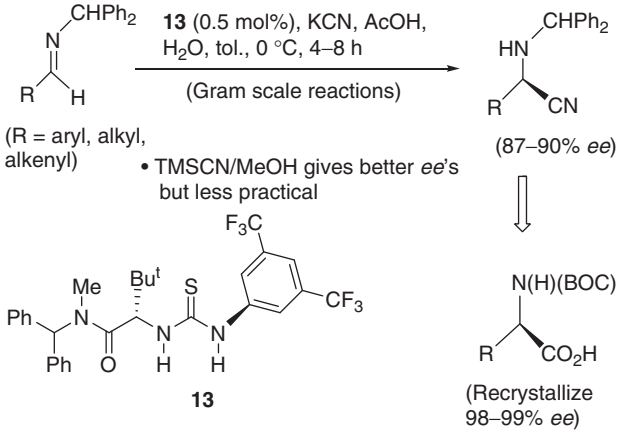


5.36.3 Additions of HCN to Imines

Excellent reviews[46–48] of this subject have recently been published and only the most practical reactions are covered here. Traditional Strecker reactions are carried out in water under slightly acidic conditions (equation 11).[49] A notable variation is the use of ammonium chloride and catalytic alumina in a nonaqueous medium under sonication.[50,51] Lanthanide trifluoromethanesulfonates (especially $Yb(OTf)_3$) catalyze the addition of TMSCN to a wide variety of aldimines, which are often formed *in situ*.[52]

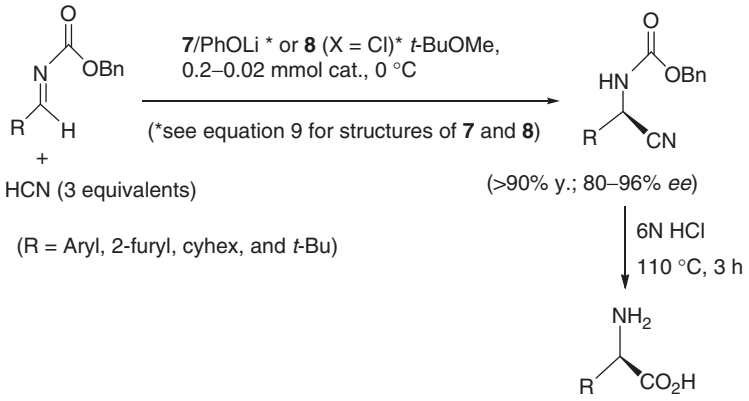


(11)



Among the many papers that deal with the asymmetric addition of HCN to imines, Jacobsen's work is particularly noteworthy.[53–55] Searching through a library of dipeptide-urea catalysts, his group discovered general enantioselective methods for the syntheses of a wide variety of aminonitriles from aldehyde and ketone imines (equation 12). Use of aluminum salen,[56] aluminum binaphtholate,[57] and Ti(IV)–peptide–imine complexes[58] as catalysts for these reactions have also been reported. In the only report of addition of HCN to hydrazones (equation 12b), an erbium complex (**12**) of readily available phenyl-2,6-bis-oxazolinylpyridine (PYBOX) ligand is used.[59] The *ee*'s in these reactions are generally modest. Jacobsen also reported[60] a scalable procedure (equation 13) that uses a thiourea catalyst (**13**) at 0.5 mol% loading for the syntheses of a wide variety of natural and unnatural amino acids. This procedure is compatible with the use of KCN and acetic acid as a source of HCN, and has many practical benefits for the syntheses of several amino acids that are not available via conventional methods including hydrogenations.

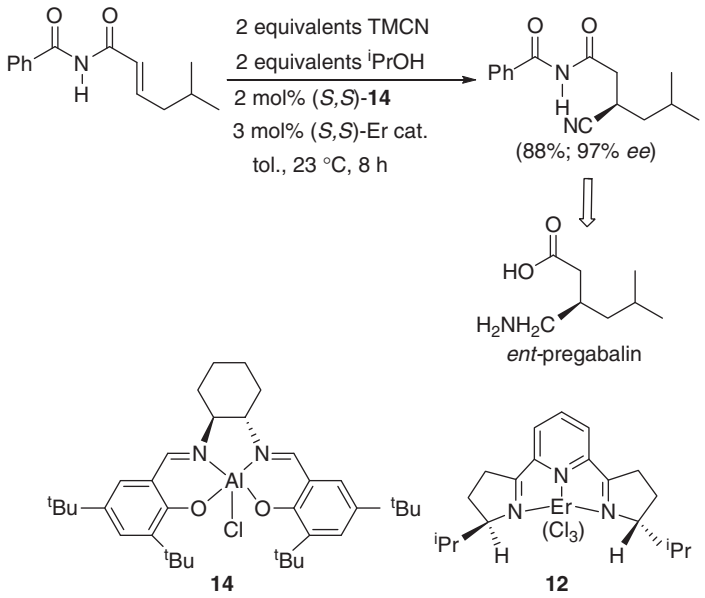
(12a)



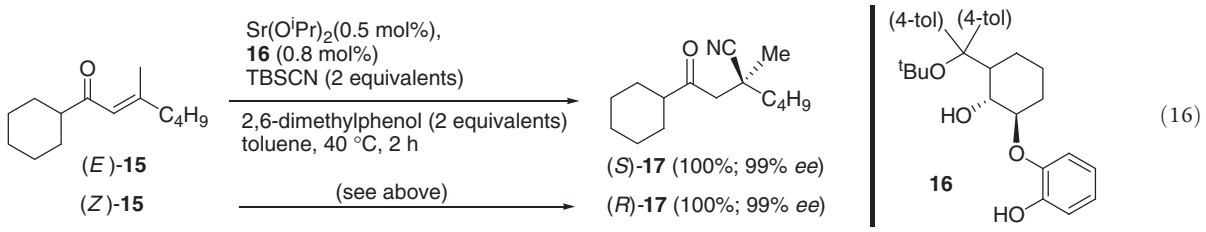
(12b)

(13)

Another procedure with potential applications for the large-scale synthesis of amino acids depends on the enantioselective hydrocyanation of *N*-benzyloxycarbonyl aldimines catalyzed by Ru[(*S*)-(Phe)]$_2$[(*S*)-(BINAP)]/C_6H_5OLi or a bimetallic complex [Li(Ru[(*S*)-(Phe)]$_2$[(*S*)-(BINAP)])]Cl (equation 14).[61] These systems y. aminonitriles in 92–99% *ee*. The reactions are carried out in *tert*-$C_4H_9OCH_3$ with a substrate-to-catalyst molar ratio in the range of 500–5000 at -20 to 0 °C, and excellent y. and selectivities are obtained. The product aminonitriles are easily hydrolyzed to the respective amino acids. The Ru-catalyst **7**/PhOLi is also effective for cyanosilylations of α-ketoesters.[62]

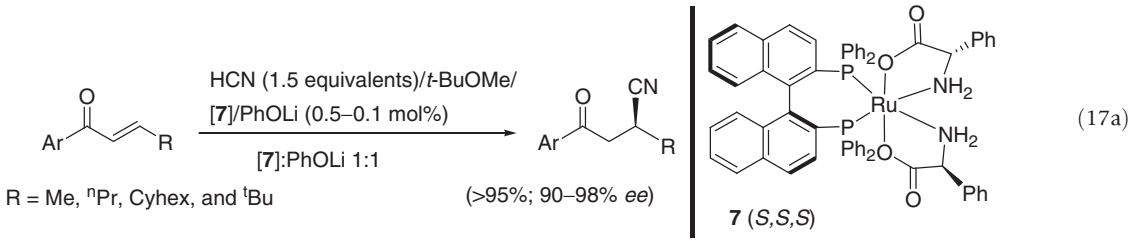


(14)

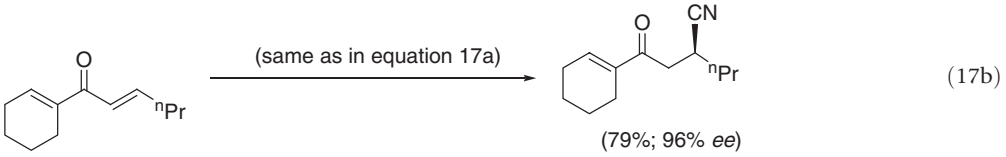


5.36.4 1,4-Additions of HCN to α,β-Unsaturated Carbonyl Compounds

In addition to Nagata's exhaustive review in *Organic Reactions*,[14] which covers all of the early work, a more recent update on these reactions has appeared.[13] Only the most recent work that deals with asymmetric addition of HCN or an equivalent reagent is covered here.

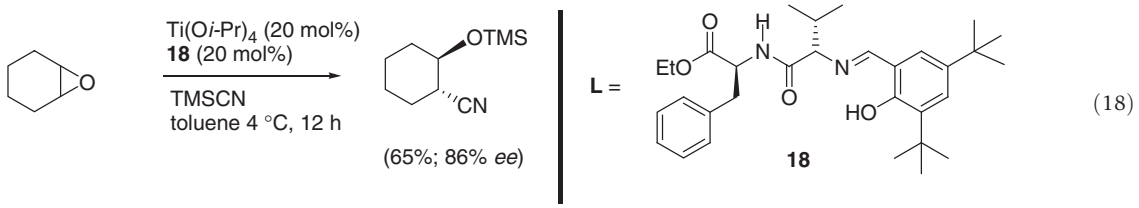


The first notable example of an enantioselective conjugate addition of HCN to α,β-unsaturated carbonyl compounds was reported by Jacobsen, who showed that an aluminum salen complex catalyzes this reaction with excellent y. and enantioselectivity. The high catalyst loading in the original protocol (10% Al) can be overcome by using a mixed catalytic system (**12** + **14**) that also employs a (PYBOX)$ErCl_3$ complex, presumably to activate the electrophile (equation 15).[63–65] Subsequently, Shibasaki reported the use of a Gd complex derived from a sugar diol (similar to **9** shown in equation 10) for related addition of HCN to α,β-unsaturated *N*-acylpyrroles.[66] Optimization of the ligand (e.g., **16**) and metal (Sr) has enabled further extensions of this chemistry to introduce all-carbon quaternary centers by addition of HCN to β,β-disubstituted carbonyl compounds (equation 16).[67] Note that the (*Z*) and (*E*) alkenes give opposite enantiomers in this highly stereospecific reactions. Spectacular y. (>96%), catalytic efficiencies (0.1 mol%), and selectivities (91–98% *ee*) have been reported in a Ru-catalyzed asymmetric hydrocyanation of α,β-unsaturated ketones (equations 17a and 17b).[68] A more recent study reports conjugate asymmetric HCN addition to nitroalkenes catalyzed by Ti–salen complexes (up to 84% *ee*).[69]

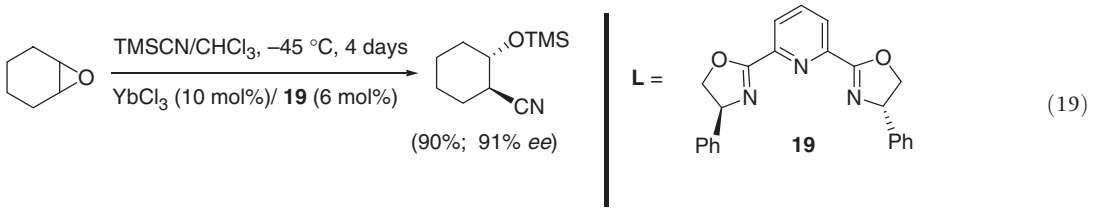


(15)

(16)

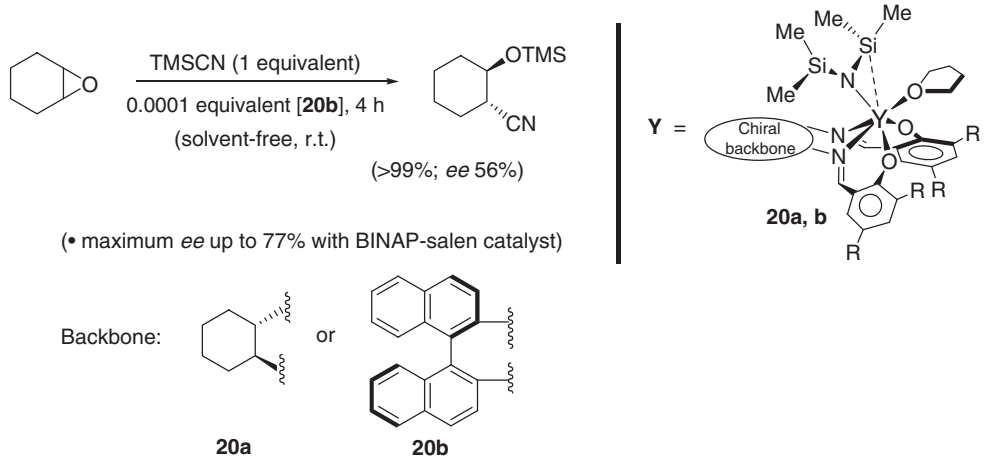


(17a)



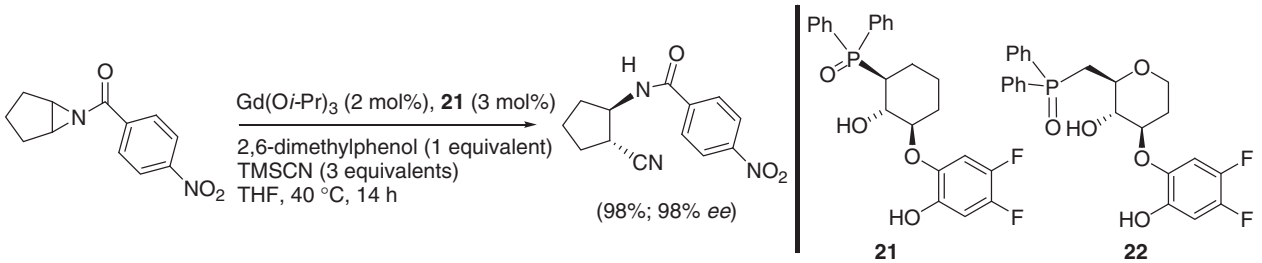
(17b)

5.36.5 Ring-Opening Reactions of Epoxides and Aziridines

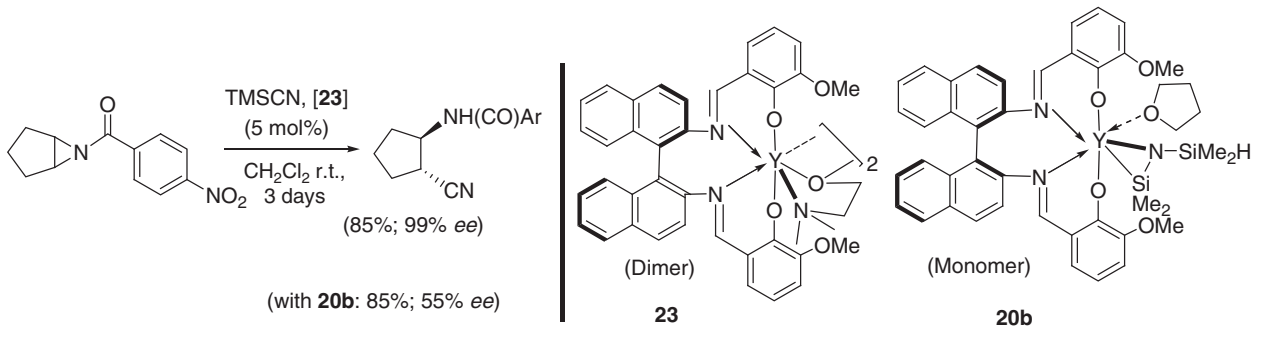


Enantioselective ring-opening reactions of epoxides with TMSCN or HCN remains a challenge,[6] even though related reactions with nitrogen and oxygen nucleophiles have been among the most practical methods in asymmetric catalysis.[70] The best results in the area are depicted in equations 18–20, and use Ti,[71] Yb,[72] or Y[6] catalysts to effect this transformation. The yttrium catalysts are remarkably efficient (0.01 mol%) in these reactions, but the enantioselectivity remains modest (equation 20).[6] Shibasaki has reported the use of an Sm(III) complex for the ring-opening of an α,β-epoxycarboxamide.[73]

(18)



(19)

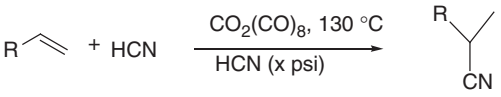


(20)

Aziridines with activating *N*-substituents (4-nitrobenzenesulfonyl, *N*-tosyl, and *N*-benzoyl) are known to undergo ring-opening reactions in highly polar media.[74] Catalysts used for this process include $LiClO_4$,[75] *n*-Bu_4NF,[76] $Y(CN)_3$, or $Yb(CN)_3$.[77] Enantioselective ring-opening reactions of aziridines with TMSCN, as compared to the corresponding reactions of epoxides, have been better developed. The Gd complex derived from ligand **21** (2 mol%), initially developed for the syntheses of ketone cyanohydrins,[38] effect desymmetrization of an aziridine in essentially quantitative y. and over 98% *ee* (equation 21).[78] A slight variation in the structure of the ligand (**22**) gives a slightly inferior catalyst that affords the opposite enantiomer of the product nitrile.[79] Salen yttrium complexes (e.g., **20b**) that showed exceptional activity in ring-opening reactions of epoxides (equation 20) are only marginally effective for the TMSCN-mediated ring-opening of aziridines. Yet, a related dimeric complex **23**, designed on the basis of a mechanistic rationale, works well for this reaction (equation 22).[80] Incidentally, complex **23** catalyzes a rare regiodivergent parallel kinetic resolution of chiral aziridines giving two different azide adducts (each ~99% *ee*) in reactions with $TMSN_3$ from each of the enantiomers.[81] Structural studies on the catalyst and kinetic investigations suggest a bimetallic mode of activation in these reactions.

(21)

(22)



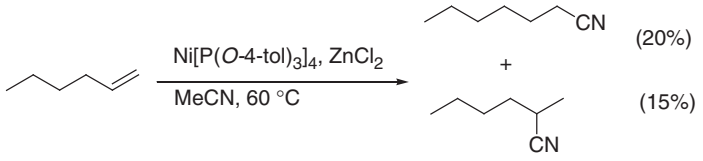
5.36.6 Hydrocyanation of Alkenes

An exhaustive review on the subject of hydrocyanation of alkenes and alkynes that deal with various aspects of synthesis, mechanism, stereochemistry, and specific examples of different substrate types has recently (2011) been published and the reader

is encouraged to consult this article for details.[3] This review also contains an extensive tabular survey that includes most of the examples published until the end of 2010.

5.36.6.1 Hydrocyanation of Unactivated Alkenes

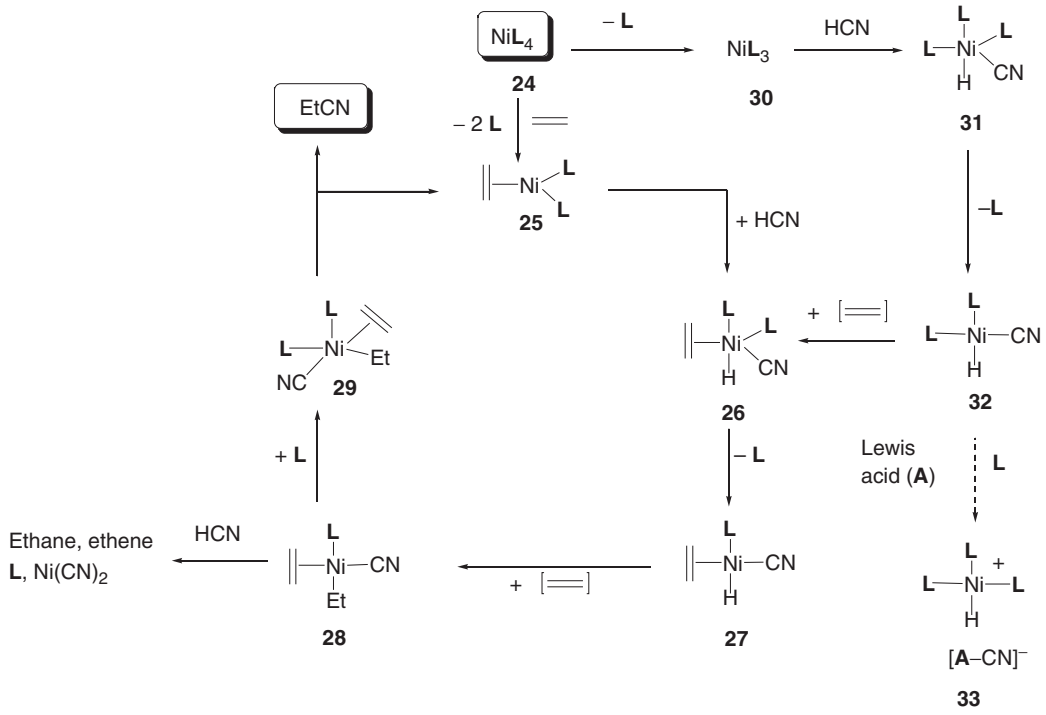
The addition of HCN to unactivated alkenes is a sluggish reaction that proceeds only at high temperatures in the gas phase even in the presence of a catalyst. A homogeneous catalyst, $Co_2(CO)_8$, facilitates the addition of HCN to alkenes in a Markovnikov fashion at 130°.[82] Propene and 1-butene give the corresponding branched nitriles in 65% and 67% conversions at 130°, respectively, and at moderate pressures in an autoclave (equation 23). As the size of the alkyl group on the double bond increases, the conversions decrease. The addition of Ph_3P increases the y. 2-Butene gives a low y. (up to 24%) of 2-butanenitrile under these conditions.



R	x	Time (h)	Conversion (%)
Me	110	15	65
n-Pr	40	8	67
n-Bu	46	8	5
n-Bu	43	8	24[a]

[a]With added Ph_3P.

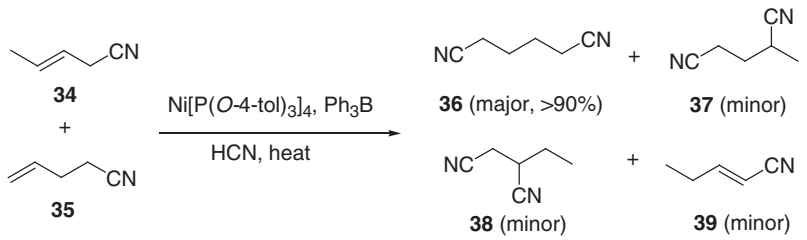
(23)



The best results in the hydrocyanation of unactivated alkenes are obtained with $Ni[P(OAr)_3]_n$ ($n=3$, Ar = 2-MeC_6H_4; $n=4$, 4-MeC_6H_4) that show favorable ligand dissociation kinetics needed for the alkene activation. These reactions generally give low turnover numbers (ton). Since the disclosure of homogeneous Ni(0)[83] and Pd(0)[84] catalysts for alkene hydrocyanation, the use of Lewis acids to promote this reaction has received a great deal of attention. The half-life of propene hydrocyanation by $Ni[P(O\text{-}2\text{-tolyl})_3]_3$ is ~60 min at 0°.[9] The addition of Lewis acids dramatically alters the rate of the reaction, with $AlCl_3$ having the most pronounced effect: the half-life at −25 °C is 10 min. Triphenylboron slows down the reaction, yet produces the best terminal to internal selectivity in the hydrocyanation of propene (89:11). Hydrocyanation of 1-hexene catalyzed by $Ni[P(O\text{-}4\text{-tolyl})_3]_4$ in the presence of excess ligands and a promoter Lewis acid such as $ZnCl_2$ gives the two nitriles in a terminal to internal ratio of 4:3 (equation 24).[85] The increased activity in the presence of an added ligand is thought to be due to the prevention of the formation of the catalytically inactive $L_2Ni(CN)_2$ species (see Section 5.36.6.1.1). In many hydrocyanation reactions slower addition of HCN helps to slow down this deactivation process. The Lewis acid promoter acts as a cyanide acceptor from one of the organometallic intermediates, and has a pronounced effect on the branched to linear ratio of products. Among the Lewis acids, $ZnCl_2$ gives one of the best selectivities in favor of the terminal nitrile (terminal:internal = 78:22), whereas $AlCl_3$ is the best for internal nitrile (terminal:internal = 69:31). In the hydrocyanation of hexene with $Ni[P(O\text{-}2\text{-tolyl})_3]_3$ in the presence of $(4\text{-tolyl})_3B$, the regioselectivity for the terminal product increases to 91%. Likewise, using *p*-cresol as the solvent gives a higher proportion of the linear product (terminal:internal = 86:14) as compared to acetonitrile (terminal:internal = 78:22).[85] Isobutylene and 2,3-dimethyl-1-butene give a terminal to branched ratio of 99:1.

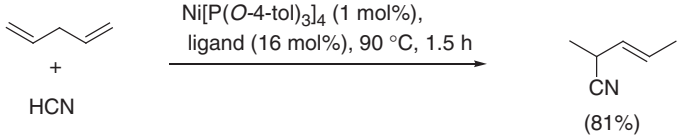
(24)

5.36.6.1.1 Mechanism of the Ni(0)-catalyzed hydrocyanation of ethylene



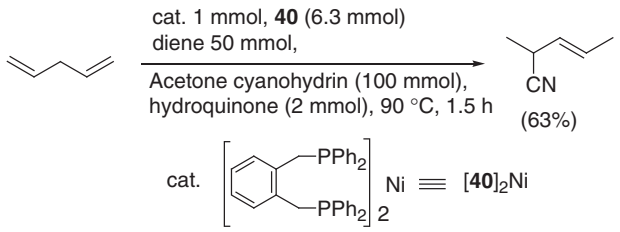
The mechanism of alkene hydrocyanation has been studied in great detail (Scheme 2).[9] The typical hydrocyanation catalysts are zero-valent triarylphosphite–nickel complexes, $Ni[P(OAr)_3]_n$ ($n=3$, 4). These catalysts tolerate a broad range of substrates and functional groups. The initial step is the dissociation of one of the arylphosphite ligands from the NiL_4 complex (**24**) to give a coordinatively unsaturated Ni-complex (**30**) that readily forms an alkene adduct **25**. Olefins form complexes with $L_2Ni(0)$ with equilibrium constants decreasing in the order of ethylene > styrene > propene > 1-hexene > disubstituted alkenes. Oxidative addition of HCN to this complex gives **26**. This intermediate can also be arrived at first by oxidative addition of HCN to **30** and subsequent substitution of a ligand in **31** by the alkene. Loss of a ligand from **26** gives **27**. The insertion of ethylene into the metal–hydrogen bond gives **28** with a σ-bonded ethyl group and a π-bonded ethylene. With excess ligands, complex **29** is produced and it proceeds to give the product EtCN along with the active catalyst. The final step is essentially irreversible unless the

Scheme 2 Mechanism of the Ni-catalyzed hydrocyanation of ethylene (see text for details). Reproduced from RajanBabu, T. V. *Org. React.* **2011**, *75*, 1–73, with permission from Wiley.



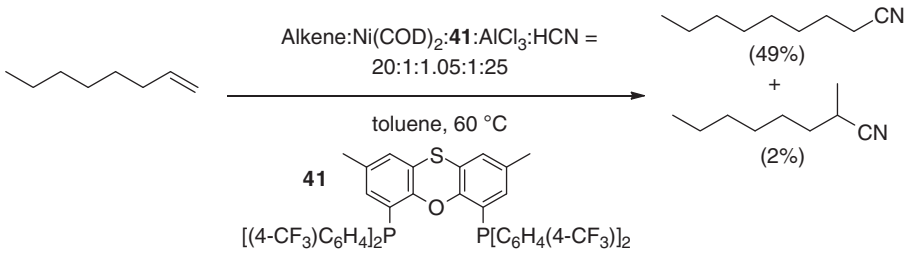
product is an allyl cyanide. If the starting alkene is electron-deficient (e.g., tetrafluoroethylene or acrylonitrile), the reductive elimination from **29** is slow and the turnover is essentially blocked. Intermediate **28** is also the source of a deleterious side reaction to form catalytically inactive $Ni(CN)_2$ if excess HCN is present in the medium. Several of the intermediates in the catalytic cycle have been identified using low temperature spectroscopic techniques.[9]

Hydrocyanation of a mixture of 3-pentenenitrile (**34**) and 4-pentenenitrile (**35**) is an important step in the DuPont process for the manufacture of adiponitrile from 1,3-butadiene (BD) and many protocols for this reaction have been described in the patent literature.[9] In this process, a mixture of mononitriles obtained from Ni(0)-catalyzed hydrocyanation of BD (see Section 5.36.6.2) is treated with HCN and a mixture of a $Ni[P(O\text{-}2\text{-}Ar)_3]_3$ and Ph_3B (equation 25).[86,87] Because the isomerization of the internal alkene **34** to the terminal alkene **35**, catalyzed by the $[(ArO)_3P]_2NiH(CN)$ (**32**, Scheme 2), is faster than the hydrocyanation of the former; the major product formed is adiponitrile (**36**) with minor amounts of other dinitriles formed under the reaction conditions. More robust[88] chelating phosphites based on various biaryl scaffolds have since been developed for these reactions.



(25)

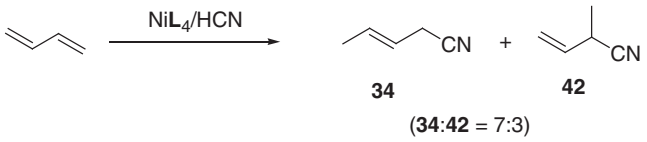
Nonconjugated dienes under similar conditions undergo hydrocyanation to give major products in which the terminal alkene is isomerized (equation 26).[89] The reaction (equation 27) using ligand **40** illustrates the use of an HCN surrogate, acetone cyanohydrin, in a hydrocyanation reaction.



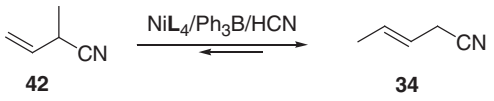
(26)

(27)

Rigid bidentate phosphines with an optimum bite-angle of more than 100° show pronounced activity for the hydrocyanation of unactivated alkenes in the presence of Lewis acids.[90,91] Thus, $Ni(COD)_2$, in the presence of a diphosphine **41** and $AlCl_3$, effects the hydrocyanation of 1-octene up to a ratio of 49:2 for the terminal to internal isomeric nitriles (equation 28).[91]

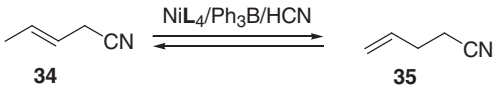


(28)

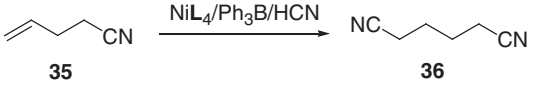


Alkenes attached to halogen, oxygen, carbonyl substituents, or other electron-withdrawing groups do not react with HCN under Ni(0)-catalysis. Mechanistic studies indicate that the final reductive elimination step is retarded by these substituents.[9]

5.36.6.2 Hydrocyanation of Conjugated Dienes



Hydrocyanation of 1,3-dienes are best carried out using homogeneous nickel complexes even though Cu[92,93] and Co[94] salts and complexes are known to effect this reaction. The classic example, which represents a very successful commercial application[95] of this process, is DuPont's production of the nylon-66 precursor, adiponitrile, via hydrocyanation of BD (equations 29–32).[9,83] This discovery sparked many seminal mechanistic investigations on transition metal-catalyzed reactions.[86,96–100] Concepts that emerged from these studies include the proposal that many catalytic processes proceed through coordinatively unsaturated 16-electron (or lower) intermediates,[101] and the importance of steric (e.g., ligand cone-angle θ) and electronic effects (e.g., Tolman χ-factor) on ligand substitution reactions.[95,99,102] Because of the huge commercial interest in this reaction, much of the work appears in the patent literature. Only the most relevant results where full details of the preparative aspects are available are discussed here.



(29)

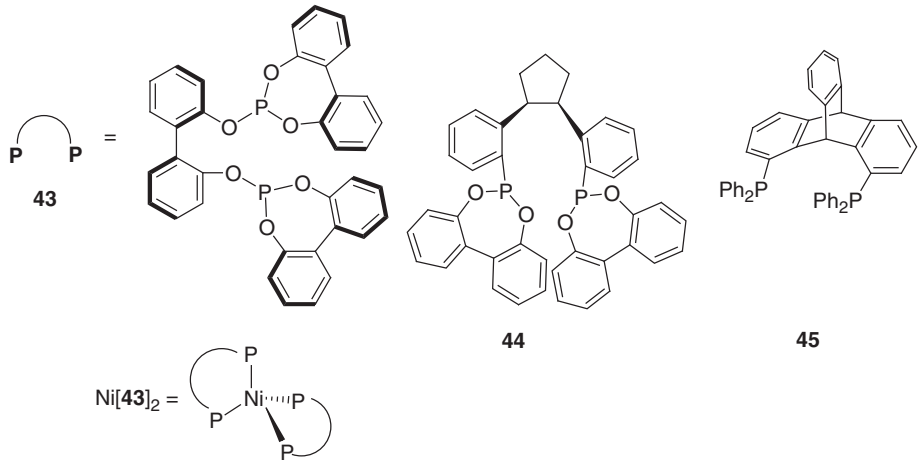
(30)

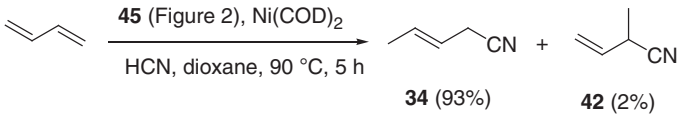
(31)

(32)

As shown in the accompanying equations, a triarylphosphite nickel complex catalyzes the hydrocyanation of butadiene in a multistep process to give an overall anti-Markovnikov addition of two molecules of HCN to butadiene. The reaction is carried out in two stages. In the initial hydrocyanation, butadiene gives mostly a ~2:1 mixture of isomeric C5 nitriles, 3-pentenenitrile (**34**), and 2-methyl-3-butenenitrile (**42**), which are resistant to further reaction with HCN in the absence of a Lewis acid (equation 29). In the second stage, the initial product is isomerized to a mixture of 3- and 4-pentenenitriles (**42** and **34**) using a $Ni[P(OAr)_3]_n$ ($n=3$ or 4) complex and a Lewis acid such as Ph_3B or $ZnCl_2$ (equation 30). Concurrent isomerization of **34** to **35** and anti-Markovnikov HCN addition to **35** follows (equations 31 and 32). Under optimum conditions, the hydrocyanation of **35** proceeds faster than all the other reactions, and adiponitrile is formed in very high y. and selectivity. The added Lewis acid promoter increases the rate of hydrocyanation of **35** and controls the selectivities in the isomerization reactions.[86,87] Major side-products, 2-methylglutaronitile and ethylsuccinonitrile (ES), which arise from hydrocyanation of various intermediates, are formed only in very small amounts under the production conditions.

New ligands and complexes (**Figure 2**) that show improved efficiency and selectivity in the hydrocyanation of BD continue to appear in the literature. A robust complex, $Ni[43]_2$, is more efficient in the initial hydrocyanation of butadiene as compared to the more air-sensitive $Ni[P(O\text{-}4\text{-tolyl})_3]_4$, yielding more than four times the turnover of the latter.[88] Two other recently developed ligands are also shown in **Figure 2**. The Ni-complexes of the phosphonate ligand **44** shows excellent activity and high selectivity in the hydrocyanation of butadiene.[103] The triptycene-based ligand **45** with a large bite-angle is exceptionally good in giving a high y. and a very high ratio (93:2) of 3-pentenenitrile to 2-methyl-3-butenenitrile, especially when the reaction is carried out in dioxane (equation 33).[104] As might be inferred, Ni(0)-complexes of ligands **44** and **45** are also good catalysts for the conversion of 2-methyl-3-butenenitrile to 3-pentenenitrile even in the absence of Lewis acids.





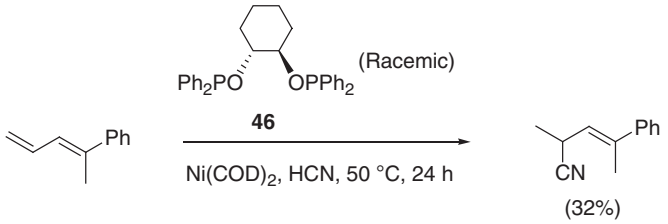


Figure 2 New ligands and complexes for hydrocyanation of 1,3-butadiene.

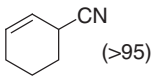
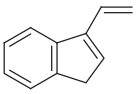
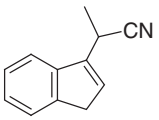
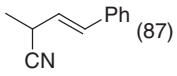
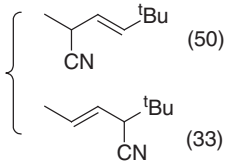
(33)

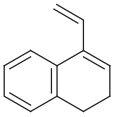


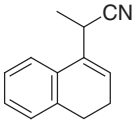












Hydrocyanations of other dienes catalyzed using $Ni[P(OAr)_3]_n$ ($n=3$ or 4) have been reported. These include 1-vinyl-1-cyclohexene, norbornadiene (NBD), dicyclopentadiene, allene, 1,5-cyclooctadiene (COD), 1,3-COD, cyclopentadiene,[9] 1,3-cyclohexadiene,[100] 1-methyl-BD, 2-methyl-BD, and 1,4-dimethyl-BD[89] (**Table 1**).

trans-Cyclohexane-1,2-diol-derived bis-1,2-diarylphosphinites (e.g., **46**, equation 34) are good ligands in Ni(0)-catalyzed hydrocyanations of 1,3-dienes.[105] The examples shown in equation 34 and the accompanying table are typical. Depending on the structure of the diene, both 1,2- and 1,4-additions are observed. Sequential additions of 1,3-cyclohexadiene and HCN to a catalyst prepared from the ligand and $Ni(COD)_2$ give the expected product in >95% y. Higher temperatures are needed for more substituted, though less reactive, dienes, such as 1-phenyl-1-methyl-BD and 2,6-dimethylnona-2,6,8-triene.

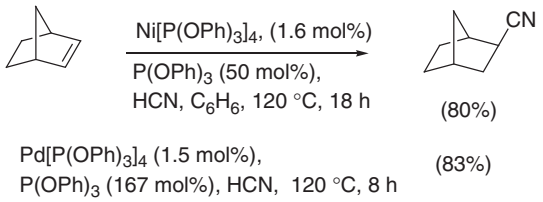
5.36.6.3 Hydrocyanation of Vinylarenes

Hydrocyanations of styrene and various other vinylarenes have been investigated in detail.[9,106,107] With Ni[P(*O*-4-tolyl)$_3$]$_4$, the branched nitrile (**47**) is obtained as the major product (equation 35). High activity and selectivity for the branched isomer (**47**) has been observed using finely tuned xantphos ligands (e.g., **41**) having a natural bite-angle of 105–106°.[91] Several other catalysts that give very high regio- and enantioselectivity are discussed below (see Section 5.36.6.5).

Ar	Yield (%)	**47:48**
4-^{i}BuC$_6$H$_4$	68	90:10
6-OMe-2-naphthyl	93	95:5

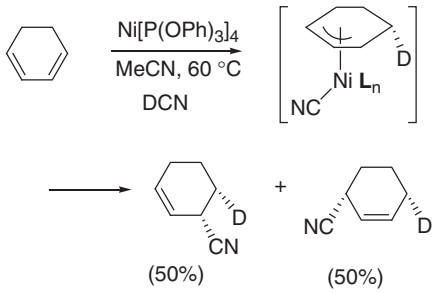


(35)

(36)

5.36.6.4 Hydrocyanation of Strained Alkenes

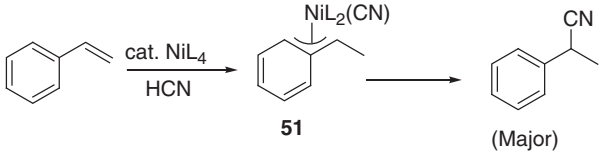
Hydrocyanation of norbornene is catalyzed by both Pd[P(OPh)$_3$]$_4$[84] and Ni[P(OPh)$_3$]$_4$[108,84] to give exclusively the *exo*-adduct (equation 37).



(37)

5.36.6.5 Asymmetric Hydrocyanation of Alkenes

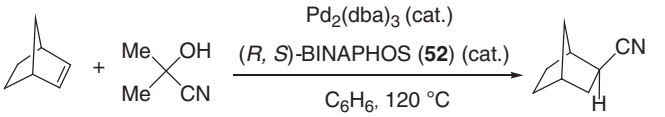
Markovnikov addition of HCN to an alkene can, in principle, serve as an entry into chiral intermediates that can be transformed into a wide array of useful products.[106,109] In spite of the extensive work on hydrocyanation of alkenes, only limited research activity has been directed toward finding an asymmetric variation of this reaction.



5.36.6.5.1 Regio- and stereoselectivity

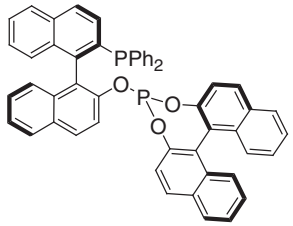
The stereoselectivity of hydrocyanation has been studied in some detail and it has been established that the addition of HCN to olefins is stereospecifically *syn*.[85,100] Addition of HCN to *tert*-butylethylene leads to anti-Markovnikov addition of HCN with a regioselectivity of more than 99%.[85] Addition of DCN to (*E*)-1-deutero-2-(*tert*-butylethylene) leads to predominantly the *erythro* product, confirming the *syn*-addition mode.[100] Addition of DCN to 1,3-cyclohexadiene results in a smooth conversion to two monodeuterated nitriles, which are 1,2- and 1,4-addition products (equation 38) even in the absence of a Lewis acid.[100] The fact that recovered cyclohexadiene does not contain any deuterium suggests that the initial metal hydride addition is irreversible in this case. It has been shown that the addition of $HNiL_3(CN)$ [L=P(*O*-2-tolyl)$_3$] to butadiene is also essentially irreversible.[86] Careful analysis of the products from 1,3-cyclohexadiene suggests that a *syn*-addition of DCN takes place in 1,2- and 1,4-fashions with equal propensity.

(38)



Vinylarenes, similar to conjugated dienes, give η^3-benzylnickel cyanides (e.g., **51**, equation 39) leading to overall Markovnikov addition via reductive elimination.

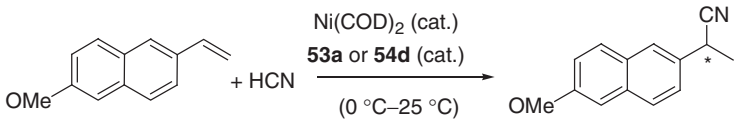
(39)



5.36.6.5.2 Asymmetric hydrocyanation of bicyclo[2.2.1]heptanes

Most of the early studies on the transition metal-catalyzed asymmetric hydrocyanation of alkenes dealt with the Ni(0)-[110] or Pd(0)[108,111]-catalyzed hydrocyanation of norbornene or its derivatives. Although high facial selectivities are observed, only modest enantioselectivities and y. are obtained in this reaction. A Pd-catalyzed hydrocyanation of norbornene using the (*R*,*S*)-BINAPHOS ligand **52** gives 48% *ee* for the indicated 2*S*-product (equation 40).[112]

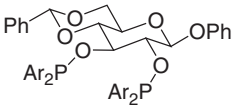
(52% y.; 48% *ee*)



52 [(*R*, *S*)-BINAPHOS]

(40)

5.36.6.5.3 Asymmetric hydrocyanation of vinylarenes



An important class of compounds that can be readily prepared from vinylarenes via the asymmetric hydrocyanation route is the 2-arylpropionitriles, precursors for the widely used anti-inflammatory 2-arylpropionic acids, such as naproxen and ibuprofen. The highest enantioselectivities have been obtained for the asymmetric hydrocyanation of vinylarenes using carbohydrate-based [arylphosphinite]nickel complexes as catalysts. Using the 2,3-disubstituted D-*gluco*-diarylphosphinite ligand **53**, for example, the naproxen precursor, 6-methoxy-2-vinylnaphthalene (MVN), is hydrocyanated with complete regioselectivity in 85–95% *ee* (*S*) (equation 41).[113,106] This catalyst system is remarkably active, giving a maximum reaction rate of 2000 turnovers per hour (turnover = moles of alkene/mole of Ni/unit time) and overall 700–800 total turnovers at room temperature (rt). The fructose-derived ligands **54** gave the opposite enantiomer, (*R*)-**55**.

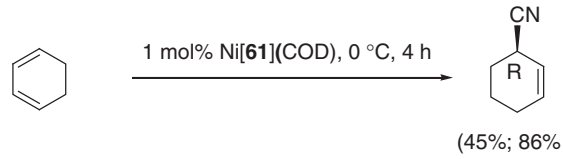
54d Ar^1 = Ph; $Ar^2 = 3,5\text{-}(CF_3)_2\text{-}C_6H_3$

Tr = Ph_3C

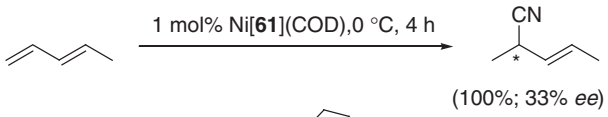
A key finding of this work is the importance of ligand electronic effects in asymmetric catalysis. These studies provided some of the first unequivocal examples of electronic tuning of an asymmetric catalyst. A study of the effect of the aryl substituents on phosphorus shows a pronounced increase in the enantioselectivity as the electron-withdrawing power of the substituent increases.[114] For example, the *ee* in the hydrocyanation of MVN increases from 16% to 91% as the aromatic *meta*-substituents in **53** are varied in the series Me, H, F, CF_3 ($\sigma_m = -0.07$, 0, 0.34, and 0.43, respectively). However, ligand electronic asymmetry appears to be important in the fructose-based phosphinite ligand system **54**.[115] In this case, the electronic differentiation of the two phosphorus sites is used to maximize the enantioselectivity. Thus, the incorporation of a more electron-withdrawing aryl group in the C_4 position rather than in the C_3 position is crucial in obtaining the highest *ee*'s. For example, for ligand **54** (equation 41) the following selectivities are observed: **54a**, 56% *ee*; **54b**, 43% *ee*; **54c**, 58% *ee*; and **54d**, 89% *ee*. A detailed account of the origin of these remarkable ligand effects and its relation to the mechanism of the asymmetric hydrocyanation has been published,[113] and the original paper can be consulted for details. Further scope of the reaction for syntheses of various styrene derivatives is also discussed therein.

Studies of the reaction mechanism (Scheme 3) using a series of ligands **53** with electronically different substituents on the aromatic groups on phosphorus implicate a Ni[53](COD) catalyst composition (**56**) as the resting state in the absence of HCN.[113] However, as judged using NMR spectroscopy, the enantioselectivity does not depend on the differentiation of the *Re* and *Si* faces of the vinylarene in a Ni[53](vinylarene) complex **57** that is formed from **56** by ligand exchange. All of the possible diastereomers of **57** can be detected using ^{31}P NMR. Deuterium labeling studies suggest that the rate of reductive elimination from a Ni[53](benzyl)CN complex **60** to give the product **55** increases relatively to β-hydride elimination (**60** to **59**) as the electron-withdrawing power of the aryl substituent on phosphorus increases. Other key observations made during the mechanistic studies are summarized in Scheme 3.

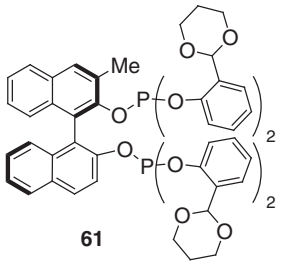


Scheme 3 Details of the mechanism of the Ni-catalyzed hydrocyanation of a vinylarene. Reproduced from RajanBabu, T. V. *Org. React.* **2011**, *75*, 1–73, with permission from Wiley.

The relationship between higher enantioselectivities and electron-withdrawing aryl substituents remains speculative because the rates of many of the fundamental processes are largely unknown. Although the steric effects are determinants of the sense of stereoinduction, the data clearly show that an electronic component that is also present in this NiL$_n$-catalyst system can be used to enhance the inherent preference for the (*S*)-nitriles. A series of kinetic and isotopic labeling studies suggests that the barrier for alkene insertion and/or reductive elimination (Scheme 3) is disproportionately lower for the *S*-pathway as the electron density at nickel is reduced, and this is the origin of the enhanced enantioselectivity.

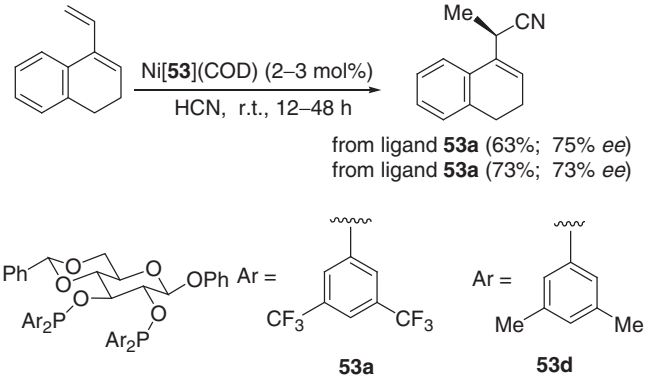


The enantioselectivities in cases other than MVN have been modest even with the best ligands (% *ee*'s: 4-methylstyrene, 70; 4-phenylstyrene, 68; 4-phenoxystyrene, 60; 4-*i*-butylstyrene, 56; 4-methoxystyrene, 52; 4-chlorostyrene, 40; 4-fluorostyrene, 28; 4-trifluorostyrene, 14; acenaphthene, 59; 1-vinylnaphthalene, 68; 2-vinylnaphthalene, 77).

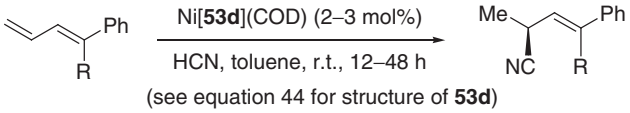


5.36.6.5.4 Asymmetric hydrocyanation of 1,3-dienes

Asymmetric hydrocyanation of 1,3-dienes continues to be a challenge. 1,3-Cyclohexadiene undergoes asymmetric hydrocyanation in the presence of a Ni(0)-complex of a binaphthol-derived phosphite **61** (equation 42).[116] For the same complex, 1-methylbutadiene gives an *ee* of 33% (equation 43).



(42)



(43)

The D-glucose-derived ligands **53a** and **53d** are moderately effective for the asymmetric hydrovinylation of special classes of 1,3-dienes shown in equations 44 and 45.[105]

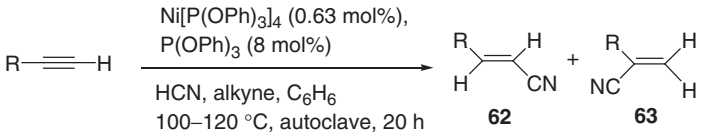
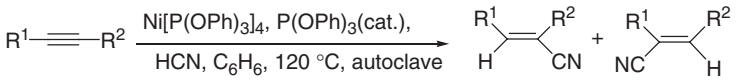
5.36.7 Hydrocyanation of Alkynes



5.36.7.1 Addition of HCN

A major manufacturing process for acrylonitrile used to be the addition of HCN to acetylene (equation 46) until it was replaced by the cooxidation of propylene and ammonia (the SOHIO process).[117]

(46)



The mechanism of the Ni(0)(arylphosphite)$_n$-catalyzed hydrocyanation of acetylene is thought to be similar to that of alkene hydrocyanation, including the *syn*-stereoselectivity.[118,119] In the Ni[P(OAr)$_3$]$_4$-catalyzed addition of HCN to straight-chain terminal alkynes with moderately sized substituents, mostly the branched products are formed (equation 47).[118,119] This reflects the increased stability of the secondary Cσ–Ni bonding compared to the Cσ–Ni bond with a primary carbon. *tert*-Butyl and phenyl acetylenes give mostly terminal nitriles. In hydrocyanations of alkynes containing heteroatoms on one of the substituents there is a slight preference for the nitriles in which the CN group is attached to the same carbon (**64**) carrying this substituent (equation 48).[120] Hydrocyanation of internal alkynes favors branched nitriles in which the nitrile group is attached to the least hindered position. Bulky substituents direct the cyano group to the terminal position, indicating that there is also a pronounced steric effect on the regioselectivity of this reaction. A similar trend is observed in silyl-substituted alkynes with 1-triphenylsilyl-1-hexyne giving exclusively the terminal nitrile.[121] Trimethylsilylacetylene gives a terminal to internal ratio of 25:75 and *tert*-butyldimethylsilylacetylene gives a ratio of 35:65. The size of the silyl group can be used to control the regioselectivity in hydrocyanation reactions of disubstituted acetylenes.[122] In many of these reactions, acetone cyanohydrin can be used in the place of the toxic HCN (for example in reactions of silylacetylenes, equation 47 or of alkynols, equation 48), thus making this a preparatively useful reaction for the syntheses of vinyl nitrile intermediates.[10,123]

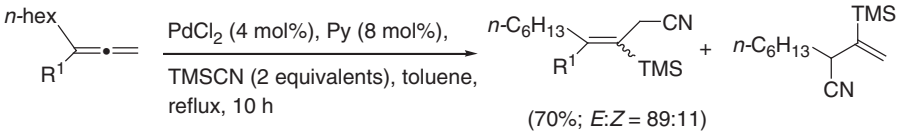
(48)

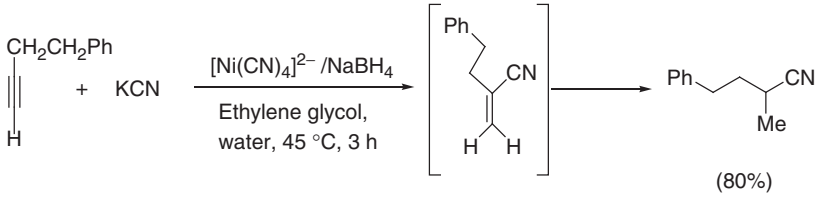
5.36.7.2 Addition of TMSCN



Addition of TMSCN to terminal alkynes in a synthetically useful reaction that is also catalyzed by $PdCl_2$ in the presence of pyridine (Py) (equation 49).[124] The reaction is regioselective with the more highly substituted nitrile as the major product, which arises via a *syn*-addition of TMSCN to the alkyne, giving predominantly the *Z*-alkene. A less general Ni(0)-catalyzed addition is complicated by competitive addition of TMSCN to the initial product yielding pyrrole carbonitriles.

R	Yield	**66:67**
Ph	90	95:5
n-C_6H_{13}	41	85:15
TMSO$(CH_2)_2$	34	88:12
4-MeOC_6H_4	90	95:15
2-naphthyl	90	95:5

(49)



Allenes also react with TMSCN in the presence of a $PdCl_2$/Py catalyst to afford vinylsilanes in which silicon is bound to the central carbon of the allene (equation 50).[125]

(50)

5.36.7.3 Cyanonickelate-Catalyzed Hydrocyanation of Alkynes

Treatment of an alkyne with KCN, a reducing agent such as Zn or $NaBH_4$, and a catalytic amount of $Ni(CN)_4^{2-}$ leads to alkyne hydrocyanation and subsequent hydrogenation of the initially formed unsaturated nitrile (equation 51).[126,127] Attractive features of this system include the use of an air- and moisture-stable catalyst precursor, the use of the cyanide ion as both a reagent and a ligand for the catalyst, and the ease of separating an aqueous catalyst solution from the product and substrate. One major drawback is the low catalyst turnover (<8 mol RCN mol^{-1} Ni).

(51)

5.36.8 Scope, Limitations, and Future Prospects

Apart from additions to carbonyl compounds (including 1,4-additions to α,β-unsaturated carbonyl derivatives), imines, and aziridines, synthetically useful hydrocyanation reactions are limited to vinylarenes, certain types of 1,3-dienes, and alkynes. Isomerization of double bonds under hydrocyanation conditions limits the utility of internal and unconjugated dienes. Unactivated alkenes are less reactive and need Lewis acids to promote the reaction. Although the $Co_2(CO)_8$-mediated reactions give selective Markovnikov products from terminal alkenes, high temperatures, prolonged reaction times, and low turnovers in the catalyst are major drawbacks of this otherwise worthwhile hydrofunctionalization reaction.[128] A systematic investigation of the co-mediated reaction might be a highly profitable area for future research. The regioselectivity in the hydrocyanation of internal alkynes is poor, even though terminal silyl substitution and judicious use of alkynes carrying heteroatom-substituted side-chains do provide a synthetically viable route to complex vinyl nitriles. Reactions of allenes have not been explored to a great extent. Asymmetric hydrocyanation is another potentially important area that has been poorly developed. Enantioselectivities above 90% *ee* have been achieved only for vinylnaphthalene derivatives. Substituted dienes, which undergo hydrocyanation reactions even in the absence of Lewis acids, could serve as highly valuable precursors if the problems of regio- and stereoselectivities can be solved. Alkenes carrying electron-withdrawing substituents do not participate in metal-catalyzed hydrocyanation reactions. These substrates are ideally suited for the base or Lewis acid-catalyzed reactions and remarkable progress has been achieved in this area. Finally, the toxicity of HCN is an important consideration, even though with proper precautions it can be readily handled safely. Use of acetone cyanohydrin and TMSCN as surrogates for the toxic HCN should alleviate some of the safety concerns.
